Circuit Extraction for ZX-Diagrams Can Be #P-Hard

Abstract

The ZX-calculus is a graphical language for reasoning about quantum computation using ZX-diagrams, a certain flexible generalisation of quantum circuits that can be used to represent linear maps from m to n qubits for any $m, n \geq 0$. Some applications for the ZX-calculus, such as quantum circuit optimisation and synthesis, rely on being able to efficiently translate a ZX-diagram back into a quantum circuit of comparable size. While several sufficient conditions are known for describing families of ZX-diagrams that can be efficiently transformed back into circuits, it has previously been conjectured that the general problem of *circuit extraction* is hard. That is, that it should not be possible to efficiently convert an arbitrary ZX-diagram describing a unitary linear map into an equivalent quantum circuit. In this paper we prove this conjecture by showing that the circuit extraction problem is **#P**-hard, and so is itself at least as hard as strong simulation of quantum circuits. In addition to our main hardness result, which relies specifically on the circuit representation, we give a representation-agnostic hardness result. Namely, we show that any oracle that takes as input a ZX-diagram description of a unitary and produces samples of the output of the associated quantum computation enables efficient probabilistic solutions to NP-complete problems.

1 Introduction

Quantum circuit notation is widely used in the field of quantum computing to denote computations to be executed on a quantum computer. While quantum circuits are a useful tool for representing computations on a quantum computer, they are somewhat inconvenient for reasoning about computations (such as proving equalities or doing simplifications); and for representing computations in alternative models like the one-way model of measurement-based quantum computation (MBQC) [40], or surface code lattice surgery [31].

ZX-diagrams are an alternative, more general representation of quantum computations, which allow complex operations to be described using a few simple generating operators. ZX-diagrams come with an equational theory, called the *ZX-calculus* [11], which allows one to perform many useful calculations graphically, without resorting to concrete matrix computations. While ZX-diagrams can be seen as an extension of circuits [12], they also readily admit encodings of the one-way model [23] and lattice surgery [20], and allow one to reason more easily about such procedures. There are several known *complete* axiomatisations of the ZX-calculus [37, 49], where any true equality of linear maps can be proved graphically. For a review on the ZX-calculus we refer to [47].

The ZX-calculus has been used in a variety of areas. It was used to optimise T-count [34, 18], braided circuits [29] and MBQC [4]; to find a new normal form for Clifford circuits [22]; to do more effective classical simulation using stabiliser decompositions [35]; and to reason about surface codes [26, 27], mixed-state quantum computations [9], natural language processing [10], condensed matter systems [14], counting problems [21, 44] and spin-networks [24].

As a strict extension of quantum circuit language, ZX-diagrams may express operations in a form that do not correspond directly to a quantum circuit. This added flexibility makes it easier to find novel strategies to simplify quantum circuits, but it comes at a cost: given a ZX-diagram representing a unitary linear map, it might be non-trivial to transform it back into a circuit of comparable size. Such a translation might however be necessary if, for instance, we want to run the computation described by a ZX-diagram on a gate-based quantum computer.

We refer to the above problem, as the *circuit extraction* problem: given a ZX-diagram which denotes a unitary operator U, find a unitary circuit (*i.e.*, a quantum circuit without measurements) that implements U. In recent years, some progress has been made on this problem [22, 34, 4, 41, 33, 19]. However, all known methods for efficient extraction of circuits from ZX-diagrams rely on additional conditions, in particular requiring there to be some kind of *flow* on the diagram, a concept imported from MBQC [6]. Such conditions allow the diagram to be rewritten incrementally into a unitary circuit. Since many ZX-calculus rewrites preserve these conditions, it is possible to perform optimisation of quantum circuits using ZX-calculus rules and still recover circuits efficiently.

However, it is worth trying to generalise these conditions as much as possible, or even remove them. For instance, it was noted in [34] that a certain transformation of ZX-diagrams would decrease the T-count (an important metric for quantum circuit optimisation), but in the process broke the invariant (the existence of a gflow), preventing a circuit from being extracted efficiently using known techniques. Given all this it is then natural to wonder about the following question:

Is there some efficient procedure to translate any unitary ZX-diagram into a quantum circuit?

In this paper we present strong evidence that there is no such efficient procedure, by showing that the circuit extraction problem is **#P**-hard in the worst case. The complexity class **#P** contains for instance the problem of strong simulation of quantum circuits, and counting the number of satisfying solutions to a Boolean formula, so **#P**-hard problems are expected to be intractable. We prove **#P**-hardness by giving an encoding of Boolean formulae into unitary ZX-diagrams in such a way that extracting a polysize circuit provides a solution to the associated **#SAT** instance. A consequence of our result is that if there were a polynomial time algorithm for circuit extraction, then $\mathbf{P} = \mathbf{NP}$.

Alternatively, since there is an evident translation from a ZX-diagram into a quantum circuit with postselection, this result can equivalently be seen as expressing the hardness of translating a postselected circuit that is promised to be proportional to a unitary into a

circuit without postselection. While intuitively this seems likely to be hard, particularly in light of Aaronson's landmark result that **PostBQP** = **PP** [1], our hardness result seems to be quite different in nature due to the unitarity promise. In particular, the postselection does not seem to be the "source of power" in our proof: the measurement outcomes corresponding to the post-selections in our circuits occur with some bounded probability, independent of the problem size.

One could ask how much our hardness result is tied to the fact that we require a procedure that produces quantum circuits from ZX-diagrams. Especially, when considering that in most cases we are not interested in the circuit itself, but instead we simply want to sample the output of the quantum computation. Perhaps one could find some other procedure to "program" a quantum computer using a ZX-diagram describing a unitary and obtain samples of measurement outcomes. We show that an efficient such procedure is unlikely to exist for arbitrary ZX-diagrams, by finding that such a procedure allows you to probabilistically solve **NP**-hard problems. So if there were some way to generically translate unitary ZX-diagrams into procedures which could be realised in polynomial time on a quantum computer, it would follow that the entire polynomial hierarchy is in **BQP**, and in particular that **NP** $\subseteq$ **BQP**.

The paper is structured as follows. We start by covering preliminaries on quantum circuits, ZX-diagrams and the necessary complexity theory in Section 2. Then in Section 3 we formally define the circuit extraction problem and prove it is hard. Section 4 considers several variations on circuit extraction, and in Section 5 we find some upper bounds on the hardness of circuit extraction. We end with some concluding remarks in Section 6.

2 Preliminaries

2.1 Quantum circuits

Since we wish to extract "a circuit" from a ZX-diagram, it will be helpful to first consider what we actually mean by a circuit.

In quantum computational theory, a "circuit" is a description of a computational process consisting of operations which may be decomposed as a sequence of primitive "gates" and "measurements", which act on one or more qubits to change the states of those qubits. The state-space of a qubit is identified with unit vectors of the finite-dimensional Hilbert space $\mathcal{H}_2 \cong \mathbb{C}^2$; the state of k qubits in parallel is described by the tensor product $\mathcal{H}_2^{\otimes k}$. A "gate" is an operation which is applied to one or more qubits and implements a unitary transformation $U : \mathcal{H}_2^{\otimes k} \to \mathcal{H}_2^{\otimes k}$ on the associated state space. A "measurement" is an operation which transforms a state $|\psi\rangle \in \mathcal{H}_2^{\otimes k}$ to some state $p_j^{-1/2}\,\Pi_j|\psi\rangle$ where $\{\Pi_1, \Pi_2, \ldots\}$ is a set of projections that sum up to the identity operator I, the p_j gives the probability of observing that particular measurement outcome and is given by $p_j = \langle\psi|\Pi_j|\psi\rangle$, and the index j provides the classical "outcome" indicating which transformation occurred. A gate or measurement acting on a small number of qubits can be applied to a larger set of qubits by taking the tensor product with an appropriate number of identity operators. A "circuit" is then a composition of such gates and measurements on some number of qubits, acting in sequence or in parallel, to describe more complex (and in general, non-deterministic and irreversible) transformations of a quantum state-space. To define a reasonable model of computational complexity using quantum circuits, one usually elaborates the above with a description of how one would specify a circuit as part of a family of unitary operators, acting on inputs of various sizes. For our purposes, it will suffice to require that the coefficients of the gates be efficiently computable, and in particular provided explicitly in some representation which suffices to approximate them to $O(\text{poly}(n))$ bits of precision in time $O(\text{poly}(n))$ for an n qubit circuit.

It will be convenient to refer to one specific such gate-set – an infinite set $\mathcal{B}$ of gates, consisting of the single-qubit gates Z_α for arbitrary angles α, the single-qubit Hadamard gate H and the two-qubit gate CNOT:

$$Z_\alpha = \begin{pmatrix} 1 & 0 \\ 0 & e^{i\alpha} \end{pmatrix} \qquad H = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix} \qquad \text{CNOT} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix}. \tag{1}$$

This gate set forms a *universal* gate set, meaning that a unitary acting on any number of qubits can be written as a circuit consisting of these gates [38]. Other universal gate-sets exist, but so long as one considers gate sets whose parameters are efficiently computable from some input parameters and which act only on a bounded numbers of qubits (*e.g.*, at most two or three qubits), the size of a circuit to represent a given unitary operator can only vary by a constant factor, so that for the purpose of complexity theory, the details of the specific gate set chosen are not important.

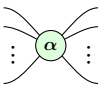
A circuit which contains no measurements, and therefore consists entirely of unitary gates, is called a "unitary circuit". A unitary circuit is reversible, and "deterministic" in the sense that an idealised realisation of such a circuit will transform the state-space in the same way each time. As this is a convenient feature for the design and analysis of quantum algorithms, much of the literature on quantum algorithms concerns itself with unitary circuits, and much of the design of quantum computers is concerned with how to reliably implement unitary circuits.

2.2 ZX-diagrams

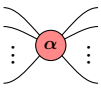
We provide a brief overview of ZX-diagrams. For a review see [47], and for a book-length introduction see Ref. [13].

ZX-diagrams form a diagrammatic language similar to the familiar quantum circuit notation. A *ZX-diagram* (or simply *diagram*) consists of *wires* and *spiders*. Wires entering the diagram from the left are *inputs*; wires exiting to the right are *outputs*. Given two diagrams we can compose them by joining the outputs of the first to the inputs of the second, or form their tensor product by simply stacking the two diagrams [11, 12].

Spiders are linear operations which can have any number of input or output wires. There are two varieties: Z-spiders depicted as green dots and X-spiders depicted as red dots:



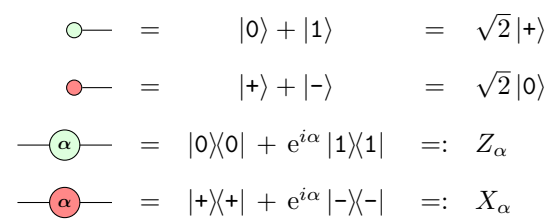
$$:= |0\cdots0\rangle\langle 0\cdots0| + e^{i\alpha}|1\cdots1\rangle\langle 1\cdots1|$$



$$:= |+\cdots+\rangle\langle +\cdots+| + e^{i\alpha}|-\cdots-\rangle\langle -\cdots-| \tag{2}$$

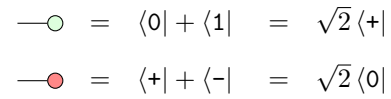
Here $|0\rangle$ and $|1\rangle$ represent the standard basis vectors of $\mathbb{C}^2$ which are the eigenvectors of the Pauli Z matrix; the states $|\pm\rangle := \frac{1}{\sqrt{2}}(|0\rangle \pm |1\rangle)$ are sometimes referred to as the "Hadamard basis", and are eigenvectors of the Pauli X matrix. If you are reading this document in monochrome or otherwise have difficulty distinguishing green and red, Z spiders will appear lightly-shaded and X darkly-shaded. Note that here the number of inputs and outputs do not have to match. When $\alpha = 0$, we will not write the phase on the spider.

▶ **Example 2.1.** We can immediately write down some simple state preparations and unitaries in the ZX-calculus:



(3)

We can also represent the effects that are dual to the states above using spiders:



(4)

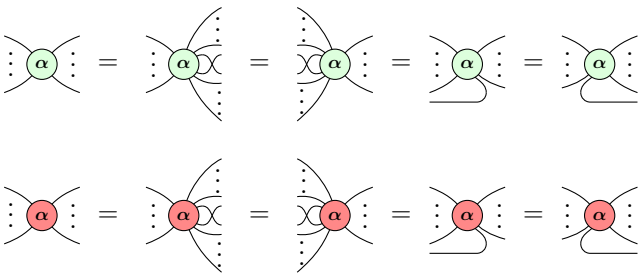
In the diagrams above we write explicit scalars to represent a proportionality constant. In this paper (non-zero) scalar factors will not be important. However, do note it is always possible to represent any scalar as an explicit ZX-diagram (of constant size). For this reason, our results will also apply to other proposed normalisations of the ZX generators, such as those in Refs. [17, 14, 24].

We can compose ZX-diagrams in two ways, either horizontally by connecting the wires together, which corresponds to the regular composition of linear maps, or vertically, which corresponds to the tensor product of linear maps. Any ZX-diagram is built by composing spiders (and permutations of wires) together in these ways.

On a formal level we consider a ZX-diagram D with n inputs and m outputs as a morphism $D : n \to m$ in a category. This category is the compact-closed *PROP* (symmetric monoidal category where the objects correspond to natural numbers and the tensor is addition) freely generated by the Z- and X-spider generators. The interpretation as a linear map is then a strongly monoidal functor into the category of Hilbert spaces, which is fully specified by the interpretation of the spiders (2). This level of formality won't be needed in this paper. The interested reader can look at for instance Refs. [11, 9, 8].

A more intuitive way to view ZX-diagrams is as tensor networks [39]: the spiders are the tensors, and a connection between spiders denotes a contracted index.

The Z- and X-spiders satisfy the following symmetries:



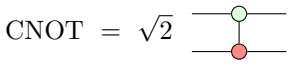
(5)

Here we are writing an equality of ZX-diagrams. This is to be understood as saying that the linear maps these ZX-diagrams represent are equal. In particular: in each equality the number of open wires extending to the left is the same, and similarly for the number of open wires extending to the right. Because of these symmetries we can treat ZX-diagrams as (labeled) undirected graphs: if we attach labeled nodes to the open wires at the input and output to distinguish their roles, arbitrary topological deformations of the diagram do not affect its interpretation as a linear map.

It is often convenient to introduce a symbol – a yellow square – for the Hadamard gate. This is defined by the equation:

(6)

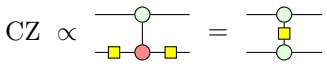
The CNOT gate also has a straightforward representation as a ZX-diagram:



(7)

Here we are allowed to draw a horizontal wire as per the symmetries (5) whether this wire is an input or an output is irrelevant.

Seeing as we can represent Z_α, H and CNOT gates as ZX-diagrams, we can represent the gate set $\mathcal{B}$ of Eq. (1), and hence we can in fact represent any unitary as a ZX-diagram. The above demonstrates that ZX-diagrams can be used as an alternative representation for quantum circuits. However, ZX-diagrams are also more versatile than unitary circuits. Consider for example the following construction of the CZ gate as a ZX-diagram:



(8)

The right-hand-side demonstrates a different diagrammatic construction for CZ, that does not immediately look circuit-like, with the Hadamard-box representing some sort of interaction of two qubits rather than the evolution of a single qubit.

In fact, this versatility is reflected in the property that ZX-diagrams are universal for *all* linear maps between any number of qubits [11]. To see this, note that we can represent states as in Eq. (3). By composing tensor products of these states with some unitary we can write down any quantum state. By the map-state duality of quantum theory (i.e. the Choi-Jamiołkowski isomorphism), we can then also write every linear map, see for instance [47] for the details.

The universality of the gate-set $\mathcal{B}$ and of the ZX-calculus means that any unitary operator on some fixed number of qubits may be represented by some "gadget" in the ZX calculus, consisting of some fixed diagram of finite size – though as the example of CZ in Eq. (8) shows, there may also be "gadgets" which represent a unitary operator which do *not* consist of sequential and parallel composition of gates. Indeed, even the representation of the CNOT is by a simple "gadget" of two nodes, which is not describable as a composition of the other single-node "gadgets". In this respect, ZX-diagrams represent a more versatile notation than a conventional circuit notation. This raises the question of how, given a representation of some unitary U as a ZX-diagram, one might find another representation of U which consists of just compositions from the universal gate-set $\mathcal{B}$. This is the problem that this paper is concerned with.

ZX-diagrams are more than just a notation for unitary circuits (and non-unitary operators more generally): they may be used to perform computations. Specifically, ZX-diagrams come with a set of graphical rewrite rules, which may be used to find equivalent diagrams which represent the same state or operator, just as one might manipulate an algebraic expression. This rewrite system is *complete* [37, 49]: unlike other circuit diagrams, one may show that two equivalent ZX-diagrams are equivalent though transformations of diagrams alone. The possible advantage of this is that ZX-diagrams can often concisely represent operators which have a very large number of non-zero coefficients, and so that this reasoning can be done efficiently while it could not be done using the matrices directly. For instance, one of the rewrite rules we will use in this paper is *spider fusion*:

(9)

These rules say that we can fuse together adjacent spiders of the same colour.

While these rewrite rules are not immediately relevant to our results, the fact that it is possible to compute with ZX-diagrams is the motivation for considering this particular representation of unitary circuits, and also motivates the concept of considering different ZX-diagrams which represent the same unitary transformation. We refer the interested reader to [47] for an overview.

2.3 Circuit extraction

In the above section we saw that we can get ZX-diagrams directly from quantum circuits. We can also get ZX-diagrams from considering measurement patterns in the *one-way model* [40]. In the one-way model of quantum computation we start with a large *graph state*, on which we then do subsequent measurements, where the choice of measurement angle and axis may depend on previous measurement outcomes. This leads to another universal model of quantum computation. The one-way model can be straightforwardly represented in the ZX-calculus [23, 4].

An important property of a one-way computation is that we can perform a computation deterministically, so that we perform the same overall computation regardless of individual measurement outcomes. A sufficient property for ensuring that deterministic processes are possible on a given resource state is that its underlying graph has a property known as *gflow* [6]. This is an efficiently verifiable combinatorial condition on the entangled resource.

When we represent a one-way computation with gflow as a ZX-diagram, the gflow ensures that certain "local" parts of the diagram correspond to individual unitary gates, in a way which can be iteratively translated into an actual unitary circuit. In this case we can hence *extract* a unitary quantum circuit from the ZX-diagram that represents the one-way computation. See for instance [22, 4, 41] for several variations on this idea.

Measurement-based quantum computation like the one-way model is a type of non-unitary quantum computation. Another type of non-unitary model is given by doing *lattice surgery* in the surface code [30, 20]. A lattice surgery procedure can also be represented as a ZX-diagram [20]. Just as in the one-way model, there is a flow condition that ensures such a calculation is deterministic, and that the resulting ZX-diagram can be step-by-step rewritten into a unitary circuit [19].

We see that there are several quantum computational models that can be written in terms of ZX-diagrams, which can be rewritten into a unitary quantum circuit efficiently when they satisfy some condition. The type of flow condition required for these procedures ensures that the diagram can't get "too wild" in the middle, so that we can stepwise rewrite the diagram into something that looks more like a circuit. A natural question to ask then is how much we can weaken such additional conditions, and in particular if we can transform a ZX-diagram into a circuit efficiently in the most general setting, where the only condition we require of the ZX-diagram is that it is proportional to a unitary. The main result of this paper is that such a general efficient procedure most likely does not exist.

2.4 Background on computational complexity

Finally, we provide some background on computational complexity. We assume knowledge of **P**, the boolean satisfiability problem **SAT**, oracle machines, **NP** and nondeterministic Turing machines (NTMs) in general. Our results concern *Cook reductions* (in fact, usually Cook[1] reductions). A Cook reduction from a problem **X** to another problem **Z** is an algorithm for solving **X** using a deterministic Turing machine which halts in polynomial time, but which may query an oracle (in the case of a Cook[1] reduction, exactly once) for **Z**. This implies that, modulo some polynomial-time computation, the problem **Z** is at least as hard as **X**; and that if $\mathbf{Z} \in \mathbf{P}$, we also have $\mathbf{X} \in \mathbf{P}$. In symbols we may write $\mathbf{X} \in \mathbf{P}^{\mathbf{Z}}$. Our results will generally concern problems **Z** related to ZX-diagrams and problems **X** which are at least **NP**-hard (*i.e.*, they suffice to solve **SAT**).

Quantum circuits form a model of computation, which may be considered to generate random outcomes through measurement operations. Note that, just as with the study of boolean circuits as a model of computation, one often considers a quantum circuit to be described by some polynomial-time computable procedure (a sort of "effective blueprint"), which for a given $n \geq 0$ requires time $\mathrm{poly}(\log n)$ to produce a circuit taking inputs of size n. While this constraint is not essential when considering a single circuit on its own (the description of the circuit itself is a finite specification), this constraint prevents us from considering what might otherwise seem like "quantum algorithms" for uncomputable problems (in the same way that one must for boolean circuits). Additionally, to prevent unbounded computational power from being hidden elsewhere in the description of a quantum circuit, one often imposes constraints on the gates and measurements allowed in a circuit. For instance, requiring that gates only act on a small constant number of qubits, and that for parametrised gates like Z_α the parameter α is efficiently computable. The class **BQP** consists of decision problems which can be decided with bounded error (with error probability less than, say, $\frac{1}{3}$) by quantum circuit families satisfying these reasonable constraints. This class represents the decision problems that can be practically solved by an (idealised) quantum computer.

It is not expected that either of **NP** or **BQP** contain the other. So if we can reduce in polynomial time (by many-to-one or oracle reductions) an **NP**-complete problem to some problem **X**, then we expect **X** to be intractable for quantum computers. Certain modifications of the quantum computational model do allow for more difficult problems to be solved, however. For instance, **PostBQP** is the class of problems which may be solved with bounded error by a uniform quantum circuit family, *conditioned on some other measurement* yielding a specific outcome (which occurs with non-zero probability). This "conditioning" restriction is known as *postselection*, and appears to be operationally very powerful, as **PostBQP** coincides with the class **PP**, of decision problems for which a "yes" instance is accepted on more than half of the branches of some NTM halting in polynomial time.

The class **P** is closed under oracles: a deterministic Turing machine equipped with an oracle for some problem in **P** cannot decide more problems in polynomial time than a normal Turing machine, so that $\mathbf{P}^{\mathbf{P}} = \mathbf{P}$. The same is true for **BQP**: any decision problem solvable (with bounded error) by a uniform family of quantum circuits, can also be solved (with bounded error) by some other family of quantum circuits without oracle access, so that $\mathbf{BQP}^{\mathbf{BQP}} = \mathbf{BQP}$. The same is not true, however, for **NP**: it is not known whether $\mathbf{NP}^{\mathbf{NP}}$ (the class of decision problems, for which there is an NTM with an oracle for a problem in **NP**, halts in polynomial time and accepts in some branch precisely for "yes" instances) is equal to **NP**. It is widely conjectured that $\Sigma_2^{\mathrm{p}} := \mathbf{NP}^{\mathbf{NP}} \neq \mathbf{NP}$, and indeed that $\Sigma_3^{\mathrm{p}} := \mathbf{NP}^{\Sigma_2^{\mathrm{p}}} = \mathbf{NP}^{\mathbf{NP}^{\mathbf{NP}}} \neq \mathbf{NP}^{\mathbf{NP}}$, and so forth. The union of $\Sigma_n^{\mathrm{p}} := \mathbf{NP}^{\Sigma_{n-1}^{\mathrm{p}}}$ for all $n > 1$, defines the class **PH**, called the *polynomial hierarchy* [42].

The hardness results which we are most concerned with involve problems in **#P**: the class of problems which may be reduced to counting the number of accepting branches of some NTM on a given input. In particular, we are interested in the problem **#SAT**, of counting the number of "solutions" $x \in \{0,1\}^n$ to an instance of **SAT**, presented as a formula for a function $f : \{0,1\}^n \to \{0,1\}$, where a "solution" satisfies $f(x) = 1$. The problem **#SAT** is **#P**-complete [46], as is tensor contraction over the natural numbers [15], and "strong simulation" (*i.e.*, precise estimation of explicit measurement probabilities) of uniform quantum circuit families [48]. The **#P**-completeness here means that a Cook reduction from any of these problems to some problem **Z**, establishes that there is a Cook reduction from *any* problem $\mathbf{X} \in \mathbf{\#P}$ to **Z**. in this case we say then that **Z** is "**#P**-hard". The computational power of **#P** is considered to be significantly greater than that of **NP**. In particular, Toda [43] showed that $\mathbf{PH} \subseteq \mathbf{P}^{\mathbf{\#P}}$.

3 Proof of hardness of Circuit extraction

We now present the central problem of our work.

CircuitExtraction
Input: A ZX-diagram D with n inputs and outputs and at most k wires and/or spiders, and a set $\mathcal{G}$ of unitary gates (each acting on at most $O(1)$ qubits).
Promise: The operator denoted by D is proportional to a unitary.
Output: Either **(a)** a poly(n,k)-size circuit C, expressed as a sequence of gates from $\mathcal{G}$ and expressing an n-qubit unitary that is proportional to the operator denoted by D, if such a circuit exists; or **(b)** a message that no such circuit exists, if that is the case.

Note that here we make no assumptions on the specific gate set $\mathcal{G}$, apart from the computability of the coefficients as described in Section 2.1, and that the number of qubits which is bounded by some constant. One might object to the requirement that the output list of gates must be polynomially related to the size of the input ZX-diagram: however, as we are interested in whether the extraction problem can be solved efficiently, the restriction on the size of C follows from the time required to represent it as a list of gates.

▶ Remark 3.1. For a finite gate set we can consider the gate set $\mathcal{G}$ as being supplied as concrete matrices, while for an infinite set we could consider it as being supplied as an efficient procedure for translating a "gate label" into a matrix. For concreteness sake we can take $\mathcal{G} = \mathcal{B}$, the gate set (1). This gate set contains the parametrised gate Z_α. Formally a circuit will then specify these phases α via some efficiently computable procedure.

The above problem can of course also be stated for any related graphical language for quantum operations, such as the ZH-calculus [3] or the ZW-calculus [28]. Since such diagrams can be efficiently translated into one another, these problems are of equivalent hardness. There are some other reasonable variations we can consider of **CircuitExtraction** that we will discuss in the next section.

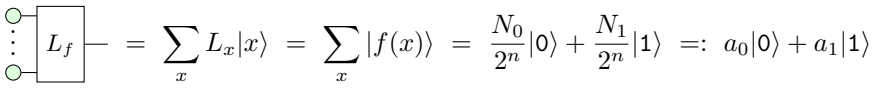
We will now show that **CircuitExtraction** is **#P**-hard. We do this by building a diagram that is proportional to a unitary based on a **SAT** instance, and showing that the resulting matrix the diagram represents is uniquely determined by the number of solutions of the instance.

Let $f : \{0,1\}^n \to \{0,1\}$ be a Boolean formula with poly(n) terms. We say a bit string $x \in \{0,1\}^n$ is a *solution* to f when $f(x) = 1$. The first step will be to build a ZX-diagram that implements the linear map L_f that takes n qubits to 1 qubit by $L_f|x\rangle = |f(x)\rangle$. We can of course represent f as a tree of AND and NOT operations so that to construct L_f it suffices to find linear maps that implement AND and NOT on $|x\rangle$.

We may consider ZX diagrams for "quantum" versions of the boolean logical AND gate and NOT gate, *i.e.*, linear operators such that $\mathrm{NOT}|0\rangle = |1\rangle$, $\mathrm{NOT}|1\rangle = |0\rangle$, and $\mathrm{AND}|x, y\rangle \mapsto |x \cdot y\rangle$. We could just appeal to the universality of ZX-diagrams to establish that there are diagrams that represent these operations, but for completeness sake let us give some concrete diagrams to realise these operations (up to a constant factor):

NOT $=$ 
AND $\propto$ 
The NOT gate is just an X_π gate, but the AND is more complicated. It is based on the representation of the CCZ gate from [35] that uses 4 T gates. Its correctness can be verified by inputting $|0\rangle$ and $|1\rangle$ on the inputs and seeing that it has the correct action on all these inputs.

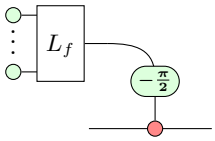
By combining these diagrammatic gadgets for NOT and AND we can build the operation L_f as a ZX-diagram using poly(n) spiders. Now, note that:



(10)

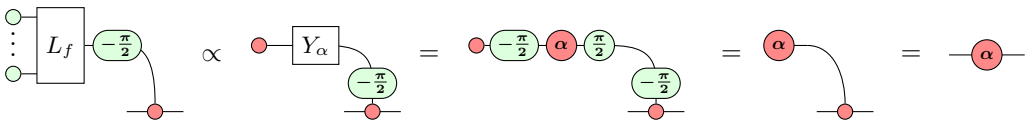
where N_1 is the number of solutions of f, $N_0 = 2^n - N_1$ is the number of "non-solutions" of f, and we set $a_0 = N_0/N$ and $a_1 = N_1/N$ for $N := 2^n = N_0 + N_1$. The resulting state is not normalised: to normalise it we should multiply both sides by $(a_0^2 + a_1^2)^{-1/2}$.

We use the "state" described in Eq. (10) as the input of a controlled operation. By choosing the controlled operation appropriately, we will be left with something proportional to a unitary. We may for instance consider the following diagram:



(11)

To see this is unitary first recall that a Y rotation over an angle α applied to $|0\rangle$ gives $Y_\alpha|0\rangle = \cos(\frac{\alpha}{2})|0\rangle + \sin(\frac{\alpha}{2})|1\rangle$. Hence the state of Eq. (10), when properly normalised, can be written as $Y_\alpha|0\rangle$ for $\alpha = 2\sin^{-1}\left(\frac{a_1}{\sqrt{a_0^2+a_1^2}}\right)$. We can then calculate:



(12)

In the above, we use the relation $Y_\alpha = Z_{-\frac{\pi}{2}} X_\alpha Z_{\frac{\pi}{2}}$, and some simple ZX-calculus rewrites (namely that  and ). Hence, the diagram of Eq. (11) is proportional to an X_α rotation where α is uniquely determined by the number of solutions to f. Note that this operation can be easily represented (with at most three gates) using a gate-set such as $\{H, Z_\alpha, \mathrm{CNOT}\}$, in which the set of values of allowed angles α include those that may arise in the diagram of Eq. (12) for some number of solutions N_1 to the formula f; such an operation will be representable using other gate-sets as well.[1]

[1] Note that the gate-set described here cannot be a single, finite gate set for all values of n. However, the angles α arising out of instances of satisfiability in this way can be specified in $O(n)$ bits, precisely by

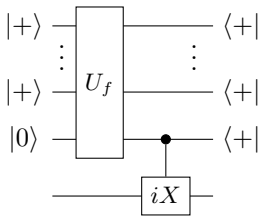
▶ **Theorem 3.2.** **CircuitExtraction** *is* **#P**-*hard.*

Proof. **#SAT** is a **#P**-complete problem, so it suffices to show that we can count the number of solutions to a Boolean formula using a call to an oracle which solves **CircuitExtraction**. Given a Boolean formula $f : \{0,1\}^n \to \{0,1\}$ with $\text{poly}(n)$ terms, construct the diagram of Eq. (11). The diagram here for L_f uses $\text{poly}(n)$ of the diagrammatic gadgets for NOT and AND, and hence the complete diagram consists of $\text{poly}(n)$ spiders, each of which may be restricted to having at most 3 wires. We may apply the **CircuitExtraction** oracle on this diagram subject to a suitable gate set that can exactly generate the possible X-rotations X_α which may arise. As C is a single-qubit circuit with at most $\text{poly}(n)$ gates, we can calculate the unitary it implements, up to any required precision $2^{-O(\text{poly}(n))}$, in polynomial time. We know that the operation realised is of the form X_α, so to determine the value of N_1, it suffices to estimate the entries of the resulting X_α to within an error of $\frac{1}{2\sqrt{2}}$. Determining the value of $a_1/\sqrt{a_0^2 + a_1^2}$ to $2n$ bits of precision is sufficient to do this. ◀

▶ **Corollary 3.3.** *If there is a polynomial time algorithm for* **CircuitExtraction***, then* $\mathbf{P} = \mathbf{P}^{\#\mathbf{P}}$*. In particular, the polynomial hierarchy collapses to the first level:* $\mathbf{P} = \mathbf{NP} = \mathbf{PH}$.

Proof. If **CircuitExtraction** can be done in polynomial time, then the above shows that we can solve **#SAT** in polynomial time, and hence $\mathbf{NP} \subseteq \mathbf{P}^{\#\mathbf{P}} = \mathbf{P}$. ◀

▶ Remark 3.4. Our construction of the diagram we use to prove our result might seem somewhat arbitrary. To motivate it some more, first realise that instead of the function L_f, we could have used the standard unitary quantum oracle for a Boolean function U_f which acts on $n+1$ qubits via $U_f|x,b\rangle = |x, b \oplus f(x)\rangle$. We can get L_f out of U_f by post-selecting the top n qubits to $\langle +|$. Using the language of post-selection, we may then present a circuit version of Eq. (11):



(13)

The top part is calculating the number of solutions, while the bottom part ensures that this information is fed into a qubit in such a way that the overall operation is proportional to a unitary. The choice of iX is for the sake of simplicity: any unitary U that satisfies $U = -U^\dagger$ would also suffice, such as iY or iZ.

▶ Remark 3.5. Even though we can view the diagram as a post-selected circuit, this does not seem to be where the power of the procedure comes from, as it is for instance in Aaronson's characterisation $\mathbf{PostBQP} = \mathbf{PP}$ [1]. In our setting the probability of observing the "correct" outcome is bounded from below by a constant, and does not depend on n. This means in particular that by doing repeat-until-success we could with high probability implement the circuit Eq. (13) on a quantum computer. However, this does not allow you to solve **#SAT**, as adjacent possibilities of the rotation angle α are exponentially close. So rather, the power of the procedure comes from getting an explicit description of the circuit which allows us to exactly calculate the rotation angle.

characterising them in the way we have, by relating some integer ranging in $\{0, 1, \ldots, 2^n\}$ via inverse trigonometric functions. For remarks on what can be achieved with finite gate-sets, the reader may be interested in the related problem **ApproxCircuitExtraction**, in Section 4.

4 Variations on extraction

There are several variations on circuit extraction which we can consider, all of which also turn out to be hard.

The essential trick we used in our proof is that our resulting circuit has just *one* qubit, and hence a description of a unitary on it can easily be transformed into the actual unitary it implements by just multiplying all the resulting matrices. But of course the same statement remains true if we have slightly more than one qubit, say a logarithmic amount in the size of the **SAT** instance. We also see that it then doesn't matter if our circuit contains auxiliary qubits, measurements, or classically-controlled corrections. All of these can be efficiently calculated as long as the number of qubits is small enough. Therefore, let's define the following variant of circuit extraction.

AuxCircuitExtraction
Input: A ZX-diagram D with n inputs and outputs and at most k wires and/or spiders, and a set $\mathcal{G}$ of unitary gates (each acting on at most $O(1)$ qubits).
Promise: The operator denoted by D is proportional to a unitary.
Output: Either **(a)** a deterministic n-qubit circuit implementing the unitary of the input ZX-diagram, described as a $\mathrm{poly}(n,k)$ length list of gates, auxiliary qubit preparations, measurements, and classical corrections, with at most $O(\log k)$ auxiliary qubits; or **(b)** a message that no such circuit exists, if that is the case.

▶ **Theorem 4.1. AuxCircuitExtraction** *is* **#P***-hard.*

Proof. We construct the same diagram as in the proof of Theorem 3.2 to solve a **#SAT** instance, except that we can no longer assume that the final circuit will act only on a single qubit: instead it may act on up to $O(\log k)$ qubits, including the operations on the auxiliary qubits. The size of the matrices involved when trying to calculate the resulting unitary is $O(2^{\log \mathrm{poly}(k)}) = O(\mathrm{poly}(k))$, where here k is the size of the input diagram. We may then still multiply the matrices together in polynomial time to obtain sufficiently precise estimates of the coefficients. ◀

One might also object that requiring the output unitary to *exactly* represent the ZX-diagram is too strong – in particular, impossible in general even with an approximately universal, finite gate set – and wish for an approximate output instead. We say that a unitary operator $\tilde{U}$ is an ε*-approximation* of another unitary U for some $\varepsilon > 0$, if $\|\tilde{U} - e^{i\alpha}U\| < \varepsilon$ for some global phase α. Here, $\|M\|$ denotes the operator norm of M: the largest singular value of M.

ApproxCircuitExtraction
Input: A ZX-diagram D with n inputs and outputs and at most k wires and/or spiders, a set $\mathcal{G}$ of unitary gates (each acting on at most $O(1)$ qubits), and a precision parameter $\varepsilon > 0$.
Promise: The operator denoted by D is proportional to a unitary.
Output: Either **(a)** a $\mathrm{poly}(n, k, \log(1/\varepsilon))$-size circuit C, expressed as a sequence of gates from $\mathcal{G}$ and expressing an n-qubit unitary $\tilde{U}$ which is an ε-approximation to either the operator denoted by D, or some operator proportional to it; or **(b)** a message that no such circuit exists, if that is the case.

▶ **Theorem 4.2. ApproxCircuitExtraction** *is* **#P***-hard.*

Proof. For a given **SAT** instance $f : \{0,1\}^n \to \{0,1\}$ we again construct the same diagram as in the proof of Theorem 3.2 which denotes a unitary X_α, where α allows us to determine the number of solutions to f. This diagram has $\mathrm{poly}(n)$ spiders. Set $\varepsilon = 2^{-cn}$ for some large enough constant c. Then applying **ApproxCircuitExtraction** gives rise to a circuit, which has $\mathrm{poly}(\mathrm{poly}(n), \log(1/2^{-cn})) = \mathrm{poly}(n)$ gates. We can hence just multiply out the matrices in order to determine the unitary U it implements. This unitary U approximates X_α to degree 2^{-cn}. Since the top left entry of X_α is real, we can first multiply U by the appropriate global phase to ensure it is also real. If we have picked c large enough then the entries of U are then within $\frac{1}{2}2^{-n}$ of that of X_α so that we can determine α by rounding to the nearest allowed value. ◀

Note that, even for exponentially small angles α as might arise when f has few solutions, circuits of polynomial size do *exist* for X_α when $\mathcal{G}$ is an approximately universal gate-set: using the Solovay–Kitaev algorithm [36, 16] or any of its many refinements (see *e.g.* Ref. [5] and references therein), we may synthesise circuits approximating X_α to any precision ε in time scaling polynomially in $\log(1/\varepsilon)$. The difficulty of **ApproxCircuitExtraction** stems from determining *which* angle α to approximate. One might nevertheless want to consider a variation on **ApproxCircuitExtraction** with a polynomial dependence on $1/\varepsilon$ instead of $\log 1/\varepsilon$. We believe this variant will still be hard: see Remark 4.4.

Let us consider one final variation on extraction. One could argue that the reason that we end up with a hard problem in these instances, is because requiring the output to be some kind of circuit is too restrictive. The ultimate goal of circuit extraction is that we wish for the ZX-diagram to be run on a quantum computer in order to obtain some probability distribution over outcomes; but the complexity of **CircuitExtraction** and its variations seems to arise from the complexity of finding a precise description of the procedure to do so. Cutting out the middle-man, we may consider *any* process which takes as input a unitary ZX-diagram, and produces bit strings as output whose distribution conforms with the one we expect from the unitary.

UnitaryZXSampling
Input: A ZX-diagram D with n inputs and outputs and at most k wires and/or spiders.
Promise: The operator denoted by D is proportional to some unitary U.
Output: A sample $x \in \{0,1\}^n$ from a probability distribution, given by (or sufficiently close to) $|\langle x|U|0\cdots 0\rangle|^2$.

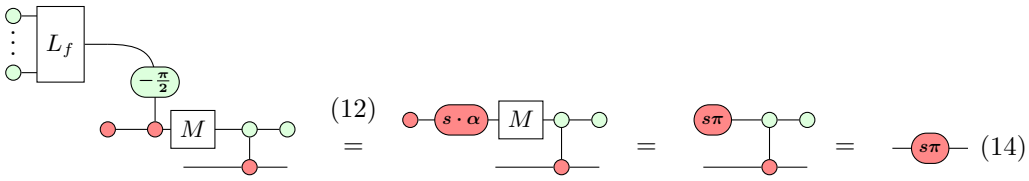
It is clear that **UnitaryZXSampling** is at least as hard as **BQP**: we could just input a ZX-diagram that directly represents a quantum circuit, in which case this problem is equivalent to simulating that circuit. The reason we write here that the probabilities just have to be "sufficiently close" is because the exact number doesn't matter for the following theorem. (For instance: we could allow the probability to additively deviate by 1/3 from the true value.)

▶ **Theorem 4.3.** *There is a randomised polynomial reduction from* **NP** *to* **UnitaryZX-Sampling**. *In other words: with access to a* **PromiseUnitaryZXSampling** *oracle – which produces the expected output if the input diagram is unitary and arbitrary output otherwise – we can with high probability solve* **NP***-complete problems.*

Proof. **SAT** is an **NP**-complete problem. To randomly reduce **NP** it however suffices to consider the problem **USAT** by the Valiant–Vazirani theorem [45]. **USAT** asks us to determine whether a Boolean formula is satisfiable, given the promise that it has at most one solution. Using the randomised reduction from **SAT** to **USAT**, we consider how to solve **USAT** using a **PromiseUnitaryZXSampling** oracle.

Let $f : \{0,1\}^n \to \{0,1\}$ be a Boolean formula that has at most one solution. Construct the diagram Eq. (11) as in the previous proofs: as a unitary this implements the identity iff f is not satisfiable, and X_α for some fixed angle $\alpha > 0$ when f is satisfiable. In the latter case, the value of α is exponentially small, but known precisely, as f has exactly one solution in this case. So we can say the circuit implements $X_{s\cdot\alpha}$ where $s \in \{0,1\}$ encodes whether f is satisfiable or not.

Let M be the one-qubit (non-unitary) matrix that maps $|0\rangle \mapsto |0\rangle$ and $X_\alpha|0\rangle \mapsto |1\rangle$, so that in particular $MX_{s\cdot\alpha}|0\rangle = |s\rangle$. By universality of ZX-diagrams we can find some (constant sized) diagram to represent M. We can then calculate:



Here the last step is just spider fusion (9). We see then that the ZX-diagram on the left in Eq. (14) implements either the identity, or an X_π operation (that is to say, a NOT operation), depending on whether f is satisfiable. When we feed this ZX-diagram to an oracle for **PromiseUnitaryZXSampling**, we get either the output `0` or `1`, where a `0` indicates with high probability that the circuit is the identity, and a `1` indicates that the circuit is a NOT operation. We can repeatedly call the oracle to get additional samples to increase our confidence in the result.

Now suppose f is a general instance of **SAT**, which may have more than one solution. Using the Valiant–Vazirani reduction multiple times we probabilistically produce different Boolean formulae $f_1, \ldots, f_m$. If f is not satisfiable, then none of the f_j will be satisfiable either and this is what the **PromiseUnitaryZXSampling** will tell us as well. If f *is* satisfiable, then a significant fraction of the f_j will have a unique solution, so that our oracle tells us they are satisfiable. For the other f_j the oracle will return some arbitrary output. So by picking m large enough there will with high probability be some f_j that will be uniquely satisfiable, and so we can conclude that f is satisfiable as well.

Hence, we can determine with arbitrary high probability whether a **SAT** instance is satisfiable using enough calls to **PromiseUnitaryZXSampling**. ◀

▶ Remark 4.4. For **ApproxCircuitExtraction** we allowed a polynomial dependence on $\log 1/\varepsilon$ for the circuit size. We believe this is reasonable as the Solovay–Kitaev algorithm allows you to find a $\mathrm{poly}(\log 1/\varepsilon)$-sized circuit when approximating a unitary. However, one can also consider the hardness of the problem when we allow the circuit size to depend on $\mathrm{poly}(1/\varepsilon)$, or even when the circuit size does not depend at all on the error. One might suspect that this could change the hardness of the problem. (As an analogy: one may compute the permanent of an $n \times n$ matrix with positive entries to within a multiplicative error of ε in time $\mathrm{poly}(n, 1/\varepsilon)$ [32], despite the exact problem being **#P**-complete.) However, note that if we can approximately do circuit extraction up to some *constant* error (say $\varepsilon = 1/10$), we can feed the resulting circuit to a quantum computer in order to solve **UnitaryZXSampling**. Hence, even if we were to relax **ApproxCircuitExtraction** to allow an output circuit of size $\mathrm{poly}(1/\varepsilon)$, an efficient algorithm for **ApproxCircuitExtraction** would imply that **NP** $\subseteq$ **BQP** by Theorem 4.3.

▶ Remark 4.5. If we knew that the number of solutions to the **SAT** instance was some other fixed number, then we could pick a different matrix M' to boost the state up to X_π gate as in the proof of Theorem 4.3. If we pick M' "slightly wrong", then the resulting diagram will just be close to X_π. One might think that we could use such a procedure to try and determine the number of solutions to f by doing binary search on the number of solutions, and so boost the power of **UnitaryZXSampling** to **#P**. However, the problem with this is that the resulting diagrams are not proportional to a unitary most of the time. There might be some way around this issue, so that **UnitaryZXSampling** is still **#P**-hard: we leave this as an open problem.

▶ Remark 4.6. Note that if we were to consider a version of **UnitaryZXSampling**, without the promise of unitarity, such an oracle would be as powerful as **PostBQP**, since we can represent any ZX-diagram as a post-selected quantum circuit (and conversely). In our case, the power again comes not so much from postselection, as being able to take advantage of the versatility of ZX-diagrams to gain access, in some way, to extract very precise information regarding a **#P** problem.

5 Upper bounding the complexity of CircuitExtraction

Given that **CircuitExtraction** is **#P**-hard, one might ask whether or not the problem is **#P**-complete (or more precisely: $\mathbf{FP}^{\mathbf{\#P}}$-complete since we are not making a decision but rather outputting a circuit), in the sense that a Turing machine with access to a **#P** oracle would be able to solve it, for some given polynomial upper bound on circuit size and some given gate-set (perhaps with suitable restrictions), in polynomial time. We have not managed to prove such a completeness result. We will however present the following upper bounds on decision problem versions of circuit extraction, relying on techniques from [2] that relate calculating amplitudes of quantum circuits to counting complexity problems.

First, consider the following decision problem: given a ZX-diagram, and a circuit, determine whether the circuit implements a unitary which is proportional to that represented by the ZX-diagram (whether by a factor of $\mathrm{e}^{i\theta}$ for some angle θ, or a more general complex number). This problem is in $\mathbf{coNP}^{\mathbf{\#P}}$. To sketch why this is, consider a circuit C representing a unitary U, and a ZX diagram D representing an operator V. If a_0 and a_1 are two non-zero coefficients from U, and b_0 and b_1 are the corresponding (non-zero) pair of coefficients from the matrix V represented by D, then $U \propto V$ only if $a_0/b_0 = a_1/b_1$ for all possible such pairs. We also require that for any coefficient a in U which is zero, the corresponding coefficient b of V is also zero. Taken together, this implies that for all corresponding pairs of coefficients of U and V we should have $a_0 b_1 = a_1 b_0$. This is also sufficient for $U \propto V$ to hold. Now, a **#P** oracle allows one to calculate coefficients[2] of ZX-diagrams and circuits. Hence, if $U \not\propto V$, an NTM with access to a **#P** oracle can non-deterministically find a witness that these two operators are not in fact proportional to one another. Thus, determining whether a circuit does *not* represent a unitary which is denoted (up to scalar factors) by a ZX-diagram, is in $\mathbf{NP}^{\mathbf{\#P}}$.

The above result has a simple corollary: determining whether a ZX-diagram is proportional to a unitary itself belongs to $\mathbf{coNP}^{\mathbf{\#P}}$. We may see this by the fact that a ZX-diagram denoting an operator V, which is proportional to a unitary, satisfies $VV^\dagger \propto I$. We may

[2] In this case, it is not necessary to compute complete information about a_0, a_1, b_0, and b_1: it suffices to compute information about individual components of the products $a_0 b_1$ and $a_1 b_0$ when considering these as numbers in some number field over $\mathbb{Q}$. See Ref. [2] for the details.

represent $VV^\dagger$ by composing the diagram D with its adjoint (which is the left-to-right mirror image of D, with all phase angles negated). This composite diagram may easily be computed, at which point we may ask whether the operator it represents is proportional to the identity by a non-zero scalar factor. As we note above, this problem is in $\mathbf{coNP}^{\#\mathbf{P}}$.

Finally, using these ideas, we may consider the decision problem of determining for a ZX-diagram D denoting an operator V and some gate set $\mathcal{G}$ and polynomial length bound N, whether *there exists* a circuit of at most N gates over $\mathcal{G}$ which implements V (up to a scalar). This problem is in $\mathbf{NP}^{\mathbf{NP}^{\#\mathbf{P}}}$: for an NTM with access to an $\mathbf{NP}^{\#\mathbf{P}}$ oracle, it suffices to make a nondeterministic guess at a circuit of length N (where each gate may be the identity operator, or some gate $G \in \mathcal{G}$ acting on a non-deterministically chosen set of qubits) and then query the oracle to determine whether the circuit realises V. A deterministic Turing machine, with access to an oracle for this problem, could then solve **CircuitExtraction** in polynomial time using standard techniques, using the oracle to facilitate a search for a circuit to realise D.

These observations represent the most straightforward approach to determining an upper bound for the circuit extraction problem, and seem to place it at a level of complexity significantly higher than $\mathbf{P}^{\#\mathbf{P}}$. If we conceive of **#P** as broadly representing the complexity of evaluating a tensor network, a superficial analogy between **CircuitExtraction** and boolean circuit minimisation [25, 7] would seem to suggest that **CircuitExtraction** is likely to be hard for some complexity class higher than $\mathbf{P}^{\#\mathbf{P}}$ (barring some collapse of complexity classes).

6 Conclusion

In this paper we studied the problem of extracting a quantum circuit description from a unitary ZX-diagram. We've shown that this problem is **#P**-hard by reducing **#SAT** to an application of circuit extraction. We've also studied some variations where we allow auxiliary qubits, classical control, and/or approximate synthesis of the desired unitary, and have shown that these problems are also **#P**-hard. In addition, we studied the hardness of a machine that takes in a unitary ZX-diagram and outputs measurement samples from that ZX-diagram, and have shown that such a machine allows one to probabilistically solve **NP**-hard problems.

A conclusion to be drawn from our results is that if we want some efficient procedure to transform a unitary ZX-diagram into a quantum circuit, then we will have to have some additional information about the structure of the ZX-diagram. In the known procedures for efficient circuit extraction [4, 41, 19], this additional information takes the form of a kind of "flow" on the diagram that prevents parts of the diagram from becoming too unwieldy. An immediate question then is if there are other types of, more general, promises on the structure of the diagram which then allow you to extract a circuit from it.

Aaronson showed that sampling from a post-selected quantum circuit is hard [1]. Our results imply that some other tasks surrounding *unitary* post-selected circuits (that is, circuits which perform a unitary transformation conditioned on some post-selection) are hard. However, this hardness seems to stem not from the post-selection itself, as the post-selections can be simulated with high probability in our case. Rather, the hardness seems to stem from a hypothetical ability to find an equivalent, deterministic way to realise the same operation – which implies an ability to extract difficult-to-access information about the input diagram.

A question related to circuit extraction from ZX-diagrams is circuit extraction from deterministic measurement patterns (in for instance the one-way model or lattice surgery). When we have a deterministic measurement pattern, we can represent each branch of the computation by a ZX-diagram denoting a unitary. Our hardness proof does however not

immediately translate to this setting, as it might be that the fact that all of these ZX-diagrams are branches of the same measurement pattern forces some kind of structure on the diagrams that might make it easier to rewrite them into circuits. The diagrams we used to show hardness of circuit extraction are as far as we are aware not representable as branches of some deterministic measurement pattern, so that we can't use the same proof. We leave it for future work to determine the hardness of extracting unitary circuits from deterministic measurement patterns.

Hiding Pebbles When the Output Alphabet Is Unary

Gaëtan Douéneau-Tabot
IRIF, Université Paris Cité & Direction générale de l'armement – Ingénierie de projets, France

Abstract

Pebble transducers are nested two-way transducers which can drop marks (named "pebbles") on their input word. Blind transducers have been introduced by Nguyên et al. as a subclass of pebble transducers, which can nest two-way transducers but cannot drop pebbles on their input.

In this paper, we study the classes of functions computed by pebble and blind transducers, when the output alphabet is unary. Our main result shows how to decide if a function computed by a pebble transducer can be computed by a blind transducer. We also provide characterizations of these classes in terms of Cauchy and Hadamard products, in the spirit of rational series. Furthermore, pumping-like characterizations of the functions computed by blind transducers are given.

1 Introduction

Transducers are finite-state machines obtained by adding outputs to finite automata. In this paper, we assume that these machines are always deterministic and have finite inputs, hence they compute functions from finite words to finite words. In particular, a *deterministic two-way transducer* consists of a two-way automaton which can produce outputs. This model computes the class of *regular functions*, which is often considered as one of the functional counterparts of *regular languages*. It has been largely studied for its numerous regular-like properties: closure under composition [4], equivalence with logical transductions [9] or regular transducer expressions [5], decidable equivalence problem [11], etc.

Pebble transducers and blind transducers. Two-way transducers can only describe functions whose output size is at most linear in the input size. A possible solution to overcome this limitation is to consider nested two-way transducers. In particular, the nested model of *pebble transducers* has been studied for a long time (see e.g. [10, 8]).

A *k-pebble transducer* is built by induction on $k \geq 1$. For $k = 1$, a 1-pebble transducer is just a two-way transducer. For $k \geq 2$, a k-pebble transducer is a two-way transducer that, when on any position i of its input word, can launch a $(k-1)$-pebble transducer. This submachine works on the original input where position i is marked by a "pebble". The original two-way transducer then outputs the concatenation of all the outputs returned by the submachines that it has launched along its computation. The intuitive behavior of a 3-pebble transducer is depicted in Figure 2. It can be seen as program with 3 nested loops. The class of word-to-word functions computed by k-pebble transducers for some $k \geq 1$ is

known as *polyregular functions*. It has been quite intensively studied over the past few years due to its regular-like properties such as closure under composition [8], equivalence with logical interpretations [3] or other transducer models [2], etc.

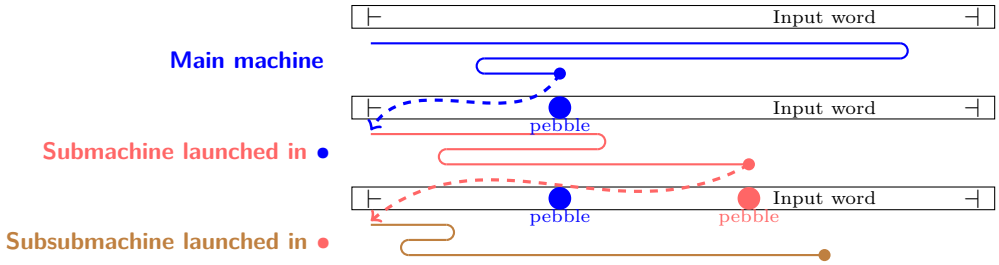

Figure 1 Behavior of a 3-pebble transducer.

A subclass of pebble transducers named *blind transducers* was recently introduced in [13]. For $k = 1$, a 1-blind transducer is just a two-way transducer. For $k \geq 2$, a k-blind transducer is a two-way transducer that can launch a $(k-1)$-blind transducer like a k-pebble transducer. However, there is no pebble marking the input of the submachine (i.e. it cannot see the position i from which it was called). The behavior of a 3-blind transducer is depicted in Figure 2. It can be seen as a program with 3 nested loops which cannot see the upper loop indexes. We call *polyblind functions* the class of functions computed by blind transducers. It is closed under composition and deeply related to lambda-calculus [12].

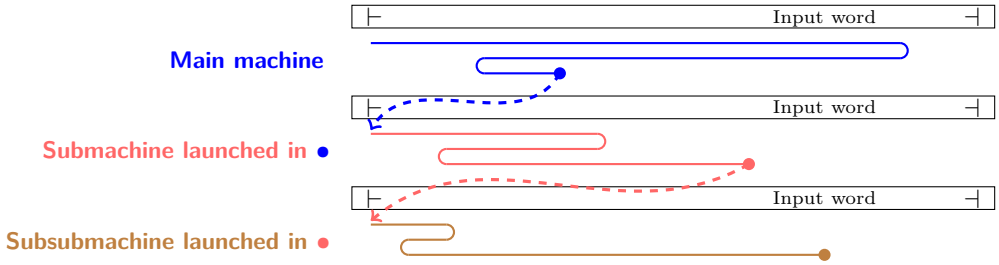

Figure 2 Behavior of a 3-blind transducer.

We study here polyregular and polyblind functions whose output alphabet is unary. Up to identifying a word with its length, we thus consider functions from finite words to $\mathbb{N}$. With this restriction, we show that one can decide if a polyregular function is polyblind, and connect these classes of functions to *rational series*.

Relationship with rational series. Rational series over the semiring $(\mathbb{N}, +, \times)$. are a well-studied class of functions from finite words to $\mathbb{N}$. They can be defined as the closure of (unary output) regular functions under sum $+$, Cauchy product $\copyright$ (product for formal power series) and Kleene star $*$ (iteration of Cauchy products). It is also well known that rational series are closed under Hadamard product $\circledH$ (component-wise product) [1].

The first result of this paper states that polyregular functions are exactly the subclass of rational series "without star", that is the closure of regular functions under $+$ and $\copyright$ ($\circledH$ can also be used but it is not necessary). This theorem is obtained by combining several former works. Our second result establishes that polyblind functions are exactly the closure of regular functions under $+$ and $\circledH$. It is shown in a self-contained way.

The aforementioned classes are depicted in Figure 3. All the inclusions are strict and this paper provides a few separating examples (some of them were already known in [6]).

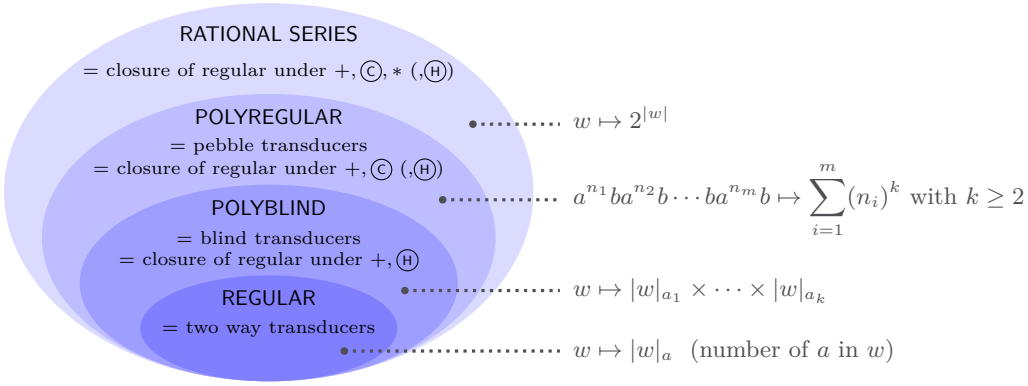

Figure 3 Classes of functions from finite words to $\mathbb{N}$ studied in this paper.

Class membership problems. We finally show how to decide whether a polyregular function with unary output is polyblind. It is by far the most involved and technical result of this paper. Furthermore, the construction of a blind transducer is effective, hence this result can be viewed as program optimization. Indeed, given a program with nested loops, our algorithm is able to build an equivalent program using "blind" loops if it exists.

In general, decision problems for transductions are quite difficult to solve, since contrary to regular languages, there are no known "canonical" objects (such as a minimal automaton) to represent (poly)regular functions. It is thus complex to decide an intrinsic property of a function, since it can be described in several seemingly unrelated manners. Nevertheless, the membership problem from rational series to polyregular (resp. regular) functions was shown to be decidable in [7, 6]. It is in fact equivalent to checking if the output of the rational series is bounded by a polynomial (resp. a linear function) in its input's length.

However, both polyregular and polyblind functions can have polynomial growth rates. To discriminate between them, we thus introduce the new notion of *repetitiveness* (which is a pumping-like property for functions) and show that it exactly captures the polyregular functions that are polyblind. The proof is a rather complex induction on the depth $k \geq 1$ of the k-pebble transducer representing the function. We show at the same time that repetitiveness is decidable and that a blind transducer can effectively be built whenever this property holds. Partial results were obtained in [6] to decide "blindness" of the functions computed by 2-pebble transducers. Some of our tools are inspired by this paper, such as the use of bimachines and factorization forests. Nevertheless, our general result requires new proof techniques (e.g. the induction techniques which insulate the term of "highest growth rate" in the function) and concepts (e.g. repetitiveness).

Outline. We first describe in Section 2 the notions of pebble and blind transducers. In the case of unary outputs, we recall the equivalent models of pebble, marble and blind bimachines introduced in [6]. These bimachines are easier to handle in the proofs, since they manipulate a monoid morphism instead of having two-way moves. In Section 3 we recall the definitions of sum $+$, Cauchy product Ⓒ, Hadamard product Ⓗ and Kleene star $*$ for rational series. We then show how to describe polyregular and polyblind functions with these operations. Finally, we claim in Section 4 that the membership problem from polyregular to polyblind functions is decidable. The proof of this technical result is sketched in sections 5 and 6. Due to space constraints we focus on the most significant lemmas.

2 Preliminaries

$\mathbb{N}$ is the set of nonnegative integers. If $i \leq j$, the set $[i{:}j]$ is $\{i, i{+}1, \dots, j\} \subseteq \mathbb{N}$ (empty if $j < i$). The capital letter A denotes an alphabet, i.e. a finite set of letters. The empty word is denoted by ε. If $w \in A^*$, let $|w| \in \mathbb{N}$ be its length, and for $1 \leq i \leq |w|$ let $w[i]$ be its i-th letter. If $I = \{i_1 < \cdots < i_\ell\} \subseteq [1{:}|w|]$, let $w[I] \coloneqq w[i_1] \cdots w[i_\ell]$. If $a \in A$, let $|w|_a$ be the number of letters a occurring in w. We assume that the reader is familiar with the basics of automata theory, in particular one-way and two-way automata, and monoid morphisms.

Two-way transducers. A deterministic two-way transducer is a deterministic two-way automaton (with input in A^*) enhanced with the ability to produce outputs (from B^*) when performing a transition. The output of the transducer is defined as the concatenation of these productions along the unique accepting run on the input word (if it exists): it thus describes a (partial) function $A^* \to B^*$. Its behavior is depicted in Figure 4. A formal definition can be found e.g. in [6]. These machines compute the class of *regular functions*.

Figure 4 Behavior of a two-way transducer.

▶ **Example 2.1.** The function $a_1 \cdots a_n \mapsto a_1 \cdots a_n \# a_n \cdots a_1$ can be computed by a two-way transducer which reads its input word from left to right and then from right to left.

From now on, the output alphabet B of our machines will always be a singleton. By identifying B^* and $\mathbb{N}$, we assume that the functions computed have type $A^* \to \mathbb{N}$.

▶ **Example 2.2.** Given $a \in A$, the function $\mathsf{nb}_a : A^* \to \mathbb{N}, w \mapsto |w|_a$ is regular.

Blind and pebble transducers. Blind and pebble transducers extend two-way transducers by allowing to "nest" such machines. A 1-blind (resp. 1-pebble) transducer is just a two-way transducer. For $k \geq 2$, a k-blind (resp. k-pebble) transducer is a two-way transducer which, when performing a transition from a position $1 \leq i \leq |w|$ of its input $w \in A^*$, can launch a $(k{-}1)$-blind (resp. $(k{-}1)$-pebble) transducer with input w (resp. $w[1{:}i{-}1]\underline{w[i]}w[i{+}1{:}|w|]$ i.e. w where position i is marked). The two-way transducer then uses the output of this submachine as if it was the output produced along its transition. The intuitive behaviors are depicted for $k = 3$ in figures 1 and 2. Formal definitions can be found e.g. in [13, 6].

▶ **Example 2.3.** Let $a_1, \dots, a_k \in A$, then $\mathsf{nb}_{a_1,\dots,a_k} : w \mapsto |w|_{a_1} \times \cdots \times |w|_{a_k}$ can be computed by a k-blind transducer. The main transducer processes its input from left to right, and it calls inductively a $(k{-}1)$-blind transducer for $\mathsf{nb}_{a_1,\dots,a_{k-1}}$ each time it it sees an a_k.

▶ **Example 2.4.** The function $2\text{-}\mathsf{powers} : a^{n_1} b \cdots a^{n_m} b \mapsto \sum_{i=1}^{m} n_i^2$ can be computed by a 2-pebble transducer. Its main transducer ranges over all the a of the input, and calls a 1-pebble (= two-way) transducer for each a, which produces n_i if the a is in the i-th block (it uses the pebble to detect which block is concerned). Similarily, the function $k\text{-}\mathsf{powers} : a^{n_1} b \cdots a^{n_m} b \mapsto \sum_{i=1}^{m} n_i^k$ for $k \geq 1$ can be computed by a k-pebble transducer.

▶ **Definition 2.5.** *We define the class of* polyregular functions *(resp.* polyblind functions*) as the class of functions computed by a k-pebble (resp. k-blind) transducer for some $k \geq 1$.*

It is not hard to see that polyblind functions are a subclass of polyregular functions. Indeed, a blind transducer is just a pebble transducer "without pebbles".

Bimachines. In this paper, we shall describe formally the regular, polyregular and polyblind functions with another computation model. A *bimachine* is a transducer which makes a single left-to-right pass on its input, but it can use a morphism into a finite monoid to check regular properties of the prefix (resp. suffix) ending (resp. starting) in the current position. This notion of bimachines enable us to easily use algebraic techniques in the proofs, and in particular *factorization forests* over finite monoids.

▶ **Definition 2.6.** *A bimachine* $\mathcal{M} \coloneqq (A, M, \mu, \lambda)$ *is:*

- *an input alphabet* A*, a finite monoid* M *and a monoid morphism* $\mu : A^* \to M$*;*
- *an output function* $\lambda : M \times A \times M \to \mathbb{N}$*.*

$\mathcal{M}$ computes $f : A^* \to \mathbb{N}$ defined by $f(w) \coloneqq \sum_{i=1}^{|w|} \lambda(\mu(w[1{:}i{-}1]), w[i], \mu(w[i{+}1{:}|w|]))$ for $w \in A^*$. The production of each term of this sum is depicted intuitively in Figure 5.

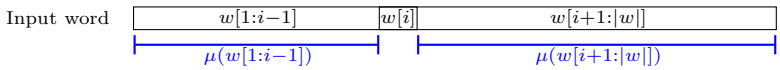

Figure 5 Behavior of a bimachine when producing $\lambda(\mu(w[1{:}i{-}1]), w[i], \mu(w[i{+}1{:}|w|]))$.

When dealing with bimachines, we consider without loss of generality total functions such that $f(\varepsilon) = 0$ (the domains of two-way transducers are regular languages [14], and the particular image of ε does not matter). In this context, it is well known that regular functions of type $A^* \to \mathbb{N}$ are exactly those computed by bimachines (in other words, it means that regular functions and rational functions are the same). Now we recall how [6] has generalized this result to k-blind and k-pebble transducers. Intuitively, a *bimachine with external functions* is a bimachine enriched with the possibility to launch a submachine for each letter of the input (it outputs the sum of all the outputs returned by these submachines).

▶ **Definition 2.7** ([6])**.** *A* bimachine with external pebble (*resp.* external blind*, resp.* external marble) functions $\mathcal{M} = (A, M, \mu, \mathfrak{H}, \lambda)$ *consists of:*

- *an input alphabet* A*;*
- *a finite monoid* M *and a morphism* $\mu : A^* \to M$*;*
- *a finite set* $\mathfrak{H}$ *of external functions* $\mathfrak{h} : (A \uplus \underline{A})^* \to \mathbb{N}$ *(resp.* $A^* \to \mathbb{N}$*, resp.* $A^* \to \mathbb{N}$*);*
- *an output function* $\lambda : M \times A \times M \to \mathfrak{H}$*.*

Given $1 \leq i \leq |w|$ a position of $w \in A^*$, let $\mathfrak{h}_i \coloneqq \lambda(\mu(w[1{:}i{-}1]), w[i], \mu(w[i{+}1{:}|w|])) \in \mathfrak{H}$. A bimachine $\mathcal{M}$ with external pebble functions computes a function $f : A^* \to \mathbb{N}$ defined by $f(w) \coloneqq \sum_{1 \leq i \leq |w|} \mathfrak{h}_i(w[1{:}i{-}1]\underline{w[i]}w[i{+}1{:}|w|])$. Intuitively, it means that for each position $1 \leq i \leq |w|$, $\mathcal{M}$ calls an external function $\mathfrak{h}_i$ (depending on a regular property of $w[1{:}i{-}1]$,$w[i]$ and $w[i{+}1{:}|w|]$) with input $w[1{:}i{-}1]\underline{w[i]}w[i{+}1{:}|w|]$ (that is "w with a pebble on position i"), and uses the result $\mathfrak{h}_i(w[1{:}i{-}1]\underline{w[i]}w[i{+}1{:}|w|])$ of this function in its own output.

For a bimachine with external blind (resp. marble) functions, the output is defined by $f(w) \coloneqq \sum_{1 \leq i \leq |w|} \mathfrak{h}_i(w)$ (resp. $f(w) \coloneqq \sum_{1 \leq i \leq |w|} \mathfrak{h}_i(w[1{:}i])$). In this case $\mathcal{M}$ calls $\mathfrak{h}_i$ with argument w (resp. the prefix of w ending in position i).

▶ **Definition 2.8** ([6])**.** *Given* $k \geq 1$*, a* k*-pebble (resp.* k*-blind, resp.* k*-marble) bimachine is:*

- *for* $k = 1$*, a bimachine (withtout external functions, see Definition 2.6);*
- *for* $k \geq 2$*, it a bimachine with external pebble (resp. external blind, resp. external marble) functions (see Definition 2.7) which are computed by* $(k{-}1)$*-pebble (resp.* $(k{-}1)$*-blind, resp.* $(k{-}1)$*-marble) bimachines. These* $(k{-}1)$*-bimachines are implicitly fixed and given by the external functions of the main bimachine.*

▶ Remark 2.9. For pebble bimachines, a natural question is whether the inner bimachines can ask which pebble was dropped by which ancestor, or whether they can only see that "there is a pebble". Both models are in fact equivalent, since the number of pebbles is bounded.

Now we recall in Theorem 2.10 that pebble and blind bimachines are respectively equivalent to the aforementioned pebble and blind transducers. More interestingly, the marble bimachines (which call "prefixes") also correspond to pebble transducers. In our proofs, we shall preferentially use the marble model to represent polyregular functions.

▶ **Theorem 2.10** ([6]). *For all $k \geq 1$, k-pebble transducers, k-pebble bimachines and k-marble bimachines compute the same class of functions. Furthermore, k-blind transducers and k-blind bimachines compute the same class of functions.*

3 From pebbles to rational series

The class of *rational series* (which are total functions $A^* \to \mathbb{N}$) is the closure of regular functions under sum, Cauchy product and Kleene star. It is well known that it can be described by *weighted automata*, furthermore this class is closed under Hadamard product (see e.g. [1, Theorem 5.5]). Let us recall the definition of these operations for $f, g : A^* \to \mathbb{N}$:

- the sum $f + g : w \mapsto f(w) + g(w)$;
- the Cauchy product $f \copyright g : w \mapsto \sum_{i=0}^{|w|} f(w[1{:}i])g(w[i{+}1{:}|w|])$;
- the Hadamard product $f \hadamard g : w \mapsto f(w)g(w)$;
- if and only if $f(\varepsilon) = 0$, the Kleene star $f^* := \sum_{n \geq 0} f^n$ where $f^0 : \varepsilon \mapsto 1, u \neq \varepsilon \mapsto 0$ is neutral for Cauchy product and $f^{n+1} := f \copyright f^n$.

▶ **Example 3.1.** In Example 2.3 we have $\mathsf{nb}_{a_1,\dots,a_k} = \mathsf{nb}_{a_1} \hadamard \cdots \hadamard \mathsf{nb}_{a_k}$.

▶ **Example 3.2.** Let $f, g : \{a, b\}^* \to \mathbb{N}$ defined by $f(wa) = 2$ for $w \in A^*$ and $f(w) = 0$ otherwise; $g(a^n bw) = n$ for $w \in A^*$ and $g(w) = 0$ otherwise. It is easy to see that $f \copyright g(a^{n_1} b \cdots a^{n_m} b) = \sum_{i=1}^{m} n_i(n_i{-}1)$. Hence $2\text{-}\mathsf{powers} = \mathsf{nb}_a + f \copyright g$ (see Example 2.4).

We are now ready to state the first main results of this paper. The first one shows that polyregular functions correspond to the subclass of rational series where the use of star is disallowed (and it also corresponds to rational series whose "growth" is polynomial).

▶ **Theorem 3.3.** *Let $f : A^* \to \mathbb{N}$, the following conditions are (effectively) equivalent:*

1. *f is polyregular;*
2. *f is a rational series with polynomial growth, i.e. $f(w) = \mathcal{O}(|w|^k)$ for some $k \geq 1$;*
3. *f belongs to the closure of regular functions under sum and Cauchy product;*
4. *f belongs to the closure of regular functions under sum, Cauchy and Hadamard products.*

Proof sketch. $1 \Leftrightarrow 2$ follows from [7, 6]. For $2 \Rightarrow 3$, it is shown in [1, Exercise 1.2 of Chapter 9] that the rational series of polynomial growth can be obtained by sum and Cauchy products from the characteristic series of rational languages (which are regular functions). Having $3 \Rightarrow 4$ is obvious. Finally for $4 \Rightarrow 2$, it suffices to note that regular functions have polynomial growth, and this property is preserved by $+, \copyright$ and $\hadamard$. ◀

Note that Hadamard products do not increase the expressive power of this class. However, removing Cauchy products gives polyblind functions, as shown in Theorem 3.4.

▶ **Theorem 3.4.** *Let $f : A^* \to \mathbb{N}$, the following conditions are equivalent:*

1. *f is polyblind;*
2. *f belongs to the closure of regular functions under sum and Hadamard product.*

Proof sketch. We first show $1 \Rightarrow 2$ by induction on $k \geq 1$ when f is computed by a k-blind bimachine. For $k = 1$, it is obvious. Let us describe the induction step from $k \geq 1$ to $k+1$. Let f be computed by a bimachine $\mathcal{M} = (A, M, \mu, \mathfrak{H}, \lambda)$, with external blind functions computed by k-blind bimachines. Given $\mathfrak{h} \in \mathfrak{H}$, let $f'_{\mathfrak{h}}$ be the function which maps $w \in A^*$ to the cardinal $|\{1 \leq i \leq |w| : \lambda(\mu(w[1{:}i{-}1]), w[i], \mu(w[i{+}1{:}|w|])) = \mathfrak{h}\}|$. Then $f'_{\mathfrak{h}}$ is a regular function and $f = \sum_{\mathfrak{h} \in \mathfrak{H}} f'_{\mathfrak{h}} \circledH \mathfrak{h}$. The result follows by induction hypothesis.

For $2 \Rightarrow 1$, we show that functions computed by blind bimachines are closed under sum and Hadamard product. For the sum, we use the blind transducer model to simulate successively the computation of the two terms of a sum. For the Hadamard product, we show by induction on $k \geq 1$ that if f is computed by a k-blind bimachine and g is polyblind, then $f \circledH g$ is polyblind. If $k = 1$, we transform the bimachine for f in a blind bimachine computing $f \circledH g$ by replacing each output $n \in \mathbb{N}$ by a call to a machine computing $n \times g$. If $k \geq 2$, using the notations of the previous paragraph we have $f = \sum_{\mathfrak{h} \in \mathfrak{H}} f'_{\mathfrak{h}} \circledH \mathfrak{h}$, thus $f \circledH g = \sum_{\mathfrak{h} \in \mathfrak{H}} f'_{\mathfrak{h}} \circledH (\mathfrak{h} \circledH g)$. By induction hypothesis, each $\mathfrak{h} \circledH g$ is polyblind. Hence we compute $f \circledH g$ by replacing in $\mathcal{M}$ each external function $\mathfrak{h}$ by the function $\mathfrak{h} \circledH g$. ◀

We conclude this section by recalling that polyregular (resp. polyblind) functions with unary output enjoy a "pebble minimization" property, which allows to reduce the number of nested layers depending on the growth rate of the output.

▶ **Definition 3.5.** *We say that a function $f : A^* \to \mathbb{N}$ has* growth at most k *if $f(w) = \mathcal{O}(|w|^k)$.*

▶ **Theorem 3.6** ([7, 6, 13])**.** *A a polyregular (resp. polyblind) function f can be computed by a k-pebble (resp. k-blind) transducer if and only it has growth at most k. Furthermore this property can be decided and the construction is effective.*

▶ Remark 3.7. The result also holds for blind transducers with non-unary outputs [13]. However, it turns out to be false for pebble transducers with non-unary outputs (unpublished work of the author of [2]).

In the next section, we complete the decidability picture by solving the membership problem from polyregular to polyblind functions.

4 Membership problem from polyregular to polyblind

In this section, we state the most technical and interesting result of this paper, which consists in deciding if a polyregular function is polyblind. We also give in Theorem 4.6 a semantical characterization of polyregular functions which are polyblind, using the notion of *repetitiveness*. Intuitively, a k-repetitive function is a function which, when given two places in a word where the same factor is repeated, cannot distinguish between the first and the second place. Hence its output only depends on the total number of repetitions of the factor.

▶ **Definition 4.1** (Repetitive function)**.** *Let $k \geq 1$. We say that $f : A^* \to \mathbb{N}$ is* k-repetitive *if there exists $\eta \geq 1$, such that the following holds for all $\alpha, \alpha_0, u_1, \alpha_1, \ldots, u_k, \alpha_k, \beta \in A^*$ and $\omega \geq 1$ multiple of η. Let $W : \mathbb{N}^k \to A^*$ defined by:*

$$W : X_1, \ldots, X_k \mapsto \left(\alpha_0 \prod_{i=1}^{k} {u_i}^{\omega X_i} \alpha_i \right).$$

and let $w \coloneqq W(1, \ldots, 1)$. Then there exists a function $F : \mathbb{N}^k \to \mathbb{N}$ such that for all $\overline{X} \coloneqq X_1, \ldots, X_k \geq 3$ and $\overline{Y} \coloneqq Y_1, \ldots, Y_k \geq 3$, we have:

$$f(\alpha w^{2\omega-1} W(\overline{X}) w^{\omega-1} W(\overline{Y}) w^{\omega} \beta) = F(X_1 + Y_1, \ldots, X_k + Y_k).$$

▶ Remark 4.2. If f is k-repetitive, f is also $(k-1)$-repetitive, by considering an empty u_k.

Let us now give a few examples in order so see when this criterion holds, or not.

▶ **Example 4.3.** The function $\mathsf{nb}_{a_1,\dots,a_k}$ (see Example 2.3) is k-repetitive for all $k \geq 1$.

▶ **Example 4.4.** If $f : A^* \to \mathbb{N}$ where $A = \{a\}$ is a singleton, then f is k-repetitive for all $k \geq 1$. Indeed, $\alpha w^{2\omega-1} W(\overline{X}) w^{\omega-1} W(\overline{Y}) w^\omega \beta \in A^*$ is itself a function of $X_1+Y_1, \dots, X_k+Y_k$, hence so is its image $f(\alpha w^{2\omega-1} W(\overline{X}) w^{\omega-1} W(\overline{Y}) w^\omega)$.

▶ **Example 4.5.** For all $k \geq 2$, the function $k\text{-powers} : a^{n_1} b \cdots a^{n_m} b \mapsto \sum_{i=1}^m n_i^k$ is not 1-repetitive. Let us choose any $\omega \geq 1$ and fix $\alpha = \beta := \varepsilon$, $u_1 := a$ and $\alpha_0 = \alpha_1 := b$, then:

$$\begin{aligned} k\text{-powers}(W(X_1, Y_1)) &= k\text{-powers}\left((ba^\omega b)^{2\omega-1} b a^{\omega X_1} b (ba^\omega b)^{\omega-1} b a^{\omega Y_1} b (ba^\omega b)^\omega\right) \\ &= \omega^k(4\omega - 2) + \omega^k X_1^k + \omega^k Y_1^k \end{aligned}$$

which is *not* a function of $X_1 + Y_1$ for $k \geq 2$.

We are now ready to state our main result of this paper.

▶ **Theorem 4.6.** *Let $k \geq 1$ and $f : A^* \to \mathbb{N}$ be computed by a k-pebble transducer. Then f is polyblind if and only if it is k-repetitive. Furthermore, this property can be decided and one can effectively build a blind transducer for f when it exists.*

▶ Remark 4.7. By Theorem 3.6, we can even build a k-blind transducer.

Theorem 4.6 provides a tool to show that some polyregular functions are not polyblind:

▶ **Example 4.8.** By Example 4.5, the polyregular function $k\text{-powers}$ is not k-repetitive for $k \geq 2$. Therefore it is not polyblind. Also note that it is computable by a k-pebble transducer, but not by an ℓ-pebble transducer for $\ell < k$ (Theorem 3.6).

An immediate consequence of Theorem 4.6 is obtained below for functions which have both a unary output alphabet and a unary input alphabet. This result was already obtained by the authors of [13] using other techniques, in an unpublished work.

▶ **Corollary 4.9.** *Polyblind and polyregular functions over a unary input alphabet coincide.*

Proof. Polyregular functions with unary input are k-repetitive by Example 4.4. ◀

5 Repetitive functions and permutable bimachines

The rest of this paper is devoted to the proof of Theorem 4.6. Since k-pebble transducers and k-marble bimachines compute the same functions (Theorem 2.10), it follows directly from Theorem 5.1 below (the notions used are defined in the next sections).

From now on, we assume that a k-marble bimachine uses the same morphism $\mu : A^* \to M$ in its main bimachine, and inductively in all its submachines computing the external functions. We do not lose any generality here, since it is always possible to get this situation by taking the product of all the morphisms used. We also assume that μ is surjective (we do no lose any generality, since it is possible to replace M by the image $\mu(M)$).

▶ **Theorem 5.1.** *Let $k \geq 2$ and $f : A^* \to \mathbb{N}$ be computed by $\mathcal{M} = (A, M, \mu, \mathfrak{H}, \lambda)$ a k-marble bimachine. The following conditions are equivalent:*

1. *f is polyblind;*
2. *f is k-repetitive;*
3. *$\mathcal{M}$ is $2^{3|M|}$-permutable (see Definition 5.11) and the function f'' (built from Proposition 6.1) is polyblind.*

Furthermore this property is decidable and the construction is effective.

Let us now give the skeleton of the proof of Theorem 5.1, which is rather long and involved. The propositions on which it relies are shown in the two following sections.

Proof of Theorem 5.1. $1 \Rightarrow 2$ follows from Proposition 5.2. For $2 \Rightarrow 3$, if f is k-repetitive then $\mathcal{M}$ is $2^{3|M|}$-permutable by Proposition 5.12. Then Proposition 6.1 gives $f = f' + f''$ where f' is polyblind and f'' is computable by a $(k-1)$-marble bimachine. By Proposition 5.2, f' is $(k-1)$-repetitive. Since f is also $(k-1)$-repetitive, then $f'' = f - f'$ is also $(k-1)$-repetitive by Claim 5.3. Thus by induction hypothesis f'' is polyblind. For $3 \Rightarrow 1$, since in Proposition 6.1 we have $f = f' + f''$ where f' and f'' are polyblind, then f is (effectively) polyblind. The decidability is also obtained by induction: one has to check that $\mathcal{M}$ is $2^{3|M|}$-permutable (which is decidable) and inductively that f'' is polyblind. ◀

Now we present the tools used in this proof. We first show that polyblind functions are repetitive. Then we introduce the notion of *permutability*, and show that repetitive functions are computed by permutable marble bimachines.

5.1 Polyblind functions are repetitive

Intuitively, a blind transducer cannot distinguish between two "similar" iterations of a given factor in a word, since it cannot drop a pebble for doing so. We get the following using technical but conceptually easy pumping arguments.

▶ **Proposition 5.2.** *A polyblind function is k-repetitive for all $k \geq 1$.*

Proof idea. We first show that a regular function (computed by a bimachine without external functions) is k-repetitive for all $k \geq 1$. In this case, η is chosen as the idempotent index of the monoid used by the bimachine. Then, it is easy to conclude by noting that k-repetitiveness is preserved under sums and Hadamard products. ◀

The induction which proves Theorem 5.1 also requires the following result. Its proof is obvious since k-repetitiveness is clearly preserved under subtractions.

▷ Claim 5.3. If f, g are k-repetitive and $f - g \geq 0$, then it is k-repetitive.

5.2 Repetitive functions are computed by permutable machines

In this subsection, we show that k-marble bimachines which compute k-repetitive functions have a specific property named *permutability* (which turns out to be decidable).

Productions. We first introduce the notion of *production*. In the rest of this paper, the notation $\{\!\{\cdots\}\!\}$ represents a multiset (i.e. a set with multiplicities). If S is a set and m is a multiset, we write $m \subseteq S$ to say that each element of m belongs to S (however, there can be multiplicities in m but not in S). For instance $\{\!\{1, 1, 2, 3, 3\}\!\} \subseteq \mathbb{N}$.

▶ **Definition 5.4** (Production). *Let $\mathcal{M} = (A, M, \mu, \mathfrak{H}, \lambda)$ be a k-marble bimachine, $w \in A^*$. We define the* production *of $\mathcal{M}$ on $\{\!\{i_1, \dots, i_k\}\!\} \subseteq [1{:}|w|]$ as follows if $i_1 \leq \cdots \leq i_k$:*

- *if $k = 1$, $\mathsf{prod}^w_{\mathcal{M}}(\{\!\{i_1\}\!\}) \coloneqq \lambda(\mu(w[1{:}i_1{-}1]), w[i_1], \mu(w[i_1{+}1{:}|w|])) \in \mathbb{N}$;*
- *if $k \geq 2$, let $\mathfrak{h} \coloneqq \lambda(\mu(w[1{:}i_k{-}1]), w[i_k], \mu(w[i_k{+}1{:}|w|])) \in \mathfrak{H}$ and $\mathcal{M}_{\mathfrak{h}}$ be the $(k{-}1)$-marble bimachine computing $\mathfrak{h}$. Then $\mathsf{prod}^w_{\mathcal{M}}(\{\!\{i_1, \cdots, i_k\}\!\}) \coloneqq \mathsf{prod}^{w[1:i_k]}_{\mathcal{M}_{\mathfrak{h}}}(\{\!\{i_1, \dots, i_{k-1}\}\!\})$.*

The value $\mathsf{prod}^w_{\mathcal{M}}(\{\!\{i_1, \cdots, i_k\}\!\})$ with $i_1 \leq \cdots \leq i_k$ thus corresponds to the value output when doing a call on position i_k, then on i_{k-1}, etc. Now let $\{\!\{I_1, \dots, I_k\}\!\}$ be a multiset of sets of positions of w (i.e. for all $1 \leq i \leq k$ we have $I_i \subseteq [1{:}|w|]$). We define the production of $\mathcal{M}$ on $\{\!\{I_1, \dots, I_k\}\!\}$ as the combination of all possible productions on positions among these sets:

$$\mathsf{prod}^w_{\mathcal{M}}(\{\!\{I_1, \dots, I_k\}\!\}) \coloneqq \sum_{\substack{\{\!\{i_1,\dots,i_k\}\!\} \subseteq [1:|w|] \\ \text{with } i_j \in I_j \text{ for } 1 \leq j \leq k}} \mathsf{prod}^w_{\mathcal{M}}(\{\!\{i_1, \dots, i_k\}\!\}).$$

▶ Remark 5.5. Note that we no longer have $i_1 \leq \cdots \leq i_k$.

By rewriting the sum which defines the function f from $\mathcal{M}$, we get the following.

▶ **Lemma 5.6.** *Let $\mathcal{M}$ be a k-marble bimachine computing a function $f : A^* \to \mathbb{N}$. Let $w \in A^*$ and $J_1, \dots J_n$ be a partition of $[1{:}|w|]$:*

$$f(w) = \sum_{\{\!\{I_1,\dots,I_k\}\!\} \subseteq \{J_1,\dots,J_n\}} \mathsf{prod}^w_{\mathcal{M}}(\{\!\{I_1, \dots, I_k\}\!\}).$$

Following the definition of bimachines, the production $\mathsf{prod}^w_{\mathcal{M}}(\{\!\{i_1, \cdots, i_k\}\!\})$ should only depend on $w[i_1], \dots, w[i_k]$ and of the image under μ of the factors between these positions. Now we formalize this intuition in a more general setting.

▶ **Definition 5.7** (Multicontext). *Given $x \geq 0$, an x-*multicontext *consists of two sequences of words $v_0, \cdots, v_x \in A^*$ and $u_1, \cdots, u_x \in A^*$. It is denoted $v_0[\![u_1]\!]v_1 \cdots [\![u_x]\!]v_x$.*

Let $w \coloneqq v_0u_1 \cdots u_kv_k \in A^*$. For $1 \leq i \leq k$, let $I_i \subseteq [1{:}|w|]$ be the set of positions corresponding to u_i. We define the production on the multicontext $v_0[\![u_1]\!]v_1 \cdots [\![u_k]\!]v_k$ by:

$$\mathsf{prod}_{\mathcal{M}}(v_0[\![u_1]\!]v_1 \cdots [\![u_k]\!]v_k) \coloneqq \mathsf{prod}^w_{\mathcal{M}}(\{\!\{I_1, \dots, I_k\}\!\}). \tag{1}$$

As stated in Proposition-Definition 5.8, this quantity only depends on the u_i and the images of the v_i under the morphism μ of $\mathcal{M}$, which leads to a new notion of productions.

▶ **Proposition-Definition 5.8.** *Let $\mathcal{M} = (A, M, \mu, \mathfrak{H}, \lambda)$ be a k-marble bimachine. Let $v_0u_1 \cdots u_kv_k \in A^*$ and $v'_0u_1 \cdots u_kv'_k \in A^*$ be such that $\mu(v_i) = \mu(v'_i)$ for all $0 \leq i \leq k$. Then: $\mathsf{prod}_{\mathcal{M}}(v_0[\![u_1]\!]v_1 \cdots [\![u_k]\!]v_k) = \mathsf{prod}_{\mathcal{M}}(v'_0[\![u_1]\!]v'_1 \cdots [\![u_k]\!]v'_k)$. Let $m_i \coloneqq \mu(v_i) = \mu(v'_i)$, we define $\mathsf{prod}_{\mathcal{M}}(m_0[\![u_1]\!]m_1 \cdots [\![u_k]\!]m_k)$ as the previous value.*

▶ Remark 5.9. In the following, we shall directly manipulate multicontexts of the form $m_0[\![u_1]\!]m_1 \cdots [\![u_x]\!]m_x$ with $m_i \in M$ and $u_i \in A^*$. Note that an x-multicontext and a y-multicontext can be concatenated to obtain an $(x + y)$-multicontext.

We finally introduce the notion of (x, K)-*iterator*, which corresponds to an x-multicontext in which the words u_i have length at most $K \geq 0$ and have idempotent images under μ. Recall that $e \in M$ is *idempotent* if and only if $ee = e$.

▶ **Definition 5.10** (Iterator). *Let $x, K \geq 0$ and $\mu : A^* \to M$. An (x, K)-*iterator *for μ is an x-multicontext of the form $m_0 (\prod_{i=1}^{x} e_i[\![u_i]\!]e_im_i)$ such that $m_0, \dots, m_x \in M$ and $u_1, \dots, u_x \in A^*$ are such that for all $1 \leq i \leq x$, $|u_i| \leq K$ and $e_i = \mu(u_i) \in M$ is idempotent.*

Permutable k-marble bimachines. We are now ready to state the definition of *permutability* for marble bimachines. Intuitively, this property means that, under some idempotency conditions, $\mathsf{prod}_{\mathcal{M}}(m_0[\![u_1]\!]m_1 \cdots [\![u_k]\!]m_k)$ only depends on the 1-multicontexts of each $[\![u_i]\!]$, which are $m_0\mu(u_1)\cdots m_i[\![u_i]\!]m_{i+1}\mu(u_{i+1})\cdots m_k \in M$ for $1 \leq i \leq k$. In particular, it does not depend on the relative position of the u_i nor on the m_i which separate them. Hence, it will be possible to simulate a permutable k-marble bimachine by a k-blind bimachine which can only see the 1-multicontext of one position at each time.

▶ **Definition 5.11.** *Let $\mathcal{M}$ be a k-marble bimachine using a surjective morphism $\mu : A^* \to M$. Let $K \geq 0$, we say that $\mathcal{M}$ is* K-permutable *if the following holds whenever $\ell + x + r = k$:*

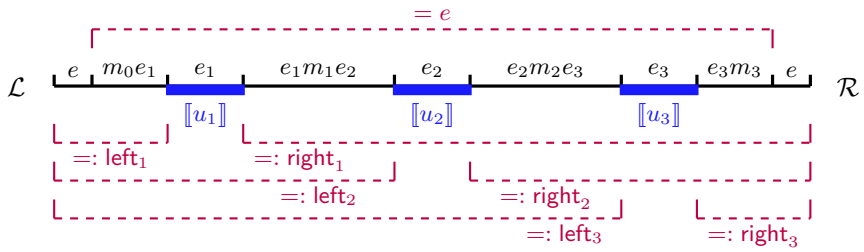
- *for all (ℓ, K)-iterator $\mathcal{L}$ and (r, K)-iterator $\mathcal{R}$;*
- *for all (x, K)-iterator $m_0\left(\prod_{i=1}^{x} e_i[\![u_i]\!]e_i m_i\right)$ such that $e := m_0\left(\prod_{i=1}^{x} e_i m_i\right)$ idempotent;*
- *for all $1 \leq j \leq x$, define the left and right contexts:*

$$\mathsf{left}_j := e\left(\prod_{i=1}^{j} m_{i-1}e_i\right) \quad \text{and} \quad \mathsf{right}_j := \left(\prod_{i=j}^{x} e_i m_i\right)e.$$

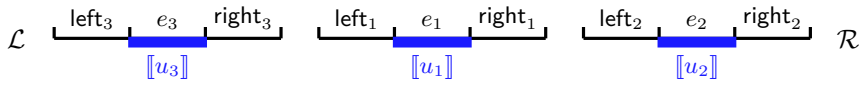
Then if σ is a permutation of $[1{:}x]$, we have:

$$\mathsf{prod}_{\mathcal{M}}\left(\mathcal{L}\; em_0\left(\prod_{i=1}^{x} e_i[\![u_i]\!]e_i m_i\right)e\;\mathcal{R}\right) = \mathsf{prod}_{\mathcal{M}}\left(\mathcal{L}\left(\prod_{i=1}^{x} \mathsf{left}_{\sigma(i)}\,[\![u_{\sigma(i)}]\!]\,\mathsf{right}_{\sigma(i)}\right)\mathcal{R}\right).$$

An visual description of permutability is depicted in Figure 6.



(a) Initial multicontext and definition of the left_j / right_j for $1 \leq j \leq 3$.



(b) Multicontext which separates the factors using the left_j / right_j and σ.

Figure 6 Productions which must be equal in Definition 5.11, with $x = 3$ and $\sigma = (3, 1, 2)$.

The next result follows from a technical proof based on iteration techniques (it can be understood as a kind of pumping lemma on iterators).

▶ **Proposition 5.12.** *Let $\mathcal{M}$ be a k-marble bimachine computing a k-repetitive function. Then $\mathcal{M}$ is K-permutable for all $K \geq 0$.*

Let us finally note that being K-permutable (for a fixed K) is a decidable property. Indeed, it suffices to range over all $\ell + x + r = k$ and (ℓ, K)-, (x, K)- and (r, K)-iterators (there are finitely many of them, since they correspond to bounded sequences which alternate between monoid elements and words of bounded lengths), and compute their productions.

6 From permutable bimachines to polyblind functions

The purpose of this section is to show Proposition 6.1, which allows us to perform the induction step in the proof of Theorem 5.1, by going from k to $k-1$ marbles.

▶ **Proposition 6.1.** *Let $\mathcal{M} = (A, M, \mu, \mathfrak{H}, \lambda)$ be a $2^{3|M|}$-permutable k-marble bimachine computing a function $f : A^* \to \mathbb{N}$. One can build a polyblind function $f' : A^* \to \mathbb{N}$ and a function $f''A^* \to \mathbb{N}$ computed by a $(k-1)$-marble bimachine such that $f = f' + f''$.*

Proof overview. It follows from Equation 2 and Lemma 6.14 that:

$$\begin{aligned} f &= (\mathsf{sum\text{-}dep}_{\mathcal{M}} + \mathsf{sum\text{-}ind}_{\mathcal{M}}) \circ \mathsf{forest}_{\mu} \quad \text{(see Theorem 6.5 for the definition of } \mathsf{forest}_{\mu}\text{)} \\ &= \underbrace{\mathsf{sum\text{-}ind}'_{\mathcal{M}} \circ \mathsf{forest}_{\mu}}_{=:f'} + \underbrace{(\mathsf{sum\text{-}dep}_{\mathcal{M}} + \mathsf{sum\text{-}ind}''_{\mathcal{M}}) \circ \mathsf{forest}_{\mu}}_{=:f''} \end{aligned}$$

By Lemma 6.14 one has $f'' \geq 0$. Furthermore, $\mathsf{sum\text{-}ind}'_{\mathcal{M}}$ is polyblind, hence f' is polyblind since the class of polyblind functions is closed under pre-composition by regular functions (even when the outputs are not unary, see [13]). Similarly, it follows from lemmas 6.12 and 6.14 that $\mathsf{sum\text{-}dep}_{\mathcal{M}}$ and $\mathsf{sum\text{-}ind}''_{\mathcal{M}}$ are polyregular with growth at most $k-1$ (see Definition 3.5), hence so is their sum and its pre-composition by a regular function [2]. Thus f'' is polyregular and has growth at most $k-1$. By theorems 2.10 and 3.6, it can be computed by a $(k-1)$-marble bimachine. ◀

Now we give the statements and the proofs of lemmas 6.12 and 6.14. An essential tool is the notion of *factorization forest*, which is recalled below.

6.1 Factorization forests

If $\mu : A^* \to M$ is a morphism into a finite monoid and $w \in A^*$, a *factorization forest* (called *μ-forest* in the following) of w is an unranked tree structure defined as follows.

▶ **Definition 6.2** (Factorization forest [15])**.** *Given a morphism $\mu : A^* \to M$ and $w \in A^*$, we say that $\mathcal{F}$ is a* μ-forest *of w if:*

- *either $\mathcal{F} = a$ and $w = a \in A$;*
- *or $\mathcal{F} = \langle \mathcal{F}_1 \rangle \cdots \langle \mathcal{F}_n \rangle$, $w = w_1 \cdots w_n$ and for all $1 \leq i \leq n$, $\mathcal{F}_i$ is a μ-forest of $w_i \in A^+$. Furthermore, if $n \geq 3$ then $\mu(w_1) = \cdots = \mu(w_n)$ is an idempotent of M.*

▶ Remark 6.3. If $\langle \mathcal{F}_1 \rangle \cdots \langle \mathcal{F}_n \rangle$ is a μ-forest, then so is $\langle \mathcal{F}_i \rangle \langle \mathcal{F}_{i+1} \rangle \ldots \langle \mathcal{F}_j \rangle$ for $1 \leq i \leq j \leq n$. The empty forest ε is the unique μ-forest of the empty word ε.

We shall use the standard tree vocabulary of "height" (a leaf is a tree of height 1), "child", "sibling", "descendant" and "ancestor" (both defined in a non-strict way: a node is itself one of its ancestors/descendants), etc. We denote by $\mathsf{Nodes}(\mathcal{F})$ the set of nodes of $\mathcal{F}$. In order to simplify the statements, we identify a node $\mathfrak{t} \in \mathsf{Nodes}(\mathcal{F})$ with the subtree rooted in this node. Thus $\mathsf{Nodes}(\mathcal{F})$ can also be seen as the set of subtrees of $\mathcal{F}$, and $\mathcal{F} \in \mathsf{Nodes}(\mathcal{F})$. We say that a node is *idempotent* if is has at least 3 children (see Definition 6.2).

Given $\mu : A^* \to M$, we denote by $\mathsf{Forests}_{\mu}(w)$ the set of μ-forests of $w \in A^*$. If $K \geq 0$, let $\mathsf{Forests}^K_{\mu}(w)$ be the μ-forests of w of height at most K. Note that $\mathsf{Forests}_{\mu}(w)$ is a set of tree structures which can also be seen as a language over $\widehat{A} := A \uplus \{\langle, \rangle\}$. Indeed, a forest of w can also be seen as "the word w with brackets" in Definition 6.2.

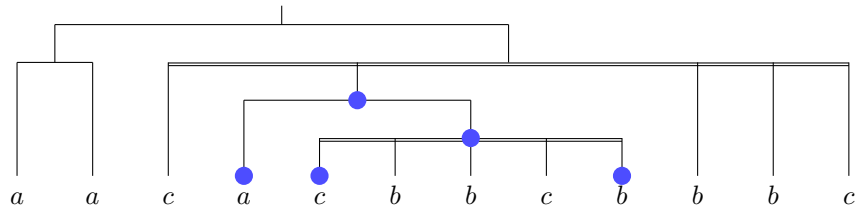


Figure 7 The μ-forest $\langle aa\rangle\langle c\langle a\langle cbbcb\rangle\rangle bbc\rangle$ on $aacacbbcbbbc$.

▶ **Example 6.4.** Let $A = \{a, b, c\}$, $M{=}(\{1, -1, 0\}, \times)$ with $\mu(a) \coloneqq -1$ and $\mu(b) \coloneqq \mu(c) \coloneqq 0$. Then $\mathcal{F} \coloneqq \langle aa\rangle\langle c\langle a\langle cbbcb\rangle\rangle bbc\rangle \in \mathsf{Forests}^5_\mu(aacacbbcbbbc)$ (we dropped the brackets around single letters for more readability) is depicted in Figure 7. Double lines are used to denote idempotent nodes (i.e. with more than 3 children).

A celebrated result states that for any word, a forest of bounded height always exist and it can be computed by a bimachine (with non-unary output alphabet), or a two-way transducer. The following theorem can also be found in [2, Lemma 6.5].

▶ **Theorem 6.5** ([15]). *Given a morphism $\mu : A^* \to M$, we have $\mathsf{Forests}^{3|M|}_\mu(w) \neq \varnothing$ for all $w \in A^*$. Furthermore, one can build a two-way transducer (with a non-unary output alphabet) which computes a total function $\mathsf{forest}_\mu : A^* \to (\widehat{A})^*, w \mapsto \mathcal{F} \in \mathsf{Forests}^{3|M|}_\mu(w)$.*

6.2 Iterable nodes and productions

We define the iterable nodes $\mathsf{Iters}(\mathcal{F}) \subseteq \mathsf{Nodes}(\mathcal{F})$ as the set of nodes which have both a left and a right sibling. Such nodes are thus exactly the middle children of idempotent nodes.

▶ **Definition 6.6.** *Let $\mathcal{F} \in \mathsf{Forests}_\mu(w)$, we define inductively the* iterable nodes *of $\mathcal{F}$:*
- *if $\mathcal{F} = a \in A$ is a leaf, $\mathsf{Iters}(\mathcal{F}) \coloneqq \varnothing$;*
- *otherwise if $\mathcal{F} = \langle\mathcal{F}_1\rangle \cdots \langle\mathcal{F}_n\rangle$, then:*

$$\mathsf{Iters}(\mathcal{F}) \coloneqq \{\mathcal{F}_i : 2 \leq i \leq n{-}1\} \cup \bigcup_{1\leq i\leq n} \mathsf{Iters}(\mathcal{F}_i).$$

Now we define a notion of *skeleton* which selects the right-most and left-most children.

▶ **Definition 6.7.** *Let $\mathcal{F} \in \mathsf{Forests}_\mu(w)$ and $\mathfrak{t} \in \mathsf{Nodes}(\mathcal{F})$, we define the* skeleton *of $\mathfrak{t}$ by:*
- *if $\mathfrak{t} = a \in A$ is a leaf, then $\mathsf{Skel}(\mathfrak{t}) \coloneqq \{\mathfrak{t}\}$;*
- *otherwise if $\mathfrak{t} = \langle\mathcal{F}_1\rangle \cdots \langle\mathcal{F}_n\rangle$, then $\mathsf{Skel}(\mathfrak{t}) \coloneqq \{\mathfrak{t}\} \cup \mathsf{Skel}(\mathcal{F}_1) \cup \mathsf{Skel}(\mathcal{F}_n)$.*

Intuitively, $\mathsf{Skel}(\mathfrak{t}) \subseteq \mathsf{Nodes}(\mathcal{F})$ contains all the descendants of $\mathfrak{t}$ except those which are descendant of a middle child. We then define the frontier of $\mathfrak{t}$, denoted $\mathsf{Fr}_\mathcal{F}(\mathfrak{t}) \subseteq \{1, \ldots, |w|\}$ as the set of positions of w which belong to $\mathsf{Skel}(\mathfrak{t})$ (when seen as leaves of $\mathcal{F}$).

▶ **Example 6.8.** In Figure 7, the top-most blue node $\mathfrak{t}$ is iterable. Furthermore $\mathsf{Skel}(\mathfrak{t})$ is the set of blue nodes, $\mathsf{Fr}_\mathcal{F}(\mathfrak{t}) = \{4, 5, 9\}$ and $w[\mathsf{Fr}_\mathcal{F}(\mathfrak{t})] = acb$.

Using the frontiers, we can naturally lift the notion of productions of a k-marble bimachine from multisets of sets of positions to multisets of nodes in a forest.

▶ **Definition 6.9.** *Let $\mathcal{M} = (A, M, \mu, \mathfrak{H}, \lambda)$ be a k-marble bimachine, $w \in A^*$, $\mathcal{F} \in \mathsf{Forests}_\mu(w)$ and $\mathfrak{t}_1, \ldots, \mathfrak{t}_k \in \mathsf{Nodes}(\mathcal{F})$. We let $\mathsf{prod}^\mathcal{F}_\mathcal{M}(\{\!\{\mathfrak{t}_1, \ldots, \mathfrak{t}_k\}\!\}) \coloneqq \mathsf{prod}^w_\mathcal{M}(\{\!\{\mathsf{Fr}_\mathcal{F}(\mathfrak{t}_1), \ldots, \mathsf{Fr}_\mathcal{F}(\mathfrak{t}_k)\}\!\})$.*

Using Lemma 5.6, we can recover the function f from the productions over the nodes. Lemma 6.10 roughly ranges over all possible tuples of calling positions of $\mathcal{M}$.

▶ **Lemma 6.10.** *Let $f : A^* \to \mathbb{N}$ be computed by a k-marble bimachine $\mathcal{M} = (A, M, \mu, \mathfrak{H}, \lambda)$. If $w \in A^*$ and $\mathcal{F} \in \mathsf{Forests}_\mu(w)$, we have:*

$$f(w) = \sum_{\{\!\{\mathfrak{t}_1,\dots,\mathfrak{t}_k\}\!\} \subseteq \mathsf{Iters}(\mathcal{F}) \cup \{\mathcal{F}\}} \mathsf{prod}^{\mathcal{F}}_{\mathcal{T}}\left(\{\!\{\mathfrak{t}_1, \dots, \mathfrak{t}_k\}\!\}\right).$$

Proof. It follows from [6] that for all $w \in A^*$ and $\mathcal{F} \in \mathsf{Forests}_\mu(w)$, the set of frontiers $\{\mathsf{Fr}_{\mathcal{F}}(\mathfrak{t}) : \mathfrak{t} \in \mathsf{Iters}(\mathcal{F}) \cup \{\mathcal{F}\}\}$ is a partition of $[1{:}|w|]$. We then apply Lemma 5.6. ◀

6.3 Dependent multisets of nodes

The multisets $\{\!\{\mathfrak{t}_1, \dots, \mathfrak{t}_k\}\!\} \subseteq \mathsf{Iters}(\mathcal{F}) \cup \{\mathcal{F}\}$ of Lemma 6.10 will be put into two categories. The *independent* multisets are those whose nodes are distinct and "far enough" in $\mathcal{F}$. The remaining ones are said *dependent*; their number is bounded by a polynomial of degree $k-1$.

▶ **Definition 6.11** (Independent multiset)**.** *Let $\mu : A^* \to M$, $w \in A^*$ and $\mathcal{F} \in \mathsf{Forests}_\mu(w)$, we say that a multiset $\mathfrak{T} \coloneqq \{\!\{\mathfrak{t}_1, \dots, \mathfrak{t}_k\}\!\} \subseteq \mathsf{Iters}(\mathcal{F})$ is* independent *if for all $1 \leq i \neq j \leq k$:*

- *$\mathfrak{t}_i$ is not an ancestor of $\mathfrak{t}_j$;*
- *$\mathfrak{t}_i$ is not the immediate left sibling of an ancestor of $\mathfrak{t}_j$;*
- *$\mathfrak{t}_i$ is not the immediate right sibling of an ancestor of $\mathfrak{t}_j$.*

Note that if $\mathfrak{T}$ is independent, then $\mathcal{F} \notin \mathfrak{T}$ since it is not an iterable node. We denote by $\mathsf{Ind}^k(\mathcal{F})$ the set of independent multisets. Conversely, let $\mathsf{Dep}^k(\mathcal{F})$ be the set of multisets $\{\!\{\mathfrak{t}_1, \dots, \mathfrak{t}_k\}\!\} \subseteq \mathsf{Iters}(\mathcal{F}) \cup \{\mathcal{F}\}$ which are *dependent* (i.e. not independent). By Lemma 6.10, if $\mathcal{M} = (A, M, \mu, \mathfrak{H}, \lambda)$ computes $f : A^* \to \mathbb{N}$ and $\mathcal{F} \in \mathsf{Forests}_\mu(w)$, then:

$$f(w) = \sum_{\mathfrak{T} \in \mathsf{Ind}^k(\mathcal{F})} \mathsf{prod}^{\mathcal{F}}_{\mathcal{M}}(\mathfrak{T}) + \sum_{\mathfrak{T} \in \mathsf{Dep}^k(\mathcal{F})} \mathsf{prod}^{\mathcal{F}}_{\mathcal{M}}(\mathfrak{T}) \tag{2}$$

The idea is now to compute these two sums separately. We begin with the second one.

▶ **Lemma 6.12.** *Given a k-marble bimachine $\mathcal{M} = (A, M, \mu, \mathfrak{H}, \lambda)$, the following function is (effectively) polyregular and has growth at most $k-1$:*

$$\mathsf{sum\text{-}dep}_{\mathcal{M}} : (\widehat{A})^* \to \mathbb{N}, \mathcal{F} \mapsto \begin{cases} \displaystyle\sum_{\mathfrak{T} \in \mathsf{Dep}^k(\mathcal{F})} \mathsf{prod}^{\mathcal{F}}_{\mathcal{M}}(\mathfrak{T}) & \text{if } \mathcal{F} \in \mathsf{Forests}^{3|M|}_\mu(w) \text{ for some } w \in A^*; \\ 0 & \text{otherwise.} \end{cases}$$

▶ Remark 6.13. For this result, we do not need to assume that $\mathcal{M}$ is permutable.

6.4 Independent multisets of nodes

In order to complete the description of f from Equation 2, it remains to treat the productions over independent multisets of nodes. When $\{\!\{\mathfrak{t}_1, \dots, \mathfrak{t}_k\}\!\} \in \mathsf{Ind}^k(\mathcal{F})$, all the $\mathfrak{t}_i$ must be distinct, hence we shall denote it by a set $\{\mathfrak{t}_1, \dots, \mathfrak{t}_k\}$. We define the counterpart of $\mathsf{sum\text{-}dep}_{\mathcal{M}}$:

$$\mathsf{sum\text{-}ind}_{\mathcal{M}} : (\widehat{A})^* \to \mathbb{N}, \mathcal{F} \mapsto \begin{cases} \displaystyle\sum_{\mathfrak{T} \in \mathsf{Ind}^k(\mathcal{F})} \mathsf{prod}^{\mathcal{F}}_{\mathcal{M}}(\mathfrak{T}) & \text{if } \mathcal{F} \in \mathsf{Forests}^{3|M|}_\mu(w) \text{ for some } w \in A^*; \\ 0 & \text{otherwise.} \end{cases}$$

▶ **Lemma 6.14.** *Given a k-marble bimachine $\mathcal{M}$ which is $2^{3|M|}$-permutable, one can build a polyblind function $\mathsf{sum\text{-}ind}'_{\mathcal{M}} : (\widehat{A})^* \to \mathbb{N}$ and a polyregular function $\mathsf{sum\text{-}ind}''_{\mathcal{M}} : (\widehat{A})^* \to \mathbb{N}$ with growth at most $k-1$, such that $\mathsf{sum\text{-}ind}_{\mathcal{M}} = \mathsf{sum\text{-}ind}'_{\mathcal{M}} + \mathsf{sum\text{-}ind}''_{\mathcal{M}}$.*

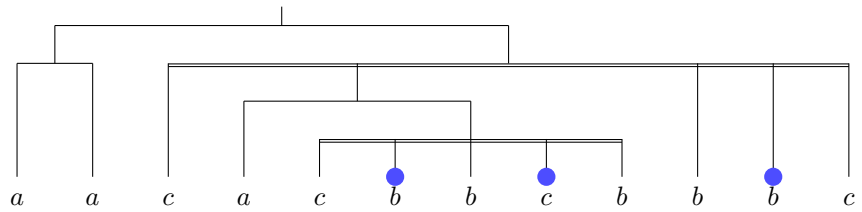
If $\mathsf{sum\text{-}ind}_{\mathcal{M}}$ was a polynomial, then $\mathsf{sum\text{-}ind}'_{\mathcal{M}}$ should roughly be its term of highest degree and $\mathsf{sum\text{-}ind}''_{\mathcal{M}}$ corresponds to a corrective term.

The rest of this section is devoted to the proof of Lemma 6.14. In order to simplify the notations, we extend a morphism μ to its μ-forests by $\mu(\mathcal{F}) \coloneqq \mu(w)$ when $\mathcal{F} \in \mathsf{Forests}_\mu(w)$. Given $\mathsf{t} \in \mathsf{Nodes}(\mathcal{F})$, we denote by $\mathsf{depth}^{\mathcal{F}}(\mathsf{t})$ its depth in the tree structure $\mathcal{F}$ (the root has depth 1, and it is defined inductively as usual). Now we introduce the notion of *linearization* of $\mathsf{t} \in \mathsf{Nodes}(\mathcal{F})$, which is used to describe $w[\mathsf{Fr}_{\mathcal{F}}(\mathsf{t})]$ as a 1-multicontext.

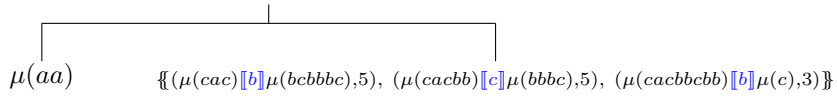
▶ **Definition 6.15** (Linearization). *Let $\mu : A^* \to M$, $w \in A^*$ and $\mathcal{F} \in \mathsf{Forests}_\mu(w)$. The* linearization *of $\mathsf{t} \in \mathsf{Nodes}(\mathcal{F})$ is a 1-multicontext $m[\![u]\!]m'$ defined by induction:*

- *if $\mathsf{t} = \mathcal{F}$ then $\mathsf{lin}^{\mathcal{F}}(\mathsf{t}) \coloneqq [\![w[\mathsf{Fr}_{\mathcal{F}}(\mathcal{F})]]\!]$;*
- *otherwise $\mathcal{F} = \langle \mathcal{F}_1 \rangle \cdots \langle \mathcal{F}_n \rangle$, and $\mathsf{t} \in \mathsf{Nodes}(\mathcal{F}_i)$ for some $1 \leq i \leq n$. We define:* $\mathsf{lin}^{\mathcal{F}}(\mathsf{t}) \coloneqq \mu(\mathcal{F}_1) \cdots \mu(\mathcal{F}_{i-1})\, \mathsf{lin}^{\mathcal{F}_i}(\mathsf{t}) \mu(\mathcal{F}_{i+1}) \cdots \mu(\mathcal{F}_n)$.

We finally introduce the notion of *architecture*. Intuitively, it is a simple tree which describes the positions of a set of nodes $\mathfrak{T} \in \mathsf{Ind}^k(\mathcal{F})$ in its forest $\mathcal{F}$. We build it inductively on the example depicted in Figure 8. At the root, we see that there is no node of $\mathfrak{T}$ in the left subtree, hence we replace it by its image under μ. The right subtree is an idempotent node whose leftmost and rightmost subtrees have no node in $\mathfrak{T}$. We thus replace this idempotent node by a leaf containing the multiset of the linearizations and depths of the $\mathsf{t} \in \mathfrak{T}$. Since our machine $\mathcal{M}$ is permutable, this simple information will be enough to recover $\mathsf{prod}^{\mathcal{F}}_{\mathcal{M}}(\mathfrak{T})$.



(a) In blue, a set $\mathfrak{T}$ of 3 independent nodes in the forest from Figure 7.



(b) The corresponding architecture.

Figure 8 A set of independent nodes and its architecture.

▶ **Definition 6.16** (Architecture). *Let $w \in A^*$, $\mathcal{F} \in \mathsf{Forests}_\mu(w)$ and $\mathfrak{T} \in \mathsf{Ind}^k(\mathcal{F})$. We define the* architecture *of $\mathfrak{T}$ in $\mathcal{F}$ by induction as follows:*

- *if $\mathcal{F} = \varepsilon$, then $k = 0$. We define $\mathsf{arc}^{\mathcal{F}}(\mathfrak{T}) \coloneqq \varepsilon$;*
- *if $\mathcal{F} = a$, then $k = 0$. We define $\mathsf{arc}^{\mathcal{F}}(\mathfrak{T}) \coloneqq \mu(a)$;*
- *otherwise $\mathcal{F} = \langle \mathcal{F}_1 \rangle \cdots \langle \mathcal{F}_n \rangle$ with $n \geq 1$:*
  - *if $k = 0$, we set $\mathsf{arc}^{\mathcal{F}}(\mathfrak{T}) = \langle \mu(\mathcal{F}) \rangle$;*
  - *else if $\mathfrak{T}_1 \coloneqq \mathfrak{T} \cap \mathsf{Nodes}(\mathcal{F}_1) \neq \varnothing$, then $\mathfrak{T}_1 \in \mathsf{Ind}^{|\mathfrak{T}_1|}(\mathcal{F}_1)$ (since $\mathcal{F}_1 \notin \mathfrak{T}$ by iterability) and $\mathfrak{T} \setminus \mathfrak{T}_1 \in \mathsf{Ind}^{k-|\mathfrak{T}_1|}(\langle \mathcal{F}_2 \rangle \cdots \langle \mathcal{F}_n \rangle)$ (since $\mathcal{F}_2 \notin \mathfrak{T}$ by independence). We set:* $\mathsf{arc}^{\mathcal{F}}(\mathfrak{T}) \coloneqq \langle \mathsf{arc}^{\mathcal{F}_1}(\mathfrak{T}_1) \rangle\, \mathsf{arc}^{\langle \mathcal{F}_2 \rangle \cdots \langle \mathcal{F}_n \rangle}(\mathfrak{T} \setminus \mathfrak{T}_1)$.

- *else if* $\mathfrak{T}_n \coloneqq \mathfrak{T} \cap \mathsf{Nodes}(\mathcal{F}_n) \neq \varnothing$*, we define symmetrically:* $\mathsf{arc}^{\mathcal{F}}(\mathfrak{T}) \coloneqq \mathsf{arc}^{\langle \mathcal{F}_1 \rangle \cdots \langle \mathcal{F}_{n-1} \rangle}(\mathfrak{T} \setminus \mathfrak{T}_n) \langle \mathsf{arc}^{\mathcal{F}_n}(\mathfrak{T}_n) \rangle$
- *else* $\mathfrak{T}_1 = \mathfrak{T}_n = \varnothing$ *but* $k > 0$*, thus* $n \geq 3$ *and* $\mu(\mathcal{F})$ *is idempotent. We define:* $\mathsf{arc}^{\mathcal{F}}(\mathfrak{T}) \coloneqq \langle \{\!\{ (\mathsf{lin}^{\mathcal{F}}(\mathfrak{t}), \mathsf{depth}^{\mathcal{F}}(\mathfrak{t})) : \mathfrak{t} \in \mathfrak{T} \}\!\} \rangle$

Given a morphism, the set of architectures over bounded-height forests is finite.

▷ Claim 6.17. The set $\mathsf{Arcs}_\mu^{3|M|} \coloneqq \{\mathsf{arc}^{\mathcal{F}}(\mathfrak{T}) : \mathfrak{T} \in \mathsf{Ind}^k(\mathcal{F}), \mathcal{F} \in \mathsf{Forests}_\mu^{3|M|}(w), w \in A^*\}$ is finite, given $k \geq 0$ and a morphism $\mu : A^* \to M$.

Proof. The architectures from $\mathsf{Arcs}_\mu^{3|M|}$ are tree structures of height at most $3|M|$. Furthermore they have a branching bounded by $k+3$ and their leaves belong to a finite set (they are either idempotents $e \in M$, or multisets of at most k elements of the form $(m[\![u]\!]m', d)$ with $m, m' \in M$, $|u| \leq 2^{3|M|}$ and $1 \leq d \leq 3|M|$). ◁

Using the permutability of the k-marble bimachine, we show that the production over a set of independent nodes only depends on its architecture. This result enables us to define the notion of production over an architecture.

▶ **Proposition-Definition 6.18.** *Let* $\mathcal{M} = (A, M, \mu, \mathfrak{H}, \lambda)$ *be a* $2^{3|M|}$*-permutable* k*-marble bimachine. Let* $w, w' \in A^*$, $\mathcal{F} \in \mathsf{Forests}_\mu^{3|M|}(w)$ *and* $\mathcal{F}' \in \mathsf{Forests}_\mu^{3|M|}(w')$, $\mathfrak{T} \in \mathsf{Ind}^k(\mathcal{F})$ *and* $\mathfrak{T}' \in \mathsf{Ind}^k(\mathcal{F}')$ *such that* $\mathbb{A} \coloneqq \mathsf{arc}^{\mathcal{F}}(\mathfrak{T}) = \mathsf{arc}^{\mathcal{F}'}(\mathfrak{T}')$*. Then* $\mathsf{prod}_{\mathcal{M}}^{\mathcal{F}}(\mathfrak{T}) = \mathsf{prod}_{\mathcal{M}}^{\mathcal{F}'}(\mathfrak{T}')$.
We define $\mathsf{prod}_{\mathcal{M}}(\mathbb{A})$ *as the above value.*

By using the previous statements, we get for all $w \in A^*$ and $\mathcal{F} \in \mathsf{Forests}_\mu^{3|M|}(w)$:

$$\begin{aligned}\mathsf{sum\text{-}ind}_{\mathcal{M}}(\mathcal{F}) &= \sum_{\mathfrak{T} \in \mathsf{Ind}^k(\mathcal{F})} \mathsf{prod}_{\mathcal{M}}^{\mathcal{F}}(\mathfrak{T}) = \sum_{\mathbb{A} \in \mathsf{Arcs}_\mu^{3|M|}} \sum_{\substack{\mathfrak{T} \in \mathsf{Ind}^k(\mathcal{F}) \\ \mathsf{arc}^{\mathcal{F}}(\mathfrak{T}) = \mathbb{A}}} \mathsf{prod}_{\mathcal{M}}^{\mathcal{F}}(\mathfrak{T}) \\ &= \sum_{\mathbb{A} \in \mathsf{Arcs}_\mu^{3|M|}} \mathsf{prod}_{\mathcal{M}}(\mathbb{A}) \times \mathsf{count}_{\mathbb{A}}(\mathcal{F})\end{aligned}$$

where $\mathsf{count}_{\mathbb{A}}(\mathcal{F}) \coloneqq |\{\mathfrak{T} \in \mathsf{Ind}^k(\mathcal{F}) : \mathsf{arc}^{\mathcal{F}}(\mathfrak{T}) = \mathbb{A}\}|$. It describes the number of multisets of independent nodes which have a given architecture. Now we show how to compute this function as a sum of a polyblind function and a polyregular function with lower growth.

▶ **Lemma 6.19.** *Let* $\mu : A^* \to M$*. Given an architecture* $\mathbb{A} \in \mathsf{Arcs}_\mu^{3|M|}$*, one can build:*

- *a polyblind function* $\mathsf{count}'_{\mathbb{A}} : (\widehat{A})^* \to \mathbb{N}$*;*
- *a polyregular function* $\mathsf{count}''_{\mathbb{A}} : (\widehat{A})^* \to \mathbb{N}$ *with growth at most* $k-1$*;*

such that $\mathsf{count}_{\mathbb{A}}(\mathcal{F}) = \mathsf{count}'_{\mathbb{A}}(\mathcal{F}) + \mathsf{count}''_{\mathbb{A}}(\mathcal{F})$ *for all* $\mathcal{F} \in \mathsf{Forests}_\mu^{3|M|}(w)$ *and* $w \in A^*$.

To conclude the proof of Lemma 6.14, we define the function (which is polyblind):

$$\mathsf{sum\text{-}ind}'_{\mathcal{M}} \coloneqq \sum_{\mathbb{A} \in \mathsf{Arcs}_\mu^{3|M|}} \mathsf{prod}_{\mathcal{M}}(\mathbb{A}) \times \mathsf{count}'_{\mathbb{A}}.$$

We define similarly the following function which is polyregular and has growth at most $k-1$:

$$\mathsf{sum\text{-}ind}''_{\mathcal{M}} = \sum_{\mathbb{A} \in \mathsf{Arcs}_\mu^{3|M|}} \mathsf{prod}_{\mathcal{M}}(\mathbb{A}) \times \mathsf{count}''_{\mathbb{A}}.$$

7 Outlook

This paper provides a technical solution to a seemingly difficult membership problem. This result can be interpreted both in terms of nested transducers (i.e. programs with visible or blind recursive calls) and in terms of rational series. We conjecture that the new techniques introduced here (especially the induction techniques), and the concepts of productions on words and forests, give an interesting toolbox to tackle other decision problem for transducers such as equivalence or membership issues. It could also be interesting to characterize polyblind functions as the series computed by specific weighted automata over $(\mathbb{N}, +, \times)$.

Regular Expressions for Tree-Width 2 Graphs

Amina Doumane
CNRS, LIP, ENS Lyon, France

Abstract

We propose a syntax of regular expressions, which describes languages of tree-width 2 graphs. We show that these languages correspond exactly to those languages of tree-width 2 graphs, definable in the counting monadic second-order logic (CMSO).

1 Introduction

Regular word languages form a robust class of languages. One of the witnesses for this robustness is the variety of equivalent formalisms defining them. They can be described by finite automata, by monadic second-order (MSO) formulas, by regular expressions or by finite monoids [3, 6, 10]. Each of these formalisms has some advantages, depending on the context where it is used. For example, MSO is close to natural language, regular expressions define regular languages via their closure properties, automata have good algorithmic properties and can be used as actual algorithms to decide membership in a language, etc. Similarly, regular tree languages have equivalent formalisms, for various kinds of trees [11, 13, 9].

We will here further generalize the structures considered, by moving to graphs of bounded tree-width. Intuitively, they can be thought of as "graphs which resemble trees". In this framework, we already know that counting MSO (CMSO), an extension of MSO with counting predicates, and recognizability by algebra are equivalent [1, 2], yielding a notion that could be called "regular languages of graphs of tree-width k". Engelfriet [7] also proposes a regular expressions formalism matching this class, but by his own admission, these expressions closely mimic the behavior of CMSO. The main feature missing in Engelfriet's regular expressions is a mechanism for iteration, which is the central operator for word regular expressions: the Kleene star.

In this paper, we propose a syntax of regular expressions for languages of tree-width 2 graphs, that follow more closely the spirit of regular expressions on words, using Kleene-like iterations. This constitutes a first step towards the long term objective of obtaining such expressions for languages of graphs of tree-width k. We believe the case of tree-width 2 is already a significant step in itself. Graphs of tree-width 2 form a robust class of graphs with several interesting characterizations. One of them is the characterization via the forbidden minor K_4, the complete graph with four vertices. By the Robertson-Seymour theorem [12], it is known that for every $k \in \mathbb{N}$, the class of tree-width k graphs is characterized by a finite set of excluded minors. However, this result is not constructive, and only the forbidden minors for $k \leq 3$ are known.

Let us now give more intuition about our expressions for graphs of tree-width 2. Our Kleene-like iteration is defined in terms of least fixed points $\mu x.\, e$. However without restriction, such an operator is too powerful and takes us outside of the CMSO-definable graphs. This phenomenon actually already happens on words: with an arbitrary fixed point, we can write $\mu x.\, (axb)$, defining the non-regular language $\{a^n x b^n \mid n \in \mathbb{N}\}$. The Kleene star on words can be seen as a restriction of the least fixed point operator: only fixed points of the form $\mu x.\, ex$ are allowed, where x does not appear in e. Here the idea is the same, but our restriction will be more involved, and will require a fine understanding of the structure of tree-width 2 graphs.

This work was inspired by the work of Gazdag and Németh [8] on regular expressions for bisemigroups and binoids. One of the main difference with our work is that their operators are only associative, while the operations generating our graphs satisfy more properties.

The paper is structured as follows. Sec. 2 is a preliminary section where we introduce graphs of tree-width 2, the logic CMSO and recognizability by algebra, which are known to be equivalent. In Sec 3, we introduce regular expressions, explain the condition that the iteration should satisfy, and give some examples to illustrate it. At the end of this section, we state our main result, which says that this formalism is equivalent to the two introduced in the preliminary section. We introduce in Sec. 4 the logic CMSO^r, an extension of CMSO with a very restricted form of quantification over relations, and show that it is equivalent to CMSO. Based on this, we show in section 5 that regularity implies CMSO-definability. Finally, we show in section 6 that recognizability implies regularity, proving our main result.

2 Preliminaries

Let Σ_1 and Σ_2 be two disjoint sets of *unary* and *binary* letters respectively. Throughout the paper, we work with the alphabet $\Sigma = \Sigma_1 \cup \Sigma_2$.

2.1 Tree-width 2 graphs

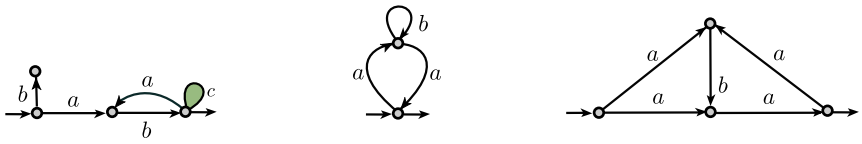
▶ **Definition 1** (Graphs). *A* graph G *is a tuple* $(V, E_1, E_2, s, t, l_1, l_2, \iota, o)$*, where* V *is a set of* vertices*,* E_1 *and* E_2 *are two disjoint sets of* unary *and* binary edges*,* $s : E_1 \uplus E_2 \to V$ *and* $t : E_1 \to V$ *are a* source *and a* target *functions specifying the source and the target of each edge*[1]*,* $l_1 : E_1 \to \Sigma_1$ *and* $l_2 : E_2 \to \Sigma_2$ *are* labeling functions *indicating the label of each edge,* ι *is the* input *vertex and* o *is the* output *vertex,* ι *and* o *are the* interface vertices *of* G*. All the vertices of* G *which are not interface vertices are called* inner vertices*. The* interface of G *is the pair* (ι, o) *if* $\iota \neq o$*, or the vertex* ι *otherwise. An* a-edge *is an edge labeled by the letter* a*. We say that* G *is* unary *if* $\iota = o$*, and* binary *otherwise. The* interface *of a binary edge* e *is* $(s(e), t(e))$*, the interface of a unary edge* e *is* $s(e)$*. An* interface in G *is a list of vertices of length* 1 *or* 2*. A graph is* empty *if it has no edges, and if all its vertices are interface vertices.*

▶ Remark 2. What we call here a graph is what is usually called a hypergraph (because of the unary edges) with interface. We depict graphs with unlabeled ingoing and outgoing arrows to denote the input and the output, respectively.

▶ **Definition 3** (Paths). *A* path p *of* G *is a non-repeating list* $(v_0, e_1, v_1, \ldots, e_n, v_n)$ *where* v_i *is a vertex of* G *and* e_i *is an edge of* G*, such that the interface of* e_i *is either* (v_{i-1}, v_i) *or* (v_i, v_{i-1})*, for every* $i \in [1, n]$*. The path* p *is* directed *if the interface of* e_i *is* (v_{i-1}, v_i) *for every* $i \in [1, n]$*. The vertex* v_0 *is the* input *of* p*,* v_n *is its* output *and* (v_0, v_n) *its* interface*. The path* p *is* safe *if it does not contain an interface vertex of* G *as an inner vertex.*

[1] For unary edges, we specify only their source.

▶ **Example 4.** Here are some examples of graphs. The c-edge in the graph G a unary edge.



▶ **Definition 5** (tw_2 graphs). *Consider the signature σ containing the binary operations $\cdot$ and $\|$, the unary operations $^\circ$ and* dom*, and the nullary operations* 1 *and* $\top$*. We define* tw_2 terms *as the terms generated by the signature σ and the alphabet Σ:*

$$t, u := \ a \ \mid \ t{\cdot}u \ \mid \ (t \parallel u) \ \mid \ t^\circ \ \mid \ \mathsf{dom}(t) \ \mid \ 1 \ \mid \ \top \qquad\qquad a \in \Sigma$$

We define the graph of a term t, $\mathcal{G}(t)$, by induction on t, by letting:

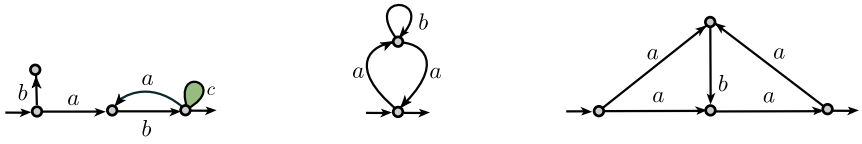
$\mathcal{G}(1) =$ $\mathcal{G}(\top) =$  $\mathcal{G}(a) =$  $\mathcal{G}(b) =$ 
and interpreting the operations of the syntax as follows:

$G{\cdot}H =$  $G \parallel H =$ 

$\mathsf{dom}(G) =$  $G^\circ =$ 
In the picture above, we represent the graph G by an arrow from its input to its output. For example, the graph dom*(G) is obtained from G by relocating the output to the input. We usually write tu instead of $t{\cdot}u$ and give priorities to the symbols of σ so that $ab \| c$ parses to $(a{\cdot}b) \| c$. We define the set of* tw_2 graphs *as the graphs of the terms above. The graphs of a and $a \parallel 1$, where $a \in \Sigma$, are called* atomic*.*

We will sometimes identify terms with the graphs they generate. For example we may say that $(a \parallel b)$ is binary or connected to say that its graph is so.

▶ **Example 6.** Below, from left to right, two tw_2 graphs and a graph which is not tw_2.



$\mathsf{dom}(b)a(a^\circ \parallel b)c$ $\qquad$ $a(b \parallel 1)a$ $\qquad$ No corresponding term

▶ Remark 7. The tw_2 graphs are exactly those graphs whose skeleton[2] has tree-width 2 [4].

▶ **Definition 8** (Graph languages). *Sets of graphs are called* graph languages*. A graph language is* unary *or binary if all its graphs have this arity.*

2.2 Counting monadic second-order logic

We introduce CMSO, the *counting monadic second-order logic*, which is used to describe graph languages.

[2] The skeleton of a graph is the graph obtained by forgetting the labels and the orientation of the edges, and by adding an edge between the input and the output.

▶ **Definition 9** (The logic CMSO). *Let $\mathcal{V}$ be the relational signature which contains two binary symbols* source *and* target*, two unary symbols* input *and* output *and a unary symbol a for each (unary or binary) letter $a \in \Sigma$.*

Let $\mathbb{X}_1$ be a countable set of first-order variables *and $\mathbb{X}_2$ a countable set of* set variables *The formulas of* CMSO *are defined as follows:*

$$\varphi, \psi := \ r(x_1, \ldots, x_n) \ \mid \ x \in X \ \mid \ x = y \ \mid \ \exists x.\varphi \ \mid \ \exists X.\varphi \ \mid \ \varphi \vee \psi \ \mid \ \neg\varphi \ \mid \ (|X| \equiv k) \ [m]$$

where r is an n-ary symbol of $\mathcal{V}$, $x_1, \ldots, x_n, x \in \mathbb{X}_1$, $X \in \mathbb{X}_2$ and $k, m \in \mathbb{N}$. Free and bound variables *are defined as usual. A* sentence *is a formula without free variables. We use the usual syntactic sugar, for example $\varphi \Rightarrow \psi$ as a shortcut for $\neg\varphi \vee \psi$.*

We define the semantics of CMSO formulas. To handle free variables, CMSO formulas are interpreted over *pointed graphs*.

▶ **Definition 10** (Semantics of CMSO). *Let G be a graph and Γ be a set of variables. An* interpretation *of Γ in G is a function mapping each first-order variable of Γ to an edge or vertex of G, and each set variables to a a set of edges and vertices of G. A* pointed graph *is a pair $\langle G, I\rangle$ where G is a graph and I is an interpretation of a set of variables Γ in G. If Γ is empty, we denote it simply as G. Let φ be a* CMSO *formula whose free variables are Γ and let $\langle G, I\rangle$ be a pointed graph such that I is an interpretation of Γ. We define the* satisfiability relation $\langle G, I\rangle \models \varphi$ *as usual, by induction on the formula φ. Here is an example of the semantics of some* CMSO *formulas:*

$\mathsf{source}(v, e)$:	*the source of the edge e is the vertex v.*	$\mathsf{input}(v)$:	*v is the input of G.*
$\mathsf{target}(e, v)$:	*the target of the edge e is the vertex v.*	$\mathsf{output}(v)$:	*v is the output of G.*
$(\lvert X\rvert = k)[m]$:	*the size of X is congruent to k modulo m.*	$a(e)$:	*e is an a-edge.*

If φ is a sentence, we define $\mathcal{L}(\varphi)$, the graph language of φ *as follows:*

$$\mathcal{L}(\varphi) = \{G \ \mid \ G \text{ is a graph and } G \models \varphi\}.$$

▶ **Definition 11** (CMSO definability). *A graph language is* CMSO definable *if it is the graph language of a* CMSO *sentence.*

▶ **Example 12.** The language of graphs having an a-edge from the input to the output is definable in CMSO, by the following formula for instance:

$$\varphi := \ \exists e.\ \exists i.\ \exists o.\ \mathsf{input}(i) \wedge \mathsf{output}(o) \wedge a(e) \wedge \mathsf{source}(i, e) \wedge \mathsf{target}(e, o)$$

Note that the graphs of this language may not be tw_2 graphs.

▶ **Example 13.** The set of tw_2 graphs is a CMSO definable language. Indeed, tw_2 graphs are those graphs which exclude K_4, the complete graph with four vertices, as minor. The set of graphs which exclude a fixed set of minors can be easily defined in CMSO [5].

The set of tw_2 graphs having an a-edge from the input to the output is definable in CMSO, by the conjunction of the formula φ of Ex. 12 and the formula defining tw_2 graphs.

We state below a *localization result*, which allows us to transform a CMSO sentence into another one which talks only about a part of the original graph.

▶ **Proposition 14.** *Let φ be a* CMSO *sentence, $x, y \in \mathbb{X}_1$ and $X \in \mathbb{X}_2$. There is a* CMSO *formula $\varphi_{|(x,X,y)}$ such that, for every graph G and interpretation $I : (x \mapsto s, X \mapsto H, y \mapsto t)$, such that (s, H, t) is a subgraph of G, we have:*

$$\langle G, I\rangle \models \varphi|_{(x,X,y)} \qquad \Leftrightarrow \qquad (s, H, t) \models \varphi$$

▶ Remark 15. There is another presentation of the syntax of CMSO, where we remove first-order variables and the formulas including them, and add the following formulas:

$$X \subseteq Y \quad \text{and} \quad r(X_1 \dots, X_n) \quad \text{where } r \text{ is an } n\text{-ary symbol of } \mathcal{V}.$$

The formula $X \subseteq Y$ is interpreted as "X is a subset of Y" and $r(X_1 \dots, X_n)$ as "for each i, X_i is a singleton containing x_i and $r(x_1 \dots, x_n)$". This presentation is more convenient in proofs by induction as there are less cases to analyze.

2.3 Recognizability

We can specify languages of graphs by means of σ-algebras, generalizing to graphs the notion of recognizability by monoids. A *σ-algebra* $\mathcal{A}$ is the collection of a set D called its *domain*, and for each n-ary operation o of σ, a function $o^{\mathcal{A}} : D^n \to D$. A homomorphism $h : \mathcal{A} \to \mathcal{B}$ between two σ-algebras $\mathcal{A}$ and $\mathcal{B}$ is a function from the domain of $\mathcal{A}$ to the domain of $\mathcal{B}$ which preserves the operations of σ. Note that the set of tw_2 graphs, where the operations of σ are interpreted as in Def. 5, forms a σ-algebra which we denote by $\mathcal{G}_{\mathsf{tw}_2}$.

▶ **Definition 16** (Recognizability). *We say that a language L of tw_2 graphs is* recognizable *if there is a σ-algebra $\mathcal{A}$ with finite domain, a homomorphism $h : \mathcal{G}_{\mathsf{tw}_2} \to \mathcal{A}$ and a subset P of the domain of $\mathcal{A}$ such that $L = h^{-1}(P)$.*

▶ **Theorem 17.** *If a language of tw_2 graphs is CMSO definable, then it is recognizable.*

2.4 Operations on graph languages

The operations of σ can be lifted from graphs to graph languages in the natural way. We say that an operation on graph languages is CMSO *compatible* if, whenever its arguments are CMSO definable, then so is its result.

▶ **Proposition 18.** *Union and the operations of σ are CMSO compatible.*

We define two additional operations: *substitution* and *iteration*.

▶ **Definition 19** (Substitution and iteration). *Let x be a letter, L and M be tw_2 graph languages and let be G a tw_2 graph. We define the set of graphs $G[L/x]$ by induction on G as follows:*

$$x[L/x] = L, \quad a[L/x] = a \ (a \neq x) \quad \text{and} \quad o(G_1 \dots, G_n)[L/x] = o(G_1[L/x], \dots, G_n[L/x])$$

where o is an n-ary operation of σ. We define $M[L/x]$ as:

$$M[L/x] = \bigcup_{G \in M} G[L/x]$$

We define similarly the simultaneous substitution $M[\vec{L}/\vec{x}]$, where $\vec{L}$ and $\vec{x}$ are respectively a list of tw_2 graph languages and a list of letters of the same length.

For every $n \geq 1$, we define the language $L^{n,x}$ and the iteration $\mu x.L$ as follows:

$$L^{1,x} := L, \qquad L^{n+1,x} =: L[L^{n,x}/x] \cup L^{n,x}, \qquad \mu x.L := \bigcup_{n \geq 1} L^{n,x}.$$

▶ Remark 20. Substitution and iteration are not CMSO compatible in general. For instance, the iteration of the CMSO language $\{axb\}$, which is the set $\{a^n x b^n \mid n \in \mathbb{N}\}$, is not CMSO definable. However, under a *guard condition* that we introduce later, we recover CMSO compatibility.

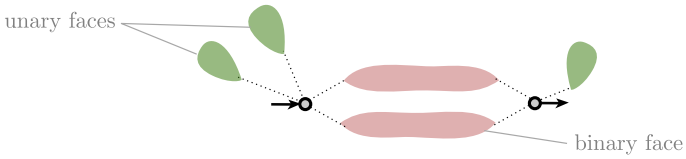
We finally consider two restricted forms of iteration called *Kleene* and *parallel iteration*.

▶ **Definition 21** (Kleene and parallel iteration). *We define the* Kleene iteration L^+ *and the* parallel iteration $L^{\|}$ *of a language L as follows, where x is a letter not appearing in L:*

$$L^+ = (\mu x.\ L{\cdot}x)[L/x], \qquad L^{\|} = (\mu x.\ L \,\|\, x)[L/x].$$

2.5 Pure graphs and modules

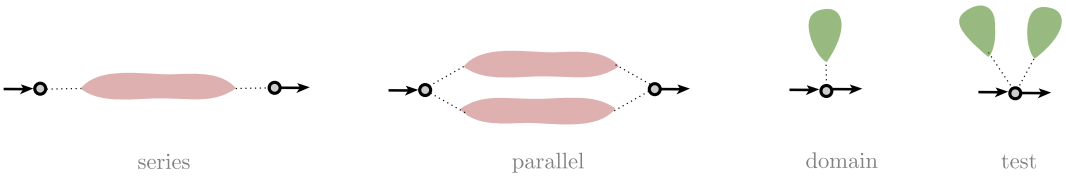
▶ **Definition 22** (Pure graphs.). *Let G be a graph. If we remove the interface vertices of G we obtain one or several connected components which we call the* faces *of G. The* arity of a face *is the number of interface vertices of G it is incident to.*



We say that G is pure *if it has at least one face and all it faces have the same arity as itself. We say that G is* prime *if it has exactly one face, and* composite *if it has at least two faces.*

▶ Remark 23. Pure graphs are connected and non-empty. Not all graphs are pure.

▶ **Definition 24** (Type of a pure graph). *The* type *of a pure graph is a pair specifying its arity and whether it is prime or composite. We say that a graph is* series *if it is binary and prime,* parallel *if it is binary and composite,* domain *if it is unary and prime and* test *if it is unary and composite. We denote by* $\mathsf{s}, \mathsf{p}, \mathsf{d}$ *and* t *the type series, parallel, domain and test respectively. Series, parallel domain and test graphs look like this:*



A graph language is (of type) series, parallel, domain *or* test *if* ***all*** *its graphs have this type.*

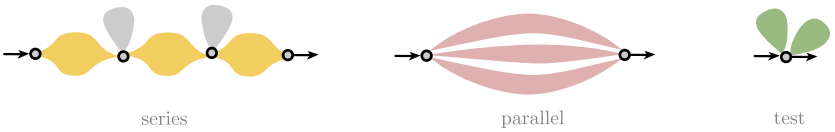
There is a canonical way to decompose pure graphs of type series, parallel and test.

▶ **Proposition 25** ([4]). *Let G be a pure graph. The graph G has the following shape:*

$$\begin{aligned} G &:= P_0 \cdot U_1 \cdot P_1 \ldots U_n \cdot P_n && \text{if } G \text{ is series,} \\ G &:= S_0 \,\|\, \cdots \,\|\, S_n && \text{if } G \text{ is parallel,} \\ G &:= D_0 \,\|\, \cdots \,\|\, D_n && \text{if } G \text{ is test,} \end{aligned}$$

P_j being parallel or atomic, U_i unary, S_i series and D_i domain, for all $j \in [0, n], i \in [1, n]$.

Here is a picture illustrating this proposition:

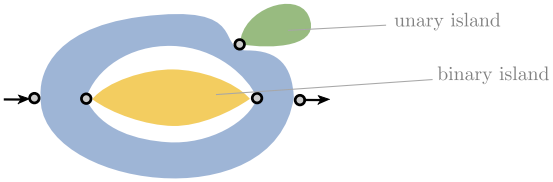


▶ **Definition 26** (Contexts). *Let* $\mathbb{S}$ *be a set of* special (unary and binary) letters*, and let* $n \geq 1$*. An* n-context *is a graph such that* n *of its edges, called* holes*, are numbered from* 1 *to* n*, and labeled by* n *distinct special letters. We call* 1*-contexts simply* contexts*.*

Let C *be an* n*-context whose holes are* $h_1 \dots, h_n$ *and let* $H_1, \dots, H_n$ *be graphs such that* h_i *and the* H_i *have the same arity, for all* $i \in [1, n]$*. We define* $C[H_1, \dots, H_n]$ *as the graph obtained from the disjoint union of* C *and* $H_1, \dots, H_n$*, by removing the holes of* G*, and for every* $i \in [1, n]$ *identifying the input of* h_i *with the input of* H_i*, the output of* h_i *with the output of* H_i*, and by letting its interface of to be that of* C*.*

▶ **Definition 27** (Islands and modules). *An* island *of a graph* G *is a graph* H *such that there is a context* C *satisfying* $G = C[H]$*. A* module *is a island which is pure. Two islands (or modules) of a graph are* parallel *if they have the same interface.*
Since modules are pure, we can speak of series, parallel, domain and test modules of a graph.

The following picture illustrates a unary and binary island of a graph.



▶ Remark 28. Our notion of modules is different from the one usually used in graph theory, more precisely in the setting of *modular decompositions*.

▶ Remark 29. The parallel composition of two islands of a graph G with the same interface is also an island of G with the same interface. Similarly, the parallel composition of two modules of a graph G with the same interface is also a module of G with the same interface. This justifies the following definition.

▶ **Definition 30** (Maximal islands and modules). *Let* G *be a graph and* I *an interface in* G*. The* maximal island at I *is the parallel composition of all the islands of* G *whose interface is* I*, we denote it by* $\mathsf{max\text{-}island}_G(I)$*. The* maximal module at I *is the parallel composition of all the modules of* G *whose interface is* I*, we denote it by* $\mathsf{max\text{-}module}_G(I)$*.*

▶ Remark 31. The maximal module at a given interface does not always exist.

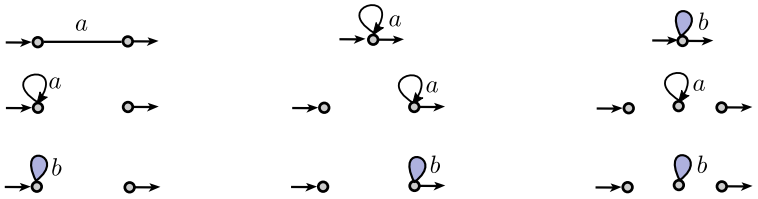
▶ **Proposition 32.** *Being series, parallel, domain, test, an island, a module, a maximal island, a maximal module are* CMSO *definable properties.*

3 Regular expressions for tw_2 graphs

3.1 Regular expressions for word and multiset graphs

▶ **Definition 33** (Word and multiset alphabets). *Let* Σ_{w} *be the set of terms whose graphs have the following form, where* $a, b \in \Sigma_2$ *and* $c \in \Sigma_1$*:*

Let Σ_{m} *be the set of terms whose graphs have the following form, where* $a \in \Sigma_2$ *and* $b \in \Sigma_1$*:*



Word graphs *are the graphs generated from those of* Σ_{w} *by series composition, and* multiset graphs *are the graphs generated from those of* Σ_{m} *by parallel composition.*

▶ **Example 34.** Below, from left to right, a word graph and two multiset graphs.

▶ **Definition 35** (Word an multiset expressions)**.** Word expressions *are defined as follows:*

$$e, f := a \mid e \cdot f \mid e \cup f \mid e^{+} \qquad (a \in \Sigma_{\mathsf{w}})$$

Multiset pre-expressions *are defined as follows:*

$$e, f := a \mid (e \parallel f) \mid e \cup f \mid e^{\parallel} \qquad (a \in \Sigma_{\mathsf{m}})$$

Multiset expressions *are those pre-expressions, where each sub-term appearing under a parallel iteration, is built using a single element* $a \in \Sigma_{\mathsf{m}}$ *(all the other operations are allowed). The graph language of an expressions is defined as usual.*

▶ Remark 36. To see why the condition on multiset regular expressions is useful, consider the expression $e = (a \parallel b)$. The language of its parallel iteration is the set of multiset graphs which have the same number of a-edges and b-edges, and this is not a CMSO definable language.

3.2 Context-free expressions

▶ **Definition 37** (Context-free expressions)**.** *We define* context-free expressions *as the set of terms generated by the following syntax:*

$$\begin{aligned} e, f := \quad & e_{\mathsf{w}} \mid e_{\mathsf{m}} \\ & \mid e \cdot f \mid (e \parallel f) \mid e^{\circ} \mid \mathsf{dom}(e) \mid 1 \mid \top \\ & \mid e \cup f \mid e[f/x] \mid \mu x.e \end{aligned}$$

where e_{w} *and* e_{m} *are respectively word and multiset regular expressions. We define the* language *of a context-free expression* e*, denoted* $\mathcal{L}(e)$*, by induction on* e*, interpreting the operations of the syntax as described in Sec. 2.4.*

Regular expressions for tw_2 *graphs* will be defined as a restriction of context-free expressions, where substitution and iteration are allowed only under a *guard condition* that we shall explain in the following.

3.3 The guard condition

▶ **Definition 38** (Guarded letters)**.** *Let* G *be a graph and* x *a letter. We say that:*

- x *is* s-guarded *in* G *if* x *is binary and every* x*-labeled edge of* G *is parallel to a module.*
- x *is* p-guarded *in* G *if* x *is binary and no* x*-labeled edge of* G *is parallel to a module.*

- *x is* d*-guarded in G if x is unary.*
- *x is* t*-guarded in G if x is unary and no x-labeled edge of G is parallel to a module.*

Let $\tau \in \{\mathsf{s}, \mathsf{p}, \mathsf{d}, \mathsf{t}\}$ be a type and L a graph language. We say that x is τ-guarded *in L if it is τ-guarded in every graph of L.*

▶ **Definition 39** (Guard condition)**.** *Let x be a letter, M a tw_2 graph language and L a pure language of type τ. The substitution $M[L/x]$ is guarded if x is τ-guarded in M. The iteration $\mu x.L$ is guarded if x is τ-guarded in L.*

We say that the iteration $\mu x.L$ is of type τ *if L is of type τ.*

▶ **Definition 40** (Regular expression)**.** *A* regular expression *is a context-free expression where every substitution and iteration is guarded. A language of graphs is* regular *if it is the language of some regular expression.*

▶ Remark 41. When L is test and x is a unary letter, then $\mu x.L$ is always guarded.

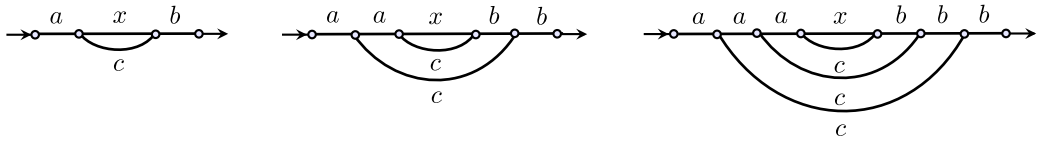
▶ **Proposition 42.** *We can decide if a context-free expression is regular.*

▶ Remark 43. Be aware that prop. 42 is about deciding a syntactic property of e, namely that the iterations and substitutions are guarded. However, the problem of determining if a context-free expression *defines a* CMSO *language* is undecidable. This apparent contradiction comes from the fact that some context-free expressions, which are not guarded, define CMSO languages, as we shall see in the upcoming examples.

3.4 Examples

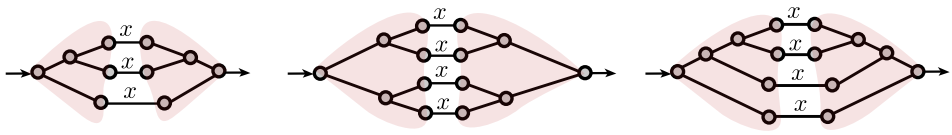
▶ **Example 44.** The iteration $\mu x.axb$ is not guarded. Indeed, the language of axb is series, as it contains a single series graph G. However, the letter x is not s-guarded in G, because it is not parallel to any module of G. The graph of this iteration look like this:

▶ **Example 45.** The iteration $\mu x.a(x \parallel c)b$ is guarded. Indeed the language of $a(x \parallel c)b$ is series, actually it contains a single graph G, depicted below left, which is series. The letter x is s-guarded in G, because it is parallel to a module, namely the c-edge. The graph of this iteration look like this:



Note the similarity between the graph language of $\mu x.axb$ and that of $\mu x.a(x \parallel c)b$: the former is obtained by forgetting the c-edges of the latter. Yet, the latter is CMSO definable, while the former is not. In the case of $\mu x.a(x \parallel c)b$, the c-edges will guide a CMSO formula to relate the a-edges and the b-edges of the same iteration depth. This is the main intuition behind the guard condition for series languages.

▶ **Example 46.** The iteration $\mu x.(axa \parallel axa)$ is guarded. Indeed, the language of $(axa \parallel axa)$ is parallel, as it contains a unique graph G (the left graph below) which is parallel. The letter x is p-guarded because all the occurrences of x are not parallel to any module of G. Note that the graphs of this expression have the following shape: they all start with a binary tree whose edges are labeled by a, end ends with the mirror image of this tree, while the corresponding leafs are connected by an x-edge. Those trees are colored in red below.



At first glance, this expression dos not seem to be CMSO definable, as it seems that we need to test whether a graph starts and ends with the same tree. We will see however that the language of this expression, as those of all regular expressions, is CMSO definable.

The guard condition is not "perfect", in the sense that some non-guarded context-free expressions might generate CMSO definable languages, as shown in the following example.

▶ **Example 47.** The context-free expression $(\mu x.axb)[1/a, 1/x, 1/b]$ is not regular because the iteration $\mu x.axb$ is not guarded. However its language, the graph of 1, is CMSO definable.

▶ Remark 48. Intuitively, the guard condition allows only those graphs where series and parallel operations alternate. This why we add the word and multiset expressions: to allow graphs where we can iterate only series or parallel operations respectively.

3.5 Main result

The main result of this paper is the following theorem:

▶ **Theorem 49.** *Let L be a language of* tw_2 *graphs. We have:*

$$L \text{ is recognizable} \quad \Leftrightarrow \quad L \text{ is CMSO definable} \quad \Leftrightarrow \quad L \text{ is regular}$$

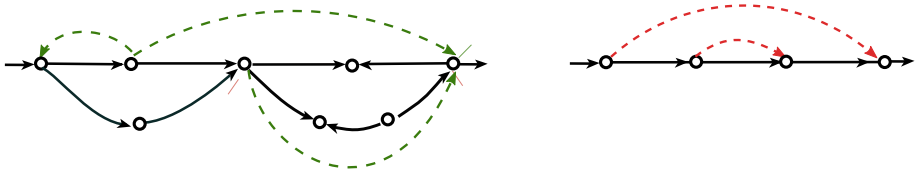
Thanks to Thm. 17, CMSO definability implies recognizablity. We show that regularity implies CMSO definability in Sec. 5 and that recognizabilty implies regularity in Sec. 6.

4 Companion relations

▶ **Definition 50** (Companion relation). *Let G be a graph. Two paths of G are* orthogonal *if they do not share any edge, and whenever they share a vertex, it is necessarily an interface vertex of one of them. A set of paths is a* set of orthogonal paths *if its paths are pairwise orthogonal.*

A relation R on the vertices of G is a companion relation *if there is a set of orthogonal paths P such that $(v, w) \in R$ iff (v, w) is the interface of a path $p \in P$. We say that p is a* witness *for (v, w), and that P is a* witness *for the relation R.*

▶ **Example 51.** The relation indicated by the green dotted arrows below is a companion relation. This is not the case for the one indicated by the red dotted arrows.



We introduce CMSO^r, an extension of CMSO where quantification over companion relations is possible.

▶ **Definition 52** (The logic CMSO^r). *Let $\mathbb{X}_r$ be a set of* relation variables*, whose elements are denoted $R, S, \ldots$. The formulas of CMSO^r are of the following form:*

$$\varphi := \mathsf{CMSO} \mid \exists R.\ \varphi \mid (x, y) \in R \qquad (R \in \mathbb{X}_r,\ x, y \in \mathbb{X}_1).$$

As for CMSO, we need to define the semantics of a formula over pointed graphs to handle free variables.

▶ **Definition 53** (Semantics of CMSO^r). *Let G be a graph and Γ be a set of variables. An interpretation of Γ is as usual, but here every relation variable is mapped to a binary relation on the vertices of G. We define the* satisfiability relation $\langle G, I\rangle \models \varphi$ *as usual, by induction on the formula φ. The only new cases are the quantification $\exists R$ which is interpreted as "there exists a companion relation R on the vertices of the graph", and the formulas $(x, y) \in R$ which are interpreted as "there is a pair of vertices (x, y) in R".*

4.1 The logic CMSO^r have the same expressive power as CMSO

To guess a companion relation in CMSO, we show how to encode a set of guarded paths by a collection of sets called a *footprint*.

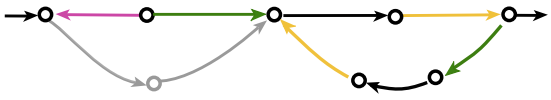
▶ **Definition 54** (Frontier edges of a path). *Let $p = (v_0, e_1, v_1, \ldots, e_n, v_n)$ be a path. If $n > 1$, we call e_1 the* opening edge *of p and e_n its* closing edge*. If $n = 0$, we call e_0 its* single edge*. Opening, closing and single edges are called the* frontier edges *of p, the other edges are called its* inner edges*.*

▶ **Definition 55** (Footprint). *A* footprint *in a graph G is the following collection of data: a partition of the vertices of G into* non-path *and* path *vertices, a partition of edges into* non-path *and* path *edges, a partition of path edges into* frontier *and* inner *edges, a partition of frontier edges into* opening, closing and single *edges and a partition of path edges into* direct *and* inverse *edges.*

The partition of path edges into direct and inverse ones provides them with a new orientation: they conserve their original orientation if they are direct, or get reversed (we swap the source and target) if they are inverse edges.

Let $\mathbb{F}$ be a footprint. A path p is encoded by $\mathbb{F}$ if its edges and vertices are path edges and path vertices of $\mathbb{F}$, if its inner, frontier, opening, closing and single edges are edges of the corresponding sets in $\mathbb{F}$. Moreover, p must form a directed path with the new orientation dictated by $\mathbb{F}$.

▶ **Example 56.** We represent below a footprint in the left graph of Ex. 51. Non-path edges and vertices are grey, path vertices are black, opening edges are green, closing edges are yellow, single edges are pink and all the other inner edges are black. For path edges, we display the new orientation induced by the footprint instead of the original one. The set of paths encoded by this footprint are a witness that the green relation of Ex. 51 is a companion relation.



▶ **Proposition 57.** *Let G be a graph and P a set of orthogonal paths of G. There is a footprint $\mathbb{F}$ such that P is the set of paths encoded by $\mathbb{F}$.*

▶ **Corollary 58.** *If a language is CMSO^r definable then it is* CMSO *definable.*

5 Regular implies CMSO definable

▶ **Theorem 59.** *If a language is regular, then it is* CMSO *definable.*

To prove Thm. 59, we proceed by induction on regular expressions. The cases of word and multiset regular expressions follow from the similar result for words and commutative words. The cases of union and the operations of the signature σ follow from Prop. 18. We are left with the cases of substitution and iteration; the rest of this section is dedicated to proving the following proposition.

▶ **Proposition 60.** *Let x be a letter and L and M be languages of* tw_2 *graphs. We have:*

$$M[L/x] \text{ is guarded and } L \text{ and } M \text{ are } \mathsf{CMSO}\text{-definable} \Rightarrow M[L/x] \text{ is } \mathsf{CMSO}\text{-definable.}$$
$$\mu x.L \text{ is guarded and } L \text{ is } \mathsf{CMSO}\text{-definable} \Rightarrow \mu x.L \text{ is } \mathsf{CMSO}\text{-definable.}$$

We handle the case of iteration, the case of substitution being similar. We show first that the iteration of a CMSO definable language, without any guard condition, is definable in an extension of CMSO where we are allowed to quantify existentially over sets of subgraphs of the input graph, which we call CMSO^d. This logic is obviously strictly more expressive then CMSO, because it amounts to quantify over sets of sets. Based on this, we show that the *guarded iteration* of a CMSO definable language is definable in CMSO^r, the extension of CMSO with companion relations defined in the previous section. This concludes the proof, the logic CMSO^r being equivalent to CMSO.

5.1 Iteration of CMSO formulas is CMSO^d definable

5.1.1 Decompositions

When a graph is in the iteration $\mu x.L$ of some language L, it is possible to structure it into a tree shaped decomposition, such that each part of this decomposition "comes from L". In the following, we define such decompositions.

▶ **Definition 61** (Independent graphs)**.** *Let G be a graph and H, K be subgraphs of G. We say that H and K are* independent *if they do not share any edge; and whenever they share a vertex, it is necessarily an interface vertex of both H and K.*

▶ **Definition 62** (Decompositions)**.** *A* decomposition *of G is a set $\mathcal{D}$ of modules of G such that $G \in \mathcal{D}$ and for every pair of graphs in $\mathcal{D}$, they are either independent, or module one of the other. We call the graphs of a decomposition its* components*. We call* the interfaces of $\mathcal{D}$ *the set of interfaces of its components.*

Let H and K be components of a decomposition $\mathcal{D}$. We say that H is a child *of K, if H is a module of K, and if there is no component C of $\mathcal{D}$, distinct from H and K, such that H is a module of C and C is a module of K.*

The graph G is called the head *of $\mathcal{D}$. A component of $\mathcal{D}$ is a* leave *if it does not contain another component of $\mathcal{D}$ as a module.*

▶ **Definition 63** (Body of a component)**.** *Let G be a graph, $\mathcal{D}$ a decomposition of G and C a component of $\mathcal{D}$.*

The body *of C is the subgraph of G whose vertices are those of C minus the* ***inner*** *vertices of its children; and whose edges are those of C minus those of its children.*

*The x-*body of C *is the graph whose interface is the interface of C, whose vertices are the vertices of the body of C, and whose edges are the edges of the body of C plus, for each child F of C, an x-edge whose interface is the interface of F. We denote it by x-$\mathsf{body}_{\mathcal{D}}(C)$.*

▶ **Definition 64** (L-decompositions). *Let L be a graph language. An L-decomposition of a graph G is a decomposition of G such that the x-body of each of its components is in L.*

▶ Remark 65. The body of a component is a subgraph of G, but its x-body is not a subgraph of G in general, because of the added x-edges.

▶ **Proposition 66.** *Let L be a graph language. We have:*

$$G \in \mu x.L \qquad \Leftrightarrow \qquad \exists \mathcal{D}. \quad \mathcal{D} \text{ is an } L\text{-decomposition of } G.$$

5.1.2 The logic CMSO^d

Let φ be a CMSO formula defining a graph language L. Using Prop 66, we can express that a graph G is in the iteration $\mu x.L$ by guessing a decomposition $\mathcal{D}$ of G, and ensuring that the x-body of each component satisfies φ. But guessing a set of subgraphs is not expressible in CMSO. This is why we introduce CMSO^d, an extension of CMSO where this is allowed.

▶ **Definition 67** (CMSO^d logic). *Let $\mathbb{X}_d$ be a set of* graph set variables*, whose elements are denoted $\mathcal{X}, \mathcal{Y} \ldots$. The formulas of* CMSO^d *are of the following form:*

$$\varphi := \mathsf{CMSO} \mid \exists \mathcal{X}.\ \varphi \mid (s, Z, t) \in \mathcal{X} \qquad\qquad (\mathcal{X} \in \mathbb{X}_d, \quad Z \in \mathbb{X}_2, \quad s, t \in \mathbb{X}_1).$$

Free and bound variables are defined as usual. As for CMSO, we need to define the semantics of a formula over pointed graphs to handle free variables.

▶ **Definition 68** (Semantics of CMSO^d). *Let G be a graph and Γ be a set of variables.*

An interpretation of Γ *is a function mapping every first-order variable of Γ to an edge or vertex of G, every set variable to a set of edges and vertices of G, and every graph set variable to a set of subgraphs of G.*

We define the satisfiability relation $\langle G, I\rangle \models \varphi$ *as usual, by induction on φ. The only new cases compared to* CMSO *are the quantification $\exists \mathcal{X}$ which is interpreted as "there exists a set of subgraphs $\mathcal{X}$", and the formulas $(s, Z, t) \in \mathcal{X}$ which are interpreted as "the graph whose input is s, whose output is t and whose set of edges and vertices is Z, is an element of $\mathcal{X}$".*

▶ **Proposition 69.** *There is a* CMSO^d *formula* $\mathsf{decomp}(\mathcal{X})$*,* without graph set quantification*, such that for every graph G and every set of subgraphs $\mathcal{D}$ of G, we have:*

$$\langle G, \mathcal{X} \mapsto \mathcal{D}\rangle \models \mathsf{decomp}(\mathcal{X}) \quad \Leftrightarrow \quad \mathcal{D} \text{ is a decomposition of } G.$$

5.1.3 Iteration is expressible in CMSO^d

Given a CMSO formula φ, we construct a formula $[\![\varphi]\!]$ having $\mathcal{X}$ as unique free variable, which expresses the fact that the x-body the head of the decomposition $\mathcal{X}$ satisfies φ. To construct $[\![\varphi]\!]$, we need the following definition.

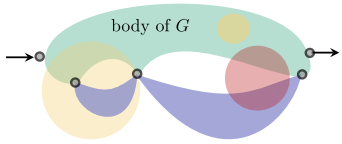
▶ **Definition 70** (Complete sets). *Let $\mathcal{D}$ be a decomposition of a graph G.*

Let H be a set of edges and vertices of G. We say that H is complete *if, whenever it contains an edge or an inner vertex of a child C of G (seen as a component of $\mathcal{D}$), then it contains all the edges and inner vertices of C.*

Let K be a set of edges and vertices of the x-body of G. We denote by $\mathsf{complete}_{\mathcal{D}}(K)$ the set of edges and vertices of G, obtained from K by replacing every x-edge coming from a child C of G by the set of edges and inner vertices C.

▶ Remark 71. Note that if H is complete, there is a set S such that $H = \mathsf{complete}_{\mathcal{D}}(S)$.

Here is a picture illustrating complete sets. The green part is the body of G and the purple modules are its children. The yellow sets are complete, but the pink one is not.



▶ **Proposition 72.** *The following formulas are* CMSO^d *definable:*

$\mathsf{child}_{\mathcal{X}}(Y)$	:	*Y is the set of edges and inner vertices of a child of the input graph w.r.t. the decomposition $\mathcal{X}$.*
$\mathsf{is\text{-}complete}_{\mathcal{X}}(Y)$	:	*Y is complete wrt $\mathcal{X}$.*
$\mathsf{body\text{-}edge}_{\mathcal{X}}(Y)$	:	*Y is a singleton containing an edge from the body of the input graph wrt $\mathcal{X}$.*
$\mathsf{source}_{\mathcal{X}}(Y,Z)$	:	$\mathsf{child}_{\mathcal{X}}(Z)$ *and Y is a singleton containing the input of the corresponding child.*
$\mathsf{target}_{\mathcal{X}}(Y,Z)$	:	*the same as above, where input should be replaced by output.*
$\mathsf{choice}_{\mathcal{X}}(Y,Z)$	:	*Z contains all the body elements of Y, and for every child contained in Y, Z contains exactly one element of this child.*

We construct the formula $[\![\varphi]\!]$ by induction on the structure of φ. We suppose that φ is build using the syntax of CMSO where only set variables are allowed.

▶ **Definition 73.** *Let φ be a* CMSO *formula whose free variables are Γ. We define the* CMSO^d *formula $[\![\varphi]\!]$, whose free variables are $\Gamma \cup \{\mathcal{X}\}$, by induction as follows:*

$$
\begin{array}{lcl}
[\![\varphi \vee \psi]\!] & = & [\![\varphi]\!] \vee [\![\psi]\!] \\
[\![\neg\varphi]\!] & = & \neg\, [\![\varphi]\!] \\
[\![(|Y| \equiv k)[m]]\!] & = & \exists Z.\ \mathsf{choice}_{\mathcal{X}}(Y,Z) \wedge (|Z| \equiv k)[m] \\
[\![Y \subseteq Z]\!] & = & Y \subseteq Z \\
[\![a(Y)]\!] & = & a(Y) \qquad (a \neq x) \\
[\![x(Y)]\!] & = & \mathsf{child}_{\mathcal{X}}(Y) \vee (\mathsf{body\text{-}edge}_{\mathcal{X}}(Y) \wedge x(Y)) \\
[\![\exists Y.\ \varphi]\!] & = & \exists Y.\ \mathsf{is\text{-}complete}_{\mathcal{X}}(Y) \wedge [\![\varphi]\!] \\
[\![\mathsf{source}(Y,Z)]\!] & = & (\mathsf{body\text{-}edge}_{\mathcal{X}}(Z) \wedge \mathsf{source}(Y,Z)) \vee (\mathsf{child}_{\mathcal{X}}(Z) \wedge \mathsf{source}_{\mathcal{X}}(Y,Z)) \\
[\![\mathsf{target}(Y,Z)]\!] & = & (\mathsf{body\text{-}edge}_{\mathcal{X}}(Z) \wedge \mathsf{target}(Y,Z)) \vee (\mathsf{child}_{\mathcal{X}}(Z) \wedge \mathsf{target}_{\mathcal{X}}(Y,Z))
\end{array}
$$

Transfer results are results of this form: to check that a transformation $\mathsf{f}(G)$ of a structure G satisfies a formula φ, construct a formula $\mathsf{f}^{-1}(\varphi)$ that G should satisfy. The proposition below is a transfer result, where the transformation is the x-body.

▶ **Proposition 74.** *Given a* CMSO *sentence φ defining, there is a* CMSO^d *formula $[\![\varphi]\!]$ having $\mathcal{X}$ as unique free variable, such that for every graph G and every decomposition $\mathcal{D}$ of G* whose components are non-empty*:*

$$\langle G, \mathcal{X} \mapsto \mathcal{D} \rangle \models [\![\varphi]\!] \qquad \Leftrightarrow \qquad x\text{-}\mathsf{body}_{\mathcal{D}}(G) \models \varphi.$$

The formula $[\![\varphi]\!]$ expresses the fact that the x-body of the head of a decomposition satisfies φ. Using this formula and the localization construction of Prop. 14, we construct a formula $\mu x.L$ saying that the x-body of **all** the components of a decomposition satisfy φ.

▶ **Definition 75.** *If φ is a* CMSO *formula, we let $\mu x.\varphi$ be the following* CMSO^d *formula:*

$$\mu x.\varphi := \exists \mathcal{X}.\ \mathsf{decomp}(\mathcal{X}) \quad \wedge \quad \forall s.\forall Z.\ \forall t.\ (s,Z,t) \in \mathcal{X} \ \Rightarrow\ [\![\varphi]\!]\,|_{(s,Z,t)}$$

The following proposition says that the language of $\mu x.\varphi$ is the iteration of that of φ.

▶ **Proposition 76.** *If φ is a* CMSO *formula defining a language of non-empty graphs, then:*

$$\mathcal{L}(\mu x.\varphi) = \mu x.\mathcal{L}(\varphi).$$

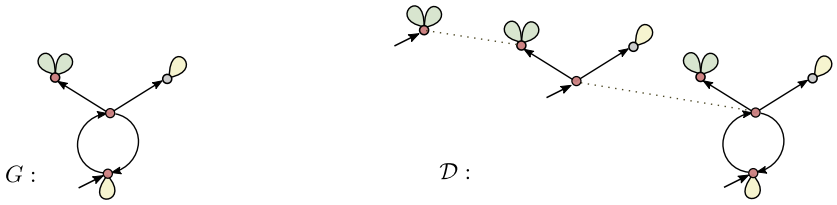
▶ **Corollary 77.** *If L is* CMSO *definable then $\mu x.L$ is* CMSO^d *definable.*

5.2 Guarded iteration of CMSO languages is CMSO^r

The idea here is that when the iteration $\mu x.L$ is guarded, L-decompositions can be encoded by sets of edges and vertices and by companion relations.

5.2.1 The case of test languages

Let $\mu x.L$ be a guarded iteration of type *test*, $G \in \mu x.L$ and $\mathcal{D}$ an L-decomposition of G. Suppose that G is the left graph below, and that the red vertices are the interfaces[3] of $\mathcal{D}$.



We claim that, thanks to the guard condition, this information is enough to reconstruct the whole decomposition $\mathcal{D}$. More precisely, we claim that the components of $\mathcal{D}$ are exactly the maximal modules of G, whose interfaces are the red vertices, as depicted above.

▶ **Definition 78.** *Let G be a graph and S be a set of vertices of G. We define $\mathcal{D}_{\mathsf{t}}(S)$ as the set of maximal modules of G, whose type is test, and whose interfaces belong to S.*

▶ **Proposition 79.** *Let $\mu x.L$ be a guarded iteration of type test. We have:*

$$G \in \mu x.L \qquad \Leftrightarrow \qquad \exists S.\ \ S \text{ is a set of vertices of } G \text{ and } \mathcal{D}_{\mathsf{t}}(S) \text{ is an } L\text{-decomposition of } G.$$

Proof. ($\Rightarrow$) Follows from Prop. 66. To prove ($\Leftarrow$), we define the property P_n as follows:

$$P_n : \qquad \forall G.\ \ G \in L^{n,x} \ \Rightarrow\ \exists S.\ \ S \text{ is a set of vertices of } G \text{ and } \mathcal{D}_{\mathsf{t}}(S) \text{ is an } L\text{-decomposition of } G.$$

We prove, by induction on n, that P_n is valid for every $n \geq 1$, and this is enough to conclude.

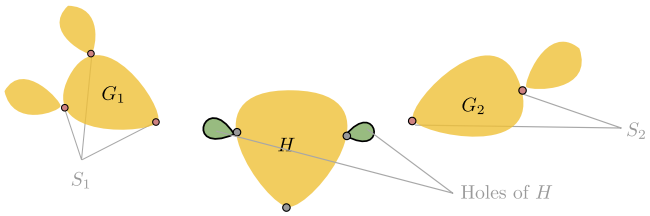
[3] Recall that test graphs are unary, hence all the components of a decomposition of G are unary.

When $n = 1$, take S to be the singleton containing the interface of G. We have that $\mathcal{D}_{\mathsf{t}}(S) = \{G\}$ and since $G \in L$, we have that $\mathcal{D}_{\mathsf{t}}(S)$ is an L-decomposition of G.

Let $G \in L^{n+1,x}$. By definition, there is a k-context H and graphs $G_1, \dots, G_k$ such that:

$$G = H[G_1, \dots, G_k], \quad H[x, \dots, x] \in L \quad \text{and} \quad G_i \in L^{n,x}, \text{ for } i \in [1, k].$$

Thanks to the guard condition, there is no module of H parallel to a hole of H. For every $i \in [1, k]$, let S_i be the set of vertices provided by the induction hypothesis applied to the graph G_i. Here is a picture illustrating these notations:



The set of subgraphs $\mathcal{D}$ defined below is an L-decomposition of G.

$$\mathcal{D} := \mathcal{D}_{\mathsf{t}}(S_1) \cup \cdots \cup \mathcal{D}_{\mathsf{t}}(S_k) \cup \{G\}$$

To conclude we only need to find a set of vertices S of G such that $\mathcal{D}_{\mathsf{t}}(S) = \mathcal{D}$. Let $S = S_1 \cup \cdots \cup S_k \cup \{\iota\}$, where ι is the interface of G. Let us show that $\mathcal{D}_{\mathsf{t}}(S) = \mathcal{D}$. This is a consequence of the following lemma:

▶ **Lemma 80.** *Let C be a context, K a graph and I an interface in H of the same arity as the hole of C. Suppose that the hole of C is not parallel to any module. We have:*

$$\mathsf{max\text{-}module}_{C[K]}(I) = \mathsf{max\text{-}module}_{K}(I)$$ ◀

▶ **Theorem 81.** *Suppose that $\mu x.L$ is a guarded iteration of type test. We have:*

$$L \textit{ is } \mathsf{CMSO} \textit{ definable} \quad \Rightarrow \quad \mu x.L \textit{ is } \mathsf{CMSO} \textit{ definable}$$

Proof. Let φ be a CMSO formula whose language is L. We transform the CMSO^d formula $\mu x.\varphi$ of Def. 75, whose language is $\mu x.L$, into a CMSO formula $\mu x^g.\varphi$ of the same language. The formula $\mu x^g.\varphi$ is obtained by replacing the quantification $\exists \mathcal{X}.$ by the set quantification $\exists S.$, and by replacing every sub-formula of $\mu x.\varphi$ of the form $(s, Z, t) \in \mathcal{X}$ by this formula:

$$(s = t) \ \wedge \ s \in S \ \wedge \ \text{“}(s, Z, t) \text{ is a maximal module”}$$

The last part of this formula is expressible in CMSO thanks to Prop. 32. The language of $\mu x^g.\varphi$ is the set of graphs for which we can find an L-decomposition encoded by a set of vertices S, and this is precisely the language $\mu x.L$ thanks to Prop. 79. ◀

5.2.2 The case of domain languages

Let $\mu x.L$ be a guarded iteration of type *domain*, $G \in \mu x.L$ and $\mathcal{D}$ an L-decomposition of G. Contrarily to the test case, the interfaces of $\mathcal{D}$ are not enough to reconstruct $\mathcal{D}$. Indeed, in this case, a component of $\mathcal{D}$ whose interface is v is not necessarily the maximal module at v, but some domain module of interface v, among possibly many others. A way to determine if a domain module is in the decomposition is to check whether it contains an interface of the decomposition. This works only for the components which are not the leaves of the decomposition. This is why we need to say explicitly which domain modules are the leaves. We do so by *coloring* the edges of the later.

In the following, we show that a set of vertices of a graph (representing the interfaces of a decomposition) together with a coloring of this graph (indicating which modules are leaves), is enough to recover the decomposition.

▶ **Definition 82** (Coloring, active modules.). *A* coloring *of a graph G is a set of its edges called* leaf edges. *A module of G is* active *if it contains a leaf edge.*

▶ **Definition 83** ($\mathcal{D}_{\mathsf{d}}(S, \mathsf{col})$). *Let G be a graph, S a set of vertices and* col *a coloring of G. We let $\mathcal{D}_{\mathsf{d}}(S, \mathsf{col})$ bet the set of active modules of G of type* d*, whose interfaces belong to S.*

▶ **Proposition 84.** *Let $\mu x.L : \mathsf{d}$ be a guarded iteration. We have:*

$$G \in \mu x.L \quad \Leftrightarrow \quad \exists S, \mathsf{col}. \quad \begin{array}{l} S \text{ is a set of vertices and } \mathsf{col} \text{ a coloring of } G \text{ such that} \\ \mathcal{D}_{\mathsf{d}}(S, \mathsf{col}) \text{ is an } L\text{-decomposition of } G. \end{array}$$

Proof. Similar to the proof of prop. 79. ◀

As in the previous section, we use Prop. 84 to get the following theorem.

▶ **Theorem 85.** *Suppose that $\mu x.L : \mathsf{d}$ be a guarded iteration. We have:*

$$L \text{ is } \mathsf{CMSO} \text{ definable} \quad \Rightarrow \quad \mu x.L \text{ is } \mathsf{CMSO} \text{ definable}$$

5.2.3 The case of parallel languages

The case of guarded iterations of type parallel is similar to the test case. Let $\mu x.L$ be a guarded iteration of type parallel, $G \in \mu x.L$ and $\mathcal{D}$ an L-decomposition of G. We show that the interfaces I of $\mathcal{D}$ is enough to recover the whole decomposition $\mathcal{D}$, because its components are the maximal modules of G whose interfaces belong to I. However, in this case, I is no longer a set of vertices, but a set of pairs of vertices, that is a relation on the vertices of G. We will show that this relation is necessarily a companion relation. Using this result and the fact that CMSO and CMSO^r have the same expressive power, we prove that the iteration is CMSO definable.

▶ **Definition 86** ($\mathcal{D}_{\mathsf{p}}(R)$). *Let G be a graph and R a relation on the vertices of G. We define $\mathcal{D}_{\mathsf{p}}(R)$ as the set of maximal modules of G, whose type is parallel, and whose interfaces belong to S.*

▶ **Proposition 87.** *Let $\mu x.L$ be a guarded iteration of type parallel. We have:*

$$G \in \mu x.L \quad \Leftrightarrow \quad \exists R. \quad \begin{array}{l} R \text{ is a set of vertices of } G \text{ and} \\ \mathcal{D}_{\mathsf{p}}(R) \text{ is an } L\text{-decomposition of } G. \end{array}$$

▶ **Proposition 88.** *Let $\mu x.L$ be an iteration of type parallel and let G a graph. The interfaces of every L-decomposition of G form a companion relation.*

Proof. We prove by induction on $n \geq 1$ that the interfaces of every L-decomposition of depth n of some graph G form a companion relation, witnessed by a set of paths P, such that the interface of G is witnessed by two parallel paths of P.

When $n = 1$, the decomposition $\mathcal{D}$ is reduced to the graph G. Since G is parallel, it has two parallel paths whose interface is the interface of G. Take P to be these two paths.

Suppose that $\mathcal{D}$ is a decomposition of depth $n + 1$. Hence it is of the form:

$$\mathcal{D} = \mathcal{D}_1 \cup \ldots \mathcal{D}_k \cup \{G\}$$

where $\mathcal{D}_i$ is an L-decomposition of depth at most n, of a graph G_i, for every $i \in [1,k]$. Let P_i be the set of paths provided by the induction hypothesis for $\mathcal{D}_i$, and let p_i, q_i be the two paths witnessing the interface of G_i, for $i \in [1,k]$.

We set $H := x\text{-}\mathsf{body}_{\mathcal{D}}(G)$. Since H is parallel, it has two parallel paths p and q whose interface is the interface of H. We transform the paths p and q of H into the paths p' and q' of G as follows. The paths p' and q' are obtained from p and q respectively by the following procedure: if e is an x-edge of H which is substituted by some G_i, then replace e by the path of p_i. Let P be the following set of paths:

$$P = (P_1 \setminus \{p_1\}) \cup \ldots (P_k \setminus \{p_k\}) \cup \{p', q'\}\,.$$

The set P is orthogonal and witnesses the interfaces of $\mathcal{D}$. Moreover, the interface of G is witnessed by two parallel paths of P, namely p' and q'. This concludes the proof. ◀

▶ **Theorem 89.** *Suppose that $\mu x.L$ is a guarded iteration of type parallel. We have:*

$$L \text{ is } \mathsf{CMSO} \text{ definable} \quad \Rightarrow \quad \mu x.L \text{ is } \mathsf{CMSO} \text{ definable}$$

5.2.4 The case of series languages

Let $\mu x.L$ be a guarded iteration of type series, G a graph in $\mu x.L$ and $\mathcal{D}$ an L-decomposition of G whose set of interfaces is I. As for the domain case, the set I is not enough to reconstruct the decomposition $\mathcal{D}$, and we need a coloring of the graph to determine which modules are the leaves of the decomposition $\mathcal{D}$. We show also that the set of interfaces I is a companion relation, which will be enough to conclude.

▶ **Definition 90** ($\mathcal{D}_{\mathsf{s}}(R, \mathsf{col})$)**.** *Let G be a graph, R a relation on the vertices of G and* col *a coloring of G. We let $\mathcal{D}_{\mathsf{s}}(R, \mathsf{col})$ bet the set of active modules of G of type series, whose interfaces belong to R.*

▶ **Proposition 91.** *Let $\mu x.L$ be a guarded iteration of type series. We have:*

$$G \in \mu x.L \quad \Leftrightarrow \quad \exists R, \mathsf{col}. \quad \begin{array}{l} R \text{ is a relation on the vertices of } G, \\ \mathsf{col} \text{ is a coloring of } G \text{ and} \\ \mathcal{D}_{\mathsf{s}}(R, \mathsf{col}) \text{ is an } L\text{-decomposition of } G. \end{array}$$

▶ **Proposition 92.** *Let $\mu x.L$ be a guarded iteration of type series and let G be a graph. The interfaces of every L-decomposition of G form a companion relation.*

▶ **Theorem 93.** *Suppose that $\mu x.L$ is a guarded iteration of type series. We have:*

$$L \text{ is } \mathsf{CMSO} \text{ definable} \quad \Rightarrow \quad \mu x.L \text{ is } \mathsf{CMSO} \text{ definable}$$

6 Recognizable implies regular

▶ **Theorem 94.** *If a language of tw_2-graphs is recognizable, then it is regular.*

We proceed gradually, by showing that this result holds for *domain-free graphs*, for *domain-free* graphs, then for tw_2 graphs.

▶ **Definition 95** (Domain-free)**.** *A graph is* domain-free *if all its domain modules are atomic.*

To give an example of how these proofs work, suppose that we have the following property:

▶ **Proposition 96.** *If a language of domain-free graphs is recognizable, then it is regular.*

Using Prop. 96, let us show the following property:

▶ **Proposition 97.** *If a language of domain graphs is recognizable, then it is regular.*

Proof. Let L be a language of domain graphs, $\mathcal{A}$ an algebra whose domain is D, $h : \mathbb{G}_{\mathsf{tw}_2}(\Sigma) \to \mathcal{A}$ a homomorphism and $F \subseteq D$ such that $h^{-1}(F) = L$. Let us show that L_v, the set of graphs over Σ whose image is v, is regular for every $v \in D$.

We associate every $v \in D$ with a new letter x_v and let $\Gamma := \{x_v \mid v \in D\}$. If $Q \subseteq D$, we denote by X_D the letters of Γ corresponding to these elements. We extend the homomorphism h to tw_2-graphs over the alphabet $\Sigma \cup \Gamma$ by letting $h(x_v) = v$ for every $x_v \in \Gamma$.

Let $v \in D$, $Q \subseteq D$ and $X \subseteq \Gamma$. We define the set of graphs $L_v^{Q,X}$ as follows. We let G be in this set if and only if:

- G is a domain graph over the alphabet $\Sigma \cup X$,
- the image of G is v,
- the image of the strict domain modules of G belong to Q.

Let us show that $L_v^{Q,X}$ is regular when $X_Q \cap X = \emptyset$. We proceed by induction on the size of Q. Suppose that $Q = \emptyset$. This case is based on the following lemma, obtained by case analysis on the graph G.

▶ **Lemma 98.** *Let G be a domain graph whose domain modules, distinct from G itself, are all atomic. There is a domain-free graph H such that $G = \mathsf{dom}(H)$.*

For every $w \in D$, let M_w^X be the set of domain-free graphs over the alphabet $\Sigma \cup X$ whose image is w. By Lem. 98, we have the following equation:

$$L_v^{\emptyset,X} = \bigcup_{\substack{w \in D \\ \mathsf{dom}(w)=v}} \mathsf{dom}(M_w)$$

which concludes the base case, thanks to Prop. 96. To handle the inductive case, we notice the following equality:

$$L_v^{Q\cup\{w\},X} = L_v^{Q,X\cup\{x_w\}}[\mu x_w.\ L_w^{Q,X\cup\{x_w\}}/x_w][L_w^{Q,X}/x_w] \qquad \blacktriangleleft$$

7 Conclusion

We are interested in studying the complexity-theoretic properties of our expressions. For instance understanding the complexity of deciding whether an expression is guarded, and what are the costs of translations between different formalisms (expressions, CMSO, algebra). This can help us get a better grasp of what role these expressions can play, and what is the fine interplay between these different formalisms. As stated in the introduction, this work on tree-width 2 graphs is meant to constitute a first step towards the case of tree-width k.

Abstract

We study synthesis of reactive systems interacting with environments using an infinite data domain. A popular formalism for specifying and modelling such systems is register automata and transducers. They extend finite-state automata by adding registers to store data values and to compare the incoming data values against stored ones. Synthesis from nondeterministic or universal register automata is undecidable in general. However, its register-bounded variant, where additionally a bound on the number of registers in a sought transducer is given, is known to be decidable for universal register automata which can compare data for equality, i.e., for data domain $(\mathbb{N}, =)$. This paper extends the decidability border to the domain $(\mathbb{N}, <)$ of natural numbers with linear order. Our solution is generic: we define a sufficient condition on data domains (regular approximability) for decidability of register-bounded synthesis. The condition is satisfied by natural data domains like $(\mathbb{N}, <)$. It allows one to use simple language-theoretic arguments and avoid technical game-theoretic reasoning. Further, by defining a generic notion of reducibility between data domains, we show the decidability of synthesis in the domain $(\mathbb{N}^d, <^d)$ of tuples of numbers equipped with the component-wise partial order and in the domain $(\Sigma^*, \prec)$ of finite strings with the prefix relation.

1 Introduction

Synthesis. Reactive synthesis aims at the automatic construction of an interactive system from its specification. A system is usually modelled as a transducer. In each step, it reads an input from the environment and produces an output. In this way, the transducer, reading an infinite sequence of inputs, produces an infinite sequence of outputs. Specifications are modelled as a language of desirable input-output sequences. The synthesis problem then asks to automatically construct a transducer whose input-output sequences belong to a given specification. Traditionally [30, 4], the inputs and outputs have been modelled as letters from a finite alphabet. This, however, limits the application of synthesis. Recently researchers have started investigating synthesis of systems working on data domains [12, 24, 15, 25, 2, 14].

Automata as specifications. In the finite-alphabet setting, specifications are usually given as logical formulas and a synthesiser performs a series of translations: first, from the formula to an automaton, then from the automaton to a game, and finally it searches for a winning strategy in the game. It is the second step, from automata to games, that captures the game-theoretic essence of synthesis, whereas the first step is an orthogonal problem of finding a convenient logical formalism. In the context of synthesis over data domains, this first step is problematic as there is no decidable, and expressive enough, logic having a corresponding automaton model. For that reason, in this paper we focus on the second step and use automata for specifications.

Register automata. A well-studied automata formalism for specifying and modelling data systems are register automata and transducers [22, 28, 23, 33]. Register automata extend classical finite-state automata to infinite alphabets $\mathbb{D}$ by introducing a finite number of *registers*. In each step, the automaton reads a data value $\ell \in \mathbb{D}$, compares it with the values held in its registers, then depending on this comparison it decides to store ℓ into some of its registers, and finally moves to a successor state. This way, it builds a sequence of *configurations* (pairs of state and register values) representing its run on reading a word from $\mathbb{D}^\omega$: it is accepting if the visited states satisfy a certain condition, e.g. parity. Transducers are similar except that in each step they also output the content of one register.

Universal register automata. Unlike classical finite-state automata, the expressive power of register automata depends on whether they are deterministic, nondeterministic, or universal (a.k.a. co-nondeterministic). Among these, universal register automata suit synthesis best. First, they can specify request-grant properties: every requested data shall be eventually outputted. This is a key property in reactive synthesis, and in the data setting it can be expressed by a universal register automaton but not by a nondeterministic one. Furthermore, universal register automata are closed, in linear time, under intersection. Hence they allow for succinct conjunction of properties, which is desirable in synthesis as specifications usually consist of many independent properties. Finally, in the register-free setting universal automata are often used to obtain synthesis methods feasible in practice [26, 31, 17, 4].

Data domains with order. Another factor affecting expressivity of register automata is the data-comparison operators. Originally, register automata compared data for equality only, i.e., operated in data domain $(\mathbb{D}, =)$ [22]. This limits synthesis applications as we cannot specify priority arbiters [8] that should give a resource to a requesting process with the lowest ID. Such properties require data domains with linear order $<$ (in addition to $=$). Further, there are data domains with dense order, like $(\mathbb{Q}, <)$, and those with discrete order, like $(\mathbb{N}, <)$. The domain $(\mathbb{Q}, <)$ is well-suited for abstracting physical phenomena like changing temperature in a room. However, for abstracting hardware, the domain $(\mathbb{N}, <)$ suits better as it excludes Zeno-like behaviours (when a process ID gets infinitely closer to another ID but never reaches it). The domain $(\mathbb{N}, <)$ is also interesting from the theoretical point of view as it demands new proof techniques.

Known synthesis results for register automata. Already for $(\mathbb{D}, =)$, the synthesis problem of register transducers from universal register automata is undecidable [12, 15]. Decidability is recovered in the deterministic case [15, 14], but, as argued above, universal automata are more desirable in synthesis. To circumvent undecidability, the works [24, 15, 25] studied *register-bounded* synthesis: given a universal register automaton *and a bound* k on the number

of transducer registers, return a k-register transducer realising the automaton or "No" if no such transducer exists. They showed the decidability of register-bounded for $(\mathbb{D}, =)$, and it is not hard to adapt their techniques to $(\mathbb{Q}, <)$ and other oligomorphic domains [6], however the domain $(\mathbb{N}, <)$ remained elusive. Tables 1 and 2 summarise known and new results, where DRA/NRA/URA stand for deterministic/nondeterministic/universal register automata.

Contributions. We prove that register-bounded synthesis is decidable for $(\mathbb{N}, <)$ in time doubly exponential in the number of registers of the specification automaton and of the sought transducer. Our procedure is effective: it constructs a transducer if one exists. When the total number of registers is fixed, it is ExpTime-c, matching the complexity of classical (register-free) synthesis. This result generalises the works of [15, 25, 24] on $(\mathbb{D}, =)$. We then extend the decidability boundary farther to include the domain $(\mathbb{N}^d, <^d)$ of tuples of naturals with the component-wise partial order, and the domain $(\Sigma^*, \prec)$ of strings with the prefix relation.

Technical contributions. Our proof technique is generic and greatly simplifies the task of proving new synthesis decidability results by removing the need to reason about synthesis alltogether. We now describe the technique in detail.

The key idea of existing approaches [24, 15, 25] is to reduce the register-bounded synthesis problem in a data domain to a two-player Church game with a finite alphabet and an ω-regular winning condition. In such a game, two players alternately play for an infinite number of rounds. Adam, modelling the environment, picks a test over the k registers describing how its input data compares with the current content of the registers of a sought transducer. Eve, modelling the system, picks a subset of the k registers, meant to store the data, and a register whose value is meant for output. No data are manipulated in the game. Infinite plays in the game induce infinite sequences of tests, assignments, and outputs over the k registers, called *action words*; they are over a *finite* alphabet. Action words are meant to abstract data words; an action word is *feasible* if there is at least one data word that satisfies all its tests and assignments. The reduction ensures that any strategy of Eve winning in the game can be converted into a k-register transducer realising the specification, and vice versa. To this end, the game winning condition declares a play to be won by Eve if all data words satisfying the action word induced by the play are accepted by the specification automaton. In particular, a play whose action word is *un*feasible is won by Eve as it does not correspond to any environment-system interaction in the data domain. In the case of $(\mathbb{D}, =)$, such winning conditions are known to be ω-regular [24, 15, 25]. However, in $(\mathbb{N}, <)$ the set of feasible action words is not ω-regular [14], and neither is the winning condition. Such winning conditions could be expressed by nondeterministic ωS automata [5], but games with such objectives are not known to be decidable, to the best of our knowledge.

To overcome the latter obstacle, we introduce the notion of ω-regularly approximable (*regapprox*) data domains. A regapprox data domain has an ω-regular over-approximation of the set of feasible action words that is exact on the lasso-shaped action words (of the form

uv^ω). Thus, in regapprox domains the set of feasible lasso-shaped action words is ω-regular. This allows us to avoid dealing with non-ω-regularity and reduce synthesis to solving classic ω-regular games. Our first technical contribution is the generic decidability result:

For regapprox domains, register-bounded synthesis from URA is decidable.

The procedure is constructive: for realisable specifications it outputs a transducer. Note that all oligomorphic domains [6], e.g. $(\mathbb{D}, =)$ and $(\mathbb{Q}, <)$, are regapprox, because their sets of feasible action words are ω-regular, so our result subsumes works [15, 25, 24]. For $(\mathbb{N}, <)$, we construct its over-approximation relying on the result [14], and then instantiate the theorem.

There are many domains with discrete order resembling $(\mathbb{N}, <)$: the domain $(\mathbb{Z}, <)$ of integers, the domain $(\mathbb{N}^d, <^d)$ of tuples of naturals with the component-wise partial order, and even the domain $(\Sigma^*, \prec)$ of strings with the prefix relation. To further simplify decidability proofs on these domains, we define a natural and generic notion of reducibility between data domains. Intuitively, a data domain $\mathbb{D}$ *reduces* to $\mathbb{D}'$ if there is a rational transduction that relates action words in $\mathbb{D}$ and $\mathbb{D}'$ while preserving feasibility. Our second technical contribution is the reduction result:

If $\mathbb{D}$ reduces to $\mathbb{D}'$, and $\mathbb{D}'$ is regapprox, then $\mathbb{D}$ is regapprox.

This implies that a synthesis procedure for $\mathbb{D}'$ can be used to solve synthesis in $\mathbb{D}$. We illustrate the technique by reducing to $(\mathbb{N}, <)$ the domains $(\mathbb{N}^d, <^d)$ and $(\Sigma^*, \prec)$. The reduction for $(\Sigma^*, \prec)$ relies on the work [10]. These reductions entail the decidability of register-bounded synthesis on these domains.

Related works. We already mentioned the works [24, 15, 25, 13] on synthesis of register transducers in domains $(\mathbb{D}, =)$ and $(\mathbb{Q}, <)$, and that our result generalises them for the case of URAs. The paper [14] studies *Church's synthesis* for DRA specifications, where a *data* strategy not necessarily with finitely-many states is sought. However, they show that considering register transducers is sufficient, with with the number of registers equal that of the specification automaton. Hence our register-bounded synthesis procedure for URAs can also be used to solve the Church's synthesis problem.

Another formalism for specifications of data systems is that of *variable automata* [20]. The paper [16] studies synthesis of symbolic transducers from specifications given in a fragment of nondeterministic variable automata. They solve synthesis for data domain $(\mathbb{Q}, <)$ and leave the domain $(\mathbb{N}, <)$ for future work. Variable automata are incomparable with register automata, and their particular fragment cannot express request-grant properties of arbiters that we believe is desirable in synthesis.

Our proof techniques resemble those from some works on satisfiability of data logics. Constraint LTL [11] extends Linear Temporal Logic (LTL) by atoms allowing one to compare data values within the horizon or pre-defined length. The satisfiability of this logic is decidable for data domains $(\mathbb{D}, =)$, $(\mathbb{Q}, <)$, $(\mathbb{N}, <)$ [11], and $(\Sigma^*, \prec)$ [10]. Their proof technique relies on the abstraction of data values at different moments by relations between each other. For the data domain $(\mathbb{N}, <)$, they additionally prove that considering lasso-shaped witnesses of satisfiability is sufficient. Our generic synthesis result uses a similar idea by defining regapprox domains. We note that formulas in Constraint LTL can always be translated into universal register automata (which are more expressive) [32]. Hence our approach can be used to solve register-bounded synthesis from Constraint LTL.

The papers [19, 27] suggest a sound/incomplete procedure to synthesis from Temporal Stream Logic. This logic extends LTL by adding the atoms that are either first-order predicate terms or are assignments of variables to a first-order function term. Similarly, transducers

can test data using the predicate terms and update its values by the function terms. A transducer satisfies a specification if it does so under *every* interpretation of predicates and functions. It is possible to model domains like $(\mathbb{D}, =)$ and $(\mathbb{Q}, <)$ in their formalism, by encoding the axioms for $>$ and $=$ into specification. This would give a sound/*in*complete synthesis approach. Our approach is less general but retains the completeness.

More generally, our notion of regular approximation echoes a general idea common to verification techniques, for example of programs manipulating data variables (see, e.g., [21]), to abstract concrete behaviours by regular ones. When an over-approximation is used, it is guaranteed that if the abstract program satisfies some safety properties, so does the concrete program. This yields sound algorithm which are not necessarily complete. Here in the context of register automata, instead, we require that the over-approximation is exact on lasso-like executions, and show that this implies completeness (for the synthesis problem).

2 Synthesis Problem

Let $\mathbb{N} = \{0, 1, \dots\}$ denote the set of natural numbers including 0.

Data domain and data words. A *data domain* is a tuple $\mathcal{D} = (\mathbb{D}, P, C, c_0)$ consisting of an infinite countable set $\mathbb{D}$ of *data values*, a finite set P of interpreted *predicates* (predicate names with arities and their interpretations) which must contain the equality predicate $=$, a finite set $C \subset \mathbb{D}$ of *constants*, and a distinguished *initialiser* constant $c_0 \in C$. For example, $(\mathbb{N}, \{<, =\}, \{0\}, 0)$ is the data domain of natural numbers with the usual interpretation of $<$, $=$, and 0. In the tuple notation, we often omit the brackets, as well as the mention of $=$ and of c_0 when the initialiser constant is clear from the context. E.g., we write $(\mathbb{N}, <, 0)$ for $(\mathbb{N}, \{<, =\}, \{0\}, 0)$. Another familiar example is $(\mathbb{Z}, <, 0)$, which is the data domain of integers with the usual $<$, $=$, and 0. Throughout the paper we assume that the satisfiability problem of quantifier-free formulas built on the signature (P, C) is decidable in $\mathcal{D}$, and whenever we state complexity results, the satisfiability problem is additionally assumed to be decidable in PSpace. This is the case for all data domains considered in this paper. Finally, *data words* are infinite sequences $\mathit{d}_0\mathit{d}_1 \dots \in \mathbb{D}^\omega$, and for two sets I and O and a language $L \subseteq (I \cdot O)^\omega$, we call I and O its *input* and *output* alphabets respectively.

Action words. Fix a data domain $\mathcal{D} = (\mathbb{D}, P, C, c_0)$ and a finite set R of elements called *registers*. A register *valuation* (over $\mathcal{D}$) is a mapping $\nu : R \to \mathbb{D}$. Given a valuation ν, a variable x (not necessarily in R), and a data value $\mathit{d} \in \mathbb{D}$, define $\nu[x \leftarrow \mathit{d}]$ to be the valuation $R \cup \{x\} \to \mathbb{D}$ that maps x to d and every $r \in R \setminus \{x\}$ to $\nu(r)$. We extend this notation to any finite set $A = \{a_1, \dots, a_n\}$ by letting $\nu[A \leftarrow \mathit{d}] = \nu[a_1 \leftarrow \mathit{d}] \dots [a_n \leftarrow \mathit{d}]$.

A *test* (over $\mathcal{D}$) is a conjunction ($\wedge$) of distinct literals over predicates P and constants C, encoded as a set of literals $p(x_1, \dots, x_a)$ and $\neg p(x_1, \dots, x_a)$, where $p \in P$, a is the arity of p and $x_1, \dots, x_a \in R \cup C \cup \{\star\}$. The symbol $\star$ is a fresh symbol used as a placeholder for incoming data values. By convention, $\wedge\varnothing = \top$, and the empty set encodes the test that is always true. Depending on the context, we use the formula or set notation. A register valuation $\nu : R \to \mathbb{D}$ and data value $\mathit{d} \in \mathbb{D}$ *satisfy* a test φ, written $\nu, \mathit{d} \models \varphi$, if $\nu[\star \leftarrow \mathit{d}]$ satisfies φ, where predicates and constants are interpreted in the data domain $\mathcal{D}$. A test φ is *maximal* if it specifies the relation between all variables and constants wrt. the predicates, i.e. it is a maximally consistent conjunction of literals: $\varphi = \bigwedge_{\substack{p \in P \\ p \text{ of arity } r}} \bigwedge_{\substack{x_1, \dots, x_r \\ \in R \cup C \cup \{\star\}}} l_{p, x_1, \dots, x_r}$, where $l_{p, x_1, \dots, x_r} \in \{p(x_1, \dots, x_r), \neg p(x_1, \dots, x_r)\}$. Maximal tests are mutually exclusive: a

given valuation cannot satisfy simultaneously two of them. Observe that a test is equivalent to a (possibly exponential) disjunction of maximal ones. Let $\mathsf{Tst}_R^{\mathcal{D}}$ denote the set of all possible tests over registers R in domain $\mathcal{D}$, and $\mathsf{MTst}_R^{\mathcal{D}} \subset \mathsf{Tst}_R^{\mathcal{D}}$ the subset of maximal ones.

▶ Example. Consider domain $(\mathbb{N}, <, 0)$ and $R = \{r\}$. Atomic formulas are $r < \star$, $\star = r$, $r < 0$, $\star = 0$, etc. The test $0 < r \wedge r < \star$ specifies that the content of register r is strictly positive and that the incoming data is greater than it. It is not maximal, since it does not contain the atoms $0 < \star$, $\neg(\star = r)$, $\neg(\star = 0)$, $\neg(r = 0)$. For readability, we write $0 < r < \star$.

An *assignment* is a set $\mathsf{asgn} \subseteq R$ of registers meant to store the current input data value. Let $\mathsf{Asgn}_R = 2^R$ denote the set of all possible assignments. An *action* is a pair $(\mathsf{tst}, \mathsf{asgn}) \in \mathsf{Tst}_R \times \mathsf{Asgn}_R$. We now describe how valuations are updated: given a valuation ν, a data value $\mathscr{d}$, a test tst and an assignment asgn, we say that the valuation ν' is the *successor* of ν following action $(\mathsf{tst}, \mathsf{asgn})$ on reading $\mathscr{d}$, written $\nu \xrightarrow{\mathscr{d},\mathsf{tst},\mathsf{asgn}} \nu'$, if the data value satisfies the test, i.e. $\nu, \mathscr{d} \models \mathsf{tst}$, and $\nu' = \nu[\mathsf{asgn} \leftarrow \mathscr{d}]$.

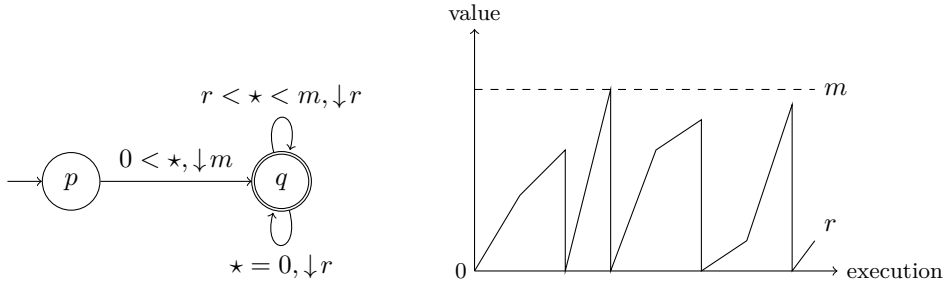
An *automaton action word*, or simply *action word*, is an infinite sequence of actions $\bar{a} = (\mathsf{tst}_0, \mathsf{asgn}_0)(\mathsf{tst}_1, \mathsf{asgn}_1) \ldots \in (\mathsf{Tst}_R \times \mathsf{Asgn}_R)^\omega$. It is *feasible* by a sequence of valuation-data pairs $(\nu_0, \mathscr{d}_0)(\nu_1, \mathscr{d}_1) \ldots$ if $\nu_0 : r \in R \mapsto c_0$, i.e. ν_0 maps every $r \in R$ to c_0, and for all i: $\nu_i \xrightarrow{\mathscr{d}_i,\mathsf{tst}_i,\mathsf{asgn}_i} \nu_{i+1}$. We then say that the data word $\mathscr{d}_0\mathscr{d}_1 \ldots$ is *compatible* with $\bar{a}$. Let $\mathsf{AW}_R^{\mathcal{D}}$ denote the set of action words over R in $\mathcal{D}$, and $\mathsf{FEAS}_R^{\mathcal{D}}$ the subset of feasible ones. We may write either AW_R, or $\mathsf{AW}^{\mathcal{D}}$ or just AW when $\mathcal{D}$, R or both are clear from the context, similarly for FEAS.

▶ Example. Consider domain $(\mathbb{N}, <, 0)$ and $R = \{r\}$. For $r \in R$, the assignment $\{r\}$ is denoted $\downarrow r$. The action word $(0 < \star, \downarrow r)(\star < r, \downarrow r)^\omega$ is unfeasible in $(\mathbb{N}, <, 0)$, because it requires having an infinite chain of strictly decreasing values, which is not possible since $\mathbb{N}$ is well-founded. The same action word can be interpreted in $(\mathbb{Z}, <, 0)$ and in $(\mathbb{Q}, <, 0)$ and there it is feasible, as well as in $(\mathbb{Q}_+, <, 0)$ since $\mathbb{Q}_+$ is dense.

Register automata. A register automaton over data domain $\mathcal{D}$ is a tuple $S = (Q, q_0, R, \delta, \alpha)$, where Q is a finite set of *states* containing the *initial* state q_0, R is a finite set of *registers*, $\delta \subseteq Q \times \mathsf{Tst}_R \times \mathsf{Asgn}_R \times Q$ is a *transition relation*, and $\alpha : Q \to \{1, ..., c\}$ is a *priority function* where c is the priority *index*. A *configuration* of S is a pair $(p, \nu) \in Q \times \mathbb{D}^R$; it is *initial* if $p = q_0$ and $\nu : r \in R \mapsto c_0$. The configuration (q, ν') is a *successor* of (p, ν) on reading data value $\mathscr{d} \in \mathbb{D}$ and taking transition $p' \xrightarrow{\mathsf{tst},\mathsf{asgn}} q' \in \delta$, written $(p, \nu) \xrightarrow[S]{\mathscr{d},\mathsf{tst},\mathsf{asgn}} (q, \nu')$ or simply $(p, \nu) \xrightarrow[S]{\mathscr{d}} (q, \nu')$, if $p = p'$, $q = q'$ and $\nu \xrightarrow{\mathscr{d},\mathsf{tst},\mathsf{asgn}} \nu'$, i.e. $\nu, \mathscr{d} \models \mathsf{tst}$ and $\nu' = \nu[\mathsf{asgn} \leftarrow \mathscr{d}]$.

A *run* of S over a data word $\mathscr{d}_0\mathscr{d}_1 \ldots$ is a sequence of configurations $\rho = (q_0, \nu_0)(q_1, \nu_1) \ldots$ such that (q_0, ν_0) is initial and for every i, (q_{i+1}, ν_{i+1}) is a successor of (q_i, ν_i) on reading $\mathscr{d}_i$, on taking some transition $q_i \xrightarrow{\mathsf{tst}_i,\mathsf{asgn}_i} q_{i+1} \in \delta$. We then say that the automaton action word $(\mathsf{tst}_0, \mathsf{asgn}_0)(\mathsf{tst}_1, \mathsf{asgn}_1) \ldots$ *labels* ρ; note that it is feasible by $\nu_0\mathscr{d}_0\nu_1\mathscr{d}_1 \ldots$. The run ρ is *accepting* if the maximal priority appearing infinitely often in $\alpha(q_0)\alpha(q_1) \ldots$ is even, otherwise it is *rejecting*. A data word may have several runs of S. For *universal* register automata, abbreviated URA, a word is *accepted* if all its runs are accepting; for *nondeterministic* automata, there should be at least one accepting run. The set of all data words over $\mathcal{D}$ accepted by S is called the *language* of S and denoted $L(S)$. We may write $L_{\mathcal{D}}(S)$ to emphasise that $L(S)$ is defined over $\mathcal{D}$.

A *finite (parity) automaton* (without registers) is a tuple $(\Sigma, Q, q_0, \delta, \alpha)$, where Σ is a finite alphabet, $\delta \subseteq Q \times \Sigma \times Q$, and the definition of runs, accepted words, and language is standard. Such automata operate on words from Σ^ω.



(a) A register automaton over $(\mathbb{N}, <, 0)$ (state q is accepting). **(b)** An example of the sequence of values taken by registers r and m along the run.

Figure 1 A register automaton whose action words do not form an ω-regular language.

Syntactical language of a register automaton. A register automaton $S = (Q, q_0, R, \delta, \alpha)$ can be treated syntactically, it then induces a universal finite automaton $S_{synt} = (\Sigma, Q, q_0, \delta, \alpha)$ with $\Sigma = \mathsf{Tst}_R \times \mathsf{Asgn}_R$. Note that since S_{synt} is universal, words that have no run are accepted. Notice that the language of S_{synt} may contain action words which are not feasible.

▶ Example. Consider the automaton of Figure 1a. Its syntactical language is

$$(0 < \star, \downarrow m)\big((r < \star < m, \downarrow r) \mid (0 = \star, \downarrow r)\big)^\omega$$

which includes not only feasible but also unfeasible action words, e.g. $(0 < \star, \downarrow m)(r < \star < m, \downarrow r)^\omega$. The feasible accepted action words have the form

$$(0 < \star, \downarrow m) \prod_{i=1}^{\infty} \big((r < \star < m, \downarrow r)^{n_i}(0 = \star, \downarrow r)\big)$$

such that the numbers $(n_i)_i$ are uniformly bounded by some value; the bound corresponds to the first read data value. This language is not ω-regular but an ωB-language [5].

Register transducers. A *k-register transducer* is a tuple $T = (Q, q_0, R, \delta)$, where Q, q, R ($|R| = k$) are as in automata but $\delta : Q \times \mathsf{MTst} \to \mathsf{Asgn} \times R \times Q$. Note that δ is a total function; moreover, since we restrict to maximal tests, exactly one test holds per incoming data value, so the transducers are deterministic and complete. A configuration is a pair $(p, \nu) \in Q \times \mathbb{D}^R$. From configuration (p, ν), on reading $\mathscr{d} \in \mathbb{D}$, the transducer takes the unique transition $p \xrightarrow{\mathsf{tst},\mathsf{asgn}|r} q$ such that $\nu, \mathscr{d} \models \mathsf{tst}$, updates its configuration to (q, ν') where $\nu \xrightarrow{\mathscr{d},\mathsf{tst},\mathsf{asgn}} \nu'$, and outputs the value $\nu'(r)$. Note that the output is produced *after* assignment. We then write $(p, \nu) \xrightarrow[T]{\mathscr{d},\mathsf{tst},\mathsf{asgn}|r,\nu'(r)} (q, \nu')$, or simply $(p, \nu) \xrightarrow[T]{\mathscr{d}|\nu'(r)} (q, \nu')$. A *run* of T on an input data word $\mathscr{d}_0^{\mathsf{i}}\mathscr{d}_1^{\mathsf{i}}\ldots$ is a sequence $(q_0, \nu_0)(q_1, \nu_1)\ldots$ such that (q_0, ν_0) is initial and for all $i \geq 0$, $(q_i, \nu_i) \xrightarrow{\mathscr{d}_i^{\mathsf{i}},\mathsf{tst}_i,\mathsf{asgn}_i|r_i,\mathscr{d}_i^{\mathsf{o}}} (q_{i+1}, \nu_{i+1})$ for some unique $\mathscr{d}_i^{\mathsf{o}} \in \mathbb{D}$. The sequence $\mathscr{d}_0^{\mathsf{o}}\mathscr{d}_1^{\mathsf{o}}\ldots$ is the *output word* of T on reading $\mathscr{d}_0^{\mathsf{i}}\mathscr{d}_1^{\mathsf{i}}\ldots$; since the transducers are deterministic and have a run on every input word, the output word is uniquely defined. The sequence $\mathscr{d}_0^{\mathsf{i}}\mathscr{d}_0^{\mathsf{o}}\mathscr{d}_1^{\mathsf{i}}\mathscr{d}_1^{\mathsf{o}}\ldots$ is called the *input-output word*. We then say that the *transducer action word* $\mathsf{tst}_0(\mathsf{asgn}_0, r_0)\mathsf{tst}_1(\mathsf{asgn}_1, r_1)\ldots \in \big(\mathsf{MTst}\cdot(\mathsf{Asgn} \times R)\big)^\omega$ is *feasible* by $(\nu_0, \mathscr{d}_0^{\mathsf{i}}, \mathscr{d}_0^{\mathsf{o}})(\nu_1, \mathscr{d}_1^{\mathsf{i}}, \mathscr{d}_1^{\mathsf{o}})\ldots$. It is naturally associated with the automaton action word $(\mathsf{tst}_0, \mathsf{asgn}_0)(\star = r_0, \varnothing)(\mathsf{tst}_1, \mathsf{asgn}_1)(\star = r_1, \varnothing)\ldots$, which is then feasible by $\nu_0\mathscr{d}_0^{\mathsf{i}}\nu_1\mathscr{d}_0^{\mathsf{o}}\nu_1\mathscr{d}_1^{\mathsf{i}}\nu_2\mathscr{d}_1^{\mathsf{o}}\ldots$. The set of all transducer action words over R in data domain $\mathcal{D}$ is denoted by $\mathsf{TW}_R^{\mathcal{D}}$. The *language* $L(T)$ consists of all input-output words of T.

A *finite transducer* is a standard Mealy machine: it is a tuple $(\Sigma, \Gamma, Q, q_0, \delta)$, where Σ and Γ are finite input and output alphabets, $\delta : Q \times \Sigma \to \Gamma \times Q$, and the definition of language is standard. Treating a register transducer T syntactically gives a finite transducer denoted T_{synt} of the same structure as T with $\Sigma = \mathsf{MTst}_R$ and $\Gamma = \mathsf{Asgn}_R \times R$.

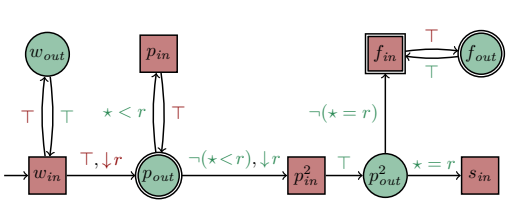
Synthesis problem. Fix a data domain $(\mathbb{D}, P, C, c_0)$. A register transducer T *realises* a register automaton S if $L(T) \subseteq L(S)$. The *register-bounded synthesis problem* is:

- input: $k \in \mathbb{N}$ and a URA S;
- output: yes iff there exists a k-register transducer which realises S.

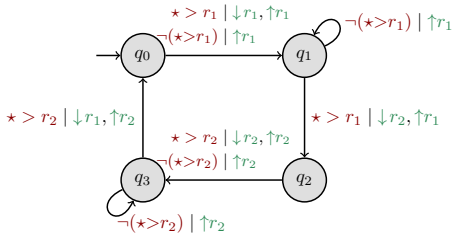
In this paper, when the synthesis problem is decidable, we are able to synthesise, i.e., effectively construct, a transducer realising the specification. We now make two remarks. First, notice that the number of transducer states is finite but unconstrained. Thus, register-bounded synthesis generalises classical register-free synthesis from (data-free) ω-regular specifications. Second, observe that transducers are complete, and therefore produce an ouptput word on every input word. Thus, a specification for which some input words do not have an associated output word is unrealisable. It is known that in the finite-alphabet case, the refined synthesis problem of good-enough synthesis [1], which requires a transducer to react only to inputs that belong to the domain of the specification, is still decidable. However, the good-enough register-bounded synthesis is undecidable [13, Chapter 8].

▶ Example. We illustrate the synthesis problem by describing a specification, its URA, and a register transducer realising it.

Let us start with the specification of priority arbiters. Such an arbiter reads an ID of a process requesting the resource, and outputs an ID of a process to whom the resource is granted. The specification requires that every requesting process is either acknowledged consecutively twice on the output, or this is done for a process of higher ID. We model the specification using the URA over $(\mathbb{N}, <, 0)$ with a single register from Figure 2a.



(a) URA for the priority-arbiter specification.



(b) Register transducer realising the specification.

Figure 2 A URA specification and a transducer implementing it.

The automaton reads words interleaving between arbiter data input and output, so its states are partitioned into box states (for reading input) and circle states (for reading output). The double-circle states are rejecting and can be visited only finitely often. Thus, a run looping in wait states w_{in} and w_{out} is accepting. Branching is universal, hence some run always loops around w_{in} and w_{out}. On reading an ID of a requesting process, a copy of the automaton moves from w_{in} to a pending state p_{out} while storing the ID into register r. It stays in states p_{out} and p_{in} as long as the request is not acknowledged, and such an infinite run is rejecting. If the request is eventually acknowledged (transitions from p_{out} to a sink state s_{in}), the run dies, so it is accepting. If a run reaches the failure state f_{in}, it is rejecting.

Figure 2b depicts a transducer with two registers r_1 and r_2 realising the above specification. On the left of the vertical bar are the tests over the inputs received by the transducer (in red), and on the right is the output action performed by the transducer (in green). For example, from state q_0 to q_1, if the input data $\mathbb{d}$ is larger than the data stored in register r_1, the transducer stores it into r_1, and outputs the content of r_1. The transducer uses one register to store the maximal value seen so far, while outputting the content of the other register, and the roles of these registers interchange as the transducer transits along the states. Thus, the instance of register-bounded synthesis with the described URA and $k = 2$ has a positive answer. However, when $k = 1$ the answer is negative.

3 Sufficient Condition for Decidable Synthesis for URA

In this section, we first show a reduction from register-bounded synthesis to (register-free) finite-alphabet synthesis. In the following, we fix a data domain $\mathcal{D}$. Given a specification S (as a URA over $\mathcal{D}$) and a bound k, we show how to construct a finite-alphabet specification $W^{\mathsf{F}}_{S,k}$ on action words over k registers, which is realisable by a finite-alphabet transducer iff S is realisable by a k-register transducer (Lemma 1). The main idea is to see the actions of the URA and of the sought k-register transducer as finite-alphabet letters. In particular, the specification $W^{\mathsf{F}}_{S,k}$ accepts a transducer action word $\bar{a}_k$ iff every action word $\bar{a}_S$ of the specification S, such that both $\bar{a}_k$ and $\bar{a}_S$ are feasible by the same data word, is accepted by S_{synt}. One can compose automata and transducer action words through a form of parallel product, which allows to talk about their joint feasibility. Then, in general, $W^{\mathsf{F}}_{S,k}$ is not necessarily ω-regular, and in a second step, we provide sufficient conditions on the data domain making synthesis wrt. $W^{\mathsf{F}}_{S,k}$ decidable, namely, that it can be under-approximated by an ω-regular language which coincides with $W^{f}_{S,k}$ over lasso words (Section 3.1). We obtain a general decidability result for data domains having this property (Theorem 4). We then instantiate this result for data domain $(\mathbb{N}, <, 0)$ (Section 3.2).

In the following, we fix a URA S with registers R_S and a disjoint set R_k consisting of k registers, and let $R = R_S \uplus R_k$. Given a transducer action word $\bar{a}_k = \mathsf{tst}^k_0\,(\mathsf{asgn}^k_0, r^k_0)\ldots \in \mathsf{TW}^{\mathcal{D}}_{R_k}$ and an automaton action word $\bar{a}_S = (\mathsf{tst}^{S\mathsf{i}}_0, \mathsf{asgn}^{S\mathsf{i}}_0)(\mathsf{tst}^{S\mathsf{o}}_0, \mathsf{asgn}^{S\mathsf{i}}_0)\ldots \in \mathsf{AW}^{\mathcal{D}}_{R_S}$, the product $\bar{a}_k \otimes \bar{a}_S$ of $\bar{a}_k$ and $\bar{a}_S$ is the automaton action word over registers R defined as $(\mathsf{tst}^k_0 \wedge \mathsf{tst}^{S\mathsf{i}}_0, \mathsf{asgn}^k_0 \cup \mathsf{asgn}^{S\mathsf{i}}_0)((\star = r^k_0) \wedge \mathsf{tst}^{S\mathsf{o}}_0, \mathsf{asgn}^{S\mathsf{i}}_0)\ldots$, which is essentially the parallel product of $\bar{a}_S$ and of the automaton word associated with $\bar{a}_k$.

We now show how to abstract a data specification given as URA S with registers R_S by a *finite-alphabet* specification over k-register transducer action words. Let $\mathsf{FEAS}^{\mathcal{D}}_R$ be the set of automata action words over R feasible in $\mathcal{D}$, then we define

$$W^{\mathsf{F}}_{S,k} = \left\{\bar{a}_k \in \mathsf{TW}_{R_k} \mid \forall \bar{a}_S \in \mathsf{AW}_{R_S} : \bar{a}_k \otimes \bar{a}_S \in \mathsf{FEAS}^{\mathcal{D}}_R \;\Rightarrow\; \bar{a}_S \in L(S_{synt})\right\}.$$

Thus, $W^{\mathsf{F}}_{S,k}$ *rejects* a feasible transducer action word $\bar{a}_k$ iff there is an automaton action word $\bar{a}_S$ feasible by the same data word as $\bar{a}_k$ and rejected by S.

▶ **Lemma 1.** *These two are equivalent:*

- *a URA S is realisable by a k-register transducer,*
- *$W^{\mathsf{F}}_{S,k}$ is realisable (by a finite-alphabet transducer).*

Proof. $\Rightarrow$: Assume that S is realisable by a register transducer T, i.e. $L_{\mathcal{D}}(T) \subseteq L_{\mathcal{D}}(S)$. Let $\bar{a}_k \in L(T_{synt})$, and let $\bar{a}_S \in \mathsf{AW}_{R_S}$ such that $\bar{a}_k \otimes \bar{a}_S \in \mathsf{FEAS}^{\mathcal{D}}_R$. Then, $\bar{a}_k \otimes \bar{a}_S$ is feasible by some input-output data word $w = \mathbb{d}^{\mathsf{i}}_0\mathbb{d}^{\mathsf{o}}_0\mathbb{d}^{\mathsf{i}}_1\mathbb{d}^{\mathsf{o}}_1\ldots$. By definition of the product, both $\bar{a}_k$ and $\bar{a}_S$ are feasible by w. Since $L_{\mathcal{D}}(T) \subseteq L_{\mathcal{D}}(S)$, if $\bar{a}_S$ labels a run of S on w, it means that it is accepting otherwise $w \notin L_{\mathcal{D}}(S)$ since S is a universal automaton. Thus, $\bar{a}_S \in L(S_{synt})$.

$\Leftarrow$: Conversely, assume that $W^{\mathsf{F}}_{S,k}$ is realisable by some finite transducer M, and let T be the associated register transducer, i.e. such that $T_{synt} = M$. Let $w \in L_{\mathscr{D}}(T)$ and let $\bar{a}_k$ be the action word labelling the run of T on w. Let $\bar{a}_S$ be an action word labelling a run of S on w if it exists (it might be that w is accepted by S by having no run on it). Then, $\bar{a}_k \otimes \bar{a}_S$ is feasible by w. By definition of $W^{\mathsf{F}}_{S,k}$, it means that $\bar{a}_S \in L(S_{synt})$, so $\bar{a}_S$ labels an accepting run of S on w. Overall, all runs of S on w are accepting, so $w \in L_{\mathscr{D}}(S)$. Thus, $L_{\mathscr{D}}(T) \subseteq L_{\mathscr{D}}(S)$, i.e. T realises S. ◀

3.1 General Decidability Result

In $(\mathbb{N}, <, 0)$, $W^{\mathsf{F}}_{S,k}$ is not ω-regular in general. To overcome this obstacle, we define the notion of ω-regularly approximable data domains. Such domains have an ω-regular equi-realisable subset of $W^{\mathsf{F}}_{S,k}$.

Let $lasso_R$ be the set of lasso-shaped[1] action words over a given set of registers R; we write *lasso* when R is clear. A data domain $\mathbb{D}$ is *ω-regularly approximable* (*regapprox*) if for every R there exists an ω-regular language $\mathsf{QFEAS}_R \subseteq (\mathsf{Tst}_R \times \mathsf{Asgn}_R)^\omega$ satisfying

$$\mathsf{QFEAS}_R \cap lasso_R \;\subseteq\; \mathsf{FEAS}_R \;\subseteq\; \mathsf{QFEAS}_R$$

and recognisable by a nondeterministic Büchi automaton that can be effectively constructed given R. The definition implies that FEAS_R and QFEAS_R coincide on lasso words. Such a set QFEAS_R is called *regular approximation* and written as QFEAS when R is clear.

▶ Example. The data domains $(\mathbb{D}, =)$ and $(\mathbb{Q}, <)$ are regapprox because their sets FEAS_R for every R are ω-regular, so there is no need to approximate them. On these domains, to check whether a given action word is feasible, one can track the relations between the registers and check if the read tests are consistent with these relations. For instance, if $r_1 < r_2$ but we read the test $* = r_1 = r_2$, then the action word is unfeasible.

The domain $(\mathbb{N}, <, 0)$ is also regapprox. Here, it is not sufficient to track the relations between the registers. We also need to ensure that between any two stored data values only a bounded number of different values is inserted along the action word. (Recall the example on page 7 with Figure 1a.) However, when an action word is lasso-shaped, it suffices to check the absence of an *infinite* number of such insertions. The latter can be checked by an ω-regular automaton, which allows for proving the regapproximability of $(\mathbb{N}, <, 0)$.

Finally, consider the data domain $(\mathbb{N}, \{S, =\}, \{0\}, 0)$, where S is the successor relation, i.e. $S(a, b)$ holds iff $a = b + 1$. This domain is not regapprox. Intuitively, this is because the domain allows for counting, which enables non ω-regular phenomena even in lasso words. We prove this by contradiction. Consider the following ω-regular language of action words over a single register r:

$$L \;=\; \big\{ \big(S(*, r), {\downarrow}r\big)^n \big(S(r, *), {\downarrow}r\big)^m \big(* = 0 = r, \varnothing\big)^\omega \mid n, m \in \mathbb{N} \big\},$$

i.e. the value in r is incremented n times, then decremented m times, then compared to zero and not updated. L contains feasible as well as unfeasible action words. Every feasible word of L has $n = m$, hence $\mathsf{FEAS} \cap L$ is not ω-regular. Moreover, every word of L is a lasso, thus $L \cap lasso = L$. Let us assume that the data domain is regapprox, witnessed by QFEAS for $R = \{r\}$. Since $\mathsf{QFEAS} \cap lasso = \mathsf{FEAS} \cap lasso$ by definition, we get

$$\mathsf{QFEAS} \cap L = \mathsf{QFEAS} \cap lasso \cap L = \mathsf{FEAS} \cap lasso \cap L = \mathsf{FEAS} \cap L.$$

The language $\mathsf{QFEAS} \cap L$ is ω-regular, but $\mathsf{FEAS} \cap L$ is not. Contradiction. Therefore $(\mathbb{N}, \{S, =\}, \{0\}, 0)$ is not regapprox. ◀

[1] A word w is *lasso-shaped* (or regular, or ultimately periodic) if it is of the form $w = uv^\omega$ for some finite words u and v.

Given a URA S with registers R_S and k, we define

$$W^{\mathsf{QF}}_{S,k} = \{\bar{a}_k \mid \forall \bar{a}_S \colon \bar{a}_k \otimes \bar{a}_S \in \mathsf{QFEAS}_R \;\Rightarrow\; \bar{a}_S \in L(S_{synt})\},$$

where $R = R_S \uplus R_k$. The definition of $W^{\mathsf{QF}}_{S,k}$ differs from $W^{\mathsf{F}}_{S,k}$ only in using QFEAS_R instead of FEAS_R. Since $\mathsf{FEAS}_R \subseteq \mathsf{QFEAS}_R$, we have $W^{\mathsf{QF}}_{S,k} \subseteq W^{\mathsf{F}}_{S,k}$.

We now show that $W^{\mathsf{QF}}_{S,k}$ is ω-regular (which essentially follows from ω-regularity of QFEAS and S_{synt}), and estimate the size of an automaton recognising $W^{\mathsf{QF}}_{S,k}$ and the time needed to construct it. For that we use the following terminology for functions of asymptotic growth: a function is $poly(t)$ if it is $O(t^\kappa)$, $exp(t)$ if it is $O(2^{t^\kappa})$, and $2exp(t)$ if it is $O(2^{2^{t^\kappa}})$, for a constant $\kappa \in \mathbb{N}$. When $poly$, exp, and $2exp$ are used with several arguments, the maximal among them shall be taken for t. The construction and complexity analysis rely on standard automata techniques; see the full version for details.

▶ **Lemma 2.** *Let S be a URA and let $k \geq 1$. Then, $W^{QF}_{S,k}$ is ω-regular. Moreover, $W^{QF}_{S,k}$ is recognisable by a universal co-Büchi automaton with $O(2^k Nnc)$ many states that can be constructed in time $poly(N, n, exp(r, k))$, where n, r, and c are the number of states, registers, and priorities in S, and N is the number of states in a nondeterministic Büchi automaton recognising $QFEAS_{R_S \uplus R_k}$.*

We now prove that $W^{\mathsf{F}}_{S,k}$ and $W^{\mathsf{QF}}_{S,k}$ are equi-realisable. For ω-regular specifications (like $W^{\mathsf{QF}}_{S,k}$) there is no distinction between realisability by finite- and infinite-state transducers [7]. This is not known for $W^{\mathsf{F}}_{S,k}$ specifications over domains such as $(\mathbb{N}, <, 0)$; we leave this question for future work, and in this paper focus on realisability by *finite-state* transducers.

▶ **Lemma 3.** *$W^{F}_{S,k}$ is realisable by a finite-state transducer iff $W^{QF}_{S,k}$ is realisable by a finite-state transducer.*

Proof. Direction $\Leftarrow$ follows from the inclusion $\mathsf{FEAS} \subseteq \mathsf{QFEAS}$, which implies $W^{\mathsf{QF}}_{S,k} \subseteq W^{\mathsf{F}}_{S,k}$. Consider direction $\Rightarrow$. Let T be a finite-state transducer that T does not realise $W^{\mathsf{QF}}_{S,k}$. We show that T does not realise $W^{\mathsf{F}}_{S,k}$ either. First, we have that $L(T) \not\subseteq W^{\mathsf{QF}}_{S,k}$, so the language $\{\bar{a}_k \otimes \bar{a}_S \in \mathsf{AW}^{\mathcal{D}}_R \mid \bar{a}_k \in L(T) \wedge \bar{a}_k \otimes \bar{a}_S \in \mathsf{QFEAS} \wedge \bar{a}_S \notin L(S_{synt})\}$ is nonempty. Since QFEAS and $L(S_{synt})$ are ω-regular, and since T is a finite-state transducer, this language is ω-regular. Thus, it contains a lasso-shaped word $\bar{a}_k \otimes \bar{a}_S$; by definition of the product, both $\bar{a}_k$ and $\bar{a}_S$ are then lasso-shaped. Since $\mathsf{QFEAS} \cap \mathit{lasso} \subseteq \mathsf{FEAS}$, we get that $\bar{a}_S$ is feasible, i.e. $\bar{a}_k \otimes \bar{a}_S \in \{\bar{a}_k \otimes \bar{a}_S \mid \bar{a}_k \in L(T) \wedge \bar{a}_k \otimes \bar{a}_S \in \mathsf{FEAS} \wedge \bar{a}_S \notin L(S_{synt})\}$, which implies that $L(T) \not\subseteq W^{\mathsf{F}}_{S,k}$: T does not realise $W^{\mathsf{F}}_{S,k}$. ◀

We are now able to prove the main result of this paper.

▶ **Theorem 4.** *Let $\mathcal{D}$ be a regapprox data domain such that for every set of registers R, one can construct a nondeterministic Büchi automaton with n_{QF} states recognising $QFEAS_R$ in time $f(|R|)$ for some function f. Then:*

- *register-bounded synthesis for URAs over $\mathcal{D}$ is decidable in time $exp(exp(k, r), n_{QF}, n, c) + f(k + r)$, where n is the number of states of the URA, c its number of priorities, r its number of registers, k is the number of transducer registers. It is ExpTime-c for fixed r and k.*
- *For every positive instance of the register-bounded synthesis problem, one can construct, within the same time complexities, a register transducer realising the specification.*

Proof. Lemmas 1,2,3 reduce register-bounded synthesis to (finite-alphabet) synthesis for the ω-regular specification $W^{\mathsf{QF}}_{S,k}$. Since synthesis wrt. to ω-regular specifications is decidable, we get the decidability part of the theorem. Let us now study the complexity. Let R_S

be the set of r registers of the URA and R_k be a disjoint set of k registers. First, one needs to construct an automaton recognising $\mathsf{QFEAS}_{R_S \cup R_k}$. This is done by assumption in time $f(k+r)$. Then, one can apply Lemma 2 and get that $W^{\mathsf{QF}}_{S,k}$ can be recognised by universal co-Büchi automaton A with $O(2^k n_{qf} nc)$ states, which can be constructed in time $poly(n_{qf}, n, exp(r,k))$. A universal co-Büchi automaton with m states can be determinised into a parity automaton with $exp(m)$ states and $poly(m)$ priorities (see e.g. [29]). Recall that the alphabet of A is $\mathsf{Tst}_k \cup (\mathsf{Asgn}_k \times R_k)$. Hence by determinising A, and seeing it as a two-player game arena, we get a parity game with $exp(k)$ edges (corresponding to the actions of Adam and Eve), $exp(exp(k), n_{\mathsf{QF}}, n, c))$ states, and $poly(exp(k), n_{\mathsf{QF}}, n, c))$ priorities. The latter can be solved in polynomial time in the number of its states, as the number of priorities is logarithmic in the number of states (see e.g. [9]), giving the overall time complexity $exp(exp(k), n_{\mathsf{QF}}, n, c))$ for solving the game. If we sum this to the complexity of constructing an automaton for $W^{\mathsf{QF}}_{S,k}$ plus the complexity for construction an automaton for QFEAS, we get $exp(exp(k), n_{\mathsf{QF}}, n, c)) + poly(n_{\mathsf{QF}}, n, exp(r,k)) + f(r+k)$, which is $exp(exp(k,r), n_{\mathsf{QF}}, n, c)) + f(r+k)$. If both r and k are fixed, then $exp(k,r)$ and $f(r+k)$ are constants, so the complexity is exponential only. It is folklore that the hardness holds in the register-free setting (for $r = k = 0$). See for example [18, Proposition 6] for a proof in the finite word setting over a finite alphabet (which straightforwardly generalises to infinite words). There, the proof is done for nondeterministic finite automata, but by determinacy, hardness also holds for universal automata, as they are dual.

Now, if a URA specification is realisable for some given k, then by Lemmas 1 and 3, $W^{\mathsf{QF}}_{S,k}$ is realisable by a finite-alphabet transducer M. Since $W^{\mathsf{QF}}_{S,k} \subseteq W^{\mathsf{F}}_{S,k}$, M also realises the specification $W^{\mathsf{F}}_{S,k}$. The mapping $\cdot_{synt}$ which turns a register transducer into a finite-alphabet transducer is bijective, and hence there exists a register transducer T such that $T_{synt} = M$. The proof of Lemma 1 exactly shows that T realises S, hence we are done. ◀

3.2 Register-bounded Synthesis over Data Domain $(\mathbb{N}, <, 0)$

We instantiate Theorem 4 for the data domain $(\mathbb{N}, <, 0)$. In [14], though there was no general notion of ω-regular approximability for data domains, it was implicitly used for $(\mathbb{N}, <, 0)$. The following fact follows from [14, Thm.8] after adapting to our notions.[2]

▶ **Fact 5.** For all R, $(\mathbb{N}, <, 0)$ has a witness QFEAS_R of ω-regular approximability expressible by a nondeterministic parity automaton with $exp(|R|)$ states and $poly(|R|)$ priorities, which can be constructed in time $exp(|R|)$.

A parity automaton can be translated to a nondeterministic Büchi automaton with a quadratic number of states, so we can instantiate Theorem 4 on domain $(\mathbb{N}, <, 0)$ and get:

▶ **Theorem 6.** *For a URA in $(\mathbb{N}, <, 0)$ with r registers, n states, and c priorities, k-register-bounded synthesis is solvable in time $exp(exp(r,k), n, c)$: it is singly exponential in n and c, and doubly exponential in r and k. It is ExpTime-c for fixed k and r.*

[2] Strictly speaking, their paper considers maximal tests only. However, using their deterministic automaton for QFEAS_R over action words with maximal tests, we can construct a *non*det. automaton recognising quasi-feasible action words with all tests, incl. partial ones. Our nondet. automaton, on reading a partial test, *guesses* its completion into a maximal test and simulates the original automaton on it.

4 Reducibility Between Data Domains

Theorem 6 relies on the study of feasibility of action words in $(\mathbb{N}, <, 0)$ of [14], which requires some effort. Such a study could in principle be generalised to domains such as $\mathbb{Z}$-tuples, as well as finite strings with the prefix relation, by leveraging the results of [10]. However, this would come at the price of a high level of technicality. We choose a different path, and introduce a notion of reducibility between domains, which allows us to reuse the study of $(\mathbb{N}, <, 0)$ and yields a compositional proof of the decidability of register-bounded synthesis for the quoted domains.

▶ **Definition.** A data domain $\mathcal{D}$ *reduces* to a data domain $\mathcal{D}'$ if for every finite set of registers R, there exists a finite set of registers R' and a rational relation[3] K between R-automata action words in $\mathcal{D}$ and R'-automata action words in $\mathcal{D}'$ that *preserves feasibility*, in the sense that for every R-action word $\bar{a} \in (\mathsf{Tst}_R^{\mathcal{D}}\mathsf{Asgn}_R)^\omega$: $\bar{a}$ is feasible in $\mathcal{D}$ iff there exists an R'-action word in $K(\bar{a}) \in (\mathsf{Tst}_{R'}^{\mathcal{D}'}\mathsf{Asgn}_{R'})^\omega$ feasible in $\mathcal{D}'$.[4]

▶ Remark. Reducibility is a transitive relation, since rational relations are closed under composition [3, Theorem 4.4], and feasibility preservation is transitive.

Since K is rational and preserves feasibility, for all R, $K^{-1}(\mathsf{QFEAS}_{R'})$ is a witness of regapproximability, where R' is as in the above definition (see the proof below for details), thus we get:

▶ **Lemma 7.** *If $\mathcal{D}$ reduces to $\mathcal{D}'$ and $\mathcal{D}'$ is regapprox, then $\mathcal{D}$ is regapprox.*

Proof. Let R be a fixed set of registers, and let R' be a set of registers satisfying the definition of reducibility. Let FEAS (respectively, FEAS') be the set of R-action words feasible in $\mathcal{D}$ (resp., feasible R'-action words in $\mathcal{D}'$).

Our goal is to define an ω-regular set QFEAS (for R) s.t. $\mathsf{QFEAS} \cap \mathit{lasso} \subseteq \mathsf{FEAS} \subseteq \mathsf{QFEAS}$. Since $\mathcal{D}'$ is regapprox, there is an ω-regular set QFEAS' (for R') s.t. $\mathsf{QFEAS}' \cap \mathit{lasso} \subseteq \mathsf{FEAS}' \subseteq \mathsf{QFEAS}'$. Define $\mathsf{QFEAS} = K^{-1}(\mathsf{QFEAS}')$; as the preimage of an ω-regular set by a rational relation, it is (effectively) ω-regular, thus satisfying one of the condition for $\mathcal{D}$ to be regapprox.

We now show that $\mathsf{FEAS} \subseteq \mathsf{QFEAS}$. Before proceeding, notice that $\mathsf{FEAS} = K^{-1}(\mathsf{FEAS}')$, since K preserves feasibility. Since $\mathsf{FEAS}' \subseteq \mathsf{QFEAS}'$, we have $K^{-1}(\mathsf{FEAS}') \subseteq K^{-1}(\mathsf{QFEAS}')$, hence $\mathsf{FEAS} \subseteq \mathsf{QFEAS}$.

It remains to show that $\mathsf{QFEAS} \cap \mathit{lasso} \subseteq \mathsf{FEAS}$. The inclusion $\mathsf{QFEAS}' \cap \mathit{lasso} \subseteq \mathsf{FEAS}'$ implies $K^{-1}(\mathsf{QFEAS}' \cap \mathit{lasso}) \subseteq K^{-1}(\mathsf{FEAS}') = \mathsf{FEAS}$ (the latter equality is because $\mathsf{FEAS} = K^{-1}(\mathsf{FEAS}')$). We prove that $\mathsf{QFEAS} \cap \mathit{lasso} \subseteq K^{-1}(\mathsf{QFEAS}' \cap \mathit{lasso})$, which entails the desired result. Pick an arbitrary $\bar{a} \in \mathsf{QFEAS} \cap \mathit{lasso}$. Since K is rational, $K(\bar{a})$ is ω-regular. Moreover, QFEAS' is ω-regular, which entails that $K(\bar{a}) \cap \mathsf{QFEAS}'$ is ω-regular as well. Since $\bar{a} \in K^{-1}(\mathsf{QFEAS}')$, the intersection $K(\bar{a}) \cap \mathsf{QFEAS}'$ is nonempty. Since $K(\bar{a}) \cap \mathsf{QFEAS}'$ is ω-regular and nonempty, it contains a lasso word $\bar{a}'$. Thus, $\bar{a}' \in K(\bar{a}) \cap \mathsf{QFEAS}' \cap \mathit{lasso}$, hence $\bar{a} \in K^{-1}(\mathsf{QFEAS}' \cap \mathit{lasso})$. ◀

As a direct consequence of Lemma 7 and Theorem 4, we get the following result:

[3] Given two finite alphabets Σ and Γ, a relation $K \subseteq \Sigma^\omega \times \Gamma^\omega$ is rational if there exists an ω-regular language $L \subseteq (\Sigma \cup \Gamma)^\omega$ such that $K = \{(\mathrm{proj}_\Sigma(u), \mathrm{proj}_\Gamma(u)) \mid u \in L\}$. This is equivalent to saying that it can be computed by a nondeterministic asynchronous finite-state transducer over input Σ with output in Γ^*. See, e.g., [3, Section 3].

[4] Note that we do not forbid the existence of unfeasible action words in the image.

▶ **Theorem 8.** *If a data domain $\mathcal{D}$ reduces to a regapprox data domain, then register-bounded synthesis is decidable for $\mathcal{D}$. Moreover, for any positive instance of the register-bounded synthesis problem over $\mathcal{D}$, one can effectively construct a register transducer realising the specification of that instance.*

4.1 Adding Labels to Data Values

As a first application, we show that one can equip data values with labels from a finite alphabet while preserving regapproximability. By Theorem 8, this yields decidability of register-bounded synthesis for such domains.

Formally, given a data domain $\mathcal{D} = (\mathbb{D}, P, C, c_0)$ and a finite alphabet Σ, we define the domain of Σ-labeled data values over $\mathcal{D}$ as $\Sigma \times \mathcal{D} = (\Sigma \times \mathbb{D}, P \cup \{\mathsf{lab}_\sigma \mid \sigma \in \Sigma\}, \Sigma \times C, (\sigma_0, c_0))$, where $\sigma_0 \in \Sigma$ is a fixed but arbitrary element of Σ and, for each $\sigma \in \Sigma$, $\mathsf{lab}_\sigma(\gamma, d)$ holds if and only if $\gamma = \sigma$.

▶ **Lemma 9.** *For all finite alphabet Σ and data domain $\mathcal{D}$, $\Sigma \times \mathcal{D}$ reduces to $\mathcal{D}$.*

Proof. Wlog we assume that the set of constants C is the singleton $\{c_0\}$ (modulo adding new predicates to P). Let $\Sigma = \{\sigma_0, \sigma_1, \ldots, \sigma_n\}$, where σ_0 is such that (σ_0, c_0) is the initialiser of $\Sigma \times \mathcal{D}$. We first define an encoding at the level of data words. Let $\mu : \Sigma \to \mathbb{D}$ be an injective mapping such that $\mu(\sigma_0) = c_0$. A data word u over $\mathcal{D}$ is a μ-encoding of $v = (\sigma_{i_1}, \ell_1)(\sigma_{i_2}, \ell_2)\ldots$ if it is equal to $\mu(\sigma_1)\ldots\mu(\sigma_n)\mu(\sigma_{i_1})\ell_1\mu(\sigma_{i_2})\ell_2\ldots$. The data word u is a *valid encoding* of v if it is a μ-encoding of v for some μ.

Now, the idea is to define a rational relation K from action words $\bar{a}$ over $\Sigma \times \mathcal{D}$ to actions words $\bar{b}$ over $\mathcal{D}$ such that $\bar{a}$ is feasible by some u iff there exists $\bar{b}$ such that $(\bar{a}, \bar{b}) \in K$ and $\bar{b}$ is feasible by a valid encoding of u. Let R be a set of registers and assume $\bar{a}$ is built over R. Let $R' = \{r_\sigma \mid \sigma \in \Sigma\} \uplus R$. Then, any $\bar{b}$ such that $(\bar{a}, \bar{b}) \in K$ should ensure that the n first data values are distinct and store them in $r_{\sigma_1}, \ldots, r_{\sigma_n}$ respectively. So, we require that $\bar{b}$ is of the form $\bar{b} = b_\Sigma \cdot b_{\bar{a}}$ where $b_\Sigma = (\mathsf{tst}_{\sigma_1}, \downarrow r_{\sigma_1}) \ldots (\mathsf{tst}_{\sigma_n}, \downarrow r_{\sigma_n})$ such that for all $1 \leq i \leq n$, $\mathsf{tst}_i = \bigwedge_{1 \leq j \leq i} \star \neq r_{\sigma_j}$. The second part $b_{\bar{a}}$ is an encoding of the tests and assignments of $\bar{a} = (\mathsf{tst}_0, \mathsf{asgn}_0)(\mathsf{tst}_1, \mathsf{asgn}_1)\ldots$. It is of the form $b_{\bar{a}} = (\mathsf{tst}_0^{lab}, \varnothing)(\mathsf{tst}_0^{data}, \mathsf{asgn}_0)(\mathsf{tst}_1^{lab}, \varnothing)(\mathsf{tst}_1^{data}, \mathsf{asgn}_1)\ldots$, where for all $i \geq 0$:

- for every predicate $p \in P$ of arity n, for every $x_1, \ldots, x_n \in R \cup \{\star\}$: if $(\neg)p(x_1, \ldots, x_n) \in \mathsf{tst}_i$, then $(\neg)p(x_1, \ldots, x_n) \in \mathsf{tst}_i^{data}$, and
- for all $\sigma \in \Sigma$ and $x \in R \cup \{\star\}$: $\mathsf{lab}_\sigma(x) \in \mathsf{tst}_i^{lab}$ iff $(r_\sigma = x) \in \mathsf{tst}_i$.

Correctness follows from the construction; see the extended paper for details. ◀

The latter result combined with Theorem 8 yields:

▶ **Corollary 10.** *Let $\mathcal{D}$ be an regapprox data domain and Σ be a finite alphabet, then register-bounded synthesis is decidable for $\Sigma \times \mathcal{D}$.*

4.2 Quantifier-Free Interpretations

When the relation between valuations over $\mathcal{D}$ and over $\mathcal{D}'$ is local, it is more convenient to operate directly at the level of tests. To that end, we define a notion of quantifier-free interpretation (see [13, Section 12.3.6] for a presentation of the notion in the context of data words), that allows us to encode elements of $\mathcal{D}$ as tuples of elements of $\mathcal{D}'$.

A *quantifier-free interpretation* (or *interpretation* for short) of dimension $l \geq 1$ with signature (P, C) over a data domain $\mathcal{D}' = (\mathbb{D}', P', C')$ is given by quantifier-free formulas over signature (P', C'). The formula $\phi_{\text{domain}}(x_1, \ldots, x_l)$ defines the domain $\mathbb{D} =$

$\{(\mathcal{d}_1, \dots, \mathcal{d}_l) \mid \mathcal{D}' \models \phi_{\text{domain}}(\mathcal{d}_1, \dots, \mathcal{d}_l)\}$. Then, for each constant symbol $c \in C$, the formula $\phi_c(x_1, \dots, x_l)$ defines the encodings[5] of c as the tuples $(\mathcal{d}_1^c, \dots, \mathcal{d}_l^c) \in \mathbb{D}$ that satisfy ϕ_c, i.e. such that $\mathcal{D}' \models \phi_c(\mathcal{d}_1^c, \dots, \mathcal{d}_l^c)$. Finally, for each predicate $p \in P$ of arity a (including $=$), the formula $\phi_p(x_1^1, \dots, x_l^1, \dots, x_1^a, \dots, x_l^a)$ defines the predicate $p^{\mathcal{D}} = \left\{(\mathcal{d}_1^1, \dots, \mathcal{d}_l^1, \dots, \mathcal{d}_1^a, \dots, \mathcal{d}_l^a) \,\middle|\, \mathcal{D}' \models \phi_R(\mathcal{d}_1^1, \dots, \mathcal{d}_l^1, \dots, \mathcal{d}_1^a, \dots, \mathcal{d}_l^a)\right\}$.

▶ **Lemma 11.** $(\mathbb{Z}, <, 0)$ *can be defined as a 2-dimensional interpretation of* $(\mathbb{N}, <, 0)$.

Proof. The encoding consists of two copies of $\mathbb{N}$, one for positive and one for negative integers, whose order is reversed. Formally, $\phi_{domain}(x_1, x_2) \coloneqq x_1 = 0 \vee x_2 = 0$. Then, $\phi_0(x_1, x_2) \coloneqq x_1 = 0 \wedge x_2 = 0$; $\phi_=((x_1, x_2), (y_1, y_2)) \coloneqq x_1 = y_1 \wedge x_2 = y_2$ and $\phi_<((x_1, x_2), (y_1, y_2)) \coloneqq (x_2 = y_2 = 0 \wedge x_1 < y_1) \vee (x_1 = y_1 = 0 \wedge x_2 > y_2) \vee (x_1 = 0 \wedge y_1 > 0)$. Then, $(\mathbb{Z}, <, 0)$ is isomorphic to this structure, through the bijection $n \geq 0 \mapsto (n, 0)$ and $n < 0 \mapsto (0, -n)$. ◀

More generally, d-uples of integers can be easily encoded. In the following, we fix $d \geq 1$. For $(n_1, ..., n_d), (m_1, ..., m_d) \in \mathbb{Z}^d$, define $(n_1, ..., n_d) <^d (m_1, ..., m_d)$ iff for all $i \in \{1, ..., d\}$, $n_i \leq m_i$ and $n_j < m_j$ for some $j \in \{1, \dots, d\}$; it is a partial order on $\mathbb{Z}^d$. The predicate $=^d$ is defined as expected.

▶ **Lemma 12.** $(\mathbb{Z}^d, =^d, <^d, 0^d)$ *can be defined as a d-dimensional interpretation of* $(\mathbb{Z}, <, 0)$.

Proof. Any tuple belongs to the domain, so we let $\phi_{\text{domain}} \coloneqq \top$. Then, $\phi_0(x_1, \dots, x_d) \coloneqq \bigwedge_{1 \leq i \leq d} x_i = 0$, $\phi_=((x_1, \dots, x_d), (y_1, \dots, y_d)) \coloneqq \bigwedge_{1 \leq i \leq d} x_i = y_i$, and similarly for $\phi_<$. ◀

The following theorem allows us to lift our results to the two domains above:

▶ **Theorem 13.** *If $\mathcal{D}$ is a quantifier-free interpretation over $\mathcal{D}'$, then $\mathcal{D}$ reduces to $\mathcal{D}'$.*

Proof (Sketch). We outline the proof, and refer to the extended paper for details. Let $\mathcal{D}' = (\mathbb{D}', P', C')$ be a data domain, and $\mathcal{D}$ be an interpretation over $\mathcal{D}'$ of dimension $l \geq 1$ with signature (P, C). The main idea is, given a set of registers R, to consider l copies of this set, meant to store each dimension of the interpretation. We also add l copies of C to store the encoding of constants, and, since tests are conducted before assignment, l registers to store each component of the input tuple. Overall, an action word $\bar{a}$ over R is sent to one over $(R \cup C \cup \{d\}) \times \{1, \dots, l\}$, where d is a fresh register variable. Then we construct the sought relation K as follows: first, it prefixes its image with a sequence of actions that store the encoding of constants in the corresponding registers, check that they indeed satisfy their respective ϕ_c, and ensure that all registers in $R \times \{1, \dots, l\}$ are initialised with the encoding of c_0. Note that the formulas are not necessarily conjuncts, so we put them in disjunctive normal form and consider all tests that are conjuncts of the DNF. Then, each action is processed separately: an action $(\mathsf{tst}, \mathsf{asgn})$ of $\bar{a}$ is associated with a sequence of $2l + 1$ actions that consist in reading each component of the input data value $\star$, store it in the corresponding copy of d, check that $\star$ indeed belongs to the domain (ϕ_{domain}), and that it satisfies tst (using the $(\phi_p)_{p \in P}$ to encode the predicates). Again, this implies converting the formulas in DNF, so a given action is in general associated with multiple ones. Since K consists in adding a prefix and then processing each action separately, it is rational. Moreover, it preserves feasibility; more precisely for any action word $\bar{a}$, each of its corresponding data word can be associated with its encoding in $K(\bar{a})$. ◀

By Theorems 6, 13 and 8, as well as Lemma 11, we get:

[5] Note that we do not assume the encoding to be unique.

▶ **Corollary 14.** *Register-bounded synthesis is decidable for* $(\mathbb{Z}, <, 0)$.

Then, since $(\mathbb{Z}, <, 0)$ reduces to $(\mathbb{N}, <, 0)$, and reducibility is transitive, we get, by Lemma 12 and Theorems 13 and 8:

▶ **Corollary 15.** *Register-bounded synthesis is decidable for* $(\mathbb{Z}^d, =^d, <^d, 0^d)$.

▶ Remark. One can similarly show that $\mathbb{N}^d$ reduces to $\mathbb{N}$. More generally, the above method allows one to lift decidability of register-bounded synthesis to tuples of data values where predicates are applied component-wise. Besides, note that $\mathbb{N}^d$ also reduces to $\mathbb{Z}^d$, by restricting $\mathbb{Z}^d$ to nonnegative values.

4.3 Finite Strings with the Prefix Relation

In this section, we show that synthesis is decidable over the data domain $(\Sigma^*, =, \prec, \epsilon)$, where Σ is a finite alphabet and $\prec$ denotes the prefix relation, leveraging a result of [10] that encodes prefix constraints as integer ones. This still requires some work, as we cannot use the notion of interpretation: a string valuation is encoded as an integer valuation with a *quadratic* number of registers. In the sequel, Σ is a fixed finite set of size $l \geq 2$.

First, $(\Sigma^*, =, \prec, \epsilon)$ reduces to the richer domain $(\Sigma^*, =, \mathit{clen}_=, \mathit{clen}_<, \epsilon)$, where, given $u, v \in \Sigma^*$, $\mathit{clen}(u, v)$ denotes the length of the longest common prefix of u and v, and, for $\triangleleft \in \{<, =\}$, $\mathit{clen}_\triangleleft(u, v, u', v')$ holds whenever $\mathit{clen}(u, v) \triangleleft \mathit{clen}(u', v')$. The reduction is direct, and follows the same lines as [10, Lemma 3]: $u \prec v$ is encoded as $(\mathit{clen}(u, u) = \mathit{clen}(u, v)) \wedge (\mathit{clen}(u, u) < \mathit{clen}(v, v))$, and K is a morphism on tests and the identity over assignments.

▶ **Lemma 16.** $(\Sigma^*, =, \prec, \epsilon)$ *reduces to* $(\Sigma^*, =, \mathit{clen}_=, \mathit{clen}_<, \epsilon)$.

Note also that satisfiability of tests over both domains is decidable, and NP-complete [10, Lemma 7]. It now remains to show that $(\Sigma^*, =, \mathit{clen}_=, \mathit{clen}_<, \epsilon)$ reduces to $(\mathbb{N}, =, <, 0)$. The proof draws on ideas similar to that of [10, Lemmas 8,9], which mainly relies on [10, Lemmas 5,6]. Here, it remains to lift them to our synthesis framework, and ensure that feasibility is preserved despite the dependencies induced by registers.

▶ **Lemma 17.** $(\Sigma^*, =, \mathit{clen}_=, \mathit{clen}_<, \epsilon)$ *reduces to* $(\mathbb{N}, =, <, 0)$.

Proof. We describe the main ideas of the proof; a full proof can be found in the extended version. From [10, Lemma 5,6], we know that a string valuation is characterised by the length of the longest common prefixes of all its pairs of values, when prefix constraints are concerned. This allows to encode Σ^* in $\mathbb{N}$: given a set R of registers, we introduce a register $\pi_{r,s}$ for each $(r, s) \in R' = (R \cup \{\mathsf{x}\})^2$, where x is an additional register name that denotes the input data value $\star$ in Σ^*. Along the execution, a register $\pi_{r,s}$ is meant to contain $\mathit{clen}(\nu(r), \nu(s))$. Note that in particular, $\pi_{r,r}$ contains the length of the word stored in r. At each step, we read a sequence of $|R|$ integers that each corresponds to the value of $\mathit{clen}(\star, r)$ for some $r \in R$, that we store in the corresponding register $\pi_{\star,r}$. We then check that they satisfy the *clen* constraints, as well as the properties of [10, Proposition 2]. The latter consist in logical formulas that can be encoded as tests in $(\mathbb{N}, =, <, 0)$, as they only use $=$ and $<$.

Using [10, Lemma 6], from a sequence of integer valuations (called *counter valuations* in [10]) that satisfy those properties, we can reconstruct a sequence of string valuations. As the integer valuations additionally satisfy the *clen* constraints, so does the string valuations. Thus, if an image R'-action word is feasible, the original action word is feasible. The converse direction is easier: given a sequence $\nu_0\nu_1\ldots$ of string valuations that is compatible with the R-action word, at step i one fills each $\pi_{r,s}$ with $\mathit{clen}(\nu_i(r), \nu_i(s))$. ◀

By Theorems 6 and 8, we get:

▶ **Corollary 18.** *Register-bounded synthesis is decidable for* $(\Sigma^*, =, \prec, \epsilon)$.

▶ Remark 19 (Complexity analysis). Note that the data domains in Corollaries 14, 15 and 18 all reduce to $(\mathbb{N}, <, 0)$ (all via some rational relations K depending on a set of registers R). The time complexities of those corollaries depend on the complexities of constructing, given a set of registers R, a nondeterministic Büchi automaton recognising $K^{-1}(\mathsf{QFEAS}_R^{(\mathbb{N},<,0)})$ for all the rational relations K defined in the proofs of those corollaries. It can be seen from those proofs that for any such rational relation K, it is possible to construct a nondeterministic Büchi transducer A_K with polynomially many states in $|R|$ recognising K. By taking the synchronized product of A_K with a nondeterministic automaton recognising $\mathsf{QFEAS}_R^{(\mathbb{N},<,0)}$, say of size n_{qf}, and by projecting it on its inputs, one obtains a nondeterministic Büchi automaton recognising $K^{-1}(\mathsf{QFEAS}_R^{(\mathbb{N},<,0)})$. It can be computed in time $poly(n_{qf})$. By Fact 5 and Theorem 4, one gets that the time complexities of k-register-bounded synthesis for data domains $(\mathbb{Z}, =, <, 0)$, $(\mathbb{Z}^d, =^d, <^d, 0^d)$ (for a fixed d) and $(\Sigma^*, =, \prec, \epsilon)$ is doubly exponential in k and r the number of registers of the specification, and singly exponential in the number of states of the URA and its number of priorities.

5 Conclusion

We have shown that register-bounded synthesis from specifications expressed by universal register-automata over $(\mathbb{N}, <, 0)$ is decidable within the same time complexity class as the case of URA over $(\mathbb{N}, =)$, completing the picture on synthesis from register automata over $(\mathbb{N}, =)$ and $(\mathbb{N}, <, 0)$: (unbounded) synthesis is undecidable for nondeterministic register automata [15], decidable for deterministic register automata over $(\mathbb{N}, =)$ [15] and over $(\mathbb{N}, <)$ [14], and register-bounded synthesis is decidable for URA over $(\mathbb{N}, =)$ [24, 15, 25] and $(\mathbb{N}, <, 0)$ (this paper), and undecidable for nondeterministic register automata [15]. We also get decidability for the data domains of integers, of tuples of integers and of finite words with the prefix relation, by reducing them to $(\mathbb{N}, <, 0)$. A simple complexity analysis (Remark 19) yields a doubly exponential decision procedure for register-bounded synthesis over these domains. Systematising this complexity analysis calls for a notion of polynomial reduction between data domains, that we leave for future work.

There are other challenging future research directions: first, universal automata, as argued in the introduction, are well suited for synthesis, and have been show in the register-free setting to be amenable to synthesis procedures which are feasible in practice [26, 31, 17, 4]. We plan on investigating extensions of these works to the register setting. In particular, our synthesis algorithm first reduces the problem to a synthesis problem over a *finite* alphabet with a specification given by a universal co-Büchi automaton. The latter problem is classically solved by reduction to a parity game obtained by determinising the universal co-Büchi automaton, e.g. by using Safra's determinization procedure. It is an interesting question whether Safraless procedures from [26, 31, 17] could be combined with our game reduction to get more practical algorithms. Another challenging research direction is to consider synthesis problems from logical specifications instead of automata, as the nice correspondences between automata and logics for word languages over finite alphabets do not carry over to data words. Nevertheless, URA encompass Constraint LTL [32], and we believe their expressive power could allow one to target other temporal-like logics with data.

Abstract

We study problems connected to first-order logic in graphs of bounded twin-width. Inspired by the approach of Bonnet et al. [FOCS 2020], we introduce a robust methodology of *local types* and describe their behavior in contraction sequences – the decomposition notion underlying twin-width. We showcase the applicability of the methodology by proving the following two algorithmic results. In both statements, we fix a first-order formula $\varphi(x_1, \ldots, x_k)$ and a constant d, and we assume that on input we are given a graph G together with a contraction sequence of width at most d.

- One can in time $\mathcal{O}(n)$ construct a data structure that can answer the following queries in time $\mathcal{O}(\log \log n)$: given $w_1, \ldots, w_k$, decide whether $\varphi(w_1, \ldots, w_k)$ holds in G.
- After $\mathcal{O}(n)$-time preprocessing, one can enumerate all tuples $w_1, \ldots, w_k$ that satisfy $\varphi(x_1, \ldots, x_k)$ in G with $\mathcal{O}(1)$ delay.

In the first case, the query time can be reduced to $\mathcal{O}(1/\varepsilon)$ at the expense of increasing the construction time to $\mathcal{O}(n^{1+\varepsilon})$, for any fixed $\varepsilon > 0$. Finally, we also apply our tools to prove the following statement, which shows optimal bounds on the VC density of set systems that are first-order definable in graphs of bounded twin-width.

- Let G be a graph of twin-width d, A be a subset of vertices of G, and $\varphi(x_1, \ldots, x_k, y_1, \ldots, y_l)$ be a first-order formula. Then the number of different subsets of A^k definable by φ using l-tuples of vertices from G as parameters, is bounded by $O(|A|^l)$.

Acknowledgements The authors thank Rose McCarty and Felix Reidl for many initial discussions on the type approach to first-order logic on graphs of bounded twin-width.

1 Introduction

Twin-width is a graph parameter recently introduced by Bonnet et al. [7]. Its definition is based on the concept of a *contraction sequence*: a sequence of partitions of the vertex set of the graph that starts with the partition into singletons, where every subsequent partition is

obtained from the previous one by merging two parts ending with the partition with one part. The main idea lies in measuring the *width* of a contraction sequence: it is the smallest integer d such that at every step, every part of the current partition is *impure* – neither completely adjacent nor completely non-adjacent – towards at most d other parts of that partition. The *twin-width* of a graph G is the smallest possible width of a contraction sequence of G. Thus, one may thinkthat a graph of bounded twin-width can be gradually "folded" into a single part so that at every point, every part has a non-trivial interaction with only a bounded number of other parts.

We remark that while twin-width was originally defined for graphs, the idea can be, and has been, generalized to any classes of binary relational structures, for instance ordered graphs [4] or permutations [8]. In this work we focus on the graph setting for simplicity. However, all our results lift to arbitrary structures over a fixed relational signature in which all relation symbols have arities at most two.

Since its recent introduction, multiple works have investigated combinatorial, algorithmic, and model-theoretic aspects of twin-width. In this work we are mostly interested in the two last ones. As proved by Bonnet et al. [7], provided a graph G is given together with a contraction sequence of width bounded by a constant, every property expressible in first-order logic can be verified in linear time on G; in other words, the model-checking problem for first-order logic can be solved in linear fixed-parameter tractable time. Further, bounded twin-width is preserved under transductions: if a class of graphs $\mathscr{C}$ has bounded twin-width, then any class that can be obtained from $\mathscr{C}$ by a fixed (first-order) transduction also has bounded twin-width [7]. Finally, as proved by Bonnet et al. [4], classes of *ordered* graphs that have bounded twin-width exactly coincide with those that are *monadically NIP*, that is, do not transduce all graphs. All these results witness that twin-width is a model-theoretically important notion and a vital element of the emerging structural theory for graphs based around the notion of a (first-order) transduction. See [8, 13] for further discussion.

In this work we take a closer look at the model-checking algorithm for graphs of bounded twin-width, proposed in [7]. The basic technical notion used there is that of a *morphism tree*. While this is not explicit in [7], it is clear that morphism trees are combinatorial objects representing strategies in a form of an Ehrenfeucht-Fraïsse game, and basic operations on morphism trees correspond to manipulations on strategies. Mirroring the standard approach taken in finite model theory, one should be able to define a notion of a *type* suited for the setting of contraction sequences, as well as a corresponding model of an Ehrenfeucht-Fraïsse game that can be used to argue about properties of types such as compositionality. Providing robust foundations for such a type-based methodology for contraction sequences is the main goal of this work.

We remark that the type/game based perspective of the approach of [7], which we explained above, was recently briefly outlined in [5, Section 5].

Our contribution. We introduce the notion of a *local type* that is suited for describing first-order properties of tuples of vertices in vertex-partitioned graphs. Intuitively speaking, the rank-k local type of a tuple $\mathbf{w}$ in a graph G with vertex partition $\mathcal{P}$ is the set of all quantifier rank k formulas satisfied by $\mathbf{w}$, where we restrict quantification as follows. Whenever a new vertex, say z, is quantified, one has to specify the part $P \in \mathcal{P}$ which contains z, but at depth i of quantification one can quantify only over parts that are at distance at most 2^{k-i} from parts containing already quantified vertices (including vertices of $\mathbf{w}$). Here, we mean the

distance in the *impurity graph*: the graph on parts of $\mathcal{P}$ where two parts of $\mathcal{P}$ are adjacent if and only if they are neither completely adjacent nor completely non-adjacent. This definition mirrors, in logical terms, the morphism trees of Bonnet et al. [7]. In particular, it applies the same idea that the radius of quantification decreases exponentially with the depth.

We prove a set of fundamental lemmas for manipulation of local types upon consecutive steps in a contraction sequence. These reflect the mechanics of morphism trees of [7], but by basing the argumentation essentially on Ehrenfeucht-Fraïssé games, the obtained explanation is arguably simpler and more insightful. Also, contrary to [5, 7], the introduced toolbox applies to tuples of vertices, and not only to single parts in the contraction sequence. This is important in our applications, which we discuss next.

We use the toolbox of local types to give the following algorithmic results on first-order expressible problems in graphs of bounded twin-width. The first one concerns the problem of *query answering*, and the second concerns the problem of *query enumeration*. In both theorems we assume that the graph is *specified through* a contraction sequence; this is explained in Section 2. For a tuple of parameters $\mathbf{p}$, the notation $\mathcal{O}_{\mathbf{p}}(\cdot)$ hides factors depending on $\mathbf{p}$.

▶ **Theorem 1.** *Suppose we are given an n-vertex graph G specified through a contraction sequence $\mathcal{P}_1, \ldots, \mathcal{P}_n$ of width d, and a first-order formula $\varphi(\mathbf{x})$, where $\mathbf{x}$ is a set of variables. Then one can construct in time $\mathcal{O}_{d,\varphi}(n)$ a data structure that can answer the following queries in time $\mathcal{O}_{d,\varphi}(\log\log n)$: given $\mathbf{w} \in V(G)^{\mathbf{x}}$, decide whether $G \models \varphi(\mathbf{w})$.*

▶ **Theorem 2.** *Suppose we are given an n-vertex graph G specified through a contraction sequence $\mathcal{P}_1, \ldots, \mathcal{P}_n$ of width d, and a first-order formula $\varphi(\mathbf{x})$, where $\mathbf{x}$ is a set of variables. Then after preprocessing in time $\mathcal{O}_{d,\varphi}(n)$, one can enumerate all tuples $\mathbf{w} \in V(G)^{\mathbf{x}}$ such that $G \models \varphi(\mathbf{w})$ with $\mathcal{O}_{d,\varphi}(1)$ delay.*

Note that in Theorem 1 there is a factor of the form $\mathcal{O}_{d,\varphi}(\log\log n)$ appearing in the query time. This is a consequence of using a data structure for orthogonal range queries of Chan [9] that supports queries in time $\mathcal{O}(\log\log n)$. As explained in [19], there is also a simple data structure for orthogonal range queries that, for any fixed $\varepsilon > 0$, offers query time $\mathcal{O}(1/\varepsilon)$ at the expense of increasing the construction time and the space complexity to $\mathcal{O}(n^{1+\varepsilon})$. By replacing the usage of the data structure of Chan with this simple data structure, we may obtain the same tradeoff in Theorem 1: The query time is reduced to $\mathcal{O}(1/\varepsilon)$, while the construction time and the space complexity is increased to $\mathcal{O}(n^{1+\varepsilon})$; this holds for any fixed $\varepsilon > 0$.

Theorems 1 and 2 mirror classic results on evaluation and enumeration of monadic second-order queries on trees [2, 10, 14] (which imply analogous results for graphs of bounded treewidth and of bounded cliquewidth), and of first-order queries on classes of bounded expansion [11, 15] and nowhere dense classes [22]. Therefore, we believe that the applications discussed above witness the robustness of the developed methodology.

As another application, we prove optimal bounds on *VC density* of set systems definable in graphs of bounded twin-width. Suppose $\varphi(\mathbf{x}, \mathbf{y})$ is a first-order formula with free variables partitioned into $\mathbf{x}$ and $\mathbf{y}$. For a graph G and a subset of vertices A, we define the *Stone space*

$$S^{\varphi}(A) \coloneqq \{\, \{\, \mathbf{a} \in A^{\mathbf{x}} \mid G \models \varphi(\mathbf{a}, \mathbf{b}) \,\} \;:\; \mathbf{b} \in V(G)^{\mathbf{y}} \,\}.$$

In other words, every tuple $\mathbf{b} \in V(G)^{\mathbf{y}}$ gives rise to the subset $\varphi(A, \mathbf{b}) \subseteq A^{\mathbf{x}}$ consisting of those tuples $\mathbf{a}$ that together with $\mathbf{b}$ satisfy φ. Then the Stone space $S^{\varphi}(A)$ consists of all sets $\varphi(A, \mathbf{b})$ that can be defined in this way. See for example [18] for a discussion of this notion and its applications.

In general graphs, $S^{\varphi}(A)$ can be as large as the whole powerset of A^x. However, under various structural assumptions, it will be typically much smaller. For instance, suppose that the twin-width of G is bounded by a constant d. Then by combining the results of Bonnet et al. [7] with that of Baldwin and Shelah [3], one can argue that the VC dimension of $S^{\varphi}(A)$, regarded as a set system over universe $A^{\mathbf{x}}$, is bounded by a constant depending only on d and φ. Consequently, by the Sauer-Shelah Lemma [21, 23], the cardinality of $S^{\varphi}(A)$ is bounded polynomially in $|A|$. However, the degree of this polynomial bound, which is known as the *VC density* (studied for example in [1]), still depends on d and φ, and in a quite non-explicit way. We prove that in fact, there is a much sharper upper bound: the VC density is bounded by just the number of variables in $\mathbf{y}$.

▶ **Theorem 3.** *Let G be a graph of twin-width at most d, A be a subset of vertices of G, and $\varphi(\mathbf{x}, \mathbf{y})$ be a first-order formula. Then*

$$|S^{\varphi}(A)| \leqslant \mathcal{O}_{d,\varphi}\left(|A|^{|\mathbf{y}|}\right).$$

It is easy to see (see e.g. [18]) that even in edgeless graphs one cannot hope for a bound better than $|A|^{|\mathbf{y}|}$, and therefore the bound of Theorem 3 is asymptotically optimum.

Theorem 3 mirrors analogous results for monadic second-order formulas on classes of bounded treewidth or cliquewidth [16], and for first-order formulas on classes of bounded expansion and nowhere dense classes [18]. We remark that the case $|\mathbf{x}| = |\mathbf{y}| = 1$ follows from the fact that classes of bounded twin-width are closed under first-order transductions, combined with known linear upper bounds on the *neighborhood complexity*[1] in classes of bounded twin-width [6, 20]. Tackling multiple free variables requires a better understanding of types for tuples of vertices, which is exactly where our methodology of local types comes into play.

Organization. After preliminaries in Section 2, we present the framework of local types in Section 3. Then we prove Theorem 1 in Sections 4. Theorems 2 is proved in Section 5. Theorem 3 is deferred to the full version, due to space constraints. Easy proofs of statements marked with ♠ are also deferred to the full version.

2 Preliminaries

Graphs. In this paper we work with finite, undirected graphs and we use standard graph notation. By $|G|$ we denote the number of vertices of a graph G.

A pair of disjoint vertex subsets $A, B \subseteq V(G)$ is *complete* if every vertex of A is adjacent to every vertex of B, and *anti-complete* if there is no edge with one endpoint in A and the other one in B. The pair A, B is *pure* if it is complete or anti-complete, and *impure* otherwise.

[1] In our notation, bounds on neighborhood complexity exactly correspond to the case when $\mathbf{x} = \{x\}$, $\mathbf{y} = \{y\}$, and $\varphi(x, y)$ just checks that x and y are adjacent.

A *trigraph* is a structure in which there is a vertex set and every pair of distinct vertices is bound by exactly one of the following three symmetric relations: adjacency, non-adjacency, and impurity. Thus, graphs are trigraphs without impurities. Given a partition of $\mathcal{P}$ of the vertex set of a graph G, we define the *quotient trigraph* $G/\mathcal{P}$ as the trigraph on vertex set $\mathcal{P}$ where distinct $A, B \in \mathcal{P}$ are adjacent if the pair A, B is complete in G, non-adjacent if the pair is anti-complete, and impure towards each other if A, B is impure. For a trigraph H, its *impurity graph* $\mathsf{Imp}(H)$ is the graph on vertex set H where two vertices $u, v \in V(H)$ are considered adjacent if they are impure towards each other in H.

Contraction sequences. Let G be a graph on n vertices. A *contraction sequence* for G is a sequence $\mathcal{P}_1, \ldots, \mathcal{P}_n$ of partitions of the vertex set of G such that:

- $\mathcal{P}_1$ is the partition into singletons;
- $\mathcal{P}_n$ is the partition with one part;
- for each $t \in [n]$, $t > 1$, $\mathcal{P}_t$ is obtained from $\mathcal{P}_{t-1}$ by taking some two parts $A, B \in \mathcal{P}_{t-1}$ and *contracting* them: replacing them with a single part $A \cup B \in \mathcal{P}_t$.

Indices $t \in [n]$ will be called *times*. The *width* of the contraction sequence $\mathcal{P}_1, \ldots, \mathcal{P}_n$ is the maximum degree in graphs $\mathsf{Imp}(G/\mathcal{P}_t)$, at all times $t \in [n]$. The *twin-width* of G is the minimum possible width of a contraction sequence of G.

If G is supplied with a total order $\leqslant$ on $V(G)$, then a subset of vertices A is *convex* if it forms an interval in $\leqslant$, that is, if $a, b \in A$ then also $c \in A$ whenever $a \leqslant c \leqslant b$. A partition is convex if all its parts are convex, and a contraction sequence is convex if all its partitions are convex.

Additional notation for partitions and contraction sequences. Fix a graph G with a partition $\mathcal{P}$ of its vertices. We will use the following notation.

Denote $G_{\mathcal{P}} \coloneqq G/\mathcal{P}$ and $G^{\mathsf{imp}}_{\mathcal{P}} \coloneqq \mathsf{Imp}(G_{\mathcal{P}})$. By $\mathrm{dist}_{\mathcal{P}}(\cdot,\cdot)$ we denote the distance function in $G^{\mathsf{imp}}_{\mathcal{P}}$: for $A, B \in \mathcal{P}$, $\mathrm{dist}_{\mathcal{P}}(A, B)$ is the minimum length of a path in $G^{\mathsf{imp}}_{\mathcal{P}}$ connecting A and B, and $+\infty$ if there is no such path. We extend this notation to subsets, or tuples of elements of $\mathcal{P}$: $\mathrm{dist}_{\mathcal{P}}(X, Y)$ denotes the minimum, over all A occurring in X and B occurring in B, of $\mathrm{dist}_{\mathcal{P}}(A, B)$.

For a set of parts $\mathcal{F} \subseteq \mathcal{P}$ and a radius parameter $r \in \mathbb{N}$, the *r-vicinity* of $\mathcal{F}$, denoted $\mathsf{Vicinity}^r_{\mathcal{P}}(\mathcal{F})$, is the trigraph induced in $G_{\mathcal{P}}$ by all parts at distance at most r from any part belonging to $\mathcal{F}$, that is

$$\mathsf{Vicinity}^r_{\mathcal{P}}(\mathcal{F}) \coloneqq G_{\mathcal{P}}[\{A \in \mathcal{P} \mid \mathrm{dist}_{\mathcal{P}}(A, \mathcal{F}) \leqslant r\}].$$

We may use notation $\mathsf{Vicinity}^r_{\mathcal{P}}(\cdot)$ for single parts or tuples of parts with the obvious meaning.

For brevity, whenever a graph G and its contraction sequence $\mathcal{P}_1, \ldots, \mathcal{P}_n$ are clear from the context, we fix the following notation. First, in all the notation defined above, concerning partitions, we write s in the subscript instead of $\mathcal{P}_s$. So for instance we write G_s to denote $G_{\mathcal{P}_s}$, and G^{imp}_s to denote $G^{\mathsf{imp}}_{\mathcal{P}_s}$, and $\mathrm{dist}_s(\cdot,\cdot)$ to denote $\mathrm{dist}_{\mathcal{P}_s}(\cdot,\cdot)$, etc.

Fix a finite set of variables $\mathbf{x}$. For a pair of times $s, t \in [n]$, $s \leqslant t$, and a tuple of parts $\mathbf{u} \in \mathcal{P}_s^{\mathbf{x}}$, we define the tuple $\mathbf{u}\langle s \to t\rangle \in \mathcal{P}_t^{\mathbf{x}}$ as follows: for each $y \in \mathbf{x}$, $\mathbf{u}\langle s \to t\rangle(y)$ is the unique part of $\mathcal{P}_t$ that contains $\mathbf{u}(y)$. For a tuple $\mathbf{u} \in V(G)^{\mathbf{x}}$ of vertices and $s \in [n]$, by $\mathbf{u}\langle s\rangle \in \mathcal{P}_s^{\mathbf{x}}$ we denote the unique tuple whose y-component, for $y \in \mathbf{x}$, is the part of $\mathcal{P}_s$ containing $\mathbf{u}(y)$.

For $s \in [n-1]$, by B_{s+1} we denote the unique part of $\mathcal{P}_{s+1}$ that is the union of two parts in $\mathcal{P}_s$. For a parameter $r \in \mathbb{N}$, we define the *r-relevant region* in G_s as follows:

$$\mathsf{Relevant}_s^r := G_s[\{C \in \mathcal{P}_s \mid C \subseteq B_{s+1}, \text{ or } C \in \mathcal{P}_{s+1} \text{ and } \mathrm{dist}_{s+1}(C, B_{s+1}) \leqslant r\}].$$

In other words, $\mathsf{Relevant}_s^r$ is the trigraph induced in G_s by the two parts of $\mathcal{P}_s$ that get contracted into B_{s+1} and all parts of $\mathcal{P}_s$ that stay intact in $\mathcal{P}_{s+1}$ and are at distance at most r from B_{s+1} in G_{s+1}^{imp}.

Note that we have $|\mathsf{Relevant}_s^p| \leqslant \mathcal{O}_{d,p}(1)$ for all $s \in [n-1]$. The next lemma shows that the p-relevant regions can be computed efficiently.

▶ **Lemma 4 (♠).** *Suppose a graph G on vertex set $[n]$ is provided through a convex contraction sequence $\mathcal{P}$ of width d. Then for a given $p \in \mathbb{N}$, one can in time $\mathcal{O}_{d,p}(n)$ compute the trigraphs $\mathsf{Relevant}_s^p$ for all $s \in [n-1]$.*

Specifying a graph through its contraction sequence. In all algorithmic statements we will assume that a graph is given by specifying its contraction sequence together with some auxiliary information encoding the edge relation. We now make this precise.

Let $\mathcal{P}_1, \ldots, \mathcal{P}_n$ be a contraction sequence of a graph G. We assume that every part participating in the partitions $\mathcal{P}_1, \ldots, \mathcal{P}_n$ (that is, every element of the union $\mathcal{P}_1 \cup \cdots \cup \mathcal{P}_n$, where each $\mathcal{P}_i$ is viewed as a set of sets of vertices) is specified through a unique identifier taking a single machine word. For $\mathcal{P}_1$, the identifiers of (singleton) parts coincide with identifiers of the corresponding vertices. Then sequence $\mathcal{P}_1, \ldots, \mathcal{P}_n$ is represented by providing the following information for every time $s \in [n]$, $s > 1$:

- The identifiers of the two parts $A, A' \in \mathcal{P}_{s-1}$ that get contracted at time s, and the identifier of the obtained part $B = A \cup A' \in \mathcal{P}_s$.
- A list of identifiers of parts $C \in \mathcal{P}_s$ such that the pair B, C is impure in G (that is, the impurities incident to B in $\mathsf{Imp}(G/\mathcal{P}_s)$).
- For each part C on the list above, the relation (completeness, anti-completeness, or impurity) between C and A and between C and B in $G/\mathcal{P}_{s-1}$.

It is easy to see that this representation uniquely defines the graph G. Since the representation takes $\mathcal{O}_d(1)$ machine words at any time s, we can thus represent an n-vertex graph of twin-width d using $\mathcal{O}_d(n)$ machine words.

We now show that, for a graph given through a contraction sequence, one can reindex the vertex set using integers from $[n]$ so that the contraction sequence becomes convex.

▶ **Lemma 5 (♠).** *Suppose a graph G is given by specifying a contraction sequence $\mathcal{P}_1, \ldots, \mathcal{P}_n$ of width d. Then one can in time $\mathcal{O}_d(n)$ compute a bijection $\eta \colon V(G) \to [n]$ such that mapping G and $\mathcal{P}_1, \ldots, \mathcal{P}_n$ through η yields an isomorphic graph G' on vertex set $[n]$ and its contraction sequence $\mathcal{P}'_1, \ldots, \mathcal{P}'_n$ such that $\mathcal{P}'_1, \ldots, \mathcal{P}'_n$ is convex in the natural order on integers in $[n]$.*

Note that if a graph is reindexed using Lemma 5, then every part participating in the resulting contraction sequence is an interval in $[n]$. Hence, as the identifier of a part we can simply use a pair of vertices – the left endpoint and the right endpoint – and such identifiers can be computed in time $\mathcal{O}_d(n)$ by scanning the contraction sequence. We will therefore assume that contraction sequences are convex with respect to a fixed ordering of the vertices, and the (convex) parts are identified by their endpoints.

First-order logic. We fix a countable set of variables, together with its enumeration. If Ω is a set and $\mathbf{x}$ is a finite set of variables, then an $\mathbf{x}$-*tuple* with entries in Ω is a function from $\mathbf{x}$ to Ω. Tuples are by convention denoted with boldface small letters, e.g. $\mathbf{u}$ or $\mathbf{v}$. The set of all $\mathbf{x}$-tuples with entries in Ω is denoted by $\Omega^{\mathbf{x}}$. When $\mathbf{a} \in \Omega^{\mathbf{x}}$ is an $\mathbf{x}$-tuple and $b \in \Omega$, then by $\mathbf{a}b$ we denote the $(\mathbf{x} \cup \{y\})$-tuple that extends $\mathbf{a}$ and maps the first variable (according to the fixed enumeration of all variables) y not in $\mathbf{x}$, to b.

We consider standard first-order logic on graphs by modeling them as relational structures where the universe is the vertex set and there is a single binary predicate signifying adjacency. For a graph G, a formula $\varphi(\mathbf{x})$, where $\mathbf{x}$ is the set of free variables of φ, and a tuple of vertices $\mathbf{w} \in V(G)^{\mathbf{x}}$, we write $G \models \varphi(\mathbf{w})$, or $G, \mathbf{w} \models \varphi(\mathbf{x})$, to denote that $\mathbf{w}$ satisfies $\varphi(\mathbf{x})$ in G. We sometimes consider formulas with an explicitly partitioned set of free variables, e.g., $\varphi(\mathbf{x}, \mathbf{y})$. Sentences are formulas with no free variables.

Logical types. While the usual definition of a logical type of quantifier rank k of a tuple $\mathbf{a}$ of vertices of G is the set of all formulas $\varphi(\mathbf{x})$ such that $G \models \varphi(\mathbf{a})$, we will rely on a definition which is more suitable for our purposes and is well known to be equivalent, by the result of Ehrenfeucht and Fraïssé (see for example [12]).

Let $\mathbf{x}$ be a finite set of variables. An *atomic type with variables* $\mathbf{x}$ is a maximal consistent set S of formulas of the form $x = y$, $x \neq y$, $E(x, y)$, $\neg E(x, y)$, where $x, y \in \mathbf{x}$. Here by *consistent* we mean that there is some graph G and a tuple $\mathbf{w} \in V(G)^{\mathbf{x}}$ that satisfies all formulas occurring in the atomic type (this is decidable, as it is sufficient to consider graphs G with $|G| \leqslant |\mathbf{x}|$).

For $\mathbf{a} \in V(G)^{\mathbf{x}}$, the *atomic type of* $\mathbf{a}$ *in* G is the atomic type with variables $\mathbf{x}$ which consists of all formulas of the form $E(x, y)$ or $x = y$, where $x, y \in \mathbf{x}$, such that $G, \mathbf{a} \models x = y$ or $G, \mathbf{a} \models E(x, y)$.

▶ **Definition 6.** *Let G be a graph $\mathbf{x}$ a finite set of variables and $k \in \mathbb{N}$. For every $\mathbf{a} \in V(G)^{\mathbf{x}}$ we define its* type of quantifier rank k*, denoted* $\mathrm{tp}^k(\mathbf{a})$*, as follows.*

- *If $k = 0$, then $\mathrm{tp}^0(\mathbf{a})$ is the atomic type of $\mathbf{a}$ in G.*
- *If $k > 0$, then $\mathrm{tp}^k(\mathbf{a}) = \{\mathrm{tp}^{k-1}(\mathbf{a}b) \mid b \in V(G)\}$.*

For $k \geqslant 1$ we also set $\mathrm{tp}^k(G) = \{\mathrm{tp}^{k-1}(a) \mid a \in V(G)\}$.

This definition is usually intuitively explained in terms of Ehrenfeucht-Fraïssé games. Namely, two $\mathbf{x}$-tuples $\mathbf{a}$ and $\mathbf{b}$ of vertices of two graphs G and H, respectively, have equal types of quantifier rank k if and only if Duplicator wins the k-round game on the graphs G and H, where the initial pebbles in G and H are placed on the vertices occurring in $\mathbf{a}$ and in $\mathbf{b}$, respectively. Indeed, suppose $\mathrm{tp}^k(\mathbf{a}) = \mathrm{tp}^k(\mathbf{b})$, where $k > 0$, and that Spoiler places a pebble on a vertex c of G. Then, since $\mathrm{tp}^{k-1}(\mathbf{a}c) \in \mathrm{tp}^k(\mathbf{a})$ by definition and $\mathrm{tp}^k(\mathbf{a}) = \mathrm{tp}^k(\mathbf{b})$, we have that there is some $d \in \mathrm{tp}^k(\mathbf{b})$ such that $\mathrm{tp}^{k-1}(\mathbf{b}d) \in \mathrm{tp}^k(\mathbf{b})$. Then Duplicator responds by placing the pebble on the vertex d, and we have that $\mathrm{tp}^{k-1}(\mathbf{a}c) = \mathrm{tp}^{k-1}(\mathbf{b}d)$ so, by inductive assumption, Duplicator wins in the $k-1$ round game from the current configuration, which shows that Duplicator has a winning strategy in the k round game starting from $\mathbf{a}$ and $\mathbf{b}$. The implication in the other direction proceeds similarly.

As is well known, the set of types of $\mathbf{x}$-tuples of quantifier rank k that are realized by some tuple $\mathbf{a}$, in some graph, is non-computable, even though this set has size bounded in terms of $\mathbf{x}$ and k. To overcome this problem, the usual solution is to define the set of abstract types (that may not be realized as actual types), which is computable from $\mathbf{x}$ and k, has bounded size, and contains all types that may arise. This is done as follows.

Define $\mathsf{Types}^0_{\mathbf{x}}$ as the set of all atomic types over $\mathbf{x}$ and $\mathsf{Types}^k_{\mathbf{x}} := \{M \mid M \subseteq \mathsf{Types}^{k-1}_{\mathbf{x}y}\}$. Note that for any G and any $\mathbf{a} \in V(G)^{\mathbf{x}}$ it holds that $\mathrm{tp}^k(\mathbf{a}) \in \mathsf{Types}^k_{\mathbf{x}}$, but $\mathsf{Types}^k_{\mathbf{x}}$ can also contain objects which are not realized by any tuple of vertices $\mathbf{a}$ of any graph.

For a graph G we set $\mathsf{Types}^k_{\mathbf{x}}(G) := \{\mathrm{tp}^k(\mathbf{a}) \mid \mathbf{a} \in V(G)^{\mathbf{x}}\}$. Note that we have $\mathrm{tp}^k(G) = \mathsf{Types}^{k-1}_x(G)$.

The following is well known and follows from the fact that our definition of types is equivalent to the usual definition of types using formulas.

▶ **Proposition 7.** *Let G be a graph, $\mathbf{x}$ a set of variables and $k \in \mathbb{N}$.*

- $|\mathsf{Types}^k_{\mathbf{x}}(G)| = \mathcal{O}_{k,\mathbf{x}}(1)$,
- *For any $\mathbf{a} \in V(G)^{\mathbf{x}}$ and any first-order formula $\varphi(\mathbf{x})$ of quantifier rank at most k one can determine whether $G \models \varphi(\mathbf{a})$ from $\mathrm{tp}^k(\mathbf{a})$ in time $\mathcal{O}_{k,\mathbf{x}}(1)$.*
- *For any first-order sentence φ of quantifier rank at most k one can determine whether $G \models \varphi$ from $\mathrm{tp}^k(G)$ in time $\mathcal{O}_k(1)$.*

3 Local types

In this section we define local types of quantifier rank k for partitioned graphs, or *local k-types* for short. They provide a framework for the results proved in the rest of the paper. The key lemmas are Lemma 14 and Lemma 16 and their corollaries Lemma 15 and Lemma 17.

3.1 Local types for partitioned graphs

Let G be a graph and $\mathcal{P}$ be a partition of its vertex set, and let $\mathbf{x}$ be a set of variables. For an $\mathbf{x}$-tuple $\mathbf{a} \in V(G)$ write $\mathbf{a}\langle\mathcal{P}\rangle$ for the $\mathbf{x}$-tuple $\mathbf{u} \in \mathcal{P}^{\mathbf{x}}$ such that $\mathbf{u}(x)$ is the part containing $\mathbf{a}(x)$, for all $x \in \mathbf{x}$.

▶ **Definition 8.** *Let G be a graph, $\mathcal{P}$ be a partition of its vertex set, $\mathbf{x}$ a nonempty set of variables, and $k \in \mathbb{N}$. For any $\mathbf{a} \in V(G)^{\mathbf{x}}$ we define the* local k-type of $\mathbf{a}$*, denoted* $\mathrm{ltp}^k_{\mathcal{P}}(\mathbf{a})$*, as follows:*

- $\mathrm{ltp}^0_{\mathcal{P}}(\mathbf{a})$ *is the atomic type of $\mathbf{a}$ together with the $\mathbf{x}$-tuple $\mathbf{a}\langle\mathcal{P}\rangle \in \mathcal{P}^{\mathbf{x}}$ of parts of $\mathcal{P}$ corresponding to $\mathbf{a}$,*
- *for $k > 0$, let $\mathrm{ltp}^k_{\mathcal{P}}(\mathbf{a}) = \{\mathrm{ltp}^{k-1}_{\mathcal{P}}(\mathbf{a}b) \mid b \in w$ for some $w \in \mathcal{P}$ with $\mathrm{dist}_{\mathcal{P}}(\mathbf{a}\langle\mathcal{P}\rangle, w) \leqslant 2^{k-1}\}$.*

As with usual types of quantifier-rank k defined in the previous section, it is often convenient to think about equality of local types in terms of games. We now briefly describe the corresponding variant of Ehrenfeucht-Fraïssé games game. This game will be played on a single graph G with a fixed partition $\mathcal{P}$ of its vertex set (one can also imagine it being played on two copies of the same graph with the same partition). The starting position of the game is determined by two $\mathbf{x}$-tuples $\mathbf{a}$ and $\mathbf{b}$ of vertices of G (where $\mathbf{x}$ is nonempty) such that for every $y \in \mathbf{x}$ we have that $\mathbf{a}(y)$ is in the same part of $\mathcal{P}$ as $\mathbf{b}(y)$. The game is played for k rounds as the usual Ehrenfeucht-Fraïssé game with the following extra restrictions on the moves of the players: (1) In the ith round, Spoiler picks one of the tuples $\mathbf{a}$ and $\mathbf{b}$, and he will then proceed to extending it. Suppose that he picks $\mathbf{a}$, the other case being symmetric. Spoiler then picks a vertex a in any part $P \in \mathcal{P}$ such that $\mathrm{dist}_{\mathcal{P}}(P, Q) \leqslant 2^{k-1}$, where Q is some part containing a vertex of $\mathbf{a}$. He then appends a to $\mathbf{a}$ to form the tuple $\mathbf{a}a$. (2) Duplicator replies by picking a vertex b in the same part P and extending the other tuple $\mathbf{b}$ to $\mathbf{b}b$. The game then continues to the next round, with $\mathbf{a}a$ and $\mathbf{b}b$ forming the new position. Duplicator wins after k rounds if the two tuples have equal atomic types.

It is not difficult to see that Duplicator wins the k-round game described above, starting from the configuration $\mathbf{a}$ and $\mathbf{b}$, if and only if $\mathrm{ltp}^k_{\mathcal{P}}(\mathbf{a}) = \mathrm{ltp}^k_{\mathcal{P}}(\mathbf{b})$. This is made formal in the following proposition, whose proof is an immediate consequence of Definition 8.

▶ **Proposition 9.** *Let G be a graph and $\mathcal{P}$ be a partition of the vertices of G, and let $\mathbf{x}$ a tuple of variables and $k \in \mathbb{N}$. Then the following holds for any $\mathbf{a}, \mathbf{b} \in V(G)^{\mathbf{x}}$:*

- $\mathrm{ltp}^0_{\mathcal{P}}(\mathbf{a}) = \mathrm{ltp}^0_{\mathcal{P}}(\mathbf{b})$ *if and only if the atomic types of $\mathbf{a}$ and $\mathbf{b}$ are the same, and $\mathbf{a}\langle\mathcal{P}\rangle = \mathbf{b}\langle\mathcal{P}\rangle$;*
- *If $k > 0$ then $\mathrm{ltp}^k_{\mathcal{P}}(\mathbf{a}) = \mathrm{ltp}^k_{\mathcal{P}}(\mathbf{b})$ if and only if for any $P \in \mathcal{P}$ with $\mathrm{dist}_{\mathcal{P}}(\mathbf{a}\langle\mathcal{P}\rangle, P) \leqslant 2^{k-1}$ the following holds: for any $c \in P$ there exists $c' \in P$ such that $\mathrm{ltp}^{k-1}_{\mathcal{P}}(\mathbf{a}c) = \mathrm{ltp}^{k-1}_{\mathcal{P}}(\mathbf{b}c')$, and conversely, for any $c' \in P$ there exists $c \in P$ such that $\mathrm{ltp}^{k-1}_{\mathcal{P}}(\mathbf{a}c) = \mathrm{ltp}^{k-1}_{\mathcal{P}}(\mathbf{b}c')$.*

We will also need to have an abstract set containing all types which could potentially occur for any $k \in \mathbb{N}$ and $\mathbf{u} \in \mathcal{P}^{\mathbf{x}}$. Note that this includes also types which are not realized in G (or even in any graph).

▶ **Definition 10.** *Let $\mathbf{x}$ be a nonempty set of variables and $k \in \mathbb{N}$. Fix a graph G together with a vertex-partition $\mathcal{P}$. For $\mathbf{u} \in \mathcal{P}^{\mathbf{x}}$ we define $\mathsf{Types}^0_{\mathbf{u},\mathcal{P}} := \{(\alpha, \mathbf{u}) \mid \alpha$ is an atomic type with variables $\mathbf{x}\}$. For $k > 0$ let M be the set of all parts w of $\mathcal{P}$ with $\mathrm{dist}_{\mathcal{P}}(\mathbf{u}, w) \leqslant 2^{k-1}$ and let $M' := \bigcup_{w \in M} \mathsf{Types}^{k-1}_{\mathbf{u}w,\mathcal{P}}$. We then define*

$$\mathsf{Types}^k_{\mathbf{u},\mathcal{P}} := \{S \mid S \subseteq M'\}.$$

Define also $\mathsf{Types}^k_{\mathbf{u},\mathcal{P}}(G) := \{\mathrm{ltp}^k(\mathbf{a}) \mid \mathbf{a} \in V(G)^{\mathbf{x}}, \mathbf{u} = \mathbf{a}\langle\mathcal{P}\rangle\}$.

Then $\mathsf{Types}_{\mathbf{u},\mathcal{P}}(G)$ is the set of all local k-types realized in $\mathbf{u}$, and is a subset of $\mathsf{Types}^k_{\mathbf{u},\mathcal{P}}$.

3.2 Properties of local types

In this section we establish the properties of local k-types used in the rest of the paper.

In the rest of this paper, we assume that we have fixed a graph G and a contraction sequence $\mathcal{P}_1, \ldots, \mathcal{P}_n$ of G. We write $\mathrm{ltp}^k_s(\cdot)$ to denote $\mathrm{ltp}^k_{\mathcal{P}_s}(\cdot)$, $\mathsf{Types}_{\mathbf{u},s}(\cdot)$ to denote $\mathsf{Types}_{\mathbf{u},\mathcal{P}}(\cdot)$, and $\mathrm{dist}_s(\cdot,\cdot)$ to denote $\mathrm{dist}_{\mathcal{P}_s}(\cdot,\cdot)$.

The following two lemmas establish some basic properties of local k-types. The proof of Lemma 11 follows immediately from the definition.

▶ **Lemma 11.** *The following holds at any time $s \in [n]$ and $k \geqslant 1$.*

- *If $\mathrm{ltp}^k_s(\mathbf{a}) = \mathrm{ltp}^k_s(\mathbf{b})$, then $\mathrm{ltp}^{k-1}_s(\mathbf{a}) = \mathrm{ltp}^{k-1}_s(\mathbf{b})$.*
- *If $\mathrm{ltp}^k_s(\mathbf{a}) = \mathrm{ltp}^k_s(\mathbf{b})$, then $\mathbf{a}\langle s\rangle = \mathbf{b}\langle s\rangle$.*

▶ **Lemma 12 (♠).** *Let $s \in [n]$ be a time and $\mathbf{x}$ a tuple of variables, and $k \geqslant 0$. Then $|\mathsf{Types}^k_{\mathbf{u},s}| \leqslant \mathcal{O}_{d,k,\mathbf{x}}(1)$, for all $\mathbf{u} \in \mathcal{P}^{\mathbf{x}}_s$. Moreover, given vicinity $\mathsf{Vicinity}^{2^k}_s(\mathbf{u})$, one can compute $\mathsf{Types}^k_{\mathbf{u},s}$ in time $\mathcal{O}_{d,k,\mathbf{x}}(1)$.*

The following lemma relates local types for partitioned graphs to usual first-order types, as defined in the preliminaries.

▶ **Lemma 13 (♠).** *Let $\mathbf{x}$ be a tuple of variables and $\mathbf{a} \in V(G)^{\mathbf{x}}$. One can compute $\mathrm{tp}^k(\mathbf{a})$ from $\mathrm{ltp}^k_n(\mathbf{a})$ in time $\mathcal{O}_{k,d,\mathbf{x}}(1)$.*

The next lemma is a version of compositionality of local types and plays a key role in computing local types.

▶ **Lemma 14.** *Fix two disjoint sets of variables* $\mathbf{x}$ *and* $\mathbf{y}$*. Let* $\mathbf{a}, \mathbf{a}' \in V^{\mathbf{x}}$ *and* $\mathbf{b}, \mathbf{b}' \in V^{\mathbf{y}}$ *be such that* $\mathrm{ltp}^k_s(\mathbf{a}) = \mathrm{ltp}^k_s(\mathbf{a}')$ *and* $\mathrm{ltp}^k_s(\mathbf{b}) = \mathrm{ltp}^k_s(\mathbf{b}')$*. Let* $\mathbf{u} = \mathbf{a}\langle s\rangle$ *and* $\mathbf{v} = \mathbf{b}\langle s\rangle$ *and assume that* $\mathrm{dist}_s(\mathbf{u}, \mathbf{v}) > 2^k$*. Then* $\mathrm{ltp}^k_s(\mathbf{ab}) = \mathrm{ltp}^k_s(\mathbf{a'b'})$*.*

Proof. We prove the statement by induction on k. For $k = 0$, to prove that $\mathrm{ltp}^0_s(\mathbf{ab}) = \mathrm{ltp}^0_s(\mathbf{a'b'})$, we have to show that the atomic types of $\mathbf{ab}$ and $\mathbf{a'b'}$ are the same. Fix an atomic formula $\varphi(x, y)$, with $x, y \in \mathbf{x} \cup \mathbf{y}$. We show that $G, \mathbf{ab} \models \varphi(x, y)$ if and only if $G, \mathbf{a'b'} \models \varphi(x, y)$. If x and y both belong to $\mathbf{x}$ then the conclusion follows by assumption that $\mathrm{ltp}^0_s(\mathbf{a}) = \mathrm{ltp}^0_s(\mathbf{a}')$. The same holds if x and y both belong to $\mathbf{y}$.

So, by symmetry, it is enough to consider the case when $x \in \mathbf{x}$ and $y \in \mathbf{y}$. Since by our assumption $\mathrm{dist}_s(\mathbf{u}, \mathbf{v}) > 2^0 = 1$, any part of $\mathbf{u}$ is pure to any part $\mathbf{v}$, and so in particular the part $\mathbf{a}(x)\langle s\rangle$ is pure towards $\mathbf{b}(y)\langle s\rangle$. Because $\mathbf{a}(x), \mathbf{a}'(x) \in \mathbf{a}(x)\langle s\rangle$ and $\mathbf{b}(y), \mathbf{b}'(y) \in \mathbf{b}(y)\langle s\rangle$, this implies that $G, \mathbf{ab} \models \varphi(x, y)$ if and only if $G, \mathbf{a'b'} \models \varphi(x, y)$, as required.

For $k > 0$, let c be a vertex in a part $w = c\langle s\rangle$ such that $\mathrm{dist}_s(\mathbf{uv}, w) \leqslant 2^{k-1}$. Our task is to show that there exists $c' \in w$ such that $\mathrm{ltp}^{k-1}_s(\mathbf{ab}c) = \mathrm{ltp}^{k-1}_s(\mathbf{a'b'}c')$. Since $\mathrm{dist}_s(\mathbf{u}, \mathbf{v}) > 2^k$, exactly one of $\mathrm{dist}_s(\mathbf{u}, w) \leqslant 2^{k-1}$ and $\mathrm{dist}_s(\mathbf{v}, w) \leqslant 2^{k-1}$ has to hold; without loss of generality assume that $\mathrm{dist}_s(\mathbf{u}, w) \leqslant 2^{k-1}$ holds. Since $\mathrm{ltp}^k_s(\mathbf{a}) = \mathrm{ltp}^k_s(\mathbf{a}')$, there exists $c' \in w$ such that $\mathrm{ltp}^{k-1}_s(\mathbf{a}c) = \mathrm{ltp}^{k-1}_s(\mathbf{a}'c')$. Because $\mathrm{dist}_s(\mathbf{u}, \mathbf{v}) > 2^k$ and $\mathrm{dist}_s(\mathbf{u}, w) \leqslant 2^{k-1}$, we have $\mathrm{dist}_s(\mathbf{u}w, \mathbf{v}) > 2^{k-1}$, so we can apply the induction hypothesis to $\mathbf{a}c$, $\mathbf{a}'c'$ and $\mathbf{b}$, $\mathbf{b}'$, which yields that $\mathrm{ltp}^{k-1}_s(\mathbf{ab}c) = \mathrm{ltp}^{k-1}_s(\mathbf{a'b'}c')$, as desired. ◀

The following lemma follows directly from Lemma 14, except for the part about efficient computation.

▶ **Lemma 15.** *Let* $s \in [n]$ *be a time and* $\mathbf{x}$ *and* $\mathbf{y}$ *are disjoint sets of variables. Suppose* $\mathbf{u} \in \mathcal{P}^{\mathbf{x}}_s$ *and* $\mathbf{v} \in \mathcal{P}^{\mathbf{y}}_s$ *are tuples of parts such that* $\mathrm{dist}_s(\mathbf{u}, \mathbf{v}) > 2^k$*. Then there is a function* $f \colon \mathsf{Types}^k_{\mathbf{u},s} \times \mathsf{Types}^k_{\mathbf{v},s} \to \mathsf{Types}^k_{\mathbf{uv},s}$ *such that for every pair of tuples* $\mathbf{a} \in V^{\mathbf{x}}$ *and* $\mathbf{b} \in V^{\mathbf{y}}$ *satisfying* $\mathbf{u} = \mathbf{a}\langle s\rangle$ *and* $\mathbf{v} = \mathbf{b}\langle s\rangle$*, we have*

$$\mathrm{ltp}^k_s(\mathbf{ab}) = f(\mathrm{ltp}^k_s(\mathbf{a}), \mathrm{ltp}^k_s(\mathbf{b})).$$

Moreover, given k*,* $\mathbf{u}$*,* $\mathbf{v}$*, and the vicinity* $\mathsf{Vicinity}^{2^k}_s(\mathbf{uv})$*, one can compute* f *in time* $\mathcal{O}_{d,k,\mathbf{x},\mathbf{y}}(1)$*.*

Regarding the computation of function f in the above lemma, by "computing f in time $\mathcal{O}_{d,k,\mathbf{x},\mathbf{y}}(1)$" we do not mean just evaluating f on any given input in desired time, but constructing the whole input-output table for f. The reason why this can be computed from k, $\mathbf{u}$, $\mathbf{v}$ and $\mathsf{Vicinity}^{2^k}_s(\mathbf{uv})$ in time $\mathcal{O}_{d,k,\mathbf{x},\mathbf{y}}(1)$ is that the input and output sets have size bounded by $\mathcal{O}_{d,k,\mathbf{x},\mathbf{y}}(1)$ and the proof in Lemma 14 uses only information from $\mathsf{Vicinity}^{2^k}_s(\mathbf{uv})$. A concrete approach to implementing this computation similar to that of [7] can be found in the full version.

The next lemma will allow us to determine how the k-type of a tuple $\mathbf{a}$ develops over time.

▶ **Lemma 16.** *Let* $s \in [n]$ *be a time and let* $\mathbf{a} \in V^{\mathbf{x}}$*,* $\mathbf{a}' \in V^{\mathbf{x}}$ *be two tuples of vertices such that* $\mathrm{ltp}^k_s(\mathbf{a}) = \mathrm{ltp}^k_s(\mathbf{a}')$*. Then* $\mathrm{ltp}^k_{s+1}(\mathbf{a}) = \mathrm{ltp}^k_{s+1}(\mathbf{a}')$*.*

Proof. By induction on k. For $k = 0$ note that $\mathrm{ltp}^0_s(\mathbf{a}) = \mathrm{ltp}^k_s(\mathbf{a}')$ implies that atomic types of $\mathbf{a}$ and $\mathbf{a}'$ are the same and $\mathbf{a}\langle s\rangle = \mathbf{a}'\langle s\rangle$. It is easily seen that then also $\mathbf{a}\langle s+1\rangle = \mathbf{a}'\langle s+1\rangle$, as desired.

For $k > 0$, let $\mathbf{u} = \mathbf{a}\langle s+1\rangle = \mathbf{a}'\langle s+1\rangle$. We need to show that for any $w \in \mathcal{P}_{s+1}$ with $\mathrm{dist}_{s+1}(\mathbf{u}, w) \leqslant 2^{k-1}$ and any $b \in w$ there is $b' \in w$ such that $\mathrm{ltp}^{k-1}_{s+1}(\mathbf{a}b) = \mathrm{ltp}^{k-1}_{s+1}(\mathbf{a}'b')$, and symmetrically, that for any $b' \in w$ there is $b \in w$ such that $\mathrm{ltp}^{k-1}_{s+1}(\mathbf{a}b) = \mathrm{ltp}^{k-1}_{s+1}(\mathbf{a}'b')$. We focus on the first option; the proof of the second one is analogous. Let $v = b\langle s\rangle$. We distinguish two possibilities:

- $\mathrm{dist}_s(\mathbf{u}, v) \leqslant 2^{k-1}$: In this case, since $\mathrm{ltp}^k_s(\mathbf{a}) = \mathrm{ltp}^k_s(\mathbf{a}')$, there exists $b' \in v$ such that $\mathrm{ltp}^{k-1}_s(\mathbf{a}b) = \mathrm{ltp}^{k-1}_s(\mathbf{a}'b')$. Then by induction hypothesis it follows that $\mathrm{ltp}^{k-1}_{s+1}(\mathbf{a}b) = \mathrm{ltp}^{k-1}_{s+1}(\mathbf{a}'b')$, as desired.
- $\mathrm{dist}_s(\mathbf{u}, v) > 2^{k-1}$: In this case we note that $\mathrm{ltp}^k_s(\mathbf{a}) = \mathrm{ltp}^k_s(\mathbf{a}')$ implies that $\mathrm{ltp}^{k-1}_s(\mathbf{a}) = \mathrm{ltp}^{k-1}_s(\mathbf{a}')$, and we set $b' := b$. We can now apply Lemma 14 to $\mathbf{a}$, $\mathbf{a}'$ and b, b' to see that $\mathrm{ltp}^{k-1}_s(\mathbf{a}b) = \mathrm{ltp}^{k-1}_s(\mathbf{a}'b')$, and by induction hypothesis it follows that $\mathrm{ltp}^{k-1}_s(\mathbf{a}b) = \mathrm{ltp}^{k-1}_s(\mathbf{a}'b')$, as desired. ◀

Lemma 16 implies that there exists a function which maps $\mathrm{ltp}^k_s(\mathbf{a})$ to $\mathrm{ltp}^k_{s+1}(\mathbf{a})$, and by induction we get the following lemma.

▶ **Lemma 17.** *Let $s, t \in [n]$ be times with $s \leqslant t$. Suppose $\mathbf{u} \in \mathcal{P}^{\mathbf{x}}_s$ and let $\mathbf{v} = \mathbf{u}\langle s \to t\rangle$. Then there exists a function $f \colon \mathsf{Types}^k_{\mathbf{u},s} \to \mathsf{Types}^k_{\mathbf{v},t}$ such that for every tuple $\mathbf{a} \in V^{\mathbf{x}}$ satisfying $\mathbf{u} = \mathbf{a}\langle s\rangle$, we have*

$$\mathrm{ltp}^k_t(\mathbf{a}) = f(\mathrm{ltp}^k_s(\mathbf{a})).$$

Moreover, if $t = s+1$, then given k, $\mathbf{u}$, $\mathbf{v}$ and the relevant region $\mathsf{Relevant}^{2^k(|\mathbf{x}|+1)}_s$, one can compute f in time $\mathcal{O}_{d,k,\mathbf{x}}(1)$, provided that for every $y \in \mathbf{x}$ we have that $\mathbf{v}(y) \in \mathsf{Relevant}^{2^k|\mathbf{x}|}_s$.

As in the case of Lemma 15, the whole input-output table of function f can be computed in time $\mathcal{O}_{d,k,\mathbf{x},\mathbf{y}}(1)$ from k, $\mathbf{u}$, $\mathbf{v}$ and $\mathsf{Relevant}^{2^k}_s$, since the proof of Lemma 16 uses only information from $\mathsf{Relevant}^{2^k(|\mathbf{x}|+1)}_s$. Again, a concrete approach to implementing this computation similar to that of [7] can be found in the full version.

We will also use the fact that when going from time s to $s+1$ the local k-types of tuples in parts which are not in the trigraph $\mathsf{Relevant}^{2^k}_s$ are not affected.

▶ **Lemma 18 (♠).** *Let $\mathbf{x}$ be a finite set of variables, $s \in [n]$ a time, $k \in N$ and let $\mathbf{u} \in \mathcal{P}^{\mathbf{x}}_s$ be such for every $y \in \mathbf{x}$ it holds that $\mathbf{u}(y) \notin V(\mathsf{Relevant}^{2^k}_s)$. Then $\mathbf{u}\langle s \to s+1\rangle = \mathbf{u}$, and for every $\mathbf{a}$ with $\mathbf{u} = \mathbf{a}\langle s\rangle$ we have that $\mathrm{ltp}^k_s(\mathbf{a}) = \mathrm{ltp}^k_{s+1}(\mathbf{a})$. In particular, $\mathsf{Types}^k_{\mathbf{u},s+1}(G) = \mathsf{Types}^k_{\mathbf{u},s}(G)$.*

Model checking on graphs of bounded twin-width. With the machinery from the previous subsection we can now reprove the result of [7] that the first-order model checking problem on any class $\mathcal{C}$ of graphs of twin-width at most d is solvable in time $\mathcal{O}_{d,\varphi}(n)$, provided that the contraction sequence of the input graph G is provided together with G.

▶ **Theorem 19.** *Let G be a graph on n vertices represented through its contraction sequence $\mathcal{P}_1, \ldots, \mathcal{P}_n$ of width d. Then for any sentence φ of quantifier rank q one can decide whether $G \models \varphi$ in time $\mathcal{O}_{d,\varphi}(n)$.*

Proof. Let q be the quantifier rank of φ and set $k := q-1$ and $r := 2^k$. We will show how to compute the set $\mathsf{Types}^k_x(G)$ in desired time, and since $\mathrm{tp}^q(G) = \mathsf{Types}^{q-1}_x(G)$, the result will follow by Proposition 7.

As a preprocessing step, the algorithm computes in time $\mathcal{O}_{d,k}(n)$ the trigraphs $\mathsf{Relevant}^r_s$ for all $s \in [n-1]$; this can be done due to Lemma 4. For the rest of the proof, let us for any time $s \in [n]$ denote by T_s the set of all sets of realized types at time s, i.e. $T_s := \{\mathsf{Types}^k_{w,s}(G) \mid w \in \mathcal{P}_s\}$.

The algorithm first computes T_1 by computing $\mathsf{Types}^k_{w,1}(G)$ for each $w \in \mathcal{P}_1$; since each such part w contains exactly one vertex, this can be done in time $\mathcal{O}_k(1)$ for any w, and so this takes time $\mathcal{O}_k(n)$ in total. From this point on the algorithm will proceed through times 2 to n and for every time s it will compute T_s from T_{s-1}. By Lemma 18, any part w of $\mathcal{P}_{s-1}$ which is not in $\mathsf{Relevant}^{2^k}_{s-1}$ is the same in $\mathcal{P}_s$ as in $\mathcal{P}_{s-1}$ and we have that $\mathsf{Types}^k_{w,s-1}(G) = \mathsf{Types}^k_{w,s}(G)$, which means that the computation only needs to be performed on parts from $\mathsf{Relevant}^{2^k}_{s-1}$. We distinguish the following two possibilities:

- If v, w are the two parts of $\mathcal{P}_{s-1}$ which get contracted into a part $u \in \mathcal{P}_s$, then the algorithm applies the function from Lemma 17 to all members of $\mathsf{Types}^k_{v,s-1}(G)$ and $\mathsf{Types}^k_{w,s-1}(G)$ and collects the results into $\mathsf{Types}^k_{u,s}(G)$.
- If w is any other part in $\mathsf{Relevant}^r_{s-1}$, then the algorithm applies the function from Lemma 17 to all members of $\mathsf{Types}^k_{w,s-1}$ and collects the results into $\mathsf{Types}^k_{w,s}(G)$.

In each of the above cases the computation can be done in time $\mathcal{O}_{d,k}(1)$, since each application of the function from Lemma 17 can be done in time $\mathcal{O}_{d,k,1}(1)$ and by Lemma 12 we have that $|\mathsf{Types}^k_{w,s-1}(G)| \leqslant \mathcal{O}_{d,k}(1)$. Moreover, since $|\mathsf{Relevant}^r_{s-1}| \leqslant \mathcal{O}_{d,k}(1)$, the computation of T_s from T_{s-1} can be done in time $\mathcal{O}_{d,k}(1)$. There are $n-1$ steps to obtain T_n and so the whole computation takes time $\mathcal{O}_{d,k}(n)$. Now T_n contains only $\mathsf{Types}^k_{w,n}(G)$ where w is the only part of $\mathcal{P}_n$. By Lemma 13, from each local k-type in $\mathsf{Types}^k_{w,n}(G)$ one can compute the corresponding k-type from $\mathsf{Types}^k_x(G)$ in time $\mathcal{O}_k(1)$. This finishes the proof. ◀

4 Query answering

In this section we prove Theorem 1. For the remainder of this section let us fix a graph G and a contraction sequence $\mathcal{P}_1, \ldots, \mathcal{P}_n$ of G of width d, where $n = |V(G)|$. In all algorithmic statements that follow, we assume that G and $\mathcal{P}$ are given on input.

Throughout this section our data structures work with the standard word RAM model.

4.1 Proximity oracle

For vertices $u, v \in V(G)$ and $r \in \mathbb{N}$, we define

$$\mathsf{firstClose}_r(u,v) = \min\{t \mid \mathrm{dist}_t(u\langle t\rangle, v\langle t\rangle) \leqslant r\}.$$

In other words, $\mathsf{firstClose}_r(u,v)$ is the first time t such that the parts of $\mathcal{P}_t$ containing u and v are at distance at most r in the impurity graph G^{imp}_t. Note that whenever $u \neq v$, we have $1 < \mathsf{firstClose}_r(u,v) \leqslant n$. The main goal of this section is to construct an auxiliary data structure for answering queries about the values of $\mathsf{firstClose}_r(\cdot,\cdot)$. This is described in the lemma below.

▶ **Lemma 20.** *For a given $r \in \mathbb{N}$, one can in time $\mathcal{O}_{d,r}(n)$ compute a data structure that can answer the following queries in time $\mathcal{O}_{d,r}(\log\log n)$: given $u, v \in V(G)$, output $\mathsf{firstClose}_r(u,v)$.*

By Lemma 5, we may assume that the vertex set $V(G)$ is equal to $[n]$, and $\mathcal{P}$ is a convex contraction sequence for the usual order on $[n]$. In particular, pairs of vertices can be identified with points in a plane, and intuitively, every pair of sets $A, B \subseteq V(G)$ corresponds

to a rectangle $A \times B \subseteq [n] \times [n]$. This correspondence will be important in the proof of Lemma 20, whose key technical component is the data structure for *orthogonal range queries* due to Chan [9], for manipulating rectangles in a plane. (We remark that the applicability of this data structure in the context of twin-width has already been observed in [19].) Let us recall the setting.

A *rectangle* is a set of pairs of integers of the form $\{(x, y) \colon a \leqslant x \leqslant a', b \leqslant y \leqslant b'\}$ for some integers a, a', b, b'. In all algorithmic statements that follow, every rectangle is represented by such a quadruple (a, a', b, b'). In the problem of orthogonal range queries, we are given a list of pairwise disjoint rectangles $\mathcal{R} = \{R_1, \ldots, R_m\}$, all contained in $[n] \times [n]$, and the task is to set up a data structure that can efficiently answer the following queries: given $(x, y) \in [n] \times [n]$, output the index of the rectangle in $\mathcal{R}$ that contains (x, y), or output $\perp$ if there is no such rectangle. Chan proposed the following data structure for this problem.

▶ **Theorem 21** ([9]). *Assuming $|\mathcal{R}| = \mathcal{O}(n)$, there is a data structure for the orthogonal range queries that takes $\mathcal{O}(n)$ space, can be initialized in time $\mathcal{O}(n)$, and can answer every query in time $\mathcal{O}(\log \log n)$.*

We remark that there is also a simple data structure for orthogonal range queries that for any fixed $\varepsilon > 0$, achieves query time $\mathcal{O}(1/\varepsilon)$ at the expense of space complexity and initialization time $\mathcal{O}(n^{1+\varepsilon})$. See the appendix of [19] for details. As we mentioned in Section 1, replacing the usage of the data structure of Chan with this simple data structure results in an analogous tradeoff in Theorem 1.

We reduce the statement of Lemma 20 to the result of Chan using the following lemma.

▶ **Lemma 22** (♠). *One can in time $\mathcal{O}_{d,r}(n)$ compute a list $\mathcal{Q}$ of pairs of the form (R, t), where $R \subseteq [n] \times [n]$ is a rectangle and $t \in [n]$, such that the following holds:*

- *the rectangles in pairs from $\mathcal{Q}$ form a partition of $[n] \times [n]$, and*
- *for each $(u, v) \in [n] \times [n]$, if $(R, t) \in \mathcal{Q}$ is the unique pair satisfying $(u, v) \in R$, then we have $\mathsf{firstClose}_r(u, v) = t$.*

Lemma 20 follows from Lemma 22 as follows. Let $\mathcal{Q}$ be the list provided by Lemma 22; note that $|\mathcal{Q}| \leqslant \mathcal{O}_{d,r}(n)$, because this is an upper bound on the running time of the algorithm computing $\mathcal{Q}$. Let $\mathcal{R}$ be the list of rectangles appearing in the pairs from $\mathcal{Q}$. Set up a data structure of Theorem 21 for $\mathcal{R}$ and, additionally, for each $R \in \mathcal{R}$ remember the unique $t \in [n]$ such that $(R, t) \in \mathcal{Q}$. Then upon query $(u, v) \in [n] \times [n]$, it suffices to use the data structure of Theorem 21 to find the unique $R \in \mathcal{R}$ containing (u, v) and return the associated integer t.

4.2 The tree of r-close $\mathbf{x}$-tuples

In this section we are going to construct an auxiliary data structure for handling local types. Fix a number $k \in \mathbb{N}$; this is the quantifier rank of the types we would like to tackle. Denote $r := 2^k$. Also fix a finite set $\mathbf{x}$ of variables, an n-vertex graph G, together with a contraction sequence $\mathcal{P}_1, \ldots, \mathcal{P}_n$.

For $s \in [n]$ and a tuple $\mathbf{u} \in \mathcal{P}_s^{\mathbf{x}}$, we call $\mathbf{u}$ *r-close* at the time s if one cannot partition $\mathbf{u}$ into two nonempty tuples $\mathbf{u}', \mathbf{u}''$ such that $\mathrm{dist}_s(\mathbf{u}', \mathbf{u}'') > r$. Equivalently, if one considers an auxiliary graph on vertex set $\mathbf{u}$ where two parts are connected iff they are at distance at most r in G_s^{imp}, then $\mathbf{u}$ is r-close iff this auxiliary graph is connected. Note that if $\mathbf{u} \in \mathcal{P}_s^{\mathbf{x}}$ is r-close at the time s, then for every t with $s \leqslant t \leqslant n$, the tuple $\mathbf{u}\langle s \to t\rangle$ is also r-close at the time t.

For $s \in [n]$ with $s > 1$, by B_s denote the part of $\mathcal{P}_s$ that is the union of two parts in $\mathcal{P}_{s-1}$. Let $T_{r,\mathbf{x}}$ be the set consisting of all pairs of the form $(\mathbf{u}, s)$ such that $s \in [n]$, $\mathbf{u} \in \mathcal{P}_s^{\mathbf{x}}$ is r-close at the time s, and at least one of the following conditions is satisfied:

- $s = 1$; or
- $s > 1$ and $\mathrm{dist}_s(B_s, \mathbf{u}) \leqslant r$; or
- $s < n$ and $\mathrm{dist}_{s+1}(B_{s+1}, \mathbf{u}\langle s \to s+1\rangle) \leqslant r$.

Note that as $\mathbf{u}$ is assumed to be r-close, if the second condition holds then $\mathbf{u} \subseteq \mathsf{Vicinity}_s^{r|\mathbf{x}|}(B_s)$, and if the third condition holds then $\mathbf{u}\langle s \to s+1\rangle \subseteq \mathsf{Vicinity}_{s+1}^{r|\mathbf{x}|}(B_{s+1})$. Since the trigraphs $\mathsf{Vicinity}_s^{r|\mathbf{x}|}(B_s)$ and $\mathsf{Vicinity}_{s+1}^{r|\mathbf{x}|}(B_{s+1})$ are of size $\mathcal{O}_{d,k,\mathbf{x}}(1)$, it follows that $T_{r,\mathbf{x}}$ contains $\mathcal{O}_{d,k,\mathbf{x}}(n)$ elements in total: n elements for $s = 1$ and $\mathcal{O}_{d,k,\mathbf{x}}(1)$ elements for each $1 < s \leqslant n$.

We consider an ancestor relation $\preccurlyeq$ on $T_{r,\mathbf{x}}$ defined as follows:

$$(\mathbf{v}, t) \preccurlyeq (\mathbf{u}, s) \qquad \text{if and only if} \qquad s \leqslant t \text{ and } \mathbf{u}\langle s \to t\rangle = \mathbf{v}.$$

It is easy to see $T_{r,\mathbf{x}}$ together with $\preccurlyeq$ defines a rooted tree whose tree order is $\preccurlyeq$. The root is $(\mathbf{r}, n)$, where $\mathbf{r}$ is the unique tuple of $\mathcal{P}_n^{\mathbf{x}}$, the one that maps all variables of $\mathbf{x}$ to the unique part of $\mathcal{P}_n$. From now on we identify the set $T_{r,\mathbf{x}}$ with the tree it induces. Therefore, we call the elements of $T_{r,\mathbf{x}}$ *nodes* and the child-parent pairs in $T_{r,\mathbf{x}}$ the *edges* of $T_{r,\mathbf{x}}$.

▶ **Definition 23.** *We call $T_{r,\mathbf{x}}$ the* tree of r-close $\mathbf{x}$-tuples *associated with G and the contraction sequence $\mathcal{P}_1, \ldots, \mathcal{P}_n$.*

Recall that $r = 2^k$, and $k \in \mathbb{N}$ is fixed. For every node $(\mathbf{u}, s) \in T_{r,\mathbf{x}}$, let $\mathsf{Types}_{\mathbf{u},s}^k$ be the set of all possible k-local types of tuples $\mathbf{w} \in V(G)^{\mathbf{x}}$ satisfying $\mathbf{u} = \mathbf{w}\langle s\rangle$. By Lemma 12, there is a constant $M = \mathcal{O}_{d,k,\mathbf{x}}(1)$ such that $|\mathsf{Types}_{\mathbf{u},s}^k| \leqslant M$ for every node $(\mathbf{u}, s)$, and $\mathsf{Types}_{\mathbf{u},s}^k$ can be computed in time $\mathcal{O}_{d,k,\mathbf{x}}(1)$ given access to G_s and $\mathbf{u}$.

Consider nodes $(\mathbf{u}, s), (\mathbf{v}, t) \in T_{r,\mathbf{x}}$ such that $(\mathbf{v}, t)$ is the parent of $(\mathbf{u}, s)$. Let $e = ((\mathbf{u}, s), (\mathbf{v}, t))$ be the corresponding edge of $T_{r,\mathbf{x}}$. By Lemma 17, there exists a function $f_e \colon \mathsf{Types}_{\mathbf{u},s}^k \to \mathsf{Types}_{\mathbf{v},t}^k$ such that for every tuple $\mathbf{w} \in V(G)^{\mathbf{x}}$ with $\mathbf{u} = \mathbf{w}\langle s\rangle$, we have

$$\mathrm{ltp}_t^k(\mathbf{w}) = f_e(\mathrm{ltp}_s^k(\mathbf{w})). \tag{1}$$

We now verify that all the objects introduced above can be computed efficiently.

▶ **Lemma 24 (♠).** *One can in time $\mathcal{O}_{d,k,\mathbf{x}}(n)$ compute the nodes and the edges of $T_{r,\mathbf{x}}$ (where $r = 2^k$) as well as, for every edge e of $T_{r,\mathbf{x}}$, the function f_e.*

We can finally state and prove the main result of this section.

▶ **Lemma 25.** *One can in time $\mathcal{O}_{d,k,\mathbf{x}}(n)$ construct a data structure that can answer the following queries in time $\mathcal{O}_{d,k,\mathbf{x}}(1)$: given $\mathbf{w} \in V(G)^{\mathbf{x}}$, two nodes $(\mathbf{v}, t) \preccurlyeq (\mathbf{u}, s)$ of $T_{r,\mathbf{x}}$ such that $\mathbf{u} = \mathbf{w}\langle s\rangle$ and $\mathbf{v} = \mathbf{w}\langle t\rangle$, and the type $\mathrm{ltp}_s^k(\mathbf{w})$, output the type $\mathrm{ltp}_t^k(\mathbf{w})$.*

Proof. Using Lemma 24 construct the tree $T_{r,\mathbf{x}}$ and functions f_e for the edges of $T_{r,\mathbf{x}}$. By Lemma 12, there is a constant $M = \mathcal{O}_{d,k,\mathbf{x}}(1)$ such that $|\mathsf{Types}_{\mathbf{u},s}^k| \leqslant M$ for every node $(\mathbf{u}, s)$. Let $I \coloneqq [M]$ be an indexing set of size M. Since for every node $(\mathbf{u}, s)$ we have $|\mathsf{Types}_{\mathbf{u},s}^k| \leqslant M$, we can set an arbitrary injection $\iota_{\mathbf{u},s} \colon \mathsf{Types}_{\mathbf{u},s}^k \to I$. For an edge $e = ((\mathbf{u}, s), (\mathbf{v}, t))$, we set

$$g_e \coloneqq \iota_{\mathbf{u},s}^{-1} \,;\, f_e \,;\, \iota_{\mathbf{v},t}.$$

Thus, g_e is a function from I to I that, intuitively, is just f_e reindexed using the index set I. Clearly, functions $\iota_{\mathbf{u},s}$ and g_e defined above can be computed in total time $\mathcal{O}_{d,k,\mathbf{x}}(n)$.

We will use the following result proved in [17].

▶ **Theorem 26** (Theorem 5.1 of [17]). *Let S be a semigroup and T be a rooted tree with edges labelled with elements of S. Then one can in time $|S|^{\mathcal{O}(1)} \cdot |T|$ construct a data structure that can answer the following queries in time $|S|^{\mathcal{O}(1)}$: given nodes $u, v \in T$ such that v is an ancestor of u, output the (top-down) product of elements of S associated with the edges on the path from v to u. The data structure uses $|S|^{\mathcal{O}(1)} \cdot |T|$ space.*

Let S be the semigroup of functions from I to I with the product defined as $f \cdot g = g; f$. Thus, the functions g_e form a labelling of edges of $T_{r,\mathbf{x}}$ with elements of S. Apply Theorem 26 to this S-labelled tree, and let $\mathbb{S}$ be the obtained data structure. Now, to answer a query about nodes $(\mathbf{u}, s)$, $(\mathbf{v}, t)$, and type $\alpha = \mathrm{ltp}^k_s(\mathbf{w})$ as in the lemma statement, it suffices to apply the following procedure:

- Compute $\tilde{\alpha} \coloneqq \iota_{\mathbf{u},s}(\alpha)$.
- Query $\mathbb{S}$ to compute the compositions of functions g_e along the path from $(\mathbf{u}, s)$ to $(\mathbf{v}, t)$ in $T_{r,\mathbf{x}}$. Call the resulting function h.
- Compute $\tilde{\beta} \coloneqq h(\tilde{\alpha})$.
- Output $\beta \coloneqq \iota^{-1}_{\mathbf{v},t}(\tilde{\beta})$.

The correctness of the procedure follows from a repeated use of (1), and it is clear that the running time is $\mathcal{O}_{d,k,\mathbf{x}}(1)$. ◀

4.3 Data structure

With all the tools prepared, we can prove Theorem 1.

Let k be the quantifier rank of φ. We set up two auxiliary data structures:

- The data structure of Lemma 20 for radius parameter $r = 2^k$. Call this data structure $\mathbb{P}$.
- For every $\mathbf{z} \subseteq \mathbf{x}$, the data structure of Lemma 25 for parameter k and the set of variables $\mathbf{z}$. Call this data structure $\mathbb{W}_{\mathbf{z}}$.

Moreover, using Lemma 4, we compute for each time $s \in [n-1]$ the trigraph $\mathsf{Relevant}^p_s$, where $p \coloneqq r(|\mathbf{x}| + 1)$. These objects constitute our data structure, so by Lemmas 20, 25, and 4, the construction time is $\mathcal{O}_{d,\varphi}(n)$ as promised. It remains to show how to implement queries.

Suppose we are given a tuple $\mathbf{w} \in V(G)^{\mathbf{x}}$ and we would like to decide whether $G \models \varphi(\mathbf{w})$. By Lemma 13, to answer this it suffices to compute $\mathrm{ltp}^k_n(\mathbf{w})$. In the following, for $\mathbf{z} \subseteq \mathbf{x}$, by $\mathbf{w}_{\mathbf{z}}$ we denote the restriction of $\mathbf{w}$ to the variables of $\mathbf{z}$.

For each time $s \in [n]$, let H_s be the graph on vertex set $\mathbf{x}$ such that $y, y' \in \mathbf{x}$ are adjacent in H_s if and only if $\mathrm{dist}_s(\mathbf{w}\langle s\rangle(y), \mathbf{w}\langle s\rangle(y')) \leqslant r$. The following are immediate:

- For all $1 \leqslant s \leqslant t \leqslant n$, H_t is a supergraph of H_s. That is, if $y, y' \in \mathbf{x}$ are adjacent in H_s, then they are also adjacent in H_t.
- If $\mathbf{z} \subseteq \mathbf{x}$ is such that $H_s[\mathbf{z}]$ is connected for some $s \in [n]$, then $\mathbf{w}_{\mathbf{z}}\langle s\rangle$ is r-close at the time s.

Using the data structure $\mathbb{P}$, we may compute $\mathsf{firstClose}_r(y, y')$ for all $\{y, y'\} \in \binom{\mathbf{x}}{2}$ in total time $\mathcal{O}_{d,\varphi}(\log \log n)$. Let $S \subseteq [n]$ be the set of all those numbers, and include 1 and n in S in addition. Thus $|S| \leqslant 2 + \binom{|\mathbf{x}|}{2} \leqslant \mathcal{O}_\varphi(1)$. We imagine S as ordered by the standard order $\leqslant$, hence we may talk about consecutive elements of S.

Note that the knowledge of the numbers $\mathsf{firstClose}_r(y, y')$ for $\{y, y'\} \in \binom{\mathbf{x}}{2}$ allows us to compute the graphs H_s for all $s \in S$. Further, observe that if $t \in [S]$ is such that $s \leqslant t < s'$ for some $s, s' \in S$ that are consecutive in S, then $H_t = H_s$.

Let L be the set of all pairs of the form $(\mathbf{z}, s)$ where $s \in S$, $\mathbf{z}$ is a connected component of H_s, and either $s = 1$ or $\mathbf{z}$ is not connected in H_{s-1}. Clearly, L has size $\mathcal{O}_{d,\varphi}(1)$ and can be computed in time $\mathcal{O}_{d,\varphi}(1)$. Observe the following.

▷ Claim 27. For each $(\mathbf{z}, s) \in L$, we have $(\mathbf{w}_{\mathbf{z}}\langle s\rangle, s) \in T_{r,\mathbf{z}}$. If moreover $s > 1$, then for every $\mathbf{y} \subseteq \mathbf{z}$ that is a connected component of H_{s-1}, we have $(\mathbf{w}_{\mathbf{y}}\langle s-1\rangle, s-1) \in T_{r,\mathbf{y}}$.

Proof. If $s = 1$, then $\mathbf{z}$ being a connected component of H_1 means that $\mathbf{z}$ is a constant tuple. Hence $\mathbf{w}_{\mathbf{z}}\langle 1\rangle$ is r-close at the time 1, implying that $(\mathbf{w}_{\mathbf{z}}\langle 1\rangle, 1) \in T_{r,\mathbf{z}}$.

Assume then that $s > 1$. As $\mathbf{z}$ is not connected in H_{s-1} and is connected in H_s, it follows that for every connected component $\mathbf{y}$ of H_{s-1} that is contained in $\mathbf{z}$, we have $\mathrm{dist}_s(\mathbf{w}_{\mathbf{y}}\langle s\rangle, B_s) \leqslant r$, and in particular $\mathrm{dist}_s(\mathbf{w}_{\mathbf{z}}\langle s\rangle, B_s) \leqslant r$. The latter statement implies that $(\mathbf{w}_{\mathbf{z}}\langle s\rangle, s) \in T_{r,\mathbf{z}}$ due to fulfilling the second condition in the definition of $T_{r,\mathbf{z}}$. Further, since $\mathbf{y}$ is a connected component of H_{s-1}, $\mathbf{w}_{\mathbf{y}}\langle s-1\rangle$ is r-close at the time $s-1$. So $(\mathbf{w}_{\mathbf{y}}\langle s-1\rangle, s-1) \in T_{r,\mathbf{y}}$ due to fulfilling the third condition in the definition of $T_{r,\mathbf{y}}$. ◁

We now compute the types $\mathrm{ltp}^k_s(\mathbf{w}_{\mathbf{z}})$ for all $(\mathbf{z}, s) \in L$. We do this in any order on L with non-decreasing s, hence when processing $(\mathbf{z}, s)$ we may assume that the corresponding types have already been computed for all $(\mathbf{y}, t) \in L$ with $t < s$.

Assume first that $s = 1$. Then $(\mathbf{z}, 1) \in L$ means that $\mathbf{z}$ is a connected component of H_1, which in turn means that $\mathbf{w}_{\mathbf{z}}$ is a constant tuple. In this case $\mathrm{ltp}^k_1(\mathbf{w}_{\mathbf{z}})$ can be computed trivially.

Assume then that $s > 1$. Since $(\mathbf{z}, s) \in L$, we have that $\mathbf{z}$ is a connected component of H_s, but in H_{s-1}, $\mathbf{z}$ breaks into two or more smaller connected components.

Consider any such component $\mathbf{y}$; that is, $\mathbf{y}$ is a connected component of H_{s-1} that is contained in $\mathbf{z}$. By Claim 27, we have $(\mathbf{w}_{\mathbf{y}}\langle s-1\rangle, s-1) \in T_{r,\mathbf{y}}$. Let then $t \leqslant s-1$ be the smallest time such that $\mathbf{y}$ is a connected component of H_t; clearly we have $t \in S$ and $(\mathbf{y}, t) \in L$. By Claim 27 again, $(\mathbf{w}_{\mathbf{y}}\langle t\rangle, t) \in T_{r,\mathbf{y}}$. Since the type $\mathrm{ltp}^k_t(\mathbf{w}_{\mathbf{y}})$ has been already computed before, we may use one query to $\mathbb{W}_{\mathbf{y}}$ to compute the type $\mathrm{ltp}^k_{s-1}(\mathbf{w}_{\mathbf{y}})$.

Having performed the procedure described above for every connected component $\mathbf{y}$ of H_{s-1} that is contained in $\mathbf{z}$, we may repeatedly use Lemma 15 to compute the type $\mathrm{ltp}^k_{s-1}(\mathbf{w}_{\mathbf{z}})$. Note that for different components $\mathbf{y}, \mathbf{y}'$ as above, we have $\mathrm{dist}_{s-1}(\mathbf{w}_{\mathbf{y}}\langle s-1\rangle, \mathbf{w}_{\mathbf{y}'}\langle s-1\rangle) > r$ due to $\mathbf{y}$ and $\mathbf{y}'$ being non-adjacent in H_{s-1}. Furthermore, all trigraphs required in the applications of Lemma 15 can be easily deduced from the trigraph $\mathsf{Relevant}^p_{s-1}$ and the description of the contraction performed at the time $s-1$; these are stored in our data structure.

Finally, it remains to apply Lemma 17 to compute the type $\mathrm{ltp}^k_s(\mathbf{w}_{\mathbf{z}})$ from $\mathrm{ltp}^k_{s-1}(\mathbf{w}_{\mathbf{z}})$. Again, the trigraphs needed in this application can be easily deduced from $\mathsf{Relevant}^p_{s-1}$ and the contraction performed at the time $s-1$. This finishes the computation of types $\mathrm{ltp}^k_s(\mathbf{w}_{\mathbf{z}})$ for all $(\mathbf{z}, s) \in L$; note that the running time is $\mathcal{O}_{d,\varphi}(1)$.

Finally, let t be the smallest time such that $\mathbf{x}$ is connected in H_t. Such t exists since $\mathbf{x}$ is connected in H_n. Clearly, $t \in S$. By definition we have $(\mathbf{x}, t) \in L$, so the type $\mathrm{ltp}^k_t(\mathbf{w})$ has been computed. By Claim 27, $(\mathbf{w}\langle t\rangle, t) \in T_{r,\mathbf{x}}$. So we can now use the data structure $\mathbb{W}_{\mathbf{x}}$ one last time to compute $\mathrm{ltp}^k_n(\mathbf{w})$. This finishes the proof of Theorem 1.

5 Query enumeration

In this section we prove Theorem 2, which we recall below for convenience.

▶ **Theorem 2.** *Suppose we are given an n-vertex graph G specified through a contraction sequence $\mathcal{P}_1, \ldots, \mathcal{P}_n$ of width d, and a first-order formula $\varphi(\mathbf{x})$, where $\mathbf{x}$ is a set of variables. Then after preprocessing in time $\mathcal{O}_{d,\varphi}(n)$, one can enumerate all tuples $\mathbf{w} \in V(G)^{\mathbf{x}}$ such that $G \models \varphi(\mathbf{w})$ with $\mathcal{O}_{d,\varphi}(1)$ delay.*

First, we need to define our notion of enumerators, and prepare some tools for working with them.

Enumerators. Let $x_1, \ldots, x_n$ be a sequence of elements. An *enumerator* of the sequence $x_1, \ldots, x_n$ is a data structure that implements a single method, such that at the ith invocation of the method, it outputs the element x_j of the sequence, where $j = i \mod n$, and reports an "end of sequence" message if $j = 0$. We say that the enumerator has *delay* t if each invocation takes at most t computation steps, including the steps needed to output the element x_j (assuming each element has a fixed representation). An enumerator for a set X is an enumerator for any sequence $x_1, \ldots, x_n$ with $\{x_1, \ldots, x_n\} = X$ and $n = |X|$. Enumerators for Cartesian products and disjoint unions of sets can be obtained in an obvious way:

▶ **Lemma 28.** *Suppose we are given an enumerator for a set X with delay t and an enumerator for a set Y with delay t', where $t, t' \geqslant 1$. Then we can construct in time $\mathcal{O}(1)$ an enumerator with delay $t + t' + \mathcal{O}(1)$ for the set $X \times Y$ and – if X and Y are disjoint – for the set $X \uplus Y$.*

We will also construct enumerators for disjoint unions of families of sets, as follows.

▶ **Lemma 29.** *Suppose $X_1, \ldots, X_n$ are pairwise disjoint, nonempty sets, such that X_i has an enumerator $\mathcal{E}_i$ with delay t. Suppose furthermore we have an enumerator for the sequence $\mathcal{E}_1, \ldots, \mathcal{E}_n$ with delay t'. Then one can construct, in time $\mathcal{O}(1)$ an enumerator for the set $\bigcup_{1 \leqslant i \leqslant n} X_i$ with delay $t + t' + \mathcal{O}(1)$.*

Finally, we will use the following lemma, proved in [17, Lemma 7.15].

▶ **Lemma 30.** *Fix a finite set Q of size q and a set of functions $\mathcal{F} \subseteq Q^Q$. There is a constant c computable from q and an algorithm that, given a rooted tree T, in which each edge vw (v child of w) is labelled by a function $f_{vw} \colon Q \to Q$, computes in time $c \cdot |T|$ a collection $(\mathcal{E}_w)_{w \in V(T)}$ of enumerators, where each $\mathcal{E}_w$ is an enumerator with delay c that enumerates all descendants v of w such that the composition of the functions labeling the edges of the path from v to w, belongs to $\mathcal{F}$.*

This yields the following.

▶ **Corollary 31 (♠).** *Fix a number q. There is a constant c computable from q and an algorithm that, given a rooted tree T, in which each node v is labeled by a set X_v with $|X_v| \leqslant q$ and a set $Y_v \subseteq X_v$, and each edge vw (v child of w) is labelled by a function $f_{wv} \colon X_v \to X_w$, computes in time $c \cdot |T|$ a collection $(\mathcal{E}^\tau_w)_{w \in V(T), \tau \in X_w}$ of enumerators, where each $\mathcal{E}^\tau_w$ is an enumerator with delay c that enumerates all descendants v of w such that there is some $\sigma \in Y_v$ that is mapped to τ by the composition $f \colon X_v \to X_w$ of the functions labeling the edges of the path from v to w.*

Proof of Theorem 2. We now proceed to the proof of Theorem 2.

Fix a number k, a set of variables $\mathbf{x}$, an n-vertex graph G, together with its contraction sequence $\mathcal{P}_1, \ldots, \mathcal{P}_n$. Denote $r := 2^k$.

For every $s \in [n]$ and $\mathbf{x}$-tuple $\mathbf{u} \in \mathcal{P}_s^{\mathbf{x}}$, and local type $\tau \in \mathsf{Types}^k_{\mathbf{u},s}$, denote

$$S^\tau_{\mathbf{u},s} := \{\mathbf{w} \in V(G)^{\mathbf{x}} \mid \mathbf{w}\langle s\rangle = \mathbf{u} \text{ and } \operatorname{ltp}^k_s(\mathbf{w}) = \tau\}.$$

Recall that the root of $T_{r,\mathbf{x}}$ is the pair $(\mathbf{r}, n)$, where $\mathbf{r}$ is the constant $\mathbf{x}$-tuple with all components equal to the unique part of $\mathcal{P}_n$. Then $S^\tau_{\mathbf{r},n}$ is the set of all $\mathbf{x}$-tuples $\mathbf{w} \in V(G)^{\mathbf{x}}$ with $\operatorname{ltp}^k_n(\mathbf{w}) = \tau$. From Lemma 13 and Lemma 7 we get:

▶ **Lemma 32.** *Fix a formula $\varphi(\mathbf{x})$ of quantifier-rank k. Then there is a set $\Gamma \subseteq \mathsf{Types}^n_{\mathbf{r},n}$ such that $\varphi(G) := \{\mathbf{w} \in V(G)^{\mathbf{x}} \mid G \models \varphi(\mathbf{w})\}$ is the disjoint union of the family of sets $\{S^\tau_{\mathbf{r},n} \mid \tau \in \Gamma\}$.*

Therefore, an enumerator for $\varphi(G)$ can be obtained by concatenating enumerators for the sets $S^\tau_{\mathbf{r},n}$, for $\tau \in \Gamma$. Note that here we are concatenating only $\mathcal{O}_{k,d,\mathbf{x}}(1)$ enumerators, by Lemma 12, so, by applying Lemma 28 repeatedly, the resulting enumerator can be obtained in time $\mathcal{O}_{k,d,\mathbf{x}}(1)$ and has delay $\mathcal{O}_{k,d,\mathbf{x}}(1)$. So to prove Theorem 2, it suffices to prove that we can efficiently compute an enumerator for each of the sets $S^\tau_{\mathbf{r},n}$.

Recall that $T_{r,\mathbf{x}}$ is the tree of r-close $\mathbf{x}$-tuples (see Def. 23), and can be computed in time $\mathcal{O}_{d,k,\mathbf{x}}(n)$, by Lemma 24. In the following proposition, we will show how to compute enumerators for all of the sets $S^\tau_{\mathbf{u},s}$, for $(\mathbf{u}, s) \in T_{r,\mathbf{x}}$. All the enumerators jointly will be computed in time $\mathcal{O}_{d,k,\mathbf{x}}(n)$.

▶ **Proposition 33.** *Fix a nonempty set $\mathbf{x}$ of variables and $k \in \mathbb{N}$. Assume G is a graph on n vertices provided on input through a contraction sequence $\mathcal{P}_1, \ldots, \mathcal{P}_n$ of width d. Then one can in time $\mathcal{O}_{d,k,\mathbf{x}}(n)$ construct a data structure that associates, to every node $(\mathbf{u}, s)$ of $T_{r,\mathbf{x}}$ and every local type $\tau \in \mathsf{Types}^k_{\mathbf{u},s}$, an enumerator for all tuples in $S^\tau_{\mathbf{u},s}$ with delay $\mathcal{O}_{d,k,\mathbf{x}}(1)$.*

As noted above, Theorem 2 follows from Proposition 33, using Lemma 32. The rest of Section 5 is devoted to proving Proposition 33.

We prove Proposition 33 by induction on $|\mathbf{x}|$. So suppose the statement holds for all strict subsets of $\mathbf{x}$. Recall that we may construct the tree $T_{r,\mathbf{x}}$, in time $\mathcal{O}_{d,k,\mathbf{x}}(n)$, using Lemma 24.

Let v, u be two nodes of $T_{r,\mathbf{x}}$ with $v = (\mathbf{v}, t)$ and $u = (\mathbf{u}, s)$ and $u \preccurlyeq v$. By Lemma 25, there is a function $f_{vu} \colon \mathsf{Types}^k_{\mathbf{v},t} \to \mathsf{Types}^k_{\mathbf{u},s}$ such that for every $\mathbf{w} \in V(G)^{\mathbf{x}}$, with $\mathbf{u} = \mathbf{w}\langle t\rangle$ we have $f_{vu}(\operatorname{ltp}^k_t(\mathbf{w})) = \operatorname{ltp}^k_s(\mathbf{w})$.

For a tuple $\mathbf{w} \in V(G)^{\mathbf{x}}$, let $s \in [n]$ be the first time such that $\mathbf{w}\langle s\rangle$ is r-close at time s, where $r = 2^k$. We then say that $\mathbf{w}$ *registers* at $(\mathbf{u}, s)$, where $\mathbf{u} = \mathbf{w}\langle s\rangle$. By Claim 27, in this case, the pair $(\mathbf{u}, s)$ is a node of $T_{r,\mathbf{x}}$.

For each node $(\mathbf{u}, s)$ of $T_{r,\mathbf{x}}$ and type $\tau \in \mathsf{Types}^k_{\mathbf{u},s}$, denote:

$$R^\tau_{\mathbf{u},s} = \{\mathbf{w} \in V(G)^{\mathbf{x}} \mid \mathbf{w} \text{ registers at } (\mathbf{u}, s) \text{ and } \operatorname{ltp}^k_s(\mathbf{w}) = \tau\}.$$

Fix a node $(\mathbf{u}, s) \in T_{r,\mathbf{x}}$ and a type $\tau \in \mathsf{Types}^k_{\mathbf{u},s}$. Clearly, every tuple $\mathbf{w} \in S^\tau_{\mathbf{u},s}$ registers at exactly one descendant $v = (\mathbf{v}, t)$ of $u = (\mathbf{u}, s)$ (possibly, $v = u$), and moreover, $f_{vu}(\operatorname{ltp}^k_t(\mathbf{w})) = \tau$. This proves the following.

▶ **Lemma 34.** *For every node $u \in T_{r,\mathbf{x}}$ and type $\tau \in \mathsf{Types}^k_u$, the set S^τ_u is the disjoint union of all the sets R^σ_v, for $v \in T_{r,\mathbf{x}}$ with $v \succcurlyeq u$ and $\sigma \in \mathsf{Types}^k_v$ such that $f_{vu}(\sigma) = \tau$.*

We prove the following two lemmas.

▶ **Lemma 35 (♠).** *For every given node $u = (\mathbf{u}, s) \in T_{r,\mathbf{x}}$ and type $\tau \in \mathsf{Types}^k_{\mathbf{u},s}$, an enumerator for the set $R^\tau_{\mathbf{u},s}$ with delay $\mathcal{O}_{d,k,\mathbf{x}}(1)$ can be constructed in time $\mathcal{O}_{d,k,\mathbf{x}}(1)$.*

▶ **Lemma 36 (♠).** *One can construct in time $\mathcal{O}_{d,k,\mathbf{x}}(n)$ a collection of enumerators $\mathcal{E}^\tau_u$, one per each node $u = (\mathbf{u}, s) \in T_{r,\mathbf{x}}$ and type $\tau \in \mathsf{Types}^k_{\mathbf{u},s}$, where $\mathcal{E}^\tau_u$ has delay $\mathcal{O}_{d,k,\mathbf{x}}(1)$ and enumerates all descendants $v = (\mathbf{v}, t)$ of u in $T_{r,\mathbf{x}}$ such that there is some $\sigma \in \mathsf{Types}^k_{\mathbf{v},t}$ with $f_{vu}(\sigma) = \tau$ and $R^\sigma_{\mathbf{v},t} \neq \emptyset$.*

Combining Lemma 34, Lemma 35, Lemma 36 and Lemma 29 yields the required collection of enumerators for each of the sets $S^k_{\mathbf{u},s}$, thus proving Proposition 33 and Theorem 2. The proof of Lemma 36 uses Corollary 31, and is omitted, due to space constraints. We now sketch the proof of Lemma 35.

Proof sketch for Lemma 35. The case when u is a leaf, that is, $s = 1$, is easily solved, since in this case $R^\tau_{\mathbf{u},s}$ is either empty, or consists of a single tuple. In the case when u is an inner node, consider the set

$$\mathcal{V} := \{\mathbf{v} \in \mathcal{P}^{\mathbf{x}}_{s-1} \mid \mathbf{v}\langle s-1 \to s\rangle = \mathbf{u}\}.$$

It is easy to see that $\mathcal{V}$ has size $\mathcal{O}_{k,\mathbf{x},d}(1)$, and can be computed in this time, given $u \in T_{r,\mathbf{x}}$.

Fix $\mathbf{v} \in \mathcal{V}$, and consider the graph $H_{\mathbf{v}}$ with vertices $\mathbf{x}$ where any two distinct $y, y' \in \mathbf{x}$ are adjacent whenever $\mathrm{dist}_s(\mathbf{v}(y), \mathbf{v}(y')) \leqslant r$. Let $C_{\mathbf{v}}$ denote the set of connected components of $H_{\mathbf{v}}$, where each connected component is viewed as a set $\mathbf{y} \subseteq \mathbf{x}$ of vertices of $H_{\mathbf{v}}$. Then each of the sets $C_{\mathbf{v}}$, can be computed in time $\mathcal{O}_{k,\mathbf{x},d}(1)$, given $(\mathbf{u}, s) \in T_{r,\mathbf{x}}$ and $\mathbf{v} \in \mathcal{V}$. Call a tuple $\mathbf{v} \in \mathcal{V}$ *disconnected* if $H_{\mathbf{v}}$ is such. Note that if $\mathbf{v}$ is disconnected and $\mathbf{y} \in C_{\mathbf{v}}$, then $|\mathbf{y}| < |\mathbf{x}|$.

Fix a disconnected tuple $\mathbf{v} \in \mathcal{V}$ and $\mathbf{y} \in C_{\mathbf{v}}$. Denote by $\mathbf{v}_{\mathbf{y}}$ the restriction of $\mathbf{v}$ to $\mathbf{y}$. Note that the pair $(\mathbf{v}_{\mathbf{y}}, s-1)$ is a node of $T_{r,\mathbf{y}}$. Indeed, by assumption, $\mathrm{dist}_s(B_s, \mathbf{u}) \leqslant r$ holds, so $\mathrm{dist}_s(B_s, \mathbf{v}\langle s \to s+1\rangle) \leqslant r$, and in particular $\mathrm{dist}_s(B_s, \mathbf{v}_{\mathbf{y}}\langle s \to s+1\rangle) \leqslant r$. Moreover, $\mathbf{v}_{\mathbf{y}}$ is r-close, since $\mathbf{y}$ is a connected component of $H_{\mathbf{v}}$. As $|\mathbf{y}| < |\mathbf{x}|$, by inductive assumption, we have already computed enumerators for the sets $S^\sigma_{\mathbf{v}_{\mathbf{y}},s-1}$, for all adequate local types σ.

From Lemma 15 we deduce that the set $R^\tau_{\mathbf{u},s}$ is the disjoint union of sets of the form $S^{\bar\tau}_{\mathbf{v},s-1}$, where:

1. $\mathbf{v} \in \mathcal{V}$ is disconnected;
2. $\bar\tau := (\tau_{\mathbf{y}} : \mathbf{y} \in C_{\mathbf{v}})$ is a tuple of types with $\tau_{\mathbf{y}} \in \mathsf{Types}^k_{\mathbf{v}_y,s-1}$ and which is "merged" into the type τ, using the function from Lemma 15;
3. the set $S^{\bar\tau}_{\mathbf{v},s-1}$ is a Cartesian product of the sets $S^{\tau_{\mathbf{y}}}_{\mathbf{v}_{\mathbf{y}},s-1}$.

Since for the sets $S^{\tau_{\mathbf{y}}}_{\mathbf{v}_{\mathbf{y}},s-1}$ we have enumerators by inductive assumption, by Lemma 28, we can compute in time $\mathcal{O}_{k,d,\mathbf{x}}(1)$ an enumerator for the set $S^{\bar\tau}_{\mathbf{v},s-1}$, with delay $\mathcal{O}_{k,d,\mathbf{x}}(1)$. Finally, we obtain an enumerator for $R^\tau_{\mathbf{u},s}$, by concatenating the $\mathcal{O}_{k,d,\mathbf{x}}(1)$ enumerators for the sets $S^{\bar\tau}_{\mathbf{v},s-1}$. This finishes the proof sketch for Lemma 35. ◀

Abstract

A pushdown vector addition system with states (PVASS) extends the model of vector addition systems with a pushdown store. A PVASS is said to be *bidirected* if every transition (pushing/popping a symbol or modifying a counter) has an accompanying opposite transition that reverses the effect. Bidirectedness arises naturally in many models; it can also be seen as a overapproximation of reachability. We show that the reachability problem for *bidirected* PVASS is decidable in Ackermann time and primitive recursive for any fixed dimension. For the special case of one-dimensional bidirected PVASS, we show reachability is in PSPACE, and in fact in polynomial time if the stack is polynomially bounded. Our results are in contrast to the *directed* setting, where decidability of reachability is a long-standing open problem already for one dimensional PVASS, and there is a PSPACE-lower bound already for one-dimensional PVASS with bounded stack.

The reachability relation in the bidirected (stateless) case is a congruence over $\mathbb{N}^d$. Our upper bounds exploit saturation techniques over congruences. In particular, we show novel elementary-time constructions of semilinear representations of congruences generated by finitely many vector pairs. In the case of one-dimensional PVASS, we employ a saturation procedure over bounded-size counters.

We complement our upper bound with a TOWER-hardness result for arbitrary dimension and k-EXPSPACE hardness in dimension $2k + 6$ using a technique by Lazić and Totzke to implement iterative exponentiations.

1 Introduction

The reachability problem for infinite-state systems is one of the most basic and well-studied tasks in verification. Given an infinite-state system and two configurations c_1 and c_2 in the system, it asks: Is there a run from c_1 to c_2? *Pushdown systems* (PDS) and *vector addition systems with states* (VASS) are prominent models for which the reachability problem has been studied extensively. Each of them features a finite set of control states and a storage mechanism that holds an unbounded amount of information. In a PDS, there is a stack where we can push and pop letters. In a VASS, there is a set of counters which can

be *incremented* and *decremented*, but not tested for zero. Reachability in both models is understood in isolation [5, 11, 37, 12, 38], but the reachability problem for their *combination* is a long-standing open problem.

Pushdown VASS. A *pushdown VASS* (PVASS) combines PDS and VASS. A PVASS consists of finitely many control states and has access to both a pushdown stack (as in PDS) and counters (as in VASS). A PVASS is *d-dimensional* if it has d counters. A PVASS is a natural combination of the simple building blocks of PDS and VASS. The reachability problem for PVASS has remained a long-standing open problem [39, 50, 15], even if we combine a pushdown with a single counter.

Bidirectedness. A step toward deciding reachability is to first study natural relaxations of the reachability relation. A relaxation that has recently attracted attention is *bidirectedness*. Bidirectedness assumes that for each transition from state p to q in our infinite-state system, there exists a transition from q to p with opposite effect. For example, in bidirected pushdown systems, for each transition from p to q pushing γ on the stack, there is a transition from q to p that pops γ. Likewise, in bidirected VASS, if there is a transition from p to q that adds some vector $\boldsymbol{v} \in \mathbb{Z}^d$ to counters, then there is a transition from q to p adding $-\boldsymbol{v}$. It turns out that several tasks in program analysis can be formulated or practically approximated as reachability in bidirected pushdown systems [8, 54] or bidirected multi-pushdown systems [51, 52, 55, 40, 41, 31]. Bidirected systems have also been considered in algorithmic group theory as an algorithmic framework to provide simple algorithms for the membership problem in subgroups [42].

Reachability in bidirected systems is usually considerably more efficient than in the general case. In bidirected pushdown systems, reachability can be solved in almost linear time [8] whereas a truly subcubic algorithm for the general case is a long-standing open problem [26, 9]. Reachability in bidirected VASS is equivalent to the uniform word problem in finitely presented commutative semigroups, which is EXPSPACE-complete [43]. A separate polynomial time algorithm for bidirected two-dimensional VASS was given in [41]. Moreover, recent results on reachability in bidirected valence systems shows complexity drops across a large variety of infinite-state systems [21]: For almost every class of systems studied in [21], the complexity of bidirected reachability is lower than in the general case (the only exception being pushdown systems, where the complexity is P-complete in both settings). For example, reachability in bidirected $\mathbb{Z}$-VASS, and even in bidirected $\mathbb{Z}$-PVASS, is in P [21].

However, little is known about bidirected PVASS. They have recently been studied in [31], where decidability of reachability in *dimension one is shown*. However, as in the non-bidirected case, decidability of reachability in bidirected PVASS is hitherto not known.

Contributions. We show that in bidirected PVASS (of arbitrary dimension), reachability is decidable. Moreover, we provide an Ackermann complexity upper bound, and show that in any fixed dimension, reachability is primitive recursive.

▶ **Theorem 1.1.** *Reachability in bidirected pushdown VASS is in* ACKERMANN*, and primitive recursive (in* F_{4d+11}*) if the dimension d is fixed.*

Here, $(\mathsf{F}_\alpha)_\alpha$ is an ordinal-indexed hierarchy of fast-growing complexity classes [48], including $\mathsf{F}_3 = \mathsf{TOWER}$ and $\mathsf{F}_\omega = \mathsf{ACKERMANN}$. The formal definition of the hierarchy can be found in Section 4.3. A recurring theme in our upper bounds is that saturation techniques, the standard method to analyze pushdown systems, combine surprisingly well with counters

in the bidirected setting. Saturation is used in each of our upper bounds. In Section 3, we begin the exposition with a short, self-contained proof that reachability is decidable in bidirected PVASS. It shows that non-reachability is always certified by an inductive invariant of a particular saturation procedure. In Section 4, we show the Ackermann upper bound. Here, we saturate a congruence relation that encodes the reachability relation. The upper bound relies on two key ingredients. First, we use results about Gröbner bases of polynomial ideals to show that in elementary time, one can construct a Presburger formula for the congruence generated by finitely many vector pairs. This construction serves as one step in the saturation. To show termination in Ackermannian time, we rely on a technique from [16] to bound the length of strictly ascending chains of upward closed sets of vectors. Here, the difficulty is to transfer this bound from chains of upward closed sets to chains of congruences.

In Section 5 we present a PSPACE algorithm for bidirected PVASS in dimension one.

▶ **Theorem 1.2.** *Reachability in 1-dimensional bidirected pushdown VASS is in* PSPACE*.*

Here, we rely on an observation from [31] that reachability in bidirected one-dimensional PVASS reduces to (i) coverability in bidirected one-dimensional PVASS and (ii) reachability in one-dimensional bidirected $\mathbb{Z}$-PVASS. Since (ii) is known to be in P [21], we show that (i) can be done in PSPACE. For this, we use saturation to compute, for each state pair (p, q), three bounds on counter values that determine whether coverability holds. We show that these bounds have at most exponential absolute value, which yields a PSPACE procedure.

Finally in Section 6, we show that reachability in bidirected PVASS is TOWER-hard. For this, we adapt a technique from [33] that shows a TOWER lower bound for general PVASS.

▶ **Theorem 1.3.** *Reachability in bidirected PVASS is* TOWER*-hard, and* k*-*EXPSPACE*-hard in dimension* $2k + 6$*.*

Related work. The model of pushdown VASS is surrounded by extensions and restrictions of the storage mechanism for which decidability is understood, the most prominent being the recent Ackermann-completeness for reachability in VASS [11, 37, 12, 38]. If instead of the stack, we have a counter with zero tests, then reachability is still decidable [47, 4]. Here, decidability even holds if we have a zero-testable counter and one additional counter that can be reset [18, 17]. Furthermore, the extension of VASS by *nested zero tests*, where for each $i \in \{1, \ldots, d\}$, we have an instruction that tests all counters $1, \ldots, i$ for zero simultaneously, also allows deciding reachability [47, 3] and can be seen as a special case of pushdown VASS [1]. Another decidability result concerns the *coverability problem*: Here, we are given a configuration c_1 and a control state q and want to know whether from c_1, one can reach some configuration in control state q. It is known that the reachability problem for d-dimensional PVASS reduces to coverability in $(d + 1)$-dimensional PVASS, and that coverability in 1-dimensional PVASS is decidable [39]. According to [15], the latter problem is PSPACE-hard and in EXPSPACE. Furthermore, if the counters in a PVASS are allowed to go negative during a run, then we speak of an *integer PVASS* ($\mathbb{Z}$-PVASS). For these, reachability is known to be decidable [25] and NP-complete [24]. However, if we extend the model of PVASS by allowing resets on the counters, then even coverability is undecidable in dimension one [50].

For VASS, several generalizations of bidirectedness have been studied. It is EXPSPACE-complete whether given two configurations are mutually reachable [35]. Moreover, if two configurations are mutually reachable, then their distance is at most doubly exponential (linear for fixed dimension) in their size [36]. Furthermore, for cyclic VASS (where each transition can be reversed by some execution), it is known that the reachability set has a semilinear representation of at most exponential size [6]. Let us note that in the VASS/Petri net literature, sometimes [6] (but not entirely consistently [35]) the term *reversible* is used to mean bidirected. However, this clashes with the reversibility notion in dynamical systems [30].

2 Preliminaries

Vectors and semilinear sets. We denote integer vectors by bold letters $\boldsymbol{x}$. The maximum norm of $\boldsymbol{x}$ is denoted by $\|\boldsymbol{x}\|$. The i-th unit vector is denoted by $\boldsymbol{e}_i$. The componentwise order $\leq$ on $\mathbb{N}^d$ is a *well-quasi order (wqo)*, i.e. for any infinite sequence $\boldsymbol{x}_1, \boldsymbol{x}_2, \dots$ over $\mathbb{N}^d$ there exist $i < j$ with $\boldsymbol{x}_i \leq \boldsymbol{x}_j$. We write $\boldsymbol{x} < \boldsymbol{y}$ if $\boldsymbol{x} \leq \boldsymbol{y}$ and $\boldsymbol{x} \neq \boldsymbol{y}$. This implies that the set $\min(X)$ of minimal elements in any $X \subseteq \mathbb{N}^d$ is finite. We denote by $X{\uparrow} = \{\boldsymbol{y} \in \mathbb{N}^k \mid \exists \boldsymbol{x} \in X \colon \boldsymbol{x} \leq \boldsymbol{y}\}$ the *upwards closure* of X. We also write $\boldsymbol{x}{\uparrow}$ for $\{\boldsymbol{x}\}{\uparrow}$. A *congruence* on a commutative monoid $(M, +)$, for example $M = \mathbb{N}^d$, is an equivalence relation $\mathcal{Q} \subseteq M \times M$ where $(a, b) \in \mathcal{Q}$ implies $(a + c, b + c) \in \mathcal{Q}$ for all $a, b, c \in M$. We also write $a \sim_{\mathcal{Q}} b$ instead of $(a, b) \in \mathcal{Q}$.

For $X \subseteq \mathbb{N}^k$ we denote by X^* the *submonoid* generated by X. A set $L \subseteq \mathbb{N}^k$ is *linear* if it is of the form $L = \boldsymbol{b} + P^*$ for some base vector $\boldsymbol{b} \in \mathbb{N}^k$ and some finite set $P \subseteq \mathbb{N}^k$ of period vectors. Finite unions of linear sets are called *semilinear*. It is well-known that a set is semilinear if and only if it is definable in *Presburger arithmetic*, i.e. first-order logic over $(\mathbb{N}, +, \leq, 0, 1)$. Furthermore, one can effectively convert between these formats in elementary time: While defining semilinear sets in Presburger arithmetic is straightforward, for the converse we can use Cooper's quantifier elimination [10] running in triply exponential time [44], see also [23] for an excellent overview. We will confuse a semilinear S with its representation, which is either a list of base and period vectors for each linear set or a defining Presburger formula, and denote by $\|S\|$ the size of its representation.

Pushdown VASS. A *d-dimensional pushdown VASS (PVASS)* is a tuple $\mathcal{P} = (Q, \Gamma, T)$ where Q is a finite set of states, Γ is a finite stack alphabet, and $T \subseteq Q \times \mathbb{Z}^d \times \mathsf{Op}(\Gamma) \times Q$ is a finite set of transitions. Here $\mathsf{Op}(\Gamma) = \{a, \bar{a} \mid a \in \Gamma\} \cup \{\varepsilon\}$ is the set of operations on the stack. A configuration over $\mathcal{P}$ is a tuple $(q, \boldsymbol{x}, s) \in Q \times \mathbb{N}^d \times \Gamma^*$. The *one-step relation* $\to$ is the smallest binary relation on configurations such that for all $(p, \boldsymbol{v}, \alpha, q) \in T$ and $\boldsymbol{x} \in \mathbb{N}^d$ with $\boldsymbol{x} + \boldsymbol{v} \geq \boldsymbol{0}$ we have: (i) If $\alpha \in \Gamma \cup \{\varepsilon\}$ then $(p, \boldsymbol{x}, s) \to (q, \boldsymbol{x} + \boldsymbol{v}, s\alpha)$ (ii) if $\alpha = \bar{a}$ then $(p, \boldsymbol{x}, sa) \to (q, \boldsymbol{x} + \boldsymbol{v}, s)$. Its transitive-reflexive closure is denoted by $\xrightarrow{*}$. We say that $\mathcal{P}$ is *bidirected* if $(p, \boldsymbol{v}, \alpha, q) \in T$ implies $(q, -\boldsymbol{v}, \bar{\alpha}, p) \in T$ where we set $\bar{\bar{a}} = a$ for $a \in \Gamma$ and $\bar{\varepsilon} = \varepsilon$. The *reachability problem* for bidirected PVASS asks: Given a bidirected PVASS $\mathcal{P}$ and two states s, t, does $(s, \boldsymbol{0}, \varepsilon) \xrightarrow{*} (t, \boldsymbol{0}, \varepsilon)$ hold?

The counter updates $\boldsymbol{u}$ in a PVASS transition $(p, \boldsymbol{u}, q)$ can be given in either unary or binary encoding since there are logspace translations in both directions: To add a binary encoded number u to a counter we push the binary notation of u to the stack, and repeatedly decrement the stack counter while incrementing u. Since this computation is deterministic, the simulation also works for bidirected PVASS.

For the Ackermann upper bound it is convenient to use pushdown VASS with a single state. A *pushdown VAS (PVAS)* $\mathcal{P} = (\Gamma, T)$ in dimension d consists of a finite stack alphabet Γ and a finite set of transitions $T \subseteq \mathbb{N}^d \times \mathbb{N}^d \times (\Gamma \cup \bar{\Gamma} \cup \{\varepsilon\})$. Here, a configuration is a pair $(\boldsymbol{x}, s) \in \mathbb{N}^d \times \Gamma^*$. The effect of a transition $(\boldsymbol{u}, \boldsymbol{v}, \alpha)$ is subtracting $\boldsymbol{u}$ from the d counters, assuming that the counters stay non-negative, and then adding $\boldsymbol{v}$. A PVAS $\mathcal{P}$ is bidirected if $(\boldsymbol{u}, \boldsymbol{v}, a) \in T$ implies $(\boldsymbol{v}, \boldsymbol{u}, \bar{a}) \in T$. A bidirected PVASS in dimension d can be simulated by a bidirected PVAS in dimension $d + 2$ where the two additional counters add up to the number of states and specify the current state. Hence, one can reduce the reachability problem for bidirected PVASS to the reachability problem for bidirected PVAS: Given a bidirected PVAS $\mathcal{P}$ and two vectors $\boldsymbol{s}, \boldsymbol{t} \in \mathbb{N}^d$, does $(\boldsymbol{s}, \varepsilon) \xrightarrow{*} (\boldsymbol{t}, \varepsilon)$ hold?

3 Decidability

In this section, we present a simple and self-contained proof that reachability is decidable in bidirected PVASS. Consider the reachability relation between configurations with empty stack. For any states p, q, define the set $R_{p,q} \subseteq \mathbb{N}^d \times \mathbb{N}^d$ with

$$R_{p,q} = \{(\boldsymbol{u}, \boldsymbol{v}) \mid \boldsymbol{u}, \boldsymbol{v} \in \mathbb{N}^d,\ (p, \boldsymbol{u}, \varepsilon) \xrightarrow{*} (q, \boldsymbol{v}, \varepsilon)\}.$$

We will prove that each $R_{p,q}$ is semilinear, for which we rely on the fact that these sets are slices. A *slice* is a subset $S \subseteq \mathbb{N}^k$ such that if $\boldsymbol{u}, \boldsymbol{u}+\boldsymbol{v}, \boldsymbol{u}+\boldsymbol{w} \in S$ for some $\boldsymbol{u}, \boldsymbol{v}, \boldsymbol{w} \in \mathbb{N}^k$, then $\boldsymbol{u}+\boldsymbol{v}+\boldsymbol{w} \in S$. Observe that each $R_{p,q} \subseteq \mathbb{N}^{2d}$ is a slice. This is because if $(\boldsymbol{u}, \boldsymbol{v}), (\boldsymbol{u}+\boldsymbol{u}_1, \boldsymbol{v}+\boldsymbol{v}_1), (\boldsymbol{u}+\boldsymbol{u}_2, \boldsymbol{v}+\boldsymbol{v}_2) \in R_{p,q}$, then there is a run

$$(p, \boldsymbol{u}+\boldsymbol{u}_1+\boldsymbol{u}_2, \varepsilon) \xrightarrow{*} (q, \boldsymbol{v}+\boldsymbol{v}_1+\boldsymbol{u}_2, \varepsilon) \xrightarrow{*} (p, \boldsymbol{u}+\boldsymbol{v}_1+\boldsymbol{u}_2, \varepsilon) \xrightarrow{*} (q, \boldsymbol{v}+\boldsymbol{v}_1+\boldsymbol{v}_2, \varepsilon),$$

where the middle part exists due to bidirectedness. Thus, the pair $(\boldsymbol{u}+\boldsymbol{u}_1+\boldsymbol{u}_2, \boldsymbol{v}+\boldsymbol{v}_1+\boldsymbol{v}_2)$ belongs to $R_{p,q}$. The following was first shown in [14, Proposition 7.3].

▶ **Theorem 3.1** (Eilenberg & Schützenberger 1969). *Every slice is semilinear.*

This seems to be stronger than the somewhat better-known fact that each congruence on $\mathbb{N}^d$ is semilinear: Observe that every congruence on $\mathbb{N}^d$, seen as a subset of $\mathbb{N}^{2d}$, is a slice. In the case of congruences, a relatively simple proof was obtained by Hirshfeld [27]. We present a proof of Theorem 3.1 that combines ideas from both [14] and [27] and is (in our opinion) simpler than each.

For a set $X \subseteq \mathbb{N}^k$, let $\min X$ be the set of minimal elements of X, with respect to the usual component-wise ordering $\leq$ on $\mathbb{N}^k$. Since this ordering is a well-quasi ordering, $\min X$ is finite for every set X. Suppose $S \subseteq \mathbb{N}^k$ is a slice. For each $\boldsymbol{u} \in S$, let $S - \boldsymbol{u} := \{\boldsymbol{v} \in \mathbb{N}^k \mid \boldsymbol{u}+\boldsymbol{v} \in S\}$. Then $\boldsymbol{u} \leq \boldsymbol{v}$ implies $S - \boldsymbol{u} \subseteq S - \boldsymbol{v}$. Consider for each $\boldsymbol{u} \in S$ the submonoid

$$M_{\boldsymbol{u}} = (\min(S - \boldsymbol{u} \setminus \{\boldsymbol{0}\}))^*.$$

In other words, $M_{\boldsymbol{u}}$ is the submonoid of $\mathbb{N}^k$ generated by the non-zero minimal elements of $S - \boldsymbol{u}$. Note that for $\boldsymbol{u}, \boldsymbol{v} \in S$, we have $M_{\boldsymbol{u}} = M_{\boldsymbol{v}}$ if and only if $(S - \boldsymbol{u} \setminus \{\boldsymbol{0}\})\uparrow = (S - \boldsymbol{v} \setminus \{\boldsymbol{0}\})\uparrow$. Since S is a slice, we have $\boldsymbol{u} + M_{\boldsymbol{u}} \subseteq S$ for every $\boldsymbol{u} \in S$. Since $\boldsymbol{u} \in \boldsymbol{u} + M_{\boldsymbol{u}}$, we trivially have

$$S = \bigcup_{\boldsymbol{u} \in S} \boldsymbol{u} + M_{\boldsymbol{u}}.$$

Since each $\boldsymbol{u} + M_{\boldsymbol{u}}$ is semilinear, it suffices to show that S is covered by finitely many sets $\boldsymbol{u} + M_{\boldsymbol{u}}$. We first observe that if $\boldsymbol{u} \leq \boldsymbol{v}$ and $M_{\boldsymbol{u}} = M_{\boldsymbol{v}}$, then $\boldsymbol{u} + M_{\boldsymbol{u}}$ already covers $\boldsymbol{v} + M_{\boldsymbol{v}}$.

▶ **Lemma 3.2.** *Let $\boldsymbol{u}, \boldsymbol{v} \in S$. If $\boldsymbol{u} \leq \boldsymbol{v}$ and $M_{\boldsymbol{u}} = M_{\boldsymbol{v}}$, then $\boldsymbol{v} + M_{\boldsymbol{v}} \subseteq \boldsymbol{u} + M_{\boldsymbol{u}}$.*

Proof. We will use the following claim: For every $\boldsymbol{w} \in S$ with $\boldsymbol{u} \leq \boldsymbol{w} \leq \boldsymbol{v}$, we have $M_{\boldsymbol{u}} = M_{\boldsymbol{w}} = M_{\boldsymbol{v}}$. Indeed, since $M_{\boldsymbol{u}} = M_{\boldsymbol{v}}$, we have $\min(S - \boldsymbol{u} \setminus \{\boldsymbol{0}\}) = \min(S - \boldsymbol{v} \setminus \{\boldsymbol{0}\})$. Moreover, since S is a slice, we have $S - \boldsymbol{u} \subseteq S - \boldsymbol{w} \subseteq S - \boldsymbol{v}$. Therefore, $\min(S - \boldsymbol{w} \setminus \{\boldsymbol{0}\})$ coincides with $\min(S - \boldsymbol{u} \setminus \{\boldsymbol{0}\})$ and $\min(S - \boldsymbol{v} \setminus \{\boldsymbol{0}\})$, which implies $M_{\boldsymbol{w}} = M_{\boldsymbol{u}} = M_{\boldsymbol{v}}$.

Let us prove the lemma. We proceed by induction on $\|\boldsymbol{v} - \boldsymbol{u}\|$. If $\boldsymbol{u} = \boldsymbol{v}$, then we are done. Otherwise, there exists an $\boldsymbol{m} \in \min(S - \boldsymbol{u} \setminus \{\boldsymbol{0}\})$ such that $\boldsymbol{u} + \boldsymbol{m} \leq \boldsymbol{v}$. By our claim, we have $M_{\boldsymbol{u}} = M_{\boldsymbol{u}+\boldsymbol{m}} = M_{\boldsymbol{v}}$. Therefore, induction implies $\boldsymbol{v} \in \boldsymbol{u} + \boldsymbol{m} + M_{\boldsymbol{u}+\boldsymbol{m}}$. But since $\boldsymbol{m} \in M_{\boldsymbol{u}}$ and $M_{\boldsymbol{u}+\boldsymbol{m}} \subseteq M_{\boldsymbol{u}}$, this implies $\boldsymbol{v} \in \boldsymbol{u} + M_{\boldsymbol{u}}$. ◀

The following implies semilinearity of S.

▶ **Lemma 3.3.** *There is a finite set $F \subseteq S$ such that $S = \bigcup_{\boldsymbol{u} \in F} \boldsymbol{u} + M_{\boldsymbol{u}}$.*

Proof. Suppose not. Then there is an infinite sequence $\boldsymbol{u}_1, \boldsymbol{u}_2, \ldots \in S$ such that each set $\boldsymbol{u}_i + M_{\boldsymbol{u}_i}$ contributes a new element. By Dickson's lemma $\boldsymbol{u}_1, \boldsymbol{u}_2, \ldots$ contains a subsequence $\boldsymbol{v}_1, \boldsymbol{v}_2, \ldots$ with $\boldsymbol{v}_i \leq \boldsymbol{v}_{i+1}$ for all $i \geq 1$. Since then $S - \boldsymbol{v}_1 \subseteq S - \boldsymbol{v}_2 \subseteq \cdots$, the sequence $(S - \boldsymbol{v}_1 \setminus \{\boldsymbol{0}\})\uparrow \subseteq (S - \boldsymbol{v}_2 \setminus \{\boldsymbol{0}\})\uparrow \subseteq \cdots$ becomes stationary, again by Dickson's lemma, and therefore also the sequence $M_{\boldsymbol{v}_1}, M_{\boldsymbol{v}_2}, \ldots$. By Lemma 3.2, this means that only finitely many terms in the sequence $\boldsymbol{v}_1 + M_{\boldsymbol{v}_1}, \boldsymbol{v}_2 + M_{\boldsymbol{v}_2}, \ldots$ contribute new elements, a contradiction. ◀

Saturation invariants. We have seen that the reachability relations $R_{p,q}$ are all semilinear. However, since the semilinearity proof is non-constructive, this does not explain how to decide reachability. Nevertheless, we shall use semilinearity to show that in case of non-reachability, there exists a certificate. This yields a decision procedure consisting of two semi-algorithms in the style of Leroux's algorithm for reachability in VASS [34]: One semi-algorithm enumerates potential runs, and one enumerates potential certificates for non-reachability.

We assume that we are given a bidirected d-dimensional PVASS with state set Q and stack alphabet Γ. We may assume that all transitions are of the form $p \xrightarrow{\gamma} q$ or $p \xrightarrow{\bar{\gamma}} q$ for $\gamma \in \Gamma$ or $p \xrightarrow{\boldsymbol{v}} q$ for $\boldsymbol{v} \in \mathbb{Z}^d$. Our certificates for non-reachability will be in the form of what we call saturation invariants. Imagine a (non-terminating) naive saturation algorithm that attempts to compute the sets $R_{p,q}$ by adding vector pairs one-by-one to finite sets $F_{p,q}$. It would start with $F_{p,q} = \emptyset$ and then add pairs: For each transition $p \xrightarrow{\boldsymbol{v}} q$ and each vector $\boldsymbol{u} \in \mathbb{N}^d$ with $\boldsymbol{u} + \boldsymbol{v} \in \mathbb{N}^d$, it would add the pair $(\boldsymbol{u}, \boldsymbol{u} + \boldsymbol{v})$ to $F_{p,q}$. Moreover, if $(\boldsymbol{u}, \boldsymbol{v}) \in F_{p,q}$ and $(\boldsymbol{v}, \boldsymbol{w}) \in F_{q,r}$, it would add $(\boldsymbol{u}, \boldsymbol{w})$ to $F_{p,r}$. Finally, if there are transitions $p \xrightarrow{\gamma} p'$ and $q' \xrightarrow{\bar{\gamma}} q$ and there is a $(\boldsymbol{u}, \boldsymbol{v}) \in F_{p',q'}$, then it would add $(\boldsymbol{u}, \boldsymbol{v})$ to $F_{p,q}$.

Intuitively, a saturation invariant is a forward inductive invariant of this naive saturation algorithm. Let us make this precise. For subsets $R_1, R_2 \subseteq \mathbb{N}^d \times \mathbb{N}^d$, we define

$$R_1 \circ R_2 = \{(\boldsymbol{u}, \boldsymbol{w}) \in \mathbb{N}^d \times \mathbb{N}^d \mid \exists \boldsymbol{v} \in \mathbb{N}^d \colon (\boldsymbol{u}, \boldsymbol{v}) \in R_1,\ (\boldsymbol{v}, \boldsymbol{w}) \in R_2\}.$$

A *saturation invariant* consists of a family $(I_{p,q})_{(p,q) \in Q^2}$ of sets $I_{p,q} \subseteq \mathbb{N}^d \times \mathbb{N}^d$ for which

1. For each transition $p \xrightarrow{\boldsymbol{v}} q$, $\boldsymbol{v} \in \mathbb{Z}^d$, each $\boldsymbol{u} \in \mathbb{N}^d$ with $\boldsymbol{u} + \boldsymbol{v} \in \mathbb{N}^d$, we have $(\boldsymbol{u}, \boldsymbol{u} + \boldsymbol{v}) \in I_{p,q}$.
2. For each $p, q, r \in Q$, we have $I_{p,q} \circ I_{q,r} \subseteq I_{p,r}$.
3. For each $p, p', q, q' \in Q$ for which there are transitions $p \xrightarrow{\gamma} p'$, $q' \xrightarrow{\bar{\gamma}} q$ for some $\gamma \in \Gamma$, we have $I_{p',q'} \subseteq I_{p,q}$.

There is a natural ordering of such families $(I_{p,q})_{(p,q) \in Q^2}$ defined by inclusion: We write $(I_{p,q})_{(p,q) \in Q^2} \leq (J_{p,q})_{(p,q) \in Q^2}$, if $I_{p,q} \subseteq J_{p,q}$ for each $p, q \in Q$. In this sense, we can speak of a smallest saturation invariant.

▶ **Lemma 3.4.** *The family $(R_{p,q})_{(p,q) \in Q^2}$ is the smallest saturation invariant.*

Proof. By induction on the length of a run, it follows that $(R_{p,q})_{(p,q) \in Q^2}$ is included in every saturation invariant. Moreover, $(R_{p,q})_{(p,q) \in Q^2}$ is clearly a saturation invariant itself. ◀

Our certificates will consist of saturation invariants defined in Presburger arithmetic. A family $(I_{p,q})_{(p,q) \in Q^2}$ is *Presburger-definable* if for each $(p, q) \in Q^2$, the set $I_{p,q}$ is semilinear. According to Theorem 3.1, the family $(R_{p,q})_{(p,q) \in Q^2}$ is Presburger-definable. Therefore, the following is a direct consequence of Lemma 3.4.

▶ **Theorem 3.5.** *For each $s, t \in Q$, we have $(\boldsymbol{0}, \boldsymbol{0}) \notin R_{s,t}$ if and only if there exists a Presburger-definable saturation invariant $(I_{p,q})_{(p,q) \in Q^2}$ such that $(\boldsymbol{0}, \boldsymbol{0}) \notin I_{s,t}$.*

Algorithm 1 Algorithm for bidirected reachability in PVAS.

Data: Bidirected d-dim. PVAS $\mathcal{P} = (\Gamma, T)$
$R_0 := \mathsf{Cong}(\{(\boldsymbol{u}, \boldsymbol{v}) \mid (\boldsymbol{u}, \boldsymbol{v}, \varepsilon) \in T\})$;
for $i = 1, 2, \ldots$ **do**
  $R_i \leftarrow R_{i-1}$;
  for $(\boldsymbol{u}, \boldsymbol{u}', a) \in T$ *and* $(\boldsymbol{v}', \boldsymbol{v}, \bar{a}) \in T$ **do**
    $R_i \leftarrow R_i \cup \{(\boldsymbol{x} + \boldsymbol{u}, \boldsymbol{y} + \boldsymbol{v}) \mid (\boldsymbol{x} + \boldsymbol{u}', \boldsymbol{y} + \boldsymbol{v}') \in R_{i-1},\ \boldsymbol{x}, \boldsymbol{y} \in \mathbb{N}^d\}$;
  $R_i \leftarrow \mathsf{Cong}(R_i)$;
  if $R_i = R_{i-1}$ **then return** R_i;

This yields our algorithm: One semi-algorithm enumerates transition sequences and terminates if one of them is a run witnessing $(s, \mathbf{0}, \varepsilon) \xrightarrow{*} (t, \mathbf{0}, \varepsilon)$. The other semi-algorithm enumerates Presburger-definable families $(I_{p,q})_{(p,q)\in Q^2}$ in the form of Presburger formulas. Using Presburger arithmetic, it is then easy to check whether (i) $(I_{p,q})_{(p,q)\in Q^2}$ is a saturation invariant and (ii) $(\mathbf{0}, \mathbf{0}) \notin I_{s,t}$. If a saturation invariant is found, the semi-algorithm reports non-reachability. By Theorem 3.5, one of the two semi-algorithms must terminate.

4 Ackermann upper bound

In this section, we show that reachability in bidirected PVASS is solvable in Ackermann time in the general case and in primitive recursive complexity in every fixed dimension.

One way to avoid enumeration in the algorithm of Section 3 would be to start with the semilinear one-step relation described in the first condition of saturation invariants, and then to enlarge it according to the second and third condition. Moreover, one could take the slice closure (the smallest slice that includes the current set) after each enlargement. Since slices satisfy an ascending chain condition [14, Corollary 12.3], this would ensure termination. In fact, computing the slice closure of a semilinear set is possible with an algorithm by Grabowski [22]. Unfortunately, the latter is itself based on enumeration and we are not aware of any complexity bounds for computing slice closures. Therefore, we use an analogous algorithm that uses congruences instead of slices. Since congruences can be encoded in polynomial ideals, we can tap into the rich toolbox of Gröbner bases to compute the congruence generated by a semilinear set.

4.1 The saturation algorithm

In the following we will work with pushdown VAS instead of pushdown VASS. Our decision procedure for bidirected reachability relies on the crucial fact that the reachability relation $R_{\mathcal{P}} = \{(\boldsymbol{s}, \boldsymbol{t}) \in \mathbb{N}^d \times \mathbb{N}^d \mid (\boldsymbol{s}, \varepsilon) \xrightarrow{*} (\boldsymbol{t}, \varepsilon)\}$ of a bidirected pushdown VAS $\mathcal{P}$ is a congruence: It is always reflexive, transitive and additive, even for directed pushdown VAS, and symmetric for bidirected systems. Therefore, whenever we have found an underapproximation $R \subseteq R_{\mathcal{P}}$ we can replace R by the smallest congruence containing R. The smallest congruence containing a set $R \subseteq \mathbb{N}^d \times \mathbb{N}^d$ is denoted by $\mathsf{Cong}(R)$. We also say that R is a *basis of* (or *generates*) $\mathsf{Cong}(R)$. Recall that every congruence on $\mathbb{N}^d$ is a slice. Therefore, congruences are semilinear and ascending chains of congruences stabilize.

Algorithm 1 is a saturation algorithm that computes a semilinear representation for $R_{\mathcal{P}}$. The sets R_i are maintained by semilinear representations or Presburger formulas. Since in this section we only prove elementary complexity bounds, we can use both formats

interchangeably. Observe that the update in line 5 and the equality test in line 7 can be expressed in Presburger arithmetic. The computation of $\mathsf{Cong}(\cdot)$ will be explained in the next subsection. Consider the values of R_i for $i \geq 1$ after line 6 of Algorithm 1. They form an ascending chain of congruences $(R_i)_{i\geq 1}$, which implies that the algorithm must terminate. For the correctness one can prove by induction on i that $(\boldsymbol{x}, \boldsymbol{y}) \in R_i$ if and only if there exists a run between $(\boldsymbol{x}, \varepsilon)$ and $(\boldsymbol{y}, \varepsilon)$ whose stack height does not exceed i. Moreover, if the algorithm terminates after k iterations then $R_k = R_{\mathcal{P}}$.

We will use a primitive recursive algorithm (which is elementary in fixed dimension) to compute $\mathsf{Cong}(R_i)$ from a semilinear representation for R_i. Using the tools from [49] we can then prove upper bounds for the length of the ascending chain.

4.2 Semilinear representations for congruences

In this section, we present an algorithm that, for a given semilinear representation for a set $R \subseteq \mathbb{N}^d \times \mathbb{N}^d$, computes a semilinear representation for $\mathsf{Cong}(R)$. Its run time is bounded by a tower of exponentials in $\|R\|$ of height $O(d)$ (Theorem 4.4). Note that for bidirected VASS, it is known that in exponential space, one can compute a semilinear representation of the reachability set [32, 6]. In other words, one can compute in exponential space a representation of the congruence class of a given vector $\boldsymbol{x} \in \mathbb{N}^d$. In contrast, our algorithm computes a semilinear representation of the entire congruence.

Let the function $\exp^k$ be inductively defined by $\exp^0(x) = x$ and $\exp^{k+1}(x) = \exp^k(2^x)$. In the following we show how to compute a semilinear representation for a congruence $\mathcal{Q}$ given by a semilinear basis $R \subseteq \mathbb{N}^d \times \mathbb{N}^d$ in time $\exp^{O(d)}(\|R\|)$. In fact, we can assume that R is *finite* since a linear set $L = \boldsymbol{b} + P^*$ is contained in $\mathsf{Cong}(F_L)$ where $F_L = \{\boldsymbol{b}, \boldsymbol{b}+\boldsymbol{p} \mid \boldsymbol{p} \in P\}$, and, therefore, a semilinear set $\bigcup_{i=1}^m L_i$ generates the same congruence as $\bigcup_{i=1}^m F_{L_i}$. The semilinear representation of $\mathcal{Q}$ will be obtained by induction on the dimension d via a decomposition of $\mathbb{N}^d$ into smaller regions. A *region* is a linear set $L = \boldsymbol{b} + P^* \subseteq \mathbb{N}^d$ where $P \subseteq \{\boldsymbol{e}_1, \ldots, \boldsymbol{e}_d\}$. Its *dimension* is $|P|$. In particular all sets $\boldsymbol{b}{\uparrow} = \boldsymbol{b} + \{\boldsymbol{e}_1, \ldots, \boldsymbol{e}_d\}^*$ are regions. For a region $L = \boldsymbol{b} + P^*$ and a congruence $\mathcal{Q}$, we define the congruence $\mathcal{Q}_L = \{(\boldsymbol{x}, \boldsymbol{y}) \in (P^*)^2 \mid (\boldsymbol{b} + \boldsymbol{x}, \boldsymbol{b} + \boldsymbol{y}) \in \mathcal{Q}\}$ on the submonoid P^*.

A submonoid $S \subseteq \mathbb{N}^k$ is *subtractive* if $\boldsymbol{x}, \boldsymbol{y} \in S$ and $\boldsymbol{x} \leq \boldsymbol{y}$ implies $\boldsymbol{y} - \boldsymbol{x} \in S$. For example, the non-negative restriction $G \cap \mathbb{N}^k$ of a group $G \subseteq \mathbb{Z}^k$ is a subtractive submonoid. The following lemma is well-known, see [14, Proposition 7.1] or the full version [20] for a proof.

▶ **Lemma 4.1.** *Every subtractive submonoid $S \subseteq \mathbb{N}^k$ is of the form $S = M^*$ where M is the finite set of the minimal nonzero elements in S.*

Eilenberg and Schützenberger observed that for every slice S there exists an element $\boldsymbol{s} \in S$ such that $S - \boldsymbol{s}$ is a subtractive submonoid [14, Proposition 7.2]. As a consequence, for every congruence $\mathcal{Q}$ on $\mathbb{N}^d$ there exists $\boldsymbol{b} \in \mathbb{N}^d$ such that $\mathcal{Q}_{\boldsymbol{b}\uparrow}$ is a subtractive submonoid. We provide an elementary bound on $\boldsymbol{b}$.

▶ **Lemma 4.2.** *Given a finite basis R for a congruence $\mathcal{Q}$ on $\mathbb{N}^d$, one can compute in elementary time a vector $\boldsymbol{b} \in \mathbb{N}^d$ and a finite set $M \subseteq \mathbb{N}^{2d}$ such that $\mathcal{Q}_{\boldsymbol{b}\uparrow} = M^*$.*

Gröbner bases. It remains to compute a semilinear representation of $\mathcal{Q}$ on the complement of $\boldsymbol{b}{\uparrow}$. We will decompose $\mathbb{N}^d \setminus \boldsymbol{b}{\uparrow}$ into disjoint $(d-1)$-dimensional regions L_j, compute bases for the restrictions $\mathcal{Q}_{L_j}$, and proceed inductively. To compute the bases for $\mathcal{Q}_{L_j}$, we will exploit the well-studied connection between congruences on $\mathbb{N}^d$ and binomial ideals [43]. Let $\mathbb{Z}[\boldsymbol{x}]$ be the polynomial ring in the variables $\boldsymbol{x} = (x_1, \ldots, x_d)$ over $\mathbb{Z}$. We write $\boldsymbol{x}^{\boldsymbol{u}}$ for

the monomial $x_1^{\boldsymbol{u}(1)} \cdots x_d^{\boldsymbol{u}(d)}$. An *ideal* is a nonempty set $I \subseteq \mathbb{Z}[\boldsymbol{x}]$ such that $f, g \in I$ and $h \in \mathbb{Z}[\boldsymbol{x}]$ implies $f + g, hf \in I$. An ideal I is finitely represented by a *basis* B, i.e. I is the smallest ideal containing B. By Hilbert's basis theorem any ideal $I \subseteq \mathbb{Z}[\boldsymbol{x}]$ has a finite basis. One of the main tools in computer algebra for handling polynomial ideals are *Gröbner bases*, e.g. to solve the ideal membership problem. We defer the reader to [2] for details on Gröbner bases and only mention the properties required for our purposes. A Gröbner basis is defined with respect to an admissible monomial ordering, e.g. a lexicographic ordering on the monomials. Buchberger's algorithm [7] computes for a given basis for an ideal I the *unique reduced* Gröbner basis for I in doubly exponential space [13].

A basis R for a congruence $\mathcal{Q}$ on $\mathbb{N}^d$ can be translated into the polynomial ideal $I \subseteq \mathbb{Z}[\boldsymbol{x}]$ generated by $B_R = \{\boldsymbol{x}^{\boldsymbol{u}} - \boldsymbol{x}^{\boldsymbol{v}} \mid (\boldsymbol{u}, \boldsymbol{v}) \in R\}$. It is known that $\boldsymbol{s} \sim_{\mathcal{Q}} \boldsymbol{t}$ if and only if $\boldsymbol{x}^{\boldsymbol{s}} - \boldsymbol{x}^{\boldsymbol{t}} \in I$ [43, Lemma 1 and 2]. Moreover, the reduced Gröbner basis of I with respect to an admissible monomial order always consists of differences of monomials $\boldsymbol{x}^{\boldsymbol{s}} - \boldsymbol{x}^{\boldsymbol{t}}$ [29, Theorem 2.7].

The following lemma can be reduced to two known applications of Gröbner bases. Let $I \subseteq \mathbb{Z}[\boldsymbol{x}]$ be an ideal. For a subsequence $\boldsymbol{y}$ of $\boldsymbol{x}$ we call $I \cap \mathbb{Z}[\boldsymbol{y}]$ the *elimination ideal*, which is indeed an ideal in $\mathbb{Z}[\boldsymbol{y}]$. For $\boldsymbol{b} \in \mathbb{N}^d$ we define the *ideal quotient* $I : \boldsymbol{x}^{\boldsymbol{b}} = \{p \in \mathbb{Z}[\boldsymbol{x}] \mid p\boldsymbol{x}^{\boldsymbol{b}} \in I\}$, which is also an ideal. It is known that one can compute Gröbner bases for $I \cap \mathbb{Z}[\boldsymbol{y}]$ and $I : \boldsymbol{x}^{\boldsymbol{b}}$ in elementary time [2, Section 6], see the full version [20] for more details.

▶ **Lemma 4.3.** *Given a finite basis R for a congruence $\mathcal{Q}$ on $\mathbb{N}^d$ and a region $L \subseteq \mathbb{N}^d$, one can compute in elementary time a finite basis for $\mathcal{Q}_L$.*

We are ready to compute a semilinear representation of $\mathsf{Cong}(R)$ in $\exp^{O(d)}(n)$ time. We proceed by induction over d. Using Lemma 4.2 we can write $\mathcal{Q}_{\boldsymbol{b}\uparrow} = M^*$. We decompose $\mathbb{N}^d = \bigcup_{i=0}^m L_j$ into regions where $L_0 = \boldsymbol{b}\uparrow$ and $L_1, \ldots, L_m$ are $(d-1)$-dimensional regions. By Lemma 4.3 we can compute bases for $\mathcal{Q}_{L_i}$ for $i \in [1, m]$ and by induction hypothesis semilinear representations for $\mathcal{Q}_{L_i}$. In this way, we obtain semilinear representations for the restrictions $Q_i = \mathcal{Q} \cap L_i^2$ for each $i \in [0, m]$. Finally, we can express $\boldsymbol{s} \sim_{\mathcal{Q}} \boldsymbol{t}$ by a Presburger formula that says that there exists a sequence of intermediate vectors of length $2(m+1)$ where adjacent elements are related by an R-step or are contained in some relation Q_i.

▶ **Theorem 4.4.** *Given a semilinear basis R for a congruence $\mathcal{Q}$ on $\mathbb{N}^d$, one can compute a semilinear representation for $\mathcal{Q}$ in time $\exp^{c_1 d}(n)$ for some absolute constant c_1.*

4.3 Ascending chains of congruences

To bound the length of the chain of congruences R_i in Algorithm 1 we use a *length function theorem* [49, Theorem 3.15], see also [16]. In general, such theorems allow to derive complexity bounds for algorithms whose termination arguments are based on well-quasi orders.

Fast-growing complexity classes. In the following we state a simplified version of [49, Theorem 3.15], which is sufficient for our application. We start by introducing fast-growing functions and complexity classes. Recall that the Cantor normal form of an ordinal $\alpha \leq \omega^\omega$ is the unique representation $\alpha = \omega^{\alpha_1} + \cdots + \omega^{\alpha_p}$ where $\alpha > \alpha_1 \geq \cdots \geq \alpha_p$. In this form α is a limit ordinal if and only if $p > 0$ and $\alpha_p > 0$. A *fundamental sequence* for a limit ordinal λ is a sequence $(\lambda(x))_{x<\omega}$ of ordinals with supremum λ. Given a limit ordinal $\lambda \leq \omega^\omega$ whose Cantor normal form is $\lambda = \beta + \omega^{k+1}$, we use the standard fundamental sequence $(\lambda(x))_{x<\omega}$, defined inductively as $\omega^\omega(x) = \omega^{x+1}$ and $(\beta + \omega^{k+1})(x) = \beta + \omega^k \cdot (x+1)$. Given a function $h \colon \mathbb{N} \to \mathbb{N}$ the *Hardy hierarchy* $(h^\alpha)_{\alpha \leq \omega^\omega}$ relative to h is defined by

$$h^0(x) = x, \qquad h^{\alpha+1}(x) = h^\alpha(h(x)), \qquad h^\lambda(x) = h^{\lambda(x)}(x).$$

Using the Hardy functions $(H^\alpha)_\alpha$ relative to $H(x) = x + 1$ we can define the *fast-growing* complexity classes $(\mathsf{F}_\alpha)_\alpha$ from [48]. We denote by $\mathcal{F}_{<\alpha}$ the class of functions computed by deterministic Turing machines in time $O(H^\beta(n))$ for some $\beta < \omega^\alpha$. By F_α we denote the class of decision problems solved by deterministic Turing machines in time $O(H^{\omega^\alpha}(p(n)))$ for some function $p \in \mathcal{F}_{<\alpha}$. We define $\mathsf{PRIMITIVE\text{-}RECURSIVE} = \bigcup_{k<\omega} \mathsf{F}_k$ and $\mathsf{ACKERMANN} = \mathsf{F}_\omega$.

Controlled bad sequences. By Dickson's lemma, any sequence of vectors $\boldsymbol{x}_1, \boldsymbol{x}_2, \dots$ with $x_i \not\leq x_j$ for all $i < j$ must be finite. Such a sequence is also called *bad*. To obtain complexity bounds on the length of bad sequences we need to restrict to sequences that do not grow in an uncontrolled fashion. In the following let $g\colon \mathbb{N} \to \mathbb{N}$ be *monotone*, *strictly inflationary*, i.e. $g(x) > x$ for all x, and *super-homogeneous*, i.e. $g(xy) \geq g(x) \cdot y$ for all $x, y \geq 1$. A sequence of vectors $\boldsymbol{x}_0, \boldsymbol{x}_1, \dots, \boldsymbol{x}_\ell$ is (g,n)-*controlled* if $\|\boldsymbol{x}_i\| \leq g^i(n)$ for all $i \in [0, \ell]$. The following statement follows from [49, Theorem 3.15] and [49, Eq. (3.13)].

▶ **Theorem 4.5.** *Any (g,n)-controlled bad sequence over $\mathbb{N}^k$ has length at most $g^{\omega^k}(nk)$.*

A *chain* in $\mathbb{N}^k$ is a sequence $S_0 \subsetneq S_1 \subsetneq \cdots \subsetneq S_\ell$ of subsets $S_i \subseteq \mathbb{N}^k$. The chain is (g,n)-*controlled* if for each $i \in [0, \ell-1]$ there exists $\boldsymbol{s}_i \in S_{i+1} \setminus S_i$ with $\|\boldsymbol{s}_i\| \leq g^i(n)$. A set $X \subseteq \mathbb{N}^k$ is *upwards closed* if $X = X{\uparrow}$. Observe that any (g,n)-controlled chain of upwards closed sets in $\mathbb{N}^k$ is bounded by $1 + g^{\omega^k}(nk)$ since we obtain a (g,n)-controlled bad sequence $\boldsymbol{s}_0, \boldsymbol{s}_1, \dots, \boldsymbol{s}_{\ell-1}$ by picking arbitrary $\boldsymbol{s}_i \in S_{i+1} \setminus S_i$ with $\|\boldsymbol{s}_i\| \leq g^i(n)$.

Translating congruences into upwards closed sets. The key trick in our upper bound for ascending chains of congruences is to translate congruences into upwards closed sets. This allows us to translate bounds on the length of ascending chains of upward closed sets into corresponding bounds for congruences. The translation works as follows. To each congruence $\mathcal{Q}$ on $\mathbb{N}^d$, we associate the upwards closed set $U(\mathcal{Q}) \subseteq \mathbb{N}^{4d}$ with

$$U(\mathcal{Q}) = \{(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{u}, \boldsymbol{v}) \mid (\boldsymbol{x}, \boldsymbol{y}) \in \mathcal{Q},\ (\boldsymbol{x} + \boldsymbol{u}, \boldsymbol{y} + \boldsymbol{v}) \in \mathcal{Q},\ (\boldsymbol{u}, \boldsymbol{v}) \neq (\boldsymbol{0}, \boldsymbol{0})\}{\uparrow}.$$

Clearly $\mathcal{Q}_1 \subseteq \mathcal{Q}_2$ implies $U(\mathcal{Q}_1) \subseteq U(\mathcal{Q}_2)$. In fact, strict inclusion is also preserved:

▶ **Lemma 4.6.** *Let $\mathcal{Q}_1$ and $\mathcal{Q}_2$ be congruences with $\mathcal{Q}_1 \subseteq \mathcal{Q}_2$. Then (i) $U(\mathcal{Q}_1) \subseteq U(\mathcal{Q}_2)$ and (ii) for each $\boldsymbol{q} \in \mathcal{Q}_2 \setminus \mathcal{Q}_1$, there is a $\boldsymbol{p} \in U(\mathcal{Q}_2) \setminus U(\mathcal{Q}_1)$ with $\|\boldsymbol{p}\| \leq \|\boldsymbol{q}\|$.*

Proof. Statement (i) is immediate. For statement (ii) let $(\boldsymbol{s}, \boldsymbol{t}) \in \mathcal{Q}_2 \setminus \mathcal{Q}_1$ be minimal. Since $(\boldsymbol{0}, \boldsymbol{0}) \in \mathcal{Q}_1$ we must have $(\boldsymbol{s}, \boldsymbol{t}) \neq (\boldsymbol{0}, \boldsymbol{0})$ and there exists $(\boldsymbol{x}, \boldsymbol{y}) \in \mathcal{Q}_1$ with $(\boldsymbol{x}, \boldsymbol{y}) < (\boldsymbol{s}, \boldsymbol{t})$. We choose such a vector $(\boldsymbol{x}, \boldsymbol{y})$ in which $(\boldsymbol{u}, \boldsymbol{v}) := (\boldsymbol{s}, \boldsymbol{t}) - (\boldsymbol{x}, \boldsymbol{y})$ is minimal. Clearly, $(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{u}, \boldsymbol{v}) \in U(\mathcal{Q}_2)$. We claim that $(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{u}, \boldsymbol{v}) \notin U(\mathcal{Q}_1)$. Towards a contradiction, suppose that there exists $(\boldsymbol{x}_1, \boldsymbol{y}_1, \boldsymbol{u}_1, \boldsymbol{v}_1) \leq (\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{u}, \boldsymbol{v})$ with $(\boldsymbol{x}_1, \boldsymbol{y}_1) \in \mathcal{Q}_1$, $(\boldsymbol{u}_1, \boldsymbol{v}_1) \neq (\boldsymbol{0}, \boldsymbol{0})$, and $(\boldsymbol{x}_1 + \boldsymbol{u}_1, \boldsymbol{y}_1 + \boldsymbol{v}_1) \in \mathcal{Q}_1$. Since $\mathcal{Q}_1$ is a congruence we have

$$\begin{aligned}\boldsymbol{x} + \boldsymbol{u}_1 = (\boldsymbol{x} - \boldsymbol{x}_1) + \boldsymbol{x}_1 + \boldsymbol{u}_1 &\sim_{\mathcal{Q}_1} (\boldsymbol{x} - \boldsymbol{x}_1) + \boldsymbol{y}_1 + \boldsymbol{v}_1 \\ &\sim_{\mathcal{Q}_1} (\boldsymbol{x} - \boldsymbol{x}_1) + \boldsymbol{x}_1 + \boldsymbol{v}_1 = \boldsymbol{x} + \boldsymbol{v}_1 \sim_{\mathcal{Q}_1} \boldsymbol{y} + \boldsymbol{v}_1.\end{aligned}$$

If $(\boldsymbol{u}_1, \boldsymbol{v}_1) = (\boldsymbol{u}, \boldsymbol{v})$ then this contradicts $(\boldsymbol{x} + \boldsymbol{u}, \boldsymbol{y} + \boldsymbol{v}) = (\boldsymbol{s}, \boldsymbol{t}) \notin \mathcal{Q}_1$. If $(\boldsymbol{u}_1, \boldsymbol{v}_1) < (\boldsymbol{u}, \boldsymbol{v})$ then $(\boldsymbol{s}, \boldsymbol{t}) = (\boldsymbol{x} + \boldsymbol{u}_1, \boldsymbol{y} + \boldsymbol{v}_1) + (\boldsymbol{u} - \boldsymbol{u}_1, \boldsymbol{v} - \boldsymbol{v}_1)$ contradicts the minimality of $(\boldsymbol{u}, \boldsymbol{v})$. ◀

If $(\mathcal{Q}_i)_{i \leq \ell}$ is a (g,n)-controlled chain of congruences in $\mathbb{N}^d$ then by Lemma 4.6, $(U(\mathcal{Q}_i))_{i \leq \ell}$ is a (g,n)-controlled chain of upwards closed subsets of $\mathbb{N}^{4d}$ and thus has length at most $1 + g^{\omega^{4d}}(4dn)$. Hence, the same bound applies to $(\mathcal{Q}_i)_{i \leq \ell}$.

▶ **Lemma 4.7.** *Any (g,n)-controlled chain of congruences in $\mathbb{N}^d$ has length $\leq 1 + g^{\omega^{4d}}(4dn)$.*

Putting together Theorem 4.4 and Lemma 4.7 we can conclude that Algorithm 1 terminates after $H^{\omega^{4d+3}}(e(n))$ iterations for some elementary function $e(n)$.

▶ **Proposition 4.8.** *Reachability in bidirected pushdown VAS is in* ACKERMANN*, and in* F_{4d+3} *if the dimension d is fixed.*

The detailed complexity analysis can be found in the full version [20]. The result above also holds for bidirected pushdown *VASS* (Theorem 1.1) by simulating the state in two additional counters. Hence the complexity for dimension d increases from F_{4d+3} to F_{4d+11}.

5 One-dimensional pushdown VASS

In this section we prove that reachability is in polynomial space for bidirected 1-PVASS (Theorem 1.2). For the rest of this section consider a 1-PVASS $\mathcal{P} = (Q, \Gamma, T)$ of $|Q| = n$ states. To simplify our bounds, we assume $|\Gamma| = 2$. This can be achieved with a simple encoding: To simulate stack letters $a_1, \ldots, a_k$, we can encode each a_i by the string $ab^iab^{k-i}a$.

Preliminaries. We extend the usual component-wise ordering $\leq$ to tuples $(\mathbb{Z} \cup \{-\infty, \omega\})^k$. Given two functions $f, g \colon X \to (\mathbb{Z} \cup \{-\infty, \omega\})^k$, we write $f \leq g$ to denote that $f(x) \leq g(x)$ for each $x \in X$. We define the *one-step $\mathbb{Z}$ relation* $\hookrightarrow$ for $\mathcal{P}$ similarly to the one-step relation $\to$ but with a $\mathbb{Z}$-counter, i.e., we do not require the counter to remain non-negative. A *path from p to q* consists of the initial state p and a sequence of transitions of $\mathcal{P}$, such that it induces a run $(p_1, x_1, w_1) \hookrightarrow (p_2, x_2, w_2) \hookrightarrow \ldots \hookrightarrow (p_j, x_j, w_j)$, with the requirement that $p_1 = p$, $x_1 = 0$ and $w_1 = w_j = \varepsilon$. Given such a path P, we let

- $\mathit{MaxSH}(P) = \max_i |w_i|$ be the maximum stack height along P,
- $w(P) = x_j$ be the value of the counter at the end of P, and
- $m(P) = \min_i x_i$ be the minimum value of the counter along P. Note that $m(P) \leq 0$, as the counter is 0 at the beginning of P.

We also write $\overline{P}$ for the reverse of P. We denote by $\{p \rightsquigarrow q\}$ the set of paths from p to q, and let $\{p \rightsquigarrow q\}_k = \{P \in \{p \rightsquigarrow q\} \colon \mathit{MaxSH}(P) \leq k\}$ be the set of such paths with stack height at most k. Given two paths P_1 and P_2, we write $P_1 \leq P_2$ to denote that $(m(P_1), w(P_1)) \leq (m(P_2), w(P_2))$.

We say that a state q is reachable from a state p if $(p, \mathbf{0}, \varepsilon) \xrightarrow{*} (q, \mathbf{0}, \varepsilon)$. We say that q is *$\mathbb{Z}$-reachable* from p if there is a path $P \in \{p \rightsquigarrow q\}$ with $w(P) = 0$ (hence state reachability implies $\mathbb{Z}$-reachability). Given additionally a natural number $i \in \mathbb{N}$, we say that p *covers* (q, i) if $(p, 0, \varepsilon) \xrightarrow{*} (q, i + j, \varepsilon)$ for some $j \geq 0$. Thus reachability implies coverability for $i = 0$. The following is a simpler proof of a reduction observed in [31]: For bidirected 1-PVASS, reachability reduces to coverability and $\mathbb{Z}$-reachability.

▶ **Lemma 5.1.** *For any two states p, q of $\mathcal{P}$, we have that p reaches q iff (i) p covers $(q, 0)$, (ii) q covers $(p, 0)$, and (iii) p $\mathbb{Z}$-reaches q.*

Proof. Clearly if p reaches q then conditions (i)-(iii) hold, so we only need to argue about the reverse direction. If p does not cover $(q, 1)$, since p covers $(q, 0)$, we have that p reaches q, and we are done. Similarly, if q does not cover $(p, 1)$, we have that q reaches p and thus we are done. Finally, assume that p covers $(q, 1)$ and q covers $(p, 1)$, and let P_p and P_q be the corresponding paths witnessing coverability. Let P be a path witnessing that p $\mathbb{Z}$-reaches q. We construct the path H_ℓ witnessing the reachability of q from p as $H_\ell = (P_p \circ P_q)^\ell \circ P \circ (\overline{P_p} \circ \overline{P_q})^\ell$, where ℓ is chosen such that $w((P_p \circ P_q)^\ell) \geq -m(P)$. ◀

In light of Lemma 5.1, for Theorem 1.2, it suffices to show that for bidirected 1-PVASS, both $\mathbb{Z}$-reachability and coverability can be decided in PSPACE. The former is known already: Reachability in $\mathbb{Z}$-PVASS belongs to NP [24]; in the bidirected case, it is even decidable in P [21]. Thus, the rest of this section is devoted to deciding coverability in PSPACE.

▶ **Lemma 5.2.** *Coverability in 1-dimensional bidirected pushdown VASS is in* PSPACE.

Summary functions. We define a summary function $\gamma_k \colon Q \times Q \to (\mathbb{Z}_{\leq 0} \cup \{-\infty\}) \times (\mathbb{Z} \cup \{-\infty, \omega\})$, parametric on $k \in \mathbb{N}$, as $\gamma_k(p,q) = (a,b)$, where a and b are defined as follows.

$$a = \max(\{m(P) \colon P \in \{p \rightsquigarrow q\}_k\}) \qquad b = \sup(\{w(P) \colon P \in \{p \rightsquigarrow q\}_k \text{ and } m(P) = a\})$$

with the convention that $\max(\emptyset) = \sup(\emptyset) = -\infty$. We occasionally write $\gamma_k(p,q) = (a, \_)$ to denote that $\gamma_k(p,q) = (a,b)$ for some b. We further define a summary function $\delta_k \colon V \to (\mathbb{Z}_{\leq 0} \cup \{-\infty\})$, parametric on $k \in \mathbb{N}$, as follows.

$$\delta_k(p) = \max(\{m(P) \colon P \in \{p \rightsquigarrow p\}_k \text{ and } w(P) > 0\})$$

Recall that we use $n = |Q|$ for the number of states in $\mathcal{P}$. It is well-known that in any pushdown system of n states (and only two stack letters), a shortest path between two states has length $2^{O(n^2)}$ (e.g. this follows by inspecting a proof of the pumping lemma for context-free languages [28, Lemma 6.1]; a precise bound was obtained in [45]). Since both the weight and the minima of any path are lower-bounded by minus the length of the path, if $\{p \rightsquigarrow q\}_k \neq \emptyset$, then a shortest path in $\{p \rightsquigarrow q\}_k$ witnesses $\gamma_k(p,q) = (a,b)$ where a and b are at most exponentially negative. This is established in the following lemma.

▶ **Lemma 5.3.** *Consider any two states p, q and natural number k, and let $\gamma_k(p,q) = (a,b)$. If $a > -\infty$ then $a, b \geq -\beta$, for $\beta = 2^{O(n^2)}$.*

The bidirectedness of $\mathcal{P}$ also leads to the following lemma.

▶ **Lemma 5.4.** *Consider any two states p, q and natural number k, and let $\gamma_k(p,q) = (a,b)$. There exists a constant α independent of $\mathcal{P}$ and k, such that, if $b > 2^{\alpha n^2}$, then $b = \omega$.*

The intuition behind the summary functions γ_k and δ_k is as follows. Lemma 5.3 and Lemma 5.4 hint on an algorithm to decide coverability by saturating γ_k iteratively for increasing k. The lemmas state that the finite values of γ_k are exponentially bounded, and thus the process is guaranteed to reach a fixpoint within exponentially many iterations. An obstacle to this approach is that γ_k may fail to capture paths that are useful in subsequent iterations. In particular, $\gamma_k(p,q)$ misses paths that can reach q with a larger counter at the cost of a lower minima on the way. The following lemma shows that δ_k captures the effects of all paths missed by γ_k, and allows the two summaries to be *mutually* saturated.

▶ **Lemma 5.5.** *For any states p, q, let $\gamma_k(p,q) = (a,b)$, and assume there exists a path $P \in \{p \rightsquigarrow q\}_k$ with $w(P) > b$. Then $\delta_k(p) \geq m(P)$.*

Moreover, the values of δ_k are also exponentially bounded, and thus the mutual saturation can be carried out in polynomial space.

▶ **Lemma 5.6.** *For any state p, if $\delta_k(p) > -\infty$ then $\delta_k(p) \geq -\beta$, for $\beta = 2^{O(n^2)}$.*

In the remainder of this section we describe the saturation procedure for γ_k and δ_k.

Finite graphs. We consider weighted finite graphs $G = (V_G, E_G, w_G)$ where $w_G \colon E_G \to \mathbb{Z}$. Moreover, we assume that every connected component of G is strongly connected. By a small abuse we extend some of the above notation on $\mathcal{P}$ to such graphs. Given two nodes u, v in G, we write $\{u \rightsquigarrow v\}^G$ for the set of paths from u to v in G. We similarly extend the summary functions to γ^G and δ^G, defined by the corresponding paths $P \in \{u \rightsquigarrow v\}^G$.

▶ **Lemma 5.7.** *Given a graph G as above, the summary functions γ^G and δ^G can be computed in polynomial time.*

Computing γ_k and δ_k. We now describe a dynamic-programming algorithm for computing γ_k and δ_k, for increasing values of k. We let $\Gamma_\perp = \Gamma \cup \{\perp\}$, where $\perp$ is a special symbol, and assume without loss of generality that every transition in $\mathcal{P}$ that manipulates the counter does not affect the stack. Afterwards we will argue that the algorithm terminates within exponentially many iterations.

1. We start with $k = 0$. We construct a graph G_0 that consists of nodes $\langle p, \perp\rangle$ where p is a state of $\mathcal{P}$. Moreover, G_0 contains the corresponding transitions of $\mathcal{P}$ that do not manipulate the stack. In particular, for every transition $(p, i, \varepsilon, q) \in T$ we have an edge $\langle p, \perp\rangle \xrightarrow{i} \langle q, \perp\rangle$ in G_0. We use Lemma 5.7 to compute γ^{G_0} and δ^{G_0}, and report that, for all states p and q, we have $\gamma_0(p, q) = \gamma^{G_0}(\langle p, \perp\rangle, \langle q, \perp\rangle)$ and $\delta_0(p) = \delta^{G_0}(\langle p, \perp\rangle)$.
2. We repeat the following until γ^{G_k} and δ^{G_k} have converged. We construct a graph G_k as follows. For every state p and every $\sigma \in \Gamma_\perp$, we have a node $\langle p, \sigma\rangle$ in G_k. We then do the following.
   a. Let $\delta^{G_{k-1}}(\langle p, \perp\rangle) = c$. We insert a node $\langle p', \sigma\rangle$, and if $-\infty < c$, we insert two edges manipulating the counter $\langle p, \sigma\rangle \xrightarrow{c} \langle p', \sigma\rangle$ and $\langle p', \sigma\rangle \xrightarrow{-c+1} \langle p, \sigma\rangle$.
   b. For every state q, let $\gamma^{G_{k-1}}(\langle p, \perp\rangle, \langle q, \perp\rangle) = (a, b)$. If $-\infty < a$, we insert a node $\langle p, q, \sigma\rangle$ and two edges manipulating the counter $\langle p, \sigma\rangle \xrightarrow{a} \langle p, q, \sigma\rangle$ and $\langle p, q, \sigma\rangle \xrightarrow{-a+b'} \langle q, \sigma\rangle$, where $b' = b$ if $b < \omega$ and $b' = 0$ otherwise.
3. Finally, for each stack letter $\sigma \in \Gamma$, we connect nodes of the form $\langle p, \perp\rangle$ and $\langle q, \sigma\rangle$ using the transitions of $\mathcal{P}$ that manipulate the stack. That is, for every transition $(p, 0, \sigma, q) \in T$, we insert an edge $\langle p, \perp\rangle \to \langle q, \sigma\rangle$, and for every transition $(p, 0, \overline{\sigma}, q) \in T$, we insert an edge $\langle p, \sigma\rangle \to \langle q, \perp\rangle$.
4. We use Lemma 5.7 to compute γ^{G_k} and δ^{G_k}, and report that, for all states p and q, we have $\gamma_k(p, q) = \gamma^{G_k}(\langle p, \perp\rangle, \langle q, \perp\rangle)$ and $\delta_k(p) = \delta^{G_k}(\langle p, \perp\rangle)$.

We first argue that the graphs G_k consist of strongly connected components, and thus Lemma 5.7 is applicable.

▶ **Lemma 5.8.** *For all $k \in \mathbb{N}$, every connected component of G_k is strongly connected.*

Given some $\sigma \in \Gamma_\perp$ and $k \geq 1$, we denote by $G_k \restriction \sigma$ the subgraph of G_k induced by the nodes whose last element is σ. It follows directly from the construction of G_k that, for every pair of states p, q of $\mathcal{P}$ and $\sigma \in \Gamma_\perp$, for every path P that goes from $\langle p, \sigma\rangle$ to $\langle q, \sigma\rangle$ and is contained in $G_k \restriction \sigma$, there is a path $H \in \{p \rightsquigarrow q\}_{k-1}$ with $P \leq H$. In turn, this implies that the summary functions γ^{G_k} and δ^{G_k} are always dominated by paths in $\mathcal{P}$ of stack height at most k, i.e., for all states p and q, we have $\gamma^{G_k}(\langle p, \perp\rangle, \langle q, \perp\rangle) \leq \gamma_k(p, q)$ and $\delta^{G_k}(\langle p, \perp\rangle) \leq \delta_k(p)$ for all $k \in \mathbb{N}$. The following lemma states that γ^{G_k} and δ^{G_k} compute γ_k and δ_k exactly, by arguing that γ^{G_k} and δ^{G_k} also dominate all paths of $\mathcal{P}$ with stack height at most k. In turn, this establishes the correctness of the algorithm.

▶ **Lemma 5.9.** *For all $k \in \mathbb{N}$ and states $p, q \in Q$, we have $\gamma_k(p, q) = \gamma^{G_k}(\langle p, \perp\rangle, \langle q, \perp\rangle)$ and $\delta_k(p) = \delta^{G_k}(\langle q, \perp\rangle)$.*

Thus, to decide whether p covers $(q, 0)$, we saturate γ_k and δ_k and check whether $\gamma_k(p, q) = (0, \_)$. The termination and complexity of the algorithm follows from the boundedness of the finite values of γ_k and δ_k (Lemma 5.3, Lemma 5.4 and Lemma 5.6), which concludes Lemma 5.2.

▶ **Lemma 5.10.** *The above algorithm terminates and uses polynomial space.*

Finally, note that if we have a polynomial bound on the stack height, then the saturation procedure runs in polynomial time, which also leads to reachability in polynomial time (a closer analysis yields an $O(n^3)$ bound per iteration). In particular, the PSPACE-hardness proof for 1-dimensional *directed* PVASS from [15] cannot be directly transferred to bidirected PVASS: The 1-PVASS constructed in [15] has a polynomially bounded stack height. See the full version [20] for details on how exactly the reduction fails. Without a bound on the stack height, the saturation might indeed take exponential time: There are 1-dimensional bidirected PVASS on which shortest coverability witnesses require an exponential stack height (see the full version [20] for an example).

6 Tower lower bound

In this section, we show that reachability in bidirected PVASS is TOWER-hard with respect to elementary reductions, and k-EXPSPACE-hard in dimension $2k + 6$. Recall that TOWER is the class of all problems computable by deterministic Turing machines in time (or space) bounded by a tower of exponentials of elementary height.

Lower bound for directed PVASS. We first recall the TOWER-hardness proof by Lazić and Totzke [33] for reachability in directed PVASS. They reduce the $\exp^n(1)$-bounded halting problem for counter programs of size n, which is TOWER-complete with respect to elementary reductions (which allow us to replace the parameter n with an arbitrary elementary function $e(n)$) [19]. A *counter program* is a finite sequence of commands which manipulate non-negative counters, initially set to zero. The commands include increments $x := x + 1$, decrements $x := x - 1$, conditionals **if** $x = 0$ **then goto** L_1 **else goto** L_2 (where L_1 and L_2 are line numbers), and **halt**. If a counter of value 0 is decremented, the program aborts. The $\exp^n(1)$-bounded halting problem asks whether given a counter program of size n, starting from the first command and all counters set to zero, a command **halt** can be reached using a run during which all counters are bounded by $\exp^n(1)$ and are all zero at the end.

As in most lower bounds for vector addition systems and their extensions, for each counter x we store a complement counter $\bar{x}$, maintaining the invariant $x + \bar{x} = B$ for some (large) bound B. This can be achieved by complementing every in/decrement of x by a de/increment of $\bar{x}$, and vice versa. Then, a zero test **if** $x = 0$ **then goto** L_1 **else goto** L_2 can be replaced by guessing whether $x = 0$ and $x \neq 0$: In the former case we add and subtract B to x and continue with L_1. In the latter case we add and subtract B to $\bar{x}$ and continue with L_2.

The challenge is to implement the addition (and subtraction) with a large number B, here $B = \exp^n(1)$, using a polynomially large system. Suppose we have counters $c_1, \ldots, c_n$ with complement counters $\bar{c}_1, \ldots, \bar{c}_n$ satisfying $c_k + \bar{c}_k = \exp^k(1)$ for all k. Lazić and Totzke [33] show how to construct for all $k = 1, \ldots, n$ a $\mathrm{poly}(k)$-sized PVASS that adds $\exp^k(1)$ to c_k. It operates by pushing exactly $\exp^{k-1}(1)$ many zeros to the stack, repeatedly incrementing the $\exp^{k-1}(1)$-bit binary counter on the stack, while simultaneously decrementing c_k, and finally popping exactly $\exp^{k-1}(1)$ many ones from the stack. Observe that the operations on the

stack can be implemented with the help of c_{k-1} that can be in/decremented by $\exp^{k-1}(1)$ by induction hypothesis. Before simulating the counter program, each complement counter $\bar{c}_k$ has to be set to $\exp^k(1)$, which can be done in a similar fashion.

Simulation by bidirected systems. In the following we will make the above construction outlined by Lazić and Totzke [33] explicit and show that the simulation is correct even after making the PVASS bidirected. To this end we need the following argument already found in Post's undecidability proof of the word problem for Thue systems [46, Lemma II]. Consider a deterministic transition system where the final state does not have any outgoing transitions. To such a system we now add reverse edges to make it bidirected. Clearly, any original run is present in the bidirected system. Conversely, consider a run to the final state in the bidirected system, which may use the new reverse edges. It cannot end on a reverse edge, since there is no outgoing forward edge from the final state. So as long as the run contains reverse edges, at least one of these edges must be followed by one in the forward direction. Let us call them $p \xrightarrow{\bar{a}} q$ and $q \xrightarrow{b} r$. As the original system was deterministic q has exactly one outgoing edge, and hence $(q \xrightarrow{b} r) = (q \xrightarrow{a} p)$. Since the effects of $\bar{a}$ and b cancel out, we can omit both of them from the run. Iterating this argument eventually yields a run with no reverse edges. It follows that adding reverse edges to a fully deterministic system does not change its reachability set (this was originally shown by Mayr and Meyer [43] for their proof of EXPSPACE-hardness of reachability for bidirected VAS).

The construction of Lazić and Totzke is not fully deterministic. However, it only uses very restricted nondeterminism that will not impact our simulation of the counter machine.

Gadget construction. Since we also want to show a k-EXPSPACE lower bound for dimension $2k+6$, we use a slightly more refined analysis: We will assume that two numbers k and n are given as input and construct a system that simulates counters bounded by $\exp^k(n)$ instead of $\exp^k(1)$ as in Lazić and Totzke.

In the following a *gadget* G consists of a PVASS and two distinguished terminal states s and t. We consider vectors $\boldsymbol{x} \in \mathbb{N}^{2k}$ where the first k components are viewed the values of k counters $c_1, \ldots, c_k$ and the last k components are the values of k complementary counters $\bar{c}_1, \ldots, \bar{c}_k$. Without further mention, any update on a counter c is always understood with complementary update on $\bar{c}$ so that the sums $c_i + \bar{c}_i$ remain constant.

Given two numbers k, n (in unary), we will inductively construct a gadget G_k with stack alphabet Γ_k. This gadget will allow us to add $\exp^k(n)$ to a counter. The gadget's size will grow exponentially in k (and polynomially in n), and later, we improve the construction to grow only polynomially in k. The gadget G_1 simply increments c_1 by 2^n. Assuming G_{k-1} is already constructed, we construct the gadget G_k. The gadget $\bar{G}_{k-1}$ is obtained from G_{k-1} by reversing all transitions, and interchanging its terminal states. Its behavior is inverse to that of G_{k-1}, as it subtracts $\exp^{k-1}(n)$ from c_{k-1}. Let $Z_{k-1} = G_{k-1} \circ \bar{G}_{k-1}$ be the gadget obtained by composing G_{k-1} with $\bar{G}_{k-1}$, which is a zero test of c_{k-1}. We can naturally view G_{k-1}, $\bar{G}_{k-1}$ and Z_{k-1} as gadgets with $2k$ counters, where c_k and $\bar{c}_k$ are untouched. The gadget G_k is displayed in Figure 1 where $\mathtt{0}$ and $\mathtt{1}$ are fresh stack symbols and Inc_k is a subprocedure which increments the binary counter on the stack.

To prove correctness of the gadget G_k we need a bit of notation. For brevity we write $[x_1, \ldots, x_k]$ for $(x_1, \ldots, x_k, \exp^1(n) - x_1, \ldots, \exp^k(n) - x_k)$. Our gadgets will always assume that the "lower" counters c_j are set to zero and that the invariant is satisfied. A counter vector of the form $[0, \ldots, 0, x_i, \ldots, x_k]$ is called *i-initialized*. Moreover, we call a run $(s, \boldsymbol{u}, w) \xrightarrow{*} (t, \boldsymbol{v}, w')$ in a gadget *i-initialized* if either $\boldsymbol{u}$ or $\boldsymbol{v}$ is i-initialized.

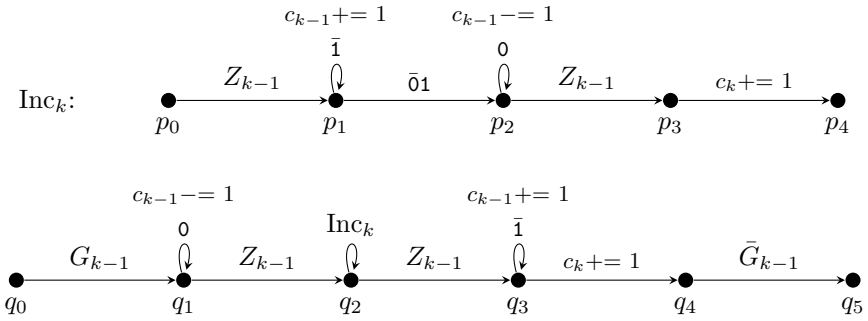

Figure 1 Gadgets Inc$_k$ and G_k.

▶ **Proposition 6.1.** *The k-initialized runs in G_k from q_0 to q_5 are precisely the runs*

$$(q_0, [0, \dots, 0], w) \xrightarrow{*}_{G_k} (q_5, [0, \dots, 0, \exp^k(n)], w) \quad \text{for } w \in \Gamma_{k-1}^*.$$

Next we will analyse the bidirected version of G_k. In order to distinguish the original transitions from the reverse transitions we define for a PVASS G the relations $\leftrightarrow_G = \rightarrow_G \cup \leftarrow_G$ and $\overset{*}{\leftrightarrow}_G$, denoting the reflexive transitive closure of $\leftrightarrow_G$. Similarly to the argument by Post [46, Lemma II], we can prove the following:

▶ **Proposition 6.2.** *Let $\boldsymbol{u}, \boldsymbol{v} \in \mathbb{N}^{2k}$ where $\boldsymbol{u}$ or $\boldsymbol{v}$ is k-initialized.*

- *If $(q_0, \boldsymbol{u}, w) \overset{*}{\leftrightarrow}_{G_k} (q_5, \boldsymbol{v}, w')$ then $(q_0, \boldsymbol{u}, w) \xrightarrow{*}_{G_k} (q_5, \boldsymbol{v}, w')$.*
- *If $q \in \{q_0, q_5\}$ and $(q, \boldsymbol{u}, w) \overset{*}{\leftrightarrow}_{G_k} (q, \boldsymbol{v}, w')$ then $\boldsymbol{u} = \boldsymbol{v}$ and $w = w'$.*

We need to reduce the size of G_k so that it can be constructed in time polynomial in k. Since G_k uses ten copies of the subgadget G_{k-1} (each zero test Z_{k-1} uses two copies of G_{k-1}), we cannot simply insert G_{k-1} by copying it, as this would induce exponential growth of the number of states of our system. Instead, we instantiate each gadget G_{k-1} once. Then, whenever a gadget would be used between two states p, q, we push a fresh stack symbol $t_{p,q}$ and move to G_{k-1}. When exiting G_{k-1} we pop $t_{p,q}$ and return to q. Since this symbol is unique for every pair of states, it uniquely determines where we can leave the gadget to, even if there are multiple incoming and outgoing transitions at the gadget G_{k-1}. Finally, one can verify that Proposition 6.2 still holds for this adapted version of G_k.

Simulating the counter program. We are ready to finish the lower bound proof. We are given a counter program of size n with three counters x_1, x_2, x_3 and want to reduce the $\exp^{k+1}(n)$-bounded halting problem to the reachability problem for bidirected PVASS using $2k + 6$ counters. To this end, we construct the gadget G_{k+1} three times: Each of these three instances has, instead of c_{k+1} (and its complement), a counter x_i (and its complement) for some $i \in \{1, 2, 3\}$. However, the three instances of G_{k+1} share the counters $c_1, \dots, c_k$ (and their complements). Thus, in total, we have $2 \cdot k + 2 \cdot 3 = 2k + 6$ counters. If k is fixed, this yields our k-EXPSPACE lower bound ([19]). If k is part of the input, the problem becomes TOWER-complete. We start by initializing the complement counters $\bar{c}_1, \dots, \bar{c}_k$ in sequence, using variants of the gadgets G_i that (i) operate on the balance counter $\bar{c}_i$ instead of c_i, (ii) do not decrement c_i when incrementing $\bar{c}_i$, and (iii) operate on the lower $i - 1$ counters as normal. Similarly we initialize $\bar{x}_1, \bar{x}_2, \bar{x}_3$ to $\exp^{k+1}(n)$. Finally, in order to have an all-zero configuration in the final state, we de-initialize these counters before entering the final state.

Increments and decrements in the counter program are directly translated into counter updates in the PVASS. A conditional **if** $x_i = 0$ **then goto** L_1 **else goto** L_2 is replaced by a nondeterministic guess of whether $x_i = 0$ or $x_i \neq 0$, verifying this (in)equality, and jumping

to L_1 or L_2. Here we use variants of the zero tests $Z_{k+1} = G_{k+1} \circ \bar{G}_{k+1}$ which on their highest level operate on x and $\bar{x}$ (instead of c_{k+1} and $\bar{c}_{k+1}$). The question of reachability of **halt** is then a reachability instance on the bidirected version of the PVASS.

If the counter program halts then we can find a corresponding computation in the PVASS. Conversely, consider a successful run of the bidirected PVASS which uses a minimal number of reverse transitions. By Proposition 6.2 we can assume that no gadget G_{k+1} and $\bar{G}_{k+1}$ (and their variants) is entered and exited through the same terminal state. Furthermore, any subrun passing through such a gadget can be assumed to use only forward transitions. Hence the only reverse transitions remaining are from increments or decrements. Observe that the last occurrence of such a reverse transition $\bar{\tau}$ must be followed by its corresponding forward transition τ. Hence we can cancel τ with $\bar{\tau}$, contradiction.

7 Conclusion

We have shown that the reachability problem in bidirected pushdown VASS is decidable, with an Ackermann upper bound and a TOWER lower bound. Moreover, in the one-dimensional case, the problem is in PSPACE, whereas P-hardness was shown in [21]. Thus, the exact complexity, both in the general and the one-dimensional case, remains open.

Another direction for future research is to study bidirected versions of other infinite-state models. For example, pushdown VASS are the simplest level in a hierarchy of infinite-state models for which decidability of the reachability problem is open [53]. Perhaps the techniques from this paper can be applied to show decidability of all levels in the bidirected setting.

Abstract

We consider the distributed control synthesis problem for systems with locks. The goal is to find local controllers so that the global system does not deadlock. With no restriction this problem is undecidable even for three processes each using a fixed number of locks. We propose two restrictions that make distributed control decidable. The first one is to allow each process to use at most two locks. The problem then becomes complete for the second level of the polynomial time hierarchy, and even in PTIME under some additional assumptions. The dining philosophers problem satisfies these assumptions. The second restriction is a nested usage of locks. In this case the synthesis problem is NEXPTIME-complete. The drinking philosophers problem falls in this case.

1 Introduction

Synthesis of distributed systems has a big potential since such systems are difficult to write, test, or verify. The state space and the number of different behaviors grow exponentially with the number of processes. This is where distributed synthesis can be more useful than centralized synthesis, because an equivalent, sequential system may be very big. The other important point is that distributed synthesis produces by definition a distributed system, while a synthesized sequential system may not be implementable on a given distributed architecture. Unfortunately, very few settings are known for which distributed synthesis is decidable, and those that we know require at least exponential time.

The problem was first formulated by Pnueli and Rosner [27]. Subsequent research showed that, essentially, the only decidable architectures are pipelines, where each process can send messages only to the next process in the pipeline [20, 23, 11]. In addition, the complexity is non-elementary in the size of the pipeline. These negative results motivated the study of distributed synthesis for asynchronous automata, and in particular synthesis with so called causal information. In this setting the problem becomes decidable for co-graph action alphabets [12], and for tree architectures of processes [14, 25]. Yet the complexity

is again non-elementary, this time w.r.t. the depth of the tree. Worse, it has been recently established that distributed synthesis with causal information is undecidable for unconstrained architectures [17]. Distributed synthesis for (safe) Petri nets [10] has encountered a similar line of limited advances, and due to [17], is also undecidable in the general case, since it is inter-reducible to distributed synthesis for asynchronous automata [3]. This situation raised the question if there is any setting for distributed synthesis that covers some standard examples of distributed systems, and is manageable algorithmically.

In this work we consider distributed systems with locks; each process can take or release a lock from a pool of locks. Locks are one of the most classical concepts in distributed systems. They are also probably the most frequently used synchronization mechanism in concurrent programs. We formulate our results in a control setting rather than synthesis – this avoids the need for a specification formalism. The objective is to find a local strategy for each process so that the global system does not get stuck. For unrestricted systems with locks we hit again an undecidability barrier, as for the models discussed above. Yet, we find quite interesting restrictions making distributed control synthesis for systems with locks decidable, and even algorithmically manageable.

The first restriction we consider is to limit the number of locks available to each process. The classical example are dining philosophers, where each philosopher has two locks corresponding to the left and the right fork. Observe that we do not limit the total number of processes, or the total number of locks in the system. We show that the complexity of this synthesis problem is at the second level of the polynomial hierarchy. The problem gets even simpler when we restrict it to strategies that cannot block a process when all locks are available. We call them *locally live strategies*. We obtain an NP-algorithm for locally live strategies, and even a Ptime algorithm when the access to locks is *exclusive*. This means that once a process tries to acquire a lock it cannot switch to some other action before getting the lock.

The second restriction is nested lock usage. This is a very common restriction in the literature [19], simply saying that acquiring and releasing locks should follow a stack discipline. Drinking philosophers [4] are an example of a system of this kind. We show that in this case distributed synthesis is Nexptime-complete, where the exponent in the algorithm depends only on the number of locks.

We formalize the distributed synthesis problem as a control problem [28]. A process is given as a transition graph where transitions can be local actions, or acquire/release of a lock. Some transitions are controllable, and some are not. A controller for a process decides which controllable transitions to allow, depending on the local history. In particular, the controller of a process does not see the states of other processes. Our techniques are based on analyzing patterns of taking and releasing locks. In decidable cases there are finite sets of patterns characterizing potential deadlocks.

The notion of patterns resembles locking disciplines [7], a tool frequently used to prevent deadlocks. An example of a locking discipline is "take the left fork before the right one" in the dining philosophers problem. Our results allow to check if a given locking discipline may result in a deadlock, and in some cases even list all deadlock-avoiding locking disciplines.

In summary, the main results of this work are:

- Σ_2^P-completeness of the deadlock avoidance control problem for systems where each process has access to at most 2 locks.
- An NP algorithm when additionally strategies need to be locally live.
- A Ptime algorithm when moreover lock access is exclusive.
- A Nexptime algorithm and the matching lower bound for the nested lock usage case.
- Undecidability of the deadlock avoidance control problem for systems with unrestricted access to locks.

Related work

Distributed synthesis is an old idea motivated by the Church synthesis problem [5]. Actually, the logic CTL has been proposed with distributive synthesis in mind [6]. Given this long history, there are relatively few results on distributed synthesis. Three main frameworks have been considered: synchronous networks of input/output automata, asynchronous automata, Petri games.

The synchronous network model has been proposed by Pnueli and Rosner [27]. They established that controller synthesis is decidable for pipeline architectures and undecidable in general. The undecidability result holds for very simple architectures with only two processes. Subsequent work has shown that in terms of network shape pipelines are essentially the only decidable case [20, 23, 11]. Several ways to circumvent undecidability have been considered. One was to restrict to local specifications, specifying the desired behavior of each automaton in the network separately. Unfortunately, this does not extend the class of decidable architectures substantially [23]. A further-going proposal was to consider only input-output specifications. A characterization, still very restrictive, of decidable architectures for this case is given in [13].

The asynchronous (Zielonka automata) model was proposed as a reaction to these negative results [12]. The main hope was that causal memory helps to prevent undecidability arising from partial information, since the synchronization of processes in this model makes them share information. Causal memory indeed allowed to get new decidable cases: co-graph action alphabets [12], connectedly communicating systems [24], and tree architectures [14, 25]. There is also a weaker condition covering these three cases [16]. This line of research suffered however from a very recent result showing undecidability in the general case [17].

Distributed synthesis in the Petri net model, Petri games, has been proposed recently in [10]. The idea is that some tokens are controlled by the system and some by the environment. Once again causal memory is used. Without restrictions this model is inter-reducible with the asynchronous automata model [3], hence the undecidability result [17] applies. The problem is EXPTIME-complete for one environment token and arbitrary many system tokens [10]. This case stays decidable even for global safety specifications, such as deadlock, but undecidable in general [9]. As a way to circumvent the undecidability, bounded synthesis has been considered in [8, 18], where the bound on the size of the resulting controller is fixed in advance. The approach is implemented in the tool ADAMSYNT [15].

The control formulation of the synthesis problem comes from the control theory community [28]. It does not require to talk about a specification formalism, while retaining most useful aspects of the problem. A frequently considered control objective is avoidance of undesirable states. In the distributed context, deadlock avoidance looks like an obvious candidate, since it is one of the most basic desirable properties. The survey [32] discusses the relation between the distributed control problem and Church synthesis. Some distributed versions of the control problem have been considered, also hitting the undecidability barrier very quickly [29, 31, 30, 1].

We would like to mention two further results that do not fit into the main threads outlined above. In [33] the authors consider a different synthesis problem for distributed systems: they construct a centralized controller for a scheduler that would guarantee absence of deadlocks. This is a very different approach to deadlock avoidance. Another recent work [2] adds a new dimension to distributed synthesis by considering communication errors in a model with synchronous processes that can exchange their causal memory. The authors show decidability of the synthesis problem for 2 processes.

Outline of the paper

In the next section we define systems with locks, strategies, and the control problem. We introduce locally live strategies as well as the 2-lock, exclusive, and nested locking restrictions. This permits to state the main results of the paper. The following three sections consider systems with the 2-lock restriction. First, we briefly give intuitions behind the Σ_2^p-completeness in the general case. Section 4 presents an NP algorithm for the distributed synthesis problem for locally live strategies. Section 5 gives a PTIME algorithm under the exclusive restriction. Next, we consider the nested locking case, and show that the problem is NEXPTIME-complete. Finally, we prove that without any restrictions the synthesis problem for systems with locks is undecidable. The full version can be found at `https://arxiv.org/4272787`.

2 Main definitions and results

A *lock-sharing system* is a distributed system with components (processes) synchronizing over locks. Processes do not communicate, but they synchronize using locks from a global pool. Some transitions of processes are uncontrollable, intuitively the environment decides if such a transition is taken. The goal is to find a local strategy for each process so that the entire system never deadlocks. The strategy can observe only local transitions – it does not see transitions performed by other processes, nor states other processes are in. While the system is finite state, the challenge comes from the locality of strategies. Indeed, the unrestricted problem is undecidable. The main contribution of this work are restrictions that make the problem decidable, and even solvable in PTIME.

In this section we define lock-sharing systems, strategies, and the deadlock avoidance control problem, that is the topic of this paper. We then introduce restrictions on the general problem and state the main decidability and complexity results.

A finite-state *process* p is an automaton $\mathcal{A}_p = (S_p, \Sigma_p, T_p, \delta_p, init_p)$ with a set of locks T_p that it can acquire or release. The transition function $\delta_p : S_p \times \Sigma_p \dot{\to} Op(T_p) \times S_p$ associates with a state from S_p and an action from Σ_p an operation on some lock and a new state; it is a partial function. The lock operations are acquire ($\mathtt{acq}_t$) or release ($\mathtt{rel}_t$) some lock t from T_p, or do nothing: $Op(T_p) = \{\mathtt{acq}_t, \mathtt{rel}_t \mid t \in T_p\} \cup \{nop\}$. Figure 1 gives an example.

A *local configuration* of process p is a state from S_p together with the locks p currently owns: $(s, B) \in S_p \times 2^{T_p}$. The initial configuration of p is $(init_p, \emptyset)$, namely the initial state with no locks. A transition between configurations $(s, B) \xrightarrow{a,op} (s', B')$ exists when $\delta_p(s, a) = (op, s')$ and one of the following holds:

- $op = nop$ and $B = B'$;
- $op = \mathtt{acq}_t$, $t \notin B$ and $B' = B \cup \{t\}$;
- $op = \mathtt{rel}_t$, $t \in B$, and $B' = B \setminus \{t\}$.

A *local run* $(a_1, op_1)(a_2, op_2) \cdots$ of $\mathcal{A}_p$ is a finite or infinite sequence over $\Sigma_p \times Op(T_p)$ such that there exists a sequence of configurations $(init_p, \emptyset) = (s_0, B_0) \xrightarrow{(a_1,op_1)}_p (s_1, B_1) \xrightarrow{(a_2,op_2)}_p \cdots$ While the run is determined by the sequence of actions, we prefer to make lock operations explicit. We write $Runs_p$ for the set of runs of $\mathcal{A}_p$.

A *lock-sharing system* $\mathcal{S} = ((\mathcal{A}_p)_{p \in Proc}, \Sigma^s, \Sigma^e, T)$ is a set of processes together with a partition of actions between *controllable* and *uncontrollable* actions, and a set T of locks. We have $T = \bigcup_{p \in Proc} T_p$, for the set of all locks. Controllable and uncontrollable actions belong to the system and to the environment, respectively. We write $\Sigma = \bigcup_{p \in Proc} \Sigma_p$ for the set of actions of all processes and require that (Σ^s, Σ^e) partitions Σ. The sets of states and action alphabets of processes should be disjoint: $S_p \cap S_q = \emptyset$ and $\Sigma_p \cap \Sigma_q = \emptyset$ for $p \neq q$. The sets of locks are not disjoint, in general, since processes may share locks.

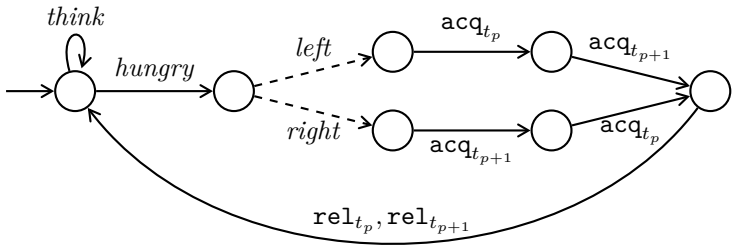

Figure 1 A dining philosopher p. Dashed transitions are controllable.

▶ **Example 1.** The dining philosophers problem can be formulated as control problem for a lock-sharing system $\mathcal{S} = ((\mathcal{A}_p)_{p\in Proc}, \Sigma^s, \Sigma^e, T)$. We set $Proc = \{1, \dots, n\}$ and $T = \{t_1, \dots, t_n\}$ as the set of locks. For every process $p \in Proc$, process $\mathcal{A}_p$ is as in Figure 1, with the convention that $t_{n+1} = t_1$. Actions in Σ^s are marked by dashed arrows. These are controllable actions. The remaining actions are in Σ^e. Once the environment makes a philosopher p hungry, she has to get both the left (t_p) and the right (t_{p+1}) fork to eat. She may however choose the order in which she takes them; actions *left* and *right* are controllable.

A *global configuration* of $\mathcal{S}$ is a tuple of local configurations $C = (s_p, B_p)_{p\in Proc}$ provided the sets B_p are pairwise disjoint: $B_p \cap B_q = \emptyset$ for $p \neq q$. This is because a lock can be taken by at most one process at a time. The initial configuration is the tuple of initial configurations of all processes.

Such systems are *asynchronous*, with transitions between two configurations done by a single process: $C \xrightarrow{(p,a,op)} C'$ if $(s_p, B_p) \xrightarrow{(a,op)}_p (s'_p, B'_p)$ and $(s_q, B_q) = (s'_q, B'_q)$ for every $q \neq p$. A global run is a sequence of transitions between global configurations. Since our systems are deterministic we usually identify a global run by the sequence of transition labels. A global run w *determines a local run* of each process: $w|_p$ is the subsequence of p's actions in w.

A *control strategy* for a lock-sharing system is a tuple of local strategies, one for each process: $\sigma = (\sigma_p)_{p\in Proc}$. A *local strategy* σ_p says which actions p can take depending on a local run so far: $\sigma_p : Runs_p \to 2^{\Sigma_p}$, provided $\Sigma^e \cap \Sigma_p \subseteq \sigma_p(u)$, for every $u \in Runs_p$. This requirement says that a strategy cannot block environment actions.

A local run u of a system *respects* σ_p if for every non-empty prefix $v(a, op)$ of u, we have $a \in \sigma_p(v)$. Observe that local runs are affected only by the local strategy. A global run w respects σ if for every process p, the local run $w|_p$ respects σ_p. We often say just σ-run, instead of "run respecting σ".

As an example consider the system for two philosophers from Example 1. Suppose that both local strategies always say to take the *left* transition. So $hungry^1, left^1, \mathtt{acq}^1_{t_1}, \mathtt{acq}^1_{t_2}$ is a local run of process 1 respecting the strategy; similarly $hungry^2, left^2, \mathtt{acq}^2_{t_2}, \mathtt{acq}^2_{t_1}$ for process 2. (We use superscripts to indicate the process doing an action.) The global run $hungry^1, hungry^2, left^1, left^2, \mathtt{acq}^1_{t_1}, \mathtt{acq}^2_{t_2}$ respects the strategy and blocks, since each philosopher needs a lock the other one owns.

▶ **Definition 2** (Deadlock avoidance control problem). *A σ-run w* leads to a deadlock in *σ if w cannot be prolonged to a σ-run. A control strategy σ is* winning *if no σ-run leads to a deadlock in σ. The* deadlock avoidance control problem *is to decide if for a given system there is some winning control strategy.*

In this work we consider several variants of the deadlock avoidance control problem. Maybe surprisingly, in order to get more efficient algorithms we need to exclude strategies that can block a process by itself:

▶ **Definition 3** (Locally live strategy). *A local strategy σ_p for process p is* locally live *if every local σ_p-run u can be prolonged to a σ_p-run: there is some $b \in \Sigma_p$ such that ub is a local run respecting σ_p. A strategy σ is* locally live *if every local strategy is so.*

In other words, a locally live strategy guarantees that a process does not block if it runs alone. Coming back to Example 1: a strategy always offering one of the *left* or *right* actions is locally live. A strategy that offers none of the two is not. Observe that blocking one process after the hungry action is a very efficient strategy to avoid a deadlock, but it is not the intended one. This is why we consider locally live to be a desirable property rather than a restriction.

Note that being locally live is not exactly equivalent to a strategy always proposing at least one outgoing transition. In our semantics, a process blocks if it tries to acquire a lock that it already owns, or to release a lock it does not own. But it becomes equivalent thanks to the following remark:

▶ Remark 4. We can assume that each process keeps track in its state which locks it owns. Note that this assumption does not compromise the complexity results when the number of locks a process can access is fixed. We will not use this assumption in Section 6, where a process can access arbitrarily many locks (in nested fashion).

Without any restrictions our synthesis problem is undecidable.

▶ **Theorem 5.** *The deadlock avoidance control problem for lock-sharing systems is undecidable. It remains so when restricted to locally live strategies.*

We propose two cases when the control problem becomes decidable. The two are defined by restricting the usage of locks.

▶ **Definition 6** (2LSS). *A process $\mathcal{A}_p = (S_p, \Sigma_p, T_p, \delta_p, init_p)$* uses two locks *if $|T_p| = 2$. A system $\mathcal{S} = ((\mathcal{A}_p)_{p \in Proc}, \Sigma^s, \Sigma^e, T)$ is 2LSS if every process uses two locks.*

Note that in the above definition we do not bound the total number of locks in the system, just the number of locks per process. The process from Figure 1 is 2LSS. Our first main result says that the control problem is decidable for 2LSS.

▶ **Theorem 7.** *The deadlock avoidance control problem for 2LSS is Σ_2^p-complete.*

For the lower bound we use strategies that take a lock and then block. This does not look like a very desired behavior, and this is the reason for introducing the concept of locally live strategies. The second main result says that restricting to locally live strategies helps.

▶ **Theorem 8.** *The deadlock avoidance control problem for 2LSS is in* NP *when strategies are required to be locally live.*

We do not know if the above problem is in Ptime. We can get a Ptime algorithm under one more assumption.

▶ **Definition 9** (Exclusive systems). *A process p is* exclusive *if for every state $s \in S_p$: if s has an outgoing transition with some $\mathtt{acq}_t$ operation then all outgoing transitions of s have the same $\mathtt{acq}_t$ operation. A system is exclusive if all its processes are.*

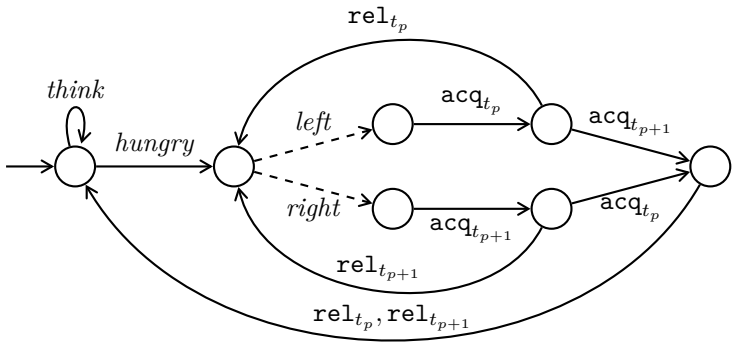

Figure 2 A flexible philosopher p. She can release a fork if the other fork is not available.

▶ **Example 10.** The process from Figure 1 is exclusive, while the one from Figure 2 is not. The latter has a state with one $\texttt{acq}_{t_{p+1}}$ and one $\texttt{rel}_{t_p}$ outgoing transition. Observe that in this state the process cannot block, and has the possibility to take a lock at the same time. Exclusive systems do not have such a possibility, so their analysis is much easier.

▶ **Theorem 11.** *The deadlock avoidance control problem for exclusive 2LSS is in* PTIME*, when strategies are required to be locally live.*

Without local liveness, the problem stays Σ_2^p-hard for exclusive 2LSS. Our last result uses a classical restriction on the usage of locks:

▶ **Definition 12** (Nested-locking)**.** *A local run is* nested-locking *if the order of acquiring and releasing locks in the run respects a stack discipline, i.e., the only lock a process can release is the last one it acquired. A local strategy is nested-locking if all local runs respecting the strategy are nested-locking. A strategy is nested-locking if all local strategies are nested-locking.*

The process from Figure 1 is nested-locking, while the one from Figure 2 is not.

▶ **Theorem 13.** *The deadlock avoidance control problem is* NEXPTIME*-complete when strategies are required to be nested-locking.*

3 Two locks per process

We give some intuitions as to why the deadlock avoidance problem for 2LSS is Σ_2^p-complete (Theorem 7).

When every process uses only two locks there are only few patterns of local lock usage that are relevant for deadlocks. A finite local run u of process p using locks t_1, t_2 can be of one of the following four types:

- p owns both locks at the end of u;
- p owns no lock at the end of u;
- p owns only one lock, say t_1, at the end of u, and the last lock operation of u is $\texttt{acq}_{t_1}$;
- p owns only one lock, say t_1, at the end of u, and the last lock operation of u is $\texttt{rel}_{t_2}$.

A *pattern* of a run is its type, and the set of available actions at the end. If a run reaches a deadlock then the only available actions are to acquire locks owned by other processes.

We fix a 2LSS $(\{\mathcal{A}_p\}_{p\in Proc}, \Sigma^s, \Sigma^e, T)$ over the set of processes *Proc*. We assume that it satisfies Remark 4.

Given a strategy $\sigma = (\sigma_p)_{p \in Proc}$, we call a local σ-run *risky* if it ends in a state from which every outgoing action allowed by σ acquires some lock (this includes states with no outgoing transition). A local σ-run is *neutral* if it ends in a configuration (s, B) with $B = \emptyset$.

▶ **Definition 14.** *We define the* pattern *of a* ***risky*** σ_p*-run* u_p *as follows. Let* T_{owns} *be the set of locks that* p *owns after executing* u_p *and* T_{blocks} *the set of locks that outgoing transitions allowed by* σ_p *after* u_p *need to acquire.*

The pattern of u_p *is the tuple* $(T_{owns}, T_{blocks}, ord)$ *with:*

- *If* u_p *is of the form* $u_1(a, \mathtt{acq}_{t_1})u_2(b, \mathtt{rel}_{t_2})u_3$ *with no action on* t_1 *in* u_2 *and no action on either* t_1 *or* t_2 *in* u_3 *then* $ord = (t_1, t_2)$*.*
- *Otherwise* $ord = \bot$*.*

Note that in light of Remark 4, T_{owns} *and* T_{blocks} *are necessarily disjoint. Furthermore if* ord *is of the form* (t_1, t_2) *then* $T_{owns} = \{t_1\}$*, and either* $T_{blocks} = \emptyset$ *or* $T_{blocks} = \{t_2\}$*.*

A strategy $\sigma = (\sigma_p)_{p \in Proc}$ respects *a family of sets of patterns* $(Patt_p)_{p \in Proc}$ *if for all* $p \in Proc$*, the patterns of all risky* σ_p*-runs belong to* $Patt_p$*.*

In this definition, T_{owns} and T_{blocks} serve as witnesses of deadlock configurations, in which all required locks are owned by another process, and no lock is owned by two different processes. Further, the *ord* component indicates the fourth case described before the definition.

Our key result in this part is Lemma 15. It gives simple, necessary and sufficient, conditions on the family of patterns of local σ-runs $(u_p)_{p \in Proc}$ that lead to a deadlock under a suitable scheduling. The difficulty is to verify if there exists a global run which is a combination of those local runs. For that, all processes must own disjoint sets of locks at the end. The rest can be inferred from the types of runs listed above.

We describe how to schedule local runs into a global one depending on the four types listed before Definition 14.

- In the first case we can assume that p's run is scheduled at the end of the global run, as it ends up keeping both locks anyway, so no other process will use them after p.
- In the second case, we can assume that p's run is scheduled at the beginning of the global run, as it is neutral.
- In the third case, we can split p's run in two parts: a first, neutral part which can be scheduled at the beginning, and a second part in which p acquires t_1 and there is no lock operation afterwards. The second part can be scheduled at the end, because no other process will use t_1 after p.
- In the final case, p acquires t_1, never releases it but later uses t_2. This can be a problem if for instance another process does the same with t_1 and t_2 reversed. The first process that takes its first lock would prevent the other from finishing its local run. We express these constraints by requiring the existence of a global order in which process take locks without releasing them.

▶ **Lemma 15.** *Let* $\sigma = (\sigma_p)_{p \in Proc}$ *be a control strategy. For all* p *let* $Patt_p$ *be the set of patterns of local risky* σ_p*-runs of* p*. The control strategy* σ *is* ***not*** *winning if and only if there exists for each* p *a pattern* $(T^p_{owns}, T^p_{blocks}, ord_p) \in Patt_p$ *such that:*

- $\bigcup_{p \in Proc} T^p_{blocks} \subseteq \bigcup_{p \in Proc} T^p_{owns}$*,*
- *the sets* T^p_{owns} *are pairwise disjoint,*
- *there exists a total order* $\leq$ *on* T *such that for all* p*, if* $ord_p = (t, t')$ *then* $t \leq t'$*.*

Proof. Suppose σ is not winning, let u be a run ending in a deadlock. For each process p let u_p be the corresponding local run. The local run u_p is risky, as otherwise u_p could be extended in a longer run consistent with σ. Thus u_p has a pattern $(T^p_{owns}, T^p_{blocks}, ord_p) \in Patt_p$.

We check that those patterns $(u_p)_{p \in Proc}$ meet the requirements of the lemma. Clearly as we are in a deadlock, all locks that some process wants are taken, hence the first condition is satisfied. Furthermore, no two processes can own the same lock, implying the second condition. Finally, let $\leq$ be a total order on locks given by the order of the last operations on each lock in u: we set $t \leq t'$ iff the last operation on t in u is before the last one on t'. Let p be a process, and suppose ord_p is (t, t'). Then u_p has the form $u_1(a, \mathtt{acq}_t)u_2(b, \mathtt{rel}_{t'})u_3$ with no action on t in u_2 or u_3. Hence, $t \leq t'$.

The other direction is a bit more complicated. Suppose that for each p there is a pattern $(T^p_{owns}, T^p_{blocks}, ord_p) \in Patt_p$ such that those patterns satisfy all three conditions of the lemma. Let $\leq$ be a suitable total order on locks for the third condition, and let $<$ be its strict part. For every p there exists a risky local run u_p yielding the chosen pattern for p.

We start by executing all neutral runs u_p one by one in some order. All locks are free after these executions.

For all p such that $T^p_{owns} = \{t\}$ and $ord_p = \bot$, we can decompose u_p as $u_1(a, \mathtt{acq}_t)u_2$ with no action on locks in u_2. We execute all runs u_1, which are neutral and thus leave all locks free after execution.

Finally, we execute all u_p such that $ord_p \neq \bot$ in increasing order on the first component of ord_p according to $\leq$. For all such p, let $(t, t') = ord_p$, so we have $T^p_{owns} = \{t\}$ and $t < t'$. As all T^p_{owns} are disjoint, before executing u_p all locks greater or equal to t according to $\leq$ are free. In particular, t and t' are free, thus we can execute u_p. In the end all locks are free except the ones belonging to T^p_{owns} for those processes p.

Now we execute the remaining part of the u_p with $T^p_{owns} = \{t\}$ and $ord_p = \bot$ (referred to as $(a, \mathtt{acq}_t)u_2$ before). Those runs do not contain any action on locks besides the first acquire. As all T^p_{owns} are disjoint, the locks they acquire are free, hence all those runs can be executed.

The remaining runs are the ones such that $T^p_{owns} = \{t, t'\}$. As all T^p_{owns} are disjoint, both these locks are free, hence u_p can be executed as p can only use these two locks.

We have combined all local runs into one global run reaching a configuration where all processes have to acquire a lock from $\bigcup_{p \in Proc} T^p_{blocks}$ to keep running, and all locks in $\bigcup_{p \in Proc} T^p_{owns}$ are taken. As $\bigcup_{p \in Proc} T^p_{blocks} \subseteq \bigcup_{p \in Proc} T^p_{owns}$, we have reached a deadlock. ◀

The algorithm for Theorem 7 proceeds in four phases:

- guess a set of patterns $Patt_p$, one for each process p,
- check that there are local strategies σ_p such that the patterns of all runs belong to $Patt_p$,
- let the adversary guess a pattern in each $Patt_p$,
- check whether those patterns satisfy the conditions of Lemma 15.

The alternation between guessing and adversarial guessing yields a Σ^p_2 algorithm.

The lower bound is obtained by a reduction from $\exists\forall$-SAT. The system controls existential variables, the environment controls universal ones. There are two locks for each variable, acquiring one of them is interpreted as choosing the value of the variable. Note that this construction relies on processes that take a lock and then block on their own in states with no outgoing transitions. In the following section we will forbid such unnatural behavior by considering only locally live strategies.

We use some extra processes to enforce that the system wins if and only if the valuation given by the choices of the two players satisfies the SAT formula. The interesting part is that even though it looks like the guessing values of variables is done concurrently by the system and the environment, the whole setting enforces a $\exists\forall$ dependency.

4 Two locks per process with locally live strategies

We describe how to solve the control problem for 2LSS and locally live strategies in NP, as stated in Theorem 8.

We fix a 2LSS satisfying the assumption discussed in Remark 4. We will show that the relevant information about a strategy σ can be formalized as a finite lock graph G_σ and a lockset family $Locks_\sigma$; the latter is a family of sets of sets of locks (see definitions below). This information is very similar to the one described by patterns in the previous section. As we work with locally live strategies, the set of possible patterns of local runs is more restricted and we can view this more conveniently as a graph.

Our algorithm first guesses an abstract lock graph G and lockset family $Locks$. Then it performs two checks:

Step 1 check if there is some strategy σ with $G = G_\sigma$ and $Locks = Locks_\sigma$, and

Step 2 check if there is no deadlock scheme for G and $Locks$ (see Definition 21 below).

A deadlock scheme is some kind of forbidden situation. It is easy to get a co-NP algorithm for the second step: just guess the scheme and check that it has the right shape. The challenge is to do this in PTIME. This is necessary if we want to get an NP algorithm.

We introduce now some notions in order to define G_σ and $Locks_\sigma$ conveniently. Consider a local run u of a process p:

$$(init_p, \emptyset) = (s_0, B_0) \xrightarrow{(a_1, op_1)}_p (s_1, B_1) \cdots \xrightarrow{(a_i, op_i)}_p (s_i, B_i) \ .$$

We say that u *has set of locks* B if $B = B_i$. A σ_p-run u is B*-locked* by the local strategy σ_p if every transition in $\sigma_p(u)$ has as operation $\mathtt{acq}_t$ for some $t \in B$. Process p is B*-lockable* by σ_p if it has a neutral, B-locked σ_p-run.

The intuition is that in order to get a deadlock, a B-lockable process can be scheduled first. It can do a run leading to a state where it requires some of the locks in B without holding any locks. So, the process will be blocked if we ensure that all locks in B are already taken. For example, consider the process in Figure 1. The run *hungry*, *left* is $\{t_p\}$-locked, as the unique next action is $\mathtt{acq}_{t_p}$. The process is $\{t_p\}$-lockable by σ_p if e.g. σ_p always chooses the *left* action. Indeed, in this case the run *hungry*, *left* is a neutral σ_p-run, which is $\{t_p\}$-locked. Process p is not $\{t_{p+1}\}$-lockable by a strategy σ_p choosing always the *left* action, as there is no neutral σ_p-run leading to $\mathtt{acq}_{t_{p+1}}$.

▶ **Definition 16** (Lockset family $Locks_\sigma$)**.** *A* lockset *for a local strategy σ_p is a set $L_p \subseteq 2^{T_p}$ of sets B such that p is B-lockable by σ_p. A* lockset family *for σ is $Locks_\sigma = (L_p)_{p \in Proc}$.*

▶ **Definition 17** (Lock graph G_σ)**.** *For a strategy σ, a* lock graph $G_\sigma = \langle T, E_\sigma \rangle$ *has an edge $t_1 \xrightarrow{p} t_2$ whenever there is some σ_p-run u of p that has $\{t_1\}$ and is $\{t_2\}$-locked. If there is such a run u where the last lock operation in u is $\mathtt{acq}_{t_1}$ then the edge is called* green*, and otherwise it is called* blue*.*

We will say that σ allows *a blue edge $t_1 \overset{p}{\hookrightarrow} t_2$ or a green edge $t_1 \overset{p}{\mapsto} t_2$. We write $t_1 \xrightarrow{p} t_2$ when the color of the edge is irrelevant.*

For example, a strategy choosing the *left* action in Figure 1 yields the green edge $t_p \overset{p}{\mapsto} t_{p+1}$. Lockset families say on which sets of locks each process can block while not holding any lock. An edge $t_1 \xrightarrow{p} t_2$ in the lock graph corresponds to a run of p where P owns lock t_1 (the source of the edge) and waits for the other lock t_2 (the target of the edge).

A lockset represents a run of the second type in the previous section, a green edge a run of the third type, and a blue edge a run of the fourth type with no similar run of the third type. The first type cannot appear in a deadlock when strategies are locally live, as processes always have an available action.

Since we have assumed nothing about how strategies are given, it is not clear how to compute G_σ. Instead of restricting to, say, finite memory strategies, we will work with arbitrary lock graphs and lockset families. This is possible thanks to Lemma 19 below, that allows to check if a graph is the lock graph of some strategy. For this we need to define lockset families and lock graphs abstractly. Notice that the size of both these objects is bounded, as the set of locks per process is fixed for 2LSS.

▶ **Definition 18.** *A* lockset family *is a tuple of sets of locks indexed by processes* $(L_p)_{p\in Proc}$*, with* $L_p \subseteq 2^{T_p}$*. A* lock graph *is an edge-labeled graph* $G = \langle T, E \subseteq T\times Proc\times\{blue, green\}\times T\rangle$ *where nodes are locks from the set* T *and every edge is labeled by a process and a color. A cycle in* G *is called* proper *if all its edges are labeled by different processes. It is denoted as* green *if it contains at least* ***one*** *green edge; otherwise, so if* ***all*** *edges are blue, it is denoted* blue.

At this point we have enough notions to carry out the first step on page 10.

▶ **Lemma 19.** *Given a lock graph* G *and a lockset family Locks, it is decidable in* Ptime *if there is a locally live strategy* σ *such that* $G = G_\sigma$ *and* $Locks_\sigma = Locks$*.*

The proof is by reduction to model-checking a fixed-size MSOL formula over a given regular tree. For every process p we need to check if there is a local strategy σ_p satisfying the conditions imposed by G and $Locks = (L_p)_{p\in Proc}$. Consider the regular tree of all local runs of process p. The formula says that there is a strategy tree inside this regular tree such that L_p contains exactly those sets B such that the subtree has some neutral, B-locked path; and for every edge in G labelled by p there is a path of the required shape in the subtree. This can be expressed by an MSOL formula of constant size, as the process uses only 2 locks. From the MSOL formula we get a tree automaton of constant size. The emptiness check of its product with the tree automaton accepting the unfolding of the automaton $\mathcal{A}_p$ can be done in Ptime.

In the rest of the section we discuss the second step. We first define a Z-deadlock scheme for some set Z of locks. Intuitively, this is a situation showing that there is a run blocking all locks in Z. Then a deadlock scheme is a Z-deadlock scheme for some Z big enough to block all processes.

▶ **Definition 20** (Z-deadlock scheme)**.** *Let* $G = \langle T, E\rangle$ *be a lock graph,* $Locks = (L_p)_{p\in Proc}$ *a lockset family, and* Z *a set of locks. We define* $Proc_Z$ *as the set of processes whose both accessible locks are in* Z*,* $Proc_Z = \{p \in Proc : T_p \subseteq Z\}$*. A* Z-deadlock scheme *is a function* $ds_Z : Proc_Z \to E \cup \{\bot\}$ *such that:*

- *For all* $p \in Proc_Z$*, if* $ds_Z(p) \neq \bot$ *then* $ds_Z(p)$ *is an edge of* G *labeled by* p*.*
- *If* $p \in Proc_Z$ *and* $L_p = \emptyset$ *then* $ds_Z(p) \neq \bot$*.*
- *For all* $t \in Z$ *there exists a unique* $p \in Proc_Z$ *such that* $ds_Z(p)$ *is an outgoing edge from* t*.*
- *The subgraph of* G*, restricted to* $ds_Z(Proc_Z)$ *does not contain any blue cycle.*

The main point of this definition is that for every lock in Z there is an outgoing edge in ds_Z. Intuitively, it means that we have a run where every lock from Z is taken, and every process in $Proc_Z$ requires a lock from Z.

▶ **Definition 21** (Deadlock scheme)**.** *A* deadlock scheme *for* G *and* $Locks = (L_p)_{p\in Proc}$ *is a* Z*-deadlock scheme such that for every process* $p \in Proc \setminus Proc_Z$ *there is* $B \in L_p$ *with* $B \subseteq Z$*.*

Thus a deadlock scheme represents a situation where all processes are blocked, since every process not in $Proc_Z$ can be brought into a state where it needs a lock from Z, but all these locks are taken.

The next lemma says that the absence of deadlock schemes characterizes winning strategies. We could reuse the patterns defined above to obtain a shorter proof but we prefer to give a slightly longer but elementary one.

▶ **Lemma 22.** *A locally live control strategy σ is winning if and only if there is no deadlock scheme for its lock graph G_σ and its lockset family $Locks_\sigma$.*

Proof. Suppose σ is not winning. Then there exists a global σ-run u leading to a deadlock. As a consequence, in the deadlock configuration all processes must be trying to acquire some lock that is already taken.

We then construct a deadlock scheme (BT, ds) as follows. Let BT be the set of locks taken in the deadlock configuration, and for all $p \in Proc$, define $ds(p)$ as:

- $\bot$ if p does not own any lock in the deadlock configuration,
- $t_1 \xrightarrow{p} t_2$ if p owns t_1 and is trying to acquire t_2 in the deadlock configuration (the color of the edge is determined by the run, it is irrelevant for the argument).

Clearly for all $p \in Proc$ the value $ds(p)$ is either $\bot$ or a p-labeled edge of the lock graph G_σ.

Suppose $ds(p) = \bot$, and let t_1, t_2 be the two locks accessible by p. As the final configuration is a deadlock, all actions allowed by σ_p are necessarily $\texttt{acq}_{t_1}$ or $\texttt{acq}_{t_2}$. So p is $\{t_1, t_2\}$-lockable. Furthermore, as we are in a deadlock, the lock(s) blocking p are in BT (if they were free, p would be able to advance), therefore p is BT-lockable.

For every $t \in BT$, there is a process p holding t in the final configuration. As we are in a deadlock, p is trying to acquire its other accessible lock t' (recall that the definition of control strategy demands that at least one action be available to each process at all times). Thus $ds(p)$ is an edge from t to t'. Furthermore t' cannot be free as we are in a deadlock, thus $t' \in BT$. There are no other outgoing edges from t as no other process can hold t while p does.

Finally let $t_1 \xrightarrow{p_1} t_2 \cdots \xrightarrow{p_k} t_{k+1}$ be a cycle with $t_1 = t_{k+1}$ in the subgraph of G_σ restricted to BT and $ds(Proc)$. One of the locks t_i was the last lock taken in the run u (say by process p_i). We show now by contradiction that the edge $t_i \xrightarrow{p_i} t_{i+1}$ is green. If p_i would have released t_{i+1} after the last $\texttt{acq}_{t_i}$ in u, then p_{i+1} would have done its last $\texttt{acq}_{t_{i+1}}$ later, a contradiction. The subgraph of G_σ restricted to BT and $ds(Proc)$ has therefore no blue cycles, therefore (BT, ds) is a deadlock scheme.

For the other direction, suppose we have a deadlock scheme (BT, ds) for the lock graph G_σ. As $(BT, ds(Proc))$ does not contain a blue cycle, we can pick a total order $\leq$ on locks such that for all blue edges $t_1 \overset{p}{\hookrightarrow} t_2 \in ds(Proc)$, we have $t_1 \leq t_2$.

By definition of the lock graph, for each process $p \in Proc$ we can take a local run u_p of $\mathcal{A}_p$ respecting σ with the following properties.

- If $ds(p) = \bot$ then p is BT-lockable. So there exists a neutral run u_p leading to a state where all outgoing transitions require locks from BT.
- If $ds(p) = t_p^1 \xrightarrow{p} t_p^2$ then there is u_p of the form $u_p^1(a, \texttt{acq}_{t_p^1})u_p^2(a', \texttt{acq}_{t_p^2})$ without $\texttt{rel}_{t_p^1}$ transition in u_p^2. Moreover if $ds(p)$ is green then we know that there is no $\texttt{rel}_{t_p^2}$ transition in u_p^2.

We now combine these runs to get a run respecting σ ending in a deadlock configuration. For each process p such that $ds(p) = \bot$, execute the local run u_p. Since u_p is neutral, all locks are available after executing it. The only possible actions of p after this run are to acquire some locks from BT.

Next, for every process p such that $ds(p)$ is a green edge, execute the local run u_p^1. This is also a neutral run. After this run p is in a state where σ_p allows to take lock t_p^1, but p does not own any lock.

Next, in increasing order according to $\leq$, for every lock t with an outgoing blue edge $ds(p) = t \overset{p}{\hookrightarrow} t'$ execute the run u_p, except for the last $\mathtt{acq}_{t'}$ action. After this run lock t is taken by p, and all actions allowed by σ_p are $\mathtt{acq}_{t'}$ actions. Since there is only one outgoing edge from every lock, and since we are respecting the order $\leq$, both t and t' are free before executing that run. Hence it is possible to execute this run.

Finally, we come back to processes p such that $ds(p)$ is a green edge. For every such process we execute $\mathtt{acq}_{t_p^1}$ followed by u_p^2. This is possible because t_p^1 is free as there is a unique outgoing edge from t_p^1. After executing these runs every process p with $ds(p) \neq \bot$ is in a state when the only possible action is $\mathtt{acq}_{t_p^2}$.

At this stage all locks that are sources of edges from $ds(Proc)$ are taken. Since every lock in BT is a source of an edge, all locks from BT are taken. Thus no process p with $ds(p) = \bot$ can move as it needs some lock from BT. Similarly, no process p with $ds(p) \neq \bot$ can move, as they need locks pointed by targets of the edges $ds(p)$, and these are in BT too. So we have constructed a run respecting σ and reaching a deadlock. ◀

From now on we concentrate on deciding if there is some deadlock scheme for a given graph G along with a lockset family *Locks*. Our approach will be to repeatedly eliminate edges from G or add locks to Z, and construct a deadlock scheme on Z at the same time.

As a preparatory step we observe that we can almost ignore the lockset family. Examining the definition of Z-deadlock scheme we see that the only information about *Locks* it uses is whether $L_p = \emptyset$ or not. Hence we call a process *solid* if $L_p = \emptyset$, and *fragile* otherwise. The second condition in the definition of Z-deadlock scheme becomes: if $p \in Proc_Z$ is solid then $ds_Z(p) \neq \bot$.

The next lemma gives an important composition principle for deadlock schemes. Suppose we already have a set of "kernel" locks Z on which we know how to construct a Z-deadlock scheme. Then the lemma says that in order to get a deadlock scheme for G it is enough to consider the remaining part $G \setminus Z$.

▶ **Lemma 23.** *Let $Z \subseteq T$ be such that there is no edge labeled by a solid process from a lock of Z to a lock of $T \setminus Z$ in G. Suppose $ds_Z : Proc_Z \to E \cup \{\bot\}$ is a Z-deadlock scheme. Then there is a deadlock scheme for G if and only if there is one equal to ds_Z over $Proc_Z$.*

The rest of the proof is a sequence of stages. We start with $H = G$ and $Z = \emptyset$. At each stage we remove some edges in H or extend Z. This process continues till some obstacle to the existence of a deadlock scheme is found, or till Z is big enough to be a deadlock scheme. We use three invariants:

▶ **Invariant 1.** *G admits a deadlock scheme if and only if H does.*

▶ **Invariant 2.** *There are no edges labeled by a solid process from Z to $T \setminus Z$ in H.*

▶ **Invariant 3.** *There exists a Z-deadlock scheme.*

▶ **Proposition 24.** *There is a polynomial time algorithm to decide if a lock graph G and a lockset family Locks have a deadlock scheme.*

The final argument behind Theorem 8 is as follows. We start by non-deterministically guessing G and *Locks*. These are of polynomial size with respect to the size of the 2LSS. We can check in polynomial time that there exists a strategy σ giving G and *Locks* (Lemma 19). If that is not the case, we reject the input. Otherwise we check if G and *Locks* admit a deadlock scheme (Proposition 24). By Lemma 22, the strategy σ is winning if and only if the check says that there is no deadlock scheme in G and *Locks*.

5 Solving the exclusive case in PTIME

In this section we study exclusive 2LSS. We have shown an NP algorithm for the deadlock avoidance control problem when restricting to locally live strategies. Here we show that the problem is in PTIME if the 2LSS is exclusive (Definition 9). This is possible because the exclusive assumption simplifies the structure of lock graphs, and makes the lockset family unnecessary.

Throughout this section we fix an exclusive 2LSS, call it $\mathcal{S}$. The exclusive property prohibits situations as in Figure 2 where a state has one outgoing $\texttt{acq}_{t_{p+1}}$ transition, and one $\texttt{rel}_{t_p}$ transition. Compared to the previous section we do not need to make a difference between solid and fragile processes. We can even ignore colors on the arrows. This is a consequence of the following two lemmas.

▶ **Lemma 25.** *Let σ be a locally live control strategy and G_σ its lock graph. For all $t_1, t_2 \in T$, if G_σ has a blue edge $t_1 \overset{p}{\hookrightarrow} t_2$ then it has a green edge $t_2 \overset{p}{\mapsto} t_1$.*

▶ **Lemma 26.** *Let σ be a locally live control strategy and G_σ its lock graph. For every edge $t_1 \overset{p}{\to} t_2$ in G, process p is $\{t_1, t_2\}$-lockable.*

Thanks to these simplifications there is a much more direct way of checking if a strategy is winning. Take a locally live strategy σ. Consider a decomposition of G_σ into strongly connected components (SCC). We say that an SCC is a *direct deadlock* if it contains at least two nodes, and:

- either it has an edge that is not a double edge: $t_1 \xrightarrow{p} t_2$ but not $t_1 \xleftarrow{p} t_2$, for some p;
- or all edges in the component are double edges and there is a proper cycle, i.e., all edges are labeled by different processes.

A *deadlock* SCC is a direct deadlock SCC or an SCC that can reach some direct deadlock SCC. Let BT_σ be the set of all the locks appearing in some deadlock SCC. We obtain a simple characterization of winning strategies.

▶ **Proposition 27.** *A strategy σ is winning if and only if there exists a process that is not BT_σ-lockable.*

Building on this result we can give a method to decide if there is a winning strategy in the system $\mathcal{S}$. For every process p and every set of edges between two locks of p we check if there is a local strategy inducing exactly these edges. This can be done in a similar way as Lemma 19. We say that an edge la belled by p is *unavoidable* if all the local strategies σ_p induce this edge. Let $G_\mathcal{S}$ be the graph whose nodes are locks and edges are unavoidable edges.

We calculate a set $BT_\mathcal{S}$ in a similar way as BT_σ in the previous proposition except that we use slightly more general basic SCCs of $G_\mathcal{S}$. A *direct semi-deadlock SCC* is either a direct deadlock SCC or an SCC containing at least two nodes, only double edges, and two locks t_1 and t_2 such that for some process p not inducing a double edge between t_1, t_2 in $G_\mathcal{S}$: every strategy for p induces at least one edge between t_1 and t_2. Then a *semi-deadlock SCC* is an SCC that can reach some direct semi-deadlock SCC, or is itself a direct semi-deadlock SCC.

Let $BT_\mathcal{S}$ be the set of locks appearing in semi-deadlock SCCs of $G_\mathcal{S}$. Theorem 11 follows from the next proposition.

▶ **Proposition 28.** *Let $\mathcal{S}$ be an exclusive 2LSS. There is a winning locally live strategy for the system if and only if there exists a locally live strategy σ_p for some process p preventing it from acquiring any lock from $BT_\mathcal{S}$.*

The algorithm computes $BT_{\mathcal{S}}$, and then checks if for some process p the condition from the proposition holds. This check amounts to solving a safety game on a finite graph – the transition graph of process p.

6 Nested-locking strategies

We switch to another decidable case, where we require that locks are acquired and released in stack-like manner. Our goal is Theorem 13 saying that the deadlock avoidance control problem is NEXPTIME-complete when restricted to nested-locking strategies (cf. Definition 12).

In the context of this section we cannot assume that a process knows which locks it has (cf. Remark 4). In consequence, it is not realistic to require that a strategy is locally live. Yet, the lower bound works also for locally live strategies.

We will use some notions about local runs as defined on page 10.

▶ **Definition 29.** *A* stair decomposition *of a local run u is*

$$u = u_1 \mathtt{acq}_{t_1} u_2 \mathtt{acq}_{t_2} \dots u_k \mathtt{acq}_{t_k} u_{k+1}$$

where in the configuration reached by $u_1 \mathtt{acq}_{t_1} u_2 \mathtt{acq}_{t_2} \dots u_i$ the set of locks held by the process is $\{t_1, \dots, t_{i-1}\}$ for every $i > 0$, and there is no operation on t_i in $u_{i+1} \dots u_{k+1}$. (We omit the actions associated with each operation as they are irrelevant here).

Every nested-locking run has a unique stair decomposition.

Without the locally live assumption we may have runs simply ending because there are no outgoing actions. Recall that given a strategy σ, a *risky σ-run* is a local σ-run ending in a state from which every outgoing action allowed by σ acquires some lock. We define patterns of risky local runs that will serve as witnesses of reachable deadlocks.

▶ **Definition 30.** *Consider a stair decomposition $u_1 \mathtt{acq}_{t_1} u_2 \mathtt{acq}_{t_2} \cdots u_k \mathtt{acq}_{t_k} u_{k+1}$ of a risky σ-run u of a process p. Suppose the run is T_{blocks}-blocked, and let $T_{owns} = \{t_1, \dots, t_k\}$. We associate with u a* stair pattern *$(T_{owns}, T_{blocks}, \preceq)$, where $\preceq$ is the smallest partial order on the set T_p of locks of p satisfying: for all i, for all $t \in T_p$, if the last operation on t in the run is after the last $\mathtt{acq}_{t_i}$ then $t_i \preceq t$. A* behavior *of σ is a family of sets of stair patterns $(\mathcal{P}_p)_{p \in Proc}$, where $\mathcal{P}_p$ is the set of stair patterns of local risky σ-runs of p.*

Similarly to Lemma 22 we can show that the family of patterns for a strategy determines if it is winning.

▶ **Lemma 31.** *A nested-locking control strategy σ with behavior $(\mathcal{P}_p)_{p \in Proc}$ is **not** winning if and only if for every $p \in Proc$ there is a stair pattern $(T^p_{owns}, T^p_{blocks}, \preceq^p) \in \mathcal{P}_p$ such that:*

- $\bigcup_{p \in Proc} T^p_{blocks} \subseteq \bigcup_{p \in Proc} T^p_{owns}$,
- *the sets T^p_{owns} are pairwise disjoint,*
- *there exists a total order $\preceq$, on the set of all locks T, compatible with all $\preceq^p$.*

Similarly to Lemma 19 we can check if there is a strategy whose set of patterns has only patterns from a given family. Observe that the depth of nesting is bounded by the number of locks.

▶ **Lemma 32.** *Given a lock-sharing system $((\mathcal{A}_p)_{p \in Proc}, \Sigma^s, \Sigma^e, T)$, a process $p \in Proc$ and a set of patterns $\mathcal{P}_p$, we can check in polynomial time in $|\mathcal{A}_p|$ and $2^{|T|}$ whether there exists a nested-locking local strategy σ_p with set of patterns included in $\mathcal{P}_p$.*

▶ **Proposition 33.** *The deadlock avoidance control problem is decidable for lock-sharing systems with nested-locking strategies in non-deterministic exponential time.*

Proof. The decision procedure guesses a set of patterns $\mathcal{P}_p$ for each process p, of size at most $2^{2|T|}|T|! \leq 2^{O(|T|\log(|T|)}$. Then it checks if there exist local strategies yielding subsets of those sets of patterns. This takes exponential time by Lemma 32. If the result is negative then the procedure rejects. Otherwise, it checks if some condition from Lemma 31 does not hold. It it finds one then it accepts, otherwise it rejects.

Clearly, if there is a winning nested-locking strategy then the procedure can accept by guessing the family of patterns corresponding to this strategy. For this family the check from Lemma 32 does not fail, and one of the conditions of Lemma 31 must be violated.

Conversely, if the decision procedure concludes that there exists a winning strategy, then let $(\mathcal{P}_p)_{p\in Proc}$ be the guessed family of sets of patterns. We know that there exists a strategy σ with behaviors $(\mathcal{P}'_p)_{p\in Proc}$ such that $\mathcal{P}'_p \subseteq \mathcal{P}_p$ for all $p \in Proc$. Furthermore, as there are no patterns in $(\mathcal{P}_p)_{p\in Proc}$ satisfying the requirements of Lemma 31, there cannot be any in the $\mathcal{P}'_p$ either. Hence σ is a winning strategy. ◀

7 Undecidability for unrestricted lock-sharing systems

In this section we show that the deadlock avoidance control problem for lock-sharing systems is undecidable for three processes with a fixed number of locks. Three locks used in non-nested fashion allow to synchronize two processes in lock-step manner. This is an essential ingredient for the undecidability proof.

We have defined lock-sharing systems so that initially all locks are free. First we show the undecidability result supposing that we are allowed to start with a designated distribution of locks. Later we describe how to implement initial lock distributions using extra locks.

▶ **Lemma 34.** *The control problem for lock-sharing systems with 3 processes, fixed initial configuration and fixed number of locks per process is undecidable.*

The proof uses the usual recipe for the undecidability of distributed synthesis [26, 27]. Two processes P and $\overline{P}$ synchronize with a third process C over a stream of bits chosen by their strategy. The process C is partially controlled by the environment, which selects non-deterministically an interleaving of the two streams and parses the interleaving with a finite automaton. This is enough to get undecidability by a reduction from an infinite Post Correspondence Problem (PCP).

Consider an instance $(\alpha_i, \beta_i)_{i\in I}$ of PCP on the alphabet $\{0, 1\}$. A solution is an infinite sequence $i_1 i_2 \ldots \in I^\omega$ such that $\alpha_{i_1}\alpha_{i_2}\ldots = \beta_{i_1}\beta_{i_2}\ldots$. The two streams sent by P and $\overline{P}$ to C, are $\alpha = \alpha_{i_1} i_1 \alpha_{i_2} i_2 \ldots$ and $\beta = \beta_{j_1} j_1 \beta_{j_2} j_2 \ldots$, resp. With finite memory C can check equality of the two words $(\alpha_{i_1}\alpha_{i_2}\cdots = \beta_{j_1}\beta_{j_2}\ldots)$ or equality of the two index sequences $(i_1 i_2 \ldots = j_1 j_2 \ldots)$. Since P and $\overline{P}$ are not aware of what C does, the streams are fixed by the strategies and do not depend on what C is checking.

The locks used in the proof are $\{c, s_0, s_1, p, \overline{c}, \overline{s}_0, \overline{s}_1, \overline{p}\}$. Process C and P use locks from $\{c, s_0, s_1, p\}$ to synchronize and similarly for C, $\overline{P}$ and $\{\overline{c}, \overline{s}_0, \overline{s}_1, \overline{p}\}$.

It remains to explain the synchronization mechanism. The two processes P and C synchronize over a bit of information, say bit 0, by executing specific finite runs using the locks $\{s_0, c, p\}$ in non-nested fashion. Initially, C owns $\{s_0, c\}$ and P owns $\{p\}$. First, C releases lock s_0 and P acquires it, which we denote as $C \xrightarrow{s_0} P$. Here, P is waiting for C to release s_0, and the two actions $\texttt{rel}_{s_0}$ of C and $\texttt{acq}_{s_0}$ of P are ordered. The rest of the run follows a similar pattern: at each step, one of the processes is waiting to take a lock released by the other process. With the same notation, the run proceeds with $P \xrightarrow{p} C$, and continues until each process owns the same locks it owned at the start: each lock is sent

twice, from its initial owner to the other process, and back. To sum up, the exchange of bit 0 between C and P corresponds to $C \xrightarrow{s_0} P \xrightarrow{p} C \xrightarrow{c} P \xrightarrow{s_0} C \xrightarrow{p} P \xrightarrow{c} C$. In other words, processes C and P respectively perform two local runs:

$$C: \texttt{rel}_{s_0}\,\texttt{acq}_p\,\texttt{rel}_c\,\texttt{acq}_{s_0}\texttt{rel}_p\,\texttt{acq}_c \qquad P: \texttt{acq}_{s_0}\texttt{rel}_p\,\texttt{acq}_c\,\texttt{rel}_{s_0}\texttt{acq}_p\texttt{rel}_c$$

Observe that P and C need to execute these sequences in lock-step manner, as one of the two processes waits for a lock from the other.

In order to synchronize over bit 1, the two processes perform a similar synchronization, using s_1 instead of s_0. The communication between C and $\overline{P}$ is identical, except that it uses locks from $\{\overline{c}, \overline{s}_0, \overline{s}_1, \overline{p}\}$.

In each round, P and C must agree beforehand on a bit they are going to synchronize on, either s_0 or s_1. Otherwise the two processes get blocked, and $\overline{P}$ will get blocked too, as it needs locks held by C. A bit stream between C and P is encoded as a concatenation of such runs, and similarly for $C, \overline{P}$. The content of the two bit streams is chosen by the strategies of $P, \overline{P}, C$. Since the strategy has infinite memory, there is no upper bound on the complexity of the streams. Interestingly, two locks are not enough for two processes to synchronize over a bit stream.

▶ **Lemma 35.** *There is a polynomial-time reduction from the control problem for lock-sharing systems with initial configuration to the control problem where all locks are initially free. The reduction adds $|Proc|$ new locks.*

We sketch the proof idea. Assume that we have pairwise disjoint sets $(I_p)_{p \in Proc}$ of locks, and a lock-sharing system $\mathcal{S}$ in which each process p initially owns exactly the locks in I_p. We build another lock-sharing systems $\mathcal{S}_\emptyset$ that starts with all locks initially free, makes every process acquire all locks in I_p, and then simulates $\mathcal{S}$.

It is important that the initialization phase of $\mathcal{S}_\emptyset$ does not interfere with the simulation of $\mathcal{S}$. We ensure this by using one additional lock k_p per process, called the "key" of p.

For process p, the initialization sequence consists of three steps.

1. First, p takes one by one (in a fixed arbitrary order), all its initial locks in I_p.
2. Second, p takes and releases, one by one (in a fixed arbitrary order) all the keys of the other processes $(k_q)_{q \neq p}$.
3. Finally, p acquires its key k_p and keeps it forever.

After acquiring k_p process p reaches the initial state in $\mathcal{S}$.

In order to prevent the initialization phase to create extra deadlocks, there is a local *nop* loop on every state of the initialization sequence. This way, a deadlock may only occur if all processes have finally completed their initialization sequences. Note that the initialization phase does not interfere with the simulation of $\mathcal{S}$. This is because the exchange of keys guarantees that up to the moment where a process p has completed the initialization in $\mathcal{S}_\emptyset$, no other process has used any lock from I_p.

8 Conclusions

Motivated by a recent undecidability result for distributed control synthesis [17] we have considered a model for which the problem has not been investigated yet. With hindsight it is strange that the well-studied model of lock synchronization has not been considered in the context of distributed synthesis. One reason may be the "non-monotone" nature of the synthesis problem. It is not the case that for a less expressive class of systems the problem is necessarily easier because the controllers get less powerful, too.

The two decidable classes of lock-sharing systems presented here are rather promising. Especially because the low complexity results cover already non-trivial problems. All our algorithms are based on analyzing lock patterns. While in this paper we consider only finite state processes, the same method applies to more complex systems, as long as solving the centralized control problem in the style of Lemma 19 is decidable. This is for example the case for pushdown systems.

There are numerous directions that need to be investigated further. We have focused on deadlock avoidance because this is a central property, and deadlocks are difficult to discover by means of testing or verification. Another option is partial deadlock, where some, but not all, processes are blocked. The concept of Z-deadlock scheme from Definition 20 should help here, but the complexity results may be different. Reachability, and repeated reachability properties need to be investigated, too.

We do not know if the upper bound from Theorem 8 is tight. The algorithm for verifying if there is a deadlock in a given strategy graph, Proposition 24, is already quite complicated, and it is not clear how to proceed when a strategy is not given.

Another research direction is to consider probabilistic controllers. It is well known that there are no symmetric solutions to the dining philosophers problem but there is a randomized one [21, 22]. Symmetric solutions are quite important for resilience issues as it is preferable that every process runs the same code. The Lehmann-Rabin algorithm is essentially the system presented in Figure 2 where the choice between *left* and *right* is made randomly. This is one of the examples where randomized strategies are essential. Distributed synthesis has a potential here because it is even more difficult to construct distributed randomized systems and prove them correct.

University of Oxford, UK

Weiqiang Yuan
EPFL, Lausanne, Switzerland

Abstract

We use results from communication complexity, both new and old ones, to prove lower bounds for unambiguous finite automata (UFAs). We show three results.

1. *Complement:* There is a language L recognised by an n-state UFA such that the complement language $\overline{L}$ requires NFAs with $n^{\tilde{\Omega}(\log n)}$ states. This improves on a lower bound by Raskin.
2. *Union:* There are languages L_1, L_2 recognised by n-state UFAs such that the union $L_1 \cup L_2$ requires UFAs with $n^{\tilde{\Omega}(\log n)}$ states.
3. *Separation:* There is a language L such that both L and $\overline{L}$ are recognised by n-state NFAs but such that L requires UFAs with $n^{\Omega(\log n)}$ states. This refutes a conjecture by Colcombet.

1 Introduction

Given two finite automata recognising languages $L_1, L_2 \subseteq \Sigma^*$ a basic question is to determine the *state complexity* of various language operations. How many states are needed in an automaton that recognises the union $L_1 \cup L_2$? How about the intersection $L_1 \cap L_2$? The complement $\overline{L}_1 := \Sigma^* \setminus L_1$? The answer depends on the type of automaton considered, such as deterministic (DFA), nondeterministic (NFA), or unambiguous (UFA). Recall that a UFA is an NFA that has at most one accepting computation on any input.

State complexities have been extensively studied for various types of automata and language operations; see, e.g., [9, 15] and their references, or the excellent compendium on Wikipedia [22]. For example, complementing an NFA with n states may require 2^n states [3], even for automata with binary alphabet [14]. Surprisingly, several extremely basic questions about UFAs remain open. For example, it was shown only in 2018 by Raskin [20] that the state complexity for UFA complementation is not polynomial: for any $n \in \mathbb{N}$ there exists a language L recognised by an n-state UFA such that any UFA (or even NFA) that recognises $\overline{L}$ has at least $n^{(\log\log\log n)^{\Omega(1)}}$ states. This superpolynomial blowup refuted a conjecture that it may be possible to complement UFAs with a polynomial blowup [5].

In this paper, as our main results, we prove three new blowup theorems.

▶ **Theorem 1** (Complement). *For every $n \in \mathbb{N}$ there is a language $L \subseteq \{0,1\}^*$ recognised by an n-state UFA such that any NFA that recognises $\overline{L}$ requires $n^{\tilde{\Omega}(\log n)}$ states.*

▶ **Theorem 2** (Union). *For every $n \in \mathbb{N}$ there are languages $L_1, L_2 \subseteq \{0,1\}^*$ recognised by n-state UFAs such that any UFA that recognises $L_1 \cup L_2$ requires $n^{\tilde{\Omega}(\log n)}$ states.*

▶ **Theorem 3** (Separation). *For every $n \in \mathbb{N}$ there is a language $L \subseteq \{0,1\}^*$ such that both L and $\overline{L}$ are recognised by n-state NFAs but any UFA that recognises L requires $n^{\Omega(\log n)}$ states.*

Discussion of main results. **Theorem 1** upgrades Raskin's slightly-superpolynomial bound into a quasipolynomial bound $n^{\tilde{\Omega}(\log n)}$. (Here we use the notation $\tilde{\Omega}(m)$ to suppress $\mathrm{poly}(\log m)$ factors.) However, we note that Raskin's language is unary, $|\Sigma| = 1$, while ours is binary, $|\Sigma| = 2$, and hence the two results are incomparable in this sense. As for positive results, it is known that the trivial 2^n upper bound for UFA complementation can be improved: the complement of any n-state UFA can be recognised by a UFA with at most $\mathrm{poly}(n) \cdot 2^{n/2}$ states [15, 13]. Closing the exponential gap here between the lower and upper bounds remains a tantalising open problem. It was highlighted as one of the foremost challenges in the recent Dagstuhl workshop *Unambiguity in Automata Theory* [6].

Theorem 2 establishes the first superpolynomial lower bound for the union operation. Letting $\sqcup$ denote disjoint union, observe that

$$L_1 \cup L_2 \;=\; L_1 \sqcup (L_2 \cap \overline{L}_1). \tag{1}$$

Since disjoint union and intersection are polynomial for UFAs, it follows from (1) and Theorem 2 that the same $n^{\tilde{\Omega}(\log n)}$ lower bound holds for complementing UFAs. However, we stress that Theorem 1 has a stronger conclusion than this, since it proves a lower bound against NFAs, not just UFAs. The observation (1) also yields the upper bound $\mathrm{poly}(n) \cdot 2^{n/2}$ by using the complement construction from [15, 13].

Theorem 3 refutes a conjecture by Colcombet [5, Conjecture 2]. Indeed, he conjectured that for any pair of NFAs recognising languages L_1, L_2 such that $L_1 \cap L_2 = \emptyset$, there is a polynomial-sized UFA that recognises some L that *separates* L_1 and L_2 in the sense that $L_1 \subseteq L$ and $L \cap L_2 = \emptyset$. Theorem 3 refutes this even in the special case $L_1 = \overline{L}_2$. Related separability questions are classical in formal language theory and have attracted renewed attention; see, e.g, [8] and the references therein. Separating automata have also been used recently to elegantly describe quasipolynomial time algorithms for solving parity games in an automata theoretic framework; see [4, Chapter 3] and [7].

1.1 Technique: Communication complexity

Our three main theorems rely on results – both new and old – in communication complexity; see [18, 19] for the standard textbooks. In communication complexity, one studies functions of the form $F\colon \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$ that determine the following two-party communication problem: Alice holds $x \in \{0,1\}^n$, Bob holds $y \in \{0,1\}^n$, and their goal is to output $F(x,y)$ while communicating as few bits as possible between them. Communication complexity is a classical tool to prove lower bounds for automata. Indeed, it is well known that if the language $\{xy : F(x,y) = 1\}$ is recognised by a small DFA (resp. NFA, UFA) then F admits an efficient deterministic (resp. nondeterministic, unambiguous) protocol. We revisit this connection in light of recent developments in communication complexity.

Theorem 1 is a ***relatively straightforward consequence*** of a recent result of Balodis et al. [2]. They exhibited a two-party function whose co-nondeterministic communication complexity is nearly quadratic in its unambiguous complexity (which matches an upper bound due to Yannakakis [23]). We translate this separation into the language of automata theory, virtually in a black-box fashion.

Theorem 2, by contrast, is our ***main technical contribution***. We will show that it follows from the following analogous communication result, which we prove in this paper.

▶ **Theorem 4.** *For every $m \in \mathbb{N}$ there exists a function $F(x, y)$ with unambiguous communication complexity at most m such that the logical-or of two copies of F, namely, $F^{\vee}(xx', yy') \coloneqq F(x, y) \vee F(x', y')$, has unambiguous communication complexity $\tilde{\Omega}(m^2)$.*

This is a new result in communication complexity; the unambiguous complexity of $F^{\vee}$ has not been studied previously. We prove Theorem 4 using the popular *query-to-communication lifting* technique that has been wildly successful in the past decade to prove communication lower bounds (including in [2]). In this technique, one starts by proving a lower bound on the query (aka decision tree) complexity of a boolean function $f\colon \{0,1\}^n \to \{0,1\}$. A lifting theorem (e.g., [12]) then transforms f into an analogous communication problem F in such a way that the communication complexity of F is characterised by the query complexity of f. This reduces the task of proving communication lower bounds into the much easier task of proving query lower bounds.

Interestingly, our proof of Theorem 4 formalises a kind of *converse* to the observation (1) above (saying that union can be computed via a complement). Namely, we show that unambiguously computing the union necessarily requires computing a complement, and therefore we can rely on an existing query lower bound for complementation [11].

Theorem 3, finally, is a straightforward consequence of a classical quadratic separation between two-sided nondeterministic communication complexity and unambiguous communication complexity due to Razborov [21].

1.2 Bonus result: Approximate nonnegative rank

Along the way to Theorem 4 we inadvertently stumbled upon another separation result that addresses a question raised by Kol et al. [16]. They studied the *ϵ-approximate nonnegative rank* $\mathrm{rk}^{+}_{\epsilon}(M)$ of a nonnegative matrix $M \in \mathbb{R}^{n\times n}$. Here, $\mathrm{rk}^{+}_{\epsilon}(M)$ is defined as the least nonnegative rank $\mathrm{rk}^{+}(N)$ of a matrix $N \in \mathbb{R}^{n\times n}$ such that $|M_{ij} - N_{ij}| \le \epsilon$ for all i, j; see Section 3 for precise definitions. In particular, Kol et al. [16] asked whether for all error parameters $0 < \epsilon < \delta < 1/2$ and boolean matrices $M \in \{0,1\}^{n\times n}$ we have the polynomial relationship $\mathrm{rk}^{+}_{\epsilon}(M) \le O(\mathrm{rk}^{+}_{\delta}(M)^C)$ where $C = C(\epsilon, \delta)$ is a constant. In short, does approximate nonnegative rank admit efficient error reduction? (It is known that the more usual notion, *approximate rank*, does [1].) We provide the following negative answer.

▶ **Theorem 5** (No efficient error reduction)**.** *For every $m \in \mathbb{N}$ there exists a boolean matrix M with $\mathrm{rk}^{+}_{1/4}(M) \le m$ but such that $\mathrm{rk}^{+}_{10^{-5}}(M) \ge m^{\tilde{\Omega}(\log m)}$.*

Previously, a negative answer was known only for *partial* boolean matrices $M \in \{0, 1, *\}^{n\times n}$ that allow "don't care" entries $M_{ij} = *$ [12]. Our Theorem 5 still leaves open the possibility (also raised by [16]) that, for a total boolean matrix M, we can bound $\mathrm{rk}^{+}_{\epsilon}(M)$ as a polynomial function of $\mathrm{rk}^{+}_{\delta}(M) + \mathrm{rk}^{+}_{\delta}(\overline{M})$ where $\overline{M}$ is the boolean complement.

1.3 Open problems

Our quasipolynomial lower bounds for automata are not known to be tight; in all cases the best known upper bounds are exponential. Curiously enough, the analogous communication results are tight for communication protocols. This suggests two opportunities.

- Can other techniques from communication complexity improve the lower bounds further? Perhaps via multi-party communication complexity?
- Can techniques for proving upper bounds on communication complexity be adapted to prove upper bounds on the size of automata?

1.4 Definitions of automata

An *NFA* is a quintuple $\mathcal{A} = (Q, \Sigma, \delta, I, F)$, where Q is the finite set of states, Σ is the finite alphabet, $\delta \subseteq Q \times \Sigma \times Q$ is the transition relation, $I \subseteq Q$ is the set of initial states, and $F \subseteq Q$ is the set of accepting states. We write $q \xrightarrow{a} r$ to denote that $(q, a, r) \in \delta$. A finite sequence $q_0 \xrightarrow{a_1} q_1 \xrightarrow{a_2} \cdots \xrightarrow{a_n} q_n$ is called a *run*; it can be summarized as $q_0 \xrightarrow{a_1 \cdots a_n} q_n$. The NFA $\mathcal{A}$ *recognizes* the language $L(\mathcal{A}) := \{w \in \Sigma^* \mid \exists\, q_0 \in I \,.\, \exists\, f \in F \,.\, q_0 \xrightarrow{w} f\}$. The NFA $\mathcal{A}$ is a *DFA* if $|I| = 1$ and for every $q \in Q$ and $a \in \Sigma$ there is exactly one q' with $q \xrightarrow{a} q'$. The NFA $\mathcal{A}$ is a *UFA* if for every word $w = a_1 \cdots a_n \in \Sigma^*$ there is at most one *accepting* run for w, i.e., a run $q_0 \xrightarrow{a_1} q_1 \xrightarrow{a_2} \cdots \xrightarrow{a_n} q_n$ with $q_0 \in I$ and $q_n \in F$. Any DFA is a UFA.

2 UFA Complementation

In this section we prove Theorem 1.

▶ **Theorem 1** (Complement). *For every $n \in \mathbb{N}$ there is a language $L \subseteq \{0,1\}^*$ recognised by an n-state UFA such that any NFA that recognises $\overline{L}$ requires $n^{\tilde{\Omega}(\log n)}$ states.*

The proof uses concepts from communication complexity, in particular a recent result from [2] and a nondeterministic lifting theorem from [12]. We start by recalling these tools.

2.1 DNFs and nondeterministic protocols

Unambiguous DNFs. Let $D = C_1 \vee \cdots \vee C_m$ be an n-variate boolean formula in disjunctive normal form (DNF). DNF D has *width* k if every C_i is a conjunction of at most k literals. We call such D a *k-DNF*. For conjunctive normal form (CNF) formulas the width and k-CNFs are defined analogously. DNF D is said to be *unambiguous* if for every input $x \in \{0,1\}^n$ at most one of the conjunctions C_i evaluates to true, $C_i(x) = 1$. For any boolean function $f\colon \{0,1\}^n \to \{0,1\}$ define

- $\mathrm{C}_1(f)$ as the least k such that f can be written as a k-DNF;
- $\mathrm{C}_0(f)$ as the least k such that f can be written as a k-CNF;
- $\mathrm{UC}_1(f)$ as the least k such that f can be written as an unambiguous k-DNF.

Note that $\mathrm{C}_0(f) = \mathrm{C}_1(\neg f)$. The following recent result separates two of these measures.

▶ **Theorem 6** ([2, Theorem 1]). *For every $k \in \mathbb{N}$ there exists a function $f\colon \{0,1\}^n \to \{0,1\}$ where $n \leq \mathrm{poly}(k)$ and such that $\mathrm{UC}_1(f) \leq k$ and $\mathrm{C}_0(f) \geq \tilde{\Omega}(k^2)$.* ◀

In words, for every k there is an unambiguous k-DNF such that any equivalent CNF requires width $\tilde{\Omega}(k^2)$. The bound is almost tight, as every unambiguous k-DNF has an equivalent k^2-CNF; see [10, Section 3].

Nondeterministic protocols and rectangle covers. Next we recall standard notions from two-party communication complexity; see [18, 19] for textbooks. Consider a two-party function $F\colon X \times Y \to \{0,1\}$. A set $A \times B \subseteq X \times Y$ (with $A \subseteq X$ and $B \subseteq Y$) is called a *rectangle*. Rectangles $R_1, \ldots, R_k$ *cover* a set $S \subseteq X \times Y$ if $\bigcup_i R_i = S$. For $b \in \{0,1\}$, the *cover number*

$\mathrm{Cov}_b(F)$ is the least number of rectangles that cover $F^{-1}(b)$. The *nondeterministic (resp., co-nondeterministic) communication complexity* of F is defined as $\mathrm{N}_1(F) \coloneqq \log_2 \mathrm{Cov}_1(F)$ (resp., $\mathrm{N}_0(F) \coloneqq \log_2 \mathrm{Cov}_0(F)$). Note that $\mathrm{N}_0(F) = \mathrm{N}_1(\neg F)$. The nondeterministic communication complexity can be interpreted as the number of bits that two parties (Alice and Bob), holding inputs $x \in X$ and $y \in Y$, respectively, need to communicate in a nondeterministic (i.e., based on guessing and checking) protocol in order to establish that $F(x,y) = 1$; see [18, Chapter 2] for details.

Nondeterministic lifting. Next we formulate a *lifting theorem*, which allows us to transfer lower bounds on the DNF width of an n-bit boolean function f to the nondeterministic communication complexity of a related two-party function F. We first choose a small two-party function $g\colon \{0,1\}^b \times \{0,1\}^b \to \{0,1\}$, often called a *gadget*. Then we compose f with g to construct the function $F \coloneqq f \circ g^n$ that maps $\{0,1\}^{bn} \times \{0,1\}^{bn} \to \{0,1\}$ where Alice gets as input $x \in \{0,1\}^{bn}$, Bob gets as input $y \in \{0,1\}^{bn}$, and their goal is to compute

$$F(x,y) \;\coloneqq\; f(g(x_1,y_1),\dots,g(x_n,y_n)) \qquad \text{where } x_i, y_j \in \{0,1\}^b.$$

The following is a nondeterministic lifting theorem [12, 10].

▶ **Theorem 7** ([10, Theorem 4]). *For any $n \in \mathbb{N}$ there is a gadget $g\colon \{0,1\}^b \times \{0,1\}^b \to \{0,1\}$ with $b = \Theta(\log n)$ such that for any function $f\colon \{0,1\}^n \to \{0,1\}$ we have, for $F \coloneqq f \circ g^n$,*

$$\mathrm{N}_0(F) \;=\; \Omega(\mathrm{C}_0(f) \cdot b)$$

(and thus also $\mathrm{N}_1(F) = \Omega(\mathrm{C}_1(f) \cdot b)$). ◀

Protocols can simulate automata. Finally, we need a simple folklore connection between automata and protocols. To formalise this, we tacitly identify a function $F\colon \{0,1\}^{m_1} \times \{0,1\}^{m_2} \to \{0,1\}$ with the language $F^{-1}(1) \;=\; \{xy \in \{0,1\}^{m_1+m_2} \mid F(x,y) = 1\}$.

▶ **Lemma 8.** *If a two-party function $F\colon \{0,1\}^{m_1} \times \{0,1\}^{m_2} \to \{0,1\}$ admits an NFA with s states, then $\mathrm{Cov}_1(F) \le s$ (that is, $\mathrm{N}_1(F) \le \log s$).*

Proof. Let $\mathcal{A} = (Q, \Sigma, \delta, I, F)$ be an NFA with $L(\mathcal{A}) = \{xy \in \{0,1\}^{m_1+m_2} \mid F(x,y) = 1\}$. We show that $F^{-1}(1)$ is covered by at most $|Q|$ rectangles. Indeed, $F^{-1}(1)$ equals

$$\bigcup_{q \in Q} \left(\{x \in \{0,1\}^{m_1} \mid \exists\, q_0 \in I \,.\, q_0 \xrightarrow{x} q\}\right) \times \left(\{y \in \{0,1\}^{m_2} \mid \exists\, f \in F \,.\, q \xrightarrow{y} f\}\right).$$

(Alternatively, in terms of a nondeterministic protocol, the first party, holding $x \in \{0,1\}^{m_1}$, produces a run for x from an initial state to a state q and then sends the name of q, which takes $\log_2 |Q|$ bits, to the other party. The other party then produces a run for y from q to an accepting state.) ◀

2.2 Proof of Theorem 1

For $k \in \mathbb{N}$, let $f\colon \{0,1\}^n \to \{0,1\}$ be the function from Theorem 6. That is, f has an unambiguous k-DNF with $k = n^{\Omega(1)}$ (hence, $\log n = O(\log k)$) and $\mathrm{C}_0(f) = \tilde{\Omega}(k^2)$. Let $g\colon \{0,1\}^b \times \{0,1\}^b \to \{0,1\}$ with $b = \Theta(\log n)$ and $F \coloneqq f \circ g^n\colon \{0,1\}^{bn} \times \{0,1\}^{bn} \to \{0,1\}$ be the two-party functions from the lifting theorem Theorem 7. We will show that Theorem 1 holds for the language $F^{-1}(1)$.

First we argue that F has an unambiguous DNF of small width. Indeed, g and $\neg g$ have unambiguous $2b$-DNFs, which can be extracted from the deterministic decision tree of g. By plugging these unambiguous $2b$-DNFs for g and $\neg g$ into the unambiguous k-DNF for f (and "multiplying out"), one obtains an unambiguous $2bk$-DNF, say D, for F.

Over the $2bn$ variables of F, there exist at most $(2(2bn)+1)^{2bk}$ different conjunctions of at most $2bk$ literals. So D consists of at most $n^{O(bk)}$ conjunctions. From D we obtain a UFA $\mathcal{A}$ that recognizes $F^{-1}(1) \subseteq \{0,1\}^{2bn}$, as follows. Each initial state of $\mathcal{A}$ corresponds to a conjunction in D. When reading the input $x \in \{0,1\}^{2bn}$, the UFA checks that the corresponding assignment to the variables satisfies the conjunction represented by the initial state. This check requires at most $O(bn)$ states for each initial state. Thus, $\mathcal{A}$ has at most $n^{O(bk)} = 2^{\tilde{O}(k)} =: N$ states in total. (We use N in place of n in the statement of Theorem 1.)

On the other hand, by Theorem 7, we have $\mathrm{N}_0(F) = \Omega(\mathrm{C}_0(f) \cdot b) = \tilde{\Omega}(k^2)$. So by Lemma 8 any NFA that recognizes $F^{-1}(0)$ has at least $2^{\tilde{\Omega}(k^2)}$ states. Any NFA that recognizes $\{0,1\}^* \setminus L(\mathcal{A})$ can be transformed into an NFA that recognizes $F^{-1}(0) = \{0,1\}^{2bn} \setminus L(\mathcal{A})$ by taking a product with a DFA that has $2bn+2$ states. It follows that any NFA that recognizes $\{0,1\}^* \setminus L(\mathcal{A})$ has at least $2^{\tilde{\Omega}(k^2)}/(2bn+2) = 2^{\tilde{\Omega}(k^2)} = N^{\tilde{\Omega}(\log N)}$ states. ◀

3 UFA Union

In this section, we prove Theorem 2.

▶ **Theorem 2** (Union). *For every $n \in \mathbb{N}$ there are languages $L_1, L_2 \subseteq \{0,1\}^*$ recognised by n-state UFAs such that any UFA that recognises $L_1 \cup L_2$ requires $n^{\tilde{\Omega}(\log n)}$ states.*

We follow the same high-level approach that we already saw in Section 2. Namely, we will first show that computing the $\vee$-operation is hard for unambiguous DNFs and then lift that hardness to unambiguous protocols, which then implies the same hardness for UFAs. There are, however, two challenges in carrying out this plan.

1. It is an open problem to prove an unambiguous lifting theorem. That is, it is not known whether the unambiguous communication complexity of $f \circ g^n$ is at least $\Omega(\mathrm{UC}_1(f))$. To circumvent this issue, we study instead a *linear relaxation* of unambiguous DNFs. These objects are called *conical juntas* and they do admit a lifting theorem [12, 17].
2. There is no existing result showing that the $\vee$-operation is hard for unambiguous DNFs and/or conical juntas. We show a result of this type. The proof is by a reduction to the hardness of negating conical juntas, which *is* a known result [11].

3.1 Conical juntas

A nonnegative function $h\colon \{0,1\}^n \to \mathbb{R}_{\geq 0}$ is a *d-junta* if h depends on at most d variables. For example, a conjunction of d literals is a d-junta. Moreover, we say $f\colon \{0,1\}^n \to \mathbb{R}_{\geq 0}$ is a *conical d-junta* if it can be written as a nonnegative linear combination of d-juntas. Equivalently, f is a conical d-junta if it can be written as $f = \sum_i w_i C_i$ where each C_i is a width-d conjunction and $w_i \in \mathbb{R}_{\geq 0}$ are nonnegative coefficients. For example, if f can be written as an unambiguous d-DNF, $f = C_1 \vee \cdots \vee C_m$, then $f = \sum_i C_i$ is a conical d-junta with 0/1 coefficients. The *nonnegative degree* of f, denoted $\deg^+(f)$, is the least d such that f is a conical d-junta. In particular, if f is boolean-valued, then $\deg^+(f) \leq \mathrm{UC}_1(f)$.

We also need to work with *approximate* conical juntas that compute a given function only to within some point-wise error $\epsilon > 0$. This is important because the available lifting theorems for $\deg^+$ incur some error, and hence we need to prove lower bounds that are robust to this error. Indeed, we define the *ϵ-approximate nonnegative degree* of f, denoted $\deg^+_\epsilon(f)$, as the least nonnegative degree of a conical junta g such that

$$|f(x) - g(x)| \;\leq\; \epsilon \qquad \text{for all } x \in \{0,1\}^n.$$

▶ Remark. An awkward aspect of working with approximate conical juntas is that the error parameter ϵ is not well behaved. For $0 < \epsilon < \delta < 1/2$ we of course have $\deg^+_\delta(f) \leq \deg^+_\epsilon(f)$ but it is not a priori clear whether the converse inequality holds with a modest loss in the degree. In fact, in Section 5, we will end up showing that there can be a polynomial gap between the nonnegative degrees corresponding to two different error parameters – and this is related to our bonus result discussed in the introduction. As a consequence, our theorems in this section have to track the error parameters with some care.

Linear programming formulation. Approximate nonnegative degree can be captured using an LP. Write $\mathcal{C}^n_d$ for the set of all conjunctions of width at most d over n variables. In the (Primal) programme below, we have a variable $w_C \in \mathbb{R}$ for every $C \in \mathcal{C}^n_d$. In the associated (Dual) programme, we have a variable $\Phi(x) \in \mathbb{R}$ for each $x \in \{0,1\}^n$.

$$\begin{aligned} \min \quad & \epsilon \\ \textit{subject to} \quad & \textstyle|\sum_C w_C C(x) - f(x)| \;\leq\; \epsilon, && \forall x \in \{0,1\}^n \\ & w_C \;\geq\; 0, && \forall C \in \mathcal{C}^n_d \end{aligned} \tag{Primal}$$

$$\begin{aligned} \max \quad & \langle \Phi, f\rangle \;\coloneqq\; \textstyle\sum_x \Phi(x) f(x) \\ \textit{subject to} \quad & \|\Phi\| \;\coloneqq\; \textstyle\sum_x |\Phi(x)| \;\leq\; 1 \\ & \langle \Phi, C\rangle \;\leq\; 0, && \forall C \in \mathcal{C}^n_d \end{aligned} \tag{Dual}$$

We have that $\deg^+_\delta(f) \leq d$ iff the optimal value of (Primal) is at most δ. Alternatively, by strong LP duality, we have $\deg^+_\delta(f) > d$ iff there exists a feasible solution Φ to (Dual) such that $\langle \Phi, f\rangle > \delta$. It is typical to think of such feasible $\Phi\colon \{0,1\}^n \to \mathbb{R}$ as a *dual certificate* that witnesses a lower bound on approximate nonnegative degree.

3.2 Hardness of $\vee$

The goal of this subsection is to prove Theorem 9 below, which states that the $\vee$-operation is hard for unambiguous DNFs and even approximate conical juntas. Given an n-bit boolean function f we define a $2n$-bit function by $f^\vee(xy) \coloneqq f(x) \vee f(y)$ where $x, y \in \{0,1\}^n$.

▶ **Theorem 9** (Hardness of $\vee$). *For every $m \in \mathbb{N}$, there exists a boolean function $f\colon \{0,1\}^n \to \{0,1\}$ with $n \leq \mathrm{poly}(m)$ such that $\mathrm{UC}_1(f) \leq m$ and $\deg^+_{1.5\times 10^{-5}}(f^\vee) \geq \tilde{\Omega}(m^2)$.*

We show Theorem 9 by combining two lemmas, Lemmas 10 and 11, below. The first lemma, proved in [11], states that unambiguous DNFs are hard to negate, even by approximate conical juntas. The second lemma, which remains for us to prove, states that, for conical juntas, computing $f^\vee$ is at least as hard as computing the negation $\neg f$. Hence Theorem 9 follows immediately by combining these lemmas.

▶ **Lemma 10** (Hardness of ¬ [11, Lemma 8]). *For every $m \in \mathbb{N}$, there exists a boolean function $f\colon \{0,1\}^n \to \{0,1\}$ with $n \le \mathrm{poly}(m)$ such that $\mathrm{UC}_1(f) \le m$ and $\deg^+_{0.05}(\neg f) \ge \tilde{\Omega}(m^2)$.* ◀

▶ **Lemma 11** ($\vee$ harder than $\neg$). *For every $\delta > 0$ there exists an $\epsilon = \epsilon(\delta) > 0$ such that for every boolean function f, we have $\deg^+_\epsilon(f^\vee) \ge \Omega(\deg^+_\delta(\neg f))$. Moreover, $\epsilon \coloneqq \left(\frac{\ln(1+\delta)}{\lceil \log_{3/4} \delta \rceil}\right)^2$.*

It remains to prove Lemma 11. We do it in two steps. In Claim 12 we show that the approximate nonnegative degree of $f^\vee$ is at least that of $2 - f$ by exhibiting a dual certificate. Then in Claim 13 we show that the approximate nonnegative degree of $2 - f = 1 + \neg f$ is at least that of $\neg f$ via a powering trick. The error parameter ϵ will degrade in both of these steps. (We will later see that this degradation is, in fact, unavoidable; see Section 5.)

▷ Claim 12. We have $\deg^+_{\epsilon^2}(f^\vee) \ge \deg^+_\epsilon(2 - f)$ for any boolean-valued f and error ϵ.

Proof. Let $d \coloneqq \deg^+_\epsilon(2 - f)$ and let $\Phi\colon \{0,1\}^n \to \{0,1\}$ be a dual certificate witnessing this. That is, $\langle \Phi, 2 - f\rangle > \epsilon$, $\|\Phi\| \le 1$, and $\langle \Phi, C\rangle \le 0$ for all $C \in \mathcal{C}^n_{d-1}$. To construct a dual certificate $\Phi^\vee\colon \{0,1\}^{2n} \to \{0,1\}$ witnessing $\deg^+_{\epsilon^2}(f^\vee) \ge d$, we consider the negated tensor product (which was found by an educated guess)

$$\Phi^\vee(x,y) \;\coloneqq\; -\Phi(x)\Phi(y).$$

It remains to check that this is feasible for the dual programme and also that $\langle \Phi^\vee, f^\vee\rangle > \epsilon^2$.

1. $\|\Phi^\vee\| = \sum_{x,y} |\Phi^\vee(x,y)| = \sum_{x,y} |\Phi(x)\Phi(y)| = \sum_{x,y} |\Phi(x)| \cdot |\Phi(y)| = \|\Phi\|^2 \le 1$.
2. For any conjunction $C \in \mathcal{C}^{2n}_{d-1}$, we write $C(x,y) = C_1(x)C_2(y)$ where $C_1, C_2 \in \mathcal{C}^n_{d-1}$. Now

$$\begin{aligned}
\langle \Phi^\vee, C\rangle &= \textstyle\sum_{x,y} \Phi^\vee(x,y)C(x,y) \\
&= \textstyle\sum_{x,y} -\Phi(x)\Phi(y) \cdot C_1(x)C_2(y) \\
&= -\big[\textstyle\sum_x \Phi(x)C_1(x)\big]\big[\textstyle\sum_y \Phi(y)C_2(y)\big] \\
&= -\langle \Phi, C_1\rangle \langle \Phi, C_2\rangle \\
&\le 0.
\end{aligned}$$

3. Observe that $\langle \Phi, -f\rangle \ge \langle \Phi, 2 - f\rangle$ since $1 \in \mathcal{C}^n_{d-1}$ for the constant-1 function. Thus

$$\begin{aligned}
\langle \Phi^\vee, f^\vee\rangle &= \textstyle\sum_{x,y} \Phi^\vee(x,y) f^\vee(x,y) \\
&= \textstyle\sum_{x,y} -\Phi(x)\Phi(y)(f(x) + f(y) - f(x)f(y)) \\
&= \textstyle\sum_{x,y} -\Phi(x)\Phi(y)(2f(x) - f(x)f(y)) \\
&= \textstyle\sum_x -\Phi(x)f(x) \cdot \big[\sum_y \Phi(y)(2 - f(y))\big] \\
&= \langle \Phi, -f\rangle \cdot \langle \Phi, 2 - f\rangle \\
&\ge \langle \Phi, 2 - f\rangle \cdot \langle \Phi, 2 - f\rangle && \text{(above observation)} \\
&> \epsilon^2.
\end{aligned}$$

   where the third equality holds since we have $\sum_{x,y} \Phi(x)\Phi(y)f(x) = \sum_{x,y} \Phi(x)\Phi(y)f(y)$ by exchanging x and y. ◁

▷ Claim 13. For any $\delta > 0$ define $\epsilon \coloneqq \frac{\ln(1+\delta)}{\lceil \log_{3/4} \delta \rceil} > 0$. Then for any boolean-valued function f we have $\deg^+_\epsilon(1 + f) \ge \Omega(\deg^+_\delta(f))$.

Proof. We may assume $\delta < 1/2$ (and hence $\epsilon < 1/4$) as otherwise the claim is trivial. Suppose $\deg^+_\epsilon(1 + f) = d$ is witnessed by a conical d-junta g that ϵ-approximates $1 + f$. Define $g' \coloneqq ((g + \epsilon)/2)^k$ where the exponent is $k \coloneqq \lceil \log_{3/4} \delta \rceil$. By multiplying out the terms in

this definition, we see that g' has nonnegative degree $kd = O(d)$. We claim that g' is a δ-approximation of f. Indeed, if $f(x) = 0$, then $g'(x) \le (1/2+\epsilon)^k \le (3/4)^k \le \delta$. If $f(x) = 1$, then $1 \le (g(x)+\epsilon)/2 \le 1+\epsilon$, and thus $1 \le g'(x) \le (1+\epsilon)^k \le \exp(\epsilon k) \le 1+\delta$. ◁

Proof of Lemma 11. Using Claim 12 and Claim 13 (but with $\neg f$ in place of f), we have, for any $\delta > 0$ and $\epsilon := \frac{\ln(1+\delta)}{\lceil \log_{3/4} \delta \rceil}$:

$$\deg^+_{\epsilon^2}(f^\vee) \;\ge\; \deg^+_\epsilon(2-f) \;=\; \deg^+_\epsilon(1+\neg f) \;\ge\; \Omega(\deg^+_\delta(\neg f)).$$ ◀

3.3 Unambiguous protocols and nonnegative rank

Our goal will be to *lift* the hardness of the $\vee$-operation (Theorem 9) to communication complexity. In this subsection, we recall the concepts that are needed for this goal, namely, unambiguous protocols, (approximate) nonnegative rank, and a lifting theorem from nonnegative degree to nonnegative rank [12, 17].

Unambiguous protocols. Recall from Section 2.1 the notions of nondeterministic protocols and rectangle covers. For a two-party function $F\colon X \times Y \to \{0,1\}$, the *partition number* $\mathrm{Par}_1(F)$ is the least number of *pairwise disjoint* rectangles that cover $F^{-1}(1)$. Note that $\mathrm{Cov}_1(F) \le \mathrm{Par}_1(F)$. The *unambiguous communication complexity* of F is defined as $\mathrm{U}_1(F) := \log_2 \mathrm{Par}_1(F)$. Note that $\mathrm{N}_1(F) \le \mathrm{U}_1(F)$. Unambiguous communication complexity can be interpreted as the least communication cost of a nondeterministic protocol that has at most one accepting computation on every input. We also have the following folklore lemma, proved the same way as Lemma 8, which states that UFAs are simulated by unambiguous protocols.

▶ **Lemma 14.** *If a two-party function $F\colon \{0,1\}^{m_1} \times \{0,1\}^{m_2} \to \{0,1\}$ admits an UFA with s states, then $\mathrm{Par}_1(F) \le s$ (that is, $\mathrm{U}_1(F) \le \log s$).* ◀

Nonnegative rank. We often think of a two-party function $F\colon X \times Y \to \{0,1\}$ as a boolean matrix $F \in \{0,1\}^{X\times Y}$, sometimes called the *communication matrix* of F. For a nonnegative matrix $M \in \mathbb{R}^{X\times Y}_{\ge 0}$ we define its *nonnegative rank*, denoted $\mathrm{rk}^+(M)$, as the least r such that M can be written as a sum of r nonnegative rank-1 matrices, i.e., $M = \sum_{i=1}^r u_i v_i^{\mathrm{T}}$, where $u_i \in \mathbb{R}^X_{\ge 0}$ and $v_i \in \mathbb{R}^Y_{\ge 0}$ are nonnegative vectors. Note that for a boolean matrix F,

$$\mathrm{Par}_1(F) \;\ge\; \mathrm{rk}^+(F) \qquad \text{and thus} \qquad \mathrm{U}_1(F) \;\ge\; \log \mathrm{rk}^+(F). \tag{2}$$

Indeed, if $F^{-1}(1)$ can be partitioned into r rectangles, $F^{-1}(1) = R_1 \sqcup \cdots \sqcup R_r$, then F can be written as a sum of r nonnegative rank-1 matrices, $F = M_1 + \cdots + M_r$, where M_i is 1 on the rectangle R_i and 0 elsewhere. As with nonnegative degree, we define an approximate version of nonnegative rank. The *ϵ-approximate nonnegative rank* of M, denoted $\mathrm{rk}^+_\epsilon(M)$, is defined as the least $\mathrm{rk}^+(N)$ over all nonnegative matrices N that ϵ-approximate M, i.e.,

$$|M_{ij} - N_{ij}| \;\le\; \epsilon \qquad \text{for all } i,j.$$

Nonnegative lifting. Finally, we formulate a theorem that lifts lower bounds on the nonnegative degree of an n-bit boolean function f to the nonnegative rank of the composed function $F = f \circ g^n$ (which was defined in Section 2.1).

▶ **Theorem 15** ([12, 17])**.** *Fix constants $\delta > \epsilon > 0$. For any $n \in \mathbb{N}$ there is a gadget $g\colon \{0,1\}^b \times \{0,1\}^b \to \{0,1\}$ with $b = \Theta(\log n)$ such that for any $f\colon \{0,1\}^n \to \{0,1\}$ we have*

$$\log \mathrm{rk}^+_\epsilon(f \circ g^n) \;\ge\; \Omega(\deg^+_\delta(f) \cdot b).$$ ◀

3.4 Proof of Theorem 2 (and also Theorem 4)

We start with the function $f\colon \{0,1\}^n \to \{0,1\}$ given by Theorem 9 such that for $m = \mathrm{poly}(n)$,

$$\mathrm{UC}_1(f) \;\leq\; m, \tag{3}$$
$$\deg^+_{1.5\times 10^{-5}}(f^\vee) \;\geq\; \tilde{\Omega}(m^2). \tag{4}$$

We then use the gadget g on $b = \Theta(\log n)$ bits from the lifting theorem Theorem 15 to construct $F := f \circ g^n$. By the same argument as in Section 2.2 we see that the resulting $F\colon \{0,1\}^{nb} \times \{0,1\}^{nb} \to \{0,1\}$ enjoys the following upper bounds, derived from (3).

- F admits an unambiguous DNF of width $2bm = \tilde{O}(m)$.
- F admits an UFA of size $2^{\tilde{O}(m)}$.
- F admits an unambiguous protocol of cost $\mathrm{U}_1(F) \leq \tilde{O}(m)$.

On the other hand, we note that $F^\vee = (f \circ g^n)^\vee = f^\vee \circ g^n$. Hence, we may combine (2), Theorem 15, and (4) to conclude that

$$\mathrm{U}_1(F^\vee) \;\geq\; \log \mathrm{rk}^+_{10^{-5}}(F^\vee) \;\geq\; \Omega(\deg^+_{1.5\times 10^{-5}}(f^\vee)) \;\geq\; \tilde{\Omega}(m^2). \tag{5}$$

This finishes the proof of Theorem 4. We proceed with the proof of Theorem 2. To this end, we define two languages

$$L_1 \;:=\; \{xx'yy' : x,x',y,y' \in \{0,1\}^{bn} \text{ and } F(x,y) = 1\},$$
$$L_2 \;:=\; \{xx'yy' : x,x',y,y' \in \{0,1\}^{bn} \text{ and } F(x',y') = 1\}.$$

Both L_1 and L_2 admit UFAs of size $\mathrm{poly}(n) \cdot 2^{\tilde{O}(m)} = 2^{\tilde{O}(m)} =: N$. By contrast, we have $L_1 \cup L_2 = (F^\vee)^{-1}(1)$, and this union language requires UFAs of size $2^{\tilde{\Omega}(m^2)} = N^{\tilde{\Omega}(\log N)}$ by (5) and Lemma 14. This concludes the proof of Theorem 2. ◀

4 UFA Separation

In this section, we prove Theorem 3.

▶ **Theorem 3** (Separation). *For every $n \in \mathbb{N}$ there is a language $L \subseteq \{0,1\}^*$ such that both L and $\overline{L}$ are recognised by n-state NFAs but any UFA that recognises L requires $n^{\Omega(\log n)}$ states.*

Loosely speaking, in our construction, we define NFAs $\mathcal{A}_1, \mathcal{A}_2$ that recognize *(sparse) set disjointness* and its complement. For $n \in \mathbb{N}$ and $k \leq n$ we define

$$\textsc{Disj}^n_k \;:=\; \{(S,T) \mid S \subseteq [n],\ T \subseteq [n],\ |S| = |T| = k,\ S \cap T = \emptyset\}.$$

Define also $\langle \textsc{Disj}^n_k \rangle := \{\langle S\rangle\langle T\rangle \mid (S,T) \in \textsc{Disj}^n_k\}$ where $\langle S\rangle \in \{0,1\}^n$ is such that the ith letter of $\langle S\rangle$ is 1 if and only if $i \in S$, and similarly for $\langle T\rangle$. Note that $\langle S\rangle, \langle T\rangle$ each contain k times the letter 1. To prove Theorem 3 it suffices to prove the following lemma.

▶ **Lemma 16.** *For any $n \in \mathbb{N}$ let $k := \lceil \log_2 n \rceil$. There are NFAs $\mathcal{A}_1, \mathcal{A}_2$ with $n^{O(1)}$ states such that $L(\mathcal{A}_1) = \langle \textsc{Disj}^n_k \rangle$ and $L(\mathcal{A}_2) = \{0,1\}^* \setminus \langle \textsc{Disj}^n_k \rangle$. Furthermore, any UFA that recognizes $\langle \textsc{Disj}^n_k \rangle$ has at least $n^{\Omega(\log n)}$ states.*

In the rest of the section we prove Lemma 16 by following Razborov's analysis of sparse set disjointness [21]. In particular, we will give a self-contained proof of the existence of polynomial-sized NFAs for $\langle \textsc{Disj}^n_k \rangle$ and its complement, but the main argument also comes from communication complexity.

4.1 Proof of Lemma 16

First we prove the statement on UFAs. Write $\binom{[n]}{k} := \{S \subseteq [n] \mid |S| = k\}$. Let $F\colon \binom{[n]}{k} \times \binom{[n]}{k} \to \{0,1\}$ be the two-party function with $F(S,T) = 1$ if and only if $(S,T) \in \textsc{Disj}_k^n$. It is shown, e.g., in [18, Example 2.12] that the communication matrix of F has full rank, $\mathrm{rk}(F) = \binom{n}{k}$. Let $F'\colon \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$ be such that $F'(x,y) = 1$ if and only if $xy \in \langle \textsc{Disj}_k^n \rangle$. Then F is a principal submatrix of F', so $\binom{n}{k} \le \mathrm{rk}(F')$. Using (2) and Lemma 14 it follows that any UFA, say $\mathcal{A}$, that recognizes $\langle \textsc{Disj}_k^n \rangle$ has at least $\binom{n}{k} \ge (\frac{n}{k})^k$ states. With $k := \lceil \log_2 n \rceil$, it follows that $\mathcal{A}$ has $n^{\Omega(\log n)}$ states.

It is easy to see that there is an NFA, $\mathcal{A}_2$, with $n^{O(1)}$ states and $L(\mathcal{A}_2) = \{0,1\}^* \setminus \langle \textsc{Disj}_k^n \rangle$. Indeed, we can assume that the input is of the form $\langle S \rangle \langle T \rangle$; otherwise $\mathcal{A}_2$ accepts. NFA $\mathcal{A}_2$ guesses $i \in [n]$ such that $i \in S \cap T$ and then checks it.

Finally, we show that there is an NFA, $\mathcal{A}_1$, with $n^{O(1)}$ states and $L(\mathcal{A}_1) = \langle \textsc{Disj}_k^n \rangle$. We can assume that the input is of the form $\langle S \rangle \langle T \rangle$; otherwise $\mathcal{A}_1$ rejects. NFA $\mathcal{A}_1$ "hard-codes" polynomially many sets $Z_1, \dots, Z_\ell \subseteq [n]$. It guesses $i \in [\ell]$ such that $S \subseteq Z_i$ and $Z_i \cap T = \emptyset$ and then checks it. It remains to show that there exist $\ell = n^{O(1)}$ sets $Z_1, \dots, Z_\ell \subseteq [n]$ such that for any $(S,T) \in \textsc{Disj}_k^n$ there is $i \in [\ell]$ with $S \subseteq Z_i$ and $Z_i \cap T = \emptyset$. The argument uses the probabilistic method and is due to [21]; see also [18, Example 2.12]. We reproduce it here due to its elegance and brevity.

Fix $(S,T) \in \textsc{Disj}_k^n$. Say that a set $Z \subseteq [n]$ *separates* (S,T) if $S \subseteq Z$ and $Z \cap T = \emptyset$. A random set $Z \subseteq [n]$ (each i is in Z with probability $1/2$) separates (S,T) with probability 2^{-2k}. Thus, choosing $\ell := \lceil 2^{2k} \ln \binom{n}{k}^2 \rceil = n^{O(1)}$ random sets $Z \subseteq [n]$ independently, the probability that none of them separates (S,T) is

$$(1 - 2^{-2k})^\ell \;<\; e^{-2^{-2k}\ell} \;\le\; \tbinom{n}{k}^{-2}.$$

By the union bound, since $|\textsc{Disj}_k^n| < \binom{n}{k}^2$, the probability that there exists $(S,T) \in \textsc{Disj}_k^n$ such that none of ℓ random sets separates (S,T) is less than 1. Equivalently, the probability that for all $(S,T) \in \textsc{Disj}_k^n$ at least one of ℓ random sets separates (S,T) is positive. It follows that there are $Z_1, \dots, Z_\ell \subseteq [n]$ such that each $(S,T) \in \textsc{Disj}_k^n$ is separated by some Z_i. ◀

5 Bonus result: Approximate nonnegative rank

In this section, we prove Theorem 5.

▶ **Theorem 5** (No efficient error reduction). *For every $m \in \mathbb{N}$ there exists a boolean matrix M with $\mathrm{rk}^+_{1/4}(M) \le m$ but such that $\mathrm{rk}^+_{10^{-5}}(M) \ge m^{\tilde{\Omega}(\log m)}$.*

We first illustrate the idea in the context of nonnegative degree. In contrast to Theorem 9 (which states that $\vee$ is hard to approximate to within tiny error), we show that the $\vee$-operation is, in fact, easy to approximate when we allow large enough error.

▷ Claim 17. For any boolean-valued f, we have $\deg^+_{1/4}(f^\vee) \le \deg^+(f)$.

Proof. Let $g\colon \{0,1\}^{2n} \to \mathbb{R}_{\ge 0}$ be given by $g(x,y) := (f(x) + f(y))/2 + 1/4$. Then

$$g(x,y) \;=\; \begin{cases} 1/4 & \text{if } f(x) = f(y) = 0, \\ 5/4 & \text{if } f(x) = f(y) = 1, \\ 3/4 & \text{otherwise.} \end{cases}$$

Thus g is a $1/4$-approximation to $f^\vee$. Note also that $\deg^+(g) \le \deg^+(f)$, as desired. ◁

We can now repeat the same idea for nonnegative rank. In Section 3.4 we constructed a boolean matrix (two-party function) F such that $\log \mathrm{rk}^+(F) \leq \mathrm{U}_1(F) \leq m$ and $\log \mathrm{rk}^+_{10^{-5}}(F^\vee) \geq \tilde{\Omega}(m^2)$. We claim that $\log \mathrm{rk}^+_{1/4}(F^\vee) \leq O(m)$, which would finish the proof of Theorem 5. Indeed, analogously to Claim 17, we can define a nonnegative matrix by $G(xx, yy') \coloneqq (F(x,y) + F(x',y'))/2 + 1/4$. This is a $1/4$-approximation to $F^\vee$ and we have $\mathrm{rk}^+(G) \leq 2 \cdot \mathrm{rk}^+(F) + 1 \leq 2^{m+1} + 1$, as claimed.

Abstract

Over twenty years ago, Goldmann and Russell initiated the study of the complexity of the equation satisfiability problem (PolSat) and the NUDFA program satisfiability problem (ProgramSat) in finite groups. They showed that these problems are in P for nilpotent groups while they are NP-complete for non-solvable groups.

In this work we completely characterize finite groups for which the problem ProgramSat can be solved in randomized polynomial time under the assumptions of the Randomized Exponential Time Hypothesis and the Constant Degree Hypothesis. We also determine the complexity of PolSat for a wide class of finite groups. As a by-product, we obtain a classification for ListPolSat, a version of PolSat where each variable can be restricted to an arbitrary subset. Finally, we also prove unconditional algorithms for these problems in certain cases.

1 Introduction

Non-uniform deterministic finite automata (NUDFA) are a well-known concept introduced by Barrington [1], which proves its usefulness in describing important classes of languages defined by Boolean circuits such as NC^1 [2], ACC^0 and AC^0 [6]. Formally, a NUDFA (also called $\mathbf{G}$-program) over a group $\mathbf{G} = (G, \cdot)$ computing an n-ary function $f\colon \{0,1\}^n \longmapsto \{0,1\}$ consists of an l-ary polynomial $\mathbf{p}$ over $\mathbf{G}$ (i.e. the term over $\mathbf{G}$ with some variables replaced with constants from G), a set $S \subseteq G$ (the accepting set) and a sequence of l triples (instructions) of the form $\langle i_j, g_0^j, g_1^j \rangle$ where $1 \leqslant i_j \leqslant n$ and $g_0^j, g_1^j \in G$ for $0 \leqslant j \leqslant l$ (the number of the triple) such that $f(\overline{x}) = 1$ iff $\mathbf{p}(g^1_{x_{i_1}}, g^2_{x_{i_2}}, \ldots, g^l_{x_{i_l}}) \in S$. Note that this definition of NUDFA is not exactly the same as the one introduced in [1] but it is equivalent to the original one. In particular, there are obvious linear time transformations between the two program definitions. Moreover, this new definition does not change the class of languages recognized by NUDFA's over a fixed group.

The natural problem to decide whether the language recognized by a given NUDFA over a fixed group is non-empty (ProgramSat) was introduced in [14] and considered together with the problem of the existence of a solution to a given equation of polynomials over some fixed finite group (PolSat – here the input consists of polynomials $\mathbf{p}$ and $\mathbf{q}$ with variables $x_1, \ldots, x_n$, the question is whether there is some $\overline{a} \in G^n$ with $\mathbf{p}(\overline{a}) = \mathbf{q}(\overline{a})$). In the case of (finite) groups PolSat can be reduced to ProgramSat. In [14] Goldmann and Russell established a polynomial-time algorithm for ProgramSat in nilpotent groups and concluded that also PolSat for nilpotent groups is in P. On the other hand, their proof that PolSat for non-solvable groups is NP-complete implies NP-completeness of ProgramSat for such groups. This last fact was proved directly in [4]. These results reflect the ability of expressing all the functions AND_n by short polynomials of a particular group or by short NUDFA programs. It was known that over any fixed non-solvable group AND_n can be computed by NUDFAs (of size polynomial in n) [2], while over nilpotent groups NUDFAs are able to compute AND_n only of bounded arity n [5]. Note also that over solvable but non-nilpotent groups NUDFA programs are in fact able to compute all of the AND_n's [2], but sometimes these programs are of exponential length, namely $2^{\Omega(n)}$ [5].

It turned out that for a fixed group $\mathbf{G}$ the length of the shortest NUDFA program (over $\mathbf{G}$) computing AND_n plays a crucial role in classifying the computational complexity of ProgramSat($\mathbf{G}$). On the one hand, it was proved in [4] that, if the size of the shortest NUDFA program over a group $\mathbf{G}$ computing AND_n is $2^{\Omega(n)}$ (following [4] we say that $\mathbf{G}$ is AND-weak), then there exists a quasi-polynomial time algorithm solving ProgramSat($\mathbf{G}$). On the other hand, the same paper shows that, if $\mathbf{G}$ is AND-strong (i.e. for every n there exists an efficiently computable NUDFA over $\mathbf{G}$ of polynomial size computing AND_n), then ProgramSat for a wreath product $\mathbf{G} \wr \mathbb{Z}_k$ is NP-complete if $k \geqslant 4$. The problem is that determining the length of a shortest NUDFA program over a fixed group $\mathbf{G}$ computing AND_n is often highly non-trivial. Because of this difficulty with estimating the size of AND_n (occurring, in fact, in many models of computations), [5] introduced the so-called Constant Degree Hypothesis (CDH). In a circuit language it can be stated as follows: Consider a circuit of depth three where the input gates are connected to bounded fan-in AND gates followed by a layer of MOD_p gates and a MOD_q gate as output gate. Under CDH such a circuit needs size $2^{\Omega(n)}$ for computing AND_n (see [15, 16]). In this paper we will only use that CDH implies that groups of the form $\mathbf{G} = \mathbf{G}_p \rtimes \mathbf{N}$, where $\mathbf{G}_p$ is a p-group and $\mathbf{N}$ is a nilpotent group, are AND-weak (see Theorem 10 in [5]).

The difficulty of determining which groups are AND-weak is probably the reason why for almost 20 years after publishing [14] and [4] not too much progress has been made in characterizing the complexity of ProgramSat and PolSat for solvable but non-nilpotent groups. A number of results [19, 18, 11] were proved but all of them were restricted to showing polynomial time algorithms solving PolSat for some subclasses of groups with so-called Fitting length at most 2 (groups $\mathbf{G}$ having a nilpotent normal subgroup $\mathbf{N}$ such that $\mathbf{G}/\mathbf{N}$ is nilpotent), see [12] for a most comprehensive result. An important step towards the full classification of the computational complexity of ProgramSat for finite groups was made in 2020 when we proved in [20, 30, 23] that for every finite group of Fitting length at least 3 the problem PolSat (and in a consequence also ProgramSat) is not in P, unless the Exponential Time Hypothesis (ETH) fails. Shortly thereafter in [21] the first three authors gave examples of groups with Fitting length 2 and non-tractable PolSat (and ProgramSat), again, under the assumption of ETH.

This paper (among other things) gives a full characterization of finite groups for which ProgramSat is tractable in randomized polynomial time. Our classification also works for a related problem we call ListPolSat($\mathbf{G}$): given polynomials $\mathbf{p}$ and $\mathbf{q}$ with variables $x_1, \ldots, x_n$

and a list of subsets $A_1, \ldots, A_n \subseteq G$, decide whether there is $\overline{a} = (a_1, \ldots, a_n) \in A_1 \times \ldots \times A_n$ with $\mathbf{p}(\overline{a}) = \mathbf{q}(\overline{a})$. While we are not aware of any previous results on ListPolSat for finite algebras, it has been studied in the form of equations with rational constraints in [29] for word equations and in [10] for groups. Our classification of the complexity of these problems relies on both above-mentioned complexity assumptions (hypotheses): rETH and CDH.

▶ **Theorem 1.** *Under the assumption of rETH and CDH, the problems* ProgramSat($\mathbf{G}$) *and* ListPolSat($\mathbf{G}$) *for a finite group* $\mathbf{G}$ *are in* RP *if and only if there is a prime* p *and a normal* p*-subgroup* $\mathbf{G}_p$ *of* $\mathbf{G}$ *with* $\mathbf{G}/\mathbf{G}_p$ *being nilpotent.*

Note that our results partially confirm the intuition behind CDH, which was stated over 30 years ago: we show that in all cases in which there is a chance for AND-weakness, it is implied by CDH.

The proof of Theorem 1 is based on two main ideas. The first one is to show that, if some group $\mathbf{G}$ is AND-weak, then ProgramSat($\mathbf{G}$) satisfies what we call the *none-or-many property*: if a language recognized by a given program over $\mathbf{G}$ is not empty, then this language contains at least a polynomial fraction of all words (see Lemma 10). This gives us a randomized polynomial time algorithm solving ProgramSat($\mathbf{G}$) for groups which are AND-weak. Now, assuming CDH we immediately obtain the upper bound from Theorem 1. The second idea is to use polynomials witnessing the non-nilpotency of $\mathbf{G}$ to produce relatively short (of subexponential size) programs (and polynomials) expressing CNF-formulas. This, together with rETH ensures us that there is no polynomial time randomized algorithm solving ProgramSat for a group $\mathbf{G}$ which does not have a normal p-subgroup $\mathbf{G}_p$ with a nilpotent quotient $\mathbf{G}/\mathbf{G}_p$. In fact, we prove the main lemmas of this part of the proof (Lemma 14 and Theorem 16) in the much more general setting of solvable algebras (in a sense universal algebraic sense) from a so-called congruence permutable variety. We use two powerful universal algebraic tools: Tame Congruence Theory [17] and Commutator Theory [13] to prove Lemma 14, which tells us how to use non-nilpotency to produce polynomials over non-nilpotent algebras which imitate polynomials over finite fields. We conclude with a subexponential reduction from 3-CNF-SAT to ProgramSat which is based on the polynomials of small degree from [3] that describe symmetric periodic functions and were used to construct relatively small modular circuits for AND.

The situation for PolSat is more involved: indeed, we are far from getting full classification. The main reason is that in this case we cannot restrict the arguments of a polynomial to certain values. Hence, we need much more control to be able to use the polynomials from [3] in the proof of Theorem 16. In order to state Theorem 16 in the group case, we write $C_{\mathbf{G}}(\mathbf{A}) = \{\, g \in G \mid ga = ag \text{ for all } a \in A \,\}$ for the centralizer of a normal subgroup $\mathbf{A}$ of $\mathbf{G}$:

▶ **Theorem 2.** *Let* $\mathbf{G}$ *be a finite solvable group with two minimal non-trivial normal subgroups* $\mathbf{A}$ *and* $\mathbf{B}$ *such that* $|A|$ *and* $|B|$ *are coprime and* $C_{\mathbf{G}}(\mathbf{A}) \cdot C_{\mathbf{G}}(\mathbf{B}) \neq G$*. Then the problem* PolSat($\mathbf{G}$) *is not in* RP *under rETH.*

▶ **Corollary 3.** *If a finite group* $\widetilde{\mathbf{G}}$ *has a quotient as in Theorem 2, then* PolSat($\widetilde{\mathbf{G}}$) *is not in* RP *under rETH.*

Notice that the conditions for hardness in Theorem 1 and Theorem 2 are quite similar. Indeed, if we are not in the RP-case of Theorem 1, then there are two different primes in $|[\mathbf{G}, \mathbf{G}]|$ witnessed by two normal subgroups $\mathbf{A}$ and $\mathbf{B}$ of $\mathbf{G}$ (but contained in $[\mathbf{G}, \mathbf{G}]$) of coprime order with $C_{\mathbf{G}}(\mathbf{A}) \neq G \neq C_{\mathbf{G}}(\mathbf{B})$ as opposed to $C_{\mathbf{G}}(\mathbf{A}) \cdot C_{\mathbf{G}}(\mathbf{B}) \neq G$ in Theorem 2. This subtle difference prevents us from giving a classification as Theorem 1 for the case of PolSat (for details, we refer to the proof of Theorem 16). Moreover, Theorem 4 shows that this is not due to our ignorance but there are indeed groups for which PolSat is in RP and ProgramSat is not (under rETH).

▶ **Theorem 4.** *Let* $\mathbf{G}$ *be the semidirect product* $\mathbf{N} \rtimes \mathbf{H}$ *of nilpotent groups* $\mathbf{N}$ *and* $\mathbf{H}$ *and let* $|G|$ *have at most two prime factors. Then* PolSat($\mathbf{G}$) *is in* RP *under CDH. Moreover, if* $\mathbf{H}$ *is abelian,* PolSat($\mathbf{G}$) *is in* RP *unconditionally.*

Note here that the last sentence of Theorem 4 gives an unconditional upper bound for the complexity of PolSat. This together with Theorem 1 enables us to classify the computational complexity of PolSat for dihedral groups (i.e the groups of symmetries of regular polygons, where $\mathbf{D}_m = \mathbb{Z}_m \rtimes \mathbb{Z}_2$ denotes the symmetry group of the m-gon).

▶ **Corollary 5** (Classification of dihedral groups)**.**

(i) *If* $m = 2^\alpha p^\beta$ *for* $\alpha, \beta \in \mathbb{N}$ *and an odd prime* p*, then* PolSat($\mathbf{D}_m$) *is in* RP*.*

(ii) *Otherwise* PolSat($\mathbf{D}_m$) *cannot be solved in* RP *under rETH (resp.* P *under ETH).*

Furthermore, based on Theorem 2 we obtain (under the assumption of CDH and rETH) a classification of PolSat for wreath products of nilpotent groups.

▶ **Corollary 6.** *Let* $\mathbf{G}$ *and* $\mathbf{H}$ *be nilpotent groups. Under CDH and rETH,* PolSat($\mathbf{G} \wr \mathbf{H}$) *is in* RP *if an only if* $\mathbf{G}$ *is a p-group or* $|G| \cdot |H|$ *has at most two prime divisors.*

In [12] a question was asked about the computational complexity of PolSat for several examples of groups. Among them were four groups of order 24 (complexity of PolSat for groups of smaller order was known previously). In this paper we determine the computational complexity of PolSat for three of these groups: $\mathbf{D}_{12}$, $(\mathbb{Z}_2 \times \mathbb{Z}_2 \times \mathbb{Z}_3) \rtimes \mathbb{Z}_2$ and $\mathbb{Z}_3 \rtimes \mathbf{Q}$, where $\mathbf{Q}$ is the quaternion group. It turns out that PolSat for these groups is in RP (see Corollary 5 and Example 21). On the other hand, $\mathbf{S}_4$, the fourth of the groups mentioned above, was shown in [20, 23] to have non-tractable PolSat problem (assuming ETH).

2 Preliminaries

We use $[m \,..\, n]$ to denote the interval of integers $\{m, \ldots, n\}$, the difference of sets is denoted by $A - B$. We use standard notation from complexity theory, which can be found in any textbook on complexity, e.g. [27]. In particular, we write RP for randomized polynomial time (with one-sided error).

ETH and rETH. The Exponential Time Hypothesis (ETH) and its randomized version rETH (see e.g. [9]) is the conjecture that there is some $\delta > 0$ such that every (randomized) algorithm for 3-CNF-SAT needs time $\Omega(2^{\delta n})$ in the worst case where n is the number of variables of the given 3-CNF-SAT instance. By the Sparsification Lemma [25, Thm. 1] this is equivalent to the existence of some $\epsilon > 0$ such that every algorithm for 3-CNF-SAT needs (randomized) time $\Omega(2^{\epsilon(m+n)})$ in the worst case where m is the number of clauses of the given 3-CNF-SAT instance (see also [8, Thm. 14.4]). In particular, under ETH/rETH there is no (randomized) algorithm for 3-CNF-SAT running in time $2^{o(n+m)}$. Here we only consider one-sided errors; clearly our results also remain true when understanding rETH with two-sided error.

Group Theory. Throughout, we only consider finite groups $\mathbf{G}$ with underlying set (universe) G. We follow the notation of [28]. For groups $\mathbf{G}$ and $\mathbf{H}$ we write $\mathbf{H} \leqslant \mathbf{G}$ if $\mathbf{H}$ is a subgroup of $\mathbf{G}$ and $\mathbf{H} < \mathbf{G}$ if $\mathbf{H}$ is a proper subgroup of $\mathbf{G}$. For a subset $X \subseteq G$ we write $\langle X \rangle$ for the subgroup generated by X. We write $[x, y] = x^{-1}y^{-1}xy$ for the *commutator*. The commutator of subgroups $\mathbf{X}, \mathbf{Y} \leqslant \mathbf{G}$ is defined by $[\mathbf{X}, \mathbf{Y}] = \langle\, [x, y] \mid x \in X, y \in Y \,\rangle$.

Let $\mathbf{N} \leqslant \mathbf{H}$ be a normal subgroup of $\mathbf{G}$. We define the *centralizer* of $\mathbf{H}$ modulo $\mathbf{N}$ as $C_{\mathbf{G}}(\mathbf{H}/\mathbf{N}) = \{ g \in G \mid [g,h] \in N \text{ for all } h \in H \}$. The center of a group is $Z(\mathbf{G}) = C_{\mathbf{G}}(\mathbf{G})$. Nilpotent groups can be defined inductively: $\mathbf{G}$ is nilpotent of class 1 if it is abelian; $\mathbf{G}$ is *nilpotent* of class c if $\mathbf{G}/Z(\mathbf{G})$ is nilpotent of class $c-1$. A group is called a *p-group* (for p prime) if its order is p^k for some $k \in \mathbb{N}$. It is well-known that a finite group is nilpotent iff it is a direct product of p-groups (see e.g. 5.1.3 and 5.2.4 in [28]). We will use this fact without further reference. If $\mathbf{G} = \mathbf{NH}$ where $\mathbf{N}$ is a normal subgroup of $\mathbf{G}$ and $\mathbf{H}$ a subgroup with $N \cap H = \{1\}$, $\mathbf{G}$ is called a *semidirect product* and we write $\mathbf{G} = \mathbf{N} \rtimes \mathbf{H}$. Notice that $\mathbf{G}/\mathbf{N} = \mathbf{H}$ in this case. Elements of $\mathbf{N} \rtimes \mathbf{H}$ can be viewed as pairs (n,h) with $n \in N$ and $h \in H$ with the multiplication rule $(n_1,h_1)(n_2,h_2) = (n_1\, {}^{h_1}n_2, h_1h_2)$ where ${}^{h_1}n_2 = h_1n_2h_1^{-1}$ is an action (via automorphisms) of $\mathbf{H}$ on $\mathbf{N}$. We will use the following classical result (see e.g. [28, 9.1.2]):

▶ **Fact 7** (Schur-Zassenhaus Theorem). *If* $\mathbf{G}$ *is a group with a normal subgroup* $\mathbf{N}$ *and* $|N|$ *and* $|\mathbf{G}/\mathbf{N}|$ *are coprime, then* $\mathbf{G} = \mathbf{N} \rtimes \mathbf{G}/\mathbf{N}$.

To define the wreath product $\mathbf{G} \wr \mathbf{H}$ of groups $\mathbf{G}$ and $\mathbf{H}$, we start with the direct power $\mathbf{G}^H = \{ f : H \to G \}$. Now $\mathbf{H}$ has a natural left action on $\mathbf{G}^H$ given by $({}^hf)(y) = f(h^{-1}y)$ for $f \in \mathbf{G}^H$, $h \in H$ and $y \in H$. Now the *wreath product* $\mathbf{G} \wr \mathbf{H}$ is defined to be the corresponding semidirect product $\mathbf{G}^H \rtimes \mathbf{H}$.

Algebra. A finite algebra $\mathbf{A}$ is a finite universe A together with a finite number of k_i-ary fundamental operations $f_i : A^{k_i} \to A$ for $i \in I$. A *term* is a composition of fundamental operations and a *polynomial* is a term with some variables replaced by constants from A; we write $\mathrm{Pol}(\mathbf{A})$ for the set of polynomials over $\mathbf{A}$. An equivalence relation which preserves all operations of $\mathbf{A}$ is called a *congruence* (more precisely, an equivalence relation $\alpha \subseteq A \times A$ is a congruence iff for every fundamental operation f, say r-ary, of $\mathbf{A}$ and $(a_1,b_1), \ldots, (a_r,b_r) \in \alpha$ we have $(f(\overline{a}), f(\overline{b})) \in \alpha$). We usually write $a \overset{\alpha}{\equiv} b$ to express that $(a,b) \in \alpha$. For a congruence relation α on $\mathbf{A}$ the congruence class containing an element a is denoted by a/α and A/α is the set of all congruence classes of α. The congruences of an algebra $\mathbf{A}$, when ordered by inclusion (denoted by $\alpha \leqslant \beta$), form the complete lattice with the top element $1_{\mathbf{A}} = A \times A$ and the bottom element $0_{\mathbf{A}}$ consisting of all pairs (a,a) for $a \in A$. We frequently omit the subscripts in $0_{\mathbf{A}}$ and $1_{\mathbf{A}}$. Given two congruences β and γ, we write $\beta \vee \gamma$ for the *join*, which is the smallest congruence containing both β and γ. A congruence α is called *join-irreducible* iff, whenever $\alpha = \beta \vee \gamma$ for congruences β and γ, already $\alpha \in \{\beta, \gamma\}$. Note that a join-irreducible α has a unique congruence α_- such that $\alpha_- < \alpha$ and there is no β with $\alpha_- < \beta < \alpha$.

A normal subgroup $\mathbf{N}$ of a group $\mathbf{G}$ defines a congruence $\alpha_{\mathbf{N}} = \{ (a,b) \in G^2 \mid a^{-1}b \in N \}$. As $\mathbf{G}/\mathbf{N} = \mathbf{G}/\alpha_{\mathbf{N}}$, we do not distinguish between congruences and normal subgroups.

The commutator $[\mathbf{H}, \mathbf{K}]$ of normal subgroups of a group has been generalized as an operation on congruences for arbitrary algebras (see [13]) and then used to extend notions of solvability and nilpotency onto such algebras. For a precise definition of the commutator $[\alpha, \beta]$ of congruences α and β we refer to [13] and simply note that for groups it is the usual commutator. We say that a congruence α *centralizes* β modulo γ iff $[\alpha, \beta] \leqslant \gamma$. The biggest α which centralizes β modulo γ is denoted by $(\gamma : \beta)$ and called the *centralizer* of β modulo γ. In the group case this agrees exactly with the usual definition of the centralizer.

Another important concept of universal algebra derived from group theory is a *Malcev term*: it is a term $\mathbf{d}$ satisfying $\mathbf{d}(y,x,x) = \mathbf{d}(x,x,y) = y$. The existence of such a term implies many nice properties of an algebra (e.g. connected with the behaviour of commutators and the congruence lattice). In the group case, the term $\mathbf{d}(x,y,z) = xy^{-1}z$ is an example of a Malcev term. An algebra with a Malcev term is called a *Malcev algebra*.

Some of our proofs use advanced tools of universal algebra: the Commutator Theory and the Tame Congruence Theory as presented in the books [13] and [17]. The reader may find a not too long introduction to the needed notions and facts from these theories in [24].

Satisfiability problems. For the definition of a $\mathbf{G}$-program (aka. NUDFA over $\mathbf{G}$) and ProgramSat we refer to the introduction. Usually, we denote both polynomials and $\mathbf{G}$-programs by $\mathbf{p}$ and, for a simpler notation, also use $\mathbf{p}$ to denote the function $f : \{0,1\}^n \to \{0,1\}$ computed by the $\mathbf{G}$-program. For a unified treatment of ListPolSat and ProgramSat, we further define 2-ListPolSat which is like ListPolSat but the A_i all may contain only two elements. Notice that in groups, as we can multiply by inverses, we can assume that the input for these problems consists of only one polynomial (plus the lists restricting variables). Thus, in the group setting we call $\overline{a} \in G^n$ a solution to an instance $\mathbf{p}(\overline{x})$ for PolSat($\mathbf{G}$) if $\mathbf{p}(\overline{a}) = 1$. Likewise, we call some $\overline{a} \in \{0,1\}^n$ a solution for a $\mathbf{G}$-program $\mathbf{p}$ if $\mathbf{p}(\overline{a}) = 1$ (recall that $\mathbf{p}$ computes a function $\{0,1\}^n \to \{0,1\}$). It is obvious that we can treat 2-ListPolSat as a "subproblem" of ProgramSat in which NUDFA's programs have the following property: for every two instructions (i_j, g_0^j, g_1^j), (i_k, g_0^k, g_1^k) of the program, if $i_j = i_k$, then $g_0^j = g_0^k$ and $g_1^j = g_1^k$. Also note that even for general algebras PolSat($\mathbf{A}$) is the special case of ListPolSat($\mathbf{A}$) where all the A_i are A. These observations and some other well-known results are summarized as follows (see also [14, 4]):

▶ **Lemma 8.** *Let* $\mathbf{G}$ *be a group. Then*

- *If* $\mathbf{H} = \mathbf{G}/\mathbf{N}$, *then* PolSat($\mathbf{H}$) $\leqslant_{dtt}$ PolSat($\mathbf{G}$).
- *If* $\mathbf{H} \leqslant \mathbf{G}$ *or* $\mathbf{H} = \mathbf{G}/\mathbf{N}$, *then* ProgramSat($\mathbf{H}$) $\leqslant_m$ ProgramSat($\mathbf{G}$) *and* ListPolSat($\mathbf{H}$) $\leqslant_m$ ListPolSat($\mathbf{G}$).
- PolSat($\mathbf{G}$) $\leqslant_m$ 2-ListPolSat($\mathbf{G}$)
- 2-ListPolSat($\mathbf{G}$) $\leqslant_m$ ProgramSat($\mathbf{G}$) *and* 2-ListPolSat($\mathbf{G}$) $\leqslant_m$ ListPolSat($\mathbf{G}$).

Here $A \leqslant_m B$ denotes a polynomial-time many-one reduction and $A \leqslant_{dtt} B$ denotes a polynomial-time disjunctive truth-table reduction: one instance x for A is reduced to several instances $y_1, \ldots, y_k$ of B such that $x \in A$ if and only if there is some i with $y_i \in B$.

3 CDH and the Many-Solutions Property

We wish to treat NUDFA programs and polynomials (with variables restricted to lists) in a unified setting. For this we have to face the problem that programs are defined on Boolean domains whereas the domain of a variable of a polynomial is (a subset of) a group. So with an instance of ListPolSat / ProgramSat we associate an indicator function $f : \prod_{i=1}^n A_i \to \{0,1\}$ with $|A_i| \geqslant 2$ ($A_i \subseteq G$ resp. $A_i = \{0,1\}$) such that $f(\overline{x}) = 1$ iff $\overline{x}$ is a solution to the corresponding NUDFA program/polynomial equation with lists. In these cases we measure the size of f (denoted by size(f)) by the size of the smallest program/polynomial representing it (in the second case together with the sizes of lists). More precisely, in the definition of the size we take the smallest possible representation for f.

Note that independently of the model the function f was created in, if we replace some variables by constants, or restrict some of the A_i's from the domain to smaller sets $A_i' \subseteq A_i$ with $|A_i'| \geqslant 2$, we still obtain an indicator function (of possibly smaller arity) for another ListPolSat / ProgramSat instance. Moreover, the size of a function after such operations does not increase. This is the crucial property we use in Proposition 9 below. We will use the following notation:

- $f[x_J/\overline{a}]$ for a function obtained from f by substituting x_j by a_j for all $j \in J$,
- $f_{|\mathcal{B}}$ for a function obtained from f by restricting the domain of f, that is $\prod_{i=1}^n A_i$, to $\mathcal{B} = \prod_{i=1}^n B_j$ (for $B_j \subseteq A_j$),
- $f[x_i/a]$ for the substitution of one variable.

Also we combine these notations, e.g. by writing $f[x_I/\overline{b}, x_i/a]_{|\mathcal{B}}$.

Our aim is to bound the size of a general function using previous knowledge about the size for describing the AND function. In order to do so, we call $f : \prod_{i=1}^n A_i \to \{0,1\}$ with $|A_i| \geqslant 2$ for all i an n-ary *spike* if there is some $\overline{a} \in \prod_{i=1}^n A_i$ with $f(\overline{a}) = 1$ and for all $\overline{x} \neq \overline{a}$ we have $f(\overline{x}) = 0$. Let $\gamma : \mathbb{N} \to \mathbb{N}$ be the function $\gamma(n) = \min\{\,\mathrm{size}(f) \mid f \text{ is an } n\text{-ary spike}\,\}$. Notice that γ is monotone. Thus, its inverse $\gamma^{-1}(m) = \max\{\,n \in \mathbb{N} \mid \gamma(n) \leqslant m\,\}$ as a function $\mathbb{N} \to \mathbb{N}$ is well-defined and also monotone.

Sometimes we will also write $\gamma_{\mathrm{Prog},\mathbf{G}}$ or $\gamma_{\mathrm{Pol},\mathbf{G}}$ when we want to specify the model.

▶ **Proposition 9.** *Let f be an n-ary indicator function with domain $\mathcal{A} = \prod_{i=1}^n A_i$. Then either f is constant zero or $\left|f^{-1}(1)\right| / |\mathcal{A}| \geqslant 1/|\mathcal{A}|^{\gamma^{-1}(\mathrm{size}(f))}$. In particular, if $\gamma(n) \in 2^{\Omega(n)}$, then $\left|f^{-1}(1)\right| / |\mathcal{A}| \geqslant 1/\mathrm{size}(f)^{\mathcal{O}(1)}$.*

Proof. Our proof relies on the same idea as [21, Theorem 6.1]; however, we have to overcome the difficulty to deal with non-boolean domains. If f is constantly 1 the statement holds; otherwise f is non-nonstant. The idea is to successively substitute constants for variables while not increasing the density of $f^{-1}(1)$ in the full domain: If there is some $i \in [1\,..\,n]$ such that for all $a \in A_i$ the function $f[x_i/a]$ is not constant 0, we choose $b \in A_i$ such that $\left|f[x_i/b]^{-1}(1)\right|$ is minimal among all $\left|f[x_i/a]^{-1}(1)\right|$ for $a \in A_i$. Observe that $f[x_i/b]$ is not a constant function and $\left|f[x_i/b]^{-1}(1)\right| \leqslant \left|f^{-1}(1)\right| / |A_i|$. Now, we proceed by induction eventually obtaining some $I \subseteq [1\,..\,n]$ and $\overline{b} \in \prod_{i\in I} A_i$ such that $f[x_I/\overline{b}]$ is not constant, $1 \leqslant \left|f[x_I/\overline{b}]^{-1}(1)\right| \cdot \prod_{i\in I} |A_i| \leqslant \left|f^{-1}(1)\right|$, and for every $i \in [1\,..\,n] - I$ there is some $a \in A_i$ such that $f[x_I/\overline{b}, x_i/a]$ is constant zero. Now, we can restrict all remaining variables to two-element sets and we obtain a $(n - |I|)$-ary spike. As during this process the size of f does not increase, we obtain:

$$\frac{\left|f^{-1}(1)\right|}{|\mathcal{A}|} \geqslant \frac{\prod_{i\in I} |A_i|}{\prod_{i=1}^n |A_i|} = \frac{1}{\prod_{[1..n]-I} |A_i|} \geqslant \frac{1}{|\mathcal{A}|^{n-|I|}} \geqslant \frac{1}{|\mathcal{A}|^{\gamma^{-1}(\mathrm{size}(f))}}.$$ ◀

We say that ProgramSat($\mathbf{G}$), ListPolSat($\mathbf{G}$) or PolSat($\mathbf{G}$) has the *none-or-many property* if for any instance $\mathbf{p}$ of length m either $\mathbf{p}$ has no solution or a random assignment will be a solution with $1/m^{\mathcal{O}(1)}$ probability (recall that we call $\overline{a} \in G^n$ a solution to an instance $\mathbf{p}(\overline{x})$ for PolSat($\mathbf{G}$) if $\mathbf{p}(\overline{a}) = 1$ and similarly for ListPolSat($\mathbf{G}$) and ProgramSat).

▶ **Lemma 10.** *Let G be a group with $\gamma_{\mathrm{Prog},G}(n) \in 2^{\Omega(n)}$. Then, the problems* ProgramSat($\mathbf{G}$)*,* ListPolSat($\mathbf{G}$) *and* PolSat($\mathbf{G}$) *have the none-or-many property.*

In particular, ProgramSat($\mathbf{G}$)*,* ListPolSat($\mathbf{G}$) *and* PolSat($\mathbf{G}$) *are in* RP*.*

For the proof of Lemma 10 notice that a G-program for a spike is never longer than a polynomial for a spike. Therefore, the requirement $\gamma_{\mathrm{Prog},G}(n) \in 2^{\Omega(n)}$ also can be used for ListPolSat. The result for PolSat then follows by Lemma 8. For some polynomial or $\mathbf{G}$-program $\mathbf{p}$ we use Proposition 9 to get a bound $\left|\mathbf{p}^{-1}(1)\right| / |G^n| \geqslant 1/|G|^{\gamma^{-1}(|\mathbf{p}|)} \in 1/|G|^{\mathcal{O}(\log|\mathbf{p}|)} \subseteq 1/|\mathbf{p}|^{\mathcal{O}(1)}$.

▶ Remark 11. Notice that, if $\mathbf{G}$ is a group with $\gamma_{\mathrm{Prog},\mathbf{G}}(n) \in 2^{\Omega(n)}$, then by [4, Theorem 2] ProgramSat($\mathbf{G}$), ListPolSat($\mathbf{G}$) and PolSat($\mathbf{G}$) also can be solved in deterministic quasi-polynomial time (notice that [4, Theorem 2] technically is not for ListPolSat($\mathbf{G}$) but the proof can easily be adapted).

CDH-based conditional algorithms. Let us recall the consequence of the constant degree hypothesis (CDH) which has been proved in Theorem 10 of [5]:

(A) Let $\mathbf{G}_p$ be a p-group, $\mathbf{N}$ a nilpotent group and $\mathbf{G} = \mathbf{G}_p \rtimes \mathbf{N}$. If CDH is true, then every $\mathbf{G}$-program computing the n-ary AND function has length $2^{\Omega(n)}$.

Note that [5] gives a proof of CDH in the case that $\mathbf{N}$ is abelian, see (C) in Section 6 below. As an immediate consequence of Lemma 10 and (A), we obtain our next result.

▶ **Corollary 12.** *Let $\mathbf{G}_p$ be a p-group, $\mathbf{N}$ a nilpotent group and $\mathbf{G} = \mathbf{G}_p \rtimes \mathbf{N}$. If CDH is true, then* ProgramSat($\mathbf{G}$), ListPolSat($\mathbf{G}$) *or* PolSat($\mathbf{G}$) *have the none-or-many property.*

In particular, if CDH is true, then ProgramSat($\mathbf{G}$), ListPolSat($\mathbf{G}$) *and* PolSat($\mathbf{G}$) *are in* RP.

4 Lower Bounds

In this section we will prove our hardness conditions. Instead of ProgramSat we will prove intractability of 2-ListPolSat. For that we need go deeply into the local structure of finite algebras (called sometimes as Tame Congruence Theory) as described in [17]. In our setting, i.e. solvable Malcev algebras, this local structure, (relative to a pair of congruences $\alpha \prec \beta$, i.e. $\alpha < \beta$ with no congruence γ in between: $\alpha < \gamma < \beta$) reduces to a vector space over a finite field. The prime that is the characteristic of this field, is also called the *characteristic* of the pair (α, β). For a join-irreducible congruence γ we define its *characteristic* to be the characteristic of the pair (γ_-, γ).

Different characteristics of two join-irreducible congruences is one of two important ingredients we use in the proof of Theorem 16. The second one is what we call congruence collaboration: Two congruences α and β of an algebra $\mathbf{A}$ are called *collaborating* if there are 3 different elements $a, c, b \in A$ satisfying $a \overset{\alpha-\beta}{\frown} c \overset{\beta}{\frown} b$ or $a \overset{\alpha}{\frown} c \overset{\beta-\alpha}{\frown} b$, where $x \overset{R}{\frown} y$ stands for $(x, y) \in R$. Notice that in a group case any two distinct non-trivial normal subgroups are collaborating. We will also use following easy observation.

▶ **Lemma 13.** *For two congruences $\varphi \neq 1_{\mathbf{A}} \neq \psi$ of an algebra $\mathbf{A}$ we have $\varphi \cup \psi \neq 1_{\mathbf{A}}$.*

Proof. Suppose $\varphi \cup \psi = 1_{\mathbf{A}} \neq \varphi$. To see that then $(a, b) \in \psi$ for all $a, b \in A$, note first that $(a, b) \in \psi$ whenever $(a, b) \notin \varphi$. Now let $(a, b) \in \varphi$. Obviously $\varphi \neq 1_{\mathbf{A}}$ gives an element $c \in A - a/\varphi = A - b/\varphi$. But the previous case puts both (c, a) and (c, b) into ψ, so that $(a, b) \in \psi$ as claimed. ◀

Note that Lemma 13 cannot be extended to more than 2 congruences: in a finitely dimensional vector space the union of all 1-dimensional subspaces covers the entire space.

In the next Lemma we use the polynomial which witnesses the lack of a centralization to produce a polynomial of the algebra which imitates a given polynomial over the field $GF(p)$. A similar argument was used in [22].

▶ **Lemma 14.** *Let $\mathbf{A}$ be a finite solvable Malcev algebra. Moreover, let γ be a join-irreducible congruence of characteristic p such that $(\gamma_- : \gamma) \neq 1$. Then for:*

- *every pair $(e, a) \in \gamma$ of different elements,*
- *every subset $\top \subseteq A$ that is a union of $(\gamma_- : \gamma)$-cosets,*
- *and every n-ary polynomial $w(\overline{x})$ of degree s over the field $GF(p)$ that sends the set $\{0, 1\}^n$ to $\{0, 1\}$*

there is an n-ary polynomial $[w]_{\gamma, \top, a, e}$ of the algebra $\mathbf{A}$ such that

- *both the size of* $[w]_{\gamma,\top,a,e}$ *and the time needed to compute it are bounded by* $2^{O(s\cdot\log n)}$,
- *for any tuple* $\overline{x}\in A^n$ *we have*

$$[w]_{\gamma,\top,a,e}(\overline{x}) = \begin{cases} a, & \text{if } w(b_\top(x_1),\dots,b_\top(x_n)) = 1,\\ e, & \text{if } w(b_\top(x_1),\dots,b_\top(x_n)) = 0,\end{cases}$$

where $b_\top : A \longrightarrow \{0,1\}$ *is defined by* $b_\top(x) = 1$ *iff* $x\in\top$.

Proof. First put $\gamma^\star = (\gamma_- : \gamma)$ and let $\{d_0, d_1, \dots, d_r\}$ be a transversal of the quotient $\mathbf{A}/\gamma^\star$. Moreover, pick a (γ_-,γ)-minimal set V and two elements $(e',a')\in\gamma|_V-\gamma_-$. By N denote the trace of V containing both e' and a'. Note that $(\mathbf{A}|_N)/\gamma_-$ is polynomially equivalent to a one-dimensional vector space over a field of characteristic p. In fact we will use only its additive structure $((\mathbf{A}|_N)/\gamma_-,+)$ which is isomorphic to a certain power of $(\mathbb{Z}_p,+)$. We can assume that e'/γ_- is the neutral element of this group and that addition in this group is realized (modulo γ_-) by the polynomial $x+y=\mathbf{d}(x,e',y)$, where $\mathbf{d}$ is a Malcev term for $\mathbf{A}$. Note that, despite the fact that the addition defined above is guaranteed to behave nicely only modulo γ_-, the properties of the Malcev term give us that $e'+e' = \mathbf{d}(e',e',e') = e'$. Since we will be summing the large amount of summands, to keep the sum relatively short (i.e. of the length which is polynomial in the sum of the summands' lengths) we will compose the addition in a balanced binary way, i.e. the tree of a polynomial realizing the sum of m summands is supposed to be the complete binary tree with m leaves – we will point out when this is necessary. Now we use the argument for the second half of Lemma 3.1 in [22] to show that for any pair $(c,d)\notin\gamma^\star$ there is a binary polynomial $\mathbf{s}_{cd}(x,y)$ of $\mathbf{A}$, satisfying

$$\begin{aligned} \mathbf{s}_{cd}(e',y) &= e', && \text{for all } y\in A,\\ \mathbf{s}_{cd}(a',c) &\overset{\gamma_-}{\equiv} e',\\ \mathbf{s}_{cd}(a',d) &= a'. \end{aligned} \tag{1}$$

Because $(e',a')\notin\gamma_-$ and γ is join-irreducible, we know that $\gamma=\Theta(e',a')$. Now if $(c,d)\notin\gamma^\star$ then $[\Theta(c,d),\Theta(e',a')]\not\leqslant\gamma_-$ so that Exercise 6.6 in [13] supplies us with a binary polynomial $\mathbf{s}(x,y)$ of $\mathbf{A}$ such that $\mathbf{s}(e',c)\overset{\gamma_-}{\equiv}\mathbf{s}(a',c)$ but $\mathbf{s}(e',d)\overset{\gamma_-}{\not\equiv}\mathbf{s}(a',d)$. The second property gives $\Theta(\mathbf{s}(e',d),\mathbf{s}(a',d))=\gamma\ni(e',a')$ and therefore there is a unary polynomial $\mathbf{p}$ of $\mathbf{A}$ that takes the pair $(\mathbf{s}(e',d),\mathbf{s}(a',d))$ to (e',a') (see e.g. Lemma 3.2 in [24]). Now it should be easy to check that for the polynomial $\mathbf{s}_{cd}(x,y)=\mathbf{d}(\mathbf{ps}(x,y),\mathbf{ps}(e',y),e')$ we have

$$\begin{aligned} \mathbf{s}_{cd}(e',y) &= \mathbf{d}(\mathbf{ps}(e',y),\mathbf{ps}(e',y),e') &&= e',\\ \mathbf{s}_{cd}(a',c) &= \mathbf{d}(\mathbf{ps}(a',c),\mathbf{ps}(e',c),e') &&\overset{\gamma_-}{\equiv} \mathbf{d}(\mathbf{ps}(e',c),\mathbf{ps}(e',c),e') &&= e',\\ \mathbf{s}_{cd}(a',d) &= \mathbf{d}(\mathbf{ps}(a',d),\mathbf{ps}(e',d),e') &&= \mathbf{d}(a',e',e') &&= a', \end{aligned}$$

as claimed in (1).

Using the fact that $[\gamma,\gamma^\star]\leqslant\gamma_-$ we can keep conditions (1) modulo γ_- by varying the second variable modulo $\gamma^\star$:

$$\begin{aligned} \mathbf{s}_{cd}(e',y) &= e', && \text{for each } y\in A,\\ \mathbf{s}_{cd}(a',y) &\overset{\gamma_-}{\equiv} e', && \text{for each } y\in c/\gamma^\star,\\ \mathbf{s}_{cd}(a',y) &\overset{\gamma_-}{\equiv} a', && \text{for each } y\in d/\gamma^\star. \end{aligned} \tag{2}$$

Now we want c and d to range over our transversal of $\mathbf{A}/\gamma^\star$ so that for $i\neq j$ we put $\mathbf{s}_{ij}(x,y)=\mathbf{e}_V\mathbf{s}_{d_id_j}(\mathbf{e}_V(x),y)$, where $\mathbf{e}_V$ is the unary idempotent polynomial of $\mathbf{A}$ with range V. Obviously $\mathbf{s}_{ij}$ satisfies all the properties of $\mathbf{s}_{d_id_j}$ listed in (2), but the polynomial $\mathbf{s}_{ij}$ has its range contained in V and for any fixed $y\in A$ the mapping $V\ni v\longmapsto\mathbf{s}_{ij}(v,y)\in V$ is either a permutation of the (γ_-,γ)-minimal set V or collapses $\gamma|_V$ to γ_-, i.e. it is constant modulo γ_- on $\gamma|_V$-classes.

Hence, as for $v \in N$ and $y \in d_i/\gamma_-$ the map $v \longmapsto \mathbf{s}_{ij}(v,y)$ is not a permutation, we have $\mathbf{s}_{i,j}(v,y) \overset{\gamma_-}{\equiv} \mathbf{s}_{i,j}(a',y) \overset{\gamma_-}{\equiv} e' = \mathbf{s}_{i,j}(e',y)$, which allows us to replace the second line in (2) by:

$$\mathbf{s}_{ij}(v,y) \overset{\gamma_-}{\equiv} e', \quad \text{for each } v \in N \text{ and } y \in d_i/\gamma^\star. \tag{3}$$

Now for each $j = 0,\dots,r$ put $\mathbf{s}_j(v,y) = \mathbf{s}_{i_1 j}(\dots \mathbf{s}_{i_{r-1} j}(\mathbf{s}_{i_r j}(v,y),y)\dots,y)$, with $\{i_1,\dots,i_r\} = \{0,1,\dots,r\} - \{j\}$. Obviously $\mathbf{s}_j$ has its range contained in V. We will show that

$$\begin{array}{lcll} \mathbf{s}_j(e',y) & = & e', & \text{for each } \ y \in A, \\ \mathbf{s}_j(v,y) & \overset{\gamma_-}{\equiv} & e', & \text{for each } \ v \in N \text{ and } \ y \in A - d_j/\gamma^\star, \\ \mathbf{s}_j(a',y) & \overset{\gamma_-}{\equiv} & a', & \text{for each } \ y \in d_j/\gamma^\star. \end{array} \tag{4}$$

Indeed, the first and the last item follow directly from the definition of $\mathbf{s}_j$. For the middle one, note that for $v \in N$, $y \in d_{i_\ell}/\gamma^\star$, and $v' = \mathbf{s}_{i_{\ell+1} j}(\dots \mathbf{s}_{i_{r-1} j}(\mathbf{s}_{i_r j}(v,y),y)\dots,y)$ we have $v' \overset{\gamma}{\equiv} \mathbf{s}_{i_{\ell+1}}(\dots \mathbf{s}_{i_{r-1} j}(\mathbf{s}_{i_r j}(e',y),y)\dots,y) = e'$, i.e. $v' \in N$ so that (2) yields $\mathbf{s}_{i_\ell j}(v',y) \overset{\gamma_-}{\equiv} e'$, and consequently $\mathbf{s}_j(v,y) = \mathbf{s}_{i_1 j}(\dots \mathbf{s}_{i_{\ell-1} j}(\mathbf{s}_{i_\ell j}(v',y),y)\dots,y) \overset{\gamma_-}{\equiv} \mathbf{s}_{i_1 j}(\dots \mathbf{s}_{i_{\ell-1} j}(e',y)\dots,y) = e'$. This establishes (4).

Now for a positive integer m and a $\gamma^\star$-block, i.e. the product $Q_{i_1,\dots,i_n} = d_{i_1}/\gamma^\star \times \dots \times d_{i_m}/\gamma^\star \subseteq A^m$ we define $(1+m)$-ary polynomial $\mathbf{q}_{i_1,\dots,i_m}(v,y_1,\dots,y_m)$ by putting

$$\mathbf{q}_{i_1,\dots,i_m}(v,y_1,\dots,y_m) = \mathbf{s}_{i_m}(\mathbf{s}_{i_{m-1}}(\dots \mathbf{s}_{i_2}(\mathbf{s}_{i_1}(v,y_1),y_2)\dots,y_{m-1}),y_m).$$

Then we observe that due to (4) we have

$$\begin{array}{lcll} \mathbf{q}_{i_1,\dots,i_m}(e',\overline{y}) & = & e', & \text{for all } \overline{y} \in A^m, \\ \mathbf{q}_{i_1,\dots,i_m}(v,\overline{y}) & \overset{\gamma_-}{\equiv} & e', & \text{for } v \in N \text{ and } \overline{y} \notin Q_{i_1,\dots,i_m}, \\ \mathbf{q}_{i_1,\dots,i_m}(a',\overline{y}) & \overset{\gamma_-}{\equiv} & a', & \text{for } \overline{y} \in Q_{i_1,\dots,i_m}. \end{array} \tag{5}$$

Note that the length of the polynomial $\mathbf{q}_{i_1,\dots,i_m}$ is bounded by $2^{O(m)}$, as it is a composition of m polynomials of the form $\mathbf{s}_j$ each of which having the size bounded by the same constant that depends only on $\mathbf{A}$.

Now, if $Q = Q_1 \cup \dots \cup Q_l$, with each Q_i being a single n-dimensional $\gamma^\star$-block, we sum up (in a balanced binary way) the polynomials $\mathbf{q}_i(\overline{x})$ produced, as above, separately for each block Q_i to get $\mathbf{q}_Q(\overline{x})$ satisfying

$$\begin{array}{lcll} \mathbf{q}_Q(e',\overline{x}) & = & e', & \text{for each } \overline{x} \in A^m, \\ \mathbf{q}_Q(v,\overline{x}) & \overset{\gamma_-}{\equiv} & e', & \text{if } v \in N \text{ and } \overline{x} \notin Q, \\ \mathbf{q}_Q(a',\overline{x}) & \overset{\gamma_-}{\equiv} & a', & \text{if } \overline{x} \in Q. \end{array} \tag{6}$$

The balanced way in which the $\mathbf{q}_i$'s are summed up guaranties that the resulting polynomial $\mathbf{q}_Q$ has its length bounded by $2^{O(m)}$, even if there are exponentially many summands determined by the blocks contained in A^m.

Now, let w be an n-ary polynomial over the field $GF(p)$ of degree s. To produce the associated polynomial $[w]_{\gamma,\top,a,e}$ of $\mathbf{A}$ we first produce $[w]_{\gamma,\top,a',e'}$ and then compose it with a unary polynomial $\mathbf{p}(x)$ that maps a' to a and e' to e (the algebra $\mathbf{A}$ has such a polynomial $\mathbf{p}$ as $(e,a) \in \gamma = \Theta(e',a')$). To produce the required n-ary polynomial $[w]_{\gamma,\top,a',e'}$ we first construct a $(1+n)$-ary polynomial $(w)_{\gamma,\top,a',e'}$ satisfying

$$\begin{array}{lcll} (w)_{\gamma,\top,a',e'}(e',\overline{x}) & = & e', & \text{for each } \overline{x} \in A^n, \\ (w)_{\gamma,\top,a',e'}(v,\overline{x}) & = & e', & \text{if } v \in N \text{ and } w(\mathsf{b}_\top(x_1),\dots,\mathsf{b}_\top(x_n)) = 0, \\ (w)_{\gamma,\top,a',e'}(v,\overline{x}) & = & v, & \text{if } v \in V \text{ and } w(\mathsf{b}_\top(x_1),\dots,\mathsf{b}_\top(x_n)) = 1, \end{array} \tag{7}$$

to put $[w]_{\gamma,\top,a',e'}(\overline{x}) = (w)_{\gamma,\top,a',e'}(a',\overline{x})$, which, by the last two lines in (7), will do the job.

To transform the polynomial $w(\overline{x})$ over the field $GF(p)$ into $(w)_{\gamma,\top,a',e'}(a',\overline{x})$, we first assume that $w(\overline{x})$ is given as sum of monomials and that the monomials of $w(\overline{x})$ are of the form $x_{i_1}\cdot\ldots\cdot x_{i_m}$ (with $m\leqslant s$) or are constant 1 (i.e., the monomials carry no leading constant – we can achieve this by replacing $2x$ by $x+x$ etc.). When passing from w to $(w)_{\gamma,\top,a',e'}(a',\overline{x})$ the constant 1 will be represented by the unary polynomial $\mathbf{e}_V(v)$, while the monomial $x_{i_1}\cdot\ldots\cdot x_{i_m}$ turns into $\mathbf{q}_{T^m}(v,x_{i_1},\ldots x_{i_m})$. Since $\top$ has been assumed to be a join of $\gamma^\star$-cosets, $\top^m$ is obviously a sum of $\gamma^\star$-blocks. Note also that for $\overline{y}\in A^m$ we have $\mathbf{q}_{\top^m(\overline{y})}(a',\overline{y})\subseteq e'/\gamma_-\cup a'/\gamma_-$ and, due to (6), we have

$$\mathbf{q}_{\top^m(\overline{y})}(a',\overline{y})\overset{\gamma_-}{\equiv}a'\quad\text{iff}\quad\overline{y}\in\top^m\quad\text{iff}\quad\mathsf{b}_\top(y_1)\cdot\mathsf{b}_\top(y_2)\cdot\ldots\cdot\mathsf{b}_\top(y_m)=1. \tag{8}$$

Now we sum up (appropriate amount of) the polynomials $\mathbf{e}_V(v)$ and appropriate polynomials $\mathbf{q}_Q(v,x_{i_1},\ldots x_{i_m})$ to get $(w)_{\gamma,\top,a',e'}(a',\overline{x})$ (again we have to be careful to use a balanced summation tree). Next we are using the fact that there is an isomorphism of the group $\mathbb{Z}_p$ with the subgroup of $((\mathbf{A}|_N)/\gamma_-,+)$ generated by a'/γ_- that sends 1 to a'/γ_-. Applying this isomorphism to (8) we get

$$\begin{array}{lcll}(w)_{\gamma,\top,a',e'}(e',\overline{x}) & = & e', & \text{for each } \overline{x}\in A^m,\\ (w)_{\gamma,\top,a',e'}(a',\overline{x}) & \overset{\gamma_-}{\equiv} & e', & \text{if } w(\mathsf{b}_\top(x_1),\ldots,\mathsf{b}_\top(x_n))=0,\\ (w)_{\gamma,\top,a',e'}(a',\overline{x}) & \overset{\gamma_-}{\equiv} & a', & \text{if } w(\mathsf{b}_\top(x_1),\ldots,\mathsf{b}_\top(x_n))=1.\end{array} \tag{9}$$

Since there are at most $O(n^s)=O(2^{s\cdot\log n})$ monomials of degree at most s, while the polynomials $\mathbf{q}_{\top^m}$ representing them has sizes bounded by $2^{O(s)}$ the length of $(w)_{\gamma,\top,a',e'}(v,\overline{x})$ is at most $2^{O(s\cdot\log n)}$.

Finally to pass from (9) to (7) we start with reminding that for a fixed $\overline{x}\in A^n$ the mapping $V\ni v\longmapsto(w)_{\gamma,\top,a',e'}(v,\overline{x})\in V$ either permutes the set V or collapses $\gamma|_V$ to γ_-, i.e. it is constant modulo γ_- on $\gamma|_V$-classes. Thus, iterating $(w)_{\gamma,\top,a',e'}(v,\overline{x})$ in the first variable a sufficient number of times, we may additionally assume that $(w)_{\gamma,\top,a',e'}(v,\overline{x})$ is either the identity map on V or it is constant, modulo γ_-, on $\gamma|_V$-classes, depending on whether $w(\mathsf{b}(\overline{x}))$ is 1 or 0. Thus, $w(\mathsf{b}(\overline{x}))=1$ gives us the third equality in (7).

In the other case, $(w)_{\gamma,\top,a',e'}(v,\overline{x})$ collapses the entire trace N to e'/γ_- so that we have $(w)_{\gamma,\top,a',e'}(v,\overline{x})\overset{\gamma_-}{\equiv}e'$ for $v\in N$. Now we go down along the chain $0=\theta_0\prec\theta_1\prec\ldots\prec\theta_l=\gamma_-$ to show that $(w)_{\gamma,\top,a',e'}(v,\overline{x})\overset{\theta_i}{\equiv}e'$ yields $(w)_{\gamma,\top,a',e'}(v,\overline{x})\overset{\theta_{i-1}}{\equiv}e'$. Since the unary polynomial $\mathbf{f}:V\ni v\longmapsto(w)_{\gamma,\top,a',e'}(v,\overline{x})\in V$ does not permute V, $\mathbf{f}(A)=\mathbf{f}(V)\subsetneq V$. This gives that for each $i=l,\ldots,1$ the polynomial $\mathbf{f}$ collapses θ_i to θ_{i-1}, as otherwise V would properly contain a (θ_{i-1},θ_i)-minimal set. But this is impossible in view of Lemma 4.30 in [17]. Therefore, composing l times the polynomial $\mathbf{f}$ we get that this composition satisfies $(w)_{\gamma,\top,a',e'}(v,\overline{x})=e'$ so that (7) is shown. This iteration inflates the size of $(w)_{\gamma,\top,a',e'}(v,\overline{x})$ by raising it to the l-th power so that it is still bounded by $2^{O(s\cdot\log n)}$. ◀

We are going to use the following fact that is borrowed from [3] (see [21, Fact 3.4] for a recent proof).

▶ **Fact 15.** *Let p be a prime and $\nu\geqslant 1$ be an integer. Then there is a polynomial $w(\overline{x})\in GF(p)[\overline{x}]$ of degree at most $p^\nu-1$, such that for $\overline{x}\in\{0,1\}^n\subseteq\mathbb{Z}_p^n$ we have*

$$w(\overline{x})=\begin{cases}0, & \textit{if } \left|\overline{x}^{-1}(0)\right|\equiv 0 \textit{ modulo } p^\nu,\\ 1, & \textit{else.}\end{cases}$$

Now we are in a position to prove the following.

▶ **Theorem 16.** *Let* $\mathbf{A}$ *be a finite solvable Malcev algebra and* α, β *be two collaborating join-irreducible congruences of different characteristics. Then, assuming the (randomized) Exponential Time Hypothesis, the following hold:*

- *if* $(\alpha_- : \alpha) \vee (\beta_- : \beta) < 1$*, then* PolSat($\mathbf{A}$) *is not in* P *(resp.* RP*),*
- *if* $(\alpha_- : \alpha) < 1$ *and* $(\beta_- : \beta) < 1$*, then* 2-ListPolSat($\mathbf{A}$) *is not in* P *(resp.* RP*).*

More precisely, we show that under rETH there is no randomized algorithm of running time $2^{o((\log n/\log\log n)^2)}$ for these problems. Before we prove Theorem 16, let us point out how it implies Theorem 2 from the introduction:

Proof of Theorem 2. As $\mathbf{A}$ and $\mathbf{B}$ are minimal normal subgroups, they are join-irreducible. As $\mathbf{A} \neq \mathbf{B}$, they are collaborating and by assumption they are of different characteristic. The condition $C_{\mathbf{G}}(\mathbf{A}) \cdot C_{\mathbf{G}}(\mathbf{B}) \neq \mathbf{G}$ is just the same as $(\alpha_- : \alpha) \vee (\beta_- : \beta) < 1$ written in a group language (here $\mathbf{A} = \alpha$, $\mathbf{B} = \beta$ and $\alpha_- = \beta_- = \{1\}$). Now we apply Theorem 16. ◀

Proof of Theorem 16. Since α, β are collaborating, without loss of generality we may assume that there are 3 different elements $a, e, b \in A$ such that $(a, e) \in \alpha$ and $(e, b) \in \beta - \alpha$. Let $\mathbf{d}$ denote a Malcev term for $\mathbf{A}$. Observe here that

(*) for $u \in \{a, e\}$ and $v \in \{b, e\}$ we have $\mathbf{d}(u, e, v) = e$ iff $u = e = v$.

Indeed, $\mathbf{d}(a, e, e) = a$ and $\mathbf{d}(e, e, b) = b$, while $\mathbf{d}(a, e, b) = e$ would give $b = \mathbf{d}(e, e, b) \overset{\alpha}{\equiv} \mathbf{d}(a, e, b) = e$, contrary to our choice of $(b, e) \in \beta - \alpha$.

To unify our arguments for both PolSat($\mathbf{A}$) and 2-ListPolSat($\mathbf{A}$), observe that $\alpha^* = (\alpha_- : \alpha) < 1$ and $\beta^* = (\beta_- : \beta) < 1$ gives $\alpha^* \cup \beta^* \neq 1$, by Lemma 13. This allows us to pick a pair $(c, d) \in A^2$ satisfying

[P] $(c, d) \notin \alpha^* \vee \beta^*$,

[LP] $(c, d) \notin \alpha^* \cup \beta^*$,

depending on which of the two problems PolSat($\mathbf{A}$), 2-ListPolSat($\mathbf{A}$) we are considering.

With the help of Lemma 14 and Fact 15, to each 3-CNF-SAT formula $\Phi(\overline{x})$ having n variables $\overline{x} = (x_1, \ldots, x_n)$ and ℓ clauses we are going to associate two n-ary polynomials $\mathbf{t}^\Phi(\overline{x})$ and $\mathbf{s}^\Phi(\overline{x})$ of length $2^{O(\sqrt{\ell} \cdot \log \ell)}$ such that

[P] $\Phi(\overline{x})$ is satisfiable iff the equation $\mathbf{t}^\Phi(\overline{x}) = e$ has a solution $\overline{x}$ in A^n,

[LP] $\Phi(\overline{x})$ is satisfiable iff the equation $\mathbf{s}^\Phi(\overline{x}) = e$ has a solution $\overline{x}$ in the set $\{c, d\}^n$.

To do that, let p and q be the characteristics of α and β, respectively, and pick $\mu, \nu \in \mathbb{N}$ with $p^{\mu-1} \leqslant \sqrt{\ell} < p^\mu$ and $q^{\nu-1} \leqslant \sqrt{\ell} < q^\nu$. Now Fact 15 supplies us with ℓ-ary polynomials (with their variables c_i's later to be substituted by the clauses C_i's of the formula $\Phi(\overline{x})$):

- $w_p(c_1, \ldots, c_\ell) \in GF(p)[\overline{c}]$, with degree bounded by $p^\mu - 1$,
- $w_q(c_1, \ldots, c_\ell) \in GF(q)[\overline{c}]$, with degree bounded by $q^\nu - 1$,

which on $\overline{c} \in \{0, 1\}^\ell$ take values from $\{0, 1\}$, such that $w_p(\overline{c}) = 0$ iff $\left|\overline{c}^{-1}(0)\right| \equiv 0 \mod p^\mu$ (resp. $w_q(\overline{c}) = 0$ iff $\left|\overline{c}^{-1}(0)\right| \equiv 0 \mod q^\mu$).

With a 3-ary clause $C(z^1, z^2, z^3)$ we associate a polynomial $C'(z^1, z^2, z^3)$ of degree 3 over $GF(p)$ (resp. $GF(q)$) in an obvious way, so that for example the clause $z^1 \vee z^2 \vee \neg z^3$ goes to $1 - ((1 - z^1) \cdot (1 - z^2) \cdot z^3)$. Now for $\Phi(\overline{x}) = \bigwedge_{i=1}^{\ell} C_i$ we feed up the polynomials w_p and w_q by substituting C_i' for the variable c_i to produce (at most 3ℓ-ary) polynomials $w_p^\Phi(\overline{z})$ and $w_q^\Phi(\overline{z})$ of degrees bounded by $3(p^\mu - 1)$ and $3(q^\nu - 1)$, respectively. Note that again the new polynomials w_p^Φ (or w_q^Φ) on arguments from $\{0, 1\}$ return values from the same set $\{0, 1\}$, but this time 0 is taken exactly on valuations of variables in Φ under which the number of unsatisfied clauses is divisible by p^μ (or by q^ν, respectively). The important feature is that

(**) the polynomials w_p^Φ and w_q^Φ simultaneously return 0 on a valuation from the set $\{0, 1\}$ iff this valuation satisfies Φ.

Indeed, $w_p^\Phi(\overline{z}) = 0 = w_q^\Phi(\overline{z})$ tells us that the number of unsatisfied clauses in Φ is divisible both by p^μ and q^ν. Since $p \neq q$, this number is divisible by $p^\mu \cdot q^\nu > \ell$. However, there are only ℓ clauses, so that none of them is unsatisfied by $\overline{z}$.

Now with the help of Lemma 14 we are able to define

$$\mathbf{t}^\Phi(\overline{x}) = \mathbf{d}\left(\left[w_p^\Phi\right]_{\alpha,\top_\alpha,a,e}(\overline{x}), e, \left[w_q^\Phi\right]_{\beta,\top_\beta,b,e}(\overline{x})\right),$$

where a and b are as above and the sets $\top_\alpha, \top_\beta \neq \emptyset, A$ are chosen to be sums of α^*- or β^*-cosets, respectively. Since our assumption for the problem PolSat says that $\alpha^* \vee \beta^* < 1$, one way to ensure this is by putting $\top_\alpha = \top_\beta$ to be a single $\alpha^* \vee \beta^*$-coset, e.g. $d/(\alpha^* \vee \beta^*)$. Now, combining Lemma 14 with the properties (*) and (**), we know that for $\overline{x} = (x_1, \ldots, x_n) \in A^n$ we have $\mathbf{t}^\Phi(\overline{x}) = e$ iff $\Phi(\mathsf{b}(x_1), \ldots, \mathsf{b}(x_n)) = 1$, where $\mathsf{b} = \mathsf{b}_{\top_\alpha} = \mathsf{b}_{\top_\beta}$.

In case of 2-ListPolSat the polynomial $\mathbf{s}^\Phi$ is defined in a similar way, i.e. we put

$$\mathbf{s}^\Phi(\overline{x}) = \mathbf{d}\left(\left[w_p^\Phi\right]_{\alpha,\top_\alpha,a,e}(\overline{x}), e, \left[w_q^\Phi\right]_{\beta,\top_\beta,b,e}(\overline{x})\right),$$

but this time we cannot ensure $\alpha^* \vee \beta^* < 1$. Instead we can bound the range for the x_i's in A to be smaller. In fact, we restrict these ranges to $\{c, d\}$ so that, by the very same argument as before, the sets $\top_\alpha = d/\alpha^*$ and $\top_\beta = d/\beta^*$ will do the job.

Finally, Fact 15 together with Lemma 14 ensure us that the sizes of $\left[w_p^\Phi\right]_{\alpha,\top_\alpha,a,e}$, and $\left[w_q^\Phi\right]_{\beta,\top_\beta,b,e}$, and therefore of both $\mathbf{t}^\Phi(\overline{x})$ and $\mathbf{s}^\Phi(\overline{x})$, are bounded by $2^{O(\sqrt{\ell}\cdot\log\ell)}$. Thus, ETH (resp. rETH) puts both the problems PolSat($\mathbf{A}$) and 2-ListPolSat($\mathbf{A}$) outside P (resp. RP). Indeed, assume that PolSat($\mathbf{A}$) or 2-ListPolSat($\mathbf{A}$) could be decided in (randomized) time $2^{o((\log m/\log\log m)^2)}$ where m is the length of the input polynomial. Then we could decide a 3-CNF-SAT instance of length ℓ in (randomized) time

$$2^{o((\log 2^{O(\sqrt{\ell}\cdot\log\ell)}/\log\log 2^{O(\sqrt{\ell}\cdot\log\ell)})^2)} = 2^{o(\sqrt{\ell}^2\cdot\log^2\ell/\log^2(\sqrt{\ell}\cdot\log\ell))} = 2^{o(\ell)}.$$ ◀

5 A Dichotomy for ProgramSat

Proof of Theorem 1. First, consider the case that $\mathbf{G}$ has a normal p-subgroup $\mathbf{G}_p$ such that $\mathbf{G}/\mathbf{G}_p$ is nilpotent (possibly $\mathbf{G}_p$ is trivial). Then $\mathbf{G}/\mathbf{G}_p = \mathbf{H}_p \times \mathbf{H}$ for some maximal p-group $\mathbf{H}_p$ (also $\mathbf{H}_p$ might be trivial). We denote the preimage of $\mathbf{H}_p$ in $\mathbf{G}$ by $\widetilde{\mathbf{G}}_p = \mathbf{H}_p\mathbf{G}_p$. Since $|H|$ and $\left|\widetilde{G}_p\right|$ are coprime, by the Schur-Zassenhaus theorem (Fact 7), we conclude that $\mathbf{G} = \widetilde{\mathbf{G}}_p \rtimes \mathbf{H}$ and so, by Corollary 12, ListPolSat($\mathbf{G}$) and ProgramSat($\mathbf{G}$) are in RP under CDH.

On the other hand, assume that $\mathbf{G}$ is not of the above form. If $\mathbf{G}$ is non-solvable, ListPolSat($\mathbf{G}$) and ProgramSat($\mathbf{G}$) are NP-complete by [14], hence, not in RP under rETH. If $\mathbf{G}$ is solvable but does not have a nilpotent normal subgroup $\mathbf{N}$ with nilpotent quotient $\mathbf{G}/\mathbf{N}$, then [23] (for certain cases also [20, 30]) shows that PolSat($\mathbf{G}$) (hence, also ListPolSat($\mathbf{G}$) and ProgramSat($\mathbf{G}$)) is not in P under ETH. The same proof shows that these problems are not in RP under rETH (as a randomized algorithm for ListPolSat($\mathbf{G}$) or ProgramSat($\mathbf{G}$) would lead to a randomized algorithm for 3-CNF-SAT).

Finally, let $\mathbf{N}$ denote the smallest normal subgroup such that $\mathbf{G}/\mathbf{N}$ is nilpotent. Such an $\mathbf{N}$ exists and it is nilpotent as we excluded already all the other cases. Moreover, we know that $|N|$ has at least two distinct prime divisors p and q since otherwise, we would be in the RP case. Notice that $\mathbf{N}$ is the direct product of its Sylow subgroups. Thus, after taking

a quotient (recall that ListPolSat($\mathbf{G}/\mathbf{H}$) $\leqslant$ ListPolSat($\mathbf{G}$) and ProgramSat($\mathbf{G}/\mathbf{H}$) $\leqslant$ ProgramSat($\mathbf{G}$), see Lemma 8), we may assume that there are precisely two non-trivial normal subgroups $\mathbf{A}$ and $\mathbf{B}$ of $\mathbf{G}$ below $\mathbf{N}$ and $|A| = p^\alpha$ and $|B| = q^\beta$ for some $\alpha, \beta \geqslant 1$ and $\mathbf{N} = \mathbf{A} \times \mathbf{B}$. Clearly $\mathbf{A}$ and $\mathbf{B}$ are join-irreducible.

Now assume for a contradiction that $C_{\mathbf{G}}(\mathbf{A}) = G$. Observe that $C_{\mathbf{G}}(\mathbf{A}) = C_G(\mathbf{N}/\mathbf{B})$ because $[g, a] = 1$ if and only if $[g, ab] \in B$ for $b \in B$. This means that $\mathbf{N}/\mathbf{B}$ is in the center of $\mathbf{G}/\mathbf{B}$. Thus, as $\mathbf{G}/\mathbf{N} = (\mathbf{G}/\mathbf{B})/(\mathbf{N}/\mathbf{B})$ is nilpotent, this implies that $\mathbf{G}/\mathbf{B}$ is nilpotent contradicting that $\mathbf{N}$ is the smallest normal subgroup such that $\mathbf{G}/\mathbf{N}$ is nilpotent.

By symmetry we also have $C_{\mathbf{G}}(\mathbf{B}) \neq G$. Since $\mathbf{A}$ and $\mathbf{B}$ are collaborating, we have verified the requirements of Theorem 16 showing that 2-ListPolSat($\mathbf{G}$) is not in RP under rETH. By Lemma 8 also ListPolSat($\mathbf{G}$) and ProgramSat($\mathbf{G}$) are not in RP under rETH. ◀

6 Unconditional Algorithms

Proving lower bounds for a non-trivial computational model is usually a challenging task. Rare examples of results of such kind are either proven in some very restricted settings, or rely on additional assumptions. The same issue affects programs over groups and their expressiveness of AND, where essentially our knowledge can be summarized as follows:

(B) For a nilpotent group $\mathbf{N}$ there is a constant $d_{\mathbf{N}}$ such that there is no $\mathbf{N}$-program for the n-ary AND function for $n \geqslant d_{\mathbf{N}}$ ([5, Corollary to Theorem 6]).

(C) If $\mathbf{Q} = \mathbf{G}_q \rtimes \mathbf{A}$ for some q-group $\mathbf{G}_q$ and abelian group $\mathbf{A}$, then $\gamma_{\mathrm{Prog},\mathbf{Q}}(n) \in 2^{\Omega(n)}$ ([5, Corollary to Theorem 9], recall the definition of $\gamma_{\mathrm{Prog},\mathbf{Q}}(n)$ in Section 3).

Lemma 10 implies that these two cases lead to RP algorithms for ProgramSat, ListPolSat, and PolSat. In fact, for ProgramSat for nilpotent groups and for PolSat, in both cases (B) and (C), even polynomial time algorithms have been obtained [14, 12]; however, as for now, ProgramSat in case (C) is only known to have quasi-polynomial time algorithms [4].

The main aim of the next theorem is to present a new lower bound result for groups that are direct products of these presented in (B), (C), which then by Lemma 10 also leads to RP algorithms. To the best of our knowledge this is the first result going beyond the cases (B) and (C) in this direction.

▶ **Theorem 17.** *Let $\mathbf{N}$ be a nilpotent group, $\mathbf{A}$ an abelian group, $\mathbf{Q} = \mathbf{G}_q \rtimes \mathbf{A}$ for some q-group $\mathbf{G}_q$ and let $\mathbf{G} \leqslant \mathbf{N} \times \mathbf{Q}$. Then $\gamma_{\mathrm{Prog},\mathbf{G}}(n) \in 2^{\Omega(n)}$.*

The fact that this lower bound applies also to subgroups of the product will allow us to construct a series of natural examples of groups for which we achieve efficient algorithms. Of particular interest is the case that $\mathbf{A}$ is also a subgroup of $\mathbf{N}$, so there is some non-trivial interaction between $\mathbf{N}$ and $\mathbf{Q}$.

The proof of Theorem 17 relies on a similar construction as used in [7] for showing that for every low degree polynomial there is a large affine subspace on which the polynomial is constant. For the proof we need some preparation: For $\overline{a}, \overline{b} \in \prod_{i=1}^n |A_i|$ with $\overline{a} = (a_1, \ldots, a_n)$ and $\overline{b} = (b_1, \ldots, b_n)$ we define $\mathrm{HammingDist}(\overline{a}, \overline{b}) = |\{\, i \in [1\,..\,n] \mid a_i \neq b_i \,\}|$. The following easy combinatorial observation has been used in slightly different forms in [4, Theorem 2] or [21, Theorem 6.1].

▶ **Fact 18.** *Let f be an n-ary indicator function with domain $\mathcal{A} = \prod_{i=1}^n A_i$ with $|A_i| \geqslant 2$ for all i and $\mathrm{size}(f) < \gamma(n)$. Let $\overline{b} \in f^{-1}(1)$. Then there is some $\overline{a} \in f^{-1}(1)$ with $\overline{b} \neq \overline{a}$ and $\mathrm{HammingDist}(\overline{a}, \overline{b}) \leqslant \gamma^{-1}(\mathrm{size}(f)) + 1$.*

Proof. As $\mathrm{size}(f) < \gamma(n)$, there is some $\overline{c} \in f^{-1}(1)$ with $\overline{c} \neq \overline{b}$. Writing $\overline{b} = (b_1, \ldots, b_n)$ and $\overline{c} = (c_1, \ldots, c_n)$ that means $b_i \neq c_i$ for some i. Now, set $\overline{b}' = (b_1, \ldots, b_{i-1}, c_i, b_{i+1}, \ldots, b_n)$, i.e., $\overline{b}'$ agrees with $\overline{b}$ on all but the i-th coordinate. Consider some $\overline{a}$ with $f[x_i/c_i](\overline{a}) = 1$ of minimal Hamming distance k to $\overline{b}'$ (note that possibly $\overline{a} = \overline{b}'$). Then setting all variables on which $\overline{a}$ and $\overline{b}'$ agree to this constant and restricting all other variables x_j (with $a_j \neq b_j$) to $\{a_j, b_j\}$, we obtain a k-ary spike. Thus, $\mathrm{size}(f) \geqslant \gamma(k)$ and Fact 18 follows. ◀

Proof of Theorem 17. It is enough to consider $\mathbf{G} = \mathbf{N} \times \mathbf{Q}$, as lower bounds for subgroups are inferred from their containing group. We can think of a $\mathbf{G}$-program in the direct product as a system of two separate programs sharing the same variables. Thus, let $\mathbf{p}$ be an $\mathbf{N}$-program and $\mathbf{q}$ a $\mathbf{Q}$-program with variables $x_1, \ldots, x_n$ for a spike (i.e., the n-ary AND function). Without loss of generality, we can assume that the all-zero vector $\overline{0}$ is the only satisfying assignment to the conjunction of $\mathbf{p}$ and $\mathbf{q}$ (we can achieve this by simply replacing variables by their negations if necessary – this does not increase the size of the programs). Thus, we can also associate $\mathbf{p}, \mathbf{q}$ with one-element accepting sets $\{s_{\mathbf{p}}\}, \{s_{\mathbf{q}}\}$ respectively. Now we show that $|\mathbf{q}| \in 2^{\Omega(n)}$.

We will identify a vector $\overline{b} \in \{0,1\}^n$ with the subset $\overline{b}^{-1}(1)$ of $[1\,..\,n]$. By (B) there is a constant d such that no $\mathbf{N}$-program can be a d-ary spike. We are going to exploit this fact by proving that, if $\mathbf{q}$ is relatively short, then there must be a relatively large boolean cube on which $\mathbf{p}$ behaves like an AND. Note that for $\overline{b}_1, \ldots, \overline{b}_d \in \{0,1\}^n$ with $\overline{b}_i \cap \overline{b}_j = \varnothing$ for all $i \neq j$ we can simulate the behaviour of $\mathbf{p}$ on $B = \left\{ \sum_{i=1}^d \alpha_i \overline{b}_i \;\middle|\; \alpha_i \in \{0,1\} \right\}$ by creating a new d-ary program $\hat{\mathbf{p}}(y_1, \ldots, y_d) = \mathbf{p}(\sum_{i=1}^d y_i \overline{b}_i)$. Indeed, consider an instruction $\langle j, g, h\rangle$ of $\mathbf{p}$: if j is not in any of the $\overline{b}_i$ just replace it with constant g and if $j \in \overline{b}_i$ for some i replace it with the instruction $\langle i, g, h\rangle$. To find a cube of our interest we start with the following claim.

▷ Claim 19. Let $\tilde{\mathbf{Q}} = \mathbf{Q}^{2^d}$. If $|\mathbf{q}| < \gamma_{\mathrm{Prog},\tilde{\mathbf{Q}}}(n/d - 1)$, then there are $\overline{b}_1, \ldots, \overline{b}_d \in \{0,1\}^n$ with $\overline{b}_i \cap \overline{b}_j = \varnothing$ for all $i \neq j$ such that $\mathbf{q}(\overline{x}) = 1$ for all $\overline{x} \in \left\{ \sum_{i=1}^d \alpha_i \overline{b}_i \;\middle|\; \alpha_i \in \{0,1\} \right\} \subseteq \{0,1\}^n$.

Proof. For $k \in [1\,..\,d]$ consider the group $\mathbf{Q}_k = \mathbf{Q}^{2^k}$. As having more coordinates clearly gives more expressive power to a program, we have $\gamma_{\mathrm{Prog},\tilde{\mathbf{Q}}}(n) \leqslant \gamma_{\mathrm{Prog},\mathbf{Q}_k}(n)$.

Assume we already constructed $\overline{b}_1, \ldots, \overline{b}_k$ for some $k \in [0\,..\,d-1]$ (for $k = 0$ that means we have no $\overline{b}_i$'s). Let $X_k = \bigcup_{i=1}^k \overline{b}_i$. We additionally require by induction that $|X_k| \leqslant kn/d$. First observe that a new vector $\overline{b}_{k+1}$ which could extend the sequence $\overline{b}_1, \ldots, \overline{b}_k$ needs to satisfy a system of 2^k equations $\mathbf{q}(\alpha_1\overline{b}_1 + \alpha_2\overline{b}_2 + \ldots + \alpha_k\overline{b}_k + \overline{x}) = 1$, one equation for each $\overline{\alpha} \in \{0,1\}^k$. As we expect $\overline{b}_{k+1}$ to have disjoint support with all preceding $\overline{b}_i$'s, we just put $x_i = 0$ for $i \in X_k$, so that each $\mathbf{q}_\alpha(\overline{x}) = \mathbf{q}(\alpha_1\overline{b}_1 + \ldots + \alpha_k\overline{b}_k + \overline{x})$ is of arity $n - |X_k|$. Notice that we can encode those 2^k conditions as one program condition in the group $\mathbf{Q}_k = \mathbf{Q}^{2^k}$. To produce a program $\hat{\mathbf{q}}(\overline{x}) = (\mathbf{q}_\alpha(\overline{x}))_{\alpha \in \{0,1\}^k}$ with associated accepting set $\{s_{\mathbf{q}}\}^{2^k}$, we replace each instruction of $\mathbf{q}$ with one in the new domain: whenever $j \notin X_k$ we just replace $\langle j, g, h\rangle$ with $\langle j, (g, \ldots, g), (h, \ldots, h)\rangle$ and whenever $j \in \overline{b}_i$ (for some $i \in [1\,..\,k]$) we replace it by the constant $(c_\alpha)_{\alpha \in \{0,1\}^k}$, where $c_\alpha = g$ when $\alpha_i = 0$ and $c_\alpha = h$ when $\alpha_i = 1$.

Since $|\hat{\mathbf{q}}| \leqslant |\mathbf{q}| \leqslant \gamma_{\mathrm{Prog},\tilde{\mathbf{Q}}}(n/d - 1)$ and $n - |X_k| \geqslant \frac{n}{d}$, we know by Fact 18 that not only $\overline{0}$ is a solution to $\hat{\mathbf{q}}(x) = 1$ but we have another solution with Hamming weight at most $\gamma^{-1}_{\mathrm{Prog},\tilde{\mathbf{Q}}}(|\hat{\mathbf{q}}|) + 1 \leqslant \gamma^{-1}_{\mathrm{Prog},\tilde{\mathbf{Q}}}(\gamma_{\mathrm{Prog},\tilde{\mathbf{Q}}}(n/d - 1)) + 1 = n/d$. We can clearly choose this solution to become $\overline{b}_{k+1}$ and finish the induction by noticing that $|X_{k+1}| = |X_k| + \left|\overline{b}_{k+1}\right| \leqslant kn/d + n/d = (k+1)n/d$. ◁

Finally, by (C), we know that $\gamma_{\mathrm{Prog},\tilde{\mathbf{Q}}}(n) \geqslant 2^{\delta n - C}$ for some suitable constants δ and C. Assume for a contradiction that $|\mathbf{q}| \leqslant 2^{\delta n/d - C - d - 1} \leqslant \gamma_{\mathrm{Prog},\tilde{\mathbf{Q}}}(n/d - 1)$. By Claim 19 we obtain a boolean cube $B = \left\{ \sum_{i=1}^d \alpha_i \overline{b}_i \;\middle|\; (\alpha_1, \ldots, \alpha_d) \in \{0,1\}^d \right\} \subseteq \{0,1\}^n$ with $\mathbf{q}(B) = \{1\}$.

It means that the equation $\mathbf{p}(x) = 1$ has only one solution $\overline{0}$ in the set B, otherwise the system $(\mathbf{p}(\overline{x}), \mathbf{q}(\overline{x}))$ would not define the spike (with accepting set $\{(s_{\mathbf{p}}, s_{\mathbf{q}})\}$). But now to get a contradiction define a program $\hat{\mathbf{p}}(y_1, \ldots, y_d) = \mathbf{p}(y_1\overline{b}_1 + \ldots + y_d\overline{b}_d)$, which must be a d-ary spike – contrary to the choice of d. ◀

As an immediate consequence of Theorem 17 and Lemma 10 we get the following.

▶ **Corollary 20.** *Let* $\mathbf{N}$ *be a nilpotent group,* $\mathbf{A}$ *abelian,* $\mathbf{Q} = \mathbf{G}_q \rtimes \mathbf{A}$ *for some* q*-group* $\mathbf{G}_q$ *and let* $\mathbf{G} \leqslant \mathbf{N} \times \mathbf{Q}$*. Then* ProgramSat($\mathbf{G}$)*,* ListPolSat($\mathbf{G}$) *or* PolSat($\mathbf{G}$) *have the none-or-many property.*

In particular, ProgramSat($\mathbf{G}$)*,* ListPolSat($\mathbf{G}$) *and* PolSat($\mathbf{G}$) *are in* RP*.*

Proof of Corollary 5. We can apply Corollary 20 to dihedral groups of order $2^\alpha p^\beta$. Indeed, each such group is a subgroup of $\mathbf{D}_{2^\alpha} \times \mathbf{D}_{p^\beta}$, where $\mathbf{D}_{2^\alpha}$ is nilpotent and $\mathbf{D}_{p^\beta}$ is isomorphic to the semidirect product $\mathbb{Z}_{p^\beta} \rtimes \mathbb{Z}_2$. So for each such group PolSat is in RP (if $\alpha \in \{0, 1\}$ it is even in P by [18, Corollary 2]). On the other hand, all other dihedral groups $\mathbf{D}_m$ have a quotient $\mathbf{D}_k$ where k is odd and has exactly two different prime divisors. By [21, Theorem 7.1], PolSat($\mathbf{D}_k$) is not in P under ETH. The same argument also shows that it is not in RP under rETH. By Lemma 8 this transfers to $\mathbf{D}_m$. We can see this also as a consequence of Theorem 2: the minimal normal subgroups $\mathbf{A}$ and $\mathbf{B}$ are just cyclic subgroups of $\mathbb{Z}_m$ of coprime odd order. The centralizer of both of them is $\mathbb{Z}_m < \mathbf{D}_m$. Hence, Theorem 2 tells us that PolSat($\mathbf{D}_m$) is not in RP under rETH. ◀

The positive case of the proof of Corollary 5 obviously generalizes to groups $\mathbf{G}$ with a nilpotent normal subgroup $\mathbf{N}$ of order $p^\alpha q^\beta$ such that $\mathbf{G}/\mathbf{N}$ is abelian of order p^γ (just apply the Schur-Zassenhaus Theorem, Fact 7). In particular, this applies as follows:

▶ **Example 21.** Note that the complexity of PolSat for three natural examples of order 24, namely the dihedral group $\mathbf{D}_{12}$, the quaternion group $\mathbf{Q}$ acting over $\mathbb{Z}_3$ (i.e. $\mathbb{Z}_3 \rtimes \mathbf{Q}$), and the group $(\mathbb{Z}_2 \times \mathbb{Z}_2 \times \mathbb{Z}_3) \rtimes \mathbb{Z}_2$ was left unsolved in [12, Problem 3]. Now our Corollary 20 covers all of these examples.

7 Extending Randomized Algorithms for PolSat

The smallest example of a group of Fitting length two for which we know superpolynomial lower bounds under ETH is $\mathbf{D}_{15}$ [21]. We can embed $\mathbf{D}_{15}$ into the group $\mathbf{D}_3 \times \mathbf{D}_5$ which has polynomial-time decidable PolSat. On the contrary, both ProgramSat and ListPolSat share superpolynomial complexities under ETH in this case. Moreover, for a given group $\mathbf{G}$, under assumption of CDH and ETH the problem ProgramSat($\mathbf{G}$) is in P whenever ListPolSat($\mathbf{G}$) is. So, in a sense, complexities of ProgramSat and ListPolSat seem to coincide, while the complexity of PolSat may differ in certain cases. It is due to the fact that upper bounds for PolSat are not inherited by the subgroups in a very strong way:

▶ **Observation 22.** *Every group of Fitting length two can be embedded into a group with* PolSat *in* RP *under CDH. Moreover, if* $\mathbf{G}$ *is nilpotent-by-abelian, it can be embedded into a group with* PolSat *in* P *(unconditionally).*

Proof. Let $\mathbf{G}$ be a group of Fitting length two. Thus, there is some nilpotent normal subgroup $\mathbf{N}$ such that $\mathbf{G}/\mathbf{N}$ is nilpotent. Since $\mathbf{N}$ is nilpotent, we can write it as a direct product $\mathbf{N} = \mathbf{G}_{p_1} \times \cdots \times \mathbf{G}_{p_k}$ for p_i-groups $\mathbf{G}_{p_i}$. Let $\mathbf{N}_i = \prod_{j \neq i} \mathbf{G}_{p_j}$. Then $\mathbf{G}_{p_i}$ is a

normal nilpotent subgroup of $\mathbf{G}/\mathbf{N}_i$ and $(\mathbf{G}/\mathbf{N}_i)/\mathbf{G}_{p_i}$ is nilpotent. Thus, by Theorem 1 PolSat$(\mathbf{G}/\mathbf{N}_i)$ is in RP under CDH. Finally, notice that $\mathbf{G}$ embeds into the direct product $\prod_{i=1}^{k} \mathbf{G}/\mathbf{N}_i$, which by Lemma 8 has also PolSat in RP under CDH.

For the second part just observe that, if $\mathbf{G}$ is nilpotent-by-abelian, $\mathbf{G}/\mathbf{N}_i$ has a normal p_i-subgroup with abelian quotient and so by [12, Theorem 1] PolSat is in P. ◀

The unusual properties of PolSat allow us to create larger classes of groups with polynomial time algorithms than for the other two problems.

Proof of Theorem 4. We start with some preparation and decompose $\mathbf{G}$ into smaller groups. Since $|G|$ has only two prime factors, say p and q, we can write $\mathbf{N} = \mathbf{N}_q \times \mathbf{N}_p$ and $\mathbf{H} = \mathbf{H}_p \times \mathbf{H}_q$ where $\mathbf{N}_p, \mathbf{H}_p$ are p-groups and $\mathbf{N}_q, \mathbf{H}_q$ are q-groups. Notice that $\mathbf{N}_p$ and $\mathbf{N}_q$ are also normal in $\mathbf{G}$ (this is because they are characteristic subgroups of $\mathbf{N}$). We define subsets L, R, P, Q of G by putting $L = N_q H_p$, $R = N_p H_q$, $P = N_p H_p$ and $Q = N_q H_q$. Notice that we defined indeed subgroups $\mathbf{L}, \mathbf{R}, \mathbf{P}$, and $\mathbf{Q}$ since each of them is a product of a normal subgroup and a subgroup (though they might not be normal subgroups) and $LR = G = PQ$. In particular, we can write each $g \in G$ uniquely as $g = \ell r$ where $\ell \in L$ and $r \in R$. Moreover, they are all semidirect products: $\mathbf{L} = \mathbf{N}_q \rtimes \mathbf{H}_p$, $\mathbf{R} = \mathbf{N}_p \rtimes \mathbf{H}_q$, $\mathbf{P} = \mathbf{N}_p \rtimes \mathbf{H}_p$ and $\mathbf{Q} = \mathbf{N}_q \rtimes \mathbf{H}_q$, where the actions of $\mathbf{H}_p$ and $\mathbf{H}_q$ on $\mathbf{N}_p$ and $\mathbf{N}_q$ are the restrictions of the actions of $\mathbf{H}$ on $\mathbf{N}$.

We will now prove the many-solutions property for $\mathbf{G}$ by restricting the variables to the subgroups $\mathbf{L}$ and $\mathbf{R}$. However, we cannot apply Corollary 12 directly; instead, we will construct another group $\mathbf{G}_1$ with the desired properties for which we can apply Corollary 12 for ListPolSat.

We define $\mathbf{G}_1 = \mathbf{P} \rtimes \mathbf{Q}$ where the action is given by the action of $\mathbf{H}_q \leqslant \mathbf{Q}$ on $\mathbf{N}_p \leqslant \mathbf{P}$ (and $\mathbf{P}$ and $\mathbf{N}_q \leqslant \mathbf{Q}$ commute). Notice that there is a canonical bijection (in general not an isomorphism) between G and G_1 and we have $\mathbf{R} \leqslant \mathbf{G}_1$. Moreover, notice that $\mathbf{G}_1$ meets the requirements of Corollary 12 and $\mathbf{G}/\mathbf{N}_q = (\mathbf{N}_p \rtimes (\mathbf{H}_p \times \mathbf{H}_q) = (\mathbf{N}_p \rtimes \mathbf{H}_p) \rtimes \mathbf{H}_q = \mathbf{G}_1/\mathbf{N}_q$.

Our next step is to transform a polynomial $\mathbf{q} \in \mathrm{Pol}(\mathbf{G})$ to a polynomial $\theta(\mathbf{q}) \in \mathrm{Pol}(\mathbf{G}_1)$ which, when restricting variables to R, has the same solution set (this makes sense as $\mathbf{R}$ is both a subgroup of $\mathbf{G}$ and $\mathbf{G}_1$).

In order to do so, write $\mathbf{q}(\overline{x}) = g_0 h_0 \xi_1 g_1 h_1 \cdots \xi_m g_m h_m$ where $g_i \in N_q$ and $h_i \in H_p$ (i.e., $g_i h_i \in L$) and the ξ_i are constants from $\mathbf{R} = \mathbf{N}_p \rtimes \mathbf{H}_q$ or variables. We define $\theta : \mathrm{Pol}(\mathbf{G}) \to \mathrm{Pol}(\mathbf{G}_1)$ by $\theta(\mathbf{q}) = g_0 h_0 \xi_1 ({}^{h_0}g_1) h_1 \cdots \xi_m ({}^{h_0 \cdots h_{m-1}}g_m) h_m$, where ${}^{h}g = hgh^{-1}$ denotes the action of $h \in H_p$ on $g \in N_q$ (considered in $\mathbf{G}$); we view ${}^{h}g$ as a fixed element of $N_q \leqslant G_1$ and forget that it comes from the action in $\mathbf{G}$. Notice that up to a constant factor $|\theta(\mathbf{q})|$ and $|\mathbf{q}|$ are equal. We say $\overline{x}$ is a solution of $\mathbf{q}$ if $\mathbf{q}(\overline{x}) = 1$.

▷ Claim 23. Let $\overline{x} \in R^n$. Then $\overline{x}$ is a solution of $\mathbf{q}$ if and only if $\overline{x}$ is a solution of $\theta(\mathbf{q})$.

Proof. As $\mathbf{G}/\mathbf{N}_q = \mathbf{G}_1/\mathbf{N}_q$, we may assume that $\mathbf{q}(\overline{x})$ and $\theta(\mathbf{q})(\overline{x})$ are both in N_q. Then, in $\mathbf{G}$ we have

$$\begin{aligned}\mathbf{q}(\overline{x}) &= g_0 h_0 \xi_1 g_1 h_1 \cdots \xi_m g_m h_m \\ &= g_0 \, {}^{h_0\xi_1}g_1 \cdots {}^{h_0\xi_1 \cdots h_{m-1}\xi_m}g_m \cdot h_0 \xi_1 \cdots h_{m-1}\xi_m h_m \\ &= g_0 \, {}^{h_0\xi_1}g_1 \cdots {}^{h_0\xi_1 \cdots h_{m-1}\xi_m}g_m.\end{aligned}$$

On the other hand, in $\mathbf{G}_1$ we have

$$\begin{aligned}\theta(\mathbf{q})(\overline{x}) &= g_0 h_0 \xi_1 ({}^{h_0}g_1) h_1 \cdots \xi_m ({}^{h_0 \cdots h_{m-1}}g_m) h_m \\ &= g_0 \, {}^{\xi_1}({}^{h_0}g_1) \cdots {}^{\xi_1 \cdots \xi_m}({}^{h_0 \cdots h_{m-1}}g_m) \cdot h_0 \xi_1 \cdots h_{m-1}\xi_m h_m \\ &= g_0 \, {}^{\xi_1}({}^{h_0}g_1) \cdots {}^{\xi_1 \cdots \xi_m}({}^{h_0 \cdots h_{m-1}}g_m).\end{aligned}$$

Now, we can read the last line as an element of $\mathbf{G}$ interpreting ${}^{h}g = hgh^{-1}$ again as the action of $h \in H_p$ on $g \in N_q$. As in $\mathbf{G}$ the ξ_i commute with h_i modulo $\mathbf{N}_p$, which is contained in the centralizer of $\mathbf{N}_q$ in $\mathbf{G}$, we conclude that as an equality in $\mathbf{G}$ we have

$$\theta(\mathbf{q})(\overline{x}) = g_0 {}^{h_0\xi_1}g_1 \cdots {}^{h_0\xi_1\cdots h_{m-1}\xi_m}g_m.$$

This proves the claim. ◁

If a polynomial $\mathbf{q} \in \mathrm{Pol}(\mathbf{G})$ has a solution with variables restricted to R, by Claim 23, $\theta(\mathbf{q})$ also has a solution with variables restricted to R. Now, we can apply Corollary 12 (in the CDH case) or Corollary 20 (if $\mathbf{H}$ is abelian), which gives us that a polynomial fraction $1/|\theta(\mathbf{q})|^{\mathcal{O}(1)}$ of all assignments $\overline{y} \in R^n$ are satisfying for $\theta(\mathbf{q})$ (i.e., there are at least $|R|^n/|\theta(\mathbf{q})|^{\mathcal{O}(1)}$ satisfying assignments among $|R|^n$ possible assignments). By Claim 23 also at least a polynomial fraction $1/|\mathbf{q}|^{\mathcal{O}(1)}$ of all assignments $\overline{y} \in R^n$ are satisfying for $\mathbf{q}$.

By symmetry the same argument applies to a polynomial with variables restricted to L: if a polynomial $\mathbf{q} \in \mathrm{Pol}(\mathbf{G})$ with variables restricted to L has a solution, at least $1/|\mathbf{q}|^{\mathcal{O}(1)}$ of all assignments $\overline{y} \in L^n$ are satisfying for $\mathbf{q}$.

Since $\mathbf{G} = \mathbf{LR}$, we can show the none-or-many property for $\mathbf{G}$ as follows: assume $\mathbf{p}$ is a polynomial with a solution $\overline{a} = (a_1, \ldots, a_n)$. We can write each $a_i = \ell_i r_i$ with $\ell_i \in L$ and $r_i \in R$. Let $\mathbf{q}$ be the polynomial obtained from $\mathbf{p}$ by substituting every variable x_i by $\ell_i y_i$ where y_i is a new variable. We know that $\mathbf{q}$ has a solution when restricting all variables to R – hence, it has at least $|R|^n/|\mathbf{p}|^{\mathcal{O}(1)}$ solutions in R^n. For each of these solutions $\overline{r}' = (r'_1, \ldots, r'_n) \in R^n$ again we obtain a polynomial $\mathbf{r}$ from $\mathbf{p}$ by replacing each variable x_i by $z_i r'_i$ where z_i is a new variable restricted to L. Now, $\mathbf{r}$ has at least $|L|^n/|\mathbf{p}|^{\mathcal{O}(1)}$ many solutions. Since any of these solutions gives us a solution to $\mathbf{p}$, we obtain at least $|R|^n/|\mathbf{p}|^{\mathcal{O}(1)} \cdot |L|^n/|\mathbf{p}|^{\mathcal{O}(1)}$ solutions for $\mathbf{p}$.

Therefore, picking random assignments leads to an RP algorithm (like in Lemma 10). ◀

A straightforward (though not the smallest) example for Theorem 4 not covered by previous results is the wreath product $\mathbb{Z}_6 \wr \mathbb{Z}_6 = (\mathbb{Z}_6)^6 \rtimes \mathbb{Z}_6$. By Theorem 4 we know that PolSat is in RP for this group, whereas ProgramSat is not in RP under rETH by Theorem 1.

As we show in Corollary 6, we can even classify the complexity of PolSat for arbitrary wreath products. Before we outline the proof, let us remark that, if $\mathbf{G}$ is nilpotent and $\mathbf{H}$ abelian, then PolSat$(\mathbf{G} \wr \mathbf{H})$ is in RP as soon as $\mathbf{G}$ is a p-group or $|G|$ and $|H|$ only have the same two prime divisors – without requiring CDH. This is an immediate consequence of Corollary 20 and Theorem 4.

Proof sketch of Corollary 6. The CDH-based RP algorithms are due to Corollary 12 and Theorem 4. Being not in the RP case, $|G|$ has at least two prime divisors $q \neq r$. Moreover, $|H|$ has a third prime divisor $p \neq q, r$. Thus, we will find a wreath product $(\mathbb{Z}_q \times \mathbb{Z}_r) \wr \mathbb{Z}_p$ as a subgroup of a quotient of $\mathbf{G} \wr \mathbf{H}$. By [26, Theorm 4.1.10] neither $\mathbb{Z}_q \wr \mathbb{Z}_p$ nor $\mathbb{Z}_r \wr \mathbb{Z}_p$ is nilpotent. Thus, we can find covering pairs of normal subgroups $\mathbf{B}_q, \mathbf{A}_q$ and $\mathbf{B}_r, \mathbf{A}_r$ such that $C_{\mathbb{Z}_q \wr \mathbb{Z}_p}(\mathbf{B}_q/\mathbf{A}_q) \neq \mathbb{Z}_q \wr \mathbb{Z}_p$. It remains to lift them to $\mathbf{G} \wr \mathbf{H}$ and apply Corollary 3. ◀

8 Conclusion

In this paper, under the assumptions of rETH and CDH, we fully classified in which cases the computational complexity of ProgramSat and ListPolSat for finite groups is in RP. It seems that eliminating the assumptions (especially rETH) can be really hard, but there is still a chance to improve Theorem 1 by showing polynomial time deterministic algorithms instead of the randomized ones:

▶ **Problem 1.** *Is there a polynomial time* deterministic *algorithm solving* ProgramSat($\mathbf{G}$) *and* ListPolSat($\mathbf{G}$) *for* $\mathbf{G}$ *such that there is a prime* p *and a normal* p*-subgroup* $\mathbf{G}_p$ *of* $\mathbf{G}$ *with* $\mathbf{G}/\mathbf{G}_p$ *being nilpotent?*

We took a step towards full classification of the complexity of PolSat for finite groups. Our study reveals that the interactions of normal subgroups of different characteristics play a crucial role. To conclude we present an example of a group of Fitting length 2 for which the complexity of PolSat can not be resolved by our results.

▶ **Problem 2.** *What is the computational complexity of* PolSat($\mathbf{G}$) *for*

$$\mathbf{G} = (\mathbb{Z}_3 \times \mathbb{Z}_5 \times \mathbb{Z}_7) \rtimes (\mathbb{Z}_2 \times \mathbb{Z}_2),$$

where the first $\mathbb{Z}_2$ *acts on* $\mathbb{Z}_3 \times \mathbb{Z}_5$ *by inversion and the second* $\mathbb{Z}_2$ *acts on* $\mathbb{Z}_5 \times \mathbb{Z}_7$ *by inversion?*

Note that the group $\mathbf{G}$ from Problem 2 has $\mathbb{Z}_3$, $\mathbb{Z}_5$, and $\mathbb{Z}_7$ as normal subgroups of different characteristics with $C_{\mathbf{G}}(\mathbb{Z}_p) \neq G$ for $p = 3, 5, 7$ and $C_{\mathbf{G}}(\mathbb{Z}_p) \cdot C_{\mathbf{G}}(\mathbb{Z}_q) = G$ for $p \neq q$. In particular, the last property prevents us from using Theorem 2 or Corollary 3. On the other hand, four different primes dividing the size of $\mathbf{G}$ blocks Theorem 4 from being applied here. Moreover, also Corollary 12 cannot be applied here since the largest nilpotent quotient of $\mathbf{G}$ is $\mathbb{Z}_2 \times \mathbb{Z}_2$ and the kernel of the projection is clearly not a p-group.

Linearly Ordered Colourings of Hypergraphs

Tamio-Vesa Nakajima
Department of Computer Science, University of Oxford, UK

Stanislav Živný
Department of Computer Science, University of Oxford, UK

Abstract

A linearly ordered (LO) k-colouring of an r-uniform hypergraph assigns an integer from $\{1, \dots, k\}$ to every vertex so that, in every edge, the (multi)set of colours has a unique maximum. Equivalently, for $r = 3$, if two vertices in an edge are assigned the same colour, then the third vertex is assigned a larger colour (as opposed to a different colour, as in classic non-monochromatic colouring). Barto, Battistelli, and Berg [STACS'21] studied LO colourings on 3-uniform hypergraphs in the context of promise constraint satisfaction problems (PCSPs). We show two results.

First, given a 3-uniform hypergraph that admits an LO 2-colouring, one can find in polynomial time an LO k-colouring with $k = O(\sqrt{n \log \log n}/\log n)$, where n is the number of vertices of the input hypergraph. This is established by building on ideas from algorithms designed for approximate graph colourings.

Second, given an r-uniform hypergraph that admits an LO 2-colouring, we establish NP-hardness of finding an LO 3-colouring for every constant uniformity $r \geq 5$. In fact, we determine the precise relationship of polymorphism minions for all uniformities $r \geq 3$, which reveals a key difference between $r = 3, 4$ and $r \geq 5$ and which may be of independent interest. Using the algebraic approach to PCSPs, we actually show a more general result establishing NP-hardness of finding an LO $(k+1)$-colouring for LO k-colourable r-uniform hypergraphs for $k \geq 2$ and $r \geq 5$.

1 Introduction

The computational complexity of the *approximate graph colouring* problem [16] is an outstanding open problem in theoretical computer science. Given a 3-colourable graph G on n vertices, is it possible to find a k-colouring of G? On the tractability side, the current best is a polynomial-time algorithm of Kawarabayashi and Thorup [23] that finds a k-colouring with $k = k(n) = n^{0.199}$ colours. On the intractability side, the state-of-the-art for constant k has only recently been improved from $k = 4$, due to Khanna, Linial, and Safra [24] and Guruswami and Khanna [17] to $k = 5$, due to Barto, Bulín, Krokhin, and Opršal [5]. The authors of [5] introduced a general algebraic methodology for studying the computational complexity of so-called promise constraint satisfaction problems (PCSPs). Going beyond the

work in [5], for graphs with a promised higher chromatic number than three, the current best intractability results for constantly many extra colours is due to Wrochna and Živný [27], building on the work of Huang [22].

The situation is much better understood for the approximate *hypergraph* colouring problem with the classic notion of a colouring leaving no edge monochromatic. A celebrated result of Dinur, Regev, and Smyth established that finding an ℓ-colouring of a 3-uniform hypergraph that is k-colourable is NP-hard for every constant $2 \leq k \leq \ell$ [14] (and this also implies the same result on r-uniform hypergraphs for every constant uniformity $r \geq 3$).

Different variants of approximate hypergraph colourings, such as rainbow colourings, were studied, e.g. in [2, 10, 18, 19, 12], but most complexity classifications related to these problems are open. Some intractability results are also known for colourings with a super-constant number of colours. For graphs, conditional hardness was established by Dinur and Shinkar [15]. For hypergraphs, intractability results were obtained by Bhangale [9] and by Austrin, Bhanghale, and Potukuchi [1].

Barto, Battistelli, and Berg have recently studied systematically a certain type of PCSPs on non-Boolean domains and identified a very natural variant of k-colourings of 3-uniform hypergraphs, called *linearly ordered* (LO) k-colourings [4]. A k-colouring of a 3-uniform hypergraph with colours $[k] = \{1, \dots, k\}$ is an LO colouring if, for every edge, it holds that, if two vertices are coloured with the same colour, then the third vertex is coloured with a larger colour. (In the classic non-monochromatic colouring, the requirement is that the third vertex should be coloured with a *different* colour, but not necessarily a larger one.) An LO 2-colouring is thus a "1-in-3" colouring. Barto et al. asked whether finding an LO k-colouring of a 3-uniform hypergraph is NP-hard for a fixed $k \geq 3$ if the input hypergraph is promised to admit an LO 2-colouring.

Contributions

While we do not resolve the question raised in [4], we obtain non-trivial results, both positive (algorithmic) and negative (hardness).

First, we present an efficient algorithm for finding an LO colouring of a 3-uniform hypergraph with super-constantly many colours if an LO 2-colouring is promised to exist. In more detail, for a given 3-uniform hypergraph H on n vertices that admits an LO 2-colouring, we present a polynomial-time algorithm that finds an LO k-colouring of H with $k = k(n) = O(\sqrt{n \log \log n} / \log n)$ colours. As mentioned above, there are only a few results on hypergraph colourings with super-constantly many colours.

Second, we establish intractability of finding an LO 3-colouring of an r-uniform hypergraph if an LO 2-colouring is promised for every constant uniformity $r \geq 5$. In fact, we prove a more general result that finding an LO $(k+1)$-colouring of an r-uniform hypergraph admitting an LO k-colouring is intractable for every constant $k \geq 2$ and $r \geq 5$. This result is based the algebraic approach to PCSPs and in particular on minions [5]. As a matter of fact, we establish the precise relationships of the polymorphism minions of the LO 2- vs 3-colourings on r-uniform hypergraphs for $r \geq 3$, which may be of independent interest. This gives the advertised intractability result but also an impossibility result on certain types of polynomial-time reductions (namely pp-constructions [5]) between LO 2- vs 3-colourings on r-uniform hypergraphs for $r \geq 5$ and $r = 3, 4$.

2 Preliminaries

An *r-uniform hypergraph* H is a pair (V, E) where V is the set of *vertices* of the hypergraph, and $E \subseteq V^r$ is the set of *edges* of the hypergraph. In our context the order of the vertices in each edge is irrelevant. We will allow vertices to appear multiple times in edges; however, we exclude edges of form $(v, \dots, v)$ – such edges would be impossible in the problems we will consider anyway. We say that two distinct vertices u, v are *neighbours* if they both belong to some edge $e \in E$. Let $N(u)$ be the set of neighbours of u. Call a set S an *independent set* of a hypergraph H if and only if no two members of S are neighbours.

A *linearly ordered* (LO) k-colouring of an r-uniform hypergraph $H = (V, E)$ is an assignment $c : V \to [k]$ of colours from $[k] = \{1, \dots, k\}$ to the vertices of H such that, for each edge $(v_1, \dots, v_r) \in E$, the sequence $c(v_1), \dots, c(v_r)$ has a unique maximum. We omit the "k-" if the number of colours is unimportant.

▶ **Example 1.** Consider the hypergraph $H = (V, E)$, where $V = [4] = \{1, 2, 3, 4\}$ and $E = \{(1, 2, 3), (1, 2, 4)\}$. The assignment $c = \{1 \mapsto 1, 2 \mapsto 1, 3 \mapsto 2, 4 \mapsto 2\}$ is an LO 2-colouring, and $c'(x) = x$ is an LO 4-colouring. On the other hand, $c''(x) = 3 - c(x)$ is not an LO colouring at all, since both of the edges have two equal maximal elements when mapped through c''.

Finding an LO k-colouring, for constant $k \geq 3$, of a 3-uniform hypergraph that admits an LO 2-colouring was studied by Barto et al. [4] in the context of promise constraint satisfaction problems (PCSPs), which we define next.

2.1 Promise CSPs

Promise CSPs have been introduced in the works of Austrin, Guruswami, and Håstad [3] and Brakensiek and Guruswami [11]. We follow the notation and terminology of Barto, Bulín, Krokhin, and Opršal [5], adapted to structures consisting of a single relation.

An *r-ary structure* is a pair $\mathbf{D} = (D, R^{\mathbf{D}})$, where $R^{\mathbf{D}} \subseteq D^r$ and D is finite. We call D the *domain* of the structure, and $R^{\mathbf{D}}$ the *relation* of the structure. For two r-ary structures $\mathbf{A}, \mathbf{B}$, a *homomorphism from* $\mathbf{A}$ *to* $\mathbf{B}$ is a function $h : A \to B$ such that, for each $(a_1, \dots, a_r) \in R^{\mathbf{A}}$, we have $(h(a_1), \dots, h(a_r)) \in R^{\mathbf{B}}$. This is written $h : \mathbf{A} \to \mathbf{B}$. If we wish to assert only the existence of such a homomorphism, we write $\mathbf{A} \to \mathbf{B}$.

We now define the search version of the fixed-template PCSP problem. Given two r-ary structures $\mathbf{A} \to \mathbf{B}$, the problem PCSP$(\mathbf{A}, \mathbf{B})$ is the following: given an r-ary structure $\mathbf{I} \to \mathbf{A}$, find a homomorphism $h : \mathbf{I} \to \mathbf{B}$. The decision version of this problem is: given an r-ary structure $\mathbf{I}$, output YES if $\mathbf{I} \to \mathbf{B}$, and output NO if $\mathbf{I} \not\to \mathbf{A}$. Observe that the decision version can be reduced to the search version: to solve the decision version, run an algorithm for the search version, then check if it gives a correct answer. We will use PCSP$(\mathbf{A}, \mathbf{B})$ to mean the decision version when proving hardness, and the search version when showing algorithmic results.

LO colourings can be readily seen as PCSPs. First, observe that an r-uniform hypergraph can be seen as an r-ary structure. Second, define an r-ary structure $\mathbf{LO}_k^r$ with domain $[k]$, and whose relation contains a tuple $(c_1, \dots, c_r)$ if and only if the sequence $c_1, \dots, c_r$ has a unique maximum. Then, an LO k-colouring of an r-uniform hypergraph $\mathbf{H}$ is the same as a homomorphism from $\mathbf{H}$ (viewed as an r-ary structure) to $\mathbf{LO}_k^r$. Thus, the problem of finding an LO k-colouring of an r-uniform hypergraph that has an LO 2-colouring is the same as PCSP$(\mathbf{LO}_2^r, \mathbf{LO}_k^r)$.

In Section 3, we study the computational complexity of $\mathrm{PCSP}(\mathbf{LO}_2^3, \mathbf{LO}_{k(n)}^3)$, were $k(n)$ depends on the input size; here n denotes the number of vertices of the input (3-uniform) hypergraph. As in Example 1, this is obviously possible for $k(n) = n$. As our first contribution, we will present an efficient algorithm with $k(n) = O(\sqrt{n \log\log n}/\log n)$.

In Section 5, we study the computational complexity of $\mathrm{PCSP}(\mathbf{LO}_k^r, \mathbf{LO}_{k+1}^r)$ for constant uniformity $r \geq 3$ and constant arity $k \geq 2$. We establish intractability of $\mathrm{PCSP}(\mathbf{LO}_k^r, \mathbf{LO}_{k+1}^r)$ for $r \geq 5$ and $k \geq 2$, cf. Corollary 23 (for $k = 2$) and Corollary 25 (for $k \geq 2$) in Section 5. These results are based on the algebraic theory of minions [5], briefly introduced in Section 4. In fact, we establish the precise relationships of the polymorphism minions of $\mathrm{PCSP}(\mathbf{LO}_2^r, \mathbf{LO}_3^r)$ for all $r \geq 3$ (cf. Theorem 22 in Section 5).

In the full version of this paper [25] we show stronger results, namely NP-hardness of $\mathrm{PCSP}(\mathbf{LO}_k^r, \mathbf{LO}_\ell^r)$ for every constant k and ℓ with $2 \leq k \leq \ell$ and every constant uniformity $r \geq \ell - k + 4$.

3 Algorithmic results

Within this section, we will prove algorithmic results for finding LO colourings of 3-uniform hypergraphs that have LO 2-colourings, using a non-constant number of colours. We will describe two algorithms: a simpler one that uses $O(\sqrt{n})$ colours; and a more complicated one that builds on the first, that uses $O(\sqrt{n \log\log n}/\log n)$ colours. The initial algorithm is inspired by Wigderson's algorithm for the approximate graph colouring problem [26]: like that algorithm it considers a "sparse case" and a "dense case"; however, our algorithm is more complex due to the fact that an LO colouring is different to a normal graph colouring. A particularly salient difference is that our algorithm picks a high-degree *edge*, whereas Wigderson's algorithm picks a high-degree *vertex*. Our second, more complex algorithm refines the first one by selecting more than one edge at a time (similarly to the work of Berger and Rompel [8], although, like Wigderson's algorithm [26], they choose several vertices at a time, not several edges as we do), and by using an improved algorithm for finding independent sets (studied by Halldórsson [21]).

In both algorithms, the general strategy will be to colour some vertices with large colours, then to recursively colour the rest of the hypergraph. The exact choice of "large colour" is made only after the recursive colouring (since only at that point do we know how large the colours need to be). We will not keep track of the bookkeeping needed to do this, in order to make the algorithms easier to explain.

3.1 First algorithm

Fix some 3-uniform hypergraph $H = (V, E)$, with n vertices and m edges. Suppose that this hypergraph admits an LO 2-colouring c^*. We first show a way to extend a partial colouring consistent with c^* until it intersects each edge of H in zero, one or three vertices.

▶ **Lemma 2.** *There exists a polynomial-time algorithm that, given a partial LO 2-colouring c that coincides with c^* on its domain, extends c into a partial LO 2-colouring* extend(c) *that does not intersect any edge of H in exactly 2 vertices and remains consistent with c^* on its domain. The algorithm will also run in polynomial time even if c isn't consistent with c^* or even an LO 2-colouring, in which case it will return an arbitrary extension of c.*

Proof. The following algorithm suffices: while c intersects an edge (x, y, z) in precisely two vertices (say x, y), extend c with $z \mapsto 4 - c(x) - c(y)$. This algorithm clearly extends c until it intersects no edges in precisely 2 vertices. Furthermore, since c^* is an LO 2-colouring, for

each edge (x, y, z) we have $c^*(x) + c^*(y) + c^*(z) = 4$. Thus, if we assume that c is initially consistent with c^*, we can show that each extension keeps c consistent with c^*. We conclude by noting that each extension can be done in polynomial time, and that there are at most n extensions – and that this is the case even if c doesn't coincide with c^* on its domain, or isn't even an LO colouring. ◀

We now show how to find a large independent set if the hypergraph is sparse enough.

▶ **Lemma 3.** *If every edge in H contains a vertex with at most $\Delta \geq 0$ neighbours, then we can find an independent set with $n/(\Delta + 1) = \Omega(n/\Delta)$ vertices in polynomial time. This holds even if Δ happens not to be an integer.*

Proof. This condition implies that there exists at least one vertex with most Δ neighbours: if there exists at least one edge then one of the vertices in it must be this vertex; otherwise, all vertices have $0 \leq \Delta$ neighbours. By adding that vertex to the independent set, removing it and its neighbours from the hypergraph, and repeating this process until no vertices remain, we can find the required independent set. ◀

Our algorithm will colour a certain part of the hypergraph with $O(1)$ colours, colouring the rest recursively, with strictly smaller colours. The following lemma gives us a sufficient goal for the size of what must be coloured in one step.

▶ **Lemma 4.** *A recursive procedure that colours $\Omega(\sqrt{n})$ vertices (where n refers to the* current *size of the hypergraph, not the initial size) with $O(1)$ colours at each step will use $O(\sqrt{n})$ colours overall.*

Proof. Let $T(n)$ be the number of colours needed to colour a hypergraph with at most n vertices. It is sufficient to prove that $T(n) = O(\sqrt{n})$ for n a power of two, since for arbitrary n we can consider the next largest power of two, which is at most $2n$. For some such n, consider how many colours are needed to colour half the hypergraph. At each step until the hypergraph is halved, we colour at least $\Omega(\sqrt{n/2}) = \Omega(\sqrt{n})$ vertices with $O(1)$ colours. Equivalently, we colour half the hypergraph with $O(\sqrt{n})$ colours. Thus we deduce that $T(n) \leq T(n/2) + O(\sqrt{n})$. Applying the Master method of Cormen et al. [13] to the recurrence $U(n) = U(n/2) + \alpha\sqrt{n}$, where α comes from the constant hidden in the recurrence for T, we can deduce that $T(n) = O(\sqrt{n})$. (Applying this method requires satisfying the "regularity condition": $\sqrt{n/2} \leq c\sqrt{n}$ for some $c < 1$ and large enough n; this holds for $c = 1/\sqrt{2}$.) ◀

These results together help us create the algorithm we want.

▶ **Theorem 5.** *There exists a polynomial-time algorithm that finds an LO $O(\sqrt{n})$-colouring for a hypergraph with an LO 2-colouring.*

Proof. We provide a recursive algorithm.

1. If the hypergraph has no edges (x, y, z) where all of x, y and z have at least $\sqrt{n}$ neighbours, then find an independent set with $\Omega(n/\sqrt{n}) = \Omega(\sqrt{n})$ vertices, colour that independent set with a large colour, and recursively colour the rest of the hypergraph with smaller colours. This is possible by Lemma 3.
2. Otherwise, let (x, y, z) be an edge where all of x, y and z have at least $\sqrt{n}$ neighbours.
3. Iterate over $u \in \{x, y, z\}$.
4. Construct a partial colouring c_u where $c_u(u) = 2$ and $c_u(v) = 1$ for $v \in N(u)$.
5. Construct extend(c_u), and check if it is a partial LO 2-colouring. This is possible by Lemma 2.

6. If it is, colour the vertices in the domain of extend(c_u) with two large colours, depending on the colours they got in extend(c_u) (i.e. for some large enough C, colour v with $C + \text{extend}(c_u)(v)$), and then recursively colour the rest of the hypergraph with smaller colours.

We establish the correctness of this algorithm by showing its soundness and completeness.

We begin by showing completeness. The only way we could possibly fail to return something is if, for all $u \in \{x, y, z\}$, the function extend(c_u) is not a proper partial LO 2-colouring. However, for at least one $u \in \{x, y, z\}$, it must be the case that $c^*(u) = 2$, and thus that $c^*(v) = 1$ for $v \in N(u)$. Thus, for this value of u, c^* is consistent with c_u on its domain, and therefore extend(c_u) must be a proper partial LO 2-colouring.

Now we show soundness: whenever we return a colouring, we return an LO $O(\sqrt{n})$-colouring. We first show that we return an LO colouring. Observe that in the case covered in step 1, all the edges that do not intersect the independent set that we find are properly coloured recursively. Furthermore all edges that do intersect the independent set intersect it in exactly one vertex. This vertex is assigned a colour larger than the colours of the other vertices in the edge, so all such edges are also properly coloured. In the case covered in steps 2–6, note that if we return anything, then extend(c_u) is a proper partial LO 2-colouring. Note that all edges intersecting the domain of extend(c_u) in zero or three vertices are correctly coloured (either recursively, or since extend(c_u) is an LO colouring). Furthermore, since the vertices in the domain of extend(c_u) are assigned large colours, those edges that intersect this domain in one vertex are also properly coloured. Thus in this case, since no edge intersects extend(c_u) in two vertices, we also return a proper LO colouring. Thus in all cases we return an LO colouring.

To see that we return an LO $O(\sqrt{n})$-colouring, note that in all cases we colour $\Omega(\sqrt{n})$ vertices with $O(1)$ colours at each iteration (in the first case because we colour an independent set with this size; in the second because c_u must be defined on $N(u)$, which has at least $\sqrt{n}$ vertices). Thus, by Lemma 4, we use $O(\sqrt{n})$ colours overall.

We conclude by noting that this algorithm has recursive depth at most n, and does polynomial work at each step – thus it works in polynomial time. ◀

3.2 Second algorithm

As before, fix some 3-uniform hypergraph $H = (V, E)$, with n vertices and m edges, and suppose that this hypergraph admits an LO 2-colouring c^*. We first reduce our general problem to the special case of finding an LO 3-colouring for a *linear* 3-uniform hypergraph that admits an LO 2-colouring. We call a hypergraph *linear* if no pair of vertices belongs to more than one edge.

▶ **Example 6.** The hypergraph from Example 1 is not linear since vertices 1 and 2 belong to two edges.

The key property of linear hypergraphs we will use is the following: if a vertex v in an r-uniform hypergraph has d neighbours $v_1, \ldots, v_d$, then v is contained in at most d edges. This is the case since each pair (v, v_i) can belong to at most one edge, and $(v, \ldots, v)$ cannot appear as an edge. If H weren't linear, then v could have belonged to at least $\binom{d}{r-1}$ edges, one for each set of $r - 1$ of the d neighbours. (In fact, there are even more possible edges, since vertices are allowed to appear multiple times.)

▶ **Theorem 7.** *If H is a 3-uniform hypergraph with an LO 2-colouring, then we can find, in polynomial time, a linear 3-uniform hypergraph H' with an LO 2-colouring, such that an LO 3-colouring of H can be computed from an LO 3-colouring of H' in polynomial time.*

Proof. The following procedure is sufficient: while H contains two edges of form (x, y, z) and (x, y, z'), identify z with z'. This works because z and z' must be coloured the same in any LO 2-colouring of H (as, in any LO 2-colouring c, $c(x) + c(y) + c(z) = c(x) + c(y) + c(z') = 4$, and thus $c(z) = c(z')$). Thus H' also remains LO 2-colourable. Furthermore, by reversing the identifications, any LO 3-colouring of H' can be made into an LO 3-colouring of H. Finally, this procedure clearly takes polynomial time and results in a linear hypergraph H'. ◀

Thus we will assume that H is linear. We now show how to find a large independent set when the hypergraph is sparse enough, using a series of lemmata and an algorithm of Halldórsson [21].

▶ **Lemma 8.** *Suppose each edge of H has at least one vertex with at most $\Delta \geq 1$ neighbours. Then H has $\Omega(n)$ vertices with at most Δ neighbours.*

Proof. Let x be the number of vertices with at most Δ neighbours. We will show $x = \Omega(n)$ by double counting $|E|$. Note that each edge in $|E|$ contains at least one vertex with at most Δ neighbours; furthermore, each such vertex belongs to at most Δ edges (since H is linear). Thus $|E| \leq x\Delta$. Now note that each vertex with more than Δ neighbours belongs to more than $\Delta/2$ edges, and each edge contains 3 vertices. Thus $3|E| > (n - x)\Delta/2$. Therefore $(n - x)\Delta/6 < x\Delta$, which implies $x = \Omega(n)$. ◀

▶ **Lemma 9.** *Suppose all vertices in H have at most $\Delta \geq 1$ neighbours. Then H has an independent set with at least $\Omega(|E|/\Delta)$ vertices.*

Proof. Let S be the set of values mapped to 2 by c^*; note that S is an independent set. Consider the mapping $f : V \to \mathbb{N}$, where $f(u)$ is zero if $u \notin S$, and otherwise is equal to the number of edges that u belongs to. Since each edge contains exactly one vertex mapped to 2 by c^*, we deduce that $\sum_{u \in V} f(u) = \sum_{u \in S} f(u) = |E|$. Now, each value of $f(u)$ is at most Δ (since H is linear); thus we deduce that $|S|\Delta \geq \sum_{u \in S} f(u) = |E|$, and thus $|S| \geq |E|/\Delta$. ◀

▶ **Theorem 10** ([21, Theorem 4.4])**.** *There exists a polynomial-time algorithm that, if given a graph G with average degree $\overline{d}$, which has an independent set with size s, can find an independent set with size $\Omega(s \log \overline{d}/\overline{d} \log \log \overline{d})$.*

The *primal graph* $P(H)$ of H is a graph with the same vertices as H, and where two vertices are linked by an edge if and only if they are neighbours in H. Since the primal graph preserves neighbours, an independent set in H is independent in $P(H)$ and vice versa.

▶ **Example 11.** The primal graph $P(H)$ of the hypergraph H from Example 1 has $\{1, 2, 3, 4\}$ as vertices and $\{(1, 2), (2, 3), (3, 1), (2, 4), (4, 1)\}$ as edges.

▶ **Theorem 12.** *There exists a polynomial-time algorithm that, if given a linear hypergraph H with an LO 2-colouring where each vertex has most $\Delta = O(\sqrt{n/\log \log n})$ neighbours, can find an independent set with $\Omega(\sqrt{n} \log n/\sqrt{\log \log n})$ vertices.*

Proof. Consider the average degree $\overline{d}$ of the primal graph $P(H)$ of H. Observe that the independent sets of H and $P(H)$ coincide. Suppose $\overline{d} \leq \sqrt[6]{n}$. Thus $P(H)$ has $O(n\sqrt[6]{n})$ edges, and thus $O(n/\sqrt[6]{n}) = o(n)$ vertices of $P(H)$ have degree larger than $\sqrt[3]{n}$. By a simple greedy algorithm applied to the $\Omega(n)$ vertices of $P(H)$ with degree at most $\sqrt[3]{n}$ (repeatedly select the vertex with minimum degree), we can find an independent set of $P(H)$ (and thus of H) with $\Omega(n/\sqrt[3]{n})$ vertices, which is sufficient.

Now suppose $\overline{d} \geq \sqrt[6]{n}$. Note that there exists an independent set with $s = \Omega(|E|/\Delta)$ vertices. Since each edge of H gives rise to at most three edges of $P(H)$, we deduce that $\overline{d} = O(|E|/n)$. Thus $s/\overline{d} = \Omega(|E|/\Delta)/O(|E|/n) = \Omega(n/\Delta) = \Omega(\sqrt{n \log\log n})$. Also, $\log \overline{d}/\log\log \overline{d} \geq \log \sqrt[6]{n}/\log\log \sqrt[6]{n} = \Omega(\log n/\log\log n)$ for large enough n. Thus, the independent set algorithm from [21] applied to $P(H)$ will give us an independent set of $P(H)$ (and thus of H) with $\Omega(\sqrt{n}\log n/\sqrt{\log\log n})$ vertices. ◀

▶ **Corollary 13.** *If we are given instead a hypergraph where each edge has a vertex with at most $\Delta = O(\sqrt{n/\log\log n})$ neighbours, then, by applying the algorithm of Theorem 12 to the subhypergraph formed by taking only the $\Omega(n)$ vertices with at most Δ neighbours, we can still get an independent set with size $\Omega(\sqrt{n}\log n/\sqrt{\log\log n})$.*

As before, our algorithm will be recursive. We now investigate how many vertices must be coloured in one recursive step.

▶ **Lemma 14.** *A recursive procedure that colours $\Omega\left(\sqrt{n}\log n/\sqrt{\log\log n}\right)$ vertices (where n refers to the* current *size of the hypergraph, not the initial size) with $O(1)$ colours at each step will use $O(\sqrt{n\log\log n}/\log n)$ colours overall.*

Proof. Use the same strategy and notation as in Lemma 4. For n a large power of two, until halving n, in one step, we colour $\Omega(\sqrt{n/2}\log(n/2)/\sqrt{\log\log(n/2)}) = \Omega(\sqrt{n}\log n/\sqrt{\log\log n})$ vertices with $O(1)$ colours. The "large enough" part is important to get $n/2$ to the interval where $x \mapsto \sqrt{x}\log x/\sqrt{\log\log x}$ is increasing. Thus, with the same logic as before, $T(n) \leq T(n/2) + O(\sqrt{n\log\log n}/\log n)$ for large enough n. Applying the Master method of Cormen et al. [13] in the same way as in Lemma 4, $T(n) = O(\sqrt{n\log\log n}/\log n)$. (Again, we need the regularity condition: $\sqrt{n/2\log\log(n/2)}/\log(n/2) \leq c\sqrt{n\log\log n}/\log n$ for some $c < 1$ and large enough n; this can be shown for e.g. $c = 0.9$, $n \geq 6$.) ◀

With this result in hand, we now give a stronger algorithm for our problem, inspired by the strategy of Berger and Rompel [8]: we select multiple edges at once, not only one.

▶ **Theorem 15.** *There is a polynomial-time algorithm that finds an LO $O(\sqrt{n\log\log n}/\log n)$-colouring for a hypergraph that has an LO 2-colouring.*

Proof. Consider the following nondeterministic, recursive algorithm.

1. Make H linear by identifying vertices.
2. Let $k = \lceil \log_3 n \rceil$.
3. Let c_0 be an empty partial colouring.
4. For i from 1 to k:
   a. Let (x_i, y_i, z_i) be an edge for which x_i, y_i and z_i do not belong to the domain of c_{i-1}, and the minimum of the numbers of neighbours of x_i, y_i and z_i *not in the domain of* c_{i-1} is as large as possible. If such an edge does not exist, then exit this loop, setting $c_k = c_{i-1}$.
   b. Nondeterministically choose $u_i \in \{x_i, y_i, z_i\}$.
   c. Augment c_{i-1} with $u_i \mapsto 2$ and $v \mapsto 1$ for $v \in N(u_i)$; let the result of "extend"-ing this new function be c_i.

5. If c_k is not a proper LO 2-colouring, then this nondeterministic execution fails.
6. Colour the vertices in the domain of c_k with two large colours according to c_k (i.e. colour u with $C + c_k(u)$ for some large enough C). Remove the domain of c_k from H, letting the result be H'
7. If each edge in H' has a vertex with at most $O(\sqrt{n/\log\log n})$ neighbours, then find an independent set in H' with size $\Omega(\sqrt{n}\log n/\sqrt{\log\log n})$ and colour it with a large colour (but smaller then those used in the previous step), removing it from H'.
8. Recursively colour the rest of the hypergraph with smaller colours.

Since only logarithmically many nondeterministic choices from among a constant number of options are made, and polynomial work is done otherwise, this algorithm can be made into a polynomial-time deterministic one. Thus we show that it is correct, by showing that it is sound and complete.

To show completeness we need to show that at least one sequence of nondeterministic choices doesn't fail. It is therefore sufficient to show that, for one choice of $u_1, \ldots, u_k$, all of c_i are consistent with c^*. We see that, if c_{i-1} is consistent with c^*, then one choice of u_i exists that makes c_i consistent with c^* (the member of $\{x_i, y_i, z_i\}$ that is assigned 2 by c^*). Since c_0 is empty and thus consistent with c^* on its domain, we deduce inductively that one set of nondeterministic choices that keeps c_i consistent with c^* exists, and thus that the algorithm is complete.

Now we show soundness. Just as in the first algorithm, we always colour either by colouring the domain of some LO 2-colouring that doesn't intersect any edges in precisely 2 vertices with two large colours, according to that colouring; or by colouring an independent set with one large colour. (The LO colouring c_k intersects each edge in zero, one or three vertices due to the use of "extend".) We showed in the first algorithm that these procedures, followed by colouring what remains with smaller colours, lead to a proper LO colouring. We now need to show that we use $O(\sqrt{n\log\log n}/\log n)$ colours. To this end, we show that we colour $\Omega(\sqrt{n}\log n/\sqrt{\log\log n})$ vertices in each iteration – since colouring this many vertices with $O(1)$ colours at each recursive step will lead to an $O(\sqrt{n\log\log n}/\log n)$ colouring overall, as shown in Lemma 14. If the condition in step 7 is satisfied, then we clearly colour the required number of vertices; thus suppose it is not satisfied. In this case, there exists an edge e in H' whose vertices have $\Omega(\sqrt{n/\log\log n})$ neighbours. This implies that, during step a., the edge (x_i, y_i, z_i) could have been selected to be e. Since the number of neighbours of a vertex in H' is a lower bound for the number of neighbours of a vertex in H that do not belong to the domain of c_{i-1}, we find that selecting e would have made the minimum of the numbers of neighbours of x_i, y_i and z_i to have been at least $\Omega(\sqrt{n/\log\log n})$. Thus the actual values of x_i, y_i and z_i must all have at least this many neighbours not in the domain of c_{i-1}. Also, an edge is always found in step a. – since e can always be selected. This implies that c_0 is augmented by at least $\Omega(\sqrt{n/\log\log n})$ vertices at each of the $k = \Theta(\log n)$ iterations in step 4; thus c_k is defined on $\Omega(\sqrt{n}\log n/\sqrt{\log\log n})$ vertices. We thus deduce that in this case we also colour enough vertices. We conclude that the algorithm is sound.

Regarding the running time, note that if a (non-deterministic) guess in Step 4.b passes the test in Step 5, then no more guesses are made in this recursive call because the recursive call made in Step 8 cannot fail via our completeness proof. Thus the algorithm runs in polynomial time. ◀

4 Algebraic theory of fixed-template promise CSPs

We recount the algebraic theory of fixed-template PCSPs developed in [5] and specialised to structures with a single relation (of arity r).

The *p-the power* of an r-ary structure $\mathbf{A} = (A, R^{\mathbf{A}})$ is a structure $\mathbf{A}^p = (A^p, R^{\mathbf{A}^p})$ where

$$R^{\mathbf{A}^p} = \{((a_1^1, \dots, a_1^p), \dots, (a_r^1, \dots, a_r^p)) \mid (a_1^1, \dots, a_r^1) \in R^{\mathbf{A}}, \dots, (a_1^p, \dots, a_r^p) \in R^{\mathbf{A}}\}.$$

In other words, a tuple of $R^{\mathbf{A}^p}$ contains r vectors of p elements of A, such that if these are written as a matrix with r rows and p columns, each column is a member of $R^{\mathbf{A}}$. For two r-ary structures $\mathbf{A}, \mathbf{B}$, a p-ary polymorphism from $\mathbf{A}$ to $\mathbf{B}$ is a homomorphism $f : \mathbf{A}^p \to \mathbf{B}$.

▶ **Example 16.** Consider the binary structure $\mathbf{A} = ([2], R^{\mathbf{A}})$, where $R^{\mathbf{A}}$ is the binary disequality relation $\neq$ (restricted to $[2]^2$). The power $\mathbf{A}^5$ has domain $[2]^5$ and relation $\{(\mathbf{a}, \mathbf{b}) \mid \mathbf{a}, \mathbf{b} \in [2]^5, a_i \neq b_i, i = 1, \dots, 5\}$. This relation is constructed as follows: $(\mathbf{a}, \mathbf{b})$ belongs to the relation if and only if every column of a matrix with 5 columns and 2 rows constructed out of $\mathbf{a}, \mathbf{b}$ satisfies $\neq$. The matrix is the following one:

$$\begin{pmatrix} a_1 & a_2 & a_3 & a_4 & a_5 \\ b_1 & b_2 & b_3 & b_4 & b_5 \end{pmatrix}.$$

Thus, for each column to satisfy $\neq$, we must have $a_i \neq b_i$ for $i = 1, \dots, 5$, as indicated above.

Now, consider a quinary polymorphism $f : \mathbf{A}^5 \to \mathbf{A}$. This is a function $f : [2]^5 \to [2]$ that satisfies the following property: if given a matrix with 2 rows and 5 columns, such that each column is a member of $R^{\mathbf{A}}$, then by applying f to the rows of this matrix we also get a member of $R^{\mathbf{A}}$. For instance, for the matrix

$$\begin{pmatrix} 1 & 2 & 2 & 1 & 1 \\ 2 & 1 & 1 & 2 & 2 \end{pmatrix},$$

we deduce that the pair $(f(1,2,2,1,1), f(2,1,1,2,2)) \in R^{\mathbf{A}}$ i.e. $f(1,2,2,1,1) \neq f(2,1,1,2,2)$. One such polymorphism is given by selecting the values of f from $[2]$ such that $f(x_1, \dots, x_5) \equiv \sum_{i=1}^{5} x_i \pmod 2$.

The real power of this theory comes from *minions*.[1] A *minion* $\mathcal{M}$ is a sequence of sets $\mathcal{M}^{(0)}, \mathcal{M}^{(1)}, \dots$, equipped with an operation that, for $f \in \mathcal{M}^{(p)}$ and $\pi : [p] \to [q]$, yields $f_\pi \in \mathcal{M}^{(q)}$. The operation must satisfy the following conditions:

- For $f \in \mathcal{M}^{(p)}$, if $id : [p] \to [p]$ is the identity on $[p]$, then $f_{id} = f$.
- For $f \in \mathcal{M}^{(p)}$, $\pi : [p] \to [q]$ and $\sigma : [q] \to [t]$, we have $f_{\sigma \circ \pi} = (f_\pi)_\sigma$.

An important class of minion is the *polymorphism minion*. The polymorphism minion $\mathcal{M} = \mathrm{Pol}(\mathbf{A}, \mathbf{B})$ for two structures $\mathbf{A}, \mathbf{B}$ with the same arity is a minion where $\mathcal{M}^{(p)}$ is the set of p-ary polymorphisms from $\mathbf{A}$ to $\mathbf{B}$, and where, for $f : A^p \to B, \pi : [p] \to [q]$, f_π is given by $f_\pi(x_1, \dots, x_q) = f(x_{\pi(1)}, \dots, x_{\pi(p)})$. It is not difficult to check that, if $f : \mathbf{A}^p \to \mathbf{B}$ and $\pi : [p] \to [q]$, then $f_\pi : \mathbf{A}^q \to \mathbf{B}$, as required.

In order to be able to relate polymorphism minions with the complexity of PCSPs, we use *minion homomorphisms*.[2] A *minion homomorphism from $\mathcal{M}$ to $\mathcal{N}$* is a mapping ξ that takes each $\mathcal{M}^{(p)}$ to $\mathcal{N}^{(p)}$ and that satisfies the following condition: for any $\pi : [p] \to [q]$ and $f \in \mathcal{M}^{(p)}$, $\xi(f)_\pi = \xi(f_\pi)$. The following theorem links minion homomorphisms to PCSPs. In particular, minion homomorphisms capture precisely a certain type of polynomial-time reductions, know as primitive-positive constructions,[3] studied for CSPs [6] and PCSPs [5].

---

[1] In category-theoretic terms, a minion is a functor from the skeleton of the category of finite sets to the category of sets. The objects of the first category are sets $[p]$ for $p \in \mathbb{N}$, and the arrows are functions between them. The functor equivalent to a minion $\mathcal{M}$ takes $[p]$ to $\mathcal{M}^{(p)}$, and $\pi : [p] \to [q]$ to $f \mapsto f_\pi$.

[2] In category-theoretic terms, a minion homomorphism is just a natural transformation.

[3] Primitive-positive constructions (or pp-constructions, for short) capture so-called "gadget reductions", cf. [6, Section 3].

▶ **Theorem 17** ([5, Theorems 3.1 and 4.12]). *For r-ary structures $\mathbf{A}, \mathbf{B}$ and r'-ary structures $\mathbf{A}', \mathbf{B}'$, a primitive-positive construction-based polynomial-time reduction from* $\mathrm{PCSP}(\mathbf{A}', \mathbf{B}')$ *to* $\mathrm{PCSP}(\mathbf{A}, \mathbf{B})$ *exists if and only if* $\mathrm{Pol}(\mathbf{A}, \mathbf{B}) \to \mathrm{Pol}(\mathbf{A}', \mathbf{B}')$.

Unfortunately, it is usually a complex task to explicitly construct minion homomorphisms. An auxiliary construction called the *free structure* allows us to construct them more easily. For an arbitrary minion $\mathcal{M}$ and an r-ary structure $\mathbf{A} = (A, R^{\mathbf{A}})$, the *free structure* $\mathbf{F} = \mathbf{F}_{\mathcal{M}}(\mathbf{A})$ is an r-ary structure whose domain is $F = \mathcal{M}^{(|A|)}$. To construct its relation $R^{\mathbf{F}}$, first identify A with $[n]$ for $n = |A|$, and then enumerate the tuples of $R^{\mathbf{A}}$ as vectors $\mathbf{r}^1, \ldots, \mathbf{r}^k$, where $k = |R^{\mathbf{A}}|$. Construct functions $\pi_1, \ldots, \pi_r : [k] \to [n]$ where $\pi_i(j) = \mathbf{r}^j_i$. (If we were to arrange $\mathbf{r}^1, \ldots, \mathbf{r}^k$ into a matrix with r rows and k columns, then $\pi_i(1), \ldots, \pi_i(k)$ is the i-th row of the matrix.) Now, the tuple $(f_1, \ldots, f_r)$, where $f_1, \ldots, f_r \in \mathcal{M}^{(n)}$, belongs to $R^{\mathbf{F}}$ if and only if, for some $f \in \mathcal{M}^{(k)}$ we have $f_i = f_{\pi_i}$.

▶ **Example 18.** Consider some polymorphism minion $\mathcal{M}$ and the ternary structure $\mathbf{LO}_3^3$. We will construct $\mathbf{F} = \mathbf{F}_{\mathcal{M}}(\mathbf{LO}_3^3)$. The domain is $\mathcal{M}^{(3)}$. To construct the relation of $\mathbf{F}$, we first arrange the 15 tuples of $R^{\mathbf{LO}_3^3}$ into a matrix with 3 rows and 15 columns:

$$\begin{pmatrix} 2 & 1 & 1 & 3 & 1 & 1 & 3 & 2 & 3 & 1 & 2 & 1 & 3 & 2 & 2 \\ 1 & 2 & 1 & 1 & 3 & 1 & 2 & 3 & 1 & 3 & 1 & 2 & 2 & 3 & 2 \\ 1 & 1 & 2 & 1 & 1 & 3 & 1 & 1 & 2 & 2 & 3 & 3 & 2 & 2 & 3 \end{pmatrix}.$$

Row i of this matrix can be seen as a function $\pi_i : [15] \to [3]$. Now the relation $R^{\mathbf{F}}$ contains precisely the tuples $(f_{\pi_1}, f_{\pi_2}, f_{\pi_3})$ for all $f \in \mathcal{M}^{(15)}$. Substituting the definition for f_{π_i}, we find that these polymorphisms $f_{\pi_1}, f_{\pi_2}, f_{\pi_3}$ are:

$$(x, y, z) \mapsto f\,(y, x, x, z, x, x, z, y, z, x, y, x, z, y, y)$$
$$(x, y, z) \mapsto f\,(x, y, x, x, z, x, y, z, x, z, x, y, y, z, y)$$
$$(x, y, z) \mapsto f\,(x, x, y, x, x, z, x, x, y, y, z, z, y, y, z)$$

Observe that the matrix and the arguments of f are actually arranged in the same configuration, with 1 replaced by x, 2 by y and 3 by z.

The following theorem connects minion homomorphisms and the free structure.

▶ **Theorem 19** ([5, Lemma 4.4]). *If $\mathcal{M}$ is a minion and $\mathbf{A}, \mathbf{B}$ are r-ary structures, the homomorphisms $h : \mathbf{F}_{\mathcal{M}}(\mathbf{A}) \to \mathbf{B}$ are in a (natural) 1-to-1 correspondence to the minion homomorphisms $\xi : \mathcal{M} \to \mathrm{Pol}(\mathbf{A}, \mathbf{B})$.*[4] *As a consequence, $\mathbf{F}_{\mathcal{M}}(\mathbf{A}) \to \mathbf{B}$ if and only if $\mathcal{M} \to \mathrm{Pol}(\mathbf{A}, \mathbf{B})$.*

5 Hardness results

In this section we will investigate the hardness of $\mathrm{PCSP}(\mathbf{LO}_k^r, \mathbf{LO}_{k+1}^r)$. First, we will establish that $\mathrm{PCSP}(\mathbf{LO}_k^r, \mathbf{LO}_{k+1}^r)$ is NP-hard for $r \geq 5$ and $k \geq 2$. In particular, this proves intractability of $\mathrm{PCSP}(\mathbf{LO}_2^r, \mathbf{LO}_3^r)$ for $r \geq 5$. Second, we will show that $\mathrm{PCSP}(\mathbf{LO}_2^r, \mathbf{LO}_3^r)$ with $r \geq 5$ *cannot* be reduced to $\mathrm{PCSP}(\mathbf{LO}_2^r, \mathbf{LO}_3^r)$ with $r = 3$ and $r = 4$ using primitive-positive constructions (i.e. gadget reductions [5]).

[4] In category-theoretic terms, $\mathbf{F}_{-}(\mathbf{A})$ and $\mathrm{Pol}(\mathbf{A}, -)$ are functors between (in opposite directions) the category of r-ary structures and the category of minions, and $\mathbf{F}_{-}(\mathbf{A}) \dashv \mathrm{Pol}(\mathbf{A}, -)$.

We will use a hardness result of Guruswami and Trevisan [20] (stated as Theorem 20 below) on the *1-in-r exact hitting set*. An instance of this problem is an r-uniform hypergraph, and an admissible solution is a subset of its vertices. We are then asked to maximise the number of edges e for which exactly one vertex of e belongs to the chosen subset. An instance is called *α-satisfiable* if it is possible to find a subset of vertices such that a proportion of α of all the edges satisfy this condition. An instance is called *satisfiable* if it is 1-satisfiable. We will call the problem of distinguishing a satisfiable 1-in-r exact hitting set instance from one that is not even α-satisfiable the *α-gap 1-in-r exact hitting set problem*. Guruswami and Trevisan state a weaker version of the following theorem, but their proofs establish the following.

▶ **Theorem 20** ([20, Theorem 10, Theorem 12, Lemma 13])**.** *For any $\epsilon > 0$, for large enough r, the $(1/(e-\epsilon))$-gap 1-in-r exact hitting set problem is* NP*-hard.*

▶ **Corollary 21.** $\mathrm{PCSP}(\mathbf{LO}_2^r, \mathbf{LO}_3^r)$ *is* NP*-hard for large enough r.*

Proof. Observe that the instances of $(1/2)$-gap 1-in-r exact hitting set and $\mathrm{PCSP}(\mathbf{LO}_2^r, \mathbf{LO}_3^r)$ are both r-uniform hypergraphs. We show that the identity function is a reduction from the first problem to the second. For completeness, note that a satisfiable instance of 1-in-r exact hitting set is also immediately a YES-instance of $\mathrm{PCSP}(\mathbf{LO}_2^r, \mathbf{LO}_3^r)$. For soundness, consider a YES-instance of $\mathrm{PCSP}(\mathbf{LO}_2^r, \mathbf{LO}_3^r)$ i.e. an r-uniform hypergraph with an LO 2-colouring and thus also an LO 3-colouring. Under this colouring each edge either has a unique vertex assigned 3, or a unique vertex assigned 2; thus, at least half of the edges must contain exactly one 2, or at least half of the edges must contain exactly one 3. We deduce that taking either the set of vertices assigned 2, or the set of vertices assigned 3, gives us a solution that satisfies at least half the edges of the hypergraph, viewed as a hitting set instance. ◀

How can we now leverage this basic hardness result to other values of r? We will use chains of minion homomorphisms to do this. We define $\mathcal{M}_r = \mathrm{Pol}(\mathbf{LO}_2^r, \mathbf{LO}_3^r)$. Our main result in this section is the following.

▶ **Theorem 22.** *The relationships between the minions $\mathcal{M}_r = \mathrm{Pol}(\mathbf{LO}_2^r, \mathbf{LO}_3^r)$ for $r \geq 3$ are as shown in Figure 1, i.e., all homomorphisms not drawn or implied do not exist.*

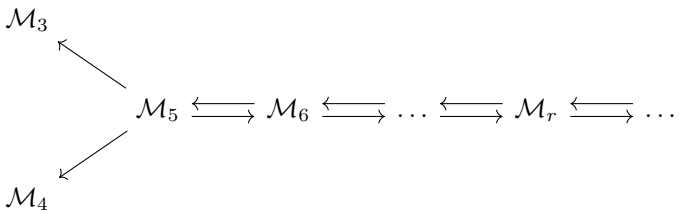

Figure 1 Minion homomorphism order of minions $\mathcal{M}_r$ for $r \geq 3$.

Combining Theorems 17 and 22 gives the following.

▶ **Corollary 23.** $\mathrm{PCSP}(\mathbf{LO}_2^r, \mathbf{LO}_3^r)$ *is* NP*-hard for $r \geq 5$. Moreover, there is no polynomial-time reduction using pp-constructions from $\mathrm{PCSP}(\mathbf{LO}_2^r, \mathbf{LO}_3^r)$ to $\mathrm{PCSP}(\mathbf{LO}_2^3, \mathbf{LO}_3^3)$ and from $\mathrm{PCSP}(\mathbf{LO}_2^r, \mathbf{LO}_3^r)$ to $\mathrm{PCSP}(\mathbf{LO}_2^4, \mathbf{LO}_3^4)$ for $r \geq 5$.*

A simple proof shows the following:

▶ **Theorem 24.** *For every $r \geq 5$ and $\ell > k \geq 2$, $\mathrm{Pol}(\mathbf{LO}_{k+1}^r, \mathbf{LO}_{\ell+1}^r) \to \mathrm{Pol}(\mathbf{LO}_k^r, \mathbf{LO}_\ell^r)$.*

Proof. Consider any p-ary polymorphism $f \in \mathrm{Pol}(\mathbf{LO}^r_{k+1}, \mathbf{LO}^r_{\ell+1})^{(p)}$. Consider the value of f for inputs $a_1, \ldots, a_p \in [k]$; due to the following matrix with $r \geq 3$ rows

$$\begin{pmatrix} a_1+1 & \ldots & a_p+1 \\ a_1 & \ldots & a_p \\ \vdots & \ddots & \vdots \\ a_1 & \ldots & a_p \end{pmatrix},$$

we can deduce that $f(a_1, \ldots, a_p) < f(a_1+1, \ldots, a_p+1) \in [\ell+1]$. This implies that $f(a_1, \ldots, a_p) \in [\ell]$. We claim this implies that f, restricted to $[k]^p$, is a polymorphism of $\mathrm{Pol}(\mathbf{LO}^r_k, \mathbf{LO}^r_\ell)$. Consider matrix of inputs a^j_i where $i \in [p]$, $j \in [r]$, such that each column $a^1_i, \ldots, a^r_i$ is a tuple of $\mathbf{LO}^r_k$. Thus each column is also a tuple of $\mathbf{LO}^r_{k+1}$. Since f is a polymorphism of $\mathrm{PCSP}(\mathbf{LO}^r_{k+1}, \mathbf{LO}^r_{\ell+1})$, we deduce that

$$(f(a^1_1, \ldots, a^1_p), \ldots, f(a^r_1, \ldots, f^r_p))$$

is a tuple of $\mathbf{LO}^r_{\ell+1}$ i.e. has a unique maximum. But we already know these values belong to $[\ell]$. Since they have a unique maximum, they are a tuple of $\mathbf{LO}^r_\ell$. Thus f, restricted to $[k]^p$, is a polymorphism of $\mathrm{Pol}(\mathbf{LO}^r_k, \mathbf{LO}^r_\ell)$.

We now claim that the map $f \mapsto f|_{[k]^p}$ taking a p-ary polymorphism to its restriction on $[k]^p$ is a minion homomorphism $\mathrm{Pol}(\mathbf{LO}^r_{k+1}, \mathbf{LO}^r_{\ell+1}) \to \mathrm{Pol}(\mathbf{LO}^r_k, \mathbf{LO}^r_\ell)$. To see why, consider any polymorphism $f \in \mathrm{Pol}(\mathbf{LO}^r_{k+1}, \mathbf{LO}^r_{\ell+1})^{(p)}$ and a function $\pi : [p] \to [q]$. What we need to prove is that

$$(f_\pi)|_{[k]^p} = (f|_{[k]^p})_\pi.$$

But note that, for $x_1, \ldots, x_p \in [k]$,

$$\begin{aligned}((f_\pi)|_{[k]^p})(x_1, \ldots, x_p) = f_\pi(x_1, \ldots, x_p) &= f(x_{\pi(1)}, \ldots, x_{\pi(p)}) \\ &= (f|_{[k]^p})(x_{\pi(1)}, \ldots, x_{\pi(p)}) = (f|_{[k]^p})_\pi(x_1, \ldots, x_p).\end{aligned}$$

This concludes the proof. ◀

Theorem 24 and Corollary 23 imply the following:

▶ **Corollary 25.** $\mathrm{PCSP}(\mathbf{LO}^r_k, \mathbf{LO}^r_{k+1})$ *is* NP*-hard for* $r \geq 5$ *and* $k \geq 2$.

In order to construct the minion homomorphisms, we first exhibit a simple necessary and sufficient condition for the existence of a minion homomorphism to $\mathrm{Pol}(\mathbf{LO}^r_2, \mathbf{LO}^r_k)$, and a sufficient condition for such a homomorphism to not exist.

▶ **Lemma 26.** *Fix* $r \geq 3$ *and* $k \geq 3$. *Consider any polymorphism minion* $\mathcal{M}$. *For any element* $f \in \mathcal{M}^{(r)}$, *let* $f_1(x, y) = f(y, x, \ldots, x)$, $f_2(x, y) = f(x, y, x, \ldots, x)$, $\ldots$, $f_r(x, y) = f(x, \ldots, x, y)$. *Now,* $\mathcal{M} \to \mathrm{Pol}(\mathbf{LO}^r_2, \mathbf{LO}^r_k)$ *if and only if there exists some* $\omega : \mathcal{M}^{(2)} \to [k]$ *such that, for all* $f \in \mathcal{M}^{(r)}$, *there exists a unique maximum value among* $\omega(f_1), \ldots, \omega(f_r)$.

Proof. We construct $\mathbf{F}_{\mathcal{M}}(\mathbf{LO}^r_2)$. The tuples of the relation of $\mathbf{LO}^r_2$ are all the r-dimensional vectors containing exactly one 2, with the other entries equal to 1. We can arrange these tuples into an r-by-r matrix where the diagonal contains 2 and all the other elements are 1. Replacing 1 with x and 2 with y, and applying f, we get the definitions of $f_1, \ldots, f_r$. Thus the relation of $\mathbf{F}_{\mathcal{M}}(\mathbf{LO}^r_2)$ contains precisely the tuples of form $(f_1, \ldots, f_r)$ for $f \in \mathcal{M}^{(r)}$.

Thus our condition amounts to the existence of a homomorphism $\omega : \mathbf{F}_{\mathcal{M}}(\mathbf{LO}^r_2) \to \mathbf{LO}^r_k$. By Theorem 19, this is equivalent to $\mathcal{M} \to \mathrm{Pol}(\mathbf{LO}^r_2, \mathbf{LO}^r_k)$. ◀

For the next lemma, call a function f *block-symmetric* with respect to a partition of the arguments of f into blocks if f is not changed by arbitrarily permuting the arguments in the blocks. For instance $(x, y, z) \mapsto x + y$ is block-symmetric with respect to the blocks $\{x, y\}$ and $\{z\}$.

▶ **Lemma 27.** *Fix $r \geq 3$ and a polymorphism minion $\mathcal{M}$. If $\mathcal{M}$ has a block-symmetric polymorphism of arity r with respect to a partition in which all blocks consist of at least two elements, then $\mathcal{M} \not\to \mathcal{M}_r$.*

Proof. We use the same notation as in the proof of Lemma 26. Let f be this block-symmetric polymorphism, and note that no polymorphism among $f_1, \ldots, f_r$ appears exactly once, due to block-symmetry. Thus, for any $\omega : \mathcal{M}^{(2)} \to [3]$, the sequence $\omega(f_1), \ldots, \omega(f_r)$ does not have a unique maximum. Applying the previous lemma gives us the required result. ◀

▶ **Theorem 28.** *For any $r \geq 5$, $\mathcal{M}_r \to \mathcal{M}_{r+1}$.*

Proof. We will establish the statement via Lemma 26. We will use the assignment $\omega : \mathcal{M}^{(2)} \to [3]$ given by $\omega(f) = f(1, 2)$. To check that this satisfies our condition, we need to investigate $\mathcal{M}_r^{(r+1)}$. Observe that an $(r + 1)$-ary polymorphism $f \in \mathcal{M}_r^{(r+1)}$ is a function from $[2]^{r+1}$ to $[3]$; if it is applied to the rows of an $r \times (r+1)$ matrix whose columns are tuples of the relation of $\mathbf{LO}_2^r$ (i.e. they contain one 2 and otherwise are 1), then the resulting values contain a unique maximum. Similarly to Barto et. al. [4], we view f as a function from the powerset of $[r + 1]$ to $[3]$. (Thus, the input tuple $(1, 2, 1, 2)$ is seen as equivalent to the input set $\{2, 4\}$.) Under this view, f is a polymorphism if and only if, for any partition $A_1, \ldots, A_r$ of $[r + 1]$, the sequence $f(A_1), \ldots, f(A_r)$ has a unique maximum element. (Observe that each part A_i corresponds to a row in the matrix mentioned earlier). To show that ω satisfies our condition, what we need to prove is that the sequence $f\{1\}, \ldots, f\{r + 1\}$ has a unique maximum. We have three cases depending on the maximum of these values.

Maximum is 3. Suppose that at least one of $f\{1\}, \ldots, f\{r+1\}$ is 3. Without loss of generality, say $f\{1\} = 3$. Suppose for contradiction that another of the values is also 3; without loss of generality, say $f\{2\} = 3$. But consider the partition $\{1\}, \{2\}, \{3, \ldots, r + 1\}, \emptyset, \ldots, \emptyset$ of $[r + 1]$ into r sets. Since f is a polymorphism, the images of these sets must have a unique maximum value. But if $f\{1\} = f\{2\} = 3$ this is impossible! So if $f\{1\} = 3$, then this is the unique maximum of the sequence $f\{1\}, \ldots, f\{r + 1\}$.

Maximum is 2. Now, suppose that all of $f\{1\}, \ldots, f\{r + 1\}$ are either 1 or 2, and that at least one of these (say $f\{1\}$) is 2. Suppose for contradiction that another value (say $f\{2\}$) is also 2. Due to the partitions $\{1\}$, $\{2\}$, $\{3, 4\}$, $\{5\}$, $\ldots$, $\{r + 1\}$; $\{1\}$, $\{2\}$, $\{3\}$, $\{4\}$, $\{5, 6\}$, $\{7\}$, $\ldots$, $\{r + 1\}$ we deduce that $f\{3, 4\} = f\{5, 6\} = 3$. This is impossible because of the partition $\{1, 2, 7, \ldots, r + 1\}, \{3, 4\}, \{5, 6\}, \emptyset, \ldots, \emptyset$. Thus in this case $f\{1\} = 2$ is the unique maximum of the sequence $f\{1\}, \ldots, f\{r + 1\}$.

Maximum is 1. Finally, suppose that $f\{1\} = \ldots = f\{r + 1\} = 1$. Consider the partitions $\{1, 2\}$, $\{3\}$, $\ldots$, $\{r + 1\}$; $\{1\}$, $\{2\}$, $\{3, 4\}$, $\{5\}$, $\ldots$, $\{r + 1\}$; and $\{1\}$, $\ldots$, $\{4\}$, $\{5, 6\}$, $\{7\}$, $\ldots$, $\{r + 1\}$. Since all the singletons have image 1, the two-element sets here must have image 2 or 3. At least two of them must therefore have the same image; if that image is 3, then we have a contradiction like in the last case. Thus suppose, without loss of generality, that $f\{1, 2\} = f\{3, 4\} = 2$. Considering the partition $\{1, 2\}, \{3, 4\}, \{5\}, \ldots, \{r + 1\}, \emptyset$, we find that $f(\emptyset) = 3$. But this cannot happen, due to partition $\emptyset, \ldots, \emptyset, \{1, \ldots, r + 1\}$. Thus this case is impossible.

Our assignment of values to polymorphisms of $\mathcal{M}_r^{(2)}$ is correct. Therefore we deduce that $\mathcal{M}_r \to \mathcal{M}_{r+1}$. ◀

▶ **Theorem 29.** *For any $r \geq 3, k \geq 3$,* $\mathrm{Pol}(\mathbf{LO}_2^{r+2}, \mathbf{LO}_k^{r+2}) \to \mathrm{Pol}(\mathbf{LO}_2^r, \mathbf{LO}_k^r)$. *In particular, for $k = 3$,* $\mathcal{M}_{r+2} \to \mathcal{M}_r$.

Proof. We use the same notation convention as in Theorem 28, and we take $\omega(f) = f(1, 2)$. Thus, we want to prove that, if f is a function that takes subsets of $[r]$ to $[k]$ such that, for any partition $A_1, \ldots, A_{r+2}$, the sequence $f(A_1), \ldots, f(A_{r+2})$ has a unique maximum, then the sequence $f\{1\}, \ldots, f\{r\}$ has a unique maximum. But consider the partition $\{1\}, \ldots, \{r\}, \emptyset, \emptyset$, and note that the largest value cannot be $f(\emptyset)$ (since $f(\emptyset)$ appears twice). Thus we deduce that one of $f\{1\}, \ldots, f\{r\}$ is the maximum, and furthermore that this maximum is strictly larger than all the other values in this sequence. Thus, $\mathcal{M}_{r+2} \to \mathcal{M}$. ◀

Proof of Theorem 22. We have $\mathcal{M}_{r+1} \to \mathcal{M}_{r+2} \to \mathcal{M}_r$, so $\mathcal{M}_{r+1} \to \mathcal{M}_r$ for every $r \geq 5$ by Theorems 28 and 29. Thus, $\mathcal{M}_5 \rightleftarrows \mathcal{M}_6 \rightleftarrows \ldots$; furthermore, by Theorem 29, we have $\mathcal{M}_5 \to \mathcal{M}_3$. Finally, by Theorem 28 and Theorem 29, we have $\mathcal{M}_5 \to \mathcal{M}_6 \to \mathcal{M}_4$.

It remains to show that (i) $\mathcal{M}_3 \not\to \mathcal{M}_r$ for any $r \geq 4$ and that (ii) $\mathcal{M}_4 \not\to \mathcal{M}_r$ for any $r \geq 3$, $r \neq 4$. An auxiliary function will be useful for both: let $f : \mathbb{N} \to \mathbb{N}$ map 0 to 2, 1 to 1, and all other values to 3.

Regarding (i), note that $\mathcal{M}_3$ has a quaternary block-symmetric polymorphism with respect to a partition in which all blocks have size 2, viz. $(a, b, c, d) \mapsto f(a + b)$. Thus, by Lemma 27, $\mathcal{M}_3 \not\to \mathcal{M}_4$. Since $\mathcal{M}_r \to \mathcal{M}_5 \to \mathcal{M}_4$ for $r \geq 4$, we deduce that $\mathcal{M}_3 \not\to \mathcal{M}_r$.

Regarding (ii), note that $\mathcal{M}_4$ has a ternary symmetric polymorphism, viz. $(a, b, c) \mapsto f(a + b + c)$. Thus, by Lemma 27, $\mathcal{M}_4 \not\to \mathcal{M}_3$. Since $\mathcal{M}_r \to \mathcal{M}_5 \to \mathcal{M}_3$ for $r \geq 3, r \neq 4$, we deduce that $\mathcal{M}_4 \not\to \mathcal{M}_r$. ◀

In Theorem 28, using Theorem 17, we showed that hardness of $\mathrm{PCSP}(\mathbf{LO}_2^r, \mathbf{LO}_3^r)$ for some large r implies hardness of $\mathrm{PCSP}(\mathbf{LO}_2^5, \mathbf{LO}_3^5)$. We now show that the same is true for $\mathrm{PCSP}(\mathbf{LO}_2^r, \mathbf{LO}_k^r)$: hardness of $\mathrm{PCSP}(\mathbf{LO}_2^r, \mathbf{LO}_k^r)$ for some large r implies hardness of $\mathrm{PCSP}(\mathbf{LO}_2^{r(k)}, \mathbf{LO}_k^{r(k)})$, for some $r(k)$ that depends only on k.

▶ **Theorem 30.** *For $k \geq 4, r \geq 4k - 3$,* $\mathrm{Pol}(\mathbf{LO}_2^r, \mathbf{LO}_k^r) \to \mathrm{Pol}(\mathbf{LO}_2^{r+1}, \mathbf{LO}_k^{r+1})$.

Note that the lower bound on r in the statement is $4k - 3$, which is worse than the bound for $k = 3$ in Theorem 28. We do not know whether a smaller bound is possible for $k > 3$.

Proof. Fix some k and let $\mathcal{N}_r = \mathrm{Pol}(\mathbf{LO}_2^r, \mathbf{LO}_k^r)$. We show that $\mathcal{N}_r \to \mathcal{N}_{r+1}$ for $r \geq 4k - 3$.

Use the same notation as in Theorem 28, and the same choice of ω; what we want to show is that if $f \in \mathcal{N}_r^{(r+1)}$ then the sequence $f\{1\}, f\{2\}, \ldots, f\{r + 1\}$ has a unique maximum. Recall that f satisfies the property that, if $A_1, \ldots, A_r$ is a partition of $\{1, \ldots, r + 1\}$, then $f(A_1), \ldots, f(A_r)$ has a unique maximum. We now split into three cases, depending on the maximum of $f\{1\}, \ldots, f\{r + 1\}$.

Maximum is k. The maximum must be unique in this case. If we suppose, contrarily and without loss of generality, that $f\{1\} = f\{2\} = k$, then the partition $\{1\}, \{2\}, \{3, \ldots, r + 1\}, \emptyset, \ldots, \emptyset$ yields our contradiction.

Maximum is 1. This case is impossible. Consider the partitions $\{1, 2\}, \{3\}, \ldots, \{r + 1\}$; $\{1\}, \{2\}, \{3, 4\}, \{5\}, \ldots, \{r + 1\}$; $\ldots$; $\{1\}, \ldots, \{4k - 3, 4k - 2\}, \{4k - 1\}, \ldots, \{r + 1\}$. These partitions exist since $4k - 2 \leq r + 1$. All of the two-element sets must be mapped to some values in $\{2, \ldots, k\}$ (they cannot be 1 since then all the parts in the previous partitions map to 1), and there are $2k - 1$ two-element sets. Thus by pidgeonhole principle three sets must be mapped to the same value. Thus suppose $f\{1, 2\} = f\{3, 4\} = f\{5, 6\}$. Considering the partition $\{1, 2\}, \{3, 4\}, \{5, 6\}, \{7\}, \ldots, \{r + 1\}, \emptyset, \emptyset$ we find that none of the images through f can be the unique maximum (since the first three and the last two are equal, and all the rest are 1). Thus we have the required contradiction.

Maximum is neither. Suppose that the maximum is $1 < k' < k$, and suppose that the maximum is not unique. Thus without loss of generality let $f\{1\} = f\{2\} = k'$. Now consider the partitions $\{1\},\{2\},\{3,4\},\{5\},\dots,\{r+1\};\dots;\{1\},\{2\},\dots,\{4k-4\},\{4k-3,4k-2\},\{4k-1\},\dots,\{r+1\}$. The two-element sets must be mapped to a value from $\{k'+1,\dots,k\}$ i.e. to one of at most $k-2$ values, and there are $2k-2$ sets. Thus at least three of these sets are assigned the same value. Suppose without loss of generality that $f\{3,4\} = f\{5,6\} = f\{7,8\}$. Then the partition $\{1\},\{2\},\{3,4\},\{5,6\},\{7,8\},\{9\},\dots,\{r+1\},\emptyset,\emptyset$ gives us a contradiction: the images of the first two sets, the next three sets, and the last two sets form equal blocks; and all other sets have images that are not greater than the images of the first two sets.

Thus, since our choice of ω is valid, by Lemma 26, we find that $\mathcal{N}_r \to \mathcal{N}_{r+1}$. ◀

6 Conclusions

The question about the complexity of $\mathrm{PCSP}(\mathbf{LO}_2^3, \mathbf{LO}_k^3)$ for constant $k \geq 3$ raised in [4] stays open. The complexity of $\mathrm{PCSP}(\mathbf{LO}_k^r, \mathbf{LO}_\ell^r)$ is open except for the hardness obtained in our work. In this paper, we show NP-hardness for $k \geq 2$, $\ell = k+1$, and any $r \geq 5$. In the full version of this paper [25], we show NP-hardness for $2 \leq k \leq \ell$ and any $r \geq \ell - k + 4$.

The minion homomorphisms (and lack thereof) between the polymorphism minions $\mathrm{Pol}(\mathbf{LO}_2^r, \mathbf{LO}_3^r)$ for various values of r have interesting implications for the complexity of PCSPs more broadly. First, if one were to prove that this problem is hard for $r = 3$ or $r = 4$, then our results imply that hardness in linearly ordered colourings does not necessarily follow from minion homomorphisms and thus in particular cannot be obtained via "gadget reductions" [5]. This is in contrast to the case of (non-promise) CSPs, where it is known [7] (cf. also [6])[5] that all NP hardness can be shown using minion homomorphisms.[6] Second, our results show that, if one proves that $\mathrm{PCSP}(\mathbf{LO}_2^r, \mathbf{LO}_\ell^r)$ is hard for some large arity r, then it is hard $\mathrm{PCSP}(\mathbf{LO}_2^{r'}, \mathbf{LO}_\ell^{r'})$ for some arity $r' = r'(\ell)$ that depends only on ℓ.

Going beyond the realm of fixed-template PCSPs [5] (which limits the number of colours by a constant), what is the smallest function $k(n)$ for which $\mathrm{PCSP}(\mathbf{LO}_2^3, \mathbf{LO}_{k(n)}^3)$ is solvable efficiently? There is no clear reason to believe that positive result from the present paper with $k(n) = O(\sqrt{n \log\log n}/\log n)$ is optimal.

Abstract

The stochastic shortest path problem (SSPP) asks to resolve the non-deterministic choices in a Markov decision process (MDP) such that the expected accumulated weight before reaching a target state is maximized. This paper addresses the optimization of the variance-penalized expectation (VPE) of the accumulated weight, which is a variant of the SSPP in which a multiple of the variance of accumulated weights is incurred as a penalty. It is shown that the optimal VPE in MDPs with non-negative weights as well as an optimal deterministic finite-memory scheduler can be computed in exponential space. The threshold problem whether the maximal VPE exceeds a given rational is shown to be EXPTIME-hard and to lie in NEXPTIME. Furthermore, a result of interest in its own right obtained on the way is that a variance-minimal scheduler among all expectation-optimal schedulers can be computed in polynomial time.

1 Introduction

Markov decision processes (MDPs) are a standard operational model comprising randomization and non-determinism and are widely used in verification, articifical intelligence, robotics, and operations research. In each state of an MDP, there is a non-deterministic choice from a set of actions. Each action is equipped with a weight and a probability distribution according to which the successor state is chosen randomly. In the analysis of systems modelled as MDPs, one typically is interested in the worst- or best-case behavior, where worst and best case range over all resolutions of the non-determinism. So, the resulting algorithmic problems on MDPs usually ask to resolve non-deterministic choices by specifying a *scheduler* such that the resulting probabilistic behavior is optimized with respect to an objective function. If the weights are used to model one of various quantitative aspects of a system such as costs, resource consumption, rewards, or utility, a frequently encountered such optimization problem is the *stochastic shortest path problem* (SSPP) [5,8]. It asks to optimize the expected

value of the accumulated weight before reaching a target state. Example applications include the analysis of worst-case expected termination times of probabilistic programs or finding the optimal controls in a motion planning scenario with random external influences.

While a solution to the SSPP provides guarantees on the behavior of a system in all environments or indicates the optimal control to maximize expected rewards, it completely disregards all other aspects of the resulting probability distribution of the accumulated weight besides the expected value. In almost all practical applications, however, the uncertainty coming with the probabilistic behavior cannot be neglected. In traffic control systems or energy grids, for example, large variability in the throughput comes at a high cost due to the risk of traffic jams or the difficulty of storing surplus energy. Also a probabilistic program employed in a complex environment might be of more use with a higher expected termination time in exchange for a lower chance of extreme termination times.

To overcome these shortcomings of the SSPP, various additional optimization problems have been studied in the literature: Optimizing conditional expected accumulated weights under the condition that certain system states are reached allows for a more fine-grained system analysis by making it possible to determine the worst- or best-case expectation in different scenarios [4, 20]. Given a probability p, quantiles on the accumulated weight in MDPs, also called *values-at-risk* in the context of risk analysis, are the best bound B such that the accumulated weight exceeds B with probability at most p in the worst or best case [11, 27]. The *conditional value-at-risk* and the *entropic value-at-risk* are more involved measures that have been studied in this context [1, 14]. They quantify how far the probability mass of the tail of the probability distribution lies above the value-at-risk. The arguably most prominent measure for the deviation of a random variable from its expected value is the *variance*. The computation of the variance of accumulated weights has been studied in Markov chains [28] and in MDPs [16, 17]. The investigations of variance in MDPs in the literature is discussed in more detail in the "Related Work" section below.

Variance-penalized expectation (VPE). In this paper, we investigate a variant of the SSPP in which the costs caused by probabilistic uncertainty are priced in to the objective function: We study the optimization of the *variance-penalized expectation* (VPE), a well-known measure that combines the expected value μ and the variance σ^2 into the single objective function $\mu - \lambda \cdot \sigma^2$ where λ is a parameter that can be varied to aim for different tradeoffs between expectation and variance. In the context of optimization problems on MDPs, the VPE has been studied, e.g., in [7, 9].

Furthermore, the VPE finds use in an area of research primarily concerned with the tradeoffs between expected performance and risks, namely, the theory of financial markets and investment decision-making: In 1952, Harry Markowitz introduced *modern portfolio theory* that evaluates portfolios in terms of expected returns and variance of the returns [18], for which he was later awarded the Nobel Prize in economics. A portfolio lies on the *Markowitz efficient frontier* if the expected return cannot be increased without increasing the variance and, vice versa, the variance cannot be decreased without decreasing the expectation. The final choice of a portfolio on the efficient frontier depends on the investors preferences. In this context, the VPE $\mu - \lambda \cdot \sigma^2$ is a simple, frequently used way to express the preference of an investor using the single parameter λ capturing the risk-aversion of the investor (see, e.g., [10]). In more involved accounts, the investor's preference is described in terms of a utility function mapping returns to utilities. For the commonly used exponential utility function $u(x) = -e^{-\alpha x}$ and normally distributed returns, the objective of an investor trying to maximize expected utility turns out to be equivalent to the maximization of the VPE with parameter $\lambda = \alpha/2$ [2, 23].

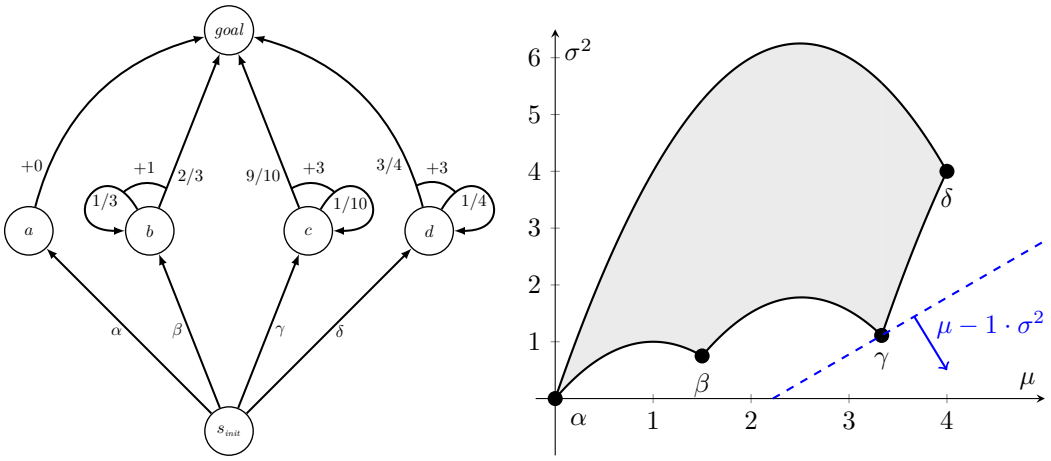

Figure 1 The left hand side shows the MDP $\mathcal{M}$ for Example 1. On the right hand side, all possible combinations of expected accumulated weight and variance for schedulers for $\mathcal{M}$ are depicted. The points corresponding to the four deterministic schedulers are marked by the corresponding action. Furthermore, the blue line indicates all points at which $\mu - 1 \cdot \sigma^2 = 20/9$ and the arrow indicates the direction in which the value of this objective function increases.

For an illustration of the VPE, consider the following example:

▶ **Example 1.** Consider the MDP $\mathcal{M}$ depicted in Figure 1 where non-trivial probability values as well as the weights accumulated are denoted next to the transitions. We want to analyze the possible trade-offs between the variance and the expected value of the accumulated weight that we can achieve in this MDP.

The only non-deterministic choice is in the state s_{init}. Choosing action α leads to *goal* with expected weight and variance 0. For the remaining actions, the accumulated weight follows a geometric distribution where in each step some weight k is accumulated and *goal* is reached with some probability p after the step. For such a distribution, it is well-known that the expected accumulated weight is k/p and the variance is $(k/p)^2 \cdot (1-p)$. Plugging in the respective values for the distributions reached after actions β, γ, and δ, we obtain the pairs of expectations and variances as depicted on the right-hand side of Figure 1. In particular, choosing γ leads to an expectation of $10/3$ and a variance of $10/9$.

Making use of randomization over two different actions τ and σ with probability p and $1-p$, respectively, for some $p \in (0,1)$, we will see in Remark 12 in Section 4 that the expected values and variances under the resulting schedulers lie on a parabolic line segment depicted in black that is uniquely determined by the expected values and variances under τ and σ. By further randomization over multiple actions, combinations of expectation and variance in the gray region in Figure 1 can be realized.

Consider now the VPE with parameter $\lambda = 1$. The dashed blue line in Figure 1 marks all points at which $\mu - 1 \cdot \sigma^2 = 20/9$. The arrow indicates in which direction the value of the VPE increases. So, it turns out that choosing action γ maximizes the VPE in this case; the slightly lower expectation compared to δ is compensated by a significantly lower variance. Geometrically, we can observe that the optimal point for the VPE for any parameter will always lie on the border of the convex hull of the region of feasible points in the μ-σ^2-plane as the VPE is a linear function of expectation and variance. For varying values of λ, also α (for $\lambda \geq 3$) and δ (for $\lambda \leq 1/13$) can constitute the optimal choice in s_{init} for the maximization of the VPE, while β is not optimal for any choice of λ as it lies in the interior of the convex hull of the feasible region. The results of Section 4 will show that in general, the optimal point for the VPE can be achieved by a deterministic finite-memory scheduler. ⌟

Contribution. The main results of this paper are the following:

1. Among all schedulers that optimize the expected accumulated weight before reaching a target, a variance-minimal scheduler can be computed in polynomial time and chosen to be memoryless and deterministic (Section 3).
2. The maximal VPE in MDPs with non-negative weights can be computed in exponential space. The maximum is obtained by a deterministic scheduler that can be computed in exponential space as well (Section 4). As memory, an optimal scheduler only needs to keep track of the accumulated weight up to a bound computable in polynomial time. As soon as the bound is reached, optimal schedulers can switch to the behavior of a variance-minimal scheduler among the expectation-minimal schedulers that can be computed by result 1.
3. The threshold problem whether the maximal VPE is greater or equal to a rational ϑ is in NEXPTIME and EXPTIME-hard (Section 4).

Related work. *Accumulated rewards.* In [16], a characterization of variance-minimal scheulders among the schedulers maximizing the expected accumulated weight in MDPs is given. Here, we provide a simpler proof based on the calculations of [28]; we moreover show how to compute such schedulers in polynomial time. [16] also contains hints for a similar characterization of discounted reward, and developments for mean payoff. Another closely related work is [17] which study the following multi-objective problem for the accumulated weight in finite-horizon MDPs: given η, ν is there a scheduler achieving an expectation of at least η, and a variance of at most ν? This problem is shown to be NP-hard, and exact pseudo-polynomial time algorithm is given for the existence of a scheduler with expectation η and variance $\leq \nu$. Furthermore, pseudo-polynomial approximation algorithms are given for optimizing the expectation under a constraint on the variance, and optimizing the variance under a constraint on the expectation.

Discounted rewards. In [12], the author proves that memoryless *moment-optimal* schedulers exist for the discounted reward, that is, schedulers that maximize the expectation, minimize the variance, maximize the third moment, and so on. Moreover, an algorithm is described to compute such schedulers. In [25], a formula for the variance of the discounted reward is given for memoryless schedulers and for the finite-horizon case, in MDPs and semi-MDPs. Variance-minimal schedulers among those maximizing the expected discounted reward until a target set is reached are studied in [29] for MDPs with varying discount factors. [31] presents a policy iteration algorithm to minimize variance of the discounted weight among schedulers achieving an expectation equal to a given constant.

Mean payoff. For mean payoff objectives, variance was studied in [26] for memoryless strategies, and algorithms were given to compute schedulers that achieve given bounds on the expectation and the variance [6]. The latter paper also considers the minimization of the variability, which is the average of the squared differences between the expected mean-payoff and each observed one-step reward. In [15], the author considers optimizing the expected mean payoff and the average variance. Average variance is defined as the limsup of the variances of the partial sums. They show how to minimize average variance among ϵ-optimal strategies for the expected mean payoff. Policy iteration algorithms were given in [30, 32] to minimize variance or variability of the mean payoff (without constraints on the expectation).

Variance-penalized expectation. The VPE was studied for finite-horizon MDPs with terminal rewards in [7]. In [9], this notion was studied for the expectation and the variability of both mean payoff and discounted rewards. [33] presents a policy iteration algorithm converging against *local* optima for a similar measure.

2 Preliminaries

We give basic definitions and present our notation (for details, see, e.g., [24]). Afterwards, we provide auxiliary results on expected frequencies used in the subsequent sections.

2.1 Notation and definitions

Notations for Markov decision processes. A *Markov decision process* (MDP) is a tuple $\mathcal{M} = (S, Act, P, s_{init}, goal, wgt)$ where S is a finite set of states, Act a finite set of actions, $P\colon S \times Act \times S \to [0,1] \cap \mathbb{Q}$ the transition probability function, $s_{init} \in S$ the initial state, $goal \in S$ a designated target state, and $wgt\colon S \times Act \to \mathbb{Z}$ the weight function. We require that $\sum_{t \in S} P(s,\alpha,t) \in \{0,1\}$ for all $(s,\alpha) \in S \times Act$. We say that action α is enabled in state s iff $\sum_{t \in S} P(s,\alpha,t) = 1$ and denote the set of all actions that are enabled in state s by $Act(s)$. In this paper, for all MDPs, we assume that $goal$ is the only *trap* state in which no actions are enabled, that $goal$ is reachable from all other states s, and that all states are reachable from s_{init}. The paths of $\mathcal{M}$ are finite or infinite sequences $s_0\,\alpha_0\,s_1\,\alpha_1\ldots$ where states and actions alternate such that $P(s_i,\alpha_i,s_{i+1}) > 0$ for all $i \geq 0$. For $\pi = s_0\,\alpha_0\,s_1\,\alpha_1\,\ldots\alpha_{k-1}\,s_k$, $wgt(\pi) = wgt(s_0,\alpha_0) + \ldots + wgt(s_{k-1},\alpha_{k-1})$ denotes the accumulated weight of π, $P(\pi) = P(s_0,\alpha_0,s_1)\cdot\ldots\cdot P(s_{k-1},\alpha_{k-1},s_k)$ its probability, and $last(\pi) = s_k$ its last state. A path is called *maximal* if it is infinite or ends in the trap state $goal$. The *size* of $\mathcal{M}$ is the sum of the number of states plus the total sum of the logarithmic lengths of the non-zero probability values $P(s,\alpha,s')$ as fractions of co-prime integers and the weight values $wgt(s,\alpha)$.

An *end component* of $\mathcal{M}$ is a strongly connected sub-MDP formalized by a subset $S' \subseteq S$ of states and a non-empty subset $\mathfrak{A}(s) \subseteq Act(s)$ for each state $s \in S'$ such that for each $s \in S'$, $t \in S$ and $\alpha \in \mathfrak{A}(s)$ with $P(s,\alpha,t) > 0$, we have $t \in S'$ and such that in the resulting sub-MDP all states are reachable from each other. An end-component is a 0-end-component if it only contains cycles whose accumulated weight is 0 (so-called 0-cycles) so that the accumulated weight is bounded on all (infinite) paths in the end component. We will further use the *mean payoff* measure as tool to classify end-components. For an infinite path ζ, the mean payoff is defined as $\mathbb{MP}(\zeta) = \liminf_{n\to\infty} \frac{1}{n} wgt(pref(\zeta,n))$ where $pref(\zeta,n)$ is the prefix of length n of ζ.

Scheduler. A *scheduler* for $\mathcal{M}$ is a function $\mathfrak{S}$ that assigns to each non-maximal path π a probability distribution over $Act(last(\pi))$. If the choice of a scheduler $\mathfrak{S}$ depends only on the current state, i.e., if $\mathfrak{S}(\pi) = \mathfrak{S}(\pi')$ for all non-maximal paths π and π' with $last(\pi) = last(\pi')$, we say that $\mathfrak{S}$ is *memoryless*. In this case, we also view schedulers as functions mapping states $s \in S$ to probability distributions over $Act(s)$. A scheduler $\mathfrak{S}$ that satisfies $\mathfrak{S}(\pi) = \mathfrak{S}(\pi')$ for all pairs of finite paths π and π' with $last(\pi) = last(\pi')$ and $wgt(\pi) = wgt(\pi')$ is called *weight-based* and can be viewed as a function from state-weight pairs $S \times \mathbb{Z}$ to probability distributions over actions. If there is a finite set X of memory modes and a memory update function $U : S \times Act \times S \times X \to X$ such that the choice of $\mathfrak{S}$ only depends on the current state after a finite path and the memory mode obtained from updating the memory mode according to U in each step, we say that $\mathfrak{S}$ is a finite-memory scheduler. A scheduler $\mathfrak{S}$ is called deterministic if $\mathfrak{S}(\pi)$ is a Dirac distribution for each path π in which case we also view the scheduler as a mapping to actions in $Act(last(\pi))$. Given a scheduler $\mathfrak{S}$, $\zeta = s_0\,\alpha_0\,s_1\,\alpha_1\ldots$ is a $\mathfrak{S}$-path iff ζ is a path and $\mathfrak{S}(s_0\,\alpha_0\ldots\alpha_{k-1}\,s_k)(\alpha_k) > 0$ for all $k \geq 0$. Given a scheduler $\mathfrak{S}$ and a finite $\mathfrak{S}$-path π, we define the residual scheduler $\mathfrak{S}{\uparrow}\pi$ by $\mathfrak{S}{\uparrow}\pi(\rho) = \mathfrak{S}(\pi \circ \rho)$ for each finite path ρ starting in $last(\pi)$.

Probability measure. We write $\Pr^{\mathfrak{S}}_{\mathcal{M},s}$ to denote the probability measure induced by a scheduler $\mathfrak{S}$ and a state s of an MDP $\mathcal{M}$. It is defined on the σ-algebra generated by the cylinder sets $Cyl(\pi)$ of all maximal extensions of a finite path $\pi = s_0\,\alpha_0\,s_1\,\alpha_1\,\ldots\alpha_{k-1}\,s_k$ starting in state s, i.e., $s_0 = s$, by assigning to $Cyl(\pi)$ the probability that π is realized under $\mathfrak{S}$, which is $\mathfrak{S}(s_0)(\alpha_0)\cdot P(s_0,\alpha_0,s_1)\cdot\mathfrak{S}(s_0\alpha_0 s_1)(\alpha_1)\cdot\ldots\cdot\mathfrak{S}(s_0\alpha_0\ldots s_{k-1})(\alpha_{k-1})\cdot P(s_{k-1},\alpha_{k-1},s_k)$. For details, see [24].

For a random variable X that is defined on (some) maximal paths in $\mathcal{M}$, we denote the expected value of X under the probability measure induced by a scheduler $\mathfrak{S}$ and state s by $\mathbb{E}^{\mathfrak{S}}_{\mathcal{M},s}(X)$. We define $\mathbb{E}^{\min}_{\mathcal{M},s}(X) = \inf_{\mathfrak{S}}\mathbb{E}^{\mathfrak{S}}_{\mathcal{M},s}(X)$ and $\mathbb{E}^{\max}_{\mathcal{M},s}(X) = \sup_{\mathfrak{S}}\mathbb{E}^{\mathfrak{S}}_{\mathcal{M},s}(X)$ where $\mathfrak{S}$ ranges over all schedulers for $\mathcal{M}$ under which X is defined almost surely. The variance of X under the probability measure determined by $\mathfrak{S}$ and s in $\mathcal{M}$ is denoted by $\mathbb{V}^{\mathfrak{S}}_{\mathcal{M},s}(X)$ and defined by

$$\mathbb{V}^{\mathfrak{S}}_{\mathcal{M},s}(X) \stackrel{\text{def}}{=} \mathbb{E}^{\mathfrak{S}}_{\mathcal{M},s}((X - \mathbb{E}^{\mathfrak{S}}_{\mathcal{M},s}(X))^2) = \mathbb{E}^{\mathfrak{S}}_{\mathcal{M},s}(X^2) - \mathbb{E}^{\mathfrak{S}}_{\mathcal{M},s}(X)^2.$$

Furthermore, for a measurable set of paths ψ with positive probability, $\mathbb{E}^{\mathfrak{S}}_{\mathcal{M},s}(X|\psi)$ denotes the conditional expectation of X under ψ. If $s = s_{init}$, we sometimes drop the subscript s.

These notations are extended to end-components of a given MDP, which are themselves seen as MDPs. We may, for instance, write $\mathbb{E}^{\min}_{\mathcal{E},s}(X)$ where $\mathcal{E}$ is an end-component of $\mathcal{M}$, and s is a state in $\mathcal{E}$, and the minimization ranges over schedulers of $\mathcal{M}$ that do not leave $\mathcal{E}$.

Accumulated weight. For maximal paths ζ of $\mathcal{M}$, we define the following random variable $\Diamond\!\!\!\!+goal$:

$$\Diamond\!\!\!\!+goal(\zeta) = \begin{cases} wgt(\zeta) & \text{if } \zeta \vDash \Diamond goal, \\ undefined & \text{otherwise.} \end{cases}$$

Recall that we only take schedulers under which a random variable is defined almost surely into account when addressing minimal or maximal expected values. For the expected value of $\Diamond\!\!\!\!+goal$ to be defined, it is necessary that $goal$ is reached almost surely. We call a scheduler $\mathfrak{S}$ with $\Pr^{\mathfrak{S}}_{\mathcal{M}}(\Diamond goal) = 1$ *proper*. So, in the definition of the maximal (or minimal) expected accumulated weight $\mathbb{E}^{\max}_{\mathcal{M}}(\Diamond\!\!\!\!+goal) = \sup_{\mathfrak{S}}\mathbb{E}^{\mathfrak{S}}_{\mathcal{M}}(\Diamond\!\!\!\!+goal)$, $\mathfrak{S}$ ranges over all proper schedulers.

2.2 Auxiliary conclusions from results on expected frequencies

In this section, we present conclusions from well-known results on the expected frequencies of state-weight pairs in MDPs in the formulation in which we use them in the paper. Let $\mathcal{M} = (S, Act, P, s_{init}, goal, wgt)$ be an MDP with weights in $\mathbb{Z}$ and let $\mathfrak{S}$ be a scheduler. For each state-weight pair $(s,w) \in S \times \mathbb{Z}$, we define the *expected frequency* $\vartheta^{\mathfrak{S}}_{s,w}$ under $\mathfrak{S}$ by

$$\vartheta^{\mathfrak{S}}_{s,w} \stackrel{\text{def}}{=} \mathbb{E}^{\mathfrak{S}}_{\mathcal{M}}(\text{number of visits to } s \text{ with accumulated weight } w)$$

where the random variable "number of visits to s with accumulated weight w" counts the number of prefixes π of a maximal paths ζ with $last(\pi) = s$ and $wgt(\pi) = w$. Note also that in MDPs $\mathcal{M}$ in which all end components have negative maximal expected mean-payoff, the expected frequencies of all state-weight pairs are finite under any scheduler.

▶ **Lemma 2.** *Let $\mathcal{M}$ be an MDP and let $\mathfrak{S}$ be a scheduler such that the expected frequency $\vartheta^{\mathfrak{S}}_{s,w}$ are finite for all state-weight pairs $(s,w) \in S \times \mathbb{Z}$. Then, there is a weight-based (randomized) scheduler $\mathfrak{T}$ with $\vartheta^{\mathfrak{S}}_{s,w} = \vartheta^{\mathfrak{T}}_{s,w}$ for all $(s,w) \in S \times \mathbb{Z}$.*

Proof sketch. Analogous to [24, Theorem 5.5.1]: For each state-weight pair (s, w) and each action $\alpha \in Act(s)$, let $\vartheta^{\mathfrak{S}}_{s,w,\alpha}$ be the expected number of times that α is chosen under $\mathfrak{S}$ after finite path ending in state s with weight w. Define the scheduler $\mathfrak{T}$ as a function from $S \times \mathbb{Z} \to \mathrm{Distr}(Act)$ by letting

$$\mathfrak{T}(s,w)(\alpha) \stackrel{\text{def}}{=} \frac{\vartheta^{\mathfrak{S}}_{s,w,\alpha}}{\vartheta^{\mathfrak{S}}_{s,w}}.$$ ◀

▶ **Corollary 3.** *Let $\mathcal{M}$ be an MDP. Let $\mathfrak{S}$ be a scheduler for which $\mathbb{E}^{\mathfrak{S}}_{\mathcal{M}}(\Diamond goal)$ and $\mathbb{V}^{\mathfrak{S}}_{\mathcal{M}}(\Diamond goal)$ are defined and for which the expected frequency $\vartheta^{\mathfrak{S}}_{s,w}$ are finite for all state-weight pairs $(s, w) \in S \times \mathbb{Z}$. Then, there is a weight-based scheduler $\mathfrak{T}$ with*

$$\mathbb{E}^{\mathfrak{S}}_{\mathcal{M}}(\Diamond goal) = \mathbb{E}^{\mathfrak{T}}_{\mathcal{M}}(\Diamond goal) \qquad \text{and} \qquad \mathbb{V}^{\mathfrak{S}}_{\mathcal{M}}(\Diamond goal) = \mathbb{V}^{\mathfrak{T}}_{\mathcal{M}}(\Diamond goal).$$

Proof. The expected value and the variance of $\Diamond goal$ under a scheduler $\mathfrak{S}$ depend only on the expected frequencies $\vartheta^{\mathfrak{S}}_{goal,w}$ with $w \in \mathbb{Z}$. ◀

In this paper, we address questions concerning the possible combinations of expected value and variance of the random variable $\Diamond goal$. Due to this corollary, we can restrict our attention to weight-based schedulers for all investigations in the sequel.

Given two scheduler $\mathfrak{S}$ and $\mathfrak{T}$, our definition of schedulers does not directly allow us to define a new scheduler $\mathfrak{R}$ that behaves according to $\mathfrak{S}$ with probability $p \in (0, 1)$ and according to $\mathfrak{T}$ with probability $1-p$. For each state-weight pair (s, w) the expected frequency under the hypothetical scheduler $\mathfrak{R}$ would be $p \cdot \vartheta^{\mathfrak{S}}_{s,w} + (1-p) \cdot \vartheta^{\mathfrak{T}}_{s,w}$. The following lemma states that a scheduler achieving these frequencies exists:

▶ **Lemma 4.** *Let $\mathcal{M}$ be an MDP as above and let $\mathfrak{S}$ and $\mathfrak{T}$ be schedulers such that the expected frequency $\vartheta^{\mathfrak{S}}_{s,w}$ and $\vartheta^{\mathfrak{T}}_{s,w}$ are finite for all state-weight pairs $(s, w) \in S \times \mathbb{Z}$. Further, let $p \in (0, 1)$. Then, there exists a scheduler $\mathfrak{R}$ such that $\vartheta^{\mathfrak{R}}_{s,w} = p \cdot \vartheta^{\mathfrak{S}}_{s,w} + (1-p) \cdot \vartheta^{\mathfrak{T}}_{s,w}$ for all state-weight pairs (s, w).*

Proof sketch. Let $\vartheta^{\mathfrak{S}}_{s,w,\alpha}$ be defined as in the proof above. We define the weight-based scheduler $\mathfrak{R}$ as follows: For all state-weight pairs (s, w) and all $\alpha \in Act(s)$, let

$$\mathfrak{R}(s,w)(\alpha) = \frac{p \cdot \vartheta^{\mathfrak{S}}_{s,w,\alpha} + (1-p) \cdot \vartheta^{\mathfrak{T}}_{s,w,\alpha}}{p \cdot \vartheta^{\mathfrak{S}}_{s,w} + (1-p) \cdot \vartheta^{\mathfrak{T}}_{s,w}}.$$

The proof of the correctness is analogous to [13, Theorem 9.12]. ◀

This lemma allows us to introduce the following notation:

▶ **Definition 5.** *Given $\mathcal{M}$, $\mathfrak{S}$ and $\mathfrak{T}$ as in the previous lemma, we denote the scheduler $\mathfrak{R}$ whose existence is stated in the lemma by $p \cdot \mathfrak{S} \oplus (1-p) \cdot \mathfrak{T}$.*

3 Minimal variance among expectation-optimal schedulers

Let us call a scheduler *expectation-optimal* if it maximizies the expectation of $\Diamond goal$ from a given state s. In this section, we prove a result that is of interest in its own right and that will play a crucial role in our investigation of the optimization of the VPE in the following section. Namely, we show how to compute a scheduler that minimizes the variance among expectation-optimal schedulers in polynomial time. Note that in MDPs with weights in $\mathbb{Z}$, the mimimization of the expectation of $\Diamond goal$ can be reduced to the maximization by multiplying all weights with -1. This change of weights does not affect the variance and hence all results of this section also apply to expectation-minimal schedulers.

We assume that in a given MDP $\mathcal{M} = (S, Act, P, s_{init}, wgt, goal)$, the maximal achievable expectation of $\Diamond goal$ is finite. This can be checked in polynomial time [3] and, when this value is finite, it is achievable by memoryless deterministic strategies. By [3], all end components E of $\mathcal{M}$ are then either 0-end components or satisfy $\mathbb{E}^{\max}_E(\mathbb{MP}) < 0$.

The algorithm proceeds as follows. First, a transformation is applied so as to ensure that the only end-components in $\mathcal{M}$ are such that the maximal achievable expected mean payoff is negative; while preserving the expectation and the variance of $\Diamond goal$ (Lemma 6). We then prune the MDP so that all actions are optimal for maximizing the expected $\Diamond goal$ (Lemma 7). It follows that all schedulers then achieve the same expected $\Diamond goal$. We then derive an equation system in which the variances at each state are unknowns, while the expectations are known constants (Lemma 8). We conclude by showing that this equation system admits a unique solution and is solvable in polynomial time. Omitted proofs can be found in [22].

▶ **Lemma 6** ([3]). *Let $\mathcal{M} = (S, Act, P, s_{init}, wgt, goal)$ be an MDP with $\mathbb{E}^{\max}_{\mathcal{M}}(\Diamond goal) < \infty$. There is a polynomial transformation which outputs an MDP $\mathcal{M}'$ with the following properties:*

1. *$\mathcal{M}'$ has no 0-end-components,*
2. *there is a mapping f from schedulers of $\mathcal{M}$ to those of $\mathcal{M}'$ such that for all* proper *schedulers $\mathfrak{S}$ for $\mathcal{M}$, $\mathbb{E}^{\mathfrak{S}}_{\mathcal{M}}(\Diamond goal) = \mathbb{E}^{f(\mathfrak{S})}_{\mathcal{M}'}(\Diamond goal)$, and $\mathbb{V}^{\mathfrak{S}}_{\mathcal{M}}(\Diamond goal) = \mathbb{V}^{f(\mathfrak{S})}_{\mathcal{M}'}(\Diamond goal)$.*
3. *there is a mapping g from schedulers of $\mathcal{M}'$ to those of $\mathcal{M}$ such that for all* proper *schedulers $\mathfrak{S}$ for $\mathcal{M}'$, $\mathbb{E}^{g(\mathfrak{S})}_{\mathcal{M}}(\Diamond goal) = \mathbb{E}^{\mathfrak{S}}_{\mathcal{M}'}(\Diamond goal)$, and $\mathbb{V}^{g(\mathfrak{S})}_{\mathcal{M}}(\Diamond goal) = \mathbb{V}^{\mathfrak{S}}_{\mathcal{M}'}(\Diamond goal)$.*

From now on, by the previous lemma, we assume that $\mathcal{M}$ only has end-components E with $\mathbb{E}^{\max}_{\mathcal{M}}(\mathbb{MP}) < 0$. We start by computing $\mathbb{E}^{\max}_{\mathcal{M}}(\Diamond goal)$ with the following equation:

$$\mu_s = \begin{cases} 0 & \text{if } s = goal, \\ \max_{a \in Act(s)} \sum_{s' \in S} P(s,a,s')(wgt(s,a) + \mu_{s'}) & \text{otherwise.} \end{cases} \qquad (*)$$

By [5], $(*)$ has the unique solution $\mu_s = \mathbb{E}^{\max}_{\mathcal{M}}(\Diamond goal)$ and this solution is computable in polynomial time via linear programming. Let us define $Act^{\max}(s)$ as the set of actions from s which satisfy $(*)$ with equality, i.e. $Act^{\max}(s) \stackrel{\text{def}}{=} \{a \in Act(s) \mid \mu_s = wgt(s,a) + \sum_{s' \in S} P(s,a,s')\mu_{s'}\}$, and let $\mathcal{M}'$ be obtained by restricting $\mathcal{M}$ to actions from $Act^{\max}$. By standard arguments (see [22]), we can show the following lemma:

▶ **Lemma 7.** *Let $(\mu_s)_{s \in S}$ be the solution of $(*)$ for an MDP $\mathcal{M}$. Let $\mathcal{M}'$ obtained from $\mathcal{M}$ as above. Then, $\mathcal{M}'$ has no end-components. Moreover, for all $s \in S$, all schedulers $\mathfrak{S}$ of $\mathcal{M}'$ achieve $\mathbb{E}^{\mathfrak{S}}_{\mathcal{M}'}[\Diamond goal] = \mu_s$.*

So, in order to find the variance-minimal scheduler among expectation optimal schedulers for $\mathcal{M}$, it is sufficient to find a variance-minimal scheduler for $\mathcal{M}'$. We derive the following lemma by adapting [28] to MDPs.

▶ **Lemma 8.** *Consider an MDP $\mathcal{M}$, and assume that there is a vector $(\mu_s)_{s \in S}$ of values such that all schedulers $\mathfrak{S}$ satisfy $\forall s \in S, \mathbb{E}^{\mathfrak{S}}_{\mathcal{M},s}(\Diamond goal) = \mu_s$. Then, $(\mathbb{V}^{\inf}_{\mathcal{M},s}(\Diamond goal))_{s \in S}$ is the unique solution of the following equation:*

$$V_s = \begin{cases} 0 & \textit{if } s = goal, \\ \min_{a \in Act(s)} \sum_{t \in S} P(s,a,t)\left((wgt(s,a) + \mu_t - \mu_s)^2 + V_t\right) & \textit{otherwise.} \end{cases} \qquad (**)$$

Note that the equation system $(**)$ is the same as the equation system used to minimize the expected accumulated weight before reaching *goal* under the weight function wgt' that assigns the non-negative weight $(wgt(s,a) + \mu_t - \mu_s)^2$ to the transition (s, α, t). So, this

equation system is solvable in polynomial time [8]. Using that all schedulers in $\mathcal{M}'$ achieve an expected accumulated weight of μ_s when starting in state s, the results of this section can be combined to the following theorem.

▶ **Theorem 9.** *Given an MDP $\mathcal{M}$ such that $\mathbb{E}^{\max}_{\mathcal{M}}[\Diamond goal] < \infty$, a memoryless deterministic, expectation-optimal scheduler $\mathfrak{S}$ such that $\mathbb{V}^{\mathfrak{S}}_{\mathcal{M},s}[\Diamond goal]$ is minimal among all expectation-optimal schedulers for any state s is computable in polynomial time.*

4 Variance-penalized expectation

The goal of this section is to develop an algorithm to compute the optimal *variance-penalized expectation* (VPE). Given a rational $\lambda > 0$, we define the VPE with parameter λ under a scheduler $\mathfrak{S}$ as

$$\mathbb{VPE}[\lambda]^{\mathfrak{S}}_{\mathcal{M}} \stackrel{\text{def}}{=} \mathbb{E}^{\mathfrak{S}}_{\mathcal{M}}(\Diamond goal) - \lambda \cdot \mathbb{V}^{\mathfrak{S}}_{\mathcal{M}}(\Diamond goal) = \mathbb{E}^{\mathfrak{S}}_{\mathcal{M}}(\Diamond goal) - \lambda \cdot \mathbb{E}^{\mathfrak{S}}_{\mathcal{M}}(\Diamond goal^2) + \lambda \cdot (\mathbb{E}^{\mathfrak{S}}_{\mathcal{M}}(\Diamond goal))^2.$$

Task. Compute the maximal variance-penalized expectation

$$\mathbb{VPE}[\lambda]^{\max}_{\mathcal{M}} \stackrel{\text{def}}{=} \sup_{\mathfrak{S}} \mathbb{VPE}[\lambda]^{\mathfrak{S}}_{\mathcal{M}}$$

where the supremum ranges over all proper schedulers. Furthermore, compute an optimal scheduler $\mathfrak{S}$ with $\mathbb{VPE}[\lambda]^{\mathfrak{S}}_{\mathcal{M}} = \mathbb{VPE}[\lambda]^{\max}_{\mathcal{M}}$.

Throughout this section, we will restrict ourselves to MDPs $\mathcal{M} = (S, Act, P, s_{init}, wgt, goal)$ with a weight function $wgt\colon S \times Act \to \mathbb{N}$, i.e., we only consider MDPs with non-negative weights. Key results established in this section do not hold in the general setting with arbitrary weights and further complications arise. In the conclusions we will briefly discuss these complications.

As before, we are only interested in schedulers that reach the goal with probability 1. If the maximal expectation $\mathbb{E}^{\max}_{\mathcal{M}}(\Diamond goal) < \infty$, it is well-known that in this case of non-negative weights, all end components of $\mathcal{M}$ are 0-end components [3,8]. Hence, w.l.o.g., we can assume that $\mathcal{M}$ has no end components throughout this section by Lemma 6. In this case, $\Diamond goal$ is defined on almost all paths under any scheduler. So, in particular the values $\mathbb{E}^{\mathfrak{S}}_{\mathcal{M}}(\Diamond goal)$ and $\mathbb{V}^{\mathfrak{S}}_{\mathcal{M}}(\Diamond goal)$ are defined for all schedulers $\mathfrak{S}$. Furthermore, as we have seen in Corollary 3, it is sufficient to consider weight-based schedulers for the optimization of VPEs. The main result of this section is the following:

▶ **Main result.** Given an MDP $\mathcal{M}$ and λ as above, the optimal value $\mathbb{VPE}[\lambda]^{\max}_{\mathcal{M}}$ and an optimal scheduler $\mathfrak{S}$ can be computed in exponential space. Given a rational ϑ, the threshold problem whether $\mathbb{VPE}[\lambda]^{\max}_{\mathcal{M}} \geq \vartheta$ is in NEXPTIME and EXPTIME-hard.

To obtain the main result, we will first prove that the maximal VPE is obtained by a deterministic scheduler (Section 4.1). This result can then be used for the EXPTIME-hardness proof for the threshold problem (Section 4.2). The key step to obtain the upper bounds of the main result is to show that optimal schedulers have to *minimize* the weight that is expected to still be accumulated after a computable bound of accumulated weight has been exceeded. We call such a bound a *saturation point* (Section 4.3). Finally, we show how to utilize the saturation point result to solve the threshold problem and to compute the optimal VPE (Section 4.4). Proofs omitted in this section can be found in [22].

▶ Remark 10. In the formulation presented here, the goal is to maximize the expected accumulated weight with a penalty for the variance. All results and proofs in this section, however, hold analogously for the variant $\sup_{\mathfrak{S}} -\mathbb{E}^{\mathfrak{S}}_{\mathcal{M}}(\Diamond goal) - \lambda \cdot \mathbb{V}^{\mathfrak{S}}_{\mathcal{M}}(\Diamond goal)$ of the maximal VPE in which the goal is to minimize the expected accumulated weight while receiving a penalty for the variance. In particular, the same saturation point works and optimal schedulers still have to minimize the expected accumulated weight as soon as the accumulated weight exceeds the saturation point. ⌟

4.1 Existence of optimal deterministic schedulers

We begin this section with a lemma describing how the variance of accumulated weight behaves under convex combinations of schedulers. This will allow us to show that the maximal VPE can be approximated by deterministic schedulers with the help of Lemma 14 describing a connection between randomization and convex combinations. This first lemma follows via basic arithmetic form the fact that the expected values of $\Diamond goal$ and $\Diamond goal^2$ depend linearly on the expected frequencies of the state-weight pairs $(goal, w)$ with $w \in \mathbb{N}$.

▶ **Lemma 11.** *Let $\mathcal{M} = (S, Act, P, s_{init}, wgt, goal)$ be an MDP with non-negative weights and no end components. Let $\mathfrak{S}$ and $\mathfrak{T}$ be two schedulers for $\mathcal{M}$. Let $p \in (0,1)$. The scheduler $\mathfrak{R} \stackrel{def}{=} p \cdot \mathfrak{S} \oplus (1-p) \cdot \mathfrak{T}$ satisfies*

$$\mathbb{V}^{\mathfrak{R}}_{\mathcal{M}}(\Diamond goal) = p \cdot \mathbb{V}^{\mathfrak{S}}_{\mathcal{M}}(\Diamond goal) + (1-p) \cdot \mathbb{V}^{\mathfrak{T}}_{\mathcal{M}}(\Diamond goal) + p \cdot (1-p) \cdot (\mathbb{E}^{\mathfrak{S}}_{\mathcal{M}}(\Diamond goal) - \mathbb{E}^{\mathfrak{T}}_{\mathcal{M}}(\Diamond goal))^2.$$

Proof sketch. The claim follows from straight-forward calculations using that the expected values of $\Diamond goal$ and $\Diamond goal^2$ depend linearly on the expected frequencies of the state-weight pairs $(goal, w)$ with $w \in \mathbb{N}$. ◀

▶ Remark 12. Given two schedulers $\mathfrak{S}$ and $\mathfrak{S}'$ under which the expectation and variance are (η, ν) and (η', ν'), respectively, such that $\eta < \eta'$, there is a unique convex combination $\mathfrak{T}$ of the two schedulers with expectation x for all $x \in [\eta, \eta']$. Viewing the variance of these convex combinations as a function $V : [\eta, \eta'] \to \mathbb{R}$, we can observe the following using the previous Lemma 11:

$$V(x) = \nu + \frac{x-\eta}{\eta'-\eta} \cdot (\nu' - \nu) + \frac{x-\eta}{\eta'-\eta} \cdot \frac{\eta'-x}{\eta'-\eta} \cdot (\eta'-\eta)^2 = \nu + \frac{x-\eta}{\eta'-\eta} \cdot (\nu'-\nu) + (x-\eta) \cdot (\eta'-x).$$

The coefficient before x^2 in this quadratic polynomial hence is always -1. ⌟

The following lemma stating the continuity of the VPE will be useful in several ways: If we manipulate schedulers at one state-weight pair at a time, we can reason about the scheduler we obtain in the limit after manipulating the scheduler at all state-weight pairs, e.g., in the proof of Theorem 15 below. Further, it will allow us to prove that there is an optimal scheduler, i.e., that the supremum in the definition of $\mathbb{VPE}[\lambda]^{\max}_{\mathcal{M}}$ is in fact a maximum.

▶ **Lemma 13** (Continuity of VPE). *Let $\mathcal{M}$ and $\lambda > 0$ be as above. The variance-penalized expectation as a function from weight-based schedulers to $\mathbb{R}$ is (uniformly) continuous in the following sense: Given $\varepsilon > 0$, there is a natural number N_ε such that for all weight-based schedulers $\mathfrak{S}$ and $\mathfrak{T}$ that agree on all state-weight pairs (s, w) with $w \leq N_\varepsilon$, we have*

$$\left| \mathbb{VPE}[\lambda]^{\mathfrak{S}}_{\mathcal{M}} - \mathbb{VPE}[\lambda]^{\mathfrak{T}}_{\mathcal{M}} \right| < \varepsilon.$$

Proof sketch. The claim follows from the fact that the probability that a high amount of weight w is accumulated under any scheduler decreases exponentially as w tends to ∞. ◀

For the final ingredient to show that deterministic schedulers approximate the optimal VPE, we take a closer look at the relation of randomization to convex combinations of schedulers. For the following lemma, let $\mathfrak{S}$ be a weight-based scheduler for an MDP $\mathcal{M}$ as before. Assume that there is a state-weight pair $(s, w) \in S \times \mathbb{N}$ reachable under $\mathfrak{S}$ such that $\mathfrak{S}$ chooses two different actions α and β with probabilities q and $1-q$, respectively, for some $q \in (0,1)$. Let $\mathfrak{S}_\alpha$ be the scheduler that agrees with $\mathfrak{S}$ on all state-weight pairs except for (s, w) and that chooses α with probability 1 at (s, w). Define $\mathfrak{S}_\beta$ analogously. The technical proof of the following lemma can be found in [22].

▶ **Lemma 14.** *Let $\mathcal{M}$, $\mathfrak{S}$, $\mathfrak{S}_\alpha$, $\mathfrak{S}_\beta$, and q be as above. There is a value $p \in (0,1)$ such that the expected frequencies of all state-weight pairs are the same under $\mathfrak{S}$ and $p \cdot \mathfrak{S}_\alpha \oplus (1-p) \cdot \mathfrak{S}_\beta$.*

▶ **Theorem 15** (Deterministic schedulers approximate optimal VPE)**.** *Let $\mathcal{M}$ be an MDP with non-negative weights and without end components and let $\lambda > 0$. For each scheduler $\mathfrak{S}$, there is a deterministic weight-based scheduler $\mathfrak{T}$ with*

$$\mathbb{VPE}[\lambda]^{\mathfrak{T}}_{\mathcal{M}} \geq \mathbb{VPE}[\lambda]^{\mathfrak{S}}_{\mathcal{M}}.$$

Proof sketch. W.l.o.g., we can assume that $\mathfrak{S}$ is weight-based by Corollary 3. At a single state-weight pair (s, w) at which $\mathfrak{S}$ makes use of randomization between, we can (potentially repeatedly) apply Lemma 14 and Lemma 11 to find a scheduler $\mathfrak{S}'$ that does not make use of this randomization but satisfies $\mathbb{VPE}[\lambda]^{\mathfrak{S}'}_{\mathcal{M}} \geq \mathbb{VPE}[\lambda]^{\mathfrak{S}}_{\mathcal{M}}$. Going through all state-weight pairs in this fashion, we can construct an infinite sequence of schedulers with non-decreasing VPE in which randomization is successively removed at all state-weight pairs. In the limit, we obtain a well defined deterministic weight-based scheduler $\mathfrak{T}$. Lemma 13 allows us to conclude that $\mathbb{VPE}[\lambda]^{\mathfrak{T}}_{\mathcal{M}} \geq \mathbb{VPE}[\lambda]^{\mathfrak{S}}_{\mathcal{M}}$. ◀

In the definition of the maximal variance-penalized expectation $\mathbb{VPE}[\lambda]^{\max}_{\mathcal{M}} = \sup_{\mathfrak{S}} \mathbb{VPE}[\lambda]^{\mathfrak{S}}_{\mathcal{M}}$, it is sufficient to let the supremum range over deterministic weight-based schedulers $\mathfrak{S}$ in the light of this theorem. For the proof of the existence of optimal schedulers, we make use of an analytic argument: Continuous functions on compact space obtain their maximum. The continuity shown in Lemma 13 applied to the space of deterministic weight-based schedulers can be reformulated as continuity with respect to a metric on this space. Namely, we define the metric $d_{\mathcal{M}}$ on the set of deterministic weight-based schedulers as follows: Given two deterministic weight-based schedulers $\mathfrak{S}$ and $\mathfrak{T}$ for $\mathcal{M}$, first let

$$m(\mathfrak{S}, \mathfrak{T}) \stackrel{\text{def}}{=} \min\{w \mid \text{there is a state } s \in S \text{ with } \mathfrak{S}(s, w) \neq \mathfrak{T}(s, w)\}.$$

We then define $d_{\mathcal{M}}(\mathfrak{S}, \mathfrak{T}) \stackrel{\text{def}}{=} 2^{-m(\mathfrak{S}, \mathfrak{T})}$. This metric indeed turns the set of deterministic weight-based schedulers into a compact space as shown in [20]:

▶ **Lemma 16** (Compactness of the space of deterministic weight-based schedulers [20])**.** *Let $\mathcal{M}$ be as above. The space of all deterministic weight-based schedulers with the topology induced by the metric $d_{\mathcal{M}}$ is compact.*

▶ **Theorem 17** (Existence of an optimal deterministic weight-based scheduler)**.** *Let $\mathcal{M}$ and $\lambda > 0$ be as above. There is a deterministic weight-based scheduler $\mathfrak{S}$ with*

$$\mathbb{VPE}[\lambda]^{\mathfrak{S}}_{\mathcal{M}} = \mathbb{VPE}[\lambda]^{\max}_{\mathcal{M}}.$$

Proof. The claim follows from Lemma 13, Theorem 15, and Lemma 16, as continuous functions on compact spaces obtain their maximum. ◀

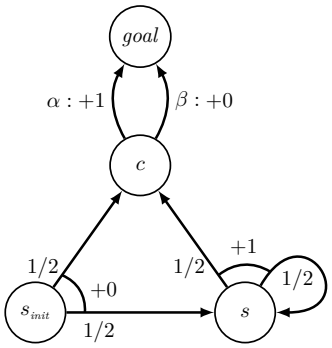

Figure 2 The MDP $\mathcal{M}$ used in Example 19.

4.2 Hardness of the threshold problem

The result that the maximal variance-penalized expectation can be achieved by a deterministic scheduler can be used for the following hardness result:

▶ **Theorem 18.** *Given an MDP $\mathcal{M}$ with non-negative weights and two rationals $\lambda, \vartheta > 0$, deciding whether $\mathbb{VPE}[\lambda]^{\max}_{\mathcal{M}} \geq \vartheta$ is EXPTIME-hard. Furthermore, for acyclic MDPs $\mathcal{M}$, the problem is PSPACE-hard.*

Proof sketch. We reduce from the following problem which is shown to be EXPTIME-hard in general and PSPACE-hard for acyclic MDPs in [11]: Given an MDP $\mathcal{M}$ and a natural number $T > 0$ such that *goal* is reached in $\mathcal{M}$ almost surely under all schedulers, decide whether there is a scheduler $\mathfrak{S}$ such that $\Pr^{\mathfrak{S}}_{\mathcal{M}}(\Diamond goal = T) = 1$.

The idea is to construct an MDP $\mathcal{M}'$ that reaches *goal* with weight T with probability $1/2$ directly and otherwise behaves like $\mathcal{M}$. By choosing λ sufficiently large, we can show that $\mathbb{VPE}[\lambda]^{\max}_{\mathcal{M}'} \geq T$ is only possible if and only if there is a scheduler with $\mathbb{V}^{\mathfrak{S}}_{\mathcal{M}}(\Diamond goal) = 0$. This scheduler then has to reach *goal* with weight T on all paths. The necessary technical calculations can be found in [22]. ◀

4.3 Saturation Point

In the sequel, we will provide a series of results that allow us to further restrict the class of deterministic schedulers that we have to consider when maximizing the variance-penalized expectation. In the end, we obtain a finite set of deterministic finite-memory schedulers among which there is a scheduler achieving the optimal variance-penalized expectation. In particular, this means that the optimum is computable.

The key step is the insight that we can provide a natural number K computable in polynomial time such that an optimal scheduler $\mathfrak{S}$ for the variance-penalized expectation has to minimize the expected accumulated weight before reaching *goal* once a weight of at least K has already been accumulated on a run. Furthermore, the behavior of $\mathfrak{S}$ after a weight of at least K has been accumulated must minimize the variance of the weight that will still be accumulated among all expectation-minimal schedulers. We call this value K a *saturation point*.

▶ **Example 19.** The MDP $\mathcal{M}$ in Figure 2 aims to provide some intuition on the results of this section. The state c in this MDP is reached with accumulated weight n with probability $(1/2)^{n+1}$ for all $n \in \mathbb{N}$. Then, the choice has to be made whether to collect weight $+1$ or

0 before moving to *goal*. We want to take a closer look at a family of special weight-based deterministic finite-memory schedulers for $\mathcal{M}$: Let $\mathfrak{S}_k$ be the scheduler that chooses action α in c if the accumulated weight is less than k and otherwise chooses action β.

For these schedulers, we can explicitly provide expectation and variance: The probability that the scheduler $\mathfrak{S}_k$ chooses α in c is $1-(1/2)^k$. As the expected accumulated weight before reaching c is 1, we obtain a total expected accumulated weight of

$$\mathbb{E}^{\mathfrak{S}_k}_{\mathcal{M}}(\Diamond goal) = 2 - \frac{1}{2^k}.$$

To obtain the variance, we compute $\mathbb{E}^{\mathfrak{S}_k}_{\mathcal{M}}(\Diamond goal^2)$:

$$\mathbb{E}^{\mathfrak{S}_k}_{\mathcal{M}}(\Diamond goal^2) = \sum_{n=0}^{k-1} \frac{1}{2^{k+1}} \cdot (n+1)^2 + \sum_{n=k}^{\infty} \frac{1}{2^{k+1}} \cdot n^2$$
$$= \sum_{n=0}^{\infty} \frac{1}{2^{k+1}} \cdot (n+1)^2 - \sum_{n=k}^{\infty} \frac{1}{2^{k+1}} \cdot (2n+1) = 6 - \frac{2k+3}{2^k}.$$

We can then easily compute the variance

$$\mathbb{V}^{\mathfrak{S}_k}_{\mathcal{M}}(\Diamond goal) = \mathbb{E}^{\mathfrak{S}_k}_{\mathcal{M}}(\Diamond goal^2) - (\mathbb{E}^{\mathfrak{S}_k}_{\mathcal{M}}(\Diamond goal))^2 = 2 + \frac{1-2k}{2^k} - \frac{1}{4^k}.$$

For $\lambda = 1$, we obtain the following VPE:

$$\mathbb{VPE}[\lambda]^{\mathfrak{S}_k}_{\mathcal{M}} = \frac{k-1}{2^{k-1}} + \frac{1}{4^k}.$$

Comparing scheduler $\mathfrak{S}_k$ to $\mathfrak{S}_{k+1}$, we obtain: $\mathbb{VPE}[\lambda]^{\mathfrak{S}_{k+1}}_{\mathcal{M}} - \mathbb{VPE}[\lambda]^{\mathfrak{S}_k}_{\mathcal{M}} = 2 - k/2^k - 3/4^k$. This difference is negative for $k \geq 2$ and positive for $k = 1$. We conclude that among the schedulers $\mathfrak{S}_k$, the scheduler $\mathfrak{S}_2$ is VPE-optimal. Interestingly, this means choosing not to accumulate the additional weight $+1$ by choosing α is better already for small amounts of accumulated weight. Intuitively, the reason is that choosing α for an accumulated weight ≥ 2 has a larger effect on the variance than on the expectation. Increasing the expectation in particular also increases the squared deviation of the path that reach *goal* with weight 1 which has probability $1/2$ under $\mathfrak{S}_k$ for $k \geq 2$. The saturation point result of this section will tell us that an optimal scheduler always has to minimize the weight that is expected to still be accumulated once sufficiently much weight has already been accumulated. ⌟

Let $\mathcal{M} = (S, Act, P, s_{init}, wgt, goal)$ be an MDP without end components and with non-negative weights as above and let $\lambda > 0$ be a rational. Before we define K and show that it can be computed in polynomial time, we need some additional notation.

For each state $s \in S$, define $e_s \stackrel{\text{def}}{=} \mathbb{E}^{\min}_{\mathcal{M},s}(\Diamond goal)$. For each state $s \in S \setminus \{goal\}$, we define the subset $Act^{\min}(s) \subseteq Act(s)$ of actions allowing to minimize the expectation analogously to $Act^{\max}$ before: $Act^{\min}(s) \stackrel{\text{def}}{=} \{\alpha \in Act(s) \mid e_s = wgt(s,\alpha) + \sum_{t \in S} P(s,\alpha,t) \cdot e_t\}$. Choosing an action not belonging to $Act^{\min}(s)$ in state s ensures that the expected accumulated weight before reaching *goal* is higher than the minimal possible value. Further, we can define the minimal amount by which choosing a non-minimizing action increases the expectation:

$$\delta \stackrel{\text{def}}{=} \min\{(wgt(s,\alpha) + \sum_{t \in S} P(s,\alpha,t) \cdot e_t) - e_s \mid s \in S \setminus \{goal\} \text{ and } \alpha \in Act(s) \setminus Act^{\min}(s)\}.$$

If the set on the right hand side is empty, all schedulers minimize the expected accumulated weight before reaching *goal* and the claims of this section hold trivially. So, we can assume that this set is non-empty. By the definition of $Act^{\min}$, we observe that $\delta > 0$.

Next, we can compute an upper bound U_1 for $\mathbb{E}^{\max}_{\mathcal{M},s}(\diamondsuit goal)$ for all states s by computing the maximal value $U_1 \stackrel{\text{def}}{=} \max_{s\in S} \mathbb{E}^{\max}_{\mathcal{M},s}(\diamondsuit goal)$.

Finally, let ε be the minimal transition probability present in $\mathcal{M}$. As $\mathcal{M}$ has no end components, the only trap state *goal* is reached within $n \stackrel{\text{def}}{=} |S|$ steps under each scheduler with probability at least ε^n. Let W be the largest weight in $\mathcal{M}$. Within n steps at most a weight of $n \cdot W$ is accumulated. We use these observations for the following two values:

- First, we can provide a value $B_{1/2}$ such that the probability that a weight above $B_{1/2}$ is accumulated under any scheduler is at most $1/2$: For this, let $b_{1/2}$ be such that $((1-\varepsilon^n))^{b_{1/2}} \leq 1/2$. This is the case if and only if $b_{1/2}$ is at least

$$\frac{\log(1/2)}{\log(1-\varepsilon^n)} = -\frac{1}{\log(1-\varepsilon^n)} < \frac{1}{\varepsilon^n}.$$

  So, we can choose $b_{1/2}$ to be $\frac{1}{\varepsilon^n}$. Then, with probability at most $1/2$, a path has length at least $n \cdot b_{1/2}$. This allows us to defined $B_{1/2} \stackrel{\text{def}}{=} b_{1/2} \cdot n \cdot W$.
- Second, we compute an upper bound U_2 for $\max_{s\in S} \mathbb{E}^{\max}_{\mathcal{M},s}(\diamondsuit goal^2)$: With probability ε^n a path has weight at most $n \cdot W$; with probability $(1-\varepsilon^n)\cdot\varepsilon^n$ it has weight at most $2 \cdot n \cdot W$; with probability $(1-\varepsilon^n)^2 \cdot \varepsilon^n$ it has weight at most $3 \cdot n \cdot W$; and so on. So, we get that $\max_{s\in S} \mathbb{E}^{\max}_{\mathcal{M},s}(\diamondsuit goal^2) \leq \sum_{i=0}^{\infty}(1-\varepsilon^n)^i \cdot \varepsilon^n \cdot ((i+1)\cdot n \cdot W)^2$. This allows us to define

$$U_2 \stackrel{\text{def}}{=} \frac{2\cdot n^2 \cdot W^2}{\varepsilon^{2n}} \geq \frac{(2-\varepsilon^n)\cdot n^2 \cdot W^2}{\varepsilon^{2n}} = \sum_{i=0}^{\infty}(1-\varepsilon^n)^i \cdot \varepsilon^n \cdot ((i+1)\cdot n \cdot W)^2.$$

We are now in the position to define the saturation point K: Let K be the least natural number with

$$K \geq B_{1/2} = \frac{n\cdot W}{\varepsilon^n} \qquad \text{and} \qquad K \geq \frac{U_1/\lambda + U_2 + 2U_1 + U_1^2/2}{\delta} + 1.$$

The definition of K is arguably a bit cumbersome, but the choices will become clear in the proof of Theorem 20. All values involved except for δ and U_1 can be computed directly from n, W, and ε in polynomial time. The values δ and U_1 require to maximize or minimize the expected value of $\diamondsuit goal$ from all states, i.e., to solve an SSPP which can be done in polynomial time by linear programming [5, 8].

▶ **Theorem 20** (Saturation point). *Let $\mathcal{M}$, $\lambda > 0$ and K be as above. Let $\mathfrak{S}$ be a scheduler with $\mathbb{VPE}[\lambda]^{\mathfrak{S}}_{\mathcal{M}} = \mathbb{VPE}[\lambda]^{\max}_{\mathcal{M}}$. Then, for each finite $\mathfrak{S}$-path π with $wgt(\pi) \geq K$, the residual scheduler $\mathfrak{S}{\uparrow}\pi$ satisfies*

$$\mathbb{E}^{\mathfrak{S}\uparrow\pi}_{\mathcal{M},last(\pi)}(\diamondsuit goal) = \mathbb{E}^{\min}_{\mathcal{M},last(\pi)}(\diamondsuit goal).$$

Proof sketch. Let $\mathfrak{S}$ be a scheduler with $\mathbb{VPE}[\lambda]^{\mathfrak{S}}_{\mathcal{M}} = \mathbb{VPE}[\lambda]^{\max}_{\mathcal{M}}$. Suppose there is a $\mathfrak{S}$-path π' with $wgt(\pi') \geq K$ such that $\mathbb{E}^{\mathfrak{S}\uparrow\pi'}_{\mathcal{M},last(\pi')}(\diamondsuit goal) > \mathbb{E}^{\min}_{\mathcal{M},last(\pi')}(\diamondsuit goal)$. Then, there must be an $\mathfrak{S}$-path π that extends π' such that $\mathfrak{S}$ chooses an action $\alpha \notin Act^{\min}(last(\pi))$ with positive probability.

The residual scheduler $\mathfrak{T}$ of $\mathfrak{S}$ after π in case $\mathfrak{S}$ chooses α then satisfies $\mathbb{E}^{\mathfrak{T}}_{\mathcal{M},last(\pi)}(\diamondsuit goal) \geq \mathbb{E}^{\min}_{\mathcal{M},last(\pi)}(\diamondsuit goal) + \delta$. We let $\mathfrak{S}'$ be a scheduler that behaves like $\mathfrak{S}$ unless $\mathfrak{S}$ chooses α after π. In this case, $\mathfrak{S}'$ minimizes the expected value of $\diamondsuit goal$ from then on. We consider the difference $\mathbb{VPE}[\lambda]^{\mathfrak{S}'}_{\mathcal{M}} - \mathbb{VPE}[\lambda]^{\mathfrak{S}}_{\mathcal{M}}$. Using the bounds U_1 and U_2 and that the probability of π is at most $1/2$ as $K \geq B_{1/2}$, we obtain a lower bound for this difference that consists of an expression in terms of U_1, U_2, and λ plus the term

$$\lambda \cdot wgt(\pi) \cdot (\mathbb{E}^{\mathfrak{T}}_{\mathcal{M},last(\pi)}(\diamondsuit goal) - \mathbb{E}^{\min}_{\mathcal{M},last(\pi)}(\diamondsuit goal)).$$

Observing that this term is greater or equal to $\lambda \cdot K \cdot \delta$, the definition of K was chosen exactly so that we can conclude that $\mathbb{VPE}[\lambda]^{\mathfrak{S}'}_{\mathcal{M}} - \mathbb{VPE}[\lambda]^{\mathfrak{S}}_{\mathcal{M}} > 0$. So, $\mathfrak{S}$ was not VPE-maximal yielding a contradiction. ◀

By the results of Section 3, there is a memoryless deterministic scheduler $\mathfrak{V}$ that minimizes the variance among all schedulers minimizing the expected accumulated weight before reaching *goal*. More precisely, for all states s, the scheduler $\mathfrak{V}$ satisfies $\mathbb{E}^{\mathfrak{V}}_{\mathcal{M},s}(\Diamond goal) = \mathbb{E}^{\min}_{\mathcal{M},s}(\Diamond goal)$ and $\mathbb{V}^{\mathfrak{V}}_{\mathcal{M},s}(\Diamond goal) = \inf_{\mathfrak{M}} \mathbb{V}^{\mathfrak{M}}_{\mathcal{M},s}(\Diamond goal)$ where the infimum ranges over all schedulers $\mathfrak{M}$ with $\mathbb{E}^{\mathfrak{M}}_{\mathcal{M},s}(\Diamond goal) = \mathbb{E}^{\min}_{\mathcal{M},s}(\Diamond goal)$. We use the existence of this scheduler in the following theorem.

▶ **Theorem 21.** *Let $\mathcal{M}$, $\lambda > 0$, K, and $\mathfrak{V}$ be as above. Let $\mathfrak{S}$ be a deterministic scheduler with $\mathbb{VPE}[\lambda]^{\mathfrak{S}}_{\mathcal{M}} = \mathbb{VPE}[\lambda]^{\max}_{\mathcal{M}}$. Let $\mathfrak{T}$ be the scheduler that agrees with $\mathfrak{S}$ on all paths π with weight less than K and that chooses actions according to the memoryless deterministic scheduler $\mathfrak{V}$ after paths π' with $wgt(\pi') \geq K$. This scheduler $\mathfrak{T}$ satisfies $\mathbb{VPE}[\lambda]^{\mathfrak{T}}_{\mathcal{M}} = \mathbb{VPE}[\lambda]^{\max}_{\mathcal{M}}$, too.*

Proof sketch. Given a scheduler $\mathfrak{S}$ with $\mathbb{VPE}[\lambda]^{\mathfrak{S}}_{\mathcal{M}} = \mathbb{VPE}[\lambda]^{\max}_{\mathcal{M}}$, and a path π with $wgt(\pi) \geq K$, we compare the scheduler $\mathfrak{S}$ to the scheduler $\mathfrak{S}'$ that behaves like $\mathfrak{S}$, but switches to the behavior of $\mathfrak{V}$ after π. We obtain that $\mathbb{VPE}[\lambda]^{\mathfrak{S}'}_{\mathcal{M}} \geq \mathbb{VPE}[\lambda]^{\mathfrak{S}}_{\mathcal{M}}$ is equivalent to $\mathbb{E}^{\mathfrak{V}}_{\mathcal{M}}(\Diamond goal^2) \leq \mathbb{E}^{\mathfrak{S}\upharpoonright\pi}_{\mathcal{M}}(\Diamond goal^2)$. This holds because $\mathbb{V}^{\mathfrak{V}}_{\mathcal{M}}(\Diamond goal) \leq \mathbb{V}^{\mathfrak{S}\upharpoonright\pi}_{\mathcal{M}}(\Diamond goal)$ as $\mathfrak{V}$ and $\mathfrak{S}\upharpoonright\pi$ achieve the same expectation. Using a continuity argument as before, we show that changing the behavior of $\mathfrak{S}$ to $\mathfrak{V}$ after all paths with weight at least K does not decrease the VPE. ◀

Put together, we have shown that the maximal VPE is obtained by a weight-based deterministic scheduler that switches to the memoryless behavior of $\mathfrak{V}$ as soon as a weight of at least K has been accumulated, which also means that it uses only finite memory.

4.4 Computation of the optimal VPE

Given an MDP $\mathcal{M} = (S, Act, P, s_{init}, wgt, goal)$ with non-negative weights and without end components and $\lambda > 0$ as before, let K be the saturation point given above. Note that K is computable in polynomial time and that hence its numerical value is at most exponential in the size of $\mathcal{M}$. We construct the following MDP $\mathcal{M}'$ that encodes the weights that are accumulated until the saturation point is exceeded into the state space: Let W be the maximal weight occurring in $\mathcal{M}$. The set of states is $S' = S \times \{0, 1, \ldots, K + W - 1\}$. The set of actions remains unchanged. The new probability transition function is given by $P'((s,w),(t,w + wgt(s,\alpha))) \stackrel{\text{def}}{=} P(s,\alpha,t)$ for all $s,t \in S$, all $w < K$, and all $\alpha \in Act(s)$. All remaining transition probabilities are 0. Note that this means that all states of the form $(goal, w)$ with $w \in \{0, 1, \ldots, K + W - 1\}$ and of the form (s, w) with $s \in S$ and $w \in \{K, K + 1, \ldots, K + W - 1\}$ are trap states in $\mathcal{M}'$. The initial state is $s'_{init} \stackrel{\text{def}}{=} (s_{init}, 0)$. The weight function is not relevant in $\mathcal{M}'$.

Let $\mathfrak{V}$ be the memoryless deterministic scheduler for $\mathcal{M}$ as in Theorem 21 that specifies the optimal behavior in order to maximize the variance-penalized expectation as soon as a weight of at least K has been accumulated. Let us call the set of weight-based deterministic schedulers for $\mathcal{M}$ that behave like $\mathfrak{V}$ after a weight of at least K has been accumulated by $\mathrm{WD}_K(\mathcal{M})$. Clearly, there is a natural one-to-one-correspondence between memoryless deterministic schedulers for $\mathcal{M}'$ and schedulers in $\mathrm{WD}_K(\mathcal{M})$.

By the results of Section 3, for each state $s \in S$, we can compute the values

$$e_s \stackrel{\text{def}}{=} \mathbb{E}^{\mathfrak{V}}_{\mathcal{M},s}(\Diamond goal) \qquad \text{and} \qquad q_s \stackrel{\text{def}}{=} \mathbb{E}^{\mathfrak{V}}_{\mathcal{M},s}(\Diamond goal^2) = \mathbb{V}^{\mathfrak{V}}_{\mathcal{M},s}(\Diamond goal) + e_s^2$$

in polynomial time. The following lemma now allows us to express the VPE in $\mathcal{M}$ in terms of reachability probabilities in $\mathcal{M}'$.

▶ **Lemma 22.** *Let $\mathcal{M}$, $\mathcal{M}'$, K and λ be as above. Given a scheduler $\mathfrak{S} \in \mathrm{WD}_K(\mathcal{M})$ also viewed as a memoryless deterministic scheduler for $\mathcal{M}'$, let*

$$\mu \stackrel{def}{=} \sum_{w<K} \Pr^{\mathfrak{S}}_{\mathcal{M}'}(\Diamond(goal, w)) \cdot w + \sum_{s\in S, w\geq K} \Pr^{\mathfrak{S}}_{\mathcal{M}'}(\Diamond(s,w)) \cdot (w + e_s). \tag{†}$$

Then,

$$\mathbb{VPE}[\lambda]^{\mathfrak{S}}_{\mathcal{M}} = \mu - \lambda \cdot \Big(\sum_{w<K} \Pr^{\mathfrak{S}}_{\mathcal{M}'}(\Diamond(goal, w)) \cdot (w-\mu)^2) + \sum_{s\in S, w\geq K} \Pr^{\mathfrak{S}}_{\mathcal{M}'}(\Diamond(s,w)) \cdot ((w-\mu)^2 + 2(w-\mu)e_s + q_s)) \Big). \tag{‡}$$

Proof. It is clear that $\mu = \mathbb{E}^{\mathfrak{S}}_{\mathcal{M}}(\Diamond goal)$. So, we have to show that

$$\begin{aligned} &\mathbb{V}^{\mathfrak{S}}_{\mathcal{M}}(\Diamond goal) = \mathbb{E}^{\mathfrak{S}}_{\mathcal{M}}((\Diamond goal - \mu)^2) \\ =& \sum_{w<K} \Pr^{\mathfrak{S}}_{\mathcal{M}'}(\Diamond(goal, w)) \cdot (w-\mu)^2) \\ &+ \sum_{s\in S, w\geq K} \Pr^{\mathfrak{S}}_{\mathcal{M}'}(\Diamond(s,w)) \cdot ((w-\mu)^2 + 2(w-\mu)e_s + q_s)). \end{aligned} \tag{∘}$$

The event $\Diamond(s,w)$ that (s,w) is reached in $\mathcal{M}'$ corresponds to the event that a path in $\mathcal{M}$ has a prefix of weight w ending in s. We denote this event in $\mathcal{M}$ also by $\Diamond(s,w)$. If $\Pr^{\mathfrak{S}}_{\mathcal{M}'}(\Diamond(s,w)) > 0$ for $w \geq K$, then

$$\begin{aligned} &\mathbb{E}^{\mathfrak{S}}_{\mathcal{M}}((\Diamond goal - \mu)^2 | \Diamond(s,w)) \\ =&\mathbb{E}^{\mathfrak{V}}_{\mathcal{M},s}((\Diamond goal + w - \mu)^2) \\ =&(w-\mu)^2 + 2(w-\mu)\cdot \mathbb{E}^{\mathfrak{V}}_{\mathcal{M},s}(\Diamond goal) + \mathbb{E}^{\mathfrak{V}}_{\mathcal{M},s}(\Diamond goal^2). \end{aligned}$$

So, the sums in equation (∘) sum up the conditional expectation of $(\Diamond goal - \mu)^2$ in $\mathcal{M}$ under the conditions that $(goal, w)$ is reached for $w < K$ or that the state s is the first one reached when the accumulated weight exceeds K with weight $w \geq K$, multiplied by the respective probabilities of the conditions. ◀

Putting everything together, we arrive at the main result.

▶ **Theorem 23.** *Let $\mathcal{M}$ and λ be as above. Given a rational ϑ, the threshold problem whether $\mathbb{VPE}[\lambda]^{\max}_{\mathcal{M}} \geq \vartheta$ is in NEXPTIME. The optimal value $\mathbb{VPE}[\lambda]^{\max}_{\mathcal{M}}$ and an optimal scheduler can be computed in exponential space.*

Proof. The threshold problem can be decided in non-deterministic exponential time as follows: Given $\mathcal{M}$ and λ, compute K in polynomial time and construct $\mathcal{M}'$ as above (of exponential size) in exponential time. Guess a memoryless deterministic scheduler $\mathfrak{S}$ for $\mathcal{M}'$ also viewed as a scheduler in $\mathrm{WD}_K(\mathcal{M})$. The reachability probabilities for all trap states in $\mathcal{M}'$ under $\mathfrak{S}$ can then be computed in time polynomial in the size of $\mathcal{M}'$. With the help of equations (†) and (‡) from Lemma 22, $\mathbb{VPE}[\lambda]^{\mathfrak{S}}_{\mathcal{M}}$ can be computed from these reachability probabilities in time polynomial in the size of $\mathcal{M}'$. If $\mathbb{VPE}[\lambda]^{\mathfrak{S}}_{\mathcal{M}} \geq \vartheta$, accept. By Theorem 21, $\mathbb{VPE}[\lambda]^{\max}_{\mathcal{M}} \geq \vartheta$ iff there is a scheduler $\mathfrak{S}$ in $\mathrm{WD}_K(\mathcal{M})$ with $\mathbb{VPE}[\lambda]^{\mathfrak{S}}_{\mathcal{M}} \geq \vartheta$. Due to the one-to-one correspondence between schedulers in $\mathrm{WD}_K(\mathcal{M})$ and memoryless deterministic schedulers for $\mathcal{M}'$, this establishes the correctness of the algorithm.

To compute the optimal value $\mathbb{VPE}[\lambda]^{\max}_{\mathcal{M}}$, we compute $\mathbb{VPE}[\lambda]^{\mathfrak{S}}_{\mathcal{M}}$ for all schedulers $\mathfrak{S}$ in $\mathrm{WD}_K(\mathcal{M})$ in the same fashion and always store the highest value found so far. As the memoryless schedulers for $\mathcal{M}'$ have an exponentially large representation, this can be done in exponential space and the optimal scheduler can be returned as well. ◀

5 Conclusion

In our results, there remains a complexity gap between the EXPTIME-lower bounds and the exponential-space and NEXPTIME-upper bounds for the optimization of the VPE in MDPs with non-negative weights and the corresponding threshold problem, respectively. Here, we want to shed some light on this complexity gap: It is well-known that the possible vectors of expected frequencies of all states in an MDP can be characterized by a linear equation system (see, e.g., [13]). Using this linear equation system for the exponentially large MDP constructed in Section 4.4 and equations (†) and (‡) from that section, the threshold problem for the maximal VPE can be reformulated as the satisfiability problem of an exponentially sized system of quadratic inequalities. The optimization problem can likewise be formulated as an exponentially large *quadratically constrained quadratic program* (QCQP). This satisfiability problem and QCQPs are NP-hard in general. The question whether the inequality system of exponential size we obtain here has a special structure which allows it to be solved in exponential time remains open here.

This observation stands in contrast to conceptually similar saturation point results straight-forwardly leading to exponential time algorithms (see, e.g., [21]). For example, the threshold problem for conditional expectations: "Given a set $T \subseteq S$, is there a scheduler $\mathfrak{S}$ with $\mathbb{E}^{\mathfrak{S}}_{\mathcal{M}}(\Diamond goal \mid \Diamond T) \geq \vartheta$?" admits a saturation point result in MDPs with non-negative weights as well [4]. Deriving a system of inequalities as above, however, leads to a system of linear inequalities after straight-forward transformations. Hence, this approach directly leads to an exponential time algorithm for the threshold problem for conditional expectations. For the VPE, the system of inequalities seems to be inherently of a polynomial nature which can be seen as an indication that the situation here is fundamentally more difficult.

Further, we restricted our attention to MDPs with non-negative weights. When allowing positive and negative weights, the key result, the existence of a saturation point, does not hold anymore. For conditional expectations and other problems relying on the existence of a saturation point, the switch to integer weights makes the problems even at least as hard as the Positivity problem for linear recurrence sequences, a number theoretic problem whose decidability has been open for many decades (see [19, 21]). The question whether such a hardness result for the threshold problem of the VPE, rendering decidability impossible without a breakthrough in number theory, can be established remains as future work.

Further possible directions of research include the investigation of the following multi-objective threshold problem: Given η and ν, is there a scheduler with expectation at least η and variance at most ν? As the variance treats good and bad outcomes symmetrically, replacing the variance in the VPE by a one-sided deviation measure, such as the lower semi-variance that only takes the outcomes worse than the expected value into account, constitutes another natural extension of this work.

Functions and References in the Pi-Calculus: Full Abstraction and Proof Techniques

Enguerrand Prebet
Université de Lyon, ENS de Lyon, UCB Lyon 1, CNRS, INRIA, LIP

Abstract

We present a fully abstract encoding of $\lambda^{\mathtt{ref}}$, the call-by-value λ-calculus with references, in the π-calculus. By contrast with previous full abstraction results for sequential languages in the π-calculus, the characterisation of contextual equivalence in the source language uses a labelled bisimilarity. To define the latter equivalence, we refine existing notions of typed bisimulation in the π-calculus, and introduce in particular a specific component to handle divergences.

We obtain a proof technique that allows us to prove equivalences between $\lambda^{\mathtt{ref}}$ programs via the encoding. The resulting proofs correspond closely to normal form bisimulations in the λ-calculus, making proofs in the π-calculus expressible as if reasoning in $\lambda^{\mathtt{ref}}$.

We study how standard and new up-to techniques can be used to reason about diverging terms and simplify proofs of equivalence using the bisimulation we introduce. This shows how the π-calculus theory can be used to prove interesting equivalences between $\lambda^{\mathtt{ref}}$ programs, using algebraic reasoning and up-to techniques.

1 Introduction

Milner [11] described the first encodings from the λ-calculus to the π-calculus for both call-by-name and call-by-value. These encodings are shown to be sound with respect to contextual equivalence, enabling the use of the π-calculus as a model to prove equivalence between λ-terms. In sequential languages like the λ-calculus or extensions thereof, contextual equivalence is often considered as the canonical equivalence. The π-calculus offers a rich theory of behavioural equivalences and preorders to reason coinductively and algebraically about processes. In the π-calculus, several powerful up-to techniques can be used and combined in a modular way to make bisimulation proofs shorter and more readable [10, 16]. Labelled bisimulations can also be refined by means of type systems.

Nevertheless, for sequential languages, while such equivalences in the π-calculus lead to sound encodings with respect to contextual equivalence, completeness does not hold, due to the parallel nature of the π-calculus. Full abstraction is obtained for stronger equivalences in the source language, generally based on trees: Lévy-Longo Trees for the call-by-name λ-calculus [18], and η-eager normal form bisimilarity for call-by-value [3]. More generally, we are not aware of full abstraction results relating a contextual equivalence in a sequential

language and a labelled bisimilarity between process terms in the encoding. Existing results either use a finer relation than contextual equivalence in the source language, or obtain full abstraction for a contextually-defined equivalence in the π-calculus [1, 21].

In this work, we study $\lambda^{\mathtt{ref}}$, the call-by-value λ-calculus with references. Our first main contribution is to characterise contextual equivalence in $\lambda^{\mathtt{ref}}$ using a labelled bisimilarity in the π-calculus. The encoding of functions is extended with references as described in [4]. To define our labelled bisimulation, we rely on *well-bracketed bisimulation* [5], wb-bisimulation for short. Wb-bisimulations enforce a well-bracketing discipline between function calls and returns, and is formalised by a type system. Using a type system limits the interactions a process can have with its environment, and thus makes the corresponding bisimulation coarser than an untyped one.

This study allows us to understand the expressiveness of wb-bisimulation and to improve it. As mentioned in [2], to capture contextual equivalence in $\lambda^{\mathtt{ref}}$, *deferred divergent terms* need to be taken into account. Intuitively such terms hide a divergence behind stuck terms, like e.g. in $(\lambda y.\,\Omega)(xV)$, where Ω is an always diverging term and V is a value: the stuck term xV prevents the β-reduction yielding Ω to be applied. Still, this term is contextually equivalent to Ω. We define an equivalent notion for typeable π-terms, called π-divergence, which is used to refine wb-bisimulation yielding a notion of *bisimulation with divergence* in the π-calculus.

Another main contribution of this work is to define this new bisimulation with divergence and to study how up-to techniques, existing and new, can be used to simplify bisimulation proofs for this new equivalence. As π-divergence is defined coinductively, up-to techniques can also be defined to enhance the proofs of divergence. We also introduce a new up-to technique, to which we return below; this technique is *compatible*, meaning that it fits in the existing theory of up-to techniques for the π-calculus.

We do not prove full abstraction with respect to contextual equivalence in $\lambda^{\mathtt{ref}}$ directly, but rather exploit its characterisation using *normal form bisimilarity* [2]. Normal form bisimulations in [2], which we call nfb in the sequel, and bisimulations with divergence in the π-calculus are strongly connected, and we can establish the following result:

> If $\mathcal{R}$ is a nfb, then the encoding of $\mathcal{R}$ is a bisimulation with divergence up to expansion in the π-calculus. (1)

This property allows us to prove that bisimilarity with divergence is complete w.r.t. nfb. Thanks to (1), when proving equivalences of $\lambda^{\mathtt{ref}}$-terms, the π-calculus machinery running under the hood is almost invisible: the bisimulations we manipulate are mainly built using (the encoding of) $\lambda^{\mathtt{ref}}$-terms. This makes π-calculus a powerful environment to prove equivalences between $\lambda^{\mathtt{ref}}$ programs. We illustrate this power via several examples throughout the paper. In some cases, we are able to compare $\lambda^{\mathtt{ref}}$ programs using equivalences which are finer, and simpler to use, than bisimulation with divergence.

We now give more details about the encoding from $\lambda^{\mathtt{ref}}$ to the π-calculus. Milner's original encoding of the untyped call-by-value λ-calculus does not handle equivalences between terms with free variables well. This issue is amended in [3] by moving to the internal π-calculus [19], where only fresh names can be transmitted. For instance, the resulting encodings of $(\lambda z.\,z)(xV)$ and xV are equivalent, which is not the case for Milner's original encoding.

Our results are based on the optimised version of the encoding of [3], where administrative reductions introduced in the encoding of the application are removed. In the optimised encoding, a stuck term like xV is translated into a process that cannot reduce. Additionally,

the translation of an evaluation context always yields an evaluation context, which is not the case in the encoding of [3]. These two properties lead to a tight statement of operational correspondence: the encoding of a $\lambda^{\mathtt{ref}}$-term can perform an internal communication only if the source term has a reduction.

When considering non-internal transitions, the picture becomes more complicated because residual processes appear. We write $[\![M]\!]_p$ for the encoding of M at p – as usual, the π-calculus encoding of a term is parametric over some name p. To illustrate operational correspondence for non-internal transitions, we have for instance $[\![E[xV]]\!]_p \xrightarrow{\overline{x}(y,q)} \gtrsim [\![V]\!]_y \mid q(z).\,[\![E[z]]\!]_p$, where E is an evaluation context and $\gtrsim$ stands for the expansion preorder. The encoding of the stuck term $E[xV]$ sends two links at x, one to its argument V (via y) and one to its continuation E (via q). Both processes are then accessible by the context, and can be executed (possibly in parallel). Intuitively, the value and continuation belong to some environment. This is close to what happens in a nfb, whereby terms are related in the presence of an environment, containing both values and contexts. Thus, it is natural to encode a nfb as a binary relation on π-calculus processes.

To prevent the context from performing unwanted transitions (like parallel calls), we use the type system for well-bracketing from [5]. Typing constraints give rise to *type-allowed* transitions. With this restriction, we obtain a typed version of operational correspondence which is in one-to-one correspondence with the clauses defining nfb. In particular, in the transition of $[\![E[xV]]\!]_p$ above, the resulting process is the encoding of the corresponding state in the nfb. Soundness and completeness of the encoding, as well as property (1), are obtained as consequences of such operational correspondence.

We explain briefly the new up-to technique we introduce. Intuitively, transitions in $\lambda^{\mathtt{ref}}$ may generate several copies of the same value, which are stored in the environment. In [2], the environment is a set, and thus duplicates are removed for free. In the standard π-calculus, these copies would be the same replicated process, and duplicates could be removed using the standard law $!P \mid !P \sim !P$. In the internal π-calculus, each copy is accessible via a distinct name. However, when these copies are only accessible by the context, it is sound to remove duplicates. The new up-to technique we introduce, called *up-to body*, formalises this idea. Together with standard up-to techniques for the pi-calculus, we use the up-to body technique to prove several examples of equivalences between $\lambda^{\mathtt{ref}}$ programs.

Paper outline

We start by presenting the necessary background: we describe $\lambda^{\mathtt{ref}}$ and normal form bisimulations from [2] in Section 2; in Section 3, we introduce the Asynchronous Internal π-calculus, AIπ, and the type system for well-bracketing. We continue with the contributions of this work, describing the encoding for $\lambda^{\mathtt{ref}}$ terms in Section 4. We also show an operational correspondence and examples that can be proved with untyped equivalences, using algebraic reasoning and standard algebraic laws. The extension of the encoding to bisimulation states, together with the definition of bisimulation with divergence, are given in Section 5, where we establish full abstraction. We present up-to techniques for wb-bisimulation in Section 6, and show how they can be used on some examples.

2 Normal Form Bisimulation for a λ-Calculus with References

We define the syntax of the λ-calculus with references, noted $\lambda^{\mathtt{ref}}$:

Terms:	$M, N ::= V \mid M\ N \mid \ell := M; N \mid\ !\ell \mid \mathtt{new}\ \ell := V\ \mathtt{in}\ M$
Values:	$V, W ::= x \mid \lambda x.\, M$
Evaluation contexts:	$E, F ::= [\cdot] \mid E\ M \mid V\ E \mid \ell := E; M$

Free variables for terms and contexts are defined as usual with $\lambda x.\, M$ as binder. We write $M\{^V/_x\}$ for the usual capture-avoiding substitution of x by V in M. And we let $\int$ range over simultaneous substitutions $\{^{V_1}/_{x_1}\} \dots \{^{V_n}/_{x_n}\}$ where $x_1, \dots, x_n$ are pairwise different variables.

Free references for terms and contexts, noted $\mathrm{fr}(M)$ and $\mathrm{fr}(E)$, are defined similarly, with $\texttt{new}\ \ell \coloneqq V\ \texttt{in}\ M$ binding ℓ in M. Notice that ℓ is not a value, meaning that in $\texttt{new}\ \ell \coloneqq V\ \texttt{in}\ M$, ℓ is local to the term M. To give access to a local reference, M may pass functions $\lambda x.\, !\ell$ and $\lambda x.\, \ell \coloneqq x$ instead of ℓ.

A store, noted $h, g, \dots$, is a partial fonction with finite domain from references to values. We write $\emptyset$ for the empty store and $\mathrm{dom}(h)$ for the set of references on which h is defined. For any ℓ, V, we write $h \uplus \ell = V$ for the store h extended with a reference ℓ containing V and $h[\ell \coloneqq V]$ for the store h with the content of ℓ updated to the value V.

The semantics are defined on *configurations* $\langle h \mid M \rangle$ where h is a store.

We assume that for all configurations $\langle h \mid M \rangle$, we have $\mathrm{fr}(M) \subseteq \mathrm{dom}(h)$ and for all $\ell \in \mathrm{dom}(h)$, $\mathrm{fr}(h(\ell)) \subseteq \mathrm{dom}(h)$. This assumption ensures that any free reference used in terms is defined in h.

Reductions between configurations are defined as follows:

$$\langle h \mid (\lambda x.\, M)V \rangle \to \langle h \mid M\{^V/_x\} \rangle \qquad (\beta)$$

$$\langle h \mid !\ell \rangle \to \langle h \mid h(\ell) \rangle \qquad \text{(Read)}$$

$$\langle h \mid \ell \coloneqq v; M \rangle \to \langle h[\ell \coloneqq v] \mid M \rangle \qquad \text{(Write)}$$

$$\langle h \mid \texttt{new}\ \ell \coloneqq v\ \texttt{in}\ M \rangle \to \langle h \uplus \ell = v \mid M \rangle \qquad \text{(Alloc)}$$

$$\langle h \mid E[M] \rangle \to \langle g \mid E[N] \rangle \qquad \text{if } \langle h \mid M \rangle \to \langle g \mid N \rangle \qquad \text{(Eval)}$$

A term M in a configuration $\langle h \mid M \rangle$ which cannot reduce is called a normal form. It can either be a value, or a stuck term of the form $E[yV]$.

▶ **Lemma 1.** *For any $\langle h \mid M \rangle$ we have:*
1. *either $\langle h \mid M \rangle \to \langle h' \mid M' \rangle$ for some $\langle h' \mid M' \rangle$*
2. *or M is a value*
3. *or M is of the form $E[yV]$.*

We write $\Rightarrow$ for $\to^*$ and we say that $\langle h \mid M \rangle$ and $\langle g \mid N \rangle$ *co-terminate* when $\langle h \mid M \rangle \Rightarrow \langle h' \mid M' \rangle$ with M' being a normal form iff $\langle g \mid N \rangle \Rightarrow \langle g' \mid N' \rangle$ with N' being a normal form. A term (resp. context) is *closed* (resp. *reference-closed*) if its set of free variables (resp. free references) is empty. A substitution $\int$ is *closing terms* $M, N, \dots$ if $M\int, N\int, \dots$ are closed.

▶ **Definition 2.** *Two reference-closed terms are contextually equivalent, written $M \asymp N$, if for all closing substitutions $\int$ and reference-closed contexts E, $\langle \emptyset \mid E[M\int] \rangle$ and $\langle \emptyset \mid E[N\int] \rangle$ co-terminate.*

To define normal form bisimulations, we need to introduce the notion of *triples*, used in [2].

We use a tilde, like in $\widetilde{V_i}$, to denote a (possibly empty) tuple. Triples are of the form $(\widetilde{V_i}, \sigma, c)$ and $(\widetilde{V_i}, \sigma, h)$ where: $\widetilde{V_i}$ is a tuple of values, σ is a stack of evaluation contexts, c is a configuration and h is a store. These are the elements being compared in a normal form bisimulation. We provide some comments about the role of triples.

The tuple $\widetilde{V_i}$ stores the values accumulated by the environment, and we write $(\widetilde{V_i}, V)$ for the tuple $\widetilde{V_i}$ extended with the additional value V. A stack of evaluation contexts σ corresponds to interrupted contexts that must be executed to complete the computation. ⊙

stands for the empty stack and $E :: \sigma$ for the stack obtained by adding E on top of σ. The store is accessible by all the other objects of the triple, values or contexts – in $(\widetilde{V_i}, \sigma, c)$, the store is part of c.

Intuitively, a triple of the form $(\widetilde{V_i}, \sigma, c)$ is active, meaning it is computing up until a normal form term is obtained, at which point the computation proceeds to triples of the form $(\widetilde{V_i}, \sigma, h)$ where the environment is carrying on the computation, deciding to call one of the accumulated functions or to resume the computation by evaluating the context at the top of the stack.

For instance, in the triple $(\widetilde{V_i}, \sigma, \langle h \mid E[yV]\rangle)$, the environment is about to get access to V and the function corresponding to y will run before eventually (in absence of divergence) returning the result that will be used by E. Thus, the "next" triple is $((\widetilde{V_i}, V), E :: \sigma, h)$: value V and context E are added to the corresponding tuple and stack, and h is kept identical while the environment is deciding for the next move. This evolution can be seen in Definitions 4 and 5.

Following [8], we first need to introduce an auxiliary relation which performs an immediate beta reduction in a term of the form VW whenever possible.

▶ **Definition 3** (Relation $\succ$). *We write $VW \succ N$ when $V = \lambda y.\, N'$ and $N = N'\{^W/_y\}$ or when $V = z$ and $N = VW$.*

We say that a term is deferred diverging if it hides a diverging behaviour behind a stuck term, e.g $(\lambda x.\, \Omega)(yV)$. This notion can be extended to triples to capture all diverging behaviours, including deferred ones, as defined below. Intuitively, a triple is diverging if it contains a diverging, possibly deferred, context or configuration.

Formally, the set of diverging triples is defined coinductively using a diverging set.

▶ **Definition 4** (Diverging set). *A set S of triples is* diverging *if the two following conditions hold:*

1. $(\widetilde{V_i}, \sigma, c) \in S$ *implies*
   - **a.** *if $c \to c'$, then $(\widetilde{V_i}, \sigma, c') \in S$*
   - **b.** *if $c = \langle h \mid V\rangle$, then $\sigma \neq \emptyset$ and $((\widetilde{V_i}, V), \sigma, h) \in S$*
   - **c.** *if $c = \langle h \mid E[yV]\rangle$, then $((\widetilde{V_i}, V), E :: \sigma, h) \in S$*
2. $(\widetilde{V_i}, \sigma, h) \in S$ *implies*
   - **a.** *for every j and fresh x, $(\widetilde{V_i}, \sigma, \langle h \mid M\rangle) \in S$ with $V_j x \succ M$*
   - **b.** *if $\sigma = E :: \sigma'$, then $(\widetilde{V_i}, \sigma', \langle h \mid E[x]\rangle) \in S$ for x fresh*

We note λ_{div} the largest diverging set.

We say that a relation $\mathcal{R}$ is a *triples relation* if the two elements of any pair of triples in $\mathcal{R}$ both contain a tuple of values and stack of the same size, and either both contain a configuration or both contain a store.

We can now define the normal form bisimulation:

▶ **Definition 5** (nfb). *A* symmetric *triples relation $\mathcal{R}$ is a normal form bisimulation when there exists a diverging set S such that:*

1. $(\widetilde{V_i}, \sigma_1, c)\ \mathcal{R}\ (\widetilde{W_i}, \sigma_2, d)$ *implies*
   - **a.** *if $c \to c'$, then $d \Rightarrow d'$ and $(\widetilde{V_i}, \sigma_1, c')\ \mathcal{R}\ (\widetilde{W_i}, \sigma_2, d')$*
   - **b.** *if $c = \langle h \mid V\rangle$, then either*
     - **i.** *$d \Rightarrow \langle g \mid W\rangle$ and $((\widetilde{V_i}, V), \sigma_1, h)\ \mathcal{R}\ ((\widetilde{W_i}, W), \sigma_2, g)$, or*
     - **ii.** *$\sigma_1 \neq \emptyset$ and $((\widetilde{V_i}, V), \sigma_1, h) \in S$*
   - **c.** *if $c = \langle h \mid E[yV]\rangle$, then either*
     - **i.** *$d \Rightarrow \langle g \mid F[yW]\rangle$ and $((\widetilde{V_i}, V), E :: \sigma_1, h)\ \mathcal{R}\ ((\widetilde{W_i}, W), F :: \sigma_2, g)$, or*
     - **ii.** *$((\widetilde{V_i}, V), E :: \sigma_1, h) \in S$*

2. $(\widetilde{V_i}, \sigma_1, h)\ \mathcal{R}\ (\widetilde{W_i}, \sigma_2, g)$ *implies*
   a. *for every* j *and fresh* x, $(\widetilde{V_i}, \sigma_1, \langle h \mid M\rangle)\ \mathcal{R}\ (\widetilde{W_i}, \sigma_2, \langle g \mid N\rangle)$ *with* $V_j x \succ M$ *and* $W_j x \succ N$
   b. *if* $\sigma_1{=}E :: \sigma_1'$ *and* $\sigma_2{=}F :: \sigma_2'$, *then* $(\widetilde{V_i}, \sigma_1', \langle h \mid E[x]\rangle)\ \mathcal{R}\ (\widetilde{W_i}, \sigma_2', \langle g \mid F[x]\rangle)$ *for* x *fresh*

Normal form bisimilarity, $\approx_\lambda$, *is the largest normal form bisimulation.*

Definition 5 reformulates the bisimulation from [2]. This gives the same equivalence while being more suitable to establish the operational correspondence of the encoding (Theorem 17). We can thus rely on the following result.

▶ **Theorem 6** (Full abstraction [2, Theorems 3,4]). *For all* $\lambda^{\mathtt{ref}}$*-terms* M, N, *we have* $(\emptyset, \odot, \langle \emptyset \mid M\rangle) \approx_\lambda (\emptyset, \odot, \langle \emptyset \mid N\rangle)$ *iff* $M \asymp N$.

This means that to prove that two reference-closed terms are contextually equivalent, we can provide a normal form bisimulation $\mathcal{R}$ relating the two terms and its corresponding diverging set S.

3 AIπ, the Asynchronous Internal π-Calculus

We present the Asynchronous Internal π-calculus, AIπ, and the type system for well-bracketing from [5]. The syntax is given by the following grammar:

Processes	$P, Q ::= \mathbf{0} \mid \overline{a}(\widetilde{b})\ P \mid a(\widetilde{b}).\, P \mid !a(\widetilde{b}).\, P \mid P \mid Q \mid (\boldsymbol{\nu} a)P \mid K\lfloor\widetilde{a}\rfloor$
Recursive definitions	$K \triangleq (\widetilde{a})\ P$

As for $\lambda^{\mathtt{ref}}$ values, $\widetilde{b}$ denotes a tuple of names. We also write $a(\_).\, P$ for $a(z).\, P$ when $z \notin \mathrm{fn}(P)$. Here, $\overline{a}(\widetilde{b})\ P$ is a bound asynchronous output, introduced in [1]. This corresponds to $(\boldsymbol{\nu}\widetilde{b})(\overline{a}\langle\widetilde{b}\rangle.\, \mathbf{0} \mid P)$ in the standard π-calculus, that is, a non-blocking output which carries bound names used in P. Constants are defined as an abstraction $(K \triangleq (\widetilde{a})\ P)$, where $\widetilde{a}$ are distinct names, bound in P. Given an abstraction $(\widetilde{a})\ P$, we note $((\widetilde{a})\ P)\lfloor\widetilde{b}\rfloor$ the process $P\{\widetilde{b}/\widetilde{a}\}$. Thus $K\lfloor\widetilde{a}\rfloor$ represents the process in the definition of K substituted with the names $\widetilde{a}$ (as expressed by the rule Cst in the operational semantics).

The full set of rules defining the Labelled Transition System (LTS) is given in Figure 1. Symmetric rules for Par and Comm have been omitted. It is similar to that of Iπ with the additional rules:

$$\textsc{Async}\ \frac{P \xrightarrow{\mu} P'}{\overline{a}(\widetilde{b})\ P \xrightarrow{\mu} \overline{a}(\widetilde{b})\ P}\quad \widetilde{b} \cap (\mathrm{fn}(\mu) \cup \mathrm{bn}(\mu)) = \emptyset,\ a \notin \mathrm{bn}(\mu) \qquad \textsc{AComm}\ \frac{P \xrightarrow{a(\widetilde{b})} P'}{\overline{a}(\widetilde{b})\ P \xrightarrow{\tau} (\boldsymbol{\nu}\widetilde{b})P'}$$

AComm allows P to communicate with the bound output, and Async allows P to perform any action that does not involve the names bound by the output.

Our type system is based on Milner's *sorting*. Names are split into *sorts*. In our case, we will use 3 sorts: F,R,C. The sorting function Σ is defined by $\Sigma(\mathtt{F}) = (\mathtt{F}, \mathtt{C})$ and $\Sigma(\mathtt{R}) = \Sigma(\mathtt{C}) = \mathtt{F}$. We call *function names*, ranged over with $w, x, y, z, \ldots$, names in F, *reference names*, ranged over with $\ell, \ell', \ldots$, names in R, and *continuation names*, ranged over with $p, q, r, \ldots$, names in C.

On top of the sorting, we adapt the type system for well-bracketing from [5] to AIπ. The type system imposes that continuation names are *receptive linear*, meaning that they can be used only once in output and once in input (hence linear) and the input is immediately

$$\textsc{Inp}\ \frac{}{a(\widetilde{b}).\,P \xrightarrow{a(\widetilde{b})} P} \qquad \textsc{Out}\ \frac{}{\overline{a}(\widetilde{b})\ P \xrightarrow{\overline{a}(\widetilde{b})} P} \qquad \textsc{Async}\ \frac{P \xrightarrow{\mu} P'}{\overline{a}(\widetilde{b})\ P \xrightarrow{\mu} \overline{a}(\widetilde{b})\ P}\ \begin{array}{l}\widetilde{b} \cap (\mathrm{fn}(\mu) \cup \mathrm{bn}(\mu)) = \emptyset \\ a \notin \mathrm{bn}(\mu)\end{array}$$

$$\textsc{AComm}\ \frac{P \xrightarrow{a(\widetilde{b})} P'}{\overline{a}(\widetilde{b})\ P \xrightarrow{\tau} (\boldsymbol{\nu}\widetilde{b})P'} \qquad \textsc{Rep}\ \frac{a(\widetilde{b}).\,P \xrightarrow{\mu} P'}{!a(\widetilde{b}).\,P \xrightarrow{\mu} P' \mid\, !a(\widetilde{b}).\,P} \qquad \textsc{Res}\ \frac{P \xrightarrow{\mu} P'}{(\boldsymbol{\nu}a)P \xrightarrow{\mu} (\boldsymbol{\nu}a)P'}\ a \notin \mathrm{fn}(\mu) \cup \mathrm{bn}(\mu)$$

$$\textsc{Par}\ \frac{P \xrightarrow{\mu} P'}{P \mid Q \xrightarrow{\mu} P' \mid Q}\ \mathrm{bn}(\mu) \cap \mathrm{fn}(Q) = \emptyset \qquad \textsc{Comm}\ \frac{P \xrightarrow{a(\widetilde{b})} P' \qquad Q \xrightarrow{\overline{a}(\widetilde{b})} Q'}{P \mid Q \xrightarrow{\tau} (\boldsymbol{\nu}\widetilde{b})(P' \mid Q')} \qquad \textsc{Cst}\ \frac{P\{\widetilde{b}/\widetilde{a}\} \xrightarrow{\mu} P'}{K\lfloor \widetilde{b} \rfloor \xrightarrow{\mu} P'} K \triangleq (\widetilde{a})\ P$$

Figure 1 Labelled Transition Semantics for AIπ.

available as soon as it is created (hence receptive). Additionally, creations and communications at continuation names behave in a well-bracketed manner, meaning that the communication will first occur at the name created last.

We use two constants, noted $\triangleright_{\mathtt{F}}$ and $\triangleright_{\mathtt{C}}$, defined as follows:

$$\begin{array}{ll} \triangleright_{\mathtt{C}} \triangleq (p,q)\ p(x).\overline{q}(y)\ y \triangleright_{\mathtt{F}} x & \text{with } p,q \text{ being continuation names} \\ \triangleright_{\mathtt{F}} \triangleq (x,y)\ !x(z,p).\overline{y}(w,q)\ (q \triangleright_{\mathtt{C}} p \mid w \triangleright_{\mathtt{F}} z) & \text{with } x,y \text{ being function names} \end{array}$$

These constants represent a link, also called forwarder or dynamic wire [17], which transforms outputs at the first name into outputs at the second. As their usage only differs in the linearity of continuation names and the arity, we often use the same symbol $\triangleright$ to denote both $\triangleright_{\mathtt{F}}$ and $\triangleright_{\mathtt{C}}$.

$$\textsc{wb-Nil}\ \frac{}{\emptyset \vdash_{\mathrm{wb}} \mathbf{0}} \qquad \textsc{wb-AOutC}\ \frac{\rho \vdash_{\mathrm{wb}} P}{p : \mathtt{o}, \rho \vdash_{\mathrm{wb}} \overline{p}(y)\ P} \qquad \textsc{wb-AOutF}\ \frac{p : \mathtt{i}, \rho \vdash_{\mathrm{wb}} P}{\rho \vdash_{\mathrm{wb}} \overline{x}(y,p)\ P} \qquad \textsc{wb-AOutR}\ \frac{\rho \vdash_{\mathrm{wb}} P}{\rho \vdash_{\mathrm{wb}} \overline{\ell}(y)\ P}$$

$$\textsc{wb-InpC}\ \frac{p : \mathtt{o} \vdash_{\mathrm{wb}} P \qquad p \neq q}{q : \mathtt{i}, p : \mathtt{o} \vdash_{\mathrm{wb}} q(y).\,P} \qquad \textsc{wb-InpF}\ \frac{p : \mathtt{o} \vdash_{\mathrm{wb}} P}{\emptyset \vdash_{\mathrm{wb}} x(y,p).\,P,\ !x(y,p).\,P} \qquad \textsc{wb-InpR}\ \frac{p : \mathtt{o} \vdash_{\mathrm{wb}} P}{p : \mathtt{o} \vdash_{\mathrm{wb}} \ell(y).\,P}$$

$$\textsc{wb-ResC1}\ \frac{\rho, p : \star, \rho' \vdash_{\mathrm{wb}} P}{\rho, \rho' \vdash_{\mathrm{wb}} (\boldsymbol{\nu}p)P} \qquad \textsc{wb-ResC2}\ \frac{\rho \vdash_{\mathrm{wb}} P}{\rho \vdash_{\mathrm{wb}} (\boldsymbol{\nu}p)P}\ p \notin \rho \qquad \textsc{wb-ResFR}\ \frac{\rho \vdash_{\mathrm{wb}} P}{\rho \vdash_{\mathrm{wb}} (\boldsymbol{\nu}y)P,\ (\boldsymbol{\nu}\ell)P}$$

$$\textsc{wb-Par}\ \frac{\rho \vdash_{\mathrm{wb}} P \qquad \rho' \vdash_{\mathrm{wb}} Q}{\rho'' \vdash_{\mathrm{wb}} P \mid Q}\ \rho'' \in \mathtt{inter}(\rho;\rho') \qquad \textsc{wb-FwC}\ \frac{}{p : \mathtt{i}, q : \mathtt{o} \vdash_{\mathrm{wb}} p \triangleright_{\mathtt{C}} q} \qquad \textsc{wb-FwF}\ \frac{}{\emptyset \vdash_{\mathrm{wb}} x \triangleright_{\mathtt{F}} y}$$

Figure 2 Type system for well-bracketing.

We present the typing rules for well-bracketing in Figure 2. Judgements are of the form $\rho \vdash_{\text{wb}} P$ with ρ being a stack. In rules WB-INPF and WB-RESFR, the conclusion is of the form $\rho \vdash_{\text{wb}} P, Q$ to indicate that both $\rho \vdash_{\text{wb}} P$ and $\rho \vdash_{\text{wb}} Q$ can be inferred from the premise.

A stack is a sequence of *tagged* names, the tag being either $\mathtt{i}, \mathtt{o}$ or $\star$ denoting respectively input, output and both capabilities. Upon creation, a continuation comes with both capabilities (WB-RESC1), that are used once as input and output (WB-INPC and WB-AOUTC). In WB-AOUTF, a continuation is created and its input capability is passed to P, while its output capability is sent by the communication. This capability can then be used after the input in WB-INPF. As continuation names are receptive, inputs cannot appear after another input (WB-INPF and WB-INPC).

Intuitively, a stack expresses the expected usage of the free continuation names in a process. Stacks are given by the following grammars:

$$\rho \ ::= \ \rho^{\mathtt{o}} \mid \rho^{\mathtt{i}} \qquad \rho^{\mathtt{o}} \ ::= \ p : \mathtt{o}, \rho^{\mathtt{i}} \mid p : \star, \rho^{\mathtt{o}} \mid \emptyset \qquad \rho^{\mathtt{i}} \ ::= \ p : \mathtt{i}, \rho^{\mathtt{o}} \mid \emptyset$$

Moreover, a name may appear at most once in a stack, so we will say that a name is $\mathtt{o}$-*tagged* in ρ when the name appears with tag $\mathtt{o}$ in ρ and similarly for $\mathtt{i}$ and $\star$.

As a $\star$-tagged name represents both output and input capabilities, a stack can be seen as an alternation of input- and output-tagged names. For instance, if we have

$$p_1 : \mathtt{o}, p_2 : \mathtt{i}, p_3 : \star, p_4 : \mathtt{o} \vdash_{\text{wb}} P$$

then $p_1, \ldots, p_4$ are the free continuation names in P; among these, p_1 will be used first, as an output at p_1; then p_2 will be used, in an input interaction with the environment. P possesses both the output and the input capability on p_3, and will use both capabilities by performing a reduction at p_3; the computation for P terminates with an output at p_4.

Thus, to compose two processes P and Q in parallel, the usage of continuations of $P \mid Q$ is an interleaving of the ones of P and Q (WB-PAR). Names with capabilities shared between P and Q can be used as synchronisation point. Formally, the interleaving of two stacks is described by the following definition:

▶ **Definition 7.** *The interleaving relation is defined as a ternary relation between stacks, written* $\rho \in \mathtt{inter}(\rho_1 \ ; \ \rho_2)$*, and defined as follows:*

- $\emptyset \in \mathtt{inter}(\emptyset; \emptyset)$
- $\rho \in \mathtt{inter}(\rho_1 \ ; \ \rho_2)$ *implies* $\rho \in \mathtt{inter}(\rho_2 \ ; \ \rho_1)$*.*
- $\rho \in \mathtt{inter}(\rho_1 \ ; \ \rho_2)$ *implies* $p : \eta, \rho \in \mathtt{inter}(p : \eta, \rho_1 \ ; \ \rho_2)$*, where* $\eta \in \{\mathtt{o}, \mathtt{i}, \star\}$ *and* $p : \eta, \rho_1$ *is a stack.*
- *Whenever* $\rho \in \mathtt{inter}(\rho^{\mathtt{i}}; \rho^{\mathtt{o}})$*, we have* $p : \star, \rho \in \mathtt{inter}(p : \mathtt{o}, \rho^{\mathtt{i}} \ ; \ p : \mathtt{i}, \rho^{\mathtt{o}})$*.*

Even though the grammar allows it, it is not possible to type a process $\rho \vdash P$ with ρ ending with $p : \mathtt{i}$ or $p : \star$.

As continuation names are used linearly, when both input and output are present in the process, i.e., when the name is $\star$-tagged in the stack, this name should not be observable. We call *clean* a stack where no name is $\star$-tagged. We note $\mathtt{c}(\rho)$ the clean stack obtained by removing all $\star$-tagged names from ρ, and $\rho \vDash_{\text{wb}} P$ when there exists ρ' with $\rho' \vdash_{\text{wb}} P$ and $\mathtt{c}(\rho') = \rho$. Using clean stacks, we can define *typed transitions*.

▶ **Definition 8.** *When $\rho \vDash_{\text{wb}} P$, we write $[\rho; P] \xrightarrow{\mu} [\rho'; P']$ if $P \xrightarrow{\mu} P'$ and one of the following holds:*

1. $\mu = \overline{p}(x)$ *and* $\rho = p : \mathtt{o}, \rho'$
2. $\mu = p(x)$ *and* $\rho = p : \mathtt{i}, \rho'$
3. $\mu = \overline{x}(y, p)$ *and* $\rho' = p : \mathtt{i}, \rho$
4. $\mu = x(y, p)$ *and* $\rho' = p : \mathtt{o}, \rho$
5. $\mu \in \{\ell(x), \overline{\ell}(x), \tau\}$ *and* $\rho' = \rho$.

▶ **Lemma 9** (Subject reduction)**.** *If $[\rho; P] \xrightarrow{\mu} [\rho'; P']$, then for any Q with $\rho \vDash_{\text{wb}} Q$ and $Q \xrightarrow{\mu} Q'$, we have $\rho' \vDash_{\text{wb}} Q'$.*

A relation $\mathcal{R}$ is *wb-typed* if for any $(\rho, P, Q) \in \mathcal{R}$, we have $\rho \vDash_{\text{wb}} P$ and $\rho \vDash_{\text{wb}} Q$. We define the typed version of the expansion preorder, written $\gtrsim_{wb}$, by restricting to typed transitions. As usual, we write $\xrightarrow{\widehat{\tau}}$ for $\xrightarrow{\tau} \cup \mathit{id}$ and $\xrightarrow{\widehat{\mu}}$ for $\xrightarrow{\mu}$ otherwise. The weak variants of the transitions are defined by chaining with $\Rightarrow \stackrel{\text{def}}{=} \xrightarrow{\tau}^*$: for instance, $\stackrel{\mu}{\Longrightarrow} \stackrel{\text{def}}{=} \Rightarrow \xrightarrow{\mu} \Rightarrow$.

▶ **Definition 10** (Wb-expansion)**.** *A wb-typed relation $\mathcal{R}$ is a* wb-expansion *when $(\rho, P, Q) \in \mathcal{R}$ implies:*

- *If we have $[\rho; P] \xrightarrow{\mu} [\rho'; P']$, then there exists Q' such that $Q \xrightarrow{\widehat{\mu}} Q'$ and $(\rho', P', Q') \in \mathcal{R}$.*
- *If we have $[\rho; Q] \xrightarrow{\mu} [\rho'; Q']$, then there exists P' such that $P \stackrel{\mu}{\Longrightarrow} P'$ and $(\rho', P', Q') \in \mathcal{R}$.*

We note $\gtrsim_{wb}$ the largest wb-expansion.

We omit ρ, writing $P \gtrsim_{wb} Q$ when ρ is obvious from the context. This typed expansion is coarser than its untyped variant, which is written $\gtrsim$ [19].

Wb-bisimulation, and wb-bisimilarity noted $\approx_{\text{wb}}$, are defined as wb-expansion by replacing $Q \xrightarrow{\widehat{\mu}} Q'$ with $Q \stackrel{\widehat{\mu}}{\Longrightarrow} Q'$ in Definition 10. The untyped version is written $\approx$.

4 Encoding Terms and Values in AIπ

In this section, we describe the encoding of $\lambda^{\mathtt{ref}}$-terms into AIπ processes. This leads to a clean operational correspondence where the encoding of a term may perform a unique transition according to the case distinction of Lemma 1.

We define the encoding in Figure 3. The encoding $[\![M]\!]$ of a term M is defined as an abstraction $(p)\ P$, and we use the notation $[\![M]\!]_q$ (resp. $[\![V]\!]^{\mathtt{v}}_y$) to note $[\![M]\!] \lfloor q \rfloor$ (resp. $[\![V]\!]^{\mathtt{v}} \lfloor y \rfloor$). Intuitively, $[\![M]\!]_p$ is a computation that returns a value at p while $[\![V]\!]^{\mathtt{v}}_y$ is a value that can be accessed at y.

This encoding extends the one from [3] with the additional constructs for handling references. A reference is represented by an output transmitting the stored value. Access to a reference is performed by receiving that output and emitting it back (possibly updated).

To remove any ambiguity in the rules, we consider that M (appearing in $[\![MN]\!]$, $[\![\ell \coloneqq M; N]\!]$ and $[\![VM]\!]$) cannot be a value. This distinction enables optimisations that intuitively remove some communications signaling the end of a subcomputation. This is reminiscent of the colon translation from [15], in the setting of continuation-passing style translations. For any reference-closed configurations $\langle h \mid M \rangle$, we have $p : \mathtt{o} \vdash_{\text{wb}} [\![\langle h \mid M \rangle]\!]_p$.

We extend the encoding to evaluation contexts as shown in Figure 4. When an evaluation context is applied to a non-value term, its encoding correspond to encode the context first and then apply it to the encoding of the term:

▶ **Lemma 11.** *For any E M such that M is not a value, we have $[\![E[M]]\!]_p = [\![E]\!][\![M]\!]]_p$.*

Functions

$$[\![V]\!] \stackrel{\text{def}}{=} (p)\ \overline{p}(y)\ [\![V]\!]^{\mathrm{v}}_y \qquad [\![xV]\!] \stackrel{\text{def}}{=} (p)\ \overline{x}(z,q)\ ([\![V]\!]^{\mathrm{v}}_z \mid q \rhd p)$$

$$[\![(\lambda x.\, N)V]\!] \stackrel{\text{def}}{=} (p)\ (\boldsymbol{\nu} y, w)([\![\lambda x.\, N]\!]^{\mathrm{v}}_y \mid [\![V]\!]^{\mathrm{v}}_w \mid \overline{y}(w', r')\ (w' \rhd w \mid r' \rhd p))$$

$$[\![VM]\!] \stackrel{\text{def}}{=} (p)\ (\boldsymbol{\nu} y)([\![V]\!]^{\mathrm{v}}_y \mid (\boldsymbol{\nu} r)([\![M]\!]_r \mid r(w).\, \overline{y}(w', r')\ (w' \rhd w \mid r' \rhd p)))$$

$$[\![MN]\!] \stackrel{\text{def}}{=} (p)\ (\boldsymbol{\nu} q)([\![M]\!]_q \mid q(y).\, (\boldsymbol{\nu} r)([\![N]\!]_r \mid r(w).\, \overline{y}(w', r')\ (w' \rhd w \mid r' \rhd p)))$$

Imperative constructs

$$[\![!\ell]\!] \stackrel{\text{def}}{=} (p)\ \ell(w).\, (\overline{\ell}(y)\ y \rhd w \mid \overline{p}(z)\ z \rhd w) \qquad [\![\ell \coloneqq V; N]\!] \stackrel{\text{def}}{=} (p)\ \ell(\_).\, (\overline{\ell}(y)\ [\![V]\!]^{\mathrm{v}}_y \mid [\![N]\!]_p)$$

$$[\![\ell \coloneqq M; N]\!] \stackrel{\text{def}}{=} (p)\ (\boldsymbol{\nu} q)([\![M]\!]_q \mid q(w).\, \ell(\_).\, (\overline{\ell}(y)\ y \rhd w \mid [\![N]\!]_p))$$

$$[\![\texttt{new}\ \ell \coloneqq V\ \texttt{in}\ N]\!] \stackrel{\text{def}}{=} (p)\ (\boldsymbol{\nu} q)([\![V]\!]_q \mid q(z).\, (\boldsymbol{\nu} \ell)(\overline{\ell}(y)\ y \rhd z \mid [\![N]\!]_p))$$

Configurations

$$[\![h]\!] \stackrel{\text{def}}{=} \prod_{\ell_0 \in \widetilde{\ell}} (\overline{\ell_0}(y)\ [\![h(\ell_0)]\!]^{\mathrm{v}}_y) \text{ with } \widetilde{\ell} = \mathrm{dom}(h) \qquad [\![\langle h \mid N \rangle]\!] \stackrel{\text{def}}{=} (p)\ (\boldsymbol{\nu} \widetilde{\ell})([\![h]\!] \mid [\![N]\!]_p)$$

where $[\![V]\!]^{\mathrm{v}}$ is defined as:

$$[\![\lambda x.\, N]\!]^{\mathrm{v}} \stackrel{\text{def}}{=} (y)\ !y(x, q).\, [\![N]\!]_q \qquad [\![x]\!]^{\mathrm{v}} \stackrel{\text{def}}{=} (y)\ y \rhd x$$

Figure 3 Encoding of terms and configurations into AIπ.

$$[\![[\cdot]]\!] \stackrel{\text{def}}{=} [\cdot] \qquad [\![FN]\!] \stackrel{\text{def}}{=} (p)\ (\boldsymbol{\nu} q)([\![F]\!]_q \mid q(y).\, (\boldsymbol{\nu} r)([\![N]\!]_r \mid r(w).\, \overline{y}(w', r')\ (w' \rhd w \mid r' \rhd p)))$$

$$[\![\ell \coloneqq F; N]\!] \stackrel{\text{def}}{=} (p)\ (\boldsymbol{\nu} q)([\![F]\!]_q \mid q(w).\, \ell(\_).\, (\overline{\ell}(y)\ y \rhd w \mid [\![N]\!]_p))$$

$$[\![VF]\!] \stackrel{\text{def}}{=} (p)\ (\boldsymbol{\nu} y)([\![V]\!]^{\mathrm{v}}_y \mid (\boldsymbol{\nu} r)([\![F]\!]_r \mid r(w).\, \overline{y}(w', r')\ (w' \rhd w \mid r' \rhd p)))$$

Figure 4 Encoding of evaluation contexts.

Proof. We proceed by induction on E:

1. when $E = [\cdot]$, the result is immediate.
2. when $E = FN$, we have

$$[\![E[M]]\!]_p = (\boldsymbol{\nu} q)([\![F[M]]\!]_q \mid q(y).\, (\boldsymbol{\nu} r)([\![N]\!]_r \mid r(w).\, \overline{y}(w', r')\ (w' \rhd w \mid r' \rhd p))).$$

By induction, we have that $[\![F[M]]\!]_q = [\![F]\!][[\![M]\!]]_q$ and thus:

$$\begin{aligned}[\![E[M]]\!]_p &= (\boldsymbol{\nu} q)([\![F]\!][[\![M]\!]]_q \mid q(y).\, (\boldsymbol{\nu} r)([\![N]\!]_r \mid r(w).\, \overline{y}(w', r')\ (w' \rhd w \mid r' \rhd p))) \\ &= [\![E]\!][[\![M]\!]]_p\end{aligned}$$

3. when $E = VF$, we have

$$[\![E[M]]\!]_p = (\boldsymbol{\nu} y, r)([\![V]\!]^{\mathrm{v}}_y \mid [\![F[M]]\!]_r \mid r(w).\, \overline{y}(w', r')\ (w' \rhd w \mid r' \rhd p)).$$

   By induction, we have that $[\![F[M]]\!]_r = [\![F]\!][[\![M]]\!]_r$.
   So $[\![E[M]]\!]_p = (\boldsymbol{\nu} y, r)([\![V]\!]^{\mathrm{v}}_y \mid [\![F]\!][[\![M]]\!]_r \mid r(w).\, \overline{y}(w', r')\ (w' \rhd w \mid r' \rhd p)) = [\![E]\!][[\![M]]\!]_p$.
4. when $E = \ell \coloneqq F; N$, then $[\![E[M]]\!]_p = (\boldsymbol{\nu} q)([\![F[M]]\!]_q \mid q(w).\, \ell(\_).\, (\overline{\ell}(y)\ y \rhd w \mid [\![N]\!]_p))$.
   By induction, we have that $[\![F[M]]\!]_q = [\![F]\!][[\![M]]\!]_q$.
   So $[\![E[M]]\!]_p = (\boldsymbol{\nu} q)([\![F]\!][[\![M]]\!]_q \mid q(w).\, \ell(\_).\, (\overline{\ell}(y)\ y \rhd w \mid [\![N]\!]_p)) = [\![E]\!][[\![M]]\!]_p$. ◀

Because we distinguish between values and non-values in the encoding, the previous lemma does not hold when M is a value. In that case, the encoding performs some "optimisations". To relate the two processes, we need that on the encoding, forwarders act like substitutions.

▶ **Lemma 12.** *We have*

1. $(\boldsymbol{\nu} x)([\![M]\!]_p \mid x \rhd y) \gtrsim [\![M\{y/\!/x\}]\!]_p$
2. $(\boldsymbol{\nu} x)([\![V]\!]^{\mathrm{v}}_z \mid x \rhd y) \gtrsim [\![V\{y/\!/x\}]\!]^{\mathrm{v}}_z$
3. $(\boldsymbol{\nu} p)([\![M]\!]_p \mid p \rhd q) \gtrsim [\![M]\!]_q$
4. $(\boldsymbol{\nu} y)([\![V]\!]^{\mathrm{v}}_y \mid x \rhd y) \gtrsim [\![V]\!]^{\mathrm{v}}_x$

Lemma 12 is proved by induction on the encoding of M or V to prove the four properties in conjonction. Indeed, there are dependencies between these properties which prevent us from treating them separately. This result is proved for the optimised encoding of the plain call-by-value λ-calculus [3] and it extends to the additional constructs of $\lambda^{\mathtt{ref}}$. As a result of the optimisation, we have the following lemma when applying a context to a value:

▶ **Lemma 13.** *For any value V and context E, $[\![E]\!][[\![V]\!]]_p \gtrsim [\![E[V]]\!]_p$.*

Proof. We proceed by induction on E:

- when $E = [\cdot]$, this is trivial.
- When $E = (\lambda x.\, M)\ [\cdot]$, we have

$$\begin{aligned}[\![E]\!][[\![V]\!]]_p &= (\boldsymbol{\nu} y, r)([\![\lambda x.\, M]\!]^{\mathrm{v}}_y \mid [\![V]\!]_r \mid r(w).\, \overline{y}(w', r')\ (w' \rhd w \mid r' \rhd p)) \\ &\to (\boldsymbol{\nu} y, w)([\![\lambda x.\, M]\!]^{\mathrm{v}}_y \mid [\![V]\!]^{\mathrm{v}}_w \mid \overline{y}(w', r')\ (w' \rhd w \mid r' \rhd p)) = [\![E[V]]\!]_p\end{aligned}$$

  As this transition is deterministic by construction, we obtain that $[\![E]\!][[\![V]\!]]_p \gtrsim [\![E[V]]\!]_p$. This also holds for the three following cases.
- When $E = x\ [\cdot]$, we have

$$\begin{aligned}[\![E]\!][[\![V]\!]]_p &= (\boldsymbol{\nu} y, r)([\![x]\!]^{\mathrm{v}}_y \mid [\![V]\!]_r \mid r(w).\, \overline{y}(w', r')\ (w' \rhd w \mid r' \rhd p)) \\ &\to^2 (\boldsymbol{\nu} y, w, w', r')([\![x]\!]^{\mathrm{v}}_y \mid \overline{x}(w'', r'')\ (w'' \rhd w' \mid r'' \rhd r') \mid [\![V]\!]^{\mathrm{v}}_w \mid w' \rhd w \mid r' \rhd p) \\ &\gtrsim (\boldsymbol{\nu} y)[\![x]\!]^{\mathrm{v}}_y \mid \overline{x}(w'', r'')\ (\boldsymbol{\nu} w, w', r')(w'' \rhd w' \mid w' \rhd w \mid [\![V]\!]^{\mathrm{v}}_w \mid r'' \rhd r' \mid r' \rhd p) \\ &\gtrsim (\boldsymbol{\nu} w)(\overline{x}(w'', r'')\ ([\![V]\!]^{\mathrm{v}}_{w''} \mid r'' \rhd p)) = [\![xV]\!]_p\end{aligned}$$

- When $E = [\cdot]\ M$, we have

$$\begin{aligned}[\![E]\!][[\![V]\!]]_p &= (\boldsymbol{\nu} q)([\![V]\!]_q \mid q(y).\, (\boldsymbol{\nu} r)([\![N]\!]_r \mid r(w).\, \overline{y}(w', r')\ (w' \rhd w \mid r' \rhd p))) \\ &\to (\boldsymbol{\nu} y)([\![V]\!]^{\mathrm{v}}_y \mid (\boldsymbol{\nu} r)([\![N]\!]_r \mid r(w).\, \overline{y}(w', r')\ (w' \rhd w \mid r' \rhd p))) = [\![xV]\!]_p\end{aligned}$$

- When $E = \ell \coloneqq [\cdot]; M$, we have

$$\begin{aligned}[\![E]\!][[\![V]\!]]_p &= (\boldsymbol{\nu} q)([\![V]\!]_q \mid q(w).\, \ell(\_).\, (\overline{\ell}(y)\ y \rhd w \mid [\![N]\!]_p)) \\ &\to (\boldsymbol{\nu} w)([\![V]\!]^{\mathrm{v}}_w \mid \ell(\_).\, (\overline{\ell}(y)\ y \rhd w \mid [\![N]\!]_p)) \\ &\gtrsim \ell(\_).\, (\overline{\ell}(y)\ (\boldsymbol{\nu} w)([\![V]\!]^{\mathrm{v}}_w \mid y \rhd w) \mid [\![N]\!]_p) \\ &\gtrsim \ell(\_).\, (\overline{\ell}(y)\ [\![V]\!]^{\mathrm{v}}_y \mid [\![N]\!]_p) = [\![E[V]]\!]_p\end{aligned}$$

- when $E = F\ M$ or $V\ F$ or $\ell := F; M$ with $F \neq [\cdot]$, then $F[V]$ is not a value, so $[\![E[V]]\!]_p = [\![E']\!][[\![F[M]]\!]]_p$ for some E' and the result follows by induction as $\gtrsim$ is a congruence. ◀

We can now establish operational correspondence.

▶ **Proposition 14** (Untyped Operational Correspondence). *For any M, h with $\mathrm{dom}(h) = \widetilde{\ell}$ and fresh q_0, $[\![\langle h \mid M\rangle]\!]_{q_0}$ has exactly one immediate transition, and exactly one of the following clauses holds:*

1. *$\langle h \mid M\rangle \to \langle h' \mid N\rangle$ and $[\![\langle h \mid M\rangle]\!]_{q_0} \xrightarrow{\tau} P$ with $P \gtrsim [\![\langle h' \mid N\rangle]\!]_{q_0}$*
2. *M is a value, $[\![\langle h \mid M\rangle]\!]_{q_0} \xrightarrow{\overline{q_0}(x_0)} P$ and $P = (\boldsymbol{\nu}\widetilde{\ell})([\![h]\!] \mid [\![M]\!]^{\mathtt{v}}_{x_0})$.*
3. *M is of the form $E_0[yV_0]$ for some E_0, y and V_0, and we have $[\![\langle h \mid M\rangle]\!]_{q_0} \xrightarrow{\overline{y}(x_0,p_0)} P$ with $P \gtrsim (\boldsymbol{\nu}\widetilde{\ell})([\![h]\!] \mid [\![V_0]\!]^{\mathtt{v}}_{x_0} \mid p_0(z).\,[\![E_0[z]]\!]_{q_0})$.*

In the first case, the τ transition is deterministic, so we can prove that the following holds: $[\![\langle h \mid M\rangle]\!]_{q_0} \gtrsim [\![\langle h' \mid N\rangle]\!]_{q_0}$.

Using the existing equivalences in AIπ from Section 3, we can prove that the encodings of two $\lambda^{\mathtt{ref}}$-terms are equivalent. The equivalence and preorder used here are finer than bisimilarity with divergence which is sound as stated in Section 5. These examples show how the standard theory of the π-calculus is enough to prove interesting properties of $\lambda^{\mathtt{ref}}$-terms. These properties do not require us to use the triples defined in Section 5 nor to take into account the possibility of deferred divergence.

▶ **Example 15** (Unused reference). For any reference ℓ, value V and any term M with $\ell \notin \mathrm{fr}(M)$, we have $[\![\mathtt{new}\ \ell := V\ \mathtt{in}\ M]\!]_p \gtrsim [\![M]\!]_p$.

Proof. We write

$$\begin{aligned}[\![\mathtt{new}\ \ell := V\ \mathtt{in}\ M]\!]_p &\gtrsim [\![\langle \emptyset \mid \mathtt{new}\ \ell := V\ \mathtt{in}\ M\rangle]\!]_p \\ &\gtrsim [\![\langle \ell = V \mid M\rangle]\!]_p && \text{by Proposition 14} \\ &\gtrsim (\boldsymbol{\nu}\ell)(\overline{\ell}(y)\ [\![V]\!]^{\mathtt{v}}_y) \mid [\![M]\!]_p \gtrsim [\![M]\!]_p\end{aligned}$$

We use $\gtrsim$ to perform a deterministic reduction and then to use simple laws and remove inaccessible processes. This result can be extended in presence of store by congruence, giving $[\![\langle h \mid \mathtt{new}\ \ell := V\ \mathtt{in}\ M\rangle]\!]_p \gtrsim [\![\langle h \mid M\rangle]\!]_p$. ◀

▶ **Example 16** (One-use context). Let $f_1 \stackrel{\mathrm{def}}{=} \lambda x.\,\mathtt{if}\ !\ell = \mathtt{tt}\ \mathtt{then}\ \ell := \mathbf{ff}; \mathtt{tt}\ \mathtt{else}\ \mathbf{ff}$ and $f_2 \stackrel{\mathrm{def}}{=} \lambda x.\,\mathtt{tt}$ and $E = [\cdot]\ (x\lambda y.\,y)$. Then $[\![\mathtt{new}\ \ell := \mathtt{tt}\ \mathtt{in}\ E[f_1]]\!]_p \approx [\![E[f_2]]\!]_p$

Proof. By Proposition 14 and congruence of $\gtrsim$ we have:

$$\begin{aligned}[\![E[f_2]]\!]_p &\gtrsim \overline{x}(z,q)\ ([\![\lambda y.\,y]\!]^{\mathtt{v}}_z \mid q(w).\,[\![f_2 w]\!]_p) \\ &\gtrsim \overline{x}(z,q)\ ([\![\lambda y.\,y]\!]^{\mathtt{v}}_z \mid q(w).\,[\![\mathtt{tt}]\!]_p)\end{aligned}$$

Using standard laws for $\gtrsim$, we relate the encoding of the first program to the same process:

$$\begin{aligned}[\![\mathtt{new}\ \ell := \mathtt{tt}\ \mathtt{in}\ E[f_1]]\!]_p &\gtrsim (\boldsymbol{\nu}\ell)([\![\ell = \mathtt{tt}]\!] \mid \overline{x}(z,q)\ ([\![\lambda y.\,y]\!]^{\mathtt{v}}_z \mid q(w).\,[\![f_1 w]\!]_p)) \\ &\gtrsim \overline{x}(z,q)\ ([\![\lambda y.\,y]\!]^{\mathtt{v}}_z \mid q(w).\,[\![\langle \ell = \mathtt{tt} \mid f_1 w\rangle]\!]_p) \\ &\gtrsim \overline{x}(z,q)\ ([\![\lambda y.\,y]\!]^{\mathtt{v}}_z \mid q(w).\,[\![\langle \ell = \mathbf{ff} \mid \mathtt{tt}\rangle]\!]_p) \\ &\gtrsim \overline{x}(z,q)\ ([\![\lambda y.\,y]\!]^{\mathtt{v}}_z \mid q(w).\,[\![\mathtt{tt}]\!]_p)\end{aligned}$$

Note that we are outside AIπ because we are using constants ($\mathbf{tt}$, $\mathbf{ff}$). Adapting our setting to simple types can be done by having sorts $\mathtt{F}, \mathtt{R}, \mathtt{C}$ and forwarders $\triangleright_{\mathtt{C}}, \triangleright_{\mathtt{F}}$ for each type T, the forwarders being defined inductively on T instead of being constants. ◀

$$[\![\widetilde{V}_i]\!]^{\mathtt{v}}_{\widetilde{x}} \stackrel{\text{def}}{=} \prod_i [\![V_i]\!]^{\mathtt{v}}_{x_i} \qquad \text{with } \widetilde{x} = \widetilde{x_i}$$

$$[\![E_1 :: \cdots :: E_n]\!]_{\widetilde{pq}} \stackrel{\text{def}}{=} \prod_{i\leq n} p_i(z).\,[\![E_i[z]]\!]_{q_i} \qquad \text{with } \widetilde{pq} = p_1, q_1, \ldots, p_n, q_n$$

$$[\![(\widetilde{V}_i, \sigma, h)]\!]_{\widetilde{x};\widetilde{pq}} \stackrel{\text{def}}{=} (\boldsymbol{\nu}\widetilde{\ell})([\![\widetilde{V}_i]\!]_{\widetilde{x}} \mid [\![\sigma]\!]_{\widetilde{pq}} \mid [\![h]\!]) \qquad \text{with } \widetilde{\ell} = \mathrm{dom}(h)$$

$$[\![(\widetilde{V}_i, \sigma, \langle h \mid M\rangle)]\!]_{\widetilde{x};q_0,\widetilde{pq}} \stackrel{\text{def}}{=} (\boldsymbol{\nu}\widetilde{\ell})([\![\widetilde{V}_i]\!]_{\widetilde{x}} \mid [\![\sigma]\!]_{\widetilde{pq}} \mid [\![h]\!] \mid [\![M]\!]_{q_0}) \qquad \text{with } \widetilde{\ell} = \mathrm{dom}(h)$$

Figure 5 Encoding for triples.

5 A π-Calculus Characterisation of Contextual Equivalence in $\lambda^{\mathtt{ref}}$

We can now move on to show our full abstraction result. To do so, we first extend the encoding to the triples defined in Section 2. This leads to an operational correspondence similar to Proposition 14 but for triples (Theorem 17). However, thanks to triples, it is possible to state Theorem 17 without using explicit AIπ constructs, so that each transition relates the encoding of triples. The bisimulation with divergence can then be defined and shown fully abstractly using mainly the operational correspondence theorem.

We describe in Figure 5 the encoding of triples (Section 2). It builds on the encoding in Figure 3, with values being encoded as expected. To encode σ, every evaluation context E in σ is encoded as the process $p(z).\,[\![E[z]]\!]_q$ so that, intutively, $E[z]$ can be executed as soon as the input at p is triggered. Both $[\![(\widetilde{V}_i, \sigma, c)]\!]_{\widetilde{x};q_0,\widetilde{pq}}$ and $[\![(\widetilde{V}_i, \sigma, h)]\!]_{\widetilde{x};\widetilde{pq}}$ are typeable with stacks that we write $\rho_{q_0,\widetilde{pq}}$ and $\rho_{\widetilde{pq}}$ respectively.

▶ **Theorem 17** (Operational Correspondence)**.**
We relate transitions for the encoding of both kind of triples:
When $[\rho; [\![(\widetilde{V}_i, \sigma, c)]\!]_{\widetilde{x};q_0,\widetilde{pq}}] \xrightarrow{\mu} [\rho'; P]$ *with* $\widetilde{x} = \widetilde{x_i}$ *and* $\widetilde{pq} = p_1, q_1, \ldots, p_n, q_n$ *then:*

1. *either* $c \to c'$, $\mu = \tau$ *and* $P \gtrsim [\![(\widetilde{V}_i, \sigma, c')]\!]_{\widetilde{x};q_0,\widetilde{pq}}$
2. *or* $c = \langle h \mid V_0\rangle$, $\mu = \overline{q_0}(x_0)$ *and* $P \gtrsim [\![((\widetilde{V}_i, V_0), \sigma, h)]\!]_{x_0,\widetilde{x};\widetilde{pq}}$
3. *or* $c = \langle h \mid E_0[y\ V_0]\rangle$, $\mu = \overline{y}(x_0, p_0)$ *and* $P \gtrsim [\![((\widetilde{V}_i, V_0), E_0 :: \sigma, h)]\!]_{x_0,\widetilde{x};p_0,q_0,\widetilde{pq}}$

When $[\rho; [\![(\widetilde{V}_i, \sigma, h)]\!]_{\widetilde{x};\widetilde{pq}}] \xrightarrow{\mu} [\rho'; P]$ *with* $\widetilde{x} = \widetilde{x_i}$ *and* $\widetilde{pq} = p_1, q_1, \ldots, p_n, q_n$ *then:*

1. *either* $\mu = x_j(z, q_0)$ *and* $P \gtrsim [\![(\widetilde{V}_i, \sigma, \langle h \mid N\rangle)]\!]_{\widetilde{x};q_0,\widetilde{pq}}$ *with* $V_j z \succ N$.
2. *or* $\sigma = E_1 :: \sigma'$ *and* $\mu = p_1(z)$ *and* $P \gtrsim [\![(\widetilde{V}_i, \sigma', \langle h \mid E_1[z]\rangle)]\!]_{\widetilde{x};q_1,p_2,q_2,\ldots,p_n,q_n}$

The following result is useful for the full abstraction proof.

▶ **Corollary 18.** *If* $[\![(\widetilde{V}_i, \sigma, c)]\!]_{\widetilde{x};q_0,\widetilde{pq}} \Rightarrow P'$, *then there exists a configuration* c' *with* $c \Rightarrow c'$ *and* $P' \gtrsim [\![(\widetilde{V}_i, \sigma, c')]\!]_{\widetilde{x};q_0,\widetilde{pq}}$.

Note that we rely on untyped expansion, which does not make any assumption about sequentiality of processes, in Theorem 17 and Corollary 18. This shows the robustness of the encoding.

The following example shows that by contrast with the encoding of configurations, the τ transition in the first case of Theorem 17 is not deterministic.

▶ **Example 19.** $[\![(\{\lambda z.\,\ell \coloneqq z\}, \odot, \langle \ell = y \mid !\ell\rangle)]\!]_{x_1;q_0} \not\gtrsim [\![(\{\lambda z.\,\ell \coloneqq z\}, \odot, \langle \ell = y \mid y\rangle)]\!]_{x_1;q_0}$.

Indeed, as the π-calculus is concurrent, the encoding of $\lambda z.\, \ell := z$ may be executed to change the content of ℓ before the read is executed. However, we can recover this result by using $\gtrsim_{wb}$ which forbids the concurrent transitions. This makes $\gtrsim_{wb}$ useful to handle reductions for triples.

We now introduce the notion of divergence for π-terms. This leads to the definition of bisimulation with divergence which coarsens $\approx_{\mathrm{wb}}$ to account for divergent terms. The induced equivalence for $\lambda^{\mathtt{ref}}$-terms corresponds to nfb.

A *wb-typed set* is a set of pairs (ρ, P) with ρ clean and $\rho \vDash_{\mathrm{wb}} P$.

▶ **Definition 20** (π_{div}). *A wb-typed set S is π-divergent if whenever we have $(\rho, P) \in S$, then $\rho \neq \emptyset$ and for all μ, ρ', P' with $[\rho; P] \xrightarrow{\mu} [\rho'; P']$, we have $(\rho', P') \in S$.*

We write π_{div} for the largest π-divergent set.

Intuitively, the computation ends when the stack gets empty, meaning there is no pending continuation. Processes in π_{div} thus correspond to processes which cannot terminate, hence the name of π-divergence.

The following example shows that the divergence of a process depends on the stack used to type it.

▶ **Example 21.** Let us consider

$$P \stackrel{\mathrm{def}}{=} (\boldsymbol{\nu} x)(p_1(z).\, \overline{x}(y, r_1)\ r_1 \rhd q_1 \mid p_2(z).\, \overline{q_2}(y)\ x(y', r).\, \overline{r}(z')\ \mathbf{0}),$$

$$\rho_1 = p_1 : \mathtt{i}, q_1 : \mathtt{o}, p_2 : \mathtt{i}, q_2 : \mathtt{o}, \quad \rho_2 = p_2 : \mathtt{i}, q_2 : \mathtt{o}, p_1 : \mathtt{i}, q_1 : \mathtt{o}.$$

We have both $\rho_1 \vDash_{\mathrm{wb}} P$ and $\rho_2 \vDash_{\mathrm{wb}} P$.

$[\rho_1; P] \xrightarrow{p_1(z)} [\rho'; P']$ is the only typed-allowed transition and P' has no typed-allowed transition. Thus, $(\rho_1, P) \in \pi_{\mathrm{div}}$.

On the other hand, $[\rho_2; P] \xrightarrow{p_2(z)} \xrightarrow{\overline{q_2}(y)} \xrightarrow{p_1(z_0)} \xrightarrow{\tau} \xrightarrow{\tau} \xrightarrow{\overline{q_1}(z')} [\emptyset; P']$. So $(\rho_2, P) \notin \pi_{\mathrm{div}}$.

▶ **Definition 22.** *A wb-typed symmetric relation $\mathcal{R}$ is a* bisimulation with divergence *if there exists a π-divergent set S such that whenever we have $(\sigma, P, Q) \in \mathcal{R}$ and $[\sigma; P] \xrightarrow{\mu} [\sigma'; P']$, then one of the following holds:*

1. *there exists Q' with $Q \stackrel{\widehat{\mu}}{\Longrightarrow} Q'$ and $(\sigma', P', Q') \in \mathcal{R}$;*
2. *μ is an output and $(\sigma', P') \in S$.*

We write $\approx_{\mathrm{div}}$ for the largest bisimulation with divergence. We write $P \approx^{\rho}_{\mathrm{div}} Q$ when $(\rho, P, Q) \in \approx_{\mathrm{div}}$.

Bisimilarity with divergence is coarser than wb-bisimilarity and thus also coarser than the untyped bisimilarity.

To establish soundness, we rely on Theorem 17 (operational correspondence). The set of triples whose encoding is π-diverging is itself diverging, so we can prove that the relation induced by $\approx_{\mathrm{div}}$ is a nfb.

▶ **Theorem 23** (Soundness). *If $[\![M]\!]_p \approx^{p:\mathtt{o}}_{\mathrm{div}} [\![N]\!]_p$, then $M \asymp N$.*

The completeness is proved by showing that the encoding of a divergent set is π-divergent up to $\gtrsim$ and then Property (1) from the introduction, namely that the encoding of a nfb is a bisimulation with divergence up to $\gtrsim$.

▶ **Theorem 24** (Completeness). *If $M \asymp N$, then $[\![M]\!]_p \approx^{p:\mathtt{o}}_{\mathrm{div}} [\![N]\!]_p$.*

6 Up-to Techniques for $\approx_{\text{div}}$ in AIπ, and Applications

Up-to techniques are defined as functions from relations to relations. The idea of up-to techniques is to weaken the requirement by applying the up-to technique to the relation $\mathcal{R}$ in clause 1 of Definition 22. Standard up-to techniques like up-to expansion or up-to context can be adapted to our typed setting as in [5].

Similar up-to techniques for sets can also be defined and exploited for π-divergent sets. In order for up-to context to be sound, we must forbid contexts where the hole is guarded by a replicated input. Indeed, replicated input may only be typed with an empty set so they cannot be diverging. This is similar to $\lambda^{\mathtt{ref}}$, where Ω is divergent but $\lambda x.\,\Omega$ is not.

Thanks to up-to techniques, to prove that two processes are equivalent, we can give $\mathcal{R}$, a bismulation with divergence up to using S, a π-divergent set up to. This is used in the equivalences proven in Section 6.2.

6.1 A new up-to technique for AIπ: up-to body

In AIπ, functions are encoded as a replicated process of the form $!x(y,p).\,T$, which we denote T^x. When identical calls result in the same value being sent, it creates copies of that value, leading to processes of the form $T^x \mid T^y \mid \ldots \mid T^z$, with $x, y, \ldots, z$ being all different names. This behaviour makes bisimulations infinite, as they would need to contain processes with an arbitrary number of processes in parallel, despite all of them sharing the same body. We introduce a new technique, up-to body, which allows us to remove these duplicated copies. Indeed, it is sound to keep only one copy when comparing processes: any discriminating interaction with the environment involving multiple copies can be mimicked by a similar interaction with only one copy. The up-to body technique is defined by the following rule:

$$\frac{(\rho,\ E[T_1^x],\ F[T_2^x]) \in \mathcal{R}}{(\rho,\ E[T_1^z \mid T_1^x],\ F[T_2^z \mid T_2^x]) \in \mathtt{body}(\mathcal{R})}\, x, z \notin \mathrm{n}(E) \cup \mathrm{n}(F) \cup \mathrm{fn}(T_1) \cup \mathrm{fn}(T_2)$$

Up-to body differs from up-to context because we keep the possibly different evaluation contexts, E and F. These contexts correspond to private resources shared among the copies. In our case, the private resource is the local store, but this technique can be exported to the plain π-calculus. The technique for sets is defined similarly, with $(\rho, E[T^z \mid T^x]) \in \mathtt{body}(S)$ whenever $(\rho, E[T^x]) \in S$ and $x, z \notin \mathrm{n}(E) \cup \mathrm{fn}(T)$.

Using up-to body, it is possible to prove the analog of (1) from Section 1 but using normal form bisimulations from [2] instead of the formulation we have given in Definition 5.

We now present a simple example that demonstrates the use of up-to body.

▶ **Example 25.** $\mathtt{new}\ \ell \coloneqq z\ \mathtt{in}\ \lambda x.\,\lambda y.\,!\ell \asymp \lambda x.\,\lambda y.\,z$

Proof. We reason using the soundness of the encoding, and define

$$\begin{aligned}\mathcal{R} = \{&(\rho_q, [\![\mathtt{new}\ \ell \coloneqq z\ \mathtt{in}\ \lambda x.\,\lambda y.\,!\ell]\!]_q, [\![\lambda x.\,\lambda y.\,z]\!]_q),\\ &(\emptyset, [\![(\lambda x.\,\lambda y.\,!\ell,), \odot, \ell = z]\!]_{x_0}, [\![(\lambda x.\,\lambda y.\,z,), \odot, \emptyset]\!]_{x_0})\\ &(\emptyset, [\![(\lambda x.\,\lambda y.\,!\ell, \lambda y.\,!\ell), \odot, \ell = z]\!]_{x_0,x_1}, [\![(\lambda x.\,\lambda y.\,z, \lambda y.\,z), \odot, \emptyset]\!]_{x_0,x_1})\}.\end{aligned}$$

We can show that $\mathcal{R}$ is a bisimulation with divergence up to $\gtrsim_{wb}$, context and body. The up-to body technique makes it possible to stop the relation after the third pair. ◀

6.2 Examples

We now present an example that involves the encoding of triples, but does not require us to take into account deferred divergences. To validate the laws below, we thus rely on $\approx_{\text{wb}}$ which is included in $\approx_{\text{div}}$ (Definition 22).

▶ **Example 26** (Optimised access)**.** Two consecutive read and/or write operations can be transformed into an equivalent single operation.

For any pair (f_1, f_2) from the following (() is the unique inhabitant of the unit type):

$$\begin{array}{ll}
\big(f_1 = \lambda().\, \ell \coloneqq !\ell, & f_2 = \lambda().\, ()\big) \\
\big(f_1 = \lambda n.\, \lambda m.\, \ell \coloneqq n; \ell \coloneqq m, & f_2 = \lambda n.\, \lambda m.\, \ell \coloneqq m\big) \\
\big(f_1 = \lambda n.\, \ell \coloneqq n; !\ell, & f_2 = \lambda n.\, \ell \coloneqq n; n\big) \\
\big(f_1 = \lambda().\, \texttt{let}\ x = !\ell\ \texttt{in}\ \texttt{let}\ y = !\ell\ \texttt{in}\ M, & f_2 = \lambda().\, \texttt{let}\ x = !\ell\ \texttt{in}\ M\{x/y\}\big)
\end{array}$$

we have for any E, y, V_0, we have $[\![\texttt{new}\ \ell \coloneqq V_0\ \texttt{in}\ E[y\ f_1]]\!]_{q_1} \approx_{\text{wb}} [\![\texttt{new}\ \ell \coloneqq V_0\ \texttt{in}\ E[y\ f_2]]\!]_{q_1}$.

Proof. First, we have that $[\![((f_1,), E :: \odot, \ell \coloneqq V_0)]\!]_{x;p_1,q_1} \approx_{\text{wb}} [\![((f_2,), E :: \odot, \ell \coloneqq V_0)]\!]_{x;p_1,q_1}$ using $(f_i,)$ to denote the singleton containing f_i. Indeed, we define a relation $\mathcal{R}$ as follows:

$$\mathcal{R} = \{(\rho_{\widetilde{pq}},\ [\![((\widetilde{V_i}, f_1), \sigma, h \uplus \ell = V)]\!]_{\widetilde{x};\widetilde{pq}}, [\![((\widetilde{V_i}, f_2), \sigma, h \uplus \ell = V)]\!]_{\widetilde{x};\widetilde{pq}}) \mid \text{ for all } \widetilde{V_i}, \sigma, h, V, \widetilde{x}, \widetilde{pq}\}$$

and we show that $\mathcal{R}$ is a *wb*-bisimulation up to $\gtrsim_{wb}$ and evaluation context.

Then we use Theorem 17 to show

$$[\![\texttt{new}\ \ell \coloneqq V_0\ \texttt{in}\ E[x\ f_i]]\!]_{q_1} \gtrsim [\![(\emptyset, \odot, \langle \ell = V_0 \mid E[y\ f_i]\rangle)]\!]_{q_1} \xrightarrow{\overline{y}(x,p_1)} \gtrsim [\![(f_i,), E :: \odot, \ell = V_0)]\!]_{x;p_1,q_1}$$

with the output being the only transition that the intermediate process can perform. ◀

The proof of this law could become even simpler by adopting the type system of [4]: we could prove prove directly that $[\![f_1]\!]_p$ and $[\![f_2]\!]_p$ are equivalent.

Relation $\mathcal{R}$ above would have the same base if we were to reason in the source language. If we were to show $\texttt{new}\ \ell \coloneqq V\ \texttt{in}\ E[y\ f_1] \asymp \texttt{new}\ \ell \coloneqq V\ \texttt{in}\ E[y\ f_2]$ using nfb, we would need to add triples with the same normal form term on both sides.

We present some examples involving deferred divergence from the literature.

▶ **Example 27.** $\langle \emptyset \mid x\ V\ \Omega\rangle \asymp \langle \emptyset \mid \Omega\rangle$, where V is a value and Ω is an always diverging term.

Proof. Take $\mathcal{R} = \{(\rho_q, [\![\langle \emptyset \mid x\ V\ \Omega\rangle]\!]_q, [\![\langle \emptyset \mid \Omega\rangle]\!]_q)\}$ and $S = \{(\rho_r, [\![\Omega]\!]_r)\}$.

S is π-divergent, so $\gtrsim_{wb}\texttt{ctxt}(S)$ is too, where $\texttt{ctxt}$ stands for the up-to context technique. Then we show that $\mathcal{R}$ is a bisimulation with divergence up to context with $\gtrsim_{wb}\texttt{ctxt}(S)$ as the π-divergent set.

$[\rho_q; [\![\langle \emptyset \mid x\ V\ \Omega\rangle]\!]_q] \xrightarrow{\overline{x}(y,p)} [\rho_{p,q}; P]$ is the only type-allowed transition.

By Theorem 17, we know that $P \gtrsim [\![(\{V\}, [\cdot]\ \Omega :: \odot, \emptyset)]\!]_{y;pq}$.

As $(\rho_{p,q}, [\![(\{V\}, [\cdot]\ \Omega :: \odot, \emptyset)]\!]_{y;pq}) \in \texttt{ctxt}(S)$, we indeed have $(\rho_{p,q}, P) \in \gtrsim_{wb}\texttt{ctxt}(S)$. ◀

▶ **Example 28** (Example 9 from [2])**.**

$$V_1 = \lambda x.\, \texttt{if}\ !\ell\ \texttt{then}\ \Omega\ \texttt{else}\ k \coloneqq \mathbf{tt} \qquad W_1 = \lambda x.\, \Omega$$

$$V_2 = \lambda f.\, f\ V_1; \texttt{if}\ !k\ \texttt{then}\ \Omega\ \texttt{else}\ \ell \coloneqq \mathbf{tt} \qquad W_2 = \lambda f.\, f\ W_1$$

We have $\texttt{new}\ \ell \coloneqq \mathbf{ff}\ \texttt{in}\ \texttt{new}\ k \coloneqq \mathbf{ff}\ \texttt{in}\ V_2 \asymp W_2$.

Proof. Given a context E, we write E^n for $E :: E :: \cdots :: E :: \odot$ with n occurences of E.

Let $E \stackrel{\text{def}}{=} (\lambda().\,\texttt{if}\ !k\ \texttt{then}\ \Omega\ \texttt{else}\ \ell \coloneqq \mathbf{tt})[\cdot]$, and $F \stackrel{\text{def}}{=} (\lambda().\,())[\cdot]$. We define $\mathcal{R}$ as

$$
\begin{array}{lll}
\{(\rho_q, & [\![\texttt{new}\ \ell \coloneqq \mathbf{ff}\ \texttt{in new}\ k \coloneqq \mathbf{ff}\ \texttt{in}\ V_2]\!]_q, & [\![W_2]\!]_q), \\
(\emptyset, & [\![(V_2,), \odot, \ell = \mathbf{ff} \uplus k = \mathbf{ff}]\!]_{x_2}, & [\![(W_2,), \odot, \emptyset]\!]_{x_2})\} \bigcup \\
\{(\rho_{\widetilde{pq}}, & [\![(V_1, V_2), E^n, \ell = \mathbf{ff} \uplus k = \mathbf{ff}]\!]_{\widetilde{x_i};\widetilde{pq}}, & [\![(W_1, W_2), F^n, \emptyset]\!]_{\widetilde{x_i};\widetilde{pq}}), \\
(\rho_{q_0,\widetilde{pq}}, & [\![(V_1, V_2), E^n, \langle \ell = \mathbf{ff} \uplus k = \mathbf{tt} \mid ()\rangle]\!]_{\widetilde{x_i};q_0,\widetilde{pq}}, & [\![(W_1, W_2), F^n, \langle \emptyset \mid \Omega\rangle]\!]_{\widetilde{x_i};q_0,\widetilde{pq}}), \\
(\rho_{\widetilde{pq}}, & [\![(V_1, V_2), E^n, \ell = \mathbf{tt} \uplus k = \mathbf{ff}]\!]_{\widetilde{x_i};\widetilde{pq}}, & [\![(W_1, W_2), F^n, \emptyset]\!]_{\widetilde{x_i};\widetilde{pq}}) \\
 & & \mid \text{ for all } \widetilde{pq}, n \text{ with } |\widetilde{pq}| = 2n\ \}
\end{array}
$$

and S as $\{(\rho_q, [\![\Omega]\!]_q),\ (\rho_{\widetilde{pq}}, [\![(V_1, V_2), E^n, \ell = \mathbf{ff} \uplus k = \mathbf{tt}]\!]_{\widetilde{x_i};\widetilde{pq}})$ for all $\widetilde{pq}, n$ with $|\widetilde{pq}| = 2n\}$.

$\mathcal{R}$ is a bisimulation up to $\gtrsim_{wb}$, context and body. Multiple calls to V_1, W_1 create multiples continuations, but thanks to up-to body, multiples calls to V_2, W_2 do not create multiples copies of V_1, W_1. All in all, we have the same number of pairs in the candidate bisimulation relation as in the relation in [2]. ◀

By modifying this example so as to allocate the references inside V_2, we get Example 15 from [8]. In that case, V_2 does not have free reference names. This makes it possible to use up-to parallel composition between the encoding of V_2 and V_1 preventing multiples calls to V_2. This usage of up-to parallel composition is similar to the up-to separation technique introduced in [8].

7 Related and Future Works

7.1 Related works

The equivalence in [8] is similar to nfb, for an extension of $\lambda^{\texttt{ref}}$. It is also fully abstract w.r.t. contextual equivalence. Up-to techniques for nfb are defined in [2], and used to prove several equivalences between $\lambda^{\texttt{ref}}$ programs. We can redo essentially the same proofs in our setting. Both works use techniques that are specific to nfb or its variant, and are arguably less standard than the up-to techniques we exploit in the π-calculus. In particular, the *up-to separation* from [8] is expressible using up-to context in the π-calculus.

A full abstraction result for PCF programs in AIπ is presented in [1], using a contextual equivalence in a typed setting. The type system captures closely the behaviour of the encoding of PCF terms, in the sense that any process whose type is the translation of a PCF type is behaviourally equivalent to the encoding of a source term, and in particular cannot be stateful. It seems difficult to find a labelled bisimilarity for this equivalence, and thus to use proof techniques as in our paper.

Our encoding is based on the one of [3], which has been used to show a close connection between operational game semantics and the π-calculus for call-by-value in [7]. Both works focus on this stateless calculus to show the correspondence with Lassen trees.

The type system of Section 3 is inspired by evaluation stacks used to ensure the bracketed condition in game semantics [9]. Game semantics can also be used to provide a fully abstract model for RefML, which is a language similar to $\lambda^{\texttt{ref}}$ [12, 13]. By being more operational, our approach is usable more directly to reason about $\lambda^{\texttt{ref}}$ programs. This is similar to operational game semantics which are complete for recursion-free programs with integer references [6].

7.2 Future works

The type system of [4] makes it possible to reason about references in a parallel setting. We believe that its addition to our type system would allow us to extend our full abstraction result to *open references*, i.e., references that can be returned by functions.

It would be interesting to see whether $\approx_{\text{div}}$ characterises a contextually-defined equivalence in AIπ. In comparison, such a result holds for $\approx_{\text{wb}}$ [5]: this equivalence corresponds to a typed barbed equivalence with a notion of *typed barb* to restrict the visibility of observables. One lead would be limiting barbs to be only outputs on continuation names. This may work only for the image of the encoding, but not for all typeable processes.

We would like to see whether the techniques we have developed can be exploited in other languages. Idealized ALGOL has both functional and imperative aspects, so our techniques may adapt to it. When extending $\lambda^{\mathtt{ref}}$ with control operators [20], well-bracketing is not required, so we can weaken the type system to simply ensure sequentiality. Because of the links with game semantics, object-oriented languages [14] can be interesting too.

Abstract

We settle two long-standing open problems about Conway's Life, a two-dimensional cellular automaton. We solve the Generalized grandfather problem: for all $n \geq 0$, there exists a configuration that has an nth predecessor but not an $(n+1)$st one. We also solve (one interpretation of) the Unique father problem: there exists a finite stable configuration that contains a finite subpattern that has no predecessor patterns except itself. In particular this gives the first example of an unsynthesizable still life. The new key concept is that of a spatiotemporally periodic configuration (agar) that has a unique chain of preimages; we show that this property is semidecidable, and find examples of such agars using a SAT solver.

Our results about the topological dynamics of Game of Life are as follows: it never reaches its limit set; its dynamics on its limit set is chain-wandering, in particular it is not topologically transitive and does not have dense periodic points; and the spatial dynamics of its limit set is non-sofic, and does not admit a sublinear gluing radius in the cardinal directions (in particular it is not block-gluing). Our computability results are that Game of Life's reachability problem, as well as the language of its limit set, are PSPACE-hard.

1 Introduction

Conway's Game of Life is a famous two-dimensional cellular automaton defined by John Horton Conway in 1970 and popularized by Martin Gardner [14]. A cellular automaton can be thought of as zero-player game: the board is set up, and a simple rule determines the dynamics. In the case of Game of Life, the board is the two-dimensional infinite grid, where some grid cells are *live*, and some are *dead* (or *empty*); the evolution rule, executed simultaneously in all cells, is that a dead cell becomes live if it has exactly three live (cardinal or diagonal) neighbors, and a live cell stays live if and only if it has two or three live neighbors.

Iterating this rule gives rise to very complicated dynamics. Engineering patterns with interesting behaviors, and searching for such patterns by computer, has been an ongoing effort since the invention of the rule. For readers interested in delving into this world, we cite the very recent (and freely available) book [19] of Johnston and Greene. One result that

exemplifies the complexity of Game of Life is that it is *intrinsically universal* [10], meaning that Game of Life can simulate any two-dimensional cellular automaton f (including proper self-simulation), so that the states of f correspond to large blocks with special content, and one step of f is simulated in multiple steps of Game of Life.

Game of Life can be thought of as a mathematical *complex system*, namely it is a system where complex global behavior arises from interacting (simple) local rules. Such systems can be notoriously difficult to study. We can often use computer simulations to make empirical observations about typical and eventual behavior, but it can be very difficult to actually prove that a particular behavior persists on larger scales (even if it seems like its failure would require a massive conspiracy). Usually one can only successfully analyze systems that are very simple [13], or their behavior simulates a phenomenon that is mathematically well-understood, say of an algebraic [8] or number theoretic [20] nature, or the systems are specifically constructed for some purpose [23]. Due to intrinsic universality, it seems unlikely that Game of Life fits in any of these classes.

Indeed, for Game of Life, despite decades of study by enthusiasts, almost no non-trivial mathematical results exist that state limitations on its eventual behavior. In other words, as a dynamical system, we know very little about it. From computer simulations, one can conclude that Game of Life is highly "chaotic", and one can make educated guesses about things like the typical population density after a large number of iterations; however, it is very hard to make such claims rigorous. Rigorous results about Game of Life do exist, but they concern mostly the behavior of Game of Life on nice configurations (the engineering feats discussed above are of this type), and no known pattern behaves predictably in a general context; alternatively, they deal with one-step or static behavior [12].

In this paper, we study Game of Life through its *agars*, which are the Game of Life community's term for spatiotemporally periodic points. More specifically, we observe that a simple algorithm (essentially Wang's partial algorithm from [32]) can be used to find all agars with small enough periodicity parameters that have a unique chain of predecessors. We then study finite patches of these agars, and find some with interesting backwards forcing properties. Namely, these patterns behave deterministically in the (a priori nondeterministic) backwards dynamics of Game of Life. This intuitively allows us to study the "last iterations" of Game of Life (after an unknown number of steps), and leads to a wealth of results about how Game of Life behaves "in the limit".

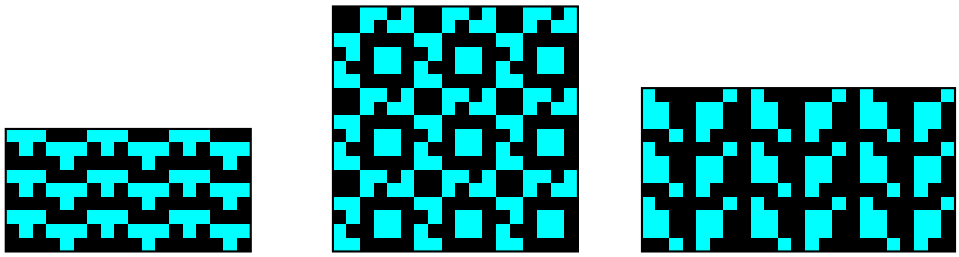
One practical difficulty is that the algorithm we use is not of the usual kind, but rather it is in the class $\mathrm{FP}^{\mathrm{NP}}$ of problems that are solvable in polynomial time with an NP oracle. Throughout this work, modern SAT solvers have constantly impressed and even humbled us by how freely they can be used as such oracles.[1] While their role is not very explicit in the final write-up of the paper, this work would not have been possible without them.

We do not expect the method of studying the eventual dynamics through self-enforcing patterns to be specific to Game of Life. Indeed, one can apply it directly to any cellular automaton rule (with any number of dimensions), and the idea can presumably be adapted to other systems as well. The reason we study a single example cellular automaton is that the results require us to find a "witness", usually a self-enforcing agar, and there is no *a priori* bound on how long this pattern-crunching will take – or whether it will succeed at all – for a particular rule. A single agar also tends to only work for a single rule or trivial

[1] For example, in our experience, general-purpose constraint-solvers and our own CA-specific solvers often fail even on the basic problem of finding a Game of Life preimage, while SAT solvers happily tell us, say, whether a preimage exists with particular constraints, and can find preimages for higher powers of Life.

modifications thereof. The choice of precisely Game of Life as the example rule to study is not mathematically motivated, it is simply a well-known simple rule that has already been studied extensively. Some of our programs are available on GitHub at [30], for readers interested in trying the methods out on other rules.

1.1 The protagonists



(a) Köynnös. **(b)** Kynnös. **(c)** Marching band.

Figure 1 Patches of the agars. A 3-by-3 grid of the repeating patterns is shown for each. Cyan cells are live.

We begin with a brief discussion of the agars that we use to prove our results. These will be explained in more detail in separate sections.

Figure 1a shows the pattern we call köynnös[2]. The infinite agar obtained by repeating this pattern infinitely in each direction has no preimage other than itself; we say it is *self-enforcing*. Up to symmetries there are exactly 11 self-enforcing agars of size 6×3. Köynnös has the special property that it is impossible to stabilize a finite difference to this configuration: if one modifies the agar in finitely many cells, the difference spreads at the speed of light (one column of cells per time step, which is the maximal speed at which information can be transmitted by Game of Life). We say it *cannot be stabilized from the inside*.

Figure 1b shows the pattern we call kynnös[3]. The corresponding infinite agar is again self-enforcing. Up to symmetries there are at least 52 self-enforcing agars of size 6×6 (we were unable to finish the search, so it is possible that more exist). Kynnös has two special properties. First, it contains a finite patch such that if a configuration has this patch in its image, then the configuration already had that patch in place, i.e. one cannot synthesize it from any other patch. Second, unlike köynnös, it can be stabilized from the inside.

Figure 1c shows the pattern we call marching band[4]. This agar has temporal period two. Its most important property is that an infinite south half-plane of this pattern must shrink if there is a difference on its border, meaning that in the nondeterministic inverse dynamics of Game of Life, an infinite south half-plane of this pattern "marches" to the north.

To find the marching band, we searched through all $w \times h$-patterns such that the corresponding agar with periods $(w, 0)$ and $(0, h)$ is temporally (exactly) t-periodic, for the parameter range $2 \leq w \leq 9$, $2 \leq h \leq 5$, $2 \leq t \leq 3$. There were no self-enforcing agars with temporal period 3 in this range, and there were exactly 14 self-enforcing agars with period 2. The marching band is the only one that has the marching property in any direction.

[2] Finnish for vine.
[3] Finnish for that which is tilled.
[4] English for marssiorkesteri.

1.2 Results

Denote by $g : \{0,1\}^{\mathbb{Z}^2} \to \{0,1\}^{\mathbb{Z}^2}$ the Game of Life cellular automaton, where dead cells are represented by 0 and live cells by 1. In this section, we list all our new technical contributions about g. The reader should consult Section 2 for precise definitions of terms used in this section. First, we solve the Generalized grandfather problem: for all $n \geq 0$, there exists a configuration that has an nth predecessor but not an $(n+1)$st one.

▶ **Theorem 1** (Generalized grandfather problem). *For each $n \geq 0$, there exists $x \in \{0,1\}^{\mathbb{Z}^2}$ with $g^{-n}(x) \neq \emptyset$ and $g^{-(n+1)}(x) = \emptyset$.*

The case of $n = 0$ (that g is not surjective) was resolved by R. Banks in 1971, only a year after the introduction of Game of Life. Conway stated the Grandfather problem, namely the case $n = 1$ of the above, in 1972, and promised \$50 in the *Lifeline* newsletter [31] for its solution. This stayed open until 2016, when the cases $n \in \{1, 2, 3\}$ were proved by the user mtve of the ConwayLife forum. We note (see Lemma 16 for the proof) that while Theorem 1 refers to infinite configurations, the analogous statements for finite patterns or finite-population configurations are equivalent to it. Cellular automata satisfying the conclusion of Theorem 1 are sometimes called "unstable" [24], though we avoid this terminology here, as "stable" has another meaning in Game of Life jargon.

More specifically, we prove the following two results, which strengthen Theorem 1 in different directions. The first result is proved using köynnös and is based on the fact it cannot be stabilized from the inside. The notation $g^{-n}(p)$ for a finite pattern p of shape $D \subset \mathbb{Z}^2$ stands for the set of patterns of shape $D + [-n, n]^2$ that evolve into p in n steps.

▶ **Theorem 1.1.** *There exists a polynomial time algorithm that, given $n \geq 0$ in unary, produces a finite pattern p with $g^{-n}(p) \neq \emptyset$ and $g^{-(n+1)}(p) = \emptyset$.*

The algorithm is very simple: change the value of one cell in the agar, apply the Game of Life rule n times, and pick the central $[-30-6n, 30+6n] \times [-27-8n, 27+8n]$-patch of the resulting configuration as p. An example with $n = 28$ is shown in Figure 2 (with insufficient padding: the periodic background should extend 164 cells further to the left and right, and 220 cells up and down).

Figure 2 A "level-29 orphan" obtained by perturbing köynnös: these angry deities could be found 28 seconds after the Big Bang, then went extinct.

The second result is proved using kynnös, and is based on the facts that kynnös admits a self-enforcing patch and that it can be stabilized from the inside. The following was first pointed out by Adam Goucher [16].

▶ **Theorem 1.2.** *For any large enough n, there exists an $n \times n$ pattern which appears in the kth image of Game of Life, but does not appear in its $(k+1)$st image, where $2^{n^2/368-O(n)} \leq k \leq 2^{n^2}$.*

This is (up to a suitable equivalence relation) the optimally slow growth rate for higher level orphans. The same idea can be used to obtain the following results about the limit set of Game of Life. Also called the eventual image, it is the set of configurations with arbitrarily long chains of predecessors. The language of the limit set refers to the set of finite patterns occurring in it.

▶ **Theorem 2.** *The limit set of Game of Life has PSPACE-hard language.*

The language might well be much harder. Even for one-dimensional cellular automata it can be Π_1^0-complete [6, 18]; we do not know if Game of Life reaches this upper bound.

We also obtain information about the symbolic dynamical nature of the limit set. A set of configurations is sofic if it can be defined by Wang tiles, or squares with colored edges: in a valid tiling of $\mathbb{Z}^2$, colors of adjacent edges are required to match, and the tiles can additionally be marked with 0 and 1 to project each valid tiling to a binary configuration. The set of those projections is called a sofic shift. Sofic systems form a large and varied class of subshifts, for example their one-dimensional projections can be essentially arbitrary (subject only to an obvious computability condition) [11, 1]. We show that the limit set of Game of Life cannot be defined by a tile set in this way.

▶ **Theorem 3.** *The limit set of Game of Life is not sofic.*

Besides illuminating the iterated images of Game of Life and its limit set, the self-enforcing kynnös patch itself solves a second open problem, namely the Unique father problem stated by John Conway in [31, 5]: is there a still life (a finite-population configuration that is a fixed point of g) whose only predecessor is itself, "with some fading junk some distance away not being counted"? We solve one interpretation of this problem.

▶ **Theorem 4** (Unique father problem)**.** *There exists a finite still life configuration x that contains a finite subpattern p such that every preimage of x also has subpattern p.*

One can also imagine stronger variants of the Unique father problem: for example, we could require p to contain all live cells of x, or all cells in their convex hull. These stay open.

Theorem 4 also tells us something about the dynamics of Game of Life *restricted to* its limit set, i.e. its limit dynamics. The chain-wandering property essentially means that there is a finite pattern that occurs in the limit set of Game of Life, but never returns to itself under the dynamics no matter how we fill the surrounding infinite plane. In fact, we are even allowed to completely rewrite the entire configuration on every step, apart from the domain of the pattern.

▶ **Theorem 5.** *Game of Life is chain-wandering on its limit set.*

Much is known about the kinds of things that can happen in Game of Life orbits, in particular it is well known that Game of Life is computationally universal and can simulate any cellular automaton. Nevertheless, to our knowledge all existing methods of simulating unbounded computation require the rest of the configuration to be empty (or at least stay out of the way). With our methods, we can enforce computations in a finite region (conditioned on its end state) even when it is completed into an infinite configuration by an adversary.

▶ **Theorem 6.** *The reachability problem of Game of Life is PSPACE-hard, i.e. given two finite patterns $p, q \in \{0,1\}^D$ whose domain D has polynomial extent, it is PSPACE-hard to tell whether there exists a configuration x with $x|D = p$ and $g^n(x)|D = q$ for some $n \geq 0$.*

Finally, the properties of the marching band's backwards dynamics imply that the limit set contains patterns that cannot be "glued" together too close: there are two $n \times n$ patterns such that no configuration of the limit set contains both of them separated by a distance less than $n/15$.

▶ **Theorem 7.** *For all large enough n there exist patterns $p, q \in \{0,1\}^{[0,n-1]^2}$ such that p and q appear in the limit set, but $p \sqcup \sigma_{(0,\lfloor n/15 \rfloor)}(q)$ does not.*

▶ **Corollary 8.** *The limit set of Game of Life is not block-gluing (thus has none of the gluing properties listed in [4]).*

1.3 Programs

Some of the programs we used can be found on GitHub at [30]. We have included Python scripts enumerating self-enforcing agars, and scripts checking the claimed properties of our three agars. In particular one can find implementations of Algorithms 1 and 2. The scripts use the PySAT [28] library to call the Minisat [26] SAT solver (the library supports many other solvers as well).

2 Definitions

Our intervals are discrete. To simplify formulas, we denote by

$$\begin{bmatrix} a & b & c & d \\ e & f & g & h \end{bmatrix} = ([-a, b] \times [-c, d]) \setminus ([-e, f] \times [-g, h])$$

a rectangular discrete annulus when the second rectangle fits fully inside the first, that is, $-a \leq -e \leq f \leq b$ and $-c \leq -g \leq h \leq d$.

We assume some familiarity with topological and symbolic dynamics and give only brief definitions, see e.g. [22] for a basic reference. We denote by S a finite *alphabet*. A *configuration* or *point* is an element of $S^{\mathbb{Z}^d}$. More generally, a *pattern* (or sometimes *patch* in more informal contexts) is a function $p : \mathrm{dom}(p) \to S$, where $\mathrm{dom}(p) \subset \mathbb{Z}^d$ is the *domain* of p. If $S \subset \mathbb{N}$, then by $\sum p$ we denote the sum $\sum_{\vec{v} \in \mathrm{dom}(p)} p(\vec{v})$. For $\vec{v} \in \mathbb{Z}^d$, a pattern p and $D \subset \mathbb{Z}^d$, we write $q = p|D$ for the restriction $\mathrm{dom}(q) = D \cap \mathrm{dom}(p), q(\vec{v}) = p(\vec{v})$. A pattern is *finite* if its domain is, and a configuration is *finite* if its sum as a pattern is finite. If p, q are patterns with disjoint domains, define $p \sqcup q = r$ by $\mathrm{dom}(r) = \mathrm{dom}(p) \cup \mathrm{dom}(q), r|\mathrm{dom}(p) = p, r|\mathrm{dom}(q) = q$. The *extent* of a pattern is the minimal hypercube containing the origin and its domain. For two patterns, write $\mathrm{eq}(q, q')$ for the set of vectors $\vec{v} \in \mathrm{dom}(q) \cap \mathrm{dom}(q')$ such that $q(\vec{v}) = q'(\vec{v})$, and $\mathrm{diff}(q, q')$ for those that satisfy $q(\vec{v}) \neq q'(\vec{v})$. For computer science purposes, we note that patterns with polynomial extent have an efficient encoding as binary strings.

The *full shift* is the set of all configurations $S^{\mathbb{Z}^d}$ with the product topology (where S has the discrete topology), under the action of $\mathbb{Z}^d$ by homeomorphisms $\sigma_{\vec{v}}(x)_{\vec{u}} = x_{\vec{v}+\vec{u}}$ called *shifts*. We use the same formula to define $\sigma_{\vec{v}}(p)$ for patterns p (of course shifting the domain correspondingly). A pattern p defines a *cylinder* $[p] = \{x \in S^{\mathbb{Z}^d} \mid x|\mathrm{dom}(p) = p\}$. Cylinders defined by finite patterns are a base of the topology, and their finite unions are exactly the clopen sets. The *symbol partition* is the clopen partition $\{[s] \mid s \in S\}$ where s is

identified with the pattern $p : \{\vec{0}\} \to S$ with $p(\vec{0}) = s$. The space $S^{\mathbb{Z}^d}$ is homeomorphic to the Cantor space, and is metrizable. One possible metric is $\mathrm{dist} : (S^{\mathbb{Z}^2})^2 \to \mathbb{R}$, $\mathrm{dist}(x, y) = 2^{-\sup\{n \mid x|[-n,n]\times[-n,n]=y|[-n,n]\times[-n,n]\}}$ with $2^{-\infty} = 0$.

A *cellular automaton* (or *CA*) is a continuous self-map $f : S^{\mathbb{Z}^d} \to S^{\mathbb{Z}^d}$ that commutes with the shifts. The *neighborhood* is a set $N \subset \mathbb{Z}^d$ such that $f(x)_{\vec{0}}$ is determined by $x|N$; a finite neighborhood always exists by the Curtis-Hedlund-Lyndon theorem [17]. It is easy to show that there is always a unique *minimal neighborhood* under inclusion. A state $0 \in S$ is *quiescent* if $f(0^{\mathbb{Z}^d}) = 0^{\mathbb{Z}^d}$. A *subshift* is a closed subset X of $S^{\mathbb{Z}^d}$ invariant under shifts. Its *language* is the set of finite patterns p such that $[p] \cap X \neq \emptyset$, and we say these patterns *appear* or *occur* in the subshift. Patterns that do not appear in $f(S^{\mathbb{Z}^d})$ are usually called *orphans*. We say p is a *level-n orphan* if it appears in $f^{n-1}(S^{\mathbb{Z}^d})$ but not in $f^n(S^{\mathbb{Z}^d})$ (so the usual orphans are level-1). The *limit set* of a cellular automaton f is $\Omega(f) = \bigcap_n f^n(S^{\mathbb{Z}^d})$. It is a subshift invariant under f. A *subshift of finite type* is a subshift of the form $\bigcap \sigma_{\vec{v}}(C)$ where C is clopen. A *sofic shift* is a subshift which is the image of a subshift of finite type under a shift-commuting continuous function.

We are mainly interested in $d = 2$, $S = \{0, 1\}$, and the *Game of Life* cellular automaton $g : \{0, 1\}^{\mathbb{Z}^2} \to \{0, 1\}^{\mathbb{Z}^2}$ defined by

$$g(x)_{\vec{v}} = 1 \iff (x_{\vec{v}} = 0 \wedge \sum(x|\vec{v} + K) = 3) \\ \vee(x_{\vec{v}} = 1 \wedge \sum(x|\vec{v} + K) \in \{2, 3\}),$$

where $K = [-1, 1]^2 \setminus \{(0, 0)\}$.

A *fixed point* (of a CA f) is $x \in S^{\mathbb{Z}^d}$ such that $f(x) = x$. In the context of Game of Life these are also called *stable configurations* or *still lifes*. *Spatial* and *temporal* generally refer respectively to the $\mathbb{Z}^d$-action of shifts and the action of a CA. In particular a *spatially periodic point* is a configuration $x \in S^{\mathbb{Z}^d}$ which has a finite orbit under the shift dynamics, and *temporal periodicity* means $f^n(x) = x$ for some $n \geq 1$. Spatiotemporal periodicity means that both hold; in the Game of Life context spatiotemporal points are also called *agars*.

If $f : X \to X$ is a continuous function, an *ϵ-chain from x to y* is $x = x_0, x_1, \ldots, x_k = y$ with $k \geq 1$ such that $\mathrm{dist}(f(x_i), x_{i+1}) < \epsilon$ for $0 \leq i < k$. We say f is *chain-nonwandering* if for all $\epsilon > 0$ and $x \in X$ there is an ϵ-chain from x to itself; otherwise f is *chain-wandering*. (In the literature, chain-nonwandering is more commonly known as chain-recurrence, but both terms are logical.) We say f is *topologically transitive* if for all nonempty open sets U, V we have $f^n(U) \cap V \neq \emptyset$ for some n. It is *sensitive* (to initial conditions) if there exists $\epsilon > 0$ such that for all $x \in X$ and $\delta > 0$ there exists $y \in X$ with $\mathrm{dist}(x, y) < \delta$ and $n \in \mathbb{N}$ such that $\mathrm{dist}(f^n(x), f^n(y)) \geq \epsilon$. We say f has *dense periodic points* if its set of temporally periodic points is dense.

3 Proofs

We begin by introducing a formalism for forced cells in the preimages of a given pattern or configuration. The general topological idea is the following: if we have a zero-dimensional space X and a family of closed sets $\mathcal{I}$ which is closed under arbitrary intersections and contains the empty set, then to any continuous $f : X \to X$ we can associate a map $\hat{f} : \mathcal{I} \to \mathcal{I}$ by

$$\hat{f}(A) = \bigcap\{B \in \mathcal{I} \mid f^{-1}(A) \subset B\}. \tag{1}$$

We call this the *dual map* of f with respect to $\mathcal{I}$.

In our situation, $X = S^{\mathbb{Z}^d}$ and $f : S^{\mathbb{Z}^d} \to S^{\mathbb{Z}^d}$ is a cellular automaton. We define three families of subsets of $S^{\mathbb{Z}^d}$:

- $\mathcal{I}$ consists of the cylinders $[p] \subset S^{\mathbb{Z}^d}$ defined by all patterns p, plus the empty set $\emptyset$, which we denote by $\top$. The entire space $S^{\mathbb{Z}^d}$, which is the cylinder of the empty pattern, is denoted by $\bot$.
- $\mathcal{F} \subset \mathcal{I}$ consists of all cylinders $[p]$ defined by finite patterns p.
- $\mathcal{C} \subset \mathcal{I}$ consists of the singletons $[x] = \{x\}$ for full configurations $x \in S^{\mathbb{Z}^d}$.

Note that $\mathcal{F} \cap \mathcal{C} = \emptyset$. The family $\mathcal{F}$ is naturally stratified into finite subsets $\mathcal{F}_M = \{[p] \mid p \in S^M\}$, where $M \subset \mathbb{Z}^d$ ranges over finite sets. For a cylinder $[p] \in \mathcal{I}$, equation (1) defines $\hat{f}([p]) \in \mathcal{I}$ as the cylinder $[q]$, where q contains exactly those cells whose values are the same in all f-preimages of p, or $\top$ if p has no f-preimages (i.e. is an orphan). Also, $\hat{f}(\top) = \top$.

▶ **Example 9.** Consider $S = \{0, 1, 2\}$ and the cellular automaton $f : S^{\mathbb{Z}} \to S^{\mathbb{Z}}$ defined by

$$f(x)_0 = \begin{cases} 2, & \text{if } x_0 = 2, \\ \min(x_0, x_1), & \text{otherwise.} \end{cases}$$

The minimal neighborhood of f is $N = \{0, 1\}$. The pattern $p = 002$ of domain $\{0, 1, 2\}$ has preimages $f^{-1}(p) = \{0020, 0021, 0022, 1020, 1021, 1022\}$ of domain $\{0, 1, 2, 3\}$. Thus $\hat{f}([p]) = [q]$, where $q = 02$ has domain $\{1, 2\}$, since the values of these cells are the same in all preimages. The pattern $p' = 102$ has no preimages, so $\hat{f}([p']) = \top$.

We define a partial order on $\mathcal{I}$ by $[p] \leq [q]$ whenever $[q] \subset [p]$, and $\alpha \leq \top$ for all $\alpha \in \mathcal{I}$. The intuition is that $[p] \leq [q]$ corresponds to the pattern q specifying more cells than p, and thus containing more information. As the empty set $\top$ in a sense specifies the maximal amount of information – a contradiction – it is the largest element. Note that $\mathcal{C}$ consists of the maximal elements of $\mathcal{I} \setminus \{\top\}$.

We give $\mathcal{I}$ the topology with basis sets $U_p = \{\alpha \in \mathcal{I} \mid [p] \leq \alpha\}$ for $[p] \in \mathcal{F}$ as well as $\{\top\}$, making $\top$ an isolated point. This space is not Hausdorff (T_2), indeed it only satisfies the Kolmogorov (T_0) separation axiom. The induced topology on $\mathcal{C}$ is the standard compact Cantor topology, and $\mathcal{F}$ is a dense subset of $\mathcal{I} \setminus \{\top\}$. Every nonempty open set contains $\top$: "the contradiction is dense".

▶ **Lemma 10.** *The dual map $\hat{f} : \mathcal{I} \to \mathcal{I}$ is continuous.*

We are simply saying that if a (possibly infinite) pattern forces some particular value in some cell in the preimage, then actually some finite patch already forces it. The proof is a straightforward compactness argument.

Proof. Continuity at $\top$ is obvious. We show continuity at a cylinder $[p] \in \mathcal{I}$. Suppose first that $\hat{f}([p]) = [q]$, and let $[r] \in \mathcal{F}$ be such that $[q] \in U_r$. This means that p forces the pattern q in its f-preimages, and r is a finite subpattern of q. There exists a finite subpattern s of p that forces r, for otherwise we could take larger and larger subpatterns of p along with two preimages that disagree on $\mathrm{dom}(r)$, and in the limit obtain two preimages of p that disagree on $\mathrm{dom}(r)$. Hence $\hat{f}(U_s) \subset U_r$.

Suppose then that $\hat{f}([p]) = \top$, meaning that p is an orphan. It is well known that p contains a finite subpattern r that is also an orphan. Then $\hat{f}(U_r) = \{\top\}$. ◀

We list some other easy properties of $\hat{f}$. For $\alpha, \beta \in \mathcal{I}$ write $\alpha \parallel \beta$ for $\alpha \cap \beta \neq \top$. In the case of cylinders, this means that the corresponding patterns agree on the intersection of their domains. For a pattern p, write $f(p)$ for the pattern obtained by applying the local rule

of f (with the minimal neighborhood) in every position whose neighborhood is contained in the domain of p (and only those positions are included in the domain of $f(p)$). Note that with this definition $f([p]) \subset [f(p)]$, and the inclusion may be strict.

▶ **Lemma 11.**

- *$\mathcal{F} \cup \{\top\}$ is preserved under $\hat{f}$. Indeed, we have $\hat{f}(\mathcal{F}_M) \subset \mathcal{F}_{M+N} \cup \{\top\}$ where N is the minimal neighborhood of f.*
- *$\hat{f}$ is monotone, i.e. $\alpha \leq \beta$ implies $\hat{f}(\alpha) \leq \hat{f}(\beta)$.*
- *$\hat{f} \circ \hat{g} \leq \widehat{f \circ g}$ pointwise.*
- *for all $\alpha \in \mathcal{I}$, either $\hat{f}(\alpha) = \top$ or $\hat{f}(\alpha) = [p]$ with $[f(p)] \leq \alpha$; in particular $[f(p)] \parallel \alpha$ in the latter case.*
- *for all $\alpha \in \mathcal{I}$, we have $\hat{f}(\sigma_{\vec{v}}(\alpha)) = \sigma_{\vec{v}}(\hat{f}(\alpha))$.*

The next few results refer to $\mathrm{FP}^{\mathrm{NP}}$, the class of function problems solvable in deterministic polynomial time with the help of an oracle that can solve an NP decision problem in one step. Of course, the oracle can be invoked repeatedly to construct NP certificates in a polynomial number of steps. This class naturally captures the method of using SAT solvers as black boxes to compute preimages of finite patterns.

▶ **Lemma 12.** *For a fixed CA f, given $p \in \mathcal{F}$, the image $\hat{f}([p])$ can be computed in $\mathrm{FP}^{\mathrm{NP}}$. It remains computable if f is also given as input.*

Proof. Since $\hat{f}(\mathcal{F}_M) \subset \mathcal{F}_{M+N}$, we only need to determine which coordinates in $M + N$ are forced in preimages. This requires at most $1 + |M + N|$ calls to an NP oracle: one to request a preimage, and for each $\vec{v} \in M + N$, one to request a pair of preimages which differ at $\vec{v}$. ◀

The proof above is the easiest way to get the theoretical result, but for practical purposes we give Algorithm 1, which tends to find the $\hat{f}$-image much quicker (and is just as quick to implement). It is written for an "incremental oracle", meaning we can only *add* constraints to it (represented by the set F) when we make a new query. In this case, we compute a single f-preimage q of the input pattern p, and then compute additional preimages that differ from q on progressively smaller sets of cells. Modern SAT solvers tend to support such incremental access – of course, on the side of theory it is easy to see that the class $\mathrm{FP}^{\mathrm{NP}}$ is the same whether or not queries are restricted to be incremental.

Algorithm 1 Finding $\hat{f}([p])$ for a finite pattern $p \in S^M$.

```
function HatCA(f, p)
    Let O ← NP oracle.
    if O finds a pattern q ∈ f^{-1}(p) then
        Let D ← M + N.
        Let F ← {(q, D)}.
        loop
            if O finds a pattern q' ∈ f^{-1}(p) with q'|E ≠ r|E for all (r, E) ∈ F then
                Let D ← D ∩ eq(q, q').
                Let F ← F ∪ {(q', D)}
            else
                return q|D
    else
        return ⊤
```

Our results rely on the existence of patterns p that force large patterns into their preimages, meaning that $\hat{f}([p])$ is large in the sense of $\leq$. We say a pattern p is *self-enforcing* under f if $[p] \leq \hat{f}([p])$. In a slight abuse of terminology, we also say that a temporally t-periodic configuration $x \in S^{\mathbb{Z}^d}$ is *self-enforcing* if $\widehat{(f^t)}([x]) = [x]$. A self-enforcing agar is then a spatially and temporally periodic configuration that has a unique chain of preimages.

▶ **Lemma 13.** *The set of all pairs (f, x) such that f is a CA on $S^{\mathbb{Z}^d}$ and $x \in S^{\mathbb{Z}^d}$ is a self-enforcing agar is recursively enumerable.*

Proof. Let $x \in S^{\mathbb{Z}^d}$ be a self-enforcing agar with spatial periods $n_1\vec{e}_1, \ldots, n_d\vec{e}_d$ and temporal period t. Denote the iterated CA by $h = f^t$, and let $B = [0, n_1 - 1] \times \cdots \times [0, n_d - 1]$. We need to find a certificate for $\hat{h}([x]) = [x]$. For this, observe that by continuity of $\hat{h}$ there is a finite subpattern p of x such that $\hat{h}([y]) \geq [x|B]$ for every configuration $y \in [p]$. This implies $\hat{h}([p]) \geq [x|B]$. By Lemma 12, this latter inequality can be checked in $\mathrm{FP}^{\mathrm{NP}}$.

We claim that p is a certificate that x is a self-enforcing agar. Let $\vec{v} \in V = \langle n_1\vec{e}_1, \ldots, n_d\vec{e}_d \rangle$ be arbitrary. We compute

$$\hat{h}([x]) = \sigma_{\vec{v}}(\hat{h}([x])) \geq \sigma_{\vec{v}}(\hat{h}([p])) \geq \sigma_{\vec{v}}([x|B]) = [x|\vec{v} + B],$$

and since $\mathbb{Z}^d = \bigcup_{\vec{v} \in V}(\vec{v} + B)$, this implies $\hat{h}([x]) = [x]$. ◀

▶ Remark 14. The semi-algorithm described in the proof is not very practical: given an agar, we have no information about how large the certificate could be, so for each agar we either need to guess some certificate size, or we have to keep trying increasingly large certificates. Our implementation runs in parallel a search for other periodic preimages for the agar – if such a preimage exists, then clearly the agar does not enforce itself, and we can stop looking for a certificate. We omit the pseudocode.

Most agars in the range we searched were either self-enforcing or had another periodic preimage. There exist two-dimensional cellular automata whose set of self-enforcing agars is not computable (by a relatively simple reduction from the tiling problem of Wang tiles [2], which we omit), but we do not know whether this is the case for Game of Life.

Say a pattern $p \subset S^M$ is *locally fixed* for the CA f if there exists a pattern $q \in S^{M+N}$ (where N is the minimal neighborhood of f) such that $p = q|M = f(q)|M$.

▶ **Lemma 15.** *For every CA f on $S^{\mathbb{Z}^d}$, every locally fixed pattern $p \in S^M$ admits a unique maximal self-enforcing subpattern. For a fixed CA g, given p, a vector $\vec{v} \in \mathbb{Z}^d$ and $n \geq 1$ in unary, it can be computed in $\mathrm{FP}^{\mathrm{NP}}$ for the CA $f = \sigma_{\vec{v}} \circ g^n$.*

Proof. Since p has finitely many subpatterns and the empty pattern is trivially self-enforcing, p admits at least one maximal self-enforcing subpattern. If $D, D' \subset M$ satisfy $\hat{f}([p|D]) \geq [p|D]$ and $\hat{f}([p|D']) \geq [p|D']$, then $\hat{f}([p|D \cup D']) \geq [p|D \cup D']$ by monotonicity of $\hat{f}$. Thus $q = p|E$ for $E = \bigcup\{D \subset M \mid \hat{f}([p|D]) \geq [p|D]\}$ is the unique self-enforcing subpattern.

Then fix g, and let p, $\vec{v}$ and n be given. We apply Algorithm 2 to the CA $f = \sigma_{\vec{v}} \circ g^n$. On each iteration of the loop, the algorithm replaces p with the maximal subpattern forced by p (here we use the fact that p is locally fixed). Since q is a subpattern forced by itself, by monotonicity it is also forced by each of these subpatterns, and thus remains a subpattern on each iteration. Since q is maximal and p has finitely many subpatterns, the algorithm eventually converges on q.

Finally, Algorithm 2 is in $\mathrm{FP}^{\mathrm{NP}}$, since the number of iterations of the loop is at most $|M|$, and $\textsc{HatCA}(f, p)$ is in $\mathrm{FP}^{\mathrm{NP}}$ with respect to these parameters. ◀

Algorithm 2 Finding the maximal self-enforcing subpattern of a locally fixed pattern $p \in S^M$.

```
function SelfEnforcingSubpattern(p)
    loop
        Let q ← HatCA(f, p)|M.
        if q = p then
            return q
        else
            Let p ← q.
```

To conclude this section, we show that in the formulation of the Generalized grandfather problem (which we prove as Theorem 1), it makes no difference whether we consider unrestricted configurations, finite configurations or finite patterns. This is well-known in cellular automata theory.

▶ **Lemma 16.** *Let $f : S^{\mathbb{Z}^d} \to S^{\mathbb{Z}^d}$ be a cellular automaton with a quiescent state $0 \in S$, and $n \in \mathbb{N}$. The following are equivalent:*

1. *There exists a finite configuration $x \in S^{\mathbb{Z}^d}$ such that $f^{-n}(x)$ contains a finite configuration, and $f^{-(n+1)}(x) = \emptyset$.*
2. *There exists $x \in S^{\mathbb{Z}^d}$ such that $f^{-n}(x) \neq \emptyset$ and $f^{-(n+1)}(x) = \emptyset$.*
3. *There exists a finite pattern p such that $f^{-n}(p) \neq \emptyset$ and $f^{-(n+1)}(p) = \emptyset$.*

Proof. The implication 1 $\implies$ 2 is clear, and 2 $\implies$ 3 is the classical compactness argument that we used to prove Lemma 10.

We prove 3 $\implies$ 1. Take an arbitrary $q \in f^{-n}(p)$, and complete it into a finite configuration $y \in S^{\mathbb{Z}^d}$ by setting $y_{\vec{v}} = 0$ for all $\vec{v} \in \mathbb{Z}^d \setminus \mathrm{dom}(q)$. Then $x = f^n(y)$ satisfies the conditions of item 1: $f^{-n}(x)$ contains the finite configuration y, while $f^{-(n+1)}(x) = \emptyset$ since x contains an occurrence of p. ◀

3.1 Köynnös

We begin by studying köynnös, which we recall is obtained from the 6×3 pattern

$$P = \begin{matrix} 1 & 1 & 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 1 & 1 & 1 \\ 0 & 0 & 0 & 0 & 1 & 0 \end{matrix}$$

by repeating P horizontally and vertically to define an infinite 6×3-periodic configuration $x^P \in \{0,1\}^{\mathbb{Z}^2}$. Observe that every 0 in x^P is surrounded by exactly four 1s, and every 1 by exactly three 1s. Thus we have $g(x^P) = x^P$, so that x^P is indeed an agar. Moreover, we claim that x^P has no other predecessors than itself: $g^{-1}(x^P) = \{x^P\}$. This is due to the following lemma.

▶ **Lemma 17.** *Let x be in the spatial orbit of köynnös. Then $\hat{g}(x|[-12,17] \times [-12,14]) \geq x|[-8,13] \times [-9,10]$.*

Proof. Applying Algorithm 1 to $\sigma_{\vec{v}}(x^P)|[-12,17] \times [-12,14]$ for all $\vec{v} \in [0,5] \times [0,2]$ gives the result. The intersection of the domains of the patterns $\hat{g}(x|[-12,17] \times [-12,14])$ for such $x = \sigma_{\vec{v}}(x^P)$ is shown in Figure 3, and clearly contains the rectangle $[-8,13] \times [-9,10]$. ◀

Put concretely, the lemma states that if R is a periodic continuation of P of size 30×27 and Q is its predecessor, then P must occur at the center of Q (and indeed many more cells are forced, even beyond what we state in the lemma). This is indeed a certificate for x^P

being a self-enforcing agar, as in the proof of Lemma 13: for any predecessor $y \in g^{-1}(x^P)$ and cell $\vec{v} \in \mathbb{Z}^d$, Lemma 17 gives $\sigma_{\vec{v}}(y)|[-8,13] \times [-9,10] = \sigma_{\vec{v}}(x^P)|[-8,13] \times [-9,10]$, so in particular $y_{\vec{v}} = x^P_{\vec{v}}$.

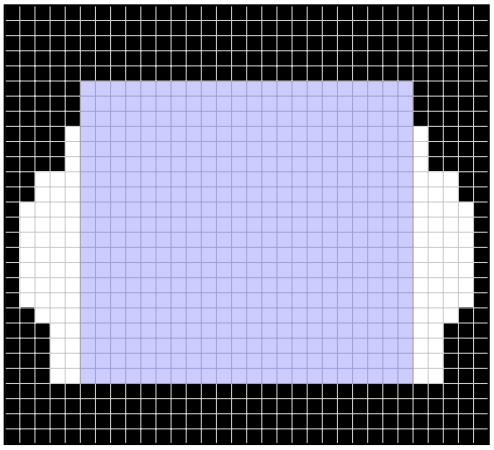


Figure 3 The intersection of the domains of $\hat{g}(x|[-12,17] \times [-12,14])$ for x in the spatial orbit of köynnös, drawn in white inside $[-13,18] \times [-13,15]$. The area $[-8,13] \times [-9,10]$ is highlighted in blue.

As a corollary of Lemma 17, finite perturbations of x^P can never be erased by g. We prove a stronger claim: all finite perturbations spread to the left and right at a speed of one column per time step. In particular, köynnös cannot be stabilized from the inside. We note that, as the agar kynnös studied in the next section does not possess this property, we cannot use it to prove Theorem 1.1, at least with the same method.

▶ **Lemma 18.** *Consider a rectangle $R = [-n_W, n_E] \times [-n_S, n_N]$ and the surrounding annulus $A = \left[\begin{smallmatrix} n_W+1 & n_E+1 & n_S+1 & n_N+1 \\ n_W & n_E & n_S & n_N \end{smallmatrix}\right]$ of thickness 1. Let p be a pattern such that the domain of $g(p)$ contains $A \cup R$, and suppose $p|A = g(p)|A = x^P|A$. If $\mathrm{diff}(x^P, g(p)) \cap R \subset [a,b] \times \mathbb{Z}$, then $\mathrm{diff}(x^P, p) \cap R \subset [a+1, b-1] \times \mathbb{Z}$.*

Note that we may have $b - a \leq 1$, in which case the conclusion becomes $\mathrm{diff}(x^P, p) \cap R = \emptyset$, or equivalently, $x^P|R = p|R$.

Proof. Since the orbit of köynnös and g are left-right symmetric, it is enough to prove that $\mathrm{diff}(x^P, p) \cap R \subset (-\infty, b-1]$. We prove the contrapositive: suppose there exists $(i,j) \in \mathrm{diff}(x^P, p) \cap R$ for some $i \geq b$, and let i be maximal. We split into cases based on the congruence class of i modulo 6, that is, the column of P that i lies in. Note that the bottom left cell of P is at the origin in x^P, and the domain of P is the rectangle $[0,5] \times [0,2]$. If $i \in \{0,2,3\} + 6\mathbb{Z}$, we choose j as maximal, and otherwise we choose it as minimal.

We handle the case $i \in 2 + 6\mathbb{Z}$, the others being similar or easier. If $j \in 3\mathbb{Z}$, then $p_{(i+1,j+1)} = x^P_{(i+1,j+1)} = 1$ has four other 1s in its neighborhood, and becomes 0 in $g(p)$. If $j \in 1 + 3\mathbb{Z}$, then $p_{(i+1,j)} = x^P_{(i+1,j+1)} = 1$ has four or five other 1s in its neighborhood, and becomes 0 in $g(p)$. If $j \in 2 + 3\mathbb{Z}$, then $p_{(i+1,j+1)} = x^P_{(i+1,j+1)} = 0$ has three 1s in its neighborhood, and becomes 1 in $g(p)$. In each case $\mathrm{diff}(x^P, g(p))$ intersects $\{i+1\} \times \mathbb{Z}$. ◀

For any $D \subset \mathbb{Z}^2$, the subpattern of köynnös of shape $D + [0,29] \times [0,26]$ forces the subpattern of shape $D + [4,25] \times [3,22]$ to occur in its g-preimage, by Lemma 17. By Lemma 18, we force more: a non-köynnös area inside a hollow patch of köynnös expands horizontally under g, so under $\hat{g}$ the horizontal extent of the hole must shrink. We do not give a precise statement for this general fact, and only apply the lemma in the case of annuli.

▶ **Lemma 19.** *Let x be in the orbit of köynnös. Suppose the following inequalities hold:*

$$m_W - n_W \geq 30, m_E - n_E \geq 30, m_S - n_S \geq 27, m_N - n_N \geq 27.$$

Denote $Q = x|\left[\begin{smallmatrix} m_W & m_E & m_S & m_N \\ n_W & n_E & n_S & n_N \end{smallmatrix}\right]$. If $n_E + n_W \geq 2$, then

$$\hat{g}(Q) \geq x|\begin{bmatrix} m_W - 4 & m_E - 4 & m_S - 3 & m_N - 4 \\ n_W - 1 & n_E - 1 & n_S + 4 & n_N + 3 \end{bmatrix}$$

while if $n_E + n_W \in \{0, 1\}$ we have

$$\hat{g}(Q) \geq x|[-(m_W - 4), m_E - 4] \times [-(m_S - 3), m_N - 4]$$

One may consider the latter case a special case of the former: there too, the hole shrinks horizontally by two steps, and since its width is at most two it disappears.

Proof. The inequalities simply state that the annulus Q is thick enough that each of its cells is part of a 30×27 rectangle contained in Q. From Lemma 17, we get $\hat{g}(Q) \geq x|A$, where $A = \left[\begin{smallmatrix} m_W - 4 & m_E - 4 & m_S - 3 & m_N - 4 \\ n_W + 4 & n_E + 4 & n_S + 4 & n_N + 3 \end{smallmatrix}\right]$ is a slightly thinner annulus. If there is no g-preimage for Q, then $\hat{g}(Q) = \top$ and we are done. Suppose then that it has a preimage R. Since $R \geq \hat{g}(Q) \geq x|A$, both Q and R agree with x on the thickness-1 annulus $\left[\begin{smallmatrix} n_W + 5 & n_E + 5 & n_S + 5 & n_N + 4 \\ n_W + 4 & n_E + 4 & n_S + 4 & n_N + 3 \end{smallmatrix}\right] \subset A$. Lemma 18 implies that R agrees with x on $\left[\begin{smallmatrix} m_W - 4 & m_E - 4 & m_S - 3 & m_N - 4 \\ n_W - 1 & n_E - 1 & n_S + 4 & n_N + 3 \end{smallmatrix}\right]$, as claimed. ◀

We now prove Theorem 1.1, and thus give the first proof of Theorem 1. In fact, we give a simple formula that produces configurations that have an nth preimage, but no $(n+1)$st one.

▶ **Lemma 20.** *Let x be in the orbit of köynnös, and suppose $\emptyset \neq \operatorname{diff}(y, x) \subset B = [0, a] \times [0, n]$ where $a \in \{0, 1\}$. Then*

$$p = g^k(y)|[-30 - 6k, 30 + a + 6k] \times [-27 - 8k, 27 + n + 8k]$$

appears in the kth image of g, but not in the $(k+1)$st.

Proof. By definition, p appears in the kth image of g. It suffices to show its $\hat{g}^{k+1}$-image is $\top$. Namely, we then have $\widehat{g^{k+1}}(p) \geq \hat{g}^{k+1}(p) = \top$ by Lemma 11, which means precisely that p has no g^{k+1}-preimage.

Let q be the restriction of p to

$$\begin{bmatrix} 30 + 6k & 30 + a + 6k & 27 + 8k & 27 + n + 8k \\ k & a + k & k & n + k \end{bmatrix}.$$

Observe that q agrees with x because g has radius 1, so by Lemma 19 and induction, we can deduce that

$$\hat{g}^j(q) \geq x|\begin{bmatrix} 30 + 6k - 4j & 30 + a + 6k - 4j & 27 + 8k - 3j & 27 + n + 8k - 4j \\ k - j & a + k - j & k + 4j & n + k + 3j \end{bmatrix}$$

for all $j \leq k$. This is because for $j \leq k - 1$ we have

$$\begin{aligned} 30 + 6k - 4j - (k - j) &\geq 30, & 30 + a + 6k - 4j - (a + k - j) &\geq 30, \\ 27 + 8k - 3j - (k + 4j) &\geq 27, & 27 + n + 8k - 4j - (n + k + 3j) &\geq 27, \end{aligned}$$

and thus we can inductively apply the lemma. But in

$$\hat{g}^k(q) \geq x|\begin{bmatrix} 30 + 2k & 30 + a + 2k & 27 + 5k & 27 + n + 4k \\ 0 & a & 5k & n + 4k \end{bmatrix}$$

the annulus still has sufficient thickness (i.e. the inequalities still hold for $j = k$), so we can apply the second case of the lemma to get

$$\hat{g}^{k+1}(q) \geq x|[-(26+2k), 26+2k] \times [-(24+5k), 23+n+4k] = r.$$

By Lemma 11 we have $\hat{g}^{k+1}(p) \geq \hat{g}^{k+1}(q) \geq r$, and by the same lemma we either have $\hat{g}^{k+1}(p) = \top$ (as desired), or

$$g^{k+1}(\hat{g}^{k+1}(p)) \leq g^{k+1}(\widehat{g^{k+1}}(p)) \parallel p.$$

But since the speed of light is 1 and x is a fixed point, we have

$$g^{k+1}(r) \geq x|[-(25+k), 25+k] \times [-(23+4k), 22+n+3k] \geq x|[-k, a+k] \times [-k, n+k]$$

and $x|[-k, a+k] \times [-k, n+k] \parallel p$. But Lemma 18 applied k times to y implies that $\mathrm{diff}(x, g^k(y))$, and thus $\mathrm{diff}(x, p)$, intersects $[-k, a+k] \times [-k, n+k]$, a contradiction. Thus we indeed must have $\hat{g}^{k+1}(p) = \top$. ◀

3.2 Kynnös

Denote by

$$Q = \begin{array}{cccccc} 0 & 0 & 1 & 1 & 0 & 1 \\ 0 & 0 & 1 & 0 & 1 & 1 \\ 1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 1 & 1 & 0 \\ 1 & 0 & 0 & 1 & 1 & 0 \\ 1 & 1 & 0 & 0 & 0 & 0 \end{array}$$

the fundamental domain of kynnös, and by $x^Q \in \{0,1\}^{\mathbb{Z}^2}$ the associated 6×6-periodic configuration with $g(x^Q) = x^Q$. The following lemma states that it contains a self-enforcing patch (it is essentially a more precise stement of Theorem 4).

▶ **Lemma 21.** *There is a finite set $D \subset \mathbb{Z}^2$ such that $p = x^Q|D$ satisfies $\hat{g}(p) = p$. Furthermore, there is a finite-support configuration $x \in [p]$ with $g(x) = x$.*

The patch p is shaped like a 22×28 rectangle with 8 cells missing from each corner. It is depicted in Figure 4, together with the still life x containing it. The patch was found by simply applying the function of Algorithm 2 to the 70×70-patches of the agars we found during our searches. Kynnös was the first configuration that yielded a nonempty self-enforcing patch, which we then optimized to its current size. This lemma directly implies Theorem 4, and almost directly Theorem 5.

Proof of Theorem 5. Let y be the finite-support configuration obtained by taking x from the previous lemma and adding a glider that is just about to hit the kynnös patch. It can be checked by simulation that the patch can be annihilated this way. Observe that y is in the limit set $\Omega(g)$: simply shoot the glider from infinity. If $\epsilon > 0$ is very small, in any ϵ-chain starting from y we see the patch destroyed. It is impossible to reinstate it, as the existence of a first step in the chain where it appears again contradicts Lemma 21. ◀

As stated, kynnös can be stabilized from both inside and outside. Figure 5 shows a still life configuration containing a "ring" of kynnös with a hole of 0-cells inside it. From the figure it is easy to deduce the existence of such rings of arbitrary size and thickness.

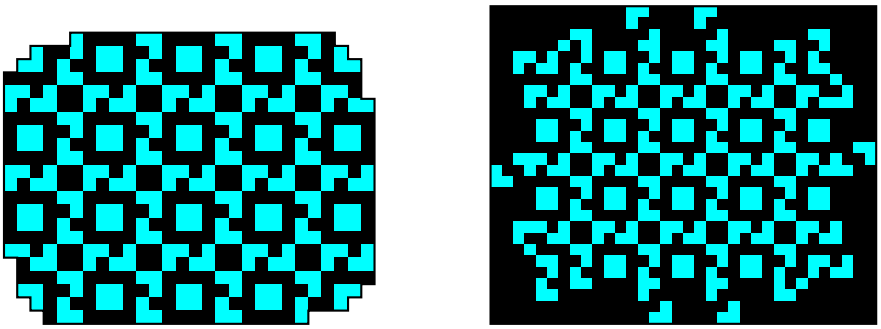

Figure 4 A self-enforcing patch of kynnös and a still life containing it. The still life has the minimal number of live cells, 306, of any still life containing the patch. The number was minimized by Oscar Cunningham. [7]

Note that if the ring is at least 22 cells thick, then its interior is completely surrounded by a ring-shaped self-enforcing pattern consisting of translated, rotated and partially overlapping copies of the 28×22 self-enforcing patch, through which no information can pass without destroying it forever. If we then replace the empty cells inside the ring with an arbitrary pattern, the resulting finite pattern P occurs in the limit set $\Omega(g)$ if and only if the interior pattern evolves periodically under g. Namely, if the pattern occurs in $\Omega(g)$, then it has an infinite sequence of preimages, each of which must contain the self-enforcing kynnös ring. The interior has a finite number of possible contents (2^m for an interior of m cells), so it must evolve into a periodic cycle, of which P is part. From this idea, and some engineering with gadgets found by other researchers and Life enthusiasts, we will obtain Theorems 1.2, 2 and 3. The first one was essentially proved by Adam Goucher [16]. Note the difference between these rings and the köynnös annuli of Section 3.1: the latter force strictly smaller versions of themselves in their preimages, and do not admit nontrivial periodically evolving interiors.

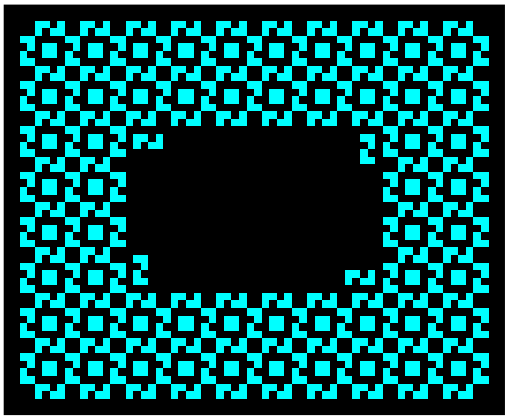

Figure 5 A stable ring of kynnös.

Proof of Theorem 1.2. Given integers $k, m \geq 1$ with k odd, we construct a configuration $x \in \{0,1\}^{\mathbb{Z}^2}$ such that the support of $g^n(x)$ is contained in $[0, 32k+73] \times [0, 46m]$ for all $n \geq 0$, and $g^{48 \cdot 4^{(2k+1)m}}(x)$ is not g-periodic. When the support of $g^{48 \cdot 4^{(2k+1)m}}(x)$ is surrounded by a kynnös ring of width 22, the resulting pattern has a $48 \cdot 4^{(2k+1)m}$th preimage, but not arbitrarily old preimages. If we choose $k = 23s$ and $m = 16s$ for some $s \geq 0$, the resulting

pattern has size $(736s + O(1)) \times (736s + O(1))$, and the chain of preimages has length $48 \cdot 4^{736s^2+16s}$. Choosing $s = n/736 - O(1)$ yields the lower bound, and the upper bound is the trivial one (even ignoring the fact we do not modify the boundaries).

The main components of x are the *period-48 glider gun* [27], which produces one glider every 48 time steps, and the *quadri-snark* [29], which emits one glider at a 90 degree angle for every 4 gliders it receives. The support of x consists of a single period-48 gun aimed at a sequence of $(2k+1)m$ quadri-snarks, each of which receives the gliders the previous one emits. They effectively implement a quaternary counter with values in $[0, 4^{(2k+1)m} - 1]$. The glider emitted by the final quasi-snark will collide with the kynnös ring, ensuring that the pattern right before the impact does not occur in the limit set $\Omega(g)$, but has a chain of preimages of length at least $48 \cdot 4^{(2k+1)m}$. An example pattern and a schematic for $m = n = 2$ are given in Figure 6. It is easy to extrapolate to arbitrary $m, n \geq 1$ from the figure. ◀

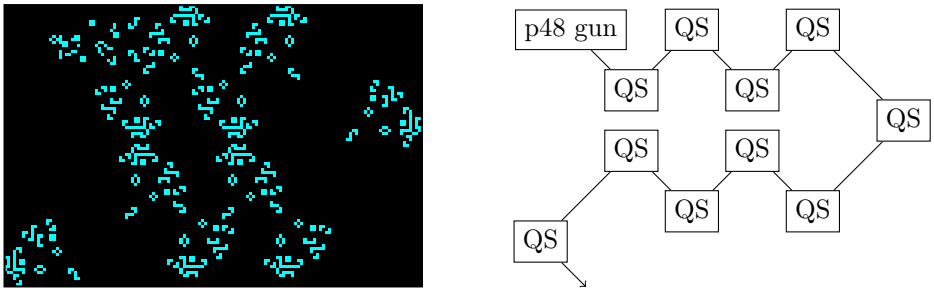

Figure 6 A configuration corresponding to $k = m = 2$ in the proof of Theorem 1.2.

To implement more complex Life patterns with desired properties, we use the fact that Life is *intrinsically universal*, that is, capable of simulating all $\mathbb{Z}^2$ cellular automata. Formally, for any other CA $f : \Sigma^{\mathbb{Z}^2} \to \Sigma^{\mathbb{Z}^2}$, there are numbers $K, T \geq 1$ and an injective function $\tau : \Sigma \to \{0,1\}^{K \times K}$ such that for all configurations $x \in \Sigma^{\mathbb{Z}^2}$ we have $g^T(\tau(x)) = \tau(f(x))$, where τ is applied cellwise in the natural way. We use the simulation technique of [10], which allow us to easily simulate patterns with *fixed boundary conditions*. This means that any rectangular pattern $R \in \Sigma^{a \times b}$ can be simulated by a finite-support configuration of g in such a way that simulated cells whose f-neighborhood is not completely contained in the rectangle $[0, a-1] \times [0, b-1]$ are forced to retain their value.

Proof of Theorem 2. Let $L \subset \{0,1\}^*$ be a PSPACE-hard language decidable in linear space, such as TQBF. Define a Turing machine M as follows. Given input $w \in \{0,1\}^*$, M determines whether $w \in L$ using at most $|w|$ additional tape cells and without modifying w. If $w \in L$, then it erases the additional tape cells and returns to its initial state, thus looping forever. If $w \notin L$, then M stays in a rejecting state forever. We simulate M by a cellular automaton f in a standard way: each cell is either empty, or contains a tape symbol and possibly the state of the computation head.

Next, we simulate the CA f by g as described above. Given a word $w \in \{0,1\}^*$, let $P(w)$ be the pattern corresponding to a simulated initial configuration of M on input w with $|w|$ additional tape cells and fixed boundary conditions, surrounded by a kynnös ring. If $w \in L$, then $P(w)$ occurs in the limit set $\Omega(g)$, since it can be completed into a g-periodic configuration in which the simulated M repeatedly computes $w \in L$. If $w \notin L$, then $P(w)$ does not occur in $\Omega(g)$, since the interior of the ring eventually evolves into a simulated configuration with M in a rejecting state, never returning to $P(w)$. ◀

Extending $P(w)$ by zeroes on all sides (resp. repeating it periodically), we obtain that it is PSPACE-hard whether a given finite-support configuration (resp. periodic configuration) appears in the limit set.

Proof of Theorem 6. Let L be as in the previous proof, and let M be a Turing machine that, on input $w \in \{0,1\}^*$, decides $w \in L$ using no additional tape cells. Then M erases the entire tape and enters an accepting or rejecting state depending on the result of the computation. We simulate M by g as in the previous proof. Given $w \in \{0,1\}^*$, let p be the pattern corresponding to a tape of M containing w and an initial state, and q the one corresponding to $|w|$ blank tape cells and an accepting state of M, both surrounded by a ring of kynnös of the same dimensions. Then q is reachable from p if and only if $w \in L$: if q is to be reached, the ring of p must stay intact, enclosing a correct simulation of M. ◀

Of course, again by extending the resulting patterns by 0-cells (resp. repeating them periodically), we obtain PSPACE-hardness of reachability between two given finite-support (resp. periodic) configurations, i.e. given the full descriptions of two configurations $x, y \in \{0,1\}^{\mathbb{Z}^2}$, the question of whether $g^n(x) = y$ for some $n \geq 0$. However, this reachability problem is in fact even Σ_1^0-complete (resp. PSPACE-complete) directly by intrinsic universality. For the case of finite configurations, one needs a variant of intrinsic universality where the zero state of an arbitrary cellular automaton is represented by an all-zero pattern; such a variant was proved in [15].

Proof of Theorem 3. Let M be a two-dimensional Turing machine whose tape alphabet has two distinguished values, denoted a and b. When M is initialized on a rectangular tape containing only as and bs, it repeatedly checks whether its left and right halves are equal, destroying the tape if they are not. We again simulate M by a CA f, and then f by g. Then a simulated rectangular tape with the head of M in its initial state, surrounded by a kynnös ring, is in $\Omega(g)$ if and only if the two halves of the tape are equal.

It was proved in [21] that for all sofic shifts $X \subset S^{\mathbb{Z}^2}$ there exists an integer $C > 1$ with the following property. For all $n \geq 1$ and configurations $x^1, \dots, x^{C^n} \in X$, there exist $i \neq j$ such that the configuration $y = (x^i|[0,n-1]^2) \sqcup (x^j|\mathbb{Z}^2 \setminus [0,n-1]^2)$ is in X. Assuming for a contradiction that $\Omega(g)$ is sofic, consider the configurations $x(P) \in \Omega(g)$ for $P \in \{a,b\}^{n \times n}$ that contain a kynnös ring and a simulated tape of M with two identical P-halves. Based on the above, when n is large enough that $2^{n^2} > C^{Kn}$, we can swap the right half of one $x(P)$ with that of another to obtain a configuration $y \in \Omega(g)$ containing a simulated tape of M with unequal halves inside a kynnös ring, a contradiction. ◀

We remark that a weaker version of Theorem 1.2 (where 1/368 is replaced by a much smaller, or even implicit, constant) could also be proved by intrinsic universality.

3.3 The marching band

Let $h = g^2$. Denote by

$$R = \begin{matrix} 1 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 1 & 1 & 0 & 0 & 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 & 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 & 1 & 0 & 0 & 0 \end{matrix}$$

the fundamental domain of the marching band, and by $x^R \in \{0,1\}^{\mathbb{Z}^2}$ the associated 8×4-periodic configuration with $h(x^R) = x^R$. The following is proved just like Lemma 17. Note that the forced region extends outside the original pattern.

▶ **Lemma 22.** *Let x be in the spatial orbit of the marching band. Then $\hat{h}(x|[0,47]\times[0,43]) \geq x|[10,29]\times[-1,44]$.*

Proof of Theorem 7. Let x be in the orbit of x^R, and let $p = x|[-a,b]\times[-c,d]$. By the previous lemma, as long as $a+b \geq 48$ and $c+d \geq 44$ we have $\hat{h}(p) = x|[-(a-10),b-18]\times[-(c+1),d+1]$. Iterating this we get

$$\hat{h}^n(x|[-10n,18n+47]\times[0,43]) \geq x|[0,47]\times[-n,n+43].$$

Denote $S = [-10n,18n+47]\times[0,43]$. Let $P = x|S$ and $Q = \sigma_{\vec{u}}(x)|\vec{v}+S$ for some $\vec{u}\in\mathbb{Z}^2$ and $\vec{v} = (0,2n)$. Both patterns appear in the limit set of g, since they are extracted from a fixed point of $h = g^2$. Observe that since the domains of $\hat{h}^n(P)$ and $\hat{h}^n(Q)$ intersect, we can pick the shift $\vec{u}$ so that one of the forced bits is different in some position in $\hat{h}^n(P)$ and $\hat{h}^n(Q)$, which clearly means $\hat{h}^n(P\sqcup Q) = \top$.

Now, P and Q each fit inside a $29n\times 29n$ rectangle (if $n\geq 47$), and the patterns cannot be glued in the limit set with gluing distance at most $2n$, since the glued pattern should have an nth h-preimage. This gives the statement. ◀

4 Chaotic conclusions

There are several definitions of topological chaos. We refer the reader to [3] for a survey. Briefly, a system is called Auslander-Yorke chaotic if it is topologically transitive and is sensitive to initial conditions, and Devaney chaotic if it is Auslander-Yorke chaotic and additionally has dense periodic points. As far as we know, before our results it was open whether Game of Life exhibits these types of chaos on its limit set; the following corollary shows that it does not.

▶ **Theorem 23.** *The Game of Life restricted to its limit set is not topologically transitive, and does not have dense periodic points.*

Proof. Either of these properties clearly implies chain-nonwanderingness, contradicting Theorem 5. ◀

Two other standard notions of chaos are Li-Yorke chaos and positive entropy (we omit the definitions). Game of Life exhibits these trivially, since it admits a glider. More generally, intrinsic universality implies that it exhibits any property of spatiotemporal dynamics of cellular automata that is inherited from subsystems of finite-index subactions of the spacetime subshift. Sensitivity in itself is also sometimes considered a notion of chaos. This remains wide open.

▶ **Question 1.** *Is Game of Life sensitive to initial conditions?*

One can also ask about chaos on "typical configurations". For example, take the uniform Bernoulli measure (or some other distribution) as the starting point, and consider the trajectories of random configurations. We can say essentially nothing about this setting.

In our topological dynamical context, a natural way to formalize this problem is through the *generic limit set* as defined in [25]. It is a subset of the phase space of a dynamical system that captures the asymptotic behavior of topologically large subsets of the space. We omit the exact definition, but for a cellular automaton f, this is a nonempty subshift invariant under f [9]. It follows that the generic limit set is contained in the limit set, and that the language of the generic limit set of g contains the letter 0 (because the singleton subshift $\{1^{\mathbb{Z}^2}\}$ is not g-invariant).

We say a cellular automaton f on $S^{\mathbb{Z}^d}$ is *generically nilpotent* if its generic limit set contains only one configuration, which must then be the all-s configuration for a quiescent state $s \in S$. This is equivalent to the condition that every finite pattern can be extended into some larger pattern p such that for large enough $n \in \mathbb{N}$, we have $f^n(x)_{\vec{0}} = s$ for all $x \in [p]$. By the previous observation, if Game of Life were generically nilpotent, we would have $s = 0$. We strongly suspect that it is not generically nilpotent, i.e. the symbol 1 occurs in the generic limit set. However, we have been unable to show this.

▶ **Question 2.** *Is Game of Life generically nilpotent?*

Chaos is usually discussed for one-dimensional dynamical system, but we find its standard ingredients, such as topological transitivity and periodic points, quite interesting. We have been unable to resolve most of these.

▶ **Question 3.** *Is the limit set of Game of Life topologically transitive as a subshift?*

▶ **Question 4.** *Does the limit set of Game of Life have dense totally periodic points as a subshift?*

Abstract

We develop a (co)algebraic framework to study a family of process calculi with monadic branching structures and recursion operators. Our framework features a uniform semantics of process terms and a complete axiomatisation of semantic equivalence. We show that there are uniformly defined fragments of our calculi that capture well-known examples from the literature like regular expressions modulo bisimilarity and guarded Kleene algebra with tests. We also derive new calculi for probabilistic and convex processes with an analogue of Kleene star.

1 Introduction

The theory of processes has a long tradition, notably in the study of concurrency, pioneered by seminal works of Milner [30, 29] and many others [2]. In labelled transition systems, a popular model of computation in process theory, processes branch nondeterministically. This means that any given action or observation transitions a starting state into any member of a predetermined set of states. In Milner's CCS [29], nondeterminism appears as a binary operation that constructs from a pair of programs e and f the program $e + f$ that nondeterministically chooses between executing either e or f. This acts precisely like the join operation in a semilattice. In fact, elements of a free semilattice are exactly sets, as the free semilattice generated by a collection X is the set $\mathcal{P}^+_\omega X$ of finite nonempty subsets of X [26]. This is our first example of a more general phenomenon: the type of branching in models of process calculi can often be captured with an algebraic theory.

A second example appears in the probabilistic process algebra literature, where the process denoted $e +_p f$ flips a weighted coin and runs e with probability p and f with probability $1 - p$. The properties of $+_p$ are axiomatised and studied in convex algebra, an often revisited algebraic theory of probability [1, 47, 35, 46]. The free convex algebra on a set X is the set $\mathcal{D}_\omega X$ of finitely supported probability distributions on X [46, 11, 23].

A third example is guarded Kleene algebra with tests (GKAT), where the process $e +_b f$ proceeds with e if a certain Boolean predicate b holds and otherwise proceeds with f, emulating the `if-then-else` constructs of imperative programming languages [27, 8, 28]. If the predicates are taken from a finite Boolean algebra $2^{\mathtt{At}}$, the free algebra of `if-then-else` clauses on a set X is the function space $X^{\mathtt{At}}$. This explains why adjacency sets for tree models of GKAT programs take the form of functions $\mathtt{At} \to X$.

This paper proposes a framework in which these languages can be uniformly described and studied. We use the *algebra of regular behaviours* (or ARB) introduced in [30] as a prototypical example. ARB employs nondeterministic choice as a branching operation, prefixing of terms by atomic actions, a constant representing deadlock, variables, and a recursion operator for each variable. Specifications are interpreted using structural operational semantics in the style of [34], which sees the set `Exp` of all process terms as one large labelled transition system. This is captured succinctly as a *coalgebra*, in this case a function

$$\beta : \mathtt{Exp} \to \mathcal{P}(V + A \times \mathtt{Exp}) \tag{1}$$

Only finitely branching processes can be specified in ARB, so we will replace $\mathcal{P}$ with $\mathcal{P}_\omega$ in (1). From a technical point of view, $\mathcal{P}_\omega$ is the monad on the category **Sets** of sets and functions presented by the algebraic theory of semilattices with bottom.

By substituting the finite powerset functor in (1) with other monads presented by algebraic theories, we obtain a parametrised family of process types that covers the examples above and a general framework for studying the processes of each type. Instantiating the framework with an algebraic theory gives a fully expressive specification language for processes and a complete axiomatisation of behavioural equivalence for specifications.

One striking feature of many of the specification languages we construct is that they contain a fragment consisting of nonstandard analogues of regular expressions. We call these expressions *star expressions* and the fragment composed of star expressions the *star fragment*. Star fragments extend several existing analogues of basic regular algebra found in the process theory literature, including basic process algebra [5] and Andova's probabilistic basic process algebra [1], by adding recursion operators modelled after the Kleene star.

Milner is the first to notice the star fragment of ARB in [30]. He observes that the algebra of processes denoted by star expressions is more unruly than Kleene's algebra of regular languages, and that it is not clear what the appropriate axiomatisation should be. He offers a reasonable candidate based on Salomaa's first axiomatisation of Kleene algebra [39], but ultimately leaves completeness as an open problem. This problem has been subjected to many years of extensive research [15, 14, 16, 3, 20, 19]. A potential solution has recently been announced by Clemens Grabmayer and will appear in the upcoming LICS.

Replacing nondeterministic choice with the `if-then-else` branching structure of GKAT, we obtain the process behaviours explored in the recent rethinking of the language [40]. This makes the open problem of axiomatising GKAT (without the use of extremely powerful axioms like the *Uniqueness Axiom* of [44]), stated first in [44] and again in [40], yet another problem of axiomatising an algebra of star expressions. Our general characterisation of star expressions puts all these languages under one umbrella, and shows how they are derived canonically from a single abstract framework.

In summary, the contributions of this paper are as follows:

- We present a family of process types parametrised by an algebraic theory (Section 2) together with a uniform syntax and operational semantics (Section 3). We show how these can be instantiated to concrete algebraic theories, including guarded semilattices and pointed convex algebras. These provide, respectively, a calculus of processes capturing control flow of simple imperative programs and a calculus of probabilistic processes.

- We define an associated denotational semantics and show that it agrees with the operational semantics (Section 4). This coincidence result is important in order to prove completeness of the uniform axiomatisation we propose for each process type (Section 5).
- Finally, we study the star fragment of our parameterised family and propose a sound axiomatisation for this fragment (Section 6). We show that star fragments of concrete instances of our calculi yield known examples in the literature, e.g. Guarded Kleene Algebra with tests (GKAT) [44, 40] and probabilistic processes of Stark and Smolka [45].

Related work is surveyed in Section 7, and future research directions are discussed in Section 8.

2 A Parametrised Family of Process Types

In this section, we present a family of process types parametrised by a certain kind of algebraic theory. The processes we care about are stateful, meaning they consist of a set of states and a suitably structured set of transitions between states. Stateful systems fit neatly into the general framework of *universal coalgebra* [37], which stipulates that the type of structure carried by the transitions can be encoded in an endofunctor on the category **Sets** of sets and functions. Formally, given a functor $B : \mathbf{Sets} \to \mathbf{Sets}$, a *$B$-coalgebra* is a pair (X, β) consisting of a set X of *states* and a *structure* map $\beta : X \to BX$. A *coalgebra homomorphism* $h : (X, \beta) \to (Y, \vartheta)$ is a function $h : X \to Y$ satisfying $\vartheta \circ h = B(h) \circ \beta$. Many types of processes found in the literature coincide with B-coalgebras for some B, and so do their homomorphisms. For example, finitely branching labelled transition systems are $\mathcal{P}_\omega(A \times \mathrm{Id})$-coalgebras, and deterministic Moore automata are $O \times \mathrm{Id}^A$-coalgebras [36].

In this paper, we consider coalgebras for functors of the form

$$B_M := M(V + A \times \mathrm{Id}) \tag{2}$$

for fixed sets V and A and a specific kind of functor $M : \mathbf{Sets} \to \mathbf{Sets}$. Intuitively, there are two layers to the process behaviours we care about: one layer consists of either an *output variable* in V or an *action* from A that moves on to another state, and the other layer (encoded by M) combines output variables and action steps in a structured way.

▶ **Example 1.** When $M = \mathcal{P}_\omega$, we obtain Milner's nondeterministic processes [30]. Coalgebras for $B_{\mathcal{P}_\omega}$ are functions of the form $\beta : X \to \mathcal{P}_\omega(V + A \times X)$, or labelled transition systems with an additional decoration by variables. Write $x \xrightarrow{a} y$ to mean $(a, y) \in \beta(x)$ and $x \Rightarrow v$ to mean $v \in \beta(x)$. The image below posits a well-defined $B_{\mathcal{P}_\omega}$-coalgebra

Its state space is $\{x_1, x_2, x_2\}$, A includes a_1 and a_2, and v is a variable in V.

Algebraic Theories and Their Monads

We are particularly interested in B_M-coalgebras when M is the functor component of a monad (M, η, μ) that is presented by an algebraic theory capturing a type of branching. A monad consists of natural transformations $\eta : \mathrm{Id} \Rightarrow M$ and $\mu : MM \Rightarrow M$, called the *unit* and *multiplication* respectively, satisfying two laws: $\mu \circ \eta_M = \mathrm{id}_M = \mu \circ M(\eta)$ and $\mu_M \circ \mu = M(\mu) \circ \mu$. For our purposes, an *algebraic theory* is a pair (S, E) consisting of a polynomial endofunctor $S = \coprod_{\sigma \in I} \mathrm{Id}^{n_\sigma}$ on **Sets** called an *algebraic signature* and a set E of equations in the signature S. An element σ of I should be thought of as an operation

with arity n_σ. An algebraic theory (S, E) *presents* a monad (M, η, μ) if there is a natural transformation $\rho : SM \Rightarrow M$ such that for any set X, (MX, ρ_X) is the free (S, E)-algebra on X. That is, (MX, ρ_X) satisfies E and for any S-algebra (Y, φ) also satisfying E and any function $h : X \to Y$, there is a unique S-algebra homomorphism $\hat{h} : (MX, \rho_X) \to (Y, \varphi)$ such that $h = \hat{h} \circ \eta$. This universal property implies that any two presentations of a given algebraic theory are isomorphic, so we speak simply of "the" monad presented by an algebraic theory.

▶ **Example 2.** The finite powerset functor is part of the monad $(\mathcal{P}_\omega, \{-\}, \bigcup)$ that is presented by the theory of semilattices (with bottom). The theory of semilattices is the pair $(1+\mathrm{Id}^2, \mathsf{SL})$, since the arity of a constant operation is 0 and $+$ is a binary operation, and SL consists of

$$x + 0 \overset{(\mathsf{SL1})}{=} x \qquad x + x \overset{(\mathsf{SL2})}{=} x \qquad x + y \overset{(\mathsf{SL3})}{=} y + x \qquad x + (y + z) \overset{(\mathsf{SL4})}{=} (x + y) + z$$

Not every algebraic theory has such a familiar presentation as the theory of semilattices, but it is nevertheless true that every algebraic theory presents a monad. If we let S^*X denote the set of S-*terms*, expressions built from X and the operations in S, then (S, E) automatically presents the monad (M, η, μ) where $MX = (S^*X)/\mathsf{E} := \{[q]_\mathsf{E} \mid q \in S^*X\}$ is the set of E-congruence classes of S-terms, η computes congruence classes of variables, and μ evaluates terms. This is witnessed by letting the transformation ρ be the restriction of μ to the operations of S on S-terms. We take this to be the default presentation of an arbitrary algebraic theory.

Our aim is to develop a (co)algebraic framework for studying B_M-coalgebras when M is the functor part of a monad presented by an algebraic theory. We will make three assumptions about the algebraic theories. First, we rule out the case of M being the constant 1 functor.

▶ **Assumption 1.** *The theory* E *is* nontrivial*, meaning that the equation* $x = y$ *is not a consequence of* E *for distinct* x *and* y*.*

This is equivalent to requiring that the unit η is injective. That is, the E-congruence classes $[x]_\mathsf{E}$ and $[y]_\mathsf{E}$ in MX are distinct for distinct variables x and y in X.

Second, we assume the existence of a constant symbol denoting deadlock, which might occur when recursing on unguarded programs.

▶ **Assumption 2.** *Algebraic theories contain a designated constant* 0*.*

Finally, to keep the specifications of processes finite, we make the following assumption despite the fact that it has no bearing on the results presented before Section 5.

▶ **Assumption 3.** *Each operation from* S *has a finite arity.*

We conclude this section with examples of algebraic theories and the monads they present.

▶ **Example 3.** For a fixed finite set $\mathtt{At}$ of *atomic tests*, the algebraic theory of *guarded semilattices* is the pair $(1 + \coprod_{b \subseteq \mathtt{At}} \mathrm{Id}^2, \mathsf{GS})$, where GS consists of the equations

$$x +_b x \overset{(\mathsf{GS1})}{=} x \qquad x +_\mathtt{At} y \overset{(\mathsf{GS2})}{=} x \qquad x +_b y \overset{(\mathsf{GS3})}{=} y +_{\bar{b}} x \qquad (x +_b y) +_c z \overset{(\mathsf{GS4})}{=} x +_{bc} (y +_c z)$$

Here, $+_b$ is the binary operation associated with the subset $b \subseteq \mathtt{At}$, $\bar{b} := \mathtt{At} \setminus b$, and $bc := b \cap c$. The theory of guarded semilattices is presented by the monad $((1 + \mathrm{Id})^\mathtt{At}, \lambda\xi.(-), \Delta^*)$, where $(\lambda\xi.x)(\xi) = x$ and $\Delta^*(F)(\xi) = F(\xi)(\xi)$. The idea is that $+_b$ acts like an `if-then-else` clause in an imperative program. This is reflected in a free guarded semilattice $((1 + X)^\mathtt{At}, \rho_X)$, where for a pair of maps $h_1, h_2 : \mathtt{At} \to X$ we define

$$\rho_X(h_1 +_b h_2)(\xi) := \begin{cases} h_1(\xi) & \text{if } \xi \in b \\ h_2(\xi) & \text{otherwise} \end{cases}$$

The theory of guarded semilattices dates back to the algebras of `if-then-else` clauses studied in [28, 27, 8, 7]. For instance, guarded semilattices are examples of *McCarthy algebras*, introduced by Manes in [27].[1]

▶ **Example 4.** The theory of *pointed convex algebras* studied in [12] is $(1 + \coprod_{p\in[0,1]} \mathrm{Id}^2, \mathsf{CA})$, where CA consists of the equations

$$x +_p x \overset{(\mathsf{CA1})}{=} x \qquad x +_1 y \overset{(\mathsf{CA2})}{=} x \qquad x +_p y \overset{(\mathsf{CA3})}{=} y +_{\bar{p}} x \qquad (x +_p y) +_q z \overset{(\mathsf{CA4})}{=} x +_{pq} (y +_{\frac{q\bar{p}}{1-pq}} z)$$

Here, $+_p$ is the binary operation with index $p \in [0,1]$, $\bar{p} := 1 - p$, and $pq \neq 1$. This theory presents the pointed finite subprobability distribution monad $(\mathcal{D}_\omega(1 + \mathrm{Id}), \delta_{(-)}, \sum)$, where

$$\mathcal{D}_\omega(1 + X) = \left\{ \theta : X \to [0,1] \;\middle|\; \begin{array}{c} \{x \mid \theta(x) > 0\} \text{ is finite} \\ \sum_{x\in X} \theta(x) \leq 1 \end{array} \right\}$$

for any set X, and for any $x \in X$, $\theta \in \mathcal{D}_\omega(1 + X)$, and $\Theta \in \mathcal{D}_\omega(1 + \mathcal{D}_\omega(1 + X))$,

$$\delta_x(y) = [x = y?] \qquad \sum(\Theta)(\theta) = \sum_{y\in X} \Theta(\theta) \cdot \theta(y)$$

This is witnessed by the transformation ρ that takes 0 to the trivial subdistribution and computes the Minkowski sum $\rho_X(\theta +_p \psi) = p\cdot\theta + (1-p)\cdot\psi$ for each $p \in [0,1]$, $\theta, \psi \in \mathcal{D}_\omega(1+X)$.

▶ **Example 5.** The theory of *pointed convex semilattices* studied in [12, 49, 10] combines the theory of semilattices and the theory of convex algebras. It has both a binary operation $+$ mimicking nondeterministic choice and the probabilistic choice operations $+_p$ indexed by $p \in [0,1]$. Formally, it is given by the pair $(1 + \mathrm{Id}^2 + \coprod_{p\in[0,1]} \mathrm{Id}^2, \mathsf{CS})$, where CS is the union of SL, CA, and the distributive law

$$(x + y) +_p z \overset{(\mathsf{D})}{=} (x +_p z) + (y +_p z)$$

This theory presents the pointed convex powerset monad $(\mathcal{C}, \eta^{\mathcal{C}}, \mu^{\mathcal{C}})$, where $\mathcal{C}X$ is the set of finitely generated convex subsets of $\mathcal{D}_\omega(1 + X)$ containing δ_0, and for $x \in X$ and $Q \in \mathcal{C}\mathcal{C}X$,

$$\eta^{\mathcal{C}}(x) = \{p\cdot\delta_x \mid p \in [0,1]\} \qquad \mu^{\mathcal{C}}(Q) = \bigcup_{\Theta\in Q} \left\{ \sum_{U\in\mathcal{C}_0 X} \Theta(U) \cdot \theta_U \;\middle|\; (\forall U \in \mathcal{C}_0 X)\ \theta_U \in U \right\}$$

The witnessing transformation $\rho^{\mathcal{C}}$ takes 0 to $\{\delta_0\}$, computes the Minkowski sum (extended to subsets) in place of $+_p$, and interprets the $+$ operation as the convex union

$$\rho^{\mathcal{C}}_X(U + V) = \{p\cdot\theta_1 + (1-p)\cdot\theta_2 \mid p \in [0,1], \theta_1 \in U, \theta_2 \in V\}$$

3 Specifications of Processes

Fix an algebraic theory (S, E) presenting a monad (M, η, μ). In this section, we give a syntactic and uniformly defined specification system for B_M-coalgebras and an associated operational semantics. We are primarily concerned with the specifications of finite processes, and indeed the process terms we construct below denote processes with finitely many states. The converse is also true, that every finite B_M-coalgebra admits a specification in the form of a process term, but we defer this result to Section 5 because of its relevance to the completeness theorem there.

[1] More information on the theory of guarded semilattices can be found in [42, Appendix A].

$$\epsilon(v) = \eta(v) \qquad \epsilon(\sigma(e_1, \ldots, e_n)) = \sigma(\epsilon(e_1), \ldots, \epsilon(e_n))$$
$$\epsilon(ae) = \eta((a, e)) \qquad \epsilon(\mu v\ e) = \epsilon(e)[\mu v\ e // v]$$

Figure 1 Operational semantics of process terms. Here, $v \in V$, $a \in A$, and $e, e_i \in \mathtt{Exp}$.

The syntax of our specifications consists of variables from an infinite set V, actions from a set A, and operations from S. The set $\mathtt{Exp}$ of *process terms* is given with the grammar

$$e, e_i ::= 0 \mid v \mid \sigma(e_1, \ldots, e_n) \mid ae \mid \mu v\ e$$

where $v \in V$, $a \in A$, and σ is an S-operation. Abstractly, process terms form the initial Σ_M-algebra $(\mathtt{Exp}, \alpha)$, where $\Sigma_M : \mathbf{Sets} \to \mathbf{Sets}$ is the functor defined by

$$\Sigma_M := S + V + A \times \mathrm{Id} + V \times \mathrm{Id}$$

and the algebra map $\alpha : \Sigma_M \mathtt{Exp} \to \mathtt{Exp}$ evaluates Σ_M-terms.

Intuitively, the symbol 0 is the designated constant of S denoting the *deadlock* process, which takes no action. Output variables are used in one of two ways, depending on the expression in which they appear. A variable v is *free* in an expression e if it does not appear within the scope of μv and *bound* otherwise. If v is free in e, then v denotes "output v". Otherwise, v denotes a *goto* statement that returns the computation to the μv that binds v. The process $\sigma(e_1, \ldots, e_n)$ is the process that branches into $e_1, \ldots, e_n$ using an n-ary operation σ as the branching constructor. The expression ae denotes the process that performs the action a and then proceeds with e. Finally, $\mu v\ e$ denotes recursion in the variable v.

Small-step Semantics

Next we give a small-step (operational) semantics to process terms that is uniformly defined for the process types in our parametrised family. Many of the algebraic theories we consider lack a familiar presentation, which ultimately prevents the corresponding semantics from taking the traditional form of a set of inference rules describing transition relations. We take an abstract approach instead by defining a B_M-coalgebra structure $\epsilon : \mathtt{Exp} \to B_M \mathtt{Exp}$ that mirrors the intuitive descriptions of the executions of process terms above. The formal description of ϵ is summarised in Figure 1.

The operational interpretation of the recursion operators requires further explanation. Intuitively, $\mu v\ e$ performs the process denoted by e until it reaches an exit in channel v, at which point it loops back to the beginning. However, this is really only an accurate description of recursion in v when e performs an action before exiting in v. For example, the process $\mu v\ v$ not only never exits in channel v, but it also never performs any action at all. Thus, the operational interpretation of $\mu v\ v$ is indistinguishable from that of deadlock. We deal with this issue as follows: if an exit in channel v is immediately reached by a branch of e, then we replace that exit with deadlock in $\mu v\ e$. Formally, we say that a variable v is *guarded* in a process term e if (i) $e \in V \setminus \{v\}$, (ii) $e = af$ or (iii) $e = \mu v\ f$ for some $f \in \mathtt{Exp}$, or (iv) either $e = \mu u\ e_1$ or (v) $e = \sigma(e_1, \ldots, e_n)$ and v is guarded in e_i for each $i \leq n$. In our calculus, we syntactically allow for recursion in unguarded variables, but one should keep in mind that those variables are ultimately deadlock under the recursion operator.

The operational interpretation of recursion is formally defined using a *guarded syntactic substitution operator* $[g//v] : B_M\mathtt{Exp} \to B_M\mathtt{Exp}$,[2] a variant of the usual syntactic substitution of variables. Given $g \in \mathtt{Exp}$, we first define $[g//v]$ by induction on $S^*(V + A \times \mathtt{Exp})$ as

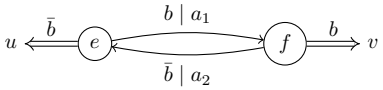
$$u[g//v] = \begin{cases} \eta(u) & u \neq v \\ \eta(0) & u = v \end{cases} \qquad \begin{aligned} (a, f)[g//v] &= (a, f[g/v]) \\ \sigma(p_1, \ldots, p_n)[g//v] &= \sigma(p_1[g//v], \ldots, p_n[g//v]) \end{aligned}$$

where $u \in V$, $p_i \in S^*(V + A \times \mathtt{Exp})$, $f \in \mathtt{Exp}$, and $[g/v]$ replaces free occurrence of v with g. The following lemma completes the description of the operational semantics of process terms.

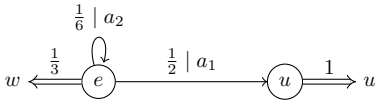
▶ **Lemma 6.** *For any $g \in \mathtt{Exp}$ and $v \in V$, the map $[g//v]$ factors uniquely through $B_M\mathtt{Exp}$.*

Formally, the map ϵ assigns to each process term e an E-congruence class $\epsilon(e)$ of terms from $S^*(V + A \times \mathtt{Exp})$. A term from $S^*(V + A \times \mathtt{Exp})$ is a combination of variables v and transition-like pairs (a, e_i), so there is often only a small conceptual leap from the coalgebra structure ϵ to a more traditional representation of transitions as decorated arrows. We provide the following examples as illustrations of this phenomenon, as well as the specification languages and operational semantics of terms defined above.[3]

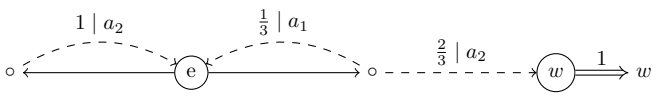
▶ **Example 7.** The *algebra of control flows*, or ACF, is obtained from the theory of guarded semilattices of Example 3 and $M = (1 + Id)^{\mathtt{At}}$. Given a structure map $\beta : X \to B_{(1+\mathrm{Id})^{\mathtt{At}}}X$ and $b \subseteq \mathtt{At}$, write $x \xrightarrow{b|a} y$ if $\beta(x)(\xi) = (a, y)$ for all $\xi \in b$, and $x \overset{b}{\Rightarrow} v$ if $\beta(x)(\xi) = v$ for all $\xi \in b$. The operational semantics returns the constant map $\lambda\xi.v$ given a variable $v \in V$ and interprets conditional choice as guarded union. For example, let $e = \mu w\ (a_1(v +_b a_2 w) +_b u)$ and $f = v +_b a_2 e$. The process denoted by e is



▶ **Example 8.** The *algebra of probabilistic actions*, or APA, is obtained from the theory of pointed convex algebras of Example 4 and $M = \mathcal{D}_\omega(1 + Id)$. For a structure map $\beta : X \to B_{\mathcal{D}_\omega(1+\mathrm{Id})}X$, write $x \xrightarrow{k|a} y$ when $\beta(x)(a, y) = k$ and $e \overset{k}{\Rightarrow} v$ when $\beta(e)(v) = k$. The operational semantics returns the Dirac distribution δ_v for $v \in V$ and interprets probabilistic choice as the Minkowski sum. The process denoted by $e = \mu v\ (a_1 u +_{\frac{1}{2}} (a_2 v +_{\frac{1}{3}} w))$ is



▶ **Example 9.** The *algebra of nondeterministic probabilistic actions*, or ANP, is obtained from the theory of pointed convex semilattices of Example 5. For a structure map $\beta : X \to B_{\mathcal{C}}X$, write $x \to\!\circ\xrightarrow{k|a} y$ to mean there is a $\theta \in \beta(x)$ such that $\theta(a, y) = k$, and $x \overset{k}{\Rightarrow} v$ to mean there is a $\theta \in \beta(x)$ with $\theta(v) = k$. The operational semantics returns $\eta^{\mathcal{C}}(v)$ given $v \in V$, interprets nondeterministic choice as convex union, and replaces probabilistic choice with Minkowski sum. For example, $e = \mu v\ ((a_1 v +_{\frac{1}{3}} a_2 w) + a_2 v)$ denotes



[2] Technically, it is only partially defined. See [42, Appendix C] for details.
[3] See [42, Appendix B] in the full version of the paper.

$$\zeta(\gamma(v)) = [v]_{\mathsf{E}} \qquad \zeta(\gamma(\sigma(t_1,\ldots,t_n))) = [\sigma(\zeta(t_1),\ldots,\zeta(t_n))]_{\mathsf{E}}$$
$$\zeta(\gamma(a,t)) = [(a,t)]_{\mathsf{E}} \qquad \zeta(\gamma(\mu v\ t)) = \zeta(t)\{\gamma(\mu v\ t)//v\}$$

Figure 2 The Σ_M-algebra structure of (Z,γ). Here, $v \in V$, $a \in A$, $t, t_i \in Z$ for $i \leq n$, and σ is an n-ary operation from S. By Lambek's lemma [25], $\zeta : Z \to B_M Z$ is a bijection, so the first three equations determine $\gamma : V + SZ + A \times V \to Z$. The fourth is a behavioural differential equation [36].

4 Behavioural Equivalence and the Final Coalgebra

In this section, we relate the operational semantics arising from the coalgebra structure on $\mathtt{Exp}$ in the previous section to a denotational semantics, which arises through the definition of a suitable algebra structure on the domain of process behaviours.

For an arbitrary functor $B : \mathbf{Sets} \to \mathbf{Sets}$, a *behaviour* is a state of the *final* B-coalgebra (Z,ζ), the unique (up to isomorphism) coalgebra (if it exists) such that there is exactly one homomorphism $!_\beta : (X,\beta) \to (Z,\zeta)$ from every B-coalgebra (X,β). It follows from general considerations that the functor B_M admits a final coalgebra [37]. The universal property of the final B_M-coalgebra produces the homomorphism $!_\epsilon : (\mathtt{Exp},\epsilon) \to (Z,\zeta)$. The behaviour $!_\epsilon(e)$ is called the *final (coalgebra) semantics* of e, also known as its operational semantics [38].

For example, the final $B_{\mathcal{P}_\omega}$-coalgebra consists of bisimulation equivalence classes of finite and infinite labelled trees of a certain form [4]. In this setting, $(\mathtt{Exp},\epsilon)$ is a labelled transition system and the final semantics $!_\epsilon$ constructs a tree from a process term by unrolling. Intuitively, this captures the behaviour of a specification by encoding all possible actions and outgoing messages at each time-step in its execution.

In addition to forming the state space of the final B_M-coalgebra, the set of process behaviours also carries the structure of a Σ_M-algebra (Z,γ), summarised in Figure 2. Now, $(\mathtt{Exp},\alpha)$ is the *initial* Σ_M-algebra, which in particular means there is a unique algebra homomorphism $[\![-]\!] : (\mathtt{Exp},\alpha) \to (Z,\gamma)$. The behaviour $[\![e]\!]$ is called the *initial (algebra) semantics* of e [18], and provides a denotational semantics to our process calculus.

The algebra structure $\gamma : \Sigma_M Z \to Z$ of (Z,γ) can be seen as a reinterpretation of the programming constructs of the language $\mathtt{Exp}$ that mimics the operational semantics of process terms. The basic constructs are the content of the first three equations in Figure 2: output variables are evaluated so as to behave like the variables of $(\mathtt{Exp},\epsilon)$, the behaviour at performs a and moves on to t, and $\sigma(t_1,\ldots,t_n)$ branches into the behaviours $t_1,\ldots,t_n$ with additional structure determined by the operation σ. Interpreting recursive behaviours like $\mu v\ t$ requires coalgebraic analogues of syntactic and guarded syntactic substitution from Section 3.

For a given behaviour $s \in Z$ and a variable $v \in V$, the *behavioural substitution* of s for v is the map $\{s/v\} : Z \to Z$ defined by the identity

$$\zeta(t\{s/v\}) = \begin{cases} \zeta(s) & \zeta(t) = [v]_{\mathsf{E}} \\ [u]_{\mathsf{E}} & \zeta(t) = [u]_{\mathsf{E}} \neq [v]_{\mathsf{E}} \\ [(a, r\{s/v\})]_{\mathsf{E}} & \zeta(t) = [(a,r)]_{\mathsf{E}} \\ \sigma(\zeta(t_1\{s/v\}),\ldots,\zeta(t_n\{s/v\})) & \zeta(t) = [\sigma(\zeta(t_1),\ldots,\zeta(t_n))]_{\mathsf{E}} \end{cases}$$

for any $t \in Z$. The *guarded behavioural substitution* of s for v is constructed in analogy with guarded syntactic substitution from the previous section. We start by defining guarded behavioural substitution in $S^*(V + A \times Z)$ as

$$u\{s//v\} = \begin{cases} u & u \neq v \\ 0 & u = v \end{cases} \qquad \begin{aligned} (a,r)\{s//v\} &= (a, r\{s/v\}) \\ \sigma(r_1,\ldots,r_n)\{s//v\} &= \sigma(r_1\{s//v\},\ldots,r_n\{s//v\}) \end{aligned}$$

where $u \in V$, $a \in A$, and $r, r_i \in Z$ for $i \leq n$. This map lifts to an operator $B_M Z \to B_M Z$ for the same reason as the guarded syntactic substitution operator. This completes the description of the algebraic structure of (Z, γ) in Figure 2.

▶ **Theorem 10.** *Let* $[\![-]\!]$ *be the unique algebra homorphism* $(\mathtt{Exp}, \alpha) \to (Z, \gamma)$. *For any process term* $e \in \mathtt{Exp}$, *we have* $!_\epsilon(e) = [\![e]\!]$.

In other words, the final semantics given with respect to operational rules in Exp coincides with the initial semantics given with respect to the programming constructs in Z. Consequently, we write $[\![-]\!]$ in place of $!_\epsilon$ and simply refer to $[\![e]\!]$ as the semantics of e.

5 An Axiomatisation of Behavioural Equivalence

An important corollary of Theorem 10 is that behavioural equivalence is a Σ_M-congruence on $(\mathtt{Exp}, \alpha)$, meaning that it is preserved by all the program constructs of Σ_M. This opens the door to the possibility of deriving behavioural equivalences between process terms from just a few axioms. The purpose of this section is to show that all behavioural equivalences between process terms can be derived from the equations in E presenting (M, η, μ) as well as three axiom schemas concerning the recursion operators.

The first two out of the three recursion axiom schemas are

$$\text{(R1)} \quad \mu v\ e = e[\mu v\ e//v] \qquad\qquad \text{(R2)} \quad \frac{w \text{ not free in } e}{\mu v\ e = \mu w\ (e[w/v])}$$

Above, $e[\mu v\ e//v]$ is the expression obtained by replacing every guarded free occurrence of v in e with the expression $\mu v\ e$ and every unguarded occurrence of v in e with 0, in analogy with the operator on $B_M\mathtt{Exp}$ of the same name.[4]

The axiom (R1) essentially allows for a sort of guarded unravelling of recursive terms. This has the effect of identifying $\mu v\ v$ with 0, for example, as well as $\mu v\ av$ with $a(\mu v\ av)$. The latter satisfies our intuition that $\mu v\ av$ should solve the recursive specification $x = ax$ in the indeterminate x. The axiom (R2) allows for recursion variables to be swapped for fresh variables. This amounts to the observation that pairs of terms like $\mu v\ av$ and $\mu w\ aw$ should both denote the unique solution to $x = ax$.

The third recursion axiom schema can be stated in the form of the proof rule

$$\text{(R3)} \quad \frac{g = e[g/v] \quad v \text{ guarded in } e}{g = \mu v\ e}$$

We let R denote the set of equations derived from (R1)-(R3), and we let $\equiv$ denote the smallest congruence in $(\mathtt{Exp}, \alpha)$ containing the set of equations derived from E and R. When we refer to examples like ARB, ACF, APA, and ANP, we are often identifying each of these with their associated algebras $(\mathtt{Exp}/{\equiv}, \hat{\alpha})$ of process terms modulo $\equiv$.

[4] Indeed, the identity $\epsilon(e[\mu v\ e//v]) = \epsilon(e)[\mu v\ e//v]$ holds for all $e \in \mathtt{Exp}$ and $v \in V$ [42, Lemma C.9].

Soundness

We would like to argue that $\equiv$ is *sound* with respect to behavioural equivalence, meaning that $[\![e]\!] = [\![f]\!]$ whenever $e \equiv f$. This is indeed the case, and can be derived from the fact that the set of congruence classes of process terms itself forms a B_M-coalgebra. For an arbitrary function $h : X \to Y$, call the set $\ker(h) := \{(x, y) \mid h(x) = h(y)\}$ the *kernel* of h.

▶ **Lemma 11.** *The congruence $\equiv$ is the kernel of a coalgebra homomorphism.*

We write $[-]_\equiv : \mathtt{Exp} \to \mathtt{Exp}/{\equiv}$ for the quotient map and $(\mathtt{Exp}/{\equiv}, \bar{\epsilon})$ for the coalgebra structure on $\mathtt{Exp}/{\equiv}$ making $[-]_\equiv$ a coalgebra homomorphism (there is at most one such coalgebra structure [37]). As $[\![-]\!]$ is the unique coalgebra homomorphism $(\mathtt{Exp}, \epsilon) \to (Z, \zeta)$, and because there is also a coalgebra homomorphism $!_{\bar{\epsilon}} : (\mathtt{Exp}/{\equiv}, \bar{\epsilon}) \to (Z, \zeta)$, it must be the case that $!_{\bar{\epsilon}} \circ [-]_\equiv = [\![-]\!]$. By Lemma 11, if $e \equiv f$, then $[\![e]\!] = !_{\bar{\epsilon}}([e]_\equiv) = !_{\bar{\epsilon}}([f]_\equiv) = [\![f]\!]$. This establishes the following.

▶ **Theorem 12** (Soundness). *Let $e, f \in \mathtt{Exp}$. If $e \equiv f$, then $[\![e]\!] = [\![f]\!]$.*

Soundness allows us to derive at least a subset of all the behavioural equivalences between process terms from the axioms in E and R. If our aspiration were simply to have a set of behaviour-preserving code-transformations, then we could simply stop here and be satisfied, since in principle we could see the axioms of E and R as rewrite rules that satisfy this purpose.

Completeness

Aiming a bit higher than deriving only a subset of the behavioural equivalences between process terms, we move on to show the converse of Theorem 12, that $\equiv$ is *complete* with respect to behavioural equivalence. We use [41, Lemma 5.1], which can be stated as follows.

▶ **Lemma 13.** *Let $B : \mathbf{Sets} \to \mathbf{Sets}$ be an endofunctor with a final coalgebra (Z, ζ), and let $\mathbf{C}$ be a class of B-coalgebras. If $\mathbf{C}$ is closed under homomorphic images*[5] *and has a final object (E, ε), then $!_\varepsilon : E \to Z$ is injective.*

A *subcoalgebra* of a B-coalgebra (X, β) is an injective map $\iota : U \hookrightarrow X$ such that $\beta|_U$ factors through $B(\iota)$. A B-coalgebra is *locally finite* if every of its states is contained in (the image of) a finite subcoalgebra. We instantiate Lemma 13 in the case where $B = B_M$, $(E, \varepsilon) = (\mathtt{Exp}/{\equiv}, \bar{\epsilon})$, and $\mathbf{C}$ is the class of locally finite B_M-coalgebras. Completeness of $\equiv$ with respect to behavioural equivalence follows shortly after, for if $[\![e]\!] = [\![f]\!]$, then $!_{\bar{\epsilon}}([e]_\equiv) = !_{\bar{\epsilon}}([f]_\equiv)$. By Lemma 13, $!_{\bar{\epsilon}}$ is injective, so $[e]_\equiv = [f]_\equiv$ or equivalently $e \equiv f$. To establish the converse of Theorem 12, it suffices to show that our choices of (E, ε) and $\mathbf{C}$ satisfy the hypotheses of Lemma 13.

Before we continue, we would like to remind the reader of Assumption 3, that S only has operations of finite arity, as up until now it has not been strictly necessary.

▶ **Lemma 14.** *The coalgebra $(\mathtt{Exp}, \epsilon)$ is locally finite.*

Proof. Given $e \in \mathtt{Exp}$, we construct a subcoalgebra of $(\mathtt{Exp}, \epsilon)$ that has a finite set of states that includes e. To this end, define $U : \mathtt{Exp} \to \mathcal{P}_\omega(\mathtt{Exp})$ by

$$U(v) = \{v\} \qquad U(ae) = \{ae\} \cup U(e) \qquad U(\sigma(e_1, \ldots, e_n)) = \{\sigma(e_1, \ldots, e_n)\} \cup \bigcup_{i<n} U(e_i)$$

$$U(\mu v\ e) = \{\mu v\ e\} \cup U(e)[\mu v\ e//v] = \{\mu v\ e\} \cup \{f[\mu v\ e//v] \mid f \in U(e)\}$$

[5] Ie., if $(X, \beta) \in \mathbf{C}$ and $h : (X, \beta) \to (Y, \vartheta)$, then $(h[X], \vartheta|_{h[X]}) \in \mathbf{C}$.

Note that $e \in U(e)$ for all $e \in \mathtt{Exp}$ and that $U(e)$ is finite. We begin with following claim, which says that the outgoing transitions of e are given in terms of expressions from $U(e)$: for any $e \in \mathtt{Exp}$, there is a representative S-term $p \in \epsilon(e)$ such that $p \in S^*(V + A \times U(e))$. This can be seen by induction on the construction of e, the only interesting case being in the inductive step $\mu v\ e$. Here, let $p \in \epsilon(e)$ and observe that $p[\mu v\ e//v]$ is a representative of $\epsilon(\mu v\ e)$ in $S^*(V + A \times U(\mu v\ e))$.

To finish the proof of the lemma, fix an $e \in \mathtt{Exp}$ and define a sequence of sets beginning with $U_0 = \{e\}$ and proceeding with

$$U_{n+1} = U_n \cup \bigcup_{e_0 \in U_n} \{g \mid (\exists a \in A)(\exists p \in \epsilon(e_0) \cap S^*(V + A \times U(e_0)))\ (a, g) \text{ appears in } p\}$$

Then $U_0 \subseteq U_1 \subseteq \cdots \subseteq U(e)$ and the latter set is finite, so $U := \bigcup U_n$ is finite and contained in $U(e)$. We define a coalgebra structure $\epsilon_U : U \to B_M U$ by taking $\epsilon_U(e) = [p]_{\mathsf{E}}$ where if $e \in U_n$, then p is a representative of $\epsilon(e)$ in $S^*(V + A \times U_{n+1})$. Since $S^*(V + A \times U_{n+1}) \subseteq S^*(V + A \times U)$, this defines a B_M-coalgebra structure on U. Where $\iota : U \hookrightarrow \mathtt{Exp}$, we have $\epsilon(\iota(e)) = \epsilon(e) = B_M(\iota)\ \epsilon_U(e)$, so (U, ϵ_U) is a finite subcoalgebra of $(\mathtt{Exp}, \epsilon)$ containing e. ◀

The class of locally finite coalgebras is closed under homomorphic images: if (X, β) is locally finite and $h : (X, \beta) \to (Y, \vartheta)$ is a surjective homomorphism, then for any $y \in Y$ and $x \in X$ such that $h(x) = y$, and for any finite subcoalgebra U of (X, β) containing x, $h[U]$ is a finite subcoalgebra of (Y, ϑ) containing y [21]. Since y was arbitrary, it follows from Lemma 11 that $(\mathtt{Exp}/{\equiv}, \bar{\epsilon})$ is locally finite.

What remains to be seen among the hypotheses of Lemma 13 is that $(\mathtt{Exp}/{\equiv}, \bar{\epsilon})$ is the *final* locally finite coalgebra, meaning that for any locally finite coalgebra (X, β) there is a unique coalgebra homomorphism $(X, \beta) \to (\mathtt{Exp}/{\equiv}, \bar{\epsilon})$. Every homomorphism from a locally finite coalgebra is the union of its restrictions to finite subcoalgebras, so it suffices to see that every finite subcoalgebra of (X, β) admits a unique coalgebra homomorphism into $(\mathtt{Exp}/{\equiv}, \bar{\epsilon})$.

To this end, we make use of an old idea, possibly originating in the work of Salomaa [39]. We associate with every finite coalgebra a certain system of equations whose solutions (in $\mathtt{Exp}/{\equiv}$) are in one-to-one correspondence with coalgebra homomorphisms into $(\mathtt{Exp}/{\equiv}, \bar{\epsilon})$. Essentially, if a system admits a unique solution, then its corresponding coalgebra admits a unique homomorphism into $(\mathtt{Exp}/{\equiv}, \bar{\epsilon})$. This would then establish finality.

▶ **Definition 15.** *A* (finite) system of equations *is a sequence of the form* $\{x_i = e_i\}_{i \le n}$ *where* $x_i \in V$ *and* $e_i \in \mathtt{Exp}$ *for* $i \le n$*, and none of* $x_1, \ldots, x_n$ *appear as bound variables in any of* $e_1, \ldots, e_n$*. A system of equations* $\{x_i = e_i\}_{i \le n}$ *is* guarded *if* $x_1, \ldots, x_n$ *are guarded in* e_i *for each* $i \le n$*. A* solution *to* $\{x_i = e_i\}_{i \le n}$ *is a function* $\phi : \{x_1, \ldots, x_n\} \to \mathtt{Exp}$ *such that*

$$\phi(x_i) \equiv e_i[\phi(x_1)/x_1, \ldots, \phi(x_n)/x_n]$$

for all $i \le n$ *and* $x_1, \ldots, x_n$ *do not appear free in* $\phi(x_i)$ *for any* $i \le n$*.*

Every finite B_M-coalgebra (X, β) gives rise to a guarded system of equations in the following way: for each $p \in S^*(V + A \times X)$, define $p^\dagger$ inductively as

$$v^\dagger = v \qquad (a, e)^\dagger = ae \qquad \sigma(f_1, \ldots, f_n)^\dagger = \sigma(f_1^\dagger, \ldots, f_n^\dagger)$$

and for each $x \in X$, let p_x be a representative of $\beta(x)$. The[6] system of equations *associated with* (X, β) is then defined to be $\{x = p_x^\dagger\}_{x \in X}$. We treat the elements of X as variables in these equations, and note that by definition every $y \in X$ is guarded in $p_x^\dagger$.

[6] Technically speaking, there could be many systems of equations associated with a given coalgebra. We say "the" system of equations because any two have the same set of solutions up to E.

▶ **Theorem 16.** *Let (X, β) be a finite B_M-coalgebra and $\phi : X \to \mathtt{Exp}$ a function. Then the composition $[-]_{\equiv} \circ \phi : X \to \mathtt{Exp}/{\equiv}$ is a B_M-coalgebra homomorphism if and only if ϕ is a solution to the system of equations associated with (X, β).*

Proof. We begin by observing that $\bar{\epsilon} : \mathtt{Exp}/{\equiv} \to B_M\mathtt{Exp}/{\equiv}$ is a bijection. Indeed, the map $(-)^{\heartsuit} : B_M\mathtt{Exp} \to \mathtt{Exp}/{\equiv}$ defined to be the unique map satisfying

$$[v]_{\mathsf{E}}^{\heartsuit} = [v]_{\equiv} \qquad [(a, e)]_{\mathsf{E}}^{\heartsuit} = [ae]_{\equiv} \qquad [\sigma(p_1, \ldots, p_n)]_{\mathsf{E}}^{\heartsuit} = \sigma([p_1]_{\mathsf{E}}^{\heartsuit}, \ldots, [p_n]_{\mathsf{E}}^{\heartsuit})$$

is its inverse. By construction, $\bar{\epsilon}([p]_{\mathsf{E}}^{\heartsuit}) = [p]_{\mathsf{E}}$ for any $p \in S^*(V + A \times \mathtt{Exp})$, so it suffices to see that $\bar{\epsilon}([e]_{\equiv})^{\heartsuit} = [e]_{\equiv}$ for all $e \in \mathtt{Exp}$. This can be done by induction on the construction of e, and again the only interesting case is $\mu v\ e$. For this case, observe that

$$\begin{aligned}
\bar{\epsilon}([\mu v\ e]_{\equiv})^{\heartsuit} &= (B_M([-]_{\equiv})(\epsilon(e)[\mu v\ e//v]))^{\heartsuit} \\
&= (B_M([-]_{\equiv})(\epsilon(e[\mu v\ e//v])))^{\heartsuit} \\
&= (\bar{\epsilon}([e[\mu v\ e//v]]_{\equiv}))^{\heartsuit} && ([-]_{\equiv} \text{ a coalg. homom.}) \\
&= (\bar{\epsilon}([e]_{\equiv})[[\mu v\ e]_{\equiv}//v])^{\heartsuit} \\
&= \bar{\epsilon}([e]_{\equiv})^{\heartsuit}[[\mu v\ e]_{\equiv}//v] && (*) \\
&= [e[\mu v\ e//v]]_{\equiv} && (\text{induct. hyp.}) \\
&= [\mu v\ e]_{\equiv} && (\mathsf{R1})
\end{aligned}$$

We have used several properties of syntactic substitution in the above calculation; see [42, Appendix C] for details. We have also used that guarded syntactic substitution commutes with $(-)^{\heartsuit}$ in (*), but this follows from an easy induction on terms in $S^*(V + A \times (\mathtt{Exp}/{\equiv}))$.

Now let $\{x = p_x^{\dagger}\}_{x \in X}$ be the system of equations associated with the coalgebra (X, β). Observe that for any $x, y \in X$, if y appears in p_x, then it is guarded in $p_x^{\dagger}$. This means that $\phi : X \to \mathtt{Exp}$ is a solution to $\{x = p_x^{\dagger}\}_{x \in X}$ if and only if $\phi(x) \equiv p_x^{\dagger}[\phi(y)//y]_{y \in X}$. Now, if $\beta(x) = [p_x]_{\mathsf{E}}$, we see that

$$\begin{aligned}
(B_M([-]_{\equiv} \circ \phi)(\beta(x)))^{\heartsuit} &= (B_M([-]_{\equiv}) \circ B_M(\phi)([p_x]_{\mathsf{E}}))^{\heartsuit} && (\text{functoriality}) \\
&= (B_M([-]_{\equiv})([p_x]_{\mathsf{E}}[\phi(y)//y]_{y \in X}))^{\heartsuit} && (B_M(\phi) \text{ an alg. homom.}) \\
&= ([p_x]_{\mathsf{E}}[[\phi(y)]_{\equiv}//y]_{y \in X})^{\heartsuit} \\
&= [p_x^{\dagger}[\phi(y)//y]_{y \in X}]_{\equiv}
\end{aligned}$$

Thus, ϕ is a solution to the system $\{x = p_x^{\dagger}\}_{x \in X}$ if and only if

$$[-]_{\equiv} \circ \phi(x) = (-)^{\heartsuit} \circ B_M([-]_{\equiv} \circ \phi) \circ \beta(x) \tag{3}$$

for every $x \in X$. The maps $(-)^{\heartsuit}$ and $\bar{\epsilon}$ are inverse to one another, so Equation (3) is equivalent to the identity $\bar{\epsilon} \circ [-]_{\equiv} \circ \phi = B_M([-]_{\equiv} \circ \phi) \circ \beta$. This identity is the defining property of a coalgebra homomorphism of the form $[-]_{\equiv} \circ \phi$. ◀

As a direct consequence of Theorem 16, we see that a finite subcoalgebra $U \hookrightarrow \mathtt{Exp}$ of $(\mathtt{Exp}, \epsilon)$ is a solution to the system of equations associated with $(U, \epsilon|_U)$.

▶ **Example 17.** The system of equations associated with the automaton in Example 7 is the two-element set $\{x_1 = a_1x_2 +_b u, x_2 = v +_b a_2x_1\}$. The map $\phi : \{x_1, x_2\} \to \mathtt{Exp}$ defined by $\phi(x_1) = \mu w\ (a_1(v +_b a_2w) +_b u)$ and $\phi(x_2) = v +_b a_2\ \phi(x_1)$ is a solution.

Theorem 16 establishes a one-to-one correspondence between solutions to systems and coalgebra homomorphisms as follows. Say that two solutions ϕ and ψ to a system $\{x_i = e_i\}_{i \leq n}$ are $\equiv$-*equivalent* if $\phi(x_i) \equiv \psi(x_i)$ for all $i \leq n$. Starting with a solution $\phi : X \to \mathtt{Exp}$ to the system associated with (X, β), we obtain the homomorphism $[-]_\equiv \circ \phi$ using Theorem 16. A pair of solutions ϕ and ψ are $\equiv$-equivalent if and only if $[-]_\equiv \circ \phi = [-]_\equiv \circ \psi$, so up to $\equiv$-equivalence the correspondence $\phi \mapsto [-]_\equiv \circ \phi$ is injective. Going in the opposite direction and starting with a homomorphism $\psi : (X, \beta) \to (\mathtt{Exp}/{\equiv}, \bar{\epsilon})$, let e_x be a representative of $\psi(x)$ for each $x \in X$ and define $\phi := \lambda x.e_x$. Then ϕ is a solution to (X, β), and $[-]_\equiv \circ \phi = \psi$. Thus, up to $\equiv$-equivalence, solutions to systems are in one-to-one correspondence with coalgebra homomorphisms into $(\mathtt{Exp}/{\equiv}, \bar{\epsilon})$.

Say that a system *admits a unique solution up to* $\equiv$ if it has a solution and any two solutions to the system are $\equiv$-equivalent. Since, up to $\equiv$-equivalence, solutions to a system associated with a coalgebra (X, β) are in one-to-one correspondence with coalgebra homomorphisms $(X, \beta) \to (\mathtt{Exp}/{\equiv}, \bar{\epsilon})$, it suffices for the purposes of satisfying the hypotheses of Lemma 13 to show that every finite guarded system of equations admits a unique solution up to $\equiv$. The following theorem is a generalisation of [30, Theorem 5.7].

▶ **Theorem 18.** *Every finite guarded system of equations admits a unique solution up to* $\equiv$.

The proof is a recreation of the one that appears under [30, Theorem 5.7] with the more general context of our paper in mind. Remarkably, the essential details of the proof remain unchanged despite the jump in the level of abstraction between the two results.

Completeness of $\equiv$ with respect to behavioural equivalence is now a direct consequence of Lemma 13 and Theorems 16 and 18.

▶ **Corollary 19** (Completeness). *Let* $e, f \in \mathtt{Exp}$. *If* $[\![e]\!] = [\![f]\!]$, *then* $e \equiv f$.

One way to interpret this theorem is that the algebra $(\mathtt{Exp}/{\equiv}, \hat{\alpha})$ of process terms modulo $\equiv$ is isomorphic to a subalgebra of (Z, γ), or dually $(\mathtt{Exp}/{\equiv}, \bar{\epsilon})$ is a subcoalgebra of (Z, ζ). It is in this sense that ARB, ACF, APA, and ANP are algebras of behaviours.

6 Star Fragments

In this section we study a fragment of our specification languages consisting of *star expressions*. These include primitive actions from A, a form of sequential composition, and analogues of the Kleene star. We do not aim to give a complete axiomatisation of behavioural equivalence for star expressions, as even in simple cases this is notoriously difficult. Nevertheless, we think it is valuable to extrapolate from known examples a speculative axiomatisation independent of the specification languages from previous sections.

Fix an algebraic theory (S, E) and assume S consists of only constants and binary operations. Its *star fragment* is the set $\mathtt{SExp}$ of expressions given by the grammar

$$e, e_i ::= c \mid \mathsf{1} \mid a \mid e_1 +_\sigma e_2 \mid e_1 e_2 \mid e^{(\sigma)}$$

where $a \in A$, c is a constant in S, and σ is a binary S-operation.

The star fragment of an algebraic theory is a fragment of $\mathtt{Exp}$ in the sense that star expressions can be thought of as shorthands for process terms, as we explain next. In this translation, we fix a distinguished variable $\underline{u} \in V$, called the *unit*, which will denote successful termination, and we also fix a variable v distinct from the unit, which will appear in the fixpoint. The translation of star expressions to process terms is defined to be

$$\mathsf{1} \mapsto \underline{u} \qquad a \mapsto a\underline{u} \qquad e_1 +_\sigma e_2 \mapsto \sigma(e_1, e_2) \qquad e_1 e_2 \mapsto e_1[e_2/\underline{u}] \qquad e^{(\sigma)} \mapsto \mu v\, (e[v/\underline{u}] +_\sigma \underline{u})$$

$$\ell(c) = [c]_{\mathsf{E}} \qquad \ell(e_1 +_\sigma e_2) = \sigma(\ell(e_1), \ell(e_2))$$
$$\ell(1) = [\checkmark]_{\mathsf{E}} \qquad \ell(ef) = p(\ell(f), [(a_1, e_1 f)]_{\mathsf{E}}, \dots, [(a_n, e_n f)]_{\mathsf{E}})$$
$$\ell(a) = [(a, 1)]_{\mathsf{E}} \qquad \ell(e^{(\sigma)}) = p([0]_{\mathsf{E}}, [(a_1, e_1 e^{(\sigma)})]_{\mathsf{E}}, \dots, [(a_n, e_n e^{(\sigma)})]_{\mathsf{E}}) +_\sigma [\checkmark]_{\mathsf{E}}$$

Figure 3 The coalgebra structure map $\ell : \mathtt{SExp} \to L_M \mathtt{SExp}$. Here, c is a constant of S, σ is a binary operation of S, $a \in A$, and $e, e_i \in \mathtt{SExp}$. In the last two equations, $\ell(e) = [p(\checkmark, (a_1, e_1), \dots, (a_n, e_n))]_{\mathsf{E}}$ for some $p \in S^*(\{\checkmark\} + A \times \mathtt{SExp})$.

Sequential composition of terms is associative and distributes over branching operations on the right-hand side[7]: for any $e_1, e_2, f \in \mathtt{SExp}$, $(e_1 +_\sigma e_2)f$ and $e_1 f +_\sigma e_2 f$ translate to the same process term. Similarly, the intuitively correct identities $\mathtt{1}e = e = e\mathtt{1}$ hold modulo translation, as well as the identity $0e = 0$.[8]

The operational semantics for star expressions is given by an L_M-coalgebra $(\mathtt{SExp}, \ell)$ in Figure 3, where $L_M = M(\{\checkmark\} + A \times \mathrm{Id})$. Abstractly, the operational interpretation $\ell(e)$ of a star expression e is obtained by translating e into a process term (also called e) and then identifying $\underline{a}$ with $\checkmark$ in $\epsilon(e)$. While the notation is somewhat opaque at this level of generality, in specific instances the map ℓ amounts to a familiar transition structure.

▶ **Example 20.** The star fragment of ACF from Example 3 and Example 7 coincides with GKAT, the algebra of programs introduced in [24] and studied further in [44, 40]. Instantiating $\mathtt{SExp}$ in this context reveals the syntax

$$e_i ::= 0 \mid \mathtt{1} \mid a \mid e_1 +_b e_2 \mid e_1 e_2 \mid e^{(b)}$$

for $b \subseteq \mathtt{At}$ and $a \in A$. This is nearly the syntax of GKAT, the only difference being the presence of $\mathtt{1}$ and 0 instead of Boolean constants $b \subseteq \mathtt{At}$. This is merely cosmetic, as we can just as well define $b := \mathtt{1} +_b 0$.

In this context, $M = (1 + \mathrm{Id})^{\mathtt{At}}$, and so $L_M \cong (2 + A \times \mathrm{Id})^{\mathtt{At}}$, which is the precise coalgebraic signature of the automaton models of GKAT expressions. It is readily checked that the operational semantics of GKAT also coincides with the operational semantics of the star fragment of ACF given above.

▶ **Example 21.** The star fragment of APA from Example 4 and Example 8 is a subset of the calculus of programs introduced in [11], but with an iteration operator for each $p \in [0, 1]$. Instantiating $\mathtt{SExp}$ in this context reveals the syntax

$$e_i ::= 0 \mid \mathtt{1} \mid a \mid e_1 +_p e_2 \mid e_1 e_2 \mid e^{(p)}$$

for $p \in [0, 1]$ and $a \in A$. The process $e^{(p)}$ can be thought of as a generalised Bernoulli process that runs e until it reaches $\checkmark$ and then flips a weighted coin to decide whether to start from the beginning of e or to terminate successfully.

We now provide a candidate axiomatisation for the star fragment while leaving the question of completeness open. Say that a star expression e is *guarded* if the unit is guarded in e as an expression in $\mathtt{Exp}$. We define E^* to be the theory consisting of E, the axiom schema

$$(\mathsf{E}^*1) \quad 1e = e1 = e \qquad (\mathsf{E}^*3) \quad e_1(e_2 e_3) = (e_1 e_2)e_3$$
$$(\mathsf{E}^*2) \quad ce = c \qquad (\mathsf{E}^*4) \quad (e +_\tau 1)^{(\sigma)} = (e +_\tau 0)^{(\sigma)}$$

[7] But not on the left-hand side! Observe the difference between the processes $a(b + c)$ and $ab + ac$ here.
[8] But not $e0 = 0$! See also the previous footnote.

and the inference rules

$$(\mathsf{E}^*5)\quad \frac{e \text{ is guarded}}{e^{(\sigma)} = ee^{(\sigma)} +_\sigma 1} \qquad (\mathsf{E}^*6)\quad \frac{g = eg +_\sigma f \qquad e \text{ is guarded}}{g = e^{(\sigma)} f}$$

In the specific cases where $\mathsf{E} = \mathsf{SL}$ and $\mathsf{E} = \mathsf{GS}$, E^* is equivalent to the candidate axiomatisations for the star fragments of ARB [30] and ACF [44, 40].[9]

There is a difference between our axioms and the axioms in [30, 44, 40]: instead of (E^*5), all equations of the form $e^{(\sigma)} = ee^{(\sigma)} +_\sigma 1$ appear in loc cit, even those where e is unguarded. We adopt (E^*5) instead because the unrestricted version of (E^*5) fails to be sound for the star expressions of APA. For example, if $e = 1 +_{\frac{1}{3}} a$, then $ee^{(1/2)} +_{\frac{1}{2}} 1 \xrightarrow{7/12} \checkmark$ while $e^{(\frac{1}{2})} \xrightarrow{1/2} \checkmark$.

We are confident that a completeness result can be obtained in several instances of the framework for the axiomatisation we have suggested above. However, in several cases this cannot happen. For example, there is no way to derive the identity $((a +_{\frac{1}{2}} 1) + b)^* = ((a +_{\frac{1}{2}} 0) + b)^*$ from CS^* (see Example 5) despite these expressions being behaviourally equivalent. What is likely missing from CS is a number of axioms that would allow 1 to be moved to the top level of every S-term (and then replaced by 0 using (E^*4)). Algebraic theories where this is doable are called *skew-associative*, which we define formally as follows.

▶ **Definition 22.** *An algebraic theory (S, E) consisting of constants and binary operations is called* skew-associative *if for any pair of binary operations σ_1, τ_1, there is a pair of binary operations σ_2, τ_2 such that $\sigma_1(x, \tau_1(y, z)) = \tau_2(\sigma_2(x, y), z)$ appears in E.*

Many of the examples we care about are skew-associative, including the theories of semilattices, guarded semilattices, and convex algebras.

▶ **Question 1.** *Assume (S, E) is a skew-associative algebraic theory. If e and f are behaviourally equivalent star expressions, is it true that $\mathsf{E}^* \vdash e = f$?*

7 Related Work

Our framework can be seen as a generalisation of Milner's ARB [30] that reaches beyond nondeterministic choice and covers several other process algebras already identified in the literature. For example, instantiating our framework in the theory of pointed convex algebras produces the algebra we have called APA (see Example 8), which only differs from the algebra PE of Stark and Smolka [45] in the axiom (R1). In loc cit, the requirement that the variable be guarded in the recursed expression is absent because recursion is computed as a least fixed point in their semantics. This is not how we interpret recursion. We have included the guardedness requirement because it is necessary for the soundness of the axiom in our semantics: for example, where $e = u +_{\frac{1}{2}} v$, we have $\mu v\ e \xrightarrow{1/2} u$ and $e[\mu v\ e/v] \xrightarrow{3/4} u$. In contrast, both $\mu v\ e$ and $e[\mu v\ e/v]$ exit in u with probability 1 in [45].

For another example, instantiating our framework in the theory CS of pointed convex semilattices gives ANP (see Example 5), which differs from the calculus of Mislove, Ouaknine, and Worrell [31] on two points. Firstly, their axiomatisation contains an unguarded version of (R1), like in [45]. Secondly, the underlying algebraic theory of [31] corresponds to CS extended with the axiom $x +_p 0 = 0$. The resulting theory is known in the literature as that of *convex semilattices with top* [11].

[9] See [42, Appendix F] for details.

Star expressions for non-deterministic processes appeared in the work of Milner [30] as a fragment of ARB and can be thought of as a bisimulation-focused analogue of Kleene's regular expressions for NFAs. While the syntaxes of Milner's star expressions and Kleene's regular expressions are the same, there are several important differences between their interpretations. For example, sequential composition is interpreted as the variable substitution $ef := e[f/\underline{u}]$ in Milner's paper, which fails to distribute over $+$ on the left. A notable insight from [30] is that, despite these differences, an iteration operator $(-)^*$ can be defined for Milner's star expressions that satisfies many of the same identities as the Kleene star. Given a variable v distinct from the unit and a process term e of ARB in which at most the unit is free,

$$e^* = \mu v\ (e[v/\underline{u}] + \underline{u})$$

defines the iteration operator in Milner's star fragment of ARB. In Section 6, we generalised this construction of Milner for the more general process types that we considered in this paper. Our proposed axiomatization is also inspired by Milner's work. We expect completeness of our general calculus will be a hard problem, as completeness in the instantiation to ARB was open for decades despite the extensive literature on the subject [15, 14, 16, 3, 20].

There are clear parallels between our work and the thesis of Silva [43], in which a family of calculi is introduced that includes one-exit versions of ARB, ACF, and APA (see Examples 2, 7, and 8). The main difference is that our framework is parametric on a finitary monad on **Sets** whereas Silva's is centered around one particular theory (semilattices). However, her work considers general polynomial functors on **Sets**, which we have not yet done in our paper. We could achieve a similar level of generality by replacing $A \times \mathrm{Id}$ in our signatures Σ_M, B_M, and L_M with an arbitrary polynomial functor.

Our results are also in the same vein as the work of Myers on coalgebraic expressions [32]. Coalgebraic expressions generalise the calculi of [43] to arbitrary finitary coalgebraic signatures on a variety of algebras, and furthermore have totally defined recursion operators similar to ours. However, the focus of the framework of coalgebraic expressions is on language semantics, achieved by lifting the coalgebraic signature to a variety. This distinguishes the framework from our approach: we focus on bisimulation semantics. This focus is also the reason we interpret our B_M-coalgebras in **Sets** and not in the Kleisli category of the monad M, as is done in [22] to capture trace semantics of coalgebras.

Finally, there is also a notable connection to the iterative theories of Elgot [13, 6, 7, 33]. Theorem 18 in particular implies that our process algebras are examples of iterative algebras.

8 Future Work

In this paper, we introduced a family of process types whose branching structure is determined by an algebraic theory. We provided each process type with a fully expressive specification language paired with a sound and complete axiomatisation of behavioural equivalence.

There are several instantiations of our framework that we have not yet explored and are of interest. For example, processes with multiset branching given by the theory of commutative monoids produces nondeterministic processes with a simplistic notion of resources. Another example is nondeterministic weighted processes with branching captured by the monad arising from the weak distributive law between the free semimodule and powerset monads [9]. Yet another instantiation arises from the theory of monoids (presenting the list monad), which produces processes related to breadth-first search algorithms.

Star fragments offer a uniform construction of Kleene-like algebras for a variety of paradigms of computing. However, our framework does not suggest an axiomatisation of the star fragment that combines nondeterministic and probabilistic choice, as the theory CS is

not skew-associative (see Definition 22). We would like to expand our framework to include this fragment as it provides an interesting but nonstandard interpretation of a part of the language ProbNetKAT used to verify probabilistic networks [17].

We would also like to investigate the question at the end of Section 6 of whether E^* is complete for skew-associative theories. In particular, we believe that a connection can be made to the work of Grabmayer and Fokkink [20] on LLEE-charts, which provides a completeness theorem for the so-called 1-free expressions of the star fragment of ARB. Our process algebras also have uniformly defined 1-free star fragments, and it is not difficult to give 1-free versions of the axiomatisation E^*. We intend to suitably generalise LLEE-charts to arbitrary skew-associative theories and prove completeness theorems for 1-free star fragments.

Finally, we would like to know whether our operational semantics for process terms is an instance of the mathematical operational semantics introduced by Turi and Plotkin [48].

The Dimension Spectrum Conjecture for Planar Lines

D. M. Stull ✉
Department of Computer Science, Northwestern University, Evanston, IL, USA

Abstract

Let $L_{a,b}$ be a line in the Euclidean plane with slope a and intercept b. The dimension spectrum $\mathrm{sp}(L_{a,b})$ is the set of all effective dimensions of individual points on $L_{a,b}$. Jack Lutz, in the early 2000s posed the *dimension spectrum conjecture*. This conjecture states that, for every line $L_{a,b}$, the spectrum of $L_{a,b}$ contains a unit interval.

In this paper we prove that the dimension spectrum conjecture is true. Specifically, let (a, b) be a slope-intercept pair, and let $d = \min\{\dim(a, b), 1\}$. For every $s \in [0, 1]$, we construct a point x such that $\dim(x, ax + b) = d + s$. Thus, we show that $\mathrm{sp}(L_{a,b})$ contains the interval $[d, 1 + d]$.

1 Introduction

The effective dimension, $\dim(x)$, of a point $x \in \mathbb{R}^n$ gives a fine-grained measure of the algorithmic randomness of x. Effective dimension was first defined by J. Lutz [5], and was originally used to quantify the sizes of complexity classes. Unsurprisingly, because of its strong connection to (classical) Hausdorff dimension, effective dimension has proven to be geometrically meaningful [3, 15, 1, 9]. Indeed, an exciting line of research has shown that one can prove classical results in geometric measure theory using effective dimension [7, 10, 11, 13]. Importantly, these are not effectivizations of known results, but new results whose *proofs* rely on effective methods. Thus, it is of considerable interest to investigate the effective dimensions of points of geometric objects such as lines.

Let $L_{a,b}$ be a line in the Euclidean plane with slope a and intercept b. Given the point-wise nature of effective dimension, one can study the *dimension spectrum* of $L_{a,b}$. That is, the set

$$\mathrm{sp}(L_{a,b}) = \{\dim(x, ax + b) \,|\, x \in \mathbb{R}\}$$

of all effective dimensions of points on $L_{a,b}$. In the early 2000s, Jack Lutz posed the *dimension spectrum conjecture* for lines. That is, he conjectured that the dimension spectrum of every line in the plane contains a unit interval.

The first progress on this conjecture was made by Turetsky.

▶ **Theorem 1** (Turetsky [18]). *The set of points $x \in \mathbb{R}^n$ with $\dim(x) = 1$ is connected.*

This immediately implies that $1 \in \mathrm{sp}(L_{a,b})$ for every line $L_{a,b}$. The next progress on the dimension spectrum conjecture was by Lutz and Stull [11]. They showed that the effective dimension of points on a line is intimately connected to problems in fractal geometry. Among other things, they proved that $1+d \in \mathrm{sp}(L_{a,b})$ for every line $L_{a,b}$, where $d = \min\{\dim(a, b), 1\}$. Shortly thereafter, Lutz and Stull [12] proved the dimension spectrum conjecture for the special case where the effective dimension and strong dimension of (a, b) agree.

In this paper, we prove that dimension spectrum conjecture is true. For every $s \in (0,1)$, we construct a point x such that $\dim(x, ax+b) = d + s$, where $d = \min\{\dim(a,b), 1\}$. This, combined with the results of Lutz and Stull, imply that

$$[d, 1+d] \subseteq \mathrm{sp}(L_{a,b}),$$

for every planar line $L_{a,b}$. The proof of the conjecture builds on the techniques of [11]. The primary difficulty of the conjecture is the case when the dimension of x is less than the difficulty of the line (a,b). We expand on the nature of this $\dim(x) < \dim(a,b)$ obstacle in Section 3.1. Our main technical contribution is showing how to overcome this difficulty by encoding the information of a into our point x. Further complications arise in the "high-dimensional" case, i.e., when $\dim(a,b) > 1$. In this case, we combine the encoding idea with a non-constructive argument.

Apart from its intrinsic interest, recent work has shown that the effective dimensions of points has deep connections to problems in classical analysis [10, 11, 13, 17, 8]. Lutz and Lutz [7] proved the point-to-set principle, which characterizes the Hausdorff dimension of a *set* by effective dimension of its *individual points*. Lutz and Stull [11], using the point-to-set principle, showed that lower bounds on the *effective* dimensions of points on a line are intimately related to well-known problems of classical geometric measure theory such the Kakeya and Furstenberg conjectures.

The structure of the paper is as follows. In Section 2, we recall the basic definitions and results of Kolmogorov complexity and effective dimension we need. In Section 3, we recall the strategy of Lutz and Stull [11] to give strong lower bounds on the effective dimension of points on a line. In Sections 3 and 3.1 we give intuition about this strategy, and discuss why it is not enough to settle the dimension spectrum conjecture.

In Section 4, we prove the dimension spectrum conjecture for lines with effective dimension at most one. We also give a brief overview of this proof, and how it overcomes the strategy discussed in Section 3. In Section 5, we prove the dimension spectrum conjecture for lines with effective dimension greater than one. We also give intuition of this proof, and how it overcomes the difficulties when the line is high-dimensional.

Finally, in the conclusion, we discuss open questions and avenues for future research.

2 Preliminaries

The *conditional Kolmogorov complexity* of a binary string $\sigma \in \{0,1\}^*$ given binary string $\tau \in \{0,1\}^*$ is

$$K(\sigma|\tau) = \min_{\pi \in \{0,1\}^*} \{\ell(\pi) : U(\pi, \tau) = \sigma\} ,$$

where U is a fixed universal prefix-free Turing machine and $\ell(\pi)$ is the length of π. The *Kolmogorov complexity* of σ is $K(\sigma) = K(\sigma|\lambda)$, where λ is the empty string. Thus, the Kolmogorov complexity of a string σ is the minimum length program which, when run on a universal Turing machine, eventually halts and outputs σ. We stress that the choice of universal machine effects the Kolmogorov complexity by at most an additive constant (which, especially for our purposes, can be safely ignored). See [4, 16, 2] for a more comprehensive overview of Kolmogorov complexity.

We can extend these definitions to Euclidean spaces by introducing "precision" parameters [9, 7]. Let $x \in \mathbb{R}^m$, and $r, s \in \mathbb{N}$. The *Kolmogorov complexity of x at precision r* is

$$K_r(x) = \min \{K(p) \,:\, p \in B_{2^{-r}}(x) \cap \mathbb{Q}^m\} .$$

The *conditional Kolmogorov complexity of x at precision r given $q \in \mathbb{Q}^m$* is

$$\hat{K}_r(x|q) = \min\{K(p) : p \in B_{2^{-r}}(x) \cap \mathbb{Q}^m\} .$$

The *conditional Kolmogorov complexity of x at precision r given $y \in \mathbb{R}^n$ at precision s* is

$$K_{r,s}(x|y) = \max\left\{\hat{K}_r(x|q) : q \in B_{2^{-r}}(y) \cap \mathbb{Q}^n\right\} .$$

We abbreviate $K_{r,r}(x|y)$ by $K_r(x|y)$.

The *effective Hausdorff dimension* and *effective packing dimension*[1] of a point $x \in \mathbb{R}^n$ are

$$\dim(x) = \liminf_{r\to\infty} \frac{K_r(x)}{r} \quad \text{and} \quad \mathrm{Dim}(x) = \limsup_{r\to\infty} \frac{K_r(x)}{r} .$$

Intuitively, these dimensions measure the density of algorithmic information in the point x.

By letting the underlying fixed prefix-free Turing machine U be a universal *oracle* machine, we may *relativize* the definition in this section to an arbitrary oracle set $A \subseteq \mathbb{N}$. The definitions of $K_r^A(x)$, $\dim^A(x)$, $\mathrm{Dim}^A(x)$, etc. are then all identical to their unrelativized versions, except that U is given oracle access to A. Note that taking oracles as subsets of the naturals is quite general. We can, and frequently do, encode a point y into an oracle, and consider the complexity of a point *relative* to y. In these cases, we typically forgo explicitly referring to this encoding, and write e.g. $K_r^y(x)$.

Among the most used results in algorithmic information theory is the *symmetry of information*. In Euclidean spaces, this was first proved, in a slightly weaker form in [7], and in the form presented below in [11].

▶ **Lemma 2.** *For every $m, n \in \mathbb{N}$, $x \in \mathbb{R}^m$, $y \in \mathbb{R}^n$, and $r, s \in \mathbb{N}$ with $r \geq s$,*

(i) $\left|K_r(x|y) + K_r(y) - K_r(x,y)\right| \leq O(\log r) + O(\log\log\|y\|)$.

(ii) $|K_{r,s}(x|x) + K_s(x) - K_r(x)| \leq O(\log r) + O(\log\log\|x\|)$.

2.1 Initial segments versus K-optimizing rationals

For $x = (x_1, \ldots, x_n) \in \mathbb{R}^n$ and a precision $r \in \mathbb{N}$, let $x\restriction r = (x_1\restriction r, \ldots, x_n\restriction r)$, where each

$$x_i\restriction r = 2^{-r}\lfloor 2^r x_i \rfloor$$

is the truncation of x_i to r bits to the right of the binary point. For $r \in (0,\infty)$, let $x\restriction r = x\restriction\lceil r\rceil$.

We can relate the complexity $K_r(x)$ of x at precision r and the *initial segment complexity* $K(x\restriction r)$ of the binary representation of x. Lutz and Stull [11] proved the following lemma, and its corollaries, relating these two quantities. Informally, it shows that, up to a logarithmic error, the two quantities are equivalent.

▶ **Lemma 3.** *For every $m, n \in \mathbb{N}$, there is a constant c such that for all $x \in \mathbb{R}^m$, $p \in \mathbb{Q}^n$, and $r \in \mathbb{N}$,*

$$|\hat{K}_r(x|p) - K(x\restriction r \,|\, p)| \leq K(r) + c .$$

This has the following two useful corollaries.

[1] Although effective Hausdorff was originally defined by J. Lutz [6] using martingales, it was later shown by Mayordomo [14] that the definition used here is equivalent. For more details on the history of connections between Hausdorff dimension and Kolmogorov complexity, see [2, 15].

▶ **Corollary 4.** *For every $m \in \mathbb{N}$, there is a constant c such that for every $x \in \mathbb{R}^m$ and $r \in \mathbb{N}$,*

$$|K_r(x) - K(x\restriction r)| \leq K(r) + c\,.$$

▶ **Corollary 5.** *For every $m, n \in \mathbb{N}$, there is a constant c such that for all $x \in \mathbb{R}^m$, $y \in \mathbb{R}^n$, and $r, s \in \mathbb{N}$,*

$$|K_{r,s}(x|y) - K(x\restriction r \,|\, y\restriction s)| \leq K(r) + K(s) + c\,.$$

3 Previous Work

The proof of our main theorem will use the tools and techniques introduced by Lutz and Stull [11]. In this section we will state the main lemmas needed for this paper. We will devote some time giving intuition about each lemma. In Subsection 3.1, we give an informal discussion on how to combine these lemmas to give bounds on the effective dimensions of points on a line. We will also discuss where these tools break down, motivating the techniques introduced in this paper.

The first lemma, informally, states the following. Suppose that $L_{a,b}$ intersects $(x, ax+b)$ and the complexity of (a,b) is low (item (i)). Further assume that (item (ii)), if $L_{u,v}$ is any other line intersecting $(x, ax+b)$ such that $\|(a,b) - (u,v)\| < 2^{-m}$ then either

1. u, v is of high complexity, or
2. u, v is very close to a, b.

Then it is possible to compute an approximation of (a,b) given an approximation of $(x, ax+b)$ and first m bits of (a,b). Indeed, we can simply enumerate over all low complexity lines, since we know that the only candidate is essentially (a,b).

▶ **Lemma 6** (Lutz and Stull [11])**.** *Suppose that $A \subseteq \mathbb{N}$,$a, b, x \in \mathbb{R}$, $m, r \in \mathbb{N}$, $\delta \in \mathbb{R}_+$, and $\varepsilon, \eta \in \mathbb{Q}_+$ satisfy $r \geq \log(2|a| + |x| + 5) + 1$ and the following conditions.*

(i) *$K_r^A(a,b) \leq (\eta + \varepsilon)\, r$.*

(ii) *For every $(u,v) \in B_{2^{-m}}(a,b)$ such that $ux + v = ax + b$,*

$$K_r^A(u,v) \geq (\eta - \varepsilon)\, r + \delta \cdot (r - t)\,,$$

whenever $t = -\log \|(a,b) - (u,v)\| \in (0, r]$.

Then,

$$K_r^A(a,b,x) \leq K_r(x, ax+b) + K_{m,r}(a,b \,|\, x, ax+b) + \frac{4\varepsilon}{\delta} r + K(\varepsilon, \eta) + O(\log r)\,.$$

The second lemma which will be important in proving our main theorem is the following. It is essentially the approximation version of the simple geometric fact that any two lines intersect at a single point. In other words, if $ax + b = ux + v$ and you are given an approximation of (a,b) and an approximation of (u,v), then you can compute an approximation of x. Moreover, the quality of the approximation of x depends linearly on the distance between (u,v) and (a,b).

▶ **Lemma 7** ([11])**.** *Let $a, b, x \in \mathbb{R}$. For all $u, v \in B_1(a,b)$ such that $ux + v = ax + b$, and for all $r \geq t := -\log \|(a,b) - (u,v)\|$,*

$$K_r(u,v) \geq K_t(a,b) + K_{r-t,r}(x|a,b) - O(\log r)\,.$$

The primary function of this lemma is to give a lower bound on the complexity of any line intersecting $(x, ax+b)$, i.e., ensuring condition (ii) of the previous lemma.

Finally, we also need the following oracle construction of Lutz and Stull. The purpose of this lemma is to show that we can lower the complexity of our line (a, b), thus ensuring item (i) of Lemma 6. Crucially, we can lower this complexity using only the information contained in (a, b).

▶ **Lemma 8** ([11]). *Let $r \in \mathbb{N}$, $z \in \mathbb{R}^2$, and $\eta \in \mathbb{Q} \cap [0, \dim(z)]$. Then there is an oracle $D = D(r, z, \eta)$ satisfying*

- **(i)** *For every $t \leq r$, $K_t^D(z) = \min\{\eta r, K_t(z)\} + O(\log r)$.*
- **(ii)** *For every $m, t \in \mathbb{N}$ and $y \in \mathbb{R}^m$, $K_{t,r}^D(y|z) = K_{t,r}(y|z) + O(\log r)$ and $K_t^{z,D}(y) = K_t^z(y) + O(\log r)$.*

3.1 Combining the lemmas

We now briefly discuss the strategy of [11] which combines the above lemmas to give non-trivial bounds on the effective dimension of points on a line. Suppose (a, b) is a line with $\dim(a, b) = d$, and x is a point with $\dim^{a,b}(x) = s$. We will also make the crucial assumption that $d \leq s$. Roughly, Lutz and Stull showed that, for sufficiently large r

$$K_r(x, ax + b) \geq (s + d)r.$$

The strategy is as follows. Note that to simplify the exposition, all inequalities in this discussion will be approximate. Using Lemma 8, we find an oracle D which reduces the complexity of (a, b) to some $\eta \leq d$, i.e., $K_r^D(a, b) = \eta r$. Combining this with Lemma 7, we get a lower bound on every line (u, v) intersecting $(x, ax + b)$. That is, we show for any such line,

$$K_r^D(u, v) \geq \eta t + s(r - t) - O(\log r)$$

By our choice of η, this implies that

$$K_r^D(u, v) > \eta r$$

In particular, relative to D, both conditions of Lemma 6 are satisfied and we have the sufficient lower bound.

In the previous sketch, it was crucial that the dimension of (a, b) was less than s, in order for the lower bound from Lemma 7 to be useful. In the case where $\dim(a, b)$ is much larger than $\dim^{a,b}(x)$, this strategy breaks down, and further techniques are required.

We also note that this seems to be a very deep issue. As discussed in the Introduction, the point-to-set principle of J. Lutz and N. Lutz [7] allows us to translate problems from (classical) geometric measure theory into problems of effective dimension. The same issue discussed in this section occurs when attacking the notorious Kakeya and Furstenberg set conjectures using the point-to-set principle. While resolving this obstacle in full generality is still elusive, we are able to get around it in the context of the Dimension Spectrum Conjecture.

4 Low-Dimensional Lines

In this section, we prove the spectrum conjecture for lines with $\dim(a, b) \leq 1$.

▶ **Theorem 9.** *Let $(a, b) \in \mathbb{R}^2$ be a slope-intercept pair with $\dim(a, b) \leq 1$. Then for every $s \in [0, 1]$, there is a point $x \in \mathbb{R}$ such that*

$$\dim(x, ax + b) = s + \dim(a, b).$$

We begin by giving an intuitive overview of the proof.

4.1 Overview of the proof

As mentioned in Section 3.1, the main obstacle of the Dimension Spectrum Conjecture occurs when the dimension of x is lower than the dimension of the line (a, b). As mentioned in Section 3.1, in general, this issue is still formidable. However, in the Dimension Spectrum Conjecture, we are given the freedom to specifically construct the point x, allowing us overcome this obstacle.

The most natural way to construct a sequence x with $\dim^{a,b}(x) = s$ is to start with a random sequence, and pad it with long strings of zeros. This simple construction, unfortunately, does not seem to work.

We are able to overcome the obstacle by padding the random sequence *with the bits of* a, instead of with zeros. Thus, given an approximation $(x, ax + b)$ we trivially have a decent approximation of a (formalized iin Lemma 10). This allows us, using Lemma 6, to restrict our search for (a, b) to a smaller set of candidate lines.

4.2 Proof for low-dimensional lines

Fix a slope-intercept pair (a, b), and let $d = \dim(a, b)$. Let $s \in (0, d)$. Let $y \in \mathbb{R}$ be random relative to (a, b). Thus, for every $r \in \mathbb{N}$,

$$K_r^{a,b}(y) \geq r - O(\log r).$$

Define the sequence of natural numbers $\{h_j\}_{j\in\mathbb{N}}$ inductively as follows. Define $h_0 = 1$. For every $j > 0$, let

$$h_j = \min\left\{h \geq 2^{h_{j-1}} : K_h(a, b) \leq \left(d + \frac{1}{j}\right) h\right\}.$$

Note that h_j always exists. For every $r \in \mathbb{N}$, let

$$x[r] = \begin{cases} a[r - \lfloor sh_j \rfloor] & \text{if } r \in (\lfloor sh_j \rfloor, h_j] \text{ for some } j \in \mathbb{N} \\ y[r] & \text{otherwise} \end{cases}$$

where $x[r]$ is the rth bit of x. Define $x \in \mathbb{R}$ to be the real number with this binary expansion.

One of the most important aspects of our construction is that we encode (a subset of) the information of a into our point x. This is formalized in the following lemma.

▶ **Lemma 10.** *For every $j \in \mathbb{N}$, and every r such that $sh_j < r \leq h_j$,*

$$K_{r-sh_j,r}(a, b \,|\, x, ax + b) \leq O(\log h_j).$$

Proof. By definition, the last $r - sh_j$ bits of x are equal to the first $r - sh_j$ bits of a. That is,

$$\begin{aligned} x[sh_j]\, x[sh_j + 1] \ldots x[r] &= a[0]\, a[1] \ldots a[r - sh_j] \\ &= a{\restriction}(r - sh_j). \end{aligned}$$

Therefore, since additional information cannot increase Kolmogorov complexity,

$$\begin{aligned} K_{r-sh_j,r}(a \,|\, x, ax + b) &\leq K_{r-sh_j,r}(a \,|\, x) \\ &\leq O(\log h_j). \end{aligned}$$

Note that, given $2^{-(r-sh_j)}$-approximations of a, x, and $ax + b$, it is possible to compute an approximation of b. That is,

$$K_{r-sh_j}(b \,|\, a, x, ax + b) \leq O(\log h_j).$$

Therefore, by Lemma 2 and the two above inequalities,

$$\begin{aligned} K_{r-sh_j,r}(a,b \,|\, x, ax+b) &= K_{r-sh_j,r}(a \,|\, x, ax+b) \\ &\quad + K_{r-sh_j,r}(b \,|\, a, x, ax+b) + O(\log r) \\ &\leq O(\log h_j) + K_{r-sh_j,r}(b \,|\, a, x, ax+b) + O(\log r) \\ &\leq O(\log h_j). \end{aligned}$$ ◀

The other important property of our construction is that (a, b) gives no information about x, beyond the information specifically encoded into x.

▶ **Lemma 11.** *For every $j \in \mathbb{N}$, the following hold.*

1. $K_t^{a,b}(x) \geq t - O(\log h_j)$, *for all* $t \leq sh_j$.
2. $K_r^{a,b}(x) \geq sh_j + r - h_j - O(\log h_j)$, *for all* $h_j \leq r \leq sh_{j+1}$.

Proof. We first prove item (1). Let $t \leq sh_j$. Then, by our construction of x, and choice of y,

$$\begin{aligned} K_t^{a,b}(x) &\geq K_t^{a,b}(y) - h_{j-1} - O(\log t) \\ &\geq t - O(\log t) - \log h_j - O(\log t) \\ &\geq t - O(\log h_j). \end{aligned}$$

For item (2), let $h_j \leq r \leq sh_{j+1}$. Then, by item (1), Lemma 2 and our construction of x,

$$\begin{aligned} K_r^{a,b}(x) &= K_{h_j}^{a,b}(x) + K_{r,h_j}^{a,b}(x) - O(\log r) && \text{[Lemma 2]} \\ &\geq sh_j + K_{r,h_j}^{a,b}(x) - O(\log r) && \text{[Item (1)]} \\ &\geq sh_j + K_{r,h_j}^{a,b}(y) - O(\log r) \\ &\geq sh_j + r - h_j - O(\log r), \end{aligned}$$ ◀

and the proof is complete.

We now prove bounds on the complexity of our constructed point. We break the proof into two parts. In the first, we give lower bounds on $K_r(x, ax+b)$ at precisions $sh_j < r \leq h_j$. Intuitively, the proof proceeds as follows. Since $r > sh_j$, given $(x, ax + b)$ to precision r immediately gives a 2^{-r+sh_j} approximation of (a, b). Thus, we only have to search for candidate lines (u, v) which satisfy $t = \|(a, b) - (u, v)\| < 2^{-r+sh_j}$. Then, because of the lower bound on t, the complexity $K_{r-t}(x)$ is maximal. In other words, we are essentially in the case that the complexity of x is high. Thus, we are able to use the method described in Section 3.1. We now formalize this intuition in the proof.

▶ **Lemma 12.** *For every $\gamma > 0$ and all sufficiently large $j \in \mathbb{N}$,*

$$K_r(x, ax+b) \geq (s+d)r - \gamma r,$$

for every $r \in (sh_j, h_j]$.

Proof. Let $\eta \in \mathbb{Q}$ such that

$$d - \gamma/4 < \eta < d - \gamma^2.$$

Let $\varepsilon \in \mathbb{Q}$ such that

$$\varepsilon < \gamma(d - \eta)/16.$$

Note that

$$\frac{4\varepsilon}{1-\eta} \leq \frac{\gamma}{4}$$

We also note that, since η and ε are constant,

$$K(\eta, \varepsilon) = O(1).$$

Let $D = D(r, (a,b), \eta)$ be the oracle of Lemma 8 and let $\delta = 1 - \eta$.

Let (u, v) be a line such that $t := \|(a,b) - (u,v)\| \geq r - sh_j$, and $ux + v = ax + b$. Note that $r - t \leq sh_j$. Then, by Lemma 7, Lemma 8 and Lemma 11(1),

$$\begin{aligned}
K_r^D(u,v) &\geq K_t^D(a,b) + K_{r-t,r}^D(x \,|\, a,b) - O(\log r) && \text{[Lemma 7]}\\
&\geq K_t^D(a,b) + K_{r-t,r}(x \,|\, a,b) - O(\log r) && \text{[Lemma 8]}\\
&\geq K_t^D(a,b) + r - t - O(\log r). && \text{[Lemma 11(1)]}
\end{aligned}$$

There are two cases by Lemma 8. For the first, assume that $K_t^D(a,b) = \eta r$. Then

$$\begin{aligned}
&\geq \eta r + r - t - O(\log r) && \text{[Definition of dim]}\\
&= (\eta - \varepsilon) r + r - t && [r \text{ is large}]\\
&\geq (\eta - \varepsilon) r + (1 - \eta)(r - t)
\end{aligned}$$

For the second, assume that $K_t^D(a,b) = K_t(a,b)$. Then

$$\begin{aligned}
K_r^D(u,v) &\geq K_t(a,b) + r - t - O(\log r)\\
&\geq dt - o(t) + r - t - O(\log r) && \text{[Definition of dim]}\\
&= \eta r + (1-\eta) r - t(1-d) - \varepsilon r && [r \text{ is large}]\\
&\geq \eta r - \varepsilon r + (1-\eta)(r-t) && [d > \eta]\\
&\geq (\eta - \varepsilon) r + (1-\eta)(r-t). && (1)
\end{aligned}$$

Therefore, in either case, we may apply Lemma 6,

$$\begin{aligned}
K_r(x, ax+b) &\geq K_r^D(a,b,x) - K_{r-sh_j,r}(a,b\,|, x, ax+b) && \text{[Lemma 6]}\\
&\qquad - \frac{4\varepsilon}{1-\eta} r - K(\eta,\varepsilon) - O(\log r)\\
&\geq K_r^D(a,b,x) - K_{r-sh_j,r}(a,b \,|\, x, ax+b) - \frac{\gamma}{4} r - \frac{\gamma}{8} r\\
&= K_r^D(a,b,x) - K_{r-sh_j,r}(a,b \,|\, x, ax+b) - \frac{3\gamma}{8} r. && (2)
\end{aligned}$$

By Lemma 11(1), our construction of oracle D, and the symmetry of information,

$$\begin{aligned}
K_r^D(a,b,x) &= K_r^D(a,b) + K_r^D(x \,|\, a,b) - O(\log r) && \text{[Lemma 2]}\\
&= K_r^D(a,b) + K_r(x \,|\, a,b) - O(\log r) && \text{[Lemma 8(ii)]}\\
&\geq \eta r + K_r(x \,|\, a,b) - O(\log r) && \text{[Lemma 8(i)]}\\
&\geq \eta r + sh_j - O(\log r) && \text{[Lemma 11(1)]}\\
&\geq \eta r + sh_j - \frac{\gamma}{4} r. && (3)
\end{aligned}$$

Finally, by Lemma 10,

$$K_{r-sh_j,r}(a,b \mid x, ax+b) \leq \frac{\gamma}{8}r. \tag{4}$$

Together, inequalities (2), (3) and (4) imply that

$$\begin{aligned}
K_r(x, ax+b) &\geq K_r^D(a,b,x) - K_{r-sh_j,r}(a,b\,|,x,ax+b) - \frac{3\gamma}{8}r \\
&\geq \eta r + sh_j - \frac{\gamma}{4}r - \frac{\gamma}{8}r - \frac{3\gamma}{8}r \\
&\geq dr - \frac{\gamma}{4}r + sh_j - \frac{3\gamma}{4}r \\
&\geq dr + sh_j - \gamma r \\
&\geq (s+d)r - \gamma r,
\end{aligned}$$

and the proof is complete. ◀

We now give lower bounds on the complexity of our point, $K_r(x, ax+b)$, when $h_j < r \leq sh_{j+1}$. Intuitively, the proof proeeds as follows. Using the previous lemma, we can, given a 2^{-h_j}-approximation of $(x, ax+b)$, compute a 2^{-h_j}-approximation of (a,b). Thus, we only have to compute the last $r-h_j$ bits of (a,b). Importantly, since $r > h_j$, the last $r-h_j$ bits of x are maximal. Hence, we can simply lower the complexity of the last $r-h_j$ bits of (a,b) to roughly $s(r-h_j)$. Thus, we are again, essentially, in the case where $\dim(x) \geq \dim(a,b)$ and the techniques of Section 3.1 work. We now formalize this intuition.

▶ **Lemma 13.** *For every $\gamma > 0$ and all sufficiently large $j \in \mathbb{N}$,*

$$K_r(x, ax+b) \geq (s+d)r - \gamma r,$$

for every $r \in (h_j, sh_{j+1}]$.

Proof. Recall that we are assuming that $s < d$. Let $\hat{s} \in \mathbb{Q} \cap (0,s)$ be a dyadic rational such that

$$\gamma/8 < s - \hat{s} < \gamma/4.$$

Let $\hat{d} \in \mathbb{Q} \cap (0, \dim(a,b))$ be a dyadic rational such that

$$\gamma/8 < \dim(a,b) - \hat{d} < \gamma/4.$$

Define

$$\alpha = \frac{s(r-h_j) + \dim(a,b)h_j}{r},$$

and $\eta \in \mathbb{Q} \cap (0, \alpha)$ by

$$\eta = \frac{\hat{s}(r-h_j) + \hat{d}h_j}{r}.$$

Finally, let $\varepsilon = \gamma^2/64$. Note that

$$\begin{aligned}
\alpha - \eta &= \frac{s(r-h_j) + dh_j - \hat{s}(r-h_j) - \hat{d}h_j}{r} \\
&= \frac{(s-\hat{s})(r-h_j) + (d-\hat{d})h_j}{r} \\
&\leq \frac{\frac{\gamma}{4}(r-h_j) + \frac{\gamma}{4}h_j}{r} \\
&= \frac{\gamma}{4}
\end{aligned} \tag{5}$$

Similarly,

$$\begin{aligned}\alpha - \eta &= \frac{s(r-h_j) + \dim(a,b)h_j - \hat{s}(r-h_j) - \hat{d}h_{j-1}}{r} \\ &= \frac{(s-\hat{s})(r-h_j) + (\dim(a,b) - \hat{d})h_j}{r} \\ &> \frac{\frac{\gamma}{8}(r-h_j) + \frac{\gamma}{8}h_j}{r} \\ &= \frac{\gamma}{8} \end{aligned} \tag{6}$$

In particular,

$$\frac{4\varepsilon}{\alpha - \eta} \leq \gamma/4. \tag{7}$$

We also note that

$$K(\varepsilon, \eta) \leq K(\gamma, \hat{s}, \hat{d}, r, h_j) \leq O(\log r), \tag{8}$$

since j was chosen to be sufficiently large and γ is constant.

Finally, let $D = D(r, (a,b), \eta)$ be the oracle of Lemma 8. Note that we chose D so that, roughly, D lowers the complexity of the last $r - h_j$ bits of (a,b) to $s(r-h_j)$.

Let (u,v) be a line such that $t := \|(a,b) - (u,v)\| \geq h_j$, and $ux + v = ax + b$. Then, by Lemmas 7, 8 and 11,

$$\begin{aligned} K_r^D(u,v) &\geq K_t^D(a,b) + K_{r-t,r}^D(x \,|\, a,b) - O(\log r) && \text{[Lemma 7]} \\ &\geq K_t^D(a,b) + K_{r-t,r}(x \,|\, a,b) - O(\log r) && \text{[Lemma 8]} \\ &\geq K_t^D(a,b) + s(r-t) - O(\log r). && \text{[Lemma 11(1)]} \end{aligned}$$

There are two cases. In the first, $K_t^D(a,b) = \eta r$. Then,

$$\begin{aligned} K_r^D(u,v) &\geq \eta r + s(r-t) - O(\log r) \\ &\geq (\eta - \varepsilon)r + s(r-t) \\ &\geq (\eta - \varepsilon)r + (\alpha - \eta)(r-t). \end{aligned}$$

In the other case, $K_t^D(a,b) = K_t(a,b)$. Then,

$$\begin{aligned} K_r^D(u,v) &\geq K_t(a,b) + s(r-t) - O(\log r) \\ &\geq dt - o(t) + s(r-t) - O(\log r) && \text{[Definition of dim]} \\ &= dh_j + d(t-h_j) + s(r-t) - o(r) \\ &= dh_j + d(t-h_j) + s(r-h_j) - s(t-h_j) - o(r) \\ &= \alpha r + (d-s)(t-h_j) - o(r) \\ &= \eta r + (\alpha - \eta)r + (d-s)(t-h_j) - o(r) \\ &\geq \eta r + (\alpha - \eta)(r-t) - o(r) \\ &\geq (\eta - \varepsilon)r + (\alpha - \eta)(r-t). \end{aligned}$$

Therefore we may apply Lemma 6, which yields

$$\begin{aligned}
K_r^D(a,b,x) &\leq K_r(x, ax+b) + K^D_{h_j,r}(a,b,x \,|\, x, ax+b) && \text{[Lemma 6]}\\
&\quad + \frac{4\varepsilon}{\alpha-\eta} r + K(\varepsilon,\eta) + O(\log r)\\
&\leq K_r(x, ax+b) + K^D_{h_j,r}(a,b,x \,|\, x, ax+b)\\
&\quad + \frac{\gamma}{4} r + \frac{\gamma}{8} r && \text{[Choice of } \eta, \varepsilon\text{]}\\
&= K_r(x, ax+b) + K^D_{h_j,r}(a,b,x \,|\, x, ax+b) + \frac{3\gamma}{8} r. && (9)
\end{aligned}$$

By Lemma 11, and our construction of oracle D,

$$\begin{aligned}
K_r^D(a,b,x) &= K_r^D(a,b) + K_r^D(x \,|\, a,b) - O(\log r) && \text{[Lemma 2]}\\
&= \eta r + K_r(x \,|\, a,b) - O(\log r) && \text{[Lemma 8]}\\
&\geq \eta r + s h_j + r - h_j - O(\log r) && \text{[Lemma 11(2)]}\\
&\geq \alpha r - \frac{\gamma}{4} r + s h_j + r - h_j - O(\log r)\\
&\geq s(r - h_j) + d h_j - \frac{\gamma}{4} r + s h_j + r - h_j - O(\log r)\\
&\geq (1+s) r - (1-d) h_j - \frac{\gamma}{4} r. && (10)
\end{aligned}$$

By Lemmas 12, and 2, and the fact that additional information cannot increase Kolmogorov complexity

$$\begin{aligned}
K_{h_j,r}(a,b,x \,|\, x, ax+b) &\leq K_{h_j,h_j}(a,b,x \,|\, x, ax+b)\\
&= K_{h_j}(a,b,x) - K_{h_j}(x, ax+b) && \text{[Lemma 2]}\\
&= K_{h_j}(a,b) + K_{h_j}(x \mid a,b)\\
&\qquad - K_{h_j}(x, ax+b) && \text{[Lemma 2]}\\
&= K_{h_j}(a,b) + s h_j - K_{h_j}(x, ax+b) && \text{[Lemma 11]}\\
&\leq K_{h_j}(a,b) + s h_j - (s+d) h_j + \frac{\gamma}{16} h_j && \text{[Lemma 12]}\\
&\leq d h_j + h_j/j - d h_j + \frac{\gamma}{16} r && \text{[Definition of } h_j\text{]}\\
&\leq \frac{\gamma}{8} r && (11)
\end{aligned}$$

Combining inequalities (9), (10) and (11) , we see that

$$\begin{aligned}
K_r(x, ax+b) &\geq K_r^D(a,b,x) - \frac{\gamma}{8} r - \frac{3\gamma}{8} r\\
&\geq (1+s) r - (1-d) h_j - \frac{\gamma}{4} r - \frac{\gamma}{4} r\\
&\geq (1+s) r - (1-d) h_j - \gamma r.
\end{aligned}$$

Note that, since $d \leq 1$, and $h_j \leq r$,

$$\begin{aligned}
(1+s) r - h_j(1-d) - (s+d) r &= r(1-d) - h_j(1-d)\\
&= (r - h_j)(1-d)\\
&\geq 0.
\end{aligned}$$

Thus,

$$\begin{aligned} K_r(x, ax+b) &\geq (1+s)r - h_j(1-d) - \gamma r \\ &\geq (s+d)r - \gamma r, \end{aligned}$$

and the proof is complete for the case $s < \dim(a,b)$. ◀

We are now able to prove our main theorem of this section.

▶ **Theorem 9.** *Let $(a,b) \in \mathbb{R}^2$ be a slope-intercept pair with $\dim(a,b) \leq 1$. Then for every $s \in [0,1]$, there is a point $x \in \mathbb{R}$ such that*

$$\dim(x, ax+b) = s + \dim(a,b).$$

Proof. Let $(a,b) \in \mathbb{R}^2$ be a slope-intercept pair with

$$d = \dim(a,b) \leq 1.$$

Let $s \in [0,1]$. If $s = 0$, then

$$\begin{aligned} K_r(a, a^2+b) &= K_r(a) + K_r(a^2+b \,|\, a) + O(\log r) \\ &= K_r(a) + K_r(b \,|\, a) + O(\log r) \\ &= K_r(a,b) + O(\log r), \end{aligned}$$

and so the conclusion holds.

If $s = 1$, then by [11], for any point x which is random relative to (a,b),

$$\dim(x, ax+b) = 1 + d,$$

and the claim follows.

If $s \geq d$, then Lutz and Stull [11] showed that for any x such that

$$\dim^{a,b}(x) = \dim(x) = s,$$

we have $\dim(x, ax+b) = s + d$.

Therefore, we may assume that $s \in (0,1)$ and $s < d$. Let x be the point constructed in this section. Let $\gamma > 0$. Let j be large enough so that the conclusions of Lemmas 12 and 13 hold for these choices of (a,b), x, s and γ. Then, by Lemmas 12 and 13,

$$\begin{aligned} \dim(x, ax+b) &= \liminf_{r\to\infty} \frac{K_r(x, ax+b)}{r} \\ &\geq \liminf_{r\to\infty} \frac{(s+d)r - \gamma r}{r} \\ &= s + d - \gamma. \end{aligned}$$

Since we chose γ arbitrarily, we see that

$$\dim(x, ax+b) \geq s + d.$$

For the upper bound, let $j \in \mathbb{N}$ be sufficiently large. Then

$$\begin{aligned} K_{h_j}(x, ax+b) &\leq K_{h_j}(x, a, b) \\ &= K_{h_j}(a,b) + K_{h_j}(x \,|\, a, b) \\ &\leq dh_j + sh_j \\ &= (d+s)h_j. \end{aligned}$$

Therefore,

$$\dim(x, ax+b) \leq s + d,$$

and the proof is complete. ◀

5 High-Dimensional Lines

In this section we prove the following theorem.

▶ **Theorem 14.** *Let $(a,b) \in \mathbb{R}^2$ be a slope-intercept pair with $\dim(a,b) > 1$.. Then for every $s \in [0,1]$, there is a point $x \in \mathbb{R}$ such that*

$$\dim(x, ax+b) = 1 + s.$$

5.1 Overview of proof

In this case, we again apply essential insight of the proof for low-dimensional lines, namely, encoding (a subset of) the information of a into x. However, when $\dim(a,b) > 1$ constructing x as before potentially causes a problem. Specifically, in this case, the previous construction might cause $\dim(x, ax+b)$ to become too large.

The overcome this, we rely on a non-constructive argument. More specifically, we begin as in the construction of x in the low-dimensional case. However at stage j of our construction, we do not add all $h_j - sh_j$ bits of a to x. Instead we consider the $m = h_j - sh_j$ strings $\mathbf{x_0}, \ldots, \mathbf{x_m}$, where

$$\mathbf{x_n}[i] = \begin{cases} 0 & \text{if } 0 \leq i < m-n \\ \frac{1}{a}[i-(m-n)] & \text{if } m-n \leq i \leq m \end{cases} \tag{*}$$

and look at the extension of x with the bits of $\mathbf{x_n}$.

Using a discrete, approximate, version of the intermediate value theorem, we are able to conclude that there is some extension $x' = x\mathbf{x_n}$ such that

$$\min_{sh_j \leq r \leq h_j} |K_r(x', ax'+b) - (1+s)r|$$

is sufficiently small. We then carry on with the argument of the low-dimensional lines until sh_{j+1}.

5.2 Proof for high-dimensional lines

In order to prove Theorem 14, we will, given any slope-intercept pair (a,b) and $s \in (0,1)$, construct a point $x \in [0,1]$ such that $\dim(x, ax+b) = 1+s$.

Our construction is best phrased as constructing an infinite binary sequence $\mathbf{x}$, and then taking x to be the unique real number whose binary expansion is $\mathbf{x}$. We now recall terminology needed in the construction. We will use bold variables to denote binary strings and (infinite) binary sequences. If $\mathbf{x}$ is a (finite) binary string and $\mathbf{y}$ is a binary string or sequence, we write $\mathbf{x} \prec \mathbf{y}$ if $\mathbf{x}$ is a prefix of $\mathbf{y}$.

Let (a,b) be a slope intercept pair and let $d = \dim(a,b)$. Define the sequence of natural numbers $\{h_j\}_{j \in \mathbb{N}}$ inductively as follows. Define $h_0 = 2$. For every $j > 0$, let

$$h_j = \min\left\{h \geq 2^{h_{j-1}} : K_h(a,b) \leq \left(d + 2^{-j}\right) h\right\}.$$

We define our sequence $\mathbf{x}$ inductively. Let $\mathbf{y}$ be a random, relative to (a,b), binary sequence. That is, there is some constant c such that

$$K^{a,b}(y\restriction r) \geq r - c, \tag{12}$$

for every $r \in \mathbb{N}$. We begin our inductive definition by setting $\mathbf{x}[0 \dots 2] = \mathbf{y}[0 \dots 2]$. Suppose we have defined $\mathbf{x}$ up to h_{j-1}. We then set

$$\mathbf{x}[r] = \mathbf{y}[r], \text{ for all } h_{j-1} < r \leq sh_j.$$

To specify the next $h_j - sh_j$ bits of $\mathbf{x}$, we use the following lemma, which we will prove in the next section.

▶ **Lemma 15.** *For every sufficiently large j, there is a binary string $\mathbf{z}$ of length $h_j - sh_j$ such that*

$$\min_{sh_j < r \leq h_j} |K_r(x, ax+b) - (1+s)r| < \frac{r}{j},$$

where x is any real such that $\mathbf{xz} \prec x$. Moreover, $\mathbf{z}$ is of the form (*) of Section 5.1.

For now, we assume the truth of this lemma. If the current j is not sufficiently large, take $\mathbf{z}$ to be the string of all zeros. Otherwise, if j is sufficiently large, we let $\mathbf{z}$ be such a binary string. We then set

$$\mathbf{x}[r] = \mathbf{z}[r - sh_j], \text{ for all } sh_j < r \leq h_j,$$

completing the inductive step. Finally, we let $x_{a,b,s}$ be the real number with binary expansion $\mathbf{x}$.

▶ **Proposition 16.** *Let $x = x_{a,b,s}$ be the real we just constructed. Then for every j,*
1. $K^{a,b}_{sh_j}(x) \geq sh_j - O(\log h_j)$, *and*
2. $K_r(x \mid a, b) \geq sh_j + r - h_j$, *for every $h_j \leq r < sh_{j+1}$.*

We now show, again assuming Lemma 15, that $\dim(x, ax+b) = 1+s$, where $x = x_{a,b,s}$ is the point we have just constructed.

We begin by proving an upper bound on $\dim(x, ax+b)$. Note that this essentially follows from our choice of $\mathbf{z}$.

▶ **Proposition 17.** *Let (a, b) be a slope intercept pair, $s \in (0,1)$ and $\gamma \in \mathbb{Q}$ be positive. Let $x = x_{a,b,s}$ be the point we have just constructed. Then*

$$\dim(x, ax+b) \leq (1+s) + \gamma.$$

Proof. Let j be sufficiently large. By our construction of x,

$$\min_{sh_j < r \leq h_j} |K_r(x, ax+b) - (1+s)r| < \frac{\gamma r}{4} \tag{13}$$

Therefore,

$$\begin{aligned}
\dim(x, ax+b) &= \liminf_r \frac{K_r(x, ax+b)}{r} \\
&\leq \liminf_j \min_{sh_j < r \leq h_j} \frac{K_r(x, ax+b)}{r} \\
&\leq \liminf_j \min_{sh_j < r \leq h_j} \frac{(1+s)r + \gamma r/4}{r} \\
&= \liminf_j \min_{sh_j < r \leq h_j} 1 + s + \gamma/4 \\
&= 1 + s + \frac{\gamma}{4}.
\end{aligned}$$

◀

We break the proof of the lower bound on $\dim(x, ax+b)$ into two parts. In the first, we give lower bounds on $K_r(x, ax+b)$ on the interval $r \in (sh_j, h_j]$. Note that this essentially follows from inequality (13).

▶ **Proposition 18.** *Let (a,b) be a slope intercept pair, $s \in (0,1)$, $\gamma \in \mathbb{Q}$ be positive and j be sufficiently large. Let $x = x_{a,b,s}$ be the point we have just constructed. Then*

$$K_r(x, ax+b) \geq (1+s-\gamma)r$$

for all $sh_j < r \leq h_j$

We now give lower bounds on $K_r(x, ax+b)$ on the interval $r \in (h_{j-1}, sh_j]$. The proof of this lemma is very similar to the analogous lemma for low-dimensional lines (Lemma 13). Intuitively, the proof is as follows. Using the previous lemma, we can, given a 2^{-h_j}-approximation of $(x, ax+b)$, compute a 2^{-h_j}-approximation of (a,b) *with a small amount of extra bits*. Having done so, we have to compute the last $r-h_j$ bits of (a,b). Importantly, since $r > h_j$, the last $r-h_j$ bits of x are maximal. Thus, we can simply lower the complexity of the last $r-h_j$ bits of (a,b) so that the complexity of these bits is roughly $s(r-h_j)$. Thus, we are again, morally, in the case where $\dim(x) \geq \dim(a,b)$ and the techniques of Section 3.1 work.

▶ **Lemma 19.** *Let (a,b) be a slope intercept pair, $s \in (0,1)$, $\gamma \in \mathbb{Q}$ be positive and j be sufficiently large. Let $x = x_{a,b,s}$ be the point we have just constructed. Then*

$$K_r(x, ax+b) \geq (1+s-\gamma)r$$

for all $h_{j-1} < r \leq sh_j$

Proof. Intuitively, we will use the approximation of $(x, ax+b)$ at precision h_{j-1} to compute (a,b) at precision h_{j-1}. Then we will only search for candidate lines within $2^{-h_{j-1}}$ of (a,b). Formally, the argument proceeds as follows.

We first show that we can compute (a,b) to within $2^{-h_{j-1}}$ with an approximation of $(x, ax+b)$, with few additional bits of information. By Lemma 2 and inequality (13)

$$\begin{aligned}
K_{h_{j-1},r}(a,b,x \mid x, ax+b) &\leq K_{h_{j-1},h_{j-1}}(a,b,x \mid x, ax+b) + O(\log h_j)) \\
&= K_{h_{j-1}}(a,b,x) - K_{h_{j-1}}(x, ax+b) && \text{[Lemma 2]} \\
&\leq K_{h_{j-1}}(a,b,x) - (1+s)h_{j-1} + \frac{\gamma}{4}h_{j-1} && \text{[(13)]} \\
&= K_{h_{j-1}}(a,b) + K_{h_{j-1}}(x \mid a,b) \\
&\qquad - (1+s)h_{j-1} + \frac{\gamma}{4}h_{j-1} && \text{[Lemma 2]} \\
&\leq dh_{j-1} + h_j 2^{-j} + K_{h_{j-1}}(x \mid a,b) \\
&\qquad - (1+s)h_{j-1} + \frac{\gamma h_{j-1}}{4} && \text{[Definition } h_j\text{]} \\
&\leq dh_{j-1} + h_j 2^{-j} + sh_{j-1} \\
&\qquad - (1+s)h_{j-1} + \frac{\gamma h_{j-1}}{4} && \text{[Proposition 16]} \\
&\leq dh_j + sh_{j-1} \\
&\qquad - (1+s)h_{j-1} + \frac{\gamma h_{j-1}}{2} && [j \text{ large}] \\
&\leq dh_j - h_j + \frac{\gamma h_{j-1}}{2}. && (14)
\end{aligned}$$

Thus, we can, given a 2^{-r} approximation of $(x, ax+b)$, compute a $2^{-h_{j-1}}$-approximation of (a,b) with

$$(d-1)h_j + \frac{\gamma h_{j-1}}{2}$$

additional bits of information. Knowing (a,b) to precision h_{j-1} allows us to search for candidate lines within $2^{-h_{j-1}}$ of (a,b), i.e., using Lemma 6 with $m = h_{j-1}$.

Let $\hat{s} \in \mathbb{Q} \cap (0,s)$ be a dyadic rational such that

$$\gamma/8 < s - \hat{s} < \gamma/4.$$

Let $\hat{d} \in \mathbb{Q} \cap (0, \dim(a,b))$ be a dyadic rational such that

$$\gamma/8 < \dim(a,b) - \hat{d} < \gamma/4.$$

Define

$$\alpha = \frac{s(r-h_{j-1}) + dh_{j-1}}{r}.$$

Define

$$\eta = \frac{\hat{s}(r-h_{j-1}) + \hat{d}h_{j-1}}{r}.$$

Finally, let $\varepsilon = \gamma^2/64$. Note that

$$\begin{aligned}
\alpha - \eta &= \frac{s(r-h_{j-1}) + dh_{j-1} - \hat{s}(r-h_{j-1}) - \hat{d}h_{j-1}}{r} \\
&= \frac{(s-\hat{s})(r-h_{j-1}) + (d-\hat{d})h_{j-1}}{r} \\
&\leq \frac{\frac{\gamma}{4}(r-h_{j-1}) + \frac{\gamma}{4}h_{j-1}}{r} \\
&= \frac{\gamma}{4} \qquad (15)
\end{aligned}$$

Similarly,

$$\begin{aligned}
\alpha - \eta &= \frac{s(r-h_{j-1}) + dh_{j-1} - \hat{s}(r-h_{j-1}) - \hat{d}h_{j-1}}{r} \\
&= \frac{(s-\hat{s})(r-h_{j-1}) + (d-\hat{d})h_{j-1}}{r} \\
&> \frac{\frac{\gamma}{8}(r-h_{j-1}) + \frac{\gamma}{4}h_{j-1}}{r} \\
&= \frac{\gamma}{8} \qquad (16)
\end{aligned}$$

In particular,

$$\frac{4\varepsilon}{\alpha - \eta} \leq \gamma/4. \qquad (17)$$

We also note that

$$K(\varepsilon, \eta) \leq K(\gamma, \hat{s}, \hat{d}, r, h_{j-1}) \leq O(\log r), \qquad (18)$$

since j was chosen to be sufficiently large and γ is constant.

Let $D = D(r, (a, b), \eta)$ be the oracle of Lemma 8. We now show that the conditions of Lemma 6 are satisfied for these choices $a, b, \eta, \varepsilon, r$ and $\delta = \alpha - \eta$, $m = h_{j-1}$ and $A = D$.

Let (u, v) be a line such that $t := \|(a, b) - (u, v)\| \geq h_{j-1}$, and $ux + v = ax + b$. Then, by Lemmas 7, 8, and Proposition 16,

$$\begin{aligned}
K_r^D(u, v) &\geq K_t^D(a, b) + K_{r-t,r}^D(x \,|\, a, b) - O(\log r) && \text{[Lemma 7]} \\
&\geq K_t^D(a, b) + K_{r-t,r}(x \,|\, a, b) - O(\log r) && \text{[Lemma 8]} \\
&\geq K_t^D(a, b) + s(r - t) - O(\log r). && \text{[Proposition 16]}
\end{aligned}$$

By Lemma 8, there are two cases. In the first, $K_t^D(a, b) = \eta r$, and so

$$\begin{aligned}
K_r^D(u, v) &\geq K_t^D(a, b) + s(r - t) - O(\log r) \\
&= \eta r + s(r - t) - O(\log r) \\
&\geq (\eta - \varepsilon)r + s(r - t) && [j \text{ is large}] \\
&\geq (\eta - \varepsilon)r + \delta(r - t) && [\gamma \text{ is small}]
\end{aligned}$$

In the second case, $K_t^D(a, b) = K_t(a, b)$, and so

$$\begin{aligned}
K_r^D(u, v) &\geq K_t^D(a, b) + s(r - t) - O(\log r) \\
&\geq dt - o(t) + s(r - t) - O(\log r) && \text{[Definition of dim]} \\
&= dh_{j-1} + d(t - h_{j-1}) + s(r - t) - o(r) \\
&= dh_{j-1} + d(t - h_{j-1}) + s(r - h_{j-1}) - s(t - h_{j-1}) - o(r) \\
&= \alpha r + d(t - h_{j-1}) - s(t - h_{j-1}) - o(r) && \text{[Definition of } \alpha] \\
&= \eta r + (\alpha - \eta)r + (d - s)(t - h_{j-1}) - o(r) \\
&\geq \eta r + (\alpha - \eta)r - o(r) && [d > 1,\, t > h_{j-1}] \\
&\geq \eta r + (\alpha - \eta)(r - t) - o(r) && [\alpha > \eta] \\
&\geq (\eta - \varepsilon)r + \delta(r - t) && [j \text{ is large}]
\end{aligned} \tag{19}$$

Therefore, in either case, we may apply Lemma 6, relative to D which yields

$$\begin{aligned}
K_r^D(a, b, x) &\leq K_r(x, ax + b) + K_{h_j,r}(a, b, x \,|\, x, ax + b) \\
&\quad + \frac{4\varepsilon}{\alpha - \eta} r + K(\varepsilon, \eta) + O(\log r) && \text{[Lemma 6]} \\
&\leq K_r(x, ax + b) + dh_j - h_j + \frac{\gamma h_{j-1}}{2} \\
&\quad + \frac{4\varepsilon}{\alpha - \eta} r + K(\varepsilon, \eta) + O(\log r) && [(14)] \\
&\leq K_r(x, ax + b) + dh_j - h_j + \frac{\gamma h_{j-1}}{2} \\
&\quad + \frac{4\varepsilon}{\alpha - \eta} r + O(\log r) && [(18)] \\
&\leq K_r(x, ax + b) + dh_j - h_j + \frac{\gamma h_{j-1}}{2} \\
&\quad + \frac{\gamma r}{4} + O(\log r) && [(17)] \\
&\leq K_r(x, ax + b) + dh_j - h_j + \frac{3\gamma r}{4} + O(\log r) && (20)
\end{aligned}$$

By Lemma 11, and our construction of oracle D,

$$\begin{aligned}
K^D_r(a,b,x) &= K^D_r(a,b) + K^D_r(x \,|\, a,b) - O(\log r) && \text{[Lemma 2]}\\
&= \eta r + K_r(x \,|\, a,b) - O(\log r) && \text{[Lemma 8]}\\
&\geq \eta r + sh_j + r - h_j - O(\log r) && \text{[Lemma 11(2)]}\\
&\geq \alpha r - \frac{\gamma}{4} r + sh_j + r - h_j - O(\log r)\\
&\geq s(r-h_j) + dh_j - \frac{\gamma}{4} r + sh_j + r - h_j - O(\log r)\\
&\geq (1+s)r - (1-d)h_j - \frac{\gamma}{4} r. && (21)
\end{aligned}$$

Rearranging (20) and combining this with (21), we see that

$$\begin{aligned}
K_r(x, ax+b) &\geq K^D_r(a,b,x) - dh_j + h_j - \frac{3\gamma r}{4} - O(\log r) && \text{[(20)]}\\
&\geq (1+s)r - (1-d)h_j - \frac{\gamma}{4} r\\
&\qquad - dh_j + h_j - \frac{3\gamma r}{4} - O(\log r) && \text{[(21)]}\\
&= (1+s)r - \gamma r - O(\log r) && \blacktriangleleft
\end{aligned}$$

We are now able to prove that the Dimension Spectrum Conjecture holds for high dimensional lines.

Proof of Theorem 14. Let $(a,b) \in \mathbb{R}^2$ be a slope-intercept pair with

$$d = \dim(a,b) > 1.$$

Let $s \in [0,1]$. In the case where $s = 0$, Turetsky showed (Theorem 1) that $1 \in \mathrm{sp}(L_{a,b})$, i.e., there is a point x such that $\dim(x, ax+b) = 1$. In the case where $s = 1$, Lutz and Stull [11] showed than any point x which is random relative to (a,b) satisfies

$$\dim(x, ax+b) = 2.$$

Therefore, we may assume that $s \in (0,1)$. Let $x = x_{a,b,s}$ be the point constructed in this section. By Propositions 17 and 18 and Lemma 19, for every γ,

$$|\dim(x, ax+b) - (1+s)| < \gamma.$$

Thus, by the definition of effective dimension,

$$\dim(x, ax+b) = 1 + s,$$

and the proof is complete. ◀

5.3 Proof Sketch of Lemma 15

To complete the proof of the main theorem of this section, we now prove Lemma 15. Recall that this states that, for every j, after setting $\mathbf{x}[h_{j-1} \ldots sh_j] = \mathbf{y}[h_{j-1} \ldots sh_j]$, the following holds.

▶ **Lemma 15.** *For every sufficiently large j there is a binary string $\mathbf{z}$ of length $h_j - sh_j$ such that*

$$\min_{sh_j < r \leq h_j} |K_r(x, ax+b) - (1+s)r| < \frac{r}{j},$$

where x is any real such that $\mathbf{xz} \prec x$. Moreover, $\mathbf{z}$ is of the form (*) of Section 5.1.

Let $m = h_j - sh_j$. For each $0 \leq n \leq m$, define the binary string $\mathbf{x_n}$ of length m by

$$\mathbf{x_n}[i] = \begin{cases} 0 & \text{if } 0 \leq i < m - n \\ \frac{1}{a}[i - (m-n)] & \text{if } m - n \leq i \leq m \end{cases}$$

Thus, for example $\mathbf{x_0}$ is the binary string of m zeros, while $\mathbf{x_m}$ is the binary string containing the m-bit prefix of $\frac{1}{a}$.

Let x be the real number such that $\mathbf{x}\mathbf{x_0} \prec x$, and whose binary expansion contains only zeros after sh_j. For each $1 \leq n \leq m$, let x_n be the real number defined by

$$x_n = x + 2^{-h_j+n}/a.$$

Therefore, for every n,

$$(x_n, ax_n + b) = (x_n, ax + b + 2^{-h_j+n}).$$

Since the binary expansion of x satisfies $x[r] = 0$ for all $r \geq sh_j$, we have, for every n,

$$\mathbf{x}\mathbf{x_n} \prec x_n \tag{22}$$

In other words, the binary expansion of x_n up to index h_j is just the concatenation of $\mathbf{x}$ and $\mathbf{x_n}$.

We now collect a few facts about our points x_n.

▶ **Lemma 20.** *For every n, r such that $0 \leq n \leq m$ and $sh_j \leq r \leq h_j$ the following hold.*

1. $K_{n,h_j}(a \,|\, x_n) \leq O(\log h_j)$.
2. *For every n and $n' > n$,*

$$|K_r(x_{n'}, ax_{n'} + b) - K_r(x_n, ax_n + b)| < n' - n + \log(r).$$

3. $K_{r-sh_j,r}(a, b \mid x_m, ax_m + b) \leq O(\log r)$.

Note that the constants implied by the big oh notation depend only on a.

6 Conclusion and Future Directions

The behavior of the effective dimension of points on a line is not only interesting from the algorithmic randomness viewpoint, but also because of its deep connections to geometric measure theory. There are many avenues for future research in this area.

The results of this paper show that, for any line $L_{a,b}$, the dimension spectrum $\mathrm{sp}(L_{a,b})$ contains a unit interval. However, this is not, in general, a tight bound. It would be very interesting to have a more thorough understanding of the "low end" of the dimension spectrum. Stull [17] showed that the Hausdorff dimension of points x such that

$$\dim(x, ax + b) \leq \alpha + \frac{\dim(a, b)}{2}$$

is at most α. Further investigation of the low-end of the spectrum is needed.

It seems plausible that, for certain lines, the dimension spectrum contains an interval of length greater than one. For example, are there lines in the plane such that $\mathrm{sp}(L)$ contains an interval of length strictly greater than 1?

Another interesting direction is to study the dimension spectrum of particular classes of lines. One natural class is the lines $L_{a,b}$ whose slope and intercept are both in the Cantor set. By restricting the lines to the Cantor set, or, more generally, self-similar fractals, might give enough structure to prove tight bounds not possible in the general case.

Additionally, the focus has been on the effective (Hausdorff) dimension of points. Very little is known about the effective *strong* dimension of points on a line. The known techniques do not seem to apply to this question. New ideas are needed to understand the strong dimension spectrum of planar lines.

Finally, it would be interesting to broaden this direction by considering the dimension spectra of other geometric objects. For example, can anything be said about the dimension spectrum of a polynomial?
