increases the utility of both incident nodes, we call this an *improving move*. A network without improving moves is referred to as *pairwise stable* [33] or *stable* for short[3]. If there are no improving edge additions or removals we call the network *stable against edge addition* and *stable against edge removal*, respectively.

For a host network H, we define $\mathcal{S}(H)$ as the set of all pairwise stable states. For measuring the efficiency lost by letting agents form the network selfishly, we use the *Price of Anarchy* (PoA) [38] and *Price of Stability* (PoS) [7] defined as

$$\mathrm{PoA}_n \coloneqq \max_{H\in\mathcal{G}_n}\max_{G\in\mathcal{S}(H)}\frac{\mathrm{SW}(\mathrm{OPT}_H)}{\mathrm{SW}(G)} \quad \text{and} \quad \mathrm{PoS}_n \coloneqq \max_{H\in\mathcal{G}_n}\min_{G\in\mathcal{S}(H)}\frac{\mathrm{SW}(\mathrm{OPT}_H)}{\mathrm{SW}(G)}.$$

We will call this model *Social Distancing Network Creation Game* (SDNCG). In Section 2 we will restrict the host networks to complete networks K_n. We will call this restricted variant *complete Social Distancing Network Creation Game* (K-SDNCG).

1.2 Related Work

Variants of game-theoretic network formation models have been studied extensively for decades and we refer to Jackson [32] for an overview.

Closest to our work is the literature on the Network Creation Game (NCG) by Fabrikant et al. [23]. This influential model can be seen as the unilateral inverted variant of the K-SDNCG. There, an agent can buy any incident edge without the consent of the other endpoint for the price of $\alpha > 0$. Each agent aims at minimizing its cost, which is defined as the sum of α times the number of bought edges and the sum of hop-distances to all agents. The authors of [23] show that Nash equilibria always exist, i.e., complete networks are stable for $\alpha \leq 2$ and stars are stable for $\alpha \geq 2$. However, besides these generic examples finding Nash equilibria is challenging since the NCG and many of its variants do not belong to the class of potential games [39, 37]. Besides finding equilibria, also computing a best possible strategy is challenging, since this problem was shown to be NP-hard in [23]. However, such strategies can be efficiently approximated with greedy strategy changes [40]. Regarding the quality of equilibrium states the authors of [23] show that the PoA is in $\mathcal{O}(\sqrt{\alpha})$, that the PoA for tree Nash equilibria is constant, and that the PoS is at most $\frac{4}{3}$. Later, a series of papers [2, 20, 43, 42, 4, 12, 5] improved the PoA bounds, with the best general upper bound of $2^{\mathcal{O}\sqrt{\log n}}$ by Demaine et al. [20]. The latter also proved that the PoA is constant for $\alpha \in \mathcal{O}(n^{1-\varepsilon})$ for any fixed $\varepsilon > \frac{1}{\log n}$. For large α, it was shown by Bilò and Lenzner [12] that for $\alpha > 4n - 13$ all Nash equilibria must be trees and this bound was recently improved by Dippel and Vetta [21] to $\alpha > 3n - 3$. This implies a constant PoA for $\alpha > 3n - 3$. Finally, Álvarez and Messegué [5] established a constant PoA for $\alpha > n(1 + \varepsilon)$, for any $\varepsilon > 0$.

The NCG was generalized by Demaine et al. [19] by introducing a host network that specifies which edges can be bought. They show that the PoA deteriorates by providing a lower bound of $\Omega(\min\{\alpha/n, n^2/\alpha\})$ and an upper bound of $\mathcal{O}(\sqrt{\alpha})$, for $\alpha < n$, and $\mathcal{O}(\min\{\sqrt{n}, n^2/\alpha\})$, for $\alpha \geq n$. Interestingly, no results on the existence of equilibria are known. Recently, a further generalization that allows weighted host networks was proposed by Bilò et al. [11]. This variant has a tight PoA of $(\alpha + 2)/2$ for metric weights. Later a

[3] As shown by Corbo and Parkes [18] for bilateral Network Creation Games, pairwise stability is equivalent to pairwise Nash stability, which is a refinement of the Nash equilibrium: it must be stable against unilateral deviations and it must be stable against joint strategy changes by coalitions of agents of size two. The strategy space of any agent $i \in V$ is the power set of $V \setminus i$. An edge $\{u, v\}$ is formed if and only if v is in agent u's strategy and u is in agent v's strategy.

tight bound of $\Theta(\alpha)$ was shown for arbitrary weights [24]. Also a bilateral variant of the NCG was studied by Corbo and Parkes [18]. There, similar to our model, edges can only be established by bilateral consent of the involved nodes and both nodes have to pay α. The authors of [18] prove existence of pairwise stable networks, i.e., complete networks are stable for $\alpha \leq 1$ and stars are stable for $\alpha \geq 1$, they give a tight PoA bound of $\Theta(\min\{\sqrt{\alpha}, n/\sqrt{\alpha}\})$, and they show that the PoS is 1. To the best of our knowledge, the bilateral variant with a given host network has not yet been studied. Recently, also a bilateral variant modeling the formation of social networks was introduced [10].

The idea of a game-theoretic model of network formation in a context of spreading risk is not new. Goyal et al. [28] study a setting where a node is attacked and this attack spreads to all vulnerable neighbors. Agents strategically create edges and immunize themselves to maximize their connected component post attack. For this model, also the efficient computation of best strategies [26] and a variant with probabilistic spread [17] was studied. Moreover, there has been much research in the context of financial contagion, where agents benefit from collaborating, but also suffer from the risk of cascading failure arising with the collaboration [3, 30, 15, 1]. In particular, Blume et al. [13] developed an elegant model where nodes form a network and then some randomly chosen nodes fail and this failure then spreads with some probability via the edges. The utility is a linear combination of the node degree and the risk of failing in the second phase. The virtue of this model is that utilities are based on a random process that realistically models the spread of a contagious infection. However, the major downside of this model is that the computation of the random process is #P-complete. Thus, this model does not yield a realistic prediction of real-world behavior.

While analyzing our model for general host networks, we consider Maximum Routing-Cost Spanning Trees. Routing costs have been studied much in mathematics, mostly under the name of the *Wiener index* [48]. Trees were of special interest and there has been much research on the Wiener index of trees with different properties. But although spanning trees minimizing the Wiener index were studied extensively, the concept of spanning trees maximizing the Wiener index received little attention [22, 49]. However, it was shown that finding or even approximating a tree maximizing the Wiener index is NP-hard [16, 27].

1.3 Our Contribution

We introduce the Social Distancing Network Creation Game (SDNCG), a game-theoretic model in which selfish agents try to maximize their utility by strategically connecting to other agents and thereby creating a network. Each agent values direct connections to other agents but at the same time wants to maximize the distances to all other agents in order to lower their exposure and increase their reaction time to risks appearing in the network. In contrast to the similar model by Blume et al. [13], our model, while not modeling a perfectly realistic spread of the infection, has the advantage of an efficiently computable utility function. By using the distance to the other agents as part of the utility, it also accounts for reaction time: If an infection breaks out far away, an agent has more time to prepare or react to it. Another virtue of our model is that it is the inverse to the well-known Network Creation Game [23] and its bilateral variant [18]. Hence, we can study and compare the game-theoretic properties of the inverted models. To the best of our knowledge, this is one of the rare cases where both the minimization and the maximization of a utility function have a natural interpretation.

Our results and the comparison with the inverted models are summarized in Table 1. We analyze two variants of the SDNCG. For the K-SDNCG, where we assume a complete host network, we characterize optimal and several stable networks and show that the PoS is 1. We provide an improving response cycle, which implies that equilibrium existence

Table 1 An overview of our results (yellow) and a comparison with the results for the inverted models (white). BNCG abbreviates the bilateral NCG by Corbo and Parkes [18] whereas H-NCG denotes the NCG on a host network by Demaine et al. [19]. $N_2 := \frac{(n-1)^2}{4}$, $N_3 := \frac{(n-2)n(n+2)}{24}$, H denotes the host network, P_n, K_n, S_n are the path, clique, and star networks on n nodes, respectively.

for the (K-)SDNCG cannot be derived from potential function arguments. Finally, derive several bounds for the PoA which are tight for $\alpha \geq \frac{n}{2}$, asymptotically tight for $\alpha \leq \sqrt{n}$, and asymptotically tight up to a log-factor for $\alpha \leq \frac{n}{6} - 3$.

For the SDNCG on arbitrary host networks we utilize Maximum Routing-Cost Spanning Trees for characterizing optimal networks for $\alpha \leq 1$. As our main result, we show that their locally optimal variant, the Swap-Maximal Routing-Cost Spanning Trees, and hence also Maximum Routing-Cost Spanning Trees, are pairwise stable for $\alpha \leq \frac{n}{3}$. We prove that computing the MRCST is NP-hard, while the SMRCST can be constructed efficiently. Thus, for the significant range of $1 \leq \alpha \leq \frac{n}{3}$, we not only have guaranteed equilibrium existence on any host graph, but we can compute stable states efficiently. This is in stark contrast to what is known for the inverse model studied by Demaine et al. [19]. Additionally, we approximate optimal networks and we derive several (tight) bounds on the PoA and the PoS.

Compared with the NCG [23] and the bilateral NCG [18], we find that the results for the K-SDNCG regarding optimal and stable networks are analogous but reversed, with the spanning path taking over the role of the spanning star. Moreover, our PoA results for both the K-SDNCG and the SDNCG show that our maximization variant has a significantly worse PoA that is linear or almost linear in n, compared to the PoA upper bounds of $o(n^{\varepsilon})$ and $\mathcal{O}(\sqrt{\alpha}, n/\sqrt{\alpha})$ for the NCG and the bilateral NCG, respectively. As main take away from our paper, this implies that under social distancing the agents' selfish behavior has significantly more impact on the quality of the equilibria. This calls for strong coordination mechanisms governing the network formation to avoid detrimental stable states.

2 Complete Host Networks

We analyze the properties of the K-SDNCG, i.e., the SDNCG on complete host networks. First, we characterize optimal networks and give some examples for stable networks, dependent on the relation between n and α. After that, we show several bounds on the PoA and PoS.

2.1 Stable and Optimal Networks

Intuitively, for small α the distance utility dominates the social welfare. Hence, the path should be the optimum since it maximizes the total distances. For large α, the edge utility dominates, which leads to the clique being optimal since it maximizes the number of edges. Now we show that this intuition is indeed true. Moreover, the optimal construction is unique.

▶ **Theorem 1.** *For $\alpha < \frac{n}{3}$, the unique social optimum is the path. For $\alpha > \frac{n}{3}$, the unique optimum is the clique. For $\alpha = \frac{n}{3}$, the clique and the path are the only social optima.*

Proof Sketch. [See [25] for the full proof.] Šoltés and Ľubomír [50] showed that for a fixed number of nodes and edges, the network maximizing the summed distances is unique and contains a clique and a path with at least two edges between one endpoint of the path and the clique. We call this a *PathClique*. (Note that the clique can be empty, resulting in just a path) For a visualization, we refer to Figure 1. Note, that the social optimum has to be such

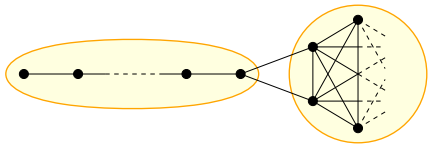

Figure 1 This figure shows a PathClique. It consists of a path (left) and a clique (right), which are connected by at least two edges between one endpoint of the path and some nodes of the clique.

a network, since for every other network, there is a PathClique with the same number of edges but larger summed distances and therefore a larger social welfare.

Let G be a PathClique but neither a clique nor a path and let v be the endpoint of the path that is connected to the clique. Observe that removing an edge between v and the clique results in a PathClique. (This is still true if there are only two edges connecting v to the clique: Removing one of these edges makes the remaining neighbor of v in the clique the new endpoint of the path and reduces the size of the clique by 1.) Similarly, adding an edge between v and the clique (or between the neighbor of v on the path and the clique if v is fully connected to the clique) yields a PathClique, too. Now, it is easy to calculate that either adding or removing edges improves the social welfare.

Thus, only the path and the clique are possibly optimal. ◀

Next, we have a look at the existence of pairwise stable networks. Similar to the social optimum, for small α, agents prefer large distances over many incident edges and therefore should remove as many edges as possible, leading to only trees being stable. Interestingly, the restrictions of pairwise stability lead to all trees being stable for small α, even if the distances are very small (like in a star). This is shown by the next theorem.

▶ **Theorem 2** (Stable Networks)**.**
(1) *For $\alpha \leq 1$, every tree is pairwise stable. For $\alpha < 1$, any pairwise stable network is a tree.*
(2) *For $\alpha \geq 1$, the clique is pairwise stable.*
(3) *For $\alpha \leq \frac{n-1}{2}$, the path is pairwise stable.*
(4) *For $\alpha > \frac{n}{2}$, the clique is the only pairwise stable network.*

Proof of (4). Let V be a set of n agents and $G = (V, E)$ be a stable network. Let $v \in V$ be a node having minimum total distances, i.e., for all $v' \in V$, we have $d_G(v, V) \leq d_G(v', V)$. Let $N_G[v]$ denote the closed neighborhood of v.

Now suppose, the network induced by $N_G[v]$ is not a clique. Then there are two neighbors x, y of v with $\{x, y\} \notin E$. We observe that for each node $z \in V$, the distances $d_G(v, z)$ and $d_G(x, z)$ can only differ by 1, since v and x are neighbors. By choice of v, there are at least as many nodes that are closer to v than nodes that are closer to x. Therefore, there are at most $\frac{n}{2}$ many nodes that are closer to x. Adding an edge between x and y can, for node y, only shorten distances to nodes which are closer to x than to v. Thus, this edge shortens the distances from y by at most $\frac{n}{2}$. The same holds for node x. Therefore, for $\alpha > \frac{n}{2}$, this edge would improve the utility of agents x and y and, thus, G would not be stable. This contradicts our assumption. Thus, $N_G[v]$ must induce a clique.

Now let x be a neighbor of v. Since x is connected to all neighbors of v, we have $d_G(x, V) \leq d_G(v, V)$, i.e., also x minimizes pairwise distances. Hence, $N_G[x]$ also induces a clique, leading to $N_G[v] = N_G[x]$. By induction, since G is connected, it must be a clique. ◀

Theorem 2 implies that socially optimal networks are also stable. In fact, they are stable for a wide range of α-values. The clique is stable for $\alpha \geq 1$, meeting the bound below which only trees are stable. Similarly, the path is stable for $\alpha \leq \frac{n-1}{2}$, almost meeting the lower bound for only the clique being stable. Additionally, we observe that we only need two networks (path and clique) to provide pairwise stable networks for all possible values of α.

For further constructions, we need the following definition. Let G be a network. We call G' a *clique network* of G, if it can be obtained by replacing each node of G by a clique of size at least 2 and for each edge of G connect the two corresponding cliques fully bipartite. By using only constant-size cliques, some properties of G (density, length of shortest paths) are preserved while the network is more stable against edge removal.

▶ **Theorem 3.** *Let G be a clique network. For $\alpha \geq 1$, G is stable against edge removal.*

Finally, we show that stable states may not be found by simply letting agents iteratively play improving moves, i.e., via a sequential process of improving strategy changes. Figure 2 provides an example of a cyclic sequence of improving moves. This also implies that both the K-SDNCG and the SDNCG do not belong to the class of potential games [45], i.e., the existence of equilibria cannot be proven via potential function arguments.

▶ **Theorem 4.** *The Social Distancing Network Creation Game is not a potential game.*

Proof. This is shown by the existence of improving cycles. See Figure 2 for an example. ◀

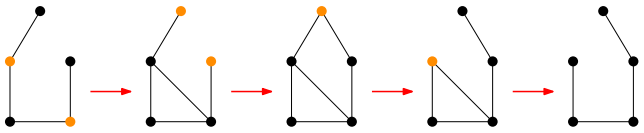

Figure 2 This figure shows a cyclic sequence of improving moves performed by $n = 5$ agents for $\alpha = 2.5$. In each step, the nodes responsible for the next change are highlighted in orange. Note that the last step is isomorphic to the first step.

2.2 Price of Anarchy and Price of Stability

In this section, we give a series of bounds for the Price of Anarchy and the Price of Stability.

▶ **Theorem 5** (Price of Anarchy).

(1) *The Price of Anarchy is in* $\mathcal{O}(n)$.

(2) *For* $\alpha \leq 1$, *the Price of Anarchy is in* $\Theta(n)$.

(3) *For* $1 < \alpha \leq \sqrt{n}$, *the Price of Anarchy is in* $\Theta(n)$.

(4) *For* $\sqrt{n} \leq \alpha \leq \frac{n}{6} - 3$, *the Price of Anarchy is in* $\Omega\left(\frac{n}{\log n}\right)$.

(5) *For* $\frac{n}{6} - 3 < \alpha \leq \lfloor \frac{n}{2} \rfloor - 2$, *the Price of Anarchy is in* $\Omega\left(\sqrt{n}\right)$.

(6) *For* $\alpha \geq \frac{n}{2}$, *the Price of Anarchy is 1.*

Proof of (3). We construct a star-like network with cliques as leaves in the following way. Let $c \coloneqq \lceil \alpha \rceil + 2$. Additionally, let $K_1, \ldots, K_d$ be $d \coloneqq \lfloor \frac{n-2}{c} \rfloor$ cliques containing $c-2$ nodes and $v_1, v_1', v_2, v_2', \ldots, v_d, v_d'$ be $2d$ nodes. Let furthermore M be a clique of size $n - cd$. We now define our network G as

$$V_G \coloneqq \bigcup_{i=1}^{d} V_{K_i} \cup \bigcup_{i=1}^{d} \{v_i, v_i'\} \cup V_M$$

$$E_G \coloneqq \bigcup_{i=1}^{d} E_{K_i} \cup E_M \cup \bigcup_{i=1}^{d} \{\{v_i, v_i'\}\} \cup \bigcup_{i=1}^{d} \bigcup_{v \in K_i} \{\{v, v_i\}, \{v, v_i'\}\} \cup \bigcup_{i=1}^{d} \bigcup_{v \in M} \{\{v, v_i\}, \{v, v_i'\}\}.$$

We essentially connect the outer cliques $K_1, \ldots, K_d$ to the center clique M via d 2-cliques and each connection is fully bipartite (see Figure 3). Since $n = |V_G|$, G is a network of the desired size.

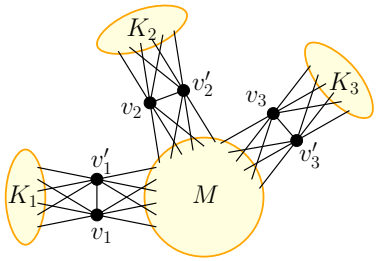

Figure 3 The figure shows a star-like clique network, where the center is formed by a clique M and each ray consists of two nodes v_i, v_i' and a clique K_i.

We now show that G is pairwise stable. We see that G is a clique network. Because of Theorem 3 and $\alpha > 1$, G is stable against edge removal. On the other hand, adding an edge shortens distances to at least $|K_i| = c - 2 \geq \alpha$ nodes which means a distance decrease of at least α for the two incident nodes. This also does not increase their utility. Therefore, G is pairwise stable.

For the center clique M, we see that $|V_M| = n - cd = n - c\left\lfloor \frac{n-2}{c} \right\rfloor$ and therefore $2 \leq |V_M| < n - (n-2-c) = c+2$. With this and $1 < \alpha \leq \sqrt{n}$, we obtain

$$\begin{aligned}|E_G| &= d\binom{c-2}{2} + \binom{|V_M|}{2} + 2d + d(c-2)2 + d|V_M|2 \\ &= \left\lfloor \frac{n-2}{\lceil\alpha\rceil+2} \right\rfloor \left(\frac{\lceil\alpha\rceil(\lceil\alpha\rceil-1)}{2} + 2 + 2\lceil\alpha\rceil + 2|V_M| \right) + \frac{|V_M|(|V_M|-1)}{2} \\ &\in \Theta(\alpha n)\end{aligned}$$

and $d_G(V_G, V_G) \in \Theta(n^2)$.

For $\alpha < \sqrt{n}$, the socially optimal network is the path. With the previous calculations, we can now bound the Price of Anarchy as

$$\text{PoA} \geq \frac{2\alpha(n-1) + \Theta(n^3)}{2\alpha\Theta(\alpha n) + \Theta(n^2)} = \frac{\Theta(n^3)}{\Theta(n^2)} \in \Omega(n).$$

From (1), we have $\text{PoA} \in \mathcal{O}(n)$ and therefore $\text{PoA} \in \Theta(n)$. ◀

Proof of (4). Let $d = \lfloor \log n \rfloor - 1$. Then, the d-dimensional hypercube is represented by G_H with $V_{G_H} = \{0,1\}^d$ and $E_{G_H} = \{\{v,x\} \mid v,x \in V \wedge d_H(v,x) = 1\}$ where $d_H(v,x)$ denotes the Hamming Distance between v and x. Let G be a clique network for G_H with $|V_G| = n$ such that the sizes of the cliques replacing the nodes of G_H differ by at most 1. Observe, that each clique is of size 2 or 3 if $2 \cdot 2^d \leq n < 3 \cdot 2^d$ and of size 3 or 4 if $3 \cdot 2^d \leq n < 4 \cdot 2^d$. By Theorem 3 and since $\alpha \geq 1$, we know that G is stable against edge removal. We now show that adding an edge shortens the total distances for the incident nodes by at least $\frac{n}{6} - 3$.

Let $v, x \in V_G$ such that $e \coloneqq \{v,x\} \notin E_G$ and let $v', x' \in V_{G_H}$ be the nodes corresponding to the cliques that contain v and x, respectively. Therefore, $e' \coloneqq \{v', x'\} \notin E_{G_H}$, which implies $d_H(v', x') \geq 2$. By symmetry of the hypercube, we can assume w.l.o.g. that

$$v' = \underbrace{00\ldots0}_{d_H(v,x)}\ \underbrace{0\ldots00}_{d-d_H(v,x)} \qquad \text{and} \qquad x' = \underbrace{11\ldots1}_{d_H(v,x)}\ \underbrace{0\ldots00}_{d-d_H(v,x)}\ .$$

Adding e' to G_H decreases the distances from v' to another node $y' \in V_{G_H}$ if and only if $d_H(v', y') \geq d_H(x,y) + 2$. The difference in distance can only come from the first $d_H(v', x')$ bits of the label since the remaining bits are equal for v' and x'. Let ℓ be the number of the first $d_H(v', x')$ bits of y' equal to 1. Then, $d_H(v', x') - \ell$ is the number of the first $d_H(v', x')$ bits of y' equal to 0. We obtain $d_H(v', y') - d_H(x', y') = \ell - (d_H(v', x') - \ell) = 2\ell - d_H(v', x')$. Thus, adding e' to G_H shortens the distance from v' to y' by $2\ell - d_H(v', x') - 1$.

The number of nodes where exactly ℓ of the first $d_H(v', x')$ bits are equal to 1 is $\binom{d_H(v',x')}{\ell} \cdot 2^{d-d_H(v',x')}$. Therefore, we get a distance decrease for v' of

$$\begin{aligned}&d_{G_H}(v', V_{G_H}) - d_{G_H+e'}(v', V_{G_H}) \\ &= \sum_{\ell=\left\lceil \frac{d_H(v',x')}{2} \right\rceil + 1}^{d_H(v',x')} \binom{d_H(v',x')}{\ell} \cdot 2^{d-d_H(v',x')} \cdot (2\ell - d_H(v',x') - 1) \overset{\text{steps omitted}}{\geq} \frac{2^d}{4}.\end{aligned}$$

Observe that the distances from v to all nodes in other cliques in G are exactly the same as the distances from v' to all other nodes in G_H. The same holds for $G + e$ and $G_H + e'$, with the exception of the distances from v to the (at most 3) nodes in the same clique as x. We distinguish two cases:

If $2 \cdot 2^d \leq n < 3 \cdot 2^d$, each clique consists of 2 or 3 nodes. Therefore, we have a distance decrease of at least

$$d_G(v, V_G) - d_{G+e}(v, V_G) \geq 2(d_{G_H}(v', V_{G_H}) - d_{G_H+e'}(v', V_{G_H})) - 3 \geq \frac{2^d}{2} - 3 \geq \frac{n}{6} - 3.$$

If $3 \cdot 2^d \leq n < 4 \cdot 2^d$, each clique consists of 3 or 4 nodes. This means, we have a distance decrease of at least

$$d_G(v, V_G) - d_{G+e}(v, V_G) \geq 3(d_{G_H}(v', V_{G_H}) - d_{G_H+e'}(v', V_{G_H})) - 3 \geq 3\frac{2^d}{4} - 3 \geq \frac{n}{6} - 3.$$

Thus, edge additions are not beneficial for the incident agents if $\alpha \leq \frac{n}{6} - 3$ and we conclude that the constructed network is stable for $1 \leq \alpha \leq \frac{n}{6} - 3$. We also see that the number of edges m is in $\Theta(n \log n)$ and the distance $d(V_G, V_G)$ is in $\Theta(n^2 \log n)$. Since the social optimum for $1 \leq \alpha \leq \frac{n}{6} - 3$ is the path P_n, we get for the Price of Anarchy:

$$\text{PoA}_n \geq \frac{SW(P_n)}{SW(G)} = \frac{\alpha(n-1) + \Theta(n^3)}{\alpha\Theta(n \log n) + \Theta(n^2 \log n)} \in \Omega\left(\frac{n}{\log n}\right). \quad \blacktriangleleft$$

Proof of (5). We construct a path of cliques in the following way. Let $2 \leq d \leq \frac{n-6}{2}$ be some even number and $c = \left\lfloor \frac{n-6}{d} \right\rfloor$. Furthermore, let $K_1, \ldots, K_d$ be d cliques consisting of c or $c+1$ nodes, such that $\sum_{i=1}^{d} |V_{K_i}| = n - 6$ and $\sum_{i=1}^{\frac{d}{2}} |V_{K_i}| = \left\lceil \frac{n-6}{2} \right\rceil$ and $\sum_{i=\frac{d}{2}+1}^{d} |V_{K_i}| = \left\lfloor \frac{n-6}{2} \right\rfloor$, and $v_1, v_1', v_2, v_2', v_3, v_3'$ be 6 more nodes. We now define the network G as

$$V_G \coloneqq \bigcup_{i=1}^{d} V_{K_i} \cup \{v_1, v_1', v_2, v_2', v_3, v_3'\},$$

$$E_G \coloneqq \bigcup_{i=1}^{d} E_{K_i} \cup \{\{v_1, v_1'\}, \{v_2, v_2'\}, \{v_3, v_3'\}\} \cup \{\{v, x\} \mid v \in \{v_2, v_2'\} \wedge x \in \{v_1, v_1', v_3, v_3'\}\}$$
$$\cup \bigcup_{i=1}^{\frac{d}{2}-1} \{\{v, x\} \mid v \in K_i \wedge x \in K_{i+1}\} \cup \bigcup_{v \in K_{\frac{d}{2}}} \{\{v, v_1\}, \{v, v_1'\}\}$$
$$\cup \bigcup_{i=\frac{d}{2}+1}^{d-1} \{\{v, x\} \mid v \in K_i \wedge x \in K_{i+1}\} \cup \bigcup_{v \in K_{\frac{d}{2}+1}} \{\{v, v_3\}, \{v, v_3'\}\}.$$

Figure 4 shows a sketch of G.

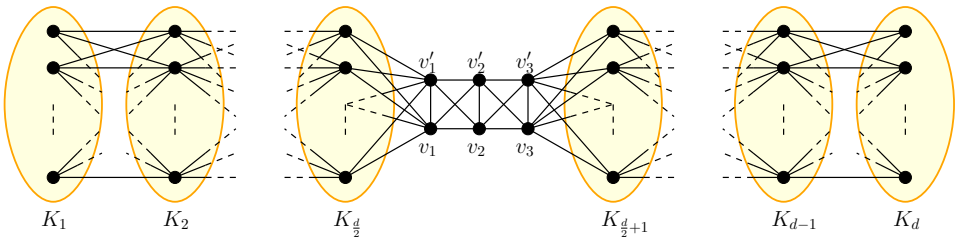

Figure 4 The figure shows clique network for a path consisting of d cliques $K_1, \ldots, K_d$ highlighted in yellow with 6 additional nodes in the middle. Note, that edges inside the cliques are not shown in this figure.

We observe that G is stable against edge removal because of Theorem 3, since $\alpha > \frac{n}{6} - 3 \geq 1$ and G being a clique network for the path. We now show that adding an edge is also not an improving move.

We quickly see that, for a node v, adding an edge into the 2-neighborhood always shortens distances the least. We therefore only have to consider these edges. We observe that adding an edge between v_1 and v_3 (or because of symmetry, v_1' or v_3') decreases distances from v_1 to v_3 and all nodes in $K_{\frac{d}{2}+1}, \dots, K_d$ and decreases distances from v_3 to v_1 and all nodes in $K_1, \dots, K_{\frac{d}{2}}$ by exactly 1. This means, we get

$$d_G(v_1, V) - d_{G+\{v_1,v_3\}}(v_1, V) = 1 + \sum_{i=\frac{d}{2}+1}^{d} |V_{K_i}| = \left\lfloor \frac{n}{2} \right\rfloor - 2 \quad \text{and}$$

$$d_G(v_3, V) - d_{G+\{v_1,v_3\}}(v_3, V) = 1 + \sum_{i=1}^{\frac{d}{2}} |V_{K_i}| = \left\lceil \frac{n}{2} \right\rceil - 2.$$

Every other edge we could add decreases distances to all the cliques of one side of the path, resulting in larger distance decreases. This means that adding an edge is not an improving move for $\alpha \leq \left\lfloor \frac{n}{2} \right\rfloor - 2$. Therefore, G is pairwise stable for the desired values of α.

We now evaluate the number of edges. We have $|E_{K_i}| \in \Theta(c^2)$. The number of edges between two neighboring cliques is also in $\Theta(c^2)$. This means that the total number of edges is $|E_G| \in \Theta(dc^2)$. We also see that the diameter of G is d and therefore $d_G(V, V) \in \mathcal{O}(dn^2)$. If we choose $d = 2\left\lfloor \frac{\sqrt{n}}{2} \right\rfloor$, we have $d \in \Theta(\sqrt{n})$ and $c \in \Theta(\sqrt{n})$. Since $\alpha \in \Theta(n)$, we get for the Price of Anarchy

$$\text{PoA}_n \geq \frac{\alpha(n-1) + \Theta(n^3)}{\alpha\Theta(dc^2) + \mathcal{O}(dn^2)} \in \Omega\left(\frac{n^3}{n^{\frac{5}{2}} + n^{\frac{5}{2}}}\right) = \Omega\left(\sqrt{n}\right). \qquad \blacktriangleleft$$

We have established that the Price of Anarchy is relatively high for $\alpha \leq \frac{n}{2}$. It even meets the trivial upper bound of $\mathcal{O}(n)$ for a large range of α. In contrast to the high PoA values, we observe that the Price of Stability is independent of α and best possible.

▶ **Theorem 6.** *The Price of Stability is 1.*

From an efficiency point-of-view, the huge gap between the PoA and the PoS suggests that having an outside force assigning an initial strategy to all players is beneficial. That way, stability and optimal social welfare can be guaranteed. Without such coordination, the players could end up in socially bad equilibria or in a cyclic sequence of improving moves.

3 General Host Networks

We now analyze the SDNCG on arbitrary connected but not necessarily complete host networks. First, we analyze socially optimal networks and then we investigate the existence of pairwise stable networks. We prove our main result that establishes equilibrium existence on any connected host network for a wide parameter range of α. Finally, we derive bounds on the Price of Anarchy and the Price of Stability. Additionally, we show that computing the social optimum and the Maximum Routing-Cost Spanning Tree is NP-hard while computing a Swap-Maximal Routing-Cost Spanning Tree can be done in polynomial time.

3.1 Stable and Optimal Networks

While for the K-SDNCG, we only have two possible social optima (dependent on α), this gets more complicated for general host networks. Of course, if they exist on general host networks, then the optima for the K-SDNCG are still the most efficient networks. Intuitively,

if the host network does not contain a Hamilton path, then the social optimum should be a tree if α is small enough. Since all trees have the same number of edges, the social welfare of a tree is only influenced by the total distances. Remember that the spanning tree maximizing the total distances is by definition the Maximum Routing-Cost Spanning Tree (MRCST). We now show, that this intuition is indeed correct.

▶ **Theorem 7** (Social Optimum). *Let H be a connected host network containing n nodes.*

(1) *If H contains a Hamilton path, then this path is the social optimum for $\alpha \leq \frac{n}{3}$. The Hamilton path is the unique social optimum if $\alpha < \frac{n}{3}$.*

(2) *For $\alpha \leq 1$, the MRCST of H is socially optimal.*

(3) *For $\alpha > \frac{1}{24}(n-2)n(n+2)$, H itself is the unique social optimum.*

Contrasting statement (3) from Theorem 7, we observe that for $\alpha < \frac{1}{24}(n-2)n(n+2)$, the host network is not necessarily the social optimum. Consider the host network $H \coloneqq C_n$ for even n, i.e., an even cycle with n nodes. In the proof of (3), we see that $\mathrm{SW}(P_n) > \mathrm{SW}(C_n)$, implying that C_n cannot be the social optimum. In fact, in this example, P_n is the optimum since there are only two possible states (up to isomorphism): P_n and C_n itself. This is in stark contrast to the K-SDNCG, where the host network is optimal for $\alpha \geq \frac{n}{3}$.

Since finding a MRCST is NP-hard [16], finding the social optimum for a given host network must also be NP-hard.

▶ **Theorem 8** (Computational Hardness). *Computing the social optimum for a connected host network H is NP-hard.*

Next, we discuss stable networks. In contrast to the K-SDCNG, it is not obvious that pairwise stable networks are guaranteed to exist for any connected host network. However, we can directly transfer the result that spanning trees are stable for small α. For large α, similar to the clique being the unique stable network for $\alpha > \frac{n}{2}$ for complete host networks, as shown in Theorem 2, we show that the whole host network is pairwise stable. However, in contrast to the K-SDNCG, this is true only for much larger values of α.

▶ **Theorem 9** (Stable Networks). *Let H be a connected host network containing n nodes.*

(1) *For $\alpha \leq 1$, every spanning tree of H is pairwise stable. For $\alpha < 1$, spanning trees are the only pairwise stable networks.*

(2) *For $\alpha > \frac{1}{4}(n-1)^2$, H is the only pairwise stable network.*

Contrasting statement (2) of Theorem 9, using $H \coloneqq C_n$ for odd n and $\alpha < \frac{1}{4}(n-1)^2$ shows that the host network is not necessarily pairwise stable. This example also shows that the optimum is not necessarily stable: For $\alpha \geq \frac{1}{4}(n-1)^2$ and $H \coloneqq C_n$ as the host network, C_n is the only pairwise stable network but it is not the optimum for $\alpha < \frac{1}{24}(n-2)n(n+2)$. This is another significant difference to the K-SDNCG.

Now that we characterized stable networks for extreme α-values, the question remains whether stable states also exist for in-between values. For the K-SDNCG, the path is stable up to $\alpha < \frac{n-1}{2}$. This is, of course, still true for non-complete host networks if they contain a Hamilton path. Since a Hamilton path (if it exists) is the MRCST, it is natural to suspect that the MRCST properties at least partially ensure stability for some $\alpha \geq 1$. However, even if true, the MRCST is still NP-hard to compute. Hence, in quest of an efficiently computable stable network, we introduce a less strict variant of MRCSTs which is only locally optimal: Swap-Maximal Routing-Cost Spanning Trees. Remember, a SMRCST is a spanning tree whose summed distances cannot be increased by removing one edge and adding another edge.

As our main result, we now show that SMRCSTs (and therefore MRCSTs, too) are indeed stable beyond $\alpha \leq 1$. Note, that for the inverse model of the NCG on an arbitrary host network [19], so far no equilibrium existence statement is known.

▶ **Theorem 10.** *Let H be a connected host network containing n nodes. Then for $\alpha \leq \frac{n}{3}$, any Swap-Maximal Routing-Cost Spanning Tree is pairwise stable.*

Proof Sketch. [See [25] for the full proof.]
Let G with $V_G = V_H$ and $E_G \subseteq E_H$ be a SMRCST. Since G is a tree, we only have to consider edge additions. We show that adding any edge decreases the summed distances for at least one of the endpoints of the edge by at least $\frac{n}{3}$. This is sufficient to show the claim.

Let $e_1 \in E_H \setminus E_G$ be an edge not contained in the SMRCST. Adding e_1 would form a cycle of length $d \in \mathbb{N}$ consisting of nodes $v_1, \ldots, v_d \in V$, with v_1 and v_d being the nodes incident to e_1. Let E_C be the set of all edges on this cycle. Removing all edges in E_C from G would create d trees rooted in $v_1, \ldots, v_d$, respectively. Furthermore, let $x_1, \ldots, x_d$ be the number of nodes in each of the d trees. See Figure 5 for an illustration.

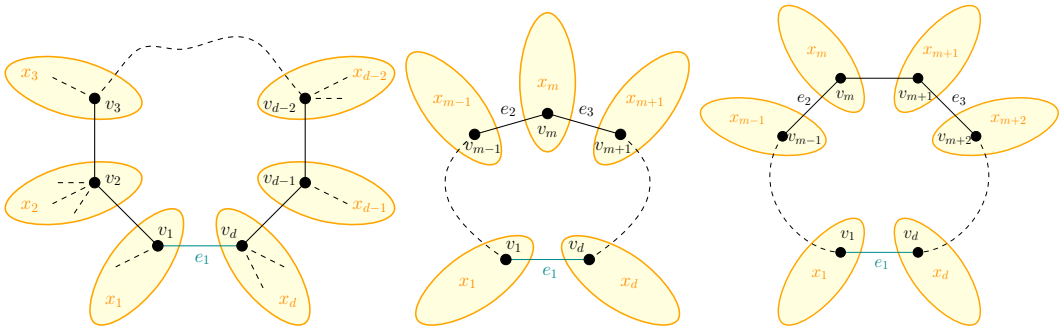

Figure 5 This figure shows the cycle formed by adding e_1 to the SMRCST. The cycle is of length d and contains the nodes $v_1, \ldots, v_d$. Every other node is contained in one of the subtrees rooted in one of the nodes on the cycle. These subtrees are represented in yellow. The number of nodes contained in the subtree rooted in v_i is x_i. Middle and right: the cycle for d being odd or even, respectively, and the two special edges e_2 and e_3.

Since G is a tree, there is exactly one path between each pair of nodes (which is also the shortest). For each edge $e \in E_G$, we define $d_G(e)$ as the number of paths between two nodes in G which include e. We then can express the total distances as

$$d_G(V, V) = 2 \sum_{e \in E_G} d_G(e).$$

Note, that each path between two nodes contributes twice to the total distances (one for each node), which leads to the factor of 2.

Let $x \coloneqq (x_1, \ldots, x_d)$. We now define for each edge $e \in E_C$ on the cycle

$$c_e(x) \coloneqq \sum_{e' \in E_C} d_{G+e_1-e}(e') = \sum_{i=1}^{d-1} \sum_{j=i+1}^{d} x_i x_j d_{G+e_1-e}(v_i, v_j).$$

This is the contribution of all the edges on the cycle to the total distances, if we add e_1 to it and instead remove e from it. Note, that c_{e_1} is the value for the original network since $G + e_1 - e_1 = G$. We see that c_e does not depend on the structure of the subtrees rooted in the v_i but only on the number of nodes in each subtree. Since the number of paths going over an edge that is not on the cycle does not change when we add e_1 and remove e, we have

$$\begin{aligned} d_G(V,V) - d_{G+e-e_1}(V,V) &= 2\sum_{e' \in E}(d_G(e') - d_{G+e-e_1}(e')) \\ &= 2\sum_{e' \in E_C}(d_G(e') - d_{G+e-e_1}(e')) + 2\sum_{e' \in E_G \setminus E_C}(d_G(e') - d_{G+e-e_1}(e')) \\ &= 2c_{e_1}(x) - 2c_e(x). \end{aligned}$$

We know that G is a SMRCST of H. This implies $d_G(V,V) \geq d_{G'}(V,V)$ for any other spanning tree G' that can be obtained from G by an edge swap. We therefore also have

$$\forall e \in E_C \colon c_{e_1}(x) \geq c_e(x). \tag{1}$$

Now, we use the previous observations to formulate and solve a minimization problem that yields the desired bound. We start with some definitions.

We call $x = (x_1, \ldots, x_d) \in \mathbb{N}^d$, with $x_i \geq 1$ and $\sum_{i=1}^{d} x_i = n$, a *node distribution*. For each edge $e \in E_C$, we call $c_e(x)$ (defined above) the *cost* of e. And lastly, we define the *distance decrease* Δd as

$$\Delta d(x) \coloneqq \max \left\{ \sum_{i=1}^{\lfloor \frac{d-1}{2} \rfloor} (d-2i)x_i, \sum_{i=1}^{\lfloor \frac{d-1}{2} \rfloor} (d-2i)x_{d-i+1} \right\}. \tag{2}$$

The goal then is: Find a node distribution x that fulfills (1) and minimizes $\Delta d(x)$. Observe that this indeed yields a lower bound for the distance decrease when adding e to G. If we show that this is at least $\frac{n}{3}$, we have proved the statement.

Let $x = (x_1, \ldots, x_d) \in \mathbb{N}^d$ be a node distribution minimizing $\Delta d(x)$. For $d \leq 4$, it is easy to show that $\Delta d(x) \geq \frac{n}{3}$. For further steps, we allow $x \in \mathbb{R}^d_{\geq 1}$. Note, that this only allows for smaller minima and therefore still yields a lower bound for the original problem.

The high level idea of the following steps is that we can redistribute weights of the node distribution x without changing $\Delta(x)$ or violating 1 and thereby reducing the number of variables contained in x by setting most x_i to 1. We now make a case distinction.

Case d odd: Let $m = \frac{d+1}{2}$ and $e_2 \coloneqq \{v_{m-1}, v_m\}$ and $e_3 \coloneqq \{v_m, v_{m+1}\}$. Thus, v_m is the node equidistant from v_1 and v_d in C and e_2 and e_3 are the edges on C incident to v_m. (see Figure 5 (middle)) We will only consider the two constraints

$$c_{e_1}(x) \geq c_{e_2}(x) \quad \text{and} \quad c_{e_1}(x) \geq c_{e_3}(x). \tag{3}$$

Again, this still yields a lower bound for the original problem.

We define the node distributions $x^{(1)}, x^{(2)}, x^{(3)}$ such that for all $1 \leq i \leq d$

$$x_i^{(1)} \coloneqq \begin{cases} x_1 + \sum_{p=2}^{m-2} \frac{m-1-p}{m-2}(x_p - 1) & \text{if } i = 1, \\ x_{m-1} + \sum_{p=2}^{m-2} \frac{p-1}{m-2}(x_p - 1) & \text{if } i = m-1, \\ x_m & \text{if } i = m, \\ x_{m+1} + \sum_{p=m+2}^{d-1} \frac{d-p}{m-2}(x_p - 1) & \text{if } i = m+1, \\ x_d + \sum_{p=m+2}^{d-1} \frac{p-m-1}{m-2}(x_p - 1) & \text{if } i = d, \\ 1 & \text{else,} \end{cases}$$

(w.l.o.g. we assume $x_1^{(1)} \geq x_d^{(1)}$ and $(2m-3)x_1^{(1)} + x_{m-1}^{(1)} = (2m-3)x_d^{(1)} + x_{m+1}^{(1)}$)

$$x_i^{(2)} \coloneqq \begin{cases} x_1^{(1)} & \text{if } i = 1 \text{ or } i = d, \\ x_{m-1}^{(1)} & \text{if } i = m-1 \text{ or } i = m+1, \\ x_m^{(1)} + (2m-4)\left(x_1^{(1)} - x_d^{(1)}\right) & \text{if } i = m, \\ 1 & \text{else,} \end{cases}$$

$$x_i^{(3)} \coloneqq \begin{cases} x_m^{(2)} + 2\frac{2m-4}{2m-3}\left(x_{m-1}^{(2)} - 1\right) & \text{if } i = m, \\ x_1^{(2)} + \frac{1}{2m-3}\left(x_{m-1}^{(2)} - 1\right) & \text{if } i = 1 \text{ or } i = d, \\ 1 & \text{else.} \end{cases}.$$

It can be shown iteratively that $\Delta d(x) = \Delta d\left(x^{(1)}\right) = \Delta d\left(x^{(2)}\right) = \Delta d\left(x^{(3)}\right)$ and that $c_{e_1}\left(x^{(i)}\right) \geq c_{e_2}\left(x^{(i)}\right)$ and $c_{e_1}\left(x^{(i)}\right) \geq c_{e_3}\left(x^{(i)}\right)$ for $1 \leq i \leq 3$. This means, $x^{(3)}$ is also a solution of the minimization problem. Because of $x^{(3)}$ only having 2 variables left $\left(x_1^{(3)} = x_d^{(3)} \text{ and } x_m^{(3)}\right)$, it is easy to show $\Delta d\left(x^{(3)}\right) \geq \frac{n}{3}$.

Case d even: Let $m = \frac{d}{2}$ and $e_2 \coloneqq \{v_{m-1}, v_m\}$ and $e_3 \coloneqq \{v_{m+1}, v_{m+2}\}$. (see Figure 5 (right)) Again, we will only consider the two constraints

$$c_{e_1}(x) \geq c_{e_2}(x) \text{ and } c_{e_1}(x) \geq c_{e_3}(x). \tag{4}$$

The rest of the reasoning is analogous to the odd case. ◀

Next, we show that we can find a SMRCST in polynomial time via Algorithm 1 and even guarantee some bounds on the social welfare of the resulting network. Our algorithm employs

Algorithm 1 Computes a SMRCST for a given connected host network.

Input: connected host network H
Output: SMRCST T
1 $\mathsf{P} \leftarrow$ `greedyLongPath` (H);
2 $\mathsf{T} \leftarrow$ *extend* P *to form a spanning tree of* H;
3 **while** $\exists e \in E_\mathsf{T}, e' \in E_\mathsf{H} \setminus E_\mathsf{T} : d_{\mathsf{T}-e+e'}(V_\mathsf{H}, V_\mathsf{H}) > d_\mathsf{T}(V_\mathsf{H}, V_\mathsf{H})$ **do**
4 $\quad \mathsf{T} \leftarrow \mathsf{T} - e + e'$
5 **end**

a greedy algorithm developed by Karger et al. [36] which can find a path of length at least $\frac{|E_H|}{|V_H|}$ in $\mathcal{O}(|E_H|)$ as a subroutine for initialization. We call this subroutine *greedyLongPath*. This will help us to derive bounds on the total distances of the computed SMRCST later. For extending the path to a spanning tree in line 2 of Algorithm 1, we can simply iterate over all edges and add them to the network if they do not close a cycle.

▶ **Theorem 11.** *Let H be a connected network containing n nodes and m edges. Then Algorithm 1 finds a Swap-Maximal Routing-Cost Spanning Tree of H in runtime $\mathcal{O}(n^5 m)$.*

Proof. It is easy to see that, by construction, T is always a spanning tree of H. The condition in the while-loop ensures that all possible swaps are tried. This means that the while-loop ends if and only if T is a SMRCST. Therefore if the while-loop stops, the result is correct.

In every iteration in which the while-loop does not stop, the total distances of T increase by at least 1. Since the tree maximizing the total distances is the path, we get its total distances $\frac{1}{3}(n-1)n(n+1) \in \mathcal{O}(n^3)$ as an upper bound for the number of iterations.

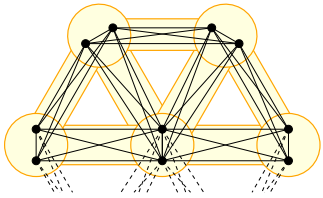

Figure 6 This figure shows a clique network (black) for a wheel network (yellow).

The runtime of Algorithm 1 is clearly dominated by the while-loop. Since T has $n-1$ edges which can be removed and $E_H \setminus E_T$ has $\mathcal{O}(m)$ possible edges to add, the number of possible swaps is in $\mathcal{O}(nm)$. For each swap, the total distances can be computed in $\mathcal{O}(n)$ [44]. Therefore computing the condition can be done in $\mathcal{O}(n^2m)$. Altering the current solution in the body of the while-loop only takes $\mathcal{O}(n)$ when using adjacency lists. Since there are at most $\mathcal{O}(n^3)$ iterations of the while-loop, the overall runtime is in $\mathcal{O}(n^5m)$. ◀

For the K-SDNCG, the social optima were also stable. For general host networks, this is not necessarily the case. However, we can show that for $\alpha \leq \frac{n}{3}$ there are stable states which approximate the social welfare better than with the trivial factor of $\mathcal{O}(n)$.

▶ **Theorem 12** (OPT-Approximation via the MRCST). *Let H be a connected host network containing n nodes and m edges and T be the MRCST of H.*

(1) *We have* $\frac{\mathrm{SW}(\mathrm{OPT}_H)}{\mathrm{SW}(T)} \in \mathcal{O}\left(\frac{m}{n}\right)$.

(2) *For* $\alpha \in \mathcal{O}\left(\frac{n^2}{m}\right)$, *we have* $\frac{\mathrm{SW}(\mathrm{OPT}_H)}{\mathrm{SW}(T)} \in \mathcal{O}(1)$.

(3) *For* $\alpha \in \omega\left(\frac{n^2}{m}\right)$, *we have* $\frac{\mathrm{SW}(\mathrm{OPT}_H)}{\mathrm{SW}(T)} \in \mathcal{O}\left(\min\left\{\frac{m}{n}, \alpha\frac{n}{m}\right\}+1\right)$.

Since finding the MRCST is NP-hard [16], these are only existence results. However, the next theorem yields a bound for dense networks and the computed SMRCST from Algorithm 1.

▶ **Theorem 13.** *Let H be a connected host network containing n nodes and m edges and T be the SMRCST obtained by Algorithm 1. Then for $\alpha \in \mathcal{O}(n)$, we have* $\frac{\mathrm{SW}(\mathrm{OPT}_H)}{\mathrm{SW}(T)} \in \mathcal{O}\left(\frac{n^4}{m^2}\right)$.

This means, for $\alpha \leq \frac{n}{3}$ and a dense host network, we can compute a state which is pairwise stable and also has a favorable social welfare.

3.2 Price of Anarchy and Price of Stability

We derive several bounds on the PoA and the PoS for the SDNCG. For the K-SDNCG, the PoA is already quite high for small α. The next Theorem shows that this gets even worse for general host networks since the PoA is linear up to $\alpha \leq n$ and super-constant for $\alpha \in o(n^2)$.

▶ **Theorem 14** (Price of Anarchy).

(1) *The Price of Anarchy is in $\mathcal{O}(n)$.*

(2) *For $\alpha < 1$, the Price of Anarchy is in $\Theta(n)$.*

(3) *For $1 \leq \alpha \leq n$, the Price of Anarchy is in $\Theta(n)$.*

(4) *For $n < \alpha \leq n^2$, the Price of Anarchy is in $\Omega\left(\frac{n^2}{\alpha}\right)$.*

(5) *For $\frac{1}{4}(n-1)^2 < \alpha \leq \frac{1}{24}(n-2)n(n+2)$, the Price of Anarchy is in $\Theta(1)$.*

(6) *For $\alpha > \frac{1}{24}(n-2)n(n+2)$, the Price of Anarchy is 1.*

Proof of (3) and (4). Let $W = (V_W, E_W)$ be a wheel network on $n' \coloneqq \lfloor \frac{n}{2} \rfloor$ nodes, i.e.,

$$V_W \coloneqq \{v_1, \dots, v_{n'}\} \quad \text{and}$$
$$E_W \coloneqq \{\{v_1, v_i\} \mid 2 \leq i \leq n'\} \cup \{\{v_i, v_{i+1}\} \mid 2 \leq i \leq n'\} \cup \{\{v_2, v_{n'}\}\}.$$

We then define the host network H as the clique network obtained by replacing every node of W by a clique of size 2. (See Figure 6 for an illustration.) For odd n, we instead replace the central node by a clique of size 3. We see that H contains n nodes, $\Theta(n)$ edges, and most importantly a Hamilton path. We also know that H is stable because of Theorem 3 and since no edge can be added. This yields the following lower bound for the Price of Anarchy

$$\text{PoA} \geq \frac{SW(P)}{SW(H)} = \frac{\alpha(n-1) + \Theta(n^3)}{\alpha\Theta(n) + \Theta(n^2)} \in \Omega\left(\min\left\{n, \frac{n^2}{\alpha}\right\}\right),$$

which proves the claim. ◀

▶ **Theorem 15** (Price of Stability)**.**
(1) *The Price of Stability is in* $\mathcal{O}(n)$*.*
(2) *For* $\alpha \leq 1$*, the Price of Stability is 1.*
(3) *For* $1 < \alpha \leq \frac{n}{3}$*, the Price of Stability is in* $\mathcal{O}(\sqrt{n})$*.*
(4) *For* $\frac{1}{4}(n-1)^2 < \alpha \leq \frac{1}{24}(n-2)n(n+2)$*, the Price of Stability is in* $\Theta(1)$*.*
(5) *For* $\alpha > \frac{1}{24}(n-2)n(n+2)$*, the Price of Stability is 1.*

4 Conclusion

We introduced and analyzed a natural game-theoretic model for network formation governed by social distancing. Besides modeling this timely issue, our model resembles the inverse compared to the well-known (bilateral) Network Creation Game [23, 18]. Thus, via our analysis we could explore the impact of inverting the utility function in a non-trivial strategic game. We find that this inverts some of the properties, like the rough structure of optimum states, while it also yields non-obvious insights. First of all, for the variant with non-complete host networks we could show a strong equilibrium existence result, whereas no such result is known for the inverse model. Moreover, we established that the PoA is significantly higher in the (K-)SDCNG compared to the (bilateral) NCG. This demonstrates that the impact of the agents' selfishness is higher under social distancing, which calls for external coordination.

The most obvious open question for future work is to settle the equilibrium existence. Do pairwise stable states exist for all connected host networks H and α? Another research direction would be to consider the unilateral variant of the SDNCG. While this no longer realistically models the formation of social networks, it might still yield interesting insights and it allows for studying stronger solution concepts like the Nash equilibrium or strong Nash equilibria, similar to [34, 6]. Also, altering the utility function, e.g., to using the maximum distance instead of the summed distances, or the probability of infection, similar to [13], seems promising. Finally, also considering weighted host networks, as in [11], where the edge weight models the benefit of the social interaction, would be an interesting generalization.

Approximating Observables Is as Hard as Counting

Abstract

We study the computational complexity of estimating local observables for Gibbs distributions. A simple combinatorial example is the average size of an independent set in a graph. A recent work of Galanis et al (2021) established NP-hardness of approximating the average size of an independent set utilizing hardness of the corresponding optimization problem and the related phase transition behavior. We instead consider settings where the underlying optimization problem is easily solvable. Our main contribution is to classify the complexity of approximating a wide class of observables via a generic reduction from approximate counting to the problem of estimating local observables. The key idea is to use the observables to interpolate the counting problem.

Using this new approach, we are able to study observables on bipartite graphs where the underlying optimization problem is easy but the counting problem is believed to be hard. The most-well studied class of graphs that was excluded from previous hardness results were bipartite graphs. We establish hardness for estimating the average size of the independent set in bipartite graphs of maximum degree 6; more generally, we show tight hardness results for general vertex-edge observables for antiferromagnetic 2-spin systems on bipartite graphs. Our techniques go beyond 2-spin systems, and for the ferromagnetic Potts model we establish hardness of approximating the number of monochromatic edges in the same region as known hardness of approximate counting results.

1 Introduction

Can we efficiently estimate the average size of an independent set in an input graph $G = (V, E)$? Moreover, can we do so without utilizing a sampling algorithm for generating a random independent set?

In this paper, for a broad class of problems captured by Gibbs distributions, we address the relationship between the computational complexity of approximating local observables (such as estimating the average size of an independent set) and the computational complexity of approximating the partition function (such as estimating the total number of independent sets). It is a standard technique in the area to reduce estimating observables to approximate counting, by first implementing an approximate sampler and then using an unbiased estimator of the desired observable. The focus of this paper is the converse, where there is no previously

known technique to answer the following question: does an algorithm for local observables yield an algorithm for the partition function? We prove, in a broad setting, that these two genres of problems are computationally equivalent.

Previous work of [9] only achieved this indirectly; they showed hardness of approximating local observables (in fact, only for a certain observable, called magnetization, see below for definitions) utilizing the hardness of MaxCut. Here, we show a direct reduction from the observable problem to the partition-function problem, relating therefore more crisply the two problems. This allows us to obtain hardness results in several new regimes (in particular,not covered by [9]) where the counting problem is hard but there is no underlying hard optimization problem.

An interesting setting to highlight the usefulness of our reduction is *bipartite* independent sets. In this example there is no corresponding hard optimization problem (as the maximum independent set problem is poly-time solvable in bipartite graphs), and hence to prove hardness we need to utilize hardness of approximate counting results. Another pertinent example for our results are attractive graphical models, these are equivalent to ferromagnetic spin systems in statistical physics. The simplest case is the ferromagnetic Ising model and its generalization known as the Potts model. In the Ising/Potts model on a graph (see Section 1.1 for more precise definitions), the configurations of the model are the collection of labellings σ of the vertices with q spins (colours), each weighted as $\beta^{m(\sigma)}$ where $m(\sigma)$ is the number of monochromatic edges and β is a parameter > 1 (so that labellings with many monochromatic edges are favored). Because of the attractiveness assumption that $\beta > 1$, once again, there is no corresponding hard optimization problem for this problem (contrast this with the case $\beta < 1$ where the largest weight labellings have the smallest number of monochromatic edges). Nevertheless, using our new reduction, we show that hardness of the associated approximate counting problem implies hardness of estimating the (weighted) average of the monochromatic edges in the Potts model.

Our two illustrative examples, the average size of an independent set and the number of monochromatic edges in the Ising/Potts model, are instances of a local observable in statistical physics; specifically they correspond to the magnetization and susceptibility, respectively. The behavior of observables is fundamental to the study of phase transitions, e.g., see [1, 4].

We begin giving more precise definitions for our initial example of *bipartite* independent sets, before considering the ferromagnetic Potts model, and finally generalizing to arbitrary local observables in general 2-spin systems. For a graph $G = (V, E)$ let $\mathcal{I}_G$ denote the set of independent sets (of all sizes) of G, and let $\mu := \mu_G$ denote the uniform distribution over $\mathcal{I}_G$. Denote the average independent set size by $\mathcal{M}(G) = \mathbf{E}_{\sigma\sim\mu}\big[|\sigma|\big]$; this corresponds to the magnetization in statistical physics (and hence the choice of notation $\mathcal{M}$). We say that an algorithm is an FPRAS for the average independent set size if given a graph $G = (V, E)$ and parameters $\epsilon, \delta > 0$, the algorithm outputs an estimate EST which is within a multiplicative factor $(1 \pm \epsilon)$ of the desired quantity $\mathcal{M}(G)$, with probability $\geq 1 - \delta$, and runs in time $\mathrm{poly}(|V|, 1/\epsilon, \log(1/\delta))$. One can also consider an FPRAS for estimating $|\Omega|$, the number of independent sets of the input graph G; we refer to this as an efficient approximate counting algorithm.

It is a classical result [14] that an efficient approximate counting algorithm is polynomial-time interreducible with an efficient algorithm for approximate sampling from μ. In turn, efficiently estimating the average independent set size of a graph G is easily reduced to approximate sampling from the uniform distribution μ_G. The challenging aspect, and the focus of this paper, is the *reverse* implication. Can we estimate the typical size of an independent set without utilizing an approximate sampling algorithm? We will show it is *not* possible, i.e., hardness of approximate counting (and hence approximate sampling) implies hardness of estimating the average independent set size.

For graphs of maximum degree 5, Weitz [20] presented an FPTAS for approximating the number of independent sets, which yields an efficient approximate sampling scheme; note an FPTAS is the deterministic analog of an FPRAS, i.e., it achieves $\delta = 0$. Very recently, Chen et al. [5] proved that the simple MCMC algorithm known as the Gibbs sampler (or Glauber dynamics) has $O(n \log n)$ mixing time for this same class of graphs of maximum degree 5. Hence, one immediately obtains an FPRAS for the average independent set size $\mathcal{M}(G)$.

On the other side, for graphs of maximum degree 6, Sly [18] proved that approximating the number of independent sets is NP-hard, by a reduction from max-cut. Schulman et al. [16] showed #P-hardness for exact computation of the average independent set size. Moreover, recent work of Galanis et al. [9] shows that approximating the average independent-set size is also NP-hard for graphs of maximum degree 6. The proof of [9] does not directly relate approximate counting and estimating the average independent set size; instead [9] also shows a (more sophisticated) reduction from max-cut and utilizes the associated gadgets used in Sly's inapproximability result [18].

This begets the question: are these problems still intractable when restricted to *bipartite graphs*? For bipartite graphs there is no longer a hard optimization problem, such as max-cut, that one can utilize as a starting point for a hardness reduction. However, approximately counting independent sets is considered to be intractable on bipartite graphs of maximum degree 6; in particular, it is is #BIS-hard [3] where #BIS refers to the problem of approximately counting independent sets on general bipartite graphs (with potentially unbounded degree). There are now a multitude of approximate counting problems which share the same #BIS-hardness status or are even #BIS-equivalent, e.g., see [6, 3, 11, 7].

We present a general approach for reducing approximate counting to approximating averages. This yields hardness for approximating the average independent-set size in *bipartite graphs* of maximum degree 6.

▶ **Theorem 1.** *Let $\Delta \geq 6$ be an integer. There is no* FPRAS *for the average independent-set size on* bipartite *graphs of maximum degree Δ unless* #BIS *admits an* FPRAS*.*

Note that the #BIS-hardness result of Theorem 1 gives a weaker guarantee than those shown in [9] where they obtain in some cases constant-factor inapproximability results (using the constant-factor NP-hardness of the optimization problem). This difference is inherent with the #BIS-hardness assumption, i.e., that there is no FPRAS for #BIS. Moreover, an algorithm which approximates #BIS within any poly(n)-factor implies an FPRAS, and obtaining constant-factor inapproximability results for magnetization on bipartite graphs would require (among other things) hardness of #BIS within an exponential-factor.

Our results extend to the hard-core model on weighted independent sets, and to general 2-spin antiferromagnetic models. These more general results are detailed in Section 1.2.

1.1 Ferromagnetic Potts Model

Ferromagnetic spin systems, which are equivalent to attractive undirected graphical models, are an interesting class of models to illustrate our new proof technique on. In ferromagnetic models there is no hard optimization problem as the maximum likelihood configurations are trivial assignments (setting all vertices to the same spin/label). Consequently, to obtain hardness results for computing averages in ferromagnetic models we need to work directly from hardness of approximate counting results, which we can do using our new approach.

The most well-studied examples of ferromagnetic models are the Ising and Potts models. Given a graph G and an integer $q \geq 2$, configurations of the Ising/Potts model are the collection Ω of assignments $\sigma : V(G) \to [q]$ where $[q] = \{1, \ldots, q\}$ are the labels of the q spins. The case $q = 2$ corresponds to the Ising model and the case $q \geq 3$ is the Potts model.

The models are parameterised by an edge activity[1] $\beta > 0$. The weight of an assignment σ is defined as $w_{G;q,\beta}(\sigma) = \beta^{m_G(\sigma)}$ where $m_G(\sigma) = |\{(u,v) \in E : \sigma(u) = \sigma(v)\}|$ is the number of edges which are monochromatic in σ. Finally, the Gibbs distribution is defined as $\mu_{G;q,\beta}(\sigma) = w_{G;q,\beta}(\sigma)/Z_{G;q,\beta}$ where the normalising factor $Z_{G;q,\beta} := \sum_{\tau:V(G)\to[q]} w(\tau)$ is the partition function. In this paper, we restrict attention to the case $\beta > 1$ which is the ferromagnetic (attractive) case, and hence the most likely configurations are the q monochromatic configurations (all vertices are assigned the same spin).

For the Ising and Potts models, the analog of the average independent set size is the average number of vertices assigned spin 1. This quantity $\mathcal{M}_{q,\beta}(G)$, known as the magnetization, is trivial in these cases since, due to the Ising/Potts models symmetry among spins, it holds that $\mathcal{M}_{q,\beta}(G) = n/q$. The simplest and most natural observable to consider is the average number of monochromatic edges under the Potts distribution, i.e., the quantity

$$\mathcal{S}_{q,\beta}(G) := \mathbf{E}_{\sigma\sim\mu_{G;q,\beta}}[m_G(\sigma)]$$

which is known as the *susceptibility*. Sinclair and Srivastava [17] showed that exact computation of the susceptibility in the ferromagnetic Ising model is #P-hard.

For the Ising model a classical result of Jerrum and Sinclair [13] presents an efficient sampling scheme for all G, all β. This yields an efficient algorithm for approximating averages in the Ising model (this holds for any local observables as defined subsequently in Section 1.2). In contrast for the Potts model (for any $q \geq 3$) approximating the partition function becomes computationally intractable for large β as we detail below.

The Potts model with $q \geq 3$ spins undergoes a computational phase transition on bipartite graphs of maximum degree Δ at the following critical point $\beta_c(q,\Delta) = \frac{q-2}{(q-1)^{1-2/\Delta}-1}$. In [10] it was established that for all $q, \Delta \geq 3$ and $\beta > \beta_c(q,\Delta)$ approximating the partition function of the ferromagnetic Potts model is #BIS-hard on bipartite graphs of maximum degree Δ. Using our general counting-to-observables reduction we show that approximating the average number of monochromatic edges under the Potts distribution is as hard as approximating the partition function for the ferromagnetic Potts model.

▶ **Theorem 2.** *Let $q, \Delta \geq 3$ be integers and $\beta > \beta_c(q,\Delta)$. There is no* FPRAS *for the susceptibility in the q-state Potts model on bipartite graphs of maximum degree Δ, unless* #BIS *admits an* FPRAS.

1.2 General 2-spin systems

Theorem 1 for independent sets is a special case of a general result for arbitrary 2-spin antiferromagnetic systems. Such spin systems are parameterized by three parameters, β, γ and λ; the first two are edge activities and control the strength of the spin interactions between neighboring vertices, and the third is a vertex activity (a.k.a. external field) that favors one spin over the other.

More precisely, for a graph $G = (V, E)$, $\beta, \gamma \geq 0$ which are not both equal to zero and $\lambda > 0$, let $\mu_{G;\beta,\gamma,\lambda}$ denote the Gibbs distribution on G with edge activities β, γ and external field λ, i.e., for $\sigma : V \to \{0,1\}$ we have

$$\mu_{G;\beta,\gamma,\lambda}(\sigma) = \frac{\lambda^{|\sigma|}\beta^{m_0(\sigma)}\gamma^{m_1(\sigma)}}{Z_{G;\beta,\gamma,\lambda}},$$

[1] We remark that β is usually used to denote the so-called inverse temperature of the Potts model; here to have consistent notation with general 2-spin systems presented in Section 1.2 we take β to be the exponent of the inverse temperature.

where $|\sigma|$ is the number of vertices with spin 1, and $m_0(\sigma), m_1(\sigma)$ denote the number of edges in G whose endpoints are assigned under σ the pair of spins $(0,0)$ and $(1,1)$, respectively.

The parameter pair (β,γ) is called *antiferromagnetic* if $\beta\gamma \in [0,1)$ and at least one of β,γ is non-zero, and it is called ferromagnetic, otherwise. Note that the hard-core model on independent sets weighted by $\lambda > 0$ is the case $\beta = 1, \gamma = 0$ (under the convention that $0^0 \equiv 1$). Our earlier example of unweighted independent sets corresponds to the hard-core model with $\lambda = 1$. The antiferromagnetic Ising model is the special case $0 < \beta = \gamma < 1$.

Our results apply to general "vertex-edge observables" defined as follows.

▶ **Definition 3.** *Let (β,γ) be antiferromagnetic and $\lambda > 0$. For real numbers a, b, c, the* (a,b,c) vertex-edge observable *of a graph G in the 2-spin system corresponding to (β,γ,λ) is given by*

$$\mathcal{O}_{\beta,\gamma,\lambda}(G) = \mathbf{E}_{\sigma\sim\mu_{G;\beta,\gamma,\lambda}}\big[o_G(\sigma)\big], \text{ where } o_G(\sigma) = a|\sigma| + bm_0(\sigma) + cm_1(\sigma).$$

The observable is trivial on general graphs *if any of the following hold: (i) $a = b = c = 0$, (ii) $\beta = 0$ and $a = c = 0$, (iii) $\gamma = 0$ and $a = b = 0$, (iv) $\beta = \gamma$, $\lambda = 1$ and $b + c = 0$. We say that the observable is* trivial on bipartite graphs *if either any of the above hold, or $\beta = \gamma$ and $\lambda = 1$. Otherwise, we say that the observable is* non-trivial.

Notice that by setting $(a,b,c) = (1,0,0)$ we obtain the magnetization $\mathcal{M}_{\beta,\gamma,\lambda}(G)$, which in the special case of the hard-core model with $\lambda = 1$ is the average size of an independent set. Furthermore, by setting $(a,b,c) = (0,1,1)$ we obtain the susceptibility, denoted by $\mathcal{S}_{\beta,\gamma,\lambda}(G)$, which is the average number of monochromatic edges.

The terminology "trivial" is applied liberally here and meant to convey that there is an efficient algorithm for the relevant parameters. In particular, while cases (i)-(iii) are degenerate, case (iv) corresponds to the Ising model without an external field. A classical (and highly non-trivial) result of Jerrum and Sinclair [13] presented an FPRAS for the ferromagnetic Ising model on any graph, any $\beta > 1$. Moreover, for bipartite graphs, the subcase $\beta < 1$ (antiferromagnetic) can be reduced to an equivalent $\beta > 1$ (ferromagnetic) system.

We next define the range of parameters (β,γ,λ) where our inapproximability results for vertex-edge observables apply; these are precisely the parameters where the hard-core and the antiferromagnetic Ising models exhibit non-uniqueness on the infinite Δ-regular tree (for general 2-spin systems this threshold corresponds to what is known as up-to-Δ non-uniqueness, which captures the computational phase transition).

▶ **Definition 4.** *Let $\Delta \geq 3$ be an integer. We let $\mathcal{N}_\Delta$ be the set of (β,γ,λ) such that (β,γ) is antiferromagnetic, and the (unique) fixpoint $x^* > 0$ of the function $f(x) = \frac{1}{\lambda}\big(\frac{\beta x+1}{x+\gamma}\big)^{\Delta-1}$ satisfies $|f'(x^*)| > 1$. The region $\mathcal{N}_\Delta$ is known as the* non-uniqueness region.

Note there is an efficient sampling/counting algorithm for graphs of maximum degree Δ, roughly[2], for (β,γ,λ) outside the parameter region $\mathcal{N}_\Delta$ [15, 5]. Inside $\mathcal{N}_\Delta$, it is NP-hard to approximate the partition function on graphs of maximum degree Δ [19] and it is #BIS-hard to approximate the partition function on *bipartite* graphs of maximum degree Δ [3]. We prove that it is also hard to compute any non-trivial vertex-edge observable in exactly this same region where the corresponding counting problem is hard.

[2] More precisely, the (strict) uniqueness region is defined as those $\beta,\gamma,\lambda)$ where the fixpoint x^* in Definition 4 satisfies the (strict) inequality $|f'(x^*)| < 1$. For certain monotonicity reasons, the algorithm for max-degree Δ graphs demands that (β,γ,λ) lie in the intersection of these uniqueness regions for all degrees $d \leq \Delta$, see [15] for details.

▶ **Theorem 5.** *Let $\Delta \geq 3$ be an integer and $(\beta, \gamma, \lambda) \in \mathcal{N}_\Delta$. Then, for any vertex-edge observable that is non-trivial on bipartite graphs, there is no* FPRAS *on bipartite graphs of maximum degree Δ unless* #BIS *admits an* FPRAS.

We stress that the above result holds for bipartite graphs. The previous work of Galanis et al. [9] showed hardness for general antiferromagnetic 2-spin systems in the same non-uniqueness region but on general graphs, only for the magnetization, and only achieved the stronger constant-factor hardness for a dense set of λ.

We begin by establishing Theorem 2 for hardness of approximating the susceptibility for the ferromagnetic Potts model, see Section 2. We then present the refinements to establish Theorems 5 for general 2-spin antiferromagnetic systems in Section 3; Theorem 1 follows as a corollary of Theorem 5.

2 Hardness of Susceptibility for the Ferromagnetic Potts model

Let $q, \Delta \geq 3$ be integers and $\beta > \beta_c(q, \Delta)$. To prove Theorem 5, we will assume the existence of an FPRAS for the susceptibility of Potts with parameters q, β on maximum degree Δ graphs and show how to obtain an FPRAS for the partition function of the Potts model with parameters q, β^* on bipartite graphs of maximum degree 3 for some $\beta^* > \beta_c(q, 3)$; the latter problem is #BIS-hard by [10].

To aid the presentation, it will be convenient to consider the following computational problems and use the notion of AP-reduction between counting problems [6]; roughly, for two problems A, B, the notation $A \leq_{\text{AP}} B$ means that the existence of an FPRAS for B implies the existence of an FPRAS for A. In the first computational problem that will be relevant, the parameters are q, β, Δ as detailed below.

Name #Susc(q, β, Δ).
Instance A bipartite graph G with max degree Δ.
Output The susceptibility on G with parameters q, β, i.e., the value $\mathcal{S}_{q,\beta}(G)$.

In the second, the parameter is going to be just q; note that the problem allows the edge activity to be part of the input.

Name #SuscCubic(q).
Instance A cubic bipartite graph H, and a rational edge activity $\hat{\beta} \geq 1$.
Output The susceptibility on H with parameters $q, \hat{\beta}$, i.e., the value $\mathcal{S}_{q,\hat{\beta}}(H)$.

The key ingredient underpinning our proof approach is captured by the following lemma, whose proof is given in Section 2.3. Roughly, the lemma asserts that, despite the fact that the parameter β is fixed, with appropriate gadget constructions we can "shift" it in a fine-tuned way to any desired $\hat{\beta}$. In turn, this allows us to do an appropriate integration of the observable (viewed as a function of the parameter $\hat{\beta}$) to recover the partition function of a #BIS-hard problem; we will refer loosely to this integration technique as *interpolation*.

▶ **Lemma 6.** *Let $q, \Delta \geq 3$ be integers and $\beta > \beta_c(q, \Delta)$ be an arbitrary real. Then,*

$$\#\text{SuscCubic}(q) \leq_{\text{AP}} \#\text{Susc}(q, \beta, \Delta).$$

Before proceeding with outlining the proof of the key Lemma 6, we first present the interpolation-scheme idea that allows us to conclude Theorem 2 from Lemma 6.

Proof of Theorem 2 (assuming Lemma 6). Let $\beta^* > \beta_c(q,3)$ be an arbitrary rational number and consider the problem #PottsCubic(q,β^*), i.e., the problem of approximating the partition function $Z_{G;q,\beta^*}$ on cubic bipartite graphs G. From [10, Theorem 3], we have that #PottsCubic(q,β^*) is #BIS-hard. From Lemma 6, we have that for $\beta > \beta_p(q,\Delta)$ it holds that #SuscCubic$(q) \leq_{\mathrm{AP}}$ #Susc(q,β,Δ), so to prove the theorem it suffices to show that #PottsCubic$(q,\beta^*) \leq_{\mathrm{AP}}$ #SuscCubic(q).

Let G be an instance of #PottsCubic(q,β^*) with n vertices and m edges, and $\epsilon > 0$ be the desired relative error that we want to approximate $Z_{G;q,\beta^*}$. Since $\frac{\partial \log Z_{G;q,\hat{\beta}}}{\partial \hat{\beta}} = \frac{1}{\hat{\beta}}\mathcal{S}_{q,\hat{\beta}}(G)$, we have

$$\log Z_{G;q,\beta^*} = \int_1^{\beta^*} \tfrac{1}{\hat{\beta}}\mathcal{S}_{q,\hat{\beta}}(G)\mathrm{d}\hat{\beta}. \tag{1}$$

Let $M = \lceil (10q\hat{\beta}m/\epsilon)^4 \rceil$ and for $i = 0,1,\ldots,M$, consider the sequence of edge parameters $\hat{\beta}_i = 1 + i\frac{\beta^*-1}{M}$. It is a standard fact that the function $\log Z_{G;\hat{\beta}}$ is convex with respect to $\hat{\beta}$ (the second derivative is equal to the variance of the number of monochromatic edges) and therefore the function $\frac{1}{\hat{\beta}}\mathcal{S}_{q,\hat{\beta}}(G)$ is increasing. Therefore, from the standard technique of approximating integrals with rectangles, we obtain from (1) that

$$\frac{1}{M}\sum_{i=0}^{M-1}\frac{\mathcal{S}_{G;q,\hat{\beta}_i}}{\hat{\beta}_i} \leq \log Z_{G;\beta^*} \leq \frac{1}{M}\sum_{i=1}^{M}\frac{\mathcal{S}_{q,\hat{\beta}_i}(G)}{\hat{\beta}_i}.$$

Using the bound $m/q \leq \mathcal{S}_{q,\hat{\beta}}(G) \leq m$ that holds for all $\hat{\beta} \geq 1$, we obtain that

$$\log Z_{G;q,\beta^*} = \big(1 \pm \frac{\epsilon}{10}\big)\sum_{i=1}^{M}\frac{\mathcal{S}_{q,\hat{\beta}_i}(G)}{\hat{\beta}_i}.$$

Using the presumed oracle for #SuscCubic(q) we can compute $\hat{S}_i$ such that $\hat{S}_i = (1 \pm \frac{\epsilon}{10Mm})\mathcal{S}_{q,\hat{\beta}_i}(G)$ for $i \in [M]$, and therefore the quantity $\hat{Z} = \exp\big(\sum_{i\in[M]}\frac{\mathcal{S}_{q,\hat{\beta}_i}(G)}{\hat{\beta}_i}\big)$ is a $(1\pm\epsilon)$-factor approximation to $Z_{G;q,\beta^*}$. This completes the AP-reduction, and therefore the proof as well. ◀

In the rest of Section 2, we focus on proving Lemma 6.

2.1 Proof overview of Lemma 6

In this section, we give the proof overview of Lemma 6 which as we saw in the previous section is the key ingredient to carry out the interpolation-scheme idea. We highlight here some of the key ideas (with a non-technical overview), which are also used to prove the analogous Lemma for obtaining our inapproximability results for 2-spin systems.

To prove Lemma 6, we will use three different types of gadgets.

The first type of gadgets, that have also been used in previous inapproximability results, are the so-called "phase gadgets", which are almost Δ-regular bipartite graphs with a relatively small number of degree $\Delta - 1$ vertices (the so-called "ports"). This type of gadget exploits the phase transitions of the model and has q-ary behaviour, in the sense that a typical sample from their Gibbs distribution is in one of the q ordered phases, favoring one spin over the others. Aside from this q-ary behaviour, another feature of these gadgets is that they are convenient to maintain the degree of the vertices in our constructions small, using the ports to make connections between gadgets.

The second type of gadgets are paths; these allow us to interpolate the edge activity β. The key point is that long paths induce some small edge-interaction β between their endpoints (bigger than but close to 1) and by using a big number of them (in parallel-style connections) we can achieve a target edge activity $\hat{\beta}$ with arbitrary good precision; here, the ports of the phase gadgets allow us to do these parallel connections without exceeding the degree bound Δ. This is a crucial ingredient in implementing the new reduction idea.

The final type of gadgets consists of the so-called edge-interaction gadgets. Each such gadget has two vertices, say ρ, ρ', which we also refer to as ports. We are interested in two quantities of these gadgets (cf. Definition 9):

- the effective edge activity, i.e., the relative ratio of the aggregate weight of configurations where $\sigma(u) = \sigma(v)$ versus $\sigma(u) \neq \sigma(v)$. Note that this ratio is always bigger than 1, due to the ferromagnetic interaction.
- the susceptibility gap, i.e., the difference between the expected susceptibility conditioned on $\sigma(u) = \sigma(v)$ and the susceptibility conditioned on $\sigma(u) \neq \sigma(v)$.

We prove the existence of pairs of susceptibility gadgets which have roughly equal induced edge parameters but different susceptibility gaps. The equality between the induced edge parameters allows us to use them as probes (without changing the underlying distribution) for "susceptibility" between two vertices s, t, i.e., the probability that s, t have the same colour, in a graph G. That is, we can invoke a presumed oracle for susceptibility when we use the first gadget (by identifying s, t with the terminals) and get a "reading" for susceptibility, and do the same for the second and get a second "reading"; the difference between the two readings gives us information about the probability that s, t have the same colour in the original graph G.

The reason that these susceptibility gadgets are useful is that analysing the susceptibility of the other two types of gadgets is deeply unpleasant and, in fact, it is not even known how to obtain susceptibility estimates for the phase gadgets (since their analysis in earlier works builds upon second moment methods that give rather crude bounds in our setting). Hence, by the subtraction trick above, we have the required modularity to avoid such refined considerations.

That said, establishing the existence of pairs of susceptibility gadgets with the required properties has various challenges and the proof is based on an elaborate construction which finishes by a contradiction argument via Cauchy's functional equation. Fortunately, this ground work has been largely done in [9], though in our setting we need to consider edge gadgets instead of vertex gadgets, which complicates the underlying functions involved in the proofs. We believe that these constructions can be used to strengthen the results of [9] and obtain inapproximability for multi-spin systems such as colourings or the antiferromagnetic Potts model.

These ideas suitably adapted apply to obtain our inapproximability results for antiferromagnetic 2-spin systems. The difference for 2-spin systems is that the interpolation is quite trickier, since in the setting there it is harder to make vertex or edge activities that are close to 1 and do the interpolation (in contrast to the paths used above which is the fairly natural choice). Instead, to do the interpolation, we use a pair of trees whose induced vertex activities (at the root) are sufficiently close and which are attached (in appropriate numbers) to the ports of the phase gadgets to imitate the effect of an external field close to 1. We are then able to interpolate in terms of λ by a suitable implementation of the subtraction trick idea; we again need to depart from [9] (where 2-spin models were also considered) since the construction there does not yield a suitable interpolation parameter. The final new ingredient

is to account for the general vertex-edge observables, since a key fact used in [9] is that the magnetization is an appropriate derivative of the log-partition function, which is no longer the case for general vertex-edge observables.

We now state more formally the above ingredients and show how to combine these and conclude the proof of Lemma 6.

2.2 The gadgets

2.2.1 Bipartite phase gadgets for the Potts model

For integers t, n, Δ, we let $\mathcal{G}^t_{n,\Delta}$ be the distribution on bipartite graphs where there are n vertices with degree Δ on each side, and t vertices of degree $\Delta-1$ on each side. For a graph $G \in \mathcal{G}^t_{n,\Delta}$, we denote the set of vertices with degree Δ by U and by W those with degree $\Delta-1$, so that $|U| = 2n$ and $|W| = 2t$. We will refer to set W as the *ports* of G. For $\sigma : U \to [q]$, we define the *phase* $\mathcal{Y}(\sigma)$ of the configuration σ as the most frequent color (breaking ties arbitrarily), i.e., which has the most occupied vertices under σ, i.e.,

$$\mathcal{Y}(\sigma) = \arg\max_{i\in[q]} |\sigma^{-1}(i)|.$$

Let $p > 1/q$ be given from $p = \frac{x}{x+q-1}$ where $x > 1$ is the largest solution of $x = \left(\frac{\beta x+q-1}{x+\beta+q-2}\right)^{\Delta-1}$, cf. [10, Footnote 5]. For a colour $i \in [q]$, we define the product measure $Q^i_W(\cdot)$ on configurations $\tau : W \to [q]$, given by

$$Q^i_W(\tau) = p^{|\tau^{-1}(i)|}\left(\tfrac{1-p}{q-1}\right)^{|W|-|\tau^{-1}(i)|}.$$

We will need the following two properties from the phase gadget G for some sufficiently small $\epsilon > 0$. Let $\mu := \mu_{G;q,\beta}$.

1. The q phases appear with roughly equal probability, i.e., $\left|\mu(\mathcal{Y}(\sigma) = i) - \frac{1}{q}\right| \le \epsilon$ for $i \in [q]$.
2. For $i \in [q]$ and any $\tau : W \to [q]$, $\left|\frac{\mu\left(\sigma_W=\tau \mid \mathcal{Y}(\sigma)=i\right)}{Q^i_W(\tau)} - 1\right| \le \epsilon$.

Let $\mathcal{G}^{t,\epsilon}_{n,\Delta}$ denote the set of graphs $G \in \mathcal{G}^t_{n,\Delta}$ satisfying Items 1 and 2. The following lemma is shown in [10].

▶ **Lemma 7** ([10, Lemma 28]). *Let $q, \Delta \ge 3$ be integers and $\beta > \beta_c(q,\Delta)$. Then, there is a randomized algorithm that, on input integer $t \ge 1$ and $\epsilon > 0$, outputs in time $\mathrm{poly}(t, \frac{1}{\epsilon})$ an integer n and a graph G that belongs to $\mathcal{G}^{t,\epsilon}_{n,\Delta}$, with probability $\ge 3/4$.*

2.2.2 Edge-interaction/susceptibility gadgets

▶ **Definition 8.** *An* edge-interaction gadget *is a connected series-parallel graph $\mathcal{E}$ with two distinct vertices ρ, ρ' that have degree one. We will refer to ρ, ρ' as the* ports *of $\mathcal{E}$.*

▶ **Definition 9.** *Let $\mathcal{E}$ be an edge-interaction gadget with ports ρ, ρ', and $\mu = \mu_{\mathcal{E};\beta}$. We denote by $B_{\mathcal{E}} = B_{\mathcal{E}}(\beta)$ the* effective interaction *of the gadget, i.e., $B_{\mathcal{E}} = \frac{\mu(\sigma_\rho=\sigma_{\rho'}=1)}{\mu(\sigma_\rho=1,\sigma_{\rho'}=2)}$ and by $S_{\mathcal{E}} = S_{\mathcal{E}}(\beta)$ the* susceptibility gap *of the gadget, i.e., $S_{\mathcal{E}} = \mathbf{E}_{\sigma\sim\mu}[m_{\mathcal{E}}(\sigma) \mid \sigma_\rho = \sigma_{\rho'}] - \mathbf{E}_{\sigma\sim\mu}[m_{\mathcal{E}}(\sigma) \mid \sigma_\rho \ne \sigma_{\rho'}]$.*

The following "interaction" gadget will allow us to change the edge interaction parameter to any desired value.

▶ **Lemma 10.** *Let $q \ge 2$ be an integer and $\beta > 1$ be a real. There is an algorithm, which, on input a rational $r \in (0, 1/2)$, outputs in time poly$(\mathrm{bits}(r))$ a path $\mathcal{P}$ of length $O(|\log r|)$, such that $0 < B_{\mathcal{P}} - 1 < r$.*

The proof of Lemma 10 is given in Section C.1.2 of the full version. The following lemma gives pairs of edge-interaction gadgets which have almost the same edge interaction but different susceptibility gaps; this difference in the susceptibility gaps while maintaining the edge interaction will be the key to read off the susceptibility by subtraction.

▶ **Lemma 11.** *Let $q \geq 3$ be an integer and $\beta > 1$ be a real. For any arbitrarily small constant $\delta > 0$, there exist constants $S, \Xi > 0$ and $B \in (1, 1+\delta)$ such that the following holds. There is an algorithm, which, on input a rational $r \in (0, 1/2)$, outputs in time poly$(\text{bits}(r))$ a pair of edge-interaction gadgets $\mathcal{E}_1, \mathcal{E}_2$, each of maximum degree 3 and size $O(|\log r|)$, such that*

$$|B_{\mathcal{E}_1} - B|, |B_{\mathcal{E}_2} - B| \leq r, \text{ but } |S_{\mathcal{E}_1} - S_{\mathcal{E}_2}| \geq S.$$

Moreover, the susceptibility gaps $|S_{\mathcal{E}_1}|, |S_{\mathcal{E}_2}|$ are upper-bounded in absolute value by the constant Ξ, i.e., $|S_{\mathcal{E}_1}|, |S_{\mathcal{E}_2}| \leq \Xi$.

The proof of Lemma 11 generalises the techniques from [9], and is given in Section C.3 of the full version.

2.3 The reduction – proof of Lemma 6

Let $q, \Delta \geq 3$ be integers and $\beta > \beta_c(q, \Delta)$. Let H be a cubic bipartite graph which is input to the problem #Susc(q) of Section 2. For integers $n, t \geq 1$ and rational $\epsilon > 0$, let $G \in \mathcal{G}^{t,\epsilon}_{n,\Delta}$ be a bipartite phase gadget satisfying Items 1 and 2 of Section 2.2.1. Let $\mathcal{E}$ be an edge-interaction gadget with effective interaction $B_{\mathcal{E}}$ and susceptibility gap $S = S_{\mathcal{E}}$. Let $\mathcal{P}$ be a path with effective edge interaction $B_{\mathcal{P}}$.

For an integer ℓ satisfying $\ell < t/3$, we define the graph $H^{\ell}_{G,\mathcal{E},\mathcal{P}}$ as follows. For each vertex v of H replace it with a distinct copy of G, denoted by G_v; we also use U_v, W_v to denote the sets corresponding to U, W in G_v. Moreover for each $\{u, v\}$ of H, add a matching of size $\ell + 1$ between W_u and W_v, and replace ℓ edges of the matching by (distinct) copies of the path $\mathcal{P}$ and the last edge of the matching by the gadget $\mathcal{E}$. Since H is bipartite, this constuction can clearly be done so that the final graph $H^{\ell}_{G,\mathcal{E},\mathcal{P}}$ obtained this way is bipartite. Let $H^{\ell}_{G,\mathcal{P}}$ be the graph with the copies of the susceptibility gadget removed.

The lemma below relates the susceptibility $\mathcal{S}_{q,\beta}(H^{\ell}_{G,\mathcal{E},\mathcal{P}})$ with the susceptibility of $\mathcal{S}_{q,\hat{\beta}}(H)$, for some appropriate $\hat{\beta}$ that is a function of the parameters q, Δ, β and $\ell, B_{\mathcal{E}}, B_{\mathcal{P}}$; we expain how the lemma corresponds to the overview of Section 2.1 right after its statement. The following piece of notation will be useful: for a graph J and a subgraph J' of J, given a configuration $\sigma : V(J) \to [q]$, it will be convenient to denote by $m_{J'}(\sigma) = \sum_{e=\{u,v\} \in E(J')} \mathbf{1}\{\sigma(u) = \sigma(v)\}$ the number of monochromatic edges of J' under σ.

▶ **Lemma 12.** *Let $q, \Delta \geq 3$ be integers and $\beta > \beta_c(q, \Delta)$. There are constants $1 > R_0 > R_1 > 0$ so that the following holds for any path $\mathcal{P}$ with edge interaction $B_{\mathcal{P}}$, any edge-interaction gadget $\mathcal{E}$ with effective interaction $B_{\mathcal{E}}$ and susceptibility gap $S_{\mathcal{E}}$, and any integers ℓ, t with $t \geq 3(\ell + 1)$.*

For a cubic bipartite graph H, for any $\epsilon \leq \frac{1}{(5q|V(H)|)^2}$, any integer n and phase gadget $G \in \mathcal{G}^{t,\epsilon}_{n,\Delta}$, for $\mu := \mu_{H^{\ell}_{G,\mathcal{E},\mathcal{P}}}$ and $\epsilon' = 10q|V(H)|\epsilon$, it holds that

$$\mathcal{S}_{q,\beta}(H^{\ell}_{G,\mathcal{E},\mathcal{P}}) = \mathcal{A}_{\mathcal{E}}|E(H)| + \mathbf{E}_{\sigma\sim\mu}[m_{H^{\ell}_{G,\mathcal{P}}}(\sigma)] + (1 \pm \epsilon')S_{\mathcal{E}}\big[(A_0 - A_1)\mathcal{S}_{q,\hat{\beta}}(H) + A_1|E(H)|\big],$$

where $A_{\mathcal{E}} = \mathbf{E}_{\sigma\sim\mu_{\mathcal{E}}}[m_{\mathcal{E}}(\sigma) \mid \sigma_\rho = \sigma_{\rho'}]$ and

$$\hat{\beta} := \big(\tfrac{1+(B_{\mathcal{P}}-1)R_0}{1+(B_{\mathcal{P}}-1)R_1}\big)^{\ell}\big(\tfrac{1+(B_{\mathcal{E}}-1)R_0}{1+(B_{\mathcal{E}}-1)R_1}\big), \qquad A_j := \tfrac{B_{\mathcal{E}}}{B_{\mathcal{E}} + \frac{1-R_j}{R_j}} \text{ for } j \in \{0, 1\}.$$

To give a bit of intuition behind the expression of $\mathcal{S}_{q,\beta}(H^{\ell}_{G,\mathcal{E},\mathcal{P}})$, recall that the vertices of H are replaced with copies of the bipartite phase gadgets G and that for each pair of neighboring vertices in H we connect the corresponding copies of G using the appropriate number of the gadgets $\mathcal{E},\mathcal{P}$. The point here is that the bipartite gadgets are so large that each one of them is with very high probability in one of the q phases (cf. Item 1 in Section 2.2.1) and therefore in the Gibbs distribution of $H^{\ell}_{G,\mathcal{E},\mathcal{P}}$ (with parameters q,β) they behave like meta-vertices which are in one of q states, analogously to a Potts model on H with q spins and a new edge activity $\hat{\beta}$, which is ultimately determined by the $\mathcal{E},\mathcal{P}$-connections and the (induced) probability distributions on the ports of the bipartite phase gadgets (conditioned on the phase, cf. Item 2 in Section 2.2.1). This explains (at an intuitive level) the presence of the quantity $\mathcal{S}_{q,\hat{\beta}}(H)$; the remaining terms are offsets to account for the addition of the various gadgets. Of those, the most complicated is the term $\mathbf{E}_{\sigma\sim\mu}[m_{H^{\ell}_{G,\mathcal{P}}}(\sigma)]$ which involves the contribution to the susceptibility from edges in the graph $\mathbf{E}_{\sigma\sim\mu}[m_{H^{\ell}_{G,\mathcal{P}}}(\sigma)]$ which is hard to get a neat expression since the average is taken over the complicated distribution μ. This is where the idea of having a pair of susceptibility gadgets $(\mathcal{E}_1,\mathcal{E}_2)$ with the same effective interaction but different susceptibility gaps will come into play (in the proof of Lemma 6 below): by subtracting the susceptibilities for the graphs $H^{\ell}_{G,\mathcal{E}_1,\mathcal{P}}$ and $H^{\ell}_{G,\mathcal{E}_2,\mathcal{P}}$ between these, the terms corresponding to $\mathbf{E}_{\sigma\sim\mu}[m_{H^{\ell}_{G,\mathcal{P}}}(\sigma)]$ will cancel (since $\mathcal{E}_1,\mathcal{E}_2$ have roughly the same effective interaction $B_{\mathcal{E}_1},B_{\mathcal{E}_2}$) allowing us to approximate the target quantity $\mathcal{S}_{q,\hat{\beta}}(H)$ (since $\mathcal{E}_1,\mathcal{E}_2$ have substantially different susceptibility gaps $S_{\mathcal{E}_1},S_{\mathcal{E}_2}$). That said, the proof of Lemma 12 is on the technical side and is deferred to Section B of the full version.

To finish the proof of Lemma 6, we need the following crude bound on the change of susceptibility when we slightly change the values of the edge activities on a subset of the edges. To state the lemma, for a graph G with edge-activity vector $\boldsymbol{\beta}=\{\beta_e\}_{e\in E(H)}$, define the weight of an assignment $\sigma:V(G)\to[q]$ as $w(\sigma)=\prod_{e=\{u,v\}\in E(G)}(\beta_e)^{\mathbf{1}\{\sigma(u)=\sigma(v)\}}$, and let $\mu_{G;q,\boldsymbol{\beta}}(\sigma)=w(\sigma)/Z_{G;q,\boldsymbol{\beta}}$ denote the corresponding Gibbs distribution, where $Z_{G;q,\boldsymbol{\beta}}$ is the normalizing constant.

▶ **Lemma 13.** *Let H be a graph and F be a subgraph of H on the same set of vertices. Suppose that $\boldsymbol{\beta}=\{\beta_e\}_{e\in E(H)},\boldsymbol{\beta}'=\{\beta'_e\}_{e\in E(H)}$ are edge activity vectors such that $\beta_e=\beta'_e=\beta$ for $e\in E(F)$, and $\beta_e=\beta_0$, $\beta'_e=\beta_1$ for $e\notin E(F)$. Then, for $\mu:=\mu_{H;q,\boldsymbol{\beta}}$ and $\mu':=\mu'_{H;q,\boldsymbol{\beta}}$, it holds that*

$$\Big|\mathbf{E}_{\sigma\sim\mu}[m_F(\sigma)]-\mathbf{E}_{\sigma\sim\mu'}[m_F(\sigma)]\Big|\leq|E(H)|^2|\beta_0-\beta_1|.$$

Proof. Suppose without loss of generality that $\beta_0\geq\beta_1$; by the monotonicity of the ferromagnetic Potts model we have that $\mathbf{E}_{\sigma\sim\mu}[m_F(\sigma)]\geq\mathbf{E}_{\sigma\sim\mu'}[m_F(\sigma)]$ (see, e.g., [12, Theorems 1.16 & 3.21]). For a configuration $\sigma:V(H)\to[q]$, let $w(\sigma),w'(\sigma)$ denote its weight under the edge activity vectors $\boldsymbol{\beta}$ and $\boldsymbol{\beta}'$, respectively. Consider an edge $e\in E(F)$. Then, using that for reals $a>b>0$ it holds that $|a^k-b^k|\leq k|a-b|a^k$, we obtain that for every σ it holds that

$$0<w(\sigma)-w'(\sigma)=\beta^{m_F(\sigma)}\big(\beta_0^{|E(H)|-m_F(\sigma)}-(\beta_1)^{|E(H)|-m_F(\sigma)}\big)\leq|E(H)|(\beta_0-\beta_1)w(\sigma)$$

By summing over σ, it follows also that $Z_{G;q,\boldsymbol{\beta}'}\leq Z_{G;q,\boldsymbol{\beta}}$, and combining these we obtain that

$$\mathbf{E}_{\sigma\sim\mu}[m_F(\sigma)]-\mathbf{E}_{\sigma\sim\mu'}[m_F(\sigma)]\leq\frac{\sum_\sigma m_F(\sigma)\big(w(\sigma)-w'(\sigma)\big)}{Z_{G;q,\boldsymbol{\beta}}}\leq|E(H)|^2(\beta_0-\beta_1).\qquad\blacktriangleleft$$

We now give the proof of Lemma 6 which we restate here.

▶ **Lemma 6.** *Let $q, \Delta \geq 3$ be integers and $\beta > \beta_c(q, \Delta)$ be an arbitrary real. Then,*

$\#\mathsf{SuscCubic}(q) \leq_{\mathrm{AP}} \#\mathsf{Susc}(q, \beta, \Delta)$.

Proof. Let H be a cubic bipartite graph and $\hat{\beta} > 1$ be the inputs to $\#\mathsf{SuscCubic}(q)$, and let $\eta \in (0,1)$ be the desired relative error that we want to approximate $\mathcal{S}_{q,\hat{\beta}}(H)$. We may assume that $\hat{\beta} \geq \beta_0 = \left(\frac{q-1}{3}\right)^{1/\Delta}$; for $\hat{\beta} < \beta_0$, a fairly standard coupling argument shows that Glauber dynamics converges rapidly to the Gibbs distribution $\mu_{H;q,\hat{\beta}}$, see for example [2, Theorem 1.1], and therefore it can be used to approximate $\mathcal{S}_{q,\hat{\beta}}(H)$ in time $poly\big(V(H), \frac{1}{\eta}, \mathrm{bits}(\hat{\beta})\big)$ using rejection sampling. For some of the bounds below, it will also be convenient to assume that $|V(H)|, |E(H)|$ are bigger than a sufficiently large constant (otherwise, we can just brute-force).

Let $1 > R_0 > R_1 > 0$ be the constants in Lemma 12, and let $\delta \in (0,1)$ be a rational constant such that for all $B \in (1, 1+\delta)$, it holds that $\frac{1+(B-1)R_0}{1+(B-1)R_1} \leq \beta_0 < \hat{\beta}$. Note that the choice of δ is a constant depending on q, Δ but independent of H and $\hat{\beta}$. By Lemma 11, there are constants $B \in (1, 1+\delta)$, $S > 0$ and an algorithm, which, on input a rational $r \in (0, 1/2)$, outputs in time $poly(\mathrm{bits}(r))$ a pair of susceptibility gadgets $\mathcal{E}_1, \mathcal{E}_2$, each of maximum degree 3 and size $O(|\log r|)$, such that

$$|B_{\mathcal{E}_1} - B|, |B_{\mathcal{E}_2} - B| \leq r, \text{ but } |S_{\mathcal{E}_1} - S_{\mathcal{E}_2}| \geq S. \tag{2}$$

Let $\epsilon = \frac{\eta}{|E(H)|^5}$ and $t = \left\lceil \left(\frac{|E(H)| \log \hat{\beta}}{\epsilon\delta(B-1)}\right)^4 \right\rceil$. By Lemma 7, there is an algorithm that outputs in time $poly(t, \frac{1}{\epsilon})$ an integer n and a graph $G \in \mathcal{G}^{t,\epsilon}_{n,\Delta}$ (satisfying Items 1 and 2). Use the algorithm of Lemma 11 to obtain gadgets $\mathcal{E}_1, \mathcal{E}_2$ satisfying (2) for $r = \frac{\epsilon^4}{10\delta(R_0-R_1)\beta_0}$. Moreover, use Lemma 10, to obtain in time $poly(\mathrm{bits}(r))$ an edge interaction gadget with $1 < B_{\mathcal{P}} < 1 + \epsilon$. Let ℓ be the smallest positive integer such that

$$\left(\tfrac{1+(B_{\mathcal{P}}-1)R_0}{1+(B_{\mathcal{P}}-1)R_1}\right)^{\ell} \left(\tfrac{1+(B-1)R_0}{1+(B-1)R_1}\right) > \hat{\beta}$$

and note that such an integer exists by the choice of δ since the l.h.s. for $\ell = 0$ is smaller than $\hat{\beta}$, and each of the fractions is bigger than 1 from $R_0 > R_1$ and $B > 1$. In fact, we have that $\ell = O(\frac{1}{\epsilon} \log \hat{\beta})$, where the implicit constants depend only on q, Δ. It follows in particular that $\ell < t/3$.

For $i \in \{1, 2\}$, consider now the graphs $\widehat{H}_i = H^{\ell}_{G,\mathcal{P},\mathcal{E}_i}$ and let $\mu_i = \mu_{\widehat{H}_i;q,\beta}$. From Lemma 12, we have that

$$\mathcal{S}_{q,\beta}(\widehat{H}_i) = \mathcal{A}_{\mathcal{E}_i}|E(H)| + \mathbf{E}_{\sigma\sim\mu_i}[m_{H^{\ell}_{G,\mathcal{P}}}(\sigma)] + (1 \pm \eta^2) S_{\mathcal{E}_i} \Big[\big(A^{(i)}_0 - A^{(i)}_1\big) \mathcal{S}_{q,\hat{\beta}_i}(H) + A^{(i)}_1 |E(H)| \Big],$$

where $A_{\mathcal{E}_i} = \mathbf{E}_{\sigma\sim\mu_{\mathcal{E}_i}}[m_{\mathcal{E}_i}(\sigma) \mid \sigma_\rho = \sigma_{\rho'}]$ and

$$\hat{\beta}_i := \left(\tfrac{1+(B_{\mathcal{P}}-1)R_0}{1+(B_{\mathcal{P}}-1)R_1}\right)^{\ell} \left(\tfrac{1+(B_{\mathcal{E}_i}-1)R_0}{1+(B_{\mathcal{E}_i}-1)R_1}\right), \qquad A^{(i)}_j := \frac{B_{\mathcal{E}_i}}{B_{\mathcal{E}_i} + \frac{1-R_j}{R_j}} \text{ for } j \in \{0,1\}.$$

From (2), we have that $\hat{\beta}_i = (1 \pm \epsilon^3)\hat{\beta}$, and therefore from Lemma 13, we have that

$$\big|\mathbf{E}_{\sigma\sim\mu_1}[m_{H^{\ell}_{G,\mathcal{P}}}(\sigma)] - \mathbf{E}_{\sigma\sim\mu_2}[m_{H^{\ell}_{G,\mathcal{P}}}(\sigma)]\big| \leq |E(H^{\ell}_{G,\mathcal{E},\mathcal{P}})|\epsilon^3 \leq \epsilon^2,$$
$$|\mathcal{S}_{q,\hat{\beta}_i}(H) - \mathcal{S}_{q,\hat{\beta}}(H)| \leq |E(H)|^2\epsilon^3 \leq \epsilon^2$$

Using (2), we also have that

$$A^{(i)}_0 = (1 \pm \epsilon)A_0, A^{(i)}_1 = (1 \pm \epsilon^2)A_i, \text{ where } A_j := \frac{B}{B + \frac{1-R_j}{R_j}} \text{ for } j \in \{0,1\}.$$

We can invoke the oracle for $\mathcal{S}_{q,\beta}(\widehat{H}_i)$ to compute $\hat{\mathcal{S}}_i$ such that $\hat{\mathcal{S}}_i = (1 \pm \epsilon^2)\mathcal{S}_{q,\beta}(\widehat{H}_i)$. Note also that $\mathcal{E}_i$ has size $poly(\text{bits}(r))$ and therefore we can invoke the oracle for $\#\mathsf{Susc}(q, \Delta, \beta)$ to compute $\hat{A}_{\mathcal{E}_i}, \hat{S}_{\mathcal{E}_1}$ such that $\hat{A}_{\mathcal{E}_i} = (1 \pm \epsilon^2)A_{\mathcal{E}_i}$ and $\hat{S}_{\mathcal{E}_i} = (1 \pm \epsilon^2)S_{\mathcal{E}_i}$.[3] It follows that

$$\hat{S} = \frac{1}{A_0 - A_1}\Big(\frac{(\hat{\mathcal{S}}_1 - \hat{\mathcal{S}}_2) - |E(H)|(\hat{A}_{\mathcal{E}_1} - \hat{A}_{\mathcal{E}_2})}{\hat{S}_{\mathcal{E}_1} - \hat{S}_{\mathcal{E}_2}} - A_1|E(H)|\Big)$$

is within a factor of $(1 \pm \eta)$ of the susceptibility $\mathcal{S}_{q,\hat{\beta}}(H)$, as needed. This finishes the reduction and therefore the proof of Lemma 6. ◀

3 Hardness of vertex-edge observables for 2-spin systems

Throughout this section, we will fix integer $\Delta \geq 3$, and antiferromagnetic $(\beta, \gamma, \lambda) \in \mathcal{N}_\Delta$ in the non-uniqueness region. We will also fix an (a, b, c) vertex-edge observable that is non-trivial on bipartite graphs.

3.1 The interpolation scheme

Analogously to Section 2, it will be convenient to consider the following computational problems.

Name $\#\mathsf{Observable2Spin}(\beta, \gamma, \lambda, a, b, c)$.
Instance A bipartite graph G with max degree Δ.
Output The (a, b, c) vertex-edge observable on G with parameters β,γ,λ, i.e., the value $\mathcal{O}_{\beta,\gamma,\lambda}(G)$.

In the second, the parameter is going to be the edge activity $\alpha < 1$ of an antiferromagnetic Ising model; note that the problem allows the vertex activity to be part of the input.

Name $\#\mathsf{MagnetIsingCubic}(\alpha)$.
Instance A cubic bipartite graph H, and a rational vertex activity $\hat{\lambda} > 0$.
Output The magnetization on H for the Ising model with parameters $\alpha, \hat{\lambda}$, i.e., the value $\mathcal{M}_{\alpha,\alpha,\hat{\lambda}}(H)$.

We now show the following analogue of the interpolation scheme in Lemma 6.

▶ **Lemma 14.** *Let $\Delta \geq 3$ be an integer and $(\beta, \gamma, \lambda) \in \mathcal{N}_\Delta$. Then, there is $\alpha \in (0, 1)$ such that for any (a, b, c) vertex-edge observable that is not trivial on bipartite graphs,*

$$\#\mathsf{MagnetIsingCubic}(\alpha) \leq_{\text{AP}} \#\mathsf{Observable2Spin}(\beta, \gamma, \lambda, a, b, c).$$

Assuming the key Lemma 14, the proof of Theorem 5 can be done analogously to Theorem 2, interpolating now in terms of the vertex activity $\hat{\lambda}$. We defer the proof to Section A of the full version.

[3] For $\hat{A}_{\mathcal{E}_i}$, just invoke the oracle on the graph obtained from $\mathcal{E}_i$ by identifying ρ_i and ρ_i'; this graph has maximum degree at most 3 since ρ_i, ρ_i' both have degree 1. Observe that $S_{\mathcal{E}_i} = 2A_{\mathcal{E}_i} - \mathcal{S}_{q,\beta}(\mathcal{E}_i)$ and therefore we can obtain the desired $\hat{S}_{\mathcal{E}_i}$ by using a further oracle call on $\mathcal{E}_i$ to approximate $\mathcal{S}_{q,\beta}(\mathcal{E}_i)$.

3.2 The gadgets

In this section, we outline the gadgets that will be used to prove Lemma 14. These are analogous to those presented in the case of the Potts model, especially the phase gadgets. To account for general vertex-edge observables, we refine appropriately the field-gadget idea of [9], by now paying attention to the so-called observable gap (cf. Definition 17).

3.2.1 Bipartite phase gadgets for antiferromagnetic 2-spin systems

We follow the same notation as in Section 2.2.1 to denote for integers t, n, Δ the class $\mathcal{G}^t_{n,\Delta}$ of bipartite graphs where there are n vertices with degree Δ on each side, and t vertices of degree $\Delta - 1$ on each side. For a graph $G \in \mathcal{G}^t_{n,\Delta}$, we denote its bipartition by (U^+, U^-) where U^+, U^- are vertex sets with $|U^+| = |U^-| = n$, and we denote by W^+, W^- the sets of vertices with degree $\Delta - 1$ on each side of the bipartition, so that $|W^+| = |W^-| = t$. We will refer to set $W = W^+ \cup W^-$ as the *ports* of G. For $\sigma : U \to \{0, 1\}$, we define the *phase* $\mathcal{Y}(\sigma)$ of the configuration σ as the side of the bipartite graph which has the most occupied vertices under σ, i.e.,

$$\mathcal{Y}(\sigma) = \arg \max_{i \in \{+,-\}} |\sigma^{-1}(1) \cap U^i|.$$

It is known that for $(\beta, \gamma, \lambda) \in \mathcal{N}_\Delta$ the system of equations $x = \frac{1}{\lambda}\left(\frac{\beta y+1}{y+\gamma}\right)^{\Delta-1}, y = \frac{1}{\lambda}\left(\frac{\beta x+1}{x+\gamma}\right)^{\Delta-1}$ has a unique solution with $y > x > 0$, see, e.g., [8, Lemma 7]. Let $q_+ = \frac{1}{1+x}$, $q_- = \frac{1}{1+y}$ and note that q_+, q_- are distinct numbers in the interval $(0, 1)$. Define the product distributions $Q^+_W(\cdot), Q^-_W(\cdot)$ by

$$Q^{\pm}_W(\tau) = (q_{\pm})^{|\tau^{-1}(1) \cap W^+|}(1 - q_{\pm})^{|\tau^{-1}(0) \cap W^+|}(q_{\mp})^{|\tau^{-1}(1) \cap W^-|}(1 - q_{\mp})^{|\tau^{-1}(0) \cap W^-|}. \tag{3}$$

We will need the following two properties from the phase gadget G for some sufficiently small $\epsilon > 0$. Let $\mu := \mu_{G;\beta,\gamma,\lambda}$.

1. The phases appear with roughly equal probability, i.e., $|\mu(\mathcal{Y}(\sigma) = \pm) - \frac{1}{2}| \le \epsilon$.
2. For any $\tau : W \to \{0, 1\}$, $\left|\frac{\mu(\sigma_W = \tau \mid \mathcal{Y}(\sigma) = \pm)}{Q^{\pm}_W(\tau)} - 1\right| \le \epsilon$.

Let $\mathcal{G}^{t,\epsilon}_{n,\Delta}$ denote the set of graphs $G \in \mathcal{G}^t_{n,\Delta}$ satisfying Items 1 and 2. The following lemma is is shown in [3].

▶ **Lemma 15** ([3, Lemma 9]). *Let $\Delta \ge 3$ and $(\beta, \gamma, \lambda) \in \mathcal{N}_\Delta$. Then, there is a randomized algorithm that, on input integer $t \ge 1$ and $\epsilon > 0$, outputs in time $\mathrm{poly}(t, \frac{1}{\epsilon})$ an integer n and a graph G that belongs to $\mathcal{G}^{t,\epsilon}_{n,\Delta}$, with probability $\ge 3/4$.*

3.2.2 Field gadgets with observable gaps

We adopt the following definition of "field" gadgets from [9].

▶ **Definition 16.** *For $\lambda \ne \frac{1-\beta}{1-\gamma}$, a* field gadget *is a rooted tree $\mathcal{T}$ whose root ρ has degree one. When $\lambda = \frac{1-\beta}{1-\gamma}$, a field gadget consists of a rooted bipartite graph obtained from a rooted tree where some of the leaves have been replaced by a distinct cycle of length four (by identifying the leaf with a vertex of the cycle).*

▶ **Definition 17.** *Let $\mathcal{T}$ be a field gadget rooted at ρ, and $\mu = \mu_{\mathcal{T};\beta,\gamma,\lambda}$. We denote by $R_{\mathcal{T}} = R_{\mathcal{T}}(\beta, \gamma, \lambda)$ the* effective field *of the gadget, i.e., $R_{\mathcal{T}} = \frac{1}{\lambda}\frac{\mu(\sigma_\rho=1)}{\mu(\sigma_\rho=0)}$ and by $O_{\mathcal{T}} = O_{\mathcal{T}}(\beta, \gamma, \lambda)$ the* observable gap *of the gadget, i.e., $O_{\mathcal{T}} = \mathbf{E}_{\sigma\sim\mu}[\, o_{\mathcal{T}}(\sigma) \mid \sigma_\rho = 1] - a - \mathbf{E}_{\sigma\sim\mu}[\, o_{\mathcal{T}}(\sigma) \mid \sigma_\rho = 0]$.*

The division by λ in the definition of the effective field of a gadget is to avoid double-counting the contribution of the root later on.

▶ **Lemma 18.** *Let (β,γ,λ) be antiferromagnetic such that at least one of $\beta\neq\gamma$ or $\lambda\neq 1$ holds. There are constants $C,\tilde{R}>0$ with $\tilde{R}\neq 1$ and an algorithm which, on input a rational $r\in(0,1/2)$, outputs in time poly$(\mathrm{bits}(r))$ field gadgets $\mathcal{T}_+,\mathcal{T}_-$, each of maximum degree 3 and size $O(|\log r|)$, such that*

$$R_{\mathcal{T}_+} > R_{\mathcal{T}_-} + r/2 \text{ and } |R_{\mathcal{T}_+}-\tilde{R}|,\ |R_{\mathcal{T}_-}-\tilde{R}|\leq r.$$

▶ **Theorem 19.** *Let (β,γ,λ) be antiferromagnetic, and consider any non-trivial vertex-edge observable on general graphs. There exist constants $\hat{R},\hat{O},\Xi>0$ and an algorithm, which, on input a rational $r\in(0,1/2)$, outputs in time poly$(\mathrm{bits}(r))$ a pair of field gadgets $\mathcal{T}_1,\mathcal{T}_2$, each of maximum degree 3 and size $O(|\log r|)$, such that*

$$|R_{\mathcal{T}_1}-\hat{R}|,\ |R_{\mathcal{T}_2}-\hat{R}|\leq r,\ \text{ but } |O_{\mathcal{T}_1}-O_{\mathcal{T}_2}|\geq\hat{O}.$$

Moreover, the observable gaps $O_{\mathcal{T}_1},O_{\mathcal{T}_2}$ are upper-bounded in absolute value by the constant Ξ.

The proofs of Lemma 18 and Theorem 19 follow closely the approach in [9], and are therefore deferred to Section C.3 of the full version.

3.3 The reduction

Let H be a cubic bipartite graph which is input to the problem #MagnetIsingCubic(α) of Section 3.1, for some constant $\alpha\in(0,1)$ to be specified. For integers $n,t\geq 1$ and rational $\epsilon>0$, let $G\in\mathcal{G}^{t,\epsilon}_{n,\Delta}$ be a bipartite phase gadget satisfying Items 1 and 2 of Section 3.2.1. Let $\mathcal{T}_+,\mathcal{T}_-,\mathcal{T}$ be field gadgets. Note that the gadgets $\mathcal{T}_+,\mathcal{T}_-$ serve a different role to that of $\mathcal{T}$, and in particular they will be used to interpolate over the vertex activity $\hat{\lambda}$.

To achieve this, for integers ℓ_+,ℓ_- satisfying $t\geq 5+\max\{\ell_+,\ell_-\}$, we define the graph $H^{\ell_+,\ell_-}_{G,\mathcal{T}_+,\mathcal{T}_-,\mathcal{T}}$ as follows. For each vertex v of H replace it with a distinct copy of G, denoted by G_v; we denote by $U^{\pm}_v,W^{\pm}_v$ the sets corresponding to $U^{\pm},W^{\pm}$ in G_v. Moreover, for each $v\in V(H)$, attach one copy of the gadget $\mathcal{T}$ and ℓ_+ copies of the gadget $\mathcal{T}_+$ on mutually distinct vertices of W^+ by identifying them with the corresponding roots. Similarly, attach ℓ_- copies of the gadget $\mathcal{T}_-$ on mutually distinct vertices of W^-. Let $\mathcal{T}_v$ be the copy of $\mathcal{T}_v$ corresponding to v, and w_v be its root. Let $W_{\mathcal{T}}=\{w_v\mid v\in V(H)\}$ be the set of all these roots. Further, for each edge $\{u,v\}$ of H, add an edge between W^+_u and W^+_v, and an edge between W^-_u and W^-_v.

Let $H^{\ell_+,\ell_-}_{G,\mathcal{T}_+,\mathcal{T}_-}$ be the graph without the internal vertices and edges of the copies of gadget $\mathcal{T}$, i.e., we keep only the roots $W_{\mathcal{T}}$ of the gadgets in $H^{\ell_+,\ell_-}_{G,\mathcal{T}_+,\mathcal{T}_-}$. The following piece of notation will be useful: for a graph J and a subgraph J' of J, given a configuration $\sigma:V(J)\to[q]$, it will be convenient to denote by $m_{J'}(\sigma)=\sum_{e=\{u,v\}\in E(J')}\mathbf{1}\{\sigma(u)=\sigma(v)\}$ the number of monochromatic edges of J' under σ.

The following lemma relates the value of the observable $\mathcal{O}_{\beta,\gamma,\lambda}(H^{\ell_+,\ell_-}_{G,\mathcal{T}_+,\mathcal{T}_-,\mathcal{T}})$ with the magnetization $\mathcal{S}_{\alpha,\hat{\lambda}}(H)$, for some appropriate $\hat{\lambda}$ that is a function of the parameters β,γ,λ and $\ell_+,\ell_-,R_{\mathcal{T}_+},R_{\mathcal{T}_+},R_{\mathcal{T}}$. Analogously to Section 2.3, for a graph J and a subgraph J' of J, given a configuration $\sigma:V(J)\to[q]$, it will be convenient to denote by $o_{J'}(\sigma)=a|\sigma_{V(J')}|+bm_0(\sigma_{V(J')})+cm_1(\sigma_{V(J')})$ the contribution of J' to the value of the observable on J.

▶ **Lemma 20.** *Let $\Delta \geq 3$ be an integer, $(\beta,\gamma,\lambda) \in \mathcal{N}_\Delta$, and (a,b,c) be a vertex-edge observable. Then, there are constants $q_+, q_- \in (0,1)$ with $q_+ > q_-$ and $\alpha \in (0,1)$ so that the following holds for any field gadgets $\mathcal{T}_+, \mathcal{T}_-, \mathcal{T}$ with effective fields R_+, R_-, R and observable gaps O_1, O_2, O, and any positive integers ℓ_+, ℓ_-, t with $t \geq 5 + \max\{\ell_+, \ell_-\}$.*

For a cubic bipartite graph H, for any $\epsilon \leq \frac{1}{(5|V(H)|)^2}$, any integer n and phase gadget $G \in \mathcal{G}^{t,\epsilon}_{n,\Delta}$, for $\mu := \mu_{H^{\ell_+,\ell_-}_{G,\mathcal{T}_+,\mathcal{T}_-,\mathcal{T}}}$ and $\epsilon' = 10|V(H)|\epsilon$, it holds that

$$\mathcal{O}_{\beta,\gamma,\lambda}(H^{\ell_+,\ell_-}_{G,\mathcal{T}_+,\mathcal{T}_-,\mathcal{T}}) = \mathcal{A}|V(H)| + \mathbf{E}_{\sigma\sim\mu}\big[o_{H^{\ell_+,\ell_-}_{G,\mathcal{T}_+,\mathcal{T}_-}}(\sigma)\big] + (1\pm\epsilon')O\big[(q_+ - q_-)\mathcal{M}_{\alpha,\hat{\lambda}}(H) + q_-|V(H)|\big],$$

where $\mathcal{A} = \mathbf{E}_{\sigma\sim\mu_\mathcal{T}}[o_\mathcal{T}(\sigma) \mid \sigma_\rho = 0]$ and $\hat{\lambda} := \big(\frac{q_+R+1-q_+}{q_-R+1-q_-}\big)\big(\frac{q_+R_++1-q_+}{q_-R_++1-q_-}\big)^{\ell_+}/\big(\frac{q_+R_-+1-q_+}{q_-R_-+1-q_-}\big)^{\ell_-}$.

The proof of Lemma 20 builds upon similar ideas to that of Lemma 12 (see in particular the discussion around there for how this blends with the overview of Section 2.1) and is deferred to Section B of the full version.

We will need the following bound on the change of the observable value when we change the vertex activities of a subset of the vertices. Namely, let $G = (V,E)$ be a graph and (β,γ) be antiferromagnetic. For a vertex-activity vector $\boldsymbol{\lambda} = \{\lambda_v\}_{v\in V}$, define the Gibbs distribution $\mu_{G;\beta,\gamma,\boldsymbol{\lambda}}(\sigma) \propto \beta^{m_0(\sigma)}\gamma^{m_1(\sigma)}\prod_{v\in V;\,\sigma(v)=1}\lambda_v$ for $\sigma : V \to \{0,1\}$.

▶ **Lemma 21** (Minor adaptation of [9, Lemma 35])**.** *Let (β,γ) be antiferromagnetic, $\lambda,\lambda_1,\lambda_2 > 0$, and (a,b,c) be a vertex-edge observable. Let $G = (V,E)$ be a graph and $S \subseteq V$. For $i \in \{1,2\}$, let $\boldsymbol{\lambda}_i$ be the field vector on V, where every $v \in S$ has activity λ_i, whereas every $v \in V\backslash S$ has activity λ. Let μ_i be the Gibbs distribution on G with parameters $\beta,\gamma,\boldsymbol{\lambda}_i$. Then, for every subgraph F of G, it holds that*

$$\big|\mathbf{E}_{\sigma\sim\mu_2}[o_F(\sigma)] - \mathbf{E}_{\sigma\sim\mu_1}[o_F(\sigma)]\big| \leq 2\big(|a|+|b|+|c|\big)\big(|V(G)|^2 + |E(G)|^2\big)\left|\frac{\lambda_2}{\lambda_1} - 1\right|.$$

We now have all the ingredients to prove Lemma 14.

▶ **Lemma 14.** *Let $\Delta \geq 3$ be an integer and $(\beta,\gamma,\lambda) \in \mathcal{N}_\Delta$. Then, there is $\alpha \in (0,1)$ such that for any (a,b,c) vertex-edge observable that is not trivial on bipartite graphs,*

$$\#\mathsf{MagnetIsingCubic}(\alpha) \leq_{\mathrm{AP}} \#\mathsf{Observable2Spin}(\beta,\gamma,\lambda,a,b,c).$$

Proof. Let $K = |a|+|b|+|c|$ and q_+, q_-, α be the constants from Lemma 20; recall that $\alpha \in (0,1)$ and $1 > q_+ > q_- > 0$. Let H be a cubic bipartite graph and $\hat{\lambda} > 1$ be the inputs to $\#\mathsf{MagnetIsingCubic}(\alpha)$, and let $\eta \in (0,1)$ be the desired relative error that we want to approximate $\mathcal{M}_{\alpha,\hat{\lambda}}(H)$.

By Lemma 18 and Theorem 19, there exist constants $\tilde{R}, \hat{R}, \hat{O}, C > 0$ with $\tilde{R} \neq 1$ and polynomial time algorithms, which on input rationals $r, r' \in (0,1/2)$, output in time $poly(\mathrm{bits}(r), \mathrm{bits}(r'))$ pairs of field gadgets $(\mathcal{T}_+,\mathcal{T}_-)$ and $(\mathcal{T}_1,\mathcal{T}_2)$ satisfying

$$\begin{aligned} &R_+ > R_- + Cr \text{ and } |R_+ - \tilde{R}|,\ |R_- - \tilde{R}| \leq r,\\ &|R_1 - \hat{R}|,\ |R_2 - \hat{R}| \leq r, \text{ but } |O_1 - O_2| \geq \hat{O}, \end{aligned} \tag{4}$$

where R_+, R_-, R_1, R_2 are the effective fields of $\mathcal{T}_+, \mathcal{T}_-, \mathcal{T}_1, \mathcal{T}_2$ and O_1, O_2 are the observable gaps of $\mathcal{T}_1, \mathcal{T}_2$, respectively.

Let $\epsilon = \frac{\eta}{|V(H)|^8}$ and $t = \big\lceil\big(\frac{1}{\epsilon}|V(H)|^2\log\hat{\lambda}\big)^6\big\rceil$. By Lemma 7, there is an algorithm that outputs in time $poly(t, \frac{1}{\epsilon})$ an integer n and a graph $G \in \mathcal{G}^{t,\epsilon}_{n,\Delta}$ (satisfying Items 1 and 2). Let also $\mathcal{T}_+, \mathcal{T}_-$ be field gadgets satisfying (4) for $r = \frac{|\tilde{R}-1|}{10}\epsilon^4$. Consider also the integers $\ell_+, \ell_- = \ell$,

where ℓ is an integer specified according to whether $\hat{\Lambda} = \hat{\lambda}/\big(\frac{q_+\hat{R}+1-q_+}{q_-\hat{R}+1-q_-}\big)$ is bigger than 1. Suppose first that $\hat{\Lambda} \geq 1$. Since $R_+ > R_-$ and $q_+ > q_-$, we have that $\frac{q_+R_++1-q_+}{q_-R_++1-q_-} > \frac{q_+R_-+1-q_+}{q_-R_-+1-q_-}$, and we pick ℓ to be the smallest positive integer such that

$$\big(\tfrac{q_+R+1-q_+}{q_-R+1-q_-}\big)\big(\tfrac{q_+R_++1-q_+}{q_-R_++1-q_-}\big)^{\ell}/\big(\tfrac{q_+R_-+1-q_+}{q_-R_-+1-q_-}\big)^{\ell} \geq \hat{\lambda}. \tag{5}$$

If $\hat{\Lambda} < 1$, then we pick ℓ to be the small positive integer so that

$$\big(\tfrac{q_+R+1-q_+}{q_-R+1-q_-}\big)\big(\tfrac{q_+R_-+1-q_+}{q_-R_-+1-q_-}\big)^{\ell}/\big(\tfrac{q_+R_++1-q_+}{q_-R_++1-q_-}\big)^{\ell} \leq \hat{\lambda},$$

In either case, using the lower bound $R_+ - R_- > Cr$ from (4), we have that $\ell = O(\frac{1}{r}\log\hat{\lambda})$ where the implicit constant depends only on $\beta, \gamma, \lambda, \Delta$. In particular, we have that $t \geq 5 + \max\{\ell_+, \ell_-\}$. In the argument below, we assume w.l.o.g. that $\hat{\Lambda} \geq 1$; otherwise, just apply the same argument by swapping the roles of the gadgets $\mathcal{T}_+, \mathcal{T}_-$ in the construction below.

For $i \in \{1,2\}$, consider now the graphs $\widehat{H}_i = H^{\ell_+,\ell_-}_{G,\mathcal{T}_+,\mathcal{T}_-,\mathcal{T}_i}$ and let $\mu_i = \mu_{\widehat{H}_i;\beta,\gamma,\lambda}$. For convenience, let also F denote the graph $H^{\ell_+,\ell_-}_{G,\mathcal{T}_+,\mathcal{T}_-}$, and note that F is a subgraph of both $\widehat{H}_1, \widehat{H}_2$. From Lemma 20, we have that for $i \in \{1,2\}$, for $\epsilon' = 10|V(H)|\epsilon$, it holds that

$$\mathcal{O}_{\beta,\gamma,\lambda}(\widehat{H}_i) = \mathcal{A}_i|V(H)| + \mathbf{E}_{\sigma\sim\mu_i}\big[o_F(\sigma)\big] + (1\pm\epsilon')O_i\big[(q_+ - q_-)\mathcal{M}_{\alpha,\hat{\lambda}_i}(H) + q_-|V(H)|\big], \tag{6}$$

where $\mathcal{A}_i = \mathbf{E}_{\sigma\sim\mu_{\mathcal{T}_i}}[o_{\mathcal{T}_i}(\sigma) \mid \sigma_{\rho_i} = 0]$ and $\hat{\lambda}_i := \big(\frac{q_+R_i+1-q_+}{q_-R_i+1-q_-}\big)\big(\frac{q_+R_++1-q_+}{q_-R_++1-q_-}\big)^{\ell_+}/\big(\frac{q_+R_-+1-q_+}{q_-R_-+1-q_-}\big)^{\ell_-}$. From (2), we have that $\hat{\lambda}_i = (1\pm\epsilon^3)\hat{\lambda}$, and therefore from Lemma 21, we have that

$$\big|\mathbf{E}_{\sigma\sim\mu_1}[o_F(\sigma)] - \mathbf{E}_{\sigma\sim\mu_2}[o_F(\sigma)]\big| \leq |E(H^{\ell}_{G,\mathcal{E},\mathcal{P}})|\epsilon^3 \leq \epsilon^2,$$
$$|\mathcal{M}_{\alpha,\hat{\lambda}_1}(H) - \mathcal{M}_{\alpha,\hat{\lambda}_2}(H)| \leq 2K\big(|V(H)|^2 + |E(H)|^2\big)\epsilon^3 \leq \epsilon^2.$$

We now invoke the oracle for $\mathcal{M}_{\beta,\gamma,\lambda}(\widehat{H}_i)$ to compute $\hat{\mathcal{M}}_i$ such that $\hat{\mathcal{M}}_i = (1\pm\epsilon^2)\mathcal{M}_{\beta,\gamma,\lambda}(\widehat{H}_i)$. By exploiting the tree structure of the field gadgets $\mathcal{T}_1, \mathcal{T}_2$ (cf. Definition 16), and since they both have size $poly(\text{bits}(r))$, we can compute the values $\mathcal{A}_1, \mathcal{A}_2$ exactly in time $poly(|V(H)|, \frac{1}{\eta})$ by fairly routine dynamic programming techniques. Combining these with (6), it follows that

$$\hat{M} = \frac{1}{q_+ - q_-}\Big(\frac{(\hat{\mathcal{M}}_1 - \hat{\mathcal{M}}_2) - |V(H)|(\mathcal{A}_1 - \mathcal{A}_2)}{O_1 - O_2} - q_-|E(H)|\Big)$$

is within a factor of $(1\pm\eta)$ of the susceptibility $\mathcal{M}_{\alpha,\hat{\lambda}}(H)$, as needed. This finishes the reduction and therefore the proof of Lemma 6. ◀

Abstract

Given $1 \leq \ell < k$ and $\delta \geq 0$, let $\mathbf{PM}(k, \ell, \delta)$ be the decision problem for the existence of perfect matchings in n-vertex k-uniform hypergraphs with minimum ℓ-degree at least $\delta\binom{n-\ell}{k-\ell}$. For $k \geq 3$, the decision problem in general k-uniform hypergraphs, equivalently $\mathbf{PM}(k, \ell, 0)$, is one of Karp's 21 NP-complete problems. Moreover, for $k \geq 3$, a reduction of Szymańska showed that $\mathbf{PM}(k, \ell, \delta)$ is NP-complete for $\delta < 1 - (1 - 1/k)^{k-\ell}$. A breakthrough by Keevash, Knox and Mycroft [STOC '13] resolved this problem for $\ell = k - 1$ by showing that $\mathbf{PM}(k, k-1, \delta)$ is in P for $\delta > 1/k$. Based on their result for $\ell = k - 1$, Keevash, Knox and Mycroft conjectured that $\mathbf{PM}(k, \ell, \delta)$ is in P for every $\delta > 1 - (1 - 1/k)^{k-\ell}$.

In this paper it is shown that this decision problem for perfect matchings can be reduced to the study of the minimum ℓ-degree condition forcing the existence of fractional perfect matchings. That is, we hopefully solve the "computational complexity" aspect of the problem by reducing it to a well-known extremal problem in hypergraph theory. In particular, together with existing results on fractional perfect matchings, this solves the conjecture of Keevash, Knox and Mycroft for $\ell \geq 0.4k$.

1 Introduction

As arguably the most natural extension of graph objects to hypergraphs, matchings have attracted a great deal of attention from both mathematicians and theoretical computer scientists. However, the study of hypergraph matching problems is still a challenging task. One particular reason for this is that finding the maximal matchings in k-uniform hypergraphs for $k \geq 3$ (e.g. 3-partite 3-uniform hypergraphs) is famously NP-complete [14], in contrast to the tractability in the graph case (Edmonds' blossom algorithm [5]).

Hypergraph matchings also find exciting applications in other fields, e.g. the Existence Conjecture of Block Designs [16, 8], Ryser's Conjecture on Latin Squares and Samuels' Conjecture in Probability Theory. For applications on practical problems, one prime example is that Asadpour, Feige and Saberi [2] used hypergraph perfect matchings to study the *Santa Claus problem*.

In this paper we continue the study of the decision problem of perfect matchings in dense hypergraphs, initiated by Karpiński, Ruciński and Szymańska [15]. Given $k \geq 2$, a *k-uniform hypergraph* (or k-graph) H consists of a vertex set $V(H)$ and an edge set $E(H)$, where each edge in $E(H)$ is a set of k vertices of H. A subset $M \subseteq E(H)$ is a *matching* if every two edges from M are vertex-disjoint. A matching in H is called *perfect* if it covers all vertices

of H. Given a k-graph H with an ℓ-element vertex set S (where $0 \le \ell \le k-1$) we define $\deg_H(S)$ to be the number of edges containing S. The *minimum ℓ-degree* $\delta_\ell(H)$ of H is the minimum of $\deg_H(S)$ over all ℓ-element sets of vertices in H.

The following decision problem was raised by Keevash, Knox and Mycroft [18], generalizing a problem of Karpiński, Ruciński and Szymańska [15] for the case $\ell = k-1$.

▶ **Problem 1.** *Given integers $\ell < k$ and $\delta \in [0,1]$, denote by $\boldsymbol{PM}(k,\ell,\delta)$ the problem of deciding whether there is a perfect matching in a given k-graph H on $n \in k\mathbb{N}$ vertices with $\delta_\ell(H) \ge \delta\binom{n-\ell}{k-\ell}$.*

The motivating fact is that for $k \ge 3$, $\mathbf{PM}(k,\ell,0)$ is equivalent to the problem for general k-graphs, so is NP-complete; on the other hand $\mathbf{PM}(k,\ell,\delta)$ is trivially in P when δ is large (e.g., when $\delta > 1-1/k$ by the result of [9]) because all such k-graphs contain perfect matchings. Therefore, it is natural to ask for the point where the behavior changes. A reduction of Szymańska [22] showed that $\mathbf{PM}(k,\ell,\delta)$ is NP-complete for $k \ge 3$ and $\delta < 1-(1-1/k)^{k-\ell}$. In a breakthrough paper, Keevash, Knox and Mycroft [18] conjectured that $1-(1-1/k)^{k-\ell}$ is the turning point and verified the case $\ell = k-1$.

▶ **Conjecture 2** (Keevash, Knox and Mycroft [18])**.** *For $1 \le \ell < k$, $\boldsymbol{PM}(k,\ell,\delta)$ is in P for every $\delta > 1-(1-1/k)^{k-\ell}$.*

Recently, Han and Treglown [13] showed that the conjecture holds for $0.5k \le \ell \le (1+\ln(2/3))k \approx 0.59k$. In this paper we verify Conjecture 2 for all $\ell \ge 0.4k$. In fact, our main result reduces the conjecture to the study of the minimum-degree-type threshold for the existence of a perfect fractional matching in k-graphs. To illustrate this, we introduce the following definitions.

Given a k-graph $H = (V,E)$, a *fractional matching* in H is a function $\omega : E \to [0,1]$ such that for each $v \in V(H)$ we have that $\sum_{e \ni v} w(e) \le 1$. Then $\sum_{e \in E(H)} w(e)$ is the *size* of w. If the size of w in H is n/k then we say that w is a *perfect fractional matching*. Given $k,\ell \in \mathbb{N}$ such that $\ell \le k-1$, define $c^*_{k,\ell}$ to be the smallest number c such that every k-graph H on n vertices with $\delta_\ell(H) \ge (c+o(1))\binom{n-\ell}{k-\ell}$ contains a perfect fractional matching. The following is our main result.

▶ **Theorem 3.** *Suppose $k,\ell \in \mathbb{N}$ such that $1 \le \ell \le k-1$. Then for any $\delta \in (c^*_{k,\ell},1]$, $\mathbf{PM}(k,\ell,\delta)$ is in P. That is, for any $\delta \in (c^*_{k,\ell},1]$, there exists a constant $c = c(k)$ such that there is an algorithm with running time $O(n^c)$ which given any n-vertex k-graph H with $\delta_\ell(H) \ge \delta\binom{n-\ell}{k-\ell}$, determines whether H contains a perfect matching.*

In fact, in [13] a similar result was proved for $\delta \in (\delta^*,1]$ where $\delta^* = \max\{c^*_{k,\ell},1/3\}$. Comparing with their result, Theorem 3 drops the extra $1/3$ and thus extends the result to large values of ℓ, e.g., for $\ell > (1+\ln(2/3))k$.

For the parameter $c^*_{k,\ell}$, Alon, Frankl, Huang, Rödl, Ruciński, and Sudakov [1] in 2012 made the following conjecture.

▶ **Conjecture 4** ([1])**.** *For all $\ell,k \in \mathbb{N}$, $c^*_{k,\ell} = 1-(1-1/k)^{k-\ell}$.*

They [1] verified the case $k-\ell \le 4$. The conjecture was further validated by Kühn, Osthus and Townsend [19, Theorem 1.7] for $\ell \ge k/2$ and by Han [10, Theorem 1.5] for $\ell = (k-1)/2$. In a recent work, Frankl and Kupavskii [6] verified this conjecture for $\ell \ge 0.4k$. Unfortunately, despite the efforts from experts in the field, Conjecture 4 is still open and appears to be very challenging for small values of ℓ. In fact, Conjecture 4 is also closely related to an old conjecture of Erdős on the size of the largest matching in hypergraphs (in particular, results of [6, 10] are corollaries of the corresponding progresses on the conjecture of Erdős).

Combining Theorem 3 with the current status on $c^*_{k,\ell}$ we get the following corollary.

▶ **Corollary 5.** *Conjecture 2 holds for $\ell \geq 0.4k$ and for $k - \ell \leq 4$.*

Thus, by Theorem 3, Conjecture 2 holds for all cases when $c^*_{k,\ell} = 1-(1-1/k)^{k-\ell}$, that is, whenever Conjecture 4 holds. Indeed, it is not hard to show that if $\delta > c^*_{k,\ell}$, then the k-graph contains a matching that covers all but exactly k vertices (see Theorem 11). Given this, our result can be viewed as the efficient detection of a certain class of *divisibility constructions* that prevents the existence of perfect matchings. As a consequence, we reduce the decision problem to an extremal problem on the existential problem of a perfect fractional matching, which can be recognized as a resolution on the "computational complexity" aspect of this problem.

We now give an overview of the minimum-degree-type conditions as well as the divisibility constructions.

1.1 Minimum degree conditions and divisibility barriers

The minimum degree conditions forcing a perfect matching have been studied extensively over the last two decades. Focusing on the asymptotical thresholds, all known results support the following conjecture raised by Hàn, Person and Schacht [9]. Note that this corresponds to the case when the decision problem is trivially in P (a trivial algorithm that always outputs yes).

▶ **Conjecture 6** (Hàn–Person–Schacht, [9])**.** *Given $1 \leq \ell < k$, if a k-graph H on n vertices satisfies $\delta_\ell(H) \geq (\max\{1/2, c^*_{k,\ell}\} + o(1))\binom{n-\ell}{k-\ell}$, then H contains a perfect matching.*

The conjecture has attracted a great deal of attention and so far has been verified for $\ell \geq 3k/8$ by Frankl and Kupavskii [6] and a handful of pairs (k, ℓ). Note that this conjecture is slightly weaker than our problem, as e.g. for certain values of ℓ, it *suffices* to show that $c^*_{k,\ell} \leq 1/2$, rather than determining the precise value of $c^*_{k,\ell}$ (and this is the reason that the known record on Conjecture 6 by [6] is slightly wider than that for the conjecture on $c^*_{k,\ell}$).

In fact under the assumption $\delta_\ell(H) \geq (c^*_{k,\ell} + o(1))\binom{n-\ell}{k-\ell}$, Chang, Ge, Han and Wang [3] recently proved that one can find a matching in H of size $n/k-1$ (see Theorem 11). However, such H may or may not have a perfect matching, and, prior to this work, it is not clear how to characterize these two types of k-graphs. To understand this, what is interesting to our problem is the divisibility constructions that achieve the bound $1/2$ in the above conjecture. Consider an n-vertex set V with a bipartition $X \dot\cup Y$, where X and Y have almost equal size subject to that $|Y|$ is odd. Now define a k-graph H_0 on V with the edge set consisting of all k-tuples that contain an even number of vertices in Y. It is not hard to see that $\delta_\ell(H) \approx \frac{1}{2}\binom{n-\ell}{k-\ell}$ and H_0 has no perfect matching. To see this, note that any matching in H_0 covers an even number of vertices in Y, so not the entire Y.

One can actually construct such partitions for an arbitrary number of parts. For certain sizes of parts, divisibility conditions similar to the parity issue in the above example prevent the existence of perfect matchings. Thus, our result and algorithm can be viewed as efficient detection of such constructions. Indeed, in the Keevash–Knox–Mycroft proof of Conjecture 2 for $\ell = k-1$, they designed efficient algorithms to exhibit a number of $(O(n^{k+1}))$ such partitions and tested the divisibility (solubility) for each of them. In contrast, we show that one can focus on one partition and prove a sufficient and necessary condition for the existence of a perfect matching solely on that partition. This will be made clear in Section 2.

1.2 Related work

The decision problem for perfect matchings in dense hypergraphs was first raised by Karpiński, Ruciński and Szymańska [15] for the case $\ell = k-1$, where they formulated the problem as $\mathbf{PM}(k,\delta)$ which is equivalent to $\mathbf{PM}(k,k-1,\delta)$ in this paper. They showed that $\mathbf{PM}(k,1/2-\varepsilon)$ is in P for some absolute $\varepsilon > 0$, thus showing that $1/2$ is not the turning point for the change of behavior, while Szymańska's [22] reduction showed that $\mathbf{PM}(k,\delta)$ is NP-complete when $\delta < 1/k$. This leaves a hardness gap for $\delta \in [1/k, 1/2)$. Significant progress was made by Keevash–Knox–Mycroft [17, 18] who showed that $\mathbf{PM}(k,\delta)$ is in P for $\delta > 1/k$. This hardness problem was fully settled by Han [11] who proved that $\mathbf{PM}(k,1/k)$ is in P. Very recently, this result was strengthened by Han and Keevash [12], who showed that the minimum $(k-1)$-degree condition can be weakened to $n/k - c$ for any constant $c > 0$ and their algorithm can actually output the perfect matching provided that one exists.

The similar decision problem for Hamilton cycles (spanning cycles) has also been studied. First, it is well-known that it is NP-complete to determine if a (2-)graph has a Hamilton cycle. A k-graph C is called a tight cycle if its vertices can be listed in a cyclic order so that the edges are all consecutive k-tuples. For tight Hamilton cycles in dense k-graphs, it is shown that there is no such hardness gap as for perfect matchings. That is, it is showed that by Rödl, Ruciński and Szemerédi [21] for n-vertex k-graph H, if $\delta_{k-1}(H) \geq (1/2+o(1))n$ then H contains a tight Hamilton cycle, i.e., the decision problem is trivially in P; on the other hand, Garbe and Mycroft [7] showed that there exists a constant C such that if $\delta_{k-1}(H) \geq n/2 - C$, then the decision problem of tight Hamilton cycles is NP-complete. However, such hardness gap is shown to exist for looser cycles [7].

Han and Treglown [13] considered the similar decision problem for F-factors[2] in graphs and k-graphs. In particular, they determined the turning point for the F-factor problem for graphs and thus disproved a conjecture of Yuster [23].

2 A partition lemma and a structural theorem

To prove Theorem 3, we shall establish a structural theorem (Theorem 9) for perfect matchings, namely, we exhibit a sufficient and necessary condition for the existence of perfect matchings, which, in addition, can be checked in polynomial time. In turn, the heart of the proof of the structural theorem is the lattice-based absorption method developed by Han [11], which features a vertex partition of the given k-graph (Lemma 8).

The first key definition is the *reachability* introduced by Lo and Markström [20] for the absorption property we need for building the perfect matching.

2.1 Reachability

Let H be an n-vertex k-graph. For $i \in \mathbb{N}$ and $\beta \in (0,1)$, we say that two vertices u and v in $V(H)$ are (β,i)-*reachable in* H if there are at least βn^{ik-1} $(ik-1)$-sets S such that both $H[S\cup\{u\}]$ and $H[S\cup\{v\}]$ have perfect matchings. We refer to such a set S as a *reachable* $(ik-1)$-*set for* u *and* v. We say a vertex set $U \subseteq V(H)$ is (β,i)-*closed in* H if any two vertices $u,v \in U$ are (β,i)-reachable in H. Given any $v \in V(H)$, define $\tilde{N}_{\beta,i}(v,H)$ to be the set of vertices in $V(H)$ that are (β,i)-reachable to v in H.

[2] Given k-graphs F and H, an F-factor in H is a set of vertex-disjoint copies of F whose union covers $V(H)$.

2.2 Index vector and robust vector

Given an n-vertex k-graph H and integer $r \geq 0$, let $\mathcal{P} = \{V_0, V_1, \dots, V_r\}$ be a partition of $V(H)$ into disjoint vertex sets, namely, $\dot{\bigcup}_{0\leq i\leq r} V_i = V(H)$. In this paper, every partition has an implicit ordering of its parts.

Next we introduce the index vectors and edge-lattices. Given a k-graph H and a partition $\mathcal{P} = \{V_0, V_1, \dots, V_s, V_{s+1}, \dots, V_r\}$ of $V(H)$, the *index vector* $\mathbf{i}_{\mathcal{P}}(e) \in \mathbb{Z}^r$ of an edge $e \in E(H)$ with respect to $\mathcal{P}$ is the vector whose coordinates are the sizes of the intersections of e with each part of $\mathcal{P}$ *except* V_0, namely, $\mathbf{i}_{\mathcal{P}}(e)|_i = |e \cap V_i|$ for $i \in [r]$, where $\mathbf{v}|_i$ is defined as the ith digit of $\mathbf{v}$. For any $\mathbf{v} = \{v_1, \dots, v_r\} \in \mathbb{Z}^r$, let $|\mathbf{v}| := \sum_{i=1}^r v_i$. Here we say that $\mathbf{v} \in \mathbb{Z}^r$ is a *k-vector* if it has non-negative coordinates and $|\mathbf{v}| = k$. In previous works, for $\mu > 0$, the set of μ-robust vectors (denoted by $I^{\mu}_{\mathcal{P}}(H)$) is defined as the vectors $\mathbf{i} \in \mathbb{Z}^r$ such that H contains at least μn^k edges whose index vectors are equal to $\mathbf{i}$. In this paper we need a more detailed description of robust vectors – where we need to distinguish the roles of two different groups of V_i.

▶ **Definition 7** (μ-robust vectors). *Let $\mathcal{P} = \{V_0, V_1, \dots, V_s, V_{s+1}, \dots, V_r\}$ be a partition of $V(H)$. Given $\mu > 0$, define $I^{\mu}_{\mathcal{P}}(H) := I^{\mu}_{\mathcal{P},1}(H) \cup I^{\mu}_{\mathcal{P},2}(H)$ as the union of the following two sets:*

1. *the set $I^{\mu}_{\mathcal{P},1}(H)$ consists of all k-vectors $\mathbf{i} \in \mathbb{Z}^r$ such that $\mathbf{i}|_i = 0$ for $i \in \{0, 1, \dots, s\}$ and H contains at least μn^k edges e with $\mathbf{i}_{\mathcal{P}}(e) = \mathbf{i}$;*
2. *the set $I^{\mu}_{\mathcal{P},2}(H)$ consists of all k-vectors $\mathbf{i} \in \mathbb{Z}^r$ such that $\mathbf{i}|_i = 1$ for some $i \in [s]$, $\mathbf{i}|_j = 0$ for $j \in \{0, 1, \dots, s\} \setminus \{i\}$ and every vertex $v \in V_i$ is in at least μn^{k-1} edges e with $\mathbf{i}_{\mathcal{P}}(e) = \mathbf{i}$.*

The new ingredient of this definition is the assumption (2), which helps us to classify the vertices which do not enjoy the reachability information.

Now we are ready to state our partition lemma, which outputs a refined partition compared to the partition lemmas in [11, 13]. Throughout the paper, we write $\alpha \ll \beta \ll \gamma$ to mean that it is possible to choose the positive constants α, β, γ from right to left. More precisely, there are increasing functions f and g such that, given γ, whenever we choose some $\beta \leq f(\gamma)$ and $\alpha \leq g(\beta)$, the subsequent statement holds. Hierarchies of other lengths are defined analogously.

▶ **Lemma 8.** *Given integers $k \geq 3$, $C > 0$ and real $\delta > 0$, suppose we have $1/n_0 \ll \mu \ll \beta \ll \delta' \ll \delta, 1/k, 1/C$. Given an n-vertex k-graph H with $n \geq n_0$ and $\delta_\ell(H) \geq \delta\binom{n-\ell}{k-\ell}$, there is a partition $\mathcal{P}$ of $V(H)$ as*

$$\mathcal{P} = \{V_0, V_1, \dots, V_s, V_{s+1}, \dots, V_r\}$$

such that with $c := \lfloor 1/\delta \rfloor$

1. *$s \leq 2^{\binom{c+k-2}{k-1}}$ and $r - s \leq c$,*
2. *$|V_0| \leq k^{2^{\binom{c+k-2}{k-1}}} \left(k\binom{k+2^{\binom{c+k-2}{k-1}}+c-1}{k} + \binom{c+k-2}{k-1}C \right)$ and $|\bigcup_{0\leq i\leq s} V_i| \leq c\delta' n$,*
3. *for $1 \leq i \leq s$, $|V_i| \geq (k-1)|V_0| + k\binom{k+2^{\binom{c+k-2}{k-1}}+c-1}{k} + \binom{c+k-2}{k-1}C$,*
4. *for $1 \leq i \leq s$, there exists $\mathbf{i} \in I^{\mu}_{\mathcal{P},2}(H)$ such that $\mathbf{i}|_i = 1$,*
5. *for $s+1 \leq i \leq r$, $|V_i| \geq \delta' n/2$ and V_i is $(\beta, 2^c)$-closed in $H[\bigcup_{s+1\leq i\leq r} V_i]$.*

In particular, such a partition $\mathcal{P}$ of H can be found in time $O(n^{2^{c-1}k+1})$.

2.3 Lattices, solubility and the structural theorem

Keevash, Knox and Mycroft [18] introduced the following notions, which help us to transfer the divisibility problem to an algebraic setting as follows.

Given a partition $\mathcal{P}$ of m parts, denote by $L^{\mu}_{\mathcal{P}}(H)$ the *lattice* (additive subgroup) in $\mathbb{Z}^m$ generated by $I^{\mu}_{\mathcal{P}}(H)$. We write $L^m_{\max}$ for the lattice generated by all k-vectors, that is, $L^m_{\max} := \{\mathbf{v} \in \mathbb{Z}^m : k \text{ divides } |\mathbf{v}|\}$.

Suppose $L \subset L^{|\mathcal{P}|}_{\max}$ is a lattice in $\mathbb{Z}^{|\mathcal{P}|}$, where $\mathcal{P}$ is a partition of a set V. The *coset group* of $(\mathcal{P}, L)$ is $Q = Q(\mathcal{P}, L) := L^{|\mathcal{P}|}_{\max}/L$. For any $\mathbf{i} \in L^{|\mathcal{P}|}_{\max}$, the *residue* of $\mathbf{i}$ in Q is $R_Q(\mathbf{i}) := \mathbf{i} + L$. For any $A \subseteq V$ of size divisible by k, the *residue* of A in Q is $R_Q(A) := R_Q(\mathbf{i}_{\mathcal{P}}(A))$.

Let $q \in \mathbb{N}$. A (possibly empty) matching M in H of size at most q is a *q-solution* for $(\mathcal{P}, L^{\mu}_{\mathcal{P}}(H))$ (in H) if $\mathbf{i}_{\mathcal{P}}(V(H) \setminus V(M)) \in L^{\mu}_{\mathcal{P}}(H)$; we say that $(\mathcal{P}, L^{\mu}_{\mathcal{P}}(H))$ is *q-soluble* if it has a q-solution. We also need a strengthening of this definition as follows. Given a set $U \subset V(H)$, we define that $(\mathcal{P}, L^{\mu}_{\mathcal{P}}(H))$ is *(U, q)-soluble* if there is a matching M in H such that M covers U and M is a $(|U| + q)$-solution.

In our proof, we shall pick a suitable $\mu > 0$ and let q be an upper bound of the order of the coset group $Q = L^{|\mathcal{P}|}_{\max}/L^{\mu}_{\mathcal{P}}(H)$ (then a trivial bound is $q = \binom{r+k-1}{k}$, the number of ee) and U be the part V_0. Then we show that H has a perfect matching if and only if $(\mathcal{P}, L^{\mu}_{\mathcal{P}}(H))$ is (V_0, q)-soluble.

▶ **Theorem 9** (Structural Theorem). *Let $k, \ell, q \in \mathbb{N}$ where $\ell \le k-1$ and let $\gamma > 0$ be given. There exist $n_0, C := C(k, q) \in \mathbb{N}$ and $\beta, \mu > 0$ such that*

$$1/n_0 \ll \beta, \mu \ll \delta' \ll \gamma, c^*_{k,\ell}, 1/q, 1/C, 1/k. \tag{1}$$

Let H be an n-vertex k-graph with $\delta_\ell(H) \ge (c^*_{k,\ell} + \gamma)\binom{n-\ell}{k-\ell}$, where $n \ge n_0$ and k divides n. Suppose $\mathcal{P}$ is a partition of $V(H)$ satisfying Lemma 8 (1)-(5) with $\delta = c^*_{k,\ell}$. Moreover, suppose $|Q(\mathcal{P}, L^{\mu}_{\mathcal{P}}(H))| \le q$. Then H contains a perfect matching if and only if $(\mathcal{P}, L^{\mu}_{\mathcal{P}}(H))$ is (V_0, q)-soluble.

3 Highlights of the proof: a comparison with the Han–Treglown proof

The basic idea for establishing the structural theorem is to distinguish the roles of *robust* and *non-robust* edges: to avoid the divisibility barriers, we may have to use edges with certain (combination of) index vectors. For some index vectors $\mathbf{v}$ there are many edges e with $\mathbf{i}_{\mathcal{P}}(e) = \mathbf{v}$, namely, there are many "replacements" even when we are forbidden from using, say, a small number of such edges. For other index vectors $\mathbf{v}$ there are few edges e with $\mathbf{i}_{\mathcal{P}}(e) = \mathbf{v}$, so we have to be careful when using such edges. In fact, the algebraic setting allows us to show that one can restrict the attention to only a *constant* number of such non-robust edges (using the lattice and coset group arguments), and thus this can be tested by brute force. Then the rest of the proof follows from the lattice-based absorption argument. Roughly speaking, it reserves a small matching which can be used to turn an almost perfect matching to a perfect matching given certain divisibility condition on the leftover vertices.

In [13] Han and Treglown proved our Theorem 3 under the additional assumption that $\delta > 1/3$, which gives a resolution of Conjecture 2 for $0.5k \le \ell \le 0.59k$. Embarrassingly, this does not solve the conjecture for $\ell = k-2$, which might be considered as the easiest case after the resolution of the case $\ell = k-1$. Below we shall first outline the proof in [13], and then explain our innovation compared with their approach and how such an improvement is achieved.

The partition lemma used in [13] is Lemma 12 in this paper (which we use as a building block to establish our partition). The key problem is that when $\ell < k-1$, one can not apply Lemma 12 directly to the k-graph H, as in H there might be a set W of vertices v which are not reachable to many vertices, namely, $|\tilde{N}_{\beta,i}(v,H)|$ is small for any proper choice of $\beta > 0$ and $i \in \mathbb{N}$. However, it is straightforward to show that $|W|$ is small, and (after some work) we can apply Lemma 12 with $S = V(H) \setminus W$ and get a partition of $V(H) \setminus W$. Now we face the following challenge.

▶ **Problem.** *Suppose $|W| = \Omega(n)$. How do we find a matching M covering W so that $H - V(M)$ has a perfect matching (or conclude that none exists)?*

The problem is trivial if $|W|$ is a constant, for which we can do brute force search for a matching M of constant size, which involves $O(n^{|W|})$ possibilities; otherwise it is hopeless without further assumptions.

Furthermore, it was not clear how to deal with the vertices of W by absorption, as $|W|$ might be smaller than the threshold for μ-robustness but still a small linear size, i.e., $\varepsilon n \le |W| < \mu n$, so that every vector touching W will not be recorded as a μ-robust vector. The proof in [13] avoided the "decision" part of the problem by assuming $\delta > 1/3$, so that when W is non-empty $V(H) \setminus W$ is closed, in which case H always contains a perfect matching (so any matching M covering W will work). Therefore, the problem is left open for $\delta < 1/3$ (i.e., for $\ell > (1 + \ln(2/3))k \approx 0.595k$).

We also note that the existence of W is not a problem in the existential results in the literature. For previous works on sufficient (minimum-degree-type) conditions for perfect matchings, those vertices can be put into a small matching of small linear size, whose removal does not affect much the minimum-degree conditions, guaranteeing that the absorption can proceed after the removal of this small matching.

Our new proof can be seen as a considerable refinement to the previous approach, where we strengthen our control on both the partition and the μ-robust vectors. As mentioned earlier, our new proof features a finer partition lemma (Lemma 8) than previous ones, where we classify vertices in W as well. More precisely, we first partition $S := V(H) \setminus W$, the set of vertices which are 1-reachable to $\Omega(n)$ other vertices, by Lemma 12 and denote the partition by $\mathcal{P}_1 = \{W_1, \dots, W_d\}$. Then we classify vertices of W according to their edge distributions in $\mathcal{P}_1$, that is, we obtain a partition of W by collecting vertices with common robust edge vectors together, so that the partition satisfies Definition 7 (2). Next we put the clusters that are too small (smaller than a certain constant) to a trash set V_0 in a recursive manner. This results a trash set V_0 of constant order, and because we have no control on V_0 at all, we will check how to match V_0 by brute force in time $O(n^{|V_0|})$. Now the good point is that all clusters survived from this greedy process have a good (though still constant) size (Lemma 8 (3)), which is enough (and crucial) for a (refined) absorption argument to work in later proofs. Since all the above procedures can be done in polynomial time, we get the desired polynomial-time algorithm for the decision problem $\mathbf{PM}(k, \ell, \delta)$.

4 Proof of Theorem 3

Now we prove Theorem 3. Recall that $c^*_{k,\ell} \ge c^*_{k,k-1} = 1/k$. Then $\lfloor 1/c^*_{k,\ell} \rfloor \le k$. Let $C := C(k, q)$ be given by Theorem 9 and let

$$q := \binom{k + 2^{\binom{2k-2}{k-1}} + k - 1}{k}.$$

Suppose we have constants satisfying the hierarchy (1).

Both Lemma 8 and Theorem 9 require that n is larger than a constant n_0, and by custom k-graphs with less than n_0 vertices can be tested by brute force. By Lemma 8, in time $O(n^{2^{k-1}k+1})$ we can find a partition $\mathcal{P}$ satisfying Lemma 8 (1)-(5). Because of Lemma 8 (1), we know $r \le k + 2^{\binom{2k-2}{k-1}}$ and obtain that $|Q(\mathcal{P}, L^{\mu}_{\mathcal{P}}(H))| \le \binom{r+k-1}{k} \le q$ (no matter what $L^{\mu}_{\mathcal{P}}(H)$ actually is). Then by Theorem 9, to determine if H contains a perfect matching it suffices to test if $(\mathcal{P}, L^{\mu}_{\mathcal{P}}(H))$ is (V_0, q)-soluble. This can be done by testing whether any matching M of size at most $|V_0| + q$ covering V_0 is a solution of $(\mathcal{P}, L^{\mu}_{\mathcal{P}}(H))$, in time $O(n^{|V_0|+q})$. The overall time is polynomial in n because

$$q = \binom{k + 2^{\binom{2k-2}{k-1}} + k - 1}{k}$$

and

$$|V_0| \le k^{2^{\binom{2k-2}{k-1}}} \left(k \binom{2^{\binom{2k-2}{k-1}} + 2k - 1}{k} + \binom{2k-2}{k-1} C \right),$$

where we recall that $C := C(k, q)$ only depends on k.

Organization. The rest of this paper is organized as follows. Note that it remains to prove Lemma 8 and Theorem 9. We collect and prove a number of auxiliary results in Section 5, and give a proof of Lemma 8 in Section 6. In Section 7, we prove an absorbing lemma, which is an important component of the proof of Theorem 9. The proof of Theorem 9 is presented in Section 8.

5 Useful tools

In this section we collect together some results that will be used in our proof of Theorem 9. When considering ℓ-degree together with ℓ'-degree for some $\ell' \neq \ell$, the following proposition is very useful.

▶ **Proposition 10.** *Let $0 \le \ell \le \ell' < k$ and H be a k-graph. If $\delta_{\ell'}(H) \ge x\binom{n-\ell'}{k-\ell'}$ for some $0 \le x \le 1$, then $\delta_{\ell}(H) \ge x\binom{n-\ell}{k-\ell}$.*

Proof. Since $\ell \le \ell'$, we count $\delta_\ell(H)$ by

$$\begin{aligned}
\delta_\ell(H) &\ge \delta_{\ell'}(H) \binom{n-\ell}{\ell'-\ell} \frac{1}{\binom{k-\ell}{\ell'-\ell}} \\
&\ge x \binom{n-\ell'}{k-\ell'} \binom{n-\ell}{\ell'-\ell} \frac{1}{\binom{k-\ell}{\ell'-\ell}} \\
&\ge x \binom{n-\ell}{k-\ell} \binom{k-\ell}{\ell'-\ell} \frac{1}{\binom{k-\ell}{\ell'-\ell}} = x \binom{n-\ell}{k-\ell}
\end{aligned}$$

where the last inequality is from $\binom{a}{b}\binom{b}{c} = \binom{a}{c}\binom{a-c}{b-c}$. ◀

5.1 Almost perfect matchings

Let $k, \ell \in \mathbb{N}$ where $\ell \le k-1$. Given $D \in \mathbb{N}$, define $\delta(k, \ell, D)$ as the smallest number δ such that every k-graph H on $n \in k\mathbb{N}$ vertices with $\delta_\ell(H) \ge (\delta + o(1))\binom{n-\ell}{k-\ell}$ contains a matching covering all but at most D vertices. It is proved in [13] that $\delta(k, \ell, k) \le \max\{1/3, c^*_{k,\ell}\}$. We need the extra term $1/3$ removed, which was very recently proved by Chang, Ge, Han and Wang [3].

▶ **Theorem 11** ([3]). *Let k, ℓ be integers such that $1 \le \ell \le k-1$ and $\gamma > 0$, then there exists $n_0 \in \mathbb{N}$ such that the following holds for $n \ge n_0$. Suppose H is an n-vertex k-graph with $\delta_\ell(H) \ge (c^*_{k,\ell} + \gamma)\binom{n-\ell}{k-\ell}$, then H contains a matching M that covers all but at most $2k-\ell-1$ vertices. In particular, when $n \in k\mathbb{N}$, M is a perfect matching or covers all but exactly k vertices, namely, $\delta(k,\ell,k) \le c^*_{k,\ell}$.*

To build the partition, we need the following partition lemma from [13].

▶ **Lemma 12** ([13, Lemma 6.3]). *Given $\delta' > 0$, integers $c, k \ge 2$ and $0 < \alpha \ll 1/c, \delta'$, there exists a constant $\beta > 0$ such that the following holds for all sufficiently large n. Assume H is an n-vertex k-graph and $S \subseteq V(H)$ is such that $|\tilde{N}_{\alpha,1}(v,H) \cap S| \ge \delta' n$ for any $v \in S$. Further, suppose every set of $c+1$ vertices in S contains two vertices that are $(\alpha,1)$-reachable in H. Then in time $O(n^{2^{c-1}k+1})$ we can find a partition $\mathcal{P}$ of S into $V_1, \dots, V_r$ with $r \le \min\{c, 1/\delta'\}$ such that for any $i \in [r]$, $|V_i| \ge (\delta' - \alpha)n$ and V_i is $(\beta, 2^{c-1})$-closed in H.*

To deal with the vertices that are reachable to few other vertices, we collect them by the following greedy process. Note that a similar lemma was used in [4].

▶ **Lemma 13.** *Let integers $c, k \ge 2$ be given and suppose $1/n \ll \delta' \ll \alpha, 1/k, 1/c$. Assume that H is a k-graph on n vertices satisfying that every set of $c+1$ vertices contains two vertices that are $(2\alpha,1)$-reachable in H. Then in time $O(cn^{k+1})$ we can find a set of vertices $S \subseteq V(H)$ with $|S| \ge (1-c\delta')n$ such that $|\tilde{N}_{\alpha,1}(v, H[S])| \ge \delta' n$ for any $v \in S$.*

We remark that in the above lemma it is important to obtain the conclusion on $\tilde{N}_{\alpha,1}(v, H[S])$ rather than $\tilde{N}_{\alpha,1}(v) \cap S$. Indeed, in the latter one the reachable sets are still defined in H, so may contain vertices in $V(H) \setminus S$. This is not strong enough in our later proof (see Lemma 14 and its proof).

Proof. Let H be a k-graph on n vertices satisfying the condition of Lemma 13. We greedily identify vertices with few "reachable neighbors" and remove the vertex together with the vertices reachable to it from H. Set $V_0 := V(H)$. First, for every two vertices $u, v \in V(H)$, we determine if they are $(\alpha,1)$-reachable in H, which can be done by testing if any $(k-1)$-set is a reachable set in time $O(n^{k-1})$. Summing over all pairs of vertices, this step can be done in time $O(n^{k+1})$. Then we check if there is a vertex $v_0 \in V_0$ such that $|\tilde{N}_{\alpha,1}(v_0, H)| < \delta' n$ in time $O(n^2)$. If there exists such a vertex v_0, then let $A_0 := \{v_0\} \cup \tilde{N}_{\alpha,1}(v_0, H)$ and let $V_1 := V_0 \setminus A_0$. Next, we check V_1, that is, if there exists a vertex $v_1 \in V_1$ such that $|\tilde{N}_{\alpha,1}(v_1, H[V_1])| < \delta' n$, then let $A_1 := \{v_1\} \cup \tilde{N}_{\alpha,1}(v_1, H[V_1])$ and let $V_2 := V_1 \setminus A_1$ and repeat the procedure until no such v_j exists.

Suppose we stop and obtain a set of vertices $v_0, \dots, v_s$. We claim that $s < c$ and thus $|\bigcup_{0 \le i \le s} A_i| \le c\delta' n$. Indeed, otherwise consider $v_0, \dots, v_c$, the first $c+1$ of them and we shall show that every pair of them is not $(2\alpha,1)$-reachable in H, contradicting our assumption. Given $0 \le i < j \le c$, as $v_j \notin \tilde{N}_{\alpha,1}(v_i, H[V_i])$, v_i and v_j have less than αn^{k-1} 1-reachable sets in $H[V_i]$. Also, because $\delta' \ll \alpha, 1/c$, there are at most $c\delta' n \cdot n^{k-2} \le \alpha n^{k-1}$ 1-reachable sets in $H \setminus H[V_i]$. These two together yield that v_i and v_j are not $(2\alpha,1)$-reachable in H.

This greedy procedure needs to recompute $\tilde{N}_{\alpha,1}(v, H[V_i])$ at each time and can be done in time $O(cn^{k+1})$. Set $S := V(H) \setminus (\bigcup_{0 \le i \le s} A_i)$. We have $|S| \ge (1-c\delta')n$ and $|\tilde{N}_{\alpha,1}(v, H[S])| \ge \delta' n$ for every $v \in S$. ◀

6 Proof of Lemma 8

Let H be an n-vertex k-graph and define

$$1/n_0 \ll \mu \ll \beta \ll \alpha \ll \gamma, \delta' \ll \delta, 1/k, 1/C.$$

Assume $n \geq n_0$ and k divides n. Write $c := \lfloor 1/\delta \rfloor$, then by Proposition 10 we have

$$(c+1)\delta_1(H) > (c+1)\delta\binom{n-1}{k-1} > (1+\gamma)\binom{n-1}{k-1}.$$

Thus every set of $c+1$ vertices of $V(H)$ contains two vertices that are $(2\alpha, 1)$-reachable, as otherwise, by the inclusion-exclusion principle and $\alpha \ll \gamma, \delta$

$$n \geq (c+1)\delta_1(H) - \binom{c+1}{2} \cdot 2\alpha n^{k-1} \geq (1+\gamma)\binom{n-1}{k-1} - (c+1)^2\alpha n^{k-1} > n$$

a contradiction.

By Lemma 13, we find $S \subseteq V(H)$ with $|S| \geq (1-c\delta')n$ such that $|\tilde{N}_{\alpha,1}(v, H[S])| \geq \delta' n$ for any $v \in S$, in time $O(n^{k+1})$. Let $V' := V(H) \setminus S$ and thus $|V'| \leq c\delta' n$. Apply Lemma 12 to $H[S]$, and in time $O(n^{2^{c-1}k+1})$ we find a partition $\mathcal{P}_1$ of S into $W_1, \ldots, W_d$ with $d \leq c$ such that for $i \in [d]$, $|W_i| \geq (\delta' - \alpha)n$ and W_i is $(\beta, 2^{c-1})$-closed in $H[S]$.

Let I_d^{k-1} be the set of all $(k-1)$-vectors on $\mathcal{P}_1$ and note that $|I_d^{k-1}| = \binom{d+k-2}{d-1}$. Let $\mathcal{I}$ be the collection of all subsets of I_d^{k-1} and clearly $|\mathcal{I}| = 2^{|I_d^{k-1}|} = 2^{\binom{d+k-2}{d-1}}$. We classify the vertices in V' by the types of the edges in which they are contained. Indeed, for $I \in \mathcal{I}$, let V_I be the collection of vertices $v \in V'$ such that the following two properties hold:

- for every $\mathbf{i} \in I$, there are at least μn^{k-1} edges e of H such that $v \in e$ and $\mathbf{i}_{\mathcal{P}_1}(e \setminus \{v\}) = \mathbf{i}$;
- for every $\mathbf{i} \notin I$, there are fewer than μn^{k-1} edges e of H such that $v \in e$ and $\mathbf{i}_{\mathcal{P}_1}(e \setminus \{v\}) = \mathbf{i}$.

Clearly this defines a partition of V'. Moreover, note that $V_\emptyset = \emptyset$ – this is because any vertex in $V_\emptyset$ has vertex degree at most $2\binom{d+k-2}{d-1}\mu n^{k-1} < \delta_1(H)$, violating the minimum degree assumption. In particular, this implies 4. Note that this partition can be built by reading the edges for each $v \in V'$, so in time $O(n^k)$. Next we collect the parts that are too small and put them into a trash set V_0 in a recursive manner.

We first sort V_I, $I \in \mathcal{I}$ such that $|V_I|$ is increasing. Next, starting from $V_0 = \emptyset$, we *recursively* check in time $O(|\mathcal{I}|n)$ if next V_I, $I \in \mathcal{I}$ in the sequence satisfies that

$$|V_I| < (k-1)|V_0| + b, \text{ where } b := k\binom{k + 2^{\binom{c+k-2}{c-1}} + c - 1}{k} + \binom{c+k-2}{c-1}C$$

and if yes, put all vertices of V_I to V_0 (note here that V_0 is dynamic). Because $|\mathcal{I}| = 2^{\binom{d+k-2}{d-1}}$, straightforward computation shows that after the process we have

$$|V_0| \leq \frac{k^{|\mathcal{I}|}-1}{k-1}b \leq k^{2^{\binom{c+k-2}{c-1}}}\left(k\binom{k + 2^{\binom{c+k-2}{c-1}} + c - 1}{k} + \binom{c+k-2}{c-1}C\right).$$

At last, in constant time we remove the empty clusters and relabel the parts V_I's to $V_1, \ldots, V_s$, and relabel the parts of $\mathcal{P}_1$ as $V_{s+1}, \ldots, V_r$. The resulting partition satisfies all desired properties in the lemma and the overall running time is $O(n^{2^{c-1}k+1})$.

7 An absorption lemma

The following result guarantees our collection $\mathcal{E}_{abs}$ of absorbing sets in the proof of Theorem 9. The absorption method is by now a standard way to turn an almost spanning structure to a spanning one. Here we use a variant called *lattice-based absorption method*, developed by Han [11]. We remark that the following lemma is very similar to that [11, Lemma 3.4], and the only difference is because of our refined definition of robust vectors $I_{\mathcal{P}}^{\mu}(H)$.

▶ **Lemma 14** (Absorption Lemma). *Suppose $k \geq 3$, $\delta > 0$ and let $t := 2^{\lfloor 1/\delta \rfloor}$. Suppose that*

$$1/n \ll 1/c' \ll \beta, \mu \ll 1/t, 1/k.$$

Let H be an n-vertex k-graph with a partition $\mathcal{P}$ of $V(H)$ satisfying Lemma 8 (1)-(5), where $n \geq n_0$ and k divides n. Let $n_1 := |\bigcup_{s+1\leq i\leq r} V_i|$ (where r, s are from the statement of Lemma 8). Then there is a family $\mathcal{E}_{abs}$ consisting of at most $c' \log n_1$ disjoint tk^2-sets such that for each $A \in \mathcal{E}_{abs}$, $H[A]$ contains a perfect matching and every k-set $S \subseteq V(H)$ with $\mathbf{i}_{\mathcal{P}}(S) \in I^{\mu}_{\mathcal{P}}(H)$ has at least $\sqrt{\log n_1}$ absorbing tk^2-sets in $\mathcal{E}_{abs}$.

Proof. Roughly speaking, in the proof we first exhibit a large number of absorbing sets for each k-set S with $\mathbf{i}_{\mathcal{P}}(S) \in I^{\mu}_{\mathcal{P}}(H)$, and then show that the desired family $\mathcal{E}_{abs}$ can be obtained by standard probabilistic arguments. Our first task is to prove the following claim.

▷ Claim 15. Any k-set S with $\mathbf{i}_{\mathcal{P}}(S) \in I^{\mu}_{\mathcal{P}}(H)$ has at least $\mu^{t+1}\beta^{k+1}n_1^{tk^2}$ absorbing tk^2-sets which consist of vertices in $\bigcup_{s+1\leq i\leq r} V_i$ only.

Proof. We split the proof into two cases regarding to $I^{\mu}_{\mathcal{P},1}(H)$ and $I^{\mu}_{\mathcal{P},2}(H)$. Note that all reachable sets will be constructed with vertices in $\bigcup_{s+1\leq i\leq r} V_i$ only.

▶ **Case 1.** *Suppose $\mathbf{i} \in I^{\mu}_{\mathcal{P},1}(H)$.*

For a k-set $S = \{y_1, \ldots, y_k\}$ with $\mathbf{i}_{\mathcal{P}}(S) = \mathbf{i}$, we construct absorbing tk^2-sets for S as follows. We first fix an edge $W = \{x_1, \ldots, x_k\}$ in H such that $\mathbf{i}_{\mathcal{P}}(W) = \mathbf{i}$ and $W \cap S = \emptyset$. Note that we have at least $\mu n^k - kn_1^{k-1} > \frac{\mu}{2}n^k$ choices for such an edge. Without loss of generality, we may assume that for all $i \in [k]$, x_i, y_i are in the same part V_j of $\mathcal{P}$ for $j > s$. Recall that by Lemma 8 (5) V_j is (β, t)-closed in $H[\bigcup_{s+1\leq i\leq r} V_i]$. Since x_i is (β, t)-reachable to y_i, there are at least βn_1^{tk-1} $(tk-1)$-sets T_i such that both $H[T_i \cup \{x_i\}]$ and $H[T_i \cup \{y_i\}]$ have perfect matchings. We pick disjoint reachable $(tk-1)$-sets for each x_i, y_i, $i \in [k]$ greedily, while avoiding the existing vertices. Since the number of existing vertices is at most $tk^2 + k$, we have at least $\frac{\beta}{2}n_1^{tk-1}$ choices for such $(tk-1)$-sets in each step. Note that $W \cup T_1 \cup \cdots \cup T_k$ is an absorbing set for S. First, it contains a perfect matching because each $T_i \cup \{x_i\}$ for $i \in [k]$ spans t vertex-disjoint edges. Second, $H[W \cup T_1 \cup \cdots \cup T_k \cup S]$ also contains a perfect matching and each $T_i \cup \{y_i\}$ for $i \in [k]$ spans t vertex-disjoint edges. There were at least $\frac{\mu}{2}n_1^k$ choices for W and at least $\frac{\beta}{2}n_1^{tk-1}$ choices for each T_i. Thus we find at least

$$\frac{\mu}{2}n^k \times \frac{\beta^k}{2^k}n_1^{tk^2-k} \times \frac{1}{(tk^2)!} \geq \mu\beta^{k+1}n_1^{tk^2}$$

absorbing tk^2-sets for S.

▶ **Case 2.** *Suppose $\mathbf{i} \in I^{\mu}_{\mathcal{P},2}(H)$.*

Suppose $S = \{v_1, y_2, \ldots, y_k\}$ with $\mathbf{i}_{\mathcal{P}}(S) = \mathbf{i}$ and $v_1 \in V_i$ for some $i \in [s]$. We construct absorbing tk^2-sets for S as follows. We fix an edge with vertex set $W = \{v_1, x_2, \ldots, x_k\}$ for $x_2, \ldots, x_k \in \bigcup_{s+1\leq j\leq r} V_j \setminus \{y_2, \ldots, y_k\}$ such that $\mathbf{i}_{\mathcal{P}}(W) = \mathbf{i}_{\mathcal{P}}(S) = \mathbf{i}$ and $W \cap S = \{v_1\}$. Note that by Lemma 8 (4) we have at least $\mu n^{k-1} - (k-1)n_1^{k-2} > \frac{\mu}{2}n^{k-1}$ choices for W (and $x_2, \ldots, x_k$ are in $\bigcup_{s+1\leq i\leq r} V_i$, by the definition of $I^{\mu}_{\mathcal{P},2}(H)$). Without loss of generality, we may assume that for all $i \in \{2, \ldots, k\}$, x_i, y_i are in the same part V_j of $\mathcal{P}$, $j > s$. Since x_i is (β, t)-reachable to y_i, there are at least βn_1^{tk-1} $(tk-1)$-sets T_i in $V(H) \setminus V_0$ such that both $H[T_i \cup \{x_i\}]$ and $H[T_i \cup \{y_i\}]$ have perfect matchings. We pick disjoint reachable $(tk-1)$-sets in $V(H) \setminus V_0$ for each x_i, y_i, $i \in \{2, \ldots, k\}$ greedily, while avoiding the existing vertices. Since the number of existing vertices is at most $tk(k-1) + (k-1)$, we have at least

$\frac{\beta}{2}n_1^{tk-1}$ choices for such $(tk-1)$-sets in each step. At last, let us pick a matching M of size t in H that is vertex disjoint from the existing vertices (the purpose is to let the absorbing set contain exactly tk^2 vertices). For the number of choices for $V(M)$, we can sequentially choose disjoint edges satisfying any μ-robust edge vector $\mathbf{i} \in I^{\mu}_{\mathcal{P},1}(H)$ and infer that there are at least $\frac{1}{2}\mu^t n^{tk}$ choices.

Note that each choice of $(W \setminus \{v_1\}) \cup T_2 \cup \cdots \cup T_k \cup V(M)$ is an absorbing set for S. First, it contains a perfect matching because each $T_i \cup \{x_i\}$ for $i \in \{2, \ldots, k\}$ spans t vertex-disjoint edges and M is a matching. Second, $H[W \cup T_1 \cup \cdots \cup T_k \cup S]$ also contains a perfect matching as each $T_i \cup \{y_i\}$ for $i \in \{2, \ldots, k\}$ spans t vertex-disjoint edges, W is an edge and M is a matching. There were at least $\frac{\mu}{2}n_1^{k-1}$ choices for W and at least $\frac{\beta}{2}n_1^{tk-1}$ choices for each T_i and $\frac{1}{2}\mu^t n^{tk}$ choices for $V(M)$. Thus we find at least

$$\frac{\mu}{2}n^k \times \left(\frac{\beta}{2}n_1^{tk-1}\right)^{k-1} \times \frac{1}{2}\mu^t n^{tk} \times \frac{1}{(tk^2)!} \geq \mu^{t+1}\beta^k n_1^{tk^2}$$

absorbing tk^2-sets for S, with vertices from $\bigcup_{s+1\leq i\leq r} V_i$ only. ◁

Continuing the proof of Lemma 14, we pick a family $\mathcal{E}$ of tk^2-sets by including every tk^2-subset of $\bigcup_{s+1\leq i\leq r} V_i$ with probability $p = c' n_1^{-tk^2} \log n_1$ independently, uniformly at random. Then the expected number of elements in $\mathcal{E}$ is $p\binom{n_1}{tk^2} \leq \frac{c'}{tk^2}\log n_1$ and the expected number of intersecting pairs of tk^2-sets is at most

$$p^2\binom{n_1}{tk^2} \times tk^2 \times \binom{n_1}{tk^2-1} \leq \frac{c'^2(\log n_1)^2}{n_1} = o(1).$$

Then by Markov's inequality, with probability at least $1 - 1/(tk^2) - o(1)$, $\mathcal{E}$ contains at most $c' \log n_1$ sets and they are pairwise vertex disjoint.

For every k-set S with $\mathbf{i}_{\mathcal{P}}(S) \in I^{\mu}_{\mathcal{P}}(H)$, let X_S be the number of absorbing sets for S in $\mathcal{E}$. Then by Claim 15,

$$\mathbb{E}(X_S) \geq p\mu^{t+1}\beta^{k+1}n_1^{tk^2} = \mu^{t+1}\beta^{k+1}c' \log n_1.$$

By Chernoff's bound,

$$\mathbb{P}\left(X_S \leq \frac{1}{2}\mathbb{E}(X_S)\right) \leq \exp\left\{-\frac{1}{8}\mathbb{E}(X_S)\right\} \leq \exp\left\{-\frac{\mu^{t+1}\beta^{k+1}c' \log n_1}{8}\right\} = o(n^{-k}),$$

since $1/c' \ll \beta, \mu \ll 1/m$. Thus, with probability $1 - o(1)$, for each k-set S with $\mathbf{i}_{\mathcal{P}}(S) \in I^{\mu}_{\mathcal{P}}(H)$, there are at least

$$\frac{1}{2}\mathbb{E}(X_S) \geq \frac{\mu^{t+1}\beta^{k+1}c' \log n_1}{2} > \sqrt{\log n_1}$$

absorbing sets for S in $\mathcal{E}$. We obtain $\mathcal{E}_{abs}$ by deleting the elements of $\mathcal{E}$ that are not absorbing sets for any k-set S and thus $|\mathcal{E}_{abs}| \leq |\mathcal{E}| \leq c' \log n_1$. ◀

8 Proof of Theorem 9

Now we are ready to prove Theorem 9. Let H be an n-vertex k-graph, and let $\mathcal{P}$ be a partition given by Lemma 8 satisfying (1)-(5). We first prove the forward implication.

8.1 Proof of the forward implication of Theorem 9

If H contains a perfect matching M, then $\mathbf{i}_{\mathcal{P}}(V(H) \setminus V(M)) = \mathbf{0} \in L^{\mu}_{\mathcal{P}}(H)$. Let M' be the smallest submatching of M that covers V_0, so $|M'| \leq |V_0|$. We shall show that there exists a matching $M'' \subset (M \setminus M')$ such that $|M''| \leq q$ and $\mathbf{i}_{\mathcal{P}}(V(H) \setminus V(M' \cup M'')) \in L^{\mu}_{\mathcal{P}}(H)$, implying that $(\mathcal{P}, L^{\mu}_{\mathcal{P}}(H))$ is (V_0, q)-soluble.

Indeed, suppose that $M'' \subset (M \setminus M')$ is a smallest matching such that $\mathbf{i}_{\mathcal{P}}(V(H) \setminus V(M' \cup M'')) \in L^{\mu}_{\mathcal{P}}(H)$ and $|M''| = m \geq q$. Let $M'' = \{e_1, \ldots, e_m\}$ and consider the $m+1$ partial sums

$$\sum_{i=1}^{j} \mathbf{i}_{\mathcal{P}}(e_i) + L^{\mu}_{\mathcal{P}}(H),$$

for $j = 0, 1, \ldots, m$. Since $|Q(\mathcal{P}, L^{\mu}_{\mathcal{P}}(H))| \leq q \leq m$, two of the sums must be in the same coset. That is, there exist $0 \leq j_1 < j_2 \leq m$ such that

$$\sum_{i=j_1+1}^{j_2} \mathbf{i}_{\mathcal{P}}(e_i) \in L^{\mu}_{\mathcal{P}}(H).$$

So the matching $M^* := M' \setminus \{e_{j_1+1}, \ldots, e_{j_2}\}$ satisfies that $\mathbf{i}_{\mathcal{P}}(V(H) \setminus V(M^* \cup M')) \in L^{\mu}_{\mathcal{P}}(H)$ and $|M^*| < |M''|$, a contradiction.

8.2 Proof of the backward implication of Theorem 9

We first introduce the following useful constant. Given a set I of k-vectors in $\mathbb{Z}^r$, and $m \in \mathbb{N}$, consider the set J of all m'-vectors that are in the lattice in $\mathbb{Z}^r$ generated by I with $0 \leq m' \leq m$. That is, for any $\mathbf{v} \in J$, there exist $a_{\mathbf{i}} \in \mathbb{Z}$, $\mathbf{i} \in I$ such that

$$\mathbf{v} = \sum_{\mathbf{i} \in I} a_{\mathbf{i}} \mathbf{i}$$

Then let $C^* := C^*(r, k, I, m)$ be the maximum of $|a_{\mathbf{i}}|$ over all such $\mathbf{v}$. Furthermore, let $C_{\max} := C_{\max}(k, m)$ be the maximum of $C^* = C^*(r, k, I, m)$ over all $r \leq r_0(k) := 2^{\binom{2k-1}{k-1}} + k$ and all families of k-vectors $I \subseteq \mathbb{Z}^r$.

Now we start the proof. Recall that $c^*_{k,\ell} \geq c^*_{k,k-1} = 1/k$. Then $\lfloor 1/c^*_{k,\ell} \rfloor \leq k$. Define constants

$$t := 2^k \quad \text{and} \quad C := C_{\max}(k, kq + k).$$

Define an additional constant $c' > 0$ so that

$$1/n_0 \ll 1/c' \ll \beta, \mu \ll \delta' \ll 1/k, 1/q, 1/C, 1/t.$$

Let $n \geq n_0$ be a multiple of k. Let H be as in the statement of the theorem and $\mathcal{P}$ be a partition of $V(H)$ satisfying Lemma 8 (1)-(5), where the C therein is as defined above. In particular, Property (5) and the choice of t imply that for $s+1 \leq i \leq r$, $|V_i| \geq \delta' n/2$ and V_i is (β, t)-closed in $H[\bigcup_{s+1 \leq i \leq r} V_i]$. Furthermore, assume that $(\mathcal{P}, L^{\mu}_{\mathcal{P}}(H))$ is (V_0, q)-soluble, that is, there is a matching M_1 of size at most $|V_0| + q$ such that M_1 covers V_0 and it is a $(|V_0| + q)$-solution, that is,

$$\mathbf{i}_{\mathcal{P}}(V(H) \setminus V(M_1)) \in L^{\mu}_{\mathcal{P}}(H).$$

Let $n_1 := |\bigcup_{s+1\le i\le r} V_i|$. We first apply Lemma 14 to H and get a family $\mathcal{E}_{abs}$ consisting of at most $c' \log n_1$ disjoint tk^2-sets such that every k-set S of vertices with $\mathbf{i}_{\mathcal{P}}(S) \in I^{\mu}_{\mathcal{P}}(H)$ has at least $\sqrt{\log n_1}$ absorbing tk^2-sets in $\mathcal{E}_{abs}$.

Note that $V(M_1)$ may intersect $V(\mathcal{E}_{abs})$ in at most $(|V_0|+q)k$ absorbing sets of $\mathcal{E}_{abs}$. Let $\mathcal{E}_0$ be the subfamily of $\mathcal{E}_{abs}$ obtained from removing the tk^2-sets that intersect $V(M_1)$. Let M_0 be the perfect matching on $V(\mathcal{E}_0)$ that is the union of the perfect matchings on each member of $\mathcal{E}_0$. Note that every k-set S with $\mathbf{i}_{\mathcal{P}}(S) \in I^{\mu}_{\mathcal{P}}(H)$ has at least $\sqrt{\log n_1} - (|V_0|+q)k$ absorbing sets in $\mathcal{E}_0$.

Next we want to "store" some disjoint edges for each k-vector in $I^{\mu}_{\mathcal{P}}(H)$ for later steps, and at the same time we also cover the rest vertices of $\bigcup_{1\le i\le s} V_i$ (recall that V_0 is covered by M_1). More precisely, set $C' := C^*(r,k,I^{\mu}_{\mathcal{P}}(H), kq+k) \le C$. Note that Lemma 8 (3) guarantees that for each $i \in [s]$, V_i has at least $\binom{2k-2}{k-1}C$ uncovered vertices. We construct a matching M_2 in $H \setminus V(M_0 \cup M_1)$ which consists of C' disjoint edges e with $\mathbf{i}_{\mathcal{P}}(e) = \mathbf{i}$ for every $\mathbf{i} \in I^{\mu}_{\mathcal{P}}(H)$ and also cover the rest vertices of $\bigcup_{1\le i\le s} V_i$ by μ-robust edges. So

$$|M_2| \le \binom{k+r-1}{k} C' + \left|\bigcup_{1\le i\le s} V_i\right|.$$

Note that the process is possible because H contains at least μn^k edges for each $\mathbf{i} \in I^{\mu}_{\mathcal{P},1}(H)$ and every vertex in $\bigcup_{1\le i\le s} V_i$ is in at least μn^{k-1} edges for $\mathbf{i} \in I^{\mu}_{\mathcal{P},2}(H)$ and

$$|V(M_0\cup M_1\cup M_2)| \le tk^2c' \log n_1 + (|V_0|+q)k + \left(\binom{k+r-1}{k} C' + \left|\bigcup_{1\le i\le s} V_i\right|\right) k < \mu n_1 < \mu n, \tag{2}$$

which allow us to choose desired edges in a greedy manner. Moreover, for every $i \in [s]$, the number of μ-robust index vectors $\mathbf{i}$ such that $\mathbf{i}|_i = 1$ is at most $\binom{2k-2}{k-1}$, and thus the process above needs at most $\binom{2k-2}{k-1}C$ uncovered vertices from V_i, which is okay by our construction[3].

Let $H' := H \setminus V(M_0 \cup M_1 \cup M_2)$ and $n' := |H'|$. So $n' \ge n - \mu n$ and by $\delta(k,\ell,k) \le c^*_{k,\ell}$ due to Theorem 11,

$$\delta_\ell(H') \ge \delta_\ell(H) - \mu n^{k-\ell} \ge (\delta(k,\ell,k) + \gamma/2)\binom{n'-\ell}{k-\ell}.$$

By the definition of $\delta(k,\ell,k)$, we have a matching M_3 in H covering all but at most k vertices. Let U be the set of vertices in H' uncovered by M_3. We are done if $U = \emptyset$. Otherwise because k divides n we have $|U| = k$.

We write $Q := Q(\mathcal{P}, L^{\mu}_{\mathcal{P}}(H))$ for brevity. Recall that $\mathbf{i}_{\mathcal{P}}(V(H) \setminus V(M_1)) \in L^{\mu}_{\mathcal{P}}(H)$. Note that by definition, the index vectors of all edges in M_2 are in $I^{\mu}_{\mathcal{P}}(H)$. So we have $\mathbf{i}_{\mathcal{P}}(V(H) \setminus V(M_1 \cup M_2)) \in L^{\mu}_{\mathcal{P}}(H)$, namely, $R_Q(V(H) \setminus V(M_1 \cup M_2)) = \mathbf{0} + L^{\mu}_{\mathcal{P}}(H)$. Thus,

$$\sum_{e\in M_0\cup M_3} R_Q(e) + R_Q(U) = \mathbf{0} + L^{\mu}_{\mathcal{P}}(H).$$

Suppose $R_Q(U) = \mathbf{v}_0 + L^{\mu}_{\mathcal{P}}(H)$ for some $\mathbf{v}_0 \in L^d_{\max}$; so

$$\sum_{e\in M_0\cup M_3} R_Q(e) = -\mathbf{v}_0 + L^{\mu}_{\mathcal{P}}(H).$$

[3] Remark. This is where we need Lemma 8 (3), the lower bound of $|V_i|$, $i \in [s]$.

We use the following claim proved in [13] (earlier versions appeared in [11, 18]). Its proof is via the coset arguments and is very similar to the one used in the proof of the forward implication.

▷ Claim 16 ([13, Claim 5.1]). There exist $e_1, \dots, e_p \in M_0 \cup M_3$ for some $p \le q-1$ such that

$$\sum_{i\in[p]} R_Q(e_i) = -\mathbf{v}_0 + L^{\mu}_{\mathcal{P}}(H). \tag{3}$$

That is, we have $\sum_{i\in[p]} \mathbf{i}_{\mathcal{P}}(e_i) + \mathbf{i}_{\mathcal{P}}(U) \in L^{\mu}_{\mathcal{P}}(H)$. Let $Y := \bigcup_{i\in[p]} e_i \cup U$ and thus $|Y| = pk + k \le qk + k$. We now complete the perfect matching by absorption. Since $\mathbf{i}_{\mathcal{P}}(Y) \in L^{\mu}_{\mathcal{P}}(H)$, we have the following equation

$$\mathbf{i}_{\mathcal{P}}(Y) = \sum_{\mathbf{v}\in I^{\mu}_{\mathcal{P}}(H)} a_{\mathbf{v}}\mathbf{v},$$

where $a_{\mathbf{v}} \in \mathbb{Z}$ for all $\mathbf{v} \in I^{\mu}_{\mathcal{P}}(H)$. Since $|Y| \le qk+k$, by the definition of C', we have $|a_{\mathbf{v}}| \le C'$ for all $\mathbf{v} \in I^{\mu}_{\mathcal{P}}(H)$. Noticing that $a_{\mathbf{v}}$ may be negative, we can assume $a_{\mathbf{v}} = b_{\mathbf{v}} - c_{\mathbf{v}}$ such that one of $b_{\mathbf{v}}, c_{\mathbf{v}}$ is $|a_{\mathbf{v}}|$ and the other is zero for all $\mathbf{v} \in I^{\mu}_{\mathcal{P}}(H)$. So we have

$$\sum_{\mathbf{v}\in I^{\mu}_{\mathcal{P}}(H)} c_{\mathbf{v}}\mathbf{v} + \mathbf{i}_{\mathcal{P}}(Y) = \sum_{\mathbf{v}\in I^{\mu}_{\mathcal{P}}(H)} b_{\mathbf{v}}\mathbf{v}.$$

This equation means that given a family $\mathcal{E} = \{W^{\mathbf{v}}_1, \dots, W^{\mathbf{v}}_{c_{\mathbf{v}}} : \mathbf{v} \in I^{\mu}_{\mathcal{P}}(H)\}$ of disjoint k-subsets of $V(H) \setminus Y$ such that $\mathbf{i}_{\mathcal{P}}(W^{\mathbf{v}}_i) = \mathbf{v}$ for all $i \in [c_{\mathbf{v}}]$, we can regard $V(\mathcal{E}) \cup Y$ as the union of disjoint k-sets $\{S^{\mathbf{v}}_1, \dots, S^{\mathbf{v}}_{b_{\mathbf{v}}} : \mathbf{v} \in I^{\mu}_{\mathcal{P}}(H)\}$ such that $\mathbf{i}_{\mathcal{P}}(S^{\mathbf{v}}_j) = \mathbf{v}$, $j \in [b_{\mathbf{v}}]$ for all $\mathbf{v} \in I^{\mu}_{\mathcal{P}}(H)$. Since $c_{\mathbf{v}} \le C'$ for all $\mathbf{v}$ and $V(M_2) \cap Y = \emptyset$, we can choose the family $\mathcal{E}$ as a subset of M_2. In summary, starting with the matching $M_0 \cup M_1 \cup M_2 \cup M_3$ leaving U uncovered, we delete the edges $e_1, \dots, e_p$ from $M_0 \cup M_3$ given by Claim 16 and then leave $Y = \bigcup_{i\in[p]} V(e_i) \cup U$ uncovered. Next we delete the family $\mathcal{E}$ of edges from M_2 and leave $V(\mathcal{E}) \cup Y$ uncovered. Finally, we regard $V(\mathcal{E}) \cup Y$ as the union of at most

$$|M_2| + qk + k \le \sqrt{\log n_1}/2$$

k-sets S each with $\mathbf{i}_{\mathcal{P}}(S) \in I^{\mu}_{\mathcal{P}}(H)$.

Note that by definition, Y may intersect at most $qk + k$ absorbing sets in $\mathcal{E}_0$, which cannot be used to absorb those sets we obtained above. Since each k-set S has at least $\sqrt{\log n_1} - (|V_0| + q)k > \sqrt{\log n_1}/2 + qk + k$ absorbing tk^2-sets in $\mathcal{E}_0$, we can greedily match each S with a distinct absorbing tk^2-set $E_S \in \mathcal{E}_0$ for S. Replacing the matching on $V(E_S)$ in M_0 by the perfect matching on $H[E_S \cup S]$ for each S gives a perfect matching in H.

Fully Functional Parameterized Suffix Trees in Compact Space

Arnab Ganguly

Abstract

Two equal length strings are a parameterized match (p-match) iff there exists a one-to-one function that renames the symbols in one string to those in the other. The *Parameterized Suffix Tree* (PST) [Baker, STOC' 93] is a fundamental data structure that handles various string matching problems under this setting. The PST of a text $T[1,n]$ over an alphabet Σ of size σ takes $O(n \log n)$ bits of space. It can report any entry in (parameterized) (i) suffix array, (ii) inverse suffix array, and (iii) longest common prefix (LCP) array in $O(1)$ time. Given any pattern P as a query, a position i in T is an occurrence iff $T[i, i+|P|-1]$ and P are a p-match. The PST can count the number of occurrences of P in T in time $O(|P| \log \sigma)$ and then report each occurrence in time proportional to that of accessing a suffix array entry. An important question is, *can we obtain a compressed version of PST that takes space close to the text's size of $n \log \sigma$ bits and still support all three functionalities mentioned earlier*? In SODA' 17, Ganguly et al. answered this question partially by presenting an $O(n \log \sigma)$ bit index that can support (parameterized) suffix array and inverse suffix array operations in $O(\log n)$ time. However, the compression of the (parameterized) LCP array and the possibility of faster suffix array and inverse suffix array queries in compact space were left open. In this work, we obtain a compact representation of the (parameterized) LCP array. With this result, in conjunction with three new (parameterized) suffix array representations, we obtain the first set of PST representations in $o(n \log n)$ bits (when $\log \sigma = o(\log n)$) as follows. Here $\varepsilon > 0$ is an arbitrarily small constant.

- Space $O(n \log \sigma)$ bits and query time $O(\log_\sigma^\varepsilon n)$;
- Space $O(n \log \sigma \log\log_\sigma n)$ bits and query time $O(\log\log_\sigma n)$; and
- Space $O(n \log \sigma \log_\sigma^\varepsilon n)$ bits and query time $O(1)$.

The first trade-off is an improvement over Ganguly et al.'s result, whereas our third trade-off matches the optimal time performance of Baker's PST while squeezing the space by a factor roughly $\log_\sigma n$. We highlight that our trade-offs match the space-and-time bounds of the best-known compressed text indexes for exact pattern matching and further improvement is highly unlikely.

1 Introduction

Text Indexing is a classical problem in Computer Science with numerous applications. The objective is to pre-process a text $T[1,n]$ over an alphabet Σ of size σ to create a data structure, such that for any pattern P given as a query, we can count/report all the positions in T where P appear as a substring. The suffix trees and suffix arrays (along with Longest Common

Prefix array, LCP array in short) are the most widely-known text indexes [21, 37, 28]. They occupy $\Theta(n)$ words of space (equivalently, $\Theta(n \log n)$ bits) and can count the number of occurrences in time $\tilde{O}(|P|)$. The time for per occurrence reporting is a constant for both structures. Although the space is linear in the number of words, there is an $O(\log_\sigma n)$ factor blowup when we consider the actual text size, which is $n\lceil \log \sigma \rceil$ bits. This factor is not negligible when $\sigma \ll n$. For example, the space occupied by the suffix tree of the human genome, even with very efficient implementation, such as in [27], requires about 40 GB of space, whereas the genome occupies less than 1GB.

To address the above issue, Grossi and Vitter [20] and Ferragina and Manzini [7] introduced succinct/compressed space alternatives, respectively known as *Compressed Suffix Array* (CSA) and *FM Index*. They can answer counting queries in $\tilde{O}(|P|)$ time and reporting in $\tilde{O}(1)$ time per occurrence. In some sense, both structures exploit the so-called *rank-preserving property* of suffixes/leaves. Specifically, consider two leaves/suffixes in the sub-tree of a non-root node in the *classical* suffix tree. If one were to chop off the first character of the suffixes corresponding to these leaves, thus leading to two different suffixes, the relative ordering of the first two suffixes within the suffix tree would be the same as their chopped counterparts. This crucial property leads to an efficient implementation of *Last-to-Front (LF) mapping*, which is defined as follows: *given the leaf i corresponding to a suffix starting at position t in the text,* $\mathsf{LF}(i)$ *is the leaf corresponding to the suffix starting at position* $(t-1)$. The LF mapping (or its inverse Ψ function) plays a pivotal role in the working of FM-Index and CSA and their subsequent improvements. Later, Sadakane [35] showed that by storing $O(n)$ extra bits, we could also compute the LCP of any two suffixes in $\tilde{O}(1)$ time, leading to the first fully functional suffix tree representation in $O(n \log \sigma)$ bits – i.e., it can report suffix array, inverse suffix array and LCP values. See [30] for further reading.

For numerous variants of the text indexing problem [1, 3, 18, 23, 32, 36] (such as parameterized matching, order-preserving matching, two-dimensional matching, cartesian tree matching, etc.), although linear space indexes are known, designing succinct/compressed indexes has been challenging [4, 5, 10, 13, 15, 11, 17, 12, 14, 25, 26, 24, 33]. We focus on the parameterized matching problem [1] defined as follows: two equal-length strings X and Y are a parameterized match (p-match) if and only if there exists a one-to-one function $f : \Sigma \to \Sigma$ such that $Y[i] = f(X[i])$ for every $i \in [1, |Y|]$. For example, $xyxz$ and $yzyx$ are p-match, but $xyxz$ and $xywz$ are not p-match. The indexing version is to count/report all substrings of $T[1, n]$ that p-match with a query pattern P. An index of size $\Theta(n \log n)$ bits, namely *parameterized suffix tree* (PST), has been known due to Baker [1]. However, the problem of designing a space-efficient avatar of PST turns out to be challenging because the above described *rank-preserving property* is no longer valid here. To that end, Ganguly et al. [16] proposed the Parameterized Burrows-Wheeler Transform (pBWT) that can support (parameterized) LF mapping in $O(\log \sigma)$ time using space close to $n \log \sigma$ bits. This led to the first sub-linear space index $\big($when $\log \sigma = o(\log n)\big)$ that can support (parameterized) suffix array and inverse suffix array operations in $\tilde{O}(1)$ time. Although this index is a significant achievement, it does not support LCP queries. In this paper, we augment this missing functionality, leading to the first fully functional PST representation in compact space. Besides this, we present three new space-time trade-offs (for suffix array access and its inverse operation) that are clear improvements over the previous results.

1.1 Baker's Parameterized Suffix Tree

We will use the following terminologies: for a string S, $|S|$ is its length, $S[i], 1 \le i \le |S|$, is its ith character and $S[i, j] = S[i] \circ S[i + 1] \circ \cdots \circ S[j]$, where $\circ$ denotes *concatenation*. If $i > j$, $S[i, j]$ denotes an empty string. Also, S_i denotes the circular suffix starting at position i. Specifically, S_i is S if $i = 1$ and is $S[i, |S|] \circ S[1, i - 1]$ otherwise.

Baker [1] introduced the following encoding scheme for matching strings over Σ. Let \$ be a special character in Σ. A string S is encoded into a string $\mathsf{prev}(S)$ of length $|S|$ by replacing the first occurrence of every character (other than \$) in S by 0 and any other occurrence by the difference in text position from its previous occurrence. Specifically, for any $i \in [1, |S|]$, $\mathsf{prev}(S)[i] = S[i]$ if $S[i] = \$$; otherwise, $\mathsf{prev}(S)[i] = (i - j)$, where $j < i$ is the last occurrence of $S[i]$ before i. If j does not exist, then $\mathsf{prev}(S)[i] = 0$. For example, $\mathsf{prev}(xy\$x) = 00\$3$. Note that $\mathsf{prev}(S)$ is a string over $\Sigma' = \{\$, 0, 1, \ldots, |S| - 1\}$, and can be computed in time $O(|S| \log \sigma)$.

▶ **Convention 1.** *In Σ', the integer characters are lexicographically smaller than \$. An integer character i comes before another integer character j iff $i < j$.*

▶ **Fact 2** ([1])**.** *Two (equal length) strings S and S' are a p-match iff $\mathsf{prev}(S) = \mathsf{prev}(S')$. Also a string P and a prefix of S are a p-match iff $\mathsf{prev}(P)$ is a prefix of $\mathsf{prev}(S)$.*

The parameterized Suffix Tree (PST) of $T[1, n]$ is a compacted trie of all strings in $\mathcal{P} = \{\mathsf{prev}(T[k, n]) \mid 1 \leq k \leq n\}$. For convenience, we assume that $T[n] = \$$ and $T[i] \neq \$$ for all $i \neq n$. Each edge is labeled with a string over Σ'. We use $\mathsf{str}(u)$ to denote the concatenation of edge labels on the path from the root to node u and $\mathsf{strLen}(u) = |\mathsf{str}(u)|$. Clearly, PST consists of n leaves (one per each encoded suffix) and at most $n - 1$ internal nodes. We use ℓ_i to denote the ith leftmost leaf and $\mathsf{str}(\ell_i)$ to denote the ith lexicographically smallest string in $\mathcal{P}$. Also, $\mathsf{PSA}[1, n]$ is an associated array called the parameterized suffix array, where $\mathsf{PSA}[i] = j$ and $\mathsf{PSA}^{-1}[j] = i$ iff $\mathsf{prev}(T[j, n]) = \mathsf{str}(\ell_i)$. Let $\mathsf{plcp}(i, j)$ be $\mathsf{strLen}(u)$, where u is the lowest common ancestor (LCA) of ℓ_i and ℓ_j; equivalently the length of the LCP of $\mathsf{prev}(T_{\mathsf{PSA}[i]})$ and $\mathsf{prev}(T_{\mathsf{PSA}[j]})$. The parameterized LCP array $\mathsf{PLCP}[1, n)$ is defined as follows: $\mathsf{PLCP}[i] = \mathsf{plcp}(i, i + 1)$. See Figure 1 for an illustration. Since $\mathsf{plcp}(i, j)$ is the smallest element in $\mathsf{PLCP}[i, j - 1]$, by maintaining an $O(n)$-bit range minimum query data structure [8] over PLCP, we can compute $\mathsf{plcp}(i, j)$ for any i, j in $O(1)$ time.

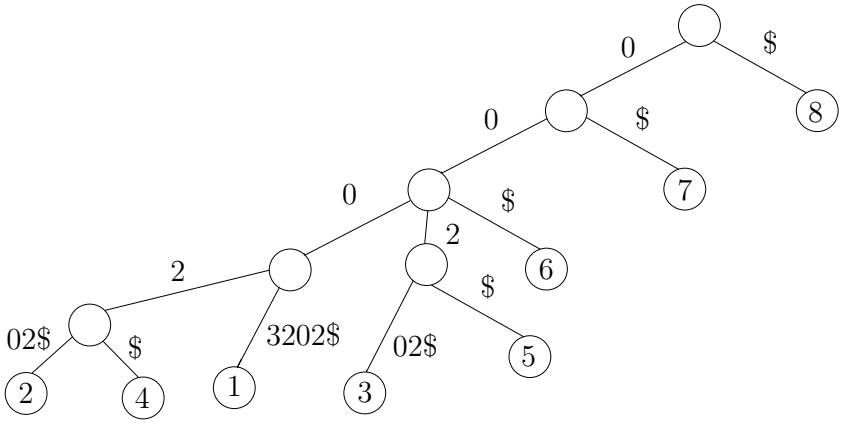
To answer a pattern matching query P (which is a string over $\Sigma - \{\$\}$), traverse the PST from the root and find the highest node u_P (if it exists) such that $\mathsf{str}(u_P)$ is prefixed by $\mathsf{prev}(P)$. This step takes $O(|P| \log \sigma)$ time. Then, find the range $[sp, ep]$ of leaves (called the suffix range of P) under u_P (this can be found in constant time by pre-processing the tree). Output $ep - sp + 1$ as the answer to counting and output $\{\mathsf{PSA}[i] \mid sp \leq i \leq ep\}$ as the answer to reporting. If u_P does not exist, we conclude that P does not have any p-match within T.

We refer to [6, 9, 29] for several other (linear space) data structures for parameterized pattern matching.

1.2 Compact Encoding of Parameterized Suffix Array

The parameterized LF mapping is defined as $\mathsf{PLF}(i) = \mathsf{PSA}^{-1}[\mathsf{PSA}[i] - 1]$. In [16], Ganguly et al. showed that one can implement PLF in $O(\log \sigma)$ time using an $n \log \sigma + o(n \log \sigma) + O(n)$ bit index. Their index constitutes the parameterized Burrows-Wheeler Transform (PWBT), which is an array of length n, such that $\mathsf{PBWT}[i]$ stores the number of distinct characters in (the prefix of) $T_{\mathsf{PSA}[i]}$ until the first occurrence $T[\mathsf{PSA}[i] - 1]$. See Figure 1 for an illustration.

By maintaining a Wavelet Tree [19] over PBWT, coupled with a succinct encoding [31] of the structure of the PST, they showed that PSA can be represented in $n \log \sigma + O\big(n + (n/\Delta) \log n\big)$ bits to support $\mathsf{PSA}[\cdot]/\mathsf{PSA}^{-1}[\cdot]$ queries in $t_{\mathsf{PSA}} = O(\Delta \cdot \log \sigma)$ time for any



i	T_i	prev(T_i)	prev$(T_{\mathsf{PSA}[i]})$	$T_{\mathsf{PSA}[i]}$	PSA$[i]$	f$_i$	PBWT$[i]$	W$[i]$	PLF(i)	$\Psi(i)$
1	xyzxzwz$	0003202$	000202$5	yzxzwz$x	2	8	3	4	3	4
2	yzxzwz$x	000202$5	0002$504	xzwz$xyz	4	5	2	3	4	5
3	zxzwz$xy	00202$50	0003202$	xyzxzwz$	1	3	$	3	8	1
4	xzwz$xyz	0002$504	00202$50	zxzwz$xy	3	2	4	2	1	2
5	zwz$xyzx	002$0043	002$0043	zwz$xyzx	5	2	3	2	2	6
6	wz$xyzxz	00$00432	00$00432	wz$xyzxz	6	8	2	4	5	7
7	z$xyzxzw	0$004320	0$004320	z$xyzxzw	7	4	4	3	6	8
8	$xyzxzwz	$0003202	$0003202	$xyzxzwz	8	∅	3	$	7	3

Figure 1 The text is $T[1,8] = xyzxzwz\$$, where $\Sigma = \{w, x, y, z, \$\}$.

$\Delta = O(\log_\sigma n)$ fixed in advance. For example, $O(n \log \sigma)$ bits of space and $O(\log n)$ query time by fixing $\Delta = \log_\sigma n$. This is the first succinct/compact space representation of PSA.[1] However, it does not support $\mathsf{plcp}(\cdot, \cdot)$ queries.

1.2.1 Challenges in Making PLF Computation Faster

Note that the product of space (in bits) and query time of Ganguly et al.'s PSA is always $\Theta(n \log n \log \sigma)$. A natural question is: *can we obtain better trade-offs*?

The current index is limited primarily because its main component for computing parameterized LF mapping needs to support queries of the following type: $\mathsf{RangeCount}_{\mathsf{PBWT}}(i, j, x, y) = |\{k \mid k \in [i, j], \mathsf{PBWT}[k] \in [x, y]\}|$. From the 4-sided range counting lower bound [34], any $O(n \log^{O(1)} \sigma)$-bit data structure needs $\Omega(1 + \log \sigma / \log \log n)$ time. This time becomes a bottleneck when it comes to some of the advanced suffix sampling techniques that are used for speeding up (classical) suffix array queries using additional space (as listed in Theorem 3); in fact, to adapt these techniques, LF mapping needs to be implemented in $O(1)$ time. Therefore, to prove Theorem 3, we need a new set of techniques.

1.2.2 Challenges in Compressing Parameterized LCP Array

Sadakane's LCP compression framework [35] for traditional text indexing relies on the following: *if two suffixes begin with the same character, their LCP after chopping the first character will be one less than their original LCP, and these two suffixes will retain*

[1] A succinct index for a data of size Z bits is a data structure having $Z + o(z)$ bits. On the other hand, a compact index needs $O(Z)$ bits.

their relative lexicographic rank after chopping. This allows one to compactly encode the LCP information. Unfortunately, this is not true for parameterized strings. For e.g., let $X = wxywabcdwx\$$ and $Y = abcdwx\$$ be two suffixes of T, then their respective prev encodings are $\mathsf{prev}(X) = 0003000058\$$ and $\mathsf{prev}(Y) = 000000\$$; hence, their p-LCP is 3. After chopping the first characters, the respective prev encodings are $000000058\$$ and $00000\$$, resulting in a p-LCP value of 5. Thus, chopping the first character can increase LCP; in fact, it can also decrease or even remain the same! Moreover, the order of the suffix may switch (as seen in this example), which adds to the difficulty. In short, the previous techniques are not adequate for compressing parameterized LCP array.

1.3 Our Results: Fully Functional PST in Compact Space

The suffix range $[sp, ep]$ of a pattern P can be computed in $O(|P| \log \sigma)$ time using Ganguly et al.'s index [16]; so we focus on speeding up suffix array queries and reporting LCP. We overcome the $O(\log \sigma)$ bottleneck of parameterized LF mapping by using its inverse, the Ψ-function, defined as $\Psi(i) = j$ iff $\mathsf{PLF}(j) = i$. This allows us to remove the dependence on 4-sided range-queries, instead of using simpler $\mathsf{partialRank}$ and select queries, which can be supported in $O(1)$ time using succinct space. With this, we implement Ψ-function in $O(1)$ time and thereby obtain three trade-offs, with space-time product near $n \log \sigma$. For our LCP framework, we essentially reduce a parameterized LCP query to a traditional LCP query; this allows us to leverage Sadakane's framework [35].

In summary, we have the following theorem.

▶ **Theorem 3.** *For the parameterized suffix tree of a text $T[1, n]$ over an alphabet of size σ, the following space-time trade-offs are possible in the word RAM model of computation with word-size $\Omega(\log n)$, where $\varepsilon > 0$ is an arbitrarily small constant.*

Index Size (in bits)	***Query Time (t_{PSA})***
$O(n \log \sigma)$	$O(\log_\sigma^\varepsilon n)$
$O(n \log \sigma \log \log_\sigma n)$	$O(\log \log_\sigma n)$
$O(n \log \sigma \log_\sigma^\varepsilon n)$	$O(1)$

All three basic queries (i.e., $\mathsf{PSA}[\cdot], \mathsf{PSA}^{-1}[\cdot]$ and $\mathsf{plcp}(\cdot, \cdot)$) are supported in $O(t_{\mathsf{PSA}})$ time.

Note that Baker's original definition also includes "*static characters*" for which the match has to be done in the traditional way. For the simplicity of exposition, we assume that all characters in Σ, except \$ are parameterized characters. We remark that our index can be extended to incorporate static characters without any sacrifice in time or space.

Outline. We start in Section 2 with a weaker version of Theorem 3 without the LCP claims. Specifically, we show that using an $O(n \log \sigma)$ bit index, we can support PSA and PSA^{-1} queries in $O(\log_\sigma n)$ time. Note that this is already a factor $(\log \sigma)$ faster than what is achievable using Ganguly et al.'s index [16]. Using more intricate techniques, we obtain the $\mathsf{PSA}[\cdot]/\mathsf{PSA}^{-1}[\cdot]$ trade-offs in Sections 3 and 4. Finally, the technique for encoding the LCP array is in Section 5.

2 Our Framework: A Compact Space Index

Let's start with a few definitions that we are going to use throughout this paper.

▶ **Definition 4.** *Define the following (see Figure 1 for an illustration):*

Notation	***Definition***
$\Psi(i)$	$\mathsf{PSA}^{-1}[1]$ *if* $\mathsf{PSA}[i] = n$, *else* $\mathsf{PSA}^{-1}[\mathsf{PSA}[i]+1]$
$\mathsf{PLF}(i)$	$\mathsf{PSA}^{-1}[n]$ *if* $\mathsf{PSA}[i] = 1$, *else* $\mathsf{PSA}^{-1}[\mathsf{PSA}[i]-1]$
f_i	$\varnothing$ if $i = n$, *else the first occurrence of* $T[\mathsf{PSA}[i]]$ *in* $T_{1+\mathsf{PSA}[i]}$
$\mathsf{W}[i]$	\$ if $i = n$, *else number of zeroes in* $\mathsf{prev}(T_{1+\mathsf{PSA}[i]})[1, \mathsf{f}_i]$
$\mathsf{PBWT}[i]$	$\mathsf{W}[\mathsf{PLF}(i)]$

Our goal is to prove the following theorem in this section.

▶ **Theorem 5.** *By using an $O(n \log \sigma)$-bit index, we can compute $\Psi(i)$ in $O(1)$ time.*

Before we prove this, we will see how we can use it to achieve an $O(n \log \sigma)$-bit index that supports PSA and PSA^{-1} queries in $O(\log_\sigma n)$ time. We explicitly store $\mathsf{PSA}[i]$ iff it equals n or is a multiple of $\Delta = \lceil \log_\sigma n \rceil$. Additionally, we store a bit-vector $B[1, n]$ as follows: set $B[i] = 1$ iff $\mathsf{PSA}[i]$ has been explicitly stored. For reporting, a $\mathsf{PSA}[j]$ can be retrieved in $O(1)$ time if $B[j] = 1$. Otherwise, we repeatedly apply Ψ starting from j until we reach an index $j' = \Psi\big(\ldots \Psi\big(\Psi\big(j\big)\big) \ldots\big)$ such that $B[j'] = 1$ (i.e., $\mathsf{PSA}[j']$ is explicitly stored). If the Ψ operation was applied k times, we get $\mathsf{PSA}[j] = \mathsf{PSA}[j'] - k$. The time complexity is $O(k)$. For PSA^{-1} queries, we store $\mathsf{PSA}^{-1}[i]$ if i equals n or if i is a multiple of Δ. To compute $\mathsf{PSA}^{-1}[j]$, we first find the largest number $j' \leq j$, such that j' is a multiple of Δ. Compute $j'' = \mathsf{PSA}^{-1}[j']$ from the sampled-PSA^{-1} in $O(1)$ time. Let $k = j - j' < \Delta$. Starting from j'' carry out k successive Ψ operations and report the final index as $\mathsf{PSA}^{-1}[j]$ in $O(k)$ time. Finally, $k < \Delta = \lceil \log_\sigma n \rceil$. The (extra) space needed is $(n/\Delta) \log n = O(n \log \sigma)$ bits. Other trade-offs may be obtained by tuning Δ, which is what we will do using a more sophisticated sampling technique along with a modified version of Theorem 5; details are in Section 4.

2.1 Succinct Data-Structure Toolkit

▶ **Fact 6** ([31]). *A tree having m nodes can be stored in $2m + o(m)$ bits, such that if each node is labeled by its pre-order rank, the following operations can be supported in $O(1)$ time:*

- $\mathsf{pre\text{-}order}(u)/\mathsf{post\text{-}order}(u)$ = *pre-order/post-order rank of node u.*
- $\mathsf{parent}(u)$ = *parent of node u.*
- $\mathsf{nodeDepth}(u)$ = *number of edges on the path from the root to u.*
- $\mathsf{lca}(u, v)$ = *lowest common ancestor (LCA) of two nodes u and v.*
- $\mathsf{lmostLeaf}(u)/\mathsf{rmostLeaf}(u)$ = *leftmost/rightmost leaf in the subtree rooted at u.*
- $\mathsf{levelAncestor}(u, D)$ = *ancestor of u such that* $\mathsf{nodeDepth}(u) = D$.

Also, we can find the pre-order rank of the ith leftmost leaf in $O(1)$ time.

▶ **Fact 7** ([2]). *Given an array $A[1, t]$ over $\Sigma = \{1, 2, \ldots, \sigma\}$, by storing an $O(t \log \sigma)$-bit structure, we can support the following operation in $O(1 + \log \frac{\log \sigma}{\log t})$ time:*

$\mathsf{rank}_A(i, c) =$ *number of occurrences of c in $A[1, i]$*

Additionally, the following operations can be supported in $O(1)$ time:

- *access $A[i]$*
- $\mathsf{partialRank}_A(i) = \mathsf{rank}(i, A[i])$, *i.e., the number of occurrences of $A[i]$ is the range $[1, i]$*
- $\mathsf{select}_A(i, c)$ = *the i^{th} occurrence of c in A*

2.2 Proof of Theorem 5

From their definitions, we observe: $\Psi(i) = j \iff \mathsf{PLF}(j) = i$, and $\mathsf{W}[i] = \mathsf{PBWT}[\Psi(i)]$. Additionally, we use $\chi(i)$ to denote the number of suffixes k such that $\Psi(k) \leq \Psi(i)$ and $\mathsf{W}[k] = \mathsf{W}[i]$. Based on these, it is easy to see that if $j = \Psi(i)$, then j is the $\chi(i)^{th}$ occurrence of $\mathsf{W}[i]$ in PBWT. Given $\chi(i)$, we can compute $\Psi(i)$ as:

$$\Psi(i) = \mathsf{select}_{\mathsf{PBWT}}\Big(\chi(i), \mathsf{W}[i]\Big)$$

Note that arrays $\mathsf{PBWT}[1, n]$ and $\mathsf{W}[1, n]$ take $O(\log \sigma)$ bits per entry. Therefore, we preprocess them into compact data structures that support access/select queries in $O(1)$ time (see Fact 7). Therefore, given $\chi(i)$, we can compute $\Psi(i)$ in constant time. To this end, we present the following lemma, which completes the proof of Theorem 5.

▶ **Lemma 8.** *By using an $O(n \log \sigma)$-bit data structure, we can compute $\chi(i)$ in $O(1)$ time.*

The rest of the section is dedicated to proving Lemma 8. For brevity, throughout we use "suffix i" to denote the suffix corresponding to leaf ℓ_i in the PST.

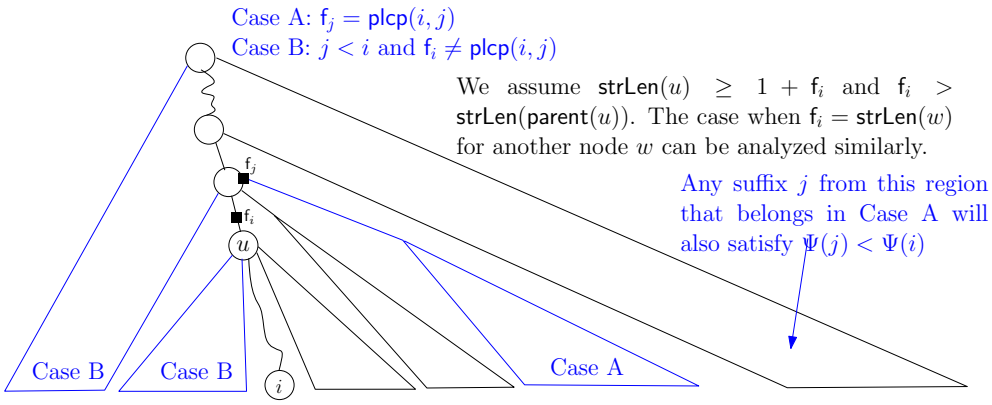
▶ **Lemma 9.** *Let $i < n$. Suppose u is the highest node on the path from the root to ℓ_i such that $\mathsf{f}_i \leq \mathsf{strLen}(u) - 1$. Then, for any leaf ℓ_j in the subtree of u, we have $\mathsf{f}_j = \mathsf{f}_i$*

Proof. Let $d = \mathsf{plcp}(i, j)$. Since $d \geq \mathsf{strLen}(u) \geq \mathsf{f}_i + 1$, we have $\mathsf{prev}\big(T_{\mathsf{PSA}[i]}[1, d]\big) = \mathsf{prev}\big(T_{\mathsf{PSA}[j]}[1, d]\big)$, i.e., the suffixes starting at $\mathsf{PSA}[i]$ and $\mathsf{PSA}[j]$ p-match until their first d characters. Clearly, the first occurrence of $T[\mathsf{PSA}[i]]$ in $T_{1+\mathsf{PSA}[i]}$ must be the same as the first occurrence of $T[\mathsf{PSA}[j]]$ in $T_{1+\mathsf{PSA}[j]}$, i.e., $\mathsf{f}_i = \mathsf{f}_j$. ◀

▶ **Lemma 10.** *If $\mathsf{W}[i] = \mathsf{W}[j]$, then $\Psi(j) < \Psi(i)$ iff*

- **Case A:** *either* $\mathsf{f}_j = \mathsf{plcp}(i, j)$
- **Case B:** *or,* $\mathsf{f}_j \neq \mathsf{plcp}(i, j)$, $j < i$, *and* $\mathsf{f}_i \neq \mathsf{plcp}(i, j)$

Proof. Recall Convention 1. Let $d = \mathsf{plcp}(i, j)$. If $\mathsf{f}_i = \varnothing$ or $\mathsf{f}_j = \varnothing$, then $\mathsf{W}[i] \neq \mathsf{W}[j]$. So, $\mathsf{f}_i, \mathsf{f}_j < n$. Also, $\mathsf{prev}(T_{\mathsf{PSA}[i]})[d+1] \neq \mathsf{prev}(T_{\mathsf{PSA}[j]})[d+1]$, by the definition of LCP. We now prove both cases (see Figure 2 for an illustration).



Blue suffixes are those suffixes j such that $\Psi(j) < \Psi(i)$

Figure 2 Illustration of Lemma 10.

- If $\mathsf{f}_j = d$, then $\mathsf{prev}(T_{\mathsf{PSA}[j]})[d+1] = d$ and $\mathsf{prev}(T_{\mathsf{PSA}[\Psi(j)]})[d] = 0$. From Lemma 9, we conclude $\mathsf{f}_i \geq d$. Moreover, $\mathsf{f}_i \neq d$ because $\mathsf{prev}(T_{\mathsf{PSA}[i]})[d+1] \neq d$ (by the definition of LCP). Therefore, $\mathsf{f}_i > d$. This implies $\mathsf{prev}(T_{\mathsf{PSA}[i]})[d+1] \neq 0$; otherwise, $\mathsf{W}[i] \neq \mathsf{W}[j]$, a contradiction. Consequently, either $\mathsf{prev}(T_{\mathsf{PSA}[\Psi(i)]})[d] > 0$ or $\mathsf{prev}(T_{\mathsf{PSA}[\Psi(i)]})[d] = \$$. Finally, note that $\mathsf{plcp}\big(\Psi(i), \Psi(j)\big) \geq d-1$. So after removing the first character of the two suffixes, their first $(d-1)$ characters will p-match. Hence, $\Psi(j) < \Psi(i)$ when $\mathsf{f}_j = \mathsf{plcp}(i,j)$.
- Now, assume $\mathsf{f}_j \neq d$. If $\mathsf{f}_j < d$, then $\mathsf{f}_i = \mathsf{f}_j$ (from Lemma 9) and $\mathsf{plcp}\big(\Psi(i), \Psi(j)\big) = d-1$. Then, $\Psi(j) < \Psi(i)$ iff $j < i$ because $\mathsf{prev}(T_{\mathsf{PSA}[\Psi(i)]})[d] = \mathsf{prev}(T_{\mathsf{PSA}[i]})[d+1]$ and $\mathsf{prev}(T_{\mathsf{PSA}[\Psi(j)]})[d] = \mathsf{prev}(T_{\mathsf{PSA}[j]})[d+1]$. If $\mathsf{f}_j > d$, then $\mathsf{prev}(T_{\mathsf{PSA}[j]})[d+1] = \mathsf{prev}(T_{\mathsf{PSA}[\Psi(j)]})[d]$. Also, $\mathsf{f}_i \geq d$ (from Lemma 9), implying either $\mathsf{prev}(T_{\mathsf{PSA}[\Psi(i)]})[d] = \mathsf{prev}(T_{\mathsf{PSA}[i]})[d+1]$ or $\mathsf{prev}(T_{\mathsf{PSA}[\Psi(i)]})[d] = 0$. The latter happens only when $\mathsf{f}_i = \mathsf{plcp}(i,j)$. Hence, we have $\Psi(j) < \Psi(i)$ when $j < i$ and $\mathsf{f}_i \neq \mathsf{plcp}(i,j)$.

This concludes the proof. ◀

To compute $\chi(i)$, we count the number n_A and n_B of Case A and B suffixes respectively; note that the cases are disjoint. Then, $\chi(i) = 1 + n_A + n_B$. We provide an overview first.

First, we locate the edge on which f_i lies, i.e., locate the edge $(\mathsf{parent}(u), u)$, such that $\mathsf{strLen}(\mathsf{parent}(u)) < 1 + \mathsf{f}_i \leq \mathsf{strLen}(u)$. This is facilitated by associating a bit with each node and set it to 1 iff $\mathsf{strLen}(\mathsf{parent}(\cdot)) < 1 + \mathsf{f}_j \leq \mathsf{strLen}(\cdot)$ for some suffix j in its sub-tree. Therefore, u is the lowest ancestor of ℓ_i that is associated with 1. By maintaining an $O(n)$ bit structure, we can answer this query in $O(1)$ time (see Lemma 11).

For counting n_A, we walk the path from root to $\mathsf{parent}(u)$, and for each node x on this path find out the number of suffixes j satisfying Case A: $\mathsf{f}_j = \mathsf{strLen}(x)$. Note that we afford to store f_j explicitly, instead store if f_j lies on an edge from node x to its child node y. Luckily, that's enough for us – for any suffix j, if $\mathsf{f}_j = \mathsf{strLen}(x)$ lies on the edge (x, y), then for all suffixes j' in the subtree of y, we have $f_{j'} = \mathsf{strLen}(x)$ (by Lemma 9). So, the count can be obtained via a simple unary encoding of suffixes of this kind. For counting Case B: $j < i$ and $\mathsf{f}_i \neq \mathsf{plcp}(i,j)$, walk from root to a node v; here, $v = u$ if $\mathsf{f}_i > \mathsf{strLen}(u)$, and $v = \mathsf{parent}(u)$ if $\mathsf{f}_i = \mathsf{strLen}(u)$. Initialize n_B to the number of leaves that lie to the left of this path. Then, add the number of leaves lying to the left of ℓ_i within the sub-tree of v to n_B. Note that for Cases A and B, we must consider only the suffixes j satisfying $\mathsf{W}[j] = \mathsf{W}[i]$; this is achieved by collecting suffixes based on their $\mathsf{W}[\cdot]$ values into different trees. Finally, we cannot afford to walk the path; therefore, we rely on the result in Lemma 12.

▶ **Lemma 11.** *Consider a compacted tree τ having L leaves, where each node is associated with a 0 or 1. By using an $O(L)$-bit data structure, given a query leaf ℓ, we can find the lowest ancestor v (if it exists) of ℓ associated with a 1 in $O(1)$ time.*

▶ **Lemma 12.** *Consider a compacted tree τ having L leaves, where each node w is associated with an integer $g(w) \geq 0$. For any node v, we have $\sum_{u \in \mathcal{S}_v} g(u) \leq L_v$, where $\mathcal{S}_v$ is the set of nodes in the subtree of v and L_v is the number of leaves in the subtree of v. By using an $O(L)$-bit data structure, given a query leaf ℓ, we can compute $G(\ell) = \sum_v g(v)$ in $O(1)$ time, where v is an ancestor of ℓ.*

The proofs of Lemmas 11 and 12 (deferred to Section 2.3) relies on mostly standard techniques from succinct data structures. Next we present the implementation details of $\chi(i)$ computation.

The Data Structure. To compute $\chi(i)$, we only need to consider those suffixes k, such that $\mathsf{W}[k] = \mathsf{W}[i]$. To this end, we create (at most) σ compacted tries $\mathsf{PST}_1, \mathsf{PST}_2, \ldots, \mathsf{PST}_\sigma$, where PST_α is the compacted trie of the strings in $\{\mathsf{prev}(T[\mathsf{PSA}[k], n]) \mid \mathsf{W}[k] = \alpha\}$. We do not store these trees explicitly; rather, we store their topology with succinct functionalities using Fact 6.

We pre-process each PST_α using Lemma 11 as follows: associate each node w in PST_α with 1 if $\mathsf{strLen}(\mathsf{parent}(w)) \leq \mathsf{f}_i < \mathsf{strLen}(w)$ for some leaf ℓ_i under w with $\mathsf{W}[i] = \alpha$. We also pre-process PST_α using Lemma 12 as follows: associate a node w with the number β_w, where β_w is the number of suffixes i in the subtree of w in PST_α such that $\mathsf{f}_i = \mathsf{strLen}(w)$. Note that $\sum_w \beta_w$ over all nodes w in all the trees is $O(n_\alpha)$, where n_α is the number of leaves in PST_α. The space needed for all such PST_α trees combined is $O(n)$ bits. Finally, we store a partial-rank data structure (Fact 7) on W. The total space needed is $O(n \log \sigma)$ bits.

Query Processing. Given i, in $O(1)$ time, we first jump to the corresponding leaf $\ell_{i'}$ in $\mathsf{PST}_{\mathsf{W}[i]}$ by using the $\mathsf{partialRank}_{\mathsf{W}}(i)$ query. Now locate the highest node u in $\mathsf{PST}_{\mathsf{W}[i]}$ such that $1 + \mathsf{f}_i \leq \mathsf{strLen}(u)$ in $O(1)$ time using Lemma 11. We consider the following two scenarios separately. To determine which case a suffix falls in, we store a bit-vector $F[1, n]$, such that $F[i] = 1$ iff the suffix i belongs to the first case. In each of the following cases, we can compute $\chi(i)$ in $O(1)$ time, which completes the proof of Lemma 8.

Case 1: $\mathsf{strLen}(\mathsf{parent}(u)) < \mathsf{f}_i < \mathsf{strLen}(u)$ for an ancestor node u of ℓ_i.
Let j be such that $\mathsf{W}[j] = \mathsf{W}[i]$. Applying Lemma 10, $\Psi(j) < \Psi(i)$ if either $j < i$ or $\mathsf{f}_j = \mathsf{plcp}(i, j)$. Thus, $\chi(i) = i' + \sum_v \beta_v$, where v is an ancestor of $\ell_{i'}$. The last term can be computed in $O(1)$ time using Lemma 12.

Case 2: $\mathsf{f}_i = \mathsf{strLen}(u)$ for an ancestor node u of ℓ_i.
Let j be such that $\mathsf{W}[j] = \mathsf{W}[i]$. Applying Lemma 10, $\Psi(j) < \Psi(i)$ if either (1) $j < i$ and $\mathsf{plcp}(i, j) \neq \mathsf{f}_i$, or (2) $\mathsf{f}_j = \mathsf{plcp}(i, j)$. Let w be the child of u on the path to $\ell_{i'}$. Using Fact 6, in $O(1)$ time, we compute $\mathsf{lmostLeaf}(u)$ and $\mathsf{lmostLeaf}(w)$, which are respectively the leftmost leaf in the subtree of u and the subtree of w. Thus,

$$\chi(i) = i' - (\mathsf{lmostLeaf}(w) - \mathsf{lmostLeaf}(u)) + \sum_v \beta_v$$

where v is an ancestor of $\ell_{i'}$. The last term can be computed in $O(1)$ time using Lemma 12. This completes the proof of Lemma 8.

2.3 Proofs of Lemma 11 and Lemma 12

We rely on standard techniques from succinct data structures. For both lemmas, we employ the following marking scheme. Starting from the leftmost leaf, every $C = c\lceil \log L \rceil$ leaves form a group, where c is a constant to be decided later. (The last group may have fewer than C leaves.) Mark the LCA of the first and last leaf of each group. The number of marked nodes is $O(L/C)$ [22].

We prove Lemma 11 first. At each marked node, we store the depth of its nearest ancestor (including itself) which is associated with a 1. Traverse the subtree τ_{u^*} of a marked node u^* in pre-order, and create a bit-string B_{u^*} as follows: when entering the subtree of a node w, append 1 if w is associated with a 1, followed by a 0 to B_{u^*}. Additionally, for every $i \in [1, L_{u^*}]$, store $A_{u^*}[i] =$ node depth of the nearest ancestor of $\ell_{u^*,i}$ associated with a 1 if the ancestor is in τ_{u^*}, else $A_{u^*}[i] = -1$. For each marked node u^*, maintain a pointer to the corresponding A_{u^*} and B_{u^*} pair. Pre-process τ_{u^*} with Fact 6. Lastly, we maintain a

bit-vector to detect in $O(1)$ time whether a leaf has an ancestor associated with 1, or not. The total space as before can be bounded by $O(L)$ bits. Given a query leaf ℓ_k, we check whether ℓ_k has an ancestor associated with 1 or not. Assume that it does. Then, we first locate the lowest marked node v^* as described earlier. Let d^* be the node depth stored at v^*. Let $k' = k - C\lfloor k/C \rfloor$. Check the k'th entry of the satellite array of v^*, and let it be d'. If $d' >= 0$, then the desired node is given by $\mathsf{levelAncestor}(\ell, d')$, else the desired node is given by $\mathsf{levelAncestor}(\ell, d^*)$.

Now, we prove Lemma 12. At each marked node u^*, store $G(u^*)$. Since the number of marked nodes is at most $\lceil L/C \rceil$, the space needed is $O(\frac{L}{C} \log L) = O(L)$ bits. Let τ_{u^*} be the subtree rooted at a marked node u^*. Note that τ_{u^*} has at most $2C$ nodes. Traverse tree τ_{u^*} in pre-order, and create a bit-string B_{u^*} as follows: when entering the subtree of a node w, append $g(w)$ in unaryto B_{u^*}. Additionally, for every $i \in [1, L_{u^*}]$, store $A_{u^*}[i] = G(\ell_{u^*,i})$, where L_{u^*} is the number of leaves in the subtree of u^*, and $\ell_{u^*,i}$ is the i^{th}-leftmost leaf in τ_{u^*}. The space needed to store the array A_{u^*} is $O(C \log C)$ bits. Note that $|B_{u^*}| \leq 2C$; hence, the number of possible such bit-strings is at most 2^{2C}. We store all possible combinations of A_{u^*} and B_{u^*}, which requires $O(2^{2C} C \log C)$ bits, which is $o(L)$ bits for $c = 1/4$. For each marked node u^*, maintain a pointer to the corresponding A_{u^*} and B_{u^*} pair, which requires $\frac{L}{C} \log(2^{2C}) = O(L)$ bits. Finally, pre-process τ_{u^*} with Fact 6. The total space needed is $O(L)$ bits. Given a query leaf ℓ_k, we first locate the lowest marked node $v^* = \mathsf{lca}(\ell_x, \ell_y)$ of ℓ_k, where $x = 1 + C\lfloor k/C \rfloor$, $y = \min\{L, C(1 + \lfloor k/C \rfloor)\}$. Let d^* be the value stored at v^*. Let $k' = k - C\lfloor k/C \rfloor$. Check the k'th entry of the satellite array of v^*, and let it be d'. Then, $G(\ell_k) = d^* + d'$ is computed in $O(1)$ time.

3 Generalized Ψ Function

We start with a definition that we are going to use throughout this section, as well as a couple of lemmas that will form the backbone of the indexes to achieve the three trade-offs.

▶ **Definition 13.** *Define* $\Psi^k(i) = \mathsf{PSA}^{-1}[\mathsf{PSA}[i] + k]$.

Our main arsenal to obtain the three trade-offs is the following version of Theorem 5, which enables the computation of "some" $\Psi^k(\cdot)$ in time faster than $O(k)$.

▶ **Lemma 14.** *For any predefined integer* Δ*, we can construct an* $O(n \log \sigma)$*-bit structure* $\mathsf{DS}(\Delta)$ *that computes* $\Psi^\Delta(i)$ *for any* i *with* $\mathsf{PSA}[i]$ *being a multiple of* Δ *in* $O(1)$ *time.*

We prove this lemma in this section. Let's start with the intuition. Note that in Lemma 14, if one is willing to relax the time to $O(\Delta)$, we can simply apply Theorem 5 Δ times. Here, we will chop off the first Δ characters of a suffix, where the characters are from Σ. To reduce the time to $O(1)$, the main idea is to consider a character from the alphabet Σ^Δ; clearly, chopping off one character from Σ^Δ is equivalent to chopping off Δ characters from Σ. Note that each character from Σ^Δ requires $\Delta \log \sigma$ bits for representation; however, since we sample $\approx n/\Delta$ suffixes, the total space will still be $O((n/\Delta) \cdot \Delta \log \sigma) = O(n \log \sigma)$ bits. The proof techniques are similar to that of Theorem 5.

▶ **Definition 15.** *A suffix is* Δ*-sampled if its starting position is a multiple of* Δ*. Let* S_Δ *be the collection of all* Δ*-sampled suffixes of* T*, i.e.,* $S_\Delta = \{T_\Delta, T_{2\Delta}, \dots\}$*. Let* $n_\Delta = |S_\Delta|$ *be the number of* Δ*-sampled suffixes. A* Δ*-sampled parameterized suffix array, denoted as* $\mathsf{PSA}_\Delta[1, n_\Delta]$*, stores the starting position of the suffixes in lexicographic order of their* prev*-encoding.*

▶ **Definition 16.** *Let $B_\Delta[1,n]$ be a bitmap, such that $B_\Delta[i] = 1$ iff $\mathsf{PSA}[i]$ is a multiple of Δ.*

▶ **Lemma 17.** *Given $i \in [1, n_\Delta]$, we can find a $j \in [1,n]$, such that $\mathsf{PSA}[j] = \mathsf{PSA}_\Delta[i]$ in $O(1)$ time by maintaining an $O(n)$-bit space structure.*

Proof. We maintain a bit-vector $B_\Delta[1,n]$ using Fact 7, where $B_\Delta[i] = 1$ iff $T_{\mathsf{PSA}[i]}$ is Δ-sampled. The total space needed is $O(n)$ bits. Observe that $T_{\mathsf{PSA}_\Delta[i]}$ is exactly the i^{th} Δ-sampled suffix in lexicographic order; thus, $j = \mathsf{select}_{B_\Delta}(i,1)$. ◀

▶ **Definition 18.** *Let $T_{\mathsf{PSA}[i]}$ be a Δ-sampled suffix. Define the following:*

Notation	***Definition ($\circ$ denotes concatenation)***
$\Psi^\Delta(i)$	$\mathsf{PSA}^{-1}[\mathsf{PSA}[i] + \Delta]$
$\mathsf{PLF}^\Delta(i)$	$\mathsf{PSA}^{-1}[\mathsf{PSA}[i] - \Delta]$
$\mathsf{W}^\Delta[i]$	$\mathsf{W}[i] \circ \mathsf{W}[\Psi(i)] \circ \cdots \circ \mathsf{W}[\Psi^{\Delta-1}(i)]$
$\mathsf{PBWT}^\Delta[i]$	$\mathsf{PBWT}[\mathsf{PLF}^{\Delta-1}(i)] \circ \mathsf{PBWT}[\mathsf{PLF}^{\Delta-2}(i)] \circ \cdots \circ \mathsf{PBWT}[i]$

▶ **Observation 19.** *Let $T_{\mathsf{PSA}[i]}$ be a Δ-sampled suffix. The following observations can be deduced from the above definitions:*

- $\Psi^\Delta(i) = j$ *iff* $\mathsf{PLF}^\Delta(j) = i$
- *If* $\Psi^\Delta(i) = j$, *then* $\mathsf{PBWT}^\Delta[i] = \mathsf{W}^\Delta[j]$

▶ **Definition 20.** *Let $T_{\mathsf{PSA}[i]}$ be a Δ-sampled suffix. Define*

$$\chi^\Delta(i) = |\{k, \text{ where } T_{\mathsf{PSA}[k]} \text{ is } \Delta\text{−sampled}, \Psi^\Delta(k) \leq \Psi^\Delta(i) \text{ and } \mathsf{W}^\Delta[k] = \mathsf{W}^\Delta[i]\}|$$

Reduction from function Ψ^Δ to χ^Δ. Using Observation 19, it is easy to see that if $j = \Psi^\Delta(i)$, then j is the $\chi^\Delta(i)^{th}$ occurrence of $\mathsf{W}^\Delta[i]$ in PBWT^Δ. Given $\chi^\Delta(i)$, we can compute $\Psi^\Delta(i)$ as: $\Psi^\Delta(i) = \mathsf{select}_{B_\Delta}\left(\mathsf{select}_{\mathsf{PBWT}^\Delta}\left(\chi^\Delta(i), \mathsf{W}^\Delta[i]\right), 1\right)$

Note that the arrays $\mathsf{PBWT}^\Delta[1, n_\Delta]$ and $\mathsf{W}^\Delta[1, n_\Delta]$ take $O(\Delta \log \sigma)$ bit per entry. We preprocess them into compact data structures that support access/select queries in $O(1)$ time (see Fact 7). The space needed is $O(n_\Delta \cdot \Delta \log \sigma) = O(n \log \sigma)$ bits. Thus, given $\chi^\Delta(i)$, we can compute $\Psi^\Delta(i)$ in constant time. To this end, we present the following lemma,which completes the proof of Lemma 14.

▶ **Lemma 21.** *Let $T_{\mathsf{PSA}[i]}$ be a Δ-sampled suffix. By using an $O(n \log \sigma)$-bit data structure, we can compute $\chi^\Delta(i)$ in $O(1)$ time.*

3.1 Proof of Lemma 21

For the ease of notation, let $i_d = \Psi^d(i)$, $j_d = \Psi^d(j)$, and $L_d = \mathsf{plcp}(i_d, j_d)$, where $d \in [1, \Delta]$. Let $i_0 = i$, $j_0 = j$, and $L_0 = \mathsf{plcp}(i,j)$. Our proof hinges on Lemma 22, which says, for any two suffixes $T_{\mathsf{PSA}[i]}$ and $T_{\mathsf{PSA}[j]}$ such that $i < j$ and $\mathsf{W}^\Delta[i] = \mathsf{W}^\Delta[j]$, the relative order between i and j can change at most once while applying the Ψ-operation Δ number of times.

▶ **Lemma 22.** *Consider two Δ-sampled suffixes $T_{\mathsf{PSA}[i]}$ and $T_{\mathsf{PSA}[j]}$ such that $i < j$, and $\mathsf{W}^\Delta[i] = \mathsf{W}^\Delta[j]$.*

- *If there exists a $\gamma \in [1, \Delta - 1]$ such that $i_\gamma > j_\gamma$, then $\forall \gamma' \in [\gamma + 1, \Delta]$, $i_{\gamma'} > j_{\gamma'}$.*
- *Consider the minimum $\gamma \in [1, \Delta]$ such that $i_\gamma > j_\gamma$, then $\mathsf{f}_{j_{\gamma-1}} = L_{\gamma-1}$.*

Proof. We prove the first part of the lemma; the second part follows directly. Consider the smallest $\gamma \in [1, \Delta - 1]$ such that $\Psi^{\gamma}(i) > \Psi^{\gamma}(j)$. Since $\Psi^{\gamma-1}(i) < \Psi^{\gamma-1}(j)$, we have $\mathsf{str}(\ell_{j_{\gamma-1}})[1 + L_{\gamma-1}] > \mathsf{str}(\ell_{i_{\gamma-1}})[1 + L_{\gamma-1}]$. Then, $\mathsf{str}(\ell_{j_\gamma})[1 + L_\gamma] = 0 < \mathsf{str}(\ell_{i_\gamma})[1 + L_\gamma]$; otherwise, applying Lemma 9, it is easy to show that $\mathsf{W}^{\Delta}[i] \neq \mathsf{W}^{\Delta}[j]$. For the purpose of contradiction, consider the smallest $\gamma' > \gamma$ such that $\Psi^{\gamma'}(i) < \Psi^{\gamma'}(j)$. Note that $L_{\gamma'-1} = L_\gamma - (\gamma' - \gamma - 1)$. Hence, $\mathsf{str}(\ell_{j_{\gamma'-1}})[1 + L_{\gamma'-1}] = 0 < \mathsf{str}(\ell_{i_{\gamma'-1}})[1 + L_{\gamma'-1}]$. Since $\Psi^{\gamma'}(i) < \Psi^{\gamma'}(j)$, applying Lemma 9, $\mathsf{str}(\ell_{i_{\gamma'}})[1 + L_{\gamma'}] = 0$ and $\mathsf{f}_{i_{\gamma'}} = L_{\gamma'}$, which contradicts $\mathsf{W}^{\Delta}[i] = \mathsf{W}^{\Delta}[j]$. This completes the proof. ◀

Using Lemmas 9, 10, and 22, we get the following.

▶ **Lemma 23.** *Consider two Δ-sampled suffixes $T_{\mathsf{PSA}[i]}$ and $T_{\mathsf{PSA}[j]}$ such that $i < j$, and $\mathsf{W}^{\Delta}[i] = \mathsf{W}^{\Delta}[j]$. If there exists a $\gamma \in [1, \Delta]$ such that $i_\gamma > j_\gamma$, then*

- *$i_\Delta > j_\Delta$, and*
- *for any k such that $T_{\mathsf{PSA}[k]}$ is Δ-sampled, $\mathsf{W}^{\Delta}[i] = \mathsf{W}^{\Delta}[k]$, and $\mathsf{plcp}(k, j) > \mathsf{plcp}(i, j)$, we have $i_\Delta > k_\Delta$.*

To compute $\chi^{\Delta}(i)$, note that we only need to consider those suffixes k, such that $\mathsf{W}^{\Delta}[k] = \mathsf{W}^{\Delta}[i]$. To this end, we create (at most) σ^{Δ} compact tries $\mathsf{PST}^{\Delta}_1, \mathsf{PST}^{\Delta}_2, \ldots, \mathsf{PST}^{\Delta}_{\sigma^\Delta}$, where PST_α is the compacted trie of the strings in

$$\{\mathsf{prev}(T[\mathsf{PSA}[k], n]) \mid \mathsf{W}^{\Delta}[k] = \alpha \text{ and } T_{\mathsf{PSA}[k]} \text{ is } \Delta \text{ sampled}\}$$

We do not store these trees explicitly; rather, we maintain the data-structure of Fact 6 for each tree topology. Note that given a leaf k in PST, where $T_{\mathsf{PSA}[k]}$ is Δ sampled, we can jump to its corresponding leaf k' in $\mathsf{PST}_{\mathsf{W}^\Delta}$ in $O(1)$ time using an $O(n \log \sigma)$ structure (the bit-array B_Δ, and Fact 7 over W^{Δ}).

Consider a tree PST^{Δ}_x. Let the number of suffixes lying in this tree be m_x. For any leaf j' in PST^{Δ}_x, let $\mathsf{map}(j')$ be the equivalent leaf in PST. Consider a node u in PST^{Δ}_x. For each $\gamma \in [1, \Delta]$ we write two numbers $G_\gamma(u)$ and $H_\gamma(u)$ defined as:

- $G_\gamma(u)$ = the number of leaves j' in the subtree of u such that $\mathsf{f}_{j_\gamma} = \mathsf{strLen}(u)$, where $j = \mathsf{map}(j')$
- If $\mathsf{f}_{j_\gamma} \neq \mathsf{strLen}(\mathsf{parent}(u))$, where j' is a leaf in the subtree of u and $j = \mathsf{map}(j')$, then $H_\gamma(u) = 0$. Else, $H_\gamma(u)$ = the number of leaves k' in the subtree of $\mathsf{parent}(u)$ such that $\mathsf{f}_{k_\gamma} \neq \mathsf{strLen}(\mathsf{parent}(u))$ and $\mathsf{pre\text{-}order}(\ell_{k'}) < \mathsf{pre\text{-}order}(u)$, where $k = \mathsf{map}(k')$

Note that $\sum_u G_\gamma(u) \leq m_x$ and $\sum_u H_\gamma(u) \leq m_x$ (using Lemmas 22 and 23). Hence, $\sum_u G_\gamma(u)$ and $\sum_u H_\gamma(u)$ over $\gamma \in [1, \Delta]$ can be stored in $O(m_x \Delta)$ bits using unary encoding. To compute $\chi^{\Delta}(i)$, we first jump to the corresponding leaf i' in $\mathsf{PST}^{\Delta}_{\mathsf{W}^\Delta[i]}$ in $O(1)$ time. Let $\mathcal{U}$ be the set of ancestors of $\ell_{i'}$ Now, $\chi(i) = i' + \sum_{\gamma=1}^{\Delta} \sum_{u \in \mathcal{U}} G_u(\ell_{i'}) - \sum_{\gamma=1}^{\Delta} \sum_{u \in \mathcal{U}} H_u(\ell_{i'})$, which can be computed in $O(1)$ time using (slightly adapted versions of) Lemmas 11 and 12. Since $\sum_{x=1}^{\sigma^\Delta} m_x = n_\Delta$, the total space is $O(n \log \sigma)$ bits; recall that m_x is the number of suffixes in PST^{Δ}_x. This concludes the proof.

4 Achieving the Three Trade-offs of PSA

We prove the trade-offs using the result in Lemma 14 as a black box. Additionally, we will use the sampled PSA and sampled PSA^{-1} in Lemma 24 for all the three cases. Let $\lambda = 2^{\lceil \log \log_\sigma n \rceil}$, the next highest power of 2 greater than or equal to $\log_\sigma n$. The strategy for computing $\mathsf{PSA}[i]$ is the same as before (refer to Section 2), i.e., find the smallest $k < \lambda$, such that $\mathsf{PSA}[i] = \mathsf{PSA}[j] - k$, where $j = \Psi^k(i)$ and $B_\lambda[j] = 1$, but in fewer number of steps.

▶ **Lemma 24** (Sampled PSA and PSA^{-1}). *A sampled-*PSA *is a structure that supports the following query: for any i, it reports* $\mathsf{PSA}[i]$ *if* $\mathsf{PSA}[i]$ *is a multiple of λ, and ∞ otherwise. Similarly, a sampled-*PSA^{-1} *is a structure that computes* $\mathsf{PSA}^{-1}[i]$ *for any i which is a multiple of λ. We can maintain them in $O(n \log \sigma)$ bits and answer queries in $O(1)$ time.*

Proof. Note that the sampled-PSA^{-1} is an array of size $O(n/\lambda)$ in which each entry can be recorded using $\lceil \log n \rceil$ bits and accessed in $O(1)$ time. For the sampled-PSA, we maintain the bitmap $B_\lambda[1, n]$ in Definition 16 by choosing $\Delta = \lambda$. Additionally, we associate $\mathsf{PSA}[i]$ with those i's where $B_\lambda[i] = 1$. The space required is $(n + (n/\lambda) \log n) = O(n \log \sigma)$ bits, and the query can be easily handled in $O(1)$ time. ◀

4.1 Achieving $t_{\mathsf{PSA}} = O(\log^{\varepsilon}_{\sigma} n)$ using $O(n \log \sigma)$ bits

Let Δ_t be $(\log^{\varepsilon}_{\sigma} n)^t$ rounded to the next highest power of 2. We maintain $\mathsf{DS}(\Delta_t)$ and $B_{\Delta_t}[1, n]$ for $t = 0, 1, 2, 3, \ldots, 1/\varepsilon$. (Recall Lemma 14 and Definition 16 for definitions of this data structures.) The space is $1/\varepsilon \times O(n \log \sigma)$ bits, as desired.

To compute $\mathsf{PSA}[i]$, we initialize $k = 0, j = i, t = 0$ and follow the steps below.

1. If $B_\lambda[j] = 1$, access $\mathsf{PSA}[j]$ in $O(1)$ time from the sampled-PSA and report $\mathsf{PSA}[j] - k$.
2. Else if $B_{\Delta_{t+1}}[j] = 1$, update $t \leftarrow t + 1$ and go to Step 1.
3. Else we compute $j' = \Psi^{\Delta_t}(j)$ using $\mathsf{DS}(\Delta_t)$ in $O(1)$ time, update $j \leftarrow j'$, $k \leftarrow k + \Delta_t$, and then we repeat from Step 2.

Then, the number of times we perform (constant time) $\Psi^{\Delta_t}(\cdot)$ operations on $\mathsf{DS}(\Delta_t)$ is at most $\Delta_{t+1}/\Delta_t = \log^{\varepsilon}_{\sigma} n$. Therefore, the overall time complexity is $O(\frac{1}{\varepsilon} \log^{\varepsilon}_{\sigma} n)$.

Note that the algorithm for $\mathsf{PSA}[i]$ computes several j's, starting with $j = i$, such that the j computed after t^{th} "step 1" guarantees that $\mathsf{PSA}[j] \geq \mathsf{PSA}[i]$ is the smallest number divisible by Δ_t. Therefore, the correctness follows from that fact that $\mathsf{PSA}[i]$ is $\mathsf{PSA}[j] - k$.

The computation of $\mathsf{PSA}^{-1}[\cdot]$ is analogous, but in the reverse order, as desired. Specifically, we perform queries on $\mathsf{DS}(\Delta_t)$'s, in descending order of t.

4.2 Achieving $t_{\mathsf{PSA}} = O(\log \log_{\sigma} n)$ using $O(n \log \sigma \log \log_{\sigma} n)$ bits

We maintain $\mathsf{DS}(\Delta_t)$ structure of Lemma 14 and $B_{\Delta_t}[1, n]$, where $\Delta_t = 2^t$, for $t = 0, 1, 2, 3, \ldots, \log \lambda$, where $\lambda = 2^{\lceil \log \log_{\sigma} n \rceil}$ as defined in Lemma 24. The space is $O(n \log \sigma) \times \log \lambda$ bits, as desired.

To compute $\mathsf{PSA}[i]$, we initialize $k = 0, j = i, t = 0$ and follow the steps below.

1. If $B_\lambda[j] = 1$, access $\mathsf{PSA}[j]$ in $O(1)$ time from the sampled-PSA and report $\mathsf{PSA}[j] - k$.
2. Else if $B_{\Delta_{t+1}}[j] = 1$, update $t \leftarrow t + 1$ and go to Step 1.
3. Else compute $j' = \Psi^{\Delta_t}(j)$ using $\mathsf{DS}(\Delta_t)$ in $O(1)$ time, update $j \leftarrow j'$ and $k \leftarrow k + \Delta_t$. Then update $t \leftarrow t + 1$ and go to Step 1.

We perform at most $\log \lambda$ constant-time operations on $\mathsf{DS}(\cdot)$, hence $t_{\mathsf{PSA}} = O(\log \log_{\sigma} n)$. The computation of $\mathsf{PSA}^{-1}[\cdot]$ (and correctness proof) is analogous as in the previous section.

4.3 Achieving $t_{\mathsf{PSA}} = O(1)$ using $O(n \log \sigma \log^{\varepsilon}_{\sigma} n)$ bits

Here we use Lemma 25, which is a slight modification of Lemma 14. We remark that the proof is rather straightforward given the proof of Lemma 14; so, we omit it.

▶ **Lemma 25.** *For any predefined integers Δ and $\delta < \Delta$ (both are powers of 2), we can construct an $O(n \log \sigma)$-bit structure that computes $\Psi^{\delta}(i)$ for any i with $(\mathsf{PSA}[i] + \delta)$ being a multiple of δ in $O(1)$ time. We call this data structure $\mathsf{DS}(\Delta, \delta)$.*

We define an array $E^{\delta}_{\Delta}[1, n]$ such that $E^{\delta}_{\Delta}[i]$ is

- $-\infty$ if $\mathsf{PSA}[i]$ is not a multiple of Δ
- an integer $f \in [0, \Delta/\delta)$, such that $(\mathsf{PSA}[i] + f \cdot \delta)$ is a multiple of Δ.

Let Δ_t be $(\log^{\varepsilon}_{\sigma} n)^t$ rounded to the next highest power of 2. We store $\mathsf{DS}(\Delta_{t+1}, f \cdot \Delta_t)$ for all $t \in [0, 1/\varepsilon]$ and $f \in [0, \Delta_{t+1}/\Delta_t)$. Additionally, we store $E^{\Delta_t}_{\Delta_{t+1}}[1, n]$ for all $t \in [0, 1/\varepsilon]$. Therefore, the total space is $n/\varepsilon \times O\big(\log \sigma \log^{\varepsilon}_{\sigma} n + \log(\log^{\varepsilon}_{\sigma} n)\big)$ bits.
To compute $\mathsf{PSA}[i]$, we initialize $k = 0, j = i, t = 0$ and follow the steps below.

1. If $B_{\lambda}[j] = 1$, access $\mathsf{PSA}[j]$ in $O(1)$ time from the sampled-PSA and report $\mathsf{PSA}[j] - k$.
2. Else if $B_{\Delta_{t+1}}[j] = 1$, update $t \leftarrow t + 1$ and go to Step 1.
3. Else find f from $E^{\Delta_t}_{\Delta_{t+1}}[1, n]$, such that $(\mathsf{PSA}[i] + f \cdot \Delta_t)$ is a multiple of Δ_{t+1}. Compute $j' = \Psi^{f \cdot \Delta_t}(j)$ using $\mathsf{DS}(\Delta_{t+1}, f \cdot \Delta_t)$ in $O(1)$ time, update $j \leftarrow j'$ and $k \leftarrow k + f \cdot \Delta_t$. Then go to Step 2.

We issue at most one (constant time) query on $\mathsf{DS}(\Delta_t, \cdot)$ per t. Therefore, $t_{\mathsf{PSA}} = O(1/\varepsilon)$. The computation of $\mathsf{PSA}^{-1}[\cdot]$ (and correctness proof) is analogous to the discussion in the previous two sections.

5 Encoding Parameterized Longest Common Prefix (pLCP) Array

Recall that $\mathsf{PLCP}[i] = \mathsf{plcp}(i, i+1)$ for $1 \le i < n$. We introduce a new encoding scheme, which converts a string S to a string $\mathsf{encode}(S)$ over an alphabet $\Sigma'' = \{0, 1, \ldots, \sigma\}$ as follows. We replace each character $S[i]$ with 0 if i is the first occurrence of $S[i]$, else replace it with the number of distinct characters in $S[j, i]$, where $j < i$ is the rightmost occurrence of $S[i]$ before i. For example, $\mathsf{encode}(xyxxzyx) = 0021033$. For any two strings S and S', $\mathsf{encode}(S) = \mathsf{encode}(S')$ iff $\mathsf{prev}(S) = \mathsf{prev}(S')$; the proof is straightforward using mathematical induction.

Let $T' = \mathsf{encode}(T)$. Let $\mathsf{SA}_{T'}[1, n]$ be the suffix array of T', i.e., $\mathsf{SA}_{T'}[i] = j$ and $\mathsf{SA}^{-1}_{T'}[j] = i$ iff the i^{th} lexicographically smallest suffix of T' starts at position j. Also, let $\mathsf{lcp}_{T'}(i, j)$ be the length of the longest common prefix of the suffixes of T' starting at $\mathsf{SA}_{T'}[i]$ and $\mathsf{SA}_{T'}[j]$. The following is immediate from known results on encoding suffix trees.

▶ **Fact 26** ([20, 35]). *We can answer $\mathsf{SA}_{T'}[\cdot]$ and $\mathsf{SA}^{-1}_{T'}[\cdot]$ queries as follows:*

- *in $\mathsf{t}_{\mathsf{SA}} = O(\log^{\varepsilon}_{\sigma} n)$ time using an $O(n \log \sigma)$-bit index*
- *in $\mathsf{t}_{\mathsf{SA}} = O(\log \log_{\sigma} n)$ time using an $O(n \log \sigma \log \log_{\sigma} n)$-bit index*
- *in $\mathsf{t}_{\mathsf{SA}} = O(1)$ time using an $O(n \log \sigma \log^{\varepsilon}_{\sigma} n)$-bit index*

Moreover, we can answer $\mathsf{lcp}_{T'}(\cdot, \cdot)$ queries in $O(t_{\mathsf{t}_{\mathsf{SA}}})$ time using $O(n)$ extra bits.

We have the following crucial lemma.

▶ **Lemma 27.** *Let x_i be the smallest number such that the number of distinct characters in $T_{\mathsf{PSA}[i]}[1, \mathsf{PLCP}[i]]$ and $T_{\mathsf{PSA}[i]}[1, x_i]$ are the same. Then,*

$$\mathsf{PLCP}[i] = x_i + \mathsf{lcp}_{T'}\Big(\mathsf{SA}^{-1}_{T'}\big[\mathsf{PSA}[i] + x_i\big], \mathsf{SA}^{-1}_{T'}\big[\mathsf{PSA}[i+1] + x_i\big]\Big)$$

Proof. Since $\mathsf{PLCP}[i] \geq x_i$, $y_i = \mathsf{PLCP}[i] - x_i$ is the length of the longest common prefix of the strings obtained by deleting the first x_i characters of $\mathsf{prev}(T_{\mathsf{PSA}[i]})$ and $\mathsf{prev}(T_{\mathsf{PSA}[i+1]})$ respectively. Equivalently, y_i is the longest common prefix of the suffixes of $\mathsf{encode}(T)$ starting at positions $\mathsf{PSA}[i] + x_i$ and $\mathsf{PSA}[i+1] + x_i$ respectively. The proof follows from the definition of x_i. ◀

▶ **Theorem 28.** *Suppose* $\mathsf{PSA}[\cdot]$ *and* $\mathsf{SA}^{-1}_{T'}[\cdot]$ *values are accessible in times* $\mathsf{t_{PSA}}$ *and* $\mathsf{t_{SA}}$ *respectively, we can compute* $\mathsf{PLCP}[i] = x_i + y_i$ *for any* i *in time* $O(\mathsf{t_{SA}} + \mathsf{t_{PSA}})$ *using an* $O(n \log \sigma)$*-bit structure. We can also support* $\mathsf{plcp}(\cdot, \cdot)$ *queries in the same time.*

Proof. We first describe the structure for computing x_i. If $\sigma > \log n$, we store x_i explicitly in $\log n$ bits if $x_i > \sigma \log n$ and in $O(\log(\sigma \log n))$ bits otherwise. All x_i's that are larger than $\sigma \log n$ can be stored in $O(n)$ bits as they are no more than $n/\log n$. The space needed for the rest is $n \log(\sigma \log n) = O(n \log \sigma)$ bits. If $\sigma \leq \log n$, maintain an array C, where $C[i] = T_{\mathsf{PSA}[i]}[x_i]$ and a rank-select data structure (Fact 7) over T. The space is $O(n \log \sigma)$ bits. Since x_i is the first occurrence of $C[i]$ in $T[\mathsf{PSA}[i], n]$, we compute $x_i = \mathsf{select}_T\big(\mathsf{rank}_T\big(\mathsf{PSA}[i] - 1, C[i]\big) + 1, C[i]\big) - \mathsf{PSA}[i] + 1$ in time $t_{\mathsf{PSA}} + O(\log(\log \sigma / \log \log n)) = O(t_{\mathsf{PSA}})$.

We now focus on computing y_i. Find $j = \mathsf{SA}^{-1}_{T'}[\mathsf{PSA}[i] + x_i]$ and $k = \mathsf{SA}^{-1}_{T'}[\mathsf{PSA}[i+1] + x_i]$ in time $O(\mathsf{t_{SA}} + \mathsf{t_{PSA}})$. From Lemma 27, we have $y_i = \mathsf{lcp}_{T'}(j, k)$. We handle $\mathsf{lcp}_{T'}(\cdot, \cdot)$ queries in time $O(t_{\mathsf{SA}})$ using $O(n)$ extra bits [35].

Finally, to answer $\mathsf{plcp}(\cdot, \cdot)$ queries, we maintain a Range Minimum Query (RMQ) structure [8] of size $2n + o(n)$ over the PLCP array with $O(1)$ query time. Then, given any i and $j > i$, compute $k = \arg\min\{\mathsf{PLCP}[k] \mid k \in [i, j)\}$ and report $\mathsf{plcp}(i, j) = \mathsf{PLCP}[k]$. ◀

Theorem 3 follows from Theorem 28, Fact 26, and the trade-offs in Section 4.

Abstract

The generic homomorphism problem, which asks whether an input graph G admits a homomorphism into a fixed target graph H, has been widely studied in the literature. In this article, we provide a fine-grained complexity classification of the running time of the homomorphism problem with respect to the clique-width of G (denoted cw) for virtually all choices of H under the Strong Exponential Time Hypothesis. In particular, we identify a property of H called the signature number $s(H)$ and show that for each H, the homomorphism problem can be solved in time $\mathcal{O}^*(s(H)^{\mathrm{cw}})$. Crucially, we then show that this algorithm can be used to obtain essentially tight upper bounds. Specifically, we provide a reduction that yields matching lower bounds for each H that is either a projective core or a graph admitting a factorization with additional properties – allowing us to cover all possible target graphs under long-standing conjectures.

1 Introduction

A *homomorphism* from a graph G to a graph H is an edge-preserving mapping from the vertices of G to the vertices of H. Homomorphisms are fundamental constructs which have been studied from a wide variety of perspectives [2, 3, 13]. Our focus here will be on the

class of problems which ask whether an input n-vertex graph G admits a homomorphism to a fixed target graph H. This "meta-problem" – which we simply call $\textsc{Hom}(H)$ – captures, among others, the classical c-Coloring problems when H is set to the complete graph on c vertices. Famously, Hell and Nešetřil [15] proved that $\textsc{Hom}(H)$ is polynomial-time solvable if H is bipartite or has a loop, and NP-complete otherwise.

While the aforementioned result provides a basic classification of the complexity of $\textsc{Hom}(H)$, it does not say much in terms of how quickly one can actually solve these problems. Indeed, the usual assumption that $\mathsf{P} \neq \mathsf{NP}$ is not sufficient to obtain tight bounds for the running times of algorithms. While upper bounds can be straightforwardly obtained by designing a suitable algorithm, the corresponding lower bounds usually rely on the Exponential Time Hypothesis (ETH) or the Strong Exponential Time Hypothesis (SETH), which allows for even tighter bounds [18, 19, 23]. It is not difficult to design a brute-force algorithm for the homomorphism problem that runs in time $\mathcal{O}^*(|V(H)|^n)$ for every choice of H, and thanks to the breakthrough result of Cygan et al. we now know that this running time is essentially tight under the Exponential Time Hypothesis (ETH) [6] as long as one considers only the dependency on n and $|V(H)|$.

Still, it is often possible to circumvent this lower bound and obtain significantly better runtime guarantees. One approach to do so is to consider restrictions on the class of targets: if H is a complete graph then $\textsc{Hom}(H)$ can be solved in time $\mathcal{O}^*(2^n)$, and there are also several algorithms that achieve running times of the form $\mathcal{O}^*(\alpha(H)^n)$ where $\alpha(H)$ is some structural parameter of H [12, 29, 30]. The other is to exploit the properties of the input graph G, which are commonly captured by a suitably defined structural parameter. The most commonly used graph parameter in this respect is *treewidth* [28], which informally measures how "tree-like" a graph is.

When considering treewidth, it is once again not difficult to obtain an algorithm that runs in time $\mathcal{O}^*(|V(H)|^{\mathrm{tw}})$, where tw is the treewidth of G; as before, it was much more difficult to show that this is essentially optimal. The first SETH-based tight lower bound in this setting was actually shown for special cases of the related problem of $\textsc{LHom}(H)$, where each vertex in the graph G comes with a list of admissible targets for the homomorphism [9]; this was later lifted to a full classification [24]. A nearly-complete SETH-based lower bound result for $\textsc{Hom}(H)$ itself was only obtained recently by Okrasa and Paweł Rzążewski [25]; in particular, the result covers all targets which are so-called *projective cores*. It is known that almost all graphs are projective cores [16, 25, 31], and it is worth noting that the authors showed that their result can be lifted to all targets under long-standing conjectures on the properties of projective cores [21, 22].

While treewidth is the most prominent structural graph parameter, it is not the most general[1] one that can be used to efficiently solve $\textsc{Hom}(H)$. Indeed, standard dynamic programming techniques can be used to obtain a $\mathcal{O}^*((2^{|V(H)|})^{\mathrm{cw}})$ time algorithm for the problem, where cw stands for *clique-width* [4]: a well-studied graph parameter that is bounded not only on all graph classes of bounded treewidth, but also on well-structured dense classes such as complete graphs. But is this basic algorithm generally optimal (mirroring the situation for treewidth [25]), or can one obtain better runtime dependencies on clique-width?

Contribution. Our aim is to obtain a detailed understanding of the fine-grained complexity of $\textsc{Hom}(H)$ in terms of the clique-width of G and the fixed target H. As a starting point for our investigation, we note that Lampis used the SETH to obtain tight bounds for c-Coloring

[1] There is a hierarchy of graph parameters (see, e.g., [1, Figure 1]), where parameter $\mathbb{A}$ is more general than parameter $\mathbb{B}$ if there are graph classes of bounded $\mathbb{A}$ and unbounded $\mathbb{B}$ but the opposite is not true.

with respect to clique-width [20]. Interestingly, already for this special case, the upper and lower bounds differ from those of the aforementioned simple dynamic programming algorithm: if H is a complete graph, then $\textsc{Hom}(H)$ can be solved in time $\mathcal{O}^*((2^{|V(H)|}-2)^{\mathrm{cw}})$ [20] and this is tight under the SETH. However, as noted by Piecyk and Rzążewski [27], it was not at all obvious how these bounds can be lifted to general choices of H.

In order to achieve our goals we need to improve upon the basic dynamic programming idea to identify a "hopefully correct" base of the exponent for every choice of H. Towards our first result, we identify a structural property of H called the *signature number* (denoted $s(H)$) which, intuitively, captures the number of non-trivial neighborhood classes of vertex subsets in H (the *signature set*). We then obtain a non-trivial dynamic programming algorithm that solves $\textsc{Hom}(H)$ in time where the base of the exponent is precisely the signature number. We note that $s(H)$ is $2^{|V(H)|}-2$ for complete graphs H, and so this result also provides a succinct and broader explanation for the running time of Lampis' algorithm [20].

▶ **Theorem 1.** *Let H be a fixed graph. $\textsc{Hom}(H)$ can be solved in time $\mathcal{O}^*(s(H)^{\mathrm{cw}(G)})$ for each input graph G, assuming an optimal clique-width expression of G is provided as part of the input.*

With this upper bound, we proceed to the main technical contribution of this paper: establishing a corresponding lower bound under the SETH. The main difficulty here is that we need a reduction that is delicate on one hand, since it needs to preserve the clique-width, but is on the other hand also flexible enough to work for many different choices of H; moreover, the reduction has to rely on the signature numbers of these graphs in some way.

To provide an intuitive description of the reduction, let us focus for now on the case where H is a projective core. On a high level, the main building block is an *S-gadget* which, given an arbitrary set S of pairs of vertices in H and two vertices p and q of the input graph G, ensures that every homomorphism f satisfies $(f(p), f(q)) \in S$. After providing a generic construction for such S-gadgets which is clique-width preserving and works for every valid choice of H, we use these to obtain *implication gadgets* and *or gadgets* which restrict how a solution homomorphism can behave on a selected set of vertices in G. The formalization of these gadgets is the main technical hurdle towards the desired result; once that is done, we can lift the idea used in the earlier reduction of Lampis [20] that established clique-width lower bounds for c-Coloring by reducing from Constraint Satisfaction (CSP) to $\textsc{Hom}(H)$. One crucial distinction in our reduction is that we use elements of the signature set (as opposed to color sets) to represent domain values in the CSP instance.

To lift these considerations to cases where H is not a projective core, we unfortunately need to add an extra layer of complexity. Similarly as in the previous treewidth-based lower bound for $\textsc{Hom}(H)$ [25], one can base this step on conjectures of Larose and Tardif [21,22] that classify all remaining targets as certain graph products with special properties (notably, all of the factors must be "truly projective"). The approach used for treewidth [25] was then to essentially repeat all steps of the proof for projective cores, with the added difficulty that one uses the properties of products instead of dealing directly with projective cores.

While this approach could be used here as well, instead we unify the two cases (H being a projective core, and H being a product) by defining the notion of W-projectivity for some factor W of H. In particular, if H is a projective core then it itself is H-projective, while if H is a product with truly projective factor H_i then it is H_i-projective. As our main result, we obtain an SETH-based lower bound which essentially shows that for each W-projective graph H, $s(W)$ is the optimal base of the clique-width exponent for solving $\textsc{Hom}(H)$:

▶ **Theorem 2.** *Let H be a fixed non-trivial core with prime factorization $H_1 \times \ldots \times H_m$. Assume that H is H_i-projective for some $i \in [m]$. Then there is no algorithm solving $\textsc{Hom}(H)$ in time $\mathcal{O}^*((s(H_i) - \varepsilon)^{\mathrm{cw}(G)})$ for any $\varepsilon > 0$, unless the* SETH *fails.*

By also deliberately considering prime factorizations in the algorithm which we provide for Theorem 1, we can obtain an upper bound on the complexity of $\textsc{Hom}(H)$ that matches the lower bound from Theorem 2. For a discussion explicitly relating these complexity bounds in the context of the aforementioned conjectures of Larose and Tardif, we refer to Section 6.

2 Preliminaries

We use standard terminology for graph theory [7]. Let $[i]$ denote the set $\{1, \ldots, i\}$. For a mapping $f : A \to B$ and $A' \subseteq A$, let $f|_{A'}$ denote the restriction of f to A'. We will use the $\mathcal{O}^*(\cdot)$ notation to suppress factors polynomial in the input size.

Homomorphisms and Cores

For two graphs G and H, a *homomorphism* from G to H is a mapping $h : V(G) \to V(H)$, such that for every $uv \in E(G)$ we have $h(u)h(v) \in E(H)$. If there exists a homomorphism from G to H, we denote this fact by $G \to H$, and if h is a homomorphism from G to H, we denote that by $h : G \to H$. If there is no homomorphism from G to H, we write $G \not\to H$. If $G \to H$ and $H \to G$, we say that G and H are *homomorphically equivalent*. In particular, since the composition of homomorphisms is a homomorphism, if G and H are homomorphically equivalent, then for every graph F we have that $F \to G$ if and only if $F \to H$. It is straightforward to verify that homomorphic equivalence is an equivalence relation on the class of all graphs. On the other hand, if $G \not\to H$ and $H \not\to G$ for some graphs G, H, we say that G and H are *incomparable*.

We say that a graph H is a *core* if every homomorphism $h : H \to H$ is an automorphism. Equivalently, H is a core if for every proper induced subgraph H' of H it holds that $H \not\to H'$. We say that a core H' is a *core of* H if H' is an induced subgraph of H and $H \to H'$. Clearly, each core graph is a core of itself. Each graph has a unique (up to isomorphism) core, and the core of H can be equivalently defined as the smallest (with respect to the number of vertices) graph that is homomorphically equivalent with H [16].

A graph H is *ramified* if $N(u) \not\subseteq N(v)$ for every two distinct vertices u, v of H. Observe that each core is ramified; otherwise one could define $f : H \to H$ that is an identity on all vertices of H but u and set $f(u) = v$. This would be a homomorphism to a proper subgraph of H, contradicting the fact that H is a core.

We say that a graph H is *trivial* if its core has at most two vertices.

▶ **Observation 3** ([15])**.** *A graph H is trivial if and only if it is either bipartite or contains a vertex with a loop.*

Proof. It is straightforward to observe that there exist three trivial cores: K_1, K_2, and K_1^*, where by K_1^* we denote the graph that consists of one vertex with a loop.

If H contains a vertex with a loop, then K_1^* is the core of H. If H is bipartite, then the core of H is either K_1 (if H has no edges) or K_2 (since mapping the vertices of one bipartition class to one vertex of K_2, and another bipartition graph to the other, is a homomorphism).

For the other direction, assume that H is a non-bipartite loopless graph. Since it is loopless, K_1^* cannot be its core. Clearly, H has at least one edge, and therefore $H \not\to K_2$ Moreover, H contains an odd cycle C_{2k+1} as a subgraph, hence, $C_{2k+1} \to H$. If now $H \to K_2$, composition of these homomorphism gives that $C_{2k+1} \to K_2$, which is equivalent to stating that C_{2k+1} is 2-colorable, a contradiction. ◀

Observe that trivial cores H correspond precisely to the polynomial cases of the $\textsc{Hom}(H)$ problem. Since our aim is to focus on the NP-hard cases of the problem, from here onward we will assume that the target graph is non-trivial.

Signature Sets

For a vertex v of a graph H, let $N_H(v)$ denote the set of neighbors of v in H. If the graph is clear from the context, we will omit the subscript H and write $N(v)$.

For a non-empty set $T \subseteq V(H)$ we say that $S(T)$ is the *signature set of* T if $S(T) = \bigcap_{t \in T} N(t)$. We say that a non-empty set $S \subseteq V(H)$ is a *signature set*, if there exists T such that $S = S(T)$. We denote by $\mathcal{S}(H)$ the set of all signature sets of H, and we note that $\{V(H), \emptyset\} \cap \mathcal{S}(H) = \emptyset$.

▶ **Observation 4.** *If T is a proper non-empty subset of $V(H)$, and $a \in T$, $b \in S(T)$, then $ab \in E(H)$. Moreover, for non-empty subsets $A, B \subseteq V(H)$, $S(A \cup B) = S(A) \cap S(B)$.*

We note that the operation of taking a signature set is reversible on $\mathcal{S}(H)$:

▶ **Observation 5.** *For every $A \in \mathcal{S}(H)$, $S(S(A)) = A$.*

Proof. By the definition of signature set, $A \times S(A) \subseteq E(H)$, so $A \subseteq S(S(A))$. For the converse direction observe that as $A \in \mathcal{S}(H)$, there exists a non-empty subset T of $V(H)$ such that $A = S(T)$. Pick any $x \in S(S(A))$, then $E(H) \supseteq \{x\} \times S(A) = \{x\} \times S(S(T)) \supseteq \{x\} \times T$. Hence by definition $x \in S(T) = A$. ◀

Let the *signature number* of H, denoted $s(H)$, be defined as $|\mathcal{S}(H)|$. As mentioned in the introduction, the signature number will play a crucial role in our upper and lower bounds.

Observe that, if H is a target and hence non-trivial, for every nonempty $T \subseteq V(H)$ we have that $S(T) \cap T = \emptyset$. From that it is easy to see that $V(H)$ never belongs to $\mathcal{S}(H)$. Since, by definition, $\emptyset \notin \mathcal{S}(H)$, we get the following bounds for $s(H)$.

▶ **Observation 6.** *Let H be a graph with no loops. Then $s(H) \leqslant 2^{|V(H)|} - 2$.*

Notice that since $2^{|V(H)|} - 2$ is the number of all proper non-empty subsets of $V(H)$, the equality in Observation 6 holds if and only if H is a clique.

If $S \in \mathcal{S}(H)$, we call T such that $S(T) = S$ a *witness* of S. Clearly, we can have distinct T_1, T_2 such that $S(T_1) = S(T_2)$, however, notice that in such a case there exists $T = T_1 \cup T_2$ such that $S(T) = S(T_1) = S(T_2)$. Hence, there exists a unique maximal (with respect to inclusion) witness of S, and we denote it by $M(S)$. In fact, it is not difficult to see that $M(S) = \{v \in V(H) \mid S \subseteq N_H(v)\}$; for $S(M(S)) = S$ to hold, it is clearly necessary that $S \subseteq N_H(v)$ for all $v \in M(S)$. On the other hand, as $M(S)$ is maximal all v for which this is true are contained in $M(S)$.

In this way signature sets and their witnesses are in one-to-one correspondence. While not necessary to obtain our algorithmic and lower bounds for $\textsc{Hom}(H)$ parameterized by clique-width, this offers an alternative perspective on the role of signatures in our results.

In fact, the signature number could equivalently be defined as the "maximal witness number" and signature sets could be replaced by maximal witnesses in all our proofs: Let $\mathcal{M}(H) = \{M(S) : S \in \mathcal{S}(H)\}$.

▶ **Observation 7.** $\mathcal{S}(H) = \mathcal{M}(H)$.

Proof. Let T be a fixed non-empty subset of $V(H)$ such that $S(T) \neq \emptyset$. Observe that the definition and the maximality of $M(S(T))$ implies that $S(S(T)) = \bigcap_{t \in S(T)} N(t) = M(S(T))$ Since T and $S(T)$ are non-empty, we get that $\mathcal{S}(H) \supset \mathcal{M}(H)$. For the other direction observe that $M(M(S(T))) = S(T)$. Assume the contrary, then there exists a vertex $v \notin S(T)$ such that $N(v) \supset M(S(T))$. However, $T \subset M(S(T)) \subset N(v)$ meaning that $v \in S(T)$, a contradiction. Thus, $\mathcal{S}(H) = \mathcal{M}(H)$. ◀

We note that if H is a core graph, we can also bound the minimum cardinality of $\mathcal{S}(H)$.

▶ **Observation 8.** *Let H be a core graph, $H \neq K_1$. Then $s(H) \geqslant |V(H)|$.*

Proof. Observe that if H is a core distinct from K_1, then it does not contain isolated vertices. Therefore, for each $v \in V(H)$ we have $N(v) \in \mathcal{S}(H)$. On the other hand, since H is a core, it is ramified. In particular, for every distinct $v, w \in V(H)$ we have $N(v) \neq N(w)$. Hence different vertices give rise to different signature sets. ◀

Clique-Width and Clique-Width Expressions

For a positive integer k, we let a *k-graph* be a graph whose vertices are labeled by $[k]$. For convenience, we consider a graph to be a k-graph with all vertices labeled by 1. We call the k-graph consisting of exactly one vertex v (say, labeled by i) an initial k-graph and denote it by $i(v)$.

The *clique-width* of a graph G is the smallest integer k such that G can be constructed from initial k-graphs by means of iterative application of the following three operations:

1. Disjoint union (denoted by $\oplus$);
2. Relabeling: changing all labels i to j (denoted by $\rho_{i \to j}$);
3. Edge insertion: adding an edge from each vertex labeled by i to each vertex labeled by j ($i \neq j$; denoted by $\eta_{i,j}$).

A construction of a k-graph G using the above operations can be represented by an algebraic term composed of $\oplus$, $p_{i \to j}$ and $\eta_{i,j}$ (where $i \neq j$ and $i, j \in [k]$). Such a term is called a k-expression defining G, and we often view it as a tree with each node labeled with the appropriate operation. Conversely, we call the k-graph that arises from a k-expression its *evaluation*. The *clique-width* of G is the smallest integer k such that G can be defined by a k-expression which we then also call a *clique-width expression* of G.

Many graph classes are known to have constant clique-width; examples include all graph classes of constant treewidth and co-graphs [5]. Moreover a fixed-parameter algorithm is known to compute a k-expression of the input where k is bounded in $f(\mathrm{cw})$ [26].

3 Algorithm

As our first contribution, we obtain an algorithm that will play a crucial role for upper-bounding the fine-grained complexity of $\textsc{Hom}(H)$.

▶ **Theorem 1.** *Let H be a fixed graph. $\textsc{Hom}(H)$ can be solved in time $\mathcal{O}^*(s(H)^{\mathrm{cw}(G)})$ for each input graph G, assuming an optimal clique-width expression of G is provided as part of the input.*

Proof. Assume, w.l.o.g., that G is connected and $|V(G)| > 1$. We will describe a dynamic program that proceeds in a leaf-to-root fashion along the provided k-expression σ of G. For a subexpression $\tau \subseteq \sigma$, we denote the evaluation of τ by G_τ, and by $V_\tau^i \subseteq V(G_\tau)$ the vertex

set that has label i in G_τ. We say that i is a *live label* in τ if there is an edge of G which is incident to V_τ^i and does not appear in G_τ. Denote the set of live labels in τ by L_τ. Since G is connected, $L_\tau \neq \emptyset$ for any proper subexpression τ of σ.

For each subexpression τ of σ, we will compute a set P_τ consisting of functions $p\colon L_\tau \to \mathcal{S}(H)$ where $p \in P_\tau$ if and only if there exists a homomorphism h_p from G_τ to H such that $p(i) \subseteq S(h_p(V_\tau^i))$, $i \in L_\tau$. We will say that $p \in P_\tau$ *describes* the homomorphism h_p in τ or, equivalently, that h_p *witnesses* p in τ. Intuitively, we will use $p(i)$ to preemptively store the images of the neighbors of V_τ^i in the final graph G – that is why we store not only the exact signature, but all signatures that occur as subsets. We remark that storing the "current" images of the neighbors of V_τ^i in G_τ would be sufficient to obtain a conceptually simpler fixed-parameter algorithm parameterized by clique-width, but in that case it is not obvious how one can avoid a quadratic dependency on clique-width in the exponent.

Observe that for any homomorhism $h\colon G_\tau \to H$, images of vertices with live labels should be connected in H with images of their future neighbors. In particular, for any $i \in L_\tau$, $S(h(V_\tau^i)) \neq \emptyset$ and hence $S(h(V_\tau^i)) \in \mathcal{S}(H)$. Therefore h is described in τ by some $p \in P_\tau$. By definition, $L_\sigma = \emptyset$ and hence G is homomorphic to H if and only if P_σ contains the empty mapping, i.e., if $P_\sigma = \{\emptyset\}$ (as opposed to $P_\sigma = \emptyset$). It remains to show how to correctly compute each P_τ. To do so, we distinguish based on the outermost operation of τ:

(a) $\tau = i(v)$ for some $i \in [\mathrm{cw}(G)]$. In this case $L_\tau = \{i\}$, and P_τ contains all functions $p : \{i\} \mapsto \mathcal{S}(H)$ such that $p(i) \subseteq N_H(u)$ for some $u \in V(H)$.

(b) $\tau = \rho_{i\to j}(\tau')$ and $P_{\tau'}$ has already been computed. If $i \notin L_{\tau'}$, we can correctly set $L_\tau = L_{\tau'}$ and $P_\tau = P_{\tau'}$. If $i \in L_{\tau'}$ and $j \notin L_{\tau'}$, then $L_\tau = (L_{\tau'} \setminus \{i\}) \cup \{j\}$ and

$$P_\tau = \left\{ p\colon L_\tau \to \mathcal{S}(H) \;\middle|\; \exists p' \in P_{\tau'} : \quad p(\ell) = \begin{cases} p'(\ell) & \text{if } \ell \neq j \\ p'(i) & \text{if } \ell = j \end{cases} \right\}.$$

Finally, if $\{i, j\} \subseteq L_{\tau'}$, then $L_\tau = L_{\tau'} \setminus \{i\}$ and $P_\tau = \{p'|_{L_\tau} \mid p' \in P_{\tau'} \wedge p'(i) = p'(j)\}$.

For correctness in the last case, let h be a homomorphism from G_τ to H and $S_\ell \in \mathcal{S}(H)$ be such that $S_\ell \subseteq S(h(V_\tau^\ell))$, $\ell \in L_\tau$. Observe that $V_\tau^\ell = V_{\tau'}^\ell$ for $\ell \in L_\tau \setminus \{j\}$ and $V_\tau^j = V_{\tau'}^j \cup V_{\tau'}^i$. In particular, $S_j \subseteq S(h(V_{\tau'}^i))$ and $S_j \subseteq S(h(V_{\tau'}^j))$. By definition of $P_{\tau'}$, there exists $p' \in P_{\tau'}$ such that $p'(\ell) = S_\ell$ for $\ell \in L_\tau \setminus \{j\}$ and $p'(i) = p'(j) = S_j$. The function $p \in P_\tau$, defined by $p = p'|_{L_\tau}$, satisfies $p'(\ell) = S_\ell$, $\ell \in L_\tau$.

On the other hand, fix some $p \in P_\tau$. Let $p' \in P_{\tau'}$ be a function such that p arises from p' in the construction of P_τ. Consider a witness h of p' in τ'. For every $\ell \in L_\tau \setminus \{j\}$ we have $V_\tau^\ell = V_{\tau'}^\ell$ and so $p(\ell) = p'(\ell) \subseteq S(h(V_\tau^\ell))$. Moreover, $p(j) = p'(j) \subseteq S(h(V_{\tau'}^j))$ and $p(j) = p'(i) \subseteq S(h(V_{\tau'}^i))$. By Observation 4, we have $p(j) \subseteq S(h(V_{\tau'}^i)) \cap S(h(V_{\tau'}^j)) = S(h(V_{\tau'}^i \cup V_{\tau'}^j)) = S(h(V_\tau^j))$. Hence p witnesses h in τ.

(c) $\tau = \tau^{(1)} \oplus \tau^{(2)}$ where $P_{\tau^{(1)}}$ and $P_{\tau^{(2)}}$ have already been computed. In this case $L_\tau = L_{\tau^{(1)}} \cup L_{\tau^{(2)}}$. We define

$$P_\tau = \{p = p_1 \cup p_2 \mid p_1 \in P_{\tau^{(1)}} \wedge p_2 \in P_{\tau^{(2)}} \wedge (\forall \ell \in L_{\tau^{(1)}} \cap L_{\tau^{(2)}} : p_1(\ell) = p_2(\ell))\}$$

Intuitively, we construct a homomorphism on the disjoint union of two subgraphs by "gluing together" the homomorphisms on the subgraphs. If the subgraphs share any live labels, after this step they will all be treated equally. For this reason we require the images of the neighbors of such labels to be the same in both subgraphs.

For correctness, let h be a homomorphism from G_τ to H and $S_\ell \in \mathcal{S}(H)$ be such that $S_\ell \subseteq S(h(V_\tau^\ell))$, $\ell \in L_\tau$. Observe that for every $\ell \in L_{\tau^{(1)}} \cap L_{\tau^{(2)}}$, $V_\tau^\ell \supseteq V_{\tau^{(i)}}^\ell$, so $S_\ell \subseteq S(h(V_{\tau^{(i)}}^\ell))$, $i = 1, 2$. By definition, there exists $p_i \in P_{\tau^{(i)}}$ such that $p_i(\ell) = S_\ell$ for $\ell \in L_{\tau^{(i)}}$, $i = 1, 2$. For $p = p_1 \cup p_2$ we have $p(\ell) = S_\ell$, $\ell \in L_\tau$.

For the converse, fix some $p \in P_\tau$. Let $p_1 \in P_{\tau^{(1)}}$, $p_2 \in P_{\tau^{(2)}}$ be functions such that $p = p_1 \cup p_2$. Let h_i be a witness of p_i in $\tau^{(i)}$, $i = 1, 2$. We define $h = h_1 \cup h_2$. Since G_τ doesn't contain edges between $V(G_{\tau^{(1)}})$ and $V(G_{\tau^{(2)}})$, h is a homomorphism from G_τ to H. For all $\ell \in L_{\tau^{(1)}} \setminus L_{\tau^{(2)}}$, we have $p(\ell) = p_1(\ell) \subseteq S(h_1(V_\tau^\ell)) = S(h(V_\tau^\ell))$, similarly for $\ell \in L_{\tau^{(1)}} \setminus L_{\tau^{(2)}}$. For $\ell \in L_{\tau^{(1)}} \cap L_{\tau^{(2)}}$, we have $p(\ell) = p_i(\ell) \subseteq S(h_i(V_{\tau^{(i)}}^\ell))$, $i = 1, 2$, so $p(\ell) \subseteq S(h_1(V_{\tau^{(1)}}^\ell)) \cap S(h_2(V_{\tau^{(2)}}^\ell)) = S(h(V_\tau^\ell))$. Hence h is a witness of p in τ.

(d) $\tau = \eta_{i,j}(\tau')$ and $P_{\tau'}$ has already been computed. In this case $L_\tau = L_{\tau'} \setminus I$ where $I \subseteq \{i, j\}$ is the set of live labels in τ' that are no longer live labels in τ. We set $P_\tau = \{p : L_\tau \to \mathcal{S}(H) \mid \exists p' \in P_{\tau'} \colon \big(p'(i) \supseteq S(p'(j)) \wedge p|_{L_\tau \setminus \{i,j\}} = p'|_{L_\tau \setminus \{i,j\}} \wedge p(i) \subseteq p'(i) \wedge p(j) \subseteq p'(j)\big)\}$.

Intuitively, we can add the edges between two live labels if and only if there are edges between their images in H. Our restriction on p' is an expression of this condition in terms of images of neighbors and their signatures. Indeed, for correctness, let h be a homomorphism from G_τ to H and $S_\ell \in \mathcal{S}(H)$ be such that $S_\ell \subseteq S(h(V_\tau^\ell))$, $\ell \in L_\tau$. There exists $p' \in P_{\tau'}$ such that $p'(\ell) = S_\ell$ for all $\ell \in L_\tau \setminus \{i, j\}$, $p'(i) = S(h(V_\tau^i))$ and $p'(j) = S(h(V_\tau^j))$. As h is a homomorphism, we have $h(V_{\tau'}^i) \times h(V_{\tau'}^j) \subseteq E(H)$, which means that $S(h(V_{\tau'}^j)) \supseteq h(V_{\tau'}^i)$, i.e. $p'(j) \supseteq h(V_{\tau'}^i)$. Then $S(p'(j)) \subseteq S(h(V_{\tau'}^i)) = p'(i)$ and hence p' gives rise to $p \in P_\tau$ such that $p(\ell) = S_\ell$, $\ell \in L_\tau$.

On the other hand, let $p \in P_\tau$ arise from $p' \in P_{\tau'}$. Consider a witness $h \colon G_{\tau'} \to H$ of p' in τ'. To see that h preserves edges between $V_{\tau'}^i$ and $V_{\tau'}^j$, recall that $p'(i) \supseteq S(p'(j))$, so $S(h(V_{\tau'}^i)) \supseteq p'(i) \supseteq S(p'(j)) \supseteq S(S(h(V_{\tau'}^j))) \supseteq h(V_{\tau'}^j)$. Hence $h(V_{\tau'}^i) \times h(V_{\tau'}^j) \subseteq E(H)$ and h is a homomorphism from G_τ to H. By construction, for every $\ell \in L_\tau$ it holds that $p(\ell) \subseteq p'(\ell) \subseteq S(h(V_\tau^\ell))$, so h witnesses p in τ.

It is easy to verify that $|P_\tau| \leqslant s(H)^{\mathrm{cw}(G)}$ for each subexpression τ of σ. This means that in each step, the computation requires time $\mathcal{O}(\mathrm{cw}(G) s(H)^2 s(H)^{\mathrm{cw}((G))})$. Overall this yields a complexity of $\mathcal{O}(|V(G)| \mathrm{cw}(G) s(H)^2 s(H)^{\mathrm{cw}((G))}) \subseteq \mathcal{O}^*(s(H)^{\mathrm{cw}(G)})$. ◀

4 On Products and Projectivity

While Theorem 1 will serve as the upper bound that will match our target SETH-based lower bounds for $\textsc{Hom}(H)$ for the "most difficult" choices of H, in many cases one can in fact supersede the algorithm's runtime by exploiting well-known properties of target graphs.

As a simple example showcasing this, consider the *wheel* graph W_6 (see Figure 1). Since W_6 is 3-colorable, it holds that $W_6 \to K_3$, and since K_3 is a core and an induced subgraph of W_6, it is the core of W_6. We recall that if H is a core of H', then for every graph G it holds that $G \to H$ if and only if $G \to H'$. Hence, having an instance G of $\textsc{Hom}(W_6)$, we can compute a core of W_6 (since we assume that the target graph is fixed, this can be done in constant time), and use Theorem 1 for $H = K_3$ to decide whether $G \to W_6$ in total running time $\mathcal{O}^*(s(K_3)^{\mathrm{cw}(G)})$. As $s(K_3) < s(W_6)$ (as showcased in Figure 1), this yields a better running time bound than the direct use of Theorem 1. While this example shows that the signature number can decrease by taking an induced subgraph, we remark that it can never increase.

▶ **Observation 9.** *Let H and H' be graphs such that H is an induced subgraph of H'. Then $s(H) \leqslant s(H')$.*

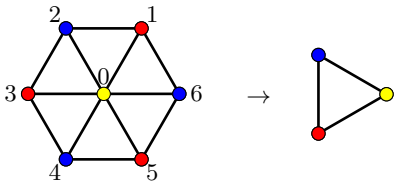

Figure 1 The graphs W_6 (left) and K_3 (right). Colors on the vertices of W_6 indicate the homomorphism $h : W_6 \to K_3$. We note that $\{\{0\}\} \cup \{\{0, i\} \mid i \in [6]\} \subseteq \mathcal{S}(W_6)$. Since K_3 is a clique, we have $s(K_3) = 6 < 7 \leqslant s(W_6)$.

Proof. Given a connected graph Q without loops, one may consider an equivalence relation $\sim_Q$ on the set of proper nonempty subsets of $V(Q)$ defined as follows: $V_1 \sim_Q V_2$ if and only if V_1 and V_2 have the same signature sets in Q. Observe that $s(Q)$ is equal to the number of equivalence classes of $\sim_Q$. Hence to prove the claim, it suffices to show that whenever two sets belong to different equivalence classes of $\sim_H$, they also belong to different equivalence classes of $\sim_{H'}$. For this, consider any two proper non-empty subsets V_1 and V_2 of $V(H)$ such that $V_1 \nsim_H V_2$. Without loss of generality, we assume that there exists $v \in (\bigcap_{t \in V_1} N_H(t)) \setminus (\bigcap_{t \in V_2} N_H(t))$. Then $vt \in E(H) \subseteq E(H')$ for every $t \in V_1$, i.e., v belongs to the signature set of V_1 in H'. On the other hand, $vt_0 \notin E(H)$ for some $t_0 \in V_2$. As H is induced subgraph of H', it means that $vt_0 \notin E(H')$, so v doesn't belong to the signature set of V_2 in H' and hence $V_1 \nsim_{H'} V_2$. ◀

At this point, we may ask whether the procedure of simply computing the unique core H of the fixed target H' and then applying Theorem 1 for H could yield a tight upper bound for $\textsc{Hom}(H')$. Unfortunately, the situation is more complicated than that, and we need to introduce a few important notions in order to capture the problem's fine-grained complexity.

Let the *direct product* $H_1 \times H_2$ of graphs H_1, H_2 be the graph defined as follows:

$$V(H_1 \times H_2) = V(H_1) \times V(H_2),$$
$$E(H_1 \times H_2) = \{(x_1, x_2)(y_1, y_2) : x_i y_i \in E(H_i) \text{ for every } i \in \{1, 2\}\}.$$

We call H_1 and H_2 the *factors* of $H_1 \times H_2$. Clearly, the operation $\times$ is commutative, and since it is also associative, we can naturally extend the definition of direct product to more than two factors, i.e., $H_1 \times H_2 \times \ldots \times H_m = H_1 \times (H_2 \times \ldots \times H_m)$. Note that for every graph H that contains at least one edge, it holds that $H \times K_1^* = H$.

In the remaining part of the paper we will often consider vertices that are tuples. If such a vertex is an argument of some function and in cases where this does not lead to confusion, we omit one pair of brackets; similarly, we omit internal brackets in nested tuples where this does not lead to confusion. Moreover, for any graph H and for an integer ℓ, we denote by H^ℓ the graph $\overbrace{H \times \ldots \times H}^{\ell}$. As an example, instead of writing $((x_1, x_2), y_1) \in ((H_1 \times H_1) \times H_2)$, we write $(x_1, x_2, y_1) \in (H_1^2 \times H_2)$.

If $H = H_1 \times \ldots \times H_m$ for some graphs $H_1, \ldots, H_m$, we say that $H_1 \times \ldots \times H_m$ is a *factorization* of H. A graph H on at least two vertices is *prime* if the fact that $H = H_1 \times H_2$ for some graphs H_1, H_2 implies that $H_1 = K_1^*$ or $H_2 = K_1^*$. If H has a factorization $H_1 \times \ldots \times H_m$ such that for every $i \in [m]$ the graph H_i is prime, we call $H_1 \times \ldots \times H_m$ a *prime factorization* of H.

▶ **Theorem 10** ([8, 14]). *Any connected non-bipartite graph with more than one vertex has a unique prime factorization (into factors with possible loops).*

Consider a graph $H_1 \times \ldots \times H_m$, and let $i \in [m]$. A mapping $\pi_i : V(H_1 \times \ldots \times H_m) \to V(H_i)$ such that $\pi_i(x_1, \ldots, x_\ell) = x_i$ is called the (i-th) *projection* of $H_1 \times \ldots \times H_m$. Clearly, such a mapping is always a homomorphism.

▶ **Observation 11.** *Let $G, H_1, \ldots, H_m$ be graphs. Then $G \to H_1 \times \ldots \times H_m$ if and only if for every $i \in [m]$ we have $G \to H_i$.*

Proof. Let $f : G \to H_1 \times \ldots \times H_m$. Then for every $i \in [m]$ (by $[m]$ we denote the set of integers $\{1, \ldots, m\}$) we have a homomorphism $f_i : G \to H_i$. Conversely, if for every $i \in [m]$ we have $g_i : G \to H_i$, then we can define $g : G \to H_1 \times \ldots \times H_m$ as $g(x) = (g_1(x), \ldots, g_m(x))$. ◀

Crucially, in some cases Observation 11 allows us to improve the bounds given by Theorem 1 even if H is a core, simply by considering all possible factorizations of H.

▶ **Corollary 12.** *Let H be a graph with factorization $H_1 \times \ldots \times H_m$, and let G be an instance graph of Hom(H). Assuming that the clique-width expression σ of G of width $\mathrm{cw}(G)$ is given, the Hom(H) problem can be solved in time $\max_{i \in [m]} \mathcal{O}^*\big(s(H_i)^{\mathrm{cw}(G)}\big)$.*

Proof. Observe that if G is an instance of Hom(H), by Theorem 1 for every $i \in [m]$ we can decide whether $G \to H_i$ in time $\mathcal{O}^*\big(s(H_i)^{\mathrm{cw}(G)}\big)$. Then, if G is a yes-instance of Hom(H_i) for every $i \in [m]$, we return that G is a yes-instance of Hom(H). Otherwise, we return that G is a no-instance of Hom(H). The correctness of this procedure follows from Observation 11. ◀

On the other hand, the notion of signature sets we introduced in the previous section behaves multiplicatively with respect to taking direct product of graphs.

▶ **Observation 13.** *Let $H = H_1 \times H_2$. Then $\mathcal{S}(H) = \mathcal{S}(H_1) \times \mathcal{S}(H_2)$.*

Proof. We prove that $\mathcal{S}(H)$ is of form $\{S(T_1) \times S(T_2) : T_i \subseteq V(H_i), S(T_i) \neq \emptyset \text{ for } i = 1, 2\}$.

Let T_1 and T_2 be some subsets of, respectively, $V(H_1)$ and $V(H_2)$. Clearly,

$$S(T_1) \times S(T_2) = [\bigcap_{t \in T_1} N(t)] \times [\bigcap_{t' \in T_2} N(t')] = \bigcap_{(t,t') \in T_1 \times T_2} N(t, t') = S(T_1 \times T_2). \tag{1}$$

Therefore, if $S(T_1)$ and $S(T_2)$ are non-empty, we get that $S(T_1) \times S(T_2) \in \mathcal{S}(H)$.

To see that $\mathcal{S}(H) \subseteq \mathcal{S}(H_1) \times \mathcal{S}(H_2)$, we show that for every $T \subseteq V(H)$ set $S(T)$ is of the form $S(T_1) \times S(T_2)$ for some T_1, T_2. Define T_1 and T_2 to be minimal sets such that $T \subseteq T_1 \times T_2$. Hence, by (1), $S(T_1) \times S(T_2) = S(T_1 \times T_2) \subseteq S(T)$. On the other hand, for every $(s, s') \in S(T)$ we have $s \in \bigcap_{t \in T_1} N(t)$ and $s' \in \bigcap_{t' \in T_2} N(t')$, so the equality follows. ◀

It follows from Observation 13 that if H is a graph with factorization $H_1 \times \ldots \times H_m$, then $s(H) = s(H_1) \cdot \ldots \cdot s(H_m)$. Therefore if there exist at least two factors H_i, H_j such that $s(H_i), s(H_j) > 1$, Corollary 12 yields a better running time than Theorem 1.

In order to analyze the possible matching lower bounds for our algorithms, in the remaining part of the section, we focus only on connected non-trivial cores H that are provided with their unique prime factorization $H_1 \times \ldots \times H_m$; if H is prime, we technically consider this factorization to be $H \times K_1^*$ (noting that this is not a prime factorization, and that K_1^* is the only non-simple graph in this article). We note that the factors of a core must satisfy some necessary conditions.

▶ **Observation 14** ([25])**.** *Let H be a connected, non-trivial core with factorization $H = H_1 \times \ldots \times H_m$ such that $H_i \neq K_1^*$ for all $i \in [m]$. Then for every $i \in [m]$ the graph H_i is a connected non-trivial core, incomparable with H_j for $j \in [m] - \{i\}$.*

Observation 14 in particular implies that if H is a connected non-trivial graph with factorization $H_1 \times \ldots \times H_m$, then at least one of the factors H_i must be non-trivial, and that K_1 and K_2 never appear as factors of a connected non-trivial graph.

In the remaining part of this section we introduce a few more important definitions, in particular, the well-established notion of *projectivity* for non-trivial graphs H.

We say that a homomorphism $f : H^\ell \to H$, for some $\ell \geqslant 2$, is *idempotent* if for each $x \in V(H)$ it holds that $f(x, \ldots, x) = x$. Graph H is *projective* if for every $\ell \geqslant 2$, every idempotent homomorphism $f : H^\ell \to H$ is a projection. We note that every projective graph on at least three vertices must be connected, ramified, non-bipartite and prime [22].

Here, we introduce a generalization of the projectivity property for non-trivial cores, which turns out to be the central component required to establish the lower bound for our problem. As a first step towards this, we lift the notion of idempotency as follows. Let H be a connected, non-trivial prime core, and let W be either a connected core on at least three vertices incomparable with H, or the graph K_1^*. Let $f : A \to H$ be a homomorphism where $A = H^\ell \times W$; observe that ℓ is uniquely determined by either W being incomparable with the prime core H, or W being K_1^*. We say that f is *H-idempotent* if for each $x \in V(H), y \in V(W)$ it holds that $f(x, \ldots, x, y) = x$.

Now, let us consider a non-trivial core H which admits a prime factorization $H_1 \times \ldots \times H_m$ and let $i \in [m]$. We say that H is *H_i-projective* if H_i is non-trivial and every H_i-idempotent homomorphism $f : H_1 \times \ldots \times H_{i-1} \times H_i^\ell \times H_{i+1} \times \ldots \times H_m \to H_i$ is a projection. In other words, for every homomorphism $f : H_1 \times \ldots H_{i-1} \times H_i^\ell \times H_{i+1} \times \ldots \times H_m \to H_i$ such that for every $x \in V(H_i), y_j \in V(H_j)$ for $j \in [m] - \{i\}$ it holds that $f(y_1, \ldots, y_{i-1}, x, \ldots, x, y_{i+1}, \ldots, y_m) = x$, we must have that there exists $q \in \{i, \ldots, i + \ell - 1\}$ such that $f \equiv \pi_q$. Recall that if H is a non-trivial projective core, then it must be prime, so $H \times K_1^*$ is its only possible factorization. It is straightforward to verify that in a such case H is H-projective.

Since the direct product of graphs is commutative, if $H = H_1 \times \ldots \times H_m$ is H_i-projective for some $i \in [m]$, to simplify the notation we will often assume w.l.o.g. that $i = 1$.

5 Hardness

In this section, we focus on establishing the desired lower bounds, stated below.

▶ **Theorem 2.** *Let H be a fixed non-trivial core with prime factorization $H_1 \times \ldots \times H_m$. Assume that H is H_i-projective for some $i \in [m]$. Then there is no algorithm solving $\textsc{Hom}(H)$ in time $\mathcal{O}^*((s(H_i) - \varepsilon)^{\mathrm{cw}(G)})$ for any $\varepsilon > 0$, unless the* SETH *fails.*

We divide our proof into two main steps. First, we show that in our setting, instead of considering the $\textsc{Hom}(H)$ problem, we may focus on the Homomorphism Extension problem, denoted $\textsc{HomExt}(H)$. For a fixed H, $\textsc{HomExt}(H)$ takes as an instance a pair (G', h'), where $h' : V' \to V(H)$ is a mapping from some $V' \subseteq V(G')$. We ask whether there exists *an extension* of h' to G', i.e., a homomorphism $h : G' \to H$ such that $h|_{V'} \equiv h'$.

The $\textsc{HomExt}(H)$ is clearly a generalization of the $\textsc{Hom}(H)$ problem. However, as the first step of our proof, we show that if H is a fixed non-trivial core, each instance (G', h') of $\textsc{HomExt}(H)$ can be transformed in polynomial time into an instance G of $\textsc{Hom}(H)$, such that $\mathrm{cw}(G')$ and $\mathrm{cw}(G)$ differ only by a constant.

▶ **Theorem 15.** *Let H be a fixed non-trivial core. Given an instance (G', h') of $\textsc{HomExt}(H)$, we can construct an equivalent instance G of $\textsc{Hom}(H)$ such that $\mathrm{cw}(G) \leqslant \mathrm{cw}(G') + |V(H)|$.*

Proof. Let $V' \subseteq V(G')$ be the domain of h'. We construct G by taking a copy $\hat{G}'$ of G' and a copy $\hat{H}$ of H. Then, for every $v \in V'$ we add all the edges with one endpoint in v and another one in $N_{\hat{H}}(h'(v))$.

Observe that if there exists an extension $h : G' \to H$ of h', then h can be also extended to G, by setting $h(v) = v$ for every $v \in V(\hat{H})$. Indeed, let $uv \in E(G)$. If $u, v \in V(\hat{G}')$, then $h(u)h(v) \in E(H)$, by definition of the extension of h' to G'. If $u, v \in V(\hat{H})$, then $h(u)h(v) = uv \in E(H)$. Finally, assume that $u \in V(\hat{G}'), v \in V(\hat{H})$. Note that, by definition of G, this can happen only if $u \in V'$ and v is adjacent to $h'(u)$. Hence, $h(u)h(v) = h'(u)v \in E(H)$.

For the reverse direction, assume that there exists a homomorphism $f : G \to H$. We show that there exists an extension $h : G' \to H$ of h'. Let $\sigma : H \to H$ be a restriction of f to H. Since H is a core, σ is an automorphism of H. We claim that $g = \sigma^{-1} \circ f : G \to H$, restricted to G', is an extension of h'. Clearly, g is a composition of homomorphisms, so also a homomorphism. Therefore, it remains to show that for every $v \in V'$ we have $h'(v) = g(v)$. Since H is a core, and $N_H(h'(v)) \subseteq N_G(v)$, we have that $f(v) = f(h'(v))$. It follows that $g(v) = \sigma^{-1} \circ f(v) = \sigma^{-1} \circ f(h'(v)) = g(h'(v))$. However, recall that for every $u \in V(H)$ we have that $g(u) = u$, so in particular, $g(h'(v)) = h'(v)$.

To see that $\mathrm{cw}(G) \leqslant \mathrm{cw}(G') + |V(H)|$, observe that we added exactly $|V(H)|$ vertices to G'. This means we can modify a clique-width expression σ for G' to obtain a clique-width expression of G as follows. Each added vertex is introduced with a designated label that is distinct from all labels used in σ. Then each subexpression of σ that introduces a vertex of G' can be replaced by an expression that introduces the vertex and inserts all required edges to the added vertices. Finally, one can insert the missing edges between added vertices. ◀

As the second step, we prove the following theorem.

▶ **Theorem 16.** *Let H be a fixed non-trivial core with prime factorization $H_1 \times \ldots \times H_m$. Assume that H is H_i-projective for some $i \in [m]$. Then there is no algorithm solving* HomExt*(H) in time $\mathcal{O}^*((s(H_i) - \varepsilon)^{\mathrm{cw}(G')})$ for any $\varepsilon > 0$, unless the SETH fails.*

Before we proceed to the proof of Theorem 16, we show that it implies Theorem 2.

Theorem 16 → Theorem 2: Let H be a non-trivial core with a prime factorization $H_1 \times \ldots \times H_m$. W.l.o.g. assume that H is H_1-projective. Suppose that Theorem 2 does not hold, i.e., there exists an algorithm A that solves every instance G of Hom(H) in time $\mathcal{O}^*((s(H_1) - \varepsilon)^{\mathrm{cw}(G)})$.

Let (G', h') be an instance of HomExt(H). We use Theorem 15 to transform (G', h') into an equivalent instance G of Hom(H), such that $\mathrm{cw}(G) \leqslant \mathrm{cw}(G') + |V(H)|$. Then, we use A to decide whether $G \to H$ in time

$$\mathcal{O}^*\left((s(H_1) - \varepsilon)^{\mathrm{cw}(G)} = \mathcal{O}^*\left((s(H_1) - \varepsilon)^{\mathrm{cw}(G')} \cdot (s(H_1) - \varepsilon)^{|V(H)|}\right)\right.\!.$$

Since H is a fixed graph, $(s(H_1) - \varepsilon)^{|V(H)|}$ is a constant, and therefore $\mathcal{O}^*\left((s(H_1) - \varepsilon)^{\mathrm{cw}(G)}\right) = \mathcal{O}^*\left((s(H_1) - \varepsilon)^{\mathrm{cw}(G')}\right)$. Since $G \to H$ if and only if (G', h') is a yes-instance of HomExt(H), we get a contradiction with Theorem 16.

We will prove Theorem 16 for $i = 1$, which covers other cases by commutativity of direct products. We begin by constructing certain gadgets that will be used later. Let H be a fixed core with factorization $H_1 \times \ldots \times H_m$. We define $W = H_2 \times \ldots \times H_m$ if $m \geqslant 2$, and $W = K_1^*$ otherwise. Clearly, $H_1 \times W$ is a (not necessarily prime) factorization of H. Moreover, if for some graph G we have a homomorphism $f : G \to H_1 \times \ldots, \times H_m$, for $i \in [m]$ we denote by f_i the homomorphism $\pi_i \circ f : G \to H_i$.

Let S be a set of pairs of vertices of H_1, and let $w, w' \in V(W)$. We say that a tuple (F, h', p, q), such that F is a graph, $h' : V' \to H$ is a mapping with domain $V' \subseteq V(F)$, and $p, q \in V(F)$, is an (S, w, w')-*gadget* if

(S1) for every extension $h : F \to H$ of h', it holds that $(h_1(p), h_1(q)) \in S$,

(S2) for every pair $(s_1, s_2) \in S$ there exists an extension $h : F \to H$ of h' such that $h(p) = (s_1, w)$ and $h(q) = (s_2, w')$.

▶ **Lemma 17.** *Let H be a non-trivial connected core with factorization $H_1 \times W$, let $S \subseteq V(H_1)^2$, and let $w, w' \in V(W)$. Assume that H is H_1-projective. Then there exists an (S, w, w')-gadget.*

Proof. Let $S = \{(s_1^1, s_2^1), \ldots, (s_1^\ell, s_2^\ell)\}$. Define

$$F = H_1^\ell \times W, \quad \text{and} \quad p = (s_1^1, \ldots, s_1^\ell, w), \quad \text{and } q = (s_2^1, \ldots, s_2^\ell, w').$$

Let $V' = \{(x, x, \ldots, x, y) \mid x \in V(H_1), y \in V(W)\}$, and let $h'(x, \ldots, x, y) = (x, y)$. We claim that (F, h', p, q) is an (S, w, w')-gadget.

The condition 1 follows from the fact that H is H_1-projective. Indeed, observe that if $h : F \to H_1 \times W$ is an extension of h', then h_1 must be H_1-idempotent, and hence a projection on one of the ℓ first coordinates. Therefore, we must have $(h_1(p), h_1(q)) \in S$.

For (S2), take any $(s_1^i, s_2^i) \in S$ and let $h : F \to H_1 \times W$, $h(x) = (\pi_i(x), \pi_{\ell+1}(x))$. Clearly, h is an extension of h', and it is easy to verify that $h(p) = (s_1^i, w)$ and $h(q) = (s_2^i, w')$. ◀

We say that $S \subseteq V(H_1)^2$ is *proper*, if for every coordinate there exist two elements is S that differ on that coordinate, i.e., S is not of the form $\{s\} \times U$ nor $U \times \{s\}$ for some $s \in V(H_1)$ and $U \subseteq V(H_1)$. Note that if S is proper and (F, h', p, q) is an (S, w, w')-gadget, then neither p nor q belong to the domain of h'.

For fixed vertices $a, b \in V(H_1)$, let $S_{a,b} = \{(a', b') : a' \neq a, b' \in V(H_1)\} \cup \{(a, b)\}$. We call the $(S_{a,b}, w, w')$-gadget (F, h', p, q) an $((a, b), w, w')$-*implication-gadget*. Intuitively, an $((a, b), w, w')$-implication-gadget works as the implication $a \Rightarrow b$, since in every homomorphism $h : F \to H$ that extends h', if $h_1(p) = a$, then $h_1(q) = b$.

Let $a, b, c \in V(H_1)$, $w \in V(W)$, and let t be an integer. A triple (F, h', R) such that F is a graph, $h' : V' \to H_1 \times W$ is a partial mapping from some $V' \subseteq V(F)$, and R is a subset of $V(F)$ of cardinality t is an *t-or-gadget with domain* $((a, b, c), w)$ if

(O1) for every homomorphism $h : F \to H$ that is an extension of h', and for every $u \in R$ we have that $h_1(u) \in \{a, b, c\}$ and there exists $v \in R$ such that $h_1(v) = a$,

(O2) for every $v \in R$ there exists a homomorphism $h : F \to H$ that is an extension of h', such that $h(v) = (a, w)$ and for every $u \in R - \{v\}$ it holds that $h(u) \in \{(b, w), (c, w)\}$.

▶ **Lemma 18.** *Let H be a non-trivial core with factorization $H_1 \times W$. Assume that H is H_1-projective. Then for every distinct $a, b, c \in V(H_1)$, every $w \in V(W)$ and every t, there exists a t-or-gadget (F, h', R) with domain $((a, b, c), w)$.*

Proof. We consider separately the cases $t = 1$ and $t = 2$. Observe that in case $t = 1$ our gadget needs to be a graph that has a vertex $r \in R$ that is always mapped to (a, w). Hence, we set $F = K_1$, $R = V(F)$, and $h'(v) = (a, w)$ for $v \in V(F)$.

If $t = 2$, let $S = \{(a, b), (b, a), (a, a)\}$, we introduce an independent set $R = \{r_1, r_2\}$ and (S, w, w)-gadget (F, h', r_1, r_2). To see that (F, h', R) satisfies 1, consider any extension $f : F \to H$ of h'. As (F, h', r_1, r_2) is (S, w, w)-gadget, we have $(f_1(r_1), f_1(r_2)) \in \{(a, b), (a, a), (b, a)\}$. For 2, recall that by the property 2 of S-gadget there exist extensions $f^{(1)}$ and $f^{(2)}$ of h' such that $(f_1^{(1)}(r_1), f_1^{(1)}(r_2)) = (a, b)$ and $(f_1^{(2)}(r_1), f_1^{(2)}(r_2)) = (b, a)$.

Assume then that $t \geqslant 2$, and let

$$\begin{aligned} S &= \{a,b,c\}^2 - \{(b,c),(c,b)\}, \\ S_{\text{left}} &= \{(a,a),(a,b),(a,c),(c,a),(c,c)\}, \\ S_{\text{right}} &= \{(a,a),(a,b),(b,a),(b,b),(c,a)\} \end{aligned}$$

be subsets of $V(H_1)^2$. We introduce an independent set $R = \{r_1, \ldots, r_t\}$ of t vertices and one copy of (S_{left}, w, w)-gadget (F_1, h'_1, p_1, q_1) from r_1 to r_2. Then, for $j \in \{2, \ldots, t-2\}$, we introduce an (S, w, w)-gadget (F_j, h'_j, p_j, q_j) from r_j to r_{j+1} (we note that if $t \leqslant 3$, we do not introduce these). Last, we introduce one copy of (S_{right}, w, w)-gadget $(F_{t-1}, h'_{t-1}, p_{t-1}, q_{t-1})$ from r_{t-1} to r_t. We note that sets S, S_{left}, and S_{right} are proper, so the domains of the partial mappings h'_j, $j \in \{1, \ldots, t-1\}$, are pairwise disjoint. In particular, the union $h' = \bigcup_{j=1}^{t} h'_j$ is a well-defined mapping. We define F to be the union of all the graphs from the introduced gadgets and claim that (F, h', R) is a t-or-gadget. We first show that 1 holds. Assume that there exists an extension $f : F \to H$ of h', and $j' \in [t]$ such that $f_1(r_{j'}) \notin \{a,b,c\}$. This implies that there exists $j \in \{j'-1, j'\}$ such that $(f_1(r_j), f_1(r_{j+1})) \notin S'$ for any $S' \in \{S_{\text{left}}, S, S_{\text{right}}\}$. This is a contradiction with (F, h'_j, p_j, q_j) being an (S', w, w)-gadget, as it violates 1.

Now assume that there exists an extension $f : F \to H$ of h' such that for every $j \in [t]$ we have that $f_1(r_j) \in \{b,c\}$. The definition of S_{left} and S_{right}, respectively, implies that $f_1(r_1) = c$ and $f_1(r_t) = b$. Hence, there exists $j \in [t-1]$ such that $f_1(r_j) = c$ and $f_1(r_{j+1}) = b$. However, observe that the pair (c,b) does not belong to set S', for $S' \in \{S_{\text{left}}, S, S_{\text{right}}\}$, and since we introduced an S'-gadget from r_j to r_{j+1}, this leads to a contradiction.

To see that 2 holds as well, fix some $r_j \in R$ and define

$$f'(r_\ell) = \begin{cases} (a,w), & \text{if } \ell = j, \\ (c,w), & \text{if } \ell < j, \\ (b,w), & \text{if } \ell > j, \end{cases}$$

If $j = 1$, then since $(a,b) \in S_{\text{left}}$, $(b,b) \in S$ and $(b,b) \in S_{\text{right}}$, the property 2 asserts that we can construct a homomorphism $f : F \to H$ that extends h' and f'. The same holds also if $j = t$, (since $(c,c) \in S_{\text{left}}$, $(c,c) \in S$ and $(c,a) \in S_{\text{right}}$), and if $1 < j < t$ (since $(c,c) \in S_{\text{left}}$, $(c,c),(c,a),(a,b),(b,b) \in S$ and $(b,b) \in S_{\text{right}}$). ◀

Finally, all that remains is to prove Theorem 16. Our reduction generalizes the construction used by Lampis [20] to reduce an SETH lower-bounded constraint satisfaction problem to k-Coloring. Intuitively speaking, in that construction possible variable assignments are encoded by mapping specified vertices to arbitrary non-trivial subsets of the colors. The straightforward generalization of this approach to our setting would be to map to non-trivial subsets of $V(H)$. However, the structure of H allows only certain configurations of subsets as images for the specified vertices in a solution for $\text{Hom}(H)$ – which is precisely where the signature sets come into play.

Let $q, B \geqslant 2$ be integers. We will reduce from the q-CSP-B problem that is defined as follows. An instance of q-CSP-B consists of a set X of variables and a set C of q-constraints. A q-constraint $c \in C$ is a q-tuple of elements from X and a set $P(c)$ of q-tuples of elements from $[B]$ (i.e., $P(c) \subseteq [B]^q$). The q-CSP-B problem asks whether there exists an assignment $\gamma : X \to [B]$, such that each constraint is satisfied, i.e., if $c = ((x_1, \ldots, x_q), P(c)) \in C$, then $(\gamma(x_1), \ldots, \gamma(x_q)) \in P(c)$. Note that we can assume that q-constraints in our q-CSP-B instance may have less than q vertices, as it is always possible to add at most $q-1$ dummy variables to X and add them to constraints that are of smaller size.

We will use the following theorem.

▶ **Theorem 19** ([20]). *For any $B \geqslant 2, \varepsilon > 0$ we have the following: assuming the SETH, there exists q such that n-variable q-CSP-B cannot be solved in time $\mathcal{O}^*((B-\varepsilon)^n)$.*

We have all the tools to perform the final reduction.

Proof of Theorem 16. Recall that it is sufficient to prove the theorem when $H = H_1 \times W$ is non-trivial H_1-projective core ($W = K_1^*$ if $H = H_1$). Fix $\varepsilon > 0$ and set $B = s(H_1)$. As H is H_1-projective, H_1 is non-trivial and hence contains at least three distinct vertices a, b and c. In particular, $B \geqslant 3$ by Observation 8. Since $H = H_1 \times W$ is a non-trivial core, W must have at least one edge ww' (it may happen that $w = w'$). From now on a, b, c, w and w' are fixed. Let q be the smallest number such that q-CSP-B on n variables cannot be solved in time $\mathcal{O}^*((B-\varepsilon)^n)$ assuming the SETH, given by Theorem 19.

Let φ be an instance of q-CSP-B, where $X = \{x_1, \ldots, x_n\}$ is the set of variables and $C = \{c_0, \ldots, c_{m-1}\}$ is the set of constraints. For every $j \in \{0, \ldots, m-1\}$ denote by X_j the set of variables that appear in the constraint c_j. Let $P(c_j) = \{f_1^j, \ldots, f_{p_j}^j\}$ be the set of assignments from X_j to $[B]$ that satisfy the constraint c_j. Let $L = m(n|H_1| + 1)$, and let $\lambda : [B] \to \mathcal{S}(H_1)$ be some fixed bijection.

We construct the instance G_φ of HomExt(H). For each $j \in \{0, \ldots L-1\}$, let $j' = j \mod m$. Let $R_j = \{r_1^j, \ldots, r_{p_{j'}}^j\}$, where each vertex r_k^j corresponds to the assignment $f_k^{j'}$. We introduce the $p_{j'}$-or-gadget (F_j, h'_j, R_j) with domain $((a,b,c), w)$.

For each $x_i \in X_{j'}$, and for each $f_k^{j'} \in P(c_{j'})$ we do the following:

1. Let $y = f_k^{j'}(x_i) \in [B]$. Construct an independent set $V_i^{j,k}$ of $|\lambda(y)|$ vertices and an independent set $U_i^{j,k}$ of $|S(\lambda(y))|$ vertices.
2. For each $d \in \lambda(y)$ select a distinct vertex $z \in V_i^{j,k}$ and add an $((a,d), w, w')$-implication-gadget from r_k^j to z. For each $d \in S(\lambda(y))$ select a distinct vertex $z \in U_i^{j,k}$ and add an $((a,d), w, w')$-implication-gadget from r_k^j to z.
3. Connect all vertices of $U_i^{j,k}$ with all vertices of previously constructed sets $V_i^{\ell,k'}$ for $\ell < j$ and $k' \in [p_\ell]$.

The partial mapping h' is the union of all the partial mappings that are introduced by all the gadgets. This finishes the construction of the instance (G_φ, h') of HomExt(H).

▷ Claim 20. If φ is a yes-instance of q-CSP-B, then there exists a homomorphism $h : G_\varphi \to H$ that extends h'.

Proof of Claim. If φ is a yes-instance of q-CSP-B, then there exists an assignment $\gamma : X \to [B]$ satisfying each constraint. We define $h : G_\varphi \to H$ as follows.

Fix $j \in \{0, \ldots, L-1\}$, and consider the or-gadget (F_j, h'_j, R_j). Recall that the set $P(c_{j'})$ consists of all assignments of variables in $X_{j'}$ that satisfy the constraint $c_{j'}$. Therefore, there exists an assignment $f_k^{j'} \in P(c_{j'})$ such that $\gamma|_{X_{j'}} \equiv f_k^{j'}$. Consider the vertex r_k^j that corresponds to that assignment. By the property 2 of the or-gadget, we know that there exists a H-coloring of F_j that extends h', such that (i) $h_1(r_k^j) = a$ and (ii) for every $r_{k'}^j \in R_j, k' \neq k$ we have that $h_1(r_{k'}^j) \in \{b, c\}$.

Let $x_i \in X_{j'}$ and let $y = f_k^{j'}(x_i) \in [B]$. Since for each $d \in \lambda(y)$ there exists a vertex $z \in V_i^{j,k}$ such that there is an $((a,d), w, w')$-implication-gadget from r_k^j to z, the condition (i) implies that $h_1(V_i^{j,k}) = \lambda(y)$. We color the vertices of $V_i^{j,k}$ in a way that $h(V_i^{j,k}) = \lambda(y) \times \{w\}$.

Also, since for each $d \in S(\lambda(y))$ there exists a vertex $z \in U_i^{j,k}$ such that there is an (a,d)-implication-gadget from r_k^j to z, the condition (i) implies that $h_1(U_i^{j,k}) = S(\lambda(y))$. We color the vertices of $U_i^{j,k}$ in a way that $h(U_i^{j,k}) = S(\lambda(y)) \times \{w'\}$.

Because of (ii), the implication gadgets from $r_{k'}$ to the vertices of $V_i^{j,k'} \cup U_i^{j,k'}$ do not put any constraints on the coloring of the sets $V_i^{j,k'}$ and $U_i^{j,k'}$. Therefore, for each $v \in V_i^{j,k'}$ we set $h(v)$ to be any vertex from $\lambda(y)$. Similarly, for each $u \in U_i^{j,k'}$ we set $h(u)$ to be any vertex from $S(\lambda(y))$. Since $(b,x),(c,x) \in S_{a,b}$ for any $x \in V(H_1)$, property 2 applied to the implication gadgets asserts that since $h(r_{k'}) \in \{b,c\}$, we can always extend this mapping to a homomorphism of the whole gadget to H.

It remains to argue that the edges between the sets $V_i^{j_1,k_1}$ and $U_i^{j_2,k_2}$ are mapped to edges of H, for any $j_1 < j_2$ and k_1, k_2. However, observe that since γ is an extension of some $f_{k_1}^{j_1'} \in S_{j_1'}$ and $f_{k_2}^{j_2'} \in S_{j_2'}$, we must have $f_{k_1}^{j_1'}(x_i) = f_{k_2}^{j_2'}(x_i) = y$. Hence, h maps every $v \in V_i^{j_1,k_1}$ to some element of $\lambda(y) \times \{w\}$, and every $u \in U_i^{j_2,k_2}$ to some element of $S(\lambda(y)) \times \{w'\}$. By Observation 4, and since $ww' \in E(W)$, we get that $h(v)h(u) \in E(H)$. That concludes the proof of the claim. ◁

▷ Claim 21. If there exists a homomorphism $h : G_\varphi \to H$ that extends h', then φ is a yes-instance of q-CSP-B.

Proof of Claim. We will define the assignment $\gamma : X \to [B]$ that makes every constraint from C satisfied.

Fix $j \in \{0,\ldots,L-1\}$, and consider the $p_{j'}$-or-gadget (F_j, h'_j, R_j). By the property 1 of the or-gadget, there exists $k_j \in [p_{j'}]$ such that $h_1(r_{k_j}^j) = a$. Implication gadgets whose p-vertices were identified with $r_{k_j}^j$ assert that $h_1(V_i^{j,k_j}) \in \mathcal{S}(H)$ and $h_1(U_i^{j,k_j})$ is the signature of $h_1(V_i^{j,k_j})$. Then, by Observation 5, $h_1(V_i^{j,k_j})$ is a signature of $h_1(U_i^{j,k_j})$. Denote $h_1(U_i^{j,k_j})$ by T_i^j, then $h_1(V_i^{j,k_j}) = S(T_i^j)$ and $S(S(T_i^j)) = T_i^j$ Let $y_i^j = f_{k_j}^{j'}(x_i)$ be the *candidate assignment* for $x_i \in X_{j'}$ at index j, recall that $y_i^j = \lambda^{-1}(S(T_i^j))$.

Let $i \in [n]$ be fixed and let $j_1, j_2 \in [L], j_1 < j_2$ be such that $x_i \in X_{j_1'} \cap X_{j_2'}$. Observe that in such case $T_i^{j_1} \supseteq T_i^{j_2}$. Indeed, denote $k_1 = k_{j_1}$, $k_2 = k_{j_2}$, then we have (1) $h_1(V_i^{j_1,k_1}) = S(T_i^{j_1})$ and $h_1(U_i^{j_1,k_1}) = T_i^{j_1}$, and (2) $h_1(V_i^{j_2,k_2}) = S(T_i^{j_2})$ and $h_1(U_i^{j_2,k_2}) = T_i^{j_2}$. Recall that each vertex from $U_i^{j_2,k_2}$ is adjacent to each vertex from $V_i^{j_1,k_1}$. Since h_1 is a homomorphism, the same holds for their images: each vertex from $T_i^{j_2}$ is adjacent to each vertex from $S(T_i^{j_1})$. Then $S(T_i^{j_2}) \supseteq S(T_i^{j_1})$, so $T_i^{j_1} = S(S(T_i^{j_1})) \supseteq S(S(T_i^{j_2})) \supseteq T_i^{j_2}$.

We say that the index $j_1 \in \{0,\ldots,L-1\}$ is *problematic* for i if there is $j_2 > j_1$ such that $x_i \in X_{j_1'} \cap X_{j_2'}$ and $T_i^{j_1} \neq T_i^{j_2}$. Since for each variable we have at most $|H_i|$ problematic indices, there are at most $|H_i| \cdot n$ problematic indices for all variables. Since $L = m(|H_i| \cdot n + 1)$, by pigeonhole principle we get that there exists a set $J \subseteq \{0,\ldots,L-1\}$ of m consecutive indices such that none of them is problematic for any i. For every $i \in [n]$, we fix some $j \in J$ such that $x_i \in X_{j'}$ and set $\gamma(x_i) = y_i^j$ (observe that the choice of j does not matter).

We claim that γ is an assignment that satisfies every constraint from φ. Indeed, for any $j' \in [m]$ there exists $j \in J$ such that $j' = j \mod m$. For every $i \in X_{j'}$, we have $\gamma(x_i) = y_i^j = f_{k_j}^{j'}(x_i)$, so γ satisfies the constraint $c_{j'}$. ◁

Finally, it remains to adapt the arguments of Lampis [20] to establish the desired linear clique-width bound.

▷ Claim 22. G_φ can be constructed in time polynomial in $|\varphi|$, and we have $\mathrm{cw}(G_\varphi) \leqslant n + f(\varepsilon,\nu)$ for some function f, where $\nu = |V(H)|$.

Proof of Claim. Observe that any (S,w,w')-gadget constructed as in Lemma 17 for $i = 1$ has at most $|V(H_i)|^{|S|-1} \cdot |V(H)| \leqslant \nu^{|S|}$ vertices. In particular, we can ensure that every implication gadget in G_φ has at most $\nu^{\mathcal{O}(\nu^2)}$ vertices. Moreover, we will assume that all the

or-gadgets of G_φ are constructed as in Lemma 18 and the subgadgets for S, S_{left} and S_{right} contain at most ν^7 vertices. Then for every $j \in \{0, \ldots, L-1\}$, $p_{j'}$-or-gadget (F_j, h'_j, R_j) has at most $(p_{j'} - 1) \cdot \nu^7$ vertices.

For fixed H and $\varepsilon > 0$ we have that $B = s(H_i) \leqslant 2^{|V(H_i)|} - 2$ and q is a constant that only depends on B, ε (that is, on $|V(H_i)|$, ε). Each constraint of the $q - \text{CSP} - B$ instance has at most B^q satisfying assignments. In particular, the number of vertices in each or-gadget is upper-bounded by $B^q \cdot \nu^7$. Therefore, it is not hard to see that the whole construction can be performed in polynomial time, if H is fixed and ε is a constant. For clique-width we use the following labels:

1. n *main* labels, representing the variables of φ.
2. A single *done* label. Its informal meaning is that a vertex that receives this label will not be connected to anything else not yet introduced in the graph.
3. $B^q \cdot \nu^7$ *constraint work* labels.
4. $qB^q \cdot \nu^{\mathcal{O}(\nu^2)}$ *variable-constraint incidence work* labels.

To give a clique-width expression we will describe how to build the graph, following essentially the steps given in the description of the construction by maintaining the following invariant: before starting iteration j, all vertices of the set $W_i^j = \bigcup_{j'<j} \bigcup_{k \in [p_{j'}]} V_i^{j',k}$ have label i, and all other vertices have the *done* label. This invariant is vacuously satisfied before the first iteration, since the graph is empty. Suppose that for some $j \in \{0, \ldots, L-1\}$ the invariant is true. We use the $B^q \cdot \nu^7$ constraint work labels to introduce the vertices of the $p_{j'}$-or-gadget (F_j, h'_j, R_j), giving each vertex a distinct label. We use join operations to construct the internal edges of the or-gadget. Then, for each variable x_i that appears in the current constraint we do the following: we use $B^q \cdot \nu^{\mathcal{O}(\nu^2)}$ of the variable-constraint incidence work labels to introduce for all $k \in [p_{j'}]$ the vertices of $V_i^{j,k}$ and $U_i^{j,k}$ as well as the implication gadgets connecting these to r_k^j. Again we use a distinct label for each vertex, but the number of vertices (including internal vertices of the implication gadgets) is $B^q \cdot \nu^{\mathcal{O}(\nu^2)}$, so we have sufficiently many labels to use distinct labels for each of the q variables of the constraint. We use join operations to add the edges inside all implication gadgets. Then we use join operations to connect $U_i^{j,k}$ to all vertices W_i^j. This is possible, since the invariant states that all the vertices of W_i^j have the same label i. We then rename all the vertices of $U_i^{j,k}$ for all k to the done label, and do the same also for internal vertices of all implication gadgets. We proceed to the next variable of the same constraint and handle it using its own $B^q \cdot \nu^{\mathcal{O}(\nu^2)}$ labels. Once we have handled all variables of the current constraint, we rename all vertices of each $V_i^{j,k}$ to label i for all k. We then rename all vertices of the $p_{j'}$-or-gadget (F_j, h'_j, R_j) gadget to the done label and increase j by 1. It is not hard to see that we have maintained the invariant and constructed all edges induced by the vertices introduced in steps up to j, so repeating this process constructs the graph. ◁

Together the claims imply Theorem 16 in the following way: For an arbitrary instance of q-CSP-B, our construction produces an instance of HomExt(H), and the instances are equivalent by Claim 20 and Claim 21. If one could solve HomExt(H) in $\mathcal{O}^*((s(H_i)-\varepsilon)^{\text{cw}(G)})$ for some $\varepsilon > 0$, one could use our construction to solve q-CSP-B, and by our choice of B and Claim 22 this procedure would have complexity $\mathcal{O}^*((B-\varepsilon)^{n+c})$ for some constant c. By our choice of q according to Theorem 19, this contradicts the SETH. ◀

6 Summary and Concluding Remarks

Extensions and Corollaries. We observe that Corollary 12 can be combined with Theorem 2 to obtain the following statement, which summarizes our results.

▶ **Theorem 23.** *Let H' be a fixed graph with the non-trivial connected core H. Let $H_1 \times \ldots \times H_m$ be the prime factorization of H. Let $i \in [m]$ be such that $s(H_i) = \max_{j\in[m]} s(H_j)$. Let G be an instance of Hom(H').*

1. *Assuming a clique-width expression σ of G of width $\mathrm{cw}(G)$ is given, the Hom(H') problem can be solved in time $\max_{i\in[m]} \mathcal{O}^*(s(H_i)^{\mathrm{cw}(G)})$.*
2. *Assuming that H is H_i-projective, there is no algorithm to solve Hom(H') in time $\max_{i\in[m]} \mathcal{O}^*((s(H_i)-\varepsilon)^{\mathrm{cw}(G)})$ for any $\varepsilon > 0$, unless the SETH fails.*

We note that the restriction to connected targets can be avoided by known properties of homomorphisms to disconnected graphs [25]; on the algorithmic side, one branches over all connected components of H, while for the lower bound one considers the component with maximum signature number.

It is clear that obtaining a full complexity classification with respect to clique-width may require weakening the assumption in the second statement of Theorem 23. We recall that an analogous situation occurs in the work of Okrasa and Rzążewski [25]; as mentioned in the introduction, the authors obtain the SETH-conditioned tight complexity bound for the Hom(H) problem parameterized by treewidth for all targets H, assuming two conjectures of Larose and Tardif [21,22]. The notion of H_i-projectivity allows us to restate these conjectures as one, which is not only sufficient in our setting but is also weaker in the sense of it being implied by the former two conjectures, but not necessarily equivalent to them.

▶ **Conjecture 1.** *Let H be a non-trivial core with prime factorization $H_1 \times \ldots \times H_m$ and let $i \in [m]$. Then H is H_i-projective.*

Using Conjecture 1, we can restate our main result as follows.

▶ **Theorem 24.** *Let H' be a fixed graph with the non-trivial connected core H. Let $H_1 \times \ldots \times H_m$ be the prime factorization of H. Let G be an instance of Hom(H').*

1. *Assuming the clique-width expression σ of G of width $\mathrm{cw}(G)$ is given, the Hom(H') problem can be solved in time $\max_{i\in[m]} \mathcal{O}^*(s(H_i)^{\mathrm{cw}(G)})$.*
2. *Assuming that Conjecture 1 holds, there is no algorithm to solve Hom(H') in time $\max_{i\in[m]} \mathcal{O}^*((s(H_i)-\varepsilon)^{\mathrm{cw}(G)})$ for any $\varepsilon > 0$, unless the SETH fails.*

We also observe that since each non-trivial projective core H is H-projective, in this case we already obtain a tight complexity bound.

▶ **Corollary 25.** *Let H' be a fixed graph with the non-trivial connected projective core H. Let G be an instance of Hom(H').*

1. *Assuming the clique-width expression σ of G of width $\mathrm{cw}(G)$ is given, the Hom(H') problem can be solved in time $\mathcal{O}^*(s(H)^{\mathrm{cw}(G)})$.*
2. *There is no algorithm to solve Hom(H') in time $\mathcal{O}^*((s(H)-\varepsilon)^{\mathrm{cw}(G)})$ for any $\varepsilon > 0$, unless the SETH fails.*

Generalizations and Other Research Directions. We remark that our hardness reduction is via HomExt(H), and in fact our algorithm can also easily be adapted to this setting (by removing all records that do not adhere to the partial mapping from the input graph to H) without an increase in complexity. However, since the dichotomy between P and NP-complete cases of HomExt(H) is more complicated (see [11], studied as the graph-retract problem) there exist target graphs H that are not covered by Theorem 24. On a similar note, let us also point out that setting up the SETH-conditioned tight complexity bounds for clique-width for a more general list problem LHom(H) [10,27] is widely open.

Another direction that is very closely related to our results is to determine similarly tight complexity bounds for the *rank-width* (rw) of the input graph: rank-width [17, 26] is a graph parameter that is known to be asymptotically equivalent to clique-width and is in fact used as an approximation of clique-width that can be computed in fixed-parameter tractable time. Our results together with the known relationship between clique-width and rank-width imply an upper bound of $\mathcal{O}^*(s(H)^{2^{\mathrm{rw}}+1})$ and a SETH lower bound of $(s(H)-\varepsilon)^{\mathrm{rw}}$ on the complexity of $\textsc{Hom}(H)$ for projective H parameterized by the rank-width of the input.

Sublinear Dynamic Interval Scheduling (On One or Multiple Machines)

Paweł Gawrychowski

Karol Pokorski
Institute of Computer Science, University of Wrocław, Poland

Abstract

We revisit the complexity of the classical Interval Scheduling in the dynamic setting. In this problem, the goal is to maintain a set of intervals under insertions and deletions and report the size of the maximum size subset of pairwise disjoint intervals after each update. Nontrivial approximation algorithms are known for this problem, for both the unweighted and weighted versions [Henzinger, Neumann, Wiese, SoCG 2020]. Surprisingly, it was not known if the general exact version admits an exact solution working in sublinear time, that is, without recomputing the answer after each update.

Our first contribution is a structure for Dynamic Interval Scheduling with amortized $\tilde{\mathcal{O}}(n^{1/3})$ update time. Then, building on the ideas used for the case of one machine, we design a sublinear solution for any constant number of machines: we describe a structure for Dynamic Interval Scheduling on $m \geq 2$ machines with amortized $\tilde{\mathcal{O}}(n^{1-1/m})$ update time.

We complement the above results by considering Dynamic Weighted Interval Scheduling on one machine, that is maintaining (the weight of) the maximum weight subset of pairwise disjoint intervals. We show an almost linear lower bound (conditioned on the hardness of Minimum Weight k-Clique) for the update/query time of any structure for this problem. Hence, in the weighted case one should indeed seek approximate solutions.

1 Introduction

The Interval Scheduling (IS) problem is often used as one of the very first examples of problems that can be solved with a greedy approach. In this problem, we have a set of jobs, the i-th job represented by an interval (s_i, f_i). Given n such intervals, we want to find a maximum size subset of pairwise disjoint intervals. In this context, disjoint intervals are usually called compatible. This admits a natural interpretation as a scheduling problem, where each request corresponds to a job that cannot be interrupted and requires exclusive access to a machine. Then, the goal is to schedule as many jobs as possible using a single machine. The folklore greedy algorithm solves this problem in $\mathcal{O}(n)$ time, assuming that the intervals are sorted by the values of f_i [19]. While it may appear to be just a puzzle, interval scheduling admits multiple applications in areas such as logistics, telecommunication, manufacturing, or personnel scheduling. For more applications and a detailed summary of different variants of interval scheduling, we refer to [21].

In many real-world applications, there is a need for maintaining the input under certain updates (for example, insertions and deletions of items), so that we can report the optimal solution (or its cost) after each operation. The goal is to avoid the possibly very expensive

recalculation of the answer (which surely takes at least linear time in the size of the input) by maintaining some kind of additional structure. The first step in this line of research is to design a structure with sublinear update/query time. Then, the next goal is to bring down the time complexities to polylogarithmic (in the size of the input). Examples of problems in which this has been successfully accomplished include dynamic graph connectivity [16, 17, 23], dynamic longest increasing subsequence [13, 20], dynamic suffix array [2, 18], dynamic graph clustering [10], and many others. For some dynamic problems no such solutions are known, and we have tools for proving (conditional) polynomial hardness for dynamic algorithms [14].

This suggests the following Dynamic Interval Scheduling (DIS) problem, in which we want to maintain a set S of intervals subject to insert and delete operations. After each update, we should report the size of the maximum size subset of pairwise compatible intervals. Note that reporting the subset itself might be not feasible, as it might contain $\Omega(n)$ intervals. Similarly, neither is explicitly maintaining this subset, as an update might trigger even $\Omega(n)$ changes in the unique optimal subset. Thus, the challenge is to maintain an implicit representation of the current solution that avoids recomputing the answer after each update, that is, supports each update in sublinear time. Besides being a natural extension of a very classical problem, we see this question as possibly relevant in practical application in which we need to cope with a dynamically changing set of jobs.

1.1 Previous work

Surprisingly, to the best of our knowledge, the complexity of general exact DIS was not considered in the literature. However, Gavruskin et al. [12] considered its restricted version, in which there is an extra constraint on the set S. Namely, it should be *monotonic* at all times: for any two intervals $(s_i, f_i), (s_j, f_j) \in S$ we should have $s_i < s_j$ and $f_i < f_j$ or vice versa. Under such assumption, there is a structure with $\mathcal{O}(\log^2 n)$ amortized time per update and $\mathcal{O}(\log n)$ amortized time per query. Alternatively, the update time can be decreased to $\mathcal{O}(\log n)$ if the query only returns if a given interval belongs to the optimal solution.

For the general version of DIS, Henzinger, Neumann and Wiese [15] designed an efficient approximation algorithm that maintains an $(1 + \epsilon)$-approximate solution in polylogarithmic time. The dependency on ϵ has been very recently improved from exponential to polynomial by Compton, Mitrović and Rubinfeld [7]. In fact, both solutions work for the weighted version of the problem, called Dynamic Weighted Interval Scheduling (DWIS). In this problem, each interval has its associated weight, and the goal is to maintain a subset of pairwise compatible intervals with the largest total weight. Note that the static version of this problem, called Weighted Interval Scheduling (WIS), can be solved by a straightforward dynamic programming algorithm [19] (but the greedy strategy no longer works now that we have weights). This brings the challenge of determining if the unweighted (and weighted) version of the problem admits an efficient exact solution.

A natural generalization of interval scheduling is to consider multiple machines. In such a problem, there is a shared set of jobs to process, each job can be either discarded or scheduled on one of the available m machines. Jobs scheduled on each machine must be pairwise compatible. The goal is to maximize the number (or the total weight) of scheduled intervals. IS on multiple machines (IS+) can be solved by extending the greedy algorithm considering intervals by the earliest end time. For each considered interval, if no machine is free at the respective time, the interval is discarded. If there are some free machines, the interval is assigned to the available machine that was busy at the latest. A direct implementation of this approach incurs a factor of m in the running time, but this can be avoided [6, 11]. The weighted version of the problem (WIS+) can be formulated and solved as a min-cost flow

problem [3, 5]. For the dynamic version, Compton, Mitrović and Rubinfeld [7] extend their methods for maintaining an approximate answer to multiple machines, however, their bounds are mostly relevant for the unweighted case. A related (but not directly connected) question is to maintain the smallest number of machines necessary to schedule all jobs in the current set [12].

1.2 Our contribution

In this paper, we consider dynamic interval scheduling on one and multiple machines. We show that the unweighted version of the problem admits a sublinear dynamic solution, and furthermore, we make non-trivial progress on decreasing the exponent in the time complexity of the solution.

The starting point is a simple structure for the general DIS problem with $\mathcal{O}(\sqrt{n}\log n)$ amortized update/query time. This is then improved to $\tilde{\mathcal{O}}(n^{1/3})$ amortized update/query time. For multiple machines, we begin with $m = 2$, and show how to solve the corresponding problem, denoted DIS2, in $\tilde{\mathcal{O}}(\sqrt{n})$ amortized time per update. Next, we use this solution to solve the general DIS+ problem in $\tilde{\mathcal{O}}(n^{1-1/m})$ amortized time per update. While designing a solution working in $\tilde{\mathcal{O}}(n^{1-1/(m+1)})$ time is not very difficult, our improved time bounds require some structural insight that might be of independent interest.

▶ **Theorem 1.** *There is a date structure for Dynamic Interval Scheduling on $m \geq 1$ machines that supports any update in $\tilde{\mathcal{O}}(\max(n^{1/3}, n^{1-1/m}))$ amortized time.*

We complement the above result by a (conditional) lower bound for the weighted version of the problem, even with $m = 1$. We show that, for every $\epsilon > 0$, under the Minimum Weight $(2\ell+1)$-Clique Hypothesis, it is not possible to maintain a structure that solves DWIS in $\mathcal{O}(n^{1-\epsilon})$ time per operation. This shows an interesting difference between the static and dynamic complexities of the unweighted and weighted versions: despite both IS and WIS admitting simple efficient algorithms, DIS admits a sublinear solution while DWIS (probably) does not.

1.3 Techniques and ideas

A natural approach to DIS is to efficiently simulate the execution of the greedy algorithm.

▶ **Definition 2.** *For an interval $I_i = (s_i, f_i)$, the* leftmost compatible *interval $LC(I_i)$ is the interval $(s_{i'}, f_{i'}) \in S$ with the smallest $f_{i'}$ such that $s_{i'} \geq f_i$ or $\perp$ if there is no such interval.*

Note that if the greedy algorithm includes I_i in the solution then it also includes $\mathrm{LC}(I_i)$. Thus, it is easy to prove that if I_i is the interval with the smallest f_i in S, then the (optimal) solution generated by the greedy algorithm is $\{I_i, \mathrm{LC}(I_i), \mathrm{LC}^2(I_i), \dots\}$.

One can consider a forest in which each interval is represented as a node and an interval I_i has parent $\mathrm{LC}(I_i)$. By creating an artificial root and connecting all forest roots' to it, we make this representation a tree. We call it *the greedy tree* (of S). The answer to the DIS query is the length of the longest path from any node to the root in the tree. We know this is actually the path from the earliest ending interval thanks to the greedy algorithm.

A standard approach used in dynamic problems is splitting the current input into several smaller parts and recomputing some information only in the part containing the updated item. Then, the answer is obtained by using the information precomputed for every part. An attempt to use such an approach for DIS could be as follows. We partition S into parts, either by the start or the end times, and in every part we precompute the result of running the

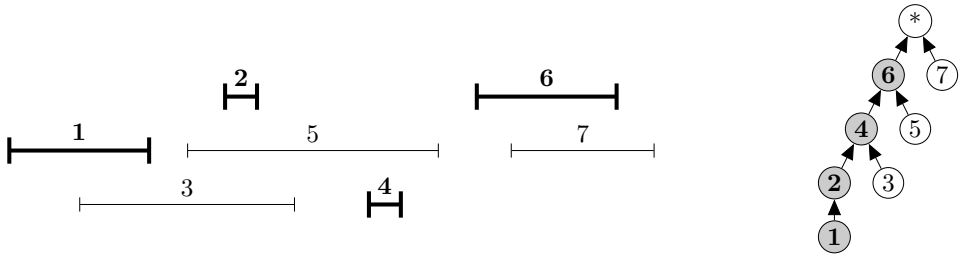

Figure 1 An input instance for DIS with the optimal solution generated by the greedy algorithm marked using bold lines and the corresponding greedy tree.

greedy algorithm from every possible state. The goal is to accelerate running the algorithm by being able to jump over the parts. For $m = 1$, we can simply maintain the greedy tree, as it allows us to simulate running the greedy algorithm not only from the interval with the smallest end time but in fact from an arbitrary interval I_i. We call this *resuming the greedy algorithm from* I_i. This allows us to jump over the whole part efficiently, and by appropriately balancing the size of each part we obtain a data structure with $\tilde{\mathcal{O}}(n^{1/2})$ time per update. This is described in detail in Appendix A. A similar approach works for $m > 1$, except that instead of the greedy tree we need to preprocess the answer for every m-tuple of intervals, resulting in $\tilde{\mathcal{O}}(n^{1-1/(m+1)})$ time per update.

We improve on this basic idea for both $m = 1$ and $m > 1$. For $m = 1$, we design a way to solve the decremental variant of DIS in only (amortized) polylogarithmic time per update, and couple this with maintaining a buffer of the most recent insertions. For $m = 2$, the greedy tree is no longer sufficient to capture all possible states of the greedy algorithm. However, by a careful inspection, we prove that for a part consisting of n intervals, instead of precomputing the answers for all $\Theta(n^2)$ possible states, it is enough to consider only $\mathcal{O}(n)$ carefully selected states. For $m > 2$, we further extend this insight by identifying only $\mathcal{O}(n^{1-1/m})$ states, called *compressible*. Interestingly, using these states to simulate the greedy algorithm starting from an arbitrary state requires a separate $\mathcal{O}(n^2)$ precomputation, hence we need to consider the case $m = 2$ separately.

2 Interval scheduling on one machine

For our structures, it is sufficient that s_i and f_i characterizing intervals are pairwise comparable but to simplify the presentation, we assume that $s_i, f_i \in \mathbb{R}_+$. One can also use an order maintenance structure [4, 9] to achieve worst-case constant time comparisons between endpoints even if we only assume that when inserting an interval (s_i, f_i) we know just the endpoints of existing intervals in S that are the nearest predecessors of s_i and f_i. We make endpoints of all intervals pairwise distinct with the standard perturbation. We assume that each insert operation returns a handle to the interval which can later be used to delete.

Our structures work in epochs. At the beginning of each epoch, we set N to be the number of intervals in S. When the number of intervals is outside range $[\frac{N}{2}, 2N]$, the new epoch begins. At the beginning of an epoch, we construct an additional data structure $\mathcal{D}$ of all intervals in S by a sequence of inserts in any order. These reconstructions have no impact on the amortized update time complexity as n actual operations are turned into $\mathcal{O}(n)$ insertions and deletions. We maintain $\mathcal{D}$ during the epoch.

We maintain a global successor structure storing all intervals sorted by their end time that enables efficient computation of $\mathrm{LC}(\cdot)$. There are k separators that split the universe of coordinates into parts of similar size. Intervals are assigned into parts $\mathcal{P}_0, \mathcal{P}_1, \ldots, \mathcal{P}_k$ by their

start time. Some intervals are *internal* (if they fully fit in the part) and other are *external* (otherwise). Both $\tilde{\mathcal{O}}(n^{1/2})$ and $\tilde{\mathcal{O}}(n^{1/3})$ structures are able to efficiently find the internal result for an interval I_i in a part, that is how many intervals the greedy algorithm can choose from I_i until reaching the exit (the last selected) interval of the part, so DIS query is solved by iterating over these parts and applying the exit of one part as an input to the next one.

We recommend reading Appendix A, where we introduce the above idea by showing a simpler but slower algorithm. Here we extend this approach and present a data structure showing the following.

▶ **Theorem 3.** *There is a data structure for DIS that supports any sequence of n insert/delete/query on intervals in $\tilde{\mathcal{O}}(n^{1/3})$ amortized time per each operation.*

The separators are chosen such that each part has size at most $2N^{2/3}$ and for any two consecutive parts $\mathcal{P}_j$ and $\mathcal{P}_{j+1}$ at least one has size at least $\frac{1}{2}N^{2/3}$. Thus, there are always $\mathcal{O}(n^{1/3})$ parts. More details on how to maintain this partition are provided in Appendix A.

Since our goal is to achieve $\tilde{\mathcal{O}}(n^{1/3})$ update time and parts are larger, we cannot afford to recompute the whole part from scratch for every update in it (as we did in Appendix A). Instead, we keep internal intervals of a part in two structures: a decremental structure and a buffer. External intervals are only kept in the global balanced binary search tree containing all the intervals. We first sketch the idea and describe the details in the following subsections.

The decremental structure of each part contains $\mathcal{O}(n^{2/3})$ intervals, has no information about buffer intervals, can be built in $\tilde{\mathcal{O}}(n^{2/3})$ time and allows deletions in $\mathcal{O}(\text{polylog}\, n)$ time. The buffer $\mathcal{B}_j \subseteq \mathcal{P}_j$ contains only at most $N^{1/3}$ last inserted internal intervals in $\mathcal{P}_j$. Each operation in a part leads to the recomputation of information associated with the buffer in $\tilde{\mathcal{O}}(n^{1/3})$ time. When $\mathcal{B}_j$ overflows, we rebuild the decremental structure from scratch using all internal intervals from the part and clear the buffer. Such recomputation happens every $\Omega(n^{1/3})$ updates inside a part. This way the update time of our solution can still be within the claimed bound.

As the optimal solution may use intervals both from the decremental collection and the buffer interchangeably, we need to combine information stored for these sets. For buffer intervals, we can afford to precompute the whole internal result and the exit of the part being fully aware of the content of the decremental collection. However, we also need to "notify" intervals of the decremental collection about potential better solutions that can be obtained by switching to buffer intervals. For this we store an additional structure of total size of $\tilde{\mathcal{O}}(n^{1/3})$, recomputed every update in a part, specifying for which intervals of the decremental collection there exists an "interesting" buffer interval.

2.1 Active and inactive intervals

▶ **Definition 4.** *An interval $I_i = (s_i, f_i)$ in a collection C of intervals is* active *if there is no other $(s_{i'}, f_{i'}) \in C$ such that $s_i \leq s_{i'} \leq f_{i'} \leq f_i$. Otherwise I_i is* inactive.

▶ **Lemma 5.** *For any set S of intervals and an interval $I_i \in S$, the greedy algorithm for IS resumed from I_i chooses (after I_i) only active intervals from S.*

Proof. Assume there are two intervals $I_1 = (s_1, f_1)$ and $I_2 = (s_2, f_2)$ such that $s_2 < s_1 < f_1 < f_2$. I_1 is considered earlier by the greedy algorithm. If it is scheduled, I_2 can no longer be scheduled as I_1 and I_2 are overlapping. If it is not, I_2 also can not be scheduled as the set of compatible intervals with I_2 is the subset of the compatible intervals with I_1. ◀

A collection of only active intervals is monotonic by definition. This provides a natural linear order on the active intervals in the collection: $(s_i, f_i) \prec (s_{i'}, f_{i'}) \Leftrightarrow s_i < s_{i'} \Leftrightarrow f_i < f_{i'}$. This allows us to focus on describing how to maintain the subset of active intervals inside a collection and only look for the solution of (D)IS in this subset.

The decremental structure $\mathcal{D}_j$ in each part only allows rebuilding and deletions. We maintain set of active intervals $\mathcal{A}_j \subseteq \mathcal{D}_j$ in the decremental collection. When an interval from $\mathcal{A}_j$ is deleted, the set should report new active intervals. We stress that the decremental structure is not aware of any buffer intervals of $\mathcal{P}_j$ and in order to determine if a particular interval is active in the decremental collection we do not take into account any buffer intervals.

▶ **Lemma 6.** *There is a structure that allows maintaining the subset of active intervals in a delete-only or insert-only collection of size n in $\mathcal{O}(\log n)$ amortized time per insertion/deletion and can be built in $\mathcal{O}(n \log n)$ time.*

Proof. Each interval (s_i, f_i) is translated into a point $(s_i, -f_i)$ in a plane. We say that point (x, y) *dominates* point (x', y') if $x > x' \wedge y > y'$. Point (x', y') is then *dominated by* (x, y). We say that a point is *dominated* if there is a point that dominates it. The interval is active in the collection if and only if the point representing it is not dominated. The set of non-dominated points forms a linear order: the larger x-coordinate implies the smaller y-coordinate. We store the front of non-dominated points in a predecessor/successor structure. Additionally, we maintain a range search tree indexed by x storing in each node the points of the appropriate range of x-coordinates and what is the point with the maximum y among them.

We start by describing the insert-only structure. When a point (x, y) is inserted, we search for its predecessor (x_ℓ, y_ℓ) and its successor (x_r, y_r) in the front of non-dominated points. This way we can either find if (x, y) is dominated by (x_r, y_r) or if it dominates (x_ℓ, y_ℓ). We then update the front and the range search tree appropriately.

To build the delete-only structure, we insert points one by one in any order as described above. When a point (x, y) is deleted, we search for its predecessor (x_ℓ, y_ℓ) and its successor (x_r, y_r) in the front and find what are the points in the range (x_ℓ, x_r) that become non-dominated, that is what are new maximums of nodes in the range search tree after removal of (x, y) from appropriate nodes. These new non-dominated points are added to the front and each interval from the decremental structure is activated only at most once. Thus, the time charged to each interval in the collection is bounded by $\mathcal{O}(\log n)$. ◀

2.2 Decremental structure

For $I_i \in \mathcal{P}_j$, we define LC-DECR(I_i) to be the next greedy choice in $\mathcal{A}_j$ after I_i.

▶ **Proposition 7.** *The set of greedy predecessors of I_i ($\{I_{i'} : \text{LC-DECR}(I_{i'}) = I_i\}$) forms a continuous range of active intervals in $\mathcal{A}_j$.*

Proof. For any active intervals I_1, I_2, we have $I_1 \prec I_2 \Rightarrow \text{LC-DECR}(I_1) \preceq \text{LC-DECR}(I_2)$, so if there are three active intervals $I_1 \prec I_3 \prec I_2$ such that LC-DECR$(I_1) =$ LC-DECR(I_2) then also LC-DECR$(I_3) =$ LC-DECR(I_1). ◀

Intervals of $\mathcal{A}_j$ form a forest where a node representing an interval I_i is the parent of $I_{i'}$'s node when LC-DECR$(I_{i'}) = I_i$. As in the previous section, we add an auxiliary interval to make this representation a tree, we denote it $\mathcal{T}_j$ and call it *a greedy tree of the part $\mathcal{P}_j$*. Greedy predecessors of I_i are the children of node I_i in the greedy tree. We stress that the greedy tree is built only for the intervals of the decremental collection.

We internally represent the greedy tree as an augmented top tree $\mathfrak{T}_j$ [1]. This allows maintaining underlying fully dynamic forest (updates are insertions/deletions of edges and changes to node/edge weights). Because deletions and activations of intervals in the decremental structure may change values of LC-DECR$(\cdot)$ for many nodes, we slightly alter the structure as described in Section 2.3. This is also one of the reasons why one cannot apply techniques described in [12] to solve even the decremental variant of DIS despite being able to efficiently maintain the (monotonic) set of active intervals.

When $I_i \in \mathcal{A}_j$ is to be deleted, its children $C = c_1 \prec c_2 \prec \cdots \prec c_\ell$ have to connect to other nodes of the greedy tree. Let $I_{k+1} = \text{LC-DECR}(I_i)$ before deletion and $I_1 \prec I_2 \prec \cdots \prec I_k$ are the intervals activated after removing I_i. Note that $I_k \prec I_{k+1}$. Nodes other than the elements of C do not change their parents.

We first observe that $I_1, I_2, \ldots, I_{k+1}$ are the only possible parents for nodes in C, remind the fact that $I_{i'} \prec I_{i''} \Rightarrow \text{LC}(I_{i'}) \preceq \text{LC}(I_{i''})$ and use Proposition 7 to see that some (possibly empty) prefix of children sequence $(c_1, c_2, \ldots, c_{r_1})$ has to be connected to I_1, then the next range $(c_{r_1+1}, c_{r_1+2}, \ldots, c_{r_2})$ has to be connected to I_2 and so on until finally some suffix of children sequence $(c_{r_k+1}, c_{r_k+2}, \ldots, c_\ell)$ has to be connected to I_{k+1}. We use binary search on the children sequence to find indices $r_1, r_2, \ldots, r_k$ in this order. We update the parents of the nodes in the found ranges in the greedy tree as described in Section 2.3 and it takes $\mathcal{O}(\text{polylog}\, n)$ per each **activated** interval.

Using the appropriate query to the top tree, we can resume the execution of the greedy algorithm restricted to $\mathcal{A}_j$ from any $I_i \in \mathcal{A}_j$ in $\mathcal{O}(\text{polylog}\, n)$ time.

2.3 Top tree

The underlying information maintained in $\mathfrak{T}_j$ is chosen to compute the following:

- weighted level ancestors,
- nearest marked ancestors,
- the total path weight from a node to the root (the sum of weights).

The discussion on how to maintain information that allows efficient computation of the above in $\mathfrak{T}_j$ can be found in [1].

$\mathfrak{T}_j$ represents an underlying modified greedy tree $\overline{\mathcal{T}}_j$, namely, we binarize the tree by reorganizing the children of each non-leaf node and adding auxiliary nodes as presented in Figure 2. A node in such a modified greedy tree that represents an actual interval has a weight 1, all other auxiliary nodes have a weight 0. The weight of the path between nodes is the sum of the weights of the nodes on the path (including the endpoints). This way, the weight of a path from a node representing an interval I_i to the root of the modified greedy tree represents the number of intervals chosen by the greedy algorithm from I_i.

$\mathcal{A}_j$ is always monotonic so we use $\prec$ order on children. This way, we can update values of LC-DECR$(\cdot)$ for a range of children of a node in $\mathcal{O}(\text{polylog}\, n)$ time by the appropriate splits and joins in $\mathfrak{T}_j$. Apart from auxiliary nodes, pre-order traversals of $\mathcal{T}_j$ and $\overline{\mathcal{T}}_j$ are equal.

$\overline{\mathcal{T}}_j$ and $\mathfrak{T}_j$ are only internal representations of $\mathcal{T}_j$ that enable efficient implementation of the necessary operations. Any updates of $\mathcal{T}_j$ are naturally translated into updates of $\overline{\mathcal{T}}_j$ and $\mathfrak{T}_j$ or were described above. We proceed with describing the further details on $\mathcal{T}_j$.

▶ **Definition 8.** *For an interval $I_i \in \mathcal{A}_j$, we define its* depth *as the depth in $\mathcal{T}_j$. The set of intervals of the same depth d is called* a layer d *in $\mathcal{T}_j$ (or $\mathcal{P}_j$).*

Note that if we traverse the greedy tree in BFS order (visiting children left-to-right) we obtain exactly $\prec$ order. Thus, when comparing two intervals on the same layer we can just see which one is earlier in the pre-order traversal of $\mathcal{T}_j$. This way we can treat layers as sorted collections of intervals (actually, subranges of $\prec$).

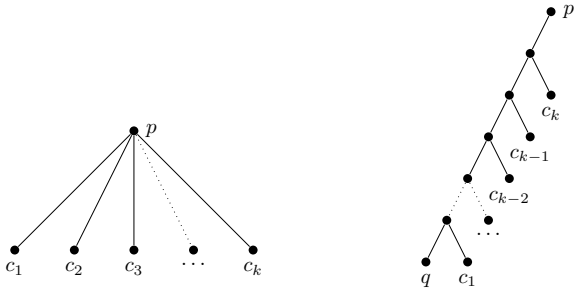

Figure 2 A part of a greedy tree is shown on the left and the modified greedy tree represented by $\mathfrak{T}_j$ is shown on the right. We assume $c_1 \prec c_2 \prec c_3 \prec \ldots \prec c_k$. One can retrieve i-th child of a node by querying for the level ancestor from node q (ignoring the weights of nodes).

▶ Remark 9. We already have all the ingredients for the algorithm to solve the delete-only DIS variant in $\mathcal{O}(\text{polylog}\, n)$ time. In this case, we do not partition intervals nor use a buffer. Instead, we only use the top tree representing the greedy tree of all the active intervals in the whole decremental collection of intervals.

Similarly, we remind that the structure for maintaining the subset of active intervals can be also maintained for the insert-only variant of DIS (Lemma 6). Now we also observe that we can maintain the greedy tree when the intervals are only inserted. A new interval I_i may only improve $\text{LC}(\cdot)$ for some continuous range of intervals and we can binary search the endpoints of this range. To account for the cost of reconnecting these nodes, which may have many different parents, we observe that for any insertion, there is only at most one interval that loses a child in the greedy tree and is not deactivated. We charge the time of reconnection of the range of its children to the insertion of I_i. We charge the time needed to reconnect other nodes to the insertion of their (deactivated, thus actually deleted) parent. This establishes the time complexity of the insert-only variant of DIS to be $\mathcal{O}(\text{polylog}\, n)$.

2.4 Buffer

▶ **Definition 10.** *For intervals $I_1 \in \mathcal{A}_j$ and $I_2 \in \mathcal{B}_j$, we say that* I_1 directly wants to switch *to I_2 if and only if all the following conditions hold:*

- *I_1 ends earlier than I_2,*
- *I_1 and I_2 are compatible,*
- *$I_2 \prec$ LC-DECR(I_1).*

The aim of the above definition is to capture that sometimes the value of $\text{LC}(\cdot)$ may be different from LC-DECR$(\cdot)$. Note that if I_1 directly wants to switch to I_2 it does not necessarily imply that $\text{LC}(I_1) = I_2$. It just means that I_2 is (in sense of $\prec$) a better next greedy choice for I_1 than it appears from the computation in the decremental collection. Note that it also means that the greedy algorithm resumed from any node in the subtree of I_1 in the greedy tree will not choose LC-DECR(I_1). Thus we define the following.

▶ **Definition 11.** *For intervals $I_1 \in \mathcal{A}_j$, $I_2 \in \mathcal{B}_j$ we say that* I_1 wants to switch *to I_2 if and only if there exists an integer $k \geq 0$ such that LC-DECR$^k(I_1)$ directly wants to switch to I_2.*

▶ **Proposition 12.** *For an interval $I_i \in \mathcal{B}_j$, there exist an integer d such that the set of intervals in $\mathcal{A}_j$ that directly want to switch to I_i is either:*

- *a continuous range of a layer d,*
- *a suffix of layer d and a prefix of layer $d+1$.*

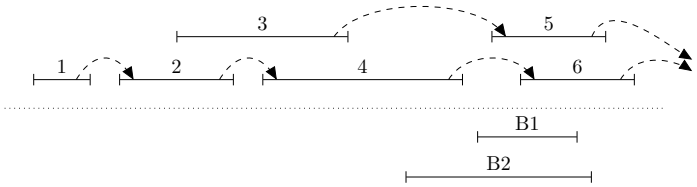

Figure 3 Part of an instance of DIS. Intervals in the decremental collection are shown above the dotted line and buffer intervals are below. Dashed arrows connect intervals with their respective LC-DECR(·). Here intervals 1, 2, 3 and 4 want to switch to B1 (3 and 4 directly) and interval 3 wants to (directly) switch to B2.

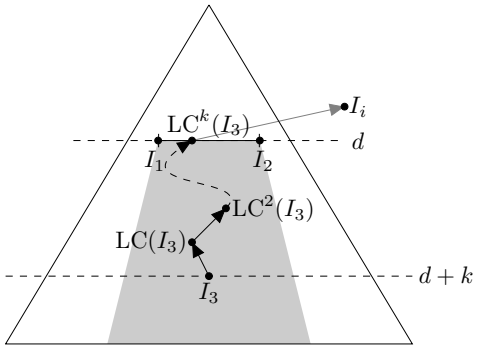

Figure 4 Indirect possibility of switching to $I_i \in \mathcal{B}_j$ for $I_3 \in \mathcal{A}_j$. Nodes of d-th layer in range from I_1 to I_2 directly want to switch to I_i. In the gray area are the nodes that want to switch to I_i.

Proof. Let $I_1 \prec I_3 \prec I_2$ and assume that I_1 and I_2 want to switch to I_i. Then, also I_3 wants to switch to I_i: I_i ends earlier than LC-DECR(I_3) because I_1 wants to switch and I_3 can switch to I_i because I_2 can. This shows that the nodes that want to switch to I_i form a continuous range in $\prec$. Active intervals that directly want to switch to any particular I_i are pairwise overlapping. Indeed, consider two such intervals $I_1 \prec I_2$. If they are compatible then $\mathrm{LC}(I_1) \preceq I_2$, so $\mathrm{LC}(I_1)$ ends earlier than any buffer interval compatible with I_2 to the right of I_2, a contradiction. This also proves that a node and its parent in the greedy tree cannot both directly want to switch to the same buffer interval thus completing the proof. ◀

Proposition 12 shows that the actual size of the information needed to notify the intervals from $\mathcal{A}_j$ that want to directly switch to a particular buffer interval is short. For each buffer interval, it is enough to remember endpoints of at most two ranges.

We also want to efficiently maintain information also indirect switching. Intervals that want to switch to I_i are the nodes in subtree of any node in ranges from Proposition 12. For range from I_1 to I_2 on layer d that wants to directly switch to I_i, any node I_3 on layer $d' = d + k \geq d$ satisfying $I_1 \preceq \text{LC-DECR}^k(I_3) \preceq I_2$ wants to switch to I_i, see Figure 4. We use a 2D range search tree indexed by depth and intervals of $\mathcal{A}_j$ in $\prec$ order. The structure allows us to store a collection of three-sided rectangles, so that given query point we can check if it is contained in at least one of the rectangles. To mark nodes as in Figure 4 we add $[d, +\infty) \times [I_1, I_2]$ to the tree.

An interval may want to switch to multiple intervals but the actual switching point for any $I_i \in \mathcal{A}_j$ is the earliest in $\prec$ (the deepest in $\mathcal{T}_j$) interval that wants to directly switch to a buffer interval on the path from I_i to the root in $\mathcal{T}_j$. We can deduce the actual earliest

switching to buffer interval from any $I_i \in \mathcal{A}_j$ on layer d in $\mathcal{O}(\text{polylog}\, n)$ time by using a binary search on depth $d' \leq d$, each time querying the 2D range search tree if a point (d', I_i) is covered by at least one rectangle. The result for the prefix of the path until reaching the buffer can be obtained from the top tree $\mathfrak{T}_j$. We recreate the whole range search tree after an update in the part.

For any $I_i \in \mathcal{B}_j$ we store the total length of the path to the root of $\mathcal{T}_j$ (this is the internal result for I_i in $\mathcal{P}_j$) and the latest actual interval of $\mathcal{P}_j$ just before reaching the root (this is the exit for I_i in $\mathcal{P}_j$). This information is recomputed for all buffer intervals in $\mathcal{P}_j$ using dynamic programming by iterating the buffer intervals by decreasing end times as follows. For $I_i \in \mathcal{B}_j$, we compute $\text{LC}(I_i)$ and if it is a buffer interval, we use its exit result and its internal result plus 1 as the information for I_i (and, by the order of the computation, we already know these). If $\text{LC}(I_i) \in \mathcal{A}_j$, we query the decremental collection for the next buffer interval after I_i selected by the greedy algorithm as described above and combine its result with the prefix of the traversed path from $\text{LC}(I_i)$ in the decremental collection. This is computed in $\tilde{\mathcal{O}}(n^{1/3})$ time.

3 Interval scheduling on multiple machines

We stress that we assume that there are constant number of machines thus we are going to ignore $\mathcal{O}(\text{poly}\, m)$ factors in time complexities. The difference between naive application of standard techniques and our algorithms is negligible when m is large.

As the main idea of our algorithm is to efficiently simulate the folklore greedy algorithm for IS+ (described in [6, 11]), we now remind it. The intervals are considered separately by the earliest end time. For each considered interval, if there is no available machine at the time, the job is rejected. Otherwise, it is accepted and assigned the available machine that was busy at the latest time. The proof of correctness is a standard exchange argument.

The state of a partial execution (up to some time t) of the greedy algorithm can be fully described by the sequence of length m, where i-th entry describes which interval was last scheduled on i-th machine before or at time t. Some of the entry intervals to $\mathcal{P}_j$ may not belong to $\mathcal{P}_{j-1}$ if some machine had not accepted any intervals in $\mathcal{P}_{j-1}$. At the same time, we want to preprocess information only for tuples of intervals from $\mathcal{P}_j$, thus we need the following additional notation.

▶ **Definition 13.** *The* greedy state G_t *(at time t) is the (multi)set of m input intervals. Each element $I_i = (s_i, f_i) \in G_t$ means that at time t there is a machine that was busy up to time f_i. We use elements $\overline{I_i}$ to indicate that there is a machine which was busy up to time s_i.*

$\overline{\cdot}$ indicates that the particular machine is blocked for all intervals that start too early. Thus, despite each interval can only be selected once, we may want to mark that some machines are busy up to the same time. For this reason, we decided to use multisets for greedy states. $\overline{(s_i, f_i)}$ can be simulated by an artificial interval $(-\infty, s_i)$.

The greedy algorithm only considers values of t that are end times of intervals $I_i = (s_i, f_i)$ in the input. We slightly abuse the notation and use G_k to denote the greedy state at time f_k and assume the intervals are ordered according to the order of the IS+ algorithm i.e. $f_1 < f_2 < \ldots < f_n$. To not consider cases with $|G_k| < m$ we add m pairwise overlapping intervals all ending earlier than the beginning of any actual input interval.

If $G_{k-1} \neq G_k$, exactly one element of G_{k-1} needs to be updated to obtain G_k. It is the one that is ending the latest among the elements of G_{k-1} compatible with I_k. One can see the same from a slightly different perspective. Let us assume that i is the index for which

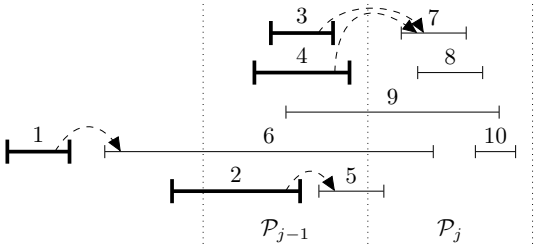

Figure 5 Translation of an exit greedy state $G = \{1, 2, 3, 4\}$ from part $\mathcal{P}_{j-1}$. Each interval of G is rounded to the earliest starting interval in $\mathcal{P}_j$ that is later than the end of the interval (denoted by dashed directed edge). Thus, we can assume that the entry greedy state in $\mathcal{P}_j$ is $\{\overline{5}, \overline{6}, \overline{7}, \overline{7}\}$.

$\mathrm{LC}(I_i)$ is the earliest ending interval among G_k. Then $G_k = G_{k+1} = \ldots = G_{k'-1} \neq G_{k'}$ and $G_{k'} = G_k \setminus \{I_i\} \cup \{\mathrm{LC}(I_i)\}$. We call $G_{k'}$ the *next greedy state after* G_k and denote it $\textsc{Next}(G_k)$. Because $\mathrm{LC}(\cdot)$ can be computed in $\mathcal{O}(\mathrm{polylog}\, n)$ time using the appropriate structure as described in Appendix A, we iterate through all candidates for I_i in the greedy state and thus have the following.

▶ **Corollary 14.** *$\textsc{Next}(G_k)$ can be computed in $\tilde{\mathcal{O}}(m)$ time for any G_k.*

We use insights from Section 2 and Appendix A and split the intervals into $\mathcal{O}(n^{1-1/m})$ parts of size at most $\mathcal{O}(n^{1/m})$. We restrict $\mathrm{LC}(\cdot)$ to only consider intervals in the same part as the argument of the operation (it can return $\perp$). We build an additional structure for internal intervals in each part and rebuild it every update in the part. As in the case of interval scheduling on one machine, our goal is to be able to efficiently handle (in $\mathcal{O}(\mathrm{polylog}\, n)$ time) a query for the internal result (the number of accepted intervals) and the exit greedy state from the part for a given entry greedy state G_k in the part – we call this the *part query from the greedy state G_k*.

Notice that during the execution of the greedy algorithm up to $\mathcal{P}_{j-1}$, it may happen that some machine will not accept any new interval in $\mathcal{P}_{j-1}$, so the exit greedy state coming from $\mathcal{P}_{j-1}$ may contain intervals also from earlier parts. Let us now describe how to translate such an exit greedy state coming from $\mathcal{P}_{j-1}$ into an entry greedy state of $\mathcal{P}_j$, so we can later only consider the content of one part. We observe that the decisions of the greedy algorithm only depend on the relative order of endpoints of the considered intervals. If a machine was busy up to time t and there are no intervals starting before time $t' > t$, we can safely assume that the machine is busy up to time t' without changing the execution of the greedy algorithm. Thus, we round up the end of each interval in the greedy state to the earliest start of some interval in $\mathcal{P}_j$. See Figure 5. We stress that the result of rounding is not necessarily part of the solution generated by our algorithm. It just indicates times up to which the machines are busy. After computing the exit greedy state for $\mathcal{P}_j$, we inspect if there are machines that have not accepted any intervals from $\mathcal{P}_j$ and revert the rounding for these.

We stick to Definition 4, but we cannot make direct use of Lemma 5 because in the case of multiple machines it may happen that inactive intervals are part of the optimal solution. As these intervals may not form a monotonic collection, we redefine $\prec$ order as follows: $(s_1, f_1) \prec (s_2, f_2) \Leftrightarrow f_1 < f_2$. We still maintain the greedy tree $\mathcal{T}_j$ and the top tree $\mathfrak{T}_j$[1] as described for one machine. We identify intervals with the nodes representing them in $\mathcal{T}_j$.

[1] We could also use simpler structures as we only need a subset of operations provided by the top tree and we can afford to rebuild the structure from scratch every update.

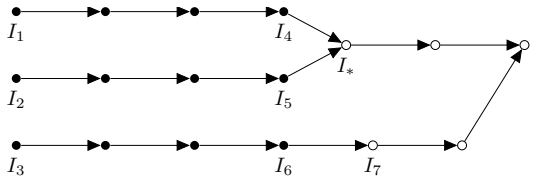

Figure 6 Lemma 16 for $G = \{I_1, I_2, I_3\}$. Here we assume $I_6 \prec I_* \prec I_7$. Elements of $\mathrm{N}(\cdot, \mathrm{I}_*)$ are filled dots. We have $\textsc{Next}^9(G) = \{I_4, I_5, I_6\}$ and $I_* \in \textsc{Next}^{10}(G)$.

▶ **Lemma 15.** *Let $I_i = (s_i, f_i)$ be an inactive interval and let $I_{i'} = (s_{i'}, f_{i'})$ be the latest (in $\prec$) interval contained inside I_i. If $I_i \in G_i$ then also $I_{i'} \in G_i$.*

Proof. Any interval compatible with I_i is also compatible with $I_{i'}$ and $I_{i'}$ ends earlier than I_i. This means that if I_i is accepted then also $I_{i'}$ is (at time $f_{i'}$). From time $f_{i'}$ up to time f_i the machine that accepted $I_{i'}$ cannot accept other interval: it would have to start after $f_{i'}$ and end before f_i thus violating our assumption that $I_{i'}$ is the latest interval contained inside I_i. This implies that $I_{i'} \in G_i$. ◀

▶ **Lemma 16.** *Let $G = \{I_1, I_2, \ldots, I_m\}$ be a greedy state for which all elements are active intervals. Let $I_* = (s_*, f_*)$ be the earliest (in $\prec$) interval being a common ancestor of any pair of elements of G. Let $\mathrm{N}(I_i, I_*)$ be a prefix of $\{I_i, LC(I_i), LC^2(I_i), \ldots\}$ intervals preceding I_* and let $\mathrm{S}(I_i, I_*)$ be the latest of $\mathrm{N}(I_i, I_*)$.*

Then $\mathrm{N}(I_1, I_*) \cup \mathrm{N}(I_2, I_*) \cup \ldots \cup \mathrm{N}(I_m, I_*)$ are the only elements scheduled by the greedy algorithm for IS+ resumed from G before reaching time f_*. Additionally, just before time f_* the greedy state of the algorithm is $\{\mathrm{S}(I_i, I_*) : i \in \{1, 2, \ldots, m\}\}$.

Proof. First, we make a technical note that thanks to the artificial root added to form the greedy tree, the interval I_* always exists.

The candidates for values of $\textsc{Next}(G_t)$ are G_ts with exactly one of the intervals replaced by its $\mathrm{LC}(\cdot)$ assigned to the same machine. Thus, by using this reasoning inductively for $\textsc{Next}^k(G)$ for increasing k, we observe that when moving forward along the path from any $I_i \in G$ to the root in the greedy tree, at least until reaching some interval $\succeq I_*$, all the traversed intervals will be scheduled on the same machine as I_i. Additionally, for different $I_{i'}, I_{i''} \in G$, the paths from $I_{i'}$ and $I_{i''}$ in the greedy tree do not share any nodes that are $\prec I_*$ (by definition). This way, all and the only elements that are included in some greedy state after G before considering I_* are the elements of $\mathrm{N}(I_i, I_*)$ and also just before considering I_* all the latest elements of $\mathrm{N}(\cdot, I_*)$ are in the greedy state. See Figure 6. ◀

If the elements of greedy state G are all active, we can naively compute I_* as in Lemma 16 by checking LCAs of all pairs of intervals in G in the greedy tree and then proceeding to the last interval before I_* independently from each node to obtain the last greedy state before reaching I_* as in Figure 6. Thus we have the following.

▶ **Corollary 17.** *Let $G = \{I_1, I_2, \ldots, I_m\}$ be a greedy state with only active intervals and let I_* be defined as in Lemma 16. It is possible to compute both the smallest k for which $I_* \in \textsc{Next}^k(G)$ and the value of $\textsc{Next}^k(G)$ itself in $\tilde{\mathcal{O}}(m^2)$ time.*

3.1 An $\tilde{\mathcal{O}}(n^{1/2})$-time algorithm for two machines

In this section, we focus on describing an efficient algorithm for dynamic interval scheduling on two machines and prove the following.

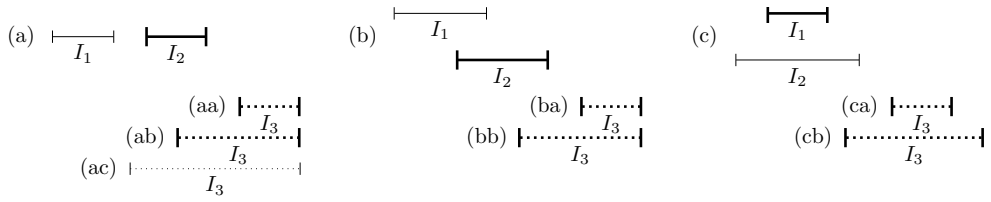

Figure 7 Three possible forms of a greedy state and cases as in Lemma 19. Active intervals are marked with bold lines and potential cases for I_3 are marked with dotted lines. Note that I_1 in forms (a) and (b) may be either active or inactive.

▶ **Theorem 18.** *There is a data structure for DIS2 that supports any sequence of n insert/delete/query on intervals in $\tilde{\mathcal{O}}(n^{1/2})$ amortized time per each operation.*

▶ **Lemma 19.** *There are only three possible forms of a greedy state for two machines.*
(a) $\{I_1, I_2\}$ *where* $I_1 \prec I_2$, I_1 *and* I_2 *are compatible and* I_2 *is active,*
(b) $\{I_1, I_2\}$ *where* I_1 *ends earlier than* I_2, I_1 *and* I_2 *are overlapping and* I_2 *is active,*
(c) $\{I_1, I_2\}$ *where an active interval* I_1 *is fully contained inside (an inactive)* I_2.

Proof. First we assume, without losing generality, that the greedy algorithm considered at least two intervals and resumes from the greedy state G_2 that is of the form (a) and $I_1 = (s_1, f_1)$, $I_2 = (s_2, f_2)$. One can easily prepend any instance of DIS+ with few intervals to achieve this.

Let assume that the next accepted interval by the greedy algorithm is $I_3 = (s_3, f_3)$ and the next greedy state after G_2 is G_3. There are three cases (see Figure 7):
(aa) $f_2 < s_3$ – then I_3 is an active interval and $G_3 = \{I_1, I_3\}$ is of the form (a),
(ab) $s_2 < s_3 < f_2$ – then I_3 is an active interval and $G_3 = \{I_2, I_3\}$ is of the form (b),
(ac) $s_3 < s_2$ – then I_3 is an inactive interval and $G_3 = \{I_2, I_3\}$ is of the form (c).
We now proceed to similar analysis of what are the forms of next greedy states that can be reached from states of the form (b) and (c).

If G_2 is of the form (b) then I_3 is either compatible with I_2 (case (ba)) and G_3 is of the form (a), or it overlaps with I_2 (case (bb)) and G_3 is of the form (b). Note that I_3 can not overlap with I_1 as then I_3 would be rejected.

Similarly, if G_2 is of the form (c) then I_3 is either compatible with I_2 (case (ca)) and G_3 is of the form (a), or it overlaps with I_2 (case (cb)) and G_3 is of the form (b).

No other forms than (a), (b) or (c) are reachable from (a) and this concludes the proof. ◀

We now describe our algorithm for DIS2. For each part it maintains the following:
- $B[I_i]$ for all active intervals I_i – the result of part query from the greedy state $\{I_i, I_{i'}\}$ of the form (b) where $I_{i'}$ is direct successor (in $\prec$ order),
- $C[I_i]$ for all inactive intervals I_i – the result of part query from the greedy state $\{I_i, I_{i'}\}$ of the form (c) where $I_{i'}$ is the latest (in $\prec$ order) active interval fully inside I_i.

When a part is updated, $B[\cdot]$ and $C[\cdot]$ structures are rebuilt from scratch. Computation of $B[I_i]$ or $C[I_i]$ is nothing else than answering a part query for the appropriate greedy state. We ask these queries in decreasing order of the sum of indices (in $\prec$ order) of the two intervals of the greedy state. This way, during the recomputation of $B[\cdot]$ and $C[\cdot]$ structures, whenever the algorithm is going to use some other result of $B[\cdot]$ or $C[\cdot]$ it is already computed as the queried sum of indices will be larger.

Additionally, for each active interval I_i we precompute the earliest (in $\prec$) interval $I_{i'}$ not on the path from I_i to the root of $\mathcal{T}_j$. We do this using dynamic programming, inspecting all the intervals in decreasing order of $\prec$ and it takes $\tilde{\mathcal{O}}(n^{1/2})$ time. Similarly, we precompute the number of intervals on the path from I_i to the latest interval ending earlier than $I_{i'}$.

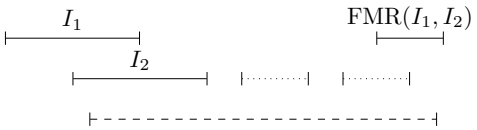

Figure 8 Both dotted intervals are accepted by the machine that accepted I_2 and the dashed interval overlaps with I_1 so is rejected. The left dotted interval in the example is $I_{i'''}$, the solution of the subproblem from the computation of FMR(I_1, I_2).

We now describe how to answer the part query from a greedy state G_i following the proof of Lemma 19 and considering all forms of G_i.

If G_i is of the form (a) we focus on finding the greedy state $G_{i'} = \textsc{Next}^k(G_i)$ for which k is the smallest such that $I_1 \notin \textsc{Next}^k(G_i)$. If I_1 is replaced in $G_{i'}$ by an active interval $I_{i'}$, it has to be the earliest (in $\prec$) interval overlapping with an interval $I_{i''}$ on the path from I_2 to the root in $\mathcal{T}_j$ (it can also be I_2 itself). We know which one and what is the contribution to the internal result as we precomputed it. Moreover, we observe that $G_{i'} = \{I_{i'}, I_{i''}\}$ and its part result is stored in $B[I_{i''}]$ so we just read the result from there. If I_1 is replaced in $G_{i'}$ by an inactive interval $I_{i'}$ it has to be the earliest (in $\prec$) interval compatible with I_1. Then $G_{i'} = \{I_{i'}, I_{i''}\}$ where $I_{i''}$ is the latest (in $\prec$ order) active interval fully inside $I_{i'}$. Thus, we read the part result for $G_{i'}$ from $C[I_{i'}]$.

If G_i is of the form (b), then $\textsc{Next}(G_i)$ is either of the form (a) for which we proceed as described above or of the form (b) but with both greedy state intervals active (case (bb) of the proof of Lemma 19), for which we use Corollary 17 to reach the greedy state of the form (a) and later proceed as described above.

If G_i is of the form (c), then $\textsc{Next}(G_i)$ is either of the form (a) or (b) and we proceed as described above.

3.2 An $\tilde{\mathcal{O}}(n^{1-1/m})$-time algorithm for $m \geq 3$ machines

Surprisingly, before we start describing the final algorithm for $m \geq 3$ machines, we need an additional building block for the two machine case.

▶ **Definition 20.** *For a collection of intervals S, for $I_1 \prec I_2$ from S, we define the* first machine replacement *$FMR(I_1, I_2)$ to be the interval in S which replaces I_1 in the greedy state when resuming the greedy execution from the greedy state $\{I_1, I_2\}$ on two machines. In other words, $FMR(I_1, I_2)$ is the earliest ending accepted interval after I_2 that will be scheduled on the same machine as I_1 by the greedy algorithm for IS+.*

Within the desired time bounds, for $m \geq 3$, we can afford recomputing FMR$(\cdot, \cdot)$ in parts from scratch for every pair of intervals in the updated part, as long as this recomputation takes $\tilde{\mathcal{O}}(|\mathcal{P}_j|^2)$ time. We could not do the same for $m = 2$.

▶ **Lemma 21.** *The values of $FMR(\cdot, \cdot)$ for all pairs of intervals in a collection of n intervals, can be computed in $\tilde{\mathcal{O}}(n^2)$ time.*

Proof. Assuming that intervals in part are ordered by $\prec$ and given names $I_1, I_2, \ldots$ in line with this order, we compute FMR$(I_{i'}, I_{i''})$ in decreasing order of the sum of $i' + i''$ indices. To compute FMR$(I_{i'}, I_{i''})$, for $I_{i'} = (s_{i'}, f_{i'})$ and $I_{i''} = (s_{i''}, f_{i''})$ we first find the earliest ending interval $I_{i'''}$ that ends later than $I_{i''}$ and is compatible with $I_{i'}$. To solve this subproblem we take a geometric view: each interval (s_i, f_i) is converted into a point (s_i, f_i) in 2D plane, the goal is to find the point with smallest y-coordinate above and to the right of $(s_{i'}, f_{i''})$. This

is solved by a 2D range search tree indexed by (x, y)-coordinates storing the appropriate result. Thus, the subproblem is solved. We proceed with the computation of $\mathrm{FMR}(I_{i'}, I_{i''})$. We have two cases: either $I_{i'''}$ is overlapping with $I_{i''}$ and then $\mathrm{FMR}(I_{i'}, I_{i''}) = I_{i'''}$ or $I_{i'''}$ is compatible with $I_{i''}$ and then $\mathrm{FMR}(I_{i'}, I_{i''}) = \mathrm{FMR}(I_{i'}, I_{i'''})$ which is already known by the order of the computation. We can also compute the number of intervals chosen by the greedy algorithm when resumed from state $\{I_{i'}, I_{i''}\}$ until reaching $\mathrm{FMR}(I_{i'}, I_{i''})$ (just 1 or the number chosen from $I_{i'}, I_{i'''}$ plus 1 depending on the above cases). ◀

As it turns out, the values of $\mathrm{FMR}(\cdot, \cdot)$ play important role in the algorithm for $m \geq 3$. We want to preprocess tuples of possible entry greedy states for a part to be able to efficiently answer part queries. The problem is that we have $\mathcal{O}(n^{1/m})$ intervals in each part, but we aim at $\tilde{\mathcal{O}}(n^{1-1/m})$ time complexity. Thus, we cannot precompute part queries for all possible greedy states. Instead, we carefully select specific *compressible* greedy states for which part query results are actually stored and design an algorithm that can push the simulation forward to the next compressible state or the exit state from the part.

▶ **Definition 22.** *Let $G_t = \{I_1, I_2, \ldots, I_m\}$ be a greedy state. We assume $I_1 \preceq I_2 \preceq \ldots \preceq I_m$. We say that G_t is* compressible *if at least one of the following conditions hold:*
(a) *I_m is inactive,*
(b) *I_m is active and exists active interval I_p such that $LC(I_p) = I_m$,*
(c) *$I_m = FMR(I_1, I_{m-1})$.*

▶ **Lemma 23.** *In a part of n intervals for DIS+ on m machines, there are only $\mathcal{O}(n^{m-1})$ compressible greedy states.*

Proof. We consider all the forms of the compressible greedy state as in Definition 22.
(a) from Lemma 15 we know that the greedy state also contains the latest interval fully inside I_m and thus we can forget this interval, so there are $\mathcal{O}(n^{m-1})$ such states,
(b) there is an edge (I_p, I_m) in the greedy tree of $\mathcal{P}_j$, we can store $(m-2)$-tuple of other intervals and the identifier of the appropriate edge, so there are $\mathcal{O}(n^{m-1})$ such states,
(c) we forget I_m as it is equal to $\mathrm{FMR}(I_1, I_{m-1})$, so there are $\mathcal{O}(n^{m-1})$ such states. ◀

Note that we can decompress the representations from Lemma 23 in $\mathcal{O}(m)$ time to obtain a full greedy state of size m. Also, by taking into account the sizes of the parts, we obtain that there are only $\mathcal{O}(n^{1-1/m})$ compressible greedy states for n intervals in S.

For an update in $\mathcal{P}_j$, we recompute part query results for all compressible greedy states in $\mathcal{P}_j$. As in Section 3.1, we do this using dynamic programming, in decreasing order of the sum of indices of the uncompressed state. The problem of computing the results for the states stored in the dynamic programming table is once again translated into the general query that has m-tuple as an input and has to push the simulation forward either to the next part or at least to a compressible greedy state from which we read the already preprocessed result and combine it with the traversed prefix of the path. We proceed with describing how to solve this general query.

We distinguish three forms of the greedy state $G = \{I_1, I_2, \ldots, I_m\}$ for $I_1 \preceq I_2 \preceq \ldots \preceq I_m$:
(*) I_m is inactive,
(**) there is $1 < p \leq m$ such that all intervals $I_p, I_{p+1}, \ldots, I_m$ are active,
(***) all $I_1, I_2, \ldots, I_m$ are active.

For case (*), we compute $G' = \textsc{Next}(G)$. Either the latest accepted interval in G' is inactive and then G' is compressible of type (a) or it is active, thus G' is of the form (**) or (***) and we proceed with it as described below.

For case (***), we use Corollary 17 to find the earliest greedy state $G' = \textsc{Next}^k(G)$ for which $I_* \in G'$. We observe that such G' is compressible of type (b), as both I_* and at least one of its children are elements of G'.

We now consider case (**). We compute $G' = \textsc{Next}(G)$ and consider the following subcases depending on the latest accepted interval I_+ in G':

(1) I_+ is inactive,
(2) I_+ is active, overlapping with I_m and $I_1 \in G'$,
(3) I_+ is active, overlapping with I_m and $I_1 \notin G'$,
(4) I_+ is active and not overlapping with I_m.

In case (1), we see that G' is compressible of type (a). In case (2), we observe that $I_+ = \mathrm{FMR}(I_1, I_m)$, so G' is compressible of type (c). In case (3), we observe that G' remains of type (**), but with smaller p. We proceed with computing $\textsc{Next}(G')$ until we reach any other case, which happens after at most $\mathcal{O}(m)$ iterations. In case (4), we observe that $G' = G \setminus \{I_m\} \cup \{I_+\}$ and I_+ is compatible with every other interval from G'. We read $\mathrm{FMR}(I_1, I_+)$ and push the simulation forward until reaching the first greedy state G'' with accepted interval I_{++} that will be scheduled on a different machine than I_m. Notice that if I_{++} is active then it is compatible with I_1 so $I_{++} = \mathrm{FMR}(I_1, I_m)$. As $m \geq 3$, I_{++} will replace $I_{m-1} \neq I_1$ in the greedy state thus G'' is compressible of type (c) and if I_{++} is inactive then G'' is compressible of type (a).

4 Lower bound for Dynamic Weighted Interval Scheduling

The Minimum Weight k-Clique problem is to find, in an edge-weighted graph, a clique of exactly k nodes having the minimum total weight of edges.

The following hypothesis about Minimum Weight k-Clique problem was formulated.

▶ **Conjecture 24** (Min Weight $(2\ell+1)$-Clique Hypothesis [22]). *There is a constant $c > 1$ such that, on a Word-RAM with $\mathcal{O}(\log n)$-bit words, finding a k-Clique of minimum total edge weight in an n-node graph with non-negative integer edge weights in $[1, n^{ck}]$ requires $n^{k-o(1)}$ time.*

The Minimum Weight $(2\ell+1)$-Cycle problem is to find, in an edge-weighted graph, a cycle consisting exactly $2\ell+1$ edges having the minimum total weight.

▶ **Theorem 25** ([22]). *If there is an integer $\ell \geq 1$ and a constant $\epsilon > 0$ such that Minimum Weight $(2\ell+1)$-Cycle in a directed weighted n-node $m = \Theta(n^{1+1/\ell})$-edge graph can be solved in $O(mn^{1-\epsilon} + n^2)$ time, then the Min Weight $(2\ell+1)$-Clique Hypothesis is false.*

Based on the above, we formulate the following.

▶ **Theorem 26.** *Unless the Min Weight $(2\ell+1)$-Clique Hypothesis is false, for all $\epsilon > 0$ there is no algorithm for DWIS problem with $O(n^{1-\epsilon})$ update and query time.*

Proof. As in [22], we use the fact that Minimum Weight $(2\ell+1)$-Cycle is still hard if restricted only to k-circle layered graphs, that is k-partite graphs in which, for each $i \in [k]$, all edges from nodes in i-th part end in $(i \bmod k+1)$-th part.

We reduce Minimum Weight $(2\ell+1)$-Cycle in a weighted $(2\ell+1)$-circle layered graph to DWIS. The input instance has n nodes and $m = \Theta(n^{1+1/\ell})$ edges of integer weights in range $[n^{c\ell} = W]$ for large enough c. We enumerate parts from 1 to $2\ell+1$ and we enumerate nodes independently in each parts starting from 0. For all $p \in [2\ell]$, for all edges from u-th node in p-th part to v-th node in $(p+1)$-th part, we insert an interval $[(p-1)n + u,\ pn + v)$ of weight $(f_i - s_i)(2\ell+1)(W+1) + (W - w)$ where w is the edge weight.

The optimal cycle has to go through some node s in the first part. We guess this node by inserting an interval $[-1, s)$ of weight $(f_i - s_i)(2\ell+1)(W+1)$ and, for all edges from u-th node in $(2\ell+1)$-th part to s of weight w, we insert an interval $[2\ell \cdot n + u,\ (2\ell+1) \cdot n)$ of weight $(f_i - s_i)(2\ell+1)(W+1) + (W-w)$. To start with another choice of s, we delete the corresponding intervals before inserting the new ones.

The selection of edge weights in our instance guarantees that the optimal solution maximizes the total length of chosen intervals and then minimizes the weight resulting from weights of edges in the graph, as each unit of length increases the value of the solution by $(2\ell+1)(W+1)$ while the additional gain from edge weights is, in total, at most $(2\ell+1)W$.

The only possibility to obtain the value of at least $(2\ell+1)(W+1)n$ is to choose the intervals spanning the whole interval $[-1, (2\ell+1)n)$ in the created instance. Such selection ensures that an interval representing node s in the first part is selected, as well as all intervals representing the edges on the cycle, including the last edge going to the first part represented by the interval with $f_i = (2\ell+1)(W+1)$. Because in this scenario there is no gap nor overlap in coordinates of the selected intervals, any two consecutive edges share a common node, so they form a $(2\ell+1)$-cycle. Thus, there is 1-1 correspondence between $(2\ell+1)$-cycles going through node s in the first part and solutions of weight at least $(2\ell+1)(W+1)n$. Nodes of the optimal $(2\ell+1)$-cycle can be deduced by inspecting endpoints of the selected intervals.

To solve Minimum Weight $(2\ell+1)$-Cycle by the above reduction we invoked $\mathcal{O}(m)$ insertions and deletions to DWIS structure. By choosing the input instance to have $\ell = \frac{1}{\epsilon}$ and $n = c\ell$ for large enough c, and assuming (ad absurdum) that these $\mathcal{O}(m) = \mathcal{O}(n^{1+\epsilon})$ operations took $\mathcal{O}(m \cdot m^{1-\epsilon})$ time, we obtained $\mathcal{O}(n^{2+\epsilon-\epsilon^2})$-time algorithm for the Minimum Weight $(2\ell+1)$-Cycle problem, thus violating Theorem 25. ◀

A An $\tilde{\mathcal{O}}(n^{1/2})$-time algorithm for one machine

Here we show a simple structure that already needs a subset of the ideas used in more complicated and faster structures described in the paper. We show the data structure for DIS showing the following.

▶ **Theorem 27.** *There is a data structure for DIS that supports any sequence of n insert/delete operations in $\mathcal{O}(\sqrt{n}\log n)$ amortized time per update.*

We choose the set of *separators* $x_1 < x_2 < \cdots < x_k$. Separators split the universe of coordinates into $k+1$ *parts*: $\mathcal{P}_0, \mathcal{P}_1, \ldots, \mathcal{P}_k$. Assuming that $x_{k+1} = +\infty$, each part $\mathcal{P}_j$ contains intervals (s_i, f_i) with $x_j \le s_i < x_{j+1}$. Thus, at any time parts represent partition of intervals. We define the *size* of a part as the number of intervals in it. Intervals store references to parts in which are contained.

Separators (and pointers to the appropriate parts) are stored in a predecessor/successor data structure (we use balanced binary search trees [8] [2]) and are chosen to satisfy the following invariant: each part has size at most $2\sqrt{N}$ and for every two consecutive parts $\mathcal{P}_j$ and $\mathcal{P}_{j+1}$ at least one has size at least $\frac{1}{2}\sqrt{N}$. Thus, there are $\mathcal{O}(\sqrt{n})$ parts at any time and local rebuild of parts of size $\mathcal{O}(\sqrt{n})$ happens after $\Omega(\sqrt{n})$ operations affecting the part. As these rebuilds are simply appropriate separate insertions, the amortized update time complexity does not change.

Intervals in part $\mathcal{P}_j$ satisfying $f_i < x_{j+1}$ are called *internal* and all the others are called *external*. Internal intervals are stored in predecessor/successor data structures: sorted by s_i and, separately, sorted by f_i. Additionally, we have the same structures defined globally, for all the intervals in S. This allows to compute $\mathrm{LC}(I_i)$ in $\mathcal{O}(\log n)$ time.

For each internal interval I_i in part $\mathcal{P}_j$ we store its leftmost compatible internal interval in the same part, denoted by $\text{LC-INT}(I_i)$ (either $\mathrm{LC}(I_i)$ or $\perp$ in case $\mathrm{LC}(I_i) \notin \mathcal{P}_j$ or is external). Additionally, we store the information to resume the greedy execution from an internal interval I_i to the latest interval in the same part. This includes: $\text{RES-INT}(I_i)$ – the largest $r \geq 0$ such that $\text{LC-INT}^r(I_i) \neq \perp$ and $\text{EXIT-INT}(I_i) = \mathrm{LC}^{\text{RES-INT}(I_i)-1}(I_i)$.

When the content of $\mathcal{P}_j$ is updated, all the above values for intervals of $\mathcal{P}_j$ are recomputed naively from scratch: we start with computing $\text{LC-INT}(\cdot)$ in decreasing order of f_i. We set $\text{LC-INT}((s_i, f_i))$ to be the interval I' with the smallest $f_{i'}$ among intervals with $s_{i'} \geq f_i$ or $\perp$ if there is no such interval. We update which interval is I' whenever the computation of $\text{LC-INT}(\cdot)$ proceeds to smaller values of f_i by querying the appropriate part structure (containing only internal intervals) sorted by s_i. Overall, this naive recomputation of all information for all internal intervals in the part takes $\mathcal{O}(\sqrt{n}\log n)$ time.

With the above, we can resume the greedy algorithm from any I_i in any $\mathcal{P}_j$ until reaching the earliest interval in the solution outside $\mathcal{P}_j$ in $\mathcal{O}(\log n)$ time. For an external interval I_i it is enough to proceed to $\mathrm{LC}(I_i)$ to exit $\mathcal{P}_j$. If I_i is internal, we increase the total result by the number of selected intervals in the part (the internal result for I_i) and proceed to $I_{i'} = \mathrm{LC}(\text{EXIT-INT}(I_i))$. $I_{i'}$ may already be in some further part or it may be an external interval in $\mathcal{P}_j$ and then we proceed to $\mathrm{LC}(I_{i'}) \notin \mathcal{P}_j$.

To answer a DIS query, we simulate the execution of the greedy algorithm starting from the earliest ending interval and traversing the parts as described above. The query as described takes $\mathcal{O}(\sqrt{n}\log n)$ time.

To insert an interval (s_i, f_i) to S, we first locate the appropriate part $\mathcal{P}_j$ in the separators structure, insert the interval into $\mathcal{P}_j$, recompute the additional information associated with $\mathcal{P}_j$ and update the global structures. All these takes $\mathcal{O}(\sqrt{n}\log n)$ time. During insertion, it may happen that $\mathcal{P}_j$ becomes too large. In this case, if the size reached s, we naively find (using an appropriate predecessor/successor structure) $\lceil \frac{s}{2} \rceil$-th value x in the set of s_is of all intervals in $\mathcal{P}_j$ and add x as the new separator. This splits $\mathcal{P}_j$ into two new parts, which we recompute from scratch. This, again, works in $\mathcal{O}(\sqrt{n}\log n)$ time.

Deletion of an interval of $\mathcal{P}_j$ is similar and in the case of underflow of pair $\mathcal{P}_j$ and $\mathcal{P}_{j+1}$ or $\mathcal{P}_{j-1}$ and $\mathcal{P}_j$, we merge the parts by removing the separator between them and recompute the new part.

[2] If for all intervals s_i, f_i are small integers bounded by U, we could use y-fast tries [24]. This way we could achieve $\mathcal{O}(\sqrt{n}\log\log U)$ amortized time per operation.

Galloping in Fast-Growth Natural Merge Sorts

Abstract

We study the impact of sub-array merging routines on merge-based sorting algorithms. More precisely, we focus on the *galloping* sub-routine that TimSort uses to merge monotonic (non-decreasing) sub-arrays, hereafter called *runs*, and on the impact on the number of element comparisons performed if one uses this sub-routine instead of a naive merging routine.

The efficiency of TimSort and of similar sorting algorithms has often been explained by using the notion of *runs* and the associated *run-length entropy*. Here, we focus on the related notion of *dual runs*, which was introduced in the 1990s, and the associated *dual run-length entropy*. We prove, for this complexity measure, results that are similar to those already known when considering standard run-induced measures: in particular, TimSort requires only $\mathcal{O}(n + n\log(\sigma))$ element comparisons to sort arrays of length n with σ distinct values.

In order to do so, we introduce new notions of *fast-* and *middle-growth* for natural merge sorts (i.e., algorithms based on merging runs). By using these notions, we prove that several merge sorting algorithms, provided that they use TimSort's galloping sub-routine for merging runs, are as efficient as TimSort at sorting arrays with low run-induced or dual-run-induced complexities.

1 Introduction

In 2002, Tim Peters, a software engineer, created a new sorting algorithm, which was called TimSort [20] and was built on ideas from McIlroy [17]. This algorithm immediately demonstrated its efficiency for sorting actual data, and was adopted as the standard sorting algorithm in core libraries of widespread programming languages such as Python and Java. Hence, the prominence of such a custom-made algorithm over previously preferred *optimal* algorithms contributed to the regain of interest in the study of sorting algorithms.

$$S = (\underbrace{12, 7, 6, 5}_{\text{first run}}, \underbrace{5, 7, 14, 36}_{\text{second run}}, \underbrace{3, 3, 5, 21, 21}_{\text{third run}}, \underbrace{20, 8, 5, 1}_{\text{fourth run}})$$

Figure 1 A sequence and its *run decomposition* computed by a greedy algorithm: for each run, the first two elements determine if the run is non-decreasing or decreasing, then the run continues with the maximum number of consecutive elements that preserve its monotonicity.

Among the best-identified reasons behind the success of TimSort are the fact that this algorithm is well adapted to the architecture of computers (e.g., for dealing with cache issues) and to realistic distributions of data. In particular, the very conception of TimSort makes it particularly well-suited to sorting data whose *run decompositions* [3, 9] (see Figure 1) are simple. Such decompositions were already used in 1973 by Knuth's NaturalMergeSort [14, Section 5.2.4], which adapted the traditional MergeSort algorithm as follows: NaturalMergeSort is based on splitting arrays into monotonic subsequences, also called *runs*, and on merging these runs together. Thus, all algorithms sharing this feature of NaturalMergeSort are also called *natural* merge sorts.

In addition to being a natural merge sort, TimSort includes many optimisations, which were carefully engineered, through extensive testing, to offer the best complexity performances. As a result, the general structure of TimSort can be split into three main components: (i) a variant of an insertion sort, which is used to deal with *small* runs, e.g., runs of length less than 32, (ii) a simple policy for choosing which *large* runs to merge, (iii) a sub-routine for merging these runs, based on a so-called *galloping* strategy. The second component has been subject to an intense scrutiny these last few years, thereby giving birth to a great variety of TimSort-like algorithms, such as α-StackSort [2], α-MergeSort [7], ShiversSort [22] (which *predated* TimSort), adaptive ShiversSort [13], PeekSort and PowerSort [19]. On the contrary, the first and third components, which seem more complicated and whose effect might be harder to quantify, have often been used as black boxes when studying TimSort or designing variants thereof.

In what follows, we focus on the third component and prove that it is very efficient: whereas TimSort requires $\mathcal{O}(n + n\log(\rho))$ comparisons to sort arrays of length n that can be decomposed as a concatenation of ρ non-decreasing arrays, this component makes TimSort require only $\mathcal{O}(n + n\log(\sigma))$ comparisons to sort arrays of length n with σ distinct values.

Context and related work

The success of TimSort has nurtured the interest in the quest for sorting algorithms that would be both excellent all-around and adapted to arrays with few runs. However, its *ad hoc* conception made its complexity analysis harder than what one might have hoped, and it is only in 2015, a decade after TimSort had been largely deployed, that Auger et al. [2] proved that TimSort required $\mathcal{O}(n\log(n))$ comparisons for sorting arrays of length n.

This is optimal in the model of sorting by comparisons, if the input array can be an arbitrary array of length n. However, taking into account the run decompositions of the input array allows using finer-grained complexity classes, as follows. First, one may consider only arrays whose run decomposition consists of ρ monotonic runs. On such arrays, the best worst-case time complexity one may hope for is $\mathcal{O}(n + n\log(\rho))$ [16]. Second, we may consider even more restricted classes of input arrays, and focus only on those arrays that consist of ρ runs of lengths $r_1, \ldots, r_\rho$. In that case, every comparison-based sorting algorithm requires at least $n\mathcal{H} + \mathcal{O}(n)$ element comparisons on average, where $\mathcal{H}$ is defined as $\mathcal{H} = H(r_1/n, \ldots, r_\rho/n)$ and $H(x_1, \ldots, x_\rho) = -\sum_{i=1}^{\rho} x_i \log_2(x_i)$ is the general entropy function [3, 13, 17]. The number $\mathcal{H}$ is called the *run-length entropy* of the array.

Since the early 2000s, several natural merge sorts were proposed, all of which were meant to offer easy-to-prove complexity guarantees: ShiversSort, which runs in time $\mathcal{O}(n\log(n))$; α-StackSort, which, like NaturalMergeSort, runs in time $\mathcal{O}(n + n\log(\rho))$; α-MergeSort, which, like TimSort, runs in time $\mathcal{O}(n + n\mathcal{H})$; adaptive ShiversSort, PeekSort and PowerSort, which run in time $n\mathcal{H} + \mathcal{O}(n)$.

Except TimSort, these algorithms are, in fact, described only as policies for deciding which runs to merge, the actual sub-routine used for merging runs being left implicit: since choosing a naive merging sub-routine does not harm the worst-case time complexities considered above, all authors identified the cost of merging two runs of lengths m and n with the sum $m + n$, and the complexity of the algorithm with the sum of the costs of the merges performed.

One notable exception is that of Munro and Wild [19]. They compared the running times of TimSort and of TimSort's variant obtained by using a naive merging routine instead of TimSort's galloping sub-routine. However, and although they mentioned the challenge of finding distributions on arrays that might benefit from galloping, they did not address this challenge, and focused only on arrays with a low entropy $\mathcal{H}$. As a result, they unsurprisingly observed that the galloping sub-routine looked *slower* than the naive one.

Galloping turns out to be very efficient when sorting arrays with few distinct values, a class of arrays that had also been intensively studied. As soon as 1976, Munro and Spira [18] proposed a complexity measure $\mathcal{H}^*$ related to the run-length entropy, with the property that $\mathcal{H}^* \leqslant \log_2(\sigma)$ for arrays with σ values. They also proposed an algorithm for sorting arrays of length n with σ values by using $\mathcal{O}(n + n\mathcal{H}^*)$ comparisons. McIlroy [17] then extended their work to arrays representing a permutation π, identifying $\mathcal{H}^*$ with the run-length entropy of π^{-1} and proposing a variant of Munro and Spira's algorithm that would use $\mathcal{O}(n + n\mathcal{H}^*)$ comparisons in this generalised setting. Similarly, Barbay et al. [4] invented the algorithm QuickSynergySort, which aimed at minimising the number of comparisons, achieving a $\mathcal{O}(n + n\mathcal{H}^*)$ upper bound and further refining the parameters it used, by taking into account the interleaving between runs and dual runs. Yet, all of these algorithms require $\omega(n + n\mathcal{H})$ element moves in the worst case.

Furthermore, as a side effect of being rather complicated and lacking a proper analysis, except that of [19] that hinted at its inefficiency, the galloping sub-routine has been omitted in various mainstream implementations of natural merge sorts, in which it was replaced by its naive variant. This is the case, for instance, in library TimSort implementations of the programming languages Swift [8] and Rust [21]. On the contrary, TimSort's implementation in other languages, such as Java [6], Octave [24] or the V8 JavaScript engine [25], and PowerSort's implementation in Python [23] include the galloping sub-routine.

Contributions

We study the time complexity of various natural merge sort algorithms in a context where arrays are not just parametrised by their lengths. More precisely, we focus on a decomposition of input arrays that is dual to the decomposition of arrays into monotonic runs, and that was proposed by McIlroy [17].

Consider an array A that we want to sort in a *stable* manner, i.e., in which two elements can always considered to be distinct, if only because their positions in A are distinct. Without loss of generality, we identify the values $A[1], A[2], \ldots, A[n]$ with the integers from 1 to n, thereby making A a permutation of the set $\{1, 2, \ldots, n\}$. A common measure of presortedness consists in subdividing A into distinct monotonic *runs*, i.e., partitioning the set $\{1, 2, \ldots, n\}$ into intervals $R_1, R_2, \ldots, R_\rho$ on which the function $x \mapsto A[x]$ is monotonic.

Here, we adopt a dual approach, which consists in partitioning the set $\{1, 2, \ldots, n\}$ into the *increasing* runs $S_1, S_2, \ldots, S_\sigma$ of the inverse permutation A^{-1}. These intervals S_i are already known under the name of *shuffled up-sequences* [3, 15] or *riffle shuffles* [17]. In order to underline their connection with runs, we say that these intervals are the *dual runs* of A, and we denote their lengths by s_i. The process of transforming an array into a permutation and then extracting its dual runs is illustrated in Figure 2.

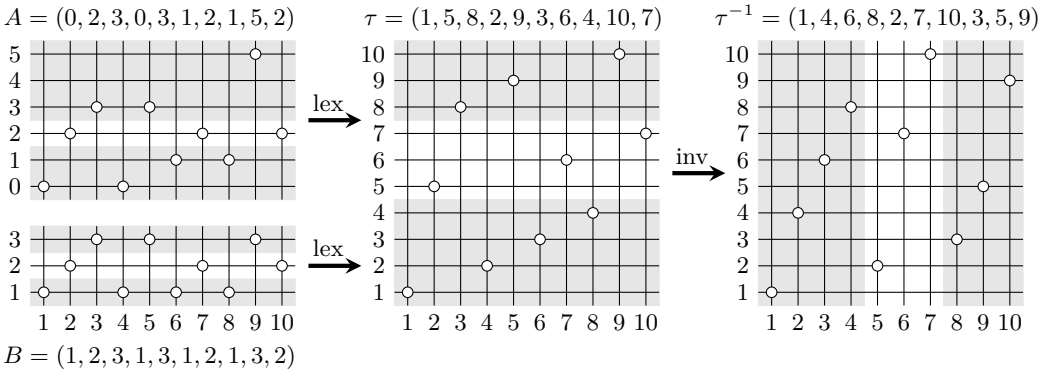

Figure 2 The arrays A and B are lexicographically equivalent to the permutation τ. Their dual runs, represented with gray and white horizontal stripes, have respective lengths 4, 3 and 3. The mappings $A \mapsto \tau$ and $B \mapsto \tau$ identify them with the dual runs of τ, i.e., with the runs of the permutation τ^{-1}. Note that A has only 3 dual runs, although it takes 5 distinct values.

When A is *not* a permutation of $\{1, 2, \ldots, n\}$, the dual runs of A are simply the maximal intervals S_i such that A is non-decreasing on the set of positions $\{j : A[j] \in S_i\} \subseteq \{1, 2, \ldots, n\}$. The length of a dual run is then defined as the cardinality of that set of positions. Thus, two lexicographically equivalent arrays have dual runs of the same lengths: this is the case, for instance, of the arrays A, B and τ in Figure 2.

In particular, we may see τ and B as canonical representatives of the array A: these are the unique permutation of $\{1, 2, \ldots, n\}$ and the unique array with values in $\{1, 2, \ldots, \sigma\}$ that are lexicographically equivalent with A. More generally, an array that contains σ distinct values cannot have more than σ dual runs.

Note that, in general, there is no non-trivial connection between the runs of a permutation and its dual runs. For instance, a permutation with a given number of runs may have arbitrarily many (or few) dual runs, and conversely.

In this article, we prove that, by using TimSort's galloping sub-routine, several natural merge sorts require $\mathcal{O}(n + n\mathcal{H}^*)$ comparisons, or even $n\mathcal{H}^* + \mathcal{O}(n)$ comparisons, where $\mathcal{H}^* = H(s_1/n, \ldots, s_\sigma/n) \leqslant \log_2(\sigma)$ is called the *dual run-length entropy* of the array, s_i is the length of the dual run S_i, and H is the general entropy function already mentioned above.

This legitimates using TimSort's arguably complicated galloping sub-routine rather than its naive alternative, in particular when sorting arrays that are constrained to have relatively few distinct values.

This also subsumes results that have been known since the 1970s. For instance, adapting the optimal constructions for alphabetic Huffman codes by Hu and Tucker [12] or Garsia and Wachs [10] to *merge trees* (described in Section 3) already provided sorting algorithms working in time $n\mathcal{H} + \mathcal{O}(n)$.

Our new results rely on notions that we call *fast-* and *middle-growth* properties, and which are found in natural merge sorts like α-MergeSort, α-StackSort, adaptive ShiversSort, ShiversSort, PeekSort, PowerSort or TimSort. More precisely, we prove that merge sorts require $\mathcal{O}(n + n\mathcal{H})$ comparisons *and* element moves when they possess the fast-growth property, thereby encompassing complexity results that were proved separately for each of these algorithms [1, 7, 13, 19], and $\mathcal{O}(n + n\mathcal{H}^*)$ comparisons when they possess the fast- or middle-growth property, which is a completely new result.

Finally, we prove finer complexity bounds on the number of comparisons used by adaptive ShiversSort, ShiversSort, NaturalMergeSort, PeekSort and PowerSort, which require only $n\mathcal{H}^* + \mathcal{O}(n + n\log(\mathcal{H}^* + 1))$ comparisons, nearly matching the $n\mathcal{H}+\mathcal{O}(n)$ (or $n\log_2(n)+\mathcal{O}(n)$ and $n\log_2(\rho) + \mathcal{O}(n)$, in the cases of ShiversSort and NaturalMergeSort) complexity upper bound they already enjoy in terms of comparisons and element moves. These results are summarised in Table 1.

Table 1 Element moves and comparisons needed by various algorithms using appropriate galloping sub-routines to sort arrays of length n with ρ runs, run-length entropy $\mathcal{H}$ and dual run-length entropy $\mathcal{H}^*$.

Algorithm	Element moves	Element comparisons
ShiversSort	$n\log_2(n) + \mathcal{O}(n)$	$n\mathcal{H}^* + \mathcal{O}(n + n\log(\mathcal{H}^* + 1))$
α-StackSort	$\mathcal{O}(n + n\log_2(\rho))$	$\mathcal{O}(n + n\min\{\log_2(\rho), \mathcal{H}^*\})$
NaturalMergeSort	$n\log_2(\rho) + \mathcal{O}(n)$	$n\min\{\log_2(\rho), \mathcal{H}^*\} + \mathcal{O}(n + n\log(\mathcal{H}^* + 1))$
α-MergeSort	$\mathcal{O}(n + n\mathcal{H})$	$\mathcal{O}(n + n\min\{\mathcal{H}, \mathcal{H}^*\})$
TimSort	$3n\mathcal{H}/2 + \mathcal{O}(n)$	$\mathcal{O}(n + n\min\{\mathcal{H}, \mathcal{H}^*\})$
adaptive ShiversSort	$n\mathcal{H} + \mathcal{O}(n)$	$n\min\{\mathcal{H}, \mathcal{H}^*\} + \mathcal{O}(n + n\log(\mathcal{H}^* + 1))$
PeekSort	$n\mathcal{H} + \mathcal{O}(n)$	$n\min\{\mathcal{H}, \mathcal{H}^*\} + \mathcal{O}(n + n\log(\mathcal{H}^* + 1))$

2 The galloping sub-routine for merging runs

Here, we describe the galloping sub-routine that the algorithm TimSort uses to merge adjacent non-decreasing runs. This sub-routine is a blend between a naive merging algorithm, which requires $a + b - 1$ comparisons to merge runs A and B of lengths a and b, and a dichotomy-based algorithm, which requires $\mathcal{O}(\log(a + b))$ comparisons in the best case, and $\mathcal{O}(a + b)$ comparisons in the worst case. It depends on a parameter $\mathbf{t}$, and works as follows.

When merging runs A and B into one large run C, we first need to find the least integers k and ℓ such that $B[0] < A[k] \leqslant B[\ell]$: the $k + \ell$ first elements of C are $A[0], A[1], \ldots, A[k-1]$, $B[0], B[1], \ldots, B[\ell - 1]$, and the remaining elements of C are obtained by merging the sub-array of A that spans positions k to a and the sub-array of B that spans positions ℓ to b. Computing k and ℓ efficiently is therefore a crucial step towards reducing the number of comparisons required by the merging sub-routine (and, thus, by the sorting algorithm).

This computation is a special case of the following problem: if one wishes to find a secret integer $m \geqslant 1$ by choosing integers $x \geqslant 1$ and testing whether $x \geqslant m$, what is, as a function of m, the least number of tests that one must perform? Bentley and Yao [5] answer this question by providing simple strategies, which they number $\mathsf{B}_0, \mathsf{B}_1, \ldots$:

B_0: choose $x = 1$, then $x = 2$, and so on, until one chooses $x = m$, thereby finding m in m queries;

B_1: first use B_0 to find $\lceil\log_2(m)\rceil + 1$ in $\lceil\log_2(m)\rceil + 1$ queries, i.e., choose $x = 2^k$ until $x \geqslant m$, then compute the bits of m (from the most significant bit of m to the least significant one) in $\lceil\log_2(m)\rceil - 1$ additional queries; Bentley and Yao call this strategy a *galloping* (or *exponential search*) technique;

B_{k+1}: like B_1, except that one finds $\lceil\log_2(m)\rceil + 1$ by using B_k instead of B_0.

Strategy B_0 uses m queries, B_1 uses $2\lceil\log_2(m)\rceil$ queries (except for $m = 1$, where it uses one query), and each strategy B_k with $k \geqslant 2$ uses $\log_2(m) + o(\log(m))$ queries. Thus, if m is known to be arbitrarily large, one should favour some strategy B_k (with $k \geqslant 1$) over the

naive strategy B_0. However, when merging runs taken from a permutation chosen uniformly at random over the $n!$ permutations of $\{1, 2, \ldots, n\}$, the integer m is frequently small, which makes B_0 suddenly more attractive. In particular, the overhead of using B_1 instead of B_0 is a prohibitive $+20\%$ or $+33\%$ when $m = 5$ or $m = 3$, as illustrated in the black cells of Table 2.

Table 2 Comparison requests needed by strategies B_0 and B_1 to find a secret integer $m \geqslant 1$.

m	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17
B_0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17
B_1	1	2	**4**	4	**6**	6	6	6	8	8	8	8	8	8	8	8	10

McIlroy [17] addresses this issue by choosing a parameter $\mathbf{t}$ and using a blend between the strategies B_0 and B_1, which consists in two successive steps C_1 and C_2:

C_1: one first follows B_0 for up to $\mathbf{t}$ steps, thereby choosing $x = 1$, $x = 2$, …, $x = \mathbf{t}$ (if $m \leqslant \mathbf{t} - 1$, one stops after choosing $x = m$);

C_2: if $m \geqslant \mathbf{t} + 1$, one switches to B_1 (or, more precisely, to a version of B_1 translated by $\mathbf{t}$, since the precondition $m \geqslant 1$ is now $m \geqslant \mathbf{t} + 1$).

Once such a parameter $\mathbf{t}$ is fixed, McIlroy's mixed strategy allows retrieving m in $\mathsf{cost}_{\mathbf{t}}(m)$ queries, where $\mathsf{cost}_{\mathbf{t}}(m) = m$ if $m \leqslant \mathbf{t} + 2$, and $\mathsf{cost}_{\mathbf{t}}(m) = \mathbf{t} + 2\lceil \log_2(m - \mathbf{t}) \rceil$ if $m \geqslant \mathbf{t} + 3$. In practice, however, we will replace this cost function by the following simpler upper bound.

▶ **Lemma 1.** *For all $\mathbf{t} \geqslant 0$ and $m \geqslant 1$, we have $\mathsf{cost}_{\mathbf{t}}(m) \leqslant \mathsf{cost}^*_{\mathbf{t}}(m)$, where*

$$\mathsf{cost}^*_{\mathbf{t}}(m) = \min\{(1 + 1/(\mathbf{t} + 3))m, \mathbf{t} + 2 + 2\log_2(m + 1)\}.$$

Proof. Since the desired inequality is immediate when $m \leqslant \mathbf{t} + 2$, we assume that $m \geqslant \mathbf{t} + 3$. In that case, we already have $\mathsf{cost}_{\mathbf{t}}(m) \leqslant \mathbf{t} + 2(\log_2(m - \mathbf{t}) + 1) \leqslant \mathbf{t} + 2 + 2\log_2(m + 1)$, and we prove now that $\mathsf{cost}_{\mathbf{t}}(m) \leqslant m + 1$. Indeed, let $u = m - \mathbf{t}$ and let $f \colon x \mapsto x - 1 - 2\log_2(x)$. The function f is positive and increasing on the interval $[7, +\infty)$. Thus, it suffices to check by hand that $(m+1) - \mathsf{cost}_{\mathbf{t}}(m) = 0, 1, 0, 1$ when $u = 3, 4, 5, 6$, and that $(m+1) - \mathsf{cost}_{\mathbf{t}}(m) \geqslant f(u) > 0$ when $u \geqslant 7$. It follows, as expected, that $\mathsf{cost}_{\mathbf{t}}(m) \leqslant m + 1 \leqslant (1 + 1/(\mathbf{t} + 3))m$. ◀

The above discussion immediately provides us with a cost model for the number of comparisons performed when merging two runs.

▶ **Proposition 2.** *Let A and B be two non-decreasing runs of lengths a and b, with values in $\{1, 2, \ldots, \sigma\}$. For each integer $i \leqslant \sigma$, let $a_{\to i}$ (respectively, $b_{\to i}$) be the number of elements in A (respectively, in B) with value i. Using a merging sub-routine based on McIlroy's mixed strategy for a fixed parameter $\mathbf{t}$, we need at most*

$$1 + \sum_{i=1}^{\sigma} \mathsf{cost}^*_{\mathbf{t}}(a_{\to i}) + \mathsf{cost}^*_{\mathbf{t}}(b_{\to i})$$

element comparisons to merge the runs A and B.

Proof. First, assume that $a_{\to i} = 0$ for some $i \geqslant 2$. Replacing every value $j \geqslant i + 1$ with the value $j - 1$ in both arrays A and B does not change the behaviour of the sub-routine and decreases the value of σ. Moreover, the function $\mathsf{cost}^*_{\mathbf{t}}$ is sub-additive, i.e., we have $\mathsf{cost}^*_{\mathbf{t}}(m) + \mathsf{cost}^*_{\mathbf{t}}(m') \geqslant \mathsf{cost}^*_{\mathbf{t}}(m + m')$ for all $m \geqslant 0$ and $m' \geqslant 0$. Hence, without loss of generality, we assume that $a_{\to i} \geqslant 1$ for all $i \geqslant 2$. Similarly, we assume without loss of generality that $b_{\to i} \geqslant 1$ for all $i \leqslant \sigma - 1$.

Under these assumptions, the array C that results from merging A and B consists of $a_{\to 1}$ elements from A, then $b_{\to 1}$ elements from B, $a_{\to 2}$ elements from A, $b_{\to 2}$ elements from B, $\dots$, $a_{\to \sigma}$ elements from A and $b_{\to \sigma}$ elements from B. Thus, the galloping sub-routine consists in discovering successively the integers $a_{\to 1}, b_{\to 1}, a_{\to 2}, b_{\to 2}, \dots, a_{\to \sigma}$, each time using McIlroy's strategy based on the two steps C_1 and C_2; checking whether $a_{\to 1} = 0$ requires one more comparison than prescribed by McIlroy's strategy, and the integer $b_{\to \sigma}$ does not need to be discovered once the entire run A has been scanned be the merging sub-routine. ◀

We simply call $\mathbf{t}$-*galloping sub-routine* the merging sub-routine based on McIlroy's mixed strategy for a fixed parameter $\mathbf{t}$; when the value of $\mathbf{t}$ is irrelevant, we simply omit mentioning it. Then, the quantity

$$1 + \sum_{i=1}^{\sigma} \mathsf{cost}^*_{\mathbf{t}}(a_i) + \mathsf{cost}^*_{\mathbf{t}}(b_i)$$

is called the ($\mathbf{t}$-)*galloping cost* of merging A and B. By construction, this cost never exceeds $1 + 1/(\mathbf{t}+3)$ times the *naive cost* of merging A and B, which is simply defined as $a + b$. Below, we study the impact of using the galloping sub-routine instead of the naive one, which amounts to replacing naive merge costs by their galloping variants.

Note that using this new galloping cost measure is relevant only if the cost of element comparisons is significantly larger than the cost of element (or pointer) moves. For example, even if we were lucky enough to observe that each element in B is smaller than each element in A, we would perform only $\mathcal{O}(\log(a+b))$ element comparisons, but as many as $\Theta(a+b)$ element moves.

Updating the parameter $\mathbf{t}$

We assumed above that the parameter $\mathbf{t}$ did not vary while the runs A and B were being merged with each other. This is not how $\mathbf{t}$ behaves in TimSort's implementation of the galloping sub-routine. Instead, the parameter $\mathbf{t}$ is initially set to a constant ($\mathbf{t} = 7$ in Java), and may change during the algorithm as follows. In step C_2, after using the strategy B_1, and depending on the value of m that we found, one may realise that using B_0 might have been less expensive than using B_1. In that case, the value of $\mathbf{t}$ increases by 1, and otherwise (i.e., if using B_1 was indeed a smart move), it decreases by 1 (with a minimum of 0).

When sorting a random permutation, changing the value of $\mathbf{t}$ in that way decreases the average overhead of sometimes using B_1 instead of B_0 to a constant. More generally, even in the worst case, this overhead is linear in n.

▶ **Proposition 3.** *Let $\mathcal{A}$ be a stable natural merge sort algorithm, and let A be an array of length n. Let c_1 be the number of comparisons that $\mathcal{A}$ requires to sort A when it uses the naive sub-routine, and let c_2 be the number of comparisons that $\mathcal{A}$ requires to sort A when it uses the galloping sub-routine with TimSort's update policy for the parameter $\mathbf{t}$. We have $\mathsf{c}_2 \leqslant \mathsf{c}_1 + \mathcal{O}(n)$.*

Proof. Below, we group the comparisons that $\mathcal{A}$ performs while sorting A into *steps*, which we will consider as individual units. Steps are formed as follows. Let R and R' be consecutive runs that $\mathcal{A}$ is about to merge, and let us subdivide their concatenation $R \cdot R'$ into σ dual runs $S_1, S_2, \dots, S_\sigma$ (note that these are the dual runs of $R \cdot R'$ and not the dual runs of A, i.e., some elements of R may belong to a given dual run S_i of $R \cdot R'$ while belonging to distinct dual runs or A).

Each step consists of those comparisons used to discover the elements of R (resp., R') that belong to a given dual run S_i. Thus, the comparisons used to merge R and R' are partitioned into $2\sigma - 1$ steps: in the first step, we discover those elements of R that belong to S_1; in the second step, those elements of R' that belong to S_1; then, those elements of R that belong to S_2 ; ...; and, finally, those elements of R that belong to S_σ.

Let $s_1, s_2, \ldots, s_\ell$ be the steps into which the comparisons performed by $\mathcal{A}$ are grouped. By construction, each step s_i consists in finding an integer $m_i \geqslant 1$ (or, possibly, $m_i = 0$ if s_i is the first step of a merge between two consecutive runs). If $\mathcal{A}$ uses TimSort's update policy, the step s_i consists in using McIlroy's strategy for a given parameter $\mathbf{t}(s_i)$ that depends on s_i. We also denote by $\mathbf{t}(s_{\ell+1})$ the parameter value obtained after $\mathcal{A}$ has finished sorting the array A.

Strategy B_0 requires m_i comparisons to find that integer m_i, and McIlroy's strategy requires m_i comparisons if $m_i \leqslant \mathbf{t}(s_i)$, up to $m_i + 1$ comparisons if $\mathbf{t}(s_i) + 1 \leqslant m_i \leqslant \mathbf{t}(s_i) + 6$, and up to $m_i - 1$ comparisons if $m_i \geqslant \mathbf{t}(s_i) + 7$. Since $\mathbf{t}(s_{i+1}) = \mathbf{t}(s_i)$ in the first case, $\mathbf{t}(s_{i+1}) = \mathbf{t}(s_i) + 1$ in the second case and $\mathbf{t}(s_{i+1}) = \max\{0, \mathbf{t}(s_i) - 1\}$ in the third case, McIlroy's strategy never uses more than $m_i + \mathbf{t}(s_{i+1}) - \mathbf{t}(s_i)$ comparisons. Consequently, the overhead of using TimSort's update policy instead of a naive merging sub-routine is at most $\mathbf{t}(s_{\ell+1}) - \mathbf{t}(s_1)$.

Moreover, let $\mu_i = m_1 + m_2 + \ldots + m_i$ for all $i \leqslant \ell$. We show by induction on τ that, whenever $\mathbf{t}(s_i) = \mathbf{t}(s_1) + \tau$, we have $2\mu_i \geqslant \tau^2$. Indeed, if $\tau \geqslant 1$ and if s_i is the first step for which $\mathbf{t}(s_i) = \mathbf{t}(s_1) + \tau$, we have $\mathbf{t}(s_{i-1}) = \mathbf{t}(s_1) + \tau - 1$. It follows that $2\mu_{i-1} \geqslant (\tau - 1)^2$ and $m_i \geqslant \mathbf{t}(s_1) + \tau \geqslant \tau$, which proves that $2\mu_i \geqslant (\tau - 1)^2 + 2\tau = \tau^2 + 1$. Thus, we conclude that $\mathbf{t}(s_\ell + 1) - \mathbf{t}(s_1) \leqslant \sqrt{2\mu_\ell}$.

Finally, μ_ℓ is equal to the number of element comparisons that $\mathcal{A}$ would perform if it used the naive merging strategy, i.e., $\mu_\ell = \mathsf{c}_1$. No merge sort requires more than $\mathcal{O}(n^2)$ comparisons, and therefore $\mu_\ell = \mathcal{O}(n^2)$, which is why the overhead of using TimSort's update policy is at most $\mathbf{t}(s_{\ell+1}) - \mathbf{t}(s_1) \leqslant \sqrt{2\mu_\ell} = \mathcal{O}(n)$. ◀

Deciding whether our results remain valid when $\mathbf{t}$ is updated like in TimSort remains an open question. However, in Section 5.3, we propose and study the following alternative update policy: when merging runs of lengths a and b, we set $\mathbf{t} = \lceil \log_2(a + b) \rceil$.

3 A fast-growth property and its consequences

In this section, we focus on two novel properties of stable natural merge sorts, which we call *fast-growth* and *middle-growth*. These properties capture all TimSort-like natural merge sorts invented in the last decade, and explain why these sorting algorithms require only $\mathcal{O}(n + n\mathcal{H})$ element moves and $\mathcal{O}(n + n \min\{\mathcal{H}, \mathcal{H}^*\})$ element comparisons. We will prove in subsequent sections that many algorithms have these properties.

When applying a stable natural merge sort on an array A, the elements of A are clustered into monotonic sub-arrays called *runs*, and the algorithm consists in repeatedly merging consecutive runs into one larger run until the array itself contains only one run. Consequently, each element may undergo several successive merge operations. *Merge trees* [3, 13, 19] are a convenient way to represent the succession of runs that ever occur while A is being sorted.

▶ **Definition 4.** *The* merge tree *induced by a stable natural merge sort algorithm on an array A is the binary rooted tree $\mathcal{T}$ defined as follows. The nodes of $\mathcal{T}$ are all the runs that were present in the initial array A or that resulted from merging two runs. The runs of the initial array are the leaves of $\mathcal{T}$, and when two consecutive runs R_1 and R_2 are merged with each other into a new run $\overline{R}$, the run R_1 spanning positions immediately to the left of those of R_2, they form the left and the right children of the node $\overline{R}$, respectively.*

Such trees ease the task of referring to several runs that might not have occurred simultaneously. In particular, we will often refer to the i^{th} *ancestor* or a run R, which is just R itself if $i = 0$, or the parent, in the tree $\mathcal{T}$, of the $(i-1)^{\text{th}}$ ancestor of R if $i \geqslant 1$. That ancestor will be denoted by $R^{(i)}$.

Before further manipulating these runs, let us first present some notation about runs and their lengths, which we will frequently use. We will commonly denote runs with capital letters, possibly with some index or adornment, and we will then denote the length of such a run with the same small-case letter and the same index or adornment. For instance, runs named R, R_i, Q' and $\overline{S}$ will have respective lengths r, r_i, q' and $\overline{s}$.

▶ **Definition 5.** *We say that a stable natural merge sort algorithm $\mathcal{A}$ has the* fast-growth property *if it satisfies the following statement:*

> *There exist an integer $\ell \geqslant 1$ and a real number $\theta > 1$ such that, for every merge tree $\mathcal{T}$ induced by $\mathcal{A}$ and every run at depth ℓ or more in $\mathcal{T}$, we have $r^{(\ell)} \geqslant \theta r$.*

We also say that $\mathcal{A}$ has the middle-growth property *if it satisfies the following statement:*

> *There exists a real number $\kappa > 1$ such that, for every merge tree $\mathcal{T}$ induced by $\mathcal{A}$, every integer $h \geqslant 0$ and every run R of height h in $\mathcal{T}$, we have $r \geqslant \kappa^h$.*

Since every node of height $h \geqslant 1$ in a merge tree is a run of length at least 2, each algorithm with the fast-growth property also has the middle-growth property: indeed, it suffices to choose $\kappa = \min\{2, \theta\}^{1/\ell}$. As a result, the former property is stronger than the latter one, and indeed it has stronger consequences.

▶ **Theorem 6.** *Let $\mathcal{A}$ be a stable natural merge sort algorithm with the fast-growth property. If $\mathcal{A}$ uses either the galloping or the naive sub-routine for merging runs, it requires $\mathcal{O}(n + n\mathcal{H})$ element comparisons and moves to sort arrays of length n and run-length entropy $\mathcal{H}$.*

Proof. Let $\ell \geqslant 1$ and $\theta > 1$ be the integer and the real number mentioned in the definition of the statement "$\mathcal{A}$ has the fast-growth property". Let A be an array of length n with ρ runs of lengths $r_1, r_2, \ldots, r_\rho$, let $\mathcal{T}$ be the merge tree induced by $\mathcal{A}$ on A, and let d_i be the depth of the run R_i in the tree $\mathcal{T}$.

The algorithm $\mathcal{A}$ uses $\mathcal{O}(n)$ element comparisons and element moves to delimit the runs it will then merge and to make them non-decreasing. Then, both the galloping and the naive merging sub-routine require $\mathcal{O}(a + b)$ element comparisons and moves to merge two runs A and B of lengths a and b. Therefore, it suffices to prove that $\sum_{R \in \mathcal{T}} r = \mathcal{O}(n + n\mathcal{H})$.

Consider some leaf R_i of the tree $\mathcal{T}$, and let $k = \lfloor d_i/\ell \rfloor$. The $(k\ell)^{\text{th}}$ ancestor of R_i is a node R of size $r \geqslant \theta^k r_i$, and thus $n \geqslant r \geqslant \theta^k r_i$. Hence, $d_i + 1 \leqslant \ell(k+1) \leqslant \ell\,(\log_\theta(n/r_i) + 1)$, and we conclude that

$$\sum_{R \in \mathcal{T}} r = \sum_{i=1}^{\rho} (d_i + 1) r_i \leqslant \ell \sum_{i=1}^{\rho} (r_i \log_\theta(n/r_i) + r_i) = \ell(n\mathcal{H}/\log_2(\theta) + n) = \mathcal{O}(n + n\mathcal{H}). \quad \blacktriangleleft$$

A similar, weaker result also holds for algorithms with the middle-growth property.

▶ **Theorem 7.** *Let $\mathcal{A}$ be a stable natural merge sort algorithm with the middle-growth property. If $\mathcal{A}$ uses either the galloping or the naive sub-routine for merging runs, it requires $\mathcal{O}(n \log(n))$ element comparisons and moves to sort arrays of length n.*

Proof. Let us borrow the notations used when proving Theorem 6, and let $\kappa > 1$ be the real number mentioned in the definition of the statement "$\mathcal{A}$ has the middle-growth property". Like in the proof of Theorem 6, it suffices to show that $\sum_{R \in \mathcal{T}} r = \mathcal{O}(n \log(n))$.

The $d_i{}^{\text{th}}$ ancestor of a run R_i is the root of $\mathcal{T}$, and thus $n \geqslant \kappa^{d_i}$. Hence, $d_i \leqslant \log_\kappa(n)$, and we conclude that

$$\sum_{R\in\mathcal{T}} r = \sum_{i=1}^{\rho}(d_i+1)r_i \leqslant \sum_{i=1}^{\rho}(\log_\kappa(n)+1)r_i = (\log_\kappa(n)+1)n = \mathcal{O}(n\log(n)). \qquad \blacktriangleleft$$

Theorems 6 and 7 provide us with a simple framework for recovering well-known results on the complexity of many algorithms. By contrast, Theorem 8 consists in new complexity guarantees on the number of element comparisons performed by algorithms with the middle-growth property, provided that they use the galloping sub-routine.

▶ **Theorem 8.** *Let $\mathcal{A}$ be a stable natural merge sort algorithm with the middle-growth property. If $\mathcal{A}$ uses the galloping sub-routine for merging runs, it requires $\mathcal{O}(n + n\mathcal{H}^*)$ element comparisons to sort arrays of length n and dual run-length entropy $\mathcal{H}^*$.*

Proof. All comparisons performed by the galloping sub-routine are of the form $A[i] \leqslant^? A[j]$, where i and j are positions such that $i < j$. Thus, the behaviour of $\mathcal{A}$, i.e., the element comparisons and element moves it performs, is invariant under lexicographic equivalence, as illustrated in Figure 2. Consequently, starting from an array A of length n with σ dual runs $S_1, S_2, \ldots, S_\sigma$, we create a new array B of length n with σ distinct values, setting $B[j] \stackrel{\text{def}}{=\!=} i$ whenever $A[j]$ belongs to the dual run S_i, and we may now assume that A coincides with B. This assumption allows us to directly use Proposition 2, whose presentation would have been more complicated if we had referred to dual runs of an underlying array instead of referring directly to distinct values.

Now, let $\kappa > 1$ be the real number mentioned in the definition of the statement "$\mathcal{A}$ has the middle-growth property". Let A be an array of length n and whose values are integers from 1 to σ, let $s_1, s_2, \ldots, s_\sigma$ be the lengths of its dual runs, and let $\mathcal{T}$ be the merge tree induced by $\mathcal{A}$ on A.

The algorithm $\mathcal{A}$ uses $\mathcal{O}(n)$ element comparisons to delimit the runs it will then merge and to make them non-decreasing. We prove now that merging these runs requires only $\mathcal{O}(n + n\mathcal{H}^*)$ comparisons. For every run R in $\mathcal{T}$ and every integer $i \leqslant \sigma$, let $r_{\to i}$ be the number of elements of R with value i. In the galloping cost model, merging two runs R and R' requires at most

$$1 + \sum_{i=1}^{\sigma} \mathsf{cost}^*_{\mathbf{t}}(r_{\to i}) + \mathsf{cost}^*_{\mathbf{t}}(r'_{\to i})$$

element comparisons. Since less than n such merge operations are performed, and since $n = \sum_{i=1}^{\sigma} s_i$ and $n\mathcal{H}^* = \sum_{i=1}^{\sigma} s_i \log(n/s_i)$, it remains to show that

$$\sum_{R\in\mathcal{T}} \mathsf{cost}^*_{\mathbf{t}}(r_{\to i}) = \mathcal{O}(s_i + s_i\log(n/s_i))$$

for all $i \leqslant \sigma$. Then, since $\mathsf{cost}^*_{\mathbf{t}}(m) \leqslant (\mathbf{t}+1)\mathsf{cost}^*_0(m)$ for all parameter values $\mathbf{t} \geqslant 0$ and all $m \geqslant 0$, we assume without loss of generality that $\mathbf{t} = 0$.

Now, consider some integer $h \geqslant 0$, let $\mathcal{R}_h$ be the set of runs at height h in $\mathcal{T}$, and let $\mathsf{C}_0(h) = \sum_{R\in\mathcal{R}_h} \mathsf{cost}^*_0(r_{\to i})$. Since no run in $\mathcal{R}_h$ descends from another one, we already have

$$\mathsf{C}_0(h) \leqslant 2\sum_{R\in\mathcal{R}_h} r_{\to i} \leqslant 2s_i \text{ and } \sum_{R\in\mathcal{R}_h} r \leqslant n.$$

Moreover, by definition of κ, each run $R \in \mathcal{R}_h$ is of length $r \geqslant \kappa^h$, and thus $|\mathcal{R}_h| \leqslant n/\kappa^h$.

Then, consider the constant $\lambda = \lceil \log_\kappa(n/s_i) \rceil$ and the functions $f\colon x \mapsto \mathbf{t}+2+2\log_2(x+1)$ and $g\colon x \mapsto x\, f(s_i/x)$. Both f and g are positive and concave on the interval $(0, +\infty)$, thereby also being increasing. It follows that, for all $h \geqslant 0$,

$$\begin{aligned}\mathsf{C}_0(\lambda+h) &\leqslant \sum_{R\in\mathcal{R}_{\lambda+h}} f(r_{\to i}) \leqslant |\mathcal{R}_{\lambda+h}|\, f\big(\textstyle\sum_{R\in\mathcal{R}_{\lambda+h}} r_{\to_i}/|\mathcal{R}_{\lambda+h}|\big) \leqslant g\big(|\mathcal{R}_{\lambda+h}|\big)\\ &\leqslant g\big(n/\kappa^{\lambda+h}\big) \leqslant g\big(s_i\kappa^{-h}\big) = \big(2+2\log_2(\kappa^h+1)\big)s_i\kappa^{-h}\\ &\leqslant \big(2+2\log_2(2\kappa^h)\big)s_i\kappa^{-h} = \big(4+2h\log_2(\kappa)\big)s_i\kappa^{-h}.\end{aligned}$$

The inequalities on the first line respectively hold by definition of cost_1^*, because f is concave, and because f is increasing and $\sum_{R\in\mathcal{R}_h} r_{\to_i} \leqslant s_i$; the inequalities on the second line hold because g is increasing and $|\mathcal{R}_h| \leqslant n/\kappa^h$.

We conclude that

$$\begin{aligned}\sum_{R\in\mathcal{T}} \mathsf{cost}_0^*(r_{\to i}) = \sum_{h\geqslant 0} \mathsf{C}_0(h) &= \sum_{h=0}^{\lambda-1} \mathsf{C}_0(h) + \sum_{h\geqslant 0} \mathsf{C}_0(\lambda+h)\\ &\leqslant 2\lambda s_i + 4s_i \sum_{h\geqslant 0} \kappa^{-h} + 2\log_2(\kappa) s_i \sum_{h\geqslant 0} h\kappa^{-h}\\ &\leqslant \mathcal{O}\big(s_i(1+\log(n/s_i))\big) + \mathcal{O}\big(s_i\big) + \mathcal{O}\big(s_i\big) = \mathcal{O}\big(s_i + s_i\log(n/s_i)\big).\end{aligned}$$

◀

4 PowerSort has the fast-growth property

In this section, we prove that PowerSort and many TimSort-like algorithms enjoy the fast- or middle-growth properties. To that aim, we first define the run merge policy of PowerSort, by introducing the notion of *power* of a run endpoint or of a run, and then characterising the merge trees that PowerSort induces.

▶ **Definition 9.** *Let A be an array of length n, whose run decomposition consists of runs $R_1, R_2, \ldots, R_\rho$, ordered from left to right. For all integers $i \leqslant \rho$, let $e_i = r_1 + \ldots + r_i$. We also abusively set $e_{-1} = -\infty$ and $e_{\rho+1} = n$.*

When $0 \leqslant i \leqslant \rho$, we denote by $\mathbf{I}(i)$ the half-open interval $(e_{i-1}+e_i, e_i+e_{i+1}]$. The power *of e_i, which we denote by p_i, is then defined as the least integer p such that $\mathbf{I}(i)$ contains an element of the set $\{kn/2^{p-1} : k \in \mathbb{Z}\}$. Thus, we (abusively) have $p_0 = -\infty$ and $p_\rho = 0$.*

Finally, let $R_{i\ldots j}$ be a run obtained by merging consecutive runs $R_i, R_{i+1}, \ldots, R_j$. The power *of the run R is defined as $\max\{p_{i-1}, p_j\}$.*

The notion of power quickly comes with nice properties, two of which we mention now.

▶ **Lemma 10.** *For each non-empty sub-interval I of the set $\{0, \ldots, \rho\}$, there exists a unique integer $i \in I$ such that $p_i \leqslant p_j$ for all $j \in I$.*

Proof. Assume that the integer i is not unique. Since e_0 is the only endpoint with power $-\infty$, we know that $0 \notin I$. Then, let a and b be elements of I such that $a < b$ and $p_a = p_b \leqslant p_j$ for all $j \in I$, and let $p = p_a = p_b$. By definition of p_a and p_b, there exist odd integers k and ℓ such that $kn/2^{p-1} \in \mathbf{I}(a)$ and $\ell n/2^{p-1} \in \mathbf{I}(b)$. Since $\ell \geqslant k+1$, the fraction $(k+1)n/2^{p-1}$ belongs to some interval $\mathbf{I}(j)$ such that $a \leqslant j \leqslant b$. But since $k+1$ is even, we know that $p_j < p$, which is absurd. Thus, our initial assumption is invalid, which completes the proof. ◀

▶ **Lemma 11.** *Let $R_1, \ldots, R_\rho$ be the run decomposition of an array A. There is exactly one tree $\mathcal{T}$ that is induced on A and in which every inner node has a smaller power than its children. Furthermore, for every run $R_{i\ldots j}$ in $\mathcal{T}$, we have $\max\{p_{i-1}, p_j\} < \min\{p_i, p_{i+1}, \ldots, p_{j-1}\}$.*

Proof. Given a merge tree $\mathcal{T}$, let us prove that the following statements are equivalent:
S_1: each inner node of $\mathcal{T}$ has a smaller power than its children;
S_2: each run $R_{i\dots j}$ that belongs to $\mathcal{T}$ has a power that is smaller than all of $p_i, \dots, p_{j-1}$;
S_3: if a run $R_{i\dots j}$ is an inner node of $\mathcal{T}$, its children are the two runs $R_{i\dots k}$ and $R_{k+1\dots j}$ such that $p_k = \min\{p_i, \dots, p_{j-1}\}$.

First, if S_1 holds, we prove S_3 by induction on the height h of the run $R_{i\dots j}$. Indeed, if the restriction of S_3 to runs of height less than h holds, let $R_{i\dots k}$ and $R_{k+1\dots j}$ be the children of a run $R_{i\dots j}$ of height h. If $i < k$, the run $R_{i\dots k}$ has two children $R_{i\dots \ell}$ and $R_{\ell+1\dots k}$ such that $p_\ell = \min\{p_i, \dots, p_{k-1}\}$, and the powers of these runs, i.e., $\max\{p_{i-1}, p_\ell\}$ and $\max\{p_\ell, p_k\}$, are greater than the power of $R_{i\dots k}$, i.e., $\max\{p_{i-1}, p_k\}$, which proves that $p_\ell > p_k$. It follows that $p_k = \min\{p_i, \dots, p_k\}$, and one proves similarly that $p_k = \min\{p_k, \dots, p_{j-1}\}$, thereby showing that S_3 also holds for runs of height h.

Then, if S_3 holds, we prove S_2 by induction on the depth d of the run $R_{i\dots j}$. Indeed, if the restriction of S_2 to runs of depth less than d holds, let $R_{i\dots k}$ and $R_{k+1\dots j}$ be the children of a run $R_{i\dots j}$ of depth d. Lemma 10 and S_3 prove that p_k is the unique smallest element of $\{p_i, \dots, p_{j-1}\}$, and the induction hypothesis proves that $\max\{p_{i-1}, p_j\} < p_k$. It follows that both powers $\max\{p_{i-1}, p_k\}$ and $\max\{p_k, p_j\}$ are smaller than all of $p_i, \dots, p_{k-1}, p_{k+1}, \dots, p_{j-1}$, thereby showing that S_2 also holds for runs of depth d.

Finally, if S_2 holds, let $R_{i\dots j}$ be an inner node of $\mathcal{T}$, with children $R_{i\dots k}$ and $R_{k+1\dots j}$. Property S_2 ensures that $\max\{p_{i-1}, p_j\} < p_k$, and thus that $\max\{p_{i-1}, p_j\}$ is smaller than both $\max\{p_{i-1}, p_k\}$ and $\max\{p_k, p_j\}$, i.e., that $R_{i\dots j}$ has a smaller power that its children, thereby proving S_1.

In particular, once the array A and its run decomposition $R_1, \dots, R_\rho$ are fixed, S_3 provides us with a deterministic top-down construction of the unique merge tree $\mathcal{T}$ induced on A and that satisfies S_1: the root of $\mathcal{T}$ must be the run $R_{1\dots\rho}$ and, provided that some run $R_{i\dots j}$ belongs to $\mathcal{T}$, where $i < j$, Lemma 10 proves that the integer k mentioned in S_3 is unique, which means that S_3 unambiguously describes the children of $R_{i\dots j}$ in the tree $\mathcal{T}$.

This proves the first claim of Lemma 11, and the second claim of Lemma 11 follows from the equivalence between the statements S_1 and S_2. ◀

This leads to the following characterisation of the algorithm PowerSort, which is proved in [19, Lemma 4] and which we consider as an alternative definition of PowerSort.

▶ **Definition 12.** *In every merge tree that PowerSort induces, inner nodes have a smaller power than their children.*

▶ **Lemma 13.** *Let $\mathcal{T}$ be a merge tree induced by PowerSort, let R be a run of $\mathcal{T}$ with power p, and let $R^{(2)}$ be its grandparent. We have $2^{p-2}r < n < 2^p r^{(2)}$.*

Proof. Let $R_{i\dots j}$ be the run R. Without loss of generality, we assume that $p = p_j$, the case $p = p_{i-1}$ being entirely symmetric. Lemma 11 states that all of $p_i, \dots, p_{j-1}$ are larger than p. Thus, the union of intervals $\mathbf{I}(i) \cup \dots \cup \mathbf{I}(j) = (e_{i-1} + e_i, e_j + e_{j+1}]$ does not contain any element of the set $\mathcal{S} = \{kn/2^{p-2} : k \in \mathbb{Z}\}$. The bounds $e_{i-1} + e_i$ and $e_j + e_{j+1}$ are therefore contained between two consecutive elements of $\mathcal{S}$, i.e., there exists an integer ℓ such that

$$\ell n/2^{p-2} \leqslant e_{i-1} + e_i \leqslant e_j + e_{j+1} < (\ell+1)n/2^{p-2},$$

and we conclude that

$$r = e_j - e_{i-1} \leqslant (e_j + e_{j+1}) - (e_{i-1} + e_i) < n/2^{p-2}.$$

We prove now that $n \leqslant 2^p r^{(2)}$. To that end, we assume that both R and its parent are left children, the other possible cases being symmetric. There exist integers u and v such that the parent of R is $R_{i\ldots u}$, and its grandparent is $R_{i\ldots v}$. Hence, $\max\{p_{i-1}, p_u\} < \max\{p_{i-1}, p_j\} = p$, which shows that $p_u < p_j = p$. Thus, both intervals $\mathbf{I}(j)$ and $\mathbf{I}(u)$, which are subintervals of $(2e_{i-1}, 2e_v]$, contain elements of the set $\mathcal{S}' = \{kn/2^{p-1} : k \in \mathbb{Z}\}$. This means that there exist two integers k and ℓ such that $2e_{i-1} < kn/2^{p-1} < \ell n/2^{p-1} \leqslant 2e_v$, from which we conclude that

$$r^{(2)} = e_v - e_{i-1} > (\ell - k)n/2^p \geqslant n/2^p. \qquad \blacktriangleleft$$

▶ **Theorem 14.** *The algorithm PowerSort has the fast-growth property.*

Proof. Let $\mathcal{T}$ be a merge tree induced by PowerSort. Then, let R be a run in $\mathcal{T}$, and let p and $p^{(3)}$ be the respective powers of the runs R and $R^{(3)}$. Definition 12 ensures that $p \geqslant p^{(3)} + 3$, and therefore Lemma 13 proves that

$$2^{p^{(3)}+1} r \leqslant 2^{p-2} r < n < 2^{p^{(3)}} r^{(5)}.$$

This means that $r^{(5)} \geqslant 2r$, and therefore that PowerSort has the fast-growth property. ◀

For the sake of conciseness, we only list which algorithms were found to have the fast- or middle-growth property. Proofs that they do can be found in the complete version of this article [11].

▶ **Theorem 15.** *The algorithms TimSort, α-MergeSort, PeekSort and adaptive ShiversSort have the fast-growth property.*

An immediate consequence of Theorems 6 and 8 is that these algorithms sort arrays of length n and run-length entropy $\mathcal{H}$ in time $\mathcal{O}(n + n\mathcal{H})$ – which was already well-known – and that, if used with the galloping merging sub-routine, they only need $\mathcal{O}(n + n\mathcal{H}^*)$ comparisons to sort arrays of length n and dual run-length entropy $\mathcal{H}^*$ – which is a new result.

▶ **Theorem 16.** *The algorithms NaturalMergeSort, ShiversSort and α-StackSort have the middle-growth property.*

Theorem 8 proves that, if these three algorithms are used with the galloping merging sub-routine, they only need $\mathcal{O}(n + n\mathcal{H}^*)$ comparisons to sort arrays of length n and dual run-length entropy $\mathcal{H}^*$. By contrast, observe that they can be implemented by using a stack, following TimSort's own implementation, but where only the two top runs of the stack could be merged. It is proved in [13] that such algorithms may require $\omega(n + n\mathcal{H})$ comparisons to sort arrays of length n and run-length entropy $\mathcal{H}$. Hence, Theorem 6 shows that these three algorithms do *not* have the fast-growth property.

5 Refined complexity bounds for PowerSort

One weakness of Theorem 8 is that it cannot help us to distinguish the complexity upper bounds of those algorithms that have the middle-growth property, although the constants hidden in the $\mathcal{O}$ symbol could be dramatically different. In this section, we study these constants, thereby focusing on upper bounds of the type $\mathsf{c}n\mathcal{H}^* + \mathcal{O}(n)$ or $\mathsf{c}n(1+o(1))\mathcal{H}^* + \mathcal{O}(n)$.

Since sorting arrays of length n, in general, requires at least $\log_2(n!) = n\log_2(n) + \mathcal{O}(n)$ comparisons, and since $\mathcal{H}^* \leqslant \log_2(n)$ for all arrays, we already know that $\mathsf{c} \geqslant 1$ for any such constant c. Below, we focus on finding matching upper bounds in two regimes: first using a fixed parameter $\mathbf{t}$, thereby obtaining a constant $\mathsf{c} > 1$, and then letting $\mathbf{t}$ depend on the lengths of those runs that are being merged, in which case we reach the constant $\mathsf{c} = 1$.

5.1 A tight middle-growth property

Below, we aim at computing the least constant that might lie hidden in the $\mathcal{O}(n + n\mathcal{H}^*)$ upper bound of Theorem 8. If we were to simply extract that constant from the proof we gave, this constant would depend directly on the real number κ mentioned in the definition of the statement "$\mathcal{A}$ has the middle-growth property". To that aim, we make that statement more precise.

▶ **Definition 17.** *We say that a stable natural merge sort algorithm $\mathcal{A}$ has the* tight *middle-growth property if it satisfies the following statement:*

> *There exists an integer $\theta \geqslant 0$ such that, for every merge tree $\mathcal{T}$ induced by $\mathcal{A}$, every integer $h \geqslant 0$ and every run R of height h in $\mathcal{T}$, we have $r \geqslant 2^{h-\theta}$.*

Since every node of height $h \geqslant 1$ in a merge tree is a run of length at least 2, each algorithm with the tight middle-growth property also has the middle-growth property: indeed, it suffices to choose $\kappa = 2^{1/(\theta+1)}$. The tight middle-growth property is incomparable with the fast-growth property since, for instance, adaptive ShiversSort and PeekSort fail to have the tight middle-growth property. In practice, we might also introduce a related notion of tight fast-growth property, which would be useful when evaluating the constant hidden in the $\mathcal{O}(n + n\mathcal{H})$ upper bound on the complexity of sorting algorithms.

▶ **Theorem 18.** *The algorithm PowerSort has the tight middle-growth property.*

Proof. Let $\mathcal{T}$ be a merge tree induced by PowerSort and let R be a run in $\mathcal{T}$ at depth at least h. We will prove that $r^{(h)} \geqslant 2^{h-4}$.

If $h \leqslant 4$, the desired inequality is immediate. Then, if $h \geqslant 5$, let n be the length of the array on which $\mathcal{T}$ is induced. Let also p and $p^{(h-2)}$ be the respective powers of the runs R and $R^{(h-2)}$. Definition 12 and Lemma 13 prove that $2^{p^{(h-2)}+h-4} \leqslant 2^{p-2} \leqslant 2^{p-2}r < n < 2^{p^{(h-2)}}r^{(h)}$. ◀

5.2 Using a fixed parameter $\mathbf{t}$

Following the structure of Section 3, we prove now that each algorithm with the tight middle-growth property, such as PowerSort, enjoys excellent upper bounds on the number of element comparisons it requires.

▶ **Theorem 19.** *Let $\mathcal{A}$ be a stable natural merge sort algorithm with the tight middle-growth property. For each parameter $\mathbf{t} \geqslant 0$, if $\mathcal{A}$ uses the $\mathbf{t}$-galloping sub-routine for merging runs, it requires at most $(1 + 1/(\mathbf{t}+3))n\mathcal{H}^* + \log_2(\mathbf{t}+1)n + \mathcal{O}(n)$ element comparisons to sort arrays of length n and dual run-length entropy $\mathcal{H}^*$.*

Proof. Let us follow a variant of the proof of Theorem 8. Let θ be the integer mentioned in the definition of the statement "$\mathcal{A}$ has the tight middle-growth property", let $\mathcal{T}$ be the merge tree induced by $\mathcal{A}$ on an array A of length n, and let $s_1, s_2, \ldots, s_\sigma$ be the lengths of the dual runs of A. Like in the proof of Theorem 8, we just need to prove that

$$\sum_{R \in \mathcal{T}} \mathsf{cost}^*_{\mathbf{t}}(r_{\to i}) \leqslant (1 + 1/(\mathbf{t}+3))s_i \log_2(n/s_i) + s_i \log_2(\mathbf{t}+1) + \mathcal{O}(s_i)$$

for all $i \leqslant \sigma$.

Then, let $\mathcal{R}_h$ be the set of runs at height h in $\mathcal{T}$. By construction, no run in $\mathcal{R}_h$ descends from another one, which proves that

$$\sum_{R \in \mathcal{R}_h} r_{\to i} \leqslant s_i \text{ and that } \sum_{R \in \mathcal{R}_h} r \leqslant n.$$

Since each run $R \in \mathcal{R}_h$ is of length $r \geqslant 2^{h-\theta}$, it follows that $|\mathcal{R}_h| \leqslant n/2^{h-\theta}$.

Then, consider the function

$$\mathsf{C}_{\mathbf{t}}(h) = \sum_{R \in \mathcal{R}_h} \mathsf{cost}^*_{\mathbf{t}}(r_{\to i}).$$

We noted above that

$$\mathsf{C}_{\mathbf{t}}(h) \leqslant (1 + 1/(\mathbf{t}+3)) \sum_{R \in \mathcal{R}_h} r_{\to i} \leqslant (1 + 1/(\mathbf{t}+3))s_i$$

for all $h \geqslant 0$.

Let also $f\colon x \mapsto \mathbf{t} + 2 + 2\log_2(x+1)$, $g\colon x \mapsto x\, f(s_i/x)$ and $\mu = \lceil \log_2((\mathbf{t}+1)n/s_i) \rceil$. Both functions f and g are positive, concave and increasing on $(0, +\infty)$, which shows that

$$\begin{aligned}
\mathsf{C}_{\mathbf{t}}(\mu+\theta+h) &\leqslant \sum_{R \in \mathcal{R}_{\mu+\theta+h}} f(r_{\to i}) \leqslant |\mathcal{R}_{\mu+\theta+h}|\, f\big(\textstyle\sum_{R \in \mathcal{R}_{\mu+\theta+h}} r_{\to i} / |\mathcal{R}_{\mu+\theta+h}|\big) \leqslant g\big(|\mathcal{R}_{\mu+\theta+h}|\big) \\
&\leqslant g\big(n/2^{\mu+h}\big) \leqslant g\big(2^{-h} s_i/(\mathbf{t}+1)\big) \\
&\leqslant \big(\mathbf{t} + 2 + 2\log_2\big(2^h(\mathbf{t}+1)+1\big)\big) 2^{-h} s_i/(\mathbf{t}+1) \\
&\leqslant \big(\mathbf{t} + 2 + 2(h(\mathbf{t}+1)+1)\big) 2^{-h} s_i/(\mathbf{t}+1) \leqslant (4+2h) 2^{-h} s_i.
\end{aligned}$$

We conclude that

$$\begin{aligned}
\sum_{R \in \mathcal{T}} \mathsf{cost}^*_{\mathbf{t}}(r_{\to i}) = \sum_{h \geqslant 0} \mathsf{C}_{\mathbf{t}}(h) &= \sum_{h=0}^{\mu+\theta-1} \mathsf{C}_{\mathbf{t}}(h) + \sum_{h \geqslant 0} \mathsf{C}_{\mathbf{t}}(\mu+\theta+h) \\
&\leqslant (1 + 1/(\mathbf{t}+3))(\mu+\theta)s_i + 4s_i \sum_{h \geqslant 0} 2^{-h} + 2s_i \sum_{h \geqslant 0} h 2^{-h} \\
&\leqslant (1 + 1/(\mathbf{t}+3))(\log_2(n/s_i) + \log_2(\mathbf{t}+1))s_i + \mathcal{O}(s_i) \\
&\leqslant (1 + 1/(\mathbf{t}+3))\log_2(n/s_i)s_i + \log_2(\mathbf{t}+1)s_i + \mathcal{O}(s_i).
\end{aligned}$$

◀

5.3 Using a parameter $\mathbf{t}$ with logarithmic growth

The upper bound provided by Theorem 19 is minimal when $\mathbf{t} = \Theta(\mathcal{H}^*)$, in which case it simply becomes $n\mathcal{H}^* + \log_2(\mathcal{H}^*+1)n + \mathcal{O}(n)$. However, computing $\mathcal{H}^*$ before starting the actual sorting process is not reasonable. Instead, we update the parameter $\mathbf{t}$ as follows, which will provide us with a slightly larger upper bound.

▶ **Definition 20.** *We call* logarithmic *galloping sub-routine the merging sub-routine that, when merging adjacent runs of lengths a and b, performs the same comparisons and element moves as the $\mathbf{t}$-galloping sub-routine for $\mathbf{t} = \lceil \log_2(a+b) \rceil$.*

▶ **Theorem 21.** *Let $\mathcal{A}$ be a stable natural merge sort algorithm with the tight middle-growth property. If $\mathcal{A}$ uses the logarithmic galloping sub-routine for merging runs, it requires at most $n\mathcal{H}^* + 2\log_2(\mathcal{H}^*+1)n + \mathcal{O}(n)$ element comparisons to sort arrays of length n and dual run-length entropy $\mathcal{H}^*$.*

Proof. Let us refine and adapt the proofs of Theorems 8 and 19. Let θ be the integer mentioned in the definition of the statement "$\mathcal{A}$ has the tight middle-growth property", let $\mathcal{T}$ be the merge tree induced by $\mathcal{A}$ on an array A of length n, and let $s_1, s_2, \ldots, s_\sigma$ be the lengths of the dual runs of A.

Using a parameter $\mathbf{t} = \lceil \log_2(r) \rceil$ to merge runs R' and R'' into one run R requires at most

$$1 + \sum_{i=1}^{\sigma} \mathsf{cost}^*_{\lceil \log_2(r) \rceil}(r'_{\to i}) + \mathsf{cost}^*_{\lceil \log_2(r) \rceil}(r''_{\to i})$$

element comparisons. Given that

$$\begin{aligned}\mathsf{cost}^*_{\lceil \log_2(r) \rceil}(r'_{\to i}) &\leqslant \min\{(1 + 1/\log_2(r))r'_{\to i}, \log_2(r) + 3 + 2\log_2(r'_{\to i} + 1)\} \\ &\leqslant \min\{(1 + 1/\log_2(r))r'_{\to i}, 3\log_2(r+1) + 3\},\end{aligned}$$

and that $r'_{\to i} + r''_{\to i} = r_{\to i}$, this makes a total of at most

$$1 + \sum_{i=1}^{\sigma} \mathsf{cost}^*_{\log}(r, r_{\to i})$$

element comparisons, where $\mathsf{cost}^*_{\log}(r, m) = \min\{(1 + 1/\log_2(r))m, 6\log_2(r+1) + 6\}$.

Then, let $\mathcal{T}^*$ denote the tree obtained after removing the leaves of $\mathcal{T}$. We focus on proving that

$$\sum_{R \in \mathcal{T}^*} \mathsf{cost}^*_{\log}(r, r_{\to i}) \leqslant s_i \log_2(n/s_i) + 2s_i \log_2(\log_2(2n/s_i)) + \mathcal{O}(s_i)$$

for all $i \leqslant \sigma$. Indeed, finding the run decomposition $R_1, R_2, \ldots, R_\rho$ of A requires $n-1$ comparisons, and $\rho - 1 \leqslant n - 1$ merges are then performed, which will make a total of up to

$$\begin{aligned}2n + \sum_{R \in \mathcal{T}^*} \sum_{i=1}^{\sigma} \mathsf{cost}^*_{\log}(r, r_{\to i}) &\leqslant 2n + \sum_{i=1}^{\sigma} s_i \log_2(n/s_i) + 2s_i \log_2(\log_2(n/s_i) + 1) + \mathcal{O}(s_i) \\ &\leqslant n\mathcal{H}^* + 2\log_2(\mathcal{H}^* + 1)n + \mathcal{O}(n)\end{aligned}$$

comparisons, the latter inequality being due to the concavity of the function $x \mapsto \log_2(x+1)$.

Then, let $\mathcal{R}_h$ be the set of runs at height h in $\mathcal{T}$, and let

$$\mathsf{C}_{\log}(h) = \sum_{R \in \mathcal{R}_h} \mathsf{cost}^*_{\log}(r, r_{\to i}).$$

No run in $\mathcal{R}_h$ descends from another one, and each run $R \in \mathcal{R}_h$ has length $r \geqslant 2^{\max\{1, h-\theta\}}$, which proves that $|\mathcal{R}_h| \leqslant n/2^{h-\theta}$ and that

$$\mathsf{C}_{\log}(h) \leqslant \sum_{R \in \mathcal{R}_h} (1+1/\log_2(r))r_{\to i} \leqslant \sum_{R \in \mathcal{R}_h} (1+1/\max\{1, h-\theta\})r_{\to i} \leqslant (1+1/\max\{1, h-\theta\})s_i.$$

Finally, let $z = n/s_i \geqslant 1$, and consider the constant $\nu = \lceil \log_2(z\log_2(2z)) \rceil + \theta$ and the functions $f\colon x \mapsto 1 + \log_2(x+1)$ and $g\colon x \mapsto x\, f(n/x)$. Both functions f and g are concave, positive and increasing on $(0, +\infty)$, which proves that

$$\begin{aligned}\mathsf{C}_{\log}(\nu + h)/6 \leqslant \sum_{R \in \mathcal{R}_{\nu+h}} f(r) &\leqslant |\mathcal{R}_{\nu+h}|\, f\big(\textstyle\sum_{R \in \mathcal{R}_{\nu+h}} r/|\mathcal{R}_{\nu+h}|\big) \leqslant g(|\mathcal{R}_{\nu+h}|) \leqslant g(n/2^{\nu-\theta+h}) \\ &\leqslant g\big(2^{-h}s_i/\log_2(2z)\big) = 2^{-h}s_i f(2^h z\log_2(2z))/\log_2(2z) \\ &\leqslant 2^{-h}s_i\big(1 + \log_2(2^h(2z)^2)\big)/\log_2(2z) = 2^{-h}(h+1)s_i/\log_2(2z) + 2^{1-h}s_i \\ &\leqslant (h+3)2^{-h}s_i,\end{aligned}$$

where the inequality between the second and third line simply comes from the fact that

$$1 + 2^h z \log_2(2z) \leqslant 1 + 2^{h+1} z^2 \leqslant 2^h (1 + 2z^2) \leqslant 2^h \times (2z)^2$$

whenever $h \geqslant 0$ and $z \geqslant 1$.

It follows that

$$\sum_{h=1}^{\theta} \mathsf{C}_{\log}(h) + \sum_{h \geqslant 0} \mathsf{C}_{\log}(\nu + h) \leqslant 2\theta s_i + 6 \sum_{h \geqslant 0} (h+3) 2^{-h} s_i = \mathcal{O}(s_i),$$

whereas

$$\sum_{h=1}^{\nu-\theta-1} \mathsf{C}_{\log}(\theta + h) \leqslant \sum_{h=1}^{\nu-1} (1 + 1/h) s_i \leqslant ((\nu - 1) + 1 + \ln(\nu - 1)) s_i = (\nu + \ln(\nu)) s_i.$$

Thus, we conclude that

$$\begin{aligned} \sum_{R \in \mathcal{T}^*} \mathsf{cost}^*_{\log}(r, r_{\to i}) = \sum_{h \geqslant 1} \mathsf{C}_{\log}(h) &\leqslant s_i(\nu + \ln(\nu)) + \mathcal{O}(s_i) \\ &\leqslant s_i \log_2(z) + s_i \log_2(\log_2(2z)) + s_i \log_2(\log_2(2z^2)) + \mathcal{O}(s_i) \\ &\leqslant s_i \log_2(z) + 2 s_i \log_2(\log_2(2z)) + \mathcal{O}(s_i). \end{aligned}$$

◀

It is of course possible to marginally improve our update policy in order to approach the $n\mathcal{H}^* + \log_2(\mathcal{H}^* + 1)n + \mathcal{O}(n)$ upper bound. For instance, choosing $\mathbf{t} = \tau\lceil \log_2(a+b) \rceil$ for a given constant $\tau \geqslant 1$ provides us with an $n\mathcal{H}^* + (1 + 1/\tau) \log_2(\mathcal{H}^* + 1)n + \log_2(\tau) + \mathcal{O}(n)$ upper bound, and choosing $\mathbf{t} = \lceil \log_2(a+b) \rceil \times \lceil \log_2(\log_2(a+b)) \rceil$ further improves that upper bound. However, such improvements soon become negligible in comparison with the overhead of having to compute the value of $\mathbf{t}$.

Finally, and like in Section 4, we list a few algorithms that enjoy similar complexity upper bounds. Proofs that they do can be found in the complete version of this article [11].

▶ **Theorem 22.** *The algorithms* NaturalMergeSort *and* ShiversSort *have the tight middle-growth property.*

▶ **Theorem 23.** *Theorems 19 and 21 remain valid if we consider the algorithms* PeekSort *and* adaptive ShiversSort *instead of an algorithm with the tight middle-growth property.*

By contrast, we conjecture that no choice policy for the parameters $\mathbf{t}$ would provide us with $(1 + o(1))n\mathcal{H}^* + \mathcal{O}(n)$ upper bounds on the number of element comparisons performed by TimSort, α-StackSort or α-MergeSort. However, finding precise characterisations of the best constants c that could be achieved for these algorithms is a wide open question.

6 Conclusion: An idealistic galloping cost model

In the above sections, we observed the impact of using a galloping sub-routine for a fixed or a variable parameter $\mathbf{t}$. Although choosing a constant value of $\mathbf{t}$ (e.g., $\mathbf{t} = 7$, as advocated in [17]) already leads to very good results, letting $\mathbf{t}$ vary, for instance by using the logarithmic variant of the sub-routine, provides us with even better complexity guarantees, with an often negligible overhead of $\mathcal{O}(n \log(\mathcal{H}^* + 1) + n)$ element comparisons: up to a small error, this provides us with the following *idealistic* cost model for run merges, allowing us to simultaneously identify the parameter $\mathbf{t}$ with $+\infty$ and with a constant.

▶ **Definition 24.** *Let A and B be two non-decreasing runs with $a_{\to i}$ (respectively, $b_{\to i}$) elements of value i for all $i \in \{1, 2, \ldots, \sigma\}$. The* idealistic galloping cost *of merging A and B is defined as the quantity*

$$\sum_{i=1}^{\sigma} \mathsf{cost}^*_{\mathsf{ideal}}(a_{\to i}) + \mathsf{cost}^*_{\mathsf{ideal}}(b_{\to i}),$$

where $\mathsf{cost}^*_{\mathsf{ideal}}(m) = \min\{m, \log_2(m+1) + \mathcal{O}(1)\}$.

Indeed, abusively identifying the real number of element comparisons performed while runs A and B with this idealistic galloping cost, we may prove that every stable natural merge sort with the tight middle-growth property (but also related algorithms such as PeekSort and adaptive ShiversSort) requires at most $n\mathcal{H}^* + \mathcal{O}(n)$ element comparisons to sort arrays of length n and dual run-length entropy $\mathcal{H}^*$.

We think that this idealistic cost model is both simple and precise enough to allow studying the complexity of natural merge sorts in general, provided that they use the galloping sub-routine. Thus, it would be interesting to use that cost model in order to study, for instance, the least constant c for which various algorithms such as TimSort or α-MergeSort require up to $\mathsf{c}n(1 + o(1))\mathcal{H}^* + \mathcal{O}(n)$ element comparisons.

We also hope that this simpler framework will foster the interest for the galloping merging sub-routine of TimSort, and possibly lead to amending Swift and Rust implementations of TimSort to include that sub-routine, which we believe is too efficient in relevant cases to be omitted.

Abstract

Bipartite testing has been a central problem in the area of property testing since its inception in the seminal work of Goldreich, Goldwasser, and Ron. Though the non-tolerant version of bipartite testing has been extensively studied in the literature, the tolerant variant is not well understood. In this paper, we consider the following version of tolerant bipartite testing problem: Given two parameters $\varepsilon, \delta \in (0,1)$, with $\delta > \varepsilon$, and access to the adjacency matrix of a graph G, we have to decide whether G can be made bipartite by editing at most εn^2 entries of the adjacency matrix of G, or we have to edit at least δn^2 entries of the adjacency matrix to make G bipartite. In this paper, we prove that for $\delta = (2 + \Omega(1))\varepsilon$, tolerant bipartite testing can be decided by performing $\widetilde{\mathcal{O}}\left(1/\varepsilon^3\right)$ many adjacency queries and in $2^{\widetilde{\mathcal{O}}(1/\varepsilon)}$ time complexity. This improves upon the state-of-the-art query and time complexities of this problem of $\widetilde{\mathcal{O}}\left(1/\varepsilon^6\right)$ and $2^{\widetilde{\mathcal{O}}(1/\varepsilon^2)}$, respectively, due to Alon, Fernandez de la Vega, Kannan and Karpinski, where $\widetilde{\mathcal{O}}(\cdot)$ hides a factor polynomial in $\log(1/\varepsilon)$.

1 Introduction

The field of property testing refers to the model where the main goal is to design efficient algorithms that reads only "small" part of the input. Over the past few years, the field has had very rapid growth, and several interesting techniques and results have emerged. See, for example, the new property testing book by Goldreich [11] for an introduction to property testing.

The field of graph property testing was first introduced in the seminal work of Goldreich, Goldwasser, and Ron [12]. In that work, the authors studied various interesting and important problems in dense graphs and testing bipartiteness was one of them. In non-tolerant variant

of bipartiteness testing, we are given a dense graph G and a proximity parameter $\varepsilon \in (0,1)$ as the input, and the goal is to decide if G is bipartite, or do we need to modify at least εn^2 many entries of the adjacency matrix of G to make it bipartite, using as few queries to the adjacency matrix of G as possible.

Due to the fundamental nature of the problem, *bipartite testing* has been extensively studied over the past two decades [12]. Though there are several works on non-tolerant testing of various graph properties across all models in graph property testing [12, 13, 7], there are very few works related to their tolerant counterparts (See, for example, the property testing book by Goldreich [11] for an extensive list of various results). To the best of our knowledge, this is the first time tolerant bipartite testing has been *explicitly* studied in the literature.

Now we formally define the notion of *bipartite distance* and state our main result. Then we discuss our result vis-a-vis the related works.

▶ **Definition 1.1** (Bipartite distance). *A* bipartition *of a graph G is a function $f : V(G) \to \{L, R\}$, where $V(G)$ denotes the vertex set of G* [1]*. The* bipartite *distance of G with respect to the bipartition f is denoted and defined as*

$$d_{bip}(G, f) := \left[\sum_{v \in V : f(v) = L} |N(v) \cap f^{-1}(L)| + \sum_{v \in V : f(v) = R} |N(v) \cap f^{-1}(R)| \right].$$

Here $N(v)$ denotes the neighborhood of v in G. Informally, $d_{bip}(G, f)$ measures the distance of the graph G from being bipartite, with respect to the bipartition f. The *bipartite distance* of G is defined as the minimum bipartite distance of G over all possible bipartitions f of G, that is,

$$d_{bip}(G) := \min_{f} d_{bip}(G, f).$$

Now we are ready to formally state our result.

▶ **Theorem 1.2** (Main result). *Given query access to the adjacency matrix of a dense graph G with n vertices and a proximity parameter $\varepsilon \in (0,1)$, there exists an algorithm that, with probability at least $\frac{9}{10}$, decides whether $d_{bip}(G) \leq \varepsilon n^2$ or $d_{bip}(G) \geq (2+\Omega(1))\varepsilon n^2$, by sampling $\mathcal{O}\left(\frac{1}{\varepsilon^3} \log \frac{1}{\varepsilon}\right)$ many vertices in $2^{\mathcal{O}\left(\frac{1}{\varepsilon} \log \frac{1}{\varepsilon}\right)}$ time, and performs $\mathcal{O}\left(\frac{1}{\varepsilon^3} \log^2 \frac{1}{\varepsilon}\right)$ many queries.*

1.1 Our result in the context of literature

Recall that non-tolerant bipartite testing refers to the problem where we are given query access to the adjacency matrix of an unknown graph G and a proximity parameter $\varepsilon \in (0,1)$, and the objective is to decide whether $d_{bip}(G) = 0$ or $d_{bip}(G) \geq \varepsilon n^2$. The problem of non-tolerant bipartite testing in the dense graph model was first studied in the seminal work of Goldreich, Goldwasser, and Ron [12], and they showed that it admits an algorithm with query complexity $\widetilde{\mathcal{O}}\left(1/\varepsilon^3\right)$. Later, Alon and Krivelevich [4] improved the query complexity of the problem to $\widetilde{\mathcal{O}}\left(1/\varepsilon^2\right)$. They further studied the problem of testing c-colorability of dense graph. Note that bipartite testing is a special case of testing c-colorability, when $c = 2$. They proved that c-colorability can be tested by performing $\widetilde{\mathcal{O}}\left(1/\varepsilon^4\right)$ many queries, for $c \geq 3$. This bound was later improved to $\widetilde{\mathcal{O}}\left(1/\varepsilon^2\right)$ by Sohler [18]. On the other hand, for

[1] L and R denote left and right respectively.

non-tolerant bipartite testing, Bogdanov and Trevisan [6] proved that $\Omega(1/\varepsilon^2)$ and $\Omega(1/\varepsilon^{3/2})$ many adjacency queries are required by any non-adaptive and adaptive testers, respectively. Later, Gonen and Ron [14] further explored the power of adaptive queries for bipartiteness testing. Bogdanov and Li [5] showed that bipartiteness can be tested with one-sided error in $\mathcal{O}(1/\varepsilon^c)$ queries, for some constant $c < 2$, assuming a conjecture [2].

Though the non-tolerant variant of bipartite testing is well understood, the query complexity of the tolerant version (even for restricted cases like we consider in Theorem 1.2) has not yet been addressed in the literature. From the result of Alon, Vega, Kannan and Karpinski [1],for estimating MaxCut [3] for any given ε $(0 < \varepsilon < 1)$, it implies that that the bipartite distance of a (dense) graph G can be estimated up to an additive error of εn^2, by performing $\widetilde{\mathcal{O}}\left(1/\varepsilon^6\right)$ many queries (see Appendix A for details, and in particular, see Corollary A.2). Even for the tolerant version that we consider in Theorem 1.2, their algorithm does not give any bound better than $\widetilde{\mathcal{O}}\left(1/\varepsilon^6\right)$. Note that Alon, Vega, Kannan and Karpinski [1] improved the result of Goldreich, Goldwasser, and Ron [12], who were the first to prove that MaxCut can be estimated with an additive error of εn^2 by performing $\widetilde{\mathcal{O}}(1/\varepsilon^7)$ many adjacency queries and with time complexity $2^{\widetilde{\mathcal{O}}(1/\varepsilon^3)}$. Though we improve the bound for tolerant bipartite testing (for the restricted case as stated in Theorem 1.2) substantially from the work of Alon et al. [1], we would like to note that this is the first work that studies tolerant bipartite testing explicitly.

1.2 Other related works

Apart from the dense graph model, this problem has also been studied in other models of property testing. Goldreich and Ron [13] studied the problem of bipartiteness testing for bounded degree graphs, where they gave an algorithm of $\widetilde{\mathcal{O}}(\sqrt{n})$ queries, where n denotes the number of vertices of the graph. Later, Kaufman, Krivelevich and Ron [15] studied the problem in the general graph model and gave an algorithm with query complexity $\widetilde{\mathcal{O}}\left(\min\left\{\sqrt{n}, n^2/m\right\}\right)$, where m denotes the number of edges of the graph. Few years back, Czumaj, Monemizadeh, Onak, and Sohler [7] studied the problem for planar graphs (more generally, for any minor-free graphs), where they employed a random walk based technique, and proved that constant number of queries are enough for bipartiteness testing. Apart from bipartite testing, there have been extensive works related to property testing in the dense graph model and its connection to the regularity lemma [3, 2, 9].

1.3 Organization

In Section 2, we present an overview of our algorithm along with a brief description of its analysis. In Section 3, we formally describe our algorithm, followed by its correctness analysis in Section 4. Finally, we conclude in Section 5. The proofs that are omitted in the main text are either presented in the appendix or in the full version of the paper [10].

1.4 Notations

All graphs considered here are undirected, unweighted, and have no self-loops or parallel edges. For a graph $G = (V(G), E(G))$, $V(G)$ and $E(G)$ denote the vertex and edge sets of G respectively. For a vertex $v \in V(G)$, $N_G(v)$ denotes the neighborhood of a vertex v in

[2] The conjecture is that if the graph G is ε-far from bipartite, then an induced subgraph on $\widetilde{\mathcal{O}}(1/\varepsilon)$ many random vertices would be $\widetilde{\Omega}(\varepsilon)$-far from being bipartite with probability at least 1/2.

[3] MaxCut of a graph G denotes the size of the largest *cut* in G.

G, and we will write it as $N(v)$ when the graph G is clear from the context. Since we are only considering undirected graphs, we write an edge as $\{u, v\} \in E(G)$. For a set of pairs of vertices Z, we will denote the set of vertices present in at least one pair in Z by $V(Z)$. For a function $f : V(G) \to \{L, R\}$, $f^{-1}(L)$ and $f^{-1}(R)$ represent the set of vertices that are mapped to L and R by f respectively. We denote by $\binom{V(G)}{2}$ the set of unordered pairs of the vertices of G. Finally, $a = (1 \pm \varepsilon)b$ represents $(1 - \varepsilon)b \leq a \leq (1 + \varepsilon)b$.

2 Overview of the proof of Theorem 1.2

In this section, we give an overview of our algorithm. The detailed description of the algorithm is presented in Section 3, while its analysis is presented in Section 4. We will prove the following theorem, which is our main technical result.

▶ **Theorem 2.1.** *There exists an algorithm* Tol-Bip-Dist(G, ε) *that given adjacency query access to a dense graph G with n vertices and a parameter $\varepsilon \in (0, 1)$, decides with probability at least $9/10$, whether $d_{bip}(G) \leq \varepsilon n^2$ or $d_{bip}(G) \geq (2 + k)\varepsilon n^2$, by sampling $\mathcal{O}(\frac{1}{k^5\varepsilon^2} \log \frac{1}{k\varepsilon})$ many vertices in $2^{\mathcal{O}(\frac{1}{k^3\varepsilon} \log \frac{1}{k\varepsilon})}$ time, using $\mathcal{O}(\frac{1}{k^8\varepsilon^3} \log^2 \frac{1}{k\varepsilon})$ many queries to the adjacency matrix of G.*

Note that Theorem 2.1 implies Theorem 1.2, by taking $k = \Omega(1)$.

2.1 Brief description of the algorithm

Assume C_1, C_2, C_3 are three suitably chosen large absolute constants. At the beginning of our algorithm, we generate t many subsets of vertices $X_1, \ldots, X_t$, each with $\lceil \frac{C_2}{k^3\varepsilon} \log \frac{1}{k\varepsilon} \rceil$ many vertices chosen randomly, where $t = \lceil \log \frac{C_1}{k\varepsilon} \rceil$. Let $\mathcal{C} = X_1 \cup \ldots \cup X_t$. Apart from the X_i's, we also randomly select a set of pairs of vertices Z, with $|Z| = \lceil \frac{C_3}{k^5\varepsilon^2} \log \frac{1}{k\varepsilon} \rceil$. We find the neighbors of each vertex of Z in $\mathcal{C}$. Then for each vertex pair in Z, we check whether it is an edge in the graph or not. Loosely speaking, the set of edges between $\mathcal{C}$ and $V(Z)$ [4] will help us generate partial bipartitions, restricted to $X_i \cup V(Z)$'s, for each $i \in [t]$, and the edges among the pairs of vertices of Z will help us in estimating the bipartite distance of some *specific kind* of bipartitions of G. Here we would like to note that no further query will be performed by the algorithm. The set of edges with one vertex in $\mathcal{C}$ and the other in $V(Z)$, and the set of edges among the vertex pairs in Z, when treated in a *specific* manner, will give us the desired result. Observe that the number of adjacency queries performed by our algorithm is $\mathcal{O}(\frac{1}{k^8\varepsilon^3} \log^2 \frac{1}{k\varepsilon})$.

For each $i \in [t]$, we do the following. We consider all possible bipartitions $\mathcal{F}_i$ of X_i. For each bipartition f_{ij} (of X_i) in $\mathcal{F}_i$, we extend f_{ij} to a bipartition of $X_i \cup V(Z)$, say f'_{ij}, such that both f_{ij} and f'_{ij} are identical with respect to X_i. Moreover, we assign $f'_{ij}(z)$ (to either L or R), for each $z \in V(Z) \setminus X_i$, based on the neighbors of z in X_i. To design a rule of assigning $f'_{ij}(z)$, for each $z \in V(Z) \setminus X_i$ for our purpose, we define the notions of *heavy* and *balanced* vertices, with respect to a bipartition (see Definitions 4.1 and 4.2). Heavy and balanced vertices are defined in such a manner that when the bipartite distance of G is at most εn^2 (that is, G is ε-close), we can infer the following interesting connections. Let f be a bipartition of $V(G)$ such that $d_{bip}(G, f) \leq \varepsilon n^2$. We will prove that the total number of edges, with no endpoints in X_i and whose at least one endpoint is a balanced vertex with respect to f, is bounded (see Claim 4.12). Moreover, if we generate a bipartition f' such that

[4] Recall that $V(Z)$ denotes the set of vertices present in at least one pair in Z.

f and f' differ for *large* number of heavy vertices, then the bipartite distance with respect to f' cannot be small. To guarantee the correctness of our algorithm, we will prove that a heavy vertex v with respect to f, can be detected and $f(v)$ can be determined, with probability at least $1 - o(k\varepsilon)$. Note that the testing of being a heavy vertex will be performed only for the vertices in $V(Z)$. We will see shortly how this will help us to guarantee the completeness of our algorithm.

Finally, our algorithm computes ζ_{ij}, that is, the fraction of vertex pairs in Z that are monochromatic [5] edges with respect to f'_{ij}. If we find at least one i and j such that $\zeta_{ij} \leq \left(2 + \frac{k}{20}\right)\varepsilon$, the algorithm decides that $d_{bip}(G) \leq \varepsilon n^2$. Otherwise, it will report that $d_{bip}(G) \geq (2+k)\varepsilon n^2$.

2.2 Completeness

Let us assume that the bipartite distance of G is at most εn^2, and let f be a bipartition of $V(G)$ that is optimal. Let us now focus on a particular $i \in [t]$, that is, an X_i. Since we are considering all possible bipartitions $\mathcal{F}_i$ of X_i, there exists a $f_{ij} \in \mathcal{F}_i$, such that f_{ij} and f are identical with respect to X_i. To complete our argument, we introduce (in Definition 4.3) the notion of SPECIAL bipartition $\textsc{Spl}_i^f : V(G) \to \{L, R\}$, with respect to f by f_{ij} such that $f(v)$, $f_{ij}(v)$ and $\textsc{Spl}_i^f(v)$ are identical for each $v \in X_i$, and at least $1 - o(k\varepsilon)$ fraction of heavy vertices, with respect to f, are mapped identically both by f and $\textsc{Spl}_i^f$. We shall prove that the bipartite distance of G with respect to $\textsc{Spl}_i^f$ is at most $\left(2 + \frac{k}{50}\right)\varepsilon n^2$ (see Lemma 4.6). Now let us think of generating a bipartition f''_{ij} of $V(G)$ such that, for each $v \in V(G) \setminus X_i$, if we determine $f''_{ij}(v)$ by the same rule used by our algorithm to determine $f_{ij}(z)$, for each $z \in V(Z) \setminus X_i$. Note that our algorithm does not find f''_{ij} explicitly, it is used only for the analysis purpose. The number of heavy vertices, with respect to the bipartition f, that have different mappings by f and f''_{ij}, is at most $o(k\varepsilon n)$ with constant probability. So, with a constant probability, f''_{ij} is a SPECIAL bipartition with respect to f by f_{ij}. Note that, if we take $|Z| = \mathcal{O}(\frac{1}{k^5\varepsilon^2} \log \frac{1}{k\varepsilon})$ many random vertex pairs and determine the fraction χ_{ij}^f of pairs that form monochromatic edges with respect to the SPECIAL bipartition f''_{ij}, we can show that $\chi_{ij}^f \leq (2 + \frac{k}{20})\varepsilon$, with probability at least $1 - 2^{-\Omega(\frac{1}{k^3\varepsilon} \log \frac{1}{k\varepsilon})} \geq \frac{9}{10}$. However, we are not finding either f''_{ij} or χ_{ij}^f explicitly. We just find ζ_{ij}, that is, the fraction of vertex pairs in Z that are monochromatic edges with respect to f'_{ij}. But the above argument still holds, since Z is chosen randomly and there exists a f''_{ij}, such that $f''_{ij}(z) = f'_{ij}(z)$, for each $z \in V(Z)$, and the probability distribution of ζ_{ij} is identical to that of χ_{ij}^f.

2.3 Soundness

Let us now consider the case when the bipartite distance of G is at least $(2+k)\varepsilon n^2$, and f be any bipartition of $V(G)$. To prove the soundness of our algorithm, we introduce the notion of DERIVED *bipartition* $\textsc{Der}_i^f : V(G) \to \{L, R\}$ with respect to f by f_{ij} (see Definition 4.4), such that $f(v)$, $f_{ij}(v)$ and $\textsc{Der}_i^f(v)$ are identical for each $v \in X_i$. Observe that the bipartite distance of G with respect to any DERIVED bipartition is at least $(2+k)\varepsilon n^2$ as well. Similar to the discussion of the completeness, if we generate a bipartition f''_{ij} of $V(G)$, f''_{ij} will be a DERIVED bipartition, with respect to f by f_{ij}. If we take $|Z| = \mathcal{O}(\frac{1}{k^5\varepsilon^2} \log \frac{1}{k\varepsilon})$ many random pairs of vertices and determine the fraction χ_{ij}^f of pairs that form monochromatic edges with respect to the DERIVED bipartition f''_{ij}, we can prove that $\chi_{ij}^f \leq \left(2 + \frac{k}{20}\right)\varepsilon$ holds, with

[5] An edge is said to be monochromatic with respect to f'_{ij} if both its endpoints have the same f'_{ij} values.

probability at most $2^{-\Omega(\frac{1}{k^3\varepsilon}\log\frac{1}{k\varepsilon})}$. We want to re-emphasize that we are not determining f''_{ij}, as well as χ^f_{ij} explicitly. The argument follows due to the facts that Z is chosen randomly and there exists an f''_{ij} such that $f'_{ij}(z) = f''_{ij}(z)$, for each $z \in V(Z)$, and the probability distribution of ζ_{ij} is identical to that of χ^f_{ij}. Using the union bound, we can say that the algorithm rejects with probability at least $\frac{9}{10}$.

3 Algorithm for Tolerant Bipartite Testing (Proof of Theorem 2.1)

In this section, we formalize the ideas discussed in Section 2, and prove Theorem 2.1.

Formal description of algorithm Tol-Bip-Dist(G, ε)

Step-1 Let C_1, C_2, C_3 be three suitably chosen large constants and $t := \lceil \log \frac{C_1}{k\varepsilon} \rceil$.

(i) We start by generating t many subset of vertices $X_1, \ldots, X_t \subset V(G)$, each with $\lceil \frac{C_2}{k^3\varepsilon} \log \frac{1}{k\varepsilon} \rceil$ many vertices, sampled randomly without replacement [6].

(ii) We sample $\lceil \frac{C_3}{k^5\varepsilon^2} \log \frac{1}{k\varepsilon} \rceil$ many random pairs of vertices, with replacement, and denote those sampled pairs of vertices as Z. Note that $X_1, \ldots, X_t, Z$ are generated independent of each other.

(iii) We find all the edges with one endpoint in $\mathcal{C} = X_1 \cup X_2 \cup \ldots X_t$ and the other endpoint in one of the vertices of $V(Z)$ [7], by performing $\mathcal{O}\left(\frac{1}{k^8\varepsilon^3}\log^2\frac{1}{k\varepsilon}\right)$ many adjacency queries.

Step-2 (i) Let $\{a_1, b_1\}, \ldots \{a_\lambda, b_\lambda\}$ be the pairs of vertices of Z, where $\lambda = \lceil \frac{C_3}{k^5\varepsilon^2} \log \frac{1}{k\varepsilon} \rceil$. Now we find the pairs of Z that are edges in G, by performing adjacency queries to all the pairs of vertices of Z (after this step, the algorithm does not make any query further).

(ii) For each $i \in [t]$, we do the following:

(a) Let $\mathcal{F}_i$ denote the set of all possible bipartitions of X_i, that is,

$$\mathcal{F}_i = \left\{ f_{ij} : X_i \to \{L, R\} : j \in \left[2^{|X_i|-2}\right] \right\}.$$

(b) For each bipartition f_{ij} (of X_i) in $\mathcal{F}_i$, we extend f_{ij} to $f'_{ij} : X_i \cup Z \to \{L, R\}$ to be a bipartition of $X_i \cup Z$, such that the mapping of each vertex of X_i are identical in f_{ij} and f'_{ij}, and is defined as follows:

$$f'_{ij}(z) = \begin{cases} f_{ij}(z), & z \in X_i \\ L, & z \notin X_i \text{ and } \left|N(z) \cap f_{ij}^{-1}(R)\right| > \left|N(z) \cap f_{ij}^{-1}(L)\right| + \frac{k\varepsilon|X_i|}{225000} \\ R, & z \notin X_i \text{ and } \left|N(z) \cap f_{ij}^{-1}(L)\right| > \left|N(z) \cap f_{ij}^{-1}(R)\right| + \frac{k\varepsilon|X_i|}{225000} \\ \text{L or } R \text{ arbitrarily}, & \text{otherwise} \end{cases}$$

Note that this step can be performed from the adjacency information between the vertices of $\mathcal{C}$ and Z, which have already been computed before.

(c) We now find the fraction of the vertex pairs of Z that are edges and have the same label with respect to f'_{ij}, that is,

$$\zeta_{ij} = 2 \cdot \frac{\left|\left\{\{a_\ell, b_\ell\} : \ell \in [\lambda], \{a_\ell, b_\ell\} \in E(G) \text{ and } f'_{ij}(a_\ell) = f'_{ij}(b_\ell)\right\}\right|}{\lambda}$$ [8].

(d) If $\zeta_{ij} \leq \left(2 + \frac{k}{20}\right)\varepsilon$, we Accept G as ε-close to being bipartite, and Quit the algorithm.

---

[6] Since we are assuming n is sufficiently large with respect to $\frac{1}{\varepsilon}$, sampling with and without replacement are the same.

[7] Recall that $V(Z)$ denotes the set of vertices present in at least one pair in Z.

(iii) If we arrive at this step, then $\zeta_{ij} > \left(2 + \frac{k}{20}\right)\varepsilon$, for each $i \in [t]$ and $f_{ij} \in \mathcal{F}_i$ in Step-(ii). We REJECT and declare that G is $(2+k)\varepsilon$-far from being bipartite.

We split the analysis of algorithm TOL-BIP-DIST(G, ε) into five parts:

Completeness: If G is ε-close to being bipartite, then TOL-BIP-DIST(G, ε) reports the same, with probability at least $\frac{9}{10}$.

Soundness: If G is $(2+k)\varepsilon$-far from being bipartite, then TOL-BIP-DIST(G, ε) reports the same, with probability at least $\frac{9}{10}$.

Sample Complexity: The sample complexity of TOL-BIP-DIST(G, ε) is $\mathcal{O}(\frac{1}{k^5\varepsilon^2}\log\frac{1}{k\varepsilon})$.

Query Complexity: The query complexity of TOL-BIP-DIST(G, ε) is $\mathcal{O}(\frac{1}{k^8\varepsilon^3}\log^2\frac{1}{k\varepsilon})$.

Time Complexity: The time complexity of TOL-BIP-DIST(G, ε) is $2^{\mathcal{O}(\frac{1}{k^3\varepsilon}\log\frac{1}{k\varepsilon})}$.

The last three quantities can be computed from the description of TOL-BIP-DIST(G, ε). In **Step-1(i)**, we sample vertices of G to generate $t = \lceil \log \frac{C_1}{k\varepsilon} \rceil$ subsets, each with $\lceil \frac{C_2}{k^3\varepsilon}\log\frac{1}{k\varepsilon} \rceil$ many vertices. Thereafter in **Step-1(ii)** and **Step-1(iii)**, we randomly choose $\lceil \frac{C_3}{k^5\varepsilon^2}\log\frac{1}{k\varepsilon} \rceil$ many pairs of vertices and perform adjacency queries for each vertex in any pair of Z to every X_i. Thus the sample complexity of TOL-BIP-DIST(G, ε) is $\mathcal{O}(\frac{1}{k^5\varepsilon^2}\log\frac{1}{k\varepsilon})$ and query complexity is $\mathcal{O}(\frac{1}{k^8\varepsilon^3}\log^2\frac{1}{k\varepsilon})$. The time complexity of the algorithm is $2^{\mathcal{O}(\frac{1}{k^3\varepsilon}\log\frac{1}{k\varepsilon})}$, which follows from **Step-2(ii)**, that dominates the running time.

4 Proof of Correctness of TOL-BIP-DIST(G, ε)

Before proceeding to the proof, we introduce some definitions for classifying the vertices of the graph, with respect to any particular bipartition, into two categories:

(i) ***heavy*** vertex, and

(ii) ***balanced*** vertex.

These definitions will be mostly used in the proof of completeness. Informally speaking, a vertex v is said to be **heavy** with respect to a bipartition f, if it has *substantially* large number of neighbors in one side of the bipartition (either L or R), as compared to the other side.

▶ **Definition 4.1** (Heavy vertex). *A vertex $v \in V$ is said to be L-**heavy*** with respect to a bipartition f, *if it satisfies two conditions:*

(i) $\left|N(v) \cap f^{-1}(L)\right| \geq \left|N(v) \cap f^{-1}(R)\right| + \frac{k\varepsilon n}{150}$;

(ii) *If* $\left|N(v) \cap f^{-1}(R)\right| \geq \frac{1}{(1+\frac{k}{200})}\frac{k\varepsilon n}{150}$, *then*

$$\left|N(v) \cap f^{-1}(L)\right| \geq (1 + \tfrac{k}{200})\left|N(v) \cap f^{-1}(R)\right|;$$

*We define R-**heavy** vertices analogously. The union of the set of L-**heavy** and R-**heavy** vertices, with respect to a bipartition f, is defined to be the set of heavy vertices (with respect to f), and is denoted by $\mathcal{H}_f$.*

*Similarly, a vertex v is said to be **balanced** if the number of neighbors of v are* similar *in both L and R, with respect to a bipartition f. We define it formally as follows:*

▶ **Definition 4.2** (Balanced vertex). *A vertex $v \in V$ is said to be* **balanced** with respect to a bipartition f, *if $v \notin \mathcal{H}_f$, that is, it satisfies at least one of the following conditions:*

(i) Type 1: $\left|\left|N(v) \cap f^{-1}(R)\right| - \left|N(v) \cap f^{-1}(L)\right|\right| < \frac{k\varepsilon n}{150}$;

(ii) Type 2: *Either*

$$\left|N(v)\cap f^{-1}(L)\right| \leq \left|N(v)\cap f^{-1}(R)\right| < (1+\frac{k}{200})\left|N(v)\cap f^{-1}(L)\right|,$$

or,

$$\left|N(v)\cap f^{-1}(R)\right| \leq \left|N(v)\cap f^{-1}(L)\right| < (1+\frac{k}{200})\left|N(v)\cap f^{-1}(R)\right|.$$

The set of balanced vertices of type 1 with respect to f is denoted as $\mathcal{B}_f^1$, and the set of balanced vertices of type 2 with respect to f is denoted as $\mathcal{B}_f^2$. The union of $\mathcal{B}_f^1$ and $\mathcal{B}_f^2$ is denoted by $\mathcal{B}_f$. Note that $\mathcal{B}_f^1$ and $\mathcal{B}_f^2$ may not be disjoint.

In order to prove the completeness (in Section 4.1), we also use a notion of SPECIAL *bipartition* to be defined below. The definition of SPECIAL bipartition is based on an optimal bipartition f of $V(G)$, and notions of heavy and balanced vertices. We would also like to note that, later in Lemma 4.6, we show that when $d_{bip}(G) \leq \varepsilon n^2$, the bipartite distance of G with respect to any SPECIAL bipartition is bounded by $(2+\frac{k}{50})\varepsilon n^2$.

▶ **Definition 4.3** (SPECIAL bipartition)**.** *Let $d_{bip}(G) \leq \varepsilon n^2$, and $f : V(G) \to \{L,R\}$ be an optimal bipartition of $V(G)$, that is, $d_{bip}(G,f) \leq \varepsilon n^2$, and there does not exist any bipartition g such that $d_{bip}(G,g) < d_{bip}(G,f)$. For an X_i selected in* **Step-1(i)** *of the algorithm, let $f_{ij} \in \mathcal{F}_i$ be the bipartition of X_i such that $f\mid_{X_i} = f_{ij}$. Then bipartition $\textsc{Spl}_i^f : V(G) \to \{L,R\}$ is said to be a* SPECIAL **bipartition** *with respect to f by f_{ij} such that*

- $\textsc{Spl}_i^f \mid_{X_i} = f\mid_{X_i} = f_{ij}$;
- *There exists a subset $\mathcal{H}'_f \subset \mathcal{H}_f$ such that $\left|\mathcal{H}'_f\right| \geq (1-o(k\varepsilon))\left|\mathcal{H}_f\right|$, and for each $v \in \mathcal{H}'_f$, $\textsc{Spl}_i^f(v)$ is defined as follows:*

$$\textsc{Spl}_i^f(v) = \begin{cases} R, & v \notin X_i \text{ and } v \text{ is } L-\text{heavy} \\ L, & v \notin X_i \text{ and } v \text{ is } R-\text{heavy} \end{cases}$$

- *For each $v \notin (\mathcal{H}'_f \cup X_i)$, $\textsc{Spl}_i^f(v)$ is set to L or R arbitrarily.*

In our proof of the soundness theorem (in Section 4.2), we need the notion of DERIVED *bipartition*. Unlike the definition of SPECIAL bipartition, the definition of DERIVED bipartition is more general, in the sense that it is not defined based on either any optimal bipartition, or on heavy or balanced vertices.

▶ **Definition 4.4** (DERIVED bipartition)**.** *Let $f : V(G) \to \{L,R\}$ be a bipartition of $V(G)$. For an X_i selected in* **Step-1(i)** *of the algorithm, let $f_{ij} \in \mathcal{F}_i$ be the bipartition of X_i such that $f\mid_{X_i} = f_{ij}$. A bipartition $\textsc{Der}_i^f : V(G) \to \{L,R\}$ is said to be* DERIVED *bipartition with respect to f by f_{ij}, if $\textsc{Der}_i^f \mid_{X_i} = f\mid_{X_i} = f_{ij}$.*

4.1 Proof of Completeness

In this section, we prove the following theorem:

▶ **Theorem 4.5.** *Let us assume G is ε-close to being bipartite. Then* TOL-BIP-DIST(G,ε) *reports the same, with probability at least* $9/10$.

The proof of Theorem 4.5 will cricially use the following lemma, which says that the bipartite distance of G with respect to any SPECIAL bipartition is bounded by a $\left(2+\frac{k}{50}\right)\varepsilon n^2$.

▶ **Lemma 4.6** (SPECIAL bipartition lemma). *Let f be a bipartition such that $d_{bip}(G,f) \leq \varepsilon n^2$ and there does not exist any bipartition g such that $d_{bip}(G,g) < d_{bip}(G,f)$. For any* SPECIAL *bipartition* $\textsc{Spl}_i^f$ *with respect to f, we have*

$$d_{bip}(G, \textsc{Spl}_i^f) \leq \left(2 + \frac{k}{50}\right) \varepsilon n^2.$$

We will prove the above lemma later. For now, we want to establish (in Lemma 4.8) that there exists an $i \in [t]$ and a$f_{ij} \in \mathcal{F}_i$ which can be thought of as a *random restriction* of some SPECIAL bipartition with respect to f by f_{ij}. In other words, Lemma 4.8 basically states that if G is ϵ-close to being bipartite, then the extension according to the rule in **Step-2(ii)(b)** of the mapping obtained by restricting an optimal bipartition to a random X_i is likely to correspond to a SPECIAL bipartition, and therefore, the number of monochromatic edges (with respect to a SPECIAL bipartition) in the randomly picked Z is likely to be low with respect to that bipartition. Thus, ζ_{ij} must be low for some i, j with high probability.

To prove Lemma 4.8, we need the following lemma (Lemma 4.7) about heavy vertices. In Lemma 4.7, we basically prove that a heavy vertex with respect to a bipartition f will have significantly more neighbors in the part of X_i, that corresponds to the heavy side of that vertex (with respect to f). Basically, if a vertex v is L-heavy with respect to f, it has more neighbors in the subset of X_i on the L-side as compared to the subset of X_i on the R-side of f.

▶ **Lemma 4.7** (Heavy vertex lemma). *Let f be a bipartition of G. Consider a vertex $v \in V$.*

- **(i)** *For every L-heavy vertex v, $\left|N(v) \cap f^{-1}(L) \cap X_i\right| - \left|N(v) \cap f^{-1}(R) \cap X_i\right| \geq \frac{k^2\varepsilon|X_i|}{225000}$ with probability at least $1 - o(k\varepsilon)$.*
- **(ii)** *For every R-heavy vertex v, $\left|N(v) \cap f^{-1}(L) \cap X_i\right| - \left|N(v) \cap f^{-1}(R) \cap X_i\right| \geq \frac{k^2\varepsilon|X_i|}{225000}$ with probability at least $1 - o(k\varepsilon)$.*

We would like to note that Lemma 4.7 holds for any bipartition. However, we will use it only for completeness with resepct to an optimal bipartition f.

▶ **Lemma 4.8.** *If $d_{bip}(G) \leq \varepsilon n^2$, then there exists an $i \in [t]$ and $f_{ij} \in \mathcal{F}_i$ such that $\zeta_{ij} \leq \left(2 + \frac{k}{20}\right)\varepsilon$ holds, with probability at least $1 - o(k\varepsilon)$.*

Proof. Let f be an optimal bipartition such that $d_{bip}(G,f) \leq \varepsilon n^2$. First, consider a SPECIAL bipartition $\textsc{Spl}_i^f$, and consider a set of random vertex pairs Y such that $|Y| = |Z|$. Now consider the fraction of monochromatic edges of Y, with respect to the bipartition $\textsc{Spl}_i^f$, that is,

$$\chi_{ij}^f = 2 \cdot \frac{\left|\left\{\{a,b\} \in Y : \{a,b\} \in E(G) \text{ and } \textsc{Spl}_i^f(a) = \textsc{Spl}_i^f(b)\right\}\right|}{|Y|}.$$

▶ **Observation 4.9.** *$\chi_{ij}^f \leq \left(2 + \frac{k}{20}\right)\varepsilon$ holds, with probability at least $9/10$.*

Proof. By Lemma 4.6, we know that when $d_{bip}(G) \leq \varepsilon n^2$, $d_{bip}(G, \textsc{Spl}_i^f) \leq \left(2 + \frac{k}{50}\right)\varepsilon n^2$. So, $\mathbb{E}[\chi_{ij}^f] \leq \left(2 + \frac{k}{50}\right)\varepsilon$. Using Chernoff bound (see Lemma B.1), we can say that

$$\mathbb{P}\left(\chi_{ij}^f \geq \left(2 + \frac{k}{20}\right)\varepsilon\right) \leq \frac{1}{2^{\Omega\left(\frac{1}{k^3\varepsilon}\log\frac{1}{k\varepsilon}\right)}} \leq \frac{1}{10}.$$ ◀

Now, we claim that bounding χ_{ij}^f is equivalent to bounding ζ_{ij}.

▷ Claim 4.10. For any $i \in [t]$, there exists a bipartition $f_{ij} \in \mathcal{F}_i$ such that the probability distribution of ζ_{ij} is identical to that of χ^f_{ij}, for some SPECIAL bipartition f with respect to f_{ij}, with probability at least $1/2$.

As $t = \mathcal{O}(\log \frac{1}{k\varepsilon})$, the above claim implies that there exists an $i \in [t]$ and $f_{ij} \in \mathcal{F}_i$ such that the probability distribution of ζ_{ij} is identical to that of χ^f_{ij}, with probability at least $1 - o(k\varepsilon)$.

Now we prove Claim 4.10. Recall the procedure of determining ζ_{ij} as described in **Step 2** of algorithm TOL-BIP-DIST(G, ε) presented in Section 3.

Fact 1: For any vertex $v \in \mathcal{H}_f \cap Z$, $\text{SPL}^f_i(v) = f'_{ij}(v)$, with probability at least $1 - o(k\varepsilon)$, where $\mathcal{H}_f$ denotes the set of heavy vertices of X_i with respect to the bipartition f. This follows according to Claim 4.7, along with the definition of $f'_{ij}(z)$.

Fact 2: Consider a bipartition $f_{ij} \in \mathcal{F}_i$ of X_i, and its extension $f^{'}_{ij}$ to $X_i \cup Z$, as considered in the algorithm. Assume a bipartition $f^{''}_{ij}$ of $V(G)$, constructed by extending f'_{ij} according to the rule of **Step-2(ii)(b)** of the algorithm. From Heavy vertex lemma (Lemma 4.7), we know that the expected number of vertices in $\mathcal{H}_f$ such that $f^{''}_{ij}(v) \neq f(v)$, is at most $o(k\varepsilon)\,|\mathcal{H}_f|$. Using Markov inequality, we can say that, with probability at least $\frac{1}{2}$, the number of vertices in $\mathcal{H}_f$ such that $f^{''}_{ij}(v) \neq f(v)$, is at most $o(k\varepsilon)\,|\mathcal{H}_f|$. Thus, with probability at least $\frac{1}{2}$, there exists a set of vertices $\mathcal{H}'_f$ such that $f^{''}_{ij}(v) = f(v)$ holds for at least $(1 - o(k\varepsilon))\left|\mathcal{H}'_f\right|$ vertices. Note that the bipartition $f^{''}_{ij}$ is a SPECIAL bipartition f with respect to f_{ij}.

From **Fact 1** and **Fact 2**, we can deduce that, there exists a SPECIAL bipartition SPL^f_i such that $\text{SPL}^f_i(v) = f'_{ij}(v)$ for each $z \in Z$.

Since we choose Z uniformly at random, Lemma 4.8 follows. ◀

According to the description of algorithm TOL-BIP-DIST(G, ε), the algorithm reports that $d_{bip}(G) \leq \varepsilon n^2$, if there exists a ζ_{ij} such that $\zeta_{ij} \leq \left(2 + \frac{k}{20}\right)\varepsilon$, for some $i \in [t]$ and $j \in [2^{|X_i|-2}]$. Hence, by Lemma 4.8, we are done with the proof of the completeness theorem (Theorem 4.5).

Now we focus on proving SPECIAL bipartition lemma (Lemma 4.6) and Heavy vertex lemma (Lemma 4.7), starting with the proof of SPECIAL bipartition lemma.

Proof of SPECIAL bipartition lemma (Lemma 4.6)

The idea of the proof relies on decomposing the bipartite distance with respect to a SPECIAL bipartition into a sum of three terms and then carefully bounding the cost of each of those parts individually.

Let us first recall the definition of bipartite distance of G with respect to a special bipartition SPL^f_i.

$$d_{bip}(G, \text{SPL}^f_i) = \left|\left\{(u,v) \in E(G) : \text{SPL}^f_i(u) = \text{SPL}^f_i(v)\right\}\right|. \tag{1}$$

By abuse of notation, here we are denoting $E(G)$ as the set of ordered edges.

We will upper bound $d_{bip}(G, \text{SPL}^f_i)$ as the sum of three terms defined below. Here $\mathcal{H}_f$ and $\mathcal{B}_f$ denote the set of heavy vertices and balanced vertices (with respect to f), as defined in Definition 4.1 and Definition 4.2, respectively. Also, $\mathcal{H}'_f \subseteq \mathcal{H}_f$ denotes the set of vertices of $\mathcal{H}_f$ that are mapped according to f, as defined in the definition of SPECIAL bipartition in Definition 4.3. The three terms that are used to upper bound $d_{bip}(G, \text{SPL}^f_i)$ are as follows:

(a) $D_{\mathcal{H}'_f \cup X_i, \mathcal{H}'_f \cup X_i} = \left|\left\{(u,v) \in E(G) : u \in \mathcal{H}'_f \cup X_i \ \& \ v \in \mathcal{H}'_f \cup X_i, \textsc{Spl}_i^f(u) = \textsc{Spl}_i^f(v)\right\}\right|$;

(b) $D_{\mathcal{H}_f \setminus (\mathcal{H}'_f \cup X_i), V(G)} =$
$\left|\left\{(u,v) \in E(G) : u \in \mathcal{H}_f \setminus (\mathcal{H}'_f \cup X_i), \& \ v \in V(G), \textsc{Spl}_i^f(u) = \textsc{Spl}_i^f(v)\right\}\right|$;

(c) $D_{\mathcal{B}_f \setminus X_i, V(G)} = \left|\left\{(u,v) \in E(G) : u \in \mathcal{B}_f \setminus X_i \text{ and } v \in V(G), \textsc{Spl}_i^f(u) = \textsc{Spl}_i^f(v)\right\}\right|$.

Now from Equation 1 along with the above definitions, we can upper bound $d_{bip}(G, \textsc{Spl}_i^f)$ as follows:

$$d_{bip}(G, \textsc{Spl}_i^f) \leq D_{\mathcal{H}'_f \cup X_i, \mathcal{H}'_f \cup X_i} + D_{\mathcal{H}_f \setminus (\mathcal{H}'_f \cup X_i), V(G)} + D_{\mathcal{B}_f \setminus X_i, V(G)}. \tag{2}$$

We now upper bound $d_{bip}(G, \textsc{Spl}_i^f)$ by bounding each term on the right hand side of the above expression separately, via the two following claims which we will prove later.

▷ Claim 4.11.

(i) $D_{\mathcal{H}'_f \cup X_i, \mathcal{H}'_f \cup X_i} \leq d_{bip}(G, f) - \Pi$, where

$$\Pi := \left[\sum_{v \in \mathcal{B}_f \setminus X_i : f(v) = L} |N(v) \cap f^{-1}(L)| + \sum_{v \in \mathcal{B}_f \setminus X_i : f(v) = R} |N(v) \cap f^{-1}(R)|\right];$$

(ii) $D_{\mathcal{H}_f \setminus (\mathcal{H}'_f \cup X_i), V(G)} \leq o(k\varepsilon)n^2$;

▷ Claim 4.12. $D_{\mathcal{B}_f \setminus X_i, V(G)} \leq 2\left(1 + \frac{k}{400}\right)\Pi + \frac{k\varepsilon n^2}{150}$.

Assuming Claim 4.11 and Claim 4.12 hold, along with Equation 2, $d_{bip}(G, \textsc{Spl}_i^f)$ can be upper bounded as follows:

$$\begin{aligned} d_{bip}(G, \textsc{Spl}_i^f) &\leq d_{bip}(G, f) - \Pi + o(k\varepsilon)n^2 + 2\left(1 + \frac{k}{400}\right)\Pi + \frac{k\varepsilon n^2}{150} \\ &\leq d_{bip}(G, f) + \Pi + \frac{k}{200}\Pi + \frac{k\varepsilon n^2}{100}. \end{aligned}$$

Note that $\Pi \leq d_{bip}(G, f)$ and $d_{bip}(G, f) \leq \varepsilon n^2$. Hence, we can say the following:

$$d_{bip}(G, \textsc{Spl}_i^f) \leq \left(2 + \frac{k}{50}\right)\varepsilon n^2.$$

So, we are done with the proof of the SPECIAL bipartition lemma. We are left with the proofs of Claim 4.11 and Claim 4.12.

Proof of Claim 4.11. (i) We use the following observation in our proof. The observation follows due to the fact that the bipartition f considered is an optimal bipartition.

▶ **Observation 4.13.** *Let v be a L-heavy vertex v with respect to f. Then $f(v) = R$. Similarly, for every R-heavy vertex v with respect to f, $f(v) = L$.*

Following the definition of SPECIAL bipartition, we know that there exists a set of vertices $\mathcal{H}'_f \subset \mathcal{H}_f$ such that $\left|\mathcal{H}'_f\right| \geq (1 - o(k\varepsilon))\left|\mathcal{H}_f\right|$, and for each $v \in \mathcal{H}'_f$, the following holds:

$$\textsc{Spl}_i^f(v) = \begin{cases} R, & v \notin X_i \text{ and } v \text{ is } L - \text{heavy} \\ L, & v \notin X_i \text{ and } v \text{ is } R - \text{heavy} \end{cases}$$

By Observation 4.13, we know that for every $v \in \mathcal{H}'_f$, $\textsc{Spl}_i^f(v) = f(v)$. Moreover, for each $v \in X_i$, $\textsc{Spl}_i^f(v) = f(v)$, following the definition of SPECIAL bipartition $\textsc{Spl}_i^f$. Thus, for every $v \in \mathcal{H}'_f \cup X_i$, we have $\textsc{Spl}_i^f(v) = f(v)$. Hence,

$$\begin{aligned}
&D_{\mathcal{H}'_f \cup X_i, \mathcal{H}'_f \cup X_i} \\
&= \left|\left\{(u,v) \in E(G) : u \in \mathcal{H}'_f \cup X_i \text{ and } v \in \mathcal{H}'_f \cup X_i, \textsc{Spl}_i^f(u) = \textsc{Spl}_i^f(v)\right\}\right| \\
&= \left|\left\{(u,v) \in E(G) : u \in \mathcal{H}'_f \cup X_i, \text{ and } v \in \mathcal{H}'_f \cup X_i, f(u) = f(v)\right\}\right| \\
&\qquad\qquad \left(\because \text{for every } v \in \mathcal{H}'_f \cup X_i,\ \textsc{Spl}_i^f(v) = f(v)\right) \\
&= d_{bip}(G,f) - \\
&\qquad \left[\sum_{v \in V \setminus (\mathcal{H}'_f \cup X_i) : f(v) = L} |N(v) \cap f^{-1}(L)| + \sum_{v \in V \setminus (\mathcal{H}'_f \cup X_i) : f(v) = R} |N(v) \cap f^{-1}(R)|\right] \\
&\leq d_{bip}(G,f) - \left[\sum_{v \in \mathcal{B}_f \setminus X_i : f(v) = L} |N(v) \cap f^{-1}(L)| + \sum_{v \in \mathcal{B}_f \setminus X_i : f(v) = R} |N(v) \cap f^{-1}(R)|\right] \\
&= d_{bip}(G,f) - \Pi.
\end{aligned}$$

(ii) By the definition of $\mathcal{H}'_f$, we know that $\left|\mathcal{H}_f \setminus (\mathcal{H}'_f \cup X_i)\right|$ is upper bounded by $o(k\varepsilon)\,|\mathcal{H}_f|$. Following the definition of $D_{\mathcal{H}_f \setminus (\mathcal{H}'_f \cup X_i), V(G)}$, we can say the following:

$$\begin{aligned}
&D_{\mathcal{H}_f \setminus (\mathcal{H}'_f \cup X_i), V(G)} \\
&= \left|\left\{(u,v) \in E(G) : u \in \mathcal{H}_f \setminus (\mathcal{H}'_f \cup X_i) \text{ and } v \in V(G), \textsc{Spl}_i^f(u) = \textsc{Spl}_i^f(v)\right\}\right| \\
&\leq \left|\mathcal{H}_f \setminus (\mathcal{H}'_f \cup X_i)\right| \times |V(G)| = o(k\varepsilon)\,|\mathcal{H}_f| \times n \leq o(k\varepsilon) n^2.
\end{aligned}$$

The last inequality follows as $|\mathcal{H}_f|$ is at most n. ◁

Proof of Claim 4.12. Observe that

$$\begin{aligned}
&D_{\mathcal{B}_f \setminus X_i, V(G)} \\
&= \left|\left\{(u,v) \in E(G) : u \in \mathcal{B}_f \setminus X_i \text{ and } v \in V(G), \textsc{Spl}_i^f(u) = \textsc{Spl}_i^f(v)\right\}\right| \\
&\leq |\{(u,v) \in E(G) : u \in \mathcal{B}_f \setminus X_i \text{ and } v \in V(G)\}| = \sum_{v \in \mathcal{B}_f \setminus X_i} |N(v)|
\end{aligned}$$

As $\mathcal{B}_f = \mathcal{B}_f^1 \cup \mathcal{B}_f^2$, we have

$$D_{\mathcal{B}_f \setminus X_i, V(G)} \leq \sum_{v \in \mathcal{B}_f^1 \setminus X_i} |N(v)| + \sum_{v \in \mathcal{B}_f^2 \setminus X_i} |N(v)|\,. \tag{3}$$

We will bound $D_{\mathcal{B}_f \setminus X_i, V(G)}$ by bounding $\sum_{v \in \mathcal{B}_f^1 \setminus X_i} |N(v)|$ and $\sum_{v \in \mathcal{B}_f^2 \setminus X_i} |N(v)|$ separately, which we prove in the following claim:

▷ Claim 4.14. Consider T_1 and T_2 defined as follows:

$$T_1 = 2\left(\sum_{v \in f^{-1}(L) \cap (\mathcal{B}_f^1 \setminus X_i)} \left|N(v) \cap f^{-1}(L)\right| + \sum_{v \in f^{-1}(R) \cap (\mathcal{B}_f^1 \setminus X_i)} \left|N(v) \cap f^{-1}(R)\right|\right) + \frac{k\varepsilon n^2}{150},$$

$$T_2 = \left(2 + \frac{k}{200}\right)\left(\sum_{v \in f^{-1}(L) \cap (\mathcal{B}_f^2 \setminus X_i)} \left|N(v) \cap f^{-1}(L)\right| + \sum_{v \in f^{-1}(R) \cap (\mathcal{B}_f^2 \setminus X_i)} \left|N(v) \cap f^{-1}(R)\right|\right).$$

Then

(i) For balanced vertices of **Type 1**, we have

$$\sum_{v \in \mathcal{B}_f^1 \setminus X_i} |N(v)| \leq T_1$$

(ii) For balanced vertices of **Type 2**, we have

$$\sum_{v \in \mathcal{B}_f^2 \setminus X_i} |N(v)| \leq T_2$$

See the full version of the paper [10] for the proof of the above claim. Using Claim 4.14 and Equation (3), we get

$$\begin{aligned} & D_{\mathcal{B}_f \setminus X_i, V(G)} \\ &= \sum_{v \in \mathcal{B}_f^1 \setminus X_i} |N(v)| + \sum_{v \in \mathcal{B}_f^2 \setminus X_i} |N(v)| \\ &\leq T_1 + T_2 \\ &\leq 2\left(1 + \frac{k}{400}\right)\Pi + \frac{k\varepsilon n^2}{150} \end{aligned}$$

The last inequality follows from the definitions of T_1, T_2 and Π. ◁

Proof of Heavy vertex lemma (Lemma 4.7)

Before proceeding to prove the Heavy vertex lemma, we will first prove two intermediate claims that will be crucially used in the proof of the lemma. The first claim states that when we consider a bipartition f of G, if a vertex $v \in G$ has a *large* number of neighbors on one side of the partition defined by f, the proportion of its neighbors in X_i on the same side of f will be approximately preserved, where X_i is a set of vertices picked at random in **Step-1(i)** of the algorithm Tol-Bip-Dist(G, ε). The result is formally stated as follows:

▷ Claim 4.15. Let f be a bipartition of G. Consider a vertex $v \in V$.

(i) Suppose $\left|N(v) \cap f^{-1}(L)\right| \geq \frac{k\varepsilon n}{150}$. Then, with probability at least $1 - o(k\varepsilon)$, we have

$$\left|N(v) \cap f^{-1}(L) \cap X_i\right| = \left(1 \pm \tfrac{k}{500}\right)\left|N(v) \cap f^{-1}(L)\right| \tfrac{|X_i|}{n}.$$

(ii) Suppose $\left|N(v) \cap f^{-1}(R)\right| \geq \frac{k\varepsilon n}{150}$. Then, with probability at least $1 - o(k\varepsilon)$, we have

$$\left|N(v) \cap f^{-1}(R) \cap X_i\right| = \left(1 \pm \tfrac{k}{500}\right)\left|N(v) \cap f^{-1}(R)\right| \tfrac{|X_i|}{n}.$$

The next claim is in similar spirit as that of Claim 4.15. Instead of considering vertices with large number of neighbors, it considers the case when a vertex has *small* number of neighbors on one side of a bipartition f.

▷ Claim 4.16. Let f be a bipartition of G. Consider a vertex $v \in V$.

(i) Suppose $\left|N(v) \cap f^{-1}(L)\right| \leq \frac{1}{1+\frac{k}{200}} \frac{k\varepsilon n}{150}$. Then, with probability at least $1 - o(k\varepsilon)$, we have

$$\left|N(v) \cap f^{-1}(L) \cap X_i\right| \leq \tfrac{1}{1+\frac{k}{300}} \tfrac{k\varepsilon |X_i|}{150}.$$

(ii) Suppose $\left|N(v) \cap f^{-1}(R)\right| \leq \frac{1}{1+\frac{k}{200}} \frac{k\varepsilon n}{150}$. Then, with probability at least $1 - o(k\varepsilon)$, we have

$$\left|N(v) \cap f^{-1}(R) \cap X_i\right| \leq \frac{1}{1+\frac{k}{300}} \frac{k\varepsilon |X_i|}{150}.$$

Claim 4.15 and Claim 4.16 can be proved by using large deviation inequalities (stated in Appendix B), and the proofs can be found in the full version of the paper [10].

Assuming Claim 4.15 and Claim 4.16 hold, we now prove the Heavy vertex lemma (Lemma 4.7).

Proof of Lemma 4.7. We will only prove (i) here, which concerns the L-heavy vertices. (ii) can be proved in similar fashion.

We first characterize L-heavy vertices into two categories:

(a) Both $\left|N(v) \cap f^{-1}(L)\right|$ and $\left|N(v) \cap f^{-1}(R)\right|$ are large, that is, $\left|N(v) \cap f^{-1}(L)\right| \geq \frac{k\varepsilon n}{150}$ and $\left|N(v) \cap f^{-1}(R)\right| \geq \frac{1}{1+\frac{k}{200}} \frac{k\varepsilon n}{150}$. Also, $\left|N(v) \cap f^{-1}(L)\right| \geq \left(1 + \frac{k}{200}\right) \left|N(v) \cap f^{-1}(R)\right|$.

(b) $\left|N(v) \cap f^{-1}(L)\right|$ is large and $\left|N(v) \cap f^{-1}(R)\right|$ is small, that is, $\left|N(v) \cap f^{-1}(L)\right| \geq \frac{k\varepsilon n}{150}$ and $\left|N(v) \cap f^{-1}(R)\right| \leq \frac{1}{1+\frac{k}{200}} \frac{k\varepsilon n}{150}$.

Case (a): Here $\left|N(v) \cap f^{-1}(L)\right| \geq \left(1 + \frac{k}{200}\right) \frac{k\varepsilon n}{150}$, and $\left|N(v) \cap f^{-1}(R)\right| \geq \frac{k\varepsilon n}{150}$. From Claim 4.15, the following hold, with probability at least $1 - o(k\varepsilon)$:

$$\left|N(v) \cap f^{-1}(L) \cap X_i\right| = \left(1 \pm \frac{k}{500}\right) \left|N(v) \cap f^{-1}(L)\right| \frac{|X_i|}{n}$$

and

$$\left|N(v) \cap f^{-1}(R) \cap X_i\right| = \left(1 \pm \frac{k}{500}\right) \left|N(v) \cap f^{-1}(R)\right| \frac{|X_i|}{n}.$$

So, with probability at least $1 - o(k\varepsilon)$, we have the following

$$\begin{aligned}
&\left|N(v) \cap f^{-1}(L) \cap X_i\right| - \left|N(v) \cap f^{-1}(R) \cap X_i\right| \\
&\geq \left(1 - \frac{k}{500}\right) \left|N(v) \cap f^{-1}(L)\right| \frac{|X_i|}{n} - \left(1 + \frac{k}{500}\right) \left|N(v) \cap f^{-1}(R)\right| \frac{|X_i|}{n} \\
&\geq \left(1 - \frac{k}{500} - \frac{1 + \frac{k}{500}}{1 + \frac{k}{200}}\right) \frac{\left|N(v) \cap f^{-1}(L)\right| |X_i|}{n} \\
&\qquad\qquad \left(\because \left|N(v) \cap f^{-1}(L)\right| \geq (1 + \frac{k}{200}) \left|N(v) \cap f^{-1}(R)\right|\right) \\
&\geq \frac{k}{1500} \times \frac{k\varepsilon\, |X_i|}{150} \\
&\geq \frac{k^2 \varepsilon\, |X_i|}{225000} \qquad\qquad (\because\ k \leq 100)
\end{aligned}$$

Case (b): Here $\left|N(v) \cap f^{-1}(L)\right| \geq \frac{k\varepsilon n}{150}$ and $\left|N(v) \cap f^{-1}(R)\right| \leq \left(\frac{1}{1+\frac{k}{200}}\right) \frac{k\varepsilon n}{150}$. So, from Claim 4.15 and Claim 4.16, the following hold, with probability at least $1 - o(k\varepsilon)$:

$$\left|N(v) \cap f^{-1}(L) \cap X_i\right| = \left(1 \pm \frac{k}{500}\right) \left|N(v) \cap f^{-1}(L)\right| \frac{|X_i|}{n}$$

and

$$\left|N(v) \cap f^{-1}(R) \cap X_i\right| \leq \frac{1}{1 + \frac{k}{300}} \frac{k\varepsilon\, |X_i|}{150}.$$

Thus, with probability at least $1 - o(k\varepsilon)$, we have the following:

$$\begin{aligned}
&\left|N(v) \cap f^{-1}(L) \cap X_i\right| - \left|N(v) \cap f^{-1}(R) \cap X_i\right| \\
&\geq (1 - \frac{k}{500}) \left|N(v) \cap f^{-1}(L)\right| \frac{|X_i|}{n} - \frac{1}{1 + \frac{k}{300}} \frac{k\varepsilon |X_i|}{150} \\
&= (1 - \frac{k}{500}) \frac{k\varepsilon |X_i|}{150} - \frac{1}{1 + \frac{k}{300}} \frac{k\varepsilon |X_i|}{150} \\
&\geq \frac{1}{1500} \left(2k - \frac{k^2}{100}\right) \frac{k\varepsilon |X_i|}{150} \\
&\geq \frac{k^2 \varepsilon |X_i|}{225000} \qquad (\because\ k \leq 100)
\end{aligned}$$

This completes the proof of part (i) of Lemma 4.7. ◀

4.2 Proof of Soundness

In this section, we prove the following theorem:

▶ **Theorem 4.17.** *Let us assume that G is $(2+k)\varepsilon$-far from being bipartite. Then* Tol-Bip-Dist(G, ε) *reports the same, with probability at least* $9/10$.

Assume f be a bipartition of $V(G)$. Now let us consider a DERIVED bipartition Der_i^f with respect to f by f_{ij}, and choose a set of random vertex pairs Y such that $|Y| = |Z|$. Let χ_{ij}^f denote the fraction of vertex pairs of Y that are monochromatic with respect to the bipartition Der_i^f, that is,

$$\chi_{ij}^f = 2 \cdot \frac{\left|\left\{\{a,b\} \in Y : \{a,b\} \in E(G) \text{ and } \text{Der}_i^f(a) = \text{Der}_i^f(b)\right\}\right|}{|Y|}.$$

▶ **Observation 4.18.** *$\chi_{ij}^f \leq \left(2 + \frac{k}{20}\right)\varepsilon$ holds with probability at most $\frac{1}{10N}$, where $N = 2^{\mathcal{O}(\frac{1}{k^3\varepsilon} \log \frac{1}{k\varepsilon})}$.*

Proof. Since G is $(2+k)\varepsilon$-far from being bipartite, the same holds for the bipartition Der_i^f as well, that is, $d_{bip}(G, \text{Der}_i^f) \geq (2+k)\varepsilon n^2$. So, $\mathbb{E}[\chi_{ij}^f] \geq (2+k)\,\varepsilon$. Using Chernoff bound (see Lemma B.1), we can say that, $\mathbb{P}\left(\chi_{ij}^f \leq \left(2 + \frac{k}{20}\right)\varepsilon\right) \leq \frac{1}{10N}$. Since $|Z| = \mathcal{O}\left(\frac{1}{k^5\varepsilon^2} \log \frac{1}{k\varepsilon}\right)$, the result follows. ◀

We will be done with the proof by proving the following claim, that says that bounding χ_{ij}^f is equivalent to bounding ζ_{ij}.

▷ Claim 4.19. For any $i \in [t]$, and any $f_{ij} \in \mathcal{F}_i$, the probability distribution of ζ_{ij} is identical to that of χ_{ij}^f for some DERIVED bipartition with respect to f by f_{ij}.

Proof. Consider a bipartition $f_{ij} \in \mathcal{F}_i$ of X_i, and the bipartition f_{ij}' of $X_i \cup Z$, constructed by extending f_{ij}, as described in the algorithm. For the sake of the argument, let us construct a new bipartition f_{ij}'' of $V(G)$ by extending the bipartition f_{ij}', following the same rule of **Step-2 (ii) (b)** of the algorithm. Observe that $f_{ij}''(v) = f_{ij}(v)$, for each $v \in X_i$. Thus f_{ij}'' is a DERIVED bipartition with respect to some f by f_{ij}. Hence, the claim follows according to the way we generate ζ_{ij}, along with the fact that Z is chosen uniformly at random by the algorithm in **Step-1 (ii)**. ◁

Let us now define a pair (X_i, f_{ij}), with $i \in [t]$ and $f_{ij} \in \mathcal{F}_i$ as a **configuration**. Now we make the following observation which follows directly from the description of the algorithm.

▶ **Observation 4.20.** *Total number of possible configurations is* $N = 2^{\mathcal{O}(\frac{1}{k^3\varepsilon}\log\frac{1}{k\varepsilon})}$.

Note that Claim 4.19 holds for a particular $f_{ij} \in \mathcal{F}_i$. Recall that in **Step-2(iii)**, our algorithm Tol-Bip-Dist(G, ε) reports that G is $(2+k)\varepsilon$-far if $\zeta_{ij} > \left(2 + \frac{k}{20}\right)\varepsilon$, for all $i \in [t]$ and $f_{ij} \in \mathcal{F}_i$. So, using the union bound, along with Observation 4.18, Claim 4.19 and Observation 4.20, we are done with the proof of Theorem 4.17.

5 Conclusion

We believe that our result will certainly improve the current understanding of (tolerant) bipartite testing in the dense graph model. However, one may wonder whether the analysis can be improved to show that the algorithm (presented in Section 3) can decide whether $d_{bip}(G) \leq \varepsilon n^2$ or $d_{bip}(G) \geq c\varepsilon n^2$ for any $c > 1$. There is a bottleneck in our technique as we are bounding error due to the balanced vertices by the sum of degrees of the balanced vertices (as done in Claim 4.12). Because of this reason, it is not obvious if our algorithm (and its analysis) can be used to get a result, like Theorem 2.1, for all $c > 1$ with the same query complexity.

On a different note, we can decide $d_{bip}(G) \leq \varepsilon n^2$ or $d_{bip}(G) \geq (1+k)\varepsilon n^2$ by using $\widetilde{\mathcal{O}}\left((1/k\varepsilon)^6\right)$ queries, which can be derived from the work of Alon, Vega, Kannan and Karpinski [1] (see Corollary A.3 in Appendix A). Hence, any algorithm that solves the general bipartite distance problem with query complexity $o\left((1/k\varepsilon)^6\right)$, will be of huge interest.

A Bipartite distance estimation with query complexity $\widetilde{\mathcal{O}}(1/\varepsilon^6)$

Formally, we state the following theorem.

▶ **Theorem A.1.** *Given an unknown graph G on n vertices and any approximation parameter $\varepsilon \in (0,1)$, there is an algorithm that performs $\widetilde{\mathcal{O}}(1/\varepsilon^6)$ adjacency queries, and outputs a number $\widehat{d}_{bip}(G)$ such that, with probability at least $9/10$, the following holds:*

$$d_{bip}(G) - \varepsilon n^2 \leq \widehat{d}_{bip}(G) \leq d_{bip}(G) + \varepsilon n^2,$$

where $d_{bip}(G)$ denotes the bipartite distance of G.

We have the following two corollaries of the above theorem.

▶ **Corollary A.2.** *There exists an algorithm that given adjacency query access to a graph G with n vertices and a parameter $\varepsilon \in (0,1)$ such that, with probability at least $9/10$, decides whether $d_{bip}(G) \leq \varepsilon n^2$ or $d_{bip}(G) \geq (2+\Omega(1))\varepsilon n^2$ using $\widetilde{\mathcal{O}}\left(1/\varepsilon^6\right)$ many queries to the adjacency matrix of G.*

▶ **Corollary A.3.** *There exists an algorithm that given adjacency query access to a graph G with n vertices and a parameter $\varepsilon \in (0,1)$ such that, with probability at least $9/10$, decides whether $d_{bip}(G) \leq \varepsilon n^2$ or $d_{bip}(G) \geq (1+k)\varepsilon n^2$ using $\widetilde{\mathcal{O}}\left((1/k\varepsilon)^6\right)$ many queries to the adjacency matrix of G.*

To prove Theorem A.1, we first discuss the connection between MaxCut and bipartite distance of a graph G. Then we use the result for MaxCut estimation by Alon, Vega, Kannan and Karpinski [1].

Connection between MaxCut and $d_{bip}(G)$

For a graph $G = (V, E)$ on the *vertex* set V and *edge* set E, let S be a subset of V. We define

$$\textsc{Cut}(S) := |\ \{\{u,v\} \in E \ \mid\ |\{u,v\} \cap S| = 1\}\ |$$

Maximum Cut (henceforth termed as MaxCut), denoted by $M(G)$, is a partition of the vertex set V of G into two parts such that the number of edges crossing the partition is maximized, that is,

$$M(G) := \max_{S \subseteq V} \textsc{Cut}(S).$$

The following equation connects MaxCut and the bipartite distance of a graph G:

$$d_{bip}(G) = |E(G)| - M(G). \tag{4}$$

So, $d_{bip}(G)$ can be estimated by estimating $|E(G)|$ and $M(G)$.

Result on edge estimation

Observe that estimating $|E(G)|$ with εn^2 additive error is equivalent to *parameter estimation problem* in probability theory, see Mitzenmacher and Upfal [17, Section 4.2.3].

▶ **Proposition A.4** (Folklore). *Given any graph G on n vertices and an input parameter $\varepsilon \in (0,1)$, the size of the edge set $E(G)$ can be estimated within an additive εn^2 error, with probability at least $9/10$, using $\mathcal{O}(1/\varepsilon^2)$ many adjacency queries to G.*

MaxCut estimation by using $\widetilde{\mathcal{O}}(1/\varepsilon^6)$ queries

Let $G = (V, E)$ be an n vertex graph. Both Alon, Vega, Kannan and Karpinski [1] and Mathieu and Schudy [16] showed that if S is a t-sized random subset of V, where $t = O\left(\frac{1}{\varepsilon^4} \log \frac{1}{\varepsilon}\right)$, then, with probability at least $\frac{9}{10}$, we have the following:

$$\left| \frac{M(G\,|_S)}{t^2} - \frac{M(G)}{n^2} \right| \leq \frac{\varepsilon}{2}$$

where $G\,|_S$ denotes the induced graph of G on the vertex set S. So, the above inequality tells us that if we can get an $\varepsilon t^2/2$ additive error to $M(G\,|_S)$, then we can get an εn^2 additive estimate for $M(G)$. Observation A.5 implies that using $O\left(t/\varepsilon^2\right) = O\left(\frac{1}{\varepsilon^6} \log \frac{1}{\varepsilon}\right)$ many adjacency queries to $G\,|_S$, we can get an $\varepsilon t^2/2$ additive estimate to $M(G\,|_S)$. Therefore, the query complexity of MaxCut algorithms of Alon, Vega, Kannan and Karpinski [1] and Mathieu and Schudy [16] is at most $O\left(\frac{1}{\varepsilon^6} \log \frac{1}{\varepsilon}\right)$.

Now we state and prove the following observation.

▶ **Observation A.5** (Folklore). *For a graph G with n vertices and an approximation parameter $\varepsilon \in (0,1)$, $\Theta\left(n/\varepsilon^2\right)$ many adjacency queries to G are sufficient to get an εn^2 additive approximation to* MaxCut *$M(G)$, with probability at least $9/10$.*

Proof. We sample t many pairs of vertices $\{a_1, b_1\}, \ldots, \{a_t, b_t\}$ uniformly at random and independent of each other, where $t = \Theta(n/\varepsilon^2)$. Thereafter, we perform t many adjacency queries to those sampled pairs of vertices. Now fix a subset $S \subset V(G)$ and let us denote $(S, \overline{S})$ to be the set of edges between S and $\overline{S}$.

Let us now define a set of random variables, one for each sampled pair of vertices as follows:

$$X_i = \begin{cases} 1, & \text{if } \{a_i, b_i\} \in (S, \overline{S}) \\ 0, & \text{Otherwise} \end{cases}$$

We will output $\max_{S \subset V(G)} \widehat{M_S}$ as our estimate of $M(G)$, where $\widehat{M_S} = \frac{\binom{n}{2}}{t} \sum_{i=1}^{t} X_i$.

Let us denote $X = \sum_{i=1}^{t} X_i$. Note that

$$\mathbb{E}[X_i] = \mathbb{P}(X_i = 1) = \frac{\left|(S, \overline{S})\right|}{\binom{n}{2}},$$

and hence

$$\mathbb{E}\left[\widehat{M}_S\right] = \frac{\binom{n}{2}}{t}\mathbb{E}\left[\sum_{i=1}^{t} X_i\right] = \left|(S, \overline{S})\right|.$$

Using Hoeffding's Inequality (see Lemma B.2), we can say that

$$\mathbb{P}\left(\left|\left|(S, \overline{S})\right| - \widehat{M}_S\right| \geq \frac{\varepsilon n^2}{10}\right) \leq \mathbb{P}\left(|X - \mathbb{E}[X]| \geq \frac{\varepsilon t}{10}\right) \leq 2e^{-\Theta(\varepsilon^2 t^2/t)} \leq 2e^{-\Theta(n)}.$$

Using union bound over all $S \subset V(G)$, we can show that with probability at least $3/4$, for each $S \subset V(G)$, $\widehat{M}_S$ approximates $\left|(S, \overline{S})\right|$ with εn^2 additive error. Therefore $\max_{S \subset V(G)} \widehat{M}_S$ estimates $M(G)$ with additive error εn^2, with probability at least $3/4$. ◀

B Large Deviation Inequalities

▶ **Lemma B.1** (Chernoff-Hoeffding bound, see [8]). *Let $X_1, \ldots, X_n$ be independent random variables such that $X_i \in [0, 1]$. For $X = \sum_{i=1}^{n} X_i$ and $\mu_l \leq \mathbb{E}[X] \leq \mu_h$, the followings hold for any $0 < \varepsilon < 1$:*

(i) $\mathbb{P}(X \geq (1+\varepsilon)\mu_h) \leq \exp\left(\frac{-\varepsilon^2 \mu_h}{3}\right)$.

(ii) $\mathbb{P}(X \leq (1-\varepsilon)\mu_l) \leq \exp\left(\frac{-\varepsilon^2 \mu_l}{3}\right)$.

▶ **Lemma B.2** (Hoeffding's Inequality, see [8]). *Let $X_1, \ldots, X_n$ be independent random variables such that $a_i \leq X_i \leq b_i$ and $X = \sum_{i=1}^{n} X_i$. Then, for all $\delta > 0$,*

$$\mathbb{P}(|X - \mathbb{E}[X]| \geq \delta) \leq 2\exp\left(\frac{-2\delta^2}{\sum_{i=1}^{n}(b_i - a_i)^2}\right).$$

Homomorphism Tensors and Linear Equations

Abstract

Lovász (1967) showed that two graphs G and H are isomorphic if and only if they are *homomorphism indistinguishable* over the class of all graphs, i.e. for every graph F, the number of homomorphisms from F to G equals the number of homomorphisms from F to H. Recently, homomorphism indistinguishability over restricted classes of graphs such as bounded treewidth, bounded treedepth and planar graphs, has emerged as a surprisingly powerful framework for capturing diverse equivalence relations on graphs arising from logical equivalence and algebraic equation systems.

In this paper, we provide a unified algebraic framework for such results by examining the linear-algebraic and representation-theoretic structure of tensors counting homomorphisms from labelled graphs. The existence of certain linear transformations between such homomorphism tensor subspaces can be interpreted both as homomorphism indistinguishability over a graph class and as feasibility of an equational system. Following this framework, we obtain characterisations of homomorphism indistinguishability over several natural graph classes, namely trees of bounded degree, graphs of bounded pathwidth (answering a question of Dell et al. (2018)), and graphs of bounded treedepth.

Acknowledgements We thank Andrei Bulatov for many fruitful discussions on the foundations of theory developed here and its relation to the algebraic theory of valued constraint satisfaction problems. Moreover, we thank Jan Böker for discussions about linear systems of equations and basal graphs. Finally, we thank the anonymous reviewers for suggestions for improvement.

1 Introduction

Representations in terms of homomorphism counts provide a surprisingly rich view on graphs and their properties. Homomorphism counts have direct connections to logic [14, 17, 27], category theory [12, 34], the graph isomorphism problem [13, 14, 27], algebraic characterisations of graphs [13], and quantum groups [32]. Counting subgraph patterns in graphs has a wide range of applications, for example in graph kernels (see [24]) and motif counting (see [1, 33]). Homomorphism counts can be used as a flexible basis for counting all kinds of substructures [11], and their complexity has been studied in great detail (e.g. [8, 9, 11, 39]). It has been argued in [18] that homomorphism counts are well-suited as

a theoretical foundation for analysing graph embeddings and machine learning techniques on graphs, both indirectly through their connection with graph neural networks via the Weisfeiler–Leman algorithm [14, 35, 46] and directly as features for machine learning on graphs. The latter has also been confirmed experimentally [4, 25, 37].

The starting point of the theory is an old result due to Lovász [27]: two graphs G, H are isomorphic if and only if for every graph F, the number $\hom(F, G)$ of homomorphisms from F to G equals $\hom(F, H)$. For a class $\mathcal{F}$ of graphs, we say that G and H are *homomorphism indistinguishable* over $\mathcal{F}$ if and only if $\hom(F, G) = \hom(F, H)$ for all $F \in \mathcal{F}$. A beautiful picture that has only emerged in the last few years shows that homomorphism indistinguishability over natural graph classes, such as paths, trees, or planar graphs, characterises a variety of natural equivalence relations on graphs.

Broadly speaking, there are two types of such results, the first relating homomorphism indistinguishability to logical equivalence, and the second giving algebraic characterisations of homomorphism equivalence derived from systems of linear (in)equalities for graph isomorphism. Examples of logical characterisations of homomorphism equivalence are the characterisation of homomorphism indistinguishability over graphs of treewidth at most k in terms of the $(k + 1)$-variable fragment of first-order logic with counting [14] and the characterisation of homomorphism indistinguishability over graphs of treedepth at most k in terms of the quantifier-rank-k fragment of first-order logic with counting [17]. Results of this type have also been described in a general category theoretic framework [12, 34]. Examples of equational characterisations are the characterisation of homomorphism indistinguishability over trees in terms of fractional isomorphism [13, 14, 44], which may be viewed as the LP relaxation of a natural ILP for graph isomorphism, and a generalisation to homomorphism indistinguishability over graph of bounded treewidth in terms of the Sherali–Adams hierarchy over that ILP [3, 13, 21, 14, 31]. Further examples include a characterisation of homomorphism indistinguishability over paths in terms of the same system of equalities by dropping the non-negativity constraints of fractional isomorphism [13], and a characterisation of homomorphism indistinguishability over planar graphs in terms of quantum isomorphism [32]. Remarkably, quantum isomorphism is derived from interpreting the same system of linear equations over C*-algebras [2].

1.1 Results

Two questions that remained open in [13] are (1) whether the equational characterisation of homomorphism indistinguishability over paths can be generalised to graphs of bounded pathwidth in a similar way as the characterisation of homomorphism indistinguishability over trees can be generalised to graphs of bounded treewidth, and (2) whether homomorphism indistinguishability over graphs of bounded degree suffices to characterise graphs up to isomorphism. In this paper, we answer the first question affirmatively.

▶ **Theorem 1.** *For every $k \geq 1$, the following are equivalent for two graphs G and H:*

1. *G and H are homomorphism indistinguishable over graphs of pathwidth at most k.*
2. *The $(k+1)$-st level relaxation $\mathsf{L}^{k+1}_{\mathrm{iso}}(G, H)$ of the standard ILP for graph isomorphism has a rational solution.*

The detailed description of the system $\mathsf{L}^{k+1}_{\mathrm{iso}}(G, H)$ is provided in Section 5. In fact, we also devise an alternative system of linear equations $\mathsf{PW}^{k+1}(G, H)$ characterising homomorphism indistinguishability over graphs of pathwidth at most k. The definition of this system turns out to be very natural from the perspective of homomorphism counting, and as we explain later, it forms a fruitful instantiation of a more general representation-theoretic framework for homomorphism indistinguishability.

Moreover, we obtain an equational characterisation of homomorphism indistinguishability over graphs of bounded treedepth. The resulting system $\mathsf{TD}^k(G,H)$ is very similar to $\mathsf{L}^k_{\mathrm{iso}}(G,H)$ and $\mathsf{PW}^k(G,H)$, except that variables are indexed by (ordered) k-tuples of variables rather than sets of at most k variables, which reflects the order induced by the recursive definition of treedepth.

▶ **Theorem 2.** *For every $k \geq 1$, the following are equivalent for two graphs G and H:*

1. *G and H are homomorphism indistinguishable over graphs of treedepth at most k,*
2. *The linear systems of equations $\mathsf{TD}^k(G,H)$ has a non-negative rational solution,*
3. *The linear systems of equations $\mathsf{TD}^k(G,H)$ has a rational solution.*

Along with [17], the above theorem implies that the logical equivalence of two graphs G and H over the quantifier-rank-k fragment of first-order logic with counting can be characterised by the feasibility of the system $\mathsf{TD}^k(G,H)$ of linear equations.

We cannot answer the second open question from [13], but we prove a partial negative result: homomorphism indistinguishability over trees of bounded degree is strictly weaker than homomorphism indistinguishability over all trees.

▶ **Theorem 3.** *For every integer $d \geq 1$, there exist graphs G and H such that G and H are homomorphism indistinguishable over trees of degree at most d, but G and H are not homomorphism indistinguishable over the class of all trees.*

In conjunction with [13], the above theorem yields the following corollary: counting homomorphisms from trees of bounded degree is strictly less powerful than the classical Colour Refinement algorithm [20], in terms of their ability to distinguish non-isomorphic graphs.

To prove these results, we develop a general theory that enables us to derive some of the existing results as well as the new results in a unified algebraic framework exploiting a duality between algebraic varieties of "tensor maps" derived from homomorphism counts over families of rooted graphs and equationally defined equivalence relations, which are based on transformations of graphs in terms of unitary or, more often, pseudo-stochastic or doubly-stochastic matrices. (We call a matrix over the complex numbers *pseudo-stochastic* if its row and column sums are all 1, and we call it *doubly-stochastic* if it is pseudo-stochastic and all its entries are non-negative reals.) The foundations of this theory have been laid in [13] and, mainly, [32]. Some ideas can also be traced back to the work on homomorphism functions and connection matrices [15, 28, 29, 40], and a similar duality, called Galois connection there, that is underlying the algebraic theory of constraint satisfaction problems [6, 7, 42, 47].

1.2 Techniques

To explain our core new ideas, let us start from a simple and well-known result: two symmetric real matrices A, B are co-spectral if and only if for every $k \geq 1$ the matrices A^k and B^k have the same trace. If A, B are the adjacency matrices of two graph G, H, the latter can be phrased graph theoretically as: for every k, G and H have the same number of closed walks of length k, or equivalently, the numbers of homomorphisms from a cycle C_k of length k to G and to H are the same. Thus, G and H are homomorphism indistinguishable over the class of all cycles if and only if they are co-spectral. Note next that the graphs, or their adjacency matrices A, B, are co-spectral if and only if there is a unitary matrix U (or orthogonal matrix, but we need to work over the complex numbers) such that $UA = BU$. Now, in [14, 13] it was proved that G, H are homomorphism indistinguishable over the class of all paths if and only if there is a pseudo-stochastic matrix X such that $XA = BX$, and they are homomorphism indistinguishable over the class of all trees if and only if there is

a doubly-stochastic matrix X such that $XA = BX$. From an algebraic perspective, the transition from a unitary matrix in the cycle result to a pseudo-stochastic in the path result is puzzling: where unitary matrices are very natural, pseudo-stochastic matrices are much less so from an algebraic point of view. Moving on to the tree result, we suddenly add non-negativity constraints – where do they come from? Our theory presented in Section 3 provides a uniform and very transparent explanation for the three results. It also allows us to analyse homomorphism indistinguishability over d-ary trees, for every $d \geq 1$, and to prove that it yields a strict hierarchy of increasingly finer equivalence relations.

Now suppose we want to extend these results to edge coloured graphs. Each edge-coloured graph corresponds to a family of matrices, one for each colour. Theorems due to Specht [41] and Wiegmann [45] characterise families of matrices that are simultaneously equivalent with respect to a unitary transformation. Interpreted over coloured graphs, the criterion provided by these theorems can be interpreted as homomorphism indistinguishability over coloured cycles. One of our main technical contributions is a variant of these theorems that establishes a correspondence between simultaneous equivalence with respect to pseudo-stochastic transformations and homomorphism indistinguishability over coloured paths. The proof is based on basic representation theory, in particular the character theory of semisimple algebras.

Interpreting graphs of bounded pathwidth in a "graph-grammar style" over coloured paths using graphs of bounded size as building blocks, we give an equational characterisation of homomorphism indistinguishability over graphs of pathwidth at most k. After further manipulations, we even obtain a characterisation in terms of a system of equations that are derived by lifting the basic equations for paths in a Sherali–Adams style. (The basic idea of these lifted equations goes back to [3].) This answers the open question from [13] stated above. In the same way, we can lift the characterisations of homomorphism indistinguishability over trees to graphs of treewidth k, and we can also establish a characterisation of homomorphism indistinguishability over graphs of "cyclewidth" k, providing a uniform explanation for all these results. Finally, we combine these techniques to prove a characterisation of homomorphism indistinguishability over graphs of treedepth k in terms of a novel system of linear equations.

2 Preliminaries

We briefly state the necessary definitions and, along the way, introduce our notation. We assume familiarity with elementary definitions from graph theory and linear algebra. As usual, let $\mathbb{N} = \{1, 2, 3, \dots\}$, $[n] = \{1, \dots, n\}$, and $(n) = (1, \dots, n)$. All mentioned graphs are simple, loopless, and undirected.

2.1 Labelled Graphs and Tensor Maps

Labelled and Bilabelled Graphs. For $\ell \in \mathbb{N}$, an *ℓ-labelled* graph $\boldsymbol{F}$ is a tuple $\boldsymbol{F} = (F, \boldsymbol{v})$ where F is a graph and $\boldsymbol{v} \in V(F)^\ell$. The vertices in $\boldsymbol{v}$ are not necessarily distinct, i.e. vertices may have several labels.

The operation of *gluing* two ℓ-labelled graphs $\boldsymbol{F} = (F, \boldsymbol{u})$ and $\boldsymbol{F}' = (F', \boldsymbol{u}')$ yields the ℓ-labelled graph $\boldsymbol{F} \odot \boldsymbol{F}'$ obtained by taking the disjoint union of F and F' and pairwise identifying the vertices $\boldsymbol{u}_i$ and $\boldsymbol{v}_i$ to become the i-th labelled vertex, for $i \in [\ell]$, and removing any multiedges in the process. In fact, since we consider homomorphisms into simple graphs, multiedges can always be omitted. Likewise, self-loops can also be disregarded since the number of homomorphisms $F \to G$ where F has a self-loop and G does not is always zero. We henceforth tacitly assume that all graphs are simple.

For $\ell_1, \ell_2 \in \mathbb{N}$, an (ℓ_1, ℓ_2)-*bilabelled graph* $\boldsymbol{F}$ is a tuple $(F, \boldsymbol{u}, \boldsymbol{v})$ for $\boldsymbol{u} \in V(F)^{\ell_1}$, $\boldsymbol{v} \in V(F)^{\ell_2}$. If $\boldsymbol{u} = (u_1, \ldots, u_{\ell_1})$ and $\boldsymbol{v} = (v_1, \ldots, v_{\ell_2})$, it is usual to say that the vertex u_i, resp. v_i, is labelled with the i-th *in-label*, resp. *out-label*.

The *reverse* of an (ℓ_1, ℓ_2)-bilabelled graph $\boldsymbol{F} = (F, \boldsymbol{u}, \boldsymbol{v})$ is defined to be the (ℓ_2, ℓ_1)-bilabelled graph $\boldsymbol{F}^* = (F, \boldsymbol{v}, \boldsymbol{u})$ with roles of in- and out-labels interchanged. The *concatenation* or *series composition* of an (ℓ_1, ℓ_2)-bilabelled graph $\boldsymbol{F} = (F, \boldsymbol{u}, \boldsymbol{v})$ and an (ℓ_2, ℓ_3)-bilabelled graph $\boldsymbol{F}' = (F', \boldsymbol{u}', \boldsymbol{v}')$, $\ell_3 \in \mathbb{N}$, denoted by $\boldsymbol{F} \cdot \boldsymbol{F}'$ is the (ℓ_1, ℓ_3)-bilabelled graph obtained by taking the disjoint union of F and F' and identifying for all $i \in [\ell_2]$ the vertices $\boldsymbol{v}_i$ and $\boldsymbol{u}'_i$. The in-labels of $\boldsymbol{F} \cdot \boldsymbol{F}'$ lie on $\boldsymbol{u}$ while its out-labels are positioned on $\boldsymbol{v}'$. The *parallel composition* of (ℓ_1, ℓ_2)-bilabelled graphs $\boldsymbol{F} = (F, \boldsymbol{u}, \boldsymbol{v})$ and $\boldsymbol{F}' = (F', \boldsymbol{u}', \boldsymbol{v}')$ denoted by $\boldsymbol{F} \odot \boldsymbol{F}'$ is obtained by taking the disjoint union of F and F' and identifying $\boldsymbol{u}_i$ with $\boldsymbol{u}'_i$, and $\boldsymbol{v}_j$ with with $\boldsymbol{v}'_j$ for $i \in [\ell_1]$ and $j \in [\ell_2]$.

Tensors and Tensor Maps. For a set V and $k \in \mathbb{N}$, the set of all functions $X \colon V^k \to \mathbb{C}$ forms a complex vector space denoted by $\mathbb{C}^{V^k}$. We call the elements of $\mathbb{C}^{V^k}$ the k-*dimensional tensors* over V. We identify 0-dimensional tensors with scalars, i.e. $\mathbb{C}^{V^0} = \mathbb{C}$. Furthermore, 1-dimensional tensors are vectors in $\mathbb{C}^V$, 2-dimensional tensors are matrices in $\mathbb{C}^{V \times V}$, et cetera.

A k-*dimensional tensor map on graphs* is a function φ that maps graphs G to k-dimensional tensors $\varphi_G \in \mathbb{C}^{V(G)^k}$. A k-dimensional tensor map φ is *equivariant* if for all isomorphic graphs G and H, all isomorphisms f from G to H, and all $\boldsymbol{v} \in V(G)^k$ it holds that $\varphi_G(\boldsymbol{v}) = \varphi_H(f(\boldsymbol{v}))$.

Homomorphism Tensors and Homomorphism Tensor Maps. For graphs F and G, let $\hom(F, G)$ denote the number of homomorphisms from F to G, i.e. the number of mappings $h \colon V(F) \to V(G)$ such that $v_1 v_2 \in E(F)$ implies $h(v_1)h(v_2) \in E(G)$. For an ℓ-labelled graph $\boldsymbol{F} = (F, \boldsymbol{v})$ and $\boldsymbol{w} \in V(G)^\ell$, let $\hom(\boldsymbol{F}, G, \boldsymbol{w})$ denote the number of homomorphisms h from F to G such that $h(\boldsymbol{v}_i) = \boldsymbol{w}_i$ for all $i \in [\ell]$. Analogously, for an (ℓ_1, ℓ_2)-bilabelled graph $\boldsymbol{F}' = (F', \boldsymbol{u}, \boldsymbol{v})$ and $\boldsymbol{x} \in V(G)^{\ell_1}$, $\boldsymbol{y} \in V(G)^{\ell_2}$, let $\hom(F', G, \boldsymbol{x}, \boldsymbol{y})$ denote the number of homomorphisms $h \colon F' \to G$ such that $h(\boldsymbol{u}_i) = \boldsymbol{x}_i$ and $h(\boldsymbol{v}_j) = \boldsymbol{y}_j$ for all $i \in [\ell_1]$, $j \in [\ell_2]$. More succinctly, we write $\boldsymbol{F}_G \in \mathbb{C}^{V(G)^\ell}$ for the *homomorphism tensor* defined by letting $\boldsymbol{F}_G(\boldsymbol{w}) \coloneqq \hom(\boldsymbol{F}, G, \boldsymbol{w})$ for all $\boldsymbol{w} \in V(G)^\ell$. Similarly, for a bilabelled graph $\boldsymbol{F}'$, $\boldsymbol{F}'_G \in \mathbb{C}^{V(G)^{\ell_1} \times V(G)^{\ell_2}}$ is the matrix defined as $\boldsymbol{F}'_G(\boldsymbol{x}, \boldsymbol{y}) \coloneqq \hom(\boldsymbol{F}, G, \boldsymbol{x}, \boldsymbol{y})$ for all $\boldsymbol{x} \in V(G)^{\ell_1}$, $\boldsymbol{y} \in V(G)^{\ell_2}$.

Letting this construction range over all right-hand side graphs G, the map $G \mapsto \boldsymbol{F}_G$ becomes a tensor map, the *homomorphism tensor map* induced by $\boldsymbol{F}$. It is easy to see that homomorphism tensor maps are equivariant.

Homomorphism tensors give rise to the complex vector spaces of our main interest and their endomorphisms. For a set $\mathcal{R}$ of ℓ-labelled graphs, the tensors $\boldsymbol{R}_G$ for $\boldsymbol{R} \in \mathcal{R}$ span a subspace of $\mathbb{C}^{V(G)^\ell}$, which is denoted by $\mathbb{C}\mathcal{R}_G$. Moreover, the tensors $\boldsymbol{S}_G$ for an (ℓ, ℓ)-bilabelled graph $\boldsymbol{S}$ induces an endomorphisms of $\mathbb{C}^{V(G)^\ell}$.

▶ **Example 4.** For $k \geq 1$, let $\boldsymbol{1}^k$ denote the labelled graph consisting of k isolated vertices with distinct labels $(1, \ldots, k)$. Then, $\boldsymbol{1}^k_G$ is the uniform tensor in $\mathbb{C}^{V(G)^k}$ with every entry equal to 1. Let $\boldsymbol{A}$ denote the $(1,1)$-bilabelled graph $\left(\begin{smallmatrix}1\\ \bullet\end{smallmatrix}\!\!-\!\!\begin{smallmatrix}2\\ \bullet\end{smallmatrix}, (1), (2)\right)$. For every graph G, the matrix $\boldsymbol{A}_G$ is the adjacency matrix of G.

Algebraic and Combinatorial Operations on Homomorphism Tensor Maps. Tensor maps naturally admit a variety of algebraic operations. These include linear combination, complex conjugation, and permutation of coordinates, which are readily defined. Crucially, many operations when applied to homomorphism tensor maps correspond to operations on (bi)labelled graphs. This observation due to [30, 32] is illustrated by the following examples.

- *Sum of Entries = Dropping Labels.* Given a k-labelled graph $\boldsymbol{F} = (F, \boldsymbol{u})$, let $\mathrm{soe}(\boldsymbol{F})$ denote the 0-labelled graph $(F, ())$. Then, for every graph G, $\mathrm{soe}(\boldsymbol{F})_G = \hom(F, G) = \sum_{\boldsymbol{v} \in V(G)^k} \boldsymbol{F}_G(\boldsymbol{v}) =: \mathrm{soe}(\boldsymbol{F}_G)$.
- *Matrix Product = Series Composition.* Let an (ℓ_1, ℓ_2)-bilabelled graph $\boldsymbol{F} = (F, \boldsymbol{u}, \boldsymbol{v})$ and an (ℓ_2, ℓ_3)-bilabelled graph $\boldsymbol{F}' = (F', \boldsymbol{u}', \boldsymbol{v}')$ be given. Then for every graph G, vertices $\boldsymbol{x} \in V(G)^{\ell_1}$, and $\boldsymbol{y} \in V(G)^{\ell_2}$, $(\boldsymbol{F} \cdot \boldsymbol{F}')_G(\boldsymbol{x}, \boldsymbol{y}) = \sum_{\boldsymbol{w} \in V(G)^{\ell_2}} \boldsymbol{F}_G(\boldsymbol{x}, \boldsymbol{w}) \boldsymbol{F}'_G(\boldsymbol{w}, \boldsymbol{y}) =: (\boldsymbol{F}_G \cdot \boldsymbol{F}'_G)(\boldsymbol{x}, \boldsymbol{y})$. A similar operation corresponds to the matrix-vector product, where $\boldsymbol{F}'$ is assumed to be ℓ_2-labelled.
- *Schur Product = Parallel Composition.* The parallel composition $\boldsymbol{F} \odot \boldsymbol{F}'$ of two k-labelled graphs $\boldsymbol{F} = (F, \boldsymbol{u})$ and $\boldsymbol{F}' = (F', \boldsymbol{u}')$ corresponds to the Schur product of the homomorphism tensors. That is, for every graph G and $\boldsymbol{v} \in V(G)^k$, $(\boldsymbol{F} \odot \boldsymbol{F})_G(\boldsymbol{v}) = \boldsymbol{F}_G(\boldsymbol{v}) \boldsymbol{F}'_G(\boldsymbol{v}) =: (\boldsymbol{F}_G \odot \boldsymbol{F}'_G)(\boldsymbol{v})$. Moreover, the *inner-product* of ℓ-labelled graphs $\boldsymbol{F}$, $\boldsymbol{F}'$ can be defined by $\langle \boldsymbol{F}, \boldsymbol{F}' \rangle := \mathrm{soe}(\boldsymbol{F} \odot \boldsymbol{F}')$. It corresponds to the standard inner-product on the tensor space.

2.2 Representation Theory of Involution Monoids

We recall standard notions from representation theory, cf. [26]. A *monoid* Γ is a possibly infinite set equipped with an associative binary operation and an identity element denoted by 1_Γ. An example for a monoid is the *endomorphism monoid* $\operatorname{End} V$ for a vector space V over $\mathbb{C}$ with composition as binary operation and id_V as identity element. A *monoid representation* of Γ is a map $\varphi \colon \Gamma \to \operatorname{End} V$ such that $\varphi(1_\Gamma) = \mathrm{id}_V$ and $\varphi(gh) = \varphi(g)\varphi(h)$ for all $g, h \in \Gamma$. The representation is *finite-dimensional* if V is finite-dimensional. For every monoid Γ, there exists a representation, for example the *trivial representation* $\Gamma \to \operatorname{End}\{0\}$ given by $g \mapsto \mathrm{id}_{\{0\}}$.

Let $\varphi \colon \Gamma \to \operatorname{End}(V)$ and $\psi \colon \Gamma \to \operatorname{End}(W)$ be two representations. Then φ and ψ are *equivalent* if there exists a vector space isomorphism $X \colon V \to W$ such that $X\varphi(g) = \psi(g)X$ for all $g \in \Gamma$. Moreover, φ is a *subrepresentation* of ψ if $V \leq W$ and $\psi(g)$ restricted to V equals $\varphi(g)$ for all $g \in \Gamma$. A representation φ is *simple* if its only subrepresentations are the trivial representation and φ itself. The *direct sum* of φ and ψ denoted by $\varphi \oplus \psi \colon \Gamma \to \operatorname{End}(V \oplus W)$ is the representation that maps $g \in \Gamma$ to $\varphi(g) \oplus \psi(g) \in \operatorname{End}(V) \oplus \operatorname{End}(W) \leq \operatorname{End}(V \oplus W)$. A representation φ is *semisimple* if it is the direct sum of simple representations.

Let $\varphi \colon \Gamma \to \operatorname{End} V$ be a representation with subrepresentations $\psi' \colon \Gamma \to \operatorname{End} V'$ and $\psi'' \colon \Gamma \to \operatorname{End} V''$. Then the restriction of φ to $V' \cap V''$ is a representation as well, called the *intersection of ψ' and ψ''*. For a set $S \subseteq V$, define the *subrepresentation of φ generated by S* as the intersection of all subrepresentations $\psi' \colon \Gamma \to \operatorname{End} V'$ of φ such that $S \subseteq V'$.

The *character* of a representation φ is the map $\chi_\varphi \colon \Gamma \to \mathbb{C}$ defined as $g \mapsto \operatorname{tr}(\varphi(g))$. Its significance stems from the following theorem, which can be traced back to Frobenius and Schur [16]. For a contemporary proof, consult [26] from whose Theorem 7.19 the statement follows.

▶ **Theorem 5** (Frobenius–Schur [16]). *Let Γ be a monoid. Let $\varphi \colon \Gamma \to \operatorname{End}(V)$ and $\psi \colon \Gamma \to \operatorname{End}(W)$ be finite-dimensional semisimple representations. Then φ and ψ are equivalent if and only if $\chi_\varphi = \chi_\psi$.*

The monoids studied in this work are equipped with an additional structure which ensures that their finite-dimensional representations are always semisimple: An *involution monoid* is a monoid Γ with a unary operation $^*\colon \Gamma \to \Gamma$ such that $(gh)^* = h^*g^*$ and $(g^*)^* = g$ for all $g, h \in \Gamma$. Note that $\operatorname{End} V$ is an involution monoid with the adjoint operation $X \mapsto X^*$. Representations of involution monoids must preserve the involution operations. Thereby, they correspond to representations of $*$-algebras.

▶ **Lemma 6.** *Let Γ be an involution monoid. Every finite-dimensional representation of Γ is semisimple.*

Proof. Let $\varphi\colon \Gamma \to \operatorname{End} V$ be a finite-dimensional representation of Γ. It suffices to show that for every subrepresentation $\psi\colon \Gamma \to \operatorname{End} W$ of φ there exists a subrepresentation $\psi'\colon \Gamma \to \operatorname{End} W'$ of φ such that $\varphi = \psi \oplus \psi'$, i.e. φ acts as ψ on W and as ψ' on W'. Set W' to be the orthogonal complement of W in V. It has to be shown that $\varphi(g) \in \operatorname{End} V$ for every $g \in \Gamma$ can be restricted to an endomorphism of W'. Let $w \in W$ and $w' \in W'$ be arbitrary. Then $\langle \varphi(g)w', w\rangle = \langle w', \varphi(g)^*w\rangle = \langle w', \varphi(g^*)w\rangle = 0$ since $\varphi(g^*)$ maps $W \to W$ and $W \perp W'$. Hence, the $\operatorname{im}\varphi(g)$ is contained in the orthogonal complement of W, which equals W'. Clearly, $\varphi = \psi \oplus \psi'$. ◀

2.3 Path and Cycle Decompositions of Bilabelled Graphs

We recall the well-studied notions of path and tree decompositions. For illustrating subsequent arguments, we introduce cycle decompositions.

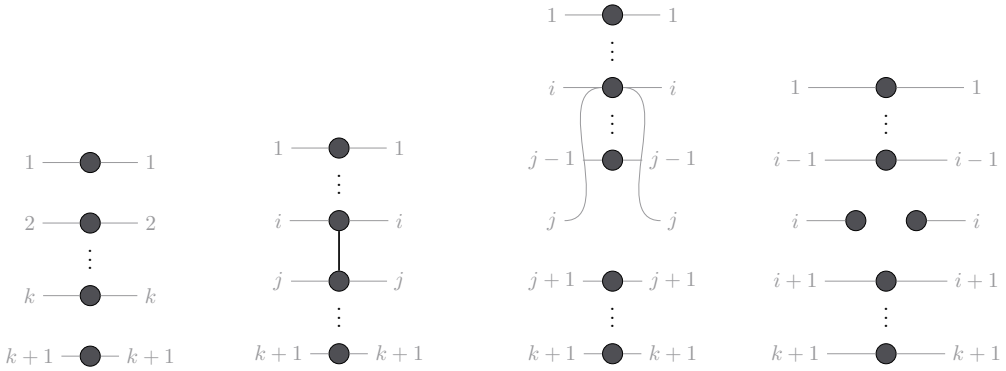
▶ **Definition 7.** *A* decomposition *of a graph G is a pair (F, β) where F is a graph and β is map $V(F) \to 2^{V(G)}$ such that*

1. *the union of the $\beta(v)$ for $v \in V(F)$ is equal to $V(G)$,*
2. *for every edge $e \in E(G)$ there exists $v \in V(F)$ such that $e \subseteq \beta(v)$,*
3. *for every vertex $u \in V(G)$ the set of vertices $v \in V(F)$ such that $u \in \beta(v)$ is connected in F.*

The sets $\beta(v)$ for $v \in V(F)$ are called the *bags of* (F, β). The *width* of (F, β) is the maximum over all $|\beta(v)| + 1$ for $v \in V(F)$. A decomposition (F, β) is called a *tree decomposition* if F is a tree, a *path decomposition* if F is a path, and a *cycle decomposition* if F is a cycle. The *tree- / path- / cyclewidth* of a graph G is the minimum width of a tree/path/cycle decomposition of G.

Let $k \in \mathbb{N}$. A *leaf bag* of a path decomposition (P, β) is a bag $\beta(v)$ such that $v \in V(P)$ has degree 1. A *path decomposition* of a $(k+1, k+1)$-bilabelled graph $\boldsymbol{F} = (F, \boldsymbol{u}, \boldsymbol{v})$ is a path decomposition (P, β) of the underlying graph F such that the leaf bags consist precisely of the vertices occurring (possibly repeatedly) in $\boldsymbol{u}$ and in $\boldsymbol{v}$, respectively. A $(k+1, k+1)$-bilabelled graph $\boldsymbol{F}$ is said to be of *pathwidth at most k* if its underlying graph admits a path decomposition of width at most k with this property.

Let $\mathcal{PW}^k$ denote the set of all $(k+1, k+1)$-bilabelled graphs of pathwidth at most k. Every unlabelled graph F of pathwidth at most k can be turned into a $(k+1, k+1)$-bilabelled graph $\boldsymbol{F} = (F, \boldsymbol{u}, \boldsymbol{v})$ of pathwidth at most k by assigning labels to the vertices $\boldsymbol{u}, \boldsymbol{v} \in V(F)^{k+1}$ in the leaf bags. The set $\mathcal{PW}^k$ is closed under concatenation and taking reverses. The *identity graph* $\boldsymbol{I} = (I, (1, \dots, k+1), (1, \dots, k+1))$ with $V(I) = [k+1]$, $E(I) = \emptyset$ is the multiplicative identity under concatenation. Hence, $\mathcal{PW}^k$ forms an involution monoid. A generating set for $\mathcal{PW}^k$ under these operations is called a k-basal set:



(a) Identity graph $\boldsymbol{I}$. **(b)** Adjacency graph $\boldsymbol{A}^{ij}$. **(c)** Identification graph $\boldsymbol{I}^{ij}$. **(d)** Forgetting graph $\boldsymbol{F}^{i}$.

Figure 1 Basal graphs from Lemma 9 in wire notation of [32]: A vertex carries in-label (out-label) i if it is connected to the number i on the left (right) by a wire. Actual edges and vertices of the graph are depicted in black.

▶ **Definition 8.** *A finite set $\mathcal{B}^k$ of $(k+1,k+1)$-bilabelled graphs is called a* k-basal set *if it satisfies the following properties:*

1. $\mathcal{B}^k \subseteq \mathcal{PW}^k$,
2. *the identity graph $\boldsymbol{I}$ is contained in $\mathcal{B}^k$,*
3. *for every $\boldsymbol{B} \in \mathcal{B}$, the reverse graph $\boldsymbol{B}^*$ also belongs to $\mathcal{B}$, and,*
4. *every $\boldsymbol{P} \in \mathcal{PW}^k$ can be obtained by concatenating a sequence of elements from $\mathcal{B}$.*

Concrete examples of k-basal sets can be constructed for every k as described in Lemma 9 and Figure 1. In fact, in all what follows, every k-basal set can be assumed to be this particular k-basal set.

▶ **Lemma 9.** *The set $\mathcal{B}^k$ consisting of the following $(k+1,k+1)$-bilabelled graphs is k-basal. For $1 \leq i \neq j \leq k+1$,*

- *the* identity graph $\boldsymbol{I} = (I, (1,\dots,k+1), (1,\dots,k+1))$ *with* $V(I) = [k+1]$, $E(I) = \emptyset$,
- *the* adjacency graphs $\boldsymbol{A}^{ij} = (A^{ij}, (k+1), (k+1))$ *with* $V(A^{ij}) = [k+1]$ *and* $E(A) = \{ij\}$,
- *the* identification graphs $\boldsymbol{I}^{ij} = (I^{ij}, (1,\dots,i,i+1,\dots,j-1,i,j+1,\dots,k+1), (1,\dots,i,i+1,\dots,j-1,i,j+1,\dots,k+1))$ *with* $V(I^{ij}) = [k+1] \setminus \{j\}$ *and* $E(I^{ij}) = \emptyset$, *and*
- *the* forgetting graphs $\boldsymbol{F}^{i} = (F^i, (1,\dots,k+1), (1,\dots,i-1,i',i+1,\dots,k+1))$ *with* $V(F^i) = [k+1] \cup \{i'\}$ *and* $E(F^i) = \emptyset$.

Proof. Items 1 and 3 of Definition 8 are clear. For Item 4, observe that every $\boldsymbol{P} = (P, \boldsymbol{v}, \boldsymbol{v}) \in \mathcal{PW}^k$ such that all vertices of $\boldsymbol{P}$ are labelled with corresponding in- and out-labels coinciding can be written as the concatenation of $\prod_{ij \in I} \boldsymbol{A}^{ij}$ for $I = E(P)$ with the $\boldsymbol{I}^{ij}$ for all $i \neq j$ such that $\boldsymbol{v}_i = \boldsymbol{v}_j$. Arbitrary $\boldsymbol{Q} \in \mathcal{PW}^k$ can then be obtained as the concatenation of such $\boldsymbol{P}$ interleaved with $\boldsymbol{F}^i$ for certain i. This corresponds to linking adjacent bags of the path decomposition together. ◀

Crucial is the following proposition which is immediate from the above observations:

▶ **Proposition 10.** *Let $\mathcal{B}^k$ denote a k-basal set. If F is a graph of pathwidth at most k then there exist $\boldsymbol{B}^1,\dots,\boldsymbol{B}^r \in \mathcal{B}^k$ such that* $\hom(F,G) = \operatorname{soe}(\boldsymbol{B}^1_G \cdots \boldsymbol{B}^r_G)$ *for all graphs G.*

The constructions for graphs of bounded pathwidth carry over to graphs of bounded cyclewidth (Definition 7). Let $\boldsymbol{F} = (F, \boldsymbol{u}, \boldsymbol{v})$ be a $(k+1,k+1)$-bilabelled graph of pathwidth at most k. Let $\boldsymbol{F}^{\mathrm{id}}$ denote the $(k+1)$-labelled graph obtained by identifying the elements

of $\boldsymbol{u}$ and $\boldsymbol{v}$ element-wise. Every unlabelled graph C of cyclewidth k can be associated with a $(k+1, k+1)$-bilabelled graph $\boldsymbol{C}$ of pathwidth k such that C is the unlabelled graph underlying $\boldsymbol{C}^{\mathrm{id}}$. Observe that $\mathrm{soe}(\boldsymbol{F}^{\mathrm{id}}) = \mathrm{tr}(\boldsymbol{F})$.

▶ **Proposition 11.** *Let $\mathcal{B}^k$ denote a k-basal set. If F is a graph of cyclewidth at most k then there exist $\boldsymbol{B}^1, \dots, \boldsymbol{B}^r \in \mathcal{B}^k$ such that $\hom(F, G) = \mathrm{tr}(\boldsymbol{B}^1_G \cdots \boldsymbol{B}^r_G)$ for all graphs G.*

3 Homomorphisms from Trees, Paths, and Trees of Bounded Degree

Two graphs G, H with adjacency matrices $\boldsymbol{A}_G$, $\boldsymbol{A}_H$ are isomorphic if and only if there is a matrix X over the non-negative integers such that $X\boldsymbol{A}_G = \boldsymbol{A}_H X$ and $X\mathbf{1} = X^T\mathbf{1} = \mathbf{1}$, where $\mathbf{1}$ is the all-ones vector. Writing the constraints as linear equations whose variables are the entries of X, we obtain a system $\mathsf{F}_{\mathrm{iso}}(G, H)$ that has a non-negative integer solution if and only if G and H are isomorphic. A combination of results from [44] and [14] shows that $\mathsf{F}_{\mathrm{iso}}(G, H)$ has a non-negative rational solution if and only if G and H are homomorphism indistinguishable over the class of trees, and by [13], $\mathsf{F}_{\mathrm{iso}}(G, H)$ has an arbitrary rational solution if and only if G and H are homomorphism indistinguishable over the class of paths. We devise a more general framework connecting homomorphism indistinguishability and $\mathsf{F}_{\mathrm{iso}}(G, H)$-style equations, with paths and trees as two special cases. On the way, we characterise homomorphism indistinguishability over trees of bounded degree.

The prime objects of our study are sets $\mathcal{R}$ of 1-labelled graphs. For a fixed target graph G, the corresponding homomorphism tensors yield a subspace $\mathbb{C}\mathcal{R}_G \leq \mathbb{C}^{V(G)}$. Since algebraic operations on 1-dimensional tensors (i.e. vectors) and combinatorial operations on 1-labelled graphs correspond to each other, cf. Section 2.1, the existence of *linear transformations* $X \colon \mathbb{C}\mathcal{R}_G \to \mathbb{C}\mathcal{R}_H$ respecting these algebraic operations is central to conceptualising homomorphism indistinguishability of G and H as solvability of *linear equations*.

▶ **Definition 12.** *Recall the definition of $\boldsymbol{A}$ from Example 4. Let $\mathcal{R}$ denote a set of 1-labelled graphs containing the one-vertex graph.*

1. *The set $\mathcal{R}$ is* $\boldsymbol{A}$-invariant *if for all $\boldsymbol{R} \in \mathcal{R}$ also $\boldsymbol{A} \cdot \boldsymbol{R} \in \mathcal{R}$. Combinatorially, $\boldsymbol{A}$-invariance means that for every labelled graph $\boldsymbol{R} = (R, u) \in \mathcal{R}$, the labelled graph $\boldsymbol{A} \cdot \boldsymbol{R}$ obtained by adding a fresh vertex u' to R, adding the edge uu', and placing the label on u', is also in $\mathcal{R}$.*
2. *The set $\mathcal{R}$ is* inner-product compatible *if for all $\boldsymbol{R}, \boldsymbol{S} \in \mathcal{R}$ there exists $\boldsymbol{T} \in \mathcal{R}$ such that $\langle \boldsymbol{R}, \boldsymbol{S} \rangle = \mathrm{soe}(\boldsymbol{T})$. Combinatorially, the homomorphism counts from the graph obtained by gluing $\boldsymbol{R}$ and $\boldsymbol{S}$ and forgetting labels, are equal to the homomorphism counts from another graph in $\mathcal{R}$.*

Examples of sets satisfying the above two properties include the set $\mathcal{P}$ of 1-labelled paths where the label is placed on a vertex of degree at most 1, the set $\mathcal{T}$ of 1-labelled trees where the label is placed on an arbitrary vertex, and the set $\mathcal{T}^d$ of 1-labelled d-ary trees with label on a vertex of degree at most 1, where a tree is *d-ary* if its vertices have degree at most $d+1$.

▶ **Theorem 13.** *Let $\mathcal{R}$ be an inner-product compatible set of 1-labelled graphs containing the one-vertex graph. Let G and H be two graphs. Then the following are equivalent:*

1. *G and H are homomorphism indistinguishable over $\mathcal{R}$, that is, for all $\boldsymbol{R} = (R, u) \in \mathcal{R}$, $\hom(R, G) = \hom(R, H)$.*
2. *There exists a unitary[1] map $U \colon \mathbb{C}\mathcal{R}_G \to \mathbb{C}\mathcal{R}_H$ such that $U\boldsymbol{R}_G = \boldsymbol{R}_H$ for all $\boldsymbol{R} \in \mathcal{R}$.*

[1] A map $U \colon V \to W$ is *unitary* if $U^*U = \mathrm{id}_V$ and $UU^* = \mathrm{id}_W$ for $U^* \colon W \to V$ the adjoint of U.

3. *There exists a pseudo-stochastic*[2] *map* $X\colon \mathbb{C}\mathcal{R}_G \to \mathbb{C}\mathcal{R}_H$ *such that* $X\boldsymbol{R}_G = \boldsymbol{R}_H$ *for all* $\boldsymbol{R} \in \mathcal{R}$.

If furthermore $\mathcal{R}$ *is* $\boldsymbol{A}$*-invariant then the conditions above are equivalent to the following:*

4. *There exists a pseudo-stochastic matrix* $X \in \mathbb{Q}^{V(H)\times V(G)}$ *such that* $X\boldsymbol{A}_G = \boldsymbol{A}_H X$ *and* $X\boldsymbol{R}_G = \boldsymbol{R}_H$ *for all* $\boldsymbol{R} \in \mathcal{R}$.

Proof. Suppose that Item 1 holds. Since $\mathcal{R}$ is inner-product compatible, for all $\boldsymbol{R}, \boldsymbol{S} \in \mathcal{R}$ there exists $\boldsymbol{T} = (T, v) \in \mathcal{R}$ such that

$$\langle \boldsymbol{R}_G, \boldsymbol{S}_G \rangle = \langle \boldsymbol{R}, \boldsymbol{S} \rangle_G = (\operatorname{soe} \boldsymbol{T})_G = \hom(T, G) = \hom(T, H) = \langle \boldsymbol{R}_H, \boldsymbol{S}_H \rangle .$$

Thus, by a Gram–Schmidt argument, there exists U with the properties in Item 2. Conversely, supposing that Item 2 holds, let $\boldsymbol{R} = (R, u) \in \mathcal{R}$. It holds that $U\mathbf{1}_G = \mathbf{1}_H$, because $\mathcal{R}$ contains the one-vertex graph $\mathbf{1}$. Since U is unitary, $\mathbf{1}_G = U^*\mathbf{1}_H$. Hence,

$$\hom(R, G) = \langle \mathbf{1}_G, \boldsymbol{R}_G \rangle = \langle \mathbf{1}_H, U\boldsymbol{R}_G \rangle = \langle \mathbf{1}_H, \boldsymbol{R}_H \rangle = \hom(R, H).$$

This shows that Items 1 and 2 are equivalent. Inspecting the above arguments more closely shows that Item 3 is also equivalent with these.

Now suppose additionally that $\mathcal{R}$ is $\boldsymbol{A}$-invariant. It remains to show that in this case Item 4 is equivalent with the first three assertions. For all graphs G, $\mathbb{C}\mathcal{R}_G$ is an $\boldsymbol{A}_G$-invariant subspace of $\mathbb{C}^{V(G)}$. Since $\boldsymbol{A}_G$ is symmetrical, it preserves the direct sum decomposition $\mathbb{C}^{V(G)} = \mathbb{C}\mathcal{R}_G \oplus (\mathbb{C}\mathcal{R}_G)^\perp$. Given U as in Item 2, define X as the map acting like U on $\mathbb{C}\mathcal{R}_G$ and annihilating $(\mathbb{C}\mathcal{R}_G)^\perp$. Let $\boldsymbol{R} \in \mathcal{R}$ be arbitrary. Then $\boldsymbol{A} \cdot \boldsymbol{R} \in \mathcal{R}$ and hence,

$$X\boldsymbol{A}_G\boldsymbol{R}_G = U\boldsymbol{A}_G\boldsymbol{R}_G = \boldsymbol{A}_H\boldsymbol{R}_H = \boldsymbol{A}_H U\boldsymbol{R}_G = \boldsymbol{A}_H X\boldsymbol{R}_G.$$

For $v \in (\mathbb{C}\mathcal{R}_G)^\perp$, $X\boldsymbol{A}_G v = 0 = \boldsymbol{A}_H X v$. Thus, $X\boldsymbol{A}_G = \boldsymbol{A}_H X$.

Finally, $X\mathbf{1}_G = U\mathbf{1}_G = \mathbf{1}_H$ since $\mathcal{R}$ contains the one-vertex graph, and $X^T\mathbf{1}_H = \overline{U^*\mathbf{1}_H} = \overline{\mathbf{1}_G} = \mathbf{1}_G$, so X is pseudo-stochastic. The just constructed matrix X may a priori have non-rational entries. However, since Item 4 is essentially a linear system of equations with rational coefficients, it holds that whenever it has a complex solution, it also has a solution over the rationals. This is a consequence of Cramer's rule. The converse, i.e. that Item 4 implies Item 1, follows analogously to the implication from Item 2 to Item 1. ◀

As an easy application of Theorem 13, we recover the characterisation of indistinguishability with respect to path homomorphisms [13].

▶ **Corollary 14.** *Two graphs* G *and* H *are homomorphism indistinguishable over the class of paths if and only if there exists a pseudo-stochastic* $X \in \mathbb{Q}^{V(H)\times V(G)}$ *such that* $X\boldsymbol{A}_G = \boldsymbol{A}_H X$.

The classical characterisation [43] of homomorphism indistinguishability over trees involves a non-negativity condition on the matrix X. While such an assumption appears natural from the viewpoint of solving the system of equations for fractional isomorphism, it lacks an algebraic or combinatorial interpretation. Using Theorem 13, we reprove this known characterisation and give an alternative description that emphasises its graph theoretic origin.

[2] Let I and J be finite sets. Fix vector spaces $V \leq \mathbb{C}^I$ and $W \leq \mathbb{C}^J$ such that the all-ones vectors $\mathbf{1}_I \in V$ and $\mathbf{1}_J \in W$. Then a map $X\colon V \to W$ is *pseudo-stochastic* if $X\mathbf{1}_I = \mathbf{1}_J$ and $X^*\mathbf{1}_J = \mathbf{1}_I$ for X^* the adjoint of X.

▶ **Corollary 15.** *Let G and H be two graphs. G and H are homomorphism indistinguishable over the class of trees if and only if there exists a pseudo-stochastic matrix $X \in \mathbb{Q}^{V(H)\times V(G)}$ such that $X\boldsymbol{A}_G = \boldsymbol{A}_H X$ and one of the following equivalent conditions holds:*

1. *$X \geq 0$ entry-wise,*
2. *$X\boldsymbol{T}_G = \boldsymbol{T}_H$ for all 1-labelled trees $\boldsymbol{T} \in \mathcal{T}$,*
3. *X preserves the Schur product on $\mathbb{C}\mathcal{T}_G$, i.e. $X(u \odot v) = (Xu) \odot (Xv)$ for all $u, v \in \mathbb{C}\mathcal{T}_G$.*

The key graph-theoretic observation is the following: Every labelled tree can be obtained from the one-vertex graph $\mathbf{1}$ by adding edges and identifying trees at their labels. Put algebraically, the set $\mathcal{T}$ of 1-labelled trees is the closure of $\{\mathbf{1}\}$ under Schur products and multiplication with $\boldsymbol{A}$. Hence, Items 2 and 3 are equivalent. Moreover, Theorem 13 implies the equivalence between Item 2 and homomorphism indistinguishability over the class of trees. The missing equivalence between Items 1 and 2 is deferred to the full version.

Finally, Theorem 13 also gives a characterisation of homomorphism indistinguishability over the class of bounded degree trees. Let $d \geq 1$. The set $\mathcal{T}^d$ of d-ary trees with label on a vertex of degree one or zero is closed under *guarded Schur products*, i.e. the d-ary operation $\circledast^d$ defined as $\circledast^d(\boldsymbol{R}^1, \dots, \boldsymbol{R}^d) \coloneqq \boldsymbol{A} \cdot (\boldsymbol{R}^1 \odot \cdots \odot \boldsymbol{R}^d)$ for $\boldsymbol{R}^1, \dots, \boldsymbol{R}^d \in \mathcal{T}^d$. This operation induces a d-ary operation on $\mathbb{C}\mathcal{T}_G^d$ for every graph G, i.e. $\circledast_G^d(u_1, \dots, u_d) \coloneqq \boldsymbol{A}_G(u_1 \odot \cdots \odot u_d)$ for $u_1, \dots, u_d \in \mathbb{C}\mathcal{T}_G^d$.

▶ **Corollary 16.** *Let $d \geq 1$. Let G and H be graphs. Then the following are equivalent:*

1. *G and H are homomorphism indistinguishable over the class of d-ary trees.*
2. *There exists a pseudo-stochastic matrix $X \in \mathbb{Q}^{V(H)\times V(G)}$ such that $X\boldsymbol{A}_G = \boldsymbol{A}_H X$ and $X\boldsymbol{T}_G = \boldsymbol{T}_H$ for all $\boldsymbol{T} \in \mathcal{T}^d$.*
3. *There exists a pseudo-stochastic matrix $X \in \mathbb{Q}^{V(H)\times V(G)}$ such that X preserves $\circledast^d$ on $\mathbb{C}\mathcal{T}_G^d$, i.e. $X(\circledast_G^d(u_1, \dots, u_d)) = \circledast_H^d(Xu_1, \dots, Xu_d)$ for all $u_1, \dots, u_d \in \mathbb{C}\mathcal{T}_G^d$.*

The systems of equations in Corollary 16 are parametrised by the nested subspaces $\mathbb{C}\mathcal{T}_G^d$ for $d \geq 1$. The following theorem asserts that there exist graphs G for which the inclusions in the chain

$$\mathbb{C}\mathcal{P}_G = \mathbb{C}\mathcal{T}_G^1 \subseteq \mathbb{C}\mathcal{T}_G^2 \subseteq \cdots \subseteq \mathbb{C}\mathcal{T}_G^d \subseteq \mathbb{C}\mathcal{T}_G^{d+1} \subseteq \cdots \subseteq \mathbb{C}\mathcal{T}_G \subseteq \mathbb{C}^{V(G)}$$

are strict. Conceptually, this is due to the fact that $\mathcal{T}^d$ is only closed under the guarded Schur product $\circledast^d$ while $\mathcal{T}$ is closed under arbitrary Schur products.

▶ **Theorem 17.** *For every integer $d \geq 1$, there exists a graph H such that $\mathbb{C}\mathcal{T}_H^d \neq \mathbb{C}\mathcal{T}_H^{d+1}$.*

The proof of the above theorem can be modified to show that homomorphism indistinguishability over trees of bounded degree is a strictly weaker notion than homomorphism indistinguishability over trees. As a consequence, it is not possible to simulate the 1-dimensional Weisfeiler–Leman algorithm (also known as Colour Refinement, [19]) by counting homomorphisms from trees of any fixed bounded degree.

▶ **Theorem 3.** *For every integer $d \geq 1$, there exist graphs G and H such that G and H are homomorphism indistinguishable over trees of degree at most d, but G and H are not homomorphism indistinguishable over the class of all trees.*

The key step underlying the proofs of Theorems 3 and 17 is the construction of graphs whose (adjacency matrix) eigenspaces behave nicely with respect to the Schur product. Both proofs are deferred to the full version.

4 Representations of Involution Monoids and Homomorphism Indistinguishability

Let $\boldsymbol{F}_1, \dots, \boldsymbol{F}_m$ be (ℓ, ℓ)-bilabelled graphs for some $\ell \in \mathbb{N}$. The closure of $\{\boldsymbol{F}_1, \dots, \boldsymbol{F}_m\}$ under concatenation and taking reverses gives rise to an involution monoid $\mathcal{F}$. If a target graph G is fixed, every bilabelled graph $\boldsymbol{F} \in \mathcal{F}$ yields a homomorphism tensor $\boldsymbol{F}_G$. The association $\boldsymbol{F} \mapsto \boldsymbol{F}_G$ is thus a representation[3] of the involution monoid $\mathcal{F}$. This representation-theoretic viewpoint constitutes a compelling framework for analysing homomorphism tensors.

Recall from Section 2.3 that for an (ℓ, ℓ)-bilabelled graph $\boldsymbol{F}$, the ℓ-labelled graph obtained from $\boldsymbol{F}$ by identifying the in- and out-labels pairwise is denoted by $\boldsymbol{F}^{\mathrm{id}}$. Let $\mathcal{F}^{\mathrm{id}}$ denote the set of all unlabelled graphs underlying graphs of the form $\boldsymbol{F}^{\mathrm{id}}$, $\boldsymbol{F} \in \mathcal{F}$. Then, the character χ_G of the representation of $\mathcal{F}$ induced by G tabulates all homomorphism numbers of the form $\hom(F, G)$ for $F \in \mathcal{F}^{\mathrm{id}}$. Given two target graphs G and H, the equality of characters χ_G and χ_H coincides thus with homomorphism indistinguishability over the class $\mathcal{F}^{\mathrm{id}}$.

On the other hand, equality of characters is, under mild representation-theoretic assumptions, a necessary and sufficient condition for two representations to be equivalent. The equivalence of the representation induced by G and H, when explicitly stated, yields a system of linear equations $X\boldsymbol{F}_G = \boldsymbol{F}_H X$ with $\boldsymbol{F} \in \{\boldsymbol{F}_1, \dots, \boldsymbol{F}_m\}$ where the desired solution X is a unitary matrix. This interpretation forms a useful template for homomorphism indistinguishability results: homomorphism indistinguishability over the class $\mathcal{F}^{\mathrm{id}}$ is equivalent to the existence of a unitary matrix satisfying a suitably defined system of linear equations. Indeed, this template yields Theorem 19 below, a characterisation of homomorphism indistinguishability over graphs of bounded cyclewidth, by setting the generators $\boldsymbol{F}_1, \dots, \boldsymbol{F}_m$ to form a k-basal set.

The following theorem about involution monoid representations due to Specht [41], in particular its generalisation due to Wiegmann [45], forms the main tool for obtaining the results of this section. Let $\mathsf{A} = (A_1, \dots, A_m)$ be a sequence of matrices in $\mathbb{C}^{I \times I}$ for some finite index set I. Let Σ_{2m} denote the finite alphabet $\{x_i, y_i \mid i \in [m]\}$. Let Γ_{2m}denote the infinite set of all words over Σ_{2m}. Equipped with the extension to Γ_{2m} of the map swapping x_i and y_i for all $i \in [m]$, Γ_{2m} can be thought of as a *free involution monoid*. For a word $w \in \Gamma_{2m}$, let w_{A} denote the matrix obtained by substituting $x_i \mapsto A_i$ and $y_i \mapsto A_i^*$ for all $i \in [m]$ and evaluating the matrix product. The substitution $w \mapsto w_{\mathsf{A}}$ is a representation of Γ_{2m}.

▶ **Theorem 18** (Specht [41], Wiegmann [45]). *Let I and J be finite index sets. Let $\mathsf{A} = (A_1, \dots, A_m)$ and $\mathsf{B} = (B_1, \dots, B_m)$ be two sequences of matrices such that $A_i \in \mathbb{C}^{I \times I}$ and $B_i \in \mathbb{C}^{J \times J}$ for $i \in [m]$. Then the following are equivalent:*

1. *There exists a unitary $U \in \mathbb{C}^{J \times I}$ such that $UA_i = B_i U$ and $UA_i^* = B_i^* U$ for every $i \in [m]$.*
2. *For every word $w \in \Gamma_{2m}$, $\operatorname{tr}(w_{\mathsf{A}}) = \operatorname{tr}(w_{\mathsf{B}})$.*

Note that the given matrices need not be symmetric. Moreover, it is easy to see that trace equality for words of length at most $\mathcal{O}(n^2)$ suffice to imply trace equality for all words in Γ_{2m}. See [38] for a tighter bound. Finally note that although Theorem 18 is stated as a result involving matrices, the underlying bases are in fact irrelevant.

[3] Phrased in the language of [28], this representation of an involution monoid is a representation of the *concatenation algebra* $\mathcal{F}$.

Our first result follows by applying Wiegmann's theorem to the $(k+1, k+1)$-bilabelled graphs of a k-basal set (Definition 8). This yields an equational characterisation of homomorphism indistinguishability over the class of graphs of cyclewidth at most k.

▶ **Theorem 19.** *Let $k \geq 1$. Let $\mathcal{B}^k$ denote a k-basal set. Let G and H be a graphs. Then the following are equivalent:*

1. *G and H are homomorphism indistinguishable over the class of cyclewidth at most k.*
2. *There exists a unitary matrix $U \in \mathbb{C}^{V(H)^{k+1} \times V(G)^{k+1}}$ such that $U\boldsymbol{B}_G = \boldsymbol{B}_H U$ for all $\boldsymbol{B} \in \mathcal{B}^k$.*

Proof. Let $\boldsymbol{B}^1, \dots, \boldsymbol{B}^m$ be an enumeration of the finite set $\mathcal{B}^k$. Define A and B by setting $A_i \coloneqq \boldsymbol{B}^i_G$ and $B_i \coloneqq \boldsymbol{B}^i_H$ for $i \in [m]$. Recall that the k-basal set $\mathcal{B}^k$ is closed under taking reverses. The theorem immediately follows by an application of Theorem 18 on the matrix sequences A and B, along with Proposition 11. ◀

In contrast to $\mathcal{F}^{\mathrm{id}}$, let $\mathcal{F}^{\mathrm{un}}$ denote the set of all unlabelled graphs underlying graphs $\boldsymbol{F} \in \mathcal{F}$. Although the class $\mathcal{F}^{\mathrm{un}}$ is combinatorially more natural than $\mathcal{F}^{\mathrm{id}}$, it invokes the operator soe on the representations instead of the tr operator, which is algebraically better understood. This technical difficulty is overcome by considering, instead of the original involution monoid representation, its subrepresentation generated by the all-ones vector. In this manner, the *useful spectrum* used in [13] to characterise homomorphism indistinguishability over paths receives an algebraic interpretation. The equivalence of these subrepresentations amounts to the desired solutions being pseudo-stochastic matrices instead of unitary matrices. Formally, we prove the following sum-of-entries analogue of Theorem 18.

▶ **Theorem 20.** *Let I and J be finite index sets. Let $\mathsf{A} = (A_1, \dots, A_m)$ and $\mathsf{B} = (B_1, \dots, B_m)$ be two sequences of matrices such that $A_i \in \mathbb{C}^{I \times I}$ and $B_i \in \mathbb{C}^{J \times J}$ for $i \in [m]$. Then the following are equivalent:*

1. *There exists a pseudo-stochastic matrix $X \in \mathbb{C}^{J \times I}$ such that $XA_i = B_i X$ and $XA_i^* = B_i^* X$ for all $i \in [m]$.*
2. *For every word $w \in \Gamma_{2m}$, $\operatorname{soe}(w_{\mathsf{A}}) = \operatorname{soe}(w_{\mathsf{B}})$.*

Theorem 20 is implied by Lemma 21, which provides a sum-of-entries analogue of Theorem 5. As it establishes a character-theoretic interpretation of the function soe, it may be of independent interest.

▶ **Lemma 21.** *Let Γ be an involution monoid. Let I and J be finite index sets. Let $\varphi\colon \Gamma \to \mathbb{C}^{I \times I}$ and $\varphi\colon \Gamma \to \mathbb{C}^{J \times J}$ be representations of Γ. Let $\varphi'\colon \Gamma \to V$ and $\psi'\colon \Gamma \to W$ denote the subrepresentations of φ and of ψ generated by $\mathbf{1}_I$ and $\mathbf{1}_J$, respectively. Then the following are equivalent:*

1. *For all $g \in \Gamma$, $\operatorname{soe}\varphi(g) = \operatorname{soe}\psi(g)$.*
2. *There exists a unitary pseudo-stochastic $U\colon V \to W$ such that $U\varphi'(g) = \psi'(g)U$ for all $g \in \Gamma$.*
3. *There exists a pseudo-stochastic $X \in \mathbb{C}^{J \times I}$ such that $X\varphi(g) = \psi(g)X$ for all $g \in \Gamma$.*

Proof. Suppose that Item 1 holds. The space V is spanned by the vectors $\varphi(g)\mathbf{1}_I$ for $g \in \Gamma$ while W is spanned by $\psi(g)\mathbf{1}_J$ for $g \in \Gamma$. For $g, h \in \Gamma$ it holds that

$$\langle \varphi(g)\mathbf{1}_I, \varphi(h)\mathbf{1}_I \rangle = \langle \mathbf{1}_I, \varphi(g^*h)\mathbf{1}_I \rangle = \operatorname{soe}\varphi(g^*h) = \operatorname{soe}\psi(g^*h) = \langle \psi(g)\mathbf{1}_J, \psi(h)\mathbf{1}_J \rangle .$$

Hence, V and W are spanned by vectors whose pairwise inner-products are respectively the same. Thus, by a Gram–Schmidt argument, there exists a unitary $U\colon V \to W$ such that $U\varphi(g)\mathbf{1}_I = \psi(g)\mathbf{1}_J$ for all $g \in \Gamma$. This immediately implies that $U\varphi'(g) = \psi'(g)U$ for $g \in \Gamma$. Furthermore, $U\mathbf{1}_I = U\varphi(1_\Gamma)\mathbf{1}_I = \psi(1_\Gamma)\mathbf{1}_J = \mathbf{1}_J$ and $U^*\mathbf{1}_J = \mathbf{1}_I$ since U is unitary. Thus, Item 2 holds.

Suppose now that Item 2 holds. By Lemma 6, write $\varphi = \varphi' \oplus \varphi''$ and $\psi = \psi' \oplus \psi''$. By assumption, there exists a unitary $U\colon V \to W$ such that $U\varphi'(g) = \psi'(g)U$ for all $g \in \Gamma$. Extend U to X by letting it annihilate $V^\perp$. Then $X\varphi(g) = (U \oplus 0)(\varphi' \oplus \varphi'')(g) = U\varphi'(g) \oplus 0 = \psi'(g)U \oplus 0 = \psi(g)X$ for all $g \in \Gamma$. Since U is pseudo-stochastic and $\mathbf{1}_I \in V$ and $\mathbf{1}_J \in W$, X is pseudo-stochastic as well. Hence, Item 3 holds. That Item 3 implies Item 1 is immediate. ◀

Paralleling Theorem 19, we now apply the sum-of-entries version of Specht's theorem to characterise homomorphism indistinguishability over the class of graphs of bounded pathwidth.

▶ **Theorem 22.** *Let $k \geq 1$. Let $\mathcal{B}^k$ denote a k-basal set. Let G and H be a graphs. Then the following are equivalent:*

1. *G and H are homomorphism indistinguishable over the class graphs of pathwidth at most k,*
2. *There exists a pseudo-stochastic matrix $X \in \mathbb{Q}^{V(H)^{k+1} \times V(G)^{k+1}}$ such that $X\boldsymbol{B}_G = \boldsymbol{B}_H X$ for all $\boldsymbol{B} \in \mathcal{B}^k$.*

Let $\mathsf{PW}^{k+1}(G, H)$ denote the system of linear equations in Item 2 above with the basal set from Lemma 9. It comprises $n^{\mathcal{O}(k^2)}$ variables and $\left|\mathcal{B}^k\right| \cdot n^{\mathcal{O}(k^2)} = \mathcal{O}(k^2 \cdot n^{\mathcal{O}(k^2)})$ equations.

5 Comparison with Known Systems of Linear Equations

Towards understanding the power and limitations of convex optimisation approaches to the graph isomorphism problem, the level-k Sherali–Adams relaxation of $\mathsf{F}_{\text{iso}}(G, H)$, denoted by $\mathsf{F}^k_{\text{iso}}(G, H)$, was studied in [3]. The system $\mathsf{L}^{k+1}_{\text{iso}}(G, H)$ is another closely related system of interest [21]. Every solution for $\mathsf{F}^{k+1}_{\text{iso}}(G, H)$ yields a solution to $\mathsf{L}^{k+1}_{\text{iso}}(G, H)$, and every solution to $\mathsf{L}^{k+1}_{\text{iso}}(G, H)$ yields a solution to $\mathsf{F}^k_{\text{iso}}(G, H)$ [21]. In [3, 21], it was shown that the system $\mathsf{L}^{k+1}_{\text{iso}}(G, H)$ has a non-negative solution if and only if G and H are indistinguishable by the k-dimensional Weisfeiler–Leman algorithm. Following the results of [14, 13], the feasibility of $\mathsf{L}^{k+1}_{\text{iso}}(G, H)$ is thus equivalent to homomorphism indistinguishability over graphs of treewidth at most k.

Dropping non-negativity constraints in $\mathsf{F}_{\text{iso}}(G, H)$ yields a system of linear equations whose feasibility characterises homomorphism indistinguishability over the class of paths [13]. It was conjectured ibidem that dropping non-negativity constraints in $\mathsf{L}^{k+1}_{\text{iso}}(G, H)$ analogously characterises homomorphism indistinguishability over graphs of pathwidth at most k. One direction of this conjecture was shown in [13]: the existence of a rational solution to $\mathsf{L}^{k+1}_{\text{iso}}(G, H)$ implies homomorphism indistinguishability over graphs of pathwidth at most k.

We resolve the aforementioned conjecture by showing that the system of equations $\mathsf{L}^{k+1}_{\text{iso}}(G, H)$ is feasible if and only if the system of equations $\mathsf{PW}^{k+1}(G, H)$ stated in Theorem 22 is feasible. The proof repeatedly makes use of the observation that the equations in $\mathsf{L}^{k+1}_{\text{iso}}(G, H)$ can be viewed as equations in $\mathsf{PW}^{k+1}(G, H)$ where specific k-basal graphs model the continuity and compatibility equations of $\mathsf{L}^{k+1}_{\text{iso}}(G, H)$. Building on Theorem 22, we obtain the following theorem implying Theorem 1.

▶ **Theorem 23.** *For $k \geq 1$ and graphs G and H, the following are equivalent:*

1. *G and H are homomorphism indistinguishable over the class of graphs of pathwidth at most k.*
2. *The system of equations $\mathsf{PW}^{k+1}(G,H)$ has a rational solution.*
3. *The system of equations $\mathsf{L}^{k+1}_{\mathrm{iso}}(G,H)$ has a rational solution.*

Moreover, we show that $\mathsf{PW}^{k+1}(G,H)$ has a non-negative rational solution if and only if $\mathsf{L}^{k+1}_{\mathrm{iso}}(G,H)$ has a non-negative rational solution. Consequently, the system of linear equations $\mathsf{PW}^{k+1}(G,H)$ has a non-negative rational solution if and only if G and H are homomorphism indistinguishable over graphs of treewidth at most k. Hence, the systems of equations $\mathsf{PW}^{k+1}(G,H)$, for $k \in \mathbb{N}$, form an alternative well-motivated hierarchy of linear programming relaxations of the graph isomorphism problem. The details are deferred to the full version.

6 Multi-Labelled Graphs and Homomorphisms from Graphs of Bounded Treewidth and -depth

By considering k-labelled graphs, we complete the picture emerging in Sections 3 and 4, where respectively 1-labelled and (k,k)-bilabelled graphs were considered. In virtue of a generalisation of Theorem 13, a representation-theoretic characterisation of indistinguishability with respect to the k-dimensional Weisfeiler–Leman algorithm (k-WL, see [19] for its definition) is obtained. Amounting [14] to a characterisation of homomorphism indistinguishability over the class of graphs of treewidth at most k, this goal is achieved by constructing, given a k-WL colouring, a representation-theoretic object, the *colouring algebra*, such that two graphs are not distinguished by k-WL if and only if the associated colouring algebras are isomorphic. It turns out that the well-known algebraic characterisation of 2-WL indistinguishability formulated in the language of coherent algebras [10] is a special case of this correspondence. Finally, a combination of the techniques developed in this article yields an equational characterisation of homomorphism indistinguishability over graphs of bounded treedepth. We set off by generalising Definition 12:

▶ **Definition 24.** *A set of k-labelled graphs $\mathcal{R}$ is* inner-product compatible *if $\mathbf{1}^k \in \mathcal{R}$ and for all $\boldsymbol{R}, \boldsymbol{S} \in \mathcal{R}$ there exists $\boldsymbol{T} \in \mathcal{R}$ such that $\langle \boldsymbol{R}, \boldsymbol{S} \rangle = \operatorname{soe} \boldsymbol{T}$.*

For example, the class $\mathcal{TW}^k$ of k-labelled graphs of treewidth k with all labels in a single bag is inner-product compatible. Another example is the class of 2-labelled planar graphs with labels placed on neighbouring vertices of the boundary of a single face. The following main theorem for k-labelled graphs can be derived analogously to Theorem 13.

▶ **Theorem 25.** *Let $k \geq 1$. Let $\mathcal{R}$ be an inner-product compatible set of k-labelled graphs. Let G and H be two graphs. Then the following are equivalent:*

1. *G and H are homomorphism indistinguishable over $\mathcal{R}$, that is for all $\boldsymbol{R} = (R, \boldsymbol{v}) \in \mathcal{R}$, $\hom(R,G) = \hom(R,H)$.*
2. *There exists a unitary $U \colon \mathbb{C}\mathcal{R}_G \to \mathbb{C}\mathcal{R}_H$ such that $U\boldsymbol{R}_G = \boldsymbol{R}_H$ for all $\boldsymbol{R} \in \mathcal{R}$.*
3. *There exists a pseudo-stochastic $X \in \mathbb{Q}^{V(H)^k \times V(G)^k}$ such that $X\boldsymbol{R}_G = \boldsymbol{R}_H$ for all $\boldsymbol{R} \in \mathcal{R}$.*

It turns out that Theorem 25 yields a characterisation of 2-WL indistinguishability in terms of coherent algebras (see [10, 23]): Given a graph G, let $X = (V(G); R_1, \dots, R_s)$ denote the binary relational structure encoding the 2-WL colouring of G. More precisely, each relation $R_i \subseteq V(G) \times V(G)$ corresponds to one of the 2-WL colour classes of G. The *adjacency algebra* $\mathbb{C}\mathcal{A}_G$ *of* G is the $\mathbb{C}$-span of the matrices A_i with $A_i(u,v) = 1$ iff $(u,v) \in R_i$ and zero otherwise. It follows from the properties of 2-WL [10, Theorem 2.3.6] that $\mathbb{C}\mathcal{A}_G$ is closed

under matrix products, Schur products, and Hermitian conjugations. In other words, it forms a *coherent algebra*. This construction yields the following algebraic characterisation of 2-WL indistinguishability [10, Proposition 2.3.17]: Two graphs G and H are 2-WL indistinguishable if and only if $\mathbb{C}\mathcal{A}_G$ and $\mathbb{C}\mathcal{A}_H$ are *isomorphic as coherent algebras*, i.e. there exists a vector space isomorphism $X\colon \mathbb{C}\mathcal{A}_G \to \mathbb{C}\mathcal{A}_H$ such that X respects the matrix and the Schur product. That is, for all $A, B \in \mathbb{C}\mathcal{A}_G$, $X(A \cdot B) = X(A) \cdot X(B)$ and $X(A \odot B) = X(A) \odot X(B)$.

Along these lines, it may be argued that adjacency algebras as coherent algebras are the adequate algebraic objects to capture 2-WL indistinguishability. For higher-dimensional WL we propose a similar construction: Informally, G and H are k-WL indistinguishable if and only if certain involution monoid representations closed under Schur products are isomorphic. The aforementioned characterisation of 2-WL will be recovered as a special case in Corollary 28.

More precisely, given a graph G with k-ary relational structure $X = (V(G); R_1, \dots, R_s)$ corresponding to its k-WL colouring, define its *k-WL colouring algebra* $\mathbb{C}\mathcal{A}^k_G$ as the $\mathbb{C}$-span of the tensors $A_i \in \mathbb{C}^{V(G)^k}$ with $A_i(\boldsymbol{u}) = 1$ iff $\boldsymbol{u} \in R_i$ and zero otherwise. The colouring algebra has a rich algebraic structure and is closed under various operations. In particular, it has an interpretation in terms of homomorphism tensors: Let $\mathcal{TW}^k$ denote the set of all k-labelled graphs of treewidth at most k where the labelled vertices all lie in the same bag. Furthermore, let $\mathcal{PWS}^k$ denote the set of (k,k)-bilabelled graphs $\boldsymbol{F} = (F, \boldsymbol{u}, \boldsymbol{v})$ such that F has a path decomposition of width at most k with $\boldsymbol{u}$ and $\boldsymbol{v}$ representing respectively the vertices in the leaf bags.[4] As before, $\mathcal{PWS}^k$ forms an involution monoid under concatenation and taking reverses. These observations are summarised in the following Theorem 26.

▶ **Theorem 26.** *Let G be a graph and let $k \geq 1$. Then*
1. $\mathbb{C}\mathcal{TW}^k_G = \mathbb{C}\mathcal{A}^k_G$,
2. $\mathbb{C}\mathcal{TW}^k_G$ *is closed under Schur products,*
3. *The map $\mathcal{PWS}^k \to \mathrm{End}(\mathbb{C}\mathcal{A}^k_G)$ is a subrepresentation of the involution monoid representation $\mathcal{PWS}^k \to \mathbb{C}^{V(G)^k \times V(G)^k}$ defined as $\boldsymbol{P} \mapsto \boldsymbol{P}_G$.*

The involved proof of Theorem 26 is deferred to the full version. Finally, a representation-theoretic characterisation of k-WL indistinguishability extending [14] can be obtained.

▶ **Theorem 27.** *Let $k \geq 1$. Let G and H be two graphs. Then the following are equivalent:*
1. *G and H are k-WL indistinguishable.*
2. *G and H are homomorphism indistinguishable over the class of graphs of treewidth at most k.*
3. *There exists an isomorphism of $\mathcal{PWS}^k$-representations $X\colon \mathbb{C}\mathcal{A}^k_G \to \mathbb{C}\mathcal{A}^k_H$ respecting the Schur product. That is, for all $A, B \in \mathbb{C}\mathcal{A}^k_G$ and $\boldsymbol{P} \in \mathcal{PWS}^k$, $X(A \odot B) = X(A) \odot X(B)$ and $X(\boldsymbol{P}_G A) = \boldsymbol{P}_H X(A)$.*

To illustrate that the colouring algebra for 2-WL coincides with the coherent algebra, we conclude with inferring Corollary 28 from Theorem 27.

▶ **Corollary 28** (e.g. [10, Proposition 2.3.17])**.** *Let G and H be graphs. Then G and H are 2-WL indistinguishable if and only if there exists a vector space isomorphism $X\colon \mathbb{C}\mathcal{A}_G \to \mathbb{C}\mathcal{A}_H$ such that X respects the matrix and the Schur product. That is, for all $A, B \in \mathbb{C}\mathcal{A}_G$, $X(A \cdot B) = X(A) \cdot X(B)$ and $X(A \odot B) = X(A) \odot X(B)$.*

[4] Observe that this is in contrast to Section 2.3, where the set $\mathcal{PW}^k$ of $(k+1, k+1)$-bilabelled graphs with underlying graphs of pathwidth at most k was considered. There, the labels are carried by vertices in the intersection of two adjacent bags, while here the labelled vertices must only lie in the same bag.

As a final application of our theory, we infer an equational characterisation of homomorphism indistinguishability over graphs of bounded treedepth. The *treedepth* [36] of a graph F is defined as the minimum height of an elimination forest of F, i.e. of a rooted forest T with $V(T) = V(F)$ such that every edge in F connects vertices that are in an ancestor-descendent relationship in T. In [17], it was shown that homomorphism indistinguishable over graphs of treedepth at most k corresponds to equivalence over the quantifier-rank-k fragment of first order logic with counting quantifiers. We extend this characterisation by proposing a linear system of equations very similar to the one for bounded pathwidth.

Let $k \geq 1$. For graphs G and H, consider the following system of equations $\mathsf{TD}^k(G, H)$ with variables $X(\boldsymbol{w}, \boldsymbol{v})$ for every pair of tuples $\boldsymbol{w} \in V(H)^\ell$ and $\boldsymbol{v} \in V(G)^\ell$ for $0 \leq \ell \leq k$. A length-ℓ pair $(\boldsymbol{w}, \boldsymbol{v})$ is said to be a *partial pseudo-isomorphism* if $\boldsymbol{v}_i = \boldsymbol{v}_{i+1} \iff \boldsymbol{w}_i = \boldsymbol{w}_{i+1}$ for all $i \in [\ell - 1]$ and $\{\boldsymbol{v}_i, \boldsymbol{v}_j\} \in E(G) \iff \{\boldsymbol{w}_i, \boldsymbol{w}_j\} \in E(H)$ for all $i, j \in [\ell]$. Note that in contrary to the partial isomorphisms appearing in [13], partial pseudo-isomorphism only need to preserve the equality of consecutive vertices in the domain tuple.

$\mathsf{TD}^k(G, H)$

$$\sum_{v' \in V(G)} X(\boldsymbol{w}w, \boldsymbol{v}v') = X(\boldsymbol{w}, \boldsymbol{v}) \quad \text{for all } w \in V(H) \text{ and } \boldsymbol{v} \in V(G)^\ell,\ \boldsymbol{w} \in V(H)^\ell \text{ where } 0 \leq \ell < k. \tag{TD1}$$

$$\sum_{w' \in V(H)} X(\boldsymbol{w}w', \boldsymbol{v}v) = X(\boldsymbol{w}, \boldsymbol{v}) \quad \text{for all } v \in V(G) \text{ and } \boldsymbol{v} \in V(G)^\ell,\ \boldsymbol{w} \in V(H)^\ell \text{ where } 0 \leq \ell < k. \tag{TD2}$$

$$X((), ()) = 1 \tag{TD3}$$

$$X(\boldsymbol{w}, \boldsymbol{v}) = 0 \quad \text{whenever } (\boldsymbol{w}, \boldsymbol{v}) \text{ is not a partial pseudo-isomorphism} \tag{TD4}$$

The proof of the following theorem is deferred to the full version.

▶ **Theorem 2.** *For every $k \geq 1$, the following are equivalent for two graphs G and H:*

1. *G and H are homomorphism indistinguishable over graphs of treedepth at most k,*
2. *The linear systems of equations $\mathsf{TD}^k(G, H)$ has a non-negative rational solution,*
3. *The linear systems of equations $\mathsf{TD}^k(G, H)$ has a rational solution.*

7 Concluding Remarks

We have developed an algebraic theory of homomorphism indistinguishability that allows us to reprove known results in a unified way and derive new characterisations of homomorphism indistinguishability over bounded degree trees, graphs of bounded treedepth, graphs of bounded cyclewidth, and graphs of bounded pathwidth. The latter answers an open question from [13].

Homomorphism indistinguishabilities over various graph classes can be viewed as similarity measures for graphs, and our new results as well as many previous results show that these are natural and robust. Yet homomorphism indistinguishability only yields equivalence relations, or families of equivalence relations, and not a "quantitative" distance measure. For many applications of graph similarity, such quantitative measures are needed. Interestingly, we can derive distance measure both from homomorphism indistinguishability and from the equational characterisations we study here. For a class $\mathcal{F}$ of graphs, we can consider the *homomorphism embedding* that maps graphs G to the vector in $\mathbb{R}^{\mathcal{F}}$ whose entries are the numbers $\hom(F, G)$ for graphs $F \in \mathcal{F}$. Then a norm on the space $\mathbb{R}^{\mathcal{F}}$ induces a graph (pseudo)metric. Such metrics give a generic family of graph kernels (see [18]). On the

equational side, a notion like fractional isomorphism induces a (pseudo)metric on graphs where the distance between graphs G and H is $\min_X \|X\boldsymbol{A}_G - \boldsymbol{A}_H X\|$, where X ranges over all doubly-stochastic matrices. It is a very interesting question whether the correspondence between the equivalence relations for homomorphism indistinguishability and feasibility of the systems of equations can be extended to the associated metrics. In the special case of isomorphism and homomorphism indistinguishability over all graphs, the theory of graph limits provides some answers [28]. This has recently been extended to fractional isomorphism and homomorphism indistinguishability over trees [5].

Downsampling for Testing and Learning in Product Distributions

Nathaniel Harms

Abstract

We study distribution-free property testing and learning problems where the unknown probability distribution is a product distribution over $\mathbb{R}^d$. For many important classes of functions, such as intersections of halfspaces, polynomial threshold functions, convex sets, and k-alternating functions, the known algorithms either have complexity that depends on the support size of the distribution, or are proven to work only for specific examples of product distributions. We introduce a general method, which we call *downsampling*, that resolves these issues. Downsampling uses a notion of "rectilinear isoperimetry" for product distributions, which further strengthens the connection between isoperimetry, testing and learning. Using this technique, we attain new efficient distribution-free algorithms under product distributions on $\mathbb{R}^d$:

1. A simpler proof for non-adaptive, one-sided monotonicity testing of functions $[n]^d \to \{0,1\}$, and improved sample complexity for testing monotonicity over unknown product distributions, from $O(d^7)$ [Black, Chakrabarty, & Seshadhri, SODA 2020] to $\widetilde{O}(d^3)$.
2. Polynomial-time agnostic learning algorithms for functions of a constant number of halfspaces, and constant-degree polynomial threshold functions;
3. An $\exp(O(d\log(dk)))$-time agnostic learning algorithm, and an $\exp(O(d\log(dk)))$-sample tolerant tester, for functions of k convex sets; and a $2^{\widetilde{O}(d)}$ sample-based one-sided tester for convex sets;
4. An $\exp\left(\widetilde{O}(k\sqrt{d})\right)$-time agnostic learning algorithm for k-alternating functions, and a sample-based tolerant tester with the same complexity.

1 Introduction

In property testing and learning, the goal is to design algorithms that use as little information as possible about the input while still being correct (with high probability). This includes using as little information as possible about the probability distribution against which correctness is measured. Information about the probability distribution could be in the form

of guarantees on this distribution (e.g. it is guaranteed to be uniform, or Gaussian), or in the form of samples from the distribution. So we want to minimize the requirements on this distribution, as well as the number of samples used by the algorithm.

Progress on high-dimensional property testing and learning problems is usually made by studying algorithms for the uniform distribution over the hypercube $\{\pm 1\}^d$, or the standard Gaussian distribution over $\mathbb{R}^d$, as the simplest case. For example, efficiently learning intersections of halfspaces is a major open problem in learning theory [23, 33], and progress on this problem has been made by studying the uniform distribution over the hypercube $\{\pm 1\}^d$ and the Gaussian as special cases [30, 34, 38]. Another important example is the class of degree-k polynomial threshold functions (PTFs). Unlike intersections of halfspaces, these can be efficiently learned in the PAC model [33], but *agnostic* learning is more challenging. Again, progress has been made by studying the hypercube [22]. An even more extreme example is the class of convex sets, which are not learnable in the distribution-free PAC model, because they have infinite VC dimension, but which become learnable under the Gaussian [34]. The uniform distribution over the hypercube and the Gaussian are both examples of *product distributions*, so the next natural question to ask is, can these results be generalized to any *unknown* product distribution? A partial answer was given by Blais, O'Donnell, & Wimmer [10] for some of these classes; in this paper we resolve this question.

Similar examples appear in the property testing literature. Distribution-free property testing and testing functions with domain $\mathbb{R}^d$ are emerging trends in the field (e.g. [2, 21, 29, 19, 26, 9]). Testing monotonicity is one of the most well-studied problems in property testing, and recent work [6] has extended this study to product distributions over domain $\mathbb{R}^d$. Work of Chakrabarty & Seshadhri [17], Khot, Minzer, & Safra [32], and Black, Chakrabarty, & Seshadhri [5, 6] has resulted in efficient $o(d)$-query algorithms for the hypercube $\{\pm 1\}^d$ [32] and the hypergrid $[n]^d$. Black, Chakrabarty, & Seshadhri [6] showed that testing monotonicity over unknown product distributions on $\mathbb{R}^d$ could be done with $\widetilde{O}(d^{5/6})$ queries and $O(d^7)$ samples. Their "domain reduction" method is intricate and specialized for the problem of testing monotonicity. We improve[1] the sample complexity to $\widetilde{O}(d^3)$ using a much simpler proof. We also generalize the testers of [18, 15] for convex sets and k-alternating functions, respectively, and provide new testers for arbitrary functions of convex sets.

This paper provides a general framework for designing distribution-free testing and learning algorithms under product distributions on $\mathbb{R}^d$, which may be finite or continuous. An algorithm is *distribution-free under product distributions* if it does not require any prior knowledge of the probability distribution, except the guarantee that it is a product distribution. The technique in this paper, which we call *downsampling*, improves upon previous methods (in particular, [6, 10]), in a few ways. It is more general and does not apply only to a specific type of algorithm [10] or a specific problem [6], and we use it to obtain many other results. It is conceptually simpler. And it allows quantitative improvements over both [10] and [6].

Organization

This paper is presented as an extended abstract, with the results, techniques, and definitions described in the main text, and most of the proofs given in the full version of the paper. We present our result for testing monotonicity in this extended abstract, as an example application of our techniques. In Section 1.1, we describe the main results of this paper in

[1] An early version of this paper proved a weaker result, with two-sided error and worse sample complexity.

context of the related work. In Section 1.2, we briefly describe the main techniques in the paper. Section 2 presents the definitions and lemmas required by the main results. Section 3 gives the proofs for our results on testing monotonicity. The remaining proofs are in the full version. For simplicity, continuous distributions are treated in the main text and the method for extending the results to finite distributions are handled separately.

1.1 Results

See Table 1 for a summary of our results on property testing, and Table 2 for a summary of our results on learning. Some standard definitions are as follows.

For a set $\mathcal{P}$ of distributions over X and a set $\mathcal{H}$ of functions $X \to \{\pm 1\}$, a *distribution-free* property testing algorithm for $\mathcal{H}$ under $\mathcal{P}$ is a randomized algorithm that is given a parameter $\epsilon > 0$. It has access to the input probability distribution $\mathcal{D} \in \mathcal{P}$ via a *sample oracle*, which returns an independent sample from $\mathcal{D}$. It has access to the input function $f : X \to \{\pm 1\}$ via a *query oracle*, which given query $x \in X$ returns the value $f(x)$. A *two-sided* distribution-free testing algorithm must satisfy:

1. If $f \in \mathcal{H}$ then the algorithm accepts with probability at least $2/3$;
2. If f is ϵ-far from $\mathcal{H}$ with respect to μ then the algorithm rejects with probability at least $2/3$.

A *one-sided* algorithm must accept with probability 1 when $f \in \mathcal{H}$. An (ϵ_1, ϵ_2)-*tolerant* tester must accept with probability at least $2/3$ when $\exists h \in \mathcal{H}$ such that $\mathbb{P}_{x \sim \mu}[f(x) \neq h(x)] \leq \epsilon_1$ and reject when f is ϵ_2-far from $\mathcal{H}$ with respect to μ.

In the *query model*, the queries to the query oracle can be arbitrary. In the *sample model*, the tester queries a point $x \in X$ if and only if x was obtained from the sample oracle. A tester in the query model is *adaptive* if it makes its choice of query based on the answers to previous queries. It is *non-adaptive* if it chooses its full set of queries in advance, before obtaining any of the answers. The *sample complexity* of an algorithm is the number of samples requested from the sample oracle. The *query complexity* of an algorithm is the number of queries made to the query oracle.

Let $\mathcal{H}$ be a set of functions $X \to \{\pm 1\}$ and let $\mathcal{P}$ be a set of probability distributions over X. A learning algorithm for $\mathcal{H}$ under $\mathcal{P}$ (in the *non-agnostic* or *realizable*) model is a randomized algorithm that receives a parameter $\epsilon > 0$ and has *sample access* to an input function $f \in \mathcal{H}$. Sample access means that the algorithm may request an independent random example $(x, f(x))$ where x is sampled from some input distribution $\mathcal{D} \in \mathcal{P}$. The algorithm is required to output a function $g : X \to \{\pm 1\}$ that, with probability $2/3$, satisfies the condition $\mathbb{P}_{x \sim \mathcal{D}}[f(x) \neq g(x)] \leq \epsilon$.

In the *agnostic* setting, the algorithm instead has sample access to an input distribution $\mathcal{D}$ over $X \times \{0, 1\}$ whose marginal over X is in $\mathcal{P}$ (i.e. it receives samples of the form $(x, b) \in X \times \{0, 1\}$). The algorithm is required to output a function $g : X \to \{\pm 1\}$ that, with probability $2/3$, satisfies the following condition: $\forall h \in \mathcal{H}$,

$$\mathbb{P}_{(x,b) \sim \mathcal{D}}[g(x) \neq b] \leq \mathbb{P}_{(x,b) \sim \mathcal{D}}[h(x) \neq b] + \epsilon \,.$$

A *proper* learning algorithm is one whose output must also satisfy $g \in \mathcal{H}$; otherwise it is *improper*.

1.1.1 Testing Monotonicity

Testing monotonicity is the problem of testing whether an unknown function $f : X \to \{0, 1\}$ is monotone, where X is a partial order. It is one of the most commonly studied problems in the field of property testing. Previous work on this problem has mostly focused on uniform

probability distributions (exceptions include [1, 28, 16, 9]) and finite domains. However, there is growing interest in property testing for functions on domain $\mathbb{R}^d$ ([2, 21, 29, 19, 26, 9]) and [6] generalized the problem to this domain.

Testing monotonicity under product distributions has been studied a few times. Ailon & Chazelle [1] gave a distribution-free monotonicity tester for real-valued functions under product distributions on $[n]^d$, with query complexity $O(\frac{1}{\epsilon}d2^d \log n)$. Chakrabarty *et al.* [16] improved this to $O(\frac{1}{\epsilon}d \log n)$ and gave a matching lower bound. This lower bound applies to the *real-valued* case. For the *boolean-valued* case, monotonicity testers under the uniform distribution on $\{\pm 1\}^d$ [17, 32] and $[n]^d$ [5, 6] are known with query complexity $o(d)$. In [6], an $o(d)$-query tester was given for domain $\mathbb{R}^d$. That paper showed that there is a one-sided, non-adaptive, distribution-free monotonicity tester under product distributions on $\mathbb{R}^d$, with query complexity $O\left(\frac{d^{5/6}}{\epsilon^{4/3}} \operatorname{poly}\log(d/\epsilon)\right)$ and sample complexity $O((d/\epsilon)^7)$. In this paper we improve the sample complexity to $\widetilde{O}((d/\epsilon)^3)$, while greatly simplifying the proof.

▶ **Theorem 1.1.** *There is a one-sided, non-adaptive ϵ-tester for monotonicity of functions $\mathbb{R}^d \to \{0,1\}$ that is distribution-free under (finite or continuous) product distributions, using*

$$O\left(\frac{d^{5/6}}{\epsilon^{4/3}} \operatorname{poly}\log(d/\epsilon)\right)$$

queries and $O(\frac{d^3}{\epsilon^3}\log(d/\epsilon))$ samples.

The main result of [6] is a "domain reduction" lemma, which shows that for any function $f : [n]^d \to \{0,1\}$, the distance to monotonicity (under the uniform distribution) is not significantly reduced by sampling a random subgrid S of $[n]^d$ with sides of length $k = O(d^7)$ and restricting f to the domain S. To prove this lemma, [6] develops specialized structural tools for analyzing the "violation graph" of f. The violation graph is a standard object in the study of testing monotonicity. Its vertices are points in the domain, and its edges are "violations of monotonicity": pairs of points $x \prec y$ in the partial order where $f(x) > f(y)$. The distance of f to monotonicity is related to the size of the maximum matching in this graph (due to a result of [25]). The main technical challenge of [6] is to show how to find large matchings in the violation graph under the random restriction to a subgrid, for which they do a "line-by-line analysis" to show how to preserve many of the matched endpoints on each line in the grid. Compared to the technique in our paper, their proof is highly specialized to testing monotone functions, and requires a much more technical analysis. Our result replaces this domain reduction method with a simpler and more general 2-page argument, and gives a different generalization to the distribution-free case. See Section 3 for the proofs.

1.1.2 Learning Functions of Halfspaces

Intersections of k halfspaces have VC dimension $\Theta(dk \log k)$ [14, 20], so the sample complexity of learning is known, but it is not possible to efficiently find k halfspaces whose intersection is correct on the sample, unless $\mathsf{P} = \mathsf{NP}$ [13]. Therefore the goal is to find efficient "improper" algorithms that output a function other than an intersection of k halfspaces. Several learning algorithms for intersections of k halfspaces actually work for arbitrary functions of k halfspaces. We will write $\mathcal{B}_k$ for the set of all functions $\{0,1\}^k \to \{0,1\}$, and for any class $\mathcal{F}$ of functions we will write $\mathcal{B}_k \circ \mathcal{F}$ as the set of all functions $x \mapsto g(f_1(x), \ldots, f_k(x))$ where $g \in \mathcal{B}_k$ and each $f_i \in \mathcal{F}$. Then for $\mathcal{H}$ the class of halfspaces, Klivans, O'Donnell, & Servedio [33] gave a (non-agnostic) learning algorithm for $\mathcal{B}_k \circ \mathcal{H}$ over the uniform distribution on $\{\pm 1\}^d$ with complexity $d^{O(k^2/\epsilon^2)}$, Kalai, Klivans, Mansour, & Servedio [30] presented an agnostic algorithm with complexity $d^{O(k^2/\epsilon^4)}$ in the same setting using "polynomial regression".

Table 1 Testing results.

	$\mathsf{unif}(\{\pm 1\}^d)$	$\mathsf{unif}([n]^d)$	Gaussian	$\forall$ Products
1-Sided Testing Monotonicity (Query model)	$\widetilde{O}\left(\frac{\sqrt{d}}{\epsilon^2}\right)$ [32]	$\widetilde{O}\left(\frac{d^{5/6}}{\epsilon^{4/3}}\right)$ [6]	$\widetilde{O}\left(\frac{d^{5/6}}{\epsilon^{4/3}}\right)$ [6]	$\widetilde{O}\left(\frac{d^{5/6}}{\epsilon^{4/3}}\right)$ queries, $\widetilde{O}\left(\left(\frac{d}{\epsilon}\right)^3\right)$ samples (Thm. 1.1)
1-Sided Testing Convex Sets (Sample model)	–	–	$\left(\frac{d}{\epsilon}\right)^{(1+o(1))d}$ $2^{\Omega(d)}$ [18]	$\left(\frac{d}{\epsilon}\right)^{(1+o(1))d}$ (Thm. 1.4)
Tolerant Testing Functions of k Convex Sets (Sample model)	–	–	–	$\left(\frac{dk}{\epsilon}\right)^{O(d)}$ (Thm. 1.5)
Tolerant Testing k-Alternating Functions (Sample model)	–	$\left(\frac{dk}{\tau}\right)^{O\left(\frac{k\sqrt{d}}{\tau^2}\right)}$ $\tau = \epsilon_2 - 3\epsilon_1$ [15]	–	$\left(\frac{dk}{\tau}\right)^{O\left(\frac{k\sqrt{d}}{\tau^2}\right)}$ $\tau = \epsilon_2 - \epsilon_1$ (Thm. 1.8)

Polynomial regression is a powerful technique, so it is important to understand when it can be applied. Blais, O'Donnell, & Wimmer [10] studied how to generalize it to arbitrary product distributions. With their method, they obtained an agnostic learning algorithm for $\mathcal{B}_k \circ \mathcal{H}$ with complexity $(dn)^{O(k^2/\epsilon^4)}$ for product distributions $X_1 \times \cdots \times X_d$ where each $|X_i| = n$, and complexity $d^{O(k^2/\epsilon^4)}$ for the "polynomially bounded" continuous distributions. This is not a complete generalization, because, for example, on the grid $[n]^d$ its complexity depends on n. This prevents a full generalization to the domain $\mathbb{R}^d$. Their algorithm also requires some prior knowledge of the support or support size. We use a different technique and fully generalize the polynomial regression algorithm to arbitrary product distributions. See the full version for the proof.

▶ **Theorem 1.2.** *There is an improper agnostic learning algorithm for $\mathcal{B}_k \circ \mathcal{H}$, which is distribution-free under (continuous or finite) product distributions over $\mathbb{R}^d$, with time complexity*

$$\min\left\{\left(\frac{dk}{\epsilon}\right)^{O\left(\frac{k^2}{\epsilon^4}\right)}, O\left(\frac{1}{\epsilon^2}\left(\frac{3dk}{\epsilon}\right)^d\right)\right\}.$$

1.1.3 Learning Polynomial Threshold Functions

Degree-k PTFs are another generalization of halfspaces. A function $f : \mathbb{R}^d \to \{\pm 1\}$ is a degree-k PTF if there is a degree-k polynomial $p : \mathbb{R}^d \to \mathbb{R}$ such that $f(x) = \operatorname{sign}(p(x))$. Degree-$k$ PTFs can be PAC learned in time $d^{O(k)}$ using linear programming [33], but agnostic learning is more challenging. Diakonikolas *et al.* [22] previously gave an agnostic learning algorithm for degree-k PTFs in the uniform distribution over $\{\pm 1\}^d$ with time complexity $d^{\psi(k,\epsilon)}$, where

$$\psi(k,\epsilon) := \min\left\{O(\epsilon^{-2^{k+1}}), 2^{O(k^2)}\left(\log(1/\epsilon)/\epsilon^2\right)^{4k+2}\right\}.$$

The main result of that paper is an upper bound on the noise sensitivity of PTFs. Combined with the reduction of [10], this implies an algorithm for the uniform distribution over $[n]^d$ with complexity $(dn)^{\psi(k,\epsilon)}$ and for the Gaussian distribution with complexity $d^{\psi(k,\epsilon)}$.

Table 2 *Learning results. All learning algorithms are agnostic except that of [38]. The PTF result for the Gaussian follows from the two cited works but is not stated in either. All statements are informal, see references for restrictions and qualifications. For PTFs,* $\psi(k,\epsilon) := \min\left\{O(\epsilon^{-2^{k+1}}), 2^{O(k^2)}\left(\log(1/\epsilon)/\epsilon^2\right)^{4k+2}\right\}$.

	$\mathsf{unif}(\{\pm1\}^d)$	$\mathsf{unif}([n]^d)$	Gaussian	$\forall$ Products
Functions of k Convex Sets	$\Omega(2^d)$	–	$d^{O\left(\frac{\sqrt{d}}{\epsilon^4}\right)}, 2^{\Omega(\sqrt{d})}$ [34]	$O\left(\frac{1}{\epsilon^2}\left(\frac{6dk}{\epsilon}\right)^d\right)$ (Thm. 1.6)
Functions of k Halfspaces	$d^{O\left(\frac{k^2}{\epsilon^4}\right)}$ [30]	$(dn)^{O\left(\frac{k^2}{\epsilon^4}\right)}$ [10]	$d^{O\left(\frac{\log k}{\epsilon^4}\right)}$, poly $\left(d, \left(\frac{k}{\epsilon}\right)^k\right)$ [34, 38] (Intersections only)	$\left(\frac{dk}{\epsilon}\right)^{O\left(\frac{k^2}{\epsilon^4}\right)}$ (Thm. 1.2)
Degree-k PTFs	$d^{\psi(k,\epsilon)}$ [22]	$(dn)^{\psi(k,\epsilon)}$ [22, 10]	$d^{\psi(k,\epsilon)}$ [22, 10]	$\left(\frac{dk}{\epsilon}\right)^{\psi(k,\epsilon)}$ (Thm. 1.3)
k-Alternating Functions	$2^{\Theta\left(\frac{k\sqrt{d}}{\epsilon}\right)}$ [8]	$\left(\frac{dk}{\tau}\right)^{O\left(\frac{k\sqrt{d}}{\tau^2}\right)}$ (Testing) [15]	–	$\left(\frac{dk}{\epsilon}\right)^{O\left(\frac{k\sqrt{d}}{\epsilon^2}\right)}$ (Thm. 1.7)

Our agnostic learning algorithm for degree-k PTFs eliminates the dependence on n and works for any unknown product distribution over $\mathbb{R}^n$, while matching the complexity of [22] for the uniform distribution over the hypercube. See the full version for the proof.

▶ **Theorem 1.3.** *There is an improper agnostic learning algorithm for degree-k PTFs, which is distribution-free under (finite or continuous) product distributions over* $\mathbb{R}^d$*, with time complexity*

$$\min\left\{\left(\frac{kd}{\epsilon}\right)^{\psi(k,\epsilon)}, O\left(\frac{1}{\epsilon^2}\left(\frac{9dk}{\epsilon}\right)^d\right)\right\}.$$

1.1.4 Testing & Learning Convex Sets

One of the first properties (sets) of functions $\mathbb{R}^d \to \{0,1\}$ to be studied in the property testing literature is the set of indicator functions of convex sets, i.e. functions $f : \mathbb{R}^d \to \{0,1\}$ where $f^{-1}(1)$ is convex. Write $\mathcal{C}$ for this class of functions. This problem has been studied in various models of testing [36, 35, 18, 4, 7]. In this paper we consider the *sample-based* model of testing, where the tester receives only random examples of the function and cannot make queries. This model of testing has received a lot of recent attention (e.g. [2, 4, 12, 18, 27, 29, 37, 9]), partly because it matches the standard sample-based model for learning algorithms.

Chen *et al.* [18] gave a sample-based tester for $\mathcal{C}$ under the Gaussian distribution on $\mathbb{R}^d$ with one-sided error and sample complexity $(d/\epsilon)^{O(d)}$, along with a lower bound (for one-sided testers) of $2^{\Omega(d)}$. We match their upper bound while generalizing the tester to be distribution-free under product distributions. See the full version for proofs.

▶ **Theorem 1.4.** *There is a sample-based one-sided* ϵ*-tester for* $\mathcal{C}$ *which is distribution-free under (finite or continuous) product distributions that uses at most* $O\left(\left(\frac{6d}{\epsilon}\right)^d\right)$ *samples.*

A more powerful kind of tester is an (ϵ_1, ϵ_2)-*tolerant* tester, which must accept (with high probability) any function that is ϵ_1-close to the property, while rejecting functions that are ϵ_2-far. Tolerantly testing convex sets has been studied by [3] for the uniform distribution

over the 2-dimensional grid, but not (to the best of our knowledge) in higher dimensions. We obtain a sample-based tolerant tester (and distance) approximator for convex sets in high dimension. In fact, recall that $\mathcal{B}_k$ is the set of all functions $\{0,1\}^k \to \{0,1\}$ and $\mathcal{B}' \subset \mathcal{B}_k$ any subset, so $\mathcal{B}' \circ \mathcal{C}$ is any property of functions of convex sets. We obtain a distance approximator for any such property:

▶ **Theorem 1.5.** *Let $\mathcal{B}' \subset \mathcal{B}_k$. There is a sample-based algorithm, which is distribution-free under (finite or continuous) product distributions, that approximates distance to $\mathcal{B}' \circ \mathcal{C}$ up to additive error ϵ using $O\left(\frac{1}{\epsilon^2}\left(\frac{3dk}{\epsilon}\right)^d\right)$ samples. Setting $\epsilon = (\epsilon_2 - \epsilon_1)/2$ we obtain an (ϵ_1, ϵ_2)-tolerant tester with sample complexity $O\left(\frac{1}{(\epsilon_2-\epsilon_1)^2}\left(\frac{6dk}{\epsilon_2-\epsilon_1}\right)^d\right)$.*

General distribution-free learning of convex sets is not possible, since this class has infinite VC dimension. However, they can be learned under the Gaussian distribution. Non-agnostic learning under the Gaussian was studied by Vempala [38, 39]. Agnostic learning under the Gaussian was studied by Klivans, O'Donnell, & Servedio [34] who presented a learning algorithm with complexity $d^{O(\sqrt{d}/\epsilon^4)}$, and a lower bound of $2^{\Omega(\sqrt{d})}$.

Unlike the Gaussian, there is a trivial lower bound of $\Omega(2^d)$ in arbitrary product distributions, because any function $f : \{\pm 1\}^d \to \{0,1\}$ belongs to this class. However, unlike the general distribution-free case, we show that convex sets (or any functions of convex sets) can be learned under unknown product distributions.

▶ **Theorem 1.6.** *There is an agnostic learning algorithm for $\mathcal{B}_k \circ \mathcal{C}$, which is distribution-free under (finite or continuous) product distributions over $\mathbb{R}^d$, with time complexity $O\left(\frac{1}{\epsilon^2} \cdot \left(\frac{6dk}{\epsilon}\right)^d\right)$.*

1.1.5 Testing & Learning k-Alternating Functions

A k-alternating function $f : X \to \{\pm 1\}$ on a partial order X is one where for any chain $x_1 < \cdots < x_m$ in X, f changes value at most k times. Learning k-alternating functions on domain $\{\pm 1\}^d$ was studied by Blais *et al.* [8], motivated by the fact that these functions are computed by circuits with few negation gates. They show that $2^{\Theta(k\sqrt{d}/\epsilon)}$ samples are necessary and sufficient in this setting. Canonne *et al.* [15] later obtained an algorithm for (ϵ_1, ϵ_2)-tolerant testing k-alternating functions, when $\epsilon_2 > 3\epsilon_1$, in the uniform distribution over $[n]^d$, with query complexity $(kd/\tau)^{O(k\sqrt{d}/\tau^2)}$, where $\tau = \epsilon_2 - 3\epsilon_1$.

We obtain an agnostic learning algorithm for k-alternating functions that matches the query complexity of the tester in [15], and nearly matches the complexity of the (non-agnostic) learning algorithm of [8] for the uniform distribution over the hypercube. See the full version for proofs.

▶ **Theorem 1.7.** *There is an agnostic learning algorithm for k-alternating functions, which is distribution-free under (finite or continuous) product distributions over $\mathbb{R}^d$, that runs in time at most*

$$\min\left\{\left(\frac{dk}{\epsilon}\right)^{O\left(\frac{k\sqrt{d}}{\epsilon^2}\right)}, O\left(\frac{1}{\epsilon^2}\left(\frac{3kd}{\epsilon}\right)^d\right)\right\}.$$

We also generalize the tolerant tester of [15] to be distribution-free under product distributions, and eliminate the condition $\epsilon_2 > 3\epsilon_1$.

▶ **Theorem 1.8.** *For any $\epsilon_2 > \epsilon_1 > 0$, let $\tau = (\epsilon_2 - \epsilon_1)/2$, there is a sample-based (ϵ_1, ϵ_2)-tolerant tester for k-alternating functions using $\left(\frac{dk}{\tau}\right)^{O\left(\frac{k\sqrt{d}}{\tau^2}\right)}$ samples, which is distribution-free under (finite or continuous) product distributions over $\mathbb{R}^d$.*

1.2 Techniques

What connects these diverse problems is a notion of rectilinear surface area or isoperimetry that we call "block boundary size". There is a close connection between learning & testing and various notions of isoperimetry or surface area (e.g. [17, 33, 34, 32]). We show that testing or learning a class $\mathcal{H}$ on product distributions over $\mathbb{R}^d$ can be reduced to testing and learning on the *uniform* distribution over $[r]^d$, where r is determined by the block boundary size, and we call this reduction "downsampling". The name *downsampling* is used in image and signal processing for the process of reducing the resolution of an image or reducing the number of discrete samples used to represent an analog signal. We adopt the name because our method can be described by analogy to image or signal processing as the following 2-step process:

1. Construct a "digitized" or "pixellated" image of the function $f : \mathbb{R}^d \to \{\pm 1\}$ by sampling from the distribution and constructing a grid in which each cell has roughly equal probability mass; and
2. Learn or test the "low-resolution" pixellated function.

As long as the function f takes a constant value in the vast majority of "pixels", the low resolution version seen by the algorithm is a good enough approximation for testing or learning. The block boundary size is, informally, the number of pixels on which f is not constant.

This technique reduces distribution-free testing and learning problems to the uniform distribution in a way that is conceptually simpler than in the prior work [10, 6]. However, some technical challenges remain. The first is that it is not always easy to bound the number of "pixels" on which a function f is not constant – for example, for PTFs. Second, unlike in the uniform distribution, the resulting downsampled function class on $[r]^d$ is not necessarily "the same" as the original class – for example, halfspaces on $\mathbb{R}^d$ are not downsampled to halfspaces on $[r]^d$, since the "pixels" are not of equal size. Thus, geometric arguments may not work, unlike the case for actual images.

A similar technique of constructing "low-resolution" representations of the input has been used and rediscovered ad-hoc a few times in the property testing literature, but only for the uniform distribution over $[n]^d$ [31, 36, 24, 12, 15], or the Gaussian in [18]. With this paper, we aim to provide a unified and generalized study of this simple and powerful technique.

1.3 Block Boundary Size

Informally, we define the *r-block boundary size* $\mathsf{bbs}(\mathcal{H}, r)$ of a class $\mathcal{H}$ of functions $\mathbb{R}^d \to \{0, 1\}$ as the maximum number of grid cells on which a function $f \in \mathcal{H}$ is non-constant, over all possible $r \times \cdots \times r$ grid partitions of $\mathbb{R}^d$ (which are not necessarily evenly spaced) – see Section 2 for formal definitions. Whether downsampling can be applied to $\mathcal{H}$ depends on whether

$$\lim_{r \to \infty} \frac{\mathsf{bbs}(\mathcal{H}, r)}{r^d} \to 0\,,$$

and the complexity of the algorithms depends on how large r must be for the non-constant blocks to vanish relative to the whole r^d grid. A general observation is that any function class $\mathcal{H}$ where downsampling can be applied can be learned under unknown product distributions with a finite number of samples; for example, this holds for convex sets even though the VC dimension is infinite.

▶ **Proposition 1.9.** *Let $\mathcal{H}$ be any set of functions $\mathbb{R}^d \to \{0,1\}$ (measurable with respect to continuous product distributions) such that*

$$\lim_{r\to\infty} \frac{\mathsf{bbs}(\mathcal{H}, r)}{r^d} = 0\,.$$

Then there is some function $\sigma(d,\epsilon)$ such that $\mathcal{H}$ is distribution-free learnable under product distributions, up to error ϵ, with $\sigma(d,\epsilon)$ samples.

For convex sets, monotone functions, k-alternating functions, and halfspaces, $\mathsf{bbs}(\mathcal{H}, r)$ is easy to calculate. For degree-k PTFs, it is more challenging – it requires proving a bound on the number of unevenly-spaced grid cells in $\mathbb{R}^d$ in which a degree-k multivariate polynomial might take the value 0; this result may be of independent interest.

We obtain this result by proving a more general lemma. We say that a function $f : \mathbb{R}^d \to \{0,1\}$ induces a connected component S if for every $x, y \in S$ there is a continuous curve in $\mathbb{R}^d$ from x to y such that $f(z) = f(x) = f(y)$ for all z on the curve, and S is a maximal such set. Then we prove a general lemma that bounds the block boundary size by the number of connected components induced by functions $f \in \mathcal{H}$.

▶ **Lemma 1.10** (Informal, see full version). *Suppose that for any axis-aligned affine subspace A of affine dimension $n \le d$, and any function $f \in \mathcal{H}$, f induces at most k^n connected components in A. Then for $r = \Omega(dk/\epsilon)$, $\mathsf{bbs}(\mathcal{H}, r) \le \epsilon \cdot r^d$.*

This lemma in fact generalizes all computations of block boundary size in this paper (up to constant factors in r). Using a theorem of Warren [40], we get the following corollary:

▶ **Corollary 1.11** (Informal, see full version). *Let $p : \mathbb{R}^d \to \mathbb{R}$ be a degree-k polynomial, and let $\epsilon > 0$. For $r \ge 3\sqrt{24}dk/\epsilon$ and any $r \times \cdots \times r$ grid partition of $\mathbb{R}^d$, p takes value 0 in at most ϵr^d grid cells.*

1.4 Polynomial Regression

The second step of downsampling is to find a testing or learning algorithm that works for the uniform distribution over the (not necessarily evenly-spaced) hypergrid. Most of our learning results use *polynomial regression*. This is a powerful technique introduced in [30] that performs linear regression over a vector space of functions that approximately spans the hypothesis class. This method is usually applied by using Fourier analysis to construct such an approximate basis for the hypothesis class [10, 22, 15]. This was the method used, for example, by Blais, O'Donnell, & Wimmer [10] to achieve the poly(dn)-time algorithms for intersections of halfspaces.

We take the same approach but we use the Walsh basis for functions on domain $[n]^d$ (see e.g. [11]) instead of the bases used in the prior works. We show that if one can establish bounds on the noise sensitivity in the Fourier basis for the hypothesis class restricted to the uniform distribution over $\{\pm 1\}^d$, then one gets a bound on the number of Walsh functions required to approximately span the "downsampled" hypothesis class. In this way, we establish that if one can apply standard Fourier-analytic techniques to the hypothesis class over the *uniform* distribution on $\{\pm 1\}^d$ and calculate the block boundary size, then the results for the hypercube essentially carry over to product distributions on $\mathbb{R}^d$.

An advantage of this technique is that both noise sensitivity and block boundary size grow at most linearly during function composition: for functions $f(x) = g(h_1(x), \ldots, h_k(x))$ where each h_i belongs to the class $\mathcal{H}$, the noise sensitivity and block boundary size grow at most linearly in k. Therefore learning results for $\mathcal{H}$ obtained in this way are easy to extend to arbitrary compositions of $\mathcal{H}$, which is how we get our result for intersections of halfspaces.

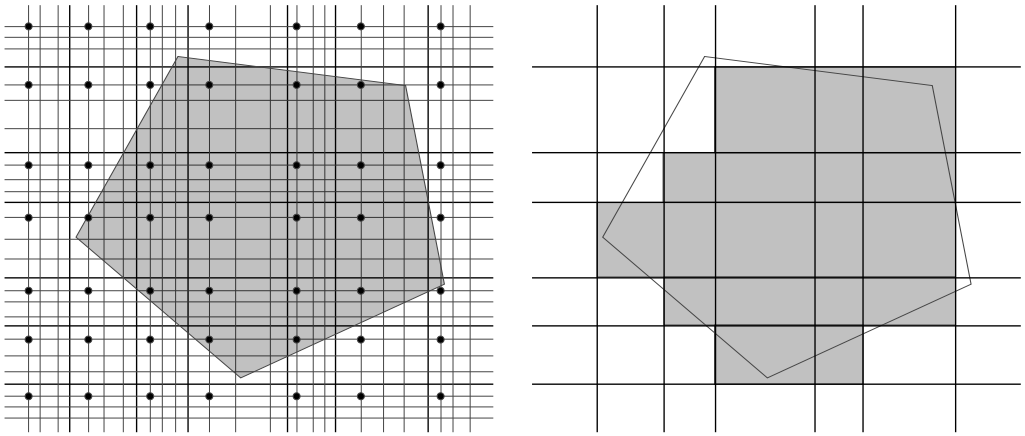

Figure 1 Left: Random grid X (pale lines) with induced block partition (thick lines) and blockpoint values (dots), superimposed on $f^{-1}(1)$ (gray polygon). Right: f^{coarse} (grey) compared to f (polygon outline).

2 Downsampling

We will now introduce the main definitions, notation, and lemmas required by our main results. The purpose of this section is to establish the main conceptual component of the downsampling technique: that functions with small enough block boundary size can be efficiently well-approximated by a "coarsened" version of the function that is obtained by random sampling. See Figure 1 for an illustration of the following definitions.

▶ **Definition 2.1** (Block Partitions). *An* r-block partition *of* $\mathbb{R}^d$ *is a pair of functions* $\mathsf{block} : \mathbb{R}^d \to [r]^d$ *and* $\mathsf{blockpoint} : [r]^d \to \mathbb{R}^d$ *obtained as follows. For each* $i \in [d], j \in [r-1]$ *let* $a_{i,j} \in \mathbb{R}$ *such that* $a_{i,j} < a_{i,j+1}$ *and define* $a_{i,0} = -\infty, a_{i,r} = \infty$ *for each* i*. For each* $i \in [d], j \in [r]$ *define the interval* $B_{i,j} = (a_{i,j-1}, a_{i,j}]$ *and a point* $b_{i,j} \in B_{i,j}$*. The function* $\mathsf{block} : \mathbb{R}^d \to [r]^d$ *is defined by setting* $\mathsf{block}(x)$ *to be the unique vector* $v \in [r]^d$ *such that* $x_i \in B_{i,v_i}$ *for each* $i \in [d]$*. The function* $\mathsf{blockpoint} : [r]^d \to \mathbb{R}^d$ *is defined by setting* $\mathsf{blockpoint}(v) = (b_{1,v_1}, \ldots, b_{d,v_d})$*; note that* $\mathsf{blockpoint}(v) \in \mathsf{block}^{-1}(v)$ *where* $\mathsf{block}^{-1}(v) = \{x \in \mathbb{R}^d : \mathsf{block}(x) = v\}$.

▶ **Definition 2.2** (Block Functions and Coarse Functions). *For a function* $f : \mathbb{R}^d \to \{\pm 1\}$*, we define* $f^{\mathsf{block}} : [r]^d \to \{\pm 1\}$ *as* $f^{\mathsf{block}} := f \circ \mathsf{blockpoint}$ *and* $f^{\mathsf{coarse}} : \mathbb{R}^d \to \mathbb{R}$ *as* $f^{\mathsf{coarse}} := f^{\mathsf{block}} \circ \mathsf{block} = f \circ \mathsf{blockpoint} \circ \mathsf{block}$*. For any set* $\mathcal{H}$ *of functions* $\mathbb{R}^d \to \{\pm 1\}$*, we define* $\mathcal{H}^{\mathsf{block}} := \{f^{\mathsf{block}} \mid f \in \mathcal{H}\}$*. For a distribution* μ *over* $\mathbb{R}^d$ *and an* r*-block partition* $\mathsf{block} : \mathbb{R}^d \to [r]^d$ *we define the distribution* $\mathsf{block}(\mu)$ *over* $[r]^d$ *as the distribution of* $\mathsf{block}(x)$ *for* $x \sim \mu$.

▶ **Definition 2.3** (Induced Block Partitions). *When* μ *is a product distribution over* $\mathbb{R}^d$*, a* random grid X *of length* m *is the grid obtained by sampling* m *points* $x_1, \ldots, x_m \in \mathbb{R}^d$ *independently from* μ *and for each* $i \in [d], j \in [m]$ *defining* $X_{i,j}$ *to be the* j^{th}*-smallest coordinate in dimension* i *among all sampled points. For any* r *that divides* m *we define an* r*-block partition depending on* X *by defining for each* $i \in [d], j \in [r-1]$ *the point* $a_{i,j} = X_{i,mj/r}$ *so that the intervals are* $B_{i,j} := (X_{i,m(j-1)/r}, X_{i,mj/r}]$ *when* $j \in \{2, \ldots, r-1\}$ *and* $B_{i,1} = (-\infty, X_{i,m/r}], B_{i,r} = (X_{i,m(r-1)/r}, \infty)$*; we let the points* $b_{i,j}$ *defining* blockpoint *be arbitrary. This is the* r*-block partition* induced *by* X.

▶ **Definition 2.4** (Block Boundary Size). *For a block partition* $\mathsf{block} : \mathbb{R}^d \to [r]^d$*, a distribution* μ *over* $\mathbb{R}^d$*, and a function* $f : \mathbb{R}^d \to \{\pm 1\}$*, we say* f *is* non-constant *on a block* $v \in [r]^d$ *if there are sets* $S, T \subset \mathsf{block}^{-1}(v)$ *such that* $\forall s \in S, t \in T : f(s) = 1, f(t) = -1$*; and* S, T *have positive measure (in the product of Lebesgue measures). For a function* $f : \mathbb{R}^d \to \{\pm 1\}$ *and a number* r*, we define the* r*-block boundary size* $\mathsf{bbs}(f, r)$ *as the maximum number of blocks on which* f *is non-constant, where the maximum is taken over all* r*-block partitions* $\mathsf{block} : \mathbb{R}^d \to [r]^d$*. For a set* $\mathcal{H}$ *of functions* $\mathbb{R}^d \to \{\pm 1\}$*, we define* $\mathsf{bbs}(\mathcal{H}, r) := \max\{\mathsf{bbs}(f, r) \mid f \in \mathcal{H}\}$.

The *total variation distance* between two distributions μ, ν over a finite domain $\mathcal{X}$ is defined as

$$\|\mu - \nu\|_{\mathsf{TV}} := \frac{1}{2} \sum_{x \in \mathcal{X}} |\mu(x) - \nu(x)| = \max_{S \subseteq \mathcal{X}} |\mu(S) - \nu(S)| .$$

The essence of downsampling is apparent in the next proposition. It shows that the distance of f to its coarsened version f^{coarse} is bounded by two quantities: the fraction of blocks in the r-block partition on which f is not constant, and the distance of the distribution $\mathsf{block}(\mu)$ to uniform. When both quantities are small, testing or learning f can be done by testing or learning f^{coarse} instead. The uniform distribution over a set S is denoted $\mathsf{unif}(S)$:

▶ **Proposition 2.5.** *Let* μ *be a continuous product distribution over* $\mathbb{R}^d$*, let* X *be a random grid, and let* $\mathsf{block} : \mathbb{R}^d \to [r]^d$ *be the induced* r*-block partition. Then, for any measurable* $f : \mathbb{R}^d \to \{\pm 1\}$*, the following holds with probability 1 over the choice of* X*:*

$$\mathop{\mathbb{P}}_{x \sim \mu} [f(x) \neq f^{\mathsf{coarse}}(x)] \leq r^{-d} \cdot \mathsf{bbs}(f, r) + \|\mathsf{block}(\mu) - \mathsf{unif}([r]^d)\|_{\mathsf{TV}} .$$

Proof. We first establish that, with probability 1 over X and $x \sim \mu$, if $f(x) \neq f^{\mathsf{coarse}}(x)$ then f is non-constant on $\mathsf{block}(x)$. Fix X and suppose there exists a set Z of positive measure such that for each $x \in Z, f(x) \neq f^{\mathsf{coarse}}(x)$ but f is not non-constant on $\mathsf{block}(x)$, i.e. for $V = \mathsf{block}^{-1}(\mathsf{block}(x))$, either $\mu(V \cap f^{-1}(1)) = \mu(V)$ or $\mu(V \cap f^{-1}(-1)) = \mu(V)$. Then there is $v \in [r]^d$ such that for $V = \mathsf{block}^{-1}(v)$, $\mu(Z \cap V) > 0$. Let $y = \mathsf{blockpoint}(v)$. If $\mu(V \cap f^{-1}(f(y)) = \mu(V)$ then $\mu(Z \cap V) = 0$, so $\mu(V \cap f^{-1}(f(y)) = 0$. But for random X, the probability that there exists $v \in [r]^d$ such that $\mu(V \cap f^{-1}(\mathsf{blockpoint}(v))) = 0$ is 0, since $\mathsf{blockpoint}(v)$ is random within V.

Assuming that the above event occurs,

$$\begin{aligned}\mathop{\mathbb{P}}_{x \sim \mu} [f(x) \neq f^{\mathsf{coarse}}(x)] &\leq \mathop{\mathbb{P}}_{x \sim \mu} [f \text{ is non-constant on } \mathsf{block}(x)] \\ &\leq \mathop{\mathbb{P}}_{v \sim [r]^d} [f \text{ is non-constant on } v] + \|\mathsf{block}(\mu) - \mathsf{unif}([r]^d)\|_{\mathsf{TV}} .\end{aligned}$$

Since $v \sim [r]^d$ is uniform, the probability of hitting a non-constant block is at most $r^{-d} \cdot \mathsf{bbs}(f, r)$. ◀

Next we give a bound on the number of samples required to ensure that $\mathsf{block}(\mu)$ is close to uniform. We need the following lemma.

▶ **Lemma 2.6.** *Let* μ *be continuous probability distribution over* $\mathbb{R}$*,* $m, r \in \mathbb{N}$ *such that* r *divides* m*, and* $\delta \in (0, 1/2)$*. Let* X *be a set of* m *points sampled independently from* μ*. Write* $X = \{x_1, \ldots, x_m\}$ *labeled such that* $x_1 < \cdots < x_m$ *(and write* $x_0 = -\infty$*). Then for any* $i \in [r]$*,*

$$\mathbb{P}\left[\mu\left(x_{(i-1)(m/r)}, x_{i(m/r)}\right] < \frac{1-\delta}{r}\right] \leq 4 \cdot e^{-\frac{\delta^2 m}{32r}} .$$

Proof. We assume that $i-1 \le r/2$. If $i-1 > r/2$ then we can repeat the following analysis with the opposite ordering on the points in X. Write $x^* = x_{(i-1)\frac{m}{r}}$ and $\beta = \mu(-\infty, x^*]$. First suppose that $(1-\delta/2)\frac{i-1}{r} < \beta < (1+\delta/2)\frac{i-1}{r} \le (1+\delta/2)/2$; we will bound the probability of this event later.

Let $t \in \mathbb{R}$ be the point such that $\mu(x^*, t] = (1-\delta)/r$ (which must exist since μ is continuous). Let $\eta = \frac{\delta}{1-\delta} \ge \delta$. Write $X^* = \{x \in X : x > x^*\}$. The expected value of $|X^* \cap (x^*, t]|$ is $|X^*|\frac{1-\delta}{r(1-\beta)} = \left(1 - \frac{i-1}{r}\right)\frac{1-\delta}{r(1-\beta)}$, where the factor $1-\beta$ in the denominator is due to the fact that each element of X^* is sampled from μ conditional on being larger than x^*. The event $\mu(x^*, x_{i(m/r)}] < (1-\delta)/r$ occurs if and only if $|X^* \cap (x^*, t]| > m/r$, which occurs with probability

$$\mathbb{P}\left[|X^* \cap (x^*, t]| > \frac{m}{r}\right] = \mathbb{P}\left[|X^* \cap (x^*, t]| > m\left(1 - \frac{(i-1)}{r}\right)\frac{1-\delta}{r(1-\beta)}(1+\eta)\right]$$

where

$$\begin{aligned} 1+\eta = \frac{(1-\beta)}{(1-\delta)\left(1-\frac{i-1}{r}\right)} &\ge \frac{\left(1-(1+\delta/2)\frac{i-1}{r}\right)}{(1-\delta)\left(1-\frac{i-1}{r}\right)} = \frac{1}{1-\delta}\left(1 - \frac{(\delta/2)(i-1)}{r-(i-1)}\right) \\ &\ge \frac{1-\delta/2}{1-\delta} = 1 + \frac{\delta}{2(1-\delta)} \ge 1+\delta/2\,. \end{aligned}$$

Since the expected value satisfies

$$|X^*|\frac{1-\delta}{r(1-\beta)} \ge \frac{m}{r}(1-\frac{i-1}{r})\frac{2(1-\delta)}{1-\delta/2} \ge \frac{m}{r}(1-\delta/2) \ge \frac{m}{2r}\,,$$

the Chernoff bound gives

$$\mathbb{P}\left[|X^* \cap (x^*, t]| > \frac{m}{r}\right] \le \exp\left(-\frac{\delta^2|X^*|(1-\delta)}{3\cdot 4\cdot r(1-\beta)}\right) \le e^{-\frac{\delta^2 m}{3\cdot 4\cdot 2r}}\,.$$

Now let $t \in \mathbb{R}$ be the point such that $\mu(x^*, t] = (1+\delta)/r$. The expected value of $|X^* \cap (x^*, t]|$ is now $|X^*|\frac{1+\delta}{r(1-\beta)}$. The event $\mu(x^*, x_{i(m/r)}] > (1+\delta)/r$ occurs if and only if $|X^* \cap (x^*, t]| < m/r$, which occurs with probability

$$\mathbb{P}\left[|X^* \cap (x^*, t]| < \frac{m}{r}\right] = \mathbb{P}\left[|X^* \cap (x^*, t]| < m\left(1 - \frac{i-1}{r}\right)\frac{1+\delta}{r(1-\beta)}(1-\eta)\right]$$

where

$$\begin{aligned} 1-\eta = \frac{1-\beta}{(1+\delta)(1-\frac{i-1}{r})} &\le \frac{1-(1+\delta/2)\frac{i-1}{r}}{(1+\delta)\left(1-\frac{i-1}{r}\right)} = \frac{1}{1+\delta}\left(1 + \frac{(\delta/2)(i-1)}{r-(i-1)}\right) \\ &\le \frac{1+\delta/2}{1+\delta} = 1 - \frac{\delta/2}{1+\delta} \le 1 - \frac{\delta}{4}\,. \end{aligned}$$

The expected value satisfies $|X^*|\frac{1+\delta}{r(1-\beta)} > m/r$, so the Chernoff bound gives

$$\mathbb{P}\left[|X^* \cap (x^*, t]| < \frac{m}{r}\right] \le \exp\left(-\frac{\delta^2|X^*|(1+\delta)}{2\cdot 4^2\cdot r(1-\beta)}\right) \le e^{-\frac{\delta^2 m}{2\cdot 4^2}}\,.$$

It remains to bound the probability that $(1-\delta/2)\frac{i-1}{r} < \beta < (1+\delta/2)\frac{i-1}{r}$. Define $t \in \mathbb{R}$ such that $\mu(-\infty, t] = (1+\delta/2)\frac{i-1}{r}$. $\beta = \mu(-\infty, x^*] \ge (1+\delta/2)\frac{i-1}{r}$ if and only if $x^* > t$, i.e. $|X \cap (-\infty, t]| < \frac{i-1}{r}$. The expected value of $|X \cap (-\infty, t]|$ is $m\frac{(1+\delta/2)(i-1)}{r}$, so for $\eta = \frac{\delta/2}{1+\delta/2} \ge \delta/3$, the Chernoff bound implies

$$\begin{aligned} \mathbb{P}\left[|X \cap (-\infty, t]| < m\frac{i-1}{r}\right] &= \mathbb{P}\left[|X \cap (-\infty, t]| < m\frac{(1+\delta/2)(i-1)}{r}(1-\eta)\right] \\ &\le e^{-\frac{\delta^2 m(1+\delta/2)(i-1)}{18r}} \le e^{-\frac{\delta^2 m}{18r}}\,. \end{aligned}$$

Now define $t \in \mathbb{R}$ such that $\mu(-\infty, t] = (1-\delta/2)\frac{i-1}{r}$. $\beta = \mu(-\infty, x^*] \leq (1-\delta/2)\frac{i-1}{r}$ if and only if $x^* < t$, i.e. $|X \cap (-\infty, t]| > \frac{i-1}{r}$. The expected value of $|X \cap (-\infty, t]|$ is $m\frac{(1-\delta/2)(i-1)}{r}$, so for $\eta = \frac{\delta}{2-\delta} \geq \delta/2$,

$$\mathbb{P}\left[|X \cap (-\infty, t]| > m\frac{i-1}{r}\right] = \mathbb{P}\left[|X \cap (-\infty, t]| > m\frac{(1-\delta/2)(i-1)}{r}(1+\eta)\right]$$
$$\leq e^{-\frac{\delta^2 m(1-\delta/2)(i-1)}{2\cdot 4r}} \leq e^{-\frac{\delta^2 m}{4^2 r}}.$$

The conclusion then follows from the union bound over these four events. ◀

▶ **Lemma 2.7.** *Let $\mu = \mu_1 \times \cdots \times \mu_d$ be a product distribution over $\mathbb{R}^d$ where each μ_i is continuous. Let X be a random grid with length m sampled from μ, and let $\mathsf{block} : \mathbb{R}^d \to [r]^d$ be the r-block partition induced by X. Then*

$$\mathop{\mathbb{P}}_{X}\left[\|\mathsf{block}(\mu) - \mathsf{unif}([r]^d)\|_{\mathsf{TV}} > \epsilon\right] \leq 4rd \cdot e^{-\frac{\epsilon^2 m}{18rd^2}}$$

Proof. For a fixed grid X and each $i \in [d]$, write $p_i : [r] \to [0,1]$ be the probability distribution on $[r]$ with $p_i(z) = \mu_i(B_{i,z})$. Then $\mathsf{block}(\mu) = p_1 \times \cdots \times p_d$.

Let $\delta = \frac{4\epsilon}{3d}$. Suppose that for every $i, j \in [d] \times [r]$ it holds that $\frac{1+\delta}{r} \leq p_i(j) \geq \frac{1-\delta}{r}$. Note that $d\delta = \frac{4\epsilon}{3} \leq \ln(1+2\epsilon) \leq 2\epsilon$. Then for every $v \in [r]^d$,

$$\mathop{\mathbb{P}}_{u\sim\mu}[\mathsf{block}(u) = v] = \prod_{i=1}^{d} p_i(v_i) \begin{cases} \leq (1+\delta)^d r^{-d} \leq e^{d\delta} r^{-d} \leq (1+2\epsilon) r^{-d} \\ \geq (1-\delta)^d r^{-d} \geq (1-d\delta) r^{-d} \geq (1-2\epsilon) r^{-d}. \end{cases}$$

So

$$\|\mathsf{block}(\mu) - \mathsf{unif}([r]^d)\|_{\mathsf{TV}} = \frac{1}{2}\sum_{v\in[r]^d} |\mathop{\mathbb{P}}_{u\sim\mu}[\mathsf{block}(u) = v] - r^{-d}| \leq \frac{1}{2}\sum_{v\in[r]^d} 2\epsilon r^{-d} = \epsilon.$$

By Lemma 2.6 and the union bound, the probability that there is some $i \in [d], j \in [r]$ that satisfies $p_i(j) < (1-\delta)/r$ is at most $4rd \cdot e^{-\frac{\epsilon^2 m}{18rd^2}}$. ◀

3 Testing Monotonicity

3.1 Testing Monotonicity on the Hypergrid

A good introduction to downsampling is the following short proof of the main result of Black, Chakrabarty, & Seshadhri [6]. In an earlier work, [5], they gave an $O((d^{5/6}/\epsilon^{4/3}) \operatorname{poly}\log(dn))$ tester for the domain $[n]^d$, and in the later work they showed how to reduce the domain $[n]^d$ to $[r]^d$ for $r = \operatorname{poly}(d/\epsilon)$.

Our monotonicity tester will use as a subroutine the following tester for *diagonal* functions. For a hypergrid $[n]^d$, a *diagonal* is a subset of points $\{x \in [n]^d : x = v + \lambda\vec{1}, \lambda \in \mathbb{Z}\}$ defined by some $v \in [n]^d$. A function $f : [n]^d \to \{0,1\}$ is a *diagonal function* if it has at most one 1-valued point in each diagonal.

▶ **Lemma 3.1.** *There is an ϵ-tester with one-sided error and query complexity $O\left(\frac{1}{\epsilon}\log^2(1/\epsilon)\right)$ for diagonal functions on $[n]^d$.*

Proof. For each $t \in [n]$ let D_t be the set of diagonals with length t. For any $x \in [n]^d$ let $\mathrm{diag}(x)$ be the unique diagonal that contains x. For input $f : [n]^d \to \{0,1\}$ and any $x \in [n]^d$, let $R(x) = \frac{|\{y \in \mathrm{diag}(x) : f(y)=1\}|}{|\mathrm{diag}(x)|}$.

Suppose that f is ϵ-far from diagonal. Then f must have at least ϵn^d 1-valued points; otherwise we could set each 1-valued point to 0 to obtain the constant 0 function. Now observe

$$\begin{aligned}\mathop{\mathbb{E}}_{x\sim[n]^d}[R(x)] &= \mathop{\mathbb{E}}_{x\sim[n]^d}\left[\sum_{t=1}^{n}\sum_{L\in D_t}\mathbf{1}\left[\mathrm{diag}(x)=L\right]\frac{|\{y\in L : f(y)=1\}|}{t}\right]\\ &= \sum_{t=1}^{n}\sum_{L\in D_t}\mathop{\mathbb{P}}_{x\sim[n]^d}[x\in L]\frac{|\{y\in L : f(y)=1\}|}{t} = \sum_{t=1}^{n}\sum_{L\in D_t}\frac{t}{n^d}\frac{|\{y\in L : f(y)=1\}|}{t}\\ &= \frac{1}{n^d}|\{y\in[n]^d : f(y)=1\}| \geq \epsilon\,.\end{aligned}$$

For each i, define $A_i = \left\{x \in [n]^d : \frac{1}{2^i} < R(x) \leq \frac{1}{2^{i-1}}\right\}$. Let $k = \log(4/\epsilon)$. Then

$$\begin{aligned}\epsilon \leq \mathbb{E}\left[R(x)\right] &\leq \sum_{i=1}^{\infty}\frac{|A_i|}{n^d}\max_{x\in A_i}R(x) \leq \sum_{i=1}^{\infty}\frac{|A_i|}{n^d 2^{i-1}} \leq \sum_{i=1}^{k}\frac{|A_i|}{n^d 2^{i-1}} + \sum_{i=k+1}^{\infty}\frac{1}{2^{i-1}}\\ &\leq \sum_{i=1}^{k}\frac{|A_i|}{n^d 2^{i-1}} + \frac{1}{2^{k-1}} \leq \sum_{i=1}^{k}\frac{|A_i|}{n^d 2^{i-1}} + \frac{\epsilon}{2}\\ \implies \frac{\epsilon}{2} &\leq \sum_{i=1}^{k}\frac{|A_i|}{n^d 2^{i-1}}\,.\end{aligned}$$

Therefore there is some $\ell \in [k]$ such that $|A_\ell| \geq \frac{\epsilon n^d 2^{\ell-1}}{2k}$.

The tester is as follows. For each $i \in [k]$:

1. Sample $p = \frac{k}{\epsilon 2^{i-2}}\ln(6)$ points $x_1, \ldots, x_p \sim [n]^d$.
2. For each $j \in [p]$, sample $q = 2^{i+2}\ln(12)$ points $y_1, \ldots, y_q$ from $\mathrm{diag}(x_i)$ and reject if there are two distinct 1-valued points in the sample.

The query complexity of the tester is $\sum_{i=1}^{k} 4^2\ln(6)\ln(12)\frac{k}{\epsilon 2^i}2^i = O\left(\frac{1}{\epsilon}\log^2(1/\epsilon)\right)$.

The tester will clearly accept any diagonal function. Now suppose that f is ϵ-far from having this property, and let $\ell \in [k]$ be such that $|A_\ell| \geq \frac{\epsilon n^d 2^{\ell-2}}{k}$. On iteration $i = \ell$, the algorithm samples $p = \frac{k}{\epsilon 2^{\ell-2}}\ln(6)$ points $x_1, \ldots, x_p$. The probability that $\forall j \in [p], x_j \notin A_\ell$ is at most

$$\left(1 - \frac{|A_\ell|}{n^d}\right)^p \leq \left(1 - \frac{\epsilon 2^{\ell-2}}{k}\right)^p \leq \exp\left(-\frac{\epsilon p 2^{\ell-2}}{k}\right) \leq 1/6\,.$$

Now assume that there is some $x_j \in A_\ell$, so that $R(x_j) > 2^{-\ell}$. Let $A, B \subset \mathrm{diag}(x_j)$ be disjoint subsets that partition the 1-valued points in $\mathrm{diag}(x_i)$ into equally-sized parts. Then for y sampled uniformly at random from $\mathrm{diag}(x_j)$, $\mathbb{P}\left[y \in A\right], \mathbb{P}\left[y \in B\right] \geq 2^{-(\ell+1)}$. The probability that there are at least 2 distinct 1-valued points in $y_1, \ldots, y_q$ sampled by the algorithm is at least the probability that one of the first $q/2$ samples is in A and one of the last $q/2$ samples is in B. This fails to occur with probability at most $2(1 - 2^{-(\ell+1)})^{q/2} \leq 2e^{-q2^{-(\ell+2)}} \leq 1/6$. So the total probability of failure is at most $2/6 = 1/3$. ◀

▶ **Theorem 3.2.** *There is a non-adaptive monotonicity tester on domain $[n]^d$ with one-sided error and query complexity $\widetilde{O}\left(\frac{d^{5/6}}{\epsilon^{4/3}}\right)$.*

Proof. Set $r = \lceil 4d/\epsilon \rceil$, and assume without loss of generality that r divides n. Partition $[n]$ into r intervals $B_i = \{(i-1)(n/r)+1, \ldots, i(n/r)\}$. For each $v \in [r]^d$ write $B_v = B_{v_1} \times \cdots \times B_{v_d}$. Define $\mathsf{block} : [n]^d \to [r]^d$ where $\mathsf{block}(x)$ is the unique vector $v \in [r]^d$ such that $x \in B_v$. Define $\mathsf{block}^{-\downarrow}(v) = \min\{x \in B_v\}$ and $\mathsf{block}^{-\uparrow}(v) = \max\{x \in B_v\}$, where the minimum and maximum are with respect to the natural ordering on $[n]^d$. For $f : [n]^d \to \{0,1\}$, write $f^{\mathsf{block}} : [r]^d \to \{0,1\}$, $f^{\mathsf{block}}(v) = f(\mathsf{block}^{-\downarrow}(v))$. We may simulate queries v to f^{block} by returning $f(\mathsf{block}^{-\downarrow}(v))$. We will call $v \in [r]^d$ a *boundary block* if $f(\mathsf{block}^{-\downarrow}(v)) \neq f(\mathsf{block}^{-\uparrow}(v))$.

The test proceeds as follows: On input $f : [n]^d \to \{0,1\}$ and a block $v \in [r]^d$, define the following functions:

$$g : [n]^d \to \{0,1\}, \qquad g(x) = \begin{cases} f^{\mathsf{block}}(\mathsf{block}(x)) & \text{if } \mathsf{block}(x) \text{ is not a boundary block} \\ f(x) & \text{if } \mathsf{block}(x) \text{ is a boundary block.} \end{cases}$$

$$b : [r]^d \to \{0,1\}, \qquad b(v) = \begin{cases} 0 & \text{if } v \text{ is not a boundary block} \\ 1 & \text{if } v \text{ is a boundary block.} \end{cases}$$

$$h : [r]^d \to \{0,1\}, \qquad h(v) = \begin{cases} f^{\mathsf{block}}(v) & \text{if } v \text{ is not a boundary block} \\ 0 & \text{if } v \text{ is a boundary block.} \end{cases}$$

Queries to each of these functions can be simulated by 2 or 3 queries to f. The tester performs:

1. Test whether $g = f$, or whether $\mathsf{dist}(f,g) > \epsilon/4$, using $O(1/\epsilon)$ queries.
2. Test whether b is diagonal, or is $\epsilon/4$-far from diagonal, using Lemma 3.1, with $O\left(\frac{1}{\epsilon}\log^2(1/\epsilon)\right)$ queries.
3. Test whether h is monotone or $\epsilon/4$-far from monotone, using the tester of Black, Chakrabarty, & Seshadhri with $\widetilde{O}\left(\frac{d^{5/6}}{\epsilon^{4/3}}\right)$ queries.

▷ Claim 3.3. If f is monotone, the tester passes all 3 tests with probability 1.

Proof of claim. To see that $g = f$, observe that if $v = \mathsf{block}(x)$ is not a boundary block then $f(\mathsf{block}^{-\downarrow}(v)) = f(\mathsf{block}^{-\uparrow}(v))$. If $f(x) \neq f^{\mathsf{block}}(\mathsf{block}(x))$ then $f(x) \neq f(\mathsf{block}^{-\downarrow}(v))$ and $f(x) \neq f(\mathsf{block}^{-\uparrow}(v))$ while $\mathsf{block}^{-\downarrow}(v) \preceq x \preceq \mathsf{block}^{-\uparrow}(v)$, and this is a violation of the monotonicity of f. Therefore f will pass the first test with probability 1.

To see that f passes the second test with probability 1, observe that if f had 2 boundary blocks in some diagonal, then there are boundary blocks $u, v \in [r]^d$ such that $\mathsf{block}^{-\uparrow}(u) \prec \mathsf{block}^{-\downarrow}(v)$. But then there is $x, y \in [n]^d$ such that $\mathsf{block}(x) = u, \mathsf{block}(y) = v$ and $f(x) = 1, f(y) = 0$; since $x \preceq \mathsf{block}^{-\uparrow}(u) \prec \mathsf{block}^{-\downarrow}(v) \preceq y$, this contradicts the monotonicity of f. So f has at most 1 boundary block in each diagonal.

To see that h is monotone, it is sufficient to consider the boundary blocks, since all other values are the same as f^{block}. Let $v \in [r]^d$ be a boundary block, so there exist $x, y \in [n]^d$ such that $\mathsf{block}(x) = \mathsf{block}(y)$ and $f(x) = 1, f(y) = 0$. Suppose $u \prec v$ is not a boundary block (if it is a boundary block then $h(u) = h(v) = 0$). If $h(u) = 1$ then $f(\mathsf{block}^{-\downarrow}(u)) = 1$, but $\mathsf{block}^{-\downarrow}(u) \prec \mathsf{block}^{-\downarrow}(v) \preceq y$ while $f(\mathsf{block}^{-\downarrow}(u)) > f(y)$, a contradiction. So it must be that $h(u) = 0$ whenever $u \prec v$. For any block $u \in [r]^d$ such that $v \prec u$, we have $0 = h(v) \leq h(u)$, so monotonicity holds. Since the tester of Black, Chakrabarty, & Seshadhri has one-sided error, the test passes with probability 1. ◁

▷ Claim 3.4. If g is $\epsilon/4$-close to f, b is $\epsilon/4$-close to diagonal, and h is $\epsilon/4$-close to monotone, then f is ϵ-close to monotone.

Proof of claim. Let $h^{\mathsf{coarse}} : [n]^d \to \{0,1\}$ be the function $h^{\mathsf{coarse}}(x) = h(\mathsf{block}(x))$. Suppose that $f(x) \neq h^{\mathsf{coarse}}(x)$. If $v = \mathsf{block}(x)$ is not a boundary block of f then $h^{\mathsf{coarse}}(x) = h(v) = f^{\mathsf{block}}(v) = g(x)$, so $f(x) \neq g(x)$. If v is a boundary block then $h^{\mathsf{coarse}}(x) = h(v) = 0$ so $f(x) = 1$, and $b(v) = 1$.

Suppose for contradiction that there are more than $\frac{\epsilon}{2}r^d$ boundary blocks $v \in [r]^d$, so there are more than $\frac{\epsilon}{2}r^d$ 1-valued points of b. Any diagonal function has at most dr^{d-1} 1-valued points. Therefore the distance of b to diagonal is at least

$$r^{-d}\left(\frac{\epsilon}{2}r^d - dr^{d-1}\right) = \frac{\epsilon}{2} - \frac{d}{r} = \frac{\epsilon}{2} - \frac{\epsilon}{4} = \frac{\epsilon}{4}\,,$$

a contradiction. So f has at most $\frac{\epsilon}{2}r^d$ boundary blocks. Now

$$\mathsf{dist}(f, h^{\mathsf{coarse}}) = \mathsf{dist}(f,g) + \mathop{\mathbb{P}}_{x\sim[n]^d}[f(x) = 1, \mathsf{block}(x) \text{ is a boundary block}] \leq \frac{\epsilon}{4} + r^{-d}\cdot\frac{\epsilon r^d}{2} = \frac{3}{4}\epsilon\,.$$

Let $p : [r]^d \to \{0,1\}$ be a monotone function minimizing the distance to h, and let $p^{\mathsf{coarse}} : [n]^d \to \{0,1\}$ be the function $p^{\mathsf{coarse}}(x) = p(\mathsf{block}(x))$. Then

$$\mathsf{dist}(h^{\mathsf{coarse}}, p^{\mathsf{coarse}}) = \mathop{\mathbb{P}}_{x\sim[n]^d}[h(\mathsf{block}(x)) \neq p(\mathsf{block}(x))] = \mathop{\mathbb{P}}_{v\sim[r]^d}[h(v) \neq p(v)] \leq \epsilon/4\,.$$

Finally, the distance of f to the nearest monotone function is at most

$$\mathsf{dist}(f, p^{\mathsf{coarse}}) \leq \mathsf{dist}(f, h^{\mathsf{coarse}}) + \mathsf{dist}(h^{\mathsf{coarse}}, p^{\mathsf{coarse}}) \leq \frac{3}{4}\epsilon + \frac{1}{4}\epsilon = \epsilon\,. \qquad \lhd$$

These two claims suffice to establish the theorem. ◀

3.2 Monotonicity Testing for Product Distributions

The previous section used a special case of downsampling, tailored for the uniform distribution over $[n]^d$. We will call a product distribution $\mu = \mu_1 \times \cdots \times \mu_d$ over $\mathbb{R}^d$ *continuous* if each of its factors μ_i are continuous (i.e. absolutely continuous with respect to the Lebesgue measure). The proof for discrete distributions is in the full version.

▶ **Theorem 1.1.** *There is a one-sided, non-adaptive ϵ-tester for monotonicity of functions $\mathbb{R}^d \to \{0,1\}$ that is distribution-free under (finite or continuous) product distributions, using*

$$O\left(\frac{d^{5/6}}{\epsilon^{4/3}}\operatorname{poly}\log(d/\epsilon)\right)$$

queries and $O(\frac{d^3}{\epsilon^3}\log(d/\epsilon))$ samples.

Proof. We follow the proof of Theorem 3.2, with some small changes. Let $r = \lceil 16d/\epsilon \rceil$. The tester first samples a grid X with length $m = O\left(\frac{rd^2}{\epsilon^2}\log(rd)\right)$ and constructs the induced $(r+2)$-block partition, with cells labeled $\{0,\ldots,r+1\}^d$. We call a block $v \in \{0,\ldots,r+1\}^d$ *upper extreme* if there is some $i \in [d]$ such that $v_i = r+1$, and we call it *lower extreme* if there is some $i \in [d]$ such that $v_i = 0$ but v is not upper extreme. Call the upper extreme blocks U and the lower extreme blocks L. Note that $[r]^d = \{0,\ldots,r+1\}^d \setminus (U \cup L)$.

For each $v \in [r]^d$, we again define $\mathsf{block}^{-\uparrow}(v), \mathsf{block}^{-\downarrow}(v)$ as, respectively, the supremal and infimal point $x \in \mathbb{R}^d$ such that $\mathsf{block}(x) = v$. The algorithm will ignore the extreme blocks $U \cup L$, which do not have a supremal or an infimal point. Therefore it is not defined whether these blocks are boundary blocks.

By Lemma 2.7, with probability at least 5/6, we will have $\|\mathsf{block}(\mu) - \mathsf{unif}(\{0,\dots,r+1\})\|_{\mathsf{TV}} \le \epsilon/8$. We define b, h as before, with domain $[r]^d$. Define g similarly but with domain $\mathbb{R}^d$ and values

$$g(x) = \begin{cases} 1 & \text{if } \mathsf{block}(x) \in U \\ 0 & \text{if } \mathsf{block}(x) \in L \\ f(x) & \text{if } \mathsf{block}(x) \in [n]^d \text{ is a boundary block} \\ f^{\mathsf{block}}(\mathsf{block}(x)) & \text{otherwise.} \end{cases}$$

If f is monotone, it may now be the case $f \neq g$, but we will have $f(x) = g(x)$ for all x with $\mathsf{block}(x) \in [r]^d$, where the algorithm will make its queries. The algorithm will test whether $f(x) = g(x)$ on all x with $\mathsf{block}(x) \in [r]^d$, or $\epsilon/8$-far from this property, which can be again done with $O(1/\epsilon)$ samples. Note that if f is $\epsilon/8$-close to having this property, then

$$\begin{aligned} \mathsf{dist}_\mu(f,g) &\le \mathop{\mathbb{P}}_{x\sim\mu}\left[\mathsf{block}(x) \notin [n]^d\right] + \epsilon/8 \\ &\le \frac{d(r+2)^{d-1}}{(r+2)^d} + \epsilon/8 + \|\mathsf{block}(\mu) - \mathsf{unif}([r]^d \cup U \cup L)\|_{\mathsf{TV}} \\ &\le \frac{\epsilon}{16} + \frac{\epsilon}{8} + \frac{\epsilon}{4} \le \frac{\epsilon}{2}\,. \end{aligned}$$

The algorithm then procedes as before, with error parameter $\epsilon/2$. To test whether $g = f$, the algorithm samples from μ and throws away any sample $x \in \mathbb{R}^d$ with $\mathsf{block}(x) \notin [r]^d$. It then tests b and h using the uniform distribution on $[r]^d$. It suffices to prove the following claim, which replaces Claim 3.4.

▷ Claim 3.5. If g is $\epsilon/2$-close to f, b is $\epsilon/16$-close to diagonal, and h is $\epsilon/8$-close to monotone, then f is ϵ-close to monotone.

Proof of claim. Let $p : [r]^d \to \{0,1\}$ be a monotone function minimizing the distance to h. Then $p(v) \neq h(v)$ on at most $\frac{\epsilon r^d}{8}$ blocks $v \in [r]^d$. Define $p^{\mathsf{coarse}} : \mathbb{R}^d \to \{0,1\}$ as $p^{\mathsf{coarse}}(x) = p(\mathsf{block}(x))$ when $\mathsf{block}(x) \in [r]^d$, and $p^{\mathsf{coarse}}(x) = g(x)$ when $\mathsf{block}(x) \in U \cup L$. Note that p^{coarse} is monotone.

By the triangle inequality,

$$\mathsf{dist}_\mu(f, p^{\mathsf{coarse}}) \le \mathsf{dist}_\mu(f,g) + \mathsf{dist}_\mu(g, p^{\mathsf{coarse}})\,.$$

From above, we know $\mathsf{dist}_\mu(f,g) \le \epsilon/2$. To bound the second term, observe that since b is $\epsilon/16$-close to diagonal, there are at most

$$\frac{\epsilon}{16}r^d + dr^{d-1} \le \frac{\epsilon}{16}r^d + \frac{d}{r}r^d \le \frac{\epsilon}{16}r^d + \frac{\epsilon}{16}r^d = \frac{\epsilon}{8}r^d$$

boundary blocks. Then observe that if $g(x) \neq p^{\mathsf{coarse}}(x)$ then $\mathsf{block}(x) \in [r]^d$ and either $\mathsf{block}(x)$ is a boundary block, or $g(x) = f^{\mathsf{block}}(\mathsf{block}(x)) = h(\mathsf{block}(x))$ and $h(\mathsf{block}(x)) \neq p(\mathsf{block}(x))$. Then

$$\begin{aligned} \mathsf{dist}_\mu(g, p^{\mathsf{coarse}}) &\le \left(\frac{1}{(r+2)^d}\sum_{v\in[r]^d} \mathbf{1}\left[v \text{ is a boundary block, or } h(v) \neq p(v)\right]\right) \\ &\quad + \|\mathsf{block}(\mu) - \mathsf{unif}(\{0,\dots,r+1\}^d)\|_{\mathsf{TV}} \\ &\le \frac{\epsilon r^d}{8r^d} + \frac{\epsilon r^d}{8r^d} + \frac{\epsilon}{4} \le \frac{\epsilon}{2}\,. \end{aligned}$$

A Fixed-Parameter Algorithm for the Kneser Problem

Ishay Haviv
School of Computer Science, The Academic College of Tel Aviv-Yaffo, Tel Aviv, Israel

Abstract

The Kneser graph $K(n,k)$ is defined for integers n and k with $n \geq 2k$ as the graph whose vertices are all the k-subsets of $\{1,2,\ldots,n\}$ where two such sets are adjacent if they are disjoint. A classical result of Lovász asserts that the chromatic number of $K(n,k)$ is $n-2k+2$. In the computational Kneser problem, we are given an oracle access to a coloring of the vertices of $K(n,k)$ with $n-2k+1$ colors, and the goal is to find a monochromatic edge. We present a randomized algorithm for the Kneser problem with running time $n^{O(1)} \cdot k^{O(k)}$. This shows that the problem is fixed-parameter tractable with respect to the parameter k. The analysis involves structural results on intersecting families and on induced subgraphs of Kneser graphs.

We also study the Agreeable-Set problem of assigning a small subset of a set of m items to a group of ℓ agents, so that all agents value the subset at least as much as its complement. As an application of our algorithm for the Kneser problem, we obtain a randomized polynomial-time algorithm for the Agreeable-Set problem for instances that satisfy $\ell \geq m - O(\frac{\log m}{\log\log m})$. We further show that the Agreeable-Set problem is at least as hard as a variant of the Kneser problem with an extended access to the input coloring.

1 Introduction

The Kneser graph $K(n,k)$ is defined for integers n and k with $n \geq 2k$ as the graph whose vertices are all the k-subsets of $[n] = \{1,2,\ldots,n\}$ where two such sets are adjacent if they are disjoint. In 1955, Kneser [17] observed that there exists a proper coloring of the vertices of $K(n,k)$ with $n-2k+2$ colors and conjectured that fewer colors do not suffice, that is, that its chromatic number satisfies $\chi(K(n,k)) = n-2k+2$. The conjecture was proved more than two decades later by Lovász [19] as a surprising application of the Borsuk-Ulam theorem from algebraic topology [2]. Following this result, topological methods have become a common and powerful tool in combinatorics, discrete geometry, and theoretical computer science (see, e.g., [22]). Several alternative proofs of Kneser's conjecture were provided in the literature over the years (see, e.g., [23]), and despite the combinatorial nature of the conjecture, all of them essentially rely on the topological Borsuk-Ulam theorem. One exception is a proof by Matoušek [21], which is presented in a combinatorial form, but is yet inspired by a discrete variant of the Borsuk-Ulam theorem known as Tucker's lemma.

In the computational KNESER problem, we are given an access to a coloring of the vertices of $K(n,k)$ with $n-2k+1$ colors, and the goal is to find a monochromatic edge, i.e., two vertices with the same color that correspond to disjoint sets. Since the number of colors used by the input coloring is strictly smaller than the chromatic number of $K(n,k)$ [19], it follows that every instance of the problem has a solution. However, the topological proofs of the lower bound on the chromatic number of $K(n,k)$ are not constructive, in the sense that they do not supply an efficient algorithm for finding a monochromatic edge. By an efficient algorithm we mean that its running time is polynomial in n, whereas the number of vertices $\binom{n}{k}$ might be exponentially larger. Hence, it is natural to assume that the input coloring is given as an access to an oracle that given a vertex of $K(n,k)$ returns its color. Alternatively, the coloring can be given by some succinct representation, e.g., a Boolean circuit that computes the color of any given vertex.

The question of determining the complexity of the KNESER problem was proposed by Deng, Feng, and Kulkarni [6], who asked whether it is complete in the complexity class PPA. This complexity class belongs to a family of classes that were introduced by Papadimitriou [26] in the attempt to characterize the mathematical arguments that lie behind the existence of solutions to search problems of TFNP. The complexity class TFNP, introduced in [25], is the class of all total search problems in NP, namely, the search problems in which a solution is guaranteed to exist and can be verified in polynomial running time. Papadimitriou has introduced in [26] several subclasses of TFNP, each of which consists of the total search problems that can be reduced to a problem that represents some mathematical argument. In particular, the class PPA (Polynomial Parity Argument) corresponds to the simple fact that every (undirected) graph with maximum degree 2 that has a vertex of degree 1 must have another degree 1 vertex. Hence, PPA is defined as the class of all problems in TFNP that can be efficiently reduced to the LEAF problem, in which given a succinct representation of a graph with maximum degree 2 and given a vertex of degree 1 in the graph, the goal is to find another such vertex.

In recent years, it has been shown that the complexity class PPA perfectly captures the complexity of several total search problems for which the existence of the solution relies on the Borsuk-Ulam theorem. Indeed, Filos-Ratsikas and Goldberg [9, 10] proved that the Consensus Halving problem with inverse-polynomial precision parameter is PPA-complete and derived the PPA-completeness of some classical problems, such as the Splitting Necklace problem with two thieves and the Discrete Sandwich problem. The PPA-hardness of the Consensus Halving problem was further extended to a constant precision parameter in a recent work of Deligkas, Fearnley, Hollender, and Melissourgos [4]. Another PPA-complete problem, studied in [15] and closely related to the KNESER problem, is the SCHRIJVER problem which given a coloring of the Schrijver graph $S(n,k)$ with fewer colors than its chromatic number asks to find a monochromatic edge. Note that $S(n,k)$ is the induced subgraph of $K(n,k)$ on the collection of all k-subsets of $[n]$ with no two consecutive elements modulo n, and that its chromatic number is equal to that of $K(n,k)$ [27]. Despite the progress in understanding the complexity of total search problems related to the Borsuk-Ulam theorem, the question of [6] on the complexity of the KNESER problem is still open. The question of determining the complexity of its extension to Kneser hypergraphs was recently raised by Filos-Ratsikas, Hollender, Sotiraki, and Zampetakis [11].

The study of the KNESER problem has been recently motivated by its connection to a problem called AGREEABLE-SET that was introduced by Manurangsi and Suksompong [20] and further studied by Goldberg, Hollender, Igarashi, Manurangsi, and Suksompong [14]. This problem falls into the category of resource allocation problems, where one assigns items

from a given collection $[m]$ to ℓ agents that have different preferences. The preferences are given by monotone utility functions that associate a non-negative value to each subset of $[m]$. In the Agreeable-Set setting, the agents act as a group, and the goal is to collectively allocate a subset of items that is agreeable to all of them, in the sense that every agent likes it at least as much as it likes the complement set. The authors of [20] proved that for every ℓ agents with monotone utility functions defined on the subsets of $[m]$, there exists a subset $S \subseteq [m]$ of size

$$|S| \leq \min\left(\left\lfloor \frac{m+\ell}{2} \right\rfloor, m\right) \tag{1}$$

that is agreeable to all agents, and that this bound is tight in the worst case. They initiated the study of the Agreeable-Set problem that given an oracle access to the utility functions of the ℓ agents, asks to find a subset $S \subseteq [m]$ that satisfies the worst-case bound given in (1) and that is agreeable to all agents. Note that for instances with $\ell \geq m$, the collection $[m]$ forms a proper solution.

Interestingly, the proof of [20] for the existence of a solution to the Agreeable-Set problem relies on the chromatic number of Kneser graphs. In fact, the proof implicitly shows that the Agreeable-Set problem is efficiently reducible to the Kneser problem, hence the Kneser problem is at least as hard as the Agreeable-Set problem. An alternative existence proof, based on the Consensus Halving theorem [28], was given by the authors of [14]. Their approach was applied there to show that the Agreeable-Set problem can be solved in polynomial time when the utility functions of the agents are additive and when the number ℓ of agents is a fixed constant. The complexity of the problem in the general case is still open.

1.1 Our Contribution

Our main result concerns the parameterized complexity of the Kneser problem. We prove that the problem is fixed-parameter tractable with respect to the parameter k, namely, it can be solved on an input coloring of a Kneser graph $K(n,k)$ in running time $n^{O(1)} \cdot f(k)$ for some function f.

▶ **Theorem 1.** *There exists a randomized algorithm that given integers n and k with $n \geq 2k$ and an oracle access to a coloring $c : \binom{[n]}{k} \to [n-2k+1]$ of the vertices of the Kneser graph $K(n,k)$, runs in time $n^{O(1)} \cdot k^{O(k)}$ and returns a monochromatic edge with probability $1 - 2^{-\Omega(n)}$.*

It should be mentioned that the notion of fixed-parameter tractability is used here in a slightly different manner than in the parameterized complexity literature (see, e.g., [3]). This is because Theorem 1 deals with the parameterized complexity of a total search problem, rather than a decision problem, and because its input is given as an oracle access. In fact, borrowing the terminology of this area, our algorithm for the Kneser problem can be viewed as a randomized polynomial Turing kernelization algorithm for the problem (see, e.g., [12, Chapter 22]). Namely, we show that the problem of finding a monochromatic edge in a Kneser graph $K(n,k)$ can essentially be reduced by a randomized efficient algorithm to finding a monochromatic edge in a Kneser graph $K(n',k)$ for $n' = O(k^4)$ (see Section 3.4 for the precise details).

The analysis of the algorithm given in Theorem 1 relies on properties of induced subgraphs of Kneser graphs (see Section 3.1). The proofs involve a stability result due to Hilton and Milner [16] of the celebrated Erdös-Ko-Rado theorem [8] (see Theorem 9) and an idea recently applied by Frankl and Kupavskii [13] in the study of maximal degrees in induced subgraphs of Kneser graphs. An overview of the proof of Theorem 1 is given in Section 1.2.

Our next result provides a simple deterministic algorithm for the KNESER problem that is particularly useful for Kneser graphs $K(n,k)$ with k close to $n/2$. Its analysis is based on the chromatic number of Schrijver graphs [27].

▶ **Theorem 2.** *There exists an algorithm that given integers n and k with $n \geq 2k$ and an oracle access to a coloring $c : \binom{[n]}{k} \to [n-2k+1]$ of the vertices of the Kneser graph $K(n,k)$, returns a monochromatic edge in running time polynomial in $\binom{n-k+1}{k} \leq n^{\min(k,n-2k+1)}$.*

We proceed by presenting our results on the AGREEABLE-SET problem. First, as applications of Theorems 1 and 2, using the relation from [20] between the AGREEABLE-SET and KNESER problems, we obtain the following algorithmic results.

▶ **Theorem 3.** *There exists a randomized algorithm for the AGREEABLE-SET problem that given an oracle access to an instance with m items and ℓ agents ($\ell < m$), runs in time $m^{O(1)} \cdot k^{O(k)}$ for $k = \lceil \frac{m-\ell}{2} \rceil$ and returns a proper solution with probability $1 - 2^{-\Omega(m)}$.*

▶ **Theorem 4.** *There exists an algorithm for the AGREEABLE-SET problem that given an oracle access to an instance with m items and ℓ agents ($\ell < m$), returns a proper solution in running time polynomial in $\binom{m-k+1}{k} \leq m^{\min(k,m-2k+1)}$ for $k = \lceil \frac{m-\ell}{2} \rceil$.*

We apply Theorems 3 and 4 to show that the AGREEABLE-SET problem can be solved in polynomial time for certain families of instances. By Theorem 3, we obtain a randomized efficient algorithm for instances in which the number of agents ℓ is not much smaller than the number of items m, namely, for $\ell \geq m - O(\frac{\log m}{\log \log m})$. By Theorem 4, we obtain an efficient algorithm for instances with a constant number of agents, providing an alternative proof for a result of [14].

We finally explore the relations between the AGREEABLE-SET and KNESER problems. As already mentioned, there exists an efficient reduction from the AGREEABLE-SET problem to the KNESER problem [20]. Here we provide a reduction in the opposite direction. However, for the reduction to be efficient we reduce from a variant of the KNESER problem with an extended type of queries, which we call *subset queries* and define as follows. For an input coloring $c : \binom{[n]}{k} \to [n-2k+1]$ of a Kneser graph $K(n,k)$, a subset query is a pair (i,B) of a color $i \in [n-2k+1]$ and a set $B \subseteq [n]$, and the answer on the query (i,B) determines whether B contains a vertex colored i, that is, whether there exists a k-subset $A \subseteq B$ satisfying $c(A) = i$. We prove the following result (see Section 2.1 for the computational input model of the problems).

▶ **Theorem 5.** *There exists a polynomial-time reduction from the KNESER problem with subset queries to the AGREEABLE-SET problem.*

1.2 Proof Overview of Theorem 1

We present here the main ideas of our fixed-parameter algorithm for the KNESER problem. Suppose that we are given, for $n \geq 2k$, an oracle access to a coloring $c : \binom{[n]}{k} \to [n-2k+1]$ of the vertices of the Kneser graph $K(n,k)$ with $n-2k+1$ colors. As mentioned before, since the chromatic number of $K(n,k)$ is $n-2k+2$ [19], the coloring c must have a monochromatic edge. Such an edge can clearly be found by an algorithm that queries the oracle for the colors of all the vertices. However, the running time of such an algorithm is polynomial in $\binom{n}{k}$, so it is not fixed-parameter with respect to the parameter k.

A natural attempt to improve on this running time is to consider a randomized algorithm that picks uniformly and independently at random polynomially many vertices of $K(n,k)$ and checks if any two of them form a monochromatic edge. However, it is not difficult to see that

there exist colorings of $K(n,k)$ with $n-2k+1$ colors for which a small fraction of the vertices are involved in all the monochromatic edges, implying that the success probability of this randomized algorithm is negligible on them. To see this, consider the canonical coloring of $K(n,k)$, in which for every $i \in [n-2k+1]$ the vertices $A \in \binom{[n]}{k}$ with $\min(A) = i$ are colored i, and the remaining vertices, those contained in $[n] \setminus [n-2k+1]$, are colored $n-2k+2$. By recoloring the vertices of the last color class with arbitrary colors from $[n-2k+1]$, we get a coloring of $K(n,k)$ with $n-2k+1$ colors such that every monochromatic edge has an endpoint in a collection of $\binom{2k-1}{k}$ vertices. This implies that the probability that two random vertices chosen uniformly and independently from $\binom{[n]}{k}$ form a monochromatic edge may go to zero faster than any inverse polynomial in n.

While the above coloring shows that all the monochromatic edges can involve vertices from a small set, one may notice that this coloring is very well structured, in the sense that each color class is quite close to a trivial intersecting family, i.e., an intersecting family all of whose members share a common element. This is definitely not a coincidence. It is known that large intersecting families of k-subsets of $[n]$ are "essentially" contained in trivial intersecting families. Indeed, the classical Erdös-Ko-Rado theorem [8] asserts that the largest size of an intersecting family of k-subsets of $[n]$ is $\binom{n-1}{k-1}$, attained by, and only by, the n largest trivial families (for $n > 2k$). Moreover, Hilton and Milner [16] proved a stability result for the Erdös-Ko-Rado theorem, saying that if an intersecting family of sets from $\binom{[n]}{k}$ is not trivial then its size cannot exceed $\binom{n-1}{k-1} - \binom{n-k-1}{k-1} + 1$, which is much smaller than the largest possible size of an intersecting family when n is sufficiently larger than k (see Theorem 9 and Remark 10). More recently, it was shown by Dinur and Friedgut [7] that every intersecting family can be made trivial by removing not more than $\tilde{c} \cdot \binom{n-2}{k-2}$ of its members for a constant $\tilde{c}$ (see [18] for an exact $\binom{n-3}{k-2}$ bound on the number of sets that should be removed, provided that $n \geq \tilde{c} \cdot k$ for a constant $\tilde{c}$). Hence, our strategy for finding a monochromatic edge in $K(n,k)$ is to learn the structure of the large color classes which are close to being intersecting. We use random samples from the vertex set of the graph in order to identify the common elements of the trivial families that "essentially" contain these color classes. Roughly speaking, this allows us to repeatedly reduce the size of the ground set $[n]$ of the given Kneser graph and to obtain a small subgraph, whose size depends only on k, that is expected to contain a monochromatic edge. Then, such an edge can simply be found by querying the oracle for the colors of all the vertices of this subgraph.

With the above idea in mind, let us consider an algorithm that starts by selecting uniformly and independently at random polynomially many vertices of $K(n,k)$ and queries the oracle for their colors. Among the $n-2k+1$ color classes, there must be a non-negligible one that includes at least $\frac{1}{n-2k+1} \geq \frac{1}{n}$ fraction of the vertices. It can be shown, using the Chernoff-Hoeffding bound, that the samples of the algorithm can be used to learn a color $i \in [n-2k+1]$ of a quite large color class. Moreover, the samples can be used to identify an element $j \in [n]$ that is particularly popular on the vertices colored i (say, that belongs to a constant fraction of them) in case that such an element exists. Now, if the coloring satisfies that (a) there exists an element j that is popular on the vertices colored i and, moreover, (b) this element j belongs to *all* the vertices that are colored i, then it suffices to focus on the subgraph of $K(n,k)$ induced by the vertices of $\binom{[n]\setminus\{j\}}{k}$. Indeed, condition (b) implies that the restriction of the given coloring to this subgraph uses at most $n-2k$ colors. Since this subgraph is isomorphic to $K(n-1,k)$, its chromatic number is $n-2k+1$, hence it has a monochromatic edge. By repeatedly applying this procedure, assuming that the conditions (a) and (b) hold in all iterations, we can eliminate elements from the ground set $[n]$ and obtain smaller and smaller Kneser graphs that still have a monochromatic edge.

When the ground set becomes sufficiently small, one can go over all the remaining vertices and efficiently find the required edge. We now turn to address the case where at least one of the conditions (a) and (b) does not hold.

For condition (a), suppose that in some iteration the algorithm identifies a color i that appears on a significant fraction of vertices, but no element of $[n]$ is popular on these vertices. In this case, one might expect the color class of i to be so far from being intersecting, so that the polynomially many samples would include with high probability a monochromatic edge of vertices colored i. It can be observed that the aforementioned stability results of the Erdös-Ko-Rado theorem yield that a non-negligible fraction of the vertices of a large color class with no popular element lie on monochromatic edges. However, in order to catch a monochromatic edge with high probability we need here the stronger requirement, saying that a non-negligible fraction of the *pairs* of vertices from this color class form monochromatic edges. We prove that this indeed holds for color classes of $K(n,k)$ that include at least, say, $\frac{1}{n}$ fraction of the vertices, provided that $n \geq \tilde{c} \cdot k^4$ for some constant $\tilde{c}$. The proof uses the Hilton-Milner theorem and borrows an idea of [13] (see Lemma 12 and Corollary 13).

For condition (b), suppose that in some iteration the algorithm identifies a color i of a large color class and an element j that is popular in its sets but does not belong to all of them. In this case, we can no longer ensure that the final Kneser graph obtained after all iterations has a monochromatic edge, as some of its vertices might be colored i. To handle this situation, we show that every vertex $A \in \binom{[n]}{k}$ with $j \notin A$ has a lot of neighbors colored i. Hence, if the algorithm finds at its final step, or even earlier, a vertex A colored i satisfying $j \notin A$, where i and j are the color and element chosen by the algorithm in a previous iteration, then it goes back to the ground set of this iteration and finds using additional polynomially many random vertices from it a neighbor of A colored i, and thus a monochromatic edge (see Lemma 14 and Corollary 15).

To summarize, our algorithm for the Kneser problem repeatedly calls an algorithm, which we refer to as the "element elimination" algorithm, that uses polynomially many random vertices to identify a color i of a large color class. If no element of $[n]$ is popular on this color class then the random samples provide a monochromatic edge with high probability and we are done. Otherwise, the algorithm finds such a popular $j \in [n]$ and focuses on the subgraph obtained by eliminating j from the ground set. This is done as long as the size of the ground set is larger than $\tilde{c} \cdot k^4$ for a constant $\tilde{c}$. After all iterations, the remaining vertices induce a Kneser graph $K(n',k)$ for $n' \leq \tilde{c} \cdot k^4$, and the algorithm queries for the colors of all of its vertices in time polynomial in $\binom{n'}{k} \leq k^{O(k)}$. If the colors that were chosen through the iterations of the "element elimination" algorithm do not appear in this subgraph, then it must contain a monochromatic edge which can be found by an exhaustive search. Otherwise, this search gives us a vertex A satisfying $c(A) = i$ and $j \notin A$ for a color i associated with an element j by one of the calls to the "element elimination" algorithm. As explained above, given such an A it is possible to efficiently find with high probability a vertex that forms with A a monochromatic edge. This gives us a randomized algorithm with running time $n^{O(1)} \cdot k^{O(k)}$ that finds a monochromatic edge with high probability. The full description of the algorithm and its analysis are presented in Section 3.

1.3 Outline

The rest of the paper is organized as follows. In Section 2, we gather several definitions and results that will be used throughout the paper. In Section 3, we present and analyze our randomized fixed-parameter algorithm for the Kneser problem and prove Theorem 1. In Section 4, we present a simple deterministic algorithm for the Kneser problem and prove Theorem 2. Due to space limitation, we omit the proofs of our results on the Agreeable-Set problem, which can be found in the full version of the paper.

2 Preliminaries

2.1 Computational Models

In this work we consider total search problems whose inputs involve functions that are defined on domains of size exponential in the parameters of the problems. For example, the input of the KNESER problem is a coloring $c : \binom{[n]}{k} \to [n-2k+1]$ of the vertices of the Kneser graph $K(n,k)$ for $n \geq 2k$. For such problems, one has to specify how the input is given. We consider the following two input models.

- In the *black-box input model*, an input function is given as an oracle access, so that an algorithm can query the oracle for the value of the function on any element of its domain. This input model is used in the current work to present our algorithmic results, reflecting the fact that the algorithms do not rely on the representation of the input functions.
- In the *white-box input model*, an input function is given by a succinct representation that can be used to efficiently determine the values of the function, e.g., a Boolean circuit or an efficient Turing machine. This input model is appropriate to study the computational complexity of problems, and in particular, to show membership and hardness results with respect to the complexity class PPA.

Reductions form a useful tool to show relations between problems. Let P_1 and P_2 be total search problems. We say that P_1 is (polynomial-time) reducible to P_2 if there exist (polynomial-time) computable functions f, g such that f maps any input x of P_1 to an input $f(x)$ of P_2, and g maps any pair (x, y) of an input x of P_1 and a solution y of $f(x)$ with respect to P_2 to a solution of x with respect to P_1. For problems P_1 and P_2 in the black-box input model, one has to use the notion of *black-box reductions*. A (polynomial-time) black-box reduction satisfies that the oracle access needed for the input $f(x)$ of P_2 can be simulated by a (polynomial-time) procedure that has an oracle access to the input x. In addition, the solution $g(x, y)$ of x in P_1 can be computed (in polynomial time) given the solution y of $f(x)$ and the oracle access to the input x. In the current work we will use black-box reductions to obtain algorithmic results for problems in the black-box input model. For more details on these concepts, we refer the reader to [1, Section 2.2] (see also [5, Sections 2 and 4] for related discussions).

2.2 Kneser and Schrijver Graphs

Consider the following definition.

▶ **Definition 6.** *For a family $\mathcal{F}$ of non-empty sets, let $K(\mathcal{F})$ denote the graph on the vertex set $\mathcal{F}$ in which two vertices are adjacent if they represent disjoint sets.*

For a set X and an integer k, let $\binom{X}{k}$ denote the family of all k-subsets of X. Equipped with Definition 6, the *Kneser graph* $K(n,k)$ can be defined for integers n and k with $n \geq 2k$ as the graph $K(\binom{[n]}{k})$. A set $A \subseteq [n]$ is said to be *stable* if it includes no two consecutive elements modulo n, that is, it forms an independent set in the cycle C_n with the numbering from 1 to n along the cycle. For integers n and k with $n \geq 2k$, let $\binom{[n]}{k}_{\text{stab}}$ denote the collection of all stable k-subsets of $[n]$. The *Schrijver graph* $S(n,k)$ is defined as the graph $K(\binom{[n]}{k}_{\text{stab}})$. Equivalently, it is the induced subgraph of $K(n,k)$ on the vertex set $\binom{[n]}{k}_{\text{stab}}$.

The chromatic numbers of the graphs $K(n,k)$ and $S(n,k)$ were determined, respectively, by Lovász [19] and by Schrijver [27] as follows.

▶ **Theorem 7** ([19, 27])**.** *For all integers $n \geq 2k$, $\chi(K(n,k)) = \chi(S(n,k)) = n - 2k + 2$.*

The computational search problem associated with the Kneser graph is defined as follows.

▶ **Definition 8.** *In the computational* KNESER *problem, the input is a coloring* $c : \binom{[n]}{k} \to [n-2k+1]$ *of the vertices of the Kneser graph* $K(n,k)$ *with* $n-2k+1$ *colors for integers* n *and* k *with* $n \geq 2k$*, and the goal is to find a monochromatic edge, i.e.,* $A, B \in \binom{[n]}{k}$ *satisfying* $A \cap B = \emptyset$ *and* $c(A) = c(B)$*. In the black-box input model, the input coloring is given as an oracle access that for a vertex* A *returns its color* $c(A)$*. In the white-box input model, the input coloring is given by a Boolean circuit that for a vertex* A *computes its color* $c(A)$*.*

The existence of a solution to every instance of the KNESER problem follows from Theorem 7.

2.3 Intersecting Families

For integers n and k with $n \geq 2k$, let $\mathcal{F} \subseteq \binom{[n]}{k}$ be a family of k-subsets of $[n]$. We call $\mathcal{F}$ *intersecting* if for every two sets $F_1, F_2 \in \mathcal{F}$ it holds that $F_1 \cap F_2 \neq \emptyset$. The Erdös-Ko-Rado theorem [8] asserts that every intersecting family $\mathcal{F} \subseteq \binom{[n]}{k}$ satisfies $|\mathcal{F}| \leq \binom{n-1}{k-1}$. This bound is tight and is attained, for each $i \in [n]$, by the family $\{A \in \binom{[n]}{k} \mid i \in A\}$. An intersecting family of sets is said to be *trivial* if its members share a common element. Hilton and Milner [16] proved the following stability result for the Erdös-Ko-Rado theorem, providing an upper bound on the size of any non-trivial intersecting family.

▶ **Theorem 9** (Hilton-Milner Theorem [16])**.** *For all integers* $k \geq 2$ *and* $n \geq 2k$*, every non-trivial intersecting family of* k*-subsets of* $[n]$ *has size at most* $\binom{n-1}{k-1} - \binom{n-k-1}{k-1} + 1$*.*

▶ Remark 10. The bound given in Theorem 9 is tight. To see this, for an arbitrary k-subset F of $[n]$ and for an arbitrary element $i \notin F$, consider the family $\mathcal{F} = \{A \in \binom{[n]}{k} \mid A \cap F \neq \emptyset,\ i \in A\} \cup \{F\}$. The family $\mathcal{F}$ is intersecting and non-trivial, and its size coincides with the bound given in Theorem 9. Note that $|\mathcal{F}| \leq k \cdot \binom{n-2}{k-2}$, provided that $k \geq 3$.

2.4 Chernoff-Hoeffding Bound

We need the following concentration result (see, e.g., [24, Theorem 2.1]).

▶ **Theorem 11** (Chernoff-Hoeffding Bound)**.** *Let* $0 < p < 1$*, let* $X_1, \ldots, X_m$ *be* m *independent binary random variables satisfying* $\Pr[X_i = 1] = p$ *and* $\Pr[X_i = 0] = 1 - p$ *for all* i*, and put* $\overline{X} = \frac{1}{m} \cdot \sum_{i=1}^{m} X_i$*. Then, for any* $\mu \geq 0$*,*

$$\Pr\left[|\overline{X} - p| \geq \mu\right] \leq 2 \cdot e^{-2m\mu^2}.$$

3 A Fixed-Parameter Algorithm for the Kneser Problem

In this section we present and analyze our randomized fixed-parameter algorithm for the KNESER problem. We start with a couple of lemmas on induced subgraphs of Kneser graphs that will play a central role in the analysis of the algorithm. We then describe an algorithm, called "element elimination", which forms a main ingredient in our algorithm for the KNESER problem, and then use it to present the final algorithm and to prove Theorem 1.

3.1 Induced Subgraphs of Kneser Graphs

The following lemma shows that in a large induced subgraph of $K(n,k)$ whose vertices do not have a popular element, a random pair of vertices forms an edge with a non-negligible probability. Its proof uses the Hilton-Milner theorem (Theorem 9) and can be found in the full version of the paper. Recall that for a family $\mathcal{F} \subseteq \binom{[n]}{k}$, we let $K(\mathcal{F})$ stand for the subgraph of $K(n,k)$ induced by $\mathcal{F}$ (see Definition 6).

▶ **Lemma 12.** *For integers $k \geq 3$ and $n \geq 2k$, let $\mathcal{F}$ be a family of k-subsets of $[n]$ of size $|\mathcal{F}| \geq k^2 \cdot \binom{n-2}{k-2}$ and let $\gamma \in (0,1]$. Suppose that every element of $[n]$ belongs to at most γ fraction of the sets of $\mathcal{F}$. Then, the probability that two random sets chosen uniformly and independently from $\mathcal{F}$ are adjacent in $K(\mathcal{F})$ is at least*

$$\frac{1}{2}\cdot\left(1-\gamma-\frac{k}{|\mathcal{F}|}\cdot\binom{n-2}{k-2}\right)\cdot\left(1-\frac{k^2}{|\mathcal{F}|}\cdot\binom{n-2}{k-2}\right).$$

As a corollary of Lemma 12, we obtain the following.

▶ **Corollary 13.** *For integers $k \geq 3$ and $n \geq 8k^4$, let $\mathcal{F}$ be a family of k-subsets of $[n]$ of size $|\mathcal{F}| \geq \frac{1}{2n}\cdot\binom{n}{k}$ and let $\gamma \in (0,1]$. Suppose that every element of $[n]$ belongs to at most γ fraction of the sets of $\mathcal{F}$. Then, the probability that two random sets chosen uniformly and independently from $\mathcal{F}$ are adjacent in $K(\mathcal{F})$ is at least $\frac{3}{8}\cdot(\frac{3}{4}-\gamma)$.*

Proof. Observe that the assumptions $|\mathcal{F}| \geq \frac{1}{2n}\cdot\binom{n}{k}$ and $n \geq 8k^4$ imply that

$$\frac{k^2}{|\mathcal{F}|}\cdot\binom{n-2}{k-2} \leq \frac{2nk^2}{\binom{n}{k}}\cdot\binom{n-2}{k-2} = \frac{2k^3(k-1)}{n-1} \leq \frac{1}{4}.$$

Applying Lemma 12, we obtain that the probability that two random sets chosen uniformly and independently from $\mathcal{F}$ are adjacent in $K(\mathcal{F})$ is at least $\frac{1}{2}\cdot(1-\gamma-\frac{1}{4})\cdot(1-\frac{1}{4}) = \frac{3}{8}\cdot(\frac{3}{4}-\gamma)$. ◀

The following lemma shows that if a large collection of vertices of $K(n,k)$ has a quite popular element, then every vertex that does not include this element is adjacent to many of the vertices in the collection.

▶ **Lemma 14.** *For integers $k \geq 2$ and $n \geq 2k$, let $X \subseteq [n]$ be a set, let $\mathcal{F}$ be a family of k-subsets of X, and let $\gamma \in (0,1]$. Let $j \in X$ be an element that belongs to at least γ fraction of the sets of $\mathcal{F}$, and suppose that $A \in \binom{[n]}{k}$ is a set satisfying $j \notin A$. Then, the probability that a random set chosen uniformly from $\mathcal{F}$ is disjoint from A is at least*

$$\gamma - \frac{k}{|\mathcal{F}|}\cdot\binom{|X|-2}{k-2}.$$

Proof. Let $\mathcal{F} \subseteq \binom{X}{k}$ be a family as in the lemma, and put $\mathcal{F}' = \{F \in \mathcal{F} \mid j \in F\}$. By assumption, it holds that $|\mathcal{F}'| \geq \gamma\cdot|\mathcal{F}|$. Suppose that $A \in \binom{[n]}{k}$ is a set satisfying $j \notin A$. Observe that the number of sets $B \in \binom{X}{k}$ with $j \in B$ that intersect A does not exceed $|A \cap X|\cdot\binom{|X|-2}{k-2} \leq k\cdot\binom{|X|-2}{k-2}$. It thus follows that the number of sets of $\mathcal{F}$ that are disjoint from A is at least

$$|\mathcal{F}'| - k\cdot\binom{|X|-2}{k-2} \geq \gamma\cdot|\mathcal{F}| - k\cdot\binom{|X|-2}{k-2}.$$

Hence, a random set chosen uniformly from $\mathcal{F}$ is disjoint from A with the desired probability. ◀

As a corollary of Lemma 14, we obtain the following.

▶ **Corollary 15.** *For integers $k \geq 2$ and n, let $X \subseteq [n]$ be a set of size $|X| \geq 8k^3$, let $\mathcal{F}$ be a family of k-subsets of X of size $|\mathcal{F}| \geq \frac{1}{2|X|}\cdot\binom{|X|}{k}$, and let $\gamma \in (0,1]$. Let $j \in X$ be an element that belongs to at least γ fraction of the sets of $\mathcal{F}$, and suppose that $A \in \binom{[n]}{k}$ is a set satisfying $j \notin A$. Then, the probability that a random set chosen uniformly from $\mathcal{F}$ is disjoint from A is at least $\gamma - \frac{1}{4}$.*

Proof. Observe that the assumptions $|\mathcal{F}| \geq \frac{1}{2|X|} \cdot \binom{|X|}{k}$ and $|X| \geq 8k^3$ imply that

$$\frac{k}{|\mathcal{F}|} \cdot \binom{|X|-2}{k-2} \leq \frac{2|X|k}{\binom{|X|}{k}} \cdot \binom{|X|-2}{k-2} = \frac{2k^2(k-1)}{|X|-1} \leq \frac{1}{4}.$$

Applying Lemma 14, we obtain that the probability that a random set chosen uniformly from $\mathcal{F}$ is disjoint from A is at least $\gamma - \frac{1}{4}$. ◀

3.2 The Element Elimination Algorithm

A main ingredient in our fixed-parameter algorithm for the KNESER problem is the "element elimination" algorithm given by the following theorem. It will be used to repeatedly reduce the size of the ground set of a Kneser graph while looking for a monochromatic edge.

▶ **Theorem 16.** *There exists a randomized algorithm that given integers n and k, a set $X \subseteq [n]$ of size $|X| \geq 8k^4$, a set of colors $C \subseteq [n-2k+1]$ of size $|C| = |X| - 2k + 1$, and an oracle access to a coloring $c : \binom{X}{k} \to [n-2k+1]$ of the vertices of $K(\binom{X}{k})$, runs in time polynomial in n and returns, with probability $1 - 2^{-\Omega(n)}$,*

- **(a)** *a monochromatic edge of $K(\binom{X}{k})$, or*
- **(b)** *a vertex $A \in \binom{X}{k}$ satisfying $c(A) \notin C$, or*
- **(c)** *a color $i \in C$ and an element $j \in X$ such that for every $A \in \binom{[n]}{k}$ with $j \notin A$, a random vertex B chosen uniformly from $\binom{X}{k}$ satisfies $c(B) = i$ and $A \cap B = \emptyset$ with probability at least $\frac{1}{16n}$.*

Proof. For integers n and k, let $X \subseteq [n]$, $C \subseteq [n-2k+1]$, and $c : \binom{X}{k} \to [n-2k+1]$ be an input satisfying $|X| \geq 8k^4$ and $|C| = |X| - 2k + 1$ as in the statement of the theorem. It can be assumed that $k \geq 3$. Indeed, Theorem 7 guarantees that $K(\binom{X}{k})$ has either a monochromatic edge or a vertex whose color does not belong to C, hence for $k \leq 2$, an output of type (a) or (b) can be found by querying the oracle for the colors of all the vertices in time polynomial in n. For $k \geq 3$, consider the algorithm that given an input as above acts as follows (see Algorithm 1).

The algorithm first selects uniformly and independently m random sets $A_1, \ldots, A_m \in \binom{X}{k}$ for $m = n^3$ (see lines 1–2) and queries the oracle for their colors. If the sampled sets include two vertices that form a monochromatic edge, then the algorithm returns such an edge (output of type (a); see line 5). If they include a vertex whose color does not belong to C, then the algorithm returns it (output of type (b); see line 10). Otherwise, the algorithm defines $i^* \in C$ as a color that appears on a largest number of sampled sets A_t (see lines 13–16). It further defines $j^* \in X$ as an element that belongs to a largest number of sampled sets A_t with $c(A_t) = i^*$ (see lines 17–20). Then, the algorithm returns the pair (i^*, j^*) (output of type (c); see line 21).

It is clear that the algorithm runs in time polynomial in n. We turn to prove that for every input, the algorithm returns a valid output, of type (a), (b), or (c), with probability $1 - 2^{-\Omega(n)}$. We start with the following lemma that shows that if the input coloring has a large color class with no popular element, then with high probability the algorithm returns a valid output of type (a).

▶ **Lemma 17.** *Suppose that the input coloring c has a color class $\mathcal{F} \subseteq \binom{X}{k}$ of size $|\mathcal{F}| \geq \frac{1}{2|X|} \cdot \binom{|X|}{k}$ such that every element of X belongs to at most half of the sets of $\mathcal{F}$. Then, Algorithm 1 returns a monochromatic edge with probability $1 - 2^{-\Omega(n)}$.*

Algorithm 1 Element Elimination Algorithm (Theorem 16).

Input: Integers n and $k \geq 3$, a set $X \subseteq [n]$ of size $|X| \geq 8k^4$, a set of colors $C \subseteq [n-2k+1]$ of size $|C| = |X| - 2k + 1$, and an oracle access to a coloring $c : \binom{X}{k} \to [n-2k+1]$ of $K(\binom{X}{k})$.
Output: (a) A monochromatic edge of $K(\binom{X}{k})$, or (b) a vertex $A \in \binom{X}{k}$ satisfying $c(A) \notin C$, or (c) a color $i \in C$ and an element $j \in X$ such that for every $A \in \binom{[n]}{k}$ with $j \notin A$, a random vertex B chosen uniformly from $\binom{X}{k}$ satisfies $c(B) = i$ and $A \cap B = \emptyset$ with probability at least $\frac{1}{16n}$.

1: $m \leftarrow n^3$
2: pick uniformly and independently at random sets $A_1, \ldots, A_m \in \binom{X}{k}$
3: **for all** $t, t' \in [m]$ **do**
4: **if** $c(A_t) = c(A_{t'})$ and $A_t \cap A_{t'} = \emptyset$ **then**
5: **return** $\{A_t, A_{t'}\}$ ▷ output of type (a)
6: **end if**
7: **end for**
8: **for all** $t \in [m]$ **do**
9: **if** $c(A_t) \notin C$ **then**
10: **return** A_t ▷ output of type (b)
11: **end if**
12: **end for**
13: **for all** $i \in C$ **do**
14: $\widetilde{\alpha}_i \leftarrow \frac{1}{m} \cdot |\{t \in [m] \mid c(A_t) = i\}|$
15: **end for**
16: $i^* \leftarrow$ an $i \in C$ with largest value of $\widetilde{\alpha}_i$
17: **for all** $j \in X$ **do**
18: $\widetilde{\gamma}_{i^*,j} \leftarrow \frac{1}{m} \cdot |\{t \in [m] \mid c(A_t) = i^* \text{ and } j \in A_t\}|$
19: **end for**
20: $j^* \leftarrow$ a $j \in X$ with largest value of $\widetilde{\gamma}_{i^*,j}$
21: **return** (i^*, j^*) ▷ output of type (c)

Proof. Let $\mathcal{F}$ be as in the lemma. Applying Corollary 13 with $\gamma = \frac{1}{2}$, using the assumptions $k \geq 3$ and $|X| \geq 8k^4$, we obtain that two random sets chosen uniformly and independently from $\mathcal{F}$ are adjacent in $K(\mathcal{F})$ with probability at least $\frac{3}{8} \cdot (\frac{3}{4} - \gamma) = \frac{3}{32}$. Further, the fact that $|\mathcal{F}| \geq \frac{1}{2|X|} \cdot \binom{|X|}{k}$ implies that a random vertex chosen uniformly from $\binom{X}{k}$ belongs to $\mathcal{F}$ with probability at least $\frac{1}{2|X|}$. Hence, for two random vertices chosen uniformly and independently from $\binom{X}{k}$, the probability that they both belong to $\mathcal{F}$ is at least $(\frac{1}{2|X|})^2$, and conditioned on this event, their probability to form an edge in $K(\mathcal{F})$ is at least $\frac{3}{32}$. This implies that the probability that two random vertices chosen uniformly and independently from $\binom{X}{k}$ form a monochromatic edge in $K(\binom{X}{k})$ is at least $(\frac{1}{2|X|})^2 \cdot \frac{3}{32} = \frac{3}{128|X|^2}$.

Now, by considering $\lfloor m/2 \rfloor$ pairs of the random sets chosen by Algorithm 1 (line 2), it follows that the probability that no pair forms a monochromatic edge does not exceed

$$\left(1 - \frac{3}{128|X|^2}\right)^{\lfloor m/2 \rfloor} \leq e^{-3 \cdot \lfloor m/2 \rfloor / (128|X|^2)} \leq 2^{-\Omega(n)},$$

where the last inequality follows by $|X| \leq n$ and $m = n^3$. It thus follows that with probability $1 - 2^{-\Omega(n)}$, the algorithm returns a monochromatic edge, as required. ◀

We next handle the case in which every large color class of the input coloring has a popular element. To do so, we first show that the samples of the algorithm provide a good estimation for the fraction of vertices in each color class as well as for the fraction of vertices that share any given element in each color class. For every color $i \in C$, let α_i denote the fraction of vertices of $K(\binom{X}{k})$ colored i, that is,

$$\alpha_i = \frac{|\{A \in \binom{X}{k} \mid c(A) = i\}|}{\binom{|X|}{k}},$$

and let $\widetilde{\alpha}_i$ denote the fraction of the vertices sampled by the algorithm that are colored i (see line 14). Similarly, for every $i \in C$ and $j \in X$, let $\gamma_{i,j}$ denote the fraction of vertices of $K(\binom{X}{k})$ colored i that include j, that is,

$$\gamma_{i,j} = \frac{|\{A \in \binom{X}{k} \mid c(A) = i \text{ and } j \in A\}|}{\binom{|X|}{k}},$$

and let $\widetilde{\gamma}_{i,j}$ denote the fraction of the vertices sampled by the algorithm that are colored i and include j. Let E denote the event that

$$|\alpha_i - \widetilde{\alpha}_i| \leq \frac{1}{2|X|} \text{ and } |\gamma_{i,j} - \widetilde{\gamma}_{i,j}| \leq \frac{1}{2|X|} \text{ for all } i \in C,\ j \in X. \tag{2}$$

By a standard concentration argument, we obtain the following lemma.

▶ **Lemma 18.** *The probability of the event E is $1 - 2^{-\Omega(n)}$.*

Proof. By the Chernoff-Hoeffding bound (Theorem 11) applied with $\mu = \frac{1}{2|X|}$, the probability that an inequality from (2) does not hold is at most

$$2 \cdot e^{-2m/(4|X|^2)} \leq 2 \cdot e^{-n/2},$$

where the inequality follows by $|X| \leq n$ and $m = n^3$. By the union bound over all the colors $i \in C$ and all the pairs $(i, j) \in C \times X$, that is, over $|C| \cdot (1 + |X|) \leq n^2$ events, we get that all the inequalities in (2) hold with probability at least $1 - 2n^2 \cdot e^{-n/2} = 1 - 2^{-\Omega(n)}$, as required. ◀

We now show that if every large color class of the input coloring has a popular element and the event E occurs, then the algorithm returns a valid output.

▶ **Lemma 19.** *Suppose that the coloring c satisfies that for every color class $\mathcal{F} \subseteq \binom{X}{k}$ of size $|\mathcal{F}| \geq \frac{1}{2|X|} \cdot \binom{|X|}{k}$ there exists an element of X that belongs to more than half of the sets of $\mathcal{F}$. Then, if the event E occurs, Algorithm 1 returns a valid output.*

Proof. Assume that the event E occurs. If Algorithm 1 returns an output of type (a) or (b), i.e., a monochromatic edge or a vertex whose color does not belong to C, then the output is verified before it is returned and is thus valid. So suppose that the algorithm returns a pair $(i^*, j^*) \in C \times X$. Recall that the color i^* is defined by Algorithm 1 as an $i \in C$ with largest value of $\widetilde{\alpha}_i$ (see line 16). Since the colors of all the sampled sets belong to C, it follows that $\sum_{i \in C} \widetilde{\alpha}_i = 1$, and thus

$$\widetilde{\alpha}_{i^*} \geq \frac{1}{|C|} \geq \frac{1}{|X|}, \tag{3}$$

where the last inequality follows by $|C| = |X| - 2k + 1 \leq |X|$.

Let $\mathcal{F}$ be the family of vertices of $K(\binom{X}{k})$ colored i^*, i.e., $\mathcal{F} = \{A \in \binom{X}{k} \mid c(A) = i^*\}$. Since the event E occurs (see (2)), it follows from (3) that

$$|\mathcal{F}| = \alpha_{i^*} \cdot \binom{|X|}{k} \geq \left(\widetilde{\alpha}_{i^*} - \frac{1}{2|X|}\right) \cdot \binom{|X|}{k} \geq \frac{1}{2|X|} \cdot \binom{|X|}{k}.$$

Hence, by the assumption of the lemma, there exists an element $j \in X$ that belongs to more than half of the sets of $\mathcal{F}$, that is, $\gamma_{i^*,j} > \frac{1}{2}$. Since the event E occurs, it follows that this j satisfies $\widetilde{\gamma}_{i^*,j} > \frac{1}{2} - \frac{1}{2|X|}$. Recalling that the element j^* is defined by Algorithm 1 as a $j \in X$ with largest value of $\widetilde{\gamma}_{i^*,j}$ (see line 20), it must satisfy $\widetilde{\gamma}_{i^*,j^*} > \frac{1}{2} - \frac{1}{2|X|}$, and using again the fact that the event E occurs, we derive that $\gamma_{i^*,j^*} \geq \widetilde{\gamma}_{i^*,j^*} - \frac{1}{2|X|} > \frac{1}{2} - \frac{1}{|X|} \geq \frac{3}{8}$ (using $|X| \geq 8$).

By $k \geq 3$ and $|X| \geq 8k^4$, we can apply Corollary 15 with $\mathcal{F}$, j^*, and $\gamma = \frac{3}{8}$ to obtain that for every set $A \in \binom{[n]}{k}$ with $j^* \notin A$, the probability that a random set chosen uniformly from $\mathcal{F}$ is disjoint from A is at least $\gamma - \frac{1}{4} = \frac{1}{8}$. Since the probability that a random set chosen uniformly from $\binom{X}{k}$ belongs to $\mathcal{F}$ is at least $\frac{1}{2|X|}$, it follows that the probability that a random set B chosen uniformly from $\binom{X}{k}$ satisfies $c(B) = i^*$ and $A \cap B = \emptyset$ is at least $\frac{1}{2|X|} \cdot \frac{1}{8} = \frac{1}{16|X|} \geq \frac{1}{16n}$. This implies that (i^*, j^*) is a valid output of type (c), as required. ◀

Equipped with Lemmas 17, 18, and 19, we are ready to derive the correctness of Algorithm 1 and to complete the proof of Theorem 16. If the input coloring c has a color class $\mathcal{F} \subseteq \binom{X}{k}$ of size $|\mathcal{F}| \geq \frac{1}{2|X|} \cdot \binom{|X|}{k}$ such that every element of X belongs to at most half of the sets of $\mathcal{F}$, then, by Lemma 17, the algorithm returns with probability $1 - 2^{-\Omega(n)}$ a monochromatic edge, i.e., a valid output of type (a). Otherwise, the input coloring c satisfies that for every color class $\mathcal{F} \subseteq \binom{X}{k}$ of size $|\mathcal{F}| \geq \frac{1}{2|X|} \cdot \binom{|X|}{k}$ there exists an element of X that belongs to more than half of the sets of $\mathcal{F}$. By Lemma 18, the event E occurs with probability $1 - 2^{-\Omega(n)}$, implying by Lemma 19 that with such probability, the algorithm returns a valid output. It thus follows that for every input coloring the algorithm returns a valid output with probability $1 - 2^{-\Omega(n)}$, and we are done. ◀

3.3 The Fixed-Parameter Algorithm for the Kneser Problem

We turn to present our fixed-parameter algorithm for the KNESER problem and to complete the proof of Theorem 1.

Proof of Theorem 1. Suppose that we are given, for integers $n \geq 2k$, an oracle access to a coloring $c : \binom{[n]}{k} \to [n - 2k + 1]$ of the vertices of the Kneser graph $K(n, k)$. Our algorithm has two phases, as described below (see Algorithm 2).

In the first phase, the algorithm repeatedly applies the "element elimination" algorithm given in Theorem 16 (Algorithm 1). Initially, we define

$$s = \max(n - 8k^4, 0), \quad X_0 = [n], \quad \text{and} \quad C_0 = [n - 2k + 1].$$

In the lth iteration, $0 \leq l < s$, we call Algorithm 1 with n, k, X_l, C_l, and with the restriction of the given coloring c to the vertices of $\binom{X_l}{k}$ to obtain with probability $1 - 2^{-\Omega(n)}$,

(a) a monochromatic edge $\{A, B\}$ of $K(\binom{X_l}{k})$, or

(b) a vertex $A \in \binom{X_l}{k}$ satisfying $c(A) \notin C_l$, or

(c) a color $i_l \in C_l$ and an element $j_l \in X_l$ such that for every $A \in \binom{[n]}{k}$ with $j_l \notin A$, a random vertex B chosen uniformly from $\binom{X_l}{k}$ satisfies $c(B) = i_l$ and $A \cap B = \emptyset$ with probability at least $\frac{1}{16n}$.

Algorithm 2 The Algorithm for the KNESER Problem (Theorem 1).

Input: Integers n, k with $n \geq 2k$ and an oracle access to a coloring $c : \binom{[n]}{k} \to [n-2k+1]$ of $K(n,k)$.
Output: A monochromatic edge of $K(n,k)$.

1: $s \leftarrow \max(n - 8k^4, 0)$, $X_0 \leftarrow [n]$, $C_0 \leftarrow [n-2k+1]$ ▷ $|C_0| = |X_0| - 2k + 1$
2: **for all** $l = 0, 1, \ldots, s-1$ **do** ▷ first phase
3: **call** Algorithm 1 with n, k, X_l, C_l, and with the restriction of c to $\binom{X_l}{k}$
4: **if** Algorithm 1 returns an edge $\{A, B\}$ with $c(A) = c(B)$ **then** ▷ output of type (a)
5: **return** $\{A, B\}$
6: **end if**
7: **if** Algorithm 1 returns a vertex $A \in \binom{X_l}{k}$ with $c(A) = i_r \notin C_l$ **then** ▷ output of type (b)
8: **for all** $t \in [n^2]$ **do**
9: pick uniformly at random a set $B_t \in \binom{X_r}{k}$
10: **if** $c(B_t) = i_r$ and $A \cap B_t = \emptyset$ **then**
11: **return** $\{A, B_t\}$
12: **end if**
13: **end for**
14: **return** "failure"
15: **end if**
16: **if** Algorithm 1 returns a pair $(i_l, j_l) \in C_l \times X_l$ **then** ▷ output of type (c)
17: $X_{l+1} \leftarrow X_l \setminus \{j_l\}$, $C_{l+1} \leftarrow C_l \setminus \{i_l\}$ ▷ $|C_{l+1}| = |X_{l+1}| - 2k + 1$
18: **end if**
19: **end for**
20: query the oracle for the colors of all the vertices of $K(\binom{X_s}{k})$ ▷ second phase
21: **if** there exists a vertex $A \in \binom{X_s}{k}$ of color $c(A) = i_r \notin C_s$ **then**
22: **for all** $t \in [n^2]$ **do**
23: pick uniformly at random a set $B_t \in \binom{X_r}{k}$
24: **if** $c(B_t) = i_r$ and $A \cap B_t = \emptyset$ **then**
25: **return** $\{A, B_t\}$
26: **end if**
27: **end for**
28: **return** "failure"
29: **else**
30: find $A, B \in \binom{X_s}{k}$ satisfying $c(A) = c(B)$ and $A \cap B = \emptyset$ ▷ exist by Theorem 7 [19]
31: **return** $\{A, B\}$
32: **end if**

As will be explained shortly, if the output of Algorithm 1 is of type (a) or (b) then we either return a monochromatic edge or declare "failure", and if the output is a pair (i_l, j_l) of type (c) then we define $X_{l+1} = X_l \setminus \{j_l\}$ and $C_{l+1} = C_l \setminus \{i_l\}$ and, as long as $l < s$, proceed to the next call of Algorithm 1. Note that the sizes of the sets X_l and C_l are reduced by 1 in every iteration, hence we maintain the equality $|C_l| = |X_l| - 2k + 1$ for all l. We now describe how the algorithm acts in the lth iteration for each type of output returned by Algorithm 1.

If the output is of type (a), then the returned monochromatic edge of $K(\binom{X_l}{k})$ is also a monochromatic edge of $K(n,k)$, so we return it (see lines 4–6).

If the output is of type (b), then we are given a vertex $A \in \binom{X_l}{k}$ satisfying $c(A) = i_r \notin C_l$ for some $r < l$. Since $i_r \notin C_l$, it follows that $j_r \notin X_l$, and thus $j_r \notin A$. In this case, we pick uniformly and independently n^2 random sets from $\binom{X_r}{k}$ and query the oracle for their colors. If we find a vertex B that forms together with A a monochromatic edge in $K(n,k)$, we return the monochromatic edge $\{A, B\}$, and otherwise we declare "failure" (see lines 7–15).

If the output of Algorithm 1 is a pair (i_l, j_l) of type (c), then we define, as mentioned above, the sets $X_{l+1} = X_l \setminus \{j_l\}$ and $C_{l+1} = C_l \setminus \{i_l\}$ (see lines 16–18). Observe that for $0 \leq l < s$, it holds that $|X_l| = n - l > n - s = 8k^4$, allowing us, by Theorem 16, to call Algorithm 1 in the lth iteration.

In case that all the s calls to Algorithm 1 return an output of type (c), we arrive to the second phase of the algorithm. Here, we are given the sets X_s and C_s that satisfy $|X_s| = n - s \leq 8k^4$ and $|C_s| = |X_s| - 2k + 1$, and we query the oracle for the colors of each and every vertex of the graph $K(\binom{X_s}{k})$. If we find a vertex $A \in \binom{X_s}{k}$ satisfying $c(A) = i_r \notin C_s$ for some $r < s$, then, as before, we pick uniformly and independently n^2 random sets from $\binom{X_r}{k}$ and query the oracle for their colors. If we find a vertex B that forms together with A a monochromatic edge in $K(n,k)$, we return the monochromatic edge $\{A, B\}$, and otherwise we declare "failure" (see lines 21–28). Otherwise, all the vertices of $K(\binom{X_s}{k})$ are colored by colors from C_s. By Theorem 7, the chromatic number of $K(\binom{X_s}{k})$ is $|X_s| - 2k + 2 > |C_s|$. Hence, there must exist a monochromatic edge in $K(\binom{X_s}{k})$, and by checking all the pairs of its vertices we find such an edge and return it (see lines 30–31).

We turn to analyze the probability that Algorithm 2 returns a monochromatic edge. Note that whenever the algorithm returns an edge, it checks that it is monochromatic and thus ensures that it forms a valid solution. Hence, it suffices to show that the algorithm declares "failure" with probability $2^{-\Omega(n)}$. To see this, recall that the algorithm calls Algorithm 1 at most $s < n$ times, and that by Theorem 16 the probability that its output is not valid is $2^{-\Omega(n)}$. By the union bound, the probability that any of the calls to Algorithm 1 returns an invalid output is $2^{-\Omega(n)}$ too. The only situation in which Algorithm 2 declares "failure" is when it finds, for some $r < s$, a vertex $A \in \binom{[n]}{k}$ with $c(A) = i_r$ and $j_r \notin A$, and none of the n^2 sampled sets $B \in \binom{X_r}{k}$ satisfies $c(B) = i_r$ and $A \cap B = \emptyset$ (see lines 7–15, 21–28). However, assuming that all the calls to Algorithm 1 return valid outputs, the rth run guarantees, by Theorem 16, that a random vertex B uniformly chosen from $\binom{X_r}{k}$ satisfies $c(B) = i_r$ and $A \cap B = \emptyset$ for the given A with probability at least $\frac{1}{16n}$. Hence, the probability that the algorithm declares "failure" does not exceed $(1 - \frac{1}{16n})^{n^2} \leq e^{-n/16} = 2^{-\Omega(n)}$. Using again the union bound, it follows that the probability that Algorithm 2 either gets an invalid output from Algorithm 1 or fails to find a vertex that forms a monochromatic edge with a set A as above is $2^{-\Omega(n)}$. Therefore, the probability that Algorithm 2 successfully finds a monochromatic edge is $1 - 2^{-\Omega(n)}$, as desired.

We finally analyze the running time of Algorithm 2. In its first phase, the algorithm calls Algorithm 1 at most $s < n$ times, where the running time needed for each call is, by Theorem 16, polynomial in n. It is clear that the other operations made throughout this phase can also be implemented in time polynomial in n. In its second phase, the algorithm enumerates all the vertices of $K(\binom{X_s}{k})$. This phase can be implemented in running time polynomial in n and in the number of vertices of this graph. The latter is $\binom{|X_s|}{k} \leq |X_s|^k \leq (8k^4)^k = k^{O(k)}$. It thus follows that the total running time of Algorithm 2 is $n^{O(1)} \cdot k^{O(k)}$, completing the proof. ◀

3.4 Turing Kernelization for the Kneser Problem

As mentioned in the introduction, our algorithm for the Kneser problem can be viewed as a randomized polynomial Turing kernelization algorithm for the problem. In what follows we extend on this aspect of the algorithm.

We start with the definition of a Turing kernelization algorithm as it is used in the standard context of parameterized complexity (see, e.g., [12, Chapter 22]). A decision parameterized problem P is a language of pairs (x, k) where k is an integer referred to as the parameter of P. For a decision parameterized problem P and a computable function f, a Turing kernelization algorithm of size f for P is an algorithm that decides whether an input (x, k) belongs to P in polynomial time given an oracle access that decides membership in P for instances (x', k') with $|x'| \leq f(k)$ and $k' \leq f(k)$. The kernelization algorithm is said to be polynomial if f is a polynomial function.

The Kneser problem, however, is a total search problem whose input is given as an oracle access. Hence, for an instance of the Kneser problem associated with integers n and k, we require a Turing kernelization algorithm to find a solution using an oracle that finds solutions for instances associated with integers n' and k' that are bounded by a function of k. We further require the algorithm to be able to simulate the queries of the produced instances using queries to the oracle associated with the original input. Note that we have here two different types of oracles: the oracle that solves the Kneser problem on graphs $K(n', k')$ with bounded n', k' and the oracle that supplies an access to the instance of the Kneser problem.

We claim that the proof of Theorem 1 shows that the Kneser problem admits a randomized polynomial Turing kernelization algorithm in the following manner. Given an instance of the Kneser problem, a coloring $c : \binom{[n]}{k} \to [n-2k+1]$ of the vertices of a Kneser graph $K(n, k)$ for integers n and k with $n \geq 2k$, the first phase of Algorithm 2 runs in time polynomial in n and either finds a monochromatic edge or produces a ground set $X_s \subseteq [n]$ and a set of colors $C_s \subseteq [n-2k+1]$ satisfying $|C_s| = |X_s| - 2k + 1$ and $|X_s| = O(k^4)$ (see lines 2–19). In the latter case, the restriction of the input coloring c to the vertices of the graph $K(\binom{X_s}{k})$ is not guaranteed to use only colors from C_s, as required by the definition of the Kneser problem. Yet, by applying the oracle to this restriction of c, simulating its queries using the access to the coloring c of $K(n, k)$, we either get a monochromatic edge in $K(\binom{X_s}{k})$ or find a vertex whose color does not belong to C_s. In both cases, a solution to the original instance can be efficiently found with high probability. Indeed, if a monochromatic edge is returned then it forms a monochromatic edge of $K(n, k)$ as well. Otherwise, as shown in the analysis of Algorithm 2, a vertex $A \in \binom{X_s}{k}$ whose color does not belong to C_s can be used to efficiently find with high probability a vertex $B \in \binom{[n]}{k}$ such that $\{A, B\}$ is a monochromatic edge (see lines 21–28).

4 An Algorithm for the Kneser Problem Based on Schrijver Graphs

In this section we present the simple deterministic algorithm for the Kneser problem given in Theorem 2. Let us first state a simple fact on the number of vertices in Schrijver graphs (see Section 2.2). We include a quick proof for completeness.

▶ **Fact 20.** *For integers $k \geq 2$ and $n \geq 2k$, the number of vertices in $S(n, k)$ is*

$$\binom{n-k+1}{k} - \binom{n-k-1}{k-2}.$$

Proof. Recall that the vertex set $\binom{[n]}{k}_{\text{stab}}$ of $S(n, k)$ is the collection of all k-subsets of $[n]$ with no two consecutive elements modulo n. We first observe that the number of k-subsets of $[n]$ with no two consecutive elements, allowing both 1 and n to be in the subsets, is $\binom{n-k+1}{k}$. To see this, identify the subsets of $[n]$ with their characteristic vectors in $\{0, 1\}^n$, and in every such vector, interpret the zeros as balls and the ones as separations between bins. It

follows that every such set corresponds to a partition of $n-k$ identical balls into $k+1$ bins, where no bin but the first and last is empty. The number of those partitions is equal to the number of partitions of $n-2k+1$ identical balls into $k+1$ bins, which is $\binom{n-k+1}{k}$. Finally, to obtain the number of vertices of $S(n,k)$, one has to subtract the number of k-subsets of $[n]$ with no two consecutive elements that include both 1 and n. The latter is equal to the number of $(k-2)$-subsets of $[n-4]$ with no two consecutive elements, which by the above argument equals $\binom{n-k-1}{k-2}$, so we are done. ◀

Equipped with Fact 20, we are ready to prove Theorem 2.

Proof of Theorem 2. Consider the algorithm that given integers n and k with $n \geq 2k$ and an oracle access to a coloring $c : \binom{[n]}{k} \to [n-2k+1]$ of the vertices of the Kneser graph $K(n,k)$, enumerates all vertices of the Schrijver graph $S(n,k)$, i.e., the sets of $\binom{[n]}{k}_{\text{stab}}$, and queries the oracle for their colors. Then, the algorithm goes over all pairs of those vertices and returns a pair that forms a monochromatic edge. The existence of such an edge follows from Theorem 7, which asserts that $\chi(S(n,k)) = n-2k+2$. The running time of the algorithm is polynomial in the number of vertices of $S(n,k)$, which by Fact 20 does not exceed $\binom{n-k+1}{k} = \binom{n-k+1}{n-2k+1} \leq n^{\min(k,n-2k+1)}$. ◀

Abstract

The theory of proof systems in general, and interactive proofs in particular, has been immensely influential. Such proof systems allow a prover to convince a verifier whether a given statement is true or not – namely to solve a decision problem. In this work we initiate a study of interactive proofs for *search problems*.

More precisely, we consider a setting in which a client C, given an input x, would like to find a solution y satisfying $(x, y) \in R$, for a given relation R. The client wishes to delegate this work to an (untrusted) advisor A, who has more resources than C. We seek solutions in which the communication from A is short, and, in particular, shorter than the length of the output y. (In particular, this precludes the trivial solution of the advisor sending y and then proving that $(x, y) \in R$ using a standard interactive proof.)

We show that such search delegation schemes exist for several problems of interest including (1) longest common subsequence (LCS) and edit distance, (2) parsing context-free grammars and (3) k-SAT.

1 Introduction

Interactive proofs, conceived by Goldwasser, Micali and Rackoff [13], allow a prover to convince a verifier that a given computational statement of the form $x \in L$ is true, where L is a language. They require that if the statement is true, then there is a strategy that will convince the verifier to accept with high probability; whereas if the statement is false, then the verifier should reject with high probability no matter what the prover does. Interactive proofs have had an incredible and enduring impact on complexity theory, cryptography, and beyond.

While interactive proofs help the verifier to determine whether a given statement is true or not, often we are interested in actually finding a solution: fixing some relation R of interest, we would like given an input x to find a solution $y \in R(x)$, where $R(x) := \{y : (x, y) \in R\}$. In other words, we are interested in solving *search problems*.

In this work, we consider a setting in which a computationally bounded client C is given an input x and would like to find some $y \in R(x)$ with help from a powerful advisor A.[1] We refer to a protocol for this setting as a "search delegation scheme" and note that the notion has immediate connections to cloud computing. Continuing the parallel to interactive proofs, our main focus is on protocols in which the advisor is viewed as untrusted. However, as discussed below, protocols that assume a trusted advisor are also non-trivial, and arguably even more natural.

One trivial approach to designing search delegation schemes is for the advisor to simply compute some $y \in R(x)$, send y to the client, and then prove that indeed $y \in R(x)$. The downside of this solution is that y may be so long that just sending y may already be extremely costly. Thus, in this work we are interested in search delegation schemes with *laconic* advisors, i.e. advisors that are restricted to sending a short (h-bit) hint, where $h \ll |y|$ is a parameter. Note that an h-bit hint can at most increase the probability with which the client successfully computes some $y \in R(x)$ by a multiplicative factor of 2^h. We seek to understand how much of this increase is actually realizable, and for which values of h.

The restriction that the advisor can only send a short hint makes the construction of search delegation schemes, even with a trusted advisor, algorithmically non-trivial. Moreover, given a search delegation scheme with a trusted advisor, we can in many cases upgrade the scheme (using interactive proofs or arguments generically and in a black-box way) to provide correctness guarantees to the client even when interacting with an untrusted advisor. In fact protocols for trusted advisors comprise the technical heart of our constructions, even those for untrusted advisors.

Before proceeding, we mention several prior works that can be cast as studying proof-systems for search problems, but with communication that is as long as the solution. First, the search version of NP (e.g., finding a satisfying solution to a formula, or a 3-coloring of a graph), often referred to as FNP or PC [11], consists of search problems whose solutions are efficiently verifiable. However, no distinction is made between the hint length vs. the length of the solution. There are also several works in cryptographic contexts that consider using interaction for solving search problems (e.g., [10, 8, 4]). Additionally, there has been a study of fine-grained complexity and approximation that connects the fine-grained hardness of approximation to interactive proof systems for space-bounded computation [7]. However, in these works the communication is as large as the output y (similarly to the canonical solution in which the result is sent by the advisor and then verified).

1.1 Search Delegation

We define a search delegation scheme as follows:

▶ **Definition 1.** *A* search delegation scheme *for a relation $R \subseteq \{0,1\}^* \times \{0,1\}^*$ consists of a client C and an advisor A. The two parties interact (possibly using randomness) on common input x and at the end of the interaction the client outputs a string denoted by $(C, A)(x)$. The delegation scheme has completeness error $c = c(|x|)$ and soundness error $s = s(|x|)$ if:*

- *(Completeness:) For every input x such that $R(x) \neq \emptyset$, it holds that $(C, A)(x) \in R(x)$ with probability at least $1 - c(|x|)$.*
- *(Soundness:) For every input x and every (potentially malicious) advisor A^*, it holds that $(C, A^*)(x) \in R(x) \cup \{\perp\}$ with probability at least $1 - s(|x|)$.*

[1] We use the nomenclature of client/advisor rather than verifier/prover since the goal of the interaction is not to prove correctness but rather to find a solution. Nevertheless, we emphasize that the role of the client (resp., advisor) is analogous to that of the verifier (resp., prover).

Here and throughout this work the $\perp$ symbol represents a "reject" by the client. In case the errors are not specified explicitly we default to *perfect completeness* (i.e., $c \equiv 0$) and *negligible soundness error* (i.e. $s(n) = n^{-\omega(1)}$).

The main resources that we focus on are the running time of the client, and the amount of communication between the parties (a secondary goal is bounding the running time of the (honest) advisor).

1.1.1 Variant Definitions

As discussed above, we will mainly be interested in search delegation schemes in which the communication complexity is less than the output length of the relation. Given this, Definition 1 is interesting even if we only require completeness to hold (without any guarantees against cheating advisors). We refer to schemes satisfying this weaker definition as *honest-advisor search delegation schemes*.

Actually, it will be convenient to present many of the protocols in this work as such honest-advisor search delegation schemes. Note that in case the relevant relation R has an efficient interactive proof for proving that $(x, y) \in R$ (with communication $\ll |y|$), then we can easily "bootstrap" an honest-advisor scheme into a full-fledged one. See Section 5 for details.

We will also sometimes consider a relaxation of the soundness condition of Definition 1 in which soundness is only required to hold only against malicious advisors A^* that are polynomially bounded. This is similar to the notion of computationally sound proofs, aka arguments, from the literature. We refer to protocols satisfying this weaker notion as computational search delegation schemes.

Lastly we remark that in contrast to standard interactive proofs, it is not clear how to reduce the completeness and soundness errors in search delegation schemes. The problem is that if the basic protocol is repeated, each invocation may yield a different candidate solution. While in general we do not know how to check which (if any) of the solutions is valid, in cases for which there *is* an (efficient) method of doing so, we can reduce the errors by repetition.

1.2 Our Results

We construct search delegation schemes for a number of problems of interest from the literature. In all of our schemes the client is given a hint whose length is sub-linear in the output length of the problem, and runs in significantly less time than the best known algorithms for the problem.

1.2.1 Longest Common Subsequence and Edit Distance

A *common subsequence* between strings $x \in \Sigma^n$ and $y \in \Sigma^m$, over an alphabet Σ, is a string z that appears in both x and y as a (possibly non-contiguous) sub-string. The *longest common subsequence* (LCS) problem asks, given x and y, to find a common subsequence of maximal length. When $n = m$, it is known that LCS requires $n^{2-o(1)}$ time if the strong exponential time hypothesis (SETH) holds [1].

The *edit distance* (Edit) problem is a related and central problem with important applications to computational biology. We consider a search version of the problem in which the goal is, given strings x and y, to find a minimal sequence of operations for transforming x into y, where the allowed operations are single-character insertions, deletions, and substitutions. Similar to LCS, there is a known running time lower bound for Edit of $n^{2-o(1)}$ based on SETH [5].

Our first result is an honest-advisor search delegation schemes for solving both LCS and Edit. We show how to solve both problems given a sub-linear hint string and so that the client runs in $o(n \cdot m)$ time. More generally, for every parameter a, we construct a protocol with an a-bit hint and running time $O\big(n+m+a+\frac{n \cdot m}{a} \cdot \log(n \cdot m)\big)$. For example, specializing to the case that $n = m$ and taking $a = n/\mathsf{polylog}(n)$ we get sub-linear communication $n/\mathsf{polylog}(n)$ with quasi-linear client running time.

Furthermore, using cryptographic techniques we can bootstrap the protocols to hold against computationally bounded cheating advisors, with essentially the same parameters (assuming the existence of collision-resistant hash functions and using additional rounds of interaction).

1.2.2 Parsing Context-Free Grammars

Context-free grammars are a computational model which is particular well suited for describing programming language structure. A context-free grammar is composed of production rules of the form $A \to \alpha$, where A is a variable and α is a string composed of variables and "terminals" (aka alphabet symbols). A word is derived by a grammar by applying production rules starting with some initial variable by replacing each occurrence of a variable using a corresponding production rule for that variable. The final word, composed only of terminals (i.e., after all variables have been replaced), is said to be derived by the grammar. We follow the convention that variables are described in upper case and terminals in lowercase.

A derivation tree (aka parse tree) is a tree describing the derivation of the word - namely, the root of the tree is labeled by the initial variable and the children of each vertex are labeled based on a production rule applied to the label of the parent. Thus, the leaves of the tree are labeled by the terminals of the derived word. The important computational task of *parsing* is, given a description of a grammar and a word w, to output a derivation tree describing the derivation of w using the grammar (or to output $\perp$ if the word cannot be derived by the grammar).

The best known algorithm for parsing context-free grammars (in Chomsky[2] normal form), due to Valiant [20], takes time $O(n^{\omega_b})$, where $\omega_b \geq 2$ is the exponent for Boolean matrix multiplication[3]. There is also evidence that a substantially faster algorithm does not exist [17, 2].

As our second main result, we construct a search delegation scheme for context-free parsing (of Chomsky normal form grammars) with sub-linear communication and quasi-linear work for the client. In more detail, for every parameter a, we construct a full-fledged search delegation scheme (even against computationally unbounded cheating advisors) in which the advisor sends a bits and the clients running time is $\tilde{O}(a + n^{\omega_b}/a^{\omega_b - 1})$. For example with $a = n/\mathsf{polylog}(n)$ we get quasi-linear client time, and for $a = n^{\frac{\omega_b - 2}{\omega_b - 1}} < \sqrt{n}$ we obtain a quadratic-time client with $\tilde{O}(\sqrt{n})$ communication.

---

[2] A grammar is in Chomsky normal form if the production rules only have one of the following three forms: $A \to BC$, $A \to a$, or $A \to \varepsilon$, where ε denotes the empty string. Recall that any grammar can be readily modified to be in Chomsky normal form.

[3] Boolean matrix multiplication is defined similarly to standard matrix multiplication except that the inner product operation is replaced by an OR of ANDs. The boolean matrix multiplication exponent is defined as the minimum number, ω_b, such that a $n^{\omega_b + o(1)}$ algorithm exists. The best known upper bound on ω_b is roughly 2.37286 [3].

1.2.3 k-SAT

The search version of the k-SAT problem is to find a satisfying assignment for a given k-CNF formula (i.e., a CNF boolean formula whose clauses contain at most k literals). The problem is well-known to be NP complete when $k \geq 3$. Moreover if SETH holds, then for all $\epsilon > 0$ there exists k such that k-SAT cannot be solved in time $O(2^{(1-\epsilon)n})$.

Nevertheless, there has been a fascinating line of work studying non-trivial algorithms for k-SAT for fixed constant k. The current fastest algorithm for k-SAT builds on PPSZ [14]. The PPSZ algorithm [19] is another classical, albeit slightly slower, algorithm whose running time is $\approx 2^{c_k \cdot n}$, where c_k tends to $1 - \Theta(1/k)$.

A naive approach for a search delegation scheme for k-SAT would be for the advisor to simply specify the value of a of the variables and then having the client solve the residual formula using a generic k-SAT algorithm. For example, using PPSZ we would obtain a client run-time of $\approx 2^{c_k \cdot (n-a)}$.

We give a non-trivial improvement on this scheme, in which given an a-bit hint, the client runs in time $2^{c_k \cdot n - a + o(n)}$. Denoting the run-time of the best known algorithm for k-SAT by $2^{c'_k \cdot n + o(n)}$, we get that the client beats the performance of the naive solution whenever $a > \frac{c_k - c'_k}{1 - c'_k} \cdot n$. We remark that for this result we assume the server and client have access to shared randomness of length $\Omega(n)$.

1.2.4 Separations

In addition to these positive results, we also give negative results indicating that solving a search problem (finding $y \in R(x)$) with a short hint can be much harder than solving the corresponding decision problem (i.e. checking whether a given y satisfies $y \in R(x)$). Our separation results all depend on cryptographic assumptions and are based on the elementary fact that an a-bit hint can boost an algorithm's success probability by at most a multiplicative factor of 2^a.

1.3 Organization

In Section 2 we describe our delegation protocols for LCS and Edit. We continue in Section 3 to describe our protocol for parsing context-free grammars, and in Section 4 we describe our protocol for k-SAT.

2 LCS and Edit Distance

The Longest Common Subsequence (LCS) problem asks, given strings $x \in \Sigma^n$ and $y \in \Sigma^m$ (over a common alphabet Σ), to find increasing sequences $i_1, \ldots, i_\ell \in [n]$ and $j_1, \ldots, j_\ell \in [m]$, for ℓ as big as possible, such that $x_{i_k} = y_{j_k}$ for all $k \in [\ell]$. The best known algorithms for LCS run in worst-case $O(n \cdot m)$ time, and when $m = n$ this is nearly optimal – LCS requires $n^{2-o(1)}$ time if the strong exponential time hypothesis (SETH) holds [1].

The search version of the Edit Distance problem, which we denote by Edit, asks, given strings $\mathbf{x} \in \Sigma^n$ and $\mathbf{y} \in \Sigma^m$, to find a minimum length sequence of operations that transforms $\mathbf{x}$ into $\mathbf{y}$, where allowed operations are single character insertions, deletions, and substitutions. Edit is also known to be solvable in $O(n \cdot m)$ time, and to require at least $n^{2-o(1)}$ time if SETH holds [5].

In this section we construction search delegation protocols for both LCS and Edit.

▶ **Theorem 2.** *For every $a = a(n, m)$, there is an honest-advisor search delegation scheme for* LCS *and for* Edit *in which the advisor sends an a-bit hint, and the client runs in time $O\big(n + m + a + \frac{nm \log(nm)}{a}\big)$.*

Furthermore assuming collision-resistant hash functions, the protocols can be improved to an untrusted-advisor search delegation scheme with computational soundness.

We start in Section 2.1 with an overview for the protocol for LCS. The remaining sections are devoted to the formal proof of Theorem 2. Since the protocols for LCS and Edit are similar, we present a common framework that captures both problems and is described in Section 2.2.

2.1 Protocol Overview

The idea underlying both protocols is to use trusted advice to facilitate a "divide-and-conquer" approach. This yields an honest advisor delegation protocol which in turn can be transformed, via Corollary 16, to a full-fledged protocol with computational soundness (assuming the existence of collision resistant hash functions).

For sake of this overview, we restrict our attention to LCS and describe a simple protocol with short advice ($O(\log(n) + \log(m))$ bits) that reduces the client's work by a factor of 2. The protocol for Edit is very similar and for both protocols the client's work can be further reduced by recursion, see the subsequent subsections for details.

Given input $(\mathbf{x}, \mathbf{y}) \in \{0,1\}^n \times \{0,1\}^m$, the trusted advisor first computes a longest common subsequence $\mathbf{z}$. Fix a partial mapping $\mu : [n] \to [m]$ from the coordinates of $\mathbf{x}$ to those of $\mathbf{y}$ that correspond to the subsequence $\mathbf{z}$ (i.e., $x_i = y_{\mu(i)}$, for every i for which $\mu(i)$ is defined).

The advisor finds and sends indices $i^\star \in [n]$ and $j^\star \in [m]$ such that no index $i < i^\star$ of $\mathbf{x}$ is mapped to an index $j > j^\star$ of $\mathbf{y}$. One option is that this is due to the fact that $\mu(i^\star) = j^\star$, but this does not have to be the case (e.g., if i^* is not mapped at all).[4] The specific choice of $i^\star$ and $j^\star$ will be crucial for bounding the client's runtime, but we defer the discussion of how they are chosen for the moment.

The indices $i^\star$ and $j^\star$ now define two LCS instances that the client solves directly (i.e., using the standard dynamic programming based algorithm for LCS): the first is $\mathbf{x}[1, i^\star - 1]$ vs. $\mathbf{y}[1, j^\star - 1]$ and the second is $\mathbf{x}[i^\star + 1, n]$ vs. $\mathbf{y}[j^\star + 1, n]$. Denote the solution found for the former by $\mathbf{z}_L$ and for the latter by $\mathbf{z}_R$.

Assuming that $i^\star$ was not mapped to $j^\star$, the client simply outputs $\mathbf{z}_L \circ \mathbf{z}_R$ and in case $i^\star$ was mapped to $j^\star$ it outputs $\mathbf{z}_L \circ \mathbf{x}[i^\star] \circ \mathbf{z}_R$. (Since we assume the advisor is trusted, it can simply specify whether or not $i^\star$ is mapped to $j^\star$.) It is straightforward to see that the output of the client is a valid solution – namely, a longest common subsequence for $\mathbf{x}$ and $\mathbf{y}$. The more important challenge is analyzing the efficiency of the protocol.

First note that if we use a time $c \cdot n \cdot m$ algorithm for LCS, for some constant c, we obtain a client that runs in time roughly: $c \cdot i^\star \cdot j^\star + c \cdot (n - i^\star) \cdot (m - j^\star)$. Note that for some values of $i^\star$ and $j^\star$ (e.g., $i^\star = j^\star = 0$) this gives no saving! Fortunately, we are able to show that there always exist $i^\star$ and $j^\star$ such that:

$$i^\star \cdot j^\star + (n - i^\star) \cdot (m - j^\star) \leq \frac{nm}{2}, \tag{1}$$

which in turn implies a factor 2 saving for the client.

To see that Equation (1) holds we consider two cases:

[4] Actually, it will be convenient to allow $i^\star$ and $j^\star$ to be real numbers rather than integers, but the reader can ignore this subtlety for the overview.

Case 1

There is an index $i < n/2$ that is mapped, via μ, to an index $j > n/2$. We fix $i^\star$ and $j^\star$ to be such indices. Note that since $i^\star$ is mapped to $j^\star$ they satisfy that $i < i^\star$ cannot be mapped to $j > j^\star$. Moreover:

$$i^\star \cdot j^\star + (n - i^\star) \cdot (m - j^\star) = \frac{1}{2}\big(n \cdot m + (n - 2i^\star) \cdot (m - 2j^\star)\big) \leq \frac{nm}{2},$$

where the equality can be verified by elementary arithmetic manipulations and the inequality follows from the fact that $n - 2i^\star < 0$ and $m - 2j^\star > 0$.

Case 2

There is no index $i < n/2$ that is mapped to $j^\star > m/2$. In such case, we define $i^\star = n/2$ and $j = n/2$. Note that by definition, there is no $i < i^\star$ that is mapped to $j > j_\star$. It is now straightforward that:

$$i^\star \cdot j^\star + (n - i^\star) \cdot (m - j^\star) = \frac{nm}{2}.$$

Thus, in both cases we obtain a factor 2 savings in the client's runtime as desired. In the full protocol, described below, we obtain a further savings by essentially recursing on both LCS instances rather than solving them directly.

2.2 The Minimum Cost String Alignment Problem

A cost function is a function $c : \mathbb{Z} \times \mathbb{Z} \to \mathbb{R}$. The two cost functions that we focus on are $c_{\mathsf{LCS}}(a, b) \stackrel{\text{def}}{=} a + b$ and $c_{\mathsf{Edit}}(a, b) \stackrel{\text{def}}{=} \max(a, b)$.

▶ **Definition 3.** *The* Minimum Cost String Alignment problem *with respect to a cost function c, denoted* MCSA$[c]$*, is a relation consisting of all pairs $\big((\mathbf{x}, \mathbf{y}), (\mathbf{i}, \mathbf{j})\big)$ for which, if $\mathbf{x} \in \Sigma^n$ and $\mathbf{y} \in \Sigma^m$,*

- $\mathbf{i} \subseteq [n]^\ell$, $\mathbf{j} \subseteq [m]^\ell$ *for some* $\ell \in \mathbb{Z}^+$*;*
- $i_1 < \cdots < i_\ell$ *and* $j_1 < \cdots < j_\ell$*;*
- $x_{i_k} = y_{j_k}$ *for all* $k \in [\ell]$*; and*
- $\mathbf{i}$ *and* $\mathbf{j}$ *minimize* $\sum_{k=1}^{\ell+1} c(i_k - i_{k-1} - 1, j_k - j_{k-1} - 1)$ *subject to the prior three constraints, where we define* $i_0 = j_0 = 0$*,* $i_{\ell+1} = n + 1$*, and* $j_{\ell+1} = m + 1$*.*

▶ Remark 4. To facilitate recursion, we will often consider MCSA instances where the strings $\mathbf{x}$ and $\mathbf{y}$ are most naturally viewed as substrings of larger strings, i.e. $\mathbf{x} = \mathbf{X}_I$ and $\mathbf{y} = \mathbf{Y}_J$. In these cases, we will view the symbols of $\mathbf{x}$ and $\mathbf{y}$ as indexed not by some $[n]$ and $[m]$, but by I and J respectively. The definition naturally extends to this setting, and we will frequently use this generalization.

The following two propositions show that LCS and Edit are special cases of MCSA with respect to different cost functions.

▶ **Proposition 5.** LCS *is the same as* MCSA$[c_{\mathsf{LCS}}]$.

Proof. For any common subsequence $x_{i_1} = y_{j_1}, \ldots, x_{i_\ell} = y_{j_\ell}$ of $\mathbf{x} \in \Sigma^n$ and $\mathbf{y} \in \Sigma^m$, define $i_0 = j_0 = 0$, $i_{\ell+1} = n + 1$, and $j_{\ell+1} = m + 1$ as in Definition 3

We have

$$\begin{aligned}
&\sum_{k=1}^{\ell+1} c_{\mathsf{LCS}}(i_k - i_{k-1} - 1, j_k - j_{k-1} - 1) \\
=&\sum_{k=1}^{\ell+1} i_k - i_{k-1} + j_k - j_{k-1} - 2 \\
=&i_{\ell+1} - i_0 + j_{\ell+1} - j_0 - 2\ell - 2 \\
=&n + m - 2\ell,
\end{aligned}$$

which is minimized when ℓ is maximized. ◀

▶ **Proposition 6.** Edit *is the same as* $\mathsf{MCSA}[c_{\mathsf{Edit}}]$.

Proof. Suppose $x_{i_1} = y_{j_1}, \ldots, x_{i_\ell} = y_{j_\ell}$ is a common subsequence of $\mathbf{x}, \mathbf{y}$. Define $i_0 = j_0 = 0$, $i_{\ell+1} = n+1$, and $j_{\ell+1} = m+1$ as in Definition 3. Then one way of editing $\mathbf{x}$ into $\mathbf{y}$ is by editing $\mathbf{x}_{(i_{k-1}, i_k)}$ into $\mathbf{y}_{(j_{k-1}, j_k)}$ for each $k \in [\ell+1]$, which takes at most $\max(i_k - i_{k-1} - 1, j_k - j_{k-1} - 1)$ operations.

On the other hand, suppose we are given a minimal sequence of operations $\mathcal{O} = (\mathsf{op}_1, \ldots, \mathsf{op}_d)$ that edits $\mathbf{x}$ into $\mathbf{y}$. This leads to a categorization of the symbols of $\mathbf{x}$ as unchanged, modified, or deleted; and a similar categorization of the symbols of $\mathbf{y}$ as unchanged from $\mathbf{x}$, modified from $\mathbf{x}$, or inserted. The unchanged symbols of $\mathbf{x}$ and of $\mathbf{y}$ form a common subsequence $x_{i_1} = y_{j_1}, \ldots, x_{i_\ell} = y_{j_\ell}$ and partition the original operation sequence into $\ell + 1$ subsequences $\mathcal{O}_1, \ldots, \mathcal{O}_{\ell+1}$ such that for each $k \in [\ell + 1]$, $\mathcal{O}_k$ edits $\mathbf{x}_{(i_{k-1}, i_k)}$ into $\mathbf{y}_{(j_{k-1}, j_k)}$. By the minimality of $\mathcal{O}$, each $\mathcal{O}_k$ must contain either only insertions and modifications or only deletions and modifications. Thus we have $\left|\mathcal{O}_k\right| = \max\left(i_k - i_{k-1} - 1, j_k - j_{k-1} - 1\right)$. ◀

The following proposition is a standard exercise in dynamic programming, whose proof we omit (see, e.g., [9]).

▶ **Proposition 7.** LCS *and* Edit *can be solved on input* $\mathbf{x}, \mathbf{y} \in \Sigma^n \times \Sigma^m$ *in* $O(n \cdot m)$ *time.*

The main technical lemma of Section 2 is a search delegation scheme for $\mathsf{MCSA}[c]$. running time.

▶ **Lemma 8.** *For every cost function* c *such that* $\mathsf{MCSA}[c]$ *is solvable in* $O(n \cdot m)$ *time and for every* $a = a(n, m)$*, there is an honest-advisor search delegation scheme for* $\mathsf{MCSA}[c]$ *that uses* a *bits of advice, and runs in time* $O\left(n + m + a + \frac{nm \log(nm)}{a}\right)$.

Furthermore assuming collision-resistant hash functions, this can be improved to an untrusted-advisor search delegation scheme with computational soundness.

2.3 Solution-Dependent Optimal Substructure

From this point on, we fix some cost function c such that $\mathsf{MCSA}[c]$ is solvable in $O(n \cdot m)$ time, and simply write MCSA in place of $\mathsf{MCSA}[c]$. We fix a specific c here because not all functions c necessarily have a $O(n \cdot m)$ time algorithm, however, both LCS and Edit do (see Proposition 7).

The main lemma in this section is that if some optimal alignment of $\mathbf{x}$ to $\mathbf{y}$ matches x_i with y_j, then any alignment of $\mathbf{x}$ to $\mathbf{y}$ that matches x_i with y_j is optimal if and only if it optimally aligns $\mathbf{x}_{<i}$ to $\mathbf{y}_{<j}$ and $\mathbf{x}_{>i}$ to $\mathbf{y}_{>j}$.

▶ **Proposition 9.** *Let* $\big((\mathbf{x},\mathbf{y}),(\mathbf{i},\mathbf{j})\big) \in \mathsf{MCSA}$ *with* $\mathbf{i} = (i_1,\ldots,i_\ell)$ *and* $\mathbf{j} = (j_1,\ldots,j_\ell)$.

For any $k \in [\ell]$, *any* $\ell_L, \ell_R \in \mathbb{Z}^+$, *any* $(\mathbf{i}'_L,\mathbf{j}'_L) \in [i_k-1]^{\ell_L} \times [j_k-1]^{\ell_L}$, *and any* $(\mathbf{i}'_R,\mathbf{j}'_R) \in [i_k+1,n]^{\ell_R} \times [j_k+1,m]^{\ell_R}$, *we have*

$$\big(\mathbf{i}'_L \circ i_k \circ \mathbf{i}'_R,\ \mathbf{j}'_L \circ j_k \circ \mathbf{j}'_R\big) \in \mathsf{MCSA}\big(\mathbf{x},\mathbf{y}\big)$$

if and only if $(\mathbf{i}'_L,\mathbf{j}'_L) \in \mathsf{MCSA}(\mathbf{x}_{<i_k},\mathbf{y}_{<j_k})$ *and* $(\mathbf{i}'_R,\mathbf{j}'_R) \in \mathsf{MCSA}(\mathbf{x}_{>i_k},\mathbf{y}_{>j_k})$.

Proof. By definition, the "total cost" of $\big(\mathbf{i}'_L \circ i_k \circ \mathbf{i}'_R,\ \mathbf{j}'_L \circ j_k \circ \mathbf{j}'_R\big)$ with respect to $(\mathbf{x},\mathbf{y})$ is the sum of the cost of $(\mathbf{i}'_L,\mathbf{j}'_L)$ with respect to $(\mathbf{x}_{<i_k},\mathbf{y}_{<j_k})$ and the cost of $(\mathbf{i}'_R,\mathbf{j}'_R)$ with respect to $(\mathbf{x}_{>i_k},\mathbf{y}_{>j_k})$. ◀

2.4 Our Protocol

Following the discussion in the introduction, we assume first that the advisor is honest. Suppose we are given an input $(\mathbf{x},\mathbf{y}) \in \Sigma^n \times \Sigma^m$ and have an advice budget of $a = a' \cdot \log(nm)$.

The advice in our protocol consists of an ordered rooted binary tree $\mathcal{T}$ with $O(a)$ vertices, such that:

- Every vertex v of $\mathcal{T}$ is labeled with a pair of intervals $(v.I, v.J)$ with $v.I \subseteq [n]$ and $v.J \subseteq [m]$. The root v_0 has $v_0.I = [n]$ and $v_0.J = [m]$.
- Every internal vertex v of $\mathcal{T}$ is additionally labeled with either:
  - (Case 1) $(v.i, v.j) \in v.I \times v.J$; or
  - (Case 2) $(v.i_1, v.i_2, v.j_1, v.j_2) \in v.I^2 \times v.J^2$.

  such that if $v.L$ and $v.R$ denote the left and right children of v, and if $(\mathbf{i}_L,\mathbf{j}_L)$ and $(\mathbf{i}_R,\mathbf{j}_R)$ are arbitrary elements of $\mathsf{MCSA}(\mathbf{x}_{v.L.I},\mathbf{y}_{v.L.J})$ and $\mathsf{MCSA}(\mathbf{x}_{v.R.I},\mathbf{y}_{v.R.J})$ respectively, then either:
  - (Case 1) $(\mathbf{i}_L \circ v.i \circ \mathbf{i}_R,\ \ \mathbf{j}_L \circ v.j \circ \mathbf{j}_R) \in \mathsf{MCSA}(\mathbf{x}_{v.I},\mathbf{y}_{v.J})$; or
  - (Case 2) $(\mathbf{i}_L \circ v.i_1 \circ v.i_2 \circ \mathbf{i}_R,\ \ \mathbf{j}_L \circ v.j_1 \circ v.j_2 \circ \mathbf{j}_R) \in \mathsf{MCSA}(\mathbf{x}_{v.I},\mathbf{y}_{v.J})$.

  This property gives a means to compute a solution to $\mathsf{MCSA}(\mathbf{x}_{v.I},\mathbf{y}_{v.J})$ in $O(1)$ time given any solutions to $\mathsf{MCSA}(\mathbf{x}_{v.L.I},\mathbf{y}_{v.L.J})$ and $\mathsf{MCSA}(\mathbf{x}_{v.R.I},\mathbf{y}_{v.R.J})$. Thus if we have solutions to $\mathsf{MCSA}(\mathbf{x}_{\ell.I},\mathbf{y}_{\ell.J})$ for all leaf nodes $\ell \in \mathcal{T}$, then we can compute a solution to $\mathsf{MCSA}(\mathbf{x},\mathbf{y})$ in time $O(|\mathcal{T}|)$.
- For every internal vertex v of $\mathcal{T}$, $v.L.I$ and $v.R.I$ are disjoint subsets of $v.I$. Similarly $v.L.J$ and $v.R.J$ are disjoint subsets of $v.J$, such that

$$|v.L.I| \cdot |v.L.J| + |v.R.I| \cdot |v.R.J| \le \frac{|v.I| \cdot |v.J|}{2}. \tag{2}$$

- Every vertex v of $\mathcal{T}$ with depth less than $\lfloor \log a' \rfloor$ satisfies $\min\big(|v.I|, |v.J|\big) = O(1)$.

2.4.1 Solving MCSA(x, y) given $\mathcal{T}$

As alluded to in the second property of $\mathcal{T}$, the client directly solves $\mathsf{MCSA}\big(\mathbf{x}_{\ell.I},\mathbf{y}_{\ell.J}\big)$ for every leaf node ℓ in $\mathcal{T}$. This takes time

$$O\Big(\sum_{\ell} |\ell.I| \cdot |\ell.J|\Big).$$

We split this sum into two sums: one over leaves of depth less than $\lfloor \log a' \rfloor$ and the other over leaves of depth at least $\lfloor \log a' \rfloor$.

- (Low-Depth Leaves) For low depth leaves ℓ, we bound $|\ell.I| \cdot |\ell.J|$ by $O(|\ell.I| + |\ell.J|)$. This is justified by the last property of $\mathcal{T}$, which asserts that either $|\ell.I|$ or $|\ell.J|$ is a constant. Now, we bound

$$\sum_{\text{low-depth } \ell} |\ell.I| + |\ell.J| \leq n + m,$$

  using the fact that $v.L.I$ and $v.R.I$ (respectively $v.L.J$ and $v.R.J$) are disjoint subsets of $v.I$ (respectively $v.J$).
- (High-Depth Leaves) By Equation (2), we know that

$$\sum_{\text{depth-}d \text{ leaves } \ell} |\ell.I| \cdot |\ell.J| \leq n \cdot m \cdot 2^{-d},$$

  and thus

$$\sum_{d \geq \lfloor \log a \rfloor} \sum_{\text{depth-}d \text{ leaves } \ell} |\ell.I| \cdot |\ell.J| \leq \frac{2nm}{a'}.$$

Finally, using the second property of $\mathcal{T}$, the client processes its leaf solutions into a solution to $\mathsf{MCSA}(\mathbf{x}, \mathbf{y})$. This takes time $O(|\mathcal{T}|) = O(a)$.

In total, the client's runtime is

$$O\left(n + m + a + \frac{nm}{a \log(nm)}\right).$$

2.4.2 Constructing $\mathcal{T}$

We construct $\mathcal{T}$ iteratively. On input $\mathbf{x} \in \Sigma^n, \mathbf{y} \in \Sigma^m$, start with a tree that consists only of a root vertex labeled with $I = [n]$ and $J = [m]$.

We say that a leaf vertex ℓ is $\mathsf{expandable}$ if either $\min(|\ell.I|, |\ell.J|) \geq 2$. For any interval $[a, b] \subseteq \mathbb{Z}$, let $\mathsf{middle}(I)$ denote $(a + b)/2$.

While there is an expandable leaf of $\mathcal{T}$:

1. Pick an expandable leaf of minimum-depth, and call it ℓ.
2. Compute $(\mathbf{i}, \mathbf{j}) \in \mathsf{MCSA}(\mathbf{x}_{\ell.I}, \mathbf{y}_{\ell.J})$.
3. Do either of the following (at least one will be applicable), defining i_0 and j_0 as $\min(I) - 1$ and $\min(J) - 1$ respectively, and defining $i_{|\mathbf{i}|+1}$ and $j_{|\mathbf{i}|+1}$ as $\max(I) + 1$ and $\max(J) + 1$ respectively:
   - **Case 1**: For some k, (i_k, j_k) "crosses" $(\mathsf{middle}(\ell.I), \mathsf{middle}(\ell.J))$. That is, either $i_k \leq \mathsf{middle}(\ell.I)$ and $j_k \geq \mathsf{middle}(\ell.J)$, or $i_k \geq \mathsf{middle}(\ell.I)$ and $j_k \leq \mathsf{middle}(\ell.J)$.
     In this case, add child nodes $v.L$ and $v.R$ to v, with $v.L.I = v.I \cap (-\infty, i_k)$, $v.L.J = v.J \cap (-\infty, j_k)$, $v.R.I = v.I \cap (i_k, \infty)$, and $v.R.J = v.J \cap (j_k, \infty)$. Set $v.i = i_k$ and $v.j = j_k$.
   - **Case 2:** For some k, $i_k \leq \mathsf{middle}(v.I) < i_{k+1}$ and $j_k \leq \mathsf{middle}(v.J) < j_{k+1}$.
     In this case, add child nodes $v.L$ and $v.R$ to v, with $v.L.I = v.I \cap (-\infty, i_k)$, $v.L.J = v.J \cap (-\infty, j_k)$, $v.R.I = v.I \cap (i_{k+1}, \infty)$, and $v.R.J = v.J \cap (j_{k+1}, \infty)$. Set $v.i_1 = i_k$, $v.i_2 = i_{k+1}$, $v.j_1 = j_k$, and $v.j_2 = j_{k+1}$.

   To see that one of the above cases will always be possible, let k^* and $\hat{k}$ be such that $i_{k^*} \leq \mathsf{middle}(I) < i_{k^*+1}$ and $j_{\hat{k}} \leq \mathsf{middle}(J) < j_{\hat{k}+1}$. If $k^* = \hat{k}$ then we are in case 2. Otherwise we are in case 1.

   The labelings of the children of v ensure the second property of $\mathcal{T}$ by Proposition 9. The last property of $\mathcal{T}$ is guaranteed by the fact that we always expand a lowest-depth expandable leaf.

We now turn to the third property of $\mathcal{T}$, i.e. establishing that Equation (2) holds. This is easy to see in Case 2. In Case 1, observe that either $|v.L.I| \leq |v.I|/2$ and $|v.L.J| \geq |v.J|/2$ or $|v.L.I| \geq |v.I|/2$ and $|v.L.J| \geq |v.J|/2$. We then have

$$\begin{aligned}|v.L.I| \cdot |v.L.J| + |v.R.I| \cdot |v.R.J| &\leq |v.L.I| \cdot |v.L.J| + \big(|v.I| - |v.L.I|\big) \cdot \big(|v.J| - |v.L.J|\big) \\ &= \frac{|v.I| \cdot |v.J|}{2} + \frac{1}{2} \cdot \big(|v.I| - 2|v.L.I|\big) \cdot \big(|v.J| - 2|v.L.J|\big) \\ &\leq \frac{|v.I| \cdot |v.J|}{2},\end{aligned}$$

as desired.

2.4.3 Advisor Efficiency

We note that the advisor's messages can be computed in linear time given any $(\mathbf{i}, \mathbf{j}) \in \mathsf{MCSA}(\mathbf{x}, \mathbf{y})$. Thus the advisor's running time is dominated by the cost of finding such a $(\mathbf{i}, \mathbf{j})$, which by Proposition 7 takes time $O(n \cdot m)$.

3 Parsing Context-Free Grammars

We start with background on context-free grammars in Section 3.1. Then, in Section 3.2 we state our main result and prove it in Section 3.3.

3.1 Context-Free Grammars

We first define context-free grammars. Parts of the following overview are directly based on [12]. See the standard textbook [15] for more detailed background.

▶ **Definition 10** (Context-free grammar). *A* context-free grammar *is a tuple $G = (V, \Sigma, R, A_{\mathsf{start}})$ such that V is a (finite) set of symbols, referred to as* variables*; Σ is a (finite) set of symbols, referred to as* terminals*; $R \subseteq V \times (V \cup \Sigma)^*$ is a (finite) relation, where each $(A, \alpha) \in R$ is referred to as a* production rule *and is denoted by $A \to \alpha$; $A_{\mathsf{start}} \in V$ is a variable that is referred to as the* start variable*.*

Let $G = (V, \Sigma, R, A_{\mathsf{start}})$ be a context-free grammar, and let $\alpha, \beta \in (V \cup \Sigma)^*$ be strings of terminals and variables. We say that α directly yields β, denoted by $\alpha \Rightarrow \beta$, if there exists a production rule $A \to \gamma$ in R such that β is obtained from α by replacing exactly one occurrence of the variable A in α with the string $\gamma \in (V \cup \Sigma)^*$. We say that α yields β, denoted $\alpha \overset{*}{\Rightarrow} \beta$ if there exists a finite sequence of strings $\alpha_0, \ldots, \alpha_k \in (V \cup \Sigma)^*$ such that $\alpha_0 = \alpha$, $\alpha_k = \beta$, and $\alpha_0 \Rightarrow \ldots \Rightarrow \alpha_k$.

A grammar is said to be in *Chomsky normal form* if all of the production rules are of the form: (1) $A \to B \circ C$, where A, B and C are variables, (2) $A \to a$, where A is a variable and a is a terminal, or (3) $A \to \varepsilon$, where A is a variable and ε denotes the empty string. We note that every context-free grammar can be transformed into Chomsky normal form (with at most a quadratic blowup in the size of the grammar).

3.1.1 Derivation Tree

Let $G = (V, \Sigma, R, A_{\mathsf{start}})$ be a context-free grammar. For $A \in V$ and $\alpha \in (V \cup \Sigma)^*$, a derivation tree, corresponding to the derivation[5] $A \overset{*}{\Rightarrow} \alpha$, is a rooted, directed, ordered, and labeled tree T (with edges oriented away from the root) that satisfies the following properties:

[5] The literature usually focuses on derivations trees for words composed of terminals only whereas we allow for a mix of variables and terminals.

- Each internal vertex is labeled by some variable, and the root is labeled by the variable A.
- Each leaf is labeled by a terminal or variable, where the i^{th} leaf is labeled by the i^{th} symbol of α.
- For every internal vertex v, if v is labeled by A' and its children are labeled by $\alpha_1, \ldots, \alpha_d \in (V \cup \Sigma)$ (where d denotes the number of children of v), then the production rule $A' \to \alpha_1 \circ \cdots \circ \alpha_k$ must belong to R, where $\circ$ denotes concatenation.

Note that for every derivation $A \stackrel{*}{\Rightarrow} \alpha$ there exists (at least one) corresponding derivation tree.

3.1.2 Parsing

The *parsing* problem is, given a grammar G and a word $w \in \Sigma^n$, to find a derivation tree corresponding to the fact that G derives w, or output $\perp$ if no such tree exists. A more general problem also considered in the literature is outputting *all* of the derivation trees corresponding to w but we focus here on the simpler task of finding *some* derivation tree. Thus, a parser for a grammar G is an algorithm that given as input a word w outputs a corresponding derivation tree, or $\perp$ if no such tree exists. As customary, we view the grammar as constant size and measure the complexity as a function of the input length.

We rely on the following result due to Valiant [20]:

▶ **Theorem 11** ([20]). *Every context-free grammar in Chomsky normal form has a time $O(n^{\omega_b})$ parser.*

Here and throughout, ω_b is the exponent for Boolean matrix multiplication (i.e., matrix multiplication in which the inner product operations is replaced with an OR of ANDs). The current known upper bound on ω_b is equal to the best known bound on ω [3] , the standard exponent for matrix multiplication.

Trees and the Lewis-Stearns-Hartmanis Lemma

In this section we only consider trees that are rooted, directed, and ordered (such as derivation trees defined above). Thus, throughout this section, whenever we say tree, we mean a rooted, directed, and ordered tree (with edges oriented away from the root). Note that the fact that the tree is ordered induces an ordering of its leaves. We define the arity of a tree to be the maximal number of children of any vertex in the tree. We follow the data-structure literature and define a subtree of a tree T as a tree consisting of a node in T and all of its descendants in T.[6] We use $L(T)$ to denote the number of leaves in the tree T.

The classic Lewis-Stearns-Hartmanis Lemma [18] shows that every binary tree on n leaves has a subtree with between $n/3$ and $2n/3$ leaves. We use here a more general form of this lemma, given by Goldreich *et al.* [12] who show that for every desired parameter t, any binary tree has a subtree with approximately t leaves (actually [12] further generalize to trees of different constant arity):

▶ **Lemma 12** ([12, Lemma 2.5]). *Let T be a binary tree and let $t \in [L(T)]$. Then, there exists a subtree T' of T with $L(T') \in [t/2, t]$ leaves.*

(The Lewis-Stearns-Hartmanis lemma corresponds to the special case when $t = 2n/3$.)

[6] This definition differs from the graph-theoretic definition that defines a subtree as any connected subgraph of a tree. For example, the root of a tree is a subtree in the graph theoretic sense but not according to our definition (unless the tree has exactly one vertex).

3.2 Delegating Context-Free Parsing

▶ **Theorem 13.** *Let G be a context-free grammar in Chomsky normal form. Then, for every parameter $a = a(n)$, there exists a search delegation scheme for the parsing problem for G, where the client runs in time $O(n^{\omega_b}/a^{\omega_b-1} + a \cdot \log n)$ and the communication complexity is $O(a \cdot \log n)$.*

For example, taking $a = n/\mathsf{polylog}(n)$, we obtain a quasi-linear time client with sub-linear communication. Alternatively, taking $a = n^{\frac{\omega_b-2}{\omega_b-1}} < \sqrt{n}$ we obtain a quadratic-time client with $\tilde{O}(\sqrt{n})$ communication.

3.3 Proof of Theorem 13

Let $G = (V, \Sigma, R, A_{\mathsf{start}})$ be a context-free grammar in Chomsky normal form. Recall that our task is to construct a delegation scheme for finding a derivation tree for a given word w derived by G. However, to facilitate recursion, we will actually solve a more general problem where the word $w \in (\Sigma \cup V)^*$ can be a mix of terminals and variables.

Consider a derivation tree T for $w \in (\Sigma \cup V)^*$. Since the grammar is in Chomsky normal form, the tree is binary and so for a given parameter t, Lemma 12 guarantees that T has a subtree T' of size roughly t. More precisely, a subtree T' with between $t/2$ and t leaves. Let x' be the substring of x corresponding to the tree T'.

We first construct an honest-advisor delegation scheme and then show how to deal with an untrusted advisor. In the scheme, the advisor first finds x' within x – that is, indices i and j such that $x' = x[i+1, \ldots, j]$). The advisor also finds the variable A associated with the root of T' in the derivation tree T. The advisor sends (i, j, A) to the client. The client is now left with two tasks:

- Find the derivation tree T' corresponding to $A \stackrel{*}{\Rightarrow} x'$.
- Find a derivation tree T'' corresponding to $A_{\mathsf{start}} \stackrel{*}{\Rightarrow} x[1, \ldots, i-1] \circ S \circ x[j+1, \ldots, n]$.

We solve the first of these directly, that is, by invoking a context-free parser (as in Theorem 11). The second problem is solved recursively. Note that two resulting derivation trees T' and T'' can be easily grafted together to construct a derivation tree corresponding to $A_{\mathsf{start}} \stackrel{*}{\Rightarrow} x$. However, some care needs to be given also for this task, since we do not want to process the entire tree T' again just for grafting. Rather, we ensure that the tree is represented using a data structure so that the grafting takes $O(1)$ time (e.g., using pointers). We also note that the base case of the recursion is solved by directly invoking a context-free parser.

Denote by $W(n, a)$ the running time of the client if we allow a recursive calls (and note that the corresponding communication complexity is $O(a \cdot \log n)$. Given the time $c \cdot n^{\omega_b}$ context-free parser of Theorem 11, where c is some constant, we have:

$$W(n, a) \leq c \cdot t^{\omega_b} + W(n - t/2, a - 1) + O(\log n). \tag{3}$$

Expanding, we see that any solution to Equation (3) must satisfy

$$W(n, a) \leq c \cdot a \cdot t^{\omega_b} + c \cdot (n - a \cdot t/2)^{\omega_b} + O(a \cdot \log n).$$

Setting the parameter $t = 2n/a$, we obtain:

$$W(n, a) \leq c \cdot a \cdot (2n/a)^{\omega_b} + O(a \cdot \log n) = O(n^{\omega_b}/a^{\omega_b-1} + a \cdot \log n).$$

3.3.1 Coping with cheating advisors

In order to deal with a dishonest advisor, we note that given a candidate derivation tree, there is a linear (in the size of the tree) time algorithm that checks that its validity (by simply checking that each vertex is consistent with the grammar). Thus, we can easily transform our protocol to handle dishonest advisors by having the client check its answer and outputting $\perp$ in case the generated tree is invalid.

4 k-SAT

In this section, we construct a search delegation scheme for k-SAT, where k is some constant. Recall that an instance of k-SAT is a CNF formula on n variables $(x_1, \ldots, x_n)$ with m clauses, each of which is a disjunction of at most k literals (variables or their negations).

A trivial delegation scheme for k-SAT on a given formula $\varphi : \{0,1\}^n \to \{0,1\}$ is to simply send the first a bits of a satisfying assignment for φ. This reduces the number of variables to $n - a$, so if $T_k(n)$ denotes the time to solve an n-variable k-SAT instance, this hint reduces the client's running time to $T_k(n-a)$. In particular, if $T_k(n) = 2^{c_k \cdot n}$ for some $c_k < 1$, then a bits of hint yield a factor $2^{c_k \cdot a}$ speedup.

We achieve an improved factor 2^a speedup for a specific k-SAT algorithm due to [19], which we henceforth refer to as PPSZ. PPSZ is relatively simple, and has a running time that is close to the state of the art algorithm due to Hansen *et al.* [14].

▶ **Theorem 14.** *Let $(c_k)_{k \in \mathbb{Z}^+}$ be constants such that the analyzed running time of the PPSZ algorithm for k-SAT, with success probability*[7] *$\frac{1}{2}$, is $2^{c_k n + o(n)}$. Then, for every $a = a(n)$ and $\kappa = \kappa(n) \leq n^{O(1)}$, there exists a search delegation scheme in which the advisor sends a bits and the client's run-time is $2^{c_k \cdot n - a + o(n)}$, assuming the advisor and client have access to a shared $\mathsf{poly}(n)$-length random string. The completeness error is $2^{-\kappa}$ and the soundness error is 0.*

To prove Theorem 14, roughly speaking, we observe that PPSZ can be viewed as a nondeterministic polynomial-time algorithm that uses $c_k n$ bits of nondeterminism - in other words, an exhaustive search for a $c_k n$-bit string. Such an emulation clearly takes $\tilde{O}(2^{c_k n})$ time. The hint in our protocol then consists of the first a bits of this nondeterminism rather than the first a bits of a satisfying assignment for φ.

This description is not completely accurate – PPSZ is actually a randomized algorithm. Each choice of randomness defines an exhaustive search problem such such that the exhaustive search has noticeable probability of yielding a satisfying assignment for φ. We describe PPSZ in a way that elucidates this structure in Appendix A.

Finally, we can deal with an untrusted advisor by simply verifying that at the end we have actually found a satisfying assignment to φ.

5 From Honest Advisor to Dishonest Advisor

In this section we describe a simple transformation from an honest-advisor search delegation to a full-fledged one (i.e., secure against an untrusted advisor).

[7] Since we can amplify success probability by repetition, c_k would be the same if we we required success probability as small as $1/\mathsf{poly}(n)$ or as large as $1 - 2^{-\mathsf{poly}(n)}$.

▶ **Lemma 15.** *Suppose that the relation $R \subseteq \{0,1\}^n \times \{0,1\}^m$ has an honest-advisor search delegation scheme with communication $c_{\mathsf{srch}} = c_{\mathsf{srch}}(n,m)$ and client running time $t_{\mathsf{srch}} = t_{\mathsf{srch}}(n,m)$. Suppose also that membership in the relation R can be verified by an interactive proof with communication $c_{\mathsf{prf}} = c_{\mathsf{prf}}(n,m)$ and verifier running time $t_{\mathsf{prf}} = t_{\mathsf{prf}}(n,m)$. Then, R has a full-fledged search delegation scheme with $c_{\mathsf{srch}} + c_{\mathsf{prf}}$ communication and $t_{\mathsf{srch}} + t_{\mathsf{prf}}$ client run-time.*

In case the interactive proof for R is only computationally sound, then the resulting delegation scheme is also only computationally sound.

Proof. Follows immediately by first running the honest-advisor protocol and then checking the solution using the interactive proof. ◀

For example, using Kilian's [16] celebrated argument-system we obtain the following corollary:

▶ **Corollary 16.** *Suppose that the relation $R \subseteq \{0,1\}^n \times \{0,1\}^m$ is decidable in polynomial-time and has an honest-advisor search delegation scheme with communication $c_{\mathsf{srch}} = c_{\mathsf{srch}}(n,m)$ and client running time $t_{\mathsf{srch}} = t_{\mathsf{srch}}(n,m)$. Then, assuming that there exist collision-resistant hash functions, the relation R has a computationally sound delegation scheme with communication $c_{\mathsf{srch}} + \mathsf{poly}(\kappa, \log(n+m))$ and verifier runtime $\tilde{O}(n+m) + \mathsf{poly}(\kappa, \log(n+m))$, where κ denotes a cryptographic security parameter.*

A PPSZ with Hints: Details

In this section we provide details about PPSZ and its analysis. We then discuss how a hint can be used to achieve optimal savings up to an additive log factor. We focus our attention on k-SAT instances that are *sparse* (the number of clauses is linear in the number of variables) and have *unique solutions* because when $k \geq 5$ there is a randomized reduction from general k-SAT to this restricted subset of instances [6].

PPSZ Overview

PPSZ has the following high-level structure. It first performs a polynomial-time "conditioning" step on the input formula k-CNF formula φ that produces an equivalent formula φ_s that has more clauses. Then PPSZ runs Search (see Algorithm 1) on φ_s. This produces I random candidate values of $(\pi, y) \in S_n \times \{0,1\}^n$ (where, as usual, S_n denotes the group of

permutations over $[n]$). Each pair is fed into the algorithm MODIFY (see Algorithm 2) until MODIFY produces a satisfying assignment to φ_s (and hence to φ). At a high level, MODIFY goes through the variables of φ_s one by one (in an order specified by π), and iteratively simplifies φ_s by setting the i^{th} variable to y_i. If at any stage there is a "unital" clause (a clause with exactly one variable x), then x is set to 1 if the clause is (x) and to 0 if the clause is $(\neg x)$. When this happens, we say that x is forced.

PPSZ Analysis

Let z denote the unique satisfying assignment to φ, and let $Forced(\varphi, \pi, y)$ denote the set of forced variables when running MODIFY(φ, π, y).

PPSZ prove that for $\pi \leftarrow S_n$, we have

$$\mathbb{E}_\pi\left[\left|Forced(\varphi_s, \pi, z)\right|\right] \geq (1 - c_k)n,$$

where c_k is some constant.

Call $\pi \in S_n$ good if $\left|Forced(\varphi_s, \pi, z)\right| \geq (1 - c_k)n - 1$. If SEARCH happens to sample a good π, then there is a $\approx 2^{-c_k n}$ probability that y will be sampled to agree with z outside of $Forced(\varphi_s, \pi, z)$, which causes MODIFY to terminate with a satisfying assignment for φ.

Finally, a random π is good with probability at least $1/n$. To see this, let F denote $\left|Forced(\varphi_s, \pi, z)\right|$. Markov's inequality then implies (because F is $[0, n]$-valued) that $\Pr\left[F \geq \mathbb{E}[F] - 1\right] \geq 1/n$.

Thus after $I = 2^{c_k n} \cdot \mathsf{poly}(n)$ trials, MODIFY will with overwhelming probability output a satisfying assignment for φ.

Algorithm 1 The SEARCH Algorithm from [19].

```
SEARCH(formula φ, integer I):
for i ∈ [1, I] do
    pick y uniformly at random {0,1}^n
    pick π uniformly at random
    z=MODIFY(φ, π, y)
    if z satisfies φ then
        return z
    end if
end for
return Unsatisfied
```

▶ **Lemma 17.** *Let c_k denoting the constant in the exponent of the running time of the PPSZ algorithm for k-SAT. Let $\kappa = \kappa(n) \leq n^{O(1)}$ denote a statistical security parameter.*

There for any $a = a(n)$, there is an honest-advisor search delegation scheme for k-SAT with:

- *completeness error $2^{-\kappa}$;*
- *a bits of communication;*
- *$\mathsf{poly}(n)$ bits of shared randomness; and*
- *client running time of $2^{c_k n - a} \cdot \mathsf{poly}(n)$.*

Proof Sketch. In our protocol, we assume that the advisor and client have access to shared randomness, which determines a sequence of permutations $\pi_1, \pi_2, \ldots \in S_n$. The advisor first sends the client an i such that π_i is good. With all but $2^{-\kappa}$ probability, i is $O(\kappa \log n)$, so this constitutes just $\log \kappa + \log \log n + O(1)$ bits of communication.

Algorithm 2 The MODIFY algorithm from [19].

MODIFY(formula φ, permutation π, assignment y):
$\varphi_0 = \varphi$
for $i \in [1, n]$ **do**
  if φ_{i-1} contains the unit clause $(x_{\pi[i]})$ **then**
    $z_{\pi[i]} = 1$
  else if φ_{i-1} contains the unit clause $(\bar{x}_{\pi[i]})$ **then**
    $z_{\pi[i]} = 0$
  else
    $x_i = y_i$
  end if
  $\varphi_i = \varphi_{i-1}$ with $x_{\pi_i} = z_{\pi_i}$
end for
return z

Algorithm 3 The MODIFY' algorithm.

MODIFY'(formula φ, permutation π, settings y):
$\varphi_0 = \varphi$
$j = 0$
for $i \in [1, n]$ **do**
  if φ_{i-1} contains the unit clause $(x_{\pi[i]})$ **then**
    $z_{\pi[i]} = 1$
  else if φ_{i-1} contains the unit clause $(\bar{x}_{\pi[i]})$ **then**
    $z_{\pi[i]} = 0$
  else
    $x_i = y_j$
    $j = j + 1$
  end if
  $\varphi_i = \varphi_{i-1}$ with $x_{\pi_i} = z_{\pi_i}$
end for
return z

Next, let $j_1, \ldots, j_{n'} \in [n]$ denote indices such that on input (φ_s, π_i, z), MODIFY assigns unforced values to $x_{j_1}, \ldots, x_{j_{n'}}$ (in that order). Because π_i is good, we have $n' \leq c_k n + 1$. If the total remaining advice budget is a, then the advisor sends $z_{j_1}, \ldots, z_{j_a}$ and n'.

Upon receiving $\big((y_1, \ldots, y_a), n'\big)$, the client then repeatedly samples $y_{a+1}, \ldots, y_{n'}$, computes $z := \text{MODIFY}'\big(\varphi_s, \pi_i, (y_1, \ldots, y_{n'})\big)$ and hopes for a successful trial, i.e. one in which z is a satisfying assignment for φ (this happens with probability at least $2^{-c_k n - 1}$ over the choice of $y_{a+1}, \ldots, y_{n'}$). After $\approx \kappa \cdot 2^{c_k n}$ trials, the client will have at least one successful trial with all but $2^{-\kappa}$ probability. ◀

Understanding the Moments of Tabulation Hashing via Chaoses

Jakob Bæk Tejs Houen
BARC, Department of Computer Science, University of Copenhagen, Denmark

Mikkel Thorup
BARC, Department of Computer Science, University of Copenhagen, Denmark

Abstract

Simple tabulation hashing dates back to Zobrist in 1970 and is defined as follows: Each key is viewed as c characters from some alphabet Σ, we have c fully random hash functions $h_0, \ldots, h_{c-1} : \Sigma \to \{0, \ldots, 2^l - 1\}$, and a key $x = (x_0, \ldots, x_{c-1})$ is hashed to $h(x) = h_0(x_0) \oplus \ldots \oplus h_{c-1}(x_{c-1})$ where $\oplus$ is the bitwise XOR operation. The previous results on tabulation hashing by Pătraşcu and Thorup [J.ACM'11] and by Aamand et al. [STOC'20] focused on proving Chernoff-style tail bounds on hash-based sums, e.g., the number keys hashing to a given value, for simple tabulation hashing, but their bounds do not cover the entire tail. Thus their results cannot bound moments. The paper Dahlgaard et al. [FOCS'15] provides a bound on the moments of certain hash-based sums, but their bound only holds for constant moments, and we need logarithmic moments.

Chaoses are random variables of the form $\sum a_{i_0,\ldots,i_{c-1}} X_{i_0} \cdot \ldots \cdot X_{i_{c-1}}$ where X_i are independent random variables. Chaoses are a well-studied concept from probability theory, and tight analysis has been proven in several instances, e.g., when the independent random variables are standard Gaussian variables and when the independent random variables have logarithmically convex tails. We notice that hash-based sums of simple tabulation hashing can be seen as a sum of chaoses that are not independent. This motivates us to use techniques from the theory of chaoses to analyze hash-based sums of simple tabulation hashing.

In this paper, we obtain bounds for all the moments of hash-based sums for simple tabulation hashing which are tight up to constants depending only on c. In contrast with the previous attempts, our approach will mostly be analytical and does not employ intricate combinatorial arguments. The improved analysis of simple tabulation hashing allows us to obtain bounds for the moments of hash-based sums for the mixed tabulation hashing introduced by Dahlgaard et al. [FOCS'15]. With simple tabulation hashing, there are certain inputs for which the concentration is much worse than with fully random hashing. However, with mixed tabulation, we get logarithmic moment bounds that are only a constant factor worse than those with fully random hashing for any possible input. This is a strong addition to other powerful probabilistic properties of mixed tabulation hashing proved by Dahlgaard et al.

1 Introduction

Hashing is a ubiquitous tool of randomized algorithms which dates all the way back to the 1950s [12]. A hash function is a random function, $h\colon U \to R$, that assigns a random hash value, $h(x) \in R$, to every key, $x \in U$. When designing algorithms and data structures, it is often assumed that one has access to a uniformly random hash function that can be evaluated in constant time. Even though this assumption is very useful and convenient, it is unfortunately also unrealistic. It is thus a natural goal to find practical and efficient constructions of hash functions that provably have guarantees akin to those of uniformly random hashing.

If we want implementable algorithms with provable performance similar to that proven assuming uniformly random hashing, then we have to find practical and efficient constructions of hash functions with guarantees akin to those of uniformly random hashing. An example of this is simple tabulation hashing introduced by Zobrist in 1970 [27]. The scheme is efficient and easy to implement, and Pătraşcu and Thorup [22] proved that it could replace uniformly random hashing in many algorithmic contexts. The versatility of simple tabulation does not stem from a single probabilistic power like k-independence (it is only 3-independent), but from an array of powers that have different usages in different applications. Having one hash function with multiple powers has many advantages. One is that we can use the same hash function implementation for many purposes. Another is that hash functions are often an inner-loop bottleneck, and then it is an advantage if the same hash value can be used for multiple purposes. Also, if we have proved that a simple hash function has some very different probabilistic properties, then, morally, we would expect it to possess many other properties to be uncovered as it has happened over the years for simple tabulation (see, e.g., [3, 4]). Finally, when we hash a key, we may not even know what property is needed, e.g., with weighted keys, we may need one property to deal with a few heavy keys, and another property to deal with the many light keys, but when we hash the key, we may not know if it is heavy or light.

One of the central powers proved for simple tabulation in [22] is that it has strong concentration bounds for hash-based sums (will be defined shortly in Section 1.1). The concentration holds only for quite limited expected values, yet this suffices for important applications in classic hash tables. Recently, Aamand et al. [2] introduced tabulation-permutation, which is only about twice as slow as simple tabulation, and which offers general concentration bounds that hold for all hash-based sums regardless of the expected size. An issue with tabulation-permutation is that it is not clear if it possesses the other strong powers of simple tabulation.

A different way to go is to construct increasingly strong schemes, each inheriting all the nice properties of its predecessors. In this direction, [21] introduced twisted tabulation strengtening simple tabulation, and [9] introduced mixed tabulation strengthening twisted tabulation. Each new scheme was introduced to get some powers not available with the predecessor. In particular, mixed tabulation has some selective full-randomness that is needed for aggregating statistics over hash-based k-partitions. These applications also needed concentration bounds for hash-based sums, but [9] only provided some specialized suboptimal concentration bounds.

In this paper, we do provide strong concentration bounds for mixed tabulation hashing which can then be used in tandem with all the other strong properties of simple, twisted, and mixed tabulation. In fact our bounds are more general than the strong concentration bounds proved in [2] for tabulation-permutation. More precisely, the concentration bounds in [2]

are Chernoff-style tail bounds that hold with high probability, while what we do is to show moment bounds that imply such tail bounds as special cases. Indeed the key to our results for mixed tabulation is a much stronger understanding of the moments of simple tabulation.

Below we proceed to describe our new mathematical understanding, including the relevance of chaoses. We will contextualize this with other work later in Section 1.6.

1.1 Moment bounds for hash-based sums

In this paper, we will focus on analyzing hash-based sums. More precisely, we consider a fixed *value function*, $v\colon U \times R \to \mathbb{R}$, and define the random variable $X_x = v(x, h(x))$ for every key $x \in U$. We are then interested in proving concentration bounds for the sum $X = \sum_{x\in U} X_x = \sum_{x\in U} v(x, h(x))$. It should be noted that the randomness of X derives from the hash function h, thus the results will depend on the strength of h.

This is quite a general problem, and at first glance, it might not be obvious why this is a natural construction to consider, but it does generalize a variety of well-studied constructions:

1. Let $S \subseteq U$ be a set of balls and assign a weight, $w_x \in \mathbb{R}$, for every ball, $x \in S$. The goal is to distribute the balls, S, into a set of bins $R = [m]$.[1] For a bin, $y \in [m]$, we define the value function $v_y\colon U \times [m] \to \mathbb{R}$ by $v_y(x, j) = w_x\,[j = y]\,[x \in S]$, then $X = \sum_{x\in U} v_y(x, h(x)) = \sum_{x\in S} w_x\,[h(x) = y]$ will be the weight of the balls hashing to bin y.[2]
2. Instead of concentrating on a single bin, we might be interested in the total weight of the balls hashing below some threshold l. This is useful for sampling, for if $h(x)$ is uniform in $[m]$, then $\Pr[h(x) < l] = l/m$. We then define the value function $v\colon U \times [m] \to \mathbb{R}$ by $v(x, j) = w_x\,[j < l]\,[x \in S]$, then $X = \sum_{x\in U} v(x, h(x)) = \sum_{x\in S} w_x\,[h(x) < l]$ will be precisely the total weight of the balls hashing below l.

The first case appears when one tries to allocate resources, and the second case arises in streaming algorithms, see, e.g., [1]. In any case, X ought to be concentrated around the mean $\mu = \mathrm{E}[X]$. If h is a uniformly random hash function then this will be the case under mild assumptions about v but it cannot otherwise be assumed a priori to be the case.

There are two natural ways to quantify the concentration of X, either we bound the tail of X, i.e., we bound $\Pr[|X - \mu| \geq t]$ for all $t \geq 0$, or we bound the central moments of X, i.e., we bound the p-th moment $\mathrm{E}[|X - \mu|^p]$ for all $p \geq 2$. If we have a bound on the tail that is exponentially decreasing, we can bound the central moments of X for all $p \geq 2$. Unfortunately, some of the prior works [2, 11, 25] prove bounds on the tail that are exponentially decreasing but also has an additive term of the form $n^{-\gamma}$ where $\gamma = O(1)$. It will then only be possible to give strong bounds for the central moments of X for $p = O(1)$. This is not necessarily a fault of the hash function but a defect of the analysis. In contrast, if we prove strong bounds for the central moments of X for $p = O(\log n)$ then we can use Markov's inequality to prove a bound the tail that is exponentially decreasing but with an additive term of the form $n^{-\gamma}$ where $\gamma = O(1)$. Thus in some sense, it is more robust to bound the moments compared to bounding the tail.

We can use the classic k-independent hashing framework of Wegman and Carter [26] as an easy way to obtain a hash function that has bounds on the central moments as a uniformly random hash function. A random hash function, $h\colon U \to R$, is k-independent if $(h(x_0), \ldots, h(x_{k-1}))$ is uniformly distributed in R^k for any k distinct keys $x_0, \ldots, x_{k-1} \in U$.

[1] For a positive integer $m \in \mathbb{N}$ we define $[m] = \{0, \ldots, m-1\}$.
[2] For a statement P we let $[P]$ be 1 if P is true and 0 otherwise.

The p-th central moment $\mathrm{E}[(X-\mu)^p]$ of X for a k-independent hash function h is the same as the p-th central moment of X for a fully random hash function when p is an even integer less than k. We shall, however, focus on simple and fast hashing schemes that are not even 4-independent, and yet we will show strong moment bounds.

1.2 Tabulation Hashing

Simple tabulation hashing dates back to 1970 and was first introduced by Zobrist for optimizing chess computers [27]. In simple tabulation hashing, we view the universe, U, to be of the form $U = \Sigma^c$ for some alphabet, Σ, and a positive integer c. Let $T\colon \{0,\dots,c-1\}\times\Sigma \to [2^l]$ be a uniformly random table, i.e., each value is chosen independently and uniformly at random from the set $[2^l]$. A simple tabulation hash function, $h\colon \Sigma^c \to [2^l]$, is then defined by

$$h(\alpha_0,\dots,\alpha_{c-1}) = \bigoplus_{i=0}^{c-1} T(i,\alpha_i)\ ,$$

where $\oplus$ is the bitwise XOR-operation, i.e., addition when $[2^l]$ is identified with the Abelian group $(\mathbb{Z}/2\mathbb{Z})^l$. We say that h is a simple tabulation hash function with c characters. With 8- or 16-bit characters, the random table T fits in cache, and then simple tabulation is very fast, e.g., in experiments, [22] found it to be as fast as two to three multiplications.

The moments of simple tabulation hashing have been studied in multiple papers. Braverman et al. [7] showed that for a fixed bin the 4th central moment is close to that achieved by truly random hashing. Dahlgaard et al. [10] generalized this to any constant moment p. Their proof works for any p but with a doubly exponential dependence on p, so their bound is only useful for $p = O(1)$. In this paper, we obtain bounds for all the moments of hash-based sums for simple tabulation hashing which are tight up to constants depending only on c.

Previous work has just treated c as a constant, hidden in O-notation. However, c does provide a fundamental trade-off between evaluation time with c lookups and the space $cU^{1/c}$. We therefore find it relevant to elucidate how our moment bounds depend on c even though we typically choose $c = 4$.

Mixed tabulation hashing was introduced by Dahlgaard et al. [9]. As in simple tabulation hashing, we view the universe, U, to be of the form $U = \Sigma^c$ for some alphabet, Σ, and a positive integer c. We further assume that the alphabet, Σ, has the form $\Sigma = [2^k]$. Let $h_1\colon \Sigma^c \to [2^l]$, $h_2\colon \Sigma^c \to \Sigma^d$, and $h_3\colon \Sigma^d \to [2^l]$ be independent simple tabulation hash functions. A mixed tabulation hash function, $h\colon \Sigma^c \to [2^l]$, is then defined by

$$h(x) = h_1(x) \oplus h_3(h_2(x))\ .$$

As in simple tabulation hashing, $\oplus$ is the bitwise XOR-operation. We call h a mixed tabulation hash function with c characters and d derived characters. We note that h_1 and h_2 can be combined in a single simple tabulation hash function $\Sigma^c \to [2^l]\times\Sigma^d$, and then h is implemented with only $c+d$ lookups.

With simple tabulation hashing, there are certain inputs for which the concentration is much worse than with fully random hashing. However, with mixed tabulation, even if we have just $d = 1$ derived character, we get logarithmic moment bounds that, for $c = O(1)$, are only a constant factor worse than those with fully-random hashing for any input assuming that hash range at most polynomial in the key universe.

Getting within a constant factor is very convenient within algorithm analysis, where we typically only aim for O-bounds that are tight within a constant factor.

1.3 Relation between Simple Tabulation and Chaoses

A *chaos* of order c is a random variable of the form

$$\sum_{0\leq i_0<\ldots<i_{c-1}<n} a_{i_0,\ldots,i_{c-1}} \prod_{j\in[c]} X_{i_j} \ ,$$

where $(X_i)_{i\in[n]}$ are independent random variables and $(a_{i_0,\ldots,i_{c-1}})_{0\leq i_0<\ldots<i_{c-1}<n}$ is a multi-indexed array of real numbers. And a *decoupled chaos* of order c is a random variable of the form

$$\sum_{i_0,\ldots,i_{c-1}\in[n]} a_{i_0,\ldots,i_{c-1}} \prod_{j\in[c]} X_{i_j}^{(j)} \ ,$$

where $(X_i^{(j)})_{i\in[n],j\in[c]}$ are independent random variables and $(a_{i_0,\ldots,i_{c-1}})_{i_0,\ldots,i_{c-1}\in[n]}$ is a multiindexed array of real numbers. Chaoses have been studied in different settings, e.g., when the variables are standard Gaussian variables [17, 18], when the variables have logarithmically concave tails [5], and when the variables have logarithmically convex tails [16].

From the definition of a chaos and simple tabulation hashing it might not be immediately clear that there is connection between the two. But we can rewrite the expression for hash-based sums of simple tabulation hashing as follows

$$\begin{aligned}\sum_{x\in\Sigma^c} v(x,h(x)) &= \sum_{\alpha_0,\ldots,\alpha_{c-1}\in\Sigma} v((\alpha_0,\ldots,\alpha_{c-1}),h(\alpha_0,\ldots,\alpha_{c-1}))\\ &= \sum_{j_0,\ldots,j_{c-1}\in[m]} \sum_{\alpha_0,\ldots,\alpha_{c-1}\in\Sigma} v\left((\alpha_0,\ldots,\alpha_{c-1}),\bigoplus_{i\in[c]} j_i\right) \prod_{i\in[c]} [T(i,\alpha_i)=j_i] \ .\end{aligned}$$

We then notice that $\sum_{\alpha_0,\ldots,\alpha_{c-1}\in\Sigma} v\left((\alpha_0,\ldots,\alpha_{c-1}),\bigoplus_{i\in[c]} j_i\right) \prod_{i\in[c]} [T(i,\alpha_i)=j_i]$ is a decoupled chaos of order c for any $(j_i)_{i\in[c]}$, thus hash-based sums of simple tabulation hashing can be seen as a sum of chaoses. Now since the random variables, $([T(i,\alpha_i)=j])_{j\in[m]}$, are not independent then the chaoses are not independent either which complicates the analysis. Nonetheless, this realization inspires us to use techniques from the study of chaoses to analyze the moments of tabulation hashing, in particular, our approach will be analytical in contrast with the combinatorial approach of the previous papers. We will expand further on the techniques in Section 1.5.

1.4 Our Results

When proving and stating bounds for the p-th moment of a random variable it is often more convenient and more instructive to do it in terms of the p-norm of the random variable. The p-norm of a random variable is the p-th root of the p-th moment of the random variable and is formally defined as follows:

▶ **Definition 1** (p-norm). *Let $p\geq 1$ and X be a random variable with $\mathrm{E}[|X|^p]<\infty$. We then define the p-norm of X by $\|X\|_p = \mathrm{E}[|X|^p]^{1/p}$.*

Our main contributions of this paper are analyses of the moments of hash-based sums of simple tabulation hashing and mixed tabulation hashing. To do this we first had to analyze the moments of hash-based sums of fully random hashing which as far as we are aware have not been analyzed tightly before.

1.4.1 The Moments of Fully Random Hashing

Previously, the focus has been on proving Chernoff-like bounds by using the moment generating function but a natural, different approach would be to use moments instead. Both the Chernoff bounds [8] and the more general Bennett's inequality [6] bound the tail using the Poisson distribution. More precisely, let $v\colon U \times [m] \to \mathbb{R}$ be a value function that satisfies that $\sum_{j\in[m]} v(x,j) = 0$ and define the following two parameters M_v and σ_v^2 which will be important throughout the paper as follows:

$$M_v = \max_{x\in U, j\in[m]} |v(x,j)| \ , \tag{1}$$

$$\sigma_v^2 = \frac{\sum_{x\in U, j\in[m]} v(x,j)^2}{m} \ . \tag{2}$$

Bennett's inequality specialized to our setting then says that for a fully random hash function h

$$\begin{aligned}\Pr\left[\left|\sum_{x\in U} v(x,h(x))\right| \geq t\right] &\leq 2\exp\Big(-\tfrac{\sigma_v^2}{M_v^2}\mathcal{C}\Big(\tfrac{tM_v}{\sigma_v^2}\Big)\Big) \\ &\leq \begin{cases} 2\exp\Big(-\frac{t^2}{3\sigma_v^2}\Big) & \text{if } t \leq \frac{\sigma_v^2}{M_v} \\ 2\exp\Big(-\frac{t}{2M_v}\log\Big(1+\frac{tM_v}{\sigma_v^2}\Big)\Big) & \text{if } t > \frac{\sigma_v^2}{M_v} \end{cases} \ , \end{aligned} \tag{3}$$

where $\mathcal{C}(x) = (x+1)\log(x+1) - x$.[3]

This inspires us to try to bound the p-norms of X_v with the p-norms of the Poisson distribution. To do this we will introduce the function $\Psi_p(M,\sigma^2)$ which is quite technical but we will prove that $\Psi_p(1,\lambda)$ is equal up to a constant factor to the central p-norm of a Poisson distributed variable with mean λ. One should think of $\Psi_p(M,\sigma^2)$ as a p-norm version of $\frac{\sigma_v^2}{M_v^2}\mathcal{C}\Big(\frac{tM_v}{\sigma_v^2}\Big)$ which appears in Bennett's inequality.

▶ **Definition 2.** *For $p \geq 2$ we define the function $\Psi_p\colon \mathbb{R}_+ \times \mathbb{R}_+ \to \mathbb{R}_+$ as follows*

$$\Psi_p(M,\sigma^2) = \begin{cases} \left(\frac{\sigma^2}{pM^2}\right)^{1/p} M & \text{if } p < \log\frac{pM^2}{\sigma^2} \\ \frac{1}{2}\sqrt{p}\sigma & \text{if } p < e^2\frac{\sigma^2}{M^2} \\ \frac{p}{e\log\frac{pM^2}{\sigma^2}} M & \text{if } \max\Big\{\log\frac{pM^2}{\sigma^2}, e^2\frac{\sigma^2}{M^2}\Big\} \leq p \end{cases} .$$

▶ Remark 3. When p is *small* then case 1 and 2 apply while for *large* p case 3 applies. If $2 < e^2\frac{\sigma^2}{M^2}$ then we always have that $p > \log\frac{pM^2}{\sigma^2}$ for $2 \leq p$, hence only case 2 and 3 apply. Similarly, if $e^2\frac{\sigma^2}{M^2} \leq 2$ then $p \geq e^2\frac{\sigma^2}{M^2}$ for all $2 \leq p$, hence only case 1 and 3 apply. This shows that the cases disjoint and cover all parameter configurations.

The definition $\Psi_p(M,\sigma^2)$ might appear strange but it does in fact capture the central p-norms of Poisson distributed random variables. This is stated more formally in the following lemma.

▶ **Lemma 4.** *There exist universal constants K_1 and K_2 satisfying that for a Poisson distributed random variable, X, with $\lambda = \mathrm{E}[X]$*

$$K_2\Psi_p(1,\lambda) \leq \|X-\lambda\|_p \leq K_1\Psi_p(1,\lambda) \ ,$$

for all $p \geq 2$.

[3] Here and throughout the paper $\log(x)$ will refer to the natural logarithm.

Bennett's inequality shows that we can bound the tail of $\sum_{x\in U} v(x,h(x))$ and Lemma 4 shows that $\Psi_p(M,\sigma^2)$ captures the central p-norms of the Poisson distribution. It is therefore not so surprising that we are to bound the p-norms of $\sum_{x\in U} v(x,h(x))$ using $\Psi_p(M,\sigma^2)$.

▶ **Theorem 5.** *Let $h\colon U \to [m]$ be a uniformly random function, let $v\colon U\times[m]\to\mathbb{R}$ be a fixed value function, and assume that $\sum_{j\in[m]} v(x,j) = 0$ for all keys $x\in U$. Define the random variable $X_v = \sum_{x\in U} v(x,h(x))$. Then for all $p\geq 2$*

$$\|X_v\|_p \leq L\Psi_p\left(M_v,\sigma_v^2\right) \ ,$$

where $L\leq 16e$ is a universal constant.

To get a further intuition for $\Psi_p(M,\sigma^2)$ is is instructive to apply Markov's inequality and compare the tail bound to Bennett's inequality. More precisely, assume that $\|Y-\mathrm{E}[Y]\|_p \leq L\Psi_p(M,\sigma^2)$ for a constant L and for all $p\geq 2$. Then we can use Markov's inequality to get the following tail bound for all $t>0$

$$\begin{aligned}\Pr\Big[\Big|Y-\mathrm{E}[Y]\Big|\geq t\Big] &\leq \left(\frac{\|Y-\mathrm{E}[Y]\|_p}{t}\right)^p \\ &\leq \begin{cases} \frac{L^2\sigma^2}{2t^2} & \text{if } t\leq L\max\left\{M,\frac{e\sigma}{\sqrt{2}}\right\} \\ \exp\left(-\frac{4t^2}{e^2L^2\sigma^2}\right) & \text{if } L\frac{e\sigma}{\sqrt{2}}\leq t\leq L\frac{e^2\sigma^2}{2M} \\ \exp\left(-\frac{t}{LM}\log\left(\frac{2tM}{L\sigma^2}\right)\right) & \text{if } L\max\left\{\frac{e^2\sigma^2}{2M},M\right\}\leq t \end{cases} \ . \end{aligned} \tag{4}$$

In order to obtain these bounds p is chosen as follows: If $t\leq \max\left\{M,\frac{e\sigma}{\sqrt{2}}\right\}$ then $p=2$ and otherwise p is chosen such that $\|Y-\mathrm{E}[Y]\|_p \leq e^{-1}t$. More precisely, we have that

$$p = \begin{cases} 2 & \text{if } t\leq L\max\left\{M,\frac{e\sigma}{\sqrt{2}}\right\} \\ \frac{4t^2}{e^2L^2\sigma^2} & \text{if } L\frac{e\sigma}{\sqrt{2}}\leq t\leq L\frac{e^2\sigma^2}{2M} \\ \frac{t}{LM}\log\left(\frac{2tM}{L\sigma^2}\right) & \text{if } L\max\left\{\frac{e^2\sigma^2}{2M},M\right\}\leq t \end{cases} \ .$$

We see that Equation (4) gives the same tail bound as Bennett's inequality, Equation (3), up to a constant in the exponent.

We also prove a matching lower bound to Theorem 5 which shows that $\Psi_p(M,\sigma^2)$ is the correct function to consider.

▶ **Theorem 6.** *Let $h\colon U\to[m]$ be a uniformly random function, then there exists a value function, $v\colon U\times[m]\to\mathbb{R}$, where $\sum_{j\in[m]} v(x,j)=0$ for all keys $x\in U$, such that the random variable $X_v=\sum_{x\in U} v(x,h(x))$ satisfies that for all $p\leq L_1|U|\log(m)$*

$$\left\|\sum_{x\in U} v(x,h(x))\right\|_p \geq L_2\Psi_p\left(M_v,\sigma_v^2\right) \ ,$$

where L_1 and L_2 are a universal constant.

1.4.2 The Moments of Tabulation Hashing

We analyze the p-norms of hash-based sums for simple tabulation hashing, and our analysis is the first that provides useful bounds for non-constant moments. Furthermore, it is also the first analysis of simple tabulation hashing that does not assume that c is constant. We

obtain an essentially tight understanding of this problem and show that simple tabulation hashing only works well when the range is large. This was also noted by Aamand et al. [2] and they solve this deficiency of simple tabulation hashing by introducing a new hashing scheme, tabulation-permutation hashing. We show that it is also possible to break the bad instances of simple tabulation hashing by using mixed tabulation hashing.

We introduce a bit of notation to make the theorems cleaner. We will view a value function $v\colon \Sigma^c \times [m] \to \mathbb{R}$ as a vector, more precisely, we let

$$\|v\|_q = \left(\sum_{x\in\Sigma^c}\sum_{j\in[m]} |v(x,j)|^q\right)^{1/q}$$

for all $q \in [1,\infty]$. For every key $x \in \Sigma^c$ we define $v[x]$ to be the sub-vector v restricted to x, more precisely, we let

$$\|v[x]\|_q = \left(\sum_{j\in[m]} |v(x,j)|^q\right)^{1/q}$$

for all $q \in [1,\infty]$.

1.4.2.1 Simple Tabulation Hashing

Our main result for simple tabulation hashing is a version of Theorem 5.

▶ **Theorem 7.** *Let $h\colon \Sigma^c \to [m]$ be a simple tabulation hash function, $v\colon \Sigma^c \times [m] \to \mathbb{R}$ a value function, and assume that $\sum_{j\in[m]} v(x,j) = 0$ for all keys $x \in \Sigma^c$. Define the random variable $V_v^{\text{simple}} = \sum_{x\in\Sigma^c} v(x,h(x))$. Then for all $p \geq 2$*

$$\left\|V_v^{\text{simple}}\right\|_p \leq L_1\Psi_p\left(K_c\gamma_p^{c-1}M_v, K_c\gamma_p^{c-1}\sigma_v^2\right) ,$$

where $K_c = (L_2c)^{c-1}$, L_1 and L_2 are universal constants, and

$$\gamma_p = \frac{\max\left\{\log(m) + \log\left(\frac{\sum_{x\in\Sigma^c}\|v[x]\|_2^2}{\max_{x\in\Sigma^c}\|v[x]\|_2^2}\right)/c, p\right\}}{\log\left(e^2m\left(\max_{x\in\Sigma^c}\frac{\|v[x]\|_1^2}{\|v[x]\|_2^2}\right)^{-1}\right)}$$

It is instructive to compare this result to Theorem 5 for fully random hashing. Ignoring the constant K_c, the result for simple tabulation hashing corresponds to the result for fully random hashing if we group keys into groups of size γ_p^{c-1}.

The definition of γ_p is somewhat complicated because of the generality of the theorem, but we will try to explain the intuition behind it. The expression $\max_{x\in\Sigma^c}\frac{\|v[x]\|_1^2}{\|v[x]\|_2^2}$ measures how spread out the mass of the value function is. It was also noted in the previous analysis by Aamand et al. [2] that this measure is naturally occurring. In fact, their result needs that $\max_{x\in\Sigma^c}\frac{\|v[x]\|_1^2}{\|v[x]\|_2^2} \leq m^{1/4}$. If we consider the example from the introduction of hashing below a threshold $l \leq m$ where each key, $x \in \Sigma^c$, has weight w_x, then the value function, v, will be $v(x,j) = w_x\left([j<l] - \frac{l}{m}\right)$ for $x \in \Sigma^c, j \in [m]$, and we then get that

$$\max_{x\in\Sigma^c}\frac{\|v[x]\|_1^2}{\|v[x]\|_2^2} = 4l\left(1-\frac{l}{m}\right) \leq 4l .$$

This correctly measures that the mass of the value function is mostly concentrated to the l positions of $[m]$.

The expression $\frac{\sum_{x\in\Sigma^c}\|v[x]\|_2^2}{\max_{x\in\Sigma^c}\|v[x]\|_2^2}$ is a measure for how many keys that have significant weight. This also showed up in the previous analyses of simple tabulation hashing [2, 22]. If we again consider the example from before, we get that

$$\frac{\sum_{x\in\Sigma^c}\|v[x]\|_2^2}{\max_{x\in\Sigma^c}\|v[x]\|_2^2} = \frac{\sum_{x\in\Sigma^c} w_x^2}{\max_{x\in\Sigma^c} w_x^2} \ .$$

We can summarize the example in the following corollary.

▶ **Corollary 8.** *Let $h\colon \Sigma^c \to [m]$ be a simple tabulation hash function, assign a weight, $w_x \in \mathbb{R}$, to every key, $x \in \Sigma^c$, and consider a threshold $l \leq m$. Define the random variable $V_v^{\text{simple}} = \sum_{x\in\Sigma^c} w_x\left([h(x) < l] - \frac{l}{m}\right)$. Then for all $p \geq 2$*

$$\left\|V_v^{\text{simple}}\right\|_p \leq \Psi_p\left(K_c\gamma_p^{c-1}\max_{x\in\Sigma^c}|w_x|\,, K_c\gamma_p^{c-1}\left(\sum_{x\in\Sigma^c} w_x^2\right)\frac{l}{m}\left(1-\frac{l}{m}\right)\right) \ ,$$

where $K_c = L_1\left(L_2 c\right)^{c-1}$, L_1 and L_2 are universal constants, and

$$\gamma_p = \frac{\max\left\{\log(m) + \log\left(\frac{\sum_{x\in\Sigma^c} w_x^2}{\max_{x\in\Sigma^c} w_x^2}\right)/c, p\right\}}{\log\left(\frac{e^2 m}{4l}\right)}$$

A natural question is how close Theorem 7 is to being tight. We show that if $\log(m) + \log\left(\frac{\sum_{x\in\Sigma^c}\|v[x]\|_2^2}{\max_{x\in\Sigma^c}\|v[x]\|_2^2}\right)/c = O\left(\log\left(1 + m\left(\max_{x\in\Sigma^c}\frac{\|v[x]\|_1^2}{\|v[x]\|_2^2}\right)^{-1}\right)\right)$ then the result is tight up to a universal constant depending only c. Formally, we prove the following lemma.

▶ **Theorem 9.** *Let $h\colon \Sigma^c \to [m]$ be a simple tabulation hash function, and $2 \leq p \leq L_1|\Sigma|\log(m)$, then there exists a value function, $v\colon U\times[m]\to\mathbb{R}$, where $\sum_{j\in[m]} v(x,j) = 0$ for all keys $x \in \Sigma^c$, and for which*

$$\left\|\sum_{x\in\Sigma^c} v(x,h(x))\right\|_p \geq K_c'\Psi_p\left(\gamma_p^{c-1}M_v, \gamma_p^{c-1}\sigma_v^2\right) \ ,$$

where $K_c' = L_1^c$ and L_1 is a universal constant, and

$$\gamma_p = \max\left\{1, \frac{p}{\log\left(e^2 m\left(\max_{x\in\Sigma^c}\frac{\|v[x]\|_1^2}{\|v[x]\|_2^2}\right)^{-1}\right)}\right\}$$

1.4.2.2 Mixed Tabulation Hashing

The results of simple tabulation hashing work well when the range is large and when the mass of the value function is on few coordinates. We show that mixed tabulation hashing works well even if the range is small.

▶ **Theorem 10.** *Let $h\colon \Sigma^c \to [m]$ be a mixed tabulation function with $d \geq 1$ derived characters, $v\colon \Sigma^c\times[m]\to\mathbb{R}$ a value function, and assume that $\sum_{j\in[m]} v(x,j) = 0$ for all keys $x \in \Sigma^c$. Define the random variable $V_v^{\text{mixed}} = \sum_{x\in\Sigma^c} v(x,h(x))$. For all $p \geq 2$ then*

$$\left\|V_v^{\text{mixed}}\right\|_p \leq \Psi_p\left(K_c\gamma_p^c M_v, K_c\gamma_p^c\sigma_v^2\right) \tag{5}$$

where $K_c = L_1\left(L_2 c\right)^c$, L_1 and L_2 are universal constants, and

$$\gamma_p = \max\left\{1, \frac{\log(m)}{\log(|\Sigma|)}, \frac{p}{\log(|\Sigma|)}\right\} \ .$$

Usually, in hashing contexts, we do not map to a much larger domain, i.e., we will usually have that $m \leq |U|^\gamma$ for some constant $\gamma \geq 1$. If this is the case then we can obtain the following nice tail bound for mixed tabulation hashing by using Markov's inequality.

▶ **Corollary 11.** *Let $h\colon \Sigma^c \to [m]$ be a mixed tabulation function with $d \geq 1$ derived characters, $v\colon \Sigma^c \times [m] \to \mathbb{R}$ a value function, and assume that $\sum_{j\in[m]} v(x,j) = 0$ for all keys $x \in \Sigma^c$. Define the random variable $V_v^{\text{mixed}} = \sum_{x\in\Sigma^c} v(x,h(x))$. If $m \leq |U|^\gamma$ for a value $\gamma \geq 1$ then for all $t \geq 0$*

$$\Pr\left[\left|V_v^{\text{mixed}}\right| \geq t\right] \leq \exp\left(-\frac{\sigma_v^2}{M_v^2}\mathcal{C}\left(\frac{tM_v}{\sigma_v^2}\right)/K_{c,\gamma}\right) + |U|^{-\gamma} \ ,$$

where $\mathcal{C}(x) = (x+1)\log(x+1) - x$, $K_{c,\gamma} = L_1\left(L_2c^2\gamma\right)^c$, and L_1 and L_2 are universal constants.

Proof. The idea is to combine Theorem 10 and Markov's inequality. We use Theorem 10 for $2 \leq p \leq \gamma\log|U|$ to get that

$$\left\|V_v^{\text{mixed}}\right\|_p \leq \Psi_p\left(K_c\gamma_p^c M_v, K_c\gamma_p^c\sigma_v^2\right) \ ,$$

where we can bound γ_p by

$$\gamma_p = \max\left\{1, \frac{\log(m)}{\log(|\Sigma|)}, \frac{p}{\log(|\Sigma|)}\right\} \leq c\gamma \ .$$

So we have that

$$\left\|V_v^{\text{mixed}}\right\|_p \leq \Psi_p\left(\left(L_2c^2\gamma\right)^c M_v, \left(L_2c^2\gamma\right)^c\sigma_v^2\right) \ .$$

Now by the same method as in Equation (4), we get the result. ◀

1.4.2.3 Adding a query element

In many cases, we would like to prove that these properties continue to hold even when conditioning on a query element. An example would be the case where we are interested in the weight of the elements in the bin for which the query element, q, hashes to, i.e., we would like that $\sum_{x\in S} w_x\,[h(x) = h(q)]$ is concentrated when conditioning on q. Formally, this corresponds to having the value function $v\colon \Sigma^c \times [m] \times [m]$ defined by $v(x,j,k) = w_x\,[x \in S]\,[j = k]$ and then proving concentration on $\sum_{x\in\Sigma^c\setminus\{q\}} v(x,h(x),h(q))$ when conditioning on q. We show that this holds both for simple tabulation and mixed tabulation.

▶ **Theorem 12.** *Let $h\colon \Sigma^c \to [m]$ be a simple tabulation hash function and let $q \in \Sigma^c$ be a designated query element. Let $v\colon \Sigma^c \times [m] \times [m] \to \mathbb{R}$ a value function, and assume that $\sum_{j\in[m]} v(x,j,k) = 0$ for all keys $x \in U$ and all $k \in [m]$. Define the random variable $V_{v,q}^{\text{simple}} = \sum_{x\in\Sigma^c\setminus\{q\}} v(x,h(x),h(q))$ and the random variables*

$$M_{v,q} = \max_{x\in\Sigma^c\setminus\{q\}, j\in[m]} |v(x,j,h(q))| \ ,$$
$$\sigma_{v,q}^2 = \frac{1}{m}\sum_{x\in\Sigma^c\setminus\{q\}}\sum_{j\in[m]} v(x,j,h(q))^2 \ ,$$

which only depend on the randomness of $h(q)$. Then for all $p \geq 2$

$$\mathrm{E}\left[\left(V_{v,q}^{\text{simple}}\right)^p \,\middle|\, h(q)\right]^{1/p} \leq \Psi_p\left(K_c\gamma_p^{c-1}M_{v,q}, K_c\gamma_p^{c-1}\sigma_{v,q}^2\right) \ ,$$

where $K_c = L_1 (L_2 c)^{c-1}$, L_1 *and* L_2 *are universal constants, and*

$$\gamma_p = \frac{\max\left\{\log(m) + \log\left(\frac{\sum_{x\in\Sigma^c}\|v[x]\|_2^2}{\max_{x\in\Sigma^c}\|v[x]\|_2^2}\right)/c, p\right\}}{\log\left(e^2 m \left(\max_{x\in\Sigma^c}\frac{\|v[x]\|_1^2}{\|v[x]\|_2^2}\right)^{-1}\right)} .$$

▶ **Theorem 13.** *Let* $h\colon \Sigma^c \to [m]$ *be a mixed tabulation hash function and let* $q \in \Sigma^c$ *be a designated query element. Let* $v\colon \Sigma^c \times [m] \times [m] \to \mathbb{R}$ *a value function, and assume that* $\sum_{j\in[m]} v(x,j,k) = 0$ *for all keys* $x \in U$ *and all* $k \in [m]$*. Define the random variable* $V_{v,q}^{\text{simple}} = \sum_{x\in\Sigma^c\setminus\{q\}} v(x,h(x),h(q))$ *and the random variables*

$$M_{v,q} = \max_{x\in\Sigma^c\setminus\{q\}, j\in[m]} |v(x,j,h(q))| ,$$

$$\sigma_{v,q}^2 = \frac{1}{m}\sum_{x\in\Sigma^c\setminus\{q\}}\sum_{j\in[m]} v(x,j,h(q))^2 ,$$

which only depend on the randomness of $h(q)$*. For all* $p \geq 2$ *then*

$$\mathrm{E}\left[\left(V_{v,q}^{\text{simple}}\right)^p \,\middle|\, h(q)\right]^{1/p} \leq \Psi_p\left(K_c\gamma_p^c M_{v,q}, K_c\gamma_p^c\sigma_{v,q}^2\right) \tag{6}$$

where $K_c = L_1 (L_2 c)^c$, L_1 *and* L_2 *are universal constants, and*

$$\gamma_p = \max\left\{1, \frac{\log(m)}{\log(|\Sigma|)}, \frac{p}{\log(|\Sigma|)}\right\} .$$

1.5 Technical Overview

1.5.1 Fully Random Hashing

1.5.1.1 Sub-Gaussian bounds

A random variable X is said to be sub-Gaussian with parameter σ if $\|X\|_p \leq \sqrt{p}\sigma$ for all $p \geq 2$. It is a well-known fact that the sum of independent bounded random variables are sub-Gaussian. In the context of fully random hashing, we have that

$$\left\|\sum_{x\in U} v(x,h(x))\right\|_p \leq \sqrt{4p}\sqrt{\sum_{x\in U}\|v[x]\|_\infty^2} . \tag{7}$$

A natural question is whether this is the best sub-Gaussian bound we can get. If we are just interested in the contribution to a single bin, i.e., $v(x,j) = w_x([j=0] - \frac{1}{m})$, then we can obtain a better sub-Gaussian bound. By using the result of Oleszkiewicz [20], we get that

$$\left\|\sum_{x\in U} v(x,h(x))\right\|_p \leq L\sqrt{\frac{p}{\log m}}\sqrt{\sum_{x\in U} w_x^2} , \tag{8}$$

where L is a universal constant. This shows that Equation (7) can be improved in certain situations. We improve on this by proving a generalization of Equation (8). We show that

$$\left\|\sum_{x\in U} v(x,h(x))\right\|_p \leq L\sqrt{\frac{p}{\log\left(\frac{e^2 m\sum_{x\in U}\|v[x]\|_\infty^2}{\sum_{x\in U}\|v[x]\|_2^2}\right)}}\sqrt{\sum_{x\in U}\|v[x]\|_\infty^2} , \tag{9}$$

where L is a universal constant. It is easy to check that if $v(x,j) = w_x([j=0] - \frac{1}{m})$ then it reduces to Equation (8) and that it is stronger than Equation (7).

1.5.1.2 Moments for general random variables

As part of our analysis we develop a couple of lemmas for general random variables which might be of independent interest. We prove a lemma that provides a simple bound for weighted sums of independent and identically distributed random variables.

▶ **Lemma 14.** *Let $(X_i)_{i\in[n]}$ and X be independent and identically distributed symmetric random variables, and let $(a_i)_{i\in[n]}$ be a sequence of reals.*[4] *If $p \geq 2$ is an even integer then*

$$\left\| \sum_{i\in[n]} a_i X_i \right\|_p \leq K \sup \left\{ \frac{p}{s} \left(\frac{\sum_{i\in[n]} a_i^s}{p} \right)^{1/s} \|X\|_s \;\middle|\; 2 \leq s \leq p \right\} ,$$

where $K \leq 4e$ is a universal constant.

If we consider Laplace distributed random variables then it is possible to show that Lemma 14 is tight up to a universal constant. Thus a natural question to ask is whether Lemma 14 is tight, i.e., can we prove a matching lower bound. But unfortunately, if you consider Gaussian distributed variables then we see that Lemma 14 is not tight. It would be nice if there existed a simple modification of Lemma 14 which had a matching lower bound.

1.5.1.3 Moments of functions of random variables

As part of the analysis of tabulation hashing, we will need to analyze random variables of the form $\Psi_p(X, Y)$ where X and Y are random variables. More precisely, we have to bound $\|\Psi_p(X, Y)\|_p$. It is not immediately clear how one would do this but we prove a general lemma that helps us in this regard.

▶ **Lemma 15.** *Let $f\colon \mathbb{R}^n_{\geq 0} \to \mathbb{R}_{\geq 0}$ be a non-negative function which is monotonically increasing in every argument, and assume that there exist positive reals $(\alpha_i)_{i\in[n]}$ and $(t_i)_{i\in[n]}$ such that for all $\lambda \geq 0$*

$$f(\lambda^{\alpha_0} t_0, \ldots, \lambda^{\alpha_{n-1}} t_{n-1}) \leq \lambda f(t_0, \ldots, t_{n-1}) .$$

Let $(X_i)_{i\in[n]}$ be non-negative random variables. Then for all $p \geq 1$ we have that

$$\|f(X_0, \ldots, X_{n-1})\|_p \leq n^{1/p} \max_{i\in[n]} \left(\frac{\|X_i\|_{p/\alpha_i}}{t_i} \right)^{1/\alpha_i} f(t_0, \ldots, t_{n-1}) .$$

If we can choose $t_i = \|X_i\|_{p/\alpha_i}$ for all $i \in [n]$, then we get the nice expression

$$\|f(X_0, \ldots, X_{n-1})\|_p \leq n^{1/p} f(\|X_0\|_{p/\alpha_0}, \ldots, \|X_{n-1}\|_{p/\alpha_{n-1}}) .$$

Now the result is natural to compare to the triangle inequality that says that $\|X + Y\|_p \leq \|X\|_p + \|Y\|_p$, which corresponds to considering $f(x, y) = x + y$, and to Cauchy-Schwartz that says that $\|XY\|_p \leq \|X\|_{2p} \|Y\|_{2p}$, which corresponds to $f(x, y) = xy$. These two examples might point to that the $n^{1/p}$ is superfluous, but by considering $f(x_0, \ldots, x_{n-1}) = \max\{x_0, \ldots, x_{n-1}\}$ and Gaussian distributed variables, it can be shown that Lemma 15 is tight up to a constant factor.

[4] A symmetric random variable, X, is a random variable that is symmetric around zero, i.e., $\Pr[X \geq t] = \Pr[-X \geq t]$ for all $t \geq 0$.

1.5.2 Tabulation Hashing

1.5.2.1 Symmetrization

The analyses of chaoses have mainly focused on two types of chaoses: Chaoses generated by non-negative random variables and chaoses generated by symmetric random variables. It might appear strange that focus has not been on chaoses generated by mean zero random variables. The reason is that a symmetrization argument reduces the analysis of chaoses generated by mean zero random variables to the analysis of chaoses generated by symmetric random variables. More precisely, a standard symmetrization shows that

$$2^{-c}\left\|\sum_{i_0,\dots,i_{c-1}\in[n]} a_{i_0,\dots,i_{c-1}}\prod_{j\in[c]}\varepsilon_{i_j}^{(j)}X_{i_j}^{(j)}\right\|_p \leq \left\|\sum_{i_0,\dots,i_{c-1}\in[n]} a_{i_0,\dots,i_{c-1}}\prod_{j\in[c]}X_{i_j}^{(j)}\right\|_p \leq 2^c\left\|\sum_{i_0,\dots,i_{c-1}\in[n]} a_{i_0,\dots,i_{c-1}}\prod_{j\in[c]}\varepsilon_{i_j}^{(j)}X_{i_j}^{(j)}\right\|_p,$$

where $(\varepsilon_i^{(j)})_{i\in[n],j\in[n]}$ are independent Rademacher variables.[5]

In our case, we can assume that $v(x,h(x))$ is a mean zero random variable but is not necessarily symmetric. We can remedy this by using the same idea of symmetrization. We define $\varepsilon\colon \Sigma^c\to\{-1,1\}$ to be a simple tabulation sign function, more precisely, we have a fully random table, $T_\varepsilon\colon [c]\times\Sigma\to\{-1,1\}$, and ε is then defined by $\varepsilon(\alpha_0,\dots,\alpha_{c-1})=\prod_{i\in[c]}T(i,\alpha_i)$. We then prove that for all $p\geq 2$

$$2^{-c}\left\|\sum_{x\in\Sigma^c}\varepsilon(x)v(x,h(x))\right\|_p \leq \left\|\sum_{x\in\Sigma^c}v(x,h(x))\right\|_p \leq 2^c\left\|\sum_{x\in\Sigma^c}\varepsilon(x)v(x,h(x))\right\|_p. \tag{10}$$

The power of symmetrization lies in the fact that we get to assume that v is symmetric in the analysis without actually changing the value functions.

Somewhat surprisingly, we are able to improve the moment bound of Dahlgaard et al. [9] just by using symmetrization. Their result has a doubly exponential dependence on the size of the moment, p, which stems from a technical counting argument where they bound the number of terms which does not have an independent factor when expanding the expression $\left(\sum_{x\in\Sigma^c}v(x,h(x))\right)^p$. It appears difficult to directly improve their counting argument but by using Equation (10) we are able to circumvent this. Thus, just by using symmetrization and the insights of Dahlgaard et al. [9] we obtain the following result.

▶ **Lemma 16.** *Let $h\colon\Sigma^c\to[m]$ be a simple tabulation function, $\varepsilon\colon\Sigma^c\to\{-1,1\}$ be a simple tabulation sign function, and $v\colon\Sigma^c\times[m]\to\mathbb{R}$ be a value function. Then for every real number $p\geq 2$*

$$\left\|\sum_{x\in\Sigma^c}v(x,h(x))\right\|_p \leq 2^c\left\|\sum_{x\in\Sigma^c}\varepsilon(x)v(x,h(x))\right\|_p \leq \sqrt{4p}^c\sqrt{\sum_{x\in\Sigma^c}\|v[x]\|_\infty^2}.$$

[5] A Rademacher variable, ε, is a random variable chosen uniformly from the set $\{-1,1\}$, i.e., $\Pr[\varepsilon=-1]=\Pr[\varepsilon=1]=\frac{1}{2}$.

1.5.2.2 General value functions

For most applications of hashing, we are either interested in the number of balls landing in a bin or in the number of elements hashing below a threshold. But we are studying the more general setting where we have a value function. A natural question is whether it is possible to obtain a simpler proof for the simpler settings. We do not believe this to be the case since the general setting of value functions will naturally show up when proving results by induction on c. More precisely, let us consider the case where we are interested in the number of elements from a set, $S \subseteq \Sigma^c$, that hash to 0. We then want to bound $\sum_{x\in S}\left([h(x)=0]-\frac{1}{m}\right) = \sum_{x\in\Sigma^c}[x\in S]\left([h(x)=0]-\frac{1}{m}\right)$. This can be rewritten as[6]

$$\sum_{x\in\Sigma^c}[x\in S]\left([h(x)=0]-\tfrac{1}{m}\right) = \sum_{\alpha\in\Sigma}\sum_{y\in\Sigma^{c-1}}[(y,\alpha)\in S]\left([h(y)\oplus T(c-1,\alpha)=0]-\tfrac{1}{m}\right) .$$

So if we define the value function $v'\colon \Sigma\times[m]\to\mathbb{R}$ by

$$v'(\alpha,j) = \sum_{y\in\Sigma^{c-1}}[(y,\alpha)\in S]\left([h\oplus j=0]-\tfrac{1}{m}\right) ,$$

then we get that $\sum_{x\in S}\left([h(x)=0]-\frac{1}{m}\right) = \sum_{\alpha\in\Sigma} v'(\alpha, T(c-1,\alpha))$. Thus, we see that general value functions are natural to consider in the context of tabulation hashing.

Instead of shying away from general value functions, we embrace them. This force us look at the problem differently and guides us in the correct direction. Using this insight naturally leads us to use Equation (9) and we prove the following moment bound, which is strictly stronger than Lemma 16.

▶ **Lemma 17.** *Let $h\colon\Sigma^c\to[m]$ be a simple tabulation function, $\varepsilon\colon\Sigma^c\to\{-1,1\}$ be a simple tabulation sign function, and $v\colon\Sigma^c\times[m]\to\mathbb{R}$ be value function. Then for every real number $p\geq 2$*

$$\left\|\sum_{x\in\Sigma^c}\varepsilon(x)v(x,h(x))\right\|_p \leq \sqrt{K_c\frac{p\left(\max\{p,\log(m)\}\right)^{c-1}}{\log\left(1+\frac{m\sum_{x\in\Sigma^c}\|v[x]\|_\infty^2}{\sum_{x\in\Sigma^c}\|v[x]\|_2^2}\right)^c}}\sqrt{\sum_{x\in\Sigma^c}\|v[x]\|_\infty^2} ,$$

where $K_c=(Lc)^c$ for a universal constant L.

This statement is often weaker than Theorem 7 but perhaps a bit surprisingly, we will use Lemma 17 as an important step in the proof of Theorem 7.

1.5.2.3 Sum of squares of simple tabulation hashing

A key element when proving Theorem 7 is bounding the sums of squares

$$\sum_{j\in[m]}\left(\sum_{x\in\Sigma^c}v(x,h(x)\oplus j)\right)^2 . \tag{11}$$

This was also one of the main technical challenges for the analysis of Aamand et al. [2]. Instead of analyzing Equation (11), we will analyze a more general problem: Let $v_i\colon\Sigma^c\times[m]\to\mathbb{R}$ be a value function $i\in[k]$, we then want to understand the random variable.

$$\sum_{\substack{j_0,\dots,j_{k-1}\in[m]\\ \bigoplus_{i\in[k]}j_i=0}}\sum_{x_0,\dots,x_{k-1}\in\Sigma^c}\prod_{i\in[k]}v_i(x_i,j_i\oplus h(x_i)) \tag{12}$$

[6] For a partial key $y=(\beta_0,\dots,\beta_{c-2})\in\Sigma^{c-1}$, we let $h(y)=\bigoplus_{i\in[c-1]}T(i,\beta_i)$.

If we have $k = 2$ and $v_0 = v_1$ then this corresponds to Equation (11). By using a decoupling argument, it is possible to reduce the analysis of Equation (12) to the analysis of hash-based sums for simple tabulation hashing. We can then use Lemma 17 to obtain the following lemma.

▶ **Lemma 18.** *Let $h\colon \Sigma^c \to [m]$ be a simple tabulation function, $\varepsilon\colon \Sigma^c \to \{-1, 1\}$ be a simple tabulation sign function, and $v_i\colon \Sigma^c \times [m] \to \mathbb{R}$ be a value function for $i \in [k]$. For every real number $p \geq 2$*

$$\left\| \sum_{j\in[m]} \left(\sum_{x\in\Sigma^c} \varepsilon(x) v(x, h(x)) \right)^2 \right\|_p \leq \left(\frac{Lc \max\{p, \log(m)\}}{\log\left(\frac{e^2 m \sum_{x\in\Sigma^c} \|v[x]\|_2^2}{\sum_{x\in\Sigma^c} \|v[x]\|_1^2} \right)} \right)^c \sum_{x\in\Sigma^c} \|v[x]\|_2^2 \ ,$$

where L is a universal constant.

1.5.2.4 Proving the main result

The proof of Theorem 7 is by induction on c. We will use Theorem 5 on one of the characters while fixing the other characters. This will give us an expression of the form

$$\left\| \Psi_p \left(\max_{\alpha\in\Sigma, j\in[m]} \left| \sum_{y\in\Sigma^{c-1}} v((y,\alpha), h(y) \oplus j) \right|, \frac{\sum_{\alpha\in\Sigma, j\in[m]} \left(\sum_{y\in\Sigma^{c-1}} v((y,\alpha), h(y)\oplus j) \right)^2}{m} \right) \right\|_p .$$

By applying Lemma 15, we bound this by

$$\Psi_p \left(\left\| \max_{\alpha\in\Sigma, j\in[m]} \left| \sum_{y\in\Sigma^{c-1}} v((y,\alpha), h(y)\oplus j) \right| \right\|_p, \left\| \frac{\sum_{\alpha\in\Sigma, j\in[m]} \left(\sum_{y\in\Sigma^{c-1}} v((y,\alpha), h(y)\oplus j) \right)^2}{m} \right\|_p \right) .$$

We will bound $\left\| \max_{\alpha\in\Sigma, j\in[m]} \left| \sum_{y\in\Sigma^{c-1}} v((y,\alpha), h(y)\oplus j) \right| \right\|_p$ by using the induction hypothesis, and we bound $\left\| \frac{\sum_{\alpha\in\Sigma, j\in[m]} \left(\sum_{y\in\Sigma^{c-1}} v((y,\alpha), h(y)\oplus j) \right)^2}{m} \right\|_p$ by using Lemma 18. While this sketch is simple, the actual proof is quite involved and technical since one has to be very careful with the estimates.

1.6 Mixed Tabulation Hashing in Context

Our concentration bounds for mixed tabulation hashing are similar to those Aamand et al. [2] for their tabulation-permutation hashing scheme and the schemes also have very similar efficiency, roughly a factor 2 slower than simple tabulation and orders of magnitude faster than any alternative with similar known concentration bounds. We shall make a more detailed comparison with tabulation-permutation in Section 1.6.1.

As mentioned in the beginning of the introduction, the big advantage of proving concentration bounds for mixed tabulation hashing rather than for tabulation-permutation is that mixed tabulation hashing has many other strong probabilistic properties that can now be used in tandem with strong concentration. This makes mixed tabulation an even stronger candidate to replace abstract uniform hashing in real implementations of algorithms preserving many of the asymptotic performance guarantees.

Mixed tabulation inherits all the nice probabilistic properties known for simple and twisted tabulation[7]. Dahlgaard et al. [9] introduced mixed tabulation hashing to further get good statistics over k-partitions as used in classic streaming algorithms for counting of distinct elements by Flajolet et al. [13, 14, 15], and for fast set similarity in large-scale machine learning by Li et al. [19, 23, 24].

Selective full randomness with mixed tabulation

The main result of Dahlgaard et al. [9] for mixed tabulation is that it has a certain kind of selective full randomness (they did not have a word for it). An ℓ-bit mask M with don't cares is of the form $\{0,1,?\}^\ell$. An ℓ-bit string $B \in \{0,1\}^\ell$ matches M if it is obtained from M by replacing each ? with a 0 or a 1. Given a hash function returning ℓ-bit hash values, we can use M to select the set Y of keys that match M. Consider a mixed tabulation hash function $h : \Sigma^c \to \{0,1\}^\ell$ using d derived characters. The main result of Dahlgaard et al. [9, Theorem 4] is that if the expected number of selected keys is less than $|\Sigma|/2$, then, w.h.p., the free (don't care) bits of the hash values of Y are fully random and independent. More formally,

▶ **Theorem 19** (Dahlgaard et al. [9, Theorem 4]). *Let $h : \Sigma^c \to \{0,1\}^\ell$ be a mixed tabulation hash function using d derived characters. Let M be an ℓ-bit mask with don't cares. For a given key set $X \subseteq \Sigma^c$, let Y be the set of keys from X with hash values matching M. If $\mathrm{E}[|Y|] \leq |\Sigma|/(1+\Omega(1))$, then the free bits of the hash values in Y are fully random with probability $1 - O(|\Sigma|^{1-\lfloor d/2 \rfloor})$.*

The above result is best possible in that since we only have $O(|\Sigma|)$ randomness in the tables, we cannot hope for full randomness of an asymptotically larger set Y.

In the applications from [9], we also want the size of the set Y to be concentrated around its mean and by Corollary 11, the concentration is essentially as strong as with fully random hashing and it holds for any $d \geq 1$.

In [9] they only proved weaker concentration bounds for the set Y selected in Theorem 19. Based on the concentration bounds for simple tabulation by Pătraşcu and Thorup [22], they proved that if the set Y from 19 had $\mathrm{E}[Y] \in [|\Sigma|/8, 3|\Sigma|/4]$, then within the same probability of $1 - O(|\Sigma|^{1-\lfloor d/2 \rfloor})$, it has

$$|Y| = \mathrm{E}[Y]\left(1 \pm O\left(\sqrt{\frac{\log|\Sigma|(\log\log|\Sigma|)^2}{|\Sigma|}}\right)\right). \tag{13}$$

With Corollary 11, for $\mathrm{E}[Y] = \Theta(|\Sigma|)$, we immediately tighten (13) to the cleaner

$$|Y| = \mathrm{E}[Y]\left(1 \pm O\left(\sqrt{\frac{\log|\Sigma|}{|\Sigma|}}\right)\right). \tag{14}$$

[7] This is not a black box reduction, but both twisted and mixed tabulation hashing applies simple tabulation to a some changed keys, so any statement holding for arbitrary sets of input keys is still valid. Moreover, mixed tabulation with one derived character corresponds to mixed tabulation applied to keys with an added 0-character head, and having more derived characters does not give worse results.

While the improvement is "only" a factor $(\log\log|\Sigma|)^2$, the important point here is that (14) is the asymptotic bound we would get with fully-random hashing. Also, while Dahlgaard et al. only proved (13) for the special case of $\mathrm{E}[Y] \in [|\Sigma|/8, 3|\Sigma|/4]$, our (14) is just a special case of Corollary 11 which holds for arbitrary values of $\mathrm{E}[Y]$ and arbitrary value functions.

Dahlgaard et al. presented some very nice applications of mixed tabulation to problems in counting and machine learning and machine learning. The way they use Theorem 19 is rather subtle.

1.6.1 Mixed Tabulation Hashing Versus Tabulation-Permutation Hashing

As mentioned earlier, our new concentration bounds are similar to those proved by Aamand et al. [2] for their tabulation-permutation hashing scheme. However, now we also have moment bounds covering the tail, and we have the first understanding of what happens when c is not constant. It is not clear if this new understanding applies to tabulation-permutation. As discussed above, the advantage of having the concentration bounds for mixed tabulation hashing is that we can use them in tandem with the independence result from Theorem 19, which does not hold for tabulation-permutation.

Tabulation-permutation is similar to mixed tabulation hashing in its resource consumption. Consider the mapping $\Sigma^c \to \Sigma^c$. Tabulation-permutation first uses simple tabulation $h : \Sigma^c \to \Sigma^c$. Next it applies a random permutation $\pi_i : \Sigma \overset{1-1}{\to} \Sigma$ to each output character $h(x)_i$, that is, $x \mapsto (\pi_1(h(x)_1), \ldots, \pi_c(h(x)_c)$. Aamand et al. [2] also suggest tabulation-1permutation hashing, which only permutes the most significant character. This scheme does not provide concentration for all value functions, but it does work if we select keys from intervals.

Aamand et al. [2] already made a thorough experimental and theoretical comparison between tabulation-permutation, mixed tabulation, and many other schemes. In this comparison, mixed tabulation played the role of a similar scheme with not as strong known concentration bounds. In the experiments, mixed tabulation hashing with c derived characters performed similar to tabulation-permutation in speed. Here we proved stronger concentration bounds for mixed tabulation even with a single character, where it should perform similar to tabulation-1permutation (both use $c + 1$ lookups). Both mixed tabulation hashing and tabulation-permutation hashing were orders of magnitude faster than any alternative with similar known concentration bounds. We refer to [2, 10] for more details. In particular, [10] compares mixed tabulation with popular cryptographic hash functions that are both slower and have no guarantees in these algorithmic contexts.

One interesting advantage of mixed tabulation hashing over tabulation-permutation hashing is that mixed tabulation hashing, like simple tabulation hashing, only needs randomly filled character tables. In contrast, tabulation-permutation needs tables that represent permutations. Thus, all we need to run mixed tabulation hashing is a pointer to some random bits. These could be in read-only memory shared across different applications. Read-only memory is much less demanding than standard memory since there can be no write-conflicts, so we could imagine some special large, fast, and cheap read-only memory, pre-filled with random bits, e.g., generated by a quantum-device. This would open up for larger characters, e.g., 16- or 32-bit characters, and it would free up the cache for other applications.

Abstract

Range-aggregate query is an important type of queries with numerous applications. It aims to obtain some structural information (defined by an *aggregate function* $F(\cdot)$) of the points (from a point set P) inside a given query range B. In this paper, we study the range-aggregate query problem in high dimensional space for two aggregate functions: (1) $F(P \cap B)$ is the farthest point in $P \cap B$ to a query point q in $\mathbb{R}^d$ and (2) $F(P \cap B)$ is the minimum enclosing ball (MEB) of $P \cap B$. For problem (1), called *In-Range Farthest Point (IFP) Query*, we develop a bi-criteria approximation scheme: For any $\epsilon > 0$ that specifies the approximation ratio of the farthest distance and any $\gamma > 0$ that measures the "fuzziness" of the query range, we show that it is possible to pre-process P into a data structure of size $\tilde{O}_{\epsilon,\gamma}(dn^{1+\rho})$ in $\tilde{O}_{\epsilon,\gamma}(dn^{1+\rho})$ time such that given any $\mathbb{R}^d$ query ball B and query point q, it outputs in $\tilde{O}_{\epsilon,\gamma}(dn^{\rho})$ time a point p that is a $(1-\epsilon)$-approximation of the farthest point to q among all points lying in a $(1+\gamma)$-expansion $B(1+\gamma)$ of B, where $0 < \rho < 1$ is a constant depending on ϵ and γ and the hidden constants in big-O notations depend only on ϵ, γ and Polylog(nd). For problem (2), we show that the IFP result can be applied to develop query scheme with similar time and space complexities to achieve a $(1+\epsilon)$-approximation for MEB. To the best of our knowledge, these are the first theoretical results on such high dimensional range-aggregate query problems. Our results are based on several new techniques, such as *multi-scale construction* and *ball difference range query*, which are interesting in their own rights and could be potentially used to solve other range-aggregate problems in high dimensional space.

1 Introduction

Range search is a fundamental problem in computational geometry and finds applications in many fields like database systems and data mining [4, 27]. It has the following basic form: Given a set of n points P in $\mathbb{R}^d$, pre-process P into a data structure so that for any query range B from a certain range family (*e.g.,* spheres, rectangles, and halfspaces), it reports or counts the number of the points in $P \cap B$ efficiently. Range search allows us to obtain some basic information of the points that lie in a specific local region of the space.

In many applications, it is often expected to know more information than simply the number of points in the range. This leads to the study of range-aggregate query [2, 3, 6, 10, 13, 20, 21, 23, 25, 26, 32], which is a relatively new type of range search. The goal of

49th International Colloquium on Automata, Languages, and Programming (ICALP 2022).

range-aggregate query is to obtain more complicated structural information (such as the diameter, the minimum enclosing ball, and the minimum spanning tree) of the points in the query range. Range-aggregate query can be generally defined as follows: Given a point set P, pre-process P into a data structure such that for any range B in a specific family, it outputs $F(P \cap B)$, where $F(\cdot)$ is a given *aggregate function* that computes a certain type of information or structure of $P \cap B$ like "diameter","minimum enclosing ball", and "minimum spanning tree". Range-aggregate queries have some interesting applications in data analytics and big data [16, 28, 29, 32], where it is often required to retrieve aggregate information of the records in a dataset with keys that lie in any given (possibly high dimensional) range.

In this paper, we study the range-aggregate query problem in high dimensions for spherical ranges. Particularly, we consider two aggregate functions for any $\mathbb{R}^d$ query ball B: (1) $F(P \cap B)$ is the farthest point in $P \cap B$ to a query point q in $\mathbb{R}^d$ and (2) $F(P \cap B)$ is the minimum enclosing ball (MEB) of $P \cap B$. We will focus in this paper on problem (1), called the *In-Range Farthest Point (IFP) Query*, and show that an efficient solution to IFP query also yields efficient solutions to the MEB problems. We start with some definitions.

▶ **Definition 1** (Approximate IFP (AIFP)). *Let P be a set of n points in $\mathbb{R}^d$, q be a point and B be a d-dimensional (closed) ball. A point $p \in P$ is a bi-criteria (ϵ, γ)-approximate in-range farthest point (or AIFP) of $q \in P$ in B, if there exists a point set P' such that the following holds, where ϵ and γ are small positive constants, and $B(1+\gamma)$ is the ball concentric with B and with radius $(1+\gamma)r$: (1) $P \cap B \subseteq P' \subseteq P \cap B(1+\gamma)$; (2) $p \in P'$; and (3) for any $p' \in P'$, $(1-\epsilon)\|p'-q\| \leq \|p-q\|$.*

Defining AIFP in this way enables us to consider all points in B and exclude all points outside of $B(1+\gamma)$. Points in the fuzzy region $B(1+\gamma) \setminus B$ may or may not be included in the farthest point query. Note that allowing fuzzy region is a commonly used strategy to deal with the challenges in many high dimensional similarity search and range query problems. For example, consider the classic near neighbor search problem, which is equivalent to spherical emptiness range search: Given a query sphere B in $\mathbb{R}^d$, report a data point p that lies in B if such a data point exists. In high dimensional space, obtaining an exact solution to such a query is very difficult. A commonly used technique for this problem is the Locality Sensitive Hashing (LSH) scheme [12]. Given a query ball B, LSH could report a data point in $B(1+\epsilon)$ for some given factor $\epsilon > 0$. In other words, a fuzzy region $B(1+\epsilon) \setminus B$ is allowed. Similarly, we can define approximate MEB for points in a given range with a fuzzy region.

▶ **Definition 2** (Minimum Enclosing Ball (MEB)). *Let P be a set of n points in $\mathbb{R}^d$. A d-dimensional (closed) ball B is an enclosing ball of P if $P \subset B$ and B is the minimum enclosing ball (MEB) of P if its radius r is the smallest among all enclosing balls. A ball B' is a $(1+\epsilon)$-approximate MEB of P for some constant $\epsilon > 0$ if it is an enclosing ball of P and its radius is no larger than $(1+\epsilon)Rad(P)$, where $Rad(P)$ is the radius of the MEB of P.*

▶ **Definition 3** (Approximate MEB (AMEB)). *Let P be a set of n points and B be any ball with radius r in $\mathbb{R}^d$. A ball B' with radius r' is a bi-criteria (ϵ, γ)-approximate MEB (or AMEB) of P in range B, if there exists a point set P' such that the following holds, where γ and ϵ are small positive constants: (1) $P \cap B \subseteq P' \subseteq P \cap B(1+\gamma)$; and (2) B' is a $(1+\epsilon)$-approximate MEB of P'.*

In this paper, we will focus on building a data structure for P so that given any query ball B and a point $q \in \mathbb{R}^d$, an AIFP of q in $P \cap B$ can be computed efficiently (*i.e.,* in sub-linear time in terms of n). Below are the main theorems of this paper. Let $\epsilon > 0, \gamma > 0$, $0 < \delta < 1$ be any real numbers.

▶ **Theorem 4.** *For any set P of n points in $\mathbb{R}^d$, it is possible to build a data structure of size $O_{\epsilon,\gamma}(dn^{1+\rho}\log\delta^{-1}Polylog(nd))$ in $O_{\epsilon,\gamma}(dn^{1+\rho}\log\delta^{-1}Polylog(nd))$ pre-processing time, where $0<\rho<1$ is a small constant depending on ϵ and γ. With this data structure, it is then possible to find a (ϵ,γ)-AIFP of any given query point q and query ball B in $O_{\epsilon,\gamma}(dn^{\rho}\log\delta^{-1}Polylog(nd))$ time with probability at least $1-\delta$.*

Note: In the above result, the relationship between ρ and ϵ,γ has a rather complicated dependence on several constants of p-stable distribution, which is inherited from the underlying technique of Locality Sensitive Hashing (LSH) scheme [12]. This indicates that for any ϵ,γ, we have $0<\rho<1$ and ρ approaches 1 as ϵ,γ approach 0.

We will also show how to use the AIFP data structure to answer MEB queries efficiently.

▶ **Theorem 5.** *For any set P of n points in $\mathbb{R}^d$, it is possible to build a data structure of size $O_{\epsilon,\gamma}(dn^{1+\rho}\log\delta^{-1}Polylog(nd))$ in $O_{\epsilon,\gamma}(dn^{1+\rho}\log\delta^{-1}Polylog(nd))$ pre-processing time, where $0<\rho<1$ is a small constant depending on ϵ and γ. With this data structure, it is then possible to find a (ϵ,γ)-AMEB for any query ball B in $O_{\epsilon,\gamma}(dn^{\rho}\log\delta^{-1}Polylog(nd))$ time with probability at least $1-\delta$.*

To our best knowledge, these are the first results on such range-aggregate problems in high dimensions. Each data structure has only a near linear dependence on d, a sub-quadratic dependence on n in space complexity, and a sub-linear dependence on n in query time.

Our Method. The main result on AIFP is based on several novel techniques, such as *multi-scale construction* and *ball difference range query*. Briefly speaking, multi-scale construction is a general technique that allow us to break the task of building an AIFP query data structure into a number of "constrained" data structures. Each such data structure is capable of correctly answering an AIFP query given that some assumption about the query holds (for example, the distance from q to its IFP is within a certain range). Multi-scale construction uses a number of "constrained" data structures of small size to cover all possible cases of a query, which leads to a data structure that can handle any arbitrary queries. Multi-scale construction is independent of the aggregate function, and thus has the potential be used as a general method for other types of range-aggregate query problems in high dimensional space. Another important technique is a data structure for the ball difference range query problem, which returns a point, if there is one, in the difference of two given query balls. The ball difference data structure is the building block for the constrained AIFP data structures, and is interesting in its own right as a new high dimensional range search problem.

Related Work. There are many results for the ordinary farthest point query problem in high dimensional space [11, 17, 19, 24]. However, to the best of our knowledge, none of them is sufficient to solve the IFP problem, and our result is the first one to consider the farthest point problem under the query setting. Our technique for the IFP problem also yields solutions to other range-aggregate queries problems, including the MEB query problem.

A number of results exist for various types of the range-aggregate query problem in fixed dimensional space. In [6], Arya, Mount, and Park proposed an elegant scheme for querying minimum spanning tree inside a query range. They showed that there exists a bi-criteria (ϵ_q,ϵ_w)-approximation with a query time of $O(\log n+(1/\epsilon_q\epsilon_w)^d)$. In [23], Nekrich and Smid introduced a data structure to compute an ϵ-coreset for the case of orthogonal query ranges and aggregate functions satisfying some special properties. Xue [30] considered the colored closest-pair problem in a (rectangular) range and obtained a couple of data structures with near linear size and polylogarithmic query time. Recently, Xue *et. al.* [31] further studied

more general versions of the closest-pair problem and achieved similar results. For the MEB problem under the range-aggregate settings, Brass *et al.* are the first to investigate the problem in 2D space, along with other types of aggregate functions (like width and the size of convex hull) [10]. They showed that it is possible to build a data structure with $O(n \cdot polylog(n))$ pre-processing space/time and $O(polylog(n))$ query time.

All the aforementioned methods were designed for fixed dimensional space, and thus are not applicable to high dimensions. Actually, range aggregation has rarely been considered in high dimensions, except for a few results that may be viewed as loosely relevant. For example, Abbar *et al.* [1] studied the problem of finding the maximum diverse set for points inside a ball with fixed radius around a query point. Their ideas are seemingly useful to our problem. However, since their ball always has the same fixed radius, their techniques are not directly applicable. In fact, a main technical challenge of our problem is how to deal with the arbitrary radius and location of the query range, which is overcome by our multi-scale construction framework. Another related work by Aumüller *et. al.* [8] has focused on random sampling in a given range. The technique is also not directly applicable to IFP.

1.1 Overviews of the Main Ideas

Below we describe the main ideas of our approaches. For simplicity, in the following we ignore the fuzziness of the query range. We approach the AIFP query problem by first looking at an easier version: given ball B and point q, find an approximate farthest point in $P \cap B$ to q, with the (strong) assumption that the radius of B is a fixed constant $r_B > 0$, and that the distance between q and its IFP in $P \cap B$ is within a range of $(d_{min}, d_{max}]$, where $d_{max} > d_{min} > 0$ are fixed constants. We call such a problem a constrained AIFP problem. We use a tuple (r_B, d_{min}, d_{max}) to denote such a constraint.

To solve the constrained AIFP problem, we develop a data structure for the *ball difference (BD) range query* problem, which is defined as follows: given two balls B_{in} and B_{out}, find a point that lies in $P \cap B_{in} \setminus B_{out}$. With such a data structure, it is possible to reduce an AIFP query with constraint (r_B, d_{min}, d_{max}) to a series of BD queries. Below we briefly describe the idea. Let $r_0 = d_{min}$, and for $i = 1, 2, 3 \ldots$, let $r_i = (1 + \epsilon) r_{i-1}$, where $\epsilon > 0$ is an approximation factor. For $i = 0, 1, \ldots$, we try to determine whether there is a point in $P \cap B$ whose distance to q is larger than r_i. Note that this can be achieved by a BD query with $B_{in} := B$ and B_{out} being the ball centered at q and with radius r_i. By iteratively doing this, eventually we will reach an index j such that it is possible to find a point $p \in B \cap P$ that satisfies the condition of $\|p - q\| > r_j$, but no point lies in $P \cap B$ whose distance to q is larger than $r_{j+1} = (1 + \epsilon) r_j$. Thus, p is a $(1 - O(\epsilon))$-approximate farthest point to q in $P \cap B$. From the definition of constrained AIFP query, it is not hard to see that this process finds the AIFP after at most $O(\log_{1+\epsilon} \frac{d_{max}}{d_{min}})$ iterations. Every BD data structure supports only B_{in} and B_{out} with fixed radii. This means that we need to build $O(\log_{1+\epsilon} \frac{d_{max}}{d_{min}})$ BD data structures for answering any AIFP query with constraint (r_B, d_{min}, d_{max}).

With the constrained AIFP data structure, we then extend it to a data structure for answering general AIFP queries. Our main idea is to use the aforementioned multi-scale construction technique to build a collection of constrained data structures, which can effectively cover (almost) all possible cases of the radius of B and the farthest distance from q to any point in $B \cap P$. More specifically, for any AIFP query, it is always possible to either answer the query easily without using any constrained data structures, or find a constrained data structure such that the AIFP query satisfies the constraint (r_B, d_{min}, d_{max}), and thus can be used to answer the AIFP query.

For AMEB query, we follow the main idea of Badoiu and Clarkson [9], and show that an AMEB query is reducible to a series of AIFP queries. More discussions are left to Section 5.

2 Constrained AIFP Query

In this section, we discuss how to construct a data structure to answer constrained AIFP queries. Particularly, given any ball B and point q satisfying the constraint (r_B, d_{min}, d_{max}),

- the radius of B is r_B,
- the distance from q to its farthest point to $P \cap B$ is within the range of $(d_{min}, d_{max}]$,

the data structure can find the AIFP to q in $P \cap B$ in sub-linear time (with high probability).

In the following, we let $\epsilon > 0$ be an approximation factor, $\gamma > 0$ be a factor that controls the region fuzziness and $0 < \delta < 1$ be a factor controlling the query success probability. The main result of this section is summarized as the following lemma.

▶ **Lemma 6.** *Let P be a set of n points in $\mathbb{R}^d$. It is possible to build a data structure for P with size $O_{\epsilon,\gamma}(dn^{1+\rho} \log \delta^{-1} \log(d_{max}/d_{min}))$ in $O_{\epsilon,\gamma}(dn^{1+\rho} \log \delta^{-1} \log(d_{max}/d_{min}))$ time, where $0 < \rho < 1$ is a real number depending on ϵ and γ, and the constants hidden in the big-O notation depend only on ϵ, γ. Given any query (B, q) that satisfies the constraint of (r_B, d_{min}, d_{max}), with probability at least $1 - \delta$, the data structure finds an (ϵ, γ)-AIFP for q in $P \cap B$ within time $O_{\epsilon,\gamma}(dn^{\rho} \log \delta^{-1} \log(d_{max}/d_{min}))$.*

In the following, we consider an AIFP query that satisfies constraint (r_B, d_{min}, d_{max}). As mentioned in last section, it is possible to reduce a constrained AIFP query to a series of *ball difference(BD) range queries*, which report a point in P that lies (approximately) in $B_{in} \setminus B_{out}$ for a given pair of $\mathbb{R}^d$ balls (B_{in} and B_{out}), or return NULL if no such point exists. Below, we describe the reduction using a ball-peeling strategy. We consider a series of balls $B_0, B_1, B_2, \ldots$ concentric at q with an exponentially increasing radius. Let $\xi > 0$ be a to-be-determined approximation factor, and $B_0 := \mathcal{B}(q, d_{min})$ which is the ball centered at q with radius d_{min}. For integer $i > 0$, let $B_{i+1} = B_i(1 + \xi)$ which is the ball obtained by enlarging the radius of B_i by a factor of $(1 + \xi)$. [1] For $i = 0, 1, 2, \ldots$, repeatedly perform a BD query with $B_{in} := B$ and $B_{out} := B_i$, until an index j is encountered such that the BD query reports a point p_j that lies in $P \cap B \setminus B_j$, but returns NULL when trying to find a point in $P \cap B \setminus B_{j+1}$. If ξ is a small enough constant, it is not hard to see that p_j is a good approximation of the IFP to q in $P \cap B$. Note that in this process, no more than $\log_{1+\xi}(d_{max}/d_{min})$ BD queries are required. This is because the distance between q and any point in B is at most d_{max}. Thus, it is not necessary to increase the radius of B_{out} to be more than d_{max} in the BD range query. The bound on the number of BD range queries then follows from the facts that the series of BD range queries starts with a B_{out} ball of radius d_{min} and each time the radius of B_{out} is increased by a factor of $1 + \xi$. This process is similar to peel a constant portion of B_{in} each time by B_{out}. See Figure 1 for an illustration.

The above discussion suggests that a constrained AIFP data structure can be built through (approximate) BD query data structures, which have the following definition. Let $\xi > 0$ be an approximation factor. A data structure is called ξ-error BD for a point set P, if given any balls B_{in} and B_{out}, it answers the following query (with high success probability):

[1] Throughout this paper we use similar notations. Let q be any point and $x > 0$ be real number. Then, $\mathcal{B}(q, x)$ denotes the ball centered at q and with radius x. Let B be any ball. For real number $y > 0$, we let $B(y)$ denote the ball obtained by enlarging (or shrinking if $y < 1$) the radius of B by a factor of y.

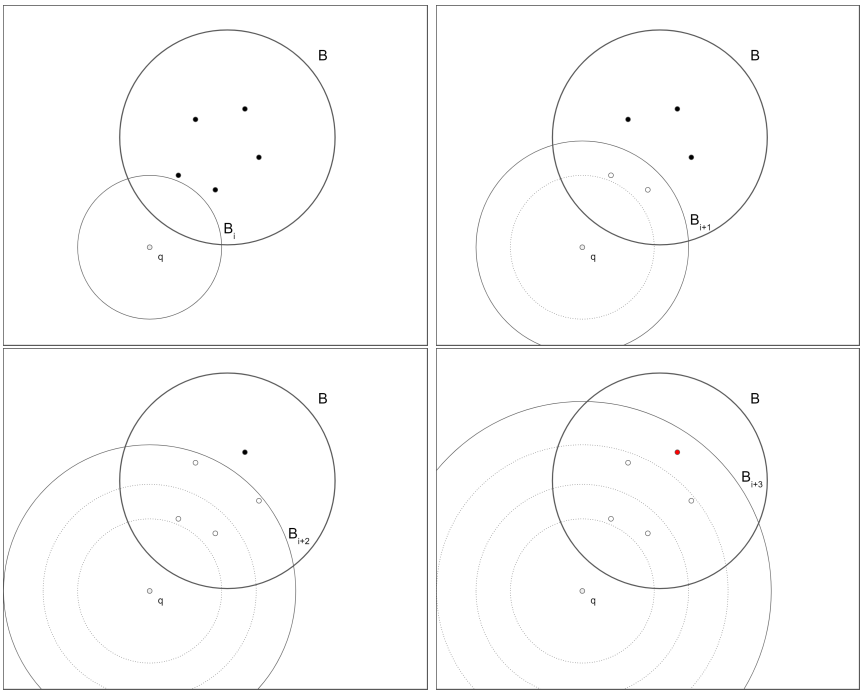

Figure 1 An illustration of answering a constrained AIFP query using BD queries.

1. If there exists a point in $P \cap (B_{in} \setminus B_{out})$, the data structure returns a point in $P \cap (B_{in}(1+\xi) \setminus B_{out}((1+\xi)^{-1}))$.
2. Otherwise, it returns a point in $P \cap (B_{in}(1+\xi) \setminus B_{out}((1+\xi)^{-1}))$ or NULL.

The details of how to construct a ξ-error BD data structure is left to the next subsection. Below is the main result of the BD query data structure for $\xi > 0$, fixed constant $r_{in} > 0, r_{out} > 0$ and success probability controlling factor $0 < \delta < 1$.

▶ **Lemma 7.** *It is possible to build a ξ-error BD query data structure of size $O_\xi(dn^{1+\rho}\log\delta^{-1})$ in $O_\xi(dn^{1+\rho}\log\delta^{-1})$ time, where $0 < \rho < 1$ depends only on ξ. The query time of this data structure is $O_\xi(dn^{\rho}\log\delta^{-1})$. For any pair of query balls B_{in} and B_{out} with radius r_{in} and r_{out}, respectively, the data structure answers the query with success probability at least $1-\delta$.*

Note that each BD query data structure works only for query balls B_{in} and B_{out} with fixed radii r_{in} and r_{out}, respectively. This means that the constrained AIFP data structure should consist of multiple BD data structures with different values of r_{in} and r_{out}.

From the above discussion, we know that a constrained AIFP data structure can be built by constructing a sequence of $\log(d_{max}/d_{min})$ BD data sturctures with $r_{in} := r_B$ and r_{out} being $d_{min}, (1+\xi)d_{min}, (1+\xi)^2 d_{min}, \ldots$. Such a data structure will allow us to answer constrained AIFP queries using the ball peeling strategy.

Given any constants $\epsilon > 0$, $\gamma > 0$, $0 < \delta < 1$, and constraint (r_B, d_{min}, d_{max}), the following Algorithm 1 builds a constrained AIFP data structure for a given point set P. The data structure is simply a collection of BD query data structures.

With such a collection of BD query data structures, we can answer any constrained AIFP query satisfying (r_B, d_{min}, d_{max}) by applying the ball peeling strategy mentioned before. The algorithm is formally described as the Algorithm 2 below.

Algorithm 1 Build-CAIFP($P; \epsilon, \gamma, \delta; r_B, d_{min}, d_{max}$).

Input: A $\mathbb{R}^d$ point set P with cardinality n. Constants $\epsilon > 0, \gamma > 0, 0 < \delta < 1$. Constraint tuple (r_B, d_{min}, d_{max}).
Output: A number of BD-Query data structures built with different parameters.

1: Let $\xi = \min\{(1-\epsilon)^{-1/2}-1, \gamma\}$. Construct a sequence of real numbers $r_0, r_1, r_2, \ldots, r_m$, by letting $r_0 = d_{min}$, m be the integer such that $r_0(1+\xi)^{m-1} < d_{max}$ and $r_0(1+\xi)^m \geq d_{max}$, $r_i = (1+\xi)r_{i-1}$ for $i = 1, 2, \ldots, m$, and $\delta' = \delta/m$.
2: **FOR** $i = 0, 1, 2, \ldots, m$, build a ξ-error BD query data structure for query balls with radii $r_{in} = r_B$ and $r_{out} = r_i$, with query success probability at least $1 - \delta'$.

Algorithm 2 Query-CAIFP(B, q).

Input: A constrained AIFP query (B, q) with constraint (r_B, d_{min}, d_{max}).
Output: A point p_{ans} that is an approximate farthest point in $B \cap Q$ to p, or NULL if no such point exists.

1: Initialize variable $p_{ans} \leftarrow$ NULL.
Note: In the following, we use m and r_i for $i = 0, 1, \ldots, m$ as in Algorithm 1.
2: **For** i from 0 to m: Make a query $(B, B_{out,i})$ to the BD-Query data structure BD_i, by letting $B_{out,i} := \mathcal{B}(q, r_i)$. If the query answer is NULL, **Return** p_{ans}. Otherwise update p_{ans} to be the query answer.
3: **Return** p_{ans}.

By some simple calculation, we know that the probability that all the BD queries in Algorithm 2 are successful is at least $1 - \delta$, and when this happens, the output point p_{ans} is an (ϵ, γ)-AIFP of q in $B \cap P$. This is summarized as the following lemma.

▶ **Lemma 8.** *With probability at least $1 - \delta$, Algorithm 2 outputs a point $p_{ans} \in B(1+\gamma)$ such that for any $q \in B \cap P$, $\|p_{ans} - p\| \geq (1-\epsilon)\|q - p\|$.*

Next we analyze the space/time complexity of the AIFP scheme. The query data structure is a combination of $m = O_{\epsilon,\gamma}(\log(d_{max}/d_{min}))$ BD data structures. From the discussion of BD data structures (see Lemma 7), every BD query data structure we build has space/time complexity $O_{\epsilon,\gamma}(dn^{1+\rho}\log\delta^{-1})$ where $0 < \rho < 1$ depends only on ϵ, γ. Each BD query takes $O_{\epsilon,\gamma}(dn^{\rho}\log\delta^{-1})$ time. Lemma 6 then follows.

2.1 The BD Query Scheme

In this subsection we present the BD query scheme. To our best knowledge, this is the first theoretical result to consider the BD range search problem. A very special case of BD query called the "annulus queries" where the two balls are co-centered is studied in [7]. Nonetheless, the technique is not directly applicable to general BD queries. Our BD range query scheme is based on the classic Locality Sensitive Hashing (LSH) technique [15, 5, 12] which has been a somewhat standard technique for solving the proximity problems in high dimensional space. The main idea of LSH is to utilize a family of hash functions (called an LSH family) that have some interesting properties. Given two points p and q in $\mathbb{R}^d$, if we randomly pick a function h from the LSH family, the probability that the event of $h(p) = h(q)$ happens will be high if $\|p - q\|$ is smaller than a threshold value, and the probability for the same event will be lower if $\|p - q\|$ is larger. Such a property of the LSH family allows us to develop hashing and bucketing based schemes to solve similarity search problems in high dimensional space. Below is the definition of an LSH family.

▶ **Definition 9.** *Let $0 < r_1 < r_2$ and $1 > \mathsf{P}_1 > \mathsf{P}_2 > 0$ be any real numbers. A family $\mathcal{H} = \{h : \mathbb{R}^d \to U\}$, where U can be any set of objects, is called $(r_1, r_2, \mathsf{P}_1, \mathsf{P}_2)$-sensitive, if for any $p, q \in \mathbb{R}^d$.*

1. *if $\|p - q\| \leq r_1$, then $Pr_{\mathcal{H}}[h(p) = h(q)] \geq \mathsf{P}_1$,*
2. *if $\|p - q\| > r_2$, then $Pr_{\mathcal{H}}[h(p) = h(q)] \leq \mathsf{P}_2$.*

It was shown in [12] that for any dimension d and any $r > 0, c > 1$, an $(r, cr, \mathsf{P}_1, \mathsf{P}_2)$-sensitive family $\mathcal{H}$ exists, where $1 > \mathsf{P}_1 > \mathsf{P}_2 > 0$ depends only on c. Every hash function $h(p) : \mathbb{R}^d \to \mathbb{Z}$ maps a point p in $\mathbb{R}^d$ to an integer, and $h(p)$ has the form $h(p) = \lfloor \frac{a \cdot p + b}{r} \rfloor$ for some $\mathbb{R}^d$ vector a and integers b, r. It takes $O(d)$ time to sample a hash function h from such a family and compute $h(p)$. Our data structure will make use of two such families. Let $\mathcal{H}_{in}$ be an $(r_{in}, (1+\xi)r_{in}, \mathsf{P}_1, \mathsf{P}_2)$-sensitive family, and $\mathcal{H}_{out}$ be a $((1+\xi)^{-1} r_{out}, r_{out}, \mathsf{P}_1, \mathsf{P}_2)$-sensitive family, where **$\mathbf{0 < \mathsf{P}_1, \mathsf{P}_2 < 1}$ are constants depending only on $\boldsymbol{\xi}$**, as described in [12]. Given any BD-query (B_{in}, B_{out}) with the centers of the balls being o_{in}, o_{out} respectively, the family $\mathcal{H}_{in}$ helps us to identify points that are close enough to o_{in} (and therefore lie in B_{in}), and $\mathcal{H}_{out}$ helps us to identify points that are far away enough from o_{out} (and therefore lie outside of B_{out}).

High level idea. Our approach is based on a novel bucketing and query scheme that utilizes the properties of the LSH family. Before presenting the technical details, We first illustrate the high level idea. For convenience, we assume for now that the functions in $\mathcal{H}_{in}$ and $\mathcal{H}_{out}$ have range $\{0, 1\}$ (this is achievable by some simple modification to these hash function families). We use a randomized process to create a hybrid random hash function $S(\cdot)$ that maps any point in $\mathbb{R}^d$ to a bit string. Such a function $S(\cdot)$ is a concatenation of a number of hash functions drawn from $\mathcal{H}_{in}$ and $\mathcal{H}_{out}$. Given $p \in \mathbb{R}^d$, $S(\cdot)$ applies the aforementioned hash functions (drawn from $\mathcal{H}_{in}$ and $\mathcal{H}_{out}$) on p to obtain a bit-string. With such a function $S(\cdot)$, consider comparing the bit-strings of $S(p), S(q)$ for points $p, q \in \mathbb{R}$. Intuitively, based on the properties of $\mathcal{H}_{in}$ and $\mathcal{H}_{out}$, we know that if p, q are close enough, $S(p)$ and $S(q)$ should have many common bits in positions that are determined by functions from $\mathcal{H}_{in}$. Contrarily, if p, q are far away, $S(p)$ and $S(q)$ should have only a few common bits in positions that are determined by functions from $\mathcal{H}_{out}$.

For every point $p \in P$, we use $S(p)$ to compute a bit-string label for p, and put p into the corresponding buckets (*i.e.,* labeled with the same bit-strings). To answer a given BD query B_{in}, B_{out} with centers of the balls being o_{in}, o_{out}, respectively, we compute $S(o_{in})$ and $S(o_{out})$. Note that, based on the above discussion, we know that if a point p satisfies the condition of $p \in B_{in} \setminus B_{out}$, then $S(p)$ and $S(o_{in})$ should have many common bits in the positions determined by $\mathcal{H}_{in}$, and $S(p)$ and $S(o_{out})$ should have few common bits in the positions determined by $\mathcal{H}_{out}$. Thus, by counting the number of common bits in the labels, we can then locate buckets that are likely to contain points close to o_{in} and far away from o_{out}, *i.e.,* points are likely to be in $B_{in} \setminus B_{out}$. To achieve the desired outcome, we will create multiple set of buckets using multiple random functions $S(p)$.

Details of the Algorithms. After understanding the above general idea, we now present the data structure and the query algorithm along with the analysis. Let $\mathsf{P}'_1 = (1 + \mathsf{P}_1)/2, \mathsf{P}'_2 = (1+\mathsf{P}_2)/2, \eta = (\mathsf{P}'_1 - \mathsf{P}'_2)/3, a = \lceil (2\mathsf{P}'_1 \ln 3)/\eta^2 \rceil$. $\mathsf{P}''_1 = 2^{-2a} \cdot 4/9$, $\mathsf{P}''_2 = 2^{-2a}/3, b = \lceil \log_{1/\mathsf{P}''_2} n \rceil$, $\rho = \frac{\ln 1/\mathsf{P}''_1}{\ln 1/\mathsf{P}''_2}$, and $c = \lceil n^\rho / \mathsf{P}''_1 \rceil$. Let F_Z be a function that maps every element in $\mathbb{Z}$ randomly to 0 or 1, each with probability 1/2. The following Algorithm 3 shows how to construct a ξ-error BD range query data structure for any point set P and radii r_{in} and r_{out}. The data structure consists of c groups of buckets, each created using a random function $S(p)$ that maps a point to a bit-string of total length $2ab$.

Algorithm 3 CreateBuckets$(P, \xi, r_{in}, r_{out})$.

Input: A point set P. Parameters $\xi > 0, , r_{in} > 0, r_{out} > 0$.

Output: $\mathcal{G}_1, \mathcal{G}_2, \ldots \mathcal{G}_c$. Each $\mathcal{G}_i$ is a collection of *buckets* (*i.e.,* sets of points of P). Each bucket $G \in \mathcal{G}_i$ is labeled with *a bit-string*, which is a concatenation of sub-bit-strings $\text{LAB}_{in}(G,1)$, $\text{LAB}_{out}(G,1)$, $\text{LAB}_{in}(G,2)$, $\text{LAB}_{out}(G,2)$, ..., $\text{LAB}_{in}(G,b)$, $\text{LAB}_{out}(G,b)$. For every $p \in P$ and $i = 1, 2, \ldots, c$, p appears in one of the buckets in $\mathcal{G}_i$.

1: Initialize $\mathcal{G}_i, i = 1, 2, \ldots, c$, as empty sets. Each $\mathcal{G}_i$ will be used as a container for buckets.

2: Randomly sample abc functions from family $\mathcal{H}_{in}$, and also abc functions from family $\mathcal{H}_{out}$. Denote these functions as $h_{in,i,j,k}$ and $h_{out,i,j,k}$, for integers $1 \le i \le a, 1 \le j \le b, 1 \le k \le c$. For every $h_{in,i,j,k}$, $h_{out,i,j,k}$ and every $p \in Q$, compute $F_Z(h_{in,i,j,k}(p))$ and $F_Z(h_{out,i,j,k}(p))$.

3: **FOR** k from 1 to c:

- For every point $p \in P$, we create a bit-string $S(p)$ that concatenates $\text{LAB}_{in}(p,1), \text{LAB}_{out}(p,1), \text{LAB}_{in}(p,2), \text{LAB}_{out}(p,2), \ldots, \text{LAB}_{in}(p,b), \text{LAB}_{out}(p,b)$: For j from 1 to b, let $\text{LAB}_{in}(p,j)$, $\text{LAB}_{out}(p,j)$ be a pair of bit-strings of length a, each with the i-th bit being $F_Z(h_{in,i,j,k}(p))$, $F_Z(h_{out,i,j,k}(p))$, respectively, for $i = 1, 2, \ldots a$.
- **IF** there is already a bucket G in $\mathcal{G}_k$ with label $S(G) = S(p)$, **DO**: Put p into G.
- **ELSE, DO**: Create a new bucket G and put G into $\mathcal{G}_k$, set the label of G as $S(G) = S(p)$. Put p into G.

With the BD range query data structure created by the Algorithm 3, we can use the Algorithm 4 below to answer a BD range query for any given pair of balls (B_{in} and B_{out}). The main idea of the algorithm compute a bit-string label S for the query, then examine points in buckets with labels that satisfy certain properties (*e.g.* should have enough common bits with S). Due to the fact that we label these buckets using functions from two LSH families, it can be shown that the chance for us to find a point in $B_{in}(1+\xi) \setminus B_{out}((1+\xi)^{-1})$ from one of the examined buckets will be high if there exists a point in $B_{in} \setminus B_{out}$.

In the following we show the correctness of Algorithm 4. Consider the for loop in Step 1 of Algorithm 4 when answering a query (B_{in}, B_{out}). Using the notations from Algorithm 4, for any k from 1 to c in Step 1, we have the following lemma, which shows that if a point in P lies in (or outside of) the query range, the number of common bits between its bucket label and the label computed from the query would likely (or unlikely) be high, respectively.

▶ **Lemma 10.** *Let $p \in P$ be a point that lies in $B_{in} \setminus B_{out}$, and $q \in P$ be a point that does NOT lie in $B_{in}(1+\xi) \setminus B_{out}((1+\xi)^{-1})$. Let $S(p) = \text{LAB}_{in}(p,1), \text{LAB}_{out}(p,1), \text{LAB}_{in}(p,2), \text{LAB}_{out}(p,2), \ldots, \text{LAB}_{in}(p,b), \text{LAB}_{out}(p,b)$ and $S(q) = \text{LAB}_{in}(q,1), \text{LAB}_{out}(q,1), \text{LAB}_{in}(q,2), \text{LAB}_{out}(q,2), \ldots, \text{LAB}_{in}(q,b), \text{LAB}_{out}(q,b)$ be the labels of the bucket in $\mathcal{G}_k$ that contains p and q, respectively. For any $j = 1, 2, \ldots, b$, the following holds.*

- $Pr[COM(\text{LAB}_{in}(p,j), \text{LAB}_{in}(o_{in},j)) \ge t_1 \wedge COM(\text{LAB}_{out}(p,j), \text{LAB}_{out}(o_{out},j)) \ge t_2] \ge 4/9$.
- $Pr[COM(\text{LAB}_{in}(q,j), \text{LAB}_{in}(o_{in},j)) \ge t_1 \wedge COM(\text{LAB}_{out}(q,j), \text{LAB}_{out}(o_{out},j)) \ge t_2] \le 1/3$.

Proof. Since $p \in B_{in} \setminus B_{out}$, we have $\|p - o_{in}\| \le r_{in}$ and $\|p - o_{out}\| \ge r_{out}$. For any hash function $h_1 \in \mathcal{H}_{in}$ and $h_2 \in \mathcal{H}_{out}$, $\Pr[h_1(p) = h_1(o_{in})] \ge \mathsf{P}_1$ and $\Pr[h_2(p) = h_2(o_{out})] \le \mathsf{P}_2$. Thus, we have $\Pr[F_Z(h_1(p)) = F_Z(h_1(o_{in}))] \ge (\mathsf{P}_1 + 1)/2$ and $\Pr[F_Z(h_2(p)) = 1 - F_Z(h_2(o_{out}))] \le (1 - \mathsf{P}_2)/2$. This means that for any $i = 1, 2 \ldots, a$, the probability that the

Algorithm 4 BD-Query(B_{in}, B_{out}).

Input: Two $\mathbb{R}^d$ balls: B_{in} with center o_{in} and radius r_{in}, and B_{out} with center o_{out} and radius r_{out}. Assume that collections $\mathcal{G}_1, \mathcal{G}_2, \dots \mathcal{G}_c$ have already been generated by algorithm CreateBucket.

Output: A point $p \in Q$, or NULL.

Note: The algorithm probes a number of points in the buckets of $\mathcal{G}_1, \mathcal{G}_2, \dots \mathcal{G}_c$ until a suitable point is found as the output, or terminates and returns NULL when no such point can be found or the number of probes exceeds a certain limit.

1: Do the following, but terminate and return NULL when $3c$ points are examined: **FOR** k from 1 to c:
- Create a bit string S that concatenates $\text{LAB}_{in}(o_{in}, 1)$, $\text{LAB}_{out}(o_{out}, 1)$, $\text{LAB}_{in}(o_{in}, 2)$, $\text{LAB}_{out}(o_{out}, 2)$, …, $\text{LAB}_{in}(o_{in}, b)$, $\text{LAB}_{out}(o_{out}, b)$: For j from 1 to b, let $\text{LAB}_{in}(o_{in}, j)$, $\text{LAB}_{out}(o_{out}, j)$ be a pair of bit strings of length a, with the i-th bit of each string being $F_Z(h_{in,i,j,k}(o_{in}))$, $1 - F_Z(h_{out,i,j,k}(o_{out}))$, respectively, for $i = 1, 2, \dots a$.
- Create a bit string S' that concatenates $\text{LAB}'_{in}(1), \text{LAB}'_{out}(1), \text{LAB}'_{in}(2), \text{LAB}'_{out}(2), \dots,$ $\text{LAB}'_{in}(b), \text{LAB}'_{out}(b)$: Each of these sub bit strings is a random bit string of length a, drawn uniformly randomly from $\{0,1\}^a$.
- If there exists some integer j such that $\text{COM}(\text{LAB}_{in}(o_{in}, j), \text{LAB}'_{in}(j)) < t_1$ or $\text{COM}(\text{LAB}_{out}(o_{out}, j), \text{LAB}'_{out}(j)) < t_2$, where $\text{COM}(x, y)$ counts the number of common digits of 2 bit strings x, y, $t_1 = \mathsf{P}'_1 a - \eta a, t_2 = (1 - \mathsf{P}_2)a/2 - \eta a$ **CONTINUE.**
- If there is no bucket in $\mathcal{G}_k$ that is labeled with S', **CONTINUE.**
- Examine all the points in the bucket G in $\mathcal{G}_k$ that is labeled with S'. Stop when there a point $p \in G$ such that $p \in B_{in}(1+\xi) \setminus B_{out}((1+\xi)^{-1})$. Return p.

2: Return NULL if no point is returned in the above process.

i-th bit of $\text{LAB}_{in}(p, j)$ is the same as that of $\text{LAB}_{in}(o_{in}, j)$ is at least $\mathsf{P}'_1 = (\mathsf{P}_1 + 1)/2$. Since the hash functions to determine each of the bits are drawn independently, an estimation of $X = \text{COM}(\text{LAB}_{in}(p, j), \text{LAB}_{in}(o_{in}, j))$ can be obtained by $\Pr[F_Z(h_1(p)) = F_Z(h_1(o_{in}))] \geq (\mathsf{P}_1 + 1)/2$ using the concentration inequalities for binomial distributions. Using a variant of the Chernoff inequalities from [22], we have

$$\Pr[X \leq \mathsf{P}'_1 a - \eta a] \leq e^{-(\eta a)^2/(2\mathsf{P}'_1 a)}.$$

From the definition of the parameters, we know that $\Pr[X \leq \mathsf{P}'_1 a - \eta a] \leq 1/3$ (by simple calculation). Thus, we have $\Pr[X \geq t_1] \geq 2/3$.

Let $Y = \text{COM}(\text{LAB}_{out}(p, j), \text{LAB}_{out}(o_{out}, j))$. From $\Pr[F_Z(h_2(p)) = 1 - F_Z(h_2(o_{out}))] \leq (1 - \mathsf{P}_2)/2$ and using a similar argument as above, we can also obtain $\Pr[Y \geq t_2] \geq 2/3$ (the details are omitted). Since the hash functions are drawn independently, we have $\Pr[X \geq t_1 \wedge Y \geq t_2] \geq 4/9$.

In the following we discuss the case that $q \notin B_{in}(1+\xi) \setminus B_{out}((1+\xi)^{-1})$. This means either $\|q - o_{in}\| \geq (1+\xi) r_{in}$ or $\|q - o_{out}\| \leq (1+\xi)^{-1} r_{out}$. We first consider the case $\|q - o_{in}\| \geq (1+\xi) r_{in}$. For any hash function $h_1 \in \mathcal{H}_{in}$, $\Pr[h_1(q) = h_1(o_{in})] \leq \mathsf{P}_2$. Thus, we have $\Pr[F_Z(h_1(q)) = F_Z(h_1(o_{in}))] \leq (\mathsf{P}_2 + 1)/2$. This means that for any $i = 1, 2 \dots, a$, the probability that the i-th bit of $\text{LAB}_{in}(q, j)$ is the same as that of $\text{LAB}_{in}(o_{in}, j)$ is at most $\mathsf{P}'_2 = (\mathsf{P}_2 + 1)/2$. Again, we use a concentration inequality to obtain an estimation of $X = \text{COM}(\text{LAB}_{in}(q, j), \text{LAB}_{in}(o_{in}, j))$. Using a variant of the Chernoff inequalities from [22], we have

$$\Pr[X \geq \mathsf{P}'_2 a + \eta a] \leq e^{-(\eta a)^2/(2\mathsf{P}'_2 a + \eta a/3)}.$$

Note that $a = (2\mathsf{P}'_1 \ln 3)/\eta^2 \geq ((2\mathsf{P}'_2 + \eta/3)\ln 3)/\eta^2$, which implies that $e^{-(\eta a)^2/(2\mathsf{P}'_2 a + \eta a/3)} \leq 1/3$ (by simple calculation). Thus, we have $\Pr[X \geq \mathsf{P}'_2 a + \eta a] \leq 1/3$. Also, since $\mathsf{P}'_2 a + \eta a < \mathsf{P}'_1 a - \eta a = t_1$, we get $\Pr[X \geq t_1] \leq 1/3$. This immediately implies that $\Pr[\mathrm{COM}(\mathrm{LAB}_{in}(q,j), \mathrm{LAB}_{in}(o_{in},j)) \geq t_1 \wedge \mathrm{COM}(\mathrm{LAB}_{out}(q,j), \mathrm{LAB}_{out}(o_{out},j)) \geq t_2] \leq 1/3$.

The argument for the case $\|q - o_{out}\| \leq (1+\xi)^{-1} r_{out}$ is similar. Thus, we omit it here. This completes the proof. ◀

From the above lemma, we can conclude the following by basic calculation. For any k from 1 to c in Step 1 of Algorithm 4 (if the loop is actually executed), let $p \in P$ be a point that lies in $B_{in} \setminus B_{out}$, and $q \in P$ be a point that does NOT lie in $B_{in}(1+\xi) \setminus B_{out}((1+\xi)^{-1})$, we have the following.

▶ **Lemma 11.** *Let G_p and G_q be the buckets in $\mathcal{G}_k$ that contain p and q, respectively. The probability for G_p to be examined is no smaller than $2^{-2ab}(4/9)^b = (\mathsf{P}''_1)^b$, and the probability for the event "ALL such G_p for k from 1 to c are NOT examined" is at most $(1-(\mathsf{P}''_1)^b)^c \leq 1/e$. The probability for G_q to be examined is no larger than $2^{-2ab}(1/3)^b = (\mathsf{P}''_2)^b \leq 1/n$.*

With the above lemma, we can obtain the following lemma using an argument similar to [15] for near neighbor search with LSH. This proves the correctness of the query scheme.

▶ **Lemma 12.** *If there exists a point in P that lies in $B_{in} \setminus B_{out}$, with probability at least $1/4$, Algorithm 4 reports a point in P that lies in $B_{in}(1+\xi) \setminus B_{out}((1+\xi)^{-1})$.*

The complexity of the data structure is $O(dabcn)$, which is $O_\xi(dn^{1+\rho}\log n)$ from $a = O_\xi(1), b = O_\xi(\log n)$ and $c = O_\xi(n^\rho)$, and ρ and the constant hidden in the big-O notation depends only on ξ. The query time is $O(abcd)$, which is $O_\xi(dn^\rho \log n)$. To achieve $1-\delta$ success probability, it suffices to concatenate $O(\log \delta)$ such data structures together.

Due to space limit. we leave the proof of the above 2 lemmas and the full proof of Lemma 7 to the full version of the paper.

3 Multi-scale Construction

In this section, we present the *multi-scale construction* method, which is a standalone technique with potential to be used to other high dimensional range-aggregate query problems.

The multi-scale construction method is motivated by several high dimensional geometric query problems that share the following common feature: they are challenging in the general settings, but become more approachable if some key parameters are known in advance. The AIFP query problem discussed in this paper is such an example. In the previous section, we have shown how to construct an AIFP data structure if we fix the size of the query ball and know that the farthest distance lies in a given range.

The basic ideas behind multi-scale construction are the follows. Firstly, we know that if a problem is solvable when one or more key parameters are fixed, a feasible way to solve the general case of the problem is to first enumerate all possible cases of the problem defined by (the combinations of) the values of the parameters. Then, solve each case of the problem, and finally obtain the solution from that of all the enumerated cases. The multi-scale construction method follows a similar idea. More specifically, to obtain a general AIFP query data structure, the multi-scale construction method builds a set of constrained AIFP query data structures that cover all possible radii of B and farthest distance value. Secondly, since it is impossible to enumerate the infinite number of all possible values for these parameters, our idea is to sample a small set of fixed radii (based on the distribution of the points in P)

and build constrained AIFP data structures only for the set of sampled values. This will certainly introduce errors. However, good approximations are achievable by using a range cover technique.

Below we first briefly introduce two key ingredients of our method, Aggregation Tree and Range Cover, and then show how they can be used to form a multi-scale construction.

3.1 Aggregation Tree and Range Cover

In this subsection, we briefly introduce the two components of the multi-scale construction scheme: the *aggregation tree* and the *range cover* data structure. We first introduce aggregation tree, which is used in [18] as an ingredient of the range cover data structure. It is essentially a slight modification of the Hierarchical Well-Separated Tree (HST) introduced in [14]. Below is the definition of an aggregation tree: (1) Every node v (called *aggregation node*) represents a subset $P(v)$ of P, and the root represents P; (2)Every aggregation node v is associated with a representative point $re(v) \in P(v)$ and a size $s(v)$. Let $Dia(P(v))$ denotes the diameter of $P(v)$, $s(v)$ is a polynomial approximation of $Dia(P(v))$: $Dia(P(v)) \leq s(v)$, and $\frac{s(v)}{Dia(P)}$ is upper-bounded by a polynomial function $\mathcal{P}_{HST}(n, d) \geq 1$ (called *distortion polynomial*); (3) Every leaf node corresponds to one point in P with size $s(v) = 0$, and each point appears in exactly one leaf node; (4) The two children v_1 and v_2 of any internal node v form a partition of v with $\max\{s(v_1), s(v_2)\} < s(v)$; and (5) For every aggregation node v with parent v_p, $\frac{s(v_p)}{r_{out}}$ is bounded by the distortion polynomial $\mathcal{P}_{HST}(n, d) \geq 1$, where r_{out} is the minimum distance between points in $P(v)$ and points in $P \setminus P(v)$.

The above definition is equivalent to the properties of HST in [14], except that we have an additional distortion requirement (Item 5). See Figure 2 for example of an aggregate tree.

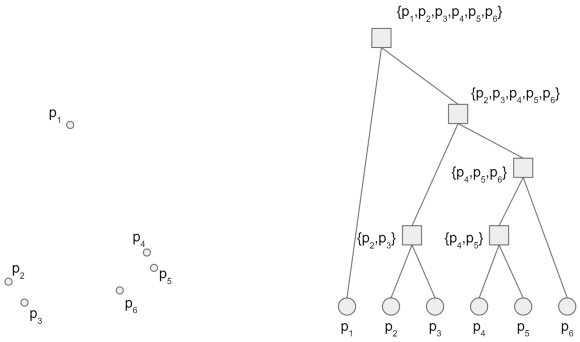

Figure 2 An illustration of an aggregation tree built for 6 points.

An aggregation tree can be constructed in $O(dn \log^2 n)$ time using the method in [14]. It is proved in [14] that the distortion polynomial is $\mathcal{P}_{HST}(n, d) = dn$. In the rest of the paper, we always assume that the distortion of an aggregation tree is $\mathcal{P}_{HST}(n, d) = dn$.

In the following, we briefly introduce range cover. Range cover is a technique proposed in [18] for solving the truth discovery problem in high dimensions. We utilize it in a completely different way to form a multi-scale construction for the AIFP query problem. Below is the algorithm (Algorithm 5). Given an aggregation tree T_p and real number parameters $\Delta \geq 8n$ and $0 < \lambda < 1$ (whose values will be determined later), the range cover algorithm creates a number of buckets for the nodes of T_P. Each bucket B_t is associated with an interval of real

Algorithm 5 RangeCover($T_P; \lambda, \Delta$).

Input: An aggregation tree T_P built over a set P of n points in $\mathbb{R}^d$; controlling factors $0 < \lambda < 1$ and an integer $\Delta \geq 4\mathcal{P}_{HST}(n, d)$.

Output: A number of buckets, where each bucket stores a number of tree nodes. Each bucket B_t is indexed by an integer t and associated with an interval $((1+\lambda)^t, (1+\lambda)^{t+1}]$.

1: For every integer t create an empty bucket B_t associated with interval $((1+\lambda)^t, (1+\lambda)^{t+1}]$. (Note that B_t will not be actually created until some tree node v is inserted into it.)

2: For every non-root node v of T_P, let v_p be its parent in T_P, r_H be $s(v_p)/\lambda$, and r_L be $\max\{s(v)/\lambda, s(v_p)/\Delta\}$. Do

- For every integer t satisfying inequality $r_L \leq (1+\lambda)^t < r_H$, insert v into bucket B_t.

number $((1+\lambda)^t, (1+\lambda)^{t+1}]$. If a value r lies in the interval of a bucket B_t, it can be shown that the diameter of every aggregation node v is small compared to r, and thus all points in $P(v)$ can be approximately viewed as one "heavy" point located at the representative point $re(v)$. Intuitively, every bucket from the range cover algorithm provides a view of P when observed from a distance r in the range of the bucket, where each node in the bucket represents a "heavy" point that is formed by the aggregation of a set of close (compared to the observing distance) clusters of points in P. Thus, the buckets of the range cover provides views of the input point set at different scales of observing distances (see Figure 3 for an illustration). The size of the output data structure is only $O(n \log n\Delta)$, as shown in [18].

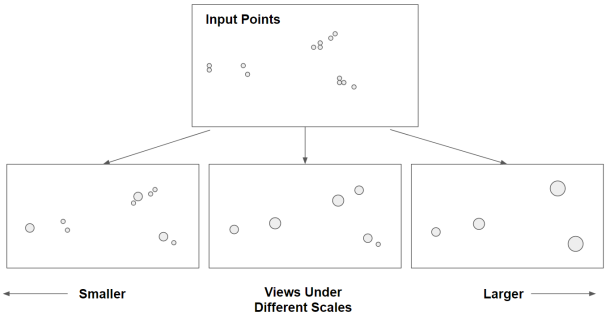

Figure 3 An illustration of range cover. The nodes in every bucket can be viewed as "heavy" points yielded by the aggregation of a set of close points. Every bucket provides a view of the input point set when observed from a certain distance. All the buckets jointly form a complete set of views of the input points at all possible scales.

Note that for many problems, fixing some key parameters also means fixing the "observing distance" of P from the perspective of solving the problem. This allows us to solve the problem based on the view of P provided by the bucket associated with the corresponding observation distance. We will show that this idea also applies to the AIFP problem.

3.2 Multi-scale Construction for AIFP

In this subsection, we use AIFP problem as an example to show how to implement multi-scale construction using the range cover data structure.

We first observe that every bucket of the range cover can be used to solve a constrained AIFP problem (with the proof given later). Given an AIFP query (B, q), if the (approximate) distance from q to a point in $P \cap B$ is known and falls in the interval of $((1+\lambda)^t, (1+\lambda)^{t+1}]$,

then the (approximate) distance from q to a point of $B_t \cap B$ (where every node v in B_t is viewed as a "heavy" point located at $re(v)$) is an AIFP of q in $P \cap B$. This means that B_t provides a good "sketch" of P that allows more efficient computation of the AIFP of q in $P \cap B$. This observation leads to the main idea of the multi-scale construction method. To obtain a general AIFP query data structure, for every bucket B_t, we construct a constrained AIFP data structure for B_t (viewed as a set of "heavy" points), exploiting the assumption that the farthest distance is in the interval of $((1+\lambda)^t, (1+\lambda)^{t+1}]$. To answer a general AIFP query, we can find the AIFP for every bucket by querying the constrained AIFP data structures associated with the bucket. In this way, we can compute AIFPs for all possible radii. When answering a general AIFP query, we first determine an approximate farthest distance of q to $P \cap B$, and then query the appropriate constrained AIFP data structures. Despite the necessity of building multiple constrained data structures, the complexity of the multi-scale construction is not high, as the total number of nodes in all buckets is only $\tilde{O}(n)$.

However, the above idea is hard to implement, because each bucket B_t is only responsible for a small range $((1+\lambda)^t, (1+\lambda)^{t+1}]$ of the possible farthest distance from q to $P \cap P$. This means that we need an accurate estimation of this distance when answering the query, which is almost as hard as the query itself. We resolve this issue by merging multiple consecutive buckets into a larger one. The resulting bucket can account for a larger range of the possible farthest distances. We then build a constrained data structure for each bucket.

This leads to the following Multi-Scale algorithm. Let $\Gamma \geq 1$ be an integer constant to be determined, and $\mathcal{A}$ be an algorithm for building a constrained data structure. In this algorithm, for each integer t, we try to merge the aggregation nodes in buckets $B_t, B_{t+1}, \ldots, B_{t+\Gamma}$ from the range cover (recall that these buckets are associated with farthest distance ranges $((1+\lambda)^t, (1+\lambda)^{t+1}], ((1+\lambda)^{t+1}, (1+\lambda)^{t+2}] \ldots, ((1+\lambda)^{t+\Gamma}, (1+\lambda)^{t+\Gamma+1}]$, respectively) into one bucket B_t^+ that could account for a larger range $((1+\lambda)^t, (1+\lambda)^{t+\Gamma+1}]$. We then use $\mathcal{A}$ to build a data structure $\mathcal{S}_t$ for every bucket B_t^+ (by viewing every node in B_t^+ as a point).

Algorithm 6 Multi-Scale($T_P; \lambda, \Delta, \Gamma; \mathcal{A}$).

Input: An aggregation tree T_P built over a set P of n points in $\mathbb{R}^d$; controlling factors $0 < \lambda < 1$, integer $\Delta \geq 4\mathcal{P}_{HST}(n,d) = 4dn$, and integer $\Gamma \geq 1$. A routine $\mathcal{A}$ which builds a constrained data structure for any given bucket B_t and point set $re(B_t^+) := \{re(v) \mid v \in B_t^+\}$.
Output: A number of buckets, with each storing a number of tree nodes. Each bucket B_t^+ is indexed by an integer t and associated with an interval $((1+\lambda)^t, (1+\lambda)^{t+\Gamma+1}]$. Each bucket B_t^+ is associated with data structure $\mathcal{S}_t$ built by $\mathcal{A}$.

1: Create a collection of buckets $\{B_t\}$ by calling RangeCover($T_P; \lambda, \Delta(1+\lambda)^\Gamma$).
2: For each integer t create an empty bucket B_t^+ associated with $((1+\lambda)^t, (1+\lambda)^{t+\Gamma+1}]$.
3: For every non-root node v of T_P, enumerated in a bottom-up manner in T_P so that the children of a node is always visited earlier than the parent node, put v into B_t^+ for every t such that the following is satisfied:
   - $s(v) \leq \lambda(1+\lambda)^t$, v appears in $B_{t'} \in \{B_t\}$ for some $t \leq t' \leq t+\Gamma$, and none of v's descendants are put in B_t^+ previously.
4: For every non-empty bucket B_t^+, create a data structure $\mathcal{S}_t$ using $\mathcal{A}$ for the point set $re(B_t^+) := \{re(v) \mid v \in B_t^+\}$.

For better understanding of this scheme, we first briefly discuss the geometric properties of the buckets created by Algorithm 6. Intuitively speaking, the aggregation nodes of every bucket provide a sketch of *almost* the whole input point set P, with the exception being points that satisfying some special isolation property. This can be briefly described as follows:

(1) The diameter of each the aggregation node (viewed as a point set) should be small to the observation distances; (2) The aggregation nodes are mutually disjoint; and (3) Every point $p \in P$ is either in one of the nodes in the bucket, or it is in an aggregation node (not in the bucket) whose distance to other nodes is large. These properties are formalized as follows. (We leave the proofs of all the following claims and lemma to the full version of the paper.)

▷ Claim 13. Let v be any aggregation node v in a created bucket B_t^+. Then, $s(v) \leq \lambda(1+\lambda)^t$.

▶ **Lemma 14.** *For any $p \in P$ and and bucket B_t^+ created by Algorithm 6, one of the following holds:*

1. *There exists exactly one aggregation node $v \in B_t^+$ such that $p \in P(v)$.*
2. *Either B_t^+ is empty or there exists no aggregation node $v \in B_t^+$ such that $p \in P(v)$. There exists an aggregation node v' in T_P such that $s(v')/\lambda \leq (1+\lambda)^t$. Furthermore, let q be any point in $P \setminus P(v')$, then $\|p-q\| > (\Delta/dn)(1+\lambda)^{t+\Gamma}$.*

Although the sketch does not fully cover P, in many problems (including AIFP) these points are either negligible or easy to handle by other means due to their special properties.

From [18], we know that the running time of Algorithm 5 and the space complexity of the output data structure is $O_\lambda(n \log n\Delta)$ (where the hidden constant in the big-O notation depends only on λ). Algorithm 6 essentially merges $\Gamma + 1$ consecutive buckets B_t, B_{t+1}, …, $B_{t+\Gamma}$ created by Algorithm 5 into one bucket B_t^+. Thus, we have the following lemma.

▶ **Lemma 15.** *Excluding the time it takes for $\mathcal{A}$ to process each B_t^+ in Step 4, the running time of Algorithm 6 and the total number of nodes in all buckets is $O_\lambda(\Gamma^2 n \log n\Delta)$, where the hidden constant in big-O notation depends only on λ.*

We conclude this subsection by providing a key lemma showing that, given a constrained AIPF query (B, q) satisfying constraint (r_B, d_{min}, d_{max}) with $d_{min} \leq r_B \leq d_{max}$, if there is a bucket B_t^+ such that $(1+\lambda)^{t+1}/(1-\lambda) < d_{min} < d_{max} \leq (1+\lambda)^{t+\Gamma} - (2+2/\lambda)r_B$ (*i.e.* the range $[d_{min}, d_{max}]$ falls in interval $((1+\lambda)^t, (1+\lambda)^{t+\Gamma+1}]$ with some gap), then, with an easy-to-handle exception, an AIFP to q in B_t^+ (by viewing every node of B_t^+ as one point) in (slightly enlarged) range B is also an AIFP of q to $P \cap B$. Formally, let $re(B_t^+) := \{re(v) \mid v \in B_t^+\}$. Let p_t be the farthest point to q in $re(B_t^+) \cap B(1+\lambda)$ if $re(B_t^+) \cap B(1+\lambda) \neq \emptyset$, and p be a $(\lambda/6, \lambda/6)$-AIFP of q in $re(B_t^+) \cap B(1+\lambda)$ [2]. Let p_N be a $(1+\lambda)$-approximate nearest neighbor of q in P.

▶ **Lemma 16.** *One of the following holds: (1) p_N is a $(2\lambda, 2\lambda)$-AIFP of q in $P \cap B$, or (2) p_t exists and $(1+\lambda)^t \leq \|q - p_t\| \leq (1+\lambda)^{t+\Gamma+1}$, and p is a $(2\lambda, 2\lambda)$-AIFP of q in $P \cap B$.*

The above lemma implies that, in Algorithm 6, if routine $\mathcal{A}$ builds a constrained AIFP data structure for farthest distance lies in interval $[(1+\lambda)^t, (1+\lambda)^{t+\Gamma+1}]$, then either this data structure can be used to answer any query with constraint (r_B, d_{min}, d_{max}) (with other parameters, like r_B and the approximate factors for constrained AIFP, set properly), or the AIFP query can be solved easily using a nearest neighbor search. In the following section, we will show how to build a general AIFP query data structure through multi-scale construction by selecting appropriate parameters. With the multi-scale data structure (together with some auxiliary data structures), we can answer an AIFP query by (1) obtaining a rough estimation of the farthest distance, and (2) querying the bucket corresponding to the estimated range.

[2] Note p could be NULL here. This could happen when bucket B_t^+ is empty or $re(B_t^+) \cap B(1+\lambda) = \emptyset$.

4 General AIFP Query

In this section, we present a general (ϵ, γ)-AIFP query scheme. In the following, let B be a closed ball with radius $r_B > 0$ and q be an arbitrary point. Let $0 < \epsilon < 1$ and $0 < \gamma < 1$ be any pair of constants and $\lambda := \min(\epsilon, \gamma)/512$. We assume that r_B is λ-*aligned*, which means that $r_B = (1+\lambda)^t$ for some integer t. The alignment assumption makes it easier to implement the multi-scale construction. Note that if r_B is not λ-aligned, we can always enlarge B a little to make r_B λ-aligned and still obtain a good approximation with carefully chosen parameters.

Our main idea is to convert each query (B, q) into one or more AIFP queries (B', q) such that it is possible to find a lower bound d_{min} and an upper bound d_{max} on the farthest distance between q and a point in $B' \cap P$. With such bounds, the AIFP can then be found by querying a pre-built constrained AIFP data structure. To ensure efficiency, the gap between d_{min} and d_{max} cannot be too large, *i.e.,* d_{max}/d_{min} should be bounded by a polynomial of n and d. Since the complexity of a constrained data structure depends on d_{max}/d_{min}, a small gap will also enable us to control the size of the data structure. We start with a simple claim.

▷ Claim 17. If the distance between q and the center o_B of B is very large compared to r_B, *i.e.* $\|q - o_B\| \geq (3+\gamma)\epsilon^{-1} r_B$, then any point in $B(1+\gamma/2)$ is an (ϵ, γ)-AIFP of q in $P \cap B$.

This claim suggests that we can safely assume that the farthest distance between q and $P \cap B$ is not too large (compared to r_B), as otherwise the AIFP can be easily found with a nearest neighbor query. This helps us establish an upper bound on the farthest distance. In the following, we let $d_{max} := (4+2\gamma)\epsilon^{-1} r_B$, and assume that $\|q - o_B\| \leq (3+\gamma)\epsilon^{-1} r_B$. From simple calculation, this implies that for any $p \in P \cap B(1+\gamma)$, we have $\|p - q\| \leq d_{max}$.

Next, we try to find a lower bound for the farthest distance. Since the full argument will be rather complicated, we will thus describe only the general idea here, and leave the details to the full version of the paper. We start with a simple case.

Case 1: $\|q - o_B\| \geq (1+\gamma/64) r_B$, *i.e.* q does not lie in B and is not very close to the boundary of B. Then, clearly the farthest distance from q to any point in $P \cap B$ is at least $(\gamma/64) r_B$. Recall that we have obtained an upper bound $d_{max} := (4+2\gamma)\epsilon^{-1} r_B$. The ratio $d_{max}/(\gamma r_B/64)$ is clearly bounded by a polynomial of n, d.

In the following, we assume that $\|q - o_B\| \leq (1+\gamma/64) r_B$, which means that q lies in B or is very close to the boundary of B. Let $p_N \in P$ be a 2-nearest neighbor of q in P (*i.e.* for any $p' \in P$, $\|p_N - q\| \leq 2\|p' - q\|$) , and denote $r_N := \|p_N - q\|$. We discuss another simple case.

Case 2: $r_N > \gamma r_B/64$. Since p_N is a 2-approximate nearest neighbor, we conclude that the distance from q to any point in $P \cap B$ is at least $\gamma r_B/128$. Again, the ratio $d_{max}/(\gamma r_B/128)$ is well bounded.

In the following, we assume that $r_N \leq \gamma r_B/64$. In order to find a good lower bound on the farthest distance, our general strategy is to examine points around p_N and see whether there exists a point p' whose distance to q is sufficiently large, but still upper bounded by $(\gamma/64) r_B$. The upper bound $(\gamma/64) r_B$ ensures that $p' \in B(1+\gamma/16)$, *i.e.* p' "approximately" lies in B, and because of the fuzziness of the region, $\|p' - p\|$ can be used as a lower bound on the farthest distance. To efficiently implement this idea, we make use of an aggregation tree T_P with distortion polynomial $\mathcal{P}_{HST}(n, d) = nd$. Later, we will use this T_P to construct the query data structure. Let v_N denote the leaf node of T_P that correspond to singleton set $\{p_N\}$. We walk along the tree path from v_N to the root of T_P, and examine the nodes

(and their associated point sets) on this path. Denote by v the highest (closest to the root) node of T_P such that $p_N \in P(v)$ and $s(v) + r_N \leq \gamma r_B/64$. Note that since $r_N \leq \gamma r_B/64$ and $s(v_N) = 0$, such a node v must exist. Since $s(v)$ is an upper bound on the diameter of $P(v)$, every point $p' \in P(v)$ satisfies inequality $\|p' - q\| \leq \gamma r_B/64$, and thus $p' \in B(1+\gamma/16)$. See Figure 4 for a illustrations of the relations between q and points in $P(v)$. We consider two more cases, depending on the value of $s(v) + r_N$.

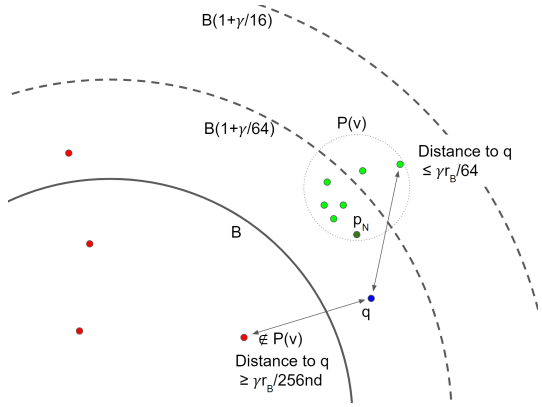

Figure 4 An illustration of points in $P(v)$, $P \setminus P(v)$ and q.

Case 3: $s(v) + r_N > \gamma r_B/512n^2d^2$. This means that $s(v) + r_N$ is at least r_B divided by a polynomial of n, d. Note that from the low distortion property of T_P, $s(v)$ is a polynomial approximation of the diameter of $P(v)$. It is possible to show by standard inequality arguments that, $s(v) + r_N$ is a polynomial approximation of q's farthest distance to any point in $P(v)$. Since $P(v) \subset B(1+\gamma/16)$, we conclude that the farthest distance from q to any point in $B(1+\gamma/16) \cap P$ is lower bounded by r_B divided by a polynomial of n, d. A careful calculation gives us an estimated lower bound $r_B/2048n^3d^3$. Since an upper bound for the farthest distance is $d_{max} = (4+2\gamma)\epsilon^{-1}r_B$, the quality of this lower bound is satisfactory because the gap between it and d_{max} is a polynomial of n, d.

Case 4: $s(v) + r_N \leq \gamma r_B/512n^2d^2$. We show that in this case, either there is a lower bound on the farthest distance, or the query can be reduced to another AIFP query where the range of farthest distances can be bounded. Let v_p be the parent of v (if v is the root of T_P, the following result still holds), then $s(v_p) + r_N \geq \gamma r_B/64$. This means that $s(v_p)$ is much larger than $s(v)$. From the property of T_P, we know that for any $p_{out} \in P \setminus P(v)$, the ratio $s(v_p)/\|p_{out} - p_N\|$ is upper bounded by the distortion polynomial $\mathcal{P}_{HST}(n, d) = nd$. In the current case, $s(v_p)/s(v)$ is indeed much larger than nd. Thus $\|p_{out} - p_N\|$ is very large compared to $s(v)$, which gives us a lower bound on $\|p_{out} - q\|$. In fact, by a careful calculation, it is possible to show that $\|q - p_{out}\| \geq \gamma r_B/256nd$ for any $p_{out} \in P \setminus P(v)$. Furthermore, since the distance between q and any point in $P(v)$ is at most $\gamma r_B/512n^2d^2$, which is much smaller than $\gamma r_B/256nd$. This implies that it is possible to use a ball centered at q to separate $P(v)$ and $P \setminus P(v)$. In fact, if let $r_{sep} := [s(v) + r_N]_\lambda$, where $[x]_\lambda$ denote the smallest real number that can be written as $(1+\lambda)^t$ for some integer t such that $(1+\lambda)^t \geq x$, then it can be shown that for every $p \in P(v)$, $p \in \mathcal{B}(q, r_{sep})$ and for every $p \in P \setminus P(v)$, $p \notin \mathcal{B}(q, (1+\gamma)r_{sep})$.

With the above argument, we divide Case 4 into 2 sub-cases. Let p_F be the actual farthest point to q in $P \cap B$. We first discuss **Case 4a**, where $p_F \in P \setminus P(v)$. From the above discussion, we have $\|q - p_F\| \geq \gamma r_B/256nd$, which gives a good lower bound on the

farthest distance. For **Case 4b** where $p_F \in P(v)$, we know that the query reduces to a problem of finding the farthest point in $p \cap \mathcal{B}(q, r_{sep})$. For this problem, it is possible to prove a $r_{sep}/8nd$ lower bound and r_{sep} upper bound on the farthest distance. The ratio of the two bounds is satisfactory.

To summarize, for Case 1,2 and 4a, let $d^{(1)}_{max} := (4+2\gamma)\epsilon^{-1}r_B$, $d^{(1)}_{min} := \gamma r_B/256nd$ and $r^{(1)}_B := r_B$, the AIFP query satisfies constraint $(r^{(1)}_B, d^{(1)}_{min}, d^{(1)}_{max})$; for Case 3, the AIFP query can be answered from constraint query $(\mathcal{B}(o_B, [(1+\gamma/16)r_B]_\lambda), q)$, which satisfies constraint $(r^{(2)}_B, d^{(2)}_{min}, d^{(2)}_{max})$, where $d^{(2)}_{min} := \gamma r_B/2048n^3d^3$, $d^{(2)}_{max} := (4+2\gamma)\epsilon^{-1}r_B$ and $r^{(2)}_B := [(1+\gamma/16)r_B]_\lambda$; for Case 4a, the AIFP query reduces to query $(\mathcal{B}(q, r_{sep}), q)$, with constraint $(r^{(3)}_B, d^{(3)}_{min}, d^{(3)}_{max})$ where $d^{(3)}_{max} := r^{(2)}_B := r_{sep}$, $d^{(3)}_{min} := d^{(3)}_{max}/8nd$. Any AIFP query can be answered from one of the three constraint queries, and we have $d^{(i)}_{max}/d^{(i)}_{min}$ no larger than $2048(4+2\gamma)n^3d^3/\epsilon$ for any $i = 1, 2, 3$.

4.1 Multi-scale Construction for General AIFP Query

In this subsection, we show how to build a Multi-Scale data structure to answer general AIFP queries. Our goal is to choose the appropriate parameters $\Gamma \geq 1$, $0 < \lambda < 1$ and $\Delta \geq 4nd$ for Algorithm 6 so that for every AIFP query with constraint $(r^{(i)}_B, d^{(i)}_{min}, d^{(i)}_{max})$, there exists a bucket B^+_t whose range $((1+\lambda)^t, (1+\lambda)^{t+\Gamma+1}]$ wholly covers the interval $[d^{(i)}_{min}, d^{(i)}_{max}]$, and the constrained AIFP data structure built for the bucket with $d_{min} := (1+\lambda)^t$ and $d_{max} := (1+\lambda)^{t+\Gamma+1}$ can be used to answer the query. Note that we have already defined $\lambda := \min(\epsilon, \gamma)/512$ and $\Delta := 4nd$. The remaining task is to determine the value of Γ.

Observe that $d^{(i)}_{max}/d^{(i)}_{min}$ is bounded by a polynomial $\mathcal{P}_{gap}(n, d) := 2048(4+2\gamma)n^3d^3/\epsilon$. Let $\Gamma' := \lceil \log_{1+\lambda} \mathcal{P}_{gap}(n, d) \rceil$, and $\Gamma_L \geq \Gamma'$ and $\Gamma_R \geq \Gamma'$ be integer parameters to be determined later. Denote by Γ the sum of Γ_L and Γ_R, *i.e.,* $\Gamma := \Gamma_L + \Gamma_R$. For every integer t, define $r_{mid}(t) := (1+\lambda)^{t+\Gamma_L}$. Therefore, we have $r_{mid}(t)/(1+\lambda)^t \geq (1+\lambda)^{\Gamma_L} \geq \mathcal{P}_{gap}(n, d)$ and $(1+\lambda)^{t+\Gamma+1}/r_{mid}(t) \geq (1+\lambda)^{\Gamma_R} \geq \mathcal{P}_{gap}(n, d)$. For any AIFP query (B, q) with constraint $(r^{(i)}_B, d^{(i)}_{min}, d^{(i)}_{max})$, it is always possible to find a bucket B^+_t such that $r^{(i)}_B = r_{mid}(t)$. Clearly, interval $((1+\lambda)^t, (1+\lambda)^{t+\Gamma+1}]$ wholly covers the interval $[d^{(i)}_{min}, d^{(i)}_{max}]$. If a constrained AIFP data structure is constructed for B^+_t with constraint $((1+\lambda)r_{mid}(t), (1+\lambda)^t, (1+\lambda)^{t+\Gamma+1})$, it can be used to answer the AIFP query (B, q). (See Lemma 16.)

To summarize the above discussions, we set the parameters of Algorithm 6 as the following. The algorithm then produces the data structure for (ϵ, γ)-AIFP query. Assume that a real number $0 < \delta < 1$ is given and we would like to achieve $1 - \delta$ query success probability.

- $\lambda := \min(\epsilon, \gamma)/512, \Gamma_L := \Gamma' + \lceil \log_{1+\lambda} 8 \rceil, \Gamma_R := \Gamma' + \lceil \log_{1+\lambda} 8 \rceil, \Gamma := \Gamma_L + \Gamma_R, \Delta := 4nd$.
- Routine $\mathcal{A}$: Given a non-empty bucket B^+_t, $\mathcal{A}$, it uses Algorithm 1 to creates a constrained $(\lambda/6, \lambda/6)$-AIFP data structure for point set $re(B^+_t)$ for constraint $((1+\lambda)r_{mid}(t), (1+\lambda)^t, (1+\lambda)^{t+\Gamma+1})$, with success probability at least $1 - \delta/4$.

Note that we let $\Gamma_L := \Gamma_R := \Gamma' + \lceil \log_{1+\lambda} 8 \rceil$. This allows more gap when fitting the interval $[d^{(i)}_{min}, d^{(i)}_{max}]$ in $((1+\lambda)^t, (1+\lambda)^{t+\Gamma+1}]$, which is required by Lemma 16.

With the multi-scale data structure constructed by Algorithm 6 using the above parameters, we are able to answer any general AIFP query by reducing it to at most three constrained $(\lambda/6, \lambda/6)$-AIFP queries (where $\lambda = \min(\epsilon, \gamma)/512$) with constraints $(r^{(i)}_B, d^{(i)}_{min}, d^{(i)}_{max})$, $i = 1, 2, 3$. From Lemma 6 and the fact that the ratio d_{max}/d_{min} satisfies $d_{max}/d_{min} = (1+\lambda)^{t+\Gamma+1}/(1+\lambda)^t = (1+\lambda)^{\Gamma+1}$, which is bounded by a polynomial of n, d, we know that $\log d_{max}/d_{min}$ is $O_{\epsilon,\gamma}(\log nd)$ and the query time is $O_{\epsilon,\gamma}(dn^\rho \log \delta^{-1} \mathrm{Polylog}(nd))$

for some $\rho < 1$ depending on ϵ, γ. The multi-scale data structure consists of multiple AIFP structures built on buckets of points with total size $O_\lambda(\Gamma^2 n \log(n\Delta))$ (from Lemma 15). From Lemma 6, we know that the complexity of the data structure is $O_{\epsilon,\gamma}(dn^{1+\rho} \log \delta^{-1} \text{Polylog}(nd))$. We leave the detailed analysis to the full version of the paper.

5 MEB Range Aggregate Query

Given any query ball B, we find the AMEB of $P \cap B$ using an iterative algorithm by Badoiu and Clarkson [9]. Their algorithm was originally designed for finding an approximate MEB for a fixed point set P. With careful analysis we show that their approach, after some modifications, can still be used to find AMEB in any given range B. Briefly speaking, our idea is to construct a small-size coreset of $P \cap B$. The MEB of the coreset is then a (ϵ, γ)-approximate MEB of $P \cap B$. The algorithm selects the coreset in an iterative fashion. It starts with an arbitrary point p from $P \cap B$. At each iteration, it performs the following operation to add a point to the coreset: (1) Compute an (approximate) MEB of the current coreset (directly using the algorithm in [9]); (2) Identify the AIFP in $P \cap B$ to the center of the current MEB, and add it to the coreset. We can show that after $O_{\epsilon,\gamma}(\log n)$ iterations, the MEB of the coreset is then a (ϵ, γ)-AMEB of $P \cap B$.

To answer an (ϵ, γ)-AMEB query with success probability at least $1 - \delta$, we will need only one (ϵ', γ')-AIFP data structure with success probability $1 - \delta / O_{\epsilon'}(\log n)$ (where ϵ', γ' depends on ϵ, γ polynomially), whose size is $O_{\epsilon,\gamma}(dn^{1+\rho} \log \delta^{-1} \text{Polylog}(nd))$ for some $\rho < 1$ depending on ϵ, γ. Every AMEB query is reduced to $O_{\epsilon'}(\log n)$ AIFP queries (the time for computing the MEB every iteration is negligible compared to AIFP queries). Thus, the query time is $O_{\epsilon,\gamma}(dn^{\rho} \log \delta^{-1} \text{Polylog}(nd))$. The detailed analysis is left to the full version of the paper.

Abstract

Financial networks model a set of financial institutions (firms) interconnected by obligations. Recent work has introduced to this model a class of obligations called credit default swaps, a certain kind of financial derivatives. The main computational challenge for such systems is known as the clearing problem, which is to determine which firms are in default and to compute their exposure to systemic risk, technically known as their recovery rates. It is known that the recovery rates form the set of fixed points of a simple function, and that these fixed points can be irrational. Furthermore, Schuldenzucker et al. (2016) have shown that finding a weakly (or "almost") approximate (rational) fixed point is PPAD-complete.

We further study the clearing problem from the point of view of irrationality and approximation strength. Firstly, we observe that weakly approximate solutions may misrepresent the actual financial state of an institution. On this basis, we study the complexity of finding a strongly (or "near") approximate solution, and show FIXP-completeness. We then study the structural properties required for irrationality, and we give necessary conditions for irrational solutions to emerge: The presence of certain types of cycles in a financial network forces the recovery rates to take the form of roots of non-linear polynomials. In the absence of a large subclass of such cycles, we study the complexity of finding an exact fixed point, which we show to be a problem close to, albeit outside of, PPAD.

1 Introduction

The International Monetary Fund says that the global financial crisis (GFC) of 2007 has had long lasting consequences, including loss of growth, large public debt and even a decline of fertility rates, see [2]. Consequently, the need to assess the *systemic risk* of the financial network cannot be overstated. For example, if banks at risk of defaults could be easily identified in the complex network of financial obligations, then spread could be preemptively avoided with appropriate countermeasures such as bailouts from central banks or regulators.

In this context, the *clearing problem* introduced in [7] plays a central role. We are given a so-called financial network, that is, a graph where vertices are banks (or, more generally, financial institutions) and weighted arcs (u, v) model direct liabilities from bank u to bank v. Each bank has also some assets external to the network, that can be used to pay its liabilities.

The question is to compute a *clearing recovery rate vector*, that is, the ratio between money available (coming from assets and payments from others) over liabilities for each bank. If this ratio is bigger than 1 for a bank, then it will be able pay its dues – in this case, we simply set its rate to 1. The banks that are in default have recovery rates smaller than 1. The problem of computing clearing recovery rates (which we will also refer to as the *clearing problem*) is well understood when there are only simple debt contracts in the network, then clearing recovery rate vectors always exist, are unique, and can be computed in polynomial time [7].

However, Eisenberg and Noe's model in [7] ignores the issue of financial derivatives that may be present in the system. The deregulation allowing banks to invest in these products is considered by many as one of the triggers of the GFC. The introduction of financial derivatives to financial networks is due to [22], where the focus is on a simple and yet widely used class of conditional obligations known as Credit Default Swaps (CDSes), the idea being to "swap" or offset a bank's credit risk with that of another institution. More specifically, a CDS has three entities: a creditor v, a debtor u and a reference bank z – u agrees to pay v a certain amount whenever z defaults. Whilst CDSes were conceived in the early 1990s as a way to protect v from the insolvency of z for direct liabilities (i.e., a (v, z)-arc in the network), they quickly became a speculative tool to bet against the creditworthiness of the reference entity and have in fact been widely used both as a hedging strategy against the infamous collateralised debt obligations, whose collapse contributed to the GFC, and pure speculation during the subsequent eurozone crisis. The clearing problem in the presence of these financial derivatives is somewhat less well-characterised: it is known that the clearing recovery rate vectors can be expressed as the fixed points of a certain function, and existence of solutions is then guaranteed via a fixed-point argument [22]. On the other hand, these fixed points can be irrational, and the computational problem is PPAD-complete [23] as long as one is interested in only a *weak* approximation of a recovery rate vector.

1.1 Our Contributions

In this paper we deepen the study of the clearing problem for financial networks with CDSes from two complementary viewpoints. Firstly, we argue that weak approximations can be misleading in this domain, as the objective under the weak approximation criterion is to find an "almost" fixed point (i.e., a point which is not too far removed from its image under the function). The risk estimate provided by this concept might be very far off the actual rate, thus changing the amount of bailout needed or even whether a bank needs rescue in the first place (see, e.g., our example in Figure 1b below). A more useful (but more difficult) objective is to obtain a strong approximation, that is, a point that is geometrically close to an actual fixed point of the function. Such a risk estimate would be actionable for a regulator, as the error could be measured in terms of irrelevant decimal places. Furthermore, the banks themselves would accept the rate when the strong approximation guarantee is negligible, whereas a weak approximation could significantly misrepresent their income and are subject to be challenged, legally or otherwise.

As our first contribution, we settle the computational complexity of computing strong approximations to the clearing problem in terms of FIXP [9], by showing that the clearing problem is complete for this class. In our reduction, we provide a series of financial network gadgets that are able to compute opportune arithmetic operations over recovery rates. Interestingly, not that many FIXP-complete problems are known, although there are a few important natural such problems (three-or-more-player Nash equilibria being a notable example). Hardness reductions for this class tend to be rather technically involved. The hardness reduction that we provide here indeed has some technical obstacles as well, although

our reduction is quite natural at a high level, and could inspire further developments in the area. Our result complements the current state of the art and completes the picture about the computational complexity of the clearing problem with financial derivatives. It shows that computing strongly approximate fixed points is harder than computing weakly approximate fixed points, which holds due to PPAD being equal to the class Linear-FIXP, which is a restriction of FIXP, and this makes PPAD (indirectly) a subclass of FIXP.

▶ **Main Theorem 1** (Informal). *Computing a strong approximation to the clearing recovery rates in a financial network with CDSes is FIXP-complete.*

The FIXP-hardness of the strong approximation problem indicates that there is an additional numerical aspect contributing to the hardness of the problem, which is not present in the weak approximation problem (where the hardness is of a combinatorial nature, due to the reducibility to the end-of-the-line problem which is canonical to PPAD). For the strong approximation problem, the nature of the underlying function for which we want to find the fixed points requires, in particular, the multiplication operation, which ultimately accounts for irrationality and super-polynomial numerical precision being necessary in order to derive whether a given point is a strong approximation to a clearing vector.

We then turn our attention towards irrational solutions with the goal to determine the source of irrationality and understand when it is possible to compute the clearing recovery rate vector exactly in the form of rational numbers. We identify a structural property of cycles in an opportunely enriched network that leads to unique irrational solutions. This property exactly differentiates the CDSes that produce and propagate irrationality of the recovery rates, that we call "switched on", from those that do not, termed "switched off". We prove the following close-to-tight characterisation of irrationality:

▶ **Main Theorem 2** (Informal). *If the financial network has only "switched on" CDSes in a cycle* and *the cycle cannot be shortcut with paths of length at most three then there exist rational values for debt and asset values for which the recovery rate vector is unique and irrational. Conversely, if every cycle of the financial network does not have any "switched on" CDSes then we can compute rational recovery rates in a polynomial number of operations, provided that we have oracle access to PPAD.*

Our proof of irrationality uses a graph "algebra" (i.e., a set of network fragments and an operation on them) that is able to generate all the possible cycle structures with the property above, which uncovers a connection between the network structure of the clearing problem and the roots of non-linear equations. For the opposite direction, we provide an algorithm that exploits the acyclic structure of financial networks with solely "switched off" CDSes. This algorithm iteratively computes the recovery rates of each strongly connected component of the network. We show that even for the simpler topologies of the financial system under consideration, the problem remains PPAD-hard, hence the need for the oracle access to PPAD.

Significance of Our Results. We see our results as important analytical tools that legislators can use to regulate financial derivatives. For example, our results contribute to the ongoing debate in the US and Europe about banning speculative uses of CDSes. In particular, they support, from a computational point of view, the call to ban so-called "naked" CDSes (as already done by the EU for sovereign debt in the wake of the Eurozone crisis, see [1]). A naked CDS is purely speculative since its creditor and debtor have no direct liabilities with the reference entity. It turns out that these CDSes add arcs between potentially unconnected nodes, thus possibly adding more of the cycles that lead to irrationality and, given that strong

approximations are out of scope due to our FIXP-hardness, it is not only combinatorially but also numerically intractable to gain insight in the systemic risk of such financial networks. A mechanism to monitor the topology of a financial network might be useful to avoid the construction of cyclical structures that include CDSes.

Both of our main results introduce significant novel technical and conceptual innovations to the field. As mentioned above, our reduction for the FIXP-hardness is somewhat more direct than in previous work we are aware of. Our reduction is direct, in the sense that it starts from the algebraic circuit defined by an arbitrary problem in FIXP. The reduction employs two main steps: We firstly force the outputs of all gates in the circuit to be in the unit cube, by essentially borrowing arguments from [9], after which we produce a series of network gadgets that preserve gate-wise the computations of said circuit; this makes the reduction conceptually straightforward in its setup.

It is worth highlighting a specific technical challenge that we overcome in our proof, as we think it sheds further light on FIXP, and in particular, on the operator basis of the algebraic circuits that are used to define the class. It is known that the circuit of problems in FIXP can be restricted without loss of generality on the arithmetic basis $\{\max, +, *\}$ [9], whereas restricting the internal signals of the circuit to the unit cube (with the toolkit developed in [9]) needs some further operators, including /. For our optimisation problem to be in FIXP, we need the rather mild and realistic assumption that our instances are *non-degenerate* as defined in [23]. The function of which the fixed points define the recovery rates of non-degenerate instances is well defined, where the non-degeneracy is needed to avoid a division by 0. It turns out that non-degeneracy is incompatible with division being part of the FIXP operator basis, i.e., it seems difficult to build such a financial network that in any sense simulates a division of two signals in an algebraic circuit. To bypass this problem, our proof shows that it is possible to substitute / in the basis with the square root operator, $\sqrt{\cdot}$, whilst keeping the function well defined. This substitution can be used to simulate division with constant large powers of 2, and this turns out to be sufficient to omit the /-operator (i.e., arbitrary division). This novel observation might be useful for other problems where division is problematic to either define the fixed point function, or the reduction.

Our second result indirectly aims at characterising the "rational fragment" of FIXP: To the best of our knowledge this is the first study in this direction. A couple of observations can be drawn from our attempt. Firstly, our sufficiency conditions for irrationality suggest that any such characterisation needs to fully capture the connection between the fixed point condition and the rational root theorem; our proof currently exploits the cyclical structure of networks with "switched on" CDSes to define one particular quadratic equation with irrational roots. Whilst this captures a large class of instances, more work is needed to give a complete characterisation (see Section 6 for a discussion). Secondly, our sufficiency conditions for rational solutions highlight a potential issue with their representation. Due to the operations in the arithmetic basis, most notably multiplication, these solutions can grow exponentially large (even though each call to the PPAD oracle returns solutions of size polynomial in their input). This observation establishes a novel connection between the Blum-Shub-Smale computational model [5] (wherein the size to store any real number is assumed to be unitary and standard arithmetic operations are executed in one time unit), the rational part of FIXP, and PPAD. Our result paves way to further research on the subject.

Further Related Work. Systemic risk in financial networks has been studied extensively in the literature [3, 8, 13, 15, 16, 17, 6, 21, 19]. Game-theoretic perspectives of financial networks are studied in [4, 20]. Fixed point computations of total search problems, are studied in [9]. FIXP-complete problems are presented in [14, 10, 12, 11].

2 Model and Preliminaries

2.1 Financial Systems

Let $N = \{1, \ldots, n\}$ be a set of n banks. Each bank $i \in N$ has *external assets*, denoted by $e_i \in \mathbb{Q}_{\geq 0}$ and $e = (e_1, \ldots, e_n)$ is the external assets vector. We consider two types of liabilities among banks: *debt contracts* and *credit default swaps (CDSes)*. A debt contract requires one bank i (debtor) to pay another bank j (creditor) a certain amount $c_{i,j} \in \mathbb{Q}_{\geq 0}$. We denote by $\mathcal{DC}$ the set of all pairs of banks participating in a debt contract. A CDS requires a debtor i to pay a creditor j on condition that a third bank called the *reference bank* R is in default, meaning that R cannot fully pay its liabilities. Formally, we associate each bank i a variable $r_i \in [0, 1]$, called the *recovery rate*, that indicates the proportion of liabilities it can pay. Having $r_i = 1$, means bank i can fully pay its liabilities, while $r_i < 1$ indicates that i is in default. In case a reference bank R of a CDS is in default, the debtor i of that CDS pays the creditor j an amount of $(1 - r_R)c^R_{i,j}$, where $c^R_{i,j} \in \mathbb{Q}_{\geq 0}$ is the face value of the CDS. We denote by $\mathcal{CDS}$ the set of all triplets participating in a credit default swap. The value $c_{i,j}$ ($c^R_{i,j}$, resp.) of a debt contract (CDS, resp.) is referred to as the *notional* of the contract. Finally we let c be a three-dimensional $(n \times n \times n)$ matrix containing all contract notionals; we do not allow any bank to have a debt contract with itself, and assume that all three banks in any CDS are distinct.

▶ **Definition 1.** *A financial system is a triplet (N, e, c), where $N = \{1, .., n\}$ is a set of banks, $e = (e_1, .., e_n) \in \mathbb{Q}^n_{\geq 0}$ is the vector of external assets, and $c \in \mathbb{Q}^{n \times n \times n}_{\geq 0}$ is the three-dimensional matrix of all contract notionals.*

The *contract graph* of $I = (N, e, c)$ is defined as a directed multigraph $G_I = (V, A)$, where $V = N$ and $A = (\cup_{k \in N} A_k) \cup A_0$ where $A_0 = \{(i, j) \mid c_{i,j} \neq 0\}$ and $A_k = \{(i, j) \mid c^k_{i,j} \neq 0\}$. Each arc $(i, j) \in A_0$ is coloured blue and each $(i, j) \in A_k$ orange. For all $(i, j, R) \in \mathcal{CDS}$ we draw a dotted orange line from node R to arc $(i, j) \in A_R$, denoting that R is the reference bank of the CDS between i and j. Finally, we label each arc with the notional of the corresponding contract, and each node with the external assets of the corresponding bank.

Given a recovery rate vector $r \in [0, 1]^n$, we define the *liabilities*, *payments*, and *assets* in a financial system as follows. The liability of a bank $i \in N$ to a bank $j \in N$ under r is denoted by $l_{i,j}(r) = c_{i,j} + \sum_{k \in N}(1 - r_k)c^k_{i,j}$. That is, we sum up the liabilities from the debt contract and all CDS contracts between i and j. We denote by $l_i(r)$ the total liabilities of i: $l_i(r) = \sum_{j \in N} l_{i,j}(r)$. The payment bank i makes to bank j under r is denoted by $p_{i,j}(r)$, where $p_{i,j}(r) = r_i \cdot l_{i,j}(r)$. The assets of a bank i under r are the total amount it possesses through its external assets and incoming payments made all by other banks, i.e., $a_i(r) = e_i + \sum_{j \in N} p_{j,i}(r)$. Our research focuses on *clearing recovery rate vectors* (CRRVs).

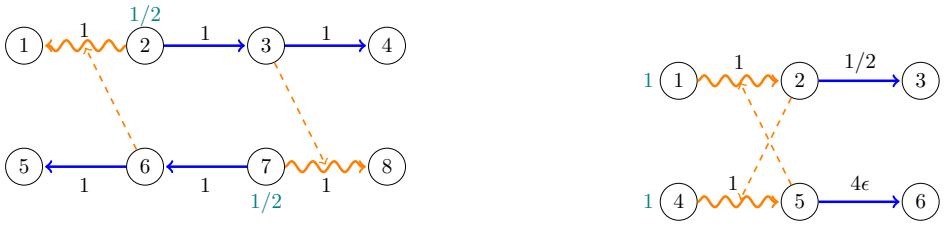
▶ **Definition 2.** *Given a financial system (N, e, c), a recovery rate vector r is called clearing if and only if for all banks $i \in N$, $r_i = \min\{1, a_i(r)/l_i(r)\}$, if $l_i(r) > 0$, and $r_i = 1$ if $l_i(r) = 0$.*

We set to 1 the recovery rate of nodes without liabilities, whereas [22] leaves these unconstrained. This is in line with the interpretation that these banks are not in default and only a cosmetic difference, as discussed in the full version of the paper [18].

We call CDS-CLEARING the problem of computing a CRRV in a given financial system with debt contracts and credit default swaps. For an instance $I \in$ CDS-CLEARING any clearing vector is a *solution* and the solution set is denoted by $\mathrm{Sol}(I)$. Let $I \in$ CDS-CLEARING and consider $f_I : [0, 1]^n \mapsto [0, 1]^n$ defined at each coordinate $i \in [n]$ by $f_I(r)_i = a_i(r)/(\max\{l_i(r), a_i(r)\})$. It is easy to see that $Sol(I)$ actually consists of the fixed point of function f_I. The existence of

at least one fixed point of f_I for every $I \in$ CDS-CLEARING was proved in [22]. Unfortunately, there exist instances of CDS-CLEARING in which all clearing vectors have irrational values, one example given in [23]. We present another example, to also illustrate our contract graphs.

▶ **Example.** *Figure 1a consists of eight banks,* $N = \{1, \ldots, 8\}$. *They all have external assets* 0 *except for banks* 2 *and* 7 ($e_j = 0$ *for* $j \neq 2, 7$, $e_2 = e_7 = 1/2$). *The set of debt contracts is* $\mathcal{DC} = \{(2,3), (3,4), (6,5), (7,6)\}$ *and the set of CDSes is* $\mathcal{CDS} = \{(2,1,6), (7,8,3)\}$. *All contract notionals are set to 1. For a recovery rate vector* r, *node 2's liability is* $l_2(r) =$



(a) CRRVs can be irrational. **(b)** Approximations of CRRVs.

Figure 1 On the left a financial system (a) with irrational solutions. On the right a financial system (b) where the weak approximate fixed point is far from the actual fixed point.

$l_{2,3}(r) + l_{2,1}(r) = c_{2,3} + (1 - r_6)c^6_{2,1} = 2 - r_6$. *For node 3, it holds* $l_3(r) = l_{3,4}(r) = c_{3,4} = 1$. *The assets of node 2 are* $a_2(r) = e_2 = 1/2$ *whereas* $a_3(r) = e_3 + p_{2,3}(r) = r_2 c_{2,3} = r_2$. *Symmetrically,* $l_7(r) = 2 - r_3, a_7(r) = 1/2$ *and* $l_6(r) = 1, a_6(r) = r_7$. *For node 1 it holds that* $a_1(r) = e_1 + p_{2,1}(r) = r_2(1 - r_6)c^6_{2,1}$ *and for node 8* $a_8(r) = r_7(1 - r_3)c^3_{7,8}$. *From the above computations and by applying the CRRV condition we get that any solution must satisfy:* $r_2 = \min\{1, 1/(2(2 - r_6))\}$, $r_6 = r_7$, $r_7 = \min\{1, 1/(2(2 - r_3))\}$, *and* $r_3 = r_2$, *implying that* $2r_2^2 - 4r_2 + 1 = 0$ *and then* $r_2 = r_3 = r_6 = r_7 = 1 - \sqrt{2}/2$ *and* $r_1 = r_5 = r_4 = r_8 = 1$.

2.2 Approximation and Complexity

Let F be a continuous function that maps a compact convex set to itself and let $\epsilon > 0$ be a small constant. A *weak ϵ-approximate fixed point* of F is a point x such that $\|x - F(x)\|_\infty < \epsilon$. A *strong ϵ-approximate fixed point* of F is a point x s.t $\exists x' : F(x') = x' \wedge \|x' - x\|_\infty < \epsilon$. Moreover, under a mild condition on the fixed point problem under consideration, known as *polynomial continuity*, a strong approximation is also a weak approximation [9], which explains the use of the terms "strong" and "weak".

Formally a *fixed point problem* Π is defined as a search problem such that for every instance $I \in \Pi$ there is an associated continuous function $F_I : D_I \to D_I$ where $D_I \subseteq \mathbb{R}^n$ (for some $n \in \mathbb{N}$) is compact and convex, such that the solutions of I are the fixed points of F_I. The problem Π is said to be *polynomially computable* if there is a polynomial q such that (i.) D_I is a convex polytope described by a set of at most $q(|I|)$ linear inequalities, each with coefficients of a size at most $q(|I|)$, and (ii.) For each x in $D_I \cap \mathbb{Q}^n$, the value $F_I(x)$ can be computed in time $q(|I| + \text{size}(x))$. Here, the "size" of a rational number means the number of bits needed to represent the numerator and the denominator in binary. Furthermore Π is said to be *polynomially continuous* if there is a polynomial q such that for each $I \in \Pi$, and rational $\epsilon > 0$, there is a rational δ of size $q(|I| + \text{size}(\epsilon))$ satisfying the following: for all $x, y \in D_I$ with $\|x - y\|_\infty < \delta$ it holds that $\|F_I(x) - F_I(y)\|_\infty < \epsilon$.

With regard to CDS-CLEARING, it is straightforward to verify that CDS-CLEARING is polynomially computable. Furthermore, [23] establishes implicitly that CDS-CLEARING is polynomially continuous under a (very) mild assumption that the authors call *non-degeneracy*.

▶ **Definition 3.** *A financial system is* non-degenerate *if and only if the following two conditions hold. Every debtor in a CDS either has positive external assets or is the debtor in at least one debt contract with a positive notional. Every bank that acts as a reference bank in some CDS is the debtor of at least one debt contract with a positive notional.*

We define CDS-CLEARING to contain only non-degenerate financial networks, both for the sake of compatibility with [23] and for the analytical convenience that non-degeneracy provides us (note that a division by 0 never occurs in $f_I(r)_i$ for these instances). In [23], it is also shown that the weak approximation version of CDS-CLEARING is PPAD-hard. The polynomial continuity of CDS-CLEARING shows that the strong approximation version of CDS-CLEARING is at least as hard as its weak approximation version. As noted above, weakly approximate fixed points may contain misleading information about whether a bank is in default or not, as shown in the next example. This motivates the study of strong approximations.

▶ **Example.** *Consider the instance in Figure 1b. It is not hard to see that* $r = (1, 1, 1, 1, 0, 1)$ *is an exact fixed point;* $r' = (1, 1 - 2\epsilon, 1, 1, 1/2 + \epsilon, 1)$ *is instead a weakly* ϵ*-approximate fixed point since* $f_2(r') = 1 - 2\epsilon$ *and* $f_5(r') = 1/2$ *implying that* $\|r' - f(r')\|_\infty \leq \epsilon$*. We observe that* r *is very far from* r' *and, in particular, as* $r'_2 = 1 - 2\epsilon < 1$*, we would conclude that 2 is in default whereas 2 can actually fully pay its liabilities since* $r_2 = 1$*.*

FIXP is the complexity class introduced to study the strong approximation and exact versions of fixed point problems [9].

▶ **Definition 4.** *The class FIXP consists of all fixed point problems* Π *that are polynomially computable, and for which for all* $I \in \Pi$ *the function* $F_I : D_I \to D_I$ *can be represented by an algebraic circuit* C_I *over the basis* $\{+, -, *, \max, \min\}$*, using rational constants, such that* C_I *computes* F_I*, and* C_I *can be constructed from* I *in time polynomial in* $|I|$*.*

The class FIXP_a *is defined as the class of search problems that are the strong approximation version of some fixed point problem that belongs to FIXP.*

The class Linear-FIXP is defined analogously to FIXP, but under the smaller arithmetic basis where only the gates $\{+, -\max, \min\}$ *and multiplication by rational constants are used.*

The classes FIXP, Linear-FIXP, and FIXP_a admit complete problems. Hardness of a search problem Π for FIXP (resp. Linear-FIXP and FIXP_a) is defined through the existence of a polynomial time computable function $\rho : \Pi' \to \Pi$, for all $\Pi \in$ FIXP (resp. FIXP_a), such that the solutions of I can be obtained from the solutions of $\rho(I)$ by applying a (polynomial-time computable) linear transformation on a subset of $\rho(I)$'s coordinates. This type of reduction is known as a *polynomial time SL-reduction*.

It is known that $\mathsf{FIXP}_a \subseteq$ PSPACE and Linear-FIXP = PPAD [9]. Consequently, the solutions of instances in Linear-FIXP are always rationals of polynomial size. An informal understanding of how the hardness of FIXP compares to PPAD (or Linear-FIXP) is as follows. PPAD captures a type of computational hardness stemming from an essentially combinatorial source. The class FIXP introduces on top of that a type of numerical hardness that emerges from the introduction of multiplication and division operations: These operations give rise to irrationality in the exact solutions to these problems, and may independently also require the computation of rational numbers of very high precision or very high magnitude.

3 FIXP-Completeness of CDS-Clearing

Our first main result shows that CDS-CLEARING and its strong approximation variant are $\mathsf{FIXP}_{(a)}$ complete. We show that we can take an arbitrary algebraic circuit and encode it in a direct way in the form of a financial system. Hence, our polynomial time hardness

reduction is implicitly defined to work from to any arbitrary fixed point problem in FIXP. The reduction is constructed by devising various financial network gadgets which enforce that certain banks in the system have recovery rates that are the result of applying one of the operators in FIXP's arithmetic base to the recovery rates of two other banks in the system: In other words, we can design our financial systems such that the interrelation between the recovery rates mimics a computation through an arbitrary algebraic circuit.

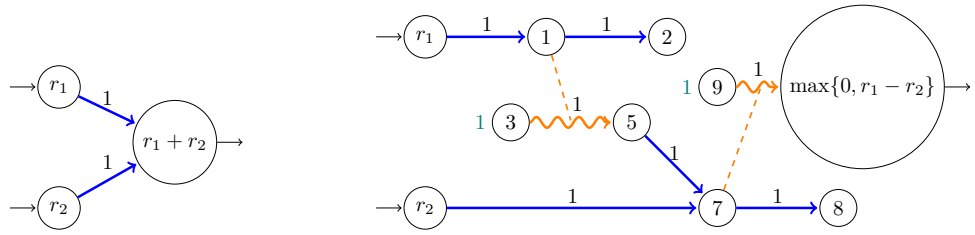
▶ **Theorem 5.** *CDS-CLEARING is FIXP-complete, and its strong approximation version is FIXP_a-complete.*

Proof Sketch. The clearing vectors for an instance $I \in$ CDS-CLEARING are the fixed points of the function f_I defined above, which can be computed using a polynomial size algebraic circuit with only $\{\max, +, *\}$, and rational constants. Note that non-degeneracy of I prevents division by 0, so that the output of the circuit is well-defined for every $x \in [0,1]^n$. This shows that CDS-CLEARING is in FIXP and that its strong approximation version is in FIXP_a.

For the FIXP-hardness of the problem, let Π be an arbitrary problem in FIXP. We describe a polynomial-time reduction from Π to CDS-CLEARING. Let $I \in \Pi$ be an instance, let $F_I : [0,1]^n \to [0,1]^n$ be I's associated fixed point function, and let C_I be the algebraic circuit corresponding to F_I. As a pre-processing step, we convert C_I to an equivalent alternative circuit C'_I that satisfies that all the signals propagated by all gates in C'_I and all the used rational constants in C'_I are contained in the interval $[0,1]$. The transformed circuit C'_I may contain two additional type of gates: Division gates and gates that computes the absolute value of the difference of two operands. We will refer to the latter type of gate as an *absolute difference gate*. The circuit C'_I will not contain any subtraction gates, and will not contain max and min gates either. The transformation procedure for C_I follows the same approach of the transformation given in Theorem 4.3 of [9] where the 3-Player Nash equilibrium problem is proved FIXP-complete, and borrows some important ideas from there. Nonetheless, there are important differences in our transformation, starting with the fact that we use a different set of types of gates in our circuit. (Details can be found in the full proof in [18].)

For notational convenience, in the remainder of the proof we may treat C'_I as the function F_I, hence we may write $C'_I(x) = y$ to denote $F_I(x) = y$. Let ρ denote the reduction to CDS-CLEARING: We construct our instance $\rho(I)$ of CDS-CLEARING (i.e., a non-degenerate financial network) from the circuit C'_I. The instance $\rho(I)$ will have the property that its clearing vectors are in one-to-one correspondence with the fixed points of C'_I, and that banks $1, \ldots, n$ in our construction correspond to the input gates of C'_I. More precisely, our construction is such that for each fixed point x of C'_I, in the corresponding clearing vector r for $\rho(I)$ it holds that $(r_1, \ldots, r_n) = x$. Our reduction works through a set of financial system *gadgets*, of which we prove that their recovery rates (under the clearing condition) must replicate the behaviour of each type of arithmetic operation that can occur in the circuit C'_I. Each of our gadgets is non-degenerate, has one or two *input banks* that correspond to the input signals of one of the types of arithmetic gate, and there is an *output bank* that corresponds to the output signal of the gate. For each of the gadgets, it holds that the output bank must have a recovery rate that equals the result of applying the respective arithmetic operation on the recovery rates of the input banks, see examples in Figure **??** ($g_{\text{pos}-}$ is a building block for the absolute difference gadget). Besides gadgets for the necessary arithmetic operations, our reduction employs an additional *duplication gadget* g_{dup} that can be used to connect the output of a particular gadget to the input of more than one subsequent gadget. A technically involved step is needed for the division gates; we replace some of the divisions in the circuit C'_I by taking successive square-roots followed by successive squaring operations, where proper

care has to be taken to ensure that the results of all these operations stay within the interval $[0, 1]$. Full definitions of our gadgets (including gadgets for squares and square roots) can be found in [18].



(a) Addition gadget g_+. **(b)** Positive subtraction gadget $g_{\text{pos}-}$ computes $\max\{0, r_1 - r_2\}$.

Figure 2 Exemplar gadgets from our reduction ρ.

In our financial system, these gadgets are then connected together according to the structure of the circuit C'_I: Output banks of (copies of) gadgets are connected to input banks of other gadgets through a single unit-cost debt contract, which mimics the propagation of a signal between two gates of the arithmetic circuit. This results in a financial system whose behaviour replicates the behaviour of the arithmetic circuit. The first layer of the financial system consists of n banks representing the n input nodes of the circuit, and the last layer of the financial system has n banks corresponding to the n output nodes of the circuit. As a final step in our reduction, the n output banks in the last layer are connected through a single unit-cost debt contract to the n input banks. This last step enforces the recovery rates of the input banks (i.e., banks $1, \ldots, n$) are equal to the recovery rates of the last layer, under the clearing requirement. Consequently, any vector of clearing recovery rates for $\rho(I)$ must then correspond to a fixed point of C'_I, where the recovery rates of the first n banks in the system equal those of the final n banks, so that $C'_I(r_1, \ldots, r_n) = (r_1, \ldots, r_n)$, i.e., $(r_1, \ldots, r_n)$ is a fixed point of C'_I. It is clear that $\rho(I)$ can be constructed in polynomial time from C'_I, and since C'_I can be constructed in polynomial time from I, the financial system $\rho(I)$ takes polynomial time to compute.

FIXP$_a$-completeness of strong approximations holds since any strong ϵ-approximation of the CRRV of $\rho(I)$ corresponds to a strong ϵ-approximate fixed point of C'_I. ◀

4 A Sufficient Structural Condition for Irrational Solutions

In this section we investigate the existence of irrational solutions in financial systems in more depth. Our starting point is the observation that irrational clearing recovery rates can only arise under certain structural conditions on the financial system (e.g., a system with no CDSes has a rational CRRV [7]). Which structural conditions must exactly hold in a financial system for irrational clearing vectors to potentially exist? In this section, we present a set of sufficient structural conditions that provides a partial answer to this question.

4.1 Switched Cycles

We define the *auxiliary graph* $G_{I,\text{aux}}$ of $I = (N, e, c)$ to be a tricoloured directed graph obtained from G_I by adding a red-coloured arc (R, i) for every $(i, j, R) \in \mathcal{CDS}$. The auxiliary graph corresponding to the instance in Figure 1b is given in Figure 3. We say that an instance I is *acyclic* if and only if its $G_{I,\text{aux}}$ contains no directed cycle. It is not hard to see that every acyclic financial system has only rational solutions. (We defer the proof to the full version [18].)

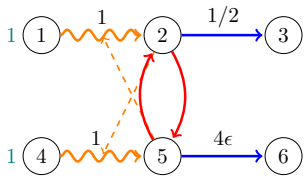


Figure 3 The auxiliary graph for the instance in Figure 1b.

We say that a node $i \in N$ is *switched off* iff it has only one incoming red arc and no outgoing blue arcs. A node $i \in N$ is *switched on* iff its incoming red arcs exceeds 1 or its incoming red arcs equals 1 and there is at least one outgoing blue arc. Note that switched on and switched off nodes are not complements of each other. A node that is not a debtor in any CDS is neither switched on nor switched off. These notions are illustrated in Figure 4.

▶ **Definition 6** (Switched Cycles). *A cycle is* red *iff it has at least one red arc. A cycle is* weakly switched *iff it is red, and for at least one red arc* (u, v) *in* C*,* v *is switched on. A cycle is* strongly switched *iff it is red, and for each red arc* (u, v) *in* C*,* v *is switched on.*

We will prove that when a non-degenerate financial system I has a strongly switched cycle (and a certain additional technical condition holds), there exist coefficients for the financial system under which all CRRVs of I are irrational. Our proof introduces a framework for formulating strongly switched cycles and consists of three main steps. Firstly, we define a set of primitive financial systems without notionals and external assets, called *fragments*. Each of these fragments has a designated start and end node. A binary concatenation operation is also introduced so to obtain financial systems that are obtainable by "stringing" together fragments. We refer to graphs obtainable through this operation as *fragment strings* or *cycles* (when the end node is linked back to the initial start node). Secondly, we equip each fragment with particular choices of rational coefficients to define *arithmetic fragments*; these allow to conveniently rewrite fragment strings, given that the objective is to preserve recovery rates at the end nodes. We prove that each of the resulting arithmetic fragment cycles has irrational CRRVs. Finally, we show that a particular class of strongly switched cycles are constructible from these fragments and for each instance I with these cycles there exist rational coefficients also for nodes and arcs not in the cycle such that all the CRRVs of I are irrational.

4.2 Fragments

We denote by $\mathcal{G}$ the set of all fragments that we will use. Few representatives of $\mathcal{G}$ are defined in Figure 5 (left), presented in our tricoloured graphical notation. Start and end nodes are indicated by short incoming and outgoing black arrows, respectively. The full description of

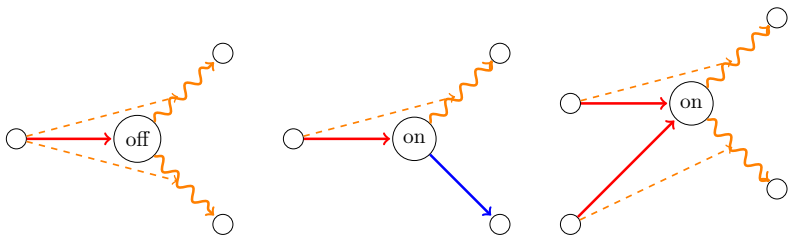

Figure 4 One switched off and two switched on nodes.

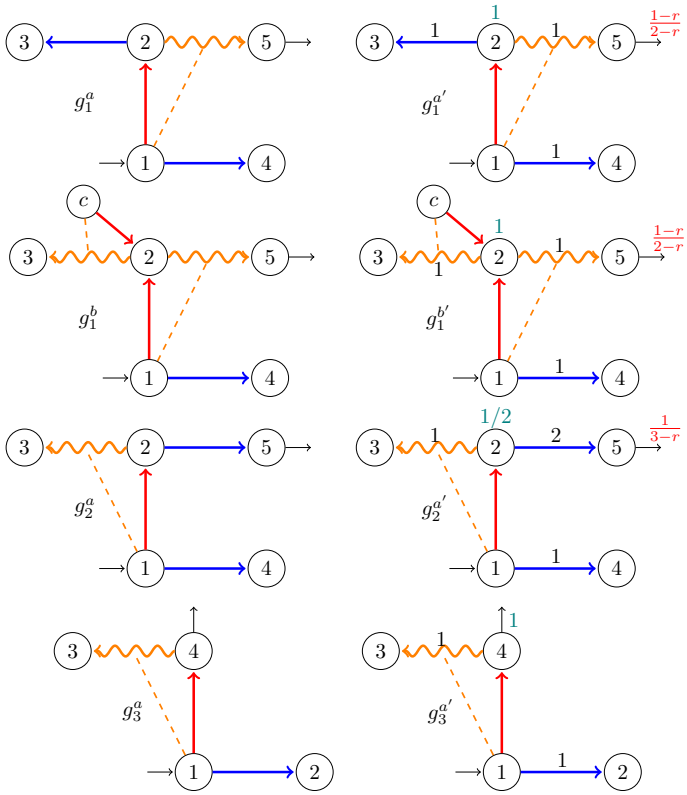

Figure 5 Some fragments in $\mathcal{G}$ (left) with their arithmetic version (right). Each fragment is labeled with its name.

$\mathcal{G}$ can be found in the full paper [18]; the additional fragments are either variants of those shown here (substituting direct liabilities with CDSes as in g_1^b vis-a-vis g_1^a) – called g_i^j, with $j \in \{a, b, c, d\}$ when $i \in [2]$ and $j \in \{a, b\}$ for $i = 3$ – or simpler configurations that just copy the recovery rate from start to end node, called d_1 and d_2.

We define a binary merging operation on ordered pairs of fragments (a, b), where every pair (a, b) is mapped to a graph obtained by taking disjoint copies of a and b, and connecting the two copies together by identifying the end node of a with the start node of b. The new start node and end node of the resulting system is the start node of the copy of a and the end node of the copy of b, respectively. We denote the result of the merge operation on fragments a and b symbolically by the notation ab. A *fragment string* is a fragment obtainable from fragments in $\mathcal{G}$ using any number of sequential applications of the merge operation. We let $\mathcal{GS}$ be the set of fragment strings (i.e., the closure of $\mathcal{G}$ under the *merge* operation). By identifying the start node with the end node of a fragment string we obtain a *fragment cycle*. The induced fragment cycle is denoted $\dot{x}g_s\dot{x}$, where $x \in \mathcal{G}$ and $g_s \in \mathcal{GS}$. Let $\mathcal{GC}$ to be the set of fragment cycles.

A fragment with fixed coefficients is called an *arithmetic fragment*, see Figure 5 (right) where we omit to show 0 external assets for some nodes. We denote by x' or x'' the arithmetic version of $x \in \mathcal{G}$. The difference between x' and x'' are minimal; for the fragments in Figure 5, the only difference between x' and x'' is that the notional for the bottom right liability (e.g., arc from node 1 to node 4 in g_1^a) is valued 2 rather than 1. The red labels at the end of an arithmetic fragment indicate the assets of the end node under any clearing vector as a

function of the recovery rate r of the start node. Importantly, both x' and x'' have the same recovery rate at the end node. The *merge* operation and notation used for fragments apply to arithmetic fragments as well. The following observation can be derived by inspection.

▶ **Observation 7.** *Let x'_1 and x'_2 be any two consecutive arithmetic fragments in a string or cycle C of arithmetic fragments. Let r be the recovery rate of the start node of x'_1 under a clearing vector of C. It holds that:*

- *If $x'_1 \in \{g_i^{j'}, g_i^{j''} : i \in [2], j \in \{a,b,c,d\}\}$ and $x'_2 \in \{g_i^{j'} : i \in [2], j \in \{a,b,c,d\}\} \cup \{d'_1, d'_2\}$, then the recovery rate of the end node of x'_1, is $(1-r)/(2-r)$ or $1/(3-r)$.*
- *If $x'_1 \in \{g_3^{j'}, g_3^{j''} : j \in \{a,b\}\}$ and $x'_2 \in \{g_i^{j''} : i \in [3], j \in \{a,b,c,d\}\}$, then the recovery rate of the end node of x'_1 is $1/(3-r)$.*

We now give a notion of equivalence between arithmetic fragment strings.

▶ **Definition 8.** *Let x_s^1, x_s^2 be two arithmetic fragment strings. We say that x_s^1 and x_s^2 are* equivalent *iff the recovery rate of the end node of x_s^1 equals the recovery rate of the end node of x_s^2 for all possible choices $r \in [0,1]$ of the recovery rate of the input nodes of x_1^s and x_2^s.*

Equivalence enables us to simplify big fragment string and cycles to simpler ones while preserving the recovery rate of the end node. This is achieved by a set of rewriting rules.

Rule 0: Replace an occurrence of a fragment $g_i^{j'}$ ($g_i^{j''}$, respectively), where $i \in [3]$ and $j \in \{a,b,c,d\}$, with the fragment $g_i^{a'}$ ($g_i^{a''}$, respectively).

Rule 1: Replace an occurrence of a fragment $g_2^{a'}$ (respectively $g_2^{a''}$) by $g_1^{a'} g_1^{a'}$ respectively $g_1^{a''} g_1^{a'}$ if the fragment $g_2^{a'}$ (or respectively $g_2^{a''}$) is followed by one of the fragments in $\{g_1^{a'}, g_2^{a'}, g_3^{a'}, d'_1, d'_2\}$.

Rule 2: Replace an occurrence of a consecutive pair of fragments $g'_3 g_i^{a''}$, where $g'_3 \in \{g_3^{a'}, g_3^{a''}\}$, and $i \in [3]$, by the fragments $g_2^{a'} g_i^{a'}$. By Observation 7, the recovery rates of the end nodes of g'_3 and $g_2^{a'}$ are identical under this substitution, under any clearing vector, so that the two fragment strings are equivalent.

Rule 3: Remove an occurrence of d'_1 or d'_2. This substitution is straightforward from the fact that both d'_1 and d'_2 just transfer the recovery rate from the start to the end node.

4.3 Irrationality of Strongly Switched Cycles

Consider any instance $I = (N, e, c)$ with auxiliary graph $G_{I,\text{aux}}$. If I has a strongly switched cycle, then this cycle is composed entirely of the fragments in $\mathcal{G}$. This is formalised as follows.

▶ **Definition 9.** *Let G' be a fragment cycle, and let C' be the unique directed cycle in G'. The fragment cycle G' is said to* agree with a cycle C of $G_{I,\text{aux}}$ *iff there is a mapping $\xi : V(G') \to V(G_{I,aux})$ with the following properties:*

- *For all $(v,w) \in E(G')$, $(\xi(v), \xi(w))$ is in $E(G_{I,aux})$ and has the same color as (v,w).*
- *ξ restricted to the domain $V(C')$ defines a bijection between $V(C')$ and $V(C)$.*
- *For each CDS (i,j,R) in G', $(\xi(i), \xi(j), \xi(R))$ is a CDS of G.*

Note that the above points imply that ξ restricted to $V(C')$ defines an arc-color-preserving isomorphism between C' and C. However, this isomorphism does not necessarily extend to node sets larger than C': nodes in $V(G') \setminus V(C')$ may be mapped by ξ to the same vertex of $G_{I,aux}$. We then define the fragment cycle $G' = G'_n \cup G'_l$ to simply *agree with a cycle C of $G_{I,aux}$, if G' agrees with C of $G_{I,aux}$ through a mapping ξ for which it additionally holds that*

- *all nodes outside C' are mapped to vertices outside C,*
- *For every pair of nodes $\{u,v\} \subseteq V(G')$, where $v \in G'_n$ and $u \in G'_l$, $\xi(u) \neq \xi(v)$, and*
- *for every node $u \in G'_l$, $\xi(u)$ has an outgoing arc pointing towards a node not in C',*

where G'_n is the set of nodes in the fragment cycle G' labelled with a number (as $1, \ldots, 5$ in Figure 5) and G'_l is the set of fragment nodes labelled with a letter (as c in Figure 5).

The notion of *simple* agreement informally requires that the neighbouring nodes of C' are sufficiently "independent" from each other and from the cycle C, under the mapping ξ. This brings us to the definition of a *simple* strongly switched cycle (which makes precise our condition on off-cycle paths between the nodes in the cycles in the informal statement of our second main theorem in the introduction).

▶ **Definition 10.** *A cycle C of $G_{I,aux}$ is a* simple *strongly switched cycle iff C is strongly switched, and for each red arc (u, v) of C there are non-red arcs (u, u') and (v, v') such that $u', v' \notin C$. Furthermore, if (u, u') or (v, v') is orange, then the reference bank R of the corresponding CDS is not in C and R has an outgoing non-red arc pointing to a node not in C.*

The fragments in $\mathcal{G}$, can represent any strongly switched cycle: If $G_{I,\text{aux}}$ has a strongly switched cycle C, then there is a fragment cycle G' consisting of fragments in $\mathcal{G}$ s.t G' agrees with C of $G_{I,\text{aux}}$. Similarly, if $G_{I,\text{aux}}$ has a simple strongly switched cycle C, then there is a fragment cycle G' consisting of fragments in $\mathcal{G}$ s.t G' simply agrees with C of $G_{I,\text{aux}}$. All switched on nodes of C correspond to the 2-labeled nodes of a g_2^j or g_1^j fragment, for some $j \in \{a, b, c, d\}$. The next lemmas show that we can set the coefficients in any strongly switched fragment cycle s.t the fragment cycle admits only irrational clearing recovery rates.

▶ **Lemma 11.** *For all fragment cycles $C \in \mathcal{GC}$ consisting of only fragments in $\{g_1^j : j \in \{a, b, c, d\}\}$, there exist coefficients s.t. the clearing recovery rate vector of C is irrational.*

Proof Sketch. Consider a fragment cycle consisting exclusively of only fragments in $\{g_1^j : j \in \{a, b, c, d\}\}$. For all $j \in \{a, b, c, d\}$, fix the coefficients of all g_1^j fragments in the cycle to obtain the arithmetic version $g_1^{j'}$. Use rewriting Rule 0 to replace all $g_1^{j'}$ occurrences by $g_1^{a'}$. The resulting arithmetic fragment cycle consists of a number of consecutive copies of $g_1^{a'}$, say k of them. Consider now any clearing vector r for the fragment cycle. We can prove by induction (details in the full paper [18]) that the end node of the ith fragment has recovery rate equal to $(f_i - rf_{i-2})/(f_{i+2} - rf_i)$, where f_i is the ith Fibonacci number, with $f_0 = 0$.

We know that the end node of the last fragment in the fragment cycle has a recovery rate that coincides with the recovery rate r of the start node of the first fragment. Therefore, in a clearing vector of recovery rates, it holds that $r = (f_n - rf_{k-2})/(f_{k+2} - rf_k)$ which is equivalent to solving the equation $r^2 f_k - (f_{k+2} + f_{k-2})r + f_k = 0$. Since $f_{k+2} + f_{k-2} = f_{k+1} + f_k + f_{k-2} = 2f_k + f_{k-1} + f_{k-2} = 3f_k$, computing the recovery rate of the initial node 1 comes down to solving the quadratic equation $r^2 - 3r + 1 = 0$. Solving this equation we obtain that the only solution in $[0, 1]$ is $r = (3 - \sqrt{5})/2$ which is irrational, thus the CRRV of the strongly switched arithmetic fragment cycle is irrational and is unique. ◀

The next lemma (proof omitted) extends the above to a larger class of arithmetic fragments.

▶ **Lemma 12.** *For all fragment cycles composed of fragments $\mathcal{G}$ in which every occurrence of a fragment in $\{g_3^j : j \in \{a, b\}\}$ is followed by a fragment in $\{g_i^j : i \in [2], j \in \{a, b, c, d\}\}$, there exist coefficients s.t the clearing recovery rate vector of C is irrational.*

▶ **Theorem 13.** *Let I be a non-degenerate financial system such that $G_{I,aux}$ has a simple strongly switched cycle. Then there exist rational coefficients for I such that all clearing vectors of I are irrational.*

Proof Sketch. Let C be a strongly switched cycle of $G_{I,\text{aux}}$ and let G' be a fragment cycle that simply agrees with C through a mapping ξ satisfying the conditions stated in Definition 9. By Lemma 12, there are coefficients for G' such that all clearing vectors of G' are irrational.

In $G_{I,\text{aux}}$, we can now set the notionals and external assets on the vertices and arcs through the mapping ξ. This assignment of coefficients is well-defined by the properties of ξ stated in Definition 9 (i.e., there are no two arcs or vertices that get assigned multiple conflicting coefficients this way). We set the remaining coefficients of $G_{I,\text{aux}}$ (i.e., the coefficients on the arcs and vertices outside the image of ξ) as follows: external assets to 0; notionals of (v, w) to 1, if $\xi^{-1}(v)$ is a node labeled with a letter, and w is not in the image of ξ, or 0 viceversa.

Let G'' denote the subgraph of G formed by the image of ξ. Note that no payments flow from G'' to any node outside G'' under any clearing vector. It then follows by Lemma 12 and the simple agreement properties, that under this setting of the coefficient of $G_{I,\text{aux}}$, every clearing vector is irrational (and in particular these irrational recovery rates emerge in the nodes of G''). This establishes our claim. ◀

5 Financial Systems with Guaranteed Rational Solutions

In the previous section, we identified a sufficient structural condition for the ability of a financial system to have irrational clearing vectors. In this section we investigate how close these conditions are to a characterisation, by attempting to answer the opposite question: Under which structural conditions are rational clearing vectors guaranteed to exist in a financial system? The answer to this relates again to the notion of switched cycles: We will show that if a given non-degenerate financial system does not possess any weakly switched cycle, then there must exist clearing vectors of the system that are rational. We investigate furthermore the computational complexity of finding a clearing vector in this case: Solutions can, informally stated, be computed by solving a linear number of PPAD-complete problems. This latter result is achieved through identifying a natural class of financial systems for which the problem of computing an exact fixed point is PPAD-complete.

The results in this section indicate that the structural conditions for irrationality formulated in the previous section do close in on a characterisation, although there is still a "gray area" left: For those instances of financial systems that do have weakly switched cycles, but do not have any simple strongly switched cycles, we are not yet able to determine by the structural interrelationships of the financial contracts whether these systems are likely to possess rational or irrational solutions. This forms an interesting remaining problem that we leave open. The main result we will prove in this section is thus the following.

▶ **Theorem 14.** *Let I be a non-degenerate financial system. If $G_{I,aux}$ does not have any weakly switched cycles, then all clearing vectors of I are rational.*

We start by showing that for a particular subclass of financial systems without weakly switched cycles, the clearing vector computation problem lies in Linear-FIXP, which is equal to PPAD, and thus the clearing vectors of such financial system must have polynomial size rational coefficients.

▶ **Definition 15.** *An instance $I = (N, e, c)$ of a financial system is said to have the* dedicated CDS debtor property *iff for every node $i \in N$ that is a debtor of at least one CDS of I, the following holds: There are no debt contracts (with a non-zero notional) in which i is the debtor, and all CDSes (with a non-zero notional) for which i is the debtor share the same reference bank.*

▶ **Lemma 16.** *(The exact computation version of)* CDS-CLEARING *restricted to non-degenerate financial systems with the dedicated CDS debtor property is PPAD-complete.*

The proof, which is omitted, works by showing that for this special case of the problem, one can rewrite function f into a function f' where multiplication is omitted. This is done by disregarding the recovery rates of those nodes that are debtors of CDSes and instead expressing their individual CDS payments in a way that does not require multiplication. Furthermore, the remaining nodes do not need multiplication under our original formulation of f. Secondly, PPAD-hardness is established from minor modifications of the proof of the main theorem in [23].

The above PPAD-completeness result (and more precisely the PPAD-membership part of the result), shows that non-degenerate instances with the dedicated CDS debtor property must have polynomial size rational solutions. We use this fact to prove Theorem 14.

Proof sketch of Theorem 14. Consider the graph D that has as its nodes the strongly connected components (SCCs) of $G_{I,\text{aux}}$, and has an arc from a node S to a node T if and only if there exists an arc in $G_{I,\text{aux}}$ that runs from a node in S to a node in T. It is clear that D is a directed acyclic graph.

We may show that we can find a rational clearing vector for $G_{I,\text{aux}}$ by finding rational clearing vectors of the separate SCCs of the system. However, both the assets and the liabilities of the nodes in a given SCC might depend on the contracts from outside the SCC that point into the SCC. Similarly, the liabilities of the nodes in the SCC might depend on arcs pointing from the SCC to external nodes. We may overcome this problem by including the outward-pointing arcs of an SCC into the subinstances that we aim to solve for, and by iterating over the SCCs according to the topological order of D: That is, we first find clearing vectors to the set $\mathcal{S}_1$ of SCCs that have no incoming arc in D. For such SCCs, the assets and liabilities of the nodes are not influenced by external arcs pointing into the SCC. We subsequently find clearing rates for the set of SCCs $\mathcal{S}_2$ that succeed $\mathcal{S}_1$ in the topological order defined by D. In general, we define $\mathcal{S}_j$ inductively as the set of SCCs that directly succeed $\mathcal{S}_{j-1}$ in the topological order defined by D, and we iteratively find clearing rates to the set of SCCs $\mathcal{S}_j$, given the clearing rates computed for $\mathcal{S}_1, \ldots, \mathcal{S}_{j-1}$, until we have obtained a clearing vector covering all nodes in the system. A crucial observation that motivates this approach is that the absence of any weakly switched cycle of $G_{I,\text{aux}}$ causes all SCCs to satisfy the dedicated CDS debtor property, and that therefore the clearing vector computation problem considered in each iteration lies in PPAD. At each iteration, we are thus guaranteed that there are rational recovery rates, and finding them requires solving a PPAD-complete problem. However, there are quite a few details required to turn the above ideas into a rigorous proof, and we defer these to the full version of this paper [18]. ◀

The procedure outlined in the proof of Theorem 14 requires solving a PPAD-complete problem in each iteration, and the number of such iterations is at most linear in the instance size. Since solving each of these problems in PPAD yields a rational solution of size polynomial in the input, one might be tempted to think that the procedure in its entirety is capable of finding a polynomial size rational solution for any financial system that has no weakly switched cycles. Unfortunately, the latter is not true: Observe that in each iteration of the procedure, the PPAD-complete problem instance that is solved, is actually constructed using the rational recovery rate vectors that are computed in the preceding iterations. The coefficients in the PPAD-complete problem instance that is to be solved in any given iteration, are thus polynomially sized in the output recovery rates of the previous iteration. Altogether, this means that the coefficient sizes potentially grow by a polynomial factor in each iteration, and that the final recovery rates output by the procedure are potentially of exponential size.

Indeed, there are examples of financial systems without weakly switched cycles for which the rational clearing vector has recovery rates that require an exponential number of bits to write down. A simple example is obtained by taking some of the gadgets in the reduction used in our FIXP-completeness result (Theorem 5). By taking a duplication gadget followed by a multiplication gadget that is connected to the two output nodes of the duplication gadget. We may then take multiple copies of these, and chain them together to form an acyclic financial system. If we now give the first node in the chain (i.e., the input node of the first duplication gadget) some small amount of positive external assets $c < 1$, this acyclic financial system essentially performs a sequence of successive squaring operations on the number c, under the unique clearing vector. The resulting recovery rates on the output nodes of the multiplication gadgets are then doubly exponentially small in magnitude, with respect to the number of squaring repetitions. Thus, the resulting clearing recovery rates require a number of bits that is exponential in the size of the financial system.

If one is willing to discard the complexity issues that arise from working with large-size rational numbers, it is possible to study the procedure in the proof of Theorem 14 in the Blum-Shub-Smale model of computation. Under this computational model, any real number takes one unit of space to store, regardless of its size. Moreover, standard arithmetic operations are assumed to take unit time.[1] The proof of Theorem 14 then implies that when one has oracle access to PPAD, it is possible to find rational clearing vectors in polynomial time under this model of computation. The class of problems polynomial time solvable under the Blum-Shub-Smale model is commonly denoted by $\mathsf{P}_{\mathbb{R}}$. Hence, we obtain the following corollary.

▶ **Corollary 17.** *The exact computation version of* CDS-CLEARING*, restricted to instances without weakly switched cycles, is in the complexity class* $P_{\mathbb{R}}^{PPAD}$.

6 Conclusions

In this paper we study two questions of significance related to the systemic risk in financial networks with CDSes, a widely used and potentially disruptive class of financial derivatives. Firstly, we settle the computational complexity of computing strong approximations of each bank's exposure to systemic risk, arguably the right notion of approximation of interest to industry – a conceptual point so far overlooked in the literature. We show that this problem is FIXP-complete. Secondly, we initiate the study of the rational fragment of FIXP by studying the conditions under which rational solutions for CDS-CLEARING exist. Our results here are not conclusive in that there is a gap between our necessary and sufficient conditions, the cycles which involve both switched on and switched off nodes being not fully understood. [2] We conjecture that for any network with a weakly switched cycle there exist rational values for assets and liabilities that lead to irrational solutions; however, our arguments and scheme cannot be easily generalised to those instances. We leave providing a full characterisation as an open problem.

Further research directions are suggested by our work. It would be interesting to study whether Corollary 17's connection between CDS-CLEARING, PPAD, and $\mathsf{P}_{\mathbb{R}}$ (i.e. polynomial time under the Blum-Shub-Smale model of computation [5]) holds more generally for the entire rational subset of problems in FIXP. Furthermore, it is interesting to pursue finding

[1] For a formal and more accurate definition of the Blum-Shub-Smale model, see the book [5].
[2] We regard the *simplicity* condition we made (i.e., about off-cycle paths between cycle nodes) as a technicality, which is less interesting and likely somewhat easier to deal with.

polynomial-time *constant* approximation algorithms of clearing recovery rate vectors: Also from an applied point of view, achieving a good approximation factor here (say with an additive approximation term of 1/100) might yield solutions that are useful in most practical circumstances and could be considered acceptable by financial institutions. We note here that a 1/2-strong approximation is easy to compute (a recovery rate vector of only 1/2s would indeed suffice).

Abstract

Box-simplex games are a family of bilinear minimax objectives which encapsulate graph-structured problems such as maximum flow [41], optimal transport [29], and bipartite matching [5]. We develop efficient near-linear time, high-accuracy solvers for regularized variants of these games. Beyond the immediate applications of such solvers for computing Sinkhorn distances, a prominent tool in machine learning, we show that these solvers can be used to obtain improved running times for maintaining a (fractional) ϵ-approximate maximum matching in a dynamic decremental bipartite graph against an adaptive adversary. We give a generic framework which reduces this dynamic matching problem to solving regularized graph-structured optimization problems to high accuracy. Through our reduction framework, our regularized box-simplex game solver implies a new algorithm for dynamic decremental bipartite matching in total time $\widetilde{O}(m \cdot \epsilon^{-3})$, from an initial graph with m edges and n nodes. We further show how to use recent advances in flow optimization [11] to improve our runtime to $m^{1+o(1)} \cdot \epsilon^{-2}$, thereby demonstrating the versatility of our reduction-based approach. These results improve upon the previous best runtime of $\widetilde{O}(m \cdot \epsilon^{-4})$ [6] and illustrate the utility of using regularized optimization problem solvers for designing dynamic algorithms.

1 Introduction

Efficient approximate solvers for graph-structured convex programming problems have led to a variety of recent advances in combinatorial optimization. Motivated by problems related to maximum flow and optimal transportation, a recent line of work [40, 30, 41, 42, 29, 13] developed near-linear time, accelerated solvers for a particular family of convex programming objectives we refer to in this paper as *box-simplex games*:

$$\min_{x\in\Delta^m}\max_{y\in[-1,1]^n} y^\top \mathbf{A}x + c^\top x - b^\top y \text{ where } \Delta^m := \{x\in\mathbb{R}^m_{\geq 0} |\, \|x\|_1 = 1\}\,. \tag{1}$$

Box-simplex games, (1), are bilinear problems where a maximization player is constrained to the box (the ℓ_∞ ball) and a minimization player is constrained to the simplex (the nonnegative ℓ_1 shell). The problem provides a convenient encapsulation of linear programming problems with ℓ_1 or ℓ_∞ structure; (1) can be used to solve box-constrained ℓ_∞ regression problems [41, 42] and maximizing over the box player yields the following ℓ_1 regression problem

$$\min_{x\in\Delta^m} c^\top x + \|\mathbf{A}x - b\|_1\,. \tag{2}$$

Furthermore, solvers for (1) and (2) are used in state-of-the-art algorithms for approximate maximum flow [41], optimal transport (OT) [29], (width-dependent) positive linear programming [7], and semi-streaming bipartite matching [5].

One of the main goals of our work is to develop efficient algorithms for solving *regularized* variants of the problems (1) and (2). An example of particular interest is the following

$$\min_{x\in\Delta^m | \mathbf{B}^\top x = d} c^\top x + \mu H(x), \text{ where } \mu \geq 0 \text{ and } H(x) := \sum_{i\in[m]} x_i \log x_i. \tag{3}$$

The case of (3) when $\mathbf{B}\in\mathbb{R}^{m\times n}$ is the (unsigned) edge-vertex incidence matrix of a complete bipartite graph, and d is a pair of discrete distributions supported on the sides of the bipartition, is known as the *Sinkhorn distance* objective. This is used in machine learning [14] as an efficiently-computable approximation to optimal transport distances: c corresponds to movement costs, and d encodes the prescribed marginals. This objective has favorable properties, e.g. differentiability [44], and there has been extensive work by both theorists and practitioners to solve (3) and analyze its properties (see e.g. [14, 4] and references therein). Choosing $\mathbf{A}$ and b to be sufficiently large multiples of $\mathbf{B}^\top$ and d, it can be shown that solutions to the following regularized variant of (2) yield approximate solutions to (3),

$$\min_{x\in\Delta^m} c^\top x + \|\mathbf{A}x - b\|_1 + \mu H(x)\,. \tag{4}$$

Beyond connections to Sinkhorn distances, there are additional reasons why it may be desirable to solve regularized box-simplex games. For example, regularization could speed up algorithms and allow high-precision solutions to be computed more efficiently. Further, obtaining a high-precision solution to a regularized version of the problem yields a more canonical and predictable approximate solution than an arbitrary low-precision approximation to the unregularized problem. Moreover, regularization potentially makes optimal solutions more stable to input changes. For box-simplex games stemming from bipartite matching we quantify this stability and show all of these properties allow regularized solvers to yield faster algorithms for a particular dynamic matching problem.

Altogether, the main contributions of this paper are the following.

1. We give improved running times for the problem of *dynamic decremental bipartite matching* (DDBM) with an *adaptive adversary*, a fundamental problem in dynamic graph algorithms. Our algorithm follows from a general black-box reduction we develop from DDBM to solving (variants of) regularized box-simplex games to high precision.
2. We give efficient solvers for (variants of) the regularized box-simplex problems (3), (4).
3. As a byproduct, we also show how to apply our new solvers (and additional tools from the literature) to obtain state-of-the-art methods for computing Sinkhorn distances.

Formally, the *DDBM* problem we consider is the following: given a bipartite graph undergoing edge deletions, maintain an *ϵ-approximate (maximum) matching*,[1] that is a matching which has size at least a $(1-\epsilon)$-fraction of the maximum (for a pre-specified) value of ϵ. Unless specified otherwise, we consider the *adaptive adversary model* where edge deletions can be specified adaptively to the matching returned. Further, we allow the matching output by the algorithm to be *fractional*, rather than integral.

We show how to reduce solving the DDBM problem to solving a sequence of regularized box-simplex games. This reduction yields a new approach to dynamic matching; this approach is inspired by prior work, e.g. [6], but conceptually distinct in that it decouples the solving of optimization subproblems from characterizing their solutions. For our specific DDBM problem, the only prior algorithm achieving an amortized polylogarithmic update time (for constant ϵ) is in the recent work of [6], which derives their dynamic algorithm as an application of the *congestion balancing* technique. Our reduction eschews this combinatorial tool and directly argues, via techniques from convex analysis, that solutions to appropriate regularized matching problems can be used dynamically as approximate matchings while requiring few recomputations. We emphasize our use of fast *high-accuracy solvers*[2] in the context of our reduction to obtain our improved runtimes, as our approach leverages structural characteristics of the exact solutions which we only show are inherited by approximate solutions when solved to sufficient accuracy.

Our work both serves as a proof-of-concept of the utility of regularized linear programming solvers as a subroutine in dynamic graph algorithms, and provides the tools necessary to solve said problems in various structured cases. This approach to dynamic algorithm design effectively separates a "stability analysis" of the solution to a suitable optimization problem from the computational burden of solving that problem to high accuracy: any improved solver would then have implications for faster dynamic algorithms as well. As a demonstration of this flexibility, we give three uses of our reduction framework (which proceed via different solvers) in obtaining our improved DDBM update time. We hope our work opens the door to exploring the use of the powerful continuous optimization toolkit, especially techniques originally designed for non-dynamic problems, for their dynamic counterparts.

Paper organization. We overview our contributions in Section 1.1, and related prior work in Section 1.2. We state preliminaries in Section 2. In Section 3.1, we describe our framework for reducing DDBM to a sequence of regularized optimization problems satisfying certain properties, and in Section 3.2 we give three different instantiations of the framework, obtaining a variety of DDBM solvers. Finally in Section 4 we provide our main algorithm for regularized box-simplex games. In the full version we provide additional discussions on a recent advancement for faster DDBM solvers, proofs for Section 3 and Section 4, and additional results for approximating Sinkhorn distances efficiently.

[1] This is sometimes also referred to as a $(1+\epsilon)$-multiplicatively approximate matching in the literature.
[2] Throughout, we typically use the term "high-accuracy" to refer to an algorithm whose runtime scales polylogarithmically in the inverse accuracy (as opposed to e.g. polynomially).

1.1 Our results

A framework for faster DDBM. We develop a new framework for solving the DDBM problem of computing an ϵ-approximate maximum matching in a dynamic graph undergoing edge deletions from an adaptive adversary. Our framework provides a reduction from this DDBM problem to solving various regularized formulations of box-simplex games.

To illustrate the reduction, suppose we have bipartite $G = (V, E)$ and, for simplicity, that we know M^*, the size of the (maximum cardinality) matching. As demonstrated in [5], solving the ℓ_1 regression problem $\min_{x \in M^* \Delta^m} -c^\top x + \|\mathbf{A}x - b\|_1$, to ϵM^* additive accuracy for appropriate choices of $\mathbf{A}$, b, and c yields an ϵ-approximate maximum cardinality matching. Intuitively, $\mathbf{A}$ and b penalize violations of the matching constraints, and c is a multiple of the all-ones vector capturing the objective of maximizing the matching size. However, ℓ_1 regression objectives do not necessarily have unique minimizers: as such the output of directly minimizing these objectives is difficult to characterize beyond (approximate) optimality. This induces difficulty in using solutions to such problems directly in dynamic graph algorithms.

Our first key observation (building upon intuition from congestion balancing [6]) is that, beyond enabling faster runtime guarantees, regularization provides more robust solutions which are resilient to edge deletions in dynamic applications. We show that if

$$x_\epsilon^* := \min_{x \in M^* \cdot \Delta^m} -c^\top x + \|\mathbf{A}x - b\|_1 + \epsilon H(x) \tag{5}$$

is the solution to the *regularized* box-simplex formulation of bipartite matching, then x_ϵ^* enjoys favorable stability properties allowing us to argue about its size under deletions.

The stability of solutions to (5) is fairly intuitive: the entropy regularizer encourages the objective to spread the matching uniformly, when all else is held equal. For example, when G is a complete bipartite graph on $2n$ vertices, standard linear programming relaxations of matching do not favor either of (i) an integral perfect matching, and (ii) a fractional matching spreading mass evenly across many edges, over the other. However, using (i) as our approximate matching on a graph undergoing deletions is substantially more unstable; an adaptive adversary can remove edges corresponding to our matching, forcing $\Omega(n)$ recomputations. On the other hand, no deletions can cause this type of instability for strategy (ii): as each edge receives weight $\frac{1}{n}$ in the fractional matching, the only way to reduce the fractional matching size by ϵn is to remove $O(\epsilon n^2)$ edges: thus $O(\epsilon^{-1})$ recomputations intuitively suffice for maintaining an ϵ-approximate matching. This distinction underlies the use of *high-accuracy* solvers in our reduction; indeed, while they obtain large matching values in an original graph, approximate solutions may not carry the same types of dynamic matching value stability. We note similar intuition motivated the approach in [6].

To make this argument more rigorous, consider using x_ϵ^* as our approximate matching for a number of iterations corresponding to edge deletions, until its size restricted to the smaller graph has decreased by a factor of $1 - O(\epsilon)$. By using strong convexity of (5) in the ℓ_1 norm, we argue that whenever the objective value of x_ϵ^* has worsened, the maximum matching size itself must have gone down by a (potentially much smaller) amount. A tighter characterization of this strong convexity argument shows that we only need to recompute a solution to slight variants of (5) roughly $\widetilde{O}(\epsilon^{-2})$ times throughout the life of the algorithm. Combined with accelerated $\widetilde{O}(\frac{m}{\epsilon})$-time solvers for regularized box-simplex games (which are slight modifications of (5)), this strategy yields an overall runtime of $\widetilde{O}(\frac{m}{\epsilon^3})$, improving upon the recent state-of-the-art decremental result of [6].

We formalize these ideas in Section 3, where we demonstrate that a range of regularization strategies (see Definition 5) such as (5) are amenable to this reduction. Roughly, as long as our regularized objective is "at least as strongly convex" as the entropic regularizer, and

closely approximates the matching value in the static setting, then it can be used in our DDBM algorithm. Combining this framework with solvers for regularized matching problems, we give three different results. The first two obtain amortized update times of roughly $\widetilde{O}(\epsilon^{-3})$, in Theorems 9 and 10 via box-simplex games and matrix scaling, respectively (though the latter holds only for dense graphs). We give an informal statement of the former here.

▶ **Theorem 1** (informal, see Theorem 9). *Let $G = (V, E)$ be bipartite, $|V| = n$, $|E| = m$, and $\epsilon \geq \text{poly}(m^{-1})$. There is a deterministic algorithm maintaining an ϵ-approximate matching in a dynamic bipartite graph with adversarial edge deletions running in time $O(m \log^5 m \cdot \epsilon^{-3})$.*

Notably, our algorithm (deterministically) returns a *fractional matching*. There is a black-box reduction from dynamic integral matching maintenance to dynamic fractional matching maintenance contained in [45], but this reduction is bottlenecked at an amortized $\widetilde{O}(\epsilon^{-4})$ runtime (see e.g. Appendix A.2, [6]). Improving this reduction is a key open problem.

High-accuracy solvers for regularized box-simplex games. To use our DDBM framework, we give a new algorithm for solving regularized box-simplex games of the form:

$$\min_{x \in \Delta^m} \max_{y \in [0,1]^n} f_{\mu,\epsilon}(x, y) := y^\top \mathbf{A}^\top x + c^\top x - b^\top y + \mu H(x) - \frac{\epsilon}{2} \left(y^2\right)^\top |\mathbf{A}|^\top x, \tag{6}$$

where ϵ and $\mu = \Omega(\epsilon)$ are regularization parameters and y^2, $|\mathbf{A}|$ are entrywise. The terms $H(x)$ and $(y^2)^\top |\mathbf{A}|^\top x$ in (6) are parts of a primal-dual regularizer proposed in [29] (and a variation of a similar regularizer of [41]) used in state-of-the-art algorithms for approximately solving (unregularized) box-simplex games. This choice of regularization enjoys favorable properties over the joint box-simplex domain, and sidesteps the infamous ℓ_∞-strong convexity barrier that has limited previous attempts at acceleration for this problem. Under relatively mild restrictions on problem parameters (see discussion at the start of Section 4), we develop a *high accuracy solver* for (6), stated informally here.

▶ **Theorem 2** (informal, see Theorem 25). *Given an instance of (6), with $\mu = \Omega(\epsilon)$, $\|\mathbf{A}\|_\infty \leq 1$, and $\sigma \geq \text{poly}(m^{-1})$ Algorithm 4 returns x with $\max_{y \in [0,1]^n} f_{\mu,\epsilon}(x, y) - f_{\mu,\epsilon}(x^\star, y^\star) \leq \sigma$ in time $\widetilde{O}(\text{nnz}(\mathbf{A}) \cdot \frac{1}{\sqrt{\mu\epsilon}})$ where $(x^\star, y^\star)$ is the optimizer of (6).*

Our solver follows recent developments in solving unregularized box-simplex games. We analyze an approximate extragradient algorithm based on the mirror prox method of [37], and prove that iterates of the regularized problem (6) enjoy multiplicative stability properties previously shown for the iterates of mirror prox on the unregularized problem [13]. Leveraging these tools, we also show the regularizer-operator pair satisfies technical conditions known as *relative Lipschitzness* and *strong monotonicity*, thus enabling a similar convergence analysis as in [13]. This yields an efficient algorithm for solving (6).

Roughly, when the scale of the problem (defined in terms of the matrix operator norm $\|\mathbf{A}\|_\infty$ and appropriate norms of b and c) is bounded,[3] our algorithm for computing a high-precision optimizer to (6) runs in $\widetilde{O}(\frac{1}{\sqrt{\mu\epsilon}})$ iterations, each bottlenecked by a matrix-vector product through $\mathbf{A}$. When $\mu \approx \epsilon$, the optimizer of the regularized variant is an $O(\epsilon)$-approximate solution to the unregularized problem (1), and hence Theorem 25 recovers state-of-the-art runtimes (scaling as $\widetilde{O}(\epsilon^{-1})$) for box-simplex games up to logarithmic factors. We achieve our improved dependence on μ in Theorem 25 by trading off the scales of the

[3] Our runtimes straightforwardly extend to depend appropriately on these norms in a scale-invariant way.

primal and dual domains. This type of argument is well-known for *separable regularizers* [9], but a key technical novelty of our paper is demonstrating a similar analysis holds for non-separable regularizers compatible with box-simplex games e.g. the one from [29], which has not previously been done. To our knowledge, Theorem 25 is the first result for solving general regularized box-simplex games to high accuracy in nearly-linear time. We develop our box-simplex algorithm and prove Theorem 25 in Section 4.

Improved rates for the Sinkhorn distance objective. We apply our accelerated solver for (6) in computing approximations to the Sinkhorn distance objective (3), a fundamental algorithmic problem in the practice of machine learning, at a faster rate. It is well-known that solving the *regularized* Sinkhorn problem (3) with μ scaling much larger than the target accuracy ϵ enjoys favorable properties in practice [14] (compared to its unregularized counterpart, the standard OT distance). In [3], the authors show that Sinkhorn iteration studied in prior work solves (3) to additive accuracy ϵ at an unaccelerated rate of $\widetilde{O}(\frac{1}{\mu\epsilon})$. For completeness we provide a proof of this result (up to logarithmic factors) in Appendix C.3 in the full version of this paper.

As a straightforward application of the solver we develop for (6), we demonstrate that we can attain an accelerated rate of $\widetilde{O}(\frac{1}{\sqrt{\mu\epsilon}})$ for approximating (3) to additive accuracy ϵ via a first-order method. More specifically, the following result is based on reducing the "explicitly constrained" Sinkhorn objective (3) to a "soft constrained" regression variant of the form (4), where our box-simplex game solver is applicable. We now state our first result on improved rates for approximating Sinkhorn distance objectives.

▶ **Theorem 3** (informal, see Theorem 11 in full version). *Let $\mu \in [\Omega(\epsilon), O(\frac{\|c\|_\infty}{\log m})]$ in (3) corresponding to a complete bipartite graph with m edges. There is an algorithm based on the regularized box-simplex game solver of Theorem 25 which obtains an ϵ-approximate minimizer to (3) in time $\widetilde{O}(m \cdot \frac{\|c\|_\infty}{\sqrt{\mu\epsilon}})$.*

By leveraging the particular structure of the Sinkhorn distance and its connection to a primitive in scientific computing and theoretical computer science known as *matrix scaling* [35, 12, 2], we give a further-improved solver for (3) in Theorem 4. This solver has a nearly-linear runtime scaling as $\widetilde{O}(\frac{1}{\mu})$, which is a high-precision solver for the original Sinkhorn objective. Our high-precision Sinkhorn solver applies powerful second-order optimization tools from [12] based on the *box-constrained Newton's method* for matrix scaling, yielding our second result on improved Sinkhorn distance approximation rates.

▶ **Theorem 4** (informal, see Theorem 12 in full version). *Let $\mu, \epsilon = O(\|c\|_\infty)$ in (3) corresponding to a complete bipartite graph with m edges. There is an algorithm based on the matrix scaling solver of [12] which obtains an ϵ-approximate minimizer to (3) in time $\widetilde{O}(m \cdot \frac{\|c\|_\infty}{\mu})$.*

We present both Theorems 3 and 4 because they follow from somewhat incomparable solver frameworks. While the runtime of Theorem 3 is dominated by that of Theorem 4, it is a direct application of a more general solver (Theorem 25), which also applies to regularized regression or box-simplex objectives where the optimum does not have a characterization as a matrix scaling. Moreover, the algorithm of Theorem 4 is a second-order method which leverages recent advances in solving Laplacian systems, and hence may be less practical than its counterpart in Theorem 3. Finally, we note that due to subtle parameterization differences for our DDBM applications, the DDBM runtime attained by using our box-simplex solver within our reduction framework is more favorable on sparse graphs ($m \ll n^2$), compared to that obtained by the matrix scaling solver.

1.2 Prior work

Dynamic matching. Dynamic graph algorithms are an active area of research in the theoretical computer science, see e.g. [27, 15, 6, 31, 17, 21, 1, 26, 19, 22, 36, 20] and references therein. These algorithms have been developed under various dynamic graph models, including the additions and deletions on *vertices* or *edges*, and *oblivious adversary* model where the updates to the graph are fixed in advance (i.e. do not depend on randomness used by the algorithm), and the *adaptive adversary* model in which updates are allowed to respond to the algorithm, potentially adversarially. We focus on surveying deterministic dynamic matching algorithms with edge streams, which perform equally well under oblivious and adaptive updates; we remark the dynamic matching algorithms have also been studied under vertex addition and deletion model in [8]. For a more in-depth discussion and corresponding developments in other settings, see [45].

Many variants of the particular dynamic problem of maintaining matchings in bipartite graphs have been studied, such as the *fully dynamic* [25], *incremental* [24, 23], and *decremental* [6] cases. However, known conditional hardness results [28, 32] suggest that attaining a polylogarithmic update time for maintaining an exact fully dynamic matching may be unattainable, prompting the study of restricted variants which require maintaining an approximate matching. The works most relevant to our paper are those of [24], which provides a $\widetilde{O}(\epsilon^{-4})$ amortized update time algorithm for computing an ϵ-approximate matching for incremental bipartite matching, and [6], which achieves a similar $\widetilde{O}(\epsilon^{-4})$ update time for decremental bipartite matching. Our main DDBM results, stated in Theorems 9 and 10, improve upon [6] by roughly a factor of ϵ^{-1} in the decremental setting.

Box-simplex games. Box-simplex games, as well as ℓ_1 and ℓ_∞ regression, are equivalent to linear programs in full generality [33], have widespread utility, and hence have been studied extensively by the continuous optimization community. Here we focus on discussing *near-linear time* approximation algorithms, i.e. algorithms which run in time near-linear in the sparsity of the constraint matrix, potentially depending inverse polynomially on the desired accuracy. Interior point methods solve these problems with polylogarithmic dependence on accuracy, but are second-order and often encounter polynomial runtime overhead in the dimension (though there are exceptions, e.g. [43] and references therein).

A sequence of early works e.g. [37, 38, 39] on primal-dual optimization developed first-order methods for solving games of the form (1). These works either directly operated on the objective (1) as a minimax problem, or optimized a smooth approximation to the objective recast as a convex optimization problem. While these techniques obtained iteration complexities near-linear in the sparsity of the constraint matrix $\mathbf{A}$, they either incurred an (unaccelerated) ϵ^{-2} dependence on the accuracy ϵ, or achieved an ϵ^{-1} rate of convergence at the cost of additional dimension-dependent factors. This was due to the notorious "ℓ_∞ strong convexity barrier" (see Appendix A, [42]), which bottlenecked classical acceleration analyses over an ℓ_∞-constrained domain. [41] overcame this barrier by utilizing the primal-dual structure of (1) through a technique called "area convexity", obtaining a $\widetilde{O}(\epsilon^{-1})$-iteration algorithm. Since then, [13] demonstrated that fine-grained analyses of the classical algorithms of [37, 39] also obtain comparable rates for solving (1). Finally, we mention that area convexity has found applications in optimal transport and positive linear programming [29, 7].

Sinkhorn distances. Since [14] proposed Sinkhorn distances for machine learning applications, a flurry of work has aimed at developing algorithms with faster runtimes for (3). A line of work by [4, 16, 34] has analyzed the theoretical guarantees of the classical Sinkhorn

matrix scaling algorithm for this problem, due to the characterization of its solution as a diagonal rescaling of a fixed matrix. These algorithms obtain rates scaling roughly as $\widetilde{O}(\|c\|_\infty^2 \epsilon^{-2})$ for solving (3) to additive accuracy ϵ. Perhaps surprisingly, to our knowledge no guarantees for solving (3) which improve as the regularization parameter μ grows are currently stated in the literature, a shortcoming addressed by this work. Finally, we remark that Sinkhorn iteration has also received extensive treatment from the theoretical computer science community, e.g. [35], due to connections with algebraic complexity; see [18] for a recent overview of these connections.

2 Preliminaries

General notation. We denote $[n] := \{1, 2, \ldots, n\}$ and let $\mathbf{0}$ and $\mathbf{1}$ denote the all-0 and all-1 vectors. Given $v \in \mathbb{R}^d$, v_i or $[v]_i$ denotes the i^{th} entry of v, and for any subset $E \subseteq [d]$ we use v_E or $[v]_E$ to denote the vector in $\mathbb{R}^d$ zeroing out v on entries outside of E. We use $([v]_i)_+ = \max([v]_i, 0)$ to denote the operation truncating negative entries. We use $v \circ w$ to denote elementwise multiplication between any $v, w \in \mathbb{R}^d$. Given matrix $\mathbf{A} \in \mathbb{R}^{m \times n}$, we use $\mathbf{A}_{ij}$ to denote its $(i,j)^{\text{th}}$ entry, and denote its i^{th} row and j^{th} column by $\mathbf{A}_{i:}$ and $\mathbf{A}_{:j}$ respectively; its nonzero entry count is $\text{nnz}(\mathbf{A})$. We use $\mathbf{diag}\,(v)$ to denote the diagonal matrix where $[\mathbf{diag}\,(v)]_{ii} = v_i$, for each i. Given two quantities M and M', for any $c > 1$ we say M is a c-approximation to M' if it satisfies $\frac{1}{c}M' \le M \le cM'$. For $\epsilon \ll 1$, we say M is an ϵ(-multiplicative)-approximation of M' if $(1-\epsilon)M' \le M \le (1+\epsilon)M'$. Throughout the paper, we use $|\mathbf{A}|$ to denote taking the elementwise absolute value of a matrix $\mathbf{A}$, and v^2 to denote the elementwise squaring of a vector v when clear from context.

Norms. $\|\cdot\|_p$ denotes the ℓ_p norm of a vector or corresponding operator norm of a matrix. In particular, $\|\mathbf{A}\|_\infty = \max_i \|\mathbf{A}_{i:}\|_1$. We use $\|\cdot\|$ interchangeably with $\|\cdot\|_2$. We use Δ^m to denote an m-dimensional simplex, i.e. $x \in \Delta^m \iff x \in \mathbb{R}^d_{\ge 0}, \|x\|_1 = 1$.

Graphs. A graph $G = (V, E)$ has vertices V and edges E; we abbreviate $n := |V|$ and $m := |E|$ whenever the graph is clear from context. For bipartite graphs, $V = L \cup R$ denotes the bipartition. We let $\mathbf{B} \in \{0,1\}^{E \times V}$ be the (unsigned edge-vertex) incidence matrix with $\mathbf{B}_{ev} = 1$ if v is an endpoint of e and $\mathbf{B}_{ev} = 0$ otherwise.

Bregman divergence. Given any convex distance generating function (DGF) $q(x)$, we use $V^q_{x'}(x) = q(x) - q(x') - \langle \nabla q(x'), x - x' \rangle \ge 0$ as its induced Bregman divergence. When the DGF is clear from context, we abbreviate $V := V^q$. By definition, V satisfies

$$\langle -\nabla V_{x'}(x), x - u \rangle = V_{x'}(u) - V_x(u) - V_{x'}(x) \text{ for any } x, x', u. \tag{7}$$

Computational model. We use the standard word RAM model, where one can perform each basic arithmetic operations on $O(\log n)$-bit words in constant time.

3 Dynamic decremental bipartite matching

Here we provide a reduction from maintaining an approximately maximum matching in a decremental bipartite graph to solving regularized matching problems to sufficiently high precision. In Section 3.1 we give this framework and then, in Section 3.2, we provide various instantiations of our framework based on different solvers, to demonstrate its versatility.

3.1 DDBM framework

Here we provide our general framework for solving DDBM, which assumes that for bipartite $G = (V, E)$ and approximate matching value M there is a canonical regularized matching problem with properties given in Definition 5; we later provide multiple such examples. Throughout this section, $\text{MCM}(E)$ denotes the size of the maximum cardinality matching on edge set E; the vertex set V is fixed throughout, so we omit it in definitions.

▶ **Definition 5** (Canonical regularized objective). *Let $G = (V, E_0)$ be a bipartite graph and $M \geq 0$ be an 8-approximation of $\text{MCM}(E_0)$. For all $E \subseteq E_0$ with $\text{MCM}(E) \geq \frac{M}{8}$, let $f_{M,E} : \mathbb{R}^E_{\geq 0} \to \mathbb{R}$,*

$$\nu^E := \min_{x \in \mathbb{R}^E_{\geq 0}} f_{M,E}(x) \text{ , and } x^E := \text{argmin}_{x \in \mathbb{R}^E_{\geq 0}} f_{M,E}(x). \tag{8}$$

*We call the set of $\{f_{M,E}\}_{\text{MCM}(E) \geq \frac{M}{8}}$ a family of (ϵ, β)-*canonical regularized objectives *(CROs) for $G(E_0)$ and M if the following four properties hold.*

1. *For all $E \subseteq E_0$ with $\text{MCM}(E) \geq \frac{M}{8}$, $-\nu^E$ is an $\frac{\epsilon}{8}$-approximation of $\text{MCM}(E)$.*
2. *For all $E \subseteq E_0$ with $\text{MCM}(E) \geq \frac{M}{8}$, $f_{M,E}$ is equivalent to f_{M,E_0} with the extra constraint that $x_{E_0 \setminus E}$ is fixed to 0 entrywise.*
3. *For any $E' \subseteq E \subseteq E_0$ with $\text{MCM}(E) \geq \frac{M}{8}$ and $\text{MCM}(E') \geq \frac{M}{8}$,*

$$f_{M,E'}(x^{E'}) - f_{M,E}(x^E) \geq \beta V^H_{x^E}(x^{E'}) \text{ where } H(x) := \sum_e x_e \log x_e \tag{9}$$

4. *For any $x \in \mathbb{R}^E_{\geq 0}$ such that $8Mx$ is a feasible matching on (V, E),*

$$8M \|x_E\|_1 - \frac{\epsilon}{128} M \leq -f_{M,E}(x) \leq 8M \|x_E\|_1 + \frac{\epsilon}{128} M. \tag{10}$$

We further define the following notion of a canonical solver for a given CRO, which solves the CRO to sufficiently high accuracy, and rounds the approximate solution to feasibility.

▶ **Definition 6** (Canonical solver). *For (ϵ, β)-CROs $\{f_{M,E}\}_{\text{MCM}(E) \geq \frac{M}{8}}$, we call $\mathcal{A}$ an $(\epsilon, \mathcal{T})$-*canonical solver *if it has subroutines* Solve *and* Round *running in $O(\mathcal{T})$ time, satisfying:*

1. Solve *finds an approximate solution $\hat{x}^E$ of $f_{M,E}$ satisfying*

$$\left(1 + \frac{\epsilon}{8}\right) \nu^E \leq f_{M,E}(\hat{x}^E) \leq \left(1 - \frac{\epsilon}{8}\right) \nu^E. \tag{11a}$$

$$\left\|\hat{x}^E - x^E\right\|_1 \leq \frac{\epsilon}{1100}. \tag{11b}$$

2. Round *takes $\hat{x}^E$ and returns $\tilde{x}^E$ where $8M\tilde{x}^E$ is a feasible matching for $G(E)$, and:*

$$\left(1 + \frac{\epsilon}{8}\right) \nu^E \leq f_{M,E}(\tilde{x}^E) \leq \left(1 - \frac{\epsilon}{8}\right) \nu^E. \tag{12a}$$

$$\tilde{x}^E \leq \hat{x}^E \text{ monotonically.} \tag{12b}$$

Our DDBM framework, Algorithm 1, uses CRO solvers satisfying the approximation guarantees of Definition 6 to dynamically maintain an approximately maximum matching. We state its correctness and runtime in Proposition 7, and defer a proof to Appendix A.1 in the full version.

In the following, we let E_0 be the original graph's edge set, and $E_1, E_2, \ldots, E_K$ be the sequence of edge sets recomputed in Line 8, before termination for E_{K+1} on Line 4.

Algorithm 1 DecMatching$(\epsilon, G = (V, E))$.

Input: $\epsilon \in (0, \frac{1}{8})$, graph $G = (V, E)$
Parameters: Family of CROs $\{f_{M,E}\}_{E \text{ is MP}}$, $(\epsilon, \mathcal{T})$-canonical solver (Solve, Round)
1 Compute M with $\frac{1}{2}\text{MCM}(E) \le M \le \text{MCM}(E)$, via the greedy algorithm
2 $\hat{x}^E \leftarrow \mathsf{Solve}(f_{M,E})$
3 $\tilde{x}^E \leftarrow \mathsf{Round}(\hat{x}^E)$, $M_{\text{est}} \leftarrow M$
4 **while** $M_{\text{est}} > \frac{1}{4}M$ **do**
5 $E_{\text{del}} \leftarrow \emptyset$
6 **while** *edge e is deleted and* $\|\tilde{x}^E_{E_{\text{del}}}\|_1 \le \frac{\epsilon}{8}\left\|\tilde{x}^E\right\|_1$ **do**
 ▷ recompute whenever the deleted approximate matching size reaches a factor $\Theta(\epsilon)$
7 $E_{\text{del}} \leftarrow E_{\text{del}} \cup \{e\}$
8 $E \leftarrow E \setminus E_{\text{del}}$, $E_{\text{del}} \leftarrow \emptyset$
9 $\hat{x}^E \leftarrow \mathsf{Solve}(f_{M,E})$ ▷ find high-accuracy minimizer of $F_{M,E}$ satisfying (11a) and (11b)
10 $\tilde{x}^E \leftarrow \mathsf{Round}(\hat{x}^E)$ ▷ round to feasible matching satisfying (12a) and (12b)
11 Compute M_{est} with $\frac{1}{2}\text{MCM}(E) \le M_{\text{est}} \le \text{MCM}(E)$, via the greedy algorithm

▶ **Proposition 7.** *Let $\epsilon \in (0, 1)$ and $M \ge 0$. Given a family of (ϵ, β)-CROs $\{f_{M,E}\}$ for $G = (V, E_0)$, and an $(\epsilon, \mathcal{T})$-canonical solver for the family, Algorithm 1 satisfies the following.*
1. *When $M_{\text{est}} > \frac{1}{4}M$ on Line 4, where M_{est} estimates $\text{MCM}(E_k)$: at any point in the loop of Lines 6 to 7, $8M\tilde{x}^{E_k}_{E_k \setminus E_{\text{del}}}$ is an ϵ-approximate matching of $G(V, E_k \setminus E_{\text{del}})$.*
2. *When $M_{\text{est}} \le \frac{1}{4}M$ on Line 4, where M_{est} estimates $\text{MCM}(E)$: $\text{MCM}(E) \le \frac{1}{2}\text{MCM}(E_0)$.*

The runtime of the algorithm is $O(m + (\mathcal{T} + m) \cdot \frac{M}{\beta\epsilon})$.

Proof sketch. We summarize proofs of the two properties, and our overall runtime bound.

Matching approximation properties. By the greedy matching guarantee in Line 4, it holds that for any E_k (the edge set recomputed in the k^{th} iteration of Line 8 before termination), its true matching size $\text{MCM}(E_k)$ must be no smaller than $\frac{M}{4}$. Consequently, we can use the CRO family to approximate the true matching size up to $O(\epsilon)$ multiplicative factors, and by the guarantee (12a), this implies $8M\tilde{x}^{E_k}_{E_k \setminus E_{\text{del}}}$ is an $O(\epsilon)$ approximation of the true matching size. Also, our algorithm's termination condition and the guarantee on M_{est} immediately imply $\text{MCM}(E_{K+1}) \le \frac{1}{2}\text{MCM}(E_0)$.

Iteration bound. We use a potential argument. Given $E_{k+1} \subset E_k$, corresponding to consecutive edge sets requiring recomputation, we use the following inequalities:

$$
\begin{aligned}
&f_{M,E_{k+1}}\left(x^{E_{k+1}}\right) - f_{M,E_k}\left(x^{E_k}\right) \overset{(i)}{\ge} \beta V^H_{x^{E_k}}\left(x^{E_{k+1}}\right) \qquad (13)\\
&\overset{(ii)}{\ge} \beta \sum_{i \in E_{\text{del}}} \left([x^{E_{k+1}}]_i \log[x^{E_{k+1}}]_i - [x^{E_k}]_i \log[x^{E_k}]_i - \left(1 + \log[x^{E_k}]_i\right) \cdot \left([x^{E_{k+1}}]_i - [x^{E_k}]_i\right)\right)\\
&\overset{(iii)}{=} \beta \sum_{i \in E_{\text{del}}} [x^{E_k}]_i \overset{(iv)}{\ge} \beta\left(\left\|\hat{x}^{E_k}_{E_{\text{del}}}\right\|_1 - \left\|\hat{x}^{E_k} - x^{E_k}\right\|_1\right) \overset{(v)}{\ge} \beta\left(\left\|\tilde{x}^{E_k}_{E_{\text{del}}}\right\|_1 - \left\|\hat{x}^{E_k} - x^{E_k}\right\|_1\right),
\end{aligned}
$$

where (i) uses the third property in (9), (ii) uses convexity of the scalar function $c \log c$, (iii) uses that $x^{E_{k+1}}_{E_{\text{del}}}$ is 0 entrywise, (iv) uses the triangle inequality, and (v) uses the monotonicity property (12b). Moreover, between recomputations we have that the ℓ_1-norm of deleted edges satisfies $\left\|\tilde{x}^{E_k}_{E_{\text{del}}}\right\|_1 = \Omega(\epsilon)$, and our solver guarantees $\left\|\hat{x}^{E_k} - x^{E_k}\right\|_1 = O(\epsilon)$. Since the overall function decrease before termination is $O(M)$ given the stopping criterion in Line 4, the algorithm terminates after $O(\frac{M}{\beta\epsilon})$ recomputations. ◀

Using this generic DDBM framework, we obtain improved decremental matching algorithms by defining families of CROs $f_{M,E(G)}$ with associated $(\epsilon, \mathcal{T})$-canonical solvers satisfying Definition 6. In Appendix A.2, we give a regularized primal-dual construction of $f_{M,E}$, and adapt the solver of Section 4 to develop a canonical solver for the family (specifically, as the subroutine Solve). Similarly, in Appendix A.3, we show how to construct an appropriate family of $f_{M,E}$ using Sinkhorn distances, and apply the matrix scaling method presented in Appendix C.2 (based on work of [12]) to appropriately instantiate Solve.

While both algorithms, as stated, only maintain an approximate fractional matchings, this fractional matching can be rounded at any point to an explicit integral matching via e.g. the cycle-canceling procedure of Proposition 3 in [5] in time $O(m \log m)$, or dynamically (albeit at amoritized cost $\widetilde{O}(\epsilon^{-4})$ using [45]). Moreover, our algorithm based on the regularized box-simplex solver (Theorem 9) is deterministic, and both work against an adaptive adversary. Repeatedly applying Proposition 7, we obtain the following overall claim.

▶ **Corollary 8.** *Let $G = (V, E(G))$ be bipartite, and suppose for any subgraph $(V, E_0 \subseteq E(G))$, we are given a family of (ϵ, β)-CROs and an $(\epsilon, \mathcal{T})$-canonical solver for the family. There is a deterministic algorithm maintaining a fractional ϵ-approximate matching in a dynamic bipartite graph with adversarial edge deletions, running in time $O\left(m \log^3 n + (\mathcal{T} + m) \cdot \frac{M}{\beta\epsilon} \cdot \log n\right)$.*

Proof. It suffices to repeatedly apply Proposition 7 until we can safely conclude $\mathrm{MCM}(E) = 0$, which by the second property can only happen $O(\log n)$ times. ◀

3.2 DDBM solvers

In this section, we demonstrate the versatility of the DDBM framework in Section 3.1 by instantiating it with different classes of CRO families, and applying different canonical solvers on these families. By using regularized box-simplex game solvers developed in this paper (see Section 4), we give an $\widetilde{O}(m\epsilon^{-3})$ time algorithm for maintaining a ϵ-multiplicatively approximate fractional maximum matching in a m-edge bipartite graph undergoing a sequence of edge deletions, improving upon the previous best running time of $\widetilde{O}(m\epsilon^{-4})$ [6]. We also use our framework to obtain different decremental matching algorithms with runtime $\widetilde{O}(n^2\epsilon^{-3})$ and $O(m^{1+o(1)}\epsilon^{-2})$, building on recent algorithmic developments in the literature on matrix scaling. The former method uses box-constrained Newton's method solvers for matrix scaling problems in [12] (these ideas are also used in Appendix C.2), and the latter uses a recent almost-linear time high-accuracy Sinkhorn-objective solver in [11], a byproduct of their breakthrough maximum flow solver. We defer readers to corresponding sections in Appendix A for omitted proofs.

Given a bipartite graph initialized at $G = (V, E_0)$ with unsigned incidence matrix $\mathbf{B} \in \{0,1\}^{E \times V}$; we denote $n := |V|$ and $m := |E_0|$. The first family of CROs one can consider is the regularized box-simplex game objective in form:

$$\min_{(x,\xi)\in\Delta^{E+1}} \max_{y\in[0,1]^V} f_{M,E}(x,\xi,y) := -\mathbf{1}_E^\top(8Mx) - y^\top\left(8M\mathbf{B}^\top x - \mathbf{1}\right) + \gamma^{\mathsf{x}} H(x,\xi) + \gamma^{\mathsf{y}}\left(y^2\right)^\top \mathbf{B}^\top x,$$

$$\text{where } \gamma^{\mathsf{x}} = \widetilde{\Theta}\left(\epsilon M\right),\ \gamma^{\mathsf{y}} = \Theta\left(\epsilon M\right),\ \text{ and}$$

$$f_{M,E}(x) := \min_{\xi \mid (x,\xi)\in\Delta^{E+1}} \max_{y\in[0,1]^V} f_{M,E}(x,\xi,y). \tag{14}$$

We prove this is a family of $(\epsilon, \gamma^{\mathsf{x}})$-CROs (see Lemma 8 in full version). The canonical solver for this family uses RemoveOverflow (Algorithm 4, [5]) as Round and uses the regularized box-simplex games developed later in this paper (see Section 4) as Solve, which finds an ϵ-approximate solution of (14) in time $\widetilde{O}(\frac{m}{\epsilon})$. Combining all these components with the DDBM framework in Corollary 8 leads to the following DDBM solver based on regularized box-simplex games.

▶ **Theorem 9.** *Let $G = (V, E)$ be bipartite and let $\epsilon \in [\Omega(m^{-3}), 1)$. There is a deterministic algorithm for the DDBM problem which maintains an ϵ-approximate matching, based on solving regularized box-simplex games, running in time $O\left(m\epsilon^{-3}\log^5 n\right)$.*

Our second CRO family is the following regularized Sinkhorn distance objective:

$$\min_{\binom{x}{x^{\mathsf{dum}}}\in\mathbb{R}^{\widetilde{E}}_{\geq 0} \mid 2|R|\widetilde{\mathbf{B}}^\top\binom{x}{x^{\mathsf{dum}}}=d} f^{\mathsf{sink}}_{M,E}(x^{\mathsf{tot}}) := 2|R|\mathbf{1}_E^\top x + \gamma H\left(x, x^{\mathsf{dum}}\right) \text{ where } \gamma = \widetilde{\Theta}\left(\epsilon M\right),$$
$$f^{\mathsf{sink}}_{M,E}(x) := \min_{x^{\mathsf{dum}}\in\mathbb{R}^{E\setminus E_0}_{\geq 0}} f^{\mathsf{sink}}_{M,E}(x, x^{\mathsf{dum}}), \tag{15}$$

where we extend graph $G = (V, E)$ to a balanced bipartite graph $\widetilde{G} = (\widetilde{V}, \widetilde{E})$ by introducing dummy vertices and edges. The extended graph allows us to write the inequality constraint $\mathbf{B}^\top x = \mathbf{1}_V$ equivalently as the linear constraint $2|R|\widetilde{\mathbf{B}}^\top\binom{x}{x^{\mathsf{dum}}} = d$ for some defined $d \in \mathbb{R}^{\widetilde{V}}$ as some properly-extended vector of $\mathbf{1}_V$. This allows us to apply known matrix scaling solver to such approximating Sinkhorn distance objective in literature.

We prove this is a family of (ϵ, γ)-CROs (see Lemma 10 in full version). The canonical solver for this family uses truncation to E as Round and uses the matrix scaling solver from [12] based on box-constrained Newton's method as Solve, which finds an ϵ-approximate solution of (15) in time $\widetilde{O}(n^2/\epsilon)$. Combining all these components with the DDBM framework in Corollary 8 leads to the following DDBM solver based on approximating Sinkhorn distances.

▶ **Theorem 10.** *Let $G = (V, E)$ be bipartite and $\epsilon \in [\Omega(m^{-3}), 1)$. There is a randomized algorithm for the DDBM problem which maintains an ϵ-approximate matching with probability $1 - n^{-\Omega(1)}$, based on matrix scaling solver of [12], running in time $\widetilde{O}\left(n^2\epsilon^{-3}\right)$.*

Alternatively, for the same (ϵ, γ)-CRO family as in (15), one can use the same Round procedure and the recent high-accuracy almost-linear time graph flow problems solver of [11] for Solve as a canonical solver. Since this new solver can find high-accuracy solutions of entropic-regularized problems of the form (15) within a runtime of $(|E_0| + O(|V|))^{1+o(1)} = m^{1+o(1)}$, this gives a third DDBM solver, which yields and improved an dependence on ϵ^{-1}.

▶ **Theorem 11.** *Let $G = (V, E)$ be bipartite and $\epsilon \in [\Omega(m^{-3}), 1)$. There is a randomized algorithm for the DDBM problem which maintains an ϵ-approximate matching with probability $1 - n^{-\Omega(1)}$, based on the Sinkhorn objective solver of [11], running in time $m^{1+o(1)}\epsilon^{-2}$.*

4 Regularized box-simplex games

In this section, we develop a high-accuracy solver for regularized box-simplex games:

$$\min_{x\in\Delta^m}\max_{y\in[0,1]^n} f_{\mu,\epsilon}(x, y) := y^\top\mathbf{A}^\top x + c^\top x - b^\top y + \mu H(x) - \frac{\epsilon}{2}\left(y^2\right)^\top|\mathbf{A}|^\top x,$$
$$\text{where } H(x) := \sum_{i\in[m]} x_i \log x_i \text{ is the standard entropic regularizer,} \tag{16}$$

where we recall absolute values and squaring act entrywise.

For ease of presentation, we make the following assumptions for some $\delta > 0$.

1. Upper bounds on entries: $\|\mathbf{A}\|_\infty \leq 1$, $\|b\|_\infty \leq B_{\max}$, $\|c\|_\infty \leq C_{\max}$. For simplicity, we assume $B_{\max} \geq C_{\max} \geq 1$; else, $C_{\max} \leftarrow \max(1, C_{\max})$ and $B_{\max} \leftarrow \max(C_{\max}, B_{\max})$.
2. Lower bounds on matrix column entries: $\max_i |\mathbf{A}_{ij}| \geq \delta$ for every $j \in [n]$.

We defer the detailed arguments of why these assumptions are without loss of generality to Appendix B in the full version. Our algorithm acts on the induced (monotone) gradient operator of the regularized box-simplex objective (16), namely $(\nabla_x f_{\mu,\epsilon}(x,y), -\nabla_y f_{\mu,\epsilon}(x,y))$, defined as

$$g_{\mu,\epsilon}(x,y) := \left(\mathbf{A}y + c + \mu(\mathbf{1} + \log(x)) - \frac{\epsilon}{2}\left|\mathbf{A}\right|(y^2), -\mathbf{A}^\top x + b + \epsilon \cdot \mathbf{diag}\,(y)\left|\mathbf{A}\right|^\top x\right). \quad (17)$$

Further, it uses the following joint (non-separable) regularizer of

$$r_{\mu,\epsilon}(x,y) := \rho \sum_{i\in[m]} x_i \log x_i + \frac{1}{\rho} x^\top \left|\mathbf{A}\right|(y^2) \quad \text{where} \quad \rho = \sqrt{\frac{2\mu}{\epsilon}}, \quad (18)$$

variants of which have been used in [41, 29, 5, 13]. When clear from context, we drop subscripts and refer to these as operator g and regularizer r. Our method is the first high-accuracy near-linear time solver for the regularized problem (16), yielding an $O(\sigma)$-approximate solution with a runtime scaling polylogarithmically in problem parameters and σ. We utilize a variant of the mirror prox [37] method for strongly monotone objectives, which appeared in [9, 13] for regularized saddle point problems with separable regularizers.

In Section 4.1, we present high-level ideas of our algorithm, which uses a mirror prox outer loop (Algorithm 2) and an alternating minimization inner loop (Algorithm 3) to implement outer loop steps; we also provide convergence guarantees. In Section 4.2, we state useful properties of the regularizer (18), and discuss a technical detail ensuring iterate stability in our method. In Section 4.3, we provide our full algorithm for regularized box-simplex games, Algorithm 4 and give guarantees in Theorem 25. Omitted proofs are in Appendix B.

4.1 Algorithmic framework

In this section, we give the algorithmic framework we use to develop our high-precision solver, which combines an outer loop inspired by mirror prox [37] with a custom inner loop for implementing each iteration. We first define an approximate solution for a proximal oracle.

▶ **Definition 12** (Approximate proximal oracle solution). *Given a convex function f over domain $\mathcal{Z}$ and $\sigma \geq 0$, we say $z' \in \mathcal{Z}$ is a* σ-approximate solution *for a proximal oracle if z' satisfies $\langle \nabla f(z'), z' - z\rangle \leq \sigma$. We denote this approximation property by $z' \leftarrow_\sigma \operatorname{argmin}_{z\in\mathcal{Z}} f$.*

We employ such approximate solutions as the proximal oracle within our "outer loop" method. Our outer loop is a variant of mirror prox (Algorithm 2) which builds upon both the mirror prox type method in [41] for solving unregularized box-simplex games and the high-accuracy mirror prox solver developed in [9, 13] for bilinear saddle-point problems on geometries admitting separable regularizers. We first give a high-level overview of the analysis, which requires bounds on two properties. First, suppose g is ν-strongly monotone with respect to regularizer r, i.e.

$$\text{for any } w, z \in \mathcal{Z},\ \langle g(w) - g(z), w - z\rangle \geq \nu \langle \nabla r(w) - \nabla r(z), w - z\rangle. \quad (19)$$

Further, suppose it is α-*relatively Lipschitz* with respect to r and Algorithm 4 (see Definition 1 of [13]), i.e. for any consecutive iterates z_{k-1}, $z_{k-1/2}$, z_k of our algorithm,[4]

$$\left\langle g(z_{k-1/2}) - g(z_{k-1}), z_{k-1/2} - z_k\right\rangle \leq \alpha\Big(V_{z_{k-1/2}}(z_k) + V_{z_{k-1}}(z_{k-1/2})\Big). \quad (20)$$

[4] This property (i.e. relative Lipschitzness restricted to iterates of the algorithm) was referred to as "local relative Lipschitzness" in [13], but we drop the term "local" for simplicity.

With these assumptions, we show that the strongly monotone mirror prox step makes progress by decreasing the divergence to optimal solution $V_{z_k}(z^\star)$ by a factor of $\frac{\alpha}{\alpha+\nu}$: this implies $\widetilde{O}(\frac{\alpha}{\nu})$ iterations suffice for finding a high-accuracy solution. We provide the formal convergence guarantee of MirrorProx in Proposition 13, which also accommodates the error of each approximate proximal step used in the algorithm. This convergence guarantee is generic and does not rely on the concrete structure of g, r in our box-simplex problem.

Algorithm 2 MirrorProx().

Input: $\frac{\sigma}{2}$-approximate proximal oracle, operator and regularizer pair (g, r) such that g is ν-strongly monotone and α-relatively Lipschitz with respect to r
Parameters: Number of iterations K

$z_0 \leftarrow \operatorname{argmin}_{z\in\mathcal{Z}} r(z)$
for $k = 1, \ldots, K$ **do**
  $z_{k-1/2} \leftarrow_{\sigma/2} \operatorname{argmin}_{z\in\mathcal{Z}} \left\{\langle g\left(z_{k-1}\right), z\rangle + \alpha V_{z_{k-1}}(z)\right\}$
  $z_k \leftarrow_{\sigma/2} \operatorname{argmin}_{z\in\mathcal{Z}} \left\{\left\langle g\left(z_{k-1/2}\right), z\right\rangle + \alpha V_{z_{k-1}}(z) + \nu V_{z_{k-1/2}}(z)\right\}$
return z_K

▶ **Proposition 13** (Convergence of Algorithm 2). *Given regularizer r with range at most Θ, suppose g is ν-strongly-monotone with respect to r (see (19)), and is α-relatively-Lipschitz with respect to r (see (20)). Let z_K be the output of Algorithm 2. Then, $V^r_{z_K}(z^\star) \le \left(\frac{\alpha}{\nu+\alpha}\right)^K \Theta + \frac{\sigma}{\nu}$.*

Given the somewhat complicated nature of our joint regularizer, we cannot solve the proximal problems required by Algorithm 2 in closed form. Instead, we implement each proximal step to the desired accuracy by using an alternating minimization scheme, similarly to the implementation of approximate proximal steps in [41, 29].

To analyze our algorithm, we use a generic progress guarantee for alternating minimization from [29] to solve each subproblem, stated below.

Algorithm 3 AltMin($\gamma^{\mathsf{x}}, \gamma^{\mathsf{y}}, \mathbf{A}, \theta, T, x_{\text{init}}, y_{\text{init}}$).

Input: $\mathbf{A} \in \mathbb{R}^{m\times n}_{\ge 0}$, $\gamma^{\mathsf{x}} \in \mathbb{R}^m$, $\gamma^{\mathsf{y}} \in \mathbb{R}^n$, $T \in \mathbb{N}$, $\theta > 0$, $x_{\text{init}} \in \Delta^m$, $y_{\text{init}} \in [0,1]^n$
Output: Approximate minimizer to $\langle(\gamma^{\mathsf{x}}, \gamma^{\mathsf{y}}), z\rangle + \theta r(z)$ for $r(z)$ in (18)

$x^{(0)} \leftarrow x_{\text{init}}$, $y^{(0)} \leftarrow y_{\text{init}}$;
for $0 \le t \le T$ **do**
  $x^{(t+1)} \leftarrow \operatorname{argmin}_{x\in\Delta^m} \left\{\langle\gamma^{\mathsf{x}}, x\rangle + \theta r(x, y^{(t)})\right\}$;
  $y^{(t+1)} \leftarrow \operatorname{argmin}_{y\in[0,1]^n} \left\{\langle\gamma^{\mathsf{y}}, y\rangle + \theta r(x^{(t+1)}, y)\right\}$;
return $(x^{(T+1)}, y^{(T)})$

▶ **Lemma 14** (Alternating minimization progress, Lemma 5 and Lemma 7, [29]). *Let $r : \mathcal{X}\times\mathcal{Y} \to \mathbb{R}$ be jointly convex, $\theta > 0$, and γ^x and γ^y be linear operators on $\mathcal{X}, \mathcal{Y}$. Define*

$$x_{\mathsf{OPT}}, y_{\mathsf{OPT}} = \operatorname{argmin}_{x\in\mathcal{X}} \operatorname{argmin}_{y\in\mathcal{Y}} f(x,y) := \langle\gamma^x, x\rangle + \langle\gamma^y, y\rangle + \theta r(x,y). \tag{21}$$

Suppose $f(x,y)$ is twice-differentiable and satisfies: for all $x' \ge \frac{1}{2}x$ entrywise, $x', x \in \mathcal{X}$ and $y', y \in \mathcal{Y}$, $\nabla^2 f(x', y') \succeq \frac{1}{\kappa} f(x,y)$. Then the iterates of Algorithm 3 satisfy

$$f(x^{(t+2)}, y^{(t+1)}) - f(x_{\mathsf{OPT}}, y_{\mathsf{OPT}}) \le \left(1 - \frac{1}{2\kappa}\right)\left(f(x^{(t+1)}, y^{(t)}) - f(x_{\mathsf{OPT}}, y_{\mathsf{OPT}})\right).$$

Combining this lemma with the structure of our regularizer (18), we obtain the following guarantees, showing Algorithm 3 finds a $\frac{\sigma}{2}$-approximate solution to the proximal oracle.

▶ **Corollary 15** (Convergence of Algorithm 3). *Let $\delta, \sigma \in (0,1)$, $\rho \geq 1$. Suppose we are given $\gamma \in \mathcal{Z}_* = \mathcal{X}_* \times \mathcal{Y}_*$ with $\max(\|\gamma^x\|_\infty, \|\gamma^y\|_1) \leq B$, and define the proximal subproblem solution $x_{\mathsf{OPT}}, y_{\mathsf{OPT}} = \operatorname{argmin}_{x \in \Delta^m} \operatorname{argmin}_{y \in [0,1]^n} f(x,y) := \langle \gamma^x, x \rangle + \langle \gamma^y, y \rangle + \theta r(x,y)$ for some $\theta > 0$. If the Hessian condition in Lemma 14 holds with a constant $\kappa > 0$, and all simplex iterates x of Algorithm 3 satisfy $x \geq \delta$ elementwise, then the algorithm finds a $\frac{\sigma}{2}$-approximate solution to the proximal oracle within $T = O\left(\log\left(\frac{\rho(B+mn\theta)^2}{\delta\sigma\theta}\right)\right)$ iterations.*

4.2 Helper lemmas

Before providing our full method and analysis, here we list a few helper lemmas, which we rely on heavily in our later development. The first characterizes a useful property of $r_{\mu,\epsilon}$, showing that its Hessian is locally well-approximated by a diagonal matrix, which induces appropriate local norms for the blocks $x \in \mathcal{X}$, $y \in \mathcal{Y}$. We use this to prove the "strong monotonicity" (Lemma 20) and "relative Lipschitzness" (Lemma 22) bounds required in Section 4.3.

▶ **Lemma 16** (Bounds on regularizer). *Suppose $\mathbf{A} \in \mathbb{R}^{m \times n}$ has $\|\mathbf{A}\|_\infty \leq 1$. For any $z = (x,y) \in \Delta^m \times [0,1]^n$, $r = r_{\mu,\epsilon}$ defined as in (18), and $\bar{x} \in \mathbb{R}^m_{>0}$, $\langle x, \mathbf{A}y \rangle \leq \|x\|_{\mathbf{diag}\left(\frac{1}{\bar{x}}\right)} \|y\|_{\mathbf{diag}\left(|\mathbf{A}|^\top \bar{x}\right)}$. Further, if $\rho \geq 3$, the matrix*

$$\mathbf{D}(x) := \begin{pmatrix} \frac{\rho}{2}\mathbf{diag}\left(\frac{1}{x}\right) & \mathbf{0} \\ \mathbf{0} & \frac{1}{\rho}\mathbf{diag}\left(|\mathbf{A}|^\top x\right) \end{pmatrix} \tag{22}$$

satisfies the following relationship with the Hessian matrix of $r(z)$:

$$\mathbf{D}(x) \preceq \nabla^2 r(z) = \begin{pmatrix} \rho \cdot \mathbf{diag}\left(\frac{1}{x}\right) & \frac{2}{\rho}\mathbf{A}\mathbf{diag}\left(y\right) \\ \frac{2}{\rho}\mathbf{diag}\left(y\right)\mathbf{A}^\top & \frac{2}{\rho}\mathbf{diag}\left(|\mathbf{A}|^\top x\right) \end{pmatrix} \preceq 4\mathbf{D}(x). \tag{23}$$

We also introduce the following notion of a padding oracle (cf. Definition 2 of [10]), which helps us control the multiplicative stability of iterates when running our algorithm.

▶ **Definition 17.** *Given $\delta > 0$, and any $\bar{z} = (\bar{x}, y) \in \Delta^m \times [0,1]^n$, a padding oracle $\mathcal{O}_\delta$ returns $z = (x,y)$ by setting $\hat{x}_i = \max(\bar{x}_i, \delta)$ coordinate-wise and letting $x = \frac{\hat{x}}{\|\hat{x}\|_1}$.*

This padding oracle has two merits which we exploit. First, the error incurred due to padding is small proportional to the padding size δ, which finds usage in proving the correctness of our main algorithm, Algorithm 4 (see Proposition 24).

▶ **Lemma 18** (Error of padding, cf. Lemma 6, [10]). *For $\delta > 0$ and $\bar{z} = (\bar{x}, y) \in \Delta^m \times [0,1]^n$ let $z = (x,y) \in \Delta^m \times [0,1]^n$ where $x = \mathcal{O}_\delta(\bar{x})$ (Definition 17), then for r in (18), and any $w \in \mathcal{Z} = \Delta^m \times [0,1]^n$, $V_z^r(w) - V_{\bar{z}}^r(w) \leq \left(\rho + \frac{8}{\rho}\right) m\delta$.*

Second, padding ensures that the iterates of our algorithm satisfy $x = \Omega(\delta)$ entrywise, i.e. no entries of our simplex iterates x are too small. This helps ensure the stability of iterates throughout one call of Algorithm 3, formally through the next lemma.

▶ **Lemma 19** (Iterate stability in Algorithm 3). *Suppose $\epsilon \leq 1$, $\rho \geq 6$, and $\alpha \geq \frac{36}{\rho}(\mu \log \frac{4}{\delta} + 3C_{\max})$. Let (x_k, y_k) denote blocks of z_k, the k^{th} iterate of Algorithm 2. In any iteration k of Algorithm 2, calling Algorithm 3 to implement Line 3, if $x_{k-1} \geq \frac{\delta}{2}$ entrywise, $x^{(t+1)} \in x_{k-1} \cdot \left[\exp\left(-\frac{1}{9}\right), \exp\left(\frac{1}{9}\right)\right]$, for all $t \in [T]$. Calling Algorithm 3 to implement Line 4, if $x_{k-1/2} \geq \frac{\delta}{4}$ entrywise, $x^{(t+1)} \in x_{k-1}^{\frac{\alpha}{\alpha+\nu}} \circ x_{k-1/2}^{\frac{\nu}{\alpha+\nu}} \cdot \left[\exp\left(-\frac{1}{9}\right), \exp\left(\frac{1}{9}\right)\right]$ for all $t \in [T]$.*

4.3 Regularized box-simplex solver and its guarantees

We give our full high-accuracy regularized box-simplex game solver as Algorithm 4, which combines Algorithm 2, Algorithm 3, and a padding step to ensure stability. For space considerations, we defer the complete statement of algorithm to the full version of the paper.

Algorithm 4 RegularizedBS$(\mathbf{A}, b, c, \epsilon, \mu, \sigma)$.

Input: $\mathbf{A} \in \mathbb{R}^{m \times n}$, $c \in \mathbb{R}^m$, $b \in \mathbb{R}^n$, accuracy $\sigma \in (m^{-10}, 1)$, $72\epsilon \leq \mu \leq 1$
Output: Approximate solution pair (x, y) to (16)

1 **Global:** $\delta \leftarrow \frac{\epsilon\sigma^2}{m^2}$, $\rho \leftarrow \sqrt{\frac{2\mu}{\epsilon}}$, $\nu \leftarrow \frac{1}{2}\sqrt{\frac{\mu\epsilon}{2}}$, $\alpha \leftarrow 18C_{\max} + 32\sqrt{\frac{\mu\epsilon}{2}}\log\frac{4}{\delta}$
2 **Global:** $T \leftarrow O\left(\log \frac{mnB_{\max}\alpha\rho}{\delta\sigma}\right)$, $K \leftarrow O\left(\frac{\alpha}{\nu}\log\left(\frac{\nu \log m}{\sigma}\right)\right)$ for appropriate constants
3 $(x_0, y_0) \leftarrow (\frac{1}{m} \cdot \mathbf{1}_m, \mathbf{0}_n)$
4 **for** $k = 1$ *to* K **do**
5 $\quad(\gamma^{\mathsf{x}}, \gamma^{\mathsf{y}}) \leftarrow \mathsf{GradBS}(x_{k-1}, y_{k-1}, x_{k-1}, y_{k-1}, 0)$
6 $\quad(x_{k-\frac{1}{2}}, y_{k-\frac{1}{2}}) \leftarrow \mathsf{AltminBS}(\gamma^{\mathsf{x}}, \gamma^{\mathsf{y}}, \alpha, x_{k-1}, y_{k-1})$
7 $\quad(\gamma^{\mathsf{x}}, \gamma^{\mathsf{y}}) \leftarrow \mathsf{GradBS}(x_{k-\frac{1}{2}}, y_{k-\frac{1}{2}}, x_{k-1}, y_{k-1}, \nu)$
8 $\quad(x^{(T+1)}, y^{(T)}) \leftarrow \mathsf{AltminBS}(\gamma^{\mathsf{x}}, \gamma^{\mathsf{y}}, \alpha + \nu, x_{k-\frac{1}{2}}, y_{k-\frac{1}{2}})$
9 $\quad x_k \leftarrow \frac{1}{\left\|\max\left(x^{(T+1)}, \delta\right)\right\|_1} \cdot \max\left(x^{(T+1)}, \delta\right)$, $y_k \leftarrow y^{(T)}$ ▷ Implement padding $\mathcal{O}_\delta(x^{(T+1)})$
10 **function** $\mathsf{GradBS}(x, y, x_0, y_0, \Theta)$
11 $\quad g^{\mathsf{x}} \leftarrow \mathbf{A}y + c + \mu(\mathbf{1} + \log(x)) - \frac{\epsilon}{2}|\mathbf{A}|(y^2)$, $g^{\mathsf{y}} \leftarrow -\mathbf{A}^\top x + b + \epsilon\mathbf{diag}(y)|\mathbf{A}|^\top x$
12 $\quad g_r^{\mathsf{x}} \leftarrow -\alpha\rho(1 + \log x_0) - \frac{\alpha}{\rho}|\mathbf{A}|y_0^2 - \Theta\rho(1 + \log x) - \frac{\Theta}{\rho}|\mathbf{A}|y^2$
13 $\quad g_r^{\mathsf{y}} \leftarrow -\frac{2\alpha}{\rho}\mathbf{diag}(y_0)|\mathbf{A}|^\top x_0 - \frac{2\Theta}{\rho}\mathbf{diag}(y)|\mathbf{A}|^\top x)$
14 $\quad$ **return** $(g^{\mathsf{x}} + g_r^{\mathsf{x}}, g^{\mathsf{y}} + g_r^{\mathsf{y}})$
15 **function** $\mathsf{AltminBS}(\gamma^{\mathsf{x}}, \gamma^{\mathsf{y}}, \theta, x^{(0)}, y^{(0)})$ ▷ Implement approximate proximal oracle via AltMin
16 $\quad$ **for** $0 \leq t \leq T$ **do**
17 $\quad\quad x^{(t+1)} \leftarrow \frac{1}{\left\|\exp\left(-\frac{1}{\theta\rho}\gamma^{\mathsf{x}} - \frac{1}{\rho^2}|\mathbf{A}|\left(y^{(t)}\right)^2\right)\right\|_1} \cdot \exp\left(-\frac{1}{\theta\rho}\gamma^{\mathsf{x}} - \frac{1}{\rho^2}|\mathbf{A}|\left(y^{(t)}\right)^2\right)$
18 $\quad\quad y^{(t+1)} \leftarrow \mathrm{med}\left(0, 1, -\frac{\rho}{2\theta} \cdot \frac{\gamma^{\mathsf{y}}}{|\mathbf{A}|^\top x^{(t+1)}}\right)$
19 $\quad$ **return** $(x^{(T+1)}, y^{(T)})$

In order to analyze the convergence of Algorithm 4, we begin by observing that the operator in (17) satisfies strong monotonicity with respect to our regularizer (18).

▶ **Lemma 20** (Strong monotonicity). *Let $\mu \geq \frac{\epsilon}{2}$ and $\rho := \sqrt{\frac{2\mu}{\epsilon}}$. The gradient operator $g_{\mu,\epsilon}$ (17) is $\nu := \frac{1}{2}\sqrt{\frac{\mu\epsilon}{2}}$-strongly monotone (see (19)) with respect to $r_{\mu,\epsilon}$ defined in (18).*

Next, we show iterate stability through each loop of alternating minimization (i.e. from Line 5 to Line 6, and Line 7 to Line 8 respectively), via Lemma 19.

▶ **Corollary 21** (Iterate stability in Algorithm 4). *Assume the same parameter bounds as Lemma 19, and that $\delta \in (0, m^{-1})$. In the k^{th} outer loop of Algorithm 4, $x_{k-1} \geq \frac{\delta}{2}$ entrywise. Further, for all iterates $x^{(t+1)}$ computed in Line 5 to Line 6 and x_{OPT} as defined in (21) with $\theta = \alpha$, $\frac{1}{2}x_{k-1} \leq x^{(t+1)}, x_{\mathsf{OPT}} \leq 2x_{k-1}$, and $x^{(t+1)}, x_{\mathsf{OPT}} \geq \frac{\delta}{4}$, entrywise. Similarly, for all iterates $x^{(t+1)}$ computed in Line 7 to Line 8 and x_{OPT} as defined in (21) with $\theta = \alpha + \nu$, $\frac{1}{2}x_{k-1/2} \leq x^{(t+1)}, x_{\mathsf{OPT}} \leq 2x_{k-1/2}$ and $x^{(t+1)}, x_{\mathsf{OPT}} \geq \frac{\delta}{4}$, entrywise.*

Under iterate stability, our next step is to prove that our operator $g_{\mu,\epsilon}$ is relatively Lipschitz with respect to our regularizer $r_{\mu,\epsilon}$ (as defined in (20)).

▶ **Lemma 22** (Relative Lipschitzness). *Assume the same parameter bounds as in Lemma 19. In the k^{th} outer loop of Algorithm 4, let $\bar{z}_k \leftarrow (x^{(T+1)}, y^{(T)})$ from Line 8 be z_k before the padding operation. Then, $x_{k-1/2}, \bar{x}_k \in [\frac{1}{2}x_{k-1}, 2x_{k-1}]$ elementwise and*

$$\left\langle g(z_{k-1/2}) - g(z_{k-1}), z_{k-1/2} - \bar{z}_k \right\rangle \leq \alpha \left(V_{z_{k-1}}(z_{k-1/2}) + V_{z_{k-1/2}}(\bar{z}_k) \right) \quad \text{for } \alpha = 4 + 32\sqrt{\frac{\mu\epsilon}{2}}.$$

Next, we give a convergence guarantee on the inner loops (from Line 5 to Line 6, and Line 7 to Line 8) in Algorithm 4, as an immediate consequence of Corollary 15.

▶ **Corollary 23** (Inner loop convergence in Algorithm 4). *Assume the same parameter bounds as in Lemma 19. For γ defined in Line 5, suppose for an appropriate constant $T = \Omega\left(\log \frac{mnB_{\max}\alpha\rho}{\delta\sigma}\right)$. Then, for all k iterate $z_{k-1/2} = (x_{k-1/2}, y_{k-1/2})$ of Line 6 satisfies*

$$\left\langle \nabla g(z_{k-1}) + \alpha \nabla V_{z_{k-1}}(z_{k-1/2}), z_{k-1/2} - w \right\rangle \leq \frac{\nu\sigma}{4}, \text{ for all } w \in \mathcal{Z}.$$

Similarly, for γ defined in Line 7, iterate $\bar{z}_k = (x_{(T+1)}, y_{(T)})$ of Line 8 satisfies

$$\left\langle \nabla g(z_{k-1}) + \alpha \nabla V_{z_{k-1}}(\bar{z}_k) + \nu \nabla V_{z_{k-1/2}}(\bar{z}_k), \bar{z}_k - w \right\rangle \leq \frac{\nu\sigma}{4}, \text{ for all } w \in \mathcal{Z}.$$

We now analyze the progress made by each outer loop of Algorithm 4. The proof is very similar to that of Proposition 13; the only difference is controlling the extra error incurred in the padding step of Line 9, which we bound via Lemma 18.

▶ **Proposition 24** (Convergence of Algorithm 4). *Assume the same parameter bounds as in Lemma 19, and that $\delta \leq \frac{\sigma}{4\rho\alpha m}$. Algorithm 4 returns z_K satisfying $V^r_{z_K}(z^\star) \leq \frac{3\sigma}{\nu}$, letting (for an appropriate constant) $K = \Omega(\frac{\alpha}{\nu}\log(\frac{\nu \log m}{\sigma}))$.*

We are now ready to prove the main theorem of this section, which gives a complete convergence guarantee of Algorithm 4 by combining our previous claims.

▶ **Theorem 25** (Regularized box-simplex solver). *Given regularized box-simplex game (16) with $72\epsilon \leq \mu \leq 1$ and optimizer $(x^\star, y^\star)$, and letting $\sigma \in (m^{-10}, 1)$,* RegularizedBS *(Algorithm 4) returns x^K satisfying $\left\|x^K - x^\star\right\|_1 \leq \frac{\sigma}{C_{\max}\log^2 m}$ and $\max_{y\in[0,1]^n} f_{\mu,\epsilon}(x^K, y) - f_{\mu,\epsilon}(x^\star, y^\star) \leq \sigma$. The total runtime of the algorithm is $O(\text{nnz}(\mathbf{A}) \cdot (\frac{C_{\max}}{\sqrt{\mu\epsilon}} + \log(\frac{m}{\sigma\epsilon})) \cdot \log(\frac{C_{\max}\log m}{\sigma}) \log(\frac{mnB_{\max}}{\sigma}))$.*

As a corollary, we obtain an approximate solver for regularized box-simplex games in the following form (which in particular does not include a quadratic regularizer):

$$\min_{x\in\Delta^m} \max_{y\in[0,1]^n} f_\mu(x,y) = y^\top \mathbf{A}^\top x + c^\top x - b^\top y + \mu H(x), \text{ where } H(x) := \sum_{i\in[m]} x_i \log x_i. \quad (24)$$

▶ **Corollary 26** (Half-regularized approximate solver). *Given regularized box-simplex game (24) with regularization parameters $72\epsilon \leq \mu \leq 1$ and optimizer $(x^\star, y^\star)$, and letting $\epsilon \in (m^{-10}, 1)$, Algorithm 4 with $\sigma \leftarrow \frac{\epsilon}{2}$ returns x^K satisfying $\max_{y\in[0,1]^n} f_\mu(x^K, y) - f_\mu(x^\star, y^\star) \leq \epsilon$. The total runtime of the algorithm is $O\left(\text{nnz}(\mathbf{A}) \cdot (\frac{C_{\max}}{\sqrt{\mu\epsilon}} + \log\left(\frac{m}{\epsilon}\right)) \cdot \log\left(\frac{C_{\max}\log m}{\epsilon}\right) \log\left(\frac{mnB_{\max}}{\epsilon}\right)\right)$.*

Abstract

We study the d-dimensional hypercube knapsack problem (d-D Hc-Knapsack) where we are given a set of d-dimensional hypercubes with associated profits, and a knapsack which is a unit d-dimensional hypercube. The goal is to find an axis-aligned non-overlapping packing of a subset of hypercubes such that the profit of the packed hypercubes is maximized. For this problem, Harren (ICALP'06) gave an algorithm with an approximation ratio of $(1 + 1/2^d + \varepsilon)$. For $d = 2$, Jansen and Solis-Oba (IPCO'08) showed that the problem admits a polynomial-time approximation scheme (PTAS); Heydrich and Wiese (SODA'17) further improved the running time and gave an efficient polynomial-time approximation scheme (EPTAS). Both the results use structural properties of 2-D packing, which do not generalize to higher dimensions. For $d > 2$, it remains open to obtain a PTAS, and in fact, there has been no improvement since Harren's result.

We settle the problem by providing a PTAS. Our main technical contribution is a structural lemma which shows that any packing of hypercubes can be converted into another *structured* packing such that a high profitable subset of hypercubes is packed into a constant number of *special* hypercuboids, called $\mathcal{V}$-Boxes and $\mathcal{N}$-Boxes. As a side result, we give an almost optimal algorithm for a variant of the strip packing problem in higher dimensions. This might have applications for other multidimensional geometric packing problems.

1 Introduction

Multidimensional geometric packing problems are well-studied natural generalizations of the classical knapsack and bin packing problems. In the d-dimensional geometric knapsack problem (d-D Gen-Knapsack), where d is a fixed constant parameter, we are given a set of n items $\mathcal{I} := \{1, 2, \ldots, n\}$. Each item $i \in [n]$ is a d-dimensional (d-D) hypercuboid with

side length $s_k(i) \in (0, 1]$ along the k^{th} dimension and profit $p(i) \in \mathbb{Q}_{>0}$. The goal is to pack a subset of hypercuboids into a d-D unit knapsack (i.e., $[0, 1]^d$) such that the profit is maximized. We need the packing of the hypercuboids to be axis-aligned and non-overlapping. In this paper, we study d-dimensional hypercube knapsack (d-D Hc-Knapsack), a special case of d-D Gen-Knapsack, where all the items are hypercubes, i.e., for all $i \in [n]$, the i^{th} hypercuboid is a hypercube of side length $s(i)$.

d-D Gen-Knapsack generalizes the classical (1-D) knapsack problem [35] and thus is NP-hard. It finds numerous applications in scheduling, ad placement, and cutting stock [18]. For 2-D Gen-Knapsack, Jansen and Zhang [27] gave a $(2 + \varepsilon)$-approximation algorithm. Gálvez et al. [18] gave a 1.89-approximation and $(3/2 + \varepsilon)$-approximation for the cardinality version (i.e., all items have the same profit). Adamaszek and Wiese [3] gave a QPTAS when the input size is quasi-polynomially bounded. Gálvez et al. [19] later gave a pseudo-polynomial time $(4/3 + \varepsilon)$-approximation. For 3-D Gen-Knapsack, the present best approximation ratio is $7 + \varepsilon$ [14]. For $d \geq 4$, Sharma [41] has given a $(1 + \varepsilon)3^d$-approximation algorithm. Interestingly for $d \geq 2$, unlike d-D Gen-Knapsack, d-D Hc-Knapsack is not a generalization of 1-D knapsack. Leung et al. [36] showed 2-D Hc-Knapsack is strongly NP-hard, using a reduction from the 3-partition problem. The NP-hardness status of d-D Hc-Knapsack for $d > 2$, was open for a long time. Recently, Lu et al. [37, 38] settled the status by showing that d-D Hc-Knapsack is also NP-hard for $d > 2$.

A related problem is d-D Hc-Binpacking where we are given d-D hypercubes and the goal is to pack them into the minimum number of unit hypercubes. Back in 2006, Bansal et al. [5] gave an APTAS for this problem. Their algorithm starts by classifying the input set into small, medium, and large items. They first pack the large items ($O(1)$ in number) near-optimally by brute force and then pack the small items using Next Fit Decreasing Height (NFDH) [11] in the gaps left in between the large items. The remaining unpacked (small and medium) items are packed into additional bins using NFDH. However, this constructive approach can not be used to devise a PTAS for d-D Hc-Knapsack. Specifically, after packing the large items, the total space left to pack the small items can be very small and this space can be fragmented among several voids in between the large items. This renders packing the small items difficult, especially if the small items occupy a small volume in the optimal solution and carry a lot of profit. This turns out to be a bottleneck case. Otherwise, if the volume of small items in an optimal solution is significant, or if their profit is not significant, or if the empty space in the optimal solution is significant, we can easily devise a PTAS. In fact, the algorithm in [5] can be adapted to devise PTASes for the special cases of d-D Hc-Knapsack: (i) cardinality case, and (ii) when each item has the profit:volume ratio in the range $[1, r]$ for a fixed constant r. However, the case of arbitrary profits remains very difficult to handle.

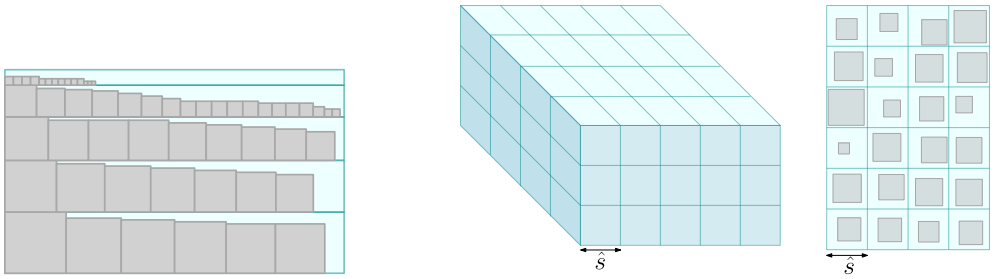
For d-D Hc-Knapsack, Harren [21] gave a $(1 + 1/2^d + \varepsilon)$-approximation algorithm, by removing a least profitable large item and using the empty space to pack the small items. Interestingly, the approximation ratio gets smaller as d grows. He also studied d-D Hc-StripPacking, where, given a set of hypercubes and a strip with a $(d - 1)$-dimensional base and unbounded height, the goal is to pack all the hypercubes while minimizing the height. He gave an APTAS for the special case of d-D Hc-StripPacking when the ratio between the shortest and longest sides of the base is bounded by a constant.

Jansen and Solis-Oba [26] gave a PTAS for 2-D Hc-Knapsack, by overcoming the above-mentioned bottleneck. They consider an optimal packing and categorize the packed items into *small, medium,* and *large* items. Then, by extending the edges of the large items, the remaining space is divided into $O(1)$ number of rectilinear regions, where each region

is classified as either *large* or *elongated* or *small*, based on the largest item intersecting or completely contained in it. Then, to make sure that a region has no items partially intersecting it, they repack all the items as follows. The *large* region is rectangular and its dimensions are much larger compared to the largest item intersecting it. Here NFDH can repack a high profitable subset of the items. An *elongated* region is again rectangular and it has one dimension much longer than the other. Here an algorithm for strip packing [28] is used to repack the items. Finally, the *small* regions are handled by applying the above transformations recursively as they can have complicated shapes (they may not be rectangular). Recently, Heydrich and Wiese [23] gave an EPTAS, effectively achieving the best-possible approximation. However, a PTAS for d-D Hc-Knapsack for $d > 2$ remains elusive as it is difficult to find such transformations for higher dimensions. Even for 3-D, the best-known approximation ratio remains $9/8$ [21]. In 2-D, many structural theorems [4, 18] show that a near-optimal solution exists where all items are packed into $O(1)$-number of rectangular regions where items are either packed as a stack or packed using NFDH. But these results do not generalize to higher dimensions. E.g., while extending the approach of *large* and *elongated* blocks of [26] to $d > 2$, we may not obtain a near-optimal structure packed in d-D hypercuboids; rather, we might obtain complicated rectilinear regions. However, prior to our work, there exist no algorithms which considered packing in such rectilinear regions.

1.1 Our Contributions

For the d-D Hc-Knapsack problem, we design a PTAS, thus settling the problem. Our main structural result intuitively says that any packing, by incurring a loss of only ε-fraction of the profit, can be transformed into $O(1)$ number of special hypercuboidal regions such that each region either contains a single large item, or contains items very small compared to its dimensions ($\mathcal{V}$-Box, see Figure 1a), or contains items placed along a multidimensional grid ($\mathcal{N}$-Box, see Figure 1b). We then provide an algorithm that guesses the arrangement of these hypercuboids and uses results of [26, 35] to find a near-optimal packing of items in these special boxes.



(a) An $\mathcal{V}$-Box is just a huge cuboid when compared to its size parameter $\hat{s}$. Each item has side length at most $\hat{s}$ and the item set assigned to it can be packed by NFDH.

(b) An $\mathcal{N}$-Box is a multidimensional grid. An item set assigned to an $\mathcal{N}$-Box can be packed by placing each item in a cell.

Figure 1 $\mathcal{V}$-Box and $\mathcal{N}$-Box.

For our structural theorem, we start with an optimal solution. First, we divide the items in the optimal packing into large, medium, and small items such that the medium items have a tiny profit and can be discarded. Then, by extending the facets of the large items, we create a non-uniform grid with $O(1)$ hypercuboidal cells. However, some items may intersect the facets of these cells. We consider the facets of all the cells and identify (based on the intersecting items) each of the facets as either *good* or *bad*. Intuitively, if we only have good facets then we can repack items so that no items intersect the facets. To get rid of the bad

facets, we merge some cells so that they form composite cells, which we call *collections* (See Figure 2). Now we need to repack the items in the *collections* which may have complex rectilinear shapes. If the collection has $k \in \{0, 1, \ldots, d\}$ long dimensions then we call it a k-elongated collection. Note that we can have $d + 1$ types of collections.

Our structural theorem can be viewed as a generalization of [26, 21]; however, due to the complicated shape of collections, we had to overcome several technical obstacles in the process. For simplicity, we explain the intuition for $d = 3$, where we obtain a packing of items into four types of rectilinear regions (collections) as in Figure 2.

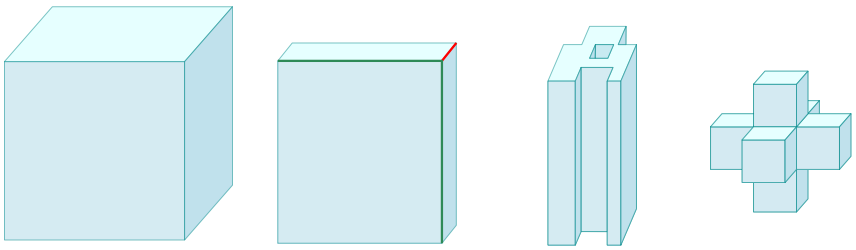


Figure 2 Repacking items inside the left-most collection is easy (using NFDH). The right-most collections are handled recursively. However, repacking the items in the other two collections is challenging (we needed a novel strip packing algorithm).

The first collection (3-elongated) is a $\mathcal{V}$-Box, i.e., all its three dimensions are long compared to the largest item packed in it. The simple NFDH algorithm suffices to repack the items inside it while losing only a few items with a small profit. Although repacking in large collections can be easily handled by NFDH, there exist no previous algorithms to repack items in the remaining types of collections. Now for $k \in [d-1]$, collections are long in at least one dimension and thus can be viewed as a type of strip (though the base may not be rectangular). Harren [21] showed how to repack items almost optimally in a d-dimensional strip with a rectangular base with a bounded aspect ratio. However, their approach doesn't trivially extend to the 1- and 2-elongated collections in Figure 2, as the base can be non-rectangular or it may not satisfy the property of bounded aspect ratio even though it is rectangular. In this paper, we circumvent this bottleneck by designing a PTAS (under resource augmentation) for d-dimensional strip packing to pack items on such complicated bases. Now we explain how we use the strip packing algorithm to pack these collections.

In the second collection (2-elongated), one dimension (marked in red) is reasonably short compared to the largest item intersecting it and the other dimensions (in green) are long. We first divide the items in the collection into large, medium, and small items and ensure that the total volume of medium items is marginal. We then consider the large items and round their sizes to up to $O(1)$ types using linear grouping [28]. The number of (rounded) large items that can fit on along the short dimension is $O(1)$. So, similar to [28], we solve an LP that represents the fractional strip packing with (rounded) large items where the items are allowed to be sliced along the long dimensions. We then convert this into an integral packing of large items using resource augmentation along the long dimensions. Then we pack as many small items as possible in the gaps left. The rest of the small items, together with the medium items, are packed on the top.

The third collection (1-elongated), though complicated, is ensured (by our construction) to have a base with a bounded aspect ratio[1]. Moreover, it can be viewed as a union of $O(1)$ number of smaller disjoint rectangles (which we call *base cells*). We again classify each item

[1] More accurately, the minimal cuboid, which completely contains the base, has bounded-aspect ratio.

in this collection as large, medium, or small. As above, we round the large items to $O(1)$ types. Note that the number of large items that can fit on the base of the strip is only a constant (due to the bounded aspect ratio). We pack them integrally by first solving the fractional LP where items are allowed to be sliced along the long dimension. Our main novelty, in this case, is the way in which we pack the small items on the top of the strip. Unlike [21], we can't use NFDH directly to pack the small items as the base isn't rectangular. Instead, we first merge a few base cells to form a larger base cell which is rectangular (we show that this is indeed possible) and is large enough to accommodate the largest item (and thus any item). Now, having at least one large base cell, we distribute the small and medium items among all the base cells so that when they are packed using NFDH in strips on these base cells, the maximum height is minimized. Observe that if we pack the items on a single base cell, we may not efficiently use the entire area of the base and this can lead to a very tall strip. Thus this process of distributing the items among all the base cells is important.

We use our near-optimal strip packing algorithm on these 1- or 2-elongated collections to repack the items while losing only a small profit. Interestingly, the strip packing algorithm for both kinds of bases (in general, for any k-elongated collection where $k \in [d-1]$) is the same; the only change is the number of short dimensions of the base that is given as a parameter to the algorithm. We provide the algorithm for d-dimensional strip packing in the full version [24].

Finally, for 0-elongated collections, we apply the above process recursively. Using a shifting argumentation, we show that $O_\varepsilon(1)$ steps of recursion is sufficient. We also show that the resulting packing is a packing into $O(1)$ number of $\mathcal{V}$-Boxes and $\mathcal{N}$-Boxes. With more technical ingenuity, these ideas can be extended to the case of $d > 3$.

We believe that our techniques will be helpful for other multidimensional geometric packing problems involving rectilinear regions that are not hypercuboids.

1.2 Related Work

For geometric bin packing, Caprara gave a 1.691^{d-1} asymptotic approximation [9]. For $d = 2$, it admits no APTAS [5] and there is a 1.406-approximation algorithm [7]. There are several other variants of bin packing such as vector packing [6, 40], strip packing [22, 16, 25], sliced packing [13, 17], mixed packing [34], etc. The knapsack problem is also studied under several generalizations such as vector knapsack [15], fair knapsack [39], and mixed knapsack [33]. Packing problems are also well-studied under guillotine cut constraints [8, 30, 31, 1, 32]. Guillotine cut also has interesting connections with the maximum independent set of rectangles problem [2, 20]. We refer the readers to [10, 29] for a survey on multidimensional packing.

1.3 Overview of the Paper

In Section 2, we present some preliminaries. Section 3 contains the result for d-D Hc-Knapsack. The result for strip packing, which will be used as a subroutine to obtain our main structural result is given in Section 3.1.2. Due to space limitations, many proofs had to be moved to the full version [24].

2 Notations and Preliminaries

Let $[n] := \{1, 2, \ldots, n\}$. For any set of items $\mathcal{I}$, we define $\hat{s}(\mathcal{I}) := \max_{i \in \mathcal{I}} s(i)$. For any k-dimensional region R, we denote its volume by $\mathrm{VOL}_k(R)$. We extend this notation to an item i or a set of items $\mathcal{I}$, i.e., $\mathrm{VOL}_d(i) = (s(i))^d$, and $\mathrm{VOL}_d(\mathcal{I}) = \sum_{i \in \mathcal{I}} \mathrm{VOL}_d(i)$. Also, the profit of a packing is the sum of the profits of the packed items $\mathcal{Q}$: $p(\mathcal{Q}) := \sum_{i \in \mathcal{Q}} p(i)$.

Consider a set of points X in $[0,1]^d$ where each point $x \in X$ can be represented as $(x_1, x_2, \ldots, x_d)$. For any set of dimensions $\mathcal{D} \subseteq [d]$, we define the projection of X onto $\mathcal{D}$ as the set $\left\{ \left(x_{d_1}, \ldots, x_{d_{|\mathcal{D}|}}\right) \mid (x_1, \ldots, x_k) \in X \right\}$, where $\left\{ d_1, \ldots, d_{|\mathcal{D}|} \right\} = \mathcal{D}$ and $d_i < d_{i+1}$ for all $i \in [|\mathcal{D}| - 1]$.

We only consider axis-aligned packing of hypercuboids and hypercubes. Thus, a d-D hypercuboid C is given by the position of its lower corner $(x_1, \ldots, x_d) \in \mathbb{R}^d$ and side lengths $\ell_1, \ldots, \ell_d \in \mathbb{R}_+$. Then, C is the cartesian product of the intervals $\prod_{i=1}^{d} [x_i, x_i + \ell_i]$, and $\mathrm{VOL}_d(C) := \prod_{i=1}^{d} \ell_i$ and its surface area is defined as the sum of the volumes of its $(d-1)$-dimensional facets, i.e., $\mathrm{SURF}_d(C) := 2\sum_{i=1}^{d} \prod_{j=1, j\neq i}^{d} \ell_j = 2\sum_{i=1}^{d} \mathrm{VOL}_d(C)/\ell_i$. A packing is a subset $\mathcal{Q} \subseteq \mathcal{I}$ of items with positions $\mathrm{pos} : \mathcal{Q} \longrightarrow [0,1]^d$. It is valid, if each item $i \in \mathcal{Q}$ with the lower corner positioned at $\mathrm{pos}(i)$ is completely included in the unit hypercube $[0,1]^d$ and each pair of items $i, j \in \mathcal{Q}$ is positioned non-overlapping.

Consider a set of items lying in d dimensional space. For any region in the d dimensional space, we define the profit of that region as the profit of the set of items *completely* contained in that region.

We will use the higher dimensional variant of the well-known Next Fit Decreasing Height (NFDH) algorithm extensively. For the sake of completeness, we will provide a brief description of the algorithm here.

NFDH is a two dimensional packing algorithm introduced in [11] for packing a given set of rectangles in a bigger rectangular region $\mathcal{R}$. Informally, it works as follows. First, it sorts the given set of rectangles in decreasing order of heights (the vertical dimension). Then, it starts off by packing the rectangles on the base of $\mathcal{R}$ side-by-side as much as possible. Then, this level is closed, i.e., the base of $\mathcal{R}$ is shifted vertically to the top of the first rectangle packed. In the next step, the remaining rectangles are packed on the new base to whatever extent is possible. This process continues.

One can easily extend the NFDH algorithm to pack hypercuboids into a bigger hypercuboidal region. Let $k \in \mathbb{N}_{\geq 2}$. For any k-dimensional hypercuboid x, let $x^{(i)}$ denote the i-dimensional hypercuboid obtained by considering only the first i dimensions of x. We can extend this notation to sets: Let J be a set of k-dimensional hypercuboids. Then $J^{(i)} = \{x^{(i)} | x \in J\}$.

We define the NFDH algorithm in k dimensions (k-NFDH) recursively as follows. If $k = 2$, then the algorithm is simply NFDH as described above. Suppose $k > 2$. Let S be a set of k-dimensional hypercuboids to be packed into a k-dimensional hypercuboidal region $\mathcal{R}$. We first sort the rectangles in decreasing order of their lengths in the k^{th} dimension. Then we pick the largest possible prefix P of S such that $P^{(k-1)}$ can be completely packed on the base of $\mathcal{R}$ using $(k-1)$-NFDH. We pack P on the base of $\mathcal{R}$, and shift the base to the top of the tallest (longest in the k^{th} dimension) item in P. We repeat this process with $S \backslash P$.

The pseudocode of k-NFDH and some illustrations have been provided in the full version [24]. We will abbreviate k-NFDH by just NFDH. The value of k will be clear from the context. Harren [21] gave a surface area based efficiency guarantee of NFDH algorithm for hypercubes.

▶ **Lemma 1** ([21]). *Consider a set S of hypercubes with side lengths at most δ and a hypercuboid C. The NFDH algorithm either packs all items from S into C or the total volume left free inside of C is at most $\delta\, \mathrm{SURF}_d(C)/2$.*

Now we define $\mathcal{V}$-Box and $\mathcal{N}$-Box.

▶ **Definition 2** ($\mathcal{V}$-Box and $\mathcal{N}$-Box). *Let B be a d-dimensional hypercuboid, $\mathcal{Q}$ be a set of items packed in it, and let $\hat{s}$ be an upper bound on the side lengths of the items in $\mathcal{Q}$. We say that B is a $\mathcal{V}$-Box if its side lengths can be written as $n_1\hat{s}, n_2\hat{s}, \ldots, n_d\hat{s}$ where $n_1, n_2, \ldots, n_d \in \mathbb{N}_+$*

and the volume of the packed items is at most $\mathrm{VOL}_d(B) - \hat{s}\frac{\mathrm{SURF}_d(B)}{2}$. *We say that* B *is an* $\mathcal{N}$*-Box if its side lengths can be written as* $n_1\hat{s}, n_2\hat{s}, \ldots, n_d\hat{s}$ *where* $n_1, n_2, \ldots, n_d \in \mathbb{N}_+$ *and the number of packed items is at most* $\prod_{i=1}^{d} n_i$.

As the side lengths are integral multiples of $\hat{s}$, the number of distinct $\mathcal{V}$-Boxes and $\mathcal{N}$-Boxes in the near-optimal structure will be polynomially bounded. The following corollary follows from Lemma 1.

▶ **Corollary 3.** *Let* B *be a* $\mathcal{V}$*-Box with the item set* $\mathcal{Q}$ *packed in it. Then these items can be repacked into* B *using NFDH.*

Proof. We can either pack all the items in $\mathcal{I}$ into B using NFDH, or, by Lemma 1, the free volume inside of B is at most $\hat{s}\,\mathrm{SURF}_d(B)/2$. The latter possibility however implies that we packed items with a volume of at least $\mathrm{VOL}_d(B) - \hat{s}\,\mathrm{SURF}_d(B)/2$, which is an upper bound on $\mathrm{VOL}_d(\mathcal{I})$ by the definition of a $\mathcal{V}$-Box. ◀

▶ **Observation 4.** *Let* B *be an* $\mathcal{N}$*-Box with the item set* $\mathcal{Q}$ *packed in it. As* $|\mathcal{Q}| \leq \prod_{i=1}^{d} n_i$, *we can divide* B *into* $\prod_{i=1}^{d} n_i$ *cells such that each cell has length* $\hat{s}$ *in each of the* d *dimensions and we can place each item in* $\mathcal{Q}$ *in one cell.*

In this paper, we will often require that a set of hypercuboidal regions forms a grid.

▶ **Definition 5.** *A* d-dimensional grid *(see Figure 3(a)) C is a subset of the set of hypercuboids* $\left\{ \prod_{i=1}^{d} [g_{i,j_i-1}\ ,\ g_{i,j_i}] \;\middle|\; 1 \leq j_i \leq n_i \text{ for all } i \in [d] \right\}$, *where each* $n_i \in \mathbb{N}_+$ *denotes the number of grid layers in the* i^{th} *dimension, and* $g_{i,0} < \cdots < g_{i,n_i}$ *for all* $i \in [d]$ *are the grid boundaries. Each hypercuboid in C is called a* cell.

Each grid C has $|C| \leq \prod_{i=1}^{d} n_i$ cells. A grid C can also be refined by splitting some cells.

▶ **Lemma 6.** *Let* C *be a* d*-D grid with* $n_1, \ldots, n_d \in \mathbb{N}_+$ *layers and boundaries* $g_{i,j} \in \mathbb{R}$ *for* $i \in [d]$ *and* $j \in [n_i]$. *Let* R *be a set of* d*-D hypercuboids. Then the region of the grid which is not intersected by* R *is a new grid with* $n'_i \leq n_i + 2|R|$ *layers in each dimension* $i \in [d]$.

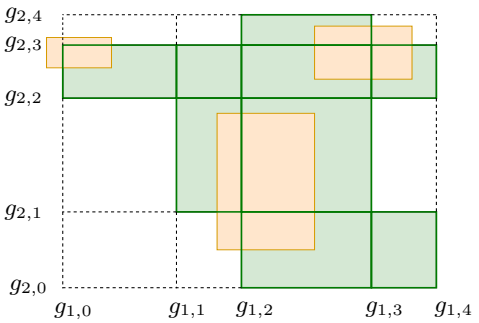
Proof. Each hypercuboid in R is the cartesian product of d intervals $\prod_{i=1}^{d} [a_i, b_i]$. The grid C can now be refined by adding the boundaries a_i and b_i in each dimension i. This increases the number of layers in each dimension by at most $2|R|$. After this refinement, each cell is either completely contained in a hypercuboid in R, and hence discarded from C, or does not intersect R. This can be seen in Figure 3(b). ◀

3 Knapsack

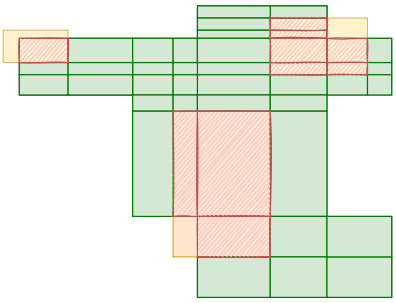
In this section, we will devise a PTAS for the d-D Hc-Knapsack problem.

3.1 Structure of a Nearly Optimal Solution

First, we prove that given an optimal packing $\mathrm{OPT}_{\text{knapsack}}(\mathcal{I})$ of the input set $\mathcal{I}$, there exists another packing containing a subset of the items packed in a simple structure which can be searched for, in polynomial time. For this, we modify the optimal packing to obtain a near-optimal packing in which all the items are packed into either $\mathcal{V}$-Boxes and $\mathcal{N}$-Boxes except for a constant number of large items. The total number of these boxes is $\mathcal{O}(1)$ and their sizes come from a set whose cardinality is polynomial in $|\mathcal{I}|$. Hence, this near-optimal packing can be searched for, in polynomial time.



(a) 3 orange rectangles partially covering a grid with 4 layers in each dimension.The dotted lines indicate the grid boundaries and the grid cells are indicated by the green rectangles.



(b) Refined grid with ≤ 10 layers in each dimension. The new grid cells are indicated in green. The shaded cells are those discarded from the refined grid as they overlap with the items.

Figure 3 Splitting the empty space inside of a grid.

▶ **Theorem 7.** *For each $0 < \varepsilon < 1/2^{d+2}$, there is a packing with the following properties:*

(i) *It consists of $\mathcal{N}$-Boxes and $\mathcal{V}$-Boxes whose total number is bounded by a constant $C_{\text{boxes}}(d, \varepsilon)$, which depends only on ε and d.*

(ii) *The number of items in the packing that are not packed in these boxes is bounded by a constant $C_{\text{large}}(d, \varepsilon)$, which depends only on ε and d.*

(iii) *The profit of the packing is at least $\left(1 - 2^{d+2}\varepsilon\right) \text{OPT}_{\text{knapsack}}(\mathcal{I})$.*

To prove the theorem, first, in Section 3.1.1, we consider a packing in an arbitrary grid (note that the knapsack can be viewed as a grid containing a single cell) and merge some of its cells into collections based on the packing of the items into the grid. The reason for choosing an arbitrary grid is that, as we will see, we recursively divide the knapsack into grids (which can have arbitrary shapes) and consider each of them separately. Then in Section 3.1.3, we show how to repack the items in a collection using NFDH or by a strip packing algorithm described in Section 3.1.2.

3.1.1 Partitioning a Grid into Collections

Consider a grid and a set of items $\mathcal{J}$ packed into it. Assume that the grid has at most N_{layer} layers in each dimension. Thus, it consists of at most $N := N_{\text{layer}}^d$ cells. Our goal is to repack (a subset of) $\mathcal{J}$ to obtain a simpler structure, by losing only a small profit. The overall grid can have a complex structure, so we consider each cell (a hypercuboid) and repack the items in the cell. However, it might be problematic to repack the items that intersect a cell only partially. Consider one such item and one of the cells it intersects. There must be a facet of this cell that cuts into this item. If this facet is orthogonal to a long dimension of the cell, then we can remove a strip of small profit and pack these intersecting items in that strip. However, an issue arises when this facet is orthogonal to a short dimension. Therefore, we merge the two cells that share this facet. Doing this iteratively, we merge some cells into a *collection of cells* or simply *collection*. See left of Figure 4.

For a cell a, we will denote the side length of the largest item of $\mathcal{J}$ partially or fully packed in it by $\hat{s}(a)$ and we denote the side lengths of the cell by $a_1, \ldots, a_d$. Furthermore, we sort the dimensions using a stable sorting algorithm [2], such that the side lengths of a

[2] A stable sorting makes the order unambiguous. This simplifies some proofs that compare the orders for different collections.

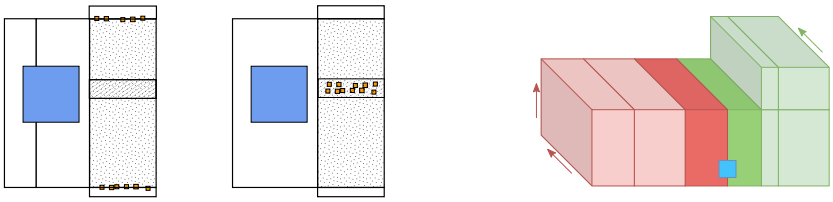


Figure 4 *(i)* The left figure shows five cells of a grid in the two-dimensional case. The orange items are small compared to the height of one of the cells (shaded with dots) they intersect. So, we transfer them to the interior of that cell by removing a least profitable strip (shaded in stripes). However, the blue item cannot fit in any of the cells it intersects, so we merge both these cells. *(ii)* The right figure demonstrates merging. An item (blue) intersects a bad facet between a 2-elongated collection (red) and a 1-elongated collection (green). After merging, we obtain a single 1-elongated collection.

in those dimensions are in non-increasing order. We will refer to that order as σ_a and thus, $a_{\sigma_a(i)}$ is the i^{th} largest side length of a. We start by defining the values which we will use to distinguish between long and short sides of a cell as

$$\alpha_d := \frac{2d}{\varepsilon}, \text{ and } \alpha_k := \frac{2}{\varepsilon}\left(C_{\text{configs}}\left(d, k, \alpha_{k+1}, N, \varepsilon\right) + 3\right) \text{ for all } k \in [d-1] \tag{1}$$

The parameter $C_{\text{configs}}\left(d, k, \alpha_{k+1}, N, \varepsilon\right)$ is a constant depending on $d, k, \alpha_{k+1}, N, \varepsilon$. Its exact value is derived in the full version [24], but for our purposes, it suffices to note that for all $k \in [d-1]$, $C_{\text{configs}}\left(d, k, \alpha_{k+1}, N, \varepsilon\right) \geq 1$ and its value gets larger when k gets smaller. Hence, $1 < 2d/\varepsilon = \alpha_d < \ldots < \alpha_1$.

Now we can define a cell a to be k-elongated for $0 \leq k \leq d$ iff k of its side lengths are long compared to some size parameter s.

▶ **Definition 8.** *A cell a is k-elongated for $k \in [0, d]$ and size parameter $s > 0$ iff*

(i) $a_{\sigma_a(i)} > \alpha_k s$ *for all* $1 \leq i \leq k$ *and*

(ii) $a_{\sigma_a(i)} \leq \alpha_i s$ *for all* $k < i \leq d$.

If a is a k-elongated cell, then for any $i \in [k]$ we call $\sigma_a(i)$ to be a *long* dimension of a and the other dimensions to be *short*. Note that for each size parameter, each cell is k-elongated for exactly one value of k. A facet of a k-elongated cell is called *good* if it is orthogonal to a long dimension and *bad* otherwise. We will see that the items that intersect only the good facets of a cell don't cause much of an issue; the complicated machinery that we devise is to deal with the items intersecting the bad facets.

For a group of cells to be merged into a collection, they should satisfy some additional properties. We define a *k-elongated collection* C as a set of cells that are k-elongated using the size of the largest item completely or partially packed in that collection as a common size parameter and are aligned in their long dimensions. More formally,

▶ **Definition 9.** *A set of cells C is a k-elongated collection if*

(i) *each cell $a \in C$ is k-elongated for the size parameter $\hat{s}(C) := \max_{c \in C}(\hat{s}(c))$,*

(ii) $\sigma_a(i) = \sigma_b(i)$ *for all* $1 \leq i \leq k$ *and all* $a, b \in C$ *and*

(iii) *the projection of a and b onto the dimension $\sigma_a(i)$ is the same for all $1 \leq i \leq k$ and all $a, b \in C$.*

(iv) *The set of cells form a path-connected region.*

By properties (i) and (ii) of a k-elongated collection, we can define the k dimensions that are long for any cell of the collection to be the long dimensions of the collection itself. Property (iii) strictly limits the arrangement of the cells in long dimensions. Thus, a larger k makes

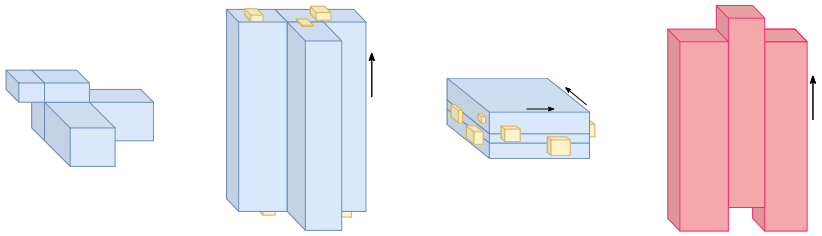

Figure 5 Different collections in 3-D with some items intersecting good facets. The arrow marks indicate the long dimensions. From left to right: 0-, 1-, 2-elongated collections, and a non-example of a collection (violates property (iii).)

the shape of the whole collection less complex (See Figure 5). A common facet between two cells $a \in C$ and $b \in D$ of two different collections C and D is called an outer facet for each of those collections. For each dimension, each cell has two facets that are orthogonal to this dimension. The facet with the lower coordinate in this dimension is called the bottom facet and the other one is called the top facet. For each long dimension of a collection the *bottom facet of the collection* is formed by the union of the bottom facets of its cells; the *top facet of the collection* is formed by the top facets of its cells.

Initially, we consider each cell of our grid as a collection containing only itself. Whenever there is an item intersecting an outer facet between two collections C and D, we will merge those collections if that facet is bad (i.e. orthogonal to a short dimension) for both of them. Such a case is visualized on the right of Figure 4. The next lemma proves that merging collections in this case will create a new collection.

▶ **Lemma 10.** *Let C be a k_C-elongated collection and let D be a k_D-elongated collection. Let $a \in C$ and $b \in D$ be two cells that have a common facet which is bad for both of them. Then $C \cup D$ is a $\min(k_C, k_D)$-elongated collection.*

Proof. Note that both k_C, k_D are strictly less than d since a, b share a common facet f which is bad for both. W.l.o.g., we will assume that $\hat{s}(C) \geq \hat{s}(D)$. Let f has side lengths $f_1, \ldots, f_d$ where f_i denotes the length in the i^{th} dimension (for simplicity, we assume f is a d-dimensional hypercuboid with a side of zero length). Note that the facet f has the same side lengths as a and b in any dimension except the dimension in which it has zero length. This implies that a and b are of almost the same shape. In the dimension orthogonal to f, both a and b have a rather short length, as f is a bad facet for both collections. Using these arguments, we can derive the following properties:

- **(i)** $a_{\sigma_f(i)} = f_{\sigma_f(i)} = b_{\sigma_f(i)}$ for all $1 \leq i \leq d-1$ (Since f is common to both a, b)
- **(ii)** $\sigma_f(i) = \sigma_a(i)$ for all $1 \leq i \leq k_C$ (Since f is bad for a which is a k_C-elongated cell)
- **(iii)** $\sigma_f(i) \in \{\sigma_a(i), \sigma_a(i+1)\}$ for all $k_C < i < d$ (explained below)
- **(iv)** $\sigma_f(i) = \sigma_b(i)$ for all $1 \leq i \leq k_D$
- **(v)** $\sigma_f(i) \in \{\sigma_b(i), \sigma_b(i+1)\}$ for all $k_D < i < d$

The property (iii) above is due to the fact that a and f have the same lengths in all dimensions except one, say $d_\perp$. So, the order of dimensions $\sigma_a(1), \sigma_a(2), \ldots, \sigma_a(d)$ can be obtained by inserting $d_\perp$ in the list $\sigma_f(1), \sigma_f(2), \ldots, \sigma_f(d-1)$ at the appropriate index but we know that this index lies after k_C since $d_\perp$ is short for a.

If we assume $k_C > k_D$, we obtain the inequality $f_{\sigma_f(k_C)} = a_{\sigma_a(k_C)} > \alpha_{k_C} \hat{s}(C)$ by (i), (ii) and Definition 8 of the k_C-elongated cell a. We also obtain the contradictory inequality $f_{\sigma_f(k_C)} = b_{\sigma_f(k_C)} \leq b_{\sigma_b(k_C)} \leq \alpha_{k_C} \hat{s}(D) \leq \alpha_{k_C} \hat{s}(C)$ by (i), (iv) and (v) and Definition 8 of the k_D-elongated cell b. Thus, our choice $\hat{s}(C) \geq \hat{s}(D)$ determines that $k_C \leq k_D$.

As $\hat{s}(C \cup D) = \hat{s}(C)$ and C is a k_C-elongated collection, we know that $C \cup D$ fulfills property (i) of Definition 9 for a k_C-elongated collection for every $a' \in C$. Let $b' \in D$. We have to show that b' is a k_C-elongated cell using the size parameter $\hat{s}(C)$ as well. For every $1 \leq i \leq k_C$ we can use Definition 9 of the k_D-elongated collection D and (i), (iv) and (ii) to prove $b'_{\sigma_{b'}(i)} = b_{\sigma_b(i)} = f_{\sigma_f(i)} = a_{\sigma_a(i)} > \alpha_{k_C}\hat{s}(C)$. For every $k_C < i \leq k_D$ we can again use Definition 9 of the collection D and properties (i), (iv) and (iii) to prove $b'_{\sigma_{b'}(i)} = b_{\sigma_b(i)} = f_{\sigma_f(i)} \leq a_{\sigma_a(i)} \leq \alpha_i\hat{s}(C)$. For every $k_D < i \leq d$ we already know that $b'_{\sigma_{b'}(i)} \leq \alpha_i\hat{s}(D) \leq \alpha_i\hat{s}(C)$ because of Definition 8 for the k_D-elongated cell b'. Thus, b' is a k_C-elongated cell using the size parameter $\hat{s}(C)$.

Now we only need to prove properties (ii) and (iii) of Definition 9 for every pair of cells in $C \cup D$ to show that it is a collection. For a pair $a', a'' \in C$ or $b', b'' \in D$ this is trivial, because C and D are k_C- or k_D-elongated collections and $k_C \leq k_D$. For the pair a and b, those properties are again trivial, because both have all their long sides on the common facet f. For any $a' \in C$ and $b' \in D$ the properties follow as the pairs a' and a, a and b, b and b' satisfy these properties. ◀

After this merging procedure, we will assign each item $x \in \mathcal{J}$ to a collection C as follows: If x is completely packed in a collection, then we assign it to that collection itself. If it is partially contained, then we assign it to one of the collections (breaking ties arbitrarily) with which it intersects only via the good outer facets. The next lemma shows that this assignment is indeed possible.

▶ **Lemma 11.** *Let G be the set of all collections that were derived after the merging procedure. Let $x \in \mathcal{J}$ be an item that is packed in the grid but isn't completely packed in any collection in G. Then there exists a collection $C \in G$ in which x is partially packed but x does not intersect any of its bad outer facets.*

Proof. First, we define an order on the set of the collections G. We associate each k_C-elongated collection $C \in G$ with the tuple of the long sides $\left(a_{\sigma_a(1)}, \ldots, a_{\sigma_a(k_C)}\right)$ for some cell $a \in C$ in a descending order. By property (iii) in the definition of a k_C-elongated collection, the tuple is independent of the choice of the cell. We now define the strict lexicographic order $\prec$ on these tuples. In other words, for a k_C-elongated collection C, a k_D-elongated collection D and cells $a \in C$ and $b \in D$, we have $C \prec D$ iff

- **(i)** $k_C < k_D$ and $a_{\sigma_a(i)} = b_{\sigma_b(i)}$ for all $1 \leq i \leq k_C$, or
- **(ii)** there is some $1 \leq k \leq \min(k_C, k_D)$ such that $a_{\sigma_a(i)} = b_{\sigma_b(i)}$ for all $i \in [k-1]$ and $a_{\sigma_a(k)} < b_{\sigma_b(k)}$.

Let $H \subseteq G$ be the set of collections where x is partially contained in. Let $C \in H$ be a maximal collection in H according to $\prec$ and let it be k_C-elongated. Now we want to prove that x does not intersect any bad outer facet of C. Assume there is a bad outer facet f of C which is intersected by x. This facet f belongs to some cells $a \in C$ and $b \in D$ where D is a different collection than C. The facet f has to be a good facet of D, because it is bad for C and the collections C and D were not merged. Let $d_\perp$ be the dimension which is orthogonal to f. Like in the proof of Lemma 10, we know that $a_i = b_i$ for all $i \in \{1, \ldots, d\} \setminus \{d_\perp\}$ because of their common facet f. As f is bad for C this contains all the sides of a that are long using the size parameter $\hat{s}(C)$. If a side of a is long using the size parameter $\hat{s}(C)$ and larger than $b_{d_\perp}$, then this side is also long using the size parameter $\hat{s}(D)$, because $b_{d_\perp}$ is already considered as long using this size parameter. Thus, we have two cases: In the first case, each side of a which is long using the size parameter $\hat{s}(C)$ is larger than $b_{d_\perp}$. Then each long side of a is also a long side of b while b has at least one additional long side $b_{d_\perp}$. Thus, we have $C \prec D$ by (i). In the second case there are only $k < k_C$ sides of a long using

the size parameter $\hat{s}(C)$ and larger than $b_{d_\perp}$. Then the k longest sides of a and b have the same size and for the $(k+1)^{\text{th}}$ longest sides we have $a_{\sigma_a(k+1)} < b_{d_\perp} = b_{\sigma_b(k+1)}$. Thus, we have $C \prec D$ by (ii). In both cases, the maximality of C is violated, and therefore no bad outer facet of C can be intersected by x. ◀

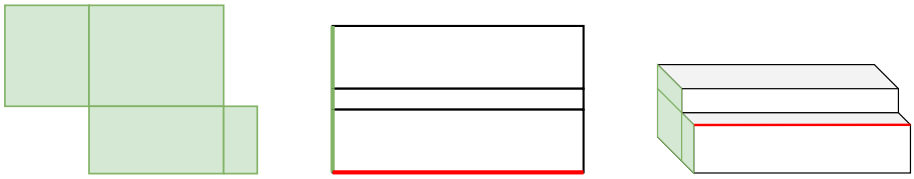
3.1.2 Strip Packing with Resource Augmentation

Before we proceed to repack the items inside of those collections, we will have a closer look at an arbitrary k-elongated collection for some $k \in [d-1]$. This constraint on k ensures that the collection is large in at least one dimension and short in at least one dimension. Thus our collection is some kind of a strip (may not be hypercuboidal). Previously, we reordered the dimensions for a collection to have the k long dimensions first; however, for the strip packing problem we assume the opposite, i.e., we suppose that the collection is short in the first $(d-k)$ dimensions and long in the last k dimensions. Each cell of this collection is the cartesian product of some intervals and property (iii) of Definition 9 ensures that the last k intervals are the same for any cell in this collection. By splitting the cartesian product for a cell after the first $(d-k)$ (short) intervals and before the last interval, we can represent the cell as $a \times B \times [h_1, h_2]$ where a is a $(d-k)$-dimensional hypercuboid that depends on the selected cell and both the $(k-1)$-dimensional hypercuboid B and the values h_1 and h_2 are common to all cells of the collection. This set of hypercuboids $\{a\}$ forms a $(d-k)$-dimensional grid A that is the projection of our collection onto the first $(d-k)$ dimensions. With these definitions, our collection can be viewed as a d-dimensional strip with base $(\cup_{a\in A} a) \times B$ and height $(h_2 - h_1)$. We would like to repack this collection using a strip packing algorithm. For this purpose, we devise an algorithm to pack hypercubes on a base (which can be extended by a slight amount in the long dimensions) with the properties described above. With this motivation, we formally define the strip packing problem and state the main result in the next few paragraphs.

Let $k \in [d-1]$. Let $\varepsilon > 0$ be some accuracy parameter and $N \in \mathbb{N}_+, \alpha \geq 1$ be some constants depending on d, ε. The input consists of a set of items $\mathcal{I}$. In the entire subsection, we abbreviate $\hat{s}(\mathcal{I})$ by $\hat{s}$.

The $(d-1)$-dimensional base on which we need to pack the input set $\mathcal{I}$ is the cartesian product $A \times B$ where A is some $(d-k)$ dimensional grid of at most N cells and B is some $(k-1)$ dimensional hypercuboid. The side length of B in the i^{th} dimension ($i \in [k-1]$) is denoted by b_i. Each side length of each cell in A has to be at most $\alpha\hat{s}$ and each b_i has to be at least $N\alpha^{d-k}\hat{s}$. As it can be seen, compared to $\hat{s}$, all the edge lengths in A are short and all the edge lengths in B are long. Hence, we refer to the dimensions of the coordinate system parallel to the edges of A as *short dimensions* and to the dimensions parallel to the edges of B as *long dimensions*. In the 3-dimensional setting, we have two possible values for k. If $k = 1$, then B vanishes and our base is just a grid of rectangles A. Such a base can be seen in Figure 6a. If $k = 2$, then B is an interval and A is just a set of non-overlapping intervals because it is 1-dimensional. In this case, the base can be visualized like in Figure 6b as a set of flat but wide rectangles, that are positioned on top of each other. So for the 3-dimensional case, we either have a complex structure through A or long sides through B but never both. In higher dimensions however, we can have both. An example for this is the base of a 4-dimensional strip in Figure 6c. By scaling every dimension equally, it is assumed that the volume of the grid A is normalized: $\text{VOL}_{d-k}(A) := \sum_{a\in A} \text{VOL}_{d-k}(a) = 1$. We also assume that any item in $\mathcal{I}$ can be packed on the base $A \times B$. The goal is to find a non-overlapping packing of the items in $\mathcal{I}$ into the region given by the set product of

A, B and h, that is $\mathrm{CONT}(A, B, h) := (\bigcup_{a \in A} a) \times B \times [0, h]$ where h is called the height of the packing. The optimal (i.e. minimal) height h for which it is possible to pack $\mathcal{I}$ in $\mathrm{CONT}(A, B, h)$ is denoted by $\mathrm{OPT}_{\mathrm{strip}}(\mathcal{I}, A, B)$.



(a) $d = 3, k = 1$. **(b)** $d = 3, k = 2$. **(c)** $d = 4, k = 2$.

Figure 6 The first two figures show two possible bases for a 3-dimensional strip. In the first figure, A is shown in green and we have no B. In the second figure, the grid A (in green) is 1-dimensional and thus simple, and B is shown in red (the long side). The last figure shows a possible 3-dimensional base with $k = 2$ of a 4-dimensional strip with A shown in green (the short sides) and B shown in red (the long side).

We only consider instances where a solution exists. Since we assume that $\mathrm{VOL}_{d-k}(A) = 1$, we have that $\hat{s} \leq 1$ as a larger item would not fit into the strip. Note that for each $i \in [k-1]$, $b_i \geq N\alpha^{d-k}\hat{s} \geq N(\alpha\hat{s})^{d-k} \geq \sum_{a \in A} \mathrm{VOL}_{d-k}(a) = \mathrm{VOL}_{d-k}(A) = 1$. In this section, we describe an algorithm based on Harren's [21] multidimensional generalization of the algorithm by Kenyon and Rémila [28] for 2-dimensional strip packing.

The differences between our algorithm and Harren's algorithm[21] can be summed up as follows: Due to the complex nature of A, we have multiple hypercuboids, each having a bounded aspect ratio. This changes the analysis of the algorithm. It also changes the details like packing the medium and small items on the top, because we have to split one strip into multiple smaller strips (having hypercuboidal bases) and distribute the items among them. The addition of very long sides in form of B, like in Figure 6b, breaks the bounded aspect ratio property in a more crucial way. Harren's algorithm first packs the large items on the base and then extends this packing along the height of the strip. This relies on the fact that, due to bounded aspect ratio, not many large items can be packed on the base, and thus we have to consider only a constant number of so-called *configurations*. If we have additional long sides in the base in form of B, we don't have such a bound on the number of large items that can fit in the base. For example, in Figure 6b, an item can be large with respect to A (shown in green), but the number of such items that can fit on the base $A \times B$ can't be bounded by a constant since the side shown in red can be arbitrarily long.

We work around this problem as follows: First, we consider $(d-k)$ dimensional packings, i.e., *configurations* of the items, on A. Then we not only extend these configurations along the height of the strip but also along each of the $(k-1)$ dimensions of B. For example, in Figure 6b, we first create one-dimensional packings on A and then extend each of these packings both in the rightward direction and along the height of the strip.

▶ **Theorem 12.** *Let $\mathcal{I}$, A and B be the input for the d-dimensional strip packing problem defined above and let $\varepsilon > 0$ be some additional accuracy parameter. Then there is an algorithm which packs all items of $\mathcal{I}$ into the region $\mathrm{CONT}(A, B + \hat{s}, h)$ where $B + \hat{s}$ is the hypercuboid B after increasing each side length by $\hat{s}$ and the height h is given by*

$$h \leq (1 + \mathcal{O}(\varepsilon)) \, \mathrm{OPT}_{\mathrm{strip}}(\mathcal{I}, A, B) + \mathcal{O}(\hat{s})$$

The constant omitted in the expression $\mathcal{O}(\varepsilon)$ is a function of k. The constant omitted in the expression $\mathcal{O}(\hat{s})$ is a function of $d, k, \alpha, N, \varepsilon$.

Due to space limitations, the detailed proof of Theorem 12 is given in the full version [24]. Our algorithm first classifies the input items into large, medium, and small items. The side lengths of large items are rounded using linear grouping [12] such that there is only a constant number of different sizes. When we try to pack a subset of large items by arranging them in the first $(d-k)$ dimensions while giving them the same position in the last k dimensions, we only have to consider a constant number of those subsets. This is because the volume of the strip in the first $(d-k)$ dimensions is small and thus only a small subset of large items is packable this way and items of the same size can be considered to be identical. For each configuration, we take a packing that only uses the first $(d-k)$ dimensions, and extend it to use also the last k dimensions by placing multiple items of the same size next to each other in those long dimensions. This creates an $\mathcal{N}$-Box from each item in each configuration. An LP is used to determine how large a configuration is extended in those k dimensions. The packings for the different configurations are treated as layers stacked on top of each other.

After the large items are packed, we use the gaps between the large items to create $\mathcal{V}$-Boxes to hold some of the small items. The remaining small items and medium items are placed in additional $\mathcal{V}$-Boxes on top of this packing. Again this needed several technical adaptations, as unlike [21], we have multiple different bases and we need to distribute the remaining items in a balanced way such that the total height is minimized. See the full version [24] for the details.

As we mentioned earlier, we use this theorem to repack a k-elongated collection Q ($k \in [d-1]$). So, we use α_{k+1} as α since we know that for every cell in $\mathcal{Q}$, the first k dimensions have length at least $\alpha_k \hat{s}(\mathcal{Q}) \geq N\alpha_{k+1}^{d-k}\hat{s}(\mathcal{Q})$ (see Remark 15 and definition of α_k) and each of the last $(d-k)$ dimensions have length at most $\alpha_{k+1}\hat{s}(\mathcal{Q})$. Now let us note a few useful remarks about the above theorem applied to our collection Q. The proofs of these remarks follow from a few lemmas in the full version [24].

▶ Remark 13. A more exact bound for the height of the packing obtained in Theorem 12 is

$$\left(1+\left(2+\max\left(3,2^{k-1}\right)\right)\varepsilon\right)\mathrm{OPT}_{\mathrm{strip}}\left(Q,A,B\right)+2\left(C_{\mathrm{configs}}\left(d,k,\alpha_{k+1},N,\varepsilon\right)+3\right)\hat{s}\left(\mathcal{Q}\right)$$

Here C_{configs} is only dependent on its parameters.

▶ Remark 14. The algorithm of Theorem 12 packs all items in $\mathcal{N}$-Boxes and $\mathcal{V}$-Boxes. The number of $\mathcal{N}$-Boxes is bounded by $C_{\mathrm{configs}}\left(d,k,\alpha_{k+1},N,\varepsilon\right)/C_{\rho}\left(d,k,\alpha_{k+1},N,\varepsilon\right)^{d-k}$ and the number of $\mathcal{V}$-Boxes by $C_{\mathrm{configs}}\left(d,k,\alpha_{k+1},N,\varepsilon\right)N2^{d-k}/C_{\rho}\left(d,k,\alpha_{k+1},N,\varepsilon\right)^{(d-k)^2}+N$. Here C_{configs} and C_{ρ} are only dependent on their parameters.

▶ Remark 15. The value $C_{\mathrm{configs}}\left(d,k,\alpha_{k+1},N,\varepsilon\right)$ from Remarks 13 and 14 has a lower bound of $C_{\mathrm{configs}}\left(d,k,\alpha_{k+1},N,\varepsilon\right) > N\alpha_{k+1}^{d-k} \geq \alpha_{k+1}$.

3.1.3 Repacking a Collection

Depending on the type of the collection, we can simplify the packing of the items assigned to each collection. Let $\mathcal{C}$ be a k-elongated collection and let $\mathcal{Q}$ be the set of items assigned to $\mathcal{C}$. Let $\hat{s} := \hat{s}\left(\mathcal{Q}\right)$. We consider the cases $k = d, 1 \leq k < d$, and $k = 0$ separately.

First of all, if $\mathcal{C}$ is a d-elongated collection, then it consists of only a single cell as it has no bad facets and hence can not be merged with any other cell. Thus we can repack (after removing only a small profit subset) it efficiently using NFDH because it is a hypercuboidal region that is large in all dimensions. The following lemma states this. The proof can be found in the full version [24].

▶ **Lemma 16.** *If $\mathcal{C}$ is a d-elongated collection, then it can be transformed into a single $\mathcal{V}$-Box with a loss of profit at most $6d\varepsilon p\left(\mathcal{Q}\right)$.*

For a k-elongated collection with $1 \leq k < d$, we can apply the strip packing algorithm of Theorem 12 as shown in the next lemma.

▶ **Lemma 17.** *A k-elongated collection with $1 \leq k < d$ can be transformed into a constant number of $\mathcal{V}$-Boxes and $\mathcal{N}$-Boxes by losing profit at most $\left(k + 7 + \max\left(6, 2^k\right)\right) \varepsilon p\left(\mathcal{Q}\right)$ where $\mathcal{Q}$ is the set of items assigned to it.*

Proof. We begin by shrinking the collection to compensate for the enlargement that the strip packing algorithm will cause. Define one of the long dimensions of the collection to be its height and let h be the length in this dimension. Let $c := 4 + \max\left(3, 2^{k-1}\right)$. We assumed $\varepsilon < 1/2^{(d+2)} < 1/(2c)$. Divide the strip into $\lfloor 1/\left(c\varepsilon\right) \rfloor$ slices along the height. After that each slice has a height of at least

$$\begin{aligned}
c\varepsilon h &= \left(4 + \max\left(3, 2^{k-1}\right)\right) \varepsilon h \\
&\geq \left(2 + \max\left(3, 2^{k-1}\right)\right) \varepsilon h + 2\varepsilon\alpha_k \hat{s} && \text{(since } h \geq \alpha_k \hat{s}\text{)} \\
&= \left(2 + \max\left(3, 2^{k-1}\right)\right) \varepsilon h + 4\left(C_{\text{configs}}\left(d, k, \alpha_{k+1}, N, \varepsilon\right) + 3\right) \hat{s} && \text{(by definition of } \alpha_k\text{)} \\
&\geq \left(2 + \max\left(3, 2^{k-1}\right)\right) \varepsilon h + 2\left(C_{\text{configs}}\left(d, k, \alpha_{k+1}, N, \varepsilon\right) + 3\right) \hat{s} + 6\hat{s}.
\end{aligned}$$

By clearing the slice with the lowest profit of items completely contained in it, we leave a gap with a height of $\left(2 + \max\left(3, 2^{k-1}\right)\right) \varepsilon h + 2\left(C_{\text{configs}}\left(d, k, \alpha_{k+1}, N, \varepsilon\right) + 3\right) \hat{s} + 4\hat{s}$. This causes a loss of profit at most $\frac{1}{\lfloor 1/(c\varepsilon) \rfloor} p\left(\mathcal{Q}\right) \leq \frac{1}{1/(c\varepsilon) - 1} p\left(\mathcal{Q}\right) \leq \frac{1}{1/(c\varepsilon) - 1/(2c\varepsilon)} p\left(\mathcal{Q}\right) = 2c\varepsilon p\left(\mathcal{Q}\right)$. The items intersecting the bottom or top facet of the collection fit in a gap of height $2\hat{s}$. We reduce the height of the collection to

$$h' := h - \left(2 + \max\left(3, 2^{k-1}\right)\right) \varepsilon h - 2\left(C_{\text{configs}}\left(d, k, \alpha_{k+1}, N, \varepsilon\right) + 3\right) \hat{s}$$

by shifting the items intersecting the (removed) region at the top into a gap of height $\left(2 + \max\left(3, 2^{k-1}\right)\right) \varepsilon h + 2\left(C_{\text{configs}}\left(d, k, \alpha_{k+1}, N, \varepsilon\right) + 3\right) \hat{s} + \hat{s}$.

For each other large dimension we create $\lceil 1/\varepsilon \rceil$ slices and clear the slice with the lowest profit, losing at most $\varepsilon p\left(\mathcal{Q}\right)$ and create a gap of width at least $\frac{1}{\lceil 1/\varepsilon \rceil} \alpha_k \hat{s} - 2\hat{s} \geq \frac{1}{1/\varepsilon + 1} \alpha_k \hat{s} - 2\hat{s} \geq \frac{\varepsilon}{2} \alpha_k \hat{s} - 2\hat{s} \geq 4\hat{s}$. Now we can shift the items intersecting the orthogonal facets into that gap and reduce the length of the collection in this direction by $\hat{s}$. After this shifting process, we will be left with a subset of items $\mathcal{Q}' \subseteq \mathcal{Q}$.

To be able to use the strip packing algorithm from Theorem 12, the base of our strip has to be in a special representation. For this, we create a $(d-k)$-dimensional grid A by projecting the cells of our collection to their $(d-k)$ short dimensions. We define B as a tuple holding the lengths in the $(k-1)$ long dimensions of the collection that are not the height. Now our base can be represented as the cartesian product $A \times B$. As a last preparation step, we scale the whole collection and the items in it by $f := 1/\operatorname{VOL}_{d-k}\left(A\right)^{1/(d-k)}$ in each dimension to normalize the volume of A to 1. Note that each value in the tuple B is at least $\alpha_k \hat{s} f \geq N \alpha_{k+1}^{d-k} \hat{s} f$ by the definition of α_k and Remark 15. Thus, we can use the strip packing algorithm Theorem 12 using the bound on the height by Remark 13 to compute a packing of height at most

$$\begin{aligned}
&\left(1 + \left(2 + \max\left(3, 2^{k-1}\right)\right) \varepsilon\right) \operatorname{OPT}_{\text{strip}}\left(Q', A, B\right) + 2\left(C_{\text{configs}}\left(d, k, \alpha_{k+1}, N, \varepsilon\right) + 3\right) \hat{s} f \\
&\leq \left(1 + \left(2 + \max\left(3, 2^{k-1}\right)\right) \varepsilon\right) h' f + 2\left(C_{\text{configs}}\left(d, k, \alpha_{k+1}, N, \varepsilon\right) + 3\right) \hat{s} f \\
&\leq h' f + \left(2 + \max\left(3, 2^{k-1}\right)\right) \varepsilon h f + 2\left(C_{\text{configs}}\left(d, k, \alpha_{k+1}, N, \varepsilon\right) + 3\right) \hat{s} f \\
&= h f.
\end{aligned}$$

After scaling back, the packing fits into our collection. ◀

Repacking 0-elongated Collections. For a 0-elongated collection, we first distinguish the items into large, medium, and small items such that the profit of medium items is very small so that they can be discarded. We then further distinguish between the cases when (i) there is a large item of very small profit or (ii) every large item has a significant profit. In the first case, we remove the large item to make enough space to repack the small items. In the second case, we use the fact that the number of large items can only be $O(1)$. So, we partition the grid into smaller grids and solve these recursively. We finally prove that we only require $O(1)$ number of recursive steps that we require are only a constant in number.

From now on, lets assume that $\mathcal{C}$ is a 0-elongated collection. To partition $\mathcal{Q}$ into large, medium, and small items, we define the following values. $\rho'_0 := 1, \rho'_{i+1} := \left(\frac{(\rho'_i)^d}{4dN\alpha_1^d}\right)^{d+1}$ and $\rho_i := \rho'_i \hat{s}$ for all $i \geq 0$. Let $\eta \in \mathbb{N}_+$ be minimal such that $p(\{ x \in \mathcal{Q} \mid \rho_\eta < s(x) < \rho_{\eta-1} \}) \leq \varepsilon p(\mathcal{Q})$. Note that $\eta \leq 1/\varepsilon$. We now partition $\mathcal{Q}$ into sets $\mathcal{S} := \{ x \in \mathcal{Q} \mid s(x) \leq \rho_\eta \}$, $\mathcal{M} := \{ x \in \mathcal{Q} \mid \rho_\eta < s(x) < \rho_{\eta-1} \}$ and $\mathcal{L} := \{ x \in \mathcal{Q} \mid \rho_{\eta-1} \leq s(x) \}$. We call $\mathcal{S}$ (resp. $\mathcal{M}, \mathcal{L}$) to be the set of small (resp. medium, large) items. Note that since $\eta \geq 1$ and $\rho_0 = \hat{s}$, the set of large items can't be empty. This simple observation will be useful later.

If there is a large item with a small profit, then after discarding that large item, the entire empty space can be divided into a constant number of $\mathcal{V}$-Boxes. It can then be shown that these $\mathcal{V}$-Boxes have enough volume to pack all the small items. This is formalized in the following lemma. The proof can be found in the full version [24].

▶ **Lemma 18.** *Suppose $\mathcal{C}$ is a 0-elongated collection. If an item in $\mathcal{L}$ has profit at most $\varepsilon p(\mathcal{Q})$, then the collection $\mathcal{C}$ can be transformed into a packing of profit at least $(1-2\varepsilon)\, p(\mathcal{Q})$ containing a constant number of large items and a constant number of $\mathcal{V}$-Boxes.*

If all the large items have a good profit (i.e., a profit of more than $\varepsilon p(\mathcal{Q})$), we cannot discard any of them to create space. Therefore, it is hard to repack the items directly so instead we will take a recursive approach using a shifting argumentation.

▶ **Lemma 19.** *Suppose $\mathcal{C}$ is a 0-elongated collection. If every item in $\mathcal{L}$ has a profit of at least $\varepsilon p(\mathcal{Q})$, then $\mathcal{C}$ can be transformed into a constant number of large items, $\mathcal{N}$-Boxes and $\mathcal{V}$-Boxes while losing profit at most $\max\left(6d+1, d+13, d+7+2^{d-1}\right) \varepsilon p(\mathcal{Q})$.*

Proof. In this case, we have at most $1/\varepsilon$ large items. We can split the area of the collection, which is not covered by the large items into a grid of at most $2/\varepsilon$ additional layers in each dimension and recursively start from Section 3.1.1 with the classification of cells and merging into collections. Each of these collections is a k-elongated collection ($k > 0$) or a 0-elongated collection. The former collections can be repacked using Lemma 16 or Lemma 17. Let's look at the 0-elongated collections. Note that the total profit of these collections is at most $(1-\varepsilon)p(\mathcal{Q})$ since we recurse only if there is a large item in $\mathcal{Q}$ of profit at least $\varepsilon p(\mathcal{Q})$. For a 0-elongated collection in this recursive step, we either use Lemma 18 if there exists a large item of small profit or, we continue the recursion. Note, that if we reach a depth of $\lceil \log_{1-\varepsilon}(\varepsilon) \rceil$ in this recursion, then we can just discard the remaining items and stop. The reason for this is that we packed in each recursive step at least one large item with a non-negligible profit, so at this maximal recursion depth, all the items over all collections have a profit at most $(1-\varepsilon)^{\lceil \log_{1-\varepsilon}(\varepsilon) \rceil}\, p(\mathcal{Q}) \leq \varepsilon p(\mathcal{Q})$.

During this process, the initial region was split into different collections, where each of those was assigned a partition of the items $\mathcal{Q}' \subseteq \mathcal{Q}$. At this point, no profit was lost except for the items that are lost at the maximal recursion depth with profit at most $\varepsilon p(\mathcal{Q})$. When repacking each collection by transforming them into large items, $\mathcal{N}$-Boxes and $\mathcal{V}$-Boxes, we

lose again some profit, which depends on the method we used for repacking. We lose at most $6d\varepsilon p(\mathcal{Q}')$ through Lemma 16, at most $\left(d+6+\max\left(6,2^{d-1}\right)\right)\varepsilon p(\mathcal{Q}')$ through Lemma 17, at most $2\varepsilon p(\mathcal{Q}')$ through Lemma 18. As those subsets for the collections are distinct the loss in this repacking step is bounded by $\max\left(6d, d+12, d+6+2^{d-1}, 2\right)\varepsilon p(\mathcal{Q})$. Noting that $2 < \max\left(6d, d+12, d+6+2^{d-1}\right)$ and adding the factor of $\varepsilon p(\mathcal{Q})$ that we may lose during the recursion proves the claim. ◀

The last thing to do is to prove, that the number of $\mathcal{N}$-Boxes and $\mathcal{V}$-Boxes that are created is constant. As those boxes are created out of the cells of the grid in Section 3.1.1, we start by bounding the size of this grid during the recursive algorithm. The following lemma follows from the fact that in each of the recursive step (having depth at most $\lceil \log_{1-\varepsilon} \varepsilon \rceil$) the number of layers increases by at most $2/\varepsilon$ in each of the dimensions. The proof can be found in the full version [24].

▶ **Lemma 20.** *Consider any grid $\mathcal{G}$ obtained during the recursive algorithm starting from the knapsack with an optimal packing as a grid with a single cell. Then the number of layers in each dimension in $\mathcal{G}$ is upper bounded by $C_{\text{layer}}(\varepsilon) := 2\left\lceil \log_{1-\varepsilon}(\varepsilon)\right\rceil/\varepsilon+1$.*

▶ Remark 21. Due to the above lemma, the bound on the number of layers also gives an upper bound $C_{\text{N}}(d,\varepsilon) := (C_{\text{layer}}(\varepsilon))^d$ on the number of cells in any grid that we consider in Section 3.1.1.

Using these results, we obtain the following lemma which bounds the number of $\mathcal{N}$-Boxes and $\mathcal{V}$-Boxes. The proof can be found in the full version [24].

▶ **Lemma 22.** *The numbers of large items, and the total number of $\mathcal{N}$-Boxes and $\mathcal{V}$-Boxes generated by the transformation of an optimal packing can be bounded by C_{large} and C_{boxes}, respectively. C_{large} and C_{boxes} are constants that depend only on d, ε.*

Now we can prove Theorem 7.

Proof of Theorem 7. Consider an optimal packing and interpret the initial knapsack as a cell of a grid with one layer in each dimension. Then we start with the procedure explained in Section 3.1.1 to classify the unit hypercube either as d-elongated or 0-elongated. By Lemmas 16, 18, and 19, we can simplify the structure of the packing and lose a profit of at most $\max(6d+1, d+13, d+8+2^{d-1})\varepsilon p(\mathcal{I}) \leq 2^{d+2}\varepsilon p(\mathcal{I})$ as we have $d \geq 2$. Lemma 22 bounds the number of $\mathcal{V}$-Boxes and $\mathcal{N}$-Boxes and the large items packed outside them. ◀

3.2 Algorithm

Using the results of Section 3.1, we can construct a PTAS for d-D Hc-Knapsack.

▶ **Theorem 23.** *Let $d \geq 2$ and $\varepsilon > 0$. There is an algorithm which returns for each instance of the d-dimensional hypercube knapsack packing problem given by a set of items a packing with profit at least $(1-\varepsilon)\,\text{OPT}_{\text{knapsack}}(\mathcal{I})$ with a running time which is polynomial in $|\mathcal{I}|$.*

Proof. Using Theorem 7 with an accuracy of $2^{-d-3}\varepsilon$ we know that there is a packing with a simple structure and profit at least $(1-\varepsilon/2)\,\text{OPT}_{\text{knapsack}}(\mathcal{I})$. Let $\mathcal{B}$ be the set of $\mathcal{N}$-Boxes and $\mathcal{V}$-Boxes in this structure, $\mathcal{L} \subseteq \mathcal{I}$ the set of items packed outside of those boxes and $\mathcal{S} \subseteq \mathcal{I}\backslash\mathcal{L}$ the set of items packed inside of them.

As the number of items in $\mathcal{L}$ is constant, there are at most $|\mathcal{I}|^{C_{\text{large}}(d,\varepsilon)}$ choices for this subset $\mathcal{L} \subseteq \mathcal{I}$. There are at most $C_{\text{boxes}}(d,\varepsilon)+1$ choices for the number of boxes in $\mathcal{B}$ and for each box there are at most:

- 2 choices whether it is a $\mathcal{V}$-Box or an $\mathcal{N}$-Box,
- $|\mathcal{I}|$ choices for the size parameter $\hat{s}$ of the box,
- $|\mathcal{I}|^d$ choices for the side lengths of the box.

All of these choices are polynomial in the number of items $|\mathcal{I}|$. Thus, by iterating over all possible choices, we can assume at this point that we know the set of items $\mathcal{L}$ and the set $\mathcal{B}$ of $\mathcal{V}$-Boxes and $\mathcal{N}$-Boxes of that nearly optimal solution. As both $|\mathcal{L}|$ and $|\mathcal{B}|$ are bounded by a constant, we can find a packing of those items and boxes in the unit hypercube in constant time. The last step left to do is to pack items from $\mathcal{I}\backslash\mathcal{L}$ in the boxes with a nearly optimal profit. We can do this by solving a special variant of the Generalized Assignment Problem (GAP) [42]. In GAP, we are given a set of one-dimensional knapsacks with a capacity each and a set of items that may have a possibly different size and profit for each knapsack. The goal in this problem is to find a feasible packing with maximal profit. We will consider our $O(1)$ number of $\mathcal{V}$-Boxes and $\mathcal{N}$-Boxes to be knapsacks. Consider a $\mathcal{V}$-Box B_V with size parameter $\hat{s}$. We set its capacity to be $\mathrm{VOL}_d(B) - \hat{s}(\mathrm{SURF}_d(B)/2)$. For any item i, we set its size with respect to B_V as $\mathrm{VOL}_d(i)$ if $s(i) \leq \hat{s}$ and ∞ otherwise. On the other hand, consider an $\mathcal{N}$-Box B_N with size parameter $\hat{s}$ and $\{n_i\}_{i\in d}$ denoting the number of cells in each dimension. We set its capacity to be $n_1 n_2 \dots n_d$. For any item i, we set its size with respect to B_N as 1 if $s(i) \leq \hat{s}$ and ∞ otherwise. The profit of any item i with respect to any box is just set as $p(i)$. This boils down to a variant of GAP with $O(1)$ number of knapsacks, which admits a PTAS [18]. Thus by solving this instance, we get a subset $\mathcal{S}' \subseteq \mathcal{I}\backslash\mathcal{L}$ with profit at least $p(\mathcal{S}') \geq (1-\varepsilon/2)\,p(\mathcal{S})$. Using Observation 4 and Corollary 3 we can ensure to pack those items inside the boxes. The total profit packed is $p(\mathcal{S}') + p(\mathcal{L}) \geq \left(1-\frac{\varepsilon}{2}\right)p(\mathcal{S}) + p(\mathcal{L}) > \left(1-\frac{\varepsilon}{2}\right)(p(\mathcal{S}) + p(\mathcal{L})) \geq \left(1-\frac{\varepsilon}{2}\right)^2 \mathrm{OPT}_{\text{knapsack}}(\mathcal{I}) \geq (1-\varepsilon)\,\mathrm{OPT}_{\text{knapsack}}(\mathcal{I})$. ◀

4 Conclusion

We have designed a PTAS for a variant of the knapsack problem (d-D Hc-Knapsack), where the items are d-dimensional hypercubes with arbitrary profits. En route, we have also developed a near-optimal algorithm for a variant of the d-dimensional hypercube strip packing problem, where the base need not be hypercuboidal, but we are allowed to extend some of the sides of the base (the long dimensions) by a small amount. Extending the techniques of [23], we believe that it might be possible to design an EPTAS for d-D Hc-Knapsack.

The knapsack problem for squares, cubes, and hypercubes is thus almost settled. Whether there exists a PTAS for the knapsack variant where items are rectangles is still open. It is also interesting to improve the current best approximation ratios ($(5+\varepsilon)$ with rotations and $(7+\varepsilon)$ without rotations [14]) for the knapsack problem where items are cuboids (3D) because of its practical relevance. Another interesting task of theoretical importance would be to improve the current best approximation ratio (which is $(3^d+\varepsilon)$ due to [41]) for the knapsack problem where items are d-dimensional hypercuboids.

Abstract

We present a faster interior-point method for optimizing sum-of-squares (SOS) polynomials, which are a central tool in polynomial optimization and capture convex programming in the Lasserre hierarchy. Let $p = \sum_i q_i^2$ be an n-variate SOS polynomial of degree $2d$. Denoting by $L := \binom{n+d}{d}$ and $U := \binom{n+2d}{2d}$ the dimensions of the vector spaces in which q_i's and p live respectively, our algorithm runs in time $\tilde{O}(LU^{1.87})$. This is polynomially faster than state-of-art SOS and semidefinite programming solvers [16, 15, 27], which achieve runtime $\tilde{O}(L^{0.5}\min\{U^{2.37}, L^{4.24}\})$.

The centerpiece of our algorithm is a dynamic data structure for maintaining the inverse of the Hessian of the SOS barrier function under the *polynomial interpolant basis* [27], which efficiently extends to multivariate SOS optimization, and requires maintaining spectral approximations to low-rank perturbations of *elementwise (Hadamard) products*. This is the main challenge and departure from recent IPM breakthroughs using inverse-maintenance, where low-rank updates to the slack matrix readily imply the same for the Hessian matrix.

1 Introduction

Polynomial optimization is a fundamental problem in many areas of applied mathematics, operations research, and theoretical computer science, including combinatorial optimization [5, 36, 4], statistical estimation [13, 14], experimental design [26], control theory [12], signal

processing [31], power systems engineering [11], discrete geometry [2, 3] and computational algebraic geometry [20]. In the most basic formulation, we are given a collection of k real n-variate polynomials $f_1, \cdots, f_k$ and an objective function $f : \mathbb{R}^n \to \mathbb{R}$, and the goal is to minimize f over the set $\mathcal{S} := \{t \in \mathbb{R}^n \mid \forall i \in \{1, \cdots, k\} : f_i(t) \geq 0\}$, that is, to find

$$\inf_{t \in \mathbb{R}^n} \{f(t) \mid t \in \mathcal{S}\}, \tag{1}$$

which is equivalent to checking polynomial nonnegativity $\sup_{c \in \mathbb{R}}\{c \mid f(t) - c \geq 0,\ \forall t \in \mathcal{S}\}$. This is then equivalent to computing $\sup_{c \in \mathbb{R}}\{c \mid f - c \in \mathcal{K}(\mathcal{S})\}$, where $\mathcal{K}(\mathcal{S})$ denotes the convex cone of all polynomials of degree at most $\deg(f)$ that are non-negative on the set $\mathcal{S}$. This is an instance of the more general conic programming:

$$\min_{x \in \mathbb{R}^N} c^\top x \text{ s.t. } Ax = b, x \in \mathcal{K}, \tag{2}$$

where $\mathcal{K} \subset \mathbb{R}^N$ is some convex cone[1]. The conic optimization problem over the cone $\mathcal{K}(\mathcal{S})$ is intractable in general because there is no simple characterization of $\mathcal{K}(\mathcal{S})$. Nevertheless, there always exists an increasing family of convex cones of *weighted sum-of-squares* polynomials that converges to any such cone $\mathcal{K}(\mathcal{S})$.

We first introduce the notion of *sum-of-squares* (SOS) polynomials: Denoting by $\mathcal{V}_{n,d}$ the vector space of all n-variate polynomials of (total) degree at most d, a polynomial $p \in \mathcal{V}_{n,2d}$ is said to be *sum-of-squares* (SOS) if it can be written as a finite sum of square polynomials, i.e., there exist $q_1, \cdots, q_\ell$ such that $p = \sum_{i=1}^{\ell} q_i^2$. The set $\Sigma_{n,2d}$ of SOS polynomials of degree at most $2d$ is a (proper) cone contained in $\mathcal{V}_{n,2d}$, of dimension $U := \dim(\mathcal{V}_{n,2d}) = \binom{n+2d}{2d}$, as the vector space $\mathcal{V}_{n,2d}$ is isomorphic to $\mathbb{R}^U$. If p can be written as $p = \sum_{i=1}^{k} f_i s_i$ for $s_1 \in \Sigma_{n,2d_1}, \cdots, \Sigma_{n,2d_k}$ and k nonzero polynomials $\mathbf{f} := (f_1, \cdots, f_k)$, then it is said to be *weighted sum-of-squares* (WSOS).

Putinar's Positivstellensatz [29] states that under mild conditions, any polynomial p that is non-negative on $\mathcal{S}$ can be written as a WSOS polynomial $\sum_{i=1}^{k} f_i s_i$, albeit with (potentially) *unbounded degree* s_i's. In WSOS optimization we consider sum-of-squares polynomials s_i with bounded degree, so the hierarchy of WSOS optimization with increasing degree (known as the Lasserre hierarchy) can be viewed as a tool for approximating general polynomial optimization. For more details of this approximation scheme for polynomial optimization, we refer the readers to the textbooks [19, 7].

This paper concerns algorithms for *(W)SOS optimization*, which is the conic optimization program (2) where the underlying cone $\mathcal{K}$ is the (W)SOS cone:

$$\min_{x \in \mathbb{R}^U} c^\top x \text{ s.t. } Ax = b, x \in \Sigma_{n,2d}, \tag{3}$$

where $x \in \mathcal{V}_{n,2d}$ is the vector of coefficients which encodes the polynomial. Henceforth, we focus on the case where $\mathcal{K} = \Sigma_{n,2d}$ is the SOS cone. See our full version for how to extend our algorithm for SOS optimization to WSOS.

The computational complexity of solving Problem 3 naturally depends on the dimensions

$$L := \dim(\mathcal{V}_{n,d}) = \binom{n+d}{d} \quad , \quad U := \dim(\mathcal{V}_{n,2d}) = \binom{n+2d}{2d} \tag{4}$$

of the underlying vector spaces (Note that $L \leq U \leq L^2$). We now turn to explain the previous approaches for SOS optimization solvers.

[1] A subset $\mathcal{K} \subset \mathbb{R}^N$ is a convex cone if $\forall\, x, y \in \mathcal{K}$ and $\alpha, \beta \in \mathbb{R}_+$, $\alpha x + \beta y \in \mathcal{K}$.

SOS Optimization as SDPs

A fundamental fact is that the *dual* SOS cone is a *slice of the SDP cone* [24]. More formally, for any *fixed bases* $\mathbf{p} = (p_1, p_2, \cdots, p_L)$ and $\mathbf{q} = (q_1, q_2, \cdots, q_U)$ to $\mathcal{V}_{n,d}$ and $\mathcal{V}_{n,2d}$ respectively, there exists a unique linear mapping $\Lambda : \mathbb{R}^U \to \mathbb{R}^{L\times L}$ satisfying

$$\Lambda(\mathbf{q}(t)) = \mathbf{p}(t)\mathbf{p}(t)^\top, \quad \forall t \in \mathbb{R}^n. \tag{5}$$

Here we define $\mathbf{p}(t) = (p_1(t), p_2(t), \cdots, p_L(t))^\top$ and $\mathbf{q}(t) = (q_1(t), q_2(t), \cdots, q_U(t))^\top$. An equivalent way to view the definition of Λ in (5) is as follows: For polynomials $p_i, p_j \in \mathbf{p}$ there are unique coefficients λ_{iju} such that $p_i p_j = \sum_{u\in U} \lambda_{iju} q_u$. These λ_{iju} define the mapping Λ unambiguously.

This in turn implies that a polynomial $s \in \mathcal{V}_{n,2d}$ (we view s as a vector in $\mathbb{R}^U$ that corresponds to its coefficients over the basis $\mathbf{q}$) is in the dual SOS cone $\Sigma^*_{n,2d}$ if and only if $\Lambda(s)$ is a *positive semidefinite* (PSD) matrix (proved by [24], see Theorem 10 for details). As [27] recently observed, the choice of the bases $\mathbf{p}, \mathbf{q}$ crucially affects the complexity of the optimization problem, more on this below.

Equation (5) implies the well-known fact that optimization over SOS polynomials (3) can be reduced to semidefinite programming

$$\min_{X\succeq 0}\{\langle C, X\rangle \mid \mathrm{tr}(A_i X) = b_i, \ \forall i \in [m]\}, \tag{SDP}$$

and can thus be solved using off-the-shelf SDP solvers. However, despite recent breakthroughs on the runtime of general SDP solvers via *interior-point methods* (IPMs) [16, 15], this SDP reformulation of (3) does not scale well for moderately large degrees, i.e., whenever $U \ll L^2$ in (4). This is because the SDP reformulation always incurs a factor of at least L^2, even when $U \ll L^2$, as this is the SDP variable size (the PSD matrix X has size $L \times L$). Indeed, for the current fast-matrix-multiplication (FMM) exponent $\omega \approx 2.37$ [21, 1], the running time of state-of-the-art SDP solvers [16, 15] for SOS optimization (Problem 3) is[2]

$$\widetilde{O}\left(L^{0.5} \cdot \min\{UL^2 + U^{2.37},\ L^{4.24}\}\right). \tag{6}$$

An alternative approach is to solve Problem 3 directly by designing an *ad-hoc* IPM for the dual SOS cone, avoiding the blowup in the SDP reformulation. This was exactly the motivation of [27]. Like all aforementioned SDP solvers, [27]'s SOS solver is based on IPMs [25], which iteratively minimize the original objective function plus a barrier function via Newton steps. When applied to the SOS Problem (3), *the choice of the specific bases* $\mathbf{p}, \mathbf{q}$ *crucially affects the structure of the (Hessian of the) barrier function* $F(s) = F(\Lambda(s))$, and hence the cost-per-iteration of the IPM. As such, choosing a "good" and efficient basis is key to a fast algorithm for (3). One of the main contribution of [27] is an efficient basis for the SOS cone, which efficiently scales to multivariate SOS, yielding an IPM whose total runtime is

$$\widetilde{O}\left(L^{0.5}U^{\omega}\right) \approx \widetilde{O}\left(L^{0.5}U^{2.37}\right). \tag{7}$$

Our main result is a polynomially faster IPM for Problem 3:

▶ **Theorem 1** (Main Result, Informal version of Theorem 16). *With current FMM exponent, there is an algorithm for solving Problem* (3)*, whose total running time is* $\widetilde{O}\left(LU^{1.87}\right)$.

Indeed, this runtime is polynomially faster than (7) and (6), as shown in Figure 1. We now turn to elaborate on the technical approach for proving Theorem 1.

[2] We use $\widetilde{O}(\cdot)$ to hide $U^{o(1)}$ and $\log(1/\delta)$ factors.

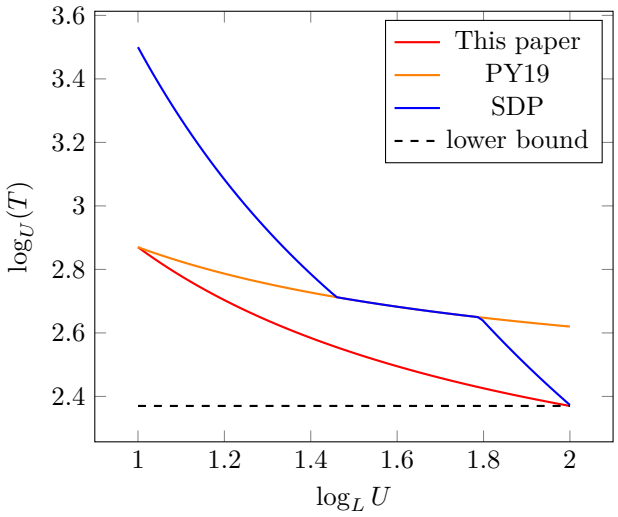

Figure 1 Overview of current running times of recent solvers for SOS. The lower bound bound stems from solving a linear system in U variables, i.e., $T = \Omega(U^\omega)$ where $\omega \approx 2.37$.

Faster IPMs via Inverse-Maintenance

Interior-Point Methods (IPMs [18, 30]) are a powerful class of second-order optimization algorithms for convex optimization, which essentially reduce a conic optimization problem (2) to solving *a sequence of slowly-changing linear systems* (via Newton steps). Since their discovery in the mid 80's, IPMs have emerged as the "gold-standard" of convex optimization, as they are known to converge fast in *both theory and practice* [35]. The main computational cost of IPMs is computing, in each iteration, the inverse of the Hessian of the underlying *barrier function* $F(s) = F(\Lambda(s))$, which naively costs at least U^ω time per iteration for the SOS optimization problem [27]. A recent influential line of work [9, 16], inspired by [37]'s seminal work, has demonstrated that *dynamically maintaining* the inverse of the Hessian matrix under *low-rank* updates using clever *data structures*, can lead to much cheaper *cost-per-iteration*. All of these results rely on a careful combination of dynamic data structures with the geometry (e.g., spectral approximation) of the underlying optimization method and barrier function. Similar techniques have been extended to other optimization problems as well [23, 38, 17, 33, 34]. This paper extends this line of work to SOS optimization.

Our Techniques

Following the framework of [27], we also choose the *polynomial interpolant basis* representation, which corresponds to a linear operator $\Lambda : \mathbb{R}^U \to \mathbb{R}^{L \times L}$ is $\Lambda(s) = P^\top \operatorname{diag}(s) P$, where $P \in \mathbb{R}^{U \times L}$ is the matrix whose entries are the evaluation of the Lagrange interpolation polynomials, through some unisolvent[3] set of points in $\mathcal{V}_{n,d}$ (see Section 3 for a formal definition). This basis induces the aforementioned convenient form of Λ, and generalizes to the multivariate case. The Hessian of the barrier function $F(s) = -\log\det(\Lambda(s))$ is given by

$$H(s) = \left(P(P^\top \operatorname{diag}(s) P)^{-1} P^\top\right)^{\circ 2} \in \mathbb{R}^{U \times U},$$

[3] Any set of points in $\mathbb{R}^n$ for which the evaluation of a polynomial in $\mathcal{V}_{n,d}$ on these points uniquely defines the polynomial.

where $A \circ B$ denotes the element-wise (Hadamard) product of two matrices. The main bottleneck of each iteration of IPMs is to compute the Hessian inverse $H(x)^{-1}$ of the Newton step, which naïvely takes $O(U^\omega)$ time.

In IPM theory, it has long been known that it suffices to compute a spectral approximation of the Hessian. We follow the "lazy update" framework in recent developments of LP and SDP solvers [9, 16], which batches together low-rank updates to $M := P(P^\top \operatorname{diag}(s)P)^{-1}P^\top$, where $\operatorname{rk}(M) = L$. In each iteration, we can compute a spectral approximation $M^{\text{new}} = M + UV^\top$, where U, V are low rank matrices with size $U \times r$ where $r \ll U$ is chosen to optimize the runtime. Since $\widetilde{M} \approx M$ implies that $\widetilde{M}^{\circ 2} \approx M^{\circ 2}$, this also gives a spectral approximation of the Hessian.

The main challenge here, compared to previous LP and SDP solvers [37, 22, 9, 16, 15], is that low-rank updates to M do not readily translate to a low-rank update to $(M^{\circ 2})^{-1}$, since Hadamard-products can *increase* the rank $\operatorname{rk}(A \circ B) \leq \operatorname{rk}(A) \cdot \operatorname{rk}(B)$, in contrast to standard matrix multiplication which does not increase the rank $\operatorname{rk}(AB) \leq \max\{\operatorname{rk}(A), \operatorname{rk}(B)\}$. This means that we cannot directly apply Woodbury's identity to efficiently update the inverse of the Hessian, which is the common approach in all aforementioned works. Instead, we employ the following property which relates rank-one Hadamard-product perturbations to standard matrix products

$$M \circ (u \cdot v^\top) = \operatorname{diag}(u) \cdot M \cdot \operatorname{diag}(v),$$

which means that we can translate the rank-r update of M into a rank-Lr update of $M^{\circ 2}$ for $r \leq L$. With some further calculations, applying Woodbury's identity on the resulting matrix, implies that we can compute $((M^{\text{new}})^{\circ 2})^{-1}$ in time

$$O\big(\mathcal{T}_{\text{mat}}(U, U, Lr)\big),$$

which is never worse than $\mathcal{T}_{\text{mat}}(U, U, U) = U^\omega$ as long as $r \leq U/L$. Modifying the amortization tools of [16] and [15], combined with basic spectral theory for Hadamard products, we show that our amortized cost per iteration is bounded by

$$O\big(U^2 + U^{\omega - 1/2} \cdot L^{1/2}\big),$$

which becomes $O\big(U^2 + U^{1.87} L^{0.5}\big)$ if we plug in the current matrix multiplication exponent.

2 Preliminaries

In this section we provide the definitions and the tools that we will use. For any integer $n > 0$, we define $[n] = \{1, 2, \cdots, n\}$. We use $\mathbb{R}_+$ and $\mathbb{R}_{\geq 0}$ to denote the set of positive and non-negative real numbers respectively. We use $0_n, 1_n \in \mathbb{R}^n$ to denote the all-zero and all-one vectors of size n.

Given a vector $v \in \mathbb{R}^n$, for any $m \leq n$, we use $v_{[:m]} \in \mathbb{R}^m$ to denote the first m entries of v. For a vector $v \in \mathbb{R}^n$, we use $\operatorname{diag}(v) \in \mathbb{R}^{n \times n}$ to denote the diagonal matrix whose diagonal entries are v. For a square matrix $A \in \mathbb{R}^{n \times n}$, we use $\operatorname{diag}(A) \in \mathbb{R}^n$ to denote the vector of the diagonal entries of A. We use $\operatorname{rk}(A)$ to denote the rank of a matrix A. We use $\ker(A)$ and $\operatorname{Im}(A)$ to denote the kernel space and the column space of A.

We say a matrix $A \in \mathbb{R}^{n \times n}$ is PSD (denoted as $A \succeq 0$) if A is symmetric and $x^\top A x \geq 0$ for all $x \in \mathbb{R}^n$. We use $\mathbb{S}^{n \times n}$ to denote the set of PSD matrices of size $n \times n$. The spectral norm of a matrix $A \in \mathbb{R}^{n \times d}$ is defined as $\|A\|_2 = \max_{x \in \mathbb{R}^d, \|x\|_2 = 1} \|Ax\|_2$. The Frobenius norm of A is defined as $\|A\|_F = \sqrt{\sum_{i \in [n]} \sum_{j \in [d]} A_{i,j}^2}$. For any PSD matrix $M \in \mathbb{S}^{n \times n}$, we define the M-norm as $\|x\|_M = \sqrt{x^\top M x}$, $\forall x \in \mathbb{R}^n$.

We use $\mathcal{T}_{\mathrm{mat}}(a,b,c)$ to denote the time to multiply two matrices of sizes $a \times b$ and $b \times c$. A basic fact of fast matrix multiplication is that $\mathcal{T}_{\mathrm{mat}}(a,b,c) = \mathcal{T}_{\mathrm{mat}}(b,c,a) = \mathcal{T}_{\mathrm{mat}}(c,a,b)$ (see e.g. [6]), and we will use these three terms interchangeably.

▶ **Fact 2** (Woodbury identity). *Let $A \in \mathbb{R}^{n\times n}, C \in \mathbb{R}^{k\times k}, U \in \mathbb{R}^{n\times k}, V \in \mathbb{R}^{k\times n}$ where A and C are invertible, then*

$$(A+UCV)^{-1} = A^{-1} - A^{-1}U(C^{-1}+VA^{-1}U)^{-1}VA^{-1}.$$

▶ **Definition 3** (Hadamard product). *For any two matrices $A, B \in \mathbb{R}^{m\times n}$, the Hadamard product $A \circ B$ is defined as*

$$(A\circ B)_{i,j} = A_{i,j}\cdot B_{i,j}, \quad \forall i \in [m], j \in [n].$$

We also use $A^{\circ 2}$ to denote $A \circ A$.

The Hadamard product has the following properties (the proofs are straightforward).

▶ **Fact 4** (Properties of Hadamard product). *For matrices $A, B \in \mathbb{R}^{m\times n}$, and vectors $x \in \mathbb{R}^m$, $y \in \mathbb{R}^n$, we have the following properties.*
1. $x^\top (A\circ B)y = \mathrm{tr}[\mathrm{diag}(x)A\,\mathrm{diag}(y)B^\top]$,
2. $A \circ (x\cdot y^\top) = \mathrm{diag}(x)\cdot A\cdot \mathrm{diag}(y)$.

▶ **Definition 5** (Spectral approximation). *For any two symmetric matrices $A, \widetilde{A} \in \mathbb{R}^{n\times n}$, any parameter $\epsilon \in (0,1)$, we say $\widetilde{A}$ and A are ϵ-spectral approximation of each other, denoted as $\widetilde{A} \approx_\epsilon A$, if we have*

$$e^{-\epsilon}\cdot x^\top Ax \le x^\top \widetilde{A}x \le e^{\epsilon}\cdot x^\top Ax, \quad \forall x \in \mathbb{R}^n.$$

Spectral approximation has the following properties.

▶ **Fact 6** (Properties of spectral approximation). *For any two PSD matrices $A, \widetilde{A} \in \mathbb{R}^{n\times n}$, any parameter $\epsilon \in (0,1)$, if $\widetilde{A} \approx_\epsilon A$, then we have*
1. *$B^\top AB \approx_\epsilon B^\top \widetilde{A}B$, for any matrix $B \in \mathbb{R}^{n\times n}$.*
2. *If both A and $\widetilde{A}$ are invertible, then $A^{-1} \approx_\epsilon \widetilde{A}^{-1}$.*
3. *$e^{-\epsilon}\,\mathrm{tr}[A] \le \mathrm{tr}[\widetilde{A}] \le e^{\epsilon}\,\mathrm{tr}[A]$.*
4. *$\widetilde{A}^{\circ 2} \approx_{2\epsilon} A^{\circ 2}$.*

Proof. The proofs of the first three claims are straightforward. We only prove the last claim.

For any vector $x \in \mathbb{R}^n$, we have

$$\begin{aligned}
x^\top A^{\circ 2}x =\ & \mathrm{tr}[\mathrm{diag}(x)A\,\mathrm{diag}(x)A] \\
=\ & \mathrm{tr}[A^{1/2}\,\mathrm{diag}(x)A\,\mathrm{diag}(x)A^{1/2}] \\
\le\ & e^{\epsilon}\cdot \mathrm{tr}[A^{1/2}\,\mathrm{diag}(x)\widetilde{A}\,\mathrm{diag}(x)A^{1/2}] \\
=\ & e^{\epsilon}\cdot \mathrm{tr}[\widetilde{A}^{1/2}\,\mathrm{diag}(x)A\,\mathrm{diag}(x)\widetilde{A}^{1/2}] \\
\le\ & e^{2\epsilon}\cdot \mathrm{tr}[\widetilde{A}^{1/2}\,\mathrm{diag}(x)\widetilde{A}\,\mathrm{diag}(x)\widetilde{A}^{1/2}] = e^{2\epsilon}\cdot x^\top \widetilde{A}^{\circ 2}x
\end{aligned}$$

where the first step follows from Fact 4, the second and the fourth steps follow from the trace invariance under cyclic permutations and the fact that $A^{1/2}$ exists when A is PSD, the third and the fifth steps follow from Part 3 of this fact.

Similarly we can prove $x^\top A^{\circ 2}x \ge e^{-2\epsilon}\cdot x^\top \widetilde{A}^{\circ 2}x$. Thus we have $A^{\circ 2} \approx_{2\epsilon} \widetilde{A}^{\circ 2}$. ◀

3 Background of sum-of-squares optimization

In this section we provide the background of sum-of-squares optimization. We refer the readers to [28, 27] for more details.

▶ **Definition 7** (Polynomial space). *We use $\mathcal{V}_{n,d}$ to denote the set of n-variate polynomials over the reals of degree at most d, where the degree means the total degree, i.e., the degree of $x_1^{d_1}\cdots x_n^{d_n}$ is $\sum_{i=1}^n d_i$.*

▶ **Definition 8** (Degree of polynomial space). *We define $L := \dim(\mathcal{V}_{n,d}) = \binom{n+d}{n}$ and $U := \dim(\mathcal{V}_{n,2d}) = \binom{n+2d}{n}$.*

After fixing a basis $(p_1, p_2, \cdots, p_L)$ of $\mathcal{V}_{n,d}$, there exists a one-to-one correspondence between any polynomial $p = \sum_{i=1}^L x_i \cdot p_i \in \mathcal{V}_{n,d}$ and the vector $[x_1, x_2, \cdots, x_L] \in \mathbb{R}^L$. From now on when the basis is clear from context, we will use $\mathcal{V}_{n,d}$ and $\mathbb{R}^L$ interchangeably, and similarly $\mathcal{V}_{n,2d}$ and $\mathbb{R}^U$ interchangeably.

▶ **Definition 9** (SOS polynomials). *A polynomial $p \in \mathcal{V}_{n,2d}$ is said to be a sum-of-squares (SOS) polynomial if p can be written as a sum of squares of polynomials, i.e. $p = \sum_{i=1}^M q_i^2$ for some $M \in \mathbb{N}$ and polynomials $q_1, q_2, \cdots, q_M \in \mathcal{V}_{n,d}$.*

We use $\Sigma_{n,2d}$ to denote the set of n-variate SOS polynomials of degree at most $2d$.

The set $\Sigma_{n,2d}$ is a closed convex and pointed cone in $\mathcal{V}_{n,2d}$ with non-empty interior (Theorem 17.1 of [24]). The SOS optimization problem requires the variable $x \in \mathbb{R}^U$ to be in the SOS cone, and it is a special case of conic programming. Given a constraint matrix $A \in \mathbb{R}^{m\times U}$ where $m \le U$, and $b \in \mathbb{R}^m$ and $c \in \mathbb{R}^U$, the SOS optimization can be written in the following primal-dual formulation:

$$\begin{aligned} \text{Primal:}\quad \min\ & \langle c, x\rangle & \text{Dual:}\quad \max\ & \langle y, b\rangle \\ \text{s.t.}\ & Ax = b & \text{s.t.}\ & A^\top y + s = c \\ & x \in \Sigma_{n,2d}\,, & & s \in \Sigma_{n,2d}^*\,. \end{aligned} \tag{SOS}$$

Here $\Sigma_{n,2d}^* := \{s \in \mathbb{R}^U \mid s^\top x \ge 0,\ \forall x \in \Sigma_{n,2d}\}$ denotes the dual cone of $\Sigma_{n,2d}$.

Nesterov in [24] noted that the dual SOS cone allows the following characterization.

▶ **Theorem 10** (Dual cone characterization, Theorem 17.1 of [24]). *For any ordered bases $\mathbf{p} = (p_1, \ldots, p_L)$ and $\mathbf{q} = (q_1, \ldots, q_U)$ of $\mathcal{V}_{n,d}$ and $\mathcal{V}_{n,2d}$, let $\Lambda : \mathbb{R}^U \to \mathbb{R}^{L\times L}$ be the unique linear mapping satisfying $\Lambda(\mathbf{q}) = \mathbf{p}\mathbf{p}^\top$.*[4] *Then the dual cone $\Sigma_{n,2d}^*$ admits the characterization under the bases $\mathbf{p}$ and $\mathbf{q}$:*

$$\Sigma_{n,2d}^* = \big\{s \in \mathbb{R}^U \mid \Lambda(s) \succeq 0\big\}. \tag{8}$$

As barrier functions for the cone of positive semidefinite matrices are well-known, this also gives rise to a barrier function for the dual SOS cone. With the standard log-det barrier for the semidefinite cone, the following function $F : \Sigma_{n,2d}^* \to \mathbb{R}$ is a barrier function for $\Sigma_{n,2d}^*$:

$$F(s) = -\log\det(\Lambda(s)).$$

Furthermore, the barrier parameter ν_F of $F(s)$ is bounded by the barrier parameter L of the original log-det barrier function ([24]).

[4] This equation means $\forall t \in \mathbb{R}^n$, $\Lambda([q_1(t), \cdots, q_U(t)]^\top) = [p_1(t), \cdots, p_L(t)]^\top \cdot [p_1(t), \cdots, p_L(t)]$.

Interpolant basis

The barrier function depends on the choice of the basis for both $\mathcal{V}_{n,d}$ and $\mathcal{V}_{n,2d}$, as the linear map Λ depends on these two bases. We follow the approach of [27] and focus on the so-called *interpolant* bases, which generalises well to multivariate polynomials and is numerically stable.

For the vector space $\mathcal{V}_{n,2d}$, consider a set of *unisolvent* points $\mathcal{T} = \{t_1, t_2, \cdots, t_U\} \subseteq \mathbb{R}^n$, which is a set points such that every polynomial in $\mathcal{V}_{n,2d}$ is uniquely determined by its values on the points in $\mathcal{T}$. For univariate polynomials any set of U points suffices, but this does not hold anymore for the multivariate case. To also ensure numerical stability, the so called (approximate) Fekete points can be used as unisolvent points [32, 8].

The interpolant basis is defined as follows. Let us fix a set of unisolvent points $\mathcal{T} = \{t_1, t_2, \cdots, t_U\} \subseteq \mathbb{R}^n$. Now every $t_u \in \mathcal{T}$ implies a Lagrange polynomial q_u which is the unique polynomial that satisfies $q_u(t_u) = 1$ and $q_u(t_v) = 0$ for all $t_v \neq t_u \in \mathcal{T}$. The Lagrange polynomials form a basis $\mathbf{q} = (q_1, \cdots, q_U)$ of $\mathcal{V}_{n,2d}$. Choose any basis $\mathbf{p} = (p_1, \ldots, p_L)$ of $\mathcal{V}_{n,d}$. Define the matrix $P \in \mathbb{R}^{U \times L}$ as

$$P_{u,\ell} = p_\ell(t_u), \quad \forall u \in [U], \ell \in [L].$$

By the definition of the Lagrange polynomials, $p_i p_j = \sum_{u=1}^{U} p_i(t_u) p_j(t_u) q_u$, so we have $\mathbf{p}\mathbf{p}^\top = P^\top \operatorname{diag}(\mathbf{q}) P$. Thus under the bases $\mathbf{p}$ and $\mathbf{q}$, the linear map $\Lambda : \mathbb{R}^U \to \mathbb{R}^{L \times L}$ takes on the following convenient form:

$$\Lambda(s) = P^\top \operatorname{diag}(s) P. \tag{9}$$

For more details on how to pick the unisolvent points and how to construct P, we refer the readers to [27] and the references therein.

4 Algorithm

Since in this paper we focus on the theoretical running time of the algorithm, for simplicity we use the barrier method (see e.g. [30, Chapter 2]) instead of the more sophisticated Skajaa–Ye Algorithm used by [27].

The dual formulation of (SOS) is equivalent to the following optimization problem

$$\min -b^\top y \quad s.t. \;\; y \in \overline{D}_F,$$

where with an abuse of the notation we define $F : \mathbb{R}^m \to \mathbb{R}_+$ to be the barrier function

$$F(y) = -\log\det(\Lambda(c - A^\top y)) \tag{10}$$

for $c \in \mathbb{R}^U$, and $A \in \mathbb{R}^{m \times U}$, and $\Lambda(s) = P^\top \operatorname{diag}(s) P$ is the linear operator defined in Eq (9). $D_F \subseteq \mathbb{R}^m$ is the domain of F, and $\overline{D}_F$ is the closure of D_F.

The barrier parameter of the barrier function F is $\nu_F = L$. The gradient and the Hessian of the barrier function F are (define $s := c - A^\top y$):

$$g(y) = A \cdot \operatorname{diag}\left(P\left(P^\top \operatorname{diag}(s) P\right)^{-1} P^\top\right),$$
$$H(y) = A \cdot \left(P\left(P^\top \operatorname{diag}(s) P\right)^{-1} P^\top\right)^{\circ 2} \cdot A^\top.$$

For any $\eta > 0$, define a function $F_\eta : \mathbb{R}^m \to \mathbb{R}$:

$$F_\eta(y) = -\eta \cdot b^\top y + F(y).$$

The gradient and the Hessian of $F_\eta(y)$ are:

$$g_\eta(y) = -\eta \cdot b + A \cdot \operatorname{diag}\left(P\left(P^\top \operatorname{diag}(s) P\right)^{-1} P^\top\right),$$
$$H_\eta(y) = A \cdot \left(P\left(P^\top \operatorname{diag}(s) P\right)^{-1} P^\top\right)^{\circ 2} \cdot A^\top.$$

Note that $H_\eta(y) = H(y)$ for any η.

In each iteration the barrier method increases η by a factor of $1 + \Theta(\frac{1}{\sqrt{L}})$, and it performs a Newton step

$$y \leftarrow y - H_\eta(y)^{-1} \cdot g_\eta(y).$$

By standard IPM theory it suffices to use a spectral approximation of the Hessian matrix in the Newton step. For more details see e.g. [30].

The main technical part of our algorithm is to efficiently maintain a matrix N that is the spectral approximation of the inverse of the Hessian matrix. To do this, we maintain another matrix $\widetilde{S}$ that is a spectral approximation of $S := P^\top \operatorname{diag}(s) P$, and we use the subroutine LowRankUpdate(Algorithm 3, Lemma 14) to update $\widetilde{S}$. After $\widetilde{S}$ is updated, we use another subroutine UpdateHessianInv (Algorithm 2, Lemma 11) to update N. A complete description of our algorithm can be found in Algorithm 1.

5 Updating Hessian inverse efficiently

In this section we prove how to update the Hessian inverse efficiently. We present the algorithm UpdateHessianInv in Algorithm 2.

▶ **Lemma 11** (Hessian inverse update). *In the algorithm UpdateHessianInv (Algorithm 2), the inputs are the maintained matrices T, N and the updates $V_1, V_2 \in \mathbb{R}^{L \times r}$ where r satisfies $Lr \le U$. The inputs satisfy that for some $\widetilde{S} \in \mathbb{S}^{L \times L}$,*

$$T = \widetilde{S}^{-1} \in \mathbb{R}^{L \times L},$$
$$N = \left(A \cdot (P \widetilde{S}^{-1} P^\top)^{\circ 2} \cdot A^\top\right)^{-1} \in \mathbb{R}^{m \times m},$$

Let $\widetilde{S}^{\text{new}} = \widetilde{S} + V_1 V_2^\top$. The algorithm outputs two matrices T^{new}, N^{new} such that

$$T^{\text{new}} = (\widetilde{S}^{\text{new}})^{-1} \in \mathbb{R}^{L \times L},$$
$$N^{\text{new}} = \left(A \cdot (P (\widetilde{S}^{\text{new}})^{-1} P^\top)^{\circ 2} \cdot A^\top\right)^{-1} \in \mathbb{R}^{m \times m}.$$

Furthermore, the algorithm takes $O(\mathcal{T}_{\text{mat}}(U, U, Lr))$ time.

Proof. We first prove the correctness by analyzing each step of the algorithm.

Step 1. Compute $\overline{V_1}, \overline{V_2} \in \mathbb{R}^{L \times r}$ and $T^{\text{new}} \in \mathbb{R}^{L \times L}$.

$$\begin{aligned} T^{\text{new}} &= T + \overline{V_1} \cdot \overline{V_2}^\top \\ &= T - T V_1 \cdot (I + V_2^\top T V_1)^{-1} \cdot V_2^\top T^\top \\ &= (\widetilde{S} + V_1 V_2^\top)^{-1} = (\widetilde{S}^{\text{new}})^{-1}, \end{aligned}$$

where the first two steps follow from algorithm description, the third step follows from the Woodbury identity (Fact 2) and $T = \widetilde{S}^{-1}$.

Thus T^{new} satisfies the requirement of the output.

Algorithm 1 Main SOS algorithm.

Parameters: $\delta \in (0,1)$, $\epsilon_N \in (0, 0.05)$, $\alpha = \frac{\epsilon_N}{20\sqrt{L}}$, $t = 40\epsilon_N^{-1}\sqrt{L}\log(L/\delta)$.
Input : $A \in \mathbb{R}^{m \times U}$, $b \in \mathbb{R}^m$, $c \in \mathbb{R}^U$
Output : A near feasible and optimal solution.

Construct $P \in \mathbb{R}^{U \times L}$ of the interpolant basis. Convert A, b, c to the interpolant basis.
Use Lemma 22 to obtain a modified dual SOS optimization problem which has an initial solution $(y, s) \in \mathbb{R}^m \times \mathbb{R}^U$ that is optimal for F_η, where $\eta = 1$.
$\widetilde{S} \leftarrow S \leftarrow P^\top \operatorname{diag}(s) P$; // $\widetilde{S}, S \in \mathbb{R}^{L \times L}$
$T \leftarrow S^{-1}$; // $T \in \mathbb{R}^{L \times L}$
$N \leftarrow \left(A(PTP^\top)^{\circ 2} A^\top\right)^{-1}$; // $N \in \mathbb{R}^{m \times m}$
$g \leftarrow -\eta \cdot b + A \cdot \operatorname{diag}\left(P(P^\top \operatorname{diag}(s) P)^{-1} P^\top\right)$; // $g \in \mathbb{R}^m$
for $i = 1, 2, \cdots, t$ **do**
  $\delta_y \leftarrow -N \cdot g$; // $\delta_y \in \mathbb{R}^m$
  $y^{\mathrm{new}} \leftarrow y + \delta_y$; // $y^{\mathrm{new}} \in \mathbb{R}^m$
  $s^{\mathrm{new}} \leftarrow c - A^\top y^{\mathrm{new}}$; // $s^{\mathrm{new}} \in \mathbb{R}^U$
  $\eta^{\mathrm{new}} \leftarrow \eta \cdot (1 + \alpha)$;
  $S^{\mathrm{new}} \leftarrow P^\top \operatorname{diag}(s^{\mathrm{new}}) P$; // $S^{\mathrm{new}} \in \mathbb{R}^{L \times L}$
  $\widetilde{S}^{\mathrm{new}}, V_1, V_2 \leftarrow \textsc{LowRankUpdate}(S^{\mathrm{new}}, \widetilde{S})$;
    // Lemma 14, $\widetilde{S}^{\mathrm{new}} \in \mathbb{R}^{L \times L}$, $V_1, V_2 \in \mathbb{R}^{L \times r_i}$ or $V_1 = V_2 =$ null
  if $V_1 = V_2 =$ null **then**
    $T^{\mathrm{new}} \leftarrow (\widetilde{S}^{\mathrm{new}})^{-1}$; // $T^{\mathrm{new}} \in \mathbb{R}^{L \times L}$
    $N^{\mathrm{new}} \leftarrow \left(A \cdot (PT^{\mathrm{new}} P^\top)^{\circ 2} \cdot A^\top\right)^{-1}$; // $N^{\mathrm{new}} \in \mathbb{R}^{m \times m}$
  else
    $T^{\mathrm{new}}, N^{\mathrm{new}} \leftarrow \textsc{UpdateHessianInv}(T, N, V_1, V_2)$;
      // Lemma 11, $T^{\mathrm{new}} \in \mathbb{R}^{L \times L}, N^{\mathrm{new}} \in \mathbb{R}^{m \times m}$
  $g^{\mathrm{new}} \leftarrow -\eta^{\mathrm{new}} \cdot b + A \cdot \operatorname{diag}\left(P\left(P^\top \operatorname{diag}(s^{\mathrm{new}}) P\right)^{-1} P^\top\right)$; // $g^{\mathrm{new}} \in \mathbb{R}^m$
  $(\eta, y, s, \widetilde{S}, T, N, g) \leftarrow (\eta^{\mathrm{new}}, y^{\mathrm{new}}, s^{\mathrm{new}}, \widetilde{S}^{\mathrm{new}}, T^{\mathrm{new}}, N^{\mathrm{new}}, g^{\mathrm{new}})$;
return (y, s)

Step 2. Compute $Y', Z' \in \mathbb{R}^{U \times (L+r)}$ and $Y, Z \in \mathbb{R}^{U \times (L+r)r}$. We prove that Y and Z satisfy $(PTP^\top)^{\circ 2} + Y \cdot Z^\top = (PT^{\mathrm{new}} P^\top)^{\circ 2}$:

$$\begin{aligned}
(PTP^\top)^{\circ 2} + Y \cdot Z^\top &= (PTP^\top)^{\circ 2} + \sum_{i=1}^r \operatorname{diag}(u_i) \cdot \left(Y' \cdot (Z')^\top\right) \cdot \operatorname{diag}(v_i) \\
&= (PTP^\top)^{\circ 2} + \left(Y' \cdot (Z')^\top\right) \circ \left(\sum_{i=1}^r u_i \cdot v_i^\top\right) \\
&= (PTP^\top)^{\circ 2} + \left(2PTP^\top + (P\overline{V_1}) \cdot (P\overline{V_2})^\top\right) \circ \left((P\overline{V_1}) \cdot (P\overline{V_2})^\top\right) \\
&= \left(PTP^\top + (P\overline{V_1}) \cdot (P\overline{V_2})^\top\right)^{\circ 2} \\
&= (PT^{\mathrm{new}} P^\top)^{\circ 2},
\end{aligned}$$

where the first step follows from the algorithm description of Y and Z, the second step follows from Part 2 of Fact 4 that $\operatorname{diag}(x) \cdot A \cdot \operatorname{diag}(y) = A \circ (x \cdot y^\top)$, the third step follows from $Y' \cdot (Z')^\top = 2PTP^\top + (P\overline{V_1}) \cdot (P\overline{V_2})$ and $(P\overline{V_1}) \cdot (P\overline{V_2}) = \sum_{i=1}^r u_i \cdot v_i^\top$ (see algorithm description of Y' and Z'), the last step follows from $T^{\mathrm{new}} = T + \overline{V_1} \cdot \overline{V_2}^\top$.

Algorithm 2 UpdateHessianInv.

Input : $T \in \mathbb{R}^{L\times L}$, $N \in \mathbb{R}^{m\times m}$, $V_1, V_2 \in \mathbb{R}^{L\times r}$
Output: $T^{\text{new}} \in \mathbb{R}^{L\times L}$, $N^{\text{new}} \in \mathbb{R}^{m\times m}$

1 // Step 1
2 $\overline{V_1} \leftarrow -TV_1 \cdot (I + V_2^\top T V_1)^{-1}$; // $\overline{V_1} \in \mathbb{R}^{L\times r}$
3 $\overline{V_2} \leftarrow TV_2$; // $\overline{V_2} \in \mathbb{R}^{L\times r}$
4 $T^{\text{new}} \leftarrow T + \overline{V_1} \cdot \overline{V_2}^\top$; // $T^{\text{new}} \in \mathbb{R}^{L\times L}$
5 // Step 2
6 $Y' \leftarrow [2PT, P\overline{V_1}]$; // $Y' \in \mathbb{R}^{U\times(L+r)}$
7 $Z' \leftarrow [P, P\overline{V_2}]$; // $Z' \in \mathbb{R}^{U\times(L+r)}$
8 $Y \leftarrow [\text{diag}(u_1)Y', \cdots, \text{diag}(u_r)Y']$, u_i is the i-th column of $P\overline{V_1}$; // $Y \in \mathbb{R}^{U\times(L+r)r}$
9 $Z \leftarrow [\text{diag}(v_1)Z', \cdots, \text{diag}(v_r)Z']$, v_i is the i-th column of $P\overline{V_2}$; // $Z \in \mathbb{R}^{U\times(L+r)r}$
10 // Step 3
11 $N^{\text{new}} \leftarrow N - N\cdot(AY)\cdot\left(I + (AZ)^\top N(AY)\right)^{-1}\cdot(AZ)^\top\cdot N$; // $N^{\text{new}} \in \mathbb{R}^{m\times m}$
12 **return** $T^{\text{new}}, N^{\text{new}}$

Step 3. **Compute $N^{\text{new}} \in \mathbb{R}^{m\times m}$.**

$$\begin{aligned} N^{\text{new}} &= N - N\cdot(AY)\cdot\left(I + (AZ)^\top N(AY)\right)^{-1}\cdot(AZ)^\top\cdot N \\ &= \left(A\cdot(PTP^\top)^{\circ 2}\cdot A^\top + (AY)\cdot(AZ)^\top\right)^{-1} \\ &= \left(A\cdot(PT^{\text{new}}P^\top)^{\circ 2}\cdot A^\top\right)^{-1}, \end{aligned}$$

where the first step follows from the algorithm description of N^{new}, the second step follows from $N = \left(A\cdot(PTP^\top)^{\circ 2}\cdot A^\top\right)^{-1}$ and the Woodbury identity (Fact 2), and the last step follows from $(PT^{\text{new}}P^\top)^{\circ 2} = (PTP^\top)^{\circ 2} + Y\cdot Z^\top$.

Thus N^{new} satisfies the requirement of the output.

Time complexity. It is easy to see that the most time-consuming step is to compute N^{new} on Line 11, and in total this step takes $O(\mathcal{T}_{\text{mat}}(m,U,Lr) + \mathcal{T}_{\text{mat}}(m,m,Lr) + (Lr)^\omega)$ time.

Since $Lr \le U$ and $m \le U$, overall this algorithm takes at most $O(\mathcal{T}_{\text{mat}}(U,U,Lr))$ time. ◀

6 Correctness

6.1 Standard results from IPM theory

We use the following two results of the barrier method that hold for any cone with a barrier function. The proofs are standard, (see e.g., [30, Section 2.4]). For completeness we include a proof in the full version.

▶ **Lemma 12** (Invariance of Newton step, [30]). *Consider the following optimization problem:* $\min -b^\top y$ *s.t.* $y \in \overline{D}_F$, *where* $F : \mathbb{R}^m \to \mathbb{R}_+$ *is a barrier function with barrier parameter* ν_F, $D_F \subseteq \mathbb{R}^m$ *is the domain of* F, *and* $\overline{D}_F$ *is the closure of* D_F. *For any* $\eta \ge 1$, *define* $F_\eta(y) = -\eta b^\top y + F(y)$. *Let* $g_\eta(y) \in \mathbb{R}^m$ *and* $H(y) \in \mathbb{R}^{m\times m}$ *denote the gradient and the Hessian of* F_η *at* y.

Let $0 < \epsilon_N \le 0.05$ *be a parameter. If a feasible solution* $y \in D_F$, *a parameter* $\eta > 0$, *and a positive definite matrix* $\widetilde{H} \in \mathbb{S}^{n\times n}$ *satisfy the following:*

$$\|g_\eta(y)\|_{H(y)^{-1}} \le \epsilon_N, \quad \widetilde{H} \approx_{0.02} H(y).$$

Then $\eta^{\text{new}} = \eta\cdot(1 + \frac{\epsilon_N}{20\sqrt{\nu_F}})$, $y^{\text{new}} = y + \delta_y$ *where* $\delta_y = -\widetilde{H}^{-1}g_{\eta^{\text{new}}}(y)$ *satisfy* $y^{\text{new}} \in D_F$ *and*

$$\|\delta_y\|_{H(y)} \le 2\epsilon_N, \quad \|g_{\eta^{\text{new}}}(y^{\text{new}})\|_{H(y^{\text{new}})^{-1}} \le \epsilon_N.$$

▶ **Lemma 13** (Approximate optimality, [30]). *Consider the following optimization problem:* $\min -b^\top y$ *s.t.* $y \in \overline{D}_F$, *where* $F : \mathbb{R}^m \to \mathbb{R}_+$ *is a barrier function with barrier parameter* ν_F, $D_F \subseteq \mathbb{R}^m$ *is the domain of* F, *and* $\overline{D}_F$ *is the closure of* D_F. *Let* OPT *be the optimal objective value of this optimization problem. For any* $\eta \geq 1$, *define* $F_\eta(y) = -\eta b^\top y + F(y)$. *Let* $g_\eta(y) \in \mathbb{R}^m$ *and* $H(y) \in \mathbb{R}^{m \times m}$ *denote the gradient and the Hessian of* F_η *at* y.

Let $0 < \epsilon_N \leq 0.05$. *If a feasible solution* $y \in D_F$ *satisfies* $\|g_\eta(y)\|_{H(y)^{-1}} \leq \epsilon_N$, *then we have* $-b^\top y \leq \mathrm{OPT} + \frac{\nu_F}{\eta} \cdot (1 + 2\epsilon_N)$.

6.2 Low rank update

We use the following low rank update procedure of [16] and [15], which we modify by using a cutoff when $r \geq U/L$. The proof of the following lemma can be found in [15, Theorem 10.8].

Algorithm 3 LowRankUpdate of [16].

Parameters: A real number $\epsilon_S < 0.01$.
Input : New exact matrix $S^{\mathrm{new}} \in \mathbb{R}^{L \times L}$, old approximate matrix $\widetilde{S} \in \mathbb{R}^{L \times L}$,
Output : New approximate matrix $\widetilde{S}^{\mathrm{new}} \in \mathbb{R}^{L \times L}$, update matrices $V_1, V_2 \in \mathbb{R}^{L \times r}$.

$Z_{\mathrm{mid}} \leftarrow (S^{\mathrm{new}})^{-1/2} \widetilde{S} (S^{\mathrm{new}})^{-1/2} - I$
Compute spectral decomposition $Z_{\mathrm{mid}} = X \operatorname{diag}(\lambda) X^\top$
Let $\pi : [L] \to [L]$ be a sorting permutation such that $|\lambda_{\pi(i)}| \geq |\lambda_{\pi(i+1)}|$.
if $|\lambda_{\pi(1)}| \leq \epsilon_S$ **then**
  $\widetilde{S}_{\mathrm{new}} \leftarrow \widetilde{S}$;
  return $(\widetilde{S}^{\mathrm{new}}, 0, 0)$
else
  $r \leftarrow 1$;
  while $2r \leq U/L$ and $(|\lambda_{\pi(2r)}| > \epsilon_S$ or $|\lambda_{\pi(2r)}| > (1 - 1/\log L)|\lambda_{\pi(r)}|)$ **do**
    $r \leftarrow r + 1$;
  $r \leftarrow 2r$;
  if $r \geq U/L$ **then**
    $\widetilde{S}^{\mathrm{new}} \leftarrow S^{\mathrm{new}}$; `// Here we deviate from [16]`
    return $(\widetilde{S}^{\mathrm{new}}, \mathtt{null}, \mathtt{null})$
  else
    $\lambda^{\mathrm{new}}_{\pi(i)} \leftarrow \begin{cases} 0 & \text{if } i = 1, 2, \ldots, r \\ \lambda_{\pi(i)} & \text{else} \end{cases}$
    $\Omega \leftarrow \operatorname{supp}(\lambda^{\mathrm{new}} - \lambda)$; // $|\Omega| = r$
    $V_1 \leftarrow ((S^{\mathrm{new}})^{1/2} \cdot X \cdot \operatorname{diag}(\lambda^{\mathrm{new}} - \lambda))_{:,\Omega}$; // $V_1 \in \mathbb{R}^{L \times r}$
    $V_2 \leftarrow ((S^{\mathrm{new}})^{1/2} \cdot X)_{:,\Omega}$; // $V_2 \in \mathbb{R}^{L \times r}$
    $\widetilde{S}^{\mathrm{new}} \leftarrow \widetilde{S} + (S^{\mathrm{new}})^{1/2} X \operatorname{diag}(\lambda^{\mathrm{new}} - \lambda) X^\top (S^{\mathrm{new}})^{1/2}$;
    // $\widetilde{S}^{\mathrm{new}} = \widetilde{S} + V_1 V_2^\top \in \mathbb{R}^{L \times L}$
    return $(\widetilde{S}^{\mathrm{new}}, V_1, V_2)$;

▶ **Lemma 14** (Low rank update). *The algorithm* LowRankUpdate *(Algorithm 3) has the following properties:*

(i) *The output matrix* $\widetilde{S}^{\mathrm{new}} = \widetilde{S} + V_1 V_2^\top$ *is a spectral approximation of the input matrix:* $\widetilde{S}^{\mathrm{new}} \approx_{\epsilon_S} S^{\mathrm{new}}$.

(ii) *Consider a total of t iterations of* LowRankUpdate. *Initially $\widetilde{S}^{(0)} = S^{(0)}$, and we use $(S^{(i)}, \widetilde{S}^{(i-1)})$ and $(\widetilde{S}^{(i)}, V_1^{(i)}, V_2^{(i)})$ to denote the input and the output of the i-th iteration. We define the rank r_i to be the rank of $V_1^{(i)}$ if $V_1^{(i)} \neq \texttt{null}$, and otherwise we define $r_i = U/L$.*
If the input exact matrices $S^{(0)}, S^{(1)}, \cdots, S^{(t)} \in \mathbb{R}^{L\times L}$ satisfy

$$\|(S^{(i-1)})^{-1/2} S^{(i)} (S^{(i-1)})^{-1/2} - I\|_F \leq 0.02, \ \forall i \in [t]. \tag{11}$$

Then for any non-increasing sequence $g \in \mathbb{R}_+^L$, the ranks r_i satisfy

$$\sum_{i=1}^{t} r_i \cdot g_{r_i} \leq O(t \cdot \|g\|_2 \cdot \log L).$$

Furthermore, the algorithm LowRankUpdate *takes $O(L^\omega)$ time.*

6.3 Slowly moving guarantee

In SOS optimization, the matrix $S = P^\top \operatorname{diag}(s) P$ corresponds to the slack matrix of the SDP. The following lemma proves similar to SDP, in SOS the matrix S is changing slowly. Using this lemma we will prove that the requirement Eq. (11) of Lemma 14 is satisfied, which means we can approximate the change to the slack by a low-rank matrix.

▶ **Lemma 15** (Slowly moving guarantee). *Let $c \in \mathbb{R}^U$ and $A \in \mathbb{R}^{m\times U}$ be the input to the optimization problem. Let $P \in \mathbb{R}^{U\times L}$ be the matrix of the interpolant basis.*

For any $y \in \mathbb{R}^m$ and $y^{\text{new}} = y + \delta_y \in \mathbb{R}^m$, let $s = c - A^\top y \in \mathbb{R}^U$ and $S = P^\top \operatorname{diag}(s) P \in \mathbb{R}^{L\times L}$. Similarly define s^{new} and S^{new} from y^{new}. Let $H(y) = A \cdot \big(P\big(P^\top \operatorname{diag}(s) P\big)^{-1} P^\top\big)^{\circ 2} \cdot A^\top \in \mathbb{R}^{m\times m}$. If $s, s^{\text{new}} \in \Sigma_{n,2d}^*$, then S and S^{new} are both PSD, and we have

$$\|S^{-1/2} S^{\text{new}} S^{-1/2} - I\|_F = \|\delta_y\|_{H(y)}.$$

Proof. Note that if $s, s^{\text{new}} \in \Sigma_{n,2d}^*$, then by the dual cone characterization (Theorem 10) S and S^{new} are both PSD.

For convenience we define $M = PS^{-1}P^\top \in \mathbb{R}^{U\times U}$. Note that $H(y) = A \cdot M^{\circ 2} \cdot A^\top$. We also define $\delta_s = s^{\text{new}} - s = -A^\top \delta_y$. $\forall u \in [U]$, we use $p_u \in \mathbb{R}^L$ to denote the u-th row of P.

$$\begin{aligned}
\|S^{-1/2} S^{\text{new}} S^{-1/2} - I\|_F^2 &= \|S^{-1/2}\big(S^{\text{new}} - S\big) S^{-1/2}\|_F^2 \\
&= \|S^{-1/2}\big(P \operatorname{diag}(\delta_s) P^\top\big) S^{-1/2}\|_F^2 \\
&= \operatorname{tr}\big(S^{-1}(P^\top \operatorname{diag}(\delta_s) P) S^{-1}(P^\top \operatorname{diag}(\delta_s) P)\big) \\
&= \operatorname{tr}\big(S^{-1}(\sum_{u\in U} (\delta_s)_u \cdot p_u p_u^\top) S^{-1}(\sum_{v\in U} (\delta_s)_v \cdot p_v p_v^\top)\big) \\
&= \sum_{u,v\in U} (\delta_s)_u (\delta_s)_v \cdot \operatorname{tr}\big(S^{-1} p_u p_u^\top S^{-1} p_v p_v^\top\big) \\
&= \sum_{u,v\in U} (\delta_s)_u (\delta_s)_v \cdot (p_v^\top S^{-1} p_u)^2 \\
&= \sum_{u,v\in U} (\delta_s)_u (\delta_s)_v \cdot M_{uv}^2 \ = \ \|\delta_s\|_{M^{\circ 2}}^2,
\end{aligned} \tag{12}$$

where the third step follows from $\|A\|_F^2 = \operatorname{tr}(A^\top A)$ and the cyclic property of trace, and the sixth step again follows from the cyclic property of trace.

Since $\delta_s = -A^\top \delta_y$, we have

$$\|\delta_s\|_{M^{\circ 2}}^2 = \delta_s^\top M^{\circ 2} \delta_s = \delta_y^\top A M^{\circ 2} A^\top \delta_y = \delta_y^\top H(y) \delta_y = \|\delta_y\|_{H(y)}^2. \tag{13}$$

Combining Eq. (12) and (13) we get the bound in the lemma statement. ◀

6.4 Proof of correctness

Finally we are ready to prove the correctness of Algorithm 1.

▶ **Theorem 16** (Correctness of Algorithm 1). *Consider the following optimization problem with $A \in \mathbb{R}^{m\times U}$, $b \in \mathbb{R}^m$, and $c \in \mathbb{R}^U$:*

$$\begin{aligned} \textit{Primal:}\quad & \min \langle c, x\rangle && \textit{Dual:}\quad \max \langle y, b\rangle \\ \text{s.t.}\quad & Ax = b && \text{s.t.}\quad A^\top y + s = c \\ & x \in \Sigma_{n,2d}\,, && s \in \Sigma^*_{n,2d}\,. \end{aligned}$$

Let OPT *denote the optimal objective value of this optimization problem. Assume Slater's condition and that any primal feasible $x \in \Sigma_{n,2d}$ satisfies $\|x\|_1 \le R$.*

Then for any error parameters $\delta \in (0,1)$, $\epsilon_S \le 0.01$, and $\epsilon_N \le 0.05$, Algorithm 1 outputs $x \in \Sigma_{n,2d}$ that satisfies

$$\langle c, x\rangle \le \mathrm{OPT} + \delta \cdot R\|c\|_\infty \quad \textit{and} \quad \|Ax - b\|_1 \le 8\delta L \cdot (LR\|A\|_\infty + \|b\|_1).$$

Proof. We consider the optimization problem $\min -b^\top y$ s.t. $y \in \overline{D}_F$, where $F : \mathbb{R}^m \to \mathbb{R}_+$ is the barrier function defined in Eq. (10), and $\overline{D}_F$ is the closure of the domain of F. The barrier parameter of F is $\nu_F = L$. This optimization problem is equivalent to the dual formulation and its optimal value is $-$OPT. For any η, let $F_\eta(y) = -\eta b^\top y + F(y)$.

In the beginning Algorithm 1 first uses Lemma 22 to convert the optimization problem to another form which has an initial feasible solution y that is close to the optimal solution of F_η with $\eta = 1$. The initial y satisfies $\|g_\eta(y)\|_{H(y)^{-1}} \le \epsilon_N$ by Lemma 22. Initially we also have $\widetilde{S} = S = P^\top \operatorname{diag}(s) P$ (Line 3 in Algorithm 1).

Next we prove the correctness of Algorithm 1 inductively. At each iteration, we assume the following induction hypothesis is satisfied: (1) $\|g_\eta(y)\|_{H(y)^{-1}} \le \epsilon_N$, (2) $\widetilde{S} \approx_{\epsilon_S} S$. We aim to prove that the updated y^{new}, η^{new}, S^{new}, and $\widetilde{S}^{\mathrm{new}}$ still satisfy these two conditions.

In Lemma 11 we have proved that in Algorithm 1 we always maintain $N = \big(A \cdot (P\widetilde{S}^{-1}P^\top)^{\circ 2} \cdot A^\top\big)^{-1}$. Let $\widetilde{H} = N^{-1}$, we have

$$\widetilde{H} = A \cdot \big(P\widetilde{S}^{-1}P^\top\big)^{\circ 2} \cdot A^\top \approx_{2\epsilon_S} A \cdot \big(PS^{-1}P^\top\big)^{\circ 2} \cdot A^\top = H(y),$$

where in the second step we use the induction hypothesis that $\widetilde{S} \approx_{\epsilon_S} S$, and by Fact 6 we have $\widetilde{S}^{-1} \approx_{\epsilon_S} S^{-1}$, and hence $P\widetilde{S}^{-1}P^\top \approx_{\epsilon_S} PS^{-1}P^\top$, and hence $(P\widetilde{S}^{-1}P^\top)^{\circ 2} \approx_{2\epsilon_S} (PS^{-1}P^\top)^{\circ 2}$.

The new vector y^{new} is computed as $y^{\mathrm{new}} = y + \delta_y$ where $\delta_y = -\widetilde{H}^{-1} g_\eta(y)$ (Line 8 and 9 of Algorithm 1). And η is updated to $\eta^{\mathrm{new}} = \eta \cdot (1 + \frac{\epsilon_N}{20\sqrt{L}})$ (Line 11 of Algorithm 1). Since $\|g_\eta(y)\|_{H(y)^{-1}} \le \epsilon_N$, and $\widetilde{H} \approx_{2\epsilon_S} H(y)$ where $2\epsilon_S \le 0.02$ by its definition in Algorithm 3, the requirements of Lemma 12 are satisfied, so we have

$$\|g_{\eta^{\mathrm{new}}}(y^{\mathrm{new}})\|_{H(y^{\mathrm{new}})^{-1}} \le \epsilon_N, \quad \text{and} \quad \|\delta_y\|_{H(y)} \le 2\epsilon_N.$$

This proves the first induction hypothesis.

Then using Lemma 15 and since $\epsilon_N \le 0.01$ by its definition in Algorithm 1, we have

$$\|S^{-1/2}(S^{\mathrm{new}})S^{-1/2} - I\|_F \le \|\delta_y\|_{H(y)} \le 2\epsilon_N \le 0.02.$$

Thus the input matrix S^{new} to LowRankUpdate satisfies the requirement of Eq. (11) of Lemma 14, and we have that $\widetilde{S}^{\mathrm{new}} \approx_{\epsilon_S} S^{\mathrm{new}}$. This proves the second induction hypothesis.

Finally, we know that after $t = 40\epsilon_N^{-1}\sqrt{L}\log(L/\delta)$ iterations, η becomes $(1+\frac{\epsilon_N}{20\sqrt{L}})^t \geq 2L/\delta^2$, so using Lemma 13, we have

$$b^\top y \geq \mathrm{OPT} - \frac{\nu_F}{\eta}\cdot(1+2\epsilon_N) \geq \mathrm{OPT} - \delta^2.$$

Thus the initialization lemma (Lemma 22) ensures that we have a solution $x \in \Sigma_{n,2d}$ to the original primal optimization problem which satisfies

$$\langle c, x\rangle \leq \mathrm{OPT} + \delta\cdot R\|c\|_\infty, \qquad \|Ax-b\|_1 \leq 8\delta L\cdot(LR\|A\|_\infty + \|b\|_1). \qquad \blacktriangleleft$$

7 Time complexity

7.1 Worst case time

We first bound the worst case running time of Algorithm 1. The running time of the i-th iteration depends on the updated rank r_i of LowRankUpdate, which is defined to be the size of $V_1^{(i)}$ if $V_1^{(i)} \neq \texttt{null}$, and U/L otherwise (see Lemma 14).

▶ **Lemma 17** (Worst case time of Algorithm 1). *In Algorithm 1, the initialization time is $O(U^\omega)$, and the running time in the i-th iteration is $O(\mathcal{T}_{\mathrm{mat}}(U,U,\min\{Lr_i,U\}))$.*

Proof.

Initialization time. The most time-consuming step of initialization is Line 5, where computing $N = \left(A(PTP^\top)^{\circ 2}A^\top\right)^{-1}$ takes $O(\mathcal{T}_{\mathrm{mat}}(U,U,L)+\mathcal{T}_{\mathrm{mat}}(U,U,m))$ time. This is bounded by $O(U^\omega)$ since $L, m \leq U$.

Time per iteration. In each iteration the most time-consuming steps are (1) computing S^{new} and calling LowRankUpdate on Line 12-14, (2) executing the if-clause on Line 15-20, and (3) computing g^{new} on Line 21.

1. Computing S^{new} on Line 12 takes $\mathcal{T}_{\mathrm{mat}}(U,L,L)$ time. Calling LowRankUpdate on Line 14 takes $O(L^\omega)$ time by Lemma 14.
2. In the if-clause on Line 15-20, if $V_1 = V_2 = \texttt{null}$, then $Lr_i \geq U$, and we compute $N^{\mathrm{new}} = \left(A\cdot(PT^{\mathrm{new}}P^\top)^{\circ 2}\cdot A^\top\right)^{-1}$, which takes $O(\mathcal{T}_{\mathrm{mat}}(U,U,U))$ time. Otherwise we call UpdateHessianInv on Line 19, which takes $O(\mathcal{T}_{\mathrm{mat}}(U,U,Lr_i))$ time by Lemma 11. In total the if-clause has running time $O(\mathcal{T}_{\mathrm{mat}}(U,U,\min\{Lr_i,U\}))$.
3. Computing the gradient $g = -\eta^{\mathrm{new}}\cdot b + A\cdot\mathrm{diag}\left(P\left(P^\top\mathrm{diag}(s^{\mathrm{new}})P\right)^{-1}P^\top\right)$ on Line 21 takes $O(\mathcal{T}_{\mathrm{mat}}(U,U,L))$ time since $m \leq U$.

Thus the total time per iteration is $O(\mathcal{T}_{\mathrm{mat}}(U,U,\min\{Lr_i,U\}))$. $\blacktriangleleft$

7.2 Amortized time

In this section we bound the amortized running time of Algorithm 1.

Let ω be the matrix multiplication exponent, let α be the dual matrix multiplication exponent. The current best values are $\omega \approx 2.373$ and $\alpha \approx 0.314$ [21, 10, 1]. Note that the current best values of ω and α satisfies that $\alpha \geq 5-2\omega$. We use the following modified lemma from [15]:

▶ **Lemma 18** (Helpful lemma for amortization, modified version of Lemma 10.13 of [15]). *Let t denote the total number of iterations. Let $r_i \in [L]$ be the rank for the i-th iteration for $i \in [t]$. Assume r_i satisfies the following condition: for any vector $g \in \mathbb{R}_+^L$ which is non-increasing, we have $\sum_{i=1}^t r_i \cdot g_{r_i} \leq O(t \cdot \|g\|_2)$.*

If the cost in the i-th iteration is $O(\mathcal{T}_{\mathrm{mat}}(U, U, \min\{Lr_i, U\}))$, when $\alpha \geq 5 - 2\omega$, the amortized cost per iteration is $U^{2+o(1)} + U^{\omega - 1/2 + o(1)} \cdot L^{1/2}$.

We include the proof of Lemma 18 for completeness. The main difference between this proof and that of [15] is that we cut off at U/L instead of L. Our proof makes use of the following two facts about ω and α (Lemma A.4 and Lemma A.5 of [9]).

▶ **Fact 19** (Relation of ω and α). $\omega \leq 3 - \alpha$.

▶ **Fact 20** (Upper bound of $\mathcal{T}_{\mathrm{mat}}(n, n, r)$). *For any $r \leq n$, we have that $\mathcal{T}_{\mathrm{mat}}(n, n, r) \leq n^{2+o(1)} + r^{\frac{\omega-2}{1-\alpha}} \cdot n^{2 - \frac{\alpha(\omega-2)}{(1-\alpha)} + o(1)}$.*

Proof of Lemma 18. For r_i that satisfies $r_i \leq U/L$, we have

$$\begin{aligned} \mathcal{T}_{\mathrm{mat}}(U, U, Lr_i) &\leq U^{2+o(1)} + (Lr_i)^{\frac{\omega-2}{1-\alpha}} \cdot U^{2 - \frac{\alpha(\omega-2)}{1-\alpha} + o(1)} \\ &= U^{2+o(1)} + U^{2 - \frac{\alpha(\omega-2)}{1-\alpha} + o(1)} \cdot L^{\frac{\omega-2}{1-\alpha}} \cdot r_i^{\frac{\omega-2}{1-\alpha}}, \end{aligned} \tag{14}$$

where the first step follows from Fact 20.

Define a sequence $g \in \mathbb{R}_+^L$ such that for $r \in [L]$,

$$g_r = \begin{cases} r^{\frac{\omega-2}{1-\alpha} - 1} & \text{if } r \leq U/L, \\ (U/L)^{\frac{\omega-2}{1-\alpha}} \cdot r^{-1} & \text{if } r > U/L. \end{cases}$$

Note that g is non-increasing because $\frac{\omega-2}{1-\alpha} \leq 1$ (Fact 19). Then using the condition in the lemma statement, we have

$$\begin{aligned} \sum_{i=1}^t \min\{r_i^{\frac{\omega-2}{1-\alpha}}, (U/L)^{\frac{\omega-2}{1-\alpha}}\} &= \sum_{i=1}^t r_i \cdot g_{r_i} \\ &\leq t \cdot \|g\|_2 \\ &\leq t \cdot \Big(\int_{x=1}^{U/L} x^{\frac{2(\omega-2)}{1-\alpha} - 2} \mathrm{d}x + (U/L)^{\frac{2(\omega-2)}{1-\alpha}} \cdot \int_{x=U/L}^{L} x^{-2} \mathrm{d}x \Big)^{1/2} \\ &\leq t \cdot \Big(c \cdot (U/L)^{\frac{2(\omega-2)}{1-\alpha} - 1} + (U/L)^{2(\frac{\omega-2}{1-\alpha})} \cdot (U/L)^{-1} \Big)^{1/2} \\ &= t \cdot O((U/L)^{\frac{(\omega-2)}{1-\alpha} - 1/2}), \end{aligned} \tag{15}$$

where the first step follows from the definition of $g \in \mathbb{R}^L$, the second step follows from the assumption $\sum_{t=1}^t r_i \cdot g_{r_i} \leq t \cdot \|g\|_2$ in the lemma statement, the third step follows from upper bounding the ℓ_2 norm $\|g\|_2^2 = \sum_{r=1}^L g_r^2$, and the fourth step follows $\frac{2(\omega-2)}{1-\alpha} \geq 1$ when $\alpha \geq 5 - 2\omega$, so the integral $\int_{x=1}^{U/L} x^{\frac{2(\omega-2)}{1-\alpha} - 2} \mathrm{d}x = c \cdot x^{\frac{2(\omega-2)}{1-\alpha} - 1} \big|_1^{U/L} = O\big((U/L)^{\frac{2(\omega-2)}{1-\alpha} - 1}\big)$ where $c := 1/(\frac{2(\omega-2)}{1-\alpha} - 1)$.

Thus we have

$$\begin{aligned}
&\sum_{t=1}^{t} \mathcal{T}_{\mathrm{mat}}(U,U,\min\{Lr_i,U\}) \\
&\le \sum_{t=1}^{t} \left(U^{2+o(1)} + U^{2-\frac{\alpha(\omega-2)}{1-\alpha}+o(1)} \cdot L^{\frac{\omega-2}{1-\alpha}} \cdot \min\{r_i^{\frac{\omega-2}{1-\alpha}}, (U/L)^{\frac{\omega-2}{1-\alpha}}\}\right) \\
&= t \cdot U^{2+o(1)} + U^{2-\frac{\alpha(\omega-2)}{1-\alpha}+o(1)} \cdot L^{\frac{\omega-2}{1-\alpha}} \cdot \sum_{t=1}^{t} \min\{r_i^{\frac{\omega-2}{1-\alpha}}, (U/L)^{\frac{\omega-2}{1-\alpha}}\} \\
&\le t \cdot U^{2+o(1)} + U^{2-\frac{\alpha(\omega-2)}{1-\alpha}+o(1)} \cdot L^{\frac{\omega-2}{1-\alpha}} \cdot t \cdot (U/L)^{\frac{(\omega-2)}{1-\alpha}-1/2} \\
&= t \cdot (U^{2+o(1)} + U^{\omega-1/2+o(1)} \cdot L^{1/2}),
\end{aligned}$$

where the first step follows from Eq. (14) and $\mathcal{T}_{\mathrm{mat}}(U,U,U) = U^{\omega} = U^{2-\frac{\alpha(\omega-2)}{1-\alpha}} \cdot L^{\frac{\omega-2}{1-\alpha}} \cdot (U/L)^{\frac{\omega-2}{1-\alpha}}$, the second step follows from moving summation inside, the third step follows from Eq. (15), and the last step follows from adding the terms together. ◀

Now we are ready to prove our main theorem for the amortized time of Algorithm 1.

▶ **Theorem 21** (Time of Algorithm 1). *When $\alpha \ge 5 - 2\omega$, the running time of Algorithm 1 is* $(U^2 \cdot L^{1/2} + U^{\omega-1/2} \cdot L) \cdot (\log(1/\delta) + U^{o(1)})$.

Proof. Using Lemma 17 the initialization time is $O(U^{\omega}) \le O(U^{\omega-1/2} \cdot L)$ since $U \le L^2$.

Using Lemma 14 we know that the ranks r_i indeed satisfy the requirement of Lemma 18, and since the worst case time per iteration is $O(\mathcal{T}_{\mathrm{mat}}(U,U,\min\{Lr_i,U\}))$ (Lemma 17), using Lemma 18 the time per iteration is $U^{2+o(1)} + U^{\omega-1/2+o(1)} \cdot L^{1/2}$. Since there are in total $t = 40\epsilon_N^{-1}\sqrt{L}\log(L/\delta)$ iterations, we get the total running time as claimed. ◀

7.3 Comparison with previous results

In this section we compare the running time of [27], [16, 15], and our result. We assume that $m = \Theta(U)$ when making the comparisons.

Ignoring $\log(1/\delta)$ and $U^{o(1)}$ factors, and since $L \le U \le L^2$, the running times are

$$\begin{aligned}
\text{[27] (SOS)} &: L^{0.5} \cdot U^{\omega}, \\
\text{[16, 15] (SDP)}^5 &: L^{0.5} \cdot \min\{UL^2 + U^{\omega},\ L^4 + L^{2\omega-0.5}\}, \\
\text{Ours (SOS)} &: L^{0.5} \cdot (U^2 + U^{\omega-0.5} \cdot L^{0.5}).
\end{aligned}$$

Current ω and α

Plugging in the current best values $\omega \approx 2.373$ and $\alpha \approx 0.314$, we have

$$\begin{aligned}
\text{[27] (SOS)} &: L^{0.5} \cdot U^{2.373}, \\
\text{[16, 15] (SDP)} &: L^{0.5} \cdot \min\{UL^2 + U^{2.373},\ L^{4.246}\} \\
&= L^{0.5} \cdot \begin{cases} UL^2 & \text{when } U \in (L, L^{1.457}], \\ U^{2.373} & \text{when } U \in (L^{1.457}, L^{1.789}], \\ L^{4.246} & \text{when } U \in (L^{1.789}, L^2), \end{cases} \\
\text{Ours (SOS)} &: L^{0.5} \cdot (U^2 + U^{1.873}L^{0.5}).
\end{aligned}$$

[5] When solving SOS, [16] has running time $O(L^{0.5} \cdot (UL^2 + U^{\omega} + L^{\omega})) \le O(L^{0.5} \cdot (UL^2 + U^{\omega}))$, and [15] has running time $O(L^{0.5} \cdot (U^2 + L^4) + U^{\omega} + L^{2\omega}) \le O(L^{4.5} + L^{2\omega})$ since $L \le U \le L^2$.

Note that our running time is always better than the previous results, and for several values of L and U we improve by a polynomial factor. See Figure 1 for an illustration.

8 Initialization

There exist standard techniques to transform a convex program to a form that has an easily obtainable strictly feasible point, see e.g. [39]. We follow the initialization procedure presented by [9] and [16] and adapt to SOS optimization. Similar initialization lemma exists for WSOS optimization. The proof of this lemma can be found in our full version.

Let the matrix $P \in \mathbb{R}^{U \times L}$ and the operator $\Lambda : \mathbb{R}^U \to \mathbb{R}^{L \times L}$ that $\Lambda(s) = P^\top \operatorname{diag}(s) P$ be defined as in the interpolant basis paragraph of Section 3.

▶ **Lemma 22** (Initialization). *Given an instance of* (SOS) *that fulfills Slater's condition, and let R be an upper bound on the ℓ_1-norm of the primal feasible solutions, i.e. all primal feasible x of* (SOS) *fulfill $\|x\|_1 \le R$, and let $\delta \in (0,1)$. We define $\overline{A} \in \mathbb{R}^{(m+1)\times(U+2)}$, $\overline{b} \in \mathbb{R}^{m+1}$, and $\overline{c} \in \mathbb{R}^{U+2}$ as*

$$\overline{A} = \begin{bmatrix} A & 0 & \frac{1}{R}b - A\overline{g}^0 \\ 1_U^\top & 1 & 0 \end{bmatrix}, \quad \overline{b} = \begin{bmatrix} \frac{1}{R}b \\ 1 + \langle 1_U, \overline{g}^0 \rangle \end{bmatrix}, \quad \overline{c} = \begin{bmatrix} \frac{\delta}{\|c\|_\infty} c \\ 0 \\ 1 \end{bmatrix},$$

and let

$$\overline{x}^0 = \begin{bmatrix} \overline{g}^0 \\ 1 \\ 1 \end{bmatrix} \in \mathbb{R}^{U+2}, \quad \overline{y}^0 = \begin{bmatrix} 0_m \\ -1 \end{bmatrix} \in \mathbb{R}^{m+1}, \text{ and } \overline{s}^0 = \begin{bmatrix} 1_U + \frac{\delta}{\|c\|_\infty} c \\ 1 \\ 1 \end{bmatrix} \in \mathbb{R}^{U+2},$$

where $\overline{g}^0 = g_{\Sigma^*}(\overline{s}^0_{[:U]}) \in \mathbb{R}^U$ for the gradient function $g_{\Sigma^*}(s) := \operatorname{diag}(P(P^\top \operatorname{diag}(s) P)^{-1} P^\top)$ that maps from $\mathbb{R}^U$ to $\mathbb{R}^U$. This defines the auxiliary primal-dual system

$$\begin{aligned} \min \langle \overline{c}, \overline{x} \rangle \qquad & \qquad \max \langle \overline{y}, \overline{b} \rangle \\ \overline{A}\overline{x} = \overline{b} \qquad & \qquad \overline{A}^\top \overline{y} + \overline{s} = \overline{c} \\ \overline{x} \in \Sigma_{n,2d} \times \mathbb{R}^2_{\ge 0}\,, \qquad & \qquad \overline{s} \in \Sigma^*_{n,2d} \times \mathbb{R}^2_{\ge 0}\,. \end{aligned} \tag{Aux-SOS}$$

Then $(\overline{x}^0, \overline{y}^0, \overline{s}^0)$ are feasible to the auxiliary system (Aux-SOS).

Further, under the canonical barrier (we use $\overline{a}_i$ to denote the i-th column of $\overline{A}$):

$$\overline{F}_\eta(\overline{y}) = -\eta\langle \overline{y}, \overline{b} \rangle - \log\det\Big(\Lambda\big((\overline{c} - \overline{A}^\top \overline{y})_{[:U]}\big)\Big) - \log(\overline{c}_{U+1} - \langle \overline{a}_{U+1}, \overline{y} \rangle) - \log(\overline{c}_{U+2} - \langle \overline{a}_{U+2}, \overline{y} \rangle),$$

we have that $\|\overline{g}_{\eta^0}(\overline{y}^0)\|_{\overline{H}(\overline{y}^0)^{-1}} = 0$ for $\eta^0 = 1$.

Further, for any solution $(\overline{x}, \overline{y}, \overline{s})$ to (Aux-SOS) *with duality gap $\le \delta^2$, its restriction $\widehat{x} := \overline{x}_{[:U]}$ fulfills*

$$\begin{aligned} \langle c, \widehat{x} \rangle &\le \min_{Ax = b, x \in \Sigma_{n,2d}} \langle c, x \rangle + \delta \cdot R\|c\|_\infty, \\ \|A\widehat{x} - b\|_1 &\le 8\delta L \cdot (LR\|A\|_\infty + \|b\|_1), \\ \widehat{x} &\in \Sigma_{n,2d}. \end{aligned}$$

Abstract

In the Strip Packing problem (SP), we are given a vertical half-strip $[0, W] \times [0, \infty)$ and a set of n axis-aligned rectangles of width at most W. The goal is to find a non-overlapping packing of all rectangles into the strip such that the height of the packing is minimized. A well-studied and frequently used practical constraint is to allow only those packings that are guillotine separable, i.e., every rectangle in the packing can be obtained by recursively applying a sequence of edge-to-edge axis-parallel cuts (guillotine cuts) that do not intersect any item of the solution. In this paper, we study approximation algorithms for the Guillotine Strip Packing problem (GSP), i.e., the Strip Packing problem where we require additionally that the packing needs to be guillotine separable. This problem generalizes the classical Bin Packing problem and also makespan minimization on identical machines, and thus it is already strongly NP-hard. Moreover, due to a reduction from the Partition problem, it is NP-hard to obtain a polynomial-time $(3/2 - \varepsilon)$-approximation algorithm for GSP for any $\varepsilon > 0$ (exactly as Strip Packing). We provide a matching polynomial time $(3/2 + \varepsilon)$-approximation algorithm for GSP. Furthermore, we present a pseudo-polynomial time $(1 + \varepsilon)$-approximation algorithm for GSP. This is surprising as it is NP-hard to obtain a $(5/4 - \varepsilon)$-approximation algorithm for (general) Strip Packing in pseudo-polynomial time. Thus, our results essentially settle the approximability of GSP for both the polynomial and the pseudo-polynomial settings.

1 Introduction

Two-dimensional packing problems form a fundamental research area in combinatorial optimization, computational geometry, and approximation algorithms. They find numerous practical applications in logistics [9], cutting stock [23], VLSI design [26], smart-grids [20], etc. The Strip Packing problem (SP), a generalization of the classical Bin Packing problem and also the makespan minimization problem on identical machines, is one of the central problems in this area. We are given an axis-aligned vertical half-strip $[0, W] \times [0, \infty)$ and a set of n axis-aligned rectangles (also called *items*) $I := \{1, 2, \ldots, n\}$, where for each rectangle i we are given an integral width $w_i \leq W$, and an integral height h_i; we assume the rectangles to be open sets. The goal is to pack all items such that the maximum height of the top edge of a packed item is minimized. The packing needs to be *non-overlapping*, i.e., such a packing into a strip of height H maps each rectangle $i \in I$ to a new translated open rectangle $R(i) := (left(i), right(i)) \times (bottom(i), top(i))$ where $right(i) = left(i) + w_i$, $top(i) = bottom(i) + h_i$, $left(i) \geq 0$, $bottom(i) \geq 0$, $right(i) \leq W$, $top(i) \leq H$ and for any $i, j \in I$, we must have $R(i) \cap R(j) = \emptyset$. We assume that items are not allowed to be rotated.

The best known polynomial time approximation algorithm for SP has an approximation ratio of $(5/3+\varepsilon)$ for any constant $\varepsilon > 0$ [24] and a straight-forward reduction from Partition shows that it is NP-hard to approximate the problem with a ratio of $(3/2 - \varepsilon)$ for any $\varepsilon > 0$. Maybe surprisingly, one can approximate SP better in pseudo-polynomial time: there is a pseudo-polynomial time $(5/4 + \varepsilon)$-approximation algorithm [27] and it is NP-hard to obtain a $(5/4 - \varepsilon)$-approximation algorithm with this running time [25]. Hence, it remains open to close the gap between $(5/3 + \varepsilon)$ and $(3/2 - \varepsilon)$ for polynomial time algorithms, and even in pseudo-polynomial time, there can be no $(1+\varepsilon)$-approximation for the problem for arbitrarily small $\varepsilon > 0$.

SP is particularly motivated from applications in which we want to cut out rectangular pieces of a sheet or stock unit of raw material, i.e., metal, glass, wood, or, cloth, and we want to minimize the amount of wasted material. For cutting out these pieces in practice, axis-parallel end-to-end cuts, called *guillotine cuts*, are popular due to their simplicity of operation [46]. In this context, we look for solutions to cut out the individual objects by a recursive application of guillotine cuts that do not intersect any item of the solution. Applications of guillotine cutting are found in crepe-rubber mills [42], glass industry [40], paper cutting [35], etc. In particular, this motivates studying geometric packing problems with the additional constraint that the placed objects need to be separable by a sequence of guillotine cuts (see Figure 1). Starting from the classical work by Christofides et al. [10] in 1970s, settings with such guillotine cuts are widely studied in the literature [16, 47, 6, 34, 15, 11, 17, 12]. In fact, many heuristics for guillotine packing have been developed to efficiently solve benchmark instances, based on tree-search, branch-and-bound, dynamic optimization, tabu search, genetic algorithms, etc. Khan et al. [32] mentions "a staggering number of recent experimental papers" on guillotine packing and lists several such recent experimental papers.

A related notion is k-stage packing, originally introduced by Gilmore and Gomory [23]. Here, each stage consists of either vertical or horizontal guillotine cuts (but not both). In each stage, each of the pieces obtained in the previous stage is considered separately and can be cut again by using either horizontal or vertical guillotine cuts. In k-stage packing, the number of cuts to obtain each rectangle from the initial packing is at most k, plus an additional cut to trim (i.e., separate the rectangles itself from a waste area). Intuitively, this means that in the cutting process we change the orientation of the cuts $k - 1$ times.

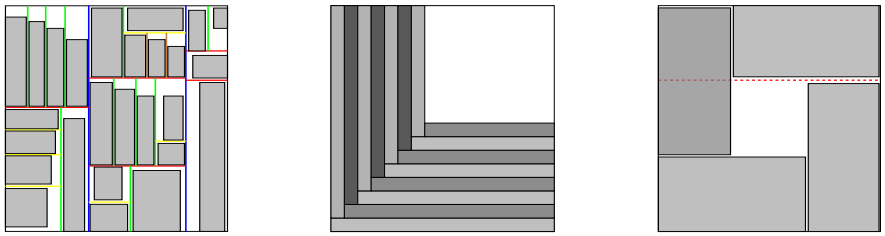

Figure 1 Packing (a) is a 5-stage guillotine separable packing, packing (b) is a $(n-1)$-stage guillotine separable packing, packing (c) is not guillotine separable as any end-to-end cut in the strip intersects a rectangle.

Therefore, in this paper, we study the Guillotine Strip Packing problem (GSP). The input is the same as for SP, but we require additionally that the items in the solution can be separated by a sequence of guillotine cuts, and we say then that they are *guillotine separable*. Like general SP without requiring the items to be guillotine separable, GSP generalizes Bin Packing (when all items have the same height) and makespan minimization on identical machines (when all items have the same width). Thus, it is strongly NP-hard, and the same reduction from Partition mentioned above yields a lower bound of $(3/2-\varepsilon)$ for polynomial time algorithms (see the full version [31] for more details). For asymptotic approximation, GSP is well understood. Kenyon and Rémila [29] gave an asymptotic polynomial time approximation scheme (APTAS) for (general) SP. Their algorithm produces a 5-stage packing (hence, guillotine separable), and thus yields an APTAS for GSP as well. Later, Seiden et al. [43] settled the asymptotic approximation status of GSP under k-stage packing. They gave an APTAS for GSP using 4-stage guillotine cuts, and showed $k=2$ stages cannot guarantee any bounded asymptotic performance ratio, and $k=3$ stages lead to asymptotic performance ratios close to 1.691. However, in the non-asymptotic setting, approximation ratio of GSP is not yet settled. Steinberg's algorithm [45] yields a 2-approximation algorithm for GSP and this is the best known polynomial time approximation algorithm for the problem.

In this paper we present approximation algorithms for GSP which have strictly better approximation ratios than the best known algorithms for SP, and in the setting of pseudo-polynomial time algorithms we even beat the lower bound that holds for SP. Moreover, we show that all our approximation ratios are essentially the best possible.

1.1 Our Contribution

We present a polynomial time $(3/2+\varepsilon)$-approximation algorithm for GSP. Due to the mentioned lower bound of $(3/2-\varepsilon)$, our approximation ratio is essentially tight. Also, we present a pseudo-polynomial time $(1+\varepsilon)$-approximation algorithm, which is also essentially tight since GSP is strongly NP-hard.

For the pseudo-polynomial time $(1+\varepsilon)$-approximation, we first prove that there exists a structured solution with height at most $(1+\varepsilon)\mathrm{OPT}$ (OPT denotes the height of the optimal solution) in which the strip is divided into $O(1)$ rectangular boxes inside which the items are *nicely packed*, e.g., horizontal items are stacked on top of each other, vertical items are placed side by side, and small items are packed greedily with the Next-Fit-Decreasing-Height algorithm [13] (see Figure 2(a) and also Figure 4. Also, refer to Section 2 for item classification). This result starkly contrasts SP (i.e., where we do not require the items to be guillotine separable): for that problem, it is already unlikely that we can prove that there

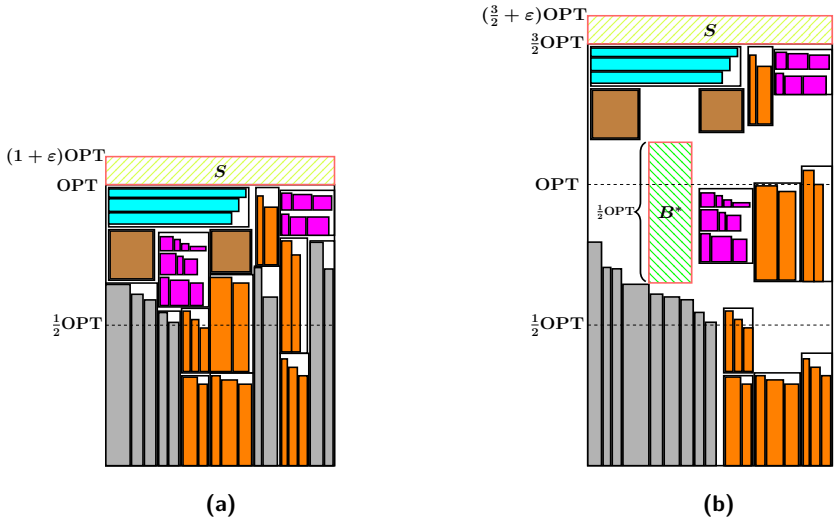

Figure 2 (a) A guillotine separable structured packing (for the pseudo-polynomial time approximation scheme) where all the items are packed nicely in containers. The tall items (dark-gray) are stacked next to each other just like the vertical items (orange); the horizontal items (blue) are stacked on top of each other, the small items (pink) are packed according to NFDH, and the large containers contain single large items (brown). (b) A guillotine separable structured packing for the polynomial time $(3/2+\varepsilon)$-approximation, where the packing from (a) is rearranged such that the tall items are *bottom-left-flushed* and there is an extra empty box B^* to accommodate some of the vertical items which we are unable to pack in polynomial time in the rest of the guessed boxes. This arises from the NP-hardness of the PARTITION problem. The yellow rectangular strip S on top of both the packings is used for packing the medium and leftover horizontal and small items.

always exists such a packing with a height of less than $5/4 \cdot \mathrm{OPT}$. If we could prove this, we could approximate the problem in pseudo-polynomial time with a better ratio than $5/4$, which is NP-hard [25].

To construct our structured packing, we start with an optimal packing and use the techniques in [32] to obtain a packing in which each item is *nicely packed* in one of a constant number of boxes and L-shaped *compartments*. We increase the height of our packing by $\varepsilon\mathrm{OPT}$ in order to round the heights of the packed items and get some leeway within the packing. Then, we rearrange the items placed inside the L-shaped compartments. Here, we crucially exploit that the items in the initial packing are guillotine separable. In particular, this property allows us to identify certain sets of items that we can swap, e.g., items on the left and the right of a vertical guillotine cut to simplify the packing, and reduce the number of boxes to $O(1)$. Then, using standard techniques, we compute a solution with this structure in pseudo-polynomial time and hence with a packing height of at most $(1+\varepsilon)\mathrm{OPT}$ (see Figure 2 (a)).

Note that we do not obtain a $(1+\varepsilon)$-approximation algorithm in polynomial time in this way. The reason is that when we pack the items into the rectangular boxes, we need to solve a generalization of PARTITION: there can be several boxes in which vertical items are placed side by side, and we need that the widths of the items in each box sum up to at most the width of the box. If there is only a single item that we cannot place, then we would need to place it on top of the packing, which can increase our packing height by up to OPT.

For our polynomial time $(3/2+\varepsilon)$-approximation algorithm, we, therefore, need to be particularly careful with the items whose height is larger than $\mathrm{OPT}/2$, which we call the *tall items*. We prove a different structural result which is the main technical contribution of

this paper: we show that there is always a $(3/2+\varepsilon)$-approximate packing in which the tall items are packed together in a *bottom-left-flushed* way, i.e., they are ordered non-increasingly by height and stacked next to each other with their bottom edges touching the base of the strip. All remaining items are nicely packed into $O_\varepsilon(1)$ boxes, and there is also an empty strip of height OPT/2 and width $\Omega_\varepsilon(W)$, see Figure 2 (b). Thus, it is very easy to pack the tall items correctly according to this packing. We pack the remaining items with standard techniques into the boxes. In particular, the mentioned empty strip allows us to make slight mistakes while we pack the vertical items that are not tall; without this, we would still need to solve a generalization of PARTITION.

In order to obtain our structural packing for our polynomial time $(3/2+\varepsilon)$-approximation algorithm, we build on the idea of the packing for the pseudo-polynomial time $(1+\varepsilon)$-approximation. Using that it is guillotine separable, we rearrange its items further. First, we move the items such that all tall items are at the bottom. To achieve this, we again argue that we can swap certain sets of items, guided by the guillotine cuts. Then, we shift certain items up by OPT/2, which leaves empty space between the shifted and the not-shifted items, see Figure 2 (b). Inside this empty space, we place the empty box of height OPT/2. Also, we use this empty space in order to be able to reorder the tall items on the bottom by their respective heights. During these changes, we ensure carefully that the resulting packing stays guillotine separable.

It is possible that also for (general) SP there always exists a structured packing of height at most $(3/2+\varepsilon)$OPT, similar to our packing. This would yield an essentially tight polynomial time $(3/2+\varepsilon)$-approximation for SP and thus solve the long-standing open problem to find the best possible polynomial time approximation ratio for SP. We leave this as an open question.

1.2 Other related work

In the 1980s, Baker et al. [2] initiated the study of approximation algorithms for strip packing, by giving a 3-approximation algorithm. After a sequence of improved approximations [13, 44], Steinberg [45] and Schiermeyer [41] independently gave 2-approximation algorithms. For asymptotic approximation, Kenyon and Rémila [29] settled SP by providing an APTAS.

SP has rich connections with important geometric packing problems [9, 30] such as 2D bin packing (2BP) [4, 33], 2D geometric knapsack (2GK) [19, 28], dynamic storage allocation [7], maximum independent set of rectangles (MISR) [22, 1], sliced packing [14, 18], etc.

In 2BP, we are given a set of rectangles and square bins, and the goal is to find an axis-aligned non-overlapping packing of all items into a minimum number of bins. The problem admits no APTAS [3], and the present best approximation ratio is 1.406 [4]. In 2GK, we are given a set of rectangular items and a square knapsack. Each item has an associated profit, and the goal is to pack a subset of items in the knapsack such that the profit is maximized. The present best polynomial time approximation ratio is 1.89 [19]. There is a pseudo-polynomial time $(4/3+\varepsilon)$-approximation [21] for 2GK. In MISR, we are given a set of (possibly overlapping) rectangles we need to find the maximum cardinality non-overlapping set of rectangles. Recently, Mitchell [36] gave the first constant approximation algorithm for the problem. Then Gálvez et al. [22] obtained a $(2+\varepsilon)$-approximation algorithm for MISR. Their algorithms are based on a recursive geometric decomposition of the plane, which can be viewed as a generalization of guillotine cuts, more precisely, to cuts with $O(1)$ bends. Pach and Tardos [38] even conjectured that for any set of n non-overlapping axis-parallel rectangles, there is a guillotine cutting sequence separating $\Omega(n)$ of them.

2BP and 2GK are also well-studied in the guillotine setting [39]. Caprara et al. [8] gave an APTAS for 2-stage SP and 2-stage BP. Later, Bansal et al. [5] showed an APTAS for guillotine 2BP. Bansal et al. [4] conjectured that the worst-case ratio between the best guillotine 2BP and the best general 2BP is 4/3. If true, this would imply a $(\frac{4}{3}+\varepsilon)$-approximation algorithm for 2BP. For guillotine 2GK, Khan et al. [32] recently gave a pseudo-polynomial time approximation scheme.

2 Pseudo-polynomial time approximation scheme

In this section, we present our pseudo-polynomial time approximation scheme (PPTAS) for GSP.

Let $\varepsilon > 0$ and assume w.l.o.g. that $1/\varepsilon \in \mathbb{N}$. We denote by OPT the height of the optimal solution. We classify the input items into a few groups according to their heights and widths similar to the classification in [32]. For two constants $1 \geq \delta > \mu > 0$ to be defined later, we classify each item $i \in I$ as:

- *tall* if $h_i > \mathrm{OPT}/2$;
- *large* if $w_i > \delta W$ and $\mathrm{OPT}/2 \geq h_i > \delta\mathrm{OPT}$;
- *horizontal* if $w_i > \delta W$ and $h_i \leq \mu\mathrm{OPT}$;
- *vertical* $w_i \leq \delta W$ and $\mathrm{OPT}/2 \geq h_i > \delta\mathrm{OPT}$;
- *medium if*
  - either $\delta\mathrm{OPT} \geq h_i > \mu\mathrm{OPT}$;
  - or $\delta W \geq w_i > \mu W$ and $h_i \leq \mu\mathrm{OPT}$;
- *small* if $w_i \leq \mu W$ and $h_i \leq \mu\mathrm{OPT}$;

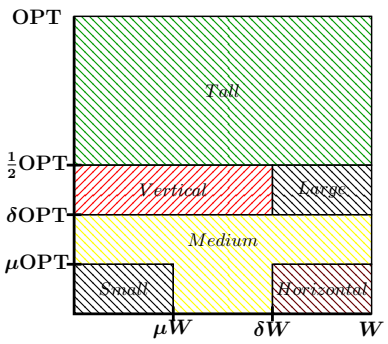

Figure 3 Item Classification: x-axis represents width and y-axis represents height.

See Figure 3 for a picture of item classification. Let $I_{tall}, I_{large}, I_{hor}, I_{ver}, I_{medium}, I_{small}$ be the set of tall, large, horizontal, medium, and small rectangles in I, respectively.

Using the following lemma, one can appropriately choose μ, δ such that the medium items occupy a marginal area. This effectively allows us to ignore them in our main argumentation.

▶ **Lemma 2.1** ([37]). *Let $\varepsilon > 0$ and $f(.)$ be any positive increasing function such that $f(x) < x$ for all $x \in (0, 1]$. Then we can efficiently find $\delta, \mu \in \Omega_\varepsilon(1)$, with $\varepsilon \geq f(\varepsilon) \geq \delta \geq f(\delta) \geq \mu$ so that the total area of medium rectangles is at most $\varepsilon(\mathrm{OPT} \cdot W)$.*

We will specify how we choose the function $f(x)$ later. In our PPTAS, we will use a packing, which is defined solely via boxes.

▶ **Definition 2.2.** *A* box B *is an axis-aligned open rectangle that satisfies* $B \subseteq [0, W] \times [0, \infty)$. *We denote by* $h(B)$ *and* $w(B)$ *the height and the width of* B*, respectively.*

Inside each box B, we will place the items *nicely,* meaning that they are either stacked horizontally or vertically, or B contains a single large item, or only small items, or only medium items. This is useful since in the first two cases, it is trivial to place a given set of items into B, and in the last two cases, it will turn out that it suffices to pack the items greedily using the Next Fit Decreasing Height (NFDH) algorithm [13] and Steinberg's algorithm [45], respectively. There will be one box with height at most $2\varepsilon\mathrm{OPT}$ that contains all medium items.

▶ **Definition 2.3** (Nice packing)**.** *Let* B *be a box and let* $I_B \subseteq I$ *be a set of items that are placed non-overlappingly inside* B*. We say that the packing of* I_B *in* B *is* nice *if the items in* I_B *are guillotine separable and additionally*

- I_B *contains only one item, or*
- $I_B \subseteq I_{hor}$ *and the items in* I_B *are stacked on top of each other inside* B*, or*
- $I_B \subseteq I_{tall} \cup I_{ver}$ *and the items in* I_B *are placed side by side inside* B*, or*
- $I_B \subseteq I_{medium}$*, or*
- $I_B \subseteq I_{small}$ *and for each item* $i \in I_B$ *it holds that* $w_i \leq \varepsilon \cdot w(B)$ *and* $h_i \leq \varepsilon \cdot h(B)$.

We will use the term *container* to refer to a box B that contains a nice packing of some set of items I_B. See Figure 4 for nice packings in different types of containers. We say that a set of boxes $\mathcal{B}$ is *guillotine separable* if there exists a sequence of guillotine cuts that separates them and that does not intersect any box in $\mathcal{B}$.

We now state the structural lemma for the PPTAS. Intuitively, it states that there exists a $(1+\varepsilon)$-approximate solution in which the input items are placed into $O_\varepsilon(1)$ boxes such that within each box the packing is nice. We remark that we will crucially use that in the optimal packing the items in I are guillotine separable. In fact, if one could prove that there exists such a packing with $O_\varepsilon(1)$ boxes and a height of $\alpha\mathrm{OPT}$ for some $\alpha < \frac{5}{4}$ also in the non-guillotine case (where neither the optimal solution nor the computed solution needs to be guillotine separable), then one would obtain a pseudo–polynomial time $(\alpha+\varepsilon)$-approximation algorithm also in this case, by using straightforward adaptations of the algorithms in, e.g., [37, 20, 27] or our algorithm in section 2.2. However, this is not possible for $\alpha < \frac{5}{4}$, unless $\mathsf{P} = \mathsf{NP}$ [25].

▶ **Lemma 2.4** (Structural lemma 1)**.** *Assume that* μ *is sufficiently small compared to* δ*. Then there exists a set* $\mathcal{B}$ *of* $O_\varepsilon(1)$ *pairwise non-overlapping and guillotine separable boxes all placed inside* $[0, W] \times [0, (1 + 16\varepsilon)\mathrm{OPT})$ *and a partition* $I = \bigcup_{B \in \mathcal{B}} I_B$ *such that for each* $B \in \mathcal{B}$ *the items in* I_B *can be placed nicely into* B*.*

We choose our function f due to Lemma 2.1 such that μ is sufficiently small compared to δ, as required by Lemma 2.4. We will prove Lemma 2.4 in the next subsection. In its packing, let $\mathcal{B}_{hor}, \mathcal{B}_{ver}, \mathcal{B}_{tall}, \mathcal{B}_{large}, \mathcal{B}_{small}$ and $\mathcal{B}_{med}$ denote the set of boxes for the horizontal, vertical, tall, large, small and medium items, respectively. Let $\mathcal{B}_{tall+ver} := \mathcal{B}_{tall} \cup \mathcal{B}_{ver}$.

2.1 Proof of Structural Lemma 1

In this section we prove Lemma 2.4. We have omitted a few proofs which can be found in the full version [31]. Our strategy is to start with a structural lemma from [32] that guarantees the existence of a structured packing of all items in $I_{hard} := I_{tall} \cup I_{large} \cup I_{hor} \cup I_{ver}$. This packing uses boxes and **L**-compartments. Note that, for now we ignore the items I_{small}. We will show how to pack them later.

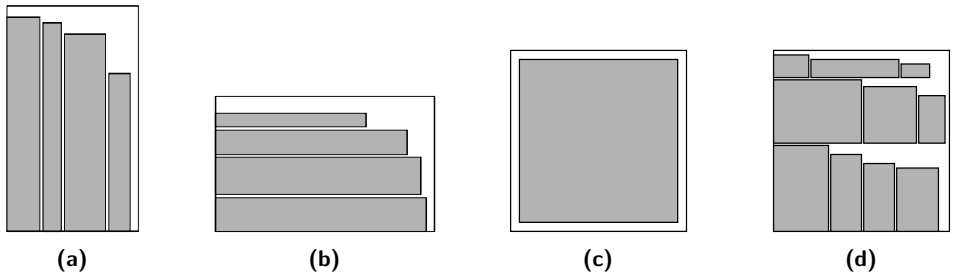

Figure 4 Nice packing of vertical, horizontal, large and small items in their respective containers.

▶ **Definition 2.5** (**L**-compartment). *An* **L***-compartment L is an open sub-region of $[0, W] \times [0, \infty)$ bounded by a simple rectilinear polygon with six edges $e_0, e_1, \ldots, e_5$ such that for each pair of horizontal (resp. vertical) edges e_i, e_{6-i} with $i \in \{1, 2\}$ there exists a vertical (resp. horizontal) line segment ℓ_i of length less than $\delta \frac{\mathrm{OPT}}{2}$ (resp. $\delta \frac{W}{2}$) such that both e_i and e_{6-i} intersect ℓ_i but no other edges intersect ℓ_i.*

Note that for an **L**-compartment, no item $i \in I_{hor}$ can be packed in its vertical arm and similarly, no item $i \in I_{ver} \cup I_{tall}$ can be packed in its horizontal arm.

The next lemma follows immediately from a structural insight in [32] for the guillotine two-dimensional knapsack problem. It partitions the region $[0, W] \times [0, \mathrm{OPT}]$ into non-overlapping boxes and **L**-compartments that admit a *pseudo-guillotine cutting sequence*. This is a sequence of cuts in which each cut is either a (normal) guillotine cut, or a special cut that cuts out an **L**-compartment L from the current rectangular piece R in the cutting sequence, such that $R \setminus L$ is a rectangle, see Figure 6. So intuitively L lies at the boundary of R.

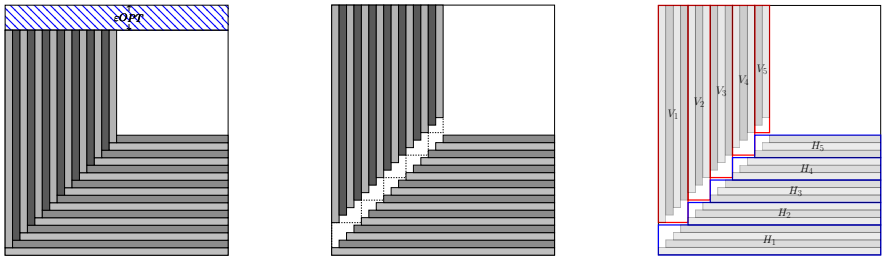

Figure 5 Using an extra $\varepsilon\mathrm{OPT}$ height, we convert a packing of items I in an **L**-compartment into another packing such that the items in I are packed in boxes $\mathcal{C}' = \mathbf{V} \cup \mathbf{H}$, which are guillotine separable and $|\mathcal{C}'| = O_\varepsilon(1)$, where $\mathbf{V} = \cup_{i=1}^{i=5} V_i$ and $\mathbf{H} = \cup_{i=1}^{i=5} H_i$.

▶ **Lemma 2.6** ([32]). *There exists a partition of $[0, W] \times [0, \mathrm{OPT}]$ into a set $\mathcal{B}_1$ of $O_\varepsilon(1)$ boxes and a set $\mathcal{L}$ of $O_\varepsilon(1)$* **L***-compartments such that*

- *the boxes and* **L***-compartments in $\mathcal{B}_1 \cup \mathcal{L}$ are pairwise non-overlapping,*
- *$\mathcal{B}_1 \cup \mathcal{L}$ admits a pseudo-guillotine cutting sequence,*
- *the items in I_{hard} can be packed into $\mathcal{B}_1 \cup \mathcal{L}$ such that for each $B \in \mathcal{B}_1$ it either contains only items $i \in I_{tall} \cup I_{large} \cup I_{ver}$ or it contains only items $i \in I_{hor}$.*

Our strategy is to take the packing due to Lemma 2.6 and transform it step by step until we obtain a packing that corresponds to Lemma 2.4. First, we round the heights of the tall, large, and vertical items such that they are integral multiples of $\delta^2\mathrm{OPT}$. Formally, for each item $i \in I_{tall} \cup I_{large} \cup I_{ver}$ we round its height to $h'_i := \left\lceil \frac{h_i}{\delta^2 \mathrm{OPT}} \right\rceil \delta^2 \mathrm{OPT}$. Let I_{hard} denote

the resulting set of items. By a shifting argument, we will show that we can still pack I_{hard} into $O_\varepsilon(1)$ guillotine separable boxes and **L**-compartments if we can increase the height of the packing by a factor $1+\varepsilon$ which also does not violate guillotine separability. Then, we increase the height of the packing by another factor $1+\varepsilon$. Using this additional space, we shift the items inside each **L**-compartment L such that we can separate the vertical items from the horizontal items (see Figure 5). Due to this separation, we can partition L into $O_\varepsilon(1)$ boxes such that each box contains only horizontal or only vertical and tall items. Note however, that they might not be packed nicely inside these boxes.

▶ **Lemma 2.7.** *There exists a partition of* $[0,W]\times[0,(1+2\varepsilon)\mathrm{OPT}]$ *into a set* $\mathcal{B}_2$ *of* $O_\varepsilon(1)$ *boxes such that*

- *the boxes in* $\mathcal{B}_2$ *are pairwise non-overlapping and admit a guillotine cutting sequence,*
- *the items in* I_{hard} *can be packed into* $\mathcal{B}_2$ *such that they are guillotine separable and each box* $B\in\mathcal{B}_2$ *either contains only items from* $I_{tall}\cup I_{large}\cup I_{ver}$*, or contains only items from* I_{hor}*.*
- *Any item* $i\in I_{tall}\cup I_{large}\cup I_{ver}$ *has height* $h'_i=k_i\delta^2\mathrm{OPT}$ *for integer* k_i*,* $k_i\leq 1/\delta^2+1$*.*

Let $\mathcal{B}_2$ be the set of boxes due to Lemma 2.7. Consider a box $B\in\mathcal{B}_2$ and let $I_{hard}(B)$ denote the items from I_{hard} that are placed inside B in the packing due to Lemma 2.7. Our goal is to partition B into $O_\varepsilon(1)$ smaller containers, i.e., the items in $I_{hard}(B)$ are packed nicely into these smaller boxes. If B contains horizontal items, then this can be done using standard techniques, e.g., by 1D resource augmentation (only in height) in [32]. This resource augmentation procedure maintains guillotine separability.

▶ **Lemma 2.8** ([32])**.** *Given a box* $B\in\mathcal{B}_2$ *such that* B *contains a set of items* $I_{hard}(B)\subseteq I_{hor}$*. There exists a partition of* B *into* $O_{\varepsilon'}(1)$ *containers* $\mathcal{B}'$ *and one additional box* B' *of height at most* $\varepsilon' h(B)$ *and width* $w(B)$ *such that the containers* $\mathcal{B}'$ *are guillotine separable and the containers* $\mathcal{B}'\cup\{B'\}$ *contain* $I_{hard}(B)$*.*

We apply Lemma 2.8 to each box $B\in\mathcal{B}_2$ that contains a horizontal item. Consider the items which are contained in their respective boxes B'. In order to avoid any confusions between constants of our algorithm and resource augmentation, we denote the constant used for resource augmentation as ε'. We choose $\varepsilon'=\varepsilon$ and then their total area is at most $\varepsilon\mathrm{OPT}\cdot W$ and therefore, all such items can be packed in a box of height at most $2\varepsilon\mathrm{OPT}$ and width W using Steinberg's algorithm [45]. But since this will possibly not result in a nice packing we apply resource augmentation (only along height) again to ensure that we get a nice packing of such horizontal items in $O_\varepsilon(1)$ containers which can all be packed in a box of height at most $3\varepsilon\mathrm{OPT}$ and width W.

Consider now a box $B\in\mathcal{B}_2$ that contains at least one item from $I_{tall}\cup I_{large}\cup I_{ver}$. Let $I_{hard}(B)\subseteq I_{tall}\cup I_{large}\cup I_{ver}$ denote the items packed inside B. We argue that we can rearrange the items in $I_{hard}(B)$ such that they are nicely placed inside $O_\varepsilon(1)$ containers. In this step we crucially use that the items in $I_{hard}(B)$ are guillotine separable.

Consider the guillotine cutting sequence for $I_{hard}(B)$. It is useful to think of these cuts as being organized in *stages:* in the first stage we do vertical cuts (possibly zero cuts). In the following stage, we take each resulting piece and apply horizontal cuts. In the next stage, we again take each resulting piece and apply vertical cuts, and so on. Since the heights of the items in $I_{hard}(B)$ are rounded to multiples of $\delta^2\mathrm{OPT}$ we can assume w.l.o.g. that the y-coordinates of the horizontal cuts are all integral multiples of $\delta^2\mathrm{OPT}$ (possibly moving the items a little bit). Assume here for the sake of simplicity that $t=1/\delta^2$ is an integer. Because of the rounding of heights of the items in $I'_{hard}(B)$, there are at most $(1/\delta^2-1)$ y-coordinates for making a horizontal cut. For a horizontal stage of cuts, for a rectangular

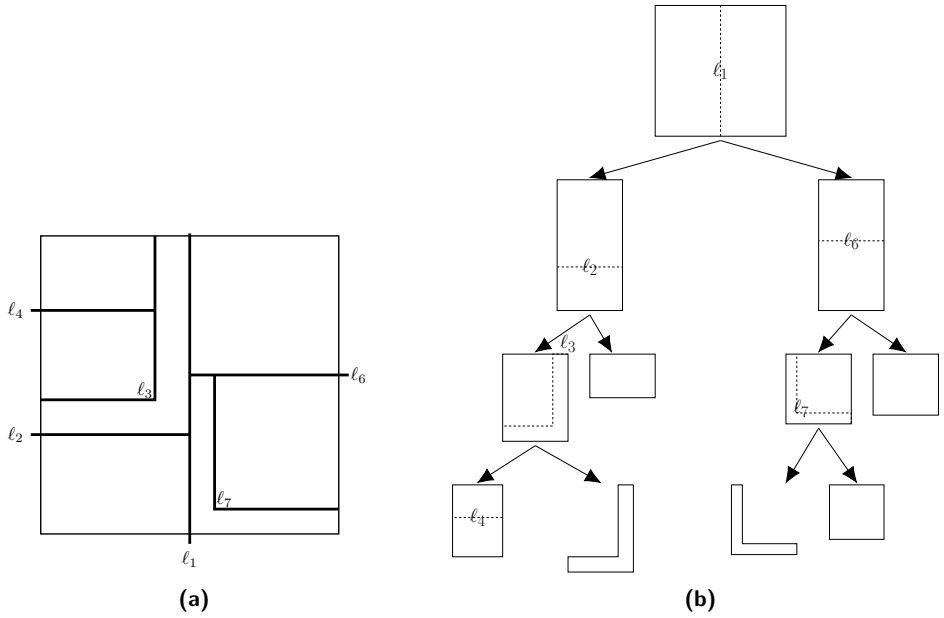

Figure 6 (a) A pseudo-guillotine cutting sequence. The first cut is l_1, and then the resulting left piece is further subdivided by ℓ_2, ℓ_3 and ℓ_4. Similarly, ℓ_6, ℓ_7 subdivide the right piece. Note that ℓ_3 and ℓ_7 are not guillotine cuts, but they cut out the corresponding **L**-compartments. (b) Step by step pseudo-guillotine cutting sequence corresponding to Figure (a). Dashed line at each level indicates a partition of a rectangle into two regions (two boxes, or one box and one **L**).

piece we define a *configuration vector* $(x_1, ..., x_{t-1})$: For each $i \in [t-1]$ if there is a horizontal cut in the piece at $y = t \cdot i$, then $x_i = 1$, otherwise $x_i = 0$. Consider $y = 0$ to be the bottom of the rectangular piece. Therefore, in each horizontal stage, for each piece there are at most $K := (2^{(1/\delta^2)})$ possible configurations. Consider the first stage (which has vertical cuts). If there are more than K vertical cuts then in two of the resulting pieces, in the second stage the same configuration of horizontal cuts is applied (see Figure 7).

We reorder the resulting pieces and their items such that pieces with the same configuration of horizontal cuts are placed consecutively. Therefore, in the first stage we need only K vertical cuts and we can have at most $(\frac{1}{\delta}2^{(1/\delta^2)})$ resulting pieces. We apply the same transformation to each stage with vertical cuts. Now observe that there can be at most $O(1/\delta)$ stages since there are at most $1/\delta$ possible tall, vertical or large items stacked on top of the other and thus at most $1/\delta$ stages with horizontal cuts. Therefore, after our transformations, we apply only $(\frac{1}{\delta}2^{(1/\delta^2)})^{\frac{1}{\delta}}$ cuts in total, in all stages in all resulting pieces. Thus, we obtain $O_\varepsilon(1)$ boxes at the end, in which the items are nicely packed. This leads to the following lemma.

▶ **Lemma 2.9.** *Given a box $B \in \mathcal{B}_2$ such that B contains a set of items $I_{hard}(B) \subseteq I_{tall} \cup I_{large} \cup I_{ver}$. There exists a partition of B into $O_\varepsilon(1)$ containers $\mathcal{B}'$ such that the containers $\mathcal{B}'$ are guillotine separable and contain the items $I_{hard}(B)$.*

We apply Lemma 2.9 to each box $B \in \mathcal{B}_2$ that contains an item from $I_{tall} \cup I_{large} \cup I_{ver}$. Thus, we obtain a packing of I_{hard} into a set of $O_\varepsilon(1)$ guillotine separable containers in which these items are nicely placed; we denote these containers by $\mathcal{B}_{hard}$. This yields directly a packing for the (original) items I_{hard} (without rounding). Finally, we partition the empty space of the resulting packing into more boxes, and one additional box that we place on top

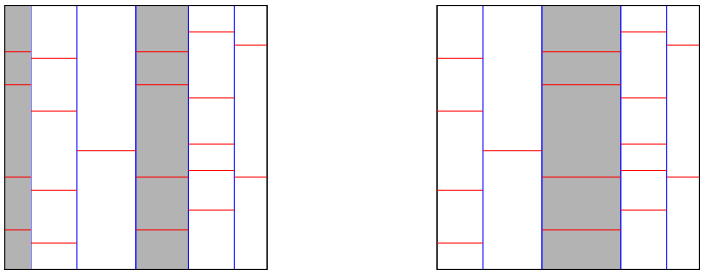

Figure 7 (a) 2 stages of guillotine cuts for a box containing vertical rectangles. (b) Since rounded heights of vertical rectangles are integral multiples of δ^2, merge configurations with same set of horizontal cuts to get $O_\delta(1)$ configurations.

of the current packing. We pack the items in I_{small} inside all these boxes. We might not be able to use some parts of the empty space, e.g., if two boxes are closer than μW to each other horizontally; however, if μ is sufficiently small compared to the number of boxes, this space is small and compensated by the additional box.

▶ **Lemma 2.10.** *Assume that μ is sufficiently small compared to δ. There exists a set of $O_\varepsilon(1)$ boxes $\mathcal{B}_{small}$, all contained in $[0, W] \times [0, (1+14\varepsilon)\mathrm{OPT}]$, such that the boxes in $\mathcal{B}_{hard} \cup \mathcal{B}_{small}$ are non-overlapping and guillotine separable and the items in I_{small} can be placed nicely into the boxes $\mathcal{B}_{small}$.*

Finally, we show the following lemma by using the fact that the medium items have area at most $\varepsilon(\mathrm{OPT} \cdot W)$ and by applying Steinberg's algorithm [45]. This completes the proof of Lemma 2.4.

▶ **Lemma 2.11.** *In time $n^{O(1)}$ we can find a nice placement of all items in I_{medium} inside one container B_{med} of height $2\varepsilon\mathrm{OPT}$ and width W.*

2.2 Algorithm

We describe now our algorithm that computes a packing of height at most $(1 + O(\varepsilon))\mathrm{OPT}$. First, we guess OPT and observe that there are at most $n \cdot h_{\max}$ possibilities, where $h_{\max} := \max_{i \in I} h_i$. Then, we guess the set of containers $\mathcal{B}$ due to Lemma 2.4 and their placement inside $[0, W] \times [0, (1 + O(\varepsilon))\mathrm{OPT})$. For each container $B \in \mathcal{B}$ we guess which case of Definition 2.3 applies to B, i.e., whether I_B contains only one item, $I_B \subseteq I_{hor}$, $I_B \subseteq I_{tall} \cup I_{ver}$, $I_B \subseteq I_{medium}$, or $I_B \subseteq I_{small}$. For each box $B \in \mathcal{B}$ for which I_B contains only one item $i \in I$, we guess i. Observe that for the remaining containers this yields independent subproblems for the sets I_{hor}, $I_{tall} \cup I_{ver}$, I_{medium}, and I_{small}. We solve these subproblems via similar routines as in [37, 20, 27].

We pack all medium items in I_{medium} into one single container B_{med} of height $2\varepsilon\mathrm{OPT}$ by Lemma 2.11. Then, for the sets I_{hor} and $I_{tall} \cup I_{ver}$ we pack their respective items into their containers using a standard pseudo-polynomial time dynamic program; we denote these containers by $\mathcal{B}_{hor}$ and $\mathcal{B}_{tall+ver}$, respectively. We crucially use that $|\mathcal{B}_{hor}| \leq O_\varepsilon(1)$ and $|\mathcal{B}_{tall+ver}| \leq O_\varepsilon(1)$. See the full version [31] for the details of packing of items in I_{hor} and $I_{tall} \cup I_{ver}$.

Finally, we pack the small items. From the proof of Lemma 2.10, apart from some items $I'_{small} \subset I_{small}$ which have area at most $\varepsilon\mathrm{OPT} \cdot W$, the other items can be packed nicely in the containers in $\mathcal{B}_{small} \setminus B_{small}$, where B_{small} has height $9\varepsilon\mathrm{OPT}$ and width W. Thus,

we use NFDH for packing the remaining small items. It can be shown that the small items which remain unpacked can be packed nicely in B_{small}, which is placed on the top of our packing.

▶ **Theorem 2.12.** *There is a $(1+\varepsilon)$-approximation algorithm for the guillotine strip packing problem with a running time of $(nW)^{O_\varepsilon(1)}$.*

3 Polynomial time $(\frac{3}{2}+\varepsilon)$-approximation

In this section, we first present the structural lemma for our polynomial time $(3/2+\varepsilon)$-approximation algorithm for guillotine strip packing. Then we describe our algorithm. We have omitted a few proofs which can be found in the full version [31].

To derive our structural lemma, we start with the packing due to Lemma 2.4. The problem is that with a polynomial time algorithm (rather than a pseudo-polynomial time algorithm) we might not be able to pack all tall items in their respective boxes. If there is even one single tall item i that we cannot pack, then we need to place i on top of our packing, which can increase the height of the packing by up to OPT.

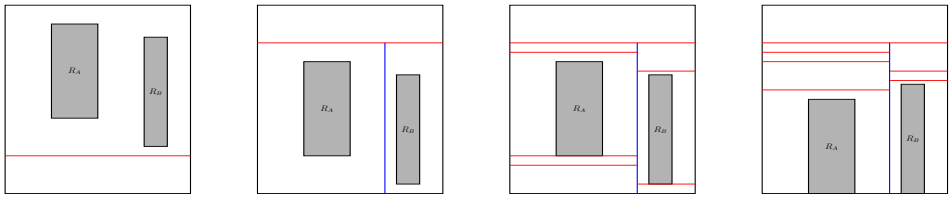

Figure 8 R_A and R_B are tall containers and by swapping the respective boxes (forming as a results of guillotine cuts) that contain them, they can be packed such that the bottoms of both containers intersect the bottom of the strip.

Therefore, we make our packing more robust to small errors when we pack the items into their boxes. In our changed packing, the tall items are *bottom-left-flushed* (see Figure 9(f)), the remaining items are packed into $O_\varepsilon(1)$ boxes, and there is one extra box B^* of height OPT/2 and width $\Omega_\varepsilon(W)$ which is empty. We will use the extra box B^* in order to compensate small errors when we pack the vertical items.

Formally, we say that in a packing, a set of items I' is *bottom-left-flushed* if they are ordered non-increasingly by height and stacked next to each other in this order within the strip $[0,W]\times[0,\infty)$ starting at the left edge of the strip, such that the bottom edge of each item $i\in I'$ touches the line segment $[0,W]\times\{0\}$. We now state the modified structural lemma for our polynomial time $(3/2+\varepsilon)$-approximation algorithm formally.

▶ **Lemma 3.1** (Structural lemma 2). *There exists a packing of the items I within $[0,W]\times[0,(3/2+O(\varepsilon))\mathrm{OPT})$ such that*

- *The items I_{tall} are bottom-left-flushed,*
- *There is a set $\mathcal{B}$ of $O_\varepsilon(1)$ containers that are pairwise non-overlapping and do not intersect the items in I_{tall},*
- *There is a partition of $I\setminus I_{tall}=\bigcup_{B\in\mathcal{B}} I_B$ such that for each $B\in\mathcal{B}$ the items in I_B can be placed nicely into B,*
- *There is a container $B^*\in\mathcal{B}$ of height OPT/2 and width $\varepsilon_1 W$ such that $I_{B^*}=\emptyset$,*
- *The items I_{tall} and the containers $\mathcal{B}$ together are guillotine separable.*

We now prove Lemma 3.1 in the following subsection.

3.1 Proof of Structural Lemma 2

We start with the packing due to Lemma 2.4 and transform it step by step. To obtain our packing, we first argue that we can ensure that all tall items are placed on the bottom of the strip, i.e., their bottom edges touch the bottom edge of the strip. Here we use that the initial packing is guillotine separable. Then we place the box B^* as follows. Suppose that there are initially C containers that cross the horizontal line with $y = \mathrm{OPT}/2$. Note that $C = O_\varepsilon(1)$ and $C \geq 1$ since at least one container is required to pack given non-zero number of items. Then, by an averaging argument we can show that there is a line segment l^* of length at least $\Omega(\frac{W}{C})$ which is the top edge of one of the containers B in the packing at some height $h^* \geq \mathrm{OPT}/2$. We push all the containers which completely lie above the line $y = h^*$ vertically upward by $\mathrm{OPT}/2$ and this creates enough space to pack B^* on top of B. After that, we take advantage of the gained extra space in order to ensure that the tall items are bottom-left-flushed.

Now we describe the proof formally. First, we define some constants. Let $g(\delta, \varepsilon) = O_\varepsilon(1)$ denote an upper bound on the number of containers in the packing obtained using Lemma 2.4, depending on ε and δ. Let $\varepsilon_1 = \frac{1}{3g(\delta,\varepsilon)}$, $\varepsilon_2 = \frac{\varepsilon}{4|\mathcal{B}_{hor}|}$, $\varepsilon_3 = \frac{\varepsilon_1}{4|\mathcal{B}_{ver}|}$, $\varepsilon_4 = \mu$, $\varepsilon_5 = \frac{\varepsilon_1\delta}{6}$, $\varepsilon_6 = \frac{\varepsilon\delta}{6}$.

Our first goal is to make sure that the tall items are all placed on the bottom of the strip $[0, W] \times [0, \infty)$. For this, we observe the following: suppose that in the guillotine cutting sequence a horizontal cut is placed. This cut separates the current rectangular piece R into two smaller pieces R_1 and R_2. Suppose that R_1 lies on top of R_2. Then only one of the two pieces R_1, R_2 can contain a tall item. Also, we obtain an alternative guillotine separable packing if we swap R_1 and R_2 – together with the items contained in them – within R. We perform this swap if R_1 contains a tall item. We apply this operation to each horizontal cut in the guillotine cutting sequence. As a result, we obtain a new packing in which all tall items are placed on the bottom of the strip (but possibly not yet bottom-left-flushed) as shown in Fig 8.

▶ **Lemma 3.2.** *There exists a set $\mathcal{B}$ of $O_\varepsilon(1)$ pairwise non-overlapping and guillotine separable boxes that are all placed inside $[0, W] \times [0, (1 + 16\varepsilon)\mathrm{OPT})$ and a partition $I = \bigcup_{B\in\mathcal{B}} I_B$ such that for each $B \in \mathcal{B}$ the items in I_B can be placed nicely into B. Also, for each box $B \in \mathcal{B}$ with $I_B \cap I_{tall} \neq \emptyset$ we have that the bottom edge of B intersects the line segment $[0, W] \times \{0\}$.*

Let $\mathcal{B}$ be the set of containers due to Lemma 3.2. We want to move some of them up in order to make space for the additional box B^*. To this end, we identify a horizontal line segment ℓ^* in the following lemma.

▶ **Lemma 3.3.** *There is a horizontal line segment ℓ^* of width at least $\varepsilon_1 W$ that does not intersect any container in $\mathcal{B}$, and such that the y-coordinate of ℓ^* is at least $\mathrm{OPT}/2$.*

Proof. Consider the containers in $\mathcal{B}$ that intersect with the horizontal line segment $\ell := [0, W] \times \{\mathrm{OPT}/2\}$ and let $p_1, ...p_k$ be the maximally long line segments on ℓ that do not intersect any container. Since the line segments $\{p_1, ...p_k\}$ are between containers in $\mathcal{B}$, we have that $k \leq |\mathcal{B}| + 1$. Therefore by an averaging argument we can find a horizontal line segment ℓ^* of width at least $\frac{W}{2(g(\delta,\varepsilon))+1} \geq \frac{W}{3g(\delta,\varepsilon)} \geq \varepsilon_1 W$ that either contains the top edge of one of these containers such that ℓ^* does not intersect any other container in $\mathcal{B}$ or ℓ^* is one of the line segments in the set $\{p_1, ..., p_k\}$. Hence, the y-coordinate of ℓ^* is at least $\mathrm{OPT}/2$. ◀

Let h^* be the y-coordinate of ℓ^*. We take all containers in $\mathcal{B}$ that lie "above h^*", i.e., that lie inside $[0, W] \times [h^*, \infty)$. We translate them up by $\mathrm{OPT}/2$. We define a container B^* which has height $\mathrm{OPT}/2$ and width $\varepsilon_1 W$ to be packed such that ℓ^* is the bottom edge of B^* (see Figure 9(b)). We then make the following claim about the resulting packing of $\mathcal{B} \cup \{B^*\}$ (we call this packing P_1).

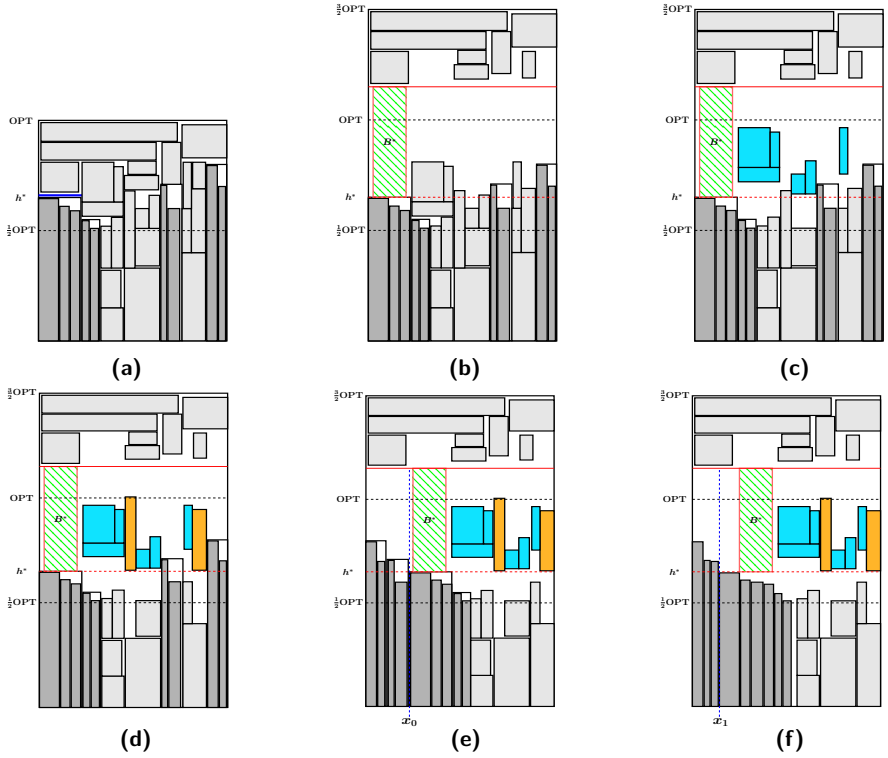

Figure 9 (a) A guillotine separable packing with items nicely packed in containers. The gray colored rectangles are the tall items and the light-gray rectangles are containers with items nicely packed inside. The blue line segment indicates l^* at height $h^\star$. (b) Items completely packed in $[h^*, \mathrm{OPT}]$ are shifted by $\frac{1}{2}\mathrm{OPT}$ vertically upward. The thick red line indicates $y = h^* + \frac{1}{2}\mathrm{OPT}$ which separates the items shifted up from the items below. The dashed red line indicates the height h^* and B^* is packed in the strip of sufficient width and lowest height h^*. (c) The containers of type 1 (colored blue) are moved accordingly so they do not intersect $y = h^\star$. (d) The containers of type 2 (colored yellow) are moved accordingly so they do not intersect $y = h^\star$. (e) The containers in $\mathcal{B}_{tall}$ are *bottom-left-flushed* while other non-tall containers are moved accordingly to the right. The blue vertical dashed line $x = x_0$ separates containers in $\mathcal{B}^+_{tall}$ to its left hand side from other containers to the right. (f) Final packing where tall items are *bottom-left-flushed* and the blue vertical dashed line $x = x_1$ separates items $i \in I_{tall}$ with $h_i > h^*$ to the left from other items and containers to the right.

▶ **Lemma 3.4.** *The packing P_1 is feasible, guillotine separable and has height* $(3/2 + O(\varepsilon))\mathrm{OPT}$.

Proof. Since $h^* > \mathrm{OPT}/2$, observe that no containers are intersecting the line $[0, W] \times \{h^* + \mathrm{OPT}/2\}$. This is because any containers which were lying above the line $[0, W] \times \{h^*\}$ before were pushed up by $\mathrm{OPT}/2$ and the height of such containers is at most $\mathrm{OPT}/2$. Thus, the first guillotine cut is applied at $y = h^* + \mathrm{OPT}/2$ so that we get two pieces R and R_{top}. For the guillotine separability of the top piece R_{top}, we use the fact that the packing to begin with was guillotine separable and we have moved a subset of the items in the initial packing vertically upwards by the same height. For the bottom piece R, which has a subset of the initial packing, we have packed B^* on the top edge (which is part of the line $[0, W] \times \{h^*\}$) of another container (say B) whose width is more than the width of B^*. In the guillotine cutting sequence of this piece without the addition of B^*, consider the horizontal cuts at height at least h^*. Note that there is no container lying completely above the line $[0, W] \times \{h^*\}$ in R.

Hence, we can remove such horizontal cuts and extend the vertical cuts that were intercepted by these horizontal cuts until they hit the topmost horizontal edge of R. Now, if we follow this new guillotine cutting sequence, we would finally have a rectangular region with only the container B. As there is no container in the region $[left(B), right(B)] \times [h^*, h^* + \mathrm{OPT}/2]$, we can pack B^* in this region without violating the guillotine separability condition. Now, observe that the height of the piece R_{top} is $(1 + O(\varepsilon))\mathrm{OPT} - h^*$ and height of the piece R is $h^* + \mathrm{OPT}/2$. Hence the height of the packing P_1 is $(3/2 + O(\varepsilon))\mathrm{OPT}$. ◀

Our next goal is to rearrange the tall items and their containers such that the tall items are bottom-left flushed. Let $\mathcal{B}_{tall} \subseteq \mathcal{B}$ denote the containers in $\mathcal{B}$ that contain at least one tall item. Consider the line segment $\ell := [0, W] \times \{h^*\}$ and observe that it might be intersected by containers in $\mathcal{B}_{tall}$. Let $\ell_1, \ell_2, ..., \ell_t$ be the connected components of $\ell \setminus \bigcup_{B \in \mathcal{B}_{tall}} B$. For each $j \in \{1, ..., t\}$ we do the following. Consider the containers in $\mathcal{B} \setminus \mathcal{B}_{tall}$ whose bottoms are contained in $\ell_j \times [\mathrm{OPT}/2, h^*]$ (we call them *type* 1 *containers*). We move them up by $h^* - \mathrm{OPT}/2$ units. There is enough space for them since the top edge of any of these containers lies below the line segment $[0, W] \times \{h^* + \mathrm{OPT}/2\}$ after shifting.

Then we take all containers in $\mathcal{B} \setminus \mathcal{B}_{tall}$ that intersect ℓ_j and also the line segment $[0, W] \times \{\mathrm{OPT}/2\}$ (*type* 2 *containers*). We move them up such that their respective bottom edges are contained in ℓ_j. Again there is enough space for this since the containers have height at most $\mathrm{OPT}/2$ and hence, their top edges cannot cross the line segment $[0, W] \times \{h^* + \mathrm{OPT}/2\}$. Note that in this step we do not necessarily move the affected containers uniformly. See Figure 9(c) and Figure 9(d) for a sketch. Note that due to the way ℓ^* is defined, no type 1 or type 2 container after being shifted overlaps with the region occupied by B^*.

One can show that the resulting packing is still guillotine separable. In particular, there is such a sequence that starts as follows: the first cut of this sequence is a horizontal cut with y-coordinate $h^* + \mathrm{OPT}/2$. For the resulting bottom piece R, there are vertical cuts that cut through the vertical edges of the containers in $\mathcal{B}_{tall}$ whose height is strictly greater than h^*, denote these containers by $\mathcal{B}^+_{tall}$. Let $R_1, ..., R_{t'}$ denote the resulting partition of R. We can rearrange our packing by reordering the pieces $R_1, ..., R_{t'}$. We reorder them such that on the left we place the pieces containing one container from $\mathcal{B}^+_{tall}$ each, sorted non-increasingly by their heights. Then we place the remaining pieces from $\{R_1, ..., R_{t'}\}$ (which hence, do not contain any containers in $\mathcal{B}^+_{tall}$), denote their union by R'. Let the left end of R' be $x = x_0$. We can assume that the guillotine cutting sequence places a vertical cut that separates R' from the other pieces in $\{R_1, ..., R_{t'}\}$ at $x = x_0$. From Lemma 3.3, we know that there is a container B (or possibly the case when $h^* = \mathrm{OPT}/2$ and we have a line segment ℓ' of width at least $\varepsilon_1 W$ on top of which we can pack B^*) whose top is at height h^*, has width at least ℓ^* which now lies to the right of x_0 in R'. Thus, the region $[left(B), left(B) + \varepsilon_1 W] \times [h^*, h^* + \mathrm{OPT}/2]$ is empty and can be used to place B^*.

We change now the placement of the containers within R'. Due to our rearrangements, no container inside R' intersects the line segment $[0, W] \times \{h^*\}$, so we can assume that R' is cut by the horizontal cut $[0, W] \times \{h^*\}$, let R'' be the resulting bottom piece and R''' be the piece above. We first show why R''' is guillotine separable. First, we separate B^* using vertical guillotine cuts at its left and right edges. Then we prove that the shifting operation for type 2 and type 1 containers does not violate guillotine separability of the packing for any region defined by some horizontal segment l_j for $j \in [t]$. Consider any type 2 container B'. Its top edge was initially lying above $y = h^*$ and its bottom below $\mathrm{OPT}/2$. Hence, before shifting this container no item could have been packed such that it was in the region $[0, W] \times [h^*, h^* + \mathrm{OPT}/2]$ and was intersecting the vertically extended line segments from the left and right edges of B' because any item packed in $[0, W] \times [h^*, \infty)$ initially was shifted

upward by OPT/2. Hence, after shifting B' such that its bottom touches $y = h^*$, after considering the cut $y = h^*$ in l_j, extend its left and right edges vertically upward to separate B' using guillotine cuts. For the type 1 containers, after the aforementioned cuts observe that all such containers have been shifted by an equal amount vertically upward and using the fact that they were guillotine separable initially, we claim that they are guillotine separable afterward. This is proved by considering the initial guillotine cuts that were separating such items and shifting the horizontal cuts upward by $h^* - \text{OPT}/2$ (equal to the distance the type 1 containers were shifted upward by).

To show that R'' is guillotine separable, observe that due to our rearrangements there are no containers that are completely contained in $R'' \cap ([0, W] \times [\text{OPT}/2, h^*])$. Therefore, we can assume that the next cuts for R'' are vertical cuts that contain all vertical edges of the boxes in $\mathcal{B}_{tall}$ that are contained in R''. Let $R''_1, ..., R''_{t''}$ denote the resulting pieces. Like above, we change our packing such that we reorder the pieces in $R''_1, ..., R''_{t''}$ non-increasingly by the height of the respective box in $\mathcal{B}_{tall}$ contained in them, and at the very right we place the pieces from $R''_1, ..., R''_{t''}$ that do not contain any container from $\mathcal{B}_{tall}$ (see Figure 9(e))

Finally, we sort the tall items inside the area $\bigcup_{B \in \mathcal{B}_{tall}} B$ non-increasingly by height so that they are bottom-left-flushed, and we remove the containers $\mathcal{B}_{tall}$ from $\mathcal{B}$ (see Figure 9(f)). We now prove that the tall items can be sorted inside the area $\bigcup_{B \in \mathcal{B}_{tall}} B$ non-increasingly by height without violating guillotine separability and feasibility. Note that the area $\bigcup_{B \in \mathcal{B}_{tall}} B$ can possibly contain some vertical items. Now, we reorder the tall items within R' such that they are sorted in non-increasing order of their heights. We do the same for all the tall items on the left of R'. There may be tall items (or vertical items) on the left hand side of R' such that for any such item, its height is less than the the tallest tall item in R'. Note that such tall items have to have a height of at most h^*. Such items can be repeatedly swapped with their neighboring tall item till they are in the correct position according to the *bottom-left-flushed* packing of the tall items, while maintaining guillotine separability. Such a swap operation between consecutive tall items ensures that all of the tall items and possibly some vertical items which were initially packed in tall containers remain inside the area $\bigcup_{B \in \mathcal{B}_{tall}} B$. We ensure that the vertical items which were packed to the left of R' get swapped so that they are packed on the right of all the tall items in a container. Now, to prove that guillotine separability of the packing is maintained after all such swapping operations, that is, after all tall items are sorted according to their heights in a non-increasing order consider the x-coordinate (say x_1) of the right edge of the shortest tall item which has height strictly greater than h^*. Observe that there were no tall containers of height strictly greater than h^* beyond $x = x_0$, which implies $x_1 \leq x_0$ and hence, now, for the guillotine cutting sequence, we can have a vertical guillotine cut at $x = x_1$ instead of at $x = x_0$, the rest being the same as mentioned before. This yields the packing claimed by Lemma 3.1.

3.2 Algorithm for polynomial time $(\frac{3}{2} + \varepsilon)$-approximation

First we guess a value OPT' such that $\text{OPT} \leq \text{OPT}' \leq (1 + \varepsilon)\text{OPT}$ in $n^{O_\varepsilon(1)}$ time (see the full version [31] for the details). In order to keep the notation light we denote OPT' by OPT. We want to compute a packing of height at most $(\frac{3}{2} + O(\varepsilon))\text{OPT}$ using Lemma 3.1.

Intuitively, we first place the tall items in a bottom-left-flushed way. Then we guess approximately the sizes of the boxes, place them in the free area, and place the items inside them via guessing the relatively large items, solving an instance of the generalized assignment problem (GAP), using NFDH for the small items, and invoking again Lemma 2.11 for the medium items. This is similar as in, e.g., [19, 28].

Formally, first we place all items in I_{tall} inside $[0, W] \times [0, (3/2 + \varepsilon)\text{OPT})$ such that they are bottom-left-flushed. Then, we guess approximately the sizes of the containers in $\mathcal{B}$. Note that in polynomial time we cannot guess the sizes of the containers exactly. Let $B \in \mathcal{B}$. Depending on the items packed inside B, we guess different quantities for B.

- If there is only one single large item $i \in I$ packed inside B then we guess i.
- If B contains only items from I_{hor} then we guess the widest item packed inside B. This defines our guessed width of B. Also, we guess all items packed inside B whose height is at least $\varepsilon_2\text{OPT}$ (at most $O(1/\varepsilon_2)$ many), denote them by I'_B. We guess the total height of the remaining items $I_B \setminus I'_B$ approximately by guessing the quantity $\hat{h}(B) := \left\lfloor \frac{h(I_B \setminus I'_B)}{\varepsilon_2 \text{OPT}} \right\rfloor \varepsilon_2\text{OPT}$. Our guessed height for B is then $\sum_{i \in I'_B} h(i) + \hat{h}(B)$.
- Similarly, if B contains only items from I_{ver} then we guess the highest item packed inside B, which defines our guessed height of B. Also, we guess all items packed inside B whose width is at least $\varepsilon_3 W$ (at most $O(1/\varepsilon_3)$ many), denote them by I'_B. We guess the total width of the remaining items $I_B \setminus I'_B$ approximately by guessing the quantity $\hat{w}(B) := \left\lfloor \frac{w(I_B \setminus I'_B)}{\varepsilon_3 \text{OPT}} \right\rfloor \varepsilon_3\text{OPT}$ and our guessed width of B is then $\sum_{i \in I'_B} w(i) + \hat{w}(B)$.
- If B contains only small items, then our guessed heights and widths of B are $\left\lfloor \frac{h(B)}{\varepsilon_4 \text{OPT}} \right\rfloor \varepsilon_4\text{OPT}$ and $\left\lfloor \frac{w(B)}{\varepsilon_4 W} \right\rfloor \varepsilon_4 W$, respectively.

Note that here $\varepsilon_2 = \frac{\varepsilon}{4|\mathcal{B}_{hor}|}$, $\varepsilon_3 = \frac{\varepsilon_1}{4|\mathcal{B}_{ver}|}$ and $\varepsilon_4 = \mu$ are chosen so that the unpacked horizontal items, unpacked vertical items and unpacked small items due to container rounding can be packed in containers B_{hor} (defined below), B^* and B_{small}, respectively.

We have at most $O_\varepsilon(1)$ containers and for each container $B \in \mathcal{B}$ we guess the type of container B and its respective width and height (depending on the type) in $n^{O_\varepsilon(1)}$ time.

Additionally, we guess three containers B_{med} of height $2\varepsilon\text{OPT}$, B_{hor} of height εOPT, and B_{small} of height $27\varepsilon\text{OPT}$ and width W each that we will use to place all medium items, and to compensate errors due to inaccuracies of our guesses for the sizes of the containers for horizontal and small items, respectively. Let $\mathcal{B}'$ denote the guessed containers (including B_{med}, B_{hor}, and B_{small}). Since $|\mathcal{B}'| = O_\varepsilon(1)$ and the containers in $\mathcal{B}'$ are not larger than the containers in $\mathcal{B}$, we can guess a placement for the containers $\mathcal{B}'$ such that together with I_{tall} they are guillotine separable. We place the containers B_{med}, B_{hor}, and B_{small} on top of the packing of rest of the containers in $\mathcal{B}'$, and I_{tall}.

▶ **Lemma 3.5.** *In time $n^{O_\varepsilon(1)}$ we can compute a placement for the containers in $\mathcal{B}'$ such that together with the items I_{tall}, they are guillotine separable.*

Next, we place the vertical items. Recall that for each container $B \in \mathcal{B}$ containing items from I_{ver} we guessed the items packed inside B whose width is at least $\varepsilon_3 W$. For each such container B we pack these items into the container $B' \in \mathcal{B}'$ that corresponds to B. With a similar technique as used for the generalized assignment problem (GAP) [19], we place all but items with width at most $\varepsilon_3 W$ for each container in I_{ver}. Further using the PTAS for this variant of GAP, we can ensure that items of total area at most $3\varepsilon_5 \cdot \text{OPT} \cdot W$ are not packed. Hence, items of total width at most $(3\varepsilon_5/\delta)W$ remain unpacked as each such item has height at least δOPT. We pack these remaining items into B^*, using that each of them has a height of at most $\text{OPT}/2$ and that their total width is at most $|\mathcal{B}'| \cdot 2\varepsilon_3 W + (3\varepsilon_5/\delta)W \leq \varepsilon_1 W = w(B^*)$. In other words, we fail to pack some of the vertical items since we guessed the widths of the containers only approximately and since our polynomial time approximation algorithm for GAP might not find the optimal packing. We use a similar procedure for the items in I_{hor} where instead of B^* we use B_{hor} in order to place the unassigned items.

▶ **Lemma 3.6.** *In time $n^{O_\varepsilon(1)}$ we can compute a placement for all items in $I_{ver} \cup I_{hor}$ in B^*, B_{hor}, and their corresponding boxes in $\mathcal{B}'$.*

For the medium items we invoke again Lemma 2.11 and we place B_{med} on top of the containers in $\mathcal{B}$ which increases the height of the packing only by $2\varepsilon\mathrm{OPT}$.

Finally, we use NFDH again to pack the small items into their corresponding containers in $\mathcal{B}'$, which we denote by $\mathcal{B}'_{small}$, and B_{small}. We need B_{small} due to inaccuracies of NFDH and of our guesses of the container sizes.

▶ **Lemma 3.7.** *In time $n^{O(1)}$ we can compute a placement for all items in I_{small} in $\mathcal{B}'_{small}$ and B_{small}.*

▶ **Theorem 3.8.** *There is a $(3/2+\varepsilon)$-approximation algorithm for the guillotine strip packing problem with a running time of $n^{O_\varepsilon(1)}$.*

4 Conclusion and Open problems

We were able to show essentially tight approximation algorithms for GSP in both the polynomial and the pseudo-polynomial settings. This was possible due to the structure of the respective optimal packings since they are guillotine separable. However, it is unclear how to obtain such a structured packing in the general case of SP, and the question remains to close the gap between the best approximation guarantee of $(5/3+\varepsilon)$ and the lower bound of $3/2$. Another interesting open problem related to guillotine cuts is to find out whether there exists a PTAS for the 2D guillotine geometric knapsack (2GGK) problem.

A Study of Weisfeiler–Leman Colorings on Planar Graphs

Sandra Kiefer
Max Planck Institute for Software Systems, Saarland Informatics Campus, Saarbrücken, Germany

Daniel Neuen
School of Computing Science, Simon Fraser University, Burnaby, Canada

Abstract

The Weisfeiler–Leman (WL) algorithm is a combinatorial procedure that computes colorings on graphs, which can often be used to detect their (non-)isomorphism. Particularly the 1- and 2-dimensional versions 1-WL and 2-WL have received much attentionattention, due to their numerous links to other areas of computer science.

Knowing the expressive power of a certain dimension of the algorithm usually amounts to understanding the computed colorings. An increase in the dimension leads to finer computed colorings and, thus, more graphs can be distinguished. For example, on the class of planar graphs, 3-WL solves the isomorphism problem. However, the expressive power of 2-WL on the class is poorly understood (and, in particular, it may even well be that it decides isomorphism).

In this paper, we investigate the colorings computed by 2-WL on planar graphs. Towards this end, we analyze the graphs induced by edge color classes in the graph. Based on the obtained classification, we show that for every 3-connected planar graph, it holds that: a) after coloring all pairs with their 2-WL color, the graph has fixing number 1 with respect to 1-WL, or b) there is a 2-WL-definable matching that can be used to transform the graph into a smaller one, or c) 2-WL detects a connected subgraph that is essentially the graph of a Platonic or Archimedean solid, a prism, a cycle, or a bipartite graph $K_{2,\ell}$. In particular, the graphs from case (a) are identified by 2-WL.

1 Introduction

The Weisfeiler–Leman (WL) algorithm [41] is a combinatorial procedure that given a graph G, computes a coloring on G which respects (and sometimes also detects) the symmetries in the graph. Its most prominent application is in theoretical [6, 8, 31] and practical approaches [2, 10, 30, 35, 36] to the graph isomorphism problem. The original algorithm by Weisfeiler and Leman is the 2-dimensional version and it colors pairs of vertices. Its generalization yields for every natural number k the k-dimensional WL algorithm k-WL, which iteratively refines a coloring of vertex k-tuples by aggregating local structural information encoded in the colors. Its final output is a coloring that is *stable* with respect to the criterion for partitioning the color classes, and graphs with different final colorings are never isomorphic.

Over the decades, fascination for the algorithm has persisted. This is to a large extent due to the discovery of numerous connections to other areas in computer science that are still being explored. For example, the algorithm has close links to linear and semidefinite

programming [4, 5, 25], homomorphism counting [11, 12], and machine learning [1, 21, 37, 39, 43]. Its expressive power can be characterized via winning strategies for the players in a particular type of Ehrenfeucht-Fraïssé game [8, 27]. Moreover, it is known that two graphs receive different final colorings with respect to k-WL if and only if the graphs can be distinguished via a formula in the counting-logic fragment C^{k+1} [8, 29].

In this work, we focus on the original version 2-WL, as introduced by Weisfeiler and Leman [41]. Besides the connections outlined for k-WL above, 2-WL has a precise correspondence to coherent configurations (see, e.g., [9]). Despite the simple and very natural concept behind the algorithm, its behavior is not well-understood and there is an extensive line of study to capture its expressive power. For example, one branch of research aims at understanding which graph properties can be detected by 2-WL. In this direction, Fürer [16] as well as Arvind et al. and Fuhlbrück et al. [3, 15] obtained insights concerning the ability of 2-WL to detect and count small subgraphs. Furthermore, the algorithm is able to detect 2-separators in graphs and implicitly computes the decomposition of a graph into its 3-connected components [32].

A related line of research analyzes which graphs are *identified* by 2-WL, i.e., on which graphs 2-WL serves as a complete isomorphism test. Positive examples include interval graphs [13] and distance-hereditary graphs [17] as well as almost all regular graphs [7]. In the light of the upper bound of 3 on the dimension of the algorithm needed to identify all planar graphs [34], there is hope that the class of planar graphs can eventually be added to the list. Towards a complete characterization of the expressive power of 2-WL, Fuhlbrück, Köbler, and Verbitsky [14] developed an algorithmic characterization of the graphs of color class size at most 4 that are identified by 2-WL.

Our Contribution. In this work, we investigate 2-WL on planar graphs. We are interested in analyzing the stable output coloring computed by 2-WL and deducing symmetries and other properties of the input graph from properties of the coloring.

As a starting point, we precisely characterize the planar graphs in which all edges receive the same color with respect to 2-WL. Since the coloring that 2-WL computes is preserved by automorphisms, edge-transitive planar graphs clearly fall into this category. As our first main result, we prove the converse of this statement: every planar graph in which all edges receive the same color with respect to 2-WL is edge-transitive. To show the implication, we reprove the classification of edge-transitive planar graphs (see, e.g., [26]) building solely on the 2-WL coloring.

Using the classification, we continue to analyze the WL coloring on general planar graphs. Since, by [32], the algorithm 2-WL implicitly computes the graph decomposition into 3-connected components, understanding 2-WL on planar graphs essentially amounts to a study of 3-connected planar graphs. Here, we can exploit a theorem due to Whitney [42], which says that all embeddings of a 3-connected planar graph are combinatorially equivalent.

Our focus lies on the following three tasks: (i) classify the subgraphs induced by edges of the same 2-WL color that can occur, (ii) analyze how these subgraphs interleave, and (iii) establish connections to properties of the entire graph G.

Let G be a 3-connected planar graph and let $C_E(G)$ denote the set of 2-WL colors that correspond to edges of G. For every $c \in C_E(G)$, denote by $G[c]$ the subgraph induced by all edges of 2-WL color c. To describe our results, it turns out to be useful to partition edge colors into three types depending on the number of faces per connected component of $G[c]$. We say that c has *Type I* if every connected component of $G[c]$ has one face, *Type II* if every connected component of $G[c]$ has two faces, and *Type III* if every connected component of $G[c]$ has at least three faces. (By the properties of 2-WL, these types indeed cover all cases that can occur.)

First, we analyze the graphs induced by edge colors c of Type III. It is not hard to see that every edge in such a graph $G[c]$ receives the same 2-WL color (when applying 2-WL to $G[c]$), and thus, by our classification, $G[c]$ is edge-transitive. However, it turns out that much stronger statements are possible, since, in the end, many edge-transitive planar graphs cannot appear as a graph $G[c]$. For example, we show that $G[c]$ is always connected. As our central result for colors of Type III, we obtain a precise classification of the possible graphs $G[c]$. An interesting consequence of this classification is that the automorphism group $\mathrm{Aut}(G)$ of G is always isomorphic to a subgroup of $\mathrm{Aut}(G[c])$. More precisely, we show that fixing the images of all vertices of $G[c]$ uniquely determines the image of every vertex of G under any automorphism of G. Hence, by only looking at the subgraph induced by a single edge color of Type III, we obtain strong insights about the symmetries of the entire graph.

On the other side of the spectrum, we prove that if all edge colors are of Type I, then G has *fixing number* at most 1, where the fixing number is the minimum number of vertices that need to be fixed pointwise so that the identity mapping is the only automorphism of G. It is known that 3-connected planar graphs have fixing number at most 3, and there is a complete characterization of those graphs of fixing number exactly 3 [34]. In our analysis of 3-connected planar graphs G in which all edge colors are of Type I, we only use 1-WL to prove that G has no non-trivial automorphisms after fixing a certain single vertex. This implies that 2-WL identifies all such graphs.

If neither of the above cases applies, then there is an edge color of Type II. Let us first remark that the graphs of many Archimedean solids fall into this category (while the edge colors in the graph of all Platonic solids are of Type III). In such a situation, the graph of the Archimedean solid is defined by edge colors c, d where one of the two colors has Type II. With this in mind, towards solving task (ii), we analyze how edge colors of Type II interleave with other edge colors. More precisely, similarly as for Type III, we aim at identifying a connected subgraph defined by two colors $c, d \in C_E(G)$, where c has Type II, that corresponds to one of the Archimedean solids, or stems from a small number of infinite graph families. We remark that, similar to the case of edge colors of Type III, if we have such a subgraph $G[c, d]$, then $\mathrm{Aut}(G)$ is isomorphic to a subgroup of $\mathrm{Aut}(G[c, d])$.

We show that either this goal can be achieved, or G has fixing number 1 or there is a *WL-definable matching*. Such a matching is given by an edge color c such that $G[c]$ is a matching graph (i.e., every vertex has degree 1) and the endpoints of every edge receive different colors. Such matchings also play a crucial role in the analysis of 2-WL on graphs of color class size 4 [14], and contracting all matching edges preserves many crucial properties related to WL such as the stable coloring, identifiability by WL, as well as the automorphism group of G. As a result, finding a WL-definable matching is beneficial since we can proceed to a smaller graph without affecting the problem at hand.

Towards the WL Dimension of Planar Graphs. The WL dimension of a graph class $\mathcal{C}$ is the minimal k such that k-WL identifies every graph from $\mathcal{C}$, i.e., k-WL serves as a complete isomorphism test for the class $\mathcal{C}$. Many classes of graphs are known to have a finite WL dimension, for example, interval graphs [13], graphs of bounded rank-width [24] as well as graphs of bounded genus [22] and, more generally, all graph classes that exclude a fixed graph as a minor [19, 20].

For planar graphs, the quest for bounds on their WL dimension was initiated by Immerman already over three decades ago [28]. In a first step, Grohe [18] proved that the dimension is finite. Analyzing Grohe's proof in detail, Redies [38] showed an upper bound of 14 on the WL dimension of planar graphs. This was further improved in [34], where it is shown

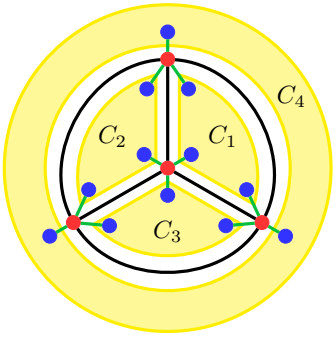

Figure 1 The visualization shows a 3-connected planar graph G and an edge color $c \in C_E(G)$ (shown in black) such that $G[c]$ is isomorphic to K_4. Also, C_1, C_2, C_3, C_4 are the vertex sets of the connected components of $G - V(G[c])$. Using regularity constraints specific to the case $G[c] \cong K_4$, one can show that the graphs induced by the C_i are all indistinguishable by 2-WL. More strongly, it actually holds for all $i, j \in [4]$, $v \in N(C_i)$ and $w \in N(C_j)$ that $\{\{\chi(v, v') \mid v' \in N(v) \cap C_i\}\} = \{\{\chi G(w, w') \mid w' \in N(w) \cap C_j\}\}$, where χ denotes the 2-WL coloring. (In the picture, this multiset contains one green edge, i.e., every $v \in V(G[c])$ has exactly one neighbor via a green edge in each adjacent C_i.)

that already 3-WL identifies all planar graphs, thus narrowing down the WL dimension of planar graphs to 2 or 3. Moreover, it was recently shown that a constant dimension of the WL algorithm suffices to identify all planar graphs in a logarithmic number of refinement rounds [23], extending previous results for 3-connected planar graphs [40]. Still, the task to determine the precise WL-dimension of the class of planar graphs remains open. A central motivation for our work is to find out whether 2-WL identifies every planar graph.

Our results suggest an inductive approach to this question. Indeed, building on the fact that 2-WL is able to detect the decomposition into 3-connected components [32], we can restrict our attention to 3-connected graphs. Given a 3-connected planar graph G, by combining the results described above, we always obtain that G has one of the following:

- **(A)** fixing number 1 under 1-WL, i.e., individualizing a single vertex and performing 1-WL (after coloring all pairs with their 2-WL color) results in a discrete coloring,
- **(B)** a WL-definable matching, or
- **(C)** a connected subgraph induced by at most two edge colors that corresponds to a Platonic or Archimedean solid or stems from a small number of infinite graph families.

In Case A, the graph G is identified by 2-WL. In Case B, we can follow the strategy outlined in [14] and move to a smaller graph by contracting the definable matching. Therefore, determining the WL dimension of the class of planar graphs boils down to defeating Case C. In this case, we obtain a connected subgraph H that is defined by at most two edge colors c and d and which we can classify precisely. Let $C_1, \dots, C_s$ denote the vertex sets of the connected components of $G - V(H)$, the graph G with the vertices in H removed (see also Figure 1). Also, let G' be a second graph that cannot be distinguished from G by 2-WL. Let H' denote the subgraph of G' induced by c and d and let $C'_1, \dots, C'_s$ denote the vertex sets of the connected components of $G' - V(H')$. Presupposing by induction that the statement holds for smaller graphs, we may assume that 2-WL identifies the subgraphs induced by $C_1, \dots, C_s$. This implies that $G[C_i]$ is isomorphic to $G'[C'_i]$ for all $i \in [s]$ (possibly after reordering the sets $C'_1, \dots, C'_s$). It is not hard to see that 2-WL identifies H and, thus, H is isomorphic to H'. Now, ideally, we want to glue all these partial isomorphisms together to obtain a global isomorphism from G to G'. Towards this end, it is our intuition that the

options for the interplay between H and the sets C_i are extremely limited due to G being planar and H being defined by few edge colors, which enforces strong regularity conditions on the interaction between H and the surrounding graph. A formalization of such a strategy for all subcases that can appear in Case C should yield that 2-WL identifies every planar graph.

2 Preliminaries

Graphs. An (undirected) *graph* is a pair $G = (V(G), E(G))$ of a finite *vertex set* $V(G)$ and an *edge set* $E(G) \subseteq \big\{\{u, v\} \,\big|\, u \neq v \in V(G)\big\}$. Unless stated explicitly otherwise, graphs are undirected. For a directed graph G', we write $\mathsf{undir}(G')$ to denote its undirected version. For $v, w \in V(G)$, we also write vw as a shorthand for $\{v, w\}$. The *neighborhood* of v in G is denoted by $N_G(v)$ and the *degree* of v in G is $\deg_G(v) \coloneqq |N_G(v)|$. If the graph G is clear from the context, we usually omit the index and simply write $N(v)$ and $\deg(v)$. For $W \subseteq V(G)$, we also define $N(W) \coloneqq \big(\bigcup_{v \in W} N(v)\big) \setminus W$. We denote by $G[W]$ the *induced subgraph* of G on the vertex set W, and define $G - W \coloneqq G[V(G) \setminus W]$. A set $S \subseteq V(G)$ is a *separator* of G if $G - S$ has more connected components than G. A *k-separator* of G is a separator of G of size k. The graph G is *k-connected* if it is connected and has no separator of size at most $k - 1$.

In our definitions of vertex sets of graphs, we use the notation $\uplus$ to denote a formal disjoint union. More precisely, for sets V and W, the set $V \uplus W$ contains $|V| + |W|$ vertices, one distinct copy of each vertex in V and one distinct copy of each vertex in W. (For ease of notation, we refer to the vertices by their original names in V and W instead of renaming them first.)

A *vertex-colored graph* is a tuple (G, λ) where G is a graph and $\lambda\colon V(G) \to C$ is a *vertex coloring*, a mapping from $V(G)$ into some set C of colors. We define the set of *arcs* of a graph G as $A(G) \coloneqq \{(v, v) \mid v \in V(G)\} \cup \{(v, w) \mid \{v, w\} \in E(G)\}$. Observe that for each $vw \in E(G)$, there are the two arcs (v, w), (w, v). An *arc-colored graph* is a tuple (G, λ), where G is a graph and $\lambda\colon A(G) \to C$ is a mapping from $A(G)$ into some set C of colors. Similarly, a *pair-colored graph* is a tuple (G, λ), where G is a graph and $\lambda\colon (V(G))^2 \to C$ is a mapping into some set of colors C.

Typically, the set C is chosen to be an initial segment $[n]$ of the natural numbers. We say a coloring λ is *discrete* if it is injective, i.e., all color classes have size 1. Finally, for a coloring λ and distinct vertices $v_1, \dots, v_\ell$, we denote by $(G, \lambda, v_1, \dots, v_\ell)$ the colored graph where each v_i for $i \in [\ell]$ is individualized. To be more precise, if λ is a vertex coloring, then $(G, \lambda, v_1, \dots, v_\ell) \coloneqq (G, \widetilde{\lambda})$ where $\widetilde{\lambda}(v_i) = (1, i)$ for all $i \in [\ell]$, and $\widetilde{\lambda}(v) = (0, \lambda(v))$ for all $v \in V(G) \setminus \{v_1, \dots, v_\ell\}$. The definitions for arc and pair colorings are analogous. We generally assume that all graphs are arc-colored even if not explicitly stated. Every (uncolored) graph can be interpreted as an arc-colored graph by assigning to every diagonal arc (v, v) the color 1 and assigning to every non-diagonal arc the color 2.

A graph is called *planar* if it can be embedded into the plane $\mathbb{R}^2$. A *plane graph* is a graph embedded into the plane. As the following statement shows, all plane realizations of a planar graph have the same number of faces, i.e., regions bounded by edges.

▶ **Theorem 1** (Euler's formula). *Let G be a connected plane graph with n vertices, m edges, and f faces. Then $n - m + f = 2$.*

We will also fall back on the following famous theorem due to Whitney.

▶ **Theorem 2** (Whitney's theorem [42]). *Up to homeomorphism, a 3-connected planar graph has a unique embedding into the plane.*

The theorem allows us to speak about faces of 3-connected planar graphs as abstract objects, since it implies that in a 3-connected planar graphs, the set of faces does not depend on a specific embedding and thus, the faces can be viewed as combinatorial objects associated with G and are uniquely defined by their sets of vertices $V(F)$ and the edges $E(F)$ bounding F. We will therefore not draw a clear distinction between this combinatorial view and the topological view of F as a region and just use whichever is most suitable for our purpose.

The Weisfeiler–Leman Algorithm. Let $\chi_1, \chi_2 \colon (V(G))^k \to C$ be colorings of the k-tuples of vertices of a graph G. We say χ_1 *refines* χ_2, denoted $\chi_1 \preceq \chi_2$, if $\chi_1(\bar{v}) = \chi_1(\bar{w})$ implies $\chi_2(\bar{v}) = \chi_2(\bar{w})$ for all $\bar{v}, \bar{w} \in (V(G))^k$. The colorings χ_1 and χ_2 are *equivalent*, denoted $\chi_1 \equiv \chi_2$, if $\chi_1 \preceq \chi_2$ and $\chi_2 \preceq \chi_1$.

Given a graph G, the algorithm 1-WL iteratively computes an isomorphism-invariant coloring of the vertices of G. In this work, we actually require an extension of 1-WL, which also takes arc colors into account. For an arc-colored graph (G, λ), we define the initial coloring computed by the algorithm via $\chi^1_0[G](v) \coloneqq \lambda(v, v)$ for all $v \in V(G)$. This coloring is refined via $\chi^1_{i+1}[G](v) \coloneqq (\chi^1_i[G](v), \mathcal{M}_i(v))$, where $\mathcal{M}_i(v)$ is a multiset defined as

$$\mathcal{M}_i(v) \coloneqq \left\{\!\!\left\{ \left(\chi^1_i[G](w), \lambda(v, w), \lambda(w, v)\right) \;\middle|\; w \in N_G(v) \right\}\!\!\right\}.$$

By definition, $\chi^1_{i+1}[G] \preceq \chi^1_i[G]$ holds for all $i \geq 0$. Hence, there is a minimal value i_∞ such that $\chi^1_{i_\infty}[G] \equiv \chi^1_{i_\infty+1}[G]$. We call $\chi^1_{i_\infty}[G]$ the *stable* coloring of G and denote it by $\chi^1_{\mathsf{WL}}[G]$. The algorithm 1-WL takes an arc-colored graph (G, λ) as input and returns $\chi^1_{\mathsf{WL}}[G]$.

We can also apply 1-WL to a pair-colored graph (G, λ). This can be done by defining $\widetilde{\lambda}(v_1, v_2) \coloneqq (1, \lambda(v_1, v_2))$ for all $v_1, v_2 \in V(G)$ with $v_1v_2 \in E(G)$, and $\widetilde{\lambda}(v_1, v_2) \coloneqq (0, \lambda(v_1, v_2))$ for all $v_1, v_2 \in V(G)$ with $v_1v_2 \notin E(G)$. Then we define $\chi^1_{\mathsf{WL}}[G, \lambda] \coloneqq \chi^1_{\mathsf{WL}}[H, \widetilde{\lambda}]$ where H is a complete graph on vertex set $V(G)$.

Next, we describe the *k-dimensional Weisfeiler–Leman algorithm* (k-WL) for $k \geq 2$. For an input graph G, let $\chi^k_0[G] \colon (V(G))^k \to C$ be the coloring where each tuple is colored with the isomorphism type of its underlying ordered subgraph. $v_i = v_j \Leftrightarrow v'_i = v'_j$ and $v_iv_j \in E(G) \Leftrightarrow v'_iv'_j \in E(G)$. If the graph comes equipped with a coloring, the initial coloring $\chi^k_0[G]$ also takes the input coloring into account. More formally, for an arc coloring λ, for $\chi^k_0[G](v_1, \ldots, v_k) = \chi^k_0[G](v'_1, \ldots, v'_k)$ to hold, we have the additional conditions $\lambda(v_i, v_j) = \lambda(v'_i, v'_j)$ for all $i, j \in [k]$ with $(v_i, v_j) \in A(G)$. For a pair coloring λ, we have the additional conditions $\lambda(v_i, v_j) = \lambda(v'_i, v'_j)$ for all $i, j \in [k]$.

We then recursively define the coloring $\chi^k_i[G]$ obtained after i rounds of the algorithm. For $\bar{v} = (v_1, \ldots, v_k) \in (V(G))^k$, let $\chi^k_{i+1}[G](\bar{v}) \coloneqq \big(\chi^k_i[G](\bar{v}), \mathcal{M}_i(\bar{v})\big)$, where

$$\mathcal{M}_i(\bar{v}) \coloneqq \left\{\!\!\left\{ \left(\chi^k_i[G](\bar{v}[w/1]), \ldots, \chi^k_i[G](\bar{v}[w/k])\right) \;\middle|\; w \in V(G) \right\}\!\!\right\}$$

and $\bar{v}[w/i] \coloneqq (v_1, \ldots, v_{i-1}, w, v_{i+1}, \ldots, v_k)$ is the tuple obtained from substituting the i-th entry of $\bar{v}$ with w. Again, there is a minimal i_∞ such that $\chi^k_{i_\infty}[G] \equiv \chi^k_{i_\infty+1}[G]$, and we set $\chi^k_{\mathsf{WL}}[G] \coloneqq \chi^k_{i_\infty}[G]$.

The algorithm k-WL takes a (pair- or arc-)colored graph G as input and returns $\chi^k_{\mathsf{WL}}[G]$. Given graphs G and H, the algorithm *distinguishes* G and H if $\{\!\{\chi^k_{\mathsf{WL}}[G](\bar{v}) \mid \bar{v} \in (V(G))^k\}\!\} \neq \{\!\{\chi^k_{\mathsf{WL}}[H](\bar{w}) \mid \bar{w} \in (V(H))^k\}\!\}$. Also, k-WL *identifies* G if it distinguishes G from every other non-isomorphic graph.

▶ **Definition 3.** *Let G be a graph and let $k \geq 2$. Then k-*WL determines arc orbits on *G if for every $(v_1, v_2) \in A(G)$, every graph H, and every $(w_1, w_2) \in A(H)$ such that $\chi^k_{\mathsf{WL}}[G](v_1, v_2, \ldots, v_2) = \chi^k_{\mathsf{WL}}[H](w_1, w_2, \ldots, w_2)$, there is an isomorphism $\varphi\colon G \cong H$ such that $\varphi(v_i) = w_i$ holds for both $i \in \{1, 2\}$.*

*Moreover, k-*WL determines pair orbits of *G if for all $v_1, v_2 \in V(G)$, every graph H, and all $w_1, w_2 \in V(H)$ such that $\chi^k_{\mathsf{WL}}[G](v_1, v_2, \ldots, v_2) = \chi^k_{\mathsf{WL}}[H](w_1, w_2, \ldots, w_2)$, there is an isomorphism $\varphi\colon G \cong H$ such that $\varphi(v_i) = w_i$ holds for both $i \in \{1, 2\}$.*

Observe that if k-WL determines arc or pair orbits of G, then it identifies G. Indeed, if for a second graph H, there is no isomorphism from G to H, the multisets of χ^k_{WL}-colors in the two graphs must be disjoint by Definition 3.

3 Edge-Transitive Planar Graphs

In this section, we classify planar graphs where all edges receive the same color with respect to 2-WL. We call an undirected graph G *edge-transitive* if for all $uv, u'v' \in E(G)$, there is an automorphism $\varphi\colon V(G) \to V(G)$ with $\varphi(u) = u'$ and $\varphi(v) = v'$. It is well-known that there are only nine edge-transitive connected planar graphs of minimum degree 3 [26]. Based on this result, one can easily classify all edge-transitive planar graphs. Clearly, all of these graphs have the property that all edges receive the same color with respect to 2-WL. In this section, we show the converse of this statement, i.e., every planar graph in which all edges receive the same color with respect to 2-WL is edge-transitive. Towards this goal, we reprove the classification from [26] relying only on 2-WL colors. More precisely, the main result in this section is the following theorem (see also Figure 2). Since 2-WL colors directed pairs and it may happen that a pair (u, v) receives a different color than (v, u), it is more convenient to consider directed graphs and demand that all directed edges receive the same color (rather than saying the pair of colors for both orientations is the same for all undirected edges).

▶ **Theorem 4.** *Let G be a connected planar (directed or undirected) graph of minimum degree at least 3 such that $\chi^2_{\mathsf{WL}}[G](v_1, w_1) = \chi^2_{\mathsf{WL}}[G](v_2, w_2)$ for all $(v_1, w_1), (v_2, w_2) \in E(G)$. Then one of the following holds:*

- **(A)** *G is isomorphic to a tetrahedron (Figure 2a), a cube (Figure 2b), a dodecahedron (Figure 2d), or an icosahedron (Figure 2e),*
- **(B)** *the undirected version $\mathsf{undir}(G)$ is isomorphic to an octahedron (Figure 2c), a cuboctahedron (Figure 2f), or an icosidodecahedron (Figure 2g), or*
- **(C)** *the undirected version $\mathsf{undir}(G)$ is isomorphic to a cube (Figure 2h), a rhombic dodecahedron (Figure 2i), or a rhombic triacontahedron (Figure 2j).*

Note that the classification includes the graphs of all Platonic solids. To prove the theorem, we distinguish two cases. Let $\chi := \chi^2_{\mathsf{WL}}[G]$ and let $C_V(G, \chi) := \{\chi(v, v) \mid v \in V(G)\}$ denote the set of *vertex colors*. Since $\chi(u, u) = \chi(u', u')$ and $\chi(v, v) = \chi(v', v')$ whenever $\chi(u, v) = \chi(u', v')$, we conclude that $1 \leq |C_V(G, \chi)| \leq 2$. First suppose $|C_V(G, \chi)| = 1$. Then $\mathsf{undir}(G)$ is d-regular for some $d \geq 3$. Since G is planar, $d \leq 5$ and thus, $d \in \{3, 4, 5\}$. A deep analysis of these three cases leads to the graphs listed in Parts A and B. Let us remark at this point that obtaining such a classification is much more challenging than for edge-transitive graphs. Indeed, the proofs for edge-transitive graphs highly exploit that the multiset of sizes of faces incident to an edge (and a vertex, respectively) is always the same. However, we cannot immediately deduce information about the size of faces from considering WL-colors and hence, we cannot directly rely on this type of argument. Instead, our arguments exploit the fact that 2-WL can detect 2-separators [32] as well as the existence of certain short cycles [15].

(h) Bicolored cube. **(i)** Rhombic dodecahedron. **(j)** Rhombic triacontahedron.

Figure 2 All edge-transitive connected planar graphs of minimum degree 3.

Also, note that the graphs listed in Part A are always undirected since d is odd. On the other hand, every graph listed in Part B also has at least one directed version that is also edge-transitive (we refer the reader to the full version [33] for details).

Finally, for the case $|C_V(G, \chi)| = 2$, it is possible to perform a reduction to the first case by defining an auxiliary graph on one of the two vertex-color classes. This results in the graphs listed in Part C. Here, it is notable that the cube appears for a second time because it is bipartite and directing all edges from one bipartition class to the other one also leads to an edge-transitive graph.

In Theorem 4, we restrict ourselves to graphs that are connected and have minimum degree at least 3. Both of these restrictions can easily be lifted as follows. Let us first consider the restriction on the degree and let G be a connected planar graph such that

$\chi^2_{\mathsf{WL}}[G](v_1, w_1) = \chi^2_{\mathsf{WL}}[G](v_2, w_2)$ holds for all $(v_1, w_1), (v_2, w_2) \in E(G)$. If G has maximum degree 2 or contains a vertex of degree at most 1, then it is easy to see that G is either a cycle or isomorphic to a star $K_{1,h}$ for some $h \geq 0$ ($h = 0$ covers the special case that G consists of a single vertex).

▶ **Definition 5.** *Let H be a graph and $s \geq 1$. The* s-subdivision of H *is the graph $H^{(s)}$ obtained from H by replacing each edge with s parallel paths of length 2. Formally, $H^{(s)}$ is the graph with vertex set $V(H^{(s)}) \coloneqq V(H) \uplus (E(H) \times [s])$ and edge set*

$$E(H^{(s)}) \coloneqq \left\{ v(e,i) \;\middle|\; e \in E(H), v \in e, i \in [s] \right\}.$$

In the remaining case, G has maximum degree at least 3 and minimum degree 2. Then it is easy to see that G is one of the graphs from Theorem 4, or an s-subdivision of one of the graphs from Parts A and B for some $s \geq 1$, a cycle C_ℓ for some $\ell \geq 3$, or the complete graph on two vertices K_2.

Finally, if G is not connected, then it is isomorphic to the disjoint union of ℓ copies of one of its connected components for some $\ell \geq 2$, because all graphs listed above can be distinguished from each other by 2-WL. Actually, it can be checked that all of the graphs are even identified by 2-WL. Overall, this gives the following corollary.

▶ **Corollary 6.** *Let G be a directed planar graph such that $\{\{\chi^2_{\mathsf{WL}}[G](v,w), \chi^2_{\mathsf{WL}}[G](w,v)\}\} = \{\{\chi^2_{\mathsf{WL}}[G](v',w'), \chi^2_{\mathsf{WL}}[G](w',v')\}\}$ holds for all $(v,w), (v',w') \in E(G)$. Then 2-WL determines arc orbits on G. In particular, G is edge-transitive.*

4 Graphs Induced by a Single Edge Color

After considering planar graphs with a single edge color with respect to 2-WL, we now wish to analyze the 2-WL coloring of arbitrary planar graphs. Since, by [32], the algorithm 2-WL implicitly computes the decomposition of a graph into 3-connected components[1], understanding 2-WL on planar graphs essentially amounts to a study of 3-connected planar graphs. Hence, we restrict our attention to those.

4.1 Edge Types

Let G be a 3-connected planar graph and set $\chi \coloneqq \chi^2_{\mathsf{WL}}[G]$. To analyze the coloring χ, we focus on subgraphs induced by a single edge color. Towards this end, let $C_V \coloneqq C_V(G,\chi) = \{\chi(v,v) \mid v \in V(G)\}$ denote the set of *vertex colors*. Similarly, let $C_E \coloneqq C_E(G,\chi) = \{\chi(v,w) \mid vw \in E(G)\}$ be the set of *edge colors*. For $C \subseteq C_E$, we define the graph $G[C]$ with

$$V(G[C]) \coloneqq \{v_1, v_2 \mid \chi(v_1,v_2) \in C\} \quad \text{and} \quad E(G[C]) \coloneqq \{v_1v_2 \mid \chi(v_1,v_2) \in C\}.$$

In case $C = \{c_1, \dots, c_\ell\}$, we also write $G[c_1, \dots, c_\ell]$ instead of $G[\{c_1, \dots, c_\ell\}]$. Observe that $G[C]$ is defined as an undirected graph. However, it may be that $\chi(v_1,v_2) \neq \chi(v_2,v_1)$ holds for some $v_1v_2 \in E(G)$. Since this information turns out to be relevant in some cases, we always assume that $G[C]$ is equipped with an arc coloring where colors are inherited from χ.

As indicated, we are particularly interested in the case $C = \{c\}$ for a single color c. Observe that the ends of c-colored edges have the same vertex color, i.e., if $\chi(v_1,w_1) = \chi(v_2,w_2) = c$, then $\chi(v_1,v_1) = \chi(v_2,v_2)$ and $\chi(w_1,w_1) = \chi(w_2,w_2)$. This implies that $1 \leq |C_V(G[c],\chi)| \leq 2$. We say that $G[c]$ is *unicolored* if $|C_V(G[c],\chi)| = 1$. Otherwise, we say that $G[c]$ is *bicolored*.

[1] For the formal and quite technical definition of this notion, we refer to [32].

To analyze 2-WL on 3-connected planar graphs, we consider the graphs $G[c]$ for suitable edge colors $c \in C_E$. Towards this end, it turns out to be useful to group the graphs $G[c]$ according to the number of faces of each connected component of $G[c]$. Note that 2-WL detects connected components of graphs. More precisely, it holds that

- all connected components in $G[c]$ have the same size because 2-WL detects, for every $w \in V(G[c])$, the set of vertices reachable in the arc-colored graph (G, χ) from w via edges uv of color c (i.e., $\chi(u,v) = c$ or $\chi(v,u) = c$), and
- all connected components in $G[c]$ have the same multiset of vertex degrees in $G[c]$ since otherwise the vertex colors and, thus, also the arc colors would be different.

In combination, all connected components of $G[c]$ have the same number of vertices and edges and hence, by Euler's formula, they also have the same number of faces. We distinguish between three types in C_E.

Type I. For the first category, we consider those graphs $G[c]$ that have only one face. To be more precise, we say that $c \in C_E$ has *Type I* if $(G[c])[A]$ has a single face for every vertex set A of a connected component of $G[c]$. It is not difficult to see that $G[c]$ is isomorphic to a disjoint union of stars $K_{1,h}$ for $h \in [n]$.

Type II. For the second category, we consider those graphs $G[c]$ where every connected component has exactly two faces. Formally, we say that $c \in C_E$ has *Type II* if $(G[c])[A]$ has exactly two faces for every vertex set A of a connected component of $G[c]$. In this case, $G[c]$ is a disjoint union of cycles of the same length. Also, it is not difficult to see that every connected component of $G[c]$ is either a directed cycle (i.e., $\chi(v_1, v_2) \neq \chi(v_2, v_1)$ holds for every edge $v_1v_2 \in E(G[c])$), or an undirected cycle in which all vertices have the same color with respect to 2-WL, or an undirected cycle with two vertex colors that alternate along the cycle.

Type III. Finally, for the last category, we consider those graphs $G[c]$ where each connected component has at least three faces. Again, to be precise, we say that $c \in C_E$ has *Type III* if $(G[c])[A]$ has at least three faces for every vertex set A of a connected component of $G[c]$.

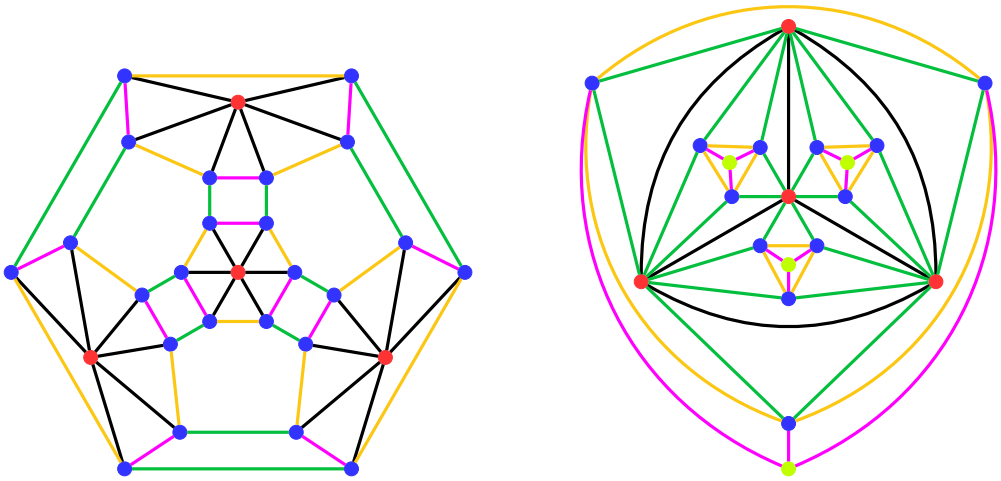
Also, we define the *type* of an edge $v_1v_2 \in E(G)$ as the type of its color $\chi(v_1, v_2)$ (note that the type of $\chi(v_1, v_2)$ is equal to the type of $\chi(v_2, v_1)$).

In the following, we derive several properties of the graphs $G[c]$ depending on the type of c, as well as properties of G depending on which types of edge colors occur. Towards this end, we also define the *type of* G as the maximal type of any edge color $c \in C_E$. So we say that G has Type III if there is some $c \in C_E$ of Type III. The graph G has Type II if there is some $c \in C_E$ of Type II, but there is no $c' \in C_E$ of Type III. Lastly, G has Type I if every $c \in C_E$ has Type I. Two example graphs are displayed in Figure 3.

4.2 Graphs of Fixing Number One

We start by investigating 3-connected planar graphs of Type I (see Figure 3a for an example). It turns out that such graphs have fixing number 1 with respect to 1-WL (after coloring all edges with their 2-WL colors), which in particular implies that 2-WL identifies all graphs of Type I. The proof is based on the following result.

▶ **Theorem 7** ([34, Lemma 23]). *Let G be a 3-connected planar graph and suppose $v_1, v_2, v_3 \in V(G)$ are pairwise distinct vertices lying on a common face of G. Then $\chi^1_{\mathsf{WL}}[G, v_1, v_2, v_3]$ is discrete.*



(a) A graph G of Type I. Each edge color $c \in C_E$ defines a graph $G[c]$ that is isomorphic to a disjoint union of stars. Individualizing an arbitrary blue vertex and performing 1-WL results in a discrete coloring. Hence, the graph is identified by 2-WL.

(b) A graph G of Type III. The edge colors black and green have Type III, yellow has Type II, and pink has Type I. Note that $G[c]$ is connected for every edge color c of Type III whereas the other edge colors induce non-connected subgraphs.

Figure 3 Two 3-connected planar graphs where all vertices and edges are colored by their 2-WL color. For visualization purposes, we only color edges and do not distinguish between potentially different colors of two arcs (v, w) and (w, v).

Here, $\chi^1_{\mathsf{WL}}[G, v_1, v_2, v_3]$ denotes the coloring computed by 1-WL after individualizing v_1, v_2, and v_3. For a vertex coloring $\lambda\colon V \to C$ and $v \in V$, we define $[v]_\lambda := \{w \in V \mid \lambda(v) = \lambda(w)\}$ as the color class of v and $\mathrm{Singles}(\lambda) := \{v \in V \mid |[v]_\lambda| = 1\}$. For a graph G and vertices $v_1, \dots, v_\ell \in V(G)$, we define

$$\mathrm{Singles}_G(v_1, \dots, v_\ell) := \mathrm{Singles}(\chi^1_{\mathsf{WL}}[G, \chi^2_{\mathsf{WL}}[G], v_1, \dots, v_\ell]).$$

In other words, $\mathrm{Singles}_G(v_1, \dots, v_\ell)$ is the set of all vertices appearing in a singleton color class after performing 1-WL on G where every pair is colored with its 2-WL-color, and where $v_1, \dots, v_\ell$ are individualized.

▶ **Lemma 8.** *Let G be a graph and let $v_1, \dots, v_\ell \in V(G)$ such that $\mathrm{Singles}_G(v_1, \dots, v_\ell) = V(G)$. Also define $k := \max\{2, \ell + 1\}$. Then k-WL determines pair orbits in G.*

The following lemma provides a sufficient condition for a 3-connected planar graph to have fixing number 1.

▶ **Lemma 9.** *Let G be a 3-connected planar graph and suppose there is a face F such that every edge $e \in E(F)$ has Type I. Then there is a vertex $v \in V(G)$ such that $\mathrm{Singles}_G(v) = V(G)$.*

Proof. Let H be a directed graph with vertex set $V(H) := V(G)$ and edge set

$$E(H) := \{(v, w) \mid vw \in E(G) \wedge \deg_{G[\chi^2_{\mathsf{WL}}[G](v,w)]}(v) = 1\}.$$

Intuitively speaking, we add a directed edge (v, w) to the graph H if w is the only neighbor of v reachable via an edge of color $\chi^2_{\mathsf{WL}}[G](v, w)$. In particular, if v is individualized, then w is also fixed after performing 1-WL.

For every edge $vw \in E(G)$ of Type I, it holds that $(v,w) \in E(H)$ or $(w,v) \in E(H)$. Hence, there are three vertices $v_1, v_2, v_3 \in V(G)$ lying on the face F of G such that $(v_1,v_2),(v_2,v_3) \in E(H)$ or $(v_1,v_2),(v_1,v_3) \in E(H)$.

Now consider the coloring $\lambda := \chi^1_{\mathsf{WL}}[G, \chi^2_{\mathsf{WL}}[G], v_1]$. Let $c := \chi^2_{\mathsf{WL}}[G](v_1,v_2)$. By definition of the edge set of H, it holds that v_2 is the only neighbor of v_1 which is adjacent via an edge of color c. Hence, $|[v_2]_\lambda| = 1$. By the same argument, $|[v_3]_\lambda| = 1$. Since v_1, v_2, v_3 all lie on the face F, it follows from Theorem 7 that λ is discrete. In other words, $\mathrm{Singles}_G(v_1) = V(G)$. ◀

▶ **Corollary 10.** *Let G be a 3-connected planar graph of Type I. Then there is a vertex $v \in V(G)$ such that $\mathrm{Singles}_G(v) = V(G)$. In particular, 2-WL determines pair orbits of G.*

We also record the following useful lemma, which is another consequence of Theorem 7.

▶ **Lemma 11.** *Let G be a 3-connected planar graph. Suppose $v_1, \dots, v_\ell \in V(G)$ form a cycle in G, i.e., $v_1v_\ell \in E(G)$ and $v_iv_{i+1} \in E(G)$ holds for all $i \in [\ell{-}1]$. Let $w \in V(G) \setminus \{v_1, \dots, v_\ell\}$. Then $\mathrm{Singles}_G(v_1, \dots, v_\ell, w) = V(G)$.*

The lemma says that in a 3-connected planar graph G, it suffices to fix a cycle and one additional vertex in order to fix the entire graph. For example, this allows us to extract from the presence of certain 2-WL-detectable subgraphs bounds on the fixing number of the entire 3-connected planar graph G. Note that in the case that the fixing number in the subgraph is 1, Lemma 8 yields that 2-WL determines pair orbits in G.

4.3 Three Faces

We now turn to edge colors of Types II and III. For both types, it is not difficult to see that it is impossible to bound the fixing number by 1 in general. Instead, our focus here lies on investigating how edge colors of the corresponding type can appear within a 3-connected planar graph.

We first focus on edge colors of Type III (see Figure 3b for an example). Let G be a 3-connected planar graph and let $c \in C_E(G,\chi)$ be an edge color of Type III, where $\chi := \chi^2_{\mathsf{WL}}[G]$. By Corollary 6, the graph $G[c]$ is edge-transitive, which already puts severe restrictions on $G[c]$. However, as it turns out, due to the planarity and 3-connectedness of G, many edge-transitive graphs can in fact not appear as subgraphs $G[c]$. In the following, we classify the graphs $G[c]$ induced by an edge color c of Type III. The following lemma is a useful tool for the proof of our classification in Theorem 13, but also an interesting insight by itself, since it also yields restrictions on how different colors c, c' of Type III can appear together in one graph G.

▶ **Lemma 12.** *Let G be a 3-connected planar graph and let $c \in C_E(G, \chi^2_{\mathsf{WL}}[G])$ be an edge color of Type III. Then $G[c]$ is connected. Moreover, for every edge color $c' \in C_E(G, \chi^2_{\mathsf{WL}}[G])$ of Type III, it holds that $V(G[c]) \cap V(G[c']) \neq \emptyset$.*

Proof Idea. We focus on the first part of the lemma. The second part can be proved using similar arguments. Let $c \in C_E(G, \chi^2_{\mathsf{WL}}[G])$ be an edge color of Type III and suppose for simplicity that $G[c]$ is unicolored. Also let $A_1, \dots, A_\ell$ denote the vertex sets of the connected components of $G[c]$ and suppose towards a contradiction that $\ell \geq 2$. Consider the auxiliary graph H with vertex set $V(H) := \{A_1, \dots, A_\ell\}$ and edges A_iA_j whenever there is a path from a vertex $v_i \in A_i$ to a vertex $v_j \in A_j$ that is internally disjoint from $A_1 \cup \dots \cup A_\ell$. Note that H is connected because G is connected. Also, we have $\chi^2_{\mathsf{WL}}[H](A_i,A_i) = \chi^2_{\mathsf{WL}}[H](A_j,A_j)$ for all $i,j \in [\ell]$, by exploiting known properties of 2-WL (see, e.g., [9, Theorem 3.1.11]). So H is 2-connected with [32, Theorem 3.15].

Now, consider the graph $G - A_1$. Since H is 2-connected, all sets $A_2, \dots, A_\ell$ are contained in the same connected component of $G - A_1$. Let X denote the vertex set of this component. We claim that $N_G(X) = A_1$. Note that $N_G(X) \neq \emptyset$ since G is connected. Let $v \in N_G(X)$ and let $w \in A_1$. Since $G[c]$ is unicolored, we conclude that $\chi^2_{\mathsf{WL}}[G](v,v) = \chi^2_{\mathsf{WL}}[G](w,w)$. Also, since $v \in N_G(X)$, there is a path from v to another vertex $v' \in A_2 \cup \dots \cup A_\ell$ that is internally disjoint from $A_1 \cup \dots \cup A_\ell$. Since this property can be detected by 2-WL, such a path also exists starting in w. But this is only possible if $w \in N_G(X)$. So overall, $N_G(X) = A_1$.

By contracting the set X to a single vertex, we obtain that adding a universal vertex to $(G[c])[A_1]$ still results in a planar graph. However, by Theorem 4, we have that $(G[c])[A_1]$ is isomorphic to one of the graphs from Figure 2a – 2g. But this gives a contradiction since it is not possible to add a universal vertex to any of those graphs while preserving planarity. So $\ell = 1$, which means that $G[c]$ is connected. ◀

▶ **Theorem 13.** *Let G be a 3-connected planar graph and let $c \in C_E(G, \chi^2_{\mathsf{WL}}[G])$ be of Type III. Then one of the following holds.*

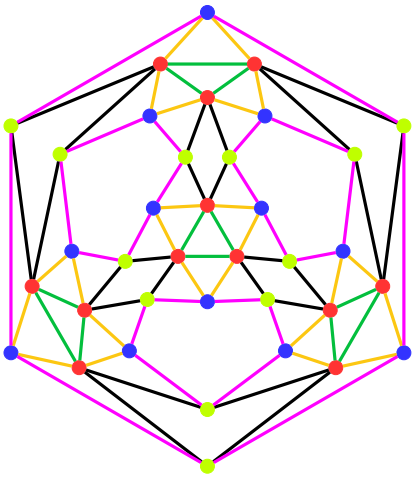
1. *$G[c]$ is bicolored and isomorphic to $K_{2,\ell}$ for some $\ell \geq 3$,*
2. *$G[c]$ is bicolored and isomorphic to a 2-subdivision of a cycle C_ℓ for some $\ell \geq 3$,*
3. *$G[c]$ is bicolored and isomorphic to a graph from Fig. 2h – 2j,*
4. *$G[c]$ is unicolored and isomorphic to a graph from Fig. 2a – 2g,*
5. *$G[c]$ is bicolored and isomorphic to a 1-subdivision of a graph from Fig. 2a – 2g, or*
6. *$G[c]$ is bicolored and isomorphic to a 2-subdivision of a graph from Fig. 2a – 2e.*

Observe that this classification is optimal in the sense that every graph listed in the theorem can actually appear as a graph $G[c]$ for some edge color c within a 3-connected planar graph. An easy way to see this is to take one of the graphs listed in the theorem, embed this graph H in the plane, place a fresh vertex v_F into every face F and connect it to all vertices lying on F. The resulting graph G is 3-connected and planar, and $H = G[c]$ for some edge color $c \in C_E(G, \chi^2_{\mathsf{WL}}[G])$.

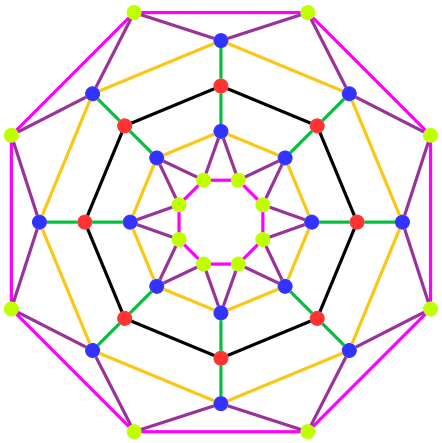
Also note that for a 3-connected planar graph G and an edge color $c \in C_E(G, \chi^2_{\mathsf{WL}}[G])$ of Type III, the automorphism group $\mathrm{Aut}(G)$ is isomorphic to a subgroup of $\mathrm{Aut}(G[c])$. Indeed, every automorphism $\gamma \in \mathrm{Aut}(G)$ naturally restricts to an automorphism $\gamma|_{V(G[c])}$ of $G[c]$ since the coloring computed by 2-WL is invariant. This gives rise to a homomorphism $\varphi\colon \mathrm{Aut}(G) \to \mathrm{Aut}(G[c])\colon \gamma \mapsto \gamma|_{V(G[c])}$. By Theorem 13 and Lemma 11, we obtain that $\mathrm{Singles}_G(w_1, \dots, w_\ell) = V(G)$ where $\{w_1, \dots, w_\ell\} = V(G[c])$. This implies that the kernel of φ is trivial, which implies that $\mathrm{Aut}(G)$ is isomorphic to a subgroup of $\mathrm{Aut}(G[c])$.

5 Disjoint Unions of Cycles

In this section, we consider 3-connected planar graphs of Type II. Let G be a 3-connected planar graph and let $\chi \coloneqq \chi^2_{\mathsf{WL}}[G]$ be the coloring computed by 2-WL. Suppose that G has Type II, i.e., there is an edge color $c \in C_E(G, \chi)$ of Type II, but there is no edge color of Type III. As before, we wish to understand in which ways edge colors of Type II can occur in G. More precisely, similarly to the case where G has Type III, our goal is to identify and classify connected subgraphs defined by few edge colors. Towards this end, we define three subcategories of edge colors of Type II. Let $c \in C_E(G, \chi)$ be of Type II. If $G[c]$ is unicolored and $\{(v,w) \mid \chi(v,w) = c\} \neq \{(v,w) \mid \chi(w,v) = c\}$ (i.e., $G[c]$ is a disjoint union of directed cycles), then we say that c has Type IIc. If c does not have Type IIc, but $G[c]$ is connected, then we say that c has Type IIb. If c does not have Type IIc, and $G[c]$ is not connected, then we say that c has Type IIa.



(a) A graph G of Type IIa where each edge color has Type IIa. The black and green edges induce a connected subgraph that is isomorphic to a parallel subdivision of a truncated tetrahedron.



(b) A graph G of Type IIb. The color black has Type IIb, yellow, violet and pink have Type IIa, and green has Type I. Note that $\mathrm{Aut}(G)$ is isomorphic to $(\mathrm{Aut}(G[\text{black}])) \times \mathbb{Z}_2$ because, after individualizing all red vertices, we can only swap the "interior" and the "exterior" region of the black cycle.

Figure 4 Two 3-connected planar graphs of Type II. All vertices and edges are colored by their 2-WL color. For visualization purposes, we only color edges and do not distinguish between potentially different colors of two arcs (v, w) and (w, v).

Let us remark that the main point of the subtypes is to distinguish between edge colors c of Type II that induce non-connected subgraphs (Type IIa) and those that induce connected subgraphs (Type IIb). The reason why we additionally single out the directed cycles (Type IIc) is that the existence of an edge color of Type IIc almost always (i.e., with the exception of one graph family) implies that the graph has fixing number 1, because individualizing a single vertex in a directed cycle fixes all other vertices on the cycle as well. In particular, we can show that every graph that contains an edge color of Type IIc is identified by 2-WL.

We also point out that the existence of an edge color of Type IIb immediately puts severe restrictions on the structure of G. For example, if $c \in C_E(G, \chi)$ is an edge of Type IIb, it can be shown that $\mathrm{Aut}(G)$ is isomorphic to a subgroup of $(\mathrm{Aut}(G[c])) \times \mathbb{Z}_2$ because, after individualizing all vertices of $G[c]$, an automorphism of G can only swap the "interior" and the "exterior" region of the cycle (see also Figure 4b).

Recall that the type of G is defined as the maximal type of any of its edge colors. We extend this definition to subtypes in the natural way. For example, G has Type IIb if there is an edge color $c \in C_E(G, \chi)$ of Type IIb, but no edge color of Type III or IIc. Two example graphs of Type II are given in Figure 4.

5.1 Directed Cycles

We start by analyzing graphs that contain an edge color c of Type IIc. As indicated above, this is a particularly well-behaved case because we can precisely classify those graphs that do not have fixing number 1. The *bipyramid (of order $m \geq 3$)* is the graph P_m^* with vertex set $V(P_m^*) \coloneqq \{u_1, u_2\} \cup \{v_i \mid i \in [m]\}$ and edge set $E(P_m^*) = \{u_i v_j \mid i \in [2], j \in [m]\} \cup \{v_i v_{i+1} \mid i \in [\ell - 1]\} \cup \{v_1 v_\ell\}$.

▶ **Lemma 14.** *Let G be a 3-connected planar graph. Also let $c \in C_E(G, \chi^2_{\mathsf{WL}}[G])$ be an edge color of Type IIc. Then there is a vertex $v \in V(G)$ such that $\mathrm{Singles}_G(v) = V(G)$, or G is isomorphic to a bipyramid.*

(a) Bicolored cube. **(b)** Chamfered tetrahedron.

Figure 5 A chamfered tetrahedron is obtained from a bicolored cube by truncating all red vertices.

▶ **Corollary 15.** *Let G be a 3-connected planar graph and suppose G contains an edge color of Type IIc. Then 2-WL determines pair orbits in G.*

Proof. If there is a vertex $v \in V(G)$ such that $\mathrm{Singles}_G(v) = V(G)$, then 2-WL determines pair orbits in G by Lemma 8. Otherwise, G is a bipyramid and it is easy to check that 2-WL determines pair orbits in G. ◀

5.2 Connected Substructures

In the remainder of this section, we analyze graphs of Type IIa and, similarly as before, aim at finding highly regular connected substructures. (Observe that if G has Type IIb, then a witnessing edge color already provides such an object). Unfortunately, we need to allow for two further possible outcomes. First, we are again satisfied with finding a vertex $v \in V(G)$ such that $\mathrm{Singles}_G(v) = V(G)$, which in particular implies that 2-WL determines pair orbits on G (see Lemma 8). As the other potential outcome, we consider *definable matchings*.

▶ **Definition 16.** *Let G be a graph and let $\chi := \chi^2_{\mathsf{WL}}[G]$. A color $c \in C_E(G,\chi)$* defines a matching *if for every $(v,w) \in \chi^{-1}(c)$, it holds that $\chi(v,v) \neq \chi(w,w)$, $\{v' \in V(G) \mid \chi(v',w) = c\} = \{v\}$, and $\{w' \in V(G) \mid \chi(v,w') = c\} = \{w\}$.*

Suppose there is some $c \in C_E(G,\chi)$ that defines a matching. Such a situation is generally beneficial since we can simply contract all edges of color c and move to a smaller graph. This operation neither changes the 2-WL coloring (see, e.g., [9, Theorem 3.1.11]) nor identification of the graph by 2-WL, as shown in the next lemma (see also [14]).

Let $c \in C_E(G,\chi)$ and let $A_1, \dots, A_\ell$ be the vertex sets of the connected components of $G[c]$. We define G/c as the graph obtained from contracting every set A_i to a single vertex. Formally, $V(G/c) := \{\{v\} \mid v \in V(G) \setminus V(G[c])\} \cup \{A_1, \dots, A_\ell\}$ and $E(G/c) := \{X_1X_2 \mid X_1, X_2 \in V(G/c), \exists v_1 \in X_1, v_2 \in X_2 \colon v_1v_2 \in E(G)\}$. We also define the pair coloring χ/c by setting $(\chi/c)(X_1,X_2) := \{\{\chi(v_1,v_2) \mid v_1 \in X_1, v_2 \in X_2\}\}$ for all $X_1, X_2 \in V(G/c)$.

▶ **Lemma 17.** *Let G be a graph and let $\chi := \chi^2_{\mathsf{WL}}[G]$. Also, let $c \in C_E(G,\chi)$ be an edge color that defines a matching. Suppose that 2-WL determines arc orbits (resp. pair orbits) on the arc-colored graph $(G/c, \lambda)$, where $\lambda(X_1,X_2) := (\chi/c)(X_1,X_2)$ for all $(X_1,X_2) \in A(G/c)$. Then 2-WL determines arc orbits (resp. pair orbits) on G.*

We now provide the main classification result of this section. We start by defining the graphs that appear in it. Let G be a 3-connected planar graph and let $W \subseteq V(G)$ be a set of vertices. We define H to be the graph obtained from G as follows. Let w be a vertex in W. First, subdivide each edge incident to w once. This gives $\ell := \deg_G(w)$ new vertices, which we call $w_1, \dots, w_\ell$ according to the unique cyclic order in any embedding of G. We then remove all edges ww_i and insert edges $w_iw_{(i+1) \bmod \ell}$ for $i \in [\ell]$, turning $w_1, \dots, w_\ell$ into a cycle. Each w_i inherits the color of w. We call these steps the *truncation* of w. One by

one, we then truncate each vertex in W. (Note that their order does not matter for the final result.) The obtained graph is H; see Figure 5 for an example. Now, we can define the following graphs.

- For every 3-connected planar graph G, the *truncated* G is obtained from G by truncating all vertices.
- A *chamfered tetrahedron* (Figure 5b) is obtained from a bicolored cube (Figure 5a) by truncating all red vertices[2].
- A *chamfered cube* is obtained from a rhombic dodecahedron (Figure 2i) by truncating all blue vertices.
- A *chamfered octahedron* is obtained from a rhombic dodecahedron (Figure 2i) by truncating all red vertices.
- A *chamfered dodecahedron* is obtained from a rhombic triacontahedron (Figure 2j) by truncating all blue vertices.
- A *chamfered icosahedron* is obtained from a rhombic triacontahedron (Figure 2j) by truncating all red vertices.

Next, let G be a planar graph. We define the *C_4-subdivision of G* to be the graph obtained from G by replacing each edge $vw \in E(G)$ with four vertices $(vw,1)$, $(vw,2)$, $(vw,3)$, $(vw,4)$ and edges $(vw,1)(vw,2)$, $(vw,2)(vw,3)$, $(vw,3)(vw,4)$, $(vw,4)(vw,1)$ and $v(vw,1)$, $w(vw,3)$.

Also, for $m \geq 2$, we define the graph C_m^* with vertex set $V(C_m^*) \coloneqq [m] \times [4]$ and edge set

$$\begin{aligned} E(C_m^*) \coloneqq \quad & \{(i,1)(i,2),(i,2)(i,3),(i,3)(i,4),(i,4)(i,1) \mid i \in [m]\} \\ & \cup \{(i,3)(i+1,1) \mid i \in [m-1]\} \cup \{(m,3)(1,1)\}. \end{aligned}$$

Finally, for $h \geq 3$, we define $K_{2,h}^*$ to be the graph with vertex set $V(K_{2,h}^*) \coloneqq \{u_1,u_2\} \uplus ([h] \times [4])$ and edge set

$$\begin{aligned} E(K_{2,h}^*) \coloneqq \quad & \{(i,1)(i,2),(i,2)(i,3),(i,3)(i,4),(i,4)(i,1) \mid i \in [h]\} \\ & \cup \{u_1(i,1) \mid i \in [h]\} \cup \{u_2(i,3) \mid i \in [h]\}. \end{aligned}$$

Examples for the last three constructions can be found in Figure 6.

Let H be a graph and $f\colon E(H) \to \mathbb{N}$ be a function. The *f-subdivision of H* is the graph $H^{(f)}$ obtained from H by replacing each edge e with $f(e)$ parallel paths of length 2 (if $f(e)=0$, the edge e remains unaltered). Formally, $H^{(f)}$ is the graph with vertex set $V(H^{(f)}) \coloneqq V(H) \uplus \{(e,i) \mid e \in E(H), i \in [f(e)]\}$ and edge set $E(H^{(s)}) \coloneqq \{e \in E(H) \mid f(e)=0\} \cup \{v(e,i) \mid e \in E(H), v \in e, i \in [f(e)]\}$. A graph G is a *parallel subdivision of H* if there is a function $f\colon E(H) \to \mathbb{N}$ such that G is isomorphic to $H^{(f)}$.

▶ **Theorem 18.** *Let G be a 3-connected planar graph of Type IIa and let $\chi \coloneqq \chi^2_{\mathsf{WL}}[G]$ be the coloring computed by 2-WL. Then one of the following options holds.*

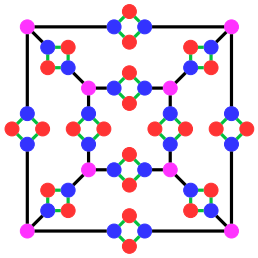
(A) *There is a vertex $v \in V(G)$ such that $\mathrm{Singles}_G(v) = V(G)$,*

(B) *there is an edge color $c \in C_E(G,\chi)$ that defines a matching, or*

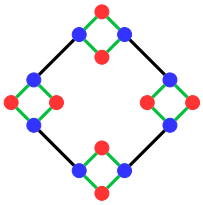
(C) *there are colors $c,d \in C_E(G,\chi)$ such that $G[c,d]$ is isomorphic to a parallel subdivision of one of the following graphs:*

1. *a truncated tetrahedron, a truncated cube, a truncated octahedron, a truncated dodecahedron, a truncated icosahedron,*
2. *an m-side prism for $m \geq 3$,*

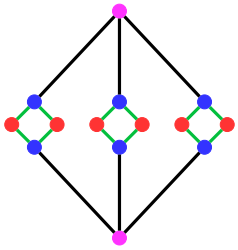
[2] The name *chamfered tetrahedron* comes from an alternative construction that obtains a chamfered tetrahedron by truncation of all edges of a tetrahedron.



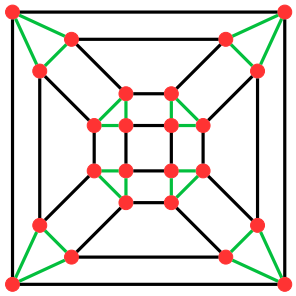
(a) C_4-subdivision of a cube.



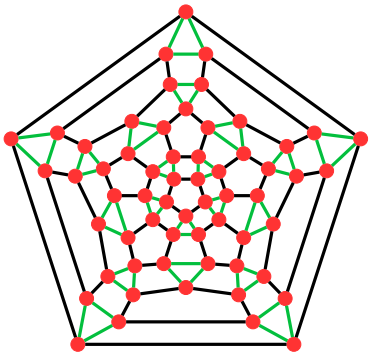
(b) C_4^*.



(c) $K_{2,3}^*$.



(d) Rhombicuboctahedron.



(e) Rhombicosidodecahedron.

Figure 6 Examples for the constructions from the classification for graphs of Type IIa.

3. *a cuboctahedron (with two edge colors), a rhombicuboctahedron, a rhombicosidodecahedron,*
4. *a C_4-subdivision of one of the graphs from Figure 2a – 2e,*
5. *a C_m^* for $m \geq 2$,*
6. *a $K_{2,h}^*$ for $h \geq 3$,*
7. *a chamfered tetrahedron, a chamfered cube, a chamfered octahedron, a chamfered dodecahedron, or a chamfered icosahedron.*

▶ Remark 19. There are four Archimedean solids that are explicitly listed neither in Theorem 13 nor in Theorem 18. These are the truncated cuboctahedron, the truncated icosidodecahedron, the snub cube, and the snub dodecahedron. The graphs corresponding to these solids have fixing number 1 under 1-WL and hence, they implicitly appear in Theorem 18, Option A.

Note that for Option C from Theorem 18, using the same arguments as for edge colors of Type III, we obtain that $\mathrm{Aut}(G)$ is isomorphic to a subgroup of $\mathrm{Aut}(G[c,d])$.

Overall, by combining Lemmas 9 and 14 and Theorems 13 and 18, we obtain that every 3-connected planar graph G satisfies one of the following options.

(A) There is some $v \in V(G)$ such that $\mathrm{Singles}_G(v) = V(G)$, which implies that 2-WL determines pair orbits of G by Lemma 8,

(B) there is an edge color $c \in C_E(G, \chi^2_{\mathsf{WL}}[G])$ that defines a matching, or

(C) there is a set $C \subseteq C_E(G, \chi^2_{\mathsf{WL}}[G])$ such that $|C| \leq 2$ and $G[C]$ is essentially a Platonic or Archimedean solid, or stems from a small number of infinite families of connected graphs.

Option C contains the graphs listed in Theorems 13 and 18, as well as the class of bipyramids from Lemma 14 and the class of cycles to cover graphs of Type IIb.

It remains an important open question whether 2-WL identifies every planar graph. With the structural insights from this paper, it now suffices to focus on Case C and, as explained above, the classification of the subgraphs $G[C]$ appearing in this case should be a crucial step to determining the WL dimension of planar graphs.

Beating Matrix Multiplication for $n^{1/3}$-Directed Shortcuts

Shimon Kogan
Weizmann Institute of Science, Rehovot, Israel

Merav Parter
Weizmann Institute of Science, Rehovot, Israel

Abstract

For an n-vertex digraph $G = (V, E)$ and integer parameter D, a *D-shortcut* is a small set H of directed edges taken from the transitive closure of G, satisfying that the diameter of $G \cup H$ is at most D. A recent work [Kogan and Parter, SODA 2022] presented shortcutting algorithms with improved diameter vs. size tradeoffs. Most notably, obtaining linear size D-shortcuts for $D = \widetilde{O}(n^{1/3})$, breaking the $\sqrt{n}$-diameter barrier. These algorithms run in $O(n^\omega)$ time, as they are based on the computation of the transitive closure of the graph.

We present a new algorithmic approach for D-shortcuts, that matches the bounds of [Kogan and Parter, SODA 2022], while running in $o(n^\omega)$ time for every $D \geq n^{1/3}$. Our approach is based on a reduction to the min-cost max-flow problem, which can be solved in $\widetilde{O}(m + n^{3/2})$ time due to the recent breakthrough result of [Brand et al., STOC 2021].

We also demonstrate the applicability of our techniques to computing the minimal chain covers and dipath decompositions for directed acyclic graphs. For an n-vertex m-edge digraph $G = (V, E)$, our key results are:

- An $\widetilde{O}(n^{1/3} \cdot m + n^{3/2})$-time algorithm for computing D-shortcuts of linear size for $D = \widetilde{O}(n^{1/3})$, and an $\widetilde{O}(n^{1/4} \cdot m + n^{7/4})$-time algorithm for computing D-shortcuts of $\widetilde{O}(n^{3/4})$ edges for $D = \widetilde{O}(n^{1/2})$.
- For a DAG G, we provide $\widetilde{O}(m + n^{3/2})$-time algorithms for computing its minimum chain covers, maximum antichain, and decomposition into dipaths and independent sets. This improves considerably over the state-of-the-art bounds by [Caceres et al., SODA 2022] and [Grandoni et al., SODA 2021].

Our results also provide a new connection between shortcutting sets and the seemingly less related problems of minimum chain covers and the maximum antichains in DAGs.

1 Introduction

This paper is concerned with time-efficient algorithms for computing directed shortcut sets. For a given n-vertex digraph $G = (V, E)$ and an integer parameter D, a D-shortcut set H is a subset of edges from the transitive closure of G, denoted as $TC(G)$, satisfying that the diameter of $G \cup H$ is at most D. The diameter of the digraph is length of the longest u-v shortest path in G over any pair $(u, v) \in TC(G)$. The key objective in this setting is to optimize the diameter vs. size tradeoff. Since their introduction by Ullman and Yannakakis [27] and Thorup [26], shortcutting sets have been studied extensively due to

their wide-range of applications for parallel, distributed, dynamic and streaming algorithms [18, 14, 11, 22, 10, 13, 4]. Their applicability is also demonstrated by the recent breakthrough results, e.g., [22, 10, 13] that use shortcuts as their core component.

Diameter vs. Size Tradeoffs of Shortcuts. Thorup conjectured [26] that any n-vertex digraph with m edges, has an D-shortcut of size $\widetilde{O}(m)$ for[1] $D = \widetilde{O}(1)$. This has been shown to hold for a restricted class of graphs, such as planar [26]. Hesse [15] refuted this conjecture for general graphs by presenting a construction of an n-vertex digraph with $m = \Theta(n^{19/17})$ edges that requires $\Omega(mn^{1/17})$ shortcut edges to reduce its diameter to below $n^{1/17}$. Up to very recently, the only known size vs. diameter tradeoff was given by a folklore randomized algorithm, attributed to Ullman and Yannakakis [27], that for every integer $D \geq 1$, provides a D-shortcut of size $O((n/D)^2 \log^2 n)$. Berman et al. [3] improved the size bound to $O((n/D)^2)$. Setting $D = O(\sqrt{n})$ provides D-shortcuts of linear size in the number of vertices of the graph. This should be compared with the lower bound result by Huang and Pettie [16] that admits an n-vertex graph for which any linear shortcut (in the number of vertices of the graph) provides a diameter of $\Omega(n^{1/6})$. Lu, Vassilevska-Williams, Wein and Xu have recently improved the lower bound for D-shortcuts with $O(m)$ edges to $D = \Omega(n^{1/8})$.

Very recently, the authors [19] presented an improved tradeoff, breaking the $\sqrt{n}$ diameter barrier for linear-size shortcuts. For any $D \leq n^{1/3}$, they provide D-shortcuts of $\widetilde{O}(n^2/D^3)$ edges. For any $D > n^{1/3}$, they provide D-shortcuts with $\widetilde{O}((n/D)^{3/2})$ edges, hence of sublinear size. The algorithms of [19] are critically based on the precomputation the transitive closure of the graph, whose $O(n^\omega)$-time computation dominates the runtime of their shortcut constructions.

Time-Efficient Shortcut Computation. Due to the algorithmic importance of shortcuts, e.g., for reachability computation, much focus has been devoted to their time-efficient computation, in almost any classical computational setting, e.g., sequential, parallel and distributed, etc. In this algorithmic context, the primary objective is to compute shortcuts *faster* than computing the transitive closure itself. The reason is that shortcuts are usually used to provide faster algorithms for reachability related problems. The latter can be trivially solved by computing the transitive closure. Hence, for shortcuts to become algorithmically applicable, say in the sequential setting, their construction should run in $o(n^\omega)$ time. In a sequence of breakthrough results, Liu, Jambulapati and Sidford [22] extended the framework of Fineman [10] to compute, in nearly linear time, a shortcut set of $\widetilde{O}(n)$ edges that reduces the diameter of the graph to $D = O(n^{1/2+o(1)})$ (i.e., almost as obtained by the folklore algorithm). They also provide a parallel implementation of their algorithm leading to the first parallel reachability algorithm with near linear work and $n^{1/2+o(1)}$ depth.

The algorithms of [19] are based on computing the transitive closure of the graph. Towards making these structures applicable in the algorithmic context, e.g., for reachability, we ask:

▶ **Question 1.1.** *Is it possible to break the $\sqrt{n}$ diameter barrier of shortcuts in $o(n^\omega)$ time?*

We answer this question in the affirmative by providing a new algorithmic approach for shortcuts, that is based on a reduction to the *minimum-cost maximum-flow* problem. Luckily, the time complexity of the latter problem has only recently improved from $\widetilde{O}(\sqrt{n}m)$ (by Lee and Sidford [21]) to $\widetilde{O}(m + n^{3/2})$ by Brand et al. [29]. We observe that the key algorithmic challenge is in computing a collection of ℓ vertex-disjoint dipaths $\mathcal{P}$ (possibly in $TC(G)$)

[1] The $\widetilde{O}(.)$ notation hides poly-log n factors.

satisfying that the length of the longest path contained in the transitive closure induced on the set of *uncovered* vertices, namely, $U = V \setminus \bigcup_{P \in \mathcal{P}} V(P)$, is bounded by $\Theta(n/\ell)$. Our min-cost max-flow based approach for computing these dipaths finds broader applications for the seemingly less related problems of minimum chain covers and maximum antichains in directed acyclic graphs. Finally, we note our time complexity of shortcuts cannot be expressed *only* as a function of the time complexity of the min-cost max-flow problem, due to other computational steps that require $\widetilde{O}(m + n^{3/2})$ time.

Chains and Antichains: Covers and Decompositions. A *chain* is a dipath in the transitive closure $TC(G)$, and an antichain is subset of vertices $I \subseteq V$ that form an independent set in $TC(G)$. The closely related notions of chains and antichains give rise to four classical graph theoretical problems that have been studied thoroughly in the literature:

- **Minimum Chain Covers (MCC):** A minimum set of chains covering all vertices in G.
- **Maximum Antichain (MA):** An antichain of maximum size[2].
- **Minimum Antichain Covers (MAC):** A minimum set of antichains covering all vertices in G.
- **Longest Chain (LC):** A dipath of largest length in $TC(G)$.

The cardinality of the MCC is also known as the *width* of the graph, denoted by $\omega(G)$. Dilworth [9] showed that the size of the MA is the same as the size of the MCC, namely, $\omega(G)$. In a somewhat dual manner, Mirsky [24] showed that the length of the LC equals to the size of the MAC. Interestingly, while there are linear time algorithms for computing the MAC and LC (e.g., by dynamic programming, [24]), no such algorithms are known for the MCC and MA problems, at least for graphs with *non-constant* width. To date, the time complexity of the existing algorithms has an inherent dependency in $\omega(G)$. For example, for the MCC problem, the classical approach computes the chains one-by-one by solving $\omega(G)$ max-flow instances. Recent work by Cáceres et al. [5, 6] has studied MCC algorithms whose complexity is parametrized on $\omega(G)$. The state-of-the-art is due to [6] that runs in $\widetilde{O}(\omega(G)^2 n + m)$ time (for solving both MCC and MA). In light of the current gap in time complexity gap for solving MAC and LC on the one hand, and for MCC and MA, on the other hand, we ask:

▶ **Question 1.2.** *Is it possible to* also *compute MCC and MA in (near) linear time?*

We answer this question, at least partially, in the affirmative by presenting linear time MCC and MA algorithms for moderately dense graphs. It is also known that MCC and MA are at least as hard as computing maximum matching in bipartite graphs. Interestingly, our algorithms use the shortcut algorithms in a black-box manner! That is, an interesting take-home message is that the MCC and MA computations can be made faster by reducing first the the diameter of the digraph.

1.1 Our Results

We provide new algorithms for diameter shortcutting that break the $\sqrt{n}$ barrier without using any matrix multiplication, running in $o(n^\omega)$ time[3]. For example, for sparse graphs, our algorithms run in $o(n^2)$ for any diameter $D = \widetilde{\Omega}(1)$. Our first result, which in fact also serves as a building block later on, computes $\sqrt{n}$-shortcuts in near linear time:

[2] I.e., maximum independent set in $TC(G)$.
[3] The state-of-the-art value for the matrix multiplication constant is $\omega = 2.372$ due to Alman and Vassilevska Williams [1]

Table 1 Prior work on MCC. $(*)$ indicates that the MCC result is implicit.

$O(\omega(G)^2 n\log n+m)$	[6](*)
$\widetilde{O}(m+n^{3/2})$	**(this paper)**

▶ **Theorem 1.3** ($\Theta(\sqrt{n})$-Shortcuts of Linear Size). *There exists a randomized algorithm that for every n-vertex digraph G with m edges computes, w.h.p., in time $\widetilde{O}(m+n^{3/2})$ a shortcut set $H\subseteq TC(G)$ satisfying that $|E(H)|=\widetilde{O}(n)$ and $\texttt{Diam}(G\cup H)=O(\sqrt{n})$.*

For dense graphs, with $\Omega(n^{3/2})$ edges, this improves the diameter bound of Liu, Jambulapati and Sidford [22] that yields D-shortcuts for diameter $D=n^{1/2+o(1)}$. We next use this improved algorithm for computing D-shortcuts for any $D=O(\sqrt{n})$, to provide the following:

▶ **Theorem 1.4** ($o(\sqrt{n})$-Shortcuts). *There exists a randomized algorithm that for every n-vertex m-edge digraph G and $D=O(\sqrt{n})$, computes, w.h.p., in time $\widetilde{O}(m\cdot n/D^2+n^{3/2})$ a D-shortcut set $H\subseteq TC(G)$ with $|E(H)|=\widetilde{O}(n^2/D^3+n)$ edges.*

For example, for $D=n^{1/3}$, we get D-shortcuts of near-linear size in $\widetilde{O}(m\cdot n^{1/3}+n^{3/2})$ time, improving on the time complexity of $O(n^\omega)$ by [19].

We also consider faster algorithms for computing shortcuts with sublinear number of edges. This turns out to be quite technically involved, as many of the tools used in Theorem 1.4 are based on adding a linear number of edges, which we cannot afford in the sublinear regime. We show:

▶ **Theorem 1.5** ($\omega(n^{1/3})$-Shortcuts of Sublinear Size). *There exists a randomized algorithm that for every n-vertex m-edge digraph G and $D=\omega(n^{1/3})$, computes, w.h.p., in time $\widetilde{O}((m+n^{3/2})\sqrt{n/D})$ a D-shortcut set $H\subseteq TC(G)$ with $|E(H)|=\widetilde{O}((n/D)^{3/2})$ edges.*

For example, for $D=n^{1/2}$, this provides D-shortcuts with $\widetilde{O}(n^{3/4})$ edges in $\widetilde{O}(m\cdot n^{1/4}+n^{7/4})$ time, improving on the time complexity of $O(n^\omega)$ by [19].

Application to Decompositions and Covers of Chains and Antichains. Recall that a chain (resp., antichain) is a dipath (resp., independent set) in $TC(G)$. A minimum chain cover (MCC) for a DAG $G=(V,E)$ is a collection of vertex-disjoint chains that cover $V(G)$. The maximum antichain is the maximum independent set in $TC(G)$. We provide the first nearly linear algorithms for moderately dense graphs, that in contrast to prior algorithms, do not depend on the width of the graph.

▶ **Theorem 1.6.** *For every n-vertex m-edge DAG $G=(V,E)$, one can compute the minimum chain cover, as well as, the maximum antichain in time $\widetilde{O}(m+n^{3/2})$, w.h.p.*

This improves over that very recent state-of-the-art running time of $O((\omega(G))^2 n\log n+m)$ by [6] for graphs of large width $\omega(G)=\widetilde{\Omega}(n^{1/4})$. More conceptually this provides a near linear-time algorithm for dense graphs, narrowing the gap to the related problems of MAC and ML for which linear time algorithms are folklore. Finally, we consider the decomposition of G into a collection of vertex-disjoint dipaths $\mathcal{P}$ and vertex-disjoint independent sets[4].

[4] Grandoni et al. [12] called this *chain and antichain decomposition*. Since this decomposition is in G and the notions of chain and antichains are usually defined in $TC(G)$, we use the terminology of dipaths

▶ **Definition 1.7** (Slight restatement of Def. 3.1 of [12]). *An (a, b)-decomposition of a directed acyclic graph (DAG) G consists of a collection $\mathcal{P} = \{P_1, \ldots, P_a\}$ of a vertex-disjoint directed paths in G, and a collection $\mathcal{Q} = \{Q_1, \ldots, Q_b\}$ of b vertex-disjoint independent sets of G such that $\bigcup_{i=1}^{a} V(P_i) \cup \bigcup_{j=1}^{b} Q_j = V(G)$.*

Grandoni et al. [12] presented an $O(n^2)$-time algorithm for computing an $(\ell, 2n/\ell)$ decomposition in G. In fact, the algorithm of [19] employed this decomposition on the transitive closure of G. We observe that by reducing to the min-cost max-flow problem, one can break the $O(n^2)$-time complexity. We show:[5]

▶ **Theorem 1.8.** *Let $G = (V, E)$ be an n-vertex DAG. For every $\ell \in [1, n]$, there is an $\widetilde{O}(|E| + n^{3/2})$-time randomized algorithm for computing an $(\ell, 2 \cdot n/\ell)$-decomposition of G.*

1.2 Technical Overview

1.2.1 A New Algorithmic Approach for Shortcuts

For the sake of presentation, we focus on the computation of a $D = O(n^{1/3})$-shortcut H of near-linear size. We start by providing a succinct description of the Kogan-Parter algorithm in [19]. Throughout, we assume, w.l.o.g., that the input graph G is a DAG, and denote its transitive closure by $TC(G)$. We note that in context of computing shortcuts of *sublinear* size, we provide an alternative reduction to DAG[6]. For a dipath P, let $H(P)$ be a 2-shortcut set for P satisfying that $\texttt{Diam}(P \cup H(P)) \leq 2$. It is well-known that one can compute $H(P)$ in nearly-linear time and that $|H(P)| = O(|P| \log |P|)$. For a path collection $\mathcal{P}$, let $V(\mathcal{P}) = \bigcup_{P \in \mathcal{P}} V(P)$. Finally, for a set of elements X and probability $p \in [0, 1]$, let $X[p]$ be the subset obtained by sampling each element of X into $X[p]$ independently w.p. p.

A Quick Recap of the $O(n^\omega)$-Time Algorithm by [19]. The algorithm starts by computing $TC(G)$ in $O(n^\omega)$-time. It then applies the decomposition algorithm Grandoni et al. [12] to partition $V(TC(G))$ into $n^{2/3}$ vertex-disjoint dipaths $\mathcal{P}$ (denoted as chains), and $2 \cdot n^{1/3}$ vertex-disjoint antichains $\mathcal{Q} = \{Q_1, \ldots, Q_k\}$. I.e., $V = V(\mathcal{P}) \cup V(\mathcal{Q})$. Letting $U = V(\mathcal{Q})$, the key property that we use in the diameter argument is that the length of a longest path of the graph[7] $TC(G)[U]$ is bounded by $k = n^{1/3}$, which indeed follows by the definition of $\mathcal{Q}$.

For a vertex v and a dipath P, let $e(v, P)$ be the edge connecting v to the *first* vertex in $V(P)$ that is reachable from v (if such exists). Let $\mathcal{P}' = \mathcal{P}[p]$ and $V' = V[p]$ for $p = n^{-1/3}$ (i.e., subsamples of dipaths and vertices). Then the output shortcut set is $H = H_1 \cup H_2$, where $H_1 = \bigcup_{P \in \mathcal{P}} P \cup H(P)$ and $H_2 = \{e(v, P) \mid v \in V', P \in \mathcal{P}'\}$. Summarizing, the key algorithmic steps can be summarized by:

- **Step 1.** Computing a collection $\mathcal{P}$ of (at most) $n^{2/3}$ *vertex-disjoint* dipaths such that the length of the longest dipath of $TC(G)[U]$ is of length $O(n^{1/3})$, where $U = V \setminus V(\mathcal{P})$.
- **Step 2.** Computing the edges $e(v, P)$ for every $v, P \in \mathcal{P}' \times V'$.

The implementation of [19] for both steps uses $TC(G)$ in a strong manner. Before explaining our approach, we sketch the size and diameter bounds of the above construction.

---

and independent sets.

[5] We provide this as an independent observation. As this decomposition is w.r.t G (rather than $TC(G)$), it is not useful for our shortcut algorithms.

[6] An alternative reduction is needed since the folklore approach of contracting each strongly connected component in G introduces linear number of edges to the shortcut.

[7] I.e., the transitive closure $TC(G)$ induced on the uncovered vertices U, namely, vertices that do not appear on $\mathcal{P}$.

Size and Diameter Bound. The size bound is immediate: the $\mathcal{P}$ are vertex-disjoint, thus $|H_1| = \widetilde{O}(n)$. W.h.p., $|V'| = \widetilde{O}(n^{2/3})$ and $|\mathcal{P}'| = \widetilde{O}(n^{1/3})$, therefore, $|H_2| = \widetilde{O}(n)$, as well.

Consider a u-v shortest path P in $G \cup H_1$ and denote its $7n^{1/3}$-length prefix (resp., suffix) by P', P'', respectively. By Chernoff, w.h.p., there exists some sampled vertex $u^* \in V(P') \cap V'$. The challenge is in showing that P'' intersects with $\Omega(n^{1/3})$ distinct paths in $\mathcal{P}$, and thus, w.h.p., intersects with at least one sampled path in $\mathcal{P}'$. This is shown by observing that (i) P'' contains at most 3 vertices from each dipath $Q \in \mathcal{P}$ (due to the addition of the shortcut $H(Q)$), and that (ii) P'' contains at most $n^{1/3}$ vertices in U. Altogether, we have some $Q^* \in \mathcal{P}'$ satisfying that $V(Q^*) \cap V(P'') \neq \emptyset$. The edge $e(u^*, Q^*) \in H_2$ then provides us an $O(n^{1/3})$-hop length dipath from u^* to $w \in V(Q^*) \cap V(P'')$.

New Approach: Shortcuts via Min-Cost Max-Flows. We focus on Step (1), as Step (2) can be implemented in $O(m \cdot n^{1/3})$ time using e.g., dynamic programming. Our goal is to show that Step (1) can be implemented in $\widetilde{O}(m + n^{3/2})$ time, which establishes Theorem 1.4 for $D = n^{1/3}$. The challenge boils down into computing a *nice* collection of dipaths which also has further independent applications, as illustrated in this paper. Denote by $\mathrm{LP}(G)$ to be the length of a longest simple dipath in G.

> **Key Task:** Compute in $o(n^\omega)$-time a collection of (at most) $n^{2/3}$ vertex-disjoint dipaths $\mathcal{P}$ in $TC(G)$, such that $\mathrm{LP}(G') = O(n^{1/3})$ where $G' = TC(G)[U]$ and $U = V \setminus V(\mathcal{P})$.

Note that the above requires to bound the length of the longest path in the graph[8] $TC(G)[U]$. This task can also be viewed as a relaxed chain and antichain decomposition (see Def. 1.7) for $\ell = n^{2/3}$, where it is required to output only chain part, while guaranteeing the remaining uncovered vertices, U, can be decomposed into $n^{1/3}$ anti-chains[9]. Clearly the challenge is that it is required to compute such (partial) decomposition in $TC(G)$ *without ever* computing it explicitly! While our goal is to solve it in $\widetilde{O}(m + n^{3/2})$ time, the decomposition algorithm of [12] runs in $O(n^2)$ even when *given* $TC(G)$. Our challenge is therefore two-folds.

We introduce ℓ-*covers* which for a given input parameter $\ell \in [1, n]$ provide a *multiset* $\mathcal{P} = \{P_1, \ldots, P_\ell\}$ of ℓ dipaths in G. Letting, $\mathrm{TotLen}(\mathcal{P}) = \sum_{P_i \in \mathcal{P}} |P_i|$ and $U = V \setminus V(\mathcal{P})$ (i.e., the total dipath lengths), then the ℓ-cover satisfies:

1. $\mathrm{TotLen}(\mathcal{P}) \leq \min\{\ell, \mathtt{Diam}(G)\} \cdot n$,
2. $\mathrm{LP}(G') \leq 2n/\ell$ where $G' = TC(G)[U]$.

Note that an ℓ-cover for $\ell = n^{2/3}$, almost fits the key task, up to one major caveat: the total path length, $\mathrm{TotLen}(\mathcal{P})$, might be super-linear, hence leading to shortcuts of super-linear size[10]. We put this technicality aside for a moment, explain first how to compute ℓ-covers *without* computing $TC(G)$, and then show how to use them to solve the key task.

Computing ℓ-Covers in Time $\widetilde{O}(m+n^{3/2}+\min\{\ell, \mathtt{Diam}(G)\}\cdot n)$. The algorithm is based on a reduction to the min-cost max-flow problem. We define a flow-instance $\widetilde{G} = (\widetilde{V}, \widetilde{E}, u, c)$ corresponding to G, where $|\widetilde{V}| = O(n), |\widetilde{E}| = O(m)$, $u \in \mathbb{Z}_{\geq 0}^{\widetilde{E}}$ and $c \in \mathbb{Z}^{\widetilde{E}}$ are the capacity and cost functions, respectively. We then apply the recent algorithm of van den Brand et al. [29] to compute the min-cost max-flow s-t flow in $\widetilde{G}$ for a given pair $s, t \in \widetilde{V}$. In their breakthrough result, [29] provided an $\widetilde{O}(m + n^{3/2})$-time randomized algorithm for this problem, provided that the edge capacities and costs are *integral*.

---

[8] The transitive closure of G induced on the vertices of U.
[9] By [24], a bounded longest path of $TC(G)[U]$ indeed guarantees the antichain decomposition of U.
[10] As we include in the output shortcut, the union of path shortcuts $H(P)$ for every $P \in \mathcal{P}$.

The desired ℓ-cover collection is then obtained by computing the flow-decomposition of the output integral flow. Since G is a DAG, this decomposition can be done in linear time in the total length of the output path collection. Finally, we translate the collection of dipaths in $\widetilde{G}$ into a collection of dipaths in G, which provides the desired ℓ-cover $\mathcal{P}$. Importantly, our flow-instance deviates from the classical flow-reductions[11] by incorporating a special gadget per vertex $v_i \in V$. We carefully set the capacity and the cost values in a way that on the one hand, allows a given vertex to participate in multiple paths, while at the same time bounding the total length of $\mathcal{P}$, and most importantly bounds the longest path length of the transitive closure induced on the uncovered vertices U, $TC(G)[U]$. Altogether, the computation of the ℓ-cover $\mathcal{P}$ takes $\widetilde{O}(m + n^{3/2} + \text{TotLen}(\mathcal{P}))$ time which by Property (1) is bounded by $\widetilde{O}(m + n^{3/2} + n \min\{\ell, \texttt{Diam}(G)\})$.

ℓ-Covers in $\widetilde{O}(m + n^{3/2})$ Time. To beat this dependency in $\text{TotLen}(\mathcal{P})$, we take the following strategy. First, we reduce the diameter of G to $d = O(\sqrt{n})$ by computing a d-shortcut set H_0 of linear size. We show that this can be done using ℓ-covers for $\ell = \sqrt{n}$, hence taking $O(m + n^{3/2})$ time. We then apply the ℓ-cover algorithm on the graph $G \cup H_0$. Since the diameter of $G \cup H$ is $O(\sqrt{n})$, we have that $\text{TotLen}(\mathcal{P}) = O(n^{3/2})$, and the entire computation takes $\widetilde{O}(m + n^{3/2})$ time.

Implementing Step (1) in $\widetilde{O}(m + n^{3/2})$ Time. So-far, we have computed a collection of $O(n^{2/3})$ dipaths $\mathcal{P}$ (in $G \cup H_0$) of total length $O(n^{3/2})$, and such that the uncovered diameter is at most $O(n^{1/3})$. It remains to turn $\mathcal{P}$ into vertex-disjoint dipaths in $TC(G)$. This can be easily done by iterating over the dipaths of $\mathcal{P}$, one by one, shortcutting the given dipath by cutting out the vertices that appear in the currently collection of vertex-disjoint dipaths. This works in $O(\text{TotLen}(\mathcal{P})) = O(n^{3/2})$ time.

Shortcuts of Sublinear-Size. In [19], it was shown that for any $D = \omega(n^{1/3})$, one can compute D-shortcuts of size $\widetilde{O}((n/D)^{3/2})$. It will be instructive to consider the case where $D = O(\sqrt{n})$ for which the construction provides shortcuts with $\widetilde{O}(n^{3/4})$ edges. The algorithm of [19] for this setting is based on sampling a collection of landmarks $V' = V[p]$ for $p = n^{1/4}$. It then defines the graph $G' = (V', E')$ where $E' = \{(u, v) \mid \text{dist}_G(u, v) \leq n^{1/4}\}$, and applies the above mentioned algorithm for computing $D' = |V'|^{1/3}$-shortcut H of size $O(|V'|)$. Since $|V'| = O(n^{3/4})$, w.h.p., this provides a shortcut of $O(n^{3/4})$ edges.

In our context, computing the graph G' takes $O(|V'|m)$ time which is too costly for our purposes. Another challenge in provide a *sublinear* reduction into DAGs. So-far, we assumed w.l.o.g. that G is a DAG, by using the following folklore reduction: shortcut each strongly connected component C to diameter 2, by connecting the all vertices of C to center vertex $v \in C$. This allows one to restrict attention to the DAG obtained by contracting each component. This reduction, however, adds $\Theta(n)$ shortcut edges, which is above our budget. Our algorithm provides an alternative reduction. Given G, we compute a DAG G' of similar size and show that any D-shortcut set H' for G' can be translated into a D-shortcut set H for G, where $|H| = O(|H'|)$. This allows us to restrict attention to DAGs. We believe this alternative reduction should be of general interest.

Our shortcut algorithm calls for a collection of additional refined tools. We introduce partial ℓ-covers that provide the desired properties (1,2), up to some slack, with respect to a given *subset* of vertices. The shortcut algorithm is then based on iteratively computing collections of partial ℓ-covers, to mimic, in some way, the effect of the single application of a shortcut computing on the virtual graph G'.

[11] E.g, where each vertex $v_i \in V$ has two copies v_i^{in} and v_i^{out} connected by a directed edge of capacity 1.

1.2.2 Minimum Chain Covers, Maximum Antichain, and More

Recall that a chain is a dipath in $TC(G)$ and an antichain is an independent set in $TC(G)$. The cardinality of the minimum chain cover (MCC) of a DAG G is denoted as the width of G, $\omega(G)$. An minimum path cover (MPC) is a minimum set of dipaths (not necessarily disjoint) in G that cover V. Prior algorithms for computing the MCC are based on iteratively solving a maximum s-t flow instance in the residual graph, each iteration provides one additional dipath to the output collection. This dipath-by-dipath approach requires solving $\omega(G)$ flow computations. Note that computation of the value of the width, $\omega(G)$, can be easily done using only $O(\log n)$ max-flow computations (by binary search). Hence, the main challenge is in the computation of chain cover itself.

Our approach is based on having a single application of the min-cost max-flow algorithm. The starting observation is that thanks to our shortcut algorithms, we can assume, w.l.o.g., that the diameter of G is $O(\sqrt{n})$. This is because we can apply the MCC algorithm on the graph $G \cup H_0$ where H_0 is the $O(\sqrt{n})$-shortcut set for G, obtained by Thm. 1.3. Since we aimed at computing *chains*, rather than dipaths in G, we can safely work on $G \cup H_0$.

Using our flow reduction, we are able to compute a collection $\mathcal{P}$ of $\omega(G)$ dipaths (these are dipaths in $G \cup H_0$), in time $\widetilde{O}(m + n^{3/2} + \text{TotLen}(\mathcal{P}))$. By the way that we set the cost of the edges in our instance, $\mathcal{P}$ covers all vertices in G. I.e., it is an MPC in $G \cup H_0$. This by itself is not enough as the dipaths of $\mathcal{P}$ are might not be vertex-disjoint, possibly with large total length, $\text{TotLen}(\mathcal{P})$.

To overcome this, we first provide an algorithm for computing a dipath cover of *minimum* total length. We introduce the notion of *minimum-length cover* (MLC): a collection of $\omega(G)$ dipaths, that covers all vertices while minimizing the *total length* of the dipaths.

Then, we provide a combinatorial argument that shows that any n-vertex DAG admits an MPC $\mathcal{P}$ of length $\text{TotLen}(\mathcal{P}) \leq n \cdot \texttt{Diam}(G)$. Since $\texttt{Diam}(G \cup H_0) = O(\sqrt{n})$, we end up with having a collection of dipaths of total length $O(n^{3/2})$. These dipaths can be transformed in vertex-disjoint chains in time $O(n^{3/2})$, in a brute-force manner (Lemma 1.15). This completes the high-level approach.

1.3 Preliminaries

Graph Notations. For an n-vertex digraph G, let $TC(G)$ denote its transitive closure. We also denote $TC(G)$. For a vertex pair $u, v \in V(G)$ where $(u, v) \in TC(G)$, let $\text{dist}_G(u, v)$ be the length (measured by the number of edges) of the shortest dipath from u to v. For $(u, v) \notin TC(G)$, $\text{dist}_G(u, v) = \infty$. For a subset $V' \subseteq V$, let $G[V']$ be the induced graph on V'. The graph *diameter* is denoted by $\texttt{Diam}(G) = \max_{(u,v)\in TC(G)} \text{dist}_G(u, v)$. We say that $u \rightsquigarrow_G v$ if there is a directed path from u to v in G, i.e., $(u, v) \in TC(G)$. A *shortcut* edge is an edge in $TC(G)$. For a vertex $v \in G$, let $N_{in}(v, H) = \{u \mid (u, v) \in G\}$ denote the incoming neighbors of v in G. The set of outgoing neighbors $N_{out}(v, G)$ is defined in an analogous manner. For a collection of paths $\mathcal{P}$, the vertices of $\mathcal{P}$ is denoted by $V(\mathcal{P}) = \bigcup_{P\in\mathcal{P}} V(P)$. For a dipath $P = [u_0, \ldots, u_k] \subseteq G$, for $j \leq q$, let $P[u_j, u_q]$ denote the path segment $P[u_j, u_{j+1}, \ldots, u_q]$. In the case where $u_j = u_0$ (resp., $u_q = u_k$), we simply write $P[\cdot, u_q]$ (reps., $P[u_j, \cdot]$). For an a-b dipath P and an b-c dipath P' the concatenation of the paths is denoted by $P \circ P'$. Let $|P|$ denote the number of edges on P (unless mentioned otherwise). For a set of elements X and $p \in [0, 1]$, let $X[p]$ be the set obtained by taking each element of X into $X[p]$ independently with probability p.

▶ **Definition 1.9.** *For a digraph G, $H \subseteq TC(G)$ is* D-shortcut *if* $\texttt{Diam}(G \cup H) \leq D$.

The following lemma computes linear 2-shortcuts for directed paths:

▶ **Lemma 1.10** (Lemma 1.1, [25]). *Given a directed path P, one can compute in $O(|P|\log|P|)$ time, a 2-shortcut $H(P)$ for P where $|H| = O(|P|\log|P|)$ edges.*

Given a digraph G, by G^+ we denote the result of contracting all strong components in G. Note that G^+ is acyclic directed graph (DAG) and can be computed in linear time.

▶ **Proposition 1.11** (Lemma 3.2, [25]). *Let H^+ be a shortcut set for G^+. One can compute in $O(|E(G)|+|H|)$-time, a shortcut set H for G such that $|H| = O(|H^+|+n)$ and $\texttt{Diam}(G\cup H) = O(\texttt{Diam}(G^+ \cup H^+))$.*

Algorithmic Tools for Flow Computation. In the *minimum-cost maximum-flow* problem, given is a connected directed graph $G = (V, E, u, c)$ with edges capacities $u \in \mathbb{R}^E_{\geq 0}$ and costs $c \in \mathbb{R}^E$ (which can be negative). The vector $x \in \mathbb{R}^E$ is an *s-t flow* for $s, t \in V$ if $x(e) \in [0, u(e)]$ for all e in E, and for each vertex $v \notin \{s, t\}$ the amount of flow entering v equals the amount of flow leaving v, i.e., $\sum_{e=(a,v)} x(e) = \sum_{e=(v,b)} x(e)$. The *cost* of a flow x is defined by $c(x) = \sum_e c(e)x(e)$. The *value* of an s-t flow is the amount of flow leaving s, i.e., $val(x) = \sum_{e=(s,v)} x_e$ (or equivalently, entering t, i.e., $\sum_{e=(v,t)} x_e$). The objective is to compute a maximum s-t flow of minimum cost denoted by $\sum_{e\in E} c_e x_e$. The following theorem was proven in [29].

▶ **Theorem 1.12** (Theorem 1.4 of [29]). *There is an algorithm* MinCostFlow(G, s, t) *that, given a n-vertex m-edge digraph $G = (V, E, u, c)$, integral edge capacities $u \in \mathbb{Z}^E_{\geq 0}$ and costs $c \in \mathbb{Z}^E$, w.h.p., computes an integral minimum cost maximum flow in time*

$$\widetilde{O}\left(m\log(||u||_\infty||c||_\infty) + n^{3/2}\log^2(||u||_\infty||c||_\infty)\right) .$$

We observe that even more recently, there have been additional breakthrough results [2, 28] that provide improved running time for sparse graphs, this however, does not effect our final time complexity.

▶ **Definition 1.13.** *For a digraph $G = (V, E)$ and a given valid s-t flow vector $x \in \mathbb{N}^E_{\geq 0}$, a* flow decomposition *is a multiset of s-t dipaths in G given by $\mathcal{Q} = \{P_1, \ldots, P_k\}$, such that for every $e \in E$, it holds that $x(e) = |\{P_i \in \mathcal{Q} \mid e \in P_i\}|$. I.e., $x(e)$ equals the number of paths in the multiset containing e.*

▶ **Lemma 1.14.** *Let $G = (V, E)$ be an n-vertex m-edge DAG and let $x \in \mathbb{N}^E_{\geq 0}$ be an integral s-t flow of value k for $s, t \in V$, then one can compute a flow decomposition of x, denoted by $\mathcal{Q}$ in $O(m + n + \sum_{e\in E} x(e))$ time.*

Dipaths to Chains. Throughout, we make use of the following procedure to translate a collection of dipaths in G into a collection of vertex-disjoint chains. The proof of the next lemma is in the full version.

▶ **Lemma 1.15.** *Let $\mathcal{P}$ be a collection of dipaths in G, there is an algorithm* DisjointChains *that in time $O(\sum_{P\in\mathcal{P}} |P|)$ computes a collection of* vertex-disjoint *chains $\mathcal{C}$ satisfying that: (i) $|\mathcal{C}| \leq |\mathcal{P}|$, (ii) $V(\mathcal{C}) = V(\mathcal{P})$ and (iii) every $C \in \mathcal{C}$ is a dipath in $TC(G)$.*

Roadmap. In Sec. 2, we introduce ℓ-covers, that serve the key algorithmic part for computing our shortcuts. In Sec. 3.1, we compute $\sqrt{n}$-shortcuts of linear size (proof of Thm. 1.3). In Sec. 3.2, we provide an algorithm that computes $n^{1/3}$-shortcut of linear size in $\widetilde{O}(mn^{1/3} + n^{3/2})$ time, and more generally prove Thm. 1.4. Then Sec. 3.3 considers the constructions of shortcuts with sublinear number of edges establishing Thm. 1.5.

2 New Notions of Dipath Decompositions

2.1 ℓ-Covers

We introduce a new notion of dipath decomposition which we denote by *ℓ-covers*. For a given parameter ℓ, the ℓ-cover is given by a multiset of ℓ dipaths in G, $\mathcal{P} = \{P_1, \ldots, P_\ell\}$, whose vertices $V(\mathcal{P})$ dominate long dipaths in G, in a way that becomes formal in Def. 2.1. As we will see, this notion is strong enough to substitute the path collection obtained by computing the chain-antichain decomposition in $TC(G)$. Missing proofs of this section are deferred to the full version. Recall that for a multiset of dipaths $\mathcal{P}$, $\text{TotLen}(\mathcal{P}) = \sum_{P_i \in \mathcal{P}} |P_i|$.

▶ **Definition 2.1** (ℓ-Covers). *For a given n-vertex digraph $G = (V, E)$ and an integer parameter $\ell \in [1, n]$, an ℓ-cover for G is a multiset of ℓ paths $\mathcal{P} = \{P_1, \ldots, P_\ell\}$ (possibly consisting of single vertices or empty), satisfying the following:*

1. $\text{TotLen}(\mathcal{P}) \leq \min(\ell \cdot n, \texttt{Diam}(G) \cdot n)$,
2. *For any dipath $P \subseteq G$, it holds that $|V(P) \cap (V \setminus V(\mathcal{P}))| \leq 2n/\ell$.*

Property (2) implies that $\text{LP}(TC(G)[U]) \leq 2n/\ell$, that is the following holds:

▶ **Corollary 2.2.** *Each path in $TC(G)[V \setminus V(\mathcal{P}]$ contains at most $2n/\ell$ vertices.*

▶ **Theorem 2.3.** *Let G be an n-vertex DAG with m edges, then for every $\ell \geq 1$, there is a randomized algorithm for computing an ℓ-cover of G, w.h.p, in time $\widetilde{O}(m + n^{3/2} + n \cdot \min\{\texttt{Diam}(G), \ell\})$.*

For our purposes of computing shortcuts, we employ the algorithm of Thm. 2.3 only in settings where $\min\{\texttt{Diam}(G), \ell\} = O(\sqrt{n})$, therefore spending only $\widetilde{O}(m + n^{3/2})$ time.

Path Decomposition via Min-Cost Max-Flow. The decomposition algorithm is based on a reduction to the *minimum cost maximum flow* problem (see Sec. 1.3). For the given DAG G, the algorithm computes a corresponding min-cost flow instance $\widetilde{G} = (\widetilde{V}, \widetilde{E}, u, c)$. At the high level, for each $v_i \in V(G)$, the graph $\widetilde{G}$ contains three inter-connected copies $v_i^{in}, v_i^{out}, v_i'$. The out-copy of the incoming G-neighbors of v_i are connected to the in-copy of v_i. In addition, $\widetilde{V}$ includes also three additional vertices, s, s' and t, where s and t are the source and target vertices given to the min-cost flow algorithms. The precise definition of $\widetilde{G}$ are specified in the pseudocode below, see also Fig. 1.

Let $x \in \mathbb{N}_{\geq 0}^{|\widetilde{E}|}$ be the output flow solution for the instance $\widetilde{G}$ obtained by applying Alg. MinCostFlow from Theorem 1.12. The algorithm then decomposes the flow x into a multiset of s-t paths $\widetilde{\mathcal{P}} = \{P_1', \ldots, P_\ell'\}$. Since without loss of generality the flow values are integrals and since $\widetilde{G}$ is a DAG, the flow decomposition of x can be computed efficiently by applying Lemma 1.14.

Finally, the output ℓ-cover $\mathcal{P}$ is obtained by mapping each $\widetilde{G}$-dipath $P_j' \in \widetilde{\mathcal{P}}$ into a corresponding G-dipath P_j. This mapping is done by applying Procedure Translate on every $P_j' \in \widetilde{\mathcal{P}}$. The output G-path $P_j = \textsf{Translate}(P_j')$ is defined as follows. The vertices s, s' and t are omitted, and each appearance of a vertex $u_j \in v_i^{in}, v_i^{out}, v_i'$ is replaced by its G-vertex v_i, we omit multiple successive occurrences of a vertex in this translation. For example, for $P' = [s, s', v_i^{in}, v_i^{out}, v_j^{in}, t]$, $\textsf{Translate}(P') = [v_i, v_j]$. For a path $P'' = [s, s', t]$, $\textsf{Translate}(P'') = \emptyset$.

The ℓ-cover is then given by the multiset $\mathcal{P} = \{\textsf{Translate}(P_j') \mid j \in \{1, \ldots, \ell\}\}$. We need the following definition. For $P_j \in \mathcal{P}$, denote $\textsf{Translate}^{-1}(P_j) = P_j'$ where $P_j' \in \widetilde{\mathcal{P}}$. Note that while each path $P_j' \in \widetilde{\mathcal{P}}$ is mapped to a *unique* G-path (given by $\textsf{Translate}(P_j')$), it

might be the case that two distinct paths $P'_i, P'_j \in \widetilde{\mathcal{P}}$ map to the same G-path. For example, $P'_i = [s, s', v_i^{in}, v'_i, v_i^{out}, t]$ and $P'_j = [s, s', v_i^{in}, v_i^{out}, t]$ both translate to the single vertex $\{v_i\}$. Therefore, we consider the $\mathsf{Translate}$ function as a bijection from the *multiset* $\widetilde{\mathcal{P}}$ to the *multiset* $\mathcal{P}$. I.e., each path $P_i \in \mathcal{P}$ is uniquely mapped to a path $P'_i = \mathsf{Translate}^{-1}(P_i)$ in the flow decomposition $\widetilde{\mathcal{P}}$ and vice-versa.

Algorithm PathCover:

Input: An n-vertex DAG G and a parameter $\ell \in \mathbb{N}_{\geq 1}$.
Output: An ℓ-cover $\mathcal{P}$ of G.

1. **Transformation to Min-Cost Max-Flow Instance.** The instance $\widetilde{G} = (\widetilde{V}, \widetilde{E}, u, c)$ with the designated source s and target t vertices are defined as follows.

   - For each vertex $v_i \in V(G)$, include three copies $v_i^{in}, v_i^{out}, v'_i$ in $\widetilde{V}$. These copies are connected by the edges $E_{0,i} = \{(v_i^{in}, v_i^{out}), (v_i^{in}, v'_i), (v'_i, v_i^{out})\}$.
     In addition, add three designated vertices s, s' and t. So overall,

     $$\widetilde{V} = \{v_i^{in}, v_i^{out}, v'_i \mid v_i \in V(G)\} \cup \{s, s', t\} .$$

   - Connect the out-copy v_j^{out} of every incoming neighbor $v_j \in N_{in}(v_i, G)$ to v_i^{in}. In the same manner, connect the in-copy v_k^{in} of every $v_k \in N_{out}(v_i, G)$ to v_i^{out}. Formally,

     $$E_1 = \{(v_j^{out}, v_i^{in}) \mid v_j \in N_{in}(v_i, G)\} \text{ and } E_2 = \{(v_j^{in}, v_i^{out}) \mid v_j \in N_{out}(v_i, G)\} .$$

   - Let $E_3 = \{(s', v_i^{in}) \mid v_i \in V(G)\} \cup \{(v_i^{out}, t) \mid v_i \in V(G)\} \cup \{(s, s'), (s', t)\}$. Then

     $$\widetilde{E} = \bigcup_i E_{0,i} \cup E_1 \cup E_2 \cup E_3.$$

   - The edge capacities $u \in \mathbb{Z}_{\geq 0}^{\widetilde{E}}$ and costs $c \in \mathbb{Z}^{\widetilde{E}}$ are defined by:
     a. $u((s, s')) = \ell$ and $u(v_i^{in}, v_i^{out}) = 1$ for every $v_i \in V$. All remaining edges e in $\widetilde{E}$ have capacity of $u(e) = \ell$.
     b. $c(v_i^{in}, v_i^{out}) = -n^3$ and $c(v_i^{in}, v'_i) = 1$ for every $v_i \in V$. All remaining edges e in $\widetilde{E}$ have cost of $c(e) = 0$.
2. Apply Algorithm $\mathsf{MinCostFlow}(\widetilde{G}, s, t)$ (Theorem 1.12), and let $x \in \mathbb{R}^{|\widetilde{E}|}$ be the output flow.
3. **Flow Decomposition.** Decompose $x \in \mathbb{R}^{|\widetilde{E}|}$ into s-t paths $\widetilde{\mathcal{P}}$ in $\widetilde{G}$ by Lem. 1.14.
4. The ℓ-cover is given by the multiset $\mathcal{P} = \{\mathsf{Translate}(P') \mid P' \in \widetilde{\mathcal{P}}\}$ (where $|\mathcal{P}| = \ell$ as each path corresponds to one unit flow in $\widetilde{G}$).

Analysis. For a path $P' \subseteq \widetilde{G}$, denote the cost of P' by $c(P') = \sum_{e \in P'} c(e)$. We start with observing that any path P' in the flow decomposition $\widetilde{\mathcal{P}}$ must have a non-positive cost. Intuitively, this holds as one can replace P', with the zero-cost path $[s, s', t]$ that has a sufficiently large capacity. Hence we have the following observation.

▶ **Observation 2.4.** *Every path $P' \in \widetilde{\mathcal{P}}$ has a non-positive cost, $c(P') \leq 0$.*

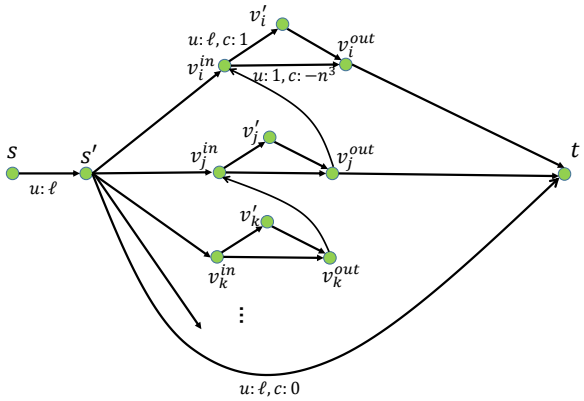

Figure 1 An illustration for the min-cost max-flow reduction. The default values for the edge capacities and costs are ℓ and 0, respectively.

Recall that $\mathcal{P} = \{P_1, \ldots, P_\ell\}$ where P_i might be equal to P_j. A vertex v_i in a path $P_j \in \mathcal{P}$ is denoted as a *principal vertex* of P_j if its corresponding flow path $\mathsf{Translate}^{-1}(P_j) \in \widetilde{\mathcal{P}}$ (i.e., the j^{th} path in $\widetilde{\mathcal{P}}$) contains the edge (v_i^{in}, v_i^{out}). We denote the number of principal vertices in $P_j \in \mathcal{P}$ by $n(P_j)$. Formally,

$$n(P_j) = |\{v_i \in V \ \mid \ (v_i^{in}, v_i^{out}) \in \mathsf{Translate}^{-1}(P_j)\}\ . \tag{1}$$

Since in our flow instance $\widetilde{G}$, the capacity of any edge $e = (v_i^{in}, v_i^{out})$ is 1, i.e., $u(e) = 1$, we have that a vertex $v_i \in V$ can be a principal vertex of at most *one* path in $\mathcal{P}$, hence:

▶ **Observation 2.5.** $\sum_{P_j \in \mathcal{P}} n(P_j) \leq n$.

▶ **Lemma 2.6.** $|\mathcal{P}| = \ell$ *and* $\mathrm{TotLen}(\mathcal{P}) \leq \min(\ell \cdot n, \mathtt{Diam}(G) \cdot n)$.

Proof. The bound of the number of paths simply follows by the fact that x is an integral flow of value ℓ, and by the definition of flow decomposition (Def. 1.13). Furthermore as G is a DAG every path of G is of length at most $n-1$. Thus $\mathrm{TotLen}(\mathcal{P}) \leq \ell \cdot n$. To show that $\mathrm{TotLen}(\mathcal{P}) \leq \mathtt{Diam}(G) \cdot n$ we make the following observation. Consider any $P_j \in \mathcal{P}$ and let u and v be two consecutive principal vertices on P_j, in the sense that the only principal vertices on the segment $P_j[u, v]$ are u and v. We then claim that $|P_j[u, v]| \leq \mathtt{Diam}(G)$.

Assume for the sake of contradiction that $|P_j[u, v]| > \mathtt{Diam}(G)$, we will show that in this case, we can replace the path $Q = \mathsf{Translate}^{-1}(P_j)$ with an alternative path $Q^* \subseteq \widetilde{G}$, that provides a strictly lower cost and the same value of flow, hence leading to a contradiction. That is, in the alternative flow solution x' we will add one unit flow over Q^* and omit one unit flow from Q. Letting $R = [u_0 = u, \ldots, u_k = v]$ be the u-v shortest path in G, then the alternative path Q^* is defined as follows:

$$Q^* = Q[., u^{out}] \circ (u^{out}, u_1^{in}) \circ T_1 \circ (u_1^{out}, u_2^{in}) \circ T_2 \circ (u_2^{out}, u_3^{in}) \circ \ldots \circ T_{k-1} \circ (u_{k-1}^{out}, u_k^{inn}) \circ Q[v^{in}, .]\ ,$$

where $T_j = (u_j^{in}, u_j') \circ (u_j', u_j^{out})$ for every $j \in \{1, \ldots, k-1\}$. Consider the flow solution x' defined by:

$$\begin{cases} x'(e) = x(e) - 1, & \text{for every } e \in Q, \\ x'(e) = x(e) + 1, & \text{for every } e \in Q^*, \\ x'(e) = x(e), & \text{otherwise .} \end{cases}$$

We first show that x' is a legal flow, and with the same value as x. This holds as all edges on the paths of T_j for $j \in \{1, \ldots, k-1\}$, have a sufficiently large capacity. Next, we show that $\sum_e c(e)x'(e) < \sum_e c(e)x(e)$, which will be in contradiction to the optimality of x.

By the definition of u and v, $c(Q[u^{out}, v^{in}]) = |P_j[u,v]| - 1$. In the same manner, $c(Q^*[u^{out}, v^{in}]) = |R| - 1$. Since $|R| < |P_j[u,v]|$, we conclude that $c(Q) > c(Q^*)$, and consequently that $\sum_e c(e)x'(e) < \sum_e c(e)x(e)$ as desired. We therefore have that $|P_j[u,v]| \leq \texttt{Diam}(G)$, and $|P_j| \leq \texttt{Diam}(G) \cdot n(P)$. Combining with Obs. 2.5, we have $\sum_{i=1}^{\ell} |P_i| \leq \texttt{Diam}(G) \cdot \sum_{i=1}^{\ell} n(P_i) \leq \texttt{Diam}(G) \cdot n$. ◀

We next show that each long dipath in G is dominated by the vertices of $V(\mathcal{P})$ (i.e., contains a bounded number of uncovered vertices).

▶ **Lemma 2.7.** *Any dipath in G contains at most $2n/\ell$ vertices of $V \setminus V(\mathcal{P})$.*

Proof. Assume by contradiction that there exists a dipath $Q \subseteq G$ that contains at least $2n/\ell$ vertices of $U = V \setminus V(\mathcal{P})$. Observe that as $|\mathcal{P}| = \ell$, by Obs. 2.5, there exists a path $P^* \in \mathcal{P}$ with $n(P^*) \leq n/\ell$ principal vertices. Therefore $c(\mathsf{Translate}^{-1}(P^*)) \geq -n^3 \cdot n/\ell$ (recall that $c((v_i^{in}, v_i^{out})) = -n^3$ for any $i \in \{1, \ldots, n\}$).

We next show that the path Q implies the existence of an s-t path Q' in $\widetilde{G}$ that has a lower cost than that of $\mathsf{Translate}^{-1}(P^*)$. The path Q' is defined based on $Q = [v_1, v_2, \ldots, v_q]$, as follows:

$$Q' = (s, s') \circ (s', v_1^{in}) \circ T_1 \circ (v_1^{out}, v_2^{in}) \circ T_2 \circ (v_2^{out}, v_3^{in}) \circ \ldots (v_{q-1}^{out}, v_q^{in}) \circ T_q \circ (v_q^{out}, t) \ ,$$

where $T_j = (v_j^{in}, v_j') \circ (v_j', v_j^{out})$ for every $v_j \in V(Q) \setminus U$, and $T_j = (v_j^{in}, v_j^{out}))$ for every $v_j \in V(Q) \cap U$. By the definition of U, $x((v_i^{in}, v_i^{out})) = 0$ for every $v_i \in U$. In addition,

$$c(Q') \leq -n^3 \cdot 2n/\ell + n \leq -n^3 \cdot n/\ell - n^3 + n < c(\mathsf{Translate}^{-1}(P^*)) \ .$$

Consider an alternative flow solution x' obtained by replacing the path P^* with the path Q' in the flow decomposition. That is, let $x'(e) = x(e) - 1$ for every $e \in \mathsf{Translate}^{-1}(P^*)$, and $x'(e) = x(e) + 1$ for every $e \in Q'$. Note that since $x((v_i^{in}, v_i', v_i^{out})) = 0$ for every $v_i \in U$, we have that x' is a legal flow of the same value as that of x, but of a strictly lower cost, as $c(\mathsf{Translate}^{-1}(P^*)) > c(Q')$. Ending with a contradiction to the optimality of x. ◀

2.2 Partial ℓ-Covers

The construction of shortcut sets of sublinear size of Theorem 1.5 calls for a variant of the ℓ-covers that we call *partial ℓ-covers*. These covers are defined w.r.t. a given subset V' of vertices that we wish to cover, in the following sense:

▶ **Definition 2.8** (Partial ℓ-Covers). *Given an n-vertex digraph $G = (V, E)$, a subset $V' \subseteq V$, and a parameter ℓ, a* partial ℓ-cover *for G w.r.t. V' is a multiset of ℓ paths $\mathcal{P} = \{P_1, \ldots, P_\ell\}$ (possibly, singletons or empty), satisfying the following:*

1. $\text{TotLen}(\mathcal{P}) \leq 8|V(\mathcal{P}) \cap V'|$,
2. *For any long dipath $P \subseteq G$, i.e., such that $|P| \geq 8|V' \cap V(\mathcal{P})|/\ell$, it holds that*

$$|V(P) \cap (V' \setminus V(\mathcal{P}))| \leq |V(P)|/4 \ .$$

▶ **Theorem 2.9.** *For any given n-vertex m-edge DAG $G = (V, E)$, $\ell \in [1, n]$ and $V' \subseteq V$, there is a randomized algorithm $\mathsf{PartialPathCover}(G, V', \ell)$ for computing an ℓ-partial cover of G w.r.t. V', w.h.p, in time $\widetilde{O}(m + n^{3/2})$.*

Algorithm PartialPathCover. The algorithm is almost equivalent to Algorithm PathCover, up to small adaptations of the min-cost max flow instance. Specifically, we define $\widetilde{G} = (\widetilde{V}, \widetilde{E}, u', c')$, with the same edge and vertex set as in Algorithm PathCover. Letting, u, c be the capacity (resp., cost) functions of Alg. PathCover, then in our reduction, we define: $c'((v_i^{in}, v_i^{out})) = -7$ for every $v_i \in V$, and $c'(e) = c(e)$ for every other edge in $\widetilde{G}$. In addition, $u'((v_i^{in}, v_i^{out})) = 0$ for every $v_i \in V \setminus V'$, and $u'(e) = u(e)$ for every other edge in $\widetilde{G}$.

The remaining algorithm is identical as Algorithm PathCover. It applies Algorithm MinCostFlow$(\widetilde{G}, s, t)$ using Theorem 1.12. The output flow solution is given by x. Then, it computes the flow-decomposition $\widetilde{\mathcal{P}}$ by applying Lemma 1.14 on x. Finally, the paths $\widetilde{\mathcal{P}}$ are translated into a *multiset* of G-paths $\mathcal{P}$, which provides the output partial ℓ-cover w.r.t. V'. The function Translate provides the bijection from the multiset $\widetilde{\mathcal{P}}$ to the multiset $\mathcal{P}$.

3 Shortcut Algorithms via Path Covers

3.1 Shortcutting to Diameter $D = O(n^{1/2})$

We start by proving Theorem 1.3, by presenting an algorithm for computing linear-size D-shortcuts for $D = O(\sqrt{n})$. This algorithm will be used later on in order to provide improved diameter bounds. By Proposition 1.11, it is sufficient to prove Theorem 1.4 for DAGs. Before presenting the improved shortcut algorithm FasterShortcutSqrtN, we also need the following definition. For a given directed path $P = [u_1, \ldots, u_k]$ and a vertex v, let u_i be the *first* vertex on P satisfying that $(v, u_i) \in TC(G)$. The edge (v, u_i) is denoted as *the first incoming edge* from v to P, represented by $e(v, P) = (v, u_i)$. Note that the augmented path $P \cup \{e(v, P)\}$ provides a directed path from v to every vertex $u \in P$ such that $(v, u) \in TC(G)$. The following result provided in [20].

▶ **Lemma 3.1** (Restatement of Lemma 2 in [20]). *Let $\mathcal{Q}$ be a collection of directed paths in a DAG. Then, one can compute the edge set $\{e(v, Q) \mid v \in V, Q \in \mathcal{Q}\}$ within $O(|\mathcal{Q}| \cdot m)$ time.*

Algorithm FasterShortcutSqrtN:

Input: An n-vertex DAG G,
Output: A shortcut set $H \subseteq TC(G)$ such that $|E(H)| = \widetilde{O}(n)$ and $\mathtt{Diam}(G \cup H) = O(\sqrt{n})$.

1. Compute ℓ-cover $\mathcal{P} = \mathsf{PathCover}(G, \ell)$, for $\ell = \Theta(\sqrt{n})$ (using Theorem 2.3).
2. Let $\mathcal{C} = \mathsf{DisjointChains}(\mathcal{P})$ (using Lemma 1.15).
3. For every $C_i \in \mathcal{C}$, let $H_i = H(C_i)$ be a shortcut set for reducing the diameter of C_i to 2 as obtained by Lemma 1.10.
4. Output $H = \bigcup_{C_i \in \mathcal{C}} C_i \cup H_i$.

▶ **Lemma 3.2** (Runtime and Size). *Algorithm* FasterShortcutSqrtN *can be implemented in time $\widetilde{O}(m + n^{3/2})$. In addition, $E(H) = \widetilde{O}(n)$, w.h.p.*

Finally, we complete the diameter argument and establish Theorem 1.3.

▶ **Lemma 3.3.** *The diameter of $G \cup H$ is at most $O(\sqrt{n})$, w.h.p.*

3.2 Shortcutting to Diameter $D = o(n^{1/2})$

In this subsection, we extend the algorithm of Sec. 3.1 to provide D-shortcuts for $D = o(n^{1/2})$. Obtaining a smaller diameter bound will entitle a cost both in terms of the running time and in the size of the shortcut set. Again, we assume that G is a DAG.

Algorithm FasterShortcutSmallDiam:

Input: An n-vertex DAG G and a diameter bound $D = o(n^{1/2})$.
Output: A shortcut set $H \subseteq TC(G)$ satisfying that $\texttt{Diam}(G \cup H) \leq D$.

1. Let $H_0 \leftarrow \mathsf{FasterShortcutSqrtN}(G)$, (using Theorem 1.3).
2. Compute ℓ-cover $\mathcal{P} = \mathsf{PathCover}(G \cup H_0, \ell)$ for $\ell = 16n/D$, (using Theorem 2.3).
3. Let $\mathcal{C} = \mathsf{DisjointChains}(\mathcal{P})$ (using Lemma 1.15).
4. For every $C_i \in \mathcal{C}$, let $H(C_i)$ be a 2-shortcut set for C_i obtained by Lemma 1.10.
5. Let $V' = V[p]$ and $\mathcal{C}' = \mathcal{C}[p]$ where $p = \Theta(\log n/D)$.
6. Applying Lemma 3.1 to compute $\widehat{H} = \{e(v, C_i) \mid v \in V', C_i \in \mathcal{C}'\}$.
7. Output $H = H_0 \cup \bigcup_{C_i \in \mathcal{C}}(C_i \cup H(C_i)) \cup \widehat{H}$.

▶ **Lemma 3.4** (Runtime and Size). *Algorithm* FasterShortcutSmallDiam *can be implemented in time* $\widetilde{O}(m \cdot n/D^2 + n^{3/2})$. *In addition,* $E(H) = \widetilde{O}(n^2/D^3)$, *w.h.p.*

▶ **Lemma 3.5** (Diameter Bound). $\texttt{Diam}(G \cup H) \leq D$, *w.h.p.*

Consider a u-v shortest path P in $G' = G \cup H_0 \cup \bigcup(C_i \cup H(C_i))$. Let P', P'' be the $(D/4)$-length prefix (resp., suffix) of P.

▶ **Lemma 3.6.** P'' *contains at most* $D/8$ *vertices from* $V \setminus V(\mathcal{C})$.

By the exact same argument as in the proof of Lemma 3.3, we also have:

▶ **Observation 3.7.** $|V(P'') \cap V(C_i)| \leq 3$ *for every* $C_i \in \mathcal{C}$.

Therefore by Lemma 3.6, P'' contains representatives vertices from $\Omega(D)$ distinct paths in $\mathcal{C}$. That is, $|\{C_i \in \mathcal{C} \mid V(C_i) \cap V(P'') \neq \emptyset\}| = \Omega(D)$. As each chain in $\mathcal{C}$ is sampled into $\mathcal{C}'$ independently with probability p, by the Chernoff bound, we have that w.h.p., P'' contains at least one vertex $y \in C_i$ for some sampled chain $C_i = [a_1, \ldots, a_k] \in \mathcal{C}'$. In addition, w.h.p., the prefix P' contains at least one sampled vertex $x \in V'$. We then have that the edge $e(x, C_i)$ is in $\widehat{H} \subseteq H$. Let $e(x, C_i) = (x, z)$ for $z \in C_i[a_1, y]$. Therefore the augmented graph $G \cup H$ contains a u-v path $Q = P[u, x] \circ (x, z) \circ C_i[z, y] \circ P[y, v]$ where

$$\begin{aligned} \text{dist}_{G \cup H}(u, v) &\leq |Q| = |P[u, x]| + 1 + |C_i[z, y]| + |P[y, v]| \\ &\leq |P'| + 1 + \text{dist}_{C_i \cup H(C_i)}(z, y) + |P''| \\ &\leq D/4 + 1 + 2 + D/4 \leq D/4 + D/4 + 3 \leq D \ . \end{aligned}$$

This concludes the proof of Theorem 1.4.

3.3 Shortcut Algorithms for Diameter $D = \Omega(n^{1/3})$

In this section, we provide a proof for Theorem 1.5 and compute D-shortcuts of sublinear size for any input $D = \omega(n^{1/3})$. We start by showing that in this case, as well, one can assume that the input graph G in Theorem 1.5 is a DAG. The standard reduction to a DAG is based on adding $\Theta(n)$ shortcut edges, thus too costly for our setting. Then, we present an algorithm that given a collection of dipaths $\mathcal{P}$ computes a D'-shortcut for each

path such that the total size of the union of shortcuts in *sublinear*. Again, as we aimed at obtaining sublinear shortcuts we cannot simply use Lemma 1.10 as is. Finally, we present Alg. FasterShortcutLargeD that computes the shortcuts given these tools.

Tool 1: Reduction to DAGs with Sublinear Size. In the full version, we show:

▶ **Theorem 3.8.** *Given a digraph $G = (V, E)$, one can compute in time $O(|V| + |E|)$ a DAG $G' = (V', E')$ such that $|V'| = O(|V|)$ and $|E'| = O(|E|)$, and in addition the following holds: Given any D-shortcut set $H' \subseteq TC(G')$ for G', one can compute in time $O(|H'|)$ a D-shortcut set $H \subseteq TC(G)$ for G such that $|H| \leq |H'|$.*

Tool 2: Shortcutting Dipaths with Sublinear Number of Edges. A crucial tool in our prior constructions is based on computing 2-shortcuts of nearly linear size for dipaths. For our purposes, we next provide an alternative scheme that provides shortcuts of sublinear size at the cost of increasing the diameter.

▶ **Lemma 3.9** (Shortcuts of Dipaths with Sublinear Size)**.** *There exists an algorithm* PathShortcut *that given a DAG G, dipath collection $\mathcal{P}$ and integer parameter d, outputs $H \subseteq TC(G)$ satisfying that for all $1 \leq i \leq t$, we have $\texttt{Diam}(P_i \cup H[V(P_i)]) = O(d)$ and $|H| = \widetilde{O}(\sum_{j=1}^{t} |P_i|/d)$. The running time is $\widetilde{O}(\sum_{P \in \mathcal{P}} |V(P|)$.*

The Shortcut Algorithm. We are now ready to present Algorithm FasterShortcutLargeD. The algorithm is given as input a DAG G and diameter bound $D = \omega(n^{1/3})$. Define:

$$t_D = \sqrt{n/D} \quad \text{and} \quad s_D = D^{3/2}/\sqrt{n} \,. \tag{2}$$

The algorithm consist of $i^* \leq t_D$ iterations (as will be shown in the analysis), where in each iteration i, the algorithm computes a partial t_D-cover $\mathcal{P}_i$ with respect to the set $V_i = V \setminus \bigcup_{j=0}^{i-1} \mathcal{P}_i$, namely, the set of vertices that are not yet covered by the current collection of paths $\bigcup_{j=0}^{i-1} \mathcal{P}_i$. It then computes an s_D-shortcut $H(P)$ for each $P \in \mathcal{P}_i$ by applying Algorithm PathShortcut of Lemma 3.9, and adds $\bigcup_{P \in \mathcal{P}_i} H(P)$ to the output shortcut H.

At the end of these iterations, we obtain $i^* \leq t_D$ path collections $\mathcal{P}_0, \ldots, \mathcal{P}_{i^*-1}$, where $|\mathcal{P}_{j-1}| \leq t_D$ for every $j \in \{1, \ldots, i^*\}$. The algorithm then defines a collection of $\Theta(t_D \log n)$ paths $\mathcal{R}$ as follows. The dipaths of the last path collection, namely, $\mathcal{P}_{i^*-1}$ is taken *entirely* into $\mathcal{R}$. In addition, each other dipath in $\bigcup_{j=1}^{i^*-2} \mathcal{P}_j$ is sampled into $\mathcal{R}$ independently with probability $p = \Theta(\log n / t_D)$. By the Chernoff bound we get that, w.h.p., $|\mathcal{R}| = \Theta(t_D \log n)$ as desired. The algorithm then adds to H, the collection of $e(v, P)$ edges for every $v, P \in V[p'] \times \mathcal{R}$ where $p' = \Theta(\log n / D)$. This completes the description of the algorithm.

Algorithm FasterShortcutLargeD:

Input: An n-vertex DAG $G = (V, E)$ and a diameter bound $D = \omega(n^{1/3})$.
Output: A shortcut set $H \subseteq TC(G)$ satisfying that $\texttt{Diam}(G \cup H) = O(D)$ and $|H| = \widetilde{O}((n/D)^{3/2})$.

1. Set $V_0 = V$, $U_0 = V$, $i = 0$, $p' = 10 \log n \cdot D^{-1}$ and $p = 10 \log n \cdot t_D^{-1}$.
2. While $|U_i| \geq \frac{n}{t_D}$ do the following:
   a. Set $\mathcal{P}_i = \text{PartialPathCover}(G, V_i, t_D)$.
   b. Set $H_i = \text{PathShortcut}(\mathcal{P}_i, s_D)$.
   c. $U_{i+1} \leftarrow V(\mathcal{P}_i) \cap V_i$, $V_{i+1} \leftarrow V_i \setminus V(\mathcal{P}_i)$, and $i \leftarrow i + 1$.

3. Set $\mathcal{R} = \bigcup_{j=0}^{i-2} \mathcal{P}_j$, $\mathcal{R}' = \mathcal{R}[p] \cup \mathcal{P}_{i-1}$ and $V' = V[p']$.
4. $\widehat{H} = \{e(v, P_i) \mid v \in V', P_i \in \mathcal{R}'\}$ (using Lemma 3.1).
5. Output $H = \bigcup_{j=0}^{i-1} H_i \bigcup \widehat{H}$.

Analysis. Recall that the index i^* indicates the largest index of the application, where $|U_{i^*}| < n/t_D$ leading to the termination of the algorithm.

▶ **Observation 3.10.** $V = \bigcup_{j=0}^{i^*-1} V(\mathcal{P}_j) \cup V_{i^*}$.

▶ **Observation 3.11.** *For every $Q \in \bigcup_{j=0}^{i^*-1} \mathcal{P}_j$, for every u-v shortest path $P \subseteq G \cup \bigcup_{j=0}^{i^*-1} H_j$ it holds that $|V(Q) \cap V(P)| = O(s_D)$.*

▶ **Lemma 3.12** (Runtime and Size). *Algorithm* FasterShortcutLargeD *can be implemented in time $\widetilde{O}((m + n^{3/2}) \cdot t_D)$. In addition, $|E(H)| = \widetilde{O}((n/D)^{3/2})$, w.h.p.*

Proof. We first claim that the While loop is applied at most t_D times. By definition, $U_j \cap V_j = \emptyset$ and $U_j \cup V_j = V_{j-1}$. In addition, since $U_j \subseteq V_{j-1}$, it holds that $U_1, U_2, \ldots, U_i$ are vertex-disjoint. Since the While loop continues only provided that $|U_i| \geq n/t_D$, there can be at most t_D applications of this loop. We will need the following observation.

▶ **Observation 3.13.** $\text{TotLen}(\mathcal{R} \cup \mathcal{P}_{i^*-1}) = O(n)$.

Runtime. We focus on a single application of the While loop and show that it can be implemented in $\widetilde{O}(m + n^{3/2})$ time, since there are at most t_D applications, the final runtime is bounded by $\widetilde{O}((m + n^{3/2})t_D)$. Step (a) is implemented in $\widetilde{O}(m + n^{3/2})$ time by Theorem 2.9. Step (b) runs in $\widetilde{O}(\text{TotLen}(\mathcal{R} \cup \mathcal{P}_{i-1})) = \widetilde{O}(n)$, by Lemma 3.9 and Observation 3.13 (we note that in fact this is the total running time of Step (b) over all the iterations of the While loop). Step (c) runs in $O(n)$ time. The runtime bound of the t_D applications of the While loop follows. We next analyze the remaining steps of the algorithm. By Observation 3.13, Step 3 is implemented in $O(n)$ time. Since $|\mathcal{R}'| = |\mathcal{R}[p]| + |\mathcal{P}_{i-1}|$, w.h.p., we have that $|\mathcal{R}'| = \widetilde{O}(t_D)$ as $|\mathcal{R}[p]| = \widetilde{O}(t_D)$ (this follows from the fact that $|\mathcal{R}| \leq t_D^2$ as there are at most t_D iterations of line 2(a) and at each iterations at most t_D paths are created) and $|\mathcal{P}_{i-1}| \leq t_D$. Using Lemma 3.1, Step 4 is implemented in $\widetilde{O}(m \cdot t_D)$.

Size. By the Chernoff bound, w.h.p., it holds that $|\widehat{H}| = |V'| \cdot |\mathcal{R}'| = |V'| \cdot (|\mathcal{R}[p]| + |\mathcal{P}_{i^*-1}|) = \widetilde{O}\left(\frac{n}{D} \cdot (t_D + t_D)\right) = \widetilde{O}((n/D)^{3/2})$. Furthermore, we also have $\sum_{j=0}^{i^*-1} |H_j| = O((n/D)^{3/2})$. This follows from the fact proven in Observation 3.13 that $\sum_{P \in \mathcal{R} \cup \mathcal{P}_{i^*-1}} |V(P)| = O(n)$. Hence, by Lemma 3.9 and Step 2(b) of the algorithm, w.h.p., we have that

$$\sum_{j=0}^{i^*-1} |H_j| = \widetilde{O}\left(s_D^{-1} \cdot \sum_{P \in \mathcal{R} \cup \mathcal{P}_{i-1}} |V(P)|\right) = \widetilde{O}(s_D^{-1} \cdot n) = \widetilde{O}((n/D)^{3/2}).$$

We conclude that $|H| = |\bigcup_{j=0}^{i^*-1} H_j \bigcup \widehat{H}| = \widetilde{O}((n/D)^{3/2})$, w.h.p. ◀

▶ **Lemma 3.14** (Diameter Bound). $\texttt{Diam}(G \cup H) = O(D)$, *w.h.p.*

Proof. Consider a u-v shortest dipath P in the graph $G' = \bigcup_{j=0}^{i^*-1} H_j \cup G$. Let P', P'' be the $8D$-length prefix and suffix of P, respectively. By the Chernoff bound, it holds that $V(P') \cap V' \neq \emptyset$, and let u^* be some arbitrary vertex in $V(P') \cap V'$. Recall that $\mathcal{P}_{i^*-1}$ is the last path collection obtained by applying Alg. PartialPathCover We next consider two cases.

Case 1: $V(P'') \cap V(\mathcal{P}_{i^*-1}) \neq \emptyset$. Let v^* be some vertex in $V(P'') \cap V(\mathcal{P}_{i^*-1})$ and let $Q \in \mathcal{P}_{i^*-1}$ be some path satisfying that $v^* \in V(Q)$. Since $Q \in \mathcal{R}'$, the edge $e(u^*, Q)$ is in $\widehat{H}$, and thus also in the output shortcut H. Let $e(u^*, Q) = (u^*, z)$ where z is the first vertex on Q such that there is a dipath from u^* to z in G. We therefore have that:

$$\begin{aligned} \mathrm{dist}_{G \cup H}(u, v) &\leq \mathrm{dist}_{G'}(u, u^*) + \mathrm{dist}_{G' \cup \widehat{H}}(u^*, z) + \mathrm{dist}_{G \cup H_{i^*-1}}(z, v^*) + \mathrm{dist}_{G'}(v^*, v) \quad (3) \\ &\leq |P'| + 1 + O(s_D) + |P''| = O(D) \ . \quad (4) \end{aligned}$$

This holds as $\mathrm{dist}_{G \cup H_{i-1}}(z, v^*) = O(s_D)$ by Lemma 3.9 and $s_D = D \cdot \sqrt{D/n} \leq D$.

Case 2: $V(P'') \cap V(\mathcal{P}_{i^*-1}) = \emptyset$. We will need the following observations.

- Observation 1: $V(P'') \subseteq \bigcup_{j=0}^{i^*-2} \mathcal{P}_j \cup V_{i^*}$. This observation follows from Obs. 3.10, as $V(P'') \cap V(\mathcal{P}_{i^*-1}) = \emptyset$.
- Observation 2: $8|U_{i^*}|/t_D \leq 8D$. This observation follows from the fact that $|U_{i^*}| \leq n/t_D$.

Hence by property (2) of Definition 2.8 of the partial ℓ-cover $\mathcal{P}_{i^*-1}$ w.r.t. V_{i^*-1} (with $\ell = t_D$), we have that:

$$\begin{aligned} |V(P'') \cap V_{i^*-1}| &= |V(P'') \cap V_{i^*}| && \text{By Observation 1.} \\ &\leq |V(P'')|/4 && \text{By property (2) of Definition 2.8 and Observation 2.} \end{aligned}$$

By Obs. 3.11, it holds that $|V(Q) \cap V(P'')| = O(s_D)$ for every $Q \in \bigcup_{j=0}^{i^*-2} \mathcal{P}_j$. Therefore, P'' must contain vertices from at least $\Omega(D/s_D) = \Omega(t_D)$ distinct paths in $\mathcal{P}' = \bigcup_{j=0}^{i^*-2} \mathcal{P}_j$. Formally, let $\mathcal{X} = \{Q \in \mathcal{P}' \mid V(Q) \cap V(P'') \neq \emptyset\}$, then $|\mathcal{X}| = \Omega(t_D)$.

Since each path in $\mathcal{X}$ is sampled into $\mathcal{R}'$ independently with probability of $p = \Theta(\log n \cdot t_D^{-1})$, by the Chernoff bound, w.h.p., $|\mathcal{X} \cap \mathcal{R}'| \neq \emptyset$. Letting $Q^* \in \mathcal{X} \cap \mathcal{R}'$, we have that there is a vertex $y \in V(Q^*) \cap V(P'')$ and in addition, the edge $e(u^*, Q^*) = (u^*, z)$ is in H, where z is the first vertex on Q^* from which there is an incoming path from u^*. Altogether by the same argument as in Case 1, we have that $\mathrm{dist}_{G \cup H}(u, v) = O(D)$. ◀

Due to lack of space, the applications of our ℓ-covers and shortcut constructions (Theorems 1.6, 1.8) appear in the full version.

Abstract

We study homomorphism polynomials, which are polynomials that enumerate all homomorphisms from a pattern graph H to n-vertex graphs. These polynomials have received a lot of attention recently for their crucial role in several new algorithms for counting and detecting graph patterns, and also for obtaining natural polynomial families which are complete for algebraic complexity classes VBP, VP, and VNP. We discover that, in the monotone setting, the formula complexity, the ABP complexity, and the circuit complexity of such polynomial families are exactly characterized by the treedepth, the pathwidth, and the treewidth of the pattern graph respectively.

Furthermore, we establish a single, unified framework, using our characterization, to collect several known results that were obtained independently via different methods. For instance, we attain superpolynomial separations between circuits, ABPs, and formulas in the monotone setting, where the polynomial families separating the classes all correspond to well-studied combinatorial problems. Moreover, our proofs rediscover fine-grained separations between these models for constant-degree polynomials.

1 Introduction

This work is a culmination of exploration of four themes in combinatorics, algorithm design, and algebraic complexity – graph algorithms, homomorphism polynomials, graph parameters, and monotone computations. While each of these themes are of independent interest, a strong interplay among them has become quite apparent in recent years, and has lead to several new advancements in algorithms and complexity.

The first theme is *graph algorithms*, where the algorithms that are relevant to this work are those corresponding to pattern detection and counting. Loosely speaking, in such problems, we look for the "presence" of a graph H, called the *pattern graph* in another graph G, called the *host graph*[1]. The notions of presence of one graph in another graph that have been the most prevalent are subgraph isomorphism, induced subraph isomorphism, and homomorphism. In detection and counting algorithms for subgraph isomorphism (resp. induced subgraph isomorphism), we want to detect and count subgraphs (resp. induced subraphs) of an n-vertex host graph which is *isomorphic* to the pattern graph. Whereas, while looking for the occurrence of the pattern graph in the host graph, if we relax the mapping to allow multiple vertices in the pattern graph to be mapped to a single vertex in the host graph, while preserving the edge relations, we get a *homomorphism* of the pattern graph in the host graph. When the notion is homomorphism, we are interested in detecting and counting homomorphisms from the pattern graph to the host graph.

All the above mentioned problems have found many applications, both in theory and practice. For instance, detecting and counting (induced) subgraph isomorphisms are used in extremal graph theory in the study of dense graphs and quasirandom graphs [10, 29, 30], and in many applications which boil down to analyzing real-world graphs. This includes finding protein interactions in biomolecular networks [1, 34], finding active chemicals of interest in the research for drug synthesis [4], advertisement targeting by finding and counting certain social structure patterns in the analysis of social networks [24, 46], and also finding user patterns for recommender services on platforms like Amazon and Yelp [47]. The homomorphism counting problem appears for instance, in statistical physics via partition functions, in graph property testing, and extremal graph theory (see [5] for a survey). When both the host graph and the pattern graph are parts of the input, then it can be shown that all these pattern detection problems are NP-complete, since they generalize the CLIQUE problem, whereas the corresponding counting problems are all known to be #P-complete. On the other hand, in almost all the real-world applications pointed out above, we have a fixed pattern graph which we are trying to detect or count in a given host graph. Thus, in this work, we focus on the setting when the pattern graph is a fixed graph, and the host graph is a part of the input. Here, in the word-RAM model with $O(\log(n))$-bit words, since the pattern graph is of a fixed size, say its number of vertices is k, all the above problems can be solved using a trivial algorithm, based on exhaustive search, that runs in time $O(n^k)$ and space $O(1)$ where n is the number of vertices in the host graph. However, in almost all the real-world applications pointed out above, the host graph is massive. Hence, one desires faster algorithms, preferably linear or even sub-linear algorithms. Hence, there is a lot of interest and advances in improving upon this trivial algorithm using ideas from combinatorics, algebraic circuits, and machine learning (see [33] for a survey, also see [3, 28] and references therein). These problems are also very interesting from the perspective of complexity theory. For instance, in the Fixed Parameter Tractability community, it is conjectured that the best known algorithms for variants of these pattern detection and counting problems cannot be further improved. If true, this would imply $\mathsf{P} \neq \mathsf{NP}$ in a rather strong way (see [27, 32, 38, 26]). Recently, it was discovered by Curticapean, Dell and Marx [11] (also see [13]) that counting subgraph isomorphisms corresponds to counting linear combinations of homomorphisms, and hence establishing that it is sufficient to just consider the homomorphism counting problem. Several advances have been attained by considering homomorphism problems [3, 23, 25, 17, 44].

[1] In this paper, the pattern graph and the host graph are always simple, undirected graphs.

Our second theme – *homomorphism polynomials*, corresponds to one of the most successful ways by which progress has been made towards homomorphism problems, and hence towards (induced) subgraph isomorphism problems too. For a pattern graph H and a host graph G, the *homomorphism polynomial* is the polynomial whose monomials enumerate homomorphisms from H to G. For using homomorphism polynomials to obtain new algorithms for the above graph problems for a pattern graph H, it suffices to consider the homomorphism polynomial from H to K_n, the clique on n vertices. Thus, we call the homomorphism polynomial from H to K_n as the *homomorphism polynomial of* H (see Definition 10). It turns out that efficient *arithmetic circuit* (see Section 2 for the definition) constructions of homomorphism polynomials can be used to obtain almost all known best algorithms for detecting induced subgraph isomorphisms as well (See [3], also [23, 25, 17, 44]). Therefore, the study of homomorphism polynomials is a crucial area of study within graph pattern detection and counting. Homomorphism polynomials also turned out to be extremely useful in algebraic complexity theory in the quest for finding natural complete polynomial families for the complexity class VP (the algebraic complexity analog of P. See [39]). Homomorphism polynomials yield polynomial families that are complete for important algebraic complexity classes such as VBP, VP, and VNP through a single framework, simply by considering different pattern graphs [15, 31, 9], making it important not only from the perspective of algorithm design, but also from the perspective of complexity theory (also see [16], where homomorphism polynomials yield several dichotomy theorems in algebraic complexity theory). Homomorphism polynomials are thus the central focus of this work too.

In our third theme, that is of *graph parameters*, the parameters relevant to this work are treewidth, pathwidth, and treedepth of graphs. Treewidth, loosely speaking, is a measure of how far a graph is from being a tree; similarly the pathwidth measures how far a graph is from being a path; and treedepth measures how far a graph is from being a star (see Section 2 for definitions). The connection between the parameters treewidth and pathwidth and counting homomorphisms was first explored in [13] (also see [3, 31]), where it is shown that when H has bounded treewidth, then there are small-sized arithmetic circuits for homomorphism polynomials, whereas when H has small pathwidth, then the corresponding homomorphism polynomials have small-sized *algebraic branching programs* (ABPs, defined in Section 2). These improved constructions for circuits and ABPs are one of the main source of advancement in finding improved algorithms for these pattern detection and counting problems [3, 23, 25, 17, 44]. The connection between the subgraph isomorphism problem and treedepth has also been explored in the context of Boolean computational models in [27] and [26], where they discuss treewidth and treedepth based upper bounds and lower bounds for counting subgraph isomorphisms for Boolean circuits and formulas. In the context of parameterized counting complexity of these problems, a stronger connection between treewidth and the complexity of counting homomorphisms was established by Dalmau and Jonsson [12] who showed a dichotomy theorem stating that when the pattern graph has bounded treewidth, then we can count homomorphisms in polynomial time. Otherwise, we can show #W[1]-hardness. Now we turn our attention to the other major application of homomorphism polynomials. It turns out that the parameters treewidth and pathwidth played a crucial role in the construction of natural complete polynomials for $\mathsf{VP}, \mathsf{VBP}$, and VNP too. More specifically, the complete polynomials for VP and VBP were homomorphism polynomials corresponding to specific pattern graphs of bounded treewidth and bounded pathwidth respectively. Thus, one sees that in the context of these pattern detection and counting problems, and in the homomorphism polynomials of interest, these graph parameters of the pattern graph ubiquitously pop up over and over again as the crucial complexity parameters. This made us wonder, to what extent do these parameters dictate the complexity of these problems and, in particular, the homomorphism polynomials.

Towards this, the starting point of our work is the observation that all the improved arithmetic circuit constructions of homomorphism polynomials based on treewidth and pathwidth, do not use any negative constants in the circuit. This brings us to our final theme, that is, of *monotone computation*.

In the Boolean setting, monotone computations refer to computations that do not involve the negation operation, the NOT gate. Similarly, in the algebraic setting for computing polynomials, monotone arithmetic circuits correspond to circuits that do not use negative constants or subtraction gates, that is, there is no cancellation involved in the circuit. Monotone computations are interesting for three main reasons. First reason is that monotone operations have favorable stability properties with respect to rounding errors [40]. Secondly, an improved monotone circuit requires combinatorial insights since it does not use any cancellations and algebraic identities. Such constructions often reveal interesting combinatorial structure about the problem at hand and lead to new combinatorial algorithms. for the problem at hand. For instance, Grenet's monotone algebraic branching program construction of the permanent polynomial [19]. Finally, the weakness of monotone models resulting from the lack of cancellations, makes them significantly easier to understand. Their computations are much better understood, both in the Boolean and the algebraic setting, and hence have been used as a starting point towards understanding the general model. Indeed, we know exponential lower bounds as well as separations between important complexity classes when we restrict ourselves to the monotone setting, in contrast to the embarrassingly poor understanding that we have in the general setting. In particular, Schnorr [40] showed an exponential lower bound for the clique polynomial, which happens to be a special case of homomorphism polynomial, where the pattern graph is a clique. Moreover, we know superpolynomial separations between complexity classes[2] mVF and mVBP [41], mVBP and mVP [20], and finally, very recently, between mVP and mVNP [45]. None of these separations are settled in the non-monotone setting. Moreover, the best known circuit lower bound in the non-monotone setting is just $\Omega(n \log n)$ [2]. Thus, it makes sense to study monotone models, both from the perspective of upper bounds – due to special interests in algorithms based on improved monotone circuits – as well as lower bounds – as a first step towards getting lower bounds for the general model. Many times, the best upper bounds come first in the monotone setting. For instance, the best known upper bound for the permanent polynomial for ABPs is a monotone construction [19]. We note that for computing homomorphism polynomials, Curticapean, Dell, and Marx gave an $O(n^{\omega})$ upper bound for all pattern graphs with treewidth $= 2$ [11], and an $O(n^{k\omega/3})$ upper bound is known for all k-vertex graphs [35], where ω is the exponent of matrix multiplication. However, for sufficiently large pattern graphs with treewidth > 2, which is almost all pattern graphs, the monotone constructions are the best known.

This motivated us to pursue the concrete question of whether these treewidth and pathwidth based improved monotone arithmetic circuits for homomorphisms polynomials can further be improved, and to what extent would these graph parameters dictate it. The answer that we discovered turns out to be conceptually quite satisfying, and settles the problem completely.

[2] $\mathsf{mVF}, \mathsf{mVBP}$ and mVP refer to the class of polynomial families computable by poly-sized monotone arithmetic formulas, monotone algebraic branching programs, and monotone arithmetic circuits, respectively. mVNP refers to the monotone analog of the complexity class VNP.

1.1 Our contributions

In this work, we fully solve the question of monotone complexity of homomorphism polynomials by showing that they are completely determined by the aforementioned graph parameters.

For arithmetic circuits, we discover that the treewidth of the pattern graph exactly determines the monotone complexity of its homomorphism polynomial, by establishing that the treewidth based upper bound in [13, 31, 3] is also a lower bound.

In what follows, the monotone arithmetic circuit (resp. ABP or formula) complexity of a polynomial refers to the size of the smallest monotone arithmetic circuit (resp. ABP or formula) computing the polynomial. Here *size* of an arithmetic circuit (resp. ABP or formula) is the number of edges in the circuit (resp. ABP or formula). See Section 2 for detailed definitions. The underlying field is $\mathbb{Q}$.

▶ **Theorem 1.** *The monotone arithmetic circuit complexity of the homomorphism polynomial for a pattern graph H is $\Theta(n^{tw(H)+1})$, where $tw(H)$ is the treewidth of H.*

In the case of algebraic branching programs, we find that the pathwidth of the pattern graph is the parameter controlling the monotone complexity of its homomorphism polynomial, again, by proving a lower bound that exactly matches the pathwidth based upper bound in [13, 31, 3].

▶ **Theorem 2.** *The monotone ABP complexity of the homomorphism polynomial for a pattern graph H is $\Theta(n^{pw(H)+1})$, where $pw(H)$ is the pathwidth of H.*

Finally, for monotone formulas, it is the treedepth of the pattern graph which governs the complexity of its homomorphism polynomial.

▶ **Theorem 3.** *The monotone formula complexity of the homomorphism polynomial for a pattern graph H is $\Theta(n^{td(H)})$, where $td(H)$ is the treedepth of H.*

Hence, we resolve the question of monotone complexity of homomorphism polynomials completely by showing that treewidth, pathwidth and treedepth exactly characterize the complexity of homomorphism polynomials for arithmetic circuits, ABPs, and arithmetic formulas respectively. This also answers the conceptual question raised earlier asking to what extent do these graph parameters dictate the complexity of these homomorphism polynomials.

The characterization, in addition to giving several new lower bounds, in particular, also allows us to collect, through a unified framework, several classical and recent results for the monotone complexity of polynomials, obtained independently using different methods, over several decades. This is simply because the above theorems imply that for every family of pattern graph with high treewidth, pathwidth, or treedepth, the corresponding homomorphism polynomial family will have high circuit complexity, ABP complexity, or formula complexity, respectively.

- As a first example, applying the observations made in the proofs of Theorem 1 and Theorem 2 to polynomial families that count colored isomorphisms from pattern families (as opposed to fixed size pattern graphs), we obtain an alternative proof for the superpolynomial separation between monotone arithmetic circuits and monotone algebraic branching programs, first discovered by Hrubes and Yehudayoff [20]. We believe that our proofs are conceptually much simpler.

- In the same spirit, we also manage to reattain the superpolynomial separation between algebraic branching programs and arithmetic formulas in the monotone setting, using simple applications of Theorem 2 and Theorem 3. This was previously known as a consequence of a result by Snir [41].
- Our characterization, in particular, also rediscovers the fine-grained separations between all these models for constant-degree polynomials. That is, for every constant d, we get a polynomial family such that it is computable by linear-sized monotone arithmetic circuits, but any monotone ABP computing it must be of size at least n^d. Analogously, for every constant d, we get a polynomial family computable by linear-sized monotone ABP but any monotone arithmetic formula computing it must be of size at least n^d. Earlier, such fine-grained separations could be obtained by applying the results of [41] and [20] together.
- Another simple application of Theorem 1 yields an exponential lower bound against monotone arithmetic circuits for the clique polynomial $\mathrm{CL}_{2n,n}$, which enumerates all cliques of size n in a $2n$-vertex clique, first proved by Schnorr [40, Theorem 4.4].

▶ Remark 4. Note that, Theorems 1, 2, and 3 have pattern graph H fixed and hence of constant size. Thus, the theorems pertain to constant degree polynomials and they do not yield superpolynomial lower bounds on homomorphism polynomials. Unlike the works that show exponential lower bounds on monotone polynomials, for instance [6, 7, 8, 42], our main goal is to obtain *tight* lower bounds on *homomorphism polynomials* for *fixed size* pattern graphs. Our proofs, however, go via the colored subgraph isomorphism polynomials for which we also get superpolynomial lower bounds by considering pattern graphs of non-constant size, see Definition 19, Theorem 20, and Theorem 21.

1.2 Limitations of known techniques

It is worth noting that in the Boolean setting, while there are known upper bounds and lower bounds based on these graph parameters for circuits and formulas for (colored) subgraph isomorphism problem, there is still an asymptotic gap between the upper bound and the corresponding lower bounds in these Boolean models (see [27, 26]). Thus, we cannot hope to translate the lower bounds in Boolean setting to the algebraic setting to get the lower bounds exactly matching the upper bounds.

An overwhelming majority of monotone arithmetic lower bounds exploit the so-called decomposition theorem (also refered to as normal form or representation theorem; see for e.g. [39, Lemma 8.7]) including the exponential monotone lower bounds for permanent [21, 37], separation between monotone VP and monotone VNP [45], as well as the superpolynomial separation between monotone arithmetic circuits and monotone ABPs [20]. However, a direct application of such a decomposition theorem fails to yield the *exact* characterization that the above theorems manage to achieve. We argue in Section 3 why these methods give asymptotically weaker lower bounds than what we desire to obtain.

For ABPs, Fournier, Malod, Szusterman, and Tavenas [18] recently gave a rank-based lower bound method for the monotone setting, inspired by [36] given in the non-commutative setting. However, in their models, the edge labels are homogeneous linear forms, which makes their method unsuitable for the tight lower bounds that we were looking for.

Finally, an approach that seems different from all these aforementioned approaches, including ours, is the one based on the concept of separating sets introduced by Schnorr [40], which also gave an exponential lower bound on the clique polynomial $\mathrm{CL}_{2n,n}$, which enumerates all cliques of size n in a $2n$-vertex clique [40, Theorem 4.4]. When the pattern is

a clique, his technique gives the optimal lower bound. However, it can be shown that, for other pattern graphs H, his proof technique, too, falls short in proving the lower bound that matches the upper bound (see full version for details). In fact, unlike Schnorr's lower bound techniques, our proofs, at a very high level, follow an abstract argument that can be shown to always give the optimal lower bound on the number of addition gates (see full version for details).

1.3 Proof ideas

At a high level, proofs to all our main theorems follow the same strategy. We discuss the case of circuits, since it already illuminates the overall idea.

The starting point towards the discovery of our proof is the fact that the upper bounds for homomorphism polynomials are all monotone and they use an optimal *tree decomposition* (see Definition 13) of the pattern graph to build the circuit. Our initial observation, which is a simple consequence of the above fact, is that *every* parse tree of such a circuit reflects a tree decomposition used to build the circuit. Moreover, since in these upper bound constructions (see [3, 13]), the whole circuit construction stems from a single tree-decomposition, all the parse trees correspond to the same tree decomposition of the pattern graph.

The above observation led us to the key question that sets the path towards our proofs:

▶ **Problem 1.** *Does an arbitrary parse tree of an arbitrary monotone circuit computing the homomorphism polynomial for an arbitrary pattern H allows us to recover a tree-decomposition of H?*

It turns out that answering the above question for homomorphism polynomials in the affirmative is difficult and most likely false. This is due of presence of non-multilinear monomials in homomorphism polynomials which correspond to those homomorphic images of the pattern graphs which are simpler than the pattern graph itself (see Definition 10). These monomials may loose the information about the pattern graph altogether, since such monomials may also result from homomorphism polynomials of other patterns. Thus, in order to be able to recover the tree decomposition, it seems imperative to work with the subgraph isomorphism polynomial instead. At a very high-level, our proof successfully answers the question – *in how many monomial computations can a single gate participate?* To give a precise bound on this, we need an even more structured polynomial – *the colored subgraph isomorphism polynomial*, where a monomial apart from encoding the pattern graph we begin with, also encodes the precise mapping from the pattern graph to the host graph that gives rise to the monomial (see Definition 11).

Before going further into the proof, one might wonder whether by going from homomorphism polynomial to the colored subgraph isomorphism polynomial, we have made the polynomial too structured as compared to the homomorphism polynomial. That is, whether the subgraph isomorphism polynomial is much harder than the homomorphism polynomial and a lower bound against the former would not yield a desired lower bound for the latter. Our first technical contribution is establishing that this is not so. We show that, as long as the the pattern graph is of constant size, the colored[3] homomorphism polynomial and colored subgraph isomorphism polynomial have the same monotone circuit complexity, monotone ABP complexity and monotone formula complexity (Lemma 15). For this, we first note

[3] It can be easily shown that the homomorphism polynomial and its colored counterpart have the same complexity.

that going from colored subgraph isomorphism polynomial to homomorphism polynomial is straight-forward. For the other direction, we note that the colored homomorphism polynomial contains a superset of the set of monomials of the colored subgraph isomorphism polynomial. To remove the other monomials present, we carefully introduce weights corresponding to edge variables and then use partial derivatives w.r.t those weight variables. We finally show that such partial derivatives can indeed be done efficiently in the the monotone circuits, monotone ABPs, as well as monotone formulas; the case of formulas require the most care.

Having established that we can indeed work with the colored subgraph isomorphism polynomial, we move on to answer Problem 1 for the colored subraph isomorphism polynomial in affirmative. Our main technical contribution is to show that, given an arbitrary parse tree of an arbitrary circuit computing the colored subgraph isomorphism polynomial for a pattern graph, there exists simple algorithm to recover its tree decomposition. The algorithm works in a bottom up fashion starting with the leaves of the parse tree and moves towards the root using a precise way to combine the *bags* of the gates it encounters along the way (see Theorem 16).

Once we have the tree decomposition, we use this tree decomposition to show that if the number of vertices in H is k, and its treewidth is $tw(H)$, a gate can participate in the computation of at most $n^{k-tw(H)-1}$ monomials. We show this by using a weakness of monotone computation that, due to the absence of cancellations, any circuit computing a polynomial cannot compute an invalid submonomial[4] at any intermediate gate along the way. This weakness is exploited in almost all known monotone lower bounds, and dates back to Jerrum and Snir [21].

For proving the lower bounds in Theorem 2 and 3 for formulas and ABPs, we are able to use the same framework as above. Instead of constructing a tree decomposition using the parse trees, we construct a *path decomposition* (Definition 13) in case of ABPs, and an *elimination tree* (Definition 14) in case of formulas. If we start with an ABP instead, it is easy to see that the same algorithm for tree decomposition yields a path instead, and, hence, we get a path decomposition (see Theorem 17). For formulas, we give a different simple algorithm to show that an elimination forest of H can be constructed using the parse tree (see Theorem 18). Using the same weakness of monotone computation, we conclude that the number of monomials whose computation a gate can participate in is upper bounded by $n^{k-pw(H)-1}$ in case of ABPs, and by $n^{k-td(H)}$ in case of formulas, where $pw(H)$ and $td(H)$ denote the pathwidth and the treedepth of H respectively.

To obtain the upper bounds claimed in Theorem 1, 2 and 3, we note that the upper bounds for circuits and ABPs that were already known are both monotone constructions, which go via the tree decomposition and the path decomposition of the pattern graph in case of circuits and ABPs respectively [13, 3, 31]. We give the formula upper bound using the elimination tree of the pattern graph. A treedepth based monotone formula upper bound is folklore in the Boolean setting.

To prove the separation between monotone complexity classes, we first note that the lower bounds on colored subgraph isomorphism polynomials also hold for pattern grpahs H of non-constant size. Consequently, pattern graphs with high pathwidth but low treewidth yield superpolynomial separation between circuits and ABPs (discussed in Theorem 20), whereas pattern graphs with high treedepth but low pathwidth give superpolynomial separation between ABPs and formulas (described in Theorem 21). For the first separation, we use a

[4] An invalid submonomial is a monomial m which does not divide any of the monomial of the target polynomial.

tree as the pattern graph, whereas for the second separation, we use path as the pattern graph. For an exponential lower bound on the clique polynomial, we simply apply Theorem 1 in combination with the fact that the treewidth of a clique on n vertices is $n-1$.

To simplify the presentation, we assume that the pattern graph is connected. The complexity for a disconnected pattern is the maximum of the complexity of its connected components.

2 Preliminaries

For basic notions in graph theory, we refer the readers to [43, 14]. We first give some definitions that set up our objects of computation and the models of computation.

▶ **Definition 5.** *A polynomial over $\mathbb{Q}$ is called* monotone *if all its coefficients are non-negative.*

Compact representations of polynomials such as the following are usually used by algorithms.

▶ **Definition 6.** *An* arithmetic circuit *over the variables $x_1, \ldots, x_n$ is a rooted DAG where each source node (also called an input gate) is labeled by one of the variables x_i or a constant $a \in \mathbb{Q}$. All other nodes (called gates) are labeled with either $+$ (addition) or $\times$ (multiplication). The circuit computes a polynomial over $\mathbb{Q}[x_1, \ldots, x_n]$ in the usual fashion. The circuit is called* monotone *if all constants are non-negative. The circuit is a* skew circuit *if for all $\times$ gates, at least one of the inputs is a variable or a constant. The circuit is a* formula *if all gates have out-degree at most one. The* size *of a circuit or skew circuit or formula is the number of edges in the circuit. The* depth *of a circuit is the number of edges in the longest path from the root to an input gate.*

Instead of skew circuits, a model that is equivalent in terms of power is usually studied in algebraic complexity.

▶ **Definition 7.** *An* Algebraic Branching Program (ABP) *is a DAG with a unique source node s and a unique sink node t. Each edge is labeled with a variable from $x_1, \ldots, x_n$ or a constant $a \in \mathbb{Q}$. Each path in the DAG from s to t corresponds to a term obtained by multiplying all the edge labels on that path. The polynomial computed by the ABP is the sum of all terms over all paths from s to t. The ABP is called* monotone *if all constants are non-negative. The* size *of the ABP is the number of edges.*

It is well-known that for any (monotone) polynomial, the size of the smallest (monotone) ABP and the size of the smallest (monotone) skew circuit are within constant factors of each other. In this paper, we will use the skew circuit definition in our proofs.

In this paper, we look at families of polynomials $(p_n)_{n \geq 0}$ and the optimal size and depth of the models computing them. In this case, the size and depth are functions of n and we are only interested in the asymptotic growth rate of these functions.

For simplicity, when proving lower bounds, we assume that all non-input gates have exactly two incoming edges (both may be from the same gate). This assumption increases the size by at most a constant factor and may increase the depth by at most a logarithmic factor.

The families of polynomials that we look at in this paper enumerate graph homomorphisms or colored isomorphisms. We first define these notions.

▶ **Definition 8.** *For graphs H and G, a* homomorphism *from H to G is a function $\phi : V(H) \mapsto V(G)$ such that $\{i,j\} \in E(H)$ implies $\{\phi(i), \phi(j)\} \in E(G)$. For an edge $e = \{i,j\}$ in H, we use $\phi(e)$ to denote $\{\phi(i), \phi(j)\}$.*

▶ **Definition 9.** *Let H be a k-vertex graph where its vertices are labeled by $[k]$ and let G be a graph where each vertex has a color in $[k]$. Then, a* colored isomorphism *of H in G is a subgraph of G isomorphic to H such that all vertices in the subgraph have different colors and for each edge $\{i, j\}$ in H, there is an edge in the subgraph between vertices colored i and j.*

Now, we are ready to define our main object of computation, the homomorphism polynomial.

▶ **Definition 10.** *For a pattern graph H on k vertices, the n-th* homomorphism polynomial *for H is a polynomial on $\binom{n}{2}$ variables x_e where $e = \{u, v\}$ for $u, v \in [n]$.*

$$\mathsf{Hom}_{H,n} = \sum_{\phi} \prod_{e \in E(H)} x_{\phi(e)}$$

where ϕ ranges over all homomorphisms from H to K_n.

Next, we define the colored isomorphism polynomial which will be crucial in our proofs. This polynomial enumerates all colored isomorphisms from a pattern to a host graph where there are n vertices of each color. This polynomial can be used to count colored isomorphisms in n-vertex host graphs by setting the variables corresponding to edges not in the host graph to 0.

▶ **Definition 11.** *For a pattern graph H on k vertices, the n-th* colored isomorphism polynomial *for H is a polynomial on $|E(H)|n^2$ variables x_e where $e = \{(i, u), (j, v)\}$ for $u, v \in [n]$ and $\{i, j\} \in E(H)$.*

$$\mathsf{ColIso}_{H,n} = \sum_{u_1,\ldots,u_k \in [n]} \prod_{\{i,j\} \in E(H)} x_{\{(i,u_i),(j,u_j)\}}$$

We notice that the labeling of H does not affect the complexity of ColIso_H. Given the polynomial ColIso_H for some labeling of H and if ψ is a relabeling of H, then the polynomial ColIso_H for the new labeling can be obtained by the substitution $x_{\{(i,u),(j,v)\}} \mapsto x_{\{(\psi(i),u),(\psi(j),v)\}}$.

For our main proofs, we need a way to analyze how a monomial is being computed in a circuit, an ABP, or a formula. For this, we use the notion of parse trees.

▶ **Definition 12.** *Let g be a gate in a circuit C. A* parse tree *rooted at g is any rooted tree which can be obtained by the following procedure, duplicating gates in C as necessary to preserve the tree structure.*

1. *The gate g is the root of the tree.*
2. *If there is a multiplication gate g in the tree, include all its children in the circuit as its children in the tree.*
3. *If there is an addition gate g in the tree, pick an arbitrary child of g in the circuit and include it in the tree.*

If the root gate of a parse tree is not mentioned, then it is assumed to be the output gate of the circuit. A parse tree witnesses the computation of some term. We note that if C is a formula, then any gate can occur at most once in any parse tree in C.

Given a parse tree T that contains a gate g, we use T_g to denote the subtree of T rooted at g. The tree obtained by removing T_g from T is called the tree outside T_g in T. Note that we can replace T_g in T with any parse tree rooted at g to obtain another parse tree.

Similarly, if we have two parse trees T and T' that both contain the same multiplication gate g from the circuit, then we can replace the left or right subtree of T_g with the left or right subtree of T'_g to obtain another parse tree. This is because both the left and right child of g in both parse trees are the same and therefore we can apply the aforementioned replacement.

Now, we define the graph parameters most crucial to our work. They are the parameters that turn out to exactly characterize the complexity of the above polynomial families in the models of computations defined above.

▶ **Definition 13.** *A* tree decomposition *of H is a tree where each vertex (called a* bag*) in the tree is a subset of vertices of H. This tree must satisfy two properties.*

1. *For every edge $\{i, j\}$ in H, there must be at least one bag in the tree that contains both i and j.*
2. *For any vertex i in H, the subgraph of the tree decomposition induced by all bags containing i must be a subtree. This subtree is called the* subtree induced by *i.*

The size of a tree decomposition is the size of the largest bag minus one. The treewidth *of H is the size of a smallest tree decomposition of H.*

A tree decomposition is called a path decomposition *if it is a path. The* pathwidth *of H is the size of a smallest path decomposition.*

▶ **Definition 14.** *For a connected graph H, an* elimination tree *of H is a rooted, directed tree that can be constructed by arbitrarily picking a vertex u in H and adding edges from the roots of elimination trees of connected components of $H - u$ to the root vertex labeled u. In particular, if H is a single vertex, then the elimination tree of H is the same single vertex graph.*

The depth *of an elimination tree is the number of vertices in the longest path from a leaf to the root. The* treedepth *of H is the depth of the smallest depth elimination tree of H.*

We note that for any graph H, its elimination tree contains exactly $|V(H)|$ vertices. All edges in the tree are directed towards the root and the vertices of the tree are uniquely labeled with the vertices of H. If T is an elimination tree for the connected graph H, then all edges in H are between vertices that are in an ancestor-descendant relationship in T.

We now state some basic facts about treewidth, pathwidth, and treedepth. We combine these facts with the lower bounds in Section 3 to obtain, for any constant k, constant-degree polynomial families having linear size circuits (ABPs resp.) but requiring $\Omega(n^k)$ size ABPs (formulas resp.), thus giving us a fine-grained separation between these models. Note that, for constant-degree polynomials, such polynomial factor separations are the best one could ask for between formulas, ABPs, and circuits, since all constant-degree polynomials are computable by polynomial-sized formulas. Moreover, we use these facts to obtain superpolynomial separations between these models for high degree polynomials.

▶ **Fact 1.** *For all graphs H, we have $tw(H) \leq pw(H) \leq td(H) - 1$.*

▶ **Fact 2.** *For any number $p \geq 1$, there is a tree X_k on $k = \frac{1}{6}(5 \cdot 3^p - 3)$ vertices that have pathwidth p.*

Proof. The tree X_2 is simply an edge. The tree X_k for $p \geq 2$ is obtained by connecting three copies of the constructed trees with pathwidth $p - 1$ to a new root vertex. ◀

▶ **Fact 3.** *All paths have pathwidth 1 and the k-vertex path has treedepth $\lceil \log_2(k + 1) \rceil$.*

3 Algebraic complexity of homomorphism polynomials

In this section, we prove Theorems 1, 2 and 3. thus achieving our main result, that is, the exact characterization for the monotone complexity of homomorphism polynomials.

▶ **Lemma 15.** *For any fixed pattern H, both the homomorphism polynomial for H and the colored isomorphism polynomial for H have the same (asymptotically) monotone arithmetic circuit complexity, monotone ABP complexity, and monotone formula complexity.*

Proof. First, we show how to obtain a circuit that computes Collso_H from one that computes Hom_H. We introduce new variables w_e for each $e \in E(H)$. Let C be a circuit that computes Hom_H over the vertex set $[k] \times [n]$. We substitute $x_{\{(i,u),(j,v)\}}$ with $x_{\{(i,u),(j,v)\}} w_{\{i,j\}}$ for all i, j, u, v if $\{i, j\} \in E(H)$. Otherwise, we set the variable to 0. Let C' be the resulting circuit. We then compute $\frac{\partial^{|E(H)|}}{\partial w_{e_1} \dots \partial w_{e_{|E(H)|}}} C'$ using the sum and product rule for partial derivatives. Then, we set $w_e = 0$ for all e. The partial differentiation ensures that all monomials must have at least one edge of each color. Setting $w_e = 0$ ensures that all monomials can only have at most one edge of each color. Therefore, the remaining monomials contain each edge in H exactly once. These are exactly those homomorphisms that correspond to colored isomorphisms. For each colored isomorphism, there are $|aut(H)|$ ways to relabel the vertices of H to obtain the same edge set. So we divide by $|aut(H)|$ to obtain Hom_H exactly. Each partial differentiation increases the size of the circuit at most by a factor of 3. Therefore, if C has size s, the final circuit has size at most $c3^{|E(H)|}s$ for some constant c.

For the other direction, given a circuit that computes Collso_H, we can replace each $x_{\{(i,u),(j,v)\}}$ with $x_{\{u,v\}}$ if $u \neq v$ and 0 otherwise. The circuit now computes Hom_H because the monomial corresponding to the homomorphism ϕ is generated by the corresponding colored isomorphism $i \mapsto (i, \phi(i))$. Also, every colored isomorphism on vertices (i, u_i) for $1 \leq i \leq k$ corresponds to a homomorphism to K_n as long as $u_i \neq u_j$ for $\{i, j\} \in E(H)$.

Notice that both constructions preserve monotonicity and yield a monotone ABP when the original circuit is a monotone ABP.

A straightforward application of the sum and product rule to compute the partial derivative does not necessarily yield a formula from a formula. While computing the partial derivative, we have to compute both f and $\partial f/\partial x$ for every sub-formula f. If $f = g + h$ for some formulas g and h, then we can simply compute $\partial f/\partial x = \partial g/\partial x + \partial h/\partial x$ without using any sub-formula more than once. When the formula $f = gh$ for some formulas g and h, we have to compute $\partial f/\partial x = g\partial h/\partial x + h\partial g/\partial x$. Therefore, we are using g and h twice, once for computing f and once for computing $\partial f/\partial x$. We can convert the resulting circuit into a formula by duplicating the sub-formulas g and h. For general formulas, this leads to a quadratic blowup in size. But, for monotone formulas computing constant-degree polynomials, we show that the size increases only by a constant factor when duplicating sub-formulas in this fashion.

First, we eliminate all gates in the formula that computes 0 and replace all gates that compute a constant by an input gate labeled with that constant. We call a multiplication gate f *trivial* if $f = ag$ for some constant a and sub-formula g. In this case, we have $\partial f/\partial x = a\partial g/\partial x$. Therefore, we do not have to make a copy of the non-constant sub-formula g. We make a copy of the input gate a here. But, we do not have to make additional copies of this input gate a later for any trivial gate encountered on the path from f to root. This is because f is not a constant and therefore it must be the other input to the trivial gate that is constant. We claim that if the monotone formula computes a polynomial of degree at most d, for any gate g, there are at most d non-trivial multiplication gates on the path

from g to the root gate. This is because each non-trivial gate increases the degree by at least one and no cancellations can occur in a monotone formula. Therefore, we can compute the partial derivative using at most $d+2$ copies of each gate in the original formula. Since the degree of the polynomials we are differentiating is at most $2|E(H)|$ and we perform $|E(H)|$ differentiations, the final formula has size $O\big((2|E(H)|+2)^{|E(H)|}s\big)$ if the original formula has size s. ◀

From now on, we can use either Collso_H or Hom_H to prove our results. For a pattern graph H, we say that an edge $\{i,j\}$ or a vertex i in H is present in a monomial over the variables of the colored isomorphism polynomial if there is a variable $x_{\{(i,u),(j,v)\}}$ for some u and v in that monomial. We also say that the edge $\{(i,u),(j,v)\}$ or the vertex (i,u) is present in that monomial in that case.

In our proofs, we restrict our attention to the multiplication gates and the input gates in parse trees. This is because our proofs consider the computation of individual monomials separately and in this case, the addition gates play no role in the computation as all of them have exactly one child in the parse tree. While proving lower bounds, we also assume that all addition and multiplication gates have exactly two incoming edges. Since we define the size of a circuit as the number of edges, this transformation changes the size only by a constant factor. In addition, with this restriction, the number of gates and the number of edges are related by constant factors. Therefore, we may lower bound either to lower bound the size of the circuit.

▶ **Theorem 16** (Theorem 1 restated). *The monotone arithmetic circuit complexity of* Hom_H *is* $\Theta\big(n^{tw(H)+1}\big)$.

Proof. The upper bound is already known (See [13], [3]).

Let H be of treewidth t. For proving the lower bound, we consider the n-th colored isomorphism polynomial for H, $\mathsf{Collso}_{H,n} = \sum_{u_1,\ldots,u_k} \prod_{i,j} x_{\{(i,u_i),(j,u_j)\}}$, where $u_1,\ldots,u_k \in [n]$ and $\{i,j\} \in E(H)$ (see Definition 11). Consider any monomial m on the vertices (i,u_i) for $1 \le i \le k$ and its associated parse tree. We assume without loss of generality that both sides of any multiplication gate computes a non-constant term (If they compute a constant, it has to be 1 and we can simply ignore this subtree). We build a tree decomposition of H from this parse tree in a bottom-up fashion. In this tree decomposition, each gate is associated with one or two bags in the decomposition. Exactly one of these bags is designated as the *root bag* of that gate. An example of this construction is shown in Figure 1 where the 4-vertex cycle is the pattern.

1. For an input gate $x_{\{(i,u),(j,v)\}}$. Add the bag $\{i,j\}$ as a leaf of the tree decomposition. For example, in Figure 1, the input gate labeled $x_{\{(1,u),(2,v)\}}$ is associated with the bag $\{1,2\}$.
2. For a multiplication gate g. Let A and B be the contents of the root bags of its left and right subtrees. Add a bag containing $A \cup B$ as the parent of those roots. For example, in Figure 1, the gate g is first associated with a bag containing $\{1,2,3\} = \{1,2\} \cup \{2,3\}$.
3. If at any gate, there are vertices (i,u) such that the monomial computed at that gate includes all edges incident on (i,u). Then add a new bag that excludes exactly all such vertices i from the current root bag and add it as a parent of the current root bag. This new bag is now considered the root bag associated with the gate g. For example, in Figure 1, we observe that at gate g, all edges incident on the vertex $(2,v)$ are included and therefore we add a new bag that removes 2 and make it the root bag associated with g.

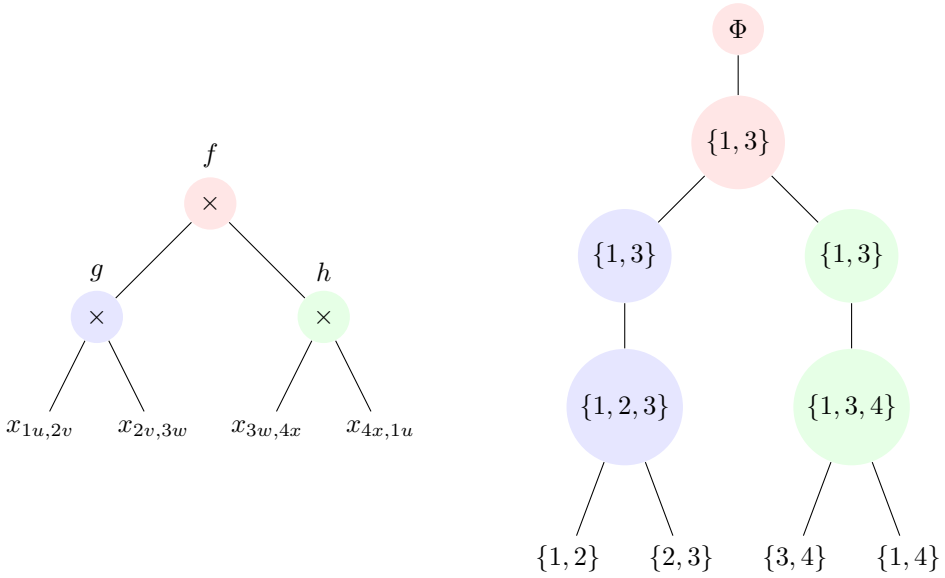

Figure 1 A tree decomposition of C_4 from a parse tree. $u, v, w, x \in [n]$.

The result is a tree decomposition of H. All edges of H are covered because all edges of H must be present in the monomial. Since a vertex is forgotten only after all edges incident on it have been multiplied, the subgraph of the tree decomposition induced by any vertex in H is a subtree.

Since H has treewidth t, the tree decomposition that we constructed must have a bag with at least $t+1$ vertices. We consider some gate g in the parse tree that is associated with a bag that contains at least $t+1$ vertices. In the following proof, we only consider the case where the bag contains exactly $t+1$ vertices. If there are more than $t+1$ vertices, then we get a better lower bound. We assume without loss of generality that these vertices are $1, \ldots, t+1$. We now claim that the gate g can only be present in parse trees of monomials m' such that m' contains vertices (i, u_i) for $1 \leq i \leq t+1$. Suppose for contradiction there is a monomial m' with a parse tree T' that contains g and has vertex (i, v_i) where $v_i \neq u_i$ for some such i. Let T be the parse tree for m. There are two cases:

1. The vertex i is forgotten at a bag associated with g: This means that both left and right subtrees of T_g compute monomials that contain (i, u_i). Now if T' contains (i, v_i) on the left subtree of T'_g, then replace right subtree of T'_g with right subtree of T_g. Else, the tree T' contains (i, v_i) on the right subtree of T'_g or outside T'_g. In both cases we replace the left subtree of T'_g with the left subtree of T_g.
2. Vertex i is not forgotten at a bag associated with g: This means that (i, u_i) appears in at least one of the subtrees of T_g and outside T_g in T. In T', if (i, v_i) appears in T'_g, then replace the tree T_g with T'_g in T. Otherwise, the vertex (i, v_i) must appear outside T'_g in T'. In this case, replace T'_g with T_g in T'.

All these new parse trees yield monomials that contain both (i, u_i) and (i, v_i). A contradiction. Notice that we can obtain exactly n^{k-t-1} colored isomorphisms that fix $t+1$ vertices. Therefore, at most n^{k-t-1} monomials of the polynomial can contain g in its parse tree. Since there are n^k monomials, this gives the required lower bound. ◀

▶ **Theorem 17** (Theorem 2 restated). *The monotone algebraic branching program complexity of* Hom_H *is* $\Theta\left(n^{pw(H)+1}\right)$.

Proof. The upper bound is already known (See [13], [3]). For the lower bound, we modify the proof of Theorem 16 to obtain a path decomposition instead. Recall that for any (monotone) polynomial, the size of the smallest (monotone) ABP and the size of the smallest (monotone) skew circuit are within constant factors of each other. We consider the parse tree for a monomial m in a skew circuit computing Hom_H and start building the path decomposition from a deepest input gate.

We give a detailed proof in the full version. ◀

▶ **Theorem 18** (Theorem 3 restated). *The monotone formula complexity of* Hom_H *is* $\Theta\left(n^{td(H)}\right)$.

Proof. We first prove the upper bound[5]. Let T be an elimination tree of depth d for H. We show how to construct a formula of size n^d for $\mathsf{Collso}_{H'}$ in a bottom-up fashion where H' is the graph obtained from T by adding all possible edges $\{i,j\}$ where i is an ancestor of j in T. Note that H' and H has the same treedepth by construction. The polynomial Collso_H can be obtained by setting extra variables in this polynomial to 1.

Let i be the label of a node in T such that the path from root to i is labeled $i_1,\ldots,i_p$ and the children of i are labeled $\ell_1,\ldots,\ell_s$. We use the notation $(i_j,u_j)_j$ where $j\in[p]$ to denote the p pairs $(i_1,u_1),\ldots,(i_p,u_p)$. We construct the formula:

$$f_i^{\{(i_j,u_j)_j\}} = \sum_u \left(\left(\prod_j x_{\{(i_j,u_j),(i,u)\}}\right) \prod_t f_{\ell_t}^{\{(i,u),(i_j,u_j)_j\}} \right)$$

where $j\in[p]$ and $t\in[s]$.

We use induction on the height c of the node i in the elimination tree to prove the size upper bound. We claim that the formula that corresponds to such a node has size $O(n^c)$ (constants hidden by the O notation depend only on H). For the base case, if i is a leaf node, this formula has size $O(n)$. If i has depth c in T, then this formula has size $O(n)\times O(n^{c-1}) = O(n^c)$ by the induction hypothesis.

If $\{i,j\}$ is not an edge in H, then we set all $x_{\{(i,u),(j,v)\}}$ to 1 in the formula. The formula corresponding to the root node in T is the required polynomial. To prove this, consider the colored subgraph isomorphism containing the vertices (i,u_i) for $1\le i\le k$. This monomial has the parse tree obtained by setting the variable u in the outermost summation for each f_i^* to u_i. For the other direction, the parse tree obtained by setting u to u_i in the outermost summation of each f_i^* generates the monomial that corresponds to the colored subgraph isomorphism on vertices (i,u_i).

We now prove the lower bound. Let d be the treedepth of H. We consider a parse tree for a monomial m in a formula computing Collso_H and build an elimination tree for H from it. An example of this construction is shown in Figure 2 where the 4-vertex path is the pattern. We associate a set of rooted trees with each gate g as follows: If the gate g is the lowest gate in the parse tree such that all edges incident on vertices $i_1,\ldots,i_r$ are present in the monomial computed at g, then make i_1 the parent of all roots of trees from the children of g. Now, make i_{j+1} the parent of i_j for $1\le j\le r-1$. We call the vertices $i_1,\ldots,i_r$ to be associated with g. If there are no such vertices for a gate g, then the forest associated

[5] We believe this construction is already known as folklore. But we present it here for the sake of completion since we couldn't find a reference for the construction.

with g is simply the union of the forests of its children. We start with empty forests initially. For any edge $\{i,j\} \in E(H)$, the gates that corresponds to i and j in this tree must belong to the path from the input gate for this edge to the root. This shows that this tree is an elimination tree for H.

In Figure 2, the input gate labeled z is such that the only edge incident on $(1,u)$ is already multiplied in at z. Therefore, we associate the vertex 1 with z and the set of trees associated with z is just the one-vertex tree 1. Also, at gate f, we have multiplied in all edges incident on $(3,w)$ and therefore, we associate 3 with f. Also, note that this vertex 3 is the parent of the roots of elimination trees from g and h.

For proving the lower bound, we consider some gate g in the parse tree of m such that g is associated with a leaf at a depth of at least d in the elimination tree. We can assume that the depth is exactly d. If it is more, then we obtain a better lower bound. Let this vertex be d. Assume without loss of generality that $1,\ldots,d$ are the vertices on the path from the root to d in the elimination tree. Let $(1,u_1),\ldots,(d,u_d)$ be the corresponding vertices in m. We claim that any monomial m' for which g appears in its parse tree must also have vertices u_j of color j for $1 \leq j \leq d$.

Suppose for contradiction that there is a monomial m' with g in its parse tree and m' has vertex (i,v_i) where $u_i \neq v_i$ for some $1 \leq i \leq d$. Let g' be the gate in T such that i is associated with g'. Now, recall that if T is an elimination tree for the connected graph H, then all edges in H are between vertices that are in an ancestor-descendant relationship in T. Thus, g' must be an ancestor of g (g' could be the same as g). Let T' be the parse tree for m'. Then, the tree T' must contain g' as well because it contains g and in a formula there is a unique path from any gate to the root. There are two cases:

1. The gate g' is an input gate: In this case, $u_i = v_i$ because a monomial cannot have two different vertices of the same color and (i,u_i) is present in g'.
2. The gate g' is a multiplication gate: In this case, the vertex (i,u_i) must appear in both subtrees of $T_{g'}$. If the vertex (i,v_i) appears in the right (left) subtree of $T'_{g'}$, then we replace the left (right) subtree of $T'_{g'}$ with the left (right) subtree of $T_{g'}$. Otherwise, the vertex (i,v_i) appears outside $T'_{g'}$ in T'. In this case, we replace the subtree $T'_{g'}$ with the subtree $T_{g'}$.

In all cases, we obtain a monomial that contains both vertices (i,u_i) and (i,v_i). A contradiction. Therefore, at most n^{k-d} monomials of the polynomial can contain the gate g in their parse tree. Since there are a total of n^k monomials, the lower bound follows.

In Figure 2, we can infer using the above argument that the input gate z can be a part of parse trees of at most n different monomials. ◀

We show how to use our characterizations to prove superpolynomial separations between various monotone models. The polynomials are *not* based on fixed pattern graphs but a natural extension of our polynomials to patterns that grow in size with the host graph.

▶ **Definition 19.** *Let $H = (H_n)$ be a family of* pattern graphs *where H_n is some graph on n vertices. Then, we define the n-th polynomial in the family* CollSo_H *as:*

$$\mathsf{CollSo}_{H_n,n} = \sum_{u_1,\ldots,u_n} \prod_{\{i,j\}} x_{\{(i,u_i),(j,u_j)\}}$$

where $u_1,\ldots,u_n \in [n]$ and $\{i,j\} \in E(H_n)$.

It is easy to see that our lower bounds for monotone circuits, monotone ABPs, and monotone formulas hold for CollSo_H for any family of pattern graphs H, where the lower bound for the n-th polynomial is given by the treewidth, pathwidth, and treedepth of H_n

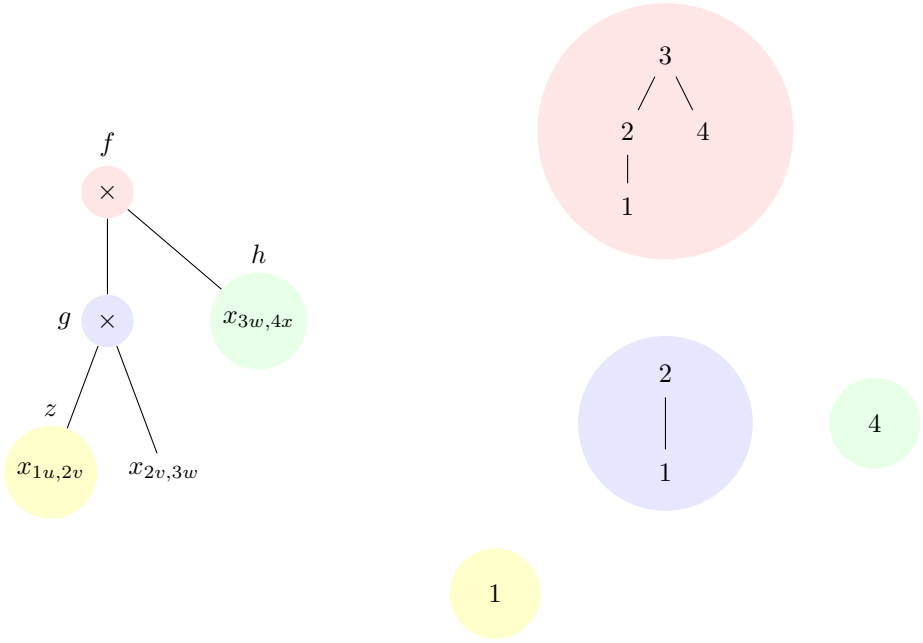

Figure 2 An elimination tree for P_4 from a parse tree. $u, v, w, x \in [n]$.

respectively. The lower bounds for Hom_H, however, does not hold because Lemma 15 causes a size blow-up that is exponential in the size of the pattern graph while constructing $\mathsf{Collso}_{H_n,n}$ from $\mathsf{Hom}_{H_n,n}$.

We now show that there are pattern families that prove a super-polynomial separation between the size complexity of monotone circuits and monotone ABPs.

▶ **Theorem 20** (Compare [20, Theorem 1, Proposition 13]). *For any $p \geq 1$ and $n = \frac{1}{6}(5 \cdot 3^p - 3)$, there is a polynomial family of degree $n-1$ on $n^3 - n$ variables such that the family has linear size monotone circuits but require $n^{\log_2(n+1)}$ size monotone ABPs.*

For the separation, the n-th polynomial in the family is simply Collso_{X_n}, where X_n are the trees whose existence is guaranteed from Fact 2. See full version for a detailed proof.

We now show that there are pattern families that prove a super-polynomial separation between the size complexity of monotone circuits and monotone ABPs.

▶ **Theorem 21** (See [41, Theorem 3.2]). *For $n \geq 2$, there is a polynomial family of degree $n-1$ on $n^3 - n$ variables such that the family has linear size monotone ABPs but require $n^{\lceil \log_2(n+1) \rceil}$ size monotone formulas.*

The n-th polynomial in the family is simply Collso_{P_n}, the path on n vertices. See full version for a detailed proof.

4 Discussion

We note that our lower bounds for colored isomorphism polynomials also hold for *counting circuits* studied by Jukna [22]. Such circuits produce the same evaluation as arithmetic circuits when variables are substituted from $\{0, 1\}$. Informally, a counting circuit is an arithmetic circuit that computes a polynomial modulo the axiom $x^2 = x$. Note that this is sufficient for counting homomorphisms or colored isomorphisms. However, the counting circuit lower

bounds do not extend to the homomorphism polynomials since the reduction between the colored isomorphism polynomial and the homomorphism polynomial in Lemma 15 use partial derivatives.

Abstract

The problem of finding the largest induced balanced bipartite subgraph in a given graph is NP-hard. This problem is closely related to the problem of finding the smallest Odd Cycle Transversal.

In this work, we consider the following model of instances: starting with a set of vertices V, a set $S \subseteq V$ of k vertices is chosen and an arbitrary d-regular bipartite graph is added on it; edges between pairs of vertices in $S \times (V \setminus S)$ and $(V \setminus S) \times (V \setminus S)$ are added with probability p. Since for $d = 0$, the problem reduces to recovering a planted independent set, we don't expect efficient algorithms for $k = o\left(\sqrt{n}\right)$. This problem is a generalization of the planted balanced biclique problem where the bipartite graph induced on S is a complete bipartite graph; [46] gave an algorithm for recovering S in this problem when $k = \Omega\left(\sqrt{n}\right)$.

Our main result is an efficient algorithm that recovers (w.h.p.) the planted bipartite graph when $k = \Omega_p\left(\sqrt{n \log n}\right)$ for a large range of parameters. Our results also hold for a natural semi-random model of instances, which involve the presence of a monotone adversary. Our proof shows that a natural SDP relaxation for the problem is integral by constructing an appropriate solution to it's dual formulation. Our main technical contribution is a new approach for construction the dual solution where we calibrate the eigenvectors of the adjacency matrix to be the eigenvectors of the dual matrix. We believe that this approach may have applications to other recovery problems in semi-random models as well.

When $k = \Omega\left(\sqrt{n}\right)$, we give an algorithm for recovering S whose running time is exponential in the number of small eigenvalues in graph induced on S; this algorithm is based on subspace enumeration techniques due to the works of [42, 8, 41].

1 Introduction

Given a graph $G = (V, E)$, the problem of finding the largest induced bipartite subgraph of G is well known to be NP-hard [64]. The problem is equivalent to the Odd Cycle Transversal problem. The problem is also related to the balanced biclique problem, where the task is

that of finding the largest induced balanced complete bipartite subgraph. This problem has a lot of practical application in computational biology [19], bioinformatics [65] and VLSI design [7].

For the worst-case instance of the problem, the work [3] gives an algorithm that computes a set with at least $\left(1-\mathcal{O}\left(\varepsilon\sqrt{\log n}\right)\right)$ fraction of vertices which induces a bipartite graph, when it is promised that the graph contains an induced bipartite graph having $(1-\varepsilon)\,n$ fraction of the vertices. The work [32] gives an efficient randomized algorithm that computes an induced bipartite subgraph having $\left(1-\mathcal{O}\left(\sqrt{\varepsilon\log d}\right)\right)$ fraction of the vertices where d is the bound on the maximum degree of the graph. They also give a matching (up to constant factors) Unique Games hardness for certain regimes of parameters. We refer to Section 1.2 for more details about these related problems.

In an effort to better understand the complexity of various computationally intractable problems, a lot of work has been focused on the special cases of the problem, and towards studying the problem in various *random* and *semi-random* models. Here, one starts with solving the problem for random instances (for graph problems this is often $G_{n,p}$ Erdős-Rényi graphs[1]). The analysis in random instances is often much simpler, and one can give algorithms with "good" approximation guarantees. The next goal in this direction is to plant a solution that is "clearly optimal" in an ambient random graph and then attempt to recover this planted solution. We, therefore, build towards the worst-case instances of the problem by progressively weakening our assumptions. We refer to the book [59] for a more detailed discussion of these models in the context of other problems like planted clique, planted bisection, k-coloring, Stochastic Block Models, and Matrix completion problems.

We start our discussion with the problem of computing a maximum clique/independent set, since it has been extensively studied in such planted models. In the planted clique/independent set problem we plant a clique/independent set of size k in an otherwise random $G_{n,p}$ graph. The work [6] presents an algorithm, which, given a graph $G \sim \mathcal{G}(n,1/2)$ with a planted clique/independent set of size k, recovers the planted clique when $k > c_1\sqrt{n}$ (where c_1 is a constant). We will refer to the planted independent set/clique problem at various points throughout the introduction

Such *random planted models* have been studied in context of other problems as well such as the planted 3-coloring problem [14, 5], planted dense subgraph problem [34, 35, 36], planted bisection and planted Stochastic Block models [16, 22, 37, 17, 21, 2], to state a few. We define a similar *random planted model* to study our problem, as stated below.

▶ **Definition 1** (Random planted model)**.** *Given n, k, d, p, our planted bipartite graph is constructed as follows,*

1. *Let V be a set of n vertices. Fix an arbitrary subset $S \subset V$ such that $|S| = k$.*
2. *Add edges arbitrarily inside S such that the resulting graph is a connected d-regular bipartite graph. Let S_1, S_2 denote the bipartite components.*
3. *For each pair of vertices in $S \times (V \setminus S)$, add an edge independently with probability p.*
4. *For each pair of vertices in $(V \setminus S) \times (V \setminus S)$, add an edge independently with probability p.*

For planted cliques, a lot of work has been done in the special case of $p = 1/2$. However, people have studied other problems such as the planted bisection problems [24], and exact recovery problems in Stochastic Block Models [2] in the harder $p = o(1)$ regimes. Therefore, we also aim to solve our problem in $p = o(1)$ regimes.

[1] For each pair of vertices, an edge is added independently with probability p.

We note that this problem is a generalization of the planted independent set and the planted balanced biclique problem. For $d = 0$, it reduces to recovering a planted independent set and hence we do not expect efficient algorithms for $k = o(\sqrt{n})$ [28, 11]. For $k = \Omega(\sqrt{n})$, both these special cases i.e the planted independent set problem [6, 26], and the planted balanced biclique problem [46] admit a polynomial-time recovery algorithm. So it is natural to consider $k = \Omega(\sqrt{n})$ as a benchmark for recovery and look for algorithms in this regime. The other consideration for interesting regimes to study the problem comes by viewing this problem as a special case of the densest k-subgraph (DkS) problem. When $d \gg pk$, the problem can be viewed as the densest k-subgraph (DkS) and for $d \ll pk$, the problem can be viewed as sparsest k-subgraph problem (studying the complement of this graph would be an instance of DkS problem). However, this general DkS problem is information-theoretically unsolvable for $d = pk$ [18]. Formally, this follows from Theorem 2.1 in the work [18], by setting $d = qk = pk$ and setting $r = 1$ where q is the edge probability within the vertices of planted subgraph and a p is the edge probability when at least one of the vertex does not belong to the planted subgraph and r is the number of clusters. Therefore we focus our attention to the case when $d \approx pk$ (also including $d = pk$). In our problem, we can hope to use the specifics of the bipartite structure in hand and recover the planted set exactly.

1.1 Our models and results

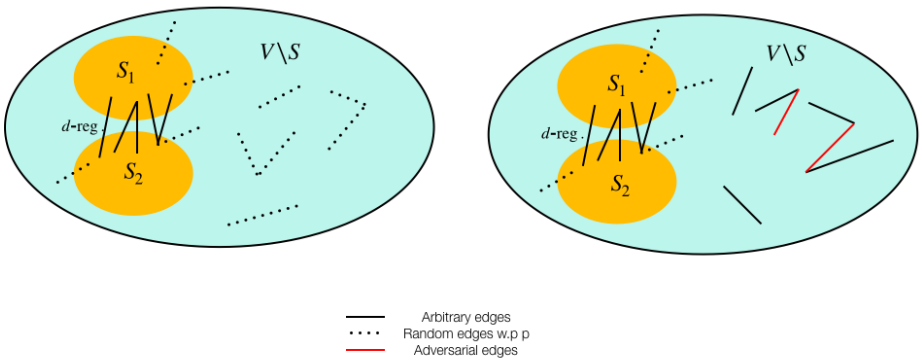

Figure 1 Random Planted model Definition 1 (left) and semi-random model Definition 2 (right).

We start by introducing our semi-random model which attempts to robustify the random planted model from Definition 1.

▶ **Definition 2** (Semi-random model). *Fix n, k, d, p, we now describe how a graph G from our semi-random model is generated,*

1. *Let V be a set of n vertices. Fix an arbitrary subset $S \subset V$ such that $|S| = k$.*
2. *Add edges arbitrarily inside S such that the resulting graph is a connected d-regular bipartite graph. Let S_1, S_2 denote the bipartite components.*
3. *For each pair of vertices in $S \times (V \setminus S)$, add an edge independently with probability p.*
4. *Arbitrarily add edges in $(V \setminus S) \times (V \setminus S)$ such that smallest eigenvalue of the matrix $\left(A_{(V\setminus S)\times(V\setminus S)} - p\mathbb{1}_{V\setminus S}\mathbb{1}_{V\setminus S}^T\right)$ is greater than $-((1/2-\alpha)/(1/2+\alpha))\,d$ where α is a small[2] positive constant (throughout this paper we assume $\alpha \leq 1/6$).*
5. *Allow a monotone adversary to add edges in $(V \setminus S) \times (V \setminus S)$ arbitrarily.*

[2] Note that the smaller the value of α, the weaker is this assumption.

▶ **Observation 3.** *Definition 2 also captures Definition 1; since in the case when $V \setminus S$ is chosen to be a $G_{(n-k),p}$ random graph, $\left(A_{(V\setminus S)\times(V\times S)} - p\mathbb{1}_{V\setminus S}\mathbb{1}_{V\setminus S}^T\right) = A_{(V\setminus S)\times(V\setminus S)} - \mathbb{E}\left[A_{(V\setminus S)\times(V\setminus S)}\right]$, and therefore the smallest eigenvalue of $\left(A_{(V\setminus S)\times(V\times S)} - p\mathbb{1}_{V\setminus S}\mathbb{1}_{V\setminus S}^T\right)$ is greater than $-2\sqrt{n}$ (as follows from the work [63]).*

Models stronger than *random planted models* have also been considered in the literature for planted problems. The work [26] studies the planted clique problem in what they call the "sandwich model". The model is constructed as per the random planted model in Definition 1, but an adversary is allowed to act on the top of that in a fashion similar to step 5 of Definition 2.

The work [24] introduced a strong adversarial *semi-random* model (referred to as the *Fiege and Kilian* model). They gave recovery algorithms for the planted clique ($k = \Omega(n)$ regimes) and for the planted bisection and planted k-coloring in this model. The work [54] further shows that one can recover the planted clique for $k = \Omega_p\left(n^{2/3}\right)$ [3] in [24] model.

In the Feige-Kilian model, step 4 allows for any arbitrary graph in $(V \setminus S) \times (V \setminus S)$. However, with no further assumptions on graph induced on $V \setminus S$, even for the special case of planted independent set problem ($d = 0$), the best known algorithm [54] works only for $k = \Omega_p\left(n^{2/3}\right)$. However, since our benchmark is $k = \Omega\left(\sqrt{n}\right)$, we look at a model with stronger assumptions than the Feige-Kilian model. In order to uniquely identify the planted graph, we need to assume that $V \setminus S$ is far from having any induced bipartite subgraphs of degree at least d. Our condition in step 4 implies that this indeed holds. This is because if the smallest eigenvalue is greater than $-d/2 + 2\sqrt{n}$, the graph is indeed far from having an induced bipartite subgraph of smallest degree d. Since otherwise, a vector having entries 1 for one side of the bipartition and -1 on the other side and 0 elsewhere achieves a Rayleigh Quotient of value $-d$ (and hence the smallest eigenvalue is at most $-d$).

We now present our main result which holds for both the random planted model (Definition 1) and semi-random model (Definition 2).

▶ **Theorem 4.** *For n, k, d, p satisfying $k = \Omega_p\left(\sqrt{n \log n}\right)$ and $p = \Omega\left(\log k/k\right)^{1/6}$ and $d \geq 2pk/3$, there exists a deterministic algorithm that takes as input an instance generated by Definition 2, and recovers the arbitrary planted set S exactly, in polynomial time and with high probability (over the randomness of the input).*

Achieving exact recovery for $k = \Omega_p\left(\sqrt{n}\right)$ is still an open problem. To the best of our knowledge, nothing is known about this problem in full generality. For the planted clique problem, recovery for $k = \Omega\left(\sqrt{n \log n}\right)$ is trivial [43]. However, such techniques don't work for our problem when $d = pk$. We prove Theorem 4 by showing that an SDP relaxation for the problem is integral, by constructing an optimal dual solution. We give an outline of the proof in Section 1.4. We leave the proof of a formal version of this theorem to the full version of the paper.

Our proofs use the spectral properties of bipartite graphs and random graphs to show the existence of an optimal dual solution having large rank. Our main technical contribution is a new approach for constructing a dual solution where we *calibrate the eigenvectors* of the adjacency matrix to be the eigenvectors of the dual matrix. We believe that this approach may have applications to other recovery problems in semi-random models as well.

[3] Ω_p hides $\mathsf{poly}\left(1/p\right)$ factors.

▶ **Theorem 5.** *For n, k, d, p, satisfying $k = \Omega_p(\sqrt{n})$, there exists a deterministic algorithm that takes as input an instance generated as per Definition 1, and recovers the arbitrary planted set S exactly with high probability (over the randomness of the input) in time exponential in the number of small eigenvalues of the adjacency matrix (eigenvalues smaller than $-d/2 + 2\sqrt{n}$) of the graph induced on S.*

We leave the proof of a formal version of this theorem to the full version of the paper.

▶ **Observation 6.** *For and many special classes of instances such as, (i) when the probability $p = \Omega(1)$, (ii) when the planted graph is a complete bipartite graph like in the balanced biclique problem (iii) when the planted bipartite graph is a d-regular random graph or (iv) more generally when the planted graph is a d-regular expander graph; the number of these small eigenvalues is a constant in the regimes of $d = \Omega(pk)$ and Theorem 5 allows efficient recovery (running time of the algorithm is polynomial in n).*

1.2 Related Work

Odd Cycle Transversal problem

The odd cycle transversal problem asks to find the smallest set of vertices in the graph such that the set has an intersection with every odd cycle of the graph. Removing these vertices will result in a bipartite graph, and hence this problem is equivalent to finding the largest induced bipartite graph. Owing to the hereditary nature of the bipartiteness property, the problem is NP-hard, as follows from the work of Yannakakis [64]. The work [64] shows that for a broad class of problems that have a structure that is hereditary on induced subgraphs, finding such a structure is NP-Complete. The optimal long code test by Khot and Bansal [10] rules out any constant factor approximation for this problem. On the algorithmic front, casting the problem as a 2-CNF deletion problem, [4] gives a reduction to the min-multicut problem. This reduction gives us an $\mathcal{O}(\log n)$ approximation due to the work [30], which was further improved to $\mathcal{O}\left(\sqrt{\log n}\right)$ in the work [3]. The work [32] gives an efficient randomized algorithm that removes only $\mathcal{O}\left(n\sqrt{\mathsf{OPT}\log d}\right)$ vertices where d is the bound on the maximum degree of the graph and OPT denotes the fraction of vertices in the optimal set. They also give a matching (up to constant factors) Unique Games hardness for certain regimes of parameters.

The problem is equivalent to finding the largest 2-colorable subgraph of a given graph and is known as the partial 2-coloring problem. The work [33] studies the problem in the Feige-Kilian semi-random model [24], where a 2-colorable graph of size $(1-\varepsilon)n$ is planted. They give an algorithm that outputs a set $\mathcal{S}'$ such that $|\mathcal{S}'| \geq \left(1 - \varepsilon c/p^2\right) n$ for $p = \Omega\left(\sqrt{\log n/n}\right)$ and $\varepsilon \leq p^2$ where c is a positive constant. Their algorithm is a partial recovery algorithm and works for the regimes when ε is small. Our results in Theorem 4 hold when $1-\varepsilon$ is small and give complete recovery for a large range of p. However, since our model in Definition 2 makes stronger assumptions than the [24] model, we don't make any comparisons.

Balanced Biclique problem

In the balanced complete bipartite subgraph problem (also called the balanced biclique problem), we are given a graph on n vertices and a parameter k, and the problem then asks whether there is a complete bipartite subgraph that is balanced with k vertices in each of the bipartite components. The problem was studied when the underlying graph is a bipartite graph, and shown to be NP-complete by a reduction from the CLIQUE problem in

the works [29, 38]. They additionally note that the balanced constraint is what makes the problem hard. If we remove the balanced constraint, the problem can be reduced to finding a maximum independent set in a bipartite graph. The latter problem admits a polynomial-time solution using the matching algorithm. The work [25] shows that this problem of finding a maximum balanced biclique is hard to approximate within a factor of $2^{(\log n)^{\delta}}$ for some $\delta > 0$, under the assumption that $\mathsf{3SAT} \notin \mathsf{DTIME}\left(2^{n^{3/4+\varepsilon}}\right)$ for some $\varepsilon > 0$. Recently, the work [53] showed that one cannot find a better approximation than $n^{1-\varepsilon}$, assuming the *Small Set Expansion Hypothesis* and that $\mathsf{NP} \nsubseteq \mathsf{BPP}$ for every constant $\varepsilon > 0$.

A related problem is the maximum edge biclique problem, where we are asked to find whether G contains a biclique with at least k edges. This problem was also shown to be NP-hard in the work [58].

Given these intractability results for general graphs, there has been some success in special classes of graphs. In graphs with constant arboricity, the work [23] gives a linear time algorithm that lists all maximal complete bipartite subgraphs. In a degree bounded graph, the work [60] gives a combinatorial algorithm for the balanced biclique problem that runs in time $\mathcal{O}\left(n2^{d}\right)$. Another systematic approach, however, is to consider planted and semi-random models for the problem. In the work [46], they study the planted version of the problem, which, they call "hidden biclique problem". Their model is similar to our model in Definition 1; however, we consider an arbitrary d-regular bipartite graph instead of a complete bipartite graph. They give a linear-time combinatorial algorithm that finds the planted hidden biclique with high probability (over the randomness of the input instance) for $k = \Omega\left(\sqrt{n}\right)$. Their algorithm builds on the "Low Degree Removal" algorithm, due to Feige and Ron [27] which finds a planted clique in linear time.

Graph problems in Semi-random and Pseudorandom models

A wide variety of random graph models and their relaxations have been a rich source of algorithmic problems on graphs. Alon and Kahale [5] sharpened the results of Blum and Spencer [14] and gave algorithms that recover a planted 3-coloring in a natural family of random 3-colorable instances. [44] extended this result and showed how to recover a 3-coloring when the input graph is pseudorandom (has some mild expansion properties) and is known to admit a random like 3-coloring. A unified spectral approach by McSherry [55] gives a single shot recovery algorithm for many problems in these random planted models. One can use the [55] framework to recover a planted random bipartite graph; however, it is not known if it will work if S is an arbitrary bipartite graph.

On the other side, we have semi-random models. Notably, the Feige-Kilian model [24] is one of the strongest semi-random models. In [24], they also give recovery algorithms for planted clique, planted k-colorable, and planted bisection problem in this model. In [54], they give a recovery algorithm for the independent set problem for large regimes of parameters. The work [40] generalizes these results to r-uniform hypergraphs in this model. There are other works [51, 52, 49, 50] that study graph partitioning in semi-random models.

A host of work has been done in various random and semi-random models for the more general densest k-subgraph problem. The works by Hajek, Wu, and Xu [34, 35, 36] study the problem when the planted dense subgraph is random and gives algorithms for exact recovery using SDP relaxations for some range of parameters. They complement these results by providing information-theoretic limits for regimes where recovery is impossible. The work by [13] studies this problem when the planted graph is arbitrary. They analyze an SDP-based method to distinguish the dense graphs from the family of $G_{n,p}$ graphs when $k \geq \sqrt{n}$. The work [39] studies the problem of densest k-subgraph in some semi-random model and gives a partial recovery algorithm for some regimes of d, k, n, p.

SDP has been the tool of choice for exact recovery in semi-random models. Starting from the fundamental works of exact recovery for the planted clique problem [26], for the planted bisection problem [24], for Stochastic Block Models [2] etc., (and many other works as have been mentioned above), are based on SDP relaxations. A natural way to analyze these SDP relaxations is by constructing an optimal dual solution to prove integrality of the primal relaxation. This idea has been explored in the works of [24, 20, 13, 1, 2, 49], to state a few. We note that the task of constructing an optimal dual solution is problem-specific, and there is no generic way of doing this.

1.3 Preliminaries

We start with some essential notation to understand the proof overview and review some well-known facts about random perturbation matrices. Then, we write our SDP relaxation to the problem and the accompanying dual SDP. We follow this up with a discussion on some well known tools from spectral graph theory such as the *threshold rank* and *spectral embedding*. We will build on these ideas in our Proof Overview Section 1.4 to show that the primal SDP is an optimal one and the primal matrix is a rank-one matrix.

1.3.1 Notation

We let $[M]_{n\times n}$ denote a matrix M of size $n \times n$. For some set of indices $R_1, R_2 \subseteq [n]$, $M_{R_1\times R_2}$ denotes a matrix of size $n \times n$ constructed out of matrix M of size $n \times n$ by copying the entries for $(i, j) \in R_1 \times R_2$ and setting rest of the entries to be 0. We let $M|_{R_1\times R_2}$ denote the matrix of size $|R_1| \times |R_2|$ constructed from a matrix M of size $n \times n$ by taking rows corresponding to R_1 and columns corresponding to R_2. The eigenvalues of a matrix M are sorted as $\lambda_1(M) \leq \lambda_2(M) \leq \ldots \leq \lambda_n(M)$. We will drop the matrix M wherever it is clear from the context. The eigenvectors are also sorted by their corresponding eigenvalues.

1.3.2 Spectral bounds on Perturbation matrices

We let A denote the adjacency matrix of the graph obtained using Definition 1. We can express the matrix A as sum of "simpler" matrices,

$$A = A_{S\times S} + A_{V\setminus S\times V\setminus S} + p\left(\mathbb{1}\mathbb{1}^T - \mathbb{1}_S\mathbb{1}_S^T - \mathbb{1}_{V\setminus S}\mathbb{1}_{V\setminus S}^T\right) + R \quad \left(R_{ij} \stackrel{\text{def}}{=} A_{ij} - \mathbb{E}[A_{ij}]\right) \tag{1}$$

where $A_{S\times S}$ represents the matrix corresponding to the planted bipartite graph, the term $p\left(\mathbb{1}\mathbb{1}^T - \mathbb{1}_S\mathbb{1}_S^T - \mathbb{1}_{V\setminus S}\mathbb{1}_{V\setminus S}^T\right)$ is the expected adjacency matrix for the random graph and R as defined above is the perturbation matrix corresponding to the random part of the graph.

▶ **Proposition 7.** *For the perturbation matrix R as defined in equation* (1) *we have that $\|R\| \leq 2\sqrt{n}$ almost surely.*

Proof. R is a symmetric random matrix and the entries R_{ij} can be treated as random variables, bounded between -1 and 1, with expectation 0 and variance $p(1-p) \leq 1/4$. Also the entries R_{ij} are independent and hence, by Theorem 1.1 in the work [63], we have $\|R\| \leq 2\sqrt{n}$ almost surely. ◀

1.3.3 SDP Relaxation

Our main results are based on analyzing the following SDP relaxation SDP 8. We construct its dual SDP 9.

▶ **SDP 8** (Primal).

$$\min \sum_{\{i,j\}\in E} 2\langle \mathbf{x}_i, \mathbf{x}_j\rangle$$

subject to

$$\sum_{i\in V} \|\mathbf{x}_i\|^2 = 1 \tag{2}$$

$$\|\mathbf{x}_i\|^2 \le 1/k \qquad \forall i \in V \tag{3}$$

$$\langle \mathbf{x}_i, \mathbf{x}_j\rangle \le 0 \qquad \forall \{i,j\} \in E\,. \tag{4}$$

▶ **SDP 9** (Dual).

$$\max\ \beta - \sum_{i\in V} \gamma_i$$

subject to

$$Y = A - \beta I + k\sum_{i\in V} \gamma_i D_i + \sum_{\{i,j\}\in E} B_{ij}\left(\mathbb{1}_{ij} + \mathbb{1}_{ji}\right) \tag{5}$$

$$B_{ij} \ge 0, \qquad \forall \{i,j\} \in E \tag{6}$$

$$Y \succeq 0\,. \tag{7}$$

In SDP 9, the Lagrange multipliers β_i's,γ_i's and B_{ij}'s are our dual variables and Y is the dual SDP matrix. By $\mathbb{1}_{ij}$ we mean an indicator matrix which is one for (i,j) entry and zero elsewhere. Similarly, D_i is an indicator matrix which is one for (i,i) entry and zero elsewhere. For clarity, we will denote $\sum_{\{i,j\}\in E} B_{ij}\left(\mathbb{1}_{ij} + \mathbb{1}_{ji}\right)$ by a matrix B.

Intended solution

We denote the primal SDP matrix by X and let $\mathbf{x}_i$ denote the vector corresponding to vertex i such that $X_{ij} = \langle \mathbf{x}_i, \mathbf{x}_j\rangle$.

Our intended integral solution to the SDP is $X = \mathbf{g}\mathbf{g}^T$, where $\mathbf{g} \in \mathbb{R}^n$ s.t $g_i = 1/\sqrt{k}$ for $i \in S_1$, $g_i = -1/\sqrt{k}$ for $i \in S_2$ and 0 otherwise. This solution is obtained by setting,

$$\mathbf{x}_i^* = \begin{cases} \hat{e}/\sqrt{k} & \text{if } i \in S_1 \\ -\hat{e}/\sqrt{k} & \text{if } i \in S_2 \\ 0 & \text{otherwise,} \end{cases} \tag{8}$$

where $\hat{e}$ is some unit vector.

Weak Duality for fixing dual variables

Let $\mathsf{SDPOPT}(G)$ denote the optimal value of the primal SDP; then from the proposed integral solution we have that,

$$\mathsf{SDPOPT}(G) \le -2\sum_{\{i,j\}\in E} \left\langle \mathbf{x}_i^*, \mathbf{x}_j^*\right\rangle = \left\langle A, \mathbf{g}\mathbf{g}^T\right\rangle = \mathbf{g}^T A\mathbf{g} = -d\,.$$

For any feasible solution to the dual SDP 9, by weak duality, we know that

$$\beta - \sum_{i\in V} \gamma_i \le \mathsf{SDPOPT}(G) \le -d\,.$$

We note that the upper bound is achievable by setting $\beta = -d$ and $\gamma_i = 0, \forall i \in V$.

We will show later that the remaining dual variables B_{ij}'s can be chosen in a way that the choice of $\beta = -d$ and $\gamma_i = 0, \forall i \in V$ yields a feasible dual solution.

▶ **Fact 10** (Folklore, also see Lemma 2.3 in [49]). *The primal solution $X = \mathbf{g}\mathbf{g}^T$ is the unique solution to SDP 8 if there exists a dual matrix Y such that it satisfies constraints in SDP 9, with $\beta = -d$ and $\gamma_i = 0, \forall i \in V$ and having* $\mathsf{rank}(Y) = n - 1$ *(i.e. $\lambda_2(Y) > 0$).*

1.3.4 Threshold rank eigenvectors

▶ **Definition 11** (Threshold rank of a graph). *For $\tau \in [0, d]$, we define threshold rank of a graph with adjacency matrix G (denoted by* $\mathsf{rank}_{\leq -\tau}(G)$*) as,*

$$\mathsf{rank}_{\leq -\tau}(G) = |\{i : \lambda_i(G) \leq -\tau\}| \ .$$

We let $P_{-\tau} = \left\{\mathbf{v}^{(1)}, \mathbf{v}^{(2)}, \ldots, \mathbf{v}^{(L_{-\tau})}\right\}$ (the bottom $L_{-\tau}$ vectors) denote the set of orthonormal eigenvectors of $A|_{S\times S}$ with eigenvalues smaller than the threshold $-\tau$, breaking ties arbitrarily where $L_{-\tau} = \mathsf{rank}_{\leq -\tau}\left(A|_{S\times S}\right)$. We call these vectors as *τ-threshold rank eigenvectors* of $A|_{S\times S}$. Next, we recall a well known fact about the threshold rank of a graph.

▶ **Fact 12** (Folklore). $\mathsf{rank}_{\leq -\tau}\left(A|_{S\times S}\right) \leq \dfrac{kd}{2\tau^2}$.

Proof. Since, $A|_{S\times S}$ is the adjacency matrix of a bipartite graph, it's eigenvalue spectrum is symmetric around 0. Therefore the number of eigenvalues with absolute value greater then or equal to τ is given by $2\,\mathsf{rank}_{\leq -\tau}\left(A|_{S\times S}\right)$ and are bounded as,

$$2\tau^2 \mathsf{rank}_{\leq -\tau}(A|_{S\times S}) \leq \sum_i \lambda_i^2(A|_{S\times S}) \leq \left\|A|_{S\times S}\right\|_F^2 = kd. \qquad \blacktriangleleft$$

We note that a similar notion of threshold rank has appeared in other works [8, 9, 12, 31] etc.

1.3.5 Spectral embedding vectors

▶ **Definition 13** (Spectral embedding vectors). *Given the planted bipartite graph S and the matrix of bottom $L_{-\tau}$ orthonormal eigenvectors $W_{-\tau}^T = \begin{bmatrix}\mathbf{v}^{(1)} & \mathbf{v}^{(2)} & \ldots & \mathbf{v}^{(L_{-\tau})}\end{bmatrix}$, we define the spectral embedding of a vertex $i \in S$ as the $L_{-\tau}$-dimensional vector given by $\mathbf{w}^{(i)} = W_{-\tau}\mathbf{e}_i$ where $\mathbf{e}_i$ is a vector with one in the i^{th} coordinate and zero elsewhere.*

Informally, these are the vectors obtained by looking at the subspace of the columns of $W_{-\tau}^T$ where the vertex i is mapped to the i^{th} column of $W_{-\tau}^T$. These spectral embedding vectors have been explored in various works on graph partitioning as [57, 45, 48] etc. It is known that these spectral embedding vectors are "well spread", formally referred to as being in an isotropic[4] position. We define these set of vectors to be in an isotropic position if $\sum_{i\in S}\mathbf{w}^{(i)} = 0$ and $\sum_{i\in S}\mathbf{w}^{(i)}\mathbf{w}^{(i)^T} = I$ where I is an $L_{-\tau}\times L_{-\tau}$ sized identity matrix. The condition that $\sum_{i\in S}\mathbf{w}^{(i)}\mathbf{w}^{(i)^T} = I$ can equivalently be written as $\sum_{i\in S}\left\langle \mathbf{y}, \mathbf{w}^{(i)}\right\rangle^2 = 1, \forall \mathbf{y}$ with $\|\mathbf{y}\|_2 = 1$.

▶ **Lemma 14** (Folklore). *The spectral embedding vectors are in an isotropic position.*

For a proof, we refer the reader to the work [47].

[4] Typically, isotropicity is a property of distribution. We say a distribution is isotropic if the mean of a random variable sampled from the distribution is zero and it's covariance matrix is an identity matrix.

1.4 Proof Overview

For the sake of simplicity, we will assume that the graph is sampled as per the random planted model (Definition 1). We will also allow an action of a monotone adversary (as in step 5) on this model; but we analyze its action separately (in Section 1.4.6). The main ideas for the semi-random model (Definition 2) are essentially the same, and the additional steps to handle them is just a technical adjustment.

In this section we give an overview of how Theorem 4 and Theorem 5 are proven. Because of page limits, the detailed proofs are deferred to the full version of the paper. In what follows, we present the main ideas which go inside these proofs.

1.4.1 Spectral Approaches

We start with some natural spectral approaches for recovering the planted set. These approaches have found some success, e.g. in recovering planted cliques/independent sets, planted bisection, planted k-colorable graphs (refer work [55] for details). We recall from our earlier discussion, that the interesting regimes for this problem are $k = \Omega(\sqrt{n})$ and $d \approx pk$.

Detecting planted bipartitions and why it is easy

We note that the *detection problem* i.e. detecting the presence of bipartite graph as constructed in the random planted model (Definition 1) against the null hypothesis of Erdős-Rényi graph $G_{n,p}$, is easy when $k = \Omega(\sqrt{n})$. Formally one notes that given two distributions

$$H_0 : G \sim G(n,p) \text{ against } H_1 : G \sim G(n,k,d,p) \text{ as per Definition 1,}$$

the spectral test, which outputs H_1 when $\lambda_1(G) \leq -d$ and H_0 otherwise, is correct almost surely for $d \approx pk$ and $k \geq c\sqrt{n}/p$ where $c > 0$ is a large enough constant. This is because for a $G_{n,p}$ graph, the smallest eigenvalue is greater than $-2\sqrt{n}$ almost surely (Claim 7), while for a graph with planted bipartite subgraph, the smallest eigenvalue is smaller than $-d$ since the vector $\mathbb{1}_{S_1} - \mathbb{1}_{S_2}$ already achieves Rayleigh Quotient of value $-d$.

The challenges in exact recovery

However, as expected, the exact recovery problem is more challenging. There are some works that look at these planted problems on an individual basis ([15],[6]). They typically rely on the spectral bounds of perturbation matrices and the framework of Davis-Kahan theorem (refer [61]) to identify eigenvector(s) indicating the planted set. However, we need a sufficient eigengap[5] to apply these results from perturbation theory. Since our planted graph S in the random planted model is an arbitrary bipartite graph, it can have any number of eigenvalues close to the smallest eigenvalue $-d$ and hence we may not have such an eigengap.

A unified spectral framework for random planted models was given by McSherry [55] (further refined in the work [62]). Here, one can check that we cannot satisfy the conditions in Observation 11 of this work [55] if the planted set has size $o(n)$. Again, the reason is because the planted bipartite graph is arbitrary. Since the planted bipartite graph can have arbitrary rank we cannot get the constants γ_1 in [55] to be small enough to recover in $o(n)$ regimes. It is also easy to verify that this framework works if the planted bipartite graph is also a random graph, for regimes of $k = \Omega(\sqrt{n})$ and $d \approx pk$ (say by choosing edge probability for the random planted bipartite graph as $p' = 2p$).

[5] Typically around the bottom eigenvector(s) or the top eigenvector(s).

A subspace enumeration style approach

Another spectral approach, inspired from the works of [42, 8, 41, 44] is to apply the *subspace enumeration* technique to recover a large fraction of planted set S. Here we first identify that the vector $\mathbf{u} = \mathbb{1}_{S_1} - \mathbb{1}_{S_2}$ has a large projection on the space spanned by τ'-threshold rank eigenvectors of A (for choice of $\tau' = d/2$). Note that this vector $\mathbf{u}$ identifies the planted set (as well as the planted bipartition), and therefore we call it the *signed indicator vector*. We then do a standard ε-net construction to find a vector $\mathbf{y}$ close to $\mathbf{u}$ and use $\mathbf{y}$ to recover a large fraction of planted set S. We can recover the remaining set of vertices by an argument due to the work [33], where they distinguish vertices by the size of matching in induced neighborhoods. Putting all this together, we can prove Theorem 5.

The running time of the procedure described above is exponential in $L_{-\tau}$ where $L_{-\tau} = \mathcal{O}(1/p)$ for $\tau = \Omega(d)$ (follows from Fact 12). Therefore, for many special classes of instances such as, (i) when the probability $p = \Omega(1)$ and $d = \Omega(pk)$, (ii) when the planted graph is a complete bipartite graph (this is the balanced biclique problem) and $d = \Omega(pk)$, (iii) when the planted bipartite graph is d-regular random graph for $d = \Omega(pk)$ or (iv) more generally when the planted graph is a d-regular expander graph for $d = \Omega(pk)$ we have $L_{-\tau} = \mathcal{O}(1)$ and this already gives us a polynomial-time algorithm.

However, as stated earlier, we want to solve the problem in $p = o(1)$ regimes. To accomplish this, we shift our focus to the SDP formulation we mentioned in SDP 8. Also, for other problems in this literature (planted clique, planted bisection, planted k-colorable, Stochastic Block models etc), only SDP's have provable guarantees of working in the presence of such monotone adversaries (refer Chapter 10 in [59] for more intuition on this).

1.4.2 Traditional SDP Analysis

Now we overview our SDP-based approach to solving the problem. We will see that the difficulties in the spectral approach will translate to showing the feasibility of the dual SDP solution. However, we have more freedom here since we have the dual variables to work with and we can use them and try to enforce the optimality of the dual solution.

Characterizing dual variables through optimality conditions

A standard technique for analyzing SDP relaxations (like our SDP 8) is to show optimality by constructing a dual solution that matches the $\mathsf{SDPOPT}(G)$ value of the primal in a manner that the dual matrix Y is positive semi-definite and has rank $n-1$, (see Fact 10).

These impose a "wish list" of desired conditions, which can be used to characterize our dual variables

1. $\beta = -d$ (Optimal objective)
2. $\langle \mathbf{g}\mathbf{g}^T, Y \rangle = 0$ (Complementary slackness)
3. $Y \succeq 0$ (Dual feasibility)
4. $\lambda_2(Y) > 0$ (Strong duality).

Using weak duality we set $\beta = -d$ and $\gamma_i = 0, \forall i \in V$ to match the optimal primal objective value of $\mathsf{SDPOPT} = -d$. We expand upon the complementary slackness condition as,

$$\langle \mathbf{g}\mathbf{g}^T, Y \rangle = \mathbf{g}^T Y \mathbf{g} = \mathbf{g}^T (A + dI)\mathbf{g} + \mathbf{g}^T B \mathbf{g} = 0 + \mathbf{g}^T B \mathbf{g} = \mathbf{g}^T B \mathbf{g}.$$

Therefore the complementary slackness condition gives us that,

$$\sum_{i \in S} \sum_{\substack{j \in S \\ \{i,j\} \in E}} B_{ij} = 0 \tag{9}$$

and since the SDP dual requires that $B_{ij} \geq 0$, it implies that $B_{ij} = 0$ for all $(i, j) \in E(S_1, S_2)$. Now using the characterization of dual variables from conditions (1) and (2), one tries to show the feasibility of the dual and the strong duality rank condition. Typically, this characterization turns out to be rather weak. So, we refer to the dual variables set so far (ensuring condition (1) and (2) are satisfied) as *weakly characterized*.

Showing optimality of dual solution through weakly characterized dual variables

For certain problems in semi-random models, such as the planted clique problem [26], community detection in SBM [2], the weak characterization above suffices. We are able to show that the weakly characterized dual solution satisfies conditions (3) and (4). This is typically done by invoking some standard results for random matrix bounds and concentration inequalities. In our setup, satisfying condition (3) requires that

$$\lambda_{\min}(Y) \geq 0 \text{ which is implied if } \lambda_{\min}(A) + d + \lambda_{\min}(B) = \lambda_{\min}(A) + d \geq 0\,. \tag{10}$$

However, in our random planted model, the smallest eigenvalue of A can be smaller than $-d - 2\sqrt{pn}$ and condition (3) may not hold (as per choice of B_{ij}'s dictated from equation (9)). Thus we need a stronger characterization of dual variables to satisfy the conditions (3) and (4). In our problem, we need to make use of the large number of unused dual variables $B'_{ij}s$ for $\{i, j\} \in E \cap \{(V \times V) \setminus (S \times S)\}$

Guessing/Constructing the dual certificate

Now we discuss an approach of making the dual matrix satisfy conditions (3) and (4) by guessing the dual variables thus giving an explicit setting of dual variables. This is typically done by assigning some sort of meaning to dual variables and guessing their values based on the input instance. This approach has found reasonable success in other recovery problems like the planted bisection problem [24], coloring semi-random graphs [20], decoding binary node labels from censored edge measurements [1], and planted sparse vertex cuts [49].

Therefore, we may expect to guess a nice setting of dual variables that satisfy equation (10). However, if one takes a deeper look at this approach, the task again reduces to applying results from perturbation theory. Again, such an approach would work if the planted bipartite graph were also a random graph or an expander, since there would only be a single eigenvector whose corresponding eigenvalue disobeys equation (10), and one could choose the dual variables constructively to handle it and make it satisfy condition (3).

However, for an arbitrary planted bipartite graph, we can have a lot of eigenvalues in the interval $[-d, -d - 2\sqrt{n}]$ (and hence the entire graph A can have a lot of eigenvalues in the interval $[-d - 2\sqrt{n}, -d]$). Therefore, we need a more principled approach to deal with the corresponding eigenvectors of the planted graph having eigenvalue close to $-d$ (as we pointed out earlier, there can be $\mathcal{O}(1/p)$ such eigenvectors).

1.4.3 Calibrating the eigenvectors

Now we present our approach towards satisfying conditions (3) and (4), which is to *calibrate the eigenvectors*. We will see that, this calibration will further complicate our requirements on the dual variables, however we will argue in Section 1.4.4 on how we manage that.

Obtaining optimality of Primal SDP by assuming existence of a certifying B

It is now clear that our Achilles' heel are the eigenvalues (and corresponding threshold rank eigenvectors[6]) of the planted graph in the interval $[-d, -d - 2\sqrt{n}]$. If we were allowed to ignore these vectors it's easy to see that equation (10) and hence condition (3) holds.

Our core idea is to extend (by padding with 0's so that they are the right length) the threshold rank eigenvectors of $A|_{S\times S}$ to be the eigenvectors of the dual matrix Y. Recall, the eigenvalues of $A|_{S\times S}$ lie in the interval $[-d, d]$. Now take a threshold rank eigenvector of $A|_{S\times S}$ (say with eigenvalue λ_l). We wish to calibrate such a threshold rank eigenvector to be an eigenvector of Y with eigenvalue $d + \lambda_l$. If we are able to achieve this calibration, we need not bother about the $2\sqrt{n}$ term since now these eigenvectors have a non-negative quadratic form[7].

The only thing at our disposal for this calibration are the unused (so far) dual variables B_{ij}'s. Denote this set of threshold rank eigenvectors of $A|_{S\times S}$ as $P_{-\tau}$. Given this set $P_{-\tau}$, achieving this calibration can be expressed as satisfying the system of equations,

$$\sum_{i\in S} \mathbf{v}_i^{(l)} \left(A_{ij} + B_{ij}\right) = 0, \quad \forall j \in V \setminus S, \forall\, \mathbf{v}^{(l)} \in P_{-\tau}\,. \tag{11}$$

- L different system of equations $\mathcal{E}_l$, one for each $\mathbf{v}^{(l)}$.
- Each system $\mathcal{E}_l$ involves $|S| \times |V \setminus S|$ variables B_{ij} where $i \in S$ and $j \in V \setminus S$.

Now, all we need is a setting of B_{ij}'s such that the system of equations is satisfied. However, this will still not be enough. We note that if this system of equations were to have a solution, we would have set some of these B_{ij} variables to non-zero values. Therefore our equation (10) would now need to be modified to showing that $\lambda_{\min}(A) + d + \lambda_{\min}(B) \geq 0$.

The way we deal with this is by noting that we can tune $\tau > 0$ apriori to be sufficiently large for this calibration such that $\lambda_{\min}(A) + d \geq \eta$ where $\eta > 0$; and now impose an additional constraint on the matrix of dual variables that $\|B\| \leq \eta$. At this point, it seems highly suspicious as whether such B_{ij}'s exist. However, if we table these considerations aside and for choice of $\tau = 2d/3$ and $\eta = \tilde{\mathcal{O}}(pk)$ we can indeed show that condition (3) and condition (4) of our "wish list" are met and we get the desired integral primal solution.

1.4.4 Setting of dual variables

In this section we show that there exists a matrix of non-negative dual variables B_{ij}'s that satisfies the system of equations (11) and $\|B\|_2 = \tilde{\mathcal{O}}(pk)$.

An LP formulation and Farkas Lemma based approach

We start by observing that the condition $\|B\|_2 = \tilde{\mathcal{O}}(pk)$ is implied by a condition that $B_{ij} \leq t = \mathcal{O}_p\left(\sqrt{\log k/k}\right), \forall (i,j) \in (S \times (V \setminus S)) \cup ((V \setminus S) \times S)$. Also, since these system of equations (11) only concerns the non-negative dual variables B_{ij}'s with $\{i,j\} \in (S \times (V \setminus S)) \cup ((V \setminus S) \times S)$, we set the rest of them to 0.

[6] For an appropriate choice of τ, which we decide later, these will be the threshold rank eigenvectors.
[7] The quadratic form of vector $\mathbf{x}$ with a matrix Y is a number given by $\mathbf{x}^T Y \mathbf{x}$

We now reorganize our collection of linear systems in (11) as follows.

- For $j \in V \setminus S$, define a system of equations $\mathcal{F}_j$.
- In all, this gives a collection of systems $\{\mathcal{F}_j\}_{j \in V \setminus S}$. Each system contains $L_{-\tau} \times |S|$ variables. In particular, the system $\mathcal{F}_j$ is expressed in the standard form $W_{-\tau}\mathbf{x} = \mathbf{b}$, where $W_{-\tau} \in \mathbb{R}^{L_{-\tau} \times k}$ is a matrix formed by stacking the vectors $\mathbf{v}^{(l)} \in P_{-\tau}$ as rows.

Fix $j \in V \setminus S$ and consider the system $\mathcal{F}_j$. The vector $\mathbf{b}$ in this system is a row vector of size $L_{-\tau} \times 1$ and has entries given by $b_l = -\sum_{i \in S} A_{ij} v_i^{(l)}, \forall l \in [L_{-\tau}]$ and $\mathbf{x}$ here is a row vector of size $k \times 1$ where the entry $x_i = B_{ij}$ (recall that we have fixed a $j \in V \setminus S$). However since B_{ij}'s are not arbitrary variables but dual variables of SDP 9, these are required to be non-negative and should only be defined for $i \in N(j)$. Since the graph on $S \times (V \setminus S)$ is random, the choice of random edges while choosing $N(j)$ (in model construction) corresponds to setting those $B_{ij} = 0$ whenever the edge is not chosen. Let $\tilde{W}_{-\tau}$ denote the submatrix after removing the columns corresponding to $i \notin N(j)$ and recall t is our upper bound on the entries of B matrix as mentioned above. We then consider the following feasibility LP formulation for this problem of finding appropriate B_{ij}'s.

▶ **LP 15.**

$$\tilde{W}_{-\tau}\mathbf{x} = \mathbf{b} \tag{12}$$

$$0 \le \mathbf{x} \le t\mathbb{1}\,. \tag{13}$$

For simplicity, consider the case $p = 1$, i.e. when $A_{ij} = 1$ for all $i \in S, j \notin S$. Then we have that for any vector $\mathbf{y} \in \mathbb{R}^{L_{-\tau}}$,

$$\mathbf{b}^T\mathbf{y} = \sum_{r \in [L_{-\tau}]} b_r y_r = -\sum_{r \in [L_{-\tau}]} \sum_{i \in S} v_i^{(r)} y_r = -\sum_{i \in S} \sum_{r \in [L_{-\tau}]} v_i^{(r)} y_r \tag{14}$$

$$= -\sum_{i \in S} \sum_{r \in [L_{-\tau}]} w_r^{(i)} y_r = -\sum_{i \in S} \left\langle \mathbf{w}^{(i)}, y \right\rangle = -\left\langle \sum_{i \in S} \mathbf{w}^{(i)}, \mathbf{y} \right\rangle = 0\,. \tag{15}$$

Using the standard variant of Farkas' Lemma, this immediately implies the existence of a solution to equation (11). However, in general, for $p < 1$, we need to do more work here.

We apply a more general version of Farkas' Lemma, and we have that satisfying this LP in the general case corresponds to showing that for some $t > 0$, the following holds.

$$\forall\, \mathbf{y} \in \mathbb{R}^{L_{-\tau}}, \forall\, \mathbf{z} \ge 0,\ \tilde{W}_{-\tau}^T\mathbf{y} + \mathbf{z} \ge 0 \implies \mathbf{b}^T\mathbf{y} + t\,\langle \mathbf{z}, \mathbb{1} \rangle \ge 0\,. \tag{16}$$

The first term in the expression, $\mathbf{b}^T\mathbf{y}$, can be expanded as in equation (14) to obtain

$$\mathbf{b}^T\mathbf{y} = -\sum_{i \in N(j)} \left\langle \mathbf{w}^{(i)}, \mathbf{y} \right\rangle \text{ and using } \left(\tilde{W}_{-\tau}^T\mathbf{y}\right)_i = \left\langle \mathbf{w}^{(i)}, \mathbf{y} \right\rangle \text{ we have } z_i \ge -\left\langle \mathbf{w}^{(i)}, \mathbf{y} \right\rangle.$$

We can give a proof by contradiction for equation (16). By contradiction there exists a $\mathbf{y}$ and a $\mathbf{z}$ such that $\mathbf{b}^T\mathbf{y} + t\,\langle \mathbf{z}, \mathbb{1} \rangle < 0$. We choose $\mathbf{z}' \le \mathbf{z}$ by setting $z_i' = \max\left\{0, -\left\langle \mathbf{w}^{(i)} \right\rangle, \mathbf{y}\right\}$ and argue that it is enough to show contradiction for $t, \mathbf{y}$ and $\mathbf{z}'$. Using the expressions for $\mathbf{b}^T\mathbf{y}$ as above, this translates to showing that

$$\sum_{i \in N(j)} \left\langle \mathbf{w}^{(i)}, \mathbf{y} \right\rangle + t \sum_{i \in N(j)} \min\left\{0, \left\langle \mathbf{w}^{(i)}, \mathbf{y} \right\rangle\right\} > 0, \tag{17}$$

has no solution. We show that equation (17) does not hold for our desired choice of $t = \mathcal{O}_p\left(\sqrt{\log k/k}\right)$.

We note that the second term in equation (17) is ≥ 0, and we wish the inequality to not hold for as small a value of t as possible; therefore, we seek an upper bound on both terms.

Structure of threshold rank/spectral embedding vectors

To upper bound the first term, it might be helpful to understand the structure of the spectral embedding vectors $\mathbf{w}^{(i)}$. Since these are intimately connected to the threshold rank eigenvectors $\mathbf{v}^{(l)}$, we use these eigenvectors to characterize them. For convenience we let $\mathbf{v}^{(l)} \in P_{-\tau}$ have unit norm, then we show that $\left\|\mathbf{v}^{(l)}\right\|_\infty = \left\|\mathbf{w}^{(i)}\right\|_\infty \leq 2/\sqrt{d}$. Since $i \in N(j)$ are sampled randomly, we can use the Hoeffding bounds to upper bound the l_∞ norm for $\sum_{i\in N(j)} \mathbf{w}^{(i)}$ and hence upper bound our first term by $\mathcal{O}_p\left(\sqrt{\log k}\right)$ with high probability. We choose our parameters such that the vectors in $P_{-\tau}$ are orthogonal to $\mathbb{1}_S$. For the embedding vectors, this translates to saying that $\sum_{i\in S} \mathbf{w}^{(i)} = 0$.

Towards bounding the second term, we use these *spectral embedding vectors*. The spectral embedding vectors are isotropic for $p = 1$ (already where we can easily show that equation (17) does not hold and we are done). However, for $p < 1$, we have $i \in N(j)$ (and corresponding embedding vectors) being sampled randomly as per $G_{n,p}$ distribution. Here, we show that by using Matrix Bernstein concentration we can get close to isotropic vectors,

$$\sum_{i\in N(j)} \left\langle \mathbf{y}, \mathbf{w}^{(i)} \right\rangle^2 \geq p/2 \quad \text{(This shows that embedding vectors are } p/2\text{-isotropic .)} \tag{18}$$

Showing existence of a solution to LP 15

Now, we look at two cases; the first case where the negative terms dominate the summand in equation (17), then we use the eigenvector structure that $\left\|\mathbf{w}^{(i)}\right\| \leq 2/\sqrt{d}$ and we are done; for the other case where the positive terms dominate, we relate the positive terms to the negative terms again using the bound we obtained from the eigenvector structure $\left\|\sum_{i\in N(j)} \mathbf{w}^{(i)}\right\| = \mathcal{O}_p\left(\sqrt{\log k}\right)$.

Therefore, we argue that we can upper bound the second term by $-\Omega_p\left(\sqrt{k}\right)$. Therefore for a choice of t as we obtained above of $t = \mathcal{O}_p\left(\sqrt{\log k/k}\right)$, equation (17) does not hold. As discussed earlier this implies that the there exists a dual such that conditions (1)-(4), equation (11) and $\|B\|_2 = \tilde{\mathcal{O}}\left(pk\right)$ holds which further implies that the primal SDP is feasible. Further, if the graph is connected; the *signed indicator vector* would be the only eigenvector with eigenvalue $-d$ (after padding to make these the eigenvectors of Y), this would be the only eigenvector of Y with eigenvalue 0. Using Fact 10, this implies that the proposed integral solution in equation (8) is the only integral solution and hence Cholesky Decomposition of our SDP matrix returns the *signed indicator vector* and thus our planted set.

1.4.5 Low degree regimes

The discussion above about SDP holds only where $d = \gamma pk$ where $\gamma \geq 2/3$. Note that this covers our interesting regimes when $d \approx pk$ where the problem is non-trivial. The other case where $d \leq 2pk/3$, can actually be trivially solved for $k = \Omega_p\left(\sqrt{n \log n}\right)$ using a degree counting argument along the lines of [43] as we discuss below.

Now we consider the regimes when $d = \gamma pk$ with $\gamma \leq 2/3$. We show that a simple algorithm that collects the bottom k degrees of the graph will work in these regimes since the vertices in S will have smaller degrees compared to vertices in $V \setminus S$.

▶ **Lemma 16.** *For $k \geq 6\sqrt{6n \log n/p}$, Algorithm 1 returns the planted set S with high probability (over the randomness of the input).*

Algorithm 1 Kucera's algorithm for recovery in low degree regimes.

Input: $G = (V, E)$, sampled as per Definition 1 with adversary as per step 5.
Output: The set of vertices in planted bipartite graph (with high probability) S.
1: Sort the degrees of the vertices in G.
2: Return $\mathcal{S}$ be the set of bottom k degrees after sorting..

Proof. For a vertex $v \in S$ the expected degree is $d + p(n-k)$. We note that this is smaller than pn since $d \leq 2pk/3$. We can upper bound the degree of v (denoted $d(v)$), with high probability (over the randomness of the input) using Chernoff bounds (Lemma 4.5, [56]) as,

$$\mathbb{P}\left[d(v) \geq d + p(n-k) + \sqrt{6pn\log n}\right] \leq \exp\left(\frac{-pn(\sqrt{6\log n}/\sqrt{pn})^2}{3}\right) = \frac{1}{n^2}.$$

Using a union bound over all $v \in S$, we have that for an any $v \in S$,

$$\mathbb{P}\left[d(v) \geq d + p(n-k) + \sqrt{6pn\log n}\right] \leq \frac{1}{n}.$$

Therefore we have with high probability (over the randomness of the input) that $d(v) \leq d + p(n-k) + \sqrt{6pn\log n}$. Similarly for a vertex $v' \notin S$ the degree can be lower bounded with high probability (over the randomness of the input) using Chernoff bounds (Lemma 4.4, [56]) as,

$$\mathbb{P}\left[d(v') \leq pn - \sqrt{6pn\log n}\right] \leq \exp\left(\frac{-pn(\sqrt{6\log n}/\sqrt{pn})^2}{2}\right) = \exp\left(-3\log n\right) = \frac{1}{n^3}.$$

Now using a union bound over all $v' \notin S$, we have with high probability (over the randomness of the input) that $d(v') \geq pn - \sqrt{6pn\log n}$. Therefore, with high probability (over the randomness of the input), the degrees differ by,

$$d(v') - d(v) \geq pk - d - 2\sqrt{6pn\log n} \geq \frac{pk}{3} - 2\sqrt{6n\log n}\,. \tag{19}$$

where we have used $d \leq 2pk/3$. It is also evident from equation (19) that for $k \geq 6\sqrt{6n\log n/p}$, with high probability (over the randomness of the input), the degree for a vertex $v \in S$ is smaller than degree of any vertex $v' \notin S$. ◀

1.4.6 Action of Adversary

Finally, we discuss the action of adversary (allowed to add edges in $(V \setminus S) \times (V \setminus S)$ for $d \geq 2pk/3$). We show that the inductive argument given by [24] also works for our case. This argument also extends to the semi-random model in Definition 11. We leave these details to the full version of the paper.

For $d \leq 2pk/3$ regimes, Algorithm 1 continues to return the planted set, since the action of adversary only amplifies the difference of degree for a vertex $v \in S$ and vertices $v' \notin S$. This argument does not extend to the semi-random model in Definition 11.

Optimal Time-Backlog Tradeoffs for the Variable-Processor Cup Game

William Kuszmaul
Massachusetts Institute of Technology, Cambridge, MA, USA

Shyam Narayanan
Massachusetts Institute of Technology, Cambridge, MA, USA

Abstract

The *p-processor cup game* is a classic and widely studied scheduling problem that captures the setting in which a p-processor machine must assign tasks to processors over time in order to ensure that no individual task ever falls too far behind. The problem is formalized as a multi-round game in which two players, a filler (who assigns work to tasks) and an emptier (who schedules tasks) compete. The emptier's goal is to minimize backlog, which is the maximum amount of outstanding work for any task.

Recently, Kuszmaul and Westover (ITCS, 2021) proposed the *variable-processor cup game*, which considers the same problem, except that the amount of resources available to the players (i.e., the number p of processors) fluctuates between rounds of the game. They showed that this seemingly small modification fundamentally changes the dynamics of the game: whereas the optimal backlog in the fixed p-processor game is $\Theta(\log n)$, independent of p, the optimal backlog in the variable-processor game is $\Theta(n)$. The latter result was only known to apply to games with *exponentially many* rounds, however, and it has remained an open question what the optimal tradeoff between time and backlog is for shorter games.

This paper establishes a tight trade-off curve between time and backlog in the variable-processor cup game. We show that, for a game consisting of t rounds, the optimal backlog is $\Theta(b(t))$ where

$$b(t) = \begin{cases} t & \text{if } t \leq \log n \\ t^{1/3} \log^{2/3}\left(\frac{n^3}{t} + 1\right) & \text{if } \log n < t \leq n^3 \\ n & \text{if } n^3 < t. \end{cases}$$

An important consequence is that the optimal backlog is $\Theta(n)$ if and only if $t \geq \Omega(n^3)$. Our techniques also allow for us to resolve several other open questions concerning how the variable-processor cup game behaves in beyond-worst-case-analysis settings.

1 Introduction

The classical p-processor cup game. The p processor cup game captures the general problem in which there are some number n of tasks competing for a smaller number p of processors [7, 21, 8, 33, 31, 37, 6, 24, 34, 35, 17, 10, 27, 1, 16, 32, 25]. A scheduler must assign tasks to processors over time in order to ensure that no individual task ever falls too far behind.

Formally, this is captured as a game with n cups, each capable of holding an arbitrarily large amount of water, and two competing players, a filler and an emptier. In each round of the game, the filler distributes p new units of water into the cups, placing at most 1 unit of water into any particular cup. The emptier then selects p distinct cups and removes up to 1 unit of water from each of them. Note that, whereas the filler may place their p units of water in fractional amounts across arbitrarily many cups, the emptier can only choose p cups per step to empty from. The emptier's goal is to minimize the backlog of the system, which is the amount of water in the fullest cup.

If one views the cup game as a scheduling problem, then the cups represent tasks, the water represents work, the filler represents an adversary that determines when work arrives, and the emptier represents a scheduler that can select p tasks to run on a given time step (we will use the terms "round" and "time step" interchangeably). Although we will primarily be interested in the cup game as a scheduling problem [7, 21, 8, 33, 31, 37, 6, 24, 34, 35, 1, 32, 17], it has also found applications to many other problems (e.g. deamortization of data structures [2, 17, 16, 3, 38, 23, 18, 26, 9], network-switch buffer management [22, 4, 39, 20], quality-of-service guarantees [7, 1, 32], etc.).

Beginning in the late 1960s, much of the early work on the p-processor cup game focused on the fixed-rate version of the game, in which the filler's behavior is the same at every round [7, 21, 8, 33, 31, 37, 6, 24, 34, 35]. In this version of the game, it is possible for the emptier to achieve a backlog of $O(1)$, both in the single-processor cup game (i.e., $p = 1$) [34, 35] and in the multi-processor cup game (i.e., $p > 1$) [7]. In recent decades, much of the research has shifted to focus on the non-fixed-rate version of the game, in which the filler is an adaptive adversary that can change their behavior from step to step [1, 16, 27, 32, 5, 19, 15]. In this setting, it is possible for the emptier to achieve backlog $O(\log n)$ [1, 16, 27], and this is known to be asymptotically optimal for all $p \leq n - \sqrt{n}$ [27]. There is also a long history of researchers applying techniques from beyond-worst-case analysis to cup games, e.g., resource augmentation [10, 27, 32, 17], smoothed analysis [27, 10], adversary restrictions [10, 27, 14, 28, 17], semi-clairvoyance [32], etc.

A repeating theme in these directions of work has been the relative difficulty of analyzing the multi-processor case in comparison to the single-processor case. As Liu discussed in his seminal 1969 paper [34], and as many later authors have subsequently reiterated [32, 7, 24, 10, 27], the difficulty of the multi-processor case stems from the fact that the emptier must remove water from p *distinct* cups, even if the vast majority of the water is in a smaller number of cups. For both the fixed-rate and the non-fixed-rate games, the optimal backlog in the multi-processor version of the game [7, 27] was proven decades after the corresponding result for the single-processor game was first shown [34, 16].

The variable-processor cup game. Recent work by Kuszmaul and Westover [29] has considered the question of what happens if the parameter p is permitted to change over time, with the filler adaptively determining both what value of p will be used at each round and where the p new units of water are placed. The resulting game, which is known as the variable-processor cup game, captures settings in which the amounts of resources available to the players fluctuate over time.[1]

The problem of what to do when computing resources fluctuate has received increasing attention in recent years due to the proliferation of shared-computing systems in which multiple users and virtual operating systems simultaneously run on a single physical multi-core machine; the fact that the machine is shared means that the amount of resources (eg., cache, processors, memory bandwidth, etc.) available to each user is constantly changing, depending on the current demands of other users. This phenomenon has led researchers to revisit problems in which computing resources have traditionally been viewed as static [36, 11, 12, 13, 30, 29].

Intuitively, the variable-processor cup game would seem to be relatively similar to its classical p-processor counterpart. Indeed, the backlog in the p-processor cup game is $O(\log n)$ regardless of the value of the parameter p, suggesting that the same should be true if p is permitted to vary. The central result of [29] is that this intuition turns out to be completely wrong: given sufficiently many time steps, the filler can actually force a backlog of $\Omega(n)$ in the variable-processor cup game, and this backlog is asymptotically optimal.

In order to achieve the backlog of $\Omega(n)$, the authors [29] construct a strategy for the filler in which the number of processors p follows a recursive "fractal-like" pattern. The recursive structure requires a relatively large number of time steps to complete – to achieve the full backlog of $\Omega(n)$, the construction requires exponentially many time steps.

The unexpectedly large backlog prompts several questions. The main open question is the problem of determining the optimal trade-off between backlog and time in the variable-processor cup game, and, in particular, what the optimal backlog is in games of polynomial lengths. In this setting, it is not even known whether the filler can achieve polynomial backlog – the best known filler strategy in this case [29] achieves backlog $2^{O(\sqrt{\log n})}$. Understanding the optimal trade-off between time and backlog in polynomial-length games is especially important since, for instance, one may have a bound on the number of rounds in a given scheduling application, which may allow for a much better guarantee on the backlog.

The authors of [29] also raise the question of whether smaller bounds on backlog can be achieved via beyond-worst-case analysis. Based on their results, they propose two directions, in particular, that seem promising. One is to place an additional restriction on the filler that p can only change at a certain rate; this would thwart the recursive structure of their lower bound construction which changes p dramatically between levels of recursion. The other is to consider the use of resource augmentation, meaning that the emptier is allowed to remove slightly more water in each time step than the filler is permitted to place into the cups. This direction seems promising due to the large amount of time required by the filling strategy of [29], since over such a large amount of time, the resource augmentation would potentially offer a large advantage to the emptier.

[1] As discussed in [29], there is no fundamental reason why the amount p of resources should fluctuate in the same way for the filler as it does for the emptier over time. However, by assuming that p is always the same for both players, one ensures that there is a fair playing field: neither player has an advantage over the other in terms of their resources.

Our results. The main result of this paper is a tight trade-off curve between time and backlog in the variable-processor cup game. We show that, for a game consisting of t rounds, the optimal backlog is $\Theta(b(t))$ where

$$b(t) = \begin{cases} t & \text{if } t \leq \log n \\ t^{1/3} \log^{2/3} \left(\frac{n^3}{t} + 1\right) & \text{if } \log n < t \leq n^3 \\ n & \text{if } n^3 < t. \end{cases} \tag{1}$$

By optimal, we mean that there exists an emptying strategy such that no filler can achieve backlog greater than $\Omega(b(t))$ after t rounds, and there exists a filling strategy such that no emptier can achieve backlog less than $O(b(t))$ after t rounds. In the case of the emptying strategy, we show that this tradeoff curve is achieved by the greedy emptying algorithm (i.e., always empty from the fullest cups).

Equation (1) comes with several interesting takeaways. The first is that in short games, of length $o(n^3)$, the emptier *can* achieve sub-linear backlog – prior to this result, it remained open whether the emptier could even ensure $o(n)$ backlog for only n rounds. The second is that in games of size $\Omega(n^3)$, the optimal backlog is $\Theta(n)$ – this resolves the open question of [29] as to whether linear backlog can be achieved in polynomial time. The third is that the optimal tradeoff between backlog and time has a somewhat unexpected polylogarithmic low-order term, which disappears only when t grows to be $\Omega(n^3)$.

By examining the inverse of the function $b(t)$, another way to think about (1) is that, for any quantity $b \leq n$, the amount of time $t(b)$ needed for an optimal filler to force a backlog of $\Omega(b)$ against an optimal emptier is

$$t(b) = \Theta\left(b + \frac{b^3}{\log^2 \frac{n}{b}}\right), \tag{2}$$

and that backlogs $b = \omega(n)$ are not achievable by the filler (the latter fact, of course, is already known due to [29]).

The second contribution of this paper is to analyze the variable-processor cup game under two forms of beyond-worst-case analysis, each of which resolves an open question posed by [29]. We begin by considering the setting in which the rate at which the filler can change p is severely limited: p is permitted to change by most ± 1 per time step, and the filler can only change p every $\text{poly}(n)$ time steps. Remarkably, this has no effect on the optimal backlog, and the filler can still force a backlog of $n/2$ in polynomial time. Next, we consider the setting in which the emptier has $\varepsilon > 0$ resource augmentation, meaning that, in each time step, the emptier is permitted to remove up to $1 + \varepsilon$ (rather than 1) units of water from each of p cups. This has a dramatic effect on the optimal backlog, reducing it to $O(\frac{1}{\varepsilon} \log n)$, which asymptotically matches the optimal backlog of the standard p-processor cup game when $\varepsilon = \Omega(1)$.

Techniques and paper outline. We formally describe the necessary preliminaries in Section 2, and provide a detailed overview of the technical ideas in the paper in Section 3.

In Section 4, we prove a result that ends up being useful in many of the later sections, namely that the greedy emptying algorithm is actually the *exact* optimal online algorithm, and that this holds no matter what the starting state of the cups is. Interestingly, our proof of greedy emptying being the optimal emptying strategy also applies to the fixed p-processor cup game, for which the result was also not previously known: in this setting, the greedy emptying algorithm was previously only known to be *asymptotically* optimal [27], and this

was only known for the starting state with all empty fills. We remark that, although the fact that greedy emptying is optimal is certainly intuitive, it actually isn't true for every variant of the cup game; notably, the greedy emptying algorithm isn't even asymptotically optimal for the fixed-rate version of the game [1].

In Section 5, we construct an asymptotically optimal strategy for the filler. The strategy achieves the bound in (1) no matter what strategy the emptier follows, and the strategy also easily generalizes the case where the filler is restricted to change p at a slow rate. This implies that the optimal backlog $b(t)$ is *at least* that in (1). While the filling algorithm works against any emptier, we focus on the filler working against the greedy emptier, which we know is optimal. We start with a warm-up (subsection 5.1) proving that one can establish $\Omega(n)$ backlog in $O(n^3)$ time, and we then generalize our techniques to apply to games of arbitrary lengths.

The remainder of the paper has been deferred to the extended version of this paper[2]. In Section 6 in the extended version, we turn our attention to proving a tight upper bound for the maximum backlog against a greedy emptier, that is, we show that $b(t)$ is *at most* that in (1). We begin by creating a variation of the variable-processor cup game, which we call the ***stone game***, in which the filler's behavior is limited in a certain combinatorially natural way. We analyze the maximum backlog of any filling strategy for the stone game by devising two potential functions and comparing their growth rates; this allows us to establish that $\Omega(n^3)$ time steps are needed to achieve backlog $\Omega(n)$ in the stone game. We then tighten the bound on backlog when there are fewer time steps by partitioning the cups into levels and arguing that a constant fraction of the levels interact especially nicely with the potential functions; this yields (1) for the stone game. Finally, we show that, if the emptier behaves greedily, then this stone game encapsulates the main problem, that is, is always advantageous to the filler in the variable-processor cup game to act as though they are in the stone game. Thus we can transfer out bounds on the stone game into bounds on the variable-processor cup game.

Section 6 is, in our opinion, the most technically involved section in our work. Perhaps the most interesting mathematical contribution in this section is to analyze the furthest backlog in the stone game by constructing two different potential functions and comparing their relative growth rates. While individual potential functions have been used to analyze cup games [10], this is the first time that comparing two potential functions has been applied to cup games.

Finally, in Section 7 in the extended version, we give a very simple analysis of the variable-processor cup game in the presence of resource augmentation. Our argument is non-constructive, employing the probabilistic method in order to show that there *exists* an emptying algorithm that achieves backlog $O(\frac{1}{\varepsilon}\log n)$ (interestingly, the same argument also gives a nontrivial bound of $O(\sqrt{t\log n})$ in the resource-augmentation-free setting). Since the greedy emptying algorithm is optimal, it must also achieve the same bound. To the best of our knowledge, this is the first example of the probabilistic method being used to analyze cup games.

2 Preliminaries

We first formally define the ***variable-processor cup game***. In this game, there are n cups of real-valued fills $x_1, \ldots, x_n$, all starting at 0, and two *adaptive* players, a filler and an emptier. At each round, the filler chooses an integer $1 \le p \le n$, chooses real numbers

[2] Available at `https://arxiv.org/abs/2205.01722`

$a_1, \ldots, a_n$ such that $0 \le a_i \le 1$ for all i and $\sum_{i=1}^{n} a_i = p$, and replaces x_i with $x_i' = x_i + a_i$ for all $1 \le i \le n$. The emptier then chooses a set $S \subset [n]$ of size p, and for each $i \in S$, replaces x_i' with $\max(0, x_i' - 1)$ but does not change x_i' for $i \notin S$. A single ***round*** (which we also call ***time step***) consists of both the filler's and emptier's moves. We define the ***state*** of the cups at a fixed round to be the current sequence $\{x_1, x_2, \ldots, x_n\}$ of the values of cups. Since the filler and emptier are adaptive, we note that two states are equivalent if the sequences are equal up to permutation. We will also say that the ***fills*** are $x_1, x_2, \ldots, x_n$ (we think of x_i as the fill of the i^{th} cup). Finally, for any state $X = \{x_1, \ldots, x_n\}$, we define the ***backlog*** of X as the maximum fill, or $\max_{1 \le i \le n} x_i$. The goal of the filler is to maximize the backlog after t rounds for some fixed t, whereas the goal of the emptier is to minimize it. We also define the ***variable-processor cup game with ε resource augmentation*** as the same as the variable-processor cup game, except that the emptier, for each $i \in S$, replaces x_i' with $\max(0, x_i' - (1 + \varepsilon))$.

Next, we define the ***negative-fill variable-processor cup game*** as the same as the variable-processor cup game, except that the emptier, for each $i \in S$, replaces x_i' with $x_i' - 1$. This may mean that some of the fills in a state become negative, which is allowed. We analogously define round, state, fills, and backlog (note that the backlog is $\max_{1 \le i \le n} x_i$, not $\max_{1 \le i \le n} |x_i|$).

Unless explicitly stated otherwise, the *standard* game refers to the variable-processor cup game, and the *negative-fill* game refers to the negative-fill variable-processor cup game. We will explicitly state whenever we talk about the fixed p-processor cup game (where $p = \sum_{i=1}^{n} a_i$ is fixed for every round), or the variable-processor cup game with $\varepsilon > 0$ resource augmentation.

We conclude this section by briefly commenting on the relationship between the standard game and the negative-fill game. It is easy to see that the optimal backlog in the standard game is at least as large as the optimal backlog in the negative-fill game. What is less obvious, but worth noting, is that the optimal backlogs in the two games are actually asymptotically *equal*. We provide a proof of this in Appendix A in the extended version. Thus, in general, either version of the game is equally valid (although the only place where we will take advantage of this in any nontrivial way will be Section 6 in the extended version).

3 Technical Overview

In this section, we provide a technical overview for both the lower and upper bound for the variable-processor cup game, as well as the upper bound for the variable-processor cup game with resource augmentation.

3.1 Overview of the Lower Bound on Backlog

In Section 5, we provide a lower bound on the backlog that the filler can achieve over t rounds. For now, let us assume that we are playing the negative-fill game and that the emptier is greedy, i.e., at each time step, if the filler fills p units of water, then the emptier empties 1 unit from the p fullest cups. We shall remove these assumptions at the end of the subsection.

Achieving backlog $\Omega(n)$ in n^3 steps. Why is this type of move good for the filler? Consider the potential function measuring the sum of squares of the fills, i.e., $\Phi(x_1, \ldots, x_n) := \sum_{i=1}^{n} x_i^2$. If we let $q = \frac{j-i+1}{2}$, so that q of the fills go up by $1/2$ and q of the fills go down by $1/2$, then it is not hard to show that Φ increases by $\frac{q}{2} \ge \frac{1}{2}$. If the filler can force this to happen for n^3 consecutive time steps, then Φ will increase to $\Omega(n^3)$, which means that at least one of the

$|x_i|$'s must be $\Omega(n)$. If the filler is careful, then it turns out they can further ensure that the cups are symmetric (i.e., for every cup with fill s there is another cup with fill $-s$). Thus if $|x_i| \geq \Omega(n)$ for some n, then a backlog of $\Omega(n)$ has been achieved.

The only way that the filler might be prevented from performing this type of move for n^3 consecutive time steps is if, at some time step, no two cups have the same fills as each other. Note, however, that the filler always adds half-integer values to cups and the emptier always subtracts integer values, which means that $x_1, \ldots, x_n$ are always half-integers. So, if the x_i's are all distinct, then $\max_{1 \leq i \leq n} |x_i| \geq \frac{n-1}{4} = \Omega(n)$. Recalling that the filler can ensure symmetry of the cups, it follows that in this case the filler has also achieved an $\Omega(n)$ backlog in only n^3 time steps.

Considering smaller backlogs. What if we only want to reach some backlog $o(n)$? We will now describe how the filler can achieve backlog $\Omega(t \log(n/t))$ in $O(t^3 \log(n/t))$ time steps. Combining this with some edge cases (which we defer to Section 5) results an optimal filling strategy for any backlog.

First, we claim that within t^3 steps, the filler can cause $\Theta(n)$ cups to have fills $\Omega(t)$. To see this, note that if at least half of the cups have fills less than t, then by the pigeonhole principle, there must exist some half-integer s with $|s| \leq t$ and $\Omega(n/t)$ cups of fill exactly s. If the filler causes half of these cups to go up in fill by $1/2$ and half of them to go down in fill by $1/2$, then the net effect on Φ will be that it increases by $\Omega(n/t)$. The filler can repeatedly force Φ to increase by $\Omega(n/t)$, while keeping the maximum backlog at t, until either t^3 steps have passed and $\Phi = \Omega(n \cdot t^2)$ or until at least half of the cups have reached backlog $\pm t$. Either way, at least $\Theta(n)$ of the cups must have fills more than $\Omega(t)$ or less than $-\Omega(t)$, and recalling again that the filler can also ensure a symmetry of the cups, it follows that a constant fraction of the cups have fills $\Omega(t)$.

Once we have cn cups of fill $\Omega(t)$, for some constant $c > 0$, the filler can focus on these cups, and force $c^2 n$ of these cups to fill $2 \cdot \Omega(t)$, then $c^3 \cdot n$ to fill $3 \cdot \Omega(t)$, and so on for a logarithmic number of phases. Overall, one can achieve backlog $\Omega(t \log(n/t))$ in $O(t^3 \log(n/t))$ time steps.[3]

The final piece: establishing that greedy emptying is optimal. To conclude our overview of the lowerbound, let us revisit the assumptions that (a) we are playing the negative-fill game, and (b) the emptier is playing greedily. The first assumption is trivial to remove, since the filler in the standard game is strictly better off than the filler in the negative-fill game. The second assumption, that the emptier is playing greedily, requires us to prove that the greedy emptying algorithm is always optimal (this ends up being useful to have for later results as well).

To prove the greedy emptying is optimal, in Section 4, we construct a specially designed poset on the possible states X of the system. Say that a state $X = \{x_1, \ldots, x_n\}$ ***weakly monopolizes*** a state $Y = \{y_1, \ldots, y_n\}$ if it is possible to order the cups such that either:

- $x_i \geq y_i$ for all i;
- or we have (a) that $x_i = y_i$ for all $i > 2$, that (b) $x_1 > y_2$, and that (b) we can get from X to Y by removing exactly 1 unit of water from cup 1 and placing some quantity $0 \leq c \leq 1$ of water into cup 2.

[3] Note that one can only do $\log(n/t)$ phases, rather than the more intuitive $\log n$ phases, since we need at least t cups to reach fill $a \cdot t$ in order for anything to reach fill $(a+1) \cdot t$.

The transitive closure of weak monopolization induces a partial ordering on the set of all possible system states, where $A \geq B$ if there is a sequence $A = A_1, A_2, \ldots, A_j = B$ such that each A_i weakly monopolizes each A_{i+1}.

We prove that, given the choice between two states A, B with $A \geq B$, the emptier should always prefer state B. Furthermore, starting from any state X, greedy emptying always results in a state B that satisfies $B \leq A$ for every other state A that the emptier could have reached from X. Thus the greedy emptying algorithm is optimal.

3.2 Overview of the Upper Bound on Backlog

In Section 6 in the extended version, we show that the greedy emptying algorithm achieves an upper bound on backlog matching the lower bound of Section 5. We first consider a filler that is restricted to only making moves of the form described in Subsection 3.1, that is, so that the net effect of each round is that some number $2q$ of cups at some height k are replaced with q cups at height $k + 1/2$ and q cups at height $k - 1/2$. We will later show that these types of moves are (essentially) always optimal for the filler, which means this restriction is actually without loss of generality. Considering this restricted filler along with a greedy emptier leads to the following simple combinatorial problem, which we call the ***stone game*** (we call it the ***stone-variant cup game*** in Section 6):

> *Suppose you have n stones on a number line, all starting at 0. At each time step t, you may pick any point k on the number line with 2 or more stones, choose any integer $q \geq 1$ such that there are at least $2 \cdot q$ stones at k, and move q of the stones at position k to position $k - 1$ and q of the stones at position k to position $k + 1$. If you repeat this for T time steps, what is the furthest that any of the n stones may be from the origin?*

Analyzing the time to get a stone to position $\Omega(n)$. To analyze the stone game, we start by considering how long it takes for some stone to reach $b := n/10$ in absolute value. Our goal is to show that one needs at least $T = \Omega(n^3)$ time steps. To highlight the relationship between the cup game and the stone game, we shall sometimes refer to the distance of the furthest stone from the origin simply as the backlog.

Let the positions of the stones be $x_1, \ldots, x_n$. We start by recalling the potential function $\Phi = \sum_{i=1}^{n} x_i^2$. One would naturally hope that Φ could help us establish a bound of $T = \Omega(n^3)$ (just as it helped us with the $T = O(n^3)$ bound in Subsection 3.1). For example, one way to prove the $\Omega(n^3)$ time bound would be to show that Φ increases by at most $O(1)$ in each step, and that Φ takes a value of at least $\Omega(n^3)$ after the final step (i.e., when backlog $b = n/10$ is achieved). Unfortunately, we run into two problems. The first problem is that even if $\max |x_i| = b = n/10$, we may still have that $\sum_{i=1}^{n} x_i^2$ is just $O(n^2)$ after the final step (as opposed to the desired $\Omega(n^3)$). The second, more difficult problem is that the number of stones we move in each direction could be large at each time step. If we move q stones right and q stones left, Φ increases by $2q$ (rather than the desired $O(1)$), which could be as large as n. Together, these two problems mean that, a priori, we can only get a trivial $T = \Omega(n)$ bound, since the change in the potential function Φ is up to n at each time step and the final potential may be as small as $\Theta(n^2)$.

The first problem can be resolved with a more careful analysis: in particular, one can show that a backlog of $\Omega(n)$ actually does imply $\Phi = \Omega(n^3)$. The key is to prove that there can never be large gaps between consecutive stones. Namely, one can show that if there exists a stone at some position $k > 0$, there must be at least one stone at position $k - 1$

or $k-2$, and likewise, if there exists a stone at $k<0$, there must be at least one stone at position $k+1$ or $k+2$. As a result, if there is a stone at $b=n/10$, there must be a stone at position either $b-1$ or $b-2$, at either $b-3$ or $b-4$, and so on, so one can show that there are $\Omega(b)$ stones at positions $b/2$ or greater. Thus, if there is a stone at position b, then $\Phi \geq \Omega(b)\cdot(b/2)^2 \geq \Omega(n^3)$, as desired.

The more difficult piece of the analysis is to show that, even though Φ can grow significantly in a single step, Φ only increases *on average* by $O(1)$ per step. An important insight here is to create a second potential function, Ψ, and compare the growth rates of Ψ and Φ. We define this new potential function $\Psi := \sum_{i<j} |x_i - x_j|$, where $x_1, \ldots, x_n$ are the locations of the n stones. In a given step of the stone game, if we move q stones up from k to $k+1$ and q stones down from k to $k-1$, the first potential function Φ increases by $2q$. However, one can show that Ψ must increase by at least $2q^2$ – the core reason for this is that the q stones that moved up now each have distance 2 from the q stones that moved down, whereas before they had distance 0. Now suppose for contradiction that Φ grows on average by some amount $\overline{q} = \omega(1)$ per step. This would mean that the average growth of Ψ per step is at least $\Omega(\overline{q}^2)$, so the final values of Ψ and Φ must satisfy $\Psi = \omega(\Phi)$. However, we know that $\Phi = \Omega(n^3)$ at the end of the game, and it is not hard to see that Ψ must be $O(n^3)$, since all of the x_i's are bounded in the range $[-O(n), O(n)]$. Thus we have a contradiction, and the average growth of Φ per step is actually $O(1)$. The fact that Φ is $\Omega(n^3)$ at the end of the game and grows by $O(1)$ on average per step is sufficient to show that the time T needed to achieve backlog $b=n/10$ in the stone game is at least $\Omega(n^3)$ time steps.

Considering smaller backlogs in the stone game. But what happens if we wish to analyze the time needed to achieve backlog k in the stone game, for $k \ll n$? If, at the end of the game, we knew that at least a constant fraction of the stones were in positions $\Omega(k)$, then we could use the same argument as the one above to show that the average growth rate of Φ is $O(1)$. Unfortunately, the number of stones at positions $\Omega(k)$ might be as small as $O(k)$. In this case, Φ could be as small as $O(k^3)$, whereas Ψ must be at least $\Omega(k^2 n)$. If the average growth of Φ were $\Theta(n/k)$ and the average growth of Ψ were $\Theta((n/k)^2)$, these values of Φ and Ψ could be obtained in $O(k^4/n)$ rounds, which is much smaller than our desired bound of $\Omega(k^3/\log^2(n/k))$.

To obtain the optimal bound of $\Omega(k^3/\log^2(n/k))$, we introduce another variant of the stone game that has what we call checkpoints: namely, we choose an integer ℓ and play the same game but now, once a stone has reached a position $a\cdot\ell$ for any $a \geq 0$, it can never go below it. In other words, if we move q stones from $a\cdot\ell$ to $a\cdot\ell+1$, rather than moving q stones from $a\cdot\ell$ down to $a\cdot\ell-1$, we keep them as is. A key insight is that, if a player wishes to get a stone to position $10\log n\cdot\ell$, the player must have the property that, for the majority of the checkpoints, the player gets at least half of the stones that reach checkpoint $a\cdot\ell$ all the way up to checkpoint $(a+1)\cdot\ell$.

We can think of the steps of the stone game (with checkpoints) as being split into subgames, where each subgame takes place between two checkpoints $a\cdot\ell$ and $(a+1)\cdot\ell$. We analyze each subgame individually by creating potential functions Φ_a, Ψ_a between each pair of checkpoints at $a\cdot\ell$ and $(a+1)\cdot\ell$. At least half of the subgames have the property that at least half of their stones make it to the next checkpoint, and this property makes each such subgame amenable to being analyzed using Φ_a and Ψ_a. By analyzing the subgames individually, we can show that the total length of the full stone game (which is the sum of the lengths of the subgames) is at least $\Omega(k^3/\log^2(n/k))$.

Finally, one can show that adding the checkpoints to the original stone game only makes it easier for the player to achieve a large backlog. This involves proving that if states X and Y have $x_i \geq y_i$ for all i, then given any stone-game operation on Y to obtain a state Y', we can generate a corresponding (but perhaps different) stone-game operation on X to obtain X', and preserve the ordering $x'_i \geq y'_i$ for all i. Thus, the $T = \Omega(k^3/\log^2(n/k))$ bound also applies to the original stone game.

Transferring bounds from the stone game to the cup game. Overall, the potential-function arguments above get optimal bounds for the *stone game* but they do not directly give bounds for the more general variable-processor cup game. The main issue is that in certain time steps in the cup game, it might be possible for the filler to make "backward" moves where both Φ and Ψ decrease considerably: in the worst case, Ψ can even decrease by up to n^2. Our analysis of the stone game relied heavily on the fact that the change in Ψ was comparable to the square of the change in Φ (in a given step), but if Ψ can decrease significantly in a single step, then our comparison of growth rates no longer works. Our fix for this is not to modify the potential functions, but rather to show that these backward moves, or any other "non-stone game" moves, are never advantageous to the filler, even in the long run.

To show that non-stone-game moves are never advantageous for the filler, we analyze the relationship between the stone game and the variable-processor cup game. Say that a sequence $X = \{x_1, \ldots, x_n\}$ of real numbers ***majorizes*** another sequence $Y = \{y_1, \ldots, y_n\}$ (where $x_1 \geq \cdots \geq x_n$ and $y_1 \geq \cdots \geq y_n$) if $x_1 + \cdots + x_i \geq y_1 + \cdots + y_i$ for all $1 \leq i \leq n$, and if $\sum_i x_i = \sum_i y_i$. We prove that, for any sequence of cup game rounds, one can create a corresponding sequence of stone game rounds such that after every round, the sequence of stone positions majorizes the sequence of cup fills. Since X majorizing Y implies that $x_1 \geq y_1$, we get that the maximum backlog after T steps of the cup game is at most the maximum backlog after T steps of the stone game. Therefore, even if we cannot utilize the potential functions on the general cup game, it suffices to look at the stone game as it will have a greater maximum backlog.

The main technical claim needed to show this majorization result is to show that if a sequence X majorizes a sequence Y, and if Y can be converted to a sequence Y' in one round of filling/greedy-emptying in the variable-processor cup game, then it is possible to convert X into some X' (also with a single round of filling/greedy emptying) such that X' majorizes Y'. This claim is quite casework-heavy and crucially uses the fact that we are in the *variable-processor* cup game. Indeed, the choice of p may have to differ between the round performed on X and the round performed on Y, and perhaps surprisingly, the claim is actually *false* in the fixed p-processor cup game.

3.3 Overview of Resource-Augmentation Analysis

In Section 7 in the extended version, we analyze the variable-processor cup game with ε resource augmentation (and non-negative fills), meaning that in each time step, the emptier is permitted to remove up to $1 + \varepsilon$ units of water from each of p cups (rather than just 1 unit of water).

We prove that even a very small amount of resource augmentation significantly decreases backlog of the game: the greedy emptying algorithm achieves backlog $O(\varepsilon^{-1} \log n)$.

The proof uses the probabilistic method. Rather than analyzing the greedy emptying algorithm directly, we instead construct a randomized emptying algorithm that, at any given moment, achieves backlog $O(\varepsilon^{-1} \log n)$ with *non-zero* probability. (Importantly, the randomized algorithm is against an *adaptive* filler, not an oblivious one.) The existence

of such a randomized algorithm non-constructively implies the existence of a deterministic emptying algorithm with the same guarantee. But we already know that the best deterministic emptying algorithm is the greedy one. Thus greedy emptying achieves backlog $O(\varepsilon^{-1} \log n)$ (deterministically).

To simplify our discussion here, let us consider only games of polynomial length (in Section 7 in the extended version we will consider arbitrary game lengths). In this case, our randomized emptying algorithm can simply take an approach that we call ***proportional emptying***: in each time step of the game, if the filler places some amount q_j of water into cup j, then the emptier empties from cup j with probability exactly q_j.

To analyze proportional emptying, we show that, at any given moment, each cup has fill $O(\varepsilon^{-1} \log n)$. Roughly speaking, the amount of water in each cup can then be modeled as a biased random walk: in each time step, the expected amount of water that the emptier removes is a factor of $1 + \varepsilon$ larger than the amount of water that the filler inserts. The bias in the random walk prevents it from ever reaching a large fill. The result is that a simple Chernoff-style analysis (modified using a variation on Azuma's martingale inequality to handle the fact that the filler is an adaptive adversary) can be used to bound the fill in each cup by $O(\varepsilon^{-1} \log n)$ (with high probability).

Interestingly, the above argument also immediately yields a nontrivial bound in the resource-augmentation-free setting. Now the amount of water in each cup follows an *unbiased* random walk. At any given time step t, one can bound the height of such random walk by $O(\sqrt{t \log n})$ with high probability. Using the fact that greedy emptying is as good as any randomized emptying strategy, it follows that greedy emptying achieves backlog $O(\sqrt{t \log n})$ in a t time step game.

4 The Greedy Emptier is Always Optimal

Intuitively, the greedy emptying algorithm (i.e., always empty from the fullest cups) should be the optimal deterministic emptying algorithm (for both the p-processor cup game and the variable-processor cup game). This intuition is known to be true for the single-processor cup game starting in a state with all empty cups (in particular, the lower and upper bounds on backlog match in this case [1]), but whether or not the intuition is correct in general has remained an open question. (We remark that there are variants of the game, for example the fixed-rate cup game, where greedy emptying is *not* optimal, even asymptotically [1].) In this section, we prove that greedy emptying is, in fact, optimal for both of the p-processor cup game and the variable-processor cup game.. That is, for any starting state of the cups, and for any game length, greedy emptying is the best possible algorithm for minimizing backlog against an adaptive filler.

For any state S and any length t, define $\mathrm{OPT}(S, t)$ to be the supremum backlog that a filler can achieve at the end of a t-step game starting at state S assuming the emptier plays optimally. That is, $\mathrm{OPT}(S, 0)$ is just the amount of water in the fullest cup of S, and $\mathrm{OPT}(S, t)$ for $t > 0$ is defined by induction as

$$\sup_{S' \text{ reachable from } S \text{ by filler}} \quad \min_{S'' \text{ reachable from } S' \text{ by emptier}} \mathrm{OPT}(S'', t-1).$$

Note that this also allows for us to talk about the ***optimal emptier***, which is the emptier that achieves backlog at most $\mathrm{OPT}(S, t)$ in any t-step game starting at any state S.

Define GREEDY(S, t) to be the supremum backlog that a filler can achieve at the end of a t-step game starting at state S, assuming the emptier plays greedily. We wish to prove that OPT$(S, t) =$ GREEDY(S, t) for all S, t. Throughout the section we shall prove all of our results for both the versions of the games with non-negative fills and the versions of the games with negative fills.

We say that a state A ***monopolizes*** a state B if it is possible to assign labels $1, 2, \ldots, n$ to the cups in A and B such that:

- cups $3, 4, \ldots, n$ contain the same amounts of water in both states;
- cup 1 in A contains more water than cup 2 in B;
- cup 1 in A contains one more unit of water than cup 1 in B;
- cup 2 in B contains c more units of water than cup 2 in A for some $0 \leq c \leq 1$.

In other words, you can get from A to B by removing 1 unit of water from cup 1 and and placing $c \leq 1$ units into cup 2, and cup 1 in A contains more water than cup 2 in B.

We say that A ***dominates*** B if it is possible to label the cups such that each cup i in A contains at least as much water as cup i in B. Finally, we say that A ***weakly monopolizes*** B if either A monopolizes B, or A dominates B.

We now prove several properties of weak monopolization in the p-processor cup game (for any p). Our first lemma says that, if A weakly monopolizes B, then for any filler move on B, there is some filler move on A that preserves the weak monopolization of A over B.

▶ **Lemma 1.** *Suppose A weakly monopolizes B. Suppose that there is a p-processor filler move that transforms B into some B'. Then there exists a p-processor filler move that transforms A into some A' such that A' weakly monopolizes B'.*

Proof. If A dominates B, then the lemma is trivial. Thus we can assume that A monopolizes B. Let q be the amount by which cup 1 in A contains more water than cup 2 in B.

Define X to be a state that we reach from A if we perform the same filler move that transforms B into B'. If cup 1 in X contains more water than cup 2 in B' then we can set $A' = X$ and be done.

Suppose cup 1 in X does not contain more water than cup 2 in B'. Then, in the transformation from B to B', the filler must have placed at least q more water into cup 2 than into cup 1. Let r be the amount of water that the filler placed into cup 1, and let $r + q + s$ (for some $s \geq 0$) the amount of water that the filler placed into cup 2.

Now define A' to be the state that one would reach from A by performing the following p-processor filler move: place $r + s$ units of water into cup 1 and $q + r$ units of water into cup 2 (and then place water into cups $3, 4, \ldots, n$ in the same way as to transform B to B'). Cup 1 in A' contains the same amount of water as cup 2 in B', and cup 2 and A' contains the same amount of water as cup 1 in B'. Thus A' and B' are equivalent states, meaning that A' weakly monopolizes B'. ◀

Our next lemma says that, if A weakly monopolizes B, and if A is then greedily emptied from, then it is possible to empty from B in such a way that the monopolization relationship is preserved.

▶ **Lemma 2.** *Suppose A weakly monopolizes B. Let A' be the state reached if a p-processor emptier greedily empties from A. Then there exists a valid p-processor emptier move on B that achieves some state B' such that A' weakly monopolizes B'.*

Proof. If A dominates B, then the lemma is trivial. Thus we can assume that A monopolizes B.

Let a_1, a_2 denote the fills of cups 1 and 2 in A, and let b_1, b_2 denote the fills of cups 1 and 2 in B. So $a_1 = b_1 + 1$, $b_2 = a_2 + c$ for some $0 \leq c \leq 1$, and $a_1 > b_2$. Furthermore, let a_1', a_2' the fills of cups 1 and 2 in A', and let b_1', b_2' denote the fills of cups 1 and 2 in B' (once we've defined it).

If the greedy emptier on A empties from neither cup 1 nor cup 2, then the same set of empties on B results in a B' that is weakly monopolized by A'.

Next consider the case where the greedy emptier on A empties from both cups 1 and 2. Then we empty from the same set of cups in B to arrive at a state B'. In the negative-fill game, is immediate to see that A' monopolizes B'. In the standard game, we must be careful about the fact that one of b_1 or a_2 might be less than 1. If $b_1 < 1$, then $b_1' = 0 \leq a_2'$, and since $a_1 > b_2$, we also have $a_1' \geq b_2'$; thus A' dominates B' in this case. If $a_2 < 1$ but $b_1 \geq 1$, then we have $a_1' = b_1' + 1$ and $b_2' = a_2' + c'$ for some $0 \leq c \leq 1$; we also have $a_1' \geq b_2'$ (since $a_1 \geq b_2$), so A' monopolizes B' in this case.

Finally, consider the case where the greedy emptier on A empties from only one of the cups 1 or 2. Since $a_1 > b_2 \geq a_2$, the emptier must empty from cup 1. Suppose we construct B' by performing the same set of empties on B as were performed on A, but we remove water from cup 2 instead of cup 1. Then $a_1' = b_1'$ and $a_2' \geq b_2'$, so A' dominates B'. This completes the proof. ◀

By combining the previous two lemmas, we can arrive at the following.

▶ **Lemma 3.** *Consider either the p-processor cup game, for some p, or the variable processor cup game (and consider either the negative-fill case or the non-negative-fill case). Suppose A weakly monopolizes B. Then for any t,*

$$\text{GREEDY}(A, t) \geq \text{OPT}(B, t).$$

Proof. We prove the lemma by induction on t. In the base case of $t = 0$, the lemma reduces to showing that A has backlog at least as large as B; this follows from the fact that A weakly monopolizes B.

Now consider some $t > 0$, and suppose the result holds for $t - 1$. For each state B' that the filler can reach from B, Lemma 1 tells us that there must exist a state A' that the filler can reach from A in such that A' weakly monopolizes B'. Moreover, Lemma 2 tells us that, if greedy emptying from A' results in some state A'', then there must be an emptying move on B' that results in a state B'' such that A'' weakly monopolizes B''.

Note that, in the previous paragraph, the filler's move from B to B' (i.e., the choice of B') fully determines A' (by the construction in Lemma 1), A'' (by greedy emptying on A'), and B'' (by the construction in Lemma 2). Thus, we will think of A', A'', B'' as being functions of B'.

Expanding out $\text{GREEDY}(A, t)$, we have

$$\text{GREEDY}(A, t) \geq \sup_{B'} \text{GREEDY}(A'', t - 1).$$

By the inductive hypothesis, since each A'' weakly monopolizes B'', we have $\text{GREEDY}(A'', t - 1) \geq \text{OPT}(B'', t - 1)$. Thus

$$\text{GREEDY}(A, t) \geq \sup_{B'} \text{OPT}(B'', t - 1).$$

Since $\sup_{B'} \text{OPT}(B'', t - 1) \geq \text{OPT}(B, t)$, the lemma follows. ◀

Recall that our goal is to upperbound $\text{GREEDY}(A,t)$ by $\text{OPT}(A,t)$ for all A,t. Thus Lemma 3 may at first seem to be backward progress, since the lemma establishes a *lower bound* on $\text{GREEDY}(A,t)$. The trick to using Lemma 3 is that we will only ever apply the lemma to states A and game lengths t for which we have already proven by induction that $\text{OPT}(A,t) = \text{GREEDY}(A,t)$; in this setting, the lemma establishes that $\text{OPT}(A,t) \geq \text{OPT}(B,t)$ which, as we shall see, ends up being critical to the proof.

▶ **Theorem 4.** *Consider either the p-processor cup game, for some p, or the variable-processor cup game (and consider either the negative-fill case or the non-negative-fill case). For all states A and game lengths t,*

$$\text{GREEDY}(A,t) = \text{OPT}(A,t).$$

Proof. We prove the theorem by induction on t with a trivial base case of $t = 0$. Consider $t > 0$, and suppose the theorem holds for $t-1$.

Consider any state A' that the filler can reach from A. Let A'' be the state reached from A' if the emptier empties greedily, and let B be the state reached from A' if the emptier empties according to OPT. Since the transformation from A' to A'' empties from cups with at least as much water as the transformation from A' to B, there must be a sequence of states $X_0, X_1, \ldots, X_k$, with $X_0 = B$ and $X_k = A''$, such that each X_i weakly monopolizes X_{i-1}. In particular, one can define the X_i's such the only difference between each X_i and X_{i+1} is that, to get from A' to X_{i+1} instead of from A' to X_i, the emptier removes water from a cup j instead of a cup k, where cup j contains less water than cup k in state A'. It is straightforward to verify that this results in each X_{i+1} weakly monopolizing each X_i: if cup k (in state A') has fill at least 1, then X_{i+1} monopolizes X_i; and otherwise, both cups k and j (in state A') have fills less than 1, and thus X_{i+1} dominates X_i.

By the inductive hypothesis, we know that $\text{OPT}(X_i, t-1) = \text{GREEDY}(X_i, t-1)$ for each X_i. Thus Lemma 3 tells us that $\text{OPT}(X_i, t-1) \geq \text{OPT}(X_{i-1}, t-1)$. By transitivity, it follows that $\text{OPT}(X_k, t-1) \geq \text{OPT}(X_0, t-1)$, and thus $\text{OPT}(B, t-1) \geq \text{OPT}(A'', t-1)$. Again applying the inductive hypothesis to deduce that $\text{OPT}(A'', t-1) = \text{GREEDY}(A'', t-1)$, we have that

$$\text{OPT}(B, t-1) \geq \text{GREEDY}(A'', t-1).$$

Thus

$$\text{GREEDY}(A,t) = \sup_{A''} \text{GREEDY}(A'', t-1) \leq \sup_{B} \text{OPT}(B, t-1) = \text{OPT}(A,t).$$

Finally, as $\text{GREEDY}(A,t) \geq \text{OPT}(A,t)$ trivially, we have $\text{GREEDY}(A,t) = \text{OPT}(A,t)$. ◀

▶ **Corollary 5.** *Theorem 4 continues to hold for the game with non-negative fills even if the emptier is given $1+\varepsilon$ resource augmentation.*

Proof. The proof of Theorem 4 continues to hold without modification. The only difference is that, now, we say that a state A monopolizes a state B if there is a ordering of the cups for which two properties hold: (1) we can take $1+\varepsilon$ unit of water from some cup 1 in A, place some amount $0 \leq c \leq 1+\varepsilon$ of water into some other cup 2 in A, and in doing so arrive at B; and (2) cup 1 in A contains more water than cup 2 in B. ◀

5 Lower Bounding Backlog

In this section, we prove the optimal lower bound on the backlog. In other words, we show that for any integer $t \geq 1$, there exists a filling strategy that can guarantee a backlog of $\Omega(b(t))$ against *any* emptying strategy, after t rounds of the variable-processor cup game, where $b(t)$ is defined as in Equation (1) in the introduction (Section 1). This result can be captured compactly in the following theorem:

▶ **Theorem 6.** *For some absolute constant $c > 0$ and any $k \leq c \cdot n$, the filler in the variable-processor cup game can force a maximum backlog of $\Omega(k)$ using only $O\left(k + \frac{k^3}{\log^2(n/k)}\right)$ time steps.*

We remark that due to the optimality of greedy emptying, which we proved in the previous section, we focus in this section on designing filling strategies that are effective against the greedy emptier.

In Subsection 5.1, we give a simple proof for obtaining $\Omega(n)$ backlog in $O(n^3)$ rounds. In Subsection 5.2, we generalize Subsection 5.1 and develop the full proof of Theorem 6.

5.1 Warmup: Achieving a $\Theta(n)$ Backlog Quickly Against a Greedy Emptier

In this subsection, we show that in only n^3 rounds, a filler can achieve a backlog of $\frac{n-1}{2}$ against a greedy emptier. While the following argument is simpler than the more refined lower bound in Subsection 5.2, it conveys much of the intuition behind the general lower bound. Here, we only consider the standard variable-processor cup game, though in subsection 5.2 we will consider both the standard and negative-fill games.

▶ **Theorem 7.** *Against a greedy emptier in the standard variable-processor cup game, the filler can achieve a backlog of $\frac{n-1}{2}$ in only n^3 rounds.*

Proof. The filler follows the following simple strategy, which will guarantee that the fills at the end of each round are half integers (i.e., integer multiples of $\frac{1}{2}$). Suppose the cups after some round, in sorted order, are $x_1 \geq x_2 \geq \cdots \geq x_n$, which are all half-integers.

If $x_i > x_{i+1}$ for all $1 \leq i \leq n-1$, then we must have that $x_i \geq x_{i+1} + \frac{1}{2}$ for all $i \leq n-1$, so $x_1 \geq \frac{n-1}{2}$. In this case, we have already achieved a backlog of $\frac{n-1}{2}$.

Otherwise, we consider the potential function $\Phi = \sum_{i=1}^{n} x_i^2$, i.e., the sum of the squares of the backlogs. Consider the smallest p such that $x_p = x_{p+1}$. We set the number of processors for the round to be p, we place 1 unit of water into each of cups $x_1, \ldots, x_{p-1}$ and we place $1/2$ unit of water into each of cups x_p, x_{p+1}. Then, the greedy emptier will empty 1 unit from each of the first $p-1$ cups and will choose to empty 1 unit from either the p^{th} cup or the $(p+1)^{\text{th}}$ cup (WLOG, they choose the $(p+1)$-th cup). This means that, over the course of the entire round, the first $p-1$ cups are unchanged, the p^{th} cup goes up by $\frac{1}{2}$, and $(p+1)^{\text{th}}$ cup goes down by $\frac{1}{2}$. The only exception is if $x_p = x_{p+1} = 0$ at the beginning, in which case one of these two cups will go up to $1/2$ and the other remains at 0. Clearly, all of the fills remain half-integers at the end of each round. If we replace x_p and $x_{p+1} = x_p$ with $x_p + \frac{1}{2}$ and $x_p - \frac{1}{2}$, then the sum of the squares of the backlogs increases by $1/2$. Otherwise, if we replace $x_p = x_{p+1} = 0$ with 0 and $1/2$ in some order, then the sum of the squares of the backlogs increases by $1/4$. Thus, at the end of each round, unless one of the backlogs was already $\frac{n-1}{2}$ or greater, Φ increases by at least $\frac{1}{4}$.

Therefore, after n^3 rounds, either at some point we will have achieved $x_1 > x_2 > \cdots > x_n$ and thus a backlog of $\frac{n-1}{2}$, or we have that $\sum_{i=1}^{n} x_i^2 \geq \frac{n^3}{4}$, which would mean that $\max x_i \geq \frac{n}{2}$, since all of the x_i's are nonnegative. As a result, there exists a filling strategy that can guarantee a $\frac{n-1}{2}$ backlog against a greedy emptier in at most n^3 rounds. ◀

5.2 The General Lower Bound

In this subsection, we prove the lower bound on the backlog for the variable-processor cup game after t rounds, showing that the optimal backlog is $\Omega(b(t))$ for $b(t)$ defined as in Equation (1). Equivalently, we show that for any integer $k \leq n$, a filler can achieve backlog $\Omega(k)$ in $O\left(k + \frac{k^3}{\log^2(n/k)}\right)$ rounds against any emptying strategy. We remark that if we are playing t rounds of the game and the filler has achieved backlog b by round $t' < t$, the filler can ensure the backlog stays at b by setting $p = n$ and filling every cup for steps $t'+1, \ldots, t$. Thus, we just need to show the filler can obtain this backlog *within* this many rounds.

Throughout this subsection, we assume that we are playing the negative-fill game, and that the emptier is always greedy. We remove both of these assumptions at the end in Theorem 6.

▶ **Lemma 8.** *Assume that the emptier is always greedy, and that at the beginning of some round, the fills are all (possibly negative) half-integers. For some integer $k \in \mathbb{Z}$ and positive integer $q \in \mathbb{N}$, suppose there are at least $2q$ cups having fill exactly $k/2$. Then, the filler can ensure that at the end of the round (i.e., after both the filler and emptier move), exactly q of the cups of fill exactly $k/2$ have increased to $(k+1)/2$, exactly q of the cups of fill exactly $k/2$ have decreased to $(k-1)/2$, and all remaining cups are unchanged.*

Proof. Suppose the cups are sorted in order $x_1 \geq x_2 \geq \cdots \geq x_n$, such that $x_i = x_{i+1} = \cdots = x_{i+2q-1} = k/2$. Also, suppose i is the smallest integer such that $x_i = k/2$, so either $x_{i-1} > k/2$ or $i = 1$. Then, the filler will set $p = i - 1 + q$ and fill the first $i-1$ cups with 1 unit of water and the cups $x_i, \ldots, x_{i+2q-1}$ each with $1/2$ unit of water. Then, if $i > 1$, the emptier is forced to empty 1 unit of water from each of the first $i-1$ cups. In addition, we have that the cups $i, i+1, \ldots, i+2q-1$ all have fills $(k+1)/2$, which is at least $1/2$ unit of water more than all later cups, which means that the emptier will remove 1 unit of water from exactly q of the cups $i, i+1, \ldots, i+2q-1$. Therefore, all cups $1, \ldots, i-1$ are unchanged (since 1 unit of water is added and then removed) and all cups $i+2q, \ldots, n$ are unchanged (since water is never added nor removed). Finally, among the cups $i, i+1, \ldots, i+2q-1$, exactly q of them will end up at $(k-1)/2$ and exactly q of them will end up at $(k+1)/2$. ◀

▶ **Lemma 9.** *Suppose that k, m are positive integers such that $4k|m$, and suppose there are at least m cups that currently have fill 0 (where $n \geq m$ is the total number of cups). Then, against a greedy emptier, the filler can ensure that at least $m/4$ cups will have fill exactly $k/2$ after $O(k^3)$ rounds.*

Proof. WLOG assume that the first m cups have fills $x_1, x_2, \ldots, x_m$, and at the start, $x_1 = x_2 = \cdots = x_m = 0$. (We do not assume the cups are sorted in order of fill.) We only ever modify the first m cups, and after each step, we will maintain the following invariants:

1. All of the fills are half-integers.
2. For each integer j, the number of cups of fill $j/2$ equals the number of cups of fill $-j/2$.
3. For each integer j, the number of cups of fill $j/2$ is always a multiple of $\frac{m}{4k}$.
4. No cup has fill greater than $k/2$ or less than $-k/2$.

Trivially, all 4 of these invariants are true at the beginning, since all the fills are 0 and $\frac{m}{4k}|m$. Our procedure is the following. Suppose that there exists some integer j such that $-k < j < k$ and the number of cups of fill $j/2$ is at least $\frac{m}{2k}$. Then, we use Lemma 8 to move $\frac{m}{4k}$ of these cups to fill $(j+1)/2$ and move $\frac{m}{4k}$ of these cups to fill $(j-1)/2$. In addition, if $j \neq 0$, then we know the number of cups of fill $-j/2$ is at least $\frac{m}{2k}$. So, in the next step, we move $\frac{m}{4k}$ of these cups to fill $(-j+1)/2$ and move $\frac{m}{4k}$ of these cups to fill $(-j-1)/2$.

When $j \neq 0$, we perform these two steps consecutively as a pair. We keep repeating these types of steps (and pairs of steps) until we can no longer do so. It is clear that the first three invariants are preserved, and the last is preserved since we only modify cups that have fill between $-(k-1)/2$ and $(k-1)/2$, and we change their fills by at most $1/2$ per round.

Now, we note that at each step, the potential function $\Phi = \sum_{i=1}^{m} x_i^2$ increases by $\frac{m}{8k}$, since

$$\frac{m}{4k} \cdot \left(\frac{j+1}{2}\right)^2 + \frac{m}{4k} \cdot \left(\frac{j-1}{2}\right)^2 - \frac{m}{2k} \cdot \left(\frac{j}{2}\right)^2 = \frac{m}{8k}.$$

This also means that if we do a pair of steps (i.e., modifying cups of fill $j/2$ and $-j/2$), the potential function Φ increases by $\frac{m}{4k}$.

Now, after $4k^3$ steps (and pairs of steps), Φ is at least $4k^3 \cdot \frac{m}{8k} = \frac{1}{2} \cdot mk^2$. But this is impossible, since all of the fills of cups 1 through m are between $k/2$ and $-k/2$, so the maximum possible value of Φ is $\frac{1}{4} \cdot mk^2$. This means that before reaching $4k^3$ of steps or pairs of steps, we must not be able to do any more steps. That is, for all j such that $-k < j < k$, there are less than $\frac{m}{2k}$ cups of fill exactly $j/2$, and because of our third invariant, this means there are at most $\frac{m}{4k}$ cups of fill exactly $j/2$. Therefore, the number of cups of fill between $-k+1$ and $k-1$ is at most $(2k-1) \cdot \frac{m}{4k} \leq \frac{m}{2}$. So, at least $\frac{m}{2}$ cups must have fill $\pm\frac{k}{2}$, and by the second invariant, this means at least $\frac{m}{4}$ cups must have fill $\frac{k}{2}$. Reaching this stage required at most $4k^3$ steps and pairs of steps, which means the filler can succeed in at most $8k^3$ steps. ◀

▶ **Corollary 10.** *Suppose k, m are positive integers such that $4k|m$, and suppose there are at least m cups that currently have fill exactly t for some real number t. Then, after $O(k^3)$ time steps, the filler can force at least $m/4$ of these cups to have fill exactly $t + \frac{k}{2}$, against a greedy emptier.*

Proof. We can apply same argument as in Lemma 9, where all of the fills are shifted up by the same number t. So, after at most $8k^3$ time steps, at least $m/4$ of the cups will have fill exactly $t + \frac{k}{2}$. ◀

From here, we are able to conclude with our main result of this section.

▶ **Theorem 6.** *For some absolute constant $c > 0$ and any $k \leq c \cdot n$, the filler in the variable-processor cup game can force a maximum backlog of $\Omega(k)$ using only $O\left(k + \frac{k^3}{\log^2(n/k)}\right)$ time steps.*

Proof. For now we will assume that the emptier is greedy, and that we are playing the negative-fill cup game. We will remove both assumptions at the end of the proof.

First, suppose $k \geq c \log n$. In this case, let $k' := \left\lceil \frac{k}{c \log(n/k)} \right\rceil \geq 2$. Also, let n' be such that $n \geq n' > \frac{n}{4}$ and $n' = k' \cdot 4^r$ for some integer $r \geq 1$.

Since there are at least $n' = k' \cdot 4^r$ cups of fill 0 at the beginning of the game, we can apply Corollary 10 with $t = 0$ and $m = n'$ to make sure there are at least $k' \cdot 4^{r-1}$ cups of fill k' after $O(k'^3)$ time steps, since $4k'|n'$. Then, we can again apply Corollary 10 with $t = k'$ and $m = n'/4$ to make sure there are at least $k' \cdot 4^{r-2}$ cups of fill $2k'$ after an additional $O(k'^3)$ time steps. We can repeat this r times until we have at least k' cups of fill $r \cdot k'$ after a total of $O(r \cdot k'^3)$ time steps. But since $r = \log_4(n'/k') = \Theta(\log(n/k \cdot \log(n/k))) = \Theta(\log(n/k))$, this means that the filler can achieve a maximum backlog of $r \cdot k' = \Theta(k)$ using only $O(r \cdot k'^3) = O(k^3/\log^2(n/k))$ time steps.

Next, suppose $k < c \log n$. In this case, set $n' = 2^k$: if $c < 1$ then $n' < n$. By Lemma 8, we can send 2^{k-1} cups to fill 1 during the first round, then 2^{k-2} of those cups to fill 2 during the second round, and so on until we have 1 cup at fill k after k rounds.

Up until now we have assumed that the filler was operating against a greedy emptying algorithm in the negative-fill cup game. However, by Theorem 4, if the emptier uses a different emptying algorithm, the filler could always modify their strategy to get equal or greater backlog in the same amount of time. So, regardless of the emptying strategy, the filler can force a maximum backlog of $\Theta(k)$ using $O\left(k + \frac{k^3}{\log^2(n/k)}\right)$ time steps, assuming we are playing the negative-fill cup game. Finally, recall that the maximum backlog that the filler can ensure in the negative-fill game is at most the maximum backlog that the filler can ensure in the standard game for any fixed number of time steps. Thus, if the filler can force a maximum backlog of $\Theta(k)$ using $O\left(k + \frac{k^3}{\log^2(n/k)}\right)$ time steps in the negative-fill game, then the filler can force the same backlog using the same number of time steps in the standard game, which completes the theorem. ◀

Finally, to conclude the section, we use the optimality of greedy emptying to resolve an open question of [29] concerning whether a filler who is limited in the speed at which they can change p can still force a large backlog.

▶ **Proposition 11.** *Consider the variable-processor cup game, starting with all empty cups (and with negative fills either allowed for disallowed). Suppose the filler is restricted to only change p once every n^c steps, for some constant $c \geq 0$, and to only change p by ± 1 at a time. Then the filler can still force a backlog of $\Omega(n)$ in polynomial time.*

Proof. Call this version of the game the *change-limited variable-processor cup game*. Notice that the proof of optimality for greedy emptying never changes the value of p used in any given step. Thus the same proof implies that greedy emptying is optimal in the change-limited variable-processor cup game. Henceforth we will assume that the emptier is greedy.

Next, observe that, no matter the value of p, the filler can always "skip" a step in the following way: the filler simply places 1 unit of water into each of the p fullest cups, forcing the greedy emptier to remove water from those cups, so that the step has no net effect.

We have already proven that, in the standard variable-processor cup game, the filler can cause backlog $\Omega(n)$ in polynomial time. The filler can use the same strategy here, but with the following modification: between any two consecutive steps that use p and q processors, respectively, the filler spends $|p - q|n^c$ steps changing the number of processors from p to q. That is, for each $i \in [p, q]$, the filler spends n^c steps with i processors, and renders each of those steps to have no net effect. The result is that, in polynomial time, the filler can force backlog $\Omega(n)$, as desired. ◀

Near-Optimal Decremental Hopsets with Applications

Jakub Łącki

Yasamin Nazari
Universität Salzburg, Austria

Abstract

Given a weighted undirected graph $G = (V, E, w)$, a hopset H of *hopbound* β and *stretch* $(1+\epsilon)$ is a set of edges such that for any pair of nodes $u, v \in V$, there is a path in $G \cup H$ of at most β hops, whose length is within a $(1+\epsilon)$ factor from the distance between u and v in G. We show the first efficient decremental algorithm for maintaining hopsets with a *polylogarithmic* hopbound. The update time of our algorithm matches the best known static algorithm up to polylogarithmic factors. All the previous decremental hopset constructions had a *superpolylogarithmic* (but subpolynomial) hopbound of $2^{\log^{\Omega(1)} n}$ [Bernstein, FOCS'09; HKN, FOCS'14; Chechik, FOCS'18].

By applying our decremental hopset construction, we get improved or near optimal bounds for several distance problems. Most importantly, we show how to decrementally maintain $(2k-1)(1+\epsilon)$-approximate all-pairs shortest paths (for any constant $k \geq 2$), in $\tilde{O}(n^{1/k})$ amortized update time[1] and $O(k)$ query time. This improves (by a polynomial factor) over the update-time of the best previously known decremental algorithm in the *constant* query time regime. Moreover, it improves over the result of [Chechik, FOCS'18] that has a query time of $O(\log\log(nW))$, where W is the aspect ratio, and the amortized update time is $n^{1/k} \cdot (\frac{1}{\epsilon})^{\tilde{O}(\sqrt{\log n})}$. For sparse graphs our construction nearly matches the best known static running time / query time tradeoff.

We also obtain near-optimal bounds for maintaining approximate multi-source shortest paths and distance sketches, and get improved bounds for approximate single-source shortest paths. Our algorithms are randomized and our bounds hold with high probability against an *oblivious* adversary.

1 Introduction

Given a weighted undirected graph $G = (V, E, w)$, a hopset H of *hopbound* β and *stretch* $(1+\epsilon)$ (or, a $(\beta, 1+\epsilon)$-hopset) is a set of edges such that for any pair of nodes $u, v \in V$, there is a path in $G \cup H$ of at most β hops, whose length is within a $(1+\epsilon)$ factor from the distance between u and v in G (see Definition 5 for a formal statement).

[1] Throughout this paper we use the notation $\tilde{O}(f(n))$ to hide factors of $O(\text{polylog}\,(f(n)))$.

Hopsets, originally defined by [13], are widely used in distance related problems in various settings, such as parallel shortest path computation [13, 15, 18, 28], distributed shortest path computation [10, 17, 29], routing tables [16], and distance sketches [14, 16]. In addition to their direct applications, hopsets have recently gained more attention as a fundamental object (e.g. [1, 4, 17, 23]), and are known to be closely related to several other fundamental objects such as additive (or near-additive) spanners and emulators [19].

A key parameter of a hopset is its hopbound. In many settings, after constructing a hopset, we can approximate distances in a time that is proportional to the hopbound. For instance, in parallel or distributed settings a hopset with a hopbound of β allows us to compute approximate single-source shortest path in β parallel rounds (e.g. by using Bellman-Ford). For many applications, such as approximate APSP (all-pairs shortest paths), MSSP (multi-source shortest paths), computing distance sketches, and diameter approximation, where we require computing distances from *many* sources, we are interested in the regime where the hopbound is polylogairthmic. Indeed, we obtain improved (and in some cases near-optimal) bounds for several of these problems in decremental settings.

In this paper, we study the maintenance of hopsets in a dynamic setting. Namely, we give an algorithm that given a weighted undirected graph G maintains a hopset of G under edge deletions. Our algorithm covers a wide range of hopbound/update time/hopset size tradeoffs. Importantly, we get the first efficient algorithm for decrementally maintaining a hopset with a *polylogarithmic* hopbound. In this case, assuming G initially has m edges and n vertices, our algorithm takes $O(mn^{\rho})$ time, given any constant $\rho > 0$, and maintains a hopset of polylogarithmic hopbound and $1+\epsilon$ stretch. This matches (up to polylogarithmic factors) the running time of the best known static algorithm [17, 18] for computing a hopset with polylogarithimic hopbound and $(1+\epsilon)$ stretch.

▶ **Theorem 1.** *Given an undirected graph $G = (V, E)$ with polynomial weights[2], subject to edge deletions, we can maintain a $(\beta, 1+\epsilon)$-hopset of size $\tilde{O}(n^{1+\frac{1}{2^k-1}})$ in total expected update time $\tilde{O}(\frac{\beta}{\epsilon} \cdot (m + n^{1+\frac{1}{2^k-1}})n^{\rho})$, where $\beta = (O(\frac{\log n}{\epsilon} \cdot (k + 1/\rho)))^{k+1/\rho+1}$, $k \geq 1$ is an integer, $0 < \epsilon < 1$ and $\frac{2}{2^k-1} < \rho < 1$.*

In the decremental setting, to the best of our knowledge, the previous state-of-the art hopset constructions have a hopbound of $2^{\tilde{O}(\log^{3/4} n)}$ [21], or $(1/\epsilon)^{\tilde{O}(\sqrt{\log n})}$ [5, 12]. As a special case, by setting $\rho = (2^k - 1)^{-1} = \frac{\log\log n}{\sqrt{\log n}}$, we can maintain a hopset with hopbound $2^{\tilde{O}(\sqrt{\log n})}$ in $2^{\tilde{O}(\sqrt{\log n})}$ amortized time. More importantly, by setting ρ and k to a constant, we can maintain a hopset of *polylogarithmic* hopbound.

While hopsets are extensively studied in other models of computation (e.g. distributed and parallel settings), their applicability in dynamic settings is less understood. Examples of results utilizing hopsets include the state-of-the art decremental SSSP algorithm for undirected graphs by Henzinger, Krinninger and Nanongkai [21], and implicit hopsets considered in [5,12]. As stated, these decremental hopset algorithms as stated only provide a *superpolylogarithmic* hopbound. It may be possible (while not discussed) to use the hop-reduction techniques of [21] (inspired by a similar technique in [5]) to obtain a wider-range of tradeoffs, however to the best of our knowledge these techniques do not lead to near-optimal size/hopbound tradeoffs[3]. Hence our result constitutes the first near-optimal decremental algorithm for maintaining hopsets with in a wide-range of settings including polylogarithmic hopbound.

---

[2] If weights are not polynomial the $\log n$ factor will be replaced with $\log W$ in the hopbound, and a factor of $\log^2 W$ will be added to the update time, where W is the aspect ratio.

[3] In particular, in all regimes the algorithm of [21] gives a hopset with size that is super-linear in number

Discussion on hopset limitations and alternative techniques. In [1] it was shown that for a $(\beta, 1+\epsilon)$-hopset with size $n^{1+\frac{1}{2^k-1}-\delta}$ for any fixed k, ϵ and $\delta > 0$ we must have[4] $\beta = \Omega_k(\frac{1}{\epsilon})^k$. Their lower bound suggests that we cannot construct a $(\beta, 1+\epsilon)$-hopset of size $\tilde{O}(n)$ with $\beta = \operatorname{poly}\log(n)$ hopbound, implying that hopsets cannot be used for obtaining optimal time (i.e. polylog amortized time) for *sparse* graphs and *very small* ϵ. However when the graph is slightly denser ($|E| = n^{1+\Omega(1)}$), the approximation factor is slightly larger (see e.g. [4,15]), or we aim to compute distances from many sources (in APSP or MSSP), using hopsets may still lead to optimal algorithms. Indeed, we show that our decremental hopsets allow us to obtain a running time matching the best static algorithm (up to polylogarithmic factors) both in $(2k-1)$-APSP and $(1+\epsilon)$-MSSP. We leave it as an open problem if hopsets can be used to obtain linear time algorithms for SSSP with *larger* approximation factors (e.g. $\epsilon \geq 1$), since as stated, the lower bound of [1] does not apply in this case.

It is worth noting that in Theorem 12 we first give a decremental algorithm that maintains static hopsets of [18] that matches the size/hopbound tradeoff in the lower bound of [1]. However, as we will see, this algorithm has a large update time, and thus we propose a new hopset with slightly worse size/hopbound tradeoff that can be maintained much more efficiently. This efficient variant has additional polylogarithmic (in aspect ratio) factors in the hopbound relative to the existentially optimal construction.

Finally, for *single source* shortest path computation in other models recently algorithms based on continuous optimization techniques are proposed (e.g. [2,3,25]) that outperform algorithms based only on combinatorial objects such as hopsets/emulators. These optimization techniques lead to much better dependence on ϵ, but are less suitable when there are many sources, as the running time scales with the number of sources. Interestingly, the authors of [2] use low-hop combinatorial structures with *larger (polylogrithmic)* stretch as a subroutine in their continuous optimization framework. Hence understanding both combinatorial and optimization directions seems crucial for distance computation in general.

1.1 Applications of Our Decremental Hopsets

To illustrate applicability of our decremental hopset algorithm, we show how it yields improved algorithms for decremetanlly maintaining shortest paths from a fixed set S of sources. We consider different variants of the problem which differ in the size of S: the single-source shortest paths (SSSP) problem ($|S| = 1$), all-pairs shortest paths (APSP) problem ($S = n$, where n is the number of vertices of the input graph), as well as the multi-source shortest paths (MSSP) problem (S is of arbitrary size), which is a generalization of the previous two.

Near-Optimal approximate APSP. We give a new decremental algorithm for maintaining approximate all-pairs shortest paths (APSP) with constant query time.

▶ **Theorem 2** (Approximate APSP). *For any constant integer*[5] $k \geq 2$, *there is a data structure that can answer* $(2k-1)(1+\epsilon)$*-approximate distance queries in a given a weighted undirected graph* $G = (V, E, w)$ *subject to edge deletions. The total expected update time*

of edges m (e.g. m^{1+p} for a parameter p), while our hopset size is $O(n^{1+p})$ for some (other but similar) parameter p, which is a constant when the hopbound is polylogarithmic. Moreover, our techniques lead to near-optimal approximate APSP, whereas it is unclear how to get comparable bounds using techniques in [21], as they do not maintain Thorup Zwick-based clusters.

[4] Ω_k hides exponential a factor of roughly $1/(k2^k)$. As written in [1] they assume k is constant (and hence the sparse hopset regime is not covered), but they also indicate that a tighter analysis could change the exact relationship between k and ϵ and hence allow a better k dependence and covering the sparse case (see Theorem 4.6 and Remark 4.7 in [1]).

[5] The k here should not be confused with the parameter k in the hopset size.

over any sequence of edge deletions is $\tilde{O}(mn^{1/k})$ and the expected size of the data structure is $\tilde{O}(m + n^{1+1/k})$. Each query for the distance between two vertices is answered in $O(k)$ worst-case time.

Our result improves upon a decremental APSP algorithm by Chechik [12] in a twofold way. First, for constant k, our update time bound is better by a $(1/\epsilon)^{O(\sqrt{\log n})}$ factor. Second, we bring down the query time from $O(\log\log(nW))$ to constant. We note that in the area of distance oracles a major goal is to preprocess a data structure that can return a distance estimate in *constant* time [11, 27, 30, 36][6].

Our results match the best known static algorithm with the same tradeoff (up to $(1+\epsilon)$ in the stretch and polylog in time) by Thorup-Zwick [34] for sparse graphs. For dense graphs there have been improvements by [36] in static settings.

Prior to [12], Roditty and Zwick [31] gave an algorithm for maintaining Thorup-Zwick distance oracles in total time $\tilde{O}(mn)$, stretch $(2k-1)(1+\epsilon)$ and $O(k)$ query time for *unweighted graphs*. Later on, Bernstein and Roditty [9] gave a decremental algorithm for maintaining Thorup-Zwick distance oracles in $O(n^{2+1/k+o(1)})$ time using emulators also only for *unweighted graphs*.

Distance Sketches. Another application of our hopsets with polylogarithmic hopbound is a near-optimal decremental algorithm for maintaining distance sketches (or distance labeling); an important tool in the context of distance computation. The goal is to store a small amount of information, a sketch, for each node, such that the distance between any pair of nodes can be approximated only using their sketches (without accessing the rest of the graph). Distance sketches are particularly important in networks, and distributed systems [16, 32], and large-scale graph processing [14]. Their significance is that at query time we only need to access/communicate the small sketches rather than having to access the whole graph. This is specially useful for processing large data when queries happen more frequently than updates.

The Thorup-Zwick [34] algorithm can be used to obtain distance sketches of expected size $O(kn^{1/k})$ (for each node) that supports $(2k-1)$-approximate queries in $O(k)$ time (in static settings), and this is known to be tight assuming a well-known girth conjecture. Our approximate APSP data structure has the additional property that the information stored for each node is a distance sketch of expected size $O(kn^{1/k})$ that supports $(2k-1)(1+\epsilon)$-approximate queries. Hence we can maintain distance sketches that almost match the guarantees of the best static algorithm. More specifically, for a fixed size our algorithm matches the best known static construction up to a $(1+\epsilon)$-factor in the stretch and polyloagrithmic factors in the update time. In decremental settings, distance oracles of [34], and hence distance sketches with the guarantees described are studied by [9, 31], but our total update time of $\tilde{O}(mn^{1/k})$ (for constant $k \geq 2$) significantly improves over these results. In particular [31] maintains these distance sketches in a total update time of $\Omega(mn)$, and [9] requires total update time of $O(n^{2+1/k+o(1)})$.

Near-Optimal $(1+\epsilon)$-MSSP. Our next result is a near-optimal algorithm for multi-source shortest paths.

[6] We need to store the original graph in addition to the distance oracle in order to update the distances and maintain correctness, however we do *not* need the whole graph for *querying distances* as we will also point out in describing the applications in maintaining distance sketches.

▶ **Theorem 3** (MSSP). *There is a data structure which given a weighted undirected graph $G = (V, E)$* explicitly *maintains $(1+\epsilon)$-approximate distances from a set of s sources in G under edge deletions, where $0 < \epsilon < \frac{1}{2}$ is a constant. Assuming that $|E| = n^{1+\Omega(1)}$ and $s = n^{\Omega(1)}$, the total expected update time is $\tilde{O}(sm)$. The data structure is randomized and works against an oblivious adversary.*

We note that total update time matches (up to polylogarithmic factors) the running time of the best known *static* algorithm for computing $(1+\epsilon)$-approximate distances from s sources for a wide range of graph densities. While for very dense graphs, using algorithms based on fast matrix multiplication is faster, the running time of our decremental algorithm matches the best known results in the static settings (up to polylogarithmic factors) whenever $ms = n^{\delta}$, for a constant $\delta \in (1, 2.37)$.

In the dynamic setting, our algorithm improves upon algorithms obtained by using hopsets of Henzinger, Krinninger and Nanongkai [21], or emulators of Chechik [12], both of which give a total update time of $O(sm \cdot 2^{\tilde{O}(\log^{\gamma} n)}), 0 < \gamma < 1$ (for a constant γ). In particular, by maintaining a hopset with polylogarithmic hopbound in $\tilde{O}(sm)$ time, we can maintain approximate SSSP from each source in $\tilde{O}(m)$ time. In contrast, in [12, 21] with hopset of hopbound $2^{\tilde{O}(\log^{\gamma} n)}$ is maintained, which if one simply applies existing techniques, results in a total update time of $m2^{\tilde{O}(\log^{\gamma} n)}$. In the general case, i.e., for very sparse graphs, the update bound of our algorithm is $sm2^{\tilde{O}(\sqrt{\log n})}$, which is similar but slightly better than the bound obtained by [21], and slightly improves over dependence on ϵ over [12].

Improved bounds for $(1+\epsilon)$-SSSP. Finally, in order to better demonstrate how our techniques compare to previous work, we show that we can obtain a slightly improved bound for decremental single-source shortest paths.

▶ **Theorem 4.** *Given an undirected and weighted graph $G = (V, E)$, there is data structure for maintaining $(1+\epsilon)$-approximate distances from a source $s_0 \in V$ under edge deletions, where $0 < \epsilon < 1$ is a constant and $|E| = n \cdot 2^{\tilde{\Omega}(\sqrt{\log n})}$. The total expected update time of the data structure is $m \cdot 2^{\tilde{O}(\sqrt{\log n})}$. There is an additional factor of $O(\frac{1}{\epsilon})^{\frac{\sqrt{\log n}}{\log\log n}}$ in the running time for non-constant ϵ.*

The amortized update time of our algorithm over all m deletions is $2^{\tilde{O}(\sqrt{\log n})}$. This improves upon the state-of-the art algorithm of [21], whose amortized update time is $2^{\tilde{O}(\log^{3/4} n)}$. We note that the techniques of [12] can also be used to obtain $(1+\epsilon)$-SSSP in amortized update time $\tilde{O}(1/\epsilon)\sqrt{\log n}$. This is close to our update time, but we get a better bound with respect to the dependence on ϵ.

Recent developments on decremental shortest paths. Recently and after a preprint of this paper was published, a decremental *deterministic* $(1+\epsilon)$-SSSP also with amortized update time of $n^{o(1)}$ was proposed by [8]. Several other recent results have also focused on deterministic dynamic shortest path algorithms or algorithms that work against an *adaptive adversary* (e.g. [6–8, 20]) most of which also use hopsets or related objects such as emulators. Our work leaves an open problem on whether hopsets with small hopbound can also be maintained and utilized deterministically[7]. This could have applications in

[7] One possible direction is considering derandomization of Throup-Zwick based clustering in static settings [34] combined with our techniques.

deterministic approximate all-pairs shortest paths, which could in turn have implications in using decremental shortest path algorithms for obtaining faster algorithms in classic/static settings (e.g. see [26]).

Hopsets vs. emulators. A majority of the previous work on dynamic distance computation are based on sparse *emulators* (e.g. [5, 9, 12]). For a graph $G = (V, E)$, an emulator $H' = (V, E')$ is a graph such that for any pair of nodes $x, y \in V$, there is a path in H' that approximates the distance between x and y on G (possibly with both multiplicative and additive factors). While there are some similarities in algorithms for constructing these objects, their analysis is different. More importantly, their maintenance and utilization for dynamic shortest paths have significant differences. An emulator approximates distances without using the original graph edges and hence we can restrict the computation to a sparser graph, whereas for using hopsets we also need the edges in the original graph. On the other hand, hopsets allow one to only consider paths with few hops.

1.2 Preliminaries and Notation

Given a weighted undirected graph $G = (V, E, w)$, and a pair $u, v \in V$ we denote the (weighted) shortest path distance by $d_G(u, v)$. We denote by $d_G^{(h)}(u, v)$ the length of the shortest path between u and v among the paths that use at most h-hops, and call this the h-hop limited distance between u and v.

In this paper, we are interested in designing *decremental* algorithms for distance problems in weighted graphs. In the decremental setting, the updates are only edge deletions or weight increases. This is as opposed to an *incremental* setting in which edges can be inserted, or a *fully dynamic* setting, in which we have both insertions and deletions. Specifically, given a weighted graph $G = (V, E, w)$, we want to support the following operations: DELETE$((u, v))$, where $(u, v) \in E$, which removes the edge (u, v), DISTANCE(s, u), which returns an (approximate) distance between a source s and any $u \in V$, and INCREASE$((u, v), \delta)$, which increases the weight of the edge (u, v) by $\delta > 0$. While our results also allow handling weight increases, in stating our theorems for simplicity we use the term *total update time* to refer to a sequence of up to m deletions.

▶ **Definition 5.** *Let $G = (V, E, w)$ be a weighted undirected graph. Fix $d, \epsilon > 0$ and an integer $\beta \geq 1$. A $(d, \beta, 1+\epsilon)$-*hopset *is a graph $H = (V, E(H), w_H)$ such that for each $u, v \in V$, where $d_G(u, v) \leq d$, we have $d_G(u, v) \leq d_{G \cup H}^{(\beta)}(u, v) \leq (1+\epsilon) d_G(u, v)$. We say that β is the* hopbound *of the hopset and $1+\epsilon$ is the* stretch *of the hopset. We also use $(\beta, 1+\epsilon)$-hopset to denote a $(\infty, \beta, 1+\epsilon)$-hopset.*

We sometimes call a $(d, \beta, 1+\epsilon)$-hopset a *d-restricted hopset*, when the other parameters are clear. We also sometimes consider hopset edges added for a specific distance range $(2^j, 2^{j+1}]$, which we call a hopset for a single distance *scale*.

In analyzing dynamic algorithms we sometimes also use a time subscript t to denote a distance (or a weight) after the first t updates. In particular we use $d_{t,G}(u, v)$ to denote the distance between u and v after t updates, and similarly use $d_{t,G}^{(h)}(u, v)$ to denote h-hop limited distance between u and v at time t.

2 Overview of Our Algorithms

The starting point of our algorithm is a known static hopset construction [18, 23]. We first review this construction. As we shall see, maintaining this data structure dynamically directly would require update time of up to $O(mn)$. Our first technical contribution is another

hopset construction that captures some of the properties of the hopsets of [18, 23], but can be maintained efficiently in a decremental setting. We then explain how by hierarchically maintaining a sequence of data structures we can obtain a near-optimal time and stretch tradeoff.

2.1 Static Hopset of [16]

In this section we outline the (static) hopset construction of Elkin and Neiman [18][8] (which is similar to [23]). We will later give a new (static) hopset algorithm that utilizes some of the properties of this construction but with modifications that allows us to maintain a *similar* hopset dynamically.

▶ **Definition 6** (Bunches and clusters). *Let $G = (V, E, w)$ be a weighted, n-vertex graph, k be an integer such that $1 \leq k \leq \log\log n$ and $\rho > 0$. We define sets $V = A_0 \supseteq A_1 \supseteq ... \supseteq A_{k+1/\rho+1} = \emptyset$. Let $\nu = \frac{1}{2^k-1}$. Each set A_{i+1} is obtained by sampling each element from A_i with probability $q_i = \max(n^{-2^i \cdot \nu}, n^{-\rho})$.*

Fix $0 \leq i \leq k + 1/\rho + 1$ and for every vertex $u \in A_i \setminus A_{i+1}$, let $p(u) \in A_{i+1}$ be the node of A_{i+1}, which is closest to u, and let $d(u, A_{i+1}) := d(u, p(u))$ (assume $d(u, \emptyset) = \infty$). We call $p(u)$ the pivot *of u. We define a* bunch *of u to be a set $B(u) := \{v \in A_i : d(u, v) < d(u, A_{i+1})\}$. Also, we define a set $C(v)$, called the* cluster *of $v \in A_i \setminus A_{i+1}$, defined as $C(v) = \{u \in V : d(u, v) < d(u, A_{i+1})\}$.*

Note that if $v \in B(u)$ then $u \in C(v)$, but the converse does not necessarily hold. The way we define the bunches and clusters here follows [18], but differs slightly from the definitions in [31, 34], where each vertex has a separate bunch and cluster defined for each level i (and stores the union of these for all levels).

The clusters are *connected* in a sense that if a node $u \in C(v)$ then any node z on the shortest path between v and u is also in $C(v)$. This property is important for bounding the running time (as also noted in [31, 34]):

▷ Claim 7. Let $u \in C(v)$, and let $z \in V$ be on a shortest path between v and u. Then $z \in C(v)$.

Proof. Let $v \in A_i$. If $z \notin C(v)$ then by definition $d(z, A_{i+1}) \leq d(v, z)$. On the other hand, since z is on the shortest path between u and v: $d(u, A_{i+1}) \leq d(z, u) + d(z, A_{i+1}) \leq d(u, z) + d(z, v) = d(u, v)$, which contradicts the fact that $u \in C(v)$. ◁

The hopset is then obtained by adding an edge (u, v) for each $u \in A_i \setminus A_{i+1}$ and $v \in B(u) \cup \{p(u)\}$, and setting the weight of this edge to be $d(u, v)$. These distances can be computed by maintaining the clusters.

▶ **Lemma 8** ([18, 23]). *Let $G = (V, E, w)$ be a weighted, n-vertex graph, k be an integer such that $1 \leq k \leq \log\log n$ and $0 < \rho, 0 < \epsilon < 1$. Assume the sets A_i and bunches are defined as in Definition 6. Define a graph $H = (V, E_H, w_H)$, such that for each $u \in A_i \setminus A_{i+1}$ and $v \in B(u) \cup \{p(u)\}$, we have an edge $(u, w) \in E_H$ with weight $d_G(u, v)$. Then H is a $(\beta, 1 + \epsilon)$-hopset of size $O(n^{1+\frac{1}{2^k-1}})$, where $\beta = (O(\frac{k+1/\rho}{\epsilon})^{k+1/\rho+1}$.*

[8] In [18] two algorithms with different sampling probabilities are given, where one removes a factor of k in the size. This factor does not impact our overall running time, so we will use the simpler version.

For reference we sketch a proof of the hopset properties in the full version. Our main result is based on a new construction consisted of a hierarchy of hopsets. Our dynamic hopset requires a new *stretch* analysis as estimates on the shortest paths are obtained from different data structures, but the *size* analysis is basically the same.

While we are generally interested in a hopset that is not much denser than the input, as we will see the running time (both in static and dynamic settings) is mainly determined by the number of clusters a node belongs to, rather than the size of the hopset. Moreover, unlike an emulator, for computing the distances using a hopset, we also need to consider the edges in G, and a small hopbound is the key to efficiency rather than the sparsity.

The hopset of [18] has some structural similarities to the emulators of [35]. One main difference is that the sampling probabilities are adjusted (lower-bounded by $n^{-\rho}$) to allow for efficient construction of these hopsets in various models, at the cost of slightly weaker size/hopbound tradeoffs. This adjustment is also crucial for our efficient decremental algorithms. Inspired by the construction described, in Section 2.2 we describe a *new static* hopset algorithm, and later in Section 2.3 we adapt it to decremental settings.

2.2 New static hopset based on path doubling and scaling

As a warm-up, before moving to our new dynamic hopset construction, we provide a simple static hopset and explain why we expect to maintain such a structure more efficiently than the structure in Section 2.1 in *dynamic settings*. Our main contribution is to maintain a dynamic hopset *efficiently* using ideas in the simple algorithm described in this section.

At a high level, computing one of the main components of the hopset of Lemma 8 involves multiple single-source shortest paths computations. Maintaining single-source shortest paths is easy in the decremental setting, if we limit ourselves to paths of low length (or allow approximation). Namely, assuming integer edge weights, one can maintain single source shortest paths up to length d under edge deletions in total $O(md)$ time.

If we simply modified the construction of the hopset of Lemma 8, and computed shortest paths up to length d instead of shortest paths of unbounded length, we would obtain a d-restricted hopset. We describe this idea in more detail in Section 3, where we show that an adaptation of the techniques by [31] allows us to maintain a d-restricted hopset in decremental settings, in total time $O(dmn^{\rho})$, for a parameter $0 < \rho < \frac{1}{2}$. However, for large d such a running time is prohibitive. In order to address this challenge, in this section we describe a static hopset, which can be computed using shortest path explorations up to only a polylogarithmic depth, yet can be used to approximate arbitrarily large distances. In the next sections we leverage this property to maintain a similar hopset in the decremental setting efficiently. This will require overcoming other obstacles, notably the fact that the dynamic shortest path problems that we need to solve are not decremental.

Path doubling. Assume that we are given a procedure $\textsc{Hopset}(G, \beta, d, \epsilon)$ that constructs a $(d, \beta, 1+\epsilon)$ hopset. In Section 3, we provide such an algorithm that uses only shortest path computation up to polylogarithmic depth. We argue that by applying the $\textsc{Hopset}(G, \beta, d, \epsilon)$ procedure *repeatedly* we can compute a full hopset, and in this process by utilizing the previously added hopset edges we can restrict our attention to short-hop paths only.

More formally, we construct a sequence of graphs $H_0, \ldots, H_{\log W}$, such that H_j is a hopset that handles pairs of nodes with distance in range $[2^{j-1}, 2^j)$, for $0 \leq j \leq \log W$. This implies that $\bigcup_{r=0}^{j} H_r$ is a $(2^j, \beta, (1+\epsilon)^j)$-hopset of G. Note that for $0 \leq j \leq \log \beta$ we can set $H_j = \emptyset$, since G covers these scales. We would like to use $G \cup_{r=0}^{j-1} H_r$ to construct H_j based on the following observation that has been previously used in other (static) models (e.g. parallel hopsets of Cohen [13]).

Consider $u, v, d_G(u,v) \in [2^{j-1}, 2^j)$, and let π be the shortest path between u and v in G. Then π can be divided into three segments π_1, π_2 and π_3, where π_1 and π_3 have length at most 2^{j-1} and π_2 consists of a single edge. But we know there is a path in $G \cup_{r=0}^{j-1} H_r$ with at most β-hops that approximates each of π_1 and π_2. Hence for constructing H_j we can compute *approximate* shortest paths by restricting our attention to paths of consisting of at most $2\beta+1$ *hops* in $G \cup_{r=0}^{j-1} H_r$.

This idea, which we call path doubling, has been previously used in hopset constructions in distributed/parallel models (e.g. [13,17,18]), but to the best of our knowledge this is the first use of this approach in a dynamic setting. Applying this idea in parallel/distributed settings is relatively straight-forward, since having bounded hop paths already leads to efficient parallel shortest path explorations (e.g. by using Bellman-Ford). However, utilizing it efficiently in dynamic settings is more involved for several reasons: we have to simultaneously maintain the clusters (including their connectivity property), apply a scaling idea on the whole structure, and handle insertions in our hopset algorithm and its analysis.

But first we describe a *scaling idea* that at a high-level allows to go from *h-hop-bounded* explorations to h-depth bounded explorations on a scaled graph.

Scaling. We review a scaling algorithm that allows us to utilize the path doubling idea. Similar scaling techniques are used in dynamic settings [5,9,21] for single-source shortest paths, but as we will see, using the scaling idea in our setting is more involved since it has to be carefully combined with other components of our construction.

This idea can summarized in the following scaling scheme due to Klein and Subramanian [24], which, roughly speaking, says that finding shortest paths of length $\in [2^{j-1}, 2^j)$ and at most ℓ hops, can be (approximately) reduced to finding paths of length at most $O(\ell)$ in a graph with in integral weights. This is done by a rounding procedure that adds a small *additive* term of roughly $\frac{\epsilon_0 w(e)}{\ell}$ to each edge e. Then for a path of ℓ hops the overall stretch will be $(1+\epsilon_0)$.

▶ **Lemma 9** ([24]). *Let $G=(V,E,w)$ be a weighted undirected graph. Let $R \geq 0$ and $\ell \geq 1$ be integers and $\epsilon_0 > 0$. We define the* scaled graph *to be a graph $\textsc{Scale}(G, R, \epsilon_0, \ell) := (V, E, \hat{w})$, such that $\hat{w}(e) = \lceil \frac{w(e)}{\eta(R,\epsilon_0)} \rceil$, where $\eta(R,\epsilon_0) = \frac{\epsilon_0 R}{\ell}$. Then for any path π in G such that π has at most ℓ hops and weight $R \leq w(\pi) \leq 2R$ we have,*

- $\hat{w}(\pi) \leq \lceil 2\ell/\epsilon_0 \rceil$,
- $w(\pi) \leq \eta(R,\epsilon_0) \cdot \hat{w}(\pi) \leq (1+\epsilon_0) w(\pi)$.

Similar scaling ideas have been used in the h-SSSP algorithm for maintaining approximate shortest paths [5]. The algorithm maintains a collection of trees and to return a distance estimate, it finds the tree that best approximates a given distance. But we note that in utilizing the scaling techniques in our final dynamic hopset construction we cannot simply maintain a *disjoint set of* bounded hop shortest path trees. We need to maintain the whole structure of the hopset on the scaled graphs together: firstly, based on definition of bunches in Lemma 8, nodes keep on leaving and joining clusters, so we cannot simply maintain a set of shortest trees from a fixed set of roots. We need to maintain the *connectivity* of clusters as described in Section 2.1 at the same time as maintaining the shortest path trees. Additionally, while we are maintaining distances over the set of clusters we also need to handle insertions introduced by smaller scales.

To maintain these efficiently, we need to apply the scaling to the whole structure, including the hopset edges added so far. But when we utilize the smaller scale hopset edges (for applying path doubling) insertions or distance decreases are introduced. As we will see, handling insertions at the same time the clusters (and the corresponding distances) are updated makes the stretch/hopbound analysis more involved.

Next we combine the scaling with the path doubling techniques. The path doubling property states that we can restrict our attention to $(2\beta+1)$-hop limited shortest path computation, and the scaling idea ensures that such $(2\beta+1)$-*hop* bounded paths in $G \cup \bigcup_{r=0}^{j-1} H_r$ correspond to paths bounded *in depth* by $d = \lceil \frac{2\ell}{\epsilon_0} \rceil = O(\frac{\beta}{\epsilon_0})$ in the scaled graph $G_{scaled} = \textsc{Scale}(G \cup \bigcup_{r=0}^{j-1} H_r, 2^j, \epsilon_0, 2\beta+1)$. Informally, this mean it is enough to construct shortest path trees up to depth ℓ on the scaled graphs in our hopset construction.

We can now summarize our new static hopset construction in Algorithm 1. Similarly to Scale, for a graph $G = (V, E, w)$ we define $\textsc{Unscale}(G, R, \epsilon, \ell)$ to be a graph (V, E, w'), where for each $e \in E$, $w'(e) = \eta(R, \epsilon) \cdot w(e)$. In static settings, the procedure $\textsc{Hopset}(G, \beta, d, \epsilon)$ for constructing a d-restricted hopset can be performed by running a $(\beta, 1+\epsilon)$-hopset construction algorithm in which the shortest path explorations are restricted to depth ℓ. In Section 3 we describe a decremental algorithm for this procedure, and describe how it leads to a $(d, \beta, 1+\epsilon)$-restricted hopset. Note that we can set $\beta = \text{poly} \log n$, and so the shortest path explorations can be bounded by a polylogairthmic value.

Algorithm 1 Simple static hopset.

for $j = 1$ *to* $\lceil \log W \rceil$ **do**
- $G_{scaled} := \textsc{Scale}(G \cup \bigcup_{r=0}^{j-1} H_r, 2^j, \epsilon_0, 2\beta+1)$
- $\hat{H} := \textsc{Hopset}(G_{scaled}, \beta, \lceil \frac{2(2\beta+1)}{\epsilon_0} \rceil, \epsilon)$
- $H_j := \textsc{Unscale}(\hat{H}, 2^j, \epsilon_0, 2\beta+1))$
- $H := H \cup H_j$

It is not hard to see that in such a static construction, three different approximation factors are combined in each scale: a $(1+\epsilon)$-stretch due to the Hopset procedure, a $(1+\epsilon_1)$-factor from the restricted hopset, and a $(1+\epsilon_0)$-factor due to scaling. This is summarized in the following lemma.

▶ **Lemma 10.** *Let G be a graph and H be a $(d, \beta, 1+\epsilon_1)$ hopset of G. Let $G_{scaled} = \textsc{Scale}(G \cup H, d, \epsilon_0, 2\beta+1)$ and let $H' = \textsc{Unscale}(\textsc{Hopset}(G_{scaled}, d, \lceil \frac{2(2\beta+1)}{\epsilon_0} \rceil, \epsilon_2))$. Then $H \cup H'$ is a $(2d, \beta, (1+\epsilon)(1+\epsilon_1)(1+\epsilon_0))$ hopset of G.*

Obtaining such a guarantee in dynamic settings is going to be more involved, since we also need to handle insertions, and at the same time ensure that the update time remains small. Moreover the stretch analysis will require combining estimates obtained by different procedures.

2.3 Near-Optimal Decremental Hopsets

In this section we describe how we can overcome the challenges of the dynamic settings in order to maintain a decremental hopset in near-optimal update-time.

The first step of our algorithm is constructing a d-restricted version of the hopset described in Section 2.1. As discussed, for this we can use the techniques by [31] to maintain a $(d, \beta, 1+\epsilon)$-hopset in $\tilde{O}(dmn^{\rho})$ total update time, where $0 < \rho < \frac{1}{2}$. Now in order to remove the time dependence on d, we use the path doubling and scaling ideas described as follows: we maintain this data structure on a sequence of scaled graphs simultaneously, and argue that this data structure gives us a hopset on G after *unscaling* the edge weights.

Sequence of restricted hopsets. Similiar to Section 3.1, our decremtnal algorithm maintains the sequence of graphs $H_0, \ldots, H_{\log W}$, where for each $0 \leq j \leq \log W$, $\bigcup_{r=0}^{j} H_r$ is a $(2^j, \beta, (1+\epsilon)^j)$-hopset of G. For *each scale* we show the following:

▶ **Lemma 11.** *Consider a graph $G = (V, E, w)$ subject to edge deletions, and parameters $0 < \epsilon < 1, \rho < \frac{1}{2}$. Assume that we have maintained $\bar{H}_j := H_1, ..., H_j$, which is a $(2^j, \beta, (1+\epsilon)^j)$-hopset of G. Then given the sequence of changes to G and $\bar{H}_j$, we can maintain a graph H_{j+1}, such that $\bar{H}_j \cup H_{j+1}$ is a $(2^{j+1}, \beta, (1+\epsilon)^{j+1})$-hopset of G. This restricted hopset can be maintained in $\tilde{O}((m+\Delta)n^\rho \cdot \frac{\beta}{\epsilon})$ total time, where m is the initial size of G, and Δ is the number of edges inserted to $\bar{H}_j$ over all updates, $\beta = (\frac{1}{\epsilon \cdot \rho})^{O(1/\rho)}$.*

Note that the lemma does not hold for *any* restricted hopset, and in dynamic settings we need to use special properties of our construction to prove this.

To prove this lemma we use the techniques of [31] to maintain the clusters. For obtaining near-optimal update time, we combine this algorithm with the path doubling and scaling ideas described earlier. However, in order to utilize these ideas, we need to deal with the fact that inserting hopset edges from smaller scales introduces *insertions*.

Handling insertions. In addition to maintaining clusters and distances decrementally, in our final construction we need to handle edge *insertions*. This is because we run it on a graph $G \cup \bigcup_{r=0}^{j-1} H_r$ (after applying scaling of Lemma 9). While edges of G can only be deleted, new edges are added to the H that we need to take into account for obtaining faster algorithms.

At a high-level, the algorithm of Roditty and Zwick [31] decrementally maintains a collection of single-source shortest path trees (up to a bounded depth) using the Even-Shiloach algorithm (ES-tree) [33] at the same time as maintaining a clustering. To handle edge insertions, we modify the algorithm to use the *monotone* ES-tree idea proposed by [21,22].

The goal of a monotone ES-tree is to support edge insertions in a limited way. Namely, whenever an edge (u, v) is inserted and the insertion of the edge causes a distance decrease in the tree, we do *not* update the currently maintained distance estimates. Still the inserted edge may impact the distance estimates in later stages by preventing some estimates from increasing after further deletions.

While it is easy to see that this change keeps the running time roughly the same as in the decremental setting, analyzing the correctness is a nontrivial challenge. This is because the existing analyses of a monotone ES-tree work under specific structural assumptions and do not generalize to any construction. Specifically, while [21] analyzed the stretch incurred by running monotone ES-trees on a hopset, the proof relied on the properties of the specific hopset used in their algorithm. Since the hopset we use is quite different, we need a different analysis, which combines the static hopset analysis, with the ideas used in [21], and also take into account the stretch incurred due to the fact that the restricted hopsets are maintained on the scaled graphs. Note also that our main hopset is not a simply a decremental maintenance of hopsets of [16], as our estimates are obtained from a *sequence of hopsets* and insertions in one scale introduce insertions in the next scale. This is why we need a new argument and cannot simply rely on arguments in [21] and [16].

Putting it together. We now go back to the setting of Lemma 11, and use a procedure similar to Algorithm 1. Given a 2^j-restricted hopset $\bar{H}_j = H_1 \cup ... \cup H_j$ for distances up to 2^j, we can now construct a graph G^j by applying the scaling of Lemma 9 to $G \cup \bar{H}_j$ and setting $R = 2^j$, $\ell = 2\beta + 1$. Then we can efficiently maintain an ℓ-restricted hopset on G^j. Then by Lemma 11 we can use this to update H_{j+1}. Importantly, ℓ is independent of R, and

thus we can eliminate the factor R to get $\tilde{O}(\beta mn^{\rho})$ total update time. Our final algorithm is a hierarchical construction that maintains the restricted hopsets on scaled graphs and the original graph simultaneously.

Stretch and hopbound analysis. As discussed, applying the path-doubling idea to the hopset analysis is straightforward in static settings (and can be to some extent separated from the rest of the analysis) as is the case in [18]. However in our adapted decremental hopset algorithm this idea needs to be combined with the properties of the monotone ES tree idea and the fact that distance estimate are obtained from a sequence of hopsets on the scaled graph. In particular, in our stretch analysis we need to divide paths into smaller segments, such that the length of some segments is obtained from smaller iterations i, and the length of some segments are obtained from this combination of monotone ES tree estimates based on path doubling and scaling. We need a careful analysis to show that the stretch obtained from these different techniques combine nicely, which is based on a threefold inductive analysis:

1. An induction on i, the iterations of the base hopset, which controls the sampling rate and the resulting size and hopbound tradeoffs.
2. An induction on the scale j, which allows us to cover all ranges of distances $[2^j, 2^{j+1}]$ by maintaining distances in the appropriate scaled graphs.
3. An induction on time t that allows us to handle insertions by using the estimates from previous updates in order to keep the distances monotone.

The overall stretch argument needs to deal with several error factors in *addition to* the base hopset stretch. First, the error incurred by using hopsets for smaller scales, which we deal with by maintaining our hopsets by setting $\epsilon' = \frac{\epsilon}{\log n}$. This introduces polylogarithmic factors in the hopbound. The second type of error comes from the fact that the restricted hopsets are maintained for scaled graphs, which implies the clusters are only approximately maintained on the original graph. This can also be resolved by further adjusting ϵ'. Finally, since we use an idea similar to the monotone ES tree of [21, 22], we may set the level of nodes in each tree is to be larger than what it would be in a static hopset. But we argue that the specific types of insertions in our algorithm will still preserve the stretch. At a high-level this is because in case of a decrease we use an estimate from time $t-1$, which we can show inductively has the desired stretch. We note that while the monotone ES tree is widely used, we always need a different construction-specific analysis to prove the correctness.

Technical differences with previous decremental hopsets. We note that while the use of monotone ES tree and the structure of the clusters in our construction are similar to [21], our algorithm has several important technical differences. First, our hopset algorithm is based on different base hopset with a polylogarithmic hopbound, which as noted is crucial for obtaining near-optimal bounds in most of our applications. Additionally, we use a different approach to maintain the hopset efficiently by using path doubling and maintaining restricted hopsets on a sequence of *scaled graphs*. Among other things, in [21] a notion of *approximate ball* is used that is rather more lossy with respect to the hopbound/stretch tradeoffs. By maintaining restricted hopsets on scaled graphs, we are also effectively preserving approximate clusters/bunches with respect to the original graph, but as explained earlier, the error accumulation combines nicely with the path-doubling idea. Moreover, [21] uses an edge sampling idea to bound the update time, which we can avoid by utilizing the sampling probability adjustments in [18], and the ideas in [31]. Finally, our algorithm is based on maintaining the clusters up to a low hop, whereas they directly maintain bunches/balls.

2.4 Applications in Decremental Shortest Paths

Our algorithms for maintaining approximate distances under edge deletions are as follows. First, we maintain a $(\beta, 1+\epsilon)$-hopset. Then, we use the hopset and Lemma 9 to reduce the problem to the problem of approximately maintaining short distances from a single source. For our application in MSSP and APSP the best update time is obtained by setting the hopbound to be polylgarithmic whereas for SSSP the best choice is $\beta = 2^{\tilde{O}(\sqrt{\log n})}$. Using this idea for SSSP and MSSP mainly involves using the monotone ES tree ideas described earlier. Maintaining the APSP distance oracle is slightly more involved but uses the same techniques as in our restricted hopset algorithm. This algorithm is based on maintaining Thorup-Zwick distance oracle [34] more efficiently. At a high-level, we maintain *both* a $(\beta, 1+\epsilon)$-hopset and Thorup-Zwick distance oracle simultaneously, and balance out the time required for these two algorithms. The hopset is used to improve the time required for maintaining the distance oracle from $O(mn)$ (as shown in [31]) to $O(\beta mn^{1/k})$, but with a slightly weaker stretch of $(2k-1)(1+\epsilon)$. Querying distances is then the same as in the static algorithm of [34], and takes $O(k)$ time. In the full version of this paper, we explain how our hopset can be used for applications in approximate shortest paths and distance sketches.

3 Decremental Hopset

In this section we describe two decremental hopset algorithms with different tradeoffs. The starting-point of our constructions are the static hopsets described in Section 2.1. But in order to get an efficient dynamic algorithm, we need to modify this construction in several ways. First we explain how we can adapt ideas by Roditty-Zwick [31] to obtain an algorithm for computing a d-restricted hopset. The total running time of this algorithm is $O(dmn^{\rho})$ (where $\rho < 1$ is a constant). While existentially this construction matches the state-of-the-art static hopsets with respect to size and hopbound tradeoffs, the update time is undesirable for large values of d, and thus in Section 3.1 we explain how we can remove this dependence from the running time at the cost of a slightly worst hopbound guarantee.

Maintaining a restricted hopset. We start by adapting the decremental algorithm by [31] that maintains the Thorup-Zwick distance oracles [34] with stretch $(2k-1)$ for pairs of nodes within distance d in $\tilde{O}(dmn^{1/k})$ total time, but we use it to obtain a d-restricted hopset. In particular, using ideas in [31], and by restricting the shortest path trees up to depth d, we can maintain a variant of the hopset defined in Lemma 8 in which the hopset guarantee only holds for nodes within distance d. In the full version, we describe how we adapt the algorithm of [31] to our settings to prove the following theorem.

▶ **Theorem 12.** *Fix $\epsilon > 0, k \geq 2$ and $\rho \leq 1$. Given a graph $G = (V, E, w)$ with integer and polynomial weights, subject to edge deletions we can maintain a $(d, \beta, 1+\epsilon)$-hopset, with $\beta = O\left(\left(\frac{1}{\epsilon} \cdot (k + 1/\rho)\right)^{k+1/\rho+1}\right)$ in $O(d(m + n^{1+\frac{1}{2^k-1}})n^{\rho})$ total time. The size/hopbound guarantee holds with high probability against an oblivious adversary.*

This algorithm has a large update time for d-restricted hopsets, when d is large. Next we show how we can eliminate this update time dependence on d, which is the main technical component of this work.

3.1 Decremental hopsets with improved update time

Next we provide a new hopset algorithm that is based on maintaining these restricted hopsets on a sequence of scaled graphs, and show how this improves the update time, in exchange for a small (polylogarithmic) loss in the hopbound.

Recall that our algorithm maintains a sequence of graphs $H_0, \ldots, H_{\log W}$, where for each $1 \leq j \leq \log W$, $H_0 \cup \ldots \cup H_j$ is a 2^j-restricted hopset of G. Instead of computing each H_j separately, we use $G \cup \bigcup_{r=0}^{j-1} H_r$ to construct H_j. The first technical challenge is making the running time independent of the distance bound 2^j, which is what we would get by directly using the algorithm of [31]. We observe that at the cost of some small approximation errors, any path of length $\in [2^{j-1}, 2^j)$ in G can be approximated by a path of at most $2\beta+1$ hops in $G \cup \bigcup_{r=0}^{j-1} H_r$. This relies on having the 2^j-restricted hopset $\bar{H}_j$, which allows us to maintain the hopset $\bar{H}_{j+1}$.

Second, while G is undergoing deletions, H_j may be undergoing edge *insertions* incurred by restricted hopset edges added for smaller scales, which we discuss next. All the missing details in this section can be found in the full-version of this paper.

Handling edge insertions. We handle edge insertions by combining of the monotone ES-tree algorithm [21] (and further used in the hopset construction of [22]). We summarize this idea and the relevant properties in the full version. As stated earlier, the algorithm itself is a simple extension of the Even-Schiloach tree. At a high-level we maintain an ES tree for each cluster and when an insertion causes the level of a node in an ES tree to decrease, we ignore the insertion and keep the same level. The more challenging aspect of using the monotone ES tree idea is proving the correctness (stretch), as this does not extend to all types of insertions but only for insertion with certain inductive structural properties. That is why even though this idea is widely used, we always need a construction-specific proof of correctness. In Theorem 14 we prove that specifically for the insertions in our final hopset algorithm the use of monotone ES tree does not violate our stretch argument.

Path doubling and scaling. We first state the path doubling idea more formally for a *static hopset* in the following lemma. However for utilizing this idea dynamically we need to combine it with other structural properties of our hopsets and the two algorithms described above.

▶ **Lemma 13.** *Given a graph $G = (V, E)$, $0 < \epsilon_1 < 1$, the set of $(\beta, 1+\epsilon_1)$-hopsets $H_r, 0 \leq r < j$ for each distance scale $(2^r, 2^{r+1}]$, provides a $(1+\epsilon_1)$-approximate distance for any pair $x, y \in V$, where $d(x, y) \leq 2^{j+1}$ using paths with at most $2\beta+1$ hops.*

This implies that it is enough to compute $(2\beta+1)$-hop limited distances in restricted hopsets for *each* scale. For using this idea in dynamic settings we have to deal with some technicalities. We should show that we can combine the rounding with the modification needed for handling insertions.

A hierarchy of restricted hopsets. We define a scaled graph using Lemma 9 as follows: $G^j := \textsc{Scale}(G \cup \bigcup_{r=0}^{j} H_r, 2^j, \epsilon_2, 2\beta+1)$. Here we set $R = 2^j, \ell = 2\beta+1$, and ϵ_2 is a parameter that we tune later. We first describe the operations performed on this scaled graph. We then explain how we can put things together for all scales to get the desired guarantees. The key insight for scaling $G \cup \bigcup_{r=0}^{j} H_r, 2^j$ is that we can obtain H_{j+1} by computing an $O(\ell)$-restricted hopset of G^j (using the algorithm of Lemma 11) and scaling back the weights of the hopset edges.

In addition to the graph G undergoing deletions, our decremental algorithm maintains the following data structures for each $1 \leq j \leq \log W$:

- The set $\bar{H}_j = \bigcup_{r=0}^{j} H_r$, union of all hopset edges for distance scales up to $[2^j, 2^{j+1}]$.
- The scaled graphs $G^1, ..., G^j$.
- Data structure obtained by constructing an $O(\beta/\epsilon_2)$-restricted hopset on G^j using Theorem 12 for the appropriate parameter $\epsilon_2 < 1$. We denote this data structure by D_j.

We update the data structures described as follows: we maintain d-restricted hopsets for $d = \lceil \frac{2(2\beta+1)}{\epsilon_2} \rceil$ starting on $j = 0, ..., \log W$ in increasing order of j to compute hopset edges H_j. After processing all the changes in scaled graph G^j, we add the inserted edges to G^{j+1}. Then we process the changes in G^{j+1} by computing a d-restricted hopset again and repeat until all distance scales of covered. As described, when the distances increase a node may join a new cluster which will lead to a set of insertions in H and in turn insertions in a sequence of graphs G^j. Note that we need to update both the restricted hopsets on the scaled graphs (denoted by D_j) and the hopset H_j for G obtained by scaling back the distances using Lemma 9. A pseudocode of this algorithm and its running time analysis can be found in the full version.

Hopset stretch and hopbound. We next show the stretch and hopbound of the hopset algorithm described for a single-scale by combining properties of the monotone ES-tree algorithm with the static hopset argument and the rounding framework.

▶ **Theorem 14.** *Given a graph $G = (V, E)$, and $0 \leq \epsilon_2 < 1$, assume that we have maintained a $(2^j, \beta, (1+\epsilon_j))$-restricted hopset $\bar{H}_j$, and let H_{j+1} be the hopset obtained by running the above algorithm on $G \cup \bar{H}_j$. Fix $0 < \delta \leq \frac{1}{8(k+1/\rho+1)}$, and consider a pair $x, y \in V$ where $d_{t,G}(x,y) \in [2^j, 2^{j+1}]$. Then for $0 \leq i \leq k + 1/\rho + 1$, either of the following conditions holds:*

1. $d^{((3/\delta)^i)}_{G \cup \bar{H}_{j+1}}(x,y) \leq (1+8\delta i)(1+\epsilon_j)(1+\epsilon_2) d_{t,G}(x,y)$ *or,*
2. *There exists $z \in A_{i+1}$ such that,*

$$d^{((3/\delta)^i)}_{G \cup \bar{H}_{j+1}}(x,z) \leq 2(1+\epsilon_j)(1+\epsilon_2) d_{t,G}(x,y).$$

Moreover, by maintaining a monotone ES tree on G^{j+1} up to depth $\lceil \frac{2(2\beta+1)}{\epsilon_2} \rceil$, and applying the rounding in Lemma 9, we can maintain $(1+\epsilon_{j+1})$-approximate single-source distances up to distance 2^{j+2} from a fixed source s on G, where $1+\epsilon_{j+1} = (1+\epsilon_j)(1+\epsilon_2)^2(1+\epsilon)$ and $\beta = (3/\delta)^{k+1/\rho+1}$.

Proof. The stretch argument is based on a threefold induction on i, j-th scale, and time t. By fixing i, j, t, and a source node s, we show that there is a $(1+\epsilon_j)$-stretch path between s and any other node with β hops (or if we are using previous scale $2\beta+1$-hops) such that each segment of this path has the desired stretch based on the inductive claim on one of these three factors. At a high level induction on i and j follows from static properties of our hopset. To show that bounded depth monotone ES tree maintains the approximate distances, we note that any segment of the path undergoing an insertion consistent of a single shortcut and the weight on such an edge is a distance estimate between its endpoints.

It is easy to see that we never underestimate distances. Roughly speaking, we either obtain an estimate from rounding estimates obtained from smaller scales, which is an upper bound on the original estimate, or we ignore a distance decrease.

We use a double induction on i and time t, and also rely on distance computed up to scaled graph G^j. First, using these distance estimates for smaller scales, we argue that when we add an edge to $\bar{H}_{j+1}$ it has the desired stretch. Let $L_{t,j}(u,v)$ denote the level of node v

in the tree rooted at u after running the monotone ES tree up to depth $D = \lceil \frac{2(2\beta+1)}{\epsilon} \rceil$ on graph G^j. This proof is based on a cyclic argument: assuming we have correctly maintained distances up to a given scale using our hopset, we show how we can compute the distances for the next scale. In particular, we first assume that based on the theorem conditions we are given $\bar{H}_j$ and have maintained all the clusters and the corresponding distances in $G^1, ..., G^j$ with stretch $1 + \epsilon_j$. This lets us analyze H_{j+1}. Then to complete the argument, we show how given the hopsets of scale $[2^j, 2^{j+1}]$, we can compute approximate SSSP distances for the next scale based on the monotone ES tree on G^{j+1}.

First, in the following claim, we observe that the edge weights inserted in the latest scale have the desired stretch by using our inductive assumption that all the shortest path trees on each cluster on $G^1, ..., G^j$ are approximately maintained. We use such distance to add edges in each cluster to construct H_{j+1}, and we observe the following about the weights on these edges:

▶ **Observation 15.** *Let $v \in B(u)$ such that $d_{t,G}(u, v) \leq 2^{j+1}$. Consider an edge (u, v) added to H_{j+1} after running the algorithm on $G^1, ..., G^j$ for $D = \lceil \frac{2(2\beta+1)}{\epsilon_2} \rceil$ rooted at node v. Let $w_{j+1}(u, v) := \min_{r=1}^{j} \eta(2^r, \epsilon_2) L_r(u, v)$, that is the unscaled edge weight. Then we have $d_{t,G}(u, v) \leq w_{j+1}(u, v) \leq (1 + \epsilon_j)(1 + \epsilon_2) d_{t,G}(u, v)$.*

This claim implies that the weights of hopset edges assigned by the algorithm correspond to approximate distance of their endpoints. Let $d_{t,j}(x, y) := \min_{r=1}^{j} \eta(2^r, \epsilon_2) L_{t,j}(x, y)$ which would be the estimate we obtain by for distance between x and y after scaling back distances on G^j. In other words this is the hop-bounded distance after running monotone ES tree on G^j and scaling up the weights.

For any time t and the base case of $i = 0$, we have three cases. If $y \in B(x)$ then edge (x, y) is in the hopset H_{j+1}, and by Observation 15 the weight assigned to this edge is at most $(1 + \epsilon_j)(1 + \epsilon_2) d_{t,G}(x, y)$. In this case the first condition of the theorem holds. Otherwise if $x \in A_1$, then $z = x$ trivially satisfies the second condition. Otherwise we have $x \in A_0 / A_1$, and by setting $z = p(x)$ we know that there is an edge $(x, z) \in \bar{H}_j$ such that $d_{t,j}(x, z) \leq (1 + \epsilon_2) d_{G \cup \bar{H}_j}(x, y)$ (by definition of $p(x)$ and using the same argument as above). Hence the second condition holds.

By inductive hypothesis assume the claim holds for i. Consider the shortest path $\pi(x, y)$ between x and y. We divide this path into $1/\delta$ segments of length at most $\delta d_{t,G}(x, y)$ and denote the a-th segment by $[u_a, v_a]$, where u_a is the node closest to x (first node of distance at least $a\delta d_{t,G}(x, y)$) and v_a is the node furthest to x on this segment (of distance at most $(a + 1)\delta d_{t,G}(x, y)$).

We then use the induction hypothesis on each segment. First consider the case where for all the segments the first condition holds for i, then there is a path of $(3/\delta)^i (1/\delta) \leq (3/\delta)^{i+1}$ hops consisted of the hopbounded path on each segment. We can show that this path satisfies the first condition for $i + 1$. In other words,

$$d^{((3/\delta)^{i+1})}_{t,G \cup \bar{H}_{j+1}}(x, y) \leq \sum_{a=1}^{1/\delta} d^{((3/\delta)^i)}_{t,G \cup \bar{H}_{j+1}}(u_a, v_a) + d^{(1)}_{t,G}(v_a, u_{a+1}) \leq (1 + 8\delta i)(1 + \epsilon_j)(1 + \epsilon_2) d_{t,G}(x, y)$$

Next, assume that there are at least two segments for which the first condition does not hold for i. Otherwise, if there is only one such segment a similar but simpler argument can be used. Let $[u_l, v_l]$ be the first such segment (i.e. the segment closest to x, where u_l is the first and v_l is the last node on the segment), and let $[u_r, v_r]$ be the last such segment.

First by inductive hypothesis and since we are in the case that the second condition holds for segments $[u_l, z_l]$ and $[u_r, v_r]$, we have,

- $d^{((3/\delta)^i)}_{t,G\cup\bar{H}_{j+1}}(u_l, z_l) \leq 2(1+\epsilon_2)(1+\epsilon_j)d_{t,G}(u_l, v_l)$, *and,*
- $d^{((3/\delta)^i)}_{t,G\cup\bar{H}_{j+1}}(v_r, z_r) \leq 2(1+\epsilon_2)(1+\epsilon_j)d_{t,G}(u_r, v_r)$

Again, we consider two cases. First, in case $z_r \in B(z_l)$ (or $z_l \in C(z_r)$), we have added a single hopset edge $(z_r, z_l) \in \bar{H}_{j+1}$. Note that $d_{t,G}(z_r, z_l) \leq 2^{j+1}$, since $d_{t,G}(z_r, z_l) \leq d_{t,G}(x, y) \leq 2^{j+1}$. Hence by Observation 15 the weight we assign to (z_r, z_l) is at most $(1+\epsilon_2)(1+\epsilon_j)d_{t,G}(z_r, z_l)$.

On the other hand, by triangle inequality, and the above inequalities (which are based on the induction hypothesis) we get,

$$d^{(1)}_{\bar{H}_{j+1}}(z_l, z_r) \leq (1+\epsilon_2)(1+\epsilon_j)d_G(z_l, z_r) \tag{1}$$

$$\leq (1+\epsilon_2)(1+\epsilon_j)[d^{((3/\delta)^i)}_{G\cup\bar{H}_{j+1}}(u_l, z_l) + d_G(u_l, v_r) + d^{((3/\delta)^i)}_{G\cup\bar{H}_{j+1}}(z_r, v_r)] \tag{2}$$

By applying the inductive hypothesis on segments before $[u_l, v_l]$, and after $[u_r, v_r]$, we have a path with at most $(3/\delta)^i$ for each of these segments, satisfying the first condition for the endpoints of the segment. Also, we have a $2(3/\delta)^i + 1$-hop path going through u_l, z_l, z_r, v_r that satisfies the first condition for u_l, v_r.

Putting all of these together, we argue that there is a path of hopbound $(3/\delta)^{i+1}$ satisfying the first condition. In particular, we have (the subscript t is dropped in the following),

$$d^{(3/\delta)^{(i+1)}}_{G\cup\bar{H}_{j+1}}(x, y) \leq \sum_{a=1}^{l-1}[d^{((3/\delta)^i)}_{G\cup\bar{H}_{j+1}}(u_a, v_a) + d^{(1)}_G(v_a, u_{a+1})] + d^{((3/\delta)^i)}_{G\cup\bar{H}_{j+1}}(u_l, z_l) \tag{3}$$

$$+ d^{(1)}_{\bar{H}_{j+1}}(z_l, z_r) + d^{((3/\delta)^i)}_{G\cup\bar{H}_{j+1}}(z_r, v_r) + d^{(1)}_G(v_r, u_{r+1}) \tag{4}$$

$$+ \sum_{a=r+1}^{1/\delta}[d^{((3/\delta)^i)}_{G\cup\bar{H}_{j+1}}(u_a, v_a) + d^{(1)}_G(v_a, u_{a+1})] \tag{5}$$

$$\leq (1+8\delta i)(1+\epsilon_j)(1+\epsilon_2)[d_G(x, u_l) + d_G(v_r, y)] + d_G(u_l, v_r) \tag{6}$$

$$+ (1+\epsilon_2)(1+\epsilon_j)[2d_G(u_l, z_l) + 2d_G(z_r, v_r)] \tag{7}$$

$$\leq (1+\epsilon_2)(1+\epsilon_j)[8\delta d_G(x, y) + (1+8\delta i)d_G(x, y)] \tag{8}$$

$$\leq (1+8\delta(i+1))(1+\epsilon_2)(1+\epsilon_j)d_G(x, y) \tag{9}$$

In the first inequality we used the induction on i for each segment, and triangle inequality. In the second inequality we are using the fact that nodes u_j, v_j for all j are on the shortest path between x and y in G, and we are replacing $d^{(1)}_{\bar{H}_{j+1}}(z_l, z_r)$ with inequality 2. In line 8 we used the fact that the length of each segment is at most $\delta \cdot d_G(x, y)$. Hence we have shown that the first condition in the lemma statement holds.

Finally, consider the case where $z_r \notin B(z_l)$. If $z_l \notin A_{i+2}$, we consider $z = p(z_l)$, where $z_l \in A_{i+2}$. We now claim that this choice of z satisfies the second lemma condition.

We have added the edge (z_l, z) to the hopset. Since $z_r \notin B(z_l)$, we have $d_{t-1,G}(z_l, p(z_l)) \leq d_{t-1,G}(z_l, z_r) \leq d_{t,G}(x, y) \leq 2^{j+1}$. Therefore we can use Observation 15 on the edge $(z_l, p(z_l))$.

$$d^{(3/\delta)^{(i+1)}}_{G\cup\bar{H}_{j+1}}(x,y) \leq \sum_{a=1}^{l-1}[d^{((3/\delta)^i)}_{G\cup\bar{H}_{j+1}}(u_a,v_a) + d^{(1)}_{G}(v_a,u_{a+1})] \tag{10}$$

$$+ d^{((3/\delta)^i)}_{G\cup\bar{H}_{j+1}}(u_l,z_l) + (1+\epsilon_2)(1+\epsilon_j)d^{(1)}_{\bar{H}_{j+1}}(z_l,z) \tag{11}$$

$$\leq (1+8\delta i)(1+\epsilon_2)(1+\epsilon_j)d_G(x,u_l) + d^{((3/\delta)^i)}_{G\cup\bar{H}_{j+1}}(u_l,z_l) \tag{12}$$

$$+ (1+\epsilon_2)(1+\epsilon_j)d_{\bar{H}_{j+1}}(z_l,z_r) \tag{13}$$

$$\leq (1+8\delta i)(1+\epsilon_2)(1+\epsilon_j)d_G(x,u_l) + d^{((3/\delta)^i)}_{G\cup\bar{H}_{j+1}}(u_l,z_l) \tag{14}$$

$$+ (1+\epsilon_2)(1+\epsilon_j)[2d^{((3/\delta)^i)}_{G\cup\bar{H}_{j+1}}(z_l,u_l) + d_G(u_l,v_r) + d^{(3/\delta)^i}_{G\cup\bar{H}_{j+1}}(v_r,z_r)] \tag{15}$$

$$\leq (1+8\delta i)(1+\epsilon_2)(1+\epsilon_j)d^{((3/\delta)^i)}_{G\cup\bar{H}_{j+1}}(x,v_r) + 6\delta(1+\epsilon_j)d_G(x,y) \tag{16}$$

$$\leq 2(1+\epsilon_2)(1+\epsilon_j)d_G(x,y) \tag{17}$$

In the last inequality we used the fact that we set $\delta < \frac{1}{8(k+1/\rho+1)}$ and thus $8\delta i < 1$. The only remaining case is when $z_\ell \in A_{i+2}$, in which case a similar reasoning follows by setting $z = z_l$.

Next, we need to prove that after adding hopset edges H_{j+1} we can maintain approximate single-source shortest path distances from a given source s to conclude the proof of this theorem. For this we need to use scaling again, and by Lemma 9 an additional $(1+\epsilon_2)$-factor will be added to the stretch. This enables us to show that Observation 15 can be used for the next scale, i.e. that we can set the weights for the next scale by maintaining the clusters and $(1+\epsilon_{j+1})$ approximate distance rooted at a source s when we have $d(s,v) \in [2^{j+1}, 2^{j+2}]$, and hence close the inductive cycle in the argument. This argument uses a similar type of case-by-case analysis as the above argument combined with path-doubling. We omit this argument here due to space limitations. The complete proof can be found in the full version of this paper. ◀

Theorem 14 allows us to hierarchically use the restricted hopsets for smaller scales to compute the distance for larger scales, that is in turn used to update the hopset edges in the larger scales. Finally, for getting the final stretch and hopbound we set the parameters $\epsilon' = \frac{\epsilon}{6\log W}, \epsilon_2 = \epsilon'$ (error incurred by rounding), and $\delta = \frac{\epsilon}{8(k+1/\rho+1)}$ (details can be found in the full version). Putting it all together we get the following theorem:

▶ **Theorem 16.** *The total update time in each scaled graph G^j, $1 \leq j \leq \log W$, over all deletions is $\tilde{O}((\beta/\epsilon')(n^{1+\frac{1}{2^k-1}} + m)n^\rho)$, and hence the total update time for maintaining $(\beta, 1+\epsilon)$-hopset with hopbound $\beta = O(\frac{\log W}{\epsilon} \cdot (k+1/\rho))^{k+1/\rho+1}$ is $\tilde{O}(\frac{\beta}{\epsilon} \cdot mn^\rho \cdot \log W)$.*

4 Applications in Decremental Approximate Shortest Path

In the full version of this paper, we use our hopsets to maintain approximate shortest paths and distance sketches. At a high level, we maintain a $(\beta, 1+\epsilon)$-hopset using the appropriate parameter settings in Theorem 16. The applications in $(1+\epsilon)$-SSSP and $(1+\epsilon)$-MSSP are straightforward extensions of Theorem 14.

In our approximate APSP data structure we simultaneously maintain a $(\beta, 1+\epsilon)$-hopset for by setting β to be polylogarithmic and a Thorup-Zwick distance oracle [34]. Our algorithm for maintaining distance oracles of [34] is similar to the restricted hopset algorithm, combined

with the rounding procedure in Lemma 9 that allows us to maintain clusters up to $O(\beta/\epsilon)$ hops. One main difference between these algorithms is in the information/distances stored and the fact that the sampling probabilities stay fixed in case of distance oracles. In order to maintain $(2k-1)(1+\epsilon)$-approximate APSP, we set the parameters ρ and k in such a way that updating the hopset and the distance oracle are roughly the same. By maintaining the distance oracle, querying distances is the same as in the static algorithm of [34], and takes $O(k)$ time, which is constant when k is constant.

Abstract

We solve the Bin Packing problem in $O^*(2^k)$ time, where k is the number of items less or equal to one third of the bin capacity. This parameter measures the distance from the polynomially solvable case of only large (i.e., greater than one third) items. Our algorithm is actually designed to work for a more general Vector Bin Packing problem, in which items are multidimensional vectors. We improve over the previous fastest $O^*(k! \cdot 4^k)$ time algorithm.

Our algorithm works by reducing the problem to finding an exact weight perfect matching in a (multi-)graph with $O^*(2^k)$ edges, whose weights are integers of the order of $O^*(2^k)$. To solve the matching problem in the desired time, we give a variant of the classic Mulmuley-Vazirani-Vazirani algorithm with only a linear dependence on the edge weights and the number of edges – which may be of independent interest.

Moreover, we give a tight lower bound, under the Strong Exponential Time Hypothesis (SETH), showing that the constant 2 in the base of the exponent cannot be further improved for Vector Bin Packing.

Our techniques also lead to improved algorithms for Vector Multiple Knapsack, Vector Bin Covering, and Perfect Matching with Hitting Constraints.

1 Introduction

NP-hard problems often have special cases that can be solved in polynomial time, e.g., Vertex Cover is tractable in graphs with the Kőnig property, Dominating Set is tractable in trees, and Longest Common Subsequence is tractable in permutations. Many of these problems remain (fixed-parameter) tractable with a distance from the polynomially solvable case taken as a parameter, e.g., Vertex Cover Above Matching [16], Dominating Set in bounded treewidth graphs [1], or Longest Common Subsequence parameterized by the maximum occurrence number [6]. In parameterized complexity, this concept is sometimes dubbed *distance from triviality* [6].

In the Bin Packing problem, we are given n *items* from $\mathbb{Q}_{\geqslant 0}$, and we have to pack them into the smallest possible number of unit-sized *bins*. It is a classic strongly NP-hard problem. When all items are *large*, i.e., greater than $1/3$, then no three items can fit into a single bin and the problem reduces to the Maximum Matching problem, and hence it can be solved in polynomial time [5].

Bannach et al. [2] are the first to study Bin Packing parameterized by the number k of *small* (i.e., $\leqslant 1/3$) items – which is the distance from the above tractable case. They give algorithms running in randomized $O^*(k! \cdot 4^k)$ time, and deterministic $O^*\big((k!)^2 \cdot 2^k\big)$ time.[1] Their randomized algorithm works even for a more general Vector Bin Packing problem, in which items are d-dimensional vectors from $\mathbb{Q}^d_{\geqslant 0}$, and a set of items fits into a bin if their coordinate-wise sum does not exceed 1 in any coordinate. (The notion of a small item is more complex in the multidimensional case; see Section 1.1 for the definition.)

We improve upon their result by giving an $O^*(2^k)$ randomized time algorithm for Vector Bin Packing. We complement it with a matching conditional lower bound, showing that the constant 2 in the base of the exponent cannot be further improved, unless the Strong Exponential Time Hypothesis (SETH) fails.

Our algorithm works by reducing the problem to finding a perfect matching of a given total weight in an edge-weighted (multi-)graph. The graph has only $O(n)$ nodes, but can have up to $O(2^k n^2)$ edges, whose weights are integers of the order of $2^k \cdot k$. To solve the matching problem in the desired $O^*(2^k)$ time, we give a variant of the classic Mulmuley-Vazirani-Vazirani algorithm [12] with only a linear dependence on the edge weights and the number of edges – which may be of independent interest.

Our techniques also lead to improved algorithms for the two other problems studied by Bannach et al. [2], i.e., the Vector Multiple Knapsack and Vector Bin Covering problems, as well as for the Perfect Matching with Hitting Constraints problem, studied by Marx and Pilipczuk [11].

1.1 Vector Bin Packing with Few Small Items

First, let us formally define Vector Bin Packing as a decision problem. We remark that (Vector) Bin Packing is also often studied as an optimization problem – especially in the context of approximation algorithm – but one can always switch between the two variants via binary search, loosing at most of a factor of $O(\log n)$ in the running time.

Vector Bin Packing

Given: a set of n items $V = \{v_1, \ldots, v_n\} \subseteq \mathbb{Q}^d_{\geqslant 0}$,
and an integer $\ell \in \mathbb{Z}_+$ denoting the number of unit-sized bins.

Decide: if the items can be partitioned into ℓ bins $B_1 \cup \cdots \cup B_\ell = V$ such that $\sum_{v \in B_i} v[j] \leqslant 1$ for every bin $i \in [\ell]$ and every dimension $j \in [d]$.[2]

Note that the assumption that bins are unit-sized is without loss of generality, as one can always independently scale each dimension in order to meet that constraint. We can also safely assume that V is a set, as one can handle multiple occurrences of the same item by introducing one extra dimensions with negligibly small but unique coordinates.

[1] We use $O^*(\cdot)$ notation to suppress factors polynomial in the input size n, i.e., $O^*(f(k)) = f(k) \cdot n^{O(1)}$.
[2] We use $[n]$ to denote the set of integers $\{1, 2, \ldots, n\}$.

Unlike in the one-dimensional Bin Packing problem, where a small item can be defined simply as smaller or equal to $1/3$, we use a more complex definition, introduced by Bannach et al. [2]. Let $V \subseteq \mathbb{Q}^d_{\geqslant 0}$ be a set of d-dimensional items. We say that a subset $V' \subseteq V$ is **3-incompatible** if no three distinct items from V' fit into a unit-sized bin, i.e., for every distinct $u, v, w \in V'$ there exists a dimension $i \in [d]$ such that $u[i] + v[i] + w[i] > 1$. Now we can define the parameterized problem that we study.

Vector Bin Packing with Few Small Items

Parameter:	the number of *small* items k.
Given:	a set of n items $V = \{v_1, \ldots, v_n\} \subseteq \mathbb{Q}^d_{\geqslant 0}$, a subset of k items $V_S \subseteq V$ such that $V_L = V \setminus V_S$ is **3-incompatible**, and an integer $\ell \in \mathbb{Z}_+$ denoting the number of unit-sized bins.
Decide:	if the items can be partitioned into ℓ bins $B_1 \cup \cdots \cup B_\ell = V$ such that $\sum_{v \in B_i} v[j] \leqslant 1$ for every bin $i \in [\ell]$ and every dimension $j \in [d]$.

We say that items in V_S are *small*, and the remaining items in $V_L = V \setminus V_S$ are *large*. Note that we assume that a subset of small items is specified in the input. This way we can study the complexity of the packing problem independently of the complexity of finding a (smallest) subset of small items. This is similar, e.g., to the standard practice for treewidth parameterization, where one assumes that a suitable tree decomposition is given in the input (see, e.g., [4]). We remark that if only the set of all items V is given, a smallest possible subset of small items can be found in $O^*(2.27^k)$ time [14] via a reduction to the 3-Hitting Set problem [2].

1.2 Our results

Our main result is an $O^*(2^k)$ time randomized algorithm for Vector Bin Packing with Few Small Items. The algorithm consists of two parts: reducing the packing problem to a matching problem, and solving the matching problem. More formally, we first prove the following.

▶ **Lemma 1.** *An n-item instance of Vector Bin Packing with k small items can be reduced, in deterministic time $O(2^k n^2 kd)$, to the problem of finding an exact-weight perfect matching in a (multi-)graph. The graph has $O(n)$ vertices, $O(2^k n^2)$ edges, and non-negative integer edge weights that do not exceed $O(2^k k)$. The target exact total weight of a matching is $O(2^k k)$.*

The above matching problem is dubbed Exact Matching, and is known to be in randomized[3] (pseudo-)polynomial time since the Mulmuley-Vazirani-Vazirani algorithm [12]. The algorithm directly solves the 0/1 weights variant of Exact Matching in simple graphs. A prior reduction of Papadimitriou and Yannakakis [15] handles arbitrary non-negative integer edge weights and multiple parallel edges. The reduction replaces each edge of weight w by a path of length $2w + 1$ with alternating 0/1 edge weights.

The reduction multiplies the number of vertices by the edge weights and by the number of edges. Further, Mulmuley-Vazirani-Vazirani is not a linear time algorithm. Hence, this would give us only a $2^{O(k)} n^{O(1)}$ time algorithm for Vector Bin Packing. This is already an improvement over the previous factorial time algorithm, but still not our desired $2^k n^{O(1)}$ running time.

[3] It is a big open problem to derandomize the algorithm, see, e.g., [18].

There are more direct and faster ways to solve the general Exact Matching problem than going through the Papadimitriou-Yannakakis reduction. It seems folklore to handle arbitrary edge weights by replacing a monomial x, corresponding to a weight-one edge in the Mulmuley-Vazirani-Vazirani algorithm, with x^w, where w is the edge weight. It remains to handle multiple parallel edges. A crucial part of the algorithm is the so-called *isolation lemma*. It assigns random *costs* to edges, ensuring that the minimum cost perfect matching of the target weight is unique, and hence it cannot cancel out in the algebraic computations. The range of costs, required to ensures that property, on one hand depends on the number of edges, and on the other hand, determines the bitsize of the costs, on which the algorithm later needs to do arithmetic.

Due to the number of edges in Lemma 1, a direct application of isolation lemma would lead to an $O^*(4^k)$ time algorithm. To mitigate this issue, we carefully apply isolation lemma to pairs of vertices, and hence the number of edges appears in the running time only as a linear additive factor.

▶ **Theorem 2.** *Given an edge-weighted multigraph with n nodes and m edges, and an integer t, a randomized Monte-Carlo algorithm can decide whether there is a perfect matching of total weight exactly t in $\widetilde{O}(t \cdot n^8 + m)$ time.*

Lemma 1 and Theorem 2 together imply our main result.

▶ **Theorem 3.** *There is a randomized Monte Carlo algorithm solving Vector Bin Packing with Few Small Items in $O^*(2^k)$ time.*

Lower bound

We show that the above result is tight, via a matching conditional lower bound, under the Strong Exponential Time Hypothesis (SETH) [7]. The hypothesis states that deciding k-CNF-SAT with n variables requires time $2^{s_k n}$ for $\lim_{k\to\infty} s_k = 1$. In particular, it implies that deciding CNF-SAT requires $2^{(1-\varepsilon)n}$ time, for every $\varepsilon > 0$. SETH is a standard hardness assumption for conditional lower bounds in fine-grained and parameterized complexity [4, 20]. We prove the following lower bound for the (non-parameterized) Vector Bin Packing problem.

▶ **Theorem 4.** *Unless SETH fails, Vector Bin Packing cannot be solved in $O^*(2^{(1-\varepsilon)n})$ time, for any $\varepsilon > 0$. This holds even restricted to instances with only two bins and dimension $d = O(n)$.*

Since $k \leqslant n$, the corollary for the parameterized version of the problem follows immediately, proving that the algorithm of Theorem 3 is tight.

▶ **Corollary 5.** *Unless SETH fails, Vector Bin Packing with Few Small Items cannot be solved in $O^*(2^{(1-\varepsilon)k})$ time, for any $\varepsilon > 0$. This holds even restricted to instances with only two bins and dimension $d = O(n)$.*

We remark that our lower bound crucially relies on multiple dimensions. The best known hardness result for the (one-dimensional) Bin Packing problem rules out only $2^{o(n)}$ time algorithms [9], assuming the Exponential Time Hypothesis (ETH) [8]. It is a big open problem whether an $O(1.99^n)$ time algorithm for Bin Packing exists. Recently, Nederlof et al. [13] gave such an algorithm for any constant number of bins. This is in contrast to Vector Bin Packing, which, as we show, requires $2^{(1-\varepsilon)n}$ time already for two bins.

Other applications

Bannach et al. [2] studied two further problems closely related to the Vector Bin Packing problem – namely, Vector Multiple Knapsack and Vector Bin Covering – under similar parameterizations.

In the Vector Multiple Knapsack problem, each item comes with a *profit*, and instead of having to pack all the items, we aim to pack a subset of the items into a fixed number of bins while maximizing the overall profit of the packed items. In the few small items regime, the fastest known algorithm so far has a running time of $O^*(k! \cdot 4^k)$, where k is the number of small items [2]. Adapting our algorithm to handle the profits and the obstacle that only a subset of items might be packed, we obtain the following theorem.

▶ **Theorem 6.** *There is a randomized Monte Carlo algorithm solving Vector Multiple Knapsack with Few Small Items in $O^*(2^k)$ time when item profits are bounded by* $\mathrm{poly}(n)$.

In the Vector Bin Covering problem, we aim to *cover* bins. Intuitively speaking, instead of packing the items into as few bins as possible, we want to partition them into as many bins as possible while satisfying a *covering constraint* for each bin. This new desired property of a solution leads to a slightly different definition of the set of small items: instead of any three large items not fitting together into a bin, now they cover a bin. So far, the fastest algorithm solving this problem parameterized by the number k of small items[4] runs in time $O^*(k! \cdot 4^k)$ [2]. We give the following improvement.

▶ **Theorem 7.** *There is a randomized Monte Carlo algorithm solving Vector Bin Covering with Few Small Items in $O^*(2^k)$ time.*

Further, our results directly imply an improved running time for the Perfect Matching with Hitting Constraints problem. This problem asks whether we can find a perfect matching in a graph using at least one edge from each of given subsets of edges. It was studied by Marx and Pilipczuk [11] as a tool for solving a subgraph isomorphism problem in forests. They gave an algorithm (for the matching problem) running in time $2^{O(k)}n^{O(1)}$, where k is the number of edge subsets. Their algorithm shares certain similarities with our Vector Bin Packing algorithm. They use, however, a less efficient encoding of subsets into edge weights (using $2k$ bits, compared to $k \log k$ bits we achieve in Lemma 9), and they only coarsely analyze the polynomial dependence on the weights when solving Exact Matching. Avoiding these two inefficiencies, we prove the following theorem.

▶ **Theorem 8.** *There is a randomized Monte Carlo algorithm solving Perfect Matching with Hitting Constraints in $O^*(2^k)$ time.*

2 From Vector Bin Packing to Exact Matching

▶ **Lemma 1.** *An n-item instance of Vector Bin Packing with k small items can be reduced, in deterministic time $O(2^k n^2 kd)$, to the problem of finding an exact-weight perfect matching in a (multi-)graph. The graph has $O(n)$ vertices, $O(2^k n^2)$ edges, and non-negative integer edge weights that do not exceed $O(2^k k)$. The target exact total weight of a matching is $O(2^k k)$.*

[4] Even though Bannach et al. do not explicitly adapt their definition of a small item to this problem, they indeed work with the same definition as we do. In the full version on arXiv [3, page 11] they write: "The large vectors have the property that every subset of three vectors cover a container."

Proof. We interpret the problem of finding a packing as the problem of finding a perfect matching with a certain total weight in an edge-weighted (multi-)graph. Intuitively, each large item is represented by a vertex, and an edge connects two large items if they fit together into a bin. The edge weight indicates a set of small items which can be packed together with the endpoints (i.e., the corresponding large items). The goal is to match (pack) all large items while achieving the total weight that corresponds to all small items being assigned to some pairing of large items.

Formally, we first add $2\ell - |V_L|$ dummy items $\langle 0, \ldots, 0\rangle \in \mathbb{Q}^d_{\geqslant 0}$ to the set V_L so that each bin will contain exactly two large items. A dummy item can be paired with another dummy item (no original large item is in that bin), or with an original large item (only one original large item is in that bin). For each large item $v \in V_L$ (including the dummy items), create a vertex u_v. For each pair of large items $v_1, v_2 \in V_L$, $v_1 \neq v_2$, and for each subset $V'_S \subseteq V_S$ of small items, introduce an edge between u_{v_1} and u_{v_2} if $v_1[\ell] + v_2[\ell] + \sum_{v \in V'_S} v[\ell] \leqslant 1$ for all $\ell \in [d]$, i.e., the small items fit together with the two large ones into a bin.[5] The weight of the edge will depend on V'_S (but not on v_1 and v_2).

We need to design the edge weights such that each collection of edges of a certain total weight corresponds to a collection of subsets of small items that form a partition of the set of all small items V_s, and vice versa. A naive, but incorrect, solution would be to label the small items with integers $1, 2, \ldots, k$, and assign to a subset $X \subseteq [k]$ the integer whose binary representation corresponds to the indicator vector of X, i.e., $\sum_{x \in X} 2^{x-1}$. It is true that, with such weights, any collection of edges whose associated subsets form a partition of V_s has the total weight $1 \ldots 1_2 = 2^k - 1$. However, the reverse statement is not true: it is possible to obtain the total weight $2^k - 1$ by, e.g., taking $2^k - 1$ edges that each allow small item 1 but no other small items.

As we will show in Lemma 9, in order to prevent such false positives, it suffices to concatenate the indicator vectors with $(\log k)$-bit counters denoting the number of elements in a set.[6] More formally, we assign to a subset $X \subseteq [k]$ the weight $|X| \cdot 2^k + \sum_{x \in X} 2^{x-1}$, i.e., the $(k + \log k)$-bit integer whose k least significant bits correspond to the indicator vector of X and the $\log k$ most significant bits form the integer equal to the cardinality of X. The target total weight $k \cdot 2^k + (2^k - 1)$ can only be achieved by summing weights given to subsets forming a partition of V_s, i.e., by assigning each small item to (exactly) one matching edge. ◀

▶ **Lemma 9.** *Fix the universe size $k \in \mathbb{N}$, and let $f : 2^{[k]} \to \mathbb{N}$ be given by*

$$f(X) = |X| \cdot 2^k + \sum_{x \in X} 2^{x-1}.$$

Then, a family $X_1, \ldots, X_n \subseteq [k]$ is a partition[7] of $[k]$ if and only if

$$f(X_1) + \cdots + f(X_n) = k \cdot 2^k + (2^k - 1).$$

---

[5] Note that it is important to add an edge for each fitting subset, and not, e.g., only for inclusion-wise maximal fitting subsets. That is because we design the edge weights so that an exact matching corresponds to a partition (and not to a cover) of the set V_s.

[6] Marx and Pilipczuk [11] solve a similar issue by concatenating the indicator vector with its reverse, i.e., they assign to X weight $\sum_{x \in X}(2^{2k-x} + 2^{x-1})$. Their approach results in weights of the order of 4^k, which is prohibitively large for achieving $O^*(2^k)$ running time.

[7] That is, $X_1 \cup \cdots \cup X_n = [k]$, and $X_i \cap X_j = \emptyset$ for every $i \neq j$.

Proof. The "partition ⇒ sum" direction follows from a simple calculation. Let us prove the "sum ⇒ partition" direction. For $i \in [k]$, let c_i denote the number of sets containing element i. We want to show that $c_i = 1$, for every i. We have

$$f(X_1) + \cdots + f(X_n) = \left(\sum_{i=1}^{k} c_i\right) \cdot 2^k + \sum_{i=1}^{k} c_i 2^{i-1}.$$

Note that the k least significant bits of the sum $f(X_1) + \cdots + f(X_n)$ are lower bounding the term $\sum_{i=1}^{k} c_i 2^{i-1}$, and the remaining bits are upper bounding the term $\sum_{i=1}^{k} c_i$, that is,

$$\sum_{i=1}^{k} c_i 2^{i-1} \geqslant 2^k - 1 = \overbrace{1\ldots1}^{k \text{ ones}}_2, \quad \text{and} \quad \sum_{i=1}^{k} c_i \leqslant k.$$

For $i = 0, 1, \ldots, k$, let $p_i = c_1 + \cdots + c_i$, with $p_0 = 0$. Observe that $p_i \geqslant i$, for every i, as otherwise there are not enough bits to set the one in every position among the i least significant bits of the sum $f(X_1) + \cdots + f(X_n)$.[8] Moreover, $p_k = \sum_{i=1}^{k} c_i \leqslant k$, and thus $p_k = k$. Last but not least, by definition, $c_i = p_i - p_{i-1}$. We have

$$\begin{aligned}
2^k - 1 &\leqslant \sum_{i=1}^{k} 2^{i-1} c_i = \sum_{i=1}^{k} 2^{i-1}(p_i - p_{i-1}) = \sum_{i=1}^{k} 2^{i-1} p_i - \sum_{i=1}^{k} 2^{i-1} p_{i-1} \\
&= \sum_{i=1}^{k} 2^{i-1} p_i - \sum_{i=0}^{k-1} 2^i p_i = 2^k p_k + \sum_{i=1}^{k} (2^{i-1} - 2^i) p_i - 2^0 p_0 = 2^k p_k - \sum_{i=1}^{k} 2^{i-1} p_i \\
&= 2^k \cdot k - \sum_{i=1}^{k} 2^{i-1} p_i \\
&\leqslant 2^k \cdot k - \sum_{i=1}^{k} 2^{i-1} i = 2^k \cdot k - \big((k-1) \cdot 2^k + 1\big) = 2^k - 1.
\end{aligned}$$

Hence, all the inequalities must be tight. In particular, $p_i = i$ for every i, and thus $c_i = 1$, i.e., each element of the universe is contained in exactly one set of the family. ◀

3 Fast Exact Weight Matching in Multigraphs

In this section we give our variant of the Mulmuley-Vazirani-Vazirani algorithm, with only a linear dependence on the edge weights and a linear additive dependence on the number of edges, proving Theorem 2.

3.1 The Pfaffian

At the heart of the matching algorithm lies a computation of the Pfaffian of a skew-symmetric matrix of certain polynomials. In order to introduce the notion of a Pfaffian properly, let us fix some definitions and notation first.

[8] It follows from the fact that the number of one-bits in the sum is less or equal to the total number of one-bits in the summands, and that this holds even if we look only at the i least significant bits.

For an $n \times n$ matrix A, we denote by $A[i,j]$ the value in the i-th row and j-th column. We say that A is skew-symmetric if and only if $A[i,j] = -A[j,i]$ for every $i,j \in [n]$. Let $\mathcal{M}$ be a perfect matching in the complete graph K_n. We can look at $\mathcal{M}$ as a sequence of edges in some arbitrary order, i.e.,

$$\mathcal{M} = (i_1, j_1), (i_2, j_2), \ldots, (i_{n/2}, j_{n/2}),$$

where, by convention, $i_k \leqslant j_k$ for any k. Now, we define the sign of $\mathcal{M}$ as follows:

$$\operatorname{sgn} \mathcal{M} = \operatorname{sgn} \begin{pmatrix} 1 & 2 & 3 & 4 & \cdots & n-1 & n \\ i_1 & j_1 & i_2 & j_2 & \cdots & i_{n/2} & j_{n/2} \end{pmatrix},$$

where the right-hand side is the sign of a permutation. One can easily show that this definition does not depend on the chosen order of the edges.

Now, we are ready to give the definition of a Pfaffian.

▶ **Definition 10** (Pfaffian). *Let A be an $n \times n$ skew-symmetric matrix. The Pfaffian of A is denoted by* $\operatorname{pf}(A)$ *and is defined as follows*

$$\operatorname{pf}(A) = \sum \left\{ \operatorname{sgn} \mathcal{M} \cdot \prod_{(i_k, j_k) \in \mathcal{M}} A[i_k, j_k] \;\middle|\; \mathcal{M} \text{ perfect matching in } K_n \right\}.$$

We note that since A is skew-symmetric, our convention that $i_k \leqslant j_k$ does not affect the definition of the Pfaffian at all – if we were to switch i_k and j_k, the sign of the matching changes, but so does the sign of the product of the weights.

Several equivalent definitions of a Pfaffian exist in the literature. However, we have chosen this one, as it immediately illustrates the connection between the Pfaffian and perfect matchings.

The Pfaffian of a matrix over an arbitrary field can be computed by, e.g., a variant of the Gaussian elimination. However, since we are dealing with polynomial matrices, we would like to avoid divisions. Fortunately, several division-free polynomial time algorithms for computing Pfaffian exist [10, 17, 19].

Incidentally, Mahajan, Subramanya, and Vinay [10] give a dynamic programming algorithm computing the Pfaffian of a matrix with entries from an arbitrary ring that makes $O(n^4)$ additions and multiplications (see also survey [17] for an alternative exposition)[9]. By analysing the structure of their algorithm, we get the following result for matrices with polynomial entries.

▶ **Theorem 11** (cf. [10], Section 4). *Given an $n \times n$ matrix A of univariate polynomials of degree at most d and integer coefficients bounded by M, the Pfaffian* $\operatorname{pf}(A)$ *can be computed in $\widetilde{O}(n^6 d \log M)$ time.*

Proof. The algorithm in [10], Section 4, is described as a weighted DAG H_A with each vertex corresponding to a state of the dynamic program. The weights on the edges are signed entries of the matrix A. There is an auxiliary starting state $s \in H_A$ and the dynamic programming value for a state $v \in H_A$ is a sum of products of weights along all the paths from s to v.

Moreover, H_A has $O(n^3)$ vertices, depth equal to $O(n)$ and indegree of each vertex equal to $O(n)$. Therefore, if the entries of A are polynomials of degree d and coefficients bounded by M, then the values of the dynamic programming states are polynomials with

[9] Urbańska's algorithm [19] runs even faster, in $O(n^{3.03})$ time. But since we care more about getting linear dependence on the target weight in our matching algorithm, rather than optimizing the polynomial dependence on n, we have chosen to use a slightly slower, yet simpler algorithm for the sake of clarity.

a degree bounded by $O(nd)$ and coefficients bounded by $O(n^n M^n)$. Hence, by using FFT, we can perform each arithmetic operation in $\widetilde{O}(n^2 d \log M)$ time. The number of arithmetic operations needed is proportional to the number of edges in H_A, which is $O(n^4)$. This yields the desired time bound. ◀

Since we do not need to compute the whole Pfaffian in the Exact Matching problem, but are only interested in the coefficient of the monomial x^t (which conveys the information about matchings of the target weight t), we can speed up the computation by a factor of n.

▶ **Corollary 12.** *Given an integer t and an $n \times n$ matrix A of univariate polynomials with integer coefficients bounded by M, a coefficient of the monomial x^t in $\mathrm{pf}(A)$ can be computed in $\widetilde{O}(n^5 t \log M)$ time.*

Proof. In the algorithm from Theorem 11, we can perform all the arithmetic operations modulo x^{t+1}. Then, the degree of the polynomials is bounded by $O(t)$ instead of $O(nd)$, and a similar analysis follows. ◀

3.2 The algorithm

We first recall the central lemma of the Mulmuley-Vazirani-Vazirani algorithm, used to deal with possible cancellations caused by varying signs in the Pfaffian definition.

▶ **Lemma 13** (Isolation Lemma, cf. [12])**.** *Let S be a finite set, and let $F \subseteq 2^S$ be a family of subsets of S. To each element $x \in S$, we assign an integer cost $c(x)$ chosen uniformly and independently at random from $\{1, \ldots, 2|S|\}$. For a subset $S' \subseteq S$, we define a total cost of S' to be $c(S') = \sum_{x \in S'} c(x)$. Then,*

$$\mathbb{P}(\textit{there is a unique minimum total cost set in } F) \geqslant \frac{1}{2}.$$

Now we are ready to present the matching algorithm.

▶ **Theorem 2.** *Given an edge-weighted multigraph with n nodes and m edges, and an integer t, a randomized Monte-Carlo algorithm can decide whether there is a perfect matching of total weight exactly t in $\widetilde{O}(t \cdot n^8 + m)$ time.*

Proof. We first present the algorithm. Then we argue its correctness and analyse the running time.

Algorithm. For every $\{u, v\} \in \binom{V}{2}$, let $E_{\{u,v\}} = \{e \in E : e \text{ connects } u \text{ and } v\}$ denote the set of (parallel) edges between nodes u and v. For an edge $e \in E$, we use $w(e) \in \mathbb{Z}_{\geqslant 0}$ to denote the weight of e. Moreover, we assume w.l.o.g. that $V = [n]$.

The algorithm works as follows.

1. Set $\lambda = 2m^n$.
2. For every $\{i, j\} \in \binom{V}{2}$, assign a cost $c(\{i, j\})$ uniformly at random from $\{1, \ldots, 2\binom{n}{2}\}$.
3. Set up an $n \times n$ matrix A of univariate polynomials: For each $i, j \in [n]$, $i \leqslant j$, put

$$A[i, j] = \lambda^{c(\{i,j\})} \sum_{e \in E_{\{i,j\}}} x^{w(e)}, \quad \text{and} \quad A[j, i] = -A[i, j].$$

4. Compute the coefficient of x^t in $\mathrm{pf}(A)$ using the algorithm from Corollary 12.
5. If the coefficient of x^t in $\mathrm{pf}(A)$ is nonzero return YES, otherwise return NO.

Correctness. We use $\mathrm{coef}_t(\mathrm{pf}(A))$ to denote the coefficient of x^t in $\mathrm{pf}(A)$. For every perfect matching $\mathcal{M}$ in the complete graph K_n, let

$$f(\mathcal{M}) = \mathrm{sgn}\ \mathcal{M} \cdot \lambda^{c(\mathcal{M})} \cdot \#\text{perfect matchings in } G \text{ of weight } t \text{ contained}^{10} \text{ in } \mathcal{M}$$

denote the contribution of matching $\mathcal{M}$ to the coefficient $\mathrm{coef}_t(\mathrm{pf}(A))$. Now, we have

$$\mathrm{coef}_t(\mathrm{pf}(A)) = \sum \{ f(\mathcal{M}) \mid \mathcal{M} \text{ perfect matching in } K_n \}. \tag{1}$$

Let F be the family of all perfect matchings in K_n that contain a perfect matching in G of weight exactly t. If $F = \emptyset$, then every summand in (1) is zero. Hence, $\mathrm{coef}_t(\mathrm{pf}(A)) = 0$ and our algorithm answers correctly.

If $F \neq \emptyset$, then by Isolation Lemma, with probability at least $1/2$, there is only one minimum cost perfect matching $\mathcal{N} \in F$.

Let $c = c(\mathcal{N})$. Observe that the number of perfect matchings in G of weight t that are contained in $\mathcal{N}$ is trivially bounded by $m^n < \lambda$. This means that $|f(\mathcal{N})| < \lambda^{c+1}$. In other words, $f(\mathcal{N})$ is divisible by λ^c, but not by λ^{c+1}. On the other hand, every other summand in (1) is divisible by λ^{c+1}, as $\mathcal{N}$ is the unique minimum cost matching. Therefore, $\mathrm{coef}_t(\mathrm{pf}(A))$ is divisible by λ^c, but not by λ^{c+1} – so it cannot be zero.

If we want to amplify the probability of giving the correct answer to $1 - 1/n^C$, for some constant $C > 0$, we repeat the algorithm $C \log n$ times.

Time cost analysis. The time needed to complete steps 1–3 is $O(n^2 + m)$. Since the coefficients of the polynomial entries of A are bounded by $2m^{n \cdot 2\binom{n}{2}} = 2^{O(n^3 \log m)}$, we get that invoking the algorithm from Corollary 12 takes $\widetilde{O}(t \cdot n^8 \log m)$ time. In total, that yields $\widetilde{O}(t \cdot n^8 + m)$ time complexity. ◀

4 Lower bound

▶ **Theorem 4.** *Unless SETH fails, Vector Bin Packing cannot be solved in $O^*(2^{(1-\varepsilon)n})$ time, for any $\varepsilon > 0$. This holds even restricted to instances with only two bins and dimension $d = O(n)$.*

Proof. Given a CNF formula with n variables and m clauses,[11] we will construct $n + 1$ instances of Vector Bin Packing such that the formula is satisfiable if and only if at least one of them is a yes-instance. Intuitively, this corresponds to guessing the number of variables set to true in a satisfying assignment. Formally, for $t \in \{0, \ldots, n\}$, the t-th Vector Bin Packing instance is a yes-instance if and only if the formula has a satisfying assignment with exactly t variables set to true.

Let us fix t. The t-th instance consists of $n + 2$ items $V = \{v_1, \ldots, v_n, T, F\} \subseteq \mathbb{Q}^{m+2}_{\geqslant 0}$. The first n items correspond to the n variables; the remaining two items T and F are used to break the symmetry – in any feasible solution they are necessarily in two different bins, which we call the T-bin and the F-bin, respectively. Packing item v_i to the T-bin corresponds to setting variable i to true, and packing it to the F-bin corresponds to setting the variable to false.

[10] We say that a matching (in multigraph G) is contained in another matching (in the complete graph K_n) if the set of $n/2$ pairs of endpoints is the same for the two matchings.

[11] Note that, thanks to the *sparsification lemma* [8], we can assume that $m = O(n)$.

The items are $(m+2)$-dimensional. The first m dimensions correspond to clauses, and we will discuss them in a moment. Dimension $m+1$ ensures that T and F go to different bins; we have $T[m+1] = F[m+1] = 1$, and $v_i[m+1] = 0$ for every $i \in [n]$. Dimension $m+2$ ensures that (at most) t items go to the T-bin and (at most) $n-t$ items go to the F-bin; we have $T[m+2] = (n-t)/n$, $F[m+2] = t/n$, and $v_i[m+2] = 1/n$ for every $i \in [n]$.

Now, fix a clause $j \in [m]$. We set

$$v_i[j] = \begin{cases} {}^{0}\!/_{2n}, & \text{if variable } i \text{ appears in a positive literal in clause } j, \\ {}^{1}\!/_{2n}, & \text{if variable } i \text{ does not appear in clause } j, \\ {}^{2}\!/_{2n}, & \text{if variable } i \text{ appears in a negative literal in clause } j. \end{cases}$$

Let n_j denote the number of variables that appear negated in clause j. We set

$$T[j] = 1 - \frac{t + n_j - 1}{2n}, \quad \text{and} \quad F[j] = 0.$$

This ends the description of the instance. To finish the proof, it remains to show that the above items can be packed into two bins if and only if the formula has a satisfying assignment with exactly t variables set to true.

Note that there is a natural one-to-one correspondence between (not necessarily satisfying) assignments that set exactly t variables to true and (not necessarily feasible) Vector Bin Packing solutions that are feasible in the last two dimensions. We now show that, for $j \in [m]$, such an assignment satisfies clause j if and only if the corresponding solution is feasible in dimension j. The F-bin is never overfull in dimension j. To analyse the T-bin, let α, β, γ denote the numbers of variables set to true that, in clause j, appear in a positive literal, do not appear, and appear in a negative literal, respectively. Let δ denote the number of variables set to false that appear in clause j in a negative literal. Note that $t = \alpha + \beta + \gamma$, and $n_j = \gamma + \delta$. Consider the following chain of equivalent inequalities, starting with the condition saying that the T-bin is not overfull in dimension j.

$$\begin{aligned} \alpha \cdot {}^{0}\!/_{2n} + \beta \cdot {}^{1}\!/_{2n} + \gamma \cdot {}^{2}\!/_{2n} &\leqslant 1 - T[j] \\ \beta + 2\gamma &\leqslant t + n_j - 1 \\ \beta + 2\gamma &\leqslant (\alpha + \beta + \gamma) + (\gamma + \delta) - 1 \\ 1 &\leqslant \alpha + \delta \end{aligned}$$

The last inequality states that clause j is satisfied. ◀

5 Other applications

In this section we explain how the techniques presented in our paper can be adapted to also solve Vector Multiple Knapsack and Vector Bin Covering, two closely related problems to the Vector Bin Packing problem. The main difference lies in the reduction to the Exact Matching problem, which has to integrate profits of the items, or the new covering property, respectively. Further, we show that our techniques directly apply to the Perfect Matching with Hitting Constraints problem, leading to an improved running time.

Vector Multiple Knapsack

In Vector Multiple Knapsack, instead of packing all items into the smallest number of bins, we aim to place a subset of items with profits into a fixed number of bins while maximizing the profit of the packed items. Like in Vector Bin Packing, small items hinder us from solving

the problem using a polynomial time algorithm for the maximum weight perfect matching. Hence, following Bannach et al. [2], we study the problem parameterized by the number k of small items.

Vector Multiple Knapsack with Few Small Items

Parameter:	the number of *small* items k.
Given:	a set of n items $V = \{v_1, \dots, v_n\} \subseteq \mathbb{Q}^d_{\geqslant 0}$, **item profits** $p(v_1), \dots, p(v_n) \in \mathbb{Z}_+$, a subset of k items $V_S \subseteq V$ such that $V_L = V \setminus V_S$ is **3-incompatible**, an integer $\ell \in \mathbb{Z}_+$ denoting the number of unit-sized bins, and an integer $P \in \mathbb{Z}_+$, denoting the **goal profit**.
Decide:	if a subset V' of the items can be partitioned into ℓ bins $B_1 \cup \dots \cup B_\ell = V'$ such that $\sum_{v \in B_i} v[j] \leqslant 1$ for every bin $i \in [\ell]$ and every dimension $j \in [d]$, and $\sum_{v \in V'} p(v) \geqslant P$.

To solve the problem, we reduce the instance to the Exact Matching problem as in Section 2. It remains to handle the fact that only a subset of items has to be packed, and that we need to integrate the profits. We do so in the following manner: With each edge between v_1 and v_2 and the weight corresponding to $V'_S \subseteq V_S$, we associate the *cost* of $p(v_1) + p(v_2) + \sum_{v \in V'_s} p(v)$. Further, we introduce $g = n - 2 \cdot \ell$ new vertices $b_1, b_2 \dots, b_g$, called *blocker* vertices. These vertices serve as "garbage collectors" for the items which are not packed in any of the ℓ bins, i.e., they match g unpacked items, and by that block them. To do so, for each $V'_S \subseteq V_S$, each large vector v_i, and each blocker vertex b_j, introduce an edge between v_i and b_j with weight dependent on V'_S as before, and cost 0. Note that, because of the dummy items introduced in the reduction in Section 2, we can assume that each bin in an optimal solution contains exactly two large items (some original, some dummy), so we know that exactly $g = n - 2 \cdot \ell$ large items has to be handled by blockers.

Using Lemma 9, clearly, each yes-instance of the Vector Multiple Knapsack problem has a prefect matching of weight exactly $k \cdot 2^k + (2^k - 1)$ and cost at least P in the above graph, and vice versa. This is due to the equivalence of choosing ℓ edges with non-zero costs and the packing of the ℓ bins. The remaining items can be matched with the blocker vertices, and all small items are covered due to the weights.

We are left with solving the following matching problem: Given a (multi-)graph with edge weight and edge costs, find a perfect matching with a given total weight and the maximum possible total cost. This can be done with a slight modification of the algorithm of Theorem 2. Indeed, note that the algorithm already looks for a perfect matching minimizing the sum of edge costs coming from Isolation Lemma. All we have to do is to (1) combine input costs with Isolation Lemma costs, and (2) turn minimization into maximization. For (1), it suffices to put the input cost into the most significant bits, and the Isolation Lemma cost into the least significant bits of the combined edge cost. For (2), to find out what the maximum (instead of the minimum) possible total cost is, it suffices to look at the most (instead of the least) significant digit in the λ-ary representation of the coefficient $\operatorname{coef}_t(\operatorname{pf}(A))$. Last but not least, we remark that Isolation Lemma is symmetric with respect to minimization/maximization, i.e., it also ensures that the maximum total cost set is unique with probability at least $1/2$.

To analyze the running time, let $p_{\max} = \max_{v \in V} p(v)$ denote the maximum item profit. The maximum input cost of an edge is $(k+2)p_{\max}$. Hence, the coefficients of the polynomial entries of matrix A are now bounded by $2m^{(k+2)p_{\max} n \cdot 2\binom{n}{2}} = 2^{O(p_{\max} n^4 \log m)}$, and the matching algorithm takes $\widetilde{O}(t \cdot p_{\max} n^9 \log m)$ time. This leads to the following theorem.

▶ **Theorem 6.** *There is a randomized Monte Carlo algorithm solving Vector Multiple Knapsack with Few Small Items in $O^*(2^k)$ time when item profits are bounded by* $\mathrm{poly}(n)$.

Vector Bin Covering

Another set of problems asks to *cover* the largest number of bins possible. In the one-dimensional setting, covering typically refers to the bin capacity being exceeded by the set of items packed into it. This property can be extended in multiple ways to a d-dimensional case, for example by requiring that at least one dimension is exceeded. However, other properties, such as "all dimension have to be exceeded", "certain set combinations of dimensions have to be exceeded", et cetera, are possible as well. Our algorithm works for all such definitions of covering. Thus, in the following, we refer to the one chosen as the covering property $\mathcal{P}$.

Following our story line to study a parameter capturing a distance to triviality, we consider the problem variant parameterized by the number k of small items. However, the property of being a small item depends on $\mathcal{P}$, so we introduce a new definition for the covering problems: We say that a subset $V' \subseteq V$ is **3-covering** if every three distinct items from V' cover a unit-sized bin w.r.t. $\mathcal{P}$.

Vector Bin Covering with Few Small Items

Parameter:	the number of *small* items k.
Given:	a set of n items $V = \{v_1, \ldots, v_n\} \subseteq \mathbb{Q}^d_{\geqslant 0}$, a subset of k items $V_S \subseteq V$ such that $V_L = V \setminus V_S$ is **3-covering** w.r.t. $\mathcal{P}$, and an integer $\ell \in \mathbb{Z}_+$ denoting the number of unit-sized bins.
Decide:	if the items can be partitioned into ℓ bins $B_1 \cup \cdots \cup B_\ell = V$ such that $\sum_{v \in B_i} v$ satisfies $\mathcal{P}$ for every bin $i \in [\ell]$.

The algorithm proceeds similarly to the one for Vector Bin Packing. However, we have to handle the fact that a bin can contain more than two large items in this case. Thus, we first guess the number of bins ℓ_i admitting i large items for $i \in \{0, 1, 2\}$. This yields $O(\ell^3) = O(n^3)$ guesses. The remaining bins will be covered by triples of the unassigned large items. Hence, the guess has to satisfy that $\ell_0 + \ell_1 + \ell_2 + \lfloor (n - k - \ell_1 - 2\ell_2)/3 \rfloor \geqslant \ell$.

Now we construct the graph as in Section 2 with $2\ell_0 + \ell_1$ dummy items. For each $V'_S \subseteq V_S$, an edge is introduced between v_1 and v_2 if $v_1 + v_2 + \sum_{v \in V'_S} v$ covers the bin w.r.t. $\mathcal{P}$. The weight of the edge is defined by V'_S as before. Additionally, we introduce $(n - k - \ell_1 - 2\ell_2)$ *blocker* vertices, and introduce an edge of weight 0 between each blocker vertex and each large item. The blocker vertices collect all large items not being placed into bins with 0, 1, or 2 large items.

With Lemma 9 being proven, clearly, each yes-instance of the Vector Bin Covering problem has a perfect matching of weight $k \cdot 2^k + (2^k - 1)$ in the above graph, and vice versa. Indeed, a matching has to choose $(n - k - \ell_1 - 2\ell_2)$ edges between blocker vertices and large items. These are the ones greedily packed as triples. Note that this might leave up to two large items unpacked, which will be assigned to an arbitrary, already covered bin. The remaining packing is defined by the remaining matching edges as previously.

This together with Theorem 2 leads to the following result.

▶ **Theorem 7.** *There is a randomized Monte Carlo algorithm solving Vector Bin Covering with Few Small Items in $O^*(2^k)$ time.*

Perfect Matching with Hitting Constraints

The Perfect Matching with Hitting Constraints problem asks whether there exists a perfect matching in a graph using at least one edge from each given set of edges. Formally, the problem is defined as follows.

Perfect Matching with Hitting Constraints

Parameter:	the number of edge subsets k.
Given:	a graph $G = \langle V, E \rangle$, and k (not necessarily disjoint) edge subsets $E_1, \ldots, E_k \subseteq E$.
Decide:	if there is a perfect matching M in G such that there exists k *distinct* edges $e_1, \ldots, e_k \in M$ such that $e_i \in E_i$ for every $i \in [k]$.

We again reduce this problem to finding an exact weight perfect matching in a multigraph. Our approach is similar to the one of Marx and Pilipczuk [11]. However, in their reduction, they introduce larger edge weights, and, by that, obtain a larger running time. We can circumvent this using edge weights as defined in Lemma 9.

In detail, we create a copy of each edge $e \in E_i$, for each $i \in [k]$, and assign weight $1 \cdot 2^k + 2^{i-1}$ to it – i.e., we concatenate the indicator vector of the singleton $\{i\}$ with the counter set to 1, as previously. The original edge gets weight 0. The target weight is $t = k \cdot 2^k + (2^k - 1)$. Clearly, there exists a perfect matching with hitting constraints in G if and only if there is a perfect matching in the transformed graph with edge weights summing up to the correct target value t, see Lemma 9.

This together with Theorem 2 leads to the following result.

▶ **Theorem 8.** *There is a randomized Monte Carlo algorithm solving Perfect Matching with Hitting Constraints in $O^*(2^k)$ time.*

Abstract

Deciding whether a diagram of a knot can be untangled with a given number of moves (as a part of the input) is known to be NP-complete. In this paper we determine the parameterized complexity of this problem with respect to a natural parameter called defect. Roughly speaking, it measures the efficiency of the moves used in the shortest untangling sequence of Reidemeister moves.

We show that the II^- moves in a shortest untangling sequence can be essentially performed greedily. Using that, we show that this problem belongs to W[P] when parameterized by the defect. We also show that this problem is W[P]-hard by a reduction from MINIMUM AXIOM SET.

1 Introduction

A classical and extensively studied question in algorithmic knot theory is to determine whether a given diagram of a knot is actually a diagram of an unknot. This question is known as the *unknot recognition problem*. The first algorithm for this problem was given by Haken [12]. Currently, it is known that the unknot recognition problem belongs to NP ∩ co-NP but no polynomial time algorithm is known. See [13] for the NP-membership and [19] for co-NP-membership (co-NP-membership modulo Generalized Riemann Hypothesis was previously established in [16]). In addition, a quasi-polynomial time algorithm for unknot recognition has been recently announced by Lackenby [20].

One possible path for attacking the unknot recognition problem is via Reidemeister moves (see Figure 2): if D is a diagram of an unknot, then D can be untangled to a diagram U with no crossing by a finite number of Reidemeister moves. In addition, Lackenby [17] provided a polynomial bound (in the number of crossings of D) on the required number of Reidemeister moves. This is an alternative way to show that the unknot recognition problem belongs to NP, because it is sufficient to guess the required Reidemeister moves for unknotting.

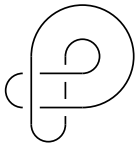

Figure 1 An example of a diagram.

However, if we slightly change our viewpoint, de Mesmay, Rieck, Sedgwick, and Tancer [23] showed that it is NP-hard to count the number of required Reidemeister moves exactly. (An anologous result for links has been shown to be NP-hard slightly earlier by Koenig and Tsvietkova [15].) More precisely, it is shown in [23] that given a digram D and a parameter k as input, it is NP-hard to decide whether D can be untangled using at most k Reidemeiser moves. For more background on unknotting and unlinking problems, we also refer to Lackenby's survey [18].

The main aim of this paper is to extend the line of research started in [23] by determining the parameterized complexity of untangling knots via Reidemeister moves. On the one hand, it is easy to see that if we consider parameterization by the number of moves, then the problem is in FPT (class of *fixed parameter tractable* problems). This happens due to a somewhat trivial reason: if a diagram D can be untangled with at most k moves, then D contains at most $2k$ crossings, thus we can assume that the size of D is (polynomially) bounded by k. In notions of parameterized complexity, this gives a kernel of size bounded by k which immediately gives the FPT membership. In the full version, we provide a bit more details; see Observation 1 in the full version.

On the other hand, we also consider parameterization with an arguably much more natural parameter called the defect (used in [23]). This parameterization is also relevant from the point of view of *above guarantee parameterization* introduced by Mahajan and Raman [21]. Here we show that the problem is W[P]-complete with respect to the defect. This is the core of the paper.

In order to state our main result more precisely, we need a few preliminaries on diagrams and Reidemeister moves. For purposes of this part of the introduction, we also assume that the reader is at least briefly familiar with complexity classes FPT and W[P]. Otherwise we refer to the end of the introduction, where we briefly overview these classes.

Diagrams and Reidemeister moves. A *diagram* of a knot is a piecewise linear map $D\colon S^1 \to \mathbb{R}^2$ in general position; for such a map, every point in $\mathbb{R}^2$ has at most two preimages, and there are finitely many points in $\mathbb{R}^2$ with exactly two preimages (called *crossings*). Locally at a crossing two arcs cross each other transversely, and the diagram contains the information of which arc passes "over" and which "under". This we usually depict by interrupting the arc that passes under. Diagrams are always considered up-to isotopy. The unique diagram without crossings is denoted U (untangled). See Figure 1 for an example of a diagram.

Let D be a diagram of a knot. *Reidemeister moves* are local modifications of the diagram depicted in Figure 2. We distinguish Reidemeister moves of types I, II, and III as depicted in the figure. In addition, for types I and II, we distinguish whether the moves remove crossings (types I^- and II^-) or whether they introduce new crossings (types I^+ and II^+).

A diagram D is a *diagram of an unknot* if it can be transformed to the untangled diagram U by a finite sequence of Reidemeister moves. (This is well known to be equivalent to stating that the lift of the diagram to $\mathbb{R}^3$, keeping the underpasses/overpasses, is ambient isotopic to

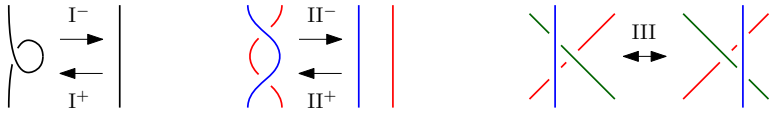

Figure 2 Reidemeister moves.

the unknot, that is standardly embedded S^1 in $\mathbb{R}^3$.) The diagram on Figure 1 is a diagram of an unknot. Diagrams may be encoded purely combinatorially as 4-regular plane graphs (with some additional combinatorial information) and the size of this encoding is comparable to the number of crossings. Similarly, the Reidemeister moves can be encoded by purely combinatorial data. For more details we refer to Sections 2 and 3 of the full version.

Parameterization via defect. As we discussed earlier, parameterization in the number of Reidemeister moves has the obvious disadvantage that once we fix k, the problem becomes trivial for arbitrarily large inputs (they are obviously a NO instance). We also see that if we have a diagram D with n crossings and want to minimize the number of Reidemeister moves to untangle D, presumably the most efficient way is to remove two crossings in each step, thus requiring at least $n/2$ steps. This motivates the following definition of the notion of defect.

Given a diagram D, by an *untangling* of D we mean a sequence $\mathcal{D} = (D_0, \dots, D_\ell)$ such that $D = D_0$; D_{i+1} is obtained from D_i by a Reidemeister move; and $D_\ell = U$ is the diagram with no crossings. Then we define the *defect* of an untangling $\mathcal{D}$ as above as

$$\operatorname{def}(\mathcal{D}) := 2\ell - n$$

where n is the number of crossings in D. Note that ℓ is just the number of Reidemeister moves in the untangling. It is easy to see that $\operatorname{def}(\mathcal{D}) \geq 0$ and $\operatorname{def}(\mathcal{D}) = 0$ if and only if all moves in the untangling are II^- moves. Therefore, $\operatorname{def}(\mathcal{D})$ in some sense measures the number of "extra" moves in the untangling beyond the trivial bound. (Perhaps, a more accurate expression for this interpretation would be $\ell - n/2 = \frac{1}{2}\operatorname{def}(\mathcal{D})$ but this is a minor detail and it is more convenient to work with integers.) In addition, it is possible to get diagrams with arbitrarily large number of crossings but with defect bounded by a constant (even for defect 0 this is possible). The defect also plays a key role in the reduction in [23] which suggests that the hardness of the untangling really depends on the defect.

As we have seen above, asking the question whether a diagram can be untangled with defect at most k is same as asking if it can be untangled in $k/2$ moves above the trivial, but tight lower bound of $n/2$. This fits perfectly in the framework of above guarantee parameterization, which was introduced by Mahajan and Raman [21] for Max-Sat and Max-Cut problems. In this framework, when there is a trivial lower bound for the solution in terms of the size of the input, parameterizing by solution size trivially gives an FPT algorithm by either giving a trivial answer if the input is large, or bounding size of the input by a function of the solution size. Hence, for those problems, it makes more sense to parameterize above a tight lower bound. The paradigm of above guarantee parameterization has been very successful in the field of parameterized complexity and many results have been obtained [1, 4, 5, 9, 10, 11, 22].

For these reasons, we find the defect to be a more natural parameter than the number of Reidemeister moves. Therefore, we consider the following problem.

▶ **Problem** (UNKNOTTING VIA DEFECT).

INPUT	A diagram D of a knot.
PARAMETER	k.
QUESTION	Can D be untangled with defect at most k?

▶ **Theorem 1.** *The problem* UNKNOTTING VIA DEFECT *is W[P]-complete.*

The proof of Theorem 1 consists of two main steps: W[P]-membership and W[P]-hardness. Both of them are non-trivial.

For W[P]-membership, roughly speaking, the idea is to guess a small enough set of *special* crossings on which we perform all possible Reidemeister moves, while we remove other crossings in a greedy fashion. In order to succeed with such an approach we will need some powerful and flexible enough lemmas on changing the ordering of Reidemeister moves in some untangling by swapping them. In Section 2 we provide an algorithm for W[P]-membership but we only sketch why it works correctly. For more details, we refer to Sections 4 and 5 of the full version.

For W[P]-hardness, we combine some techniques that were quite recently used in showing parameterized hardness of problems in computational topology [2, 3], along with the tools in [23] for lower bounding the defect. Namely, we use a reduction from the MINIMUM AXIOM SET problem, which proved to be useful in [2, 3]. Roughly speaking, from an instance I of the MINIMUM AXIOM SET problem, we need to build a diagram which has a small defect if and only if I admits a small set of axioms. For the "if" part, we use properties of Brunnian rings to achieve our goal. For the "only if" part, we need to lower bound the defect of our construction. We use the tools from [23] to show that the defect (of some subinstances) is at least 1. Then we use the very simple but powerful boosting lemma (Lemma 9) that shows that the defect is actually high. We describe the reduction in Section 4 and we sketch in a bit more detail why it may work. We refer to the Section 6 of the full version for a proof of correctness.

We conclude this part of introduction by proving a lemma on the properties of the defect which we will use soon after. Given a Reidemeister move m, let us define the *weight* of this move $w(m)$ via the following table:

Type of the move	II^-	I^-	III	I^+	II^+
$w(m)$	0	1	2	3	4

▶ **Lemma 2** (Lemma 3 in full version). *Let $\mathcal{D}$ be an untangling of a diagram D. Then* $\mathrm{def}(\mathcal{D})$ *equals to the sum of the weights of the Reidemeister moves in $\mathcal{D}$.*

The lemma is proved in the full version by a simple induction.

A brief overview of the parameterized complexity classes. Here we briefly overview the notions from parameterized complexity needed for this paper. For further background, we refer the reader to monographs [6, 7, 8]. A *parameterized problem* is a language $L \subseteq \Sigma^* \times \mathbb{N}$, where Σ^* is the set of strings over a finite alphabet Σ and the input strings are of the form (x, k). Here the integer k is called *the parameter*. In the rest of the paper, given an input for a parameterized problem, n denotes the size of the input and k denotes the value of the parameter on this input.

A parameterized problem belongs to the class FPT (fixed parameter tractable) if it can be solved by a deterministic Turing machine in time $f(k) \cdot n^c$ where $c > 0$ is some constant and $f(k)$ is some computable function of k. In other words, if we fix k, then the problem

can be solved in polynomial time while the degree of the polynomial does not depend on k. This is, of course, sometimes not achievable and there is a wider class XP of problems, that can be solved in time $O(n^{f(k)})$ by a deterministic Turing machine. The problems in XP are still polynomial time solvable for fixed k, however, at the cost that the degree of the polynomial depends on k.

Somewhere in between FPT and XP there is an interesting class W[P]. A parameterized problem belongs to the class W[P] if it can be solved by a nondeterministic Turing machine in time $h(k) \cdot n^c$ provided that this machine makes only $O(f(k) \log n)$ non-deterministic choices where $f(k), h(k)$ are computable functions and $c > 0$ is some constant. Given an algorithm for some computational problem Π, we say that this algorithm is a *W[P]-algorithm* if it is represented by a Turing machine satisfying the conditions above.

Given two parameterized problems Π and Π', we say that Π reduces to Π' via an *FPT-reduction* if there exist computable functions $f\colon \Sigma^* \times \mathbb{N} \to \Sigma^*$ and $g\colon \Sigma^* \times \mathbb{N} \to \mathbb{N}$ such that (i) $(x,k) \in \Pi$ if and only if $(f(x,k), g(x,k)) \in \Pi'$ for every $(x,k) \in \Sigma^* \times \mathbb{N}$; (ii) $g(x,k) \leq g'(k)$ for some computable function g'; and (iii) there exists computable function h and a fixed constant $c > 0$ such that for all input string, $f(x,k)$ can be computed by a deterministic Turing-machine in $O(h(k)n^c)$ steps. Our definition of reduction is consistent with [8, Definition 2.1] or [6, Definition 13.1], though some authors, e.g., [7, Definition 20.2.1] require $g(x,k) = g'(k)$ in (ii).

The classes FPT, W[P] and XP are closed under FPT-reductions. A problem Π is said to be *C-hard* where C is a parameterized complexity class, if all problems in C can be FPT-reduced to Π. Moreover, if $\Pi \in$ C, we say that Π is *C-complete*.

2 An algorithm for W[P]-membership

In this section we provide the algorithm used to prove W[P]-membership in Theorem 1.

Brute force algorithm. First, let us however look at a brute force algorithm for Unknotting via defect which does not give W[P]-membership. Spelling it out will be useful for explaining the next steps. We will exhibit this algorithm as a non-deterministic algorithm, which will be useful for comparison later on. In the algorithm, D is a diagram, and k is an integer, not necessarily positive. Also, given a diagram D and a feasible Reidemeister move m, then $D(m)$ denotes the diagram obtained from D after performing m.

BruteForce(D,k):

1. If $k < 0$, then output No. If $D = U$ is a diagram without crossings and $k \geq 0$, then output Yes. In all other cases continue to the next step.
2. (Non-deterministic step.) Enumerate all possible Reidemeister moves $m_1, \ldots, m_t$ in D up to isotopy. Make a "guess" which move m_i is the first to perform. Then, for such m_i, run BruteForce$(D(m_i), k - w(m_i))$.

Therefore, altogether, the algorithm outputs Yes, if there is a sequence of guesses in step 2 which eventually yields Yes in step 1.

It can be easily shown that the algorithm terminates because whenever step 2 is performed, either $k - w(m_i) < k$, or m_i is a Π^- move, $k - w(m_i) = k$, but $D(m_i)$ has fewer crossings than D.

It can be also easily shown by induction that this algorithm provides a correct answer due to Lemma 2. Indeed, step 1 clearly provides a correct answer, and regarding step 2, if $D(m_i)$ can be untangled with defect at most $k - w(m_i)$, then Lemma 2 shows that D

can be untangled with defect at most k. Because, this way we try all possible sequences of Reidemeister moves, the algorithm outputs `Yes` if and only if D can be untangled with defect at most k.

On the other hand, this algorithm (unsurprisingly) does not provide W[P]-membership as there are at least $n/2$ Reidemeister moves, which is unbounded in k. Thus not all moves can be guessed non-deterministically.

Naive greedy algorithm. In order to fix the problem with the previous algorithm, we want to reduce the number of non-deteministic steps. It turns out that the problematic non-deterministic steps in the previous algorithm are those where k does not decrease. (Because the other steps appear at most k times.) Therefore, we want to avoid non-deterministic steps where we perform a II^- move. The naive way is to perform such steps greedily and hope that if D untangles with defect at most k, there is also such a "greedy" untangling (and therefore, we do not have to search through all possible sequences of Reidemeister moves). This is close to be true but it does not really work in this naive way. Anyway, we spell this naive algorithm explicitly, so that we can easily upgrade it in the next step, though it does not always provide the correct answer to `Unknotting via defect`.

`NaiveGreedy`(D, k):

1. If $k < 0$, then output `No`. If $D = U$ is a diagram without crossings and $k \geq 0$, then output `Yes`. In all other cases continue to the next step.
2. If there is a feasible Reidemeister II^- move m, run `NaiveGreedy`$(D(m), k)$ otherwise continue to the next step.
3. (Non-deterministic step.) If there is no feasible Reidemeister II^- move, enumerate all possible Reidemeister moves $m_1, \ldots, m_t$ in D up to isotopy. Make a "guess" which m_i is the first move to perform and run `NaiveGreedy`$(D(m_i), k - w(m_i))$.

The algorithm must terminate for the same reason why `BruteForce` terminates. It can be shown that this is a W[P]-algorithm. However, we do not do this here in detail as this is not our final algorithm. The key is that the step 3 is performed at most $(k+1)$-times.

If the algorithm outputs `Yes`, then this is a correct answer from the same reason as in the case of `BruteForce`. However, as we hinted earlier, outputting `No` need not be a correct answer to `Unknotting via defect`. Indeed, there are known examples of diagrams of an unknot when untangling requires performing a II^+ move, see for example [14]. With `NaiveGreedy`, we would presumably undo such II^+ move immediately in the next step, thus we would not find any untangling using the II^+ move. We have to upgrade the algorithm a little bit to avoid this problem (and a few other similar problems).

Special greedy algorithm. The way to fix the problem above will be to guess in advance a certain subset S of so-called special crossings. This set will be updated in each non-deterministic step described above so that the newly introduced crossings will become special as well. Then, in the greedy steps we will allow to perform only those II^- moves which avoid S. (This also means that a II^+ move cannot be undone by a II^- move avoiding S in the next step.) It will turn out that we may also need to perform II^- moves on S but there will not be too many of them, thus such moves can be considered in the non-deterministic steps.

For the description of the algorithm, we introduce the following notation. Let D be a diagram of a knot and S be a subset of the crossings of D; we will refer to crossings in S as *special* crossings. Then we say that a feasible Reidemeister II^- move m is *greedy* (with respect to S), if it avoids S; that is, the crossings removed by m do not belong to S. On the other hand, a feasible Reidemeister move m is *special* (with respect to S) if it is

- a I^- or a II^- move removing only crossings in S; or
- a III move such that all three crossings affected by m are special; or
- a I^+ or a II^+ move performed on the edges with all their endpoints in S.

Given a move m in D, special or greedy with respect to S, by $S(m)$ we denote the following set of crossings in $D(m)$.

- If m is a greedy II^- move or if m is a III move, then $S(m) = S$ (under the convention that the three crossings affected by m persist in $D(m)$).
- If m is a special II^- move or a I^- move, then $S(m)$ is obtained from S by removing the crossings removed by m.
- If m is a I^+ or a II^+ move, then $S(m)$ is obtained from S by adding the crossings introduced by m.

Now, we can describe the algorithm.

SpecialGreedy(D, k):

0. (Non-deterministic step.) Guess a set S of at most $3k$ crossings in D. Then run SpecialGreedy(D, S, k).

SpecialGreedy(D, S, k):

1. If $k < 0$, then output No. If $D = U$ is a diagram without crossings and $k \geq 0$, then output Yes. In all other cases continue to the next step.

2. If there is a feasible greedy Reidemeister II^- move m with respect to S, run SpecialGreedy$(D(m), S(m), k)$ otherwise continue to the next step.

3. (Non-deterministic step.) If there is no feasible greedy Reidemeister II^- move with respect to S, enumerate all possible special Reidemeister moves $m_1, \ldots, m_t$ in D with respect to S up to isotopy. If there is no such move, that is, if $t = 0$, then output No. Otherwise, make a guess which m_i is performed first and run SpecialGreedy$(D(m_i), S(m_i), k - w(m_i))$.

The bulk of the proof of W[P]-membership in Theorem 1 will be to show that the algorithm SpecialGreedy(D, k) provides a correct answer to Unknotting via defect. Of course, if the algorithm outpus Yes, then this is the correct answer by similar arguments for the previous two algorithms. Indeed, Yes answer corresponds to a sequence of Reidemeister moves performed in step 2 or guessed in step 3 (no matter how we guessed S in step 0 and the role of S in the intermediate steps of the run of the algorithm is not important if we arrived at Yes). The defect of the untangling given by this sequence of moves is at most k by Lemma 2. On the other hand, we also need to show that if D untanlges with defect at most k, then we can guess some such untangling while running the algorithm. This is based on the following two auxiliary results.

For stating the results, we inductively define the notation $D(m_1, \ldots, m_{k-1}, m_k) := D(m_1, \ldots, m_{k-1})(m_k)$ provided that m_k is a feasible Reidemeister move in $D(m_1, \ldots, m_{k-1})$. We also say that a sequence $(m_1, \ldots, m_k)$ is a *feasible* sequence of Reidemeister moves for D if m_i is a feasible Redemeister move in $D(m_1, \ldots, m_{i-1})$ for every $i \in [k]$. Similarly, we inductively define $S(m_1, \ldots, m_{k-1}, m_k) := S(m_1, \ldots, m_{k-1})(m_k)$, provided that the move m_k is special or greedy in $D(m_1, \ldots, m_{k-1})$ with respect to $S(m_1, \ldots, m_{k-1})$. Then $(m_1, \ldots, m_k)$ is a *feasible* sequence of Reidemeister moves for the pair (D, S) if $S(m_1, \ldots, m_k)$ is well defined this way; that is, each move m_i in the sequence is special or greedy (with respect to the intermediate set $S(m_1, \ldots, m_{i-1})$ of special crossings).

▶ **Lemma 3** (Lemma 8 in full version). *Let D be a diagram of a knot and let $(m_1, \ldots, m_\ell)$ be a feasible sequence of Reidemeister moves in D. Then there is a set of crossings S in D such that $(m_1, \ldots, m_\ell)$ is feasible for (D, S).*

In addition, if this sequence induces an untangling with defect at most k, then $|S| \leq 3k$.

▶ **Theorem 4** (Theorem 9 in full version). *Let D be a diagram of a knot and S be a set of crossings in D. Let $(m_1, \dots, m_\ell)$ be a feasible sequence of Reidemeister moves for (D, S), inducing an untangling of D with defect k. Assume that there is a greedy move $\widetilde{m}$ in D with respect to S. Then there is a feasible sequence of Reidemeister moves for (D, S) starting with $\widetilde{m}$ and inducing an untangling of D with defect k.*

Roughly speaking, the idea of the proof of Lemma 3 is to add into S all crossings that will eventually become affected by some of the moves $m_1, \dots, m_\ell$ which are not II^- moves. These moves must be special. However, if we have a II^- move removing a crossing that we have already added to S, then this move also has to be special and we add the other crossing to S as well. This does not propagate further, and we can bound the number of special II^- moves which also provides a bound on S. Details are given in the full version. Proof of Theorem 4 requires more work and we sketch it in Section 3.

Correctness of the algorithm. Here we explain that the algorithm $\textsc{SpecialGreedy}(D, k)$ provides the answer YES whenever there is an untangling with defect at most k modulo Lemma 3 and Theorem 4. We also need to know that this is a W[P]-algorithm (mainly) by bounding the number of non-deterministic steps. This part is relatively straightforward and we refer to Section 4 of full version for details.

Given an input (D, k) such that D admits an untangling with defect k, by Lemma 3, there is a set of crossings S in D of size at most $3k$ such that there is a sequence $\mathcal{M}$ of Reidemeister moves feasible for (D, S) inducing an untangling of D with defect at most k. Thus it is sufficient to show that $\textsc{SpecialGreedy}(D, S, k)$ outputs YES if such a sequence for a given S exists. (In fact this is if and only if but we only need the if case.) We will show this by a double induction on k and $\mathrm{cr}(D)$, where $\mathrm{cr}(D)$ is the number of crossings in D. The outer induction is on k, the inner one is on $\mathrm{cr}(D)$. It would be sufficient to start our induction with the pair $(k, \mathrm{cr}(D)) = (0, 0)$; however, whenever $\mathrm{cr}(D) = 0$, then the algorithm outputs YES in step 1. Thus we may assume that $\mathrm{cr}(D) > 0$.

If (D, S) admits any greedy move, then we are in step 2. For every greedy move m there is a sequence of Reidemeister moves starting with m feasible for (D, S) inducing an untangling of D with defect at most k by Theorem 4. This move has weight 0. Thus by Lemma 2 there is a sequence of Reidemeister moves feasible for $(D(m), S(m))$ inducing an untangling of $D(m)$ with defect at most k. In addition $\mathrm{cr}(D(m)) < \mathrm{cr}(D)$, thus $\textsc{SpecialGreedy}(D(m), S(m), k)$ outputs YES by induction.

If (D, S) does not admit any greedy move, then we are in step 3. We in particular know that the first move in the sequence $\mathcal{M}$ must be special. We guess this move as we are in a non-deterministic step and denote it m_i (in consistence with the notation in step 3). Now, if we remove m_i from $\mathcal{M}$, this is a feasible sequence for $(D(m_i), S(m_i))$ inducing an untangling of $D(m_i)$ with defect at most $k - w(m_i)$ by Lemma 2. Thus $\textsc{SpecialGreedy}(D(m_i), S(m_i), k - w(m_i))$ outputs YES by induction, as we need.

3 Sketch for a proof of Theorem 4

Here we sketch a proof of Theorem 4. In general, the Reidemeister moves are not commutative: if (m, m') is a feasible sequence of Reidemeister moves in a diagram D, we cannot even expect that m' is feasible in D. A fortiori we cannot expect that (m', m) is feasible in D and that the resulting diagram would be the same when applying (m, m'). For the proof of Theorem 4, we need commutativity of the greedy moves under certain circumstances. In particular, we need to be able to swap the greedy moves with the neighbors so that we

can shift them both forward and backward through the sequence. Hint that this might be sometimes possible is the following: if m and m' can be performed inside disjoint balls, then they commute. In this section, we only state the lemmas on rearranging Reidemeister moves. The proofs of these lemmas (and their corollaries) are in the full version. Then we deduce Theorem 4 from the lemmas up to minor details explained in the full version.

First, we extend our earlier notation: Let D be a diagram of a knot, S be a set of crossings and $(m_1, \dots, m_k)$ be a sequence of Reidemeister moves feasible for a pair (D, S). Then by $(D, S)(m_1, \dots, m_k)$ we denote the pair (D', S') obtained by applying moves $(m_1, \dots, m_k)$ to (D, S). In our earlier notation, this means that $D' = D(m_1, \dots, m_k)$ and $S' = S(m_1, \dots, m_k)$. We also denote a II^- move removing crossings x and y by $\{x, y\}_{\mathrm{II}^-}$.

The first lemma allows to perform a greedy move m earlier in a sequence (m', m).

▶ **Lemma 5** (Lemma 10 in full version). *Let D be a diagram of a knot and S be a set of crossings in D. Let $m = \{x, y\}_{\mathrm{II}^-}$ be a II^- move in D, greedy with respect to S. Let m' be a feasible move for the pair (D, S) which avoids $\{x, y\}$. Then there is a move $\widehat{m}'$ feasible in $D(m)$ of same type as m' and the following conditions hold:*

- **(i)** *m is greedy in $D(m')$ with respect to $S(m')$, in particular m is feasible in $(D, S)(m')$*
- **(ii)** *$\widehat{m}'$ is feasible in $(D, S)(m)$; and*
- **(iii)** *$(D, S)(m, \widehat{m}') = (D, S)(m', m)$.*

Lemma 5 is proved by a careful local analysis depending on the type of m'. By a suitable induction, Lemma 5 implies the following corollary for longer sequences of moves.

▶ **Corollary 6** (Corollary 11 in full version). *Let D be a diagram, S be a set of crossings in D, $\ell \geq 2$, and $(m_1, \dots, m_\ell)$ be a feasible sequence of Reidemeister moves for the pair (D, S). Assume that m_ℓ is a II^- move which is also feasible and greedy in D with respect to S. Then there is a sequence of Reidemester moves $(m_\ell, \widehat{m}_1, \dots, \widehat{m}_{\ell-1})$ feasible for (D, S) such that*

- **(i)** *$(D, S)(m_1, \dots, m_\ell) = (D, S)(m_\ell, \widehat{m}_1, \dots, \widehat{m}_{\ell-1})$; and*
- **(ii)** *$w(m_i) = w(\widehat{m}_i)$ for $i \in [\ell - 1]$.*

We will also need a variant of Corollary 6 which allows to postpone a greedy move. The following corollary allows us to do that. (this follows from a lemma analogous to Lemma 5 which we skip here).

▶ **Corollary 7** (Corollary 13 in full version). *Let D be a diagram, S be a set of crossings in D, $\ell \geq 2$ and $(m_1, \dots, m_\ell)$ be a feasible sequence of moves for (D, S). Assume that $m_1 = \{x_1, y_1\}_{\mathrm{II}^-}$ and $m_\ell = \{x_\ell, y_\ell\}_{\mathrm{II}^-}$ are II^- moves where $x_1, y_1, x_\ell, y_\ell \notin S$ (in particular m_1 is greedy in D with respect to S). Finally, assume also that $\{x_1, x_\ell\}_{\mathrm{II}^-}$ is a feasible Reidemeister move for (D, S) (again, it must be greedy). Then, there is a feasible sequence $(\widehat{m}_2, \widehat{m}_3, \dots, \widehat{m}_{\ell-1}, m_1)$ of moves for (D, S) such that*

- **(i)** *$(D, S)(m_1, \dots, m_{\ell-1}) = (D, S)(\widehat{m}_2, \widehat{m}_3, \dots, \widehat{m}_{\ell-1}, m_1)$; and*
- **(ii)** *$w(m_i) = w(\widehat{m}_i)$ for $i \in \{2, \dots, \ell - 1\}$.*

Last, but not the least, both the corollaries above essentially only allow swapping the moves. In the corollaries above, m_i is essentially the same move as $\hat{m}_i$ up to a combinatorial description (not discussed in this extended abstract) which is a reason why we use a different notation. Such corollaries cannot be sufficient for a proof of Theorem 4 in the case that $\tilde{m}$ (from the statement of the theorem) is not in the sequence $(m_1, \dots, m_\ell)$. We also need to be able to replace some greedy moves with different ones which is the content of the following lemma.

▶ **Lemma 8** (Lemma 14 in full version). *Let D be a diagram of a knot and let $m = \{x, y\}_{\mathrm{II}^-}$, $\widetilde{m} = \{x, z\}_{\mathrm{II}^-}$ be two feasible Reidemeister moves in D where $y \neq z$. Assume also that $m' = \{w, z\}_{\mathrm{II}^-}$ is feasible in $D(m)$ with x, y, z, w mutually distinct. Then*

(i) *$\widetilde{m}' = \{w, y\}_{\mathrm{II}^-}$ is feasible in $D(\widetilde{m})$; and*

(ii) *$D(m, m') = D(\widetilde{m}, \widetilde{m}')$.*

Lemma 8 is again proved by local analysis in the full version.

Proof of Theorem 4 (sketch). First, let us assume that $\widetilde{m} = m_j$ for some $j \in [\ell]$. If $j = 1$, there is nothing to prove, thus we may assume $j \geq 2$. Then, by using Corollary 6 on the sequence $(m_1, \ldots, m_j)$, we get a sequence of moves $(m_j, \widehat{m}_1, \ldots, \widehat{m}_{j-1})$ feasible for (D, S). By item (i) of Corollary 6, the sequence $(m_j, \widehat{m}_1, \ldots, \widehat{m}_{j-1}, m_{j+1}, \ldots, m_\ell)$ is also feasible for (D, S) and induces an untangling of D. By item (ii) of Corollary 6 and Lemma 2, the defect of this sequence equals k, and that is what we need.

Thus it remains to consider the case where $\widetilde{m} \neq m_j$ for every $j \in [\ell]$. Because $\widetilde{m}$ is greedy, it is a II^- move; say $\widetilde{m} = \{x, z\}_{\mathrm{II}^-}$. Because the final diagram $D(m_1, \ldots, m_\ell)$ has no crossings, the crossings x and z have to be removed by some moves in the sequence $(m_1, \ldots, m_\ell)$. Say that a move m_i removes x and m_j removes z. Since $\widetilde{m}$ is greedy with respect to S, we get $x, z \notin S$. This also implies that $x \notin S(m_1, \ldots, m_{i-1})$ (see the full version for details). Thus m_i has to be greedy move in $D(m_1, \ldots, m_{i-1})$ with respect to $S(m_1, \ldots, m_{i-1})$. Similarly, m_j is greedy in $D(m_1, \ldots, m_{j-1})$ with respect to $S(m_1, \ldots, m_{j-1})$. Because we assume that $\widetilde{m}$ is not in the sequence $(m_1, \ldots, m_\ell)$, we get $i \neq j$; without loss of generality $i < j$. Let y and w be such that $m_i = \{x, y\}_{\mathrm{II}^-}$ and $m_j = \{w, z\}_{\mathrm{II}^-}$. As these moves are greedy, we get $y, w \notin S$ (we again refer to the full version for more detail).

Let $D' := D(m_1, \ldots, m_{i-1})$ and $S' := S(m_1, \ldots, m_{i-1})$. By Corollary 7, applied to D', S' and the sequence $(m_i, \ldots, m_j)$ feasible for (D', S'), we get another sequence $(\widehat{m}_{i+1}, \ldots, \widehat{m}_{j-1}, m_i)$ feasible for (D', S'). (For verifying the assumptions of the corollary note that $\widetilde{m}$ is feasible for (D', S') as all the moves $m_1, \ldots, m_{i-1}$ are special or greedy, thus they cannot remove x or z nor affect the arcs connecting them.) Then we get that $(\widehat{m}_{i+1}, \ldots, \widehat{m}_{j-1}, m_i, m_j, \ldots, m_\ell)$ is also feasible for (D', S') by item (i) of Corollary 7.

Next, let $D'' := D'(\widehat{m}_{i+1}, \ldots, \widehat{m}_{j-1})$ and $S'' := S'(\widehat{m}_{i+1}, \ldots, \widehat{m}_{j-1})$. By a similar argument as above, we get that $\widetilde{m}$ is feasible in (D'', S''). (Note that the moves m_i, m_j removing x and z have not been performed yet in order to get D''.) By Lemma 8 used in D'', we get that $\widetilde{m}' := \{w, y\}_{\mathrm{II}^-}$ is feasible in $(D'', S'')(\widetilde{m})$ and $(D'', S'')(m_i, m_j) = (D'', S'')(\widetilde{m}, \widetilde{m}')$. Altogether, by expanding D'' and D'

$$(m_1, \ldots, m_{i-1}, \widehat{m}_{i+1}, \ldots, \widehat{m}_{j-1}, \widetilde{m}, \widetilde{m}', m_{j+1}, \ldots, m_\ell) \tag{1}$$

is an untangling of D, feasible for (D, S). We also get that the defect of this untangling is equal to k by Lemma 2 and item (ii) of Corollary 7, when we used it. Note that all the moves m_i, m_j, $\widetilde{m}$ and $\widetilde{m}'$ are II^- moves, thus they do not contribute to the weight.

The sequence (1) is not the desired sequence yet, because it does not start with $\widetilde{m}$. However, it contains $\widetilde{m}$, thus we can further modify this sequence to the desired sequence starting with $\widetilde{m}$ as in the first paragraph of this proof. ◀

4 W[P]-hardness

In this section we sketch a proof of W[P]-hardness part of Theorem 1. This is done by an FPT-reduction from Minimum axiom set defined below.

4.1 Minimum axiom set

It is well known that the MINIMUM AXIOM SET problem is W[P]-hard; see [8, Exercise 3.20] or [7, Lemma 25.1.3] (however, let us recall that our definition of FPT-reduction is consistent with [8]).

▶ **Problem** (MINIMUM AXIOM SET).

INPUT	A finite set S, and a finite set $\mathcal{R}$ which consists of pairs of form (T, t) where $T \subseteq S$ and $t \in S$.
PARAMETER	k.
QUESTION	Does there exist a subset $S_0 \subseteq S$ of size k such that if we define inductively S_i to be the union of S_{i-1} and all $t \in S$ such that there is $T \subseteq S_{i-1}$ with $(T, t) \in \mathcal{R}$, then $\bigcup_{i=1}^{\infty} S_i = S$?

The problem above deserves a brief explanation. The elements of S are called *sentences* and the elements of $\mathcal{R}$ are relations. A relation (T, t) with $T = \{t_1, \ldots, t_m\}$ should be understood as an implication

$$t_1 \wedge t_2 \wedge \cdots \wedge t_m \Rightarrow t.$$

Given a set $S_0 \subseteq S$, let us define the *consequences* of S_0 as $c(S_0) := \bigcup_{i=1}^{\infty} S_i$ where S_i is defined as in the statement of the problem. Intuitively, $c(S_0)$ consists of all sentences that can be deduced from S_0 via the *relations* (implications) in $\mathcal{R}$. As we work with finite sets, $c(S_0) = S_i$ for some high enough i. A set A is a set of *axioms* if $c(A) = S$. Therefore, the goal of the minimum axiom set problem is to determine whether there is a set of axioms of size k. Note that the axiom sets are upward-closed: If A is an axiom set and $A \subseteq A' \subseteq S$, then A' is an axiom set as well.

The following boosting lemma is very useful in our reduction.

▶ **Lemma 9** (Boosting lemma; Lemma 15 in full version). *Let $(S, \mathcal{R})$ be an input of the minimum axiom set problem (ignoring the parameter for now). Let $\mu\colon S \to \mathbb{Z}$ be a non-negative function. Given $U \subseteq S$, let $\mu(U) = \sum_{s \in U} \mu(s)$. Assume that $\mu(U) \geq 1$ for all U such that $S \setminus U$ is not an axiom set. (Equivalently, U meets every axiom set.) Then $\mu(S) \geq k^*$ where k^* is the size of a minimum axiom set.*

Proof. Let $Z := \{s \in S\colon \mu(s) = 0\}$ be the zero set of μ. Then $\mu(Z) = 0$, thus $S \setminus Z$ is a set of axioms by the assumptions. This gives $|S \setminus Z| \geq k^*$ and, in addition, $\mu(S) = \mu(S \setminus Z) \geq |S \setminus Z| \geq k^*$ because $\mu(s) \geq 1$ for every $s \in S \setminus Z$. ◀

4.2 Construction of the reduction

Our aim is to show that there is an FPT-reduction from the MINIMUM AXIOM SET to UNKNOTTING VIA DEFECT. It is not hard to see (see the full version) that we can assume that the input $(S, \mathcal{R}, k)$ is *preprocessed*; i.e., (i) $\mathcal{R}$ does not contain relations of the form $(\emptyset, t)$; (ii) for every $s \in S$ there is a relation of a form (T, s) in $\mathcal{R}$; and (iii) $t \notin T$ for every $(T, t) \in \mathcal{R}$.

Doubling the instance. Now let $(S, \mathcal{R}, k)$ be a preprocessed instance of the MINIMUM AXIOM SET. We will need the following doubled instance: Let $\widehat{S} := \{\widehat{s}\colon s \in S\}$ be an auxiliary copy of S. Given $T = \{t_1, \ldots, t_m\} \subseteq S$, let $\widehat{T} := \{\widehat{t_1}, \ldots, \widehat{t_m}\}$. Then we define $\widehat{\mathcal{R}} := \{(\widehat{T}, \widehat{t}) : (T, t) \in \mathcal{R}\}$. Then $(S \cup \widehat{S}, \mathcal{R} \cup \widehat{\mathcal{R}}, 2k)$ is a *double* of the instance $(S, \mathcal{R}, k)$. The proof of the following observation is straightforward and it is given in the full version; see Observation 16 there.

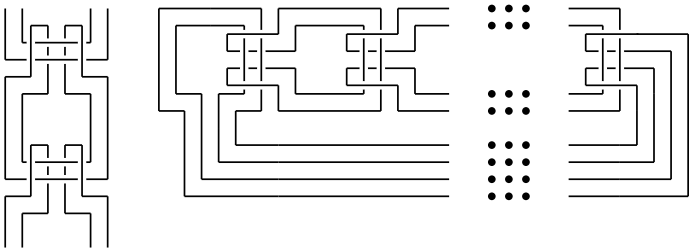

Figure 3 A Brunnian link.

▶ **Observation 10.** *The pair $(S, \mathcal{R})$ admits an axiom set of size k if and only if its double $(S \cup \widehat{S}, \mathcal{R} \cup \widehat{\mathcal{R}})$ admits an axiom set of size $2k$.*

Brunnians. A *Brunnian link* is a nontrivial link that becomes trivial whenever one of the link components is removed. We will use the following well known construction of a Brunnian link with $\ell \geq 2$ components. We take an untangled unknot and we interlace it with two "neighboring" unknots as in Figure 3, left. We repeat this ℓ-times and we get a Brunnian link with ℓ components as in Figure 3, right.

Gadgets. From now on let $(S, \mathcal{R}, k)$ be a preprocessed instance of the MINIMUM AXIOM SET and $(S \cup \widehat{S}, \mathcal{R} \cup \widehat{\mathcal{R}}, 2k)$ be its double. Our aim is to build a diagram $D(S, \mathcal{R})$ such that $D(S, \mathcal{R})$ untangles with defect $2k$ if and only if $(S, \mathcal{R})$ has an axiom set of size k. We will build $D(S, \mathcal{R})$ using several gadgets. Formally speaking, gadgets will be maps of a form $G\colon I_1 \sqcup \cdots \sqcup I_h \to \mathbb{R}^2$ where $I_1 \sqcup \cdots \sqcup I_h$ stands for a disjoint union of intervals $[0, 1]$. We will work with them in the same way as with diagrams. In particular, we assume the same transversality assumptions on crossings as for diagrams and we mark the underpasses and overpasses. We also extend the notion of arc to this setting: It is a set $G(A)$, where A is a closed subinterval of one of the intervals in $I_1 \sqcup \cdots \sqcup I_h$.

Sentence gadget. For each sentence $s \in S$ we define a sentence gadget $G(s)$ as follows. (We will also create an analogous gadget $G(\widehat{s})$ for $\widehat{s} \in \widehat{S}$ which we specify after describing $G(s)$.) We consider all relations $R \in \mathcal{R}$ of the form (T, s). Let $\ell = \ell(s)$ be the number of such relations and we order these relations as $R_1(s), \ldots, R_\ell(s)$, or simply as $R_1, \ldots, R_\ell$ if s is clear from the context (which is the case now). Note that $\ell \geq 1$ due to preprocessing.

Now we take our Brunnian link with $\ell+1$ components, which we denote by $C_0(s), \ldots, C_\ell(s)$, in the order along the Brunnians. We disconnect each component of this Brunnian link in an arc touching the outer face and we double each such disconnected component. See Figure 4, left. For the further description of the construction, we assume that our construction is rotated exactly as in the figure. (If $\ell \neq 2$, then we just modify the length of $C_0(s)$ and insert more or fewer components $C_i(s)$ in the same way as $C_1(s)$ and $C_2(s)$ are inserted for $\ell = 2$.) Now we essentially have a collection of interlacing arcs where each former component of Brunnians yields a pair of parallel arcs with four loose ends.

We merge each pair of arcs, coming from $C_i(s)$ into a single arc $\gamma_i(s)$ as follows; see Figure 4, right. For the pair coming from $C_i(s)$ for $i \neq 0$, we connect the bottom loose ends by a straight segment up to isotopy. In Figure 4, right, we have isotoped the figure a bit which will be useful in further steps of the construction, and we call this subarc the *head* of $\gamma_i(s)$. For the pair coming from $C_0(s)$, we first cross the arcs next to the top loose ends as well as next to the bottom loose ends as in the figure. Then we connect the bottom loose

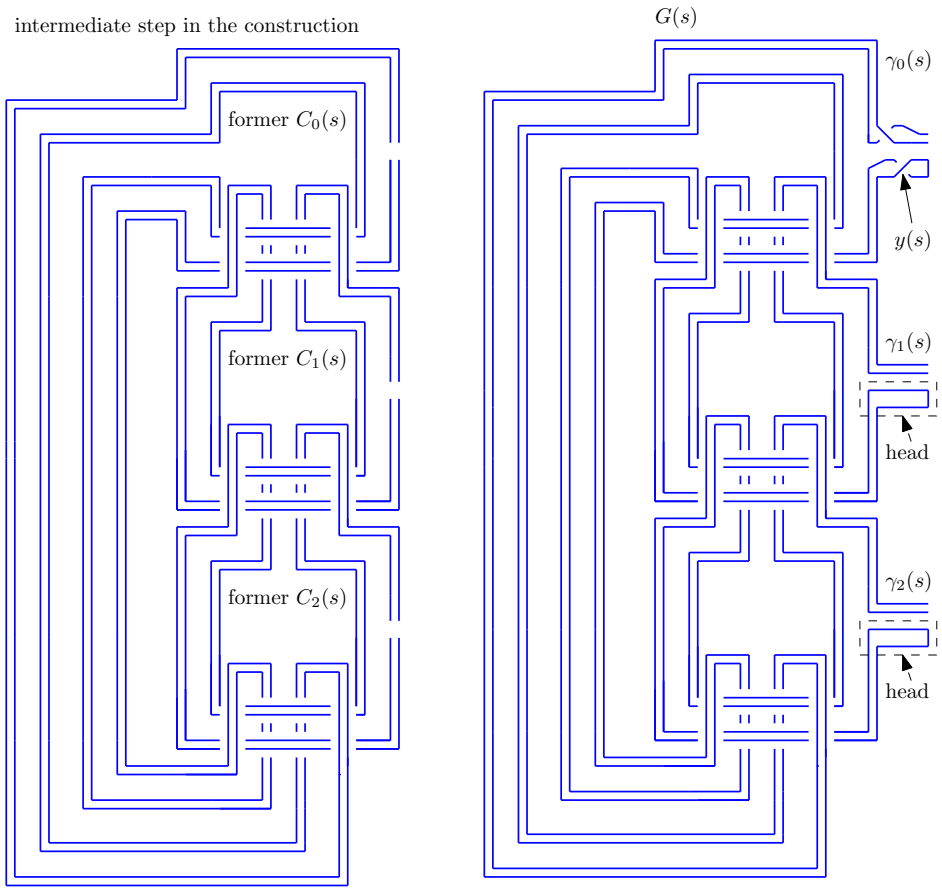

Figure 4 The sentence gadget with $\ell = 2$.

ends. Note that if we remove $\gamma_1(s), \ldots, \gamma_l(s)$ from the figure, then the crossings on $\gamma_0(s)$ can be removed by a II^- move. This finishes the construction of $G(s)$. The gadget $G(\widehat{s})$ is a mirror image of $G(s)$ along the vertical line (y-axis).

Merging gadget. We will also need a merging gadget depicted on Figure 5. We order all sentences as $s_1, \ldots, s_m$. The merging gadget consists of subgadgets $M(s_1), M(\widehat{s}_1), M(s_2), \ldots, M(s_m), M(\widehat{s}_m)$ separated by the dotted lines in the figure. Each subgadget has several loose ends. Two or four of them serve for connecting it to other subgadgets. The remaining ones come in pairs and the number of pairs equals to $\ell(s) + 1$. (Recall that this is the number of components of the sentence gadget $G(s)$.) These pairs of loose ends will be eventually connected to the loose ends of $\gamma_0(s), \ldots, \gamma_{\ell(s)}(s)$ in the top-down order.

Interconnecting the gadgets. Now, we describe how to interconnect the gadgets.

We place the sentence gadgets $G(s_1), \ldots, G(s_m)$ to the left of the merging gadget M in a top-down ordering. Similarly, we place $G(\widehat{s}_1), \ldots, G(\widehat{s}_m)$ to the right, again in a top-down ordering. First, for any $\bar{s} \in S \cup \widehat{S}$ and $i \in \{0, 2, 3, \ldots, \ell(\bar{s})\}$ (that is, $i \neq 1$), we connect $\gamma_i(\bar{s})$ with the $(i+1)$th pair of loose ends of $M(\bar{s})$ by a pair of parallel arcs as directly as possible without introducing new crossings; see Figure 7 (left).

Now we want to connect $\gamma_1(\bar{s})$ to the second pair of loose ends of $M(\bar{s})$. For simplicity, we describe this in the case $\bar{s} = s \in S$. The case $\bar{s} \in \widehat{S}$ is mirror symmetric. We pull a pair of parallel arcs from $\gamma_1(s)$ with the aim to reach $M(s)$ while obeying the following rules:

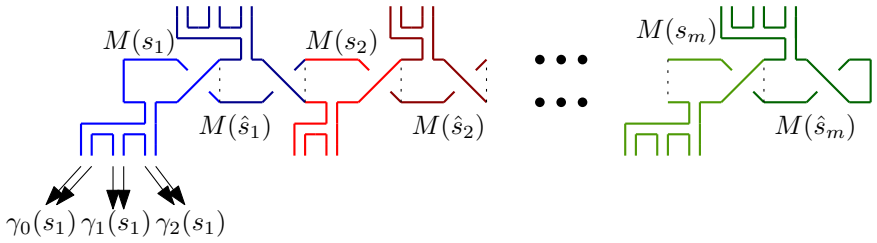

Figure 5 The merging gadget. The gadget is rotated. See also Figure 7 for correct orientation of the gadget when connecting it to other gadgets.

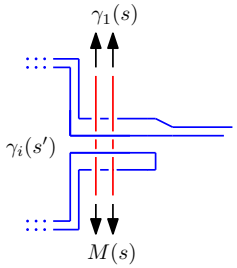

Figure 6 Interlacing the parallel arcs pulled out of $\gamma_1(s)$ with $\gamma_j(s')$.

(R1) We are not allowed to cross the merging gadget or the sentence gadgets (except the case described in the third rule below). We keep the newly introduced arcs on the left side from the merging gadget.

(R2) We are allowed to cross other pairs of parallel arcs introduced previously (when connecting $\gamma_i(s')$ to $M(s')$ for some i and s'). However, if we cross such a pair, we require that all four newly introduced crossings are resolved simultaneously (for example the new pair of parallel arcs is always above the older one). We even allow a self crossing of the newly introduced parallel arcs (but we again require that four newly introduced crossings are resolved simultaneously).

(R3) For every relation $R = (T, s')$ where $s \in T$, let $R = R_i(s')$. We interlace the newly introduced parallel arcs with $\gamma_i(s')$ as in Figure 6.

(R4) The total number of crossing is of polynomial size in the size of our instance $(S, \mathcal{R})$.

As we have quite some freedom how to perform the construction obeying the rules above, the resulting construction is not unique. An example how to get this construction systematically is sketched on Figure 7(right): The newly introduced pair of arcs is pulled little bit to the right, then we continue down towards the level of $G(s_m)$, then up towards the level of $G(s_1)$, and then back down to the original position. On this way we make a detour towards $\gamma_j(s')$ whenever we need to apply the rule (R3). Finally, we connect the parallel arcs to $M(s)$ without any further detour. This finishes the construction of $D(S, \mathcal{R})$.

A small set of axioms implies small defect. Now we very briefly sketch the easier implication that if $(S, \mathcal{R})$ admits an axiom set of size k, then $D(S, \mathcal{R})$ can be untangled with defect $2k$. For every sentence s in some fixed minimum axiom set, we unscrew the loop next to $y(s)$ (compare with Figure 4, right) and we also unscrew the loops next to $y(\widehat{s})$. This is altogether $2k$ I^- moves. If we show that the remaining crossings can be removed by II^- moves only, then we are done via Lemma 2. It is not hard to see that for s in the minimum axiom set, the initial unscrewing allows to simplify the gadget $G(s)$ essentially to $M(s)$ via II^- moves. This

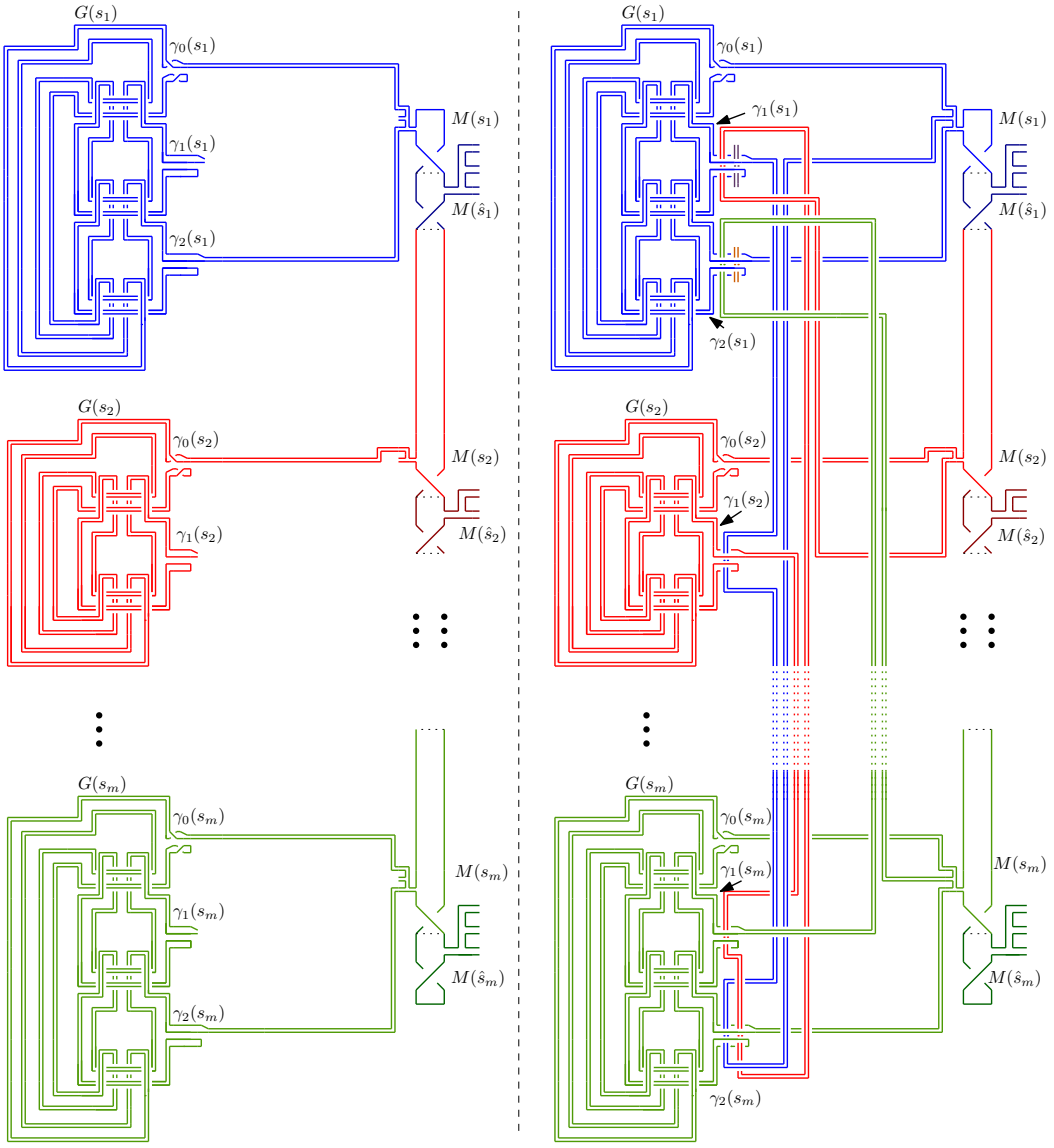

Figure 7 Left: The first step of interconnecting the gadgets – connecting $M(s)$ to the arcs $\gamma_i(s)$ for $i \neq 1$. The mirror symmetric part for $\widehat{s}$ is not displayed. Right: The second step of interconnecting the gadgets – connecting $M(s)$ to the arc $\gamma_1(s)$.

in particular releases at least one of the heads (see Figure 4, right) of the gadgets implied by the sentences in the minimum axiom set. Such a gadget can be then simplified again by II^- moves. By repeating this procedure we simplify all gadgets $G(s_1), \ldots, G(s_m)$ and analogously $G(\widehat{s}_1), \ldots, G(\widehat{s}_m)$. Then we remove remaining crossings by m more II^- moves.

Big minimum axiom sets implies big defect. It turns out that the core of the second implication in the reduction is to show the following: If the minimum axiom set for $(S, \mathcal{R})$ has size at least k, then any untangling of $D(S, \mathcal{R})$ has defect at least $2k$. For a proof of this claim we use the approach from [23] that allows to show by a local analysis that for some diagrams the defect of any untangling is strictly positive. On the other hand, this local

analysis does not show much more than that the defect is at least 1 but we need $2k$. In order to circumvent this problem we use the boosting lemma (Lemma 9) and we verify, roughly speaking, that the defect is at least 1 also for certain subdiagrams corresponding to sets of sentences U such that $S \setminus U$ is not an axiom set (as in the assumptions of Lemma 9). Then Lemma 9 implies that the defect is as high as we need.

Abstract

In the k-outconnected directed Steiner tree problem (k-DST), we are given an n-vertex directed graph $G = (V, E)$ with edge costs, a connectivity requirement k, a root $r \in V$ and a set of terminals $T \subseteq V$. The goal is to find a minimum-cost subgraph $H \subseteq G$ that has k edge-disjoint paths from the root vertex r to every terminal $t \in T$. The problem is NP-hard, and inapproximability results are known in several parameters, e.g., hardness in terms of n: $\log^{2-\varepsilon} n$-hardness for $k = 1$ [Halperin and Krauthgamer, STOC'03], $2^{\log^{1-\varepsilon} n}$-hardness for general case [Cheriyan, Laekhanukit, Naves and Vetta, SODA'12], hardness in terms of k [Cheriyan et al., SODA'12; Laekhanukit, SODA'14; Manurangsi, IPL'19] and hardness in terms of $|T|$ [Laekhanukit, SODA'14].

In this paper, we show the approximation hardness of k-DST for various parameters.

- $\Omega\left(|T|/\log|T|\right)$-approximation hardness, which holds under the standard complexity assumption NP $\neq$ ZPP. The inapproximability ratio is tightened to $\Omega\left(|T|\right)$ under the Strongish Planted Clique Hypothesis [Manurangsi, Rubinstein and Schramm, ITCS 2021]. The latter hardness result matches the approximation ratio of $|T|$ obtained by a trivial approximation algorithm, thus closing the long-standing open problem.
- $\Omega\left(2^{k/2}/k\right)$-approximation hardness for the general case of k-DST under the assumption NP $\neq$ ZPP. This is the first hardness result known for survivable network design problems with an inapproximability ratio exponential in k.
- $\Omega\left((k/L)^{L/4}\right)$-approximation hardness for k-DST on L-layered graphs for $L \leq O\left(\log n\right)$. This almost matches the approximation ratio of $O(k^{L-1} \cdot L \cdot \log|T|)$ achieved in $O(n^L)$-time due to Laekhanukit [ICALP'16].

We further extend our hardness results in terms of $|T|$ to the undirected cases of k-DST, namely the single-source k-vertex-connected Steiner tree and the k-edge-connected group Steiner tree problems. Thus, we obtain $\Omega\left(|T|/\log|T|\right)$ and $\Omega\left(|T|\right)$ approximation hardness for both problems under the assumption NP $\neq$ ZPP and the Strongish Planted Clique Hypothesis, respectively. This again matches the upper bound obtained by trivial algorithms.

1 Introduction

Fault-Tolerant and Survivable Network Design have been an active area of research for decades as enterprises depend more on communication networks and distributed computing. The need to design a network that can operate without disruption when one or more components fail has been growing dramatically. Henceforth, network scientists have formulated many models to address these problems. Amongst them, the simplest and arguably most fundamental problem in the area is the *minimum-cost k-outconnected spanning subgraph* (k-OCSS) problem that captures the problem of designing a multi-casting network with survivability property. The k-OCSS problem is a generalization of the *minimum spanning tree* and the *minimum-cost arborescence* problems, where the goal is to design a network that can operate under failures of at most $k-1$ points. More formally, k-OCSS asks to find a minimum-cost subgraph such that the root vertex is k-connected to every other vertex.

In this paper, we study the analog of k-OCSS in the presence of Steiner vertices, namely the *k-outconnected directed Steiner tree* problem (k-DST): Given a directed graph $G=(V,E)$ with cost c_e on arcs, a root vertex r and a set of terminals T, the goal is to find a minimum-cost subgraph $H \subseteq G$ such that H has k edge-disjoint paths from the root r to every terminal $t \in T$, i.e., the root remains connected to every terminal even after the removal of $k-1$ arcs. The k-DST problem is a natural generalization of the classical *directed Steiner tree* problem (DST) to high connectivity settings.

The undirected counterpart of k-DST is the *minimum-cost single source k-edge-connected Steiner tree* problem, which admits a factor-two approximation algorithm [28], and the vertex-connectivity variant admits an $O(k \log k)$-approximation algorithm due to Nutov [36]. The k-DST problem, on the other hand, has no non-trivial approximation algorithm for $k \geq 3$, except for the special case of L-layered graph, which admits $O(k^L \cdot L \cdot \log |T|)$-approximation algorithm due to Laekhanukit [33]. The cases of $k=1$ and $k=2$ are also notorious problems themselves, as both admit polylogarithmic approximation algorithms that run in quasi-polynomial time, but no polynomial-time approximation algorithms with sub-polynomial approximation. It has been long-standing open problems whether such algorithms exist for DST and 2-DST.

In this paper, we obtain several inapproximability results for k-DST. First, we show an approximation hardness of $\Omega\left(|T|/\log|T|\right)$ for k-DST under $\mathsf{NP} \neq \mathsf{ZPP}$, which holds when k is larger than $|T|$, thus implying that a trivial $|T|$-approximation algorithm for the problem is tight up to the lower order term.

▶ **Theorem 1.** *For $k > |T|$, unless $\mathsf{NP} = \mathsf{ZPP}$, it is hard to approximate the k-DST problem to within a factor of $\Omega\left(|T|/\log|T|\right)$.*

Assuming the *Strongish Planted Clique Hypothesis* (SPCH) [35], our hardness result is tight up to a constant factor, and it, indeed, rules out $f(|T|) \cdot \mathrm{poly}(n)$-time $o(|T|)$-approximation algorithm for any function f depending only on $|T|$. See discussion in the appendices of the full version of this paper.

Table 1 Summary of the results for k-DST.

Parameter	Lower Bound (This paper)	Lower Bound (Previous)	Upper Bound
Connectivity k	$\boldsymbol{\Omega\left(2^{k/2}/k\right)}$ Theorem 4	$\Omega\left(k/\log k\right)$ [34]	unknown for general $k \geq 3$
Connectivity k, Depth L	$\boldsymbol{\Omega\left((k/L)^{(1-\epsilon)L/4-2}\right)}$ Theorem 3	$\Omega\left(k/\log k\right)$ [34]	$O\left(k^{L-1} \cdot L \cdot \log \lvert T\rvert\right)$ [33]
Terminals $\lvert T\rvert$	$\boldsymbol{\Omega(\lvert T\rvert/\log \lvert T\rvert)}$ Theorem 1	$\lvert T\rvert^{1/4-\epsilon}$ [32]	$\lvert T\rvert$ folklore

▶ **Theorem 2.** *Assuming the Strongish Planted Clique Hypothesis, there is no $f(|T|)\cdot\mathrm{poly}(n)$-time $o(|T|)$-approximation algorithm for the k-DST problem.*

Next, we show that the k-DST admits no $O\left((k/L)^{L/4}\right)$-approximation algorithm even on an L-layered graph, which consists of L parts, called *layers*, and every arc joins a vertex from the i-th layer to the $(i+1)$-th layer.

▶ **Theorem 3.** *It is hard to approximate the k-DST problem on L-layered graphs $G=(V,E)$ for $\Omega(1) \leq L \leq O\left(\log |V|\right)$ to within a factor of $\Omega\left((k/L)^{(1-\epsilon)L/4-2}\right)$ for any constant $\epsilon > 0$, unless* NP = ZPP.

In addition, we obtain an approximation hardness exponential in k by setting a different parameter in the reduction, which improves upon the previously known approximation hardness of $\Omega\left(k/\log k\right)$ due to Manurangsi [34] (which is in turn based on the two previous results [32, 11]), and is the first known approximation hardness for connectivity problems whose ratio is exponential in the connectivity requirement.

▶ **Theorem 4.** *For $k < |T|$, it is hard to approximate the k-DST problem to within a factor of $\Omega\left(2^{k/2}/k\right)$, unless* NP = ZPP.

Using the technique of Cheriyan, Laekhanukit, Naves and Vetta [11], which is based on the padding technique introduced by Kortsarz, Krauthgamer and Lee [31], we extend our hardness result to the undirected counterpart of k-DST, namely, the *single source k-vertex-connected Steiner tree* problem (k-ST) (a.k.a. *undirected rooted subset k-connectivity, shorty, rooted-k-VC*) and the special case of k-DST, namely *k-edge-connected group Steiner tree* problem (k-GST).

The latter problem is a natural fault-tolerant generalization of the classical group Steiner tree problem [19], which has been studied in [29, 24, 6, 3]. To the best of our knowledge, a non-trivial approximation algorithm for this problem is known only for $k = 1, 2$. For $k \geq 3$, only a bicriteria approximation algorithm, where the connectivity requirement can be dropped by a factor $O(\log n)$, is known in [6]. Nevertheless, a trivial $|T|$-approximation algorithm exists for all values of k and we also show its tightness (up to the lower order term) for sufficiently large k.

▶ **Theorem 5.** *For $k > |T|$, unless* NP = ZPP, *it is hard to approximate the k-ST problem to within a factor of $\Omega\left(|T|/\log |T|\right)$.*

▶ **Theorem 6.** *For $k > |\mathcal{T}|$, unless* NP = ZPP, *it is hard to approximate the k-GST problem to within a factor of $\Omega\left(|\mathcal{T}|/\log |\mathcal{T}|\right)$, where $|\mathcal{T}|$ is the number of groups.*

Related work

The k-DST is well-studied in the special case where all vertices are terminals. This problem is, as mentioned, known as the k-outconnected spanning subgraph problem (k-OCSS), which admits polynomial-time algorithms due to the seminal work of Frank and Tardos [17] (also, see [16]). However, while k-OCSS is polynomial-time solvable, its undirected counterpart is NP-hard. Nevertheless, Frank-Tardos's algorithm has been used as subroutines to derive a 2-approximation algorithm for the undirected variant of k-DST and its generalization [30].

In the presence of Steiner vertices, k-DST becomes much harder to approximate. For the case of $k = 1$, the best known polynomial-time approximation algorithms are $|T|^{\epsilon}$, for any constant $\epsilon > 0$, due to the work of Charikar et al. [8], and the same approximation ratio (with an additional log factor) applies for the case $k = 2$ due to the work of Grandoni and Laekhanukit [22]. These two special cases of k-DST, especially for the case $k = 1$, have been perplexing researchers for many decades as it admits polylogarithmic approximation algorithms in quasi-polynomial-time, whereas there is no known sub-polynomial-approximation algorithm for the problems; see, e.g., [8, 23, 20, 22]. It has been a long-standing open problem whether polylogarithmic or even sub-polynomial-approximation ratios can be achieved in polynomial time. Some special cases of k-DST have been studied in the literature. Laekhanukit [33] studied the k-DST instances on L-layered graphs, and its extensions to the *L-shallow instances*, and presented an $O(k^L \cdot L \cdot \log |T|)$-approximation algorithm that runs in $n^{O(L)}$ time. Polynomial-time polylogarithmic approximation algorithms for k-DST are known in quasi-bipartite graphs [7, 37] (also, see [18, 27] for the case $k = 1$, which matches the approximation lower bound of $(1 - \epsilon) \ln k$, assuming P $\neq$ NP, inherited from the *Set Cover* problem [14, 12]).

For the undirected case of $k = 1$, namely the Steiner tree problem, it admits a 1.39-approximation algorithm due to the breakthrough result of Byrka et al. [2] and admits a $\frac{73}{60}$-approximation algorithm on quasi-bipartite graphs due to the work of Goemans et al. [21]. For $k \geq 2$, the problems on undirected graphs are branched into edge and vertex connectivity variants. This is not the case for directed graphs as there is a simple approximation-preserving reduction from edge-connectivity to vertex-connectivity and vice versa. For the edge-connectivity problem, it admits a 2-approximation algorithm by using Frank-Tardos's algorithm as subroutines when there is no Steiner vertex [30], and a 2-approximation algorithm via *iterative rounding* due to the seminal result of Jain [28], which also applies for the more general case of the *edge-connectivity survivable network design* problem. For the vertex-connectivity problem, there is a 2-approximation algorithm for $k = 2$ due to Fleischer, Jain and Williamson [15], but the problem becomes hard polynomial in k, for sufficiently large k [11], assuming P $\neq$ NP. The best known approximation algorithm for the *single-source k-vertex-connectivity* problem on undirected graphs is $O(k \log k)$ due to Nutov [36].

The network design problem where the connectivity requirements are between pairs of vertices is sometimes called point-to-point network design. A natural generalization is to extend the requirements to be between subsets of vertices, called groups. The classical problem in this genre is the well-studied *group Steiner tree* problem (see, e.g., [19, 9, 10, 25, 26, 4]). The group Steiner tree problem admits an approximation ratio of $O(\log q \log n)$ [19], which requires a probabilistic metric-tree embedding [1, 13]. This approximation ratio is almost tight as it matches the lower bound of $O(\log^{2-\epsilon} n)$, for any constant $\epsilon > 0$, due to the hardness result of Halperin and Krauthgamer [26] assuming NP $\not\subseteq$ ZPTIME$(n^{\text{polylog}(n)})$; also, see the improved hardness result in [23]. The fault-tolerant variant of the group Steiner tree problem is called the k-edge-connected group Steiner tree problem, studied in [29, 24, 6, 3]. As mentioned, true approximation algorithms for this problem are known only for $k = 1, 2$ [19, 29, 24]. For $k \geq 3$, only a bi-criteria approximation algorithm is known [6].

Organization

Section 2 is devoted to preliminary notations, definitions and facts. The reductions for k-DST are presented in Section 3, 4 and 5. We give some intuitions on the techniques in Section 3 and describe the reduction for hardness in terms of $|T|$ in Section 4 and for hardness in terms of k in Section 5. In Section 6 we briefly discuss the results for k-DST. Finally, we extend our techniques to undirected graphs and tighten the $\Omega(|T|/\log|T|)$ lower bound to $\Omega(|T|)$ under a stronger complexity hypothesis. These results are presented in the appendices of the full version of this paper.

2 Preliminaries

We use a standard graph terminology. Let $G = (V, E)$ be any graph, which can be either directed or undirected. For undirected graphs, we refer to the elements in E as the "edges" of G and denote by $\deg_G(v)$ the number of edges incident to a vertex $v \in V$. For directed graphs, we refer to the elements in E as the "arcs" of G and denote by $\text{indeg}_G(v)$ the number of arcs entering v. The notation for an edge/arc is (u, v), or sometimes $u \to v$ for an arc. For a path between vertex u and w, we call it a (u, w)-path and write it as $(u, v, \ldots, w)$ for both directed and undirected graphs, or $u \to v \to \cdots \to w$ for only directed graphs. The graphs may have multiple edges/arcs between two same vertices u and v, and both $\deg_G(v)$ and $\text{indeg}_G(v)$ count multiple ones. We drop G from the notations when it is clear from the context. When more than one graph is considered, we use $V(G)$ to clarify the vertex set of G, and $E(G)$ the edge/arc set.

k-(Edge)-Connected Directed Steiner Tree

The k-(edge)-connected directed Steiner tree problem (k-DST) is defined as follows. An input instance is of the form (k, G, r, T) where $k \in \mathbb{Z}_{\geq 1}$ is the connectivity requirement, $G = (V, E)$ is a directed graph with weight (or cost) on arcs $c : E \to \mathbb{Q}_{\geq 0}$, $r \in V$ is called root and $T \subseteq V$ is a set of terminals. A subgraph $H = (V, F)$ of G is k-connected if there exist k edge-disjoint paths in H from r to t for each terminal $t \in T$. Sometimes we also refer to a k-connected subgraph as a feasible solution to the k-DST problem. The problem is to find a k-connected subgraph $H = (V, F)$ of minimum cost $c(H) = \sum_{e \in F} c(e)$.

Here, we define the problem in terms of edge-connectivity. A vertex-connectivity variant is defined similarly except that it asks for (openly) vertex-disjoint paths instead of edge-disjoint paths. Both variants are equivalent in terms of approximability on directed graphs because there exist straightforward polynomial-time approximation-preserving reductions from any one to the other.

(Minimum) Label Cover

An instance of the label cover problem is given by an (undirected) bipartite graph $\mathcal{G} = (\mathcal{U}, \mathcal{V}, \mathcal{E})$, a set of labels $\Sigma = [g]$ and (projection) constraints $\pi_{uv} : \Sigma \to \Sigma$ on each edge $(u, v) \in \mathcal{E}$. A multilabeling $\sigma : \mathcal{U} \cup \mathcal{V} \to 2^{\Sigma}$ is a subset of labels assigned to each vertex. We say that σ *covers* an edge $(u, v) \in \mathcal{E}$ if $\pi_{uv}(a) = b$ for some $a \in \sigma(u)$ and $b \in \sigma(v)$. A multilabeling is *feasible* if it covers all the edges of $\mathcal{E}$. The problem asks for a feasible multilabeling σ with minimum cost $c(\sigma) = \sum_{u \in \mathcal{U} \cup \mathcal{V}} |\sigma(u)|$.

Manurangsi [34] proved that the label cover problem has a hardness gap in terms of the maximum degree of $\mathcal{G}$.

▶ **Theorem 7** ([34]). *For every positive integer $g > 1$, unless* NP = ZPP*, it is hard to approximate a label cover instance of maximum degree $O(g \log g)$ and alphabet size $O(g^4 \log^2 g)$ within a factor of g.*

The following corollary can be deduced straightforwardly.

▶ **Corollary 8.** *It is hard to approximate a label cover instance of maximum degree Δ and alphabet size $O\left(\Delta^4/\text{polylog}(\Delta)\right)$ to within a factor of $\Omega\left(\Delta/\log\Delta\right)$, or to within a factor of $\Omega\left(\Delta^{1-\varepsilon}\right)$ for any constant $\varepsilon > 0$, unless* NP = ZPP*.*

To obtain the hardness results on k-DST (and related problems), we present reductions from the label cover problem on an instance $(\mathcal{G} = (\mathcal{U}, \mathcal{V}, \mathcal{E}), \Sigma = [g], \pi = \{\pi_{uv} : \Sigma \to \Sigma\}_{(u,v)\in\mathcal{E}})$ of maximum degree Δ. For the ease of presentation, let $\mathcal{U} = \{u_1, u_2, \ldots\}$ and $\mathcal{V} = \{v_1, v_2, \ldots\}$.

Finally, we prepare a technical lemma for future reference. We say that a subgraph I of G is an *induced matching* if 1) I is a matching, i.e., each vertex in G is the endpoint of at most one edge in $E(I)$ and 2) I is an induced subgraph, i.e., all edges with two endpoints both in $V(I)$ are included in $E(I)$.

▶ **Lemma 9** (Folklore). *Let $G = (U, V, E)$ be a bipartite graph of maximum degree Δ. There exist a* partition *of the edges $E = E_1 \cup E_2 \cup \cdots \cup E_\Delta$ such that each E_i is a matching of G, and a partition $E'_1, E'_2, \ldots, E'_\delta$ of E for some $\delta \leq 2\Delta^2$ such that each E'_i is an induced matching. Furthermore, such partitions can be found in polynomial time.*

3 Overview of the Reductions

To give some intuitions on how our reductions work, we dedicate this section to providing an overview. We have two main reductions, which are tailored for inapproximability results in different parameters, say $|T|$ and k.

Both of the reductions inherit approximation hardness from the same source – the label cover problem, denoted by $(\mathcal{G}, \Sigma, \pi)$. We design reductions that have a one-to-one correspondence between a feasible solution to the label cover problem and that to the k-DST problem, i.e.,

- **Completeness**: Given a feasible multilabeling σ of the label cover instance $(\mathcal{G}, \Sigma, \pi)$, there is a corresponding k-connected subgraph H of G such that $c(\sigma) = c(H)$.
- **Soundness**: Given a k-connected subgraph H of the k-DST instance, there is a corresponding feasible multilabeling σ of the label cover instance $(\mathcal{G}, \Sigma, \pi)$ such that $c(\sigma) = c(H)$.

We note that certain details in the ideas mentioned below are intentionally omitted, which can be found in later chapters.

Basic Construction

First, we present the basic construction for the case $k = 1$, which is sufficient to maintain the completeness property (but not the soundness). We start by adding a root vertex r and terminal vertices t_{ij}, one for each edge $(u_i, v_j) \in \mathcal{E}$. Observe that each terminal corresponds to an edge in the label cover instance. Thus, we wish to make an (r, t_{ij})-path in G to correspond to a labeling that covers an edge in $\mathcal{G}$, which we call a *cover path*. To be more precise, if the edge (u_i, v_j) is covered by a label pair (a, b), then the corresponding *cover path* in G is the path $r \to u_i^a \to v_j^b \to v_j \to t_{ij}$ where the vertices u_i^a and v_j^b are simply added to the graph G. The appearance of the vertex $u_i^a \in V$ along the cover path can be interpreted as assigning the label a to the vertex $u_i \in \mathcal{U}$, and similarly, v_j^b means assigning the label b to

the vertex $v_j \in \mathcal{V}$. See Figure 1 for illustration. Note that any feasible multilabeling covers all the edges of $\mathcal{G}$, so we can collect all cover paths (and the involved vertices) to form a subgraph, where the root is already 1-connected to the terminals. By setting the weight of all arcs $r \to u_i^a$ and $v_j^b \to v_j$ to be 1 while leaving other arcs zero-cost, the subgraph has the same cost as the multilabeling.

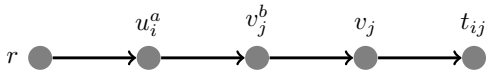

Figure 1 A cover path $(r, u_i^a, v_j^b, v_j, t_{ij})$.

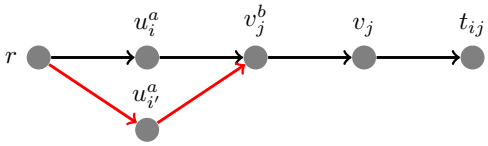

Figure 2 An illegal path $(r, u_{i'}^a, v_j^b, v_j, t_{ij})$.

However, the soundness property does not hold on the basic construction because it creates many *illegal* (r, t_{ij})-paths. Such a path goes from the root to a terminal t_{ij} by using the route that differs from $(u_i, v_j) \in \mathcal{E}$, e.g., $r \to u_{i'}^a \to v_j^b \to v_j \to t_{ij}$, where $i' \neq u_i$; see Figure 2. This means that, although a solution is feasible to the 1-DST instance, the subgraph may not have a cover path for every terminal. Thus, the corresponding multilabeling may leave some edges in the label cover instance uncovered. To ensure that at least one cover path exists for every terminal, we need to modify our instance using the *padding arc* technique.

Padding Arcs

Consider an illegal (r, t_{ij})-path in the basic construction. While we wish the (r, t_{ij})-path to visit vertices u_i^a and v_j^b, which corresponds to a satisfying labeling to the edge (u_i, v_j) in the label cover instance, the illegal path instead visits $u_{i'}^{a'}$ with $u_{i'} \neq u_i$. In particular, the illegal path exploits a cover path for some other edge $(u_{i'}, v_j)$ that share the same endpoint with (u_i, v_j).

To prevent this from happening, we construct a zero-cost *padding path* from the root to the terminal t_{ij} that shares some arcs with the illegal path. These two paths are mutually exclusive in contributing to the edge-connectivity between the root r and the terminal t_{ij}. As we set the connectivity requirement to be the same as the indegree of t_{ij}, it forces all the padding paths for t_{ij} to be used in any feasible solution. Once all the padding paths are used to form $k-1$ edge-disjoint (r, t_{ij}), the only path available is forced to be a cover path.

Size of $|T|$ and k

The construction as mentioned above yields a one-to-one correspondence between the feasible solutions to k-DST and that of the label cover problem. However, the size of the construction in terms of the parameter k (resp., $|T|$) is too large comparing to the inapproximation factor of $\Omega(\Delta/\log\Delta)$ inherited from the label cover problem. Specifically, the value of k can be as large as the number of illegal paths, and the value of $|T|$ can be as large as $|\mathcal{E}| = |\mathcal{U}| \cdot \Delta$. Therefore, we need to optimize the size of $|T|$ and k, where we use two different techniques, one for each parameter.

- To control the size of the terminal set, we partition the edge set $\mathcal{E}$ into Δ **matchings**, and only **one** terminal is constructed for **each matching** rather than having one terminal for each edge. This, thus, reduces the size of T to Δ.[1]

[1] Laekhanukit [32] applies a similar techniques using strong edge-coloring, which gives a worse factor of Δ^2.

- To control the connectivity requirement k, we partition the edge set $\mathcal{E}$ into $\delta \leq 2\Delta^2$ **induced matchings** and create a *d-ary* tree structure with δ leaves, where d is an adjustable parameter. Roughly speaking, by exploiting the tree structure, we need to add to each terminal only d *padding arcs* for each of the $O(\log_d \delta)$ layers of the tree. Thus, the connectivity requirement k is reduced to $O(d \log_d \delta)$.

Generalized to Undirected Settings

We also apply the techniques mentioned above to the undirected settings. For the undirected k-connected Steiner tree problem (k-ST), we migrate the reduction for k-DST with a hardness result in terms of $|T|$ to its vertex-connectivity version, with necessary adaptions, thus reproducing the same $|T|/\log|T|$ inapproximability. The k-connected group Steiner tree problem (k-GST) is a generalization of the k-ST problem that turns out to be one of the key components in designing approximation algorithms for k-DST [38, 22] for $k = 1, 2$. By incorporating ideas from [5], we achieved the same $q/\log q$ inapproximability for even the edge-disjoint version of k-GST where q is the number of groups. The main difficulty is that undirected edges allow new illegal paths to enter a terminal. Fortunately, by equalizing the connectivity requirement and the size of a group, it turns out we can handle the extra paths. See the appendices in the full version of this paper for a complete presentation.

4 Inapproximability in Terms of the Number of Terminals

In this section, we discuss the hardness reduction that is tailored for the parameter $|T|$. Our reduction takes as input a label cover instance $(\mathcal{G}, \Sigma, \pi)$ and then produces a k-DST instance $(k, G = (V, E), r, T)$ as an output. The reduction runs in polynomial-time, and there is a one-to-one mapping between the solutions to the two problems. Thus, the inapproximability result of label cover is mapped to the inapproximability of k-DST directly. The main focus in this section is in reducing the number of terminals by exploiting edge-disjoint paths.

Base Construction

The construction starts from a basic building block.

1. First, create a graph G with a single vertex, the root r.
2. (Refer to Figure 3) For each $u_i \in \mathcal{U}$, create in G each vertex u_i^a from $A_i = \{u_i^a : a \in \Sigma\}$; connect r to u_i^a by an arc (r, u_i^a) of cost one.
3. (Refer to Figure 4) For each $v_j \in \mathcal{V}$, create a counterpart of it (also named v_j) in G and create each vertex v_j^b from $B_j = \{v_j^b : b \in \Sigma\}$; connect v_j^b to v_j by an arc (v_j^b, v_j) of cost one.
4. (Refer to Figure 5) For each $(u_i, v_j) \in \mathcal{E}$ and $a, b \in \Sigma$, connect u_i^a to v_j^b by a zero-cost arc if $\pi_{u_i v_j}(a) = b$.

Final Construction

Finally, we have to add some zero-cost arcs so called *padding arcs* to the base construction, which are meant to enforce the constraints of the label cover problem into the k-DST instance. We first partition the edge set $\mathcal{E}$ of the graph $\mathcal{G}$ in the label cover instance into Δ matchings, denoted by $\mathcal{E}_1, \mathcal{E}_2, \ldots, \mathcal{E}_\Delta$. This step can be done in polynomial-time due to Lemma 9. We then create a set of Δ terminals corresponding to these matchings.

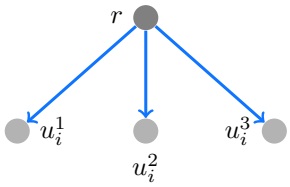

Figure 3 $\Sigma = \{1, 2, 3\}$.

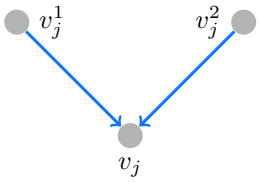

Figure 4 $\Sigma = \{1, 2\}$.

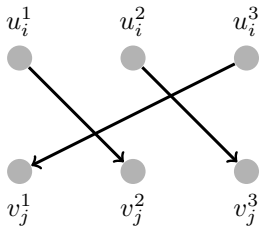

Figure 5 $\pi_{u_i v_j}(x) = x \bmod 3 + 1$.

1. For each matching $\mathcal{E}_m$, add a terminal t_m to G and connect the counterpart of each $v_j \in V(\mathcal{E}_m) \cap \mathcal{V}$ in G to t_m. (Refer to Figure 6).

Next, we add some padding arcs to form padding paths that "kills" illegal paths.

2. Instead of connecting u_i^a to v_j^b for the edges $(u_i, v_j) \in \mathcal{E}$ such that $\pi_{u_i v_j}(a) = b$ directly, we add an internal node w_{ij}^{ab} and replace the original arc (u_i^a, v_j^b) in G by arcs (u_i^a, w_{ij}^{ab}) and (w_{ij}^{ab}, v_j^b). (Here and thereafter refer to Figure 7.)
3. For each u_i^a, we connect r to u_i^a by $\deg_{\mathcal{G}}(u_i)$ copies of an arc (r, u_i^a).
4. For $1 \le m \le \Delta$, $(u_i, v_j) \in \mathcal{E}$ and $a, b \in \Sigma$ such that $\pi_{u_i v_j}(a) = b$, if $(u_i, v_j) \in \mathcal{E}_m$, then we add an arc (u_i^a, t_m); otherwise, we add an arc (w_{ij}^{ab}, t_m). Thus, we finally have $|\Sigma| \cdot |\mathcal{E}_m|$ arcs from the vertex set $\{u_i^a : u_i \in \mathcal{U}, a \in \Sigma\}$ to t_m, and $|\Sigma| \cdot (|\mathcal{E}| - |\mathcal{E}_m|)$ arcs from the internal vertex set $\left\{w_{ij}^{ab} : \pi_{u_i v_j}(a) = b\right\}$ to t_m.
5. We set $k = \max_{1 \le m \le \Delta} \text{indeg}_G(t_m)$. To make the connectivity requirement uniform, we add $k - \text{indeg}_G(t_m)$ copies of an arc (r, t_m) for each terminal t_m.

Please see Figure 7 for an illustration. Observe that the connectivity requirement k is exactly the indegree of each terminal. Thus, all of its incoming arcs are needed in any feasible solution. Now, consider the edge $(u_i, v_{j'})$ in the figure, which is not in $\mathcal{E}_m$. It is possible that a feasible solution includes the path $r \to u_i^a \to w_{ij'}^{ab'} \to v_{j'}^{b'} \to v_{j'} \to t_m$, which is an illegal path for the terminal t_m. However, if we wish to route k-edge-disjoint paths between the root r and t_m, then the arc $w_{ij'}^{ab'} \to t_m$ must be used, and the only way to use this arc is to traverse from $u_i^a \to w_{ij'}^{ab'}$. This prevents the illegal path from using this arc, meaning that it cannot be included in any k-edge-disjoint (r, t_m)-paths. Less formally, we may say that it gets killed by the padding path $r \to u_i^a \to w_{ij'}^{ab'} \to t_m$.

Why Do We Need A Matching?

Consider a terminal t_m. Our construction promises edge-disjoint cover paths from r to t_m for every edge in $\mathcal{E}_m$. However, if the edges in $\mathcal{E}_m$ do not form a matching, then two cover paths may share some edge. That is, the corresponding subgraph of a feasible multilabeling may have connectivity less than k, and the completeness property breaks.

Next, we prove the one-to-one correspondence between solutions to the two instances. Wlog., assume that any solution to the k-DST problem contains all of the zero-cost arcs.

Completeness

Given a feasible multilabeling σ of the label cover instane $(\mathcal{G}, \Sigma, \pi)$, we show that there is a corresponding feasible subgraph $H = (V, F)$ of $G = (V, E)$ such that $c(\sigma) = c(H)$. The set F consists of three types of arcs: 1) all zero-cost arcs in G; 2) the one-cost arcs (r, u_i^a) for each $u_i \in \mathcal{U}$ and $a \in \sigma(u_i)$; 3) the one-cost arcs (v_j^b, v_j) for each $v_j \in \mathcal{V}$ and $b \in \sigma(v_j)$. Clearly, $c(H) = c(\sigma)$ and the definition of F induces an injective mapping.

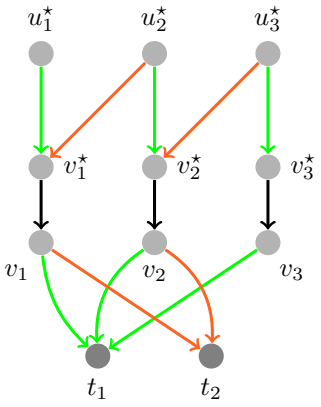

Figure 6 The terminal t_1 corresponds to the matching $\{(1,1),(2,2),(3,3)\}$ and t_2 corresponds to $\{(2,1),(3,2)\}$.

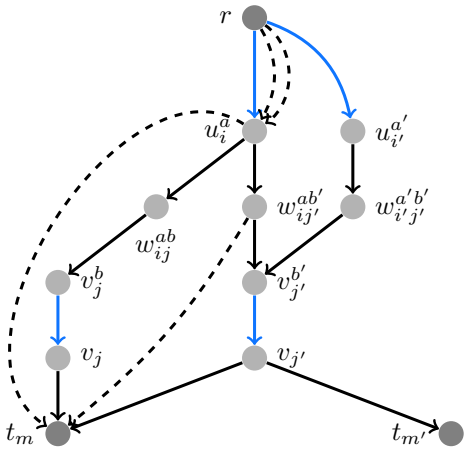

Figure 7 Padding arcs are dashed. The matching $\mathcal{E}_m$ contains the edges (u_i, v_j) and $(u_{i'}, v_{j'})$, and the matching $\mathcal{E}_{m'}$ contains the edge $(u_i, v_{j'})$.

Next we prove the feasibility of H. That is, we will show that, for any terminal t_m, there exist k edge-disjoint paths from r to t_m. We will construct a set of such paths, namely P. Note that every arc entering t_m must be contained in a distinct path in P because $\text{indeg}_H(t_m) = k$. This gives four types of paths.

- (r, t_m): The arc itself forms a path from r to t_m.
- (u_i^a, t_m): We choose one of the zero-cost arcs (r, u_i^a) to combine with (u_i^a, t_m) to constitute a path $r \to u_i^a \to t_m$. Since $\mathcal{E}_m$ is a matching, by construction we know that the arc (u_i^a, t_m) has multiplicity one in G and thus the paths in this category are edge-disjoint. After selecting paths in this way, there are still $\deg_{\mathcal{G}}(u_i) - 1$ unoccupied copies of the zero-cost arc (r, u_i^a) if $u_i \in V(\mathcal{E}_m)$; or $\deg_{\mathcal{G}}(u_i)$ unoccupied copies otherwise.
- (w_{ij}^{ab}, t_m): We choose one of the zero-cost arcs (r, u_i^a) and the arc (u_i^a, w_{ij}^{ab}) to constitute a path $r \to u_i^a \to w_{ij}^{ab} \to t_m$. If $u_i \in V(\mathcal{E}_m)$, such paths use $\deg_{\mathcal{G}}(u_i) - 1$ copies of the zero-cost arc (r, u_i^a), otherwise $\deg_{\mathcal{G}}(u_i)$ copies are used. In both cases it is valid to do so because the first two categories of path leave enough copies. It is clear that the paths up to this point are edge-disjoint.
- (v_j, t_m): In this case there is a unique $u_i \in \mathcal{U}$ such that $(u_i, v_j) \in \mathcal{E}_m$. It holds that $\pi_{u_i v_j}(a) = b$ for some $a \in \sigma(u_i), b \in \sigma(v_j)$ since σ covers the edge (u_i, v_j). We choose the one-cost arcs $(r, u_i^a) \in F$ and $(v_j^b, v_j) \in F$ to constitute a path $r \to u_i^a \to w_{ij}^{ab} \to v_j^b \to v_j \to t_m$. Since $\mathcal{E}_m$ is a matching, the paths here are edge-disjoint. Note that previous paths only use arcs added in the final construction except for arcs of the form (u_i^a, w_{ij}^{ab}), while here we only use arcs from the base construction. The construction of G guarantees (u_i^a, w_{ij}^{ab}) is not used by previous paths if $(u_i, v_j) \in \mathcal{E}_m$.

Therefore, we selected k edge-disjoint paths in H from r to t_m successfully.

Soundness

Given a k-connected subgraph $H = (V, F)$ (that contains all zero-cost arcs) of the k-DST instance (k, G, r, T), we show that there is a corresponding feasible multilabeling σ of the label cover instance $(\mathcal{G}, \Sigma, \pi)$ such that $c(\sigma) = c(H)$. The multilabeling σ is specified by checking the one-cost arcs in H, i.e., set $\sigma(u_i)$ as $\{a \in \Sigma : \text{the one-cost arc } (r, u_i^a) \text{ is in } F\}$ for $u_i \in \mathcal{U}$ and set $\sigma(v_j)$ as $\left\{b \in \Sigma : (v_j^b, v_j) \in F\right\}$ for $v_j \in \mathcal{V}$. Clearly, $c(\sigma) = c(H)$ and the definition of σ induces an injective mapping.

We prove that there exist $a_i \in \sigma(u_i)$ and $b_j \in \sigma(v_j)$ such that $\pi_{u_iv_j}(a_i) = b_j$ for each edge $(u_i, v_j) \in \mathcal{E}$. Recall that $\mathcal{E}$ is partitioned into Δ matchings $\mathcal{E}_1, \mathcal{E}_2, \ldots, \mathcal{E}_\Delta$. Let us fix an arbitrary matching $\mathcal{E}_m$ and discuss the edges inside $\mathcal{E}_m$. Consider the set S of arcs in G coming into the terminal t_m. By our construction, S contains k arcs of the following categories:

1. $|\mathcal{E}_m|$ arcs of type (v_j, t_m);
2. $|\Sigma| \cdot (|\mathcal{E}| - |\mathcal{E}_m|)$ arcs of type $(w^{a'b'}_{i'j'}, t_m)$ (one for each $(u_{i'}, w_{j'}) \notin \mathcal{E}_m$ and $a', b' \in \Sigma$ such that $\pi_{u_{i'}v_{j'}}(a') = b'$);
3. $|\Sigma| \cdot |\mathcal{E}_m|$ arcs of type (u^a_i, t_m) (one for each $(u_i, v_j) \in \mathcal{E}_m$ and $a \in \Sigma$);
4. $k - |\mathcal{E}_m| - |\Sigma| \cdot |\mathcal{E}|$ arcs of type (r, t_m).

Let P be the subgraph formed by the k edge-disjoint paths from r to t_m in H. The connectivity requirement forces that each arc in S must belong to some path in P, so we can also categorize the paths in P into the four types above. Let $P_{2\text{-}4}$ be the subgraph consisting of all type-2,3,4 paths, and P_i similarly. We prove two observations:

▷ Claim 10. We have the following facts for paths.
I: $\forall (u_{i'}, v_{j'}) \notin \mathcal{E}_m$, $\forall a', b' \in \Sigma$ such that $\pi_{u_{i'}v_{j'}}(a') = b'$, $(u^{a'}_{i'}, w^{a'b'}_{i'j'}) \in P_2 \notin P_1$.
II: $\forall (u_i, v_j) \in \mathcal{E}_m$ and $a, b \in \Sigma$ such that $\pi_{u_iv_j}(a) = b$, there are $\deg_{\mathcal{G}}(u_i)$ arcs (r, u^a_i) in $P_{2\text{-}4}$.

Proof. Note that we need a type-2 path from all $w^{a'b'}_{i'j'}$ such that $\pi_{u_{i'}v_{j'}}(a') = b'$, and using the arc $(u^{a'}_{i'}, w^{a'b'}_{i'j'})$ is the only way to enter $w^{a'b'}_{i'j'}$ to form a type-2 path. So $(u^{a'}_{i'}, w^{a'b'}_{i'j'})$ belongs to P_2 and not in P_1 (edge disjoint with P_2).

For the second claim, there are $\deg_{\mathcal{G}}(u_i) - 1$ edges $(u_i, v_{j'}) \in \mathcal{E} \setminus \mathcal{E}_m$. Plugging in Claim-I implies that there are $\deg_{\mathcal{G}}(u_i) - 1$ type-2 paths that use u^a_i. Moreover, because $(u_i, v_j) \in \mathcal{E}_m$, there is another type-3 path that use u^a_i. So, in total there are $\deg_{\mathcal{G}}(u_i)$ paths in $P_{2\text{-}4}$ that use u^a_i, and Claim-II follows. ◁

Then, fix an arbitrary $(u_i, v_j) \in \mathcal{E}_m$, we claim that the type-1 paths P_1 induce $a, b \in \Sigma$ such that $\pi_{u_iv_j}(a) = b$. Let p be the type-1 path that goes through v_j. For the path p to enter v_j, it must go through a one-cost arc (v^b_j, v_j) for some $b \in \Sigma$, and thus $b \in \sigma(v_j)$. Then, there are two ways to enter v^b_j:

1. from $w^{a'b}_{i'j}$ for some $(u_{i'}, v_j) \notin \mathcal{E}_m$ and $a' \in \pi^{-1}_{u_{i'}v_j}(b)$;
2. from w^{ab}_{ij} for $(u_i, v_j) \in \mathcal{E}_m$ and some $a \in \pi^{-1}_{u_iv_j}(b)$.

The first way is infeasible because $(u^{a'}_{i'}, w^{a'b}_{i'j}) \notin P_1$ due to Claim-I. Hence, the only way is the second and p must be exactly $r \to u^a_i \to w^{ab}_{ij} \to v^b_j \to v_j \to t_m$. Putting together Claim-II and the edge-disjointness of P_1 and $P_{2\text{-}4}$, there are $\deg_{\mathcal{G}}(u_i) + 1$ arcs (r, u^a_i) in total in P. Thus the one-cost arc (r, u^a_i) must be included in $P \subseteq H$ because there are totally $\deg_{\mathcal{G}}(u_i) + 1$ arcs (r, u^a_i) in G and thus $a \in \sigma(u_i)$. Therefore, we conclude that the arbitrarily fixed edge (u_i, v_j) is covered by $\pi_{u_iv_j}(a) = b$, where $a \in \sigma(u_i)$ and $b \in \sigma(v_j)$.

Hardness Gap

The one-to-one correspondence between solutions to the two problems is established by collecting the proofs for completeness and soundness. Furthermore, the reduction can be done in polynomial time in the size of the label cover instance and it guarantees that $|T| = \Delta$. Plugging in Corollary 8, the following inapproximability result for the k-DST problem is obtained.

▶ **Theorem 1.** *For $k > |T|$, unless* NP = ZPP*, it is hard to approximate the k-DST problem to within a factor of $\Omega\left(|T|/\log|T|\right)$.*

5 Inapproximability in Terms of the Connectivity Requirement

This section presents a hardness reduction, which is tailored for the approximation hardness in terms of the connectivity requirement k. Our reduction again takes a label cover instance $(\mathcal{G}, \Sigma, \pi)$ as an input and produces a k-DST instance $(k, G = (V, E), r, T)$. As we wish to obtain an inapproximability in terms of k, them main focus is in controlling the size of k.

Base Construction

Our reduction starts from a basic building block.

1. Let G be an empty graph. For each vertex $u_i \in \mathcal{U}$, create in G a counterpart of it (also named u_i) and a set of vertices $A_i = \{u_i^a : a \in \Sigma\}$; connect u_i to each $u_i^a \in A_i$ by an arc (u_i, u_i^a) of cost one.
2. For each vertex $v_j \in \mathcal{V}$, create in G a counterpart of it (also named v_j) and a set of vertices $B_j = \{v_j^b : b \in \Sigma\}$; connect each $v_j^b \in B_j$ to v_j by an arc (v_j^b, v_j) of cost one.
3. For each edge $(u_i, v_j) \in \mathcal{E}$, add to G a terminal t_{ij} and connect v_j to t_{ij} by a zero-cost arc (v_j, t_{ij}). For $a, b \in \Sigma$, connect $u_i^a \in A_i$ to $v_j^b \in B_j$ by a zero-cost arc if $\pi_{u_i v_j}(a) = b$.

Gadget of d-ary Arborescence

All arcs created hereafter have zero cost. By Lemma 9, $\mathcal{E}$ is partitioned into $\delta \leq 2\Delta^2$ induced matchings $\mathcal{E}_1, \mathcal{E}_2, \ldots, \mathcal{E}_\delta$. Let $d \geq 2$ be an integral parameter to be determined later. We add to G a complete d-ary out-rooted tree (arborescence) Q of height $h = \lceil \log_d \delta \rceil$ with a rooted vertex r; we set r as the root of the k-DST instance G. Choose an arbitrary order for the vertices in each layer of Q and use q_i^j to denote the j-th vertex of at the i-th layer. Note that q_0^1 is the root r. We then join each leaf q_h^j $(1 \leq j \leq \delta)$ of Q to the counterpart in G of each vertex $u_i \in V(\mathcal{E}_j) \cap \mathcal{U}$. See Figure 8 and Figure 9 for an illustration. Intuitively, if we add a padding path that passes q_i^j, all illegal paths that go through the subtree rooted at q_i^j will get killed.

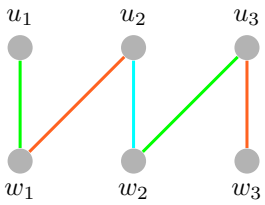

Figure 8 A bipartite graph $\mathcal{G}$ with three induced matchings: $\mathcal{E}_1 = \{(u_1, w_1), (u_3, w_2)\}$, $\mathcal{E}_2 = \{(u_2, w_1), (u_3, w_3)\}$, $\mathcal{E}_3 = \{(u_2, w_2)\}$.

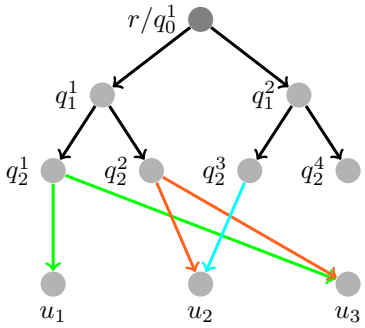

Figure 9 The gadget when $d = 2$ with induced matchings $\mathcal{E}_1, \mathcal{E}_2$ and $\mathcal{E}_3$.

Final Construction

In the final construction, we add some *padding arcs* to the based graph. These arcs form *padding paths*, which then kill all the *illegal paths* through the help of the d-ary arborescence.

1. For each arc $(q_i^j, q_{i+1}^{j'})$ of Q, we replace it by two arcs $(q_i^j, w_i^{jj'})$ and $(w_i^{jj'}, q_{i+1}^{j'})$.

We still use Q to denote the original arborescence for notational convenience.

2. For each $1 \le i \le h-1$ and j, we add $d-1$ copies of an arc (r, q_i^j) to G.
3. (Refer to Figure 10) For each terminal t_{ij}, suppose the edge (u_i, v_j) is in the group $\mathcal{E}_m$ (corresponding to q_h^m). There is a unique path in the d-ary arborescence from r to q_h^m: $(r = q_0^{j_0=1}) \to q_1^{j_1} \to q_2^{j_2} \to \cdots \to q_h^{j_h=m}$. At each level $1 \le \ell \le h$, there are $d-1$ siblings of $q_\ell^{j_\ell}$, and for each sibling $q_\ell^{j \neq j_\ell}$, we add a zero-cost arc from $w_{\ell-1}^{j_{\ell-1} j}$ to the terminal t_{ij}.

After the construction, the in-degree of each terminal t_{ij} is $h(d-1)+1$ and we set k as it.

Why Does it Work under Grouping by Induced Matchings?

For any edge $(u_i, v_j) \in \mathcal{E}_m$, now we can promise that there must be a path from r to t_{ij} going through the leaf q_h^m and the vertex $u_i \in V(G)$. Let us examine if illegal paths are bypassing either q_h^m or u_i. The padding arcs can kill illegal paths from r to t_{ij} that depart from the unique path $r \to q_1^{j_1} \to q_2^{j_2} \to \cdots \to q_h^{j_h=m} \to u_i$ at some vertex $q_\ell^{h_\ell}$ for $\ell < h$. It remains to check if there is an illegal path of the form $r \to q_1^{j_1} \to q_2^{j_2} \to \cdots \to q_h^{j_h=m} \to u_{i'} \to \cdots \to v_j \to t_{ij}$ for some $u_{i'} \neq u_i$. The existence of such $u_{i'}$ implies that $(u_{i'}, v_j) \in \mathcal{E}_m$, which contradicts that $\mathcal{E}_m$ is an induced matching.

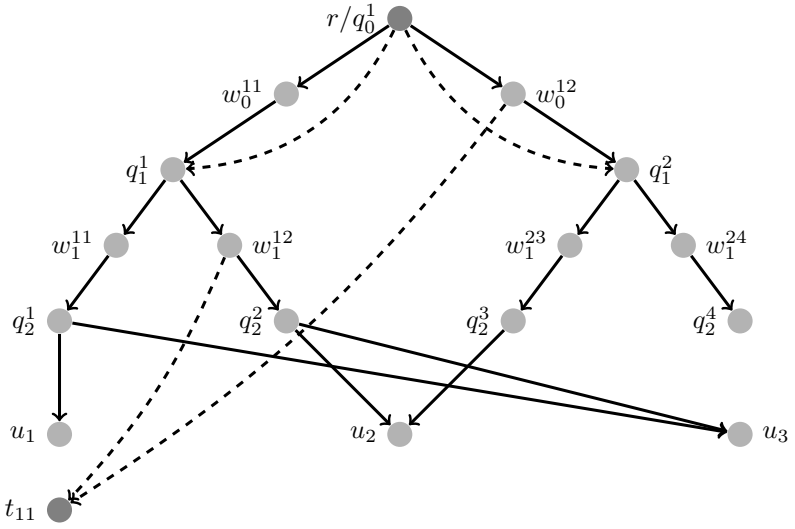

Figure 10 Padding arcs for the terminal t_{11} are dashed. Note that the vertices u_i have outgoing arcs, but not drawn here.

Completeness

Given a feasible multilabeling σ of the instance $(\mathcal{G}, \Sigma, \pi)$, we show that there is a corresponding k-connected subgraph $H = (V, F)$ of $G = (V, E)$ such that $c(\sigma) = c(H)$. The set F consists of three types of arcs: 1) all zero-cost arcs in G; 2) the one-cost arcs (u_i, u_i^a) for each $u_i \in \mathcal{U}$ and $a \in \sigma(u_i)$; 3) the one-cost arcs (v_j^b, v_j) for each $v_j \in \mathcal{V}$ and $b \in \sigma(v_j)$. Clearly, $c(H) = c(\sigma)$ and the definition of F induces an injective mapping.

Now we prove that for any terminal $t_{ij} \in T$ there are k edge-disjoint paths, denoted by P, in H from r to t_{ij}. Let $\mathcal{E}_m$ be the induced matching that contains t_{ij}. There is a unique path $p = (r = q_0^{j_0=1}) \to q_1^{j_1} \to \cdots \to q_h^{j_h=m}$ in the arborescence Q from r to q_h^m. Since $\text{indeg}_H(t_{ij}) = k$, each arc entering t_{ij} must be contained in P. We consider two cases:

1. (v_j, t_{ij}): The feasibility of σ induces $a \in \sigma(u_i)$ and $b \in \sigma(v_j)$ such that $\pi_{u_i v_j}(a) = b$, so that $(u_i, u_i^a), (u_i^a, v_j^b), (v_j^b, v_j) \in F$. Guided by the path p, we add to P the path $r \to w_0^{j_0 j_1} \to q_1^{j_1} \to w_1^{j_1 j_2} \to \cdots \to w_{h-1}^{j_{h-1} j_h = m} \to q_h^{j_h = m} \to u_i \to u_i^a \to v_j^b \to v_j \to t_{ij}$.
2. $(w_\ell^{j_\ell j'}, t_{ij})$: Here $j' \neq j_{\ell+1}$. We add to P the path $r \to q_\ell^{j_\ell} \to w_\ell^{j_\ell j'} \to t_{ij}$.

For $0 \leq \ell < h$, the type-1 path goes through $q_\ell^{j_\ell} \to w_\ell^{j_\ell j_{\ell+1}} \to q_{\ell+1}^{j_{\ell+1}}$, while each type-2 path goes through $r \to q_\ell^{j_\ell} \to w_\ell^{j_\ell j'} \to t_{ij}$ for some j'. Since $j' \neq j_{\ell+1}$, the type-1 path and the type-2 paths do not share any common arc. For the type-2 paths themselves, for each $0 \leq \ell < h$ they consume in total $d-1$ duplicates of the arc $(r, q_\ell^{j_\ell})$, which is prepared well in the second step of the final construction of G.

Soundness

Given a k-connected subgraph $H = (V, F)$ (that contains all zero-cost arcs) of the k-DST instance (k, G, r, T), we show that there is a corresponding feasible multilabeling σ of the label cover instance $(\mathcal{G}, \Sigma, \pi)$ such that $c(\sigma) = c(H)$. We define σ as follows: set $\sigma(u_i)$ as $\{a \in \Sigma : (u_i, u_i^a) \in F\}$ for $u_i \in \mathcal{U}$ and set $\sigma(v_j)$ as $\left\{b \in \Sigma : (v_j^b, v_j) \in F\right\}$ for $v_j \in \mathcal{V}$. Clearly, $c(\sigma) = c(H)$ and the definition of σ induces an injective mapping. Then we prove that σ covers all the edges in $\mathcal{E}$.

Consider an edge $(u_i, v_j) \in \mathcal{E}_m$ and its corresponding terminal t_{ij}. Let $(r = q_0^{j_0=1}) \to q_1^{j_1} \to \cdots \to q_h^{j_h=m}$ be the unique path in the arborescence Q from r to q_h^m. Let P be any set of k edge-disjoint paths from r to t_{ij} in H. The fact that $\text{indeg}_G(t_{ij}) = k = h(d-1)+1$ forces P to contain all arcs entering t_{ij}. These arcs are of two types:

1. One arc (v_j, t_{ij});
2. $h(d-1)$ arcs of $(w_\ell^{j_\ell j'}, t_{ij})$ for $0 \leq \ell < h$ and $j' \neq j_{\ell+1}$.

Let P_1 be the only path in P that uses the type-1 arc, and let P_2 be the union of paths in P that use type-2 arcs. By backtracking the paths in P_2 from t_{ij} for two steps, it holds, for $0 \leq \ell < h$ and $j' \neq j_{\ell+1}$, that $(q_\ell^{j_\ell}, w_\ell^{j_\ell j'}) \in P_2$. Thus, the path P_1 has to be $q_0^{j_0=1} \to w_0^{j_0 j_1} \to q_1^{j_1} \to \cdots \to q_h^m \to \cdots \to v_j \to t_{ij}$. Let us backtrack P_1 from v_j. The previous vertex must be v_j^b for some $b \in \Sigma$, and $u_{i'}^a$ for some $a \in \Sigma$, and $u_{i'}$, and then q_h^m. If $i' \neq i$, then by the construction of G, we know that $u_{i'} \in V(\mathcal{E}_m)$. However, it also holds that $v_j \in V(\mathcal{E}_m)$ because $(u_i, v_j) \in \mathcal{E}_m$. Thus, the induced subgraph on $V(\mathcal{E}_m)$ contains both (u_i, v_j) and $(u_{i'}, v_j)$, contradicting the matching property of $\mathcal{E}_m$. Therefore, $i' = i$, implying that $a \in \sigma(u_i), b \in \sigma(v_j)$ and $\pi_{u_i v_j}(a) = b$ because $(u_i, u_i^a), (u_i^a, v_j^b), (v_j^b, v_j) \in P_1 \subseteq P \subseteq H$.

Hardness Gap

In this subsection, we deduce approximation hardness for k-DST. Clearly, the reduction can be made in polynomial time in the size of the input label cover instance. By setting different values of the parameter d, we have the following two propositions.

▶ **Theorem 3.** *It is hard to approximate the k-DST problem on L-layered graphs $G = (V, E)$ for $\Omega(1) \leq L \leq O(\log |V|)$ to within a factor of $\Omega\left((k/L)^{(1-\epsilon)L/4-2}\right)$ for any constant $\epsilon > 0$, unless* NP = ZPP.

Proof. Let L be the height (the maximum length of paths) of the underlying graph in the k-DST instance. Recall that in the construction we have a modified d-ary arborescence and 5 base levels with vertices u_i, u_i^a, v_j^b, v_j and t_{ij}. So, $L = 2\lceil \log_d \delta \rceil + 5$. By Lemma 9, δ is at most $2\Delta^2$. Thus, $L \leq 2\lceil \log_d(2\Delta^2) \rceil + 5$. To complete the proof, we add some dummy vertices to the modified d-ary arborescence so that the height becomes exactly $2\lceil \log_d(2\Delta^2) \rceil + 5$.

We fix $d = \Delta^x \geq 2$ for some $0 < x \leq 1$. Then $k = \lceil \log_d \delta \rceil (d-1) + 1 \leq (d-1)(2\log\Delta/\log d + 1/\log d + 1) + 1 \leq (2/x + 2)\,\Delta^x$. We also have that $4/x \leq L = 2\lceil \log_d(2\Delta^2) \rceil + 5 \leq 4/x + 8$. Therefore, $(k/L)^{\frac{(1-\epsilon)L}{4} - 2} \leq \Delta^{1-\epsilon}$, and we have the claimed result on layered graphs by plugging in Corollary 8. The parameter x can be used to obtain specific values of L that we want. ◀

▶ **Theorem 4.** *For $k < |T|$, it is hard to approximate the k-DST problem to within a factor of $\Omega\left(2^{k/2}/k\right)$, unless* NP = ZPP*.*

Proof. Recall that $k = h(d-1) + 1 = \lceil \log_d \delta \rceil (d-1) + 1$ where $\delta \leq 2\Delta^2$. If we set $d = 2$, then $k = \lceil \log \delta \rceil + 1 \leq 2\log\Delta + 3$. If k is too small, then we can add dummy arcs from r to terminals to make $k \geq \log\Delta$. Plugging in Corollary 8, the claimed hardness gap follows. ◀

6 Discussion

In this paper we obtain improved inapproximability results for the k-DST problem in terms of parameters k and $|T|$. All of the results are derived from the same hardness source, the (minimum) label cover problem, which admits no $\Delta/\log\Delta$-approximation algorithm under standard complexity assumptions, where Δ is the maximum degree of the underlying bipartite graph in the label cover problem. The label cover problem also admits no $2^{\log^{1-\varepsilon} N}$-approximation algorithm for any constant $\varepsilon > 0$, where N is the underlying graph size. Note that $2^{\log^{1-\varepsilon} N} = N^{o(1)}$. If we apply the reduction in the $\Omega(|T|/\log|T|)$-hardness, then it transfers to $k^{o(1)}$ which is even worse than the previous $\Omega(k/\log k)$-hardness, not to say the factor of $\Omega(2^{k/2}/k)$ in this paper. If we apply the reduction in the $\Omega(2^{k/2}/k)$-hardness, then it transfers to $|T|^{o(1)}$ which is still much worse than $|T|^{1/4-\varepsilon}$ and $\Omega(|T|/\log|T|)$.

Abstract

Given a simple graph G and an integer k, the goal of the k-Clique problem is to decide if G contains a complete subgraph of size k. We say an algorithm approximates k-Clique within a factor $g(k)$ if it can find a clique of size at least $k/g(k)$ when G is guaranteed to have a k-clique. Recently, it was shown that approximating k-Clique within a constant factor is W[1]-hard [20].

We study the approximation of k-Clique under the *Exponential Time Hypothesis* (ETH). The reduction of [20] already implies an $n^{\Omega(\sqrt[6]{\log k})}$-time lower bound under ETH. We improve this lower bound to $n^{\Omega(\log k)}$. Using the gap-amplification technique by expander graphs, we also prove that there is no $k^{o(1)}$ factor FPT-approximation algorithm for k-Clique under ETH.

We also suggest a new way to prove the *Parameterized Inapproximability Hypothesis* (PIH) under ETH. We show that if there is no $n^{O(\frac{k}{\log k})}$-time algorithm to approximate k-Clique within a constant factor, then PIH is true.

1 Introduction

In this paper, we study the k-Clique problem: given a simple graph G and an integer k, decide whether G contains a complete subgraph of size k. As shown in [18], k-Clique is one of the most classical NP-complete problems. Its inapproximability in the classical complexity regime has also been studied extensively [10, 4, 5, 14, 11, 15, 28]. Along a long line of research, it was proved that even approximating Clique into a ratio of $n^{1-\varepsilon}$ is NP-hard.

In recent years, the hardness of approximating k-Clique has received increased attention in the parameterized complexity regime. When guaranteed that the maximum clique is of size k, people wonder if there is an algorithm which runs in $f(k)n^{O(1)}$ time, and can find a clique of size at least $k/g(k)$, for some computable functions f and g. Such an algorithm is called a $g(k)$-*FPT-approximation* for the k-Clique problem.

Previously, [6] ruled out all $g(k)$-FPT-approximation algorithms of k-Clique for any $g(k) = o(k)$ under the *Gap Exponential Time Hypothesis* (Gap-ETH) [1]. They even showed that assuming Gap-ETH, it is impossible to find a clique of size $\varepsilon(k)$ in $f(k)n^{o(\varepsilon(k))}$ time. However, as Gap-ETH is such a strong hypothesis that it already gives a gap in hardness of approximation, it is still of great interest to prove the same lower bound under an assumption without an inherent gap. People may further wonder:

Assuming ETH*, does finding a clique of size* $\varepsilon(k)$ *in* k-Clique *require* $f(k)n^{\Omega(\varepsilon(k))}$ *time?*

In a recent work [20], Lin showed that k-Clique does not admit constant factor FPT-approximation algorithms unless W[1] = FPT. This was the first successful attempt to bypass Gap-ETH to prove the hardness of approximating k-Clique. Unfortunately, [20] reduces a k-Clique instance to a constant gap k'-Clique[2] instance with $k' = 2^{k^6}$. As there is no $f(k)n^{o(k)}$ time algorithm for k-Clique assuming ETH, [20] actually ruled out $f(k)n^{o(\sqrt[6]{\log k})}$ time constant approximation algorithms for k-Clique under ETH. Comparing to [6], such a lower bound is still far beyond satisfaction, and it remains open to avoid the huge parameter blow-up in the gap-producing reduction to obtain a better lower bound.

The main result of this paper is

▶ **Theorem 1.** *Assuming* ETH*, for any constant* $c > 1$ *and any computable function* f*, no algorithm can find a clique of size* k/c *in the* k-Clique *problem in* $f(k)n^{o(\log k)}$ *time.*

As an application, we combine our main result with the classical gap-amplification technique to rule out any $k^{o(1)}$-ratio FPT-approximation algorithms for k-Clique under ETH. Let us not fail to mention that [24] recently proved similar lower bound based on a weaker hypothesis W[1] $\neq$ FPT. Our result is formally stated as follows.

▶ **Corollary 2.** *Assuming* ETH*, for any* $g(k) = k^{o(1)}$*, the* k-Clique *problem has no* $g(k)$*-FPT-approximation algorithm.*

We also study the relationship between the constant gap k-Clique problem and the *parameterized inapproximablity hypothesis* (PIH) [21], a central conjecture in parameterized complexity. Roughly speaking, PIH states that it is impossible to approximate a 2-CSP instance over k variables with alphabet $[n]$ to a constant factor in FPT time. It is known in [10] that if PIH is true, then there is no FPT algorithm for constant gap k-Clique. However, the reverse direction is not known yet. Furthermore, although PIH can be deduced from Gap-ETH via standard reductions in [7, 8], proving PIH under gap-free hypotheses (e.g. ETH, W[1] $\neq$ FPT) is still quite open and is believed to require a PCP-like theorem in parameterized complexity. We show that an almost-tight running time lower bound of constant gap k-Clique could imply PIH. Our theorem suggests a new way to prove PIH under ETH, namely, by using constant gap k-Clique as an intermediate problem. It is formally stated as follows.

▶ **Theorem 3.** *If there is no* $f(k)n^{O(\frac{k}{\log k})}$ *time algorithm for constant gap* k-Clique*, then* PIH *is true.*

---

[1] Gap-ETH states that no subexponential time algorithm can distinguish whether a 3SAT formula is satisfiable or every assignment satisfies at most $1 - \varepsilon$ fraction of clauses for some $\varepsilon > 0$.

[2] Given $k \in \mathbb{N}$, $\varepsilon \in (0, 1)$ and a simple graph G, the constant gap k-Clique problem is to decide whether G contains a K_k subgraph or G contains no $K_{\varepsilon k}$ subgraph.

1.1 Our Techniques

From 3SAT **to gap** k-Clique**.** Recall that the reduction in [20] consists of two steps. First, it reduces k-Clique to k^2-VectorSum, while introducing a quadratic blow-up of the parameter. Next, it transforms k-VectorSum to CSP on $k' = 2^{O(k^3)}$ variables $\{x_{\vec{a}_1,\ldots,\vec{a}_k} : \vec{a}_1,\ldots,\vec{a}_k \in \mathbb{F}^k\}$, and then to constant gap k'-Clique. The two steps together cause the parameter to grow from k to $2^{O(k^6)}$.

To give a tighter lower bound of constant gap k-Clique under ETH, we deal with the above two steps separately. First, we show a reduction directly from 3SAT to k-VectorSum, resulting in a tighter lower bound of k-VectorSum under ETH. Then, we give a more succinct reduction from k-VectorSum to CSP on $k' = 2^{O(k)}$ variables $\{x_{a_1,\ldots,a_k} : a_1,\ldots,a_k \in \mathbb{F}\}$, and then to constant gap k'-Clique. In our new reduction, the parameter blow-up throughout is only $2^{O(k)}$, leading to an $n^{\Omega(\log k)}$ lower bound for constant gap k-Clique.

Since the second step is more complicated, we will briefly introduce the ideas here. Given an k-VectorSum instance $(V_1,\ldots,V_k,\vec{t})$, we build a CSP instance on variable set $X = \{x_{a_1,\ldots,a_k} : a_1,\ldots,a_k \in \mathbb{F}\}$. Each variable takes value in $\mathbb{F}^m$ where m is the dimension specified by the k-VectorSum problem. In the yes-case, let $\vec{v}_1 \in V_1,\ldots,\vec{v}_k \in V_k$ be a solution that sum up to $\vec{t}$, we expect $x_{a_1,\ldots,a_k}$ to take the value $\sum_{i\in[k]} a_i\vec{v}_i$. Similar to [20], we want to make the following three types of tests:

- $\forall(a_1,\ldots,a_k),(b_1,\ldots,b_k) \in \mathbb{F}^k$, test whether $x_{a_1,\ldots,a_k} + x_{b_1,\ldots,b_k} = x_{a_1+b_1,\ldots,a_k+b_k}$.
- $\forall(a_1,\ldots,a_k) \in \mathbb{F}^k, a \in \mathbb{F}$, test whether $x_{a_1,\ldots,a_i+a,\ldots,a_k} - x_{a_1,\ldots,a_k} \in aV_i$.
- $\forall(a_1,\ldots,a_k) \in \mathbb{F}^k, a \in \mathbb{F}$, test whether $x_{a_1+a,\ldots,a_k+a} - x_{a_1,\ldots,a_k} = a\vec{t}$.

If an assignment passes most of the linearity tests, then there must be vectors $\vec{u}_1,\ldots,\vec{u}_k \in \mathbb{F}^m$ such that $x_{a_1,\ldots,a_k} = \sum_{i\in[k]} a_i\vec{u}_i$ for most $(a_1,\ldots,a_k) \in \mathbb{F}^k$. The second step is meant to guarantee that the selected vectors indeed come from the input. Finally we need the third step to check whether they sum up to $\vec{t}$.

Note that in our reduction from 3SAT to k-VectorSum, we require the dimension m to be at least $\Omega(k\log n)$. Thus in the CSP instance, we cannot simply leave the alphabet to be $\mathbb{F}^m = n^{\Omega(k)}$, which is too large. To reduce the dimension, we pick $\ell = \Theta(k + \log n)$ matrices $A_1,\ldots,A_\ell \in \mathbb{F}^{k\times m}$ independently at random, and define a new CSP problem on variable set $Y = \{y_{\vec{\alpha},\vec{\beta}} : \vec{\alpha},\vec{\beta} \in \mathbb{F}^k\}$, where each $y_{\vec{\alpha},\vec{\beta}}$ is supposed to take the value

$$\begin{aligned} y_{\vec{\alpha},\vec{\beta}} &= (\vec{\alpha}A_1x_{\vec{\beta}},\ldots,\vec{\alpha}A_\ell x_{\vec{\beta}}) \\ &= (\vec{\alpha}A_1\sum_{i\in[k]}\beta_i\vec{v}_i,\ldots,\vec{\alpha}A_\ell\sum_{i\in[k]}\beta_i\vec{v}_i) \\ &= \sum_{i\in[k],j\in[k]}\beta_i\alpha_j(A_1[j]\vec{v}_i,\ldots,A_\ell[j]\vec{v}_i) \\ &\triangleq \sum_{i\in[k],j\in[k]}\beta_i\alpha_jC_{i,j}. \end{aligned} \tag{1}$$

Now the alphabet size is only $\mathbb{F}^\ell = 2^{O(k)}n^{O(1)}$. With this idea in mind, we add local constraints to enforce that the assignment to Y is of the above quadratic form (in terms of $\alpha_1,\ldots,\alpha_k$ and $\beta_1,\ldots,\beta_k$), and then use locally decodable properties of quadratic polynomials to extract information about vectors $\vec{v}_1,\ldots,\vec{v}_k$.

In a high level, our construction generalizes that of [20] by replacing the linear code with the Reed–Muller code based on quadratic polynomials.

Expander graph production. To obtain an FPT time lower bound for k-Clique with $k^{o(1)}$ gap, we apply the standard expander graph product technique. Starting from a constant gap k-Clique instance, we amplify the gap using an expander graph H on vertex set $[k]$. The new instance contains k^t groups of vertices. Each group corresponds to a unique path of length-t random walk on H, and forms an independent set of size n^t. A vertex in a group represents a length-t sequence of vertices from the original instance. Two (sequences of) vertices are linked if and only if the vertices contained in them form a clique in the original instance. By properties of expander graphs, we get a k^t-Clique instance with gap $(\varepsilon')^t$ for some constant ε'. Take $t = o(\log k)$, we can rule out $k^{o(1)}$-ratio FPT-approximation algorithms for k-Clique under ETH.

From gap k-Clique to PIH. The proof that strong lower bound of constant gap k-Clique implies PIH goes as follows. First, we reduce constant gap k-Clique to constant gap k-Biclique in the canonical way. Next, we use a combinatorial object called disperser to amplify the gap from a constant to $\frac{k}{\log k}$. The result then follows from the Kõvári-Sós-Turán Theorem which states that every $2k$-vertex graph without a $K_{\log k, \log k}$-subgraph has at most $O((2k)^{2-\frac{1}{\log k}})$ edges.

1.2 Organization of the Paper

The paper is organized as follows. In Section 2, we put some preliminaries, including the definitions of problems, hypotheses, and some algebraic and combinatorial tools used in our proofs. In Section 3, we prove the ETH lower bound of constant gap k-Clique. In Section 4, we show how to amplify the gap to rule out $k^{o(1)}$-ratio FPT-approximation algorithms for k-Clique under ETH. In Section 5, we show how an almost-tight running time lower bound of constant gap k-Clique implies PIH. Finally, in Section 6, we conclude with a few open questions.

2 Preliminaries

2.1 Problems

Here we list all the computational problems which are relevant to our paper.

- 3SAT. The input is a 3-CNF formula φ with m clauses on n variables. The goal is to decide whether there is a satisfying assignment for φ.
- CSP. The input of a constraint satisfaction problem is a set of variables $X = \{x_1, \ldots, x_n\}$ together with a family of constraints $\{C_1, C_2, \ldots, C_m\}$ and an alphabet Σ. For every $i \in [m]$, $C_i = (\vec{s}_i, R_i)$, where $\vec{s}_i = (x_{j_1}, \ldots, x_{j_{\ell_i}})$ is an ℓ_i-tuple of variables for some $\ell_i \in [n]$, and $R_i \subseteq \Sigma^{\ell_i}$ indicates a restriction on valid assignments for those ℓ_i variables. The goal is to find an assignment $\sigma : X \to \Sigma$ such that for all $i \in [m]$, $\sigma(\vec{s}_i) \in R_i$. We call n, m, q and $|\Sigma|$ respectively the number of vertices, the number of clauses, the arity ($= \max_{i\in[m]} \ell_i$), and the alphabet size of this CSP problem.
- k-Clique. The input is an undirected graph $G = (V_1 \dot\cup \ldots \dot\cup V_k, E)$ with n vertices divided into k disjoint groups. The goal is to decide whether we can pick one vertex from each group, such that they form a clique of size k.
- k-Biclique. The input is an undirected bipartite graph $G = (V_1 \dot\cup \ldots \dot\cup V_k, U_1 \dot\cup \ldots \dot\cup U_k, E)$, where n vertices are divided into $2k$ disjoint groups. The goal is to decide whether we can pick one vertex from each group, such that they form a biclique $K_{k,k}$.

- DENSEST k-SUBGRAPH. The input is an undirected graph $G = (V_1 \dot\cup \ldots \dot\cup V_k, E)$ with n vertices divided into k disjoint groups. The goal is to pick one vertex from each group, such that they induce maximum number of edges.
- k-VECTORSUM. The input consists of k groups of vectors $V_1, \ldots, V_k \subseteq \mathbb{F}^d$ together with a target vector $\vec{t} \in \mathbb{F}^d$, where $\mathbb{F}$ is a finite field of constant size. The goal is to decide whether there exists $\vec{v}_1 \in V_1, \ldots \vec{v}_k \in V_k$ such that $\sum_{i=1}^{k} \vec{v}_i = \vec{t}$. Throughout our paper we only need the version that $\vec{t}$ equals to $\vec{0}$, and will omit it afterwards.

2.2 Hypotheses

Now we list some computational complexity hypotheses which are related to our results.

▶ **Hypothesis 4** (Exponential Time Hypothesis (ETH) [16, 17, 25])**.** 3SAT *with n variables and $m = O(n)$ clauses cannot be solved deterministically in $2^{o(n)}$ time. Moreover, this holds even when restricted to formulae in which each variable appears in at most three clauses.*

Note that the original statement in [16] is does not enforce the requirement that each variable appears in at most three clauses. For the restricted version, we first apply the Sparsification Lemma in [17], which implies that without loss of generality we can assume the number of clauses $m = O(n)$. Then we apply Tovey's reduction [25], which produces a 3SAT instance with at most $3m + n = O(n)$ variables and each variable appears in at most three clauses. Thus the restricted version is equivalent to the original statement.

The next hypothesis is *Parameterized Inapproximability Hypothesis* (PIH), a central conjecture in parameterized complexity. We state it in terms of inapproximability of DENSEST k-SUBGRAPH as follows.

▶ **Hypothesis 5** (Parameterized Inapproximability Hypothesis (PIH) [21])**.** *There exists a constant $\varepsilon > 0$ such that DENSEST k-SUBGRAPH has no $(1+\varepsilon)$ factor FPT-approximation algorithm. In other words, no algorithm can distinguish the following two cases in $f(k) \cdot n^{O(1)}$ time, for any computable function f:*

- *(Completeness.) There exist $v_1 \in V_1, \ldots, v_k \in V_k$ such that they form a clique.*
- *(Soundness.) For any $v_1 \in V_1, \ldots, v_k \in V_k$, they induce only $\binom{k}{2}/(1+\varepsilon)$ edges.*

The factor $(1+\varepsilon)$ can be replaced by any constant larger than 1, and the conjecture remains equivalent. Note that the original statement of PIH in [21] says that DENSEST k-SUBGRAPH is W[1]-hard to approximate, but for our use, we choose a relaxed form which states that it has no constant ratio FPT-approximation algorithm, as in [12].

It is worth noting that the relationship between PIH and gap k-CLIQUE is not completely known yet. If for a graph the number of edges induced by k vertices is only $\approx \varepsilon^2 \binom{k}{2}$, it cannot have a clique of size $> \varepsilon k$. Thus, PIH implies k-CLIQUE does not admit constant ratio FPT-approximation algorithms. However, the other direction is not necessarily true (forbidding small clique does not imply low edge density), and it remains an important open problem that whether PIH holds if we assume k-CLIQUE is hard to approximate within any constant factor in FPT time [12].

2.3 Low Degree Test

Let $\mathbb{F}$ be a field of prime cardinality. We say a function f is δ-close to a function class $\mathcal{F}$ if it is possible to modify at most δ fraction of values of f such that the modified function lies in $\mathcal{F}$.

The canonical low degree test proposed in [23] can query a function f at $d+2$ points, and

- accepts with probability 1 whenever f is a degree-d polynomial,
- rejects with probability at least $\varepsilon > 0$ if f is not δ-close to degree-d polynomials, where ε, δ are two constants.

Throughout our paper we will consider the function class $\mathcal{F}$ to be vector-valued degree-d polynomials, namely,

$$\mathcal{F} = \{(f_1, f_2, \ldots, f_\ell) : \mathbb{F}^m \to \mathbb{F}^\ell \mid \forall i \in [\ell], f_i \text{ is a degree-}d \text{ multivariate polynomial}\}.$$

By slightly modifying the proof in [23], the low degree test can be easily generalized to vector-valued version, as formally stated below:

▶ **Lemma 6.** *Let $d < |\mathbb{F}|/2$ and $m \in \mathbb{N}$. There is an algorithm which, by querying the function $f = (f_1, f_2, \ldots, f_\ell) : \mathbb{F}^m \to \mathbb{F}^\ell$ at $d+2$ points,*

- *accepts with probability 1 whenever f lies in $\mathcal{F}$,*
- *rejects with probability at least $\min(\delta/2, cd^{-2})$ if f is not δ-close to $\mathcal{F}$, where c, δ are two constants.*

Moreover, the queries are generated by selecting $\vec{x}, \vec{h} \in \mathbb{F}^m$ uniformly at random, and f is queried at $\{\vec{x} + i\vec{h} | 0 \le i < d+2\}$.

The proof is implicit in literature. We omit it here due to the page limitation. Readers can refer to our arxiv version [3] for a full proof.

2.4 Expander Graphs

Given a d-regular undirected graph G on n vertices, define its *normalized adjacency matrix* to be a matrix A where A_{ij} equals to the number of edges between (i, j) divided by d. Define

$$\lambda(G) = \max_{\|\vec{v}\|=1, \langle \vec{v}, \vec{1} \rangle = 0} \|A\vec{v}\|_2 .$$

G is an (n, d, λ)-expander if and only if $\lambda(G) \le \lambda$, and we have the following two Lemmas.

▶ **Lemma 7** ([2])**.** *Let G be an (n, d, λ)-expander, $\mathcal{B} \subseteq [n]$ be a set of size $\le \varepsilon n$ for some $0 < \varepsilon < 1$ and $(X_1, X_2, \ldots, X_t)$ be a sequence of random variables denoting a length-t random walk where the starting vertex is also picked uniformly at random. Then,*

$$\Pr[\forall 1 \le i \le t, X_i \in \mathcal{B}] \le ((1-\lambda)\sqrt{\varepsilon} + \lambda)^{t-1}.$$

▶ **Lemma 8** ([22])**.** *For some constants $d \in \mathbb{N}$, $\lambda < 1$ and for sufficiently large n, an (n, λ, d)-expander can be constructed in $n^{O(1)}$ time.*

2.5 Disperser

▶ **Definition 9** (Disperser [9, 26, 27])**.** *For positive integers $m, k, \ell, r \in \mathbb{N}$ and constant $\varepsilon \in (0, 1)$, an $(m, k, \ell, r, \varepsilon)$-disperser is a collection $\mathcal{I}$ of k subsets $I_1, \ldots, I_k \subseteq [m]$, each of size ℓ, such that the union of any r different subsets from the collection has size at least $(1-\varepsilon)m$.*

[3] https://arxiv.org/abs/2111.14033

Dispersers could be constructed efficiently by probabilistic methods, as in the following Lemma.

▶ **Lemma 10.** *For positive integers $m, \ell, r \in \mathbb{N}$ and constant $\varepsilon \in (0,1)$, let $\ell = \lceil \frac{3m}{\varepsilon r} \rceil$ and let $I_1, \ldots, I_k$ be random ℓ-subsets of $[m]$. If $\ln k \leq \frac{m}{r}$ then $\mathcal{I} = \{I_1, \ldots, I_k\}$ is an $(m, k, \ell, r, \varepsilon)$-disperser with probability at least $1 - e^{-m}$.*

Due to the page limitation, we also put the proof into the Appendix of our arxiv version.

3 An Improved Lower Bound for Constant Gap k-Clique under ETH

3.1 Reduction from 3SAT to k-VectorSum

To prove Theorem 1, we first need an $f(k) \cdot n^{\Omega(k)}$-time lower bound for k-VectorSum under ETH. Previously, it is known that k-Clique has no $f(k) \cdot n^{o(k)}$-time algorithms assuming ETH [8]. Combining this with the reduction from k-Clique to $\Theta(k^2)$-VectorSum [1], we only have an $f(k) \cdot n^{\Omega(\sqrt{k})}$-time lower bound for k-VectorSum under ETH. It is an interesting question whether there is an FPT reduction from k-Clique to k'-VectorSum with $k' = O(k)$. In this section, we give a reduction directly from 3SAT to k-VectorSum, which suits our purpose. Recall that in the ETH statement we can assume without loss of generality that each variable appears in at most 3 clauses, which is a key ingredient in our proof.

▶ **Theorem 11.** *There is a reduction which, for every integer $k \in \mathbb{N}$, and every 3SAT formula φ with m clauses and n variables such that each variable appears in at most 3 clauses, outputs a k-VectorSum instance $\Gamma = (\mathbb{F}, d, V_1, \ldots, V_k)$ with the following properties in $2^{O(n/k)}$ time.*

- $\mathbb{F} = \mathbb{F}_5$.
- $d = O(n)$.
- *For any $i \in [k]$, distinct $\vec{u}, \vec{v} \in V_i$ and any $a \in \mathbb{F}_5 \setminus \{0\}$, $\vec{u} \neq a \cdot \vec{v}$.*
- *For any $i \in [k]$, distinct $\vec{u}, \vec{v}, \vec{w} \in V_i$ and any $a \in \mathbb{F}_5 \setminus \{0\}, \vec{u} - \vec{w} \neq a \cdot (\vec{w} - \vec{v})$.*
- *(Completeness.) If φ is satisfiable, then there exists $\vec{v}_1 \in V_1, \ldots, \vec{v}_k \in V_k$ such that $\sum_{i=1}^{k} \vec{v}_i = \vec{0}$.*
- *(Soundness.) If φ is not satisfiable, then for any $\vec{v}_1 \in V_1, \ldots, \vec{v}_k \in V_k$, $\sum_{i=1}^{k} \vec{v}_i \neq \vec{0}$.*

▶ Remark 12. Note if the size of the produced k-VectorSum instance N appears to be only $2^{o(n/k)}$, we can use brute force to solve it in $N^k = 2^{o(n)}$ time, thus solve 3SAT in $2^{o(n)}$ time. Therefore, we only need to consider the case $N = 2^{\Theta(n/k)}$ without loss of generality, and in this case $d = O(n) = O(k \log N)$.

Proof of Theorem 11. Let $C = \mathcal{C}_1 \dot{\cup} \ldots \dot{\cup} \mathcal{C}_k$ be a partition of the clauses into k approximately equal-sized parts. We will let vectors in V_i represent partial satisfying assignments for $\mathcal{C}_i$, and use entries of vectors to check consistency of those partial assignments.

Define X to be the set of variables appearing in exactly two different parts and define Y to be the set of variables appearing in three different parts. Let $d = |X| + 2|Y|$, we associate one entry of vector to each variable $x \in X$ and two entries to each variable $y \in Y$. In the following, we abuse notation a bit and use $\vec{v}[x]$ to denote the entry in a vector $\vec{v} \in \mathbb{F}^d$ associated to a variable $x \in X$, and use $\vec{v}[y, 1], \vec{v}[y, 2]$ to denote the two entries associated to a variable $y \in Y$.

The construction of vector set V_i proceeds as follows. Let Z_i be the set of variables appearing in $\mathcal{C}_i$. For an assignment $\tau : Z_i \to \{0, 1\}$ which satisfies all clauses in $\mathcal{C}_i$, we map it to a vector $\vec{v} \in \mathbb{F}^d$ in the following way.

Let $x \in Z_i \cap X$ be a variable appearing in $\mathcal{C}_{j_1}$ and $\mathcal{C}_{j_2}$ $(j_1 < j_2)$,

- in case that $\tau(x) = 0$, set $\vec{v}[x] = 0$.
- in case that $\tau(x) = 1$, set $\vec{v}[x] = 1$ if $i = j_1$, and set $\vec{v}[x] = -1$ if $i = j_2$.

Let $y \in Z_i \cap Y$ be a variable appearing in $\mathcal{C}_{j_1}, \mathcal{C}_{j_2}$ and $\mathcal{C}_{j_3}$ $(j_1 < j_2 < j_3)$,

- in case that $\tau(y) = 0$, set $\vec{v}[y, 1] = 0$ and $\vec{v}[y, 2] = 0$.
- in case that $\tau(y) = 1$, set $\vec{v}[y, 1] = 1$ and $\vec{v}[y, 2] = 1$ if $i = j_1$; set $\vec{v}[y, 1] = -1$ and $\vec{v}[y, 2] = 0$ if $i = j_2$; and set $\vec{v}[y, 1] = 0$ and $\vec{v}[y, 2] = -1$ if $i = j_3$.

For the remaining entries of $\vec{v}$ (which are associated to variables in $(X \cup Y) \setminus Z_i$), set them to be 0.

It's easy to see the whole reduction runs in $2^{O(n/k)}$ time, and the dimension $d = O(n)$.

Now we prove the third and the fourth properties.

For two distinct vectors $\vec{u}, \vec{v} \in V_i$, suppose $\vec{u}[j] \neq \vec{v}[j]$. It must be the case that one of them is 0 and the other is ± 1. Thus they still differ after being multiplied by any $a \in \mathbb{F}_5 \setminus \{0\}$.

For three distinct vectors $\vec{u}, \vec{v}, \vec{w} \in V_i$, suppose $\vec{u}[j] \neq \vec{w}[j]$, then either $\vec{v}[j] = \vec{w}[j]$ or $\vec{v}[j] = \vec{u}[j]$. In the former case, $\vec{u}[j] - \vec{w}[j] \neq 0 = \vec{w}[j] - \vec{v}[j]$, so they still differ after being multiplied by any $a \in \mathbb{F} \setminus \{0\}$. In the latter case, suppose $\vec{u} - \vec{w} = a \cdot (\vec{w} - \vec{v})$, then $\vec{u}[j] - \vec{w}[j] = a \cdot (\vec{w}[j] - \vec{v}[j])$ will lead to $a = -1$ and thus $\vec{u} = \vec{v}$, a contradiction. Therefore, $\vec{u} - \vec{w} \neq a \cdot (\vec{w} - \vec{v})$ for any $a \in \mathbb{F}_5 \setminus \{0\}$.

Next follows the proof of completeness and soundness.

Completeness. If the 3SAT formula φ has a satisfying assignment τ, we can pick one vector $\vec{v}_i$ from each V_i according to the restriction of τ on $Z_i \cap (X \cup Y)$. Let $\vec{v} = \sum_{i=1}^{k} \vec{v}_i$ be the sum of picked vectors.

For a variable $x \in X$, let $\mathcal{C}_{j_1}, \mathcal{C}_{j_2} (j_1 < j_2)$ be the two clause parts in which x appears,

- in case that $\tau(x) = 0$, $\vec{v}[x] = 0$ since this entry equals to 0 in all vectors.
- in case that $\tau(x) = 1$, $\vec{v}[x] = 1 + (-1) = 0$ where 1 comes from $\vec{v}_{j_1}[x]$ and -1 comes from $\vec{v}_{j_2}[x]$.

For a variable $x \in Y$, let $\mathcal{C}_{j_1}, \mathcal{C}_{j_2}, \mathcal{C}_{j_3} (j_1 < j_2 < j_3)$ be the three clause parts in which x appears.

- in case that $\tau(x) = 0$, $\vec{v}[x, 1] = \vec{v}[x, 2] = 0$ since these entries equal to 0 in all vectors.
- in case that $\tau(x) = 1$, $\vec{v}[x, 1] = 1 + (-1) = 0$ where 1 comes from $\vec{v}_{j_1}[x, 1]$ and -1 comes from $\vec{v}_{j_2}[x, 1]$, and $\vec{v}[x, 2] = 1 + (-1) = 0$ where 1 comes from $\vec{v}_{j_1}[x, 1]$ and -1 comes from $\vec{v}_{j_3}[x, 1]$.

Soundness. If the 3SAT formula φ has no satisfying assignments, any collection of partial assignments satisfying individual clause parts must be inconsistent on some variable in $X \cup Y$. For any $\vec{v}_1 \in V_1, \ldots, \vec{v}_k \in V_k$, let $\vec{v} = \sum_{i=1}^{k} \vec{v}_i$.

Suppose assignments for a variable $x \in X$ which appears in $\mathcal{C}_{j_1}$ and $\mathcal{C}_{j_2}$ are inconsistent, there must be one 0 and one ± 1 in $\vec{v}_{j_1}[x]$ and $\vec{v}_{j_2}[x]$. Since this entry equals to 0 in all other vectors, it results that $\vec{v}[x] \neq 0$.

Suppose assignments for a variable $x \in Y$ which appears in $\mathcal{C}_{j_1}, \mathcal{C}_{j_2}$ and $\mathcal{C}_{j_3}$ $(j_1 < j_2 < j_3)$ are inconsistent. If the values for x specified by $\vec{v}_{j_1}$ and $\vec{v}_{j_2}$ are inconsistent, there must be one 0 and one ± 1 in $\vec{v}_{j_1}[x, 1]$ and $\vec{v}_{j_2}[x, 1]$, while in all other vectors this entry equals to 0, thus $\vec{v}[x, 1] \neq 0$. Otherwise the value for x specified by $\vec{v}_{j_1}$ and $\vec{v}_{j_3}$ must be inconsistent, there must be one 0 and one ± 1 in $\vec{v}_{j_1}[x, 2]$ and $\vec{v}_{j_3}[x, 2]$, while in all other vectors this entry equals to 0, thus $\vec{v}[x, 2] \neq 0$.

Therefore, $\sum_{i=1}^{k} \vec{v}_i \neq \vec{0}$ as desired. ◀

3.2 Reduction from k-VectorSum to Constant Gap k-Clique

▶ **Theorem 13.** *There is an FPT reduction which, given as input a* k-VectorSum *instance* $\Gamma_0 = (\mathbb{F}, d, V_1, \ldots, V_k)$ *with the following properties:*

- $\mathbb{F} = \mathbb{F}_5$,
- $d = O(k \log n)$ *where* $n = \sum_{i=1}^{k} |V_i|$ *denotes instance size,*
- *for any* $i \in [k]$, *distinct* $\vec{u}, \vec{v} \in V_i$ *and any* $a \in \mathbb{F}_5 \setminus \{0\}$, $\vec{u} \neq a \cdot \vec{v}$,
- *for any* $i \in [k]$, *distinct* $\vec{u}, \vec{v}, \vec{w} \in V_i$ *and any* $a \in \mathbb{F}_5 \setminus \{0\}, \vec{u} - \vec{w} \neq a \cdot (\vec{w} - \vec{v})$.

outputs a k'-Clique *instance* $G = (V, E)$ *such that*

- $k' \leq c^k$ *for some constant* c,
- *(Completeness.) if* Γ_0 *is a yes-instance of* k-VectorSum, *then* G *contains a clique of size* k',
- *(Soundness.) if* Γ_0 *is a no-instance of* k-VectorSum, *then* G *doesn't contain a clique of size* $\varepsilon k'$ *for some constant* $\varepsilon < 1$.

The first step of the reduction involves $\ell = 2k + 4 \log n$ matrices $A_1, \ldots, A_\ell \in \mathbb{F}^{k \times d}$. For $\alpha \in \mathbb{F}^k, v \in \mathbb{F}^d$, define a bilinear function $f(\alpha, v) = (\langle \alpha, A_1 v \rangle, \ldots, \langle \alpha, A_\ell v \rangle) \in \mathbb{F}^\ell$, where $\langle \cdot, \cdot \rangle$ denotes inner product.

▶ **Lemma 14** ([20]). *We can find* $\ell = 2k + 4 \log n$ *matrices* $A_1, A_2, \cdots, A_\ell$ *in time polynomial in* n, k, *which satisfy the following properties:*

1. *for any nonzero vector* $\vec{v} \in \mathbb{F}^d$, *there exists* $i \in [\ell]$ *such that* $A_i \vec{v} \neq \vec{0}$,
2. *for any* $i \in [k]$, *distinct* $\vec{u}, \vec{v} \in V_i$ *and nonzero* $\alpha \in \mathbb{F}^k$, $f(\alpha, \vec{u}) \neq f(\alpha, \vec{v})$,
3. *for any* $i \in [k]$, *distinct* $\vec{u}, \vec{v}, \vec{w} \in V_i$ *and* $\alpha, \alpha' \in \mathbb{F}^k, f(\alpha, \vec{u}) + f(\alpha', \vec{v}) \neq f(\alpha + \alpha', \vec{w})$.
