Contents

49th International Colloquium on Automata, Languages, and Programming (ICALP 2022).
Editors: Mikołaj Bojańczyk, Emanuela Merelli, and David P. Woodruff
Leibniz International Proceedings in Informatics
LIPICS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

Track B: Automata, Logic, Semantics, and Theory of Programming

Preface

This volume contains the papers presented at the *49th EATCS International Conference on Automata, Languages and Programming (**ICALP 2022**)*, held *hybrid* in Paris France, during July 4–8, 2022. ICALP is a series of annual conferences of the *European Association for Theoretical Computer Science (EATCS)*, which first took place in 1972.

This year, the ICALP program consisted of two tracks:

- Track A: Algorithms, Complexity, and Games
- Track B: Automata, Logic, Semantics, and Theory of Programming

In response to the call for papers, a total of 433 submissions were received: 350 for Track A and 83 for Track B. Each submission was assigned to at least three program committee members, aided by 641 external subreviewers or experts providing a quick opinion. The committees decided to accept 127 papers for inclusion in the scientific program: 103 papers for Track A and 24 for Track B. The selection was made by the program committees based on originality, quality, and relevance to theoretical computer science. The quality of the manuscripts was very high indeed, and many deserving papers could not be selected.

The EATCS sponsored awards for both a best paper and a best student paper in each of the two tracks, selected by the program committees.

The **best paper awards** were given to the following papers:

Track A: Ian Newman and Nithin Varma. *Strongly Sublinear Algorithms for Testing Pattern Freeness.*

Track B: Jakub Gajarský, Michał Pilipczuk, Wojciech Przybyszewski and Szymon Toruńczyk. *Twin-width and types.*

The **best student paper awards**, for papers that are solely authored by students, were given to the following papers:

Track A: Joakim Blikstad. *Sublinear-round Parallel Matroid Intersection*, and Jakub Tětek. *Approximate Triangle Counting via Sampling and Fast Matrix Multiplication.*

Track B: Gaëtan Douéneau-Tabot. *Hiding pebbles when the output alphabet is unary.*

Apart from the contributed talks, ICALP 2022 included invited presentations by Leslie Ann Goldberg (Professor of Computer Science at the University of Oxford), Madhu Sudan (Gordon MacKay Professor of Computer Science at Harvard University), Albert Atserias (Professor at the Universitat Politècnica de Catalunya), Constantinos Daskalakis (Professor in MIT's Electrical Engineering and Computer Science Department), Stéphan Thomassé (Professor at the Computer Science Department at Ecole Normale Supérieure de Lyon), Santosh Vempala (Frederick Storey Chair in Computing and Professor at Georgia Tech).

This volume contains all the contributed papers presented at the conference, and an abstract or paper accompanying each of the invited talks by Albert Atserias, Constantinos Daskalakis, Leslie Ann Goldberg, Madhu Sudan, Stéphan Thomassé, and Santosh Vempala.

The program of ICALP 2022 also included presentations of the EATCS Award 2022 to Patrick Cousot, the Alonzo Church Award 2022 to Dexter Kozen, the Presburger Award 2022 to Dor Minzer, the EATCS Distinguished Dissertation Awards 2022 to Alexandros Hollender, Jason Li and Jan van den Brand, as well as the announcement of new EATCS Fellows Samson Abramsky and Orna Kupferman.

49th International Colloquium on Automata, Languages, and Programming (ICALP 2022).
Editors: Mikołaj Bojańczyk, Emanuela Merelli, and David P. Woodruff
Leibniz International Proceedings in Informatics
LIPICS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

The following workshops were held as satellite events of ICALP 2022 on July 4, 2022:

- Parameterized Approximation Algorithms (PAAW)
- Combinatorial Reconfiguration
- Recent Advances on Total Search Problems
- LearnAut: 4th edition of the Learning and Automata
- Algorithmic Aspects of Temporal Graphs V
- Trends in Arithmetic Theories
- Structure Meets Power 2022
- Straight-Line Programs, Word Equations and their Interplay
- Graph Width Parameters: from Structure to Algorithms (GWP 2022)

We wish to thank all authors who submitted extended abstracts for consideration, the program committees for their scholarly effort, and all the referees who assisted the program committees in the evaluation process.

We are also grateful to the Conference General Chair, Thomas Colcombet, and his colleagues from the Research Institute on the Foundations of Computer Science, Université Paris Cité, and Fondation Sciences Mathématiques de Paris, for organizing ICALP 2022, and to CNRS, Inria, and Nomadic Lab. for sponsorships.

We would like to thank Anca Muscholl, the Chair of the ICALP Steering Committee, for her continuous support and Artur Czumaj, the president of EATCS, for his generous advice on the organization of the conference.

Organization

Program Committees

Track A

David Woodruff	CMU, (chair)
Petra Berenbrink	University of Hamburg
Sergio Cabello	University of Ljubljana
Yixin Cao	Hong Kong Polytechnic University
Sitan Chen	University of California Berkeley
Xi Chen	Columbia University
Ilias Diakonikolas	University of Wisconsin-Madison
David Doty	University of California Davis
Yuval Filmus	Technion
Cyril Gavoille	Université de Bordeaux
Sevag Gharibian	Paderborn University
Seth Gilbert	National University of Singapore
Nick Gravin	Shanghai University of Finance and Economics
Kasper Green Larsen	Aarhus University
Abhradeep Guha Thakurta	Google Research
Hamed Hatami	McGill University
Sandy Irani	University of California Irvine
Yuval Ishai	Technion
Aayush Jain	NTT Research/CMU
Ken-ichi Kawarabayashi	National Institute of Informatics
Yuqing Kong	Peking University
Michal Koucký	Charles University
Stefano Leonardi	Sapienza Universita di Roma
Nutan Limaye	IT University of Copenhagen
Frederic Magniez	CNRS
Audra Mcmillan	Apple
Slobodan Mitrovic	MIT / University of California Davis
Wolfgang Mulzer	Freie Universitat Berlin
Cameron Musco	University of Massachusetts Amherst
Anand Natarajan	MIT
Jelani Nelson	University of California Berkeley
Debmalya Panigrahi	Duke University
Richard Peng	Georgia Tech
Vijaya Ramachandran	University of Texas at Austin
Saket Saurabh	Institute of Mathematical Sciences, Chennai
Christian Sohler	University of Cologne
Thomas Steinke	Google Research
Vasilis Syrgkanis	Microsoft Research
Emanuele Viola	Northeastern University
Adrian Vladu	CNRS
Jan Vondrak	Stanford
Hoeteck Wee	NTT Research / ENS
Christian Wulf-Nilsen	University of Copenhagen

Track B

Mikołaj Bojańczyk	University of Warsaw,(chair)
Luca Aceto	Reykjavik University
Isolde Adler	University of Leeds
Antoine Amarilli	Télécom Paris
Pablo Barcelo	Catholic University of Chile
Libor Barto	Charles University
Laura Ciobanu	Heriot-Watt University
Erich Grädel	RWTH Aachen University
Christoph Haase	University of Oxford
Marcin Jurdziński	University of Warwick
Benjamin Kaminski	Saarland University
Joost-Pieter Katoen	RWTH Aachen University
Bartek Klin	University of Oxford
Naoki Kobayashi	University of Tokyo
Dexter Kozen	Cornell University
Orna Kupferman	Hebrew University
Jérôme Leroux	CNRS / University of Bordeaux
Nathan Lhote	Aix-Marseille University
Markus Lohrey	University of Siegen
Joël Ouaknine	Max Planck Institute
Prakash Panangaden	McGill University
Michael Pinsker	Vienna University of Technology
Sven Schewe	University of Liverpool
Jeffrey Shallit	University of Waterloo
Mahsa Shirmohammadi	CNRS / University of Paris
Sebastian Siebertz	University of Bremen
Alex Simpson	University of Ljubljana
Lidia Tendera	University of Opole

Organizing Committee

Thomas Colcombet, IRIF, Chair

Sandrine Cadet	Olivier Carton	Geoffroy Couteau
Hugo Férée	Irène Guessarian	Natalia Hacquart
Florian Horn	Maximilien Lesellier	Simon Mauras
Valia Mitsou	Sylvain Perifel	Amaury Pouly
Arnaud Sangnier	Sylvain Schmitz	Mahsa Shirmohammadi
Laurent Viennot		

Steering Committee

Nikhil Bansal	University of Michigan, US
Artur Czumaj	Warwick University, UK
Javier Esparza	TUM Munich, Germany
Simon Gay	University of Glasgow, UK
Leslie Ann Goldberg	Oxford University, UK
Thore Husfeldt	Lund University, Sweden & IT University of Copenhagen, Denmark
Giuseppe Italiano	Luiss University, Italy
Emanuela Merelli	University of Camerino, Italy
Anca Muscholl	Bordeaux University, France, Steering Committee Chair
Yuval Rabani	Hebrew University, Israel
Paul Spirakis	University of Liverpool, UK and University of Patras, Greece
James Worrell	University of Oxford, UK

Financial Sponsors

IRIF, CNRS, Université Paris Cité

Towards a Theory of Algorithmic Proof Complexity

Albert Atserias
Universitat Politècnica de Catalunya, Centre de Recerca Matemàtica, Barcelona, Spain

Abstract

A possibly unexpected by-product of the mathematical study of the lengths of proofs, as is done in the field of propositional proof complexity, is, I claim, that it may lead to new polynomial-time algorithms. To explain this, I will first recall the origins of proof complexity as a field, and then explain why some of the recent progress in it could lead to some new algorithms.

2012 ACM Subject Classification Theory of computation → Proof complexity

Keywords and phrases proof complexity, logic, computational complexity

Digital Object Identifier 10.4230/LIPIcs.ICALP.2022.1

Category Invited Talk

As is well known, the formulation of the P vs. NP problem has its origins in mathematical logic. Cook's original interest on the satisfiability problem for logic formulas came from its applications to automated theorem proving; this is clearly reflected in the title of his 1971 paper "On the Complexity of Theorem Proving Procedures" [4]. By viewing the satisfiability of a formula and the tautologyhood of its negation as dual concepts, it can be argued that Cook established the grounds of a general theory of duality for any problem in NP. In this general framework, satisfying assignments and formal proofs would play the roles of dual certificates, with the obvious caveat that proofs typically appear to be exponentially longer than their duals. The question whether this empirical observation about the lengths of proofs is a true fact called for a theory of proof complexity on which to build what later came to be known as Cook's Program [5, 6].

The development of Cook's Program since its formulation in the early 1970's led to many insights on the combinatorial intricacies of formal proofs. The strongest results in the area typically take the form of exponential lower bounds on the length of proofs for proof systems of practical use, including Resolution [9], Cutting Planes [13], and a few others [1, 12, 11]. To achieve this, a deep theory that explains what causes a propositional tautology to not have short proofs was developped. As part of this theory we find certain tight semantic characterizations of resource-bounded proofs [14, 2, 10] much in the same way that the completeness theorem of mathematical logic equalizes truth with proof.

In this talk I want to argue that the semantic study of proof complexity for these proof systems could also lead to new insights of algorithmic nature. Perhaps paradoxically, the starting point for this is the recent discovery that the problem of automating their proof-search is NP-hard [3, 8, 7]. In a nutshell, what these NP-hardness reductions show is that every instance of any problem in NP can be efficiently encoded into a propositional formula that is either a tautology that has a short proof, or is indistinguishable in a formal sense from a falsifiable formula. The existence of a short proof clearly comes with a short certificate. The main point is, however, that the indistinguishability from a falsifiable formula can often,

but not always, be also certified efficiently, no less than through the tools of the theory that studies which formulas fail to have short proofs.

As applications, I will discuss how this phenomenon could be used, potentially, to develop new polynomial-time algorithms for a couple of well-known combinatorial problems not obviously related to propositional logic.

Equilibrium Computation, Deep Learning, and Multi-Agent Reinforcement Learning

Constantinos Daskalakis
EECS and CSAIL, MIT, Cambridge, MA, USA

Abstract

Machine Learning has recently made significant advances in challenges such as speech and image recognition, automatic translation, and text generation, much of that progress being fueled by the success of gradient descent-based optimization methods in computing local optima of non-convex objectives. From robustifying machine learning models against adversarial attacks to causal inference, training generative models, multi-robot interactions, and learning in strategic environments, many outstanding challenges in Machine Learning lie at its interface with Game Theory. On this front, however, gradient-descent based optimization methods have been less successful. Here, the role of single-objective optimization is played by equilibrium computation, but gradient-descent based methods commonly fail to find equilibria, and even computing local approximate equilibria has remained daunting. We shed light on these challenges through a combination of learning-theoretic, complexity-theoretic, game-theoretic and topological techniques, presenting obstacles and opportunities for Machine Learning and Game Theory going forward. I will assume no Deep Learning background for this talk and present results from joint works with S. Skoulakis and M. Zampetakis [2] as well as with N. Golowich and K. Zhang [1].

1 Extended Abstract

A *multiple access channel* is a shared channel which is used by processors to access a network, a cloud server, or another shared resource. The processors do not communicate except by listening to the channel. The mechanism of the channel is straightforward: If two or more processors send messages to the channel at the same time, then these messages collide, and are not delivered successfully. However, if during some time step exactly one processor sends a message, then this message is successfully delivered and the processor receives an acknowledgement of successful delivery. A *contention-resolution protocol* is a randomised algorithm that each processor uses to decide when to send its message to the channel (and when to wait because the channel is too busy).

We consider discrete-time contention resolution protocols in which processors communicate by sending discrete messages (packets) to a multiple access channel. During each step, new messages destined for the channel arrive at processors according to a probability distribution with an overall arrival rate λ. The whole process (consisting of the arrivals, the waiting messages, and the sends) can be viewed as a Markov chain. A contention-resolution protocol is *stable* [7] if this Markov chain is positive recurrent, which means that the process has a stationary distribution (so the expected build-up of waiting messages over time is bounded).

Two models of multiple access channels are the *queueing model* and the *queue-free model*. In the queueing model, there are N fixed processors. Each processor maintains a queue of messages which it is waiting to send – messages arrive at the tail of the queue and are sent from the head. The queues assist with stability, and are appropriate for applications with fixed networks. Dynamic networks (such as multiple access channels supporting cloud computing) are better captured by the queue-free model. In the queue-free model, we assume that processors join the network according to a probability distribution and that each processor has a single message to send. Thus, we identify the processor with its message – messages arrive at each step according to a Poisson distribution with rate λ and they stay in the system until they are successfully sent.

Two kinds of contention-resolution protocol are *full-sensing protocols* [12] which constantly listen the channel, obtaining partial information (such as which steps have no sends, which steps have exactly one send, which steps have a collision, or some combination of these) and *acknowledgement-based protocols*, which are appropriate for settings where this listening is not feasible. In acknowledgement-based protocols, the only information that a processor gets is whether its own sends are successful. A popular kind of acknowledgement-based protocol is

a *backoff protocol*. A backoff protocol is associated with a send sequence $\mathbf{p} = p_0, p_1, \ldots$ where each p_i is interpreted as a probability in $(0, 1]$. During a given time step, a processor that is trying to send a message that has already had i collisions flips a coin – with probability p_i, it sends. With probability $1 - p_i$, it instead waits for a later time step. One of the best-known backoff protocol is *binary exponential backoff*, which has $p_i = 2^{-i}$ and is the basis for Ethernet [11].

The talk will mention some important recent results [13, 14, 3, 4] about full-sensing protocols, however the main focus will be on acknowledgement-based protocols and specifically on backoff protocols. In the queueing model, binary exponential backoff is known to be stable for sufficiently small arrival rate λ [7, 1]. Unfortunately, this value of λ depends on N and binary exponential backoff is unstable if λ is sufficiently large [8]. In a breakthrough result, Håstad, Leighton and Rogoff [8] showed that there is a stable backoff protocol for every $\lambda \in (0, 1)$ – in particular *polynomial backoff*, with $p_i = i^{-\alpha}$ for some $\alpha > 1$, is stable.

In the queue-free model, it is conjectured [2] that no backoff protocol is stable for any positive arrival rate λ. This question was raised by MacPhee [10] and the same is conjectured for all acknowledgement-based protocols. The conjecture for backoff protocols is known to be true when $\lambda \geq 0.42$ and the conjecture for acknowledgement-based protocols is known to be true when $\lambda \geq 0.531$ [5].

The evidence for the full conjecture concerning backoff protocols is that a backoff protocol is known to be unstable for all positive arrival rates if its send sequence $\mathbf{p} = p_0, p_1, \ldots$ decays smoothly. In particular, for the case where $1/p_j = o(c^j)$ for all $c > 1$, instability follows from work of Kelly and MacPhee [9] (which shows that in this case, with probability 1, only finitely many messages are sucessfully sent). In the case where $1/p_j = \Theta(c^j)$ for some $c > 1$ instability can be proved by generalising the proof of Aldous's seminal instability result for binary exponential backoff [2]. In the case where the send sequences has an infinite subsequence $p_{j_1}, p_{j_2}, \ldots$ satisfying $1/p_{j_k} = \omega(c^{j_k})$ for all $c > 1$ is also easily dealt with. This appears as a lemma in [6] but the method was also known to the authors of [5].

The main issue which makes it difficult to prove the full conjecture is proving instability for backoff protocols that have a send sequence that decays at an inconsistent rate or doesn't decay at all, with p_js that jump back and forth between large and small values as j increase. The main part of this talk describes new work [6] with John Lapinskas that solves this problem except in a special case. This special case has the property that the send sequences alternates between p_j's that are at least $\Omega(1)$ and p_j's that are exponentially small (but no smaller). Moreover, the large p_j's have density $1 - o(1)$ in $\{p_1, \ldots, p_n\}$ as $n \to \infty$. We therefore refer to them as "LCED" send sequences (for "largely constant with exponential decay"). These sequences are defined as follows.

▶ **Definition 1.** *A send sequence* $\mathbf{p}$ *is* LCED *("largely constant with exponential delay") if it satisfies the following properties:*

- **(i) "Largely constant":** *For all* $\eta > 0$*, there exists* $c > 0$ *such that for infinitely many* n*,* $|\{j \leq n : p_j > c\}| \geq (1 - \eta)n$.
- **(ii) "with exponential decay":** $\mathbf{p}$ *has an infinite subsequence* $(p_{\ell_1}, p_{\ell_2}, \ldots)$ *which satisfies* $\log(1/p_{\ell_x}) = \Theta(\ell_x)$ *as* $x \to \infty$.
- **(iii) "(but without super-exponential decay)":** $\log(1/p_j) = O(j)$ *as* $j \to \infty$.

The main Theorem of [6] is as follows.

▶ **Theorem 2** ([6])**.** *Let* $\mathbf{p}$ *be a send sequence which is not LCED. Then for every* $\lambda \in (0, 1)$ *the backoff protocol with arrival rate* λ *and send sequence* $\mathbf{p}$ *is unstable.*

The theorem has the following consequences.

▶ **Corollary 3** ([6]). *For every $\lambda \in (0,1)$ and every monotonically non-increasing send sequence $\mathbf{p} = p_0, p_1, \ldots$, the backoff protocol with arrival rate λ and send sequence $\mathbf{p}$ is unstable.*

▶ **Corollary 4** ([6]). *Let $\mathbf{p}$ be a send sequence. Let $m_{\mathbf{p}}(n)$ be the median of $p_0, \ldots, p_n$. Suppose that $m_{\mathbf{p}}(n) = o(1)$. Then for every $\lambda \in (0,1)$ the backoff protocol with arrival rate λ and send sequence $\mathbf{p}$ is unstable.*

The talk will conclude with a discussion of the prospects for proving the full conjecture.

1 Introduction

Sampling high-dimensional distributions is a fundamental problem of growing importance in machine learning and related fields [7, 17, 2]. Progress on efficient algorithms for sampling has led to new mathematical connections and insights into a number of areas such as probability, convex geometry and analysis. The focus of this tutorial is to survey the state-of-the-art for the most general results along with open problems. There are many interesting results for special cases that are beyond the scope of this survey.

We begin by stating the most general version of the problem in Euclidean space.

▶ **Definition 1** (Sampling Problem)**.** Given oracle access to an integrable, real-valued function $f : \mathbb{R}^n \to \mathbb{R}_+$, an initial point $x_0 \in \mathbb{R}^n$ with $f(x_0) > \beta \int f(y)dy$ and an error parameter $\varepsilon > 0$, output a point x from a distribution that is within total variation distance ε from the distribution with density proportional to $f(x)$.

A major discovery in the theory of algorithms is that the above problem can be solved in randomized polynomial time for any *logconcave* function f. Recall that a function $f : \mathbb{R}^n \to \mathbb{R}_+$ is logconcave if its logarithm is concave, i.e., for any $\lambda \in [0, 1]$ and any $x, y \in \mathbb{R}^n$,we have $f(\lambda x + (1-\lambda)y) \geq f(x)^\lambda f(y)^{1-\lambda}$. This class includes the important special cases of the uniform density over a convex body and a Gaussian restricted to a convex set. Note that we can alternatively think of a logconcave function as $e^{-f(x)}$ where now f is a convex function. As in optimization, the traditional frontier of polynomial-time algorithms for sampling has to do with convexity. In the past decade there has been progress on going beyond convexity, with appropriate weaker assumptions. Two approaches are (a) to show that isoperimetry of the target distribution suffices and (b) to use the convergence of the continuous time diffusion as a basis for proving the convergence of the discrete-time algorithm. We will illustrate these approaches later in this survey. Let us first introduce the main algorithms for the most general oracle setting.

Ball Walk

The ball walk with step-size parameter $\delta > 0$ is the following Markov Chain: at the current point x, pick a uniform random point y from the ball of radius δ centered at x; go to y with probability $\min\{1, f(y)/f(x)\}$. The starting point is chosen so that it satisfies $f(x_0) > 0$. When f is the indicator of a convex body K, this simply means that we start in K and at each step go to the proposed y only if y is also in K.

Hit-and-Run

The Hit-and-Run Markov chain is the following: at the current point x, pick a uniform random line ℓ through x, and go to a point y on the line with probability proportional to f restricted to ℓ. For a convex body, this means that we pick the next point uniformly from the chord in a random direction through the current point.

2 Mixing rates in the general oracle model

For a more detailed introduction to Markov chains in continuous state spaces, and these walks in particular, the reader is referred to [42, 36]. In this section by mixing rate we mean the rate to halve the χ^2-divergence between the current distribution and the target stationary distribution. We say that a distribution Q_0 is an M-warm start for a distribution Q if $\sup \frac{dQ_0(x)}{dQ(x)} \leq M$. A weak M-warm start is when $\chi^2(Q_0, Q) \leq M$. Recall that

$$\chi^2(P, Q) = \mathbb{E}_Q\left(\left(\frac{dP(x)}{dQ(x)} - 1\right)^2\right).$$

A key parameter in the analysis of a Markov chain is its conductance. For a Markov chain with state space K, transition kernel P and stationary distribution Q, the conductance of any measurable subset A of the state space is defined as

$$\phi(A) = \frac{\int_A P_x(K \setminus A) dQ(x)}{\min\{Q(A), Q(K \setminus A)\}}$$

and the conductance of the Markov chain itself is $\phi = \inf_A \phi(A)$. The conductance directly bounds the mixing rate.

▶ **Theorem 2** ([36]). *For a time-reversible Markov chain with conductance ϕ, the distribution after t steps satisfies*

$$\chi^2(Q_t, Q) \leq \left(1 - \frac{\phi^2}{2}\right)^t \chi^2(Q_0, Q).$$

The paper [36] developed conductance-based analysis of the convergence of Markov chains in the setting of continuous state spaces, including an important extension to the setting when the conductance $\phi(A)$ can only be bounded from below for sets A of measure larger than some threshold.

2.1 Ball walk

The ball walk has the following convergence guarantee for a convex body. We use $\widetilde{O}(\cdot)$ to suppress logarithmic terms.

▶ **Theorem 3** (Ball Walk from Warm Start in Convex Body [22]). *Let $K \subseteq \mathbb{R}^n$ be a convex body containing the unit Euclidean ball with $R^2 = \mathbb{E}_K\left(\|x - \overline{x}\|^2\right)$ for $\overline{x} = \mathbb{E}_K x$. Then the mixing time of the ball walk in K with step size $\delta = 1/\sqrt{n}$ from an $O(1)$-warm start is bounded by $\widetilde{O}(n^2R^2)$.*

This guarantee generalizes cleanly to any logconcave density.

▶ **Theorem 4** (Ball Walk from Warm Start for Logconcave Density [38]). *The mixing time of the ball walk for a target logconcave density ν such that the level set of measure $1/8$ contains a unit ball and $R^2 = \mathbb{E}_\nu\left(\|x - \overline{x}\|^2\right)$, with step size $\delta = 1/\sqrt{n}$ from an $O(1)$-warm start is bounded by $\widetilde{O}(n^2R^2)$.*

The bound above is tight up to polylogarithmic factors; a cylinder with a unit ball cross section and height R shows a lower bound of $\Omega(n^2R^2)$. Can we reduce or eliminate the dependence on R? Classical results tell us that for any convex body there is an affine transformation (the John position) that ensures that the body is sandwiched between balls of radii 1 and at most n. Since all we need to bound is the average squared distance, there is a natural transformation of space that gives a bound of $R = \sqrt{n}$.

▶ **Definition 5.** A distribution with density ν in $\mathbb{R}^n$ is said to be in *isotropic position* if a random point X drawn from ν satisfies $\mathbb{E}_\nu(x) = 0$ and $\mathbb{E}_\nu(xx^\top) = I$.

Note that in isotropic position, $R^2 = \mathbb{E}(\|x\|^2) = n$ and this implies a bound of n^3 on the mixing rate for a logconcave distribution in isotropic position. As it turns out, it is possible to show a better convergence rate, where the dependence on diameter is essentially eliminated. The theorems below work also for *near*-isotropic position, by which we mean that the eigenvalues of the covariance matrix are bounded below and above by constants (rather than all being equal to 1).

▶ **Theorem 6** (Ball Walk from Warm Start with Isotropic Target). *The mixing time of the ball walk applied to a logconcave density in isotropic position with step size $\delta = 1/\sqrt{n}$ from an $O(1)$-warm start is bounded by $\widetilde{O}(n^2)$.*

The above theorem deserves some explanation and is the culmination of a quarter century of progress on geometric isoperimetric inequalities. First, we state the corresponding theorem which establishes the rate of convergence in terms of the *isoperimetry of the target distribution.* For this we define the KLS constant.

▶ **Definition 7.** For a density ν in $\mathbb{R}^n$, the KLS constant of ν is defined as

$$\frac{1}{\psi_\nu} = \inf_{S \subset \mathbb{R}^n} \frac{\nu(\partial S)}{\min\{\nu(S), 1 - \nu(S)\}}$$

and the KLS constant for logconcave densities in $\mathbb{R}^n$ is $\psi_n = \sup\{\psi_\nu : \nu \text{ isotropic logconcave in } \mathbb{R}^n\}$.

We will discuss this constant and its significance presently. The following theorem [22] shows how it bounds the mixing rate of the ball walk.

▶ **Theorem 8** (Ball Walk and KLS [22]). *The mixing time of the ball walk applied to a logconcave density in isotropic position with step size $\delta = 1/\sqrt{n}$ from an $O(1)$-warm start is bounded by $\widetilde{O}(n^2\psi_\nu^2)$.*

Kannan, Lovász and Simonovits [21] conjectured that $\psi_n = O(1)$ for any logconcave isotropic density ν. Recently, Klartag and Lehec [25], following a line of work [21, 13, 16, 12, 32, 3], proved that $\psi_n = O(\log^5 n)$, which implies Theorem 6 above. Another way to state the underlying isoperimetric inequality is the following.

▶ **Theorem 9** (Euclidean Isoperimetry). *For any logconcave density ν in $\mathbb{R}^n$ whose covariance matrix A has largest eigenvalue λ_1 and any two disjoint subsets S_1, S_2 of $\mathbb{R}^n$ we have*

$$\nu(K \setminus S_1 \setminus S_2) \geq \frac{d(S_1, S_2)}{\psi_n \sqrt{\lambda_1}} \min\{\nu(S_1), \nu(S_2)\}$$

where $d(,)$ is Euclidean distance and ψ_n is known to be $O(\log^5 n)$ [25] and conjectured to be $O(1)$ [21].

An equivalent geometric way to state the KLS conjecture is that a hyperplane-induced subset achieves the minimum isoperimetric coefficient up to a universal constant factor. For a detailed discussion of the KLS conjecture, we refer the reader to [31]. Its full resolution remains an intriguing and fruitful open problem.

More recently, it has been shown that the complexity of isotropic transformation and volume computation can be reduced to the KLS constant.

▶ **Theorem 10** (Rounding and Volume Computation [8, 19]). *Given a convex body given in the membership oracle model, it can be brought into near-isotropic position in $\widetilde{O}(n^3\psi_n^2)$ queries and its volume can be computed to within relative error ε using $\widetilde{O}(n^3/\varepsilon^2)$ additional queries.*

We conclude this section with two questions about the analysis of the ball walk, which both seem to require the development of new tools. The first has to do with the convergence of the ball walk without a warm start. Although this does not converge quickly in general (e.g., when starting near a corner), it is conceivable that it does when started from a "nice" point. After all, the result for a warm start effectively states that "most" points are good starting points. But can we get our hands on one of them?

▶ **Question 11.** *Show that the ball walk started from the centroid of a convex body converges to its stationary distribution in polynomial time.*

The second question has to do with verifying that the ball walk has converged. This has value both theoretically and practically (to test convergence on an instance-by-instance basis rather than simply running up to the worst-case bound).

▶ **Question 12.** *Consider the ball walk in a convex body starting from a logconcave initial distribution (e.g., uniform in a ball contained inside the body). Show that the distance between the current distribution and the target can be bounded as a polynomial in the dimension and the distance to stationarity of a random one-dimensional marginal of the current distribution.*

A clean variant of this question, first proposed by Lovász, is whether the expected squared distance of a random point X_t of the ball walk from its starting point X_0 is a monotonic increasing function.

2.2 Hit-and-Run

One advantage of hit-and-run is that there is no step-size parameter. A more important property is that hit-and-run converges rapidly from *any* starting distribution (even a single point), unlike the ball walk. To see that the ball walk does not, consider starting the ball

walk near a corner, e.g., near a vertex of a cube; then the probability of making a proper step (one that moves to a different point) can be arbitrarily small. Another way to see this is to note that the conductance of small sets for the ball walk Markov chain cannot, in general, be bounded from below. For hit-and-run, the picture is dramatically different – every subset can be shown to have large conductance! In particular, hit-and-run started from an arbitrary point in the interior (e.g., close to a corner) will quickly escape the corner.

▶ **Theorem 13** (Conductance of Hit-and-Run [37]). *The conductance of hit-and-run for any convex body in $\mathbb{R}^n$ containing a unit ball and contained in a ball of radius R is $\Omega(1/(nR))$.*

As a consequence it has the same general mixing rate as the ball walk, except that the dependence on the warm start parameter is logarithmic rather than polynomial, and in particular starting from any point x_0 in the interior of K, it is logarithmic in the inverse of the distance of x_0 to the boundary of K. It is conjectured (and observed in practice [17, 2]) that Hit-and-Run also mixes in n^2 steps for a body/logconcave distribution in isotropic position. However, it is an open problem to analyze this and show a bound better than n^3 as implied by the analysis in general position.

▶ **Question 14.** *Analyze the mixing rate of Hit-and-Run for a logconcave density or convex body in isotropic position.*

To understand the difficulty of answering this question, it is useful to see the isoperimetric inequality underlying the conductance bound for hit-and-run. This is our first departure from Euclidean distance, and an indication that the natural underlying geometry is different. For two points u, v in a convex body K, we define the *cross-ratio* distance as follows. Let p, q be the endpoints of the chord induced by u, v inside K, so that their order along the chord is p, u, v, q. Then,

$$d_K(u, v) = \frac{\|u - v\| \, \|p - q\|}{\|p - u\| \, \|v - q\|}.$$

While this distance is not a true distance in that it does not satisfy the triangle inequality, the closely related Hilbert distance, $d_H(u, v) = \ln(1 + d_K(u, v))$, is a metric. We have the following isoperimetric inequality.

▶ **Theorem 15** (Cross-ratio/Hilbert Isoperimetry [35, 38]). *For any logconcave density ν in $\mathbb{R}^n$ whose support is a convex body K and any two disjoint subsets S_1, S_2 of $\mathbb{R}^n$ we have*

$$\nu(K \setminus S_1 \setminus S_2) \geq d_K(S_1, S_2)\nu(S_1)\nu(S_2).$$

This isoperimetric inequality is affine-invariant and already tight. So it is unclear how to derive a more refined inequality that takes advantage of isotropic position.

▶ **Question 16.** *Is there a corresponding KLS conjecture that would imply a better mixing rate for hit-and-run?*

2.3 A bottleneck

For both the ball walk and hit-and-run, the mixing rate from a warm start for an isotropic target is $\Omega(n^2)$; this can be seen for a hypercube. The bottleneck for the ball walk is that the largest value that the step-size parameter δ can be set to is $O(1/\sqrt{n})$. This is because setting it to a larger value leads to most steps being rejected, i.e., WHP proposed steps are outside the body. In the case of hit-and-run, we have the same bottleneck. This is because the length of a random chord through a random point in a hypercube is still only $O(1/\sqrt{n})$, so this is the effective step-size on average.

3 In search of a larger step: the Dikin walk

For the walks discussed so far, the step-size is limited by points near the boundary. This suggests the idea of taking larger steps from points that are deeper inside, e.g., at the current point, use the largest ball that has a constant probability of a random step being accepted. So points deeper inside would take larger steps. However, this has the issue that the resulting stationary distribution is no longer uniform. To correct this, one can use a Metropolis filter based on the ratios of the volumes of the balls at the current point and the proposed point. Unfortunately, this means that this effective radius or step-size must change slowly. A smoother and more elegant approach is inspired by the seminal work of Dikin for convex optimization [10]. To optimize a linear function over a polytope, he proposed constructing a "maximal" ellipsoid around the current point that would be contained in the body, taking a large, objective-improving step within this ellipsoid and repeating. This was the first "interior-point" paradigm (now called Affine Scaling); it predates the central path interior-point method pioneered by Karmarkar [24] and generalized by Nesterov and Nemirovskii [41]. For a point x in the polytope defined by $\{Ax \geq b\}$, the Dikin ellipsoid is defined as follows:

$$E(x,r) = \left\{y : (y-x)^\top \mathbf{H}(x)(y-x) \leq r^2\right\} \qquad \text{where} \qquad \mathbf{H}(x) = \sum_{i=1}^{m} \frac{a_i a_i^\top}{(a_i^\top x - b_i)^2}$$

with a_i being the i'th row (normal vector) of the constraint matrix A for $i = 1, \ldots, m$. This ellipsoid adapts to the local geometry of the polytope, and $E(x,1)$ always fully contained in it. It suggests the following Dikin random walk: at the current point x, pick a random point y in the Dikin ellipsoid $E(x,r)$; if $x \in E(y,r)$, go to y with probability $\min\{1, \mathrm{vol}(E(x,r))/\mathrm{vol}(E(y,r))\}$. Kannan and Narayanan [23] analyzed its mixing rate with a suitable choice of the radius r.

▶ **Theorem 17** (Dikin in Polytope [23]). *The mixing rate of the Dikin walk from a warm start in a polytope in $\mathbb{R}^n$ given by m inequalities is bounded by $O(mn)$.*

Notably, the mixing rate of the walk *does not* depend on the affine position of the body – the process is affine-invariant, i.e., applying the walk to an affine transformation of the input body is the same as applying the transformation to the output of the process on the same body. This means in particular that one can assume for free that the polytope is in isotropic position. This avoids dependence on the outer ball radius parameter R in the previous section.

What should the step-size r be? It is chosen to be $O(1/\sqrt{n})$ and this turns out to be necessary to ensure that the rejection probability is not too high, i.e., that the volumes of Ellipsoids corresponding to nearby points are within a constant factor. The change in the ellipsoid can be bounded using the classical optimization property of *self-concordance*, i.e., when the matrix function $\mathbf{H}(x)$ is the Hessian of a convex function. Self-concordance is a key property in the analysis of the interior-point method for linear programming [41]. In fact, the ellipsoid matrix $\mathbf{H}(x)$ is the Hessian of the convex log barrier function at x,

$$\phi(x) = -\sum_{i=1}^{m} \ln(a_i^\top x - b_i),$$

i.e., $\mathbf{H}(x) = D^2\phi(x)$. So the log-barrier interior-point method for optimization corresponds to the Dikin walk for sampling!

To make this connection a bit more precise, let us define the norm of a vector v induced by a matrix function $\mathbf{H}$ as $\|v\|_x^2 = v^\top \mathbf{H}(x) v$.

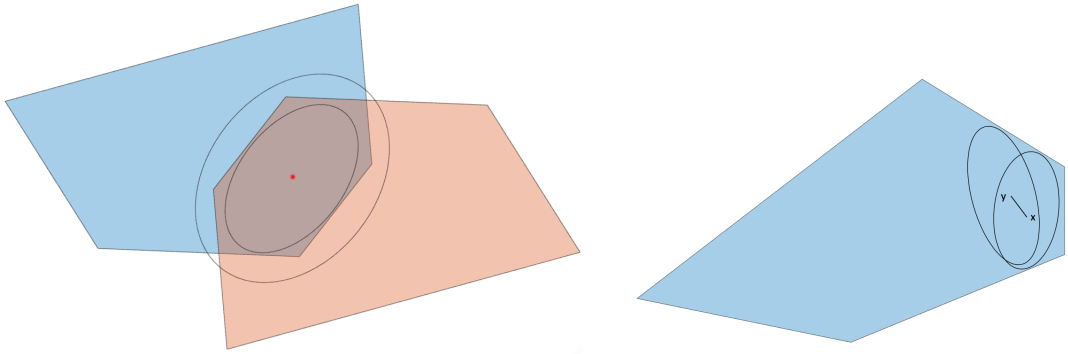

Figure 3.1 (a) $E_u(1) \subseteq K \cap (2u - K) \subseteq E_u(\sqrt{\nu})$. (b) (Strong) self-concordance measures the rate of change of Hessian.

▶ **Definition 18.** For a convex set $K \subset \mathbb{R}^n$, we say a matrix function $\mathbf{H} : K \to \mathbb{R}^{n\times n}$ is *self-concordant* if for any $x \in K$, we have

$$\left\|\mathbf{H}(x)^{-1/2} D\mathbf{H}(x)[h]\mathbf{H}(x)^{-1/2}\right\|_{\text{op}} \leq 2\|h\|_x$$

where $D\mathbf{H}(x)[h]$ is the directional derivative of $\mathbf{H}$ at x in the direction h, i.e., $D\mathbf{H}(x)[h] = \frac{d}{dt}\mathbf{H}(x + th)$. We say $\mathbf{H}$ is symmetric ν-self-concordant if $\mathbf{H}$ is self-concordant and for any $x \in K$,

$$E(x, 1) \subseteq K \cap (2x - K) \subseteq E(x, \sqrt{\nu}).$$

Self-concordance relates the change in $\mathbf{H}$ to the change in x. Many natural self-concordant barriers, including the logarithmic barrier, satisfy a much stronger condition, replacing the operator norm above by the Frobenius norm. While this makes no difference for the worst-case bound for optimization, it turns out to be crucial for sampling.

▶ **Definition 19** (Strong Self-Concordance)**.** For a convex set $K \subset \mathbb{R}^n$, we say a matrix function $\mathbf{H} : K \to \mathbb{R}^{n\times n}$ is *strongly self-concordant* if for any $x \in K$, we have

$$\left\|\mathbf{H}(x)^{-1/2} D\mathbf{H}(x)[h]\mathbf{H}(x)^{-1/2}\right\|_{F} \leq 2\|h\|_x .$$

The canonical barrier [18] satisfies strong self-concordance. The situation with two other classical barriers, namely the universal and entropic barriers has a curious connection.

▶ **Lemma 20** ([27])**.** *Let $\mathbf{H}(x)$ be the Hessian of the universal or entropic barriers. Then,*

$$\left\|\mathbf{H}(x)^{-1/2} D\mathbf{H}(x)[h]\mathbf{H}(x)^{-1/2}\right\|_{F} = O(\psi_n)\|h\|_x .$$

In fact, up to a logarithmic factor, the strong self-concordance of these barriers is *equivalent* to the KLS conjecture.

▶ **Lemma 21.** *Given any strongly self-concordant matrix function $\mathbf{H}$ on $K \subset \mathbb{R}^n$. For any $x, y \in K$ with $\|x - y\|_x < 1$, we have*

$$\|\mathbf{H}(x)^{-\frac{1}{2}}(\mathbf{H}(y) - \mathbf{H}(x))\mathbf{H}(x)^{-\frac{1}{2}}\|_F \leq \frac{\|x - y\|_x}{(1 - \|x - y\|_x)^2}.$$

The following guarantee was shown for the convergence of the generalized Dikin walk in [27].

▶ **Theorem 22** (Convergence of general Dikin walk [27]). *The mixing rate of the Dikin walk for a symmetric, strongly self-concordant matrix function with convex log determinant is* $O(n\bar{\nu})$.

This implies faster mixing and sampling for polytopes using the LS barrier [28], which is strongly self-concordant, has a convex log determinant and has $\bar{\nu} = O(n \log^3 m)$.

▶ **Theorem 23** (Quadratic Convergence of Dikin [27]). *The mixing rate of the Dikin walk based on the LS barrier for any polytope in* $\mathbb{R}^n$ *is* $\tilde{O}(n^2)$ *and each step can be implemented in* $\tilde{O}(mn^{\omega-1})$ *arithmetic operations where* ω *is the matrix multiplication exponent.*

We note that the Dikin walk with the logarithmic barrier for a polytope $\{\mathbf{A}x \geq b\}$ can be implemented in time $O(\text{nnz}(\mathbf{A}) + n^2)$ per step while maintaining the mixing rate of $O(mn)$.

The isoperimetry of the metric induced by the matrix function $\mathbf{H}$ follows by simply connecting it to the cross-ratio distance.

▶ **Lemma 24.** *For* $u, v \in K$, $d_K(u, v) \geq \frac{\|u-v\|_u}{\sqrt{\bar{\nu}}}$.

From this lemma and Theorem 15, we have that the isoperimetric coefficient for the Hessian norm distance is $\Omega(1/\sqrt{\nu})$. This bound, as well as the bound of mn for the Dikin walk with the log barrier are tight as shown by a hypercube with one of its facets duplicated $m - n$ times. However, the situation is far from clear for the weighted Dikin walk, where the log barrier is replaced by one that weights each constraint, as in the LS barrier (and effectively eliminates this bad example).

▶ **Question 25.** *What is the isoperimetric coefficient of the Hessian distance induced by the LS barrier? Does the corresponding weighted Dikin walk mix in* $\widetilde{O}(n)$ *steps?*

4 Large steps via non-Euclidean geometries

The Dikin walk and its weighted version are based on exploiting *local* geometry, where the norm is defined locally. As a direct consequence, this family of algorithms is affine-invariant. However, to ensure the correct stationary distribution and keep the probability of acceptance in the Metropolis filter reasonably large, the effective step-size is again $1/\sqrt{n}$, and the convergence rate is n^2. Is a larger step-size/smaller convergence rate possible?

To understand this, we delve further into the use of non-Euclidean geometry. So far, our random walks have only taken straight line steps in Euclidean space. The distribution of the direction of the next step depends on the current point in the case of the Dikin walk, but the step itself is still a straight line. A more drastic departure would be to use curves instead of straight lines. How?

First note that given a local metric such as the one induced by the Hessian of a convex function defines a manifold and using this metric we can define the length of a curve (a continuous path) and the distance between any two points (as the length of the shortest curve between them). Since the local metric varies, the shortest path between two points can be a curve (e.g., consider flight paths for the sphere metric). In the context of sampling polytopes, we consider the metric defined by the Hessian of the log barrier. The support of this manifold is the original polytope. Distances between points are magnified as the points get closer to the boundary. So geodesic paths tend to avoid the boundary!

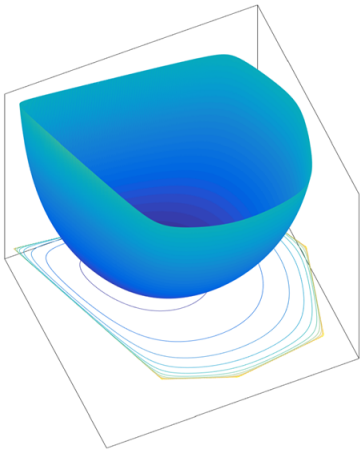

Figure 4.1 The Hessian manifold induced by the log barrier in a polytope.

How do we pick a random next step/direction? For this we can use the notion of tangent space attached to every point in a Riemannian manifold, and pick a random (Gaussian) vector in the tangent space. Then we go along the geodesic (locally shortest path) in the direction of the chosen vector along the manifold. This is the curved step. We make these notions more precise below. The main intuition for considering such a generalization is the possibility of taking larger steps unimpeded by the boundary. This family of walks have been called "geodesic" walks [31]. We will shortly see an even more natural variant. For some quick background on Riemannian geometry, we refer the reader to the appendix.

4.1 Geodesic walks

Consider an explicit polytope P and a manifold M with support P and metric induced by the Hessian of the log barrier in P. Moving to this manifold view allows us to avoid the constraint of small steps near the boundary, as there is no longer a hard boundary constraint. How large can we make the step size? This is limited by another factor, namely, when we take large steps, the filter acceptance probability (to maintain the desired target distribution) can become very small. Could we possibly avoid using a filter? To answer this, we first consider the continuous time limit of the corresponding "diffusion" process.

$$dx_t = \mu(x_t)dt + \left(2D^2\phi(x_t)\right)^{-1/2} dW_t.$$

The first term, called the *drift*, is given by

$$\mu_i(x_t) = \sum_{j=1}^{n} \frac{\partial}{\partial x_j} \left(\left(\nabla^2\phi(x_t)\right)^{-1}\right)_{ij} = D \cdot (D^2\phi(x_t)^{-1})_i$$

where $D\cdot$ is the divergence operator. The drift term is a deterministic vector field biasing the walk locally. Its purpose is to ensure that the process converges to the desired target uniform distribution. Notably, in the continuous setting, it replaces the Metropolis filter. The precise form of the drift can be derived using the Fokker-Planck equation.

▶ **Theorem 26** (Fokker-Planck equation). *For any stochastic differential equation (SDE) of the form*

$$dx_t = \mu(x_t)dt + \sqrt{H(x_t)}dW_t,$$

for a symmetric matrix function H, the probability density of the SDE is given by the diffusion equation

$$\frac{\partial}{\partial t}p(x) = -\sum_{i=1}^{n}\frac{\partial}{\partial x_i}[\mu_i(x)p(x)] + \frac{1}{2}\sum_{i=1}^{n}\sum_{j=1}^{n}\frac{\partial^2}{\partial x_i x_j}[H_{ij}(x)p(x)].$$

In discrete time, we consider the following *geodesic walk*:

$$x^{(j+1)} = \exp_{x^{(j)}}(\sqrt{h}w + \frac{h}{2}\mu(x^{(j)})), \tag{4.1}$$

where $\exp_{x^{(j)}}$ is the exponential map from the tangent space at $x^{(j)}$, $T_{x^{(j)}}M$, back to the manifold, w is a random Gaussian vector in the tangent space $T_{x^{(j)}}M$, $\mu(x^{(j)}) \in T_{x^{(j)}}M$ is the drift term and h is the step size. The Gaussian vector w has mean 0 and variance 1 in the metric at x, i.e., for any u, $\mathbb{E}_w\langle w, u\rangle_x^2 = \|x\|_x^2$. We write it as $w \sim N_x(0, I)$. This discrete walk converges to continuous diffusion as $h \to 0$ and it converges at a rate faster than the walk suggested by Euclidean coordinates, namely, $x^{(j+1)} = x^{(j)} + \sqrt{h}w + h\mu(x^{(j)})$.

Implementing this discretization leads to substantial challenges. The stationary distribution of the geodesic walk is not uniform. To get around this issue, we use rejection sampling. For step-size h chosen in advance, let $p(x \xrightarrow{w} y)$ be the probability density of going from x to y using the local step w.

Algorithm 1 Geodesic Walk.

At current point x:
Pick a Gaussian random vector $w \sim N_x(0, I)$.
Compute $y = \exp_x(\sqrt{h}w + \frac{h}{2}\mu(x))$.
Let $p(x \xrightarrow{w} y)$ be the probability density of going from x to y using the above step w.
Compute a corresponding w' s.t. $x = \exp_y(\sqrt{h}w' + \frac{h}{2}\mu(y))$.
With probability $\min\left(1, \frac{p(y \xrightarrow{w'} x)}{p(x \xrightarrow{w} y)}\right)$, go to y; otherwise, stay at x.

In this algorithm, computing the exponential map and computing the transition probability density are nontrivial steps that need the efficient solution of an ODE. Even though the walk uses a Metropolis filter in the end, the parameter h can be made as large as $n^{-3/4}$, and the overall mixing time is $O(m/h)$, leading to the first sub-quadratic mixing rate for sampling polytopes. Note that this is effectively a step-size of $\sqrt{h} = n^{-3/8} \gg n^{-1/2}$, the limitation of previous methods.

▶ **Theorem 27** (Convergence of Geodesic Walk [29]). *The geodesic walk in a polytope with the log barrier converges to the uniform density in the polytope in $O(mn^{3/4})$ steps and each step can be implemented in $\widetilde{O}(mn^{\omega-1})$ arithmetic operations.*

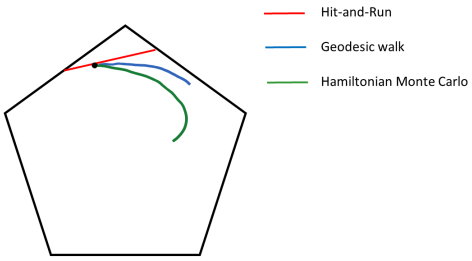

Figure 4.2 An illustration of Hit-and-run/Dikin, Geodesic walk and Hamiltonian Monte Carlo.

4.2 Riemannian Hamiltonian Monte Carlo

In the geodesic walk inspired by diffusion, in each step we choose a random direction and the drift along the entire step is determined by the (current) initial point. An even more natural discretization is to let the drift evolve along the trajectory in the chosen direction. The purpose of this modification would be to maintain the stationarity in spite of going to discrete time without introducing an explicit Metropolis filter. Can this be done? The answer is the method known as Hamiltonian Monte Carlo [40], and its manifold generalization [15]. To sample from a general distribution $e^{-H(x,y)}$. Hamiltonian Monte Carlo uses curves instead of straight lines in a time-reversible manner even if the target distribution is uniform.

▶ **Definition 28.** Given a continuous, twice-differentiable function $H : \mathcal{M} \times \mathbb{R}^n \subset \mathbb{R}^n \times \mathbb{R}^n \to \mathbb{R}$ called the *Hamiltonian*, where $\mathcal{M}$ is the x domain of H, we say $(x(t), y(t))$ follows a *Hamiltonian curve* if it satisfies the *Hamiltonian equations*

$$\begin{aligned} \frac{dx}{dt} &= \frac{\partial H(x,y)}{\partial y}, \\ \frac{dy}{dt} &= -\frac{\partial H(x,y)}{\partial x}. \end{aligned} \tag{4.2}$$

We define the map $T_\delta(x, y) \stackrel{\text{def}}{=} (x(\delta), y(\delta))$ where the $(x(t), y(t))$ follows the Hamiltonian curve with the initial condition $(x(0), y(0)) = (x, y)$.

Hamiltonian Monte Carlo is a sequence of randomly generated Hamiltonian curves.

Algorithm 2 Hamiltonian Monte Carlo.

Input: some initial point $x^{(1)} \in \mathcal{M}$.
for $k = 1, 2, \cdots, T$ **do**
  Sample $y^{(k+\frac{1}{2})}$ according to $e^{-H(x^{(k)},y)}/\pi(x^{(k)})$ where $\pi(x) = \int_{\mathbb{R}^n} e^{-H(x,y)}dy$.
  With probability $\frac{1}{2}$, set $(x^{(k+1)}, y^{(k+1)}) = T_\delta(x^{(k)}, y^{(k+\frac{1}{2})})$.
  Otherwise, $(x^{(k+1)}, y^{(k+1)}) = T_{-\delta}(x^{(k)}, y^{(k+\frac{1}{2})})$.
end
Output: $(x^{(T+1)}, y^{(T+1)})$.

▶ **Lemma 29.** *HMC has the following properties:*

1. **Energy conservation.** *For any Hamiltonian curve* $(x(t), y(t))$,

$$\frac{d}{dt}H(x(t), y(t)) = 0.$$

2. **Measure preservation.** *For any $t \geq 0$,*

$$\det\left(DT_t(x,y)\right) = 1$$

where $DT_t(x,y)$ is the Jacobian of the map T_t at the point (x,y).

3. **Time reversibility.** *For $\pi(x) = \int_{\mathbb{R}^n} e^{-H(x,y)}dy$, the probability density $p_x(x')$ of one step of HMC starting at x satisfies $\pi(x)p_x(x') = \pi(x')p_{x'}(x)$.*

Everything so far can be generalized to manifolds. To sample from the distribution $e^{-f(x)}$, we define

$$H(x,v) \stackrel{\text{def}}{=} f(x) + \frac{1}{2}\log((2\pi)^n \det g(x)) + \frac{1}{2}v^T g(x)^{-1}v \tag{4.3}$$

where g is the local metric of the manifold. In the Euclidean case, $g(x) = I$, and the Euclidean Hamiltonian is $H(x,v) = f(x) + \frac{1}{2}\|v\|^2$ and the corresponding dynamics becomes just $\frac{d^2x}{dt^2} = -\nabla f(x)$. One can view x as the position and v as the velocity. The convergence of HMC has been intensively studied in recent years, starting with [39], which established a mixing rate of $O(\kappa^2)$ for the case when f is strongly logconcave. For this setting it is now known that the optimal rate is $O(\kappa)$ [4].

We now restate the HMC equation for manifolds, as Riemannian HMC, noting that derivatives have to take the local metric into account.

▶ **Lemma 30.** *In Euclidean coordinates, the Hamiltonian equation for (4.3) can be rewritten as*

$$\begin{aligned} D_t\frac{dx}{dt} =& \mu(x), \\ \frac{dx}{dt}(0) \sim& N(0, g(x)^{-1}) \end{aligned}$$

where $\mu(x) = -g(x)^{-1}Df(x) - \frac{1}{2}g(x)^{-1}\mathrm{Tr}\left[g(x)^{-1}Dg(x)\right]$, and D_t is the covariant derivative (or Levi-Civita connection) on the manifold $\mathcal{M}$ with metric g.

With the above set-up, as long as we can compute the RHMC ODE accurately and efficiently, there is no need for a filtering step, leading to a significantly simpler implementation than that of the geodesic walk. In fact, it also gives a slightly improved mixing rate by allowing a larger time step in each iteration.

▶ **Theorem 31** (Convergence of RHMC [30])**.** *Riemannian Hamiltonian Monte Carlo in a polytope with the log barrier converges to the uniform density in the polytope in $O(mn^{2/3})$ steps.*

▶ **Question 32.** *Can the step-size of RHMC be improved so that the mixing rate is $O(m\sqrt{n})$? Can the mixing rate be improved to $\widetilde{O}(n^{1.5})$ with a weighted log barrier?*

RHMC appears to be quite practical, with recent implementations being able to sample from constrained distributions in dimension as high as 10^5 [26].

5 From diffusion to sampling: the manifold perspective

Langevin Diffusion (LD) is the following stochastic process[1]:

$$dX_t = -Df(X_t)dt + \sqrt{2}dB_t$$

[1] In this section, we use D for Euclidean derivative and reserve ∇ for manifold derivative.

where B_t is the standard Wiener process. The stationary distribution of this process is the density $\nu(x)$ proportional to $e^{-f(x)}$, a fact that can be verified using the Fokker-Planck equation for the time derivative of the density of X_t. To understand the rate of convergence, we recall two basic notions. First to measure the distance between distributions, we use the relative entropy (or KL divergence), defined as follows:

$$H_\nu(\rho) = \int \rho(x) \log \frac{\rho(x)}{\nu(x)}\, dx = \mathbb{E}_\rho \left(\log \frac{\rho}{\nu} \right).$$

In continuous time, the convergence will depend on what kind of isoperimetry is satisfied by the target density. So far we have seen Cheeger isoperimetry, which results in convergence in the χ^2-divergence. A stronger notion of isoperimetry is given by the Log-Sobolev Inequality. The relative Fisher information is defined as

$$J_\nu(\rho) = \int \rho \|\nabla \log(\frac{\rho}{\nu})\|^2 dx.$$

Note that this definition is for any Riemannian manifold.

▶ **Definition 33.** We say the distribution ν satisfies a Log-Sobolev inequality with constant α (called the log-Sobolev constant) if for every measure with density ρ we have

$$H_\nu(\rho) \leq \frac{1}{2\alpha} J_\nu(\rho).$$

For logconcave densities in $\mathbb{R}^n$, an equivalent definition up to absolute constants is the following:

$$\sqrt{\alpha} \simeq \inf_{S \subseteq \mathbb{R}^n,\, \nu(S) \leq \frac{1}{2}} \frac{\nu(\partial S)}{\nu(S)\sqrt{\log(1/\nu(S))}}$$

which looks like the Cheeger constant except for the additional log factor in the denominator – LSI requires the isoperimetric coefficient to get larger as the measure of the subset gets smaller.

A distribution that satisfies LSI has a strong convergence property in continuous time.

▶ **Theorem 34.** $H_\nu(\rho_t) \leq e^{-2\alpha t} H_\nu(\rho_0)$.

This statement bears a remarkable resemblance to convergence of Gradient Descent to the optimal solution for strongly convex functions. In fact, as noted by Wibisono [45] (see also [20]), *Langevin Diffusion is Gradient Flow in the space of measures with the Wasserstein metric and the objective being the KL-divergence to the target density.*

We discuss this in a bit more detail below, starting from the simple optimization perspective.

▶ **Lemma 35.** *Let F be a function satisfying "Gradient Dominance":*

$$\|\nabla F(x)\|^2 \geq 2\alpha(F(x) - \min_x F(x)).$$

Then, the deterministic process $dx_t = -\nabla F(x_t)dt$ converges exponentially, i.e.,

$$F(x_t) - \min F \leq e^{-2\alpha t}(F(x_0) - \min F).$$

.

Proof. We write

$$\begin{aligned}\frac{d}{dt}(F(x_t) - \min_x F(x)) &= \langle \nabla F(x_t), \frac{dx_t}{dt} \rangle \\ &= -\left\|\nabla F(x_t)\right\|^2 \\ &\leq -2\alpha \cdot (F(x_t) - \min_x F(x)).\end{aligned}$$

The conclusion follows. ◀

For $f : \mathbb{R}^n \to \mathbb{R}_+$, let ν be the density proportional to $e^{-f(x)}$ and $F(\rho) = H_\nu(\rho)$. We will apply the above lemma to this KL-divergence objective.

▶ **Lemma 36.** *For any two densities ρ, ν,*

$$\|\nabla_\rho H_\nu(\rho)\|_\rho^2 = \int \rho(x) \left\| D \log \frac{\rho(x)}{\nu(x)} \right\|^2 dx = J_\nu(\rho).$$

▶ **Theorem 37.** *Let f be a differentiable function with log-Sobolev constant α. Then the Langevin dynamics*

$$dx_t = -Df(x)dt + \sqrt{2}dW_t$$

converges exponentially in KL-divergence to the density $\nu(x) \propto e^{-f(x)}$ with mixing rate $O(1/\alpha)$, i.e., $H_\nu(\rho_t) \leq e^{-2\alpha t} H_\nu(\rho_0)$.

Proof. First, note that the Langevin SDE, by Fokker-Planck, corresponds to the following PDE:

$$\begin{aligned}\frac{d\rho(x)}{dt} &= D \cdot (\rho(x) Df) + \Delta\rho(x) \\ &= D \cdot \left(\rho(x) D \log \frac{\rho(x)}{\nu(x)} \right) \\ &= -\nabla_\rho H_\nu(\rho).\end{aligned}$$

Note that the last step above refers to the derivative with respect to the Wassterstein metric (see [44]). Next, we note that since ν satisfies the log-Sobolev inequality, $F(\rho) = H_\nu(\rho)$ satisfies the Gradient Dominance condition with parameter α. The theorem follows from Lemma 35. ◀

So far, we have only used the log-Sobolev inequality, not convexity or related properties. Will this suffice for an efficient algorithm? It was shown in [43] that this is indeed the case. The Unadjusted Langevin Algorithm (ULA) is the simple Euler discretization of Langevin dynamics, namely,

$$X_{k+1} = X_k - \delta \cdot Df(X_k) + \sqrt{2\delta} Z$$

where $Z \sim N(0, I)$ is standard Gaussian. The next theorem is for $\mathbb{R}^n$.

▶ **Theorem 38** (ULA converges under Isoperimetry [43])**.** *Assume $\nu = e^{-f}$ satisfies LSI with constant $\alpha > 0$ and Df is L-Lipschitz. Then ULA with step size $0 < \delta \leq \frac{\alpha}{4L^2}$ satisfies*

$$H_\nu(\rho_k) \leq e^{-\alpha\delta k} H_\nu(\rho_0) + \frac{8\delta n L^2}{\alpha}.$$

For any $0 < \varepsilon < 4n$, ULA with step size $\delta \leq \frac{\alpha\varepsilon}{16nL^2}$ reaches error $H_\nu(\rho_k) \leq \varepsilon$ after at most $k \geq \frac{1}{\alpha\delta} \log \frac{2H_\nu(\rho_0)}{\varepsilon}$ iterations.

Due to the simplicity and generality of the approach, Langevin Algorithms have been intensively studied in recent years for many special cases and under various additional conditions on the input [9, 5, 11, 34, 46, 6]. Here we consider an extension: what is the generalization of Langevin diffusion from Euclidean space to more general metrics?

▶ **Definition 39** (Riemannian Langevin Diffusion (RLD))**.** Let $\mathcal{M}$ be a manifold with metric g and measure $dv_g(x)$, whose density with respect to the Lebesgue measure is $\sqrt{|\det(g)|}$. For a distribution with density $\nu = e^{-F}$, Riemannian Langevin Diffusion is given by the following SDE whose stationary distribution is νdv_g:

$$dX_t = (\nabla \cdot (g^{-1}(X_t)) - \nabla F(X_t))dt + \sqrt{2g^{-1}(X_t)}dB_t.$$

Here $\nabla\cdot$ denotes the divergence with respect to the manifold and it is applied separately to each row of a matrix. When written in local Euclidean coordinates, this becomes

$$dX_t = (D \cdot (g^{-1}(X_t)) - g^{-1}(X_t)Df(X_t))dt + \sqrt{2g^{-1}(X_t)}dB_t$$

where $f(x) = F(x) - \frac{1}{2}\log\det g(x)$ and the derivative and divergence are Euclidean. When f is constant, then $Df = 0$ and we get the equation for Brownian motion on the manifold.

RLD has the same convergence guarantee in continuous time as stated by Theorem 34, with ν being the manifold stationary measure. While LD can only be applied to smooth target densities, RLD allows us to use the metric g to incorporate constraints and sample from e^{-f} subject to constraints. For example, by letting g be the log-barrier of a polytope we get to sample from densities restricted to the polytope, in continuous time. We next define the extension to a discrete time algorithm.

▶ **Definition 40** (Riemannian Langevin Algorithm (RLA))**.** To sample from the distribution $\nu dv_g(x)$ over the manifold $\mathcal{M}$, for a fixed step size ϵ, repeat:

$$y = \exp_{x_k}(-\epsilon\nabla F(x_k))$$
$$x_{k+1} = \mathfrak{B}(y, \epsilon)$$

where $\mathfrak{B}(x_0, t)$ samples from Brownian motion on the manifold, starting from x_0 after time t.

Recently, following work of [33, 1], [14] made progress on analyzing RLA in this general setting, showing that an extension of self-concordance of the metric suffices to guarantee convergence under the log-Sobolev inequality.

6 Discussion

The study of sampling has led to new tools, both for analysis and for algorithms, surprising connections with convex geometry, functional analysis and optimization, and practical algorithms in high dimension. We conclude by highlighting a few more open problems.

▶ **Question 41.** *Is there a natural KLS conjecture for Hessian manifolds?*

The close connection between diffusion and sampling raises an interesting sampling problem, namely efficiently simulating Brownian motion on manifolds.

▶ **Question 42.** *Given a metric g, an initial point x_0 and a time interval t, give an algorithm to sample from the distribution of Brownian motion on the manifold starting at x_0 for time t. For a manifold with metric g, Brownian motion is given by:*

$$dX_t = \nabla \cdot (g^{-1})dt + \sqrt{2g^{-1}}dB_t.$$

A Riemannian metrics

A manifold M can be viewed as an n-dimensional "surface" in $\mathbb{R}^k$ for some $k \geq n$.

1. Riemannian metric: For any $v, u \in T_pM$, the inner product (Riemannian metric) at p is given by $\langle v, u \rangle_p$ and this allows us to define the norm of a vector $\|v\|_p = \sqrt{\langle v, v \rangle_p}$. We call a manifold a Riemannian manifold if it is equipped with a Riemannian metric. When it is clear from context, we define $\langle v, u \rangle = \langle v, u \rangle_p$. In $\mathbb{R}^n$, $\langle v, u \rangle_p$ is the usual ℓ_2 inner product.
2. Tangent space T_pM: For any point p, the tangent space T_pM of M at point p is a linear subspace of $\mathbb{R}^k$ of dimension n. Intuitively, T_pM is the vector space of possible directions that are tangential to the manifold at x. Equivalently, it can be thought as the first-order linear approximation of the manifold M at p. For any curve c on M, the direction $\frac{d}{dt}c(t)$ is tangent to M and hence lies in $T_{c(t)}M$. For any open subset M of $\mathbb{R}^n$, we can identify T_pM with $\mathbb{R}^n$.

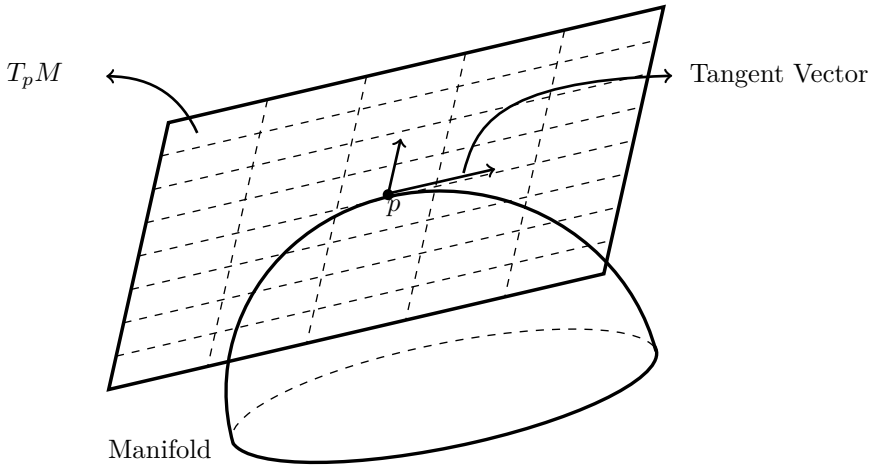

Figure A.1 Riemannian Manifold and Tangent Space.

3. Hessian manifold: We call M a Hessian manifold (induced by ϕ) if M is an open subset of $\mathbb{R}^n$ with the Riemannian metric at any point $p \in M$ defined by

$$\langle v, u \rangle_p = v^\top \nabla^2 \phi(p) u$$

where $v, u \in T_pM$ and ϕ is a smooth convex function on M.

4. Length: For any curve $c : [0, 1] \to M$, we define its length by

$$L(c) = \int_0^1 \left\| \frac{d}{dt} c(t) \right\|_{c(t)} dt.$$

5. Distance: For any $x, y \in M$, we define $d(x, y)$ be the infimum of the lengths of all paths connecting x and y. In $\mathbb{R}^n$, $d(x, y) = \|x - y\|_2$.

6. Geodesic: We call a curve $\gamma(t) : [a, b] \to M$ a geodesic if it satisfies both of the following conditions:

   a. The curve $\gamma(t)$ is parameterized with constant speed. Namely, $\left\|\frac{d}{dt}\gamma(t)\right\|_{\gamma(t)}$ is constant for $t \in [a, b]$.
   b. The curve is the locally shortest length curve between $\gamma(a)$ and $\gamma(b)$. Namely, for any family of curve $c(t, s)$ with $c(t, 0) = \gamma(t)$ and $c(a, s) = \gamma(a)$ and $c(b, s) = \gamma(b)$, we have that $\frac{d}{ds}\big|_{s=0} \int_a^b \left\|\frac{d}{dt}c(t, s)\right\|_{c(t,s)} dt = 0$.

   Note that, if $\gamma(t)$ is a geodesic, then $\gamma(\alpha t)$ is a geodesic for any α. Intuitively, geodesics are local shortest paths. In $\mathbb{R}^n$, geodesics are straight lines.
7. Exponential map: The map $\exp_p : T_pM \to M$ is defined as

   $$\exp_p(v) = \gamma_v(1)$$

   where γ_v is the unique geodesic starting at p with initial velocity $\gamma_v'(0)$ equal to v. The exponential map takes a straight line $tv \in T_pM$ to a geodesic $\gamma_{tv}(1) = \gamma_v(t) \in M$. Note that $\exp_p$ maps v and tv to points on the same geodesic. Intuitively, the exponential map can be thought as point-vector addition in a manifold. In $\mathbb{R}^n$, we have $\exp_p(v) = p + v$.
8. Parallel transport: Given any geodesic $c(t)$ and a vector v such that $\langle v, c'(0)\rangle_{c(0)} = 0$, we define the parallel transport of v along $c(t)$ by the following process: Take h to be infinitesimally small and $v_0 = v$. For $i = 1, 2, \cdots, 1/h$, we let v_{ih} be the vector orthogonal to $c'(ih)$ that minimizes the distance on the manifold between $\exp_{c(ih)}(hv_{ih})$ and $\exp_{c((i-1)h)}(hv_{(i-1)h})$. Intuitively, the parallel transport finds the vectors on the curve such that their end points are closest to the end points of v. For general vector $v \in T_{c'(0)}$, we write $v = \alpha c'(0) + w$ and we define the parallel transport of v along $c(t)$ is the sum of $\alpha c'(t)$ and the parallel transport of w along $c(t)$. For non-geodesic curve, see the definition in Fact 43.
9. Orthonormal frame: Given vector fields $v_1, v_2, \cdots, v_n$ on a subset of M, we call $\{v_i\}_{i=1}^n$ is an orthonormal frame if $\langle v_i, v_j\rangle_x = 1$ if $i = j$ and 0 otherwise. Given a curve $c(t)$ and an orthonormal frame at $c(0)$, we can extend it along the curve by parallel transport and it remains orthonormal on the whole curve.
10. Directional derivatives and the Levi-Civita connection: For a vector $v \in T_pM$ and a vector field u in a neighborhood of p, let γ_v be the unique geodesic starting at p with initial velocity $\gamma_v'(0) = v$. Define

    $$\nabla_v u = \lim_{h \to 0} \frac{u(h) - u(0)}{h}$$

    where $u(h) \in T_pM$ is the parallel transport of $u(\gamma_v(h))$ from $\gamma(h)$ to $\gamma(0)$. Intuitively, Levi-Civita connection is the directional derivative of u along direction v, *taking the metric into account*. In particular, for $\mathbb{R}^n$, we have $\nabla_v u(x) = \frac{d}{dt}u(x + tv)$. When u is defined on a curve c, we define $D_t u = \nabla_{c'(t)} u$. In $\mathbb{R}^n$, we have $D_t u(\gamma(t)) = \frac{d}{dt}u(\gamma(t))$. We reserve $\frac{d}{dt}$ for the usual derivative with Euclidean coordinates.

We list some basic facts about the definitions above.

▶ **Fact 43.** *Given a manifold M, a curve $c(t) \in M$, a vector v and vector fields u, w on M, we have the following:*

1. *(alternative definition of parallel transport) $v(t)$ is the parallel transport of v along $c(t)$ if and only if $\nabla_{c'(t)} v(t) = 0$.*

2. *(alternative definition of geodesic) c is a geodesic if and only if* $\nabla_{c'(t)} c'(t) = 0$.
3. *(linearity)* $\nabla_v(u + w) = \nabla_v u + \nabla_v w$.
4. *(product rule) For any scalar-valued function f,* $\nabla_v(f \cdot u) = \frac{\partial f}{\partial v} u + f \cdot \nabla_v u$.
5. *(metric preserving)* $\frac{d}{dt} \langle u, w \rangle_{c(t)} = \langle D_t u, w \rangle_{c(t)} + \langle u, D_t w \rangle_{c(t)}$.
6. *(torsion free-ness) For any map $c(t, s)$ from a subset of $\mathbb{R}^2$ to M, we have that* $D_s \frac{\partial c}{\partial t} = D_t \frac{\partial c}{\partial s}$ *where* $D_s = \nabla_{\frac{\partial c}{\partial s}}$ *and* $D_t = \nabla_{\frac{\partial c}{\partial t}}$.
7. *(alternative definition of Levi-Civita connection)* $\nabla_v u$ *is the unique linear mapping from the product of vector and vector field to vector field that satisfies (3), (4), (5) and (6).*

Streaming and Sketching Complexity of CSPs: A Survey

Madhu Sudan
School of Engineering and Applied Sciences, Harvard University, Cambridge, MA, USA

Abstract

In this survey we describe progress over the last decade or so in understanding the complexity of solving constraint satisfaction problems (CSPs) approximately in the streaming and sketching models of computation. After surveying some of the results we give some sketches of the proofs and in particular try to explain why there is a tight dichotomy result for sketching algorithms working in subpolynomial space regime.

Acknowledgements I want to thank Santhoshini Velusamy for introducing me to this wonderful line of research. I want to thank her and all other co-authors – Chi-Ning Chou, Sasha Golovnev, Noah Singer, Raghuvansh Saxena, Amirbehshad Shahrasbi and Ameya Velingker – for the collaborations and discussions which informed this survey. They also caught numerous errors and gave suggestions that have hopefully made this survey more readable. I want to thank the organizers of ICALP 2022 for inviting me to write this survey, and to David Woodruff in particular for the additional encouragement and nudges that were crucial to get me going.

1 Introduction

In this article we survey the current state of knowledge on the *approximability* of *constraint satisfaction problems (CSPs)* using small space *streaming* and *sketching* algorithms. We start by reviewing the definitions below before turning to the survey of results.

2 CSPs: What and Why

CSPs form an infinite class of optimization problems where the goal is to assign n variables values from a finite set while maximizing the number of constraints that can be satisfied, where each constraint looks locally at the assignment of a few variables to determine if it is satisfied on not. Different problems in the class differ based on which type of constraints are allowed. Different instances of the problem arise by applying the constraints to different subsets (or subsequences) of variables. Algorithms aim to compute, or approximate, the maximum, over all assignments, of the fraction of constraints that can be simultaneously satisfied. Resource restrictions on the algorithm (time, space, number of passes in the streaming setting) as well

as the type of constraints allow to determine the level of approximability that is feasible. In this survey we describe our knowledge of the approximability of CSPs when restricted to streaming and sketching algorithms with limited space.

We start by describing CSPs more formally. For positive integer n we use $[n]$ to denote the set $\{1, \ldots, n\}$ and $\mathbb{Z}_n$ to denote the set $\{0, \ldots, n-1\}$. A CSP problem is described by positive integers k, q and a family of functions $\mathcal{F} \subseteq \{f : \mathbb{Z}_q^k \to \{0,1\}\}$. Since k, q are implicit in $\mathcal{F}$, we refer to this problem as $\mathsf{Max\text{-}CSP}(\mathcal{F})$. Given variables $X_1, \ldots, X_n$, an assignment to the variables is a sequence $\mathbf{a} = (a_1, \ldots, a_n) \in \mathbb{Z}_q^n$. A constraint C on these variables is given by a pair $(f, (j_1, \ldots, j_k))$ where the first element of the pair $f \in \mathcal{F}$ is the choice of the type of constraint and the second element is a sequence of k *distinct* indices with $j_i, \ldots, j_k \in [n]$. An assignment $\mathbf{a}$ satisfies $C = (f, (j_1, \ldots, j_k))$ if and only if $f(a_{j_1}, \ldots, a_{j_k}) = 1$. We use $C(\mathbf{a})$ to denote the quantity $f(X_{j_1}, \ldots, X_{j_k})$. An instance of $\mathsf{Max\text{-}CSP}(\mathcal{F})$ on n variables and m constraints is given by $\Psi = (C_1, \ldots, C_m)$ with C_i being a constraint on $X_1, \ldots, X_n$ for every $i \in [m]$. Given a assignment $\mathbf{a}$ to the variables, the value on the instance Ψ at $\mathbf{a}$, denoted $\mathsf{val}_\Psi(\mathbf{a})$, is the quantity $\frac{1}{m}\sum_{i\in[m]} C_i(\mathbf{a})$, i.e., the value is the fraction of constraints of Ψ that are satisfied by $\mathbf{a}$. The value of the instance val_Ψ is defined to be the maximum value over all assignments, i.e., $\mathsf{val}_\Psi = \max_{\mathbf{a}\in[q]^n}\{\mathsf{val}_\Psi(\mathbf{a})\}$. The goal of CSP optimization algorithms is to compute, or approximate, val_Ψ given Ψ.[1]

Example. We illustrate the definition with the example of the Max-CUT problem, where given an undirected graph on vertex set $[n]$, the goal is to find a "cut" $S \sqcup \overline{S} = [n]$ that maximizes the number of edges crossing the cut (i.e, with one endpoint each in S and $\overline{S}$). This problem is captured by $q = k = 2$ and the family $\mathcal{F} = \{\oplus\}$ where $\oplus(u, v) = u + v \pmod 2$.

Note that in the example above, we could get positive integer weighted graphs also since there is no requirement that the constraints themselves be distinct. For simplicity we will assume the length on the stream is polynomial in n so that the weights are also polynomial, though as we point out later this restriction does not alter the complexity of the approximation problems much. But the graphs will not have any self-loops due to the "restriction" that the variables in a constraint have to be distinct. If one wished to consider the Max-CUT problem where self-loops are also allowed (though in the case of Max-CUT this would make no sense - since a self-loop can never be cut), then one could consider instances $\mathsf{Max\text{-}CSP}(\mathcal{F}')$ where $\mathcal{F}' = \{\oplus, F\}$ and $F(u, v) = \oplus(u, u)$ for all u, v. (So v is just a dummy variable and u is a variable which supplies both arguments to the cut function $\oplus$.) Thus while the requirement that the variables are distinct may appear as a restriction, it is not: For every family $\mathcal{F}$ there exists a family $\mathcal{F}'$ such that $\mathsf{Max\text{-}CSP}(\mathcal{F}')$ captures the $\mathsf{Max\text{-}CSP}(\mathcal{F})$ problem where variables are allowed to repeat.

We also remark that in some prior works in the Boolean setting, i.e., when $q = 2$, constraints may be applied to "literals", rather than "variables". We refer to these results as applying to Boolean CSPs over literals. In our setting we apply constraints only to variables. Again, our setting is more general than the setting of Boolean CSPs over literals in that for every family $\mathcal{F} \subseteq \{f : \mathbb{Z}_2^k \to \{0,1\}\}$ there is a family $\mathcal{F}'$ such that CSP with constraints from $\mathcal{F}$ applied to literals is the same problem as $\mathsf{Max\text{-}CSP}(\mathcal{F}')$. For example consider the Max-2-LIN problem, i.e., the CSP whose constraints are given by linear equations

[1] Throughout this paper we assume that $\mathcal{F}$ does not include the all 0 function. Such a function corresponds to placing constraints that are never satisfiable. Inclusion of such constraints in the family does not change the complexity of any of the tasks we consider since these constraints are easy to ignore.

modulo 2 on two distinct variables. Max-2-LIN is the Boolean CSP over literals over the family $\mathcal{F} = \{\oplus\}$. But if we let $\mathcal{F}' = \{\oplus, \overline{\oplus}\}$ where $\overline{\oplus}(u, v) = u + v + 1 \pmod 2$, then Max-2-LIN = Max-CSP($\mathcal{F}'$). On the other hand Max-CSP($\mathcal{F}$) is the Max-CUT problem which can not be expressed as a Boolean CSP over literals. Thus our setting is strictly richer in expressibility.

2.1 Why study CSPs?

Before going on to giving more precise descriptions of the approximation versions of CSPs and models of streaming algorithms, we digress to comment on why study CSPs at all.

CSPs do capture a host of natural optimization problems: Some familiar names of problems include the Maximum Cut problem in (undirected) graphs, the Maximum Dicut problem in directed graphs, the Maximum q-colorability problem in graphs, the Unique Games problem, etc. Each one of these problems on their own right has probably been the topic of multiple papers, and the umbrella of CSPs unifies their study. That being said this reason on its own is not as compelling as some of the other reasons we describe next – after all the study of CSPs does exclude many other natural optimization problems including problems based on connectivity in graphs such as flow maximization or congestion minimization. It also excludes global considerations such as balanced cuts or sparse cuts; and of course there are a host of non-graph-theoretic problems.

To this author, the real reason to study CSPs is that they tend to allow for finite classification. The first such result dates back to Schaefer [29] who studied the satisfiability of Boolean CSPS and showed that they exhibit a dichotomy. Feder and Vardi [17] explored the expressibility of different logics and arrived at a morally "broadest" set of problems ("Monotone Monadic SNP") that could potentially exhibit a dichotomy, and showed that this set of problems was essentially equivalent to CSPs over arbitrary finite alphabets. They posed the dichotomy of this class as an open question which was eventually resolved by Bulatov [7] and Zhuk [31] after many years of sustained attack. Subsequent works extended such classification quests to other classes of problems including optimization and counting. (See Creignou, Khanna and Sudan [15] for some of the early lines of work.) Many of these bodies are extensive, see e.g. the recent monograph by Cai and Chen [8] and references therein for vast explorations of counting problems. In optimization and approximation the work of Raghavendra [28] gives a fine dichotomy, under the "Unique Games Conjecture", that inspires some of the streaming work we describe in this survey.

Finite classifications are interesting in that they highlight the generality of some algorithms. Even the weak classification of the approximability of CSPs pointed to the general utility of the randomized rounding and Max Flow algorithms [25]. The sharp characterizations in [28] point to the power of semidefinite programming and specifically to the sum-of-squares framework of algorithms. One could also ask similar questions in the context of streaming: The dichotomy work presented in this survey does highlight the role of norm estimation algorithms in streaming optimization. Other algorithms might emerge with further exploration.

Finite classifications also point to interesting phenomena. For instance in the context of polynomial time approximability most natural problems have approximability in well separated bands of functions: constant factor approximations, polylogarithmic approximations, and polynomial approximations are common whereas very few have intermediate approximability, say to within a factor of $2^{\sqrt{\log n}}$. A finite classification implies this phenomenon - the entire infinite class of functions only shows finitely many distinct behaviors. A similar phenomenon again seems to occur with streaming algorithms – many problems have

polylogarithmic space approximation algorithms while others require polynomially growing space. Intermediate complexity is rare. CSPs again seems to validate this separation, at least in the context of sketching algorithms, as we will see in the rest of this survey.

3 Preliminaries: Approximation and Streaming

We formalize some basic notions related to approximation problems and streaming algorithms. While a reader familiar with the notion might skip ahead we recommend they make sure they understand the notions (and notations) of: (i) trivial approximation algorithms, (ii) gapped optimization problems and the notation: (γ, β)-Max-CSP($\mathcal{F}$) (iii) approximability and approximation-resistance and (iv) sketching algorithms.

3.1 Approximating CSPs

Since solving Max-CSP($\mathcal{F}$) exactly can be quite hard for most $\mathcal{F}$ we turn often to algorithms that produce approximate solutions. We discuss some basic definitions regarding these in this section. All definitions restrict algorithms to come from some resource-bounded class $\mathcal{C}$. While we defer the discussion of the specific classes considered to later sections, here we consider definitions for a generic such class $\mathcal{C}$.

The most common notion of approximation is an α-approximation algorithm for some $\alpha \in [0, 1]$. An α-approximation algorithm $\mathbf{ALG}$ for Max-CSP($\mathcal{F}$) is one that for every instance Ψ outputs a value $\mathbf{ALG}(\Psi)$ satisfying $\alpha \cdot \mathsf{val}_\Psi \leq \mathbf{ALG}(\Psi) \leq \mathsf{val}_\Psi$.[2] We say Max-CSP($\mathcal{F}$) is α-approximable in $\mathcal{C}$ if there exists $\mathbf{ALG} \in \mathcal{C}$ that is an α-approximation algorithm for Max-CSP($\mathcal{F}$).

A more refined notion of approximation that is more common in the literature proving non-existence of algorithms is associated with gapped problems. Given $0 \leq \beta < \gamma \leq 1$, we say that an algorithm $\mathbf{ALG}$ solves the "(γ, β)-approximation version of Max-CSP($\mathcal{F}$)", abbreviated (γ, β)-Max-CSP($\mathcal{F}$), if the following two conditions hold: (1) For every Ψ such that $\mathsf{val}_\Psi \geq \gamma$, we have $\mathbf{ALG}(\Psi) = 1$ and (2) For every Ψ such that $\mathsf{val}_\Psi \leq \beta$, we have $\mathbf{ALG}(\Psi) = 0$. We say that (γ, β)-Max-CSP($\mathcal{F}$) is solvable in $\mathcal{C}$ if there exists an $\mathbf{ALG} \in \mathcal{C}$ solving (γ, β)-Max-CSP($\mathcal{F}$).

Assuming $\mathcal{C}$ satisfies mild closure properties the latter notion roughly captures α-approximability precisely, while giving more detailed information. To see some flavor of the translation between the two notions, suppose Max-CSP($\mathcal{F}$) is α-approximated by $\mathbf{ALG}$. Now consider a pair γ, β with $\beta < \alpha\gamma$. Then the algorithm $\mathbf{ALG}'$ that outputs $\mathbf{ALG}'(\Psi) = 1$ if $\mathbf{ALG}(\Psi) > \beta$ and 0 otherwise solves (γ, β)-Max-CSP($\mathcal{F}$). And if $\mathcal{C}$ satisfies the closure property that $\mathbf{ALG}' \in \mathcal{C}$ whenever $\mathbf{ALG} \in \mathcal{C}$ then it follows that α-approximability in $\mathcal{C}$ implies (γ, β)-Max-CSP($\mathcal{F}$) is solvable in $\mathcal{C}$ for every $\beta < \alpha\gamma$. A rough converse is also true, again assuming some (this time more stronger) closure properties of $\mathcal{C}$ that we leave unspecified: If for some α we have that for every $\gamma \in [0, 1]$, the (γ, β)-Max-CSP($\mathcal{F}$) is solvable in $\mathcal{C}$ for $\beta = \alpha\gamma$, then for every $\epsilon > 0$ we have that Max-CSP($\mathcal{F}$) is $\alpha - \epsilon$ approximable in $\mathcal{C}$. (See [13, Proposition 2.21] for a detailed statement and proof.)

The discussion above explains why the study of (γ, β)-Max-CSP($\mathcal{F}$) (for every γ, β and $\mathcal{F}$) is at least as rich as the study of α-approximability of Max-CSP($\mathcal{F}$). But it can provide more detailed information. For instance researchers are often interested in approximating the value

[2] Note that a small space streaming algorithm has very little hope of outputting a near-optimal solution which might take $\Omega(n)$ space to represent. So we require our algorithms only to output the value achieved by the optimal, or approximately-optimal, solution.

on satisfiable, or nearly satisfiable, instances. (See for instance, [16, 4, 27] for such works in the setting of $\mathcal{C}$ being all polynomial time algorithms.) We can understand these corner cases by focussing on $\gamma = 1$ or $\gamma \to 1$ and exploring the maximal β such that (γ, β)-Max-CSP($\mathcal{F}$) is solvable in $\mathcal{C}$. For instance recent results show that for every $\beta < 1$, $(1, \beta)$-Max-DICUT is solvable in $\mathcal{C}$ when $\mathcal{C}$ is the class of polylog space bounded sketching algorithms – a result that is not captured by the single parameter approximability of the problem.

Before concluding we also highlight what is a "non-trivial" approximation. For families $\mathcal{F}$ where every constraint has at least one satisfying assignment this notion is quite simple. We say that an algorithm that outputs a constant (independent of the input Ψ) is a trivial algorithm. Note that trivial algorithms are still legitimate approximation algorithms. For instance the algorithm that always outputs $1/2$ is a $1/2$-approximation for Max-CUT – this is so since no instance Ψ of Max-CUT has $\mathsf{val}_\Psi < 1/2$. We say that an approximation ratio is non-trivial if it is not achieved by a trivial algorithm. Similarly we say that a (γ, β)-approximation is non-trivial if $\gamma < 1$ and there exists an instance Ψ with $\mathsf{val}_\Psi \leq \beta$. To quantify this notion of non-triviality we define $\rho_{\min}(\mathcal{F})$ to be $\inf_{\Psi \text{ instance of Max-CSP}(\mathcal{F})}\{\mathsf{val}_\Psi\}$. We say that a Max-CSP($\mathcal{F}$) is *approximation resistant* to $\mathcal{C}$ if for every $\alpha > \rho_{\min}(\mathcal{F})$ no algorithm $\mathbf{ALG} \in \mathcal{C}$ is an α-approximation to Max-CSP($\mathcal{F}$). Equivalently for every $\rho_{\min}(\mathcal{F}) < \beta < \gamma < 1$ it is the case that (γ, β)-Max-CSP($\mathcal{F}$) is not solvable in $\mathcal{C}$. We say Max-CSP($\mathcal{F}$) is *approximable* in $\mathcal{C}$ if it is not *approximation resistant* to $\mathcal{C}$.

In what follows we will describe works exploring the various approximation factors achievable for Max-CSP($\mathcal{F}$) for different $\mathcal{F}$ with streaming algorithms that have bounded space. We shall also explore some restrictions of streaming algorithms known as sketching algorithms. We introduce these terms below.

3.2 Streaming and Sketching algorithms

We consider the approximability of Max-CSP($\mathcal{F}$) when the input instance $\Psi = (C_1, \ldots, C_m)$ is presented as sequence of constraints to the approximating algorithm. The algorithm is restricted in the amount of space it is provided. We allow the algorithm to be randomized: in all upper bounds the algorithm will be expected to generate and store any randomness in the restricted space it is given, while in the lower bounds we will rule out algorithms that are a distribution over deterministic algorithms (and so strictly more general).

Formally a space $s(n)$-streaming algorithm for (γ, β)-Max-CSP($\mathcal{F}$) on n variables is given by a pair of functions (τ, ν) where $\Gamma : \{0,1\}^{s(n)} \times \Lambda_n \to \{0,1\}^{s(n)}$ is the state transition function and output function $\nu : \{0,1\}^{s(n)} \to \{0,1\}^{s(n)}$, where $\Lambda_n = \Lambda_n(\mathcal{F})$ denotes the set of all possible constraints of Max-CSP($\mathcal{F}$) on n variables.On input a stream $\boldsymbol{\sigma} = (C_1, \ldots, C_m) \in \Lambda_n^m$ the algorithm first computes the state $S(\boldsymbol{\sigma}) = S_m$ where $S_i = \Gamma(S_{i-1}, C_i)$ for $i \in [m]$ and $S_0 = 0$ in the deterministic case. It then outputs $\nu(S(\boldsymbol{\sigma}))$. A randomized streaming algorithm is the same except that now the initial state S_0 is distributed uniformly randomly over $\{0,1\}^{s(n)}$.

In this paper we will also focus on a restriction of streaming algorithms known as sketching algorithms. To define this notion consider the concatenation of two streams $\boldsymbol{\sigma} \circ \boldsymbol{\tau}$. By definition of a streaming algorithm the final state $S(\boldsymbol{\sigma} \circ \boldsymbol{\tau})$ can be determined from $S(\boldsymbol{\sigma})$ and $\boldsymbol{\tau}$. A sketching algorithm is one that is restricted even further in that $S(\boldsymbol{\sigma} \circ \boldsymbol{\tau})$ can be determined from $S(\boldsymbol{\sigma})$ and $S(\boldsymbol{\tau})$, i.e., there exists a composer function $C : \{0,1\}^{s(n)} \times \{0,1\}^{s(n)} \to \{0,1\}^{s(n)}$ such that for every $\boldsymbol{\sigma}, \boldsymbol{\tau} \in \Lambda_n^*$, we have $S(\boldsymbol{\sigma} \circ \boldsymbol{\tau}) = C(S(\boldsymbol{\sigma}), S(\boldsymbol{\tau}))$.

Most common sketching algorithms are obtained from so called "linear-sketching algorithms" where $C \in \Gamma_n$ is viewed as a vector in $v \in \mathbb{R}^N$ for some large N, and a stream $(C_1, \ldots, C_m)$ represents the sum of the m corresponding vectors $v_1 + \cdots + v_m$. The sketch

of a vector v is given by Av where $A \in \mathbb{R}^{N \times s}$ projects v down to some low-dimensional subspace. Ignoring bit precision issues this compresses large N dimensional inputs into small s dimensional sketches that end up giving significant information about the original input, surprisingly often. It is easy to see that such linear sketching algorithms indeed satisfy the definition of sketching.

In the rest of this article we describe the surprising effectiveness of sketching algorithms in approximating Max-CSP($\mathcal{F}$). We also describe matching lower bounds for sketching algorithms that often generalize also to give streaming lower bounds.

4 Results on Streaming CSPs

Prior to 2010, despite extensive work on streaming algorithms and lower bounds for other problems, there were no works covering CSPs. This was even noted at a workshop at Bertinoro in 2011 [21].

Lower bounds for Max-CUT

The first works focussed on lower bounds for the Max-CUT problem in independent works by Kogan and Krauthgamer [26] and Khanna, Kapralov and Sudan [22]. The former showed that there existed $\alpha < 1$ such that α-approximating Max-CUT requires $\Omega(\sqrt{n})$-space. The latter showed the tighter result showing that for every $\alpha > 1/2$, α-approximating Max-CUT requires $\Omega(\sqrt{n})$-space in the streaming setting. In other words Max-CUT is approximation resistant to $o(\sqrt{n})$ space streaming algorithms. Subsequent works focussed on the space complexity and pushed it higher. Khanna, Kapralov, Sudan and Velingker [23] pushed the space requirement up to linear at the cost of a weaker approximation; specifically they showed that there exists $\alpha < 1$ such that α-approximating Max-CUT requires $\Omega(n)$-space. Finally, in a tour-de-force work, Kapralov and Krachun [24] settled the approximability of Max-CUT essentially completely by showing it is approximation resistant to $o(n)$ space streaming algorithms.

An aside is in order here: The input to a Max-CSP($\mathcal{F}$) has length $O(m \log n)$ and even if we forbid repeated constraints m can be as large as n^k. So, a priori one could imagine space complexities of streaming algorithms being much higher than $O(n)$. But a folklore observation shows that it suffices for the streaming algorithm to maintain a random sample of $O(n/\epsilon^2)$ constraints and the optimum value on the sampled constraints is a $(1-\epsilon)$ approximation to the optimum value on the input instance.[3] Since this sample of constraints takes only $O(n \log n)$ space to store and the optimal value for this sample can be computed in $O(n)$ space (though using exponential time), it follows that $O(n \log n)$ space suffices to get α-approximation for every Max-CSP($\mathcal{F}$) problem for every $\alpha < 1$. In particular, returning to the Max-CUT problem, the space lower bound from [24] is optimal to within a logarithmic factor.

Upper bounds for Max-DICUT

While the lower bounds for Max-CUT are technically hard (especially [24]) arguably these results are not very surprising: A streaming algorithm with limited (say polylogarithmic) space seems hardly capable of understanding the global structure imposed by the many

[3] This observation also relies on the fact that the value of every instance is bounded away from 0, which in turn relies on the fact that 0 is not a constraint function in $\mathcal{F}$.

different constraints and understanding how well they can be satisfied simultaneously. Indeed the lower bounds of [22] show that $o(\sqrt{n})$ space streaming algorithms can not distinguish random graphs from random bipartite graphs with a planted bipartition. In view of such limited power to understand the global structure it would not have surprised some researchers (notably this author) if every Max-CSP($\mathcal{F}$) problem had turned out to be approximation resistant to $o(n)$-space streaming algorithms. In other words – it was conceivable in 2015 that there were no non-trivial streaming algorithms for CSPs.

A striking paper of Guruswami, Velingker and Velusamy [19] changed the picture by giving an elegant and simple algorithm for approximating Max-DICUT, the problem whose input is a directed graph on vertex set $[n]$ and the goal is to find a cut $S \sqcup \overline{S}$ that maximized the number of edges going from S to $\overline{S}$. (This problem is expressible as Max-CSP($\mathcal{F}$) for $\mathcal{F} = \{u \wedge \overline{v}\}$.) The "trivial" approximability of this problem is 1/4, but [19] gave a non-trivial 0.4-approximation algorithm for this problem using polylogarithmic space.[4] The key insight to their algorithm is that one can estimate some non-trivial global information about the input by appealing to norm estimation algorithms that have been well explored in the sketching community. In particular their work relies on algorithms for estimating the ℓ_1 norm of a vector in the "turnstile" model which go back to the work of Indyk [20]. As we will discuss later, this algorithm can be generalized arguably quite surprisingly to many other CSPs.

Tight bounds and classification of Boolean binary CSPs

While the lower bound for Max-CUT is obviously tight, the Max-DICUT approximability of .4 from [19] was not known to be tight. From the $1/2 + \epsilon$-inapproximability of Max-CUT one can deduce a $(1/2 + \epsilon)$-inapproximability, for every $\epsilon > 0$, for Max-DICUT as well (by a reduction which maps every edge from an instance of Max-CUT to a pair of directed edges between the same vertices). Neither the algorithm nor the analysis appear tight. Indeed in a subsequent work, Chou, Golovnev and Velusamy [14] managed to improve both the algorithm and the lower bound to get a tight approximability of 4/9 for Max-DICUT. Specifically they give a polylog space algorithm achieving this approximation ratio and also prove that no streaming algorithm with $o(\sqrt{n})$ space can do better! This tight result for Max-DICUT may appear accidental, but [14] go further and classify the approximability of every Boolean (i.e., with $q = 2$) CSP on literals on binary constraints (i.e., $k = 2$). In doing so their work points to some remarkable phenomena: For every $\alpha \in [0, 1]$, every CSP in the finite, but nevertheless diverse, class they consider either is α-approximable in polylogarithmic space, or is not $\alpha - \epsilon$ approximable (for every $\epsilon > 0$) with $o(\sqrt{n})$ space. And in all cases the approximation algorithm uses the ℓ_1-norm approximator in a manner similar to [19]. Together these results suggest a broader phenomenon explored and somewhat confirmed in the further work reported next.

Sketching complexity of CSPs

In joint work with Chou, Golovnev and Velusamy [13] we give a dichotomy result for all (γ, β)-Max-CSP($\mathcal{F}$) (i.e., for every $k, q, \mathcal{F}$ and every $\gamma, \beta \in [0, 1]$) for $o(\sqrt{n})$-space sketching algorithms, as described below.

[4] Throughout this article we will not spell out the exponent in polylogarithmic terms though of course the original papers give more detailed answers.

▶ **Theorem 1** ([13, Theorem 1.1]). *For every $q, k \in \mathbb{N}$, $0 \leq \beta < \gamma \leq 1$, and every $\mathcal{F} \subseteq \{\mathbb{Z}_q^k \to \{0,1\}\}$, one of the following two conditions holds: Either (γ,β)-Max-CSP($\mathcal{F}$) can be solved by a polylogarithmic space sketching algorithm, or for every $\epsilon > 0$, every sketching algorithm for $(\gamma-\epsilon,\beta+\epsilon)$-Max-CSP($\mathcal{F}$) requires $\Omega(\sqrt{n})$-space. Furthermore there is a polynomial space algorithm that decides, given γ, β and $\mathcal{F}$, which of the two conditions holds.*

A corollary to approximation resistance is the following: For every $\mathcal{F}$, either Max-CSP($\mathcal{F}$) is approximable by a polylogarithmic space sketching algorithm, or it is approximation resistant to $o(\sqrt{n})$-space sketching algorithms.[5] In the special case of $k = q = 2$ the lower bound above extends beyond sketching algorithms to all streaming algorithms ([13, Theorem 1.3]). Put together these results subsume all previous works with the exception of the linear space lower bound for Max-CUT from [24]. Even in the case of $k = q = 2$ the dichotomy is more detailed than the one in [14] in that it covers all CSPs, not just CSPs on literals, and it also talks about the solvability of all (γ,β)-Max-CSP($\mathcal{F}$) and not only the best approximation ratio. For example the results show that for every sufficiently small $\epsilon > 0$, $(1-\epsilon, 1-2\epsilon)$-Max-DICUT is solvable by a polylogarithmic space sketching algorithm while $(1-\epsilon, 1-2\epsilon+\delta)$-Max-DICUT requires $\Omega(\sqrt{n})$ space for every streaming algorithm for every $\delta > 0$. In particular it asserts that nearly satisfiable instances are detectable by small space sketching algorithms.

The sketching algorithms used for the positive result in Theorem 1 builds on the algorithm of [14], which we refer to as a "bias-based algorithm" here. We will discuss that algorithm further later, but highlight one major difference. Rather than appealing to ℓ_1-norm estimation algorithms, the new algorithm appeals to a matrix norm estimation algorithm, this time from the work of Andoni, Krauthgamer and Onak [1]. (Roughly the ℓ_1 norm given by $\|(x_1,\ldots,x_n)\|_1 = \max_{b_1,\ldots,b_n \in \{-1,+1\}} \sum_{i=1} b_i x_i$ optimizes over a Boolean domain. The matrix norm estimators allow us to optimize some problems over q-ary domains.)

While the theorem holds out the possibility that there are non-trivial approximation algorithms for (infinitely) many CSPs, this is not immediate from the theorem statement due to the lack of "explicitness" of the classification. Specifically there is no simple relationship that says given $\mathcal{F}$ what range of γ and β are "easy" (i.e., solvable in polylog space) and which ones are not. This is unfortunately inevitable. As $\mathcal{F}$ gets more complex the relationships do seem to get more complex. The results of [13] show that γ and β are determined by optimizing some $O(q^k)$ real variable linear function over the reals subject to some degree k polynomial constraints. Even in the case of Max-DICUT this leads to some degree 2 polynomials in γ and β that determine the complexity. (See [13, Example 1, Pages 21-23] for more details.) Nevertheless the conditions can be analyzed computationally, and in particular using the quantified theory of reals (using only the existential theory does not seem to suffice) to understand the complexity of (γ,β)-Max-CSP($\mathcal{F}$) for any given $\gamma, \beta, \mathcal{F}$.

Remarkably some subsequent work has managed to extract explicit results, even for infinite families of functions, by exploring the decision conditions arising from the proof of Theorem 1. For instance, Boyland, Hwang, Prasad, Singer and Velusamy [6], analyze the approximability of Max-kAND for every $k \in \mathbb{N}$ – the problem where constraints are the conjunctions of k-literals – and give an exact expression for the approximation ratio of Max-kAND. (They show Max-kAND is approximable to within a factor that roughly looks like $2^{-(k-1)}(1-O(1/k))$ - see [6] for an exact expression.) In particular this gives an infinite subfamily of CSPs that is non-trivially approximable by the algorithm from [13]. [6] also pin down the approximability of some other symmetric functions. Another work, by Chou,

[5] This corollary is not immediate from the theorem statement, but uses some additional aspects of the proof. See [13, Theorem 2.14] for details.

Golovnev, Shahrasbi, Sudan and Velusamy [10], also analyzes the sketching approximability of some linear threshold functions, giving some infinite families that are approximation-resistant to $o(\sqrt{n})$-space sketching algorithms and other infinite families that are approximable by polylog space sketching algorithms.

Streaming Lower Bounds

While the classification essentially only rules out sketching algorithms using $o(\sqrt{n})$-space for the hard problems, for a broad class of problems it even rules out non-trivial streaming algorithms. In fact for all problems it pins down the polylogarithmic space approximability to within a factor of q – we expand on this later below, but first speak about broad classes of approximation resistant problems. We start with some definitions.

We say that a distribution $\mathcal{D}$ on $\mathbb{Z}_q^k$ is one-wise independent if for every $i \in [k]$ we have that when $X = (X_1, \ldots, X_k)$ is sampled according to $\mathcal{D}$, then X_i is distributed uniformly over $\mathbb{Z}_q$. We say that $f : \mathbb{Z}_q^k \to \{0,1\}$ supports one-wise independence if there is a one-wise independent distribution $\mathcal{D}$ supported on a subset of the satisfying assignments of f, i.e., if $\mathbf{a} \in \mathbb{Z}_q^k$ has positive probability under $\mathcal{D}$ then $f(\mathbf{a}) = 1$. We say that $\mathcal{F}$ *supports one-wise independence* if every function $f \in \mathcal{F}$ supports one-wise independence. We say that $\mathcal{F}$ *weakly supports one-wise independence* if there exists $\mathcal{F}' \subseteq \mathcal{F}$ such that $\rho_{\min}(\mathcal{F}') = \rho_{\min}(\mathcal{F})$ and $\mathcal{F}'$ supports one-wise independence.

▶ **Theorem 2** ([13, Theorem 2.17]). *If $\mathcal{F}$ weakly supports one-wise independence, then $\mathcal{F}$ is approximation-resistant to $o(\sqrt{n})$-space streaming algorithms.*

Many natural families support one-wise independence. For readers familiar with some of these problems, we name some here without definitions: Max-Exact-kSAT for $k \geq 2$, Max-kOR, Max-CUT, Max-qColoring, Max-Unique-Games$_q$ to name a few. All of these problems turn out to be approximation-resistant by the above theorem.

Linear space lower bounds

Another direction of work has tried to extend the results of [24], i.e., $\Omega(n)$-space streaming lower bounds, to problems beyond Max-CUT. Here, we are far from a full understanding, but we do get approximation resistance for a (strict) subclass of families supporting one-wise independence. We define the families next.

For a function $f : \mathbb{Z}_q^k \to \{0,1\}$ and $\mathbf{a} \in \mathbb{Z}_q^k$ we define the *width of f at $\mathbf{a}$* to be $\omega_{\mathbf{a}}(f) = \frac{1}{q}|\{\theta \in \mathbb{Z}_q | f(\mathbf{a} + (\theta, \theta, \cdots, \theta)) = 1\}|$. We define the *width* of f to be the quantity $\omega(f) = \max_{\mathbf{a} \in \mathbb{Z}_q^k}\{\omega_{\mathbf{a}}(f)\}$, i.e. the maximum over $\mathbf{a}$ of the width of f at $\mathbf{a}$. (Roughly the set $L_{\mathbf{a}} = \{\mathbf{a} + (\theta, \theta, \cdots, \theta) | \theta \in \mathbb{Z}_q\}$ is a *line* through $\mathbb{Z}_q^k$ and $\omega_{\mathbf{a}}(f)$ measures the density of the intersection of this line with $f^{-1}(1)$, and the width of f is the widest such intersection.) We define the *width* of $\mathcal{F}$, denoted $\omega(\mathcal{F})$, to be the minimum over $f \in \mathcal{F}$ of the width of f. Note that $1/q \leq \omega(\mathcal{F}) \leq 1$ for every $\mathcal{F}$. Finally we say that $\mathcal{F}$ is *wide* if $\omega(\mathcal{F}) = 1$, i.e., the width is maximal.

A simple example of a wide family is the k-equality function $f_{k\mathsf{EQ}}$ where $f_{k\mathsf{EQ}}(u_1, \ldots, u_k) = 1$ if and only $u_1 = \cdots = u_k$. Note that every wide family supports one-wise independence. But there exist functions supporting one-wise independence that are not wide: For example $\oplus_3 : \mathbb{Z}_2^3 \to \{0,1\}$ given by $\oplus_3(a,b,c) = a + b + c \pmod 2$ supports one-wise independence but has width $1/2$.

The following theorem is shown in joint work with Chou, Golovnev, Velingker and Velusamy [11].

▶ **Theorem 3** ([11, Theorem 1.1]). *For every wide family $\mathcal{F}$, Max-CSP($\mathcal{F}$) is approximation-resistant to $o(n)$-space streaming algorithms.*

We will not cover any aspects of the proof of this theorem in this article, except to say that it builds on the proof of [24] following exactly the same sequence of steps, while replacing every step in their proof with ingredients needed to handle k-ary functions over non-Boolean alphabets. While the class of functions covered by this theorem is even smaller than the set covered by Theorem 2, it suffices to imply the following theorem which pins down the approximability of every Max-CSP($\mathcal{F}$) to within a factor of q.

▶ **Theorem 4** ([11, Theorem 4.3]). *For every family $\mathcal{F}$ and every $\epsilon > 0$, $(\omega(\mathcal{F}) - \epsilon, \rho(\mathcal{F}) + \epsilon)$-Max-CSP($\mathcal{F}$) requires $\Omega(n)$ space for every streaming algorithm. Consequently, for every $\mathcal{F}$ the largest α for which Max-CSP($\mathcal{F}$) is α-approximable by a $o(n)$-space streaming algorithm satisfies $\alpha \in \left[\rho_{\min}(\mathcal{F}), \frac{\rho_{\min}(\mathcal{F})}{\omega(\mathcal{F})}\right]$.*

We remark that while Theorem 4 immediately implies Theorem 3, the proof in [11] essentially derives the former from the latter using simple arguments.

4.1 Aside: Ordering CSPs

Before turning to some of the technical ingredients in the proofs we take a brief detour to cover an application of the results described above to a somewhat different class of optimization problems called ordering CSPs. We describe this class informally first: Recall that the solution space of the standard CSPs (the ones we work with in the rest of this paper) comes from a product set, namely an n-tuple of variables $(X_1, \ldots, X_n)$ takes values from $\mathbb{Z}_q \times \mathbb{Z}_q \times \cdots \times \mathbb{Z}_q$. A variation of this theme considers the setting where the variables need to be ordered, i.e., the $(X_1, \ldots, X_n)$ take on values from $\mathrm{Sym}_n = \{\pi : [n] \to [n] \mid \pi \text{ is one-to-one}\}$. (I.e., $X_i = \pi(i)$ where π is a permutation.) The natural notion of local constraints on ordering problems pick sequences of k distinct variables out of the n variables (as in standard CSPs) and look at the ordering from Sym_k induced by these k variables and constrain them. Thus a constraint function in ordering CSPs is given by $\Pi : \mathrm{Sym}_k \to \{0, 1\}$ and constraint families are a set of constraint functions. Thus for every k and every family $\mathcal{F} \subseteq \{\Pi : \mathrm{Sym}_k \to \{0, 1\}\}$ we get an ordering CSP, denoted Max-OCSP($\mathcal{F}$). (Note that unlike in standard CSPs, there is no notion of an alphabet or q in the case of ordering CSPs.)

Two examples of ordering CSPs include the Maximum Acyclic Subgraph (MAS) problem and the Betweenness problem. The former asks, given a directed graph G, to find the largest acyclic subgraph in it. This problem is captured as Max-OCSP($\{<\}$) where $<: \mathrm{Sym}_2 \to \{0, 1\}$ satisfies $<(\pi) = 1$ if and only if $\pi(1) < \pi(2)$. By placing the constraint $<(i, j)$ for every directed edge (i, j) in a graph G, we get an Max-OCSP($<$) instance that exactly captures the MAS instance. Betweenness is the ordering problem where constraints are given by a triple of variables and require that the ordering place the middle variable between the first and third (though allowing either of the first or the third to be the higher ranked variable). Once again it can be naturally formulated as an ordering CSP.

With ordering CSPs again, one can ask what is the trivial approximability of an ordering CSP and when can a ordering CSP be solved non-trivially. Both questions turn out to have simple answers though somewhat disappointing ones from the algorithmic point of view. Note that a random ordering satisfies a constraint Π with probability $\rho(\Pi) \stackrel{\text{def}}{=} \frac{1}{k!} \cdot |\Pi^{-1}(1)|$. Letting $\rho(\mathcal{F}) = \min_{\Pi \in \mathcal{F}}\{\rho(\Pi)\}$ we get that every instance of Max-OCSP($\mathcal{F}$) has value at least $\rho = \rho(\mathcal{F})$, and thus ρ-approximation is trivial. It turns out that there are no algorithms (that can do better for any $\mathcal{F}$ running in $o(n)$-space), as shown in the following theorem from joint work with Singer and Velusamy [30].

▶ **Theorem 5.** *For every k, every family $\mathcal{F} \subseteq \{\Pi : \mathrm{Sym}_k \to \{0, 1\}\}$ and every $\epsilon > 0$, every streaming $(\rho(\mathcal{F}) + \epsilon)$-approximation algorithm for Max-OCSP($\mathcal{F}$) requires $\Omega(n)$ space.*

5 Some ideas behind the proofs

5.1 The $\Omega(\sqrt{n})$ space lower bound for Max-CUT

We start with the lower bound from [22] on the Max-CUT problem. We start with some basic ideas about lower bounds. Lower bounds in streaming are typically "distributional". To prove a lower bound on (γ,β)-Max-CSP($\mathcal{F}$) for some $\gamma,\beta,\mathcal{F}$, for every sufficiently large n we construct two distributions of instances on n variables – the **YES** and **NO** distributions. The **YES** distributions are supported with probability $1-o(1)$ on instances from the set $\Gamma=\{\Psi|\mathsf{val}_\Psi\geq\gamma\}$. Similarly, the **NO** distributions are supported with probability $1-o(1)$ on instances from the set $B=\{\Psi|\mathsf{val}_\Psi\leq\beta\}$. In the case of Max-CUT we will thus consider a **YES** distribution supported (with probability one) on bipartite graphs, and **NO** instances will have cut value at most $1/2+o(1)$ (with probability $1-o(1)$). The goal is to prove that for any space s algorithm **ALG** with $s=o(\sqrt{n})$ the distribution of the final state of **ALG** in the **YES** and **NO** cases are very close in total variation distance. (For distributions $\mathcal{D},\mathcal{D}'$ supported on some set Ω the total variation distance, denoted $\|\mathcal{D}-\mathcal{D}'\|_{\mathrm{tv}}$, is the quantity $\frac{1}{2}\sum_{\omega\in\Omega}|\mathcal{D}(\omega)-\mathcal{D}'(\omega)|$.) Since the inputs are random, it suffices to consider deterministic $s(n)$-space bounded algorithms.

Both distributions are parameterized by two constants: a small $\alpha\in(0,1)$ and large, but constant, integer T. The graphs are defined on vertex set $[n]$ and have roughly $(\alpha/2)\cdot T\cdot n$ edges. These edges come as the union of T matchings $M'_1,\ldots,M'_T$, each with roughly $\alpha n/2$ edges.In the **NO** distribution these matchings will just be uniform matchings of the right size (we will get to the exact distribution of size shortly). In the **YES** distribution a random cut of $[n]$ is chosen by picking a vector $\mathbf{x}\in\{0,1\}^n$ uniformly at random and letting the cut be $\{i|x_i=1\}$. The matchings $M_1,\ldots,M_t$ are uniform subject to the condition that every matched edge crosses the cut. The lower bound is proved by a "hybrid argument" involving T steps. For $t\in\{0,\ldots,T\}$ let S^Y_t denote the state of **ALG** after seeing the first t matchings from the **YES** distribution, and similarly let S^N_t denote the state of **ALG** after the first t matchings from the **NO** distribution. By definition we have $S^Y_0=S^N_0$. The key step is to prove that for every t,

$$\|S^Y_t-S^N_t\|_{\mathrm{tv}}\text{ is small assuming }\|S^Y_{t-1}-S^N_{t-1}\|_{\mathrm{tv}}\text{ is small,}\tag{1}$$

and to use this result inductively to conclude $\|S^Y_T-S^N_T\|_{\mathrm{tv}}$ is small which shows that the two distributions are not distinguishable by small space algorithms. By construction the **YES** distribution is supported on bipartite graphs. If αT is sufficiently large then it can be argued by a standard Chernoff plus union bound that with probability $1-o(1)$, a graph from the **NO** distribution also has value at most $1/2+o(1)$ and together these suffice for the lower bound on Max-CUT. We thus turn to the proof of Equation (1).

The upper bound works by designing two-party one way communication problem that captures the added distinguishability of **YES** from **NO** conditioned on knowing $S^Y_{t-1}\approx_d S^N_{t-1}$ (where $\approx_d$ indicates that the two random variables are close in terms of total variation distance). A rough abstraction of this problem is as follows: Alice, who knows $\mathbf{x}$ must send some information about it to Bob. This information may capture information such as S^Y_{t-1} and/or S^N_{t-1}, both of which may in principle depend on $\mathbf{x}$, but should be limited to $o(\sqrt{n})$ bits. Now Bob, who gets to see M_t which is either (in the **YES** case) a random matching crossing the cut given by $\mathbf{x}$ or (in the **NO** case) a random matching, must distinguish the two.

It turns out a problem very similar to this was already defined and studied in the literature. Specifically, Gavinksy, Kempe, Kerenedis, Raz and de Wolf [18] define the Boolean Hidden Matching (BHP) problem where Alice is given a uniform vector $\mathbf{x}\in\mathbb{Z}_2^n$ and Bob is given a

matching $\widetilde{M}$ with $m = \alpha n$ edges on vertex set $[n]$ drawn uniformly among all such matchings, and a 0/1 labelling $\mathbf{w} \in \mathbb{Z}_2^m$ on the edges where in the **YES** case, the label w_e of an edge $e = (i, j)$ satisfies $w_e = x_i + x_j \pmod 2$, while in the **NO** case w_e's are uniformly random and independent. The goal of the communication is for Bob to distinguish the **YES** case from the **NO** case. [18] show that this problem requires $\Omega(\sqrt{n})$ bits of communication to achieve constant advantage in distinguishing. (The advantage of a protocol is the probability that the protocol outputs 1 in the **YES** distribution minus the probability it does so in the **NO** distribution. Specifically the [18] result shows that for every $\delta > 0$ there exists $\tau > 0$ such that for every $\alpha < 1/2$ and every sufficiently large n, every protocol that achieves advantage δ must communicate at least $\tau\sqrt{n}$ bits. These quantifiers are somewhat important as we will see below.)

To use the BHM lower bound from [18] we need to address two issues. First the input to Bob in the BHM problem is not the same as coming from the streaming problem. This problem is easy to deal with – Bob is getting more information in the BHM problem than in the motivating Max-CUT based problem, and this only makes the lower bound even stronger. Formally Bob can reduce an instance of BHM to the streaming inspired-problem by dropping all the edges e that have label $w_e = 0$. This gives Bob roughly $\alpha n/2$ edges (since each edge crosses the cut with probability roughly $1/2$ and these are roughly independent events) reducing exactly to the setting in the streaming-inspired problem.

The second and more important issue is that the BHM problem was only "roughly" motivated by the streaming problem above – we need a more careful and formal argument connecting the two. Formally we consider the random variables, S_t^Y, S_t^N and a hybrid variable $\widetilde{S}$, where $\widetilde{S}$ is the state of **ALG** on receiving $M_1, \ldots, M_{t-1}$ from the **YES** distribution and M_t from the **NO** distribution. The BHM lower bound immediately implies that $\widetilde{S} \approx_d S_t^Y$: The only difference between the two states is the tth input which comes from the **YES** distribution for S_t^Y and from the **NO** distribution for $\widetilde{S}$; and the setup of BHM allows Alice to generate and communicate S_{t-1}^Y to Bob allowing Bob to compute the final state and use **ALG** to distinguish them. To complement we also have $\|\widetilde{S} - S_t^N\|_{\text{tv}} \leq \|S_{t-1}^Y - S_{t-1}^N\|_{\text{tv}}$ by the data processing inequality: $\widetilde{S}$ is determined by S_{t-1}^Y and $M_t \sim$ **NO** while S_t^N is determined from S_{t-1}^N and M_t. We stress a subtle point here: It is crucial that M_t is independent of S_{t-1}^Y and S_{t-1}^N for this inequality to be applicable, and this does hold in our case since the **NO** distribution is independent of $\mathbf{x}$ which is the only variable connecting the different matchings in the **YES** case. (This subtlety is the reason why extensions of this proof apply only to families supporting one-wise independence, or only give sketching lower bounds.)

We also comment briefly on the choice of various parameters such as α, T, ϵ (where our goal is to prove hardness of $(1, 1/2 + \epsilon)$-Max-CUT), δ (the advantage allowed in BHM) and τ (where the space lower bound is $\tau\sqrt{n}$). We want our bound to hold for every $\epsilon > 0$ so given ϵ, we first pick α small enough for the BHM lower bound to hold. In our case it holds for every $\alpha < 1/2$. Given this choice of α we pick T large enough so that a graph from the **NO** distribution with $\alpha T n$ edges is very likely not to have a Max-CUT of fractional size more that $1/2 + \epsilon$. Given this choice we pick δ small enough so that T applications of the hybrid argument still lead to negligible advantage in distinguishing **YES** from **NO**. Finally the τ we obtain is whatever is guaranteed by the BHM lower bound for this choice of δ.

Our eventual streaming and sketching lower bounds will extend the ideas from above, but we will return to those after describing the algorithms for Max-DICUT from [19, 14].

5.2 Bias-based algorithms for Max-DICUT

The key ingredient in the algorithm of [19] for Max-DICUT is the notion of the "bias" of a graph on vertex set $[n]$. For a vertex v in a directed graph, let in-deg(v) denote the number of incoming edges into v and let out-deg(v) denote the number of outgoing edges. Now define $\mathsf{bias}(v) = \text{in-deg}(v) - \text{out-deg}(v)$, and define $\mathsf{bias}(G) = \frac{1}{2m}\sum_{v\in[n]} |\mathsf{bias}(v)|$. Thus if we term the vector $(\mathsf{bias}(v))_{v\in[n]} \in \mathbb{R}^n$ to be the bias-vector of the graph, then the bias of the graph is essentially the ℓ_1 norm of this vector up to normalization. As mentioned already, the ℓ_1-norm and hence the bias of a graph can be estimated arbitrarily well by a streaming algorithm presented with a stream of edges using an algorithm from [20]. The key to the algorithms of [19] and [14] are inequalities relating the bias of a graph to the dicut value, that allow them to output lower bounds of the value of the dicut. (For uniformity we will only talk about the fractional value here and later and use val_G to denote this quantity.)

Note that by definition $0 \leq \mathsf{bias}(G) \leq 1$ for every graph G on m vertices. [19] show that $\mathsf{val}_G \leq \frac{1+\mathsf{bias}(G)}{2}$. This inequality follows easily from the observation that every cut must leave at least $|\text{in-deg}(v) - \text{out-deg}(v)|$ of the edges incident to v uncut. Since every uncut edge may be counted twice by this process, we get a lower bound of $\frac{1}{2}\sum_v |\text{in-deg}(v) - \text{out-deg}(v)|$ on the number of uncut edges.

[19] complement upper bound above with a lower bound: For every G we must have $\mathsf{val}_G \geq \mathsf{bias}(G)$. This is "constructive" (though not in streaming sublinear space) – the greedy cut which puts all vertices with positive bias on the sink side of the cut and the rest on the source side achieves this. (A simple argument to see is iterative: Remove directed cycles from the graph one at a time till we get a DAG. This does not alter the bias. Now remove maximal length directed paths - each such path contributes one to the non-normalized bias, and also contributes at least one edge to the dicut since by maximality the source of the path must have zero indegree and the sink must have zero out degree.)

Combining the two bounds above with the lower bound $\mathsf{val}_G \geq 1/4$ for every G gives a .4 approximation algorithm: The algorithm computes $\mathsf{bias}(G)$ and outputs $\max\{\mathsf{bias}(G), 1/4\}$. To improve on this [14] give an improved lower bound on val_G when $\mathsf{bias}(G) \leq 1/3$. Their bound is also "constructive" - they consider a random dicut where each vertex of positive bias is placed on the sink side with probability $1/2 + \delta$ independently (for some parameter δ that we will optimize later). Remaining vertices are placed on the sink side with probability $1/2 - \delta$ independently. They analyze the cut produced by this rounding after optimizing over δ and use the expected size as an additional lower bound. We won't reproduce their bound or analysis here, but only comment that the analysis involves optimizing degree two rational functions in δ. This already gives them a 4/9 approximation algorithm.

The choice of a single rounding probability for all vertices in the graph is somewhat surprising. (This probability may depend on the graph and bias, but once the graph is fixed all vertices get rounded with the same probability.) It seems like a choice made for ease of analysis - optimizing a single variable δ is easier than optimizing n variables! One could nevertheless ask – could we have done better with more careful choices? The surprising result from [14] is that this won't help and indeed no $o(\sqrt{n})$-space algorithm can improve on the bound above! So somehow $\mathsf{bias}(G)$ is the right quantity to compute, and rounding independently with the same probability for all vertices (upto the choice of the preferred side) is the right algorithm!

5.3 The framework of [13]

To extend the algorithm of the previous section to problems beyond Max-DICUT, we need to understand what are notions of bias of a variable and of the whole instance for Max-CSP($\mathcal{F}$) for general $\mathcal{F}$. (In this discussion we will assume $\mathcal{F}$ has a single function f though extensions to more functions are straightforward.) Recall that in the Max-DICUT problem constraints arrive as pairs (i, j) where the edge goes from vertex i to vertex j. Thus the in-degree of a vertex could be abstract as the number of constraints in which it is the second variable, and out-degree as the number of constraints where it is the first variable. We use this to motivate a new notion of bias of a variable X_i, denoted $\mathsf{d\text{-}bias}(i)$ (for detailed bias): This will be a k dimensional vector whose jth coordinate $\mathsf{d\text{-}bias}(i)_j$ records the number of constraints in which X_i appears as the jth variable in a constraint. Considering all the biases of all vertices gives us an $n \times k$ matrix $B = B(\Psi)$ with $B(i, j) = \mathsf{d\text{-}bias}(i)_j$ that "represents" an instance Ψ.

The main idea in [13] can roughly be captured as follows: *If there exists $t \in \mathbb{N}$ and instances Ψ_g and Ψ_b on t variables with $B(\Psi_g) = B(\Psi_b)$ such that $\mathsf{val}_{\Psi_g} \geq \gamma$ and $\mathsf{val}_{\Psi_b} \leq \beta$ then Max-CSP($\mathcal{F}$) can not be solved in $o(\sqrt{n})$ space by a sketching algorithm. Else it can be solved by a polylogarithmic space linear sketching algorithm.* A priori neither statement should be obvious and we will give some idea below as to why they are true. Furthermore even if the statements are true it is not clear how to decide which of the two conditions hold (since a priori one may have to enumerate over all n and all pairs of instances to determine if the condition is true). It turns out all the issues get answered rather nicely jointly. It turns out that it suffices to consider (weighted) instances on kq variables to answer the final question, and studying the space of these instances also leads to the algorithms and the lower bounds.

Below we elaborate on this and in particular why it suffices to consider instances on a finite number of variables. We work with the simpler setting of Boolean CSPs (so $q = 2$) on literals, i.e., when constraints can be applied to variables as well as their negations. We note that the resulting setting ($|\mathcal{F}| = 1$, $q = 2$ and constraints on literals) is the case considered in a preliminary work [12], whereas the more general result comes from [13]. While the latter is a stronger result, the former offers more intuition into the proofs.

In this setting of constraints over Boolean literals, we show we only need to consider instances involving k variables – and we explain how this happens. Suppose there are two instances on n variables: Ψ_g with $\mathsf{val}_{\Psi_g} \geq \gamma$ and Ψ_b with $\mathsf{val}_{\Psi_b} \leq \beta$ satisfying $B(\Psi_g) = B(\Psi_b)$. We show how to simplify the two CSPs. From now onwards it will be convenient to think of a weighted CSP instance as being a distribution on constraints - where a constraint is chosen with probability proportional to its weight. Now, since we are considering Boolean CSPs on *literals* we can flip variables as necessary (by flipping literals in all constraints) till we get that 1^n is the assignment achieving $\mathsf{val}_{\Psi_g}(1^n) \geq \gamma$. To preserve $B(\Psi_g) = B(\Psi_b)$ we flip variables in Ψ_g and Ψ_b together. Note that this flipping preserves $\mathsf{val}_{\Psi_b} \leq \beta$. Next we observe that we can assume Ψ_g and Ψ_b are symmetric under permutations: I.e. if some constraint $C(X_1, \ldots, C_n)$ appears in Ψ_g with some probability p then for every permutation $\pi : [n] \to [n]$ the constraint $C(X_{\pi(1)}, \ldots, X_{\pi(n)})$ also appears in Ψ_g with the same probability p. (We can convert any Ψ to a Ψ' satisfying this feature as follows: To pick a random constraint of Ψ', pick a random constraint C of Ψ and a uniformly random permutation and let the constraint produced by $C(X_{\pi(1)}, \ldots, X_{\pi(n)})$.) This transformation preserves $\mathsf{val}_{\Psi_g} \geq \gamma$ since 1^n, the assignment achieving the maximum value is fixed under permutations. We also have that Ψ_b is closed under permutations since the (empty!) set of assignments that achieves value greater than β is also closed under permutations. The fact that Ψ_g and Ψ_b are symmetric under permutations make them very simple: All that determines these instances

is the distribution supported on $\mathbb{Z}_2^k$ indicating the pattern of negations of the k variables in a randomly chosen constraint. The names of the variables are no longer relevant – since they are just a uniformly random sequence of k distinct variables! Suppose $\mathcal{D}_Y$ represents the distribution on $\mathbb{Z}_2^k$ given by Ψ_g and $\mathcal{D}_N$ the distribution given by Ψ_b. We now study these distributions further and they will lead us to the answers to the three issues raised earlier.

The space of $\mathcal{D}_Y$ and $\mathcal{D}_N$

We can go back from distributions $\mathcal{D}$ over $\mathbb{Z}_2^k$ to instances $\Psi_{\mathcal{D}}$ of $\mathsf{Max\text{-}CSP}(\mathcal{F})$ on k variables $X_1, \ldots, X_k$ as follows: A random constraint of $\Psi_{\mathcal{D}}$ is of the form $f(X_1 \oplus b_1, \ldots, X_k \oplus b_k)$ where $\mathbf{b} = (b_1, \ldots, b_k) \sim \mathcal{D}$. Now the fact that $\mathcal{D}_Y$ came from an instance Ψ_g of value at least γ implies that the all 1's assignment satisfies $\Psi_{\mathcal{D}_Y}$. The fact that $B(\Psi_g) = B(\Psi_b)$ implies that $\mathcal{D}_Y$ and $\mathcal{D}_N$ have the same marginals. It remains to interpret the implication that $\Psi_b \leq \beta$: We stress that it does not mean $\Psi_{\mathcal{D}_N}$ has value less than β - indeed $\Psi_{\mathcal{D}_N}$ can have value much larger than that or even γ! The implication turns out to be exactly the following: "For every $p \in [0,1]$ if $X_1, \ldots, X_k$ are assigned values identically and independently according to $\mathsf{Bern}(p)$ (i.e., they take values in $\mathbb{Z}_2$ with $\Pr[X_i = 1] = p$), then the expected value $\mathsf{val}_{\Psi_{\mathcal{D}_N}}(X_1, \ldots, X_k) \leq \beta$." I.e., no identical and independent probabilistic assignment to the variables satisfies many constraints.

It turn out we can now capture these considerations on $\mathcal{D}_Y$ and $\mathcal{D}_N$ in a nice mathematical framework and that will lead to matching algorithms and lower bounds. Note that a distribution on $\mathbb{Z}_2^k$ can be viewed as a vector in $\mathbb{R}^{2^k}$ in a natural way, and the space of all distributions is a convex set in $\mathbb{R}^{2^k}$. Now let $S_\gamma^Y(f)$ denote the subset of this set representing distributions $\mathcal{D}$ such that $\mathsf{val}_{\Psi_{\mathcal{D}}}(1^k) \geq \gamma$. Similarly let $S_\beta^N(f)$ denote the subset of distributions $\mathcal{D}$ such that for every $p \in [0,1]$, $\mathbb{E}_{\mathbf{b} \in \mathsf{Bern}(p)^k}[\mathsf{val}_{\Psi_{\mathcal{D}}}(\mathbf{b})] \leq \beta$. Both these sets are convex sets! (In particular for every p, the constraint $\mathbb{E}_{\mathbf{b} \in \mathsf{Bern}(p)^k}[\mathsf{val}_{\Psi_{\mathcal{D}}}(\mathbf{b})] \leq \beta$ is a linear constraint on $\mathcal{D}$, though we have infinitely many such constraints.) By construction the two sets are disjoint for $\beta < \gamma$, but they may still contain distributions with matching marginals! To see this we may project these two sets to their marginals: So let $K_\gamma^Y(f) \subseteq \mathbb{R}^k$ be the set of marginals of all distributions in $S_\gamma^Y(f)$ and similarly let $K_\beta^N(f)$ be the marginals of $S_\beta^N(f)$. The discussion thus far has reduced the question: "Do there exist n and instances Ψ_1 and Ψ_2 on n variables with $B(\Psi_1) = B(\Psi_2)$ such that $\mathsf{val}_{\Psi_1} \geq \gamma$ and $\mathsf{val}_{\Psi_2} \leq \beta$?" to the much simpler and finite dimensional question "Do $K_\gamma^Y(f)$ and $K_\beta^N(f)$ intersect?". (An affirmative answer to one question implies an affirmative answer to the other.)

Before turning to show why this leads to algorithms or lower bounds we first point out that the question of the intersection of these two sets is decidable. Specifically the intersection question can be posed as polynomial inequalities in $2^k + 1$ variables (2^k from $\mathcal{D}$ and one from p) of degree at most $k + 1$ with one variable (p) being universally quantified and the rest being existentially quantified. Results in the quantified theory of reals [5] easily show how to decide this question in space polynomial in the input size, which in our case is roughly 2^k to represent the function f (and whatever else is needed to specify γ and β).

Sketching lower bound when $K_\gamma^Y(f) \cap K_\beta^N(f) \neq \emptyset$

It turns out that the existence of two distributions with matching marginals is the crux of the $\mathsf{Max\text{-}CUT}$ lower bound of [22] and so extending to other settings is a reasonable hope. Specifically the $\mathsf{Max\text{-}CUT}$ lower bound relies on $\mathcal{D}_Y = \mathsf{Unif}(\{00, 11\})$ and $\mathcal{D}_N = \mathsf{Unif}(\mathbb{Z}_2^2)$. To extend to other problems and distributions, we use the same approach of dividing a long stream of constraints into T substreams of length αn. A communication problem captures

the additional information gained by a substream while a hybrid argument combines the information gained from the substreams. Both steps turn out to be different though and we elaborate on them below.

The BHM problem could be interpreted as arising from the associated distributions above in two different ways. In both Alice gets $\mathbf{x} \in \mathbb{Z}_2^n$ and Bob's first input is a matching on $[n]$, which specifies potential constraints: Bob's second input can be interpreted in two ways: (1) For each constraint, he gets information on whether $\mathbf{x}$ satisfies the constraint or not, (2) Using the fact that $\mathcal{D}_Y$ is uniform on a subgroup of $\mathbb{Z}_2^2$, Bob gets input on which coset the variables in the constraint come from. The first interpretation doesn't seem naturally amenable to the lower bound techniques which seem more tailored to understanding inputs that are uniform in the **NO** case. The second interpretation seems restricted to groups and cosets and in particular does not seem to support $\mathcal{D}_Y$ not being uniform on a set, leave alone a subgroup. However it is possible to extend this approach beyond such algebraic settings and this is what is done in [13]. To do so they introduce the $(\mathcal{D}_Y, \mathcal{D}_N)$-Randomized Mask Detection Problem (RMD) which is again a distribution distinguishability problem in the one-way communication setting: Here Alice gets a vector $\mathbf{x} \in \mathbb{Z}_2^n$ and Bob gets a k hypermatching with $m = \alpha n$ edges. Additionally Bob gets a vector $\mathbf{w} \in \mathbb{Z}_2^{km}$, or equivalently, one vector in $\mathbb{Z}_2^k$ associated with each hyperedge of the matching. In the **YES** case this vector associated with a hyperedge is the labels of $\mathbf{x}$ restricted to the vertices incident to the hyperedge masked (i.e., xor-ed, or summed in $\mathbb{Z}_2$) by a vector $\mathbf{b} \in \mathbb{Z}_2^k$ drawn according to $\mathcal{D}_Y$. Each mask vector $\mathbf{b}$ is drawn independently for every hyperedge. The **NO** distribution is similar with the difference that now $\mathbf{b} \sim \mathcal{D}_N$ independently for each edge.

[13] give a $\Omega(\sqrt{n})$ communication lower bound for this problem to achieve any constant advantage (this time for $\alpha < 1/k$). The lower bound works in two parts. First the extend the proof from [18] to general k in the setting where $\mathcal{D}_N$ is uniform on $\mathbb{Z}_2^k$. (As noted above this setting seems amenable to their proof technique). The second part of the proof shows how to use the first part to show hardness of RMD on distributions $\mathcal{D}_1$ and $\mathcal{D}_2$ that differ in a "simple" way (in particular they differ in probabilities of at most four structured points in their support). They then complement this by showing that one can move from every $\mathcal{D}_Y$ to every $\mathcal{D}_N$ (with matching marginals) using a finite number of steps (as a function of q and k) where each step creates a "simple" difference in the sense above. A series of triangle inequalities now shows that $(\mathcal{D}_Y, \mathcal{D}_N)$-RMD is also indistinguishable to $o(\sqrt{n})$-communication protocols.

To convert the RMD lower bound into a lower bound on $\mathsf{Max\text{-}CSP}(\mathcal{F})$ we first need to interpret the RMD inputs as constraints of a $\mathsf{Max\text{-}CSP}(\mathcal{F})$ problem, and then to prove that combining T substreams preserves indistinguishability by streaming algorithms. The first step is natural: We apply constraints so that the hidden vector $\mathbf{x}$ is expected to satisfy γ fraction of the constraints in the **YES** case: Specifically if a hyperedge gives Bob the information $\mathbf{x}|_S + \mathbf{b}$ corresponding to the restriction of $\mathbf{x}$ to some sequence S of k variables masked by $\mathbf{b}$, then the resulting constraint negates literals according to $\mathbf{x}|_S + \mathbf{b}$, so that after the negations are applied, the input to the constraint is $\mathbf{b}$ which, by the condition that $\mathcal{D}_Y \in S_\gamma^Y(f)$ is expected to satisfy the constraint with probability γ. Similarly in the **NO** case every assignment is expected to satsify the constraint with probability at most β. Taking sufficiently many constraints (i.e., $\alpha T \to \infty$) allows us to apply Chernoff bounds and the union bound to conclude tight bounds on the value of the resulting CSPs in the **YES** and **NO** case.

The tricky part turns out to be the combination. When $\mathcal{D}_N$ is uniform, the same hybrid argument as in the $\mathsf{Max\text{-}CUT}$ case works and using this twice we conclude that if $\mathcal{D}_Y$ and $\mathcal{D}_N$ have uniform marginals then the resulting CSP instances are indistinguishable by $o(\sqrt{n})$ space

streaming algorithms. [13] also cover some slight extensions that allow them to cover hardness of Max-DICUT where the underlying distributions do not have uniform marginals. But for general $\mathcal{D}_Y$ and $\mathcal{D}_N$ with non-uniform marginals the method truly breaks down and produces instances of Max-CSP(f) that are distinguishable by polylogspace algorithms as pointed out by [9]. However in such cases it is possible to show that no sketching algorithm can work. This relies on an easy reduction from RMD to a T-player simultaneous communication problem where T players each get inputs independently according to the distribution of Bob's input and then need to communicate short messages to a referee whose goal is to distinguish the inputs being all from the **YES** distribution or from the **NO** distribution. This yields the lower bound of Theorem 1.

A sketching algorithm when $K^Y_\gamma(f) \cap K^N_\beta(f) = \emptyset$

We now turn to the complementary result, giving a sketching algorithm when $K^Y_\gamma(f) \cap K^N_\beta(f) = \emptyset$. If the sets do not intersect then there must be a hyperplane in $\mathbb{R}^k$ separating them. Let this plane be given by $\lambda_1, \ldots, \lambda_k$ and τ so that $\{\mathbf{a} \in \mathbb{R}^k | \sum_{i\in[k]} \lambda_i a_i \geq \tau\}$ contains $K^Y_\gamma(f)$. Since $K^Y_\gamma(f)$ and $K^N_\beta(f)$ are closed sets if they are disjoint there must be a gap separating them and so we also have $\theta > 0$ so that $\{\mathbf{a} \in \mathbb{R}^k | \sum_{i\in[k]} \lambda_i a_i \leq \tau - \theta\}$ contains $K^N_\beta(f)$.

It is natural to think of λ_i as representing a preference that the ith variable in this constraint has for taking the value 1 with higher λ_i's representing higher preferences. When the ith variable in a constraint is negated we let $-\lambda_i$ capture its preference. These preferences allow aggregation across constraints and yield the definition: For $j \in [n]$, let $\mathsf{bias}(\Psi, j)$ be the sum of the appropriate λ values over all constraints that variable j participates in. Define $\mathsf{bias}(\Psi) = \frac{1}{m}\sum_{j=1}^n |\mathsf{bias}(\Psi, j)|$. (We note that these definitions extend the Max-DICUT notions exactly). $\mathsf{bias}(\Psi)$ can be estimated as previously by appealing to ℓ_1 norm estimation algorithms. The algorithm for (γ, β)-Max-CSP($\mathcal{F}$) now reports **YES** if and only if $\mathsf{bias}(\Psi) \geq \tau - \theta/2$. This algorithm turns out to be correct, using analysis ideas that follow in a straightforward way from the construction of the convex sets. In case the reader wonders where the ℓ_1 estimator is suggested in the construction of the convex sets, this happens in the step where we passed from a general Ψ_1 and Ψ_2 with matching detailed bias matrix B, to assuming 1^n achieves the maximum value of Ψ_1. The computational challenge behind this vertex is to compute the maximal satisfying assignment, flipping literals of Ψ_1 according to this, and then computing its bias. This step is achieved computationally by the ℓ_1 norm estimation algorithm!

The general case

Up to now we focussed on the simpler case of $\mathcal{F} = \{f\}$, $q = 2$ and constraints being applied to literals. It turns out that this is the exact setting considered in the early version [12]. The extension to the general case, where $\mathcal{F}$ is not a singleton, constraints are applied only to variables, and q is general, appears in [13]. The extensions do manage to work out with no surprises (at least no unpleasant ones).

The elimination of the need to work with literals is the conceptually hard step but works out by working with qk variables which is different from k even in the Boolean case. Roughly our simplified picture of the extremal examples Ψ_1 and Ψ_2, uses two variables for each of the k positions in constraint that a variable can appear in: one corresponding to the unnegated variable X and one to the negated variable. To extend to general q we now use q variables per coordinate $i \in [k]$ – with variable $X_{i,\sigma}$ roughly capturing the "literal" $X_i + \sigma \pmod q$. The

extension to larger sets $\mathcal{F}$ is simple, we augment the detailed-bias information as well as the marginals to include information about which function $f \in \mathcal{F}$ the constraint is working with. This leads to sets $S^Y_\gamma(f)$, $S^N_\beta(f)$ that are extended to capture distributions over $\mathcal{F} \times \mathbb{Z}_q^k$ and the marginals $K^Y_\gamma(f)$, $K^N_\beta(f)$ now project to $\mathcal{F} \times [k] \times \mathbb{Z}_q$ dimensions. Somewhat surprisingly both the algorithm and the lower bounds extend to this setting with the ℓ_1 norm estimator replaced by an $\|\cdot\|_{1,\infty}$-norm estimator[6] of [1]. Deciding intersection of the two sets reduces to quantified systems with 2 alternations, and roughly $|\mathcal{F}|q^k$ variables and degree k. Perhaps the most complex part of the extension is the extension of the streaming lower bounds which work with two variants of the RMD problem. Also the reduction of the communication problems to the streaming problems is a bit delicate due to the absence of literals but works out in the end. We omit the many details, referring the reader to the original paper [13] for those.

6 Future directions

One can hope for many possible extensions to the dichotomy reported in Theorem 1. Perhaps the dichotomy extends as is to streaming algorithms (i.e., beyond sketching), perhaps even for linear space, perhaps even for randomly ordered streams, and maybe even for multipass algorithms. Unfortunately, while several extensions are still possible, the clean dichotomy does seem to fray quite a bit for each possible extension.

At the moment it is still plausible that the dichotomy extends as is to all $o(\sqrt{n})$ space streaming algorithms though there is no strong evidence in either direction. For space beyond $\sqrt{n}$ there do seem to be a number of new candidate algorithms so our expectation would be that the current dichotomy won't hold and there may exist more than two classes of problems. We note that we don't have concrete theorems proving this though. For randomly ordered streams as well as multipass algorithms there seem to be new algorithms in polylogarithmic space. This is the subject of an upcoming work by the author with Saxena, Singer and Velusamy. Finally the multipass setting seems to be the most challenging for the lower bounds. Here some remarkable works [2, 3], have shown strong space lower bounds but for progressively weak approximations. Here an interesting challenge is to establish a tight lower bound for any non-trivial CSP for arbitrarily large (but constant) number of passes.

A Brief Tour in Twin-Width

Stéphan Thomassé ✉
Univ Lyon, CNRS, ENS de Lyon, Université Claude Bernard Lyon 1, LIP UMR5668, France

Abstract

This is an introduction to the notion of twin-width, with emphasis on how it interacts with first-order model checking and enumerative combinatorics. Even though approximating twin-width remains a challenge in general graphs, it is now well understood for ordered graphs, where bounded twin-width coincides with many other complexity gaps. For instance classes of graphs with linear FO-model checking, small classes, or NIP classes are exactly bounded twin-width classes. Some other applications of twin-width are also presented.

1 Introduction

One of the most natural ways to understand discrete structures is to measure their complexity. A reasonable expectation is that the class of structures with bounded measure is not too difficult to understand and manipulate. Ideally, bounded measure classes should be simple with respect to several points of view such as "computationally hard problems can be solved efficiently" or "the number of structures of size n is a small function of n" and should also enjoy some stability like "the measure should stay bounded if one performs moderate deterministic changes to the structures".

The first difficulty to provide a general purpose complexity measures on graphs is that it quickly boils down to the basic question: What is a simple 01-matrix? Fortunately this problem has already been addressed long ago and the answer is very simple: a matrix M is complex if it contains all small matrices up to some (large) size. Consequently, the complexity measure $vc(M)$ could be the maximum k for which all 01-valued $k \times k$-matrices appear in M. This is equivalent to the well-known Vapnik-Cervonenkis dimension and indeed classes of matrices with bounded VC-dimension have moderate growth $O(2^{n^{2-\varepsilon}})$ and some problems are computationally easier (for instance the minimum hitting set problem can be approximated). Interestingly, these two properties characterize bounded VC-dimension for classes of matrices closed under submatrices. This is the bounded/unbounded VC-dimension gap, which is (arguably) the first question one should ask when investigating a class of structures.

The exact same idea can be used to measure the complexity of a permutation matrix M (exactly one 1 per row and per column): let $mt(M)$ be the maximum k for which all $k \times k$ permutation matrices appear in M. Marcus and Tardos [17], proving the Stanley-Wilf conjecture, showed that the growth of a class of permutation matrices with bounded measure mt is c^n. Using their method, Guillemot and Marx [14] showed that checking if a fixed $k \times k$ permutation matrix F is contained in an $n \times n$ permutation matrix P can be done in linear time $f(k)n$ (when both coded as permutations). Their breakthrough method was a completely new win/win scheme: they showed that unless one can detect F in P, then P can be iteratively contracted in linear time and the contraction scheme allows *then* to test if indeed F is a subpermutation of P. Note that permutation matrices are ordered

matrices, where rows and columns are linearly ordered. We showed in Twin-width IV [9] that the natural generalization of the mt parameter to general ordered matrices is the following: a matrix M has *grid rank* k if this is the maximum value for which M has a $k \times k$ block division in which every block has rank at least k.

Guillemot and Marx concluded their paper by asking if their technique for permutations could be generalized for graphs. This was the goal of our paper Twin-width I [12] where we defined the twin-width of a graph G as the minimum degree of error in a contraction sequence of G (we iteratively contract pairs of vertices, two contracted groups of vertices forming an error edge if there is both an edge and a non edge between them). Precisely, the twin-width $tww(G)$ of a graph G on n vertices is the minimum k such that: there exists a sequence of partitions $P_n, \dots, P_1$ of $V(G)$ where each P_{i-1} is obtained from P_i by merging two parts, and such that for every part X in P_j, the number of parts Y in P_j which are not homogeneous with X is at most k. Here two disjoint sets X, Y are *homogeneous* if the relation between $x \in X$ and $y \in Y$ does not depend of the choices of x, y (therefore homogeneity, and hence twin-width, is also defined for binary multirelations). So bounded twin-width corresponds to maximum degree in every *error graph* G_j which vertices are the parts of P_j and edges are the non homogeneous pairs. If we impose further that all components of graphs G_j have bounded size, we have shown in Twin-width VI [10] that the obtained parameter is equivalent to rank-width. Hence twin-width generalizes rank-width but also captures strict minor closed classes, or strict permutation graphs.

Mimicking Guillemot and Marx argument for permutations, it is not hard to show that if one has access to such a sequence $P_n, \dots, P_1$ certifying twin-width k, then one can test if some fixed graph H of size t is an induced subgraph of G in linear time $f(k,t).n$. One of the main result of Twin-width I is that we can moreover test any FO-formula of depth t in time $f(k,t).n$. Also, generalizing Marcus-Tardos' result on permutations, we could prove in Twin-width II [6] that the number of (labelled) graphs of size n with twin-width bounded by some constant is at most $c^n.n!$ (we call this a *small class*). This result implies in particular that the class of (sub)cubic graphs (degree at most 3) does not have bounded twin-width, since it is not small. But so far we have no "deterministic" construction of a cubic graph with arbitrarily high twin-width. One can naturally wonder if these two implications (easyness of FO-model checking and small property) could be equivalent to bounded twin-width.

This is unfortunately not the case: since FO-model checking can be solved in linear time on bounded degree graphs, there are classes of graphs on which FO-model checking is tractable and for which twin-width is unbounded. From the counting point of view, we conjectured in [6] the equivalence between bounded twin-width and being a small class. Sadly again, we could prove in Twin-width VII [8] that there are (countable) Cayley graphs of finitely generated groups with unbounded twin-width, while any such Cayley graph defines a small class. Thus bounded twin-width for general graphs does not seem to be equivalent to some computational complexity class, nor it seems to be definable via counting. Nevertheless, bounded twin-width is a particularly stable notion since every first order interpretation of a bounded twin-width class has also bounded twin-width. For instance squares of planar graphs have bounded twin-width.

We still have a very limited understanding of twin-width, and especially for bounded degree graphs: not only we do not have an algorithm to approximate it, but we do not know what could be a certificate of high twin-width, and we are not even able to construct by hand a cubic graph of high twin-width. So why twin-width is so hard to handle, given that it enjoys so many nice properties? The answer is that twin-width indeed corresponds to a crucial complexity gap, but for ordered graphs (a binary birelation consisting of a graph and a linear order on its vertices) rather than for graphs.

Indeed, in Twin-width IV [9] we could show that for classes of ordered graphs, bounded twin-width, linear FO-model checking and being a small class are equivalent. Moreover these three characterizations are in turn equivalent to the fact that the adjacency matrices of the graphs, ordered by their linear order, have bounded grid-rank. Finally, approximating twin-width for ordered graphs can be done in polynomial time. In particular, the bounded/unbounded twin-width gap for ordered matrices is as fundamental as the one of VC-dimension as it has many equivalent formulations coming from other domains. For instance, for ordered graphs, the NIP property in model theory coincides with bounded twin-width. Since any graph G with twin-width k has a linear order L for which (G, L) has twin-width k, the difficulty of twin-width for general graphs seems to come from the fact that we have lost the information encoded in the linear order.

Hence an appealing strategy to show that a graph G has (reasonably) bounded twin-width is to be able to guess a suitable linear order T on its vertices since we have the machinery to efficiently approximate the twin-width of the ordered graph (G, T). For instance, we could prove that minor closed classes have bounded twin-width by using a Lex-DFS to provide the linear order. We can also take advantage of the stability of twin-width by FO-interpretation. Let us illustrate this on some example: Assume that we want to approximate the twin-width of a bipartite graph G with bipartition A, B in which B is linearly ordered by $<$. We would not have a clue if B would not have been ordered, and we can directly conclude if both A and B are ordered, so what about this "semi-ordered" case? The answer is quite easy: associate to each vertex $a \in A$ the characteristic 01 vector of its neighbors in B, ordered by $<$, and sort A by lexicographic order. This is a first-order interpretation, so the order we find on A cannot increase twin-width too much. Hence now A is ordered, and twin-width can be approximated. Note that if several vertices of A have the same neighborhood, we can pairwise contract them since this does not affect twin-width. This is probably the best advice to try to compute twin-width: find an order. Is there a general algorithm to find it?

To conclude, let us observe that as a way to characterize simple matrices, twin-width is a very general tool which can apply to many topics. For instance bounded twin-width is a group invariant and finitely generated groups can have either bounded or unbounded twin-width (but again we have no explicit presentation of any unbounded twin-width group). Another field where matrices are central is linear programming. We have showed in Twin-width III [7] that when a matrix has bounded twin-width, there is a constant duality gap between minimum hitting set and maximum packing (while bounded VC-dimension only bridges the fractional gap for hitting set). We provide in the references a list of recent publications with better bounds on twin-width of classes ([1, 2, 3, 15, 18]), on computing twin-width ([4, 5]), on using twin-width for algorithms ([11, 16]) and for data-structures [20], and more topics ([13, 19, 21, 22]) that we cannot unfortunately cover here. We believe that there are many other aspects of twin-width waiting to be discovered.

Abstract

We study several questions related to diversifying search results. We give improved approximation algorithms in each of the following problems, together with some lower bounds.

1. We give a polynomial-time approximation scheme (PTAS) for a diversified search ranking problem [9] whose objective is to minimizes the discounted cumulative gain. Our PTAS runs in time $n^{2^{O(\log(1/\epsilon)/\epsilon)}} \cdot m^{O(1)}$ where n denotes the number of elements in the databases and m denotes the number of constraints. Complementing this result, we show that no PTAS can run in time $f(\epsilon) \cdot (nm)^{2^{o(1/\epsilon)}}$ assuming Gap-ETH and therefore our running time is nearly tight. Both our upper and lower bounds answer open questions from [9].
2. We next consider the Max-Sum Dispersion problem, whose objective is to select k out of n elements from a database that maximizes the dispersion, which is defined as the sum of the pairwise distances under a given metric. We give a quasipolynomial-time approximation scheme (QPTAS) for the problem which runs in time $n^{O_\epsilon(\log n)}$. This improves upon previously known polynomial-time algorithms with approximate ratios 0.5 [35, 16]. Furthermore, we observe that reductions from previous work rule out approximation schemes that run in $n^{\tilde{o}_\epsilon(\log n)}$ time assuming ETH.
3. Finally, we consider a generalization of Max-Sum Dispersion called Max-Sum Diversification. In addition to the sum of pairwise distance, the objective also includes another function f. For monotone submodular function f, we give a quasipolynomial-time algorithm with approximation ratio arbitrarily close to $(1-1/e)$. This improves upon the best polynomial-time algorithm which has approximation ratio 0.5 [16]. Furthermore, the $(1-1/e)$ factor is also tight as achieving better-than-$(1-1/e)$ approximation is NP-hard [26].

1 Introduction

A fundamental task in databases in general and in search engines in particular is the selection and ordering of the results to a given query. Suppose that we have already retrieved the set of appropriate answers S_q to a query q by a certain preliminary process. Which item from the (possibly huge) set S_q should be presented *first*? Which should be the first ten?

Besides the obvious approach of ranking the *most relevant* answers first, perhaps the second most important consideration is that the output set should satisfy certain *diversity* requirements. If a user searches for "Barcelona" it would be desirable that the first ten results contain a mix of items containing, e.g. general details of the city, tourist information, and news about the associated soccer team, even though the most relevant items in certain absolute terms may only pertain to the latter. There are various natural ways to formalize what makes a set of results diverse, and much research has gone into this *Search Diversification* topic in the past two and a half decades in various context (see e.g. [19, 3, 33, 15, 9, 39, 50, 16, 24, 12, 31, 46, 34, 1, 36, 25, 52]). Recently, there have also been extensive research efforts into algorithmic fairness (see e.g. a survey [47]). Some of these fairness notions (e.g. [21, 7]) are also closely related to diversity: a set of results that is not diverse enough (e.g. returning only pictures of members of one group when a user searches for "scientists") could be problematic in terms of fairness.

A well-known work on search diversification [19] suggests that a diverse set of results is one that satisfies the following: The k^{th} result in the list should maximize the sum[1] of: (1) the relevance to the query, and (2) the total distance to the first $k-1$ results in the list. The success of this natural notion of diversification may be attributed to the fact that it can be computed efficiently with a greedy algorithm. However, it may be a bit too simplistic and the objectives that real-world search engines seem to optimize for are actually closer to other, more complicated (to compute) notions of diversity that have been proposed in follow-up works (e.g. [9, 33, 16]).

The goal of this paper is to investigate the time complexity of computing these latter, more intricate definitions of the search diversification task. Since such problems are NP-Hard even for restricted settings, and since approximate solutions are typically acceptable in this context, our focus is on understanding their time vs. approximation trade-offs. Our results reduce the gaps in the literature, completely resolving the complexity of some of the most natural notions.

1.1 Diversified Search Ranking

The first problem we study is a diversified search ranking problem formulated by Bansal et al. [9]. Here we are given a collections $\mathcal{S}$ of subsets of $[n]$ and, for each $S \in \mathcal{S}$, a positive integer k_S. Our goal is to find a permutation $\pi : [n] \to [n]$ that minimizes the *discounted cumulative gain (DCG)* defined as

$$\mathrm{DCG}_{\mathcal{S},\mathbf{k}}(\pi) := \sum_{S \in \mathcal{S}} \frac{1}{\log(t_\pi(S)+1)}, \tag{1}$$

where $t_\pi(S)$ is defined as the earliest time the set S is covered k_S times, i.e. $\min\{i \in [n] | S \cap \pi([i])| \geq k_S\}$.

[1] To be more precise, it is a weighted average of the two terms.

This formulation relates to diversification by viewing the output π as the ranking of the documents to be shown, and each topic corresponds to a set S of documents related to that topic. With this interpretation, the DCG favors rankings that display "diverse topics as early in the ranking as possible". Bansal et al. [9] gave a polynomial-time approximation scheme (PTAS) for the problem in the special case that $k_S = 1$ for all $S \in \mathcal{S}$ with running time $n^{2^{O(\log(1/\epsilon)/\epsilon)}} m^{O(1)}$. On the other hand, for the case of general k_S's, they give a quasipolynomial-time approximation scheme with running time $n^{(\log\log n)^{O(1/\epsilon)}} m^{O(1)}$ and left as an open question whether a PTAS exists. We resolve this open question by giving a PTAS for the more general problem; the running time we obtain for this more general problem is similar to the running time obtained by Bansal et al.'s PTAS for the special case $k_S = 1$. We then show that this is indeed the best possible (under some complexity assumption).

▶ **Theorem 1.** *There is a randomized PTAS for maximizing DCG that runs in time* $n^{2^{O(\log(1/\epsilon)/\epsilon)}} \cdot m^{O(1)}$.

The above running time is doubly exponential in $1/\epsilon$, and Bansal et al. [9] asked whether this dependency is necessary even for the special case $k_S = 1$. We also answer this question by showing that the doubly exponential is necessary, assuming the Gap Exponential Time Hypothesis (Gap-ETH)[2]:

▶ **Theorem 2.** *Assuming Gap-ETH, for any function g, there is no PTAS for maximizing DCG that runs in time $g(\epsilon) \cdot (nm)^{2^{o(1/\epsilon)}}$. Moreover, this holds even when restricted to instances with $k_S = 1$ for all $S \in \mathcal{S}$.*

1.2 Max-Sum Dispersion

The second problem we consider is the so-called *Max-Sum Dispersion* problem where we are given a metric space (U, d) where $|U| = n$ and an integer $p \geq 2$. The goal is to select $S \subseteq U$ of size p that maximizes

$$\mathrm{Disp}(S) := \sum_{\{u,v\} \subseteq S} d(u, v).$$

Roughly speaking, if the metric determines how different the items are, then our goal is to pick items that are "as diverse as possible" according to the Disp objective.

The Max-Sum Dispersion problem is a classic problem that has been studied since the 80s [45, 38, 49, 35, 16]. Previous works have given 0.5-approximation algorithm for the problem in polynomial time [35, 16]. We observe that the known NP-hardness reduction, together with newer hardness of approximation results for the Densest k-Subgraph problem with perfect completeness, yields strong lower bounds for the problem. (Details are deferred to the full version [2].) For example, if we assume the Strongish Planted Clique Hypothesis [43], then no $(0.5 + \epsilon)$-approximation algorithm is possible in $n^{o(\log n)}$ time. In other words, to achieve an improvement over the known approximation ratio, the algorithm must run in $n^{\Omega(\log n)}$ time. Complementing this, we provide a quasipolynomial-time approximation scheme that runs in time $n^{O_\epsilon(\log n)}$:

▶ **Theorem 3.** *There is a QPTAS for Max-Sum Dispersion that runs in time $n^{O(\log n/\epsilon^4)}$.*

[2] Gap-ETH [23, 42] asserts that there is no $2^{o(n)}$-time algorithm to distinguish between a satisfiable n-variable 3SAT formula and one which is not even $(1 - \epsilon)$-satisfiable for some $\epsilon > 0$

1.3 Max-Sum Diversification

Finally, we consider a generalization of Max-Sum Dispersion where, in addition to the metric space (U, d), we are now also given a monotone set function f (which we can access via a value oracle) and the goal is to select a set $S \subseteq U$ of size p that maximizes

$$\mathrm{Div}(S) := \mathrm{Disp}(S) + f(S).$$

This problem is referred to as *Max-Sum Diversification*.

The Max-Sum Diversification problem is more expressive than Max-Sum Dispersion. For example, the value $f(S)$ in the objective may be used to encode how relevant the selected set S is to the given query, in addition to the diversity objective expressed by $\mathrm{Disp}(S)$.

Borodin et al. [16] gave a 0.5-approximation algorithm for the problem when f is a monotone submodular function. Since Max-Sum Diversification is a generalization of Max-Sum Dispersion, our aforementioned lower bounds also imply that improving on this 0.5 factor requires at least $n^{\Omega(\log n)}$ time. Furthermore, submodular Max-Sum Diversification is also a generalization of maximizing monotone submodular function subject to a cardinality constraint. For this problem, an $(1 - 1/e)$-approximation algorithm is known and it is also known that achieving better than this ratio is NP-hard [26]. Therefore, it is impossible to achieve a better-than-$(1 - 1/e)$ approximation even in (randomized) quasi-polynomial time, assuming NP $\not\subseteq RTIME(n^{O(\log n)})$. Here we manage to provide such a tight quasi-polynomial time approximation algorithm:

▶ **Theorem 4.** *For any $\epsilon > 0$, there exists a randomized $n^{O(\log n/\epsilon^4)}$-time $(1 - 1/e - \epsilon)$-approximation algorithm for submodular Max-Sum Diversification.*

We remark that an interesting special case of submodular Max-Sum Diversification is when f is linear, i.e. $f(S) = \sum_{u \in S} f(u)$. In this case, Gollapudi and Sharma [33] provided an approximation-preserving reduction from the problem to the Max-Sum Dispersion. Therefore, our QPTAS for the latter (Theorem 3) also yields a QPTAS for this special case of Max-Sum Dispersion.

2 Preliminaries

For a natural number n, we use $[n]$ to denote $\{1, \ldots, n\}$. We say that a randomized algorithm for a maximization problem is an α-approximation if the expected objective of the output solution is at least α times the optimum; note that we can easily get a high-probability bound with approximation guarantee arbitrarily close to α by repeating the algorithm multiple times and pick the best solution.

2.1 Concentration Inequalities

For our randomized approximation algorithms, we will need some standard concentration inequalities. First, we will use the following version of Chernoff bound which gives a tail bound on the sum of i.i.d. random variables. (See e.g. [44] for a proof.)

▶ **Lemma 5** (Chernoff bound). *Let $X_1, \ldots, X_r \in [0, 1]$ be independent random variables, $S := X_1 + \cdots + X_r$ and $\mu := \mathbb{E}[S]$. Then, for any $\delta \in [0, 1]$, we have*

$$\Pr[|S - \mu| > \delta\mu] \leq 2 \exp\left(-\frac{\delta^2 \mu}{3}\right).$$

Furthermore, for any $\delta \geq 0$, we have

$$\Pr[S > (1+\delta)\mu] \leq \exp\left(-\frac{\delta^2\mu}{2+\delta}\right).$$

It will also be convenient to have a concentration of sums of random variables that are drawn without replacement from a given set. For this, we will use (a without-replacement version of) the Hoeffding's inequality, stated below. (See e.g. [10].)

▶ **Lemma 6** (Hoeffding's inequality). *Let $X_1, \ldots, X_r$ be random variables drawn without replacement from a multiset $\mathcal{X} \subseteq [0,1]$, $A := \frac{1}{r}(X_1 + \cdots + X_r)$ and $\mu := \mathbb{E}[A]$. Then, for any $\delta \in [0,1]$, we have*

$$\Pr[|A - \mu| > \delta] \leq 2\exp\left(-2\delta^2 r\right).$$

2.2 Densest k-Subgraph

For both our Max-Sum Dispersion and Max-Sum Diversification problems, we will use as a subroutine algorithms for (variants of) the *Densest k-Subgraph (DkS)* problem. In DkS, we are given a set V of nodes, weights $w : \binom{V}{2} \to [0,1]$ and an integer k, the goal is to find a subset $T \subseteq V$ with $|T| = k$ that maximizes $\mathrm{Den}(T) := \frac{1}{|T|(|T|-1)/2}\sum_{\{u,v\}\subseteq T} w(\{u,v\})$. An *additive QPTAS* is an algorithm running in quasipolynomial time for any fixed $\epsilon > 0$ such that its output T satisfies $\mathrm{Den}(T) \geq \mathrm{OPT} - \epsilon$; Barman [11] gave such an algorithm for DkS.

We will in fact use a slightly generalized version of the problem where a subset $I \subseteq V$ of vertices is given as an input and these vertices must be picked in the solution T (i.e. $I \subseteq T$). To avoid cumbersomeness, we also refer to this generalized version as DkS. It is not hard to see[3] that Barman's algorithm [11] extends easily to this setting:

▶ **Theorem 7.** *There is an additive QPTAS for DkS that runs in time $n^{O(\log n/\epsilon^2)}$.*

DkS is a classic problem in approximation algorithms literature, and many approximation algorithms [30, 51, 29, 28, 6, 32, 13, 11] and hardness results [27, 37, 48, 4, 14, 17, 40, 20] have been proved over the years. Most of these works focus on *multiplicative* approximation; the best known polynomial-time algorithm in this setting has an approximation ratio of $n^{1/4+\epsilon}$ for any constant $\epsilon > 0$ [13] and there are evidences that achieving subpolynomial ratio in polynomial time is unlikely [40, 14, 22]. As for *additive* approximation, it is known that an approximation scheme that runs in time $n^{\tilde{o}(\log n)}$ would break the exponential time hypothesis (ETH) [17]; therefore, the running time in Theorem 7 (in terms of n) is tight up to $\mathrm{poly}\log\log n$ factor in the exponent. We provide additional discussions on related results in the full version [2].

2.3 Submodular Maximization over a Matroid Constraint

For our approximation algorithm for Max-Sum Diversification, we will also need an approximation algorithm for *monotone submodular maximization under a matroid constraint*. In this problem, we are given a monotone submodular set function $f : 2^X \to \mathbb{R}_{\geq 0}$ over a ground set X together with a matroid $\mathcal{M} = (X, \mathcal{I})$. The function f is given via a value oracle and $\mathcal{M}$ can be accessed via a membership oracle (which answers questions of the form "does

[3] In fact, in Section 5.1, we also give a more general algorithm than the one stated in Theorem 7 which can also handle an additional monotone submodular function.

S belong to $\mathcal{I}$?"). The goal is to find $S \in \mathcal{I}$ that maximizes $f(S)$. Călinescu et al. gave a randomized algorithm with approximation ratio $(1 - 1/e)$ for the problem, which we will use in our algorithm.

▶ **Theorem 8** ([18]). *There exists a randomized polynomial-time $(1 - 1/e)$-approximation algorithm for maximizing a montone submodular function over a matroid constraint.*

3 Diversified Search Ranking

In this section, we consider the diversified search ranking question as proposed in [9] and prove our upper and lower bounds (Theorems 1 and 2).

3.1 Polynomial-time Approximation Scheme

We will start by presenting our PTAS. At a high-level, our PTAS is similar to that of Bansal et al.'s: our algorithm use bruteforce to try every possible values of $\pi(1), \ldots, \pi(\exp(\tilde{O}(1/\epsilon)))$. Once these are fixed, we solve the remaining problem using linear programming (LP). We use the same LP as Bansal et al., except with a slightly more refined rounding procedure, which allows us to achieve a better approximation guarantee.

The remainder of this section is organized as follows. In Section 3.1.1, we present our LP rounding algorithm and its guarantees. Then, we show how to use it to yield our PTAS in Section 3.1.2.

3.1.1 Improved LP Rounding

For convenience in the analysis below, let us also define a more generic objective function where $\frac{1}{\log(t_\pi(S))+1}$ in Equation (1) can be replaced by any non-increasing function $f : [n] \to (0, 1]$:

$$\mathrm{DCG}^f_{\mathcal{S},\mathbf{k}}(\pi) := \sum_{S \in \mathcal{S}} f(t_\pi(S)).$$

The main result of this subsection is the following polynomial time LP rounding algorithm for the above general version of DCG:

▶ **Lemma 9.** *There exists an absolute constant C such that for any $\alpha \in (0, 0.5)$ the following holds: there is a polynomial-time algorithm that computes a ranking with expected DCG at least $(1 - \alpha) \cdot \tau_{f,\alpha}$ times that of the optimum where*

$$\tau_{f,\alpha} := \min_{t \in [n]} \frac{f\left(\frac{C \log(1/\alpha)}{\alpha} \cdot \frac{t}{f(t)}\right)}{f(t)}.$$

Informally speaking, the term $\tau_{f,\alpha}$ somewhat determines "how fast f increases". In the next section, once we fix the first u elements of the ranking, f will become $f(t) := 1/\log(t+u)$ which is "slowly growing" when u is sufficiently large. This allows us to ensure that the guarantee in Lemma 9 yields an $(1 - O(\epsilon))$-approximation as desired.

3.1.1.1 LP Formulation

To prove Lemma 9, we use the same knapsack constraint-enhanced LP as in [9], stated below. Note that the number of knapsack constraints can be super-polynomial. However, it is known that such an LP can be solved in polynomial time; see e.g. [8, Section 3.1] for more detail.

$$\text{Maximize} \qquad \sum_{S \in \mathcal{S}} \sum_{t \in [n]} (y_{S,t} - y_{S,t-1}) \cdot f(t)$$

$$\begin{aligned}
\text{subject to} \quad & \sum_{e\in[n]} x_{e,t} = 1 && \forall t \in [n] \\
& \sum_{t\in[n]} x_{e,t} = 1 && \forall e \in [n] \\
& \sum_{e\in S\subseteq A} \sum_{t'<t} x_{e,t'} \geq (k_S - |A|)\cdot y_{S,t} && \forall S \in \mathcal{S}, A \subseteq S, t \in [n] \\
& y_{S,t} \geq y_{S,t-1} && \forall S \in \mathcal{S}, t \in \{2,\dots,n\} \\
& x_{e,t}, y_{S,t} \in [0,1] && \forall e,t \in [n], S \in \mathcal{S}.
\end{aligned}$$

3.1.1.2 Rounding Algorithm

Let $\gamma \in (0, 0.1)$ be a parameter to be chosen later. Our rounding algorithm works as follows:

1. $\pi \leftarrow \emptyset$
2. For $i = 1, \dots, \lceil \log n \rceil$ do:
   a. Let $t_i = \min\{n, 2^i\}$.
   b. Let $z_{e,i} = \sum_{t\leq t_i} x^*_{e,t}$ and $p_{e,i} = \min\{1, \frac{z_{e,i}}{\gamma \cdot f(t_i)}\}$ for all $e \in [n]$.
   c. Let A_i be the set such that $e \in [n]$ is independently included w.p. $p_{e,i}$.

Finally, our permutation π is defined by adding elements from $A_1, \dots, A_{\lceil \log n \rceil}$ in that order, where the order within each A_i can be arbitrary and we do not add an element if it already appears in the permutation.

Once again, we remark that our algorithm closely follows that of [9], except that Bansal et al. simply chose their $p_{e,i}$ to be $\min\{1, O(\log^2 n) \cdot z_{e,i}\}$, whereas our $p_{e,i}$ is a more delicate $\min\{1, \frac{z_{e,i}}{\gamma \cdot f(t_i)}\}$. This allows our analysis below to produce a better approximation ratio.

3.1.1.3 Analysis

We will now proceed to analyze our proposed randomized rounding procedure. Let $\eta \in (0, 0.1)$ be a parameter to be chosen later, and let $(\mathbf{x}^*, \mathbf{y}^*)$ denote an optimal solution to the LP. For each S, let $t^*(S)$ be the largest positive integer t^* such that

$$y^*_{S,t^*-1} \leq \eta \cdot f(t^*). \tag{2}$$

We start with the following lemma, which is a refinement of [9, Lemma 1].

▶ **Lemma 10.** $\text{OPT} \leq (1+\eta) \cdot \sum_{S\in\mathcal{S}} f(t^*(S))$.

Proof. We have

$$\begin{aligned}
\text{OPT} &\leq \sum_{S\in\mathcal{S}} \sum_{t\in[n]} (y^*_{S,t} - y^*_{S,t-1}) \cdot f(t) \\
&= \sum_{S\in\mathcal{S}} \left(\sum_{t=1}^{t^*(S)-1} (y^*_{S,t} - y^*_{S,t-1}) \cdot f(t) + \sum_{t=t^*(S)}^{n} (y^*_{S,t} - y^*_{S,t-1}) \cdot f(t) \right) \\
&\leq \sum_{S\in\mathcal{S}} \left(\sum_{t=1}^{t^*(S)-1} (y^*_{S,t} - y^*_{S,t-1}) + \sum_{t=t^*(S)}^{n} (y^*_{S,t} - y^*_{S,t-1}) \cdot f(t^*(S)) \right) \\
&\leq \sum_{S\in\mathcal{S}} \left(y^*_{S,t^*(S)-1} + f(t^*(S)) \right) \\
&\overset{(2)}{\leq} \sum_{S\in\mathcal{S}} (1+\eta) \cdot f(t^*(S)).
\end{aligned}$$

◀

Next, we show via standard concentration inequalities that $|A_i|$'s has small sizes with a large probability.

▶ **Lemma 11.** *With probability* $1 - 2\exp\left(-\frac{1}{3\gamma}\right)$*, we have* $|A_i| \leq \frac{2t_i}{\gamma f(t^*)}$ *for all* $i \in [\lceil \log n \rceil]$.

Proof. Notice that $\sum_{e\in[n]} p_{e,i} \leq \frac{\sum_{e\in[n]} z_{e,i}}{\gamma f(t_i)} = \frac{t_i}{\gamma f(t_i)}$. As a result, by Chernoff bound (Lemma 5), we have

$$\Pr\left[|A_i| > \frac{2t_i}{\gamma f(t^*)}\right] \leq \exp\left(-\frac{t_i}{3\gamma f(t^*)}\right) \leq \exp\left(-\frac{t_i}{3\gamma}\right).$$

By union bound, we thus have $|A_i| \leq \frac{2t_i}{\gamma f(t^*)}$ for all $i \in [\lceil \log n \rceil]$ with probability at least

$$1 - \sum_{i\in[\lceil \log n \rceil]} \exp\left(-\frac{t_i}{3\gamma}\right) \leq 1 - 2\exp\left(-\frac{1}{3\gamma}\right). \qquad \blacktriangleleft$$

Let $i^*(S)$ denote the smallest i such that $t_i \geq t^*(S)$. We now bound the probability that S is covered (k_S times) by the end of the $i^*(S)$-th iteration of the algorithm. Our bound is stated below. We note that our bound here is not with high probability, unlike that of the analysis of [9] which yields a bound of $1 - o(1/n)$. We observe here that such a strong bound is not necessary for the analysis because we are working with a maximization problem and therefore such a high probability bound is not necessary to get a bound on the expectation of the DCG.

▶ **Lemma 12.** *Assume that* $\eta \geq 2\gamma$*. For each* $S \in \mathcal{S}$*, we have* $t_\pi(S) \leq |A_1| + \cdots + |A_{i^*(S)}|$ *with probability* $1 - \exp\left(\frac{\eta}{8\gamma}\right)$.

Proof. It suffices to show that at least k_S elements of S are selected in $A_{i^*(S)}$. Let S_g denote the set of elements $e \in S$ for which $p_{e,i^*(S)} = 1$. If $|S_g| \geq k_S$, then we are done. Otherwise, from knapsack constraint, we have

$$\sum_{e\in S\setminus S_g} z_{e,i^*(S)} \geq (k_S - |S_g|) y^*_{S,t_{i^*(S)}} \geq (k_S - |S_g|) y^*_{S,t^*(S)} \geq \eta \cdot f(t^*(S)) \cdot (k_S - |S_g|)$$
$$\geq \eta \cdot f(t_{i^*(S)}) \cdot (k_S - |S_g|),$$

where the third inequality follows from our choice of $t^*(S)$. This implies that

$$\sum_{e\in S\setminus S_g} p_{e,i^*(S)} \geq \eta/\gamma \cdot (k_S - |S_g|).$$

Recall that $\eta/\gamma \geq 2$. This means that the probability that at least k_S elements of S are selected in $A_{i^*(S)}$ is at least

$$1 - \Pr[|(S \setminus S_g) \cap A_{i^*(S)}| \leq 0.5\eta/\gamma \cdot (k_S - |S_g|)]$$
$$\leq 1 - \exp\left(-\frac{1}{8} \cdot \eta/\gamma \cdot (k_S - |S_g|)\right)$$
$$\leq 1 - \exp\left(-\frac{\eta}{8\gamma}\right),$$

where the first inequality follows from the Chernoff bound. ◀

Applying the union bound to the two previous lemmas, we immediately arrive at the following:

▶ **Lemma 13.** *Assume that $\eta \geq 2\gamma$. For all $S \in \mathcal{S}$, we have*

$$\mathbb{E}_\pi[f(t_\pi(S))] \geq \left(1 - 2\exp\left(-\frac{1}{3\gamma}\right) - \exp\left(\frac{\eta}{8\gamma}\right)\right) \cdot f\left(\frac{8t^*(S)}{\gamma f(t^*(S))}\right)$$

Finally, combining Lemmas 10 and 13 and selecting $\eta = 2\alpha, \gamma = O(\eta/\log(1/\eta))$ yields Lemma 9.

3.1.2 From LP Rounding to PTAS

As stated earlier, we may now use bruteforce to try all possible values of the first few elements in the ranking and then use our LP rounding to arrive at the PTAS:

Proof of Theorem 1. For any $\epsilon < 0.1$, we use bruteforce for the first $u = (4C/\epsilon)^{100/\epsilon}$ elements and then use Lemma 9 on the remaining instance but with $f(t) := \frac{1}{\log(t+u)}$. The expected approximation ratio we have is at least

$$\begin{aligned}
&(1-0.5\epsilon) \cdot \tau_{f,0.5\epsilon} \\
&\geq (1-0.5\epsilon) \cdot \min_{t\in[n]} f\left(\frac{4C\log(1/\epsilon)}{\epsilon} \cdot \frac{t}{f(t)}\right)/f(t) \\
&= (1-0.5\epsilon) \cdot \min_{t\in[n]} \frac{\log(t+u)}{\log\left(\frac{4C\log(1/\epsilon)}{\epsilon} \cdot \frac{t}{f(t)} + u\right)} \\
&\geq (1-0.5\epsilon) \cdot \min_{t\in[n]} \frac{\log(t+u)}{\log\left(\frac{4C\log(1/\epsilon)}{\epsilon} \cdot (t+u)\log(t+u)\right)} \\
&= (1-0.5\epsilon) \cdot \min_{t\in[n]} \frac{1}{1 + \frac{\log\left(\frac{4C\log(1/\epsilon)}{\epsilon}\right)}{\log(t+u)} + \frac{\log\log(t+u)}{\log(t+u)}} \\
&= (1-0.5\epsilon) \cdot \frac{1}{1 + \frac{\log\left(\frac{4C\log(1/\epsilon)}{\epsilon}\right)}{\log(u)} + \frac{\log\log(u)}{\log(u)}} \\
&\geq (1-0.5\epsilon) \cdot \frac{1}{1+0.1\epsilon+0.1\epsilon} \\
&\geq 1-\epsilon,
\end{aligned}$$

as desired. ◀

3.2 Running Time Lower Bound

To prove our running time lower bound, we will reduce from the *Maximum k-Coverage* problem. Recall that in Maximum k-Coverage, we are given a set $\mathcal{T} \subseteq [M]$ and an integer k; the goal is to find $T_1^*, \cdots T_k^* \in \mathcal{T}$ that maximizes $|T_1^* \cup \cdots \cup T_k^*|$. We write $\mathrm{Cov}(\mathcal{T}, k)$ to denote this optimum. Furthermore, we say that a Maximum k-Coverage is *regular* if $|T| = M/k$ for all $T \in \mathcal{T}$. Finally, we use N to denote $|\mathcal{T}| \cdot M$ which upper bound the "size" of the problem.

Manurangsi [41] showed the following lower bound for this problem:

▶ **Theorem 14** ([41]). *Assuming the Gap Exponential Time Hypothesis (Gap-ETH), for any constant $\delta > 0$, there is no $N^{o(k)}$-time algorithm that can, given a regular instance $(\mathcal{T}, k)$ distinguish between the following two cases:*

- *(YES)* $\mathrm{Cov}(\mathcal{T}, k) \geq M$.
- *(NO)* $\mathrm{Cov}(\mathcal{T}, k) \leq (1 - 1/e + \delta)M$.

Proof of Theorem 2. Fix $\delta = 0.1$. We reduce from the Maximum k-Coverage problem. Suppose that $(\mathcal{T}, k)$ is a regular Maximum k-Coverage instance; we assume w.l.o.g. that k is divisible by 10.

We construct the instance $(\mathcal{S}, \{k_S\}_{S\in\mathcal{S}})$ of the DCG maximization as follows:

- Let $n = |\mathcal{T}|$ where we associate each $j \in [n]$ with $T_j \in \mathcal{T}$.
- Let $\mathcal{S} = \{S_1, \ldots, S_M\}$ where $S_i = \{j \in [n] \mid i \in T_j\}$.
- Let $k_S = 1$ for all $S \in \mathcal{S}$.

In the YES case, let $T_{j_1}, \ldots, T_{j_k}$ be such that $|T_{j_1} \cup \cdots \cup T_{j_k}| = M$. Let $\pi^* : [n] \to [n]$ be any permutation such that $\pi^*(\ell) = j_\ell$ for all $\ell \in [k]$. From regularity of $(\mathcal{T}, k)$, there are exactly $q := M/k$ sets $S \in \mathcal{S}$ such that $t_{\pi^*}(S) = i$. Therefore, we have

$$\mathrm{DCG}_{\mathcal{S},\mathbf{k}}(\pi^*) = \sum_{i\in[k]} \frac{M}{k} \cdot \frac{1}{\log(i+1)}.$$

Let OPT^* denote the RHS quantity. Notice that

$$\mathrm{OPT}^* \le \frac{M}{\log(k+1)}. \tag{3}$$

In the NO case, consider any permutation $\pi : [n] \to [n]$. Let t_i denote the i-th smallest value in the multiset $\{t_\pi(S)\}_{S\in\mathcal{S}}$. Regularity of $(\mathcal{T}, k)$ implies that

$$t_i \ge t_{i-q} + 1 \tag{4}$$

for all $i > q$. This in turn implies that

$$t_i \ge \lceil i/q \rceil . \tag{5}$$

Furthermore, $\mathrm{Cov}(\mathcal{T}, k) \le (1 - 1/e - \delta)M \le 0.8M$ implies that

$$t_{0.8M} > k.$$

Furthermore, applying (4) to the above, we have

$$t_{0.9M} \ge t_{0.8M} + \left\lfloor \frac{0.1M}{q} \right\rfloor = k + 0.1k = 1.1k. \tag{6}$$

With the above notion, we may write $\mathrm{DCG}_{\mathcal{S},\mathbf{k}}(\pi) - \mathrm{OPT}^*$ as

$$\begin{aligned}
\mathrm{DCG}_{\mathcal{S},\mathbf{k}}(\pi) - \mathrm{OPT}^* &= \sum_{i=1}^{M} \frac{1}{\log(t_i+1)} - \sum_{i=1}^{M} \frac{1}{\log(\lceil i/q \rceil + 1)} \\
&\overset{(5)}{\ge} \sum_{i=0.9M}^{M} \left(\frac{1}{\log(t_i+1)} - \frac{1}{\log(\lceil i/q \rceil + 1)} \right) \\
&\overset{(6)}{\ge} \sum_{i=0.9M}^{M} \left(\frac{1}{\log(1.1k+1)} - \frac{1}{\log(\lceil i/q \rceil + 1)} \right) \\
&\ge \sum_{i=0.9M}^{M} \left(\frac{1}{\log(1.1k+1)} - \frac{1}{\log(k+1)} \right) \\
&= 0.1M \cdot \left(\frac{1}{\log(1.1k+1)} - \frac{1}{\log(k+1)} \right) \\
&= \Theta\left(\frac{M}{\log^2 k} \right).
\end{aligned}$$

Finally, observe also that

$$\mathrm{OPT}^* = \frac{M}{k} \cdot \sum_{i \in [k]} \frac{1}{\log(i+1)} = \frac{M}{k} \Theta\left(\frac{k}{\log k}\right) = \Theta\left(\frac{M}{\log k}\right).$$

Combining the above two inequalities, we have

$$\mathrm{DCG}_{\mathcal{S},\mathbf{k}}(\pi) \geq \left(1 + \Theta\left(\frac{1}{\log k}\right)\right) \cdot \mathrm{OPT}^*.$$

Now, suppose that there is a PTAS for maximizing DCG that runs in time $f(\epsilon) \cdot (nm)^{2^{o(1/\epsilon)}}$. If we run the algorithm with $\epsilon = \gamma / \log k$ where $\gamma > 0$ is sufficiently small constant, then we can distinguish between the YES case and the NO case in time $f(1/\log k) \cdot (nm)^{2^{o(\log k)}} \leq f(1/\log k) \cdot (nm)^{o(k)} = g(k) \cdot N^{o(k)}$ which, from Theorem 14, violates Gap-ETH. ◀

4 Max-Sum Dispersion

In this section, we provide a QPTAS for Max-Sum Dispersion (Theorem 3).

As alluded to earlier, our algorithm will reduce to the Densest k-Subgraph (DkS) problem, for which an *additive* QPTAS is known [11]. Notice here that DkS is a generalization of the Max-Dispersion problem because we may simply set $V = U, k = p$ and $w(\{u, v\}) = d(u, v)/D$ where $D := \max_{u,v} d(u, v)$ denote the diameter of the metric space. Note however that we cannot apply Theorem 7 yet because the QPTAS in that theorem offers an *additive* guarantee. E.g. if the optimum is $o(1)$, then the QPTAS will not yield anything at all unless we set $\epsilon = o(1)$, which then gives a running time $n^{\omega(\log n)}$. This example can happen when e.g. there is a single pair u, v that are very far away and then all the other pairs are close to u.

Our main technical contribution is to give a simple structural lemma that allows us to avoid such a scenario. Essentially speaking, it allows us to pick a vertex and selects all vertices that are "too far away" from it. Once this is done, the remaining instance can be reduced to DkS without encountering the "small optimum" issue described in the previous paragraph.

4.1 A Structural Lemma

Henceforth, we write $\mathrm{Disp}(S, T)$ to denote $\sum_{u \in S, v \in T} d(u, v)$ and $\mathrm{Disp}(u, T)$ as a shorthand for $\mathrm{Disp}(\{u\}, T)$. Furthermore, we use $\mathcal{B}(u, D)$ to denote $\{z \in U \mid d(z, u) \leq D\}$ and let $\overline{\mathcal{B}(u, D)} := U \setminus \mathcal{B}(u, D)$.

We now formalize our structural lemma. It gives a lower bound on the objective based on a vertex in the optimal solution and another vertex *not* in the optimal solution. Later on, by guessing these two vertices, we can reduce to DkS while avoiding the "small optimum" issue.

▶ **Lemma 15.** *Let S^{OPT} be any optimal solution of Max-Sum Dispersion and let $u^{\min}$ be the vertex in S^{OPT} that minimizes $\mathrm{Disp}(u^{\min}, S^{\mathrm{OPT}})$. Furthermore, let v be any vertex* not *in S^{OPT} and let $\Delta = d(u^{\min}, v)$. Then, we have*

$$\mathrm{Disp}(S^{\mathrm{OPT}}) \geq \frac{p(p-1)\Delta}{16}.$$

Proof of Lemma 15. Let $S^{\mathrm{OPT}}_{\mathrm{close}} := S^{\mathrm{OPT}} \cap \mathcal{B}(u^{\min}, 0.5\Delta)$. Consider two cases, based on the size of $S^{\mathrm{OPT}}_{\mathrm{close}}$:

- Case I: $|S^{\mathrm{OPT}}_{\mathrm{close}}| \leq p/2$. In this case, we have

$$\mathrm{Disp}(u^{\min}, S^{\mathrm{OPT}}) \geq \mathrm{Disp}(u^{\min}, S^{\mathrm{OPT}} \setminus S^{\mathrm{OPT}}_{\mathrm{close}}) \geq (p/2)(\Delta/2) = \Delta p/4.$$

  Furthermore, by our definition of $u^{\min}$, we have

$$\mathrm{Disp}(S^{\mathrm{OPT}}) = \frac{1}{2}\sum_{u \in S} \mathrm{Disp}(u, S^{\mathrm{OPT}}) \geq \frac{p}{2}\,\mathrm{Disp}(u^{\min}, S^{\mathrm{OPT}}).$$

  Combining the two inequalities, we have $\mathrm{Disp}(S^{\mathrm{OPT}}) \geq p^2\Delta/8$.
- Case II: $|S^{\mathrm{OPT}}_{\mathrm{close}}| > p/2$. In this case, since S^{OPT} is an optimal solution, replacing any $z \in S^{\mathrm{OPT}}_{\mathrm{close}}$ with v must not increase the solution value, i.e.

$$\begin{aligned}\mathrm{Disp}(z, S^{\mathrm{OPT}}) &\geq \mathrm{Disp}(v, S^{\mathrm{OPT}} \setminus \{z\}) \\ &\geq \mathrm{Disp}(v, S^{\mathrm{OPT}}_{\mathrm{close}} \setminus \{z\}) \\ &\geq ((p-1)/2)(0.5\Delta),\end{aligned}$$

  where the second inequality uses the fact that for any $z' \in S^{\mathrm{OPT}}_{\mathrm{close}}$ we have $d(v, z') \geq d(u, v) - d(u, z') \geq \Delta - 0.5\Delta$. From this, we once again have

$$\begin{aligned}\mathrm{Disp}(S^{\mathrm{OPT}}) = \frac{1}{2}\sum_{u \in S} \mathrm{Disp}(u, S^{\mathrm{OPT}}) \geq \frac{1}{2}\sum_{z \in S^{\mathrm{OPT}}_{\mathrm{close}}} \mathrm{Disp}(z, S^{\mathrm{OPT}}) &\geq |S^{\mathrm{OPT}}_{\mathrm{close}}| \cdot \frac{(p-1)\Delta}{8} \\ &> \frac{p(p-1)}{16\Delta},\end{aligned}$$

  where the last inequality follows from our assumption of this case. ◀

4.2 QPTAS for Max-Sum Dispersion

We now present our QPTAS, which simply guesses $u^{\min}$ and $v = \mathrm{argmax}_{z \notin S^{\mathrm{OPT}}} d(z, u)$ and then reduces the problem to DkS. By definition of v, if we let $\Delta = d(u, v)$, every point outside $\mathcal{B}(u^{\min}, \Delta)$ must be in S^{OPT}. The actual reduction to DkS is slightly more complicated than that described at the beginning of this section. Specifically, among points $\overline{\mathcal{B}(u^{\min}, \Delta)}$ that surely belong to S^{OPT}, we ignore all points outside $\mathcal{B}(u^{\min}, 20\Delta/\epsilon)$ (i.e., they do not appear in the DkS instance) and we let $\mathcal{B}(u^{\min}, 20\Delta/\epsilon) \setminus \mathcal{B}(u^{\min}, \Delta)$ be the "must pick" part. Ignoring the former can be done because the contribution to the objective from those points can be approximated to within $(1 \pm O(\epsilon))$ regardless of the points picked in the ball $\mathcal{B}(u^{\min}, \Delta)$. This is not true for the latter, which means that we need to include them in our DkS instance.

Proof of Theorem 3. Our algorithm works as follows:

1. For every distinct $u, v \in U$ do:
   a. Let $\Delta := d(u, v)$ and $\Delta^* = 20\Delta/\epsilon$.
   b. If $|\overline{\mathcal{B}(u, \Delta)}| \geq p$, then skip the following steps and continue to the next pair u, v.
   c. Otherwise, create a DkS instance where $V := \mathcal{B}(u, \Delta^*), I := V \setminus \mathcal{B}(u, \Delta)$, $k = p - |\overline{\mathcal{B}(u, \Delta^*)}|$ and w is defined as $w(\{y, z\}) := 0.5d(y, z)/\Delta^*$ for all $y, z \in V$.
   d. Use the additive QPTAS from Theorem 7 to solve the above instance to within an additive error of $\epsilon' := 0.00005\epsilon^2$. Let T be the solution found.
   e. Finally, let $S^{u,v} := T \cup \overline{\mathcal{B}(u, \Delta^*)}$.
2. Output the best solution among $S^{u,v}$ considered.

It is obvious that the running time is dominated by the running time of the QPTAS which takes $n^{O(\log n/(\epsilon')^2)} = n^{O(\log n/\epsilon^4)}$ as desired.

Next, we show that the algorithm indeed yields a $(1-\epsilon)$-approximation. To do this, let us consider $S^{\mathrm{OPT}}, u^{\min}$ as defined in Lemma 15, and let $u = u^{\min}, v := \operatorname{argmax}_{z \notin S^{\mathrm{OPT}}} d(u,z)$. Let T be the solution found by the DkS algorithm for this u, v and let $T' := T \setminus I$. We have

$$\begin{aligned}
&\mathrm{Disp}(S^{u,v}) \\
&= \mathrm{Disp}(\overline{\mathcal{B}(u,\Delta^*)}) + \mathrm{Disp}(\overline{\mathcal{B}(u,\Delta^*)}, T) + \mathrm{Disp}(T) \\
&= \mathrm{Disp}(\overline{\mathcal{B}(u,\Delta^*)}) + \mathrm{Disp}(\overline{\mathcal{B}(u,\Delta^*)}, I) + \mathrm{Disp}(\overline{\mathcal{B}(u,\Delta^*)}, T') + \mathrm{Disp}(T). \qquad (7)
\end{aligned}$$

Similarly, letting $S := S^{\mathrm{OPT}} \cap \mathcal{B}(u,\Delta^*)$ and $S' := S^{\mathrm{OPT}} \setminus I$, we have

$$\begin{aligned}
&\mathrm{Disp}(S^{\mathrm{OPT}}) \\
&= \mathrm{Disp}(\overline{\mathcal{B}(u,\Delta^*)}) + \mathrm{Disp}(\overline{\mathcal{B}(u,\Delta^*)}, I) + \mathrm{Disp}(\overline{\mathcal{B}(u,\Delta^*)}, S') + \mathrm{Disp}(S). \qquad (8)
\end{aligned}$$

Now, observe from the definition of the DkS instance (for this u, v) that for any J such that $I \subseteq J \subseteq V$, we have

$$\mathrm{Den}(J) = \frac{1}{k(k-1)/2} \cdot \frac{0.5}{\Delta^*} \mathrm{Disp}(J).$$

The additive approximation guarantee from Theorem 7 implies that $\mathrm{Den}(T) \geq \mathrm{Den}(S) - \epsilon'$. Using the above equality, we can rewrite this guarantee as

$$\mathrm{Disp}(S) - \mathrm{Disp}(T) \leq \epsilon' \cdot \Delta^* \cdot k(k-1). \qquad (9)$$

Taking the difference between Equation (8) and Equation (7) and applying Equation (9), we have

$$\begin{aligned}
\mathrm{Disp}(S^{\mathrm{OPT}}) - \mathrm{Disp}(S^{u,v}) &\leq \mathrm{Disp}(\overline{\mathcal{B}(z,\Delta^*)}, S') - \mathrm{Disp}(\overline{\mathcal{B}(z,\Delta^*)}, T') + \epsilon' \cdot \Delta^* \cdot k(k-1). \\
(\text{Our choice of } \epsilon') &\leq \mathrm{Disp}(\overline{\mathcal{B}(z,\Delta^*)}, S') - \mathrm{Disp}(\overline{\mathcal{B}(z,\Delta^*)}, T') + 0.001\epsilon\Delta \cdot p(p-1) \\
(\text{Lemma 15}) &\leq \mathrm{Disp}(\overline{\mathcal{B}(z,\Delta^*)}, S') - \mathrm{Disp}(\overline{\mathcal{B}(z,\Delta^*)}, T') + 0.1\epsilon\,\mathrm{Disp}(S^{\mathrm{OPT}}).
\end{aligned}$$

Now, since $|S'| = |T'| \leq p$ and $S', T' \subseteq \mathcal{B}(z,\Delta)$, we have

$$\begin{aligned}
\mathrm{Disp}(\overline{\mathcal{B}(z,\Delta^*)}, S') - \mathrm{Disp}(\overline{\mathcal{B}(z,\Delta^*)}, T') &\leq |\overline{\mathcal{B}(z,\Delta^*)}| \cdot |S'| \cdot ((\Delta^* + \Delta) - (\Delta^* - \Delta)) \\
&\leq 2|\overline{\mathcal{B}(z,\Delta^*)}| \cdot |S'| \cdot \Delta \\
(\text{Our choice of } \Delta^*) &\leq 0.1\epsilon \cdot |\overline{\mathcal{B}(z,\Delta^*)}| \cdot |S'| \cdot (\Delta^* - \Delta) \\
&\leq 0.1\epsilon \cdot \mathrm{Disp}(\overline{\mathcal{B}(z,\Delta^*)}, S') \\
&\leq 0.1\epsilon \cdot \mathrm{Disp}(S^{\mathrm{OPT}}).
\end{aligned}$$

Combining the above two inequalities, we get $\mathrm{Disp}(S^{u,v}) \geq (1 - 0.2\epsilon) \cdot \mathrm{Disp}(S^{\mathrm{OPT}})$, as desired. ◀

5 Max-Sum Diversification

In this section, we give our quasipolynomial-time approximation algorithm for the Max-Sum Diversification with approximation ratio arbitrarily close to $(1 - 1/e)$ (Theorem 4). In fact, we prove a slightly stronger version of the theorem where the approximation ratio for the dispersion part is arbitrarily close to 1 and that of the submodular part is arbitrarily close to $1 - 1/e$. This is stated more precisely below; note that this obviously implies Theorem 4.

▶ **Theorem 16.** *Let S^{OPT} be any optimal solution of Max-Sum Diversification. There exists a randomized $n^{O(\log n/\epsilon^4)}$-time algorithm that finds a p-size set S such that*

$$\mathbb{E}[\mathrm{Div}(S)] \geq (1-\epsilon)\,\mathrm{Disp}(S^{\mathrm{OPT}}) + (1-1/e-\epsilon)f(S^{\mathrm{OPT}}).$$

At a high-level, our algorithm for Max-Sum Diversification is very similar to that of Max-Sum Dispersion presented in the previous section. Specifically, we use a structural lemma (akin to Lemma 15) to reduce our problem to a variant of DkS. This variant of DkS additionally has a submodular function attached to it. Using techniques from DkS approximation literature, we give an algorithm for this problem by in turn reducing it to the submodular maximization problem over a partition matroid, for which we can appeal to Theorem 8.

5.1 Approximating Densest Subgraph and Submodular Function

We will start by giving an algorithm for the aforementioned extension of the DkS problem, which we call *Submodular DkS*:

▶ **Definition 17** (Submodular DkS)**.** *Given (V, I, w, k) (similar to DkS) together with a monotone submodular set function h on the ground set V (accessible via a value oracle), the goal is to find a size-k subset T where $I \subseteq T \subseteq V$ that maximizes $h(T) + \mathrm{Den}(T)$.*

We give a quasipolynomial-time algorithm with an approximation guarantee similar to QPTAS for the original DkS (i.e. Theorem 7) while also achiving arbritrarily close to $(1-1/e)$ approximation ratio for the submodular part of the objective:

▶ **Theorem 18.** *For any set T^{OPT} of size k such that $I \subseteq T^{\mathrm{OPT}} \subseteq V$, there is an $n^{O(\log n/\gamma^2)}$-time algorithm that output a size-k T such that $I \subseteq T \subseteq V$ and*

$$\mathbb{E}[h(T) + \mathrm{Den}(T)] \geq (1-1/e-\gamma)\,h(T^{\mathrm{OPT}}) + \mathrm{Den}(T^{\mathrm{OPT}}) - \gamma. \tag{10}$$

In order to facilitate the subsequent discussion and proof, it is useful to define additional notations. (Throughout, we view vectors as column vectors.)

- Let $\mathbf{W} \in \mathbb{R}^{V\times V}$ denote the vector where $\mathbf{W}_{u,v} = w(\{u,v\})$ for $u \neq v$ and $\mathbf{W}_{u,u} = 0$.
- For every $U \subseteq V$, let $\mathbf{1}(U) \in \mathbb{R}^V$ denote the indicator vector of U, i.e.

$$\mathbf{1}(U)_v = \begin{cases} 1 & \text{if } v \in U, \\ 0 & \text{otherwise.} \end{cases}$$

- For every $U \subseteq V$, let $\mathbf{w}(U) = \mathbf{W} \cdot \mathbf{1}(U) \in \mathbb{R}^V$.
- Finally, for every non-empty $U \subseteq V$, let $\overline{\mathbf{w}}(U) := \frac{1}{|U|} \cdot w(U)$ and $\overline{\mathbf{1}}(U) := \frac{1}{|U|} \cdot \mathbf{1}(U)$.

To understand our reduction, we must first describe the main ideas behind the QPTAS of [11]. (Some of these ideas also present in previous works, e.g. [5].) Let us assume for simplicity of presentation that $I = \emptyset$. Observe that DkS is, up to an appropriate scaling, equivalent to find a size-k subset T that maximizes $\overline{\mathbf{1}}(T)^T \cdot \mathbf{W} \cdot \overline{\mathbf{1}}(T) = \overline{\mathbf{1}}(T)^T \overline{\mathbf{w}}(T)$. The main observation is that, if we randomly pick a subset $U \subseteq T^{\mathrm{OPT}}$ of size $\Theta_\gamma(\log n)$, then with high probability $\|\overline{\mathbf{w}}(U) - \overline{\mathbf{w}}(T^{\mathrm{OPT}})\|_\infty \leq O(\gamma)$ and $|\overline{\mathbf{1}}(T^{\mathrm{OPT}})^T \overline{\mathbf{w}}(T^{\mathrm{OPT}}) - \overline{\mathbf{1}}(U)^T \overline{\mathbf{w}}(U)| < O(\gamma)$. Roughly speaking, [11] exploits this by "guessing" such a set U and then solves for T such that $\|\overline{\mathbf{w}}(U) - \overline{\mathbf{w}}(T)\|_\infty \leq O(\gamma)$ and $|\overline{\mathbf{1}}(T)^T \overline{\mathbf{w}}(U) - \overline{\mathbf{1}}(U)^T \overline{\mathbf{w}}(U)| < O(\gamma)$; note that (the fractional version of) this is a linear program and can be solved efficiently. [11] then shows that a fractional solution to such a linear program can be rounded to an actual size-k set without any loss in the objective function.

We further push this idea by noting that, if we randomly partition V into $V_1, \ldots, V_s$ part where $s = O_\gamma(k/\log n)$, then the intersections $U_i^{\mathrm{OPT}} := V_i \cap T^{\mathrm{OPT}}$ satisfy the two conditions from the previous paragraphs (for $T = U_i^{\mathrm{OPT}}$). Therefore, we may enumerate all sets $U_i \subseteq V_i$ of roughly expected size to construct a collection $\mathcal{P}_i$ of subsets that satisfies these two conditions. Our goal now become picking $U_1 \in \mathcal{P}_1, \ldots, U_s \in \mathcal{P}_s$ that maximizes $h(U_1 \cup \cdots \cup U_s)$. This is simply monotone submodular maximization subject to a partition matroid constraint and therefore we may appeal to Theorem 8. We remark here that the two conditions that all subsets in $\mathcal{P}_i$ satisfy already ensure that the DkS objective is close to optimum. The full proof of Theorem 18 is deferred to the full version [2].

5.2 From Submodular DkS to Max-Sum Diversification

Having provided an approximation algorithm for Submodular DkS, we can use it to approximate Max-Sum Diversification via a similar approach to the reduction from Max-Sum Dispersion to DkS in the previous section. In particular, we can prove a structural lemma for Max-Sum Diversification that is analogous to Lemma 15 for Max-Sum Dispersion. We can then use the reduction nearly identical to the one in the proof of Theorem 3 to arrive at Theorem 16. The full details are deferred to the full version [2].

6 Conclusion

In this work, we consider three problems related to diversification: DCG in diversified search ranking, Max-Sum Dispersion and Max-Sum Diversification. For DCG, we give a PTAS and prove a nearly matching running time lower bound. For Max-Sum Dispersion, we give a QPTAS and similarly provide evidence for nearly matching running time lower bounds. Finally, we give a quasi-polynomial time algorithm for Max-Sum Diversification that achieves an approximation ratio arbitrarily close to $(1 - 1/e)$, which is also tight given the $(1 - 1/e + o(1))$ factor NP-hardness of approximating Maximum k-Coverage [26]. Our algorithms for DCG and Max-Sum Diversification are randomized and it remains an interesting open question whether there are deterministic algorithms with similar running times and approximation ratios.

Abstract

Threshold signature schemes enable distribution of the signature issuing capability to multiple users, to mitigate the threat of signing key compromise. Though a classic primitive, these signatures have witnessed a surge of interest in recent times due to relevance to modern applications like blockchains and cryptocurrencies. In this work, we study round-optimal threshold signatures in the post-quantum regime and improve the only known lattice-based construction by Boneh et al. [CRYPTO'18] as follows:

- *Efficiency.* We reduce the amount of noise flooding used in the construction from $2^{\Omega(\lambda)}$ down to $\sqrt{Q}$, where Q is the bound on the number of generated signatures and λ is the security parameter. By using lattice hardness assumptions over polynomial rings, this allows to decrease the signature bit-lengths from $\widetilde{O}(\lambda^3)$ to $\widetilde{O}(\lambda)$, bringing them significantly closer to practice. Our improvement relies on a careful analysis using Rényi divergence rather than statistical distance in the security proof.
- *Instantiation.* The construction of Boneh et al. requires a standard signature scheme to be evaluated homomorphically. To instantiate this, we provide a homomorphism-friendly variant of Lyubashevsky's signature [EUROCRYPT '12] which achieves low circuit depth by being "rejection-free" and uses an optimal, moderate noise flooding of $\sqrt{Q}$, matching the above.
- *Towards Adaptive Security.* The construction of Boneh et al. satisfies only selective security, where all the corrupted parties must be announced before any signing query is made. We improve this in two ways: in the Random Oracle Model, we obtain *partial adaptivity* where signing queries can be made before the corrupted parties are announced but the set of corrupted parties must be announced *all at once*. In the standard model, we obtain full adaptivity, where parties can be corrupted at any time but this construction is in a weaker *pre-processing* model where signers must be provided correlated randomness of length proportional to the number of signatures, in an offline preprocessing phase.

1 Introduction

A threshold signature [23] distributes the signature issuing capacity among several users, so that a signature can be generated only if a sufficient number of users collaborate to sign a message. In more detail, each of N parties holds a partial signing key, and any set of parties at least as large as a given threshold $t \leq N$ can participate in a protocol to generate a signature. Security requires that a valid signature cannot be generated if fewer than t parties cooperate.

A central motivation for constructing threshold signatures is to decentralize the trust placed in the signing authority, thus reducing the risk of the signing key being compromised. While threshold signatures have been studied for a long time [43, 24, 14, 33, 31, 44, 25, 20, 15, 13, 30, 21, 32, 7], they have received renewed attention in recent years due to numerous applications in modern topics such as cryptocurrencies and blockchains. Most prior work has focused on creating distributed versions of ECDSA or Schnorr signatures [44, 31, 25, 14, 15] which are not quantum secure. From conjectured post-quantum assumptions such as those related to Euclidean lattices, much less is known, especially with optimal round complexity.

1.1 Prior Work

The thresholdisation of lattice-based signatures from the NIST post-quantum cryptography project has been investigated in [19] but the resulting candidates incur several rounds of communication. A threshold signature restricted to $t = N$ was proposed in [22] but it also involves possibly many rounds, because of aborts. To the best of our knowledge, the only lattice-based, round-optimal threshold signature construction is by Boneh et al. [9] (henceforth BGGJKRS), relying on the Learning With Errors problem (LWE). However, while this construction provided the first feasibility result for a long-standing open problem, it suffers from the following drawbacks:

1. *Noise Flooding and Impact on Parameters.* It makes use of the so-called "noise flooding" technique [34, 6, 37], which aims to hide a noise term $e \in \mathbb{Z}$ that possibly contains sensitive information, by adding to it a fresh noise term e' whose distribution has a standard deviation that is much larger than an a priori upper bound on $|e|$. To get security against attackers with success probability $2^{-o(\lambda)}$ where λ is the security parameter, the standard deviation of e' must be a factor $2^{\Omega(\lambda)}$ larger than the upper bound on $|e|$.
   Unfortunately, this precludes the use of an efficient LWE parametrisation. Concretely, one has to set the LWE noise rate α as $2^{-\Omega(\lambda)}$ so that $|e'|$ remains small compared to the working modulus q. As the best known algorithms for attacking LWE with (typical) parameters n, q, α have run-times that grow as $\exp(\widetilde{O}(n \log q / \log^2 \alpha))$ (see, e.g., [38]) this leads to setting $n \log q = \widetilde{\Omega}(\lambda^3)$. As the signature shares have bit-sizes that grow as $\Omega(n \log q)$, this leads to $\widetilde{\Omega}(\lambda^3)$-bit signature sizes – prohibitively expensive in practice.

2. *Instantiating Underlying Signature.* It requires a standard signature scheme to be evaluated homomorphically. BGGJKRS do not suggest a candidate and existing lattice based signatures are not suitable – the GPV signature scheme [35] and its practical versions [27, 51, 28] seem ill-suited, as the signing algorithm is very sequential, and the required 1-dimensional Gaussian samples are obtained via algorithms based on rejection sampling (see, e.g., [39, 56]) that are costly to transform into circuits. The other candidate is Lyubashevsky's signature scheme [46, 47]. It has the advantage of being far less sequential, but it also relies on rejection sampling: when some rejection test does not pass, then one needs to restart the signing process.

3. *Selective Security.* It only achieves a very restricted notion of *selective* security, where all the corrupted parties must be announced before any partial signing query is made. To obtain security in the more realistic *adaptive* setting, one option is to invoke complexity leveraging, which consists in guessing at the outset which parties will be corrupted. This is not only dissatisfying as a solution but also leads to a further degradation of the parameters.

1.2 Our Contributions

In this work, we improve the construction from [9] as follows:

- *Efficiency.* We decrease the noise flooding ratio from $2^{\Omega(\lambda)}$ down to $\sqrt{Q}$, where Q is the bound on the number of generated signatures. This gives a one-round threshold signature of bit-length growing as $\widetilde{O}(\lambda \log^2 Q)$, which is $\widetilde{O}(\lambda)$ for any polynomially bounded Q,[1] in contrast with $\widetilde{O}(\lambda^3)$ for the construction from [9]. These bit-lengths are obtained when relying on the ring variants of SIS and LWE [48, 50, 54, 49]. Additionally, we show that the amount of noise flooding used in this construction is *optimal*, by exhibiting an attack when a smaller noise flooding ratio is used.
- *Instantiation.* To instantiate the signature underlying BGGJKRS, we provide a homomorphism friendly variant of Lyubashevsky's signature [EUROCRYPT '12] which achieves low circuit depth. We remove the rejection sampling at the expense of adding moderate noise of size $\sqrt{Q}$, matching the above. Again, we show that this amount of flooding is optimal by demonstrating an attack when smaller flooding is used.
- *Selective versus Adaptive.* As discussed above, the construction BGGJKRS satisfies only selective security. We improve this in two ways: in the Random Oracle Model (ROM), in which a hash function is being modeled as a uniformly sampled function with the same domain and range, we obtain a notion of *partial adaptivity* where signing queries can be made before the corrupted parties are announced. However, the set of corrupted parties must be announced *all at once*. In the standard model, we obtain a construction with full adaptivity, where parties can be corrupted at any stage in the protocol. However, this construction is in a weaker *pre-processing* model where signers must be provided correlated randomness of length proportional to the number of signing queries. The informed reader may notice similarities with the "MPC with Preprocessing" model, please see [29] and references therein [2].

1.3 Technical Overview

Recap of BGGJKRS Threshold Signatures. The round-optimal threshold signatures provided by [9] are designed using a "universal thresholdizer" which enables the thresholdizing of a number of primitives. This thresholdizer is itself instantiated using a threshold version of "special" fully homomorphic encryption (FHE), which in turn can be constructed using the

[1] For many applications, the bound Q is quite limited and can be considered to be a small polynomial in λ. For example, for applications pertaining to cryptocurrencies, the bound Q may capture the total number of transactions made with a user's wallet during the lifetime of a signing key. According to statistics available at the URLs below, one transaction per day and per user is a generous upper bound. This suggests that number of signing queries in the lifecycle of the key will be quite limited. `https://www.blockchain.com/charts/n-transactions`, `https://www.statista.com/statistics/647374/worldwide-blockchain-wallet-users/`

[2] Note that we can trade the offline sharing of correlated randomness with an additional communication round in the signing protocol – however, this would destroy round optimality.

LWE assumption. In threshold fully homomorphic encryption (TFHE), the setup algorithm takes as input a threshold t and produces a set of decryption key shares $\mathsf{sk}_1, \ldots, \mathsf{sk}_N$ for the parties such that every party can perform a partial decryption using its own decryption key and any t out of N partial decryptions can be combined into a complete decryption of the ciphertext in a single round.

In more detail, the TFHE construction of BGGJKRS leverages the fact that the decryption in LWE based FHE schemes [12, 11, 36] requires to compute an inner product of the ciphertext ct with the secret key sk, followed by a rounding operation. Since inner product is a linear operation, a natural approach to thresholdize FHE decryption is by applying a Shamir t-out-of-N secret sharing to sk. This will yield N keys $\mathsf{sk}_1, \ldots, \mathsf{sk}_N$, which can be distributed to the N users. Now, to decrypt a ciphertext ct, each user can compute the inner product with its individual secret key sk_i as its partial decryption m_i. To combine any t partial decryptions into the final decryption, the combiner chooses Lagrange coefficients $\gamma_1, \ldots, \gamma_t$ so that $\sum_i \gamma_i \mathsf{sk}_i = \mathsf{sk}$. Then, she computes

$$\sum_i \gamma_i m_i = \sum_i \gamma_i \langle \mathsf{ct}, \mathsf{sk}_i \rangle = \langle \mathsf{ct}, \sum_i \gamma_i \mathsf{sk}_i \rangle = \langle \mathsf{ct}, \mathsf{sk} \rangle,$$

followed by rounding, as desired. However, this appealingly simple construction turns out to be insecure. This is because each time a party computes a partial decryption, it leaks information about its secret share sk_i via the inner product with (the public) value ct.

To get around this insecurity, a natural approach is to add noise to the partial decryption which quickly transforms a simple computation to intractable. However, care must be taken to ensure that this added noise does not affect correctness, since it is later multiplied by the Lagrange coefficients during reconstruction: the previous $\sum_i \gamma_i m_i$ will now become $\sum_i \gamma_i (m_i + e_i)$ for some noise terms e_i. BGGJKRS propose two solutions – one to use a secret sharing scheme whose reconstruction coefficients are binary, and another, to "clear the denominators" by observing that since the Lagrange coefficients are rational numbers, it is possible to scale them to be integers. The exact details are irrelevant for the current discussion and hence omitted (please refer to [9] for more details).

To use this technique to construct threshold signatures, the authors propose the following. Choose a signature scheme Sig, compute an FHE encryption $\mathsf{ct}_{\mathsf{sk}}$ of its signing key $\mathsf{Sig.sk}$ and let each signer homomorphically evaluate the signing algorithm for a message μ on this ciphertext. In more detail, given $\mathsf{ct}_{\mathsf{sk}} = \mathsf{FHE.Enc}(\mathsf{Sig.sk})$, each party first computes $\mathsf{FHE.Eval}(C, \mathsf{ct}_{\mathsf{sk}})$ where C is the circuit $\mathsf{Sig.Sign}(\mu, \cdot)$. By correctness of FHE, this yields an FHE encryption of the signature $\sigma = \mathsf{Sig.Sign}(\mathsf{Sig.sk}, \mu)$. To this ciphertext, the thresholdization trick described above may now be applied.

Modeling the Adversary and Effect on Parameters. In their analysis, BGGJKRS consider the complexity-theory security requirement of "no polynomial time attacks", corresponding to assuming attacks with advantage $\epsilon = \lambda^{-O(1)}$ and run-time $\lambda^{O(1)}$. However, for practically motivated primitives like threshold signatures, it is more meaningful to consider attackers with advantage $2^{-o(\lambda)}$ and run-time $2^{o(\lambda)}$. We choose our adversarial model so that all attacks should be exponential while all honest algorithms run in polynomial time. Compared to the complexity-theory definition of security, this provides a much more significant (and practically meaningful) hardness gap between honest and malicious parties.

For subexponentially strong attackers as described above, the noise flooding used in BGGJKRS is exponential, severely damaging the practicality of the scheme, despite the exciting developments in practical FHE [18, 57, 41, 17, 16, 26]. In more detail, the proof

requires to make the statistical distance between some noise terms e' and $e + e'$ small, so that knowing $e + e'$ is essentially the same as knowing e', which does not carry sensitive information. To get security against attackers with advantage $2^{-o(\lambda)}$, the statistical distance must be set to $2^{-\Omega(\lambda)}$ and, as a result, the standard deviation of e' must be a factor $2^{\Omega(\lambda)}$ larger than the upper bound on $|e|$.

Tightening Analysis via Rényi divergence. In this work, we examine whether this flooding noise can be improved so that the impact of flooding e by e' on efficiency is minimised. To this end, we explore using *Rényi divergence* rather than statistical distance to bound the distance between distributions in the security proof. Rényi divergence has been used in prior work as a replacement to the statistical distance in lattice based cryptography [42, 45, 8, 52, 40, 4, 10, 3, 5]. To understand why this may be beneficial, let us first see how statistical distance is used in typical security proofs of cryptography. Let $\mathcal{P}$ and $\mathcal{Q}$ be two non-vanishing probability distributions over a common measurable support X. Typical security proofs consider a hard problem relying on some ideal distribution $\mathcal{Q}$, and then replace this ideal distribution by a real world distribution $\mathcal{P}$. When the statistical distance $\Delta(\mathcal{Q}, \mathcal{P})$ between the two distributions is small, the problem remains hard, implying security. This is made rigorous by the so-called "probability preservation" property which says that for any measurable event $E \subseteq X$, we have $\mathcal{Q}(E) \geq \mathcal{P}(E) - \Delta(\mathcal{Q}, \mathcal{P})$.

Let us now define Rényi Divergence (RD). For $a \in (1, \infty)$, the RD of order a is defined by $R_a(\mathcal{P}||\mathcal{Q}) = \left(\sum_{x \in X} \frac{\mathcal{P}(x)^a}{\mathcal{Q}(x)^{a-1}}\right)^{\frac{1}{a-1}}$. It enjoys an analogous probability preservation property, though multiplicative as against additive. For $E \subseteq X$, we have $\mathcal{Q}(E) \geq \mathcal{P}(E)^{\frac{a}{a-1}} / R_a(\mathcal{P}||\mathcal{Q})$. Thus, if an event E occurs with significant probability under $\mathcal{P}$, and if the SD or the RD is small, then the event E also occurs with significant probability under $\mathcal{Q}$. As discussed in [5], probability preservation in SD is meaningful when the distance is smaller than any $\mathcal{P}(E)$ that the security proof is required to deal with – if $\mathcal{P}(E) \geq \epsilon$ for some ϵ, then we require that $\Delta(\mathcal{Q}, \mathcal{P}) < \epsilon$. The analogous requirement for RD is $R_a(\mathcal{P}||\mathcal{Q}) \leq \mathsf{poly}(1/\epsilon)$. Bai et al. [5] observed that RD is often less demanding than SD in proofs. This is because RD between distributions may be small enough to suffice for RD probability preservation while SD may be too large for the SD probability preservation to be applicable. Thus, RD can often serve as a better tool for security analysis, especially in applications with search-type security definitions, like signatures.

In this work, we study the applicability of RD analysis in the construction of threshold signatures. Building upon the above approach, we show that a limited flooding growing as $\sqrt{Q}$ suffices in BGGJKRS, where Q is the number of signing queries made by the attacker. We note that this is a substantial improvement in practice, since the number of sign queries is typically very different, and much smaller, than the run time of the adversary. Note that signature queries require active participation by an honest user and there is no reason for an honest user to keep replying after an overly high number of queries that clearly shows adversarial behavior. As a concrete example, in the NIST post quantum project [1], adversarial runtimes can go up to 2^{256} in some security levels, but the number of signature queries is always bounded by 2^{64} (which is itself an overly conservative bound in many scenarios). Thus, dependence on the number of queries is significantly better than exponential dependence on the security parameter, and this leads to a significant improvement in the signature bit size.

Optimality of our Moderate Flooding. We also show that this magnitude of flooding is necessary for this construction, by exhibiting a statistical attack when smaller noise is used. At a high level, our attack proceeds as follows. First we show that using legitimate

information available to her, the adversary can compute $\mathsf{err}_M + e_{1,M}$ where err_M is the error that results from homomorphically evaluating the signing algorithm for message M and $e_{1,M}$ is the flooding noise that is used in the partial signature of the first party. As a warmup, consider the setting where the flooding noise is randomized. Now, since the signature scheme is deterministic, the term err_M depends only on M and remains fixed across multiple queries for the same message. On the other hand, the term $e_{1,M}$ keeps changing. Using Hoeffding's bound, it is possible to estimate the average of $e_{1,M}$ across multiple queries and use this to recover err_M, leading to an attack.

This attack may be avoided by making the flooding noise a deterministic function of the message, e.g., by using a pseudo-random function evaluated on the message to generate the noise. We show that this modification is not sufficient to make the threshold signature construction secure. For this purpose, we design a signature scheme which includes "useless" information in the signature: this information does not affect correctness nor security of the signature itself, but allows us to recreate the attack described above on the resulting threshold signature. We start with a secure signature scheme $\mathsf{Sig} = (\mathsf{Sig.KeyGen}, \mathsf{Sig.Sign}, \mathsf{Sig.Verify})$ whose signing key is a uniform bit-string among those with the same number of 0's and 1's. Now, let us consider a special signature scheme $\mathsf{Sig}' = (\mathsf{Sig}'.\mathsf{KeyGen}, \mathsf{Sig}'.\mathsf{Sign}, \mathsf{Sig}'.\mathsf{Verify})$ derived from Sig by modifying the signing algorithm as follows: for $i \in [|\mathsf{Sig.sk}|]$, if $\mathsf{Sig.sk}_i = 0$, then append a 0 to the signature. Since our signing key has exactly half as many 0's as 1's, this leads to a string of $|\mathsf{Sig.sk}|/2$ zeroes being appended to every signature: this does not leak any information and does not affect correctness (it is simply ignored during verification). Now, consider using Sig' to instantiate our threshold signature scheme. Then, for any message M, the FHE ciphertext CT_{σ_M} now additionally includes homomorphically evaluated encryptions of $\{\mathsf{Sig.sk}_i\}_{i \in [|\mathsf{Sig.sk}|]:\mathsf{Sig.sk}_i = 0}$. Note that these extra encryptions are designed to be a deterministic function of the secret key so that across multiple messages, the corresponding error term (obtained via homomorphic evaluation) will not change. On the other hand, the message-dependent error terms can be assumed to change across messages. Due to this, the error term recovered by the adversary will be a sum of a fixed term (dependent only on the secret key) plus a fresh term per signature, which allows it to recreate the first attack. Please see Section 3 for more details.

Homomorphism-Friendly Signature. Next, we provide a variant of Lyubashevsky's signature scheme [47] which enjoys low circuit depth and is homomorphism friendly. As discussed above, Lyubashevsky's signature contains a rejection sampling step, whose purpose is to make the distribution of the resultant signature canonical, but this step is cumbersome to implement homomorphically. We show that by using RD analysis in place of statistical distance, analogously to the case of threshold signatures discussed above, the rejection sampling step can be replaced by noise flooding of moderate magnitude $\sqrt{Q}$. Additionally, we show that this flooding is optimal – please see Section 4 for details.

Towards Adaptive Security. Another limitation of the construction of $\mathsf{BGGJKRS}$ is that security is proved in the weak "selective" model where the adversary must announce all corrupted users before receiving the public parameters and verification key. In contrast, the more reasonable adaptive model allows the adversary to corrupt users based on the public parameters, the verification key and previous user corruptions it may have made. We briefly describe the difficulty in achieving adaptive security. At a high level, in the selective game, the challenger proceeds by simulating the partial keys corresponding to the honest parties in a "special way". The challenge in the adaptive setting is that without knowing who are the honest/corrupted parties, the challenger does not know which partial keys to program.

For more details, let us consider the case of an N-out-of-N threshold signature. In the simulation, the challenger knows which party is honest at the start of the game, e.g., player N. Now, the challenger can sample FHE secret keys $\mathsf{sk}_1, \ldots, \mathsf{sk}_{N-1}$ randomly, implicitly setting the last share as $\mathsf{sk} - \sum_{i\in[N-1]} \mathsf{sk}_i$. To invoke the unforgeability of the underlying signature scheme Sig, the challenger must "forget" the signing key $\mathsf{Sig.sk}$ at some point in the proof, and rely on the Sig challenger to return signatures, which it then encrypts using the (public key) FHE scheme. By correctness of FHE, this is the same as computing the signing circuit for a given message on the ciphertext containing the secret key, which is what happens in the real world. However, the FHE encryption of signing key $\mathsf{Sig.sk}$ is provided as part of the public parameters in the real world, which in turn means that the FHE secret key must be "forgotten" so that the FHE ciphertext of $\mathsf{Sig.sk}$ is indistinguishable from a dummy value. Yet the challenger must return legitimate partial signatures of queried messages m_j in the security game, which in turn are (noisy) partial decryptions of the FHE ciphertexts $\widehat{\sigma_j}$ of signatures σ_j. Knowing all the corrupt secret keys $\mathsf{sk}_1, \ldots, \mathsf{sk}_{N-1}$ from the outset enables the challenger to walk this tightrope successfully – it obtains σ_j from the Sig challenger, computes an FHE encryption $\widehat{\sigma_j}$ of this, computes partial decryptions using $\mathsf{sk}_1, \ldots, \mathsf{sk}_{N-1}$, floods these with appropriate noise and returns these to the adversary.

In the adaptive game, the honest player is not known at the beginning of the game so the challenger is unable to sample FHE secret key shares as described above. When requested for a partial signatures for message m_j, it can obtain the corresponding signature σ_j and can FHE encrypt it, but cannot decrypt it using secret key shares which are unavailable. To preserve correctness and indistinguishability from the real world, it is forced to return (noisy) random secret shares $\{\sigma_{i,j}\}_{i\in[N],j\in\mathsf{poly}}$ of σ_j as partial signatures, for unbounded j. Later if user 1 is corrupted (say), the adversary receives the secret key share sk_1. Now, to preserve indistinguishability, the challenger must explain the partial signatures $\{\sigma_{1,j}\}_{j\in\mathsf{poly}}$ corresponding to user 1 as $\langle \widehat{\sigma}_j, \mathsf{sk}_1 \rangle \approx \sigma_{1,j}$, which seems impossible for unbounded j.

We overcome this hurdle in the ROM by having the challenger simulate all partial keys as though corresponding to a corrupt user and when the list of corrupted parties becomes available, "program" the ROM to "explain" the returned keys in a consistent way. This yields an intermediate notion of "partial adaptivity", in which the attacker can make signing queries before corruption, but must announce its corrupted users all at once. In more detail, we modify the signing key to additionally contain a random secret share of $\mathbf{0}$, i.e., each party is provided a vector $\mathbf{v}_i$ of length N, such that $\sum_{i\in[N]} \mathbf{v}_i = \mathbf{0}$. In the scheme, to compute a partial signature for a message m_j, the partial signing algorithm first computes $r_{i,j} = H(j,K)^{\mathsf{T}}\, \mathbf{v}_i$ where $H(j,K)$ is a random vector of length N, and K is a secret value required for a technical reason that we will not discuss here. It then returns $\langle \widehat{\sigma}_j, \mathsf{sk}_i \rangle + \mathsf{noise}_{i,j} + r_{i,j}$. By linearity, it holds that $\sum_{i\in[N]} H(j,K)^{\mathsf{T}}\, \mathbf{v}_i = \mathbf{0}$, so correctness is not affected. But the unbounded programmability of the ROM helps us overcome the aforementioned impasse in the proof. Now, the challenger answers partial signature queries by returning (noisy) random secret shares $\{\sigma_{i,j}\}_{i\in[N],j\in\mathsf{poly}}$ of σ_j. When later, user 1 is corrupted, it can correctly explain the returned signatures as follows: it samples sk_1, computes $d_{1,j} = \langle \widehat{\sigma}_j, \mathsf{sk}_1 \rangle + \mathsf{noise}$ and sets $r_{1,j} = \sigma_{1,j} - d_{1,j}$. Now we may program $H(j,K)$ so that $r_{i,j} = H(j,K)^{\mathsf{T}}\, \mathbf{v}_i$ for all j – it can be checked that there are enough degrees of freedom to satisfy these equations. However, since all secrets of a user are revealed when it is corrupted, the value $H(j,K)$ is fixed when even a single user is corrupted. This is why we require that all corruptions be made simultaneously and only achieve the restricted notion of "partial" adaptivity.

We also provide a construction in the standard model which achieves full adaptivity where users can be corrupted at arbitrary points in the security game. But this construction is only secure in a weaker *pre-processing* model where the signers must be provided correlated

randomness of length proportional to the number of signing queries, in an offline pre-processing phase. We emphasize that the correlated randomness is independent of the messages to be signed later. This model is reminiscent of the "MPC with Preprocessing" model (please see [29] and references therein). We refer the reader to Section 5 for more details.

2 Preliminaries

In this section, we define some preliminaries used in our work. Please refer to the full version of the paper [2] for additional preliminaries.

▶ **Definition 1** (Threshold Signatures). *Let $P = \{P_1, \ldots, P_N\}$ be a set of N parties. A threshold signature scheme for a class of efficient access structures $\mathbb{S}$ on P is a tuple of PPT algorithms denoted by* $\mathsf{TS} = (\mathsf{TS.KeyGen}, \mathsf{TS.PartSign}, \mathsf{TS.PartSignVerify}, \mathsf{TS.Combine}, \mathsf{TS.Verify})$ *defined as follows:*

- $\mathsf{TS.KeyGen}(1^\lambda, \mathsf{A}) \to (\mathsf{pp}, \mathsf{vk}, \{\mathsf{sk}_i\}_{i=1}^N)$*: On input the security parameter λ and an access structure* A*, the* KeyGen *algorithm outputs public parameters* pp*, verification key* vk *and a set of key shares* $\{\mathsf{sk}_i\}_{i=1}^N$*.*
- $\mathsf{TS.PartSign}(\mathsf{pp}, \mathsf{sk}_i, m) \to \sigma_i$*: On input the public parameters* pp*, a partial signing key* sk_i *and a message $m \in \{0,1\}^*$, the partial signing algorithm outputs a partial signature σ_i.*
- $\mathsf{TS.PartSignVerify}(\mathsf{pp}, m, \sigma_i) \to \mathsf{accept/reject}$*: On input the public parameters* pp*, a message $m \in \{0,1\}^*$ and a partial signature σ_i, the partial signature verification algorithm outputs accept or reject.*
- $\mathsf{TS.Combine}(\mathsf{pp}, \{\sigma_i\}_{i\in S}) \to \sigma_m$*: On input the public parameters* pp *and the partial signatures $\{\sigma_i\}_{i\in S}$ for $S \in \mathsf{A}$, the combining algorithm outputs a full signature σ_m.*
- $\mathsf{TS.Verify}(\mathsf{vk}, m, \sigma_m) \to \mathsf{accept/reject}$*: On input a verification key* vk*, a message m and a signature σ_m, the verification algorithm outputs accept or reject.*

A TS scheme should satisfy the following requirements.

▶ **Definition 2** (Compactness). *A* TS *scheme for $\mathbb{S}$ satisfies compactness if there exist polynomials $\mathrm{poly}_1(\cdot), \mathrm{poly}_2(\cdot)$ such that for all λ, $\mathsf{A} \in \mathbb{S}$ and $S \in \mathsf{A}$, the following holds. For $(\mathsf{pp}, \mathsf{vk}, \{\mathsf{sk}_i\}_{i=1}^N) \leftarrow \mathsf{TS.KeyGen}(1^\lambda, \mathsf{A})$, $\sigma_i \leftarrow \mathsf{TS.PartSign}(\mathsf{pp}, \mathsf{sk}_i, m)$ for $i \in S$, and $\sigma_m \leftarrow \mathsf{TS.Combine}(\mathsf{pp}, \{\sigma_i\}_{i\in S})$, we have that $|\sigma_m| \le \mathrm{poly}_1(\lambda)$ and $|\mathsf{vk}| \le \mathrm{poly}_2(\lambda)$.*

▶ **Definition 3** (Evaluation Correctness). *A signature scheme* TS *for $\mathbb{S}$ satisfies evaluation correctness if for all $\lambda, \mathsf{A} \in \mathbb{S}$ and $S \in \mathsf{A}$, the following holds. For $(\mathsf{pp}, \mathsf{vk}, \{\mathsf{sk}_i\}_{i=1}^N) \leftarrow \mathsf{TS.KeyGen}(1^\lambda, \mathsf{A})$, $\sigma_i \leftarrow \mathsf{TS.PartSign}(\mathsf{pp}, \mathsf{sk}_i, m)$ for $i \in [N]$ and $\sigma_m \leftarrow \mathsf{TS.Combine}(\mathsf{pp}, \{\sigma_i\}_{i\in S})$, we have that $\Pr[\mathsf{TS.Verify}(\mathsf{vk}, m, \sigma_m) = accept] \ge 1 - \lambda^{-\omega(1)}$.*

▶ **Definition 4** (Partial Verification Correctness). *A signature scheme* TS *for $\mathbb{S}$ satisfies partial verification correctness if for all λ and $\mathsf{A} \in \mathbb{S}$, the following holds. For $(\mathsf{pp}, \mathsf{vk}, \{\mathsf{sk}_i\}_{i=1}^N) \leftarrow \mathsf{TS.KeyGen}(1^\lambda, \mathsf{A})$, $\Pr[\mathsf{TS.PartSignVerify}(\mathsf{pp}, m, \mathsf{TS.PartSign}(\mathsf{pp}, \mathsf{sk}_i, m)) = 1] = 1 - \lambda^{-\omega(1)}$.*

▶ **Definition 5** (Unforgeability). *A* TS *scheme is unforgeable if for any adversary $\mathcal{A}$ with runtime $2^{o(\lambda)}$, the output of the following experiment $\mathsf{Expt}_{\mathcal{A},\mathsf{TS},uf}(1^\lambda)$ is 1 with probability $2^{-\Omega(\lambda)}$:*

1. *On input the security parameter λ, the adversary outputs an access structure $\mathsf{A} \in \mathbb{S}$.*
2. *Challenger runs the $\mathsf{TS.KeyGen}(1^\lambda)$ algorithm and generates public parameters* pp*, verification key* vk *and set of N key shares $\{\mathsf{sk}_i\}_{i=1}^N$. It sends* pp *and* vk *to $\mathcal{A}$.*
3. *Adversary $\mathcal{A}$ then issues polynomial number of following two types of queries in any order*
   - *Corruption queries: $\mathcal{A}$ outputs a party $i \in [N]$ which it wants to corrupt. In response, the challenger returns the key share sk_i.*

- *Signature queries: $\mathcal{A}$ outputs a query of the form (m, i), where m is a message and $i \in [N]$, to get partial signature σ_i for m. The challenger computes σ_i as $\mathsf{TS.PartSign}(\mathsf{pp}, \mathsf{sk}_i, m)$ and provides it to $\mathcal{A}$.*

4. *At the end of the experiment, adversary $\mathcal{A}$ outputs a message-signature pair (m^*, σ^*).*
5. *The experiment outputs 1 if both of the following conditions are met: (i) Let $S \subseteq [N]$ be the set of corrupted parties, then S is a an invalid party set, i.e. $S \notin \mathsf{A}$ (ii) m^* was not queried previously as a signing query and $\mathsf{TS.Verify}(\mathsf{vk}, m^*, \sigma^*) = accept$.*

We also consider following weaker notions of unforgeability.

▶ **Definition 6** (Partially Adaptive Unforgeability). *Here, all the corruptions are done all at once. That is, Step 3, is now changed as follows:*

- *$\mathcal{A}$ issues polynomial number of signing queries of the form (m, i) adaptively and gets corresponding σ_i's.*
- *$\mathcal{A}$ outputs a set $S \subseteq [N]$ such that $S \notin \mathsf{A}$. The challenger returns $\{\mathsf{sk}_i\}_{i \in S}$.*
- *$\mathcal{A}$ continues to issue polynomial number of more signing queries of the form (m, i) adaptively, and gets corresponding σ_i.*

Rest of the steps remain the same.

▶ **Definition 7** (Selective Unforgeability). *In this case, all the corruptions happen before any signing query. That is, Step 3, is now further changed as follows:*

- *$\mathcal{A}$ outputs a set $S \subseteq [N]$ such that $S \notin \mathsf{A}$. The challenger returns $\{\mathsf{sk}_i\}_{i \in S}$.*
- *$\mathcal{A}$ issues polynomial number of signing queries of the form (m, i) adaptively, and gets corresponding σ_i.*

Rest of the steps remain the same.

▶ **Definition 8** (Robustness). *A TS scheme for $\mathbb{S}$ satisfies robustness if for all λ, the following holds. For any adversary $\mathcal{A}$ with run-time $2^{o(\lambda)}$, the following experiment $\mathsf{Expt}_{\mathcal{A},\mathsf{TS},rb}(1^\lambda)$ outputs 1 with probability $2^{-\Omega(\lambda)}$:*

- *On input the security parameter 1^λ, the adversary outputs an access structure $\mathsf{A} \in \mathbb{S}$.*
- *The challenger samples $(\mathsf{pp}, \mathsf{vk}, \mathsf{sk}_1, \ldots, \mathsf{sk}_N) \leftarrow \mathsf{TS.KeyGen}(1^\lambda, \mathsf{A})$ and provides $(\mathsf{pp}, \mathsf{vk}, \mathsf{sk}_1, \ldots, \mathsf{sk}_N)$ to $\mathcal{A}$.*
- *Adversary $\mathcal{A}$ outputs a partial signature forgery (m^*, σ_i^*, i).*
- *The experiment outputs 1 if $\mathsf{TS.PartSignVerify}(\mathsf{pp}, m^*, \sigma_i^*) = 1$ and $\sigma_i^* \neq \mathsf{TS.PartSign}(\mathsf{pp}, \mathsf{sk}_i, m^*)$.*

2.1 Rényi Divergence

▶ **Definition 9** (Rényi Divergence). *Let P and Q be any two discrete probability distributions such that $Supp(P) \subseteq Supp(Q)$. Then for $a \in (1, \infty)$, the Rényi Divergence of order a is defined by: $R_a(P||Q) = \left(\sum_{x \in Supp(P)} \frac{P(x)^a}{Q(x)^{a-1}}\right)^{\frac{1}{a-1}}$.*

The following lemma is borrowed from [5, Lemma 2.9], with the exception of the multiplicativity property for non-independent variables, which is borrowed from [53, Proposition 2].

▶ **Lemma 10.** *Let $a \in [1, \infty]$. Let P and Q denote distributions with $Supp(P) \subseteq Supp(Q)$. Then the following properties hold*

- ***Log Positivity:*** *$R_a(P||Q) \geq R_a(P||P) = 1$.*
- ***Data Processing Inequality:*** *$R_a(P^f||Q^f) \leq R_a(P||Q)$ for any function f, where P^f (resp. Q^f) denotes the distribution of $f(y)$ induced by sampling $y \leftarrow P$ (resp. $y \leftarrow Q$).*

- ***Probability preservation:*** *Let $E \subseteq Supp(Q)$ be an arbitrary event. If $a \in (1, \infty)$, then $Q(E) \geq P(E)^{\frac{a}{a-1}} / R_a(P\|Q)$.*
- ***Multiplicativity:*** *Assume that P and Q are two distributions of a pair of random variables (Y_1, Y_2). For $i \in \{1, 2\}$, let P_i (resp. Q_i) denote the marginal distribution of Y_i under P (resp. Q), and let $P_{2|1}(\cdot|y_1)$ (resp. $Q_{2|1}(\cdot|y_1)$) denote the conditional distribution of Y_2 given that $Y_1 = y_1$. Then we have:*
  - *$R_a(P||Q) = R_a(P_1||Q_1) \cdot R_a(P_2||Q_2)$ if Y_1 and Y_2 are independent for $a \in [1, \infty]$.*
  - *$R_a(P||Q) \leq R_a(P_1||Q_1) \cdot \max_{y_1 \in Y_1} R_a(P_{2|1}(\cdot|y_1)||Q_{2|1}(\cdot|y_1))$.*

We will use the following RD bounds. Note that proof tightness can often be improved by optimizing over a, as suggested in [55].

▶ **Lemma 11** ([5]). *For any n-dimensional lattice, $\Lambda \subseteq \mathbb{R}^n$ and $s > 0$, let P be the distribution $\mathcal{D}_{\Lambda,s,\mathbf{c}}$ and Q be the distribution $\mathcal{D}_{\Lambda,s,\mathbf{c}'}$ for some fixed $\mathbf{c}, \mathbf{c}' \in \mathbb{R}^n$. If $\mathbf{c}, \mathbf{c}' \in \Lambda$, let $\epsilon = 0$. Otherwise fix $\epsilon \in (0, 1)$ and assume that $s > \eta_\epsilon(\Lambda)$. Then for any $a \in (1, +\infty)$*

$$R_a(P||Q) \in \left[\left(\frac{1-\epsilon}{1+\epsilon}\right)^{\frac{2}{a-1}}, \left(\frac{1+\epsilon}{1-\epsilon}\right)^{\frac{2}{a-1}} \right] \cdot \exp\left(a\pi \frac{||\mathbf{c}-\mathbf{c}'||^2}{s^2}\right).$$

3 More Efficient Threshold Signatures from Lattices

In this section, we show how to drastically decrease the exponential flooding used in the scheme by Boneh et al. [9]. We also show that the limited flooding that we use is in fact optimal, and smaller noise would lead to an attack. For ease of exposition, the construction below is for the special case of N out of N threshold and restricted to selective security. We extend it to t out of N threshold in the full version of the paper [2] and to adaptive security in Section 5. In Section 4, we show how to instantiate the underlying signature scheme using a variant of Lyubashevsky's signature [47] with matching moderate flooding.

3.1 Optimizing the Boneh et al. scheme using the Rényi Divergence

Our scheme is similar to the one in [9] and is provided in Figure 1. The construction uses the following building blocks:

- A PRF $F : \mathcal{K} \times \{0,1\}^* \to \{0,1\}^r$, where $\mathcal{K}$ is the PRF key space and r is the bit-length of randomness used in sampling from discrete Gaussian $\mathcal{D}_s$.
- A fully homomorphic encryption scheme $\mathsf{FHE} = (\mathsf{FHE.KeyGen}, \mathsf{FHE.Enc}, \mathsf{FHE.Dec}, \mathsf{FHE.Eval})$. As in [9], we also assume that the $\mathsf{FHE.Dec}$ can be divided into two sub-algorithms: $\mathsf{FHE.decode}_0$ and $\mathsf{FHE.decode}_1$.
- A UF-CMA signature scheme $\mathsf{Sig} = (\mathsf{Sig.KeyGen}, \mathsf{Sig.Sign}, \mathsf{Sig.Verify})$.
- A context hiding homomorphic signature scheme $\mathsf{HS} = (\mathsf{HS.PrmsGen}, \mathsf{HS.KeyGen}, \mathsf{HS.Sign}, \mathsf{HS.SignEval}, \mathsf{HS.Process}, \mathsf{HS.Verify}, \mathsf{HS.Hide}, \mathsf{HS.HVerify})$ to provide robustness.
- An N out of N secret sharing scheme Share.

Correctness. From the correctness of $\mathsf{FHE.Eval}$, CT_σ is an encryption of $\mathcal{C}_M(\mathsf{Sig.sk}) = \mathsf{Sig.Sign}(\mathsf{Sig.sk}, M) = \sigma_M$, which decrypts with $\mathsf{FHE.sk}$. So, $\mathsf{FHE.decode}_0(\mathsf{FHE.sk}, \mathsf{CT}_\sigma) = \sigma_M \lfloor q/2 \rceil + e$. The signature computed by the $\mathsf{TS.Combine}$ algorithm is

$$\begin{aligned}
\mathsf{FHE.decode}_1\Big(\sum_{i=1}^{N} \sigma_i\Big) &= \mathsf{FHE.decode}_1\Big(\textstyle\sum_{i=1}^{N} \mathsf{FHE.decode}_0(\mathsf{sk}_i, \mathsf{CT}_\sigma) + \sum_{i=1}^{N} e'_i\Big) \\
&= \mathsf{FHE.decode}_1\Big(\mathsf{FHE.decode}_0\Big(\textstyle\sum_{i=1}^{N} \mathsf{sk}_i, \mathsf{CT}_\sigma\Big) + \sum_{i=1}^{N} e'_i\Big) \\
&= \mathsf{FHE.decode}_1\Big(\mathsf{FHE.decode}_0(\mathsf{FHE.sk}, \mathsf{CT}_\sigma) + \textstyle\sum_{i=1}^{N} e'_i\Big) \\
&= \mathsf{FHE.decode}_1\Big(\sigma_M \lfloor q/2 \rceil + e + \textstyle\sum_{i=1}^{N} e'_i\Big) = \sigma_M.
\end{aligned}$$

$\mathsf{TS.KeyGen}(1^\lambda)$: Upon input the security parameter λ, do the following.

1. For each party P_i, sample a PRF key $\mathsf{sprf}_i \leftarrow \mathcal{K}$.
2. Generate the signature scheme's keys $(\mathsf{Sig.vk}, \mathsf{Sig.sk}) \leftarrow \mathsf{Sig.KeyGen}(1^\lambda)$.
3. Generate the FHE keys $(\mathsf{FHE.pk}, \mathsf{FHE.sk}) \leftarrow \mathsf{FHE.KeyGen}(1^\lambda)$ and compute an FHE encryption of $\mathsf{Sig.sk}$ as $\mathsf{CT}_{\mathsf{Sig.sk}} \leftarrow \mathsf{FHE.Enc}(\mathsf{FHE.pk}, \mathsf{Sig.sk})$.
4. Generate the HS public parameters $\mathsf{HS.pp} \leftarrow \mathsf{HS.PrmsGen}(1^\lambda, 1^n)$ and the public and the signing keys $(\mathsf{HS.pk}, \mathsf{HS.sk}) \leftarrow \mathsf{HS.KeyGen}(1^\lambda, \mathsf{HS.pp})$. Here n is the bit-length of $(\mathsf{FHE.sk}, \mathsf{sprf}_i)$.
5. Share $\mathsf{FHE.sk}$ as $\{\mathsf{sk}_i\}_{i=1}^N \leftarrow \mathsf{Share}(\mathsf{FHE.sk})$ such that $\sum_{i=1}^N \mathsf{sk}_i = \mathsf{FHE.sk}$.
6. For each party P_i, randomly choose a tag $\tau_i \in \{0,1\}^*$ and compute $(\pi_{\tau_i}, \pi_i) \leftarrow \mathsf{HS.Sign}(\mathsf{HS.sk}, (\mathsf{sk}_i, \mathsf{sprf}_i), \tau_i)$.
7. Output $\mathsf{TSig.pp} = \{\mathsf{FHE.pk}, \mathsf{CT}_{\mathsf{Sig.sk}}, \mathsf{HS.pp}, \mathsf{HS.pk}, \{\tau_i, \pi_{\tau_i}\}_{i=1}^N\}$, $\mathsf{TSig.vk} = \mathsf{Sig.vk}$, $\mathsf{TSig.sk} = \{\mathsf{TSig.sk}_i = (\mathsf{sk}_i, \mathsf{sprf}_i, \pi_i)\}_{i=1}^N$.

$\mathsf{TS.PartSign}(\mathsf{TSig.pp}, \mathsf{TSig.sk}_i, M)$: Upon input the public parameters $\mathsf{TSig.pp}$, a partial signing key $\mathsf{TSig.sk}_i$ and a message M, parse $\mathsf{TSig.pp}$ as $(\mathsf{FHE.pk}, \mathsf{CT}_{\mathsf{Sig.sk}}, \mathsf{HS.pp}, \mathsf{HS.pk}, \{\tau_i, \pi_{\tau_i}\}_{i=1}^N\})$ and $\mathsf{TSig.sk}_i$ as $(\mathsf{sk}_i, \mathsf{sprf}_i, \pi_i)$ and do the following.

1. Compute $u = F(\mathsf{sprf}_i, M)$ and sample $e_i' \leftarrow \mathcal{D}_s(u)$, where $\mathcal{D}_s(u)$ represents sampling from $\mathcal{D}_s$ using u as the randomness.
2. Let $\mathcal{C}_M$ be the signing circuit, with message M being hardwired. Compute $\mathsf{CT}_\sigma = \mathsf{FHE.Eval}(\mathsf{FHE.pk}, \mathcal{C}_M, \mathsf{CT}_{\mathsf{Sig.sk}})$.
3. Compute $\sigma_i = \mathsf{FHE.decode}_0(\mathsf{sk}_i, \mathsf{CT}_\sigma) + e_i'$.
4. This step computes a homomorphic signature $\tilde{\pi}_i$ on partial signature σ_i to provide robustness. Let $\mathcal{C}_{\mathsf{PS}}$ be the circuit to compute $\mathsf{FHE.decode}_0(\mathsf{sk}_i, \mathsf{CT}_\sigma) + e_i'$ in which CT_σ is hardcoded and the FHE key share sk_i and the PRF key sprf_i are given as inputs.
   - Compute $\pi_i^* = \mathsf{HS.SignEval}(\mathsf{HS.pp}, \mathcal{C}_{\mathsf{PS}}, \pi_{\tau_i}, (\mathsf{sk}_i, \mathsf{sprf}_i), \pi_i)$.
   - Compute $\tilde{\pi}_i = \mathsf{HS.Hide}(\mathsf{HS.pk}, \sigma_i, \pi_i^*)$.
5. Output $y_i = (\sigma_i, \tilde{\pi}_i)$.

$\mathsf{TS.Combine}(\mathsf{TSig.pp}, \{y_i\}_{i\in[N]})$: Upon input the public parameters $\mathsf{TSig.pp}$ and a set of partial signatures $\{y_i\}_{i\in[N]}$, parse y_i as $(\sigma_i, \tilde{\pi}_i)$ and output $\sigma_M = \mathsf{FHE.decode}_1(\sum_{i=1}^N \sigma_i)$.

$\mathsf{TS.PartSignVerify}(\mathsf{TSig.pp}, M, y_i)$: Upon input the public parameters $\mathsf{TSig.pp}$, message M, and a partial signature y_i, parse y_i as $(\sigma_i, \tilde{\pi}_i)$ and do the following.

1. Compute $\mathsf{CT}_\sigma = \mathsf{FHE.Eval}(\mathsf{FHE.pk}, \mathcal{C}_M, \mathsf{CT}_{\mathsf{Sig.sk}})$.
2. Compute $\alpha = \mathsf{HS.Process}(\mathsf{HS.pp}, \mathcal{C}_{\mathsf{PS}})$, where $\mathcal{C}_{\mathsf{PS}}$ is as described above.
3. Parse y_i as $(\sigma_i, \tilde{\pi}_i)$ and output $\mathsf{HS.HVerify}(\mathsf{HS.pk}, \alpha, \sigma_i, \tau_i, (\pi_{\tau_i}, \tilde{\pi}_i))$.

$\mathsf{TS.Verify}(\mathsf{TSig.vk}, M, \sigma_M)$: Upon input the verification key $\mathsf{TSig.vk}$, a message M and a signature σ_M, output $\mathsf{Sig.Verify}(\mathsf{TSig.vk}, M, \sigma_M)$.

In the above, we set $s = B_{eval} \cdot \sqrt{Q\lambda}$, where $B_{eval} \leq \mathrm{poly}(\lambda)$ is a bound on the FHE decryption noise after homomorphic evaluation of the signing circuit $\mathcal{C}_M$, and Q is the bound on the number of signatures.

Figure 1 Optimization of Boneh et al Threshold Signature Scheme.

3.1.1 Unforgeability

For security, we prove the following theorem.

▶ **Theorem 12.** *Assume F is a secure PRF,* Sig *is UF-CMA secure,* FHE *satisfies semantic security ,* Share *satisfies privacy and* HS *is context hiding. Then the construction of threshold signatures in Figure 1 satisfies selective unforgeablity (Definition 7) if the flooding noise is of the size* $\mathrm{poly}(\lambda) \cdot \sqrt{Q}$*, where Q is the number of the signing queries.*

The security of the construction can be argued using a sequence of hybrids. We assume w.l.o.g. that the adversary $\mathcal{A}$ queries for all but the first key share, i.e., $S = [N] \setminus \{1\}$.

Hybrid_0: This is the real world.

Hybrid_1: Same as Hybrid_0, except that $\tilde{\pi}_1$ in $\mathsf{PartSign}$ is now generated using HS simulator as $\tilde{\pi}_1 = \mathsf{HS.Sim}(\mathsf{HS.sk}, \alpha, \sigma_1, \tau_1, \pi_{\tau_1})$, where $\alpha = \mathsf{HS.Process}(\mathsf{HS.pp}, \mathcal{C}_{\mathsf{PS}})$.

Hybrid_2: Same as Hybrid_1 except that to compute $\sigma_1 = \mathsf{FHE.decode}_0(\mathsf{sk}_1, \mathsf{CT}_\sigma) + e'_1$, the randomness u used to sample $e'_1 \leftarrow \mathcal{D}_s(u)$ is chosen uniformly randomly instead of computing it using the PRF.

Hybrid_3: Same as Hybrid_2, except that now, for signing query for $(M, 1)$, the challenger simulates σ_1 as follows:

1. Computes $\mathsf{CT}_\sigma = \mathsf{FHE.Eval}(\mathsf{FHE.pk}, \mathcal{C}_M, \mathsf{CT}_{\mathsf{Sig.sk}})$ and $\{\sigma'_i = \mathsf{FHE.decode}_0(\mathsf{sk}_i, \mathsf{CT}_\sigma)\}_{i\in[2,N]}$.
2. Computes $\sigma_M = \mathsf{Sig.Sign}(\mathsf{Sig.sk}, M)$ and set $\sigma_1 = \sigma_M \lfloor \frac{q}{2} \rceil - \sum_{i=2}^{N} \sigma'_i + e'_1$, where $e'_1 \leftarrow \mathcal{D}_s$.

Hybrid_4: Same as Hybrid_3 except that instead of sharing $\mathsf{FHE.sk}$, now the challenger generates the FHE key shares as $\{\mathsf{sk}_i\}_{i=1}^{N} \leftarrow \mathsf{Share}(\mathbf{0})$.

Hybrid_5: Same as Hybrid_4, except that $\mathsf{CT}_{\mathsf{Sig.sk}}$ in $\mathsf{TSig.pp}$ is replaced by $\mathsf{CT}_{\mathbf{0}} = \mathsf{FHE.Enc}(\mathsf{FHE.pk}, \mathbf{0})$.

Detailed proofs of indistinguishability are provided in the full version [2]. Below, we provide the proof for the main new claim in our work.

▶ **Claim 13.** *If there is an adversary that can win the unforgeability game in* Hybrid_2 *with probability* ϵ*, then its probability of winning the game in* Hybrid_3 *is at least* $\epsilon^2/2$.

Proof. Let the number of signing queries that the adversary makes be Q. The two hybrids differ only in the error term in σ_1, as shown below. In Hybrid_2, we have $\sigma_1 = \mathsf{FHE.decode}_0(\mathsf{sk}_1, \mathsf{CT}_\sigma) + e'_1$, for $e'_1 \leftarrow \mathcal{D}_s$. In Hybrid_3, we have:

$$\begin{aligned}
\sigma_1 &= \sigma_M . \lfloor q/2 \rceil - \sum_{i=2}^{N} \mathsf{FHE.decode}_0(\mathsf{sk}_i, \mathsf{CT}_\sigma) + e'_1 \\
&= \sigma_M . \lfloor q/2 \rceil - \sum_{i=1}^{N} \mathsf{FHE.decode}_0(\mathsf{sk}_i, \mathsf{CT}_\sigma) + \mathsf{FHE.decode}_0(\mathsf{sk}_1, \mathsf{CT}_\sigma) + e'_1 \\
&= \sigma_M . \lfloor q/2 \rceil - \mathsf{FHE.decode}_0(\sum_{i=1}^{N} \mathsf{sk}_i, \mathsf{CT}_\sigma) + \mathsf{FHE.decode}_0(\mathsf{sk}_1, \mathsf{CT}_\sigma) + e'_1 \\
&= \sigma_M . \lfloor q/2 \rceil - \mathsf{FHE.decode}_0(\mathsf{sk}, \mathsf{CT}_\sigma) + \mathsf{FHE.decode}_0(\mathsf{sk}_1, \mathsf{CT}_\sigma) + e'_1 \\
&= \sigma_M . \lfloor q/2 \rceil - \sigma_M . \lfloor q/2 \rceil + e + \mathsf{FHE.decode}_0(\mathsf{sk}_1, \mathsf{CT}_\sigma) + e'_1 \\
&= \mathsf{FHE.decode}_0(\mathsf{sk}_1, \mathsf{CT}_\sigma) + (e'_1 + e),
\end{aligned}$$

for some e satisfying $|e| \leq B_{eval}$. Thus, in Hybrid_2, the error term in σ_1 is e'_1, while in Hybrid_3, it is $e'_1 + e$, where, $e'_1 \leftarrow \mathcal{D}_s$, and e is the error in FHE ciphertext CT_σ.

Recall the distribution seen by the adversary – the public parameters $\mathsf{TSig.pp}$, the verification key $\mathsf{TSig.vk}$, the corrupted secret key shares $\mathsf{TSig.sk}_i$, the messages M_j and corresponding partial signatures $(\sigma_j, \tilde{\pi}_j)$. Note that since messages are chosen adaptively, their distribution depends on previous signature queries and responses, and in particular on the differently generated error terms in both hybrids. On the other hand $\mathsf{TSig.pp}$, $\mathsf{TSig.vk}$, $\{\mathsf{TSig.sk}_i\}$, $\{\tilde{\pi}_j\}$ are constructed identically in both hybrids and independently from the rest (in particular these error terms): we implicitly assume that they are fixed and known, and exclude them from the analysis. We refer to the distribution to be considered in Hybrid_2 as D_2 and in Hybrid_3 as D_3.

Let E_j be the random variables corresponding to the error term in CT_{σ_j} in the j-th response and $\mathcal{E}_j^{(2)}$ and $\mathcal{E}_j^{(3)}$ be their distributions in Hybrids 2 and 3, respectively. Similarly, let M_j be the random variable corresponding to the queried message in j-th query and $\mathcal{M}_j^{(2)}$

and $\mathcal{M}_j^{(3)}$ be their distributions in Hybrids 2 and 3, respectively. Then, from the discussion above, we have $\mathcal{E}_j^{(2)} = \mathcal{D}_s$ and $\mathcal{E}_j^{(3)} = \mathcal{D}_{s,e_j}$ for all $j \in [Q]$, where e_j is the error in CT_{σ_j} and can depend upon previous queries and responses.

Overall, we have $D_k = (\mathcal{E}_Q^{(k)}, \mathcal{M}_Q^{(k)}, \mathcal{E}_{Q-1}^{(k)}, \mathcal{M}_{Q-1}^{(k)}, \ldots, \mathcal{E}_1^{(k)}, \mathcal{M}_1^{(k)})$ for $k \in \{2,3\}$ and

$$R_a(D_2\|D_3) = R_a(\mathcal{E}_Q^{(2)}, \mathcal{M}_Q^{(2)}, \ldots, \mathcal{E}_1^{(2)}, \mathcal{M}_1^{(2)} \parallel \mathcal{E}_Q^{(3)}, \mathcal{M}_Q^{(3)}, \ldots, \mathcal{E}_1^{(3)}, \mathcal{M}_1^{(3)}). \tag{3.1}$$

Applying the multiplicativity property of the Rényi divergence (Lemma 10), we obtain that $R_a(D_2\|D_3)$ is bounded from above by

$$\begin{aligned} &\max_{x\in X} R_a(\mathcal{E}_Q^{(2)}|X=x \parallel \mathcal{E}_Q^{(3)}|X=x) \cdot R_a(\mathcal{M}_Q^{(2)}, \ldots, \mathcal{E}_1^{(2)}, \mathcal{M}_1^{(2)} \parallel \mathcal{M}_Q^{(3)}, \ldots, \mathcal{E}_1^{(3)}, \mathcal{M}_1^{(3)}) \\ = &\max_{x\in X} R_a(\mathcal{D}_s|X=x \parallel \mathcal{D}_{s,e_Q}|X=x) \cdot R_a(\mathcal{M}_Q^{(2)}, \ldots, \mathcal{E}_1^{(2)}, \mathcal{M}_1^{(2)} \parallel \mathcal{M}_Q^{(3)}, \ldots, \mathcal{E}_1^{(3)}, \mathcal{M}_1^{(3)}), \end{aligned} \tag{3.2}$$

where $X = (M_Q, E_{Q-1}, \ldots, E_1)$ and e_Q is the error term in CT_{σ_Q}; note that e_Q may depend on the sample from X (which differs in Hybrids 2 and 3) and is bounded by B_{eval}. Then applying Lemma 11 in Equation (3.2), we get

$$\begin{aligned} R_a(D_2\|D_3) &\leq \exp(a\pi\|e_Q\|^2/s^2) \cdot R_a(\mathcal{M}_Q^{(2)}, \ldots, \mathcal{E}_1^{(2)}, \mathcal{M}_1^{(2)} \parallel \mathcal{M}_Q^{(3)}, \ldots, \mathcal{E}_1^{(3)}, \mathcal{M}_1^{(3)}) \\ &\leq \exp(a\pi B_{eval}^2/s^2) \cdot R_a(\mathcal{M}_Q^{(2)}, \ldots, \mathcal{E}_1^{(2)}, \mathcal{M}_1^{(2)} \parallel \mathcal{M}_Q^{(3)}, \ldots, \mathcal{E}_1^{(3)}, \mathcal{M}_1^{(3)}). \end{aligned}$$

Further, since M_Q is a function of $E_{Q-1}, M_{Q-1}, \ldots, E_1, M_1$, the data processing inequality (Lemma 10) gives

$$\begin{aligned} &R_a(\mathcal{M}_Q^{(2)}, \mathcal{E}_{Q-1}^{(2)}, \ldots, \mathcal{E}_1^{(2)}, \mathcal{M}_1^{(2)} \parallel \mathcal{M}_Q^{(3)}, \mathcal{E}_{Q-1}^{(3)}, \ldots, \mathcal{E}_1^{(3)}, \mathcal{M}_1^{(3)}) \\ &\qquad\qquad \leq R_a(\mathcal{E}_{Q-1}^{(2)}, \ldots, \mathcal{E}_1^{(2)}, \mathcal{M}_1^{(2)} \parallel \mathcal{E}_{Q-1}^{(3)}, \ldots, \mathcal{E}_1^{(3)}, \mathcal{M}_1^{(3)}), \end{aligned}$$

Hence, we get

$$\begin{aligned} R_a(D_2\|D_3) &\leq \exp(a\pi B_{eval}^2/s^2) \cdot R_a(\mathcal{E}_{Q-1}^{(2)}, \ldots, \mathcal{E}_1^{(2)}, \mathcal{M}_1^{(2)} \parallel \mathcal{E}_{Q-1}^{(3)}, \ldots, \mathcal{E}_1^{(3)}, \mathcal{M}_1^{(3)}) \\ &\leq \exp(a\pi B_{eval}^2 Q/s^2), \end{aligned}$$

where the last inequality follows from induction.

As $s = B_{eval} \cdot \sqrt{Q\lambda}$, we get $R_a(D_2\|D_3) \leq \exp(a\pi/\lambda)$. Therefore, from the probability preservation property of the Rényi divergence (Lemma 10), we have $D_3(\mathsf{E}) \geq \frac{D_2(\mathsf{E})^{\frac{a}{a-1}}}{R_a(D_2\|D_3)} \geq D_2(\mathsf{E})^{\frac{a}{a-1}} \exp(-\frac{a\pi}{\lambda})$. The result is obtained by setting $a = 2$. ◀

3.2 On the Optimality of Our Flooding

We show that the flooding amount that we achieved is optimal for our threshold signature scheme. To argue this, we show how to attack it if the flooding amount is below $\Omega(\sqrt{Q})$. For simplicity, we restrict to the case of $N = 2$. Recall that in our construction, $\mathsf{TS.PartSign}(\mathsf{TSig.pp}, \mathsf{TSig.sk}_i, M)$ outputs $\sigma_{i,M} = \mathsf{FHE.decode}_0(\mathsf{sk}_i, \mathsf{CT}_{\sigma_M}) + e'_{i,M}$, where $\mathsf{TSig.sk}_i = (\mathsf{sk}_i, \mathsf{sprf}_i)$.[3] W.l.o.g, assume that the adversary gets the partial signing key $\mathsf{TSig.sk}_2$ and the response for any signing query is a partial signature corresponding to party P_1. For any message M of its choice, the adversary receives $\sigma_{1,M} = \mathsf{FHE.decode}_0(\mathsf{sk}_1, \mathsf{CT}_{\sigma_M}) + e'_{1,M}$. From this the adversary can compute:

[3] We focus only on the $\sigma_{i,M}$ component of PartSign's output since the second component, the HS signature of $\sigma_{i,M}$, is not relevant here.

$$\begin{aligned}\sigma_{1,M} + \mathsf{FHE.decode}_0(\mathsf{sk}_2, \mathsf{CT}_{\sigma_M}) &= \mathsf{FHE.decode}_0(\mathsf{FHE.sk}, \mathsf{CT}_{\sigma_M}) + e'_{1,M} \\ &= \sigma_M + \mathsf{err}_M + e'_{1,M},\end{aligned}$$

where err_M is the error in CT_{σ_M}. Note that if the adversary succeeds in computing err_M for polynomially many M's, then it can compute $\mathsf{FHE.sk}$.

As a warm-up, we show that if the error $e'_{1,M}$ is randomized, small and of center 0, then the adversary can indeed compute err_M. Later, we will show that even for deterministic flooding $e'_{1,M}$, there exist secure signature schemes for which the attack can be extended. Since the adversary knows the key share sk_2, it can compute $\sigma_{2,M}$ on its own and hence can compute $\sigma_M = \mathsf{TS.Combine}(\mathsf{TSig.pp}, \sigma_{1,M}, \sigma_{2,M})$. Hence, from $\sigma_M + \mathsf{err}_M + e'_{1,M}$, the adversary can compute $\mathsf{err}_M + e'_{1,M}$. Since, the signature scheme is deterministic, err_M depends only on M. Thus, if the same message is queried for signature multiple times, then each time the term err_M remains the same, but since flooding is randomized, the term $e'_{1,M}$ is different.

To compute err_M, the adversary issues all Q signing queries for the same message M and receives $\sigma^{(1)}_{1,M}, \ldots, \sigma^{(Q)}_{1,M}$, where $\sigma^{(i)}_{1,M}$ denotes the partial signature returned for message M in the ith query. From these responses the adversary gets Q different values of the form

$$w^i = \mathsf{err}_M + e'^i_{1,M} \tag{3.3}$$

Since err_M is same, taking average on both sides of Equation (3.3) over all the Q samples, we get $\frac{\sum_{i\in[Q]} w^i}{Q} = \mathsf{err}_M + \frac{\sum_{i\in[Q]} e'^i_{1,M}}{Q}$. If $|\frac{1}{Q}\sum_{i\in[Q]} e'^i_{1,M}| < 1/2$, then the adversary can recover err_M as $\mathsf{err}_M = \left\lfloor \frac{1}{Q}\sum_{i\in[Q]} w^i \right\rceil$. As $e'^1_{1,M}, \ldots, e'^Q_{1,M}$ are independently and identically distributed with mean 0, by Hoeffding's inequality, we have

$$\Pr\left[\left|\frac{\sum_{i\in[Q]} e'^i_{1,M}}{Q}\right| < 1/2\right] \geq 1 - 2\exp\left(-\frac{Q}{2s^2}\right).$$

If $Q \geq \Omega(s^2 \log\lambda)$, then $1 - 2\exp(-Q/(2s^2)) \geq 1 - \lambda^{-\Omega(1)}$, in which case the adversary can recover err_M with probability sufficiently close to 1 to recover sufficiently many err_M's to compute $\mathsf{FHE.SK}$. To prevent this, we do need s to grow at least proportionally to $\sqrt{Q}$.

3.2.1 Attack for Deterministic Error

In the argument for randomized error, the fact that $e'^i_{1,M}$ is randomized is crucial. However, as discussed in Section 1, we can extend the attack for the case of deterministic flooding as well, by exhibiting a secure signature scheme (with deterministic flooding) for which a variant of the attack can apply.

Consider a special (contrived) signature scheme $\mathsf{Sig}' = (\mathsf{Sig}'.\mathsf{KeyGen}, \mathsf{Sig}'.\mathsf{Sign}, \mathsf{Sig}'.\mathsf{Verify})$ derived from a secure signature scheme $\mathsf{Sig} = (\mathsf{Sig.KeyGen}, \mathsf{Sig.Sign}, \mathsf{Sig.Verify})$ as follows:

1. $\mathsf{Sig}'.\mathsf{KeyGen}$ is identical to $\mathsf{Sig.KeyGen}$. Let $(\mathsf{Sig.sk}, \mathsf{Sig.vk})$ be the signing and verification keys, respectively, and $\mathsf{Sig.sk}_i$ denote the ith bit of $\mathsf{Sig.sk}$ for $i \in [\ell]$, where ℓ is the bit-length of $\mathsf{Sig.sk}$.
2. $\mathsf{Sig}'.\mathsf{Sign}(\mathsf{Sig.sk}, M)$ is modified as follows:
   - Compute $\sigma_M = \mathsf{Sig.Sign}(\mathsf{Sig.sk}, M)$. Set $\sigma'_M := \sigma_M$.
   - For i from 1 to ℓ: if $\mathsf{Sig.sk}_i = 0$, then set $\sigma'_M := \sigma'_M \| \mathsf{Sig.sk}_i$.
   - Output σ'_M.

3. $\mathsf{Sig}'.\mathsf{Verify}(\mathsf{Sig.vk}, M, \sigma'_M)$ is defined as $\mathsf{Sig.Verify}(\mathsf{Sig.vk}, M, \sigma_M)$, where σ_M is obtained from σ'_M by removing all the bits after the kth bit, where k is the bit-length of signatures in Sig.

Above, we assume that the signing key of Sig is a uniform bit-string among those with the same number of 0's and 1's. Since $\mathsf{Sig.sk}$ has always $\ell/2$ bits equal to 0, the number of zeroes appended to the signature will be $\ell/2$ and hence does not leak any extra information to the adversary. Hence, it follows easily that if Sig is a secure signature scheme, then so is Sig'. However, as discussed in Section 1, our attack can be generalized to work for this setting.

3.2.1.1 The Attack

Now, consider using Sig' to instantiate our threshold signature scheme. Then, for any message M, the FHE ciphertext CT_{σ_M} now additionally includes homomorphically evaluated encryptions of $\{\mathsf{Sig.sk}_i\}_{i\in[\ell]:\mathsf{Sig.sk}_i=0}$. Let $\mathsf{CT}_{\sigma_M}, \mathsf{err}_M, e'_M$ respectively denote the encryption of σ_M, the error in CT_{σ_M} and the flooding noise added to partial decryption of CT_{σ_M}. Let $\mathsf{CT}^*, \mathsf{err}^*$ and e^*_M denote the components corresponding to $\{\mathsf{Sig.sk}_i\}_{i\in[\ell]:\mathsf{Sig.sk}_i=0}$.

For any message M, the adversary can compute $\mathsf{err}_M + e'_M$ as described previously, from which the adversary gets $\mathsf{err}^* + e^*_M$. If the adversary manages to compute err^* (for sufficiently many instances), then it can also recover $\mathsf{FHE.sk}$.

Note that err^* is independent of any message and hence is constant across different messages, while e^*_M does depend on M and is different for different messages. This gives an attack strategy. To compute err^*, the adversary issues Q signing queries on different messages $\{M_j\}_{j\in[Q]}$, and from the received partial signatures, derives the values for $w^*_j = \mathsf{err}^* + e^*_{M_j}$ for $j \in [Q]$.

Observe that the above equation is of the same form as Equation (3.3). Heuristically, one would expect the $e^*_{M_j}$ to behave as independent and identically distributed random variables with centre 0. Hence, we can argue in similar way that if $Q \geq \Omega(s^2 \log \lambda)$ then the adversary can recover err^* with probability $1 - 1/\operatorname{poly}(\lambda)$. This implies that for hiding err^*, the standard deviation parameter s must grow at least proportionally to $\sqrt{Q}$.

4 Instantiating Threshold Signatures: Rejection-Free Lyubashevsky

Here, we provide an FHE friendly variant of Lyubashevsky's signature scheme from [47]. Our construction uses a hash function $H : \{0,1\}^* \to D_H := \{\mathbf{v} : \mathbf{v} \in \{-1, 0, 1\}^k; \|\mathbf{v}\|_1 \leq \alpha\}$, modeled as a random oracle. Here α is a parameter, typically much smaller than k. The signature scheme is described in Figure 2.

Correctness. Since $\mathbf{z} = \mathbf{y} + \mathbf{Sc}$, where $\mathbf{y} \leftarrow \mathcal{D}_{\mathbf{Z}^m,\sigma}$, we have $\|\mathbf{z}\| \leq 2\sigma\sqrt{m} + \|\mathbf{Sc}\|$ with probability $1 - 2^{-\Omega(\lambda)}$, using standard Gaussian tail bounds . Since $\|\mathbf{S}\|_\infty \leq d$ and $\|\mathbf{c}\|_1 \leq \alpha$, we have $\|\mathbf{Sc}\| \leq d\alpha\sqrt{m}$. This gives us $\|\mathbf{z}\| \leq (2\sigma + d\alpha)\sqrt{m}$ with overwhelming probability. Finally, note that $H(\mathbf{Az} - \mathbf{Tc}, \mu) = H(\mathbf{A}(\mathbf{y} + \mathbf{Sc}) - \mathbf{ASc}, \mu) = H(\mathbf{Ay}, \mu) = \mathbf{c}$.

Security. We establish security via the following theorem. Because of space constraints, proof of the theorem is given in the full version of the paper [2].

▶ **Theorem 14.** *Assume that $m > \lambda + (n \log q)/\log(2d+1)$, $\sigma \geq \alpha d\sqrt{mQ}$ where Q is the maximum number of signing queries an attacker can make and $|D_H| \geq 2^\lambda$. Assume further that $\mathsf{SIS}_{q,n,m,\beta}$ is hard for $\beta = 2\gamma + 2d\alpha\sqrt{m}$. Then the construction in Figure 2 satisfies* UF-CMA *in the random oracle model.*

$\mathsf{KeyGen}(1^\lambda)$: Upon input the security parameter λ, set $q, n, m, \beta, k, d, \sigma$ such that $n = \Omega(\lambda)$ and the scheme is secure (see Theorem 14); then do the following:

1. Sample $\mathbf{A} \leftarrow \mathbb{Z}_q^{n \times m}$ and $\mathbf{S} \leftarrow \{-d, \ldots, 0, \ldots, d\}^{m \times k}$.
2. Set $\mathbf{T} = \mathbf{AS}$.
3. Output $\mathsf{vk} = (\mathbf{A}, \mathbf{T})$, $\mathsf{sk} = \mathbf{S}$.

$\mathsf{Sign}(\mathsf{sk}, \mu)$: Upon input the signing key sk and a message μ, do the following:

1. Sample $\mathbf{y} \leftarrow \mathcal{D}_{\mathbf{Z}^m, \sigma}$.
2. Set $\mathbf{c} = H(\mathbf{Ay}, \mu)$.
3. Set $\mathbf{z} = \mathbf{y} + \mathbf{Sc}$.
4. Output $(\mathbf{z}, \mathbf{c})$.

$\mathsf{Verify}(\mathsf{vk}, \mu, (\mathbf{z}, \mathbf{c}))$: Upon input the verification key vk, a message μ, and a signature $(\mathbf{z}, \mathbf{c})$, do the following:

1. Check if $\|\mathbf{z}\| \leq \gamma$, where $\gamma = (2\sigma + \alpha d)\sqrt{m}$.
2. Check if $H(\mathbf{Az} - \mathbf{Tc}, \mu) = \mathbf{c}$.
3. If both checks pass, then accept, else reject.

Figure 2 Lyubashevsky's Signature Without Aborts.

5 Adaptive Security for Threshold Signatures

As discussed in Section 1, we provide two constructions to improve the selective security achieved by [9]. Below, we describe our construction in the ROM, which satisfies partially adaptive unforgeability (Definition 6). Due to space constraints, we provide our construction in the standard model with *pre-processing* that satisfies fully adaptive unforgeability (Definition 5) in the full version.

5.1 Partially Adaptive Unforgeability

We use the same building blocks as in Section 3.1 for construction. We also use two keyed hash function modelled as random oracles: $H : \{0,1\}^\lambda \times \{0,1\}^* \to \mathbb{Z}_q^N$ and $H_1 : \{0,1\}^\lambda \times \{0,1\}^* \to \{0,1\}^r$. The construction is provided in Figure 3.

Correctness and Unforgeability. The proof of correctness is similar to that in Section 3.1 and is provided in the full version of the paper [2]. We prove partially adaptive unforgeability via the following theorem.

▶ **Theorem 15.** *Assume* Sig *satisfies unforgeability,* FHE *is semantically secure ,* HS *is context hiding and* Share *satisfies privacy. Then the* TS *construction in Figure 3 satisfies partially adaptive unforgeability (Definition 6) in ROM if the flooding error is of size* $\mathrm{poly}(\lambda)\sqrt{Q}$*, where* Q *is the upper bound on the number of signing queries.*

Proof. The security of the construction can be argued using the following hybrids:

Hybrid_0 and Hybrid_1 are the same as that in the proof of Theorem 12.

Hybrid_2: Same as Hybrid_1, except that the randomness u_i used in sampling e'_i in $\sigma_{i,M}$ is chosen uniformly randomly from $\{0,1\}^r$ and then H_1 is programmed as $H_1(\mathsf{hkey}_i, M) = u_i$. For random oracle queries for hash H_1 by the adversary $\mathcal{A}$ on an input x, the challenger first checks if $H_1(x)$ is already set. If so, then returns that value else chooses a value uniformly randomly from $\{0,1\}^r$ and saves and returns it.

$\mathsf{TS.KeyGen}(1^\lambda)$: Upon input the security parameter λ, do the following:

1. Randomly choose $K \leftarrow \{0,1\}^\lambda$ and N vectors $\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_N \in \mathbb{Z}_q^N$ such that $\sum_{i=1}^N \mathbf{v}_i = \mathbf{0}$.
2. Generate $(\mathsf{Sig.vk}, \mathsf{Sig.sk}) \leftarrow \mathsf{Sig.KeyGen}(1^\lambda)$ and $(\mathsf{FHE.pk}, \mathsf{FHE.sk}) \leftarrow \mathsf{FHE.KeyGen}(1^\lambda)$ and share $\mathsf{FHE.sk}$ into N shares as $(\mathsf{sk}_1, \mathsf{sk}_2, \ldots, \mathsf{sk}_N) \leftarrow \mathsf{Share}(\mathsf{FHE.sk})$ such that $\sum_{i=1}^N \mathsf{sk}_i = \mathsf{FHE.sk}$.
3. Compute an FHE encryption of the signing key as $\mathsf{CT}_{\mathsf{Sig.sk}} = \mathsf{FHE.Enc}(\mathsf{FHE.pk}, \mathsf{Sig.sk})$.
4. For each party P_i, randomly choose a tag $\tau_i \in \{0,1\}^*$, a hash key $\mathsf{hkey}_i \leftarrow \{0,1\}^\lambda$ and generate HS public parameters $\mathsf{HS.pp} \leftarrow \mathsf{HS.PrmsGen}(1^\lambda, 1^n)$ and HS public and signing keys as $(\mathsf{HS.pk}, \mathsf{HS.sk}) \leftarrow \mathsf{HS.KeyGen}(1^\lambda, \mathsf{HS.pp})$. Here, n is the length of input to $\mathsf{PartSign}$ circuit which depends on $(\mathsf{FHE.sk}, K, \mathbf{v}_i, \mathsf{hkey}_i)$.
5. Compute $(\pi_{\tau_i}, \pi_i) = \mathsf{HS.Sign}(\mathsf{HS.sk}, (\mathsf{sk}_i, K, \mathbf{v}_i, \mathsf{hkey}_i), \tau_i)$.
6. Output $\mathsf{TSig.pp} = (\mathsf{FHE.pk}, \mathsf{HS.pp}, \mathsf{HS.pk}, \mathsf{CT}_{\mathsf{Sig.sk}}, \{\tau_i, \pi_{\tau_i}\}_{i=1}^N)$, $\mathsf{TSig.vk} = \mathsf{Sig.vk}$, $\mathsf{TSig.sk} = \{\mathsf{TSig.sk}_i = (\mathsf{sk}_i, K, \mathbf{v}_i, \mathsf{hkey}_i, \pi_i)\}_{i=1}^N$.

$\mathsf{TS.PartSign}(\mathsf{TSig.pp}, \mathsf{TSig.sk}_i, M)$: Upon input the public parameters $\mathsf{TSig.pp}$, the key share $\mathsf{TSig.sk}_i = (\mathsf{sk}_i, K, \mathbf{v}_i, \mathsf{hkey}_i, \pi_i)$ and a message M, do the following:

1. Compute $u_i = H_1(\mathsf{hkey}_i, M)$ and sample $e_i' \leftarrow \mathcal{D}_s(u_i)$.
2. Let $\mathcal{C}_M$ be the signing circuit, with message M being hardcoded. Compute an FHE encryption of signature σ_M as $\mathsf{CT}_{\sigma_M} = \mathsf{FHE.Eval}(\mathsf{FHE.pk}, \mathcal{C}_M, \mathsf{CT}_{\mathsf{Sig.sk}})$.
3. Compute $r_{i,M} = H(K, M)^T \mathbf{v}_i$ and $\sigma_{i,M} = \mathsf{FHE.decode}_0(\mathsf{sk}_i, \mathsf{CT}_{\sigma_M}) + r_{i,M} + e_i'$.
4. This step computes a homomorphic signature $\tilde{\pi}_{i,M}$ on $\sigma_{i,M}$ to provide robustness. Let $\mathcal{C}_{\mathsf{PS}}$ be the circuit to compute $\mathsf{FHE.decode}_0(\mathsf{sk}_i, \mathsf{CT}_{\sigma_M}) + H(K, M)^T \mathbf{v}_i + e_i'$ in which CT_{σ_M} is hardcoded and the key share $\mathsf{TSig.sk}_i$ is given as the input. Compute $\pi^*_{i,M} = \mathsf{HS.SignEval}(\mathsf{HS.pp}, \mathcal{C}_{\mathsf{PS}}, \pi_{\tau_i}, (\mathsf{sk}_i, K, \mathbf{v}_i, \mathsf{hkey}_i), \pi_i)$ and $\tilde{\pi}_{i,M} = \mathsf{HS.Hide}(\mathsf{HS.pk}, \sigma_{i,M}, \pi^*_{i,M})$.
5. Output $y_{i,M} = (\sigma_{i,M}, \tilde{\pi}_{i,M})$.

Algorithms $\mathsf{TS.PartSignVerify}$, $\mathsf{TS.Combine}$ and $\mathsf{TS.Verify}$ are identical to those in Section 3.1.

Figure 3 Partially Adaptive Threshold Signature Scheme.

Hybrid_3: Same as Hybrid_2 except that the value of $H(K, M)$ for each M in pre corruption signing query is set in the reverse order, i.e., firstly partial signatures are computed and then $H(K, M)$ is set accordingly as follows:

1. The challenger computes $\mathsf{CT}_{\sigma_M} = \mathsf{FHE.Eval}(\mathsf{FHE.pk}, \mathcal{C}_M, \mathsf{CT}_{\mathsf{Sig.sk}})$.
2. It then computes $\mathsf{FHE.decode}_0(\mathsf{FHE.sk}, \mathsf{CT}_{\sigma_M})$ and generates N shares as $\{s_{i,M}\}_{i=1}^N \leftarrow \mathsf{Share}(\mathsf{FHE.decode}_0(\mathsf{FHE.sk}, \mathsf{CT}_{\sigma_M}))$.
3. Returns partial signatures as $\{\sigma_{i,M} = s_{i,M} + e_i'\}_{i=1}^N$. Also, if a message M is repeated for signing query, then the challenger uses same $\{s_{i,M}\}_{i=1}^N$ shares of $\mathsf{FHE.decode}_0(\mathsf{FHE.sk}, \mathsf{CT}_{\sigma_M})$ again.
4. When the adversary $\mathcal{A}$ outputs the set S of corrupted parties, the challenger first programs the value of $H(K, M)$ for each M in pre corruption signing queries as described next, and then provides key shares for $i \in S$ to $\mathcal{A}$.
   - Programming $H(K, M)$: $\forall i \in [N]$, compute $r_{i,M} = s_{i,M} - \mathsf{FHE.decode}_0(\mathsf{sk}_i, \mathsf{CT}_{\sigma_M})$ and solve for vector $\mathbf{b}_M \in \mathbb{Z}_q^N$ such that $\forall\ i \in [N], \mathbf{b}_M^T \mathbf{v}_i = r_{i,M}$. Set $H(K, M) = \mathbf{b}_M$. Note that since there are $N-1$ independent equations in N unknowns, such a $\mathbf{b}_M$ exists and can be computed.
5. To answer a random oracle query for hash function H on input x, the challenger first checks if the value is already set, if so then returns that value, else randomly samples a fresh vector $\mathbf{r}_x$ and sets and returns $H(x) = \mathbf{r}_x$.

Hybrid_4: Same as Hybrid_3, except that now the signing queries are answered differently. For each pre-corruption signing query for a message M, $\sigma_{i,M}$ is computed as follows:

1. The challenger computes $\sigma_M = \mathsf{Sig.Sign}(\mathsf{Sig.sk}, M)$ and generates random shares of $\sigma_M \lfloor q/2 \rceil$ as $\{s_{i,M}\}_{i=1}^N \leftarrow \mathsf{Share}(\sigma_M \lfloor q/2 \rceil)$ such that $\sum_{i=1}^N s_{i,M} = \sigma_M \lfloor q/2 \rceil$.
2. Returns $\sigma_{i,M} = s_{i,M} + e'_i$, where $e'_i \leftarrow \mathcal{D}_s$

When $\mathcal{A}$ outputs the set S of corrupted parties, the challenger does the following:

1. Let $PreQ$ be the set of messages for which signing queries were made before. Then for each $M \in PreQ$ it does the following. For each $i \in S$, computes $r_{i,M} = s_{i,M} - \mathsf{FHE.decode}_0(\mathsf{sk}_i, \mathsf{CT}_{\sigma_M})$. Computes $\mathbf{b}_M$ such that $\forall\ i \in S,\ \mathbf{b}_M^T \mathbf{v}_i = r_{i,M}$. Sets $H(K, M) = \mathbf{b}_M$. Such a $\mathbf{b}_M$ exists and can be computed since there are only $N-1$ equations to satisfy in N unknowns.
2. Returns the secret key shares $\{\mathsf{TSig.sk}_i\}_{i \in S}$.

For each post corruption signing query on message M, the challenger does the following. Let the honest party be P_a, i.e. $S = [N] \setminus \{a\}$.

1. Computes $\mathsf{CT}_{\sigma_M} = \mathsf{FHE.Eval}(\mathsf{FHE.pk}, \mathcal{C}_M, \mathsf{CT}_{\mathsf{Sig.sk}})$ and $\sigma_M = \mathsf{Sig.Sign}(\mathsf{Sig.sk}, M)$.
2. For each $i \in S$, computes $\sigma'_{i,M} = \mathsf{FHE.decode}_0(\mathsf{sk}_i, \mathsf{CT}_{\sigma_M}) + H(K, M)^T \mathbf{v}_i$ and $\sigma_{i,M} = \sigma'_{i,M} + e'_i$, where $e'_i \leftarrow \mathcal{D}_s$.
3. Returns $\sigma_{a,M} = \sigma_M \lfloor q/2 \rceil - \sum_{i \in S} \sigma'_{i,M} + e'_a$, where $e'_a \leftarrow \mathcal{D}_s$.

Hybrid_5 and Hybrid_6: are the same as Hybrid_4 and Hybrid_5, respectively, defined in the proof of Theorem 12.

In the full version of the paper we show that consecutive hybrids are indistinguishable and that the probability of the adversary winning the unforgeability game (Definition 6) is negligible in Hybrid_6. ◀

Parameterized Sensitivity Oracles and Dynamic Algorithms Using Exterior Algebras

Josh Alman
Department of Computer Science, Columbia University, New York, NY, USA

Dean Hirsch
Department of Computer Science, Columbia University, New York, NY, USA

Abstract

We design the first efficient sensitivity oracles and dynamic algorithms for a variety of parameterized problems. Our main approach is to modify the algebraic coding technique from static parameterized algorithm design, which had not previously been used in a dynamic context. We particularly build off of the "extensor coding" method of Brand, Dell and Husfeldt [STOC'18], employing properties of the exterior algebra over different fields.

For the k-Path detection problem for directed graphs, it is known that no efficient dynamic algorithm exists (under popular assumptions from fine-grained complexity). We circumvent this by designing an efficient sensitivity oracle, which preprocesses a directed graph on n vertices in $2^k \operatorname{poly}(k) n^{\omega+o(1)}$ time, such that, given ℓ updates (mixing edge insertions and deletions, and vertex deletions) to that input graph, it can decide in time $\ell^2 2^k \operatorname{poly}(k)$ and with high probability, whether the updated graph contains a path of length k. We also give a deterministic sensitivity oracle requiring $4^k \operatorname{poly}(k) n^{\omega+o(1)}$ preprocessing time and $\ell^2 2^{\omega k+o(k)}$ query time, and obtain a randomized sensitivity oracle for the task of approximately counting the number of k-paths. For k-Path detection in undirected graphs, we obtain a randomized sensitivity oracle with $O(1.66^k n^3)$ preprocessing time and $O(\ell^3 1.66^k)$ query time, and a better bound for undirected bipartite graphs.

In addition, we present the first fully dynamic algorithms for a variety of problems: k-Partial Cover, m-Set k-Packing, t-Dominating Set, d-Dimensional k-Matching, and Exact k-Partial Cover. For example, for k-Partial Cover we show a randomized dynamic algorithm with $2^k \operatorname{poly}(k) \operatorname{polylog}(n)$ update time, and a deterministic dynamic algorithm with $4^k \operatorname{poly}(k) \operatorname{polylog}(n)$ update time. Finally, we show how our techniques can be adapted to deal with natural variants on these problems where additional constraints are imposed on the solutions.

1 Introduction

The area of dynamic algorithms studies how to quickly and efficiently solve computational problems when the input data is changing. For example, if P is a property of a graph, then a dynamic graph algorithm for P is a data structure which maintains an n-node graph G,

and can handle updates which insert or remove an edge of G, and queries which ask whether G currently satisfies P. Efficient dynamic algorithms, which handle updates and queries in $n^{o(1)}$ time, have been designed for many important problems, and they are used in many applications, both as ways to analyze evolving data, and as subroutines of larger algorithms which need to iterate over and check many similar possibilities. See, for instance, the recent survey [16].

However, there are many prominent dynamic problems which would have many applications, but for which we do not have efficient algorithms. Often times, we even have conditional lower bounds from fine-grained complexity, showing that efficient dynamic algorithms for these problems are unlikely to exist (see e.g. [1, 17, 23] and [16, Section 2.1]). It has recently become popular to circumvent such lower bounds by instead designing a *sensitivity oracle* for the problem, a weaker notion which can still be used in many applications.

Let ℓ be a positive integer. A sensitivity oracle for a dynamic problem, with sensitivity ℓ, preprocesses an initial input, and must answer queries where $\leq \ell$ changes are made to the *initial* input. For example, if P is a property of a graph, then a graph algorithm for P with sensitivity ℓ is a data structure which preprocesses an initial graph G, and can handle queries where ℓ edges are updated (inserted or removed) in the initial graph G, and asks whether P is still satisfied. One can imagine "resetting" G back to its original state after each query[1].

In this paper, we study dynamic algorithms and sensitivity oracles for *parameterized* problems. Consider, for instance, the k-Path problem: given a positive integer k, in an n-node graph G (directed or undirected), determine whether there is a path of length k. This problem is NP-complete, so we should not hope for a dynamic algorithm with update time $n^{o(1)}$ (such a dynamic algorithm could be used to solve the static problem in $n^{2+o(1)}$ time!). However, k-Path is known to be fixed-parameter tractable (FPT), and can be solved in time $2^{O(k)} \cdot n^2$ [8, 26, 25], which is sufficiently efficient when k is small. We can thus hope for dynamic parameterized algorithms for the problem, with update time $f(k) \cdot n^{o(1)}$. And indeed, a recent line of work has designed efficient dynamic parameterized algorithms with such a running time for many different problems, typically by using dynamic variants on classic techniques from the parameterized algorithms literature like kernelization and color coding. For the k-Path problem in *undirected* graphs, such an algorithm is known with update time $k! \cdot 2^{O(k)} \cdot \text{polylog}(n)$ [2], and another with amortized update time $2^{O(k^2)}$ [11].

By contrast, no efficient dynamic parameterized algorithm for k-Path in *directed* graphs is known. Moreover, Alman, Mnich and Vassilevska [2] proved a conditional lower bound, that it does not have such an efficient dynamic parameterized algorithm assuming any one of three popular conjectures from fine-grained complexity theory (the 3SUM conjecture, the Triangle conjecture, and a "Layered Reachability Oracle" conjecture they introduce, which concerns a special case of a more popular hypothesis about reachability oracles).

This leads naturally to the two main questions we address in this paper. The first asks whether there is an analogue of the aforementioned line of work on sensitivity oracles for problems without efficient dynamic algorithms in the parameterized setting.

▶ **Question 1.** *Is there an efficient parameterized sensitivity oracle for k-Path in directed graphs?*

[1] Sensitivity oracles are sometimes referred to as "fault-tolerant" or "emergency planning" algorithms in the literature. For graph problems, these terms also sometimes refer to the decrement-only case (where edge updates only remove edges), but following [18, Section A.1], we use "sensitivity oracle" to refer to the fully dynamic case, where edges can be inserted and deleted.

We say that a sensitivity oracle for a parameterized problem, with parameter k, is *efficient* if its preprocessing time is $f(k) \cdot \text{poly}(n)$ for some computable function f, and its query time is $\text{poly}(\ell) \cdot g(k) \cdot n^{o(1)}$ for some computable function g (where ℓ is the sensitivity parameter, i.e., the number of updates allowed per query). In the case of k-Path in directed graphs, and other graph problems, we specifically seek such an efficient sensitivity oracle in the *fully dynamic* setting where queries can change any ℓ edges by inserting and deleting them.

It is natural to ask that the query time has a *polynomial* dependence on ℓ (rather than, say, just a $f(\ell)$ dependence), as we do here, for two reasons. First, this is the dependence one would get by converting an efficient dynamic algorithm into a sensitivity oracle. Second, with our definition, any parameterized problem with an efficient sensitivity oracle is in FPT via the algorithm where the sensitivity oracle preprocesses an empty graph and then gets the full input graph as a query (but this would not be true if an arbitrary $f(\ell)$ term were allowed in the query time). Along the way to answering Question 1, we will also address more precisely the relationship between the classes of parameterized problems with efficient dynamic algorithms, efficient sensitivity oracles, and efficient static algorithms (a.k.a. the class FPT).

To our knowledge, such a *fully dynamic* notion of sensitivity oracles for parameterized problems has not been previously studied. The closest prior work is very recent [6] which considered a similar but *only decremental* setting, wherein queries may only delete edges from the graph, and not insert new edges. They design very elegant decremental sensitivity oracles for directed k-Path and for k-Vertex Cover, but their preprocessing and query times have exponential dependence on ℓ and hence are not "efficient" as we defined above. We also give evidence that the techniques of [6] cannot extend to the fully-dynamic setting; see Section 1.2 below for more details.

The second question we address is inspired by prior work on static algorithms for k-Path. Many fundamental techniques in the literature on parameterized algorithms were first introduced to study the k-Path problem. One such technique, algebraic coding (sometimes called "monomial testing" or "multilinear monomial detection"), is used in the current fastest static randomized algorithms for k-Path, and has also been used in other applications in algebraic complexity theory [22, 25, 10, 9, 8, 21]. Nonetheless, to our knowledge, these techniques have not been used in a dynamic or sensitivity setting before.

▶ **Question 2.** *Can algebraic coding techniques from the design of parameterized algorithms be used to design efficient dynamic algorithms or sensitivity oracles?*

A positive answer to Question 2 could lead to efficient dynamic algorithms or sensitivity oracles for a host of parameterized problems.

1.1 Our results

Let $\omega < 2.373$ be such that we can multiply two $n \times n$ matrices in $O(n^\omega)$ arithmetic operations [3]. Our first main result gives a positive answer to Question 1.

▶ **Theorem 3.** *The k-Path problem in directed graphs has an efficient parameterized sensitivity oracle. It can be solved with*[2]*:*

- *a Monte Carlo randomized algorithm with preprocessing time $2^k \,\text{poly}(k) n^\omega$ and query time $\ell^2 2^k \,\text{poly}(k)$, or*

[2] We work in the word-RAM model of computation with w-bit words for $w = O(\log n)$. Hence, only $O(\ell)$ words are needed to specify the ℓ edges to change in a query, and we can achieve query times independent of n.

- *a deterministic algorithm with preprocessing time $4^k \operatorname{poly}(k) n^\omega$ and query time $\ell^2 2^{\omega k}$.*

In addition to edge insertion and deletions, these algorithms also allow for vertex failures as part of the ℓ updates per query.

Although k-Path is known to not have an efficient dynamic parameterized algorithm (assuming the aforementioned 3SUM, Triangle, or Layered Reachability Oracle hardness assumptions from fine-grained complexity), Theorem 3 shows it does have an efficient parameterized sensitivity oracle. Since the reductions used in [2] are still valid in the sensitivity setting, one corollary is that the sensitivity versions of the 3SUM, Triangle, and Layered Reachability problems have efficient algorithms (although there are simple algorithms showing this for 3SUM and Triangle which do not go through k-Path; see Section 4 for more details).

It follows from prior work [18] that assuming another popular conjecture, the Strong Exponential Time Hypothesis (SETH), there are problems in FPT which do not have efficient parameterized sensitivity oracles (one example is the counting version of the single-source reachability problem; see again Section 4 for more details). Hence, assuming popular conjectures from fine-grained complexity, it follows that the class of parameterized problems with an efficient sensitivity oracle lies *strictly between* the class of parameterized problems with an efficient dynamic algorithm, and the class FPT (i.e., both class inclusions are strict).

Our sensitivity oracle for Theorem 3 uses $\Theta(n^2)$ space (for constant k), and it is natural to wonder whether this can be improved, especially since known dynamic parameterized algorithms for many other problems use much smaller space (e.g., many which dynamically maintain a small kernel [2]). However, we prove unconditionally that the space usage of our algorithm cannot be improved:

▶ **Theorem 4.** *Any randomized or deterministic sensitivity oracle for k-Path in directed graphs which handles edge insertion queries must use $\Omega(n^2)$ space.*

We also give three additional algorithmic results to complement Theorem 3. First, we extend Theorem 3 to give an algorithm for approximately counting k-paths:

▶ **Theorem 5.** *There is a randomized efficient parameterized sensitivity oracle which approximately counts the number of k-paths in an n-node, m-edge directed graph. For any $\epsilon > 0$, it produces an estimate to the number of k-paths in the graph that, with probability $> 99\%$, is within ϵ relative error, with preprocessing time $\epsilon^{-2} \cdot 4^k \operatorname{poly}(k) \cdot \min\{mn, n^\omega\}$ and update time $O\left(\epsilon^{-2} \cdot \ell^2 \cdot 2^{\omega k}\right)$. In addition to edge insertion and deletions, it also allows for vertex failures as part of the ℓ updates per query.*

Second, we present a randomized sensitivity oracle with a better dependence on k, at the cost of a worse dependence on ℓ, but only for undirected graphs:

▶ **Theorem 6** (Undirected graphs)**.** *For the k-Path detection problem on an undirected graph G on n vertices, there exists a randomized sensitivity oracle with preprocessing time $O(1.66^k n^3)$ and query time $O(\ell^3 1.66^k)$.*

Third, we obtain the following corollary for bipartite graphs:

▶ **Corollary 7** (Undirected bipartite graphs)**.** *For the k-Path detection problem on an undirected bipartite graph, where the partition of the vertices V into the two sides $V = S \cup T$ is known in advance and holds after any updates, there exists a sensitivity oracle with $2^{k/2} \operatorname{poly}(k) n^3$ preprocessing time and $\ell^3 2^{k/2} \operatorname{poly}(k)$ query time.*

Our algorithm for Theorem 3 uses a new dynamic version of the algebraic coding technique, and more specifically, a recent implementation called "extensor coding" by Brand, Dell, and Husfeldt [10]. See Section 2.5 and 3 below for more background on this technique, and the new ideas we introduce to be able to use it in a dynamic or sensitivity setting. We are then able to use and further modify our approach to design efficient dynamic parameterized algorithms for many problems for which no such algorithm was previously known, positively answering Question 2. We present the definitions for the problems we consider, followed by the results.

▶ **Definition 8** (k-Partial Cover). *Given a collection of subsets $S_1, ..., S_n \subseteq [N]$, find the minimum size of a sub-collection T of these, for which $\left|\bigcup_{S\in T} S\right| \geq k$, or declare that no such T exists.*

▶ **Definition 9** (m-Set k-Packing). *Given subsets $S_1, ..., S_n \subseteq [N]$, all with size $|S_i| = m$, decide whether there exists a sub-collection of k sets, which are all pairwise disjoint.*

▶ **Definition 10** (t-Dominating Set). *Given an undirected graph G on n vertices, find the minimum size of a set of vertices $S \subseteq V(G)$ such that $|S \cup N(S)| \geq t$ where $N(S)$ is the set of neighbors of vertices in S, i.e., $N(S) = \bigcup_{v\in S} N(v)$.*

▶ **Definition 11** (d-Dimensional k-Matching). *Fixing a universe $U = U_1 \times U_2 \times \ldots \times U_d$, where U_i are pairwise disjoint of combined size $|\biguplus_i U_i| = N$, and given a collection of tuples $T \subseteq U$, decide whether T contains a sub-collection of k pairwise disjoint tuples. (We say the tuples $a, b \in U$ are disjoint if $a[i] \neq b[i]$ for all $i = 1, 2, \ldots, d$.)*

▶ **Definition 12** (Exact k-Partial Cover). *Given a collection of subsets $S_1, ..., S_n \subseteq [N]$, decide whether there is a sub-collection T of these, in which all sets are pairwise-disjoint, and $\left|\biguplus_{S\in T} S\right| = k$.*

▶ **Theorem 13.** *There are efficient dynamic parameterized algorithms for the following problems. We write O^* here to hide factors that are polynomial in the parameters (m, k, t) and polylogarithmic in the size of the instance (n, N).*

- *For k-Partial Cover there are dynamic algorithms, with either randomized $O^*(2^k)$ or deterministic $O^*(4^k)$ update time.*
- *For m-Set k-Packing there are dynamic algorithms, with either randomized $O^*(2^{mk})$ or deterministic $O^*(4^{mk})$ update time.*
- *For t-Dominating Set there are dynamic algorithms, with either randomized $O^*(2^t)$ or deterministic $O^*(4^t)$ update time.*
- *For d-Dimensional k-Matching there are dynamic algorithms, with either randomized $O^*(2^{(d-1)k})$ or deterministic $O^*(4^{(d-1)k})$ update time.*
- *For Exact k-Partial Cover there are dynamic algorithms, with either randomized $O^*(2^k)$ or deterministic $O^*(4^k)$ update time.*

For the proof of Theorem 13 we refer the reader to the full version.

We also explain how the results can be extended to problems with additional constraints. As a simple example, we show how we can design an efficient sensitivity oracle for the problem of detecting whether a directed graph contains a walk of length k which visits at least $k-1$ vertices. As a second example, we discuss a different problem: given a directed graph G on n vertices, two (possibly intersecting) subsets $V_1, V_2 \subseteq V$, and two positive integers μ_1, μ_2,

decide whether G contains a k-path that contains at most μ_1 vertices of V_1 and at most μ_2 vertices of V_2. For this problem we give a static deterministic algorithm running in time $4^{k+\min\{k,|V_1\cap V_2|\}}\operatorname{poly}(k)\cdot n^2$, as well as a sensitivity oracle counterpart. We refer the reader to the full version for the full discussion.

1.2 Comparison with related work

Algorithms for k-Path

The static k-Path problem has a long history. The current best upper bounds for it are a randomized $1.66^k\operatorname{poly}(n)$ algorithm in undirected graphs due to Björklund, Husfeldt, Kaski and Koivisto [8], a randomized time $2^k\operatorname{poly}(n)$ in directed (and hence also undirected) graphs due to Williams [26], and deterministic time $2.554^k\operatorname{poly}(n)$ in directed graphs due to Tsur [25].

In comparison, our randomized sensitivity oracle for directed graphs in Theorem 3 has a dependency on k (both in preprocessing and query time) of $O^*(2^k)$, so one cannot hope to improve on it without improving the best static algorithm. For undirected graphs, we give in Theorem 6 a sensitivity oracle with a dependency of $O^*(1.66^k)$, which matches the best bound of [8]. Our deterministic sensitivity oracle has a dependency of $O^*(4^k)$; we leave open the question of whether the techniques of [25] can be used in a sensitivity oracle setting to achieve $O^*(2.554^k)$.

There has also been work on the dynamic version of k-Path. However, Alman, Mnich and Vassilevska [2] showed that under the aforementioned fine-grained conjectures, there is no dynamic algorithm for *directed* graphs. At the same time, they give a deterministic dynamic algorithm for the case of *undirected* graphs, with update time $k!\cdot 2^{O(k)}\cdot\operatorname{polylog}(n)$. A subsequent result due to Chen et al. [11] presents a deterministic dynamic algorithm with amortized update time $2^{O(k^2)}$.

In comparison, our sensitivity oracle works for directed graphs just as well as for undirected graphs, and with a lower dependence on k (only $2^{O(k)}$). However, we obtain a sensitivity oracle, rather than a dynamic algorithm.

Decremental Parameterized Sensitivity Oracles

A recent paper by Bilò et al. [6] constructs decremental sensitivity oracles ("fault tolerant") for the k-Path problem (i.e., where all updates are edge deletions). They give one construction with a randomized $k^\ell 2^k\operatorname{poly}(n)$ preprocessing time and $O(\ell\min\{\ell,k+\log\ell\})$ update time, and a second construction with a lower preprocessing time of $2^k\cdot\frac{(\ell+k)^{\ell+k}}{\ell^\ell k^k}\cdot\ell\operatorname{poly}(n)$ at the expense of an increased query time of $O\left(\frac{(\ell+k)^{\ell+k}}{\ell^\ell k^k}\cdot\ell\min\{\ell,k\}\log n\right)$. They also give a deterministic algorithm, requiring $k^\ell 2.554^k\operatorname{poly}(n)$ preprocessing time and a very low $O(\ell\min\{\ell,k+\log\ell\})$ update time. Our Theorem 3 improves on the dependency on ℓ, making it polynomial in both the preprocessing and update times, and allows for both increments and decrements, while the methods of [6] are specific to decrements. We also achieve an update time which is independent of n in the word-RAM model. In [6], preprocessing is made aware of the value of ℓ, due to the superpolynomial dependence on it.

The techniques of Bilò et al. [6] also achieve a very low memory footprint for their fault-tolerant oracle, attaining at most logarithmic space dependency on n in all variants, when k and ℓ are considered constants. In contrast, we prove a lower bound, showing that one cannot hope for such dependency if increments are allowed, and that any fully dynamic sensitivity oracle must store at least $\Omega(n^2)$ bits (see Theorem 4). This suggests

that the methods used in [6] cannot be used to devise a fully dynamic sensitivity oracle. Their algorithms are based on simple and elegant combinatorial arguments; for instance, in their algorithm with a faster preprocessing time, they precompute a collection of k-paths in the graph, in a way that ensures that with high probability, if there exists a path after ℓ edge deletions, one of the precomputed paths is still valid. We instead take a very different approach based on algebraic coding.

Cover, Matching, Dominating Set, and Packing problems

We are unaware of previous work on dynamic algorithms for the problems we study here (other than k-Path in undirected graphs, which we discussed above). Instead, we compare the dependence on k in the update times of our dynamic running times with the best known dependence on k for static algorithms. In the cases where we match, it is impossible to speed up the dependence on k in our dynamic algorithms without speeding up the fastest known static algorithms.

1. For both k-Partial Cover and t-Dominating Set, the fastest known static randomized running time is $2^k \operatorname{poly}(nk)$ by Koutis and Williams [22] (where for t-Dominating Set we replace k with t in the running time), which our dynamic algorithm matches, and the fastest known static deterministic running time is $2.554^k \operatorname{poly}(kn)$, stated by Tsur [25], whereas our deterministic dynamic algorithm achieves query time $O^*(4^k)$.
2. The fastest known static randomized algorithm for m-Set k-Packing by Björklund, Husfeldt, Kaski and Koivisto [8] has the intimidating running time of

$$\left(\frac{0.108157 \cdot 2^m (1 - 1.64074/m)^{1.64076-m} m^{0.679625}}{(m-1)^{0.679623}}\right)^k n^6 \operatorname{poly}(N)$$

   This is less than $2^{mk} \operatorname{poly}(n)$, and considerably so for smaller m. For example, when $m = 3$, the running time is bounded by $1.4953^{3k} n^6 \operatorname{poly}(N)$. Due to the super-quadratic dependence on n, these techniques are unlikely to be adaptable for the dynamic case.
   In contrast, Koutis [20] proposes a static randomized algorithm running in time

$$2^{mk} n \operatorname{poly}(mk) \operatorname{polylog}(n).$$

   Our dynamic result matches this running time.
3. The fastest known static randomized algorithm for d-Dimensional k-Matching, by Björklund, Husfeldt, Kaski, and Koivisto [8], runs in time $2^{(d-2)k} \operatorname{poly}(Nk)n$. In contrast, we match only an earlier algorithm by Koutis and Williams [22], which runs in time $2^{(d-1)k} \operatorname{poly}(kdn)$. The fastest known static deterministic algorithm runs in time $2.554^{(d-1)k} \operatorname{poly}(Nn)$, stated in Tsur [25], whereas we achieve deterministic dynamic update time $O^*(4^{(d-1)k})$.
4. Exact k-Partial Cover is a natural generalization of similar problems (such as m-Set k-Packing), though we are unaware of explicit prior work on it. A slight modification of the algorithm of Koutis [20] for m-Set k-Packing solves the static problem in randomized $O^*(2^k)$ time, matching the dependence on k in our dynamic algorithm.

Dynamic Parameterized Algorithms

Efficient dynamic algorithms have previously been proposed for a number of parameterized algorithms, often using dynamic versions of classic techniques from the design of fixed-parameter tractable algorithms. These techniques include dynamic kernels [2, 5, 12, 19],

color-coding [2], dynamic elimination forests [11], dynamic branching trees [2], sketching [12], and other methods [14, 15]. To our knowledge, no previous work on dynamic parameterized algorithms has used algebraic techniques.

2 Preliminaries

2.1 Notation

For a positive integer k, write $[k] := \{1, 2, \ldots, k\}$.

We will use the asymptotic notation $O^*(T)$; its meaning will depend on context, so we will define it each time it arises. Generally, in static algorithms and preprocessing times we hide factors that are polynomial in the input parameters (k, n, etc), but when talking about update times, we will only hide factors that are polylogarithmic in the input size.

Let ω be such that two $n \times n$ matrices can be multiplied using $O(n^\omega)$ field operations[3]; it is known that we can take $\omega < 2.373$ [3].

2.2 Sensitivity Oracles

▶ **Definition 14** (sensitivity oracle). *A* sensitivity oracle *is a data structure containing two functions:*

1. *Initialization with an input instance of size n.*
2. *Query with ℓ changes (with problem-specific definition) to the* original input*. This returns the desired output on the altered input.*

The time spent in the initialization step is called the preprocessing time*, and the time spent in the query step is called the* query time*.*

In random sensitivity oracles, we assume the queries are independent of the randomness of the oracle, and thus cannot be used to fool a sensitivity oracle by obtaining the randomness used at the preprocessing phase. We say that a random sensitivity oracle errs with probability at most p, if for any pair of an initial configuration and a query, the probability of error is at most p.

We say that a sensitivity oracle for a parameterized problem, with parameter k, is *efficient* if its preprocessing time is $f(k)\,\mathrm{poly}(n)$ for some computable function f, and its query time is $\mathrm{poly}(\ell)g(k)n^{o(1)}$ for some computable function g.

2.3 Exterior algebra

A key technical tool we will make use of in our algorithms is the exterior algebra. We give a brief introduction to its definition and properties which we will use.

Given a field $\mathbb{F}$ and a positive integer k, the exterior algebra $\Lambda(\mathbb{F}^k)$ is a non-commutative ring over $\mathbb{F}$. In this paper we will be interested in the cases where $\mathbb{F}$ is either the rational numbers $\mathbb{Q}$, or a finite field $\mathbb{F}_{2^d}$ of characteristic 2.

Following the terminology of Brand, Dell and Husfeldt [10], elements of the exterior algebra are called *extensors*. Multiplication in $\Lambda(\mathbb{F}^k)$ is denoted by the wedge sign; for $x, y \in \Lambda(\mathbb{F}^k)$, their product is $x \wedge y$. The generators of this ring are $e_1, e_2, ..., e_k$, the standard basis of $\mathbb{F}^k$, and we impose the relations $e_i \wedge e_j = -e_j \wedge e_i$ for all $i, j \in [k]$ and $e_i \wedge e_i = 0$

[3] This is a slight abuse of notation. The exponent of matrix multiplication ω is typically defined as the smallest constant such that $n \times n$ matrices can be multiplied in $n^{\omega+o(1)}$ field operations, but we drop the "$o(1)$" in the exponent here for simplicity.

for all $i \in [k]$ (while the latter equation follows from the former for fields of characteristic different from 2, we still require it when $\operatorname{char}\mathbb{F} = 2$). We also require that the wedge product is bilinear[4]. Furthermore, it can be seen that the wedge product is associative[5].

Additionally, we consider any field element $a \in \mathbb{F}$ to be an element of $\Lambda(\mathbb{F}^k)$, with multiplication defined simply by $a \wedge e_i = e_i \wedge a = ae_i$.

For example, we have

$$\begin{aligned} e_1 \wedge (e_5 - e_2 + 3) \wedge e_3 &= e_1 \wedge e_5 \wedge e_3 - e_1 \wedge e_2 \wedge e_3 + 3e_1 \wedge e_3 \\ &= -e_1 \wedge e_3 \wedge e_5 - e_1 \wedge e_2 \wedge e_3 + 3e_1 \wedge e_3. \end{aligned}$$

To simplify the notation, for $I \subseteq [k]$ we also write $e_I := \bigwedge_{i \in I} e_i$, where the product is over the elements of I in ascending order, with the convention $e_\emptyset = 1$. We will sometimes also replace the wedge sign by a simple product sign, when it is clear from context that we mean the wedge product. For example, we can write $e_I := \prod_{i \in I} e_i$. Thus, the above example extensor can also be written as

$$e_1 \wedge (e_5 - e_2 + 3) \wedge e_3 = -e_{\{1,3,5\}} - e_{\{1,2,3\}} + 3e_{\{1,3\}}$$

We see that two products of the basis elements that differ only by the order of the terms can differ only in sign (e.g., $e_1 \wedge e_2 \wedge e_3 = -e_2 \wedge e_1 \wedge e_3$), and furthermore any product of e_is with a repeating factor vanishes (e.g., $e_1 \wedge e_2 \wedge e_2 = e_1 \wedge 0 = 0$). Thus, the set $\{e_I : I \subseteq [k]\}$ spans $\Lambda(\mathbb{F}^k)$ as a vector space over $\mathbb{F}$. It is in fact a basis of this vector space, and we have $\dim_{\mathbb{F}} \Lambda(\mathbb{F}^k) = 2^k$. That is, for any $x \in \Lambda(\mathbb{F}^k)$ there is a unique choice of the 2^k coefficients α_I so that $x = \sum_{I \subseteq [k]} \alpha_I e_I$. For any $x \in \Lambda(\mathbb{F}^k)$ and $T \subseteq [k]$ we denote by $[e_T]x$ the coefficient of e_T when x is represented in the basis $\{e_I : I \subseteq [k]\}$ (i.e., the value of α_T as above).

If there is a d such that all I for which $[e_I]x \neq 0$ have $|I| = d$, we say that x is a *degree-d* extensor. The space of degree-d extensors is denoted by $\Lambda^d(\mathbb{F}^k)$.

We identify any vector $v = (v[1], v[2], ..., v[k]) \in \mathbb{F}^k$ with the exterior algebra element $\sum_i v[i]e_i \in \Lambda^1(\mathbb{F}^k)$. A crucial property of the exterior algebra is that for any vector $v \in \mathbb{F}^k$ it holds that $v \wedge v = 0$. Indeed,

$$\begin{aligned} v \wedge v = \sum_{i,j} v[i]v[j]e_i \wedge e_j &= \sum_{i<j} v[i]v[j]e_i \wedge e_j + \sum_{i<j} v[i]v[j]e_j \wedge e_i \\ &= \sum_{i<j} v[i]v[j]e_i \wedge e_j - \sum_{i<j} v[i]v[j]e_i \wedge e_j = 0. \end{aligned}$$

Similarly, for any two vectors $u, v \in \mathbb{F}^k$, it holds that $u \wedge v = -v \wedge u$. It is important to notice that these properties do not hold for all elements in $\Lambda(\mathbb{F}^k)$. As an example, for $x = e_1 + e_2 \wedge e_3$ we have $x \wedge x = (e_1 + e_2 \wedge e_3) \wedge (e_1 + e_2 \wedge e_3) = e_1 \wedge e_2 \wedge e_3 + e_2 \wedge e_3 \wedge e_1 = 2e_1 \wedge e_2 \wedge e_3$. In fact, we can see that the wedge product of an even number of vectors commutes with any extensor.

Another very useful property of the exterior algebra is its connection to determinants. Let $v_1, v_2, ..., v_k \in \mathbb{F}^k$ be k vectors of dimension k, and consider their product $v_1 \wedge v_2 \wedge ... \wedge v_k$. Replace each v_i with its linear combination of the basis elements e_j and expand the product. We see that any monomial that repeats a basis element gets cancelled, and the others are all $e_{[k]}$ up to a sign. We get

$$v_1 \wedge v_2 \wedge ... \wedge v_k = \bigwedge_{i=1}^{k} \sum_{j=1}^{k} v_i[j]e_j = \sum_{\sigma \in S_k} \bigwedge_{i=1}^{k} v_i[\sigma(i)]e_{\sigma(i)} = \sum_{\sigma \in S_k} \operatorname{sgn}(\sigma) e_{[k]} \bigwedge_{i=1}^{k} v_i[\sigma(i)].$$

[4] $(a + b) \wedge c = (a \wedge c) + (b \wedge c)$ and $a \wedge (b + c) = (a \wedge b) + (a \wedge c)$.
[5] $(a \wedge b) \wedge c = a \wedge (b \wedge c)$

We recognize a determinant in the right hand side, thus showing that

$$v_1 \wedge v_2 \wedge ... \wedge v_k = \det(v_1|v_2|...|v_k)e_{[k]}. \tag{1}$$

2.4 Complexity of ring operations in the exterior algebra

We represent the elements of $\Lambda(\mathbb{F}^k)$ as the length-2^k vector of coefficients of the basis elements e_I. Addition is performed by coordinate-wise addition, hence requires $O(2^k)$ field operations. Multiplication is trickier, and there are a few important cases. All these cases were also noted and used in [10].

▶ **Proposition 15** (Skew product). *Computing $x \wedge v$ for a general extensor $x \in \Lambda(\mathbb{F}^k)$ and a vector $v \in \mathbb{F}^k$ can be done in $O(2^k \cdot k)$ field operations.*

Proof sketch. This is accomplished by simply expanding the product. ◀

▶ **Proposition 16** (General product over characteristic 2). *Computing $x \wedge y$ for any $x, y \in \Lambda(\mathbb{F}^k)$, when $\mathrm{char}(\mathbb{F}) = 2$, can be done in $O(2^k k^2)$ field operations.*

Proof sketch. Here, the ring $\Lambda(\mathbb{F}^k)$ is commutative. Then we can write $[e_I](x \wedge y) = \sum_{T \subseteq I}([e_T]x)([e_{I \setminus T}]y)$, which can be seen as a subset convolution operation. Using the fast subset convolution discovered by Björklund, Husfeldt, Kaski and Koivisto [7], we can compute this with $O(2^k k^2)$ field operations. ◀

▶ **Proposition 17** (General product over any characteristic). *Computing $x \wedge y$ for $x, y \in \Lambda(\mathbb{F}^k)$, for $\mathbb{F}$ of any characteristic, can be done in $O(2^{\omega k/2})$ field operations.*

Proposition 17 is a result of Włodarczyk [27], which reduces computing $x \wedge y$ over $\Lambda(\mathbb{F}^k)$ to k^2 multiplications in a Clifford algebra, which in turn can be embedded in matrices of size $2^{k/2} \times 2^{k/2}$.

2.5 Extensor-coding

In this subsection, we give a brief overview of the techniques recently used by Brand, Dell and Husfeldt [10] to design a randomized and a deterministic algorithm for the (static) k-Path problem; we heavily build off of these techniques in this paper.

Given a directed graph G, we denote its vertex set $V = \{v_1, ..., v_n\}$, and we denote by $W_s(G)$ the set of all walks in G of length s. Recall that walks may repeat vertices, whereas paths may not. For each edge $e \in E(G)$ we have an *edge variable* y_e, whose possible values will be in a field $\mathbb{F}$ we will pick later.

Furthermore, we define vectors $\chi : V \to \mathbb{F}^k$ by $\chi(v_i) = (1, j, j^2, \ldots, j^{k-1})$ where $j = f(i)$ for some injective function $f : [n] \to \mathbb{F}$. We call these *Vandermonde vectors*.

Given a walk in G of length s, $w = (w_1, w_2, ..., w_s) \in W_s(G)$, we define the corresponding *walk extensor* to be $\chi(w_1) \wedge y_{w_1 w_2} \wedge \chi(w_2) \wedge y_{w_2 w_3} \wedge \chi(w_3) \wedge ... \wedge y_{w_{s-1} w_s} \wedge \chi(w_s)$. We will sometimes denote the walk extensor of a walk w by $\chi(w)$.

Our goal is to compute the sum of all walk extensors for walks of length k,

$$\mathcal{Z} = \sum_{(w_1, w_2, ..., w_k) \in W_k(G)} \chi(w_1) \wedge y_{w_1 w_2} \wedge \chi(w_2) \wedge y_{w_2 w_3} \wedge \chi(w_3) \wedge ... \wedge y_{w_{k-1} w_k} \wedge \chi(w_k). \tag{2}$$

The result of this sum is seen to be proportional to the single basis element $e_{[k]}$, and by abuse of notation we will consider it as a scalar equal to that coefficient (or, more precisely, a polynomial in the y variables).

Any k-walk that is not a path does not contribute to Equation (2), because its walk extensor repeats a vector in the product. Thus, any nonzero term in the sum Equation (2) corresponds to a *k-path*.

The choice of $\chi(v_i)$ is such that for any walk $(w_1, w_2, ..., w_k)$ that is a k-path, the walk-extensor is a nonzero monomial in the y variables. This is seen using Equation (1), because $\chi(w_1) \wedge \chi(w_2) \wedge ... \wedge \chi(w_k) = e_{[k]} \det(\chi(w_1)|\chi(w_2)|...|\chi(w_k))$, which is the determinant of a Vandermonde matrix with unique columns, which is known to be nonzero.

Additionally, the monomial in the y variables given to each k-path is seen to uniquely identify the k-path (since there is a different y variable for each edge). Hence, the monomials of different k-paths cannot cancel, and we have proven:

▶ **Lemma 18.** *For a directed graph G, the value of $\mathcal{Z}$ given in Equation* (2) *is a nonzero polynomial in the y variables if and only if G contains a k-path.*

We now recall the classical DeMillo-Lipton-Schwartz-Zippel Lemma:

▶ **Lemma 19** ([13, 24, 28])**.** *Let $f \in \mathbb{F}[x_1, ..., x_n]$ be a nonzero polynomial in n variables with total degree at most d over some field $\mathbb{F}$, and let $S \subseteq \mathbb{F}$. For $a_1, a_2, ..., a_n \in S$ chosen uniformly at random, we have* $\Pr(f(a_1, a_2, ..., a_n) = 0) \leq \frac{d}{|S|}$.

Using the DeMillo-Lipton-Schwartz-Zippel Lemma, we now obtain a randomized algorithm for the k-Path detection problem, assuming we are able to efficiently compute $\mathcal{Z}$. Namely, for each $e \in E(G)$ we randomly select $y_e \in Y$ for some fixed $Y \subseteq \mathbb{F}$ of size $|Y| = 100k$, and compute $\mathcal{Z}$ as in Equation (2). If this value is nonzero, we know there is a k-path. Otherwise, there might still be a k-path, and we might have been unlucky and had the nonzero polynomial vanish for the specific choices of the y_e variables. We output that there is no k-path in this case. The probability of error is at most $\frac{k}{|Y|} = \frac{1}{100}$, and we can repeat this process to lower the probability of error as much as required.

It remains to show how to compute $\mathcal{Z}$ efficiently. We do this using dynamic programming. For any $1 \leq s \leq k$ and $1 \leq i \leq n$ we define $Q_s[i]$ as the sum of walk extensors of length s that end in v_i. Then $\mathcal{Z} = \sum_i Q_k[i]$, and we can compute the vector Q_{s+1} from Q_s by $Q_{s+1}[i] = \sum_{j:(v_j,v_i)\in E(G)} Q_s[j] \wedge y_{v_j,v_i} \wedge \chi(v_i)$. This requires kn^2 skew multiplications of extensors, each of which can be done in time $2^k \operatorname{poly}(k)$ (see Proposition 15). Thus, we can compute $\mathcal{Z}$ with $2^k \operatorname{poly}(k) n^2$ field operations, which is also the total running time of the randomized algorithm. We note that this works over any sufficiently large field $\mathbb{F}$ with $|\mathbb{F}| \geq 100k$.

Brand, Dell and Husfeldt [10] also give a deterministic variant of the algorithm, at the cost of increasing the time complexity. This is done with the beautiful idea of, for each vertex v, *"lifting"* the Vandermonde vector $\chi(v)$ to $\bar{\chi}(v) = \binom{\chi(v)}{0} \wedge \binom{0}{\chi(v)}$. By $\binom{\chi(v)}{0}$, we mean the vector of length $2k$ gotten by concatenating the vector $\chi(v)$ with k zeros. We then do the calculations in $\Lambda(\mathbb{F}^{2k})$ instead of $\Lambda(\mathbb{F}^k)$. Walk extensors of non-path walks still vanish. Now, as observed in [10], for any k-path we have

$$\bar{\chi}(w_1) \wedge \bar{\chi}(w_2) \wedge ... \wedge \bar{\chi}(w_k) = e_{[2k]} \det\left(\binom{\chi(w_1)}{0} \middle| \binom{0}{\chi(w_1)} ... \middle| \binom{\chi(w_k)}{0} \middle| \binom{0}{\chi(w_k)}\right)$$

By proper change of columns, the resulting determinant is equal to the determinant of a 2×2 block diagonal matrix, where the two diagonal blocks are identical. By basic properties of determinants, we then obtain

$$\bar{\chi}(w_1) \wedge \bar{\chi}(w_2) \wedge ... \wedge \bar{\chi}(w_k) = (-1)^{\binom{k}{2}} e_{[2k]} \det(\chi(w_1)|\chi(w_2)|...|\chi(w_k))^2. \tag{3}$$

Therefore, choosing $\mathbb{F} = \mathbb{Q}$, the walk extensors of different k-paths all have the same sign, and hence never cancel. The dynamic programming given above still works for this case, but extensor operations require $2^{2k}\,\mathrm{poly}(k)$ field operations (note we only need skew multiplications). Additionally, all numbers involved are of size at most $n^{O(k)} = 2^{O(k \log n)}$, and hence operations require only $\mathrm{poly}(k)\,\mathrm{polylog}(n)$ time, or $\mathrm{poly}(k)$ time in the word-RAM model which we assume. This produces a deterministic algorithm with running time $4^k\,\mathrm{poly}(k)n^2$.

3 Overview of our techniques

The key idea behind our algorithms is to identify appropriate sums of extensors which encode the answer to the problem (e.g., one where candidate solutions correspond to nonzero monomials), and which can be efficiently dynamically maintained. Similar to [10], we will frequently make use of the properties of exterior algebras to "nullify" repetitions (for example, of vertices in the k-Path problem, and of elements in the Exact k-Partial Cover problem). In many cases, the extensors or similar algebraic coding expressions used by the fastest known static algorithms seem difficult to efficiently maintain dynamically, and we will need to modify them, and identify useful precomputed values, to speed up our update time. While these techniques prove to be very well suited for designing sensitivity oracles and dynamic algorithms, we are unaware of previous work that uses the exterior algebra in such a way.

3.1 k-Path

For this problem, we aim to maintain $\mathcal{Z}$, the sum over walk extensors of length-k walks which we defined in Equation (2) above. Employing properties of the exterior algebra as discussed above, it is seen that any walk that is not a path (that is, a walk that repeats a vertex) does not contribute to the sum, and we thus indirectly compute a sum over only paths.

As we discussed in Section 2.5 above, Brand, Dell and Husfeldt [10] showed that computing this sum allows for extracting valuable information about the k-paths in a graph. In particular, by carefully selecting vectors or degree-2 extensors $\chi(v)$ for each vertex v, it allows for the design of randomized and deterministic algorithms for the k-path detection problem, as well as for approximately counting the number of k-paths with high probability.

Let us focus, first, on the case when our sensitivity oracle only allows for edge increments. We begin by precomputing, for each pair of vertices in the graph, a sum over the walk extensors between those vertices, so that we can "stitch" them together appropriately when new edges are inserted. Put precisely, let $W_s(u, v)$ denote the set of walks of length s from u to v, and let $Q_s[u, v]$ be the precomputed value of the sum of walk extensors for walks in $W_s(u, v)$ in the initial graph. Now suppose a new edge (v_1, v_2) is inserted. Then the additional walk extensors for walks of length s between any pair of vertices (t_1, t_2) can be computed as

$$\sum_{s'} \left(\sum_{w \in W_{s'}(t_1, v_1)} \chi(w) \right) \wedge y_{v_1, v_2} \wedge \left(\sum_{w \in W_{s-s'}(v_2, t_2)} \chi(w) \right) = \sum_{s'} Q_{s'}[t_1, v_1] \wedge y_{v_1, v_2} \wedge Q_{s-s'}[v_2, t_2].$$

At first, stitching might seem problematic, since we might need to iterate over the possible lengths of each stitched part. This is not be a problem for a single edge insertion, but leads to an exponential dependency on the number of edges inserted as we partition the total

length k between them. While this issue can be efficiently resolved with proper dynamic programming, we can circumvent this efficiently and more cleanly by instead working with sums over the walks of all possible lengths, while finally inspecting only the coefficient of $e_{[k]}$ in the resulting extensor, so that terms corresponding to paths of length other than k will either cancel out or have too low degree. Indeed, we note that only walks of length k contribute to this coefficient.

Another, more substantial problem occurs when one tries to "stitch" paths into a larger path that uses several new edges: there are $\ell!$ different orders to pass through the ℓ new edges. We combine properties of the exterior algebra with an algebraic trick (which we describe in more detail shortly) to allow computing the sum of the effects of all of these cases with only a polynomial dependence on ℓ.

In order to be able to work with only a small subset of the precomputed Q matrix, we additionally precompute the sum of walk extensors ending and beginning at each vertex (i.e., sums of rows and columns of Q), and the original sum over walk extensors in the original graph. This allows us to use only $O(\ell^2)$ precomputed values in the updating phase.

Finally, by further employing properties of the exterior algebra, we are able to combine these techniques with the inclusion-exclusion principle, to also allow edge removals, while keeping the same time and space complexities for preprocessing and updates.

We now describe the ideas in some more detail. We refer the reader to the full version for the full details. As a preprocessing, we compute an $n \times n$ matrix Q with extensor values, defined by

$$Q[i,j] = \sum_{\substack{(w_1,w_2,\ldots,w_s)\in W \\ w_1=v_i, w_s=v_j}} \chi(w_1) \wedge y_{w_1w_2} \wedge \chi(w_2) \wedge y_{w_2w_3} \wedge \chi(w_3) \wedge \ldots \wedge y_{w_{s-1}w_s} \wedge \chi(w_s)$$

where W is the set of *all walks* in the graph, which can have any length greater than 0. This is the sum of all walk extensors for walks from v_i to v_j. We then compute vectors S (resp. F) of length n, similarly computing in their ith entry the sum of walk extensors starting (resp. finishing) at each vertex v_i. That is, $S[i] = \sum_j Q[i,j]$ and $F[j] = \sum_i Q[i,j]$.

Finally, we compute $\mathcal{Z} = \sum_{i,j} Q[i,j]$, the sum of all walk extensors over all walks. $e_{[k]}\mathcal{Z}$ is exactly the value we aim to maintain after a query, as this is exactly the one used in the extensor coding technique (Section 2.5). We explain how with proper dynamic programming we can compute these values in preprocessing with $2^k \operatorname{poly}(k) n^2$ operations over $\mathbb{F}$, using only additions and skew multiplications.

Then, when prompted with a query, we aim to compute the sum over walk extensors in the updated graph, denoted $\mathcal{Z}_{\text{new}}$. Inspecting whether $e_{[k]}\mathcal{Z}_{\text{new}} \neq 0$ will let us test whether the updated graph contains a k-path.

We now begin handling a query. Given a list of ℓ updates that are each either an edge insertion or edge deletion, there are $n' \leq 2\ell$ vertices at the endpoints of the updated edges. We begin by extracting the $n' \times n'$ sub-matrix Q' of Q, and length-n' sub-vectors S', F' of S, F, gotten by taking entries corresponding to those endpoint vertices.

We next define an $n' \times n'$ matrix E_r^+ corresponding to the r-th edge insertion by setting each of its entries to 0 except for $E_r^+[i,j] = y_{i,j}$, where (v_i, v_j) is the r-th inserted edge. We similarly define E_r^- in the same way, to be the 0 matrix except for $E_r^-[i,j] = y_{i,j}$ where (v_i, v_j) is the r-th deleted edge. We then define $\Delta^+ = \sum_r E_r^+$, $\Delta^- = \sum_r E_r^-$, and $\Delta = \Delta^+ - \Delta^-$. We then compute that

$$\mathcal{Z}_{\text{new}} = \mathcal{Z} + \sum_{i=1}^{k} F'^T \Delta (Q'\Delta)^{i-1} S'.$$

This formula is crucial to our query algorithm, so we explain it in some detail here.

We first explain the correctness of this formula for the case of only increments. In this case, $\mathcal{Z}_{\text{new}} - \mathcal{Z}$ is exactly the sum of walk-extensors for walks that use the new edges. Here, upon expanding the expression when $\sum_r E_r^+$ is substituted for Δ^+, we note that $F'^T \Delta^+ S'$ counts the walks that use exactly one of the new edges. Indeed, for each r the term $F'^T E_r^+ S'$ accounts for walks passing through the r-th new edge exactly once. For counting walks that use exactly two of the newly inserted edges, we now need to compute $\sum_{r_1 \neq r_2} F'^T E_{r_1}^+ Q' E_{r_2}^+ S'$. Indeed, this expression correctly accounts for walks with nonzero walk extensors starting at any vertex, continuing through one new edge, travelling to a new edge then through it, then continuing to end at any vertex. We further note that any specific path is counted in this way exactly once.

We note that by linearity and the fact that only paths produce nonzero walk extensors, this is equal to $F'^T \Delta^+ Q' \Delta^+ S'$. That is, upon expanding the expression when $\sum_r E_r^+$ is substituted for Δ^+, we get exactly the terms we intended, plus terms accounting for walks passing through the new edges twice, which evaluate to zero in the exterior algebra. This considerably simplifies the calculations. Continuing in the same fashion, we argue we obtain

$$\mathcal{Z}_{\text{new}} - \mathcal{Z} = \sum_{i=1}^{k} F'^T \Delta^+ (Q' \Delta^+)^{i-1} S'$$

in total for the incremental case.

Consider now the general case, with both increments and decrements. Suppose w is any walk on the vertices which uses edges from the union of the original graph and the updated graph. We assume w is a path, since otherwise its walk extensor vanishes, and we need not worry about whether it appears in the sum $\mathcal{Z}_{\text{new}}$. Now suppose w has length at most k and uses a inserted edges and b removed edges.

Consider first when $a \geq 1$. In this case, w is not counted in the original sum $\mathcal{Z}$. When substituting $\Delta = \sum_j E_j^+ - \sum_j E_j^-$ into $\sum_{i=1}^{k} F'^T \Delta (Q' \Delta)^{i-1} S'$ and expanding, we see that w is counted only when all the chosen E_j^+ factors exactly correspond to the a new edges used by w, in the order they are used. It is also counted when choosing any $b' \leq b$ factors of type E_j^- that appear in w, but they must also appear in the right order, and they contribute the walk extensor of w with weight exactly $(-1)^{b'}$. In total, w is accounted for exactly $\sum_{b'=0}^{b} \binom{b}{b'} (-1)^{b'} = (1-1)^b = [b = 0]$ times[6] in $\mathcal{Z}_{\text{new}}$, which is what we want.

Now suppose $a = 0$. Then a similar argument shows that the number of times it is counted in $\sum_{i=1}^{k} F'^T \Delta (Q' \Delta)^{i-1} S'$ is exactly $\sum_{b'=1}^{b} \binom{b}{b'} (-1)^{b'} = (1-1)^b - 1 = [b = 0] - 1$. However, it is also counted in $\mathcal{Z}$ exactly once, so in total is counted $[b = 0]$ times, which is also exactly what we want.

Using this formula, we explain how we are generally able to compute $\mathcal{Z}_{\text{new}}$ in $O(\ell^2 2^{\omega k/2})$ field operations. However, we come back to this running time once we describe the specifics of the randomized and deterministic sensitivity oracles, each with its own details.

3.2 k-Partial Cover

We also make use of extensors to design fully dynamic algorithms for other parameterized problems. We focus here on one example: designing a deterministic dynamic algorithm for the k-Partial Cover problem. In this problem, we are given subsets $S_1, ..., S_n \subseteq [N]$, and wish to find the minimum number of such subsets whose union has size at least k (or report that no such collection exists).

[6] Here we use the notation $[b = 0] := \begin{cases} 1 & \text{if } b = 0, \\ 0 & \text{otherwise.} \end{cases}$

One could use a polynomial constructed by Koutis and Williams [22] for this problem, combined with similar techniques to those we used above for k-Path, to devise a deterministic dynamic algorithm with update time $O(2^{\omega k})$. However, we instead give a different polynomial which is easier to dynamically maintain, achieving a faster $O^*(4^k)$ update time.

As in the k-Path problem, we give each element in the universe $a \in [N]$ a Vandermonde vector $\chi(a) \in \mathbb{Q}^k$, then lift it to $\bar{\chi}(a) = \binom{\chi(a)}{0} \wedge \binom{0}{\chi(a)} \in \Lambda(\mathbb{Q}^{2k})$.

We introduce a single new variable z, and consider the polynomial

$$P(z) = \prod_S \left(1 + z\left[\prod_{a \in S}(1 + \bar{\chi}(a)) - 1\right]\right).$$

We argue that the solution we seek is the minimum t for which $[e_{[2k]}z^t]P \neq 0$ (that is, the coefficient of $e_{[2k]}$ in the coefficient of z^t in P). Our goal, then, will be to maintain the value of $P(z)$, and calculations will take place in polynomials over extensors, $\Lambda(\mathbb{Q}^{2k})[z]$. We also argue that $\deg P(z) \leq k$, and so is not too large to handle in update steps.

We first argue that the product in P should only be computed over sets S of cardinality less than k, as larger sets can be treated separately, knowing that the optimal solution is 1 if any such set exists in the collection. Since $P(z)$ is defined as a product over sets, to update it with a new set S of cardinality $|S| < k$, we can multiply $P(z)$ by the corresponding factor $1 + z\left[\prod_{a \in S}(1 + \bar{\chi}(a)) - 1\right]$. This seems too slow at first, since general extensor multiplication requires $O(2^{\omega k})$ time, which is more than our target $O^*(4^k)$. However, rather than computing the factor and then using general extensor multiplication, we argue that we can indirectly multiply by this factor using only additions and skew multiplications by rearranging the contributing terms, thus requiring only $O^*(4^k)$ field operations. Indeed, the product of $P(z)$ with the new factor is $(1 - z)P(z) + P(z)\prod_{a \in S}(1 + \bar{\chi}(a))$, which can be performed by separately computing $(1 - z)P(z)$ and $P(z)\prod_{a \in S}(1 + \bar{\chi}(a))$, where the latter can be computed by repeated skew-multiplications.

A new problem arises when a set S is removed. For this, we need to somehow cancel the factor in $P(z)$ corresponding to S. We show that in this case the corresponding factor has an inverse in $\Lambda(\mathbb{Q}^{2k})[z]$: we first note that it can be written as $1 + X$ for an element X that contains only extensors of degree ≥ 2, which implies that $X^{k+1} = 0$, and using this, we observe that

$$(1 + X)(1 - X + X^2 - \ldots + (-X)^k) = 1 - (-X)^{k+1} = 1,$$

so $(1 + X)^{-1} = 1 - X + X^2 - \ldots + (-X)^k$. Similar to the previous case, we argue that multiplying by this factor can also be done with $\text{poly}(k)$ additions and skew multiplications, and so can be done in $O^*(4^k)$ time.

This and all our other dynamic algorithms are described in detail in the full version.

4 Discussion on fixed-parameter complexity classes

We discuss the relationship between the following definitions.

▶ **Definition 20** (FPT). *A parameterized problem is in FPT if it is decidable in time $f(k)\,\text{poly}(n)$ for a computable function f.*

▶ **Definition 21** (FPD). *A parameterized problem is in FPD (Fixed-Parameter Dynamic) if there is a dynamic algorithm for it requiring $f(k)\,\text{poly}(n)$ preprocessing time and $g(k)n^{o(1)}$ update time, for computable functions f and g.*

▶ **Definition 22** (FPSO). *A parameterized problem is in FPSO (Fixed-Parameter Sensitivity Oracle) if there is a sensitivity oracle for it requiring $f(k)\,\mathrm{poly}(n)$ preprocessing time and $\mathrm{poly}(\ell)g(k)n^{o(1)}$ update time, for a computable function g.*

We note that FPD $\subseteq$ FPSO $\subseteq$ FPT. We can show that the inclusions are strict, at least under plausible hardness conjectures. For example, [2] shows that k-Path in directed graphs does not admit a dynamic algorithm under hardness conjectures (which are shown in this paper to be in FPSO). [18] shows that the #SSR problem does not have an efficient sensitivity oracle, assuming SETH, which in turn can be used to show that, assuming SETH, there exists an FPT problem that is not in FPSO.

We further note that many problems shown in [2] to not be in FPD can be shown to be in FPSO. As a few examples:

1. Triangle Detection, which is the problem of detecting whether a graph contains a triangle, can be solved efficiently by a sensitivity oracle by precomputing the square of the graph's adjacency matrix and computing the number of triangles in time $O(n^\omega)$, then updating the number of triangles in time $O(\ell^\omega)$ ($O(\ell)$ for triangles that use a single updated edge, $O(\ell^2)$ for triangles using two updated edges, and $O(\ell^\omega)$ for those using three updated edges).
2. Incremental st-Reachability, which is the problem of deciding whether two predetermined vertices s and t are connected in a directed graph, only allowing incremental updates, can be solved efficiently by precomputing reachability between any two vertices (for example by running BFS from all vertices in time $\mathrm{poly}(n)$), then using dynamic programming to answer a query in time $\mathrm{poly}(\ell)$ by updating the connectivity information only on the $\leq 2\ell + 2$ vertices that are either s, t or are part of any inserted edge
3. 3SUM, which is the problem of deciding whether there are 3 elements in a list that sum to 0. Here it is possible to precompute the sums of all pairs in time $O(n^2)$ (counting multiplicities), and the number of triples whose sum is 0. Then when adding or removing ℓ numbers it is possible to compute in $\mathrm{poly}(\ell)$ time the number of new solutions and the number of previous solutions that should be removed, and checking if the remaining number of solutions is nonzero.
4. k-Layered Reachability Oracle (k-LRO), the problem of deciding whether two vertices u, v are connected in a directed k-layered graph (that is, a graph whose vertices are partitioned into k parts, with edges only going from one part to the next), also has an efficient sensitivity oracle, and in fact can be seen to be equivalent to the directed k-Path problem. In particular, the same k-Path sensitivity oracle devised in this paper can be used here without any changes.

5 Open questions

We briefly discuss a few natural questions that arise.

1. Is there a fully-dynamic k-Path detection algorithm on undirected graphs with $f(k)n^{O(1)}$ preprocessing time for some computable function f, and update time $2^{O(k)}n^{o(1)}$?
   This would beat the dynamic algorithm proposed in [2] that is a simple adaptation of the original color-coding idea [4], while to the best of our knowledge, no improvement on this original color-coding idea is known to transfer to the dynamic setting. While our work shows a better dependency on k, we do not reach a truly dynamic algorithm, but rather only a sensitivity oracle.
   We note that it is unlikely that such an an algorithm exists for directed graphs, due to the conditional lower bound presented in [2].

2. Is there an efficient sensitivity oracle for the k-Tree problem?
   The k-Tree problem is as follows: given an undirected graph G on n vertices and a tree T on k vertices, determine whether T is a (not necessarily induced) subgraph of G. This problem is known to be FPT, and for example is shown in [22] to be solvable in time $2^k \operatorname{poly}(k) \operatorname{poly}(n)$, with techniques similar to those applied for the k-Path problem. However, it is unclear how to adapt the techniques here for an efficient sensitivity oracle. We conjecture that there is, in fact, no efficient sensitivity oracle for this problem. More specifically, we conjecture this for any k-Tree formed by connecting a single vertex to the beginning of $\Theta(\sqrt{k})$ paths of length $\Theta(\sqrt{k})$. We note that the techniques of [6] for a decremental sensitivity oracle work for any k-Tree just as well as they do for the k-Path problem.
3. Brand [9] noted that the algebra generated by the lifts of Vandermonde vectors, which is the algebra used in all the deterministic algorithms presented in this paper, has dimension $O(\varphi^{2k})$ where $\varphi = \frac{1+\sqrt{5}}{2}$ - much smaller than the anticipated $O(4^k)$. It is also commutative. It is an open problem whether, in light of this, multiplication in this algebra can be reduced to below $O(2^{\omega k})$. Such an algorithm will immediately improve the bounds discussed in this paper.
4. Can other techniques used to solve the static versions of the problems discussed in this paper, or other parameterized problems, be used to design faster dynamic algorithms and sensitivity oracles?

Abstract

We continue a line of work on extracting random bits from weak sources that are generated by simple processes. We focus on the model of locally samplable sources, where each bit in the source depends on a small number of (hidden) uniformly random input bits. Also known as local sources, this model was introduced by De and Watson (TOCT 2012) and Viola (SICOMP 2014), and is closely related to sources generated by AC^0 circuits and bounded-width branching programs. In particular, extractors for local sources also work for sources generated by these classical computational models.

Despite being introduced a decade ago, little progress has been made on improving the entropy requirement for extracting from local sources. The current best explicit extractors require entropy $n^{1/2}$, and follow via a reduction to affine extractors. To start, we prove a barrier showing that one cannot hope to improve this entropy requirement via a black-box reduction of this form. In particular, new techniques are needed.

In our main result, we seek to answer whether low-degree polynomials (over $\mathbb{F}_2$) hold potential for breaking this barrier. We answer this question in the positive, and fully characterize the power of low-degree polynomials as extractors for local sources. More precisely, we show that a random degree r polynomial is a low-error extractor for n-bit local sources with min-entropy $\Omega(r(n \log n)^{1/r})$, and we show that this is tight.

Our result leverages several new ingredients, which may be of independent interest. Our existential result relies on a new reduction from local sources to a more structured family, known as local non-oblivious bit-fixing sources. To show its tightness, we prove a "local version" of a structural result by Cohen and Tal (RANDOM 2015), which relies on a new "low-weight" Chevalley-Warning theorem.

1 Introduction

Randomness is a fundamental resource in many areas in computer science, such as algorithm design and cryptography. However, such tasks often assume access to a source of independent and uniform bits, while real-world physical processes (e.g., electromagnetic noise, timings of user keystrokes) generate randomness that is far from perfect. This state of affairs motivates the problem of *randomness extraction*. The goal is to design a deterministic function, called an *extractor*, that can distill a (nearly) uniform bit from any source belonging to a certain family.

▶ **Definition 1.1** (Extractor). *A function* $\mathsf{Ext} : \{0,1\}^n \to \{0,1\}$ *is an* extractor *for a family of distributions* $\mathcal{X}$ *over* $\{0,1\}^n$ *with error* ε *if, for every* $\mathbf{X} \in \mathcal{X}$*,*

$$\left|\Pr[\mathsf{Ext}(\mathbf{X}) = 1] - \frac{1}{2}\right| \leq \varepsilon.$$

Besides their practical motivation, randomness extractors (and other related pseudorandom objects such as dispersers, condensers, and expander graphs) have deep connections to coding theory, combinatorics, and complexity theory.

In order to construct an extractor for a family $\mathcal{X}$ of sources, the most general assumption one can make about $\mathcal{X}$ is that each $\mathbf{X} \in \mathcal{X}$ has some "randomness." Here, it is typical to measure the randomness of a source $\mathbf{X}$ by its min-entropy $H_\infty(\mathbf{X}) := -\log \max_x \Pr[\mathbf{X} = x]$. However, even if we assume each $\mathbf{X} \in \mathcal{X}$ has a very high amount of this very strong notion of entropy, extraction is still impossible: indeed, one cannot hope to extract from $\mathcal{X}$ even if each source $\mathbf{X} \in \mathcal{X}$ is guaranteed to have min-entropy $k \geq n - 1$ [6]. To enable extraction, one must make additional assumptions on the structure of each $\mathbf{X} \in \mathcal{X}$.

Extractors for local sources, AC^0 sources, and small-space sources

In a seminal work, Trevisan and Vadhan [18] initiated the study of randomness extraction from sources that can be sampled by "simple" processes. In addition to the generality of such sources, it can be argued that they serve a reasonable model of randomness that might actually be found in nature.

More formally, Trevisan and Vadhan studied sources that can be sampled by polynomial size circuits that are given uniform bits as input. However, extracting randomness from this class of sources requires strong computational hardness assumptions. This motivated De and Watson [9] and Viola [21] to consider *unconditional* extraction from sources sampled by more restricted, but still natural, circuit families. To this end, they introduced the notion of *local sources*. Intuitively, a local source $\mathbf{X}$ is one that can be sampled by a low-depth circuit with bounded fan-in (a low-complexity process).

▶ **Definition 1.2** (Local source [9, 21]). *A distribution* $\mathbf{X} \sim \{0,1\}^n$ *is a* d-local source *if* $\mathbf{X} = g(\mathbf{U}_m)$*, where* $\mathbf{U}_m$ *is the uniform distribution over* m *bits (for some* m*), and* $g : \{0,1\}^m \to \{0,1\}^n$ *is a function where each output bit depends on at most* d *input bits.*

Local sources are closely connected to other models of sources sampled by simple processes. Viola [21] proved that every source generated by AC^0 circuits is (close to) a convex combination of local sources with small locality and slightly lower min-entropy. More recently, Chattopadhyay and Goodman [3] showed a similar result for sources generated by bounded-width branching programs [13]. Thus, extractors for local sources also work for sources generated by these classical computational models. In fact, the current state-of-the-art extractors for sources generated by AC^0 circuits and bounded-width branching programs are extractors for 1-local sources.

A barrier at $\sqrt{n}$ min-entropy

Despite the applications above and being introduced over a decade ago, little progress has been made on constructing extractors for local sources [9, 21, 16]. In particular, all known constructions require min-entropy at least $\sqrt{n}$, and follow via a reduction to extractors for affine sources (i.e., sources that are uniform over affine subspaces of $\mathbb{F}_2^n$). Thus, there appears to be a "barrier" at $\sqrt{n}$ min-entropy, at least when using affine extractors [23]. It is natural to ask how we might break this $\sqrt{n}$ barrier, which raises the question:

Can affine extractors be used to extract from local sources with min-entropy $k \ll \sqrt{n}$?

As motivation, we start by providing strong evidence that the answer to the above question is negative. In particular, we prove the following.

▶ **Theorem 0** (Barrier result). *It is not possible to extract randomness from 2-local sources with min-entropy $k \geq \sqrt{n}$ by applying an affine extractor in a black-box manner.*

Thus, if we would like to construct extractors for local sources with min-entropy significantly below $\sqrt{n}$, new techniques are needed.

Towards breaking the $\sqrt{n}$ barrier using low-degree polynomials

While explicit extractors that break the $\sqrt{n}$ min-entropy barrier for local sources are the end goal, these still seem beyond reach. We believe that the next best thing are non-explicit extractors that are of "low complexity". Our hope is that such extractors may help us eventually construct truly explicit extractors, as non-explicit extractors are more likely to be easier to derandomize if they belong to a low complexity class. At the same time, such non-explicit extractors may have applications in complexity theory (i.e., since the current state-of-the-art circuit lower bounds are against extractors [15]). There is a long line of work [20, 11, 5, 17, 19, 2, 5, 10, 12, 7] on the power of low-complexity computational models for extracting from various families of sources.

From the forefront of "low complexity" classes, we choose to study in this work the class of low-degree $\mathbb{F}_2$-polynomials. In particular, we ask whether (non-explicit) low-degree polynomials can help break the $\sqrt{n}$ barrier for extracting from local sources, and more generally we seek to answer the following question:

▶ **Question 1.** *How powerful are low-degree $\mathbb{F}_2$-polynomials as extractors for local sources?*

Beyond being a natural algebraic class, low-degree $\mathbb{F}_2$-polynomials have a natural combinatorial interpretation. We can represent a degree-2 $\mathbb{F}_2$-polynomial f as a graph G_f on n vertices, with edges representing monomials included in f. Then, f being a good extractor for local sources translates into a parity constraint on the number of edges in certain induced subgraphs of G_f. Likewise, a degree-3 $\mathbb{F}_2$-polynomial can be represented as a 3-hypergraph, and so on. Given the correspondence between low-degree polynomials and hypergraphs with small edge sizes, we hope that tools from combinatorics can be leveraged to make our constructions explicit and break the $\sqrt{n}$ min-entropy barrier for extracting from local sources (which would also give improved extractors for small-space sources).

Our motivation to study low-degree polynomials as our "low complexity" model also comes from the work of Cohen and Tal [7], which studied the same question in the context of *affine* sources. In their work, they showed that there exist degree-r $\mathbb{F}_2$-polynomials that extract from affine sources with min-entropy $O(rn^{\frac{1}{r-1}})$, and that this is tight. To answer Question 1, we aim to provide a local source analogue of this result.

1.1 Summary of our results

In this paper, we fully characterize the power of low-degree polynomials as extractors for local sources, answering Question 1 and proving a local-source analogue of Cohen-Tal. Along the way, we rely on several new ingredients which may be of independent interest. We present these results in Section 1.1.1 and Section 1.1.2, respectively.

1.1.1 Main result

Our main result gives a tight characterization of the power of low-degree polynomials as extractors for local sources. We state it formally, below.

▶ **Theorem 1** (Main result). *For every $d, r \in \mathbb{N}$ there exist constants $C, c > 0$ such that the following holds. For every $n \in \mathbb{N}$ there exists a (not necessarily explicit) degree r polynomial $f \in \mathbb{F}_2[x_1, \ldots, x_n]$ that is an $2^{-\Omega(k)}$-extractor for d-local sources with min-entropy*

$$k \geq C(n \log n)^{1/r},$$

but for every degree r polynomial $g \in \mathbb{F}_2[x_1, \ldots, x_n]$ there exists a d-local source with min-entropy

$$k \geq c(n \log n)^{1/r}$$

on which it is constant.

Theorem 1 implies that degree-3 polynomials are already enough to extract from min-entropy $k = O((n \log n)^{1/3})$, which (non-explicitly) breaks the $\sqrt{n}$ min-entropy barrier on previous techniques (Theorem 0). Furthermore, given known reductions from AC^0 sources and small-space sources to local sources [21, 3], it also follows that low-degree polynomials can be used to break existing min-entropy barriers for extracting from these other models of weak sources. We refer the reader to the full version of this paper for a more in-depth discussion, where we also outline a different application of our result to sampling lower bounds against AC^0 (generalizing a result of Viola [22]).

While Theorem 1 is stated for constant locality d and constant degree r, we actually prove stronger results that hold for superconstant d, r. In particular, Theorem 1 follows immediately from the following two results, which provide upper and lower bounds on the entropy required to extract from d-local sources using a degree $\leq r$ polynomials (where d, r need not be constant).

▶ **Theorem 1.1** (Technical version of Theorem 1, Upper Bound). *There are universal constants $C, c > 0$ such that for all $n, d, r \in \mathbb{N}$, the following holds. With probability at least 0.99 over the choice of a random degree $\leq r$ polynomial $f \in \mathbb{F}_2[x_1, \ldots, x_n]$, it holds that f is an ε-extractor for d-local sources with min-entropy*

$$k = C2^d d^2 r \cdot (2^d n \log n)^{1/r},$$

where $\varepsilon = 2^{-\frac{ck}{r^3 2^d d^2}}$.

▶ Remark 1.3. If instead of extractors we aim to construct *dispersers*,[1] then we are able to improve the dependency on the locality d in Theorem 1.1 to hold for min-entropy $k = Cd^2 r \cdot (dn \log n)^{1/r}$.

[1] A function $\mathsf{Disp} : \{0,1\}^n \to \{0,1\}$ is a *disperser for a class of sources $\mathcal{C}$* if the support of $\mathsf{Disp}(\mathbf{X})$ is $\{0,1\}$ for all sources $\mathbf{X} \in \mathcal{C}$.

▶ **Theorem 1.2** (Technical version of Theorem 1, Lower Bound). *There are constants $C, c > 0$ such that for all $n, d, r \in \mathbb{N}$ with $r \leq c\log(n)$ and $d \leq 2^{\sqrt{\log n}}$, the following holds. For any degree $\leq r$ polynomial $f \in \mathbb{F}_2[x_1, \ldots, x_n]$, there is a d-local source $\mathbf{X} \sim \{0,1\}^n$ with min-entropy at least*

$$k \geq Cr(dn\log n)^{1/r}$$

such that $f(\mathbf{X})$ is constant.

1.1.2 Key new ingredients

Our main result follows from a collection of new ingredients, which may be of independent interest. In order to prove our upper bound on min-entropy (Theorem 1.1), we prove a new reduction from d-local sources to *d-local non-oblivious bit fixing (NOBF) sources*. Informally, a d-local NOBF source $\mathbf{X} \sim \{0,1\}^n$ of min-entropy k' is a source that has k' uniform independent bits, with all other bits depending on at most d of the k' bits.

▶ **Theorem 2** (Reduction from d-local sources to d-local NOBF sources). *There exists a universal constant $c > 0$ such that for any $n, k, d \in \mathbb{N}$, the following holds. Let $\mathbf{X} \sim \{0,1\}^n$ be a d-local source with min-entropy $\geq k$. Then $\mathbf{X}$ is ε-close to a convex combination of d-local NOBF sources with min-entropy $\geq k'$, where $\varepsilon = 2^{-ck'}$ and*

$$k' = \frac{ck}{2^d d^2}.$$

The family of d-local NOBF sources, introduced in [4], is a significant specialization of d-local sources. The above reduction shows that, at least for constant locality d, we can just focus on extracting from this simpler class - even in future explicit constructions.

To prove our lower bound on min-entropy (Theorem 1.2), we actually prove this lower bound for the special class of d-local sources known as *d-local affine sources*: such a source $\mathbf{X} \sim \mathbb{F}_2^n$ is uniform over a d-local affine subspace $X \subseteq \mathbb{F}_2^n$, which is a special type of affine subspace that admits a basis $v_1, \ldots, v_k \in \mathbb{F}_2^n$ where each coordinate $i \in [n]$ holds the value 1 in at most d of these vectors. For this special class of sources, our lower bound is actually tight, and can be viewed as a "local" version of a result by Cohen and Tal [7].

▶ **Theorem 3** (Local version of Cohen-Tal). *There exist universal constants $C, c > 0$ such that for every $n, r, d \in \mathbb{N}$ such that $r \leq c\log(n)$ and $d \leq 2^{\sqrt{\log n}}$, the following holds. For any degree r polynomial $f \in \mathbb{F}_2[x_1, \ldots, x_n]$, there exists a d-local affine subspace $X \subseteq \mathbb{F}_2^n$ of dimension*

$$k \geq Cr(dn\log n)^{1/r}$$

on which f is constant.

This is tight: there exists a degree r polynomial $g \in \mathbb{F}_2[x_1, \ldots, x_n]$ which is an extractor for d-local affine sources of dimension $k \geq Cr(dn\log n)^{1/r}$, which has error $\varepsilon = 2^{-ck/r}$.

We prove Theorem 3 by extending the techniques of Cohen and Tal [7], while leveraging a key new ingredient: a "low-weight" Chevalley-Warning theorem. This result, which may be of independent interest, shows that any small system of low-degree polynomials admits a (nontrivial) solution of low Hamming weight.

▶ **Theorem 4** (Low-weight Chevalley-Warning). *Let* $\{f_i\} \subseteq \mathbb{F}_2[x_1, \ldots, x_n]$ *be a set of polynomials with degree*[2] *at most* $D < n$ *and nonlinear degree*[3] *at most* Δ *such that* 0 *is a common solution. Then there is a common solution* $x \neq 0$ *of Hamming weight*

$$w \leq 24\Delta + 2D/\log(n/D).$$

1.2 Open problems

Our work leaves open several interesting avenues for future work. We highlight three of them:

- For any constant $r \geq 2$, does there exist an explicit $\mathbb{F}_2$-polynomial of degree r that extracts from 2-local sources of min-entropy $o(n)$?
- In Theorem 2, we showed a reduction from a d-local source of min-entropy k to a d-local non-oblivious bit fixing (NOBF) source of min-entropy $\Omega(k/2^d)$. It would be interesting to show a reduction to show a reduction from a d-local source of min-entropy k to a d-local NOBF source of min-entropy $\Omega(k/\text{poly}(d))$ (or show that such a reduction is impossible).
- Theorem 4 shows that if a collection of low-degree polynomials of total degree D and nonlinear degree Δ has the zero vector as a solution, then there exists a nonzero solution of weight at most $O(\Delta + D/\log(n/D))$. When $\Delta = 0$, this becomes asymptotically tight by the Hamming bound. Moreover, when $D = \Delta$, this will also be tight by picking the polynomial $f(x) = \sum_{1 \leq |S| \leq \Delta} \prod_{i \in S} x_i$. However, if we had $\Delta/2$ quadratic polynomials, will the upper bound of $O(\Delta)$ be tight?

2 Overview of our techniques

In this section, we provide an overview of the techniques that go into our three main results:

- An entropy *upper bound* for low-degree extraction from local sources (Theorem 1.1).
- An entropy *lower bound* for low-degree extraction from local sources (Theorem 1.2).
- A *barrier* for extracting from local sources using black-box affine extractors (Theorem 0).

Along the way, we will overview the several new key ingredients (Theorems 2, 3, and 4) that go into these main results.

2.1 Upper bounds

We begin by discussing our entropy upper bounds for low-degree extraction from local sources. By this, we mean that we upper bound the entropy *requirement* for extracting from d-local sources using degree $\leq r$ polynomials. In other words, we show that low-degree polynomials extract from local sources.

2.1.1 Low-degree extractors for local sources

We start by sketching the techniques behind our main upper bound (Theorem 1.1), which shows that most degree $\leq r$ polynomials are low-error extractors for d-local sources with min-entropy at least

$$k = O(2^d d^2 r \cdot (2^d n \log n)^{1/r}).$$

[2] The *degree* D is the sum of the degrees of the f_i's.
[3] The *nonlinear degree* is the sum of the degrees of the f_i's which have degree at least 2.

A strawman application of the probabilistic method

A natural first attempt at proving our result would use a standard application of the probabilistic method, which looks something like the following. First, let $f \in \mathbb{F}_2[x_1, \ldots, x_n]$ be a uniformly random polynomial of degree $\leq r$, meaning that each monomial of size $\leq r$ is included in f with probability $1/2$. Then, we let $\mathcal{X}$ be the family of d-local sources over $\{0,1\}^n$, each with min-entropy at least k. To prove that most of these polynomials are low-error extractors for this family, a standard application of the probabilistic method would suggest that we:

1. Prove that f is an extractor for a single $\mathbf{X} \in \mathcal{X}$ with extremely high probability.
2. Show that the family $\mathcal{X}$ does not contain too many sources.
3. Conclude, via the union bound, that f is an extractor for *every* $\mathbf{X} \in \mathcal{X}$ with high probability.

It is not too hard to complete Steps 2 and 3 in the above framework, but Step 1 turns out to be much more challenging. To see why, let us consider an arbitrary d-local source $\mathbf{X} \sim \{0,1\}^n$ with min-entropy at least k. By definition of d-local source, there exists some $m \in \mathbb{N}$ and functions $g_1, \ldots, g_n : \{0,1\}^m \to \{0,1\}$ such that each g_i depends on just d of its inputs, and such that given a uniform $\mathbf{Y} \sim \{0,1\}^m$, we have

$$\mathbf{X} = (g_1(\mathbf{Y}), g_2(\mathbf{Y}), \ldots, g_n(\mathbf{Y})).$$

Now, we want to argue that a random degree $\leq r$ polynomial $f \in \mathbb{F}_2[x_1, \ldots, x_n]$ is a low-error extractor for $\mathbf{X}$. To do so, consider the function $F : \{0,1\}^m \to \{0,1\}$ defined as

$$F(y_1, \ldots, y_m) := (f \circ g)(y_1, \ldots, y_m) = f(g_1(y_1, \ldots, y_m), \ldots, g_n(y_1, \ldots, y_m)).$$

Notice that by the definition of $\mathbf{X}$ and by Definition 1.1 of extractor, we know that F is an extractor for $\mathbf{X}$ with error ε if

$$|\mathsf{bias}(F)| := \left| \Pr_{y \sim \mathbf{U}_m} [F(y) = 1] - \Pr[F(y) = 0] \right| \leq 2\varepsilon.$$

Thus, to argue that a random degree $\leq r$ polynomial $f \in \mathbb{F}_2[x_1, \ldots, x_n]$ is a low-error extractor for $\mathbf{X}$, it suffices to argue that the function $F = f \circ g$ has low bias (with high probability over the selection of f).

Of course, the question now becomes: how can we ensure that F has low bias? We can start by noticing some properties of F. First, we know $F = f \circ g$, where f is a random degree $\leq r$ polynomial and g is a fixed function where each output bit depends on $\leq d$ input bits. Thus, it is not hard to argue that F will have degree $\leq rd$. Furthermore, since f is random and g is fixed, one may hope to argue that F is a *uniformly random* polynomial of degree $\leq rd$: in this case we would be done, since it is well-known that uniformly random low-degree polynomials have extremely low bias (with extremely high probability) [1].

Unfortunately, it is too much to hope that F is a uniformly random low-degree polynomial. Indeed, it is not hard to see that the distribution of F over degree $\leq rd$ polynomials depends heavily on the exact selection of g. Furthermore, for most selections of g, the random function F is *not* uniformly distributed over degree $\leq t$ polynomials for *any* t.

Thus, there is no obvious way to apply [1] in order to argue that F will have low bias. To proceed, it seems like we will somehow need to argue that the distribution of F over low-degree polynomials is guaranteed to have some specific *structure*, and then somehow argue that a random polynomial from any such structured distribution is guaranteed to have low-bias. Each of these steps seems quite challenging.

Reductions to the rescue

As it turns out, there is a simple trick we can use to greatly simplify the above approach. The key idea is to *reduce* local sources to a simpler class of sources. Given two familes $\mathcal{X}, \mathcal{Y}$ of distributions over $\{0,1\}^n$, we say that $\mathcal{X}$ *reduces* to $\mathcal{Y}$ if each $\mathbf{X} \in \mathcal{X}$ is (close to) a convex combination of $\mathbf{Y} \in \mathcal{Y}$.[4] Reductions are extremely useful, because of the following well-known fact: if $\mathcal{X}$ reduces to $\mathcal{Y}$, and $f : \{0,1\}^n \to \{0,1\}$ is an extractor for $\mathcal{Y}$, then f *is also an extractor for* $\mathcal{X}$.

Thus, in order to show that low-degree polynomials extract from d-local sources, a key new ingredient we use is a reduction from d-local sources to a simpler class of sources called *d-local non-oblivious bit-fixing (NOBF) sources* [4]. Using the above discussion, it then suffices to show that low-degree polynomials extract from d-local NOBF sources. Thus, we proceed by:

1. Defining local NOBF sources, and showing how we can appropriately tailor our previous attempt at the probabilistic method so that it works for local NOBF sources.
2. Providing a new reduction from local sources to local NOBF sources.

Low-degree extractors for local NOBF sources

A *d-local NOBF source* $\mathbf{X} \sim \{0,1\}^n$ is a natural specialization of a d-local source where the entropic bits of the source must show up "in plain sight" somewhere in the source.[5] More formally, a d-local NOBF source with min-entropy k is a random variable $\mathbf{X} \sim \{0,1\}^n$ for which there exist functions $g_1, \ldots, g_n : \{0,1\}^k \to \{0,1\}$ such that the following holds: each $g_i, i \in [n]$ depends on $\leq d$ input bits; for every $i \in [k]$ there is some $i' \in [n]$ such that $g_{i'}(y) = y_i$; and for uniform $\mathbf{Y} \sim \{0,1\}^k$ we have

$$\mathbf{X} = (g_1(\mathbf{Y}), g_2(\mathbf{Y}), \ldots, g_n(\mathbf{Y})).$$

In other words, some k "good" bits in $\mathbf{X}$ are uniform, and the remaining $n-k$ "bad" bits are d-local functions of the good bits.

We must now show that a random degree $\leq r$ polynomial $f \in \mathbb{F}_2[x_1, \ldots, x_n]$ extracts from d-local NOBF sources with entropy k. As in our strawman application of the probabilistic method, consider an arbitary d-local NOBF source $\mathbf{X} = (g_1(\mathbf{Y}), \ldots, g_n(\mathbf{Y}))$ and let $f \in \mathbb{F}_2[x_1, \ldots, x_n]$ be a uniformly random degree $\leq r$ polynomial. To show that f extracts from all d-local NOBF sources, recall that we just need to show that the function $F : \{0,1\}^k \to \{0,1\}$ defined as

$$F(y) := (f \circ g)(y) = f(g_1(y), \ldots, g_n(y))$$

has extremely low bias with extremely high probability. Furthermore, recall that if we can show that F itself is a uniformly random low-degree polynomial, then we know via [1] that this is true.

It is still too much to hope that F is a uniform low-degree polynomial, but F is now "close enough in structure" to one so that we can make this work. To see why, we can first assume without loss of generality (by definition of local NOBF source) that $g_1(y) = y_1, \ldots, g_k(y) = y_k$. Thus, we can define $c_S \sim \{0,1\}$ as an independent uniform bit (for each $S \subseteq [n]$ of size $\leq r$) and write

[4] By this we mean that each $\mathbf{X} \in \mathcal{X}$ can be written in the form $\mathbf{X} = \sum_i p_i \mathbf{Y}_i$, where each $\mathbf{Y}_i \in \mathcal{Y}$, $\sum_i p_i = 1$, and $\mathbf{X}$ samples from $\mathbf{Y}_i$ with probability p_i.

[5] The relationship between local sources and local *NOBF* sources is not dissimilar to the relationship between error-correcting codes and *systematic* error-correcting codes.

$$F(y) = \sum_{S\subseteq[k]:|S|\leq r} c_S \prod_{i\in S} g_i(y) + \sum_{S\subseteq[n]:|S|\leq r, S\not\subseteq[k]} c_S \prod_{i\in S} g_i(y) = A(y) + B(y),$$

where $A \in \mathbb{F}_2[y_1, \ldots, y_k]$ is a uniformly random polynomial of degree $\leq r$, and $B \in \mathbb{F}_2[y_1, \ldots, y_k]$ is a random polynomial whose selection of monomials is *not uniformly random*, but is nevertheless *independent* of the selections made by A.

Thus, to show that F has extremely low bias, it suffices to show that $A+B$ has extremely low bias. And to show that $A+B$ has extremely low bias, it suffices to show that $A+B'$ has low bias for any fixed polynomial B' induced by fixing the random monomials selected by B.

To conclude, we actually show something stronger: recalling that $A \in \mathbb{F}_2[y_1, \ldots, y_k]$ is a uniformly random polynomial of degree $\leq r$, we show that: for *any* fixed function $B^* : \{0,1\}^k \to \{0,1\}$, it holds that $A + B^*$ has low bias. This does not follow immediately from the result [1] that a random low-degree polynomial has low bias: indeed, it is more general, since [1] is the special case where $B^* = 0$. However, it *does* follow immediately from known upper bounds on the list size of Reed-Muller code [14].

In the language we are using here, an upper bound on the list size of a Reed-Muller code is equivalent to saying that for any fixed function $D \in \mathbb{F}_2[x_1, \ldots, x_k]$, A will differ from D on many inputs, with very high probability. Thus, such bounds tell us that A differs from B^* on many inputs with very high probability, and A differs from $1 + B^*$ (or rather, *equals* B^*) on many inputs with very high probability. In other words, A is completely uncorrelated with B^*, meaning that $\mathsf{bias}(A + B^*)$ is extremely small, as desired.

Thus a random low-degree polynomial f extracts from the d-local NOBF source $\mathbf{X}$ with min-entropy k with very high probability. In other words, it fails to do so with some very small probability $\delta = \delta(k)$ which decreases rapidly as k grows. By applying the union bound, we get that f extracts from the entire family $\mathcal{X}$ of d-local NOBF sources, provided $\delta(k) \cdot |\mathcal{X}| \ll 1$. All that remains is to upper bound the size of $\mathcal{X}$, which can easily be done using the d-locality of the sources.

A reduction to local NOBF sources

Above, we saw that random low-degree polynomials extract from *local NOBF sources*. To complete the proof that they also extract from more general *local sources*, recall that we need to provide a reduction from local sources to local NOBF sources. In other words, we need to show that every d-local source with min-entropy k is (close to) a convex combination of d-local NOBF sources with min-entropy $k' \approx k$. This is the main key ingredient in our result that low-degree polynomials extract from local sources (Theorem 1.1).

Our reduction works as follows. First, pick an arbitrary d-local source $\mathbf{X} \sim \{0,1\}^n$ with min-entropy k. Let k' be a parameter which is slightly smaller than k, which will be picked later. We start by arguing that $\mathbf{X}$ is (close to) a convex combination of d-local NOBF sources where there are k' good bits, but the good bits may be biased (but not constant).

Towards this end, recall that $\mathbf{X} = (g_1(\mathbf{Y}), \ldots, g_n(\mathbf{Y}))$ for some d-local functions $g_1, \ldots, g_n : \{0,1\}^m \to \{0,1\}$ and uniform $\mathbf{Y} \sim \{0,1\}^m$. The key idea is to consider the *largest possible set* $T \subseteq [n]$ of "good bits," i.e., such that $\{\mathbf{X}_i\}_{i\in T}$ are independent (and none are constants). Then, we let $T' \subseteq [m]$ be the bits of $\mathbf{Y}$ on which $\{\mathbf{X}_i\}_{i\in T}$ depend. The key observation is that *every* bit in $\mathbf{X}$ depends on *some* bit in $\{\mathbf{Y}_i\}_{i\in T'}$, by the maximality of T. Using this observation, there are *two possible cases*, over which we perform a *win-win analysis*.

First, it is possible that T contains $\geq k'$ bits. In this case, we consider fixing all bits $\{\mathbf{Y}_i\}_{i \notin T'}$. It is then not too hard to show that $\mathbf{X}$ becomes a source which contains $\geq k'$ good bits (which are mutually independent and not constants), and the remaining bad bits in $\mathbf{X}$ are deterministic d-local functions of these good bits.[6] Thus in this case, we get that $\mathbf{X}$ is a convex combination of NOBF sources of the desired type.

Second, it is possible that T contains $< k'$ bits. In this case, we consider fixing all bits $\{\mathbf{Y}_i\}_{i \in T'}$. But since all bits in $\mathbf{X}$ depend on *some* bit in this set, this fixing *decrements* the locality $d \to d-1$. And furthermore, since this fixes $|T'| \leq d|T| < dk'$ bits, the entropy only decreases from $k \to k - dk'$ by the entropy chain rule. We then recurse until we hit the first case, or until we hit $d = 1$. If we eventually hit the first case, we already know that $\mathbf{X}$ is a convex combination of NOBF sources of the desired type. On the other hand, it is easy to show that a 1-local source is actually a 1-local NOBF source! Thus we will always arrive at a (biased) d'-local NOBF source with $d' \leq d$, proving that $\mathbf{X}$ is always convex combination of NOBF sources of the desired type. Depending on when this recursion stops, we will arrive at an NOBF source with the number of good bits equal to at least

$$\min\{k', k - dk', k - d(d-1)k', \ldots, k - k' \prod_{i \in [d]} i\} \geq \min\{k', k - d^2 k'\},$$

which is always at least k' provided $k' \leq \frac{k}{2d^2}$.

Thus we see that any d-local source with min-entropy k can be written as a convex combination of d-local NOBF source with $\Omega(k/d^2)$ good bits, where the good bits are mutually independent (and nonconstant), but they may be heavily biased. So all that remains is to show that such biased d-local NOBF sources can be written as a convex combination of *unbiased* d-local NOBF sources (as they were originally defined). This step is not difficult, by applying a standard Chernoff bound. However, since each good bit depends on up to d bits, each such good bit $\mathbf{X}_i$ may have $|\mathsf{bias}(\mathbf{X}_i)| = 1 - 2 \cdot 2^{-d}$. As a result, we end up with $\Omega(\frac{k}{d^2 2^d})$ unbiased good bits.

This completes the reduction from local to local NOBF sources. Given our earlier proof sketch that low-degree polynomials extract from local NOBF sources, we finally get that low-degree polynomials also extract from local sources, as desired.

2.1.2 Low-degree dispersers for local sources

We now proceed to sketch the proof of Remark 1.3, which shows that most degree $\leq r$ polynomials are dispersers for d-local sources with min-entropy at least

$$k = O(d^2 r \cdot (dn \log n)^{1/r}).$$

This improves our min-entropy requirement for extractors (which was $k = O(2^d d^2 r \cdot (2^d n \log n)^{1/r})$) by removing two terms of the form 2^d. We use a different key idea to remove each 2^d term. While the outer exponential term 2^d is the more dramatic one to remove, it turns out that it is also the easier one. To do this, we simply note that for dispersers, we can forego the last step in our local to local NOBF reduction, which incurs a factor of 2^d by making the biased local NOBF source into an unbiased one. This improves the entropy requirement for dispersers from

$$k = O(2^d d^2 r \cdot (2^d n \log n)^{1/r}) \to k = O(d^2 r \cdot (2^d n \log n)^{1/r}).$$

[6] Technically we need to fix a little more randomness to make this happen, but this can be done without much trouble by invoking some standard tricks from the extractor literature.

Removing the inner exponential term

Next, we focus on improving the entropy requirement for dispersers from

$$k = O(d^2 r \cdot (2^d n \log n)^{1/r}) \to k = O(d^2 r \cdot (dn \log n)^{1/r}),$$

turning the inner exponential term 2^d into d. This improvement is more challenging: while our first improvement relied on improving the local to local-NOBF reduction, this improvement relies on improving the entropy requirement for dispersing from local NOBF sources.

In order to show that low-degree polynomials extract from local NOBF sources, recall that we: (1) showed that a random low-degree polynomial extracts from an arbitrary local NOBF source with extremely high probability; and (2) used a union bound over the family $\mathcal{X}$ of local NOBF sources to conclude that it extracts from *all* local NOBF sources with high probability. To get our second improvement on the min-entropy requirement for dispersers, we get improved upper bounds on the size of $\mathcal{X}$, so that our union bound is over fewer terms.

Towards this end, the key new idea is to show that in order to disperse from the family of d-local NOBF sources $\mathcal{X}$, it actually suffices to disperse from the much smaller family $\mathcal{X}'$ of so-called *d-local, degree $\leq r$ NOBF sources.*[7] This source family is the exact same as d-local NOBF sources, except it has the added restriction that the bad bits (which still depend on $\leq d$ good bits each) can each be written as a degree $\leq r$ polynomials. However, this family is significantly smaller: natural estimates on the sizes of $\mathcal{X}, \mathcal{X}'$ give

$$|\mathcal{X}| \leq \binom{n}{k} \cdot \left(\binom{k}{d} \cdot 2^{2^d} \right)^{n-k},$$
$$|\mathcal{X}'| \leq \binom{n}{k} \cdot \left(\binom{k}{d} \cdot 2^{\binom{d}{\leq r}} \right)^{n-k}.$$

After plugging in these improved size bounds, it is straightforward calculation to see that the inner 2^d term from the entropy requirement drops out. So all that remains is to show the above claim that a disperser for d-local, degree $\leq r$ NOBF sources automatically works for the more general family of d-local NOBF sources.

The key ingredient that goes into this claim is a simple lemma on polynomial decomposition. We show the following: for any function $f : \{0,1\}^n \to \{0,1\}$, any degree $\leq r$ polynomials $a_1, \ldots, a_n : \{0,1\}^k \to \{0,1\}$, and any polynomials $b_1, \ldots, b_n : \{0,1\}^k \to \{0,1\}$ that have no monomials of size $\leq r$, the following holds. There exists a polynomial $h : \{0,1\}^k \to \{0,1\}$ with no monomials of size $\leq r$ such that

$$f(a_1(y) + b_1(y), \ldots, a_n(y) + b_n(y)) = f(a_1(y), \ldots, a_n(y)) + h(y).$$

Then, given an arbitrary d-local NOBF source $\mathbf{X} \sim \{0,1\}^n$, the idea is to write it in the form

$$\mathbf{X} = (a_1(\mathbf{Y}) + b_1(\mathbf{Y}), \ldots, a_n(\mathbf{Y}) + b_n(\mathbf{Y})),$$

where $\mathbf{Y} \sim \{0,1\}^k$ is uniform and a_i, b_i are as before. Using our polynomial decomposition lemma, it then (roughly) holds that f is a disperser for $\mathbf{X}$ if f is a disperser for the simpler class of d-local, degree $\leq r$ NOBF sources. More precisely, we actually require from f a property that is ever-so-slightly stronger than being a disperser: we require that for any d-local, degree $\leq r$ NOBF source $\mathbf{X}' = (a_1(\mathbf{Y}), \ldots, a_n(\mathbf{Y}))$, it holds that the polynomial

[7] Technically, we require something slightly stronger than dispersion from such sources, but this does not make a huge difference. We will go into more details below.

$f(a_1, \ldots, a_n)$ has a monomial of degree $\leq r$. Our polynomial decomposition lemma then guarantees that f will also have this property for the more general d-local source, since the polynomial h in our decomposition lemma does not have any monomials of degree $\leq r$. Intuitively, h is not able to "destroy" the monomial of degree $\leq r$ guaranteed to pop out of $f(a_1(y), \ldots, a_n(y))$.

Thus, it suffices to "disperse" from d-local, degree $\leq r$ NOBF sources in order to disperse from more general d-local NOBF sources, meaning that we can leverage our improved bound on the size of $\mathcal{X}'$ to get our claimed improvement on the disperser's entropy requirement.

2.2 Lower bounds

We now discuss our entropy lower bounds for low-degree extraction from local sources. By this, we mean that for every degree $\leq r$ polynomial $f \in \mathbb{F}_2[x_1, \ldots, x_n]$ we can find a d-local source $\mathbf{X} \sim \{0,1\}^n$ with relatively high min-entropy k on which f is constant. In other words, we show that in order to disperse (and thus extract) from d-local sources, they must have min-entropy exceeding this value k.

We show that every degree $r \leq \Omega(\log n)$ polynomial $f \in \mathbb{F}_2[x_1, \ldots, x_n]$ must admit a d-local source $\mathbf{X} \sim \{0,1\}^n$ of min-entropy at least

$$k = \Omega(r(dn \log n)^{1/r})$$

on which it is constant. That is, we sketch the proof of our lower bound (Theorem 1.2).

In order to prove this result, we actually prove a slightly stronger result: we show that we can find a d-local source $\mathbf{X} \sim \{0,1\}^n$ with the above parameters such that it is also *affine*.

Our starting point is a tight result of Cohen and Tal [7], which shows that any degree $\leq r$ polynomial $f : \mathbb{F}_2^n \to \mathbb{F}_2$ admits a subspace $V \subseteq \mathbb{F}_2^n$ of dimension $\Omega(rn^{1/(r-1)})$ on which it is constant. Here, we obtain a (tight) granular version of their result, and show that any degree $\leq r$ polynomial f admits a d-local subspace $X \subseteq \mathbb{F}_2^n$ of dimension $k = \Omega(r(dn \log n)^{1/r})$ on which it is constant. Here, we say that V is *d-local* if V has a basis $v_1, \ldots, v_k \in \mathbb{F}_2^n$ such that for any index $i \in [n]$, at most d of these basis vectors equal 1 at this index. It is straightforward to verify that the uniform distribution $\mathbf{X}$ over V is a d-local source with min-entropy k, so we focus now on proving the existence of such a V.

At a high level, the proof of Cohen and Tal proceeds by iteratively growing a subspace V on which f is constant. At each phase, they define a set $A \subseteq \mathbb{F}_2^n$ such that f is constant over $\mathsf{span}(V, x)$ for every $x \in A$. They note that if $|A|$ has size $> 2^{\mathsf{dim}(V)}$, then of course there is some $x \in A \setminus V$ and furthermore we already know that f is constant on $\mathsf{span}(V, x)$. Thus, they can grow their monochromatic subspace by one dimension.

In order to get a lower bound on $|A|$, they note that this set can be defined as the common solutions to a small collection of low-degree polynomials. A classical result known as the *Chevalley-Warning theorem* (Theorem 5.1) then shows that $|A| \geq 2^{n-t}$, where t is the sum of degrees across the collection of polynomials. To complete their proof, they grow their subspace V until they are no longer able to show $|A| > 2^{\mathsf{dim}(V)}$.

In our lower bound, we show that f is monochromatic on a *d-local subspace*. To prove this, we start with the same approach as Cohen and Tal. However, at each phase, we add extra constraints to A which guarantee the following: if we take any $x \in A$ and add it to our current subspace V (with basis, say, $v_1, \ldots, v_{|\dim(V)|}$), then the location of the 1s appearing in vectors $x, v_1, \ldots, v_{|\dim(V)|}$ satisfy the d-locality constraint defined above. Again, as long as A is large enough, we can find some $x \in A$ that grows the dimension of our d-local subspace.

In order to ensure that A remains large for as many iterations as possible, we would like to minimize the impact of the new "locality" constraints that we have added to A. Given the description of these constraints above, we observe that these constraints are minimized if we grow V by carefully selecting vectors that have the lowest possible Hamming weight. However, we now need an upper bound on the Hamming weight of the lightest (nontrivial) common solution to a system of polynomial equations. Thus, our key new ingredient will be a result of this type, which we call a "low-weight Chevalley-Warning theorem."

A low-weight Chevalley-Warning theorem

Above, we saw how the classical Chevalley-Warning theorem is critical in lower bounding the size of A, thereby showing that there is some (nontrivial) vector $v \in A$ by which we can grow our monochromatic subspace. Now, we need an additional guarantee that there is such a $v \in A$ that also has low Hamming weight. We prove such a result, and call it a *low-weight Chevalley-Warning theorem*. Our theorem roughly says the following. Given a collection of polynomials that have cumulative degree D (and a common solution 0), if most of these polynomials have degree ≤ 1 then they admit a nontrivial solution of Hamming weight

$$w \leq O(D/\log(n/D)).$$

In order to prove our result, we start by using the CLP lemma [8] (a result which was instrumental in the recent resolution of the cap set conjecture) in order to show that for any large enough set $A \subseteq \mathbb{F}_2^n$ of common solutions to a system of polynomial equations, it holds that $A + A$ also contains a (nontrivial) common solution to this system. We then combine this result with an argument that is similar in flavor to the classical proof of the Hamming bound, and thereby obtain our low-weight Chevalley-Warning theorem. Equipped with this new ingredient, our entropy lower bound for low-degree extraction from d-local affine spaces follows immediately via the proof sketch described above.

2.3 A barrier

To conclude our overview, we provide a proof sketch of our barrier result (Theorem 0), which shows that affine extractors (applied in a black-box manner) cannot extract from local sources with min-entropy $k = \Omega(\sqrt{n})$, even if the locality is 2. More formally, to show that an affine extractor also extracts from a different family $\mathcal{Q}$ of distributions with min-entropy k, the standard technique is to show that each source $\mathbf{Q} \in \mathcal{Q}$ with min-entropy k is (close to) a convex combination of affine sources with min-entropy slightly less than k. Here, we show that this is simply not possible for local sources with min-entropy $\sqrt{n}$. In particular, we show that there is a very simple 2-local source $\mathbf{Q} \sim \{0,1\}^n$ with min-entropy $\Omega(\sqrt{n})$ that has statistical distance *exponentially close to* 1 from any convex combination of affine sources with min-entropy k'.

In more detail, we consider the 2-local "clique" source $\mathbf{Q} \sim \{0,1\}^n$ defined as follows: first, pick any $\ell \in \mathbb{N}$ and set $n := \ell + \binom{\ell}{2}$. Then, pick uniform and independent bits $\mathbf{q}_1, \ldots, \mathbf{q}_\ell \sim \{0,1\}$ and set $\mathbf{Q}$ to be the concatenation of all $\mathbf{q}_i$ over $1 \leq i \leq n$ and $\mathbf{q}_i \cdot \mathbf{q}_j$ over $1 \leq i < j \leq \ell$. Now, let $\mathbf{X} \sim \{0,1\}^n$ be a convex combination of affine sources, each with min-entropy ℓ'. We argue that $|\mathbf{Q} - \mathbf{X}| \geq 1 - 2^{-\Omega(\ell')}$ by showing that for any ℓ'-dimensional affine $\mathbb{F}_2$-subspace $S \subseteq \{0,1\}^n$, it holds that $|\mathsf{supp}(\mathbf{Q}) \cap S|/|S| \leq 2^{-\Omega(\ell')}$. That is, we wish to show that $Q = \mathsf{supp}(\mathbf{Q})$ is *subspace-evasive*.

To show that cliques are subspace-evasive, we use the following key observation: For any nonempty set $Q' \subseteq Q$ of cliques, the set $Q' + Q' := \{u + v : u \in Q', v \in Q', u \neq v\}$ (where the sum is over $\mathbb{F}_2^n$) has a "Sidon property:" each element x in $Q' + Q'$ has a unique

pair $u, v \in Q'$ such that $x = u + v$. This observation is proven by noticing that by making another copy of each coordinate of the form $\mathbf{q}_i \cdot \mathbf{q}_j$, the set Q will correspond precisely to the symmetric rank-1 matrices of $\mathbb{F}_2^{\ell \times \ell}$. Thus all the elements in $Q' + Q'$ would correspond to symmetric $\mathbb{F}_2^{\ell \times \ell}$ matrices of rank at most 2. Hence by looking at the row space of $x \in Q' + Q'$, we can precisely find its symmetric rank-1 decomposition. That is, we can find $u, v \in Q'$ such that $x = u + v$. Now, pick $Q' = Q \cap S$. Since addition is closed in S, we see that $Q' + Q' \subseteq S$. Thus $|S| \geq |Q' + Q'| \geq \binom{|Q'|}{2} \geq \Omega(|Q \cap S|^2)$. Hence we find that $|Q \cap S|/|S| \leq O(\sqrt{|S|}/|S|) = O(1/\sqrt{|S|})$, which is $2^{-\Omega(\ell')}$ as $|S| = 2^{\ell'}$.

For more details, we refer the reader to the full version of this paper.

3 Preliminaries

We briefly outline some basic notation, definitions, and facts that will be used throughout the paper. We first discuss some notation. We use log to denote the base-2 logarithm, we define $[n] := \{1, 2, \ldots, n\}$, and we write $\binom{n}{\leq r} := \sum_{i=0}^{r} \binom{n}{i}$. Given a random variable $\mathbf{X}$, we let $\mathsf{supp}(\mathbf{X})$ denote its support and write $\mathbf{X} \sim S$ to denote that $\mathsf{supp}(\mathbf{X}) \subseteq S$. Finally, we use $\mathbf{U}_m$ to denote the uniform distribution over $\{0,1\}^m$.

We now discuss some basic notions from probability. First, the *statistical distance* between two random variables $\mathbf{X}, \mathbf{Y} \sim S$ is denoted by $\Delta(\mathbf{X}, \mathbf{Y})$ and defined as $\Delta(\mathbf{X}, \mathbf{Y}) := \max_{T \subseteq S} |\Pr[\mathbf{X} \in T] - \Pr[\mathbf{Y} \in T]| = \frac{1}{2} \sum_{s \in S} |\Pr[\mathbf{X} = s] - \Pr[\mathbf{Y} = s]|$. Moreover, we say $\mathbf{X}$ and $\mathbf{Y}$ are *ε-close*, denoted $\mathbf{X} \approx_\varepsilon \mathbf{Y}$, if $\Delta(\mathbf{X}, \mathbf{Y}) \leq \varepsilon$. Finally, recalling the definition of min-entropy from the introduction, we will use the following simple fact about this quantity. The proof is straightforward, and can be found in the full version.

▶ **Lemma 3.1.** *Suppose $\mathbf{X}$ and $\mathbf{Y}$ are arbitrary random variables such that $\mathbf{Y}$ is uniformly distributed over its support. Then, for every $y \in \mathsf{supp}(\mathbf{Y})$, it holds that*

$$H_\infty(\mathbf{X}|\mathbf{Y} = y) \geq H_\infty(\mathbf{X}) - \log |\mathsf{supp}(\mathbf{Y})|.$$

4 Entropy upper bounds

In this section, we obtain upper bounds on the entropy required to extract from d-local sources using degree $\leq r$ polynomials (Theorem 1.1). To do so, we combine two key ingredients. Our first key ingredient reduces d-local sources to d-local NOBF sources:

▶ **Theorem 4.1** (Theorem 2, restated)**.** *There exists a universal constant $c > 0$ such that for any $n, k, d \in \mathbb{N}$, the following holds. Let $\mathbf{X} \sim \{0,1\}^n$ be a d-local source with min-entropy $\geq k$. Then $\mathbf{X}$ is ε-close to a convex combination of d-local NOBF sources with min-entropy $\geq k'$, where $\varepsilon = 2^{-ck'}$ and*

$$k' = \frac{ck}{2^d d^2}.$$

Our second key ingredient gives upper bounds on the entropy required to extract from d-local NOBF sources using degree $\leq r$ polynomials.

▶ **Theorem 4.2** (Low-degree polynomials extract from d-local NOBF sources)**.** *There are universal constants $C, c > 0$ such that for all $n, d, r \in \mathbb{N}$, the following holds. With probability at least 0.99 over the choice of a random degree $\leq r$ polynomial $f \in \mathbb{F}_2[x_1, \ldots, x_n]$, it holds that f is an ε-extractor for d-local NOBF sources of min-entropy*

$$k = Cr \cdot (2^d \cdot n \log n)^{1/r}$$

with error $\varepsilon = 2^{-ck/r^3}$.

By combining the above two theorems, we immediately get Theorem 1.1. Moreover, if we only care about *dispersing* (instead of *extracting*), it turns out that we can streamline our arguments and remove the 2^d terms in Theorems 4.1 and 4.2, yielding Remark 1.3.

In the remainder of this section, we focus on proving our reduction, Theorem 4.1. But before doing so, we briefly note that to prove Theorem 4.2, the main idea is to show that a random low-degree polynomial has low correlation with any fixed function. This observation follows quite readily from known bounds [14] on the list-size of Reed-Muller codes, and Theorem 4.2 is not too hard to show given this observation. For a formal proof of Theorem 4.2, we refer the reader to Section 2 and the full version of this paper, where one can also find more details regarding Remark 1.3.

4.1 A reduction from d-local sources to d-local NOBF sources

We now turn towards proving our reduction, Theorem 4.1. In order to reduce d-local sources to d-local NOBF sources, we use an intermediate model called a *biased d-local NOBF source*.

▶ **Definition 4.3** (Biased local NOBF sources). *A random variable $\mathbf{X} \sim \{0,1\}^n$ is a (δ, k)-*biased d-local NOBF source *if there exists a set $S \subseteq [n]$ of size k such that both of the following hold:*

- *The bits in $\mathbf{X}_S$ are mutually independent (but need not be identically distributed), and each $\mathbf{X}_i, i \in S$ has bias $|\Pr[\mathbf{X}_i = 1] - \Pr[\mathbf{X}_i = 0]| \leq \delta$.*
- *Every other bit $\mathbf{X}_j, j \notin S$ is a deterministic function of at most d bits in $\mathbf{X}_S$.*

▶ Remark 4.4. A d-local NOBF source with entropy k is a $(0, k)$-biased d-local NOBF source.

Given this intermediate model, we prove Theorem 4.1 by combining two lemmas. The first lemma reduces d-local sources to biased d-local NOBF sources:

▶ **Lemma 4.5.** *Let $\mathbf{X} \sim \{0,1\}^n$ be a d-local source with min-entropy $\geq k$. Then $\mathbf{X}$ is a convex combination of (δ, k')-biased d-local NOBF sources, where $\delta \leq 1 - 2^{-d}$ and $k' \geq k/(2d^2)$.*

The second lemma reduces biased d-local NOBF sources to (unbiased) d-local NOBF sources.

▶ **Lemma 4.6.** *Let $\mathbf{X} \sim \{0,1\}^n$ be a (δ, k')-biased d-local NOBF source. Then $\mathbf{X}$ is ε-close to a convex combination of $(0, k'')$-biased d-local NOBF sources, where $k'' \geq (1-\delta)k'/4$ and $\varepsilon = 2^{-k''/4}$.*

By combining these two lemmas, Theorem 4.1 follows immediately. Lemma 4.6 is not too difficult to prove by simulating each biased bit with two consecutive independent coin flips (one with bias $|1 - 2\delta|$ and one with bias 0) and applying a standard Chernoff bound over the result of the first coin flip. We refer to the full version for more details, and conclude this section by proving Lemma 4.5.

Proof of Lemma 4.5. Let $\mathbf{X} \sim \{0,1\}^n$ be a d-local source with min-entropy $\geq k$. The key observation that we will prove is that for any t, one of the following *must* hold: either

- $\mathbf{X}$ is a convex combination of (δ, t)-biased d-local NOBF sources, for $\delta \leq 1 - 2^{-d}$; or
- $\mathbf{X}$ is a convex combination of $(d-1)$-local sources with min-entropy $> k - td$.

Before we prove this key observation, let us see how we can use it to prove the desired result. First, recall that convex combinations "stack" in the following sense: if a source $\mathbf{X}$ is a convex combination of convex combinations of sources from a family $\mathcal{X}$, then $\mathbf{X}$ is just a convex combination of sources from $\mathcal{X}$. Thus, by repeatedly applying the key observation until either the first item becomes true or we arrive at a 1-local source (the "base case"), we see that $\mathbf{X}$ is a convex combination of sources $\{\mathbf{Z}_i\}$, where each $\mathbf{Z}_i$ is either:

- A (δ, t)-biased d-local NOBF source, for $\delta \leq 1 - 2^{-d}$; or
- A 1-local source with min-entropy $> k - t \cdot (d + (d-1) + \cdots + 2) = k - t \cdot (d^2 + d - 2)$.

However, it is clear from the definitions that a 1-local source with min-entropy k' is a 1-local NOBF source with min-entropy k'. Furthermore, it is easy to see that a 1-local NOBF source with min-entropy $\geq k'$ is a convex combination of 1-local NOBF sources with min-entropy exactly k', by fixing any additional random "good" bits. Thus, for any $t \leq k'$, we know that a 1-local source with min-entropy $\geq k'$ is a convex combination of (δ, t)-biased d-local NOBF sources, for $\delta \leq 1 - 2^{-d}$.

By the above discussion, we see that for any $t \leq k - t \cdot (d^2 + d - 2)$, $\mathbf{X}$ is a convex combination of (δ, t)-biased d-local NOBF sources, where $\delta \leq 1 - 2^{-d}$. Setting $t = \frac{k}{2d^2}$ yields the result.

Thus, all that remains is to prove the key observation stated at the beginning of the proof. Towards this end, let $\mathbf{X} \sim \{0,1\}^n$ be a d-local source with min-entropy $\geq k$. By definition of d-local source, there exists some ℓ and $f : \{0,1\}^\ell \to \{0,1\}^n$ such that $\mathbf{X} = f(\mathbf{Y})$ for uniform $\mathbf{Y} \sim \mathbf{U}_\ell$, such that each bit $\mathbf{X}_i$ is a deterministic function of at most d bits in $\mathbf{Y}$. In other words, there exist sets $S_1, \ldots, S_n \subseteq [\ell]$ of size d and functions $f_1, \ldots, f_n : \{0,1\}^d \to \{0,1\}^n$ such that

$$\mathbf{X} = (\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_n) = (f_1(\mathbf{Y}_{S_1}), f_2(\mathbf{Y}_{S_2}), \ldots, f_n(\mathbf{Y}_{S_n})).$$

Now, let $T \subseteq [n]$ be any set of coordinates of *maximal size* such that:

- $H_\infty(\mathbf{X}_i) > 0$ for all $i \in T$; and
- $S_i \cap S_j = \emptyset$ for any distinct $i, j \in T$.

Suppose T has size τ. Without loss of generality, assume $T = [\tau]$. We conclude with two cases.

Case (i): $\tau < t$. In this case, we fix the random variable $\mathbf{Y}_{S_1}, \ldots, \mathbf{Y}_{S_\tau}$. We know that with probability 1 over this fixing, all bits $\mathbf{X}_i, i \in [n]$ become deterministic functions of at most $d-1$ unfixed variables in $\mathbf{Y}$, by the maximality of T and its intersection property. In other words, $\mathbf{X}$ becomes a $(d-1)$-local source. Furthermore, by Lemma 3.1, we know that with probability 1 over this fixing, $\mathbf{X}$ loses $\sum_{i \in [\tau]} |S_i| = d\tau < dt$ bits of min-entropy. Thus in this case, $\mathbf{X}$ is a convex combination of $(d-1)$-local sources of min-entropy $> k - dt$.

Case (ii): $\tau \geq t$. In this case, define $\overline{S} := [n] - (\bigcup_{i \in [\tau]} S_i)$ and notice that $S_1, S_2, \ldots, S_\tau, \overline{S}$ partition the coordinates of $\mathbf{Y}$. Next, define the random variables $\mathbf{Z}_i := \mathbf{Y}_{S_i}$ for each $i \in [\tau]$, and define $\overline{\mathbf{Z}} := \mathbf{Y}_{\overline{S}}$. Notice that $\mathbf{X}_i = f_i(\mathbf{Z}_i)$ for each $i \in [\tau]$. Furthermore, it is straightforward to verify that for all $j > \tau$, there exists a set $Q_j \subseteq [\tau]$ of size at most d and a deterministic function f'_j such that $\mathbf{X}_j = f'_j(\mathbf{Z}_{Q_j}, \overline{\mathbf{Z}})$. In other words, we can rewrite $\mathbf{X}$ as

$$\begin{aligned}\mathbf{X} &= (\mathbf{X}_1, \ldots, \mathbf{X}_\tau, \mathbf{X}_{\tau+1}, \ldots, \mathbf{X}_n) \\ &= (f_1(\mathbf{Z}_1), \ldots, f_\tau(\mathbf{Z}_\tau), f'_{\tau+1}(\mathbf{Z}_{Q_{\tau+1}}, \overline{\mathbf{Z}}), \ldots, f'_n(\mathbf{Z}_{Q_n}, \overline{\mathbf{Z}})).\end{aligned}$$

Now, for each $i \in [\tau]$, define $\mathbf{A}_i := f_i(\mathbf{Z}_i)$. Furthermore, it is straightforward to show that we can define a new random variable $\mathbf{B}$ independent of $\mathbf{Y}$, and for each $i \in [\tau]$ a deterministic function g_i such that $g_i(\mathbf{A}_i, \mathbf{B}) = \mathbf{Z}_i$ for all $i \in [\tau]$. Thus, for any subset $Q \subseteq [\tau]$ we have $\mathbf{Z}_Q = g'_Q(\mathbf{A}_Q, \mathbf{B})$ for some deterministic function g'_Q. And finally, for each $j > \tau$ there must be some deterministic function ψ_j such that

$$f'_j(\mathbf{Z}_{Q_j}, \overline{\mathbf{Z}}) = \psi_j(\mathbf{A}_{Q_j}, \mathbf{B}, \overline{\mathbf{Z}}).$$

Thus we can rewrite $\mathbf{X}$ as:

$$\mathbf{X} = (\mathbf{A}_1, \ldots, \mathbf{A}_\tau, \psi_{\tau+1}(\mathbf{A}_{Q_{\tau+1}}, \mathbf{B}, \overline{\mathbf{Z}}), \ldots, \psi_n(\mathbf{A}_{Q_n}, \mathbf{B}, \overline{\mathbf{Z}})).$$

Notice that the collection $\{\mathbf{A}_i\}_{i\in[\tau]}$ are mutually independent, and each has bias at most $1 - 2^{-d}$ since it is a non-constant deterministic function of d uniform bits. Thus no matter how $\mathbf{B}, \overline{\mathbf{Z}}$ are fixed, $\mathbf{X}$ becomes a (δ, t)-biased d-local NOBF source, for $\delta \leq 1 - 2^{-d}$. ◀

5 Entropy lower bounds

In this section, we obtain lower bounds on the entropy required to extract from d-local sources using degree $\leq r$ polynomials (Theorem 1.2). To do so, we actually prove a stronger theorem, which can be viewed as a *local* version of a result by Cohen and Tal [7]. In particular, Cohen and Tal show that any low degree polynomial admits a large subspace on which it is constant. We show that this holds even for this special subclass of *local* subspaces.

▶ **Theorem 3** (Theorem 3, restated). *There exist universal constants $C, c > 0$ such that for every $n, r, d \in \mathbb{N}$ such that $r \leq c\log(n)$ and $d \leq 2^{\sqrt{\log n}}$, the following holds. For any degree r polynomial $f \in \mathbb{F}_2[x_1, \ldots, x_n]$, there exists a d-local subspace $X \subseteq \mathbb{F}_2^n$ of dimension*

$$k \geq Cr(dn\log n)^{1/r}$$

on which f is constant.

This is tight: there exists a degree r polynomial $g \in \mathbb{F}_2[x_1, \ldots, x_n]$ which is an extractor for d-local affine sources of dimension $k \geq Cr(dn\log n)^{1/r}$, which has error $\varepsilon = 2^{-ck/r}$.

Notice that this immediately implies Theorem 1.2, since (the uniform distribution over) a d-local subspace is not only an affine source, but it is also a d-local source.

The tightness claim in Theorem 3 is not too difficult to prove. To do so, one can simply use Gaussian elimination to observe that a d-local affine source is actually a d'-local *NOBF* source (for some d' that is not guaranteed to be equal to d). Then, the tightness claim follows via a standard application of the probabilistic method, using known bounds [1] on the bias of a random degree $\leq r$ polynomial.

The main part of Theorem 3 (preceding the tightness claim) is much more challenging to prove. The key new ingredient we rely on is a so-called "low-weight Chevalley-Warning theorem," which may be of independent interest. We present and prove this theorem in the following subsection. As discussed in Section 2, it is then not too difficult to use our low-weight Chevalley-Warning theorem to obtain Theorem 3, and we refer the reader to the full version for more details.

5.1 A low-weight Chevalley-Warning theorem

The classical *Chevalley-Warning theorem* guarantees that a small set of low-degree polynomials admits a common nontrivial solution:

▶ **Theorem 5.1** (Chevalley-Warning theorem [24]). *Let $\{f_i\} \subseteq \mathbb{F}_2[x_1, \ldots, x_n]$ be a set of polynomials with degree at most D such that 0 is a common solution. Then there are at least 2^{n-D} common solutions to $\{f_i\}$. In particular, if $D < n$, then there must be a nontrivial common solution.*

In this subsection, we prove a "low-weight" version of this theorem. In particular, it is natural to ask not only if $\{f_i\}$ contains a nontrivial common solution, but if $\{f_i\}$ contains a nontrivial common solution of *low Hamming weight* w. It is straightforward to use Theorem 5.1 to show that $w \leq D+1$, and we remark that this is tight in general. However, we show that if most of the polynomials in $\{f_i\}$ are linear, then we can improve this bound to roughly $w \leq O(D/\log(n/D))$.

▶ **Theorem 5.2.** *Let $\{f_i\} \subseteq \mathbb{F}_2[x_1, \ldots, x_n]$ be a set of polynomials with degree at most $D < n$ and nonlinear degree at most Δ such that 0 is a common solution. Then for any w satisfying*

$$\binom{n}{\leq \lfloor w/2 \rfloor} > 2^{D+1} \cdot \binom{n}{\leq \lfloor \Delta/2 \rfloor}, \tag{1}$$

there exists a nontrivial common solution with Hamming weight at most w.

It is straightforward to show that $w = 24\Delta + 2D/\log(n/D)$ satisfies inequality 1, yielding Theorem 4. The main ingredient that goes into the proof of Theorem 5.2 is the following lemma, which says that for any big enough set $A \subseteq \mathbb{F}_2^n$ of common solutions to a system of low-degree polynomials, it holds that $A + A$ also contains a (nontrivial) common solution.

▶ **Lemma 5.3.** *Let $\{f_i\} \subseteq \mathbb{F}_2[x_1, \ldots, x_n]$ be a set of polynomials with nonlinear degree at most Δ such that 0 is a common solution. Then for any set $A \subseteq \mathbb{F}_2^n$ of common solutions of size*

$$|A| > 2\binom{n}{\leq \lfloor \Delta/2 \rfloor}$$

it holds that $A + A$ contains a nontrivial common solution.

In order to prove this, we will make use of the CLP lemma, which was instrumental in the recent resolution of the cap set conjecture.

▶ **Lemma 5.4** (CLP lemma [8])**.** *Let $f \in \mathbb{F}_2[x_1, \ldots, x_n]$ be a polynomial of degree at most r, and let M denote the $2^n \times 2^n$ matrix with entries $M_{x,y} = f(x+y)$ for $x, y \in \mathbb{F}_2^n$. Then*

$$\mathsf{rank}(M) \leq 2\binom{n}{\leq \lfloor r/2 \rfloor}.$$

Next, we show how to prove Lemma 5.3 using Lemma 5.4. Then, we conclude this section by showing how to obtain Theorem 5.2 from Lemma 5.3.

Proof of Lemma 5.3. First, let $\{g_i\} \subseteq \{f_i\}$ be the set of polynomials in $\{f_i\}$ that have degree > 1. Notice that if $A + A$ contains a nontrivial common solution to the system $\{g_i\}$, then it also contains a nontrivial common solution to $\{f_i\}$: this follows from the linearity of the polynomials of $\{f_i\} - \{g_i\}$ and the fact that every $a \in A$ is a common solution (by definition of A). Thus, it suffices to show the result for the set $\{g_i\}$.

Next, consider the polynomial $g \in \mathbb{F}_2[x_1, \ldots, x_n]$ defined as

$$g(x) := \prod_i (1 + g_i(x)).$$

It is straightforward to verify that g has degree at most Δ, and that $g(x) = 1$ if and only if x is a common solution to $\{g_i\}$. Now, suppose for contradiction that $A + A$ contains no nontrivial common solution to $\{g_i\}$: that is, for every distinct $x, y \in A$ it holds that $g(x+y) = 0$. Then, consider the $2^n \times 2^n$ matrix M with entries $M_{x,y} = g(x+y)$ for every

$x, y \in \mathbb{F}_2^n$. Define $k := |A|$, and let $M[A, A]$ denote the $k \times k$ submatrix of M obtained by taking the rows and columns of M indexed by A. Since 0 is a common solution to $\{g_i\}$, we get that $M[A, A] = I_k$ and thus

$$\mathsf{rank}(M) \geq \mathsf{rank}(M[A, A]) = \mathsf{rank}(I_k) = k > 2\binom{n}{\leq \lfloor \Delta/2 \rfloor}$$

which directly contradicts Lemma 5.4. ◀

Finally, we conclude this subsection with our proof of Theorem 5.2.

Proof of Theorem 5.2. Let $A \subseteq \mathbb{F}_2^n$ be the collection of common solutions to $\{f_i\}$. Fix any $w \in [1, n]$ such that all nonzero common solutions to $\{f_i\}$ have weight $> w$. Then for any Hamming ball $\mathcal{B} \subseteq \mathbb{F}_2^n$ of radius $\lfloor w/2 \rfloor$, it must hold that

$$|\mathcal{B} \cap A| \leq 2\binom{n}{\leq \lfloor \Delta/2 \rfloor}, \tag{2}$$

because otherwise Lemma 5.3 tells us there exist distinct $x, y \in \mathcal{B} \cap A$ such that $x + y \in A$, and $x + y$ is a nonzero vector with weight at most $2\lfloor w/2 \rfloor \leq w$ (by the triangle inequality).

Now, given any vector $v \in \mathbb{F}_2^n$, let $\mathcal{B}(v)$ denote the Hamming ball around v of radius $\lfloor w/2 \rfloor$. We consider the quantity $\sum_{v \in A} |\mathcal{B}(v)|$, and seek to sandwich it between two inequalities. By definition of Hamming ball we know that each $|\mathcal{B}(v)| = \binom{n}{\leq \lfloor w/2 \rfloor}$, and by Theorem 5.1 we know that $|A| \geq 2^{n-D}$. Combining these observations with inequality 2, we get that

$$2^{n-D}\binom{n}{\leq \lfloor w/2 \rfloor} \leq \sum_{v \in A} |\mathcal{B}(v)| \leq 2^n \cdot 2\binom{n}{\leq \lfloor \Delta/2 \rfloor},$$

since each $u \in \mathbb{F}_2^n$ is contained by at most $2\binom{n}{\leq \lfloor \Delta/2 \rfloor}$ balls (with radius $\lfloor w/2 \rfloor$) centered at a common solution $a \in A$, by inequality 2 (i.e., consider the set $\mathcal{B}(u) \cap A$). Thus

$$\binom{n}{\leq \lfloor w/2 \rfloor} \leq 2^{D+1} \cdot \binom{n}{\leq \lfloor \Delta/2 \rfloor}.$$

In summary, we have shown that any $w \in [1, n]$ for which all nonzero common solutions to $\{f_i\}$ have weight $> w$ must satisfy the above inequality. The result follows. ◀

Abstract

We consider the problem of maintaining an approximate maximum integral matching in a dynamic graph G, while the adversary makes changes to the edges of the graph. The goal is to maintain a $(1+\varepsilon)$-approximate maximum matching for constant $\varepsilon > 0$, while minimizing the update time. In the fully dynamic setting, where both edge insertion and deletions are allowed, Gupta and Peng (see [29]) gave an algorithm for this problem with an update time of $O(\sqrt{m}/\varepsilon^2)$.

Motivated by the fact that the $O_\varepsilon(\sqrt{m})$ barrier is hard to overcome (see Henzinger, Krinninger, Nanongkai, and Saranurak [30]; Kopelowitz, Pettie, and Porat [34]), we study this problem in the *decremental* model, where the adversary is only allowed to delete edges. Recently, Bernstein, Probst-Gutenberg, and Saranurak (see [9]) gave an $O(\text{poly}(\log n/\varepsilon))$ update time decremental algorithm for this problem in *bipartite graphs*. However, beating $O(\sqrt{m})$ update time remained an open problem for *general graphs*.

In this paper, we bridge the gap between bipartite and general graphs, by giving an $O_\varepsilon(\text{poly}(\log n))$ update time algorithm that maintains a $(1+\varepsilon)$-approximate maximum integral matching under adversarial deletions. Our algorithm is randomized, but works against an adaptive adversary. Together with the work of Grandoni, Leonardi, Sankowski, Schwiegelshohn, and Solomon [26] who give an $O_\varepsilon(1)$ update time algorithm for general graphs in the *incremental* (insertion-only) model, our result essentially completes the picture for partially dynamic matching.

1 Introduction

In dynamic graph algorithms, the main goal is to maintain a key property of the graph while an adversary makes changes to the edges of the graph. An algorithm is called *incremental* if it handles only insertions, *decremental* if it handles only deletions and *fully dynamic* if it handles both insertions as well as deletions. The goal is to minimize the update time of the algorithm, which is the time taken by the algorithm to adapt to a single adversarial edge insertion or deletion and output accordingly. For incremental/decremental algorithms, one typically seeks to minimize the *total update time*, which is the aggregate sum of update times over the *entire* sequence of edge insertions/deletions.

We consider the problem of maintaining a $(1+\varepsilon)$-approximation to the maximum matching in a dynamic graph. In the fully dynamic setting, the best known update time for this problem is $O(\sqrt{m}/\varepsilon^2)$ (see Gupta and Peng [29]), and the conditional lower bounds proved in the works

of Henzinger, Krinninger, Nanongkai, and Saranurak (see [30]) and Kopelowitz, Pettie, and Porat (see [34]) suggest that $O(\sqrt{m})$ is a hard barrier to break through. For this reason, several relaxations of this problem have been studied. For example, one line of research has shown that we can get considerably faster update times if we settle for large approximation factors (see for example [13, 14, 16, 11, 41, 37, 6, 33, 27, 5, 39, 15, 8, 12, 10, 11, 7]). Another research direction has been to consider the more relaxed incremental or decremental models. In the incremental (insertion-only) setting, there have been a series of upper and lower bound results (see [17, 19, 28]), culminating in the result of Grandoni, Leonardi, Sankowski, Schwiegelshohn, and Solomon (see [26]), who gave an optimal $O_\varepsilon(m)$ *total* update time (amortized $O_\varepsilon(1)$) for $(1+\varepsilon)$-approximate maximum matching.

The decremental (deletion-only) setting requires an entirely different set of techniques. In fact, even for the special case of bipartite graphs, $O_\varepsilon(m\sqrt{m})$ total time ($O_\varepsilon(\sqrt{m})$ update time) remained the best known until recently, when Bernstein, Probst-Gutenberg, and Saranurak (see [9]) gave an $\text{poly}(\log n/\varepsilon)$ amortized update time algorithm for the case of bipartite graphs. However, achieving a similar result for general graphs remained an open problem. Our main theorem essentially closes the gap between bipartite and general graphs.

▶ **Theorem 1.** *Let G be an unweighted graph and $\varepsilon \in (0,1)$. There is a decremental algorithm with total update time $O_\varepsilon(m \cdot \text{poly}(\log n))$ (amortized $O_\varepsilon(\text{poly}(\log n))$) that maintains a matching M of size at least $(1-\varepsilon)\cdot\mu(G)$ with high probability. Here G refers to the current version of the graph and $\mu(G)$ is the size of the maximum matching of G. The algorithm is randomized but works against an adaptive adversary. The dependence on ε is $2^{O(1/\varepsilon^2)}$.*

The guarantees of our algorithm hold against an *adaptive adversary*: which is allowed to choose an update sequence adaptively. This is in contrast to an *oblivious adversary* which cannot decide its updates based on the algorithm's output. Deterministic algorithms are more desirable because they are robust against such updates, which allows them to be used as a black-box in other static/dynamic algorithms. This property doesn't hold when we have the weaker oblivious adversary assumption. Thus, even though our algorithm is *randomized* (Monte Carlo), it has has the same power as a deterministic algorithm. We refer the reader to Section 1 of [41] and the references therein for a detailed discussion on this.

Our result largely completes the picture for partially dynamic matching by showing that in general graphs one can achieve $\text{poly}(\log n)$ update time in both incremental and decremental settings. But there are a few secondary considerations that remain. Firstly, our update time is $O_\varepsilon(\text{poly}(\log n))$, rather than the $O_\varepsilon(1)$ for the incremental setting (see [26]). Secondly, both the incremental result of [26] and our decremental result for general graphs have an exponential dependence on $1/\varepsilon$, whereas incremental/decremental algorithms for bipartite graphs have a polynomial dependence on $1/\varepsilon$ (see [26, 28]). Optimizing the dependence on ε and $\text{poly}(\log(n))$ factors thus remains an interesting open question for future work.

In algorithms literature, it has been the case that efficient matching algorithms for bipartite graphs do not easily extend to general graphs. Existence of blossoms (among other things), poses a technical challenge to obtaining analogous results for the general case. Consider the polynomial time algorithms for maximum matching for bipartite graphs, the most efficient algorithm, using alternating BFS, was discovered by Hopcroft and Karp; Karzanov (see [31, 32]) in 1973. However, several new structural facts and algorithmic insights were used by Micali and Vazirani to get the same runtime for general graphs (see [36]). This is also a feature of recent work in different models, such as the streaming (see [1, 22] and [24]), fully dynamic (see [10, 11] and [14, 7]), and parallel models (see [23, 40] and [35, 3]). We refer the reader to Section 1.3 of [2] for a detailed discussion of this phenomenon.

2 High-Level Overview

Our algorithm for Theorem 1 follows the high-level framework of *congestion balancing* introduced in [9]. They used it to solve approximate decremental matching in bipartite graphs, and also to solve more general flow problems. But the framework as they used it was entirely limited to cut/flow problems. As we discuss below, extending this framework to general graphs introduces significant technical challenges. Moreover, our result shows how the key subroutine of congestion balancing is naturally amenable to a primal-dual analysis, which we hope can pave the way for this technique to be applied to other decremental problems. Throughout this paper, we will use $\tilde{O}(\cdot)$ to hide $\text{poly}(\log n)$ factors in big-oh notations.

2.1 Previous Techniques

A fractional matching is a non-negative vector $\vec{x} \in \mathbb{R}_{\geqslant 0}$ satisfying fractional matching constraints: for all $v \in V$, $\sum_{e \ni v} x(e) \leqslant 1$. The starting point of [9] is that it is sufficient to develop an $\tilde{O}_\varepsilon(m)$ algorithm that does the following: it either maintains a *fractional matching* of size at least $(1-2\varepsilon) \cdot \mu(G)$ or certifies that $\mu(G)$ has dropped by a $(1-\varepsilon)$ factor because of adversarial deletions. Since a result of [41] enables us to round any bipartite fractional matching to an integral matching of almost the same value, such a fractional algorithm yields an algorithm to maintain an integral matching of size at least $(1-3\varepsilon) \cdot \mu(G)$ in $\tilde{O}_\varepsilon(m)$ total time under adversarial deletions. To motivate why [9] consider computing a fractional matching, consider the following "lazy" algorithm that works with an integral matching: compute an $(1+\varepsilon)$ approximate integral matching M of G using a static $O(m/\varepsilon)$ algorithm, wait for $\varepsilon \cdot \mu(G)$ edges of M to be deleted and then recompute the matching. Since we assume an adaptive adversary, the update time could be as large as $\Omega(m^2/\varepsilon \cdot n)$; this is because the adversary could proceed by only deleting edges of M. As a result, the goal should be to maintain a *robust* matching that can survive many deletions. Thus, the algorithm in [9] maintains a "balanced" fractional matching $\vec{x}$ that attempts to put a low value on every edge. In order to reduce the value of $\vec{x}$ by $\varepsilon \cdot \mu(G)$, the adversary will have to delete a lot of edges from every large matching.

Balanced Fractional Matching in Bipartite Graphs. In order to ensure that the fractional matching is spread out and robust, the algorithm in [9] imposes a capacity function κ on the edges of the graph (initially, all edges have low capacity) and compute a fractional matching obeying these capacities. The main ingredient of the algorithm is the subroutine M-OR-E*(G, ε, κ) which returns one of the following in $\tilde{O}_\varepsilon(m)$ time:

1. A fractional matching $\vec{x}$ with $\sum_{e \in E} x(e) \geqslant (1-\varepsilon) \cdot \mu(G)$, $x(e) \leqslant \kappa(e)$ for all $e \in E$, or,
2. A set of edges E^* with the following two properties.
   a. The total capacity through E^* must be small: $\kappa(E^*) = O(\mu(G) \log n)$ and,
   b. For all $|M| \geqslant (1-3\varepsilon) \cdot \mu(G)$, $|M \cap E^*| \geqslant \varepsilon \cdot \mu(G)$.

Property 2a ensures that the total capacity increase is small, while Property 2b ensures that we only increase capacity on important edges that are actually needed to form a large matching. The authors of [9] show that M-OR-E*() can be used as a black-box to solve decremental matching: at each step, M-OR-E*() is used to find a large fractional matching $\vec{x}$ (this matching is then rounded using [41] to get an integral matching), or to output the set E^* along which we increase capacities. They are able to show that because of Properties 2a and 2b, the edge capacities remain small on average.

The *congestion balancing* framework of [9] consists of an outer algorithm that uses M-OR-E*() as a subroutine. The outer algorithm for bipartite graphs, with some challenges, carries over to general graphs as well. But, M-OR-E*() is significantly more challenging to

implement for general graphs, so this subroutine will be our focus for the rest of the high level review. For bipartite graphs the algorithm M-OR-E*() is easier to implement because maximum fractional matchings correspond to max flows in bipartite graphs. Hence, existing algorithms for approximate maximum flows can be used to find the approximate maximum fractional matching obeying capacity κ. Moreover, if such a fractional matching is not large, then in bipartite graphs, the set of bottleneck edges E^* is exactly a minimum cut of the graph. For general graphs, due to the odd set constraints, max flow, which was the key analytic and algorithmic tool in [9], no longer corresponds to a maximum fractional matching that avoids the integrality gap.

2.2 Our Contribution: Implementing M-or-E*() in General Graphs

At a high-level, there are several structural and computational challenges to implementing M-OR-E*() in the case of general graphs. We explain what the potential impediments are, and detail how our techniques circumvent these.

Fractional Matchings in General Graphs. In general graphs, not all fractional matchings have a large integral matching in their support and therefore, cannot be rounded to give a large matching. While fractional matchings that obey odd set constraints do avoid the integrality gap, it seems hard to compute such a matching that also obeys capacity function κ. In order to get past this, we define a candidate fractional matching that is both easy to compute as well as contains a large integral matching in its support. More concretely, our fractional matching either puts flow one through an edge, or a flow of value at most ε (technically, we put flow much smaller than ε, but for this discussion, ε is sufficient). It is known that such a fractional matching has an integrality gap of at most $1+\varepsilon$, since it obeys all small odd set constraints. Our main contributions are two structural lemmas which show that we can find our candidate matching efficiently.

1. First, given a graph G with capacity κ, we want to determine if the *value* of the maximum fractional matching obeying κ and odd set constraints (denoted $\mu(G,\kappa)$) is at least $(1-\varepsilon)\cdot\mu(G)$. In general graphs, we do this by giving a sampling theorem: let G_s be the graph created by sampling edge e with probability proportional to $\kappa(e)$, then $\mu(G_s) \geqslant \mu(G,\kappa) - \varepsilon\cdot n$ with high probability. Thus, $\mu(G_s)$ is a good proxy for $\mu(G,\kappa)$ and it can be estimated efficiently by running any integral matching algorithm on G_s.
2. Suppose we have determined at some point that $\mu(G,\kappa)$ is large, we are still left with the task of finding a fractional matching. Our next contribution is a structural theorem that enables us to deploy existing flow algorithms to find such a matching. Let M be an approximate maximum matching of G_s. Let $M_L = \{e \in M \mid \kappa(e) \leqslant \beta\}$ and $M_H = \{e \in M \mid \kappa(e) > \beta\}$, where L and H are for low and high respectively and $\beta = O(1/\text{poly}\log n)$. Let $V_L = V(M_L)$ and $V_H = V(M_H)$. Intuitively, M breaks up our vertex set into two parts: vertices matched by low capacity edges (denoted V_L) and those that are matched by high capacity edges (denoted V_H). By adding some slack to our capacity constraints (we show that some slack can be incorporated in congestion balancing framework), we are able to treat the high-capacity edges as integral and compute a matching on $G[V_H]$ using a black box for integral matching in general graphs. Additionally, we show that the maximum fractional matching on low capacity edges of $G[V_L]$ has value at least as much as $|M_L|$ up to an additive error of $\varepsilon\cdot n$. To compute this fractional matching $\vec{f}$, we show that since we are only considering edges of small capacity, small odd set constraints are automatically satisfied, so we can transform $G[V_L]$ into a *bipartite graph* and then use an existing flow algorithm. We then output $M_H + \vec{f}$, which has the property that either the flow through an edge is 1 or at most ε.

The second obstacle is finding the set E^*. Recall, for bipartite graphs, the max flow-min cut theorem gives us an easy characterization of the bottleneck edges. However, for general graphs, this characterization is unclear. To overcome this, we consider the dual of the matching LP of G_s, and show that the bottleneck edges can be identified by considering the dual constraints associated with the edges. This generalizes the cut-or-matching approach of [9]. We compute an integral matching in G_s, and since the algorithm of [20] is primal-dual, we are also able to compute approximate duals for G_s.

Additionally, there are some secondary technical challenges as well. As mentioned before, our structural theorems only guarantee preservation of matching sizes up to an additive error of $\varepsilon \cdot n$. When $\mu(G) = o(n)$, then the results, applied directly are insufficient for us. To get around this, we use a vertex sparsification technique to get $O_\varepsilon(\log n)$ multigraphs which preserve all large matchings of G, but contain only $O(\mu(G)/\varepsilon)$ vertices (this reduction was first used in [4, 18]). However, we now have to show that all of our ideas work for multigraphs as well. In proving the second structural result, we need to introduce some slack in the capacities (see Definition 19). We show that congestion balancing extends to multigraphs, and is flexible enough to handle slack in capacities. Finally, the rounding scheme of [41] cannot be applied as a black-box to any fractional matching in a general graph. Thus, unlike in the bipartite case, we instead have to embed its techniques into the congestion balancing framework.

▶ Note 2. All our structural theorems (see Lemma 15 and Lemma 26) apply to graphs G with $\mu(G) \geqslant \Omega(\varepsilon \cdot n)$. A reduction used by the authors of [18, 4] allows us to construct $O_\varepsilon(\log n)$ multigraphs $H_1, \cdots, H_\lambda$ with $O(\mu(G)/\varepsilon)$ vertices, such that for every M of G with $|M| \geqslant (1-\varepsilon) \cdot \mu(G)$ at least $(1-\varepsilon) \cdot |M|$ edges of M are present in some H_i. Thus, at a high level, we have reduced our problem to the problem of decremental matching on multigraphs with large matchings. So, it is enough to prove our structural theorems for multigraphs with large matchings. We justify this assumption formally in the full version.

3 Preliminaries

We consider the problem of maintaining an approximate maximum integral matching in a graph G in the decremental setting. Throughout the paper, we will use G to refer to the current version of the graph, and let V and E be the vertex and edge sets of G respectively. Additionally, $\mu(G)$ denotes the size of the maximum integral matching of G. During the course of the algorithm, we will maintain a fractional matching $\vec{x}$. For a set $S \subseteq E$, we let $x(S) = \sum_{e \in S} x(e)$. Given a capacity function $\kappa(e)$, we say that x obeys κ if $x(e) \leqslant \kappa(e)$ for all $e \in E$. For a vector $\vec{x}$, we use $\text{supp}(\vec{x})$ to be set of edges that are in the support of $\vec{x}$. For a fractional matching $\vec{x}$, we say that $\vec{x}$ satisfies odd set constraints if for every odd-sized $B \subseteq V$, $\sum_{e \in G[B]} x(e) \leqslant \frac{|B|-1}{2}$. Given a capacity function κ on the edges of G, we use $\mu(G, \kappa)$ to denote the value of the maximum fractional matching of G that obeys the capacity function κ and the odd set constraints. Throughout this paper, for any $\varepsilon \in (0, 1)$, we will let $\alpha_\varepsilon = \log n \cdot 2^{60/\varepsilon^2}$ and $\rho_\varepsilon = \log n \cdot 2^{40/\varepsilon^2}$. We also need the following algorithm computing $(1+\varepsilon)$-approximate matching in general graphs.

▶ **Lemma 3** ([20, 25]). *There is an $O(m/\varepsilon)$ time algorithm Static-Match() that takes as input a graph G, and returns an integral matching M of G with $|M| \geqslant (1-\varepsilon) \cdot \mu(G)$.*

Roadmap for Extended Abstract. As mentioned in the overview, the main technical contribution of our paper is an algorithm for M-or-E*() in general graphs. The rest of the extended abstract focuses exclusively on this algorithm; the details of how M-or-E*() can be used a black box to attain Theorem 1 are left for the full version.

4 Main Contribution: M-or-E*() In General Graphs

As mentioned in the overview, we need our congestion balancing framework to act on multigraphs. This motivates our next few definitions.

▶ **Definition 4.** *Given a multigraph G, for a pair of vertices u and v, define $D(u,v)$ to be the set of edges between u and v. Similarly, if e is an edge between u, v, then $D(e) \coloneqq D(u,v)$.*

▶ **Definition 5.** *Let G be a multigraph with n vertices and m edges. Let κ be a capacity function on the edges. Suppose $\vec{x}$ is a fractional matching of G ($\vec{x}$ is a vector of length m). Then, we define $\vec{x}^C$ to be a vector of support size at most $\min\left\{m, \binom{n}{2}\right\}$, where for a pair of vertices, u and v, $x^C(u,v) \coloneqq \sum_{e \in D(u,v)} x(e)$. Essentially, if $\vec{x}$ is a fractional matching on a multigraph, then $\vec{x}^C$ is a fractional matching obtained by "collapsing" all edges together. Similarly, if $\vec{y}$ is a vector of support at most $\binom{n}{2}$, then we define $\vec{y}^D$ to be an m length vector such that for every $e \in E$ between a pair of vertices u and v, $y^D(e) \coloneqq \frac{y(u,v)\cdot\kappa(e)}{\kappa(D(e))}$ (D is for distributed, and we distribute the flow among the edges in proportion to their capacity).*

▶ Remark 6. Note that in doing the transformations in Definition 5, the support size of the transformed vector is always at most m. Thus, it doesn't negatively affect our runtime.

We now state our core ingredient, which either finds a balanced fractional matching of the multigraph G, or gives a set of edges E^* along which we can increase capacity.

▶ **Lemma 7.** *Let G be a multi-graph with $\mu(G) \geqslant \varepsilon \cdot n/16$. Let κ be a capacity function on the edges of G. There is an algorithm M-OR-E*(), that takes as input $G, \kappa, \varepsilon \in (0, 1/2)$ and $\mu \geqslant (1-\varepsilon)\cdot\mu(G)$ and in time $O(m \cdot \log n/\varepsilon)$ returns one of the following.*

(a) *A fractional matching $\vec{x}$ of value at least $(1-20\varepsilon)\cdot\mu$ with the following properties.*
- **(i)** *For any $e \in supp(\vec{x})$ with $\kappa(D(e)) > 1/\alpha_\varepsilon^2$, $x(e) = \frac{\kappa(e)}{\kappa(D(e))}$, and $x(D(e)) = 1$.*
- **(ii)** *For any $e \in supp(\vec{x})$ with $\kappa(D(e)) \leqslant 1/\alpha_\varepsilon^2$, $x(e) \leqslant \kappa(e)\cdot\alpha_\varepsilon$ and $x(D(e)) \leqslant \kappa(D(e))\cdot\alpha_\varepsilon$.*

(b) *A set E^* of edges such that $\kappa(E^*) = O(\mu \log n)$ such that for any integral matching M with $|M| \geqslant (1-3\varepsilon)\cdot\mu$, we have $|M \cap E^*| \geqslant \varepsilon\mu$. Moreover, $\kappa(e) < 1$ for all $e \in E^*$. Additionally, for every pair of vertices $u, v \in V$, either $D(u,v) \cap E^* = \emptyset$ or $D(u,v) \subseteq E^*$.*

We give some intuition for Lemma 7. Recall that we need a balanced fractional matching that contains a large integral matching in its support. However, as mentioned before, in the case of general graphs, finding such a balanced fractional matching is not straightforward. In order to get past this obstacle, we define a balanced fractional matching that is easy to find and also avoids the integrality gap. We will explain how to find it in the subsequent sections. For now, we explain at a high-level, why the fractional matching $\vec{x}$ found by Lemma 7 avoids the integrality gap. Consider $\vec{x}^C$. Observe from Lemma 7(a), that for any pair of vertices $u, v \in G$, either $x^C((u,v)) = 1$ or $x^C((u,v)) \leqslant 1/\alpha_\varepsilon \leqslant \varepsilon$. Thus, $\vec{x}$ satisfies odd-set constraints for all odd sets of size at most $1/\varepsilon$. By a folklore lemma, we can then argue that $\vec{x}$ contains an integral matching of size at least $(1+\varepsilon)^{-1} \cdot \sum_{u \neq v} x^C((u,v))$.

As mentioned before M-OR-E*() will be used as a subroutine in our **decremental algorithm**. The fractional matching output by M-OR-E*() will have certain properties, we state these properties now, since they will be helpful in visualizing the fractional matching. We give a proof of these in the full version.

▶ **Property 8.** *In our decremental algorithm, M-OR-E*$(G, \mu, \kappa, \varepsilon)$ outputs a fractional matching $\vec{x}$ with the following property: consider any $u, v \in V$ and let e, e' be edges between u, v (recall that G is a multigraph). Then, $\kappa(e') = \kappa(e)$ at all times during the algorithm.*

▶ **Definition 9.** *Let G be a multigraph, let $\varepsilon \in (0,1)$, let κ be a capacity function on the edges of G and let $\vec{x}$ be a fractional matching obeying κ. Then, we split $\vec{x}$ into two parts, $\vec{x}^f$ and $\vec{x}^i$, where $\vec{x} = \vec{x}^f + \vec{x}^i$, and $\text{supp}(\vec{x}^f) = \{e \in E \mid \kappa(D(e)) \leqslant 1/\alpha_\varepsilon^2\}$ and $\text{supp}(\vec{x}^i) = \{e \in E \mid \kappa(D(e)) > 1/\alpha_\varepsilon^2\}$ ($\vec{x}^f$ stands for fractional and $\vec{x}^i$ stands for integral. Though the edges in $\vec{x}^i$ do not have integral capacity, they are large enough to round them to 1).*

We briefly give the implications of this definition, since it is instructive to state them.

▶ **Property 10.** *Let G be any multigraph and $\vec{x}$ be the matching output by M-OR-E*$(G, \mu, \kappa, \varepsilon)$,*

(a) *For $\vec{x}$, we have $x(e) \leqslant \kappa(e) \cdot \alpha_\varepsilon^2$ for all $e \in E$. This follows immediately from Lemma 7(a).*

(b) *For any pair of vertices u, v, either $D(u,v) \subseteq supp(\vec{x}^i)$ and $D(u,v) \cap supp(\vec{x}^f) = \emptyset$ or, $D(u,v) \subseteq supp(\vec{x}^f)$ and $D(u,v) \cap supp(\vec{x}^i) = \emptyset$.*

(c) *Consider $\vec{z} = \vec{x}^i$. Then $supp(\vec{z}^C)$ is a matching. This is implied by Lemma 7(ai).*

5 Ingredients for Algorithm M-or-E*()

Recall we use $\mu(G, \kappa)$ to denote the value of the maximum fractional matching of G obeying capacity function κ and the odd set constraints. As in the congestion balancing set up of [9], we want to check if $\mu(G, \kappa) \geqslant (1 - \varepsilon) \cdot \mu(G)$. But, unlike in bipartite graphs, where we can use flows to find fractional matching, there is no simple way to check if $\mu(G, \kappa) \geqslant (1 - \varepsilon)\mu(G)$ in general graphs. Our first structural result circumvents this. Let G_s be obtained by sampling every edge e with probability $p(e) = \min\{1, \kappa(e) \cdot \rho_\varepsilon\}$. We show that $\mu(G_s) \geqslant \mu(G, \kappa) - \varepsilon\mu(G)$. Thus, Static-Match$(G_s, \varepsilon)$ is used to estimate $\mu(G, \kappa)$.

At a high level, M-OR-E*() proceeds in three phases. In Phase 1, it creates G_s and computes $\mu(G_s)$. If $\mu(G_s)$ is large, then by the above $\mu(G, \kappa)$ must also be large, so the algorithm proceeds to Phase 2, where it finds a fractional matching satisfying Lemma 7(a). On the other hand, if $\mu(G_s)$ is small, then it proceeds to Phase 3, where it finds the set of edges E^* satisfying Lemma 7(b), along which it increases capacity. In the subsequent sections, we will state the main structural properties we use in each of the phases. Finally, in Section 6, we put together these ingredients to give M-OR-E*(), and prove Lemma 7.

5.1 Phase 1 of M-or-E*()

Before we formally state the main guarantees of Phase 1, we will state some standard results in matching theory, that we will use in our main result for Phase 1.

5.1.1 Some Standard Ingredients For Phase 1

The first ingredient we use is the Tutte-Berge formula.

▶ **Definition 11.** *For any multigraph G and $U \subseteq V$, $odd_G(V \setminus U)$ denotes the number of odd components in $G[V \setminus U]$.*

▶ **Lemma 12** (Tutte-Berge Formula)**.** *[38] The size of a maximum matching in a graph $G = (V, E)$ is equal to $\frac{1}{2} \min_{U \subseteq V} (|U| + |V| - odd_G(V \setminus U))$.*

Additionally, we will use some properties of the matching polytope.

▶ **Lemma 13** ([38])**.** *Let G be any multigraph, let $\vec{x}$ be a fractional matching that in addition to the fractional matching constraints, also satisfies the following for all odd-sized $U \subseteq V$: $\sum_{e \in G[U]} x(e) \leqslant \frac{|U|-1}{2}$. Then, there is an integral matching $M \subseteq supp(x)$ with $|M| = \sum_{e \in E} x(e)$.*

▶ **Definition 14.** *Let G be any multigraph, and let $S, T \subseteq V$, then $\delta_G(S,T)$ is defined as the set of edges that have one endpoint in S and the other in T. Additionally, for $S \subseteq V$, we define $\delta_G(S)$ to be the set of edges that have one end point in S, and the other in $V \setminus S$.*

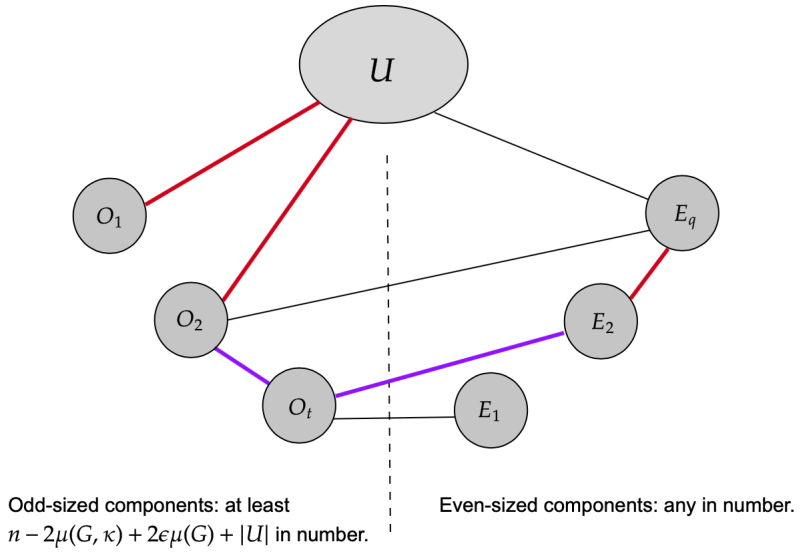

Figure 1 The figure shows the graph G, and a partition $\mathcal{P} = \{U, E_1, \cdots, E_q, O_1, \cdots, O_t\}$ satisfying properties (a) and (b) mentioned in proof of Lemma 15. The thick edges (in red and purple), are the edges in $\text{supp}(\vec{x})$, where $\vec{x}$ is the fractional matching realizing $\mu(G,\kappa)$. The purple edges (edges between the odd components, or between odd and even components) correspond to $E^{\mathcal{P}}_{\text{miss}}$, and $\sum_{e \in E^{\mathcal{P}}_{\text{miss}}} x(e) \geqslant 2 \cdot \varepsilon \cdot \mu(G)$.

5.1.2 Main Lemma for Phase 1

As mentioned earlier, in Phase 1 of M-OR-E*(), we first create a sampled graph G_s. In the following lemma, we show that $\mu(G_s)$ is a good estimate for $\mu(G,\kappa)$ with high probability.

▶ **Lemma 15.** *Let G be a multigraph with $\mu(G) \geqslant \varepsilon \cdot n/16$ where $\varepsilon \in (0, 1/2)$. Let κ be a capacity function on the edges of G, and let G_s be obtained by sampling every edge $e \in G$ with probability $p(e) = \min\{1, \kappa(e) \cdot \rho_\varepsilon\}$. Let $\mu(G,\kappa)$ be the value of the maximum fractional matching of G obeying the capacities κ, and the odd set constraints. Then, with high probability, $\mu(G_s) \geqslant \mu(G,\kappa) - \varepsilon \cdot \mu(G)$.*

Proof. We want to show that with high probability, $\mu(G_s) \geqslant \mu(G,\kappa) - \varepsilon \cdot \mu(G)$. In order to do this, by Lemma 12, it is sufficient to show that with high probability, $1 - 1/n^2$, $\frac{1}{2} \min_{U \subseteq V} (|U| + |V| - \text{odd}_{G_s}(V - U)) \geqslant \mu(G,\kappa) - \varepsilon \cdot \mu(G)$. Towards this, we consider a fixed partition $\mathcal{P}$ of V into sets $U, O_1, \cdots, O_t, E_1, \cdots, E_q$ with the following properties (see Figure 1).

(a) We have, $q \geqslant 0$ and $t > n - 2 \cdot \mu(G,\kappa) + 2\varepsilon \cdot \mu(G) + |U|$.

(b) Sets O_i for $i \in [t]$ are odd-sized sets and sets E_l for $l \in [q]$ are even-sized sets.

If $\mu(G_s) < \mu(G,\kappa) - \varepsilon \cdot \mu(G)$, then there is a partition $\mathcal{P} = \{U, O_1, \cdots, O_t, E_1, \cdots, E_q\}$ of G_s (from Lemma 12), satisfying (a) and (b) such that $G_s[V \setminus U]$ is the union of disconnected components $O_1, \cdots, O_t, E_1, \cdots, E_q$. If $G_s[V \setminus U]$ is the union of disconnected components $O_1, \cdots, O_t, E_1, \cdots, E_q$ then $\delta_{G_s}(O_i, O_l) = \emptyset$ for all $i \neq l$ and $\delta_{G_s}(O_i, E_l) = \emptyset$ for all $i \in [t]$,

$l \in [q]$. Thus, to upper bound the probability that $\mu(G_s) < \mu(G,\kappa) - \varepsilon \cdot \mu(G)$, it is sufficient to upper bound the probability that there exists a partition $\mathcal{P} = \{U, O_1, \cdots, O_t, E_1, \cdots, E_q\}$ satisfying (a) and (b), such that *none* of the edges $E^{\mathcal{P}}_{\mathsf{miss}} = \{e \mid e \in \delta_G(O_i, O_l) \text{ for } i \neq l\} \cup \{e \mid e \in \delta_G(O_i, E_l) \text{ for } i \in [t], l \in [q]\}$ are sampled in G_s. In order to bound this probability, we make the following claim.

▷ Claim 16. For a partition $\mathcal{P}$ satisfying (a) and (b), $\kappa(E^{\mathcal{P}}_{\mathsf{miss}}) \geqslant 2 \cdot \varepsilon \cdot \mu(G)$.

Proof. Let $\vec{x}$ be a fractional matching obeying odd set constraints and capacity function κ such that $\sum_{e \in E} x(e) = \mu(G,\kappa)$. We show that if $\kappa(E^{\mathcal{P}}_{\mathsf{miss}}) < 2 \cdot \varepsilon \cdot \mu(G)$, then, $x(E^{\mathcal{P}}_{\mathsf{miss}}) > \kappa(E^{\mathcal{P}}_{\mathsf{miss}})$, which will contradict the fact that $\vec{x}$ is a fractional matching obeying κ.

With this proof strategy in mind, for contradiction assume that $\kappa(E^{\mathcal{P}}_{\mathsf{miss}}) < 2 \cdot \varepsilon \cdot \mu(G) \leqslant n - 2 \cdot \mu(G,\kappa) + 2 \cdot \varepsilon \cdot \mu(G)$. The last inequality follows from the fact that $\mu(G,\kappa)$ corresponds to the value of the maximum fractional matching, so, $\mu(G,\kappa) \leqslant \frac{n}{2}$. Since $\vec{x}$ obeys odd set constraints, $\sum_{l \leqslant t} x(\delta_G(O_l)) \geqslant t$. Note that $\sum_{l \leqslant t} x(\delta_G(O_l, U)) \leqslant |U|$, otherwise for some $v \in U$, $\sum_{e \ni v} x(e) > 1$, violating the fact that $\vec{x}$ is a fractional matching. Next, we observe that $\sum_{l \leqslant t} x(\delta_G(O_l)) = x(E^{\mathcal{P}}_{\mathsf{miss}}) + \sum_{l \leqslant t} x(\delta_G(O_l, U))$. This follows from the fact that all edges emanating out of O_i in G, are incident on O_j for $j \neq i$, or E_k for some $k \in [q]$, or U. We have the following set of inequalities.

$$x(E^{\mathcal{P}}_{\mathsf{miss}}) = \sum_{l \leqslant t} x(\delta_G(O_l)) - \sum_{l \leqslant t} x(\delta_G(O_l, U)) \geqslant t - |U| > n - 2 \cdot \mu(G,\kappa) + 2 \cdot \varepsilon \cdot \mu(G)$$

The last inequality is because $\mathcal{P}$ satisfies (a) and (b). Thus, $x(E^{\mathcal{P}}_{\mathsf{miss}}) > \kappa(E^{\mathcal{P}}_{\mathsf{miss}})$. ◁

We also have a claim which allows us to only focus on $\mathcal{P}$ for which all $e \in E^{\mathcal{P}}_{\mathsf{miss}}$ have $\kappa(e) < 1/\rho_\varepsilon$. Let $\mathcal{H}^{\mathcal{P}}_{\mathsf{miss}}$ denote the event that none of the edges of $E^{\mathcal{P}}_{\mathsf{miss}}$ are sampled.

▶ **Observation 17.** *Suppose* $\kappa(e) \geqslant 1/\rho_\varepsilon$ *for any* $e \in E^{\mathcal{P}}_{miss}$, *then,* $\Pr\left(\mathcal{H}^{\mathcal{P}}_{miss}\right) = 0$.

The above observation follows from the fact that an edge e is sampled with probability $\min\{1, \kappa(e) \cdot \rho_\varepsilon\}$. From the above claim, it is sufficient to focus on $E^{\mathcal{P}}_{\mathsf{miss}}$ where all edges e have $\kappa(e) < 1/\rho_\varepsilon$, since these are the only $\mathcal{P}$ that contribute non-zero probability.

$$\begin{aligned}\Pr\left(\mathcal{H}^{\mathcal{P}}_{\mathsf{miss}}\right) &\leqslant \prod_{e \in E^{\mathcal{P}}_{\mathsf{miss}}} (1 - p(e)) \leqslant \exp\left(-\sum_{e \in E^{\mathcal{P}}_{\mathsf{miss}}} p(e)\right) = \exp\left(-\sum_{e \in E^{\mathcal{P}}_{\mathsf{miss}}} \kappa(e) \cdot \rho_\varepsilon\right) \\ &= \exp\left(-\varepsilon \cdot 2^{40/\varepsilon^2} \cdot \mu(G) \cdot \log n\right) \leqslant \exp\left(-2^{39/\varepsilon^2} \cdot \mu(G) \cdot \log n\right).\end{aligned}$$

Note that number of partitions $\mathcal{P}$ satisfying (a) and (b) are upper bounded by the number of ways of partitioning V, and it is known that a set of size n has $2^{n \cdot \log n}$ partitions. Since $n \leqslant 16 \cdot \mu(G)/\varepsilon$, the bound on the number of partitions is at most $2^{16\mu(G)/\varepsilon \cdot \log n}$ (by assumption of Lemma 15).

Thus, applying the equation above and taking a union bound over all the partitions, we know that the with probability $1 - \exp\left(-\mu(G) \cdot \log n/\varepsilon\right)$, in G_s, we have no partition $\mathcal{P} = \{U, O_1, \cdots, O_t, E_1, \cdots, E_q\}$ satisfying (a) and (b) such that $G_s[V \setminus U]$ is a union of disconnected components $O_1, \cdots, O_t, E_1, \cdots, E_q$. Thus, by Lemma 12, with high probability, $\mu(G_s) \geqslant \mu(G,\kappa) - \varepsilon \cdot \mu(G)$. ◀

5.2 Phase 2 of M-or-E*()

The algorithm proceeds to Phase 2 only if the integral matching M_s found in G_s is close to $\mu(G,\kappa)$. But note that although Phase 1 gives us a way to estimate the *value* of $\mu(G,\kappa)$ via $\mu(G_s)$ (by Lemma 15), it is unclear how to actually compute a corresponding fractional matching $\vec{x}$ that obeys capacities and odd set constraints. That is the goal of Phase 2: we show how to compute $\vec{x}$ and show that it is close in value to $\mu(G_s)$ with high probability, and therefore it is close to $\mu(G,\kappa)$ as well (by Lemma 15).

5.2.1 Preliminaries for Phase 2

Phase 2 starts by computing $M_s = \textsc{Static-Match}(G_s, \varepsilon)$ and then uses M_s to compute the desired fractional matching. We will split M_s into low capacity edges and high capacity edges, and as a result split V into vertices matched using high capacity edges, and low capacity edges. We begin by giving a formal definition of low capacity edges.

▶ **Definition 18.** *Let G be any multigraph, and let κ be a capacity function on the edges of G. Let $\varepsilon \in (0, 1/2)$. Define $E_L(G,\kappa) = \{e \in E \mid e \in D(u,v)$ and $\kappa(D(u,v)) \leqslant 1/\alpha_\varepsilon^2\}$. Intuitively, $E_L(G,\kappa)$ is the set of low total capacity edges.*

As mentioned in the high-level overview, in order to prove our probabilistic claims, we will give some slack to the capacities. This motivates our next definition.

▶ **Definition 19.** *Let G be a multigraph, and let κ be a capacity function on the edges of G. Let $\varepsilon \in (0, 1/2)$. We define the capacity function κ^+ as follows: for all $e \in E_L(G,\kappa)$, $\kappa^+(e) = \kappa(e) \cdot \alpha_\varepsilon$ and for all $e \in E \setminus E_L(G,\kappa)$, $\kappa^+(e) = \kappa(e)$.*

To make our analysis easier to follow, we need the following definition of a bipartite double cover of G.

▶ **Definition 20** (Bipartite Double Cover)**.** *Let G be a multigraph and κ be a capacity function on the edges of G. We define the $\textsc{bc}(G)$ to be the following bipartite graph with capacity function κ_{BC}.*

(a) *For every vertex $v \in V(G)$, make two copies v and v' in $V(\textsc{bc}(G))$.*

(b) *If e is an edge between $u, v \in V(G)$, then for each such e we add two edges e' and e'', one between u and v' and the other between v and u'. We let $\kappa_{BC}(e') = \kappa_{BC}(e'') = \kappa(e)$.*

We defer the proof of the following claim, relating $\mu(G)$ and $\mu(\textsc{bc}(G))$ to the full version.

▷ Claim 21. For any multigraph G, $\mu(\textsc{bc}(G)) \geqslant 2 \cdot \mu(G)$.

Next, we state the following lemma, which follows from standard techniques, and we give a formal proof of it in the full version. The lemma essentially states that a fractional matching which has low flow on all edges has a very small integrality gap.

▶ **Lemma 22.** *Let G be a multigraph, and let $\varepsilon \in (0,1)$. Let κ be a capacity function on the edges of G, with $\kappa(D(e)) \leqslant 1/\alpha_\varepsilon$ for all $e \in E(G)$. Then, $\mu(\textsc{bc}(G), \kappa_{BC}) \leqslant 2 \cdot (1+\varepsilon) \cdot \mu(G,\kappa)$, where $\mu(G,\kappa)$ is the maximum fractional matching of G obeying κ and the odd set constraints, and $\mu(\textsc{bc}(G), \kappa_{BC})$ is the maximum fractional matching of $\textsc{bc}(G)$ obeying κ_{BC}.*

Additionally, we will need the following lemma, which follows as a corollary of Lemma 12.

▶ **Proposition 23** (Extended Hall's Theorem)**.** *Let $G = (L \cup R, E)$ be a bipartite graph with $n = |L| = |R|$, then $\mu(G) = n - \max_{S \subseteq L}(|S| - |N_G(S)|)$, where $N_G(S)$ refers to the neighbourhood of S in G.*

In order to prove Lemma 26, we will use the following version of Chernoff bound.

▶ **Lemma 24** (Chernoff Bound). *[21] Let $X_1, \cdots, X_k$ be negatively correlated random variables, and let X denote their sum, and let $\mu = \mathbb{E}[X]$. Suppose $\mu_{min} \leqslant \mu \leqslant \mu_{max}$, then for all $\delta > 0$,* $\Pr(X \geqslant (1+\delta)\mu_{max}) \leqslant \left(\frac{e^{\delta}}{(1+\delta)^{\delta}}\right)^{\mu_{max}}$.

Additionally, we state the following observation. The proof follows from an application of the max-flow min-cut theorem (see [9]).

▶ **Observation 25.** *Let G be any bipartite multigraph, with vertex bipartitions S and T and capacity κ on the edges. Then, for any $C \subseteq S$, and $D \subseteq T$, we have, $|S| - |C| + |D| + \kappa(C, T \setminus D) \geqslant \mu(G, \kappa)$. Moreover, there are sets $C \subseteq S$ and $D \subseteq T$ such that equality holds.*

5.2.2 Main Result for Phase 2

We briefly give some intuition about the statement of next lemma. Recall in the high level review, we mentioned that M, the integral matching of G_s has two parts M_H, which is the high capacity part, and M_L, the low capacity part, and we defined $V_H = V(M_H)$ and $V_L = V(M_L)$. We said that congestion balancing allows us to give slack to capacities (κ^+ in Definition 19), and therefore, we can round up the capacities of M_H to 1. However, we still want to compute a fractional matching of $G[V_L]$. In order to do this, we observe that if the fractional matching in $G[V_L]$ is only on low capacity edges, then we can use flow algorithm on the low capacity edges of the bipartite graph $\text{BC}(G[V_L])$ to compute such a matching. Therefore, our main structural result for Phase 2 states that if $\vec{y}$ is a maximum fractional matching with support on the low capacity edges of $G[V_L]$, then with high probability $\sum_{e \in E} y(e) \geqslant |M_L| - \varepsilon \cdot \mu(G)$. We now state this result formally.

▶ **Lemma 26.** *Let G be a multigraph and let $\varepsilon \in (0, 1/2)$ and suppose $\mu(G) \geqslant \varepsilon \cdot n/16$. Let κ be a capacity function on the edges, and let G_s be the graph obtained from G by sampling each edge e with probability $p(e) = \kappa(e) \cdot \rho_{\varepsilon}$. Let $E_L \coloneqq E_L(G, \kappa)$. Then, with high probability, for all $W \subseteq V$, we have $\mu(\text{BC}(G_s[W] \cap E_L)) \leqslant \mu(\text{BC}(G[W] \cap E_L), \kappa^+_{BC}) + 8 \cdot \varepsilon\mu(G)$.*

▶ Remark 27. Note that by definition of E_L, all edges $e \in G[W] \cap E_L$ have $\kappa(e) \leqslant 1/\alpha_{\varepsilon}^2$. Thus, $\kappa^+_{\text{BC}}(e) = \kappa_{\text{BC}}(e) \cdot \alpha_{\varepsilon}$ for all $e \in \text{BC}(G[W] \cap E_L)$ (recall Definition 19 and Definition 18).

Before we prove it, we have the following statement as a corollary of Lemma 26.

▶ **Corollary 28.** *Let G be a multi-graph, and let $\varepsilon \in (0, 1)$. Let κ be a capacity function on the edges of G with $\kappa(e) \leqslant 1/\alpha_{\varepsilon}$ for all $e \in E(G)$. Then, with high probability, **for all** $W \subseteq V$, $\mu(G_s[W] \cap E_L) \leqslant \mu(G[W] \cap E_L, \kappa^+) + 5 \cdot \varepsilon\mu(G)$.*

Proof. The inequality in the statement follows due to the following line of reasoning.

$$
\begin{aligned}
2 \cdot \mu(G_s[W] \cap E_L) &\leqslant \mu(\text{BC}(G_s[W] \cap E_L)) \\
&\quad \text{(since } 2 \cdot \mu(H) \leqslant \mu(\text{BC}(H)), \text{ see Claim 21)} \\
&\leqslant \mu(\text{BC}(G[W] \cap E_L), \kappa^+_{\text{BC}}) + 8 \cdot \varepsilon\mu(G) \\
&\quad \text{(by Lemma 26)} \\
&\leqslant 2 \cdot (1+\varepsilon) \cdot \mu(G[W] \cap E_L, \kappa^+) + 8\varepsilon\mu(G) \\
&\quad \text{(by Lemma 22)} \\
&\leqslant 2 \cdot \mu(G[W] \cap E_L, \kappa^+) + 10 \cdot \varepsilon\mu(G).
\end{aligned}
$$

The second to last inequality follows from the fact that any fractional matching in G obeying κ^+ and odd set constraints is upper bounded by $\mu(G)$ (by Lemma 13). ◀

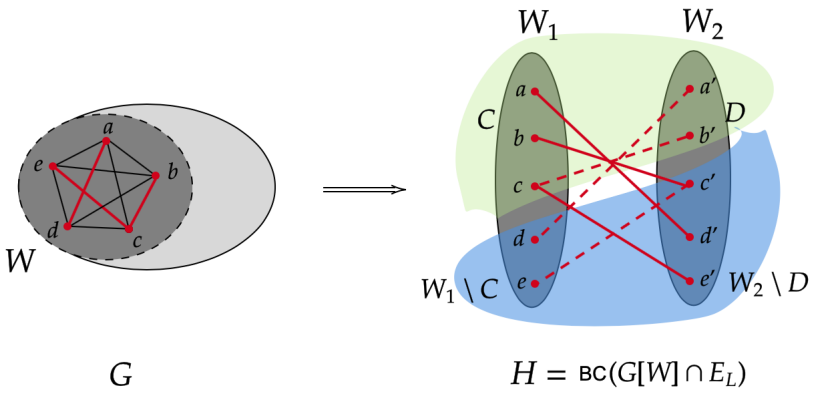

Figure 2 In the left panel, we consider the graph G, and $W = \{a, b, c, d, e\}$. The red edges correspond to the low capacity edges of $G[W]$, denoted $G[W] \cap E_L$. On the right panel, we have the bipartite graph $\text{BC}(G[W] \cap E_L)$, which has bipartitions W_1 and W_2. The solid red edges are the edges going between C and $W_2 \setminus D$, and these edges have capacity $\kappa(C, W_2 \setminus D)$.

Proof of Lemma 26. Throughout this proof we refer the reader to Figure 2. Consider a fixed $W \subseteq V$. From now, we will use H to denote $\text{BC}(G[W] \cap E_L)$ and let H_s denote $\text{BC}(G_s[W] \cap E_L)$. For the bipartite graph H, we will use W_1 and W_2 to denote the two bipartitions of H corresponding to W. We now want to prove that $\mu(H_s) \leqslant \mu(H, \kappa^+_{\text{BC}}) + 8\varepsilon\mu(G)$. To prove this, it is sufficient to show a set $C \subseteq W_1$ such that $|C| - |N_{H_s}(C)| \geqslant |W_1| - \mu(H, \kappa^+_{\text{BC}}) - 8\varepsilon\mu(G)$ with high probability. Then, by Proposition 23, we have the following inequality: $|W_1| - \mu(H, \kappa^+_{\text{BC}}) - 8\varepsilon\mu(G) \leqslant |C| - |N_{H_s}(C)| \leqslant |W_1| - \mu(H_s)$. This would prove our claim. Towards this, we consider the set $C \subseteq W$ satisfying the following equation (applying Observation 25 to H and κ^+_{BC}), and show that this is the required set.

$$|W_1| - |C| + |D| + \kappa^+_{\text{BC}}(C, W_2 \setminus D) = \mu(H, \kappa^+_{\text{BC}}). \tag{1}$$

We want to show that $|C| - |N_{H_s}(C)| \geqslant |W_1| - \mu(H, \kappa^+_{\text{BC}}) - 8\varepsilon\mu(G)$ with high probability. Let L be the set of vertices in $N_{H_s}(C) \cap W_2 \setminus D$. We know that $|N_{H_s}(C)| \leqslant |D| + |L|$. If we show that $|L| \leqslant \kappa^+_{\text{BC}}(C, W_2 \setminus D) + 8 \cdot \varepsilon\mu(G)$, then, $|N_{H_s}(C)| - 8\varepsilon \cdot \mu(G) \leqslant |D| + \kappa^+_{\text{BC}}(C, W_2 \setminus D)$. Substituting in Equation (1), we have $|W_1| - |C| + |N_{H_s}(C)| - 8\varepsilon \cdot \mu(G) \leqslant \mu(H, \kappa^+_{\text{BC}})$, which implies that $|C| - |N_{H_s}(C)| \geqslant |W_1| - 8 \cdot \varepsilon\mu(G) - \mu(H, \kappa^+_{\text{BC}})$. We now focus on bounding $|L|$.

Let $E_H(C, W_2 \setminus D)$ be the set of edges in H between C and $W_2 \setminus D$. Let X be the random variable that denotes the number of edges in $E_H(C, W_2 \setminus D)$ that are sampled in H_s. Note that X is not a sum of independent random variables. Recall that H is a subgraph of $\text{BC}(G)$, and suppose $e \in G[W] \cap E_L$ is included in G_s, then e' and e'' (recall e' and e'' are copies of e in $\text{BC}(G)$, Definition 20) are both included in H_s else both are excluded. Thus, the random variables associated with e' and e'' are correlated with each other. We instead consider an arbitrary subset of $E^*_H(C, W_2 \setminus D)$ of $E_H(C, W_2 \setminus D)$ that satisfies the following properties.

(a) For $e \in G[W]$, if $\{e', e''\} \subset E_H(C, W_2 \setminus D)$, then exactly one of e' or e'' is included in $E^*_H(C, W_2 \setminus D)$.

(b) For $e \in G[W]$, if $\{e', e''\} \cap E_H(C, W_2 \setminus D) = \{e'\}$, then only e' is included in $E^*_H(C, W_2 \setminus D)$ and if $\{e', e''\} \cap E_H(C, W_2 \setminus D) = \{e''\}$, then only e'' is included in $E^*_H(C, W_2 \setminus D)$.

We consider the random variable Y that denotes the number of edges in $E^*_H(C, W_2 \setminus D)$ that are included in H_s. Observe that Y is a sum of independent random variables satisfying the condition of Lemma 24. Moreover, $X \leqslant 2Y$. Thus, it is sufficient to upper bound the value

Y can take with high probability. Note that for any $e \in E_H(C, W_2 \setminus D)$, using the definition of H, $\kappa_{\text{BC}}(e) < 1/\alpha_\varepsilon^2$. Since $\rho_\varepsilon < \alpha_\varepsilon$, $p(e) = \rho_\varepsilon \cdot \kappa_{\text{BC}}(e) < 1$. So, we have,

$$\mathbb{E}[Y] \leqslant \sum_{e \in E^*_H(C, W_2 \setminus D)} p(e) \leqslant \rho_\varepsilon \cdot \kappa_{\text{BC}}(C, W_2 \setminus D) \leqslant \frac{\kappa^+_{\text{BC}}(C, W_2 \setminus D)}{2^{20/\varepsilon^2}}.$$

The last inequality follows from the fact that in H, $\kappa^+_{\text{BC}}(e) = \kappa_{\text{BC}}(e) \cdot \alpha_\varepsilon$ for all $e \in H$ (see Definition 19). This is because by definition of H and Definition 19, for all edges $e \in H$, the corresponding original edge in G is in $E_L(G, \kappa)$. We want to bound the $\Pr\left(Y \geqslant \frac{\kappa^+_{\text{BC}}(C, W_2 \setminus D)}{2^{20/\varepsilon^2}} + 4 \cdot \varepsilon\mu(G)\right)$. Applying Lemma 24 with $\delta = \frac{4 \cdot \varepsilon\mu(G) \cdot 2^{20/\varepsilon^2}}{\kappa^+_{\text{BC}}(C, W_2 \setminus D)}$, we have,

$$\begin{aligned}
\Pr\left(Y \geqslant \frac{\kappa^+_{\text{BC}}(C, W_2 \setminus D)}{2^{20/\varepsilon^2}} + 4 \cdot \varepsilon\mu(G)\right) &= \exp\left(\varepsilon\mu(G) - \varepsilon\mu(G) \log\left(1 + \frac{4 \cdot \varepsilon\mu(G) \cdot 2^{20/\varepsilon^2}}{\kappa^+_{\text{BC}}(C, W_2 \setminus D)}\right)\right) \\
&\leqslant \exp\left(\varepsilon\mu(G) - \varepsilon\mu(G) \log\left(1 + \varepsilon \cdot 2^{20/\varepsilon^2}\right)\right) \\
&\text{(Since } \kappa^+_{\text{BC}}(C, W_2 \setminus D) \leqslant 4 \cdot \mu(G) \text{ as proved below.)} \\
&\leqslant \exp\left(\varepsilon\mu(G) - \varepsilon\mu(G) \log\left(1 + 2^{19/\varepsilon^2}\right)\right) \\
&\text{(Using the fact that } 2^{1/\varepsilon^2} \geqslant 1/\varepsilon) \\
&= \exp\left(\varepsilon\mu(G) - 19\mu(G)/\varepsilon\right) \\
&\text{(Using the fact that } 2^{19/\varepsilon^2} \leqslant 2^{19/\varepsilon^2} + 1).
\end{aligned}$$

To see why $\kappa^+_{\text{BC}}(C, W_2 \setminus D) \leqslant 4 \cdot \mu(G)$, consider Equation (1), $\kappa^+_{\text{BC}}(C, W_2 \setminus D)$ is equal to

$$\begin{aligned}
\mu(H, \kappa^+_{\text{BC}}) - |W_1| + |C| - |D| &\leqslant 2 \cdot (1 + \varepsilon) \cdot \mu(G[W] \cap E_L(G, \kappa), \kappa^+) - |W_1| + |W_1| \\
&\leqslant 4 \cdot \mu(G).
\end{aligned}$$

The first inequality is due to Lemma 22, and the fact that $H = \text{BC}(G[W] \cap E_L(G, \kappa))$, and κ^+ satisfies the hypothesis. Finally, observe that $|L| \leqslant X \leqslant 2Y \leqslant \kappa^+_{\text{BC}}(C, W_2 \setminus D) + 8 \cdot \varepsilon\mu(G)$ with probability at least $\exp(-19\mu(G)/\varepsilon)$. Taking a union bound over all W, which are at most $2^{16 \cdot \mu(G)/\varepsilon}$ many (since by statement of the lemma, $\mu(G) \geqslant \varepsilon \cdot n/16$), we have our bound. ◀

5.3 Phase 3: Finding set E^*

The algorithm M-OR-E*() proceeds to Phase 3 if the matching found in G_s in Phase 1 is small, and hence $\mu(G, \kappa)$ is too small. In this case, we need to find a set E^* satisfying the properties of Lemma 7(b). In particular, we need to find a set E^* with $\kappa(E^*) = O(\mu(G) \log n)$ such that for every large matching M, there are a lot of edges going through E^*. In order to do this, we rely on the properties of the dual variables associated with the matching problem. The algorithm STATIC-MATCH(), luckily for us, solves both the primal as well as the dual solution. We first begin by stating the properties of the dual program, and then we state the properties of dual variables guaranteed by STATIC-MATCH().

▶ **Definition 29** ([38]). *We consider the dual of the matching linear program:*

1. *Every edge $e = (u, v)$ has a dual constraint $yz((u, v)) := y(u) + y(v) + \sum_{\substack{B \in V_{odd}, \\ e \in G[B]}} z(B)$.*
2. *We use $f(y, z) := \sum_{v \in V} y(u) + \sum_{B \subseteq V_{odd}} \frac{|B|-1}{2} z(B)$ to denote the dual objective function.*

We now describe some properties of the STATIC-MATCH(). All of the properties except Lemma 30(c) are given by the algorithm in [20]. We then show how to ensure property (c) as well by modifying the dual; see full version for details.

▶ **Lemma 30.** *There is an $O(m/\varepsilon)$ time algorithm* Static-Match() *that takes as input a graph G with m edges and a parameter $\varepsilon > 0$, and returns a matching M, and dual vectors $\vec{y}$ and $\vec{z}$ that have the following properties.*
(a) *It returns an integral matching M such that $|M| \geqslant (1-\varepsilon)\cdot\mu(G)$.*
(b) *A set Ω of laminar odd-sized sets, such that $\{B \mid z(B) > 0\} \subseteq \Omega$.*
(c) *For all odd-sized B with $|B| \geqslant 1/\varepsilon + 1$, $z(B) = 0$.*
(d) *Each $y(v)$ is a multiple of ε and $z(B)$ is a multiple of ε.*
(e) *For every edge $e \in E$, $yz(e) \geqslant 1-\varepsilon$. We say that e is* approximately covered *by $\vec{y}$ and $\vec{z}$.*
(f) *The value of the dual objective, $f(y,z)$ is at most $(1+\varepsilon)\cdot\mu(G)$.*

5.3.1 Main Guarantees of Phase 3

We now state the following helper lemma is instrumental in proving one of the two main properties of E^*, namely, that every large matching has a lot of edges passing through E^*.

▶ **Lemma 31.** *Suppose G is a graph, and let $H \subset G$ be a subgraph of G. Let $\vec{y}, \vec{z}$ be the dual variables returned on execution of* Static-Match(H, ε). *Let $E_H = \{e \in G \mid yz(e) \geqslant 1-\varepsilon\}$. For any matching M of G, then $|M \cap E \setminus E_H| \geqslant |M| - (1+\varepsilon)^2\cdot\mu(H)$.*

Proof. Suppose we scale up the dual variables $\vec{y}$ and $\vec{z}$ by a factor of $1+\varepsilon$. Then, $\vec{y}$ and $\vec{z}$ is a feasible solution for the dual matching program for the graph E_H. Thus, using weak duality, we have that $\mu(E_H) \leqslant (1+\varepsilon)f(y,z) \leqslant (1+\varepsilon)^2\cdot\mu(H)$ (this inequality follows from Lemma 30(f)). Suppose M is a matching of G with $|M\cap E\setminus E_H| < |M| - (1+\varepsilon)^2\cdot\mu(H)$ then, this implies that $|M \cap E \setminus E_H| < |M| - \mu(E_H)$. Thus, $|M| = |M\cap E_H| + |M\cap E\setminus E_H| < \mu(E_H) + |M| - \mu(E_H) = |M|$, which is a contradiction. ◀

We now define set E^*, and show that it has the property that $\kappa(E^*) = O(\mu(G)\log n)$.

▶ **Lemma 32.** *Let G be a graph multi-graph such that $\mu(G) \geqslant \varepsilon\cdot n/16$, and let κ be a capacity function on the edges of the graph. Suppose G_s is the graph obtained by sampling every edge $e \in E$ with probability $p(e) = \min\{1, \kappa(e)\cdot\rho_\varepsilon\}$. Let $\vec{y}, \vec{z}$ be the output of* Static-Match(G_s, ε). *Let $E^* = \{e \in E \mid yz(e) < 1-\varepsilon\}$. Then, for all $e \in E^*$, $\kappa(e) < 1$ and with high probability, $\kappa(E^*) = O(\mu(G)\log n)$.*

Proof. We consider the set $\mathcal{D}$ of assignments $\vec{y}, \vec{z}$ to the vertices and odd components that satisfy the following properties.
(a) For all $v \in V$, $y(v)$ is a multiple of ε, and for all $B \subset V$, $z(B)$ is a multiple of ε.
(b) Let $\Omega = \{B \subset V \mid z(B) > 0\}$, then Ω is laminar.
(c) If $z(B) > 0$ for some $B \subseteq V$, then $|B| \leqslant 1/\varepsilon$.
Observe that,

$$|\mathcal{D}| \leqslant \sum_{i=0}^{2n} \binom{n^{1/\varepsilon}}{i} \cdot \left(\frac{1}{\varepsilon}\right)^n \cdot \left(\frac{1}{\varepsilon}\right)^{2n} \leqslant n \cdot \binom{n^{1/\varepsilon}}{2n} \cdot \left(\frac{1}{\varepsilon}\right)^n \cdot \left(\frac{1}{\varepsilon}\right)^{2n} \leqslant 2^{(4/\varepsilon)\cdot n\log n}.$$

This number follows from the following argument. Since Ω is laminar, it can contain at most $2n$ sets. Moreover, from (c), we deduce that these $2n$ sets are chosen from among $n^{1/\varepsilon}$ sets. Further, from (a), we deduce that each $y(v)$ can be assigned at most $1/\varepsilon$ values, and for every $B \in \Omega$, $z(B)$ can be assigned $1/\varepsilon$ values. Therefore, for a given choice of Ω, there are at most $(1/\varepsilon)^n \cdot (1/\varepsilon)^{2n}$ choices for $\vec{y}$ and $\vec{z}$. Moreover, the above number also upper bounds the number of possible duals that can be a returned by the algorithm Static-Match(), since the duals in $\mathcal{D}$ satisfy a subset of the properties given in Lemma 30. Since $\mu(G) \geqslant \varepsilon\cdot n/16$, we can upper bound $|\mathcal{D}|$ by $2^{(32/\varepsilon^2)\cdot\mu(G)\log n}$.

Now consider a fixed $\vec{y}, \vec{z}$ that satisfies the above-mentioned properties, and let E^* be the set of edges that are not approximately covered by $\vec{y}, \vec{z}$. Note that for any $e \in E^*$, $\kappa(e) \leqslant 1/\rho_\varepsilon$. If not, then, $p(e) = 1$, and then it would be sampled in G_s, and be approximately covered by $\vec{y}, \vec{z}$ (by Lemma 30(e)). Thus, for any $e \in E^*$, $p(e) = \kappa(e) \cdot \rho_\varepsilon$. Now, suppose $\kappa(E^*) > \mu(G) \log n$. Then, observe that if $\vec{y}, \vec{z}$ is output by Static-Match(G_s, ε) (denote this event by $\mathcal{E}_{y,z}$) then none of the edges in E^* were sampled (denote this event by $\mathcal{E}_2$). Thus,

$$\begin{aligned}
\Pr(\mathcal{E}_{y,z}) &\leqslant \Pr(\mathcal{E}_2) \\
&\leqslant \prod_{e \in E^*} (1 - p(e)) \\
&\leqslant \exp\left(-\sum_{e \in E^*} \kappa(e) \cdot \rho_\varepsilon\right) \\
&\leqslant \exp\left(-2^{40/\varepsilon^2} \cdot \mu(G) \log n\right).
\end{aligned}$$

Our lemma follows by taking an upper bound over the set $\mathcal{D}$:

$$\begin{aligned}
\Pr\left(\bigcup_{\vec{y},\vec{z} \in \mathcal{D}} \mathcal{E}_{y,z}\right) &\leqslant \exp\left(-2^{40/\varepsilon^2} \cdot \mu(G) \log n\right) \cdot 2^{(32/\varepsilon^2) \cdot \mu(G) \cdot \log n} \\
&= \exp\left(-O(2^{1/\varepsilon^2} \cdot \mu(G) \cdot \log n)\right).
\end{aligned}$$

◀

6 Algorithm M-or-E*()

In this section, we give the main subroutine M-or-E*() (see Lemma 7). We first define a few terms, and then state algorithm Frac-Match(), which follows almost directly from known results, with some very minor modifications; see full version for details.

▶ **Definition 33.** *Recall Definition 18, and consider an integral matching M, define $E_L^M(G, \kappa) = E_L(G, \kappa) \cap M$, and let V_L^M be the endpoints of $E_L^M(G, \kappa)$.*

▶ **Lemma 34.** *Given a multigraph G (possibly non-bipartite), with edge capacities κ and $\varepsilon \in (0, 1)$, such that $\kappa(D(e)) \leqslant 1/\alpha_\varepsilon$ for all $e \in E$, then there is an algorithm Frac-Match() that takes as input G, κ and ε, and returns a fractional matching $\vec{x}$ such that $\sum_{e \in E} x(e) \geqslant (1 - \varepsilon) \cdot \mu(G, \kappa)$, obeying the capacities κ and the odd set constraints. The runtime of this algorithm is $O(m \cdot \log n/\varepsilon)$.*

For the purpose of the algorithm recall κ^+ in Definition 19. We now formalize M-or-E*() from Lemma 7 in Algorithm 1 below; recall that the input is a multigraph G with $\mu(G) \geqslant \varepsilon \cdot n/16$.

We now show Lemma 7 holds.

Proof of Lemma 7. We first show the runtime of the algorithm. Graph G_s can be computed in time $O(m)$. Using Lemma 30, we conclude that we can compute E^* in order $O(m/\varepsilon)$ time by running Static-Match(G_s, ε) and Lemma 34 implies that Algorithm 1 takes $O(m \cdot \log n/\varepsilon)$ time.

We show Lemma 7((a)). First observe that V_L^M and $V(M_I)$ are disjoint, and since $\vec{y}$ and $\vec{x}$ are fractional matchings, $\vec{z}$ is also a fractional matching. Note that $|M| \geqslant \mu - 7\varepsilon\mu$. Moreover, $\sum_{e \in E} x(e) \geqslant (1 - \varepsilon) \cdot \mu(G[V_L^M] \cap E_L, \kappa^+)$. This follows from applying Lemma 34

Algorithm 1 M-OR-E*$(G, \kappa, \varepsilon, \mu)$.

Include each $e \in E(G)$ independently with probability $p(e) = \min\{1, \kappa(e) \cdot \rho_\varepsilon\}$ into graph G_s.
Let M and $\vec{y}, \vec{z}$ be the output of STATIC-MATCH(G_s, ε). ▷ Phase 1
if $|M| < \mu - 7\varepsilon\mu$ **then** ▷ Phase 3
  Return $E^* = \{e \in E(G) \mid yz(e) < 1 - \varepsilon\}$.
else ▷ Phase 2
  $M_I \leftarrow M \setminus E_L(G, \kappa)$
  $\vec{y} \leftarrow M_I^D$ ▷ See Definition 5
  $\vec{x} \leftarrow$ FRAC-MATCH$(G[V_L^M] \cap E_L(G, \kappa), \kappa^+, \varepsilon)$
  Return $\vec{z} \leftarrow \vec{y} + \vec{x}$.

to $G[V_L^M] \cap E_L(G, \kappa)$ with capacity function κ^+. Recall Definition 19 and Definition 18 to see that $\kappa^+(D(e)) \leqslant 1/\alpha_\varepsilon$ for $e \in G[V_L^M] \cap E_L(G, \kappa)$, thus satisfying the requirements of Lemma 34. Next, applying Corollary 28, we have, $\mu(G_s[V_L^M] \cap E_L) \leqslant \mu(G[V_L^M] \cap E_L, \kappa^+) + 5 \cdot \varepsilon\mu(G)$. Thus, we have $\sum_{e \in E} x(e) \geqslant (1 - \varepsilon) \cdot \big(\mu(G_s[V_L^M] \cap E_L) - 5\varepsilon\mu\big) \geqslant (1 - \varepsilon) \cdot (|M \setminus M_I| - 5\varepsilon\mu)$. This is because $M \setminus M_I$ is a matching of $G_s[V_L^M] \cap E_L$. So, $\sum_{e \in E} z(e) \geqslant |M_I| + (1 - \varepsilon) \cdot (|M \setminus M_I| - 5\varepsilon\mu) \geqslant (1 - \varepsilon) \cdot (\mu - 12\varepsilon\mu) \geqslant \mu - 13\varepsilon\mu$.

We now show Lemma 7(ai) and (aii). Consider any edge $e \in \text{supp}(\vec{z})$ with $\kappa(D(e)) \leqslant 1/\alpha_\varepsilon^2$, $e \in G[V_L^M] \cap E_L(G, \kappa)$. Thus, $e \in \text{supp}(\vec{x})$, and therefore, from Lemma 34, $z(e) = x(e) \leqslant \kappa^+(e) \leqslant \kappa(e) \cdot \alpha_\varepsilon$ and $z(D(e)) = x(D(e)) \leqslant \kappa(D(e)) \cdot \alpha_\varepsilon$. Similarly, for any $e \in \text{supp}(\vec{z})$ with $\kappa(D(e)) > 1/\alpha_\varepsilon^2$, $e \in \text{supp}(\vec{y})$. By definition of $\vec{y}$, $z(e) = y(e) = \kappa(e)/\kappa(D(e))$ (recall Definition 5) and $z(D(e)) = 1$. This proves our claim.

Next, we show Lemma 7(b). First recall from the assumption of Lemma 7 that $\mu \geqslant (1-\varepsilon) \cdot \mu(G)$. From this fact and Lemma 32, we can conclude that $\kappa(E^*) = O(\mu \log n)$ and that for all $e \in E^*$, $\kappa(e) < 1$. Next, observe that $\mu(G_s) \leqslant (1+\varepsilon) \cdot |M| \leqslant (1-6\varepsilon) \cdot \mu$. Applying Lemma 31 with $H = G_s$, we have, that for any matching M' of G, $|E^* \cap M'| \geqslant |M'| - (1+\varepsilon)^2 \cdot (1-6\varepsilon) \cdot \mu$. If $|M'| \geqslant (1 - 3\varepsilon) \cdot \mu$, then we have $|E^* \cap M'| \geqslant \varepsilon \cdot \mu$. Finally, consider any pair of vertices u, v and let $e', e'' \in D(u, v)$. Then, either both e', e'' are both approximately covered by $\vec{y}, \vec{z}$ or neither of them are. This implies that either $D(u, v) \subseteq E^*$ or $D(u, v) \cap E^* = \emptyset$. ◀

Abstract

We study the online bin packing problem under two stochastic settings. In the bin packing problem, we are given n items with sizes in $(0, 1]$ and the goal is to pack them into the minimum number of unit-sized bins. First, we study bin packing under the i.i.d. model, where item sizes are sampled independently and identically from a distribution in $(0, 1]$. Both the distribution and the total number of items are unknown. The items arrive one by one and their sizes are revealed upon their arrival and they must be packed immediately and irrevocably in bins of size 1. We provide a simple meta-algorithm that takes an offline α-asymptotic proximation algorithm and provides a polynomial-time $(\alpha + \varepsilon)$-competitive algorithm for online bin packing under the i.i.d. model, where $\varepsilon > 0$ is a small constant. Using the AFPTAS for offline bin packing, we thus provide a linear time $(1 + \varepsilon)$-competitive algorithm for online bin packing under i.i.d. model, thus settling the problem.

We then study the random-order model, where an adversary specifies the items, but the order of arrival of items is drawn uniformly at random from the set of all permutations of the items. Kenyon's seminal result [SODA'96] showed that the Best-Fit algorithm has a competitive ratio of at most 3/2 in the random-order model, and conjectured the ratio to be ≈ 1.15. However, it has been a long-standing open problem to break the barrier of 3/2 even for special cases. Recently, Albers et al. [Algorithmica'21] showed an improvement to 5/4 competitive ratio in the special case when all the item sizes are greater than 1/3. For this special case, we settle the analysis by showing that Best-Fit has a competitive ratio of 1. We also make further progress by breaking the barrier of 3/2 for the *3-Partition* problem, a notoriously hard special case of bin packing, where all item sizes lie in $(1/4, 1/2]$.

1 Introduction

Bin Packing (BP) is a fundamental NP-hard combinatorial optimization problem. In BP, we are given a set of items $I := (x_1, x_2, \ldots, x_n)$ with their associated weights (also called sizes) x_i's in $(0, 1]$ and the goal is to partition them into the minimum number of sets (bins) such that the total weight of each set is at most 1. The problem has numerous applications in logistics, scheduling, cutting stock, etc. [10]. Theoretically, bin packing has been the cornerstone for approximation and online algorithms and the study of the problem has led to the development of several interesting techniques [31, 15, 33].

Generally, the performance guarantee of an offline (resp. online) bin packing algorithm $\mathcal{A}$ is measured by asymptotic approximation ratio (AAR) (resp. competitive ratio (CR)). Let $\mathrm{Opt}(I)$ and $\mathcal{A}(I)$ are the objective values returned by the optimal (offline) algorithm and algorithm $\mathcal{A}$, respectively, on input I. Then AAR (resp. CR) is defined as $R^{\infty}_{\mathcal{A}} := \limsup_{m\to\infty}\left(\sup_{I:\mathrm{Opt}(I)=m} \frac{\mathcal{A}(I)}{\mathrm{Opt}(I)}\right)$. Note that $R^{\infty}_{\mathcal{A}}$ focuses on instances where $\mathrm{Opt}(I)$ is large and avoids pathological instances with large approximation ratios where $\mathrm{Opt}(I)$ is small.

Best-Fit (BF), First-Fit (FF), and Next-Fit (NF) are the three most commonly used algorithms for BP. Given x_i as the present item to be packed, they work as follows:

- BF: Pack x_i into the *fullest possible* bin; open a new bin if necessary.
- FF: Pack x_i into the *first possible* bin; open a new bin if necessary.
- NF: Pack x_i into the *most recently opened* bin; open a new bin if necessary.

Johnson et al. [28] studied several heuristics for bin packing such as Best-Fit (BF), First-Fit (FF), Best-Fit-Decreasing (BFD), First-Fit-Decreasing (FFD) and showed their (asymptotic) approximation guarantees to be 17/10, 17/10, 11/9, 11/9, resp. Bekesi et al. [7] gave an $O(n)$ time 5/4-asymptotic approximation algorithm. Another $O(n \log n)$ time algorithm is Modified-First-Fit-Decreasing (MFFD) [29] which attains an AAR of $71/60 \approx 1.1834$. Vega and Lueker [15] gave an asymptotic fully polynomial-time approximation scheme (AFPTAS) for BP: For any $1/2 > \varepsilon > 0$, it returns a solution with at most $(1+\varepsilon)\mathrm{Opt}(I) + O(1)$ [1] bins in time $C_\varepsilon + Cn \log 1/\varepsilon$, where C is an absolute constant and C_ε depends only on ε. Karmarkar and Karp [31] gave an algorithm that returns a solution using $\mathrm{Opt}(I) + O(\log^2 \mathrm{Opt}(I))$ bins. The present best approximation is due to Hoberg and Rothvoss [25] which returns a solution using $\mathrm{Opt}(I) + O(\log \mathrm{Opt}(I))$ bins.

3-Partition problem is a notoriously hard special case of BP where all item sizes are larger than 1/4. Eisenbrand et al. [17] mentioned that "much of the hardness of bin packing seems to appear already in the special case of 3-Partition when all item sizes are in $(1/4, 1/2]$". This problem has deep connections with Beck's conjecture in discrepancy theory [45, 38]. In fact, Rothvoss [25] conjectured that these 3-Partition instances are indeed the hardest instances for bin packing and the additive integrality gap of the bin packing configuration LP for these 3-Parition instances is already $\Theta(\log n)$.

In online BP, items appear one by one and are required to be packed immediately and irrevocably. Lee and Lee [33] presented the Harmonic algorithm with competitive ratio $T_\infty \approx 1.691$, which is optimal for $O(1)$ space algorithms. For general online BP, the present best upper and lower bounds for the CR are 1.57829 [4] and 1.54278 [5], respectively.

In this paper, we focus on online BP under a stochastic setting called the *i.i.d. model* [11] where the input items are sampled from a sequence of independent and identically distributed (i.i.d.) random variables. Here, the performance of an algorithm is measured by the

[1] In bin packing and related problems, the accuracy parameter ε is assumed to be a constant. Here, the term $O(1)$ hides some constants depending on ε.

expected competitive ratio (ECR) $ER_{\mathcal{A}} := \mathbb{E}[\mathcal{A}(I_n(F))]/\mathbb{E}[\mathrm{Opt}(I_n(F))]$, where $I_n(F) := (X_1, X_2, \ldots, X_n)$ is a list of n random variables drawn i.i.d. according to some unknown distribution F with support in $(0, 1]$. Mostly, bin packing has been studied under continuous uniform (denoted by $U[a, b], 0 \leq a < b \leq 1$, where item sizes are chosen uniformly from $[a, b]$) or discrete uniform distributions (denoted by $U\{j, k\}, 1 \leq j \leq k$, where item sizes are chosen uniformly from $\{1/k, 2/k, \ldots, j/k\}$). For $U[0, 1]$, Coffman et al. [13] showed that NF has an ECR of $4/3$ and Lee and Lee [34] showed that the Harmonic algorithm has an ECR of $\pi^2/3 - 2 \approx 1.2899$. Interestingly, Bentley et al. [8] showed that the ECR of FF as well as BF converges to 1 for $U[0, 1]$. It was later shown that the expected wasted space (i.e., the number of needed bins minus the total size of items) is $\Theta(n^{2/3})$ for First-Fit [44, 12] and $\Theta(\sqrt{n}\log^{3/4} n)$ for Best-Fit [44, 35]. Rhee and Talagrand [42] exhibited an algorithm that w.h.p. achieves a packing in $\mathrm{Opt} + O(\sqrt{n}\log^{3/4} n)$ bins for any distribution F on $(0, 1]$. However, note that their competitive ratio can be quite bad when $\mathrm{Opt} \ll n$. A distribution F is said to be *perfectly packable* if the expected wasted space in the optimal solution is $o(n)$ (i.e., nearly all bins in an optimal packing are almost fully packed). Csirik et al. [14] studied the Sum-of-Squares (SS) algorithm and showed that for any perfectly packable distribution, the expected wasted space is $O(\sqrt{n})$. However, for distributions that are not perfectly packable, the SS algorithm has an ECR of at most 3 and can have an ECR of $3/2$ in the worst-case [14]. For any discrete distribution, they gave an algorithm with an ECR of 1 that runs in pseudo-polynomial time in expectation. Gupta et al. [24] also obtained similar $o(n)$ expected wasted space guarantee by using an algorithm inspired by the interior-point (primal-dual) solution of the bin packing LP. However, it remains an open problem to obtain a polynomial-time $(1 + \varepsilon)$-competitive algorithm for online bin packing under the i.i.d. model for arbitrary general distributions. In fact, the present best polynomial-time algorithm for bin packing under the i.i.d. model is BF which has an ECR of at most $3/2$. However, Albers et al. [1] showed that BF has an ECR ≥ 1.1 even for a simple distribution: when each item has size $1/4$ with probability $3/5$ and size $1/3$ with probability $2/5$.

We also study the *random-order model*, where the adversary specifies the items, but the arrival order is permuted uniformly at random. The performance measure in this model is called asymptotic random order ratio (ARR): $RR^{\infty}_{\mathcal{A}} := \limsup_{m\to\infty} \left(\sup_{I:\mathrm{Opt}(I)=m}(\mathbb{E}[\mathcal{A}(I_\sigma)]/\mathrm{Opt}(I))\right)$. Here, σ is drawn uniformly at random from $\mathcal{S}_n$, the set of permutations of n elements, and $I_\sigma := (x_{\sigma(1)}, \ldots, x_{\sigma(n)})$ is the permuted list. Random-order model generalizes the i.i.d. model [1], thus the lower bounds in the random-order model can be obtained from the i.i.d. model. Kenyon in her seminal paper [32] studied Best-Fit under random-order and showed that $1.08 \leq RR^{\infty}_{BF} \leq 3/2$. She conjectured that $RR^{\infty}_{BF} \leq 1.15$. The conjecture, if true, raises the possibility of a better alternate practical offline algorithm: first shuffle the items randomly, then apply Best-Fit. This then beats the AAR of $71/60$ of the present best practical algorithm MFFD. The conjecture has received a lot of attention in the past two decades and yet, no other polynomial-time algorithm is known with a better ARR than BF. Coffman et al. [30] showed that $RR^{\infty}_{NF} = 2$. Fischer and Röglin [21] achieved analogous results for Worst-Fit [27] and Smart-Next-Fit [39]. Recently, Fischer [9] presented an exponential-time algorithm, claiming an ARR of $(1 + \varepsilon)$.

Monotonicity is a natural property of BP algorithms, which holds if the algorithm never uses fewer bins to pack $\hat{I}$ when compared I, where $\hat{I}$ is obtained from I by increasing the item sizes. Murgolo [37] showed that while NF is monotone, BF and FF are not.

Several other problems have been studied under the i.i.d. model and the random-order model [16, 23, 18, 22, 19, 2, 20, 36, 24].

1.1 Our Contributions

Bin packing under the i.i.d. model. We achieve near-optimal performance guarantee for the bin packing problem under the i.i.d. model, thus settling the problem. For any arbitrary unknown distribution F on $(0, 1]$, we give a meta-algorithm (see Algorithm 1) that takes an α-asymptotic approximation algorithm as input and provides a polynomial-time $(\alpha + \varepsilon)$-competitive algorithm. Note that both the distribution F as well as the number of items n are unknown in this case.

▶ **Theorem 1.** *Let $\varepsilon \in (0, 1)$ be a constant parameter. For online bin packing under the i.i.d. model, where n items are sampled from an unknown distribution F, given an offline algorithm $\mathcal{A}_\alpha$ with an AAR of α and runtime $\beta(n)$, there exists a meta-algorithm (Algorithm 1) which returns a solution with an ECR of $(\alpha + \varepsilon)$ and runtime $O(\beta(n))$.* [2]

Using an AFPTAS for bin packing (e.g. [15]) as $\mathcal{A}_\alpha$, we obtain the following corollary.

▶ **Corollary 2.** *Using an AFPTAS for bin packing as $\mathcal{A}_\alpha$ in Theorem 1, we obtain an algorithm for online bin packing under the i.i.d. model with an ECR of $(1 + \varepsilon)$ for any $\varepsilon \in (0, 1/2)$.*

Most algorithms for bin packing under the i.i.d. model are based on the following idea. Consider a sequence of $2k$ items where each item is independently drawn from an unknown distribution F, and let $\mathcal{A}$ be a packing algorithm. Pack the first k items using $\mathcal{A}$; denote the packing by $\mathcal{P}'$. Similarly, let $\mathcal{P}''$ be the packing of the next k items using $\mathcal{A}$. Since each item is drawn independently from F, both $\mathcal{P}'$ and $\mathcal{P}''$ have the same properties in expectation; in particular, the expected number of bins used in $\mathcal{P}'$ and $\mathcal{P}''$ are the same. Thus, intuitively, we want to use the packing $\mathcal{P}'$ as a proxy for the packing $\mathcal{P}''$. However, there are two problems. First, we do not know n, which means that there is no way to know what a good sample size is. Second, we need to show the stronger statement that w.h.p. $\mathcal{P}' \approx \mathcal{P}''$. Note that the items in $\mathcal{P}'$ and $\mathcal{P}''$ are expected to be similar, but they may not be the same. So, it is not clear which item in $\mathcal{P}'$ is to be used as a proxy for a newly arrived item in the second half. Due to the online nature, erroneous choice of proxy items can be quite costly. Different algorithms handle this problem in different ways. Some algorithms exploit the properties of particular distributions, some use exponential or pseudo-polynomial time, etc.

Rhee and Talagrand [41, 42] used *upright matching* to decide which item can be considered as a proxy for a newly arrived item. They consider the model packing $\mathcal{P}_k$ of the first k items (let's call these the proxy items) using an offline algorithm. With the arrival of each of the next k items, they take a proxy item at random and pack it according to the model packing. Then, they try to fit in the real item using upright matching. They repeat this process until the last item is packed. However, they could only show a guarantee of $\mathrm{Opt} + O(\sqrt{n}\log^{3/4} n)$. The main drawback of [42] is that their ECR can be quite bad if $\mathrm{Opt} \ll n$ (say, $\mathrm{Opt} = \sqrt{n}$). One of the reasons for this drawback is that they don't distinguish between small and large items; when there are too many small items, the ECR blows up.

Using a similar approach, Fischer [9] obtained a $(1+\varepsilon)$-competitive randomized algorithm for the random-order model, but it takes exponential time, and the analysis is quite complicated. The exponential time was crucial in finding the optimal packing which was then used as a good proxy packing. However, prior to our work, no polynomial-time algorithm existed which achieves a $(1 + \varepsilon)$ competitive ratio.

[2] As mentioned in an earlier footnote, the $O(\cdot)$ notation hides some constants depending on ε here.

To circumvent these issues, we treat large and small items separately. However, a straightforward adaptation faces several technical obstacles. Thus our analysis required intricate applications of concentration inequalities and sophisticated use of upright matching. First, we consider the semi-random case when we know n. Our algorithm works in stages. For a small constant $\delta \in (0, 1]$, the first stage contains only $\delta^2 n$ items. These items give us an estimate of the distribution. If the packing does not contain too many large items, we show that the simple Next-Fit algorithm suffices for the entire input. Otherwise, we use a proxy packing of the set of first $\delta^2 n$ items to pack the next $\delta^2 n$ items. In the process, we pack the small and large items differently. Then we use the proxy packing of the first $2\delta^2 n$ items to pack the next $2\delta^2 n$ items and so on. In general, we use the proxy packing of the first $2^i\delta^2 n$ items to pack the next $2^i\delta^2 n$ items.

Finally, we get rid of the assumption that we know n using a doubling trick (we guess n first and keep doubling the guess if it turns out to be incorrect). However, there are several difficulties (e.g. input stopping midway of two consecutive guesses, large wasted space in the past stages). Yet, with involved technical adaptations, we can handle them (see Section 2.2).

Our algorithm is simple, polynomial-time (in fact, $O(n)$ time), and achieves essentially the best possible competitive ratio. It is relatively simpler to analyze when compared to Fischer's algorithm [9]. Also, unlike the algorithms of Rhee and Talagrand [42] as well as Fischer [9], our algorithm is deterministic. This is because, unlike their algorithms, instead of taking proxy items at random, we pack all the proxy items before the start of a stage and try to fit in the real items as they come. This makes our algorithm deterministic. Our algorithm is explained in detail in Section 2.1. The nature of the meta-algorithm provides flexibility and ease of application. See Table 1 for the performance guarantees obtained using different offline algorithms.

See Section 2 for the details of the proof and the description of our algorithm. In fact, our algorithm can easily be generalized to d-dimensional online vector packing [6], a multidimensional generalization of bin packing. See the full version for a $d(\alpha+\varepsilon)$ competitive algorithm for d-dimensional online vector packing where the i^{th} item X_i can be seen as a tuple $\left(X_i^{(1)}, X_i^{(2)}, \ldots, X_i^{(d)}\right)$ where each $X_i^{(j)}$ is independently sampled from an unknown distribution $\mathcal{D}^{(j)}$.

Bin packing under the random-order model. Next, we study BP under the random-order model. Recently, Albers et al. [1] showed that BF is monotone if all the item sizes are greater than $1/3$. Using this result, they showed that in this special case, BF has an ARR of at most $5/4$. We show that, somewhat surprisingly, in this case, BF actually has an ARR of 1 (see Section 3.1 for the detailed proof).

▶ **Theorem 3.** *For online bin packing under the random-order model, Best-Fit achieves an asymptotic random-order ratio of* 1 *when all the item sizes are in* $(1/3, 1]$.

Next, we study the 3-partition problem, a special case of bin packing when all the item sizes are in $(1/4, 1/2]$. This is known to be an extremely hard case [25]. Albers et al. [1] mentioned that "it is sufficient to have one item in $(1/4, 1/3]$ to force Best-Fit into anomalous behavior." E.g., BF is non-monotone in the presence of items of size less than $1/3$. Thus the techniques of [1] do not extend to the 3-Partition problem. We break the barrier of $3/2$ in this special case, by showing that BF attains an ARR of ≈ 1.4941.

▶ **Theorem 4.** *For online bin packing under the random-order model, Best-Fit achieves an asymptotic random-order ratio of* ≈ 1.4941 *when all the item sizes are in* $(1/4, 1/2]$.

Table 1 Analysis of Algorithm 1 depending on $\mathcal{A}_\alpha$. In the first row, C is an absolute constant and C_ε is a constant that depends on ε.

$\mathcal{A}_\alpha$	Time Complexity	Expected Competitive Ratio
AFPTAS [15]	$O(C_\varepsilon + Cn\log 1/\varepsilon)$	$(1+\varepsilon)$
Modified-First-Fit-Decreasing [29]	$O(n\log n)$	$(71/60+\varepsilon)$
Best-Fit-Decreasing [26]	$O(n\log n)$	$(11/9+\varepsilon)$
First-Fit-Decreasing [26]	$O(n\log n)$	$(11/9+\varepsilon)$
Next-Fit-Decreasing [3]	$O(n\log n)$	$(T_\infty+\varepsilon)$
Harmonic [33]	$O(n)$	$(T_\infty+\varepsilon)$
Next-Fit	$O(n)$	$(2+\varepsilon)$

We prove Theorem 4 in Section 3.2. As 3-partition instances are believed to be the hardest instances for bin packing, our result gives a strong indication that the ARR of BF might be strictly less than 3/2.

2 Online Bin Packing Problem under the i.i.d. Model

In this section, we provide the meta algorithm as described in Theorem 1. For the ease of presentation, we split this into two parts. In Section 2.1, we assume a semi-random model, i.e., we assume that the number of items n is known beforehand and design an algorithm. Later, in Section 2.2, we get rid of this assumption.

Let the underlying distribution be F. Without loss of generality, we assume that the support set of F is a subset of $(0,1]$. For any set of items J, we define $\mathcal{W}(J)$ as the sum of weights of all the items in J. For any $k \in \mathbb{N}_+$, we denote the set $\{1,2,\ldots,k\}$ by $[k]$. Let $\varepsilon \in (0,1)$ be a constant parameter and let $0 < \delta < \varepsilon/8$ be a constant. Let $\mathcal{A}_\alpha$ be an offline algorithm for bin packing with an AAR of $\alpha > 1$ and let Opt denote the optimal algorithm. For any $i \in [n]$, we call x_i to be a *large* item if $x_i \geq \delta$ and a *small* item otherwise. Let I_ℓ and I_s denote the set of large and small items in I, respectively.

2.1 Algorithm Assuming that the Value of n is Known

We now describe our algorithm which assumes the knowledge of the number of items. For simplicity, in this section we assume both n and $1/\delta^2$ to be powers of 2. Otherwise, we can round down $\delta \in [1/2^{i+1}, 1/2^i), i \in \mathbb{N}$ to $1/2^{i+1}$. Also, we will anyway get rid of the assumption on the knowledge of n in the next subsection, and there we do not need n to be a power of 2. We denote this algorithm by `Alg`. First, we give a high level idea of the algorithm. We divide the entire input into stages as follows: we partition the input set I into $m := \left(\log(1/\delta^2)+1\right)$ stages $T_0, T_1, \ldots, T_{m-1}$. The zeroth stage T_0, called the *sampling stage*, contains the first $\delta^2 n$ items, i.e., $x_1, x_2, \ldots, x_{\delta^2 n}$. For $j \in [m-1]$, T_j contains the items with index starting from $2^{j-1}\delta^2 n + 1$ till $2^j\delta^2 n$. In essence, T_0 contains the first $\delta^2 n$ items, T_1 contains the next $\delta^2 n$ items, T_2 contains the next $2\delta^2 n$ items, and so on. Note that the number of stages m is a constant. In any stage T_j, we denote the set of large items and small items by L_j and S_j, respectively. For $j \in [m-1]$, let $\overline{T_j}$ denote the set of items which have arrived before the stage T_j, i.e., $\overline{T_j} = T_0 \cup T_1 \cup \cdots \cup T_{j-1}$. Similarly, we define $\overline{L_j}$ and $\overline{S_j}$ as the set of large items and small items, respectively, in $\overline{T_j}$. Note that for any $j \in [m-1]$, $|T_j| = \left|\overline{T_j}\right|$ and since all the items are sampled independently from the same

distribution, we know that with high probability, the optimal solutions of T_j and $\overline{T_j}$ are quite similar. Since $\overline{T_j}$ would have arrived before T_j, we compute an almost optimal packing of $\overline{T_j}$ (in an offline manner) and use it as a blueprint to pack T_j.

The algorithm is as follows: first, we pack T_0, the sampling stage using Next-Fit. The sampling stage contains only a small but a constant fraction of the entire input set; hence it uses only a few number of bins when compared to the final packing but at the same time provides a good estimate of the underlying distribution. If the number of large items in the sampling stage is at most $\delta^3\mathcal{W}(T_0)$, then we continue using Next-Fit for the rest of the entire input too. Intuitively, NF performs well in this case as most of the items are small. Thus, from now on, let us assume otherwise. Now assume that we are at an intermediate point where $\overline{T_j}$ has arrived and T_j is about to arrive ($j \geq 1$). We create D_j, the set of *proxy* items, which is just a copy of $\overline{T_j}$. We pack D_j using $\mathcal{A}_\alpha$. Let this packing be denoted by $\mathcal{P}_j$. Let $B_j^{(k)}$ denote the k^{th} bin in the packing $\mathcal{P}_j$. We iterate over k and remove all the small items in the bin $B_j^{(k)}$ and create a slot in the free space of $B_j^{(k)}$. We call this slot to be an *S-slot*. When an item $x_i \in T_j$ arrives, we check if x_i is small or large

- If x_i is small, we pack it in one of the S-slots greedily, using Next-Fit. If it doesn't fit in any of the S-slots, then we create a new bin with only one S-slot spanning the entire bin (so, this bin will only be used to pack small items), and pack it there.
- If x_i is large, we remove the smallest proxy item with a size more than x_i in the packing $\mathcal{P}_j$ and pack it there. If no such proxy item exists, we open a new bin, pack x_i in there and close it, meaning that it will not be used to pack any further items.

After T_j is packed completely, we just discard the proxy items in the packing that haven't been replaced and move to the next stage. For more formal details and pseudocode for the algorithm, please refer to Algorithm 1.

We will proceed to analyze the algorithm. But first, we will discuss stochastic upright matching and a standard result on it. Using a standard probabilistic concentration lemma, we will formulate a few lemmas which are going to be very important for the analysis of the algorithm.

Stochastic Upright Matching. Rhee and Talagrand [43] studied stochastic upright matching problem in the context of analysis of bin packing algorithms. Consider a set $P = \{(x_i, y_i)\}_{i\in[2n]}$ of $2n$ points where each x_i is either $+1$ or -1 with equal probability and $y_1, y_2, \ldots, y_{2n}$ are sampled according to an i.i.d. distribution. We can define a bipartite graph $\mathcal{G}$ as follows: the vertex set is P, viewed as a set of points in $\mathbb{R}\times\mathbb{R}$. Two points $P_1 = (x_1, y_1), P_2 = (x_2, y_2)$ share an edge iff $x_1 = 1, x_2 = -1$ and $y_1 \geq y_2$.

The objective of the problem is to find a maximum matching in $\mathcal{G}$ or, in other words, minimize the number of unmatched points which we denote by $U(P)$. We denote this matching variant by $\mathcal{M}$. The following lemma shows that w.h.p., the number of unmatched points is $O(\sqrt{n}(\log n)^{3/4})$. The proof of the lemma follows from Lemma 3.1 in [43].

▶ **Lemma 5** ([43]). *Let P be an instance for $\mathcal{M}$. Then there exist constants $a, C, K > 0$ such that, $\mathbb{P}\left[U(P) \geq K\sqrt{n}(\log n)^{3/4}\right] \leq C\exp\left(-a(\log n)^{3/2}\right)$.*

Concentration Inequalities. Now we state the concentration inequalities.

▶ **Lemma 6** (Bernstein's Inequality). *Let $X_1, X_2, \ldots, X_n$ be independent random variables such that each $X_i \in [0,1]$. Then, for any $\lambda > 0$, the following inequality holds.*

$$\mathbb{P}\left[\left|\sum_{i=1}^{n} X_i - \sum_{i=1}^{n}\mathbb{E}\left[X_i\right]\right| \geq \lambda\right] \leq 2\exp\left(-\frac{\lambda^2}{2\left(\sum_{i=1}^{n}\mathbb{E}\left[X_i\right] + \lambda/3\right)}\right).$$

Algorithm 1 $\texttt{Alg}(x_1, x_2, \ldots, x_n)$: A nearly optimal algorithm for online bin packing assuming that the number of items n is known before-hand.

Input: $I_n(\mathcal{D}) = \{x_1, x_2, ..., x_n\}$.
for i= 1 to $\delta^2 n$ **do** ▷ Sampling Stage, T_0
  Pack x_i using NF.
end for
if $|L_0| \leq \delta^3 \mathcal{W}(T_0)$ **then** ▷ Very few large items
  Use NF for all remaining stages.
else
  for j= 1 to $m-1$ **do**
    $D_j \leftarrow \overline{T_j}$; $L(D_j) \leftarrow$ set of large items in D_j.
    Pack D_j using $\mathcal{A}_\alpha$.
    Let the packing be denoted by $\mathcal{P}_j$. ▷ Packing of proxy items
    $\mathcal{S}_j \leftarrow \phi$. ▷ the set of S-slots
    for bin B in $\mathcal{P}_j$ **do**
      Remove the small items in B.
      Create an S-slot H of size equal to (1−weight of all the large items in B).
      $\mathcal{S}_j \leftarrow \mathcal{S}_j \cup H$.
    end for
    for $x_i \in T_j$ **do**
      if x_i is large **then**
        if $\exists d \in L(D_j)$ such that $d \geq x_i$ **then**
          Find smallest such d.
          $L(D_j) \leftarrow L(D_j) \setminus \{d\}$.
          Pack x_i in place of d in the packing $\mathcal{P}_j$.
        else
          Open a new bin and pack x_i and close the bin.
        end if
      else
        Try packing x_i in $\mathcal{S}_j$ using Next-Fit.
        if x_i couldn't be packed **then**
          Open a new bin B' with a single S-slot of unit capacity.
          $\mathcal{S}_j \leftarrow \mathcal{S}_j \cup B'$.
          Pack x_i in B'.
        end if
      end if
    end for
  end for
end if

The following lemma is a direct implication of the results of [42, 40].

▶ **Lemma 7.** *For any $t \in [n]$, let $I(1,t)$ denote the first t items of the input set I. Then there exist constants $K, a > 0$ such that, $\mathbb{P}\left[\mathrm{Opt}(I(1,t)) \geq \frac{t}{n}\mathbb{E}\left[\mathrm{Opt}(I)\right] + K\sqrt{n}(\log n)^{3/4}\right] \leq \exp\left(-a(\log n)^{3/2}\right)$.*

The following lemmas are about how a property of a part of the input (say, the total size) compares to that of the entire input.

▶ **Lemma 8.** *For an input set I of n items drawn from a distribution independently, for any arbitrary set $J \subseteq I$ we have,* $\mathbb{P}\left[\left|\mathcal{W}(J) - \frac{|J|}{n}\mathbb{E}\left[\mathcal{W}(I)\right]\right| \geq \mathbb{E}\left[\mathcal{W}(I)\right]^{2/3}\right] \leq 2\exp\left(-\frac{1}{3}\mathbb{E}\left[\mathcal{W}(I)\right]^{1/3}\right)$.

▶ **Lemma 9.** *Let I be an input set of n items drawn from a distribution independently and let J be any subset of I. Suppose J_ℓ (resp. I_ℓ) denote the set of large items in J (resp. I). Then we have,* $\mathbb{P}\left[\left||J_\ell| - \frac{|J|}{n}\mathbb{E}\left[|I_\ell|\right]\right| \geq \mathbb{E}\left[\mathcal{W}(I)\right]^{2/3}\right] \leq 2\exp\left(-\frac{\delta}{3}\mathbb{E}\left[\mathcal{W}(I)\right]^{1/3}\right)$.

▶ **Lemma 10.** *For any $t \in \{1, 2, \ldots, n\}$, Suppose $I(1,t)$ denote the first t items of the input set I. Then there exist constants $C, a > 0$ such that with probability at least $1 - \exp\left(-a\left(\log \mathbb{E}\left[\mathrm{Opt}(I)\right]\right)^{1/3}\right)$, we have* $\mathrm{Opt}(I(1,t)) \leq (1+2\delta)\frac{t}{n}\mathbb{E}\left[\mathrm{Opt}(I)\right] + C\mathbb{E}\left[\mathrm{Opt}(I)\right]^{2/3}$.

Lemma 7 (resp. Lemmas 8 and 9) intuitively states that the optimal solution for (resp. the weight of the items of, and the number of large items in) a part of the input is almost a linear function of the length of the part. This makes sense because each item comes from the same distribution. Lemma 10 further tries to improve on Lemma 7 by bounding the lower order terms in terms of $\mathbb{E}\left[\mathrm{Opt}(I)\right]$ instead of n while losing only a small factor of $1 + 2\delta$. This is crucial since we need to bound the number of additional bins used by our algorithm in terms of $\mathbb{E}\left[\mathrm{Opt}(I)\right]$ and not in terms of n. We give the proofs of Lemmas 7–10 in the full version. As mentioned, Lemma 7 follows from [42, 40]. Lemmas 8 and 9 are simple applications of Bernstein's inequality. The high-level proof of Lemma 10 goes as follows: first we consider the optimal packing of the large items in $I(1,t)$, then we pack the small items in $I(1,t)$ greedily. If the small items open new bins then it means that all the bins (except one) are filled up to a level at least $1-\delta$. Otherwise, we don't use any extra bins. So, $\mathrm{Opt}(I(1,t)) \leq \max\{\mathrm{Opt}(I_\ell(1,t)), (1+2\delta)\mathcal{W}(I(1,t)) + 1\}$. Then we use Lemmas 7, 8 and 9 to prove Lemma 10.

With these helpful lemmas, we now proceed to analyze the algorithm. We split the analysis into the following two cases: when $|L_0| \leq \delta^3 \cdot \mathcal{W}(T_0)$ and when $|L_0| > \delta^3 \cdot \mathcal{W}(T_0)$.

2.1.1 Case 1: $|L_0| \leq \delta^3 \cdot \mathcal{W}(T_0)$

Recall that in this case, we just continue with Next-Fit for all the remaining items. To bound the Next-Fit solution, we first consider the number of bins that contain at least one large item. For this, we bound the value of $|I_\ell|$. Then we consider the bins that contain only small items and bound this value in terms of weight of all items $\mathcal{W}(I)$.

▷ Claim 11. Let $K := \mathbb{E}\left[\mathrm{Opt}(I)\right]$. For some positive constants C_1, C_2, a, we have that $\mathbb{P}\left[|I_\ell| \leq \delta \cdot \mathcal{W}(T_0) + C_1 K^{2/3}\right] \geq 1 - C_2\exp\left(-aK^{1/3}\right)$.

Proof. As the sampling stage contains $\delta^2 n$ items, $\mathbb{E}\left[|L_0|\right] = \delta^2\mathbb{E}\left[|I_\ell|\right]$. From Lemma 9, we have $\mathbb{P}\left[|L_0| \leq \delta^2\mathbb{E}\left[|I_\ell|\right] - \mathbb{E}\left[\mathcal{W}(I)\right]^{2/3}\right] \leq 2\exp\left(-(\delta/3)\cdot\left(\mathbb{E}\left[\mathcal{W}(I)\right]\right)^{1/3}\right)$, and $\mathbb{P}\left[|I_\ell| \geq \mathbb{E}\left[|I_\ell|\right] + \mathbb{E}\left[\mathcal{W}(I)\right]^{2/3}\right] \leq 2\exp\left(-(\delta/3)\cdot\mathbb{E}\left[\mathcal{W}(I)\right]^{1/3}\right)$. From the above inequalities we have, $|I_\ell| \leq \frac{1}{\delta^2}|L_0| + \left(1+\frac{1}{\delta^2}\right)\mathbb{E}\left[\mathcal{W}(I)\right]^{2/3}$ with probability at least $1 - 4\exp\left(-\frac{\delta}{3}\mathbb{E}\left[\mathcal{W}(I)\right]^{1/3}\right)$. We can use the inequalities $\mathbb{E}\left[\mathrm{Opt}(I)\right] \geq \mathbb{E}\left[\mathcal{W}(I)\right]$ and $|L_0| \leq \delta^3 \cdot \mathcal{W}(T_0)$ to conclude the proof of this claim. ◁

Now we bound the number of bins that are closed by small items. Note that Next-Fit fills each such bin up to a capacity at least $(1-\delta)$. So, the number of such bins is at most $\frac{1}{1-\delta}\mathcal{W}(I)$ when all items are packed by Next-Fit. Also, there can be at most one bin that

can be open. Thus combining all these results, (and using inequality $\frac{1}{1-\delta} \leq 1+2\delta$ for $\delta < \frac{1}{2}$) with high probability, $\mathrm{NF}(I) \leq |I_\ell| + (1+2\delta)\mathcal{W}(I) + 1 \leq \delta \cdot \mathcal{W}(T_0) + (1+2\delta)\mathcal{W}(I) + K\mathbb{E}\left[\mathrm{Opt}(I)\right]^{2/3}$, for some constant K.

Using Lemma 8, we get that with high probability, $\mathcal{W}(I) \leq \mathbb{E}\left[\mathcal{W}(I)\right] + \mathbb{E}\left[\mathcal{W}(I)\right]^{2/3}$. Using the facts $\mathcal{W}(I) \geq \mathcal{W}(T_0)$ and $\mathbb{E}\left[\mathrm{Opt}(I)\right]/2 \leq \mathbb{E}\left[\mathcal{W}(I)\right] \leq \mathbb{E}\left[\mathrm{Opt}(I)\right]$, we get,

$$\mathrm{NF}(I) \leq (1+3\delta)\mathbb{E}\left[\mathrm{Opt}(I)\right] + C_3\mathbb{E}\left[\mathrm{Opt}(I)\right]^{2/3} \tag{1}$$

with probability of at least $1 - C_4 \exp\left(-a_1\mathbb{E}\left[\mathrm{Opt}(I)\right]^{1/3}\right)$ for some constants $C_3, C_4, a_1 > 0$. When the low probability event occurs, we can use the upper bound of $\mathrm{NF}(I) \leq 2\mathrm{Opt}(I) - 1$ to obtain the competitive ratio. Let $p = C_4 \exp\left(-a_1\mathbb{E}\left[\mathrm{Opt}(I)\right]^{1/3}\right)$.

$$\begin{aligned}\mathbb{E}\left[\mathrm{NF}(I)\right] &\leq (1-p)\left((1+3\delta)\mathbb{E}\left[\mathrm{Opt}(I)\right] + K\mathbb{E}\left[\mathrm{Opt}(I)\right]^{2/3} + 1\right) + p(2\mathbb{E}\left[\mathrm{Opt}(I)\right] - 1) \\ &= (1+3\delta+2p)\mathbb{E}\left[\mathrm{Opt}(I)\right] + o(\mathbb{E}\left[\mathrm{Opt}(I)\right])\end{aligned}$$

Since $p = o(1)$ when $\mathbb{E}\left[\mathrm{Opt}(I)\right]$ tends to infinity, we obtain that the expected competitive ratio tends to at most $1 + 3\delta < 1 + \varepsilon$.

2.1.2 Case 2: $|L_0| > \delta^3 \cdot \mathcal{W}(T_0)$

We split our analysis in this case into two parts. We first analyze the number of bins used in the sampling stage T_0 and then analyze the number of bins used in the remaining stages.

Using Lemma 9, we obtain w.h.p. that $|L_0| \leq \delta^2\mathbb{E}\left[|I_\ell|\right] + \mathbb{E}\left[\mathcal{W}(I)\right]^{2/3}$. Hence,

$$\begin{aligned}\mathbb{E}\left[|I_\ell|\right] &\geq \frac{1}{\delta^2}|L_0| - \frac{1}{\delta^2}\mathbb{E}\left[\mathcal{W}(I)\right]^{2/3} \\ &\geq \delta\mathcal{W}(T_0) - \frac{1}{\delta^2}\mathbb{E}\left[\mathcal{W}(I)\right]^{2/3} && \text{(since } |L_0| > \delta^3 \cdot \mathcal{W}(T_0)\text{)} \\ &\geq \delta^3\mathbb{E}\left[\mathcal{W}(I)\right] - \left(\delta + \frac{1}{\delta^2}\right)\mathbb{E}\left[\mathcal{W}(I)\right]^{2/3} && (2)\end{aligned}$$

The last inequality follows from Lemma 8. For any $j \geq 1$, using $|T_j|/n \geq \delta^2$ and using Lemma 9, we get,

$$|L_j| \geq \delta^5\mathbb{E}\left[\mathcal{W}(I)\right] - (2+\delta^3)\mathbb{E}\left[\mathcal{W}(I)\right]^{2/3} \tag{3}$$

Each of the Eqs. (2),(3) holds with a probability of at least $1 - C\exp\left(-a\mathbb{E}\left[\mathcal{W}(I)\right]^{1/3}\right)$ for some constants $C, a > 0$.

Note that $\mathcal{W}(I) \geq \mathrm{Opt}(I)/2$. So from now on we assume that there exist constants $C_1, C_2 > 0$ which depend on δ such that w.h.p. both the following inequalities hold.

$$\mathbb{E}\left[|I_\ell|\right] \geq C_1 \cdot \mathbb{E}\left[\mathrm{Opt}(I)\right] \tag{4}$$

$$|L_j| \geq C_2 \cdot \mathbb{E}\left[\mathrm{Opt}(I)\right] \tag{5}$$

- **Analysis of the Sampling Stage:** Recall that the number of items considered in the sampling phase is $\delta^2 n$. We will bound the number of large items and the weight of items in this stage using Bernstein's inequality.
  1. Since sampling phase has $\delta^2 n$ items, $\mathbb{E}\left[|L_0|\right] = \delta^2\mathbb{E}\left[|I_\ell|\right]$. By applying Bernstein's inequality for $X_1, X_2, \ldots, X_{|T_0|}$ where X_i takes value 1 is x_i is large and 0 otherwise, we get,

$$\begin{aligned}\mathbb{P}\left[|L_0| \geq 2\delta^2\mathbb{E}\left[|I_\ell|\right]\right] &= \mathbb{P}\left[|L_0| \geq \mathbb{E}\left[|L_0|\right] + \delta^2\mathbb{E}\left[|I_\ell|\right]\right] \\ &\leq 2\exp\left(-\frac{\delta^4\mathbb{E}\left[|I_\ell|\right]^2}{2\mathbb{E}\left[|L_0|\right] + \frac{2}{3}\delta^2\mathbb{E}\left[|I_\ell|\right]}\right) \leq 2\exp\left(-\frac{1}{3}\delta^2\mathbb{E}\left[|I_\ell|\right]\right) \\ &\leq 2\exp\left(-a_1 \cdot \mathbb{E}\left[\mathrm{Opt}(I)\right]\right) \qquad \text{(from Equation (4))}\end{aligned}$$

for some constant $a_1 > 0$. So, with high probability, $|L_0| \leq 2\delta^2\mathbb{E}\left[|I_\ell|\right] \leq 2\delta\mathbb{E}\left[\mathrm{Opt}(I)\right]$.

2. Similarly, $\mathbb{E}\left[\mathcal{W}(T_0)\right] = \delta^2\mathbb{E}\left[\mathcal{W}(I)\right]$. By applying Bernstein's inequality for $X_1, X_2, \ldots, X_{|T_0|}$ where X_i takes value x_i, we get,

$$\begin{aligned}\mathbb{P}\left[\mathcal{W}(T_0) \geq 2\delta^2\mathbb{E}\left[\mathcal{W}(I)\right]\right] &= \mathbb{P}\left[\mathcal{W}(T_0) \geq \mathbb{E}\left[\mathcal{W}(S_0)\right] + \delta^2\mathbb{E}\left[\mathcal{W}(I)\right]\right] \\ &\leq 2\exp\left(\frac{-\delta^4\mathbb{E}\left[\mathcal{W}(I)\right]^2}{2\delta^2\mathbb{E}\left[\mathcal{W}(T_0)\right] + \frac{2}{3}\delta^2\mathbb{E}\left[\mathcal{W}(I)\right]}\right) \\ &\leq 2\exp\left(\frac{-\delta^2}{3}\mathbb{E}\left[\mathcal{W}(I)\right]\right) \leq 2\exp\left(\frac{-\delta^2\mathbb{E}\left[\mathrm{Opt}(I)\right]}{6}\right)\end{aligned}$$

So, with high probability we have, $\mathcal{W}(T_0) \leq 2\delta^2\mathbb{E}\left[\mathcal{W}(I)\right] \leq 2\delta^2\mathbb{E}\left[\mathrm{Opt}(I)\right]$.

Since the number of bins opened by Next-Fit $\mathrm{NF}(T_0)$ is at most $|L_0| + \frac{1}{1-\delta}\mathcal{W}(T_0) + 1$, using the bounds on the number of large items and weight of small items in sampling phase, w.h.p. we have,

$$\mathrm{NF}(T_0) \leq 2\delta\mathbb{E}\left[\mathrm{Opt}(I)\right] + \frac{2\delta^2}{1-\delta}\mathbb{E}\left[\mathrm{Opt}(I)\right] \leq 4\delta\mathbb{E}\left[\mathrm{Opt}(I)\right] \tag{6}$$

- **Analysis of the Remaining Stages:** Consider any stage T_j ($j > 0$) after the sampling stage. Note that $\left|\overline{T_j}\right| = |T_j|$. A bin can be opened in three different ways.
  1. When a new bin is opened while packing the set of proxy items D_j using $\mathcal{A}_\alpha$ (see the algorithm description in Section 2.1).
  2. When a large item can't replace a proxy item and hence a new bin is opened for it.
  3. When a small item can't fit in the set of S-slots and hence a new bin is opened with a single S-slot spanning the entire bin.

  In our analysis, first we bound the number of bins opened by $\mathcal{A}_\alpha$ for proxy items; we use Lemma 10 to obtain this bound. Then we show that the number of large items which cannot replace a proxy item would be very small by using upright matching arguments (Lemma 5). For small items, we bound the number of new bins opened by using the fact that $\mathcal{W}(S_j)$ and $\mathcal{W}(\overline{S_j})$ are very close which will be proved using Bernstein's inequality.

  Now we analyze the number of bins opened in the *first way* (say A^j_{proxy}). This is nothing but the number of bins opened by $\mathcal{A}_\alpha$ to pack $\overline{T_j}$. Since, $\mathcal{A}_\alpha$ has an AAR of α, by using Lemma 10, we have,

$$\begin{aligned}A^j_{\mathrm{proxy}} = \mathcal{A}_\alpha(\overline{T_j}) &\leq \alpha\mathrm{Opt}(\overline{T_j}) + o(\mathrm{Opt}(\overline{T_j})) \\ &\leq \alpha(1+2\delta)(\left|\overline{T_j}\right|/n)\mathbb{E}\left[\mathrm{Opt}(I)\right] + C_3\mathbb{E}\left[\mathrm{Opt}(I)\right]^{2/3} + o(\mathrm{Opt}(I)) \qquad (7)\end{aligned}$$

  with probability at least $1 - \exp\left(-a_2\log(\mathbb{E}\left[\mathrm{Opt}(I)\right])^{1/3}\right)$, for some constants $C_3, a_2 > 0$.

  We now bound the number of bins opened in the *second way*. Using Lemma 9, we get that w.h.p., $\left|\overline{L_j}\right| \geq \frac{\left|\overline{T_j}\right|}{n}\mathbb{E}\left[|I_\ell|\right] - \mathbb{E}\left[\mathcal{W}(I)\right]^{2/3}$, and $|L_j| \leq \frac{|T_j|}{n}\mathbb{E}\left[|I_\ell|\right] + \mathbb{E}\left[\mathcal{W}(I)\right]^{2/3}$. Since $\left|\overline{T_j}\right| = |T_j|$ we have,

$$|L_j| \leq \left|\overline{L_j}\right| + 2\mathbb{E}\left[\mathcal{W}(I)\right]^{2/3}. \tag{8}$$

So, w.h.p. the number of large items in T_j doesn't exceed that of those in $\overline{T_j}$ by a large number. Now consider the number of bins opened because there is no feasible proxy item that can be replaced. Let this number be A^j_{unmatch}. We can interpret this number as the number of unmatched items when we use the stochastic matching variant $\mathcal{M}$ from [43] as follows. We can interpret each item $\bar{t} \in \overline{L_j}$ as a point $P_{\bar{t}} := (+1, \bar{t})$ and each point $t \in L_j$ as a point $P_t := (-1, t)$. For simplicity, let's call the points with $+1$ as their first coordinate as *plus* points and the points with -1 as their first coordinate as *minus* points. We match a point $P_{\bar{t}}$ with P_t iff t replaced $\bar{t}$ in our algorithm. It is shown in [44] that such matching is always maximum. Hence the number of items that open new bins is at most the number of unmatched points in this maximum matching. There are two differences though. First, $\left|\overline{L_j}\right|$ may not be greater than $|L_j|$; but as we have shown, w.h.p, the difference can at most be $2\mathbb{E}\left[\mathcal{W}(I)\right]^{2/3}$. Secondly, in the matching variant $\mathcal{M}$, every point has equal chance to be a plus point or minus point. However, this is also inconsequential, since using concentration bounds for binomial random variables, we can show that the number of plus points/minus points lie in the range $\left(\mathbb{E}\left[\left|\overline{L_j}\right|\right] \pm \mathbb{E}\left[\left|\overline{L_j}\right|\right]^{2/3}\right)$ w.h.p. Hence by Lemma 5, we obtain that there exist constants a_3, C_4, K_1 s.t.

$$\mathbb{P}\left[A^j_{\text{unmatch}} \geq K_1\sqrt{\left|\overline{L_j}\right|}\left(\log\left|\overline{L_j}\right|\right)^{3/4} + 2\mathbb{E}\left[\mathcal{W}(I)\right]^{2/3} + 2\mathbb{E}\left[\left|\overline{L_j}\right|\right]^{2/3}\right] \leq C_4\exp\left(-a_3(\log\left|\overline{L_j}\right|)^{3/2}\right)$$

We can simplify the above inequality using Equations (5) and (8) and the fact that $\text{Opt}(I) \leq 2\mathcal{W}(I)$ to obtain that there exist constants $a_4, C_4, K_2 > 0$ such that,

$$\mathbb{P}\left[A^j_{\text{unmatch}} \geq K_2\mathbb{E}\left[\text{Opt}(I)\right]^{2/3}\right] \leq C_4\exp\left(-a_4(\log\mathbb{E}\left[\text{Opt}(I)\right])^{3/2}\right) \tag{9}$$

The only part left is to bound the number of bins opened by small items in *third way*. Let this number be A^j_{small}. We will bound this by using the concentration of weights of small items in $\overline{T_j}$ and T_j. Consider the random variables $X_1, X_2 \ldots X_n$ where $X_i = 0$ if x_i is large, and $X_i = x_i$ otherwise. We have that $\mathcal{W}(S_j) = \sum_{X_i : x_i \in T_j} X_i$ and $\mathcal{W}(\overline{S_j}) = \sum_{X_i : x_i \in \overline{T_j}} X_i$. By applying Bernstein's inequality (similar to Lemma 8) we get, $\mathcal{W}(S_j) \leq \frac{|T_j|}{n}\mathcal{W}(I_s) + \mathbb{E}\left[\mathcal{W}(I)\right]^{2/3}$, and $\mathcal{W}(\overline{S_j}) \geq \frac{|\overline{T_j}|}{n}\mathcal{W}(I_s) - \mathbb{E}\left[\mathcal{W}(I)\right]^{2/3}$ with a probability of at least $1 - C_5\exp\left(-a_5\mathbb{E}\left[\mathcal{W}(I)\right]^{1/3}\right)$ for some constants $C_5, a_5 > 0$. Combining both, we get,

$$\mathcal{W}(S_j) \leq \mathcal{W}(\overline{S_j}) + 2\mathbb{E}\left[\mathcal{W}(I)\right]^{2/3} \tag{10}$$

The initial allocated space for small items at the start of stage j in the packing $\mathcal{P}_j$ is $\mathcal{W}(\overline{S_j})$. Recall that $B^{(k)}_j$ denotes the k^{th} bin in the packing of $\mathcal{P}_j$. While packing the small items, if the S-slot in $B^{(k)}_j$ cannot accommodate a small item, this means that the remaining space in this S-slot is at most δ. So, the weight of small items which overflow the space allocated in packing $\mathcal{P}_j$ is at most $\mathcal{W}(S_j) - \mathcal{W}(\overline{S_j}) + \delta\left|\mathcal{P}_j\right|$ and this entire weight is packed in new bins opened exclusively for small items. Each of these bins (except possibly one) have an occupancy of at least $(1-\delta)$. Since $\mathcal{A}_\alpha$ is α-approximation algorithm, $|\mathcal{P}_j| = \mathcal{A}_\alpha(\overline{T_j}) \leq \alpha\text{Opt}(\overline{T_j}) + o(\text{Opt}(I))$. Using Equations (7) and (10) we get,

$$A^j_{\text{small}} \le \frac{1}{1-\delta}\left(\mathcal{W}(S_j) - \mathcal{W}(\overline{S_j}) + \delta \cdot \alpha \text{Opt}(\overline{T_j}) + o(\text{Opt}(I))\right) + 1$$
$$\le 2\delta \cdot \alpha \frac{|\overline{T_j}|}{n}\mathbb{E}\left[\text{Opt}(I)\right] + C_3\mathbb{E}\left[\text{Opt}(I)\right]^{2/3} + o(\text{Opt}(I)) \tag{11}$$

with high probability. Combining Equations (7), (9), and (11), the number of bins, A_j, opened in the stage j is bounded as,

$$A_j = A^j_{\text{proxy}} + A^j_{\text{unmatch}} + A^j_{\text{small}}$$
$$\le \alpha(1+4\delta)\frac{|\overline{T_j}|}{n}\mathbb{E}\left[\text{Opt}(I)\right] + C_6\mathbb{E}\left[\text{Opt}(I)\right]^{2/3} + o(\text{Opt}(I))$$
$$\le \alpha(1+4\delta)\frac{|T_j|}{n}\mathbb{E}\left[\text{Opt}(I)\right] + C_6\mathbb{E}\left[\text{Opt}(I)\right]^{2/3} + o(\text{Opt}(I)) \tag{12}$$

w.h.p., for some constant C_6. To bound the sum of all A_js, first note that the number of "remaining stages" is $m-1$ which is a constant dependent on δ. Hence, with high probability,

$$\sum_{j=1}^{m-1} A_j \le \alpha(1+4\delta)\sum_{j=1}^{m-1}\frac{|\overline{T_j}|}{n}\mathbb{E}\left[\text{Opt}(I)\right] + (m-1)\cdot C_6\mathbb{E}\left[\text{Opt}(I)\right]^{2/3} + o(\text{Opt}(I))$$
$$\le \alpha(1+4\delta)\mathbb{E}\left[\text{Opt}(I)\right] + C_7\mathbb{E}\left[\text{Opt}(I)\right]^{2/3} + o(\text{Opt}(I)) \tag{13}$$

for some constant $C_7 > 0$ dependent on δ.

In the sampling phase, we have $\text{NF}(T_0) \le 4\delta\mathbb{E}\left[\text{Opt}(I)\right]$ with high probability and in all the remaining phases we have $\sum_{j=1}^{m-1} A_j \le \alpha(1+4\delta)\mathbb{E}\left[\text{Opt}(I)\right] + C_7\mathbb{E}\left[\text{Opt}(I)\right]^{2/3} + o(\text{Opt}(I))$.

Combining both the results we get that w.h.p. the number of bins opened by `Alg` is,

$$\texttt{Alg}(I) \le \alpha(1+8\delta)\mathbb{E}\left[\text{Opt}(I)\right] + C_7\mathbb{E}\left[\text{Opt}(I)\right]^{2/3} + o(\text{Opt}(I))$$
$$\le \alpha(1+\varepsilon)\mathbb{E}\left[\text{Opt}(I)\right] + C_7\mathbb{E}\left[\text{Opt}(I)\right]^{2/3} + o(\text{Opt}(I)) \tag{14}$$

In the low probability event when Equation (14) may not hold, we can bound $\texttt{Alg}(I)$ as follows. In the sampling stage, we have that $\texttt{Alg}(T_0) \le 2\text{Opt}(I) - 1$. For the remaining stages, we bound the number of bins containing at least one large item and the number of bins containing only small items. Because we create a proxy packing at the start of each stage, each large item is packed at most m times. So, the number of bins containing at least one large item is at most $m\,|I_\ell|$. In each stage, with one possible exception, every bin opened which has only small items has an occupancy of at least $(1-\delta)$. Combining over all the stages, the number of bins which contain only small items is at most $\frac{1}{1-\delta}\mathcal{W}(I_s) + m$. Thus, we can bound the total number of bins used by `Alg` to be at most $2\text{Opt}(I) + m\,|I_\ell| + \frac{1}{1-\delta}\mathcal{W}(I_s) + m$. On the other hand, we know that $\text{Opt}(I) \ge \mathcal{W}(I) \ge \delta\,|I_\ell| + \mathcal{W}(I_s)$. Hence, we obtain that $m\,|I_\ell| + \frac{1}{1-\delta}\mathcal{W}(I_s) \le \frac{m}{\delta(1-\delta)}\text{Opt}(I)$. Combining all these, we obtain that

$$\texttt{Alg}(I) \le \left(2 + \frac{m}{\delta(1-\delta)}\right)\text{Opt}(I) + m \tag{15}$$

Now, to obtain the competitive ratio, suppose Equation (14) holds with probability $p(= 1 - o(1))$. We combine Equations (14) and (15) similar to the case when $|L_0| \le \delta^3 \cdot \mathcal{W}(T_0)$.

$$\mathbb{E}\left[\texttt{Alg}(I)\right] \le p(\alpha(1+8\delta)\mathbb{E}\left[\text{Opt}(I)\right] + o(\mathbb{E}\left[\text{Opt}(I)\right]))$$
$$+ (1-p)\left(\left(2 + \frac{m}{\delta(1-\delta)}\right)\mathbb{E}\left[\text{Opt}(I)\right] + m\right)$$
$$\le \alpha(1+\varepsilon)\mathbb{E}\left[\text{Opt}(I)\right] + o(\mathbb{E}\left[\text{Opt}(I)\right]) \qquad \text{(since } 1-p = o(1)\text{)}$$

Scaling the initial value ε to ε/α before the start of the algorithm, we obtain a competitive ratio of $\alpha + \varepsilon$.

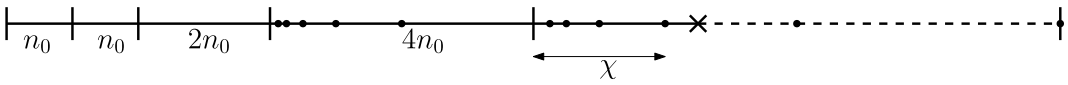

Figure 1 Doubling trick visualized. We start off with an estimate of n to be n_0 and keep doubling it. The first and second super-stages contain n_0 items each. The third super-stage contains $2n_0$ items and so on. Each super-stage is packed individually using `Alg`. The stages in each super-stage are marked by $\bullet$ (for simplicity, only the stages in the last two super-stages are marked). The $\times$ mark indicates the point where the input abruptly stopped. Notice how the fifth stage of the last super-stage is not full. Just before packing this stage, `Alg` constructs a proxy packing of χ by using $\mathcal{A}_\alpha$. But this is very lossy since χ is large compared to this last stage.

2.2 Getting Rid of the Assumption on the Knowledge of the Input Size

In this subsection, we will extend `Alg` for online bin packing with i.i.d. items to devise an algorithm that guarantees essentially the same competitive ratio without knowing the value of n. We denote this algorithm by `ImpAlg`.

We use a doubling trick as follows. We first guess the value of n to be a constant $n_0 := 1/\delta^3$. Then, we run `Alg` until $\min\{n, n_0\}$ items arrive (here, if $\min\{n, n_0\} = n$, then it means that the input stream has ended). If $n > n_0$, i.e., if there are more items to arrive, then we revise our estimate of n by doubling it, i.e., the new value of n is set as $n_1 := 2n_0$. We start `Alg` afresh on the next $\min\{n, n_1\} - n_0$ items. If $n > 2n_0$, then we set the new guess of n to be $n_2 := 2n_1 = 2^2 n_0$ and start `Alg` afresh on the next $\min\{n, n_2\} - n_1$ number of items. We continue this process of doubling our estimate of n until all the items arrive. See Figure 1 for an illustration. The pseudocode is provided in the full version.

We consider the following partition of the entire input into super-stages as follows: The first super-stage, Γ_0, contains the first n_0 items. The second super-stage, Γ_1, contains the next $n_1 - n_0$ items. In general, for $i > 0$, the $(i+1)^{\text{th}}$ super-stage, Γ_i, contains $\min\{n_i, n\} - n_{i-1}$ items which are given by $x_{n_{i-1}+1}, x_{n_{i-1}+2}, \ldots, x_{\min\{n,n_i\}}$. So, essentially, `ImpAlg` can be thought of running `Alg` on each super-stage separately. The number of super-stages is given by $\kappa := \lceil \log(n/n_0) \rceil$. The last super-stage might not be *full*, i.e., ideally, it should contain $n/2$ items but it may not. An even worse case would be when the last stage of the last super-stage is not full, i.e., when it contains fewer than $|\Gamma_{\tau-1}|/2$ items where $\Gamma_{\tau-1}$ is the last super-stage. To see why this is bad, note that since we had assumed the value of n in `Alg`, it was possible to make sure that the last stage had exactly $n/2$ items. This is crucial because our analysis heavily relied on the fact that $|T_j| = \left|\overline{T_j}\right|$ for any stage T_j. This meant that the item set T_j fit almost perfectly in the proxy packing of $\overline{T_j}$. But if the last stage T_{m-1} contains far fewer items than $\overline{T_{m-1}}$, then we might be opening far too many proxy bins than required (see the description of the last super-stage in Figure 1). Hence, we need a slight tweak in `Alg` in the way it packs a stage.

2.2.1 A Tweak to `Alg` in the Way in which a Stage is Packed

Recall that for any $j > 1$, we pack T_j as follows. Just before the stage T_j starts, we pack $\overline{T_j}$ using $\mathcal{A}_\alpha$ (the proxy packing). Instead of packing the entire set $\overline{T_j}$ at once, we do this in chunks. We divide the entire set $\overline{T_j}$ into $\eta := 1/\delta$ number of *equal* chunks. Let's denote these chunks by $\overline{T_j}^{(1)}, \overline{T_j}^{(2)}, \ldots, \overline{T_j}^{(\eta)}$. Suppose each chunk contains c_j number of items. We first pack $\overline{T_j}^{(1)}$ using $\mathcal{A}_\alpha$. Let this packing be denoted by $\mathcal{P}_j^{(1)}$. We pack the first c_j items of T_j by fitting them in the packing $\mathcal{P}_j^{(1)}$ just like we packed a stage in `Alg` by creating S-slots for small items and replacing a proxy item if we need to pack a large item. Then, we pack $\overline{T_j}^{(2)}$

using $\mathcal{A}_\alpha$ and fit the next c_j items of T_j in this packing just like before. We continue this process until all the items in T_j are packed. This way, if the size of T_j is very small compared to that of $\overline{T_j}$, then we only compute the proxy packing of only a few chunks and not of the entire set $\overline{T_j}$. On the other hand, if $|T_j|$ is significant when compared to $\left|\overline{T_j}\right|$, then we are anyway good since the number of chunks η is a constant. Intuitively, the optimal solution for $\overline{T_j}$ and the union of optimal solutions for η chunks $\overline{T_j}^{(1)}, \overline{T_j}^{(2)}, \ldots, \overline{T_j}^{(\eta)}$ are close enough when η is a constant. See the pseudocode of `PackStage` in the full version for details.

2.2.2 Analysis

The analyses of both `ImpAlg` and the tweak to `Alg` can be found in the full version. The intuition to why the tweak to `Alg` doesn't cause much problem has already been provided above. The analysis of `ImpAlg` is a bit complicated though. When n was known we had $O(1)$ stages. However, now we can have $\kappa := \lceil \log(n/n_0) \rceil$ number of super-stages. There can arise two problems:

- We can not analyze each super-stage individually and then sum up the performance guarantees, as we can not use union bound for a super-constant number of events. Moreover, we can't even use the analysis of `Alg` for the first few super-stages since they might only have a constant number of items. So, we consider the $\kappa_1 := \left\lceil \log(\delta^7 n) \right\rceil$ number of the initial super-stages at a time. We show that these initial super-stages contain only a small fraction of the entire input. Each of the final $(\kappa - \kappa_1)$ super-stages can be individually analyzed using the analysis of `Alg`.
- For each super-stage, we can have a constant number of S-bins (bins which contain only small items) with less occupancy. However, since the number of super-stages itself is a super-constant, this can result in a lot of wasted space. For this, we exploit the monotonicity of NF to ensure that we can pack small items from a super-stage into empty slots for small items from the previous stages.

See the full version for the details.

3 Best-Fit under the Random-Order Model

In this section, we will prove Theorems 3 and 4.

3.1 When Item Sizes are Larger than 1/3

First, let us recall upright matching and a related result that we will be using.

Upright Matching Problem. For a positive integer k, let S_k denote the set of all permutations of $[k]$. Consider a set of points P in the two-dimensional coordinate system. Suppose each item is marked as a *plus* point or a *minus* point. Let P^+ denote the set of plus points and let P^- denote the set of minus points. An edge exists between two points p^+, p^- iff $p^+ \in P^+, p^- \in P^-$ and iff p^+ lies above and to the right of p^-, i.e., both the coordinates of p^+ are greater than or equal to the corresponding coordinates of p^-. The objective is to find a maximum matching in this graph or, in other words, minimize the number of unmatched points. We denote the number of unmatched points by $U(P)$.

We will use the following variant of upright matching to prove the final result. Refer to [9] for the proof of the following lemma.

▶ **Lemma 12** ([9]). *Let $k \in \mathbb{N}$ and let $\mathcal{A} = \{a_1, a_2, \ldots, a_{2k}\}$ such that $a_i \geq a_{k+i}$ for all $i \in [k]$. Define a set of* plus *points $P^+ = \{(i, a_i) : i \in [k]\}$ and a set of* minus *points $P^- = \{(i, a_i) : k < i \leq 2k\}$. Suppose we randomly permute the x-coordinates of*

$P^+ \cup P^-$, i.e., for a uniform random permutation $\pi \in S_{2k}$, we redefine P^+ and P^- as $P^+ = \{(\pi(i), a_i) : i \in [k]\}$ and $P^- = \{(\pi(i), a_i) : k < i \leq 2k\}$. Let $P = P^+ \cup P^-$. Then, there exist universal constants $a, C, K > 0$ such that

$$\mathbb{P}\left[U(P) \geq K\sqrt{k}(\log k)^{3/4}\right] \leq C\exp(-a(\log k)^{3/2}) \tag{16}$$

▶ Remark 13. In the above lemma, if we change the definitions of P^+, P^- to be $P^+_{\text{new}} = \{(-\pi(i), a_i) : i \in [k]\}$, $P^-_{\text{new}} = \{(-\pi(i), a_i) : k < i \leq 2k\}$, the guarantee given by Equation (16) doesn't change since the new set $P^+_{\text{new}} \cup P^-_{\text{new}}$ can be constructed by taking a mirror image of the original set $P^+ \cup P^-$ with respect to the y-axis. Since we consider random permutations, the probability of a set and its mirror image is the same.

With the above lemma and remark at hand, we now proceed to prove Theorem 3. Albers et al. [1] showed that the asymptotic random order ratio of the Best-Fit algorithm is at most 1.25 when all the item sizes are more than 1/3. In this section, we improve it further and show that, Best-Fit for this special case under the random-order model is nearly optimal. We first show that the Modified Best-Fit algorithm [11] is nearly optimal and we analyze this using the above variant of stochastic upright matching. The Modified Best-Fit (MBF) algorithm is the same as BF except that it closes a bin if it receives an item of size less than 1/2. Shor[44] showed that MBF *dominates* BF, i.e., for any instance I, $\text{BF}(I) \leq \text{MBF}(I)$. MBF can be easily reduced to upright matching as follows. Given an instance $I = \{x_1, \ldots, x_n\}$, for any item $x_i \in I$, $x_i \in P^-$ if $x_i \leq 1/2$ with x-coordinate as $-i$ and y-coordinate as x_i, and $x_i \in P^+$ if $x_i > 1/2$ with x-coordinate as $-i$ and y-coordinate as $1 - x_i$. So, any item x_s of size $\leq 1/2$ can be matched with an item x_ℓ of size $> 1/2$ if and only if, x_ℓ arrives before x_s and the remaining space in the bin occupied by x_ℓ is more than the size of x_s.

Define an item x_i as a large item (L) if $x_i > 1/2$; otherwise, as a medium item (M) if $x_i \in (1/3, 1/2]$. We define a bin as LM-bin if it contains one large item and one medium item. We use the following lemma which was proved in [1] using the monotonicity property of BF when all item sizes are more than 1/3.

▶ **Lemma 14** ([1]). *Let I be any list that can be packed into $\text{Opt}(I)$ number of LM-bins. If Best-Fit has an AAR of α for I, then it has an AAR of α for any list of items larger than 1/3 as well.*

Consider an input instance which has an optimal packing containing only LM-bins. Consider the number of bins opened by MBF for such instances. Each large item definitely opens a new bin, and a medium item opens a new bin if and only if it can not be placed along with a large item, i.e., it is "unmatched". So, the number of bins opened by MBF equals (number of large items+number of unmatched medium items).

Now, we will prove our result.

▶ **Theorem 15.** *For any list I of items larger than 1/3, the asymptotic random order ratio $RR^{\infty}_{BF} = 1$.*

Proof. From Lemma 14, it is enough to prove the theorem for any list I that can be packed in $\text{Opt}(I)$ LM-bins. So, we can assume that I has k large items and k medium items where $\text{Opt}(I) = k$. Now consider the packing of MBF for a randomly permuted list I_σ. We have, $\text{MBF}(I_\sigma) = (k + \text{number of unmatched medium items})$. Since the optimal packing has all the items matched, we can reduce the following case into the matching variant in Lemma 12: Let ℓ_i, m_i denote the sizes of the large item and the medium item respectively in the i^{th} bin of the

optimal solution. For $i \in [k]$, we let $a_i = 1 - \ell_i$ and $a_{k+i} = m_i$ and let $\mathcal{A} = \{a_1, a_2, \ldots, a_{2k}\}$. Note that the required condition in Lemma 12, i.e., $a_i \geq a_{k+i}$ is satisfied. The arrival order is randomly sampled from S_{2k}. So, we have

$$\mathrm{MBF}(I_\sigma) = k + \frac{U(P)}{2} \leq k + K\sqrt{k}(\log k)^{3/4}$$

with probability of at least $1 - C\exp(-a(\log k)^{3/2})$ for some universal constants $a, C, K > 0$. Since MBF dominates BF we have

$$\mathbb{P}\left[\mathrm{BF}(I_\sigma) \leq k + K\sqrt{k}(\log k)^{3/4}\right] \geq 1 - C\exp(-a(\log k)^{3/2}).$$

In case the high probability event does not occur, we can use the bound of $\mathrm{BF}(I) \leq 1.7\mathrm{Opt}(I) + 2$. Let $p := C\exp(-a(\log k)^{3/2})$. Then

$$\begin{aligned}\mathbb{E}\left[\mathrm{BF}(I_\sigma)\right] &\leq p(1.7\mathbb{E}\left[k\right] + 2) + (1-p)(\mathbb{E}\left[k\right] + K\sqrt{\mathbb{E}\left[k\right]}(\log \mathbb{E}\left[k\right])^{3/4}) \\ &\leq \mathbb{E}\left[\mathrm{Opt}(I)\right] + o(\mathbb{E}\left[\mathrm{Opt}(I)\right]) \qquad \text{(since } p = o(1)\text{)}\end{aligned}$$

So, we get: $RR^{\infty}_{BF} = \limsup_{k\to\infty}\left(\sup_{I:\mathrm{Opt}(I)=k}(\mathbb{E}[\mathrm{BF}(I_\sigma)]/\mathrm{Opt}(I))\right) = 1$. This completes the proof. ◀

3.2 The 3-Partition Problem under Random-Order Model

In this section, we analyze the Best-Fit algorithm under the random-order model given that the item sizes lie in the range $(1/4, 1/2]$, and thus prove Theorem 4. We call an item *small* if its size lies in the range $(1/4, 1/3]$ and *medium* if its size lies in the range $(1/3, 1/2]$. Let I be the input list of items and let $n := |I|$. Recall that given σ, a uniform random permutation of $[n]$, I_σ denotes the list I permuted according to σ. We denote by $\mathrm{Opt}(I_\sigma)$, the number of bins used in the optimal packing of I_σ and by $\mathrm{BF}(I_\sigma)$, the number of bins used by Best-Fit to pack I_σ. Note that $\mathrm{Opt}(I_\sigma) = \mathrm{Opt}(I)$.

If there exists a set of three small items in I_σ such that they arrive as three consecutive items, we call that set to be an *S-triplet*. We call a bin to be a k-bin if it contains exactly k items, for $k \in \{1, 2, 3\}$. We sometimes refer to a bin by mentioning its contents more specifically as follows: An MS-bin is a 2-bin which contains a medium item and a small item. Similarly, an SSS-bin is a 3-bin which contains three small items. Likewise, we can define an M-bin, S-bin, MM-bin, SS-bin, MMS-bin, and MSS-bin.

Since the item sizes lie in $(1/4, 1/2]$, any bin in the optimal packing contains at most three items. For the same reason, in the packing by Best-Fit, every bin (with one possible exception) contains at least two items. This trivially shows that the ECR of Best-Fit is at most $3/2$. To break the barrier of $3/2$, we use the following observations.

- Any 3-bin must contain a small item.
- So, if the optimal solution contains a lot of 3-bins, then it means that the input set contains a lot of small items.

We will prove that if there exist many small items in the input, then with high probability, in a random permutation of the input, there exist many disjoint S-triplets.

▷ Claim 16. Let m be the number of small items in the input set I, and let X_σ denote the maximum number of mutually disjoint S-triplets in I_σ. Suppose $m \geq cn$ where $c = 0.00033$, then the following statements hold true:

1. $\mathbb{E}\left[X_\sigma\right] \geq m^3/(3n^2) \geq c^3 n/3$.
2. $X_\sigma \geq c^3 n/3 - o(n)$ with high probability.

Then, we prove that Best-Fit packs at least one small item from an S-triplet in a 3-bin or in an SS-bin.

▷ Claim 17. Let $\{S_1, S_2, S_3\}$ be an S-triplet in I such that S_3 follows S_2 which in turn follows S_1. Then, in the final packing of Best-Fit of I, at least one of S_1, S_2, S_3 is packed in a 3-bin or in an SS-bin.

But the number of SS-bins in the final packing of Best-Fit can be at most one. So, we obtain that the number of 3-bins in the Best-Fit packing is significant. With these arguments, the proof of Theorem 4 follows. The detailed proofs of the above two claims and the final theorem is given in the full version.

4 Conclusion

We studied online bin packing under two stochastic settings, namely the i.i.d. model, and the random-order model. For the first setting, we devised a meta-algorithm which takes any offline algorithm $\mathcal{A}_\alpha$ with an AAR of α (where α can be any constant ≥ 1), and produces an online algorithm with an ECR of $(\alpha + \varepsilon)$. This shows that online bin packing under the i.i.d. model and offline bin packing are almost equivalent. Using any AFPTAS as $\mathcal{A}_\alpha$ results in an online algorithm with an ECR of $(1 + \varepsilon)$ for any constant $\varepsilon > 0$. An interesting question of theoretical importance is to find whether achieving an ECR of 1 is possible or not. Another related open question is if we can settle online bin packing under the random-order model as well.

Then, we studied the analysis of the well-known Best-Fit algorithm under the random-order model. First, we proved that the ECR of Best-Fit is equal to one if all the item sizes are greater than $1/3$. Then, we improved the analysis of the Best-Fit from 1.5 to ≈ 1.4941, for the special case when the item sizes are in the range $(1/4, 1/2]$. An open question is to further improve this analysis since these instances are conjectured to be the hardest (offline) instances of bin packing. Another interesting problem would be to improve the lower bound on the ECR of Best-Fit in this model (which is currently 1.1 due to [2]).

Abstract

Motivated by placement of jobs in physical machines, we introduce and analyze the problem of online recoloring, or online disengagement. In this problem, we are given a set of n weighted vertices and a k-coloring of the vertices (vertices represent jobs, and colors represent physical machines). Edges, representing conflicts between jobs, are inserted in an online fashion. After every edge insertion, the algorithm must output a proper k-coloring of the vertices. The cost of a recoloring is the sum of weights of vertices whose color changed. Our aim is to minimize the competitive ratio of the algorithm, i.e., the ratio between the cost paid by the online algorithm and the cost paid by an optimal, offline algorithm.

We consider a couple of polynomially-solvable coloring variants. Specifically, for 2-coloring bipartite graphs we present an $O(\log n)$-competitive deterministic algorithm and an $\Omega(\log n)$ lower bound on the competitive ratio of randomized algorithms. For $(\Delta + 1)$-coloring, we present tight bounds of $\Theta(\Delta)$ and $\Theta(\log \Delta)$ on the competitive ratios of deterministic and randomized algorithms, respectively (where Δ denotes the maximum degree). We also consider a dynamic case which allows edge deletions as well as insertions. All our algorithms are applicable to the case where vertices are weighted and the cost of recoloring a vertex is its weight. All our lower bounds hold even in the unweighted case.

1 Introduction

The following situation is not uncommon in server farms, such as a data center of a cloud provider: Jobs (or virtual machines) are created and located at various physical machines, and then it turns out that some of the jobs cannot co-exist on the same machine. Such restrictions may be due to various reasons, e.g., conflicting resource requirements, security considerations etc. (cloud providers allow users to express these constraints using so-called "anti-affinity rules:" see, e.g., [1]). When such a conflict arises between co-located jobs, at least one of these jobs must migrate to another machine, at a cost. Motivated by such scenarios, in this paper we introduce and study the *Disengagement Problem*, in which disengagement (anti-affinity) requests arrive on-line, and the goal is to minimize the overall cost of job migrations.

More specifically, we abstract the problem as follows (more details in Section 2). We view the problem as an online graph coloring problem with recourse. Initially, we are given a vertex-weighted graph $G_0 = (V, \emptyset)$ of n isolated vertices, and a coloring $c_0 : V \to [k]$, where $k \in \mathbb{N}$ is a given parameter.[1] (Vertices correspond to jobs and colors correspond to machines.) The input is a sequence of edges $e_1, e_2, \ldots$ that arrive one at each step. After each step i, we are required to output a new coloring $c_i : V \to [k]$ such that under c_i, no edge in $e_1, \ldots, e_i$ is monochromatic. The cost of a given sequence of colorings $c_0, c_1, \ldots$ is the total weight of recolorings, i.e., the sum over all vertices of vertex weight times the number of times that vertex was recolored. Due to this formalization, in this paper we refer to the problem interchangeably as Vertex Recoloring or Disengagement.

Our results. We study online disengagement from the competitive analysis viewpoint [14]. (Note that an optimal offline solution never recolors a vertex more than once.) Since vertex coloring is a hard problem [16], we focus on two cases which are polynomially solvable, namely 2-colorable graphs and $(\Delta + 1)$-coloring, where Δ denotes the maximum vertex degree.

1. For 2-coloring, we give a deterministic, $O(\log n)$-competitive algorithm. We also show a matching lower bound of $\Omega(\log n)$ on the competitiveness of *randomized* algorithms.
2. For $(\Delta + 1)$-coloring, we present:
   - A deterministic, $O(\Delta)$-competitive algorithm, and a matching $\Omega(\Delta)$ lower bound.
   - A randomized, $O(\log \Delta)$-competitive algorithm, and a matching $\Omega(\log \Delta)$ lower bound.

In all the above cases, our algorithms work with weighted vertices, and our lower bounds apply even to unweighted instances.

We briefly consider the variant of *fully-dynamic* online disengagement, in which conflicts are temporary, as opposed to the semi-dynamic disengagement in which conflicts never disappear (see formalization in Section 2). It turns out that fully-dynamic disengagement is substantially harder than semi-dynamic disengagement. More specifically, even though in this case the offline cost is not bounded by n, all lower bounds of the semi-dynamic case apply as well. We also show that the special case of fully-dynamic disengagement with two colors on an odd cycle (which is of course not 2-colorable in the semi-dynamic case) is at least as hard as a certain metrical task system on an odd cycle, and hence admits a lower bound of $\Omega(n)$-competitiveness for deterministic algorithms (whereas the semi-dynamic problem on even cycles is solvable by an $O(\log n)$-competitive deterministic algorithm).

Our Techniques. For the bipartite (2-coloring) problem, our algorithm maintains a partition of the vertices into connected components. Since there are 2 colors, each connected component has exactly two legal colorings. When two components merge due to the arrival of a monochromatic edge, the algorithm must choose between the two legal colorings for that new component, where each coloring implies recoloring one of the joined components. There are two natural heuristics for choosing which component to recolor. The greedy approach is to recolor the lighter component; another approach, with an eye to the offline solution (which, knowing all future edges, recolors every vertex at most once), is to recolor so as to minimize the change from the initial coloring of the graph (as measured in weighted Hamming distance). Unfortunately, it can be shown that each of these algorithms has $\Omega(n)$ competitive ratio. However, perhaps surprisingly, by a balanced combination of these two noncompetitive approaches, we obtain an $O(\log n)$-competitive deterministic algorithm. The competitive ratio is bounded using amortized analysis.

[1] We use the notation $[k] \stackrel{\text{def}}{=} \{1, 2, \ldots, k\}$.

For $(\Delta+1)$-coloring, key observation is that vertices that are recolored by the optimal algorithm must be incident on all edges which are monochromatic by their initial coloring. Therefore, our algorithm maintains a vertex cover of the edges which are monochromatic by their initial coloring. In our algorithm, upon the arrival of an edge, only vertices in that vertex cover are allowed to change their color. This way, we limit the set of vertices that change their color. Coupling this with an upper bound on the total number of recolorings which a vertex undergoes (using Δ), we can prove a bound on the competitive ratio. Specifically, we maintain a 2-approximate weighted vertex cover using the primal-dual (local ratio) 2-competitive algorithm; when a monochromatic edge arrives, an appropriate vertex from the vertex cover is recolored by a color not taken by any of its neighbors. In the deterministic case, which achieves $O(\Delta)$-competitiveness, the new color is an arbitrary available color, and in the randomized case, the new color is a random (uniformly chosen) available color. In the latter case, some subtle probabilistic analysis shows $O(\log \Delta)$-competitiveness.

Related Work. We do not know of previous work on *competitive recoloring* of vertices: some considered recoloring, some considered competitive coloring, but this is the first work to consider both simultaneously. We review some relevant results below.

Competitive coloring. Let us start with competitive coloring. Work on online vertex coloring, starting with the paper of Lovász et al. [13], assume that vertices arrive one by one, each vertex with all its incident edges. When a vertex arrives it must be assigned a color irrevocably, maintaining a legal vertex coloring at all times. The goal is to minimize the number of colors used by the algorithm. It is known that the competitive ratio in this case is $\Theta(n/\log n)$ [9, 10].

Dynamic algorithms for recoloring. Recoloring has also been considered in the dynamic data structures setting, in which one seeks to maintain a proper coloring while minimizing the number of recolorings per vertex/edge update (arrival or departure); see, e.g., [8, 5, 15, 12]. This model differs from ours in that we do not measure costs w.r.t. the number of steps, but w.r.t. an optimal recoloring algorithm OPT for the input sequence. In particular, when $\text{OPT} \ll T$, where T is the length of the input sequence, we remain competitive against OPT (rather than T); however, in dynamic recoloring (or recoloring with recourse), a constant number of recolorings per edge arrival results in $\Omega(T)$ cost.

For general graphs, coloring a graph using a competitively-small palette (w.r.t. its chromatic number) is NP-hard; thus, restricting the set of graphs or their chromatic number is necessary for polynomial running time. This is the case for the work of Kashyop et al. [12] (who focus on bipartite graphs, max-degree bounded graphs, and graphs with bounded arboricity), and Bosek et al. [8] (who focus on interval graphs). Indeed, our work also focuses on coloring problems which can be tackled in polynomial time, namely 2-coloring and $(\Delta+1)$-coloring. However, one can also consider coloring in general graphs, using an (exponential time) oracle for graph coloring. This is the case for the works of Barba et al. [5] and Solomon and Wein [15]. The best current result, due to [15], is a deterministic algorithm that maintains a graph which is $O(\frac{\log^3 n}{d})$-competitive with respect to the number of colors (against the graph's chromatic number), while using $O(d)$ amortized recolorings per update, where d is a free parameter (allowing randomization improves this result slightly).

Dynamic graph partitioning. A problem closely related to online disengagement is "dynamic balanced graph partitioning," introduced by Avin et al. [3, 2]. In this problem vertices are located in finite-capacity clusters (servers), and communication requests arrive online.

Communication between vertices incurs cost unless the vertices are located in the same cluster. Vertices can migrate to other clusters, at a (larger) cost, and the algorithm is required to find a placement of the vertices in clusters at each step. The goal is to minimize cost, and the overall measure is the competitive ratio, possibly with resource augmentation (i.e., assuming that the capacity available to the algorithm is larger than the capacity available to the adversary). Intuitively, this problem is the flip side of disengagement: In partition, requests are to collocate vertices (subject to capacity constraints), whereas in disengagement, requests are to separate them. In [3], the fully-dynamic variant of the partition problem is considered, where collocation requests are temporary: a pair of vertices may be collocated by a request and later separated. It is shown in [3] that the competitive ratio of deterministic algorithms for the dynamic case is $O(k \log k)$ and $\Omega(k)$, where k is the capacity of a cluster (both bounds allow for resource augmentation). Recently, the semi-dynamic variant of the partition problem was considered, in which it is guaranteed that there exists a feasible placement of the vertices to clusters so that all communication is local (i.e., occurs within a cluster). In [11], tight bounds on the competitive ratios of deterministic and randomized algorithms for semi-dynamic partition are given: $\Theta(\ell \log W)$ and $\Theta(\log \ell + \log W)$, respectively, where ℓ is the number of servers and W is the server capacity .

Paper organization. The remainder of this paper is organized as follows. In Section 2 we formalize the model and introduce some notation. In Section 3 we study the bipartite case. In Section 4 we study $(\Delta + 1)$-disengagement. In Section 5 we consider fully-dynamic disengagement. We conclude in Section 6 with a few interesting open problems.

2 Model and Notation

Preliminaries. Given a natural number k, we use $[k]$ to denote $\{1, 2, \ldots, k\}$. In this paper we are concerned with colorings of vertices in graphs. Given an undirected simple graph $G = (V, E)$, a *proper k-coloring* of G is an assignment $c : V \to [k]$ such that $c(u) \neq c(v)$ for all $(u, v) \in E$.

We shall use the following definition extensively.

▶ **Definition 1.** *Let $G = (V, E)$ be a graph, and let $w : V \to \mathbb{R}^+$ be a vertex weight function. Let c, c' be two colorings of a graph G. The* weighted Hamming distance *between c and c', denoted $\delta_H(c, c')$, is defined as follows: $\delta_H(c, c') = \sum_{v\,:\,c(v)\neq c'(v)} w(v)$.*

Problem statement. In this paper, we study the following problem.

Online Disengagement (Vertex Recoloring)

Initial Input:

- A set V of n vertices with weights $w : V \to \mathbb{R}^+$
- The number of colors $k \in \mathbb{N}$
- A k-coloring c_0 of V

Online Input: In each step $i = 1, \ldots, M$, an edge e_i between two vertices of V.

Output: After each step i, a proper k-coloring of the vertices c_i w.r.t edges $\{e_1, \ldots, e_i\}$.

Goal: Minimize the total weight of vertex recolorings, i.e., $\sum_{i=1}^{M} \delta_H(c_{i-1}, c_i)$.

We use $E_i = \{e_1, e_2, ..., e_i\}$ to denote the set of edges that have arrived up to and including the ith step, and we use $G_i = (V, E_i)$ to denote the known graph after step i.

Note that in Online Disengagement, as is the case for any semi-dynamic graph problem, the input sequence length can be assumed to be finite without loss of generality, as there are only $\binom{n}{2}$ possible distinct edges connecting vertices of V.

Special cases. In this 1paperwe consider some special cases of online disengagement. The variants we consider are the following.

- In *Unweighted* Online Disengagement, all vertices have weight 1.
- In *Bipartite* Online Disengagement, we are guaranteed that the input graph is 2-colorable.
- In $(\Delta + 1)$ Online Disengagement, we are guaranteed that the maximum degree of the input graph does not exceed Δ, and the available number of colors is $\Delta + 1$.

Fully-dynamic disengagement. The problem, as stated above, is called *semi dynamic*, in the sense that edges only arrive and never leave. However, in some cases, the presence of edges restricting the solution may be temporary. In the *fully-dynamic* online disengagement variant, edges may leave too. The input and the output to the problem, as well as the cost measure, are the same, but the feasibility requirement is different: The coloring output by the algorithm after each step need be a proper coloring for $G_i = (V, E'_i)$, where $E'_i \subseteq E_i$. We discuss several different definitions of E'_i in Section 5.

3 Bipartite Disengagement

In this section we consider disengagement for bipartite graphs and $k = 2$. In other words, we are promised that the final graph G (and hence every intermediate graph) is 2-colorable, and the requirement is to find, at each step, a legal 2-coloring, while minimizing the overall cost.

Note that this case is stricter than $(\Delta + 1)$-disengagement, since the maximum degree Δ is typically large (the case $\Delta = 1$ is trivial). Indeed, we show in this section that the competitive ratio in this case is $\Theta(\log n)$. We start with an $O(\log n)$-competitive deterministic algorithm for the weighted case, and then prove an $\Omega(\log n)$ lower bound on the competitive ratio of any (randomized) algorithm that holds even in the unweighted case.

3.1 Simple approaches

Any algorithm for 2-coloring maintains, throughout its execution, the partition of the nodes into connected components. Since there are only 2 colors, each connected component has two possible proper colorings. Whenever two components are joined by a new edge, if their colorings agree (i.e. the two ends of the arriving edge are colored differently), the algorithm may output the previous coloring unaltered. Otherwise, when the edge is monochromatic, the algorithm must decide which of the two colorings is adopted by the newly created component: each coloring implies recoloring all nodes in one of the components being joined. There are two natural approaches one can consider. One approach we call "greedy" is to recolor the component of the smaller weight; another approach we call "conservative" is to choose the colorings which is closer to the initial coloring. Both approaches are not competitive, as we show below. For convenience, we refer to the two colors as red and blue.

The Greedy algorithm. First, consider the algorithm that always flips the color of the smaller component (weight-wise). Consider an input sequence of a connected component in the form of a double star:

1. Create an edge between two arbitrary red nodes. The node that stays red becomes the *red hub*, and the other one becomes the *blue hub*.

2. Do until there are no isolated nodes:
   a. Let v be some isolated node.
   b. Create a monochromatic edge between v and its matching hub.

Every isolated node is a component of size 1. When it is connected via an edge to the component of the hubs (which is at least of size 2) the algorithm flips its color. In fact, the online algorithm flips the color of every node in the graph except for the red hub (paying a cost of $n-1$), while the optimal algorithm only chooses the other coloring for the two hubs, paying a cost of 1. We conclude that the competitive ratio of the greedy algorithm is $\Omega(n)$.

The Conservative algorithm. Consider now the algorithm which always prefers the coloring that is closer (i.e, smaller Hamming distance) to the initial coloring. Assume w.l.o.g. that initially, at least half of the nodes are red. Now, we subject it to the following input sequence, which creates a connected component in the form of a chain:

1. Create an edge between two red nodes
2. Do until there are no isolated red nodes:
   a. Let v be some red, isolated node.
   b. If one of the chain end-nodes u is red, create an edge (u, v).
   c. Otherwise, create an edge between v and any of the chain end-nodes

The chain grows by one node each iteration; in half of the iterations is has an equal number of blue and red nodes. When that happens, the following holds:

1. One of the chain end-nodes is red (since the chain is of even length)
2. Flipping the colors of all of the nodes in the chain does not increase the distance from the initial coloring

Therefore, in every even iteration, a new edge connects two red nodes, to which the algorithm responds by flipping the color of every node in the chain. Overall, the algorithm pays a cost of $\Omega(n^2)$, while an optimal algorithm colors at most half of the nodes exactly once, or a cost of $O(n)$. It follows that the competitive ratio of the conservative algorithm is $\Omega(n)$ as well.

3.2 A Competitive Algorithm

While each approach discussed in Section 3.1 resulted in $\Omega(n)$ competitive ratio, the following combination of them is $O(\log n)$-competitive: If one of the two possible coloring is such that at least two-thirds of the weighted nodes will have their original color c_0 (and therefore that coloring has less than half the Hamming distance to the original coloring than the alternative), that alternative is chosen by the algorithm. Otherwise, no coloring has a significantly smaller Hamming distance, and in this case the algorithm prefers the "cheaper" coloring, i.e., the algorithm recolors the component with the smaller weight.

Pseudocode of the algorithm to be executed upon the arrival of a new edge e_i is given in Algorithm 1. For a subset of nodes V', we use $c{\restriction}_{V'}$ to denote the restriction of the coloring c to the set of nodes V'. For convenience, we write $\delta(c)$ as a shorthand for $\delta_H(c, c_0)$. We also use $\delta(c{\restriction}_{V'})$ to refer to $\delta_H(c{\restriction}_{V'}, c_0{\restriction}_{V'})$, i.e. the weighted Hamming distance between the coloring c and the initial coloring c_0 restricted to the set of nodes V'.

We consider the partition of V into connected components. Let $\mathcal{P}_i$ be the set of connected components after the arrival of e_i, and define $\mathcal{P}_0 = \{\{v\} \mid v \in V\}$. Note that in the bipartite case, the color of one node determines the coloring of all nodes in its connected component. Therefore, if e_i is monochromatic upon arrival, it necessarily connects two connected components $S_1, S_2 \in \mathcal{P}_{i-1}$ into a new component S (cf. line 5).

We now analyze the algorithm. Specifically, we prove the following theorem.

Algorithm 1 Recoloring for bipartite graphs, invoked upon arrival of edge $e_i = (u, v)$.

if $c_{i-1}(u) \neq c_{i-1}(v)$ **then**
  $c_i := c_{i-1}$
  return *// no recoloring*
end if *// otherwise, u and v belong in different components*
Let S_1, S_2 be the components of u and v in G_{i-1}, and let S be their common component in G_i
Let $w(S_i)$ be the sum of the weights of the nodes in the set S_i
Define colorings γ_1 and γ_2 by flipping the colors of components S_1 and S_2, respectively, i.e., for all $z \in V$:

$$\gamma_1(z) = \begin{cases} c_{i-1}(z), & \text{if } z \notin S_1 \\ 3 - c_{i-1}(z), & \text{if } z \in S_1 \end{cases} \quad \text{and} \quad \gamma_2(z) = \begin{cases} c_{i-1}(z), & \text{if } z \notin S_2 \\ 3 - c_{i-1}(z), & \text{if } z \in S_2 \end{cases}$$

if $\delta(\gamma_1 \restriction_S) \geq 2\delta(\gamma_2 \restriction_S)$ **then**
  $c_i := \gamma_2$
else if $\delta(\gamma_2 \restriction_S) \geq 2\delta(\gamma_1 \restriction_S)$ **then**
  $c_i \leftarrow \gamma_1$
else if $w(S_1) \geq w(S_2)$ **then**
  $c_i \leftarrow \gamma_2$
else
  $c_i \leftarrow \gamma_1$
end if

▶ **Theorem 2.** *Algorithm 1 is $O(\log n)$-competitive.*

Fix an input sequence $\{e_i\}_i$ and an optimal coloring c^*, i.e., $\delta(c^*)$ is minimal among all legal colorings of the final graph G. Denote $r := \delta(c^*)$, and let ALG denote the cost of Algorithm 1 on the given input sequence. We prove the theorem by showing that $\text{ALG} \leq O(r \log r)$.

We need some additional terminology.

- Given a connected component S and a coloring c, we say that S is *well colored* by c if $c \restriction_S = c^* \restriction_S$ is consistent with c^*. Otherwise, we say that S is *badly colored*.
- Let $R \subseteq V$ be the subset of nodes v such that $c^*(v) \neq c_0(v)$. By definitions, $w(R) = r$.

The following claim says that in every badly colored component, a significant fraction of the weight is contributed by nodes recolored by the optimum.

▶ **Proposition 3.** *For all i and all $S \in \mathcal{P}_i$, if S is badly colored then $w(S) < 3w(S \cap R)$.*

Proof. We prove the claim by induction on i, the number of edges inserted. For $i = 0$ we have that $\mathcal{P}_0$ is a collection of singletons. Let $S = \{v\} \in \mathcal{P}_0$. If S is badly colored then by definitions, $v \in R$, and hence $S \cap R = S$, proving the base case.

Assume now that the claim holds for all components in $\mathcal{P}_{i-1}$. It suffices to show that if a new component is created by the arrival of edge $e_i = (v_1, v_2)$, the claim holds for that component. So assume that S is created by merging $S_1, S_2 \in \mathcal{P}_{i-1}$, where $v_1 \in S_1$ and $v_2 \in S_2$.

If $c_{i-1}(v_1) \neq c_{i-1}(v_2)$, then $c_i = c_{i-1}$, and thus the component S is badly colored iff the components S_1, S_2 are both badly-colored (note that it cannot be that only one is badly colored, since that would imply the infeasibility of c^*). Using the induction hypothesis, if S is badly colored then

$$w(S) = w(S_1) + w(S_2) < 3(w(S_1 \cap R) + w(S_2 \cap R)) = 3w(S \cap R) \ ,$$

completing the proof for the case that $c_{i-1}(v_1) \neq c_{i-1}(v_2)$.

Assume henceforth that $c_{i-1}(v_1) = c_{i-1}(v_2)$. When the component S is formed, the algorithm considers the two colorings γ_1 and γ_2 for S, where γ_1 and γ_2 are formed from c_{i-1} by recoloring S_1 and S_2, respectively. Thus, the colorings of S under γ_1 and γ_2 are negations of one another. One of these colorings, wlog γ_1, is consistent with c^*, and thus $\delta(\gamma_1 \restriction_S) = w(S \cap R)$. Since γ_2 is the negation of γ_1, it holds that $\delta(\gamma_2 \restriction_S) = w(S) - w(S \cap R)$.

If the component S is badly colored, it must be that γ_2 is chosen. For this to happen, it must hold that $\delta(\gamma_2 \restriction_S) < 2\delta(\gamma_1 \restriction_S)$. Simplifying, we get $w(S) < 3w(S \cap R)$, completing the proof. ◀

▶ **Corollary 4.** *If a component has weight larger than $3r$, then the component is well-colored.*

Proof. By Proposition 3 and the fact that for any component S, $w(S \cap R) \leq r$. ◀

▶ **Lemma 5.** *The weight of nodes recolored by Algorithm 1 throughout the execution is at most $3r$.*

Proof. Clearly, the total weight of nodes in R which change color during the algorithm is at most $w(R) = r$. It remains to bound the weight of nodes that change color in $V \setminus R$; denote the set of those nodes by U.

Let $\mathcal{B} \subseteq 2^V$ be the collection of subsets of V which were badly-colored components in the algorithm at some point. We claim that $\mathcal{B}$ is a laminar collection – that is, for every two components $S_1, S_2 \in \mathcal{B}$ it holds that either $S_1 \subseteq S_2$, $S_2 \subseteq S_1$ or $S_1 \cap S_2 = \emptyset$. Indeed, $\mathcal{B}$ is laminar since it is contained in the collection of all connected components which are formed in the algorithm, which is itself laminar.

Since $\mathcal{B}$ is a laminar collection, there exists a subcollection $\mathcal{B}' \subseteq \mathcal{B}$ of disjoint components such that $\bigcup_{S \in \mathcal{B}} S = \bigcup_{S \in \mathcal{B}'} S$.

Consider any node $v \in U$. The coloring c^* is consistent with c_0 on this node v; thus, for this node to change color during the algorithm, it must be part of some badly-colored component at some point during the algorithm. This implies that $U \subseteq \bigcup_{S \in \mathcal{B}} S = \bigcup_{S \in \mathcal{B}'}$.

$$\begin{aligned} w(U) = \sum_{S \in \mathcal{B}'} w(U \cap S) &\leq \sum_{S \in \mathcal{B}'} w((V \setminus R) \cap S) \\ &= \sum_{S \in \mathcal{B}'} w(S \setminus R) \\ &\leq 2 \sum_{S \in \mathcal{B}'} w(S \cap R) && \text{by Proposition 3} \\ &\leq 2w(R) \;=\; 2r \;. \end{aligned}$$ ◀

Next, we define a potential function ϕ such that $\phi(i) = 6\delta(c_i)$. Note that $\phi(0) = 0$, and that ϕ is nonnegative. Following the conventional notation, denote $\Delta\phi_i = \phi(i) - \phi(i-1)$ for every $i > 0$.

For every $i \in \mathbb{N}$, let ALG_i be the cost incurred by the algorithm in step i, i.e., $\delta_H(c_i, c_{i-1})$. Define

$$I^+ \stackrel{\text{def}}{=} \{i \mid \text{ALG}_i + \Delta\phi_i > 0\} \;.$$

Then we have

$$\text{ALG} \;=\; \sum_i \text{ALG}_i \;\leq\; \sum_i (\text{ALG}_i + \Delta\phi_i) \;\leq\; \sum_{i \in I^+} (\text{ALG}_i + \Delta\phi_i) \;\leq\; \sum_{i \in I^+} 7\text{ALG}_i \;, \tag{1}$$

where the last inequality uses the fact that changing the coloring of nodes of total weight s increases the coloring's weighted Hamming distance from c_0 by at most s, and thus increases ϕ by at most $6s$.

▶ **Proposition 6.** *If $v \in V$ is recolored in step $i \in I^+$, then the weight of the connected component of v grows by a factor of at least $\frac{5}{4}$ in step i. That is, denoting by S, S' the old and new components of v respectively, it holds that $w(S') \geq \frac{5}{4} w(S)$.*

Proof. Node v changes color when some components $S_1, S_2 \in \mathcal{P}_{i-1}$ are merged to form $S \in \mathcal{P}_i$, and one of these components, wlog S_2, changes color, where $v \in S_2$. We now must show that $w(S) \geq \frac{5}{4} w(S_2)$. Denote by γ_1 and γ_2 the colorings formed from c_{i-1} by recoloring S_1 and S_2 respectively; since S_2 is recolored, the algorithm chose γ_2.

If γ_2 is chosen in line 13 of Algorithm 1, then trivially $w(S) \geq 2w(S_2) \geq \frac{5}{4} w(S_2)$ and the proof is complete.

Otherwise, the algorithm chose γ_2 in line 9 because $\delta(\gamma_1 \restriction_S) \geq 2\delta(\gamma_2 \restriction_S)$. Let us denote $s_1 = w(S_1)$, $s_2 = w(S_2)$, $x_1 = \delta(c_{i-1} \restriction_{S_1})$ and $x_2 = \delta(c_{i-1} \restriction_{S_2})$. It holds that $\delta(\gamma_1 \restriction_S) = s_1 - x_1 + x_2$ and $\delta(\gamma_2 \restriction_S) = s_2 - x_2 + x_1$. Thus,

$$s_1 + x_2 \geq s_1 - x_1 + x_2 \geq 2(s_2 - x_2 + x_1) \geq 2(s_2 - x_2) \ ,$$

and therefore $s_1 \geq 2s_2 - 3x_2$. Adding s_2 to both sides, we have that

$$s_1 + s_2 \geq 3(s_2 - x_2) \ . \tag{2}$$

Now, recall that $i \in I^+$, and thus

$$0 \ \leq \ \text{ALG}_i + \Delta\phi_i \ = \ s_2 + 6((s_2 - x_2) - x_2) \ = \ 7s_2 - 12x_2 \ . \tag{3}$$

Eq. (3) implies that $x_2 \leq \frac{7}{12} s_2$. Plugging into (2), we get $w(S) = s_1 + s_2 \geq 3s_2 - 3x_2 \geq 3s_2 - \frac{7}{4} s_2 = \frac{5}{4} s_2 = \frac{5}{4} w(S_2)$ which completes the proof of the proposition. ◀

Proof of Theorem 2. By Eq. (1), it is enough to bound $7 \sum_{i \in I^+} \text{ALG}_i$. Consider any step i in which some component $S \in \mathcal{P}_{i-1}$ is recolored, upon being connected to a second component in $\mathcal{P}_{i-1}$. Consider the subset $W \stackrel{\text{def}}{=} \left\{ u \in S \mid w(u) < \frac{w(S)}{2n} \right\}$. It holds that $w(W) \leq n \cdot \frac{w(S)}{2n} = \frac{w(S)}{2}$, and thus $w(S) \leq 2w(S \setminus W)$. Therefore,

$$\text{ALG}_i \ = \ w(S) \ \leq \ 2w\left(\left\{ u \in S \ \mid \ w(u) \geq \frac{w(S)}{2n} \right\} \right) \ . \tag{4}$$

Plugging Eq. (4) into Eq. (1), and denoting by $S_i \in \mathcal{P}_{i-1}$ the component that was recolored in step i, it thus remains only to bound the term

$$14 \sum_{i \in I^+} w\left(\left\{ u \in S_i \ \mid \ w(u) \geq \frac{w(S_i)}{2n} \right\} \right) \ . \tag{5}$$

Using Lemma 5, and denoting by U the set of nodes recolored by the algorithm, we know that $w(U) \leq 3r$. Consider a node $u \in U$: each time the node u is recolored in a step from I^+, the weight of the component containing u grows by a factor of at least $\frac{5}{4}$ (by Proposition 6). Thus, each node can be recolored in steps from I^+ at most $O(\log n)$ times before the weight of u's component exceeds $2n \cdot w(u)$. This implies that the term in Eq. (5) can be bounded by $O(\log n) \cdot w(U) = O(\log n) \cdot r$, and thus $\text{ALG} \leq O(\log n) \cdot r$, completing the proof. ◀

3.3 A Lower Bound

We present a general lower bound in the unweighted case. We note that a similar argument is used in [12] by Kashyop et al., where it is shown in the context of data structures that any deterministic algorithm that maintains a 2-coloring must perform $\Omega(n \log n)$ recolorings for the worst-case $O(n)$ edge insertions.

▶ **Theorem 7.** *The competitive ratio of any randomized algorithm for recoloring bipartite graphs is* $\Omega(\log(n))$.

Let $A(I)$ be the cost of algorithm A on an instance (input sequence) I. According to Yao's principle, it suffices to show an instance distribution D such that the expected cost of every deterministic algorithm A is $E[A(I)] = \Omega(\log n)$, where the expectation is for instances chosen by D. In the proof below we construct such a distribution.

Proof. Assume w.l.o.g. that n is a power of 2 (otherwise, we work only with $2^{\lfloor \log n \rfloor}$ nodes, leaving the others isolated). We construct an input sequence in $\log n$ phases, while maintaining the following invariant:

> After each phase h: (i) there are $n/2^h$ connected components, and (ii)each connected component is a chain of 2^h nodes.

Clearly, the invariant holds before the execution begins, when there are n isolated nodes. Note that we allow for any initial coloring.

In each phase h, for $h = 1, \ldots, \log n$, we connect segments in pairs by introducing $n/2^h$ edges: each edge connects *random endpoints* of two segments (this is the only randomization we use). This obviously maintains the invariant after phase h is completed.

Consider phase h for $h > 1$. The merging segments are of even length 2^{h-1} each, and hence each segment has exactly one endpoint of each color. It follows that by construction, each new edge is monochromatic with probability $1/2$. Therefore the expected cost incurred in phase $h > 1$ for any deterministic algorithm is

$$\frac{n}{2^h} \cdot \frac{1}{2} \cdot 2^{h-1} = \frac{n}{4} \ ,$$

because in phase h there are $n/2^h$ merges, and each merge has expected cost $\frac{1}{2} \cdot 2^{h-1}$. In summary, the cost of any deterministic algorithm on a random instance defined as above, over all phases, is at least $(\log n - 1) \cdot n/4 = \Theta(n \log n)$ (the cost of phase 1 depends on the initial coloring). On the other hand, the optimal cost for any n-node graph is never more than n: every node needs to be colored at most once, according to the final graph. The result follows. ◀

4 $\Delta + 1$ Disengagement

In this section we consider $(\Delta + 1)$-coloring, where Δ is an upper bound on the number of neighbors a node may have. We show that in this case, the competitive ratio of deterministic disengagement is $\Theta(\Delta)$ and that the randomized competitive ratio is $\Theta(\log \Delta)$.

4.1 Algorithms

We now present our algorithms for the $\Delta + 1$ disengagement problem. Algorithm 2 is used in both the deterministic and randomized versions: The only difference is the implementation of the "recolor" subroutine it invokes (Algorithm 3 and Algorithm 4). To see how the algorithm works, let us define an auxiliary graph $G'_i = (V, E'_i)$ as follows:

$$(u, v) \in E'_i \iff (u, v) \in E_i \text{ and } c_0(u) = c_0(v) \ ,$$

i.e., the auxiliary graph G'_i includes only edges that connect nodes with the same initial color. The underlying idea of Algorithm 2 is to maintain a small-weight vertex cover of G', denoted C, and apply recoloring only to nodes in C. (It turns out that there is no need to remember

Algorithm 2 $\Delta + 1$ disengagement: Upon arrival of edge (u, v) in step i.

1: **if** $c_{i-1}(u) \neq c_{i-1}(v)$ **then**
2: **return** // $c_i = c_{i-1}$, *no recoloring*
3: **else if** $|\{u, v\} \cap C| = 1$ **then**
4: let $x \in \{u, v\}$ be the node in C; recolor(x)
5: **else if** $|\{u, v\} \cap C| = 2$ **then**
6: let $x \in \{u, v\}$ be the node with the higher degree; recolor(x) // *break ties arbitrarily*
7: **else if** $\{u, v\} \cap C = \emptyset$ **then**
8: $w_i(u) \leftarrow w_{i-1}(u) - \min(w_{i-1}(u), w_{i-1}(v))$ // $w_0(v) = w(v)$ *for all* $v \in V$
9: $w_i(v) \leftarrow w_{i-1}(u) - \min(w_{i-1}(u), w_{i-1}(v))$
10: **if** $w_i(u) = 0$ **then**
11: $C \leftarrow C \cup \{u\}$; $x \leftarrow u$
12: **end if**
13: **if** $w_i(v) = 0$ **then**
14: $C \leftarrow C \cup \{v\}$; $x \leftarrow v$
15: **end if**
16: recolor(x)
17: **end if**

the initial coloring.) For a deterministic algorithm, we recolor using the procedure given in Algorithm 3: change the node's color to the first available color, where a color is said to be available if it is not taken by any neighbor. For a randomized algorithm, we choose uniformly at random among the available colors (Algorithm 4).

To maintain a light vertex cover, we use the classical 2-approximation algorithm of Bar-Yehuda and Even [4] (we can use any other algorithm which processes edges one at a time). Whenever an uncovered edge is considered, the residual weights of its endpoints are reduced by the same amount so that one of them reaches zero. The node with residual weight 0 (possibly both) is then added to C.

▶ **Theorem 8.** *Algorithm 2 with Algorithm 3 is a deterministic algorithm for* $\Delta + 1$ *disengagement with competitive ratio* $O(\Delta)$*. Algorithm 2 with Algorithm 4 is a randomized algorithm for* $\Delta + 1$ *disengagement with expected competitive ratio* $O(\log \Delta)$*.*

We first analyze the general framework of Algorithm 2.

▶ **Lemma 9.** *After every step,* C *is a vertex cover of* G'*. Moreover,* $w(C)$ *is at most twice the weight of any vertex cover of* G'*.*

Proof. We first argue that C is a vertex cover of G'. Let $e_i = (u, v) \in E'$. We consider two cases. If e_i is monochromatic upon arrival, then Algorithm 2 makes sure that if none of its endpoints are in C, then at least one of them enters C (lines 7-17), so e_i is covered by C in this case. If $c_i(u) \neq c_0(u)$, then node u was necessarily recolored at some point in the past. However, since Algorithm 2 recolors only nodes in C, we must have $u \in C$, so e_i is covered by C in this case too. Finally, the approximation bound of $w(C)$ follows from [4]. ◀

Algorithm 3 recolor(u): deterministically recolor node u with the first available color.

1: Let $S = \{c(v) \mid (u, v) \in E\}$
2: Let $c \in \{1, \ldots, \Delta + 1\} \setminus S$ // *choose arbitrarily*
3: $c(u) \leftarrow c$

Algorithm 4 recolor(u): randomly recolor node u with an available color.

1: Let $S = \{c(v) \mid (u, v) \in E\}$
2: Let $c \in_R \{1, \ldots, \Delta + 1\} \setminus S$ // *choose randomly*
3: $c(u) \leftarrow c$

▶ **Lemma 10.** *Every algorithm pays a cost of at least $w(C)/2$.*

Proof. Consider any solution to the given input. The edges in E' are monochromatic by the initial coloring, so every disengagement algorithm has to recolor at least one endpoint of every edge in E' at least once. Therefore, the set of nodes recolored by any solution is a vertex cover of G'. The result follows now from Lemma 9. ◀

We now consider the way recoloring is done. First, the deterministic version.

▶ **Lemma 11.** *Algorithm 2 with Algorithm 3 pays at most $\Delta \cdot w(C)$.*

Proof. By the code, Algorithm 2 recolors only nodes in C. Observe that a node may be recolored only when a new incident edge is introduced. Since the maximum degree of a node is Δ, the result follows. ◀

If we use randomized recoloring, we have the following. Let $H_\Delta = 1 + \frac{1}{2} + \cdots + \frac{1}{\Delta}$.

▶ **Lemma 12.** *The expected cost of Algorithm 2 with Algorithm 4 is at most $H_\Delta \cdot w(C)$*

▶ **Proposition 13.** *Consider any two distinct nonadjacent nodes $u, v \in C$. At any iteration, it holds that*

$$\Pr(c(u) = c(v)) \;\leq\; \max\left\{ \frac{1}{\Delta + 1 - \deg(u)}, \frac{1}{\Delta + 1 - \deg(v)} \right\} .$$

Proof. Let $w \in \{u, v\}$ be the node that changed its color last (since both $u, v \in C$, they both changed colors so w is always defined). It holds that:

$$\Pr(c(u)=c(v)) \;=\; \Pr(w=v)\cdot\Pr(c(u)=c(v) \mid w=v) + \Pr(w=u)\cdot\Pr(c(u)=c(v) \mid w=u) .$$

Let A_v denote the event that $w = v$, and assume that A_v holds. Let t' denote the last iteration in which v changed its color, and let $\deg'(v)$ be its degree at time t'. Then v chose its color uniformly at random from a set of available colors S whose size is at least

$$(\Delta + 1 - \deg'(v)) \;\geq\; (\Delta + 1 - \deg(v)) \;\geq\; \min\{\Delta + 1 - \deg(u), \Delta + 1 - \deg(v)\} .$$

Thus:

$$\begin{aligned}
\Pr(c_u = c_v \mid A_v) &= \sum_{S' \subseteq [\Delta+1]} \sum_{s \in S'} \Pr\left(S = S' \mid A_v\right) \cdot \Pr\left(c_u = c_v = s \mid S = S', A_v\right) \\
&\leq \sum_{S' \subseteq [\Delta+1]} \sum_{s \in S'} \Pr\left(S = S' \mid A_v\right) \cdot \Pr\left(c_u = s \mid S = S', A_v\right) \cdot \underbrace{\Pr\left(c_v = s \mid c_u = s, S = S', A_v\right)}_{=\frac{1}{|S'|}} \\
&= \sum_{S' \subseteq [\Delta+1]} \Pr\left(S = S' \mid A_v\right) \cdot \frac{1}{|S'|} \cdot \underbrace{\left(\sum_{s \in S'} \Pr(c_u = s \mid S = S', A_v) \right)}_{\leq 1} \\
&\leq \sum_{S' \subseteq [\Delta+1]} \Pr\left(S = S' \mid A_v\right) \cdot \max\left\{ \frac{1}{\Delta + 1 - \deg(u)} \;,\; \frac{1}{\Delta + 1 - \deg(v)} \right\} \\
&= \max\left\{ \frac{1}{\Delta + 1 - \deg(u)} \;,\; \frac{1}{\Delta + 1 - \deg(v)} \right\} .
\end{aligned}$$

◀

▶ **Proposition 14.** *Consider any two nonadjacent nodes $v \in C$ and $u \notin C$. At any iteration, it holds that*

$$\Pr(c(u) = c(v)) \leq \frac{1}{\Delta + 1 - \deg(v)} .$$

Proof. The proof is similar to that of Proposition 13. Observe the last iteration in which v had changed its color, and denote its degree at that iteration as $\deg'(v)$. At that time, v chose a random color from a set S of available colors, such that $|S| \geq \Delta+1-\deg'(v) \geq \Delta+1-\deg(v)$. Additionally, since $u \notin C$, it has its initial coloring $c(u) = c_0(u)$. Therefore:

$$\begin{aligned}\Pr(c_u = c_v) &\leq \sum_{S' \subseteq [\Delta+1]} \Pr(S = S') \cdot \Pr(c_v = c_u \mid S = S') \\ &\leq \sum_{S' \subseteq [\Delta+1]} \Pr(S = S') \cdot \frac{1}{|S'|} \\ &\leq \frac{1}{\Delta + 1 - \deg(v)} \sum_{S' \subseteq [\Delta+1]} \Pr(S = S') \;=\; \frac{1}{\Delta + 1 - \deg(v)} \;,\end{aligned}$$

where the second inequality is due to the fact that $\Pr(c_v = c_u \mid S = S')$ equals 0 if $c(u) \notin S'$ and equals $\frac{1}{|S'|}$ otherwise. ◀

Proof of Lemma 12. Fix the input sequence. Let X be a random variable representing the overall cost of running the algorithm, and let X^v be a random variable representing the cost incurred by recoloring a given node $v \in V$. We bound $E[X^v]$.

Since Algorithm 2 recolors only the nodes in C, consider $v \in C$. Let $e^v_1, \ldots, e^v_{\deg(v)}$ be the subsequence of input edges incident on v. Let X^v_j denote the expected cost of recoloring v due to edge e^v_j. We bound $E[X^v_j]$ as follows. Suppose that v is recolored for the first time when e_{j_0} is input (if none exists, we are trivially done). Then for $j = j_0$ we have $E[X^v_{j_0}] = w(v)$. For $j > j_0$, consider the arrival of $e^v_j = (v, u)$.

- If $u \notin C$, then v changes its color w.p $\leq \frac{1}{\Delta+1-j}$ (according to Proposition 14)
- If $u \in C$ and $j < \deg(u)$, then v does not change its color
- If $u \in C$ and $j \geq \deg(u)$, then v changes its color w.p $\leq \frac{1}{\Delta+1-j}$ (according to Proposition 13)

Therefore, the expected cost incurred by v due to e^v_j is at most $\frac{w(v)}{\Delta+1-j}$.

It follows that the expected cost incurred by the recoloring of node $v \in C$ is at most

$$E[X^v] = E\left[\sum_{j=1}^{\deg(v)} X^v_j\right] \;\leq\; w(v) + \sum_{j=j_0+1}^{\deg(v)} E\left[X^v_j\right] \;\leq\; w(v) + \sum_{j=2}^{\deg(v)} \frac{w(v)}{\Delta+1-j} \;\leq\; w(v) \cdot H_{\deg(v)} \;.$$

We can therefore summarize that the expected cost due to all nodes is at most

$$E[X] \;=\; E\left[\sum_{v \in V} X^v\right] \;=\; E\left[\sum_{v \in C} X^v\right] \;=\; \sum_{v \in C} E\left[X^v\right] \;\leq\; \sum_{v \in C} w(v) \cdot H_{\deg(v)} \;\leq\; w(C) \cdot H_\Delta \;. \blacktriangleleft$$

Proof of Theorem 8. Follows from the lower bound on the optimum cost of Lemma 10, and from the upper bounds on the cost of the deterministic algorithm (Lemma 11), and on the expected cost of the randomized algorithm (Lemma 12). ◀

We note that our deterministic algorithm does not require knowledge of Δ, but the randomized one does.

4.2 Lower Bounds for $(\Delta + 1)$-Recoloring

We now state lower bounds on the competitive ratios of deterministic and randomized algorithms for $(\Delta + 1)$-recoloring. We prove the lower bounds in unweighted instances, i.e., the weight of each node is one. We start with a deterministic lower bound.

▶ **Theorem 15.** *The competitive ratio of any deterministic algorithm solving* $(\Delta+1)$*-recoloring is* $\Omega(\Delta)$*, for any initial coloring.*

We need the following lemma.

▶ **Lemma 16.** *The optimal algorithm's cost after the* i*-th step is at most the number of non-isolated nodes in* $G_i = (V, E_i)$*.*

Proof. Since edges are constantly added to the graph G_i, any coloring that is proper for G_i is also proper for G_j, where $j \leq i$. The optimal offline algorithm can color G_i greedily using $\Delta + 1$ colors, and use this coloring until the i-th step. Since every node is recolored at most one time, and the optimal algorithm might only recolor the non-isolated nodes, its cost is at most the number of such nodes. ◀

Proof of Theorem 15. Let a deterministic algorithm be given. We construct an input sequence in phases as follows. First we choose a set of some $\Delta + 2$ nodes, denoted V'. Note that since $|V'| > \Delta + 1$, according to the pigeonhole principle, there must be at least two nodes $u, v \in V'$ with the same color. We then proceed in phases, where each phase is described as follows.

1. Do until $\exists v \in V'$ with $\deg(v) = \Delta$:
   a. Select two nodes $u_1, u_2 \in V'$ s.t. $c(u_1) = c(u_2)$
   b. Add edge (u_1, u_2)
2. Let $V_\Delta = \{v \in V' \mid \deg(v) = \Delta\}$ *(note that* $1 \leq |V_\Delta| \leq 2$*)*
3. Let $V_0 \subseteq V$ be a set of $|V_\Delta|$ isolated nodes
4. $V' \leftarrow V_0 \cup V' \setminus V_\Delta$

Note that the number of phases can be as large as we wish, since it is bounded only by the number of nodes, regardless of k and Δ. Consider the cost of the online algorithm. Every new edge is monochromatic, so it pays a cost of 1 for each new edge. After s phases, at least s nodes have left V', each with a degree of Δ. It follows that the cost of the online algorithm for s phases is at least $s \cdot \Delta/2$ (since every edge could be counted twice).

On the other hand, by Lemma 16, the optimal cost is no more than the number of non-isolated nodes. This number is bounded by the number of nodes that ever were in V', and hence, in s phases, it is at most $2s + \Delta + 2$: at most $2s$ nodes were removed from V', and at most $\Delta + 2$ nodes are in V' after s phases. It follows that for $s \gg \Delta$ phases, the competitive ratio of any deterministic algorithm is $\Omega(\Delta)$. ◀

Intuitively, in the $\Omega(\Delta)$ lower-bound proof, both Online and Offline always have to pay (a cost of at least 1) when the new edge creates a new connected component (of size 2), since it involves two nodes that still have their initial coloring. However, the Offline algorithm does not have to pay when the edge is incident on a node that Offline had already changed. We now present a lower bound for randomized algorithms.

▶ **Theorem 17.** *The competitive ratio of any randomized algorithm for* $(\Delta + 1)$*-coloring is* $\Omega(\log(\Delta))$*, assuming that in the initial coloring there are at least two nodes of each color.*

Proof of Theorem 17. Let $A(I)$ be the cost of algorithm A on an instance (input sequence) I. According to Yao's principle, if there is an instance distribution, for which the expected cost of every deterministic algorithm A is $E[A(I)] \geq L$, then for every randomized algorithm there exists an instance I such that the algorithm's expected cost on I is at least L. We construct a distribution over input sequences as follows. First we pick a random permutation $\sigma : [\Delta + 1] \to [\Delta + 1]$ of the colors. We then introduce the edges in phases as follows. In the

first phase we pick two nodes $v_0, v_1 \in V$ of color $\sigma(1)$ and connect them with an edge. In each subsequent phase i, $i \geq 2$, we pick a node v_i of color $\sigma(i)$ and connect it to all nodes $v_0, \ldots, v_{i-1}$. Clearly, after phase i, the input edges constitute a clique over $v_0, v_1, \ldots, v_i$. After phase Δ we stop (we can repeat the construction with a fresh set of $\Delta + 1$ isolated nodes).

For the cost analysis, let C_i denote the set of colors used by nodes $v_0, \ldots, v_i$ after phase i. Clearly $|C_i| = i + 1$. In particular, for any deterministic algorithm, there exists at least one color $c_i^* \in C_i \setminus \{\sigma(1), \ldots, \sigma(i)\}$. Consider now the node v_{i+1}, added in phase $i + 1$. Its color is $\sigma(i + 1)$, which is uniformly distributed over $[\Delta + 1] \setminus \{\sigma(1), \ldots, \sigma(i)\}$, and hence $\Pr[\sigma(i + 1) = c_i^*] = \frac{1}{\Delta+1-i}$. It follows that the expected number of monochromatic edges (which is the expected cost of the deterministic algorithm) in phase $i + 1$ is at least $\frac{1}{\Delta+1-i}$. Also by construction, the number of monochromatic edges in the first phase is 1. Therefore, the total expected cost across all phases is

$$E[\text{cost}] \;\geq\; 1 + \sum_{i=1}^{\Delta-1} \frac{1}{\Delta + 1 - i} \;=\; H_\Delta \;=\; O(\log \Delta) \;,$$

where H_n denotes the nth harmonic sum. On the other hand, an optimal algorithm would pay a cost of 1 by recoloring only a single node in the first iteration with the single color that is never used, namely color $\sigma(\Delta + 1)$. ◀

5 Fully-Dynamic Disengagement

In previous sections, we considered the semi-dynamic variant of the disengagement problem, in which every new edge is an additional, permanent constraint. In this section,we consider the fully-dynamic variant of the online disengagement problem (abbreviated FD below), where at every iteration i, the edge constraints may also be deleted (in FD, input sequences may be of unbounded length). It turns out that FD is more difficult than semi-dynamic disengagement. In this section we first discuss various plausible models of FD and show their equivalence, and then show that even a very simple dynamic instance forces an $\Omega(n)$ lower bound on the competitiveness of deterministic algorithms. The latter result is obtained by reduction from Metrical Task Systems.

5.1 Dynamic Models

There are several (yet equivalent) ways to define the fully-dynamic Disengagement problem:

The single edge model (SE): At iteration i upon the arrival of edge $e_i = (u, v)$, the algorithm must make sure that $c_i(u) \neq c_i(v)$, i.e, only the coloring of the last edge must be maintained.

Expiration time model (ET): Every edge arrives with a prescribed expiration time - after which it is deleted.

Edge insertions and deletions model (InD): In this model, at every iteration either an existing edge in the graph is deleted, or an non-existing one appears. The algorithm is required at every iteration to maintain a proper coloring of the graph.

We first argue that the models are essentially equivalent.

▶ **Theorem 18.** *A lower bound on the competitive ratio of (randomized) algorithms under one of the three models of dynamic disengagement, holds under the other two models as well.*

Theorem 18 is proven using the following three lemmas.

▶ **Lemma 19.** *If ρ_1 is a lower bound on the deterministic (or randomized) competitive ratio for the "SE" model, then ρ_1 is a lower bound on the deterministic (respectively, randomized) competitive ratio for the "ET" model.*

Proof. It can be easily shown that any input sequence of the "SE" model is also an input sequence of the "ET" model, with the expiration time of every edge set to 1. Since the lower bound for the special case also holds for the general case, the claim holds. ◀

▶ **Lemma 20.** *If ρ_2 is a lower bound on the deterministic (or randomized) competitive ratio for the "ET" model, then ρ_2 is a lower bound on the deterministic (respectively, randomized) competitive ratio for the "InD" model.*

Proof. It can also be demonstrated that any input sequence of the "ET" model can be represented using the "InD" model. Each time an edge is presented (or expires) in the former model, it is inserted (or deleted) in the latter model. ◀

▶ **Lemma 21.** *If ρ_3 is a lower bound on the deterministic (or randomized) competitive ratio for the "InD" model, then ρ_3 is a lower bound of the deterministic (respectively, randomized) competitive ratio for the "SE" model.*

To prove Lemma 21, we first prove the following lemma:

▶ **Lemma 22.** *Let A be a (possibly randomized) disengagement algorithm in the "SE" model, with a bounded competitive ratio. Then for any input sequence I in the "InD" model, there exists an input sequence I_D in the "SE" model such that with probability 1, A, when run on I_D, outputs a proper coloring of G_i, where $G_i = (V, E_i)$ is the graph in the "InD" model, after iteration i.*

Proof. We construct I_D by repeating the edges of E_i cyclically. Specifically, for each i, I_D contains a sequence of *phases*, where in each phase, all edges of E_i are introduced (in any order). The number of phases depends on A: we claim that for any $\varepsilon > 0$ there exists M_ε such that the probability that A outputs a proper coloring of G_i after M_ε phases is least $1 - \varepsilon$. To prove the claim, suppose, for contradiction, that for some $\varepsilon > 0$, the probability of A outputting a proper coloring of G_i after any number of phases is never more $1 - \varepsilon$. Then, with probability of at least ε, A pays at least 1 in each phase (when a monochromatic edge is inserted). The total expected cost of A is therefore unbounded. On the other hand, the optimal cost is at most $|V|$, contradicting the assumption that A has bounded competitive ratio. ◀

Proof of Lemma 21. Assume, for contradiction, that there exists an algorithm A_d for the "SE" model with a competitive ratio strictly smaller than ρ_3. We construct an algorithm A_s for the "InD" model as follows. Given input $I = \{G_1, G_2, \ldots\}$ (in the "InD" model), A_s runs A_d on input I_D (in the "SE" model) as defined in Lemma 22. According to Lemma 22, since A_d has a bounded competitive ratio, then A_d outputs a solution to E_i w.p. 1. Hence, A_s is well defined.

To analyze the cost, consider iteration i of A_s. Let c_i^m denote the output of A_d after E_i was input to it for m-th time, and let c_i denote the output of A_s in the i-th step.

Let OPT_s denote an optimal solution to I and let OPT_d denote an optimal solution to I_d. Then we have

$$\begin{aligned}
\text{cost}(A_s(I)) &= \sum_{i=1} \delta_H(c_i, c_{i-1}) \\
&\le \sum_{i=1} \sum_{m \ge 1}^{M} \delta_H\left(c_i^m, c_i^{m-1}\right) && \text{by construction} \\
&= \text{cost}(A_d(I_d)) \\
&< \rho_3 \cdot \text{cost}(\text{OPT}_d(I_d)) && \text{by assumption on competitiveness of } A_d \\
&\le \rho_3 \cdot \text{cost}(\text{OPT}_s(I)) && \text{because } \text{OPT}_s(I) \text{ is also a solution to } I_d,
\end{aligned}$$

contradicting the assumption that ρ_3 is a lower bound on the competitiveness of deterministic algorithms for the "InD" model. ◀

We note that FD is at least as hard as the semi-dynamic model.

▶ **Corollary 23.** *If ρ is a lower bound on the deterministic (or randomized) competitive ratio for semi-dynamic disengagement, then ρ is a lower bound of the deterministic (respectively, randomized) competitive ratio for fully-dynamic disengagement.*

Proof. The SD disengagement model can be directly represented by the FD "ET" model, with the expiration time of every edge set to ∞. Hence, the lower bound for the SD case also holds for the "ET" model, and according to Theorem 18, such bound holds for any of the other FD models. ◀

5.2 Full-Dynamic Disengagement and Metrical Task Systems

We now give evidence to the hardness of FD disengagement using a reduction from metrical task systems (MTS). Let us first define the terms.

In the MTS problem [7], a metric space M of n points is given. A server is always located at some point in the metric space. Requests arrive in an online fashion, where the i'th request is a cost function $f_i : M \to \mathbb{R}^+$. The algorithm responds to a request f_i by moving the server from its current location $u \in M$ to a new location $v \in M$, paying the distance between the locations in the metric space (or not moving the server, and paying nothing). Then, the algorithm must pay the cost of the current location of the server, which is $f_i(v)$. We show that FD is as hard as a particular type of an MTS.

▶ **Theorem 24.** *If there exists an $O(f(n))$-competitive algorithm for FD disengagement for every graph of n nodes with 2 colors, then there exists an $O(f(n))$-competitive algorithm for metrical task system on an odd cycle on length n.*

In [7], a lower bound of $\Omega(n)$-competitive was presented for every deterministic algorithm for MTS on every set of n points. Hence we have the following.

▶ **Corollary 25.** *Any deterministic algorithm for FD disengagement with n nodes is $\Omega(n)$-competitive.*

A lower bound of $\Omega(\log n / \log\log n)$-competitiveness for every randomized algorithm for MTS on every set of n points was given in [6]. This implies the following corollary.

▶ **Corollary 26.** *Any randomized algorithm for FD disengagement with n nodes is $\Omega\left(\frac{\log n}{\log\log n}\right)$-competitive.*

Proof of Theorem 24. We assume without loss of generality that the functions in the MTS input are in fact Kronecker delta functions: they are supported on only one point, and the cost of that point is 1. We also assume w.l.o.g. that the FD disengagement algorithm is lazy, i.e., it only recolors endpoints of the current request.

We now describe the reduction. Suppose we are given an instance $\mathcal{M}$ of MTS with an odd-cycle metric space C_1 of n points. We construct an instance $\mathcal{D}$ of FD with n points arranged in a cycle, such that the nodes of C_1 correspond to the n edges of C_2 in the natural way. The intended interpretation of nodes in C_1 is colorings in $\mathcal{D}$, where a node x of C_1 means in C_2 that only the edge corresponding to x is monochromatic (and all other edges in C_2 are bichromatic). The initial coloring in $\mathcal{D}$ is such that the only monochromatic edge in $\mathcal{D}$ is the edge corresponding to the initial position of the server in $\mathcal{M}$. Thereafter, whenever a point $x \in C_1$ is requested in $\mathcal{M}$, the corresponding edge in C_2 is requested in $\mathcal{D}$. To see that the intended interpretation is maintained, consider any algorithm ALG_D for FD. Easy induction shows that after every step, there is exactly one monochromatic edge in the odd cycle C_2: The base case holds by the initial coloring; for the induction step, note that if a non-monochromatic edge is requested, no recoloring takes place. Otherwise, the currently monochromatic edge e is requested, and ALG_D must recolor exactly one endpoint of e. If the clockwise (say) endpoint of e is recolored, then e is no longer monochromatic, and the next edge clockwise from e becomes monochromatic (and similarly for counter-clockwise), and the induction is proved.

Given the reduction, algorithm ALG_M for the MTS problem is obtained from a given algorithm ALG_D for FD by taking the MTS instance $\mathcal{M}$, reducing it online to the FD instance $\mathcal{D}$ as desribed above, running ALG_D on $\mathcal{D}$, and interpreting the responses of ALG_D back in $\mathcal{M}$. That is, whenever ALG_D moves the monochromatic edge clockwise, ALG_M moves the server clockwise, and the same for counter-clockwise. Clearly, we have that ALG_D has the same cost on $\mathcal{D}$ as ALG_M has on $\mathcal{M}$.

Finally, denoting by OPT_M and OPT_D the optimal solutions to $\mathcal{M}$ and $\mathcal{D}$ respectively, note that $\mathrm{OPT}_D \leq 2\,\mathrm{OPT}_M$: OPT_D can move the monochromatic edge whenever OPT_D moves the server, and can move the monochromatic edge clockwise and then immediately counter-clockwise to simulate paying a penalty (at a cost of 2). This completes the proof of Theorem 24. ◀

6 Conclusion

In this paper we have introduced the problem of online disengagement and determined its competitive ratio in the case that conflicts are permanent and either that the final graph is bipartite or that the number of colors is larger than the maximum degree. Many problems remain open.

A major problem we leave open is the competitive ratio in the fully-dynamic case, where conflicts are temporary.

Other natural variants that we leave for future research are the following.

- Explore further the *capacitated disengagement* case. Using the coloring formalism, in this case we assume that each color l comes with prescribed maximal capacity W_l such that in any coloring output by the algorithm, the total number (or, more generally, weight) of nodes assigned to color l does not exceed W_l.
- The *list recoloring* variant represents the case where jobs have both affinities and anti-affinities, i.e., each job is given both a subset of machines on which it may run, and disengagement requests express job separation constraints. Formally, this is modeled by requiring the colorings output by the algorithm to be list colorings. The lists may be fixed or change on-line.

- In *multiple disengagement*, disengagement requests are arbitrary sets of jobs. If the requirement is that at least one of the jobs in a conflict set is not collocated with all others, we have a hypergraph recoloring problem.
- Both Kashyop et al. [12] and Solomon and Wein [15] provide dynamic-coloring algorithms in the case of bounded (or constant) arboricity. Their methods might prove useful for the competitive recoloring case as well.

Note that all versions listed above make sense in either the static or the dynamic variants of the disengagement problem.

Abstract

The well-known Komlós conjecture states that given n vectors in $\mathbb{R}^d$ with Euclidean norm at most one, there always exists a ± 1 coloring such that the ℓ_∞ norm of the signed-sum vector is a constant independent of n and d. We prove this conjecture in a smoothed analysis setting where the vectors are perturbed by adding a small Gaussian noise and when the number of vectors $n = \omega(d \log d)$. The dependence of n on d is the best possible even in a completely random setting.

Our proof relies on a weighted second moment method, where instead of considering uniformly randomly colorings we apply the second moment method on an implicit distribution on colorings obtained by applying the Gram-Schmidt walk algorithm to a suitable set of vectors. The main technical idea is to use various properties of these colorings, including subgaussianity, to control the second moment.

1 Introduction

A central question in discrepancy theory is the following Komlós problem: given vectors $v_1, \ldots, v_n \in \mathbb{R}^d$ with Euclidean length at most 1, i.e., $\|v_i\|_2 \leq 1$ for all $i \in [n]$, find signs $x_i \in \{-1, 1\}$ for $i \in [n]$ to minimize the discrepancy $\|\sum_{i=1}^n x_i v_i\|_\infty$. The long-standing Komlós conjecture says that the discrepancy of any collection of such vectors is $O(1)$, independent of n and d. An important special case (up to scaling by $t^{1/2}$) is the Beck-Fiala problem, where the vectors $v_1, \ldots, v_n \in \{0, 1\}^d$ and each v_i has at most t ones, so $\|v_i\|_2 \leq t^{1/2}$. Here, the Komlós conjecture reduces to the Beck-Fiala conjecture [8], which says that the discrepancy is $O(t^{1/2})$. The question of either proving or disproving these conjectures has received a lot of attention, and after a long line of work, the current best bounds for the Komlos and the Beck-Fiala problem are $O((\log n)^{1/2})$ and $O((t \log n)^{1/2})$ respectively, due to Banaszczyk [4].

Motivated by the lack of progress for general worst-case instances, there has been a lot of recent work on these problems for random instances, with several interesting results and techniques, see e.g., [9, 7, 13, 10, 16, 18, 3, 14]. In this work, we consider the Komlós problem in the more general setting of smoothed analysis, where the input is generated by taking an arbitrary worst case Komlós instance and perturbing it randomly. The smoothed analysis model was first introduced by Spielman and Teng [17], and it interpolates nicely between worst case and average case analysis, and has been used extensively since then to study various problems. Recently smoothed analysis models have also been considered in discrepancy theory in a few other works [6, 11] – however the setting and focus of these results is quite different, and in particular they are not directly related to the Komlós or Beck-Fiala conjectures.

Random instances. To put our results in the proper context, we first describe the results on random instances. In general, these results depend on the different regimes of the parameters d, n and t, and we focus here on the more interesting case of $n \gg d$.

A natural model for random Beck-Fiala instances is where each entry is 1 with probability $p = t/d$, so that each column has t ones in expectation. In a surprising result, Hoberg and Rothvoss [13] showed that $\mathrm{disc}(A) \leq 1$ w.h.p.[1] if $n = \Omega(d^2 \log d)$. Independently, Franks and Saks [10] showed that $\mathrm{disc}(A) \leq 2$ w.h.p. if $n = \Omega(d^3 \log^2 d)$, for a more general class of instances. Both these results use interesting Fourier analysis based techniques.

It is not hard to see[2] that $n = \Omega(d \log d)$ is necessary for $O(1)$ discrepancy (provided p is not too small). An important step towards obtaining this optimal dependence was made by Potukuchi [15], who showed that $\mathrm{disc}(A) \leq 1$ if $n = \Omega(d \log d)$ for the dense case of $p = 1/2$, using the second moment method. However, the sparse setting with $p \ll 1$ turns out to be more subtle, and was only recently resolved by Altschuler and Weed [3] using a more sophisticated conditional second moment method together with Stein's method of exchangeable pairs. They show that $\mathrm{disc}(A) \leq 1$ w.h.p. for $n \geq \Omega(d \log d)$, for every p.

The case of Gaussian matrices with i.i.d. $\mathcal{N}(0, 1)$ entries has also been considered, where Turner, Meka and Rigollet [18] give almost tight bounds for the entire regime, and in particular show that for $n = \Omega(d \log d)$ a discrepancy bound of $1/\mathrm{poly}(d)$ holds.

The smoothed Komlós model. We now define our model formally. The input matrix is of the form $A = M + R$, where $M \in \mathbb{R}^{d \times n}$ is some worst-case matrix with columns of ℓ_2-norm at most 1 and $R \in \mathbb{R}^{d \times n}$ is a random matrix with i.i.d. Gaussian entries distributed as $\mathcal{N}(0, \sigma^2/d)$, where $\sigma \leq 1$. The σ^2/d variance ensures that each column of R has ℓ_2-norm roughly σ (and hence much less than that of M). Our goal is to understand the discrepancy of A. We will only be interested in showing the existence of a low discrepancy coloring for A, and not in algorithmically finding it (this seems far beyond the current techniques).

1.1 Results and Techniques

Our main result is the following.

▶ **Theorem 1** (Smoothed Komlós). *Let $\sigma > 0$ and $n = \frac{\omega(d \log d)}{\sigma^{4/3}}$. Then with probability $1 - o_d(1)$, the discrepancy of $M + R$ is at most $1/\mathrm{poly}(d)$, where $M \in \mathbb{R}^{d \times n}$ is an arbitrary Komlós instance and $R \in \mathbb{R}^{d \times n}$ has i.i.d. $\mathcal{N}(0, \sigma^2/d)$ entries.*

[1] This is much better than the $O(t^{1/2})$ bound in the Beck-Fiala conjecture.

[2] If we fix any coloring x and consider a random instance, a fixed row has discrepancy $O(1)$ with probability $\approx (pn)^{-1/2}$, so the probability that each row has discrepancy $O(1)$ is $(pn)^{-\Omega(d)}$. As there are (only) 2^n possible colorings, a first moment argument already requires that $2^n (pn)^{-d} = \Omega(1)$.

An interpretation of Theorem 1 is that any counter-example to the Komlós conjecture (if it exists) will be rigid, or have $n \approx d$. Also, notice that dependence of n on d in Theorem 1 is essentially the best possible, as already evident in the very special case of $M = \mathbf{0}$ and $\sigma = 1$, i.e., a random matrix with i.i.d. $\mathcal{N}(0,1)$ entries, where $n = \Omega(d \log d)$ is necessary to achieve $1/\mathrm{poly}(d)$ discrepancy, as discussed earlier.

▶ Remark 2. Our proof techniques also give a high probability bound when $n = \Omega_\sigma(d^{1+\epsilon})$ for any constant $\epsilon > 0$. However, we do not explore this direction here. It would be interesting to know if the result also holds with high probability when $n = \omega(d \log d)$, as in the (fully) random setting.

▶ Remark 3. The dependence on the noise parameter σ in $n = \Omega_d(1/\sigma)$ in Theorem 1 is necessary, otherwise this would imply an $O(1)$ bound for the worst case Komlós problem. In particular, each row of the random part R must at least have enough ℓ_1 norm to offset the discrepancy from the worst case part M (which can be $O((\log n)^{1/2})$ given the currently known results). As each entry of R has magnitude about $\sigma d^{-1/2}$, we thus require $n = \Omega_d(1/\sigma)$ for each row of $M + R$ to have discrepancy $O(1)$.

The proof of Theorem 1 is based on the classical second moment method, however, it requires several additional ideas beyond those used for random instances, to handle the effect of the worst case part and its interplay with the random part. We describe these briefly next, and discuss them in more detail in Section 1.2.

- **Weighted second moment method.** Instead of applying the second moment method to the uniform distribution on the 2^n colorings, we consider a distribution on low-discrepancy colorings for M. This is necessary as for a random coloring $x \in \{-1,1\}^n$, a typical entry of Mx will scale as $\sqrt{n/d}$, which is very unlikely to be *cancelled* by the discrepancy of the random part Rx, which typically scales as $\sigma\sqrt{n/d}$ (note that we want to show the existence of some x such that $(Rx)_i \approx -(Mx)_i$ for each coordinate $i \in [d]$).
- **Subgaussianity of colorings.** To ensure that $\|Mx\|_\infty$ is typically small, we consider the (implicit) distribution on colorings produced by the Gram-Schmidt (GS) algorithm [5] applied to M, which ensures that Mx is a 1-subgaussian vector [12] (details in Section 1.2). However, apriori the GS algorithm only guarantees that Mx is subgaussian, and says nothing about the distribution on the colorings x. For instance, it could be that any two colorings in the support have the first $9n/10$ coordinates identical, and thus look very non-random. This makes the second moment bounds much worse and harder to control. To handle this, we use a simple but useful trick to ensure that the distribution on the colorings x produced by the GS algorithm is also $O(1)$-subgaussian. Roughly, this allows us to pretend that colorings x in the GS distribution behave randomly.
- **Exploiting subgaussianity to get cancellations across rows.** Most importantly, due to the worst case part M, doing a row by row analysis as is typically done in second moment computations for random instances, only works when $n = \Omega(d^2/\sigma^2)$ (details in Section 1.2). Roughly, the problem is that considering each coordinate of Mx separately completely ignores the global properties across the different coordinates that subgaussianity of Mx implies.
  To get the optimal dependence of n on d, a key conceptual idea is to analyze *all* the rows together and use the subgaussianity of Mx and x carefully to get various cancellations across the different rows in the second moment computation. Exploiting subgaussianity also leads to various technical difficulties, as subgaussian vectors can differ from fully random Gaussian vectors in various non-trivial ways.

Notation. Throughout this paper, log denotes the natural logarithm. We use the asymptotic notation $\omega(\cdot)$ or $o(\cdot)$ where the growth is always with respect to d – sometimes to emphasize this dependence we will also write $\omega_d(\cdot)$ or $o_d(\cdot)$. We write $\mathbb{E}_{x\sim\mathcal{G}}[f(x)]$ to denote the expectation of a function f where x is sampled from the distribution $\mathcal{G}$ and we abbreviate this to $\mathbb{E}[f(x)]$ when the distribution is clear from the context. For reals $a, b \in \mathbb{R}$, the notation $[a \pm b]$ is used as a shorthand to denote the interval $[a-b, a+b]$. For a set $S \in \mathbb{R}^d$, we write $\delta S = \{\delta x \mid x \in S\}$ to denote the δ scaling of S.

1.2 Overview and Preliminaries

We now give a more detailed overview of the proof and the ideas. We also briefly describe the second moment method and some concepts we need such as subgaussianity and properties of the Gram-Schmidt algorithm.

Second moment method. The second moment method (e.g. [2]) is based on the following Paley-Zygmund inequality. For any non-negative random variable Z, we have that

$$\mathbb{P}[Z > 0] \geq \frac{(\mathbb{E}[Z])^2}{\mathbb{E}[Z^2]}.$$

So, if $\mathbb{E}[Z^2] = (1+o(1))(\mathbb{E}[Z])^2$, then this implies that $\mathbb{P}[Z > 0] \geq 1 - o(1)$.

For constraint satisfaction problems, a standard way to use this to show that most random instances are feasible is by defining $S = S(R)$ as the number of solutions to an instance R, and showing that

$$\mathbb{E}_R[S^2] = (1+o(1))(\mathbb{E}_R[S])^2, \tag{1}$$

which gives that $\mathbb{P}_R[S(R) > 0] = \mathbb{P}_R[S(R) \geq 1] \geq 1 - o(1)$.

Let us consider (1) more closely and define $S(R, x) = 1$ if x is a valid solution for instance R, and 0 otherwise. Then $S(R) = \sum_x S(R, x)$ and (1) can be written as

$$\mathbb{E}_R\left[\mathbb{P}_{x,y\sim\mathcal{U}}\left[\, S(R,x) = 1\,,\; S(R,y) = 1\,\right]\right] = (1+o(1))\left(\mathbb{E}_R\left[\mathbb{P}_{x\sim\mathcal{U}}\left[S(R,x) = 1\right]\right]\right)^2, \tag{2}$$

where $\mathcal{U}$ is the uniform distribution over all inputs.

Second moment method for smoothed Komlós. Let Δ denote the desired discrepancy bound. In our setting, denote by $S(R, x) = 1$ that $x \in \{\pm 1\}^n$ is a feasible coloring for the smoothed Komlós instance $M + R$, that is, if $\|(M+R)x\|_\infty \leq \Delta$. Roughly, this condition means that $Rx = -Mx$ and hence the discrepancy of the random part R cancels that of the worst case part M.

However, if x is chosen uniformly from $\{\pm 1\}^n$, it is not hard to see that this cannot work. The entries $(Mx)_i$ will be distributed roughly as $\mathcal{N}(0, m_i^2)$ where $m_i = (\sum_j M_{ij}^2)^{1/2}$ is the ℓ_2-norm of row i of M, and in general will be much larger (around $1/\sigma \gg 1$ times) than the entries $(Rx)_i$.

Weighted second moment. To allow a reasonable probability of Rx cancelling Mx, a natural idea is to consider a distribution that is mostly supported over colorings x with low discrepancy on M. So, we will show (2) where x, y are sampled from some another suitable distribution $\mathcal{G}$ instead of the uniform distribution $\mathcal{U}$. Similar ideas have also been used in other contexts such as [1]. Notice that this does not affect Rx, as for any fixed x, the contribution of the random part $(Rx)_i$ is still distributed as $N(0, n\sigma^2/d)$ (over the randomness of R).

A natural candidate is the distribution on colorings produced by the Gram-Schmidt (GS) walk algorithm [5]. In particular, we use the following result.

▶ **Theorem 4** ([12]). *Given vectors $v_1, \ldots, v_n \in \mathbb{R}^m$ with $\|v_j\|_2 \le 1$, the Gram-Schmidt walk algorithm outputs a random coloring $x \in \{-1,1\}^n$ such that $\sum_{j=1}^n x_j v_j$ is 1-subgaussian.*

Recall that a random vector $Y \in \mathbb{R}^m$ is α-subgaussian if for all test vectors $\theta \in \mathbb{R}^m$,

$$\mathbb{E}\big[\exp(\langle \theta, Y\rangle)\big] \le \exp\left(\frac{\alpha^2\|\theta\|_2^2}{2}\right).$$

Roughly, this means that Y looks like a Gaussian with variance at most α^2 in every direction.

Let $\mathcal{G}$ denote the (implicit) distribution over the colorings output by the GS walk algorithm. For a coloring x, let us denote $P_x := \mathbb{P}_R[S(R,x) = 1]$ and for two colorings x and y, let

$$P_{x,y} := \mathbb{P}_R\big[S(R,x) = 1\,,\, S(R,y) = 1\big].$$

Then changing the order of expectation in (2) and substituting, our goal is to show that

$$\mathbb{E}_{x,y\sim\mathcal{G}}[P_{xy}] = (1 + o(1)) \cdot \mathbb{E}_{x,y\sim\mathcal{G}}[P_x P_y]. \tag{3}$$

However, the set of low discrepancy colorings for M and the distribution $\mathcal{G}$ can be quite complicated and hard to work with. Later, we will ensure that $\mathcal{G}$ is also $O(1)$-subgaussian, which will suffice for our purposes. Let us first consider (3) more closely.

The key computation. As R has i.i.d. Gaussian entries, the quantities P_x and P_{xy} can be written in a very clean way. In particular, as $(Rx)_i \sim \mathcal{N}(0, \sigma^2 n/d)$ for any coloring x, and the $(Rx)_i$ are independent for $i \in [d]$, we can write

$$P_x \;=\; \mathbb{P}_R\left[\bigcap_{i=1}^d ((Rx)_i \in (Mx)_i \pm \Delta)\right] \;=\; \prod_{i=1}^d \mathbb{P}_R\big[g_i \in (Mx)_i \pm \Delta\big],$$

where $g_i \sim N(0, \sigma^2 n/d)$ and g_i's are independent.

Similarly, for any fixed colorings x and y, writing $g_i = (Rx)_i$ and $g_i' = (Ry)_i$ we have

$$P_{xy} = \prod_{i=1}^d \mathbb{P}_R\big[g_i \in (Mx)_i \pm \Delta\,,\, g_i' \in (My)_i \pm \Delta\big],$$

where g_i and g_i' are correlated with $\mathbb{E}[g_i g_i'] = \langle x, y\rangle \cdot \sigma^2/d$.

A standard computation of 2-dimensional gaussian probabilities over rectangles (and ignoring some less crucial terms for the discussion here) gives

$$\frac{\mathbb{P}\big[g_i \in (Mx)_i \pm \Delta\,,\, g_i' \in (My)_i \pm \Delta\big]}{\mathbb{P}\big[g_i \in (Mx)_i \pm \Delta\big] \cdot \mathbb{P}\big[g_i' \in (My)_i \pm \Delta\big]} \approx \exp\left(\frac{d\langle x, y\rangle (Mx)_i (My)_i}{\sigma^2 n^2}\right). \tag{4}$$

So to prove (3), we could try to show that for each $i \in [d]$,

$$\mathbb{E}_{x,y\sim\mathcal{G}}\left[\frac{d\langle x, y\rangle (Mx)_i (My)_i}{\sigma^2 n^2}\right] = o\left(\frac{1}{d}\right). \tag{5}$$

Indeed, as $|\langle x, y\rangle| \le n$ and $(Mx)_i, (My)_i$ are typically $O(1)$ (as Mx and My are subgaussian), setting $n = \omega(d^2/\sigma^2)$ would suffice to complete the second moment proof. However, this does not give us the optimal $d \log d$ dependence.

Next, we sketch the two ideas to obtain the optimal dependence.

Subgaussianity of the distribution $\mathcal{G}$. If x and y were random colorings, we would typically expect that $|\langle x, y\rangle| \approx \sqrt{n}$ instead of n above. To achieve this, we apply the GS walk algorithm to the $(d+n) \times n$ matrix with M in top d rows and I_n in the bottom n rows. (Note that each column still has $O(1)$ length.) This ensures that the resulting distribution $\mathcal{G}$ on the colorings x is $O(1)$-subgaussian, while ensuring that Mx is also $O(1)$-subgaussian.

Handling the rows together. Next, to exploit the subgaussianity of Mx and My, we look at all the rows together in (5) and consider

$$\sum_i \mathbb{E}_{x,y\sim\mathcal{G}}\left[\frac{d\langle x,y\rangle (Mx)_i (My)_i}{\sigma^2 n^2}\right] = \mathbb{E}_{x,y\sim\mathcal{G}}\left[\frac{d\langle x,y\rangle\langle Mx, My\rangle}{\sigma^2 n^2}\right]. \tag{6}$$

By the subgaussianity of the colorings x, y and discrepancy vectors Mx, My, we expect that $\mathbb{E}_{x,y\sim\mathcal{G}}|\langle x, y\rangle| \approx \sqrt{n}$ and $\mathbb{E}_{x,y}|\langle Mx, My\rangle| \approx \sqrt{d}$. Roughly speaking, this implies that the right side of (6) is typically $d^{3/2}/(\sigma^2 n^{3/2})$, and hence $n \gg d/\sigma^{4/3}$ suffices.

The formal argument needs some more care as $\langle x, y\rangle$ and $\langle Mx, My\rangle$ are correlated, and as we need to bound the exponential moment of $d\langle x, y\rangle\langle Mx, My\rangle/(\sigma^2 n^2)$ in (4), instead of the expectation, which gives the additional (necessary) logarithmic factor of $\log d$.

2 Proof of the Smoothed Komlós Conjecture

We use a weighted version of the second moment method as mentioned in the proof overview. Let $\mathcal{G}$ be a distribution over coloring that will be specified later. We define the following random variable S which depends only on the randomness of R,

$$S = S(R) := \mathbb{E}_{x\sim\mathcal{G}}[\mathbf{1}\{\|(M+R)x\|_\infty \le \Delta\}],$$

for some parameter $\Delta = 1/\mathrm{poly}(d)$ to be chosen later. The purpose of this variable is that the event $\{S > 0\}$ implies there exists a coloring $x \in \mathsf{supp}(\mathcal{G})$ with discrepancy at most Δ. Our goal is to show that $\mathbb{P}(S > 0) = 1 - o(1)$. As explained in the proof overview, this would follow from the Paley-Zygmund inequality if we can establish that the first moment $\mathbb{E}_R[S]$ is always positive, and the second moment satisfies $\mathbb{E}_R[S^2] = (1 + o(1)) \cdot (\mathbb{E}_R[S])^2$. We next compute the moments.

First moment computation. We can compute

$$\mathbb{E}_R[S] \;=\; \mathbb{E}_{x\sim\mathcal{G}}\mathbb{E}_R[\mathbf{1}\{\|(M+R)x\|_\infty \le \Delta\}] \;>\; 0,$$

where the strict inequality follows because fixing any outcome $x \sim \mathcal{G}$, the event $\{\|(M + R)x\|_\infty \le \Delta\}$ happens with positive probability (recall that R is a Gaussian random matrix with each entry $\mathcal{N}(0, \sigma^2/d)$).

Second moment computation. For any $i \in [d]$, denote by m_i and r_i the i^{th} row of the matrices M and R respectively. The second moment is given by

$$\begin{aligned}
\mathbb{E}_R[S^2] &= \mathbb{E}_R\left[\mathbb{E}_x[\mathbf{1}\{\|(M+R)x\|_\infty \le \Delta\}] \cdot \mathbb{E}_y[\mathbf{1}\{\|(M+R)y\|_\infty \le \Delta\}]\right] \\
&= \mathbb{E}_R\mathbb{E}_{x,y}\left[\mathbf{1}\left\{\|(M+R)x\|_\infty \le \Delta, \|(M+R)y\|_\infty \le \Delta\right\}\right] \\
&= \mathbb{E}_{x,y}\left[\mathbb{P}_R\left(\|(M+R)x\|_\infty \le \Delta, \|(M+R)y\|_\infty \le \Delta\right)\right] = \mathbb{E}_{xy}[P_{xy}],
\end{aligned}$$

where we define

$$P_{x,y} := \mathbb{P}_R(\|(M+R)x\|_\infty \le \Delta, \|(M+R)y\|_\infty \le \Delta).$$

Similarly, denoting

$$P_x := \mathbb{P}_R(\|(M+R)x\|_\infty \le \Delta),$$

we also have

$$\begin{aligned}(\mathbb{E}_R[S])^2 &= (\mathbb{E}_x \mathbb{P}_R(\|(M+R)x\|_\infty \le \Delta)) \cdot (\mathbb{E}_y \mathbb{P}_R(\|(M+R)y\|_\infty \le \Delta)) \\ &= \mathbb{E}_{x,y}\left[\mathbb{P}_R(\|(M+R)x\|_\infty \le \Delta) \cdot \mathbb{P}_R(\|(M+R)y\|_\infty \le \Delta)\right] \\ &= \mathbb{E}_{xy}[P_x \cdot P_y].\end{aligned}$$

To compare the quantities $\mathbb{E}_R[S^2]$ and $(\mathbb{E}_R[S])^2$, we first consider a distribution over colorings. A natural distribution to consider is the distribution on colorings derived from the Gram-Schmidt walk which ensures that the discrepancy vector Mx is 1-subgaussian if x is sampled from this distribution. However, we shall also need that the colorings x themselves have a subgaussian tail as well as some additional nice properties that will be useful to compute the second moment. In particular, we prove the following lemma in Section 2.1.

▶ **Lemma 5** (Truncated Gram-Schmidt Distribution). *Let $M \in \mathbb{R}^{d\times n}$ be a worst-case Komlós instance. Then, for any constant $C' > 1$ there exists a distribution $\mathcal{G}$ over colorings $x \in \{\pm 1\}^n$ satisfying the following properties:*

- *Almost Constant Euclidean Norm for the discrepancy vectors: for every $x \in \mathsf{supp}(\mathcal{G})$, we have $\|Mx\|_2 \in [r \pm \Delta]$ where $r = O(d^{1/2})$ and $\Delta = d^{-C'}$.*
- *Almost subgaussian tails for the colorings and discrepancy vectors: there exists a constant C depending on C', such that for every $u \in \mathbb{S}^{n-1}$,*

$$\mathbb{P}_{x\sim\mathcal{G}}\left[|\langle x, u\rangle| \ge t\right] \le 2d^C \cdot e^{-t^2/8} \text{ and } \mathbb{P}_{x\sim\mathcal{G}}\left[|\langle Mx, u\rangle| \ge t\right] \le 2d^C \cdot e^{-t^2/8}.$$

Since the colorings sampled from the above distribution are subgaussian, $|\langle x, y\rangle| \le n/2$ holds with high probability. To compute the second moment to a good precision, we need a careful comparison of the ratio $P_{xy}/(P_x \cdot P_y)$ for any two colorings x and y where this event occurs. We show the following bound in this case (proof in Section 2.2).

▷ Claim 6 (Strong bound). For any two colorings $x, y \in \mathsf{supp}(\mathcal{G})$, denote $\epsilon = \epsilon(x,y) = \langle x, y\rangle/n$. If $|\epsilon| \le 1/2$, then we have

$$P_{x,y} \le P_x P_y \cdot \beta(x,y) \text{ where } \beta(x,y) = \exp\left(\delta_1 + d\epsilon^2 + d\delta^2\epsilon^2 + \delta^2\epsilon \cdot \langle Mx, My\rangle\right),$$

where the scaling factor $\delta := \frac{\sqrt{d}}{\sigma\sqrt{n}}$ and the error parameter $\delta_1 \le 1/\mathrm{poly}(d)$.

When the low probability event $|\epsilon| \ge 1/2$ occurs, we use the weak bound $P_{xy} \le \min\{P_x, P_y\}$.

As x is sampled from the truncated Gram-Schmidt distribution, the probabilities P_x turn out to be almost constant for all colorings $x \in \mathsf{supp}(\mathcal{G})$ as the following claim shows.

▷ Claim 7. For any coloring $x \in \mathsf{supp}(\mathcal{G})$,

$$P_x = \exp(\delta_x) \cdot p \text{ where } p := \left(\frac{\delta\Delta}{\sqrt{2\pi}}\right)^d \exp\left(-\frac{\delta^2 r^2}{2}\right), \tag{7}$$

with the scaling factor $\delta := \frac{\sqrt{d}}{\sigma\sqrt{n}}$ and the error parameter δ_x satisfying $|\delta_x| \le \delta_1 \le 1/\mathrm{poly}(d)$.

The proof of this claim is in Section 2.2.

We now focus on the case when $|\epsilon| \leq 1/2$. When we take $x, y \sim \mathcal{G}$, as P_x and P_y are essentially constant, by Claim 6, applying the second moment method reduces to bounding $\beta(x, y)$ as defined in Claim 6. To do this, we will use the properties, as described in Lemma 5, of the underlying random variables x and Mx. The following technical lemma gives a bound on the exponential moment for such random variables.

▶ **Lemma 8.** *Let X be a non-negative random variable X that satisfies*

$$\mathbb{P}(X \geq t) \leq d^{C_1} \cdot e^{-t^2/8} \text{ for any } t > 0,$$

for some fixed constant $C_1 > 0$. Then for any $\lambda = c_2\sqrt{\log d}$ with $c_2 \geq \sqrt{32C_1}$,

$$\mathbb{E}[\exp(X^2/\lambda^2)] \leq 1 + 32C_1/c_2^2 + o_d(1).$$

We shall prove this lemma in Section 2.1.

We can now complete the proof of Theorem 1 by comparing $\mathbb{E}_R[S^2]$ and $(\mathbb{E}_R[S])^2$. We show that

▶ **Lemma 9.** *For $n = \omega(d \log d)\sigma^{-4/3}$, we have*

$$(\mathbb{E}_R[S])^2 = p^2(1 - o_d(1)) \text{ and } \mathbb{E}_R[S^2] = p^2(1 + o_d(1)).$$

The above implies that $\mathbb{E}_R[S^2] = (1 + o(1))(\mathbb{E}_R[S])^2$, and thus the Paley-Zygmund inequality implies Theorem 1 as discussed in the proof overview.

Proof of Lemma 9. For the first moment, Claim 7 implies that

$$(\mathbb{E}_R[S])^2 = \mathbb{E}_{x,y\sim\mathcal{G}}[P_x P_y] = p^2\mathbb{E}[\exp(\delta_x + \delta_y)] \geq p^2 \exp(-2\delta_1).$$

Since $0 < \delta_1 \leq 1/\text{poly}(d)$, the bound follows.

To compute the second moment, $\mathbb{E}_R[S^2] = \mathbb{E}_{x,y\sim\mathcal{G}}[P_{xy}]$, we define $\mathcal{E}$ to be the event that the colorings $x, y \sim \mathcal{G}$ satisfy $|\langle x, y\rangle| > n/2$ and compute the contribution to the expectation under $\mathcal{E}$ and its complement separately. In particular, using Claim 7 and Claim 6, we have

$$\mathbb{E}_R[S^2] = \mathbb{E}_{x,y\sim\mathcal{G}}[P_{x,y}] \leq \mathbb{P}_{x,y\sim\mathcal{G}}[\mathcal{E}] \cdot p + \mathbb{E}_{x,y\sim\mathcal{G}}\left[P_x P_y \beta(x, y) \cdot \mathbf{1}[\overline{\mathcal{E}}]\right] \tag{8}$$

For the first term in (8), since $n \geq d$, Lemma 5 implies that

$$\mathbb{P}_{x,y\sim\mathcal{G}}[\mathcal{E}] \leq \text{poly}(d) \cdot e^{-n/4} \leq e^{-n/8}.$$

Thus, using the exact bound for p from Claim 7 and that $\delta\Delta \leq \text{poly}(\sigma/d)$, the first term

$$\begin{aligned}
\mathbb{P}_{x,y\sim\mathcal{G}}[\mathcal{E}] \cdot p = p^2 \cdot \mathbb{P}[\mathcal{E}] \cdot p^{-1} &\leq p^2 \cdot e^{-n/8} \cdot \left(\frac{\sqrt{2\pi}}{\delta\Delta}\right)^d \exp\left(\frac{\delta^2 r}{2}\right) \\
&\leq p^2 \cdot e^{-n/8} \cdot \exp\left(O\left(d\log(dn/\sigma) + d^2/(\sigma^2 n)\right)\right) \\
&= p^2 \cdot o_d(1),
\end{aligned} \tag{9}$$

when $n = \omega(d \log d)\sigma^{-4/3}$. In particular, as $\sigma \leq 1$, we have $n/8 \gg d\log(dn/\sigma) + d^2/(\sigma^2 n)$.

For the second term in (8), using Claim 7, we have that $P_x = p \cdot \exp(\delta_x)$ where $|\delta_x| \leq |\delta_1| \leq 1/\text{poly}(d)$. Thus,

$$\begin{aligned}
\mathbb{E}_{x,y\sim\mathcal{G}}\left[P_x P_y \beta(x, y) \cdot \mathbf{1}[\overline{\mathcal{E}}]\right] &\leq p^2 \cdot \exp(2|\delta_1|) \cdot \mathbb{E}\left[\beta(x, y) \cdot \mathbf{1}[\overline{\mathcal{E}}]\right] \\
&\leq \exp(2|\delta_1|) \cdot \mathbb{E}\left[\beta(x, y)\right],
\end{aligned} \tag{10}$$

since $\beta(x,y)$ is a non-negative random variable. Recall from Claim 6 that $\beta(x,y) \le \exp(\delta_1) \cdot \exp(Z)$ where $\delta_1 \le 1/\mathrm{poly}(d)$ and

$$Z = d\epsilon^2 + 2\delta^2\epsilon^2 r^2 + 2\delta^2|\epsilon\langle Mx, My\rangle|.$$

Renormalizing $\overline{\epsilon} = \langle x, n^{-1/2}y\rangle$ and $\overline{\theta} = \langle Mx, r^{-1}My\rangle$ and using that $\delta = \frac{\sqrt{d}}{\sigma\sqrt{n}}$ and $r \le \sqrt{d}$, we have

$$Z \;\le\; \left(\frac{d}{n} + \frac{2d^2}{\sigma^2 n^2}\right)\cdot\overline{\epsilon}^2 + \frac{2d\sqrt{d}}{\sigma^2 n\sqrt{n}}\cdot|\overline{\epsilon}\cdot\overline{\theta}| \;\le\; (|\overline{\epsilon}| + |\overline{\theta}|)^2/\lambda_{\min}^2,$$

where we denote

$$\lambda_{\min} = \frac{1}{3}\sqrt{\min\left\{\frac{n}{d}, \frac{\sigma^2 n^2}{2d^2}, \frac{\sigma^2 n^{1.5}}{2d^{1.5}}\right\}}.$$

Note that $\lambda_{\min} = \omega_d(1)\cdot\sqrt{\log d}$ when $n = \omega(d\log d)\sigma^{-4/3}$.

We now bound the tails of $\overline{\epsilon}$ and $\overline{\theta}$, which will allow us to bound $\mathbb{E}[\exp(Z)]$. Conditioned on any outcome of $y \sim \mathcal{G}$, and as $\|y\|n^{-1/2} = 1$, the second property in Lemma 5 gives that $\mathbb{P}_{x\sim\mathcal{G}}[|\langle x, n^{-1/2}y\rangle| \ge t] \le 2d^C\exp(-t^2/8)$. Averaging over y thus gives that

$$\mathbb{P}\left[|\overline{\epsilon}| \ge t\right] \le 2d^C\cdot e^{-t^2/8}.$$

Similarly, as $\|My\|r^{-1} \le 1$ for any y in the support of $\mathcal{G}$, we have that $\mathbb{P}_{x\sim\mathcal{G}}[|\langle Mx, r^{-1}My\rangle| \ge t] \le 2d^C\exp(-t^2/8)$, and averaging over y gives that

$$\mathbb{P}\left[|\overline{\theta}| \ge t\right] \le 2d^C\cdot e^{-t^2/8}.$$

By a union bound, it follows that the random variable $X := |\overline{\epsilon}| + |\overline{\theta}|$ satisfies the tail condition of Lemma 8 with constant $C_1 = 2C$. So when $\lambda_{\min} = \omega_d(1)\cdot\sqrt{\log d}$, the parameter $c_2 := \lambda_{\min}/\sqrt{\log d}$ in Lemma 8 satisfies $32C_1/c_2^2 = o_d(1)$. Therefore, Lemma 8 implies that

$$\mathbb{E}[\beta(x,y)] \le \exp(\delta_1)\cdot\mathbb{E}[\exp(Z)] \le (1+o_d(1))(1+o_d(1)) = 1 + o_d(1).$$

Plugging the above in (10), it follows that the second term

$$\mathbb{E}_{x,y\sim\mathcal{G}}\left[P_x P_y\beta(x,y)\cdot\mathbf{1}[\overline{\mathcal{E}}]\right] \le p^2(1+o_d(1)).$$

Combining this with (8) and (9), we get that $\mathbb{E}_R[S^2] \le p^2(1+o_d(1))$. ◀

We now prove the lemmas and claims used in the proof of Theorem 1 above.

2.1 Truncated Gram-Schmidt Distribution and Exponential Moments

Proof of Lemma 5. Consider running the Gram-Schmidt walk algorithm on the matrix M stacked with the identity matrix, i.e. $\begin{pmatrix} M \\ I_n \end{pmatrix}$, and let $\mathcal{G}_0$ be the distribution over colorings obtained as an output of the algorithm.

Since each column of the stacked matrix has Euclidean norm at most 2, the properties of the Gram-Schmidt walk (Theorem 4) guarantees that $(x, Mx) \in \mathbb{R}^{n+d}$ where $x \in \{\pm 1\}^n$ and $Mx \in \mathbb{R}^d$ is 2-subgaussian. It follows that both x and Mx are 2-subgaussian as well when $(x, Mx) \sim \mathcal{G}_0$.

To obtain a distribution $\mathcal{G}$ where $\|Mx\|_2$ is almost constant for each coloring $x \in \mathsf{supp}(\mathcal{G})$, we will truncate the distribution $\mathcal{G}_0$ in such a way that the tails are also preserved up to poly(d) factors. Towards this end, we first note that with probability $1 - e^{-cd}$, we have that $\|Mx\|_2 \le c'\sqrt{d}$ for constants c and c'. This is because for any σ-subgaussian mean-zero random vector X, the Euclidean norm of $\|X\|$ has a subgaussian tail (e.g. Exercise 6.3.5 in [19]). In particular, $\mathbb{P}[\|X\|_2 \ge c_1\sigma\sqrt{d} + t] \le e^{-c_2 t^2/\sigma^2}$ for some universal constants $c_1, c_2 > 0$. Now, by a pigeonhole argument, for a large enough constant C' there exist an annulus W with width $\Delta = d^{-C'}$ and inner radius $r \le c'\sqrt{d}$ such that $\mathbb{P}_{x\sim\mathcal{G}_0}(x \in W) \ge d^{-C}$ for a constant C depending on C'.

We take the distribution $\mathcal{G}$ to be the probability measure of $\mathcal{G}_0$ conditioned on the event that $Mx \in W$. It then follows that for any coloring $x \sim \mathcal{G}$, we have $|\|Mx\|_2 - r| \le \Delta$. Moreover, since x and Mx were 2-subgaussian prior to conditioning, and the probability mass of the annulus is at least d^{-C}, conditioning can only increase the probability of any event by a factor of d^C. Thus, the tail bounds as stated in the statement of the lemma also follow. ◀

Proof of Lemma 8. The assumption on X implies that for any $t \ge 4 \cdot \sqrt{C_1 \log d}$, we have

$$\mathbb{P}(X \ge t) \le \exp(-t^2/16). \tag{11}$$

We express the expectation as an integration

$$\begin{aligned}\mathbb{E}[\exp(X^2/\lambda^2)] &= \int_0^\infty \mathbb{P}[\exp(X^2/\lambda^2) > s]ds = \int_0^\infty \mathbb{P}(X \ge \lambda\sqrt{\log s})ds \\ &\le 1 + c_3 + \int_{1+c_3}^\infty \mathbb{P}(X \ge \lambda\sqrt{\log s})ds.\end{aligned}$$

Let us set $c_3 = 32C_1/c_2^2$, so that $c_3 \le$ as $c_2 \ge \sqrt{32C_1}$. For $s \ge 1 + c_3$, we have

$$\lambda\sqrt{\log s} \ge c_2\sqrt{\log d} \cdot \sqrt{c_3/2} \ge 4 \cdot \sqrt{C_1 \log d}$$

using that $\sqrt{\log(1+x)} \ge \sqrt{x/2}$ for $x \in [0,1]$ and as $c_3 \le 1$. So the condition $t \ge 4\cdot\sqrt{C_1 \log d}$ for (11) is satisfied whenever $s \ge 1 + c_3$, and applying (11) to the above integration gives

$$\begin{aligned}\int_{1+c_3}^\infty \mathbb{P}(X \ge \lambda\sqrt{\log s})ds &\le \int_{1+c_3}^\infty \exp(-\lambda^2 \log s/16)ds \\ &= \left(\frac{\lambda^2}{16} - 1\right)^{-1} \cdot (1+c_3)^{-\lambda^2/16+1} \le \exp(-c_2^2 c_3 \log d/16).\end{aligned}$$

By our choice of c_3, the above is at most d^{-2C_1}. Thus, it follows that $\mathbb{E}[\exp(X^2/\lambda^2)] \le 1 + 32C_1/c_2^2 + d^{-2C_1}$. This proves the lemma. ◀

2.2 Proof of Claims from Section 2

Proof of Claim 6. Since the rows of R are independent, to compute the above ratio, it suffices to compute the ratio for a single row of $M + R$. Fix $i \in [d]$, and let $m = m_i$ and $r = r_i$ denote the i^{th} row and define $a = a_i(x) := -m^\top x$ and $b = b_i(y) := -m^\top y$. We want to compare the ratio of $\mathbb{P}(r^\top x \in [a \pm \Delta], r^\top y \in [b \pm \Delta])$ to $\mathbb{P}(r^\top x \in [a \pm \Delta]) \cdot \mathbb{P}(r^\top y \in [b \pm \Delta])$.

Notice that $r^\top x$ and $r^\top y$ are Gaussian random variables with mean 0, variance $1/\delta^2$, and covariance $\mathbb{E}_r[r^\top x r^\top y] = \mathbb{E}_r[x^\top r r^\top y] = \epsilon/\delta^2$. Denoting the square $K := [a \pm \Delta] \times [b \pm \Delta]$, we have that

$$\mathbb{P}(r^\top x \in [a \pm \Delta], r^\top y \in [b \pm \Delta]) = \mu_\epsilon(\delta K),$$

where μ_ϵ is the 2-dimensional centered Gaussian measure with covariance matrix $\begin{pmatrix} 1 & \epsilon \\ \epsilon & 1 \end{pmatrix}$ and δK denotes the δ scaling of K. Similarly, we can write $\mathbb{P}(r^\top x \in [a \pm \Delta]) \cdot \mathbb{P}(r^\top y \in [b \pm \Delta]) = \mu(\delta K)$, where μ is the *standard* 2-dimensional Gaussian measure.

We will compare the ratio $\mu_\epsilon(\delta K))/\mu(\delta K)$ by approximating the Gaussian measure over δK with the density at the center and show the following bound

$$\mu_\epsilon(\delta K))/\mu(\delta K) \leq \exp\left(3\alpha + \epsilon^2 + \delta^2\epsilon^2(a^2+b^2) + 2\delta^2\epsilon ab\right). \tag{12}$$

Since $(a_1(x), \ldots, a_d(x)) = Mx$ and $(b_1(x), \ldots, b_d(x)) = My$, using the above bound for all the rows $i \in [d]$, we have

$$\frac{P_{x,y}}{P_x P_y} \leq \exp\left(3d\alpha + d\epsilon^2 + \delta^2\epsilon^2 \cdot (\|Mx\|_2^2 + \|My\|_2^2) + \delta^2\epsilon \cdot \langle Mx, My\rangle\right).$$

Since $\|Mx\|_2^2 \leq d + \mathrm{poly}(1/d)$ for every $x \in \mathsf{supp}(\mathcal{G})$, taking $\delta_1 = 4d\alpha$ gives the statement of the claim. To finish the proof we prove (12) now.

Abusing notation and denoting by $\mu(s,t)$ and $\mu_\epsilon(s,t)$ the corresponding densities at $(s,t) \in \mathbb{R}^2$, we have the following explicit formula for the density μ_ϵ:

$$\mu_\epsilon(s,t) = \frac{1}{2\pi\sqrt{1-\epsilon^2}} \cdot \exp\left(-\frac{s^2+t^2-2\epsilon st}{2(1-\epsilon^2)}\right).$$

Since the edge length of the square δK is $2\delta\Delta$, whenever $|\epsilon| \leq 1/2$, a direct calculation with the densities shows that

$$\frac{\sup_{(s,t)\in\delta K}\mu(s,t)}{\inf_{(s,t)\in\delta K}\mu(s,t)} = \exp\left(2\delta^2\Delta(|a|+|b|)\right) \leq \exp\left(2\delta^2\Delta(|a|+|b|+2\Delta)\right) \leq \exp(\delta_1),$$

and that

$$\frac{\sup_{(s,t)\in\delta K}\mu_\epsilon(s,t)}{\inf_{(s,t)\in\delta K}\mu_\epsilon(s,t)} \leq \exp(4\delta^2\Delta(|a|+|b|+2\Delta)) \leq \exp(2\delta_1),$$

where δ_1 is as defined in the claim. It follows that whenever $|\epsilon| \leq 1/2$, we can use the density at the center of K to obtain

$$\begin{aligned}\frac{\mu_\epsilon(K)}{\mu(K)} &\leq \exp(3\delta_1) \cdot \frac{\mu_\epsilon(\delta a, \delta b)}{\mu(\delta a, \delta b)} = \frac{1}{\sqrt{1-\epsilon^2}} \cdot \exp\left(3\delta_1 + \frac{\delta^2\epsilon^2(a^2+b^2)}{2(1-\epsilon^2)} + \frac{\delta^2\epsilon ab}{1-\epsilon^2}\right) \\ &\leq \exp\left(3\delta_1 + \epsilon^2 + \delta^2\epsilon^2(a^2+b^2) + 2\delta^2\epsilon ab\right),\end{aligned}$$

thus proving (12). ◁

Proof of Claim 7. We have $P_x = \prod_{i\in[d]} \mathbb{P}[r_i^\top x \in [a_i \pm \Delta]]$. For any fixed $i \in [d]$, $r_i^\top x$ is distributed as $\mathcal{N}(0, 1/\delta^2)$, so after scaling the quantity $\mathbb{P}[r_i^\top x \in [a_i \pm \Delta]] = \mu(\delta \cdot I)$ where $I = [a_i \pm \Delta]$ and μ is the standard Gaussian measure in $\mathbb{R}$. Analogous to the proof of Claim 6, one can approximate the Gaussian density at any at the point in I by the center point a, and compute similarly to the proof of Claim 6 that

$$P_x = \prod_{i\in[d]} \mathbb{P}[r_i^\top x \in [a_i \pm \Delta]] = \left(\frac{\delta\Delta}{\sqrt{2\pi}}\right)^d \exp\left(\alpha_x - \frac{\delta^2\|Mx\|_2^2}{2}\right),$$

for some small error $|\alpha_x| \leq 2\delta^2\Delta(\|Mx\|_1 + d\Delta)$. As $\|Mx\|_2 \in [r \pm \Delta]$ and $r = O(\sqrt{d})$, we have that $\|Mx\|_1 = O(d)$ and the statement of the claim follows for some $\delta_x \leq |\alpha_x| + 1/\mathrm{poly}(d) \leq 1/\mathrm{poly}(d)$. ◁

3 Conclusion

For the Komlós problem, as studied in this paper, Gaussian noise is a natural way to model a smoothed analysis setting since the input vectors have Euclidean norm at most one. One can wonder whether similar results can be obtained with more general noise models, for instance, Bernoulli or other discrete noise models. Such noise models are also more conducive for smoothed analysis in other discrepancy settings, such as for the Beck-Fiala problem. The weighted second moment approach used here can also handle Bernoulli noise when the number of vectors $n \gg d^2$ but the second moment becomes difficult to control when n is smaller. It remains an interesting open problem to see if Bernoulli or other discrete noise models can be handled for the regime $n \gg d \log d$.

Abstract

Let G be a directed multi-graph on n vertices and m edges with a designated source vertex s and a designated sink vertex t. We study the (s,t)-cuts of capacity minimum+1 and as an important application of them, we give a solution to the dual edge sensitivity for (s,t)-mincuts – reporting the (s,t)-mincut upon failure or addition of any pair of edges.

Picard and Queyranne [Mathematical Programming Studies, 13(1):8-16, 1980] showed that there exists a directed acyclic graph (DAG) that compactly stores all minimum (s,t)-cuts of G. This structure also acts as an oracle for the single edge sensitivity of minimum (s,t)-cut. Dinitz and Nutov [STOC, pages 509-518, 1995] showed that there exists an $\mathcal{O}(n)$ size 2-level cactus model that stores all global cuts of capacity minimum+1. However, for minimum+1 (s,t)-cuts, no such compact structures exist till date. We present the following structural and algorithmic results on minimum+1 (s,t)-cuts.

1. There exists a pair of DAGs of size $\mathcal{O}(m)$ that compactly store all minimum+1 (s,t)-cuts of G. Each minimum+1 (s,t)-cut appears as a (s,t)-cut in one of the 2 DAGs and is 3-transversal – it intersects any path in the DAG at most thrice.
2. There exists an $\mathcal{O}(n^2)$ size data structure that, given a pair of vertices $\{u,v\}$ which are not separated by an (s,t)-mincut, can determine in $\mathcal{O}(1)$ time if there exists a minimum+1 (s,t)-cut, say (A,B), such that $\{s,u\} \in A$ and $\{v,t\} \in B$; the corresponding cut can be reported in $\mathcal{O}(|B|)$ time.
3. There exists an $\mathcal{O}(n^2)$ size data structure that solves the dual edge sensitivity problem for (s,t)-mincuts. It takes $\mathcal{O}(1)$ time to report the value of a resulting (s,t)-mincut (A,B) and $\mathcal{O}(|B|)$ time to report the cut.
4. For the data structure problems addressed in (2) and (3) above, we also provide a matching conditional lower bound. We establish a close relationship among three seemingly unrelated problems – all-pairs directed reachability problem, the dual edge sensitivity problem for (s,t)-mincuts, and 2×2 maximum flow. Assuming the directed reachability hypothesis, this leads to $\tilde{\Omega}(n^2)$ lower bounds on the space for the latter two problems.

1 Introduction

The concept of cuts of a graph is very fundamental in graph theory and has many algorithmic applications as well. There are mainly two types of cuts – global cuts and (s,t)-cuts. A set of edges whose removal disconnects a given undirected graph is called a *global* cut. Let $G = (V, E)$ be a directed multi-graph (E is a multiset) consisting of $n = |V|$ vertices and $m = |E|$ edges with a designated source vertex s and a designated sink vertex t. An (s,t)-cut of G is defined as follows.

▶ **Definition 1** ((s,t)-cut). *For a subset $C \subset V$ with $s \in C$ and $t \notin C$, the set of outgoing edges of C is called an (s,t)-cut.*

It follows from Definition 1 that for each (s,t)-cut, there exists at least one subset $C \subset V$ that defines it. For the simplicity of exposition and without causing any confusion, henceforth we shall use C to denote the corresponding (s,t)-cut as well. An edge is said to *contribute* to an (s,t)-cut C if it is an outgoing edge of C. The set of edges that have one endpoint in C and another endpoint in $\overline{C}$ is known as the *edge-set* of C, denoted by $E(C)$.

A (s,t)-cut (likewise a global cut) consisting of least number of contributing edges is called an (s,t)-mincut (likewise a global mincut).

There has been extensive research in designing efficient algorithms for global mincuts ([15, 18, 19]) as well as (s,t)-mincuts ([10, 16]). In addition, elegant graph structures have been invented that compactly store and characterize these cuts – Cactus graph for all global mincuts given by Dinitz, Karzanov, and Lomonosov [5], and a directed acyclic graph (DAG) given by Picard and Queyranne [23] for all (s,t)-mincuts. These structures can also serve as an efficient data structure for single edge sensitivity problem – to report the (s,t)-mincut (or global mincut) after the insertion/failure of an edge.

It is very natural to ask if there exists any compact structure for cuts of value greater than the value of the minimum cuts. For global minimum+1 cuts, Dinitz and Nutov answered this question in affirmative. In a seminal work [7], they showed that there exists an $\mathcal{O}(n)$ size 2-level cactus model that stores all minimum+1 cuts; they also gave a characterization of these cuts. An incremental maintenance of this structure solves the problem of maintaining minimum+2 edge connected components for any value of minimum cuts under insertion of edges; generalizing the results of Galil and Italiano [12] and Dinitz [6].

However, for minimum+1 (s,t)-cuts, to the best of our knowledge, no such compact structure exists till date. Note that the approach taken by Picard and Queyranne [23] for (s,t)-mincuts does not seem extendable for minimum+1 (s,t)-cuts. This is because their structure is based on the residual network resulting from a maximum (s,t)-flow and thus crucially exploits the equivalence between maximum flow and minimum cut (Ford and Fulkerson [10]); unfortunately, for a given minimum+1 (s,t)-cut, there is no equivalent (s,t)-flow.

While a compact structure for minimum+1 (s,t)-cuts is of significant importance from a graph theoretic perspective, equally important is a compact data structure that can efficiently answer the following fundamental query for any given edge $(u,v) \in E$.

$\boldsymbol{Q(u,v)}$**:** report a minimum+1 (s,t)-cut C, if exists, such that $u \in C$, $v \in \overline{C}$.

Interestingly, the DAG structure of Picard and Queyranne [23] for (s,t)-mincuts can answer efficiently the question stated above in case of (s,t)-mincuts. For this purpose, it crucially exploits the property that the set of (s,t)-mincuts are closed under intersection and union operations. Unfortunately, this property no longer holds for minimum+1 (s,t)-cuts, thus making it quite nontrivial to design a data structure for answering query Q.

The study of minimum+1 (s,t)-cuts has an immediate application as well. As is evident from the following fact, their study is indispensable for efficiently solving the dual edge sensitivity problem for (s,t)-mincuts.

▶ **Fact 2.** *The failure of a given pair of edges will reduce the value of (s,t)-mincut if and only if there is a minimum (s,t)-cut containing any failed edge or a minimum+1 (s,t)-cut containing both the failed edges.*

Sensitivity data structure for a given graph problem is motivated by the fact that graphs in the real world are prone to failures of vertices/edges. These failures are transient in nature. So while the set of failed vertices/edges keep changing with time, at any stage of time, the number of failed vertices/edges remains quite small. Therefore, the aim is to have a compact data structure that can efficiently report the solution of the given problem for a given set of failed vertices/edges. In a similar manner, we would like to efficiently report the solution of the given problem for a given set of newly added vertices/edges. This may help us determine which newly added vertex/edge changes the solution most significantly. In the past, many elegant fault-tolerant structures have been designed for various classical problems, like single-source reachability [17], shortest paths [4], breadth-first search [21], (s,t)-mincuts [23], all-pairs mincuts [1] etc, which can handle the failure of a single vertex/edge. It is certainly interesting and important to handle more than a single failure/addition. In this endeavour, it is quite natural to first design data structures that can handle dual failures (or dual insertions). This either helps, or exposes the difficulty, in solving the problem in its generality. It has turned out that the data structures that handle dual failures are often more complex and require deeper insight into the problem than the data structures that handle only single failure. This is evident at least for the following problems – single-source reachability [3], breadth-first search [20], shortest paths [9] etc. For the case of (s,t)-mincuts, note that the 40 years old data structure of Picard and Queyranne [23] is the only known sensitivity data structure and it can handle only a single edge failure/addition. It occupies $\mathcal{O}(m)$ space and can report the value of the resulting (s,t)-mincut and the corresponding cut in $\mathcal{O}(1)$ and $\mathcal{O}(m)$ time, respectively. No nontrivial data structure exists for the dual-edge sensitivity of (s,t)-mincuts till date.

1.1 New results and their overview

Let λ be the value of the (s,t)-mincut in G. Henceforth, we use $(\lambda+k)$ (s,t)-cut to denote a minimum+k (s,t)-cut, $k \in \{0,1\}$. Using just the sub-modularity of (s,t)-cuts (Lemma 10) and the relation between any pair of (s,t)-mincuts, we first present an alternate DAG structure, denoted by $\mathcal{D}_\lambda$, that compactly stores and characterizes all (s,t)-mincuts as follows. An (s,t)-cut in G is a (s,t)-mincut if and only if it appears as a 1-transversal cut in $\mathcal{D}_\lambda$ – the edge-set of an (s,t)-cut intersects any path in $\mathcal{D}_\lambda$ at most once. It can be easily observed that $\mathcal{D}_\lambda$, upon reversal of its edges, is identical to the DAG of Picard and Queyranne [23]. The major advantage of the approach taken for designing this alternate DAG is that it shows a way to design compact structures for $(\lambda+1)$ (s,t)-cuts using only the properties of (s,t)-cuts without exploiting the relation between cuts and flows. We now present an overview of our main results on the $(\lambda+1)$ (s,t)-cuts.

The set of minimum cuts are closed under intersection and union. This property has played a crucial role in designing compact structure as well as characterization of these mincuts – cactus graph for global mincuts by Dinitz, Karzanov, Lomonosov [5], the skeleton structure for Steiner mincuts by Dinitz and Vainshtein [8], and DAG for (s,t)-mincuts described in this paper. However, it turns out that $(\lambda+1)$ (s,t)-cuts are not closed under intersection as

well as union. Therefore, in order to design compact structure for $(\lambda+1)(s,t)$-cuts and their characterization, we analyse the relation between a pair of $(\lambda+1)(s,t)$-cuts. On the basis of the capacity of the cuts resulting from the intersection and union, each pair of $(\lambda+1)$ (s,t)-cuts is classified into exactly one of the three types – Type-1, Type-2, and Type-3. While designing compact structure for $(\lambda+1)$ (s,t)-cuts, the presence of pairs of Type-1 cuts poses a challenge in characterizing them. Likewise the presence of pairs of Type-2 cuts poses a challenge in determining the (s,t)-mincut upon the failure/addition of any pair of edges. A natural idea to conquer these challenges is to partition the set of $(\lambda+1)$ (s,t)-cuts into a *small* number of sets so that there is no pair of cuts from Type-1 (likewise Type-2) in a set. It can be observed that any arbitrary partitioning may produce a *large* number of sets which may defeat our objective of designing compact structures.

We present a technique called *covering* of (s,t)-cuts using which we can build a pair of graphs that cover all (s,t)-cuts of G and each of them has no pair of cuts from Type-1. It also helps in carefully handling pairs of cuts from Type-2. However, the covering technique works only for a graph with at most two (s,t)-mincuts, and hence can not be applied directly. In order to tackle this problem we introduce the concept of $(\lambda+1)$ (s,t)-class as follows.

▶ **Definition 3.** *A $(\lambda+1)$ (s,t)-class is a maximal set of vertices $A \subset V$ such that any pair of vertices from A are not separated by any (s,t)-mincut.*

It can be observed that the set of vertices of G that are assigned to a vertex of $\mathcal{D}_\lambda$ corresponds to a $(\lambda+1)$ (s,t)-class. We first form a partition of the set of all $(\lambda+1)$ (s,t)-cuts (excluding a set of *degenerate* cuts) with respect to the $(\lambda+1)$ (s,t)-classes. For each $(\lambda+1)$ (s,t)-class $\mathcal{W}$, we construct a new graph $G(\mathcal{W})$ that preserves all $(\lambda+1)$ (s,t)-cut of G that subdivides $\mathcal{W}$ and has at most two (s,t)-mincuts. We show that it is sufficient to work with $G(\mathcal{W})$ for each $\mathcal{W}$ to design compact structure for $(\lambda+1)$ (s,t)-cuts as well as dual edge sensitivity data structure for (s,t)-mincuts.

1. A 2-level DAG structure for $(\lambda+1)$ (s,t)-cuts. Along similar lines of $\mathcal{D}_\lambda$, we build a compact graph $\mathcal{D}_{\lambda+1}$ that stores all $(\lambda+1)$ (s,t)-cuts of $G(\mathcal{W})$. In order to establish the 1-transversality property of (s,t)-mincuts in $\mathcal{D}_\lambda$, the acyclicity of $\mathcal{D}_\lambda$ played a crucial role. Therefore, at first sight, we would expect $\mathcal{D}_{\lambda+1}$ to be acyclic and a $(\lambda+1)$ (s,t)-cut C in $G(\mathcal{W})$ to be a ℓ-transversal cut in $\mathcal{D}_{\lambda+1}$ – edge-set of C intersects any path in $\mathcal{D}_{\lambda+1}$ at most ℓ times, for some constant ℓ. We find that $\mathcal{D}_{\lambda+1}$ is not necessarily acyclic and, surprisingly enough, a $(\lambda+1)$ (s,t)-cut may appear in $\mathcal{D}_{\lambda+1}$ as an $\Omega(n)$-transversal cut. The root cause of non-acyclicity is the presence of pairs of cuts from Type-1. In order to tackle pairs of cuts from Type-1, we exploit the fact that $G(\mathcal{W})$ has at most two (s,t)-mincuts. We use the covering technique to construct a pair of graphs $G(\mathcal{W})^I$ and $G(\mathcal{W})^U$ that are Type-1 free. Now applying the same approach that was applied to obtain $\mathcal{D}_\lambda$, we construct a pair of DAGs – $\mathcal{D}_{\lambda+1}$ for graph $G(\mathcal{W})^I$ and $\mathcal{D}_{\lambda+1}$ for graph $G(\mathcal{W})^U$. This pair of DAGs is capable of characterizing each $(\lambda+1)$ (s,t)-cut in G that subdivides $\mathcal{W}$ as follows. A $(\lambda+1)$ (s,t)-cut in $G(\mathcal{W})$ appears as a *3-transversal* cut in exactly one of the two DAGs. In this way we obtain an $\mathcal{O}(m)$ size structure for compactly storing and characterizing all $(\lambda+1)$ (s,t)-cuts and it consists of two levels – (i) DAG $\mathcal{D}_\lambda$ and (ii) a pair of DAGs for each $(\lambda+1)$ (s,t)-class associated with a vertex of $\mathcal{D}_\lambda$.

Now we attempt to answer query $Q(u,v)$ using our 2-level DAG structure. Note that each 1-transversal cut in $\mathcal{D}_\lambda$ is also a (s,t)-mincut in G. Hence for the set of (s,t)-mincuts the query can be answered efficiently using a topological ordering of $\mathcal{D}_\lambda$. However, a 3-transversal cut in the pair of DAGs needs not be a $(\lambda+1)$ (s,t)-cut because of the existence of *certain* pairs of cuts from Type-2.

2. Data structure for $(\lambda+1)$ (s,t)-cuts. For each vertex u, there exists a unique (s,t)-mincut C, called *nearest (s,t)-mincut*, that keeps u on the side of s such that $C \subseteq C'$ for every other (s,t)-mincut C' that keeps u on the side of s. We can use this nearest (s,t)-mincut of u to determine if there exists a (s,t)-mincut C such that $u \in C$ and $v \in \overline{C}$ for any pair of vertices $\{u,v\}$. Unfortunately, there are multiple nearest $(\lambda+1)$ (s,t)-cuts that keep u on the side of s, and hence this approach fails.

Let $\mathcal{W}$ be the $(\lambda+1)$ (s,t)-class to which u belongs. Let C and C' be any pair of nearest $(\lambda+1)$ (s,t)-cuts of u. We show that C and C' do not *cross* in $\mathcal{W}$, that is, $\overline{C \cup C'} \cap \mathcal{W} = \emptyset$. Using this crucial insight, we are able to design an $\mathcal{O}(n^2)$ size data structure summarized in the following theorem.

▶ **Theorem 4.** *Let G be a directed multi-graph on n vertices and m edges with a designated source vertex s and a designated sink vertex t. There exists a data structure occupying $\mathcal{O}(n^2)$ space that can determine in $\mathcal{O}(k)$ time whether there exists a $(\lambda+1)$ (s,t)-cut C such that $u \in C$ and $v_1,\ldots,v_k \in \overline{C}$ for any given vertices $u, v_1,\ldots,v_k$ belonging to a $(\lambda+1)$ (s,t)-class. It can also report C in $\mathcal{O}(|\overline{C}|)$ time.*

3. An oracle for dual edge sensitivity for (s,t)-mincuts. We show that there is a data structure $\{\mathcal{F},\mathcal{I}\}$ occupying $\mathcal{O}(n^2)$ space which is capable of answering dual edge sensitivity query for (s,t)-mincuts in $\mathcal{O}(1)$ time. The data structure $\mathcal{F}$ for handling dual edge failure query is obtained as follows.

When both failed edges are not belonging to the same $(\lambda+1)$ (s,t)-class, data structures for (s,t)-mincuts are sufficient to answer the query. The main challenge arises when endpoints of both failed edges are belonging to the same $(\lambda+1)$ (s,t)-class $\mathcal{W}$. Notice that the data structure for $(\lambda+1)$ (s,t)-cut from Theorem 4 can determine whether there is a $(\lambda+1)$ (s,t)-cut in which a single failed edge is contributing, but cannot answer if both edges are contributing to a single $(\lambda+1)$ (s,t)-cut. Suppose there is a $(\lambda+1)$ (s,t)-cut C^* of G in which both failed edges, say (x,y) and (x',y'), are contributing. Then the necessary condition is that y' must not belong to the nearest $(\lambda+1)$ (s,t)-cut from x to y, and y must not belong to the nearest $(\lambda+1)$ (s,t)-cut from x' to y'. Therefore, if necessary condition holds then both edges are contributing to the union of the two nearest $(\lambda+1)$ (s,t)-cuts. However, the union needs not necessarily be a $(\lambda+1)$ (s,t)-cut because of the existence of certain pairs of $(\lambda+1)$ (s,t)-cuts from Type-2.

We employ the covering technique to tackle pairs of cuts from Type-2. Unfortunately, covering does not necessarily eliminate all Type-2 pairs of cuts like the way it does in case of Type-1 pairs. In order to tackle the problem arising due to the prevailing Type-2 pairs, we exploit the insight into the structure of $G(\mathcal{W})^I$ and $G(\mathcal{W})^U$. The end result is that, in order to determine whether any given pair of edges are contributing to a single $(\lambda+1)$ (s,t)-cut, we only have to perform a couple of nearest $(\lambda+1)$ (s,t)-cuts queries on $G(\mathcal{W})^I$ and $G(\mathcal{W})^U$.

4. Lower bound for various mincut data structures: We establish a close relationship between two seemingly unrelated problems – all-pairs directed reachability problem and dual edge sensitivity problem for (s,t)-mincuts. The classical problem of all-pairs directed reachability is defined as follows – Given a directed graph G on n vertices and m edges, preprocess it to form a data structure which can efficiently report if any given vertex v is reachable from another given vertex u. The problem becomes interesting when the underlying graph is sparse, that is, $m = o(n^2)$. It is natural to ask whether there is any data structure for the all-pairs directed reachability that takes $o(n^2)$ space and $o(m)$ query time ? Goldstein et al. [14], following the seminal work of Patrascu [22], stated a conjecture that concisely conveys the belief.

▶ **Conjecture 5** (Directed Reachability Hypothesis [14]). *Any data structure for the all-pairs reachability in a directed graph must either use $\tilde{\Omega}(n^2)$ space or $\tilde{\Omega}(m)$ query time. ($\tilde{\Omega}(.)$ denotes complexity upto polylogarithmic factors)*

We provide an $\mathcal{O}(m)$ time reduction from any instance of the all-pairs directed reachability problem for a given graph on n vertices and m edges to an instance of the dual edge sensitivity data structure for (s,t)-mincuts on a graph with $O(n)$ vertices and $\mathcal{O}(m)$ edges. Thus, assuming Conjecture 5 holds, our $\mathcal{O}(n^2)$ size data structure for dual edge sensitivity for (s,t)-mincuts is indeed the optimal size data structure for achieving $\mathcal{O}(1)$ query time. As a byproduct of this reduction, we establish conditional lower bounds on 2×2 flow tree. In particular, we show that if conjecture 5 holds, any data structure that can report the value of $(\{s,u\},\{v,t\})$-mincut for s,u,v and t being any four vertices of the graph must either use $\tilde{\Omega}(n^2)$ space or $\tilde{\Omega}(m)$ query time. An interesting implication of this result is a matching conditional lower bound for the data structure described in Theorem 4.

1.2 Related work

Benczur [2] gave an $\mathcal{O}(n^2)$ space geometric representation for all the global cuts of value within $\frac{6}{5}$ times the global minimum cut value. As an important application, this structure leads to the improvement in the time complexity of *splitting* algorithms [11].

Vazirani and Yannakakis [24] addressed the following fundamental question about (s,t)-cuts. – Is there a polynomial time algorithm to compute an (s,t)-cut of second minimum weight? They answered this question in the affirmative by showing that there is an algorithm which can compute a k^{th} minimum weight (s,t)-cut using only $\mathcal{O}(n^{2(k-1)})$ maximum flow computations. This algorithm gives an implicit structure for all (s,t)-cuts – a binary tree with ℓ leaves, that stores all (s,t)-cuts of G and the number of (s,t)-cuts is ℓ.

Another related work is on characterizing (s,t)-cuts using the polyhedron corresponding to the dual of linear programming (LP) formulation on maximum (s,t)-flow. Vazirani and Garg [13] showed that not all (s,t)-cuts can be characterized as the vertices of this polyhedron. Moreover, they modify the dual of the LP formulation by adding a polynomial number of constraints such that the corresponding polyhedron of the resulting LP formulation has all (s,t)-cuts as its vertices.

1.3 Organisation of the paper

Section 2 contains the basic preliminaries and the construction of a quotient graph for a set of $(\lambda + k)$ (s,t)-cuts. The technique of covering (s,t)-cuts is explained in Section 3. Section 4 contains the construction and properties of the alternate DAG structure for (s,t)-mincuts. The structure for $(\lambda + 1)$ (s,t)-cuts and their characterization is discussed in Section 5. The data structure for reporting $(\lambda + 1)$ (s,t)-cuts is constructed in Section 6. Section 7 contains the Oracle for dual-edge sensitivity of (s,t)-mincuts. Finally in Section 8 we give the lower bounds. Missing proofs of lemmas and theorems are provided in the full version.

2 Preliminaries

For any $X, Y \subseteq V$, the capacity of (X,Y) (denote by $c(X,Y)$) is the number of edges leaving X and entering Y; for brevity we use $c(X)$ to denote $c(X,\overline{X})$ where $\overline{X} = (V \setminus X)$. We say that an (s,t)-cut C *subdivides* $X \subseteq V$ if $C \cap X$ and $\overline{C} \cap X$ are non empty.

▶ **Definition 6** (Nearest $(\lambda+k)$ (s,t)-cut of a vertex). *The set $A \subset V$ with $s \in A$ and $t \in \overline{A}$ is said to be the nearest $(\lambda+k)$ (s,t)-cut of a vertex u if $u \in A$ and there is no $(\lambda+k)$ (s,t)-cut $B \subset V$ such that $u \in B$ and $B \subset A$. The set of all nearest $(\lambda+k)$ (s,t)-cuts of u is denoted by $N_k(u)$.*

▶ **Definition 7** (Nearest $(\lambda+k)$ (s,t)-cut for a pair of vertices). *Let A be a nearest $(\lambda+k)$ (s,t)-cut of a vertex u. For each vertex $v \in \overline{A}$, A is said to be a nearest $(\lambda+k)$ (s,t)-cut from vertex $\{u\}$ to a vertex $\{v\}$. The set of all nearest $(\lambda+k)$ (s,t)-cuts from u to v is denoted by $N_k(u,v)$.*

When $|N_1(u)| = 1$ (likewise $|N_1(u,v)| = 1$), without causing any ambiguity we use $N_1(u)$ (likewise $N_1(u,v)$) to denote the corresponding cut as well.

▶ **Definition 8** (ℓ-transversal cut). *A (s,t)-cut in a directed graph H is said to be ℓ-transversal, $\ell \geq 1$, if any path in H intersects with the edge-set of the (s,t)-cut at most ℓ times.*

▶ **Definition 9** (transpose of a graph). *Let H be a directed multi-graph with designated source vertex s and designated sink vertex t. The transpose of graph H (denoted by $(H)^{\mathcal{T}}$) is obtained by reversing the orientation of each edge of H with role of s and t swapped.*

▶ **Lemma 10** (Submodularity of cuts). *For any $A, B \subseteq V$, $c(A)+c(B) \geq c(A \cap B)+c(A \cup B)$.*

▶ **Lemma 11.** *Let A and B be any two (s,t)-mincuts in G that are crossing, that is, $A \setminus B$ as well as $B \setminus A$ are non-empty. There is no edge of G between $A \setminus B$ and $B \setminus A$.*

2.1 Quotient graph for a family of (s,t)-cuts

Let $\mathcal{C}$ be a set of $(\lambda+k)$ (s,t)-cuts in graph $G=(V,E)$ where $k \in \{0,1\}$. We define the following binary relation on the vertex set of G.

▶ **Definition 12** (Relation $R_{\lambda+k}$). *Any two vertices $\{x,y\} \in V$ are said to be related by $R_{\lambda+k}$ if and only if x and y are not separated by any $(\lambda+k)$ (s,t)-cut from $\mathcal{C}$.*

It is a simple exercise to show that $R_{\lambda+k}$ defines an equivalence relation on the vertex set. We call each equivalence class defined by $R_{\lambda+k}$ as a $(\lambda+k+1)$ (s,t)-class. It can be observed that any (s,t)-cut that subdivides a $(\lambda+k+1)$ (s,t)-class has capacity strictly larger than $\lambda+k$. The following lemma states how a $(\lambda+k)$ (s,t)-class is related to a $(\lambda+k)$ (s,t)-cut.

▶ **Lemma 13.** *A $(\lambda+k)$ (s,t)-cut can subdivide at most one $(\lambda+k)$ (s,t)-class.*

Since $R_{\lambda+k}$ is an equivalence relation, the $(\lambda+k+1)$ (s,t)-classes form a partition of the vertex set of G into disjoint subsets. Let $G_{\lambda+k}$ be the quotient graph of G obtained by contracting each of these subsets into single vertices. We call each vertex of the quotient graph as nodes. The node of $G_{\lambda+k}$ containing source s is denoted by S and the node containing sink t is denoted by T. We call an (S,T)-cut of $G_{\lambda+k}$ as (s,t)-cut without causing any ambiguity. The following theorem is immediate from the construction.

▶ **Theorem 14.** *For a directed multi-graph G and a set of $(\lambda+k)$ (s,t)-cuts $\mathcal{C}$ for any $k \in \{0,1\}$, there exists a quotient graph $G_{\lambda+k}$ of G such that $C \in \mathcal{C}$ is an (s,t)-cut in G if and only if C is a $(\lambda+k)$ (s,t)-cut in $G_{\lambda+k}$.*

An edge of $G_{\lambda+k}$ is classified as normal or *inverted* using the following definition.

▶ **Definition 15** (inverted edge for $(\lambda+k)$ (s,t)-cut). *An edge (x,y) of $G_{\lambda+k}$ is said to be an inverted edge if there exists no $(\lambda+k)$ (s,t)-cut $C \in \mathcal{C}$ such that $x \in C$ and $y \in \overline{C}$.*

▶ **Fact 16.** *For a directed multi-graph H and a set of $(\lambda+k)$ (s,t)-cuts $\mathcal{C}$, let $H_{\lambda+k}$ be the quotient graph of H. Given a pair of nodes μ, ν in graph $H_{\lambda+k}$, the contraction of all vertices which are mapped to μ or ν into a single vertex in H eliminates precisely all those $(\lambda+k)$ (s,t)-cuts from $\mathcal{C}$ that separate μ and ν.*

Consider two sets of $(\lambda+k)$ (s,t)-cuts $\mathcal{C}$ and $\mathcal{C}'$ such that $\mathcal{C} \subset \mathcal{C}'$. Let $G_{\lambda+k}$ and $G'_{\lambda+k}$ be the quotient graphs for $\mathcal{C}$ and $\mathcal{C}'$ respectively. It follows from construction of quotient graphs that there exists equivalence classes of $G_{\lambda+k}$ which are further split into multiple equivalence classes of $G'_{\lambda+k}$. Therefore, the following lemma is immediate.

▶ **Lemma 17.** *Given a directed multi-graph G, let $G_{\lambda+k}$ and $G'_{\lambda+k}$ be a pair of quotient graphs formed on the sets of $(\lambda+k)$ (s,t)-cuts $\mathcal{C}$ and $\mathcal{C}'$ respectively. If $\mathcal{C} \subset \mathcal{C}'$ then $G_{\lambda+k}$ is a quotient graph of $G'_{\lambda+k}$.*

3 A covering of all (s,t)-cuts of a special graph

We first formalize the notion of *covering* the (s,t)-cuts of a graph using the following definition.

▶ **Definition 18** (Covering all (s,t)-cuts)**.** *Given a directed multi-graph H with a designated source vertex s and a designated sink vertex t, let $F = \{H^1, H^2, \ldots, H^\ell\}$ be a finite set of directed multi-graphs, each defined on the same vertex set as that of H. F is said to cover all (s,t)-cuts of H if and only if the following conditions hold.*

1. *For each (s,t)-cut C in H, there exists a (s,t)-cut C' in H^i for a unique $1 \leq i \leq \ell$ such that $C = C'$.*
2. *For each (s,t)-cut C of finite capacity in H^i for any $1 \leq i \leq \ell$, there exists a (s,t)-cut C' in H such that $C = C'$.*

Let H be a directed multi-graph with a designated source vertex s and a designated sink vertex t that has at most two (s,t)-mincuts – $\{s\}$ and (complement of) $\{t\}$. Our aim is to compute a small family $F = \{H^1, H^2, \ldots, H^\ell\}$ that covers all (s,t)-cuts of H and satisfies the following condition – for each pair C, C' of (s,t)-cuts in H^i for any $1 \leq i \leq \ell$, either their intersection or union is not a λ (s,t)-cut.

We shall show that there exists a family $F = \{H^U, H^I\}$ of only two graphs that *covers* all (s,t)-cuts of H and satisfies the said property. We build two graph H^U and H^I from H as follows. Let x be any arbitrary vertex other than s and t of H. H^I is formed by adding infinite capacity edge from vertex s to x. In a similar way, H^U is formed by adding infinite capacity edge from vertex x to t. The following lemma ensures that H^U and H^I together cover all $(\lambda+k)$ (s,t)-cuts of H. It exploits the following simple fact – Let x be a vertex of graph H and C be any (s,t)-cut; either $x \in C$ or $x \in \overline{C}$.

▶ **Lemma 19.** *Let $\lambda' > 0$ be a finite number. C is an (s,t)-cut in H of capacity λ' if and only if C is a cut of capacity λ' in H^U or H^I.*

It follows from the construction that the first (s,t)-mincut of H, that is $\{s\}$, is present in H^U while the second (s,t)-mincut of H, that is (complement of) $\{t\}$ is present in H^I. So using Lemma 19, we can state the following theorem.

▶ **Theorem 20.** *Let $H = (V, E)$ be a directed multi-graph on n vertices and m edges with a designated source vertex s and a designated sink vertex t. Suppose H has at most two (s,t)-mincuts, $\{s\}$ and $V \setminus \{t\}$. There exists a set of graphs $F = \{H^I, H^U\}$ satisfying the following properties:*

1. *F covers all $(\lambda+k)$ (s,t)-cuts of H.*
2. *$V \setminus \{t\}$ is the only λ (s,t)-cut in H^I, and $\{s\}$ is the only λ (s,t)-cut in H^U.*

▶ Note 21. Covering technique cannot be applied to a graph H that has more than two (s,t)-mincuts. This is because, for any vertex x in H, there will be more than one (s,t)-mincuts that keep x on side of s and/or more than one (s,t)-mincuts that keep x on side of t. Therefore, there will be multiple (s,t)-mincuts in H^I or multiple (s,t)-mincuts in H^U, hence violating Theorem 20(2).

4 An alternate DAG structure storing all (s,t)-mincuts

We now present an alternate compact structure $\mathcal{D}_\lambda$ for representing and characterizing all (s,t)-mincuts of G.

Construction of $\mathcal{D}_\lambda$: Let G_λ be the quotient graph defined by all λ (s,t)-cuts of G (Theorem 14). D_λ is the graph obtained by reversing the direction of each inverted edge of G_λ. Exploiting just the elementary properties of (s,t)-mincuts alone (Lemma 11 and submodularity of cuts), we show that D_λ is acyclic. As the reader may notice, D_λ is related to the DAG of Picard and Queyranne [23] – the mapping of vertices to the nodes of the DAG is identical while the direction of each edge is flipped. Each (s,t)-mincut of G is characterized by a 1-transversal cut in D_λ as stated in the following lemma.

▶ **Lemma 22** (1-transversality property). *An (s,t)-cut is an (s,t)-mincut of G if and only if it appears as a 1-transversal cut in $\mathcal{D}_\lambda$.*

The following lemma can be proved along similar lines as Lemma 22.

▶ **Lemma 23.** *An (s,t)-cut of G is an (s,t)-mincut if and only if it appears as an (s,t)-cut with no incoming edge in $\mathcal{D}_\lambda$.*

Interestingly, $\mathcal{D}_\lambda$ can serve as a compact data structure for efficiently answering the query $Q(u,v)$ for (s,t)-mincuts as follows. Let τ be a topological ordering of $\mathcal{D}_\lambda$. For each edge (μ,ν) of $\mathcal{D}_\lambda$, $\tau(\mu) < \tau(\nu)$. Hence, it is a simple corollary of Lemma 22 that every prefix of τ is a (s,t)-mincut. Therefore, given any edge $(u,v) \in E$, there is a (s,t)-mincut in G containing it if u and v appear in different nodes of $\mathcal{D}_\lambda$ and the node containing u appears before the node containing v.

5 Structure of $(\lambda+1)$ (s,t)-cuts

In order to construct a compact structure for $(\lambda+1)$ (s,t)-cuts, we take an approach similar to the construction of $\mathcal{D}_\lambda$ for (s,t)-mincuts and construct a graph $\mathcal{D}_{\lambda+1}$ as follows.

Construction of $\mathcal{D}_{\lambda+1}$: Let $G_{\lambda+1}$ be the quotient graph defined by all $(\lambda+1)$ (s,t)-cuts (Theorem 14). $D_{\lambda+1}$ is the graph obtained by reversing the direction of each inverted edge of $G_{\lambda+1}$. Henceforth $\mathcal{D}_{\lambda+1}$ for a graph H is denoted by $\mathcal{D}_{\lambda+1}(H)$.

$\mathcal{D}_\lambda$ characterizes (s,t)-mincuts of G as 1-transversal cuts. Unfortunately, it turns out that $\mathcal{D}_{\lambda+1}(G)$ is not sufficient for characterizing $(\lambda+1)$ (s,t)-cuts in terms of ℓ-tranversal cuts for some constant ℓ as stated in the following theorem.

▶ **Theorem 24** ($\Omega(n)$-transversality). *There exists a directed multi-graph H on n vertices with a designated source vertex s and a designated sink vertex t having only two (s,t)-mincuts and a $(\lambda+1)$ (s,t)-cut C such that C appears as a $\Omega(n)$-transversal cut in $\mathcal{D}_{\lambda+1}(H)$.*

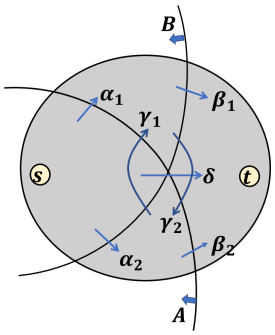

Figure 1 Contributing edges of a pair of (s,t)-cuts A and B between different regions.

We now provide a classification of all-pairs of $(\lambda+1)$ (s,t)-cuts. This classification will act as a crucial tool in the analysis of $\mathcal{D}_{\lambda+1}(G)$ as well as establishing properties of the compact structure for $(\lambda+1)$ (s,t)-cuts in Section 5.1.

Suppose A and B are any two $(\lambda+1)$ (s,t)-cuts. Using sub-modularity of cuts (Lemma 10), we arrive at the following inequality, $c(A\cap B)+c(A\cup B)\leq c(A)+c(B)=2(\lambda+1)$. Note that $c(A\cap B)\geq\lambda$ and $c(A\cup B)\geq\lambda$. This implies that the value of $c(A\cap B)+c(A\cup B)$ will always belong to $\{2\lambda,\ 2\lambda+1,\ 2\lambda+2\}$. Therefore, each pair (A,B) of $(\lambda+1)$ (s,t)-cuts can be classified uniquely into one of the three types based on the value of $c(A\cap B)+c(A\cup B)$. We now state the following lemma that will provide an alternate characterization of these three types based on the number of edges between $A\setminus B$ and $B\setminus A$.

▶ **Lemma 25.** *Suppose A and B are any two $(\lambda+1)$ (s,t)-cuts. Let γ_1 and γ_2 denote the number of edges from $A\setminus B$ to $B\setminus A$ and from $B\setminus A$ to $A\setminus B$ respectively. If $c(A\cap B)=\lambda+p$ and $c(A\cup B)=\lambda+q$ for some $p,q\geq 0$, then $\gamma_1+\gamma_2=2-p-q$.*

Proof. The cuts A and B partition G into at most 4 regions. Refer to Figure 1 for the illustration of these regions and the edges contributing to the respective cuts.

The following equations follow directly from Figure 1.

$$c(A\cap B)=\alpha_1+\alpha_2+\delta=\lambda+p \tag{1}$$
$$c(A\cup B)=\beta_1+\beta_2+\delta=\lambda+q \tag{2}$$
$$c(B)=\beta_1+\alpha_2+\gamma_2+\delta=\lambda+1 \tag{3}$$
$$c(A)=\beta_2+\alpha_1+\gamma_1+\delta=\lambda+1 \tag{4}$$

Using equations (1) and (3) we get $\alpha_1=\beta_1+\gamma_2+p-1$. Similarly using equations (1) and (4) we get $\alpha_2=\beta_2+\gamma_1+p-1$. By combining these two equalities, we get $\alpha_1+\alpha_2=\beta_1+\beta_2+\gamma_1+\gamma_2+2p-2$. Hence $\gamma_1+\gamma_2=2-p-q$, since $\alpha_1+\alpha_2=\beta_1+\beta_2+p-q$ from equations (2) and (1). ◀

Refer to Table 1 for two ways to characterize the three types of pairs of $(\lambda+1)$ (s,t)-cuts.

Table 1 Classification of any pair (A,B) of $(\lambda+1)$ (s,t)-cuts.

	$c(A\cap B)+c(A\cup B)$	$c(A\setminus B,B\setminus A)+c(B\setminus A,A\setminus B)$
Type-1	2λ	2
Type-2	$2\lambda+2$	0
Type-3	$2\lambda+1$	1

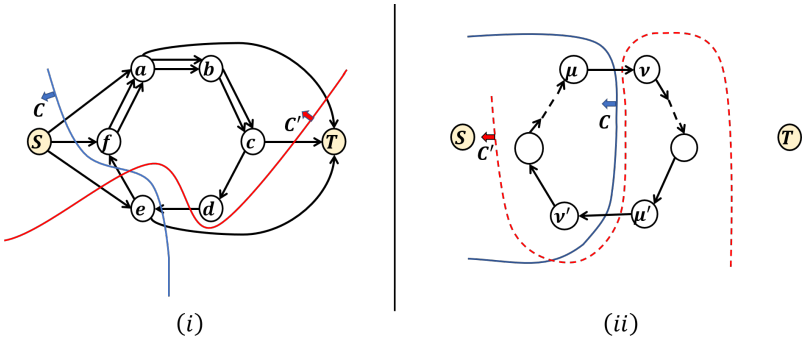

Figure 2 (i) An example of $\mathcal{D}_{\lambda+1}(G)$ with cycle $\langle a, b, c, d, e, f, a\rangle$. Note that here $\mathcal{D}_{\lambda+1}(G)$ turns out to be same as G. (ii) Cycle O in graph $\mathcal{D}_{\lambda+1}(H)$ from the proof of Lemma 27.

It follows from Theorem 24 that transversality of $(\lambda+1)$ (s,t)-cuts cannot be bounded by a constant even if a graph has at most two (s,t)-mincuts – $\{s\}$ and (complement of) $\{t\}$. In the following section, we shall first give a compact structure for $(\lambda+1)$ (s,t)-cuts for graph G assuming that G has at most two (s,t)-mincuts. Finally, we shall extend it to general graphs with the help of the structure of $\mathcal{D}_\lambda$ in Section 5.1.1.

5.1 Compact representation and characterization of $(\lambda+1)$ (s,t)-cuts

The characterization of (s,t)-mincuts crucially exploits the fact that $\mathcal{D}_\lambda$ is a DAG. Unfortunately, as shown in Figure 2(i), $\mathcal{D}_{\lambda+1}(G)$ can have cycles. The following lemma states the source of any 2-length cycle in $\mathcal{D}_{\lambda+1}$.

▶ **Lemma 26.** *If graph G does not have any pair of cuts from Type-1, then $\mathcal{D}_{\lambda+1}(G)$ cannot have a cycle of length two.*

Proof. Suppose we have a 2-length cycle $\langle \mu, \nu, \mu\rangle$ in $\mathcal{D}_{\lambda+1}(G)$. It follows from construction of $\mathcal{D}_{\lambda+1}$ that there exists a $(\lambda+1)$ (s,t)-cut C for the edge (μ,ν) such that $\mu \in C$ and $\nu \in \overline{C}$. In a similar manner there exists a $(\lambda+1)$ (s,t)-cut C' for the edge (ν,μ) such that $\nu \in C'$ and $\mu \in \overline{C'}$. It can be observed that (C, C') forms a pair of cuts from Type-1, a contradiction. ◀

In fact, the absence of pairs of $(\lambda+1)$ (s,t)-cuts from Type-1 is a sufficient condition for acyclicity as stated in the following lemma.

▶ **Lemma 27** (acyclicity property)**.** *If graph G does not have any pair of cuts from Type-1, then $\mathcal{D}_{\lambda+1}(G)$ is a directed acyclic graph.*

Proof. We begin with stating the following assertion.
$\mathcal{A}(i)$: For any graph H that has no pair of $(\lambda+1)$ (s,t)-cuts from Type 1, there is no cycle of length i in $\mathcal{D}_{\lambda+1}(H)$.
We shall now prove, by induction on i, that $\mathcal{A}(i)$ holds for all $i \geq 2$, and this would establish the lemma. The base case, $\mathcal{A}(2)$ follows directly from Lemma 26. Suppose $\mathcal{A}(j)$ holds for all $j < i$. We shall now prove that $\mathcal{A}(i)$ holds.

Suppose there is a cycle O of length i in $\mathcal{D}_{\lambda+1}(H)$ (see Figure 2(ii)). Consider any arbitrary edge (μ,ν) in this cycle. It follows from construction of $\mathcal{D}_{\lambda+1}(H)$ that there exists a $(\lambda+1)$ (s,t)-cut C of H such that $\mu \in C$ and $\nu \in \overline{C}$. Let $\mathcal{U}$ be the set of vertices of H that are mapped to either μ or ν. Contracting the set $\mathcal{U}$ into a single vertex we obtain a new graph H' from H.

It follows from Fact 16 and Lemma 17 that $\mathcal{D}_{\lambda+1}(H')$ has to be a quotient graph of $\mathcal{D}_{\lambda+1}(H)$. As a result, cycle O in $\mathcal{D}_{\lambda+1}(H)$ will be mapped to either a cycle of length strictly less than i or a single node in $\mathcal{D}_{\lambda+1}(H')$. The Induction Hypothesis rules out the possibility of the former case. We shall now rule out the possibility of the latter case. This will establish the validity of $\mathcal{A}(i)$.

The cut C must contain at least one more edge, say (μ', ν'), of cycle O because the cycle O must intersect the edge-set of C at least twice. It follows from the construction of $\mathcal{D}_{\lambda+1}(H)$ that there exists a $(\lambda+1)$ (s,t)-cut, say C', in $\mathcal{D}_{\lambda+1}(H)$ such that $\mu' \in C'$ and $\nu' \in \overline{C'}$. Since μ' and ν' belong to the same node in $\mathcal{D}_{\lambda+1}(H')$, the cut C' is not present in H'. This observation, in the light of Fact 16, implies that C' must separate μ and ν (dashed curve in Figure 2). This would imply that for the pair of cuts (C, C'), $c(C \setminus C', C' \setminus C) + c(C' \setminus C, C \setminus C') = 2$. Hence (C, C') forms a Type-1 pair of $(\lambda+1)$ (s,t)-cut in H, a contradiction. ◀

In order to have acyclic structures that collectively preserve all $(\lambda+1)$ (s,t)-cuts, Lemma 27 raises the following question – can we partition the set of $(\lambda+1)$ (s,t)-cuts such that each partition does not contain any pair of $(\lambda+1)$ (s,t)-cut from Type-1? The covering technique (Theorem 20) gives an affirmative answer to this question. In particular, it outputs just a pair of graphs $\{G^I, G^U\}$ such that all $(\lambda+1)$ (s,t)-cuts of G are covered by G^I and G^U together. Moreover, both G^U and G^I will contain exactly one (s,t)-mincut each, and this ensures that there are no pairs of $(\lambda+1)$ (s,t)-cuts from Type-1 in G^I or G^U. Therefore, it follows from Lemma 27 that $\mathcal{D}_{\lambda+1}(G^I)$ and $\mathcal{D}_{\lambda+1}(G^U)$ are acyclic. In the case when G has exactly one (s,t)-mincut, $\mathcal{D}_{\lambda+1}(G)$ itself is acyclic.

Not only $\mathcal{D}_{\lambda+1}(G^I)$ and $\mathcal{D}_{\lambda+1}(G^U)$ are acyclic but also help in characterizing $(\lambda+1)$ (s,t)-cuts as follows.

We show that each $(\lambda+1)$ (s,t)-cut of G is 3-transversal in $\mathcal{D}_{\lambda+1}(G^I)$ or in $\mathcal{D}_{\lambda+1}(G^U)$. Without loss of generality let us consider the graph $\mathcal{D}_{\lambda+1}(G^U)$. In order to accomplish 3-transversality of $(\lambda+1)$ (s,t)-cuts in $\mathcal{D}_{\lambda+1}(G^U)$, we first show that for any path in $\mathcal{D}_{\lambda+1}(G^U)$ whose first node is not S, there is no $(\lambda+1)$ (s,t)-cut which can keep both the first and the last node of the path on side of S, and remaining nodes on side of T. As a warm-up, the following lemma validates this assertion for all paths of length two.

▶ **Lemma 28.** *Let $P = \langle v_0 \neq S, v_1, v_2 \rangle$ be a path in $\mathcal{D}_{\lambda+1}(G^U)$. There can not exist any $(\lambda+1)$ (s,t)-cut C such that $v_0, v_2 \in C$ and $v_1 \in \overline{C}$.*

Proof. We give a proof by contradiction. Assume that there is such a $(\lambda+1)$ (s,t)-cut C. It follows from the construction of $\mathcal{D}_{\lambda+1}(G^U)$ that there is a $(\lambda+1)$ (s,t)-cut C' for the edge (v_1, v_2) such that $v_1 \in C'$ and $v_2 \in \overline{C'}$. It can be observed that the edge (v_1, v_2) is an edge from $C' \setminus C$ to $C \setminus C'$. Therefore, $\{C, C'\}$ cannot be a pair from Type-2. $\{C, C'\}$ cannot be pair from Type-1 as well since there is no pair of $(\lambda+1)$ (s,t)-cuts from Type-1 in $\mathcal{D}_{\lambda+1}(G^U)$. So, $\{C, C'\}$ must be a pair from Type-3. Notice that $C \cup C'$ has capacity $\lambda+1$ since the only λ (s,t)-cut in G^U is $\{s\}$. Hence, $C \cap C'$ must be containing the node S only. Since $v_0 \in C$, therefore, v_0 cannot belong to C' and hence the edge-set of C' must intersect path P again at edge (v_0, v_1). Then, in that case, there are two edges (v_0, v_1) and (v_1, v_2) between $C \setminus C'$ and $C' \setminus C$. This implies that (C, C') are from Type-1, a contradiction. ◀

Generalizing Lemma 28 for any arbitrary length path, we give the following lemma which will provide the foundation for establishing 3-transversality of $(\lambda+1)$ (s,t)-cuts.

▶ **Lemma 29.** *Let $P = \langle v_0 \neq S, v_1, \ldots, v_i \rangle$ be a simple path in $\mathcal{D}_{\lambda+1}(G^U)$. There does not exist a $(\lambda+1)$ (s,t)-cut C such that $v_0, v_i \in C$ and $v_1, \ldots, v_{i-1} \in \overline{C}$.*

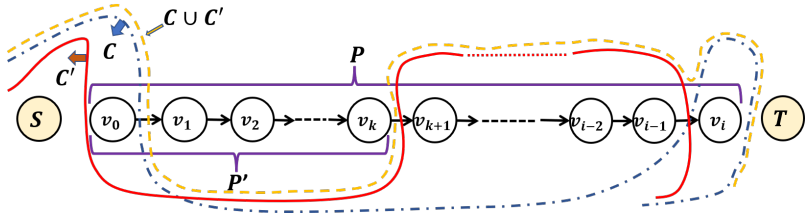

Figure 3 C: dash-dot curve, C': solid curve, $C \cup C'$: dashed curve, (v_{i-1}, v_i) is in $E(C) \cap E(C')$.

Proof. We begin with stating the following assertion.

$\mathcal{A}(i)$: There does not exist a $(\lambda+1)$ (s,t)-cut C such that $v_0, v_i \in C$ and $v_1, \ldots, v_{i-1} \in \overline{C}$ for a path $P = \langle v_0 \neq S, v_1, \ldots, v_{i-1}, v_i \rangle$ of length i.

We shall use proof by induction on the length of the path $i \geq 2$ to show that $\mathcal{A}(i)$ holds. The base case, $\mathcal{A}(2)$ follows directly from Lemma 28.

Let us now assume that $\mathcal{A}(j)$ holds for all $2 \leq j < i$. We shall prove that $\mathcal{A}(i)$ holds using a proof by contradiction. Assume to the contrary that there is a $(\lambda+1)$ (s,t)-cut C such that $v_0, v_i \in C$ and $v_1, \ldots, v_{i-1} \in \overline{C}$ (refer to Figure 3). It follows from the construction of $\mathcal{D}_{\lambda+1}(G^U)$ that there is a $(\lambda+1)$ (s,t)-cut C' for the edge (v_{i-1}, v_i) such that $v_{i-1} \in C'$ and $v_i \in \overline{C'}$. Along similar lines of the proof of Lemma 28 we can argue that (C, C') are pairs from Type-3 with $c(C \cup C') = \lambda + 1$, and edge-set of C' must be intersecting path P at least one more time before the edge (v_{i-1}, v_i). So, let (v_k, v_{k+1}), $0 \leq k < i-1$, be the first edge on P that intersects edge-set of C'. Now, there are two possible cases, either $k = 0$ and $v_{k+1} = v_1$ or $k > 0$. In the former case, it is easy to observe that two edges (v_0, v_1) and (v_{i-1}, v_i) lie between $C' \setminus C$ and $C \setminus C'$. Therefore, (C, C') must be from Type-1, a contradiction. In the latter case, observe that $v_0, \ldots, v_k \notin C'$ and $v_{k+1} \in C'$ because (v_k, v_{k+1}) is the nearest edge from v_0 in P that intersects edge-set of C'. Therefore, $v_0, v_{k+1} \in C \cup C'$ and $v_1, \ldots, v_k \notin C \cup C'$. So, we get a path $P' = \langle v_0, \ldots . v_{k+1} \rangle$ and a $(\lambda+1)$ (s,t)-cut $C \cup C'$ such that $v_0, v_{k+1} \in C \cup C'$ and $v_1, \ldots, v_k \in \overline{C \cup C'}$. Moreover, path P' has length strictly smaller than i because $k < i-1$. Therefore, $\mathcal{A}(k+1)$ fails to hold and $k+1 < i$, a contradiction. ◀

Now in the following lemma, using Lemma 29 we argue that there cannot exist any $(\lambda+1)$ (s,t)-cut C in $\mathcal{D}_{\lambda+1}(G^U)$ such that edge-set of C intersects a path P more than thrice.

▶ **Lemma 30** (3-transversality property). *Each $(\lambda+1)$ (s,t)-cut of G is 3-transversal in $\mathcal{D}_{\lambda+1}(G^I)$ or in $\mathcal{D}_{\lambda+1}(G^U)$.*

Proof. Without loss of generality let us consider $\mathcal{D}_{\lambda+1}(G^U)$. The proof is along similar lines for $\mathcal{D}_{\lambda+1}(G^I)$. We give a proof by contradiction. Assume to the contrary that there exists a $(\lambda+1)$ (s,t)-cut C in G and a path P in $\mathcal{D}_{\lambda+1}(G^U)$ such that edge-set of C intersects path P more than thrice. Then, path P can be divided into at least 5 contiguous disjoint subpaths $\{P_1, P_2, P_3, P_4, P_5\}$. For the cut C, observe that either each node of P_i is on side of S for all odd i and each node of P_i is on side of T for all even i or vice versa. In the former case, let us consider the subpath $P' = \langle P_3, P_4, P_5 \rangle$ of P. For this path P', we have each node of P_3, P_5 in C and each node of P_4 in $\overline{C}$. Moreover, S cannot belong to P_3 because by construction of $\mathcal{D}_{\lambda+1}(G^U)$ there is no incoming edge to S. Therefore, we have a path P' with first node (not S) and last node in $(\lambda+1)$ (s,t)-cut C and other nodes are in $\overline{C}$. This contradicts Lemma 29. In a similar way we can argue the latter case using subpath $P' = \langle P_2, P_3, P_4 \rangle$. ◀

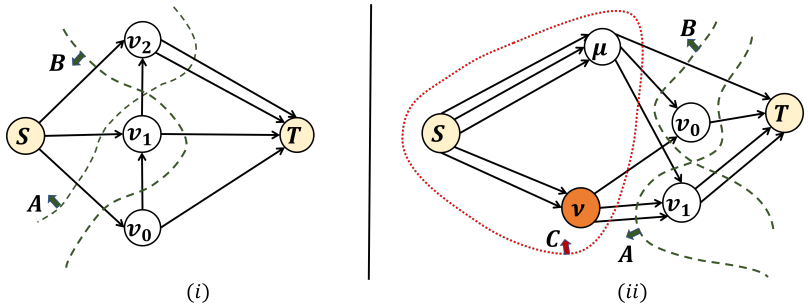

Figure 4 (i) The edge-set of $(\lambda+1)$ (s,t)-cut A intersects path $\langle S, v_1, v_2, T\rangle$ thrice; A and B are $(\lambda+1)$ (s,t)-cuts from Type-3. (ii) A 1-transversal cut $C = A \cap B$ with capacity greater than $\lambda+1$.

We also show that there are $(\lambda+1)$ (s,t)-cuts which may not appear in $\mathcal{D}_{\lambda+1}$ as 1-transversal cut (refer to Figure 4(i)). This is because, for each 3-transversal $(\lambda+1)$ (s,t)-cut A, there exists a $(\lambda+1)$ (s,t)-cut B such that A, B are pairs from Type-3. Therefore, our bound of 3-transversality is tight.

5.1.1 Extension to general graphs

The compact structure and characterization of $(\lambda+1)$ (s,t)-cuts are valid if the graph has at most two (s,t)-mincuts. However, in general, graphs can have exponential number of (s,t)-mincuts. To tackle this difficulty we explore how a $(\lambda+1)$ (s,t)-cut is related to the $(\lambda+1)$ (s,t)-classes of a graph G. There are $(\lambda+1)$ (s,t)-cuts in G which do not subdivide any $(\lambda+1)$ (s,t)-class. We call them *degenerate* $(\lambda+1)$ (s,t)-cuts. These cuts appear in $\mathcal{D}_\lambda$ and have the following characterization.

▶ **Lemma 31.** *An (s,t)-cut of G is a degenerate $(\lambda+1)$ (s,t)-cut if and only if it appears as an (s,t)-cut with exactly one incoming edge in $\mathcal{D}_\lambda$.*

Henceforth, our main focus is on the non-degenerate $(\lambda+1)$ (s,t)-cuts – cuts that subdivide $(\lambda+1)$ (s,t)-classes. It follows from Lemma 13 that each such $(\lambda+1)$ (s,t)-cut subdivides precisely one $(\lambda+1)$ (s,t)-class. Therefore, the set of all $(\lambda+1)$ (s,t)-cuts can be partitioned into disjoint subsets where each subset subdivides exactly one $(\lambda+1)$ (s,t)-class. This partitioning allows us to work separately with each $(\lambda+1)$ (s,t)-class. Let $\mathcal{W}$ be a $(\lambda+1)$ (s,t)-class. In order to build a compact structure that stores all $(\lambda+1)$ (s,t)-cuts that subdivide $\mathcal{W}$, we now define a graph $G(\mathcal{W})$ associated with $\mathcal{W}$ as follows.

Construction of $G(\mathcal{W})$: Let τ be a topological ordering of $\mathcal{D}_\lambda$ where source node S (likewise T) has the smallest (likewise highest) topological number. $G(\mathcal{W})$ is obtained by forming a quotient graph of G using τ as follows. Let μ be the node of $\mathcal{D}_\lambda$ corresponding to $\mathcal{W}$. All nodes that precede μ in the topological ordering τ are contracted into a single source node S' and every node that succeeds μ are contracted to a single sink node T'.

It is easy to observe that $s \in S'$ (likewise $t \in T'$) since $s \in S$ (likewise $t \in T$). Henceforth without causing any ambiguity we denote an (S', T')-cut in $G(\mathcal{W})$ as an (s,t)-cut in $G(\mathcal{W})$. The following lemma establishes the mapping between the $(\lambda+1)$ (s,t)-cuts of G and $G(\mathcal{W})$.

▶ **Lemma 32.** *A $(\lambda+1)$ (s,t)-cut C in G subdivides a $(\lambda+1)$ (s,t)-class $\mathcal{W}$ into $(\mathcal{W}_1, \mathcal{W}\setminus\mathcal{W}_1)$ if and only if there exists a $(\lambda+1)$ (s,t)-cut $C' = \mathcal{W}_1 \cup \{S'\}$ in $G(\mathcal{W})$.*

It is easy to observe that graph $G(\mathcal{W})$ can have at most two (s,t)-mincuts – S' and complement of T'. Therefore, we construct pair of DAGs, $\mathcal{D}_{\lambda+1}((G(\mathcal{W}))^I)$ and $\mathcal{D}_{\lambda+1}((G(\mathcal{W}))^U)$, for each $(\lambda+1)$ (s,t)-class $\mathcal{W}$. Now we summarize these structural and characterization results in the following theorem.

▶ **Theorem 33.** *For any directed multi-graph G, on n vertices and m edges with a designated source vertex s and a designated sink vertex t, there exists a 2-level DAG structure of $\mathcal{O}(m)$ size–(i) $\mathcal{D}_\lambda$ and (ii) a pair of DAGs associated with each node of $\mathcal{D}_\lambda$, such that all $(\lambda+1)$ (s,t)-cuts of G are compactly stored and characterized as follows.*

1. *a non-degenerate $(\lambda+1)$ (s,t)-cut of G subdividing a $(\lambda+1)$ (s,t)-class $\mathcal{W}$ is a 3-transversal cut in one of the two DAGs associated with $\mathcal{W}$, and*
2. *an (s,t)-cut of G is a degenerate $(\lambda+1)$ (s,t)-cut if and only if it has exactly one incoming edge in $\mathcal{D}_\lambda$.*

We now explore the possibility of answering query $Q(u,v)$ using the pair of DAGs, $\mathcal{D}_{\lambda+1}(G^I)$ or $\mathcal{D}_{\lambda+1}(G^U)$. Recall that for the case of (s,t)-mincuts, just storing a topological ordering of $\mathcal{D}_\lambda$ is sufficient to answer query $Q(u,v)$ because each 1-transversal cut in $\mathcal{D}_\lambda$ is also an (s,t)-mincut. However, a 1-transversal cut in $\mathcal{D}_{\lambda+1}(G^I)$ or $\mathcal{D}_{\lambda+1}(G^U)$ needs not be a $(\lambda+1)$ (s,t)-cut. For example, cut $A \cap B$ as shown in Figure 4(ii) is 1-transversal but has capacity $\lambda+2$. Note that A and B form a $(\lambda+1)$ (s,t)-cuts from Type-2. In the following section, we provide a compact data structure that can answer query $Q(u,v)$ even when (u,v) is not necessarily an edge.

6 Compact data structures for reporting $(\lambda+1)$ (s,t)-cuts

In this section we address the very fundamental problem of reporting any $(\lambda+1)$ (s,t)-cut C for a given pair of vertices $\{u,v\}$ such that $u \in C$ and $v \in \overline{C}$, if exists. In order to answer the query it is sufficient to verify if v is separated by at least one of the cuts from $N_1(u)$. Note that in case of (s,t)-mincut, it suffices to store the $N_0(u)$ which turns out to be unique for each vertex u. This structure occupies $\mathcal{O}(n^2)$ space and achieves $\mathcal{O}(|C|)$ time for reporting the (s,t)-mincut C such that $u \in C$ and $v \in \overline{C}$. Unfortunately, $N_1(u)$ can have more than one elements (as shown in Figure 4 that both A and B belong to $N_1(\nu)$). This is because unlike for (s,t)-mincuts, the set of all $(\lambda+1)$ (s,t)-cuts that keep a vertex u on the side of s is not closed under intersection and union operations.

In order to design compact data structure for reporting $(\lambda+1)$ (s,t)-cut, as discussed in Section 5.1.1, we work on each $(\lambda+1)$ (s,t)-class. Let $\mathcal{W}$ be a $(\lambda+1)$ (s,t)-class in graph G and $u,v \in \mathcal{W}$. Although $N_1(u)$ can have multiple elements, it can be shown using sub-modularity of cuts (Lemma 10) that $N_1(u,v)$ is unique. However, this fact alone guarantees $\mathcal{O}(|\mathcal{W}|^3)$ space data structure for determining the existence of $N_1(u,v)$ for any pair of vertices $u,v \in \mathcal{W}$. In order to achieve more compact data structure we explore how $N_1(u,v)$ is related to $N_1(u,w)$ for any $w \in \mathcal{W}$. The following lemma provides an important insight into this relationship.

▶ **Lemma 34.** *If $N_1(u,v) \neq N_1(u,w)$ for any $\{u,v,w\}$ in $\mathcal{W}$, then $\mathcal{W} \subseteq N_1(u,v) \cup N_1(u,w)$.*

Proof. The proof is by contradiction. Let $C = N_1(u,v)$ and $C' = N_1(u,w)$. Assume that there is a vertex in $\mathcal{W}$ which is also in $\overline{C \cup C'}$. In that case both $C \cap C'$ and $C \cup C'$ subdivide $\mathcal{W}$; therefore, capacity of each of them is strictly larger than λ. So it immediately follows from sub-modularity of cuts (Lemma 10) that $c(C \cap C')$ is $(\lambda+1)$. Therefore we have a $(\lambda+1)$ (s,t)-cut $C \cap C'$ which is a proper subset of at least one of C and C'. Therefore, C or C' fails to satisfy Definition 7 – a contradiction. ◀

Now let $N_1(u) = \{C_1, C_2, \ldots, C_l\}$. Consider any vertex $v \in \mathcal{W}$. If v belongs to $\bigcap_{i=1}^{l} C_i$, then $N_1(u, v)$ does not exist; otherwise, Lemma 34 implies that v is separated from u by exactly one of the cuts from $N_1(u)$. As a result the sets $\overline{C_i} \cap \mathcal{W}$ for each $i \in [l]$ are disjoint. In order to determine the position of any other vertex, $w \in \mathcal{W}$, with respect to $N_1(u, v)$, we formulate the following query.

$$\textsc{belong}(u, v, w) = \begin{cases} 1 & \text{if } N_1(u, v) \text{ exists and } w \in N_1(u, v) \\ 0 & \text{otherwise.} \end{cases}$$

For each vertex $x \in \mathcal{W} \setminus \{u\}$, if $x \in \overline{C_i}$ for any $i \in [l]$ then mark x with label i. Now if label of v and w are same, then w is not present in $N_1(u, v)$, otherwise w belongs to $N_1(u, v)$. In this way we can answer query $\textsc{belong}(u, v, w)$ in $\mathcal{O}(1)$ time. Therefore, the following lemma is immediate.

▶ **Lemma 35.** *Let $\mathcal{W}$ be a $(\lambda + 1)$ (s, t)-class and $u \in \mathcal{W}$. There exists an $\mathcal{O}(|\mathcal{W}|)$ size data structure $\mathcal{N}_{\lambda+1}(u)$ that can determine in $\mathcal{O}(k)$ time whether there exists a $(\lambda+1)$ (s, t)-cut C such that $u \in C$ and $v_1, \ldots, v_k \in \overline{C}$ for any $v_1, \ldots, v_k \in \mathcal{W}$. If C exists, the data structure can output $\overline{C} \cap \mathcal{W}$ in $\mathcal{O}(|\overline{C} \cap \mathcal{W}|)$ time.*

Moreover, given vertices $u, v_1, \ldots, v_k \in \mathcal{W}$, $\mathcal{N}_{\lambda+1}(u)$ can be used to report a $(\lambda + 1)$ (s, t)-cut C, if exists, in $\mathcal{O}(|\overline{C}|)$ time using an auxiliary $\mathcal{O}(n)$ space topological ordering of $\mathcal{D}_\lambda$ of G such that $u \in C$ and $v_1, \ldots, v_k \in \overline{C}$. Now based on Lemma 35 we construct the following data structure for $(\lambda + 1)$ (s, t)-class $\mathcal{W}$.

Description of $\mathcal{N}_{\lambda+1}$: It consists of $\mathcal{N}_{\lambda+1}(u)$ for each u in $\mathcal{W}$.

$\mathcal{N}_{\lambda+1}$ for a $(\lambda + 1)$ (s, t)-class $\mathcal{W}$ occupies $\mathcal{O}(|\mathcal{W}|^2)$ space. Each $(\lambda + 1)$ (s, t)-class is disjoint from each other. Hence by constructing $\mathcal{N}_{\lambda+1}$ for each $(\lambda + 1)$ (s, t)-class of G we get an $\mathcal{O}(n^2)$ size data structure and it completes the proof of Theorem 4. We complement this result with a conditional lower bound of $\tilde{\Omega}(n^2)$ space based on Conjecture 5.

7 Dual edge sensitivity oracle for (s, t)-mincuts

In this Section we shall present an oracle that can efficiently report (s, t)-mincut upon the failure of a pair of edges in graph G. We say that an edge (u, v) belongs to a $(\lambda+1)$ (s, t)-class $\mathcal{W}$ if both $u, v \in \mathcal{W}$.

7.1 Handling dual edge failures

Consider the failure of two edges $e = (x, y), e' = (x', y')$ in G. Suppose at least one of $\{e, e'\}$ does not belong to any $(\lambda + 1)$ (s, t)-class. In this case the value of (s, t)-mincut decreases by at least 1 if $N_0(x, y)$ or $N_0(x', y')$ exists. The value of (s, t)-mincut decreases by exactly 2 if and only if both e, e' are contributing to a single (s, t)-mincut. To determine the existence of such an (s, t)-mincut, since (s, t)-mincuts are closed under union operation, it is sufficient to verify whether $y \notin N_0(x', y')$ and $y' \notin N_0(x, y)$. So we construct a data structure, denoted by $\mathcal{N}_\lambda$, which consists of $N_0(u)$ for each vertex u of G. This $\mathcal{O}(n^2)$ space data structure achieves $\mathcal{O}(1)$ time to report the resulting value of (s, t)-mincut on failure of $\{e, e'\}$ in this case.

If e and e' belong to distinct $(\lambda + 1)$ (s, t)-classes, then it follows from Lemma 13 that the (s, t)-mincut value remains unchanged. Let us consider case when both e and e' belong to the same $(\lambda + 1)$ (s, t)-class, say $\mathcal{W}$. It follows as a simple corollary of Lemma 32 that we just need to verify if there is a $(\lambda + 1)$ (s, t)-cut in $G(\mathcal{W})$ in which e and e' are contributing. Note that the only $(\lambda + 1)$ (s, t)-class of $G(\mathcal{W})$ is $\mathcal{W}$.

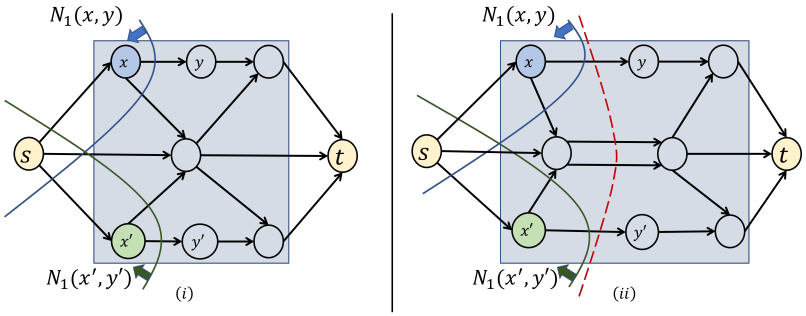

Figure 5 Graph (i) has no $\lambda+1$ (s,t)-cut containing edges (x,y) and (x',y'), but Graph (ii) does have one such cut shown by dashed curve.

Consider the data structure $\mathcal{N}_{\lambda+1}$ for $\mathcal{W}$ in $G(\mathcal{W})$. For the existence of a $(\lambda+1)$ (s,t)-cut in which both e and e' are contributing, observe that a necessary condition is that $y \notin N_1(x',y')$ and $y' \notin N_1(x,y)$. These conditions can be verified using $\mathcal{N}_{\lambda+1}$ in $\mathcal{O}(1)$ time. Upon checking these conditions, a natural approach would be to explore whether the union of these two cuts is a $(\lambda+1)$ (s,t)-cut. Unfortunately, we can not infer anything conclusively from the union of these cuts as illustrated by the two graphs in Figure 5. In both these graphs, $N_1(x,y) \cup N_1(x',y')$ is not a $(\lambda+1)$ (s,t)-cut . However, for graph (i), no $(\lambda+1)$ (s,t)-cut exists that contains the two edges; for graph (ii), there is still a $(\lambda+1)$ (s,t)-cut containing the two edges. Note that in these graphs, $N_1(x,y)$ and $N_1(x',y')$ are pairs of $(\lambda+1)$ (s,t)-cuts from Type-2. Looking at this hurdle carefully, we get the following insight. Since y, y' both lie outside $N_1(x',y') \cup N_1(x,y)$, hence $c(N_1(x,y) \cup N_1(x',y'))$ has to be $> \lambda$. Therefore, if $c(N_1(x,y) \cap N_1(x',y'))$ is also $> \lambda$, then using sub-modularity of cuts (Lemma 10), their union is bound to be a $(\lambda+1)$ (s,t)-cut and this will serve our purpose. Unfortunately, $G(\mathcal{W})$ does not ensure that $c(N_1(x,y) \cap N_1(x',y'))$ is greater than λ as shown in Figure 5.

In order to materialize the above insight, we use covering technique (Theorem 20) to build the pair of graphs $\{G(\mathcal{W})^I, G(\mathcal{W})^U\}$ that partition all $(\lambda+1)$ (s,t)-cuts of $G(\mathcal{W})$. It follows from Theorem 20(2) that the capacity of the intersection (likewise union) of each pair of $(\lambda+1)$ (s,t)-cut in $G(\mathcal{W})^I$ (likewise $G(\mathcal{W})^U$) is greater than λ. This is because the only (s,t)-mincut of $G(\mathcal{W})^I$ is $\overline{T'}$ and the only (s,t)-mincut of $G(\mathcal{W})^U$ is S'. Theorem 20(1) states that $\{G(\mathcal{W})^I, G(\mathcal{W})^U\}$ covers all the $(\lambda+1)$ (s,t)-cuts of $G(\mathcal{W})$. Therefore, if $y' \notin N_1(x,y)$ and $y \notin N_1(x',y')$ in $G(\mathcal{W})^I$ or $x \notin N_1(y',x')$ and $x' \notin N_1(y,x))$ in $(G(\mathcal{W})^U)^{\mathcal{T}}$ then there is a $(\lambda+1)$ (s,t)-cut in $G(\mathcal{W})$ in which e, e' are contributing. Now we shall establish the converse of this assertion.

Suppose there exists a $(\lambda+1)$ (s,t)-cut C in $G(\mathcal{W})$ to which both edges (x,y) and (x',y') are contributing. Without loss of generality assume that C is present in $G(\mathcal{W})^I$. It can be observed that the cuts $N_1(x,y)$ and $N_1(x',y')$ in $G(\mathcal{W})^I$ are subsets of C. Hence $y \notin N_1(x',y')$ and $y' \notin N_1(x,y)$ in $G(\mathcal{W})^I$. If C is present in $G(\mathcal{W})^U$, exactly the same analysis can be carried out on $(G(\mathcal{W})^U)^{\mathcal{T}}$. So we can state the following lemma.

▶ **Lemma 36.** *A pair of edges $e=(x,y)$, $e'=(x',y')$ from $(\lambda+1)$ class $\mathcal{W}$ are outgoing edges of a $(\lambda+1)$ (s,t)-cut in $G(\mathcal{W})$ if and only if (i) $y \notin N_1(x',y')$ and $y' \notin N_1(x,y)$ in $G(\mathcal{W})^I$ or (ii) $x \notin N_1(y',x')$ and $x' \notin N_1(y,x)$ in $(G(\mathcal{W})^U)^{\mathcal{T}}$.*

Using the data structure $\mathcal{N}_{\lambda+1}$, it requires a constant number of BELONG queries to verify the conditions mentioned in Lemma 36. Therefore, the data structure $\mathcal{F}$ for dual edge failure is as follows.

$\mathcal{F}$ consists of the following data structures:
- $\mathcal{N}_\lambda$ for graph G.
- $\mathcal{N}_{\lambda+1}$ for $G(\mathcal{W})^I$ and $(G(\mathcal{W})^U)^\mathcal{T}$ for each $(\lambda+1)$ (s,t)-class $\mathcal{W}$.

It can be observed that the resulting (s,t)-mincut value can be reported in $\mathcal{O}(1)$ time upon failure of any pair of edges from G using $\mathcal{F}$. Handling of dual edge insertion is covered in the full version of this paper. We summarize the results of this section in the following theorem.

▶ **Theorem 37.** *A directed multi-graph $G=(V,E)$, on $|V|=n$ vertices and $|E|=m$ edges with a designated source vertex s and a designated sink vertex t, can be preprocessed for constructing $\mathcal{O}(n^2)$ space Oracle $\{\mathcal{F},\mathcal{I}\}$ that takes $\mathcal{O}(1)$ time to report the value of resultant (s,t)-mincut upon*
1. *failure of any given pair of edges $(x,y),(x',y')\in E$ using $\mathcal{F}$, or*
2. *insertion of any given pair of edges $(x,y),(x',y')\in V\times V$ using $\mathcal{I}$.*

▶ Remark 38. For a $(\lambda+1)$ (s,t)-class $\mathcal{W}$ and any pair of disjoint subsets $A,B\subset\mathcal{W}$, $\mathcal{F}$ can determine in $\mathcal{O}(|A||B|)$ time if there exists a $(\lambda+1)$ (s,t)-cut C such that $A\subseteq C$ and $B\subseteq\overline{C}$. If C exists, then it is possible to report C using $\mathcal{F}$ in $\mathcal{O}((|A|+|B|)|\mathcal{W}|+|\overline{C}|)$ time.

8 Conditional lower bound for dual edge sensitivity for (s,t)-mincuts

The problem of reachability in directed graph is as follows – Given a simple directed graph G with n vertices and m edges, preprocess it to form a data structure which can efficiently report if a given vertex v is reachable from another vertex u. The reachability in G is same as reachability in G_{SCC}, a directed acyclic graph which can be obtained by contracting each of the Strongly Connected Components to a single vertex. Henceforth, we shall assume that G is a directed acyclic graph. We transform the directed acyclic graph G into a graph $\mathcal{D}$ as follows.

Construction of $\mathcal{D}$: Create two additional vertices, namely s and t. Suppose Δ_v denotes the difference in the number of incoming and outgoing edges of any vertex v of G. For each vertex v in G, if $\Delta_v>0$ we add Δ_v edges from v to t. Likewise, if $\Delta_v<0$ we add Δ_v edges from s to v. Lastly, add two additional edge(s) from s to v and v to t for all v in G. Observe that the number of edges in this graph is only $\mathcal{O}(m)$. Thus, we state the following lemma.

▶ **Lemma 39.** *For a directed graph G with n vertices and m edges, there exists a directed acyclic multi-graph $\mathcal{D}$ with $\mathcal{O}(m)$ edges and $n+2$ vertices such that a vertex v is reachable from a vertex u in G if and only if vertex v is reachable from vertex u in $\mathcal{D}$.*

The graph $\mathcal{D}$, that we have constructed, has a very interesting property. $\mathcal{D}$ is identical to the DAG $\mathcal{D}_\lambda$ that stores all (s,t)-mincuts in graph $\mathcal{D}$. We crucially exploit this property to derive an equivalence between reachability queries in graph $\mathcal{D}$ and dual edge failure (or insertion) query for (s,t)-mincut in $\mathcal{D}$. Since, the reachability structure of $\mathcal{D}$ and G is identical, we state the following lemma.

▶ **Lemma 40.** *Let G be a directed graph. A vertex v is reachable from a vertex u in G if and only if the value of (s,t)-mincut reduces by exactly 1 on removal of the edges $\{(s,u),(v,t)\}$ from graph $\mathcal{D}$ which is obtained from G using Lemma 39.*

Proof sketch. We know that $\mathcal{D}$ is same as $\mathcal{D}_\lambda$ of $\mathcal{D}$. So, removal of any edge from $\mathcal{D}$ reduces value of (s,t)-mincut by 1. Any (s,t)-cut in which both edges, $\{(s,u),(v,t)\}$, are contributing cannot be 1-transversal because of the u to v path. Every (s,t)-mincut is 1-transversal (Lemma 22), therefore, there cannot exist (s,t)-mincut in which both edges are contributing.

If there is no path from u to v, then both edges contribute to (s,t)-cut $C = \overline{R(\{u\}) \cup T}$; where $R(\{u\})$ defines the set of vertices reachable from u. We can show that C is also an (s,t)-mincut. Thus, upon removal of edges $\{(s,u),(v,t)\}$ the value of (s,t)-mincut reduces by 2. ◀

Using Conjecture 5 and Lemma 40 we state the following conditional lower bound.

▶ **Theorem 41.** *Assuming Directed Reachability Hypothesis holds, any data structure that can report the value of (s,t)-mincut for a designated source s and a designated sink t upon failure or addition of any pair of edges in a directed multi-graph with n vertices and m edges must either use $\tilde{\Omega}(n^2)$ space, or $\tilde{\Omega}(m)$ time.*

Abstract

We consider the problem of enumerating optimal solutions for two hypergraph k-partitioning problems – namely, Hypergraph-k-Cut and Minmax-Hypergraph-k-Partition. The input in hypergraph k-partitioning problems is a hypergraph $G = (V, E)$ with positive hyperedge costs along with a fixed positive integer k. The goal is to find a partition of V into k non-empty parts $(V_1, V_2, \ldots, V_k)$ – known as a k-partition – so as to minimize an objective of interest.

1. If the objective of interest is the maximum cut value of the parts, then the problem is known as Minmax-Hypergraph-k-Partition. A subset of hyperedges is a minmax-k-cut-set if it is the subset of hyperedges crossing an optimum k-partition for Minmax-Hypergraph-k-Partition.
2. If the objective of interest is the total cost of hyperedges crossing the k-partition, then the problem is known as Hypergraph-k-Cut. A subset of hyperedges is a min-k-cut-set if it is the subset of hyperedges crossing an optimum k-partition for Hypergraph-k-Cut.

We give the first polynomial bound on the number of minmax-k-cut-sets and a polynomial-time algorithm to enumerate all of them in hypergraphs for every fixed k. Our technique is strong enough to also enable an $n^{O(k)}p$-time deterministic algorithm to enumerate all min-k-cut-sets in hypergraphs, thus improving on the previously known $n^{O(k^2)}p$-time deterministic algorithm, where n is the number of vertices and p is the size of the hypergraph. The correctness analysis of our enumeration approach relies on a structural result that is a strong and unifying generalization of known structural results for Hypergraph-k-Cut and Minmax-Hypergraph-k-Partition. We believe that our structural result is likely to be of independent interest in the theory of hypergraphs (and graphs).

1 Introduction

In hypergraph k-partitioning problems, the input consists of a hypergraph $G = (V, E)$ with positive hyperedge-costs $c : E \to \mathbb{R}_+$ and a fixed positive integer k (e.g., $k = 2, 3, 4, \ldots$). The goal is to find a partition of the vertex set into k *non-empty* parts $V_1, V_2, \ldots, V_k$ so as to minimize an objective of interest. There are several natural objectives of interest in hypergraph k-partitioning problems. In this work, we focus on two particular objectives: Minmax-Hypergraph-k-Partition and Hypergraph-k-Cut:

1. In Minmax-Hypergraph-k-Partition, the objective is to minimize the maximum cut value of the parts of the k-partition – i.e., minimize $\max_{i=1}^{k} c(\delta(V_i))$; here $\delta(V_i)$ is the set of hyperedges intersecting both V_i and $V \setminus V_i$ and $c(\delta(V_i)) = \sum_{e \in \delta(V_i)} c(e)$ is the total cost of hyperedges in $\delta(V_i)$.
2. In Hypergraph-k-Cut[1], the objective is to minimize the cost of hyperedges crossing the k-partition – i.e., minimize $c(\delta(V_1, \ldots, V_k))$; here $\delta(V_1, \ldots, V_k)$ is the set of hyperedges that intersect at least two sets in $\{V_1, \ldots, V_k\}$ and $c(\delta(V_1, \ldots, V_k)) = \sum_{e \in \delta(V_1, \ldots, V_k)} c(e)$ is the total cost of hyperedges in $\delta(V_1, \ldots, V_k)$.

If the input G is a graph, then we will refer to these problems as Minmax-Graph-k-Partition and Graph-k-Cut respectively. We note that the case of $k = 2$ corresponds to global minimum cut in both objectives. In this work, we focus on the problem of enumerating all optimum solutions to Minmax-Hypergraph-k-Partition and Hypergraph-k-Cut.

Motivations and Related Problems. We consider the problem of counting and enumerating optimum solutions for partitioning problems over hypergraphs for three reasons. Firstly, hyperedges provide more powerful modeling capabilities than edges and consequently, several problems in hypergraphs become non-trivial in comparison to graphs. Although hypergraphs and partitioning problems over hypergraphs (including Minmax-Hypergraph-k-Partition) were discussed as early as 1973 by Lawler [33], most of these problems still remain open. The powerful modeling capability of hyperedges has been useful in a variety of modern applications, which in turn, has led to a resurgence in the study of hypergraphs with recent works focusing on min-cuts, cut-sparsifiers, spectral-sparsifiers, etc. [6, 8, 12, 15, 17, 18, 20, 21, 28, 32, 38]. Our work adds to this rich and emerging theory of hypergraphs.

Secondly, hypergraph k-partitioning problems are special cases of submodular k-partitioning problems. In submodular k-partitioning problems, the input is a finite ground set V, a submodular function[2] $f : 2^V \to \mathbb{R}$ provided by an evaluation oracle[3] and a positive integer k (e.g., $k = 2, 3, 4, \ldots$). The goal is to partition the ground set V into k non-empty parts $V_1, V_2, \ldots, V_k$ so as to minimize an objective of interest. Two natural objectives are of interest: (1) In Minmax-Submod-k-Partition, the objective is to minimize $\max_{i=1}^{k} f(V_i)$ and (2) In Minsum-Submod-k-Partition, the objective is to minimize $\sum_{i=1}^{k} f(V_i)$. If the given submodular function is symmetric[4], then we denote the resulting problems as Minmax-SymSubmod-k-Partition and Minsum-SymSubmod-k-Partition respectively. Since the hypergraph cut function is symmetric submodular, it follows that Minmax-Hypergraph-k-Partition is a special case of Minmax-SymSubmod-k-Partition. Moreover, Hypergraph-k-Cut is a special case of Minsum-Submod-k-Partition (this reduction is slightly non-trivial with the submodular function in the reduction being asymmetric – e.g., see [36] for the reduction). Queyranne claimed, in 1999, a polynomial-time algorithm for Minsum-SymSubmod-k-Partition for every fixed k [37], however the claim was retracted subsequently (see [24]). The complexity status of submodular k-partitioning problems (for fixed $k \geq 4$) are open, so recent works have focused on hypergraph k-partitioning problems as a stepping stone towards submodular k-partitioning [8, 12, 13, 24, 36, 41, 42]. Our work contributes to this stepping stone by advancing the state of the art in hypergraph k-partitioning problems. We emphasize that the

[1] We emphasize that the objective of Hypergraph-k-Cut is not equivalent to minimizing $\sum_{i=1}^{k} c(\delta(V_i))$.
[2] A real-valued set function $f : 2^V \to \mathbb{R}$ is submodular if $f(A) + f(B) \geq f(A \cap B) + f(A \cup B)\ \forall\ A, B \subseteq V$.
[3] An evaluation oracle for a set function f over a ground set V returns the value of $f(S)$ given $S \subseteq V$.
[4] A real-valued set function $f : 2^V \to \mathbb{R}$ is symmetric if $f(A) = f(V \setminus A)\ \forall\ A \subseteq V$.

complexity status of two other variants of hypergraph k-partitioning problems which are also special cases of Minsum-Submod-k-Partition are still open (see [36, 41, 42] for these variants).

Thirdly, counting and enumeration of optimum solutions for *graph* k-partitioning problems are fundamental to graph theory and extremal combinatorics. They have found farther reaching applications than initially envisioned. We discuss some of the results and applications for $k = 2$ and $k > 2$ now. For $k = 2$ in connected graphs, it is well-known that the number of min-cuts and the number of α-approximate min-cuts are at most $\binom{n}{2}$ and $O(n^{2\alpha})$ respectively, and they can all be enumerated in polynomial time for constant α. These combinatorial results have been the crucial ingredients of several algorithmic and representation results in graphs. On the algorithmic front, these results enable fast randomized construction of graph skeletons which, in turn, plays a crucial role in fast algorithms to solve graph min-cut [29]. On the representation front, counting results form the backbone of cut sparsifiers which in turn have found applications in sketching and streaming [2–4, 32]. A polygon representation of the family of 6/5-approximate min-cuts in graphs was given by Benczur and Goemans in 1997 (see [9–11]) – this representation was used in the recent groundbreaking $(3/2 - \epsilon)$-approximation for metric TSP [31]. On the approximation front, in addition to the $(3/2 - \epsilon)$-approximation for metric TSP [31], counting results also led to the recent 1.5-approximation for path TSP [40]. For $k > 2$, we note that fast algorithms for Graph-k-Cut have been of interest since they help in generating cutting planes while solving TSP [5, 19]. A recent series of works aimed towards improving the bounds on the number of optimum solutions for Graph-k-Cut culminated in a drastic improvement in the run-time to solve Graph-k-Cut [25–27]. Given the status of counting and enumeration results for k-partitioning in graphs and their algorithmic and representation implications that were discovered subsequently, we believe that a similar understanding in hypergraphs could serve as an important ingredient in the algorithmic and representation theory of hypergraphs.

The Enumeration Problem. There is a fundamental structural distinction between hypergraphs and graphs that becomes apparent while enumerating optimum solutions to k-partitioning problems. In connected graphs, the number of optimum k-partitions for Graph-k-Cut and for Minmax-Graph-k-Partition are $n^{O(k)}$ and $n^{O(k^2)}$ respectively and they can all be enumerated in polynomial time, where n is the number of vertices in the input graph [14, 16, 25, 27, 30, 39]. In contrast, a connected hypergraph could have exponentially many optimum k-partitions for both Minmax-Hypergraph-k-Partition and Hypergraph-k-Cut even for $k = 2$ – e.g., consider the hypergraph with a single hyperedge containing all vertices; we will denote this as the spanning-hyperedge-example. Hence, enumerating all optimum k-partitions for hypergraph k-partitioning problems in polynomial time is impossible. Instead, our goal in the enumeration problems is to enumerate *k-cut-sets* corresponding to optimum k-partitions. We will call a subset $F \subseteq E$ of hyperedges to be a k-cut-set if there exists a k-partition $(V_1, \ldots, V_k)$ such that $F = \delta(V_1, \ldots, V_k)$; we will call a 2-cut-set as a cut-set. In the enumeration problems that we will consider, the input consists of a hypergraph $G = (V, E)$ with positive hyperedge-costs $c : E \to \mathbb{R}_+$ and a fixed positive integer k (e.g., $k = 2, 3, 4, \ldots$).

1. For an optimum k-partition $(V_1, \ldots, V_k)$ for Minmax-Hypergraph-k-Partition in (G, c), we will denote $\delta(V_1, \ldots, V_k)$ as a minmax-k-cut-set. In Enum-MinMax-Hypergraph-k-Partition, the goal is to enumerate all minmax-k-cut-sets.
2. For an optimum k-partition $(V_1, \ldots, V_k)$ for Hypergraph-k-Cut in (G, c), we will denote $\delta(V_1, \ldots, V_k)$ as a min-k-cut-set. In Enum-Hypergraph-k-Cut, the goal is to enumerate all min-k-cut-sets.

We observe that in the spanning-hyperedge-example, although the number of optimum k-partitions for MINMAX-HYPERGRAPH-k-PARTITION (as well as HYPERGRAPH-k-CUT) is exponential, the number of MINMAX-k-CUT-SETs (as well as MIN-k-CUT-SETs) is only one.

1.1 Results

In contrast to graphs, whose representation size is the number of edges, the representation size of a hypergraph $G = (V, E)$ is $p := \sum_{e \in E} |e|$. Throughout, our algorithmic discussion will focus on the case of fixed k (e.g., $k = 2, 3, 4, \ldots$).

There are no prior results regarding ENUM-MINMAX-HYPERGRAPH-k-PARTITION in the literature. We recall the status of MINMAX-HYPERGRAPH-k-PARTITION. As mentioned earlier, MINMAX-HYPERGRAPH-k-PARTITION was discussed as early as 1973 by Lawler [33] with its complexity status being open until recently. We note that the objective here could be viewed as aiming to find a *fair* k-partition, i.e., a k-partition where no part pays too much in cut value. Motivated by this connection to fairness, Chandrasekaran and Chekuri (2021) [13] studied the more general problem of MINMAX-SYMSUBMOD-k-PARTITION. They gave the first (deterministic) polynomial-time algorithm to solve MINMAX-SYMSUBMOD-k-PARTITION and as a consequence, obtained the first polynomial-time algorithm to solve MINMAX-HYPERGRAPH-k-PARTITION. Their algorithm does not show any bound on the number of MINMAX-k-CUT-SETs since it solves the more general problem of MINMAX-SYMSUBMOD-k-PARTITION for which the number of optimum k-partitions can indeed be exponential (recall the spanning-hyperedge-example). Focusing on hypergraphs raises the question of whether all k-cut-sets corresponding to optimum solutions can be enumerated efficiently for every fixed k. We answer this question affirmatively by giving the first polynomial-time algorithm for ENUM-MINMAX-HYPERGRAPH-k-PARTITION.

▶ **Theorem 1.** *There exists a deterministic algorithm to solve ENUM-MINMAX-HYPERGRAPH-k-PARTITION that runs in time $O(kn^{4k^2-2k+1}p)$, where n is the number of vertices and p is the size of the input hypergraph. Moreover, the number of MINMAX-k-CUT-SETs in a n-vertex hypergraph is $O(n^{4k^2-2k})$.*

We emphasize that our result shows the first polynomial bound on the number of MINMAX-k-CUT-SETs in hypergraphs for every fixed k (in addition to a polynomial-time algorithm to enumerate all of them for every fixed k). Our upper bound of $n^{O(k^2)}$ on the number of MINMAX-k-CUT-SETs is tight – there exist n-vertex connected *graphs* for which the number of MINMAX-k-CUT-SETs is $n^{\Theta(k^2)}$.

Next, we briefly recall the status of HYPERGRAPH-k-CUT and ENUM-HYPERGRAPH-k-CUT. HYPERGRAPH-k-CUT was shown to be solvable in randomized polynomial time only recently [15, 20]; the randomized algorithms also showed that the number of MIN-k-CUT-SETs is $O(n^{2k-2})$ and they can all be enumerated in randomized polynomial time. A subsequent deterministic algorithm was designed to solve HYPERGRAPH-k-CUT in time $n^{O(k)}p$ by Chandrasekaran and Chekuri [12]. Chandrasekaran and Chekuri's techniques were extended to design the first deterministic polynomial-time algorithm to solve ENUM-HYPERGRAPH-k-CUT in [8]. The algorithm for ENUM-HYPERGRAPH-k-CUT given in [8] runs in time $n^{O(k^2)}p$. We note that this run-time has a quadratic dependence on k in the exponent of n although the number of MIN-k-CUT-SETs has only linear dependence on k in the exponent of n (since it is $O(n^{2k-2})$). So, an open question that remained from [8] is whether one can obtain an $n^{O(k)}p$-time deterministic algorithm for ENUM-HYPERGRAPH-k-CUT. We resolve this question affirmatively.

▶ **Theorem 2.** *There exists a deterministic algorithm to solve* Enum-Hypergraph-k-Cut *that runs in time* $O(n^{16k-25}p)$*, where* n *is the number of vertices and* p *is the size of the input hypergraph.*

Our algorithms for both Enum-MinMax-Hypergraph-k-Partition and Enum-Hypergraph-k-Cut are based on a structural theorem that allows for efficient recovery of optimum k-cut-sets via minimum (s,t)-terminal cuts (see Theorem 4). Our structural theorem builds on structural theorems that have appeared in previous works on Minmax-Hypergraph-k-Partition and Hypergraph-k-Cut [8, 12, 13]. Our structural theorem may appear to be natural/incremental in comparison to ones that appeared in previous works, but formalizing the theorem and proving it is a significant part of our contribution. Moreover, our single structural theorem is strong enough to enable efficient algorithms for both Enum-Hypergraph-k-Cut as well as Enum-MinMax-Hypergraph-k-Partition in contrast to previously known structural theorems. In this sense, our structural theorem can be viewed as a strong and unifying generalization of structural theorems that have appeared in previous works. We believe that our structural theorem will be of independent interest in the theory of cuts and partitioning in hypergraphs (as well as graphs).

1.2 Technical overview and main structural result

We focus on the unit-cost variant of Enum-Hypergraph-k-Cut and Enum-MinMax-Hypergraph-k-Partition in the rest of this work for the sake of notational simplicity – i.e., the cost of every hyperedge is 1. Throughout, we will allow multigraphs and hence, this is without loss of generality. Our algorithms extend in a straightforward manner to arbitrary hyperedge costs. They rely only on minimum (s,t)-terminal cut computations and hence, they are strongly polynomial-time algorithms.

Notation and background. Let $G = (V, E)$ be a hypergraph. Throughout this work, n will denote the number of vertices in G, m will denote the number of hyperedges in G, and $p := \sum_{e \in E} |e|$ will denote the representation size of G. We will denote a partition of the vertex set into h non-empty parts by an ordered tuple $(V_1, \ldots, V_h)$ and call such an ordered tuple as an h-partition. For a partition $\mathcal{P} = (V_1, V_2, \ldots, V_h)$, we will say that a hyperedge e crosses the partition $\mathcal{P}$ if it intersects at least two parts of the partition. We will refer to a 2-partition as a cut. For a non-empty proper subset U of vertices, we will use $\overline{U}$ to denote $V \setminus U$, $\delta(U)$ to denote the set of hyperedges crossing the cut $(U, \overline{U})$, and $d(U) := |\delta(U)|$ to denote the cut value of U. We observe that $\delta(U) = \delta(\overline{U})$, so we will use $d(U)$ to denote the value of the cut $(U, \overline{U})$. More generally, given a partition $\mathcal{P} = (V_1, V_2, \ldots, V_h)$, we denote the set of hyperedges crossing the partition by $\delta(V_1, V_2, \ldots, V_h)$ (also by $\delta(\mathcal{P})$ for brevity) and the number of hyperedges crossing the partition by $|\delta(V_1, V_2, \ldots, V_h)|$. We will denote the optimum value of Minmax-Hypergraph-k-Partition and Hypergraph-k-Cut respectively by

$$OPT_{\text{minmax-}k\text{-partition}} := \min \left\{ \max_{i \in [k]} |\delta(V_i)| : (V_1, \ldots, V_k) \text{ is a } k\text{-partition of } V \right\} \text{ and}$$

$$OPT_{k\text{-cut}} := \min \left\{ |\delta(V_1, \ldots, V_k)| : (V_1, \ldots, V_k) \text{ is a } k\text{-partition of } V \right\}.$$

A key algorithmic tool will be the use of fixed-terminal cuts. Let S, T be disjoint non-empty subsets of vertices. A 2-partition $(U, \overline{U})$ is an (S,T)-terminal cut if $S \subseteq U \subseteq V \setminus T$. Here, the set U is known as the source set and the set $\overline{U}$ is known as the sink set. A minimum-valued (S,T)-terminal cut is known as a *minimum* (S,T)*-terminal cut*. Since there

could be multiple minimum (S,T)-terminal cuts, we will be interested in *source minimal* minimum (S,T)-terminal cuts. For every pair of disjoint non-empty subsets S and T of vertices, there exists a unique source minimal minimum (S,T)-terminal cut and it can be found in deterministic polynomial time via standard maxflow algorithms. In particular, the source minimal minimum (S,T)-terminal cut can be found in time $O(np)$ [17].

Our technique to enumerate all MINMAX-k-CUT-SETs and all MIN-k-CUT-SETs will build on the approaches of Chandrasekaran and Chekuri for HYPERGRAPH-k-CUT and MINMAX-SYMSUBMOD-k-PARTITION [8, 12, 13]. We need the following structural theorem that was shown in [8].

▶ **Theorem 3** ([8]). *Let $G=(V,E)$ be a hypergraph and let $OPT_{k\text{-}cut}$ be the optimum value of HYPERGRAPH-k-CUT in G for some integer $k \geq 2$. Suppose $(U,\overline{U})$ is a 2-partition of V with $d(U) < OPT_{k\text{-}cut}$. Then, for every pair of vertices $s \in U$ and $t \in \overline{U}$, there exist subsets $S \subseteq U \setminus \{s\}$ and $T \subseteq \overline{U} \setminus \{t\}$ with $|S| \leq 2k-3$ and $|T| \leq 2k-3$ such that $(U,\overline{U})$ is the unique minimum $(S \cup \{s\}, T \cup \{t\})$-terminal cut in G.*

Enum-Hypergraph-k-Cut. We first focus on ENUM-HYPERGRAPH-k-CUT. We note that Theorem 3 will allow us to recover those parts V_i of an optimum k-partition $(V_1,\ldots,V_k)$ for which $d(V_i) < OPT_{k\text{-cut}}$. However, recall that our goal is *not* to recover all optimum k-partitions for HYPERGRAPH-k-CUT, but rather to recover all MIN-k-CUT-SETs (i.e., not to recover the parts of every optimum k-partition, but rather only to recover the k-cut-set of every optimum k-partition). The previous work [8] that designed an $n^{O(k^2)}p$-time deterministic enumeration algorithm achieved this by proving the following structural result: suppose $(V_1,\ldots,V_k)$ is an optimum k-partition for HYPERGRAPH-k-CUT for which $d(V_1) = OPT_{k\text{-cut}}$. Then, they showed that for every subset $T \subseteq \overline{V_1}$ satisfying $T \cap V_j \neq \emptyset$ for all $j \in \{2,\ldots,k\}$, there exists a subset $S \subseteq V_1$ with $|S| \leq 2k$ such that the source minimal minimum (S,T)-terminal cut $(A,\overline{A})$ satisfies $\delta(A) = \delta(V_1)$. This structural theorem in conjunction with Theorem 3 allows one to enumerate a candidate family $\mathcal{F}$ of $n^{O(k^2)}$ subsets of hyperedges such that every MIN-k-CUT-SET is present in the family. The drawback of their structural theorem is that it is driven towards recovering the cut-set $\delta(V_i)$ of every part V_i of every optimum k-partition $(V_1,\ldots,V_k)$. Hence, their algorithmic approach ends up with a run-time of $n^{O(k^2)}p$. In order to improve the run-time, we prove a stronger result: we show that for an *arbitrary* cut $(U,\overline{U})$ with cut value $OPT_{k\text{-cut}}$ (as opposed to only those sets V_i of an optimum k-partition $(V_1,\ldots,V_k)$), its cut-set $\delta(U)$ can be recovered as the cut-set of *any* minimum (S,T)-terminal cut for some S and T of small size. The following is the main structural theorem of this work.

▶ **Theorem 4.** *Let $G=(V,E)$ be a hypergraph and let $OPT_{k\text{-}cut}$ be the optimum value of HYPERGRAPH-k-CUT in G for some integer $k \geq 2$. Suppose $(U,\overline{U})$ is a 2-partition of V with $d(U) = OPT_{k\text{-}cut}$. Then, there exist sets $S \subseteq U$, $T \subseteq \overline{U}$ with $|S| \leq 2k-1$ and $|T| \leq 2k-1$ such that every minimum (S,T)-terminal cut $(A,\overline{A})$ satisfies $\delta(A) = \delta(U)$.*

We encourage the reader to compare and contrast Theorems 3 and 4. The former helps to recover cuts whose cut value is strictly smaller than $OPT_{k\text{-cut}}$ while the latter helps to recover *cut-sets* whose size is equal to $OPT_{k\text{-cut}}$. So, the latter theorem is weaker since it only recovers cut-sets, but we emphasize that this is the best possible that one can hope to do (as seen from the spanning-hyperedge-example). However, proving the latter theorem requires us to work with cut-sets (as opposed to cuts) which is a technical barrier to overcome. Indeed, our proof of Theorem 4 deviates significantly from the proof of Theorem 3 since we have to work with cut-sets. Our proof also deviates from the structural result in [8] that was mentioned in the paragraph above Theorem 4 since our result is stronger than

their result – our result helps to recover the cut-set $\delta(U)$ of an arbitrary cut $(U, \overline{U})$ whose cut value is $d(U) = OPT_{k\text{-cut}}$ while their result helps only to recover the cut-set $\delta(V_i)$ of a part V_i of an optimum k-partition $(V_1, \ldots, V_k)$ for Hypergraph-k-Cut whose cut value is $d(V_i) = OPT_{k\text{-cut}}$; moreover, their proof technique crucially relies on a containment property with respect to the part V_i, whereas under the hypothesis of our structural theorem, the containment property fails with respect to the set U and consequently, our proof technique differs from theirs.

Theorems 3 and 4 lead to a deterministic $n^{O(k)}$-time algorithm to enumerate all min-k-cut-sets via a divide-and-conquer approach. We describe this algorithm now: For each pair (S, T) of disjoint subsets of vertices S and T with $|S|, |T| \leq 2k-1$, compute the source minimal minimum (S, T)-terminal cut $(A, \overline{A})$; (i) if $G - \delta(A)$ has at least k connected components, then add $\delta(A)$ to the candidate family $\mathcal{F}$; (ii) otherwise, add the set A to a collection $\mathcal{C}$. We note that the sizes of the family $\mathcal{F}$ and the collection $\mathcal{C}$ are $O(n^{4k-2})$. Next, for each subset A in the collection $\mathcal{C}$, recursively enumerate all min-$k/2$-cut-sets in the subhypergraphs induced by A and $\overline{A}$ respectively[5] – denoted $G[A]$ and $G[\overline{A}]$ respectively – and add $\delta(A) \cup F_1 \cup F_2$ to the family $\mathcal{F}$ for each F_1 and F_2 being min-$k/2$-cut-set in $G[A]$ and $G[\overline{A}]$ respectively. Finally, return the subfamily of k-cut-sets from the family $\mathcal{F}$ that are of smallest size.

We sketch the correctness analysis of the above approach: let $F = \delta(V_1, \ldots, V_k)$ be a min-k-cut-set with $(V_1, \ldots, V_k)$ being an optimum k-partition for Hypergraph-k-Cut. We will show that the family $\mathcal{F}$ contains F. Let $U := \cup_{i=1}^{k/2} V_i$. We note that $\delta(U) \subseteq F$. We have two possibilities: (1) Say $d(U) = |F|$. Then, $d(U) = OPT_{k\text{-cut}}$. Consequently, by Theorem 4, the min-k-cut-set F will be added to the family $\mathcal{F}$ by step (i). (2) Say $d(U) < |F|$. Then, by Theorem 3, the set $U = \cup_{i=1}^{k/2} V_i$ will be added to the collection $\mathcal{C}$ by step (ii); moreover, $F_1 := F \cap E(G[U])$ and $F_2 := F \cap E(G[\overline{U}])$ are min-$k/2$-cut-sets in $G[U]$ and $G[\overline{U}]$ respectively and they would have been enumerated by recursion, and hence, the set $\delta(U) \cup F_1 \cup F_2 = F$ will be added to the family $\mathcal{F}$. The size of the family $\mathcal{F}$ can be shown to be $n^{O(k \log k)}$ and the run-time is $n^{O(k \log k)}p$. Using the known fact that the number of min-k-cut-sets in a n-vertex hypergraph is $O(n^{2k-2})$, we can improve the run-time analysis of this approach to $n^{O(k)}p$.

Enum-MinMax-Hypergraph-k-Partition. Next, we focus on Enum-MinMax-Hypergraph-k-Partition. There is a fundamental technical issue in enumerating minmax-k-cut-sets as opposed to min-k-cut-sets. We highlight this technical issue now. Suppose we find an optimum k-partition $(V_1, \ldots, V_k)$ for Minmax-Hypergraph-k-Partition (say via Chandrasekaran and Chekuri's algorithm [13]) and store only the minmax-k-cut-set $F = \delta(V_1, \ldots, V_k)$ but forget to store the partition $(V_1, \ldots, V_k)$; now, by knowing a minmax-k-cut-set F, can we recover *some* optimum k-partition for Minmax-Hypergraph-k-Partition (not necessarily $(V_1, \ldots, V_k)$)? Or by knowing a minmax-k-cut-set F, is it even possible to find the value $OPT_{\text{minmax-}k\text{-partition}}$ without solving Minmax-Hypergraph-k-Partition from scratch again – i.e., is there an advantage to knowing a minmax-k-cut-set in order to solve Minmax-Hypergraph-k-Partition? We are not aware of such an advantage. This is in stark contrast to Hypergraph-k-Cut where knowing a min-k-cut-set enables a linear-time solution to Hypergraph-k-Cut[6].

[5] Subhypergraph $G[A]$ has vertex set A and contains all hyperedges of G which are entirely contained within A.

[6] Suppose we know a min-k-cut-set F. Then consider the connected components $Q_1, \ldots, Q_t$ in $G - F$ and create a partition $(P_1, \ldots, P_k)$ by taking $P_i = Q_i$ for every $i \in [k-1]$ and $P_k = \cup_{j=k}^{t} Q_j$; such a k-partition $(P_1, \ldots, P_k)$ will be an optimum k-partition for Hypergraph-k-Cut.

Why is this issue significant while solving Enum-MinMax-Hypergraph-k-Partition? We recall that in our approach for Enum-Hypergraph-k-Cut, the algorithm computed a polynomial-sized family $\mathcal{F}$ containing all min-k-cut-sets and returned the ones with smallest size – the smallest size ones will exactly be min-k-cut-sets. It is unclear if a similar approach could work for enumerating minmax-k-cut-sets: suppose we do have an algorithm to enumerate a polynomial-sized family $\mathcal{F}$ containing all minmax-k-cut-sets; now, in order to return all minmax-k-cut-sets (which is a subfamily of $\mathcal{F}$), note that we need to identify them among the ones in the family $\mathcal{F}$ – i.e., we need to verify if a given subset $F \in \mathcal{F}$ of hyperedges is a minmax-k-cut-set; this verification problem is closely related to the question mentioned in the previous paragraph. We do not know how to address this verification problem directly. So, our algorithmic approach for Enum-MinMax-Hypergraph-k-Partition has to overcome this technical issue.

Our ingredient to overcome this technical issue is to enumerate *representatives* for minmax-k-cut-sets. For a k-partition $(V_1, \ldots, V_k)$ and disjoint subsets $U_1, \ldots, U_k \subseteq V$, we will call the k-tuple $(U_1, \ldots, U_k)$ to be a *k-cut-set representative* of $(V_1, \ldots, V_k)$ if $U_i \subseteq V_i$ and $\delta(U_i) = \delta(V_i)$ for all $i \in [k]$. We note that a fixed k-partition $(V_1, \ldots, V_k)$ could have several k-cut-set representatives and a fixed k-tuple $(U_1, \ldots, U_k)$ could be the k-cut-set representative of several k-partitions. Yet, it is possible to efficiently verify if a given k-tuple $(U_1, \ldots, U_k)$ is a k-cut-set representative. Moreover, knowing a k-cut-set representative $(U_1, \ldots, U_k)$ of a k-partition $(V_1, V_2, \ldots, V_k)$ allows one to recover the k-cut-set $F := \delta(V_1, \ldots, V_k)$ since $F = \cup_{i=1}^{k} \delta(U_i)$. Thus, in order to enumerate all minmax-k-cut-sets, it suffices to enumerate k-cut-set representatives of *all* optimum k-partitions for Minmax-Hypergraph-k-Partition. At this point, the astute reader may wonder if there exists a polynomial-sized family of k-cut-set representatives of all optimum k-partitions for Minmax-Hypergraph-k-Partition given that the number of optimum k-partitions for Minmax-Hypergraph-k-Partition could be exponential. For example, is there a polynomial-sized family of k-cut-set representatives of all optimum k-partitions for Minmax-Hypergraph-k-Partition in the spanning-hyperedge-example? Indeed, in the spanning-hyperedge-example, even though the number of optimum k-partitions for Minmax-Hypergraph-k-Partition is exponential, there exists a $(k!\binom{n}{k})$-sized family of k-cut-set representatives of all optimum k-partitions: consider the family $\{(\{v_1\}, \ldots, \{v_k\}) : v_1, \ldots, v_k \in V, v_i \neq v_j \ \forall \text{ distinct } i, j \in [k]\}$.

It turns out that Theorems 3 and 4 are strong enough to enable efficient enumeration of k-cut-set representatives of all optimum k-partitions for Minmax-Hypergraph-k-Partition. We describe the algorithm to achieve this: For each pair (S, T) of disjoint subsets of vertices with $|S|, |T| \leq 2k-1$, compute the source minimal minimum (S, T)-terminal cut $(U, \overline{U})$ and add U to a candidate collection $\mathcal{C}$. We note that the size of the collection $\mathcal{C}$ is $O(n^{4k-2})$. Next, for each k-tuple $(U_1, \ldots, U_k) \in \mathcal{C}^k$, verify if $(U_1, \ldots, U_k)$ is a k-cut-set representative and if so, then add the k-tuple to the candidate family $\mathcal{D}$. Finally, return $\arg\min\{\max_{i=1}^{k} d(U_i) : (U_1, \ldots, U_k) \in \mathcal{D}\}$, i.e., prune and return the subfamily of k-cut-set representatives $(U_1, \ldots, U_k)$ from the family $\mathcal{D}$ that have minimum $\max_{i=1}^{k} d(U_i)$.

We note that the size of the family $\mathcal{D}$ is $n^{O(k^2)}$ and consequently, the run-time is $n^{O(k^2)}p$. We sketch the correctness analysis of the above approach: let $(V_1, \ldots, V_k)$ be an optimum k-partition for Minmax-Hypergraph-k-Partition. We will show that the family $\mathcal{D}$ contains a k-cut-set representative of $(V_1, \ldots, V_k)$. By noting that $OPT_{\text{minmax-}k\text{-partition}} \leq OPT_{k\text{-cut}}$ and by Theorems 3 and 4, for every $i \in [k]$, we have a set U_i in the collection $\mathcal{C}$ with $U_i \subseteq V_i$ and $\delta(U_i) = \delta(V_i)$. Hence, the k-tuple $(U_1, \ldots, U_k) \in \mathcal{C}^k$ is a k-cut-set representative and it will be added to the family $\mathcal{D}$. The final pruning step will not remove $(U_1, \ldots, U_k)$ from the family $\mathcal{D}$ and hence, it will be in the subfamily returned by the algorithm.

Significance of our technique. As mentioned earlier, our techniques build on the structural theorems that appeared in previous works [8, 12, 13]. The main technical novelty of our contribution lies in Theorem 4 which can be viewed as the culmination of structural theorems developed in those previous works. We also emphasize that using minimum (s,t)-terminal cuts to solve global partitioning problems is not a new technique per se (e.g., minimum (s,t)-terminal cut is the first and most natural approach to solve global minimum cut). This technique of using minimum (s,t)-terminal cuts to solve global partitioning problems has a rich variety of applications in combinatorial optimization: e.g., (1) it was used to design the first efficient algorithm for Graph-k-Cut for fixed k [23], (2) it was used to design efficient algorithms for certain constrained submodular minimization problems [22, 35], and (3) more recently, it was used to design fast algorithms for global minimum cut in graphs as well as to obtain fast Gomory-Hu trees in unweighted graphs [1, 34]. The applicability of this technique relies on identifying and proving appropriate structural results. Our Theorem 4 is such a structural result. The merit of the structural result lies in its ability to solve two different enumeration problems in hypergraph k-partitioning which was not possible via structural theorems that were developed before. Moreover, it leads to the first polynomial bound on the number of minmax-k-cut-sets in hypergraphs for every fixed k.

Organization. In Section 1.3, we recall properties of the hypergraph cut function. In Section 2, we prove a special case of Theorem 4. In Section 3, we use this special case to prove Theorem 4. We refer the reader to the full version [7] for a discussion of related work, our algorithms to prove Theorems 1 and 2, and a lower bound example. We conclude with some open questions in Section 4.

1.3 Preliminaries

Let $G = (V, E)$ be a hypergraph. Throughout, we will follow the notation mentioned in the second paragraph of Section 1.2. For disjoint $A, B \subseteq V$, we define $E(A, B) := \{e \in E : e \subseteq A \cup B, e \cap A \neq \emptyset, e \cap B \neq \emptyset\}$, and $E[A] := \{e \in E : e \subseteq A\}$. We will repeatedly rely on the fact that the hypergraph cut function $d : 2^V \to \mathbb{R}_+$ is symmetric and submodular. We recall that a set function $f : 2^V \to \mathbb{R}$ is *symmetric* if $f(U) = f(\overline{U})$ for all subsets $U \subseteq V$ and is *submodular* if $f(A) + f(B) \geq f(A \cap B) + f(A \cup B)$ for all subsets $A, B \subseteq V$.

We will need the following partition uncrossing theorem that was proved in previous works on Hypergraph-k-Cut and Enum-Hypergraph-k-Cut (see Figure 1 for an illustration of the sets that appear in the statement of Theorem 5):

▶ **Theorem 5** ([8, 12]). *Let $G = (V, E)$ be a hypergraph, $k \geq 2$ be an integer and $\emptyset \neq R \subsetneq U \subsetneq V$. Let $S = \{u_1, \ldots, u_p\} \subseteq U \setminus R$ for $p \geq 2k - 2$. Let $(\overline{A_i}, A_i)$ be a minimum $((S \cup R) \setminus \{u_i\}, \overline{U})$-terminal cut. Suppose that $u_i \in A_i \setminus (\cup_{j \in [p] \setminus \{i\}} A_j)$ for every $i \in [p]$. Then, the following two hold:*

1. *There exists a k-partition $(P_1, \ldots, P_k)$ of V with $\overline{U} \subsetneq P_k$ such that*

$$|\delta(P_1, \ldots, P_k)| \leq \frac{1}{2} \min\{d(A_i) + d(A_j) : i, j \in [p], i \neq j\}.$$

2. *Moreover, if there exists a hyperedge $e \in E$ such that e intersects $W := \cup_{1 \leq i < j \leq p} (A_i \cap A_j)$, e intersects $Z := \cap_{i \in [p]} \overline{A_i}$, and e is contained in $W \cup Z$, then the inequality in the previous conclusion is strict.*

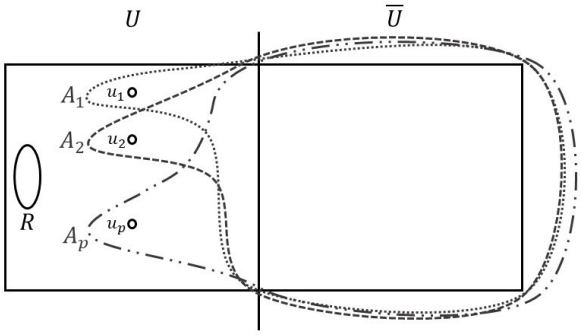

Figure 1 Illustration of the sets that appear in the statement of Theorem 5.

2 A special case of Theorem 4

The following is the main theorem of this section. Theorem 6 implies Theorem 4 in the special case where the 2-partition $(U, \overline{U})$ of interest to Theorem 4 is such that $|\overline{U}| \leq 2k-1$.

▶ **Theorem 6.** *Let $G = (V, E)$ be a hypergraph and let $OPT_{k\text{-}cut}$ be the optimum value of* Hypergraph-k-Cut *in G for some integer $k \geq 2$. Suppose $(U, \overline{U})$ is a 2-partition of V with $d(U) = OPT_{k\text{-}cut}$. Then, there exists a set $S \subseteq U$ with $|S| \leq 2k-1$ such that every minimum $(S, \overline{U})$-terminal cut $(A, \overline{A})$ satisfies $\delta(A) = \delta(U)$.*

Proof. Consider the collection

$$\mathcal{C} := \{Q \subseteq V : \ \overline{U} \subsetneq Q, \ d(Q) \leq d(U), \text{ and } \delta(Q) \neq \delta(U)\}.$$

Let S be an inclusion-wise minimal subset of U such that $S \cap Q \neq \emptyset$ for all $Q \in \mathcal{C}$, i.e., the set S is completely contained in U and is a minimal transversal of the collection $\mathcal{C}$. Proposition 7 and Lemma 8 complete the proof of Theorem 6 for this choice of S. ◀

▶ **Proposition 7.** *Every minimum $(S, \overline{U})$-terminal cut $(A, \overline{A})$ has $\delta(A) = \delta(U)$.*

Proof. Let $(A, \overline{A})$ be a minimum $(S, \overline{U})$-terminal cut. If $A = U$, then we are done, so we may assume that $A \neq U$. This implies that $S \subseteq A$ and $\overline{U} \subsetneq \overline{A}$. Since $(U, \overline{U})$ is a $(S, \overline{U})$-terminal cut, we have that $d(\overline{A}) = d(A) \leq d(U)$. Since S intersects every set in the collection $\mathcal{C}$, we have that $\overline{A} \notin \mathcal{C}$. Hence, $\delta(\overline{A}) = \delta(U)$, and by symmetry of cut-sets, $\delta(A) = \delta(U)$. ◀

▶ **Lemma 8.** *The size of the subset S is at most $2k-1$.*

Proof. For the sake of contradiction, suppose $|S| \geq 2k$. Our proof strategy is to show the existence of a k-partition with fewer crossing hyperedges than $OPT_{k\text{-cut}}$, thus contradicting the definition of $OPT_{k\text{-cut}}$. Let $S := \{u_1, u_2, \ldots, u_p\}$ for some $p \geq 2k$. For notational convenience, we will use $S - u_i$ to denote $S \setminus \{u_i\}$ and $S - u_i - u_j$ to denote $S \setminus \{u_i, u_j\}$. For a subset $X \subseteq U$, we denote the source minimal minimum $(X, \overline{U})$-terminal cut by $(H_X, \overline{H_X})$.

Our strategy to arrive at a k-partition with fewer crossing hyperedges than $OPT_{k\text{-cut}}$ is to apply the second conclusion of Theorem 5. The next few claims will set us up to obtain sets that satisfy the hypothesis of Theorem 5.

▷ Claim 9. For every $i \in [p]$, we have $\overline{H_{S-u_i}} \in \mathcal{C}$.

Proof. Let $i \in [p]$. Since S is a minimal transversal of the collection $\mathcal{C}$, there exists a set $B_i \in \mathcal{C}$ such that $B_i \cap S = \{u_i\}$. Hence, $(\overline{B_i}, B_i)$ is a $(S - u_i, \overline{U})$-terminal cut. Therefore,

$$d(\overline{H_{S-u_i}}) \leq d(B_i) \leq d(U).$$

Since $(H_{S-u_i}, \overline{H_{S-u_i}})$ is a $(S - u_i, \overline{U})$-terminal cut, we have that $\overline{U} \subseteq \overline{H_{S-u_i}}$. If $d(\overline{H_{S-u_i}}) < d(U)$, then $\delta(\overline{H_{S-u_i}}) \neq \delta(U)$ and $\overline{U} \subsetneq \overline{H_{S-u_i}}$, and consequently, $\overline{H_{S-u_i}} \in \mathcal{C}$. So, we will assume henceforth that $d(\overline{H_{S-u_i}}) = d(U)$.

Since $(H_{S-u_i} \cap \overline{B_i}, \overline{H_{S-u_i} \cap \overline{B_i}})$ is a $(S - u_i, \overline{U})$-terminal cut, we have that

$$d(H_{S-u_i} \cap \overline{B_i}) \geq d(H_{S-u_i}).$$

Since $(H_{S-u_i} \cup \overline{B_i}, \overline{H_{S-u_i} \cup \overline{B_i}})$ is a $(S - u_i, \overline{U})$-terminal cut, we have that

$$d(H_{S-u_i} \cup \overline{B_i}) \geq d(H_{S-u_i}).$$

Therefore, by submodularity of the hypergraph cut function, we have that

$$2d(U) \geq d(H_{S-u_i}) + d(B_i) \geq d(H_{S-u_i} \cap \overline{B_i}) + d(H_{S-u_i} \cup \overline{B_i}) \geq 2d(H_{S-u_i}) = 2d(U). \quad (1)$$

Therefore, all inequalities above should be equations. In particular, we have that $d(H_{S-u_i} \cap \overline{B_i}) = d(U) = d(B_i) = d(H_{S-u_i})$ and hence, $(H_{S-u_i} \cap \overline{B_i}, \overline{H_{S-u_i} \cap \overline{B_i}})$ is a minimum $(S - u_i, \overline{U})$-terminal cut. Since $(H_{S-u_i}, \overline{H_{S-u_i}})$ is a source minimal minimum $(S - u_i, \overline{U})$-terminal cut, we must have $H_{S-u_i} \cap \overline{B_i} = H_{S-u_i}$, and thus $H_{S-u_i} \subseteq \overline{B_i}$. Therefore, $B_i \subseteq \overline{H_{S-u_i}}$. Since $B_i \in \mathcal{C}$, we have $\delta(B_i) \neq \delta(U)$. However, $d(B_i) = d(U)$. Therefore $\delta(U) \setminus \delta(B_i) \neq \emptyset$. Let $e \in \delta(U) \setminus \delta(B_i)$. Since $e \in \delta(\overline{U})$, but $e \notin \delta(B_i)$, and $\overline{U} \subseteq B_i$, we have that $e \subseteq B_i$, and thus $e \subseteq \overline{H_{S-u_i}}$. Thus, we conclude that $\delta(U) \setminus \delta(\overline{H_{S-u_i}}) \neq \emptyset$, and so $\delta(\overline{H_S - u_i}) \neq \delta(U)$. This also implies that $\overline{U} \subsetneq \overline{H_{S-u_i}}$. Thus, $\overline{H_{S-u_i}} \in \mathcal{C}$. ◁

Claim 9 implies the following Corollary.

▶ **Corollary 10.** *For every $i \in [p]$, we have $u_i \in \overline{H_{S-u_i}}$.*

Proof. By definition, $S - u_i \subseteq H_{S-u_i}$, so $S \cap \overline{H_{S-u_i}} \subseteq \{u_i\}$. By Claim 9 we have that $\overline{H_{S-u_i}} \in \mathcal{C}$. Since S is a transversal of the collection $\mathcal{C}$, we have that $S \cap \overline{H_{S-u_i}} \neq \emptyset$. So, the vertex u_i must be in $\overline{H_{S-u_i}}$. ◀

Having obtained Corollary 10, the next few claims (Claims 11, 13, 14, and 15) are similar to the claims appearing in the proof of a structural theorem that appeared in [8]. Since the hypothesis of the structural theorem that we are proving here is different from theirs, we present the complete proofs of these claims here. The way in which we use the claims will also be different from [8].

The following claim will help in showing that $u_i, u_j \notin H_{S-u_i-u_j}$, which in turn, will be used to show that the hypothesis of Theorem 5 is satisfied by suitably chosen sets.

▷ Claim 11. For every $i, j \in [p]$, we have $H_{S-u_i-u_j} \subseteq H_{S-u_i}$.

Proof. We may assume that $i \neq j$. We note that $(H_{S-u_i-u_j} \cap H_{S-u_i}, \overline{H_{S-u_i-u_j} \cap H_{S-u_i}})$ is a $(S - u_i - u_j, \overline{U})$-terminal cut. Therefore,

$$d(H_{S-u_i-u_j} \cap H_{S-u_i}) \geq d(H_{S-u_i-u_j}). \quad (2)$$

Also, $(H_{S-u_i-u_j} \cup H_{S-u_i}, \overline{H_{S-u_i-u_j} \cup H_{S-u_i}})$ is a $(S - u_i, \overline{U})$-terminal cut. Therefore,

$$d(H_{S-u_i-u_j} \cup H_{S-u_i}) \geq d(H_{S-u_i}). \quad (3)$$

By submodularity of the hypergraph cut function and inequalities (2) and (3), we have that

$$\begin{aligned} d(H_{S-u_i-u_j}) + d(H_{S-u_i}) &\geq d(H_{S-u_i-u_j} \cap H_{S-u_i}) + d(H_{S-u_i-u_j} \cup H_{S-u_i}) \\ &\geq d(H_{S-u_i-u_j}) + d(H_{S-u_i}). \end{aligned}$$

Therefore, inequality (2) is an equation, and consequently, $(H_{S-u_i-u_j} \cap H_{S-u_i}, \overline{H_{S-u_i-u_j} \cap H_{S-u_i}})$ is a minimum $(S-u_i-u_j, \overline{U})$-terminal cut. If $H_{S-u_i-u_j} \setminus H_{S-u_i} \neq \emptyset$, then $(H_{S-u_i-u_j} \cap H_{S-u_i}, \overline{H_{S-u_i-u_j} \cap H_{S-u_i}})$ contradicts source minimality of the minimum $(S-u_i-u_j, \overline{U})$-terminal cut $(H_{S-u_i-u_j}, \overline{H_{S-u_i-u_j}})$. Hence, $H_{S-u_i-u_j} \setminus H_{S-u_i} = \emptyset$ and consequently, $H_{S-u_i-u_j} \subseteq H_{S-u_i}$. ◁

Claim 11 implies the following Corollary.

▶ **Corollary 12.** *For every $i, j \in [p]$, we have $u_i, u_j \notin H_{S-u_i-u_j}$.*

Proof. By Corollary 10, we have that $u_i \notin H_{S-u_i}$. Therefore, $u_i, u_j \notin H_{S-u_i} \cap H_{S-u_j}$. By Claim 11, $H_{S-u_i-u_j} \subseteq H_{S-u_i}$ and $H_{S-u_i-u_j} \subseteq H_{S-u_j}$. Therefore, $H_{S-u_i-u_j} \subseteq H_{S-u_i} \cap H_{S-u_j}$, and thus, $u_i, u_j \notin H_{S-u_i-u_j}$. ◀

The next claim will help in controlling the cost of the k-partition that we will obtain by applying Theorem 5.

▷ Claim 13. For every $i, j \in [p]$, we have $d(H_{S-u_i}) = d(U) = d(H_{S-u_i-u_j})$.

Proof. Let $a, b \in [p]$. We will show that $d(H_{S-u_a}) = d(U) = d(H_{S-u_a-u_b})$. Since $(U, \overline{U})$ is a $(S-u_a, \overline{U})$-terminal cut, we have that $d(H_{S-u_a}) \leq d(U)$. Since $(H_{S-u_a}, \overline{H_{S-u_a}})$ is a $(S-u_a-u_b, \overline{U})$-terminal cut, we have that $d(H_{S-u_a-u_b}) \leq d(H_{S-u_a}) \leq d(U)$. Thus, in order to prove the claim, it suffices to show that $d(H_{S-u_a-u_b}) \geq d(U)$.

Suppose for contradiction that $d(H_{S-u_a-u_b}) < d(U)$. Let $\ell \in [p] \setminus \{a, b\}$ be an arbitrary element (which exists since we have assumed that $p \geq 2k$ and $k \geq 2$). Let $R := \{u_\ell\}$, $S' := S - u_a - u_\ell$, and $A_i := \overline{H_{S-u_a-u_i}}$ for every $i \in [p] \setminus \{a, \ell\}$. We note that $|S'| = p-2 \geq 2k-2$. By definition, $(\overline{A_i}, A_i)$ is a minimum $(S-u_a-u_i, \overline{U})$-terminal cut for every $i \in [p] \setminus \{a, \ell\}$. Moreover, by Corollary 12, we have that $u_i \in A_i \setminus (\cup_{j \in [p] \setminus \{a,i,\ell\}} A_j)$ for every $i \in [p] \setminus \{a, \ell\}$. Hence, the sets U, R, and S', and the cuts $(\overline{A_i}, A_i)$ for $i \in [p] \setminus \{a, \ell\}$ satisfy the conditions of Theorem 5. Therefore, by the first conclusion of Theorem 5, there exists a k-partition $\mathcal{P}'$ with

$$|\delta(\mathcal{P}')| \leq \frac{1}{2} \min\{d(H_{S-u_a-u_i}) + d(H_{S-u_a-u_j}) \colon i, j \in [p] \setminus \{a, \ell\}\}.$$

By assumption, $d(H_{S-u_a-u_b}) < d(U)$ and $b \in [p] \setminus \{a, \ell\}$, so $\min\{d(H_{S-u_a-u_i}) \colon i \in [p] \setminus \{a, \ell\}\} < d(U)$. Since $(U, \overline{U})$ is a $(S-u_a-u_i, \overline{U})$-terminal cut, we have that $d(H_{S-u_a-u_i}) \leq d(U)$ for every $i \in [p] \setminus \{a, \ell\}$. Therefore,

$$\frac{1}{2} \min\{d(H_{S-u_a-u_i}) + d(H_{S-u_a-u_j}) \colon i, j \in [p] \setminus \{a, \ell\}\} < d(U) = OPT_{k\text{-cut}}.$$

Thus, we have that $|\delta(\mathcal{P}')| < OPT_{k\text{-cut}}$, which is a contradiction. ◁

The next two claims will help in arguing the existence of a hyperedge satisfying the conditions of the second conclusion of Theorem 5. In particular, we will need Claim 15. The following claim will help in proving Claim 15.

▷ Claim 14. For every $i, j \in [p]$, we have

$$d(H_{S-u_i} \cap H_{S-u_j}) = d(U) = d(H_{S-u_i} \cup H_{S-u_j}).$$

Proof. Since $(H_{S-u_i} \cap H_{S-u_j}, \overline{H_{S-u_i} \cap H_{S-u_j}})$ is a $(S - u_i - u_j, \overline{U})$-terminal cut, we have that $d(H_{S-u_i} \cap H_{S-u_j}) \geq d(H_{S-u_i-u_j})$. By Claim 13, we have that $d(H_{S-u_i-u_j}) = d(U) = d(H_{S-u_i})$. Therefore,

$$d(H_{S-u_i} \cap H_{S-u_j}) \geq d(H_{S-u_i}). \tag{4}$$

Since $(H_{S-u_i} \cup H_{S-u_j}, \overline{H_{S-u_i} \cup H_{S-u_j}})$ is a $(S - u_j, \overline{U})$-terminal cut, we have that

$$d(H_{S-u_i} \cup H_{S-u_j}) \geq d(H_{S-u_j}). \tag{5}$$

By submodularity of the hypergraph cut function and inequalities (4) and (5), we have that

$$d(H_{S-u_i}) + d(H_{S-u_j}) \geq d(H_{S-u_i} \cap H_{S-u_j}) + d(H_{S-u_i} \cup H_{S-u_j}) \geq d(H_{S-u_i}) + d(H_{S-u_j}).$$

Therefore, inequalities (4) and (5) are equations. Thus, by Claim 13, we have that

$$d(H_{S-u_i} \cap H_{S-u_j}) = d(H_{S-u_i}) = d(U),$$

and

$$d(H_{S-u_i} \cup H_{S-u_j}) = d(H_{S-u_j}) = d(U).$$ ◁

▷ Claim 15. For every $i, j, \ell \in [p]$ with $i \neq j$, we have $H_{S-u_\ell} \subseteq H_{S-u_i} \cup H_{S-u_j}$.

Proof. If $\ell = i$ or $\ell = j$ the claim is immediate. Thus, we assume that $\ell \notin \{i, j\}$. Let $Q := H_{S-u_\ell} \setminus (H_{S-u_i} \cup H_{S-u_j})$. We need to show that $Q = \emptyset$. We will show that $(H_{S-u_\ell} \setminus Q, \overline{H_{S-u_\ell} \setminus Q})$ is a minimum $(S - u_\ell, \overline{U})$-terminal cut. Consequently, Q must be empty (otherwise, $H_{S-u_\ell} \setminus Q \subsetneq H_{S-u_\ell}$ and hence, $(H_{S-u_\ell} \setminus Q, \overline{H_{S-u_\ell} \setminus Q})$ contradicts source minimality of the minimum $(S - u_\ell, \overline{U})$-terminal cut $(H_{S-u_\ell}, \overline{H_{S-u_\ell}})$).

We now show that $(H_{S-u_\ell} \setminus Q, \overline{H_{S-u_\ell} \setminus Q})$ is a minimum $(S - u_\ell, \overline{U})$-terminal cut. Since $H_{S-u_\ell} \setminus Q = H_{S-u_\ell} \cap (H_{S-u_i} \cup H_{S-u_j})$, we have that $S - u_i - u_j - u_\ell \subseteq H_{S-u_\ell} \setminus Q$. We also know that u_i and u_j are contained in both H_{S-u_ℓ} and $H_{S-u_i} \cup H_{S-u_j}$. Therefore, $S - u_\ell \subseteq H_{S-u_\ell} \setminus Q$. Thus, $(H_{S-u_\ell} \setminus Q, \overline{H_{S-u_\ell} \setminus Q})$ is a $(S - u_\ell, \overline{U})$-terminal cut. Therefore,

$$d(H_{S-u_\ell} \cap (H_{S-u_i} \cup H_{S-u_j})) = d(H_{S-u_\ell} \setminus Q) \geq d(H_{S-u_\ell}). \tag{6}$$

We also have that $(H_{S-u_\ell} \cup (H_{S-u_i} \cup H_{S-u_j}), \overline{H_{S-u_\ell} \cup (H_{S-u_i} \cup H_{S-u_j})})$ is a $(S - u_i, \overline{U})$-terminal cut. Therefore, $d(H_{S-u_\ell} \cup (H_{S-u_i} \cup H_{S-u_j})) \geq d(H_{S-u_i})$. By Claims 13 and 14, we have that $d(H_{S-u_i}) = d(V_1) = d(H_{S-u_i} \cup H_{S-u_j})$. Therefore,

$$d(H_{S-u_\ell} \cup (H_{S-u_i} \cup H_{S-u_j})) \geq d(H_{S-u_i} \cup H_{S-u_j}). \tag{7}$$

By submodularity of the hypergraph cut function and inequalities (6) and (7), we have that

$$\begin{aligned} d(H_{S-u_\ell}) + d(H_{S-u_i} \cup H_{S-u_j}) &\geq d(H_{S-u_\ell} \cap (H_{S-u_i} \cup H_{S-u_j})) + d(H_{S-u_\ell} \cup (H_{S-u_i} \cup H_{S-u_j})) \\ &\geq d(H_{S-u_\ell}) + d(H_{S-u_i} \cup H_{S-u_j}). \end{aligned}$$

Therefore, inequalities (6) and (7) are equations, so $(H_{S-u_\ell} \setminus Q, \overline{H_{S-u_\ell} \setminus Q})$ is a minimum $(S - u_\ell, \overline{U})$-terminal cut. ◁

Let $R := \{u_p\}$, $S' := S - u_p$, and $(\overline{A_i}, A_i) := (H_{S-u_i}, \overline{H_{S-u_i}})$ for every $i \in [p-1]$. By definition, $(\overline{A_i}, A_i)$ is a minimum $(S - u_i, \overline{U})$-terminal cut for every $i \in [p-1]$. Moreover, by Corollary 10, we have that $u_i \in A_i \setminus (\cup_{j \in [p-1] \setminus \{i\}} A_j)$. Hence, the sets U, R, and S', and the cuts $(\overline{A_i}, A_i)$ for $i \in [p-1]$ satisfy the conditions of Theorem 5. We will use the second conclusion of Theorem 5. We now show that there exists a hyperedge satisfying the conditions mentioned in the second conclusion of Theorem 5. We will use Claim 16 below to prove this. Let $W := \cup_{1 \le i < j \le p-1}(A_i \cap A_j)$ and $Z := \cap_{i \in [p-1]} \overline{A_i}$ as in the statement of Theorem 5.

▷ Claim 16. There exists a hyperedge $e \in E$ such that $e \cap W \neq \emptyset$, $e \cap Z \neq \emptyset$, and $e \subseteq W \cup Z$.

Proof. We note that $S \subseteq (S - u_i) \cup (S - u_j) \subseteq H_{S-u_i} \cup H_{S-u_j}$ for every distinct $i, j \in [p-1]$. Therefore, $S \cap (A_i \cap A_j) = \emptyset$ for every distinct $i, j \in [p-1]$, and thus $S \cap W = \emptyset$. Since S is a transversal of the collection $\mathcal{C}$, it follows that the set W is not in the collection $\mathcal{C}$.

By definition, $\overline{U} \subseteq A_i$ for every $i \in [p-1]$, and thus $\overline{U} \subseteq W$. Since $W \notin \mathcal{C}$, either $d(W) > d(U)$ or $\delta(W) = \delta(U)$. By Claim 9, we have that $\overline{H_{S-u_p}} \in \mathcal{C}$, and thus, $d(\overline{H_{S-u_p}}) \le d(U)$ and $\delta(\overline{H_{S-u_p}}) \neq \delta(U)$. Consequently, $d(W) \ge d(\overline{H_{S-u_p}})$, and $\delta(W) \neq \delta(\overline{H_{S-u_p}})$, and thus, $\delta(W) \setminus \delta(\overline{H_{S-u_p}}) \neq \emptyset$. Let $e \in \delta(W) \setminus \delta(\overline{H_{S-u_p}})$. We will show that this choice of e achieves the desired properties.

For each $i \in [p]$, let $Y_i := \overline{H_{S-u_i}} \setminus W$. By Claim 15, for every $i, j, \ell \in [p]$ with $i \neq j$ we have that $H_{S-u_\ell} \subseteq H_{S-u_i} \cup H_{S-u_j}$. Therefore $\overline{H_{S-u_i}} \cap \overline{H_{S-u_j}} \subseteq \overline{H_{S-u_\ell}}$ for every such $i, j, \ell \in [p]$, and hence $W \subseteq \overline{H_{S-u_\ell}}$ for every $\ell \in [p]$. Thus, $W \subseteq \overline{H_{S-u_p}}$. Since $e \in \delta(W) \setminus \delta(\overline{H_{S-u_p}})$, we have that $e \subseteq W \cup Y_p$, $e \cap W \neq \emptyset$ and $e \cap Y_p \neq \emptyset$. Therefore, in order to show that e has the three desired properties as in the claim, it suffices to show that $Y_p \subseteq Z$. We prove this next.

By definition, $Y_p \cap W = \emptyset$. By Claim 15, for every $i \in [p-1]$, we have that $\overline{H_{S-u_p}} \cap \overline{H_{S-u_i}} \subseteq \overline{H_{S-u_1}}$ and $\overline{H_{S-u_p}} \cap \overline{H_{S-u_i}} \subseteq \overline{H_{S-u_2}}$, so $\overline{H_{S-u_p}} \cap \overline{H_{S-u_i}} \subseteq \overline{H_{S-u_1}} \cap \overline{H_{S-u_2}} \subseteq W$. Thus, for every $i \in [p-1]$, $Y_p \cap Y_i \subseteq \overline{H_{S-u_p}} \cap \overline{H_{S-u_i}} \subseteq W$, so since $Y_p \cap W = \emptyset$, we have that $Y_p \cap Y_i = \emptyset$ for every $i \in [p-1]$. Therefore,

$$Y_p \subseteq \overline{W \cup \left(\bigcup_{i=1}^{p-1} Y_i\right)} = \overline{\bigcup_{i=1}^{p-1} \overline{H_{S-u_i}}} = \bigcap_{i=1}^{p-1} H_{S-u_i} = Z. \qquad \triangleleft$$

By Claim 16, there is a hyperedge e satisfying the conditions of the second conclusion of Theorem 5. Therefore, by Theorem 5, there exists a k-partition $\mathcal{P}'$ with

$$\begin{aligned} |\delta(\mathcal{P}')| &< \frac{1}{2} \min\{d(A_i) + d(A_j) : i, j \in [p-1], i \neq j\} \\ &= d(U) && \text{(By Claim 13)} \\ &= OPT_{k\text{-cut}}. && \text{(By assumption of the theorem)} \end{aligned}$$

Thus, we have obtained a k-partition $\mathcal{P}'$ with $|\delta(\mathcal{P}')| < OPT_{k\text{-cut}}$, which is a contradiction. ◀

3 Proof of Theorem 4

We prove Theorem 4 in this section. Applying Theorem 6 to $(\overline{U}, U)$ yields the following corollary.

▶ **Corollary 17.** *Let $G = (V, E)$ be a hypergraph and let $OPT_{k\text{-cut}}$ be the optimum value of Hypergraph-k-Cut in G for some integer $k \ge 2$. Suppose $(U, \overline{U})$ is a 2-partition of V with $d(U) = OPT_{k\text{-cut}}$. Then, there exists a set $T \subseteq \overline{U}$ with $|T| \le 2k - 1$ such that every minimum (U, T)-terminal cut $(A, \overline{A})$ satisfies $\delta(A) = \delta(U)$.*

We now restate Theorem 4 and prove it using Theorem 6 and Corollary 17.

▶ **Theorem 4.** *Let $G = (V, E)$ be a hypergraph and let $OPT_{k\text{-}cut}$ be the optimum value of* Hypergraph-k-Cut *in G for some integer $k \geq 2$. Suppose $(U, \overline{U})$ is a 2-partition of V with $d(U) = OPT_{k\text{-}cut}$. Then, there exist sets $S \subseteq U$, $T \subseteq \overline{U}$ with $|S| \leq 2k-1$ and $|T| \leq 2k-1$ such that every minimum (S,T)-terminal cut $(A, \overline{A})$ satisfies $\delta(A) = \delta(U)$.*

Proof. By Theorem 6, there exists a subset $S \subseteq U$ with $|S| \leq 2k-1$ such that every minimum $(S, \overline{U})$-terminal cut $(A, \overline{A})$ has $\delta(A) = \delta(U)$. By Corollary 17, there exists a subset $T \subseteq \overline{U}$ with $|T| \leq 2k-1$ such that every minimum (U,T)-terminal cut $(A, \overline{A})$ has $\delta(A) = \delta(U)$. We will show that every minimum (S,T)-terminal cut $(A, \overline{A})$ has $\delta(A) = \delta(U)$. We will need the following claim.

▷ Claim 18. Let $(Y, \overline{Y})$ be the source minimal minimum (S,T)-terminal cut. Then $\delta(Y) = \delta(U)$.

Proof. Since $(U, \overline{U})$ is a (S,T)-terminal cut, and $(Y, \overline{Y})$ is a minimum (S,T)-terminal cut, we have that

$$d(U) \geq d(Y).$$

Since $(U \cap Y, \overline{U \cap Y})$ is a $(S, \overline{U})$-terminal cut, we have that

$$d(U \cap Y) \geq d(U).$$

Since $(U \cup Y, \overline{U \cup Y})$ is a (U,T)-terminal cut, we have that

$$d(U \cup Y) \geq d(U).$$

Thus, by the submodularity of the hypergraph cut function we have that

$$2d(U) \geq d(U) + d(Y) \geq d(U \cap Y) + d(U \cup Y) \geq 2d(U).$$

Therefore, we have that $d(U \cap Y) = d(U)$, so $(U \cap Y, \overline{U \cap Y})$ is a minimum (S,T)-terminal cut. Since $(Y, \overline{Y})$ is the source minimal (S,T)-terminal cut, we have that $U \cap Y = Y$, and hence $Y \subseteq U$. Therefore, $(Y, \overline{Y})$ is a minimum $(S, \overline{U})$-terminal cut. By the choice of S, we have that $\delta(Y) = \delta(U)$. ◁

Applying Claim 18 to both sides of the partition $(U, \overline{U})$, we have that the source minimal minimum (S,T)-terminal cut $(Y, \overline{Y})$ has $\delta(Y) = \delta(U)$, and the source minimal minimum (T,S)-terminal cut $(Z, \overline{Z})$ has $\delta(Z) = \delta(U)$. Therefore, for every $e \in \delta(U)$, we have that $e \cap Y \neq \emptyset$ and $e \cap Z \neq \emptyset$.

Let $(A, \overline{A})$ be a minimum (S,T)-terminal cut. Since $(Y, \overline{Y})$ is the source minimal minimum (S,T)-terminal cut, we have that $Y \subseteq A$. Since $(Z, \overline{Z})$ is the source minimal minimum (T,S)-terminal cut, we have that $Z \subseteq \overline{A}$. Since every $e \in \delta(U)$ intersects both Y and Z, it follows that every $e \in \delta(U)$ intersects both A and $\overline{A}$, and hence, $\delta(U) \subseteq \delta(A)$. Since $(A, \overline{A})$ is a minimum (S,T)-terminal cut, $d(A) \leq d(U)$, and thus we have that $\delta(A) = \delta(U)$. ◀

4 Conclusion

We showed the first polynomial bound on the number of MINMAX-k-CUT-SETs in hypergraphs for every fixed k and gave a polynomial-time algorithm to enumerate all MINMAX-k-CUT-SETs as well as all MIN-k-CUT-SETs in hypergraphs for every fixed k. Our main contribution is

a structural theorem that is the backbone of the correctness analysis of our enumeration algorithms. In order to enumerate MINMAX-k-CUT-SETS in hypergraphs, we introduced the notion of k-cut-set representatives and enumerated k-cut-set representatives of all optimum k-partitions for MINMAX-HYPERGRAPH-k-PARTITION. Our technique builds on known structural results for HYPERGRAPH-k-CUT and MINMAX-HYPERGRAPH-k-PARTITION [8, 12, 13].

The technique underlying our enumeration algorithms is not necessarily novel – we simply rely on minimum (s,t)-terminal cuts. Using fixed-terminal cuts to address global partitioning problems is not a novel technique by itself – it is common knowledge that minimum (s,t)-terminal cuts can be used to solve global minimum cut. However, there are several problems where naive use of this technique fails to lead to efficient algorithms: e.g., multiway cut does not help in solving GRAPH-k-CUT since multiway cut is NP-hard. Adapting this technique for specific partitioning problems requires careful identification of structural properties. In fact, beautiful structural properties have been shown for a rich variety of partitioning problems in combinatorial optimization in order to exploit this technique: for example, it was used (1) to design the first efficient algorithm for GRAPH-k-CUT [23], (2) to solve certain constrained submodular minimization problems [22, 35], and (3) more recently, to design fast algorithms for global minimum cut in graphs and for Gomory-Hu tree in unweighted graphs [1, 34]. Our use of this technique also relies on identifying and proving a suitable structural property, namely Theorem 4. The advantage of our structural property is that it simultaneously enables enumeration of MIN-k-CUT-SETS as well as MINMAX-k-CUT-SETS in hypergraphs which was not possible via structural theorems that were developed before. Furthermore, it helps in showing the first polynomial bound on the number of MINMAX-k-CUT-SETS in hypergraphs for every fixed k.

We also emphasize a limitation of our technique. Although it helps in solving ENUM-HYPERGRAPH-k-CUT and ENUM-MINMAX-HYPERGRAPH-k-PARTITION, it does not help in solving a seemingly related hypergraph k-partitioning problem – namely, given a hypergraph $G = (V, E)$ and a fixed integer k, find a k-partition $(V_1, \ldots, V_k)$ of the vertex set that minimizes $\sum_{i=1}^{k} |\delta(V_i)|$. Natural variants of our structural theorem fail to hold for this objective. Resolving the complexity of this variant of the hypergraph k-partitioning problem for $k \geq 5$ remains open.

We mention an open question concerning HYPERGRAPH-k-CUT and the enumeration of MIN-k-CUT-SETS in hypergraphs for fixed k. We recall the status in graphs: the number of minimum k-partitions in a connected graph was known to be $O(n^{2k-2})$ via Karger-Stein's algorithm [30] and $\Omega(n^k)$ via the cycle example, where n is the number of vertices; recent works have improved on the upper bound to match the lower bound for fixed k – this improvement in upper bound also led to the best possible $O(n^k)$-time algorithm for GRAPH-k-CUT for fixed k [25–27]. For hypergraphs, the number of MIN-k-CUT-SETS is known to be $O(n^{2k-2})$ and $\Omega(n^k)$. Can we improve the upper/lower bound? Is it possible to design an algorithm for HYPERGRAPH-k-CUT that runs in time $O(n^k p)$?

Finding Monotone Patterns in Sublinear Time, Adaptively

Omri Ben-Eliezer

Erik Waingarten
Stanford University, CA, USA

Abstract

We investigate adaptive sublinear algorithms for finding monotone patterns in sequential data. Given fixed $2 \leq k \in \mathbb{N}$ and $\varepsilon > 0$, consider the problem of finding a length-k increasing subsequence in a sequence $f\colon [n] \to \mathbb{R}$, provided that f is ε-far from free of such subsequences. It was shown by Ben-Eliezer et al. [FOCS 2019] that the non-adaptive query complexity of the above task is $\Theta((\log n)^{\lfloor \log_2 k \rfloor})$. In this work, we break the non-adaptive lower bound, presenting an adaptive algorithm for this problem which makes $O(\log n)$ queries. This is optimal, matching the classical $\Omega(\log n)$ adaptive lower bound by Fischer [Inf. Comp. 2004] for monotonicity testing (which corresponds to the case $k = 2$). Equivalently, our result implies that testing whether a sequence decomposes into k monotone subsequences can be done with $O(\log n)$ queries.

1 Introduction

Pattern avoidance and detection in sequential data is a central problem in theoretical computer science and combinatorics [57], dating back to the seminal work of Knuth [38] (from a computer science perspective), and Simion and Schmidt [55] (from a combinatorial perspective). Studying the computational problem within the framework of sublinear algorithms, Newman, Rabinovich, Rajendraprasad, and Sohler [44, 45] considered the problem of property testing for forbidden order patterns in a sequence, where one of the central special cases they considered was that of *monotone patterns*. The property testing problem of detecting monotone patterns generalizes classical monotonicity testing in sequences, and is tightly connected to the longest increasing subsequence (LIS) problem [46].

For an integer $k \in \mathbb{N}$ and a sequence $f\colon [n] \to \mathbb{R}$, a *length-$k$ monotone subsequence of f* is a tuple of k indices, $(i_1, \ldots, i_k) \in [n]^k$, such that $i_1 < \cdots < i_k$ and $f(i_1) < \cdots < f(i_k)$. More generally, for a permutation $\pi\colon [k] \to [k]$, a *π-pattern of f* is given by a tuple of k indices $i_1 < \cdots < i_k$ such that $f(i_{j_1}) < f(i_{j_2})$ whenever $j_1, j_2 \in [k]$ satisfy $\pi(j_1) < \pi(j_2)$. A

sequence f is π-free if there are no subsequences of f with order pattern π. For a fixed $k \in \mathbb{N}$ and a pattern π of length k, the goal is to test whether a function $f\colon [n] \to \mathbb{R}$ is π-free or ε-far from π-free (that is, any π-free function g differs from f on at least εn inputs). The algorithmic task proposed in [45] and studied in this paper is as follows.

> *For $2 \leq k \in \mathbb{N}$ and $\varepsilon > 0$, design a randomized algorithm that, given query access to a function $f\colon [n] \to \mathbb{R}$, distinguishes with probability at least $9/10$ between the case that f is free of length-k monotone subsequences and the case that it is ε-far from free of length-k monotone subsequences.*

The above algorithmic formulation is equivalent to the following property testing problem (with one-sided error). For a given $2 \leq k \in \mathbb{N}$ and $f\colon [n] \to \mathbb{R}$, test whether there exists a decomposition of f into fewer than k non-increasing subsequences, or f is ε-far from having such a decomposition. The equivalence of the two formulations is a consequence of Dilworth's theorem [22]. One direction is trivial: if there exists a length-k increasing subsequence $(i_1, \ldots, i_k) \in [n]^k$, then any partition of f into fewer than k subsequences must contain two indices i_j and $i_{j'}$ within the same subsequence, hence, the subsequences are not non-increasing. The other direction follows from considering the poset $([n], \prec_f)$, where $i \prec_f j$ iff $i \leq j$ and $f(i) \geq f(j)$; every anti-chain of $\prec_f$ is an increasing subsequence of f, and every chain of $\prec_f$ is a non-increasing subsequence. If there are no length-k increasing subsequences, the maximum anti-chain of $\prec_f$ has size at most $k-1$, and by Dilworth's theorem, there is a partition of $([n], \prec_f)$ into at most $k-1$ chains, i.e., non-increasing subsequences.[1]

This paper gives an algorithm with optimal dependence in n for the above problems. We state the main theorem next, and discuss connections to monotonicity testing and to the longest increasing subsequence (LIS) problem shortly after.

▶ **Theorem 1.** *Fix $k \in \mathbb{N}$ and $\varepsilon > 0$. There exists an algorithm that, given query access to a function $f\colon [n] \to \mathbb{R}$ which is ε-far from free of length-k monotone subsequences, outputs a length-k monotone subsequence of f with probability $9/10$, with query complexity and running time of*

$$\left(k^k \cdot (\log(1/\varepsilon))^k \cdot \frac{1}{\varepsilon} \cdot \log(1/\delta)\right)^{O(k)} \cdot \log n.$$

Thus, for fixed k and ε, the query complexity and running time are of order $O(\log n)$. The above result can be stated analogously in the language of monotone decompositions.

▶ **Corollary 2.** *Fix $k \in \mathbb{N}$ and $\varepsilon > 0$. There is an algorithm with query complexity and running time $O(\log n)$ for ε-testing whether a sequence $f\colon [n] \to \mathbb{R}$ is decomposable into k monotone subsequences.*

The algorithm underlying Theorem 1 is *adaptive*[2] and solves the testing problem with one-sided error, since a length-k monotone subsequence is evidence for not being free of such subsequences. The algorithm improves on a recent result of Ben-Eliezer, Canonne, Letzter

[1] A similar equivalence, between being decomposable into k increasing (or decreasing) subsequences and not containing non-increasing (or non-decreasing, respectively) patterns of length $k+1$ holds as well. We note that all results stated here in terms of "strong" monotonicity, e.g., being increasing, will also hold for their "weak" monotonicity analogue, e.g., being non-decreasing.

[2] An algorithm is *non-adaptive* if its queries do not depend on the answers to previous queries, or, equivalently, if all queries to the function can be made in parallel. Otherwise, if the queries of an algorithm may depend on the outputs of previous queries, then the algorithm is *adaptive*.

and Waingarten [7] who gave a non-adaptive algorithm for finding length-k monotone patterns with query complexity $O_{k,\varepsilon}((\log n)^{\lfloor \log_2 k \rfloor})$, which in itself improved upon a $O_{k,\varepsilon}((\log n)^{O(k^2)})$ upper bound by [45]. The focus of [7] was on *non-adaptive* algorithms, and they gave a lower bound of $\Omega\big((\log n)^{\lfloor \log_2 k \rfloor}\big)$ queries for non-adaptive algorithms achieving one-sided error. Hence, Theorem 1 implies a natural separation between the power of adaptive and non-adaptive algorithms for finding monotone subsequences.

Theorem 1 is optimal, even among two-sided error algorithms. In the case $k = 2$, corresponding to monotonicity testing, there is a $\Omega(\log n/\varepsilon)$ lower bound (as long as, say, $\varepsilon > n^{-0.99}$) for both non-adaptive and adaptive algorithms [25, 27, 15], even with two-sided error. A simple reduction suggested in [45] shows that the same lower bound (up to a multiplicative factor depending on k) holds for any fixed $k \geq 2$. Thus, an appealing consequence of Theorem 1 is that the natural generalization of monotonicity testing, which considers forbidden monotone patterns of fixed length longer than 2, does not affect the dependence on n in the query complexity by more than a constant factor. Interestingly, [27] shows that for any adaptive algorithm for monotonicity testing on $f\colon [n] \to \mathbb{R}$ there is a non-adaptive algorithm which is at least as good in terms of query complexity (even if we only restrict ourselves to one-sided error algorithms). That is, adaptivity does not help at all for $k = 2$. In contrast, the separation between our $O(\log n)$ adaptive upper bound and the $\Omega\big((\log n)^{\lfloor \log_2 k \rfloor}\big)$ non-adaptive lower bound of [7] means this is no longer true for $k \geq 4$.

While our work settles the dependence in n in the query complexity of adaptive monotone pattern testing, and [7] settles the non-adaptive dependence in n, the following interesting question remains wide open.

▶ **Question 3.** *What is the optimal dependence of the query complexity in k and ε for the monotone subsequence testing problem discussed in this paper?*

Thus far, all known (adaptive and non-adaptive) results on this problem have a $k^{O(k^2)}$ type dependence in k in the query complexity; see Theorem 3.1 in [45] and Lemma 3.2 in [7]. The best known dependence in ε is of the form $(1/\varepsilon)^{\log_2 k + O(1)}$ for fixed k [7].

On the role of adaptivity in order pattern detection

Harnessing adaptivity to improve algorithmic performance is a notoriously difficult problem in many branches of property testing, typically requiring a good structural understanding of the task at hand. In the context of testing for forbidden order patterns, non-adaptive algorithms are quite weak: the non-adaptive query complexity is $\Omega(n^{1/2})$ for all non-monotone order patterns [45], and as high as $n^{1-1/(k-\Theta(1))}$ for almost all patterns of length k [6]. A recent (and independent) work of [47] gave new adaptive algorithms for general patterns with query complexity $n^{o(1)}$ for fixed constant $\varepsilon > 0$ and $k \in \mathbb{N}$, showing that for non-monotone patterns, too, adaptive algorithms may significantly improve upon non-adaptive ones. We note that the query complexity obtained in [47] is not polylogarithmic in n, and so their result is incomparable to ours. Their proof techniques are also very different from ours: at the core of their proof is a sophisticated sparsification framework, which makes use of a beautiful result of Marcus and Tardos [40] on pattern-avoidance in matrices.

Connections to the Longest Increasing Subsequence (LIS) problem

As an immediate consequence, Theorem 1 gives an optimal testing algorithm for the longest increasing subsequence (LIS) problem in a certain regime. The classical LIS problem asks to determine, given a sequence $f\colon [n] \to \mathbb{R}$, the maximum k for which f contains a

length-k increasing subsequence. It is very closely related to other fundamental algorithmic problems in sequences, such as computing the edit distance, Ulam distance, or distance from monotonicity (for example, the latter equals n minus the LIS length), and has been thoroughly investigated from the perspective of classical algorithms [29, 50], sublinear-time algorithms [49, 1, 54, 52, 46, 42, 2], streaming algorithms [34, 56, 30, 53, 24, 43], dynamic algorithms [18, 31, 39, 41] and massively parallel computation [36, 12]. In the property testing regime, the corresponding decision task is to distinguish between the case where f has LIS length at most k (where k is given as part of the input) and the case that f is ε-far from having such a LIS length. Theorem 1 in combination with the aforementioned $\Omega(\log n)$ lower bounds (which readily carry over to this setting) yield a tight bound on the query complexity of testing whether the LIS length is a constant.

▶ **Corollary 4.** *Fix $2 \leq k \in \mathbb{N}$ and $\varepsilon > 0$. The query complexity of ε-testing whether $f\colon [n] \to \mathbb{R}$ has LIS length at most k is $\Theta(\log n)$.*

1.1 Related Work

Considering general permutations π of length k and *exact* computation, [35] showed how to find a π-pattern in a sequence f in time $2^{O(k^2 \log k)}n$, later improved by [28] to $2^{O(k^2)}n$. In the regime $k = \Omega(\log n)$, an algorithm of [8] running in time $n^{k/4+o(k)}$ provides the state-of-the-art. The analogous *counting* problem has also been actively studied, see [26] and the references within.

For *approximate* computation of general patterns π, the works of [45, 6] investigate the query complexity of property testing for forbidden order patterns. When π is of length 2, the problem considered is equivalent to testing monotonicity, one of the most widely-studied problems in property testing, with works spanning the past two decades. Over the years, variants of monotonicity testing over various partially ordered sets have been considered, including the line $[n]$ [25, 27, 3, 48, 5], the Boolean hypercube $\{0,1\}^d$ [23, 10, 13, 14, 20, 19, 37, 4, 16, 21, 17], and the hypergrid $[n]^d$ [11, 15, 9]. We refer the reader to [32, Chapter 4] for more on monotonicity testing, and a general overview of the field of property testing (introduced in [51, 33]).

1.2 Main Ideas and Techniques

We now describe some intuition behind the proof of Theorem 1. We note that the algorithm considers several cases and combines ideas from [45] and [7] with new structural and algorithmic components. In this overview, technical details established in [45] and [7] are noted but excluded; the purpose is to highlight the challenges and novel ideas arising specifically from this work. (See the Appendix in the full-version of the work for a short technical overview of these previous results.)

Fix $k \in \mathbb{N}$ and $\varepsilon > 0$, and suppose that $f\colon [n] \to \mathbb{R}$ is ε-far from $(12\dots k)$-free, that is, ε-far from free of length-k increasing subsequences. Notice that f must contain a collection $\mathcal{C}$ of at least $\varepsilon n/k$ pairwise-disjoint increasing subsequences of length k; indeed, otherwise, greedily eliminating these subsequences gives a $(12\dots k)$-free function differing in strictly fewer than εn inputs.

For simplicity in this overview, assume that k is even and that all $\varepsilon n/k$ length-k increasing subsequences of f in $\mathcal{C}$, $(x_1, x_2, \dots, x_k) \in [n]^k$, satisfy that $|x_{k/2+1} - x_{k/2}| \geq |x_{i+1} - x_i|$ for all $i \in [k-1]$ (the non-adaptive lower bound of $\Omega_\varepsilon((\log n)^{\lfloor \log_2 k \rfloor})$ holds even in this restricted case) – intuitively, the largest "gap" in successive indices is between the $k/2$-th and $(k/2+1)$-th position. A goal, common to [45, 7] and this work, is to recursively

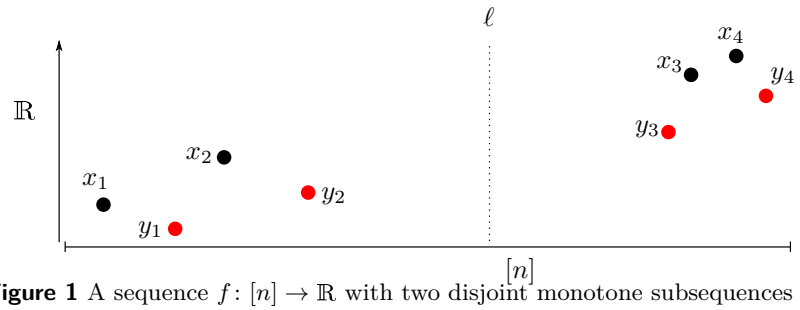

Figure 1 A sequence $f\colon [n] \to \mathbb{R}$ with two disjoint monotone subsequences of length 4, and an index $\ell \in [n]$. The sequences are $x = (x_1, x_2, x_3, x_4)$ and $y = (y_1, y_2, y_3, y_4)$. Note that both x and y have the largest gap between consecutive elements at index 2, i.e., $|x_3 - x_2|$ and $|y_3 - y_2|$ are the largest gaps between consecutive indices in x and y. Furthermore, ℓ cuts both x and y with slack.

find a $(12\dots k/2)$-pattern of indices $(i_1, \dots, i_{k/2}) \in [n]^{k/2}$, as well as $(12\dots k/2)$-pattern of indices $(i_{k/2+1}, \dots, i_k) \in [n]^{k/2}$ that can be combined into one $(12\dots k)$-pattern. Toward this recursive approach, we say that an index $\ell \in [n]$ *cuts* $(x_1, \dots, x_k)$ *with slack* if

$$x_{k/2} + \frac{x_{k/2+1} - x_{k/2}}{3} \;\le\; \ell \;\le\; x_{k/2+1} - \frac{x_{k/2+1} - x_{k/2}}{3},$$

or, informally, if ℓ lies "roughly in the middle" between $x_{k/2}$ and $x_{k/2+1}$ – which, by the above assumption, form the largest gap among consecutive indices of the increasing subsequence (see Figure 1). The index $\ell \in [n]$ allows us to recurse on an interval before ℓ, as well as an interval after ℓ. Additionally, the *width* of $(x_1, \dots, x_k)$ is set to be $\lfloor \log(x_{k/2+1} - x_{k/2}) \rfloor$. We consider the subset of $\mathcal{C}$ consisting of length-k monotone subsequences of width w which are cut by ℓ with slack,

$$\mathcal{C}_{\ell,w} = \{(x_1, \dots, x_k) \in \mathcal{C} : \text{width}(x_1, \dots, x_k) = w,\ \ell \text{ cuts } (x_1, \dots, x_k) \text{ with slack}\},$$

and note that if $(x_1, \dots, x_k) \in \mathcal{C}_{\ell,w}$, then $x_1, \dots, x_{k/2} \in [\ell - k \cdot 2^w, \ell]$ and $x_{k/2+1}, \dots, x_k \in [\ell, \ell + k \cdot 2^w]$, since $|x_{k/2+1} - x_{k/2}|$ was maximal. Motivated by this observation, the *density* of width-w copies in $\mathcal{C}$ around ℓ is measured by

$$\tau_{\mathcal{C}}(\ell, w) = \frac{1}{2^w} \cdot |\mathcal{C}_{\ell,w}|,$$

and the total density (over all widths) of $\mathcal{C}$ around ℓ is measured by

$$\tau_{\mathcal{C}}(\ell) = \sum_{w=1}^{\log n} \tau_{\mathcal{C}}(\ell, w).$$

The algorithms (ours and those in [45, 7]) proceed in a recursive manner. Each step considers an index $\ell \in [n]$ where the total density $\tau_{\mathcal{C}}(\ell)$ is high, namely at least $\Omega_k(\varepsilon)$, as well as a width w where $\tau_{\mathcal{C}}(\ell, w)$ is high. At a very high level, the algorithm can recurse on the sub-intervals $[\ell - k \cdot 2^w, \ell]$ and $[\ell, \ell + k \cdot 2^w]$, where the lower bound on $\tau_{\mathcal{C}}(\ell, w)$ implies sufficiently many increasing subsequences exist in each interval. If we choose the index ℓ and width w correctly, we have reduced the problem of finding a $(12\dots k)$-pattern to finding two $(12\dots k/2)$-patterns in subsequences of size $k \cdot 2^w$ to the left and right of ℓ which are themselves $\Omega_{\varepsilon,k}(1)$-far from free of $(12\dots, k/2)$-patterns.

While ℓ may be chosen randomly, choosing the correct width w becomes analytically trickier, and is the step where the algorithms differ. The number of possible widths w is $\Theta(\log n)$ (since these are powers of 2 between 1 and n), and a *non-adaptive* algorithm cannot know what a correct choice of w is. The non-adaptive algorithms consider all $\Theta(\log n)$ options

and recursively apply the algorithm for each width, thereby losing a $\Theta(\log n)$ factor in the query complexity at each recursive step. The main challenge of [45, 7] is obtaining the "best" lower bound on $\tau_{\mathcal{C}}(\ell, w)$ for some $w \in [\log n]$ and determining the number of recursive steps necessary. The fact that a non-adaptive algorithm must explore $\Omega(\log n)$ widths is inevitable, and what the non-adapive lower bound in [7] formalizes.

With adaptivity, the hope is that an algorithm considering an index $\ell \in [n]$ with $\tau_{\mathcal{C}}(\ell) = \Omega_k(\varepsilon)$ can choose *one* width w satisfying $\tau_{\mathcal{C}}(\ell, w) = \Omega_k(\varepsilon)$, and recurse only on that width. The algorithm may devote $\Theta_{k,\varepsilon}(\log n)$ queries to consider all $\Theta(\log n)$ possible widths, and the benefit is that recursing on a single width incurs a $\Theta_{k,\varepsilon}(\log n)$ *additive* loss in the query complexity, as opposed to the $\Theta_{k,\varepsilon}(\log n)$ multiplicative loss incurred by [45, 7]. We describe how we accomplish this next.

First, there is a simple $O_{k,\varepsilon}(\log n)$-query procedure which can choose a width $\widehat{w}$ where $\widehat{w} \geq w$. For example, for every possible width w_0, the algorithm queries $O_{k,\varepsilon}(1)$ randomly sampled indices from $[\ell - k \cdot 2^{w_0}, \ell]$ and $[\ell, \ell + k \cdot 2^{w_0}]$. Then, let $\widehat{w}$ be the largest w_0 where some increasing pair is found. The fact that the unknown $w \in [\log n]$ satisfies $\tau_{\mathcal{C}}(\ell, w) \geq \Omega_k(\varepsilon)$ implies that with high constant probability, there exists two $(x_1, \ldots, x_k), (y_1, \ldots, y_k) \in \mathcal{C}_{\ell,w}$ where indices x_1 and y_k are sampled and by an observation from [45], with high enough probability, $f(x_1) \leq f(y_k)$ (see the appendix in the full-version for a more thorough discussion on this point). This, in turn, implies $\widehat{w} \geq w$.

If the simple procedure happened to choose $\widehat{w}$ which is not much larger than w, then we may recurse on $\widehat{w}$, similarly to [45, 7]; we call this the *fitting* case. The problem is that $\widehat{w}$ may be too large, a case we refer to as *overshooting*. Consider the execution selecting a width $\widehat{w}$ which is too large, in particular, the "correct" width w satisfies $w \ll \widehat{w}$. Intuitively, the problem is the following: the promise that $\tau_{\mathcal{C}}(\ell, w) \geq \Omega_k(\varepsilon)$ ensures that the subsequence $[\ell - k \cdot 2^w, \ell + k \cdot 2^w]$ is sufficiently dense with $(12\ldots k)$-patterns; however, when $\widehat{w}$ is much larger, the subsequence $[\ell - k \cdot 2^{\widehat{w}}, \ell + k \cdot 2^{\widehat{w}}]$ is much larger than the subsequence $[\ell - k \cdot 2^w, \ell + k \cdot 2^w]$; hence, the length-$k$ increasing subsequences in $[\ell - k \cdot 2^w, \ell + k \cdot 2^w]$ constitute a tiny (at most $O_k(2^{w-\widehat{w}})$) fraction of the interval $[\ell - k \cdot 2^{\widehat{w}}, \ell + k \cdot 2^{\widehat{w}}]$ the algorithm would recurse on.

Due to the density $\tau_{\mathcal{C}}(\ell, \widehat{w})$ being potentially very small, at this point, it is not clear how to proceed with our wrong (too large) choice of $\widehat{w}$ as the width to recurse on. To overcome this, we prove a robust structural theorem, drawing a much more favorable picture as to which widths are good for recursion. The robust structural theorem asserts the following. For sufficiently many possible $\ell \in [n]$ and widths w where $\tau_{\mathcal{C}}(\ell, w) \geq \Omega_k(\varepsilon)$, *every* interval J containing $[\ell - k \cdot 2^w, \ell + k \cdot 2^w]$ has $\Omega_k(\varepsilon|J|)$ pairwise-disjoint length-k increasing subsequences. At a high level, the prior structural results ensured that $[\ell - k \cdot 2^w, \ell + k \cdot 2^w]$ is dense with $(12\ldots k)$-patterns cut by ℓ; our robust version ensures that any interval J containing $[\ell - k \cdot 2^w, \ell + k \cdot 2^w]$ remains dense with $(12\ldots k)$-patterns. In particular, the choice of interval is robust to picking a width $\widehat{w}$ which is larger than w. These length-k increasing subsequences are not cut with slack by ℓ, a condition which was crucial for [45, 7]; however, the algorithm's choice of $\widehat{w}$ means it found an increasing pair at distance $\Theta_k(2^{\widehat{w}})$. We exploit this with an adaptive algorithm in a somewhat surprising manner, which we expand on now.

New algorithm when overshooting

Let $\ell \in [n]$ be an index with $\tau_{\mathcal{C}}(\ell) \geq \Omega_k(\varepsilon)$, and let w be the unknown width where $\tau_{\mathcal{C}}(\ell, w) \geq \Omega_k(\varepsilon)$ with the above-mentioned robustness property. Suppose that the widest increasing pair $(\boldsymbol{x}, \boldsymbol{y})$ found by the algorithm (which sets $\widehat{w} \approx \log_2 |\boldsymbol{y} - \boldsymbol{x}|$), satisfies $\widehat{w} \gg w$.

Even though the algorithm has "committed" to a width $\widehat{w}$ which is too large, we will algorithmically exploit the fact that $(\boldsymbol{x}, \boldsymbol{y})$ is an increasing pair lying very far apart, and containing the interval $[\ell - k \cdot 2^w, \ell + k \cdot 2^w]$. Specifically, since $(\boldsymbol{x}, \boldsymbol{y})$ are very far away, the algorithm may fit $k-2$ intervals $J_1, \ldots, J_{k-2}$ between $\boldsymbol{x}$ and $\boldsymbol{y}$ which lie adjacent to each other, satisfying the following conditions:

- J_1 contains the interval $[\ell - k \cdot 2^w, \ell + k \cdot 2^w]$.
- J_{i+1} lies immediately after J_i, for any $i \in [k-3]$.
- $|J_{i+1}| \geq |J_i| \cdot \alpha_{k,\varepsilon}$ for all $i \in [k-3]$, and a large fixed constant $\alpha_{k,\varepsilon} > 1$.

A consequence of the robust structural theorem, and the fact that $J_1, \ldots, J_{k-2}$ have exponentially increasing lengths is that each J_i contains a collection $\mathcal{T}_i$ of $\Omega_k(\varepsilon|J_i|)$ disjoint length-k increasing subsequences. For each $i \in [k-2]$, define two sets $\mathcal{A}_i$ and $\mathcal{B}_i$ as follows. Let $\mathcal{A}_i$ be the collection of prefixes $(a_1, \ldots, a_{i+1})$ of $\mathcal{T}_i$ with $f(a_{i+1}) < f(\boldsymbol{y})$, and let $\mathcal{B}_i$ be the collection of suffixes $(a_{i+1}, \ldots, a_k)$ of $\mathcal{T}_i$ with $f(a_{i+1}) \geq f(\boldsymbol{y})$. As $|\mathcal{T}_i| = |\mathcal{A}_i| + |\mathcal{B}_i|$, one of $\mathcal{A}_i$ and $\mathcal{B}_i$ is large (i.e. has size at least $\Omega_k(\varepsilon|J_i|)$). This seemingly innocent combinatorial idea can be exploited non-trivially to find an increasing subsequence of length k. Specifically, the algorithm to handle overshooting aims to (recursively) find shorter increasing subsequences in $J_1, \ldots, J_{k-2}$, with the hope of combining them together into an increasing subsequence of length k. Concretely, for any $i \in [k-2]$, we make two recursive calls of our algorithm on J_i: one for an $(i+1)$-increasing subsequence in J_i, with values smaller than $f(\boldsymbol{y})$,[3] and a second one for a $(k-i)$-increasing subsequence in J_i whose values are at least $f(\boldsymbol{y})$. By induction, the first recursive call succeeds with good probability if $|\mathcal{A}_i|$ is large, while the second call succeeds with good probability if $|\mathcal{B}_i|$ is large. Since for any i either $|\mathcal{A}_i|$ or $|\mathcal{B}_i|$ must be large, at least one of the following must hold.

- $\mathcal{B}_1$ is large. In this case we are likely to find a length-$(k-1)$ monotone pattern in J_1 with values at least $f(\boldsymbol{y}) > f(\boldsymbol{x})$, which combines with $\boldsymbol{x}$ to form a length-k monotone pattern.
- $\mathcal{A}_{k-2}$ is large. Here we are likely to find a length-$(k-1)$ monotone pattern in J_{k-2} whose values lie below $f(\boldsymbol{y})$, which combines with $\boldsymbol{y}$ to form a length-k monotone pattern.
- There exists $i \in [k-3]$ where both $\mathcal{A}_i$ and $\mathcal{B}_{i+1}$ are large. Here we will find, with good probability, a length-$(i+1)$ monotone pattern in J_i with values below $f(\boldsymbol{y})$, and a length-$(k-i-1)$ monotone pattern in J_{i+1} with values at or above $f(\boldsymbol{y})$; together these two patterns combine to form a $(12\ldots k)$-pattern.

In all cases, a k-increasing subsequence is found with good probability. See Figure 2 for an example. The benefit is that the algorithm spends $\Theta_{k,\varepsilon}(\log n)$ queries to identify one fixed width $\widehat{w} \in [\log n]$. Then, there are $2(k-2)$ recursive calls each aiming to find an increasing subsequence of length strictly less than k. The $\Theta_{\varepsilon,k}(\log n)$ loss in the query complexity is additive per recursive step; this leads to the $\Theta_{\varepsilon,k}(\log n)$ query complexity bound which was impossible in the non-adaptive algorithms of [45, 7], as these had to explore all possible widths $\widehat{w} \in [\log n]$ in each recursive step.

Organization

The rest of the paper is organized as follows. Relevant notation can be found in Section 1.3. Section 2 establishes the stronger structural result required for our adaptive algorithm. Section 3 contains the new algorithmic components and the formal statements regarding the

[3] Technically speaking, our algorithm can be configured to only look for increasing subsequences whose values lie in some range; we use this to make sure that shorter increasing subsequences obtained from the recursive calls of the algorithm can eventually be concatenated into a valid length-k one.

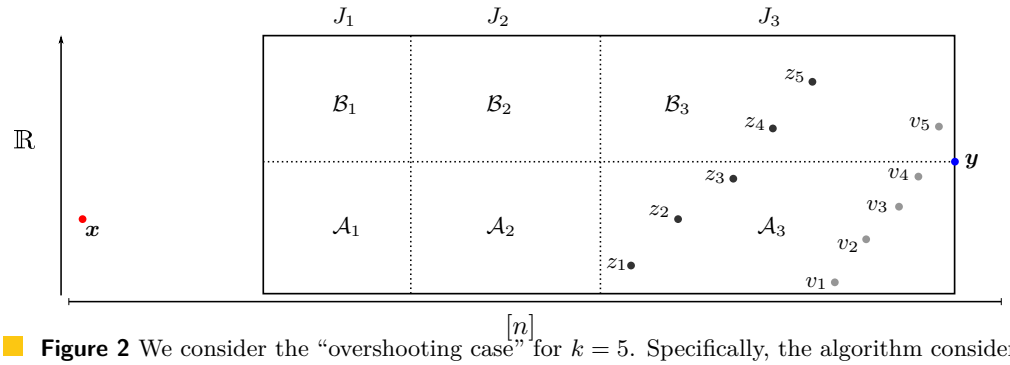

Figure 2 We consider the "overshooting case" for $k = 5$. Specifically, the algorithm considers an index $\ell \in [n]$ with $\tau_{\mathcal{C}}(\ell) = \Omega_k(\varepsilon)$ and, for some unknown $w \in [\log n]$, $\tau_{\mathcal{C}}(\ell, w) = \Omega_k(\varepsilon)$. Furthermore, in trying to identify a correct width $\widehat{w}$, the algorithm samples an increasing pair $(\boldsymbol{x}, \boldsymbol{y})$ with $\log_2 |\boldsymbol{x} - \boldsymbol{y}| \approx \widehat{w} \gg w$. The algorithm will consider at least $k-2$ geometrically increasing intervals between $\boldsymbol{x}$ and $\boldsymbol{y}$; these are displayed as J_1, J_2, and J_3; by virtue of the robust structural theorem, each J_i contains $\Omega_k(\varepsilon|J_i|)$ disjoint length-k monotone subsequences. $\mathcal{A}_i$ contains those length-k monotone subsequences where the $(i+1)$-th index is above $f(\boldsymbol{y})$ and $\mathcal{B}_i$ contains those whose $(i+1)$-th index is below $f(\boldsymbol{y})$. As an example, $(z_1, z_2, z_3, z_4, z_5) \in \mathcal{B}_4$ and $(v_1, v_2, v_3, v_4, v_5) \in \mathcal{A}_4$. The crucial properties are: (i) for all $i \in [k-2]$ any $(12\dots i)$-pattern in $\mathcal{A}_i$ and any $(12\dots(k-i))$-pattern in $\mathcal{B}_{i+1}$ may be combined into a $(12\dots k)$-pattern, (ii) any $(12\dots(k-1))$-pattern in $\mathcal{B}_1$ may be combined with $\boldsymbol{x}$ since $f(\boldsymbol{y}) > f(\boldsymbol{x})$, and (iii) any $(12\dots(k-1))$-pattern in $\mathcal{A}_4$ may be combined with $\boldsymbol{y}$. The reasoning may proceed as follows: if $|\mathcal{B}_1|$ is large, we find a $(12\dots(k-1))$-pattern and combine it with $\boldsymbol{x}$; so, assume $|\mathcal{B}_1|$ is small, which implies $|\mathcal{A}_1|$ must be large. If $|\mathcal{B}_2|$ is large, then a (12)-pattern from $\mathcal{A}_1$ and a $(12\dots(k-2))$-pattern from $\mathcal{B}_2$ may be combined; so assume $|\mathcal{B}_2|$ is small which implies $|\mathcal{A}_2|$ is large, ... Eventually, we deduce that we may assume $|\mathcal{A}_{k-2}|$ is large, and a $(12\dots(k-1))$-pattern in $\mathcal{A}_{k-2}$ may be combined with $\boldsymbol{y}$.

correctness of our algorithm and its query complexity. The appendices in the full-version provide a brief description of the previous (non-adaptive) testing results on $(12\dots k)$-freeness from [45, 7], as well as the remaining proofs, relegated from the main body due to space constraints.

1.3 Notation

All logarithms considered are base 2. We consider functions $f\colon I \to \mathbb{R}$, where $I \subseteq [n]$, as the inputs and main objects of study. An *interval* in $[n]$ is a set $I \subseteq [n]$ of the form $I = \{a, a+1, \dots, b\}$. At many places throughout the paper, we think of augmenting the image with a special character $*$ to consider $f\colon I \to \mathbb{R} \cup \{*\}$. The character $*$ can be thought of as a *masking* operation: In many cases, we will only be interested in entries x of f so that $f(x)$ lies in some prescribed (known in advance) range of values $R \subseteq \mathbb{R}$, so that entries outside this range will be marked by $*$. Whenever the algorithm queries $f(x)$ and observes $*$, it will interpret this as an incomparable value (with respect to ordering) in $\mathbb{R}$. As a result, $*$-values will never be part of monotone subsequences. We note that augmenting the image with $*$ was unnecessary in [45, 7] because they only considered non-adaptive algorithms. We say that for a fixed $f\colon I \to \mathbb{R} \cup \{*\}$, the set T is a collection of disjoint monotone subsequences of length k if it consists of tuples $(i_1, \dots, i_k) \in I^k$, where $i_1 < \dots < i_k$ and $f(i_1) < \dots < f(i_k)$ (in particular, $f(i_1), \dots, f(i_k) \neq *$), and furthermore, for any two tuples $(i_1, \dots, i_k)$ and $(i'_1, \dots, i'_k)$, their intersection (as sets) is empty. We also denote $E(T)$ as the union of indices in k-tuples of T, i.e., $E(T) = \cup_{(i_1,\dots,i_k)\in T}\{i_1, \dots, i_k\}$. Finally, we let $\mathrm{poly}(\cdot)$ denote a large enough polynomial whose degree is (bounded by) a universal constant.

2 Stronger Structural Dichotomy

In this section, we prove a robust structural dichotomy for functions $f\colon [n] \to \mathbb{R}$ that are ε-far from $(12\dots k)$-free, which strengthens the dichotomy proved in [7]. In their paper, it is shown that any f which is ε-far from $(12\dots k)$-free satisfies at least one of two conditions: either f contains many *growing suffixes*, or it can be decomposed into *splittable intervals*. In Section 2.1, we define and describe these notions and state the original (non-robust) structural result from [7]. Then, in Section 2.2, we establish a substantially stronger structural dichotomy, better suited for our purposes. The proof of the stronger dichotomy combines the original one as a black-box with additional combinatorial ideas.

2.1 The Non-Robust Structural Decomposition

For completeness, we first introduce the non-robust structural result from [7]. As the formal definitions are somewhat complicated, we start with an informal description of the growing suffixes and splittable intervals conditions. For the purpose of this discussion, let $\mathcal{C}$ be any collection of $\Theta_{k,\varepsilon}(n)$ disjoint $(12\dots k)$-copies in f. We use the notation from Section 1.2.

- **Growing suffixes:** there exist $\Omega_{k,\varepsilon}(n)$ values of $\ell \in [n]$ where $\tau_{\mathcal{C}}(\ell) \geq \Theta_k(\varepsilon)$ and $\tau_{\mathcal{C}}(\ell, w) \ll \tau_{\mathcal{C}}(\ell)$ for every $w \in [\log n]$. In words, many $\ell \in [n]$ are such that the sum of local densities, $\tau_{\mathcal{C}}(\ell)$, of $(12\dots k)$-patterns in intervals of growing widths is not too small, and furthermore, the densities are not concentrated on any small set of widths w. Any such ℓ is said to be the starting point of a growing suffix.
- **Splittable intervals (non-robust):** there exist $c \in [k-1]$ and a collection of pairwise-disjoint intervals $I_1, \dots, I_s \subset [n]$ with $\sum_{i=1}^{s} |I_i| = \Theta_{k,\varepsilon}(n)$, so that each I_i contains a dense collection of disjoint $(12\dots k)$-patterns of a particular structure. Specifically, each such interval I_i can be partitioned into three disjoint intervals L_i, M_i, R_i (in this order), each of size $\Omega_k(|I_i|)$, where I_i fully contains $\Omega_{k,\varepsilon}(|I_i|)$ disjoint copies of $(12\dots k)$-patterns, in which the first c entries lie in L_i, the last $k-c$ entries lie in R_i (none of these entries lies in M_i), and every such c entry lies below every $c+1$ entry.

Informally, the non-robust structural dichotomy from [7] asserts that any f that is ε-far from $(12\dots k)$-free either satisfies the growing suffixes condition, or the non-robust splittable intervals condition (or both). These two notions are formally defined next; the precise definition for growing suffixes is slightly more complicated than described above (but understanding it is not essential for this work, as the growing suffixes procedure from [7] will eventually only be used as a black box). For what follows, for an index $\ell \in [n]$ define $\eta_\ell = \lceil \log_2(n-\ell) \rceil$, and for any $t \in [\eta_\ell]$ set $S_t(\ell) = [a + 2^{t-1}, a + 2^t) \cap [n]$. Note that the intervals $S_1, \dots, S_{\eta_\ell}$ are a partition of $(\ell, n]$ into intervals of geometrically increasing length (except for maybe the last one). Finally, the tuple $S(\ell) = (S_t(\ell))_{t \in [\eta_\ell]}$ is called the *growing suffix* starting at ℓ.

▶ **Definition 5** (Growing suffixes (see [7], Definition 2.4)). *Let $\alpha, \beta \in [0,1]$. We say that an index $\ell \in [n]$ starts an (α,β)-*growing suffix *if, when considering the collection of intervals $S(\ell) = \{S_t(\ell) : t \in [\eta_\ell]\}$, for each $t \in [\eta_\ell]$ there is a subset $D_t(\ell) \subseteq S_t(\ell)$ of indices such that the following properties hold.*

1. *We have $|D_t(\ell)|/|S_t(\ell)| \leq \alpha$ for all $t \in [\eta_\ell]$, and $\sum_{t=1}^{\eta_\ell} |D_t(\ell)|/|S_t(\ell)| \geq \beta$.*
2. *For every $t, t' \in [\eta_a]$ where $t < t'$, if $a \in D_t(\ell)$ and $a' \in D_{t'}(\ell)$, then $f(a) < f(a')$.*

The second definition, also from [7], describes the (non-robust) splittable intervals setting.

▶ **Definition 6** (Splittable intervals (see [7], Definition 2.5)). *Let $\alpha, \beta \in (0,1]$ and $c \in [k-1]$. Let $I \subseteq [n]$ be an interval, let $T \subseteq I^k$ be a set of disjoint, length-k monotone subsequences of f lying in I, and define*

$$T^{(L)} = \{(i_1, \ldots, i_c) \in I^c : (i_1, \ldots, i_c) \text{ is a prefix of a } k\text{-tuple in } T\}, \text{ and}$$
$$T^{(R)} = \{(j_1, \ldots, j_{k-c}) \in I^{k-c} : (j_1, \ldots, j_{k-c}) \text{ is a suffix of a } k\text{-tuple in } T\}.$$

*We say that the pair (I,T) is (c,α,β)-*splittable *if $|T|/|I| \geq \beta$; $f(i_c) < f(j_1)$ for every $(i_1, \ldots, i_c) \in T^{(L)}$ and $(j_1, \ldots, j_{k-c}) \in T^{(R)}$; and there is a partition of I into three consecutive intervals $L, M, R \subseteq I$ (that appear in this order, from left to right) of size at least $\alpha|I|$, satisfying $T^{(L)} \subseteq L^c$ and $T^{(R)} \subseteq R^{k-c}$.*

A collection of disjoint interval-tuple pairs $(I_1,T_1), \ldots, (I_s,T_s)$ is called a (c,α,β)-splittable collection of T *if each (I_j,T_j) is (c,α,β)-splittable and the sets $(T_j : j \in [s])$ partition T.*

The following theorem presents the growing suffixes versus (non-robust) splittable intervals dichotomy, which is among the main structural results of [7]. We remark that in their paper, the theorem is stated with respect to two parameters, k, k_0; for our purpose it suffices to set $k_0 = k$. Also, here we allow f to take the value $*$, which is not the case in [7]. Nevertheless, as their proof takes into account only the elements of a given family T^0 of disjoint length-k increasing subsequences, which in particular are non-$*$ elements, the same proof works here.

▶ **Theorem 7** ([7], Theorem 2.2). *Let $k, n \in \mathbb{N}$, $\varepsilon \in (0,1)$, and $C > 0$, and let $I \subseteq [n]$ be an interval. Let $f\colon I \to \mathbb{R} \cup \{*\}$ be a function and let $T^0 \subseteq I^k$ be a set of at least $\varepsilon|I|$ disjoint monotone subsequences of f of length k. Then there exist $\alpha \in (0,1)$ and $p > 0$ satisfying $\alpha \geq \Omega(\varepsilon/k^5)$ and $p \leq \mathrm{poly}(k \log(1/\varepsilon))$ such that at least one of the following conditions holds.*

1. ***Growing suffixes:*** *There exists a set $H \subseteq [n]$, of indices that start an $(\alpha, Ck\alpha)$-growing suffix, satisfying $\alpha|H| \geq (\varepsilon/p)n$.*
2. ***Splittable intervals (non-robust):*** *There exist a positive integer $c < k$, a set T of disjoint length-k monotone subsequences satisfying $E(T) \subseteq E(T^0)$, and a $(c, 1/(6k), \alpha)$-splittable collection of T consisting of disjoint interval-tuple pairs $(I_1,T_1), \ldots, (I_s,T_s)$, such that $\alpha \sum_{h=1}^{s} |I_h| \geq |T^0|/p$.*

2.2 Robustifying the Structural Result

We are now ready to establish the robust structural foundations – specifically, a *growing suffixes* versus *robust splittable intervals* dichotomy – lying at the heart of our adaptive algorithm. The next lemma will eventually imply that the splittable intervals condition can be robustified by merely throwing away a subset of "bad" splittable intervals.

▶ **Lemma 8.** *Let $\alpha \in (0,1)$ and let $I \subset \mathbb{N}$ be an interval. Suppose that $I_1, \ldots, I_s \subset I$ are disjoint intervals such that $\sum_{h=1}^{s} |I_h| \geq \alpha|I|$. Then there exists a set $G \subset [s]$ such that $\sum_{h \in G} |I_h| \geq (\alpha/4)|I|$, and for every interval $J \subset I$ that contains an interval I_h with $h \in G$, $\sum_{h \in [s]\colon I_h \subset J} |I_h| \geq (\alpha/4)|J|$.*

The full proof appears in the Appendix of the full verion. The idea is to consider a minimal subset $\mathcal{J}$ of the collection of all "problematic" intervals J which *do not satisfy* the conditions of the lemma. For each $J \in \mathcal{J}$, less than an $\alpha/4$-fraction of J is covered by intervals from $\mathcal{I} = \{I_1, \ldots, I_s\}$. Conversely, as we show, the minimality of $\mathcal{J}$ entails that any element in I is covered by at most three intervals from $\mathcal{J}$. The combination of

these conditions implies that, if we remove from $\mathcal{I}$ all intervals I_j contained in some interval $J \in \mathcal{J}$, then at the end of the process $\sum_{I_j \in \mathcal{I}} |I_j| = \Omega(\alpha|I|)$, and no "problematic" choices of J survive. Thus, the set of surviving intervals from $\mathcal{I}$ satisfy the conditions of the lemma.

The robust version of the structural dichotomy is stated below; for the proof, combining the basic structural dichotomy with the last lemma, see the appendices of the full-version.

▶ **Theorem 9** (Robust structural theorem). *Let $k, n \in \mathbb{N}$, $\varepsilon \in (0,1)$, and $C > 0$, and let $I \subseteq [n]$ be an interval. Let $f : I \to \mathbb{R} \cup \{*\}$ be an array and let $T^0 \subseteq I^k$ be a set of at least $\varepsilon|I|$ disjoint length-k monotone subsequences of f. Then there exist $\alpha \in (0,1)$ and $p > 0$ with $\alpha \geq \Omega(\varepsilon/k^5)$ and $p \leq \mathrm{poly}(k \log(1/\varepsilon))$ such that at least one of the following holds.*

1. ***Growing suffixes:*** *There exists a set $H \subseteq [n]$, of indices that start an $(\alpha, Ck\alpha)$-growing suffix, satisfying $\alpha|H| \geq (\varepsilon/p)n$.*
2. ***Robust splittable intervals:*** *There exist an integer c with $1 \leq c < k$, a set T, with $E(T) \subseteq E(T^0)$, of disjoint length-k monotone subsequences, and a $(c, 1/(6k), \alpha)$-splittable collection of T, consisting of disjoint interval-tuple pairs $(I_1, T_1), \ldots, (I_s, T_s)$, such that*

$$\alpha \sum_{h=1}^{s} |I_h| \geq \frac{\varepsilon}{p} \cdot |I|.$$

Moreover, if $J \subset I$ is an interval where $J \supset I_h$ for some $h \in [s]$, then J contains at least $(\varepsilon/p)|J|$ disjoint $(12\ldots k)$-patterns from T^0.

3 The Algorithm

In this section we prove the existence of a randomized algorithm, $\texttt{Find-Monotone}_k(f, \varepsilon, \delta)$, that receives as input a function $f : I \to \mathbb{R} \cup \{*\}$ (where $I \subset \mathbb{N}$ is an interval), and parameters $\varepsilon, \delta \in (0,1)$, and satisfies the following: if f contains $\varepsilon|I|$ disjoint $(12\ldots k)$-patterns, then the algorithm outputs such a pattern with probability at least $1 - \delta$. The running time is $O_{k,\varepsilon}(\log n)$. The algorithm is described in Figure 5 below. It uses three subroutines: `Sample-Suffix`, `Find-Within-Interval`, and `Find-Good-Split`, the first of which is given in [7], and the latter two are described below, in Figures 3 and 4. The majority of the section is devoted to the proof that `Find-Monotone` indeed outputs a $(12\ldots k)$-pattern with high probability as claimed. Specifically, we shall prove the following theorem.

▶ **Theorem 10.** *Let $k \in \mathbb{N}$. The randomized algorithm $\texttt{Find-Monotone}_k(f, \varepsilon, \delta)$, described in Figure 5, satisfies the following. Given a function $f : I \to \mathbb{R} \cup \{*\}$ and parameters $\varepsilon, \delta \in (0,1)$, if f contains at least $\varepsilon|I|$ disjoint $(12\ldots k)$-patterns, then $\texttt{Find-Monotone}_k(f, \varepsilon, \delta)$ outputs a $(12\ldots k)$-pattern of f with probability at least $1 - \delta$.*

Our proof proceeds by induction on k. It relies on Lemmas 12, 13, 14, the former is taken from [7] whereas the proofs of the latter two assume that Theorem 10 holds for smaller k. We first state and prove these lemmas, and then we prove Theorem 10.

To complete the picture, in the following lemma we provide an upper bound on the query complexity and running time of `Find-Monotone`. For the proof, see the appendices of the full version.

▶ **Lemma 11.** *Let $f : I \to \mathbb{R} \cup \{*\}$, where I is an interval of length at most n. The query complexity and running time of $\texttt{Find-Monotone}_k(f, \varepsilon, \delta)$ are at most*

$$\left(k^k \cdot (\log(1/\varepsilon))^k \cdot \frac{1}{\varepsilon} \cdot \log(1/\delta)\right)^{O(k)} \cdot \log n.$$

3.1 The `Sample-Suffix` Sub-Routine

We restate Lemma 3.1 from [7] which gives the $\texttt{Sample-Suffix}_k$ subroutine, with a few adaptations to fit our needs.

▶ **Lemma 12** ([7]). *Fix $k \in \mathbb{N}$ and let $C > 0$ be a large enough constant. There exists a non-adaptive and randomized algorithm, $\texttt{Sample-Suffix}_k(f, \varepsilon, \delta)$ which takes three inputs: query access to a function $f\colon I \to \mathbb{R} \cup \{*\}$, where $I \subset \mathbb{N}$ is an interval, a parameter $\varepsilon \in (0,1)$, and an error probability bound $\delta \in (0,1)$. Suppose there exists $\alpha \in (0,1)$, and a set $H \subseteq I$ of $(\alpha, Ck\alpha)$-growing suffixes of f satisfying $\alpha|H| \geq \varepsilon|I|$. Then, $\texttt{Sample-Suffix}_k(f, \varepsilon, \delta)$ finds a length-k monotone subsequence of f with probability at least $1 - \delta$. The query complexity of $\texttt{Sample-Suffix}_k(f, \varepsilon, \delta)$ is at most $\log(1/\delta) \cdot \mathrm{polylog}(1/\varepsilon) \cdot \frac{1}{\varepsilon} \cdot \log n$.*

For additional technical remarks about Lemma 12 and `Sample-Suffix`, see the appendices of the full versions.

3.2 Handling Overshooting: The `Find-Within-Interval` Sub-Routine

In this section, we describe the `Find-Within-Interval` subroutine, addressing the overshooting case as explained in Section 1.2. As the algorithm may appear unintuitive, let us

Subroutine $\texttt{Find-Within-Interval}_k(f, \varepsilon, \delta, x, y, \mathcal{J})$.

Input: Query access to a function $f\colon I \to \mathbb{R} \cup \{*\}$, parameters $\varepsilon, \delta \in (0,1)$, two inputs $x, y \in I$ where $x < y$ and $f(x) < f(y)$, and $\mathcal{J} = (J_1, \ldots, J_{k-2})$ which is a collection of disjoint intervals appearing in order inside $[x, y]$.

Output: a sequence $i_1 < \ldots < i_k$ with $f(i_1) < \ldots < f(i_k)$, or fail.

1. For every $\kappa \in [k-2]$, let $f_\kappa, f'_\kappa\colon J_\kappa \to \mathbb{R} \cup \{*\}$ be given by:

$$f_\kappa(i) = \begin{cases} f(i) & f(i) < f(y) \\ * & \text{o.w.} \end{cases} \qquad \text{and} \qquad f'_\kappa(i) = \begin{cases} f(i) & f(i) \geq f(y) \\ * & \text{o.w.} \end{cases} \tag{1}$$

2. Call $\texttt{Find-Monotone}_{\kappa+1}(f_\kappa, \varepsilon/2, \delta/(2k))$ for every $\kappa \in [k-2]$.
3. Call $\texttt{Find-Monotone}_{k-\kappa}(f'_\kappa, \varepsilon/2, \delta/(2k))$ for every $\kappa \in [k-2]$.
4. Consider the set of all indices that are output in Lines 2 and 3, together with x and y. If $\mathcal{S}$ contains a length-k increasing subsequence among these indices, output it. Otherwise, output fail.

Figure 3 Description of the `Find-Within-Interval` subroutine.

remind the reader of the setup in which this subroutine is relevant (see also Section 1.2). By Theorem 9, either the growing suffixes condition or the splittable intervals condition hold. The former case is handled by Lemma 12, so we assume that the latter holds. Now assume that we sampled an element $\boldsymbol{x}$ which is the first element of a length-c increasing subsequence from a set L_i as described in Definition 6. We then sample, uniformly at random, elements $\boldsymbol{y}$ from $[\boldsymbol{x}, \boldsymbol{x} + 2^t]$. The splittable intervals condition implies that we will find, with high probability, an element $\boldsymbol{y}$ which is the last element of a length-$(k-c)$ increasing subsequence from R_i. In particular, $f(\boldsymbol{y}) > f(\boldsymbol{x})$. However, even if we did indeed sample such $\boldsymbol{y}$, we may have sampled many other values of $\boldsymbol{y}'$ with $f(\boldsymbol{y}') > f(\boldsymbol{x})$, and we do not know of a way of determining which of these values is the "correct" one. Instead, we take $\boldsymbol{y}_0$ to be the largest sampled $\boldsymbol{y}'$ such that $f(\boldsymbol{y}') > f(\boldsymbol{x})$. The case where $\boldsymbol{y}_0$ is close to $\boldsymbol{y}$ is taken care of by Lemma 13, so we assume that $\boldsymbol{y}_0$ is much larger than $\boldsymbol{y}$.

We now have elements $\boldsymbol{x}$ and $\boldsymbol{y}_0$, and all that we know is that they contain a large portion of an interval I_i from the splittable intervals condition. It is not hard to see (this is shown in the proof of Theorem 10) that $[\boldsymbol{x}, \boldsymbol{y}_0]$ can be partitioned into $k-2$ intervals $J_1, \ldots, J_{k-2}$, each of which contains many disjoint length-k increasing subsequences. To continue, out only hope is use the induction hypothesis to find shorter increasing subsequences in the intervals. For example, if there are many disjoint length-$(k-1)$ increasing subsequences in J_1 that lie above $\boldsymbol{x}$, then one such subsequence is likely to be detected by a recursive call to the main algorithm, and together with $\boldsymbol{x}$ it will form a length-k increasing subsequence. If there are few such length-$(k-1)$ subsequences, this means that there are many disjoint length-2 increasing subsequences in J_1 that lie below $\boldsymbol{x}$ (because for every length-k increasing subsequence, either its $(k-1)$-suffix lies above $\boldsymbol{x}$, or its 2-prefix lies above $\boldsymbol{x}$). We can then use a recursive call to detect such a sequence, and hope to complete it to a length-k subsequence using a length-$(k-2)$ subsequnece from J_2 that lies above $\boldsymbol{x}$. Continuing with this logic, it follows that with high probability we can find an increasing subsequence of length k using $\boldsymbol{x}$ and J_1, J_i and J_{i+1} for some i, or J_{k-2} and $\boldsymbol{y}_0$.

▶ **Lemma 13.** *Consider the randomized algorithm,* $\texttt{Find-Within-Interval}_k(f, \varepsilon, \delta, x, y, \mathcal{J})$, *described in Figure 3, which takes six inputs:*

- *Query access to a function* $f \colon I \to \mathbb{R} \cup \{*\}$,
- *Two parameters* $\varepsilon, \delta \in (0,1)$,
- *Two points* $x, y \in I$ *where* $x < y$ *and* $f(x) < f(y)$, *and*
- *A collection* $\mathcal{J} = (J_1, \ldots, J_{k-2})$ *of* $k-2$ *disjoint intervals that appear in order (i.e.,* J_κ *comes before* $J_{\kappa+1}$*) within the interval* $[x, y]$,

and outputs either a length-k increasing subsequence of f, *or* fail.

Suppose that for every $\kappa \in [k-2]$, *the function* $f|_{J_\kappa} \colon J_\kappa \to \mathbb{R} \cup \{*\}$, *contains* $\varepsilon |J_\kappa|$ *disjoint* $(12\ldots k)$*-patterns. Then, assuming that Theorem 10 holds for every* k' *with* $1 \le k' < k$, *the procedure* $\texttt{Find-Within-Interval}_k(f, \varepsilon, \delta, x, y, \mathcal{J})$ *outputs a length-k monotone subsequence of* f *with probability at least* $1 - \delta$.

The full proof appears in the appendices of the full version.

3.3 Handling the Fitting Case: The `Find-Good-Split` Sub-Routine

In this section, we describe the `Find-Good-Split` subroutine, which corresponds to the fitting case from Section 1.2. The proof of the lemma below appears in the appendices of the full version.

▶ **Lemma 14.** *Consider the randomized algorithm* $\texttt{Find-Good-Split}_k(f, \varepsilon, \delta, c, \xi)$, *described in Figure 4, which takes as input five parameters: (i) query access to a function* $f \colon I \to \mathbb{R} \cup \{*\}$; *(ii) two parameters* $\varepsilon, \delta \in (0,1)$; *(iii) an integer* $c \in [k-1]$; *and (iv) a parameter* $\xi \in (0,1]$; *and outputs either a length-k increasing subsequence or* fail.

Suppose that there exists an interval-tuple pair (I', T) *which is* $(c, 1/(6k), \varepsilon)$*-splittable and* $|I'|/|I| \ge \xi$. *Then, the algorithms* $\texttt{Find-Good-Split}_k(f, \varepsilon, \delta, c, \xi)$ *finds a* $(12\ldots k)$*-pattern of* f *with probability* $1 - \delta$.

3.4 The Main Algorithm

Consider the description of the main algorithm in Figure 5. The proof uses Lemma 12, Lemma 13, and Lemma 14.

Subroutine $\texttt{Find-Good-Split}_k(f, \varepsilon, \delta, c, \xi)$.

Input: Query access to a function $f\colon I \to \mathbb{R} \cup \{*\}$, parameters $\varepsilon, \delta \in (0,1)$, and $c \in [k-1]$. We let $c_1 > 1$ be a large enough (absolute) constant.

Output: a sequence $i_1 < \ldots < i_k$ with $f(i_1) < \ldots < f(i_k)$, or fail.

1. Repeat the following procedure $t = c_1 k/(\varepsilon\xi^2) \cdot \log(1/\delta)$ times:
   a. Sample $\boldsymbol{w}, \boldsymbol{z} \sim I$, and consider the functions $f_{\boldsymbol{z},\boldsymbol{w}}\colon I \cap (-\infty, \boldsymbol{z}) \to \mathbb{R} \cup \{*\}$ and $f'_{\boldsymbol{z},\boldsymbol{w}}\colon I \cap [\boldsymbol{z}, \infty) \to \mathbb{R} \cup \{*\}$ given by

$$f_{\boldsymbol{z},\boldsymbol{w}}(i) = \begin{cases} f(i) & f(i) < f(\boldsymbol{w}) \\ * & \text{o.w.} \end{cases} \quad \text{and} \quad f'_{\boldsymbol{z},\boldsymbol{w}}(i) = \begin{cases} f(i) & f(i) \geq f(\boldsymbol{w}) \\ * & \text{o.w.} \end{cases} . \quad (2)$$

   b. Run $\texttt{Find-Monotone}_c(f_{\boldsymbol{z},\boldsymbol{w}}, \varepsilon\xi/3, \delta/3)$ and $\texttt{Find-Monotone}_{k-c}(f'_{\boldsymbol{z},\boldsymbol{w}}, \varepsilon\xi/3, \delta/3)$.
2. If both runs of Line 1b are successful for some iteration and some $\boldsymbol{w}$, $\boldsymbol{z}$ and c, then we output the combination of their outputs which forms a length-k increasing subsequence of f; otherwise, output fail.

Figure 4 Description of the `Find-Good-Split` subroutine.

Proof of Theorem 10. The proof is by induction on k. For the base case of $k = 1$, recall that f has at least $\varepsilon|I|$ non-$*$ values. Thus, with probability at least $1 - \delta$, a non-$*$ value is observed after sampling $\boldsymbol{x} \sim I$ at least $(1/\varepsilon) \cdot \log(1/\delta)$ times. It follows that with probability at least $1 - \delta$, Line 2a of our main algorithm, given in Figure 5, samples $\boldsymbol{x} \neq *$ in one of its iterations. We next proceed to the inductive Step: namely, we prove Theorem 10 for $k \geq 2$, under the assumption that it holds for every k' with $1 \leq k' < k$.

Let $p = P(k \log(1/\varepsilon))$ (recall that $P(\cdot)$ is a polynomial of sufficiently large (constant) degree). Apply Theorem 9 to f.

Suppose, first, that (1) of Theorem 9 holds. So, there exists a set $H \subset [n]$ of indices that start an $(\alpha, Ck\alpha)$-growing suffix, with $\alpha|H| \geq (\varepsilon/p)n$, for some $\alpha \in (0,1)$. By Lemma 12, the call for $\texttt{Sample-Suffix}_k(f, \varepsilon/p, \delta)$ in Line 1 outputs a length-k monotone subsequence of f with probability at least $1 - \delta$.

Now suppose that (2) of Theorem 9 holds, and let $(I_1, T_1), \ldots, (I_s, T_s)$ be a $(c, 1/(6k), \alpha)$-splittable collection for some $\alpha \geq \Omega(\varepsilon/k^5)$ and $c \in [k-1]$, satisfying the robust splittable intervals condition and, moreover, that any $J \subset I$ with $J \supset I_h$ for some $h \in [s]$ contains $(\varepsilon/p)|J|$ disjoint $(12\ldots k)$-patterns. Let `Event` be the event that, for a particular iteration of Lines 2a and 2b, $\boldsymbol{x}$ is the 1-entry of some k-tuple from T_h, for some $h \in [s]$, and $\boldsymbol{y}_t$ is the $(c+1)$-entry of some (possibly other) k-tuple in T_h, where t is such that $|I_h| \leq 2^t < 2|I_h|$.

▷ Claim 15. $\mathbf{Pr}[\texttt{Event}] \geq \varepsilon\alpha/(2p)$.

Proof. For each $h \in [s]$, let A_h and B_h be the collections of 1- and $(c+1)$-entries of patterns in T_h. Then

$$\sum_{h=1}^{s} |A_h| = \sum_{h=1}^{s} |T_h| \geq \alpha \sum_{h=1}^{s} |I_h| \geq \frac{\varepsilon}{p} \cdot |I|.$$

The first inequality follows from the assumption that (I_h, T_h) is $(c, 1/(6k), \alpha)$-splittable, and the second inequality follows from the assumption that the robust splittable condition of Theorem 9 holds.

Subroutine $\texttt{Find-Monotone}_k(f, \varepsilon, \delta)$.

Input: Query access to a function $f\colon I \to \mathbb{R} \cup \{*\}$, parameters $\varepsilon, \delta \in (0,1)$. We let $c_1, c_2, c_3 > 0$ be large enough constants, and let $p = P(k \log(1/\varepsilon))$, where $P\colon \mathbb{R} \to \mathbb{R}$ is a polynomial of large enough (constant) degree.

Output: a sequence $i_1 < \ldots < i_k$ with $f(i_1) < \ldots < f(i_k)$, or fail.

1. Run $\texttt{Sample-Suffix}_k(f, \varepsilon/p, \delta)$.
2. Repeat the following for $c_1 \log(1/\delta) \cdot p \cdot k^5/\varepsilon^2$ many iterations:

   a. Sample $\boldsymbol{x} \sim I$ uniformly at random. If $f(\boldsymbol{x}) = *$, proceed to the next iteration. Otherwise, if $k = 1$ output $\boldsymbol{x}$ and proceed to Step 3, and if $k \geq 2$ proceed to the next step.

   b. For each $t \in [\log n]$, sample $\boldsymbol{y}_t \sim [\boldsymbol{x} + 2^t/(12k), \boldsymbol{x} + 2^t]$ uniformly at random. If there exists at least one t where $f(\boldsymbol{y}_t) > f(\boldsymbol{x})$, set

   $$\boldsymbol{y} = \max\left\{\boldsymbol{y}_t : t \in [\log n] \text{ and } f(\boldsymbol{y}_t) > f(\boldsymbol{x})\right\}, \tag{3}$$

   let $t^* \in [\log n]$ be the index for which $\boldsymbol{y}_{t^*} = \boldsymbol{y}$, and continue to the next line. Otherwise, i.e. if $f(\boldsymbol{y}_t) \not> f(\boldsymbol{x})$ for every t, continue to the next iteration.

   c. If $k = 2$, output $(\boldsymbol{x}, \boldsymbol{y})$ and proceed to Step 3. If $k > 2$, continue to the next line.

   d. Here $k \geq 3$. Set $\ell = 4p/\varepsilon$ and perform the following.

      i. Consider the collection $\mathcal{J}$ of $k-2$ intervals $J_1, \ldots, J_{k-2}$ appearing in order within $[\boldsymbol{x}, \boldsymbol{y}]$, given by setting, for every $i \in [k-2]$,

      $$J_i = \left[\boldsymbol{x} + \frac{2^{t^*}}{12k} \cdot \ell^{-(k-1-i)}, \boldsymbol{x} + \frac{2^{t^*}}{12k} \cdot \ell^{-(k-2-i)}\right), \tag{4}$$

      and run $\texttt{Find-Within-Interval}_k(f, \varepsilon/2p, \delta/2, \boldsymbol{x}, \boldsymbol{y}, \mathcal{J})$.

      ii. For each $t' \in [t^* - 3k \log \ell, t^*]$ do the following.

      Consider the interval $J_{t'} = [\boldsymbol{x} - 2^{t'}, \boldsymbol{x} + 2^{t'}]$, and the restricted function $g_{t'}\colon J_{t'} \to \mathbb{R} \cup \{*\}$ given by $g_{t'} = f|_{J_{t'}}$. For every $c_0 \in [k-1]$, run $\texttt{Find-Good-Split}_k(g_{t'}, \varepsilon/(c_2 k^5), \delta/2, c_0, 1/4)$.

3. If a length-k monotone subsequence of f is found, output it. Otherwise, output fail.

Figure 5 Description of the Find-Monotone subroutine.

As a result, the probability over the draw of $\boldsymbol{x} \sim I$ in Line 2a that $\boldsymbol{x} \in A_h$ is at least ε/p. Fix such an $\boldsymbol{x}$, and consider $t \in [\log n]$ for which $|I_h| \leq 2^t < 2|I_h|$. Notice that $B_h \subset [\boldsymbol{x} + 2^t/(12k), \boldsymbol{x} + 2^t]$ since $2^{t-1} \leq |I_h| < 2^t$, and that the distance between any index of A_h and B_h is at least $|I_h|/(6k) \geq 2^t/(12k)$ since (I_h, T_h) is $(c, 1/(6k), \alpha)$-splittable. Therefore, the probability over the draw of $\boldsymbol{y}_t \sim [\boldsymbol{x} + 2^t/(12k), \boldsymbol{x} + 2^t]$ that $\boldsymbol{y}_t \in B_h$ is at least $|B_h|/2^t \geq |T_h|/(2|I_h|) \geq \alpha/2$. ◁

By the previous claim, since we have $c_1 \cdot \log(1/\delta) \cdot p \cdot k^5/\varepsilon^2$ iterations of Lines 2a and 2b, with probability at least $1 - \delta/2$, Event holds in some iteration (using the lower bound $\alpha \geq \Omega(\varepsilon/k^5)$ and the choice of c_1 as a large constant).

Consider the first execution of Line 2a and Line 2b where `Event` holds (assuming such an execution exists). Let $h \in [s]$ and $t \in [\log n]$ be the corresponding parameters, i.e., h and t are set so $\boldsymbol{x}$ is the first index of a k-tuple in T_h, $\boldsymbol{y}_t$ is the $(c+1)$-th index in another k-tuple in T_h, and $|I_h| \leq 2^t < 2|I_h|$. We consider this iteration of Line 2, and assume that `Event` holds with these parameters for the rest of the proof. Notice that $\boldsymbol{y}$, as defined in (3), satisfies $\boldsymbol{y} \geq \boldsymbol{y}_t$ (as $f(\boldsymbol{y}) > f(\boldsymbol{x})$) and hence $t^* \geq t$.

Note that if $k = 2$, the pair $(\boldsymbol{x}, \boldsymbol{y})$, which is a (12)-pattern in f, is output in Line 2c, so the proof is complete in this case. From now on, we assume that $k \geq 3$. We break up the analysis into two cases: $t^* \geq t + 3k \log \ell$ and $t^* < t + 3k \log \ell$.

Suppose $t^* \geq t + 3k \log \ell$. We now observe a few facts about the collection $\mathcal{J}$ specified in (4). First, notice that $J_1, \ldots, J_{k-2}$ appear in order from left-to-right, and they lie in $[\boldsymbol{x}, \boldsymbol{y}]$ (as $\boldsymbol{y} = \boldsymbol{y}_{t^*} \in [\boldsymbol{x} + 2^{t^*}/(12k), 2^{t^*}]$). Second, in the next claim we show that for every $i \in [k-2]$, the interval J_i contains $(\varepsilon/2p)|J_i|$ disjoint $(12\ldots k)$-patterns.

▷ Claim 16. J_i contains $(\varepsilon/2p)|J_i|$ disjoint $(12\ldots k)$-patterns.

Proof. Let J_i' be the interval given by $J_i' = I_h \cup \left[\boldsymbol{x}, \boldsymbol{x} + \frac{2^{t^*}}{12k} \cdot \ell^{-(k-2-i)}\right]$. Observe that

$$|J_i' \setminus J_i| \leq 2^t + \frac{2^{t^*}}{12k} \cdot \ell^{-(k-1-i)} \leq \frac{2^{t^*}}{6k} \cdot \ell^{-(k-1-i)} = \frac{2}{\ell} \cdot \frac{2^{t^*}}{12k} \cdot \ell^{-(k-2-i)} \geq \frac{2}{\ell} \cdot |J_i'| = \frac{\varepsilon}{2p} \cdot |J_i'|,$$

where for the second inequality we used the bound $t^* - t \geq 3k \log \ell \geq \log(12) + \log k + (k-2)\log \ell$, and that $\ell = 4p/\varepsilon$. By Theorem 9, J_i' contains at least $(\varepsilon/p)|J_i'|$ disjoint $(12\ldots k)$-patterns in f. Hence, the number of disjoint $(12\ldots k)$-patterns in J_i is at least:

$$\frac{\varepsilon}{p} \cdot |J_i'| - |J_i' \setminus J_i| \geq \frac{\varepsilon}{2p} \cdot |J_i'| \geq \frac{\varepsilon}{2p} \cdot |J_i|,$$

as required. ◁

By Lemma 13, Line 2(d)i outputs a $(12\ldots k)$-pattern in f with probability at least $1 - \delta/2$. By a union bound, we obtain the desired result.

Suppose, on the other hand, that $t^* \leq t + 3k \log \ell$. In this case, as $2^{t-1} \leq |I_h| \leq 2^{t^*}$ (by choice of t), for one of the values of t' considered in Line 2(d)ii we have $2^{t'-1} \leq |I_h| < 2^{t'}$; fix this t'. The interval $J_{t'}$, defined in Line 2(d)ii, hence satisfies $|I_h|/|J_{t'}| \geq 1/4$. As a result, and since $I_h \subset J_{t'}$ (because $t \leq t^*$), the function $g\colon J \to \mathbb{R} \cup \{*\}$ contains an interval-tuple pair (I_h, T_h) which is $(c, 1/(6k), \alpha)$-splittable. By Lemma 14, once Line 2(d)ii considers $c_0 = c$, the sub-routine $\texttt{Find-Good-Split}_k(g, \varepsilon/(c_2 k^5), \delta/2, c, 1/4)$ will output a $(12\ldots k)$-pattern of $g_{t'}$ (which is also a $(12\ldots k)$-pattern of f) with probability at least $1 - \delta/2$. Hence, we obtain the result by a union bound. ◀

Abstract

We show that determining if an n-vertex graph has twin-width at most 4 is NP-complete, and requires time $2^{\Omega(n/\log n)}$ unless the Exponential-Time Hypothesis fails. Along the way, we give an elementary proof that n-vertex graphs subdivided at least $2\log n$ times have twin-width at most 4. We also show how to encode trigraphs H (2-edge colored graphs involved in the definition of twin-width) into graphs G, in the sense that every d-sequence (sequence of vertex contractions witnessing that the twin-width is at most d) of G inevitably creates H as an induced subtrigraph, whereas there exists a partial d-sequence that actually goes from G to H. We believe that these facts and their proofs can be of independent interest.

1 Introduction

A *trigraph* is a graph with some edges colored black, and some colored red. A (vertex) *contraction* consists of merging two (non-necessarily adjacent) vertices, say, u, v into a vertex w, and keeping every edge wz black if and only if uz and vz were previously black edges. The other edges incident to w become red (if not already), and the rest of the trigraph stays the same. A *contraction sequence* of an n-vertex graph G is a sequence of trigraphs $G = G_n, \ldots, G_1 = K_1$ such that G_i is obtained from G_{i+1} by performing one contraction. A *d-sequence* is a contraction sequence where all the trigraphs have red degree at most d. The *twin-width* of G, denoted by $tww(G)$, is then the minimum integer d such that G admits a d-sequence. See Figure 1 for an example of a graph admitting a 2-sequence. The *red graph* of a trigraph is obtained by simply deleting its black edges. A *partial d-sequence* is similar to a d-sequence but ends on any trigraph G_i, instead of on the 1-vertex (tri)graph G_1. Twin-width can be naturally extended to matrices over a finite alphabet (in an unordered [6], or an ordered setting [4]), and hence to any binary structure.

Surprisingly many classes turn out to be of bounded twin-width. Such is the case of graphs with bounded clique-width, H-minor free graphs for any fixed H, posets with antichains of bounded size, strict subclasses of permutation graphs, map graphs, bounded-degree string

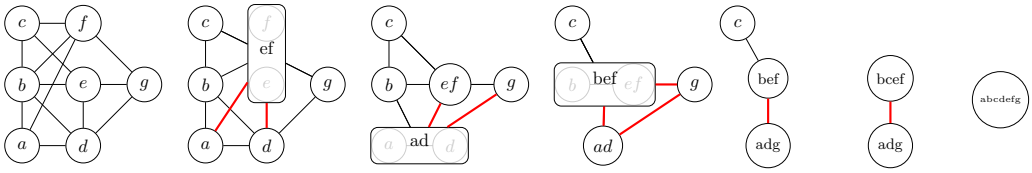

Figure 1 A 2-sequence witnessing that the initial graph has twin-width at most 2.

graphs [6], as well as $\Omega(\log n)$-subdivisions of n-vertex graphs, and some classes of cubic expanders [3]. One of the main algorithmic interests with twin-width is that first-order (FO) model checking, that is, deciding if a first-order sentence φ holds in a graph G, can be decided in fixed-parameter time (FPT) $f(|\varphi|, d) \cdot |V(G)|$ for some computable function f, when given a d-sequence of G [6]. As for most classes known to have bounded twin-width, one can compute $O(1)$-sequences in polynomial time for members of the class, the latter result unifies and extends several known results [14, 17, 18, 16, 21] for hereditary (but not necessarily monotone) classes.

For monotone (i.e., subgraph-closed) classes, the FPT algorithm of Grohe, Kreutzer, and Siebertz [20] for FO model checking on nowhere dense classes, is complemented by W[1]-hardness on classes that are somewhere dense (i.e., *not* nowhere dense) [11], and even AW[$*$]-hardness on classes that are *effectively* somewhere dense [9]. The latter results mean that, for monotone classes, FO model checking is unlikely to be FPT beyond nowhere dense classes.

The missing piece for an FO model-checking algorithm in FPT time on any class of bounded twin-width is a polynomial-time algorithm and a computable function f, that given a constant integer bound c and a graph G, either finds an $f(c)$-sequence for G, or correctly reports that the twin-width of G is greater than c. The running time of the algorithm could be $n^{g(c)}$, for some function g. However to get an FPT algorithm in the combined parameter *size of the sentence + bound on the twin-width*, one would further require that the approximation algorithm takes FPT time in c (now seen as a parameter), i.e., $g(c)n^{O(1)}$. We know such an algorithm for instance on ordered graphs (more generally, ordered binary structures) [4], graphs of bounded clique-width, proper minor-closed classes [6], but not in general graphs.

On the other hand, prior to this paper, no algorithmic lower bound was known for computing the twin-width. Our main result rules out an (exact) XP algorithm to decide $tww(G) \leqslant k$, that is, an algorithm running in time $n^{f(k)}$ for some computable function f. Indeed we show that deciding if the twin-width of a graph is at most 4 is intractable. We refer the reader to Section 2 for some context on the Exponential-Time Hypothesis (ETH), which implies that n-variable 3-SAT cannot be solved in time $2^{o(n)}$.

▶ **Theorem 1.** *Deciding if a graph has twin-width at most 4 is NP-complete. Furthermore, no algorithm running in time $2^{o(n/\log n)}$ can decide if an n-vertex graph has twin-width at most 4, unless the ETH fails.*

As far as approximation algorithms are concerned, our result only rules out a ratio better than 5/4 for determining the twin-width. This still leaves plenty of room for an $f(\mathrm{OPT})$-approximation, which would be good enough for most of the (theoretical) algorithmic applications. Note that such algorithms exist for treewidth in polytime [12] and FPT time [27], for pathwidth [12], and for clique-width via rank-width [30].

Is Theorem 1 surprising? On the one hand, it had to be expected that deciding, given a graph G and an integer k, whether $tww(G) \leqslant k$ would be NP-complete. This is the case for example of treewidth [1], pathwidth [29, 26, 28], clique-width [13], rank-width [23],

mim-width [32], and bandwidth [19]. On the other hand, the parameterized complexity of these width parameters is more diverse and harder to predict. Famously, Bodlaender's algorithm is a linear FPT algorithm to exactly compute treewidth [2] (and a non-uniform FPT algorithm came from the Graph Minor series [31]). In contrast, while there is an XP algorithm to compute bandwidth [33], an FPT algorithm is highly unlikely [10]. It is a long-standing open whether an FPT or a mere XP algorithm exist for computing clique-width exactly, or even simply if one can recognize graphs of clique-width at most 4 in polynomial time (deciding clique-width at most 3 is indeed tractable [7]).

Theorem 1 almost completely resolves the parameterized complexity of exactly computing twin-width on general graphs. Two questions remain: can graphs of twin-width at most 2, respectively at most 3, be recognized in polynomial time. Graphs of twin-width 0 are cographs, which can be recognized in linear time [22], while it was recently shown that graphs of twin-width at most 1 can be recognized in polynomial time [5]. In the course of establishing Theorem 1 we show and generalize the following, where an $(\geqslant s)$-*subdivision* of a graph is obtained by subdividing each of its edges at least s times.

▶ **Theorem 2.** *Any $(\geqslant 2\log n)$-subdivision of an n-vertex graph has twin-width at most 4.*

That those graphs have bounded twin-width was known [3], but not with the explicit bound of 4. Another family of graphs with twin-width at most 4 is the set of grids, walls, their subgraphs, and subdivisions. Even if there is no proof of that fact, sufficiently large grids, walls, or their subdivisions likely have twin-width *at least* 4; it is actually surprising that the 6×8 grid still has twin-width 3 [34]. We also believe that long subdivisions of "sufficiently complicated" graphs have twin-width *at least* 4. That would make graphs of twin-width at most 3 considerably simpler than those of twin-width at most 4, especially among sparse graphs.

Contrary to the hardness proof for treewidth [1], which involves some structural characterizations by chordal completions, and the intermediate problems Minimum Cut Linear Arrangement, Max Cut, and Max 2-SAT [19], our reduction is "direct" from 3-SAT. This makes the proven hardness of twin-width more robust, and easier to extend to restricted classes of graphs, especially sparse ones. Theorem 1 holds for bounded-degree input graphs. For instance, performing our reduction from Planar 3-SAT produces subgraphs of constant powers of the planar grid (while admittedly weakening the ETH lower bound from $2^{\Omega(n/\log n)}$ to $2^{\Omega(\sqrt{n}/\log n)}$). Hence, while the complexity status of computing treewidth on planar graphs is a famous long-standing open question, one can probably extend the NP-hardness of *twin-width at most 4* to planar graphs, by tuning and/or replacing the few non-planar gadgets of our reduction.

Let us point out that, in contrast to subset problems, there is no $2^{O(n)}$-time algorithm known to compute twin-width. The exhaustive search takes time $n^{2n+O(1)}$ by considering all sequences of $n-1$ pairs of vertices. We leave as an open question whether the ETH lower bound of computing twin-width can be brought from $2^{\Omega(n/\log n)}$ to $2^{\Omega(n)}$, or even $2^{\Omega(n\log n)}$. The latter lower bound is known to hold for Subgraph Isomorphism [8] (precisely, given a graph H and an n-vertex graph G, deciding if H is isomorphic to a subgraph of G requires time $2^{\Omega(n\log n)}$, unless the ETH fails), or computing the Hadwiger number [15] (i.e., the size of the largest clique minor).

1.1 Outline of the proof of Theorem 1

We propose a quasilinear reduction from 3-SAT. Given an n-variable instance I of 3-SAT, we shall construct an $O(n\log n)$-vertex graph $G = G(I)$ which has twin-width at most 4 if and only if I is satisfiable.

Half of our task is to ensure that no 4-sequence will exist if I is unsatisfiable. This is challenging since many contraction strategies are to be considered and addressed. We make this task more tractable by attaching *fence gadgets* to some chosen vertex subsets. The effect of the fence *enclosing* S is that no contraction can involve vertices in S with vertices outside of S, while S is not contracted into a single vertex. The *maximal or outermost* fences (we may nest two or more fence gadgets) partition the rest of the vertices. This significantly tames the potential 4-sequences of G.

Our basic building block, the *vertical set*, consists of a pair of vertices (*vertical pair*) enclosed by a fence. It can be thought of as a bit set to 0 as long as the pair is not contracted, and to 1 when the pair gets contracted. It is easy to assemble vertical sets as prescribed by an auxiliary digraph D (of maximum degree 3), in such a way that, to contract (by a partial 4-sequence) the pair of a vertical set V, one first has to contract all the vertical sets that can reach V in D. This allows to propagate and duplicate a bit in a so-called *wire* (corresponding to an out-tree in D), and to perform the logical AND of two bits.

The bit propagation originates from a variable gadget (we naturally have one per variable appearing in I) that offers two alternatives. One can contract the "top half" of the gadget of variable x_i, which then lets one contract the vertical sets in the wire of literal x_i, or one can contract instead the "bottom half" of the gadget, as well as the vertical sets in the wire of literal $\neg x_i$. Concretely, these two contraction schemes represent the two possible assignments for variable x_i. A special "lock" on the variable gadget (called *half-guards*) prevents its complete contraction, and in particular, performing contractions in both the wires of a literal and its negation.

The leaves of the literal wires serve as inputs for 3-clause gadgets. One can contract the output (also a vertical set) of a clause gadget if and only if one of its input is previously contracted. We then progressively make the AND of the clauses via a "path" of binary AND gadgets fed by the clause outputs. We eventually get a vertical set, called *global output*, which can be contracted by a partial 4-sequence only if I is satisfiable. Indeed at this point, the variable gadgets are still locked so at most one of their literals can be propagated. This ticks one of our objective off. We should now ensure that a 4-sequence is possible from there, when I is satisfiable.

For that purpose, we add a wire from the global output back to the half-guards (or locks) of the variable gadgets. One can contract the vertical sets of that wire, and in particular the half-guards. Once the variable gadgets are "unlocked," they can be fully contracted. As a consequence, one can next contract the wires of literals set to false, and *all* the remaining vertical sets involved in clause gadgets.

At this point, the current trigraph H roughly has one vertex per outermost fence with red edges linking two adjacent gadgets (and no black edge). We will guarantee that the (red) degree of H is at most 4, its number of vertices of degree at least 3 is at most βn, for some constant β. Besides we will separate gadgets by degree-2 wires of length $2\log(\beta n)$ beforehand. This is crucial so that the red graph of H is a $(2\log n')$-subdivision of an n'-vertex graph. We indeed show that such trigraphs have twin-width at most 4. A complicated proof in [3] shows that $\Theta(\log n')$-subdivisions of n'-vertex graphs have bounded twin-width. Here we give an elementary proof of a similar fact with an explicit upper bound of 4.

This finishes to describe our overall plan for the reduction and its correctness. It happens that fence gadgets are easier to build as trigraphs, while the rest of the gadgetry can be directly encoded by graphs. We thus show how to encode trigraphs by graphs, as follows. For any trigraph J whose red graph has degree at most d, and component size at most h,

there is a graph G on at most $f(d,h)\cdot|V(J)|$ vertices such that J has twin-width at most $2d$ if and only if G has twin-width at most $2d$. This uses some local replacements and confluence properties of certain partial contraction sequences.

The proofs of the theorems and lemmas marked with a $\star$ can be found in the full version.

2 Preliminaries

For i and j two integers, we denote by $[i,j]$ the set of integers that are at least i and at most j. For every integer i, $[i]$ is a shorthand for $[1,i]$. We use the standard graph-theoretic notations: $V(G)$ denotes the vertex set of a graph G, $E(G)$ denotes its edge set, $G[S]$ denotes the subgraph of G induced by S, etc. An $(\geqslant s)$-subdivision (resp. s-subdivision) of a graph G is obtained by subdividing every edge of G at least s times (resp. exactly s times).

2.1 Definitions and notations related to twin-width

A *trigraph* G has vertex set $V(G)$, black edge set $E(G)$, red edge set $R(G)$. Its *red graph* $(V(G),R(G))$ may be denoted $\mathcal{R}(G)$. The *red degree* of a trigraph is the degree of its red graph. We say that $u\in V(G)$ is a *black neighbor* (respectively *red neighbor*) of $v\in V(G)$ when $(u,v)\in E(G)$ (respectively $(u,v)\in R(G)$). A trigraph G' is an *induced subtrigraph* of trigraph G if $V(G')\subseteq V(G)$, $E(G')=E(G)\cap\binom{V(G')}{2}$, and $R(G')=R(G)\cap\binom{V(G')}{2}$. Then we say that G is a supertrigraph of G', and we may also denote G' by $G[V(G')]$. A *(partial) d-sequence* of a (tri)graph G is a (partial) contraction sequence starting at G and admitting trigraphs of red degree at most d.

The *twin-width* of a graph, introduced in [6], can be defined in the following way. A *partition sequence* of an n-vertex graph G, is a sequence $\mathcal{P}_n,\dots,\mathcal{P}_1$ of partitions of its vertex set $V(G)$, such that $\mathcal{P}_n$ is the set of singletons $\{\{v\} : v\in V(G)\}$, $\mathcal{P}_1$ is the singleton set $\{V(G)\}$, and for every $2\leqslant i\leqslant n$, $\mathcal{P}_{i-1}$ is obtained from $\mathcal{P}_i$ by merging two of its parts into one. Two parts P,P' of a same partition $\mathcal{P}$ of $V(G)$ are said *homogeneous* if either every pair of vertices $u\in P, v\in P'$ are non-adjacent, or every pair of vertices $u\in P, v\in P'$ are adjacent. Finally the twin-width of G, denoted by $tww(G)$, is the least integer d such that there is partition sequence $\mathcal{P}_n,\dots,\mathcal{P}_1$ of G with each part P of each $\mathcal{P}_i$ $(1\leqslant i\leqslant n)$ being homogeneous to every part of $\mathcal{P}_i\setminus\{P\}$ but at most d.

The reason we gave two (equivalent) definitions of twin-width is that both viewpoints are incomparably useful and convenient. To navigate between these two worlds, we use the following notations and vocabulary.

Assume there is a partial contraction sequence from (tri)graph G to trigraph H. If u is a vertex of H, then $u(G)$ denotes the set of vertices eventually contracted into u in H. We denote by $\mathcal{P}(H)$ the partition $\{u(G) : u\in V(H)\}$ of $V(G)$. If G is clear from the context, we may refer to a *part* of H as any set in $\{u(G) : u\in V(H)\}$. We say that a contraction of two vertices $u,u'\in V(H)$ *involves* a vertex $v\in V(G)$ if $v\in u(G)$ or $v\in u'(G)$. A contraction *involves* a pair of vertices v,v' if $v\in u(G)$ and $v'\in u'(G)$ (or $v\in u'(G)$ and $v'\in u(G)$). A contraction *involves* a set S, if it involves a vertex of S, or a pair of sets S,T if it involves a pair in $S\times T$.

2.2 Useful observations

The twin-width can only decrease when taking induced subgraphs or turning red into black.

▶ **Observation 3.** *Let G' be an induced subtrigraph of trigraph G. Then $tww(G')\leqslant tww(G)$.*

▶ **Observation 4.** *Let G be a trigraph and G' another trigraph obtained from G by turning some non-edges and some edges into red edges. Then $tww(G') \geqslant tww(G)$.*

Trees admit a simple 2-sequence, that gives a d-sequence on red trees of degree at most d.

▶ **Lemma 5** ([6]). *Every (black) tree has twin-width at most 2. Every red tree has twin-width at most its maximum degree.*

2.3 The Exponential-Time Hypothesis

The Exponential-Time Hypothesis (ETH) was proposed by Impagliazzo and Paturi [24] and asserts that there is no subexponential-time algorithm solving 3-SAT. More precisely, there is an $\varepsilon > 0$ such that n-variable 3-SAT cannot be solved in time $2^{\varepsilon n}$. A classic reduction [35] linear in the number of clauses, and the Sparsification Lemma [25] imply that:

▶ **Theorem 6** ([35, 25]). *The n-variable 3-SAT problem where each variable appears at most twice positively, and at most twice negatively, is NP-complete, and cannot be solved in time $2^{o(n)}$, unless the ETH fails.*

3 Long subdivisions have twin-width at most four

In [3], it is proved that the $\Omega(\log n)$-subdivision of any n-vertex graph has bounded twin-width. The proof is rather involved, relies on a characterization by *mixed minors* established in [6], and does not give an explicit constant bound. Here we give an elementary proof that any ($\geqslant 2\lceil \log n \rceil - 1$)-subdivision of an n-vertex graph has twin-width at most 4.

▶ **Theorem 7.** *Let G be a trigraph obtained by subdividing each edge of an n-vertex graph H at least $2\lceil \log n \rceil - 1$ times, and by turning red any subset of its edges as long as the red degree of G remains at most 4, and no vertex with red degree 4 has a black neighbor. Then $tww(G) \leqslant 4$.*

Proof. By no more than doubling the number of vertices of H, we can assume that n is a power of 2. Indeed, padding H with isolated vertices up to the next power of 2 does not change the quantity $\lceil \log |V(H)| \rceil$.

Let G' be a supertrigraph of G obtained by arbitrarily arranging the vertices of H (in G) at the leaves of a "virtual" full binary tree of height $\log n$. So that the red degree does not exceed 4, we so far omit the edges of the tree incident to a leaf (i.e., a vertex of H), while we

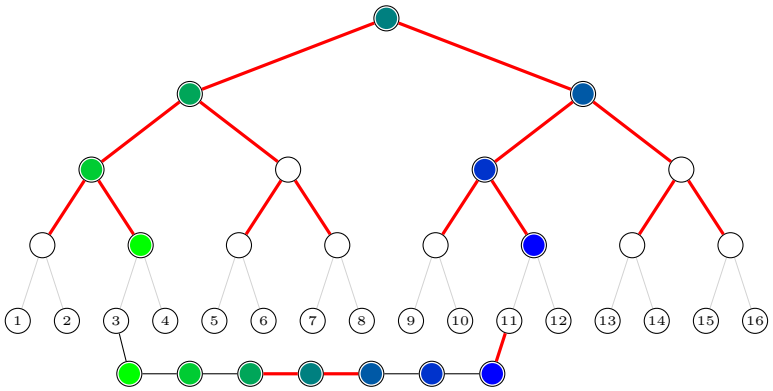

Figure 2 Contracting the pairs of vertices with the same color, from the greenest to the bluest, is a partial 4-sequence, which acts as a deletion of the subdivided edge $(3, 11)$.

put in red all the other edges of the tree. (The missing edges of the tree will naturally appear in red.) The internal nodes of the tree are all fresh vertices, not present in G. See Figures 2 and 3 for an illustration. We show that $tww(G') \leqslant 4$, hence by Observation 3, $tww(G) \leqslant 4$ since G is an induced subtrigraph of G'.

We label $1, 2, \ldots, n$ the vertices of H. If there is an edge $ij \in E(H)$, it is subdivided into a path, say, $i, s(ij,1), s(ij,2), \ldots, s(ij,z), j$ in G with $z \geqslant 2\log n - 1$. First, we repeatedly contract adjacent vertices in the middle of this path until it consists of exactly $2\log n$ edges. If $z > 2\log n - 1$, we had to contract at least one pair of adjacent vertices. Thus the vertex in the middle of the path necessarily has now two red edges incident to it. Note that the other edges of the path can be black or red indifferently. To avoid cumbersome notations, we rename the inner vertices of the path $s(ij,1), s(ij,2), \ldots, s(ij,z)$ with now $z = 2\log n - 1$.

▷ Claim 8. There is a partial 4-sequence from G' to $G' - \{s(ij,1), \ldots, s(ij,z)\}$.

Proof. Intuitively we "zip" the subdivision of ij with the walk made by the union of the path from leaf i to the root, and the path from the root to leaf j. Let $i, v_1, v_2, \ldots, v_z, j$ be the concatenation of the simple path from i to the root of the tree, and the simple path from the root to j. Its length is thus $2\log n = z + 1$. For h going from 1 to $z = 2\log n - 1$, we contract v_h and $s(ij,h)$ (see Figure 2). After each contraction, the newly formed vertex has red degree at most 4. The red degree of vertices that are neither the new vertex nor a leaf of the tree is either unchanged or at most 2. The red degree of a leaf ℓ of the tree may increase by 1. This may only happen the first time a neighbor of ℓ is involved in a contraction, and that contraction merges a black neighbor of ℓ with the parent of ℓ in the tree (like is the case for leaf 3 from Figure 2 to Figure 3). By assumption, this implies that ℓ had red degree at most 3, thus its red degree does not exceed 4. Thus, what we defined is indeed a partial 4-sequence. One can finally notice that after these z contractions, we indeed reach trigraph $G' - \{s(ij,1), \ldots, s(ij,z)\}$. ◁

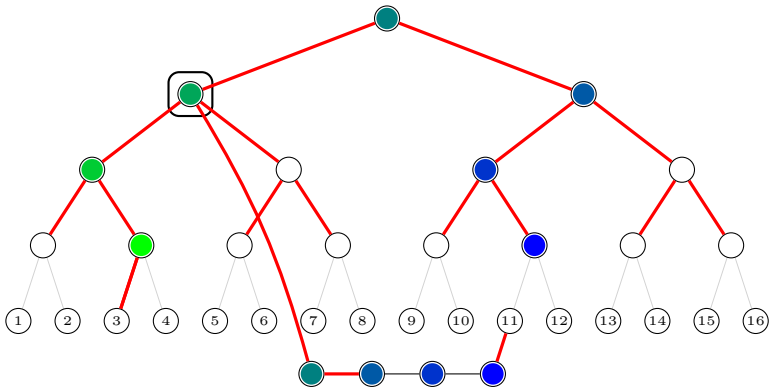

Figure 3 The picture after the first three contractions. The newly formed vertex has red degree 4.

We apply Claim 8 for each edge of H (or rather, subdivided edge in G). We are then left with a red full binary tree which admits a 3-sequence by Lemma 5. Hence there is a 4-sequence for G', and in particular, for G. ◀

We will only use the following consequence.

▶ **Lemma 9.** *Let G be a trigraph obtained by subdividing at least $2\lceil \log n \rceil - 1$ times each edge of an n-vertex graph H of degree at most 4, and by turning red all its edges. Then $tww(G) \leqslant 4$.*

4 Hardness of determining if the twin-width is at most four

Here we show the main result of the paper.

▶ **Theorem 1.** *Deciding if a graph has twin-width at most 4 is NP-complete. Furthermore, no algorithm running in time $2^{o(n/\log n)}$ can decide if an n-vertex graph has twin-width at most 4, unless the ETH fails.*

The membership to NP is ensured by the d-sequence: a polynomial-sized certificate that a graph has twin-width at most d, checkable in polynomial time. We thus focus on the hardness part of the statement, and design a quasilinear reduction from 3-SAT.

4.1 Foreword to the reduction

Let us start by a construction allowing to encode trigraphs into (plain) graphs. Given a trigraph H with red degree at most d, we can produce a graph G such that H admits a $2d$-sequence iff G admits a $2d$-sequence.

▶ **Lemma 10** ($\star$)**.** *Given any trigraph H whose red graph has degree at most d and connected components of size at most h, one can compute in time $O_{d,h}(|V(H)|)$ a graph G on $O_{d,h}(|V(H)|)$ vertices such that H has a $2d$-sequence if and only if G has a $2d$-sequence.*

In what follows, we only need the following scaled-down version.

▶ **Lemma 11.** *Given any trigraph H whose red graph is a disjoint union of 12-vertex paths and isolated vertices, one can compute in polynomial time a graph G on $O(|V(H)|)$ vertices such that H has twin-width at most 4 if and only if G has twin-width at most 4.*

Our task is now slightly simpler. Given a 3-SAT instance I, we may design a *trigraph* satisfying the requirements of Lemma 11 with twin-width at most 4 if and only if I is satisfiable.

We will motivate all the gadgets along the way, by exhibiting key properties that they impose on a potential 4-sequence. These properties readily lead to a satisfying assignment for I. We also describe partial 4-sequences to reduce most of the gadgets. However some preconditions (specifying the context in which a particular gadget stands) tend to be technical, and make more sense after the construction of G. In those cases, to avoid unnecessarily lengthy lemmas, we only give an informal strategy, and postpone the adequate contraction sequence.

4.2 Fence gadget

The vertex set of a fence gadget is $A \cup B$ with $A = \{a_1, a_2, a_3, a_4, a_5, a_6\}$ and $B = \{b_1, b_2, b_3, b_4, b_5, b_6\}$. Its black edge set consists of 13 edges: the cycles $a_1a_2a_3a_4a_5a_6a_1$ and $b_1b_2b_3b_4b_5b_6b_1$, plus the edge b_1a_6. Its red edge set consists of 11 edges: a_ib_i for each $i \in [6]$, and a_ib_{i+1} for each $i \in [5]$. A fence gadget is *attached* to a vertex subset S by making A fully adjacent to S. See Figure 4 for an illustration.

We will later nest fence gadgets. Thus we have to tolerate that F has other neighbors than S in G. Actually we even allow $V(F)$ to have neighbors outside of S and the fence gadgets surrounding F. We however always observe the following rule.

▶ **Definition 12** (Attachment rule)**.** *A fence gadget F with vertex bipartition (A, B), and attached to S, satisfies the* attachment rule *in a trigraph H if F is a connected component of $\mathcal{R}(H)$, and there is a set $X \subseteq V(H) \setminus (A \cup B \cup S)$ such that:*

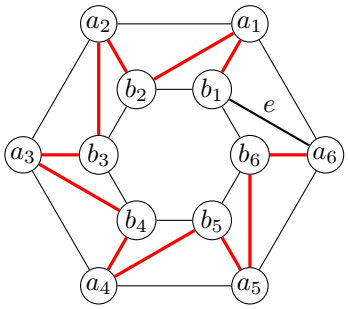

Figure 4 The fence gadget F, with $A = \{a_i \mid 1 \leqslant i \leqslant 6\}$ and $B = \{B_i \mid 1 \leqslant i \leqslant 6\}$.

- $\forall x \in A$, $N(x) \setminus V(F) = X \cup S$,
- $\forall x \in B$, $N(x) \setminus V(F) = X$, *and*
- $\forall x \in X$, $S \subset N(x)$.

Initially in G, we make sure that all the fence gadgets satisfy the attachment rule. This will remain so until we decide to contract them.

For each fence gadget F satisfying the attachment rule, there is only one adequate set X, it is $X = N(F) \setminus (V(F) \cup S)$. We denote by Y the set $V(G) \setminus (V(F) \cup S \cup X)$. We make the following observations on the three possible neighborhoods that vertices outside of F have within $V(F)$.

▶ **Observation 13.** *The fence gadget definition and the attachment rule implies:*

- $\forall x \in S$, *it holds* $N(x) \cap V(F) = A$,
- $\forall x \in X$, *it holds* $N(x) \cap V(F) = V(F) = A \cup B$, *and*
- $\forall x \in Y$, *it holds* $N(x) \cap V(F) = \emptyset$.

Henceforth we will represent every fence gadget as a brown rectangle surrounding the set S it is attached to. The vertices of X are linked to the brown rectangle, as they are fully adjacent to $S \cup V(F)$. See Figure 5 for an illustration of the attachment rule, and a compact representation of fence gadgets.

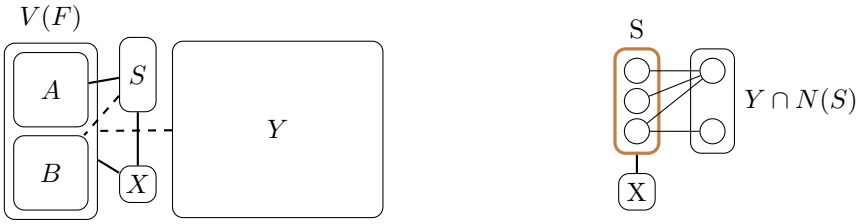

Figure 5 Left: The forced adjacencies (solid lines, all edges between the two sets) and non-adjacencies (dashed lines, no edge between the two sets), as specified by the attachment rule. Right: Symbolic representation of the fence gadget attached to S by a brown rectangle.

Constraints of the fence gadget on a 4-sequence. The following lemmas are preparatory steps for the milestone that no part in a 4-sequence of G can overlap S (that is, intersects S without containing it).

▶ **Lemma 14** ($\star$). *The first contraction involving two vertices of F results in a vertex of red degree at least 5, except if it is a contraction of some $a_i \in A$ with some $b_j \in B$.*

▶ **Lemma 15** (⋆). *If the first contraction involving two vertices of F is of some $a_i \in A$ with some $b_j \in B$, the red degree within F of the created vertex is at least 3.*

The last preparatory step is this easy lemma.

▶ **Lemma 16.** *Before a contraction involves two vertices of $V(F)$, the following holds in a partial 4-sequence:*

- *no part intersects both X and S,*
- *no part intersects both Y and S, and*
- *no part intersects both X and Y.*

Proof. By Observation 13, such a part would have red degree $|B| = 6$, $|A| = 6$, and $|A \cup B| = 12$, respectively. ◀

As a consequence we obtain the following.

▶ **Lemma 17.** *In a partial 4-sequence of G, the first contraction involving a vertex in $V(F)$ and a vertex in $V(F) \cup S$ has to be done after S is contracted into a single vertex.*

Proof. We consider the first time a vertex $u \in V(F)$ is involved in a contraction with a vertex of $V(F) \cup S$. Either (case 1) the part of u, P_u, is contracted with a part P_v containing $v \in V(F)$, or (case 2) P_u is contracted with a part P intersecting S but not $V(F)$.

In case 1, by Lemma 14, u and v hit both A and B. Thus, by Lemma 15, the red degree within F of the resulting vertex z is at least 3. Moreover z is linked by a red edge to every part within S, since S is fully adjacent to A, and fully non-adjacent to B. Thus S should at this point consist of a single part.

We now argue that case 2 is impossible in a partial 4-sequence. By Lemma 16, part P cannot intersect $X \cup Y$ (nor $V(F)$, by construction). Thus $P \subseteq S$. If $u \in A$, then the contraction of P_u and P has incident red edges toward at least 5 vertices: three vertices of A non-adjacent to u and two private neighbors of u (in the total graph) within B. If instead $u \in B$, the red degree of the contracted part is at least 6, as witnessed by two neighbors of u in B, and four non-neighbors of u in A. ◀

We can now establish the main lemma on how a fence gadget constrains a 4-sequence. Lemmas 16 and 17 have the following announced consequence: While S is not contracted into a single vertex, no part within S can be contracted with a part outside of S, and similarly vertices of X cannot be contracted with vertices of Y.

▶ **Lemma 18** (⋆). *In a partial 4-sequence, while S is not contracted to a single vertex,*

- *(i) no part intersects both S and $V(G) \setminus S$, nor*
- *(ii) both X and Y.*

Contracting the fence gadget. The previous lemmas establish some constraints that the fence gadget imposes on a supposed (partial) 4-sequence. We now see how a partial 4-sequence actually contracts a fence gadget.

Every time we are about to contract a fence gadget F attached to S, we will ensure that the following properties hold:

- no prior contraction has involved a vertex of $V(F)$,
- no red edge has one endpoint in $V(F)$ and one endpoint outside $V(F)$, and
- S is contracted into a single vertex with red degree at most 3.

In particular, the fence gadget F still satisfies the attachment rule.

▶ **Lemma 19** (⋆). *Let H be a trigraph containing a fence gadget F attached to a single vertex s of red degree at most 3. We assume that F satisfies the attachment rule in H.*

Then there is a partial 4-sequence from H to H', where H' is the trigraph obtained from H by contracting $V(F)$ into a single vertex.

4.3 Propagation, wire, and long chain

A *vertical set* V consists of two vertices x, y combined with a fence gadget F attached to $\{x, y\}$. Thus $V = \{x, y\} \cup V(F)$. We call *vertical pair* the vertices x and y. We will usually add a superscript to identify the different copies of vertical sets: Every vertex whose label is of the form u^j belongs to the vertical set V^j.

The *propagation gadget* from V^j to V^k puts all the edges between V^j and x^k (and no other edge). We call these edges an *arc from V^j to V^k*. We also say that the vertical set V^k is *guarded* by V^j. The pair V^j, V^k is said *adjacent*. Here, singleton $\{x^k\}$ plays the role of X (Definition 12) for the attachment rule of vertical set V_j.

The *propagation digraph of G*, denoted by $\mathcal{D}(G)$, has one vertex per vertical set and an arc between two vertical sets linked by an arc (in the previous sense). A (maximal) *wire* W is an induced subgraph of G corresponding in $\mathcal{D}(G)$ to a (maximal) out-tree on at least two vertices. See Figure 6 for an illustration of a wire made by simply concatenating propagation gadgets. Eventually $\mathcal{D}(G)$ will have out-degree at most 2, in-degree at most 2, and total degree at most 3.

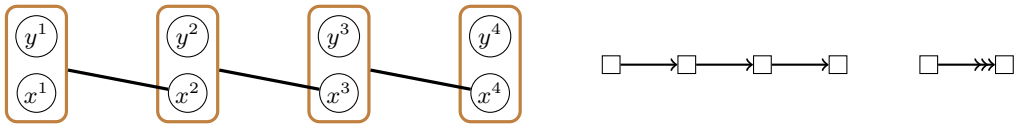

Figure 6 Left: A non-branching wire made of 4 vertical sets and 3 propagation gadgets. Every vertical set is guarded by the vertical set just to its left. Center: A more compact representation, which corresponds to the propagation digraph. Right: Symbolic representation of the long chain, that is, of the represented wire if $L = 4$.

The *children* of a vertical set V are the vertical sets that V guards. The *root of wire W* is the unique vertical set of in-degree 0 in $\mathcal{D}(W)$. The *leaves of wire W* are the vertical sets of out-degree 0 in $\mathcal{D}(W)$. A wire is said *primed* when the vertical pair of its root has been contracted.

A wire W is *non-branching* if every vertex of $\mathcal{D}(W)$ has out-degree at most 1; hence, $\mathcal{D}(W)$ is a directed path. A *long chain* is a wire W such that $\mathcal{D}(W)$ is a directed path on L vertices, where integer L will be specified later (and can be thought as logarithmic in the total number of fences which do not belong to vertical sets). Otherwise, if $\mathcal{D}(W)$ has at least one vertex with out-degree at least 2, wire W is said *branching*. A vertical set with two children is also said *branching*.

Constraints of the propagation gadget on a 4-sequence. We provide the proof that a contraction in a vertical set V is only possible when the vertical pair of all the vertical sets V' with a directed path to V in $\mathcal{D}(G)$ has been contracted.

▶ **Lemma 20.** *Let V^j and V^k be two vertical sets with an arc from V^j to V^k. In a partial 4-sequence from G, any contraction involving two vertices of V^k has to be preceded by the contraction of x^j and y^j.*

Proof. We recall the notations of Section 4.2. Let F be the fence gadget attached to $S = \{x^j, y^j\}$, X the neighborhood of $V(F)$ outside of $S \cup V(F)$, and Y the vertices that are not in $S \cup V(F) \cup X$. (We always assume that the attachment rule is satisfied.) We have $x^{j'} \in X$ and $y^k \in Y$, therefore by the second item of Lemma 18, their contraction has to be preceded by the contraction of x^j and y^j. Now applying the first item of Lemma 18 to the fence gadget F' attached to $S' = \{x^k, y^k\}$, and Lemma 17, any contraction involving a pair of V^k distinct from S' has to be preceded by the contraction of x^k and y^k. ◀

Henceforth, when we say that a contraction is *preceded* by another contraction, it includes the case that the two contractions are in fact the same. By a straightforward induction, we obtain the following from Lemma 20 (and Lemma 17).

▶ **Lemma 21.** *In a partial 4-sequence from G, any contraction involving a pair of vertices in a vertical set V has to be preceded by the contraction of the vertical pair of every vertical set V' such that there is a directed path from V' to V in $\mathcal{D}(G)$.*

Contracting wires. As the roots and leaves of wires will be connected to other gadgets, we postpone the description of how to contract wires until after building the overall construction G. Intuitively though, contracting a wire (in the vacuum) consists of contracting the vertical pair of its root, then its fence gadget by applying Lemma 19, and finally recursively contracting the subtrees rooted at its children. Since $\mathcal{D}(G)$ has total degree at most 3, every vertex has red degree at most 4 (for the at most 3 adjacent vertical sets, plus the pendant vertex of the fence gadget).

4.4 Binary AND gate

The *binary* AND *gate* (AND gadget, for short) simply consists of three vertical sets V^1, V^2, V^3 with an arc from V^1 to V^3, and an arc from V^2 to V^3. As usual, the vertical pairs of V^1, V^2, and V^3, are $\{x^1, y^1\}$, $\{x^2, y^2\}$, and $\{x^3, y^3\}$, respectively. We call the vertical sets V^1, V^2 the *inputs* of the AND gadget, and the vertical set V^3 the *output* of the AND gadget.

Constraint of the AND gadget on a 4-sequence. By Lemma 20, we readily derive:

▶ **Lemma 22.** *Assume G contains an AND gadget with inputs V^1, V^2, and output V^3. In a partial 4-sequence from G, any contraction involving two vertices of V^3 has to be preceded by the contraction of x^1 and y^1, and the contraction of x^2 and y^2.*

Contraction of an AND gadget. Once V^1 and V^2 are contracted into single vertices, one can contract the vertical pair x^3, y^3. This results in a vertex of red degree 2. Thus one can contract the fence gadget of V^3 by applying Lemma 19.

4.5 Binary OR gate

The *binary* OR *gate* (OR *gadget*) is connected to three vertical sets: two *inputs* V^1, V^2, and one *output* V^3. We start by building two vertical sets V, V' whose vertical pairs are $\{a, b\}$ and $\{c, d\}$, respectively. The edges ac and bd are added, as well as a vertex e adjacent to a and to c. Finally a fence is attached to $\{e\} \cup V \cup V'$.

The OR gadget is connected to its inputs and output, in the following way. Vertex a is made adjacent to x^1 and to y^1 (but not to their fence gadget). Similarly vertex b is linked to x^2 and y^2. Finally x^3 is adjacent to all the vertices of the OR gadget, that is, $\{e\} \cup V \cup V'$ plus the vertices of the outermost fence. See Figure 7 for a representation of the OR gadget.

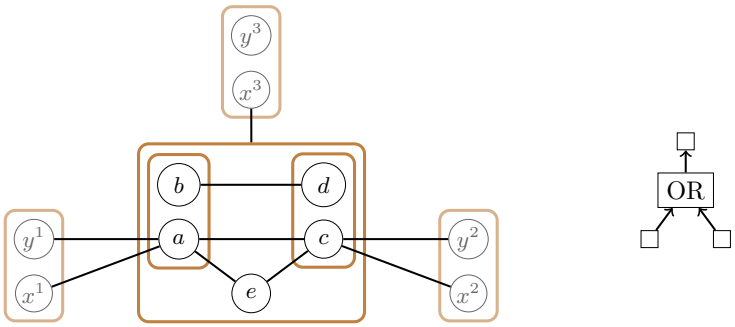

Figure 7 An OR gadget attached to inputs V^1, V^2 and output V^3, and its symbolic representation. These vertical sets are technically not part of the OR gate, so we represent them slightly dimmer.

Constraint of the OR gadget on a 4-sequence. By design, one can only start contracting the OR gadget after the vertical pair of at least one of its two inputs has been contracted. This implies that no contraction can involve V^3 before at least one the vertical pairs $\{x^1, y^1\}$ and $\{x^2, y^2\}$ is contracted.

▶ **Lemma 23.** *Assume G contains an OR gadget attached to inputs V^1 and V^2. In a partial 4-sequence from G, the contractions of a, b and of c, d have to be preceded by the contraction of x^1, y^1 or the contraction of x^2, y^2.*

Proof. Assume none of the pairs $\{a, b\}, \{c, d\}, \{x^1, y^1\}, \{x^2, y^2\}$ have been contracted. Because of the fences, by Lemma 18, all the vertices $x^1, y^1, a, b, c, d, x^2, y^2$ and e are in distinct parts. Therefore contracting a and b would create a vertex of red degree at least 5, considering the (singleton) parts of x^1, y^1, c, d, e. Symmetrically contracting c and d yields at least five red neighbors, considering the (singleton) parts of x^2, y^2, a, b, e. ◀

From Lemma 23 we get the following.

▶ **Lemma 24.** *Assume G contains an OR gadget attached to inputs V^1 and V^2. In a partial 4-sequence from G, no contraction involving a vertex of V^3 can happen before either the pair x^1, y^1 or the pair x^2, y^2 is contracted.*

Proof. Suppose neither x^1, y^1 nor x^2, y^2 is contracted. By Lemma 23, the pairs $\{a, b\}$ and $\{c, d\}$ cannot be contracted. By the first item of Lemma 18, no contraction can involve a vertex of $\{a, b, c, d, e\}$. As x^3 is adjacent to all these vertices but not y^3, one cannot contract the vertical pair $\{x^3, y^3\}$. Hence by Lemma 17 no contraction can involve a vertex of V^3. ◀

Contraction of the OR gadget. We now show how to contract the OR gate when the vertical pair of one of its inputs has been contracted.

▶ **Lemma 25.** *Assume that x^1 and y^1 have been contracted into z^1, and that z^1, x^2, and y^2 all have red degree at most 3. Then there is a partial 4-sequence that contracts the whole OR gadget to a single vertex with only three red neighbors: z^1, x^2, and y^2. (The same holds symmetrically if x^2 and y^2 have been contracted into a single vertex.)*

Proof. First contract a and b into vertex α of red degree 4. At this point the fence of $\{a, b\}$ cannot be contracted yet, as this would make the red degree of α go above 4. Hence we next contract c and d into γ, decreasing the red degree of α to 3. Note that γ has only 4 red neighbors: α, e, x^2, y^2.

By Lemma 19, we can now contract the fence gadget of $\{a, b\}$ to a single vertex. Next we contract this latter vertex with α, and the resulting vertex with t; we call α' the obtained vertex. Now γ has only red degree 3, so we can contract the fence gadget of $\{c, d\}$ to a single vertex that we further contract with γ; we call γ' the obtained vertex. We contract α' and γ' in a vertex ε of red degree 3; its three red neighbors are z^1, x^2, and y^2. Again by Lemma 19, the outermost fence of the OR gadget can be contracted into a single vertex, that we finally contract with ε. This results in a vertex with three red neighbors: z^1, x^2, and y^2.

Throughout this process the red degree of z^1, x^2, and y^2 never goes above 4. Indeed the red degree of these vertices is initially at most 3, while they have exactly one black neighbor in the entire OR gadget (so at most one part to be in conflict with). ◀

4.6 Variable gadget

The variable gadget is represented in Figure 8 (see long version for a textual description).

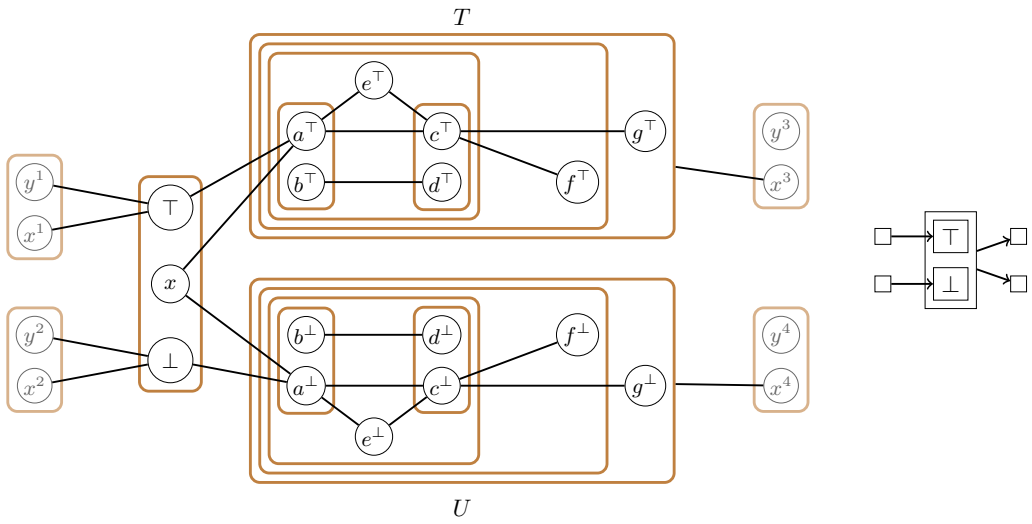

Figure 8 A variable gadget half-guarded by V^1, V^2, and with outputs V^3, V^4, and its compact representation (right).

Constraints of the variable gadget on a 4-sequence. Because of the fence gadget attached to $\{\top, x, \bot\}$, one has at some point to contract $\top$ and $\bot$ (be it with or without x). A first observation is that this has to wait that the vertical pair of V^1 or V^2 is contracted.

▶ **Lemma 26.** *Assume G has a variable gadget half-guarded by vertical sets V^1 and V^2. In a partial 4-sequence from G, the contraction of $\top$ and $\bot$ has to be preceded by the contraction of the pair x^1, y^1 or of the pair x^2, y^2.*

Proof. The pairs $\{x^1, y^1\}$, $\{x^2, y^2\}$, and $\{\top, \bot\}$ are contained in three disjoint sets S^1, S^2, S, respectively, to which a fence is attached. Thus before any of these pairs are contracted, by Lemma 18, a vertex outside $S^1 \cup S^2 \cup S$, like $a^\bot$, is in a different part than the six vertices $x^1, y^1, x^2, y^2, \top, \bot$. Therefore contracting $\top$ and $\bot$ would create a vertex with five red neighbors, considering the parts of $x^1, y^1, x^2, y^2, a^\bot$. ◀

We next show that no contraction is possible in U (resp. in T), while x and $\bot$ (resp. x and $\top$) are not contracted.

▶ **Lemma 27.** *In a partial 4-sequence, the contractions of $a^\perp$ and $b^\perp$ (resp. $a^\top$ and $b^\top$) and of $c^\perp$ and $d^\perp$ (resp. $c^\top$ and $d^\top$) have to be preceded by the contraction of x and $\perp$ (resp. x and $\top$). Therefore no contraction is possible in U (resp. T) before x and $\perp$ (resp. x and $\top$) are contracted.*

Proof. Since the two statements are symmetric, we only show it with $\perp$. Assume none of the pairs $\{x, \perp\}$, $\{a^\perp, b^\perp\}$, $\{c^\perp, d^\perp\}$ are contracted. Because of the fence gadgets, by the first item of Lemma 18, the vertices $x, \perp, a^\perp, b^\perp, c^\perp, d^\perp, e^\perp, f^\perp$ are pairwise in distinct parts. Therefore contracting $a^\perp$ and $b^\perp$ or $c^\perp$ and $d^\perp$ would create a vertex of red degree at least 5. The structure of the fence gadgets in U thus prevents any contraction. ◀

We deduce that priming the wire of $\neg x$ (resp. $+x$) can only be done after x and $\perp$ (resp. x and $\top$) are contracted.

▶ **Lemma 28.** *Assume that G has a variable gadget with outputs the vertical sets V^3 (root of the wire of $+x$) and V_4 (root of the wire of $\neg x$). In a partial 4-sequence from G, the contraction of x^4 and y^4 (resp. x^3 and y^3) has to be preceded by the contraction of x and $\perp$ (resp. x and $\top$).*

Proof. By the second item of Lemma 18 applied to the fence attached to U, the pair x^4, y^4 cannot be contracted until U is not contracted to a single vertex. Thus by Lemma 27, the pair x^4, y^4 can only be contracted after the pair $x, \perp$ is contracted. The other statement is obtained symmetrically. ◀

Contraction of the variable gadget. We show two options to contract a "half" of the variable gadget, either T and its fence, or U and its fence, into a single vertex.

▶ **Lemma 29.** *There is a partial 4-sequence that contracts x and $\top$ together, and $T \cup F^\top$ into a single vertex. Symmetrically there is a partial 4-sequence that contracts x and $\perp$ together, and $U \cup F^\perp$ into a single vertex.*

Proof. We first contract x and $\top$ into a vertex $+x$. Observe that $+x$ has exactly three red neighbors: x^1, y^1, and $a^\perp$. Thus $\{a^\top, b^\top, c^\top, d^\top, e^\top\}$ and their three fences can be contracted exactly like an OR gadget. So by Lemma 25, there is a partial 4-sequence that contracts all these vertices to a single vertex u, with three red neighbors ($+x$, $f^\top$, and $g^\top$). We can now contract u and $f^\top$ into u', followed by contracting their fence gadget $F'^\top$ into a single vertex, by Lemma 19. That pendant vertex can be contracted to u', and the result to $g^\top$, forming vertex v. Finally, again by Lemma 19, the fence $F^\top$ attached to T can be contracted into a single vertex, which can be contracted with v.

The other sequence is the symmetric. ◀

The second "half" of the variable gadget can be contracted once the vertical pairs of the *half-guards* V^1, V^2 have been contracted.

▶ **Lemma 30.** *Assume $T \cup F^\top$ (resp. $U \cup F^\perp$) has been contracted into a single vertex u, and that the pairs $\{\top, x\}$ (resp. $\{\perp, x\}$), $\{x^1, y^1\}$, and $\{x^2, y^2\}$ have been contracted into $+x$ (resp. $\neg x$), z^1, and z^2, respectively. We further assume that the red degree of z^2 (resp. z^1) is at most 3. Then there is partial 4-sequence that contracts $\top, x, \perp$ and their fence into a single vertex, and $U \cup F^\perp$ (resp. $T \cup F^\top$) into a single vertex.*

Proof. We contract $\perp$ with $+x$ into v of red degree 4. This increases the red degree of z^2 by one, which remains at most 4. We then contract $U \cup F^\perp$ into a single vertex w, like in Lemma 29. We contract u and w into y, a vertex of red degree at most 3. Now v has

degree 3. So we can contract its fence gadget by Lemma 19. We further contract v with its pendant neighbor, and finally with y. What results is a unique vertex with four red neighbors.

The other partial sequence is symmetric. ◀

4.7 Clause gadget

A *3-clause gadget* (or simply *clause gadget*) has for *inputs* three vertical sets V^1, V^2, V^3, and for *output* one vertical set V^4. It consists of combining two OR gadgets, and using long chains to make the OR gadgets *distant enough*. We add an OR gadget with input V^1 and V^2, and output V. We then add a long chain from V to V', and an OR gadget with input V' and V^3, and output V^4. The clause gadget is depicted in Figure 9. We call *first OR gadget* of the clause gadget, the one with output V, and *second OR gadget*, the one with output V^4.

Figure 9 Left: A 3-clause gadget. Right: A shorthand for the gadget.

Constraint of the clause gadget on a 4-sequence. As a consequence of Lemmas 21 and 24, we get that once a contraction involves the output, at least one of the vertical pairs of the inputs has been contracted.

▶ **Lemma 31** (⋆). *Assume G contains a clause gadget with inputs V^1, V^2, V^3 and output V^4. In a partial 4-sequence from G, any contraction involving a vertex of V^4 is preceded by the contraction of the vertical pair of one of V^1, V^2, or V^3.*

Contraction of the clause gadget. The OR gates of the clause gadgets will be contracted as specified in Lemma 25, while we wait the overall construction to describe the contraction of the wires.

4.8 Overall construction and correctness

Let $I = (C_1, \ldots, C_m)$ be an instance of 3-SAT, that is, a collection of m 3-clauses over the variables $x_1, \ldots, x_n$. We further assume that each variable appears at most twice positively, and at most twice negatively in I. The 3-SAT problem remains NP-complete with that restriction, and without $2^{o(n)}$-time algorithm unless the ETH fails; see Theorem 6. We build a trigraph H that has twin-width at most 4 if and only if I is satisfiable. As trigraph H will satisfy the condition of Lemma 11, it can be replaced by a graph G on $O(|V(H)|)$ vertices. We set L the length of the long chain to $2\lceil \log(5n+3m) \rceil = O(\log n)$, so that G has $O(n \log n)$ vertices. We now piece the gadgets described in the previous sections together.

Variable to clause gadgets. For every variable x_i, we add a variable gadget half-guarded by V_i^1, V_i^2, and with outputs V_i^3, V_i^4. We add a long chain starting at vertical set V_i^3 (resp. V_i^4), and ending at a branching vertical set from which starts two long chains stopping at vertical sets $V_i^{\top,1}$ and $V_i^{\top,2}$ (resp. $V_i^{\bot,1}$ and $V_i^{\bot,2}$). Vertical set $V_i^{\top,1}$ (resp. $V_i^{\bot,1}$) serves as the

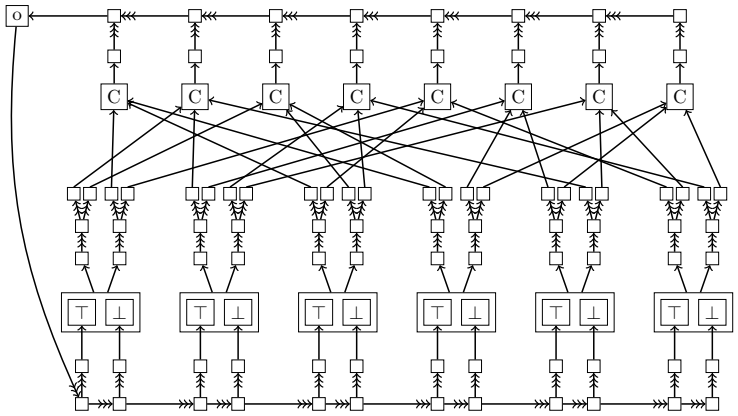

Figure 10 An example of the overall construction G on a 3-SAT instance with 6 variables and 8 clauses. The first two clauses are $\neg x_1 \vee x_3 \vee x_4$ and $x_1 \vee x_2 \vee \neg x_5$.

input of the first clause gadget in which x_i appears positively (resp. negatively), while $V_i^{\top,2}$ (resp. $V_i^{\bot,2}$) becomes the input of the second clause gadget in which x_i appears positively (resp. negatively). If a literal has only one occurrence, then we omit the corresponding vertical set, and the long chain leading to it. We nevertheless assume that each literal has at least one occurrence, otherwise the corresponding variable could be safely assigned.

Clause gadgets to global output. For every $j \in [m]$, we add a long chain from the output of the clause gadget of C_j, to a vertical set, denoted by V_j^c. For every $j \in [2, m]$, we then add a long chain starting at V_j^c and ending at V_{j-1}^c. We add an arc from V_1^c to a new vertical set V^o, which we call the *global output*.

Global output back to half-guarding the variable gadgets. For every $i \in [n]$, we add two vertical sets $V_i^{1,r}, V_i^{2,r}$, and puts a long chain starting at $V_i^{1,r}$ and ending at $V_i^{2,r}$. We add a long chain from V^o to $V_1^{1,r}$. We also add a long chain from $V_i^{2,r}$ to $V_{i+1}^{2,r}$, for every $i \in [n-1]$. Finally we add a long chain from $V_i^{a,r}$ to V_i^a for every $a \in \{1, 2\}$ and every $i \in [n]$. Recall that V_i^1 and V_i^2 are half-guarding the variable gadget of x_i.

This finishes the construction of the graph $G = G(I)$. See Figure 10 for an illustration.

If G has twin-width at most 4, then I is satisfiable. Let us consider the trigraph H obtained after the vertical pair of the global output V^o is contracted. This has to happen in a 4-sequence by the first item of Lemma 18 applied to the fence of V^o. By Lemma 21, no contraction involving vertices of the vertical sets V_i^1, V_i^2 can have happened (for any $i \in [n]$). This is because there is a directed path in the propagation digraph $\mathcal{D}(G)$ from V^o to V_i^1 and V_i^2.

Thus by Lemmas 26 and 28, for every variable x_i ($i \in [n]$), at most one of the wire of $+x_i$ and the wire of $\neg x_i$ has been primed. We can define the corresponding truth assignment $\mathcal{A}$: x_i is set to true if the wire of $\neg x_i$ is *not* primed, and to false if instead the wire of $+x_i$ is *not* primed. Besides, by Lemma 21 applied to the contraction in V^o, every vertical pair of a clause-gadget output has been contracted. Then Lemma 31 implies that the vertical pair of at least one input of each clause gadget has been contracted. But such a vertical pair can be contracted only if it corresponds to a literal set to true by $\mathcal{A}$. For otherwise, the root of the wire of that literal cannot be contracted. This implies that $\mathcal{A}$ is a satisfying assignment.

If I is satisfiable, then G has twin-width at most 4. In what follows, when we write that we *can* contract a vertex, a set, or make a sequence of contractions, we mean that there is a partial 4-sequence that does the job. Let $\mathcal{A}$ be a satisfying assignment of I. We start by contracting "half" of the variable gadget of each x_i. We add a subscript matching the variable index to the vertex and set labels of Figure 8. For every $i \in [n]$, we contract vertices x_i and $\top_i$ together, and $T_i \cup F_i^\top$ to a single vertex v_i, if $\mathcal{A}$ sets variable x_i to true, and x_i and $\bot_i$ together, and $U_i \cup F_i^\bot$ to a single vertex v_i, if instead $\mathcal{A}$ sets x_i to false. By Lemma 29, this can be done by a partial 4-sequence.

Next we contract the wire of $+x_i$ if $\mathcal{A}(x_i)$ is true, or the wire of $\neg x_i$ if $\mathcal{A}(x_i)$ is false. This is done as described in the end of Section 4.3. We contract the vertical pair of the root of the wire into z_i (the red degree of v_i goes from 1 to 2). We then contract its fence by Lemma 19. We can now contract the resulting vertex with z_i. Inductively, we contract the children of the current vertical set to single vertices, in a similar fashion. As the propagation digraph has degree at most 3, this never creates a vertex of red degree more than 4.

At the leaves of the wire (the vertical sets $V_i^{\top,1}, V_i^{\top,2}$ or $V_i^{\bot,1}, V_i^{\bot,2}$), we make an exception, and only contract the vertical pair. We then contract, by Lemma 25, all the (non-already reduced) OR gadgets (involved in clause gadgets) at least one input of which has its vertical pair contracted. After that, applying Lemma 19, we finish the contraction of the OR inputs whose vertical pairs was contracted. Next we contract each output of a contracted OR gadget into a single vertex.

In those clauses where the third literal is not satisfied by $\mathcal{A}$, the output of the clause gadget is not contracted at that point. However, as $\mathcal{A}$ is a satisfying assignment, the output of the first OR gate of the gadget is contracted. We then contract each vertical set of the long chain leading to the input of the second OR gate. We only contract the vertical pair of that input, and contract the incident OR gadget, by Lemma 25. We finally proceed by contracting the input vertical set into a single vertex, and the output vertical set into a single vertex.

At this point, each output of the clause gadgets is contracted into a single vertex. The (*not* strongly) connected component C of the propagation digraph $\mathcal{D}(G)$ containing the global output V_o is acyclic and has total degree at most 3. All the vertical sets of C with in-degree 0 (ant out-degree 1) in $\mathcal{D}(G)$ are the clause outputs, which have been contracted to single vertices. Thus each vertical set of C can be contracted to single vertices, by repeated use of Lemma 19, followed by contracting the pendant vertex (resulting from the fence contraction) with its unique (red) neighbor. Note that this process terminates by contracting the half-guards V_i^1, V_i^2 (for every $i \in [n]$). The conditions of Lemma 30 are now satisfied, so we can finish contracting each variable gadget into two vertices that we further contract together. This results in a vertex of red degree 4.

We can then contract the wire of the literal that was set to false by $\mathcal{A}$. Again, we only contract the vertical pair of the inputs of OR gates that are not contracted yet. Then we contract those OR gadgets, and finish by fully contracting the vertical set of those inputs. We next contract each output of the newly contracted OR gates. We eventually contract into a single vertex each vertical set of the long chain in clause gadgets where this was not already done.

At this point, the current trigraph H has only red edges. Thus it can be interpreted as a graph, and we write *degree* instead or *red degree*. H has $4n + 3m$ vertices of degree 3, n vertices of degree 4, and the rest of its vertices have degree 2. Because we added long chains to separate what now corresponds to vertices of degree at least 3, H is an $(\geqslant L)$-subdivision of a graph on $5n + 3m$ vertices. Since $L = 2\lceil \log(5n + 3m) \rceil$, by Lemma 9, H finally admits a 4-sequence.

Abstract

We study the basic problem of assigning memoryless workers to tasks with dynamically changing demands. Given a set of w workers and a multiset $T \subseteq [t]$ of $|T| = w$ tasks, a memoryless worker-task assignment function is any function ϕ that assigns the workers $[w]$ to the tasks T based only on the current value of T. The assignment function ϕ is said to have switching cost at most k if, for every task multiset T, changing the contents of T by one task changes $\phi(T)$ by at most k worker assignments. The goal of memoryless worker task assignment is to construct an assignment function with the smallest possible switching cost.

In past work, the problem of determining the optimal switching cost has been posed as an open question. There are no known sub-linear upper bounds, and after considerable effort, the best known lower bound remains 4 (ICALP 2020).

We show that it is possible to achieve polylogarithmic switching cost. We give a construction via the probabilistic method that achieves switching cost $O(\log w \log(wt))$ and an explicit construction that achieves switching cost $\text{polylog}(wt)$. We also prove a super-constant lower bound on switching cost: we show that for any value of w, there exists a value of t for which the optimal switching cost is w. Thus it is not possible to achieve a switching cost that is sublinear *strictly* as a function of w.

Finally, we present an application of the worker-task assignment problem to a metric embeddings problem. In particular, we use our results to give the first low-distortion embedding from sparse binary vectors into low-dimensional Hamming space.

1 Introduction

The general problem of **distributed task allocation**, where a group of agents must collectively allocate themselves to tasks, has been studied in a wide variety of settings where the agents have varying degrees of communication, memory, knowledge of the system, and faultiness (see Georgiou and Shvartsman's book [15] for a survey). In this paper we are interested in the dynamic version of a distributed task allocation problem, that is, where the demands for each task are changing over time. Dynamic task allocation has been the focus of a great deal of both empirical and theoretical work in areas such as swarm robotics [20, 32, 26, 27, 21, 23, 34] and collective insect behavior [4, 31, 30, 33, 34].

Although there are many possible variations of the dynamic task allocation problem (in particular, in terms of what the capabilities of the workers are), most share a basic common structure. For positive integers w and t, there are w workers $1, 2, \ldots, w$, and there is a multiset $T \subseteq [t]$ of $|T| = w$ tasks.[1] The multiset T changes gradually over time: in each time step, one new task is added and one old task is removed. The goal is to maintain a dynamic assignment of workers $\{1, 2, \ldots, w\}$ to tasks T such that the **switching cost** is as small as possible, i.e., the number of worker-task assignments that change each time that T changes is bounded by some small quantity.

The goal of studying dynamic distributed task allocation is to answer the following question: to what degrees are various capabilities (i.e., memory, communication, knowledge of the system, computational power, etc.) needed for the workers to guarantee a small switching cost?

Motivated in part by applications to swarm robotics and collective ant behavior, recent work [33, 34] has focused on the question of what happens when workers are *completely memoryless*. At any given moment each worker $i \in \{1, 2, \ldots, w\}$ must determine which task $\tau \in T$ they are assigned to solely as a function of the current task multiset T; the workers do not remember anything about the past system states or worker assignments. Note that this memoryless-ness requirement is sufficiently strong that it also implies communicationless-ness – indeed, if workers cannot remember where they were in previous steps, and all that each worker knows is the current multiset of tasks, then there is no worker-specific information to be shared. Being memoryless and communicationless is especially important to settings where a worker might suffer a fault and thus "reboot"; in this case, the worker can determine which task they are assigned to without relying on what was stored in its memory and without knowledge of which tasks other workers are assigned to at the moment [34].

[1] If a task j appears $m_T(j)$ times in the multiset T, then one should think of the task as having a current demand of $m_T(j)$ workers. By writing $T \subseteq [t]$ we mean that the elements of multiset T are from $\{1, 2, \ldots, t\}$, but the multiplicity of each element can be arbitrarily large.

It remains an open question [34, 33] whether memoryless workers can achieve even a *sub-linear* switching cost. In this paper we show that, not only is sub-linear switching cost possible, but it is even possible to achieve a polylogarithmic switching cost of $\text{polylog}(wt)$. We also prove a lower bound for any algorithm that wishes to parameterize by only w and not t: for any w, if $t \gg w$ is sufficiently large, then the trivial switching cost of w becomes optimal.

Formal problem statement. Throughout this paper, we shall refer to the memoryless dynamic distributed task allocation problem simply as the **worker-task assignment problem**. Formally, the worker-task assignment problem is defined as follows. There are w workers $1, 2, \ldots, w$ and t tasks $1, 2, \ldots, t$. A **worker-task assignment function** ϕ is a function that takes as input a multiset T of w tasks, and produces an assignment of workers to tasks such that the number of workers assigned to a given task $\tau \in T$ is equal to the multiplicity of τ in T.

Two task multisets T_1, T_2 of size w are said to be *adjacent* if they agree on exactly $w - 1$ elements; that is, $|T_1 \setminus T_2| = |T_2 \setminus T_1| = 1$.[2] The switching cost between two adjacent task multisets T_1, T_2 of size w is defined as the number of workers whose assignment changes between $\phi(T_1)$ and $\phi(T_2)$. The **switching cost of** ϕ is defined to be the maximum switching cost over *all* pairs of adjacent task multisets. The goal of the worker-task assignment problem is to design a worker-task assignment function with the minimum possible switching cost.

Prior work in the memoryless setting. The optimal switching cost is trivially between 1 and w. Improving either of these bounds substantially has proven difficult, however.

Su, Su, Dornhaus, and Lynch [33] initiated the study of the worker-task assignment problem and observed that assigning the workers to tasks in numerical order achieves a switching cost of $\min(t - 1, w)$. They also proved a lower bound of 2 on switching cost, and showed a matching upper bound in the case where $w \leq 6$ and $t \leq 4$.

Subsequent work by Su and Wein [34], in ICALP 2020, pushed further on the lower-bound side of the problem. They proved that a switching cost of 2 is not always possible in general. They show that, if $t \geq 5$ and $w \geq 3$, then any worker-task assignment function must have switching cost at least 3; and if t is sufficiently large in terms of w (i.e., it is a tower of height $w - 1$), then the switching cost must be at least 4.

The bounds by [33] and [34] have until now remained state-of-the-art. It remains unknown whether the optimal switching cost is small (it could be as small as 4) or large (it could be as large as $\min(t - 1, w)$). And even achieving a lower bound of 4 on switching cost [34] has required a quite involved argument.

1.1 This paper

The contributions of this paper are twofold. First, we present significant progress on the worker-task assignment problem, resulting in both a polylogarithmic upper bound and a super-constant lower bound for the optimal switching cost – our results are interesting in part because of their use of randomized techniques to construct a deterministic assignment function. Second, we explore a natural connection between the worker-task assignment problem and the metric embedding problem of densification into Hamming space, and we transform our progress on the former into new results for the latter.

[2] Let $m_A(i)$ denote the number of times element i appears in multiset A. Then, for any two multisets A and B, we define multisets $A \setminus B$, $A \cup B$, and $A \cap B$ to be such that $m_{A \setminus B}(i) = \max(0, m_A(i) - m_B(i))$, $m_{A \cup B}(i) = \max(m_A(i), m_B(i))$, and $m_{A \cap B}(i) = \min(m_A(i), m_B(i))$, for every element i.

Results on worker-task assignment. Our first result establishes that it is possible to construct a worker-task assignment function with $O(\log w \log(wt))$ switching cost. This resolves the open question as to whether memoryless worker can allocate themselves to tasks with strong worst-case guarantees.

▶ **Theorem 1.** *There exists a worker-task assignment function that achieves switching cost* $O(\log w \log(wt))$.

Theorem 1 is proven via the probabilistic method and is thus non-constructive. By replacing random hash functions with strong dispersers, however, we show that one can construct an explicit worker-task assignment function with polylogarithmic switching cost.

▶ **Theorem 2.** *There is an explicit worker-task assignment function that achieves switching cost* $O(\text{polylog}(wt))$.

Both Theorems 1 and 2 continue to hold in the more general setting where the size of T changes over time. That is, T is permitted to be any multiset of $[t]$ of size w or smaller. Two task multisets T_1, T_2 of different sizes are considered adjacent if they satisfy $\big||T_1| - |T_2|\big| = 1$ and $|(T_1 \cup T_2) \setminus (T_1 \cap T_2)| = 1$. If $|T| < w$, then our worker-task assignment function assign workers $1, \ldots, |T|$ to tasks, and leaves workers $|T| + 1, \ldots, w$ unassigned.

Finally, from the lower bounds side, we prove that no algorithm can achieve sub-linear switching cost as a function of only w. Theorem 3 says that, if t is sufficiently larger than w, then for any worker-task assignment function, there must exist a pair of adjacent task multi-sets that forces *all* of the w workers to be reassigned. In the statement of the theorem, and throughout the paper, $\text{tow}(n)$ is defined to be a tower of twos of height n (i.e., the inverse of the $\log^*$ function).

▶ **Theorem 3.** *For every* w *and* $t \geq \text{tow}(\Omega(w))$*, every worker-task assignment function has switching cost* w.

This represents the first super-constant lower bound for the switching cost of a worker-task assignment function. Another way to think about the theorem is that for every t, there is some w for which any worker-task assignment function has switching cost at least $\Omega(\log^*(t))$. Therefore our bounds leave a gap between $\log^*$ and polylog in terms of dependence on t.

An application to metric embeddings: Densification into Hamming space. The problem of embedding one metric space $\mathcal{M}_1$ into another metric space $\mathcal{M}_2$ with small distortion has been widely studied in many contexts and has found many algorithmic applications [29, 7, 9, 8, 13, 2, 6, 10, 1, 5, 19, 24, 3, 22].

Bourgain [5] initiated the study of metric embeddings (into normed spaces) by showing that $O(\log |M|)$-distortion embeddings into ℓ_2 are possible for any space M. Much of the subsequent work has focused either on embeddings between exponentially large metric spaces [29, 7, 9, 8, 13, 2, 10, 3], or on embeddings with sub-logarithmic distortion [19, 24, 3, 10].

One natural question is that of **densification**: can one embed sparse vectors from a high-dimensional ℓ_1-space into a low-dimensional ℓ_1-space? That is, if V_n^k is the set of n-dimensional vectors with k non-zero entries, what is the smallest m for which V_n^k can be embedded into m-dimensional ℓ_1-space with low distortion? Charikar and Sahai [10] were the first to consider this problem, and showed how to achieve an output dimension of $m = O((k/\epsilon)^2 \log n)$ with distortion $1 + \epsilon$. They also showed how to apply densification to the related problem of embedding arbitrary tree metrics into low-dimensional ℓ_1-space [10]. Subsequently, Berinde et al. [3] used expander graphs in order to achieve $m = O(k \log(n/k)/\epsilon^2)$ with distortion

$1+\epsilon$. They then used their densification embedding as a tool to perform sparse signal recovery [3, 17, 16, 18]. Both of the known densification algorithms [10, 3] rely on linear sketches, in which each vector $\vec{x} \in V_n^k$ is mapped to a vector of the form $\sum_i x_i \vec{b_i}$ for some set of vectors $\vec{b_1}, \ldots, \vec{b_n}$.

The prior work on densification [10, 3] has focused on embedding into ℓ_1-space. In Section 5, we consider the same problem over Hamming space, where the distance between two vectors $\vec{x}, \vec{y}$ is given by $\mathrm{Ham}(\vec{x}, \vec{y}) = |\{i \mid x_i \neq y_i\}|$. Densification over Hamming space requires new techniques due to the fact that summations of vectors (and thus linear sketches) do not behave well in Hamming space.

Let $\mathcal{H}_n^k$ denote the set of n-dimensional binary vectors with k ones. Let $\mathcal{H}_k(n)$ denote the set of k-dimensional vectors with entries from $[n]$. We show that $\mathcal{H}_n^k$ can be embedded into $\mathcal{H}_k(n)$ with distortion $O(\log n \log k)$.

▶ **Theorem 4.** *There exists a map $\phi : \mathcal{H}_n^k \to \mathcal{H}_k(n)$ such that, for every $\vec{x}, \vec{y} \in \mathcal{H}_n^k$,*

$$\mathrm{Ham}(\vec{x}, \vec{y})/2 \leq \mathrm{Ham}(\phi(\vec{x}), \phi(\vec{y})) \leq O(\log n \log k)\, \mathrm{Ham}(\vec{x}, \vec{y}).$$

The densification embedding is a simple application of the worker-task assignment problem. In order to embed a vector $\vec{x} \in \mathcal{H}_n^k$ into $\mathcal{H}_k(n)$, we simply assign the workers $\{1, 2, \ldots, k\}$ to the task set $T = \{i \mid \vec{x}_i = 1\}$, and then we construct the vector $\vec{y}$ whose i-th coordinate denotes the task in T to which worker i is assigned. This map transforms the switching cost in the worker-task assignment problem into the distortion of the metric embedding.

The densification embedding is optimal in two senses. First, the target space of the embedding must have $\Omega(k)$ coordinates simply in order to allow for distances of $\Omega(k)$. Second, when $k \ll n$, any embedding of $\mathcal{H}_n^k$ to k-dimensional Hamming space must use $\Omega(\log n)$ bits per coordinate, simply in order so that the embedding is an injection. It is not clear whether the distortion achieved by our embedding is optimal, however, and it remains open whether smaller distortion can be achieved by allowing for a larger target-space dimension.

We remark that the basic relationship between worker-task assignment and densification embeddings problem has already implicitly been observed in previous work on lower bounds, as a way to formalize what makes the worker-task assignment problem difficult [34]. In contrast, here we are using the relationship as an avenue to obtain improved upper bounds for the densification problem.

2 Technical overview

This section gives an overview of the main technical ideas in the paper. For simplicity, the section will treat the task multiset $T \subseteq [t]$ as always being a set (rather than a multiset). As discussed in Section 3, one can formally reduce from the multiset case to the set case, at the cost of t being replaced with $t' = wt$.

2.1 A warmup: The random-permutation algorithm

We begin by describing a simple assignment function that we call the **random-permutation algorithm**. The random-permutation algorithm does not necessarily achieve small switching cost, but it does have the property that for any two adjacent task sets $T_1, T_2 \subseteq [t]$, the switching cost between T_1 and T_2 is $O(\log w)$ with high probability in w.

The algorithm. The random-permutation algorithm assigns to each worker $i \in [w]$ a random permutation

$$\sigma_i = \langle \sigma_i(1), \sigma_i(2), \ldots, \sigma_i(t) \rangle$$

of the numbers $[t]$. We think of worker i as **preferring** task $\sigma_i(j)$ over task $\sigma_i(j+1)$ for all $j \in [t-1]$.

Suppose we wish to assign workers to tasks T. The random-permutation algorithm assigns the workers $1, 2, \ldots, w$ to tasks $\tau_1, \tau_2, \ldots, \tau_w \in T$ one by one in order of worker ID, assigning worker i to the task that it most prefers out of the tasks in T that have not yet been assigned a worker.

For each $i \in [w]$, we define the ***i*-remainder tasks** to be the tasks $T \setminus \{\tau_1, \ldots, \tau_i\}$. That is, the i-remainder tasks are the tasks that remain after the first i workers are assigned. This means that worker $i+1$ is assigned to the i-remainder task that it most prefers.

Analyzing expected switching cost. Let $T_1, T_2 \subseteq [t]$ be adjacent task sets of size w. We begin by showing that the expected switching cost from T_1 to T_2 is $O(\log w)$.

Let r and s be such that $T_1 = (T_2 \cup \{r\}) \setminus \{s\}$. Let ψ_1 and ψ_2 denote the assignments produced by the random permutation algorithm for T_1 and T_2, respectively. Let A_i and B_i denote the set of i-remainder tasks during the constructions of ψ_1 and ψ_2, respectively.

The key to analyzing the random-permutation algorithm is to compare the i-remainder sets A_i and B_i for each $i \in [w]$. We claim that $|A_i \setminus B_i| \leq 1$ for all $i \in [w]$. We prove this by induction on i: suppose that $A_{i-1} = (B_{i-1} \cup \{a\}) \setminus \{b\}$, and suppose for contradiction that $|A_i \setminus B_i| \geq 2$. If either ψ_1 assigns worker i to task a, or ψ_2 assigns worker i to task b, then we would be guaranteed that $|A_i \setminus B_i| \leq 1$, a contradiction. Thus ψ_1 and ψ_2 must each assign worker i to a task in $A_{i-1} \cap B_{i-1}$. But this means that, in both assignments, worker i is assigned to the task in $A_{i-1} \cap B_{i-1}$ that worker i most prefers. Thus ψ_1 and ψ_2 assign worker i to the same task, again contradicting that $|A_i \setminus B_i| \geq 2$.

We now analyze the probability of ψ_1 and ψ_2 differing in their assignment of worker i. Since A_i contains at most one element a not in B_i, the probability that worker i prefers a over all elements in B_i is at most $1/|B_i| = 1/(w-i+1)$. Similarly, since B_i contains at most one element b not in A_i, the probability that worker i prefers b over all elements in A_i is at most $1/|A_i| = 1/(w-i+1)$. By the union bound, it follows that the probability of ψ_1 and ψ_2 assigning worker i to different tasks is at most $2/(w-i+1)$.

By linearity of expectation, the expected switching cost between T_1 and T_2 is at most

$$\sum_{i=1}^{w} \frac{2}{w-i+1} = O(\log w).$$

Why a union bound fails for worst-case switching cost. By using Chernoff-style bounds, one can modify the above analysis of the random-permutation algorithm to show that, with high probability in w (i.e., probability $1 - 1/\operatorname{poly} w$), the switching cost between T_1 and T_2 is $O(\log w)$.

On the other hand, achieving a switching cost of $O(\log w)$ for *all* pairs (T_1, T_2) of adjacent task sets presents a challenge because there are $\binom{w+1}{2}\binom{t}{w+1}$ such pairs that must be considered. When $w = t/2$, the number of distinct pairs (T_1, T_2) of adjacent task sets exceeds $2^t \geq 2^w$.

Thus, the probability bounds achieved by the random-permutation algorithm are nowhere near high enough to enable a union bound over all adjacent worker-set pairs. We call this the **union-bound magnitude issue**.

2.2 An algorithm with small switching cost

We now describe a randomized assignment algorithm $\mathcal{A}$ that, with high probability in t, achieves switching cost $O(\log w \log t)$ on *all* adjacent task-sets $T_1, T_2 \subseteq [t]$ of size w. That is, with high probability, $\mathcal{A}$ produces an assignment function satisfying the requirements of Theorem 1. The algorithm $\mathcal{A}$ is called the **multi-round balls-to-bins algorithm**.

The multi-round balls-to-bins algorithm essentially flips the approach taken by the random-permutation algorithm. One can think of the random-permutation algorithm as consisting of w phases in which each phase *deterministically* assigns exactly one worker to a task, and then the phases *probablistically* incur small switching cost. In contrast, the multi-round balls-to-bins algorithm consists of $O(\log w)$ phases, where each phase *probabilistically* assigns some number of workers to tasks, and each phase *deterministically* incurs small switching cost. Whereas the failure mode of the random-permutation algorithm is that a high-switching cost may occur, the failure mode of the multi-round balls-to-bins algorithm is that some workers may be left unassigned. As we shall see later, this distinction plays an important role in solving the union-bound magnitude issue.

Structure of the multi-round balls-to-bins algorithm. We begin with a succinct description of the algorithm $\mathcal{A}$. For each i from 1 to $\log_{1.1} w$, repeat the following hashing procedure $c \log t$ many times. Initialize a hash table consisting of $w/(1.1)^i$ bins and randomly hash each unassigned worker and each unassigned task into this table. For each bin that contains at least one worker and one task, assign the minimum worker in that bin to the minimum task in that bin.

In more detail, the algorithm $\mathcal{A}$ is the composition of $O(\log w)$ sub-algorithms $\mathcal{A}_1, \mathcal{A}_2, \ldots$. Each of $\mathcal{A}_1, \mathcal{A}_2, \ldots$ are **partial-assignment** algorithms, meaning that $\mathcal{A}_i$ assigns some subset of the workers to some subset of the tasks in T, possibly leaving workers and tasks unassigned. Note that the input to algorithm $\mathcal{A}_i$ is the set of workers/tasks that remain unassigned by $\mathcal{A}_1, \ldots, \mathcal{A}_{i-1}$. Thus one can think of the input to $\mathcal{A}_i$ as being a pair (W, T) where $W \subseteq [w]$ is a set of workers, $T \subseteq [t]$ is a set of tasks, and $|W| = |T|$.

The algorithm $\mathcal{A}_1$'s responsibility is to assign enough workers to tasks so that at most $w/1.1$ workers remain unassigned. Algorithm $\mathcal{A}_2$ is then executed on the remaining (i.e., not-yet-assigned) workers and tasks, and is responsible for assigning enough workers to tasks so that at most $w/(1.1)^2$ workers remain unassigned. Continuing like this, algorithm $\mathcal{A}_i$ is executed on the workers/tasks that remain unassigned by all of $\mathcal{A}_1, \ldots, \mathcal{A}_{i-1}$, and is responsible for assigning enough workers to tasks that at most $r_i = w/(1.1)^i$ workers in W remain unassigned.

Each of the $\mathcal{A}_i$'s are randomized algorithms, meaning that they have some probability of failure. The failure mode for $\mathcal{A}_i$ is *not* high-switching cost, however. In fact, as we shall see later, each $\mathcal{A}_i$ deterministically contributes at most $O(\log w)$ to the switching cost. Instead, the way in which $\mathcal{A}_i$ can fail is that it may leave more than r_i workers unassigned. This means that the failure mode for the full algorithm $\mathcal{A}$ is that it may fail to assign all of the workers in W to tasks in T.

Applying the probabilistic method to $\mathcal{A}_1, \mathcal{A}_2, \ldots$. Before describing the partial-assignment algorithms $\mathcal{A}_i$ in detail, we first describe how our analysis of algorithm $\mathcal{A}$ overcomes the union-bound magnitude issue.

Recall that each algorithm $\mathcal{A}_i$ is responsible for reducing the number of remaining workers to $r_i = w/(1.1)^i$. We will later see that each $\mathcal{A}_i$ has a failure probability p_i that is a function of r_i and t, namely,

$$p_i = \frac{1}{t^{\Omega(r_i)}}.$$

As i grows, the failure probability p_i of $\mathcal{A}_i$ becomes larger, making it impossible to union-bound over exponentially many pairs of task sets T_1, T_2.

An important insight is that, if all of $\mathcal{A}_1, \ldots, \mathcal{A}_{i-1}$ succeed (i.e., they each assign the number of workers that they are responsible for assigning) then the number of workers and tasks that $\mathcal{A}_{i-1}$ is executed on is only $O(r_i)$. That is, if we think of the inputs to $\mathcal{A}_i$ as being pairs (W, T) where $W \subseteq [w]$ is a set of workers and $T \subseteq [t]$ is a set of tasks, the set of inputs (W, T) that algorithm $\mathcal{A}_{i-1}$ must succeed on is only the inputs for which $|W| = |T| \leq O(r_i)$. The number of such inputs is at most $t^{O(r_i)}$. In other words, even though the failure probability p_i of algorithm $\mathcal{A}_i$ increases with i, the number of inputs over which we must apply a union bound decreases. By a union bound, we can deduce that $\mathcal{A}_i$ has a high probability in t of succeeding on all relevant inputs (W, T). Combining this analysis over all of the partial-assigning algorithms $\mathcal{A}_1, \mathcal{A}_2, \ldots$, we get that the full assignment algorithm $\mathcal{A}$ also succeeds with high probability in t. In particular, we have proven that there exists a deterministic assignment function with the desired switching cost, and that such a function can be obtained with high probability by the randomized algorithm $\mathcal{A}$.

Designing $\mathcal{A}_i$. Each algorithm $\mathcal{A}_i$ is a composition of $\Theta(\log t)$ algorithms $\mathcal{A}_{i,1}, \mathcal{A}_{i,2}, \mathcal{A}_{i,3}, \ldots$, each of which individually is a partial assignment algorithm.

Each algorithm $\mathcal{A}_{i,j}$ takes a simple balls-in-bins approach to assigning some subset of the remaining workers to some subset of the remaining tasks.

In particular, $\mathcal{A}_{i,j}$ places the workers into bins $1, 2, \ldots, r_i$ by hashing each worker to a bin (using a random function from $[w]$ to $[r_i]$). Similarly, the tasks are placed into bins $1, 2, \ldots, r_i$ by hashing each task to a bin. If a bin b contains both at least one worker and at least one task, then the smallest-numbered worker in bin b is assigned to the smallest-number task in bin b.

Note that each of the algorithms $\mathcal{A}_{i,1}, \mathcal{A}_{i,2}, \mathcal{A}_{i,3}, \ldots$ are identical copies of one-another, except using different random bits. Also note all of the $\mathcal{A}_i$'s are defined in the same way as each other, except the number of bins hashed to decreases as i increases. As we shall see shortly, the reason for having $\mathcal{A}_i$ consist of $\Theta(\log t)$ sub-algorithms is to enable probability amplification later in the analysis.

Bounding the switching cost. The partial assignment algorithms $\mathcal{A}_{i,j}$ are designed to satisfy two essential properties, which we prove formally in the full proof. These two properties can then be combined to bound the switching cost of the full algorithm $\mathcal{A}$.

Compatibility: Let $I_1 = (W_1, T_1)$ and $I_2 = (W_2, T_2)$ be inputs to $\mathcal{A}_{i,j}$. Suppose I_1 and I_2 are **unit distance**, meaning that

$$|W_1 \setminus W_2| + |W_2 \setminus W_1| + |T_1 \setminus T_2| + |T_2 \setminus T_1| \leq 2.$$

Let $I_1' = (W_1', T_1')$ and $I_2' = (W_2', T_2')$ be the workers and tasks that remain unassigned when $\mathcal{A}_{i,j}$ is executed on each of I_1 and I_2, respectively. Then I_1' and I_2' are guaranteed to also be unit-distance.

Low Switching Cost: The switching cost of $\mathcal{A}_{i,j}$ is $O(1)$. That is, if $I_1 = (W_1, T_2)$ and $I_2 = (W_2, T_2)$ are inputs to $\mathcal{A}_{i,j}$, and I_1 and I_2 are unit-distance, then the worker-task assignments made by $\mathcal{A}_{i,j}$ on each of I_1 and I_2 differ by at most $O(1)$ assignments.

Consider two adjacent task sets T_1 and T_2. When we execute $\mathcal{A}$ on T_1 and T_2, respectively, we use $I_1^{i,j}$ and $I_2^{i,j}$, respectively, to denote the worker/task input that are given to partial-assignment algorithm $\mathcal{A}_{i,j}$.

The Compatibility property of the $\mathcal{A}_{i,j}$'s guarantees by induction that, for each $\mathcal{A}_{i,j}$ the worker/task inputs $I_1^{i,j}$ and $I_2^{i,j}$ are unit-distance (or zero-distance). The Low-Switching-Cost property then guarantees that each $\mathcal{A}_{i,j}$ contributes at most $O(1)$ to the switching cost of $\mathcal{A}$. Since there are $O(\log t \log w)$ $\mathcal{A}_{i,j}$'s, this bounds the total switching cost of $\mathcal{A}$ by $O(\log t \log w)$.

Deriving the success probabilities. Next we analyze the probability of $\mathcal{A}_i$ failing on a given worker/task input (W, T). Recall that the only way in which $\mathcal{A}_i$ might fail is if more than r_i workers remain unassigned after $\mathcal{A}_i$ finishes. Additionally, since we need only consider cases where $\mathcal{A}_{i-1}$ succeeds, we can assume that $r_i \le |W|, |T| \le 1.1 r_i$.

Let q denote the number of workers that $\mathcal{A}_{i,1}$ assigns to tasks. Given that $r_i \le |W|, |T| \le 1.1 r_i$, a simple analysis of $\mathcal{A}_{i,1}$ shows that $\mathbb{E}[q] \ge r_i/5$. On the other hand, using McDiarmid's inequality, one can perform a balls-in-bins style analysis in order to show that $\Pr[\mathbb{E}[q] - q > r_i/10] \le 2^{-\Omega(r_i)}$. This means that $\mathcal{A}_{i,1}$ has probability at most $2^{-\Omega(r_i)}$ of leaving more than r_i workers unassigned.

In order for $\mathcal{A}_i$ to fail (i.e., $\mathcal{A}$ leaves more than r_i workers unassigned), *all* of sub-algorithms $\mathcal{A}_{i,1}, \mathcal{A}_{i,2}, \ldots$ would have to individually fail. Since there are $\Theta(\log t)$ sub-algorithms, the probability of them all failing is

$$p_i = 2^{-\Omega(r_i \log t)} = t^{-\Omega(r_i)}.$$

This allows us to apply the probabilistic method to the $\mathcal{A}_i$'s in order to bound the probability of any $\mathcal{A}_i$ failing on any input, as desired.

An explicit construction with polylogarithmic switching cost. The multi-round balls-to-bins algorithm gives a non-explicit approach to constructing an assignment function with low switching cost. The approach is non-explicit because it relies on the probabilistic method.

In the full version of the paper[3] we show how to obtain an explicit algorithm with switching cost polylog wt. The basic idea is to replace random hash functions, used to place workers and tasks into bins, with functions obtained from pseudorandom objects called strong dispersers. Instead of trying a number of random hash functions within the $\mathcal{A}_{i,j}$'s, we instead iterate over all of the hash functions from a small family given by a strong disperser [28].

2.3 A lower bound on switching cost

Define $s_{w,t}$ to be the optimal switching cost for assignment functions that assign workers $1, 2, \ldots, w$ to multisets of w tasks from the universe $[t]$. The upper bounds in this paper establish that $s_{w,t} \le O(\log w \log(wt))$. It is natural to wonder whether smaller bounds can be achieved, and in particular, whether a small switching cost that depends only on w can be achieved.

It trivially holds that $s_{w,t} \le w$. We show that when t is sufficiently large relative to w, there is a matching lower bound of $s_{w,t} \ge w$. In fact, our lower bound only uses the evaluation of the assignment function on sets (as opposed to multisets).

Consider an assignment function ϕ that, given a multiset T of tasks with elements from $[t]$ of w tasks, produces an assignment of workers $[w]$ to tasks T. Our goal will be to find tasks $\tau_1 < \tau_2 < \cdots < \tau_{w+1}$ such that if $\phi(\{\tau_1, \ldots, \tau_w\})$ assigns worker i to task $\tau_{\pi(i)}$ for some permutation π of $[w]$, then $\phi(\{\tau_2, \ldots, \tau_{w+1}\})$ assigns worker i to task $\tau_{\pi(i)+1}$. The existence of such a configuration immediately implies that ϕ has switching cost w.

[3] https://arxiv.org/abs/2008.10709

We use an application of the hypergraph Ramsey theorem to show that, when t is large enough, a configuration of the type described in the above paragraph must exist. Let $K_t^{(w)}$ denote the complete w-uniform hypergraph on t vertices. This is just the set of w-element subsets of $[t]$, which correspond to sets of tasks. For each hyperedge $T = \{\tau_1, \ldots, \tau_w\}$, where $1 \leq \tau_1 < \cdots < \tau_w \leq t$, we color the hyperedge T by a color π where $\tau_{\pi(i)}$ is the task assigned to worker i.

This gives a coloring of the hyperedges of $K_t^{(w)}$ by $w!$ colors, each color being a permutation of $[w]$. By the hypergraph Ramsey theorem, if t is large enough in terms of w, there must exist $w+1$ vertices $\tau_1, \ldots, \tau_{w+1}$ so all the hyperedges formed by the vertices have the same color π. By examining the hyperedges $\{\tau_1, \ldots, \tau_w\}$ and $\{\tau_2, \ldots, \tau_{w+1}\}$, it follows that $\phi(\{\tau_1, \ldots, \tau_w\})$ assigns each worker i to task $\tau_{\pi(i)}$ and that $\phi(\{\tau_2, \ldots, \tau_{w+1}\})$ assigns each worker i to task $\tau_{\pi(i)+1}$, as desired.

3 Achieving switching cost $O(\log w \log(wt))$

In this section, we prove the following theorem.

▶ **Theorem 1.** *There exists a worker-task assignment function that achieves switching cost* $O(\log w \log(wt))$.

We demonstrate the existence of such a function via the probabilistic method, showing that there is a randomized construction that produces a low-switching cost worker-task assignment function with nonzero probability. In the full version of the paper, we also show how to derandomize the construction at the cost of a few extra log factors.

From multisets to sets. We begin by showing that, without loss of generality, we can restrict our attention to task multisets T that are sets (rather than multisets). We reduce from the multiset version of the problem with w workers and t tasks to the set version of the problem with w workers and wt tasks.

▶ **Lemma 5.** *Define $n = wt$. Let ϕ be a worker-task assignment function that assigns workers $[w]$ to task sets $T \subseteq [n]$ (note that ϕ is defined only on task* sets *T, and not on multisets). Let s be the switching cost of ϕ (considering only pairs of adjacent subsets of $[n]$, rather than adjacent sub-multisets). Then there exists a worker-task assignment function ϕ' assigning workers $[w]$ to task multisets $T \subseteq [t]$, such that ϕ' also has switching cost s.*

Proof. When discussing the assignment function ϕ, we think of its input task-set T as consisting of elements from $[t] \times [w]$ rather than elements of $[tw]$.

With this in mind, we construct ϕ' as follows. Given a task multiset $T \subseteq [t]$, define the set $\mathbf{S}(T) \subseteq [t] \times [w]$ to be $\bigcup_{i=1}^{t} \{(i,1), \ldots, (i, m_T(i))\}$, where $m_T(i)$ is the multiplicity of i in T. The worker-task assignment ϕ produces some bijection $\psi_{\mathbf{S}(T)} : [w] \to \mathbf{S}(T)$. Similarly, ϕ' should produce some bijection $\psi'_T : [w] \to T$. This bijection is defined naturally by projection: if $\psi_{\mathbf{S}(T)}$ assigns worker j to task (i, x), let ψ'_T assign worker j to task i.

We now compute the switching cost of ϕ'. Let T and T' be two adjacent task multisets, so $T' = T \cup \{a\} \setminus \{b\}$ for some $a, b \in [t]$. Then $\mathbf{S}(T') = \mathbf{S}(T) \cup \{(a, m_T(a)+1)\} \setminus \{(b, m_T(b))\}$, and so $\mathbf{S}(T')$ is adjacent to $\mathbf{S}(T)$. Since ϕ has switching cost s, $\psi_{\mathbf{S}(T)}$ and $\psi_{\mathbf{S}(T')}$ agree on $w - s$ workers. By construction, ψ'_T and $\psi'_{T'}$ must agree on these $w - s$ workers as well, and so it too has switching cost at most s. ◀

In the remainder of the section, we will make the assumption that T is a subset of $[n]$, and we will show how to design an assignment function with switching cost $O(\log w \log n)$ on all pairs of adjacent subsets of $[n]$. By Lemma 5, setting $n = wt$ then implies Theorem 1.

Designing an assignment function as an algorithm. It will be helpful to think of the function we construct for assigning workers to tasks as an algorithm $\mathcal{A}$, which we call the **multi-round balls-to-bins algorithm**. The algorithm $\mathcal{A}$ takes as input a set $T \subseteq [n]$ of tasks with $|T| = w$ and must produce a bijection from the workers $[w]$ to T.

The algorithm constructs this bijection in stages. Each stage is what we call a **partial assignment algorithm**, which takes as input the current sets of workers and tasks that have yet to be matched and assigns some subset of these workers to some subset of the tasks. Formally, we define a partial assignment algorithm to be any function ψ which accepts as input any pair of sets $T \subseteq [n], W \subseteq [w]$ with $|T| = |W|$ and produces a matching between some subset of T and some subset of W. After applying ψ to (T, W), there may remain some unmatched elements $T' \subseteq T$, $W' \subseteq W$. We call (T, W) the **worker-task input** to ψ and (T', W') the **worker-task output**. Since a matching must remove exactly as many elements from T as it does from W, we must also have $|W'| = |T'|$. Consequently, there is a natural notion of the **composition** of two partial assignment algorithms: the composition $\psi' \circ \psi$ applies ψ and then ψ', letting the worker-task output of ψ be the worker-task input to ψ'.

The algorithm. We recall the description of the algorithm $\mathcal{A}$. For each i from 1 to $c \log w$, repeat the following hashing procedure $c \log n$ many times. Initialize a hash table consisting of $w/(1.1)^i$ bins and randomly hash each unassigned worker and each unassigned task into this table. For each bin that contains at least one worker and one task, assign the minimum worker in that bin to the minimum task in that bin.

In more detail, our algorithm $\mathcal{A}$ is the composition of $\log_{1.1} w$ partial-assignment algorithms,

$$\mathcal{A} = \mathcal{A}_1 \circ \mathcal{A}_2 \circ \cdots \circ \mathcal{A}_{\log_{1.1} w}.$$

Let c be a large positive constant. Each $\mathcal{A}_i$ is itself the composition of $c \log n$ partial-assignment algorithms,

$$\mathcal{A}_i = \mathcal{A}_{i,1} \circ \mathcal{A}_{i,2} \circ \cdots \circ \mathcal{A}_{i,c \log n}.$$

Designing the parts. Each $\mathcal{A}_{i,j}$ assigns workers to tasks using what we call a $w/(1.1)^i$**-bin hash**, which we define as follows.

For a given parameter k, a k**-bin hash** selects functions $h_1 : [w] \to [k]$ and $h_2 : [n] \to [k]$ independently and uniformly at random. For each worker $\omega \in [w]$, we say that ω is **assigned** to bin $h_1(\omega)$. Similarly, for each $\tau \in [n]$ we say τ is assigned to $h_2(\tau)$. These functions are then used to construct a partial assignment. Given a worker-task input (W, T), we restrict our attention to only the assignments of workers in W and tasks in T. In each bin $\kappa \in [k]$ with at least one worker and one task assigned, match the smallest such worker to the smallest such task. Importantly, once h_1 and h_2 are fixed, the algorithm $\mathcal{A}_{i,j}$ uses this same pair of hash functions for every worker-task input, which (as we will see later) is what allows it to make very similar assignments for similar inputs and achieve low switching cost.

We set each $\mathcal{A}_{i,j}$ to be an independent random instance of the k-bin hash, where $k = w/(1.1)^i$. Formally, this means that the algorithm $\mathcal{A} = \mathcal{A}_{1,1} \circ \cdots \circ \mathcal{A}_{\log_{1.1} w, c \log n}$ is a random variable whose value is a partial-assignment function. Our task is thus to prove that, with non-zero probability, $\mathcal{A}$ fully assigns all workers to tasks and has small switching cost.

Analyzing the algorithm. In Section 3.2, we show that $\mathcal{A}$ *deterministically* has switching cost $O(\log w \log n)$.

Although $\mathcal{A}$ always has small switching cost, the algorithm is *not* always a legal worker-task assignment function. This is because the algorithm may sometimes act as a *partial* worker-task assignment function, leaving some workers and tasks unassigned.

In Section 3.1, we show that with probability greater than 0 (and, in fact, with probability $1 - 1/\operatorname{poly} n$), the algorithm $\mathcal{A}$ succeeds at fully assigning workers to tasks for *all* worker-task inputs (W, T). Theorem 1 follows by the probabilistic method.

3.1 Bounding the probability of failure

Call a partial-assignment algorithm ψ **fully-assigning** if for every worker/task input (W, T), ψ assigns all of the workers in W to tasks in T. That is, ψ never leaves workers unassigned.

▶ **Proposition 6.** *The multi-round balls-to-bins algorithm $\mathcal{A}$ is fully-assigning with high probability in n. That is, for any polynomial $p(n)$, if the constant c used to define $\mathcal{A}$ is sufficiently large, then $\mathcal{A}$ is fully-assigning with probability at least $1 - O(1/p(n))$.*

Proposition 6 tells us that with high probability in n, $\mathcal{A}$ succeeds at assigning all workers on *all* inputs. We remark that this is a much stronger statement than saying that $\mathcal{A}$ succeeds with high probability in n on a *given* input (W, T).

The key to proving Proposition 6 is to show that each $\mathcal{A}_i$ performs what we call $\big(w/(1.1)^i\big)$**-halving**. A partial-assignment function ψ is said to perform k**-halving** if for every worker/-task input (W, T) of size at most $1.1k$, the worker-task output (W', T') for $\psi(W, T)$ has size at most k.

If every $\mathcal{A}_i$ performs $w/(1.1)^i$-halving, then it follows that

$$\mathcal{A}_1 \circ \cdots \circ \mathcal{A}_{\log_{1.1} w}$$

is a fully-assigning algorithm. Thus our task is to show that each $\mathcal{A}_i$ performs $w/(1.1)^i$-halving with high probability in n.

We begin by analyzing the k-bin hash on a given worker/task input (W, T).

▶ **Lemma 7.** *Let ψ a randomly selected k-bin hash. Let (W, T) be a worker/task input satisfying $|W| = |T| \leq 1.1k$, and let (W', T') be the worker/task output of $\psi(W, T)$. The probability that (W', T') has size k or larger is $2^{-\Omega(k)}$.*

Proof. We may assume that $|W| = |T| \geq k$, else the conclusion is trivially true. Let X be the random variable denoting the number of worker/task assignments made by $\psi(W, T)$. Equivalently, X counts the number of bins to which at least one worker is assigned and at least one task is assigned – call these the **active bins**. We will show that $\Pr[X < \frac{k}{8}] \leq 2^{-\Omega(k)}$. Since $|W| = |T| \leq 1.1k$, this immediately implies that $|W'| = |T'| \leq 1.1k - 0.125k \leq k$ with probability $1 - 2^{-\Omega(k)}$, as desired.

We begin by computing $\mathbb{E}[X]$. For each bin $j \in [k]$, the probability no workers are assigned to bin j is $(1 - 1/k)^{|W|} \leq (1 - 1/k)^k \leq 1/e$. Similarly, the probability that no tasks are assigned to bin j is at most $(1 - 1/k)^{|T|} \leq 1/e$. The probability of bin j being active is therefore at least $1 - 2/e \geq 1/4$. By linearity of expectation, $\mathbb{E}[X] \geq k/4$.

Next we show that the random variable X is tightly concentrated around its mean. Because the bins that are active are not independent of one-another, we cannot apply a Chernoff bound. Instead, we employ McDiarmid's inequality:

▶ **Theorem 8** (McDiarmid '89 [25]). *Let $A_1, \ldots, A_m$ be independent random variables over an arbitrary probability space. Let F be a function mapping $(A_1, \ldots, A_m)$ to $\mathbb{R}$, and suppose F satisfies,*

$$\sup_{a_1, a_2, \ldots, a_m, \overline{a_i}} |F(a_1, a_2, \ldots, a_{i-1}, a_i, a_{i+1}, \ldots, a_m) - F(a_1, a_2, \ldots, a_{i-1}, \overline{a_i}, a_{i+1}, \ldots, a_m)| \leq R,$$

for all $1 \leq i \leq m$. That is, if $A_1, A_2, \ldots, A_{i-1}, A_{i+1}, \ldots, A_m$ are fixed, then the value of A_i can affect the value of $F(A_1, \ldots, A_m)$ by at most R. Then for all $S > 0$,

$$\Pr[|F(A_1, \ldots, A_m) - \mathbb{E}[F(A_1, \ldots, A_m)]| \geq R \cdot S] \leq 2e^{-2S^2/m}.$$

The number of active bins X is a function of at most $2.2 \cdot k$ independent random variables (namely, the hashes $h_1(\omega)$ for each $\omega \in W$ and the hashes $h_2(\tau)$ for each $\tau \in T$). Each of these random variables can individually change the number of active bins by at most one. It follows that we can apply McDiarmid's inequality with $R = 1$ and $m = 2.2k$. Taking $S = k/8$, we obtain

$$\Pr[|X - \mathbb{E}[X]| \geq k/8] \leq e^{-\Omega(k)}.$$

Since $\mathbb{E}[X] \geq k/4$, we have that $\Pr[X < k/8] \leq e^{-\Omega(k)}$, which completes the proof of the lemma. ◀

Our next lemma shows that each $\mathcal{A}_i$ is k-halving with high probability in n, where $k = w/(1.1)^i$.

▶ **Lemma 9.** *Let $\psi_1, \ldots, \psi_{c \log n}$ be independent random k-bin hashes, and let $\psi = \psi_1 \circ \cdots \circ \psi_{c \log n}$. With high probability in n, ψ is k-halving. That is, every worker-task input (W, T) with $|W| = |T| \leq 1.1k$ has a worker task output (W', T') with $|W'| = |T'| \leq k$.*

Proof. Fix an arbitrary worker-task input (W, T) with $|W| = |T| \leq 1.1k$. Let (W_i, T_i) denote the worker-task output after applying the first i rounds, $\psi_1 \circ \cdots \circ \psi_i$. Let p_i denote the probability that $|W_i| = |T_i| > k$.

First, we observe that $p_i \leq e^{-\Omega(k)} p_{i-1}$ for all $i > 1$. Indeed, for $|W_i| = |T_i| > k$, we must necessarily have $|W_{i-1}| = |T_{i-1}| > k$, which occurs with probability p_{i-1}, but in this situation, the probability that ψ_i produces a worker-task output of size greater than k is a further $e^{-\Omega(k)}$ by Lemma 7.

The probability that ψ fails to reduce the size of (W, T) to k or smaller is thus at most

$$p_{c \log n} \leq e^{-\Omega(ck \log n)} \leq n^{-\Omega(ck)}, \tag{1}$$

where c is treated as a parameter.

On the other hand, the number of possibilities for input pairs (W, T) satisfying $|W| = |T| \leq 1.1k$ is

$$\sum_{j=0}^{1.1k} \binom{w}{j} \binom{n}{j} \leq 1.1k \cdot w^{1.1k} n^{1.1k} \leq n^{O(k)}. \tag{2}$$

Combining (1) and (2), the probability that there exists *any* pair (W, T) of size $1.1k$ or smaller which fails to have its size reduced to k or smaller is at most $n^{O(k) - c\Omega(k)}$. If c is selected to be a sufficiently large constant, then it follows that ψ performs k-halving with probability at least $1 - n^{-\Omega(k)}$. ◀

We now prove Proposition 6.

Proof of Proposition 6. By Lemma 9, each algorithm $\mathcal{A}_i$ is $\big(w/(1.1)^i\big)$-halving with high probability in n. By a union bound, it follows that all of $\mathcal{A}_i \in \{\mathcal{A}_1, \ldots, \mathcal{A}_{\log_{1.1} w}\}$ are $\big(w/(1.1)^i\big)$-halving with high probability in n. If this occurs, then

$$\mathcal{A} = \mathcal{A}_1 \circ \cdots \circ \mathcal{A}_{\log_{1.1} w}$$

is fully-assigning, as desired. ◀

3.2 Bounding the switching cost

Recall that two worker/task inputs (W_1, T_1) and (W_2, T_2) are said to be **unit distance** if

$$W_1 \setminus W_2| + |W_2 \setminus W_1| + |T_1 \setminus T_2| + |T_2 \setminus T_1| \leq 2.$$

A partial-assignment algorithm ψ is **s-switching-cost bounded** if for all unit-distance pairs of worker/task inputs (W_1, T_1) and (W_2, T_2), the set of assignments made by $\psi(W_1, T_1)$ deterministically differs from the set of assignments made by $\psi(W_2, T_2)$ by at most s.

In this section, we prove the following proposition.

▶ **Proposition 10.** *The multi-round balls-to-bins algorithm is $O(\log w \log n)$-switching-cost bounded.*

We begin by showing that each of the algorithms $\mathcal{A}_{i,j}$ are $O(1)$-switching-cost bounded.

▶ **Lemma 11.** *For any k, the k-bin hash algorithm is $O(1)$-switching-cost bounded.*

Proof. Let ψ denote the k-bin hash algorithm. Consider unit-distance pairs of worker/task inputs (W_1, T_1) and (W_2, T_2). Changing W_1 to W_2 can change the assignments made by ψ for at most a constant number of bins. Similarly changing T_1 to T_2 can change the assignments made by ψ for at most a constant number of bins. Thus $\psi(W_1, T_1)$ differs from $\psi(W_2, T_2)$ by at most $O(1)$ assignments. ◀

Recall that $\mathcal{A}$ is the composition of the $O(\log w \log n)$ partial-assignment algorithms $\mathcal{A}_{i,j}$'s. The fact that each $\mathcal{A}_{i,j}$ is $O(1)$-switching-cost bounded does not directly imply that $\mathcal{A}$ is $O(\log w \log n)$-switching-cost bounded, however, because switching cost does not necessarily interact well with composition. In order to analyze $\mathcal{A}$, we show that each $\mathcal{A}_{i,j}$ satisfies an additional property that we call being composition-friendly.

A partial-assignment algorithm ψ is **composition-friendly**, if for all unit-distance pairs of worker/task inputs (W_1, T_1) and (W_2, T_2), the corresponding worker/task outputs (W_1', T_1') and (W_2', T_2') are also unit-distance.

Lemma 12 shows that each $\mathcal{A}_{i,j}$ is composition-friendly.

▶ **Lemma 12.** *For any k, the k-bin hash is composition-friendly.*

Proof. Although the algorithm ψ is formally only defined on input (W, T) for which $|W| = |T|$, we will abuse notation here and consider ψ even on worker/task input (W, T) satisfying $|W| \neq |T|$.[4] Define the **difference-score** of a pair of worker/task inputs $I_1 = (W_1, T_1), I_2 = (W_2, T_2)$ to be the quantity

$$d(I_1, I_2) = |W_1 \setminus W_2| + |W_2 \setminus W_1| + |T_1 \setminus T_2| + |T_2 \setminus T_1|.$$

[4] Indeed, the definition of the k-bin hash does not require a worker-task input with $|W| = |T|$. The only reason we require this equality in general is to simplify calculations, as in practice the algorithm will only be run on worker-task inputs of equal size.

We will show the stronger statement that the difference-score $d(O_1, O_2)$ of the corresponding worker/task outputs $O_1 = (W_1', T_1'), O_2 = (W_2', T_2')$ satisfies

$$d(O_1, O_2) \leq d(I_1, I_2). \tag{3}$$

It suffices to consider only two special cases: the case in which $W_2 = W_1 \cup \{\omega\}$ for some worker ω and $T_2 = T_1$; and the case in which $T_2 = T_1 \cup \{\tau\}$ for some task τ and $W_2 = W_1$. Iteratively applying these two cases to transform I_1 into I_2 implies inequality 3.

For this purpose, the roles of W and T are identical, so suppose without loss of generality that $W_2 = W_1 \cup \{\omega\}$ for some worker ω and $T_2 = T_1$. Recall that the assignment of workers and tasks to buckets is determined by some hash functions h_1, h_2 and in particular is the same whether we input W_1 or W_2. We first assign (only) the elements of W_1 and T_1 to their respective buckets, and then look at how including the assignment of ω changes the worker-task output. If h_1 assigns ω to either a bin with no tasks or a bin which already has some lexicographically smaller worker, then we will have $W_2' = W_1' \cup \{w\}$ and $T_2' = T_1'$. If h_1 assigns worker ω to a bin with no other workers and at least one task, we let the smallest such task be τ and see $W_2' = W_1'$ and $T_2' = T_1' \setminus \{\tau\}$. Finally, if h_1 assigns ω to a bin with only larger workers and at least one task, we let the minimal such worker be γ, and we see $W_2' = W_1' \cup \{\gamma\}$ and $T_2' = T_1'$. In all three cases, $d(O_1, O_2) = 1$, as desired. ◀

Next, we will show that composing composition-friendly algorithms has the effect of summing switching costs.

▶ **Lemma 13.** *Suppose that partial-assignment algorithms $\psi_1, \psi_2, \ldots, \psi_k$ are all composition-friendly, and that each ψ_i is s_i-switching-cost bounded. Then $\psi_1 \circ \psi_2 \circ \cdots \circ \psi_k$ is composition-friendly and is $(\sum_i s_i)$-switching-cost-bounded.*

Proof. By induction, it suffices to prove the lemma for $k = 2$. Let $I_1 = (W_1, T_1)$ and $I_2 = (W_2, T_2)$ be unit-distance worker/task inputs.

For $i \in \{1, 2\}$, let $I_i' = (W_i', T_i')$ be the worker/task output for $\psi_1(W_i, T_i)$, and let $I_i'' = (W_i'', T_i'')$ be the worker/task output for $\psi_2(W_i', T_i')$.

Since ψ_1 is composition friendly, its outputs I_1' and I_2' are unit distance. Since I_1' and I_2' are unit distance, and since ψ_2 is composition friendly, the outputs I_1'' and I_2'' of ψ_2 are also unit distance. Thus $\psi_1 \circ \psi_2$ is composition friendly.

Since the inputs I_1 and I_2 to ψ_1 are unit-distance, $\psi_1(I_1)$ and $\psi_1(I_2)$ differ in at most s_1 worker-task assignments. Since the inputs I_1' and I_2' to ψ_2 are also unit distance, $\psi_2(I_1')$ and $\psi_2(I_2')$ differ in at most s_2 worker-task assignments. Thus the composition $\psi_1 \circ \psi_2$ is $(s_1 + s_2)$-switching-cost bounded, as desired. ◀

We can now prove Proposition 10.

Proof of Proposition 10. By Lemma 11, each $\mathcal{A}_{i,j}$ is $O(1)$-switching-cost bounded. By Lemma 12, each $\mathcal{A}_{i,j}$ is composition friendly. Since $\mathcal{A}$ is the composition of the $O(\log w \log n)$ different $\mathcal{A}_{i,j}$'s, it follows by Lemma 13 that $\mathcal{A}$ is $O(\log w \log n)$-switching-cost bounded. ◀

4 Lower bounds on switching cost

Define $s_{w,t}$ to be the optimal switching cost for assignment functions that assign workers $1, 2, \ldots, w$ to multisets of w tasks from the universe $[t]$. The upper bounds in this paper establish that $s_{w,t} \leq O(\log w \log(wt))$. It is natural to wonder whether smaller bounds can be achieved, and in particular, whether a small switching cost that depends only on w can be achieved.

It trivially holds that $s_{w,t} \leq w$. We show that when t is sufficiently large relative to w, there is a matching lower bound of $s_{w,t} \geq w$.

▶ **Theorem 3.** *For every w and $t \geq \mathrm{tow}(\Omega(w))$, every worker-task assignment function has switching cost w.*

Proof. Given any worker-task assignment function ϕ, we can actually find high switching cost between a pair of task subsets, in which all demands are 0 or 1. For each $T \subseteq [t]$ of w tasks, ϕ produces a bijection of workers $[w]$ to tasks T. In order to lower-bound the switching cost, we produce a coloring of the complete w-uniform hypergraph with t vertices. The coloring will be designed so that, if it contains a monochromatic clique on $w+1$ vertices, then the assignment function ϕ must have worst-possible switching cost w. By applying the hypergraph Ramsey theorem, we deduce that, if t is large enough, then the coloring must contain a monochromatic $(w+1)$-clique, completing the lower bound.

Coloring the complete w-uniform hypergraph on t vertices. Let $K_t^{(w)}$ denote the complete w-uniform hypergraph on t vertices. Note that the hyperedges of $K_t^{(w)}$ are just the w-element subsets of $[t]$, which correspond to sets of tasks.

For a task set $T = \{\tau_1, \ldots, \tau_w\}$, where $1 \leq \tau_1 < \cdots < \tau_w \leq t$, we color the hyperedge T with the tuple $\pi = \langle \pi(1), \pi(2), \ldots, \pi(w) \rangle$, where $\tau_{\pi(i)}$ is the task assigned to worker i. One can think of π as a permutation of numbers $\{1, 2, \ldots, w\}$, and thus the coloring consists of at most $w!$ colors.

Monochromatic $(w+1)$-cliques imply high switching cost. The key property of the coloring C is that, if $K_t^{(w)}$ contains a monochromatic $(w+1)$-vertex clique (i.e., $K_{w+1}^{(w)}$), then ϕ must have switching cost w.

Namely, if $K_t^{(w)}$ contains a monochromatic $(w+1)$-clique, then we can find $w+1$ vertices, $\tau_1 < \tau_2 < \cdots < \tau_{w+1}$, such that every w-element subset T of these tasks is assigned the same permutation π as its color. In particular, this means that for the task-set $T_1 = \{\tau_1, \ldots, \tau_w\}$ each worker i is assigned to task $\tau_{\pi(i)}$, but for the task-set $T_2 = \{\tau_2, \ldots, \tau_{w+1}\}$ that same worker i is assigned to a different task $\tau_{\pi(i)+1}$. Thus there is a pair of adjacent task sets T_1, T_2 that exhibit switching cost w.

Finding a monochromatic clique. In order to complete the lower bound, we wish to show that, if t is sufficiently large, then the coloring contains a monochromatic $K_{w+1}^{(w)}$. To do this, we employ the hypergraph Ramsey theorem.

▶ **Theorem 14** (Theorem 1 in [12])**.** *Let $k \geq 2$ and $N \geq n \geq 2$ be positive integers. The hypergraph Ramsey number $R(k, n, N)$ is defined to be the least positive integer M such that for every k-coloring of the hyperedges of $K_M^{(n)}$, the complete n-uniform hypergraph on M vertices, contains a monochromatic copy of $K_M^{(n)}$. This quantity satisfies*

$$R(k, n, N) \leq k^{(k^{n-1})^{(k^{n-2})^{\cdots^{(k^2)^{k(N-n)+1}}}}}.$$

Applying Theorem 14, we see that if $t \geq R(w!, w, w+1)$, then the $(w!)$-coloring of $K_t^{(w)}$ contains a monochromatic $(w+1)$-clique, and the assignment function ϕ must have switching cost w, as desired. By Theorem 14, $R(w!, w, w+1) \leq \mathrm{tow}(O(w))$. which implies that that every worker-task assignment function has switching cost w when $t \geq \mathrm{tow}(\Omega(w))$. This completes the proof of Theorem 3. ◀

Another way of viewing this argument is that a worker-task assignment function with switching cost less than w gives rise to a proper $(w!)$-coloring of a certain graph, with vertex set $\binom{[t]}{w}$ and edges of the form $(\{\tau_1, \ldots, \tau_w\}, \{\tau_2, \ldots, \tau_{w+1}\})$ for $\tau_1 < \tau_2 < \cdots < \tau_{w+1}$. Such graphs are studied under the name of **shift-graphs**, see, e.g., [14, Section 3.4], where the definition and proofs of basic properties are attributed to [11]. In particular, the chromatic number of shift-graphs is known to be $(1 + o(1)) \cdot \log^{(w-1)} t$ (with the superscript denoting iteration). This gives an alternative way to complete the proof of Theorem 3 and it gives the same asymptotic bound on t in terms of w. While the chromatic number lower bound suffices to prove the switching cost bound, the nearly matching upper bound (on chromatic number) suggests that an entirely different technique would be needed in order to asymptotically improve the switching cost bound.

5 Densification into Hamming space

In this section, we apply our results on worker-task assignment to the problem of densification. In particular, we show how to embed sparse high-dimensional binary vectors into dense low-dimensional Hamming space.

Let $\mathcal{H}_n^k$ denote the set of n-dimensional binary vectors with k ones. Let $\mathcal{H}_k(n)$ denote the set of k-dimensional vectors with entries from $[n]$. We show that $\mathcal{H}_n^k$ can be embedded into $\mathcal{H}_k(n)$ with distortion $O(\log n \log k)$.

▶ **Theorem 4.** *There exists a map $\phi : \mathcal{H}_n^k \to \mathcal{H}_k(n)$ such that, for every $\vec{x}, \vec{y} \in \mathcal{H}_n^k$,*

$$\mathrm{Ham}(\vec{x}, \vec{y})/2 \leq \mathrm{Ham}(\phi(\vec{x}), \phi(\vec{y})) \leq O(\log n \log k)\, \mathrm{Ham}(\vec{x}, \vec{y}).$$

Proof. Using Theorem 1, let ψ be a worker-task assignment function mapping workers $1, 2, \ldots, k$ to a task set $T \subseteq [n]$ with switching-cost $O(\log n \log k)$.

For $\vec{x} \in \mathcal{H}_n^k$, define $T(\vec{x}) = \{i \mid \vec{x}_i = 1\}$ to be the task set consisting of the positions in $\vec{x}$ that are 1. Define $\phi(\vec{x})$ to be the k-dimensional vector whose i-th coordinate denotes the task $t \in T(\vec{x})$ to which $\psi(T(\vec{x}))$ assigns worker i. For example, if $k = 3$, $\vec{x} = \langle 0, 1, 0, 1, 1, 0\rangle$, and $\psi(T(\vec{x}))$ assigns workers $1, 2, 3$ to tasks $4, 2, 5$, respectively, then $\phi(\vec{x}) = \langle 4, 2, 5\rangle$.

Since the coordinates of $\phi(\vec{x})$ are a permutation of the positions $T(\vec{x})$ in which $\vec{x}$ is non-zero, it is necessarily the case that

$$\mathrm{Ham}(\phi(\vec{x}), \phi(\vec{y})) \geq |T(\vec{x}) \setminus T(\vec{y})| \geq \mathrm{Ham}(\vec{x}, \vec{y})/2.$$

On the other hand, since ψ has switching cost $O(\log n \log k)$, it is also the case that $\psi(\vec{x})$ and $\psi(\vec{y})$ differ by at most $O(\log n \log k)\, \mathrm{Ham}(\vec{x}, \vec{y})$ assignments, meaning that,

$$\mathrm{Ham}(\phi(\vec{x}), \phi(\vec{y})) \leq O(\log n \log k)\, \mathrm{Ham}(\vec{x}, \vec{y}).$$

This completes the proof of the theorem. ◀

We remark that Theorem 4 can be generalized to allow for the the domain space $\mathcal{H}_n^k$ to have non-binary entries. In particular, if $\mathcal{L}_n^k$ is the set of vectors with non-negative integer entries that sum to k, then there is an embedding $\phi : \mathcal{L}_n^k \to \mathcal{H}_k(n)$ such that, for $x, y \in \mathcal{L}_n^k$,

$$\ell_1(\vec{x}, \vec{y})/2 \leq \mathrm{Ham}(\phi(\vec{x}), \phi(\vec{y})) \leq O(\log n \log k)\ell_1(\vec{x}, \vec{y}).$$

This follows from the same argument as Theorem 4, except that now $T(x)$ is the *multiset* for which each element $i \in [n]$ has multiplicity $\vec{x}_i$, and now ψ is the worker-task assignment mapping workers $1, 2, \ldots, k$ to a task *multiset* $T \subseteq [n]$.

6 Open problems

We leave open the question of closing the gap between upper and lower bounds for the worker-task assignment problem: the upper bound is polylog(wt) and the lower bound is $\log^*(t)$.

One interesting parameter regime is when w and t are comparable in size (say within a polynomial factor of each other). In this regime, no super-constant lower bound is known.

Another interesting direction is the problem of densification into Hamming space. Our upper bound for the worker-task assignment problem implies an upper bound for this problem, but our lower bound does not carry over. We leave open the problem of whether there is a better upper bound or a super-constant lower bound for this problem.

Abstract

Designing efficient dynamic graph algorithms against an *adaptive* adversary is a major goal in the field of dynamic graph algorithms and has witnessed many exciting recent developments in, e.g., dynamic matching (Wajc STOC'20) and decremental shortest paths (Chuzhoy and Khanna STOC'19). Compared to other graph primitives (e.g. spanning trees and matchings), designing such algorithms for *graph spanners* and (more broadly) *graph sparsifiers* poses a unique challenge since there is no fast deterministic algorithm known for static computation and the lack of a way to adjust the output slowly (known as "small recourse/replacements").

This paper presents the first non-trivial efficient adaptive algorithms for maintaining many sparsifiers against an adaptive adversary. Specifically, we present algorithms that maintain

1. a polylog(n)-spanner of size $\tilde{O}(n)$ in polylog(n) amortized update time,
2. an $O(k)$-approximate cut sparsifier of size $\tilde{O}(n)$ in $\tilde{O}(n^{1/k})$ amortized update time, and
3. a polylog(n)-approximate spectral sparsifier in polylog(n) amortized update time.

Our bounds are the first non-trivial ones even when only the recourse is concerned. Our results hold even against a stronger adversary, who can access the random bits previously used by the algorithms and the amortized update time of all algorithms can be made worst-case by paying sub-polynomial factors. Our spanner result resolves an open question by Ahmed et al. (2019) and our results and techniques imply additional improvements over existing results, including (i) answering open questions about decremental single-source shortest paths by Chuzhoy and Khanna (STOC'19) and Gutenberg and Wulff-Nilsen (SODA'20), implying a nearly-quadratic time algorithm for approximating minimum-cost unit-capacity flow and (ii) de-amortizing a result of Abraham et al. (FOCS'16) for dynamic spectral sparsifiers.

Our results are based on two novel techniques. The first technique is a generic black-box reduction that allows us to assume that the graph is initially an expander with almost uniform-degree and, more importantly, stays as an almost uniform-degree expander while undergoing only edge deletions. The second technique is called *proactive resampling*: here we constantly *re-sample* parts of the input graph so that, independent of an adversary's computational power, a desired structure of the underlying graph can be always maintained. Despite its simplicity, the analysis of this sampling scheme is far from trivial, because the adversary can potentially create dependencies between the random choices used by the algorithm. We believe these two techniques could be useful for developing other adaptive algorithms.

1 Introduction

Dynamic graph algorithms maintain information in an input graph undergoing edge *updates*, which typically take the form of edge insertions and deletions. Many efficient algorithms have been developed in this setting, such as those for maintaining a minimum spanning tree, maximum matching, shortest distances, and sparsifiers. However, many of these algorithms are randomized and, more importantly, make the so-called *oblivious adversary assumption*, which assumes that each update given to the algorithm cannot depend on answers of the algorithm to earlier queries. In other words, the entire update sequence is fixed by some adversary in advance, and then each update is given to the algorithm one by one. This assumption is crucial for many recent advances in the design of efficient randomized algorithms for dynamic problems (e.g. [68, 63, 35, 22, 10, 1, 82, 9, 25]).

The oblivious-adversary assumption significantly limits the use of dynamic algorithms in certain interactive environments and, in particular, the setting where these dynamic algorithms are employed as *subroutines* for other algorithms. For example, the recent partially-dynamic single-source shortest paths algorithm without this assumption [21] has been used to obtain an almost-linear time approximate min-cost flow and balanced separator algorithm in the static setting (see also, e.g., [17, 16, 61, 62, 42, 43], for prior attempts in this direction). In addition, [40] pointed out that their goal of computing a (static) short cycle decomposition could have been achieved easily using existing dynamic spanner algorithms, if such algorithms worked without the oblivious-adversary assumption. Because of this, designing dynamic algorithms *without* the oblivious adversary assumption has become a major goal in the field of dynamic graph algorithms in recent years. We call such algorithms *adaptive* and say that they work against an *adaptive adversary*.

Thanks to the recent efforts in developing adaptive algorithms, such algorithms now exist for maintaining a number of graph primitives, such as minimum spanning trees with bounded worst-case update time [41, 77, 76, 88], partially-dynamic single-source shortest

paths [50, 42, 17, 18, 16, 62, 61, 60], and fully-dynamic matching [26, 27, 28, 29, 87]. This line of research on dynamic graph algorithms has also brought new insights on algorithm design in the static setting (e.g. flow, vertex connectivity, matching, and traveling salesman problem [73, 42, 86, 37, 38]). One very recent exciting application is the use of an adaptive dynamic algorithm called *expander decomposition* to compute maximum-weight matching and related problems in nearly-linear time on moderately dense graphs [86].

Graph sparsifiers

Despite the fast recent progress, very little was known for certain important primitives, like maintaining *graph sparsifiers* against an adaptive adversary. To formalize our discussion, we say that a sparsifier of a graph $G = (V, E)$ is a sparse graph $H = (V, E')$ that approximately preserves properties of G, such as all cuts (*cut sparsifiers*), all-pairs distances (*spanners*), and spectral properties (*spectral sparsifiers*). For any integer $\alpha \geq 1$, an *α-spanner* of graph $G = (V, E)$ is a subgraph H such that for any pair of nodes (u, v), the distance between u and v in H is at most α times their distance in G. An *α-cut sparsifier* of G is a sparse graph H that preserves all cut sizes up to an α factor: that is, $\delta_H(S) \in [\delta_G(S), \alpha\delta_G(S)]$ for every $S \subseteq V$, where $\delta_G(S)$ (respectively $\delta_H(S)$) is the total weight of edges between S and $V \setminus S$ in G (respectively H) for any $S \subset V$. An α-spectral sparsifier is a sparse graph that provides an even stronger guarantee than an α-cut sparsifier (see full version for the definition).

A dynamic algorithm for maintaining a spanner or a cut sparsifier is given a weighted undirected n-node graph G to preprocess, and returns a spanner or cut-sparsifier H of G. After this, it must process a sequence of *updates*, each of which is an edge insertion or deletion of G. After each update, the algorithm outputs edges to be inserted and deleted to H so that the updated H remains an α-spanner or cut-sparsifier of the updated G. The algorithm's performance is measured by the *preprocessing time* (the time to preprocess G initially); the *update time* (the time to process each update); the *stretch* (the value of α); and the *size* of the spanner (the number of edges). The update time is typically categorized into two types: *amortized case* update time and *worst case* update time. The more desirable one is the *worst-case* update time which holds for every single update. This is in contrast to an *amortized* update time which holds "on average"; i.e., for any t, an algorithm is said to have an amortized update time of t if, for any k, the total time it spends to process the first k updates is at most kt.

Spanners and cut sparsifers are fundamental objects that have been studied extensively in various settings (e.g., [5, 79, 11, 78, 44, 58, 57, 15, 53, 3, 4]). In the dynamic setting, they have been actively studied since 2005 (e.g. [7, 51, 8, 48, 23, 10, 31, 20]). A fairly tight algorithm with amortized update time for maintaining dynamic spanners was known in 2008 due to Baswana et al. [10]. For any $k \geq 1$, their algorithm maintains, with high probability, a $(2k-1)$-spanner of size $\tilde{O}(kn^{1+1/k})$ in $O(k^2 \log^2 n)$ amortized update time[1]. The stretch and size tradeoff is almost tight assuming Erdős' girth conjecture, which implies that a $(2k-1)$-spanner must contain $\Omega(n^{1+1/k})$ edges. Recently, Bernstein et al. [20] showed how to "de-amortize" the result of Baswana et al. [10], giving an algorithm that in $O(1)^k \log^3(n)$ *worst-case* update time maintains, w.h.p., a $(2k-1)$-spanner of size $\tilde{O}(n^{1+1/k})$.

We refer the reader to the full version for other related results and clear comparison. For dynamic cut sparsifiers, the only result we are aware of is [1], which maintains a $(1+\epsilon)$-cut sparsifier in polylogarithmic worst-case update time. [1] can also maintain a $(1+\epsilon)$-spectral sparsifier within the same update time, but this holds only for the amortized update time.

[1] Throughout, $\tilde{O}$ hides $O(\text{polylog}(n))$ factors. With high probability (w.h.p.) means with probability at least $1 - 1/n^c$ for any constant $c > 1$.

Similar to other dynamic algorithms, most existing dynamic spanner and cut sparsifier algorithms are *not* adaptive. The exceptions are the algorithms of [7], which can maintain a 3-spanner (respectively a 5-spanner) of size $O(n^{1+1/2})$ (respectively $O(n^{1+1/3})$) in $O(\Delta)$ time, where Δ is the maximum degree. These algorithms are deterministic, and thus work against an adaptive adversary. Since Δ can be as large as $\Omega(n)$, their update time is rather inefficient as typically polylog(n) or $n^{o(1)}$ update times are desired. Designing dynamic algorithms for this low update time is one of the major objectives of our paper.

Challenges

Developing efficient adaptive algorithms for maintaining graph sparsifiers poses great challenges in the general research program towards adaptive dynamic algorithms. First, computing many sparsifiers inherently relies on the use of randomness. Even in the static setting, existing fast algorithms for constructing cut and spectral sparsifiers are all randomized, and known deterministic algorithms require $\Omega(n^4)$ time [12, 89]. In fact, a nearly-linear time deterministic algorithm for a certain cut sparsifier would resolve a major open problem about computing the minimum cut deterministically [70, 56, 75]. Thus, in contrast to other primitives, such as the minimum spanning tree or approximate maximum matching, for which efficient deterministic algorithms exist in the static setting, there is little chance to dynamically maintain sparsifiers *deterministically*. (Deterministic dynamic algorithms always work against adaptive adversaries.)

Secondly, even if we allowed infinite update time and focused on the strictly simpler objective of minimizing the changes in the maintained sparsifier (the so-called *recourse* or *replacements* in online algorithms), it is unclear from existing techniques whether it is possible to maintain such a sparsifier against an adaptive adversary while only making (amortized) polylog(n) changes to the sparsifier per update to the input graph. For example, an $O(\log n)$-spanner of $\tilde{O}(n)$ edges can be easily maintained with $\tilde{O}(n)$ recourse per update by replacing the entire spanner by a new one after every update. Is it possible that an adversary who can see the output spanner can make a few changes to the graph so that a new $O(\log n)$-spanner has to change completely? An answer to this question is unclear. This is in contrast to many dynamic graph primitives where bounding the changes is obvious even against adaptive adversaries. For example, it can be easily shown that maintaining the minimum spanning tree requires at most one edge insertion and one edge deletion after each update to the input graph.

Designing algorithms with low recourse is a prerequisite for fast dynamic algorithms, and there are several graph problems where low-recourse algorithms were the crucial bottleneck, e.g. maximal independent set [33, 6, 36, 13, 74], planar embeddings [65, 66], and topological sorting [19].The lack of recourse-efficient algorithms makes it very challenging to maintain sparsifiers against an adaptive adversary.

1.1 Our Results

We show how to dynamically maintain both spanners, cut sparsifiers, and spectral sparsifiers against an adaptive adversary in *poly-logarithmic* update time and recourse. We summarize these results as follows:

▶ **Theorem 1** (Adaptive Spanner). *There is a randomized* adaptive *algorithm that, given an n-vertex graph undergoing edge insertions and deletions, with high probability, explicitly maintains a* polylog(n)*-spanner of size $\tilde{O}(n)$ using* polylog(n) *amortized update time.*

▶ **Theorem 2** (Adaptive Cut Sparsifier). *There is a randomized* adaptive *algorithm that, given an n-vertex graph undergoing edge insertions and deletions and a parameter $k \geq 1$, with high probability, maintains an $O(k)$-cut sparsifier of size $\tilde{O}(n)$ using $\tilde{O}(n^{1/k})$ amortized update time, which is* $\text{polylog}(n)$ *time when $k = \log n$.*

▶ **Theorem 3** (Adaptive Spectral Sparsifier). *There is a randomized* adaptive *algorithm that, given an n-vertex graph undergoing edge insertions and deletions, with high probability, maintains a* $\text{polylog}(n)$*-spectral sparsifier of size $\tilde{O}(n)$ using* $\text{polylog}(n)$ *amortized update time.*

All results above hold even against a stronger adversary, called *randomness-adaptive* in [76]. This adversary can access the random bits previously used by our algorithms (but not the future random bits). Theorem 1 is the first algorithm with $o(n)$ update time against an adaptive adversary, and answers the open problem in [2]. The only previous adaptive algorithm is by [7] which can take $O(n)$ update time. No non-trivial dynamic adaptive algorithm for cut sparsifiers and spectral sparsifiers is known before Theorems 2 and 3.

Compared to results assuming the oblivious-adversary assumption (e.g. [10, 20, 1]), our bounds are not as tight. For example, Theorem 1 does not achieve the standard $(2k-1)$-spanner with $O(n^{1+1/k})$ edges. One reason for this limitation is that it is not clear if such trade-off is possible even when we focus on the *recourse*, as discussed above. Maintaining spanners or other sparsifiers against adaptive adversaries with tight trade-offs and polylogarithmic recourse is a challenging barrier that is beyond the scope of this paper. Additionally, the sparse-spanner regime studied in this paper is generally the most useful for applications to other problems (see discussion in Section 1.2); getting a sharper trade-off would not lead to significant improvements for most of these applications.

All the above results can be *deamortized*.[2] For example, a $2^{O(\sqrt{\log n}\log\log(n))}$-spanner of size $\tilde{O}(n)$ can be maintained in $2^{O(\sqrt{\log n}\log\log(n))}$ *worst-case* update time. Also, for any k, a $2^{O(k\,\text{polylog}(k))}$-cut sparsifier of size $\tilde{O}(n)$ can be maintained in $\tilde{O}(n^{1/k})$ worst-case time. In particular, we can maintain an $O(\log^* n)$-cut sparsifier and an $O(1)$-cut sparsifier in $n^{o(1)}$ and n^{ϵ} time for any constant ϵ, respectively.

Our deamortization technique also implies, as a side result, the first non-trivial algorithm with *worst-case* update time against an oblivious adversary for maintaining spectral sparsifiers.

▶ **Theorem 4** (Oblivious Spectral Sparsifier). *There is a randomized algorithm against an oblivious adversary that, given an n-vertex graph undergoing edge insertions and deletions and $\epsilon \geq 1/\text{polylog}(n)$, with high probability, maintains a $(1+\epsilon)$-spectral sparsifier of size $n \cdot 2^{O(\sqrt{\log n})}$ using $2^{O(\log^{3/4} n)}$ worst-case update time.*

The previous algorithm by Abraham et al. [1] maintains a $(1+\epsilon)$-spectral sparsifier of size $\tilde{O}(n)$ using $\text{polylog}(n)$ amortize update time. Further [1] asked if the update time can be made worst-case. Theorem 4 answers this open question modulo $n^{o(1)}$ factors.

1.2 Applications

Our results imply several interesting applications. Our first set of applications are for the decremental $(1+\epsilon)$-approximate single-source shortest paths (SSSP) problem. There has been a line of work [17, 16, 18, 62] on fast adaptive algorithms for solving this problem.

[2] To do this, we use, e.g., the sparsification technique [49] and a sophisticated dynamic expander decomposition; see Section 2.3 for an overview.

Although all these algorithms are adaptive, they share a drawback that they cannot return the shortest path itself; they can only maintain distance estimates. Very recently, Chuzhoy and Khanna [42] showed a partial fix to this issue for some algorithms [17, 16] and consequently obtained impressive applications to static flow algorithms. Unfortunately, this fix only applies in a more restricted setting, and moreover it is not clear how the technique from [42] can be used to fix the same issue in other algorithms (e.g. [18, 62]).

We show that our main result from Theorem 1 can be employed in a consistent and simple way, such that the path-reporting issue in all previous algorithms in [17, 16, 18, 62] can be fixed. This resolves an open question posed in multiple papers [16, 62, 42]. We summarize these applications below:

▶ **Corollary 5** (Fixing the path-reporting issue of [18, 62]). *For any decremental unweighted graph $G = (V, E)$, fixed source s, and constant $\epsilon > 0$, there is an adaptive algorithm $\mathcal{B}$ that maintains the $(1+\epsilon)$-approximate distances from vertex s to every vertex $v \in V$* and supports corresponding shortest path queries. *The algorithm $\mathcal{B}$ has expected total update time $mn^{0.5+o(1)}$, distance estimate query time $O(\log\log n)$ and shortest path query time $\tilde{O}(n)$.*

Corollary 5 gives the first adaptive algorithm without the path-reporting issue that can take $o(n^2)$ total update time. The next algorithm works on weighted graphs and is near-optimal on dense graphs:

▶ **Corollary 6** (Fixing the path-reporting issue of [17, 16]). *For any decremental weighted graph $G = (V, E, w)$ with W being the ratio between maximum and minimum edge weight, fixed source s, and $\epsilon > 0$, there is an adaptive algorithm $\mathcal{A}$ that maintains the $(1+\epsilon)$-approximate distances from vertex s to every vertex $v \in V$* and supports corresponding shortest path queries. *The algorithm $\mathcal{A}$ has expected total update time $\tilde{O}(n^2 \log W)$, distance estimate query time $O(\log\log(nW))$ and shortest path query time $\tilde{O}(n \log W)$.*

Corollary 6 can be compared to two previous results [42, 43]. In [42], their algorithm requires slower $n^{2+o(1)} \log W$ total update time, and needs to assume that the input graph undergoes only *vertex* deletions which is more restrictive. So Corollary 6 strictly improves the algorithm by [42]. In [43], they use very different techniques than ours and show an algorithm with $n^{2+o(1)} \log W$ total update time, distance query time $O(\log\log(nW))$, shortest path query time $O(|P| n^{o(1)})$ when a path P is returned, and is deterministic. This algorithm is incomparable to Corollary 6. Our result has slightly faster total update time, but their algorithm is deterministic and guarantees faster shortest path query time.

By plugging Corollary 6 into the standard multiplicative weight update framework (e.g. [55, 52, 42, 73]), we get the following:

▶ **Corollary 7.** *There exist $(1+\epsilon)$-approximate algorithms with expected running time $\tilde{O}(n^2)$ for the following problems:*

1. *minimum-cost maximum s-t flow in undirected vertex-capacitated graphs, and*
2. *minimum-cost maximum s-t flow in undirected unit-edge-capacity graphs.*

Corollary 7 slightly reduces the $n^{2+o(1)}$ run time from [42, 43] to $\tilde{O}(n^2)$.[3]

The second set of applications are faster algorithms for variants of multi-commodity flow problems using Theorem 1. For example, we achieve a static $\tilde{O}((n+k)n)$-time polylog(n)-approximation algorithm for the *congestion minimization* problem with k demand pairs on unweighted vertex-capacitated graphs. This improves the $\tilde{O}((m+k)n)$-time $O(\log(n)/\log\log(n))$-approximation algorithms implied by Karakostas [69] in terms of the running time at the cost of a worse approximation ratio. See the full version for more detail.

[3] We note that the result of [43] is deterministic.

Finally, we apply Theorem 4 to the problem of maintaining *effective resistance*. Durfee et al. [47, 46] presented a dynamic algorithm with $\tilde{O}(n^{6/7})$ amortized update time for $(1+\epsilon)$-approximately maintaining the effective resistance between a fixed pair of nodes. Plugging our result in the algorithm of Durfee et al. leads to an $n^{6/7+o(1)}$ worst-case update time. (Both of these results assume an oblivious adversary.)

1.3 Techniques

To prove the above results, the first key tool is the black-box reduction in Theorem 8 that allows us to focus on *almost-uniform-degree expanders*[4]. Theorem 8 works for a large class of problems satisfying natural properties (defined in Section 2) which includes spanners, cut sparsifiers, and spectral sparsifiers. Hence the theorem uses the term "α-approximate sparsifier" without defining the exact type of sparsifier.

▶ **Theorem 8** (Informal Blackbox Reduction, see full version for the formal statements)**.** *Assume that there is an algorithm $\mathcal{A}$ that can maintain an α-approximate sparsifier on an n-vertex graph G with the following promises:*

- *G undergoes batches of edge deletions*[5] *(isolated nodes are automatically removed),*
- *G is unweighted,*
- *after each batch of deletions, G is an expander graph, and*
- *after each batch of deletions, G has almost uniform degree, i.e. the maximum degree $\Delta_{\max}$ and the minimum degree $\Delta_{\min}$ are within a* polylog(n) *factor.*

Then, there is another algorithm $\mathcal{B}$ with essentially the same amortized update time for maintaining an α-approximate sparsifier of essentially the same size on a general weighted *graph undergoing both edge insertions and deletions. If $\mathcal{A}$ is adaptive or deterministic, then so is $\mathcal{B}$.*

As it is well-known that many problems become much easier on expanders (e.g., [84, 83, 81, 67, 34, 72]), we believe that this reduction will be useful for future developments of dynamic algorithms. For example, if one can come up with an adaptive algorithm for maintaining $(1+\epsilon)$-cut sparsifiers on expanders, then one can immediately obtain the same result on general graphs.

Our second technique is a new sampling scheme called *proactive resampling*: here we constantly re-sample parts of the input graph so that, independent of an adversary's computational power, a desired structure of the underlying graph can be always maintained; see Section 2 for a high-level discussion of this technique. Since there are still few known tools for designing algorithms that work against an adaptive adversary, we expect that our technique will prove useful for the design of other adaptive algorithms in the future.

We further extend the black-box reduction from Theorem 8 to algorithms with worst-case update time, which allows us to deamortize both Theorem 1 and Theorem 2 with slightly worse guarantees. It also easily implies Theorem 4.

1.4 Subsequent Development

Since this paper has appeared in April 2020, there have been exciting subsequent developments based on techniques of this paper.

[4] Expanders are graphs with high conductance (see Section 2). Intuitively, they are "robustly connected" graphs.

[5] That means, in each iteration the algorithm is given a set $D \subset E$ of edges that are to be deleted.

Our dynamic spectral sparsifiers with $(1+\epsilon)$-approximation but large query time (see full version) has been employed as a blackbox subroutine in a line of work on faster algorithms for exact max-flow [86, 85, 54], and also in [39] for making a dynamic polylog(n)-approximate all-pairs max flow algorithm work against an adaptive adversary. In [14], the authors opened the blackbox of our spectral sparsifier and combined our dynamic expander decomposition with our sparsification techniques to obtain the first dynamic algorithms with $o(n)$ update time against an adaptive adversary for $(1+\epsilon)$-approximate global min cuts and all-pairs effective resistances. Our almost-uniform-degree expander decomposition is also used in the context of online algorithms [59].

Our proactive resampling technique has been extended in a follow-up work [30] for maintaining fully dynamic 3-spanners against an adaptive adversary, in contrast with polylog(n)-spanners.

2 Overview

All our algorithms use a common framework based on expanders, which results in a reduction from fully dynamic algorithms on general graphs to the special case of decremental algorithms on expander graphs. The reduction holds for a general class of graph problems that satisfy some criteria. These criteria are satisfied for spectral-sparsifiers, cut-sparsifiers and spanners. In this section, we define the abstract criteria needed for our reduction (See Conditions 1-5 below), so that we only need to prove our algorithm once and apply it to all these types of sparsifiers.

The overview is split into three parts. In Section 2.1 we show the reduction for amortized update time. In Section 2.2 we show how to take advantage of the reduction by designing efficient algorithms on expanders. Finally, in Section 2.3 we finish the overview with a sketch of how to extend the reduction to worst-case update-time algorithms.

2.1 Reduction to Expanders: Amortized Update Time

We now outline our black-box reduction, which can preserve several nice properties of the algorithms. That is, given an algorithm with property x running on expander, we obtain another algorithm with property x with essentially the same running time and approximation guarantee, where the property x can be "deterministic", "randomized against an adaptive adversary", or "worst-case update time". In this subsection, we focus on amortized update time: see Section 2.3 for an overview of how to extend the reduction to apply to worst-case algorithms.

The reduction holds for any graph problem that satisfies a small number of conditions. We formalize a graph problem as a function $\mathcal{H}$ that maps (G, ϵ) for a graph G and parameter $\epsilon > 0$ to a set of graphs. We say a dynamic algorithm $\mathcal{A}$ solves $\mathcal{H}(\epsilon)$ if for every input graph G, algorithm $\mathcal{A}$ maintains/computes a graph $H \in \mathcal{H}(G, \epsilon)$. For example we could define $\mathcal{H}(G, \epsilon)$ to be the set of all $(1+\epsilon)$-cut sparsifiers. So then saying "data structure $\mathcal{A}$ solves $\mathcal{H}(\epsilon)$" means that $\mathcal{A}$ maintains for any input graph an $(1+\epsilon)$-cut sparsifier.

Pertubation Property

The first property required by our reduction allows us to slightly perturb the edges, i.e. scale each edge $\{u, v\}$ by some small factor $f_{u,v}$ bounded by $1 \leq f_{u,v} \leq e^{\epsilon}$. Define $\zeta \cdot G$ to be the graph G with all edge-weights multiplied by ζ.

$$\text{Let } G' \text{ be } G \text{ scaled by up to } e^{\epsilon}, \text{ then } G' \in \mathcal{H}(G, \epsilon) \text{ and } e^{\epsilon} \cdot G \in \mathcal{H}(G', \epsilon). \tag{1}$$

Property (1) implies that $G \in \mathcal{H}(G, \epsilon)$ for all $\epsilon > 0$. For example any graph is a (potentially dense) spectral approximation or spanner of itself. The property is also useful when we want to discretize the edge weights. A common technique is to round edge weights to the nearest power of e^{ϵ} in order to discretize the set of possible edge weights without changing graph properties such as the spectrum or distances too much. Combined with the following *union* property, this also allows us to generalize algorithm for unweighted graphs to support weighted graphs.

Union Property

Say that $G = \bigcup_{i=1}^{k} G_i$ for some k and that $s_1, ..., s_k \in \mathbb{R}$. Then the union property is defined as follows:

$$\text{If } H_i \in \mathcal{H}(G_i, \epsilon) \text{ and } 0 \leq s_i, \text{ then } \bigcup_i s_i \cdot H_i \in \mathcal{H}\left(\bigcup_i s_i \cdot G_i, \epsilon\right). \tag{2}$$

Combining this property with the previous *pertubation* property (1) gives us the following reduction. Given a graph G with real edge weights from $[1, W]$, one can decompose G into graphs $G_1, ..., G_k$, such that each G_i contains edges with weights in $[e^{(i-1)\epsilon}, e^{i\epsilon})$. One can then use any algorithm that solves $\mathcal{H}$ on *unweighted* graphs to obtain $H_i \in \mathcal{H}(G'_i, \epsilon)$ for all $i = 1, ..., k$, where G'_i is the graph G_i when ignoring the edge weights. Then $\bigcup_i e^{i\epsilon} \cdot H_i \in \mathcal{H}(\bigcup_i e^{i\epsilon} \cdot G_i, \epsilon) \subset \mathcal{H}(G, \epsilon)$ by combining property (2) and (1). Thus one obtains an algorithm that solves $\mathcal{H}$ on *weighted* graphs.

Reduction for Amortized Update Time

Loosely speaking, our black-box states the following. Say that we have a data structure $\mathcal{A}_X$ on a graph X that at all times maintains a sparsifier in $\mathcal{H}(X, \epsilon)$ with amortized update time $T(\mathcal{A}_X)$, but assumes the following restricted setting: **1)** Every update to X is an edge *deletion* (no insertion), and **2)** X is always an expander. We claim that $\mathcal{A}_X$ can be converted into a *fully dynamic* algorithm $\mathcal{A}$ that works on any graph G, and has amortized update time $T(\mathcal{A}) = \tilde{O}(T(\mathcal{A}_X))$.

We first outline this black-box under the assumption that we have a dynamic algorithm that maintains a decomposition of $G = \bigcup_i G_i$ into edge disjoint expander graphs $G_1, G_2, ...$ This dynamic algorithm will have the property that whenever the main graph G is updated by an adversarial edge insertion/deletion, each expander G_i receives only edge deletions, though occasionally a new expander G_j is added to the decomposition. Thus one can simply initialize $\mathcal{A}_X$ on the expander G_j to obtain some $H_j \in \mathcal{H}(G, \epsilon)$, when G_j is added to the decomposition. Then whenever an edge deletion is performed to G_j, we simply update the algorithm $\mathcal{A}_X$ to update the graph H_j. By the union property (2) we then have that

$$H := \bigcup_i H_i \in \mathcal{H}\left(\bigcup_i G_i, \epsilon\right) = \mathcal{H}(G, \epsilon).$$

So we obtain an algorithm $\mathcal{A}$ that can maintain a sparsifier H of G. We are left with proving how to obtain this dynamic algorithm for maintaining the expander decomposition of G.

Dynamic Expander Decomposition

The idea is based on the expander decomposition and expander pruning of [80]. Their expander decomposition splits V into disjoint node sets $V_1, V_2, ...$, such that the induced subgraphs $G[V_i]$ on each V_i are expanders, and there are only $o(m)$ edges between these

expanders. In the full version we show that by recursively applying this decomposition on the subgraph induced by the inter-expander edges, we obtain a partition of the *edges* of G into a union of expanders. This means, we can decompose G into subgraphs $G_1, G_2, ...$, where each G_i is an expander and $\bigcup_i G_i = G$. We show in the full version that the time complexity of this decomposition algorithm is $\tilde{O}(m)$.

We now outline how we make this decomposition dynamic in the full version. Assume for now, that we have a decomposition of G into $G = \bigcup_i G^{(i)}$, where for all i, the graph $G^{(i)}$ has at most 2^i edges, but each $G^{(i)}$ is not necessarily an expander. Further, each $G^{(i)}$ is decomposed into expanders $G^{(i)} = \bigcup_j G^{(i)}_j$. To make this decomposition dynamic, we will first consider edge insertions where we use a technique from [64]. Every edge insertion performed by the adversary is fed into the graph $G^{(1)}$. Now, when inserting some edges into some $G^{(i)}$, there are two cases: (i) the number of edges in $G^{(i)}$ remains at most 2^i. In that case recompute the expander decomposition $G^{(i)} = \bigcup_j G^{(i)}_j$ of $G^{(i)}$. Alternatively we have case (ii) where $G^{(i)}$ has more than 2^i edges. In that case we set $G^{(i)}$ to be an empty graph and insert all the edges that previously belonged to $G^{(i)}$ into $G^{(i+1)}$. Note that on average it takes 2^{i-1} adversarial insertions until $G^{(i)}$ is updated, and we might have to pay $\tilde{O}(2^i)$ to recompute its decomposition, so the amortized update time for insertions is simply $\tilde{O}(1)$.

For edge deletions we use the expander pruning technique based on [80] (refined from [77, 76, 88]). An over-simplified description of this technique is that, for each update to the graph, we can repeatedly prune (i.e. remove) some $\tilde{O}(1)$ edges from the graph, such that the remaining part is an expander. So whenever an edge is deleted from G, we remove the edge from its corresponding $G^{(i)}_j$, and remove/prune some $\tilde{O}(1)$ extra edges from $G^{(i)}_j$, so that it stays an expander graph. These pruned edges are immediately re-inserted into $G^{(1)}$ to guarantee that we still have a valid decomposition $G = \bigcup_i G^{(i)}$. In summary, we are able to maintain a decomposition $G = \bigcup_{i,j} G^{(i)}_j$ of G into expander graphs. This decomposition changes only by creating new expanders and removing edges from existing expanders, so we can run the decremental expander algorithm $\mathcal{A}_X$ on each $G^{(i)}_j$.

Contraction Property and Reduction to Uniform Degree Expanders

Many problems are easier to solve on graphs with (near) uniform degree. Thus, we strengthen our reduction to work even if the decremental algorithm $\mathcal{A}_X$ assumes that graph X has near-uniform degree. On its own, the expander decomposition described above is only able to guarantee that for each expander the minimum degree is close to the average degree; the maximum degree could still be quite large. In order to create a (near) uniform degree expander, we split these high degree nodes into many smaller nodes of smaller degree. In order to perform this operation, we need the condition that whichever graph problem $\mathcal{H}$ we are trying to solve must be able to handle the reverse operation, i.e. when we contract many small degree nodes into a single large degree node.

$$\begin{aligned}&\text{When contracting } W \subset V \text{ in both } G \text{ and } H \in \mathcal{H}(G, \epsilon),\\ &\text{let } G' \text{ and } H' \text{ be the resulting graphs, then } H' \in \mathcal{H}(G', \epsilon).\end{aligned} \tag{3}$$

All in all, our black-box reduction shows that in order to solve a sparsification problem $\mathcal{H}$ in the fully dynamic model on general graphs, we need to **1)** show that $\mathcal{H}$ satisfies the perturbation, union, and contraction properties above (Properties 1-3) AND **2)** Design an algorithm $\mathcal{A}_X$ for $\mathcal{H}$ in the simpler setting where the dynamic updates are purely decremental (only edge deletions), and where the dynamic graph G is always guaranteed to be a near-uniform degree expander.

We now present the second main contribution of our paper, which is a new adaptive algorithm $\mathcal{A}_X$ on expanders. We conclude the overview with a discussion of the worst-case reduction (Section 2.3), for which we will need two additional properties of the problem $\mathcal{H}$.

2.2 Adaptive Algorithms on Expanders

We showed above that maintaining a sparsifier in general graphs can be reduced to the same problem in a near-uniform-degree expander. Thus, for the rest of this section we assume that $G = (V, E)$ is *at all times* a ϕ-expander with max degree $\Delta_{\max}$ and min-degree $\Delta_{\min}$, and that G is only subject to edge deletions. Let $n = |V|, m = |E|$. In this overview, we assume that $1/\phi$ and $\Delta_{\max}/\Delta_{\min}$ are $O(\text{polylog}\, n)$, and we assume $\Delta_{\min} \gg 1/\phi$. Define $\textsc{Inc}_G(v)$ to the edges incident to v in G.

We now show how to maintain a $O(\log(n))$-approximate cut-sparsifier H in G against an adaptive adversary; it is not hard to check that H is also a spanner of stretch $\tilde{O}(1/\phi)$, because a cut-sparsifier of a ϕ-expander is itself a $\tilde{\Omega}(\phi)$-expander, and hence has diameter $\tilde{O}(1/\phi)$. See full version for details.

Static Expander Construction

We first show a very simple *static* construction of $H \subseteq G$. Define $\rho = \tilde{\Theta}\left(\frac{\Delta_{\max}}{\Delta_{\min}^2 \phi^2}\right) = \tilde{\Theta}\left(\frac{1}{\Delta_{\min}}\right)$, with a sufficiently large polylog factor. Now, every edge is independently sampled into H with probability ρ, and if sampled, is given weight $1/\rho$. To see that H is a cut sparsifier, consider any cut $X, \bar{X}$, with $|X| \leq n/2$. We clearly have $\mathbb{E}[|E_H(X, \bar{X})|] = \rho |E_G(X, \bar{X})|$, so since every edge in H has weight $1/\rho$, we have the same weight *in expectation*. For a high probability bound, want to show that $\Pr[|E_H(X, \bar{X})| \sim \rho |E_G(X, \bar{X})|] \geq 1 - n^{-2|X|}$; we can then take a union bound over the $O(n^{|X|})$ cuts of size $|X|$.

Since the graph is an expander, we know that $|E_G(X, \bar{X})| \geq \text{vol}_G(X) \cdot \phi \geq |X| \cdot \Delta_{\min} \cdot \phi = \tilde{\Omega}(|X|\Delta_{\min})$. Thus, by our setting of $\rho = \tilde{\Theta}(1/\Delta_{\min})$, we have $\mathbb{E}[|E_H(X, \bar{X})|] \geq |X| \log^2(n)$. Since each edge is sampled independently, a chernoff bound yields the desired concentration bound for $|E_H(X, \bar{X})|$.

Naive Dynamic Algorithms

The most naive dynamic algorithm is: whenever the adversary deletes edge (u, v), resample all edges in $\textsc{Inc}_G(u)$ and $\textsc{Inc}_G(v)$: that is, include each such edge in H with probability ρ. Efficiency aside, the main issue with this protocol is that the adversary can cause some target vertex x to become *isolated* in H, which clearly renders H not a cut sparisifer. To see this, let $y_1, \ldots, y_k$ be the neighbors of x. The adversary then continually deletes arbitrary edges $(y_1, z) \neq (y_1, x)$, which has the effect of resampling edge (x, y_1) each time. With very high probability, the adversary can ensure within $\log(n)$ such deletions (y_1, z) that (x, y_1) is NOT included in H; the adversary then does the same for y_2, then y_3, and so on.

Slightly Less Naive Algorithm

To fix the above issue, we effectively allow vertices u and v to have separate copies of edge (u, v), where u's copy can only be deleted if u itself is resampled. Formally, every vertex v will have a corresponding set of edges S_v and we will always have $H = \bigcup_{v \in V} S_v$, where all edges in H have weight $1/\rho$. We define an operation $\textsc{SampleVertex}(v)$ that *independently* samples each edge in $\textsc{Inc}_G(v)$ into S_v with probability ρ. The naive implementation of $\textsc{SampleVertex}(v)$ takes time $O(\deg_G(v)) = O(\Delta_{\max})$ time, but an existing technique used

in [71, 45, 32] allows us to implement SAMPLEVERTEX(v) in time $O(\rho\Delta_{\max}\log(n)) = \tilde{O}(1)$. (The basic idea is that the sampling can be done in time proportional to the number of edges successfully chosen, rather than the number examined.)

The dynamic algorithm is as follows. At initialization, construct each S_v by calling SAMPLEVERTEX(v), and then set $H = \bigcup_{v\in V} S_v$. Whenever the adversary deletes edge (u, v), replace S_u and S_v with new sets SAMPLEVERTEX(u) and SAMPLEVERTEX(v), and modify $H = \bigcup_{v\in V} S_v$ accordingly. By the above discussion, the update time is clearly $\tilde{O}(1)$. We now show that this algorithm effectively guarantees a good *lower bound* on the weight of each cut in H, but might still lead to an overly high weight. Consider any cut $(X, \bar{X})$. By the expansion of G, the *average* vertex $x \in X$ has $\text{INC}_G(x) \cap E_G(X, \bar{X}) \geq \phi\Delta_{\min}$. For simplicity, let us assume that *every* vertex $x \in X$ has $\text{INC}_G(x) \cap E_G(X, \bar{X}) = \tilde{\Omega}(\phi\Delta_{\min}) = \tilde{\Omega}(\Delta_{\min})$, as we can effectively ignore the small fraction of vertices for which this is false. Now, say that an operation SAMPLEVERTEX(x) succeeds if it results in $|S_x \cap E_G(X, \bar{X})| \sim \rho|\text{INC}_G(x) \cap E_G(X, \bar{X})|$. Because of our setting for ρ and our assumption that $\text{INC}_G(x) \cap E_G(X, \bar{X}) = \tilde{\Omega}(\Delta_{\min})$, a Chernoff bound guarantees that each SAMPLEVERTEX(x) succeeds with probability $1-n^{-10}$. Now, since the adversary makes at most m updates before the graph is empty, each SAMPLEVERTEX(x) is called at most n^2 times, so there is a $1-n^{-8}$ probability that *every* call SAMPLEVERTEX(x) is successful; we call such vertices always-successful. A simple probability calculation shows that $\Pr[\text{at least } |X|/2 \text{ vertices in } X \text{ are always-successful}] \geq 1 - n^{-2|X|}$, which allows us to union bound over all cuts of size X. Thus, at all times, half the vertices in X have $|S_x \cap E_G(X, \bar{X})| \sim \rho|\text{INC}_G(x) \cap E_G(X, \bar{X})|$; assuming for simplicity that this is an "average" half of vertices, i.e. that these vertices have around half of the edges crossing the cut, we have $|E_H(X, \bar{X})| \geq |\bigcup_{x\in X} S_x \cap E_G(X, \bar{X})| \gtrsim \rho|E_G(X, \bar{X})|/2$.

The above idea already implies that we can maintain a sparse graph H where each cut is expanding, i.e. a sparse expander, against an adaptive adversary. As an expander has low diameter, H is a spanner. Therefore, we are done if our goal is a dynamic spanner algorithm.

Unfortunately, this algorithm is not strong enough for maintaining cut sparsifiers, as the algorithm may result in $|E_H(X, \bar{X})| \gg \rho|E_G(X, \bar{X})|$. Let $\Delta_{\max} \sim \sqrt{n}$, and consider the following graph G. There is a set X of size $\sqrt{n}$ such that $G[X]$ is a clique and $G[\bar{X}]$ is $\sqrt{n}$-degree-expander. There is also a $\sqrt{n}$-to-1 matching from X to $\bar{X}$: so every vertex in $y \in \bar{X}$ has *exactly one* edge e_y crossing the cut. It is easy to check that G is an expander. The adversary then does the following. For each $y \in \bar{X}$, it keeps deleting edges in $E(y, \bar{X})$ until e_y is sampled into S_y; with high probability, this occurs within $O(\log(n)/\rho)$ deletions for each vertex y. Thus, at the end, $H \supseteq \bigcup_{y\in\bar{X}} S_y$ contains all of $E_G(X, \bar{X})$.

Better Algorithm via Proactive Sampling

We now show how to modify the above algorithm to ensure that w.h.p., $|E_H(X, \bar{X})| = \tilde{O}(\rho|E_G(X, \bar{X})|)$; we later improve this to $|E_H(X, \bar{X})| = O(\rho\log(n)|E_G(X, \bar{X})|)$. We let time t refer to the tth adversarial update. As before, we always have $H = \bigcup_{v\in V} S_v$, and if the adversary deletes edge (u, v) at time t, the algorithm immediately calls SAMPLEVERTEX(u) and SAMPLEVERTEX(v). The change is that the algorithm also calls SAMPLEVERTEX(u) and SAMPLEVERTEX(v) at times $t+1, t+2, t+4, t+8, t+16, \ldots$; we call this *proactive sampling*. The proof that $|E_H(X, \bar{X})| \gtrsim \rho|E_G(X, \bar{X})|/2$ remains basically the same as before. We now upper bound $|E_H(X, \bar{X})|$.

The formal analysis is somewhat technical, but the crux if the following **key claim:** for any $(u, v) \in G$, we have that after t adversarial updates, $\Pr[(u, v) \in H \text{ at time t}] \leq 2\rho\log(t) \leq 2\rho\log(m)$. We then use the key claim as follows: consider any cut $(X, \bar{X})$. If every edge in $E_G(X, \bar{X})$ was *independently* sampled into H with probability at most $2\rho\log(m)$,

then a Chernoff bound would show that $|E_H(X, \bar{X})| \leq 4\rho \log(m)|E_G(X, \bar{X})|$ with probability at least $1 - n^{-2|X|}$, as desired. Unfortunately, even though every individual edge-sampling occurs with probability ρ, independent of everything that happened before, it is NOT the case that event $e \in H$ is independent from event $e' \in H$: the adversary is adaptive, so its sampling strategy for e' can depend on whether or not e was successfully sampled into H at an earlier time. Nonetheless, we show in the full proof that these dependencies can be disentangled.

Let us now sketch the proof for the key claim. The edge (u, v) can appear in H because it is in S_u or S_v at the time t. Let us bound the probability that $(u, v) \in S_u$ at time t. Let $T_{\text{schedule}}(u)$ be all times before t for which SampleVertex(u) has been scheduled by proactive sampling: so whenever the adversary updates an edge (u, v) at time t', times $t', t' + 1, t' + 2, t' + 4, t' + 8, \ldots$ are added to $T_{\text{schedule}}(u)$. Let $T^{t'}_{\text{schedule}}(u) \subset [t', t]$ be the state of $T_{\text{schedule}}(u)$ at time t'. Now, we say that a call to SampleVertex(u) at time t' is *relevant* if $T^{t'+1}_{\text{schedule}}(u) = \emptyset$. Observe that for (u, v) to be in S_u at time t, it must have been added during some relevant call SampleVertex(u), because every non-relevant call is followed by another call before time t which invokes again SampleVertex(u) and thereby deletes the previously sampled set S_u and replaces it by a new one. We complete the proof by claiming that there are at most $\log(t)$ relevant calls SampleVertex(u). This is because if a relevant call occurs at t', then proactive sampling adds some time t^* to $T_{\text{schedule}}(u)$ such that $(t' + t)/2 \leq t^* \leq t$; thus, there can be no relevant calls in time interval $[t', (t' + t)/2]$. So each relevant call halves the possible time interval for other relevant calls, so there are at most $\log(t)$ relevant calls.

We now briefly point out why this modified algorithm has $|E_H(X, \bar{X})| = \tilde{O}(\rho|E_G(X, \bar{X})|)$, rather than the desired $|E_H(X, \bar{X})| = O(\rho \log(n)|E_G(X, \bar{X})|)$. Consider again the graph G consisting of a vertex set X of size $\sqrt{n}$ such that $G[X]$ is a complete graph, and let $\overline{X}$ be a $\sqrt{n}$-degree expander in $G[\overline{X}]$. Additionally, we have a $\sqrt{n}$-to-one matching, i.e. every vertex in X is matched to $\sqrt{n}$ vertices in $\overline{X}$. The graph is still an expander as argued before.

Now observe that $\Delta_{\max} = 2\sqrt{n}$ and we obtain a first sparsifier H at time 0 of G where we have weight on the cut, i.e. $|E_H(X, \bar{X})|/\rho$, of size $\sim n$ (which is the number of edges crossing). In particular, the weight on edges in $|E_H(X, \bar{X}) \cap \bigcup_{x \in \overline{X}} S_x|/\rho \sim n$, i.e. the vertices in $\overline{X}$ carry half the weight of the cut in the sparsifier. But over the course of the algorithm, the adversary can delete edges in the cut $(X, \overline{X})$ that are in $G \setminus H$. Observe that the resampling events do not affect edges in $E_H(X, \bar{X}) \cap \bigcup_{x \in \overline{X}} S_x$ since none of the deleted edges is incident to any such edge (recall the $\sqrt{n}$-to-one matching). The adversary can continue until the cut only has weight in G of $|X|\Delta_{\min}\phi$ without violating the expander and min-degree guarantees. But then the weight in H on the cut is still $\sim n$ while the weight in G is only $\sim n(\Delta_{\max}/\Delta_{\min})\phi$. Thus, we only obtain a $\sim (\Delta_{\max}/\Delta_{\min})\phi$-approximation (plus a $\log n$-factor from proactive sampling might appear).

Final Algorithm

To resolve the issue above, we would like to ensure that the edges in $E_H(X, \bar{X})$ are resampled when $|E_G(X, \bar{X})|$ changes by a large amount. We achieve this with one last modification to the algorithm: for every $v \in V$, whenever $\deg_G(v)$ decreases by $\zeta = \phi\Delta_{\min}$, we run SampleVertex$(w)$ for every edge $(v, w) \in G$. It is not hard to check that each vertex will only resampled a total of $O(\Delta^2_{\max}/\zeta) = \tilde{O}(\Delta_{\max})$ additional times as a result of this change which is subsumed by $\tilde{O}(m)$ when summing over the vertices. (A naive implementation of the above modification only leads to small *amortized* update time, but this can easily be worst-case by staggering the work over several updates using round-robin scheduling.) We leave the analysis of the approximation ratio for the full version.

By using the convenient lemma which says that any cut sparsifier on an expander is also a spectral sparsifier, we also obtain an adaptive algorithm for spectral sparsifier.

2.3 Reduction to Expanders: Worst-Case Update Time

We now outline how to extend our black-box reduction to work with worst-case update time. We again assume there exists some algorithm $\mathcal{A}_X$ that maintains for any graph G a sparsifier $H \in \mathcal{H}(G, \epsilon)$, provided that G stays a uniform degree expander throughout all updates, all of which are only edge deletions.

The condition that G always remains an expander is too strong, but we can use expander pruning to maintain the property from the perspective of $\mathcal{A}_X$. Consider some deletion in G: although G may not be an expander, we can use pruning to find a subset of edges $P \subset E(G)$, such that $G \setminus P$ is an expander. We then input all edges in P as deletions to $\mathcal{A}_X$, so the graph $G \setminus P$ in question is still an expander: $\mathcal{A}_X$ thus returns $H \in \mathcal{H}(G \setminus P, \epsilon)$. Then based on property (1) and (2) it can be shown that $H \cup P \in \mathcal{H}(G, \epsilon)$. So by taking all the pruned edges together with the sparsifier H of $G \setminus P$ we obtain a sparsifier of G, even when G itself is no longer an expander.

Unfortunately this dynamic sparsifier algorithm has two downsides: (i) The maintained sparsifier is only sparse for a short sequence of updates, as otherwise the set of pruned edges becomes too large and thus the output $H \cup P$ becomes too dense. (ii) The algorithm only works on graphs that are initially an expander.

Extending the algorithm to general graphs

To extend the previous algorithm to work on general graphs, we run the static expander decomposition algorithm. As outlined before, we can decompose G into subgraphs $G_1, G_2, ...$, where each G_i is an expander and $\bigcup_i G_i = G$. We can then run the algorithm, outlined in the previous paragraph, on each of these expanders and the union of all the obtained sparsifiers will be a sparsifier of the original input G.

Similar as before, one downside of this technique is that the size of the sparsifier will increase with each update, because more and more edges will be pruned. Thus, the resulting dynamic algorithm can only maintain a sparsifier for some limited number of updates.

Extending the number of updates

A common technique for dynamic algorithms, which only work for some limited number of updates (say k updates), is to reset the algorithm after k updates. If the algorithm has preprocessing time p and update time u, then one can obtain an algorithm with amortized update time $O(p/k + u)$. However, the worst-case complexity would be quite bad, because once the reset is performed, the old sparsifier (from before the reset) must be replaced by the new one. Listing all edges of the new sparsifier within a single update would be too slow. There is a standard technique for converting such an amortized bound to an equivalent worst-case bound. The idea is to slowly translate from the old sparsifier to the new one, by only listing few edges in each update. For this we require another property for $\mathcal{H}$ that guarantees that the sparsifier stays valid, even when removing a few of its edges.

Transition Property

Consider some $H_1, H_2 \in \mathcal{H}(G, \epsilon)$, and we now want to have a slow transition from H_1 to H_2, by slowly removing edges from H_1 from the output (and slowly inserting edges of H_2). The exact property we require is as follows:

$$\text{Let } H_1, H_2 \in \mathcal{H}(G, \epsilon) \text{ and } H \subset H_1, \text{ then } (e^{\delta} - 1)H \cup H_2 \in \mathcal{H}(G, \epsilon + \delta). \tag{4}$$

Here $H \subset H_1$ represents the remaining to be removed edges (or alternatively $H_1 \setminus H$ are the remaining to be inserted edges). Exploiting this property we are able to obtain a $O(p/k + u)$ worst-case update time.

As the output grows with each update, we must perform the reset after $k = O(n)$ updates, otherwise the output becomes too dense. This is unfortunate as the preprocessing time is $p = \Omega(m)$, because one must read the entire input, which is too slow to obtain a subpolynomial update time. This issue can be fixed via a sparsification technique based on [49], presented in the full version. By using this technique, we can make sure that $m = O(n^{1+o(1)})$ and thus the preprocessing time will be fast enough to allow for $O(n^{o(1)})$ update time.

For this sparsification technique we require the following transitivity property.

Transitivity Property

$$\text{If } H \in \mathcal{H}(G, \epsilon), \text{ then } \mathcal{H}(H, \delta) \subset \mathcal{H}(G, \delta + \epsilon). \tag{5}$$

Intuitively this means that an approximation H of G and an approximation H' of H, then H' is also a (slightly worse) approximation of G.

Properties 1-5 above are precisely the properties required of a graph problem by our black-box reduction for worst-case update time. We show in the full version that the sparsifiers discussed in this paper (spectral sparsifier, cut sparsifier, spanner) satisfy all these properties.

Sparsification Technique

We now outline the sparsification technique, whose formal proof is presented in the full version. Let G be an arbitrary graph. We partition the edges of G into equally sized subgraphs $G_1, G_2, ..., G_d$ for some $d > 1$. Note that, if we have ε-approximate sparsifiers $H_1, ..., H_d$ of $G_1, ..., G_d$, then $\bigcup_i H_i$ is a ε-approximate sparsifier of G by property (2). In addition, if we have a ε-approximate sparsifier H of $\bigcup_i H_i$, then H is a (2ε)-approximate sparsifier of G by property (5). This allows us to obtain a faster algorithm as follows: If G has m edges, then each G_i has only m/d edges, so the dynamic algorithm runs faster on these sparse G_i. Further, since the H_i are sparse (let's say $O(n)$ edges), the graph $\bigcup_i H_i$ has only $O(dn)$ edges and maintaining H is also faster than maintaining a sparsifier of G directly, if $dn = o(m)$. The next idea is to repeat this trick recursively: We repeatedly split each G_i into $d = n^{o(1)}$ graphs, until the graphs have only $O(n^{1+o(1)})$ edges. This means we obtain some tree-like structure rooted at G, where each tree-node G' represents a subgraph of G and its tree-children are the d subgraphs $G'_1, ..., G'_d$ of G'. For the graphs that form leaves of this tree, we run our dynamic sparsifier algorithm. We also obtain a sparsifier H' of any non-leaf tree-node G', by running our dynamic algorithm on $\bigcup_{i=1}^{d} H'_i$, where the H'_i are sparsifiers of the child-tree-nodes G'_i of the tree-node G'. Thus all instances of our dynamic algorithm always run on sparse input graphs. However, there is one downside: When some sparsifier H'_i changes, the sparsifier H' must also change. Let's say some edge is deleted from G, then the edge is deleted from one leaf-node of the tree-structure, and this update will propagate

from the leaf-node all the way to the root of the tree. This can be problematic because when the dynamic algorithm changes some $c > 1$ many edges of the sparsifier for each edge update, then the number of updates grows exponentially with the depth of the tree-like structure. In [49] Eppstein et al. circumvented this issue by assuming an extra property which they call *stability property*, which essentially says that this exponential growth does not occur. Our modified sparsification technique no longer requires this assumption, instead we balance the parameter d carefully to make sure the blow-up of the propagation is only some sub-polynomial factor.

Abstract

Spectral independence is a recently-developed framework for obtaining sharp bounds on the convergence time of the classical Glauber dynamics. This new framework has yielded optimal $O(n \log n)$ sampling algorithms on bounded-degree graphs for a large class of problems throughout the so-called uniqueness regime, including, for example, the problems of sampling independent sets, matchings, and Ising-model configurations.

Our main contribution is to relax the bounded-degree assumption that has so far been important in establishing and applying spectral independence. Previous methods for avoiding degree bounds rely on using L^p-norms to analyse contraction on graphs with bounded connective constant (Sinclair, Srivastava, Yin; FOCS'13). The non-linearity of L^p-norms is an obstacle to applying these results to bound spectral independence. Our solution is to capture the L^p-analysis recursively by amortising over the subtrees of the recurrence used to analyse contraction. Our method generalises previous analyses that applied only to bounded-degree graphs.

As a main application of our techniques, we consider the random graph $G(n, d/n)$, where the previously known algorithms run in time $n^{O(\log d)}$ or applied only to large d. We refine these algorithmic bounds significantly, and develop fast nearly linear algorithms based on Glauber dynamics that apply to all constant d, throughout the uniqueness regime.

1 Introduction

Spectral independence method was introduced by Anari, Liu, and Oveis Gharan [2] as a framework to obtain polynomial bounds on the mixing time of Glauber dynamics. Originally based on a series of works on high-dimensional expansion [17, 9, 21, 18, 1], it has since then been developed further using entropy decay by Chen, Liu, and Vigoda [8] who obtained optimal $O(n \log n)$ mixing results on graphs of bounded maximum degree Δ whenever the

framework applies. This paper focuses on relaxing the bounded-degree assumption of [8], in sparse graphs where the maximum degree is not the right parameter to capture the density of the graph.

As a running example we will use the problem of sampling (weighted) independent sets, also known as the sampling problem from the hard-core model. For a graph $G = (V, E)$, the hard-core model with parameter $\lambda > 0$ specifies a distribution $\mu_{G,\lambda}$ on the set of independent sets of G, where for an independent set I it holds that $\mu_{G,\lambda}(I) = \lambda^{|I|}/Z_{G,\lambda}$ where $Z_{G,\lambda}$ is the partition function of the model (the normalising factor that makes the probabilities add up to 1). For bounded-degree graphs of maximum degree $d+1$ (where $d \geq 2$ is an integer), it is known that the problems of sampling and approximately counting from this model undergo a computational transition at $\lambda_c(d) = \frac{d^d}{(d-1)^{d+1}}$, the so-called uniqueness threshold [29, 27, 12]: they are poly-time solvable when $\lambda < \lambda_c(d)$, and computationally intractable for $\lambda > \lambda_c(d)$. Despite this clear complexity picture, prior to the introduction of spectral independence, the algorithms for $\lambda < \lambda_c(d)$ were based on elaborate enumeration techniques whose running times scale as $n^{O(\log d)}$ [29, 19, 22, 23]. The analysis of Glauber dynamics[1] using spectral independence in the regime $\lambda < \lambda_c(d)$ yielded initially $n^{O(1)}$ algorithms for any d [2], and then $O(n \log n)$ for bounded-degree graphs [8] (see also [7]). More recently, Chen, Feng, Yin, and Zhang [5] obtained $O(n^2 \log n)$ results for arbitrary graphs $G = (V, E)$ that apply when $\lambda < \lambda_c(\Delta_G - 1)$, where Δ_G is the maximum degree of G (see also [14] for related results when Δ_G grows like $\log n$).

The maximum degree is frequently a bad measure of the density of the graph, especially for graphs with unbounded-degree. One of the most canonical examples is the random graph $G(n, d/n)$ where the maximum degree grows with n but the average degree is d, and therefore one would hope to be able to sample from $\mu_{G,\lambda}$ for λ up to some constant, instead of $\lambda = o(1)$ that the previous results yield. In this direction, [26, 24] obtained an $n^{O(\log d)}$ algorithm based on correlation decay that applies to all $\lambda < \lambda_c(d)$ for all graphs with "connective constant" bounded by d (meaning, roughly, that for all $\ell = \Omega(\log n)$ the number of length-ℓ paths starting from any vertex is bounded by d^ℓ). The result of [24] applies to $G(n, d/n)$ for all $d > 0$. In terms of Glauber dynamics on $G(n, d/n)$, [20] showed an $n^{1+\Omega(1/\log\log n)}$ lower bound on the mixing time in the case of the Ising model; this lower bound actually applies to most well-known models, and in particular rules out $O(n \log n)$ mixing time results for the hard-core model when $\lambda = \Omega(1)$. The mixing-time lower bound on $G(n, d/n)$ has only been matched by complementary fast mixing results in models with strong monotonicity properties, see [20] for the ferromagnetic Ising model and [4] for the random-cluster model. Such monotonicity properties unfortunately do not hold for the hard-core model, and the best known results [10, 11] for Glauber dynamics on $G(n, d/n)$ give an n^C algorithm for $\lambda < 1/d$ and sufficiently large d (where C is a constant depending on d).

Our main contribution is to obtain nearly linear-time algorithms on $G(n, d/n)$, for all of the models considered in [24], i.e., the hard-core model, the monomer-dimer model (weighted matchings), and the antiferromagnetic Ising model. Key to our results are new spectral independence bounds for any $d > 0$ in the regime $\lambda < \lambda_c(d)$ for arbitrary graphs $G = (V, E)$ in terms of their "d-branching value" (which resembles the connective-constant notion of [24]). To state our main theorem for the hard-core model on $G(n, d/n)$, we first extend the definition

[1] Recall, for a graph G, the Glauber dynamics for the hard-core model iteratively maintains a random independent set $(I_t)_{t\geq 0}$, where at each step t a vertex v is chosed u.a.r. and, if $I_t \cup \{v\}$ is independent, it sets $I_{t+1} = I_t \cup \{v\}$ with probability $\frac{\lambda}{\lambda+1}$, otherwise $I_{t+1} = I_t \backslash \{v\}$. The mixing time is the maximum number (over the starting I_0) of steps t needed to get within total variation distance $1/4$ of $\mu_{G,\lambda}$, see Section 4.1 for the precise definitions.

of $\lambda_c(d)$ to all reals $d > 0$ by setting $\lambda_c(d) = \frac{d^d}{(d-1)^{d+1}}$ for $d > 1$, and $\lambda_c(d) = \infty$ for $d \in (0, 1)$. We use the term "*whp* over the choice of $G \sim G(n, d/n)$" as a shorthand for "as n grows large, with probability $1 - o(1)$ over the choice of $G(n, d/n)$". An ε-sample from a distribution μ supported on a finite set Ω is a random $\sigma \in \Omega$ whose distribution ν satisfies $\|\nu - \mu\|_{\mathrm{TV}} \leq \varepsilon$, where $\|\nu - \sigma\|_{\mathrm{TV}} = \frac{1}{2}\sum_{\sigma\in\Omega} |\nu(\sigma) - \mu(\sigma)|$.

▶ **Theorem 1.** *Let $d, \lambda > 0$ be such that $\lambda < \lambda_c(d)$. For any arbitrarily small constant $\theta > 0$, there is an algorithm such that, whp over the choice of $G \sim G(n, d/n)$, when the algorithm is given as input the graph G and an arbitrary rational $\varepsilon > 0$, it outputs an ε-sample from $\mu_{G,\lambda}$ in time $n^{1+\theta} \log \frac{1}{\varepsilon}$.*

The reader might wonder why is there no constant in front of the running time (in Theorems 1, 2, and 3) or why is there no requirement that n is sufficiently large? The assumption that n is sufficiently large is taken care of in the whp condition: there is a function $f_{d,\lambda,\theta} : \mathbb{Z} \to \mathbb{R}$ such that $\lim_{n\to\infty} f_{d,\lambda,\theta}(n) = 0$ and the "whp" means with probability $\geq 1 - f_{d,\lambda,\theta}(n)$ (the function $f_{d,\lambda,\theta}$ will have value ≥ 1 for small n, making the conclusion trivial for such n). Moreover, the family of $O(n^{1+\theta})$ algorithms from Theorem 1 can be turned into an $n^{1+o(1)}$ algorithm as follows. The function $f_{d,\lambda,\theta}$ is computable (and efficiently invertible), see Remark 35 in the full version for a discussion. Let $n_0 = 1$ and $n_k > n_{k-1}$ be such that $f_{d,\lambda,1/k}(n) \leq 1/k$ for all $n \geq n_k$. We are going to run the algorithm of Theorem 1 with $\theta = 1/k$ for $n \in \{n_{k-1}, \ldots, n_k - 1\}$. Note that the "combined" algorithm succeeds with probability $1 - o(1)$ and runs in time $n^{1+o(1)}$.

We further remark here that the algorithm of Theorem 1 (as well as Theorems 2 and 3 below) can also recognise in time $n^{1+o(1)}$ whether the graph $G \sim G(n, d/n)$ is a "good" graph, i.e., we can formulate graph properties that guarantee the success of the algorithm, are satisfied whp, and are also efficiently verifiable, see Section C.4 in the full version for details.

The key to obtaining Theorem 1 is to bound the spectral independence of $G(n, d/n)$. The main strategy that has been applied so far to bound spectral independence is to adapt suitably correlation decay arguments and, therefore, it is tempting to use the correlation decay analysis of [24]. This poses new challenges in our setting since [24] uses an L^p-norm analysis of correlation decay on trees, and the non-linearity of L^p-norms is an obstacle to converting their analysis into spectral independence bounds (in contrast, for bounded-degree graphs, the L^∞-norm is used which can be converted to spectral independence bounds using a purely analytic approach, see [7]). Our solution to work around that is to "linearise" the L^p-analysis by taking into account the structural properties of subtrees. This allows us to amortise over the tree-recurrence using appropriate combinatorial information (the d-branching values) and to bound subsequently spectral independence; details are given in Section 3, see Lemmas 10 and 12 (and equation (2) that is at the heart of the argument). Once the spectral independence bound is in place, further care is needed to obtain the fast nearly linear running time, paying special attention to the distribution of high-degree vertices inside $G(n, d/n)$ and to blend this with the entropy-decay tools developed in [8], see Section 4.2 for this part of the argument.

In addition to our result for the hard-core model, we also obtain similar results for the Ising and the matchings models. The configurations of the Ising model on a graph $G = (V, E)$ are assignments $\sigma \in \{0, 1\}^V$ which assign the spins 0 and 1 to the vertices of G. The Ising model with parameter $\beta > 0$ corresponds to a distribution $\mu_{G,\beta}$ on $\{0, 1\}^V$, where for an assignment $\sigma \in \{0, 1\}^V$, it holds that $\mu_{G,\beta}(\sigma) = \beta^{m(\sigma)}/Z_{G,\beta}$ where $m(\sigma)$ is the number of edges whose endpoints have the same spin assignment under σ, and $Z_{G,\beta}$ is the partition function of the model. The model is antiferromagnetic when $\beta \in (0, 1)$, and ferromagnetic otherwise. For $d \geq 1$, let $\beta_c(d) = \frac{d-1}{d+1}$; for $d \in (0, 1)$, let $\beta_c(d) = 0$. It is known that on

bounded-degree graphs of maximum degree $d+1$ the sampling/counting problem for the antiferromagnetic Ising model undergoes a phase transition at $\beta = \beta_c(d)$, analogous to that for the hard-core model [25, 19, 28, 13].

▶ **Theorem 2.** *Let $d, \beta > 0$ be such that $\beta \in (\beta_c(d), 1)$. For any constant $\theta > 0$, there is an algorithm such that, whp over the choice of $G \sim G(n, d/n)$, when the algorithm is given as input the graph G and an arbitrary rational $\varepsilon > 0$, it outputs an ε-sample from $\mu_{G,\beta}$ in time $n^{1+\theta} \log \frac{1}{\varepsilon}$.*

For a graph $G = (V, E)$, the matchings model with parameter $\gamma > 0$, also known as the monomer-dimer model, corresponds to a distribution $\mu_{G,\gamma}$ on the set of matchings of G, where for a matching M, it holds that $\mu_{G,\gamma}(M) = \gamma^{|M|}/Z_{G,\gamma}$ where $Z_{G,\gamma}$ is the partition function. For general graphs $G = (V, E)$ and $\gamma = O(1)$, [15, 16] gave an $O(n^2 m \log n)$ algorithm (where $n = |V|, m = |E|$), which was improved for bounded-degree graphs to $O(n \log n)$ in [8] using spectral independence. For $G(n, d/n)$, [24] gave an $O(n^{\log d})$ deterministic algorithm using correlation decay, and [14] showed that Glauber dynamics mixes in $n^{2+o(1)}$ steps in the case that $\gamma = 1$.

▶ **Theorem 3.** *Let $d, \gamma > 0$. For any constant $\theta > 0$, there is an algorithm such that, whp over the choice of $G \sim G(n, d/n)$, when the algorithm is given as input the graph G and an arbitrary rational $\varepsilon > 0$ outputs an ε-sample from $\mu_{G,\gamma}$ in time $n^{1+\theta} \log \frac{1}{\varepsilon}$.*

In the next section, we give the main ingredients of our algorithm for the hard-core model and we give the proof of Theorem 1. The proofs of Theorems 2 and 3 build on similar ideas, though there are some modifications needed to obtain the required spectral independence bounds. We give their proofs in Section B.3 of the full version.

Before proceeding let us finally mention that, to go beyond the 2-spin models studied here, the main obstacle is to establish the spectral independence bounds for graphs with potentially unbounded degrees. As it is pointed out in [24, Section 7], their correlation-decay analysis in terms of the connective constant using L^p-norms does not extend to other models in a straightforward manner, and hence it is natural to expect that the same is true for spectral independence as well.

2 Proof outline for Theorem 1

Our algorithm for sampling from the hard-core model on a graph $G = (V, E)$ is an adaptation of Glauber dynamics on an appropriate set of "small-degree" vertices U, the details of the algorithm are given in Figure 1. Henceforth, analogously to the Ising model, it will be convenient to view the hard-core model as a 2-spin model supported on $\Omega \subseteq \{0,1\}^V$, where Ω corresponds to the set of independent sets of G (for an independent set I, we obtain $\sigma \in \{0,1\}^V$ by setting $\sigma_v = 1$ iff $v \in I$).

Note that for general graphs G, implementing Steps 2 and Steps 3 of the algorithm might be difficult. The following lemma exploits the sparse structure of $G(n, d/n)$ and in particular the fact that high-degree vertices are sparsely scattered. We will use this in the proof of our main theorems to show that the algorithm $\textsc{Sample}(G, T)$ can be implemented very efficiently for appropriate D, paying only $O(\log n)$ per loop operation in Step 2 and only $O(n \log n)$ in Step 3. The *tree-excess* of a graph $G = (V, E)$ is defined as $|E| - |V| + 1$.

▶ **Lemma 4.** *Let $d > 0$ be an arbitrary real. There exist constants $D, \ell > 0$ such that the following holds whp over the choice of $G = (V, E) \sim G(n, d/n)$. Each of the connected components of $G[V \setminus U]$, where U is the set of vertices of degree $\leq D$, has size $O(\log n)$ and tree-excess at most ℓ.*

Algorithm SAMPLE(G, T).

Parameters: $D > 0$ (threshold for small/high degree vertices).

Input: Graph $G = (V, E)$, integer $T \geq 1$ (number of iterations).

1. **Initialisation:** Let U be the set of all vertices with degree $\leq D$.
   Let X_0 be the empty independent set on U.
2. **Main loop:** For $t = 1, \ldots, T$,
   - Pick a vertex u uniformly at random from U.
   - For every vertex $v \in U \backslash \{u\}$, set $X_t(v) = X_{t-1}(v)$.
   - Sample the spin $X_t(u)$ according to $\mu_{G,\lambda}\big(\sigma_u \mid \sigma_{U\backslash\{u\}} = X_t(U\backslash\{u\})\big)$, i.e., update u according to the hard-core distribution on the *whole graph* G, conditioned on the spins of $U\backslash\{u\}$.
3. **Finalisation:** Sample $\sigma \sim \mu_{G,\lambda}\big(\cdot \,\big|\, \sigma_U = X_T\big)$, i.e., extend X_T to the whole vertex set of G by sampling from $\mu_{G,\lambda}$ conditioned on the configuration on U.

Figure 1 The SAMPLE(G, T) subroutine for sampling from the hard-core distribution $\mu_{G,\lambda}$. We use the analogue of this algorithm for the Ising model with parameter β (replacing $\mu_{G,\lambda}$ by $\mu_{G,\beta}$). For the monomer-dimer model, the only difference is that the algorithm needs to update (single) edges in F, where F is the set of vertices whose both endpoints lie in U (i.e., degree $\leq D$).

Lemma 4 follows using relatively standard techniques from random graphs and is proved in Section C of the full version. Later, we will establish a more refined version of this property that will allow us to bound the mixing time of the single-site dynamics that we consider (the main loop of SAMPLE(G, T)).

The key ingredient needed to prove our main result is to show that the main loop of our sampling algorithm returns a good sample on the induced hard-core distribution on the set U. More precisely, for a graph $G = (V, E)$ and $U \subseteq V$, we let $\mu_{G,\lambda,U}(\cdot)$ denote the induced distribution on the spins of U, i.e., the marginal distribution $\mu_{G,\lambda}(\sigma_U = \cdot)$.

▶ **Lemma 5.** *Let $d, \lambda > 0$ be constants such that $\lambda < \lambda_c(d)$. For any arbitrarily small constant $\theta > 0$, there is $D > 0$ such that the following holds whp over the choice of $G \sim G(n, d/n)$.*

Let U be the set of vertices in G of degree $\leq D$. Then, for any $\varepsilon > 0$, for $T = \lceil n^{1+\theta/2} \log \frac{1}{\varepsilon} \rceil$, the main loop of SAMPLE(G, T) returns a sample X_T from a distribution which is ε-close to $\mu_{G,\lambda,U}$.

We will prove Lemma 5 in Section 4.2. With these two lemmas we are ready to prove Theorem 1.

Proof of Theorem 1. We give first the details for the more interesting case $d \geq 1$. Consider arbitrarily small $\theta > 0$ and D, ℓ as in Lemmas 4 and 5, so that whp G satisfies the properties therein. Let $\varepsilon > 0$ be the desired accuracy for sampling from $\mu_{G,\lambda}$; it is sufficient to consider $\varepsilon < 1/\mathrm{e}$. Let U be the set of vertices with degree $\leq D$, and set $T = \lceil n^{1+\theta/2} \log \frac{1}{\varepsilon} \rceil$.

By Lemma 5, whp over the choice of G, the main loop of SAMPLE(G, T) returns a configuration $X_T : U \to \{0, 1\}$ that is ε-close to $\mu_{G,\lambda,U}$. Note that each iteration of the main loop of SAMPLE(G, T) can be implemented in $O(\log n)$ time since $G[V\backslash U]$ has components of size $O(\log n)$ and tree excess at most ℓ. In particular, any vertex $u \in U$ can be adjacent to at most D of these components, and therefore the component of u in $G[(V\backslash U) \cup \{u\}]$ has

size $O(\log n)$ and tree excess at most $k = D\lceil \ell \rceil = O(1)$. We can therefore sample the spin of u under $\mu_{G,\lambda}$ conditioned on the spins of $U\backslash\{u\}$ in time $O(4^k \log n) = O(\log n)$.[2] Therefore, the main loop of $\textsc{Sample}(G,T)$ runs in time $O(T \log n)$. Analogously, the finalisation step of $\textsc{Sample}(G,T)$, i.e., extending the configuration X_T on U to a configuration σ on the whole vertex set V, can be implemented in time $O(n \log n)$ by iterating over the vertices in $V\backslash U$ and using the fact that the components of $G[V\backslash U]$ have excess at most ℓ. Therefore, the overall running time of the algorithm is bounded by $O(T \log n) + O(n \log n)$, which is less than $\lceil n^{1+\theta} \log \frac{1}{\varepsilon} \rceil$ for all sufficiently large n. It remains to note that, since X_T is ε-close to the marginal distribution of $\mu_{G,\lambda}$ on U, and the finalisation step is done perfectly conditioned on the configuration on U, the final configuration σ is ε-close to the distribution $\mu_{G,\lambda}$.

For $d < 1$, whp G consists of tree-like components of size $O(\log n)$, and therefore we can obtain a perfect sample from $\mu_{G,\lambda}$ in time $O(n \log n)$ by going through the vertices one by one and, for each vertex, taking $O(\log n)$ time to compute its marginal, conditioned on the spins already sampled. ◀

3 Spectral independence via branching values

We first introduce the notions of spectral independence and pairwise vertex influences, which we will later use to bound the mixing time of the main loop of $\textsc{Sample}(G,T)$, i.e., to prove Lemma 5. We will define the terminology in a general way that will be useful both for our analysis of the hard-core model, and for our later analysis of other models.

Let $q \geq 2$ be an integer indicating the number of spins and let V be a set of size n. We will consider distributions μ supported on a set $\Omega \subseteq [q]^V$.[3] For $S \subseteq V$, let $\Omega_S = \{\tau \in [q]^S \mid \mu(\sigma_S = \tau) > 0\}$ be the set of all partial configurations on $[q]^S$ that have non-zero marginal under μ. For $\tau \in \Omega_S$, let μ_τ be the conditional distribution on Ω induced by τ, i.e., $\mu_\tau(\cdot) = \mu(\cdot \mid \sigma_S = \tau)$. Let $\mu_{\min} = \min_{\sigma\in\Omega} \mu(\sigma)$.

For $S \subseteq V$ and $\tau \in \Omega_S$, the *influence matrix* conditioned on τ is the matrix $\mathbf{\Psi}_\tau$ whose rows and columns are indexed by $\tilde{V}_\tau = \{(v,i) \mid v \in V\backslash S,\ \mu_\tau(\sigma_v = i) > 0\}$, where the entry indexed by $(v,i),(w,k)$ equals $\mu_\tau(\sigma_w = k \mid \sigma_v = i) - \mu_\tau(\sigma_w = k)$ if $v \neq w$, and 0 otherwise. It is a standard fact that the eigenvalues of the matrix $\mathbf{\Psi}$ are all real ([2]), and we denote by $\lambda_1(\mathbf{\Psi})$ its largest eigenvalue.

▶ **Definition 6.** *Let $q \geq 2$ be an integer and V be a set of size $n \geq 2$. Let μ be a distribution supported over $\Omega \subseteq [q]^V$. Let $\eta, b > 0$. We say that μ is* η-spectrally independent *if for all $S \subset V$ and $\tau \in \Omega_S$, it holds that $\lambda_1(\mathbf{\Psi}_\tau) \leq \eta$. We say that μ is* b-marginally bounded *if for all $S \subset V$, $v \in V\backslash S$, $\tau \in \Omega_S$, and $i \in [q]$, it either holds that $\mu_\tau(\sigma_v = i) = 0$ or else $\mu_\tau(\sigma_v = i) \geq b$.*

Following [2, 7], for distributions μ induced by 2-spin systems, we work with the following notion of pairwise vertex-influence, which can be used to bound the spectral independence. For a graph $G = (V,E)$ and $\tau \in \{0,1\}^S$ for some $S \subset V$, for vertices u, v with $u \in V\backslash S$ and $0 < \mu_\tau(\sigma_u = 1) < 1$, we define the *influence* of u on v (under μ_τ) as

$$\mathcal{I}^\tau_G(u \to v) = \mu_\tau(\sigma_v = 1 \mid \sigma_u = 1) - \mu_\tau(\sigma_v = 1 \mid \sigma_u = 0).$$

[2] One "naive" way to do this is by considering a spanning tree and then brute-forcing over all $\leq 4^k$ possibilities for the endpoints of the excess edges (the spins on each edge can be set in at most 4 ways). For each of these, the marginal probability at u and the corresponding partition function can be computed using dynamic programming on the left-over tree.

[3] For an integer $k \geq 1$, we denote by $[k]$ the set $\{0, 1, \ldots, k-1\}$.

For matchings, we will work with an analogous notion from the perspective of edges (see Section B.2 of the full version). For all these models, spectral independence will be bounded by summing the absolute value of the influences of an arbitrary vertex u to the rest of the graph.

In turn, it has been shown in [7] that summing the influences of a vertex u in a graph G reduces to summing the sum of influences on the self-avoiding walk tree emanating from u, see Lemma 22 in the full version. Therefore, we only need to focus on trees arising as self-avoiding walk trees.

3.1 The branching value

We will need the following notion to capture the growth of the self-avoiding walk tree from a vertex.

▶ **Definition 7.** *Let $d > 0$ be a real number and $G = (V, E)$ be a graph. For a vertex v in G, the d-branching value S_v equals $\sum_{\ell \geq 0} N_{v,\ell}/d^\ell$, where $N_{v,\ell}$ is the number of (simple) paths with a total of $\ell + 1$ vertices starting from v (for convenience, we set $N_{v,0} = 1$).*

We will show the following lemma in Section C.1 which bounds the d'-branching value of $G(n, d/n)$ for any $d' > d$.

▶ **Lemma 8.** *Let $d \geq 1$. Then, for every $d' > d$ and $\varepsilon > 0$, whp over the choice of $G \sim G(n, d/n)$, the d'-branching value of every vertex in G is at most $\varepsilon \log n$.*

3.2 Spectral independence for the hard-core model

In this section, we bound the spectral independence of $G(n, d/n)$ in the hard-core model when $\lambda < \lambda_c(d)$. We will need the following technical lemma that can be derived from [24]. The derivation details are similar to an analogous lemma for matchings (cf. Lemma 26 in the full version), which can be found in [3, Lemma 15].

▶ **Lemma 9** ([24])**.** *Let $d > 1$ and $\lambda > 0$ be constants such that $\lambda < \lambda_c(d)$. Let $\chi \in (1, 2)$ be given from $\frac{1}{\chi} = 1 - \frac{d-1}{2} \log\left(1 + \frac{1}{d-1}\right)$ and set $a = \frac{\chi}{\chi - 1}$. Consider also the function $\Phi(y) = \frac{1}{\sqrt{y(1+y)}}$ for $y > 0$. Then, there is a constant $0 < \kappa < 1/d$ such that the following holds for any integer $k \geq 1$.*

Let $x_1, \ldots, x_k$ be reals and $x = \lambda \prod_{i=1}^{k} \frac{1}{1+x_i}$. Then $(\Phi(x))^a \sum_{i=1}^{k} \left(\frac{x}{(1+x_i)\Phi(x_i)}\right)^a \leq \kappa^{a/\chi}$.

We will show the following.

▶ **Lemma 10.** *Let $d > 1$ and $\lambda > 0$ be constants such that $\lambda < \lambda_c(d)$. Then, there is a constant $\chi > 1$ such that the following holds.*

Let $T = (V, E)$ be a tree rooted at ρ, whose d-branching value is $\leq \alpha$ and whose root has k children. Then, for the hard-core distribution on T with parameter λ, any $S \subseteq V \backslash \{\rho\}$ and $\tau \in \Omega_S$ with $0 < \mu_\tau(\sigma_\rho = 1) < 1$, it holds that

$$\sum_{v \in V} \left|\mathcal{I}_T^\tau(\rho \to v)\right| \leq W_k \alpha^{1/\chi},$$

where $W_k > 0$ is a real depending only on the degree k of the root (and the constants d, λ).

Proof. Let $\kappa \in (0, 1/d)$ and $\chi \in (1, 2)$ be the constants from Lemma 9, and $\Phi(x) = \frac{1}{\sqrt{x(1+x)}}$ be also as in Lemma 9.

We may assume without loss of generality that S is empty (and τ is trivial) by truncating the tree T using the following procedure: just remove vertices $u \in S$ with $\tau_u = 0$, and for $u \in S$ with $\tau_u = 1$ remove u and all of its neighbours. Note that for all the removed vertices v it holds that $\mathcal{I}_T^\tau(\rho \to v) = 0$, so the removal procedure does not decrease the sum of the absolute influences, while at the same time decreasing the d-branching value of the tree T. Henceforth, we will drop τ and S from notation.

To prove the lemma, we will work inductively on the depth of the tree. To this end, we first define for each vertex u in T the following values α_u and R_u; the α's capture a rooted analogue of the branching value of internal vertices within T, while the R's the marginals of the vertices in the corresponding subtrees. More precisely, if v is a leaf, set $\alpha_v = 1$ and $R_v = \lambda$; otherwise set $\alpha_v = 1 + \frac{1}{d}\sum_{i=1}^k \alpha_{v_i}$ and $R_v = \lambda \prod_{i=1}^k \frac{1}{1+R_{v_i}}$, where $v_1, \dots, v_k$ are the children of v. Note that for the root ρ we have that $\alpha_\rho = S_\rho \le \alpha$, where S_ρ is the d-branching value of ρ in the tree T. Moreover, if we denote by T_v the subtree of T rooted at v and by u the parent of v in T, then it holds that

$$R_v = \frac{\mu_{T_v,\lambda}(\sigma_v = 1)}{\mu_{T_v,\lambda}(\sigma_v = 0)} \quad \text{and} \quad \mathcal{I}_T(u \to v) = -\frac{R_v}{R_v + 1}. \tag{1}$$

The first equality is fairly standard and can be proved using induction on the height of the tree, while the second one is [7, Lemma 15] (it also follows directly from the definition of influence and the first equality).

For an integer $h \ge 0$, let $L(h)$ be the nodes at distance h from the root ρ. Let $M_k = \sqrt{1 + (1+\lambda)^k/\lambda}$, where recall that k is the degree of the root ρ. We will show that

$$\sum_{v \in L(h)} \left(\frac{\alpha_v}{\alpha_\rho}\right)^{1/\chi} \frac{\left|\mathcal{I}_T(\rho \to v)\right|}{R_v \Phi(R_v)} \le M_k (d\kappa)^{h/\chi}. \tag{2}$$

Since $\alpha_v \ge 1$ for $v \in V$, $\alpha_\rho \le \alpha$ and $R_v\Phi(R_v) \le 1$, (2) yields $\sum_{v \in L(h)} \left|\mathcal{I}_T(\rho \to v)\right| \le M_k \alpha^{1/\chi} (d\kappa)^{h/\chi}$ for all integer $h \ge 0$, and therefore summing over h, we obtain that

$$\sum_{v \in V} \left|\mathcal{I}_T(\rho \to v)\right| \le M_k \alpha^{1/\chi} \sum_{h \ge 0} (d\kappa)^{h/\chi} \le \frac{M_k \alpha^{1/\chi}}{1 - (d\kappa)^{1/\chi}},$$

which proves the result with $W_k = \frac{M_k}{1-(d\kappa)^{1/\chi}}$. So it only remains to prove (2).

We will work inductively. The base case $h = 0$ is equivalent to $M_k \ge 1/(R_\rho \Phi(R_\rho)) = \sqrt{1 + 1/R_\rho}$, which is true since from the recursion for R_ρ we have that $R_\rho \ge \lambda/(1+\lambda)^k$. For the induction step, consider $v \in L(h-1)$ and suppose it has $k_v \ge 0$ children, denoted by v_i for $i \in [k_v]$. Then, for each $i \in [k_v]$, since v is on the unique path joining ρ to v_i, it holds that (see [2, Lemma B.2])

$$\mathcal{I}_T(\rho \to v_i) = \mathcal{I}_T(\rho \to v)\mathcal{I}_T(v \to v_i),$$

so we can write

$$\begin{aligned}\sum_{v \in L(h)} \left(\frac{\alpha_v}{\alpha_\rho}\right)^{1/\chi} \frac{\left|\mathcal{I}_T(\rho \to v)\right|}{R_v \Phi(R_v)} = \\ \sum_{v \in L(h-1)} \left(\frac{\alpha_v}{\alpha_\rho}\right)^{1/\chi} \frac{\left|\mathcal{I}_T(\rho \to v)\right|}{R_v \Phi(R_v)} \sum_{i \in [k_v]} \left(\frac{\alpha_{v_i}}{\alpha_v}\right)^{1/\chi} R_v \Phi(R_v) \frac{\left|\mathcal{I}_T(v \to v_i)\right|}{R_{v_i}\Phi(R_{v_i})}.\end{aligned} \tag{3}$$

Consider an arbitrary $v \in L(h-1)$. Then, since $\frac{1}{\chi} + \frac{1}{a} = 1$, by Hölder's inequality we have that

$$\sum_{i\in[k_v]} \left(\frac{\alpha_{v_i}}{\alpha_v}\right)^{1/\chi} R_v\Phi(R_v)\frac{|\mathcal{I}_T(v \to v_i)|}{R_{v_i}\Phi(R_{v_i})} \leq \left(\sum_{i\in[k_v]} \frac{\alpha_{v_i}}{\alpha_v}\right)^{1/\chi} \left((R_v\Phi(R_v))^a \sum_{i\in[k_v]} \left(\frac{|\mathcal{I}_T(v \to v_i)|}{R_{v_i}\Phi(R_{v_i})}\right)^a\right)^{1/a}. \tag{4}$$

Note that for $x = R_v$ and $x_i = R_{v_i}$, $i \in [k_v]$, we have from (1) that $\frac{|\mathcal{I}_T(v\to v_i)|}{R_{v_i}} = \frac{1}{1+x_i}$ and $x = \lambda\prod_{i\in[k_v]} \frac{1}{1+x_i}$, so by Lemma 9 we have that

$$\left((R_v\Phi(R_v))^a \sum_{i\in[k_v]} \left(\frac{|\mathcal{I}_T(v \to v_i)|}{R_{v_i}\Phi(R_{v_i})}\right)^a\right)^{1/a} \leq \kappa^{1/\chi}.$$

By definition of the d-branching value we also have $\alpha_v = 1 + \frac{1}{d}\sum_{i\in[k_v]} \alpha_{v_i} \geq \frac{1}{d}\sum_{i\in[k_v]} \alpha_{v_i}$, so plugging these back into (4) yields

$$\sum_{i\in[k_v]} \left(\frac{\alpha_{v_i}}{\alpha_v}\right)^{1/\chi} R_v\Phi(R_v)\frac{|\mathcal{I}_T(v \to v_i)|}{R_{v_i}\Phi(R_{v_i})} \leq (d\kappa)^{1/\chi}.$$

In turn, plugging this into (3) and using the induction hypothesis yields (2), finishing the proof. ◀

▶ Remark 11. For simplicity, and since it is not important for our arguments, the constant W_k in the proof depends exponentially on the degree k of the root. With a more careful inductive proof (cf. [7, Proof of Lemma 14]), the dependence on k can be made linear. In either case, because of the high-degree vertices in $G(n, d/n)$, both bounds do not yield sufficiently strong bounds on the spectral independence of the whole distribution $\mu_{G,\lambda}$, and this is one of the reasons that we have to consider the spectral independence on the induced distribution on low-degree vertices.

Recall that for a graph $G = (V, E)$ and $U \subseteq V$, we let $\mu_{G,\lambda,U}(\cdot)$ denote the marginal distribution on the spins of U, i.e., the distribution $\mu_{G,\lambda}(\sigma_U = \cdot)$.

▶ **Lemma 12.** *Let $d \geq 1$ and $\lambda > 0$ be constants such that $\lambda < \lambda_c(d)$. Then, for any constants $D, \varepsilon > 0$, whp over the choice of $G \sim G(n, d/n)$, the marginal hard-core distribution $\mu_{G,\lambda,U}$, where U is the set of vertices in G with degree $\leq D$, is $(\varepsilon \log n)$-spectrally independent.*

Proof. Let $D, \varepsilon > 0$ be arbitrary constants, and let $d' > d$ be such that $\lambda < \lambda_c(d')$; such d' exists because the function $\lambda_c(\cdot)$ is continuous in the interval $(1, \infty)$ and $\lambda_c(d) \to \infty$ for $d \downarrow 1$. Let $\chi \in (1, 2)$ and $W = \max\{W_1, \ldots, W_D\}$ where χ and the W_k's are as in Lemma 10 (corresponding to the constants d', λ). By Lemma 8, whp all of the vertices of the graph $G = (V, E) \sim G(n, d/n)$ have d'-branching value less than $\varepsilon \log n$. We will show that the result holds for all such graphs G (for sufficiently large n).

Let U be the set of vertices in G with degree $\leq D$, and let for convenience $\mu = \mu_{G,\lambda,U}$. Consider arbitrary $S \subset U$ and $\tau \in \Omega_S$. It suffices to bound the largest eigenvalue of the influence matrix $\mathbf{\Psi}_\tau$ by $\varepsilon \log n$. Analogously to [2, 7], we do this by bounding the absolute-value row sums of $\mathbf{\Psi}_\tau$. Recall that the rows and columns of $\mathbf{\Psi}_\tau$ are indexed by $\tilde{V}_\tau = \{(v, i) \mid v \in U\backslash S, \mu_\tau(\sigma_v = i) > 0\}$, where the entry indexed by $(v, i), (w, k)$ equals $\mu_\tau(\sigma_w = k \mid \sigma_v = i) - \mu_\tau(\sigma_w = k)$ if $v \neq w$, and 0 otherwise. Consider arbitrary $(v, i) \in \tilde{V}_\tau$; our goal is to show

$$\sum_{(w,k)\in\tilde{V}_\tau} \big|\mu_\tau(\sigma_w = k \mid \sigma_v = i) - \mu_\tau(\sigma_w = k)\big| \le \varepsilon \log n. \tag{5}$$

Henceforth, we will also assume that $\mu_\tau(\sigma_v = i) < 1$ (in addition to $\mu_\tau(\sigma_v = i) > 0$), otherwise the sum on the l.h.s. is equal to 0. Then, by the law of total probability, for any $(w,k) \in \tilde{V}_\tau$ we have

$$\begin{aligned}\big|\mu_\tau(\sigma_w = k \mid \sigma_v = i) - \mu_\tau(\sigma_w = k)\big| &\le \big|\mu_\tau(\sigma_w = k \mid \sigma_v = 1) - \mu_\tau(\sigma_w = k \mid \sigma_v = 0)\big| \\ &= \big|\mathcal{I}^\tau_G(v \to w)\big|,\end{aligned}$$

where the last equality follows from the fact that μ is the marginal distribution of $\mu_{G,\lambda}$ on U. Therefore, we can bound

$$\sum_{(w,k)\in\tilde{V}_\tau} \big|\mu_\tau(\sigma_w = k \mid \sigma_v = i) - \mu_\tau(\sigma_w = k)\big| \le \sum_{w\in U} \big|\mathcal{I}^\tau_G(v \to w)\big| \le \sum_{w\in V} \big|\mathcal{I}^\tau_G(v \to w)\big|.$$

By Lemma 22 in the full version, for the self-avoiding walk tree $T = (V_T, E_T)$ from v, there is a subset $Z \subseteq V_T \backslash \{\rho\}$ and a configuration $\phi \in \{0,1\}^Z$ such that

$$\sum_{w\in V} \big|\mathcal{I}^\tau_G(v \to w)\big| \le \sum_{w\in V_T} \big|\mathcal{I}^\phi_T(v \to w)\big|,$$

where $\mathcal{I}^\phi_T(v \to \cdot)$ denotes the influence of v on the vertices of T (in the hard-core distribution $\mu_{T,\lambda}$ conditioned on ϕ). Since the d'-branching value of v (and any other vertex of G) is bounded by $\varepsilon \log n$ and the degree of v is $\le D$, by Lemma 10 applied to T, we have that

$$\sum_{w\in V_T} \big|\mathcal{I}^\phi_T(v \to w)\big| \le W(\varepsilon \log n)^{1/\chi}.$$

Since $\chi > 1$, for all sufficiently large n we have that $W(\varepsilon \log n)^{1/\chi} \le \varepsilon \log n$, which proves (5). ◀

We also record the following corollary of the arguments in Lemma 10.

▶ **Corollary 13.** *Let $\lambda > 0$ and $D > 0$ be real numbers. For a graph $G = (V, E)$, let U be the set of vertices in G with degree $\le D$ and suppose that $|U| \ge 2$. Then, the distribution $\mu := \mu_{G,\lambda,U}$ is b-marginally bounded for $b = \frac{\lambda}{\lambda + (1+\lambda)^D}$.*

Proof. By Lemma 22 in the full version, for any vertex $v \in U$ and any boundary condition τ on (a subset of) $U\backslash\{v\}$, there is a corresponding tree T and a boundary condition ϕ on T such that $\mu_\tau(\sigma_v = \cdot) = \nu_\phi(\sigma_v = \cdot)$. Since v has degree $\le D$, from the proof of Lemma 10, see in particular equation (1), we have that $\nu_\phi(\sigma_v = \cdot) \ge b$, where b is as in the lemma statement. ◀

4 Entropy factorisation for bounded-degree vertices

In this section, we show how to convert the spectral independence results of the previous section into fast mixing results for Glauber dynamics on the set of small-degree vertices on $G(n, d/n)$. Our strategy here follows the technique of [8], though to obtain nearly linear results we have to pay attention to the connected components induced by high-degree vertices and how these can connect up small-degree vertices.

4.1 Preliminaries

Entropy factorisation for probability distributions

For a real function f on $\Omega \subseteq [q]^V$, we use $\mathbf{E}_\mu(f)$ for the expectation of f with respect to μ and, for $f : \Omega \to \mathbb{R}_{\geq 0}$, $\mathrm{Ent}_\mu(f) = \mathbf{E}_\mu[f \log f] - \mathbf{E}_\mu(f) \log \mathbf{E}_\mu(f)$, with the convention that $0 \log 0 = 0$. Finally, for $S \subset V$, let $\mathrm{Ent}^S_\mu(f) = \mathbf{E}_{\tau \sim \mu_{V\setminus S}}\big[\mathrm{Ent}_{\mu_\tau}(f)\big]$ i.e., $\mathrm{Ent}^S_\mu(f)$ is the expected value of the conditional entropy of f when the assignment outside of S is chosen according to the marginal distribution $\mu_{V\setminus S}$ (the induced distribution of μ on $V\setminus S$). For convenience, when $S = V$, we define $\mathrm{Ent}^S_\mu(f) = \mathrm{Ent}_\mu(f)$. The following inequality of entropy under tensor product is a special case of Shearer's inequalities.

▶ **Fact 14.** *Let $q, k \geq 2$ be integers and suppose that, for $i \in [k]$, μ_i is a distribution supported over $\Omega_i \subseteq [q]^{V_i}$, where $V_1, \ldots, V_k$ are pairwise disjoint sets. Let $\mu = \mu_1 \otimes \cdots \otimes \mu_k$ be the product distribution on $\Omega = \Omega_1 \times \cdots \times \Omega_k$. Then, for any $f : \Omega \to \mathbb{R}_{\geq 0}$, it holds that* $\mathrm{Ent}_\mu(f) \leq \sum_{i=1}^k \mathrm{Ent}^{V_i}_\mu(f)$.

To bound the mixing time of Markov chains such as the Glauber dynamics, we will be interested in establishing inequalities for factorisation of entropy, defined as follows.

▶ **Definition 15.** *Let $q \geq 2$, $r \geq 1$ be integers and V be a set of size $n \geq r + 1$. Let μ be a distribution supported over $\Omega \subseteq [q]^V$. We say that μ satisfies the r-uniform-block factorisation of entropy with multiplier*[4] *C_r if for all $f : \Omega \to \mathbb{R}_{\geq 0}$ it holds that* $\frac{r}{n}\mathrm{Ent}_\mu(f) \leq C_r \frac{1}{\binom{n}{r}} \sum_{S \in \binom{V}{r}} \mathrm{Ent}^S_\mu(f)$.

The following lemma will be useful to bound the (r-uniform-block) factorisation multiplier for conditional distributions on sets with small cardinality.

▶ **Lemma 16** ([8, Lemma 4.2])**.** *Let $q \geq 2$ be an integer and V be a set of size $n \geq 2$. Let μ be a distribution supported over $\Omega \subseteq [q]^V$ which is b-marginally bounded for some $b > 0$. Then, for any $S \subseteq V$ and $\tau \in \Omega_{V\setminus S}$, for $f : \Omega \to \mathbb{R}_{\geq 0}$, it holds that* $\mathrm{Ent}_{\mu_\tau}(f) \leq \frac{2|S|^2 \log(1/b)}{b^{2|S|+2}} \sum_{v \in S} \mathrm{Ent}^v_{\mu_\tau}(f)$.

The r-uniform-block Glauber dynamics and its mixing time

For an integer $r = 1, \ldots, n$, the r-uniform-block Glauber dynamics for μ is a Markov chain $(X_t)_{t \geq 0}$ where $X_0 \in \Omega$ is an arbitrary configuration and, for $t \geq 1$, X_t is obtained from X_{t-1} by first picking a subset $S \in V$ of size r uniformly at random and updating the configuration on S according to

$$\mu\big(\sigma_S = \cdot \mid \sigma_{V\setminus S} = X_{t-1}(V\setminus S)\big).$$

For $\varepsilon > 0$, the mixing time of the r-uniform-block Glauber dynamics is defined as $T_{\mathrm{mix}}(\varepsilon) = \max_{\sigma \in \Omega} \min\big\{t \,\big|\, X_0 = \sigma,\ \|\nu_t - \mu\|_{\mathrm{TV}} \leq \varepsilon\big\}$, where ν_t denotes the distribution of X_t. Note, the case $r = 1$ corresponds to the single-site dynamics, where at every step the spin of a single vertex, chosen u.a.r., is updated conditioned on the spins of the remaining vertices.

[4] We note that in related works C_r is usually referred to as the "factorisation constant"; we deviate from this terminology since for us C_r will depend on n (cf. Corollary 19 and Lemma 21), and referring to it as a constant could cause confusion.

▶ **Lemma 17** (See, e.g., [8, Lemma 2.6 & Fact 3.5(4)] or [6, Lemma 3.2.6 & Fact 3.4.2])**.** *Let $q \geq 2$, $r \geq 1$ be integers and V be a set of size $n \geq r+1$. Let μ be a distribution supported over $\Omega \subseteq [q]^V$ that satisfies the r-uniform-block factorisation of entropy with multiplier C_r. Then, for any $\varepsilon > 0$, the mixing time of the r-uniform-block Glauber dynamics on μ satisfies*

$$T_{\mathrm{mix}}(\varepsilon) \leq \left\lceil C_r \frac{n}{r}\Big(\log\log\frac{1}{\mu_{\min}} + \log\frac{1}{2\varepsilon^2}\Big)\right\rceil, \text{ where } \mu_{\min} = \min_{\sigma\in\Omega}\mu(\sigma).$$

We remark that to deduce the lemma from [8] or [6], which refer to the so-called "entropy decay constant κ", one needs to use the equality $C_r\kappa = r/n$ from [8, Lemma 2.6] or [6, Lemma 3.2.6].

From spectral independence to r-uniform-block factorisation multipliers

The following theorem is shown in [8]; while the version that we state here cannot be found verbatim in [8], we explain in the appendix how to combine the results therein to obtain it.

▶ **Theorem 18** ([8])**.** *Let $q \geq 2$ be an integer and V be a set of size $n \geq 2$. Let μ be a distribution supported over $\Omega \subseteq [q]^V$ that is η-spectrally independent and b-marginally bounded for $\eta, b > 0$.*

Then, for all integers $r = 1, \ldots, n$, the distribution μ satisfies the r-uniform-block factorisation of entropy with multiplier $C_r = \frac{r}{n}\frac{\sum_{k=0}^{n-1}\Gamma_k}{\sum_{k=n-r}^{n-1}\Gamma_k}$, where $\Gamma_k = \prod_{j=0}^{k-1}\alpha_j$ for $k \in [n]$[5] and $\alpha_k = \max\left\{0, 1 - \frac{4\eta}{b^2(n-1-k)}\right\}$ for $k \in [n-1]$.

4.2 Entropy factorisation for bounded-degree vertices in the hard-core model

The first step of the analysis of Glauber dynamics for the hard-core model on the set of small-degree vertices will be to employ spectral independence results of Section 3.2 to conclude fast mixing for the r-uniform block Glauber dynamics for $r = \theta|U|$ for any arbitrarily small constant θ. This step will follow by applying the recent technology of entropy factorisation described above.

The second step is the more challenging for us. Here we need to conclude fast mixing for $r = 1$, and in particular prove that $C_1/C_r = n^{o(1)}$. This is done roughly by studying the connected components of G that arise when resampling an r-subset of the low-degree vertices; the factorisation multiplier of these components controls the ratio C_1/C_r. While this resembles the approach of [8], there is a key difference here, in that high-degree vertices are not resampled. This can not only cause potentially large components, but also imposes a deterministic lower bound on components sizes (since a component consisting of high-degree vertices will be deterministically present in the percolated graph consisting of the r-subset of low-degree vertices and all of the high-degree vertices). This lower bound on the component sizes is actually more significant than it might initially seem since the relatively straightforward bound of $\Omega(\log n)$ would unfortunately give a relatively large factorisation multiplier of $n^{\Omega(1)}$ (through Lemma 16). Instead, we need to show that components have size $o(\log n)$, which in turn requires more delicate estimates for the distribution of high-degree vertices in connected sets (see Lemma 20 below).

[5] We note that for $k = 0$, the product defining Γ_k is empty and therefore $\Gamma_0 = 1$.

We start with the following corollary of Lemma 12, which converts a spectral independence bound into a bound on the factorisation multiplier for the r-uniform-block Glauber dynamics when r scales linearly with small-degree vertices. This is analogous to [8, Lemma 2.4], where they obtain a $2^{O(\eta/b^2)}$ bound on C_r when $r = \Theta(n)$ via Theorem 18 (where η is the spectral independence bound and b is the bound on the marginals). By restricting to small-degree vertices, we obtain that b is a constant, which combined with the bound $\eta = o(\log n)$ from Lemma 12 gives the bound $C_r = n^{o(1)}$, as detailed below. The proof of the corollary is given for completeness in Section D of the full version.

▶ **Corollary 19.** *Let $d \geq 1$ and $\lambda > 0$ be constants such that $\lambda < \lambda_c(d)$. Then, for any constants $D, \theta > 0$, whp over the choice of $G \sim G(n, d/n)$, the marginal hard-core distribution $\mu_{G,\lambda,U}$, where U is the set of vertices in G with degree $\leq D$, satisfies for any integer $r \in \left[\theta|U|, |U|\right]$ the r-uniform block factorisation of entropy with multiplier $C_r \leq n^{\theta}$.*

Note that the reason that we are able to use the same θ in the bounds for r and C_r is that the bound on C_r is loose (we can obtain a sharper result since we have a bound on the spectral independence of $\varepsilon \log n$ for any $\varepsilon > 0$).

We will now refine the bound of Corollary 19 down to $r = 1$ by exploiting the fact that high-degree vertices are sparsely scattered. In particular, we will need the following lemma which is a refinement of Lemma 4. For a graph $G = (V, E)$, we say that a set $S \subseteq V$ is connected if the induced subgraph $G[S]$ is connected.

▶ **Lemma 20.** *Let $d > 0$ be an arbitrary real. There exists an $L > 0$ such that for any $\delta \in (0, 1)$, the following holds whp over the choice of $G = (V, E) \sim G(n, d/n)$. For $\Delta = 1/(\delta \log \frac{1}{\delta})$, for all integers $k \geq \delta \log n$ and any $v \in V$, there are $\leq (2\mathrm{e})^{\Delta L k}$ connected sets $S \subseteq V$ containing v with $|S| = k$. Moreover, every such set contains $\geq k/2$ vertices with degree less than $L\Delta$.*

The proof of Lemma 20 is given in Section C.3 of the full version. We are now ready to show the following.

▶ **Lemma 21.** *Let $d \geq 1$ and $\lambda > 0$ be constants such that $\lambda < \lambda_c(d)$. For any $\theta > 0$, there is a constant $D > 0$ such that whp over the choice of $G \sim G(n, d/n)$, the marginal hard-core distribution $\mu_{G,\lambda,U}$, where U is the set of vertices in G with degree $\leq D$, satisfies the 1-uniform-block factorisation of entropy with multiplier $C_1 \leq n^{\theta}$.*

Proof. Let $L > 0$ be as in Lemma 20, and consider an arbitrarily small constant $\theta > 0$. Let $\delta \in (0, 1)$ be a sufficiently small constant so that for $D = L/(\delta \log \frac{1}{\delta})$ and $b = \frac{\lambda}{\lambda + (1+\lambda)^D}$ it holds that $\frac{1}{b^{2\delta}} < \mathrm{e}^{\theta/4}$; such a constant exists since $b^{2\delta} \to 1$ as $\delta \downarrow 0$. Let $\Delta = 1/(\delta \log \frac{1}{\delta})$ and $\zeta > 0$ be a small constant so that $2(2\mathrm{e})^{L\Delta}(2\zeta)^{1/2} \leq b^2/2$.

Let U be the vertices in G with degree $\leq D$, and let $r = \lfloor \zeta |U| \rfloor + 1$. Let $\mu = \mu_{G,\lambda,U}$. By Corollary 19, we have that whp over the choice of G, there is $C_r \leq n^{\theta/3}$ such that for every $f : \Omega \to \mathbb{R}_{\geq 0}$ it holds that

$$\frac{r}{|U|}\mathrm{Ent}_{\mu}(f) \leq C_r \frac{1}{\binom{|U|}{r}} \sum_{S \in \binom{U}{r}} \mathrm{Ent}^S_{\mu}(f). \tag{6}$$

For $S \subseteq U$, let $\mathcal{C}'(S)$ denote the collection of the connected components of the graph $G[S \cup (V \backslash U)]$, viewed as vertex sets, and let $\mathcal{C}(S) = \bigcup_{R \in \mathcal{C}'(S)} \{R \cap U\}$ be the restriction of these components to the set U. Note that, for $S \subseteq U$ and $\tau \in \Omega_{U \backslash S}$, μ_τ factorises over the components of $G[S \cup (V \backslash U)]$ and in particular, applying Fact 14, we have that

$$\mathrm{Ent}^S_{\mu}(f) = \mathbf{E}_{\tau \sim \mu_{U \backslash S}}\left[\mathrm{Ent}_{\mu_\tau}(f)\right] \leq \mathbf{E}_{\tau \sim \mu_{U \backslash S}}\left[\sum_{R \in \mathcal{C}(S)} \mathrm{Ent}^R_{\mu_\tau}(f)\right].$$

Using the bound in Lemma 16, we further obtain that

$$\begin{aligned}\mathrm{Ent}_\mu^S(f) &\le \mathbf{E}_{\tau\sim\mu_{U\setminus S}}\Big[\sum_{R\in\mathcal{C}(S)}\frac{2|R|^2\log(1/b)}{b^{2|R|+2}}\sum_{u\in R}\mathrm{Ent}_{\mu_\tau}^u(f)\Big]\\ &= \sum_{R\in\mathcal{C}(S)}\sum_{u\in R}\frac{2|R|^2\log(1/b)}{b^{2|R|+2}}\mathrm{Ent}_\mu^u(f),\end{aligned}$$

where the last equality follows by linearity of expectation and the fact that $\mathbf{E}_{\tau\sim\mu_{U\setminus S}}[\mathrm{Ent}_{\mu_\tau}^u(f)] = \mathrm{Ent}_\mu^u(f)$. Plugging this bound into (6), we obtain that

$$\mathrm{Ent}_\mu(f) \le \frac{2C_r\log(1/b)}{b^2\binom{|U|-1}{r-1}}\sum_{S\in\binom{U}{r}}\sum_{R\in\mathcal{C}(S)}\sum_{u\in U}\frac{|R|^2}{b^{2|R|}}\mathrm{Ent}_\mu^u(f).$$

which yields that

$$\mathrm{Ent}_\mu(f) \le \frac{2C_r\log(1/b)}{b^2}\sum_{u\in U}\mathrm{Ent}_\mu^u(f)\sum_{k=1}^{n}\frac{k^2}{b^{2k}}\Pr[\mathcal{C}_u(S)=k], \tag{7}$$

where $\Pr[\mathcal{C}_u(S)=k]$ denotes the probability that u belongs to a set of size k in the set $\mathcal{C}(S)$, when we pick S uniformly at random from $\{S\in\binom{U}{r} \mid u\in S\}$. Define analogously $\Pr[\mathcal{C}'_u(S)=k]$ to be the probability that u belongs to a connected component of size k in the set $\mathcal{C}'(S)$. By Lemma 20, whp over $G\sim G(n,d/n)$, for all vertices u and any integer $t\ge\delta\log n$, there are at most $(2\mathrm{e})^{L\Delta t}$ connected sets of size t containing a given vertex u, and each of them contains at least $t/2$ vertices from U. In particular, for any integer $k\ge\delta\log n$, it holds that $\Pr[\mathcal{C}_u(S)=k]\le\Pr[k\le\mathcal{C}'_u(S)\le 2k]$. For all $k\le 2|U|$, the probability that a specific subset of $k/2$ vertices of U is present in $G[S\cup(V\setminus U)]$ is at most $\frac{\binom{|U|-\lceil k/2\rceil}{r-\lceil k/2\rceil}}{\binom{|U|-1}{r-1}}\le\left(\frac{r}{|U|}\right)^{k/2}\le(2\zeta)^{k/2}$. Therefore, for all $k\ge\delta\log n$, by a union bound over the connected sets of size k, we have

$$\Pr[\mathcal{C}'_u(S)=k]\le(2\mathrm{e})^{L\Delta k}2^k(2\zeta)^{k/2} = \left(2(2\mathrm{e})^{L\Delta}(2\zeta)^{1/2}\right)^k\le(b^2/2)^k,$$

where in the first inequality the first factor is the number of size-k connected sets T of G containing u, the second factor is an upper bound on the number of size $k/2$ subsets W of U that might be included in T and the final factor is the probability that W is included in S. The last inequality is by the choice of ζ. It follows that

$$\Pr[\mathcal{C}_u(S)=k]\le\Pr[k\le\mathcal{C}'_u(S)\le 2k]\le 2k(b^2/2)^k.$$

From this bound and the inequality $1/b^{2\delta}<\mathrm{e}^{\theta/4}$ by the choice of δ, we can split and bound the rightmost sum in (7) by

$$\sum_{k=1}^{n}\frac{k^2}{b^{2k}}\Pr[\mathcal{C}_u(S)=k]\le\frac{(\delta\log n)^2}{b^{2\delta\log n}}+\sum_{k\ge\delta\log n}\frac{2k^3}{2^k}\le n^{\theta/3},$$

where the last inequality holds for all sufficiently large n. In turn, plugging this into (7), we obtain that μ satisfies the 1-uniform block factorisation of entropy with multiplier $C_1=\frac{2C_r\log(1/b)}{b^2}n^{\theta/3}\le n^\theta$ for all sufficiently large n (since b is a constant and $C_r\le n^{\theta/3}$), as needed. ◀

Lemma 5 now follows easily by combining Lemmas 17 and 21. This was the last ingredient needed in the proof of Theorem 1.

Abstract

We construct data structures for extremal and pairwise distances in directed graphs in the presence of transient edge failures. Henzinger et al. [ITCS 2017] initiated the study of fault-tolerant (sensitivity) oracles for the diameter and vertex eccentricities. We extend this with a special focus on space efficiency. We present several new data structures, among them the first fault-tolerant eccentricity oracle for dual failures in subcubic space. We further prove lower bounds that show limits to approximation vs. space and diameter vs. space trade-offs for fault-tolerant oracles. They highlight key differences between data structures for undirected and directed graphs.

Initially, our oracles are randomized leaning on a sampling technique frequently used in sensitivity analysis. Building on the work of Alon, Chechik, and Cohen [ICALP 2019] as well as Karthik and Parter [SODA 2021], we develop a hierarchical framework to derandomize fault-tolerant data structures. We first apply it to our own diameter and eccentricity oracles and then show its versatility by derandomizing algorithms from the literature: the distance sensitivity oracle of Ren [JCSS 2022] and the Single-Source Replacement Path algorithm of Chechik and Magen [ICALP 2020]. This way, we obtain the first deterministic distance sensitivity oracle with subcubic preprocessing time.

1 Introduction

The problems of computing *shortest paths*, *graph diameter*, and *vertex eccentricities* are fundamental in many applications of both theoretical and applied computer science. We address these problems in the setting of *fault tolerance*. The interest in this problem setting stems from the fact that most real-world networks are prone to failures. These are unpredictable but usually small in numbers and transient due to some simultaneous repair process. However, in an error-prone network, it is not always practical to recompute distances

from scratch even if the number of edge failures is bounded. A commonly adopted solution is that of designing *f-edge fault-tolerant oracles*, that is, compact data structures that can quickly report exact or approximate extremal and pairwise distances in the network after up to f edges failed. These structures are also known as *sensitivity oracles*, where the sensitivity is the maximum number f of supported failures.

Many known fault-tolerant data structures are randomized. The algorithm that preprocesses the underlying network may depend on random bits or the correctness of the oracle's answers is only guaranteed with some probability. Besides the practical difficulties of working with (true) randomness in computing, it is an interesting question to what extend randomness as a resource is needed to obtain efficient fault-tolerant oracles. In this paper, we show that for a wide range of applications randomness can be removed with only a slight loss of performance, or even none at all in some cases. For this, we develop a novel derandomization framework and combine it with known techniques to obtain the following results.

- We present new deterministic f-edge fault-tolerant oracles that report the exact/approximate diameter and vertex eccentricities in directed graphs and we show lower bounds charting the limits of approximation vs. space and diameter vs. space trade-offs.
- We derandomize the single-failure *distance sensitivity oracle* (DSO) of Ren [32] that can report exact distance for any pair of vertices in constant time. Our result gives the first deterministic exact DSO with truly sub-cubic processing time and constant query time.
- We derandomize the algorithm of Chechik and Magen [12] for the *Single-Source Replacement Paths* (SSRP) problem on directed graphs, that is, the task of finding a shortest path from a distinguished source vertex to every target, for every possible edge failure.

We believe that our techniques are of independent interest and can help derandomize also other algorithms and data structures in the fault-tolerant domain. Throughout the paper, the underlying network is modeled by a directed graph $G = (V, E)$, possibly with weights on its edges, where V is the set of n vertices and E the set of m edges.

1.1 Diameter and Eccentricity Oracles in Directed Graphs

In Section 3, we discuss fault-tolerant oracles for the diameter and vertex eccentricities of a directed graph. We abbreviate *f-edge fault-tolerant diameter oracle* as f-FDO and *f-edge fault-tolerant eccentricity oracle* as f-FEO. In case of a single failure, $f = 1$, we shorten this to FDO and FEO, respectively. The problem of designing FDOs was originally raised by Henzinger et al. [26] and recently received some renewed interest by Bilò et al. [6]. Although the major focus of the latter work was on undirected graphs, the authors also showed that, for directed graphs, one can compute, in $\widetilde{O}(mn + n^2/\varepsilon)$ time,[1] an oracle of size[2] $O(m)$ and constant query time that guarantees a *stretch* of $1 + \varepsilon$, that is, it reports an upper bound on the value of the diameter within a factor of $1+\varepsilon$, for any $\varepsilon > 0$.

Bilò et al. [6] also gave a complementary space lower bound showing that any fault-tolerant diameter oracle with a sufficiently small stretch must take $\Omega(m)$ bits of space. However, this is not the full picture in that their construction only holds for diameter 2. We show here that in reality there is a transition happening: the larger the diameter, the more space we can save, up to a point where even $o(m)$-space oracles become possible. We aim at pinpointing this transition, starting with a generalization of the bound in [6] to diameter up to $n/\sqrt{m}$.

[1] For a non-negative function $g = g(n)$, we use $\widetilde{O}(g)$ to denote $O(g \cdot \mathsf{polylog}(n))$.
[2] Unless stated otherwise, we measure the space in the number of $O(\log n)$-bit machine words.

▶ **Theorem 1.** *Let $n, m, D \geqslant 3$ be integers with $D = O(\frac{n}{\sqrt{m}})$. Any FDO with stretch $\sigma < \frac{3}{2} - \frac{1}{D}$ on n-vertex, m-edge unweighted directed graphs of diameter D requires $\Omega(m)$ bits of space, regardless of the query time.*

Given an oracle for the fault-tolerant eccentricities with query time q, one can emulate a diameter oracle with query time nq by taking the maximum over all vertices. The information-theoretic lower bound of Theorem 1 is independent of the query time and therefore every FEO also must have size $\Omega(m)$.

Notably, Theorem 1 implies that, for any $0 < \delta \leqslant 1$ and all digraphs with $n^{1+\delta}$ edges and a relatively small diameter of $O(\sqrt{n^{1-\delta}})$, an FDO of stretch essentially $3/2$ takes $\Omega(n^{1+\delta})$ bits of space. As hinted above, this approximation vs. space trade-off no longer holds when we consider directed graphs with large diameter of $\omega(n^{5/6})$, for which we can design FDOs of quasi-linear (in n) space and negligible stretch.

▶ **Theorem 2.** *Let G be a directed graph with n vertices, m edges, and diameter $D = \omega(n^{5/6})$ and let $\varepsilon = \frac{n^{5/6}}{D} = o(1)$. There is an FDO for G with stretch $1 + \varepsilon$, preprocessing time $\widetilde{O}(mn)$, space $O(n \log^2 n)$, and constant query time.*

The gap between the stretch-size trade-offs provided in Theorem 1 and Theorem 2, respectively, suggests that there must be a threshold between $n/\sqrt{m}$ and $n^{5/6}$ where low-stretch FDOs of sub-linear size and constant query time become possible. We further narrow this gap and aim to find the smallest value for the diameter for which one can design an FDO with $o(m)$ space and constant query time. We show that this is possible for directed graphs with diameter $\omega((n^{4/3} \log n)/\sqrt{m})$. We leave it as an open problem to determine the smallest function g such that directed graphs with diameter $g(n)/\sqrt{m}$ admit an FDO with $o(m)$ space. Our results show that g is of order $\omega(n)$ and $O(n^{4/3} \log n)$.

▶ **Theorem 3.** *Let G be be a directed graph with n vertices, m edges, and diameter $\omega((n^{4/3} \log n)/(\varepsilon\sqrt{m}))$. For any $\varepsilon = \varepsilon(n, m) > 0$, there is an FDO for G with stretch $1 + \varepsilon$, preprocessing time $\widetilde{O}(mn)$, space $o(m)$, and constant query time.*

For the sake of readability, the FDOs in Section 3 are randomized. Later, in Section 4, we describe our derandomization framework and show how to apply it to both FDOs.

We now move our attention to the case multiple edge failures and give bounds in terms of f and n on the minimum space requirement of f-FDOs. Bilò et al. [6] designed an f-FDO for *undirected* graphs of stretch $f + 2$ that takes space $\widetilde{O}(fn)$. The size of this oracle is optimal up to polylogarithmic factors. In the next theorem, we show that such compact oracles are impossible for directed graphs, even when allowing arbitrarily large stretch

▶ **Theorem 4.** *Let n, f be positive integers such that $2^{f/2} = O(n)$. Any f-FDO with an arbitrary finite stretch on n-vertex directed graphs requires $\Omega(2^{f/2} n)$ bits of space, regardless of the query time.*

The lower bound of Theorem 4 marks an exponential-in-f separation between the undirected and directed setting. The directed graph used in the proof is inspired by the lower-bound construction used by Baswana et al. [3] for the *f-edge fault-tolerant Single-Source Reachability* problem. This problem asks to compute the sparsest subgraph H of a directed graph G that preserves reachability from a designated source vertex s, that is, for every vertex v and every set F of $|F| \leqslant f$ edge failures, there is path from s to v in H that avoids every edge in F if and only if there is such a path in G. Baswana et al. [3] provided a class of directed graphs for which any subgraph preserving single-source reachability with sensitivity

f has $\Omega(2^f n)$ edges. Our lower bound requires non-trivial extensions of their construction as it needs to satisfy several additional properties. For example, the directed graph in [3] has unbounded diameter, while any lower bound for FDOs requires strongly connected graphs.

We also consider the design of fault-tolerant eccentricity oracles for general directed graphs as well as directed acyclic graphs (DAGs). For the single-failure case and exact eccentricities, there is a folklore solution using the DSO of Bernstein and Karger [4] that runs in $\widetilde{O}(n^3)$ time. Henzinger et al. [26] showed how to trade stretch for running time and presented an $(1+\varepsilon)$-approximate solution with preprocessing time $\widetilde{O}(mn + n^{3/2}\sqrt{Dm/\varepsilon})$, where D denotes the diameter of the underlying graph. Both oracles build a look-up table of size $O(n^2)$ using the fact that, for any vertex v, only the failure of an edge on a shortest path tree rooted in v can change the eccentricity of v. The table allows for a constant query time but generalizing this to multiple failures $f \geqslant 2$ would take $\Omega(n^{f+1})$ space. We show how to do better than that. We give a meta-theorem that turns any exact or approximate DSO for pairwise distances into an FEO for eccentricities. Plugging in any compact DSO for multiple failures then immediately gives a space improvement for the FEO. In the following, with stretch $\sigma = 1$, we mean exact oracles.

▶ **Theorem 5.** *Let G be a (undirected or directed and possibly edge-weighted) graph with n vertices and m edges. Given access to a DSO for G with sensitivity f, stretch $\sigma \geqslant 1$, preprocessing time P, space S, and query time Q, one can construct an f-FEO for G with stretch $1 + \sigma$, preprocessing time $O(mn + P)$, space $O(n + S)$, and $O(f \cdot Q)$ query time.*

There are multiple distance oracles to choose from, all with different strengths and weaknesses. When using the DSO for of Duan and Pettie [15], we get in polynomial time a 2-approximate 2-FEO with space $O(n^2 \log^3 n)$. To the best of our knowledge, this is the first eccentricity oracle for dual failures in subcubic space. Van den Brand and Saranurak [8] gave a DSO supporting an arbitrary number of failures f. On directed graphs with integer edge weights in the range $[-M, M]$ it has polynomial space and preprocessing time, but a query time that depends both on the sensitivity and the graph size. Let $\omega < 2.37286$ be the matrix multiplication exponent [1]. Plugging the DSO in [8] into our reduction gives an f-FEO with stretch 2, $O(Mn^3)$ space[3], and query time $O(Mnf^{\omega+1})$. On undirected graphs, we can make the query time independent of n by applying the very recent DSO by Duan and Ren [17] with $O(fn^4)$ space and a query time of $f^{O(f)}$. However, the preprocessing of the latter is only polynomial for constant f. Since our reduction also applies to approximate oracles, we get, for any $f = o(\log n / \log\log n)$ and $\varepsilon > 0$, an f-FEO in polynomial time with stretch $(2 + \varepsilon)$, space $O(n^2((\log n)/\varepsilon)^f f)$ and query time $O(f^6 \log n)$ via the DSO by Chechik et al. [11].

As already mentioned above, the $\Omega(2^{f/2} n)$-bits lower bound in Theorem 4 also holds for FEOs. On DAGs, however, we can improve upon this and obtain a space requirement that is reminiscent of the one Bilò et al. [6] gave for *undirected* graphs. Note that in a DAG at most one vertex can have bounded eccentricity.

▶ **Theorem 6.** *Let G be a directed acyclic graph with, m real-weighted edges, n vertices, and a distinguished source vertex s. For any integer f, there is an f-FEO for G with stretch f, preprocessing time $\widetilde{O}(m)$, space $O(nf)$, and $O(f)$ query time.*

All the results for f-FDOs and f-FEOs are presented for edge failures. However, they also hold for vertex failures using well-known transformation techniques for directed graphs.[4]

---

[3] In [8], the space of the DSO is phrased as $O(Mn^3 \log n)$ *bits*.

[4] Indeed, we can transform the directed graph G into some graph G' with $2n$ vertices. We represent each vertex v of G with an edge (v^-, v^+) in G', and replace each edge (u, v) of G with the edge (u^+, v^-) in G'. For edge-weighted G, the weight of the new vertex-edge is set to 0 keeping eccentricities. For unweighted G, the eccentricity of v in any subgraph H of G is half the eccentricity of v^- in $H' \subseteq G'$.

1.2 Derandomization Technique

We now turn to the derandomization of fault-tolerant data structures. In Section 4, we develop the *Hierarchical Double Pivots Hitting Sets* (HDPH) algorithm as the center piece of a framework to derandomize known replacement paths algorithms and oracles. The aim of the HDPH algorithm is to compute a sequence of sets $B_1, \dots, B_{\log n} \subseteq V(G)$ such that each B_i has size $\widetilde{O}(n/2^i)$ and hits a set $\mathcal{P}_i$ of (replacement) paths each of length $\Omega(2^i)$. Unfortunately, the paths $\mathcal{P}_i$ that need to be hit by B_i are not known in advance. Our algorithm fixes this issue by iteratively computing the set of paths $\mathcal{P}_i$ using the previous sets $B_0, \dots, B_{i-1}$. The algorithm relies on the ability of the oracle we want to derandomize to be *path-reporting*, that is, to report a path representing the exact or approximate distance between the queried vertices for DSOs, the diameter for FDOs, or the vertex eccentricity for FEOs. We show how to implement the HDPH algorithm to derandomize the FDOs in Theorems 2 and 3, the DSO of Ren [32] for directed graphs with integer edge weights in the range $[1, M]$, and the algorithm of Chechik and Magen [12] for the SSRP problem in directed graphs.

Distance Sensitivity Oracles. The concept of DSOs was introduced by Demetrescu et al. [13] who showed how to compute an exact DSO of size $O(n^2 \log n)$ and constant query time in $\widetilde{O}(mn^2)$ time. Later, Bernstein and Karger [4] improved the preprocessing time to $\widetilde{O}(mn)$ and Duan and Zhang [18] reduced the space to $O(n^2)$, which is asymptotically optimal. Algebraic algorithms are known to further improve the preprocessing times, if one is willing to employ fast matrix multiplication, see [10, 23] and the references therein. For more results on approximate DSOs for both single and multiple failures, see [11, 14, 15].

We combine the HDPH framework with a recent breakthrough result by Karthik and Parter [28] to derandomize the path-reporting DSO of Ren [32] for directed graphs with integer edge weights in the range $[1, M]$. This was the first DSO that achieved a constant query time with a randomized subcubic preprocessing time of $O(Mn^{2.7233})$. On undirected graphs, the preprocessing improves to $\widetilde{O}(Mn^{(\omega+3)/2}) = O(Mn^{2.6865})$. Our derandomization of Ren's DSOs in both settings incurs a slight loss of efficiency. Nevertheless, we obtain the first deterministic DSO with constant query time and truly sub-cubic preprocessing. This improves significantly over the result by Alon, Chechik, and Cohen [2] who designed a DSO with $O(mn^{4-\alpha})$ preprocessing time and $\widetilde{O}(n^{2\alpha})$ query time, for any $\alpha \in (0, 1)$.

▶ **Theorem 7.** *For any n-vertex directed graph G with integer edge weights in the range $[1, M]$, there exists a deterministic path-reporting DSO with $O(Mn^{2.8068})$ preprocessing time and constant query time. If G is undirected, the preprocessing time decreases to $\widetilde{O}(Mn^{(\omega+6)/3}) = O(Mn^{2.7910})$.*

Recently, Gu and Ren [23] presented a new randomized DSO with a preprocessing time of $O(Mn^{2.5794})$. Unfortunately, our HDHP algorithm cannot be used to derandomize it for the following two reasons. First, the DSO of Gu and Ren is not path-reporting. Secondly, it internally relies on probabilistic polynomial identity testing. It is a long-standing open question how to derandomize this, far beyond the field of fault-tolerant data structures.

Single Source Replacement Paths Problem. In the SSRP problem we want to compute replacement paths from a designated source to each destination vertex, under each possible edge failure. Grandoni and Vassilevska Williams [21, 22] first developed an algorithm for both directed and undirected graphs with integer edge weights in the range $[1, M]$ that uses fast matrix multiplication and runs in $\widetilde{O}(Mn^{\omega})$ time. Chechik and Cohen [9] presented an $\widetilde{O}(m\sqrt{n} + n^2)$ time SSRP algorithm for *undirected* graphs that was later simplified and generalized to deal with multiple sources by Gupta et al. [24]. In this paper we use our

HDPH framework to derandomize the recent $\widetilde{O}(m\sqrt{n}+n^2)$ time randomized algorithm for *directed* graphs developed by Chechik and Magen [12], without any loss in the time complexity. Specifically, we prove the following result.

▶ **Theorem 8.** *There exists a deterministic algorithm for the Single Source Replacement Path problem in unweighted directed graphs running in time* $\widetilde{O}(m\sqrt{n}+n^2)$.

2 Preliminaries

We let $G=(V,E)$ denote a directed graph on n vertices and m edges, potentially edge-weighted by some function $w\colon E\to\mathbb{R}$. We tacitly assume that G is strongly connected, in particular, $m=\Omega(n)$. For any (weighted) directed graph H (possibly different from G), we denote by $V(H)$ and $E(H)$ the set of its vertices and edges, respectively. Let P be a path in H from $s\in V(H)$ to $t\in V(H)$, we say that P is an *s-t-path* in H. We denote by $|P|=\sum_{e\in E(P)}w(e)$ the *length* of P, that is, its total weight. If H is unweighted, we let $|P|=|E(P)|$ denote the number of its edges. For $u,v\in V(P)$, we let $P[u..v]$ denote the subpath of P from u to v. For $s,t\in V(H)$, the *distance* $d_H(s,t)$ is the minimum length of any s-t-path in H; if s and t are disconnected, we set $d_H(s,t)=+\infty$. When talking about the base graph G, we drop the subscripts if this does not create any ambiguities. The *eccentricity* of a vertex $s\in V(H)$ is $\mathrm{ecc}_H(s)=\max_{t\in V(H)}d_H(s,t)$, the *diameter* is $\mathrm{diam}(H)=\max_{s\in V(H)}\mathrm{ecc}_H(s)$. For a set $F\subseteq E(H)$ of edges, let $H-F$ be the graph obtained from H by removing all edges in F. A *replacement path* $P_H(s,t,F)$ is a shortest path from s to t in $H-F$. Its length $d_H(s,t,F)=|P_H(s,t,F)|$ is the *replacement distance*. The *fault-tolerant eccentricity* of a vertex $s\in V$ of the base graph with respect to F is $\mathrm{ecc}_{G-F}(s)$, the *fault-tolerant diameter* is $\mathrm{diam}(G-F)$.

For a positive integer f, an *f-edge fault-tolerant eccentricity oracle* (f-FEO) for G reports, upon query (s,F) with $|F|\leqslant f$, the value $\mathrm{ecc}_{G-F}(s)$. An *f-edge fault-tolerant diameter oracle* returns $\mathrm{diam}(G-F)$ upon query F. For a single edge failure, we write FEO for 1-FEO and abbreviate $F=\{e\}$ to e. For any real number $\sigma=\sigma(n,m,f)\geqslant 1$, an f-FEO is said to have *stretch* σ, or be *σ-approximate*, if the returned value $\widehat{\mathrm{ecc}}(s,F)$ on query (s,F) satisfies $\mathrm{ecc}_{G-F}(s)\leqslant\widehat{\mathrm{ecc}}(s,F)\leqslant\sigma\cdot\mathrm{ecc}_{G-F}(s)$, analogously for f-FDOs. The *preprocessing time* is the time needed to compute the data structure, its *query time* is the time needed to return an answer. For weighted graphs, we assume the weight function being such that all distances can be stored in a single word on $O(\log n)$ bits. Unless stated otherwise, we measure the *space* of the oracles in the number of words. The oracles cannot access features of graph G except those stored during preprocessing. The size of the input does not count against the space of the data structures.

3 Diameter and Eccentricity Oracles

This section discusses fault-tolerant oracles for the diameter and vertex eccentricity in directed graphs. We start by presenting space lower bounds for FDOs that guarantee a certain stretch when supporting single or multiple edge failures, respectively. In the single-failure case, the bound depends on the diameter of the graph. Roughly speaking, if the base graph has low diameter, we cannot save much space over just storing all edges. The picture changes if the diameter grows larger. We show that then we can obtain FDOs with $o(m)$ space, or even $\widetilde{O}(n)$. We then turn the discussing to eccentricity oracles for dual and multiple failures. Note that there we need to report not only one value per graph $G-F$, but one per vertex in each of those, so special techniques are needed to handle the space increase.

3.1 Space Lower Bounds for Diameter Oracles

Bilò et al. [6] showed that any FDO with a stretch $\sigma < 3/2$ on *undirected* m-edge graphs must take $\Omega(m)$ bits of space. In particular, any data structure that can distinguish between a fault-tolerant diameter of 2 and 3 has this size. Their construction transfers to directed graphs (by merely doubling each undirected edge into two directed ones). However, they do not parameterize the graphs by their diameter, namely, if the FDO has to distinguishing between diameter D and $3D/2$ for some $D \geqslant 3$. We generalize their result by showing that there is an intermediate range of D where the $\Omega(m)$-bit bound still applies. However, here the situation is more intricate in that large values of D do allow for significant space reductions.

The construction[5] by Bilò et al. [6] cannot be extended to $D \geqslant 3$. The proof of the next lemma had to be deferred to the full version due to space reasons.

▶ **Lemma 9.** *Let n, m, D be integers such that $n^2 \geqslant m \geqslant n \geqslant 4$, and $n/\sqrt{m} > D \geqslant 3$. There exists a family $\mathcal{G}$ of n-vertex directed graphs with diameter D and $\Theta(m)$ edges such that any data structure for graphs in $\mathcal{G}$ that decides whether the fault-tolerant diameter remains at D or increases to $(3D-1)/2$ for odd D (or $(3D/2)-1$ for even D) requires $\Omega(m)$ bits of space.*

It is now easy to obtain the $\Omega(m)$-bit lower bound of Theorem 1 since any FDO of stretch $\sigma < \frac{3}{2} - \frac{1}{D}$ must tell the two cases apart.

We now turn to diameter oracles that support more than one edge failure, $f > 1$. Theorem 4 states that they require space that is exponential in f, even if we allow the stretch and query time to be arbitrarily large (but finite). It follows from the next lemma together with the observation that such f-FDOs have to detect whether the edge failures disconnect the graph.

▶ **Lemma 10.** *Any data structure for n-vertex digraphs that decides for at most $2f = O(\log n)$ edge failures whether the fault-tolerant diameter is finite requires $\Omega(2^f n)$ bits of space.*

3.2 Improved Upper Bounds

The above discussion shows that for graphs with *small* diameter, there is no hope to obtain an FDO whose space is much smaller than what is needed to store the full graph. At least not while retaining good stretch at the same time. The lower bound in Theorem 1, however, breaks down for a *large* diameter. Indeed, we show next that in this regime we can do much better in terms of space, without sacrificing stretch or query time.

Theorems 2 and 3 will follow from the same construction. The initial way we present it in Lemma 12 uses randomization in the form of a well-known sampling lemma, see [22, 33]. We will later discuss how to derandomize the oracles.

▶ **Lemma 11** (Sampling Lemma)**.** *Let H be a n-vertex directed graph, $c > 0$ a positive constant, and $L \geqslant c \ln n$. Define a random set $B \subseteq V(H)$ by sampling each vertex of H independently with probability $(c \ln n)/L$. With probability at least $1 - \frac{1}{n^c}$, the cardinality of B is $O((n \log n)/L)$. Let further $\mathcal{P}$ be a set of ℓ simple paths in H, each of which spans L vertices. With probability at least $1 - \frac{\ell}{n^c}$, we have $V(P) \cap B \neq \emptyset$ for every $P \in \mathcal{P}$.*

▶ **Lemma 12.** *For any n-vertex, m-edge unweighted directed graph G with diameter $D = \omega(\log n)$ and any $\varepsilon = \varepsilon(n, m, D) > 0$, we can compute in time $\widetilde{O}(mn + n^4/(\varepsilon^3 D^3))$ an FDO with $1+\varepsilon$ stretch, $O(n + (n^{8/3} \log^2 n)/(\varepsilon^2 D^2))$ space, and constant query time.*

[5] The graph used in the proof of [6, Lemma 12] has the property that failing any edge can increase the diameter by at most 1.

Proof. Let $D = \mathrm{diam}(G)$, $b = n/(\varepsilon D)$, and $c > 0$ a sufficiently large constant. We sample a set $B \subseteq V$ of *pivots* by including each vertex independently with probability $(2bc \ln n)/n$. By Lemma 11 with $L = n/2b = \varepsilon D/2$, there are $O(b \log n)$ many pivots w.h.p.

For the graph G, compute in $\widetilde{O}(mn)$ time the $O(1)$-query time distance sensitivity oracle of Bernstein and Karger [4]. We further compute a subgraph H of G that is just the union of $|B|$ shortest-path trees, one rooted at each pivot. We iterate over the edges of H and compute the collection $\mathcal{X}$ of all those $e \in E(H)$ such that $d(b_1, b_2, e) > d(b_1, b_2)$ for some pair $(b_1, b_2) \in B \times B$. The time to compute $\mathcal{X}$ is $O(n|B|^3) = \widetilde{O}(n^4/(\varepsilon^3 D^3))$ since processing an edge in H requires $|B|^2$ calls to the DSO. Observe that any subgraph of G that exactly preserves distances between all pairs in $B \times B$ must contain all the edges of $\mathcal{X}$. Bodwin [7] showed that there are distance-preserving subgraphs with respect to $B \times B$ with at most $O(n + n^{2/3}|B|^2)$ edges. Thus, the size of $\mathcal{X}$ is bounded by $O(n + n^{2/3}|B|^2)$.

Next, we build a dictionary $\mathcal{D}_{\mathcal{X}}$ in which we store the the edges in $\mathcal{X}$ together with the maximum distance between any pair of pivots if the edge fails (or $\mathrm{diam}(G)$ if this is larger). In other words, for each $e \in \mathcal{X}$, we store $\phi(e) = \max\{\max_{b_1,b_2 \in B} d(b_1, b_2, e), \mathrm{diam}(G)\}$. Let $\mathcal{Y}$ be the set of all edges in E such that $G - e$ is no longer strongly connected. We build a dictionary $\mathcal{D}_{\mathcal{Y}}$ in which we store information about the edges $\mathcal{Y}$. It is well-known that $\mathcal{Y}$ contains $O(n)$ edges and can be computed in time $O(m)$ [27].

Recall that $b = n/(\varepsilon \,\mathrm{diam}(G))$. The oracle's output $\widehat{D}(e)$ is defined as follows: if $e \in \mathcal{Y}$, then $\widehat{D}(e) = \infty$; if $e \in \mathcal{X}$, $\widehat{D}(e) = \phi(e) + n/b$; otherwise, the oracle outputs $\widehat{D}(e) = \mathrm{diam}(G) + n/b = (1 + \varepsilon)\,\mathrm{diam}(G)$.

Evidently, the oracle is correct for all $e \in \mathcal{Y}$. It is also easy to verify that all outputs are at most $\phi(e) + n/b \leqslant \mathrm{diam}(G - e) + n/b = \mathrm{diam}(G - e) + \varepsilon\,\mathrm{diam}(G) \leqslant (1 + \varepsilon)\,\mathrm{diam}(G - e)$. To prove that they are also at least $\mathrm{diam}(G - e)$, consider a vertex pair $(u, v) \in V \times V$ such that $d(u, v, e) = \mathrm{diam}(G - e) < \infty$. With high probability[6] by Lemma 11, there exists a shortest u-v-path in $G - e$ and two pivots $b_u, b_v \in B$ on that path such that $d(u, b_u, e), d(b_v, v, e) \leqslant L = n/2b$. We have $\mathrm{diam}(G-e) = d(u, b_u, e)+d(b_u, b_v, e)+d(b_v, v, e)$. Suppose $e \notin \mathcal{X}$. Then, $d(b_u, b_v, e) = d(b_u, b_v) \leqslant \mathrm{diam}(G)$ holds and therefore $\mathrm{diam}(G - e) \leqslant \mathrm{diam}(G) + n/b = \widehat{D}(e)$. If $e \in \mathcal{X}$, then $d(b_u, b_v, e) \leqslant \phi(e)$ and $\mathrm{diam}(G - e) \leqslant \phi(e) + n/b = \widehat{D}(e)$.

There are k-element dictionaries of size $O(k)$ and $O(1)$ query time computable in time $\widetilde{O}(k)$ [25]. The dictionaries have total size $O(n+n^{2/3}|B|^2) = O(n+(n^{8/3} \log^2 n)/(\varepsilon^2 D^2))$. ◀

The oracle in Lemma 12 can also be extended to handle vertex failures. The only modification required is to add to set $\mathcal{X}$ those vertices $v \in V$ that satisfy $d(b_1, b_2, v) > d(b_1, b_2)$ for some $(b_1, b_2) \in B \times B$, and to add to $\mathcal{Y}$ to be those vertices v for which $G - v$ is not strongly connected. Suppose $D = \omega(n^{5/6})$, inserting any $\varepsilon \geqslant n^{5/6}/D = o(1)$ above gives an FDO with near linear space and $1 + o(1)$ stretch that is computable in time $\widetilde{O}(mn)$, which proves Theorem 2. Furthermore, for graphs with diameter $\omega((n^{4/3} \log n)/(\varepsilon\sqrt{m}))$, we obtain in $\widetilde{O}(mn)$ time an FDO with constant query time and $o(m)$ space (Theorem 3).

3.3 Eccentricity Oracles

We now prove Theorem 5 that constructs an f-edge fault-tolerant eccentricity oracle from a DSO supporting f failures. The improved f-FEO for DAGs can be found in the full version.

[6] We say an event occurs *with high probability* (w.h.p.) if it has success probability $1 - n^{-c}$ for some constant $c > 0$ that can be made arbitrarily large.

Let $\mathcal{D}$ be a DSO with sensitivity f and stretch σ that, on (un-)directed possibly weighted graphs, can be computed in time P, uses S space, and has a query time of Q. For any given source $s \in V$ and query set F of $|F| \leqslant f$ edges, our oracle reports an $(1+\sigma)$-approximation of the eccentricity of s in $G - F$. We simply store $\mathcal{D}$ and, for each $x \in V$, the value $ecc_G(x)$. All eccentricities in the base graph G can be obtained with a BFS from each vertex in $O(mn)$.

Upon query $(s, F = \{(x_1, y_1), \ldots, (x_f, y_f)\})$, we use $\mathcal{D}$ to compute $d(s, y_i, F)$, for all $1 \leqslant i \leqslant f$. Our estimate is $\widehat{\text{ecc}}_{G-F}(s) = \text{ecc}_G(s) + \max_{1 \leqslant i \leqslant f} d(s, y_i, F)$. The time taken to compute $\widehat{\text{ecc}}_{G-F}(s)$ is $O(f \cdot Q)$ and the space requirement of the oracle is $O(n + S)$.

Now we show that $\widehat{\text{ecc}}_{G-F}(s)$ is a $(1 + \sigma)$-approximation of $\text{ecc}_{G-F}(s)$. Let F_0 be the subset of F consisting of those edges in F that lie on some shortest-path tree T rooted in s. If F_0 is empty, we immediately get $\text{ecc}_{G-F}(s) = \text{ecc}_G(s) \leqslant \widehat{\text{ecc}}_{G-F}(s)$. Otherwise, for any $v \in V$, either $d(s, v) = d(s, v, F)$ or there exists an $(x, y) \in F_0$ such that y is an ancestor of v in T. In this latter case $d(y, v, F) \leqslant \text{ecc}_G(s)$. This proves that $d(s, v, F) \leqslant d(s, y, F) + d(y, v, F) \leqslant d(s, y, F) + \text{ecc}_G(s) \leqslant \widehat{\text{ecc}}_{G-F}(s)$. Thus, $\text{ecc}_{G-F}(s) \leqslant \widehat{\text{ecc}}_{G-F}(s)$. Next observe that $\text{ecc}_G(s) \leqslant \text{ecc}_{G-F}(s)$ and $\max_{1 \leqslant i \leqslant f} d(s, y_i, F) \leqslant \sigma \cdot \text{ecc}_{G-F}(s)$, which proves that $\widehat{\text{ecc}}_{G-F}(s) \leqslant (1 + \sigma) \cdot \text{ecc}_{G-F}(s)$.

4 Derandomization Framework

The fault-tolerant diameter oracles in Theorems 2 and 3 are randomized. They both follow from Lemma 12 which in turn relies on a random hitting set to intersect all replacement paths of a certain length. In fact, many more data structures and algorithms in the fault-tolerant setting follow a sampling-based approach similar to Lemma 11, see e.g. [9, 12, 22, 32, 33, 35]. It is an interesting question whether these algorithms can be derandomized efficiently. Currently there is no single approach to derandomize Lemma 11 in the same $O(n)$ time it uses to go through all vertices. Therefore, the literature focuses on the specific applications. The goal is to replace the sampling step by a deterministic construction of the hitting set that, while taking $\omega(n)$ time, does not (or only marginally) increase the asymptotic running time of the whole algorithm. Recently, there was some progress on notable special cases. Karthik and Parter [28] gave a derandomization for the algebraic version of the distance sensitivity oracle of Weimann and Yuster [35] with a slightly higher running time (for a detailed discussion see Lemma 15 below). Bilò et al. [5] derandomized the SSRP algorithms of Grandoni and Vassilevska Williams [22] as well as Chechik and Cohen [9]. Their derandomization succeeds in the same time bounds as the original randomized algorithm, but the technique only works for undirected graphs. Here, we develop a framework for directed graphs. We first apply it to our own FDOs and then show its versatility by also derandomizing the DSO of Ren [32] and the SSRP algorithm of Chechik and Magen [12].

We build on the work of Alon, Chechik, and Cohen [2]. We first review some technical details of their result and then describe our additions. For now, we assume the base graph G to be unweighted and only later (in Section 5) incorporate positive integer edge weights. For concreteness, consider the task in Lemma 12 of finding a set $B \subseteq V$, the pivots, such that for all $s, t \in V$ and edge $e \in E$ with replacement distance $d(s, t, e)$ at least $L = \varepsilon \operatorname{diam}(G)/2$, there exists some replacement path $P(s, t, e)$ that contains a pivot $x \in B$. Other fault-tolerant algorithms pose similar requirements on B. The technique in [2] consists of computing a small set of *critical* paths, much smaller than the set of all $O(mn^2)$ replacement paths. Once we have those, a hitting set can be computed with the folklore greedy algorithm, called GreedyPivotSelection in [2], that always selects a vertex that is contained in the most unhit paths.[7] Alternatively, one can use the blocker set algorithm of King [29].

[7] To achieve the performance of Lemma 13, one has to truncate all paths by selecting L vertices arbitrarily from each $P \in \mathcal{P}$. This is non-issue for us as, by construction, all our paths will have length $\Theta(L)$.

▶ **Lemma 13** (Alon, Chechik, and Cohen [2]). *Let $1 \leqslant L \leqslant n$ and $1 \leqslant q = \mathsf{poly}(n)$ be two integers. Let $P_1, \ldots, P_q \subseteq V$ be sets of vertices that, for every $1 \leqslant k \leqslant q$, satisfy $|P_k| \geqslant L$. The algorithm* GreedyPivotSelection *computes in time $\widetilde{O}(qL + n^2/L)$ a set $B \subseteq V$ of $|B| = O((n \log q)/L) = \widetilde{O}(n/L)$ pivots such that, for every index k, it holds that $B \cap P_k \neq \emptyset$.*

The crucial part is to quickly find the paths P_k such that hitting them is sufficient to hit all long replacement path. Of course, this could be done by computing all-pairs shortest paths in each graph $G-e$ in total time $\widetilde{O}(m^2 n)$ using Dijkstra's algorithm (or $\widetilde{O}(mn^{2.5302})$ if one is willing to use fast rectangular matrix multiplication [20, 36]). However, this is much more than the $\widetilde{O}(mn + n^4/(\varepsilon^3 \operatorname{diam}(G)^3))$ time bound we had in Lemma 12. For the applications in [2], a single set of paths and therefore a single hitting set was sufficient. Bilò et al. [5] (with slightly different requirements on the set B) were able to make do with three sets, exploiting the undirectedness of the underlying graph.

We extend this to directed graphs using a hierarchical approach to find the critical paths. Observe how the length parameter L in Lemma 13 serves two roles. The longer the paths, the longer it takes to compute B, but the *fewer* vertices suffice to intersect all paths. Additionally, we have to compute the set of critical paths which takes (at least) linear time in their length. So L has to fall just in the right range for the computation to be fast. To achieve this, we use an exponentially growing sequence of lengths $L_1, L_2, \ldots, L_{O(\log n)}$ and, instead of a single set, compute a sequence $B_1, B_2, \ldots$ of exponentially shrinking sets such that, in the i-th stage, B_i hits, again for all $s, t \in V$ and $e \in E$, some replacement path of length at least L_i. However, this poses some new difficulties because now the collection of critical paths has to be computed step by step. Imagine in the i-th stage, we have already obtained the all the subsets $\mathcal{P}_j$, $j < i$, of paths with respective lengths L_j. The key observation is that the hitting sets B_j from the previous rounds carry valuable information that can be harnessed to find the new set $\mathcal{P}_i$ faster, this then offsets the run time penalty incurred by the greater length of the new paths.

The HDPH Algorithm. We now describe the Hierarchical Double Pivots Hitting Sets (HDPH) algorithm that makes these ideas concrete. It can be seen as a "reference implementation" of the framework. For a specific application, one still has to adapt the details. The algorithm is more general than what is needed for diameter oracles in Theorems 2 and 3. For example, it also pertains to vertex failures. Later, in Section 5, we show an example how to modify the algorithm for other problems (more are found in the full version).

Let $C \geqslant 3/2$ be a constant. The aim of the HDPH algorithm is to compute a sequence of sets $B_1, \ldots, B_{\lceil \log_C n \rceil} \subseteq V$ of size $|B_i| = \widetilde{O}(n/C^i)$ such that for all vertices $s, t \in V$ and failure $f \in E \cup V$ with $d(s, t, f) \in (C^i, C^{i+1}]$ there exists a replacement path $P(s, t, f)$ that contains a pivot $z \in B_i$. It assumes access to the "APSP data" of the original graph G, that is, the distance $d(s, t)$ for all s, t and a corresponding shortest path $P(s, t)$. Also, it requires a deterministic path-reporting distance sensitivity oracle with constant query time (both for the distance and each reported edge) as a black box.

The HDPH algorithm is sketched in Algorithm 1. In lines 1 and 2 it initializes $B_i = V$ for $i \leqslant 2$. In lines 3-12, for $3 \leqslant i \leqslant \lceil \log_C n \rceil$, we iteratively compute the hitting sets B_i by using the hitting sets from the previous 3 iterations to obtain a set of shortest and replacement paths $\mathcal{P}_i$ of length $\Theta(n/C^i)$ that one needs to hit, and then use the greedy algorithm GreedyPivotSelection to compute the set of pivots B_i which hits this set of paths $\mathcal{P}_i$. The paths are defined as follows. First, in line 4 we add to $\mathcal{P}_i$ shortest paths $P(x, y)$ whose length is in the range $(C^i, C^{i+1}]$ such that $x, y \in B_{i-3} \cup B_{i-2} \cup B_{i-1}$ are pivots from the last 3 iterations. Then, in lines 5-11, for every pair of pivots $x, y \in B_{i-3} \cup B_{i-2} \cup B_{i-1}$ whose shortest path

Algorithm 1 Hierarchical Double Pivots Hitting Sets (HDPH) Algorithm.

Input: APSP data and a deterministic path-reporting DSO with $O(1)$ query time.
Output: The hitting sets $B_0, \dots, B_{\lceil \log_C n \rceil}$.

1 **for** $i \in [0, 2]$ **do**
2 $B_i \leftarrow V$
3 **for** $i \in [3, \lceil \log_C n \rceil]$ **do**
4 Let $\mathcal{P}_i = \{P(x,y) \mid x, y \in B_{i-3} \cup B_{i-2} \cup B_{i-1}$ such that $d(x,y) \in (C^{i-6}, C^{i+1}]\}$
5 **for** $x, y \in B_{i-3} \cup B_{i-2} \cup B_{i-1}$ **do**
6 **if** $d(x,y) \leqslant C^{i+1}$ **then**
7 **for** $f \in E(P(x,y)) \cup V(P(x,y))$ **do**
8 query the DSO for $d(x,y,f)$
9 **if** $d(x,y,f) \in (C^{i-6}, C^{i+1}]$ **then**
10 query the DSO for $P(x,y,f)$
11 $\mathcal{P}_i \leftarrow \mathcal{P}_i \cup \{P(x,y,f)\}$
12 $B_i \leftarrow$ GreedyPivotSelection$(\mathcal{P}_i)$
13 **return** $B_0, \dots, B_{\lceil \log_C n \rceil}$

$P(x,y)$ is of length at most C^{i+1}, and for every edge or every $f \in E(P(x,y)) \cup V(P(x,y))$ we query the DSO with (x,y,f) to compute the distance $d(x,y,f)$. If $d(x,y,f) \in (C^{i-6}, C^{i+1}]$ then we use the DSO to also report a replacement path $P(x,y,f)$ and add it to $\mathcal{P}_i$.

The next lemma proves the properties of the resulting hitting sets and the run time.

▶ **Lemma 14.** *Given the APSP data and a deterministic path-reporting DSO with $O(1)$ query time, the HDPH algorithm deterministically computes, in $\widetilde{O}(n^2)$ time, all the hitting sets B_i, with $0 \leqslant i \leqslant \lceil \log_C n \rceil$. For every $0 \leqslant i \leqslant \lceil \log_C n \rceil$, it holds that $|B_i| = \widetilde{O}(n/C^i)$. For every pair of vertices $s, t \in V$ and for every failing edge or vertex $f \in E \cup V$ such that $d(s,t,f) \in (C^i, C^{i+1}]$ there exists a pivot $z \in B_i$ such that $d(s,t,f) = d(s,z,f) + d(z,t,f)$. Finally, for every pair of vertices $s, t \in V$ such that $d(s,t) \in (C^i, C^{i+1}]$, there exists a pivot $z \in B_i$ such that $d(s,t) = d(s,z) + d(z,t)$.*

Proof. We first prove by induction that for every $i \in [0, \lceil \log_C n \rceil]$ it holds that $|B_i| = \widetilde{O}(n/C^i)$. The claim trivially holds for $i \leqslant 2$ as $B_0 = B_1 = B_2 = V$. For the inductive step, we assume that $|B_j| = \widetilde{O}(n/C^j)$ for every $j < i$. We show that the set of paths $\mathcal{P}_i$ contains $\widetilde{O}(n^2/C^i)$ paths, each of length $\Theta(C^i)$, and thus the result of the greedy algorithm $B_i \leftarrow$ GreedyPivotSelection$(\mathcal{P}_i)$ contains, by Lemma 13, at most $\widetilde{O}(n/C^i)$ vertices. Moreover, the runtime of the GreedyPivotSelection procedure is $\widetilde{O}(n^2)$.

For every $s, t \in V$, let $P(s,t)$ denote the shortest s-t-path in the APSP data. There are two places where paths are added to $\mathcal{P}_i$. In line 4, the algorithm adds shortest paths between vertices $x, y \in B_{i-3} \cup B_{i-2} \cup B_{i-1}$ whenever $d(x,y) = |P(x,y)| \in (C^{i-6}, C^{i+1}]$, and by the induction hypothesis there are $\widetilde{O}(n^2/C^{2(i-1)}) = \widetilde{O}(n^2/C^i)$ such pairs of vertices (since $|B_j| = \widetilde{O}(n/C^j)$ for every $j < i$). Thus, the claim holds for the paths in line 4. In line 11, the algorithm adds paths $P(x,y,f)$ to $\mathcal{P}_i$ only for pairs $x, y \in B_{i-3} \cup B_{i-2} \cup B_{i-1}$ and edges or vertices $f \in E(P(x,y)) \cup V(P(x,y))$ with $d(x,y) \leqslant C^{i+1}$, there are $\widetilde{O}(C^{i+1} \cdot (n^2/C^{2(i-1)})) = \widetilde{O}(n^2/C^i)$ such triples (x,y,f). The only paths added there are such that $d(x,y,f) \in (C^{i-6}, C^{i+1}]$ (due to the condition in line 9) and thus the length of $P(x,y,f)$ is $\Theta(C^i)$. So the claim holds here as well.

Next, we prove that the runtime of the algorithm is $\widetilde{O}(n^2)$. We show that a single iteration of the for loop in lines 4-16 takes $\widetilde{O}(n^2)$ time, and as there are $O(\log n)$ iterations for $i \in [3, \lceil \log_C n \rceil]$. The number of pairs $x, y \in B_{i-3} \cup B_{i-2} \cup B_{i-1}$ is $\widetilde{O}(n^2/C^{2(i-1)})$. The inner loop in lines 7-11 is executed only if $d(x,y) \leqslant C^{i+1}$, therefore the number of edges $e \in P(x,y)$ is bounded by C^{i+1} and hence the loop is executed at most $O(C^i)$ times. Each iteration of this loop uses the black-box DSO to compute $d(x,y,f)$ in $O(1)$, and only if $d(x,y,f) \in (C^{i-6}, C^{i+1}]$ then we use the DSO to actually obtain the path $P(x,y,f)$ in $O(|P(x,y,f)|) = O(C^i)$ time. This gives $\widetilde{O}(n^2)$ for the second-most outer loop. We have already seen that computing $\mathsf{GreedyPivotSelection}(\mathcal{P}_i)$ in line 12 takes $\widetilde{O}(n^2)$ time as well.

We claim that for all $s, t \in V$ and every edge or vertex $f \in E \cup V$ such that $d(s,t,f) \in (C^i, C^{i+1}]$, there exists a pivot $z \in B_i$ such that $d(s,t,f) = d(s,z,f) + d(z,t,f)$. That means, there is some s-t-replacement path that contains z. This is clear for $i \leqslant 2$. Let $3 \leqslant i \leqslant \lceil \log_C n \rceil$ and suppose the claim holds for every $j < i$. Let $P(s,t,f) = (v_0 = s, v_1, \ldots, v_k = t)$ be an replacement path with $k = d(s,t,f) \in (C^i, C^{i+1}]$. We define the prefix $P_1 = P(s,t,f)[s..v_{\lceil k/C^3 \rceil}]$ and suffix $P_2 = P(s,t,f)[v_{\lceil (1-1/C^3)k \rceil}..t]$. Both subpaths have length in $(C^{i-3}, C^{i-2}]$. It follows that there are pivots $x_1, x_2 \in B_{i-3}$ with $x_1 \in V(P_1)$, $x_2 \in V(P_2)$. (Strictly speaking, we are merely guaranteed *some* s-$v_{\lceil k/C^3 \rceil}$-replacement path that contains x_1, but we can choose $P(s,t,f)$ so that its prefix is that path; same with P_2.)

Let $P(x_1, x_2, f)$ be the replacement paths returned by the DSO on query (x_1, x_2, f). We claim that it is added to $\mathcal{P}_i$. Observe that $d(x_1, x_2, f) \geqslant d(s,t,f) - |P_1| - |P_2| \geqslant (1 - \frac{2}{C^2})C^i > C^{i-6}$, where we used the assumption $C \geqslant 3/2$ and thus $1 - \frac{2}{C^2} > C^{-6}$. Also, we have $d(x_1, x_2) \leqslant d(x_1, x_2, f) \leqslant d(s,t,f) \leqslant C^{i+1}$. If $d(x_1, x_2, f) = d(x_1, x_2)$, we may assume $P(x_1, x_2, f) = P(x_1, x_2)$, whence it was added in line 4. Otherwise, the failure $f \in V(P(x_1, x_2))$ is on the path. Since $x_1, x_2 \in B_{i-3} \cup B_{i-2} \cup B_{i-1}$, $d(x_1, x_2) \leqslant C^{i+1}$, and $d(x_1, x_2, f) \in (C^{i-6}, C^{i+1}]$ the path $P(x_1, x_2, f)$ is indeed added to $\mathcal{P}_i$ in line 11. Due to $B_i \leftarrow \mathsf{GreedyPivotSelection}(\mathcal{P}_i)$, there exists a vertex $z \in B_i$ such that z is on the path $P(x_1, x_2, f) \subseteq P(s,t,f)$ and thus $d(s,t,f) = d(s,z,f) + d(z,t,f)$.

The proof that for all $s, t \in V$ with $d(s,t) \in (C^i, C^{i+1}]$, there exists a pivot $z \in B_i$ such that $d(s,t) = d(s,z) + d(z,t)$ follows the same argument but is somewhat simpler because the subpaths P_1 and P_2 are guaranteed to be added in line 4. ◀

Derandomizing Theorems 2 and 3. Recall that the oracle in Lemma 12 has preprocessing time $\widetilde{O}(mn + n^4/(\varepsilon^3 \operatorname{diam}(G)^3))$. For its derandomization, and that of Theorems 2 and 3, it is enough to choose $C = 2$, compute APSP *only* in the original graph G, and preprocess the DSO of Bernstein and Karger[8] [4], which takes $\widetilde{O}(mn)$ time. Let i^* be the largest integer i such that $2^i < L = \varepsilon \operatorname{diam}(G)/2$. The set B_{i^*} then hits, for all $s, t \in V$ and $e \in E$ with $d(s,t,e) = \Theta(L)$, some replacement path $P(s,t,e)$, and it has the desired cardinality $\widetilde{O}(n/L)$.

5 Derandomizing Existing Sensitivity Oracles and Algorithms

We now show how the HDPH algorithm can be adapted to derandomize existing sensitivity oracles. In addition to our own technique, we also extensively use a recent breakthrough by Karthik and Parter [28] in the derandomization of fault-tolerant algorithms. We combine both tools and apply them to the distance sensitivity oracle of Ren [32] and the SSRP algorithm of Chechik and Magen [12] In the main part, we concentrate on the DSO because we think that it is a good illustration of the combination of our work and that of Karthik and Parter [28]. The treatment of the SSRP algorithm had to be deferred to the full version.

[8] Bernstein and Karger [4] derandomized their own DSO using a technique by King [29].

5.1 The Distance Sensitivity Oracle of Ren

We start with the oracle of Ren [32]. Recall that, for any two vertices $s, t \in V$ and edge $e \in E$, the replacement distance $d(s, t, e)$ is the length of a shortest s-t-path in $G - e$. A distance sensitivity oracle (DSO) is a data structure that answers query (s, t, e) with $d(s, t, e)$. Ren [32] presented an algebraic DSO with a randomized preprocessing time of $O(Mn^{2.7233})$ on graphs with positive integer edge weights in the range $[1, M]$ and $\widetilde{O}(Mn^{(\omega+3)/2}) = O(Mn^{2.6865})$ time on undirected graphs. Notably, this was the first DSO with both constant query time and subcubic preprocessing, improving over previous work [2, 4, 22, 35]. We derandomize it with a slight increase in running time and obtain a deterministic DSO in time $O(Mn^{2.8068})$ on directed graphs and $\widetilde{O}(Mn^{(\omega+6)/3}) = O(Mn^{2.7910})$ on undirected graphs.

The construction starts with a Core oracle that only reports very small distances, this is then grown iteratively to cover longer paths until the distance between all pairs of vertices are correctly determined. More formally, for a positive real r, let an *r-truncated DSO* report, upon query (s, t, e), the value $d(s, t, e)$ if it is at most r, and $+\infty$ otherwise. The Core is an n^α-truncated DSO for some carefully chosen exponent $\alpha \in (0, 1)$. Each iteration invokes the procedure Extend to turn an r-truncated DSO into an $(3/2)r$-truncated DSO. Note that we can assume $M = \widetilde{O}(n^{(3-\omega)/2})$ as otherwise the deterministic oracle in [4] with an $\widetilde{O}(mn)$ preprocessing time already achieves $\widetilde{O}(Mn^{(\omega+3)/2})$, even on directed weighted graphs. Hence, $\log_{3/2}(Mn) = O(\log n)$ rounds of growing suffice to built the full oracle.

The iterative approach has the advantage that r-truncated DSOs for small r can be computed fast. A bridging-set idea, see [36], is used for the extension. This significantly increases the query time as the oracle has to cycle through the whole bridging set to compute the distance. Ren [32] uses a clever observation, there attributed to Bernstein and Karger [4], to reduce the query time of the extended DSO back to a constant, called the Fast procedure.

Randomness is employed at two points. First, the Core uses a series random subgraphs of G. Secondly, Extend randomly samples a set of pivots to hit all replacement paths of length between r and $(3/2)r$. The subsequent reduction in query time is deterministic.[9] The Core can be derandomized using a recent result by Karthik and Parter [28]. To derandomize Extend, we adapt our technique introduced above. The key differences are that we now have to take care of the edge weights, that is, the number of vertices of a path may be much smaller than its length. Also, due to the iterative approach of not only the derandomization but the actual construction via truncated DSOs, we cannot assume to have access to all relevant paths right from the beginning. Instead, we have to make sure that all intermediary oracles are *path-reporting* and that for the construction of the current hitting set we only use paths of length at most r. The deterministic Core oracle hinges on the following lemma.

▶ **Lemma 15** (Karthik and Parter [28]). *Given a (possibly weighted) graph G on n vertices and a positive real $r = n^\alpha$ for some $\alpha \in (0, 1)$, there is a deterministic algorithm computing $k = O(r^2)$ spanning subgraphs $G_1, \dots, G_k$ of G in time $\widetilde{O}(kn^2)$ such that for any pair of vertices $s, t \in V$, edge $e \in E$, and replacement path $P(s, t, e)$ on at most r edges, there exists an index i such that G_i does not contain the edge e but all edges of $P(s, t, e)$.*

This derandomizes a construction by Weimann and Yuster [35] with the crucial difference that the latter is only required to produce subgraphs such that for all pairs of vertices s, t and edges e that admit possibly multiple replacement paths on at most r edges *at least one* (instead of all) of them survives in one of the graphs G_i in which e was removed. This

[9] The relevant [32, Section 3] is phrased as randomized, but based on the derandomizable algorithm in [4].

relaxed condition is actually enough to build an r-truncated DSO and allows one to make do with only $\widetilde{O}(r)$ random subgraphs, while we have $O(r^2)$ deterministic graphs. See also the discussion in Section 1.3 of [28]. This is the sole reason for the increased running time compared to the original result of Ren [32].

Given a graph G with integer edge weights in the range $[1, M]$, we invoke Lemma 15 to obtain the subgraphs G_i. Recall that $r = n^\alpha$ and let $\omega(1-\alpha)$ be the infimum over all w such that rectangular integer matrices with dimensions $n \times n^{1-\alpha}$ and $n^{1-\alpha} \times n$ can be multiplied using $O(n^w)$ arithmetic operations, $\omega = \omega(1)$ is the usual square matrix multiplication coefficient. Using a variant of Zwick's algorithm [36],[10] we compute APSP restricted to paths on at most r edges in time $\widetilde{O}(Mn^{\omega(1-\alpha)}r)$ per subgraph. If G is undirected, then this can be done faster, namely, in $\widetilde{O}(Mn^\omega)$ per graph with the algorithm of Shoshan and Zwick [34]. Both algorithms in [34, 36] can be adjusted to also compute the actual paths, represented as predecessor trees, which increases the running time only by logarithmic factors.

To answer a query (s, t, e) we cycle through the G_i and, in case the edge e is missing, retrieve the distance $d_{G_i}(s, t)$. By Lemma 15, the minimum over all retrieved distances is the correct replacement distance $d(s, t, e)$. If this minimum is larger than r or no distance has been retrieved at all (as the paths take more than r edges), we return $+\infty$. Since the edge weights are positive integers, every path of *length* at most r uses at most r edges, so we indeed obtain an r-truncated DSO. If an actual replacement path is requested, we return a shortest s-t-path in one of the G_i that attain the minimum. The resulting oracle has query time $\widetilde{O}(r^2)$ and a $\widetilde{O}(n^2r^2 + Mn^{\omega(1-\alpha)}r^3) = \widetilde{O}(Mn^{\omega(1-\alpha)}r^3)$ preprocessing time on directed graphs (using $\omega(1-\alpha) \geqslant 2$). On undirected graphs, this improves to $\widetilde{O}(n^2r^2 + Mn^\omega r^2) = \widetilde{O}(Mn^\omega r^2)$.

As a technical subtlety, the Fast procedure needed to reduce the query time requires *unique* shortest paths[11] of the original graph G. They can be computed in time $\widetilde{O}(M^{1/2}n^{(\omega+3)/2})$ [16, 32]. We will see later that this is not the bottleneck of the preprocessing.

▶ **Lemma 16** (Ren [32]). *From a directed graph G with integer edge weights in $[1, M]$, unique shortest paths, and an r-truncated DSO with preprocessing time P and query time Q, one can built in deterministic time $P + \widetilde{O}(n^2) \cdot Q$ a r-truncated DSO for G with $O(1)$ query time.*

Without access to unique paths, the running time increases to $P + \widetilde{O}(Mn^2) \cdot Q$, see [31]. If the oracle with query time Q (for the distance) is path-reporting (in $O(1)$ time per edge), then the new oracle is path-reporting with $O(1)$ query time (for distances and edges) [32].

We now turn to the main part, where we derandomize the Extend procedure that turns an r-truncated DSOs into $(3/2)r$-truncated DSOs. We adapt our technique to the iterative manner of construction and to the integer weights on the edges. In each stage, we only have access to a truncated DSO. Still, we show how to deterministically compute a sequence $B_1, B_2, \ldots$ of smaller and smaller sets, where B_i is used to derandomize the i-th application of Extend. Again, the construction of B_i depends on the previous sets of pivots, namely, on B_{i-2}. We first describe how to obtain the B_i satisfying certain useful properties and afterwards verify that these properties indeed suffice to make Extend deterministic.

▶ **Lemma 17.** *Let $r_1 \geqslant 1$ be a real number and define $r_{i+1} = (3/2)r_i$. For a graph G with integer edge weights in $[1, M]$, let $\{B_i\}_{i \geqslant 1}$ be a family of subsets of V, such that, for each i,*

(i) $|B_i| = \widetilde{O}(Mn/r_i)$;

[10] The algorithm in [36] is also phrased as randomized, in the same work it is explained how to derandomize it, increasing the running time only by polylogarithmic factors. The same holds for [34].

[11] By *unique shortest paths*, we mean a collection $\mathcal{P}$ containing one shortest path for each pair of vertices such that, for all $s, t \in V$, if $P(s, t) \in \mathcal{P}$ is the shortest path from s to t, then for every vertex u on $P(s, t)$, the path $P(s, u) \in \mathcal{P}$ is the prefix $P(s, t)[s..u]$ and $P(u, t) \in \mathcal{P}$ is the suffix $P(s, t)[u..t]$.

(ii) *for every pair of* $s,t \in V$ *and* $e \in E$ *with* $r_i/2 - M \leqslant d(s,t,e) \leqslant r_i$*, there exists a replacement path* $P(s,t,e)$ *that contains a vertex of* B_i*.*

With access to the shortest paths, a path-reporting r_i*-truncated DSO with* $O(1)$ *query time, and the sets* B_j *with* $j < i$*, one can compute each* B_i *deterministically in time* $\widetilde{O}(M^2n^2 + n^2r_1^2)$*.*

Proof. The proof is by induction over i. For the construction of B_i, we use the previous set B_{i-2}. We set $B_{-1} = B_0 = V$ to unify notation. Following the outline of the derandomization technique, we first assemble a set $\mathcal{P}$ of paths and then greedily compute a hitting set.

For each pair of vertices $x, y \in B_{i-2}$, we check whether the x-y-distance in the base graph G is at most r_i and, if so, retrieve a shortest path $P(x,y)$. If $P(x,y)$ additionally has length at least $r_i/18$, we add it to $\mathcal{P}$. For each edge e on $P(x,y)$ (regardless of the path being added to $\mathcal{P}$), we query the r_i-truncated DSO whether the replacement distance is $d(x,y,e) \in [\frac{r_i}{18}, r_i]$. If so, we request a corresponding replacement path $P(x,y,e)$ to add it to $\mathcal{P}$.

Due to the positive weights, those paths have at most r_i edges and can be obtained in time $O(r_i)$. Assembling $\mathcal{P}$ thus takes time $O(|B_{i-2}|^2 r_i^2)$. If $i \leqslant 2$, this is $O(n^2 r_1^2)$ since $r_2 = (3/2)r_1$. For $i \geqslant 3$, we get $\widetilde{O}((Mn/r_{i-2})^2 \cdot r_i^2) = \widetilde{O}(M^2n^2)$ instead.

We deterministically compute a hitting set B_i for $\mathcal{P}$. Since $\mathcal{P}$ contains at most $|B_{i-2}|^2 \cdot r_i$ paths with at least $r_i/(18M)$ edges each, whence $\Omega(r_i/M)$ vertices, the set B_i has $\widetilde{O}(n/(r_i/M)) = \widetilde{O}(Mn/r_i)$ vertices and is computable in time $\widetilde{O}(|\mathcal{P}| \cdot (r_i/M))$. As before, for $i \leqslant 2$, this is $\widetilde{O}(n^2r_1^2/M)$; and $\widetilde{O}(Mn^2)$ otherwise. We get a running time of $\widetilde{O}(M^2n^2 + n^2r_1^2)$.

It is left to prove that B_i indeed hits at least one replacement path for all $s,t \in V$ and $e \in E$ that satisfy $d(s,t,e) \in [\frac{r_i}{2} - M, r_i]$. Let $P(s,t,e)$ be such a path and define u to be the first vertex on $P(s,t,e)$ (starting from s) such that $d(s,u,e) \geqslant (2/9)r_i - M$. If $i \geqslant 3$, then $r_{i-2} = (4/9)r_i$, whence $d(s,u,e) \in [\frac{r_{i-2}}{2} - M, \frac{r_{i-2}}{2})$ and the induction hypothesis implies that there is *some* replacement path P' from s to u avoiding the edge e such that B_{i-2} contains one vertex of P'. Otherwise, if $i \leqslant 2$, the same fact simply follows from $B_{i-2} = V$.

The path P' is not necessarily equal to the prefix of $P(s,t,e)[s..u]$ (but they have the same length $d(s,u,e)$). Replacing $P(s,t,e)[s..u]$ with P' gives a new replacement path that now has a pivot $x \in B_{i-2}$ on its prefix. Slightly abusing notation, we use $P(s,t,e)$ to denote also the updated path. Let v be the last vertex on $P(s,t,e)$ with $d(v,t,e) \geqslant (2/9)r_i - M$. By the same argument, we can assume that the suffix of $P(s,t,e)[v..t]$ contains a pivot $y \in B_{i-2}$. In the remainder, we show that there is some replacement path $P(x,y,e)$ that is hit by a vertex in B_i. If so, replacing the middle part $P(s,t,e)[x..y]$ with $P(x,y,e)$ finally proves the existence of a replacement path from s to t avoiding e and containing a vertex of B_i.

By the choice of the pivots x, y and the assumption $d(s,t,e) \in [\frac{r_i}{2} - M, r_i]$, the replacement distance $d(x,y,e)$ satisfies

$$r_i \geqslant d(s,t,e) \geqslant d(x,y,e) \geqslant d(s,t,e) - d(s,u,e) - d(v,t,e) \geqslant d(s,t,e) - 2\left(\frac{2r_i}{9} - M\right) \geqslant \frac{r_i}{18}.$$

First, assume that the shortest path $P(x,y)$ in the base graph G does not contain the edge e. Then, $P(x,y)$ can serve as the replacement path. It has length $d(x,y) = d(x,y,e)$ between $r_i/18$ and r_i, and we added it to $\mathcal{P}$. Otherwise, it holds that $e \in P(x,y)$. Observe that $d(x,y) \leqslant d(x,y,e) \leqslant r_i$ remains true. Therefore, we have queried the r_i-truncated DSO with the triple (x,y,e). Due to $d(x,y,e) \geqslant r_i/18$, we received a replacement path $P(x,y,e)$, which we added to $\mathcal{P}$. In both cases, some replacement path is hit by B_i, as desired. ◀

At first glance, it looks like the quadratic dependence on M is too high to be used in the derandomization. However, recall that we can assume $M = \widetilde{O}(n^{(3-\omega)/2})$. Over the $O(\log n)$ rounds with $i \geqslant 3$ and with access to the appropriately truncated DSOs, we can compute the sets $B_3, B_4, \dots$ in total time $\widetilde{O}(M^2n^2) = \widetilde{O}(Mn^{(7-\omega)/2}) = \widetilde{O}(Mn^{2.5})$ even if $\omega = 2$.

The next lemma is the last tool we need to construct the deterministic DSO.

▶ **Lemma 18.** *Let G be a graph with integer edge weights in the range $[1, M]$, $r \geqslant 1$ a real number, and $B \subseteq V$ a set of $\widetilde{O}(Mn/r)$ vertices such that for every pair of $s, t \in V$ and $e \in E$ with $r/2 - M \leqslant d(s,t,e) \leqslant r$, there exists a replacement path $P(s,t,e)$ that contains a vertex of B. Given an r-truncated DSO for G with $O(1)$ query time and the set B, one can, without further preprocessing, construct an $(3/2)r$-truncated DSO with query time $\widetilde{O}(Mn/r)$. Moreover, if the r-truncated DSO is path-reporting, so is the $(3/2)r$-truncated one.*

Proof. For any query (s,t,e), let $D(s,t,e)$ denote the returned value by the r-truncated DSO. If $D(s,t,e) \neq +\infty$, we also take this as the answer of the $(3/2)r$-truncated DSO. Otherwise, define $\ell = \min_{z \in B}\{D(s,z,e) + D(z,t,e)\}$. If $\ell \leqslant (3/2)r$, we return ℓ, and $+\infty$ else. Path queries are handled in the same fashion. In the case of $D(s,t,e) \neq +\infty$, we pass on the path $P(s,t,e)$ returned by the r-truncated DSO. If $\ell \leqslant (3/2)r$, we return the concatenation of $P(s,z,e)$ and $P(z,t,e)$ for some pivot $z \in B$ that attains the minimum ℓ. The query time is $O(|B|) = \widetilde{O}(Mn/r)$ for the distance, after which the path can be returned in $O(1)$ per edge.

It is clear that the query algorithm is correct whenever $d(s,t,e) \leqslant r$ as those queries are entirely handled by the given truncated DSO. Moreover, even if $d(s,t,e) > r$, then ℓ is an upper bound for $d(s,t,e)$ because all sums $D(s,z,e) + D(z,t,e)$ correspond to some path from s to t avoiding e, but not necessarily a shortest path.

Let $P = P(s,t,e)$ be a replacement path of length between r and $(3/2)r$, u the first vertex on P (seen from s) with $d(u,t,e) \leqslant r$, and v the last vertex on P with $d(s,v,e) \leqslant r$. Note that v lies between u and t on the path, whence $d(u,v,e) \leqslant r$. We further have

$$d(u,v,e) \geqslant d(s,t,e) - d(s,u,e) - d(v,t,e) = d(u,t,e) + d(s,v,e) - d(s,t,e) \geqslant 2r - \frac{3}{2}r = \frac{r}{2}.$$

By the properties of B, there exists some replacement path from u to v avoiding e that contains a pivot $z \in B$. With the usual argument of swapping parts of the path, we can assume z lies on the middle section of $P(s,t,e)$ between u and v. By construction, we have $\max\{d(s,z,e), d(z,t,e)\} \leqslant r$ so both distances (and corresponding paths) are correctly determined by the r-truncated DSO. In summary, we get $\ell \leqslant d(s,z,e) + d(z,t,e) = d(s,t,e)$ and the returned value ℓ is indeed the correct replacement distance. ◀

We are left to prove the final running time of the construction. Let $r = n^\alpha$ be the cut-off point for the distances at which we start the iterative growing. We build the Core DSO using the $O(r^2)$ subgraphs, compute unique shortest paths in G, followed by $O(\log n)$ iterations of Extend and Fast invocations, including the computation of the B_i. First, suppose the graph G is undirected. The total time is then

$$\begin{aligned}
&\widetilde{O}(Mn^\omega r^2) + \widetilde{O}(M^{1/2} n^{(\omega+3)/2}) + \widetilde{O}(Mn^{2.5} + n^2 r^2) + \widetilde{O}(n^2) \cdot \sum_{i=1}^{O(\log n)} \widetilde{O}\left(\frac{Mn}{(3/2)^i r}\right) \\
&= \widetilde{O}\left(M^{1/2} n^{(\omega+3)/2} + Mn^{2.5} + Mn^\omega r^2 + \frac{Mn^3}{r}\right) \\
&= \widetilde{O}\left(M^{1/2} n^{(\omega+3)/2} + Mn^{\max\{2.5,\ \omega+2\alpha,\ 3-\alpha\}}\right).
\end{aligned}$$

This is minimum for $\alpha = 1 - (\omega/3)$, where we get a running time of $\widetilde{O}(Mn^{(\omega+6)/3})$.

For directed graphs, determining the best α is a bit more involved. Recall that $O(n^{\omega(1-\alpha)})$ is the time needed to multiply a $n \times n^{1-\alpha}$ matrix with an $n^{1-\alpha} \times n$ matrix. Computing the Core oracle takes time $\widetilde{O}(Mn^{\omega(1-\alpha)}r^3) = \widetilde{O}(Mn^{\omega(1-\alpha)+3\alpha})$. With a similar calculation as above, we obtain a total preprocessing time of $\widetilde{O}\big(M^{1/2}n^{(\omega+3)/2} + Mn^{\max\{2.5,\ \omega(1-\alpha)+3\alpha,\ 3-\alpha\}}\big)$. This is minimized if α solves the equation $\omega(1-\alpha) = 3-4\alpha$. Le Gall and Urrutia [19] gave the current-best estimates for the values of the function ω. This shows that $1-\alpha$ is between 0.8 and 0.85, and we have $\omega(0.8) \leqslant 2.222256$ as well as $\omega(0.85) \leqslant 2.258317$. We exploit the fact that ω is convex [30], giving

$$\omega(1-\alpha) \leqslant \frac{(\alpha-0.15)\omega(0.8) + (0.2-\alpha)\omega(0.85)}{0.85-0.8} \leqslant 2.3665 - 0.72122\alpha$$

Equating the latter with $3-4\alpha$ yields the estimate $\alpha \leqslant 0.193212$, which in turn implies a preprocessing time of $\widetilde{O}(Mn^{2.806788})$.

Abstract

We describe a nearly-linear time algorithm to solve the linear system $L_1 x = b$ parameterized by the first Betti number of the complex, where L_1 is the 1-Laplacian of a simplicial complex K that is a subcomplex of a collapsible complex X linearly embedded in $\mathbb{R}^3$. Our algorithm generalizes the work of Black et al. [SODA2022] that solved the same problem but required that K have trivial first homology. Our algorithm works for complexes K with arbitrary first homology with running time that is nearly-linear with respect to the size of the complex and polynomial with respect to the first Betti number. The key to our solver is a new algorithm for computing the Hodge decomposition of 1-chains of K in nearly-linear time. Additionally, our algorithm implies a nearly quadratic solver and nearly quadratic Hodge decomposition for the 1-Laplacian of any simplicial complex K embedded in $\mathbb{R}^3$, as K can always be expanded to a collapsible embedded complex of quadratic complexity.

1 Introduction

The dth combinatorial Laplacian of a simplicial complex K is a linear operator that acts on vectors of real numbers associated to the d-simplices of K. The dth combinatorial Laplacian is defined as

$$L_d = \partial_d^T \partial_d + \partial_{d+1} \partial_{d+1}^T,$$

where $\partial_d : C_d(K) \to C_{d-1}(K)$ is the dth boundary map of K, and $C_d(K)$ is the dth chain group of K. The dth Laplacian encodes the incidence of $(d-1)$-, d- and $(d+1)$-simplices. In particular, the 0th Laplacian L_0 is composed of a constant map $\partial_0^T \partial_0$, and the well-known graph Laplacian $\partial_1 \partial_1^T$. The graph Laplacian matrix and its algebraic properties have been extensively studied in algebraic and spectral graph theory, a topic that has flourished into a rich field with many applications in computer science such as graph clustering [25, 27], graph sparsification [29], and max flow solvers [9] (see Spielman's book and references therein [28]).

A highlight of recent advances in algorithmic spectral graph theory is nearly-linear time solvers for linear systems on the graph Laplacian that emerged as a result of decades of research [2, 4, 11, 19, 21–23, 30, 34]. These results imply nearly-linear time solvers for the more general class of symmetric diagonally dominant matrices. They also have triggered research to find out which classes of linear systems admit nearly-linear time solvers [24]. Moreover, these solvers are used for different application areas such as approximation algorithm design and numerical analysis [5, 9].

Recent work has attempted to extend the success of graph Laplacian solvers to higher dimensional Laplacians. Cohen et al. initiated this line of work by introducing a nearly-linear solver for the 1-Laplacian of collapsible complexes embedded in $\mathbb{R}^3$ [10]. Black et al. continued this work by considering complexes with trivial first homology that were subcomplexes of collapsible complexes embedded in $\mathbb{R}^3$ [3]. The solver of Black et al. implies a nearly quadratic solver for any complex with trivial first homology embedded in $\mathbb{R}^3$; they show that a complex embedded in $\mathbb{R}^3$ can be extended to a collapsible embedded complex with at most quadratic complexity.

In this paper, we extend the work of Cohen et al. and Black et al. to any subcomplex of a collapsible complex embedded in $\mathbb{R}^3$, regardless of the rank of its first homology group. The running time of our solver is nearly-linear with respect to the size of the collapsible complex, and polynomial with respect to the rank of its first homology group. The main tool in our paper is a new algorithm for computing the Hodge Decomposition of a 1-chain.

Computing the Hodge decomposition is a problem of independent interest since the Hodge decomposition has found a myriad of applications in topological data analysis, numerical analysis, and computer graphics among other areas [1, 8, 12, 13, 16, 20, 32, 33, 35]. The Hodge decomposition can be computed exactly in $O(n^\omega)$ time by solving a constant number of systems of linear equations, where ω is the matrix multiplication constant. (Approximately) computing the Hodge decomposition in nearly-linear time has been an open question with many possible applications.

Cohen et al. describe nearly-linear projection operators into the coboundary space and cycle space, which implies Hodge decomposition for complexes with trivial homology as the boundary and cycle spaces are identical in this case. In this paper, we describe projection operators into the boundary and harmonic spaces for an arbitrary subcomplex of a collapsible simplicial complex embedded in $\mathbb{R}^3$. Our boundary projection operator is key to our solver. Our results imply 1-Laplacian solvers and projection operators for any simplicial complex embedded in $\mathbb{R}^3$ that are quadratic in the size of the complex and polynomial in the first Betti number; these follow from the fact that any complex in $\mathbb{R}^3$ can be extended to a collapsible complex in $\mathbb{R}^3$ with a quadratic number of simplices [3, Corollary 3.3].

While this paper presents a positive result on extending graph Laplacian solvers to a more general class of Laplacians, a recent work by Ding et al. [15] shows that solving linear equations in arbitrary 1-Laplacians (and therefore arbitrary d-Laplacians) is as hard as solving arbitrary sparse linear equations with bounded integer entries and bounded condition number. An interesting open question is whether or not there exist fast solvers for other classes of simplicial complexes.

1.1 Our Results

Let X be a collapsible simplicial complex with a known collapsing sequence embedded in $\mathbb{R}^3$, and let K be a subcomplex of X. The first result of this paper is a 1-Laplacian solver for K. Recall that $L_1 = \partial_2\partial_2^T + \partial_1^T\partial_1$. We define $L_1^{up} = \partial_2\partial_2^T$ and $L_1^{down} = \partial_1^T\partial_1$. We refer to L_1^{up} and L_1^{down} as the up-Laplacian and down-Laplacian, respectively.

▶ **Theorem 1.** *Let X be a collapsible simplicial complex with a known collapsing sequence linearly embedded in $\mathbb{R}^3$, and let $K \subset X$ be a subcomplex of X. For any $\varepsilon > 0$, there is an operator $LaplacianSolver(X, K, \varepsilon)$ such that*

$$(1-\varepsilon)(L_1[K])^+ \preceq LaplacianSolver(X, K, \varepsilon) \preceq (L_1[K])^+.$$

where $(L_1[K])^+$ is the pseudoinverse of the 1-Laplacian $L_1[K]$. Further, for any $x \in C_1$, $LaplacianSolver(X, K, \varepsilon) \cdot x$ can be computed in $\widetilde{O}\left(\beta^3 \cdot n \cdot \log n \cdot \log(n/(\lambda_{\min}(K) \cdot \lambda_{\min}(X) \cdot \varepsilon))\right)$ [1] time, where n is the total number of simplices in X, $\lambda_{\min}(K)$ and $\lambda_{\min}(X)$ are the smallest nonzero eigenvalues of $L_1^{up}(K)$ and $L_1^{up}(X)$ respectively, and β is the rank of the first homology group of K.

This result is a generalization of Theorem 1.1 of Black et al. [3] that requires K to have trivial first homology. Their running time depends on $\log(n\kappa/\varepsilon)$, with κ being the condition number of $L_1^{up}(K)$ within the boundary space. The condition number is defined $\kappa = \lambda_{\max}(K)/\lambda_{\min}(K)$, where $\lambda_{\max}(K)$ is the largest eigenvalue of $L_1^{up}(K)$, and $\lambda_{\min}(K)$ is the smallest *nonzero* eigenvalue of $L_1^{up}(K)$. We observe that $\lambda_{\max}(K)$ is polynomially bounded with respect to the size of the complex (Lemma 29 in the full paper.) Therefore, the log dependence of the running time of Black et al.'s solver can be simplified to $\log(n/(\lambda_{\min}(K)\cdot\varepsilon))$. The running time of Theorem 1, in contrast, has an extra dependence to $\lambda_{\min}(X)$ within the log, in addition to a polynomial dependence to β. For the special case that $\beta = 0$, we can eliminate the dependence on $\lambda_{\min}(X)$ with a more careful analysis and match the running time of Black et al.

The new ingredient that makes Theorem 1 possible is an approximate projection operator onto the boundary space. Lacking this operator, the previous papers had to assume that K has trivial homology and use a projection into the cycle space instead.

▶ **Lemma 2.** *Let K be a simplicial complex linearly embedded in a collapsible complex X with a known collapsing sequence that is embedded in $\mathbb{R}^3$, and let Π_{bd} be the orthogonal projection operator into the space of boundary 1-chains in K. For any $\varepsilon > 0$, there is an operator $\widetilde{\Pi}_{bd}(\varepsilon)$, such that*

$$(1-\varepsilon)\Pi_{bd} \preceq \widetilde{\Pi}_{bd}(\varepsilon) \preceq (1+\varepsilon)\Pi_{bd}.$$

Further, for any 1-chain x, $\widetilde{\Pi}_{bd}(\varepsilon) \cdot x$ can be computed in $\tilde{O}(\beta^3 \cdot n \cdot \log n \cdot \log(\frac{n}{\lambda_{\min}(X)\cdot\varepsilon}))$ time, where β is the rank of the first homology group of K, n is the total number of simplices in X, and $\lambda_{\min}(X)$ is the smallest nonzero eigenvalue of $L_1^{up}(X)$.

A key technical challenge to achieve our projection operator onto the boundary space is computing a projection into the space of harmonic chains, formalized in part (ii) of the following lemma. Note that our approximation guarantee for projection into the harmonic space is weaker than the one for projection into the boundary space (more on this in the overview).

▶ **Lemma 3.** *Let K be a subcomplex of a collapsible simplicial complex X with a known collapsing sequence that is linearly embedded in $\mathbb{R}^3$. Let β be the rank of the first homology group of K, n be the total number of simplices in X, and $\lambda_{\min}(X)$ be the smallest nonzero eigenvalue of $L_1^{up}(X)$.*

[1] The $\tilde{O}(\cdot)$ notations hides a factor of $\log\log n$.

(i) *For any $\varepsilon > 0$, there is an $\tilde{O}(\beta^2 \cdot n \cdot \log n \cdot \log(\frac{n}{\lambda_{min}(X)\cdot\varepsilon}))$ time algorithm to compute an orthonormal set of vectors $\{\widetilde{g}_1, \ldots, \widetilde{g}_\beta\}$ such that there exists an orthonormal harmonic basis $\{g_1, \ldots, g_\beta\}$ with $\|g_i - \widetilde{g}_i\| \leq \varepsilon$ for all $1 \leq i \leq \beta$.*

(ii) *For any $\varepsilon > 0$, there exists a symmetric matrix $\widetilde{\Pi}_{hr}(\varepsilon)$ such that,*

$$\Pi_{hr} - \varepsilon I \preceq \widetilde{\Pi}_{hr}(\varepsilon) \preceq \Pi_{hr} + \varepsilon I,$$

where Π_{hr} is the orthogonal projection into the harmonic space. Moreover, for any 1-chain x, $\widetilde{\Pi}_{hr}(\varepsilon) \cdot x$ can be computed in $\tilde{O}(\beta^2 \cdot n \cdot \log n \cdot \log(\frac{n}{\lambda_{min}(X)\cdot\varepsilon}))$ time.

Our projection operators into the harmonic and boundary space, along with the projection operator of Cohen et al. [10] into the coboundary space, give all the projection operators needed to compute the Hodge decomposition of 1-chains in K.

Our harmonic projection operator is built using an orthonormal approximate harmonic basis (part (i) of Lemma 3). Dey [14] describes a nearly-linear time algorithm for computing a homology basis for a complex linearly embedded in $\mathbb{R}^3$. Black et al. [3] describe a nearly-linear time algorithm for computing a cohomology basis for subcomplexes of collapsible complexes embedded in $\mathbb{R}^3$. Our harmonic basis, though approximate, can be viewed as a complement to these two results.

1.2 Paper organization

In addition to this introduction, the main body of this paper is a background and overview section. To simplify the presentation, the bulk of the technical details are left for the full version of this paper, and the overview provides a high-level description of our approaches as well as the technical challenges and contribution of this paper. In the overview, we included references to the technical lemmas to enable easy access to the full paper.

The background section introduces standard definitions of the concepts used in this paper. We hope this section provides easy lookup for the reader while reading the overview section as well as the technical part of the paper.

2 Background

In this section, we review basic definitions from linear algebra and algebraic and combinatorial topology that are used in this paper; see references [7, 17, 18, 31] for further background.

2.1 Linear Algebra

Span, Basis. Let $V = \{v_1, \ldots, v_k\}$ be a set of vectors in $\mathbb{R}^n$. The **span** of V, denoted $\text{span}(V)$, is the subspace of $\mathbb{R}^n$ of all linear combinations of V. In particular, V spans $\mathbb{R}^n$ if any vector in $\mathbb{R}^n$ is a linear combination of the vectors in V. We say that V is a **basis** for its span if the dimension of its span equals the cardinality of V.

Linear map, projection, inverse. Let $A : \mathbb{R}^n \to \mathbb{R}^m$ be a linear map, represented by an $m \times n$ matrix. Typically, we don't make a distinction between a linear map and its matrix representation and denote both as A. The **kernel** of A is $\ker(A) := \{x \in \mathbb{R}^n : Ax = 0\}$, and the **image** of A is $\text{im}(A) = \{Ax : x \in \mathbb{R}^m\}$. The **rank** of a linear map is the dimension of its image.

We say that U and V **orthogonally decompose** W, denoted $W = U \oplus V$, if (i) any vector in U is orthogonal to any vector in V, and (ii) any vector in $x \in W$ is a unique sum of vectors in $x_U \in U$ and $x_V \in V$, i.e. $x = x_U + x_V$. The **fundamental theorem of linear**

algebra states that $\mathbb{R}^n = \text{im}(A^T) \oplus \ker(A)$ and $\mathbb{R}^m = \text{im}(A) \oplus \ker(A^T)$, where A^T is the transpose of A obtained by flipping A over its diagonal. In particular, if $A : \mathbb{R}^n \to \mathbb{R}^n$ is symmetric (i.e., $A = A^T$), then $\mathbb{R}^n = \text{im}(A) \oplus \ker(A)$.

A linear map $A : \mathbb{R}^n \to \mathbb{R}^n$ is a **projection** if it is the identity for the vectors in its image, or equivalently, $AA = A$. The map A is an **orthogonal projection** if it maps each point of $\mathbb{R}^n$ to its closest point in $\text{im}(A)$, or equivalently, $A^T = A = AA$. Note for any subspace U of $\mathbb{R}^n$ there is a unique orthogonal projection into U, denoted Π_U. If $\{u_1, \ldots, u_k\}$ is an orthonormal basis for U, the orthogonal projection into U is the linear map $\Pi_U = \sum_{i=1}^{k} u_i u_i^T$.

If a linear map $A : \mathbb{R}^n \to \mathbb{R}^m$ is bijective, it has a well-defined **inverse** denoted $A^{-1} : \mathbb{R}^m \to \mathbb{R}^n$ where $Ax = b \iff A^{-1}b = x$. More generally, the **pseudoinverse** of A is the unique linear map $A^+ : \mathbb{R}^m \to \mathbb{R}^n$ with the following properties: (i) $AA^+A = A$, (ii) $A^+AA^+ = A^+$, (iii) $(AA^+)^T = AA^+$, and (iv) $(A^+A)^T = A^+A$. Admittedly, the definition of the pseudoinverse is not very intuitive. A more intuitive description is that A^+ is the unique linear map with the following properties: (1) A^+ maps any vector $y \in \text{im}(A)$ to the unique vector $x \in \text{im}(A^T)$ such that $Ax = y$, and (2) A^+ maps any vector $y \in \ker(A^T)$ to 0. While it is not true in general that $(A + B)^+ = B^+ + A^+$ for linear maps A and B, this is true if $A^TB = B^TA = 0$; see Campbell [7], Theorem 3.1.1.

Matrix norm, singular values, Loewner order. A symmetric matrix A is **positive semi-definite** if $x^TAx \geq 0$ for each $x \in \mathbb{R}^n$. The **Loewner Order** is a partial order on the set of $n \times n$ symmetric matrices. For symmetric matrices A and B, we say $A \preceq B$ if $B - A$ is positive semidefinite.

Let $x \in \mathbb{R}^n$. Let p be a positive integer. The **p-norm** of x is $\|x\|_p = (\sum_{i=1}^{n} |x[i]|^p)^{\frac{1}{p}}$. We use the 1-norm and 2-norm in this paper. An important fact we will use throughout this paper is that $\|x\|_2 \leq \|x\|_1 \leq \sqrt{n}\|x\|_2$. For any norm $\|\cdot\|$ on $\mathbb{R}^n$, there is an accompanying **operator norm** of a matrix A defined $\|A\| = \max_{x:\|x\|=1} \|Ax\|$, or equivalently, $\|A\| = \max_{x \neq 0} (\|Ax\|/\|x\|)$. Unless otherwise specified, all norms in this paper will be the 2-norm.

The **singular value decomposition** of $A : \mathbb{R}^n \to \mathbb{R}^m$ for $m \geq n$ (resp. $m \leq n$) is a set of n (resp. m) orthornomal vectors $\{u_1, \ldots, u_n\} \subset \mathbb{R}^m$ called **left singular vectors**, n (resp. m) orthornomal vectors $\{v_1, \ldots, v_n\} \subset \mathbb{R}^n$ called **right singular vectors**, and n (resp m) real numbers $\{\sigma_1, \ldots, \sigma_n\} \subset \mathbb{R}$ called **singular values** such that $A = \sum_{i=1}^{n} \sigma_i u_i v_i^T$. The **condition number** of a linear map $A : \mathbb{R}^n \to \mathbb{R}^n$ is $\kappa(A) = |\sigma_{\max}(A)|/|\sigma_{\min}(A)|$, where $\sigma_{\max}(A)$ and $\sigma_{\min}(A)$ are the largest and smallest non-zero singular values of A.

The **eigenvectors** and **eigenvalues** of a matrix $A : \mathbb{R}^n \to \mathbb{R}^n$ are n vectors $\{v_1, \ldots, v_n\} \subset \mathbb{R}^n$ and n real numbers $\{\lambda_1, \ldots, \lambda_n\}$ such that $Av_i = \lambda_i v_i$. The singular values and right singular vectors (resp. left singular values) of a matrix $A : \mathbb{R}^n \to \mathbb{R}^n$ are the square roots of the eigenvalues and eigenvectors of A^TA (resp. AA^T). If a matrix A is symmetric, the eigenvectors of A are orthogonal, and the eigenvectors and eigenvalues of A are the left and right singular vectors and the singular values.

Determinant, Cramer's rule, unimodularity. For any $1 \leq i \leq n$, the **determinant** of an $n \times n$ matrix $A = [a_{i,j}]_{1 \leq i,j \leq n}$ can be defined via its **Laplace expansion** as $\det(A) = \sum_{j=1}^{n} \left((-1)^{i+j} \cdot a_{i,j} \cdot \det(A_{i,j})\right)$, where $A_{i,j}$ is the $(n-1) \times (n-1)$ matrix obtained by removing the ith row and jth column of A. It is well known that $\det(A) \neq 0$ if and only if A is bijective. In that case, **Cramer's rule** give an explicit formula for the solution of the linear system $Ax = b$, which is $x[i] = \det(A_i)/\det(A)$ where A_i is the matrix obtained by replacing the i^{th} column of A with b.

An $n \times n$ matrix A is **unimodular** if $\det(A) \in \{-1, +1\}$. By Cramer's rule, $Ax = b$ has an integer solution if A is unimodular and A and b have integer coefficients. An $n \times m$ matrix B is **totally unimodular** if for any square submatrix A of B, $\det(A) \in \{-1, 0, +1\}$. The 1-boundary matrix of a simplicial complex (defined below) is totally unimodular [26].

2.2 Topology

Simplicial complexes. A **simplicial complex** K is a set of finite sets such that if $\tau \in K$ and $\sigma \subset \tau$, then $\sigma \in K$. A **subcomplex** of K is a subset $L \subset K$ such that L is a simplicial complex. The **vertices** of K is the set $\cup_{\sigma \in K} \sigma$. We assume there is a fixed but arbitrary order $(v_1, \ldots, v_n)$ on the vertices of K.

An element $\sigma \in K$ with $|\sigma| = d + 1$ is a **d-simplex**. A 0-simplex is a **vertex**, a 1-simplex is an **edge**, a 2-simplex is a **triangle**, and a 3-simplex is a **tetrahedron**. The set of all d-simplices in K is denoted K_d. For two simplices $\tau \subset \sigma$, we say that τ is a **face** of σ.

Hodge decomposition, homology, cohomology. The $\mathbf{d^{th}}$ **chain group** of a simplicial complex K is the vector space $C_d(K)$ over $\mathbb{R}$ with orthonormal basis K_d, and an element of $C_d(K)$ is a **d-chain**. The $\mathbf{d^{th}}$ **boundary map** is the linear map $\partial_d : C_d(K) \to C_{d-1}(K)$ defined $\partial_d \sigma = \sum_{i=0}^{d} (-1)^i (\sigma \setminus \{v_{k_i}\})$ for each simplex $\sigma = \{v_{k_0}, \ldots, v_{k_d}\} \in K_d$, where we assume $v_{k_i} < v_{k_j}$ for $i < j$. The $\mathbf{d^{th}}$ **coboundary map** is $\partial_{d+1}^T : C_d(K) \to C_{d+1}(K)$. Elements of $\ker \partial_d$ (resp. $\ker \partial_{d+1}^T$) are **cycles** (resp. **cocyles**), and elements of $\operatorname{im} \partial_{d+1}$ (resp. $\operatorname{im} \partial_d^T$) are **boundaries** or **null-homologous cycles** (resp. **coboundaries**.) Two cycles (resp. cocycles) γ_1 and γ_2 are **homologous** (resp. **cohomologous**) if their difference $\gamma_1 - \gamma_2$ is a boundary (resp. coboundary.)

The $\mathbf{d^{th}}$ **Laplacian** is the linear map $L_d : C_d(K) \to C_d(K)$ defined $L_d = \partial_d^T \partial_d + \partial_{d+1} \partial_{d+1}^T$. The $\mathbf{d^{th}}$ **up-Laplacian** is the linear map $L_d^{up} = \partial_{d+1} \partial_{d+1}^T$, and the $\mathbf{d^{th}}$ **down-Laplacian** is the linear map $L_d^{down} = \partial_d^T \partial_d$.

A key fact of algebraic topology is that $\partial_d \partial_{d+1} = 0$, hence $\operatorname{im} \partial_{d+1} \subset \ker \partial_d$, and $\operatorname{im} \partial_d^T \subset \ker \partial_{d+1}^T$. The $\mathbf{d^{th}}$ **homology group** is the quotient group $H_d(K) = \ker \partial_d / \operatorname{im} \partial_{d+1}$, and the $\mathbf{d^{th}}$ **cohomology group** is the quotient group $H^d(K) = \ker \partial_{d+1}^T / \operatorname{im} \partial_d^T$. Since $\operatorname{im} \partial_d^T \oplus \ker \partial_d$ and $\operatorname{im} \partial_{d+1} \oplus \ker \partial_{d+1}^T$ are two orthogonal decompositions of the d-chain space, the d^{th} homology group and the d^{th} cohomology group have the same rank, which is the $\mathbf{d^{th}}$ **Betti number** of the complex, denoted $\beta_d(K)$. We say two cycles are **homologous** (resp. **cohomologous**) if they are in the same homology (resp. cohomology) class, or equivalently, if their difference is a boundary (resp. coboundary.)

The **Hodge Decomposition** is the orthogonal decomposition of the d^{th} chain group into $C_d(K) = \operatorname{im}(\partial_{d+1}) \oplus \ker(L_d) \oplus \operatorname{im}(\partial_d^T)$. The subspace $\ker(L_d)$ are the **harmonic chains**. Thus, any chain $x \in C_d(K)$ can be uniquely written as the sum $x = x_{bd} + x_{hr} + x_{cbd}$ where $x_{bd} \in \operatorname{im}(\partial_{d+1})$, $x_{hr} \in \ker(L_d)$, and $x_{cbd} \in \operatorname{im}(\partial_d^T)$.

A **d-boundary basis**, **d-coboundary basis** and **d-harmonic basis** are bases for the boundary, coboundary and harmonic spaces. A **d-homology basis** is a maximal set of cycles such that no linear combination of these cycles is a boundary. Similarly, a **d-cohomology basis** is a maximal set of cocycles such that no linear combination of these cocycles is a coboundary. We have the following fact.

▶ **Fact 4.** *A set of cycles (resp. cocycles) is a homology (resp. cohomology) basis if and only if their projection into the harmonic space is a harmonic basis.*

Two cycles (resp. cocycles) are homologous (resp. cohomologous) if they have the same harmonic part, as then their difference is a boundary (resp. coboundary). Accordingly, the previous fact implies that for any cycle (resp. cocycle) x and any homology basis

(resp. cohomology basis) Γ, there is a unique linear combination of the elements of Γ that is homologous (resp. cohomologous) to x; this is the linear combination of Γ with the same harmonic component as x.

A useful property of cohomology bases is they can be used to tell when two cycles are homologous, as described by the following fact.

▶ **Fact 5** (Busaryev et al. [6]). *Let x and y be cycles (resp. cocycles), and let P be a cohomology basis (resp. homology basis.) Then y is homologous (resp. cohomologous) to x if and only if $x \cdot p = y \cdot p$ for all $p \in P$.*

Collapsibility. Let K be a simplicial complex, σ a d-simplex of K, and τ a $(d-1)$-simplex of K that is a face of σ. If τ is not the face of any other simplex, we say that K **collapses** into $K \backslash \{\sigma, \tau\}$; we refer to (σ, τ) as a **collapse pair**. Moreover, we say that a complex collapses to itself. Inductively, we say that a complex K **collapses** into a complex K' if there is a complex K'' such that K collapses to K'' and K'' collapses to K'. We say that a complex K is **collapsible** if it collapses to a single vertex.

When a complex K collapses to a complex K', we obtain a sequence of complexes $K = K_0 \supset K_1 \supset \ldots \supset K_t = K'$, where for each $1 \leq i \leq t$, K_i can be obtained from K_{i-1} by removing one collapse pair. We refer to this sequence as a **collapsing sequence**. The complexes K and K' are homotopy equivalent if one collapses to the other, thus, K and K' have isomorphic homology group. In particular, a collapsible complex has trivial homology groups in every nonzero dimension.

Embeddability. A d-dimensional simplicial complex K is **embedded** if $K \subset R$ for R a triangulation of $\mathbb{R}^{d+1}$. Furthermore, K is **linearly embedded** if there is a homeomorphism from the underlying space $|R|$ to $\mathbb{R}^{d+1}$ that is linear on each simplex, i.e. each 1-simplex is mapped to a line segment, each 2-simplex is mapped to a triangle, etc. All embedded complexes in this paper will be linearly embedded.

We will make use of the dual graph of an embedded complex. Informally, the **dual graph** of an embedded complex is the graph K^* with vertices that are the connected components of $R \setminus K$ and edges between two vertices if there is a d-simplex in K incident to both connected components. Alternatively, the dual graph can be defined with vertices corresponding to a generating set of d-cycles of K. For this construction, see the definition of **Lefschetz set** in the paper [3].

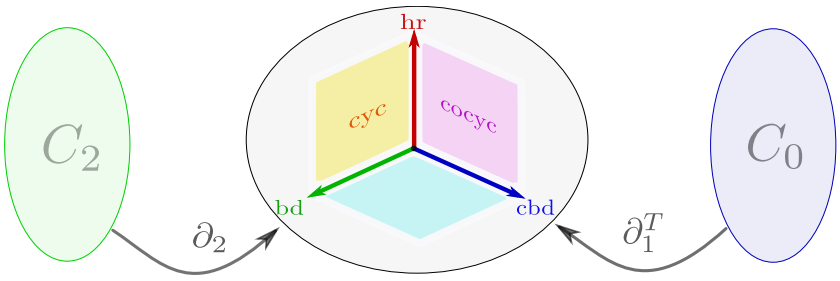
3 Overview

Let X be a collapsible simplicial complex embedded in $\mathbb{R}^3$, and let $K \subseteq X$ be a subcomplex of X. We study two closely related problems: (i) computing the Hodge decomposition of the 1-chains of K, and (ii) solving a linear system $L_1 x = b$, where L_1 is the 1-Laplacian of K (in the overview section, all the operators are with respect to K unless mentioned otherwise.) These two problems are related, as our approximate Laplacian solver uses an approximate Hodge decomposition of the input vector x. More generally, understanding the Hodge decomposition is key to understanding this paper as many proofs rely on some property of the Hodge decomposition. Therefore, we begin our overview with an introduction to the Hodge decomposition.

3.1 The Hodge Decomposition

The Hodge decomposition is a decomposition of the chain group $C_d(K)$ in terms of the kernels and images of the boundary operators ∂_d and ∂_{d+1} and their transposes. Specifically, the problems in this paper consider the first chain group $C_1(K)$, the two boundary operators ∂_2 and ∂_1, and their corresponding coboundary operators ∂_2^T and ∂_1^T. The boundary operator ∂_2 maps each (oriented) triangle to the edges in its boundary; similarly, ∂_1 maps each edge to its two endpoints. A key fact is that $\partial_1\partial_2 = 0$, or equivalently, $\text{im}(\partial_2) \subseteq \ker(\partial_1)$. This implies $\text{im}(\partial_2)$ is orthogonal to $\text{im}(\partial_1^T)$. The former subspace $\text{im}(\partial_2)$ is called the **boundary subspace**, and the latter subspace $\text{im}(\partial_1^T)$ is called the **coboundary subspace**. If K has trivial 1-homology, then $\text{im}(\partial_2) = \ker(\partial_1)$, and the boundary and coboundary spaces give a full orthogonal decomposition of $C_1(K)$, called the **Helmholtz decomposition**. Otherwise, there is a third subspace orthogonal to both the boundary and coboundary subspaces, called the **harmonic subspace**. The harmonic subspace is exactly $\ker(L_1) = \ker(\partial_1) \cap \ker(\partial_2^T)$.

The boundary, coboundary, and harmonic subspaces give a full orthogonal decomposition of $C_1(K)$ called the **Hodge decomposition**, which generalizes the Helmholtz decomposition. Thus, we can express any 1-chain x as $x = x_{cbd} + x_{bd} + x_{hr}$, where x_{cbd}, x_{bd} and x_{hr} are the coboundary, boundary and harmonic part of x and are pairwise orthogonal. The chains $x_{bd} + x_{hr}$ and $x_{cbd} + x_{hr}$ are called the **cyclic** and **cocyclic** parts of x respectively. Similarly, the space spanned by harmonic and boundary chains is called the **cycle space**, and the space spanned by harmonic and coboundary chains is called the **cocycle space**. It is implied by $\partial_1\partial_2 = 0$ that the cycle space and cocycle space are the kernels of ∂_1 and ∂_2^T, respectively. The following figure is an illustration of the Hodge decomposition. Boundary, coboundary, harmonic, cycle, and cocycle spaces are shown using the abbreviations bd, cbd, hr, cyc, and cocyc respectively.



To compute the Hodge decomposition, one seeks orthogonal projection operators into the coboundary, boundary and harmonic subspaces. Let Π_{cbd}, Π_{bd}, and Π_{hr} denote these projection operators. Cohen et al. show that for any 1-chain x, its projection into the coboundary space, $\Pi_{cbd}x$, and cycle space, $\Pi_{cyc}x$, can be approximated quickly with operators $\widetilde{\Pi}_{cbd}$ and $\widetilde{\Pi}_{cyc}$. These projection operators are a key ingredient of their 1-Laplacian solver, as well as the more recent 1-Laplacian solver described by Black et al.; however, both papers are restricted to cases where the first homology group $H_1(K) = 0$. In this paper, we show that for any x, its projection into the boundary space, $\Pi_{bd}x$, can also be approximated quickly. This new projection operator will allow us to generalize the 1-Laplacian solver of Black et al. to complexes with arbitrary first homology. We also give an approximate projection operator into the harmonic space, but our approximation guarantee for this projection operator is weaker (more below).

3.2 Laplacian Solvers

The 1-Laplacian matrix is defined $L_1 = \partial_2\partial_2^T + \partial_1^T\partial_1$. To solve a linear system $L_1 x = b$, one seeks to approximate L_1^+, the pseudoinverse of L_1. As the images of $\partial_2\partial_2^T$ and $\partial_1^T\partial_1$ are orthogonal, then $L_1^+ = (\partial_2\partial_2^T)^+ + (\partial_1^T\partial_1)^+$ (see Campbell [7, Theorem 3.1.1]). Therefore, one can approximate L_1^+ by approximating $(\partial_2\partial_2^T)^+$ and $(\partial_1^T\partial_1)^+$ individually. Computing $(\partial_1^T\partial_1)^+$ is purely a graph problem as ∂_1 is only defined with respect to the vertices and edges of a complex. Cohen et al. show how to approximate $(\partial_1^T\partial_1)^+$ for general complexes [10, Lemma 3.2]. Approximating $(\partial_2\partial_2^T)^+$ is a more challenging problem that requires taking into account the relationship between triangles and the edges. Our algorithm for approximating $(\partial_2\partial_2^T)^+$ relies on our new boundary projection operator, the collapsibility of X, and the embedding of X in $\mathbb{R}^3$.

Cohen et al. show how to approximate $(\partial_2\partial_2^T)^+$ for collapsible complexes embedded in $\mathbb{R}^3$. Black et al. generalize their work to obtain an approximate solver for a subcomplex of a collapsible complex in $\mathbb{R}^3$ provided the subcomplex has trivial homology. Their solver is based on the following general lemma regarding approximations of $(BB^T)^+$ for a general matrix B.

▶ **Lemma 6** (Black et al. [3], Lemma 4.1). *Let B be a linear operator, let $0 \le \varepsilon < 1$, and let $\widetilde{\Pi}_{\mathrm{im}(B)}$ and $\widetilde{\Pi}_{\ker^\perp(B)}$ be symmetric matrices such that $(1-\varepsilon)\Pi_{\mathrm{im}(B)} \preceq \widetilde{\Pi}_{\mathrm{im}(B)} \preceq \Pi_{\mathrm{im}(B)}$, and $(1-\varepsilon)\Pi_{\ker^\perp(B)} \preceq \widetilde{\Pi}_{\ker^\perp(B)} \preceq \Pi_{\ker^\perp(B)}$. Also, let U be a linear map such that for any $y \in \mathrm{im}(B)$, $BUy = y$. We have*

$$(1-(2\kappa+1)\varepsilon)(BB^T)^+ \preceq \widetilde{\Pi}_{\mathrm{im}(B)}U^T\widetilde{\Pi}_{\ker^\perp(B)}U\widetilde{\Pi}_{\mathrm{im}(B)} \preceq (1+\kappa\varepsilon)(BB^T)^+,$$

where κ is the condition number of BB^T within the image of B.

This lemma shows the following linear operators are sufficient for approximating $(\partial_2\partial_2^T)^+$.

- **(i)** An operator U that for 1-boundary $y \in \mathrm{im}(\partial_2)$ returns a 2-chain $x = Uy$ such that $\partial_2 x = y$. For other vectors $z \notin \mathrm{im}(\partial_2)$, U can return anything as long as U is still linear.
- **(ii)** An approximate orthogonal projection operator into $\mathrm{im}(\partial_2^T)$, the coboundary space of 2-chains.
- **(iii)** An approximate orthogonal projection operator into $\mathrm{im}(\partial_2)$, the boundary space of 1-chains.

Black et al. describe an algorithm for computing U that uses the collapsibility and embedding of the supercomplex X. Cohen et al. show that the 2-coboundary space of embedded complexes is dual to the 1-cycle space of the dual graph, hence projection into this space can be approximated using $\widetilde{\Pi}_{cyc}$. Finally, lacking an approximate projection into the boundary space of 1-chains, they needed to assume that their complex has trivial first homology (i.e. that $\mathrm{im}(\partial_2) = \ker(\partial_1)$) so that they can instead use the projection operator into the cycle space of Cohen et al. The boundary projection operator described in this paper allow us to remove that assumption to obtain a solver for any subcomplex K of X. The running time of our new solver polynomially depends on the rank of the homology group and nearly-linearly depends on the size of the complex. We give a complete analysis of our solver in Appendix D of the full paper.

In the rest of this section, we sketch the high level ideas for computing our approximate projection operators. But before we can do that, we need to explain the two notions of approximations that are used in this paper.

3.3 Loewner order approximation

We use the Loewner order on positive semidefinite matrices to specify the approximation quality of our projection and pseudoinverse operators. We see two types of approximation guarantees in this paper for an operator A: ***input-relative error bounds*** of the form $-\varepsilon I \preceq A - \widetilde{A} \preceq \varepsilon I$ and ***output-relative error bounds*** of the form $-\varepsilon A \preceq A - \widetilde{A} \preceq \varepsilon A$. Note for any vector x, an input relative error bound implies $\|(A - \widetilde{A})x\| \leq \varepsilon\|x\|$ – the error is bounded relative to the size of the input x – while an output-relative error bound implies $\|(A - \widetilde{A})x\| \leq \varepsilon\|Ax\|$ – the error is bounded relative to the size of the output Ax. An approximate operator with a small input-relative error can have arbitrarily large output-relative error, for example when x is in the kernel of A. Further, output-relative error bounds are stronger if the norm of $\|A\|$ is at most one, i.e. $\|Ax\| \leq \|x\|$, which is the case for the orthogonal projection operators of the Hodge decomposition.

We achieve an output-relative error bound for our approximation of $(L_1[K])^+$. Further, we achieve an output-relative error bound for our approximation $\widetilde{\Pi}_{bd}$ of Π_{bd}, but an input-error bound for our approximation $\widetilde{\Pi}_{hr}$ of Π_{hr}:

$$-\varepsilon I \preceq -\varepsilon\Pi_{bd} \preceq \Pi_{bd} - \widetilde{\Pi}_{bd}(\varepsilon) \preceq \varepsilon\Pi_{bd} \preceq \varepsilon I, \tag{1}$$

and

$$-\varepsilon I \preceq \Pi_{hr} - \widetilde{\Pi}_{hr}(\varepsilon) \preceq \varepsilon I. \tag{2}$$

Previously, Cohen et al. had shown approximation operators $\widetilde{\Pi}_{cbd}$ and $\widetilde{\Pi}_{cyc}$ for projecting into the coboundary and cycle spaces with output-relative error bounds:

$$-\varepsilon I \preceq -\varepsilon\Pi_{cbd} \preceq \Pi_{cbd} - \widetilde{\Pi}_{cbd}(\varepsilon) \preceq \varepsilon\Pi_{cbd} \preceq \varepsilon I, \tag{3}$$

and

$$-\varepsilon I \preceq -\varepsilon\Pi_{cyc} \preceq \Pi_{cyc} - \widetilde{\Pi}_{cyc}(\varepsilon) \preceq \varepsilon\Pi_{cyc} \preceq \varepsilon I. \tag{4}$$

We use these operators multiple times in our algorithms. For simplification, we drop the explicit mention of the parameter ε when it is clear from the context.

3.4 Projection operators

We first describe our algorithm for computing $\widetilde{\Pi}_{hr}$ (an overview of Appendices A and B of the full version of the paper). Based on that and the operator $\widetilde{\Pi}_{cbd}$ of Equation (3), we show how to compute $\widetilde{\Pi}_{bd}$ (an overview of Appendix C of the full version of the paper).

3.4.1 Harmonic projection

We compute our approximate harmonic projection operator $\widetilde{\Pi}_{hr}$ by computing an approximate orthonormal basis $\widetilde{G} = \{\widetilde{g}_1, \ldots, \widetilde{g}_\beta\}$ of the harmonic space. We then define the approximate projection into the harmonic space to be the linear map $\widetilde{\Pi}_{hr} = \sum_{i=1}^{\beta} \tilde{g}_i \tilde{g}_i{}^T$.

To compute $\widetilde{G}$, our algorithm starts with a cohomology basis $P = \{p_1, \ldots, p_\beta\}$; the algorithm for computing P is given at the end of this section. From P, it computes $\widetilde{H} = \{\widetilde{h}_1, \ldots, \widetilde{h}_\beta\}$, where $\widetilde{h}_i = \widetilde{\Pi}_{cyc} p_i$ and $\widetilde{\Pi}_{cyc}$ is the projection operator of Equation (4). The set $\widetilde{H}$ is an approximate harmonic basis, but it is not orthonormal. Next, we normalize $\widetilde{H}$ to obtain $\widetilde{N} = \{\widetilde{h}_1/\|\widetilde{h}_1\|, \ldots, \widetilde{h}_\beta/\|\widetilde{h}_\beta\|\}$. Finally, we run Gram-Schmidt on $\widetilde{N}$ to obtain $\widetilde{G}$.

To see why $\widetilde{G}$ is an approximate basis for the harmonic space, let us consider a much easier analysis assuming we can use the exact projection in the cycle space Π_{cyc} instead of the approximate projection $\widetilde{\Pi}_{cyc}$. Instead of $\widetilde{H}$, $\widetilde{N}$ and $\widetilde{G}$, let $H = \{h_1, \ldots, h_\beta\}$, $N = \{h_1/\|h_1\|, \ldots, h_\beta/\|h_\beta\|\}$ and $G = \{g_1, \ldots, g_\beta\}$ be the sets of vectors we obtain when we use the exact projection operator. In that case, $h_i = \Pi_{cyc} p_i$ is the harmonic part of p_i; this is because p_i is a cocycle, so projecting it into the cycle space is the same as projecting it into the harmonic space. It follows from Fact 4 in Section 2 that G is an exact orthonormal basis of the harmonic space, thus it defines an exact projection operator into the harmonic space.

In the real scenario where we work with the approximate projection operator $\widetilde{\Pi}_{cyc}$, two undesirable things can happen. First, we can no longer guarantee that the vectors in $\widetilde{N}$ are purely harmonic, as the error introduced by the approximate operator $\widetilde{\Pi}_{cyc}$ may be part boundary. However, this is not an issue, as we can make the boundary components of $\widetilde{N}$ sufficiently small by approximating $\widetilde{\Pi}_{cyc}$ more accurately. Second, and more importantly for our application, the spaces spanned by N and $\widetilde{N}$ can be very different, even if the vectors N and $\widetilde{N}$ are pairwise close. As an example, imagine that we have two pairs of vectors $N = \{\eta_1, \eta_2\}$ and $\widetilde{N} = \{\widetilde{\eta}_1, \widetilde{\eta}_2\}$ such that $\|\eta_i - \widetilde{\eta}_i\| < \varepsilon$ for $i = 1, 2$. We might guess that the two spaces spanned by N and $\widetilde{N}$ are similar as the vector are close, but if η_1 and η_2 are also close, then the two vectors spaces can be drastically different. Figure 1 gives an illustration of this, where N is the set of blue vectors and $\widetilde{N}$ is the set of red vectors. As illustrated in the figure, the space spanned by N and the space spanned by $\widetilde{N}$ can be drastically different.

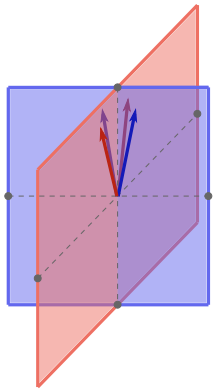


Figure 1 Pairwise closeness between a set of vectors N and $\widetilde{N}$ is not enough to guarantee the spaces spanned by N and $\widetilde{N}$ are close! The red and blue vectors are pairwise close, but the spaces they span are very different.

We can remedy this if we approximate $\widetilde{N}$ within a sufficiently small error ε of N, but this new error bound needs to take into account the similarity of the vectors in N. The question is how accurately we need to approximate $\widetilde{\Pi}_{cyc}$ to obtain a sufficently small approximation error for $\widetilde{N}$. To answer this question, we define a measure of linear independence of N called its δ-independence. Formally, we say that N is **δ-independent** if each vector $h_i/\|h_i\| \in N$ is at distance at least δ from the span of the other vectors of N. Intuitively, larger δ means N is more independent, in the sense that the elements are well-separated. The smaller the δ, the more accurately we need to approximate $\widetilde{\Pi}_{cyc}$ to ensure that N and $\widetilde{N}$ will span similar spaces. This intuition is summarized by the following lemma, showing the error in projection into N as a function of δ, ε, and β, where ε bounds the difference between N and $\widetilde{N}$.

▶ **Corollary 7.** *Let $0 < \delta < 1$, and let $0 < \varepsilon < \left(\frac{\delta}{8\beta}\right)^{\beta}$. Let $N = \{\eta_1, \ldots, \eta_\beta\}$ be a set of δ-linearly independent unit vectors, and let $\widetilde{N} = \{\widetilde{\eta}_1, \ldots, \widetilde{\eta}_\beta\}$ be a set of unit vectors such that $\|\eta_i - \widetilde{\eta}_i\| < \varepsilon$. Let $G = \{g_1, \ldots, g_\beta\}$ be the orthonormal basis that is the output of running Gram-Schmidt on N, and let $\widetilde{G} = \{\widetilde{g}_1, \ldots, \widetilde{g}_\beta\}$ be the output of running Gram-Schmidt on $\widetilde{N}$. Then $\left\|\Pi_{\text{span } N} - \Pi_{\text{span } \widetilde{N}}\right\| = \left\|\sum_{i=1}^{\beta} g_i g_i^T - \widetilde{g}_i \widetilde{g}_i^T\right\| < 2 \cdot \beta \cdot \left(\frac{8\beta}{\delta}\right)^{\beta} \varepsilon$.*

The difficulty here is actually determining a lower bound on the δ-independence of N. We have access to the cohomology basis P, but we need the (normalized) harmonic parts of P to be δ-independent. Note that P can be composed of vectors that are very strongly independent, yet their harmonic parts may only be weakly independent, for example, when the vectors of P have similar harmonic parts but very different coboundary parts.

We show that if P is composed of integer vectors with maximum length $p_{\max}$, then P being linearly independent implies that H is δ-independent for a $\delta \sim 1/(p_{\max} \cdot n_1)^{\beta}$, where n_1 is the number of edges in K. In addition to the properties of P, our proof of Lemma 8 relies on the total unimodularity of ∂_1.

▶ **Lemma 8.** *Let K be a simplicial complex with n_1 edges such that $H_1(K) = \beta$. Let $\{p_1, \ldots, p_\beta\}$ be a 1-cohomology basis for K such that each p_i is an integer vector with maximum Euclidean norm $p_{\max}$. Let h_i be the harmonic part of p_i for $1 \le i \le \beta$. Then*

(i) *$\|h_i\| \ge 1/(\sqrt{n_1} \cdot p_{\max})^{\beta}$ for each $1 \le i \le \beta$, and*

(ii) *$\{h_1/\|h_1\|, \ldots, h_\beta/\|h_\beta\|\}$ is $\left(1/(\sqrt{n_1} \cdot p_{\max})^{\beta}\right)$-independent.*

Computing a Cohomology Basis. The question remains of how to find the cohomology basis P. For this, we use an algorithm on Black et al. Dey [14] describes a nearly-linear time algorithm for computing a homology basis composed of vectors with coordinates in $\{-1, 0, +1\}$. Black et al. [3] describe an operator $C(X, K)$ that when applied to a homology basis returns a cohomology basis. We use the cohomology basis P obtained by applying the operator C to Dey's homology basis.

▶ **Lemma 9** (Dey, Lemma [14])**.** *For a 2-dimensional simplicial complex K linearly embedded in $\mathbb{R}^3$, there exists an algorithm computing a basis for $H_1(K, \mathbb{R})$ in $O(n \log n + n\beta_1)$ time, where n is the complexity of K. Further, the basis is composed of vectors with all coordinates from $\{-1, 0, +1\}$.*

▶ **Lemma 10** (Black et al., Lemma 1.1 [3])**.** *Let X be a collapsible simplicial complex in $\mathbb{R}^3$, and let $K \subset X$ be a subcomplex of X. Let β be the rank of $H_1(K)$ and let n be the total number of simplices of X. Let $\Gamma = \{\gamma_1, \ldots, \gamma_\beta\}$ be a homology basis for K. There is a linear operator $C(X, K)$ such that the set $C_\Gamma = \{C(X, K) \cdot \gamma_1, \ldots, C(X, K) \cdot \gamma_\beta\}$ is a cohomology basis for K. Furthermore, C_Γ can be computed in $O(\beta \cdot n)$ time.*

While Black et al. introduced the algorithm for computing the cohomology basis P, we bound the length of the vectors in P. We bound the length of P by combining a bound on the length of the homology basis with the following bound on the operator norm $\|C(X, K)\|$.

▶ **Lemma 11.** *There is a constant α such that $\|C(X, K)\| \le \alpha \cdot n_1^2 n_2^4 / \left(\lambda_{\min}(L_1^{up}[X])\right)$, where $\lambda_{\min}(L_1(X))$ is the smallest non-zero eigenvalue of $L_1(X)$ and n_1 and n_2 are the number of edges and triangles in X respectively.*

Note that the vectors in Dey's homology basis have bounded length as they have coefficients $\{-1, 0, 1\}$. By combining this observation, Lemma 8, and Lemma 11, we prove that the harmonic part of P are δ-independent for an appropriate value of δ. This is summarized in the following corollary.

▶ **Corollary 12.** *Let X be a collapsible complex embedded in $\mathbb{R}^3$ with a known collapsing sequence and let $K \subset X$ be a subcomplex of X. Let β be the rank of $H_1(K)$ and let n be the total number of simplices in X. There is an $O(n \log n + \beta n)$ time algorithm for computing a cohomology basis $\{p_1, \ldots, p_\beta\}$ of K with harmonic parts $\{h_1, \ldots, h_\beta\}$ such that*

(i) *each h_i has length at least δ, and*

(ii) *the set $\{h_1/\|h_1\|, \ldots, h_\beta/\|h_\beta\|\}$ is δ-linearly independent,*

where $\delta = (\lambda_{\min}(L_2^{up}(X))/(\alpha \cdot n_1^3 n_2^4))^\beta$ for a constant α.

Passing this cohomology basis P to the algorithm above, we obtain $\widetilde{H}$, $\widetilde{N}$, $\widetilde{G}$, $\widetilde{\Pi}_{hr}$ as desired. The exact approximation quality of the approximate harmonic basis and approximate harmonic projection are given in Lemma 3 in the introduction.

3.4.2 Boundary projection

It follows from the Hodge decomposition that the the projection into the boundary space can be written $\Pi_{bd} = I - \Pi_{cbd} - \Pi_{hr}$. We have approximate projections $\widetilde{\Pi}_{cbd}$ and $\widetilde{\Pi}_{hr}$ with input-relative error bounds (Equations (3) and (2) respectively), so we immediately obtain a boundary projection $\overline{\Pi}_{bd}$ with input-relative error bound defined

$$\overline{\Pi}_{bd} = I - \widetilde{\Pi}_{cbd} - \widetilde{\Pi}_{hr} \implies -\varepsilon I \preceq \Pi_{bd} - \overline{\Pi}_{bd} \preceq \varepsilon I.$$

However, we need a boundary projection operator with an output-relative bound for our solver. Unfortunately, the operator $\overline{\Pi}_{bd}$ can have arbitrarily bad output-relative error. Specifically, for any vector x that is orthogonal to the boundary space, this operator has unbounded output-relative error as $\Pi_{bd} x = 0$.

We instead use $\overline{\Pi}_{bd}$ as a starting point for a projection operator with bounded output-relative error. To that end, let's revisit the issue of input vs. output relative error. Let $x = x_{bd} + x_{cocyc}$ be any vector decomposed into its boundary and cocycle parts. The input-relative error bound of $\overline{\Pi}_{bd}$ is proportional to $\|x\| = \|x_{bd} + x_{cocyc}\|$, while for an output-relative error bound, we need the bound to be proportional to $\|\Pi_{bd} x\| = \|x_{bd}\|$. Therefore, a problem arises if x_{cocyc} is much larger than x_{bd}; provided a bound on $\|x_{cocyc}\|/\|x_{bd}\|$, we can accordingly modify the accuracy of our projection operators $\widetilde{\Pi}_{cbd}(\varepsilon)$ and $\widetilde{\Pi}_{hr}(\varepsilon)$ to ensure $\overline{\Pi}_{bd}$ has small output-relative error for x. Unfortunately, $\|x_{cocyc}\|/\|x_{bd}\|$ can be unbounded. To counteract this, we show that we can map x to a different vector x' before passing it to $\overline{\Pi}_{bd}$ such that (1) x' has the same boundary component as x (so $\Pi_{bd} \cdot x = \Pi_{bd} \cdot x'$), and (2) $\|x'_{cocyc}\|/\|x'_{bd}\|$ is bounded.

Specifically, our boundary projection operator is defined $\widetilde{\Pi}_{bd} = (I - P_\Gamma)(I - P_T)\overline{\Pi}_{bd}(I - P_T)^T(I - P_\Gamma)^T$, defined based on two operators P_T and P_Γ. The former was introduced by Cohen et al. to obtain $\widetilde{\Pi}_{cyc}$, and the latter is introduced in this paper; we sketch the ideas of both in this overview. The operator $(I - P_T)^T(I - P_\Gamma)^T$ behaves as we need: it maps x to a chain x' with the same boundary component as x and a relatively bounded cocycle part. We now describe P_T and P_Γ.

Let T be any spanning tree of the 1-skeleton of K. P_T is the operator that maps any 1-chain to the unique 1-chain with the same boundary in T. In particular, for any 1-chain x, $(I - P_T)x$ is a cycle.

Next, let $\Gamma = \{\gamma_1, \ldots, \gamma_\beta\}$ be a 1-homology basis in K. P_Γ is the operator that maps any 1-cycle to the unique linear combination of Γ that is in the same homology class. In particular, for any 1-cycle x, $(I - P_\Gamma)x$ is a boundary.

Now let $F = (I - P_T)^T(I - P_\Gamma)^T$, so $F^T = (I - P_\Gamma)(I - P_T)$. Consider any vector $x = x_{bd} + x_{cbd} + x_{hr}$. We investigate what F does to each of the three constituents of x; what can we say about Fx_{bd}, Fx_{cbd} and Fx_{hr}? In what follows, we frequently use the fact that for any linear map A, $\ker(A)$ and $\mathrm{im}(A^T)$ orthogonally decompose the domain of A.

$(I - P_T)$ maps any 1-chain to a cycle and $(I - P_\Gamma)$ maps any cycle to a boundary cycle; thus, $\mathrm{im}(F^T)$ is a subset of the boundary space. It follows that $\ker(F)$ is a superset of the orthogonal complement of the boundary space, which is the cocycle space. So, F maps any cocycle to zero, in particular, $Fx_{cbd} = 0$ and $Fx_{hr} = 0$. It remains to investigate Fx_{bd}.

P_T maps any cycle to zero, so $\ker(P_T)$ includes the cycle space; hence, $\mathrm{im}(P_T^T)$ is a subset of the orthogonal complement of the cycle space, which is the coboundary space. In particular, $\mathrm{im}(P_T^T)$ is a subset of the cocycle space. In addition, P_Γ maps all boundary cycles to zero, so $\ker(P_\Gamma)$ includes the boundary space; hence, $\mathrm{im}(P_\Gamma^T)$ is within the orthogonal complement of the boundary space, which is the cocycle space. Now consider

$$Fx_{bd} = (I - P_T)^T(I - P_\Gamma)^T x_{bd} = Ix_{bd} - P_T^T(I - P_\Gamma)^T x_{bd} - P_\Gamma^T x_{bd} = x_{bd} + x'_{cocyc},$$

and observe that x'_{cocyc} is indeed in the cocycle space as $\mathrm{im}(P_T^T)$ and $\mathrm{im}(P_\Gamma^T)$ are both within this space.

Overall, $Fx_{cbd} = 0$, $Fx_{hr} = 0$ and $Fx_{bd} = x_{bd} + x'_{cocyc}$, so Fx has the same boundary part as x. Moreover, the norm of the cocyclic part of Fx, $\|x'_{cocyc}\|$, can now be bounded by $\|F\| \cdot \|x_{bd}\|$, as it is produced by applying F to x. The proof of Lemma 3.2 in Cohen et al. and Corollary 14 of this paper provide bounds on $\|I - P_T\|$ and $\|I - P_\Gamma\|$ that are dependent on the number of simplices of X, the smallest non-zero eigenvalue of the up-Laplacian of X, and the first Betti number of K; these bounds in turn provide a bound on $\|F\|$. (Note that $\|A\| = \sqrt{\|AA^T\|}$ for any linear operator A.)

▶ **Lemma 13** (Cohen et al., Proof of Lemma 3.2 [10]). *Let K be any simplicial complex, and let T be a spanning tree of the 1-skeleton of K. Let P_T be the operator that maps any 1-chain x to the unique 1-chain on T with the same boundary, that is (i) $P_T \cdot x \in C_1(T)$, and (ii) $\partial_1 x = \partial_1 P_T \cdot x$. We have $(I - P_T)(I - P_T)^T \preceq n_1^2 I$, where n_1 is the number of edges of K. Further, for any x, $P_T \cdot x$ can be computed in $O(n_1)$ time.*

▶ **Corollary 14.** *Let X, K as defined. Let $\Gamma = \{\gamma_1, \ldots, \gamma_\beta\}$ be the homology basis of Lemma 9, and let P_Γ be the operator that for any cycle α returns the unique linear combination of the cycles of Γ that is homologous to α. We have*

$$(1 - P_\Gamma)(1 - P_\Gamma)^T \preceq \varepsilon \cdot I,$$

for $\varepsilon = (n_1 n_2 / \lambda_{\min}(X))^{c \cdot \beta}$, where $\lambda_{\min}(X)$ is the smallest non-zero eigenvalue of $L_1^{up}(X)$ and c is a constant. Further, for any vector v, $P_\Gamma \cdot v$ can be computed in $O(\beta^2 n_1 + \beta^\omega)$ time.

The accuracy and time complexity of the approximate boundary solver $\widetilde{\Pi}_{bd}$ are described in Lemma 2 in the introduction.

Stanford University, CA, USA

Abstract

We give the first *reconstruction algorithm* for decision trees: given queries to a function f that is opt-close to a size-s decision tree, our algorithm provides query access to a decision tree T where:

- T has size $S := s^{O((\log s)^2/\varepsilon^3)}$;
- $\mathrm{dist}(f, T) \leq O(\mathrm{opt}) + \varepsilon$;
- Every query to T is answered with $\mathrm{poly}((\log s)/\varepsilon) \cdot \log n$ queries to f and in $\mathrm{poly}((\log s)/\varepsilon) \cdot n \log n$ time.

This yields a *tolerant tester* that distinguishes functions that are close to size-s decision trees from those that are far from size-S decision trees. The polylogarithmic dependence on s in the efficiency of our tester is exponentially smaller than that of existing testers.

Since decision tree complexity is well known to be related to numerous other boolean function properties, our results also provide a new algorithm for reconstructing and testing these properties.

1 Introduction

We study the problem of *reconstructing* decision trees: given queries to a function f that is close to a size-s decision tree, provide fast query access to a decision tree, ideally one of size not much larger than s, that is close to f. This can be viewed as an "on the fly" variant of the problem of properly and agnostically learning decision trees, where the goal there is to output the entire decision tree hypothesis. More broadly, reconstruction algorithms, introduced by Ailon, Chazelle, Comandur, and Liu [2], can be viewed as sublinear algorithms that restore structure – in our case, that of a decision tree – in a function that has been lost due to noise.

Decision trees have long been a popular and effective model in machine learning, and relatedly, they are among the most intensively studied concept classes in learning theory. The literature on learning decision trees is vast, spanning three decades and studying the

problem in a variety of models and from a variety of perspectives [24, 41, 9, 26, 14, 8, 27, 36, 29, 39, 34, 31, 28, 22, 13, 7]. In contrast, the problem of reconstructing decision trees has thus far been surprisingly understudied.

1.1 Our contributions

We give the first reconstruction algorithm for decision trees. Our algorithm achieves a *polylogarithmic* dependence on s in its query and time complexities, exponentially smaller than the information-theoretic minimum required to learn.

▶ **Theorem 1** (Main result). *There is a randomized algorithm which, given queries to $f : \{\pm 1\}^n \to \{\pm 1\}$ and parameters $s \in \mathbb{N}$ and $\varepsilon \in (0, 1)$, provides query access to a fixed decision tree T where*

- *T has size $s^{O((\log s)^2/\varepsilon^3)}$;*
- *$\mathrm{dist}(T, f) \leq O(\mathrm{opt}_s) + \varepsilon$ w.h.p., where opt_s denotes the distance of f to the closest size-s decision tree;*
- *Every query to T is answered with $\mathrm{poly}((\log s)/\varepsilon) \cdot \log n$ queries to f and in $\mathrm{poly}((\log s)/\varepsilon) \cdot n \log n$ time.*

Notably, in the standard setting where $s = \mathrm{poly}(n)$, the query and time complexities of our algorithm are $\mathrm{polylog}(n)$ and $\tilde{O}(n)$ respectively. Previously, the only known approach was to simply properly and agnostically learn f; the current fastest such algorithm has query and time complexities $n^{O(\log \log n)}$ [7].

Our reconstruction algorithm is furthermore *local* in the sense of Saks and Seshadhri [43], allowing queries to be answered in parallel assuming a shared random string. In particular, once f, s, ε and the random string are fixed, all queries are answered consistently with a single decision tree.

1.1.1 Implications of Theorem 1 and further results

By a standard reduction, Theorem 1 gives a *tolerant tester* for decision trees:

▶ **Corollary 2** (Tolerant testing of decision trees). *There is a randomized algorithm which, given queries to $f : \{\pm 1\}^n \to \{\pm 1\}$ and parameters $s \in \mathbb{N}$ and $\varepsilon \in (0, 1)$,*

- *Makes $\mathrm{poly}((\log s)/\varepsilon) \cdot \log n$ queries to f, runs in $\mathrm{poly}((\log s)/\varepsilon) \cdot n \log n$ time, and*
- *Accepts w.h.p. if f is ε-close to a size-s decision tree;*
- *Rejects w.h.p. if f is $\Omega(\varepsilon)$-far from size-$s^{O((\log s)^2/\varepsilon^3)}$ decision trees.*

This adds to a long line of work on testing decision trees [33, 23, 19, 5, 15]. We give an overview of prior testers in Section 1.2, mentioning for now that they all have (at least) an exponentially larger dependence on s in their query and time complexities.

1.1.1.1 A new connection between tolerant testing and learning

It would be preferable if our tester can be improved to reject all f's that are far from size-s decision trees – or more strongly, if our reconstructor can be improved to provide query access to a size-s decision tree.

We show that such a tester, even one that is considerably less efficient than ours, would yield the first polynomial-time algorithm for properly learning decision trees:

▶ **Theorem 3** (Tolerant testing $\Longrightarrow$ Proper learning). *Suppose there is an algorithm which, given query access to $f : \{\pm 1\}^n \to \{\pm 1\}$ and parameters $s \in \mathbb{N}$ and $\varepsilon \in (0, 1)$,*

- *Makes $\mathrm{poly}(s, n, 1/\varepsilon)$ queries to f, runs in $\mathrm{poly}(s, n, 1/\varepsilon)$ time, and*
- *Accepts w.h.p. if f is ε-close to a size-s decision tree;*
- *Rejects w.h.p. if f is $\Omega(\varepsilon)$-far from size-s decision trees.*

Then there is a $\mathrm{poly}(s, n, 1/\varepsilon)$-time membership query algorithm for properly learning size-s decision trees with respect to the uniform distribution.

This would represent a breakthrough on a central open problem in learning theory. Recent work of Blanc, Lange, Qiao, and Tan [7] gives a $\mathrm{poly}(n) \cdot s^{O(\log \log s)}$ time algorithm, improving on the prior state of the art of $n^{O(\log s)}$ [24]. Neither [24]'s nor [7]'s algorithm goes through testing.

It is well known and easy to see that proper learning algorithms yield comparably efficient testers [25]. Theorem 3 provides an example of a converse; we find the existence of such a converse surprising, and are not aware of any previous examples.

1.1.1.2 Reconstructors and testers for other properties

Decision tree complexity is quantitatively related to numerous other complexity measures of boolean functions: Fourier degree, approximate degree, randomized and quantum query complexities, certificate complexity, block sensitivity, sensitivity, etc. Our results therefore immediately yield new reconstructors and tolerant testers for these properties. For example, we have the following:

▶ **Corollary 4** (Reconstruction of low Fourier degree functions). *There is a randomized algorithm which, given queries to $f : \{\pm 1\}^n \to \{\pm 1\}$ and parameters $d \in \mathbb{N}$ and $\varepsilon \in (0, 1)$, provides query access to a fixed function $g : \{\pm 1\}^n \to \{\pm 1\}$ where*

- *g has Fourier degree $O(d^7/\varepsilon^2)$,*
- *$\mathrm{dist}(f, g) \leq O(\mathrm{opt}_d) + \varepsilon$ w.h.p., where opt_d denotes the distance of f to closest $h : \{\pm 1\}^n \to \{\pm 1\}$ of Fourier degree d.*
- *Every query to g is answered in $\mathrm{poly}(d, 1/\varepsilon) \cdot n \log n$ time and with $\mathrm{poly}(d, 1/\varepsilon) \cdot \log n$ queries to f.*

This in turn yields a tolerant tester for Fourier degree. As in the case for decision trees, all prior testers for low Fourier degree [23, 19, 20, 5, 12, 15] have an exponential dependence on d in their query and time complexities.

Table 1 lists examples of measures for which we obtain new reconstruction algorithms, each of which in turn give new tolerant testers.

1.2 Background and comparison with prior work

As already mentioned, Theorem 1 gives the first reconstruction algorithm for decision trees. The problem of testing decision trees, on the other hand, has been intensively studied.

Testing decision trees. Recent work of Bshouty [15] gives an algorithm, running in $\mathrm{poly}(s^s, 1/\varepsilon) \cdot n$ time and using $O((s \log s)/\varepsilon)$ queries, that distinguishes between size-s decision trees from functions that are ε-far from size-s decision trees. Prior to [15], Chakraborty, García-Soriano, and Matsliah [19] gave an $O((s \log s)/\varepsilon^2)$-query algorithm, and before that Diakonikolas, Lee, Matulef, Onak, Rubinfeld, Servedio, and Wan [23] gave an $\tilde{O}(s^4/\varepsilon^2)$-query algorithm. Like [15]'s algorithm, the algorithms of [19, 23] also run in $\mathrm{poly}(s^s, 1/\varepsilon) \cdot n$ time.[1]

[1] All these testers enjoy a weak form of tolerance: they are in fact able to distinguish between functions that are $O(\mathrm{poly}(\varepsilon/s))$-close to size-$s$ decision trees from those that are ε-far from size-s decision trees. (Briefly, this is because their queries, while correlated, are each uniformly distributed.)

Table 1 Performance guarantees of our reconstruction algorithms for various complexity measures. In each row, opt_d denotes the distance from f to the closest function h such that the complexity measure of that row for h is bounded by d. In all cases, every query to g is answered in $\mathrm{poly}(d, 1/\varepsilon) \cdot n \log n$ time with $\mathrm{poly}(d, 1/\varepsilon) \cdot \log n$ queries to f.

Complexity measure	*Assumption* Query access to f that is opt_d-close to h where:	*Guarantee* Query access to g that is $O(\mathrm{opt}_d + \varepsilon)$-close to f where:
Fourier degree	$\deg(h) \leq d$	$\deg(g) \leq O(d^7/\varepsilon^2)$
Approximate degree	$\widetilde{\deg}(h) \leq d$	$\widetilde{\deg}(g) \leq O(d^9/\varepsilon^2)$
Randomized query complexity	$\mathrm{R}(h) \leq d$	$\mathrm{R}(g) \leq O(d^7/\varepsilon^2)$
Quantum query complexity	$\mathrm{Q}(h) \leq d$	$\mathrm{Q}(g) \leq O(d^{10}/\varepsilon^2)$
Certificate complexity	$\mathrm{C}(h) \leq d$	$\mathrm{C}(g) \leq O(d^5/\varepsilon^2)$
Block sensitivity	$\mathrm{bs}(h) \leq d$	$\mathrm{bs}(g) \leq O(d^8/\varepsilon^2)$
Sensitivity	$\mathrm{s}(h) \leq d$	$\mathrm{s}(g) \leq O(d^{13}/\varepsilon^2)$

Compared to these algorithms, our algorithm in Corollary 2 solves an incomparable problem with efficiency parameters that compare rather favorably with theirs. Notably, our time and query complexities both depend *polylogarithmically* on s instead of exponentially and super-linearly respectively.

Turning to the parameterized setting, Kearns and Ron [33] gave a tester with time and query complexities $\mathrm{poly}(n^n, (\log s)^n)$ that distinguishes size-s decision trees over $[0,1]^n$ from functions that are $(\frac{1}{2} - n^{-\Theta(n)})$-far from size-$\mathrm{poly}(2^n, s)$ decision trees. The parameters of this result are such that one should think of the dimension "n" as being a constant rather than an asymptotic parameter.

Property reconstruction

Property reconstruction was introduced by Ailon, Chazelle, Comandur, and Liu [2]. (See also the work of Austin and Tao [3], who termed such algorithms "repair algorithms".) Reconstruction has since been studied for a number of properties, including monotone functions [2, 43, 4], hypergraph properties [3], convexity [21], expanders [32], Lipschitz functions [30], graph connectivity and diameter [17], and error correcting codes [18]. Property reconstruction falls within the *local computation algorithms* framework of Rubinfeld, Tamir, Vardi, and Xie [42].

The paper of Blanc, Gupta, Lange, and Tan [6] designs a decision tree learning algorithm that is amenable to *learnability estimation* [35, 10]: given a training set S of *unlabeled* examples, the performance of this algorithm $\mathcal{A}$ trained on S – that is, the generalization error of the hypothesis that $\mathcal{A}$ would construct if we were to label all of S and train $\mathcal{A}$ on it – can be accurately estimated by labeling only a small number of the examples in S. Their

techniques can be used to derive a reconstruction algorithm that achieves guarantees similar to those in Theorem 1, but only for *monotone* functions f. This limitation is inherent: as noted in [6], their algorithm is fails for non-monotone functions.

1.2.1 The work of Bhsouty and Haddad-Zaknoon

Subsequent to the posting of our work to the ArXiv, Bshouty and Haddad-Zaknoon [16] have given a tester that is closely related, but incomparable, to Corollary 2. Their tester:

- Makes $\mathrm{poly}(s, 1/\varepsilon)$ queries to f, runs in $\mathrm{poly}(n, 1/\varepsilon)$ time, and
- Accepts w.h.p. if f is exactly a size-s decision tree;
- Rejects w.h.p. if f is ε-far from size-$(s/\varepsilon)^{O(\log(s/\varepsilon))}$ decision trees.

Comparing [16]'s tester to ours, their query complexity is independent of n (whereas ours has a $\log n$ dependence), and the size of decision trees in their reject condition is only $(s/\varepsilon)^{O(\log(s/\varepsilon))}$ (whereas we require $s^{O((\log s)^2/\varepsilon^3)}$).

On the other hand, our tester is tolerant and has query complexity that achieves a polylogarithmic instead of polynomial dependence on s. Furthermore, [16] does not give a reconstruction algorithm, while that is the main contribution of our work.

1.3 Future directions

We list a few concrete avenues for future work suggested by our results:

- *Tighter connections between testing and learning:* Our tester rejects functions that are $\Omega(\varepsilon)$-far from quasipoly(s) decision trees, and Theorem 3 shows that a tester that rejects functions that are $\Omega(\varepsilon)$-far from size-s decision trees would yield a comparably efficient algorithm for properly learning decision trees. A concrete avenue for future work is to narrow this gap between quasipoly(s) and s, with the ultimate goal of getting them to match.

  There are also other ways in which Theorem 3 could be strengthened: Do *non-tolerant* testers for decision trees yield proper learning algorithms? Do tolerant testers yield proper learning algorithms with *agnostic* guarantees?
- *Improved reconstruction algorithms and testers for other properties:* The reconstruction algorithms that we obtain for the properties listed in Table 1 follow by combining Theorem 1 with known relationships between these measures and decision tree complexity. It would be interesting to obtain improved parameters by designing reconstruction algorithms that are tailored to each of these properties, without going through decision trees.

  The same questions can be asked of property testers, and about properties that are not known to be quantitatively related to decision tree size. Can we achieve similar exponential improvements in the time and query complexities of non-parameterized testers by relaxing to the parameterized setting? Theorem 3 could be viewed as suggesting that for certain properties, efficient algorithms may only be possible in the parameterized setting.

Finally, we mention that there remains a large gap in the known bounds on the query complexity of non-tolerant testing of decision trees in the non-parameterized setting: the current best upper bound is $\tilde{O}(s)$ [15, 19] whereas the current best lower bound is $\Omega(\log s)$ [23, 5]. It would be interesting to explore whether our techniques could be useful in closing this exponential gap.

Notation

All probabilities and expectations are with respect to the uniform distribution unless otherwise stated; we use boldface (e.g. $\boldsymbol{x}$) to denote random variables. For two functions $f, g : \{\pm 1\}^n \to \{\pm 1\}$, we write $\mathrm{dist}(f, g)$ to denote the quantity $\Pr[f(\boldsymbol{x}) \neq g(\boldsymbol{x})]$. We say that f and g are *ε-close* if $\Pr[f(\boldsymbol{x}) \neq g(\boldsymbol{x})] \leq \varepsilon$, and *$\varepsilon$-far* otherwise.

For a function $f : \{\pm 1\}^n \to \{\pm 1\}$, a decision tree T over the same variables as f, and a node v in T, we write f_v to denote the subfunction of f obtained by restricting f according to the root-to-v path in T. We write $|v|$ to denote the depth of v within T, and so the probability that a uniform random $\boldsymbol{x} \sim \{\pm 1\}^n$ reaches v is $2^{-|v|}$.

2 Proofs of Theorem 1 and Theorem 2

Our proof of Theorem 1 has two main components:

- A structural lemma about functions f that are opt_s-close to a size-s decision tree $T^\star$. While we have no information about the structure of this tree $T^\star$ that f is opt_s-close to, we will show that f is $O(\mathrm{opt}_s + \varepsilon)$-close to a tree $T^\diamond$ of size $S = S(s, \varepsilon)$ with a very specific structure.
- An algorithmic component that leverages this specific structure of $T^\diamond$ to show that for any input $x \in \{\pm 1\}^n$, the value of $T^\diamond(x)$ can be computed with only $\log S \cdot \log n$ queries to f.

Section 2.1 will be devoted to the structural lemma and Section 2.2 to the algorithmic component. We prove Theorem 1 in Section 2.2.2, and we derive Corollary 2 as a simple consequence of Theorem 1 in Section 2.3.

2.1 Structural component of Theorem 1

▶ **Definition 5** (Noise sensitivity). *The noise sensitivity of $f : \{\pm 1\}^n \to \{\pm 1\}$ at noise rate p is the quantity*

$$\mathrm{NS}_p(f) \coloneqq \Pr[f(\boldsymbol{x}) \neq f(\boldsymbol{y})],$$

where $\boldsymbol{x} \sim \{\pm 1\}^n$ is uniform random and $\boldsymbol{y} \sim_p \boldsymbol{x}$ is a p-noisy copy of $\boldsymbol{x}$, obtained from $\boldsymbol{x}$ by independently rerandomizing each coordinate with probability p.

We assign each coordinate $i \in [n]$ of a function f a *score*, which measures the expected decrease in the noise sensitivity of f if x_i is queried:

▶ **Definition 6** (Score of a variable). *Given a function $f : \{\pm 1\}^n \to \{\pm 1\}$, noise rate $p \in (0, 1)$, and coordinate $i \in [n]$, the score of x_i is defined as*

$$\mathrm{Score}_i(f, p) = \mathrm{NS}_p(f) - \mathop{\mathbb{E}}_{\boldsymbol{b} \in \{\pm 1\}} \left[\mathrm{NS}_p(f_{x_i = \boldsymbol{b}})\right].$$

(Our notion of score is equivalent, up to scaling factors depending on p, to the notion of "noisy influence" as in defined in O'Donnell's monograph [38]. We use our definition of score as it simplifies our presentation.) We are now ready to define the tree $T^\diamond$ described at the beginning of this section and state our structural lemma.

▶ **Definition 7.** *For a function $f : \{\pm 1\}^n \to \{\pm 1\}$, parameters $d \in \mathbb{N}$ and $p \in (0,1)$, we write $T_f^{d,p}$ to denote the complete decision tree of depth d defined as follows:*

- *At every internal node v, query x_i where $i \in [n]$ maximizes $\mathrm{Score}_i(f_v, p)$.*[2]
- *Label every leaf ℓ with $\mathrm{sign}(\mathbb{E}[f_\ell])$.*

▶ **Lemma 8** (Structural lemma). *Let $f : \{\pm 1\}^n \to \{\pm 1\}$ be opt_s-close to a size-s decision tree. Then for $d = O((\log s)^3/\varepsilon^3)$ and $p = \varepsilon/(\log s)$, we have $\mathrm{dist}(f, T_f^{d,p}) \le O(\mathrm{opt}_s) + \varepsilon$.*

While Lemma 8 covers the main essence of our structural result, we'll need a slightly more robust version.

▶ **Lemma 9** (Robust version of Lemma 8). *Let $f : \{\pm 1\}^n \to \{\pm 1\}$ be opt_s-close to a size-s decision tree. For $d = O((\log s)^3/\varepsilon^3)$, $p = \varepsilon/(\log s)$, and $\tau = O(\varepsilon^3/(\log s)^3)$, let T be any complete decision tree of depth d satisfying:*

- *At every internal node v, the variable x_i that is queried at this node satisfies:*

$$\mathrm{Score}_i(f_v, p) \ge \max_{j \in [n]} \{\mathrm{Score}_j(f_v, p)\} - \tau.$$

- *Every leaf ℓ such that $|\mathbb{E}[f_\ell]| > \varepsilon$ is labeled $\mathrm{sign}(\mathbb{E}[f_\ell])$.*

Then $\mathrm{dist}(f, T) \le O(\mathrm{opt}_s + \varepsilon)$.

The proofs of Lemmas 8 and 9 are in the full version of this paper.

2.2 Algorithmic component of Theorem 1

2.2.1 Query-efficient simultaneous score estimation

We begin by designing a query-efficient subroutine that simultaneously estimates the scores of all n variables of a function f. The fact that we are able to do so with $O(\log n)$ queries, as opposed to $\Omega(n)$ as would be required by a naive approach, will be a key component in the query efficiency of our reconstructor.

▶ **Theorem 10** (Score estimator). *There is an algorithm which, given query access to a function $f : \{\pm 1\}^n \to \{\pm 1\}$, noise rate $p \in (0,1)$, accuracy parameter $\tau \in (0,1)$, and confidence parameter $\delta \in (0,1)$, for*

$$q = O\left(\frac{\log n + \log(1/\delta)}{\tau^2}\right)$$

makes $O(q)$ queries, runs in $O(qn)$ time, and returns estimates $\boldsymbol{\eta}_1, \ldots, \boldsymbol{\eta}_n$ such that, with probability at least $1 - \delta$, satisfies

$$\left|\boldsymbol{\eta}_i - \mathrm{Score}_i(f, p)\right| < \tau \quad \text{for all } i \in [n].$$

We prove Theorem 10 by first giving a 2-query algorithm, UnbiasedEstimator (Figure 1), that runs in $O(n)$ time and outputs unbiased estimates of all n scores. The algorithm of Theorem 10 takes the mean of multiple runs of that unbiased estimator, with its guarantees following from a simple concentration bound.

▶ **Lemma 11** (Analysis of UnbiasedEstimator). *For any $f : \{\pm 1\}^n \to \{\pm 1\}$ and $p \in (0,1)$, let $\boldsymbol{\eta}_1, \ldots, \boldsymbol{\eta}_n$ be the outputs of UnbiasedEstimator(f, p). Then*

$$\mathop{\mathbb{E}}_{\boldsymbol{x},\boldsymbol{y}}[\boldsymbol{\eta}_i] = \mathrm{Score}_i(f, p) \quad \text{for all } i \in [n].$$

[2] Ties are arbitrarily broken; our results hold regardless of how ties are broken.

UnbiasedEstimator(f, p):

Input: Query access to a function $f : \{\pm 1\}^n \to \{\pm 1\}$ and a noise rate $p \in (0, 1)$.
Output: Unbiased estimates of $\text{Score}_i(f, p)$ for all $i \in [n]$.

1. Choose $\boldsymbol{x} \in \{\pm 1\}^n$ uniformly at random and generate a p-noisy copy $\boldsymbol{y}$ of $\boldsymbol{x}$.
2. For each $i \in [n]$, return the estimate

$$\boldsymbol{\eta}_i = \mathbb{1}\big[f(\boldsymbol{x}) \neq f(\boldsymbol{y})\big] \cdot \left(1 - \frac{1}{1 - \frac{p}{2}} \cdot \mathbb{1}[\boldsymbol{x}_i = \boldsymbol{y}_i]\right).$$

Figure 1 UnbiasedEstimator computes unbiased estimates of the scores of all variables of a function f.

Proof. We first note that $\Pr[f(\boldsymbol{x}) \neq f(\boldsymbol{y})]$ is $\text{NS}_p(f)$ by definition. Therefore, it is enough for us to prove that

$$\mathop{\mathbb{E}}_{\boldsymbol{b} \in \{\pm 1\}} \big[\text{NS}_p(f_{x_i = \boldsymbol{b}})\big] = \frac{1}{1 - \frac{p}{2}} \cdot \Pr_{\boldsymbol{x}, \boldsymbol{y}} \left[f(\boldsymbol{x}) \neq f(\boldsymbol{y}) \text{ and } \boldsymbol{x}_i = \boldsymbol{y}_i\right]. \tag{1}$$

Given the above equation, the desired result holds by linearity of expectation and the definition of score. Consider the distribution over $(\boldsymbol{x}, \boldsymbol{y})$ conditioned on the event that $b = \boldsymbol{x}_i = \boldsymbol{y}_i$. That distribution is equivalent to if we picked $\boldsymbol{x}$ randomly from the domain of $f_{x_i = b}$ and selected $\boldsymbol{y}$ by rerandomizing each coordinate in that domain with probability p. Therefore,

$$\begin{aligned}
\text{NS}_p(f_{x_i = b}) &= \Pr_{\boldsymbol{x}, \boldsymbol{y}}[f(\boldsymbol{x}) \neq f(\boldsymbol{y}) \,|\, b = \boldsymbol{x}_i = \boldsymbol{y}_i] \\
&= \frac{1}{\Pr_{\boldsymbol{x}, \boldsymbol{y}}[b = \boldsymbol{x}_i = \boldsymbol{y}_i]} \cdot \Pr_{\boldsymbol{x}, \boldsymbol{y}}[f(\boldsymbol{x}) \neq f(\boldsymbol{y}) \text{ and } b = \boldsymbol{x}_i = \boldsymbol{y}_i].
\end{aligned}$$

We now prove Equation (1):

$$\begin{aligned}
\mathop{\mathbb{E}}_{\boldsymbol{b} \in \{\pm 1\}} \big[\text{NS}_p(f_{x_i = \boldsymbol{b}})\big] &= \mathop{\mathbb{E}}_{\boldsymbol{b} \in \{\pm 1\}} \left[\frac{1}{\Pr_{\boldsymbol{x}, \boldsymbol{y}}[\boldsymbol{b} = \boldsymbol{x}_i = \boldsymbol{y}_i]} \cdot \Pr_{\boldsymbol{x}, \boldsymbol{y}}[f(\boldsymbol{x}) \neq f(\boldsymbol{y}) \text{ and } \boldsymbol{b} = \boldsymbol{x}_i = \boldsymbol{y}_i]\right] \\
&= \frac{1}{\frac{1}{2} \cdot \Pr_{\boldsymbol{x}, \boldsymbol{y}}[\boldsymbol{x}_i = \boldsymbol{y}_i]} \mathop{\mathbb{E}}_{\boldsymbol{b} \in \{\pm 1\}} \left[\Pr_{\boldsymbol{x}, \boldsymbol{y}}[f(\boldsymbol{x}) \neq f(\boldsymbol{y}) \text{ and } \boldsymbol{b} = \boldsymbol{x}_i = \boldsymbol{y}_i]\right] \\
&= \frac{1}{\frac{1}{2} \cdot (1 - \frac{p}{2})} \cdot \frac{1}{2} \cdot \Pr_{\boldsymbol{x}, \boldsymbol{y}} \left[f(\boldsymbol{x}) \neq f(\boldsymbol{y}) \text{ and } \boldsymbol{x}_i = \boldsymbol{y}_i\right] \\
&= \frac{1}{1 - \frac{p}{2}} \cdot \Pr_{\boldsymbol{x}, \boldsymbol{y}} \left[f(\boldsymbol{x}) \neq f(\boldsymbol{y}) \text{ and } \boldsymbol{x}_i = \boldsymbol{y}_i\right].
\end{aligned}$$

Lemma 11 then holds by linearity of expectation. ◀

We now prove Theorem 10.

Proof of Theorem 10. The algorithm runs UnbiasedEstimator(f, p) q times and then outputs the means of each returned estimates. Each estimate from UnbiasedEstimator is bounded between -1 and 1. By Hoeffding's inequality, for any $i \in [n]$,

$$\Pr\left[\left|\boldsymbol{\eta}_i - \text{Score}_i(f, p)\right| \geq \tau\right] \leq -\exp_e\left(-\frac{q \cdot \tau^2}{2}\right).$$

For q as in Theorem 10, the above probability is at most δ/n. By union bound, all estimates are accurate within $\pm\tau$ with probability at least $1-\delta$.

Finally, this algorithm uses only $2q = O(q)$ queries. Each run of UnbiasedEstimator estimator takes $O(n)$ time to construct the query and compute all the estimates, so the entire algorithm takes $O(qn)$ time. ◀

2.2.2 Proof of Theorem 1

We prove Theorem 1 by providing an algorithm, Reconstructor (Figure 2), which assumes query access to a function $f : \{\pm1\}^n \to \{\pm1\}$ and provides fast query access to a tree T meeting the criteria of Theorem 1. We build off a simple observation that also underlies [6]: to determine the output of a decision tree T on a particular input z, it suffices to build the root-to-leaf path corresponding to z, which can be exponentially faster than building the entire tree. Our algorithm is different from [6]'s; as mentioned in the introduction their algorithm is tailored to monotone functions, and is known to fail for non-monotone ones. We on the other hand leverage the specific structure of T established in Section 2.1 together with the query-efficient score estimator from Section 2.2.1 in our design and analysis of Reconstructor.

Reconstructor maintains a partial tree T° containing all the root-to-leaf paths in T corresponding to queries received so far. In the pseudocode for Reconstructor, we use the notation $T^\circ_{\text{internal}}(\alpha) \in [n] \cup \{\varnothing\}$ to indicate the variable queried in $[n]$ at internal node α of the partial tree T°, or $\varnothing$ if that node has not yet been built. Similarly, $T^\circ_{\text{leaf}}(\alpha) \in \{-1, 1, \varnothing\}$ indicates the value at leaf α in T°, or $\varnothing$ if that value has not yet been decided.

Theorem 1 follows from the following two lemmas, showing the correctness and efficiency of Reconstructor respectively.

▶ **Lemma 12** (Correctness of Reconstructor). *For any $f : \{\pm1\}^n \to \{\pm1\}$, $s \in \mathbb{N}$, $\varepsilon \in (0, \frac{1}{2})$, $\delta \in (0,1)$, and sequence of inputs $z^{(1)}, \dots, z^{(m)} \in \{\pm1\}^n$, the outputs of Reconstructor are consistent with some decision tree T where*

- *T has size $s^{O((\log s)^2/\varepsilon^3)}$,*
- *$\operatorname{dist}(T, f) \le O(\operatorname{opt}_s) + \varepsilon$ with probability at least $1-\delta$.*

Proof. The outputs of Reconstructor are always consistent with T° and the depth of T° is always capped at d. Let T be the tree that T° would be if every $x \in \{\pm1\}^n$ were given as an input to Reconstructor. Then, T has size at most $2^d = s^{O((\log s)^2/\varepsilon^3)}$, and every output is consistent with T.

If all score estimates in Step 3(b)i are accurate to $\pm\frac{\tau}{2}$ and expectation estimates is Step 3c are accurate to $\pm\frac{\varepsilon}{4}$, then T meets the criteria of Lemma 9 and therefore $\operatorname{dist}(T, f) \le O(\operatorname{opt}_s) + \varepsilon$. The number of time scores are estimated in Step 3(b)i is at most the number of internal nodes of T, which is $2^d - 1$. Similarly, the number of expectation estimates in Step 3(b)i is at most the number of leaves of T, which is 2^d. By union bound over the possible failures, we see that the failure probability is at most δ. ◀

▶ **Lemma 13** (Efficiency of Reconstructor). *For any $f : \{\pm1\}^n \to \{\pm1\}$, $s \in \mathbb{N}$, $\varepsilon \in (0, \frac{1}{2})$, $\delta \in (0,1)$, particular input $z \in \{\pm1\}^n$, and*

$$q = O\left(\frac{(\log s)^9 \cdot (\log n) \cdot \log(1/\delta)}{\varepsilon^9}\right),$$

upon receiving z as input, Reconstructor$(f, s, \varepsilon, \delta)$ uses $O(q)$ queries and $O(qn)$ time to return an output.

RECONSTRUCTOR$(f, s, \varepsilon, \delta)$:

Input: Query access to a function $f : \{\pm 1\}^n \to \{\pm 1\}$, size parameter s, error parameter ε, and failure probability δ.

Output: Query access to a decision tree T that satisfies $\text{dist}(f, T) \leq O(\text{opt}_s) + \varepsilon$ with probability at least $1 - \delta$.

1. Set parameters d, p, and τ as in Lemma 9.
2. Initialize T° to be the empty partial tree.
3. Upon receiving an input $z \in \{\pm 1\}^n$:
   a. Initialize α to be the root of T°.
   b. Repeat d times.
      i. If $T^\circ_{\text{internal}}(\alpha)$ is $\varnothing$ use the estimator from Theorem 10 to compute estimates of $\text{Score}_i(f_\alpha, p)$ with additive accuracy $\pm\frac{\tau}{2}$ and failure probability $O(\frac{\delta}{2^d})$ for all $i \in [n]$ and set $T^\circ_{\text{internal}}(\alpha)$ to the variable with highest estimated score.
      ii. For $i = T^\circ_{\text{internal}}(\alpha)$, If $\overline{z}_i$ is 1, set α to its right child. Otherwise, set α to its left child.
   c. If $T^\circ_{\text{leaf}}(\alpha)$ is $\varnothing$, use random samples to estimate $\mathbb{E}[f_\ell]$ to additive accuracy $\pm\frac{\varepsilon}{4}$ with failure probability $O(\frac{\delta}{2^d})$ and set $T^\circ_{\text{leaf}}(\alpha)$ to whichever of $\{\pm 1\}$ that estimate is closer to.
   d. Output $T^\circ_{\text{leaf}}(\alpha)$.

Figure 2 RECONSTRUCTOR gives efficient query access to a decision tree is close to f with high probability.

Proof. On each input, the estimator from Theorem 10 is used up to d times. Each uses

$$q_{\text{inner}} \coloneqq O\left(\frac{\log n + \log(2^d/\delta)}{\tau^2}\right) = O\left(\frac{\log n + d + \log(1/\delta)}{\tau^2}\right)$$

queries and $O(q_{\text{inner}} n)$ time. By Hoeffding's inequality, it is sufficient to take

$$q_{\text{leaf}} \coloneqq O\left(\frac{\log(2^d/\delta)}{\varepsilon^2}\right) = O\left(\frac{d + \log(1/\delta)}{\varepsilon^2}\right)$$

random samples in Step 3c. Therefore, the total number of queries used is

$$\begin{aligned} q &= q_{\text{inner}} + q_{\text{leaf}} \\ &= O\left(\frac{\log n + d + \log(1/\delta)}{\tau^2}\right) + O\left(\frac{d + \log(1/\delta)}{\varepsilon^2}\right) \\ &= O\left(\frac{\log n + ((\log s)^3/\varepsilon^3) + \log(1/\delta)}{\varepsilon^6/(\log s)^6} + \frac{((\log s)^3/\varepsilon^2) + \log(1/\delta)}{\varepsilon^2}\right) \\ &= O\left(\frac{(\log s)^9 \cdot (\log n) \cdot \log(1/\delta)}{\varepsilon^9}\right). \end{aligned}$$

The time to prepare all queries is $O(qn)$, and all other computation is asymptotically faster. ◀

▶ Remark 14 (Local reconstruction). We remark that our reconstruction algorithm can be made local in the sense of [43]. They define a reconstruction algorithm, $\mathcal{A}$, to be local, if the output of $\mathcal{A}$ on some input z is a *deterministic* and easy to compute function of z and some small random string ρ. This allows queries to the reconstructor to be answered in parallel, as long as the random string ρ is shared. To make our reconstructor local, we note that the only place randomness is used is in generating samples consistent with some restriction α. We can set ρ to be n bits per sample the constructor might wish to generate. Since the total number of samples the reconstructor needs per input is $\mathrm{poly}(\log s, 1/\varepsilon, \log(1/\delta)) \cdot \log n$, we have

$$|\rho| = \mathrm{poly}(\log s, 1/\varepsilon, \log(1/\delta)) \cdot n \log n$$

On a particular input, the local reconstructor starts with T° being the empty tree. Whenever it wishes to produce a random sample consistent with α, it sets the $\boldsymbol{x} \in \{\pm 1\}^n$ to be next n bits of ρ and then uses $\boldsymbol{x}_\alpha$ for the sample. It's easy to see that this algorithm will keep T° consistent between different runs because it will always compute the same variable as having the highest score given some restriction. Furthermore, the analysis goes through without issue. The only difference between this analysis and one where fresh random bits are used to for each sample is that the queries of different paths may be correlated. In our proof of Lemma 12, we use a union bound to ensure all estimates obtained through sampling are accurate, and that union bound holds regardless of whether those estimates are independent.

2.3 Proof of Corollary 2

In this section we derive Corollary 2 as a simple consequence of Theorem 1. The connection between reconstruction and tolerant testing has been noted in other works (see e.g. [17, 11]); we provide a proof here for completeness.

▶ **Theorem 15** (Corollary 2 restated). *There is an algorithm which, given query access to* $f : \{\pm 1\}^n \to \{\pm 1\}$ *and parameters* $s \in \mathbb{N}$ *and* $\varepsilon, \delta \in (0, 1)$*, runs in* $\mathrm{poly}(\log s, 1/\varepsilon) \cdot n \log n \cdot \log(1/\delta)$ *time, makes* $\mathrm{poly}(\log s, 1/\varepsilon) \cdot \log n \cdot \log(1/\delta)$ *queries to* f*, and*

- *Accepts w.p. at least* $1 - \delta$ *if* f *is* ε*-close to a size-*s *decision tree;*
- *Rejects w.p. at least* $1 - \delta$ *if* f *is* $\Omega(\varepsilon)$*-far from size-*$s^{O((\log s)^2/\varepsilon^3)}$ *decision trees.*

Proof. The algorithm chooses m uniform random inputs, $\boldsymbol{x}^{(1)}, \ldots, \boldsymbol{x}^{(m)} \sim \{\pm 1\}^n$ where $m = O(\log(1/\delta)/\varepsilon^2)$. Let $\boldsymbol{b}^{(1)}, \ldots, \boldsymbol{b}^{(m)} \in \{\pm 1\}$ be the output of $\textsc{Reconstructor}(f, s, \varepsilon, \delta)$. The tester rejects if $\mathbb{E}_{\boldsymbol{i} \in [m]}[f(\boldsymbol{x}^{(\boldsymbol{i})}) \neq \boldsymbol{b}^{(\boldsymbol{i})}] > \Omega(\varepsilon)$ and accepts otherwise.

First, we consider the case where f is ε-close to a size-s decision tree (i.e. $\mathrm{opt}_s \leq \varepsilon$). By Lemma 12, with probability at least $1 - \delta$ the outputs of $\textsc{Reconstructor}$ are consistent with a tree, T, satisfying $\mathrm{dist}(T, f) \leq O(\varepsilon)$. By Hoeffding's inequality,

$$\Pr_{\boldsymbol{x}^{(1)}, \ldots, \boldsymbol{x}^{(m)}} \left[\mathop{\mathbb{E}}_{\boldsymbol{i} \in [m]} \left[f(\boldsymbol{x}^{(\boldsymbol{i})}) \neq \boldsymbol{b}^{(\boldsymbol{i})} \right] > \Omega(\varepsilon) \right] \leq \exp(-2m\varepsilon^2) \leq \delta.$$

By a union bound, the tester rejects with probability at most $\delta + \delta = 2\delta$.

We next consider the case where f is $\Omega(\varepsilon)$-far from size-$s^{O((\log s)^2/\varepsilon^3)}$ decision trees. By Lemma 12 it is guaranteed to be consistent. A similar argument to the first case shows that the probability of acceptance is at most $\delta + \exp(-2m\varepsilon^2) = 2\delta$. Finally, the efficiency of this tester is a consequence of Lemma 13 and our choice of $m = O(\log(1/\delta)/\varepsilon^2)$. ◀

3 Proof of Corollary 4

We first restate Theorem 1 with decision tree *depth* instead of *size* as the complexity measure:

▶ **Theorem 16** (Theorem 1 in terms of decision tree depth). *There is a randomized algorithm which, given query access to $f : \{\pm 1\}^n \to \{\pm 1\}$ and parameters $d \in \mathbb{N}$ and $\varepsilon \in (0,1)$, provides query access to a fixed decision tree T where*

- *T has depth $O(d^3/\varepsilon^2)$,*
- *$\mathrm{dist}(T, f) \le O(\mathrm{opt}_d) + \varepsilon$ w.h.p., where opt_d denotes the distance of f to the closest depth-d decision tree.*

Every query to T is answered in $\mathrm{poly}(d, 1/\varepsilon) \cdot n \log n$ time and with $\mathrm{poly}(d, 1/\varepsilon) \cdot \log n$ queries to f.

To see that our proof of Theorem 1 also establishes Theorem 16, we use the fact that every depth-d decision tree has size $\le 2^d$, and recall that the tree T that the algorithm of Theorem 1 provides query access to is a complete tree and hence has depth logarithmic in its size.

Decision tree depth and Fourier degree of boolean functions are known to be polynomially related:

▶ **Fact 17** (Decision tree depth vs. Fourier degree [37, 44]). *For $g : \{\pm 1\}^n \to \{\pm 1\}$ let $\deg(g)$ denote g's Fourier degree and $D(g)$ denote the depth of the shallowest decision tree that computes g. Then $\deg(g) \le D(g)$ and $D(g) \le \deg(g)^3$.*

We first observe Theorem 16 and Fact 17 already gives a quantitatively weaker version of Corollary 4 where g has degree $O(d^9/\varepsilon^2)$. To see this $f : \{\pm 1\}^n \to \{\pm 1\}$ be opt_d-close to a degree-d function $h : \{\pm 1\}^n \to \{\pm 1\}$. By Fact 17, $D(h) \le \deg(h)^3$, and so the algorithm of Theorem 16 provides query access to a decision tree $T : \{\pm 1\}^n \to \{\pm 1\}$ that is $(O(\mathrm{opt}_d) + \varepsilon)$-close to f and where the depth of T is $O(D(h)^3/\varepsilon^2) = O(\deg(h)^9/\varepsilon^2)$. Applying Fact 17 again, we conclude that $\deg(T) \le D(T) \le O(\deg(h)^9/\varepsilon^2)$.

To obtain the sharper bound of $O(\deg(h)^7/\varepsilon^2)$, we observe that the proof of Lemma 8 in fact bounds the depth of T by $O(D(h)^2 \mathrm{Inf}(h)/\varepsilon^2)$. Influence and degree of boolean functions are related via the following basic fact (see e.g. [38, Theorem 37]):

▶ **Fact 18.** *For all $h : \{\pm 1\}^n \to \{\pm 1\}$, we have $\mathrm{Inf}(h) \le \deg(h)$.*

Therefore, we can bound the degree of T by $O(D(h)^2 \mathrm{Inf}(h)/\varepsilon^2) \le O(\deg(h)^7/\varepsilon^2)$.

Guarantees for the other measures listed in Table 1 follow from similar calculations and known quantitative relationships between these measures and decision tree complexity; the current best bounds are summarized in Table 1 of [1].

4 Proof of Theorem 3

In this section, we prove the following theorem:

▶ **Theorem 19** (Tolerant testing of DTs ⇒ Proper learning of DTs). *Let $c > 0$ be an absolute constant and $\mathcal{A}$ be an algorithm with the following guarantee. Given query access to $f : \{\pm 1\}^n \to \{\pm 1\}$ and parameters $s \in \mathbb{N}$ and $\varepsilon \in (0,1)$, the algorithm $\mathcal{A}$:*

- *Accepts w.h.p. if f is ε-close to a size-s decision tree;*
- *Rejects w.h.p. if f is $(c\varepsilon)$-far from all size-s decision trees.*

Then there is an algorithm $\mathcal{B}$ with the following guarantee. Given parameters $s' \in \mathbb{N}$ and $\varepsilon' \in (0,1)$, and query access to a function $g : \{\pm 1\}^n \to \{\pm 1\}$ that is computed by a size-s' decision tree, $\mathcal{B}$ makes $\mathrm{poly}(s', n, 1/\varepsilon')$ calls to $\mathcal{A}$, each with parameters $s \leq s'$ and $\varepsilon \geq \mathrm{poly}(1/s', \varepsilon')$, and produces a decision tree which is ε'-close to g with high probability. Furthermore, the auxiliary computation that g does takes time $\mathrm{poly}(n, s', 1/\varepsilon')$.

Theorem 3 follows as a special case of Theorem 19.
We prove Theorem 19 in two steps:

1. A tolerant tester implies an algorithm for estimating the distance of any function to the class of size-s decision trees. This is well known [40] and applies to any function class, not just decision trees.
2. An algorithm for estimating distance to decision trees implies a proper learner for decision trees. Here, we take advantage of the structure of decision trees.

For a function $g : \{\pm 1\}^n \to \{\pm 1\}$ and $s \in \mathbb{N}$, we write $\mathrm{opt}_s(g)$ to denote the distance of g to the closest size-s decision tree.

▶ **Lemma 20** (Tolerant testing ⇒ distance estimation [40]). *Let c and $\mathcal{A}$ be as in Theorem 19. There exists an estimator $\mathcal{E}$ with the following guarantee. Given query access to $g : \{\pm 1\}^n \to \{\pm 1\}$ and parameters $s' \in \mathbb{N}$ and $\gamma \in (0,1)$, the estimator $\mathcal{E}$ makes c/γ calls to $\mathcal{A}$ and returns an $\boldsymbol{\eta}$ that with high probability satisfies*

$$\boldsymbol{\eta} \leq \mathrm{opt}_s(g) \leq c \cdot \boldsymbol{\eta} + \gamma.$$

Furthermore, the auxiliary computation of g takes time $O(c/\gamma)$.

Proof. The algorithm $\mathcal{E}$ runs $\mathcal{A}$ with $\varepsilon = \frac{\gamma}{c}, \frac{2\gamma}{c}, \frac{3\gamma}{c}, \ldots, 1$, and sets $\boldsymbol{\eta}$ to be the largest ε for which $\mathcal{A}(g, s, \varepsilon)$ rejects. Since $\mathcal{A}(g, s, \boldsymbol{\eta})$ rejected,

$$\boldsymbol{\eta} < \mathrm{opt}_s(g)$$

with high probability. Furthermore, since $\mathcal{A}(g, s, \boldsymbol{\eta} + \frac{\gamma}{c})$ accepted,

$$\begin{aligned}\mathrm{opt}_s(g) &< c \cdot \left(\boldsymbol{\eta} + \tfrac{\gamma}{c}\right) \\ &= c \cdot \boldsymbol{\eta} + \gamma\end{aligned}$$

with high probability. Finally, we note that $\mathcal{E}$ indeed makes c/γ calls to $\mathcal{A}$, and aside from those calls, it only needs to make a single pass over the output of those calls and return the largest ε that led to a rejection, which takes time $O(c/\gamma)$. ◀

We are now ready to state our algorithm, BuildDT (Figure 3), for properly learning size-s' decision trees. BuildDT will additionally take in a depth parameter d that will facilitate our analysis of it (looking ahead, d will be chosen to be $O(\log(s'/\varepsilon'))$ in our proof of Theorem 19).

▶ **Lemma 21** (Error of BuildDT). *For all functions $f : \{\pm 1\}^n \to \{\pm 1\}$ and parameters $s, d \in \mathbb{N}$ and $\gamma \in (0,1)$, the algorithm $\textsc{BuildDT}(f, s, d, \gamma)$ outputs a decision tree T satisfying*

$$\mathrm{dist}(T, f) \leq c^d \cdot \mathrm{opt}_s(f) + \gamma \cdot \frac{c^d - 1}{c - 1} + \frac{s}{2^{d+2}}. \tag{2}$$

BuildDT(f, s, d, γ):

Input: Query access to $f : \{\pm 1\}^n \to \{\pm 1\}$, parameters $s, d \in \mathbb{N}$ and $\gamma \in (0, 1)$.
Output: A size-s depth-d decision tree T.

1. If $s = 1$ or $d = 0$, return $\text{sign}(\mathbb{E}[f])$.
2. For each $i \in [n]$ and integers $s_0, s_1 \geq 1$ satisfying $s_0 + s_1 = s$:
   a. Use $\mathcal{E}$ from Lemma 20 to obtain estimates $\boldsymbol{\eta}(x_i = 0, s_0)$ and $\boldsymbol{\eta}(x_i = 1, s_1)$ that satisfy:
   $$\boldsymbol{\eta}(x_i = 0, s_0) \leq \text{opt}_{s_0}(f_{x_i=0}) \leq c \cdot \boldsymbol{\eta}(x_i = 0, s_0) + \gamma;$$
   $$\boldsymbol{\eta}(x_i = 1, s_1) \leq \text{opt}_{s_1}(f_{x_i=1}) \leq c \cdot \boldsymbol{\eta}(x_i = 1, s_1) + \gamma.$$
   b. Store $\text{error}(i, s_1, s_2) \leftarrow \frac{1}{2}\big(\boldsymbol{\eta}(x_i = 0, s_0) + \boldsymbol{\eta}(x_i = 1, s_1)\big)$.
3. Let $(i^\star, s_0^\star, s_1^\star)$ be the tuple that minimizes $\text{error}(i, s_0, s_1)$. Output the tree with $x_{i^\star}$ as its root, BuildDT$(f_{x_{i^\star}=0}, s_0^\star, d-1, \gamma)$ as its left subtree, and BuildDT$(f_{x_{i^\star}=1}, s_1^\star, d-1, \gamma)$ as its right subtree.

Figure 3 BuildDT computes a size-s depth-d decision tree that approximates a target function $f : \{\pm 1\}^n \to \{\pm 1\}$.

Proof. We proceed by induction on s and d. If $s = 1$, then in Step 1, BuildDT outputs the best decision tree of size 1. Therefore, $\text{dist}(T, f) \leq \text{opt}_s(f)$, satisfying Equation (2). If $d = 0$ and $s \geq 2$, then $\frac{s}{2^{d+2}} \geq \frac{2}{4} = \frac{1}{2}$. Furthermore, in Step 1, BuildDT always outputs a tree with error at most $\frac{1}{2}$. Therefore,

$$\text{dist}(T, f) \leq \frac{s}{2^{d+2}} \leq c^d \cdot \text{opt}_s(f) + \gamma \cdot \frac{c^d - 1}{c - 1} + \frac{s}{2^{d+2}}.$$

Finally, we consider the case where $d \geq 1$ and $s \geq 2$. Let T_{opt} be the size-s decision tree that is $\text{opt}_s(f)$ close to f. Let $x_{i_{\text{opt}}}$ the root of T_{opt}, and $s_{0,\text{opt}}$, $s_{1,\text{opt}}$ the sizes of the left and right subtrees of T_{opt} respectively. Since the estimates computed in Step 2a are underestimates of or equal to the true error (i.e. $\text{error}(i_{\text{opt}}, s_{0,\text{opt}}, s_{1,\text{opt}}) \leq \text{opt}_s(f)$), and since $i^\star, s_0^\star, s_1^\star$ are chosen in Step 3 to minimize the estimated error, we have

$$\text{error}(i^\star, s_0^\star, s_1^\star) \leq \text{error}(i_{\text{opt}}, s_{0,\text{opt}}, s_{1,\text{opt}}) \leq \text{opt}_s(f).$$

Finally, we bound $\text{dist}(T, f)$. Let T_0 and T_1 be the left and right subtrees of T. Then,

$$\begin{aligned}
\text{dist}(T, f) &= \tfrac{1}{2}\big(\text{dist}(T_0, f_{x_{i^\star}=0}) + \text{dist}(T_1, f_{x_{i^\star}=1})\big) \\
&\leq \tfrac{1}{2}\Big(c^{d-1} \cdot \text{opt}_{s_0^\star}(f_{x_{i^\star}=0}) + \gamma \cdot \frac{c^{d-1} - 1}{c - 1} + \frac{s_0^\star}{2^{d+1}} \\
&\quad + c^{d-1} \cdot \text{opt}_{s_1^\star}(f_{x_{i^\star}=1}) + \gamma \cdot \frac{c^{d-1} - 1}{c - 1} + \frac{s_1^\star}{2^{d+1}}\Big) \qquad \text{(Inductive hypothesis)} \\
&= c^{d-1} \cdot \tfrac{1}{2}\left(\text{opt}_{s_0^\star}(f_{x_{i^\star}=0}) + \text{opt}_{s_1^\star}(f_{x_{i^\star}=1})\right) + \gamma \cdot \frac{c^{d-1} - 1}{c - 1} + \frac{s_0^\star + s_1^\star}{2^{d+2}} \\
&\leq c^{d-1} \cdot \tfrac{1}{2}\big((c \cdot \boldsymbol{\eta}(x_{i^\star} = 0, s_0^\star) + \gamma) + (c \cdot \boldsymbol{\eta}(x_{i^\star} = 1, s_1^\star) + \gamma)\big) + \gamma \cdot \frac{c^{d-1} - 1}{c - 1} + \frac{s}{2^{d+2}} \\
&= c^d \cdot \tfrac{1}{2}\left(\boldsymbol{\eta}(x_{i^\star} = 0, s_0^\star) + \boldsymbol{\eta}(x_{i^\star} = 1, s_1^\star)\right) + c^{d-1} \cdot \gamma + \gamma \cdot \frac{c^{d-1} - 1}{c - 1} + \frac{s}{2^{d+2}}
\end{aligned}$$

$$= c^d \cdot \mathrm{error}(i^\star, s_0^\star, s_1^\star) + \gamma \cdot \frac{c^{d-1}(c-1) + c^{d-1} - 1}{c-1} + \frac{s}{2^{d+2}}$$
$$\leq c^d \cdot \mathrm{opt}_s(f) + \gamma \cdot \left(\frac{c^d - 1}{c-1}\right) + \frac{s}{2^{d+2}}.$$

The desired result holds by induction. ◀

For readability, Lemma 21 assumes that BuildDT is able to compute round($\mathbb{E}[f]$) in Step 1. To make BuildDT efficient, we would only estimate $\mathbb{E}[f]$ by querying f on uniform random inputs $\boldsymbol{x} \in \{\pm 1\}^n$. If those estimates are computed to accuracy ε', then each leaf of our tree can have up to ε' additional error. This is not an issue since it increases the total error of T, which is simply the average of the error at each leaf, by only ε'.

Finally, we prove Theorem 19:

Proof of Theorem 19. Our goal is to properly learn a size-s' decision tree $g : \{\pm 1\}^n \to \{\pm 1\}$ to accuracy ε'. To do so, we run BuildDT(g, s', d, γ), with d set to

$$d = \log(s'/\varepsilon') - 1,$$

and γ set to

$$\gamma = \frac{\varepsilon'}{2 \cdot \max(2,c)^d} = \frac{\varepsilon'}{2} \cdot (2^{-d})^{\max(1,\log c)} = \frac{\varepsilon'}{2} \cdot \left(\frac{\varepsilon'}{s'}\right)^{\max(1,\log c)}.$$

By Lemma 21, for T the tree BuildDT outputs,

$$\begin{aligned}\mathrm{dist}(T,g) &\leq c^d \cdot \mathrm{opt}_{s'}(g) + \gamma \cdot \frac{c^d - 1}{c-1} + \frac{s'}{2^{d+2}} \\ &\leq 0 + \frac{\varepsilon'}{2 \cdot \max(2,c)^d} \cdot \max(2,c)^d + \frac{s'}{2^{\log(s'/\varepsilon')+1}} \\ &\leq \frac{\varepsilon'}{2} + \frac{\varepsilon'}{2} = \varepsilon'.\end{aligned}$$

Hence, BuildDT produces the desired output. We next argue that it is efficient. During the recursion, BuildDT is called at most s' times in total. Each such call makes $O(ns')$ calls to $\mathcal{E}$. By Lemma 20, those calls to $\mathcal{E}$ each make c/ε calls to $\mathcal{A}$. Hence, the total number of calls to $\mathcal{A}$ is

$$O\left(\frac{n(s')^2}{\gamma}\right) = O\left(\frac{n(s')^2}{\varepsilon'} \cdot \left(\frac{s'}{\varepsilon'}\right)^{\max(1,\log c)}\right) = \mathrm{poly}(n, s', 1/\varepsilon').$$

The total auxiliary computation of BuildDT is bounded by the same quantity. Finally, each call to $\mathcal{A}$ is made with parameters s and ε where $s \leq s'$ and $\varepsilon = \frac{\varepsilon'}{2} \cdot \left(\frac{\varepsilon'}{s'}\right)^{\max(1,\log c)} \geq \mathrm{poly}(1/s', \varepsilon')$. ◀

Sublinear-Round Parallel Matroid Intersection

Joakim Blikstad ✉
KTH Royal Institute of Technology, Sweden

Abstract

Despite a lot of recent progress in obtaining faster sequential matroid intersection algorithms, the fastest *parallel* poly(n)-query algorithm was still the straightforward $O(n)$-round parallel implementation of Edmonds' augmenting paths algorithm from the 1960s.

Very recently, Chakrabarty-Chen-Khanna [FOCS'21] showed the lower bound that any, possibly randomized, parallel matroid intersection algorithm making poly(n) rank-queries requires $\tilde{\Omega}(n^{1/3})$ rounds of adaptivity. They ask, as an open question, if the lower bound can be improved to $\tilde{\Omega}(n)$, or if there can be sublinear-round, poly(n)-query algorithms for matroid intersection.

We resolve this open problem by presenting the first sublinear-round parallel matroid intersection algorithms. Perhaps surprisingly, we do not only break the $\tilde{O}(n)$-barrier in the rank-oracle model, but also in the weaker independence-oracle model. Our rank-query algorithm guarantees $O(n^{3/4})$ rounds of adaptivity, while the independence-query algorithm uses $O(n^{7/8})$ rounds of adaptivity, both making a total of poly(n) queries.

1 Introduction

Matroid intersection. Given two matroids[1] $\mathcal{M}_1 = (V, \mathcal{I}_1)$ and $\mathcal{M}_2 = (V, \mathcal{I}_2)$ over the same n-element ground set V (but with different notions of independence $\mathcal{I}_1, \mathcal{I}_2$), the *matroid intersection problem* is to find the largest common independent set $S^* \subseteq \mathcal{I}_1 \cap \mathcal{I}_2$. This is a fundamental discrete optimization problem that has been studied for over half a century. Matroid intersection can be used to model many important combinatorial optimization problems, such as bipartite matching, finding arborescences, spanning tree packing, etc. As such, matroid intersection is a natural avenue to study all these problems simultaneously.

Oracle access. There are two standard ways to access the matroids – *independence oracles* and *rank oracles* – and we study both in this work. In an *independence-query* we may ask if $S \subseteq V$ is independent in one of the matroids, i.e. a query of the form "Is $S \in \mathcal{I}_1$?" or "Is $S \in \mathcal{I}_2$?" In a *rank-query* we instead ask for the *rank* of $S \subseteq V$ in one of the matroids. The

[1] Matroids are a well-studied combinatorial structure which can be though of as a generalization of the notion of linear independence in vector spaces. For a formally definition, see Definition 4.

rank $\mathrm{rk}_1(S)$ with respect to the matroid $\mathcal{M}_1$ (similarly rk_2 for $\mathcal{M}_2$) is the size of the largest (or, equivalently, any maximal) independent set, w.r.t. $\mathcal{I}_1$, contained in S. Note that the rank oracle is strictly more powerful than the independence oracle, since $S \in \mathcal{I}_1$ if and only if $\mathrm{rk}_1(S) = |S|$.

Parallel matroid intersection. A parallel matroid intersection algorithm accesses the oracle in rounds. In each round, a number of queries – that may only depend on the answers to queries made in previous rounds – can be issued in parallel. There is certainly a trade-off between (1) *adaptivity*, usually measured by the number of rounds, and (2) the total number of queries. When constructing parallel algorithms the goal is often to have as few rounds of adaptivity as possible while making only polynomially many queries in total.

Previous work. Edmonds [10] showed the first polynomial algorithm for matroid intersection in the 1960s, using $O(n^3)$ independence-queries, and there has been a long line of research since then e.g. [1, 2, 3, 5, 6, 8, 9, 10, 18, 19, 21]. Many of these are based on Edmonds' framework of finding *augmenting paths* in the *exchange graph*. In the sequential setting, only recently was the quadratic $O(n^2)$-query-barrier broken, first for rank-queries by Chakrabarty-Lee-Sidford-Singla-Wong in FOCS 2019 [5] and subsequently also for independence-queries by Blikstad-v.d.Brand-Mukhopadhyay-Nanongkai in STOC 2021 [3]. The current state-of-the-art in the sequential setting are the[2] $\tilde{O}(n\sqrt{n})$ rank-query algorithm by [5] and the $\tilde{O}(n^{7/4})$ independence-query algorithm by [2].

When it comes to the *parallel* setting, there is a straightforward $O(n)$-round, $\mathrm{poly}(n)$ independence-query implementation of Edmonds' algorithm: find the (up to $O(n)$ many) augmenting paths one-by-one. Each augmenting path can be found in a single round by querying all the potential edges in the exchange graph. In some special cases of matroid intersection we can do much better: a sequence of work has shown that both bipartite matching [11, 16, 20] and subsequently linear matroid intersection [13, 20] are in RNC[3] and quasi-NC.[4]

Another line of relevant work is showing that, in the parallel setting, the *search*-problem (finding a largest common independent set S) and the *decision*-problem (just finding the size of the answer) are "equivalent" (with only $O(\mathrm{polylog}(n))$ overhead). This is not at all obvious in the parallel setting, however, a recent work from SODA 2022 by Ghosh-Gurjar-Ray [12] shows that this is indeed the case for *weighted* matroid intersection, with rank-oracle access.

In FOCS 1985, Karp-Upfal-Wigderson [15] showed that any *independence-query* algorithm, possibly randomized, that finds a maximum independent set (basis) in a *single* matroid must use $\tilde{\Omega}(n^{1/3})$ rounds of adaptivity if it makes $\mathrm{poly}(n)$ queries. They also show algorithms to find a basis of a (single) matroid in $O(\sqrt{n})$ rounds of independence-queries or a single round of the more powerful rank-queries. Arguably, this polynomial gap between the independence-query ($\tilde{\Omega}(n^{1/3})$ rounds) and rank-query ($O(1)$ rounds) for the seemingly easy problem to find a basis of a matroid illustrates that the independence-query is much weaker than the rank-query when used in parallel algorithms.

Nevertheless, a recent result from FOCS 2021 by Chakrabarty-Chen-Khanna [4] shows that even *rank-query* algorithms require a polynomial number of rounds to solve matroid intersection. In particular, they show a lower bound of $\tilde{\Omega}(n^{1/3})$ rounds of adaptivity for any, possibly randomized, $\mathrm{poly}(n)$ rank-query matroid intersection algorithm.

---

[2] We use the usual convention of hiding $\mathrm{polylog}(n)$-factors with $\tilde{O}$ and $\tilde{\Omega}$ throughout the paper.
[3] Randomized $\mathrm{polylog}(n)$ rounds of adaptivity with $\mathrm{poly}(n)$ total work.
[4] Deterministic $\mathrm{polylog}(n)$ rounds of adaptivity with $n^{O(\log n)}$ total work.

Despite efficient algorithms for some special cases of matroid intersection, the trivial $O(n)$-round algorithm has remained unbeaten in the general case. The major open question (asked, for example, by [4]) is then whether it is possible to beat the $O(n)$-round barrier, or if matroid intersection is inherently very sequential and requires $\tilde{\Omega}(n)$ rounds of adaptivity.

Our results. We answer the above question by showing the first sublinear-round parallel matroid intersection algorithms, both in the rank-oracle and independence-oracle models. In particular, we obtain the following theorem.

▶ **Theorem 1** (Sublinear-round Matroid Intersection). *There is a deterministic parallel algorithm which given two matroids $\mathcal{M}_1 = (V, \mathcal{I}_1)$ and $\mathcal{M}_2 = (V, \mathcal{I}_2)$ on the same ground set V, finds a largest common independent set $S \in \mathcal{I}_1 \cap \mathcal{I}_2$ using either*

- *$O(n^{3/4})$ rounds of polynomially many rank-queries, or*
- *$O(n^{7/8})$ rounds of polynomially many independence-queries.*

Our results, together with the lower bounds of [4, 15], imply that the true adaptivity of matroid intersection is somewhere between $n^{1/3}$ and $n^{3/4}$ (or $n^{7/8}$ for independence queries).

▶ Remark 2. Although we focus on the query-complexity in this paper, we note that the rounds and work in our algorithms are dominated, up to log-factors, by the oracle queries.

1.1 Technical Overview

The exchange graph and augmenting paths. Like many matroid intersection algorithms, we work in Edmonds' framework of finding *augmenting paths* in the *exchange graph*. The *exchange graph* $G(S)$ with respect to a common independent set $S \in \mathcal{I}_1 \cap \mathcal{I}_2$ is a directed bipartite graph, where finding a shortest (s, t)-path – called an *augmenting path* – means that we can increase the size of S by one. In a single round of $O(n^2)$ independence (or rank) queries, we can learn the entire exchange graph, and can thus find an augmenting path if one exists. This immediately gives a straightforward $O(n)$-round algorithm: *find the (up to $O(n)$ many) augmenting paths one-by-one.*

The exchange graph depends on the current common independent set S, and changes after each augmentation. In fact, if we have two disjoint augmenting paths p_1 and p_2 in $G(S)$, it is **not** necessarily the case that we can augment along both of these: augmenting along p_1 might destroy the path p_2 even if they were disjoint.[5] This forms the main difficulty in trying to beat the $O(n)$-round barrier, and illustrates the need in finding several "compatible" augmenting paths which can all be augmented along simultaneously.

Blocking flow. Cunningham [6] was the first to introduce *blocking flow* algorithms to matroid intersection, similar to Hopcroft-Karp's [14] bipartite matching or Dinitz's [7] max-flow algorithms. The idea is to run in phases, where after each phase the length of a shortest augmenting path in the exchange graph has increased. This is done by finding a maximal collection of compatible shortest augmenting paths. Both of the current state-of-the-art sequential $O(n\sqrt{n})$-rank-query [5] and $O(n^{7/4})$-independence-query [2] algorithms are based on versions of these blocking flow ideas. The $O(n\sqrt{n})$-rank-query algorithm still finds the augmenting paths in a sequential way, so it does unfortunately not seem to parallelize well.

[5] This is unlike the case of augmenting path algorithms for bipartite matching or maximum flow, where one can indeed augment along disjoint paths simultaneously.

The $O(n^{7/4})$-independence-query algorithm, on the other hand, is based on a recent notion of *augmenting sets* introduced by Chakrabarty-Lee-Sidford-Singla-Wong [5]. This notion of *augmenting sets* precisely captures what a collection of "compatible" shortest augmenting paths looks like. The authors of [5] also present an algorithm to find such augmenting sets, using independence-queries.

Our contribution is to show that a modified version of the augmenting sets algorithm of [5, Section 6] (which was later improved by [2]) can be implemented in parallel when combined with the parallel matroid-basis finding algorithms of Karp-Upfal-Wigderson [15]. Previous to this work, augmenting sets algorithms have before only been used in the sequential setting, and only in the independence-oracle model. Nevertheless, augmenting sets are what allows us to break the $O(n)$-round barrier also with rank-queries.

2 Preliminaries

We use the standard definitions of *matroid* $\mathcal{M} = (V, \mathcal{I})$; *rank* $\mathrm{rk}(X)$ for any $X \subseteq V$; *exchange graph* $G(S)$ for a *common independent set* $S \in \mathcal{I}_1 \cap \mathcal{I}_2$; and *augmenting paths* in $G(S)$ throughout this paper. For completeness, we define them below. We also need the notions of *augmenting sets* introduced by [5], which we also define in later this section.

▶ **Definition 3** (Set notation)**.** We will use $A + x$ and $A - x$ to denote $A \cup \{x\}$ respectively $A \setminus \{x\}$, as is usual in matroid intersection literature. We will also use $A + B := A \cup B$, and $A - B := A \setminus B$.

Matroids

▶ **Definition 4** (Matroid)**.** A *matroid* is a tuple $\mathcal{M} = (V, \mathcal{I})$ of a *ground set* V of n elements, and non-empty family $\mathcal{I} \subseteq 2^V$ of *independent sets* satisfying:
Downward closure: if $S \in \mathcal{I}$, then $S' \in \mathcal{I}$ for all $S' \subseteq S$.
Exchange property: if $S, S' \in \mathcal{I}$, $|S| > |S'|$, then there exists $x \in S \setminus S'$ such that $S' + x \in \mathcal{I}$.

▶ **Definition 5** (Matroid rank)**.** The *rank* of $A \subseteq V$, denoted by $\mathrm{rk}(A)$, is the size of the largest (or, equivalently, any maximal) independent set contained in A. It is well-known that the rank-function is submodular, i.e. $\mathrm{rk}(A + x) - \mathrm{rk}(A) \geq \mathrm{rk}(B + x) - \mathrm{rk}(B)$ whenever $A \subseteq B \subseteq V$ and $x \in V \setminus B$. Note that $\mathrm{rk}(A) = |A|$ if and only if $A \subseteq \mathcal{I}$.

▶ **Definition 6** (Matroid Intersection)**.** Given two matroids $\mathcal{M}_1 = (V, \mathcal{I}_1)$ and $\mathcal{M}_2 = (V, \mathcal{I}_2)$ over the same ground set V, a *common independent set* S is a set in $\mathcal{I}_1 \cap \mathcal{I}_2$. The *matroid intersection problem* asks us to find the largest common independent set. We use rk_1 and rk_2 to denote the rank functions of the corresponding matroids, and $n = |V|$ to be the size of the ground set.

The Exchange Graph

▶ **Definition 7** (Exchange graph)**.** Given two matroids $\mathcal{M}_1 = (V, \mathcal{I}_1)$ and $\mathcal{M}_2 = (V, \mathcal{I}_2)$ over the same ground set, and a common independent set $S \in \mathcal{I}_1 \cap \mathcal{I}_2$, the *exchange graph* $G(S)$ is a directed bipartite graph on vertex set $V \cup \{s, t\}$ with the following arcs (or directed edges):
1. (s, b) for $b \in V \setminus S$ when $S + b \in \mathcal{I}_1$.
2. (b, t) for $b \in V \setminus S$ when $S + b \in \mathcal{I}_2$.
3. (a, b) for $b \in V \setminus S, a \in S$ when $S - a + b \in \mathcal{I}_1$.
4. (b, a) for $b \in V \setminus S, a \in S$ when $S - a + b \in \mathcal{I}_2$.

We will denote the set of elements at distance k from s by the distance-layer D_k. Note that $D_k \subseteq V \setminus S$ when k is odd and $D_k \subseteq S$ when k is even.

▶ **Definition 8** (Shortest augmenting path)**.** A shortest (s,t)-path $p = (s, b_1, a_2, b_3, a_4, \ldots, a_{\ell-1}, b_\ell, t)$ (with $b_i \in V \setminus S$ and $a_i \in S$) in $G(S)$ is called a *shortest augmenting path*. We can *augment* S along the path p to obtain $S' = S + b_1 - a_2 + b_3 - a_4 \ldots + b_\ell$, which is well-known to also be a common independent set (with $|S'| = |S| + 1$). Conversely, there must exist a shortest augmenting path whenever S is not a largest common independent set.

Augmenting Sets

Augmenting Sets is a notion capturing a "blocking flow" in the exchange graph, and was introduced by [5], and also subsequently used in the algorithms of [2,3]. In order to efficiently find "good" augmenting sets, the algorithm works with a relaxed form of them instead, called *partial* augmenting sets. The following definitions and key properties of (partial) augmenting sets are copied from [5] where one can find the corresponding proofs.

▶ **Definition 9** (Augmenting Sets, from [5, Definition 24])**.** Let $S \in \mathcal{I}_1 \cap \mathcal{I}_2$ and $G(S)$ be the corresponding exchange graph with shortest (s,t)-path of length $\ell + 1$ (ℓ must be odd) and distance layers $D_1, D_2, \ldots, D_\ell$. A collection of sets $\Pi_\ell := (B_1, A_2, B_3, A_4, \ldots, A_{\ell-1}, B_\ell)$[6] form an *augmenting set* in $G(S)$ if the following conditions are satisfied:

(a) $A_k \subseteq D_k$ for even k, and $B_k \subseteq D_k$ for odd k.
(b) $|B_1| = |A_2| = |B_3| = \cdots = |B_\ell|$
(c) $S + B_1 \in \mathcal{I}_1$
(d) $S + B_\ell \in \mathcal{I}_2$
(e) For all even $1 \leq k \leq \ell$, we have $S - A_k + B_{k+1} \in \mathcal{I}_1$
(f) For all odd $1 \leq k \leq \ell$, we have $S - A_{k+1} + B_k \in \mathcal{I}_2$

▶ **Definition 10** (Partial Augmenting Sets, from [5, Definition 37])**.** We say that $\Phi_\ell := (B_1, A_2, B_3, A_4, \ldots, A_{\ell-1}, B_\ell)$ forms a *partial augmenting set* if it satisfies the conditions (a), (c),[7] and (e) of an *augmenting set*, plus the following two relaxed conditions :

(b) $|B_1| \geq |A_2| \geq |B_3| \geq \cdots \geq |B_\ell|$.
(f) For all odd $1 \leq k \leq \ell$, we have $\mathrm{rk}_2(S - A_{k+1} + B_k) = \mathrm{rk}_2(S)$.

▶ **Theorem 11** (from [5, Theorem 25])**.** *Let $\Pi_\ell := (B_1, A_2, B_3, A_4, \cdots, A_{\ell-1}, B_\ell)$ be the an augmenting set in the exchange graph $G(S)$. Then the set $S' := S \oplus \Pi_\ell := S + B_1 - A_2 + B_3 - \cdots - A_{\ell-1} + B_\ell$ is a common independent set.*[8]

We also need the notion of *maximal* augmenting sets, which naturally correspond to a maximal ordered collection of shortest augmenting paths, where, after augmentation, the (s,t)-distance must have increased. Together with a lemma from [6] (Lemma 14), we can see, on a high-level, how to obtain $(1-\varepsilon)$-approximation algorithms: *find "blocking flows" (i.e. maximal augmenting sets) until the (s,t)-distance is $\Omega(1/\varepsilon)$.*

▶ **Definition 12** (Maximal Augmenting Sets, from [5, Definition 35])**.** Let $\Pi_\ell = (B_1, A_2, B_3, \cdots, A_{\ell-1}, B_\ell)$ and $\tilde{\Pi}_\ell = (\tilde{B}_1, \tilde{A}_2, \tilde{B}_3, \cdots, \tilde{A}_{\ell-1}, \tilde{B}_\ell)$ be two augmenting sets in $G(S)$. We say $\tilde{\Pi}_\ell$ *contains* Π_ℓ if $B_k \subseteq \tilde{B}_k$ and $A_k \subseteq \tilde{A}_k$, for all k. An augmenting set Π_ℓ is called *maximal* if there exists no other augmenting set $\tilde{\Pi}_\ell$ containing Π_ℓ.

[6] Our indexing of the sets differ a bit from [2,5].
[7] Note that we intentionally skip item (d), unlike [5] which includes it in the definition, however they do not always maintain this property in their algorithms.
[8] Note that $|S'| = |S| + |B_1|$. In particular, an augmenting set with $|B_1| = 1$ is exactly an augmenting path. [5] shows that augmenting sets correspond exactly to a sequence of consecutive shortest augmenting paths.

▶ **Lemma 13** (from [5, Theorem 36]). *An augmenting set Π_ℓ is maximal if and only if there is no augmenting path of length at most $\ell+1$ in $G(S \oplus \Pi_\ell)$.*

▶ **Lemma 14** (Cunningham [6]). *If the length of the shortest (s,t)-path in $G(S)$ is at least $2\ell+1$, then $|S| \geq (1-O(1/\ell))r$, where r is the size of the largest common independent set.*

3 Warm-up: Finding a *Maximal* Common Independent Set

Consider first the easier problem of finding a *maximal* (instead of *maximum*) common independent set: that is we want to find a set $S \in \mathcal{I}_1 \cap \mathcal{I}_2$ such that there is no $x \in V \setminus S$ for which $S + x \in \mathcal{I}_1 \cap \mathcal{I}_2$. It is well-known that a maximal common independent set is also a $\frac{1}{2}$-approximation for the matroid intersection problem, and indeed our algorithm for a general $(1-\varepsilon)$-approximation (Section 4) will use similar ideas as our algorithm to find a *maximal* common independent set in this section.

In the sequential setting there is a very easy $O(n)$-query greedy algorithm: *Start with $S = \emptyset$ and go through all elements $x \in V$ and add them to S if $S + x$ is independent in both matroids.* However, this greedy algorithm is inherently very sequential and does not seem to adapt well to the parallel setting. Instead, we must somehow try to find several xs "in parallel" which we can all add to S simultaneously without breaking independence.

3.1 One Matroid

Let us start even simpler, and consider how to find a *maximal* independent set[9] S in a single matroid $\mathcal{M} = (V, \mathcal{I})$. It turns out that in our final matroid intersection algorithm we will many times, as a subroutinue, need to do exactly this.

Karp-Upfal-Wigderson [15] provides some simple parallel algorithms (both for rank- and independence-oracle access), whose results we present in Lemma 15. We briefly sketch their algorithms below, more details and full proofs can be found in [15, 17].

Rank Oracle. The rank-query algorithm only needs a single round. Let $\{v_1, v_2, \ldots, v_n\} = V$ be the elements of the ground set, and let $V_i = \{v_1, v_2, \ldots, v_{i-1}, v_i\}$ (so that $V_0 = \emptyset$ and $V_n = V$). Now query $\mathrm{rk}(V_i)$ for all i, and return $S = \{v_i : \mathrm{rk}(V_i) > \mathrm{rk}(V_{i-1})\}$. Intuitively, we can imagine that we go through all elements v_i one-by-one and add them to S if and only if the rank goes up.

Independence Oracle. The independence-query algorithm will need $O(\sqrt{n})$ rounds of $O(n)$ queries per round. Partition the elements of V into $\sqrt{n}$ different groups of (almost) equal size $F_1, F_2, \ldots F_{\sqrt{n}}$. If any group is independent (say F_i), then we select it, and consider the contracted matroid $\mathcal{M}/F_i$. Note that this can only happen $\sqrt{n}$ times. On the other hand, if all F_i are dependent, then we will find one element per group (that is $\sqrt{n}$ in total) which we can safely discard: If $\{v_1, v_2, \ldots, v_k\} = F_i$ are the elements of F_i, we query all prefixes, i.e. "Is $\{v_1, v_2, \ldots, v_j\} \in \mathcal{I}$?" for all j, and discard the first element v_j for which the answer is "No".

[9] Such a set S is usually called a *basis* of the matroid, and due to the exchange-property all the maximal independent sets must have the same size.

▶ **Lemma 15** (Parallel basis algorithm, [15]). *There is a deterministic parallel algorithm which given a matroids $\mathcal{M} = (V, \mathcal{I})$ finds a **maximal** independent set $S \in \mathcal{I}$ using either*

- *$O(1)$ round of $O(n)$ many rank-queries, or*
- *$O(\sqrt{n})$ rounds of $O(n)$ many independence-queries.*[10]

▶ Remark 16. Note that if we have a set $X \in \mathcal{I}$ and $Y \subseteq V \setminus X$, we can with the same algorithms as above find a maximal $Y' \subseteq Y$ such that $X + Y' \in \mathcal{I}$, even though the above algorithms are only stated as if $X = \emptyset$ and $Y = V$. This is since we can consider the contracted and restricted matroid $\mathcal{M}' = (\mathcal{M} \,/\, X) \setminus (V \setminus Y)$; and an independence/rank-query on $\mathcal{M}'$ can be simulated with the corresponding query on $\mathcal{M}$.

3.2 Two Matroids

Now we return to our problem of finding a maximal common independent set S of two matroids $\mathcal{M}_1 = (V, \mathcal{I}_1)$ and $\mathcal{M}_2 = (V, \mathcal{I}_2)$. Suppose we already have some common independent set $S \in \mathcal{I}_1 \cap \mathcal{I}_2$. We will try to add more elements to S until it becomes maximal.

Firstly, let us concentrate on the first matroid and pick a maximal set $B \subseteq V$ such that $S + B \in \mathcal{I}_1$ using Lemma 15. However, $S + B$ is not necessarily independent in the second matroid, so we would need to fix this: let $B' \subseteq B$ be a maximal subset such that $S + B' \in \mathcal{I}_2$, which we again can find using Lemma 15. Now we know $S + B' \in \mathcal{I}_1 \cap \mathcal{I}_2$ is a common independent set, so we set $S \leftarrow S + B'$, and we have made some progress (unless $B' = \emptyset$ of course).

At this point we can make a crucial observation: *we can safely discard the elements $x \in B \setminus B'$, since now $S + x \notin \mathcal{I}_2$.* Hence, for each element in B we have either (i) added it to our common independent set or (ii) discarded it. As long as $|B|$ is relatively large (say $\approx \sqrt{n}$), we have made significant progress.

On the other hand, if $|B|$ is small, we may resort to a different strategy. By the exchange property of matroids, we know that any $A \subseteq V$ such that $S + A \in \mathcal{I}_1$ has size $|A| \leq |B|$. So we can add at most $|B|$ more elements to our common independent set S before it becomes maximal. We can thus simply find these remaining (up to $|B|$ many) elements one-by-one, using one round each.

We present this two-stage strategy below in Algorithm 1, which is parametrized by the cut-off threshold p for when to consider $|B|$ small. The optimal choice of p differs depending on the oracle access (independence or rank) we have.

Adaptivity. The first stage of Algorithm 1 runs in $O(n/p \cdot \mathcal{T}_{\text{basis}})$ rounds if $\mathcal{T}_{\text{basis}}$ is the number of rounds needed to find a maximal independent set for a single matroid (Lemma 15 gives $\mathcal{T}^{\text{rank}}_{\text{basis}} = O(1)$ and $\mathcal{T}^{\text{indep}}_{\text{basis}} = O(\sqrt{n})$). This is since the size of F will decrease by $|B| \geq p$ each time the while-loop is run, which can happen at most n/p times. The second stage of Algorithm 1 runs in $O(p)$ rounds, both for independence and rank-oracle. Picking p optimally gives: $O(\sqrt{n})$ rounds of rank-queries (with $p = \sqrt{n}$); or $O(n^{3/4})$ rounds of independence-queries (with $p = n^{3/4}$). This proves Theorem 17, stated below.

▶ **Theorem 17.** *There is a deterministic parallel algorithm which given two matroids $\mathcal{M}_1 = (V, \mathcal{I}_1)$ and $\mathcal{M}_2 = (V, \mathcal{I}_2)$ on the same ground set V, finds a **maximal** common independent set $S \in \mathcal{I}_1 \cap \mathcal{I}_2$ using either*

- *$O(\sqrt{n})$ rounds of polynomially many rank-queries, or*
- *$O(n^{3/4})$ rounds of polynomially many independence-queries.*

[10] KUW [15] also provides a lower bound of $\tilde{\Omega}(n^{1/3})$ rounds for any independence-query algorithm which uses only polynomial number of queries per round, even if randomization is allowed. It remains an open problem to close this gap between $\tilde{\Omega}(n^{1/3})$ and $O(\sqrt{n})$.

Algorithm 1 Maximal Common Independent Set.

Let $S = \emptyset$ and $F = V$.
while true **do** ▷ Stage 1
  Find a maximal $B \subseteq F$ such that $S + B \in \mathcal{I}_1$ (using Lemma 15).
  if $|B| \leq p$ **then break**
  Find a maximal $B' \subseteq B$ such that $S + B' \in \mathcal{I}_2$ (using Lemma 15).
  Update $S \leftarrow S + B'$ and $F \leftarrow F - B$.
while true **do** ▷ Stage 2
  Query "Is $S + x \in \mathcal{I}_1$" and "Is $S + x \in \mathcal{I}_2$?" for all $x \in F$ in parallel.
  Pick an arbitrary $x \in F$ such that $S + x \in \mathcal{I}_1$ and $S + x \in \mathcal{I}_2$.
  if no such x exists **then break**
  Update $S \leftarrow S + x$ and $F \leftarrow F - x$.

4 Finding a *Maximum* Common Independent Set

In this section we present our sublinear-round matroid intersection algorithm.

The algorithm consists of two steps: first it finds an $(1-\varepsilon)$-approximation, and then it finds the remaining εn (which is sublinear if $1/\varepsilon$ is polynomially large in n) augmenting paths one-by-one. Each such remaining augmenting path can be found in a single round of n^2 independence (or rank) queries: in parallel query each possible edge of the exchange graph, and then see if there was an augmenting path. Indeed, when we know all the edges of the exchange graph, we do not need any more (rounds of) queries to figure out if there was an path.[11] If we skipped the $(1-\varepsilon)$-approximation step and just found all the augmenting paths one-by-one we obtain the straightforward $O(n)$-round algorithm.

The difficult part of the algorithm is how to find the $(1-\varepsilon)$-approximation in sublinear number of rounds (even when $1/\varepsilon$ is polynomially large). To do this, we would need to find many augmenting paths simultaneously, and indeed this is our strategy. Our main result of this section is this approximation algorithm which we summarize in Theorem 18 below.

▶ **Theorem 18** (Sublinear-round $(1-\varepsilon)$-approximation). *There is a deterministic parallel algorithm which given two matroids $\mathcal{M}_1 = (V, \mathcal{I}_1)$ and $\mathcal{M}_2 = (V, \mathcal{I}_2)$ on the same ground set V, finds a common independent set $S \in \mathcal{I}_1 \cap \mathcal{I}_2$ of size $|S| \geq (1-\varepsilon)r$, where r is the size of the largest common independent set, using either*

- *$O(\sqrt{n}/\varepsilon)$ rounds of polynomially many rank-queries, or*
- *$O(n^{3/4}/\varepsilon)$ rounds of polynomially many independence-queries.*

Exact algorithm. By an appropriate choice of ε ($\varepsilon = n^{-1/4}$ for rank-oracle and $\varepsilon = n^{-1/8}$ for independence-oracle), together with our discussion above, the main result (Theorem 1, restated below) of the paper – the sublinear-round exact algorithm – follows immediately from Theorem 18. The remainder of this paper will go towards proving Theorem 18, i.e. the $(1-\varepsilon)$-approximation algorithm.

▶ **Theorem 1** (Sublinear-round Matroid Intersection). *There is a deterministic parallel algorithm which given two matroids $\mathcal{M}_1 = (V, \mathcal{I}_1)$ and $\mathcal{M}_2 = (V, \mathcal{I}_2)$ on the same ground set V, finds a largest common independent set $S \in \mathcal{I}_1 \cap \mathcal{I}_2$ using either*

- *$O(n^{3/4})$ rounds of polynomially many rank-queries, or*
- *$O(n^{7/8})$ rounds of polynomially many independence-queries.*

[11] Note that if we also care about the number of rounds of work of the algorithm (and not just the rounds of *queries*), we can find the augmenting path in the exchange graph in just poly(n) rounds, as s,t-reachability is well-known to be in NC.

4.1 Blocking Flow

The approximation algorithm maintains a common independent set S and runs in $O(1/\varepsilon)$ phases, where in the i'th phase it eliminates all augmenting paths of length $2i$ by finding a blocking flow, similar to the Hopcroft-Karp's [14] bipartite matching algorithm and Dinitz's [7] max-flow algorithm. By *blocking flow* we mean a set of compatible shortest augmenting paths after which augmenting along them the (s,t)-distance in the exchange graph has increased. At the end, by Lemma 14, we will have found a common independent set S which is a $(1-\varepsilon)$-approximation, since the shortest augmenting path will have length $O(1/\varepsilon)$.

This idea of applying blocking flow algorithms to matroid intersection originates from the algorithm of Cunningham [6], but has since been improved by Chakrabarty-Lee-Sidford-Singla-Wong [5] and subsequently Blikstad [2], and it is the framework of these two later algorithms which we will follow.

▶ Remark 19. In the first phase we will eliminate all augmenting paths of length 2. This corresponds exactly to finding a *maximal* common independent set, like we did in Section 3. In general, we will show that we can implement any phase in the same round-complexity as the first phase, using similar ideas.

Beginning of a phase. In each phase, we consider a layered graph, where we let the *distance-layer* D_i denotes all the elements of distance i from the source node s in the exchange graph $G(S)$. At the beginning of a phase, the algorithm will use a single round (of $O(n^2)$ queries) to find these distance layers: simply query all potential edges of the exchange graph.

Unfortunately, knowing all the edges in the exchange graph is not sufficient to find a blocking flow, since a set of disjoint augmenting paths might not be compatible with each other. The exchange graph $G(S)$ does not capture the full structure of the matroid intersection problem, and this is where the difficulty in obtaining sublinear-round matroid intersection algorithms comes from. There is a need to be able to find many compatible augmenting paths "in parallel".

Augmenting sets. The notion of a collection of *compatible*[12] augmenting paths is captured by *augmenting sets*, as defined in Definition 9. So our goal in a phase is to find a *maximal* augmenting set (see Definition 12), which is what we formally mean by "blocking flow". After augmenting along a maximal augmenting set, Lemma 13 implies that the (s,t)-distance has increased, and we can move on to the next phase.

Our algorithm will follow the framework of [5] and [2], which are the state-of-the-art sequential independence-query approximation algorithms. The overall idea can be seen as a generalization of the warm-up *maximal* common independent set algorithm from Section 3. Instead of working with just a single distance layer in the exchange graph we now have up to $O(1/\varepsilon)$ many layers. Fortunately, layers far apart from each other can be handled relatively well in parallel, and we will see that the final adaptivity of our algorithm to find a blocking flow in a phase will not depend on the number of layers.

We start by, on a high level, summarizing how the algorithm of [2, 5] implements a phase in two stages. Our main result is how we can implement this algorithm efficiently in a parallel.

[12] That is they can all be augmented along simultaneously without breaking independence in either matroid.

1. The first stage keeps track of a *partial* augmenting set (Definition 10) which it keeps *refining* by a series of operations on adjacent distance layers in the exchange graph, to make it closer to a *maximal* augmenting set.
2. When we are "close enough" to a maximal augmenting set, the progress we make in the first stage slows down. Then we fall back to the second stage in which we find the relatively few remaining augmenting paths individually one at a time.

4.2 First Stage: Refining

The basic refining ideas and procedures in this section are the same as in [2,5]; our contribution is to show how they can be implemented in a parallel fashion.

Say we are in the phase where the (s,t)-distance is $\ell+1$, that is we have ℓ layers in our exchange graph. The algorithm keeps track of a partial augmenting set $\Phi_\ell = (B_1, A_2, B_3, \ldots, A_{\ell-1}, B_\ell)$ (see Definition 10), which it makes local improvements to, called *refining*. Essentially Φ_ℓ looks like a stair-case: B_{k+1} is a set which can be "matched" to some subset of the previous layer A_k; and similarly A_{i+1} can be "matched" to a subset of B_i. As long as Φ_ℓ is "far" from being a maximal augmenting set, the refinement procedures make significant progress. When Φ_ℓ becomes "close" to being a maximal augmenting set we move on to the second stage.

We maintain three types of elements in each layer D_k in the exchange graph.
Selected. Sets A_k and B_k form the partial augmenting set Φ_ℓ.
Removed. Sets R_k contain the discarded elements which we have deemed useless.
Fresh. Sets F_k contain the elements which are neither selected nor removed.

All elements are initially fresh, and for convenience we also define "imaginary" empty boundary layers $D_0 = D_{\ell+1} = \emptyset$, with corresponding sets $A_0, R_0, F_0, A_{\ell+1}, R_{\ell+1}, F_{\ell+1}$. Note that (A_k, R_k, F_k) forms a partition of $D_k \subseteq S$ when k is even, and that (B_k, R_k, F_k) partitions $D_k \subseteq V \setminus S$ when k is odd.

The idea of the refinement procedures is to make some local improvements to adjacent distance-layers. While doing this, we make sure that elements only change their types from *fresh* $\to$ *selected* $\to$ *removed*, but never in the other direction. In order to formalize that the removed elements are actually useless, we maintain the following *phase invariants*.

▶ **Definition 20** (Phase Invariants, from [5, Section 6.3.2])**.** The *phase invariants* are:
(a-b) $\Phi_\ell = (B_1, A_2, B_3, \ldots, A_{\ell-1}, B_\ell)$ forms a partial augmenting set.[13]
(c) For all even k, $\mathrm{rk}_1(W - R_k) = \mathrm{rk}_1(W) - |R_k|$ where $W = S - A_k + (D_{k+1} - R_{k+1})$.[14]
(d) For all odd k, $\mathrm{rk}_2(W + R_k) = \mathrm{rk}_2(W)$ where $W = S - (D_{k+1} - R_{k+1}) + B_k$.

▶ Remark 21. Invariant (c) and (d) essentially says that if R_{k+1} is useless, then so is R_k, for both even and odd layers, and thus, by induction, all removed elements are indeed useless. For example, (d) says that any element $x \in R_k$ does not increase the rank, even if we take away all non-useless elements $(D_{k+1} - R_{k+1})$ in the next layer. Hence such an x cannot be "matched" to any non-useless element in the next layer, so it is safe to discard it, since we will never be able to add it to B_k while maintaining that $(\ldots, B_k, A_{k+1}, \ldots)$ form an partial augmenting set.

[13] The naming of this invariant as (a-b) is to be consistent with [5] where this condition is split up into two separate items (a) and (b).
[14] This invariant differs from [5], where it was written in the following equivalent form: For $1 \le k \le \ell/2$, for any $X \subseteq B_{2k+1} + F_{2k+1} = D_{2k+1} - R_{2k+1}$, if $S - (A_{2k} + R_{2k}) + X \in \mathcal{I}_1$ then $S - A_{2k} + X \in \mathcal{I}_1$.

4.2.1 Refining Locally

We now present the basic refinement procedures from [5], which are operations on two neighboring layers. We note that [2] improves upon the algorithm of [5] (in the sequential setting) by considering refinement operations on **three** consecutive layers instead. Unfortunately, the three-layer refinement procedures of [2] does not seem to work efficiently in the parallel setting.

Intuitively, for an even k, `RefineAB`(k) tries to extend B_{k+1} as much as possible while it still can be "matched" from A_k in the previous layer (i.e. while $S - A_k + B_{k+1} \in \mathcal{I}_1$). After this, if $|A_k| > |B_{k+1}|$, we can remove elements from A_k and argue that they are useless (if they were useful, then it should have been possible to "match" them to something more in the next layer, but this is not the case since B_{k+1} could not be extended more). So `RefineAB`(k) extends B_{k+1} and shrinks A_k so that they are the same size. Doing so, $|A_k^{old}| - |B_{k+1}^{old}|$ elements have changed types, and this crucial observation is what allows us to measure progress. For an odd k, `RefineBA`(k) works very similarly, but now between the consecutive layers (B_k, A_{k+1}).

Algorithm 2 `RefineAB`(k) for even k. (called `Refine1` in [5, Algorithm 9])

1: Find a maximal $B \subseteq F_{k+1}$ s.t. $S - A_k + B_{k+1} + B \in \mathcal{I}_1$
2: $B_{k+1} \leftarrow B_{k+1} + B, \quad F_{k+1} \leftarrow F_{k+1} - B$
3: Find a maximal $A \subseteq A_k$ s.t. $S - A_k + B_{k+1} + A \in \mathcal{I}_1$
4: $A_k \leftarrow A_k - A, \quad R_k \leftarrow R_k + A$

Algorithm 3 `RefineBA`(k) for odd k. (called `Refine2` in [5, Algorithm 10])

1: Find a maximal $B \subseteq B_k$ s.t. $S - (D_{k+1} - R_{k+1}) + B \in \mathcal{I}_2$
2: $R_k \leftarrow R_k + B_k - B, \quad B_k \leftarrow B$
3: Find a maximal $A \subseteq F_{k+1}$ s.t. $S - (D_{k+1} - R_{k+1}) + B_k + A \in \mathcal{I}_2$
4: $A_{k+1} \leftarrow A_{k+1} + F_k - A, \quad F_k \leftarrow A$

▶ Remark 22. When we are in the first phase, that is when there is only a single layer between s and t in the graph, running `RefineAB`(0) and `RefineBA`(1) corresponds to our warm-up algorithm to find a *maximal* common independent set from Section 3. In particular `RefineAB`(0) finds a maximal B_1 such that $S + B_1 \in \mathcal{I}_1$, and `RefineAB`$(1)$ shrinks B_1 such that $S + B_1 \in \mathcal{I}_2$ too.

▶ **Lemma 23.** *`RefineAB` and `RefineBA` can each be implemented in either:*

- $O(1)$ *rounds of polynomially many rank-queries, or*
- $O(\sqrt{n})$ *rounds of polynomially many independence-queries.*

Proof. The refine procedures only need to find a maximal independent set (for a single matroid) twice, so we can apply Lemma 15. ◀

The following properties are proven in [5].

▶ **Lemma 24** (from [5, Lemmas 40-42])**.** *Both `RefineAB` and `RefineBA` preserve the phase invariants. Also: after `RefineAB`(k) is run, we have $|A_k| = |B_{k+1}|$ (unless $k = 0$). After `RefineBA`(k) is run, we have $|B_k| = |A_{k+1}|$ (unless $k = \ell$).*

▶ **Observation 25.** *Lemma 24 can be used to messure progress. In particular, after running* `RefineAB`(k)*,* $|A_k| = |B_{k+1}|$*, so a total of* $|A_k^{old}| - |B_{k+1}^{old}|$ *elements must have changed types (*$x \in A_k^{old}$ *might have been* removed*, while a* $x \in F_{k+1}^{old}$ *might have been* selected*). Similarly* `RefineBA`(k) *will change types of* $|B_k^{old}| - |A_{k+1}^{old}|$ *elements. Note that each element can only change type at most twice (from* fresh *to* selected *to* removed*), so this observation can be used to measure progress.*

4.2.2 Refining Globally

In the sequential algorithms of [2, 5], a refinement pass consists of running `RefineAB`(k) and `RefineAB`(k) for all k in sequence. However, in the parallel setting we can do better. Since `RefineAB` and `RefineBA` only change things locally in two adjacent layers, we observe that we can perform several of these refinement operations in parallel.

Algorithm 4 `Refine`().

1: In parallel, run `RefineAB`(k) for all even $0 \leq k \leq \ell$.
2: In parallel, run `RefineBA`(k) for all odd $0 \leq k \leq \ell$.

▶ **Lemma 26.** *`Refine` can be implemented in either:*
- $O(1)$ *rounds of polynomially many rank-queries, or*
- $O(\sqrt{n})$ *rounds of polynomially many independence-queries.*

The following Lemma 27 will be useful to bound the number of `Refine` calls needed in our final algorithm, and is similar to [5, Corollary 43].

▶ **Lemma 27.** *Suppose that* $|B_k| = |A_{k+1}|$ *for all odd* $1 \leq k \leq \ell - 1$ *and that* $S + B_\ell \in \mathcal{I}_2$*, before `Refine` is run. After `Refine` is run we have:*

(i) $|B_k| = |A_{k+1}|$ *for all odd* $1 \leq k \leq \ell - 1$*, still.*
(ii) $S + B_\ell \in \mathcal{I}_2$*, still.*
(iii) $|B_1'| - |B_\ell|$ *elements have changed their type, where* B_1' *is any maximal subset of* $(D_1 - R_1)$ *such that* $S + B_1' \in \mathcal{I}_1$*.*

Proof. Property (i) is true, since it is true just after we run `RefineBA`(k), by Lemma 27, and this is what is done in the last step of `Refine`. Similarly property (ii) is true, since `RefineBA`(ℓ) ensures this when "shrinking" B_ℓ (see how B is picked in Algorithm 3 line 1).

What remains is to prove property (iii). Let $(B_1^{old}, A_2^{old}, \ldots)$ be the sets before `Refine` is run. In the first line of Algorithm 4, we run `RefineAB`(2), `RefineAB`(4), `RefineAB`(6), …, which according to Lemma 24 and Observation 25, has incurred a total of $\sum |A_k^{old}| - |B_{k+1}^{old}| = |B_1^{old}| - |B_\ell^{old}|$ type-changes (the sum telescopes since we assume $|B_{k-1}^{old}| = |A_k^{old}|$).

Also note that we run `RefineAB`(0), which extends B_1 until it is a maximal subset of $D_1 \setminus R_1$ such that $S + B_1 \in \mathcal{I}_1$ (line 1 of Algorithm 2). This means that an additional $|B_1'| - |B_1^{old}|$ elements have changed their type – from *fresh* to *selected* – in the first layer, where B_1' is the value of B_1 we get after running `RefineAB`(0). Note that this B_1' is a maximal subset of $(D_1 - R_1)$ such that $S + B_1' \in \mathcal{I}_1$ (see line 1 of Algorithm 2).

Hence, in the first line of Algorithm 4, $|B_1'| - |B_\ell|$ types have changed. We might additionally change types of more elements when running the second line of Algorithm 4. ◀

▶ Remark 28. We measure progress in terms of Lemma 27. Since each element can only change types twice (from *fresh* ↦ *selected* ↦ *removed*), there will be in total $O(n)$ type-changes. If we just run `Refine`, we might need to do so $O(n)$ times (in the case when $|B_1'| - |B_\ell|$ is

constant), so this is not good enough to obtain a sublinear round parallel algorithm. Like we did in the easier case of *maximal* common independent set, we must swap to a different strategy when the progress of refining stagnates, i.e. when $|B'_1| - |B_\ell|$ is relatively small.

4.3 Second Stage: Finding the Remaining Augmenting Paths

When $|B'_1| - |B_{\ell+1}|$ is relatively small, we fall back to finding a special kind of augmenting paths one-by-one. We will show that we only need to find $|B'_1| - |B_{\ell+1}|$ many such paths before we get stuck and have found our *maximal* augmenting set (i.e. the desired blocking flow). These special kind of augmenting paths we consider are essentially augmenting paths in the exchange graph *with respect to our partial augmenting set*. They were first introduced by [2], and are called *valid paths*.

▶ **Definition 29** (Valid path, from [2, Definition 31]). $(b_i, a_{i+1}, b_{i+2}, \ldots, a_{\ell-1}, b_\ell, t)$ is a *valid path* (w.r.t. our partial augmenting set) *starting at* b_i if for all $k \geq i$:

(a) $a_k \in F_k$ for even k and $b_k \in F_k$ for odd k.
(b) $S - A_{i-1} + B_i + b_i \in \mathcal{I}_1$.
(c) $S + B_\ell + b_\ell \in \mathcal{I}_2$.
(d) $S - A_{k+1} + B_k - a_{k+1} + b_k \in \mathcal{I}_2$ for odd k.
(e) $S - A_k + B_{k+1} - a_k + b_{k+1} \in \mathcal{I}_1$ for even k.

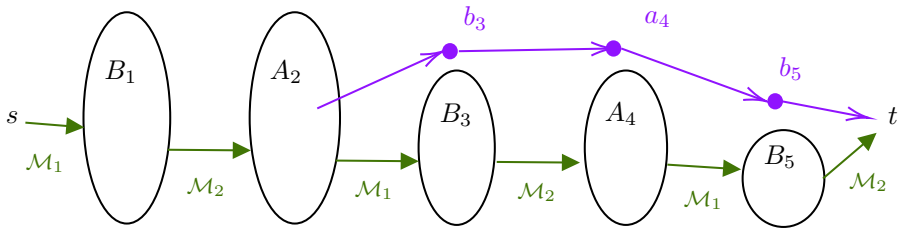

Figure 1 An example of a valid path (b_3, a_4, b_5, t) starting at b_3.

▶ Remark 30. Compare the definition of valid paths to the edges in the exchange graph from Definition 7. Essentially, items (b-e) corresponds to edges of the exchange graph $G(S + B_1 - A_2 + B_3 - A_4 + \cdots + B_\ell)$ of S *after* augmenting along our partial augmenting set. Note also that item (b) can only hold when $|A_{i-1}| > |B_i|$ (or, when $i = 1$ and $A_0 = \emptyset$ is an "imaginary" boundary set).

▶ **Lemma 31** (Augmenting along a valid path [2, Lemma 33]). *Suppose that* $|B_k| = |A_{k+1}|$ *for all odd* $1 \leq k \leq \ell - 1$ *and that* $S + B_\ell \in \mathcal{I}_2$.[15] *If* $(b_i, a_{i+1}, b_{i+2}, \ldots, b_\ell, t)$ *is a valid path starting at* b_i*, then* $(B_1, A_2, \ldots, B_{i-2}, A_{i-1}, B_i + b_i, A_{i+1} + a_{i+1}, \ldots, B_\ell + b_\ell)$ *is a partial augmenting set satisfying the phase invariants and with* $S + B_\ell + b_\ell \in \mathcal{I}_2$.

Proof sketch. It is easy to verify that all the properties in the definition of a partial augmenting set are still satisfied after the augmentation. Moreover, the phase invariants are also true, since the sets B_k and A_k are only extended by the augmentation (so an element deemed useless before remains useless). ◀

[15] These conditions are actually redundant, since they are covered by items (d) and (c) in the definition of the valid paths. However, they make the intuition slightly easier, and our algorithm maintains them.

▶ **Lemma 32.** *We can find a valid path, if one exists, in a single round of $O(n^2)$ queries.*

Proof. Finding a valid path in a single round of queries is not very different from finding a normal augmenting path. In a single round we query all potential "directed edges", that is all potential (a_k, b_{k+1}) or (b_k, a_{k+1}) pairs satisfying the items of Definition 29 (valid paths). Then we can combine these edges to form a valid path, or else determine that no valid path exist. ◀

▶ Remark 33. After augmenting along a valid path, $|B_\ell|$ increases by one. Let B_1' be any any maximal subset of $(D_1 - R_1)$ such that $S + B_1' \in \mathcal{I}_1$. Note that we always know that $|B_1'| \geq |B_1| \geq |B_\ell|$. Hence, we need to only find at most $|B_1'| - |B_\ell|$ many valid paths to augment along after we finished the first stage.

We also need the following lemma saying that if, for an element $x \in F_k$, there is no "partial" valid path $(x, \ldots, a_{\ell-1}, b_\ell, t)$ (satisfying all items of a valid path, except maybe item (b) of Definition 29), then it is safe to delete x. We prove this by showing that if x has no "out-edges" (of the form of items (c-e) in Definition 29), then it can be removed.

▶ **Lemma 34.** *Suppose that $|B_k| = |A_{k+1}|$ for all odd $1 \leq k \leq \ell - 1$ and that $S + B_\ell \in \mathcal{I}_2$. Then:*

- *If $b_\ell \in F_k$ is such that $S + B_\ell + b_\ell \notin \mathcal{I}_2$, we can safely remove it.*
- *For a given $b_k \in F_k$, if there exist no $a_{k+1} \in F_{k+1}$ such that $S - A_{k+1} + B_k - a_{k+1} + b_k \in \mathcal{I}_2$, then it is safe to remove b_k.*
- *For a given $a_k \in F_k$, if there exist no $b_{k+1} \in F_{k+1}$ such that $S - A_k + B_{k+1} - a_k + b_{k+1} \in \mathcal{I}_1$, then it is safe to remove a_k.*

Proof sketch. We must argue that the phase invariants are preserved when the elements are removed. It is straightforward to verify that phase invariants (c) and (d) hold in all these three cases. As a black-box intuition, we can imagine temporarily selecting the element x we want to remove, and then running either `RefineAB` or `RefineBA` and note that this procedure can immediately remove x again (and the refine-procedures preserves the invariants). ◀

4.4 Combining the Stages

Now we present the full algorithm of a phase, whose goal is to find a maximal augmenting set, that is a "blocking flow". Pseudo-code can be found in Algorithm 5, which is parametrized by a cut-off threshold p (which will be different for rank- and independence-query) for when to move from the first to second stage.

▶ Remark 35. After the two stages, we will have some partial augmenting set $(B_1, A_2, \ldots, B_\ell)$ such that there are no more valid paths. However, it is not yet an actual augmenting set, for instance it can be the case that $|A_k| > |B_{k+1}|$ for some k. Still, we can argue that $(B_1, A_2, \ldots, B_\ell)$ contains some *maximal augmenting set* $(\tilde{B}_1, \tilde{A}_2, \ldots, \tilde{B}_\ell)$ with $\tilde{B}_\ell = B_\ell$. So we will need a short extra clean-up step to reduce our partial augmenting set to such a maximal augmenting set.

Note that it is possible to show that we actually can directly augment along our partial augmenting set $(B_1, A_2, \ldots, B_\ell)$ which the algorithm finds (this relies on the extra properties that $|B_k| = |A_{k+1}|$ and $S + B_\ell \in \mathcal{I}_2$). That is $S' = S + B_1 - A_2 + B_2 - \cdots + B_\ell \in \mathcal{I}_1 \cap \mathcal{I}_2$ is a common independent set. Additionally $|S'| = |S| + |B_\ell|$, so we have increased the size of S as much as we would have if we found the the maximal augmenting set $(\tilde{B}_1, \tilde{A}_2, \ldots, \tilde{B}_\ell)$ instead. However, there is a critical problem with this approach: *there can be short augmenting paths in $G(S')$*. This means that such an approach will have failed to eliminate all (s,t)-paths of length $\leq \ell$. Hence the clean-up step is actually necessary.

Algorithm 5 Implementation of phase $(\ell+1)/2$.

1: In parallel query all potential edges of the exchange graph $G(S)$ (see Definition 7).
2: Find the distance layers $D_1, D_2, \dots D_\ell$.
3: Initialize $B_k = \emptyset$, $A_k = \emptyset$, $R_k = \emptyset$ and $F_k = D_k$ for all k.

4: **while** true **do** ▷ Stage 1
5: Find a maximal $B' \subseteq D_1 - R_1$ such that $S + B' \in \mathcal{I}_1$ (using Lemma 15).
6: **if** $|B'| - |B_\ell| \leq p$ **then break**
7: Call `Refine`() (Algorithm 4).

8: **while** true **do** ▷ Stage 2
9: In a single round, find a valid path if one exists (Lemma 32).
10: **if** no valid path exists **then break**
11: Augment the partial augmenting set along the found valid path (Lemma 31).

▷ Clean-up
12: Remove all elements which do not have any partial valid path from them (see Lemma 34).
13: Sequentially, call $\texttt{RefineBA}(\ell), \texttt{RefineAB}(\ell-1), \texttt{RefineBA}(\ell-2), \dots \texttt{RefineAB}(0)$
14: Augment along the *maximal augmenting set* $\Phi = (B_1, A_2, \dots, B_\ell)$:
15: that is, update $S \leftarrow S + B_1 - A_2 + B_3 + \dots + B_\ell$.

Correctness. In the beginning of Algorithm 5 the following hold: (i) the phase invariants (Definition 20); (ii) $|B_k| = |A_{k+1}|$ for all odd $1 \leq k \leq \ell - 1$; and (iii) $S + B_\ell \in \mathcal{I}_2$.

In the first stage, whenever we call `Refine`, the above properties (i-iii) are all preserved according to Lemma 27. Similarly, in the second stage, whenever we augment along a valid path, the above properties (i-iii) are also preserved, by Lemma 31.

What remains to be shown is that after the clean-up phase, $\Phi = (B_1, A_2, \dots, B_\ell)$ is a maximal augmenting set. We prove this by showing that these refine calls cannot *select* any new elements, that is they do not add any elements to the sets B_k or A_k. If we show this, then we know that $|B_\ell| = |A_{\ell-1}| = \dots = |B_1|$ after all these refine calls, as $\texttt{RefineAB}(\ell-1)$ reduced $|A_{\ell-1}|$ to match $|B_\ell|$; $\texttt{RefineBA}(\ell-2)$ reduces $|B_{\ell-2}|$ to match $|A_{\ell-1}|$; etc.

To argue that $\texttt{RefineAB}(k)$ does not select any new elements, we note that if it added b_k to B_k, it meant that $S - A_{k+1} + B_k + b_k \in \mathcal{I}_1$. However, since b_k was not removed in line 12 of the algorithm, there must have been a valid path starting from b_k, which is a contradiction. The argument for $\texttt{RefineBA}(k)$ is the same. Note that since we only remove elements, no new valid paths can occur.

Now, after $|B_1| = |A_2| = \dots = |B_\ell|$, $(B_1, A_2, \dots, B_\ell)$ forms a *maximal* augmenting set. If it did not, there must have been some path $(b_1, a_2, \dots, b_\ell)$ which we can add to it, but this is impossible, since this path would have been a valid path (starting at b_1).

Rounds of adaptivity. The first stage of Algorithm 5 runs in $O(n/p \cdot \mathcal{T}_{\texttt{Refine}})$ rounds if $\mathcal{T}_{\texttt{Refine}}$ is the number of rounds needed to run `Refine`() once (Lemma 26 gives $\mathcal{T}^{\text{rank}}_{\texttt{Refine}} = O(1)$ and $\mathcal{T}^{\text{indep}}_{\texttt{Refine}} = O(\sqrt{n})$). This is since each time we run refine we will have at least p type-changes (Lemma 27), and in total each of the n elements can change types at most twice.

The second stage of Algorithm 5 runs in $O(p)$ rounds, both for independence and rank-oracle, by Lemma 32. Picking p optimally gives: $O(\sqrt{n})$ rounds of rank-queries (with $p = \sqrt{n}$) or $O(n^{3/4})$ rounds of independence-queries (with $p = n^{3/4}$) for the first and second stages combined.

Finally the clean-up stage runs, sequentially, with $O(\ell)$ refinement operations. This takes $O(\ell)$ rounds of rank-queries or $O(\ell\sqrt{n})$ rounds of independence queries, so this depends on the number of layers. However, we argue that we can ignore this term for the interesting range of ℓ. This is because when ℓ is too large ($> \sqrt{n}$ for rank-queries and $> n^{1/4}$ for independence-queries), we know by Lemma 14 that there are only $O(1/\ell)$ many augmenting paths left in total, and we can instead find them one-by-one in at most $O(\sqrt{n})$ rounds for rank-queries or $O(n^{3/4})$ rounds for independence queries.

Concluding, we have argued that we can implement a blocking-flow phase in $O(\sqrt{n})$ rounds of rank-queries or $O(n^{3/4})$ rounds of independence-queries.

Approximation algorithm. Running Algorithm 5 for $O(1/\varepsilon)$ phases eliminates all paths in the exchange graph of length $O(1/\varepsilon)$ (Lemma 13), so by Lemma 14 we know that the common independent set S we end up with is a $(1-\varepsilon)$-approximation. The adaptivity is thus $O(\sqrt{n}/\varepsilon)$ rounds of rank-queries or $O(n^{3/4}/\varepsilon)$ rounds of independence-queries. Hence we have shown a $(1-\varepsilon)$-approximation algorithm using $O(\sqrt{n}/\varepsilon)$ rounds of (polynomially many) rank-queries or $O(n^{3/4}/\varepsilon)$ rounds of (polynomially many) independence-queries, which proves Theorem 18.

Abstract

We initiate a systematic study of algorithms that are both differentially-private and run in sublinear time for several problems in which the goal is to estimate natural graph parameters. Our main result is a differentially-private $(1+\rho)$-approximation algorithm for the problem of computing the average degree of a graph, for every $\rho > 0$. The running time of the algorithm is roughly the same (for sparse graphs) as its non-private version proposed by Goldreich and Ron (Sublinear Algorithms, 2005). We also obtain the first differentially-private sublinear-time approximation algorithms for the maximum matching size and the minimum vertex cover size of a graph.

An overarching technique we employ is the notion of *coupled global sensitivity* of randomized algorithms. Related variants of this notion of sensitivity have been used in the literature in ad-hoc ways. Here we formalize the notion and develop it as a unifying framework for privacy analysis of randomized approximation algorithms.

Acknowledgements We thank several anonymous reviewers for their valuable feedback on a preliminary version of this work. We thank Soheil Behnezhad for bringing to our attention the subtlety in the analysis of [26], first discovered by [10], and finally resolved in his recent work [3]. We also thank Jakub Tetek for bringing up several points for clarification, which we have incorporated in the current version.

1 Introduction

Graphs are frequently used to model massive data sets (e.g., social networks) where the users are the nodes, and their relationships are the edges of the graphs. These relationships often consist of sensitive information, which drives the need for privacy in this setting.

Differential Privacy (DP) [12] has become the gold standard in privacy-preserving data analysis due to its compelling privacy guarantees and mathematically rigorous definition. Informally, a randomized function computed on a graph is *differentially private* if the distribution of the function's output does not change significantly with the presence or

absence of an individual edge (or node). See [13] for a comprehensive tutorial on differential privacy.

▶ **Definition 1** (Differential-privacy). *Let $\mathcal{G}_n$ denote the set of all n-node graphs. An algorithm $\mathcal{A}$ is (ε, δ) node-DP (resp. edge-DP) if for every pair of node-neighboring (resp. edge-neighboring)*[1] *graphs $G_1, G_2 \in \mathcal{G}_n$, and for all sets $\mathcal{S}$ of possible outputs, we have that $\Pr[\mathcal{A}(G_1) \in \mathcal{S}] \leqslant e^{\varepsilon} \Pr[\mathcal{A}(G_2) \in \mathcal{S}] + \delta$. When $\delta = 0$ we simply say that the algorithm is ε-DP.*

Since the graphs appearing in modern applications are massive, it is also often desirable to design *sublinear-time* algorithms that approximate natural combinatorial properties of the graph, such as the average degree, the number of connected components, the cost of a minimum spanning tree, the number of triangles, the size of a maximum matching, the size of a minimum vertex cover, etc. For an excellent survey on sublinear-time algorithms for approximating graph parameters, we refer the reader to [29].

There has been a lot of work in developing differentially-private algorithms for estimating graph parameters in polynomial-time, with respect to *edge differential privacy*, i.e., neighboring graphs that differ by a single edge in Definition 1. Nissim, Raskhodnikova, and Smith [25] demonstrated the first edge-differentially private graph algorithms. They showed how to estimate the cost of a minimum spanning tree and the number of triangles in a graph by calibrating noise to a local variant of sensitivity called *smooth sensitivity*. Subsequent works in designing edge differentially-private algorithms for computing graph statistics include [21, 19, 23, 36]. Gupta, Ligett, McSherry, Roth and Talwar [18] gave the first edge differentially-private algorithms for classical graph optimization problems, such as vertex cover, and minimum s-t cut, by making clever use of the exponential mechanism in existing non-private algorithms that solve the same problem.

An even more desirable notion of privacy in graphs is the notion of *node differential privacy* i.e., neighboring graphs that differ by a single node and edges incident to it in Definition 1. The concept of node differentially-private algorithms for 1-dimensional functions (functions that output a single real value) on graphs was first rigorously studied independently by Kasiviswanathan, Nissim, Raskhodnikova and Smith [22], as well as, Blocki, Blum, Datta, and Sheffet [4], and Chen and Zhou [9]. Their techniques were later extended to higher-dimensional functions on graphs [28, 6]. Subsequent works have focused on developing node differentially-private algorithms for a family of network models: stochastic block models and graphons [7, 30]. A more recent line of work has focused on the continual release of graph statistics such as degree-distributions and subgraph counts in an online setting [33, 15]. Gehrke, Lui, and Pass [16] introduce a more robust notion of differential privacy called Zero-Knowledge Differential Privacy (ZKDP), which tackles the problem of auxiliary information in social networks. This work uses existing results from sublinear-time algorithms as a building block to achieve ZKDP for several graph problems. However, it is important to note that the final ZKDP mechanisms are not computable in sublinear-time.

The literature on designing differentially-private algorithms for estimating graph parameters in sublinear time is far less developed. The only paper we are aware of is due to Sivasubramaniam, Li and He [32], who give the first sublinear-time differentially-private algorithm for approximating the average degree of a graph. Our work addresses this gap

[1] Graphs $G_1 = (V, E_1)$, $G_2 = (V, E_2)$ are *node-neighboring*, denoted by $G_1 \sim_v G_2$, if there exists a vertex $v \in V$ such that $E_1(V \setminus \{v\}) = E_2(V \setminus \{v\})$. Graphs G_1 and G_2 are *edge-neighboring* i.e., $G_1 \sim_e G_2$ if there exists an edge e such that $E_1 \setminus \{e\} = E_2 \setminus \{e\}$.

by initiating a systematic study of differentially-private sublinear-time algorithms for the problems of estimating the following graph parameters: (1) the average-degree of a graph, (2) the size of a maximum matching, and (3) the size of a minimum vertex cover. As an overarching technique, we formally introduce the notion of *Coupled Global Sensitivity* and use it to analyze the privacy of our randomized approximation algorithms.

1.1 Our Results

1.1.1 Privately Approximating the Average Degree

We obtain a differentially-private sublinear-time algorithm for estimating the average degree $\bar{d}_G = \frac{\sum_{v \in V} \deg(v)}{|V|}$, of a graph $G = (V, E)$, with respect to edge-differential privacy, which achieves a multiplicative approximation of $(1+\rho)$, for any constant $\rho > 0$. Specifically, our algorithm outputs a value $\tilde{d}$ such that w.h.p. we have $(1-\rho)\bar{d}_G \leqslant \tilde{d} \leqslant (1+\rho)\bar{d}_G$, for graphs with $\bar{d}_G = \Omega(1)$. Throughout the paper we denote $|V| = n$.

We work in the *neighbor-query* model, in which we are given oracle access to a simple graph $G = (V, E)$, where the algorithm can obtain the identity of the i-th neighbor of a vertex $v \in V$ in constant time. If $i > \deg(v)$ for a particular vertex v, then $\perp$ is returned. The algorithm may also perform *degree queries*, namely for any $v \in V$ it can obtain $\deg(v)$ in constant time.

▶ **Theorem 2.** *There is an ε-edge differentially-private $(1+\rho)$-approximation algorithm for estimating the average degree $\bar{d}_G \geqslant 1$ of a graph G on n vertices that runs in time*[2] *$O(\sqrt{n} \cdot poly(\log(n)/\rho) \cdot poly(1/\varepsilon))$ where $\varepsilon^{-1} = o(\log^{1/4}(n))$.*

The problem of estimating the average degree of a graph was first studied by Feige [14], who gave a sublinear time $(2+\rho)$-approximation (multiplicative) for any constant $\rho > 0$, making $O(\sqrt{n/d_0})$ many degree queries, where d_0 is a lower bound on the number of queries. He also notes that $\Omega(\sqrt{n/d_0})$ queries are necessary for a $2 - o(1)$-approximation, and hence, for the interesting cases when we may assume $d_0 \geqslant 1$, $\Omega(n)$ degree queries are necessary[3]. Goldreich and Ron [17] subsequently gave a $(1+\rho)$-approximation using both degree and neighbor queries, running in time $\tilde{O}((n/\sqrt{m}) \cdot \mathrm{poly}(1/\rho))$. This bound is also tight, since every constant-factor approximation algorithm must make $\Omega(n/\sqrt{\rho m})$ degree and neighbor queries [17]. A simpler analysis achieving the same bounds was given by Seshadri [31]. Further, Dasgupta, Kumar and Sarlós [11] studied this problem in the model where access to the graph is via samples, in the context of massive networks where the number of nodes may not be known. They obtain a $(1+\rho)$-approximation that uses roughly $O(\log d_U \cdot \log\log d_U)$ samples where d_U is an upper bound on the maximum degree of the graph.

In recent work, Sivasubramaniam, Li and He [32] gave a sublinear-time differentially-private algorithm for approximating the average degree of a graph using Feige's [14] algorithm. Their algorithm achieves a $(2+\rho+o(1))$-approximation for every constant $\rho > 0$. They achieve this by calculating a tight bound for the global sensitivity of the final estimate of Feige's algorithm and adding Laplace noise with respect to this quantity appropriately. By contrast, we achieve a $(1+\rho)$-approximation for any constant $\rho > 0$ – assuming that the privacy parameter is $\varepsilon^{-1} = o(\log^{1/4} n)$.

[2] from here on, we use running time and number of queries interchangeably.

[3] Observe that for $\bar{d}_G = o(1)$ a multiplicative approximation algorithm that can distinguish between two graphs on n vertices, one with 0 edges, and another with, say 1 edge, must sample $\Omega(n)$ vertices, and hence cannot be running in sublinear time.

1.1.2 Privately Approximating the Size of a Maximum Matching and Minimum Vertex Cover

Given an undirected graph, a set of vertex-disjoint edges is called a *matching*. A matching M is *maximal* if M is not properly contained in another matching. A matching M is *maximum* if for any other matching M', $|M| \geqslant |M'|$. A *vertex cover* of a graph is a set of vertices that includes at least one endpoint of every edge of the graph. A *minimum* vertex cover is a vertex cover of the smallest possible size. For a minimization problem, we say that a value $\hat{y}$ is an (α, β)-approximation to y if $y \leqslant \hat{y} \leqslant \alpha y + \beta$. For a maximization problem, we say that a value $\hat{y}$ is an (α, β)-approximation to y if $\frac{y}{\alpha} - \beta \leqslant \hat{y} \leqslant y$. An algorithm $\mathcal{A}$ is an (α, β)-approximation for a value $V(x)$ if it computes an (α, β)-approximation to $V(x)$ with probability at least $2/3$ for any proper input x.

For a graph $G = (V, E)$, we work in the *bounded degree* model, where one can query an i-th neighbor ($i \in [d]$) of a vertex in constant time; denote this query as $\mathrm{Nbr}(v, i)$. Here d is the maximum degree of the graph. If $i > \deg(v)$ for a particular vertex v, then $\mathrm{Nbr}(v, i) = \perp$. We also assume query access to the degree of a vertex, i.e., one can query $\deg(v)$ for any $v \in V$ in constant time.

▶ **Theorem 3.** *There is an ε-(node and edge) differentially-private algorithm for the maximum matching problem that reports a $(2, \rho n)$-approximation with probability $1-(2/n^4+1/n^{192\varepsilon/\rho})$, and runs in expected time $\tilde{O}\left((\bar{d}+1)/\rho^2\right)$, where $\bar{d}$ is the average degree of the input graph.*

▶ **Theorem 4.** *There is an ε-(node and edge) differentially-private algorithm for the minimum vertex cover problem that reports a $(2, \rho n)$-approximation with probability $1-(2/n^4+1/n^{96\varepsilon/\rho})$, and runs in expected time $\tilde{O}\left((\bar{d}+1)/\rho^2\right)$, where $\bar{d}$ is the average degree of the input graph.*

Typically, the privacy parameter ε is a constant, and so is the approximation parameter ρ, in which case the success probability in the theorems above is $1 - 1/(\mathrm{poly}(n))$.

The question of approximating the size of a vertex cover in sublinear-time was first posed by Parnas and Ron [27], who obtained a $(2, \rho n)$-approximation in time $d^{O(\log d/\rho^3)}$, where d is the maximum degree of the graph. Nguyen and Onak [24] improved upon this result by giving a $(2, \rho n)$-approximation for the maximum matching problem, and consequently a $(2, \rho n)$-approximation for the vertex cover problem, in time $O(2^{O(d)/\rho^2})$. The result of [24] was later improved by Yoshida, Yamamoto and Ito [35], who gave an ingenious analysis of the original algorithm to achieve a running time of $O(d^4/\rho^2)$. Onak, Ron, Rosen and Rubinfeld [26] proposed a near-optimal time complexity of $\tilde{O}(\bar{d} \cdot \mathrm{poly}(1/\rho))$, where $\bar{d}$ is the average degree of a graph, but Chen, Kannan, and Khanna [10] identified a subtlety in their analysis, which proved to be crucial to their improved time complexity claim. Very recently, building on ideas from the analysis of [35], Behnezhad [3] gave a new analysis for achieving a $(2, \rho n)$-approximation to the size of maximum matching and minimum vertex cover in time $\tilde{O}((\bar{d}+1)/\rho^2)$. Behnezhad's result nearly matches the lower bound given by Parnas and Ron [27], who showed that $\Omega(\bar{d}+1)$ queries are necessary for obtaining a $(O(1), \rho n)$-estimate in the case of the maximum matching or minimum vertex cover problem.

Our final DP algorithm simply runs the non-private approximation algorithm [3] and then adds Laplace noise proportional to the Coupled Global Sensitivity (of the non-private algorithm). Thus, our time complexity is identical to the non-private approximation algorithm. We show that the added Laplace noise is small enough that it preserves the approximation guarantees of the non-private approximation algorithm.

1.2 Organization

We define and motivate the notion of Coupled Global Sensitivity as a privacy tool in Section 1.3. Then we give a high-level overview of the techniques used for our results in Section 1.4. The formal privacy and accuracy analysis of Theorem 2 are in Sections 2 and 4. The formal analysis for Theorems 3 and 4 are in the full version [5]. We conclude with some open problems in Section 5.

1.3 Coupled Global Sensitivity as a Tool in Privacy analysis

Background and Motivation. Given a query $f : \mathcal{D} \to \mathbb{R}^d$ a general mechanism to answer the query privately is to compute $f(D)$ and then add noise. The global sensitivity of a function was introduced in the celebrated paper by Dwork, McSherry, Nissim and Smith [12], who showed that it suffices to perturb the output of the function with noise proportional to the global sensitivity of the function in order to preserve differential privacy.

▶ **Definition 5** (Global sensitivity). *For a query $f : \mathcal{D} \to \mathbb{R}^d$, the global sensitivity of f (wrt the ℓ_1-metric) is given by*

$$GS_f = \max_{A,B \in \mathcal{D}: A \sim B} \|f(A) - f(B)\|_1 .$$

One can preserve differential privacy by computing $f(D)$ and adding Laplacian noise[4] scaled to the global sensitivity of f, where D is a database. However, in many contexts we may not be able to compute the function f exactly. For example, if the dataset D is very large and our algorithm needs to run in sublinear-time or if the function f is intractable e.g., $f(G)$ is the size of the minimum vertex cover. In cases where we cannot compute f exactly, an attractive alternative is to use a randomized algorithm, say $\mathcal{A}_f$, to approximate the value of f. Given an approximation algorithm $\mathcal{A}_f$ it is natural to ask whether or not we can add noise to $\mathcal{A}_f(D)$ to obtain a differentially private approximation of $f(D)$ and (if possible) how to scale the noise. We first observe that computing $\mathcal{A}_f(D)$ and adding noise scaled to the global sensitivity of f does not necessarily work. Intuitively, this is because the sensitivity of $\mathcal{A}_f$ can be vastly different from that of f. For example, suppose that $GS_f = 1$, $f(D) = n = f(D') + 1$ for neighboring datasets $D \sim D'$ and that our approximation algorithm guarantees that $0.999 \cdot f(D) \leqslant \mathcal{A}_f(D) \leqslant 1.001 \cdot f(D)$. It is possible that $A_f(D) = 1.001n$ and $A_f(D') = 0.999(n-1)$ so that $|A_f(D) - A_f(D')| \geqslant 0.002n$ which can be arbitrarily larger than GS_f as n increases.

Coupled Global Sensitivity. We propose the notion of *coupled global sensitivity* of randomized algorithms as a framework for providing general-purpose privacy mechanisms for approximation algorithms running on a database D. In this framework, our differentially-private algorithms can follow a unified strategy, in which in the first step a non-private randomized approximation algorithm $\mathcal{A}_f(D)$ is run on the dataset, and privacy is obtained by adding Laplace noise proportional with the coupled global sensitivity of $\mathcal{A}_f$[5]. The concept of coupled global sensitivity has been used implicitly in prior work on differential privacy e.g., see [1, 8]. Our work formalizes this notion as a general tool that can be used to design and analyze differentially private approximation algorithms.

[4] Here, the probability density function of the Laplace distribution $\mathrm{Lap}(\lambda)$ is $h(z) = \frac{1}{2\lambda} \exp\left(-\frac{|z|}{\lambda}\right)$.

[5] We note that this is the simplest application of CGS, and as we will see in the analysis of estimating the average degree, we can use CGS to add noise to intermediate quantities used by the randomized algorithm as well.

Notation. When $\mathcal{A}$ is a randomized algorithm we use the notation $x := \mathcal{A}(D; r)$ to denote the output when running $\mathcal{A}$ on input D with fixed random coins r. Similarly, $\mathcal{A}(D)$ can be viewed as a random variable taken over the selection of the random coins r.

▶ **Definition 6** (Coupling). *Let Z and Z' be two random variables defined over the probability spaces $\mathcal{Z}$ and $\mathcal{Z}'$, respectively. A coupling of Z and Z', is a joint variable (Z_c, Z'_c) taking values in the product space $(\mathcal{Z} \times \mathcal{Z}')$ such that Z_c has the same marginal distribution as Z and Z'_c has the same marginal distribution as Z'. The set of all couplings is denoted by* $\mathsf{Couple}(Z, Z')$.

▶ **Definition 7** (Coupled global sensitivity of a randomized algorithm). *Let $\mathcal{A} : \mathcal{D} \times \mathcal{R} \to \mathbb{R}^k$ be a randomized algorithm that outputs a real-valued vector. Then the* coupled global sensitivity *of $\mathcal{A}$ is defined as*

$$\mathsf{CGS}_{\mathcal{A}} := \max_{D_1 \sim D_2} \min_{C \in \mathsf{Couple}(\mathcal{A}(D_1), \mathcal{A}(D_2))} \max_{(z,z') \in C} \|z - z'\|_1$$

▶ Remark 8. We can try to relax the definition of Coupled Global Sensitivity as follows: $\mathsf{CGS}_{\mathcal{A},\delta}$ is the minimum value, say x such that for all neighboring inputs $D_1 \sim D_2$, there exists a coupling C such that $\Pr_{(z,z') \sim C}[|z - z'| > x] \leqslant \delta$. We need to be careful here as we need to ensure that the minimum value x is always well-defined. If we can ensure this, then we can also show that adding noise proportional to $\mathsf{CGS}_{\mathcal{A},\delta}$ preserves (ε, δ)-differential privacy.

▶ **Fact 9.** *Let $\mathcal{A} : \mathcal{D} \times \mathcal{R} \to \mathbb{R}^k$ be a randomized algorithm viewed as a function that takes as input a dataset $\mathcal{D}$ and a random string in the finite set $\mathcal{R}$, and outputs a real-valued vector. For a finite set $\mathcal{R}$, denote by $\mathsf{Sym}(\mathcal{R})$ the symmetric group of all permutations on the elements in $\mathcal{R}$. Then,*

$$\mathsf{CGS}_{\mathcal{A}} \leqslant \max_{D_1 \sim D_2} \min_{\sigma \in \mathsf{Sym}(\mathcal{R})} \max_{R \in \mathcal{R}} \|\mathcal{A}(D_1; R) - \mathcal{A}(D_2; \sigma(R))\|_1$$

The following theorem formalizes the fact that adding noise proportional to the coupled global sensitivity of a randomized algorithm preserves differential privacy (see full version [5] for a formal proof).

▶ **Theorem 10.** *Let $\mathcal{A} : \mathcal{D} \to \mathbb{R}^k$ be a randomized algorithm and define the Laplace mechanism $\mathcal{M}_L(D) = \mathcal{A}(D) + (Y_1, \ldots, Y_k)$, where Y_i are i.i.d. random variables drawn from $Lap(\mathsf{CGS}_{\mathcal{A}}/\varepsilon)$. The mechanism $\mathcal{M}_L$ preserves ε-differential privacy.*

How we use Coupled Global Sensitivity. In our algorithm for estimating the average degree we divide the algorithm into randomized sub-routines and show that the CGS of these sub-routines is small, therefore enabling us to add Laplacian noise proportional to the CGS and ensure the privacy of each sub-routine, and by composition, the privacy of the entire algorithm (See Theorem 13). Similarly, we show that the existing non-private sublinear-time algorithms for maximum matching and minimum vertex cover have small CGS, therefore enabling us to add Laplace noise proportional to the CGS to their outputs thus making them differentially-private (See full version [5]).

1.4 Technical Overview

1.4.1 Privately Estimating the Average Degree

At a high-level, our private algorithm for estimating the average degree follows the non-private variant of Goldreich and Ron [17]. However, there are several challenges that prevent us from simply being able to add Laplacian noise to the output. We overcome these challenges

by first obtaining a new non-private algorithm with the same approximation ratio as that of [17], and then further add appropriate amounts of noise in several steps of the algorithm to obtain both privacy and accuracy guarantees. We begin by describing the algorithm of [17].

The Goldreich-Ron algorithm [17]. The strategy of the original non-private algorithm in [17] is to sample a set S of vertices and partition them into buckets S_i based on their degrees. In particular, for each i we set $S_i = B_i \cap S$ where the set B_i contains all vertices of degrees ranging between $((1+\beta)^{i-1}, (1+\beta)^i]$, where $\beta = \rho/c$ for some constant $c > 1$. Intuitively, as long as $|S_i|$ is sufficiently large the quantity $|S_i|/|S|$ is a good approximation for $|B_i|/n$ with high probability. Let I denote the indices i for which $|S_i|$ is sufficiently large. We can partition edges from the graph into three sets (1) edges with both endpoints in $\bigcup_{i\in I} B_i$, (2) edges with exactly one endpoint in $\bigcup_{i\in I} B_i$, and (3) edges with no endpoints in $\bigcup_{i\in I} B_i$. When the threshold for "large buckets" is tuned appropriately one can show that (whp) type 3 edges can be ignored as there are at most $o(n)$ such edges.

We could use $(1/|S|)\sum_{i\in I}|S_i|(1+\beta)^{i-1}$ as an approximation for $\frac{1}{n}\sum_{i\in I}\sum_{v\in B_i}\deg(v)$. The previous sum counts type (1) edges twice, type (2) edges once and type (3) edges zero times. While it is okay to ignore type (3) edges there could be a lot of type (2) edges which are under-counted. To correct for type (2) edges we can instead try to produce an approximation for the sum $\frac{1}{n}\sum_{i\in I}\sum_{v\in B_i}(1+\alpha_v)\deg(v)$ where α_v denotes the fraction of type (2) edges incident to v. Intuitively, α_v is included to ensure that type (2) edges are also counted twice. For each sampled node $v \in S_i$ we can pick a random neighbor $r(v)$ of v and define $X(v) = 1$ if $r(v) \notin \bigcup_{i\in I} B_i$; otherwise $X(v) = 0$. Observe that in the expected value of the random variable is $\mathbb{E}[X(v)] = \alpha_v$. Since $|S_i|$ is reasonably large for each $i \in I$ and $\deg(u) \approx \deg(v)$ for each pair $u, v \in S_i$ we can approximate the fraction of type (2) edges incident to B_i as $W_i/|S_i|$ where $W_i = \sum_{v\in S_i} X(v)$. Finally, we can use $(1/|S|)\sum_{i\in I}|S_i|(1+W_i/|S_i|)(1+\beta)^{i-1}$ as our final approximation for the average degree.

Challenges to making the original algorithm private by adding noise naively. The first naive attempt to transform the algorithm of [17] into a differentially private approximation would be to add noise to the final output. However, the coupled global sensitivity of this algorithm is large enough that the resulting algorithm is no longer a $(1+\rho)$-approximation.

A second natural strategy to make the above algorithm differentially private is to add Laplace noise to the degree of each vertex and partition vertices in S based on their noisy degrees $\tilde{d}(v) = \deg(v) + Y_v$ where $Y_v \sim \mathrm{Lap}(6/\varepsilon)$. (Note: To ensure that the algorithm still runs in sublinear time we could utilize lazy sampling and only sample $Y_v \sim \mathrm{Lap}(6/\varepsilon)$ when needed). In particular, we can let $\tilde{S}_i = S \cap \tilde{B}_i$ where $\tilde{B}_i$ denotes the set of all nodes v with noisy degree $\tilde{d}(v)$ ranging between $((1+\beta)^{i-1}, (1+\beta)^i]$. Now we can compute $W_i = Z_i + \sum_{v\in\tilde{S}_i} X(v)$ where $Z_i \sim \mathrm{Lap}(6/\varepsilon)$ and return $(1/|S|)\sum_{i\in I}|\tilde{S}_i|(1+\frac{W_i}{|\tilde{S}_i|})(1+\beta)^{i-1}$. While the above approach would preserve differential privacy, the final output may not be accurate. The problem is that the noise Y_v may cause a node v to shift buckets. It is not a problem if $v \in B_i$ shifts to an adjacent bucket i.e., $v \in \tilde{B}_{i-1}$ or $v \in \tilde{B}_{i+1}$ since $(1-\beta)^{i-2}$ and $(1-\beta)^{i+1}$ are still reasonable approximations for the original degree $\deg(v) \in ((1+\beta)^{i-1}, (1+\beta)^i]$. Indeed, when $\deg(v)$ is sufficiently large we can argue that $(1-\beta)\deg(v) < \tilde{d}(v) < (1+\beta)\deg(v)$ with high probability. However, this guarantee does not apply when $\deg(v)$ is small. In this case the Laplace noise Y_v might dominate $\deg(v)$ yielding an inaccurate approximation. Sivasubramaniam et al. [32], made similar observations, and because of these technical barriers, their paper analyzes the simpler strategy for estimating the average degree, which yields a less accurate result. The crucial observation here is that we need to deal with vertices having small degrees in our accuracy analysis separately.

Modified non-DP algorithm achieving the same approximation ratio. To address the challenges discussed above we first propose a modification to the strategy given by [17]. While the modified algorithm is still non-private it still achieves a $(1+\rho)$-approximation for any $\rho > 0$ and is amenable to differentially private adaptations. Our algorithm now samples vertices S *without replacement* and puts them into buckets $S_i = B_i \cap S$ according to their degrees. The key modification is that we merge all of the buckets with smaller degrees i.e., $i \leqslant K$[6] into one. We redefine B_1 to denote this merged bucket and $S_1 = S \cap B_1$ and we redefine I to be the set of all indices $i > K$ such that $|S_i|$ is sufficiently large. If B_1 is not too large then all of the edges incident to B_1 can simply be ignored as the total number of these edges will be small. Otherwise, we can account for edges that are incident to B_1 by adding $\frac{1}{|S|}\sum_{v\in S_1}(1+X(v))\deg(v)$ to our final output. Since we merged all of the buckets with smaller degrees we no longer have the guarantee that $\deg(u) \approx \deg(v)$ for all $u, v \in S_1$. However, since $\deg(v)$ is reasonably small for each $v \in S_1$ the variance is still manageable. Intuitively, the sum $\frac{1}{|S|}\sum_{v\in S_1}(1+X(v))\deg(v)$ approximates $\frac{1}{n}\sum_{v\in B_1}(1+\alpha_v)\deg(v)$ where α_v now denotes the fraction of edges incident to v whose second endpoint lies outside the set $B_1 \cup \bigcup_{i\in I} B_i$.

The differentially-private modified algorithm. We now introduce our sublinear-time differentially-private algorithm to approximate the average degree in Algorithm 4. Algorithm 4 relies on three subroutines given by Algorithms 1, 2, and 3. Splitting the algorithm into separate modules simplifies the privacy analysis as we can show that each subroutine is $\varepsilon/3$-differentially private – it follows that the entire algorithm is ε-differentially private. In Algorithm 1 we add Laplace noise to the degrees of *all* vertices in the graph and then return a sample of vertices, say S (sampled uniformly without replacement) along with their noisy degrees. For simplicity we describe Algorithm 1 in a way that the running time is linear in the size of the input. We do this to make our privacy analysis simpler. However, we can implement Algorithm 1 with lazy sampling of Laplace noise Y_u when required i.e., if node u is in our sample S or if $u = r(v)$ was the randomly selected neighbor of some node $v \in S$.

Algorithm 1 **NoisyDegree**.

NoisyDegree takes G as input and returns a set of sampled vertices along with the noisy degrees of every vertex in G.

1. Uniformly and independently select $\Theta(\sqrt{n}\cdot\mathrm{poly}(\log(n)/\rho)\cdot\mathrm{poly}(1/\varepsilon))$ vertices (without replacement) from V and let S denote the set of selected vertices.
2. For every $v \in V(G)$,

$$\tilde{d}(v) = \deg(v) + Y_v\ ,$$

   where $Y_v \sim \mathrm{Lap}(6/\varepsilon)$.
3. Return $\{\tilde{d}(v)\}_{v\in V(G)}, S$

Given the output of Algorithm 1 we can partition the sample S into buckets $\tilde{S}_i = S \cap \tilde{B}_i$ using their noisy degree. Here, we define $\tilde{B}_i = \left\{v : \tilde{d}(v) \in \left((1+\beta)^{i-1}, (1+\beta)^i\right)\right\}$ and we also define a merged bucket $S_1 = S \cap \left\{v : \tilde{d}(v) \leqslant (1+\beta)^{K-1}\right\}$ containing all sampled nodes

[6] where we fix $K := \left(2 + \log_{1+\beta}\left(\frac{2|S|\sqrt{\rho}}{\beta \log_{1+\beta}(n)\sqrt{n\sqrt{\log n}}}\right)\right)$ in the sequel

with noisy degree at most $(1+\beta)^{K-1}$. Here, K is a degree threshold parameter that we can tune. Now given a size threshold parameter T we can define $I = \left\{i \geqslant K \ : \ \left|\tilde{S}_i\right| \geqslant 1.2T \cdot |S|\right\}$ to be the set of big buckets. We remark that as a special case we define $|S_1|$ to be "small" if $|S_1| < 1.2T \cdot \sqrt{|S|} \cdot |S|$ instead of $|S_1| < 1.2T \cdot |S|$. As an intuitive justification we note that (whp) for each node v with noisy degree $\tilde{d}(v) \leqslant (1+\beta)^{K-1}$ the actual degree $\deg(v)$ will not be too much larger than $(1+\beta)^{K-1}$. In this case we have $\sum_{v:\tilde{d}(v)\leqslant(1+\beta)^{K-1}} \deg(v) \leqslant |S_1| \max_{v:\tilde{d}(v)\leqslant(1+\beta)^{K-1}} \deg(v) = o(n)$ so that we can safely ignore the edges incident to S_1.

Intuitively, for each large bucket $i \in I$, Algorithm 2 computes $\tilde{\alpha}_i = W_i/|\tilde{S}_i|$ our approximation of the fraction of type (2) edges incident to $\tilde{B}_i$. If S_1 is large then type (2) edges are (re)defined to be the edges with exactly one endpoint in $\left\{v : \tilde{d}(v) \leqslant (1+\beta)^{K-1}\right\} \cup \bigcup_{i\in I} \tilde{B}_i$. To preserve differential privacy we add laplace noise to W_i i.e., $W_i = Z_i + \sum_{v\in\tilde{S}_i} X(v)$ where $Z_i \sim \mathsf{Lap}(6/\varepsilon)$. We remark that (whp) we will have $Z_i = o(|\tilde{S}_i|)$ for each large bucket $i \in I$. Thus, the addition of laplace noise will have a minimal impact on the accuracy of the final result.

Algorithm 2 NoisyBigSmallEdgeCount. Here $M_{\rho,n}$ is a degree threshold parameter and T is a size threshold parameter. Note that the relationship between the parameters K (used informally as a degree threshold parameter in the overview) and $M_{\rho,n}$ is $K = 2 + \log_{(1+\beta)}\lceil 6M_{\rho,n}/\beta\rceil$.

NoisyBigSmallEdgeCount takes as input $G, I, \{\tilde{S}_i\}_{i=1}^t, S_1, \{\tilde{d}(v)\}_{v\in V(G)}, M_{\rho,n}, T$ and returns an approximation of the fraction of edges that are between big buckets and small buckets.

1. For every $i \in I$, ▷ count the edges between buckets in I and small buckets
   a. For all $v \in \tilde{S}_i$,
      i. Pick a random neighbor of v, say $r(v)$.
      ii. If $|S_1| < 1.2T\cdot\sqrt{|S|}\cdot|S|$, i.e., if S_1 is a small bucket. Then if $\tilde{d}(r(v)) \in ((1+\beta)^{i-1}, (1+\beta)^i]$ for some $i \notin I$, then $X(v) = 1$, otherwise $X(v) = 0$.
      iii. Otherwise, S_1 is not small. Therefore, if $\tilde{d}(r(v)) \in ((1+\beta)^{i-1}, (1+\beta)^i]$ for some $i \notin I$ and $i > \log_{1+\beta}\lceil\left(\frac{6M_{\rho,n}}{\beta}\right)\rceil + 2$, then $X(v) = 1$, otherwise $X(v) = 0$.
   b. Define $W_i := \sum_{v\in\tilde{S}_i} X(v) + Z_i$ where $Z_i \sim \mathrm{Lap}(6/\varepsilon)$ and $\tilde{\alpha}_i := \frac{W_i}{|\tilde{S}_i|}$.
2. return $\{W_i\}_{i\in I}, \{\tilde{\alpha}_i\}_{i\in I}$

If the merged bucket S_1 is small then we can ignore edges incident to S_1 and Algorithm 3 will simply output $\frac{1}{|S|}\sum_{i\in I} |\tilde{S}_i| \cdot (1+\tilde{\alpha}_i) \cdot (1+\beta)^i$. In this case the output can be computed entirely from the differentially private outputs that have already been computed by Algorithms 1 and 2 without even looking at the graph G. Intuitively, for any large bucket $i \in I$ and $v \in \tilde{S}_i$ we expect that (whp) $|Y_v| = |\tilde{d}(v) - \deg(v)|$ is small enough to ensure that $(1+\beta)^{i-2} \leqslant \deg(v) \leqslant (1+\beta)^{i+1}$. Thus, $(1+\beta)^i$ is still a reasonable approximation for $\deg(v)$.

If the merged bucket S_1 is sufficiently large, then we need to account for the edges within S_1 itself as well as the fraction of edges between S_1 and small buckets. We introduce a new estimator to approximate the fraction of edges between S_1 and small buckets given by $Z + \sum_{v\in S_1}(1+X(v))\cdot\deg'(v)$ where $Z \sim \mathrm{Lap}\left(36M_{\rho,n}\left(3+\beta+\frac{1}{\beta}\right)\right)$ and $\deg'(v) = \min\{\deg(v), 6M_{\rho,n}\left(3+\beta+\frac{1}{\beta}\right)\}$ (See Algorithm 3) – the relationship between the parameters K and $M_{\rho,n}$ is $K = 2 + \log_{(1+\beta)}\lceil 6M_{\rho,n}/\beta\rceil$. The Laplace Noise term is added to preserve differential privacy. We define the clamped degrees $\deg'(v)$ to ensure that the coupled global sensitivity of the randomized subroutine computing $\sum_{v\in S_1}(1+X(v))\cdot\deg'(v)$ is upper

bounded by $12M_{\rho,n}\left(3+\beta+\frac{1}{\beta}\right)$. This way we can control the laplace noise parameters to ensure that $Z = o(|S_1|)$ with high probability so that the noise term Z does not adversely impact accuracy. Intuitively, we expect that $Y_v \leqslant M_{\rho,n}$ for all nodes v with high probability. In this case for any node $v \in S_1$ we will have $\deg'(v) = \deg(v) \leqslant 6M_{\rho,n}\left(3+\beta+\frac{1}{\beta}\right)$.

Algorithm 3 **NoisyAvgDegree**.

NoisyAvgDegree takes $\{\tilde{S}_i\}_{i=1}^t, \{\tilde{d}(v)\}_{v\in V(G)}, \{\tilde{\alpha}_i\}_{i\in I}, I, M_{\rho,n}, T$ as input and returns the noisy estimator for average degree of the graph.

1. If $|S_1| < 1.2T\cdot\sqrt{|S|}\cdot|S|$ then output $\frac{1}{|S|}\sum_{i\in I}|\tilde{S}_i|\cdot(1+\tilde{\alpha}_i)\cdot(1+\beta)^i$.
2. Else, for every $v \in S_1$,
   a. Pick a random neighbor of v, say $r(v)$.
   b. If $\tilde{d}(r(v)) \in ((1+\beta)^{i-1},(1+\beta)^i]$ for some $i \notin I$ and $i > \log_{1+\beta}\lceil\left(\frac{6M_{\rho,n}}{\beta}\right)\rceil + 2$, then $X(v) = 1$, otherwise $X(v) = 0$.
   c. Output

$$\frac{1}{|S|}\left(\sum_{i\in I}|\tilde{S}_i|\cdot(1+\tilde{\alpha}_i)\cdot(1+\beta)^i + Z + \sum_{v\in S_1}(1+X(v))\cdot\deg'(v)\right),$$

where

$$Z \sim \mathrm{Lap}\left(36M_{\rho,n}\left(3+\beta+\frac{1}{\beta}\right)\right)$$

and

$$\deg'(v) = \min\left\{\deg(v), 6M_{\rho,n}\left(3+\beta+\frac{1}{\beta}\right)\right\}$$

Algorithm 4 **Main DP Algorithm**.

Main DP Algorithm that takes graph G as input and outputs an approximation of its average degree.

1. $\{\tilde{d}(v)\}_{v\in V(G)}, S :=$ **NoisyDegree**(G) ▷ see Algorithm 1
2. For $i = 1, 2\ldots, t$, let $\tilde{S}_i = \{v \in S : \tilde{d}(v) \in ((1+\beta)^{i-1},(1+\beta)^i]\}$ where $t := \lceil\log_{(1+\beta)}(n)\rceil$.
3. Define $M_{\rho,n} := \frac{1}{3}\cdot\sqrt{\frac{\rho}{n\sqrt{\log(n)}}}\cdot\frac{|S|}{t}$, $S_1 := \cup_{i\leqslant\log_{1+\beta}\left(\frac{6M_{\rho,n}}{\beta}\right)+2}\tilde{S}_i$, and, $I = \{i > \log_{1+\beta}\left(\frac{6M_{\rho,n}}{\beta}\right)+2 : |\tilde{S}_i| \geqslant 1.2T\cdot|S|\}$ where $T := \frac{1}{2}\sqrt{\frac{\rho}{n}}\cdot\frac{\varepsilon}{(1+\varepsilon)}\cdot\frac{1}{t}$.
4. $\{W_i\}_{i\in I}, \{\tilde{\alpha}_i\}_{i\in I} :=$ **NoisyBigSmallEdgeCount**$(G, I, \{\tilde{S}_i\}_{i=1}^t)$. ▷ see Algorithm 2
5. **NoisyAvgDegree**$(G, S, \{\tilde{S}_i\}_{i=1}^t, \{\tilde{\alpha}_i\}_{i\in I}, I, M_{\rho,n}, T)$. ▷ see Algorithm 3

The full analysis of Theorem 2 can be found in Sections 2 and 4.

▶ Remark 11. A simpler algorithm for estimating the average degree was given by Seshadri [31]. The main intuition behind this algorithm is that out of m edges of a graph, there are not "too many" edges that contribute a high degree. Thus the algorithm samples vertices and a random neighbor of each sampled vertex, but it only counts edges (scaled by a factor of 2 times the degree of the sampled vertex) for which the degree of the random neighbor is higher than that of the degree of the sampled vertex.

The Coupled Global Sensitivity of the final estimate returned by this algorithm is high (proportional to the degree of the sampled vertex and its random neighbor); thus adding Laplace noise directly to the estimate would result in a very inaccurate algorithm. It is unclear how to mitigate this issue and make this algorithm differentially-private with a reasonable accuracy guarantee.

1.4.2 Privately Estimating Maximum Matching and Vertex Cover Size

At a high-level our private algorithms for estimating the maximum matching and vertex cover add laplace noise (to the outputs) proportional to the coupled global sensitivity of the randomized non-private algorithms for the corresponding problems. The challenge lies in proving the coupled global sensitivity of these non-private algorithms is small.

We first describe and analyze the coupled global sensitivity of the classical polynomial-time greedy matching algorithm. This is helpful in our analysis of the non-private sublinear-time algorithm for maximum matching in the sequel.

We then describe and give a proof sketch of the coupled global sensitivity of the non-private sublinear-time matching algorithm [3]. The formal proofs for privately estimating the maximum matching and minimum vertex cover size are in the full version [5]. Recall that d is the maximum degree and $\bar{d}$ is the average degree of the graph .

The Polynomial-time Greedy Matching Algorithm $\mathcal{A}_{MM}$. This algorithm takes as input a graph $G = (V, E)$ and a random permutation π on the set of pairs $(x, y) \in V \times V$, with $x \neq y$, and processes each pair of vertices (x, y) in the increasing order of ranks given by π, and greedily adds edges to a maximal matching whose size is finally output[7]. Since the size of the maximal matching produced is known to be at least $\frac{1}{2}$ of the size of a maximum matching, this gives a non-private 2-approximation of the size of a maximum matching in G.

CGS of the Greedy Algorithm $\mathcal{A}_{MM}$. We show that the CGS of the greedy algorithm (with respect to node-neighboring graphs) is at most 1. Note that once the ranking on the edges is fixed the maximal matching obtained by $\mathcal{A}_{MM}$ is also fixed. Let σ_I be the identity permutation over the ranking of edges, i.e., we have $\sigma_I(\pi) = \pi$. We use Fact 9 to observe that,

$$\begin{aligned}
\mathsf{CGS}_{\mathcal{A}_{MM}} &\leqslant \max_{G_1 \sim G_2} \min_{\sigma} \max_{\pi} |\mathcal{A}_{MM}(G_1; \pi) - \mathcal{A}_{MM}(G_2; \sigma(\pi))| \\
&\leqslant \max_{\substack{G_1 \sim G_2 \\ \pi}} |\mathcal{A}_{MM}(G_1; \pi) - \mathcal{A}_{MM}(G_2; \sigma_I(\pi))| \\
&= \max_{\substack{G_1 \sim G_2 \\ \pi}} |\mathcal{A}_{MM}(G_1; \pi) - \mathcal{A}_{MM}(G_2; \pi).|
\end{aligned}$$

Therefore it is sufficient to analyze the relative size of the matching obtained on node-neighboring graphs G_1, G_2 that are processed by the greedy algorithm in the order given by the same π.

Let $G_1 \sim G_2$ where v^* is such that $E(V_1 \setminus \{v^*\}) = E(V_2 \setminus \{v^*\})$. Denote the greedy matchings obtained from $\mathcal{A}_{MM}(G_1, \pi)$ as M_1 and from $\mathcal{A}_{MM}(G_2, \pi)$ as M_2. Suppose edge e^* is incident to v^* such that $e^* \in E_2$, and $e^* \notin E_1$. We will show that $||M_1| - |M_2|| \leqslant 1$, which implies that $\max_{\substack{G_1 \sim G_2 \\ \pi}} |\mathcal{A}_{MM}(G_1; \pi) - \mathcal{A}_{MM}(G_2; \pi)| \leqslant 1$, thus proving that $\mathsf{CGS}_{\mathcal{A}_{MM}} \leqslant 1$.

[7] We note that the non-private algorithms [24, 35, 26] only consider the ranking π over m edges of the graph, whereas we consider the ranking over all $\binom{n}{2}$ pairs of vertices. This is because we want to define a "global" ranking so that we can define the same ranking consistently over neighboring graphs that may have different edges.

We first claim that if $e^* \notin M_1 \cup M_2$ then $|M_1| = |M_2|$. Since the greedy algorithm considers edges in the same order, the exact same edges must have been placed in M_1 as in M_2 before $e*$ is processed. Since $e^* = (v^*, u)$ is not chosen in M_2 it must have been the case that by this time u was matched in M_2, and thus the same matched edge must occur in M_1. From here on the algorithm again must make the same choices for the edges to be placed in M_1 and M_2.

Next, we claim that if $e^* \in M_1 \cup M_2$ then $M := M_1 \oplus M_2$[8] is one connected component containing e^*. Consequently, $||M_1| - |M_2|| \leqslant 1$. Since $e^* \in M_2$ and e^* cannot be in M_1, it is clear that $e^* \in M$. Suppose for the sake of contradiction, M consists of two connected components C_1, C_2 and WLOG $e^* \in C_1$. Consider edges in C_2. By Berge's Lemma [34], C_2 is either an alternating path or an alternating even cycle, with alternating edges from M_1 and M_2. Also, the edges in C_2 exist in both G_1 and G_2 with the same ranking. Observe that since C_2 is separate from C_1 containing e^*, if we replace edges in C_2 belonging to M_2 in the original graph G_2 by edges in C_2 belonging to M_1, this is still a valid maximal matching for the graph G_2. In fact, the greedy algorithm considers edges in C_2 in the same order for both graphs G_1, G_2, so the edges in M_1 and M_2 should be the same, in other words, C_2 cannot be a part of $M = M_1 \oplus M_2$, and hence M must have only one connected component, which contains e^*. Now, since M is either an alternating path or even cycle, $||M_1| - |M_2|| \leqslant 1$.

The Local Maximum Matching Algorithm $\mathcal{A}_{\mathbf{sub-MM}}$. We describe the local algorithm implemented by [3] in Algorithm 5. We modify the original algorithm to sample vertices *without replacement*. The algorithm then calls the vertex cover oracle (denoted as $\mathcal{O}^{\pi}_{VC}$) on each sampled vertex which subsequently calls the maximal matching oracle (denoted as $\mathcal{O}^{\pi}_{MO}$) on the incident edges to determine whether the sampled vertex is in the matching fixed by the ranking of edges π. Finally, the algorithm returns an estimate of the maximum matching size based on the number of sampled vertices in the matching. We note that in [3] the same sampling algorithm simultaneously outputs an approximation to maximum matching size and minimum vertex cover size. We choose to write the sampling procedure for estimating the maximum matching size and minimum vertex cover size separately so that it is easier to understand the Coupled Global Sensitivity for outputting the two different estimators.

Algorithm 5 Local Maximum Matching algorithm $\mathcal{A}_{sub-MM}$ using Oracle access.

Input. Input Graph $G = (V, E)$.

1. Uniformly sample $s = 16 \cdot 24(\ln n)/\rho^2$ vertices from V without replacement.
2. For $i = 1 \dots s$, if $\mathcal{O}^{\pi}_{VC}(v_i) =$ True then let $X_i = 1$, otherwise let $X_i = 0$.
3. return $\tilde{M} = \frac{n}{2s}(\sum_{i \in [s]} X_i) - \frac{\rho n}{2}$.

▶ Remark 12. [3] gives an efficient simulation of the matching and vertex cover oracles which exposes edges incident to a vertex in batches only when they are needed. We assume the efficient simulation of these oracles in our algorithms.

CGS of the Local Matching Algorithm $\mathcal{A}_{\mathbf{sub-MM}}$. Our main techniques involve identifying the sources of randomness in the local algorithm itself and then coupling the random coins of the runs of the algorithm on neighboring graphs. We follow the local algorithm given by [3] which samples vertices for both matching and vertex cover size estimation. We show that the identity coupling is sufficient in this case.

[8] $M_1 \oplus M_2$ is the *symmetric difference* of sets and this is defined as the set of edges in either M_1 or M_2 but not in their intersection.

In a previous version of our paper (before we were aware of the results of [3]), we analyzed the Coupled Global Sensitivity of the local matching algorithm given by [24, 35] which samples a set of edges uniformly at random, and calls a matching oracle on each sampled edge. The matching oracle indicates whether the edge is in the greedy matching fixed by the ranking π or not. Analyzing the Coupled Global Sensitivity of this algorithm is more challenging, i.e., considering the identity permutation σ_I over the ranking of edges π and sampled edges does not work. This is because for node-neighboring graphs G_1, G_2, it could be the case that all the edges sampled from G_1 belong to the matching M_1 fixed by the ranking π, but the same edges sampled from G_2 may not be in the matching M_2 fixed by the ranking π. Thus, we need to carefully define a bijection that maps edges in the matching M_1 to edges in the matching M_2.

2 Privacy Analysis of Theorem 2

▶ **Theorem 13.** *The Algorithm 4 is ε-DP.*

Proof. We will approach the privacy analysis in a modular fashion, i.e., we will analyze each sub-routine separately and show that by composition, the entire algorithm is ε-differentially private.

In the sequel, when analyzing the coupled global sensitivity of intermediate randomized quantities, we use Fact 9.

▷ Claim 14. Algorithm NoisyDegree (see Algorithm 1) is $\varepsilon/3$-DP.

Proof. First, fix any sample S. Define the function $f_{noisy-deg} := \{\tilde{d}(v)\}_{v\in V(G)}$. Observe that the degree of a node can change by at most 1 from adding or deleting an edge, and therefore $f_{noisy-deg}$ changes by at most 2 by adding or deleting an edge, in other words, the $GS_{f_{noisy-deg}} = 2$ and we can add noise proportional to $2/\varepsilon$. ◁

▷ Claim 15. Algorithm NoisyBigSmallEdgeCount (Algorithm 2) is $\varepsilon/3$-DP.

Proof. We fix noisy degrees $\{\tilde{d}(v)\}_{v\in V(G)}$, consequently fixing the buckets $\tilde{S}_1, \ldots, \tilde{S}_t$ and set I. Define the function $f_{t,\tilde{d}} := \{f_{\tilde{S}_i,\tilde{d}}(G; r)\}_{i\in I}$, and the function $f_{\tilde{S}_i,\tilde{d}}(G; r) = \sum_{v\in\tilde{S}_i} H(r(v))$ where $H(w) = 1$ if and only if we have $\tilde{d}(w) \in ((1+\beta)^{i-1}, (1+\beta)^i]$ for some $i \notin I$ and $|S_1| < 1.2T \cdot \sqrt{|S|} \cdot |S|$ or if $\tilde{d}(w) \in ((1+\beta)^{i-1}, (1+\beta)^i]$ for some $i \notin I$ and $i > \log_{1+\beta}\lceil\left(\frac{6M_{\rho,n}}{\beta}\right)\rceil + 2$; here $r(\cdot)$ defines the random coins used to sample a neighbor of v. We analyze $CGS_{f_{\tilde{S}_i,\tilde{d}}}$, and argue that $CGS_{f_{t,\tilde{d}}} \leqslant CGS_{f_{\tilde{S}_i,\tilde{d}}}$.

First, we show that for all fixed S, $\{\tilde{d}(v)\}_{v\in S}$ and $i \in I$, the $CGS_{f_{S_i,\tilde{d}}}$ is at most 2. Consider G and G' such that edge $(u^*, v^*) \in G$, but does not exist in G'. Fix any coupling such that $r(w) = r'(w)$ for all $w \neq u^*, v^*$, where r, r' defines the random coins for sampling neighbors of w in G and G' respectively. Now we have $X(w) = H(r(w)) = H(r'(w)) = X'(w)$ for all $w \neq u^*, v^*$. Thus, $CGS_{f_{\tilde{S}_i,\tilde{d}}} = |f_{\tilde{S}_i,\tilde{d}}(G; r) - f_{\tilde{S}_i,\tilde{d}}(G'; r')| = |\sum_{v\in\tilde{S}_i} H(r(v)) - \sum_{v\in\tilde{S}_i} H(r'(v))| = |H(r(v^*)) + H(r(u^*)) - H(r'(v^*)) - H(r'(u^*))| \leqslant 2$. Now, since the differing endpoints u^*, v^* can only appear in at most one of the i-th iterations simultaneously, it is clear to see that $CGS_{f_{t,\tilde{d}}}$ is also at most 2. ◁

▷ Claim 16. Algorithm NoisyAvgDegree (Algorithm 3) is $\varepsilon/3$-DP.

Proof. We fix noisy degrees $\{\tilde{d}(v)\}_{v\in V(G)}$, and sample S consequently fixing the buckets $\tilde{S}_1, \ldots, \tilde{S}_t$ and set I, and we fix $\{\tilde{\alpha}_i\}_{i=1}^t$. Note that the first output in Line 1 given by $\frac{1}{|S|}\sum_{i\in I} |\tilde{S}_i| \cdot (1+\tilde{\alpha}_i) \cdot (1+\beta)^i$ is already private since the terms in the summation consist of

parameters that are either noisy or public or both. We need to show that the second output in Line 2c is private. In particular, define the function $f_{S_1,\tilde{d}}(G;r) := \sum_{v\in S_1}(1+H_1(r(v)))\cdot\deg'(v)$ where $\deg'(v) = \min\{\deg(v), 6M_{\rho,n}\left(3+\beta+\frac{1}{\beta}\right)\}$ and $H_1(w) = 1$ if and only if $\tilde{d}(w) \in ((1+\beta)^{i-1},(1+\beta)^i]$ for some $i \notin I$ and $i > \log_{1+\beta}\lceil\left(\frac{6M_{\rho,n}}{\beta}\right)\rceil+2$. We claim that for all fixed S and $\{\tilde{d}(v)\}_{v\in S}$, the $CGS_{f_{S_1,\tilde{d}}}$ is at most $12M_{\rho,n}\left(3+\beta+\frac{1}{\beta}\right)$. Consider G and G' such that edge $(u^*,v^*)\in G$, but does not exist in G'. Fix any coupling such that $r(w) = r'(w)$ for all $w \neq u^*, v^*$, where r, r' defines the random coins for sampling neighbors of w in G and G' respectively. Now we have $X(w) = H_1(r(w)) = H_1(r'(w)) = X'(w)$ for all $w \neq u^*, v^*$. Thus, $|f_{S_1,\tilde{d}}(G;r) - f_{S_1,\tilde{d}}(G';r')| = |\sum_{v\in\tilde{S}_1}(1+H_1(r(v)))\cdot\deg'(v) - \sum_{v\in\tilde{S}_1}(1+H_1(r'(v)))\cdot\deg'(v)| = |(1+H(r(v^*)))\cdot\deg'(v^*) + (1+H(r(u^*)))\cdot\deg'(u^*) - (1+H(r'(v^*)))\cdot\deg'(v^*) - (1+H(r'(u^*)))\deg'(u^*)| \leqslant 2\cdot 6M_{\rho,n}\left(3+\beta+\frac{1}{\beta}\right) = 12M_{\rho,n}\left(3+\beta+\frac{1}{\beta}\right)$. Note that we introduce $\deg'(v)$, to ensure that the sensitivity of $f_{S_1,\tilde{d}}$ remains small. ◁

By composition, we have that the main algorithm is ε-DP. ◀

3 Preliminaries

We state the following tail bound for a random variable drawn from the Laplace Distribution.

▶ **Fact 17.** *If* $Y \sim \mathrm{Lap}(b)$, *then*

$$\Pr[|Y| \geqslant \ell\cdot b] = \exp(-\ell)\ .$$

Next, we state a well-known fact which implies that the concentration results for sampling with replacement obtained using Chernoff bounds type methods (bounding moment generating function + Markov inequality) can be transferred to the case of sampling without replacement.

▶ **Fact 18** ([2, 20]). *Let* $X = (x_1,\ldots,x_N)$ *be a finite population of* N *points and* $X_1,\ldots,X_n$ *be a random sample drawn without replacement from* X, *and* $Y_1,\ldots,Y_n$ *be a random sample drawn with replacement from* X. *If* $f:\mathbb{R}\to\mathbb{R}$ *is continuous and convex, then*

$$\mathbb{E}\left[f\left(\sum_{i=1}^{n}X_i\right)\right] \leqslant \mathbb{E}\left[f\left(\sum_{i=1}^{n}Y_i\right)\right]\ .$$

4 Accuracy Analysis of Theorem 2

4.1 Proof Sketch of Theorem 2

In this section, we give a sketch of the accuracy analysis. The more formal proofs can be found in the full version [5].

▶ **Theorem 19.** *For every* $\rho < 1/4$, $\beta \leqslant \rho/8$, *and* $\varepsilon^{-1} = o(\log^{1/4}(n))$, *for sufficiently large* n, *the main algorithm (see Algorithm 4) outputs a value* $\tilde{d}$ *such that with probability at least* $1-o(1)$, *it holds that*

$$(1-\rho)\cdot\bar{d} \leqslant \tilde{d} \leqslant (1+\rho)\cdot\bar{d}$$

Proof. The main proof strategy conditions on S_1 being sufficiently large or not. First, consider Case 1 when $|S_1| < 1.2T\cdot\sqrt{|S|}\cdot|S|$ where T is a size threshold parameter. We first show that for $i\in I$ the noisy buckets $|\tilde{B}_i|/n$ are approximated well by $|\tilde{S}_i|/|S|$. Next we show

that the number of vertices in buckets that are significantly smaller than the size threshold are of size $O(\sqrt{n})$ (for buckets $U' := \{v \in \tilde{B}_i : (i \notin I) \wedge (i > \log_{1+\beta}\left(\frac{6M_{\rho,n}}{\beta}\right) + 2)\}$, and of size $\tilde{O}(n^{3/4})$ (for bucket $B_1 := \cup_{i<\log_{1+\beta}\left(\frac{6M_{\rho,n}}{\beta}\right)+2}\tilde{B}_i$. This leads to the corollary (see full version [5] for the formal statement) which bounds the number of edges between small buckets as roughly $\tilde{O}(\rho n + n^{3/4})$.

One of our main contributions is showing that the actual fraction of edges between sufficiently large buckets and small buckets, denoted by α_i, is approximated well by our noisy estimator $\tilde{\alpha}_i$.

▶ **Corollary 20.** *Assuming that* $\varepsilon^{-1} = o(\log^{1/4}(n))$*, for every* $i \in I$*, for sufficiently large* n*, we have that with probability at least* $1 - o(1)$*,*

1. $|\tilde{\alpha}_i - \alpha_i| \leqslant \frac{\rho}{4}\alpha_i$ *if* $\alpha_i \geqslant \rho/8$.
2. $\tilde{\alpha}_i \leqslant \rho/4$*, if* $\alpha_i \leqslant \rho/8$.

Finally, we need to show that for sufficiently large noisy buckets, the actual degrees of the vertices (sans noise) only shifts to an adjacent noisy bucket. This helps us bound the number of edges whose one endpoint resides in a sufficiently large noisy bucket. We have shown that with high probability, all approximations of edges between the different types of buckets is good, which leads to the main Lemma for Case 1.

Now consider Case 2 when $|S_1| > 1.2T \cdot \sqrt{|S|} \cdot |S|$. We show that the bucket $|B_1|/n$ is now approximated well by $|S_1|/|S|$. We introduce a different estimator for counting edges between B_1 and small buckets given by $Z + \sum_{v \in S_1}(1 + X(v)) \cdot \deg'(v)$, where $Z \sim \text{Lap}\left(36M_{\rho,n}\left(3 + \beta + \frac{1}{\beta}\right)\right)$ and $\deg'(v) = \min\{\deg(v), 6M_{\rho,n}\left(3 + \beta + \frac{1}{\beta}\right)\}$. First, we show that for every $v \in S_1$, with high probability $\deg'(v) = \deg(v)$. Our main contribution in this case is showing that our estimator (sans noise) approximates the fraction of the sum of the edges between B_1 and all vertices in the graph (denoted by E_1), and the edges between B_1 and vertices in small buckets in the graph (denoted by E_1') well (see lemma below).

▶ **Lemma 21.** *Let* $\bar{d}_1$ *be the average degree of bucket* B_1*. If* $|B_1| > 1.5T \cdot \sqrt{|S|} \cdot n$*,*

1. *If* $\bar{d}_1 \geqslant 1$*, then with probability at least* $1 - o(1)$*,*

$$\left(1 - \frac{\rho}{4}\right) \cdot \frac{|E_1| + |E_1'|}{n} < \frac{1}{|S|}\sum_{v \in S_1}(1 + X(v)) \cdot \deg(v) < \left(1 + \frac{\rho}{4}\right) \cdot \frac{|E_1| + |E_1'|}{n}$$

2. *If* $\bar{d}_1 < 1$*, and* $\bar{d} \geqslant 1$*, then with probability at least* $1 - o(1)$*,*

$$\frac{|E_1| + |E_1'|}{n} - \rho/4 < \frac{1}{|S|}\sum_{v \in S_1}(1 + X(v)) \cdot \deg(v) < \frac{|E_1| + |E_1'|}{n} + \rho/4$$

To complete this part of the proof, we show that the noise added to the estimator (denoted by Z) is small and therefore, the noisy estimator also approximates the quantity $(|E_1| + |E_1'|)/n$ well.

The rest of the analysis is similar to Case 1 and we invoke the same lemmas to show that with high probability, the approximations of edges between the rest of the sufficiently large buckets, and between the small buckets, as well as between the sufficiently large buckets and small buckets is good, thus giving us the main Lemma for Case 2.

Combining these two main lemmas proves our main theorem statement. ◀

5 Conclusions and open questions

In this work we give a differentially-private sublinear-time $(1+\rho)$-approximation algorithm for estimating the average degree of the graph. We achieve a running time comparable to its non-private counterpart, which is also tight in terms of its asymptotic behaviour with respect to the number of vertices of the graph. We also give the first differentially-private approximation algorithms for the problems of estimating maximum matching size and vertex cover size of a graph.

To analyze the privacy of our algorithms, we proposed the notion of coupled global sensitivity, as a generalization of global sensitivity, which is applicable to randomized approximation algorithms. We show that coupled global sensitivity implies differential privacy, and use it to show that previous non-private algorithms from the literature, or variants, can be made private by finely tuning the amounts of noise added in various steps of the algorithms.

We propose several directions of investigation for developing the notion of coupled global sensivity further and open problems pertaining to differentially-private sublinear-time algorithms for graphs.

Other applications and limitations of CGS. In particular, what are the limitations of the CGS method? Can we characterize the set of algorithms with small CGS? Are there other natural problems for which we already have algorithms with small CGS, and hence that are easily amenable to privacy analogues? Are there algorithms for which we can prove large lower bounds on the CGS and yet they provide differential privacy?

Better approximations for maximum matching problems. In [24, 35], the authors also give a $(1, \rho n)$-approximation of maximum matching size with a query complexity that is exponential in d. Their analysis involves iterating over a sequence of oracles to augment paths of small length, in increasing order of lengths. The matching oracle considered in this work is used only in the first iteration. Analyzing the coupled global sensitivity of that algorithm appears to be much more involved, and we leave it as an open problem.

Better time complexity guarantees for $(2, \rho n)$-approximation matching and vertex cover algorithms. Note that our results in Theorems 3 and 4 achieve an expected running time. In contrast, the results in [3] achieve a high-probability bound on the time-complexity. This can be done by running multiple instances of the resulting approximation algorithm for enough time and returning the output of the instance that terminates first (the analysis involves a simple application of Markov inequality). Achieving this step in a way that preserves privacy would result in a degradation of the privacy parameter ε, due to composition. We leave it as an open question to provide a tighter privacy vs time-complexity analysis.

The Complexity of Finding Fair Many-To-One Matchings

Niclas Boehmer

Abstract

We analyze the (parameterized) computational complexity of "fair" variants of bipartite many-to-one matching, where each vertex from the "left" side is matched to exactly one vertex and each vertex from the "right" side may be matched to multiple vertices. We want to find a "fair" matching, in which each vertex from the right side is matched to a "fair" set of vertices. Assuming that each vertex from the left side has one color modeling its attribute, we study two fairness criteria. In one of them, we deem a vertex set fair if for any two colors, the difference between the numbers of their occurrences does not exceed a given threshold. Fairness is relevant when finding many-to-one matchings between students and colleges, voters and constituencies, and applicants and firms. Here colors may model sociodemographic attributes, party memberships, and qualifications, respectively.

We show that finding a fair many-to-one matching is NP-hard even for three colors and maximum degree five. Our main contribution is the design of fixed-parameter tractable algorithms with respect to the number of vertices on the right side. Our algorithms make use of a variety of techniques including color coding. At the core lie integer linear programs encoding Hall like conditions. To establish the correctness of our integer programs, we prove a new separation result, inspired by Frank's separation theorem [Frank, Discrete Math. 1982], which may also be of independent interest. We further obtain complete complexity dichotomies regarding the number of colors and the maximum degree of each side.

1 Introduction

A many-to-one matching in a bipartite graph $G = (U \cup V, E)$ is an edge subset $M \subseteq E$ such that each vertex in U is incident to at most one edge in M. We study the computational complexity of finding a "fair" many-to-one matching and call this problem Fair Matching: Given a bipartite graph $G = (U \cup V, E)$ in which every vertex in U is colored, it asks for a many-to-one matching M such that for each $v \in V$ the vertices matched to v meet a

fairness criterion. In this work, we require that M is "left-perfect", i.e., every vertex in U is incident to exactly one edge in M. Using a slightly different formulation, Stoica et al. [24] recently studied this problem in terms of a fairness requirement derived from *margin of victory* (MoV). Generally, the margin of victory of a multiset is defined as the number of occurrences of the most frequent value minus the number of occurrences of the second most frequent value. (Given a set of colored vertices, we obtain a multiset from the occurrences of colors in it.) By requiring that the margin of victory of a set of colored vertices shall not exceed a given threshold, we prevent one color from becoming a dominating majority (see Stoica et al. [24] for a more extensive motivation of this concept). As an alternative simple fairness measure, we consider Max-Min, which is defined as the difference between the number of occurrences of the most frequent value and the number of occurrences of the least frequent value in a multiset. In a set of colored vertices with a small value of Max-Min all colors appear more or less equally often.

Which of MoV or Max-Min is more appropriate depends not only on the specific application (as discussed in the next two paragraphs) but also on the underlying data. Suppose that we have $2n$ red, $2n$ blue, and one green vertex. Then, it would be natural to deem a subset consisting of n red, n blue, and one green vertex fair (as it is in some sense the best we can hope for). Now, MoV seems to be a better fit because the MoV of the described subset is zero whereas the Max-Min value is $n-1$. In contrast, if there are $2n$ red, $2n$ blue, and $2n$ green vertices, then the same subset with n red, n blue, and one green vertex should be considered as unfair, rendering Max-Min more suitable for this color distribution than MoV. In general, Max-Min seems to be a natural choice for homogeneous data. The first example illustrates, however, that in some scenarios, MoV may serve as a viable relaxation of Max-Min.[1]

A notable application of Fair Matching emerges in the context of district-based elections. In such elections, voters (modeled by vertices in U) are divided into constituencies (modeled by vertices in V), and then each constituency elects its own representative. Here, colors can represent various attributes. For instance, colors may represent political standings. A small margin of victory is particularly desirable in this case because it will lead to close elections, holding politicians accountable for their job. One could also strive for "fair" representation of different ethnic groups or age groups by modeling ethnicity or age with colors. Other applications include the assignment of school children to schools (where colors may model sociodemographic attributes) or the assignment of reviewers to academic papers (where colors may model the level of expertise or academic background of reviewers).

Similar fairness considerations also arise in modern online systems (see, e.g., [23] for a survey). For instance, fairness is a pressing issue to counter targeted advertising or to improve recommender systems. Here one task is to ensure that the content (each perhaps represented by multiple vertices in U) falling into different categories (colors) is assigned to users (vertices in V) in a way that each user is presented with a "diverse" selection of content. Lastly, we mention that (Max-Min) Fair Matching has also applications outside of the "fairness" context: Imagine a centralized job market for companies (vertices in V) and applicants (vertices in U), each having a specific skillset (color). Firms may wish to balance between applicants with different skillsets so that employees with various skillsets may be placed into teams. For instance, it may be desirable for a software company to hire roughly the same number of frontend and backend developers.

[1] Note that the Max-Min value is at least the MoV value for any multiset.

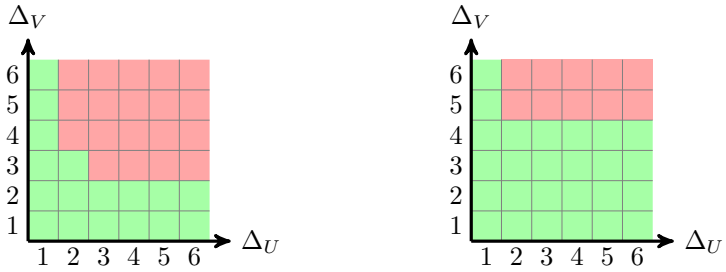

Figure 1 The complexity landscape of Max-Min Fair Matching (left) and MoV Fair Matching (right) for the maximum degree Δ_U (resp., Δ_V) in U (resp., V). Green denotes polynomial-time solvability and red denotes NP-hardness. All NP-hardness results hold for three colors.

Our Contributions. We perform a refined complexity analysis of the NP-hard Max-Min Fair Matching and MoV Fair Matching problems in terms of the size k of V, the number $|C|$ of colors, and the maximum degree Δ_U and Δ_V among vertices in U and V, respectively. Our main contribution are arguably involved FPT algorithms for the parameterization k (Section 4). At the heart of the design of our algorithms lies an integer linear program (ILP) of bounded dimension. We essentially determine whether Hall-like conditions that guarantee the existence of a fair matching are fulfilled by formulating these in a system of linear inequalities. In order to establish the correctness of our ILP formulations, we prove what we call *touching separation theorem*, getting inspiration from Frank's separation theorem on submodular and supermodular functions [14]. For MoV Fair Matching, we apply our approach in conjunction with the color coding technique [5]. To familiarize ourselves with the ideas underlying our ILPs, in Section 3, we start with a warm-up where we present ILP-based fixed-parameter tractable algorithms for the larger parameter $k + |C|$. To sum up, as it is straightforward to see that Max-Min/MoV Fair Matching are FPT with respect to the size n of U[2], we establish the fixed-parameter tractability of both problems for the two natural parameters n and k.[3] We then in Section 5 study the computational complexity of Max-Min/MoV Fair Matching with respect to Δ_U, Δ_V, and $|C|$. We show that Max-Min/MoV Fair Matching is polynomial-time solvable for $|C| = 2$ and that it becomes NP-hard for $|C| \geq 3$. Moreover, we settle all questions concerning the problems' classical complexity in terms of Δ_U and Δ_V, revealing a complete complexity landscape in this regard (see Figure 1). Finally, in Section 6, we show that Max-Min/MoV Fair Matching are linear-time solvable when every vertex in U can be matched to any vertex in V. Notably, all our algorithmic results hold even if we require that each vertex from V is matched to at least one vertex from U. This further constraint may appear when we need to divide the vertices into exactly k non-empty fair subsets. Although this constraint is seemingly simple, sometimes (e.g., in our FPT algorithm for Max-Min Fair Matching for k) non-trivial adaptions are needed.

Related Work. Stoica et al. [24] introduced three problems where the task is to partition a set of colored vertices into subsets with a small margin of victory satisfying some global size constraints. Among these three, the most general is Fair Connected Regrouping,

[2] We can enumerate all fair subsets of U in $2^n \cdot (n+k)^{O(1)}$ time. Then, Knapsack-like dynamic programming solves Fair Matching in $3^n \cdot (n+k)^{O(1)}$ time.

[3] In most described applications k is typically quite small and much smaller than n. For instance, Stoica et al. [24] performed some experiments for MoV Fair Matching to assign voters to districts with $n = 50,000$ and $k = 10$, and to assign students to schools with $n = 41,834$ and $k = 61$.

where one is given a vertex-colored graph G, an integer k, and a function that determines for each vertex which subsets it can be part of. The task is then to find a partitioning of G into k fair districts (i.e., connected components). In a follow-up work, Boehmer et al. [9] analyzed how the structure of G influences the (parameterized) computational complexity of Fair Connected Regrouping. The other two problems Stoica et al. [24] considered are special cases of Fair Connected Regrouping: One is Fair Regrouping where the connectivity constraints are dropped (corresponding to MoV Fair Matching). The other is Fair Regrouping_X, which is a special case of Fair Regrouping, where any vertex can belong to any district (corresponding to MoV Fair Matching on complete bipartite graphs; we study this special case in Section 6). They proved that Fair Regrouping is NP-hard for three colors (without any constraints on the degree of the graph) and is XP with respect to the number k of districts (i.e., polynomial-time solvable for constant k). They also showed that Fair Regrouping_X is XP with respect to the number of colors.

Coming back to Fair Matching as a matching problem, Ahmed et al. [4] proposed a global supermodular objective to model the fairness (which they call diversity) of a bipartite weighted many-to-many matching and developed a polynomial-time greedy heuristic for it. Ahmadi et al. [1] extended the work of Ahmed et al. [4] by generalizing the problem to the case where vertices can have multiple different colors and presented a pseudo-polynomial-time algorithm for it. Moreover, Dickerson et al. [13] applied this formulation of fairness to an online setting where vertices from the left side arrive over time and Ahmed et al. [3] applied it to the task of forming teams.

Fairness is also a popular topic when finding a stable many-to-one matching of vertices that have preferences over each other. Here, fairness constraints are typically modeled by imposing for each vertex from the right side certain lower and upper bounds on the number of vertices of each color that can be matched to it [7, 8, 10, 16, 18].

More broadly speaking, fairness has recently also been frequently applied to a variety of different problems from the area of combinatorial optimization. For instance, in the context of the Knapsack [22] or Maximum Coverage [6] problem, fairness means that all types are represented equally in the selected solution. For clustering, each cluster is considered fair when each type accounts for a certain fraction of vertices in it [2, 15].

The proof (or their completion) of all results marked by ($\star$) are omitted.

2 Preliminaries

For two integers $i < j \in \mathbb{N}$, let $[i, j] = \{i, i+1, \dots, j-1, j\}$ and let $[i] = [1, i]$. For a set S and an element $x \in S$, we sometimes write $S - x$ to denote $S \setminus \{x\}$.

Let $G = (U \cupdot V, E)$ be a bipartite graph, where U is the *left side* and V is the *right side* of G. Let $n := |U|$ and $k := |V|$ be the number of vertices in the left side and right side, respectively. For a vertex $w \in U \cupdot V$ and an edge set $M \subseteq E$, let $M(w)$ be the set of vertices *matched to* w in M, i.e., $M(w) = \{w' \in U \cupdot V \mid \{w, w'\} \in M\}$. We say that $M \subseteq E$ is a *many-to-one matching* in G if $|M(u)| \leq 1$ for every $u \in U$. A many-to-one matching M is *left-perfect* if $|M(u)| = 1$ for every $u \in U$. Note that we require M to be left-perfect as otherwise an empty set would constitute a trivial solution for our problem. When clear from context, we refer to a left-perfect many-to-one matching as a matching. For a vertex $w \in U \cupdot V$, let $N_G(w)$ be the set of its neighbors in G, i.e., $N_G(w) = \{w' \in U \cupdot V \mid \{w, w'\} \in E\}$. For $W \subseteq U \cupdot V$, let $N_G(W) = \bigcup_{w \in W} N_G(w)$ be the joint neighborhood of vertices from W and let $\nu_G(W) = \{w' \in U \cupdot V \mid N_G(w') \subseteq W\}$ be the set of vertices which are only adjacent to vertices in W. We drop the subscript $\cdot_G$ when it is clear from context.

Let C be the set of colors and let $\mathrm{col}\colon U \to C$ be a function that assigns a color to every vertex of U. For $U' \subseteq U$, let $U'_c \subseteq U'$ be the set of vertices $u \in U'$ of color c. For instance, given a matching M and a vertex $v \in V$, $M(v)_c$ denotes the set of vertices matched to v in M that have color c. We denote by $G_c = G[U_c \cup V]$ the graph G restricted to vertices from $U_c \cup V$. We use the shorthand $N_c(W)$ (resp., $\nu_c(W)$) for $N_{G_c}(W)$ (resp., $\nu_{G_c}(W)$).

Throughout the paper, we assume that the set C of colors is equipped with some linear order $\leq_C$, which serves as a tie breaker. So $\arg\max$ over C is well-defined. We write $\max^1$ for max and $\max^2$ for the second largest element.

We now define our two fairness measures. For a subset of vertices $U' \subseteq U$, let $\mathrm{MoV}(U') := \max^1_{c\in C} |U'_c| - \max^2_{c\in C} |U'_c|$ be the difference between the number of occurrences of the most and second most frequent color in U'. Similarly, for a subset of vertices $U' \subseteq U$, let $\mathrm{MmM}(U') := \max_{c\in C} |U'_c| - \min_{c\in C} |U'_c|$ be the difference between the number of occurrences of the most and least frequent color in U'. A subset of vertices $U' \subseteq U$ is ℓ-fair according to MoV (resp., Max-Min) if $\mathrm{MoV}(U') \leq \ell$ (resp., $\mathrm{MmM}(U') \leq \ell$).[4] A many-to-one matching M in G is ℓ-fair according to MoV (resp., Max-Min) if $M(v)$ is ℓ-fair according to MoV (resp., Max-Min) for all $v \in V$. The considered fairness notion will always be clear from context. We now define our central problem Π Fair Matching for some fairness measure Π:

Π Fair Matching	
Input:	A bipartite graph $G = (U \cup V, E)$, a set C of colors, a function $\mathrm{col}\colon U \to C$, and an integer $\ell \in \mathbb{N}$.
Question:	Is there a left-perfect many-to-one matching $M \subseteq E$ which is ℓ-fair according to the fairness measure Π?

We also sometimes consider Π Fair Matching with size constraints where additionally given two integers p and q, we require that the matching M to be found satisfies $p \leq |M(v)| \leq q$ for all $v \in V$. We refer to the case with $p = 1$ and $q = n$ as the non-emptiness constraint. This constraint is arguably crucial for some applications when we want to partition the vertices in the left side into exactly k non-empty subsets.

Let $\mathcal{I}$ be an instance of some problem and let $\mathcal{P}(\mathcal{I})$ be an integer linear program (ILP) constructed from $\mathcal{I}$. We say that $\mathcal{P}$ is *complete* if $\mathcal{P}(\mathcal{I})$ is feasible whenever $\mathcal{I}$ is a yes-instance. Conversely, we say that $\mathcal{P}$ is *sound* if $\mathcal{I}$ is a yes-instance whenever $\mathcal{P}(\mathcal{I})$ is feasible. In this work, we will make use of Lenstra's algorithm [19, 20] that decides whether an ILP of size L with p variables is feasible using $O(p^{2.5p+o(p)} \cdot |L|)$ arithmetic operations.

We assume that the reader is familiar with basic concepts in parameterized complexity (see for instance [12]). As a reminder, an FPT algorithm for a parameter k is an algorithm whose running time on input $\mathcal{I}$ is $f(k) \cdot |\mathcal{I}|^{O(1)}$ for some computable function f.

3 Warmup: FPT Algorithms for $k + |C|$

We prove that both Fair Matching problems are fixed-parameter tractable with respect to $k+|C|$: We present an integer linear programming (ILP) formulation of these problems whose number of variables is bounded in a function of the parameter $k+|C|$ and subsequently employ

[4] Notably, the definition of margin of victory of Stoica et al. [24] differs slightly from ours in that in their definition sets of vertices where the two most frequent colors have the same number of occurrences have a margin of victory of one (and not of zero). We chose our definition in accordance with Boehmer et al. [9] to be able to distinguish a tie between two colors from one color being one vertex ahead of another.

Lenstra's algorithm [19, 20]. Notably, one can upper-bound the number of "types" (according to their neighborhoods and colors) of vertices in U by $2^k \cdot |C|$. Using this observation, it is straightforward to give an ILP formulation of Max-Min/MoV Fair Matching using $O(2^k \cdot |C|)$ variables. Instead, we follow a theoretically more involved but more efficient approach. For this, we use a structural property of our problem related to Hall's theorem, which decreases the number of variables in our ILP to $O(|C| \cdot k)$. We reuse some of the results from this section in Section 4, where we prove that Max-Min/MoV Fair Matching are actually fixed-parameter tractable with respect to k.

To prove that the ILP we present in the following is complete, we use the following:

▶ **Lemma 1** (⋆). *Let $G = (U \cup V, E)$ be a bipartite graph and let M be a left-perfect many-to-one matching. Then, $|\nu(W)| \leq \sum_{v \in W} |M(v)| \leq |N(W)|$ for every $W \subseteq V$.*

For proving that our ILP is sound, we use the following:

▶ **Lemma 2.** *Let $G = (U \cup V, E)$ be a bipartite graph and let $\{z_v \in \mathbb{N} \mid v \in V\}$ be a set of integers. Suppose that $\sum_{v \in W} z_v \geq |\nu_G(W)|$ for every $W \subseteq V$ and that $\sum_{v \in V} z_v = |U|$. Then, there is a left-perfect many-to-one matching M such that $|M(v)| = z_v$ for every $v \in V$.*

Proof. Assume that the conditions stated in the lemma hold. We prove the existence of such a matching M by making use of Hall's theorem [17]. To do so, we introduce an auxiliary bipartite graph G' as follows: In G', the vertices on one of the two sides are the vertices from U. The vertices on the other side are $V' := \bigcup_{v \in V} Z_v$, where Z_v is a set of z_v vertices. There is an edge between $u \in U$ and $v' \in Z_v \subseteq V'$ if and only if $\{u, v\} \in E$. In order to apply Hall's theorem, we show that $|U'| \leq |N_{G'}(U')|$ for every $U' \subseteq U$.

Fix some $U' \subseteq U$ and let $W' = N_G(U')$. The construction of G' gives us $|N_{G'}(U')| = \sum_{v \in W'} z_v$. By the assumption of the lemma, we have $\sum_{v \in W'} z_v \geq |\nu_G(W')|$. Moreover, we have $\nu_G(W') = \nu_G(N_G(U')) \supseteq U'$. Consequently, we obtain $|N_{G'}(U')| = \sum_{v \in W'} z_v \geq |\nu_G(W')| \geq |U'|$. Hall's theorem then implies that G' admits a one-to-one matching M' which matches all vertices from U. In fact, M' is a perfect matching since $|V'| = \sum_{v \in V} z_v = |U|$ by our assumption. Now consider the matching M in G where a vertex $u \in U$ is matched to $v \in V$ if u is matched to a vertex from Z_v in M'. Then, M is a left-perfect many-to-one matching with $|M(v)| = z_v$ for every $v \in V$. ◀

Using Lemmas 1 and 2, we give an ILP formulation of Fair Matching with $O(|C| \cdot k)$ variables.

ILP formulation. Introduce a variable $z_v^c \in \mathbb{N}$ for every $v \in V$ and every $c \in C$. The variable z_v^c represents the number of vertices in U of color c that are matched to v. Suppose that the given instance admits a left-perfect ℓ-fair many-to-one matching M respecting the values of z_v^c. Then, for each $c \in C$, there is a matching M_c in G_c with $|M_c(v)| = z_v^c$ for $v \in V$ and $|M_c(u)| = 1$ for $u \in U_c$. As shown in Lemma 1, from this one can conclude that the following constraints must be fulfilled:

$$|\nu_c(W)| \leq \sum_{v \in W} z_v^c \leq |N_c(W)| \text{ for all } W \subseteq V, c \in C.$$

Next, we encode the fairness requirement. For Max-Min, we need to have that for every pair of colors the number of vertices of these two colors assigned to some vertex $v \in V$ differ by at most ℓ. Thus, we add the constraint

$$z_v^{c'} - z_v^c \leq \ell \text{ for all } v \in V \text{ and } c, c' \in C.$$

To model ℓ-fairness for MoV Fair Matching, we introduce two new binary variables $a_v^c, b_v^c \in \{0,1\}$ for all $v \in V$ and $c \in C$. Informally speaking, the intended meaning of these variables is that $a_v^c = 1$ (resp., $b_v^c = 1$) when c is the most (resp., second most) frequent color among vertices matched to v. We ensure that the values of these variables are set accordingly as follows:

$$z_v^c - z_v^{c'} \geq n(a_v^c + b_v^{c'} - 2), \quad z_v^c - z_v^{c'} \geq n(b_v^{c'} - a_v^c - 1), \text{ and } a_v^c + b_v^c \leq 1 \quad \forall v \in V, c, c' \in C;$$
$$\sum_{c \in C} a_v^c = \sum_{c \in C} b_v^c = 1 \quad \forall v \in V.$$

For the first constraint, note that it becomes $z_v^c \geq z_v^{c'}$ if $a_v^c = b_v^{c'} = 1$ and that it is always fulfilled otherwise. Similarly for the second constraint, observe that it becomes $z_v^c \geq z_v^{c'}$ if $a_v^{c'} = 0$ and $b_v^c = 1$ and that it is always fulfilled otherwise.

Finally, using a_v^c and b_v^c (and their meaning as proven above), we add the following constraint that encodes the ℓ-fairness in terms of margin of victory of $M(v)$ for all $v \in V$:

$$z_v^c - z_v^{c'} - n(2 - a_v^c - b_v^{c'}) \leq \ell \qquad \forall v \in V$$

Lastly, we can also add linear constraints ensuring that the number of vertices from U matched to each vertex $v \in V$ is between p and q: $p \leq \sum_{c \in C} z_v^c \leq q$ for all $v \in V$.

▶ **Theorem 3.** *Max-Min/MoV Fair Matching with arbitrary size constraints can be solved in* $O^\star((|C| \cdot k)^{O(|C| \cdot k)})$ *time.*

Proof. We show that an instance $(G = (U \cup V, E), C, \mathrm{col}, \ell, p, q)$ of Max-Min/MoV Fair Matching with size constraints admits an ℓ-fair left-perfect many-to-one matching if and only if the constructed ILP constructed is feasible. As described above, if the given instance is a yes-instance, there is an assignment to z_v^c satisfying all the constraints. Conversely, suppose that the ILP admits a solution $\{z_v^c \mid v \in V, c \in C\}$. Then, from our first set of constraints, we have for every $c \in C$ that $\sum_{v \in W} z_v^c \geq |\nu_c(W)|$ for every $W \subseteq V$ and $\sum_{v \in V} z_v^c = |U_c|$ (the later part follows from our first set of constraints for $W = V$). By Lemma 2, it follows that G_c has a matching M_c in which every vertex in U_c is matched and the values of z_v^c for $v \in V$ and $c \in C$ are respected. Aggregating M_c for all colors c yields a left-perfect ℓ-fair many-to-one matching for G respecting the given size constraints. Using Lenstra's algorithm [19, 20], the feasibility of the ILP can be determined in the claimed time. ◀

4 FPT Algorithms for k

In this section, we develop FPT algorithms for Max-Min/MoV Fair Matching for the parameterization $|V| = k$. We start with a discussion of the challenges for our algorithms. Afterwards, we obtain a new result on submodular and supermodular functions. Using this, in Section 4.1 we present the algorithm for Max-Min Fair Matching, and in Section 4.2 the slightly more involved algorithm for MoV Fair Matching.

The crux of our algorithms is an ILP as in Section 3. However, since we look into the parameterization without $|C|$, it would be too costly to introduce variables for each color. To illustrate our idea to work around this issue, take Max-Min Fair Matching as an example. One of the straightforward ideas how to formulate this problem as an ILP would be to introduce two variables $x_v \leq y_v$ for every vertex $v \in V$, where x_v (resp., y_v) encodes the minimum (resp., maximum) number of vertices of some color $c \in C$ matched to v. Informally speaking, to encode the ILP constraints from Section 3, we could now replace every occurrence of z_v^c with x_v (resp., y_v) if the constraint in which z_v^c occurs imposes an

upper (resp., lower) bound on z_v^c: the first set of constraints added in Section 3 translates to $\sum_{v\in W} y_v \geq \max_{c\in C} |\nu_c(W)|$ and $\sum_{v\in W} x_v \leq \min_{c\in C} |N_c(W)|$ for every $W \subseteq V$. Moreover, we add the constraint $y_v - x_v \leq \ell$ for all $v \in V$. Let $\mathcal{P}$ denote the ILP obtained this way. (See Section 4.1 for the formal construction of $\mathcal{P}$.) Although it is easy to see that $\mathcal{P}$ is complete, it turns out to be nontrivial to prove its soundness. To highlight this challenge, suppose that $\mathcal{P}$ is feasible for $\{x_v, y_v \mid v \in V\}$. To show that this implies that there is an ℓ-fair matching M, we have to show that for every color $c \in C$, the graph G_c has a matching M_c such that $x_v \leq |M_c(v)| \leq y_v$ for all $v \in V$. Unfortunately, we cannot directly apply Lemma 2 (as we were able to do in Section 3): To construct an ℓ-fair matching from $\{x_v, y_v \mid v \in V\}$ using Lemma 2, we have to show that for every color $c \in C$, there always exists a set of integers $\{z_v^c \mid v \in V\}$ with the following properties:

- **(i)** $\sum_{v\in W} z_v^c \geq |\nu_c(W)|$, $\forall W \subseteq V$
- **(ii)** $\sum_{v\in V} z_v^c = |U_c|$
- **(iii)** $x_v \leq z_v^c \leq y_v$, $\forall v \in V$.

Finding an assignment of variables z_v^c that fulfill (i) and (iii) is trivial; setting $z_v^c = y_v$ suffices because $\mathcal{P}$ dictates that $\sum_{v\in W} y_v \geq \max_{c'\in C} |\nu_{c'}(W)| \geq |\nu_c(W)|$ for every $W \subseteq V$. However, integers satisfying (i), (ii), and (iii) simultaneously are not trivially guaranteed to exist. To nevertheless prove their existence, we prove what we call the *touching separation theorem*, inspired by Frank's separation theorem [14] on submodular and supermodular functions. Our theorem implies that if there is a solution to $\mathcal{P}$, then there is an assignment of variables z_v^c satisfying (i), (ii), and (iii). Submodular and supermodular functions are defined as follows:

▶ **Definition 4.** *Let $f\colon 2^S \to \mathbb{N}$ be a set function over a set S. We say that f is submodular if $f(X)+f(Y) \geq f(X\cup Y)+f(X\cap Y)$ for every $X, Y \subseteq S$ and supermodular if $f(X)+f(Y) \leq f(X \cup Y) + f(X \cap Y)$ for every $X, Y \subseteq S$. Moreover, f is modular if f is both submodular and supermodular.*

Modular functions admit a simpler characterization, which will be useful in several proofs:

▶ **Lemma 5** (folklore, ⋆). *Let $f\colon 2^S \to \mathbb{N}$ be a set function. Then, f is modular if and only if $f(X) = f(\emptyset) + \sum_{x\in X}(f(x) - f(\emptyset))$ for every $X \subseteq S$.*

Frank's separation theorem [14] can be stated as follows: If $f\colon 2^S \to \mathbb{N}$ is submodular and $g\colon 2^S \to \mathbb{N}$ is supermodular, and $g(X) \leq f(X)$ for every $X \subseteq S$, then there exists a modular set function $h\colon 2^S \to \mathbb{N}$ such that $g(X) \leq h(X) \leq f(X)$ for every $X \subseteq S$. We prove an analogous separation theorem where the "lower-bound" function is the maximum of two functions – one being modular and the other being supermodular – and the "upper-bound" function is a modular function. (In general, the "lower-bound" function arising this way is neither submodular nor supermodular.) We additionally require that the function separating the two functions "touches" the lower-bound function. Our proof uses a rather involved induction on the size of S.

▶ **Theorem 6** (Touching separation theorem, ⋆). *Let $f, f'\colon 2^S \to \mathbb{N}$ be two modular set functions and let $g\colon 2^S \to \mathbb{N}$ be a supermodular set function. Suppose that $f(\emptyset) = f'(\emptyset) = g(\emptyset) = 0$ and $\max(f(X), g(X)) \leq f'(X)$ for every $X \subseteq S$. Then, there is a modular set function $h\colon 2^S \to \mathbb{N}$ such that $\max(f(X), g(X)) \leq h(X) \leq f'(X)$ for every $X \subseteq S$ and $h(S) = \max_{X\subseteq S} f(X) + g(S \setminus X)$.*

To apply Theorem 6, we use a supermodular function arising from a bipartite graph:

▶ **Lemma 7** (⋆). *Let $G = (U \uplus V, E)$ be a bipartite graph and let $g\colon 2^V \to \mathbb{N}$ be a set function such that $g(W) = |\nu(W)|$ for each $W \subseteq V$. Then, g is supermodular.*

4.1 Max-Min Fair Matching

We now present an FPT algorithm for Max-Min Fair Matching. As mentioned, our algorithm, which follows a similar approach as used in Section 3, builds an ILP. The difference is that the ILP constructed here involves $O(k)$ and not $\Theta(k \cdot |C|)$ variables. We prove the correctness of the ILP in Theorem 8, crucially relying on Theorem 6.

ILP formulation. We add two variables $x_v \leq y_v \in \mathbb{N}$ for every $v \in V$. The intended meaning for these variables is that for every color $c \in C$, the number of vertices from U_c matched to v is between x_v and y_v. We obtain the following constraints from Lemma 1:

$$\sum_{v \in W} y_v \geq \max_{c \in C} |\nu_c(W)| \text{ and } \sum_{v \in W} x_v \leq \min_{c \in C} |N_c(W)| \quad \forall W \subseteq V. \tag{1}$$

To encode ℓ-fairness, we add: $y_v - x_v \leq \ell$ for all $v \in V$.

▶ **Theorem 8.** *Max-Min Fair Matching can be solved in $O^\star(k^{O(k)})$ time.*

Proof. Our ILP uses $O(k)$ variables and $O(2^k)$ constraints; the construction takes $O^\star(2^k)$ time. Using Lenstra's algorithm [19, 20], it is possible to check whether the constructed ILP is feasible in $O^\star(k^{O(k)})$ time. It remains to prove the correctness of our ILP.

The completeness of our ILP follows from Lemma 1. For the soundness, suppose that $\{x_v, y_v \mid v \in V\}$ is a feasible solution for the ILP. For every color $c \in C$, we show the following: For the set $U_c \subseteq U$ of vertices of color c, there is a matching M_c in the bipartite graph $G_c = G[U_c \cup V]$ such that $x_v \leq |M_c(v)| \leq y_v$ for each $v \in V$, from which the soundness of the ILP directly follows. To show the existence of such a matching M_c, we will rely on Lemma 2. Note, however, that Lemma 2 asks for integers $\{z_v \mid v \in V\}$ meeting certain constraints, which we cannot choose arbitrarily as we have to respect the constraint $x_v \leq z_v \leq y_v$ for every $v \in V$. Let us fix some color $c \in C$. We find integers $\{z_v \mid v \in V\}$ via Theorem 6:

Let $f, f', g \colon 2^V \to \mathbb{N}$ be set functions such that $f(W) = \sum_{v \in W} x_v$ and $f'(W) = \sum_{v \in W} y_v$, and $g(W) = |\nu_c(W)|$ for each $W \subseteq V$. Note that f and f' are modular by Lemma 5 and that g is supermodular by Lemma 7. The constraints in the ILP ensure that $\max(f(W), g(W)) \leq f'(W)$ for every $W \subseteq V$. Consequently, Theorem 6 yields a set modular function $h \colon 2^V \to \mathbb{N}$ such that $\max(f(W), g(W)) \leq h(W) \leq f'(W)$ for each $W \subseteq V$ and $h(V) = \max_{W \subseteq V} f(W) + g(V \setminus W)$. Let $z_v = h(v)$ for every $v \in V$. Note that as h is modular and fulfills the constraints stated above, $\sum_{v \in W} z_v = h(W) \geq g(W) = |\nu_c(W)|$ for each $W \subseteq V$. Hence, in order to apply Lemma 2 on the integers $\{z_v \mid v \in V\}$, it remains to show that $\sum_{v \in V} z_v = h(V) = |U_c|$. Since our ILP requires that $f(W) = \sum_{v \in W} x_v \leq |N_c(W)|$ for $W \subseteq V$, we have that

$$\begin{aligned} f(W) + g(V \setminus W) &\leq |N_c(W)| + |\nu_c(V \setminus W)| \\ &= |\{u \in U_c \mid N_c(u) \cap W \neq \emptyset\}| + |\{u \in U_c \mid N_c(u) \subseteq V \setminus W\}| = |U_c|. \end{aligned}$$

Moreover, we have $f(\emptyset) + g(V) = |U_c|$, resulting in $h(V) = \max_{W \subseteq V} f(W) + g(V \setminus W) = |U_c|$ by Theorem 6. Therefore, the graph G_c admits a matching M_c with $x_v \leq |M_c(v)| \leq y_v$ for each $v \in V$ by Lemma 2. Combining these matchings yields an ℓ-fair matching in G. ◀

Non-emptiness constraint. For a matching M found by our algorithm, we may have $M(v) = \emptyset$ for some $v \in V$. So the non-emptiness constraint may be violated. Unfortunately, there is seemingly no simple linear constraint to ensure that $M(v) \neq \emptyset$ for each $v \in V$.[5]

[5] Adding $x_v > 0$ ensures that there is at least one vertex of each color matched to v. Adding $y_v > 0$ is not enough, as the ILP only ensures that for each color *at most* y_v vertices are matched to v.

Overcoming this challenge, we now develop an FPT algorithm for Max-Min Fair Matching with the non-emptiness constraint. We will build upon the ILP formulation for Theorem 8. First, observe that for $\ell = 0$, it suffices to add the constraint $y_v > 0$ for all $v \in V$ because this ensures that every vertex $v \in V$ is matched to at least $x_v = y_v > 0$ vertices of each color.

For $\ell > 0$, we develop a more involved algorithm. We will only describe its main ideas here. Suppose that there is an ℓ-fair many-to-one matching M such that $M(v) \neq \emptyset$ for each $v \in V$. By choosing an arbitrary element u_v of $M(v)$ for each $v \in V$, we obtain a matching $M^\star := \{\{u_v, v\} \mid v \in V\} \subseteq M$ with $|M^\star(v)| = 1$ for each $v \in V$. Since there are possibly $n^{\Omega(k)}$ choices for $M^\star$, we cannot assume that $M^\star$ is given. Instead, our algorithm only "guesses" some structural properties of $M^\star$, which we will incorporate into the above ILP for Max-Min Fair Matching by adding further constraints. (Our algorithm avoids guessing objects marked with a star.)

For each $v \in V$, let $\chi(v)$ be the color of $M^\star(v)$. By iterating over all possible partitions $\mathcal{V}$ of V, we first guess a partition of V according to $\chi(v)$, i.e., two vertices $v, v' \in V$ belong to the same subset of $\mathcal{V}$ if and only if $\chi(v) = \chi(v')$. For each $S \in \mathcal{V}$, let $\chi(S)$ be the color of $\chi(v)$ for an arbitrary vertex $v \in S$. Let us fix some $S \in \mathcal{V}$. We will formulate constraints that must be fulfilled when each vertex v in S is matched to $M^\star(v)$ (which has color $\chi(S)$). For this, let $U_S^\star \subseteq U_{\chi(S)}$ be the set of vertices from U of color $\chi(S)$ incident to an edge in $M^\star$ and let $G_S^\star$ be the graph obtained from $G_{\chi(S)}$ by deleting all edges incident to $U_S^\star$ and then adding the edges of $M^\star$ whose endpoint on the left side has color $\chi(S)$. Since every edge in M with an endpoint of color $\chi(S)$ is present in $G_S^\star$, these edges form a left-perfect many-to-one matching in $G_S^\star$. Thus, by Lemma 1, we should have $\sum_{v \in W} y_v \geq |\nu_{G_S^\star}(W)|$ and $\sum_{v \in W} x_v \leq |N_{G_S^\star}(W)|$ for each $W \subseteq V$ if there is a left-perfect matching containing $M^\star$ in $G_S^\star$. We need to evaluate $|\nu_{G_S^\star}(W)|$ and $|N_{G_S^\star}(W)|$ to include these constraints into our ILP. Note, however, that we cannot compute these values without $M^\star$ given. In the following, we explain how we can nevertheless incorporate these constraints by guessing further structural aspects of $M^\star$.

First, we rewrite $|\nu_{G_S^\star}(W)|$ and $|N_{G_S^\star}(W)|$ as follows:

$$|\nu_{G_S^\star}(W)| = |\nu_{\chi(S)}(W)| + |\{v \in S \cap W \mid N_{G_{\chi(S)}}(M^\star(v)) \not\subseteq W\}| \text{ and}$$
$$|N_{G_S^\star}(W)| = |N_{\chi(S)}(W)| - |\{v \in S \setminus W \mid N_{G_{\chi(S)}}(M^\star(v)) \cap W \neq \emptyset\}|.$$

To see why the first equation holds, observe that we have only deleted edges when constructing $G_S^\star$ from $G_{\chi(S)}$. Thus, we have $\nu_{G_{\chi(S)}}(W) \subseteq \nu_{G_S^\star}(W)$. Moreover, we have $u \in \nu_{G_S^\star}(W) \setminus \nu_{G_{\chi(S)}}(W)$ if and only if $u = M^\star(v)$ for some $v \in S \cap W$ (which implies that u is only adjacent to v in $G_S^\star$) and u has a neighbor outside of W in $G_{\chi(S)}$. The second equation follows similarly: As we only deleted edges, we have $N_{G_S^\star}(W) \subseteq N_{G_{\chi(S)}}(W)$. We also have $u \in N_{G_{\chi(S)}}(W) \setminus N_{G_S^\star}(W)$ if and only if $u = M^\star(v)$ for some $v \in S \setminus W$ and u has a neighbor in W in $G_{\chi(S)}$. To evaluate the second term in each of these equations, we guess a function $\mu \colon V \to 2^V$ such that $\mu(v) = N_{G_{\chi(S)}}(M^*(v))$ for each $v \in V$. For $\alpha(S, W) := |\{v \in S \cap W \mid \mu(v) \not\subseteq W\}|$ and $\beta(S, W) := |\{v \in S \setminus W \mid \mu(v) \cap W \neq \emptyset\}|$, we then have:

$$|\nu_{G_S^\star}(W)| = |\nu_{\chi(S)}(W)| + \alpha(S, W) \text{ and } |N_{G_S^\star}(W)| = |N_{\chi(S)}(W)| - \beta(S, W). \tag{2}$$

To incorporate the constraints $\sum_{v \in W} y_v \geq |\nu_{G_S^\star}(W)|$ and $\sum_{v \in W} x_v \leq |N_{G_S^\star}(W)|$, it remains to deal with $|\nu_{\chi(S)}(W)|$ and $|N_{\chi(S)}(W)|$. Note that we cannot compute $|\nu_{\chi(S)}(W)|$ or $|N_{\chi(S)}(W)|$ without $M^\star$ given. Moreover, it would be costly to guess these values (which can be $\Omega(n)$) for every $S \in \mathcal{V}$ and $W \subseteq V$ or the values of $\chi(S)$ (which can

be $\Omega(|C|)$) for every $S \in \mathcal{V}$. Instead, we relate these two values to $\max_{c\in C} |\nu_c(W)|$ and $\min_{c\in C} |N_c(W)|$ by guessing their respective differences. Although these differences may be $\Omega(n)$, we discover that we can cap them at k: When they are larger, then the arising constraints are already covered by Constraint (1) from the original ILP. Formally, we guess $X(S,W) = \min(|N_{\chi(S)}(W)| - \min_{c\in C} |N_c(W)|, k)$ and $Y(S,W) = \min(\max_{c\in C} |\nu_c(W)| - |\nu_{\chi(S)}(W)|, k)$ for each $S \in \mathcal{V}$ and $W \subseteq V$ by iterating over all possible $X, Y \colon \mathcal{V} \times 2^V \to \{0, \dots, k\}$ (for each of them we have at most $(k+1)^{k\cdot 2^k} \in O(2^{2^{O(k)}})$ choices).

To account for the constraints $\sum_{v\in W} y_v \geq |\nu_{G^\star_S}(W)|$ and $\sum_{v\in W} x_v \leq |N_{G^\star_S}(W)|$, we now add the following constraint to the ILP for each $S \in \mathcal{V}$ and $W \subseteq V$:

$$\sum_{v\in W} y_v \geq \max_{c\in C} |\nu_c(W)| - Y(S,W) + \alpha(S,W) \text{ and}$$
$$\sum_{v\in W} x_v \leq \min_{c\in C} |N_c(W)| + X(S,W) - \beta(S,W).$$

To see why these constraints must be fulfilled, we consider two cases. If $|N_{\chi(S)}(W)| - \min_{c\in C} |N_c(W)| \leq k$ (resp., $\max_{c\in C} |\nu_c(W)| - |\nu_{\chi(S)}(W)| \leq k$), then by the definition of $X(S,W)$ (resp. $Y(S,W)$) and Equation (2), we have $|N_{G^\star_S}(W)| = \min_{c\in C} |N_c(W)| + X(S,W) - \beta(S,W)$ (resp., $|\nu_{G^\star_S}(W)| = \max_{c\in C} |\nu_c(W)| - Y(S,W) + \alpha(S,W)$). Otherwise, we claim that the constraint $\sum_{v\in W} x_v \leq |N_{G^\star_S}(W)|$ (resp. $\sum_{v\in W} y_v \geq |\nu_{G^\star_S}(W)|$) is already captured by Constraint (1), since $X(S,W) = k \geq \beta(S,W)$ (resp., $Y(S,W) = k \geq \alpha(S,W)$), we have $\sum_{v\in W} x_v \leq \min_{c\in C} |N_c(W)| \leq \min_{c\in C} |N_c(W)| + X(S,W) - \beta(S,W)$ (resp., $\sum_{v\in W} y_v \geq \max_{c\in C} |\nu_c(W)| \geq \max_{c\in C} |\nu_c(W)| - Y(S,W) + \alpha(S,W)$).

Iterating over all described guesses and for each solving the constructed ILP, we get:

▶ **Theorem 9** (⋆). Max-Min Fair Matching *with the non-emptiness constraint can be solved in* $O^*(2^{2^{O(k)}})$ *time.*

4.2 MoV Fair Matching

We now develop an FPT algorithm for MoV Fair Matching for the parameter k, which also works with the non-emptiness constraint. Our algorithm has two parts. In the first part, we give an FPT algorithm (using an ILP) for an auxiliary problem called Targeted MoV Fair Matching. This is a variant of MoV Fair Matching, where for each $v \in V$, the two most frequent colors appearing in $M(v)$ are given as part of the input. We establish the soundness of the ILP for Targeted MoV Fair Matching using again Theorem 6 and Lemma 2. In the second part, we present a (randomized) parameterized reduction from MoV Fair Matching to Targeted Mov Fair Matching using the color coding technique [5]. To apply this technique, we show that the colors that appear (second) most frequently in $M(v)$ for some $v \in V$ "stand out" in a fair matching that fulfills certain conditions. Then, the color coding technique essentially allows us to determine these colors.

Part I. First, we define an auxiliary problem, which we call Targeted MoV Fair Matching. The input for MoV Fair Matching is also part of the input for Targeted MoV Fair Matching. Moreover, Targeted MoV Fair Matching takes as input two functions $\mu^1, \mu^2 \colon V \to C$. In Targeted MoV Fair Matching, we ask for an ℓ-fair matching M such that for every vertex $v \in V$, $\mu^1(v)$ (resp., $\mu^2(v)$) is the most (resp., second most) frequent color among the vertices $M(v)$ matched to v in M.

We now develop an FPT algorithm for Targeted MoV Fair Matching by means of an ILP. Let $C_{1,2} = \{\mu^1(v), \mu^2(v) \mid v \in V\}$ be the set of colors that appear (second) most frequent among the vertices matched to some vertex in V and let $C' = C \setminus C_{1,2}$ be the set

of other colors. Notably, the size of $C_{1,2}$ is linearly bounded in our parameter k. For every $v \in V$, we introduce a variable y_v which represents the number of vertices of color $\mu^2(v)$ matched to v. The values of y_v need to be chosen in a way such that, for every color $c' \in C'$, there is a matching $M_{c'}$ in $G_{c'}$ such that $|M_{c'}(v)| \leq y_v$ for all $v \in V$. By Lemma 1, we obtain the following constraint which must be fulfilled and add it to the ILP:

$$\sum_{v \in W} y_v \geq \max_{c' \in C'} |\nu_{c'}(W)| \quad \forall W \subseteq V.$$

For the vertices of colors in $C_{1,2}$, we impose constraints in the same way as in Section 3. For every $c \in C_{1,2}$ and $v \in V$, we introduce a variable z_v^c which represents the number of vertices of color c matched to v. Then, we add the following constraints according to Lemma 1.

$$|\nu_c(W)| \leq \sum_{v \in W} z_v^c \leq |N_c(W)| \quad \forall W \subseteq V, c \in C_{1,2}.$$

In case we have a lower bound $p = 1$, we additionally require that $z_v^{\mu^1(v)} \geq 1$ for all $v \in V$. Finally, we encode the ℓ-fairness: $y_v = z_v^{\mu^2(v)}$ and $z_v^{\mu^2(v)} \leq z_v^{\mu^1(v)} \leq z_v^{\mu^2(v)} + \ell$ for all $v \in V$.

In order to show the correctness of the ILP, with the help of Theorem 6, we prove the following adaptation of Lemma 2, in which we show that there exists a matching of the vertices of colors from C' to vertices from V respecting y_v for all $v \in V$.

▶ **Lemma 10** (⋆). *Let $G = (U \cup V, E)$ be a bipartite graph and let $\{z_v \in \mathbb{N} \mid v \in V\}$ be a set of integers. Suppose that $\sum_{v \in W} z_v \geq |\nu_G(W)|$ for every $W \subseteq V$. Then, there is a left-perfect many-to-one matching M such that $M(v) \leq z_v$ for every $v \in V$.*

Using Lemmas 2 and 10, we can now show that the above constructed ILP is feasible if and only if the given Targeted MoV Fair Matching is a yes-instance.

▶ **Proposition 11** (⋆). *Targeted MoV Fair Matching can be solved in $O^\star(k^{O(k^2)})$ time even with the non-emptiness constraint.*

Part II. We will employ the color coding technique to reduce MoV Fair Matching to Targeted Mov Fair Matching. To do so, we introduce another auxiliary problem called $\mathcal{Q}$-MoV Fair Matching. To define the problem, we first introduce additional notation. Suppose that M is a matching in the input graph $G = (U \cup V, E)$. Let $\mu_M^1, \mu_M^2 \colon V \to C$ be mappings such that for every vertex $v \in V$, $\mu_M^1(v)$ (resp., $\mu_M^2(v)$) is the most (resp., second most) frequent color among the vertices $M(v)$ matched to v in M. When the maximum or second maximum is achieved by more than one color, we break ties according to a fixed linear order $\leq_C$ on C. Let $\mathcal{V} = \{v^1, v^2 \mid v \in V\}$ be a set containing $2|V|$ elements and let $\mathcal{P}(M)$ be a partition of $\mathcal{V}$ into subsets $S \subseteq \mathcal{V}$ where for every $S \in \mathcal{P}(M)$, $v^i, v'^j \in S$ if and only if $\mu_M^i(v) = \mu_M^j(v')$ for $v, v' \in V$ and $i, j \in [2]$.

Using this, we define $\mathcal{Q}$-MoV Fair Matching. Here, $\mathcal{Q}$ is a partition of $\mathcal{V}$ and we assume that $\mathcal{Q}$ is fixed. The input of $\mathcal{Q}$-MoV Fair Matching is identical to the input of MoV Fair Matching. The difference is that $\mathcal{Q}$-MoV Fair Matching asks for a left-perfect ℓ-fair many-to-one matching M in G *consistent* with $\mathcal{Q}$, that is, $\mathcal{P}(M) = \mathcal{Q}$. Clearly, an instance of MoV Fair Matching is a yes-instance if and only if there exists a partition $\mathcal{Q}$ of $\mathcal{V}$ such that the corresponding $\mathcal{Q}$-MoV Fair Matching instance is a yes-instance. Since there are at most $k^{O(k)}$ ways to partition $\mathcal{V}$ (which is a set of $2k$ elements), we can afford to "guess" $\mathcal{Q}$ in our FPT algorithm. We thus focus on solving $\mathcal{Q}$-MoV Fair Matching. In particular, we assume without loss of generality that $\mathcal{Q}$ is cardinality-wise maximum – the input graph G has no ℓ-fair left-perfect many-to-one matching M such that $|\mathcal{P}(M)| > |\mathcal{Q}|$ (this assumption becomes essential in the proof of Lemma 12).

We solve $\mathcal{Q}$-MoV Fair Matching using color coding. We focus on $\ell > 0$ and omit the case $\ell = 0$. To apply the color coding method, we show a rather technical lemma stating that if a color c is among the two most frequent colors in $M(v)$ for some $v \in V$ in a certain fair matching M, then c needs to "stand out" – the number of its occurrence in the neighborhood of v in G is greater than for any other color c', unless c' also "stands out".

▶ **Lemma 12.** *Let $\mathcal{I}$ be a yes-instance of $\mathcal{Q}$-MoV Fair Matching with $\ell > 0$. Then, $\mathcal{I}$ admits an ℓ-fair left-perfect many-to-one matching M such that, for every $v \in V$ and $i \in [2]$, $|N_{\mu^i_M(v)}(v)| \geq |N_{c'}(v)|$ for every $c' \in \{c \in C \mid \forall v \in V, i \in \{1,2\}\colon c \neq \mu^i_M(v)\}$.*

Proof. For a matching M, let $\sigma(M) := \sum_{v \in V, i \in \{1,2\}} |M(v)_{\mu^i_M(v)}|$ be the total number of the occurrences of the two most frequent colors in $M(v)$ over all vertices $v \in V$. Consider an ℓ-fair matching M that maximizes $\sigma(M)$ among all ℓ-fair matchings consistent with $\mathcal{Q}$. Let $C_M := \{\mu^i_M(v) \in C \mid v \in V, i \in \{1,2\}\}$ be the set of colors which are one of the two most frequent colors in $M(v)$ for some $v \in V$ and let $C'_M := C \setminus C_M$ be the set of other colors.

Assume for the sake of contradiction that there there is some $v \in V$ and $i \in [2]$ with $\mu^i_M(v) = c \in C_M$ and color $c' \in C'_M$ such that $|N_{c'}(v)| > |N_c(v)|$. Recall that by the definition of C'_M it holds that $|M(v)_c| \geq |M(v)_{c'}|$. Consider a left-perfect matching M' obtained from M as follows. Initially, let $M' := M$. We then repeat the following procedure $|M(v)_c| - |M(v)_{c'}| + 1$ times: We delete from M' an arbitrary edge $\{u, v'\} \in M'$ such that $u \in N(v) \subseteq U$ is a vertex of color c' and v' is some vertex in $V - v$, and then add an edge $\{u, v\}$. Note that this is always possible, as $|M(v)_{c'}| \leq |M(v)_c| \leq |N_c(v)| < |N_{c'}(v)|$. We claim that M' is a left-perfect ℓ-fair matching. It is easy to verify the left-perfectness of M'. For the ℓ-fairness, since $c' \in C'_M$, for every $v' \in V - v$, the number of occurrences of the two most frequent colors in $M'(v')$ has not changed compared to $M(v')$, i.e., $\max^1_{c'' \in C} |M'(v')_{c''}| = \max^1_{c'' \in C} |M(v')_{c''}|$ and $\max^2_{c'' \in C} |M'(v')_{c''}| = \max^2_{c'' \in C} |M(v')_{c''}|$. Thus, $M'(v')$ is ℓ-fair for each $v' \in V - v$. It thus remains to show that $\max^1_{c'' \in C} |M'(v)_{c''}| - \max^2_{c'' \in C} |M'(v)_{c''}| \leq \ell$. We consider three cases:

- If $c = \mu^1_M(v)$, then as we added $|M(v)_c| - |M(v)_{c'}| + 1$ vertices of color c' to $M(v)$, we have $\max^1_{c'' \in C} |M'(v)_{c''}| = |M'(v)_{c'}| = |M(v)_c| + 1$ and $\max^2_{c'' \in C} |M'(v)_{c''}| = |M(v)_c|$, and thus $\max^1_{c'' \in C} |M'(v)_{c''}| - \max^2_{c'' \in C} |M'(v)_{c''}| = 1 \leq \ell$.
- Suppose that $c = \mu^2_M(v)$ and $\max^1_{c \in C} |M(v)_c| > \max^2_{c \in C} |M(v)_c|$. Then, we have $\max^1_{c \in C} |M'(v)_c| = \max^1_{c \in C} |M(v)_c|$ and $\max^2_{c \in C} |M(v)_c| = \max^2_{c \in C} |M(v)_c| + 1$, and thus $\max^1_{c'' \in C} |M'(v)_{c''}| - \max^2_{c'' \in C} |M'(v)_{c''}| \leq \ell - 1 \leq \ell$.
- Suppose that $c = \mu^2_M(v)$ and $\max^1_{c \in C} |M(v)_c| = \max^2_{c \in C} |M(v)_c|$. Then, we have $\max^1_{c \in C} |M'(v)_c| = \max^1_{c \in C} |M(v)_c| + 1$ and $\max^2_{c \in C} |M(v)_c| = \max^2_{c \in C} |M(v)_c|$, and thus $\max^1_{c'' \in C} |M'(v)_{c''}| - \max^2_{c'' \in C} |M'(v)_{c''}| \leq 1 \leq \ell$.

This proves the ℓ-fairness of M.

Recall that $\mu^i_M(v) = c$. We now show that the existence of M' contradicts one of our assumptions. To that end, we consider the following two cases:

- Suppose that $\mu^j_M(v') = c$ for some $v' \in V \setminus \{v\}$ and $j \in [2]$. This case contradicts the fact that $\mathcal{Q}$ is cardinality-wise maximum: To see why, note that for the set S of $\mathcal{Q}$ containing v^i (which is of size at least two, since either v'^1 or v'^2 is in S), we have $\mathcal{P}(M') = (\mathcal{P}(M) \setminus \{S\}) \cup \{S - v, \{v\}\}$, implying that $|\mathcal{P}(M')| > |\mathcal{P}(M)|$.
- Suppose that $\mu^j_M(v') \neq c$ for each $v' \in V \setminus \{v\}$ and $j \in [2]$. Observe that $\{v^i\} \in \mathcal{Q}$. The matching M' is thus consistent with $\mathcal{Q}$. Moreover, we have $\sigma(M') > \sigma(M)$, which is a contradiction. ◀

With Lemma 12 at hand, we are ready to give a randomized reduction from $\mathcal{Q}$-MoV Fair Matching to Targeted MoV Fair Matching.

▶ **Lemma 13** (⋆). *Let $\mathcal{I}$ be an instance of $\mathcal{Q}$-MoV Fair Matching. We can compute in polynomial time an instance $\mathcal{J}$ of Targeted MoV Fair Matching such that (i) $\mathcal{J}$ is a yes-instance with probability at least δ (where $1/\delta \in k^{O(k)}$) if $\mathcal{I}$ is a yes-instance and (ii) $\mathcal{J}$ is a no-instance if $\mathcal{I}$ is no-instance.*

Proof for $\ell > 0$. We describe a polynomial-time procedure to construct an instance $\mathcal{J}$ of Targeted MoV Fair Matching from a given instance $\mathcal{I} = (G = (U \cup V, E), C, \mathrm{col}, \ell)$ of $\mathcal{Q}$-MoV Fair Matching. We randomly assign each color $c \in C$ to one of the subsets in $\mathcal{Q}$ with the intended meaning that if we assign color $c \in C$ to $S \in \mathcal{Q}$, then in a matching M in $\mathcal{I}$ one of the following holds: (i) for $v^1 \in S$, c appears as the most frequent color in $M(v)$ and for $v^2 \in S$, c appears as the second most frequent color in $M(v)$ and c appears nowhere else as the most or second most frequent color or (ii) c does not appear as the most or second most frequent color in $M(v)$ for any $v \in V$. Formally let $\lambda\colon C \to \mathcal{Q}$ be a function assigning each color to a subset in $\mathcal{Q}$, where each assignment is chosen uniformly and independently at random.[6] For every $v \in V$ and $i \in [2]$ with $v^i \in S$ for some $S \in \mathcal{Q}$, we find $c_v^i = \arg\max |N_c(v)|$, where $\arg\max$ is taken over all colors c with $\lambda(c) = S$. Then, we construct an instance $\mathcal{J}$ of Targeted MoV Fair Matching, where $\mu^i(v) = c_v^i$ for every $v^i \in \mathcal{V}$. If a hypothetical matching M such that $\mu_M^i(u) = \mu^i(u) = c_v^i$ for $v \in V$ and $i \in [2]$ is not consistent with $\mathcal{Q}$, we let $\mathcal{J}$ be a trivial no-instance. Clearly, the construction of $\mathcal{J}$ takes polynomial time.

Suppose that $\mathcal{I}$ is a yes-instance. We show that in this case $\mathcal{J}$ is a yes-instance with probability at least δ with $\delta^{-1} \in k^{O(k)}$. Let M be an ℓ-fair matching for $\mathcal{I}$ that fulfills the properties described in Lemma 12 (which by Lemma 12 always exists). Assume that $\lambda(\mu_M^i(v)) = S_v^i$ holds for every $v \in V$ and $i \in [2]$, where $S_v^i \in \mathcal{Q}$ denotes the subset in $\mathcal{Q}$ to which v^i belongs. We claim that under this assumption on λ, the instance $\mathcal{J}$ constructed by our procedure is a yes-instance. In fact, we show that M is a solution of $\mathcal{J}$ (which also directly implies that there is a solution consistent with $\mathcal{Q}$ and thus that no trivial no-instance is returned). Since M is an left-perfect ℓ-fair matching in G, we only have to show that $\mu_M^i(v) = \mu^i(v) = c_v^i$ for every $v \in V$ and $i \in [2]$.

Let $C_M := \{\mu_M^i(v) \in C \mid v \in V, i \in [2]\}$ be the set of colors which are among the two most frequent colors in $M(v)$ for some $v \in V$ and let $C'_M := C \setminus C_M$ be the set of other colors. By Lemma 12, for every $v \in V$, $c' \in C'_M$, and $i \in [2]$, we have $|N_{\mu_M^i(v)}(v)| \geq |N_{c'}(v)|$. Since we always break ties according to a fixed linear order (including when we find $\mu_M^i(v)$), we have $\mu_M^i(v) = \arg\max_{c \in C'_M \cup \{\mu_M^i(v)\}} |N_c(v)|$. Recall that when constructing $\mathcal{J}$ we have defined $c_v^i = \arg\max |N_c(v)|$, where the maximum is taken over the set $C_v^i := \{c \in C \mid \lambda(c) = S_v^i\}$. By our assumption that $\lambda(\mu_M^i(v)) = S_v^i$ for every $v \in V$ and $i \in [2]$, we have $\mu_M^i(v) \in C_v^i$. We also have $c \notin C_v^i$ for every $c \in C_M \setminus \{\mu_M^i(v)\}$, which implies that $C_v^i \subseteq C'_M \cup \{\mu_M^i(v)\}$. Consequently, we obtain $c_v^i = \arg\max_{c \in C_v^i} |N_c(v)| = \mu_M^i(v)$ for every $v \in V$ and $i \in [2]$. It follows that M is a solution of $\mathcal{J}$.

Finally, observe that the probability that $\lambda(\mu_M^i(v)) = S_v^i$ for every $v \in V$ and $i \in [2]$ is at least $|\mathcal{Q}|^{-|\mathcal{Q}|} \geq (2k)^{-2k}$, since λ is chosen uniformly and independently at random. Thus, if $\mathcal{I}$ is a yes-instance, $\mathcal{J}$ is a yes-instance with probability at least $(2k)^{-2k}$.

If $\mathcal{J}$ is a yes-instance, then $\mathcal{I}$ is also a yes-instance, as, by construction of $\mathcal{J}$, a solution M for $\mathcal{J}$ needs to satisfy $\mathcal{P}(M) = \mathcal{Q}$ and is thus also a solution for $\mathcal{I}$. ◀

[6] In the language of color coding, the function λ is often described as assignments of "colors" (the "colors" in color coding are different from the colors used here).

We repeat the algorithm of Lemma 13 independently $\delta^{-1} \in k^{O(k)}$ times on the given instance $\mathcal{I}$ of $\mathcal{Q}$-Fair Matching. If $\mathcal{I}$ is a yes-instance, then at least one instance of Targeted Mov Fair Matching returned by the algorithm is a yes-instance with probability at least $1-(1-\delta)^{\delta^{-1}} \geq 1-1/e$. By Proposition 11, a yes-instance of Targeted Mov Fair Matching can be recognized in $O^\star(k^{O(k^2)})$ time. We thus have a randomized algorithm to solve $\mathcal{Q}$-MoV Fair Matching in $O^\star(k^{O(k^2)})$ time. Recall that $\mathcal{Q}$ is a partition of a $2k$-element set. So there are at most $k^{O(k)}$ choices for $\mathcal{Q}$, which gives us the following theorem (we remark that our algorithm can be derandomized using a standard method [12]):

▶ **Theorem 14.** *There is a randomized $O^\star(k^{O(k^2)})$-time algorithm to solve MoV Fair Matching even with the non-emptiness constraint.*

5 Complexity Dichotomies with respect to $|C|$ and Maximum Degree

In this section, we study the computational complexity of Max-Min/MoV Fair Matching for fixed values of Δ_U, Δ_V, and $|C|$. Recall that Δ_U (resp., Δ_V) is the maximum degree of all vertices in U (resp., V). We identify several computational dichotomies regarding these parameters (see Figure 1). We first show a dichotomy on $|C|$. In particular, Max-Min/MoV Fair Matching is polynomial-time solvable for $|C|=2$ (even if there are arbitrary lower size constraints), while it is NP-hard for $|C|=3$.

▶ **Theorem 15** (⋆). *Max-Min/MoV Fair Matching is polynomial-time solvable for $|C|=2$ and NP-hard for $|C|\geq 3$.*

The next two theorems concern complexity dichotomies with respect to Δ_U and Δ_V. All NP-hardness results here hold for three colors, while all polynomial-time results hold for an arbitrary number of colors.

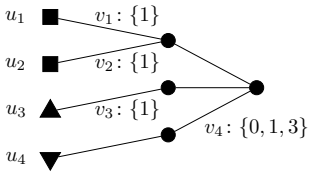
▶ **Theorem 16** (⋆). *MoV Fair Matching is polynomial-time solvable if $\Delta_U \leq 1$ or $\Delta_V \leq 4$ (even with the non-emptiness constraint) and NP-hard otherwise.*

As part of the proof of Theorem 16, we give an algorithm that solves MoV in polynomial-time for $\Delta_V \leq 4$. Our algorithm is a polynomial-time reduction to a polynomial-time solvable special case of General Factor, which we will define in the proof.

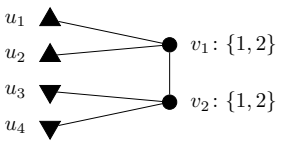
▶ **Proposition 17** (⋆). *MoV Fair Matching is polynomial-time solvable for $\Delta_V \leq 4$.*

Proof Sketch. We give a polynomial-time reduction to General Factor: In an instance of General Factor the input is an undirected graph $H=(W,F)$ and a degree list function $L\colon W \to 2^{\mathbb{N}}$ such that $L(w) \subseteq \{0,\dots,\deg_G(w)\}$ for every vertex $w \in W$. The problem asks for a spanning subgraph $H'=(W,F')$ for $F' \subseteq F$ such that $\deg_{H'}(w) \in L(w)$ for every $w \in W$. By a result of Cornuéjols [11], General Factor is polynomial-time solvable if for every $w \in W$, the degree list $L(w)$ has gaps of size at most one, i.e., $\{\min L(w), \min L(w)+1 \dots, \max L(w)\} \setminus L(w)$ does not contain any two consecutive integers. Given an instance $\mathcal{I}=(G=(U \cup V, E), C, \mathrm{col}, \ell)$ of MoV Fair Matching with $\Delta_V \leq 4$, we will construct an equivalent instance $\mathcal{J}=(H=(W,F),L)$ of this polynomial-time solvable special case of General Factor.

In the following, we give an overview of our construction. For every $v \in V$, we add a subgraph $H_v=(W_v,F_v)$ to H which contains all vertices from U adjacent to v in G ($N_G(v) \subseteq W_v$) but no other vertices from U. For the construction of H_v, we make extensive case distinctions depending on $N_G(v)$ and ℓ. See Figure 2 for two examples. The construction of H_v for all other cases are deferred to the appendix. The graph H is then the union of H_v



(a) H_v for $\ell = 0$ and $N(v)$ has two vertices of color α, one vertex of color β, and one vertex of color γ.



(b) H_v for $\ell = 1$ and $N(v)$ has two vertices of color α and two vertices of color β.

Figure 2 Exemplary constructions of H_v.

for all $v \in V$; notably, a vertex u from U may appear in multiple subgraphs H_v, in which case we identify all occurrences of u and merge them into one vertex. Moreover, for each $u \in U$, we set $L(u) = \{1\}$, which ensures that u is "matched" in every solution of $\mathcal{J}$.

To show that $\mathcal{I}$ and $\mathcal{J}$ are equivalent, it suffices to show the following for every $v \in V$:

A vertex set $S \subseteq N_G(v)$ is ℓ-fair if and only if there is a spanning subgraph $H'_v = (W_v, F'_v)$ of H_v such that $\deg_{H'_v}(u) = 1$ for every $u \in S$, $\deg_{H'_v}(u) = 0$ for every $u \in N(v) \setminus S$, and $\deg_{H'_v}(v') \in L(v')$ for every $v' \in W_v \setminus U$. $(\star)$

To see why $(\star)$ is sufficient, assume that $(\star)$ holds true. For the forward direction, suppose that $\mathcal{I}$ is a yes-instance, i.e., there is a ℓ-fair left-perfect many-to-one matching M in G. Then, $M(v) \subseteq N_G(v)$ is ℓ-fair for every $v \in V$. Hence, as we assume that $(\star)$ holds, we have a subgraph H'_v for every $v \in V$ that satisfies the degree constraints of $(\star)$. Consider a spanning subgraph H' whose edge set is the union of the edge set of H'_v over all v. It is easy to verify that H' constitutes a solution for $\mathcal{J}$. For the converse direction, suppose that $\mathcal{J}$ is a yes-instance, i.e., there is a spanning subgraph $H' = (W, F')$ with $\deg(w) \in L(w)$ for every $w \in W$. Then, the subgraph of H' induced by W_v satisfies all the degree constraints of $(\star)$. For $v \in V$, let $S_v \subseteq N_G(v)$ be the set of vertices that have a neighbor in $H'[W_v]$. By $(\star)$, S_v is ℓ-fair. Moreover, since $L(u) = \{1\}$ for every $u \in U$, every vertex appears in S_v for exactly one vertex $v \in V$. It follows that a matching M with $M(v) = S_v$ for every $v \in V$ is a ℓ-fair left-perfect many-to-one matching in $\mathcal{I}$. We remark that we can adapt our algorithm to handle the non-emptiness constraint. ◀

For Max-Min Fair Matching, we prove that fewer cases are polynomial-time solvable than for MoV Fair Matching:

▶ **Theorem 18** $(\star)$**.** *Max-Min Fair Matching is polynomial-time solvable if* $\Delta_U \leq 1$, $\Delta_V \leq 2$, *or* $(\Delta_U, \Delta_V) = (2, 3)$ *(even with the non-emptiness constraint) and NP-hard otherwise.*

6 Fair Matching on Complete Bipartite Graphs

A natural special case of Fair Matching is when the underlying graph is complete, i.e., each vertex in U can be assigned to any vertex in V. This special case is also among the three problems introduced by Stoica et al. [24] (they called it Fair Regrouping_X). Stoica et al. [24] presented a straightforward XP algorithm for MoV Fair Matching with size constraints parameterized by $|V|$ but left open the classical complexity. We partially settle this open question by proving that MoV Fair Matching on complete bipartite graphs is polynomial-time solvable even with the non-emptiness constraint. In fact, we find a precise characterization of yes-instances, which turns out to be surprisingly simple. However, it requires an intricate analysis to prove this, especially when the non-emptiness constraint is present. To simplify notation, we assume that $C = \{c_1, \ldots, c_{|C|}\}$ and that $|U_{c_i}| \geq |U_{c_{i+1}}|$ for each $i \in [1, |C| - 1]$ and set $|U_{c_i}| := 0$ for $i > |C|$.

▶ **Theorem 19** (⋆). *A MoV Fair Matching instance* $\mathcal{I} = (G = (U \cup V, E), C, \mathrm{col}, \ell)$ *with* G *being a complete bipartite graph is a yes-instance if and only if* $|U_{c_1}| \leq \ell k + \sum_{i \in [k]} |U_{c_{i+1}}|$. *With the non-emptiness constraint,* $\mathcal{I}$ *is a yes-instance if and only if it additionally satisfies:* $\ell > 0$ *and* $n \geq k$, *or* $\ell = 0$ *and* $n \geq 2k$.

▶ **Theorem 20** (⋆). *A Max-Min Fair Matching instance* $\mathcal{I} = (G = (U \cup V, E), C, \mathrm{col}, \ell)$ *with* G *being a complete bipartite graph is a yes-instance if and only if* $|U_{c_1}| \leq \ell k + |U_{c_{|C|}}|$. *With the non-emptiness constraint,* $\mathcal{I}$ *is a yes-instance if and only if it additionally satisfies:* $\ell > 0$ *and* $n \geq k$, *or* $\ell = 0$ *and* $|U_{c_1}| \geq k$.

Theorems 19 and 20 imply that Max-Min/MoV Fair Matching on a complete bipartite graph are solvable in linear time even with the non-emptiness constraint.

7 Conclusion

In this work, we have investigated the (parameterized) computational complexity of the Fair Matching problem. Two concrete directions of open questions are:

- We have provided algorithms that solve Fair Matching even if we require that every vertex in the right side is matched to at least one vertex. Can we extend our algorithms to handle arbitrary size constraints? In particular, does Fair Matching remain fixed-parameter tractable with respect to k? We have shown in Section 3 that Fair Matching is indeed FPT with respect to $k + |C|$ even for arbitrary size constraints. However, it does not seem straightforward to incorporate arbitrary size constraints in the ILPs given in Section 4. The complexity of Fair Matching on complete bipartite graphs (Section 6) is also open when arbitrary size constraints are present.
- Is Fair Matching solvable in $O^\star(2^k)$ time? Note that the ILP presented in Section 4.1 (which solves Max-Min Fair Matching without the non-emptiness constraint) is an ILP where the constraint matrix involves only zeros and ones when $\ell = 0$. Can we exploit such a structure in the constraint matrix to obtain a faster algorithm?

For future research, it would also be natural to study other variants of the Fair Matching problem. For instance, we may relax the left-perfect constraint studied in this work and consider a variant where the objective is to maximize the matching size under a fairness constraint. One may also look into other fairness notions such as proportionality constraints [21].

Abstract

We construct indistinguishability obfuscation (iO) solely under circular-security properties of encryption schemes based on the Learning with Errors (LWE) problem. Circular-security assumptions were used before to construct (non-leveled) fully-homomorphic encryption (FHE), but our assumption is stronger and requires circular randomness-leakage-resilience. In contrast with prior works, this assumption can be conjectured to be post-quantum secure; yielding the first provably secure iO construction that is (plausibly) post-quantum secure.

Our work follows the high-level outline of the recent work of Gay and Pass [STOC 2021], who showed a way to remove the heuristic step from the homomorphic-encryption based iO approach of Brakerski, Döttling, Garg, and Malavolta [EUROCRYPT 2020]. They thus obtain a construction proved secure under circular security assumption of natural homomorphic encryption schemes – specifically, they use homomorphic encryption schemes based on LWE and DCR, respectively. In this work we show how to remove the DCR assumption and remain with a scheme based on the circular security of LWE alone. Along the way we relax some of the requirements in the Gay-Pass blueprint and thus obtain a scheme that is secure under a different assumption. Specifically, we do not require security in the presence of a key-cycle, but rather only in the presence of a key-randomness cycle.

An additional contribution of our work is to point out a problem in one of the building blocks used by many iO candidates, including *all* existing provable post-quantum candidates. Namely, in the transformation from exponentially-efficient iO (XiO) from Lin, Pass, Seth and Telang [PKC 2016]. We show why their transformation inherently falls short of achieving the desired goal, and then rectify this situation by showing that *shallow* XiO (i.e. one where the obfuscator is depth-bounded) does translate to iO using LWE.

1 Introduction

The goal of program obfuscation [4, 28] is to transform an arbitrary circuit Π into an unintelligible but functionally equivalent circuit $\tilde{\Pi}$. The aforementioned works showed that strong simulation-based notions of obfuscation were impossible for general purpose functionalities. However, the seemingly weaker *indistinguishability obfuscation* (iO) was not ruled out by prior work (and has in fact been shown to be the same as the best possible notion of obfuscation [27]). In broad terms, iO requires that if two circuits Π_0 and Π_1 are two implementations of the same function, then their obfuscations are computationally indistinguishable.

Garg et al. [19, 21] presented the first candidate for general purpose iO, paving the way for numerous other candidates based on a variety of mathematical structures. Although iO appears to be a weak notion of security, it has been shown to be sufficient for numerous cryptographic applications, including ones that were previously not known to exist under other assumptions (see [6, 20, 41] for examples). The first realizations of obfuscation relied an a new algebraic object called multilinear maps [15, 19, 24], which had only recently been constructed. Furthermore, the security of these objects relied on new (and poorly understood) computational intractability assumptions, or more commonly on plain heuristics. In fact, several attacks on multilinear map candidates [14, 30] and on obfuscation constructions based on multilinear maps [12, 39] were demonstrated. To defend against these attacks, several safeguards have been (e.g., [5, 13, 17, 22, 38]) proposed. Even with these heuristic safeguards, all but the schemes based on the Gentry et al. [24] multilinear maps are known to be broken against quantum adversaries.

Towards the goal of avoiding heuristics and obtaining provably secure constructions, substantial effort was made towards obtaining iO while minimizing (with the ultimate goal of removing) the use of multilinear maps [3, 33, 34, 36, 37]. These efforts culminated in replacing the use of multilinear maps with just bilinear maps [1, 2, 31], together with an additional pseudorandom generators of constant locality over the integers with polynomial stretch. Very recently this last limitation was removed by Jain, Lin and Sahai [32]. Specifically, they obtained iO based on the combined (sub-exponential) hardness of the Learning with Errors problem (LWE), a large-modulus variant of the Learning Parity with Noise problem (LPN), the existence of a pseudorandom generator in NC_0, and in addition the hardness of the external Diffie-Hellman problem in bilinear groups (SXDH). We note that the use of the pairings makes these construction insecure against quantum adversaries.

A different approach towards provably secure iO, which is more relevant to this work, was presented by Brakerski et al. [9]. They showed an iO candidate that is based on combining certain natural *homomorphic* encryption schemes. However, their construction was *heuristic* in the sense that the security argument could only be presented in the random oracle model. In a recent work, Gay and Pass [23] showed a way to remove the heuristic step and instead rely on a concrete assumption. Their construction is proved secure under the circular security of natural homomorphic encryption schemes – specifically, they use homomorphic encryption schemes based on LWE and Decisional Composite Residuosity (DCR, also known as Paillier's assumption). In terms of assumptions, their construction assumes sub-exponential security of (i) the Learning with Error (LWE) assumption, (ii) the Decisional Composite Residuosity (DCR) assumption, and (iii) a new notion of security that they call "shielded randomness

leakage" (SRL). The latter essentially requires that a fully homomorphic encryption scheme (specifically the GSW encryption scheme [26]) remains secure even in the presence of a key-cycle with the Damgård-Jurik encryption scheme [16]. Moreover, the notion of security is not the standard semantic security, but rather a new notion of security with respect to leakage of ciphertext randomness. We note that this construction is insecure against quantum attackers because of the use of the Damgård-Jurik encryption scheme [16].[1] In this work, we ask:

Can we realize provably secure constructions of iO with (plausible) post-quantum security?

1.1 Our results

We obtain a general purpose iO construction based solely on the circular security of LWE-based encryption schemes. On a technical level, we achieve this by introducing a "packed" variant of the dual-Regev LWE-based encryption scheme, and showing novel ways of manipulating ciphertexts of this variant in conjunction with ciphertexts of an FHE scheme. This allows us to remove the need for DCR-based encryption from the construction of [9, 23]. Furthermore, our technique allows us to relax the SRL security property that is required, so that we no longer need to require SRL security with respect to a key-cycle, but rather only with respect to a key-randomness cycle. We put forth this potentially weaker assumption as an object for further study.

More concretely, the circular security assumption made in [23], and thus also in this work, is that a scheme (in particular a leveled FHE scheme) maintains this property even in the presence of some leakage on the randomness of the ciphertext. In [23] it is shown that standard GSW encryption [26] satisfies SRL security (under the LWE assumption), and the additional assumption is therefore that SRL security is maintained in the presence of a key-randomness cycle, connecting GSW to another encryption scheme. While this assumption falls into the category of "circular security assumptions", similarly to the ones that underlie bootstrapping in FHE, the concrete assumption is quite different. While in the FHE setting it was only assumed that (standard) CPA security is preserved given a key cycle, here we assume that the stronger SRL property remains intact.

Let us now state our results somewhat more precisely.

▶ **Theorem 1** (Informal). *Assume the (sub-exponential) hardness of the LWE problem, and the SRL security of GSW in the presence of a randomness-key cycle with a packed variant of dual-Regev, then there exists indistinguishability obfuscation for all circuits.*

We note that if we further assume that circular security also maintains post-quantum security, then our assumption becomes post-quantum secure; yielding the first provably secure iO construction that is post-quantum secure.

Shallow XiO. As an additional contribution, we identify a gap in the transformation of "exponentially efficient iO" (XiO), a notion introduced by Lin, Pass, Seth and Telang [35] that was used almost universally in prior work. We show that this transformation has an inherent problem that does not allow to recover the result as stated. This gap affects most known iO constructions and, in particular, *all post-quantum provably secure candidates*. We rectify this situation by showing that a fairly simple technical modification (i.e. constraining

[1] Concurrently, [23] updated their manuscript to also include a solution based on LWE. See Section 1.3 for additional discussion.

the compiler to be *shallow*) allows us to recover the prior results. Along the way, we develop a framework for analyzing composition of compressing encodings, which can be a useful perspective for future research in this area.

1.2 Technical Overview

We now provide a technical outline of our construction and its properties.

Obfuscation via Homomorphic Encryption. The connection between (fully) homomorphic encryption and obfuscation is fairly straightforward. Given a program Π to be obfuscated, we can provide a ciphertext c_Π which encrypts Π under an FHE scheme. This will allow to use homomorphism to derive $c_x = \mathsf{Enc}(\Pi(x))$ for all x. Now all that is needed is a way to decrypt c_x in a way that does not reveal any information on Π. Early works (e.g. [21] and followups) attempted to use this approach and provide a "defective" version of the secret key of the FHE scheme, but a different approach was suggested in [9].

Specifically, [9] considered a homomorphic evaluation that takes c_Π to c_{TT}, an encryption of the *entire truth table* of Π, i.e. to an encryption of a multi-bit value. By relying on prior generic transformations [35], they showed that one can reduce the task of constructing general-purpose obfuscation to the task of computing a "decryption" hint for c_{TT} with the following properties:

- Succinctness: The size of the decryption hint must be sublinear in the size of the truth table $|\mathsf{TT}|$.
- Simulatability: The decryption hint should not reveal any additional information besides the truth table TT.

The reason why this is helpful is that some so-called "packed-encryption" schemes have the property that a short ciphertext-dependent decryption hint suffices in order to decrypt the ciphertext, in a way that does not seem to leak the secret key of the scheme itself. While standard FHE schemes do not natively support packed encryption, it was shown in [8] that it is possible to use the so-called key-switching technique to switch from an FHE scheme into a packed-encryption scheme.

Alas, when instantiating the components of the [9] approach in its simplistic form described above, the decryption hint leaks information that renders the scheme insecure. To counter this issue, [9] proposed to inject another source of randomness: By adding freshly sampled ciphertexts of the packed-encryption scheme (which in their case was instantiated with the Damgård-Jurik scheme [16]) one can smudge the leakage of the decryption hint. However the size of these fresh ciphertext would largely exceed the size of the truth table TT. Therefore, [9] proposed to heuristically sample them from a random oracle, leveraging the fact that the ciphertexts of [16] are *dense*, i.e. a uniformly sampled string lies in the support of the encryption algorithm with all but negligible probability. This led to a candidate, but without a proof of security.

A Provably Secure Scheme. In a recent work, Gay and Pass [23] observed that for the purpose of constructing obfuscation, it suffices to consider schemes in the common random string (CRS) model where, importantly, the size of the CRS can exceed the size of the truth table. This allowed them to place the Damgård-Jurik ciphertexts in the CRS and therefore avoid relying on random-oracle-like heuristics.

They propose a new method to prove the security of this approach: Leveraging the structural property of the GSW scheme [26]. They showed that adding a GSW encryption of 0 to the evaluated FHE ciphertext (before key-switching to Damgård-Jurik) allows one

to program the FHE ciphertext in the security proof. To sample these GSW encryptions of 0, they propose to draw the random coins $\mathbf{r}^*$ again from the CRS and let the evaluator recompute the correct ciphertext $\mathsf{GSW.Enc}(0;\mathbf{r}^*)$.

Taken together, these new ideas allow them to prove their construction secure against the shielded randomness leakage (SRL) security of the resulting FHE scheme. Loosely speaking, SRL security requires that semantic security of an encryption scheme is retained in the presence of an oracle that leaks the randomness $\mathbf{r}_f$ of the homomorphic evaluation of the function f over the challenge ciphertext. However the randomness $\mathbf{r}_f$ is not revealed in plain to the adversary, instead it is "shielded" by the random coins of a fresh GSW ciphertext $c = \mathsf{GSW.Enc}(0;\mathbf{r}^*)$. That is, the adversary is given $(\mathbf{r}_f - \mathbf{r}^*, c)$. In fact, the adversary can obtain polynomially-many samples from this distribution, for any function f, conditioned on the fact that the adversary knows the output of $f(m^*)$, where m^* is the hidden message.

To gain confidence in the veracity of the assumption, [23] show that the GSW encryption scheme satisfies SRL security if the (plain) LWE assumption holds. However, their obfuscation scheme requires one to publish a key cycle of GSW and Damgård-Jurik (i.e. an encryption of the GSW secrey key under Damgård-Jurik and vice versa). Thus their final assumption is that SRL security is retained in the presence of such a key cycle.

Obfuscation from Circular-Secure LWE. We wish to remove the need for the Damgård-Jurik encryption scheme from the above construction paradigm. The major obstacle to overcome consists in designing an LWE-based encryption scheme that simultaneously satisfies three properties.

- Linear Homomorphism: In order to key switch the GSW ciphertext into this form, the scheme must satisfy some weak notion of homomorphism. Specifically, it must support the homomorphic evaluation of linear functions.
- Succinct Randomness: The scheme must allow us to encrypt a long message string with a short randomness, that can then function as the decryption hint.
- Dense Ciphertexts: A uniformly sampled string must lie in the support of the encryption algorithm with all but negligible probability. This will allow us to parse the CRS as a collection of ciphertexts.[2]

Unfortunately all natural lattice-based candidates seem to fail to satisfy all of these properties. In particular, for all LWE-based schemes linear homomorphism seems to be at odds with dense ciphertexts: To ensure that the noise accumulated during the homomorphic evaluation does not impact the decryption correctness, one needs to ensure a gap between the noise bound and the modulus. More concretely, ciphertext are typically of the form $(\mathbf{a}, \mathbf{a}\cdot\mathbf{s}+e+q/2\cdot\mathsf{m}) \in \mathbb{Z}_q^{n+1}$ where $e \ll q$, which makes them inherently sparse.

Our Solution: A Packed Variant of Dual-Regev that is also Dense-Friendly. We show that the above requirements can be relaxed. Our starting point is devising a "packed" version of the dual-Regev encryption scheme [25]. This scheme will not have dense ciphertexts so it does not fit the requirements from previous works. However, we will show how we can define, for the same scheme, a family of ciphertexts which are both "almost dense" and can inter-operate with the non-dense scheme, so as to allow to construct the obfuscator.

[2] Note that for the purpose of constructing the obfuscator, one could make do with a common reference string which can have an arbitrary distribution. However, the string needs to be parsed as a ciphertext with respect to *all* public-keys. Requiring dense ciphertexts is a simple requirement that implies this property.

Let us start with our packed dual-Regev scheme. To pack a k-bit plaintext $\mathbf{m} \in \{0,1\}^k$ in a dual-Regev ciphertext we construct the public key as a matrix $\mathbf{A} \in \mathbb{Z}_q^{m \times n}$, which is statistically close to uniform but is sampled together with a trapdoor τ (whose role will be explained below), and another uniformly sampled matrix $\mathbf{B} \in \mathbb{Z}_q^{k \times n}$. The encryption algorithm computes a the ciphertext as

$$(\mathbf{A} \cdot \mathbf{r} + \mathbf{e}_0, \mathbf{B} \cdot \mathbf{r} + q/2 \cdot \mathbf{m} + \mathbf{e})$$

where $\mathbf{r} \leftarrow\!\!\$\ \mathbb{Z}_q^n$ is the encryption randomness and the vectors $\mathbf{e}_0$ and $\mathbf{e}$ are the encryption noises, where the norm of both vectors is bounded by some $B \ll q$. The property of the trapdoor τ is that it allows to recover $\mathbf{r}$ from $\mathbf{A} \cdot \mathbf{r} + \mathbf{e}_0$. The (semantic) security of the scheme follows directly by definition of LWE. To decrypt, therefore, one can first use the trapdoor τ to recover $\mathbf{r}$ from the first m elements of the ciphertext, and then recompute the mask $\mathbf{B} \cdot \mathbf{r}$ and recover each individual bit by rounding to the closest multiple of $q/2$. Setting the parameters appropriately, we can guarantee that the decryption is always successful. One important property of this scheme is that the random coins $\mathbf{r} \in \mathbb{Z}_q^n$ are sufficient to recover the entire message and furthermore the size of $\mathbf{r}$ is succinct (in particular independent of k).

In terms of homomorphism, the scheme is straightforwardly additively homomorphic. Furthermore, it supports key switching from any scheme with almost-linear decryption as per [8].[3] In particular it is possible to take a (long) message encrypted under an FHE scheme such as GSW and convert it to an encryption of the same message under packed dual-Regev, using precomputed key-switching parameters.[4]

As explained above, this scheme does not have dense ciphertexts. At this point we make two crucial observations that will allow us to bypass this hurdle.

(1) In order to construct the obfuscator using the [9] approach, dense ciphertexts only need to enjoy a very limited form of homomorphism, they only need to support a single addition with a non-dense ciphertext.

This is essentially because the obfuscator has the following outline. It starts by considering the dense ciphertext from the CRS (or oracle in the case of the original [9]), and homomorphically bootstraps it into a non-dense FHE ciphertext by evaluating the decryption circuit. Let $\mathbf{m}$ be the (random) message that is induced by the process. Then, the FHE encryption of $\mathbf{m}$ is processed in order to create a non-dense *packed* encryption of $\mathbf{m} \oplus \mathsf{TT}$, where TT is the truth table of the program to be obfuscated (or, more accurately, a chunk of this truth table, partitioning into chunks is required in order to allow reusability of the keys). Then a single homomorphic addition between the dense and non-dense ciphertext would imply a packed encryption of the truth table. All of this can be performed by the evaluator of the obfuscated program, so all that is needed is the decryption hint for this final ciphertext, that would allow to recover TT.

We note importantly, that in prior approaches (including the [23] blueprint) the aforementioned bootstrapping creates a key cycle, since a packed ciphertext is bootstrapped into an FHE ciphertext, which is afterwards key-switched into a packed ciphertext. However, we notice that it suffices to provide an encryption of the (succinct) *randomness* of the dense ciphertext in order to apply bootstrapping, thus leading to a relaxed key-randomness circular assumption. Interestingly, this observation is not very useful for actual dense ciphertexts (since finding the randomness would require using the key), however, our relaxed notion of density described below will allow to apply it and thus relax the circularity notion as well.

---

[3] This is done using the by-now-standard technique of encrypting powers-of-two of the elements of the secret key of the latter scheme, so that it is possible to evaluate any inner product homomorphically.

[4] We note that the key switching parameters are quite long so it is required for our method that they are reusable.

(2) A notion of *almost-everywhere* density suffices. A ciphertext distribution is almost-everywhere dense if it is dense except for a non-dense part whose length is independent of k (the message length).

The reason that this is sufficient is that the non-dense part of the ciphertext, which we refer to as the *header*, can be generated by the obfuscator and provided to the evaluator as a part of the obfuscated program. Since the header is short, and in particular the message length k can be selected to be much longer than the header, the effect on the length of the obfuscated program will be minimal. As hinted above, since the obfuscator generates the header, it in particular also samples the randomness for the final almost-everywhere dense ciphertext. This means that the obfuscator can generate the bootstrapping parameters using this randomness without requiring a key cycle.

Dense Encryption Mode. With these observations in mind we describe an alternative encryption mode ($\mathsf{DenseEnc}$) for the packed variant of dual-Regev where the bulk of the ciphertext is dense. On input a message $\mathbf{m} \in \{0,1\}^k$, the encryption algorithm in dense mode computes the following ciphertext

$$(\mathbf{A} \cdot \mathbf{r} + \mathbf{e}_0, \mathbf{B} \cdot \mathbf{r} + q/2 \cdot \mathbf{m} + \mathbf{u})$$

where $\mathbf{r}$ and $\mathbf{e}_0$ are sampled as before and $\mathbf{u} \leftarrow\!\!\$\ [-q/4, +q/4]^k$. For convenience, we are going to split the ciphertexts into two blocks: The header $\mathbf{h}_0 \in \mathbb{Z}_q^m$ and the message carrier $(h_1, \ldots, h_k) \in \mathbb{Z}_q^k$. Foremost, observe that the decryption algorithm as described before still returns the correct message with probability 1, since it recovers the same $\mathbf{r}$ from $\mathbf{h}_0$. Furthermore, note that (for a fixed header) all vectors $(h_1, \ldots, h_k) \in \mathbb{Z}_q^k$ are in the support of the encryption algorithm. Since $k \gg m$, most of the elements of the ciphertext in the alternative encryption mode are dense.

One can verify that the aforementioned limited form of homomorphism indeed holds, namely that

$$\mathsf{dR.Enc}(\mathbf{m}) + \mathsf{dR.DenseEnc}(\mathbf{m}') \in \mathsf{dR.DenseEnc}(\mathbf{m} \oplus \mathbf{m}').$$

This is the case since

$$\begin{aligned}
&(\mathbf{A} \cdot \mathbf{r} + \mathbf{e}_0, \mathbf{B} \cdot \mathbf{r} + q/2 \cdot \mathbf{m} + \mathbf{e}) + (\mathbf{A} \cdot \mathbf{r}' + \mathbf{e}_0', \mathbf{B} \cdot \mathbf{r}' + q/2 \cdot \mathbf{m}' + \mathbf{u}) \\
&= (\mathbf{A} \cdot (\mathbf{r} + \mathbf{r}') + \mathbf{e}_0 + \mathbf{e}_0', \mathbf{B} \cdot (\mathbf{r} + \mathbf{r}') + q/2 \cdot (\mathbf{m} \oplus \mathbf{m}') + \mathbf{e} + \mathbf{u}) \\
&= (\mathbf{A} \cdot \tilde{\mathbf{r}} + \tilde{\mathbf{e}}_0, \mathbf{B} \cdot \tilde{\mathbf{r}} + q/2 \cdot (\mathbf{m} \oplus \mathbf{m}') + \tilde{\mathbf{u}})
\end{aligned}$$

where $\tilde{\mathbf{u}} = \mathbf{e} + \mathbf{u} \in [-q/4, +q/4]^k$ with all but negligible probability over the random choice of $\mathbf{u}$, for an appropriate choice of the parameters.

Doing Away with the Header. We notice that given our two observations above, the goal of the header in the obfuscation scheme is quite minimal. The header is not needed for homomorphism, and is only needed for the purpose of extracting the randomness $\mathbf{r}$ at decryption time. We then observe that decrypting packed ciphertext is done in two contexts in the scheme. The first is when we bootstrap the almost-everywhere dense ciphertext into an FHE ciphertext, and the other is when the evaluator of the obfuscated program recovers TT from the final ciphertext. For the latter there is no need for a header since the decryption hint, i.e. the respective $\mathbf{r}$ value, is provided within the obfuscated program. For the former we do not need a header of a specific structure, but rather simply an encryption of $\mathbf{r}$ that allows bootstrapping the almost-dense ciphertext. It therefore suffices to provide $\mathsf{GSW.Enc}(\mathbf{r})$ directly, which makes the header completely redundant.

On the Assumption. Equipped with the newly developed packed version of dual-Regev we can follow the [9, 23] approach, with the aforementioned modifications, to construct the obfuscator. The resulting construction can be shown secure against the assumption that the SRL security of GSW is retained in the presence of a key cycle with the packed dual-Regev encryption scheme as presented above.

We then observe that it suffices to assume SRL security with respect to key-randomness cycles, rather than key cycles. We note that this assumption is no-stronger than key-cycle SRL since given a key-cycle it is possible to homomorphically generate a key-randomness cycle, but the converse is not known to be true.

Adding this to our observation about the redundancy of the header, the assumption we require is that SRL security is retained in the presence of a key-randomness cycle between GSW and packed dual-Regev, i.e.

$$(\mathsf{GSW.Enc}(\mathbf{r}), \mathsf{dR.Enc}(\mathsf{sk}_{\mathsf{GSW}}; \mathbf{r}))\,.$$

Since dual-Regev is randomness recoverable, this assumption is syntactically weaker than SRL security in the presence of a key-cycle: Given a GSW encryption of the dual-Regev secret key, one can homomorphically compute the randomness recovery circuit to obtain a GSW encryption of the randomness $\mathbf{r}$.

1.3 Related and Follow-up Work

Subsequently to the posting of this manuscript online (but concurrently and independently) [23] updated their manuscript to include a solution based on LWE in the place of DCR. They do not make the observations that a relaxed notion of density suffices (and is preferable) and thus they explicitly construct an encryption scheme with dense ciphertexts based on the (primal) Regev encryption scheme. The resulting scheme is more involved and in particular requires the two-key circular SRL security of GSW and (primal) Regev rather than the relaxed key-randomness circularity notion.

Wee and Wichs [42], again concurrently, presented another instantiation of the [9] approach which is arguably post-quantum secure. They rely on an indistinguishability assumption between two distributions and not directly on circular security. However, the underlying machinery developed shares many similarities with our approach. Specifically, while we essentially rely on randomness that is embedded in the CRS by interpreting it as an obliviously sampled ciphertext (which thus corresponds to one encrypted with fresh randomness), their approach is to use a pseudorandom function to transform the CRS into a randomizer for the output hint.

A follow-up work by Hopkins, Jain, and Lin [29] shows counterexamples to SRL security for general functions in the presence of a 2-key cycle, as stated in [23], and the conjecture from [42]. We stress that their findings do not imply an attack against the corresponding obfuscation scheme of [42] and [23] (as also pointed out by the authors in [29]). Rather, their results show that the veracity of SRL security depends on the concrete circuit representation of the functions under consideration. As a consequence of their findings, we updated the statement of our assumption (and adapted the analysis of our scheme) with a refined version, that further restricts the power of the adversary and more tightly characterize the security of our construction. However, the iO construction is unchanged from previous versions of this work.

A few remarks about the susceptibility of our scheme to the [29] attack are in order. In short, the attack exploits the randomness homomorphism of GSW to compute a biased leakage. The SRL function consists of a bootstrapping followed by a modular reduction (modulo 2). On the other hand, our admissible class of leakage functions consists of linear

functions (modulo q) followed by a rounding (i.e. outputting the most significant bit). We are not aware of a method to establish the same correlations exploited by [29] without violating the admissibility criteria for the leakage functions. Thus, we conjecture that SRL security with respect to such leakage function holds for all natural FHE candidates (see Section 3.1 for further details).

2 Preliminaries

We denote by $\lambda \in \mathbb{N}$ the security parameter. We say that a function negl is negligible if it vanishes faster than any inverse polynomial. Given a set S, we denote by $s \leftarrow\!\$\ S$ the uniform sampling from S. We say that an algorithm is PPT if it can be implemented by a probabilistic Turing machine M running in time $\mathsf{poly}(\lambda)$. The execution of a Turing machine M on input x and with random coins fixed to r is denoted by $M(x;r)$. We say that two distributions (D_0, D_1) are computationally (statistically, resp.) indistinguishable if for all PPT (unbounded, resp.) distinguishers, the probability to tell D_0 an D_1 apart is negligible. Matrices are denoted by $\mathbf{M}$ and vectors are denoted by $\mathbf{v}$. For convenience, we define $\mathbf{Bit}(\cdot)$ as the bit decomposition operation. We denote the infinity norm of a vector $\mathbf{v}$ by $\|\mathbf{v}\|_\infty$. We recall the smudging lemma.

▶ **Lemma 2** (Smudging). *Let $B_1 = B_1(\lambda)$ and $B_2 = B_2(\lambda)$ be positive integers and let $e_1 \in [-B_1, B_1]$ be a fixed integer. Let $e_2 \leftarrow\!\$\ [-B_2, B_2]$ chosen uniformly at random. Then the distribution of e_2 is statistically indistinguishable to that of $e_2 + e_1$ as long as $B_1/B_2 = \mathsf{negl}(\lambda)$.*

2.1 Indistinguishability Obfuscation

We recall the notion of indistinguishability obfuscation (iO) from [4].

▶ **Definition 3** (Indistinguishability Obfuscation). *A PPT machine iO is an indistinguishability obfuscator for a circuit class $\{\mathfrak{C}_\lambda\}_{\lambda\in\mathbb{N}}$ if the following conditions are satisfied:*

(Functionality) For all $\lambda \in \mathbb{N}$, all circuit $\Pi \in \mathfrak{C}_\lambda$, all inputs x it holds that: $\tilde{\Pi}(x) = \Pi(x)$, where $\tilde{\Pi} \leftarrow\!\$\ \mathsf{iO}(\Pi)$.

(Indistinguishability) For all $\lambda \in \mathbb{N}$, all pairs of circuit $(\Pi_0, \Pi_1) \in \mathfrak{C}_\lambda$ such that $|\Pi_0| = |\Pi_1|$ and $\Pi_0(x) = \Pi_1(x)$ on all inputs x, it holds that the following distributions are computationally indistinguishable: $\mathsf{iO}(\Pi_0) \approx \mathsf{iO}(\Pi_1)$.

Shallow XiO. In this work we construct a weaker version of iO called (shallow) XiO, which however is sufficient (along with the LWE assumption) to construct fully-fledged iO. Loosely speaking, a shallow XiO is a indistinguishability obfuscator (with pre-processing) for $\mathsf{P}^{\mathsf{log}}/\mathsf{poly}$ with non-trivial efficiency. Here $\mathsf{P}^{\mathsf{log}}/\mathsf{poly}$ denotes the class of polynomial-size circuits with inputs of length $\eta = O(\log(\lambda))$ and by non-trivial efficiency we mean that the size of the obfuscated circuit is bounded by $\mathsf{poly}(\lambda, |\Pi|) \cdot 2^{\eta\cdot(1-\varepsilon)}$, for some constant $\varepsilon > 0$. The runtime of the obfuscator can be any polynomial in λ, $|\Pi|$, and 2^η, except that its depth should not depend on 2^η. Furthermore, we allow the obfuscator to access a large uniform random string (the pre-processing) of size even larger than the truth table of the circuit. For a formal statement, we refer the reader to the full version [10].

2.2 The GSW Fully-Homomorphic Encryption

In the following we briefly recall the encryption scheme by Gentry, Sahai, and Waters [26] (henceforth, GSW). We denote by $n = n(\lambda)$ the lattice dimension and by $q = q(\lambda)$ the modulus (which we assume for simplicity to be even). Throughout the rest of this paper, we set $m = (n+1)(\log(q)+1)$ and $d = d(\lambda)$ as a bound on the depth of the arithmetic circuit to be evaluated.

KeyGen(1^λ): Sample a uniform matrix $\mathbf{A} \leftarrow\!\$\ \mathbb{Z}_q^{n\times m}$ and a vector $\mathbf{s} \leftarrow\!\$\ \chi^n$. Set the public key to $(\mathbf{A}, \mathbf{b} = \mathbf{s}^T\mathbf{A} + \mathbf{e}^T)$, where $\mathbf{e} \leftarrow\!\$\ \chi^m$. The secret key is set to $(-\mathbf{s}, 1)$.

Enc(pk, m): On input a message $\mathsf{m} \in \{0,1\}$, sample a uniform $\mathbf{R} \leftarrow\!\$\ \{0,1\}^{m\times m}$ and compute

$$\mathbf{C} = (\mathbf{A}, \mathbf{b}) \cdot \mathbf{R} + \mathsf{m} \cdot \mathbf{G}$$

where $\mathbf{G} = (1, 2, \ldots, 2^{\log(q)-1})^T \otimes I_{(n+1)}$ and $I_{(n+1)} \in \{0,1\}^{(n+1)\times(n+1)}$ denotes the identity matrix.

Eval(pk, Π, $(c_1, \ldots, c_\mu)$): There exists a (deterministic) polynomial-time algorithm that allows one to compute any d-bounded depth arithmetic circuit $\Pi : \{0,1\}^n \to \{0,1\}$ homomorphically over a vector of ciphertexts $(c_1, \ldots, c_\mu)$. For details about this algorithm, we refer the reader to [26]. For the purpose of this work, the only relevant information is that the evaluated ciphertext $\mathbf{c}_\Pi \in \mathbb{Z}_q^{(n+1)}$ is an $(n+1)$-dimensional vector. For multiple bits of output, the resulting ciphertext is defined to be the concatenation of the single-bit ciphertexts.

Dec(sk, c): We assume without loss of generality that the input ciphertext $\mathbf{c} \in \mathbb{Z}_q^{(n+1)}$ is the output of the evaluation algorithm. Such a ciphertext defines a linear function $\boldsymbol{\ell}_\mathbf{c}$ such that

$$\boldsymbol{\ell}_\mathbf{c}(\mathsf{sk}) = q/2 \cdot \mathsf{m} + e$$

where $|e| \le \hat{B} = (m+1)^d m B$. The message m is recovered by returning the most significant bit of the output.

Note that the decryption routine of GSW consists of the application of a linear function, followed by a rounding and we refer to this property as to *almost-linear* decryption. In a slight abuse of notation, we sometimes write $\mathsf{KeyGen}(1^\lambda; q)$ to denote the above key generation algorithm with a fixed modulus q.

Alternate Encryption. For convenience we also define a modified encryption algorithm, where the output ciphertexts consists of a single column vector. An additional difference is that we sample the randomness with norm $\tilde{B} = 2^\lambda \cdot \hat{B}$.

ColEnc(pk, m): On input a message m, sample a uniform $\mathbf{r} \leftarrow\!\$\ [-\tilde{B}, +\tilde{B}]^m$ and compute

$$\mathbf{c} = (\mathbf{A}, \mathbf{b}) \cdot \mathbf{r} + (0^n, q/2) \cdot \mathsf{m}.$$

This algorithm is going instrumental for our scheme, although ciphertexts in this form no longer support the homomorphic evaluation of arbitrary circuits. The multi-bit version of such an algorithm is defined accordingly to output the concatenation of independently sampled ciphertexts. We now recall a useful Lemma from [23].

▶ **Lemma 4** (GSW Smudging). *Let* $\tilde{B} = 2^\lambda \cdot \hat{B}$. *For all* $\lambda \in \mathbb{N}$, *for all* $(\mathsf{sk}, \mathsf{pk})$ *in the support of* $\mathsf{KeyGen}(1^\lambda)$, *for all messages* $\mathbf{m} = (\mathsf{m}_1, \ldots, \mathsf{m}_\mu)$, *for all depth-*$d$ *circuit* $(\Pi_1, \ldots, \Pi_\tau)$, *the following distributions are statistically indistinguishable*

$$\left(\begin{array}{l} c_1, \ldots, c_\mu, \mathbf{r}_1^*, \ldots, \mathbf{r}_\tau^*, \\ \mathsf{Eval}(\mathsf{pk}, \Pi_1, (c_1, \ldots, c_\mu)) + \mathsf{ColEnc}(\mathsf{pk}, 0; \mathbf{r}_1^*), \ldots, \\ \mathsf{Eval}(\mathsf{pk}, \Pi_\tau, (c_1, \ldots, c_\mu)) + \mathsf{ColEnc}(\mathsf{pk}, 0; \mathbf{r}_\tau^*) \end{array}\right)$$
$$\approx \left(\begin{array}{l} c_1, \ldots, c_\mu, \mathbf{r}_1^* - \mathsf{RandEval}(\mathsf{pk}, \Pi_1, \mathbf{m}, (\mathbf{R}_1, \ldots, \mathbf{R}_\mu)), \ldots, \\ \mathbf{r}_\tau^* - \mathsf{RandEval}(\mathsf{pk}, \Pi_\tau, \mathbf{m}, (\mathbf{R}_1, \ldots, \mathbf{R}_\mu)), \\ \mathsf{ColEnc}(\mathsf{pk}, \Pi_1(\mathsf{m}_1, \ldots, \mathsf{m}_\mu); \mathbf{r}_1^*), \ldots, \mathsf{ColEnc}(\mathsf{pk}, \Pi_\tau(\mathsf{m}_1, \ldots, \mathsf{m}_\mu); \mathbf{r}_\tau^*) \end{array}\right)$$

where $c_i \leftarrow\!\$\ \mathsf{Enc}(\mathsf{pk}, \mathsf{m}_i; \mathbf{R}_i)$, $\mathbf{r}_i^* \leftarrow\!\$\ [-\tilde{B}, +\tilde{B}]^m$, *and* $\mathbf{R}_i \leftarrow\!\$\ \{0,1\}^{m \times m}$.

Randomness Homomorphism. We recall a useful property of the GSW scheme, namely that one can alternatively evaluate functions directly over the randomness of a ciphertext to obtain the same result. More formally, we say that a homomorphic encryption scheme $(\mathsf{KeyGen}, \mathsf{Enc}, \mathsf{Eval}, \mathsf{Dec})$ has randomness homomorphism for the circuit class $\{\mathfrak{C}_\lambda\}_{\lambda \in \mathbb{N}}$ if there exists an efficient algorithm $\mathsf{RandEval}$ such that for all $\Pi \in \mathfrak{C}_\lambda$, all $(\mathsf{sk}, \mathsf{pk})$ in the support of KeyGen, all vectors of messages $\mathbf{m} = (\mathsf{m}_1, \ldots, \mathsf{m}_\mu)$ and $\mathbf{R} = (\mathbf{R}_1, \ldots, \mathbf{R}_\mu)$, all ciphertexts $(c_1, \ldots, c_\mu)$ in the support of $(\mathsf{Enc}(\mathsf{pk}, \mathsf{m}_1; \mathbf{R}_1), \ldots, \mathsf{Enc}(\mathsf{pk}, \mathsf{m}_\mu; \mathbf{R}_\mu))$ it holds that

$$\mathsf{Eval}(\mathsf{pk}, \Pi, (c_1, \ldots, c_\mu)) = \mathsf{ColEnc}(\mathsf{pk}, \Pi(\mathbf{m}); \mathsf{RandEval}(\mathsf{pk}, \Pi, \mathbf{m}, \mathbf{R})).$$

Circuit Privacy. It is well known that the GSW encryption scheme satisfies the following notion of circuit privacy [7, 18, 40] (with a randomized evaluation algorithm).

▶ **Definition 5** (Circuit Privacy). *For all* $\lambda \in \mathbb{N}$, *all all* $\Pi \in \mathfrak{C}_\lambda$, *all* $(\mathsf{sk}, \mathsf{pk})$ *in the support of* KeyGen, *and all messages* m, *it holds that the following distributions are statistically indistinguishable*

$$(\mathsf{pk}, \mathsf{Enc}(\mathsf{pk}, \Pi(\mathsf{m}))) \approx (\mathsf{pk}, \mathsf{Eval}(\mathsf{pk}, \Pi, \mathsf{Enc}(\mathsf{pk}, \mathsf{m}); r)).$$

where $r \leftarrow\!\$\ \{0,1\}^\lambda$.

3 Packed Encryption from LWE

In the following we describe a packed version of the dual-Regev encryption scheme [25]. We denote by $n = n(\lambda)$ the lattice dimension, by $q = q(\lambda)$ the modulus (which we assume for simplicity to be a power of 2), and by $k = k(\lambda)$ the expansion factor. We require the existence of a public-key encryption scheme $(\mathsf{PKE.KeyGen}, \mathsf{PKE.Enc}, \mathsf{PKE.Dec})$.

$\mathsf{KeyGen}(1^\lambda, 1^k)$: Sample a uniform $k \times n$ matrix $\mathbf{B} \leftarrow\!\$\ \mathbb{Z}_q^{k \times n}$ and a key pair of a public-key encryption scheme $(\mathsf{sk}_{\mathsf{PKE}}, \mathsf{pk}_{\mathsf{PKE}}) \leftarrow\!\$\ \mathsf{PKE.KeyGen}(1^\lambda)$. The public key consists of $(\mathbf{B}, \mathsf{pk}_{\mathsf{PKE}})$ and the secret key is set to $\mathsf{sk}_{\mathsf{PKE}}$.

$\mathsf{Enc}(\mathsf{pk}, \mathbf{m})$: To encrypt a k-bit message $\mathbf{m} \in \{0,1\}^k$, sample a uniform randomness vector $\mathbf{r} \leftarrow\!\$\ \mathbb{Z}_q^n$ a noise vector $\mathbf{e} \leftarrow\!\$\ \chi^k$ and return the ciphertext

$$\mathbf{c} = (\mathsf{PKE.Enc}(\mathsf{pk}_{\mathsf{PKE}}, \mathbf{r}), \mathbf{B} \cdot \mathbf{r} + q/2 \cdot \mathbf{m} + \mathbf{e}).$$

$\mathsf{Dec}(\mathsf{sk}, \mathbf{c})$: Parse $\mathbf{c}$ as $(c_{\mathsf{PKE}}, c_1, \ldots, c_k)$ and recover the random coins by decrypting $\mathbf{r} = \mathsf{PKE.Dec}(\mathsf{sk}_{\mathsf{PKE}}, c_{\mathsf{PKE}})$. Let $\mathbf{b}_i$ be the i-th row of $\mathbf{B}$. For $i = 1 \ldots k$, compute $\mathsf{m}_i = \mathsf{Round}(c_i - \mathbf{b}_i \cdot \mathbf{r})$, where Round rounds to the nearest multiple of $q/2$, i.e. it returns 1 if the input is closer to $q/2$ and 0 otherwise. Output $\mathbf{m} = (\mathsf{m}_1, \ldots, \mathsf{m}_k)$.

Clearly, the scheme is perfectly correct since

$$\begin{aligned}
&(\mathsf{Round}(c_1 - \mathbf{b}_1 \cdot \mathbf{r}), \ldots, \mathsf{Round}(c_k - \mathbf{b}_k \cdot \mathbf{r})) \\
&= (\mathsf{Round}(q/2 \cdot \mathsf{m}_1 + e_1), \ldots, \mathsf{Round}(q/2 \cdot \mathsf{m}_k + e_k)) \\
&= (\mathsf{Round}(q/2 \cdot \mathsf{m}_1), \ldots, \mathsf{Round}(q/2 \cdot \mathsf{m}_k)) \\
&= (\mathsf{m}_1, \ldots, \mathsf{m}_k) \\
&= \mathbf{m}.
\end{aligned}$$

Extended Encryption. It is not hard to see that the scheme presented above is (bounded) additively homomorphic over $\mathbb{Z}_2^k$. To lift the class of computable functions to all linear functions over $\mathbb{Z}_q^k$, we adopt the standard trick of encrypting the message multiplied by all powers of two $(1, 2, \ldots, 2^{\log(q)})$. For convenience, we define the following augmented encryption algorithm.

$\underline{\mathsf{ExtEnc}(\mathsf{pk}, \mathbf{m}):}$ On input an ℓ-dimensional message $\mathbf{m} \in \mathbb{Z}_q^\ell$, let $\mathbf{g} = (1, 2, \ldots, 2^{\log(q)-1})^T$ and define

$$\mathbf{M} = \begin{bmatrix} \mathsf{m}_1 \cdot \mathbf{g} & \mathsf{m}_2 \cdot \mathbf{g} & \ldots & 0^{\log(q)} \\ 0^{\log(q)} & 0^{\log(q)} & \ldots & 0^{\log(q)} \\ \vdots & \vdots & \ddots & \vdots \\ 0^{\log(q)} & 0^{\log(q)} & \ldots & \mathsf{m}_\ell \cdot \mathbf{g} \end{bmatrix} \in \mathbb{Z}_q^{k \times \ell \cdot k \cdot \log(q)}.$$

Sample a uniform randomness matrix $\mathbf{R} \leftarrow\!\!\$\ \mathbb{Z}_q^{n \times \ell \cdot k \cdot \log(q)}$ and a uniform noise matrix $\mathbf{E} \leftarrow\!\!\$\ \chi^{k \times \ell \cdot k \cdot \log(q)}$. Compute

$$\mathbf{C} = \mathbf{B} \cdot \mathbf{R} + \mathbf{M} + \mathbf{E}$$

and return the ciphertext $(\mathsf{PKE.Enc}(\mathsf{pk}_{\mathsf{PKE}}, \mathbf{R}), \mathbf{C})$.

Decryption works, as before, by recovering $\mathbf{R}$ from the public-key encryption scheme and then decrypting $\mathbf{m}$ component-wise.

Almost-Everywhere Dense Encryption. For convenience, we also define an alternative encryption algorithm in the following. Note that the encryption algorithm does not take as input any message, instead it encrypts a uniform k-bit binary vector. Syntactically, this is the equivalent of a key-encapsulation mechanism.

$\underline{\mathsf{DenseEnc}(\mathsf{pk}):}$ Sample a uniform randomness vector $\mathbf{r} \leftarrow\!\!\$\ \mathbb{Z}_q^n$ and return the ciphertext

$$\mathbf{c} = (c_{\mathsf{PKE}}, c_1, \ldots, c_k) = (\mathsf{PKE.Enc}(\mathsf{pk}_{\mathsf{PKE}}, \mathbf{r}), \mathbf{B} \cdot \mathbf{r} + \mathbf{u}).$$

where $\mathbf{u} \leftarrow\!\!\$\ \mathbb{Z}_q^k$.

We highlight two facts about this algorithm that are going to be important for our later construction: (i) The decryption algorithm works for both Enc and $\mathsf{DenseEnc}$ algorithms, where the plaintext of $\mathsf{DenseEnc}$ corresponds to $(\mathsf{Round}(u_1), \ldots, \mathsf{Round}(u_k))$. In fact, the scheme satisfies perfect correctness in both cases. (ii) The domain of the elements $(c_1, \ldots, c_k)$ is *dense*, i.e. the support of the scheme spans the entire vector space $\mathbb{Z}_q^k$. Since the element c_{PKE} is small (i.e. independent of k) for an appropriate choice of the public-key encryption scheme, we refer to such a property as *almost-everywhere* density.

Semantic Security. We argue that the scheme satisfies a strong form of semantic security, i.e. the honestly computed ciphertexts are computationally indistinguishable from uniform vectors in $\mathbb{Z}_q^k$. Semantic security for the extended encryption ExtEnc and the dense encryption $\mathsf{DenseEnc}$ follows along the same lines.

▶ **Theorem 6** (Semantic Security). *If* $(\mathsf{PKE.KeyGen}, \mathsf{PKE.Enc}, \mathsf{PKE.Dec})$ *is semantically secure and the LWE assumption holds, then for all* $\lambda \in \mathbb{N}$ *and all messages* m *it holds that the following distributions are computationally indistinguishable*

$$(\mathsf{pk}, \mathsf{Enc}(\mathsf{pk}, \mathsf{m})) \approx (\mathsf{pk}, \mathsf{PKE.Enc}(\mathsf{pk}_{\mathsf{PKE}}, \mathbf{z}), \mathbf{u}).$$

where $(\mathsf{sk}, \mathsf{pk}) \leftarrow\!\$\ \mathsf{KeyGen}(1^\lambda, 1^k)$, $\mathbf{z} \leftarrow\!\$\ \mathbb{Z}_q^n$, *and* $\mathbf{u} \leftarrow\!\$\ \mathbb{Z}_q^k$.

Proof. The security of the scheme follows routinely by an invocation of semantic security of the public-key encryption scheme and an invocation of the LWE assumption. ◀

3.1 Key-Randomness SRL Security

We state a version of SRL security [23] tailored for our specific instance and adapted to the randomness-key circularity assumption (rather than the 2-key circularity, as stated in [23]).

▶ **Definition 7** (Key-Randomness SRL Security). *Let* $(\mathsf{GSW.KeyGen}, \mathsf{GSW.Enc}, \mathsf{GSW.Eval}, \mathsf{GSW.Dec})$ *be the GSW encryption scheme and* $(\mathsf{dR.KeyGen}, \mathsf{dR.Enc}, \mathsf{dR.Eval}, \mathsf{dR.Dec})$ *be the packed dual-Regev encryption scheme. Fix messages* $(\mathsf{m}_0, \mathsf{m}_1)$, *polynomials* $\tau = \tau(\lambda)$ *and* $k = k(\lambda)$ *and an adversary* $\mathcal{A} = (\mathcal{A}_1, \mathcal{A}_2)$. *Consider the following experiment.*

$\mathsf{Exp}^{(b)}_{\mathsf{SRL}}(\mathcal{A})$*:*

- *Sample* $(\bar{\mathsf{sk}}, (\bar{\mathsf{pk}}, \mathbf{B})) \leftarrow\!\$\ \mathsf{dR.KeyGen}(1^\lambda, 1^k)$ *and* $(\mathsf{sk}, \mathsf{pk}) \leftarrow\!\$\ \mathsf{GSW.KeyGen}(1^\lambda)$
- *Compute* $\mathbf{c} \leftarrow\!\$\ \mathsf{GSW.Enc}(\mathsf{pk}, \mathsf{m}_b)$
- $\{\mathbf{P}_i, \mathbf{p}_i\}_{i=1\ldots\tau} = \mathcal{A}_1(\mathsf{pk}, \mathbf{B}, \mathbf{c})$
- *Compute* $\left(\bar{c}_{\mathsf{sk}}, \bar{\mathbf{C}}_{\mathsf{sk}}\right) = \mathsf{dR.ExtEnc}(\bar{\mathsf{pk}}, \mathsf{sk}; \mathbf{S})$ *and* $\mathbf{c}_{\mathbf{S}} \leftarrow\!\$\ \mathsf{GSW.Enc}(\mathsf{pk}, \mathbf{S}; \mathbf{R}_{\mathbf{S}})$
- *For all* $i = 1 \ldots \tau$*:*
  - *Sample* $\mathbf{C}_i^* = \mathsf{ColEnc}(0; \mathbf{r}_i^*)$ *where* $\mathbf{r}_i^* \leftarrow\!\$\ [-\tilde{B}, +\tilde{B}]^{m \cdot k}$
  - *Sample* $\mathbf{t}_i \leftarrow\!\$\ \mathbb{Z}_q^n$
  - *Sample* $\mathbf{c}_{i,\mathbf{r}} = \mathsf{GSW.Enc}(\mathsf{pk}, \mathbf{S} \cdot \mathsf{Bit}(\ell_i) + \mathbf{t}_i; \mathbf{R}_i) \leftarrow\!\$\ \mathsf{GSW.Eval}(\mathsf{pk}, \cdot\mathsf{Bit}(\ell_i) + \mathbf{t}_i, \mathbf{c}_{\mathbf{S}})$
- *Output* $\mathcal{A}_2(\bar{\mathbf{C}}_{\mathsf{sk}}, \{\mathbf{c}_{i,\mathbf{r}}, \mathbf{C}_i^*, \mathbf{u}_i, \mathbf{t}_i, \mathbf{r}_{\psi,i} - \mathbf{r}_i^*\}_{i=1\ldots\tau})$

Here, letting ℓ_i *be the linear function associated with* $\mathbf{C}_i^* + \mathbf{P}_i + q/2 \cdot \mathbf{v}_i$, *we set*

$$\mathbf{r}_{\psi,i} = \mathsf{RandEval}(\mathsf{pk}, \psi_i, \mathbf{S} \cdot \mathsf{Bit}(\ell_i) + \mathbf{t}_i, \mathbf{R}_i) \text{ and}$$
$$\psi_i(\mathbf{Z}) = \mathsf{Round}\left(\mathbf{B} \cdot \mathbf{t}_i + q/2 \cdot \mathbf{p}_i + \mathbf{w}_i - \bar{\mathbf{C}}_{\mathsf{sk}} \cdot \mathsf{Bit}(\ell_i) - \mathbf{B} \cdot \mathbf{Z}\right)$$

where $\mathbf{w}_i \leftarrow\!\$\ [-q/4, q/4]^k$, $\mathbf{v}_i \leftarrow\!\$\ \{0,1\}^k$, *and* $\mathbf{u}_i = \mathbf{w}_i + q/2 \cdot \mathbf{v}_i$, *for all* $i = 1 \ldots \tau$. *We say that an adversary* $\mathcal{A}$ *is admissible if for all* $i = 1 \ldots \tau$ *it holds that* $\mathbf{P}_i \in \mathsf{GSW.Enc}(\mathsf{pk}, \mathbf{p}_i)$. *The KR-SRL assumption conjectures that it holds for all admissible PPT adversaries* $\mathcal{A}$, *all messages* $(\mathsf{m}_0, \mathsf{m}_1)$ *and all polynomials* $\tau = \tau(\lambda)$ *and* $k = k(\lambda)$ *that*

$$|\Pr[\mathsf{Exp}^{(1)}_{\mathsf{SRL}}(\mathcal{A}) = 1] - \Pr[\mathsf{Exp}^{(0)}_{\mathsf{SRL}}(\mathcal{A}) = 1]| \leq \mathsf{negl}(\lambda).$$

Since the SRL leakage depends on the specific circuit representation of the functions $(\psi_1 \ldots \psi_\tau)$, we propose a natural implementation for a class of functions that suffices to capture all possible leakage functions. Specifically, observe that ψ_i consist of a linear function (computed over $\mathbb{Z}_q$) followed by a rounding to the nearest multiple of $q/2$. Since all inputs are bit-wise encrypted the computation of modular additions (and multiplication by constants) is done via a canonical boolean circuit (see [11] for a concrete example) and the rounding is obtained by simply returning the ciphertext containing the most significant bit of the output.

4 Constructing (Shallow) XiO

In the following we present the construction of shallow XiO from the GSW scheme $(\mathsf{GSW.KeyGen}, \mathsf{GSW.Enc}, \mathsf{GSW.Eval}, \mathsf{GSW.Dec})$ and the packed version of the dual-Regev encryption $(\mathsf{dR.KeyGen}, \mathsf{dR.Enc}, \mathsf{dR.Eval}, \mathsf{dR.Dec})$ as described in Section 3.

4.1 Construction

The scheme assumes a long uniform string that is, for convenience, split in two chunks:

- A sequence of randomization vectors $(\mathbf{r}^*_1, \ldots, \mathbf{r}^*_{2^{\eta-\log(k)}})$ for the GSW scheme $\mathsf{GSW.PubCoin}$, where each $\mathbf{r}^*_i = (\mathbf{r}^*_{i,1}, \ldots, \mathbf{r}^*_{i,k}) \in [-\tilde{B}, +\tilde{B}]^{m\cdot k}$.
- A sequence of dense ciphertexts $(h_1, \ldots, h_{2^{\eta-\log(k)}})$ for packed dual-Regev scheme $\mathsf{dR.PubCoin}$, where each $h_i = (h_{i,1}, \ldots, h_{i,k}) \in \mathbb{Z}_q^k$.

On input the security parameter 1^λ and the circuit $\Pi : \{0,1\}^\eta \to \{0,1\}$, the obfuscator proceeds as follows.

Setting the Public Keys: Sample a dual-Regev key pair $(\bar{\mathsf{sk}}, \bar{\mathsf{pk}}) \leftarrow\!\!\$\ \mathsf{dR.KeyGen}(1^\lambda, 1^k)$ and GSW key pair $(\mathsf{sk}, \mathsf{pk}) \leftarrow\!\!\$\ \mathsf{GSW.KeyGen}(1^\lambda; q)$, where q is the modulus defined by the dual-Regev scheme. Compute a bit-by-bit GSW encryption $\mathbf{c}_\Pi \leftarrow\!\!\$\ \mathsf{GSWEnc}(\mathsf{pk}, \Pi)$ of the binary representation of the circuit Π.

Compute a Key Encryption: Compute a dual-Regev extended encryption of the GSW secret key $\left(\bar{c}_{\mathsf{sk}}, \bar{\mathbf{C}}_{\mathsf{sk}}\right) = \mathsf{dR.ExtEnc}(\bar{\mathsf{pk}}, \mathsf{sk}; \mathbf{S})$. where $\mathsf{sk} \in \mathbb{Z}_q^{n+1}$ and $\mathbf{S} \leftarrow\!\!\$\ \mathbb{Z}_q^{n\times\log(q)\cdot k\cdot(n+1)}$.

Decryption Hints: For all indices $i \in \{0,1\}^{\eta-\log(k)}$, do the following.

Evaluate the Circuit: Let $\Phi_{i,j} : \{0,1\}^{|\Pi|} \to \{0,1\}$ be the universal circuit that, on input a circuit description Π, returns the j-th bit of the i-th block (where each block consists of k bits) of the corresponding truth table. Compute

$$\mathbf{C}_i = \begin{bmatrix} \mathsf{GSW.Eval}(\mathsf{pk}, \Phi_{i,1}, \mathbf{c}_\Pi) \\ \cdots \\ \mathsf{GSW.Eval}(\mathsf{pk}, \Phi_{i,k}, \mathbf{c}_\Pi) \end{bmatrix} \in \mathbb{Z}_q^{k\times(n+1)}.$$

Compute the Low-Order Bits: Sample $\mathbf{r}_i \leftarrow\!\!\$\ \mathbb{Z}_q^n$ and compute $\mathbf{c}_{i,\mathbf{r}} \leftarrow\!\!\$\ \mathsf{GSW.Enc}(\mathsf{pk}, \mathbf{r}_i)$. Parse the i-th block of $\mathsf{dR.PubCoin}$ as

$$(h_{i,1}, \ldots, h_{i,k}) = \mathbf{B}\cdot\mathbf{r}_i + (u_{i,1}, \ldots, u_{i,k}) \in \mathbb{Z}_q^k$$

for some $(u_{i,1}, \ldots, u_{i,k}) \in \mathbb{Z}_q^k$. Let $\Psi_{i,j} : \{0,1\}^\lambda \to \{0,1\}$ be the circuit that, on input $\mathbf{r}_i$, computes the decryption of the j-th bit encrypted in $(h_{i,1}, \ldots, h_{i,k})$. I.e. it computes $\mathsf{Round}((h_{i,1}, \ldots, h_{i,k}) - \mathbf{B}\cdot\mathbf{r}_i)$. Compute homomorphically the matrix of ciphertexts

$$\mathbf{C}_{i,\mathsf{Round}} = \begin{bmatrix} \mathsf{GSW.Eval}(\mathsf{pk}, \Psi_{i,1}, \mathbf{c}_{i,\mathbf{r}}) \\ \cdots \\ \mathsf{GSW.Eval}(\mathsf{pk}, \Psi_{i,k}, \mathbf{c}_{i,\mathbf{r}}) \end{bmatrix} \in \mathbb{Z}_q^{k\times(n+1)}.$$

Rerandomize the Ciphertext: Parse the i-th block of $\mathsf{GSW.PubCoin}$ as $(\mathbf{r}^*_{i,1}, \ldots, \mathbf{r}^*_{i,k}) \in [-\tilde{B}, +\tilde{B}]^{m\cdot k}$ and compute

$$\mathbf{C}'_{i,\mathsf{Round}} = \mathbf{C}_{i,\mathsf{Round}} + \begin{bmatrix} \mathsf{GSW.ColEnc}(\mathsf{pk}, 0; \mathbf{r}^*_{i,1}) \\ \cdots \\ \mathsf{GSW.ColEnc}(\mathsf{pk}, 0; \mathbf{r}^*_{i,k}) \end{bmatrix} \in \mathbb{Z}_q^{k\times(n+1)}.$$

Proxy Re-Encrypt: Define $\mathbf{D}_i$ as the vector of GSW ciphertexts resulting from the homomorphic sum of $\mathbf{C}'_{i,\mathsf{Round}}$ and $\mathbf{C}_i$, i.e. $\mathbf{D}_i = \mathbf{C}'_{i,\mathsf{Round}} + \mathbf{C}_i$. Observe that $\mathbf{D}_i$ consists of k GSW ciphertexts and let $\boldsymbol{\ell}_{i,j} \in \mathbb{Z}_q^{(n+1)}$ be the linear function associated with the decryption of the j-th ciphertext. Define $\boldsymbol{\ell}_i = (\boldsymbol{\ell}_{i,1}, \ldots, \boldsymbol{\ell}_{i,k})$ and compute

$$\bar{\mathbf{c}}_i = \bar{\mathbf{C}}_{\mathsf{sk}} \cdot \mathsf{Bit}(\boldsymbol{\ell}_i) + (h_{i,1}, \ldots, h_{i,k}) \in \mathbb{Z}_q^k$$

where the function $\mathsf{Bit} : \mathbb{Z}_q^{k\cdot(n+1)} \to \{0,1\}^{\log(q)\cdot k\cdot(n+1)}$ is the bit decomposition operator.

Release Hint: Compute the i-th decryption hint as

$$\boldsymbol{\rho}_i = \mathbf{S} \cdot \mathsf{Bit}(\boldsymbol{\ell}_i) + \mathbf{r}_i \in \mathbb{Z}_q^n.$$

Output: The obfuscated circuit consists of the public keys $(\mathsf{pk}, \bar{\mathsf{pk}})$, the matrix $\bar{\mathbf{C}}_{\mathsf{sk}}$, the GSW encryption of the circuit $\mathbf{c}_\Pi$, the encryption headers $(\mathbf{c}_{1,\mathbf{r}}, \ldots, \mathbf{c}_{2^{\eta-\log(k)},\mathbf{r}})$, and the decryption hints $(\boldsymbol{\rho}_1, \ldots, \boldsymbol{\rho}_{2^{\eta-\log(k)}})$.

To evaluate the obfuscated circuit on input x, let i be the index of the block of the truth table of Π that contains $\Pi(x)$. The evaluator computes $\bar{\mathbf{c}}_i$ as specified above (note that all the operations are public, given the information included in the obfuscated circuit) and recovers $\Pi^{(i)}$ (the i-th block of the truth table of Π) by computing

$$\Pi^{(i)} = \mathsf{Round}(\bar{\mathbf{c}}_i - \mathbf{B} \cdot \boldsymbol{\rho}_i)$$

where $\mathsf{Round} : \mathbb{Z}_q^k \to \{0,1\}^k$ rounds the input to the nearest multiple of $q/2$.

Correctness. To see why the evaluation algorithm is correct, recall that

$$\bar{\mathbf{c}}_i = \bar{\mathbf{C}}_{\mathsf{sk}} \cdot \mathsf{Bit}(\boldsymbol{\ell}_i) + (h_{i,1}, \ldots, h_{i,k}).$$

First observe that $(\mathbf{r}_i, h_{i,1}, \ldots, h_{i,k})$ define a ciphertext in the support of the algorithm $\mathsf{dR.DenseEnc}(\bar{\mathsf{pk}})$, which we rewrite as

$$\begin{aligned}\mathsf{dR.DenseEnc}(\bar{\mathsf{pk}}) &= (\mathsf{PKE.Enc}(\mathsf{pk}_{\mathsf{PKE}}, \mathbf{r}_i), \mathbf{B} \cdot \mathbf{r}_i + (u_{i,1}, \ldots, u_{i,k})) \\ &= (\mathsf{PKE.Enc}(\mathsf{pk}_{\mathsf{PKE}}, \mathbf{r}_i), \mathbf{B} \cdot \mathbf{r}_i + \mathbf{u}_i)\,.\end{aligned}$$

Thus $\mathbf{C}'_{i,\mathsf{Round}}$ and $\mathbf{C}_i$ are in the support of

$$\begin{bmatrix}\mathsf{GSW.ColEnc}(\mathsf{pk}, \mathsf{Round}(u_1)) \\ \ldots \\ \mathsf{GSW.ColEnc}(\mathsf{pk}, \mathsf{Round}(u_k))\end{bmatrix} \text{ and } \begin{bmatrix}\mathsf{GSW.ColEnc}(\mathsf{pk}, \Pi_1^{(i)}) \\ \ldots \\ \mathsf{GSW.ColEnc}(\mathsf{pk}, \Pi_k^{(i)})\end{bmatrix}$$

respectively, by the evaluation correctness of the GSW scheme and by Lemma 2. Furthermore, recall that $\mathbf{D}_i = \mathbf{C}'_{i,\mathsf{Round}} + \mathbf{C}_i$. By an invocation of Lemma 2, we have that $\mathbf{D}_i$ is in the support of

$$\begin{bmatrix}\mathsf{GSW.ColEnc}(\mathsf{pk}, \mathsf{Round}(u_1)) \\ \ldots \\ \mathsf{GSW.ColEnc}(\mathsf{pk}, \mathsf{Round}(u_k))\end{bmatrix} + \begin{bmatrix}\mathsf{GSW.ColEnc}(\mathsf{pk}, \Pi_1^{(i)}) \\ \ldots \\ \mathsf{GSW.ColEnc}(\mathsf{pk}, \Pi_k^{(i)})\end{bmatrix}$$

$$\approx \begin{bmatrix}\mathsf{GSW.ColEnc}(\mathsf{pk}, \mathsf{Round}(u_1) \oplus \Pi_1^{(i)}) \\ \ldots \\ \mathsf{GSW.ColEnc}(\mathsf{pk}, \mathsf{Round}(u_k) \oplus \Pi_k^{(i)})\end{bmatrix}$$

with all but negligible probability. By the almost-linear decryption of GSW, it follows that

$$\bar{\mathbf{C}}_{\mathsf{sk}} \cdot \mathsf{Bit}(\boldsymbol{\ell}_i) = \mathbf{B} \cdot \tilde{\mathbf{s}}_i + \boldsymbol{\xi}_i + \boldsymbol{\zeta}_i + q/2 \cdot \left(\mathsf{Round}(u_1) \oplus \Pi_1^{(i)}, \ldots, \mathsf{Round}(u_k) \oplus \Pi_k^{(i)}\right)$$

where $\boldsymbol{\xi}_i$ is the decryption noise of the packed dual-Regev scheme (i.e. the subset sum of the noise terms of $\bar{\mathbf{C}}_{\mathsf{sk}}$) and $\boldsymbol{\zeta}_i$ is the decryption noise of the GSW ciphertext. It follows that $\|\boldsymbol{\xi}_i\|_\infty \leq B \cdot \log(q) \cdot k \cdot (n+1)$ and, by Lemma 2, $\|\boldsymbol{\zeta}_i\|_\infty \leq \tilde{B}$ with all but negligible probability. Note that, by linearity we have that $\tilde{\mathbf{s}}_i = \mathbf{S} \cdot \mathsf{Bit}(\boldsymbol{\ell}_i)$. Consequently, it holds that

$$\begin{aligned}
\bar{\mathbf{c}}_i &= \mathbf{B} \cdot \tilde{\mathbf{s}}_i + \boldsymbol{\xi}_i + \boldsymbol{\zeta}_i + q/2 \cdot \left(\mathsf{Round}(u_1) \oplus \Pi_1^{(i)}, \ldots, \mathsf{Round}(u_k) \oplus \Pi_k^{(i)}\right) + \mathbf{B} \cdot \mathbf{r}_i + \mathbf{u}_i \\
&= \mathbf{B} \cdot (\tilde{\mathbf{s}}_i + \mathbf{r}_i) + \boldsymbol{\xi}_i + \boldsymbol{\zeta}_i + q/2 \cdot \left(\mathsf{Round}(u_1) \oplus \Pi_1^{(i)}, \ldots, \mathsf{Round}(u_k) \oplus \Pi_k^{(i)}\right) + \mathbf{u}_i \\
&= \mathbf{B} \cdot (\tilde{\mathbf{s}}_i + \mathbf{r}_i) + q/2 \cdot \Pi^{(i)} + \mathbf{v}_i \\
&= \mathbf{B} \cdot \boldsymbol{\rho}_i + q/2 \cdot \Pi^{(i)} + \mathbf{v}_i
\end{aligned}$$

where $\mathbf{v}_i = \mathbf{u}_i + q/2 \cdot \mathsf{Round}(\mathbf{u}_i) + \boldsymbol{\xi}_i + \boldsymbol{\zeta}_i$ and $\|\mathbf{v}_i\|_\infty < q/4$ with all but negligible probability, over the random choice of $\mathbf{u}_i$. This is because $\mathbf{D}_i$ is statistically close to a fresh GSW encryption of $(\mathsf{Round}(u_1), \ldots, \mathsf{Round}(u_k)) \oplus \Pi^{(i)}$, by Lemma 4. Therefore we have that

$$\begin{aligned}
\mathsf{Round}\left(\mathbf{c}_i - \mathbf{B} \cdot \boldsymbol{\rho}_i\right) &= \mathsf{Round}\left(\mathbf{B} \cdot \boldsymbol{\rho}_i + q/2 \cdot \Pi^{(i)} + \mathbf{v}_i - \mathbf{B} \cdot \boldsymbol{\rho}_i\right) \\
&= \mathsf{Round}\left(q/2 \cdot \Pi^{(i)} + \mathbf{v}_i\right) \\
&= \mathsf{Round}\left(q/2 \cdot \Pi^{(i)}\right) \\
&= \Pi^{(i)}
\end{aligned}$$

with the same probability. Due to space constraints, we defer the analysis of our scheme to the full version [10].

Abstract

An intensive line of research on fixed parameter tractability of integer programming is focused on exploiting the relation between the sparsity of a constraint matrix A and the norm of the elements of its Graver basis. In particular, integer programming is fixed parameter tractable when parameterized by the primal tree-depth and the entry complexity of A, and when parameterized by the dual tree-depth and the entry complexity of A; both these parameterization imply that A is sparse, in particular, the number of its non-zero entries is linear in the number of columns or rows, respectively.

We study preconditioners transforming a given matrix to an equivalent sparse matrix if it exists and provide structural results characterizing the existence of a sparse equivalent matrix in terms of the structural properties of the associated column matroid. In particular, our results imply that the ℓ_1-norm of the Graver basis is bounded by a function of the maximum ℓ_1-norm of a circuit of A. We use our results to design a parameterized algorithm that constructs a matrix equivalent to an input matrix A that has small primal/dual tree-depth and entry complexity if such an equivalent matrix exists.

Our results yield parameterized algorithms for integer programming when parameterized by the ℓ_1-norm of the Graver basis of the constraint matrix, when parameterized by the ℓ_1-norm of the circuits of the constraint matrix, when parameterized by the smallest primal tree-depth and entry complexity of a matrix equivalent to the constraint matrix, and when parameterized by the smallest dual tree-depth and entry complexity of a matrix equivalent to the constraint matrix.

2012 ACM Subject Classification Mathematics of computing → Combinatorial optimization; Mathematics of computing → Matroids and greedoids; Mathematics of computing → Combinatorial algorithms

Keywords and phrases Integer programming, width parameters, matroids, Graver basis, tree-depth, fixed parameter tractability

1 Introduction

Integer programming is a problem of fundamental importance in combinatorial optimization with many theoretical and practical applications. It is known to be computationally very hard and is one of the 21 NP-complete problems in the original paper on NP-completeness by Karp [34]; the problem is known to be NP-complete even when the entries of the constraint matrix are zero and one only. On the positive side, Kannan and Lenstra [32, 41] showed that integer programming is polynomially solvable in fixed dimension, i.e., with a fixed number of variables. Another prominent tractable case is when the constraint matrix is unimodular, i.e., all determinants of its submatrices are equal to 0 or ± 1, in which case all vertices of the feasible region are integral and so linear programming algorithms can be applied.

Integer programming is known to be tractable for instances where the constraint matrix of an input integer program (IP) enjoys a certain block structure. The two most important cases are the cases of 2-stage IPs due to Hemmecke and Schultz [23], further investigated in particular in [1, 12, 27, 36, 37, 40], and n-fold IPs introduced by De Loera et al. [13] and further investigated in particular in [10, 11, 16, 22, 31, 40]. IPs of this kind appear in various contexts, see e.g. [29,38,39,44]. These (theoretical) tractability results complement well a vast number of empirical results demonstrating tractability of instances with a block structure, e.g. [2–4, 18, 19, 35, 45–47].

A more general approach to tractability of IPs with sparse constraint matrices involves depths/widths of graphs defined on columns or rows of the constraint matrices. Ganian and Ordyniak [20] initiated this line of study by showing that IPs with bounded primal tree-depth $\mathrm{td}_P(A)$ of a constraint matrix A and bounded coefficients and right hand sides $\|A, b\|_\infty$ can be solved efficiently. Levin, Onn and the second author [40] widely generalized this result by showing that IPs with bounded coefficients $\|A\|_\infty$ and bounded primal tree-depth $\mathrm{td}_P(A)$ or dual tree-depth $\mathrm{td}_D(A)$ of the constraint matrix A can be solved efficiently; such IPs include 2-stage IPs, n-fold IPs, and their generalizations. The existence of efficient algorithms in the case of constraint matrices A with bounded primal and dual tree-depth is closely linked to bounds on the norm of elements of the Graver basis of A, which is formed by minimal integer vectors of $\ker A$ in an orthant (see Section 2 for the rigorous definition). The maximum ℓ_1-norm and ℓ_∞-norm of an element of the Graver basis of A is denoted by $g_1(A)$ and $g_\infty(A)$, respectively. In particular, the following holds [40], where $\mathrm{ec}(A)$ denotes the entry complexity of a matrix A defined as the maximum number of bits needed to represent any of the entries of A.

▶ **Theorem 1.** *There exist functions $f_P, f_D : \mathbb{N}^2 \to \mathbb{N}$ such that the following holds for every matrix A: $g_\infty(A) \leq f_P(\mathrm{td}_P(A), \mathrm{ec}(A))$ and $g_1(A) \leq f_D(\mathrm{td}_D(A), \mathrm{ec}(A))$.*

Most of the existing algorithms for IPs assume that the input matrix is already given in its sparse form. This is a substantial drawback as existing algorithms cannot be applied to instances that are not sparse but can be transformed to a sparse instance, for example, the matrix in the left, whose dual tree-depth is 5, can be transformed by row operations to the matrix with dual tree-depth 2 given in the right.

$$\begin{pmatrix} 2 & 2 & 1 & 2 & 1 & 3 & 1 \\ 2 & 1 & 1 & 1 & 2 & 1 & 1 \\ 2 & 2 & 2 & 2 & 2 & 2 & 1 \\ 2 & 1 & 1 & 2 & 2 & 1 & 1 \\ 2 & 2 & 1 & 2 & 1 & 3 & 2 \end{pmatrix} \quad \to \quad \begin{pmatrix} 2 & 1 & 0 & 1 & 1 & 2 & 1 \\ 0 & 1 & 1 & 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 2 & 0 & 1 \end{pmatrix}$$

Such a transformation of an input matrix is a preconditioner as it changes an input matrix to an equivalent one that is computationally more tractable.

Preconditioning a matrix to make the problem computationally simpler, e.g., to make the feasible region not too flat in any direction, is a ubiquitous preprocessing step in mathematical programming solvers. In this paper, we are concerned with the existence and efficient computability of preconditioners to sparsity of matrices. Chan and Cooper together with the second, third and fourth authors [7,8] gave a structural characterization of matrices that are equivalent, i.e., can be transformed by row operations, to a matrix with small dual tree-depth, and used their structural results to design a fixed parameter algorithm to find such a matrix if it exists; we denote the smallest dual tree-depth of a matrix equivalent to A by $\mathrm{td}^*_D(A)$.

▶ **Theorem 2.** *There exists an algorithm parameterized by d and e that for an input matrix A with entry complexity e*

- *either outputs that $\mathrm{td}^*_D(A) > d$, or*
- *outputs a matrix A' equivalent to A such that the dual tree-depth of A' is $\mathrm{td}^*_D(A)$ and its entry complexity is $\mathcal{O}(d^2 2^{2d} e)$.*

The structural characterization given in [7,8] exhibits an interesting link to matroid theory: an equivalent matrix with small dual tree-depth exists if and only if the column matroid of the matrix, which is invariant under row operations, has small contraction*-depth (see Theorem 3 below). We remark that the term branch-depth was used in [7,8] following the terminology from [33] but as there is a competing notion of branch-depth [14], we decided to use a different name for this notion throughout the paper to avoid confusion.

In this paper, we provide a structural characterization of matrices that are equivalent to a matrix with small primal tree-depth or small incidence tree-depth (Theorems 4 and 5). We also study corresponding preconditioners and design fixed parameter algorithms for constructing an equivalent matrix with small primal tree-depth and small entry complexity and for constructing an equivalent matrix with small dual tree-depth and small entry complexity, if such a matrix exists (Theorems 7 and 8). Finally, we employ our structural results to resolve an open problem whether integer programming is fixed-parameter tractable parameterized by the largest ℓ_1-norm of the Graver basis element of a matrix A. Additionally, we show that the ℓ_1-norm of each element of the Graver basis of a matrix A is bounded by a function of the largest ℓ_1-norm of a circuit of the matrix A (Theorem 6). All these results are stated more precisely in Subsection 1.1.

The existence of appropriate preconditioners that we establish in this paper implies that integer programming is fixed parameter tractable when parameterized by

- $g_1(A)$, i.e., the ℓ_1-norm of the Graver basis of the constraint matrix,
- $c_1(A)$, i.e., the ℓ_1-norm of the circuits of the constraint matrix,

- $\mathrm{td}^*_P(A)$ and $\mathrm{ec}(A)$, i.e., the smallest primal tree-depth and entry complexity of a matrix equivalent to the constraint matrix, and
- $\mathrm{td}^*_D(A)$ and $\mathrm{ec}(A)$, i.e., the smallest dual tree-depth and entry complexity of a matrix equivalent to the constraint matrix.

We believe that our new tractability results significantly enhance the toolbox of tractable IPs as the nature of our tractability conditions substantially differ from prevalent block-structured sparsity-based tractability conditions. The importance of availability of various forms of tractable IPs can be witnessed by n-fold IPs, which were shown fixed-parameter tractable in [22], and, about a decade later, their applications has become ubiquitous, see e.g. [5, 6, 9, 10, 24, 28, 30, 39].

1.1 Our contribution

We now describe the results presented in this paper in detail; we refer the reader for the definitions of the notions not yet rigorously introduced to Section 2.

1.1.1 Characterization of depth parameters

The main structural result of [7, 8] is the following structural characterization of the existence of an equivalent matrix with small dual tree-depth in terms of the structural parameter of the column matroid, which is invariant under row operations.

▶ **Theorem 3.** *For every non-zero matrix A, it holds that the smallest dual tree-depth of a matrix equivalent to A is equal to the contraction*-depth of $M(A)$, i.e.,* $\mathrm{td}^*_D(A) = \mathrm{c}^*\mathrm{d}(A)$.

We discover structural characterizations of the existence of an equivalent matrix with small primal tree-depth and the existence of an equivalent matrix with small incidence tree-depth.

▶ **Theorem 4.** *For every matrix A, it holds that the smallest primal tree-depth of a matrix equivalent to A is equal to the deletion-depth of $M(A)$, i.e.,* $\mathrm{td}^*_P(A) = \mathrm{dd}(A)$.

▶ **Theorem 5.** *For every matrix A, it holds that the smallest incidence tree-depth of a matrix equivalent to A is equal to contraction*-deletion-depth of $M(A)$ increased by one, i.e.,* $\mathrm{td}^*_I(A) = \mathrm{c}^*\mathrm{dd}(A) + 1$.

1.1.2 Interplay of circuit and Graver basis complexity

As mentioned earlier, Graver bases play an essential role in designing efficient algorithms for integer programming. A *circuit* of a matrix A is a support-wise minimal integral vector contained in the kernel of A such that all its entries are coprime. Hence, every circuit of a matrix A is an element of the Graver basis of A and so the maximum ℓ_1-norm of an element of the Graver basis, which is denoted by $g_1(A)$, is an upper bound on the maximum ℓ_1-norm of a circuit of A, which is denoted by $c_1(A)$.

One of the open problems in the area, e.g. discussed during the Dagstuhl workshop 19041 "New Horizons in Parameterized Complexity", has been whether integer programming is fixed parameter tractable when parameterized by $g_1(A)$, the ℓ_1-norm of an element of the Graver basis of the constraint matrix A. An affirmative answer to this question follows from Theorems 6 and 8 below. We actually show that *the maximum ℓ_1-norm $g_1(A)$ of an element of the Graver basis of a matrix A is small if and only if A is equivalent to a matrix with a small dual tree-depth and small entry complexity*; the implication from left to right is given

in Theorem 1 and the other implication in Theorem 12 (recall that $c_1(A) \leq g_1(A)$ for every matrix). We summarize the relation between the the maximum ℓ_1-norm of a circuit of a matrix A, the maximum ℓ_1-norm of an element of the Graver basis of A, and the existence of an equivalent matrix with small dual tree-depth and small entry complexity in the next theorem (the second part of the theorem is given in Corollary 13).

▶ **Theorem 6.** *There exist a function $f_1 : \mathbb{N} \to \mathbb{N}$ such that the following holds for every matrix A with $\dim \ker A > 0$:*

- *the matrix A is equivalent to a matrix A' with $\mathrm{td}_D(A') \leq c_1(A)^2$ and $\mathrm{ec}(A') \leq 2\lceil c_1(A) \rceil$, and*
- *$c_1(A) \leq g_1(A) \leq f_1(c_1(A))$.*

Hence, informally speaking, the following statements are equivalent for every matrix A:

- The matrix A is equivalent to a matrix with bounded dual tree-depth and bounded entry complexity.
- The contraction*-depth of the matroid $M(A)$ is bounded.
- The ℓ_1-norm of every circuit of A is bounded.
- The ℓ_1-norm of every element of the Graver basis of A is bounded.

1.1.3 Algorithms to compute matrices with small depth parameters

We design a parameterized algorithm for computing an equivalent matrix with small primal tree-depth and small entry complexity if one exists.

▶ **Theorem 7.** *There exists a function $f : \mathbb{N}^2 \to \mathbb{N}$ and an FPT algorithm for the parameterization by d and e that, for a given rational matrix A with m rows and n columns, $m \leq n$:*

- *either outputs that A is not equivalent to a matrix with primal tree-depth at most d and entry complexity at most e, or*
- *outputs a matrix A' that is equivalent to A, its primal tree-depth is at most d and entry complexity is at most $f(d, e)$.*

We also design a parameterized algorithm for computing an equivalent matrix with small dual tree-depth and small entry complexity if one exists. Note that the algorithm described in Theorem 2 for computing an equivalent matrix with small dual tree-depth is parameterized by the dual tree-depth of the to be constructed matrix and the entry complexity of the *input* matrix while the algorithm given below is parameterized by the entry complexity of the to be constructed matrix and so the algorithm can be applied to a wider set of input matrices.

▶ **Theorem 8.** *There exists a function $f : \mathbb{N}^2 \to \mathbb{N}$ and an FPT algorithm for the parameterization by d and e that, for a given rational matrix A:*

- *either outputs that A is not equivalent to a matrix with dual tree-depth at most d and entry complexity at most e, or*
- *outputs a matrix A' that is equivalent to A, its dual tree-depth is at most d and entry complexity is at most $f(d, e)$.*

We remark that if a matrix A has entry complexity e and is equivalent to a matrix with dual tree-depth d, then there exists an equivalent matrix with dual tree-depth d and entry complexity bounded by a function of d and e (as implied by Theorem 2). However, the same is not true in the case of primal tree-depth. The entry complexity of every matrix with primal tree-depth equal to one that is equivalent to the following matrix A is linear in the number of rows of A, quite in a contrast to the case of dual tree-depth.

$$\begin{pmatrix} 1 & 2 & 0 & 0 & \cdots & 0 & 0 & 0 & 0 \\ 0 & 1 & 2 & 0 & \cdots & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 2 & \cdots & 0 & 0 & 0 & 0 \\ \vdots & \vdots & & \ddots & \ddots & & & \vdots & \vdots \\ \vdots & \vdots & & & \ddots & \ddots & & \vdots & \vdots \\ 0 & 0 & 0 & 0 & \cdots & 1 & 2 & 0 & 0 \\ 0 & 0 & 0 & 0 & \cdots & 0 & 1 & 2 & 0 \\ 0 & 0 & 0 & 0 & \cdots & 0 & 0 & 1 & 2 \end{pmatrix}$$

1.1.4 Hardness results

As our algorithmic results involve computing depth decompositions of matroids for various depth parameters in a parameterized way, we establish the computational hardness of these parameters in Theorem 18, primarily for the sake of completeness of our exposition. In particular, computing the following matroid parameters is NP-complete:

- deletion-depth,
- contraction-depth,
- contraction-deletion-depth,
- contraction*-depth, and
- contraction*-deletion-depth.

2 Preliminaries

In this section, we fix the notation used throughout the paper. We start with general notation and we then fix the notation related to graphs, matrices and matroids.

The set of all positive integers is denoted by $\mathbb{N}$ and the set of the first k positive integers by $[k]$. If A is a linear space, we write $\dim A$ for its dimension and if B is a set of vectors, we write $\mathcal{L}(B)$ for the linear hull of the vectors contained in B. If A is a linear space and K is a subspace of A, the *quotient space* A/K is the linear space of the dimension $\dim A - \dim K$ that consists of cosets of A given by K with the natural operations of addition and scalar multiplication; see e.g. [21] for further details. The quotient space A/K can be associated with a linear subspace of A of dimension $\dim A - \dim K$ formed by exactly a single vector from each coset of A given by K; we will often view the quotient space as such a subspace of A and write $w + K$ for the coset containing a vector w.

2.1 Graphs

All graphs considered in this paper are loopless simple graphs unless stated otherwise. If G is a graph, then we write $V(G)$ and $E(G)$ for the vertex set and the edge set of G, respectively; the number of vertices and edges of G is denoted by $|G|$ and $\|G\|$, respectively. If W is a subset of vertices of a graph G, then $G \setminus W$ is the graph obtained by removing the vertices of W (and all edges incident with them). If F is a subset of edges of a graph G, then $G \setminus F$ is the graph obtained by removing the edges contained in F and G/F is the graph obtained by contracting all edges contained in F and removing resulting loops and parallel edges.

We next define the graph parameter *tree-depth*, which is the central graph parameter in this paper. The *height* of a rooted tree is the maximum number of vertices on a path from the root to a leaf, and the *height* of a rooted forest, i.e., a graph whose each component

is a rooted tree, is the maximum height of its components. The *depth* of a rooted tree is the maximum number of edges on a path from the root to a leaf, and the *depth* of a rooted forest is the maximum depth of its components. The *closure* $\mathrm{cl}(F)$ of a rooted forest F is the graph obtained by adding edges from each vertex to all its descendants. Finally, the *tree-depth* $\mathrm{td}(G)$ of a graph G is the minimum height of a rooted forest F such that the closure $\mathrm{cl}(F)$ of the rooted forest F contains G as a subgraph.

2.2 Matroids

We next review basic definitions from matroid theory; for detailed information, we refer to the book of Oxley [42]. A *matroid* M is a pair $(X, \mathcal{I})$, where $\mathcal{I}$ is a non-empty hereditary collection of subsets of X that satisfies the *augmentation axiom*, i.e., if $X' \in \mathcal{I}$, $X'' \in \mathcal{I}$ and $|X'| < |X''|$, then there exists an element $x \in X'' \setminus X'$ such that $X' \cup \{x\} \in \mathcal{I}$. The set X is the *ground set* of M and the sets contained in $\mathcal{I}$ are referred to as *independent*. The *rank* of a subset X' of the ground set X, which is denoted by $r_M(X')$ or simply by $r(X')$ if M is clear from the context, is the maximum size of an independent subset of X' (it can be shown that all maximal independent subsets of X' have the same cardinality); the *rank* of the matroid M, which is denoted by $r(M)$, is the rank of its ground set. A *basis* of a matroid M is a maximal independent subset of the ground set of M and a *circuit* is a minimal subset of the ground set of M that is not independent. In particular, if X' is a circuit of M, then $r(X') = |X'| - 1$ and every proper subset of X' is independent. An element x of a matroid M is a *loop* if $r(\{x\}) = 0$, an element x is a *bridge* if it is contained in every basis of M, and two elements x and x' are *parallel* if $r(\{x\}) = r(\{x'\}) = r(\{x, x'\}) = 1$. If M is a matroid with ground set X, the *dual matroid*, which is denoted by M^* is the matroid with the same ground set X such that $X' \subseteq X$ is independent in M^* if and only if $r_M(X \setminus X') = r(M)$; in particular, $r_{M^*}(X') = r_M(X \setminus X') + |X'| - r(M)$ for every $X' \subseteq X$.

For a field $\mathbb{F}$, we say that a matroid M is $\mathbb{F}$-*representable* if every element of M can be assigned a vector from $\mathbb{F}^{r(M)}$ in such a way that a subset of the ground set of M is independent if and only if the set of assigned vectors is linearly independent. In particular, an element of M is a loop if and only if it is assigned the zero vector and two elements of M are parallel if and only if they are assigned non-zero multiples of the same non-zero vector. Such an assignment of vectors of $\mathbb{F}^{r(M)}$ to the elements of M is an $\mathbb{F}$-*representation* of M. Observe that the rank of a subset X' of the ground set is the dimension of the linear hull of the vectors assigned to the elements of X'. We say that a matroid M is $\mathbb{F}$-*represented* if the matroid M is given by its $\mathbb{F}$-representation. If a particular field $\mathbb{F}$ is not relevant in the context, we just say that a matroid M is *represented* to express that it is given by its representation.

Let M be a matroid with a ground set X. The matroid kM for $k \in \mathbb{N}$ is the matroid obtained from M by introducing $k-1$ parallel elements to each non-loop element and $k-1$ additional loops for each loop; informally speaking, every element of M is "cloned" to k copies. If $X' \subseteq X$, then the *restriction* of M to X', which is denoted by $M[X']$, is the matroid with the ground set X' such that a subset of X' is independent in $M[X']$ if and only if it is independent in M. In particular, the rank of $M[X']$ is $r_M(X')$. The matroid obtained from M by *deleting* X' is the restriction of M to $X \setminus X'$ and is denoted by $M \setminus X'$. The *contraction* of M by X', which is denoted by M/X', is the matroid with the ground set $X \setminus X'$ such that a subset X'' of $X \setminus X'$ is independent in M/X' if and only if $r_M(X'' \cup X') = |X''| + r_M(X')$. If X' is a single element set and e is its only element, we write $M \setminus e$ and M/e instead of $M \setminus \{e\}$ and $M/\{e\}$, respectively. If an $\mathbb{F}$-representation of M is given and X' is a subset of the ground set of M, then an $\mathbb{F}$-representation of M/X'

can be obtained from the $\mathbb{F}$-representation of M by considering it in the quotient space by the linear hull of the vectors representing the elements of X'. This leads us to the following definition: if M is an $\mathbb{F}$-represented matroid and A is a linear subspace of $\mathbb{F}^{r(M)}$, then the matroid M/A is the $\mathbb{F}$-represented matroid with the representation of M in the quotient space by A. Note that the ground sets of M and M/A are the same.

A matroid M is *connected* if every two distinct elements of M are contained in a common circuit. If M is an $\mathbb{F}$-represented matroid with at least two elements, then M is connected if and only if M has no loops and there do not exist two non-trivial vector spaces A and B of $\mathbb{F}^{r(M)}$ such that $A \cap B$ contains the zero vector only and every element of M is contained in A or B. A *component* of a matroid M is an inclusion-wise maximal connected restriction of M; a component is *trivial* if it consists of a single loop, and it is *non-trivial* otherwise. We often identify components of a matroid M with their element sets. Using this identification, it holds that a subset X' of a ground set of a matroid M is a component of M if and only if X' is a component of M^*. We remark that $(M^*)^* = M$ for every matroid M, and if e is an element of a matroid M, then $(M/e)^* = M^* \setminus e$ and $(M \setminus e)^* = M^*/e$.

2.3 Matrices

In this section, we define notation related to matrices. If $\mathbb{F}$ is a field, we write $\mathbb{F}^{m\times n}$ for the set of matrices with m rows and n columns over the field $\mathbb{F}$. If A is a rational matrix, the entry complexity $\mathrm{ec}(A)$ is the maximum length of a binary encoding of its entries, i.e., the maximum of $\lceil \log_2(|p|+1)\rceil + \lceil(\log_2|q|+1)\rceil$ taken over all entries p/q of A (where p and q are always assumed to be coprime). A rational matrix A is *z-integral* for $z \in \mathbb{Q}$ if every entry of A is an integral multiple of z. We say that two matrices A and A' are *equivalent* if one can be obtained from another by (equivalent) *row operations*, i.e., adding (a non-zero multiple of) one row to another and multiplying a row by a non-zero element. Observe that if A and A' are equivalent matrices, then their kernels are the same. For a matrix A, we define $M(A)$ to be the represented matroid whose elements are the columns of A. Again, if matrices A and A' are equivalent, then the matroids $M(A)$ and $M(A')$ are the same.

If A is a matrix, the *primal graph* of A is the graph whose vertices are columns of A and two vertices are adjacent if there exists a row having non-zero elements in the two columns associated with the vertices; the *dual graph* of A is the graph whose vertices are rows of A and two vertices are adjacent if there exists a column having non-zero elements in the two associated rows; the *incidence graph* of A is the bipartite graph with one part formed by rows of A and the other part by columns of A and two vertices are adjacent if the entry in the associated row and in the associated column is non-zero. The *primal tree-depth* of A, denoted by $\mathrm{td}_P(A)$, is the tree-depth of the primal graph of A, the *dual tree-depth* of A, denoted by $\mathrm{td}_D(A)$, is the tree-depth of the dual graph of A, and the *incidence tree-depth* of A, denoted by $\mathrm{td}_I(A)$, is the tree-depth of the incidence graph of A. Finally, $\mathrm{td}^*_P(A)$ is the smallest primal tree-depth of a matrix equivalent to A, $\mathrm{td}^*_D(A)$ is the smallest dual tree-depth of a matrix equivalent to A, and $\mathrm{td}^*_I(A)$ is the smallest incidence tree-depth of a matrix equivalent to A.

A *circuit* of a rational matrix A is a support-wise minimal integral vector contained in the kernel of A such that all its entries are coprime; the set of circuits of A is denoted by $\mathcal{C}(A)$. Note that a set X of columns is a circuit in the matroid $M(A)$ if and only if $\mathcal{C}(A)$ contains a vector with the support exactly equal to X. We write $c_1(A)$ for the maximum ℓ_1-norm of a circuit of A and $c_\infty(A)$ for the maximum ℓ_∞-norm of a circuit of A. Note if A and A' are equivalent rational matrices, then $\mathcal{C}(A) = \mathcal{C}(A')$ and so the parameters $c_1(\cdot)$ and $c_\infty(\cdot)$ are invariant under row operations. Following the notation from [17], we write $\dot\kappa_A$ for the least common multiple of the entries of the circuits of A. Observe that there exists a function $f : \mathbb{N} \to \mathbb{N}$ such that $\dot\kappa_A \le f(c_\infty(A))$ for every matrix A.

If $\mathbf{x}$ and $\mathbf{y}$ are two d-dimensional vectors, we write $\mathbf{x} \sqsubseteq \mathbf{y}$ if $|\mathbf{x}_i| \leq |\mathbf{y}_i|$ for all $i \in [d]$ and $\mathbf{x}$ and $\mathbf{y}$ are in the same orthant, i.e., $\mathbf{x}_i$ and $\mathbf{y}_i$ have the same sign (or they both are zero) for all $i \in [d]$. The *Graver basis* of a matrix A, denoted by $\mathcal{G}(A)$, is the set of the $\sqsubseteq$-minimal non-zero elements of the integer kernel $\ker_{\mathbb{Z}}(A)$. We use $g_1(A)$ and $g_\infty(A)$ for the Graver basis of A analogously to the set of circuits, i.e., $g_1(A)$ is the maximum ℓ_1-norm of a vector in $\mathcal{G}(A)$ and $g_\infty(A)$ is the maximum ℓ_∞-norm of a vector in $\mathcal{G}(A)$. Again, the parameters $g_1(\cdot)$ and $g_\infty(\cdot)$ are invariant under row operations as the Graver bases of equivalent matrices are the same. Note that every circuit of a matrix A belongs to the Graver basis of A, i.e., $\mathcal{C}(A) \subseteq \mathcal{G}(A)$, and so it holds that $c_1(A) \leq g_1(A)$ and $c_\infty(A) \leq g_\infty(A)$ for every matrix A.

2.4 Matroid depth parameters

We now define matroid depth parameters that will be of importance further. We start with the notion of deletion-depth and contraction-depth, which were introduced in [14].

The *deletion-depth* of a matroid M, denoted by $\mathrm{dd}(M)$, is defined recursively as follows. If M has a single element, then $\mathrm{dd}(M) = 1$. If M is not connected, then $\mathrm{dd}(M)$ is the maximum deletion-depth of a component of M. Otherwise, $\mathrm{dd}(M)$ is 1 plus the minimum deletion-depth of $M \setminus e$ where the minimum is taken over all elements e of M.

The sequence of deletions of elements witnessing that the deletion-depth of a matroid M is $\mathrm{dd}(M)$ can be visualized by a rooted tree, which we call a *deletion-decomposition tree*, defined as follows. If M has a single element, then the deletion-decomposition tree of M consists of a single vertex labeled with the single element of M. If M is not connected, then the deletion-decomposition tree is obtained by identifying the roots of deletion-decomposition trees of the components of M. Otherwise, there exists an element e such that $\mathrm{dd}(M) = \mathrm{dd}(M \setminus e) + 1$ and the deletion-decomposition tree of M is obtained from the deletion-decomposition tree of $M \setminus e$ by adding a new vertex adjacent to the root of the deletion-decomposition tree of $M \setminus e$, changing the root of the tree to the newly added vertex and labeling the edge incident with it with the element e. Observe that the height of the deletion-decomposition tree is equal to the deletion-depth of M. In what follows, we consider deletion-decomposition trees that need not to be of optimal height, i.e., its edges can be labeled by a sequence of elements that decomposes a matroid M in a way described in the definition of the deletion-depth but its height is larger than $\mathrm{dd}(M)$. In this more general setting, the deletion-depth of a matroid M is the smallest height of a deletion-decomposition tree of M.

The *contraction-depth* of a matroid M, denoted by $\mathrm{cd}(M)$, is defined recursively as follows. If M has a single element, then $\mathrm{cd}(M) = 1$. If M is not connected, then $\mathrm{cd}(M)$ is the maximum contraction-depth of a component of M. Otherwise, $\mathrm{cd}(M)$ is 1 plus the minimum contraction-depth of M/e where the minimum is taken over all elements e of M. It is not hard to show that $\mathrm{dd}(M) = \mathrm{cd}(M^*)$ and $\mathrm{cd}(M) = \mathrm{dd}(M^*)$ for every matroid M. We define a *contraction-decomposition tree* analogously to a deletion-decomposition tree; the contraction-depth of a matroid M is the smallest height of a contraction-decomposition tree of M.

We next introduce the contraction-deletion-depth, which was studied under the name of type in [15], but we decided to use the name from [14], which we find to describe the parameter in the context considered here better. The *contraction-deletion-depth* of matroid M, denoted by $\mathrm{cdd}(M)$, is defined recursively as follows. If M has a single element, then $\mathrm{cdd}(M) = 1$. If M is not connected, then $\mathrm{cdd}(M)$ is the maximum contraction-deletion-depth of a component of M. Otherwise, $\mathrm{cdd}(M)$ is 1 plus the smaller among the minimum contraction-deletion-depth of the matroid $M \setminus e$ and the minimum contraction-deletion-depth of the matroid M/e where both minima are taken over all elements e of M. Clearly, it holds that $\mathrm{cdd}(M) = \mathrm{cdd}(M^*)$, $\mathrm{cdd}(M) \leq \mathrm{dd}(M)$ and $\mathrm{cdd}(M) \leq \mathrm{cd}(M)$ for every matroid M.

One of the key parameters in our setting is that of contraction*-depth; this parameter was introduced under the name branch-depth in [33] and further studied in [8] but we decided to use a different name to avoid a possible confusion with the notion of branch-depth introduced in [14]. A *contraction*-depth* of a matroid M, denoted by $\mathrm{c}^*\mathrm{d}(M)$, is the smallest depth of a rooted tree T with exactly $r(M)$ edges with the following property: there exists a function f from the ground set of M to the leaves of T such that for every subset X of the ground set of M the total number of edges contained in paths from the root to vertices of X is at least $r(X)$. There is an alternative equivalent definition of the parameter for represented matroids. The *contraction*-depth* of a represented matroid M can be defined recursively as follows. If M has rank zero, then $\mathrm{c}^*\mathrm{d}(M) = 0$. If M is not connected, then $\mathrm{c}^*\mathrm{d}(M)$ is the maximum contraction*-depth of a component of M. Otherwise, $\mathrm{c}^*\mathrm{d}(M)$ is 1 plus the minimum contraction*-depth of a matroid obtained from the matroid M by factoring along an arbitrary one-dimensional subspace. As the contraction in the definition is allowed to be by an arbitrary one-dimensional subspace, not only by a subspace generated by an element of M, it follows that $\mathrm{c}^*\mathrm{d}(M) \leq \mathrm{cd}(M)$.

Kardoš et al. [33] established the connection between the contraction*-depth and the existence of a long circuit, which is described in Theorem 9.

▶ **Theorem 9.** *Let M be a matroid and k the size of its largest circuit. It holds that $\log_2 k \leq \mathrm{c}^*\mathrm{d}(M) \leq k^2$. Moreover, there exists a polynomial-time algorithm that for an input oracle-given matroid M outputs a contraction*-decomposition tree of depth at most k^2.*

All contractions used in the proof of the inequality $\mathrm{c}^*\mathrm{d}(M) \leq k^2$ are contractions of elements of a matroid M, i.e., the one-dimensional subspaces as in the definition of the contraction*-depth are all generated by elements of M. We remark that this implies that $\mathrm{cd}(M) \leq k^2 + 1$. The sequence of such contractions can be visualized by a *contraction*-decomposition tree* that is defined in the same way as a contraction-decomposition tree except that one-vertex trees are associated with matroids of rank zero (rather than matroids consisting of a single element), however, the edges of the tree are still labeled by some of the elements of M. Note that the minimum depth of a contraction*-decomposition tree of a matroid M is an upper bound on its contraction*-depth, however, in general, the contraction*-depth of a matroid M can be smaller than the minimum depth of contraction*-decomposition tree of M as the definition of the contraction*-depth in the case of represented matroids permits contractions by arbitrary one-dimensional subspaces.

We next introduce the parameter of contraction*-deletion-depth, which we believe to have not been yet studied previously, but which is particularly relevant in our context. To avoid unnecessary technical issues, we introduce the parameter for represented matroids only. The *contraction*-deletion-depth* of a represented matroid M, denoted by $\mathrm{c}^*\mathrm{dd}(M)$, is defined recursively as follows. If M has rank zero, then $\mathrm{c}^*\mathrm{dd}(M) = 0$; if M has a single non-loop element, then $\mathrm{c}^*\mathrm{dd}(M) = 1$. If M is not connected, then $\mathrm{c}^*\mathrm{dd}(M)$ is the maximum contraction*-deletion-depth of a component of M. Otherwise, $\mathrm{c}^*\mathrm{dd}(M)$ is 1 plus the smaller among the minimum contraction*-deletion-depth of the matroid $M \setminus e$, where the minimum is taken over all elements of M, and the minimum contraction*-deletion-depth of a matroid obtained from M by factoring along an arbitrary one-dimensional subspace. Observe that $\mathrm{c}^*\mathrm{dd}(M) \leq \mathrm{cdd}(M)$ and $\mathrm{c}^*\mathrm{dd}(M) \leq \mathrm{c}^*\mathrm{d}(M)$ for every matroid M.

Finally, if A is a matrix, the *deletion-depth*, *contraction-depth*, etc. of A is the corresponding parameter of the vector matroid $M(A)$ formed by the columns of A, and we write $\mathrm{dd}(A)$, $\mathrm{cd}(A)$, etc. for the deletion-depth, contraction-depth, etc. of the matrix A. Observe that the deletion-depth, contraction-depth etc. of a matrix A is invariant under row operations as row operations preserve the matroid $M(A)$.

3 Structural results

In this section, we prove our structural results concerning optimal primal tree-depth and optimal incidence tree-depth of a matrix. We start with presenting an algorithm, which uses a deletion-decomposition tree of the matroid associated with a given matrix to construct a matrix with small primal tree-depth that is equivalent to the given matrix.

▶ **Lemma 10.** *There exists a polynomial-time algorithm that for an input matrix A and a deletion-decomposition tree of $M(A)$ with height d outputs a matrix A' equivalent to A such that $\mathrm{td}_P(A') \leq d$.*

Proof. We establish the existence of the algorithm by proving that $\mathrm{td}_P(A') \leq d$ in a constructive (algorithmic) way. Due to space constraints, we omit some details in the arguments that follow.

Fix a matrix A and a deletion-decomposition tree T of $M(A)$ with height d. Let X be the set of non-zero columns that are labels of the vertices of T. It can be shown that the columns contained in X form a basis of the column space of the matrix A. In particular, unless A is the zero matrix, the set X is non-empty. Let A' be the matrix obtained from A by row operations such that the submatrix of A' induced by the columns of X is the unit matrix with possibly some additional zero rows. We will prove by induction on the number of columns of an input matrix A that the primal tree-depth of A' is at most d.

The base of the induction is the case when A has a single column. In this case, the primal tree-depth of A' is one and the tree T is a single vertex labeled with the only column of A, and so its height is one.

We next present the induction step. First observe that every label of a vertex of T is either in X or a loop in $M(A)$, and every label of an edge e is a linear combination of labels of the vertices in the subtree delimited by e. It follows that if x is a label of the root of T, then x is either a loop or a bridge in the matroid $M(A)$. Let B be the matrix obtained from A by deleting the column x, and let T' be the deletion-decomposition tree of $M(B)$ obtained from T by removing the label x from the root. Since the matrix B' produced by the algorithm described above for B and T' is the submatrix of A' formed by the columns different from x (possibly after permuting rows) and the vertex associated with the column x is isolated in the primal graph of A', it follows that $\mathrm{td}_P(A') = \mathrm{td}_P(B') \leq d$ (the inequality holds by the induction hypothesis). Hence, we can assume that the root of T has no label.

We now analyze the case that the root of T has a single child and no label. Let x be the label of the single edge incident with the root of T, and let B' be the matrix obtained from A' by deleting the column x. By induction, the primal tree-depth of B' is at most $d-1$, which implies that the primal tree-depth of A' is at most $\mathrm{td}_P(B') + 1 = d$.

The final case to analyze is the case when the root of T has $k \geq 2$ children (in addition to having no label). Let $Y_1, \ldots, Y_k$ be the labels of the vertices and edges of the k subtrees of T delimited by the k edges incident with the root of T, and let $B_1, \ldots, B_k$ be the submatrices of A formed by the columns contained in $Y_1, \ldots, Y_k$. Since the support of the columns contained in Y_i contains only the unit entries of the columns of A' contained in $X \cap Y_i$, the primal graph of A' contains no edge joining a column of Y_i and a column of Y_j for $i \neq j$. It follows that the primal tree-depth of A' is at most the maximum primal tree-depth of B_i, which is at most d by the induction hypothesis. It follows that $\mathrm{td}_P(A') \leq d$ as desired. ◀

We are now ready to establish the link between the optimal primal tree-depth of a matrix and the deletion-depth of the matroid associated with the matrix. Due to space constraints, the proof of Theorem 4 is sketched only.

Sketch of the proof of Theorem 4. Fix a matrix A. By Lemma 10, it holds that $\mathrm{td}^*_P(A) \leq \mathrm{dd}(A)$. So, we focus on proving that $\mathrm{dd}(A) \leq \mathrm{td}^*_P(A)$. We will show that every matrix B satisfies that $\mathrm{dd}(B) \leq \mathrm{td}_P(B)$, which implies that $\mathrm{dd}(A) \leq \mathrm{td}^*_P(A)$.

The proof that $\mathrm{dd}(B) \leq \mathrm{td}_P(B)$ proceeds by induction on the number of columns. If B has a single column, then both $\mathrm{dd}(B)$ and $\mathrm{td}_P(B)$ are equal to one. We next present the induction step. If the matroid $M(B)$ is not connected, we apply induction to each of its components and derive that each component of $M(B)$ has deletion depth at most $\mathrm{td}_P(B)$. This implies that $\mathrm{dd}(B) \leq \mathrm{td}_P(B)$.

We next assume that the matroid $M(B)$ is connected. It can be shown that the primal graph of B is also connected, which yields that there exists a column such that the matrix B' obtained by deleting this column satisfies that $\mathrm{td}_P(B') = \mathrm{td}_P(B) - 1$. The induction assumption yields that $\mathrm{dd}(B') \leq \mathrm{td}_P(B) - 1$ and the definition of the deletion-depth yields that the deletion-depth of $M(B)$ is at most the deletion-depth of $M(B')$ increased by one. This implies that $\mathrm{dd}(B) = \mathrm{dd}(M(B)) \leq \mathrm{td}_P(B)$ as desired. ◀

Before proceeding with our structural result concerning incidence tree-depth, we use the structural results presented in Lemma 10 and Theorem 4 to get a parameterized algorithm for computing an optimal primal tree-depth of a matrix over a finite field. Due to space constraints, several steps of the proof of Corollary 11 are sketched only.

▶ **Corollary 11.** *There exists an FPT algorithm for the parameterization by a finite field $\mathbb{F}$ and an integer d that for an input matrix A over the field $\mathbb{F}$,*

- *either outputs that $\mathrm{td}^*_P(A) > d$, or*
- *computes a matrix A' equivalent to A with $\mathrm{td}_P(A') \leq d$ and also outputs the associated deletion-decomposition tree of $M(A)$ with height $\mathrm{td}_P(A')$.*

Proof. The property that a matroid M has deletion depth at most d can be expressed in monadic second order logic. Specifically, there exists a monadic second order formula $\psi_d(X)$ that describes whether the deletion-depth of a restriction of the matroid M to a subset X of the elements of M is at most d. In the formula that we present, small letters are used to denote elements of a matroid and capital letters subsets of the elements. Assuming that $\psi_c(x, y)$ is a monadic second order formula describing the existence of a circuit containing two elements x and y and $\psi_C(X)$ is a monadic second order formula describing whether a subset X is a component of a matroid, The sought formula $\psi_d(\cdot)$ is defined inductively (note that $\psi_d(\emptyset)$ is true for all d):

$$\psi_1(X) \equiv \forall x, y \in X : x \neq y \Rightarrow \neg\psi_c(x, y) \qquad \text{and}$$
$$\psi_d(X) \equiv \forall X' \subseteq X : \psi_C(X') \Rightarrow \exists x \in X' : \psi_{d-1}(X' \setminus \{x\}) \qquad \text{for } d \geq 2.$$

Hliněný [25, 26] proved that all monadic second order logic properties can be tested in a fixed parameter way for matroids represented over a finite field $\mathbb{F}$ with branch-width at most d when parameterized by the property, the field $\mathbb{F}$ and the branch-width d. Since the branch-width of a matroid M is at most its deletion-depth, this establishes the existence of a fixed parameter algorithm deciding whether $\mathrm{td}^*_P(A) = \mathrm{dd}(M(A)) \leq d$ (the equality follows from Theorem 4).

To obtain the algorithm claimed to exist in the statement of the corollary, we need to extend the algorithm for testing whether the deletion-depth of an input matroid M represented over $\mathbb{F}$ is at most d to an algorithm that also outputs a deletion-decomposition tree of M with height at most d. The deletion-depth of an input matroid M is one if and only if every element of M is a loop or a bridge. Hence, if the deletion-depth of M is $d = 1$, then the deletion-depth decomposition tree of height one consists of a single vertex labeled

with all elements of M. If the deletion-depth of M is at most $d \geq 2$ and M is not connected, we first identify its components, which can be done in polynomial time even in the oracle model, then proceed recursively with each component of M and eventually merge the roots of all deletion-depth decomposition trees obtained recursively. Finally, if the deletion-depth of M is at most $d \geq 2$ and M is connected, we loop over all elements e of M and test whether $\mathrm{dd}(M \setminus e) \leq d-1$. Such an element e must exist and when it is found, we recursively apply the algorithm to $M \setminus e$ to obtain a deletion-depth decomposition tree T of $M \setminus e$ with height $d-1$, which is then extended to a deletion-depth decomposition tree of M of height d. ◀

We conclude this section by establishing a link between the optimal incidence tree-depth and the contraction*-deletion-depth of the matroid associated with the matrix. Due to space constraints, the proof of Theorem 5 is sketched only.

Proof of Theorem 5. We prove the equality as two inequalities starting with the inequality $\mathrm{c}^*\mathrm{dd}(A) \leq \mathrm{td}^*_I(A) - 1$. To prove this inequality, we show that $\mathrm{c}^*\mathrm{dd}(A) \leq \mathrm{td}_I(A) - 1$ holds for every matrix A with m rows and n columns by induction on $m+n$. The base of the induction is formed by the cases when all entries of A are zero, $n = 1$ or $m = 1$. We focus on describing the induction step, which considers the case when A is non-zero, $m \geq 2$ and $n \geq 2$. First suppose that the matroid $M(A)$ is not connected. Let $X_1, \ldots, X_k$ be the component of $M(A)$ and let $A_1, \ldots, A_k$ be the submatrices of A formed by the columns $X_1, \ldots, X_k$, respectively. The definition of the contraction*-deletion-depth implies that $\mathrm{c}^*\mathrm{dd}(A)$ is the maximum of $\mathrm{c}^*\mathrm{dd}(A_i)$. The induction hypothesis yields that $\mathrm{c}^*\mathrm{dd}(A_i) \leq \mathrm{td}_I(A_i) - 1$. Since the incidence graph of A_i is a subgraph of the incidence graph of A, it follows that $\mathrm{td}_I(A_i) \leq \mathrm{td}_I(A)$ and so $\mathrm{c}^*\mathrm{dd}(A_i) \leq \mathrm{td}_I(A) - 1$. We conclude that $\mathrm{c}^*\mathrm{dd}(A) \leq \mathrm{td}_I(A) - 1$.

The core of the inductive argument showing that $\mathrm{c}^*\mathrm{dd}(A) \leq \mathrm{td}_I(A) - 1$ is formed by the case when the matroid $M(A)$ is connected and the incidence graph of A is also connected. The definition of the tree-depth implies that there exists a vertex w of the incidence graph whose deletion decreases the tree-depth of the incidence graph by one. Let A' be the matrix obtained from A by deleting the row or the column associated with the vertex w and note that $\mathrm{td}_I(A) = \mathrm{td}_I(A') + 1$. If the vertex w is associated with a column x, the matroid $M(A')$ is the matroid obtained from $M(A)$ by deleting the element x. If the vertex w is associated with a row x, the matroid $M(A')$ is the matroid obtained from $M(A)$ by contracting by the subspace generated by the unit vector with the entry in the row x. In either case, the definition of the contraction*-deletion-depth implies that $\mathrm{c}^*\mathrm{dd}(A) \leq \mathrm{c}^*\mathrm{dd}(A') + 1$. The induction hypothesis applied to A' yields that $\mathrm{c}^*\mathrm{dd}(A') \leq \mathrm{td}_I(A') - 1$, which yields that $\mathrm{c}^*\mathrm{dd}(A) \leq \mathrm{td}_I(A') = \mathrm{td}_I(A) - 1$.

To complete the proof of the theorem, it remains to show that the inequality $\mathrm{td}^*_I(A) \leq \mathrm{c}^*\mathrm{dd}(A) + 1$ holds for every matrix A. The proof proceeds by induction on the number n of columns of A. The core of the argument is the inductive step when the matroid $M(A)$ is connected, which we present next. The definition of the contraction*-deletion-depth implies that there exists an element x of $M(A)$ such that $\mathrm{c}^*\mathrm{dd}(M(A)\setminus x) = \mathrm{c}^*\mathrm{dd}(M(A)) - 1 = \mathrm{c}^*\mathrm{dd}(A) - 1$ or there exists a one-dimensional subspace such that the contraction by this subspace yields a matroid M' such that $\mathrm{c}^*\mathrm{dd}(M') = \mathrm{c}^*\mathrm{dd}(M(A)) - 1 = \mathrm{c}^*\mathrm{dd}(A) - 1$. In the former case, let A' be the matrix obtained from A by deleting the column x. By the induction hypothesis, there exists a matrix A'' equivalent to A' such that $\mathrm{td}_I(A'') \leq \mathrm{c}^*\mathrm{dd}(A') + 1 = \mathrm{c}^*\mathrm{dd}(A)$, and let A''' be the matrix obtained from A by the same row operations using that A'' is obtained from A'. Observe that the incidence graph of A'' can be obtained from the incidence graph of A''' by deleting the vertex associated with the column x. Hence, $\mathrm{td}_I(A''') \leq \mathrm{td}_I(A'') + 1$. Since A''' is equivalent to A, it follows that

$$\mathrm{td}^*_I(A) \leq \mathrm{td}_I(A''') \leq \mathrm{td}_I(A'') + 1 \leq \mathrm{c}^*\mathrm{dd}(A) + 1.$$

We now analyze the latter case, i.e., the case that there exists a one-dimensional subspace such that the contraction by this subspace yields a matroid M' such that $\mathrm{c}^*\mathrm{dd}(M') = \mathrm{c}^*\mathrm{dd}(A) - 1$. Let A' be the matrix obtained from A by row operations such that the contracted subspace used to obtain M' is generated by the unit vector with the non-zero entry being the first entry, and let B be the matrix obtained from A' by deleting the first row. By the induction hypothesis, there exists a matrix B' equivalent to B such that $\mathrm{td}_I(B') \leq \mathrm{c}^*\mathrm{dd}(A') + 1 = \mathrm{c}^*\mathrm{dd}(A)$, and let A'' be the matrix consisting of the first row of A and the matrix B'. Observe that A'' is equivalent to A. Since the incidence graph of B' can be obtained from the incidence graph of A'' by deleting the vertex associated with the first row, it holds that $\mathrm{td}_I(A'') \leq \mathrm{td}_I(B') + 1$. Hence, it follows that

$$\mathrm{td}^*_I(A) \leq \mathrm{td}_I(A'') \leq \mathrm{td}_I(B') + 1 \leq \mathrm{c}^*\mathrm{dd}(A) + 1.$$

The proof of the theorem is now completed. ◀

4 Primal tree-depth

In this section, we present a parameterized algorithm for computing an equivalent matrix with small primal tree-depth and bounded entry complexity if such a matrix exists. Due to space constraints, details of some of the arguments used in the proof are omitted.

Proof of Theorem 7. Let $f_P(\cdot,\cdot)$ be the function from the statement of Theorem 1 and set κ_0 to be the least common multiple of the integers $1, \ldots, f_P(d,e)$. Observe that the entry of every circuit of a matrix B with $\mathrm{td}_P(B) \leq d$ and $\mathrm{ec}(B) \leq e$ divides κ_0 as $c_\infty(B) \leq f_P(d,e)$.

We next describe the algorithm from the statement of the theorem. Without loss of generality, we can assume that the rank of the input matrix A is equal to the number of its rows, in particular, A is non-zero. The algorithm starts with diagonalizing the input matrix A by selecting an arbitrary basis of the column space and performing row-operations that the selected columns form the identity matrix. The resulting matrix is denoted by A_I. If the numerator or the denominator of any (non-zero) entry of A_I does not divide κ_0, the algorithm arrives at the first conclusion of the theorem. The algorithm next multiplies each row of A_I by κ_0, This yields an integral matrix A_0 with entries between $-\kappa_0^2$ and κ_0^2.

Let $M_{\mathbb{Q}}$ be the column matroid of A_0 when viewed as a matrix over rationals and let M_p be the column matroid of A_0 when viewed as a matrix over a field $\mathbb{F}_p$ for a prime $p > \kappa_0^2$; note that such a prime p can be found algorithmically as the algorithm is parameterized by d and e. The elements of both matroids $M_{\mathbb{Q}}$ and M_p are the columns of the matrix A_0, i.e., we can assume that their ground sets are the same.

We argue that *if A is equivalent to a matrix with primal tree-depth at most d and entry complexity at most e, then the matroids $M_{\mathbb{Q}}$ and M_p are the same.* As this is the key step in the proof, we present it in full detail. If a set X of columns forms a circuit in $M_{\mathbb{Q}}$, then there exists a linear combination of the columns of X that has all coefficients integral and coprime, i.e., not all are divisible by p, and that is equal to the zero vector (in fact, there exist such coefficients that they all divide κ_0 by the definition of κ_0); it follows that the set X is also dependent in M_p. If a set X of columns is independent in $M_{\mathbb{Q}}$, let B_I be a square submatrix of A_I formed by the columns X and some of the rows such that B_I is non-singular, and let B_0 be the square submatrix of A_0 formed by the same rows and columns. By [17, Lemma 3.3], the matrix B_I^{-1} is $1/\dot{\kappa}_A$-integral and the absolute values of its entries are between $1/c_\infty(A)$ and $c_\infty(A)$. Note that both $c_\infty(A)$ and $\dot{\kappa}_A$ divide κ_0 (here, we use the definition of κ_0 and the assumption that A is equivalent to a matrix with primal tree-depth at most d and entry complexity at most e) and so this the matrix B_I^{-1} is $1/\kappa_0$-integral and the absolute values of its entries are between $1/\kappa_0$ and κ_0. Let B' be the matrix obtained from B_I^{-1} by

multiplying each entry by κ_0; note that B' is an integer matrix with entries between $-\kappa_0^2$ and κ_0^2. The definitions of the matrices B_I, B_0 and B' yield that $B'B_0$ is a diagonal matrix with all diagonal entries equal to κ_0^2. It follows that the columns X form a set independent in M_p.

We now continue the description of the algorithm. As the next step, we apply the algorithm from Corollary 11 to the matrix A_0 viewed as over the field $\mathbb{F}_p$. If the algorithm determines that the deletion-depth of A_0 is larger than d, we arrive at the first conclusion of the theorem. If it determines that the deletion-depth of A_0 is at most d, it also outputs a deletion-decomposition tree of M_p with height at most d. If the output deletion-decomposition tree is not valid for the matroid $M_{\mathbb{Q}}$, we again arrive at the first conclusion of the theorem. If the output deletion-decomposition tree is also a deletion-decomposition tree of the matroid $M_{\mathbb{Q}}$, we use the algorithm from Lemma 10 to obtain a matrix A' equivalent to A such that the primal tree-depth of A' at most the height of the deletion-decomposition tree, i.e., $\mathrm{td}_P(A') \leq d$. As the matrix A' contains a unit submatrix formed by m rows and m columns, each (non-zero) entry of A' is a fraction that can obtained by dividing two entries of a circuit of A. If the absolute value of the numerator or the denominator of any these fractions exceeds κ_0, we again arrive at the first conclusion of the theorem. Otherwise, we output the matrix A'. Note that the primal tree-depth of A' is at most d and its entry complexity is at most $2\lceil\log_2(\kappa_0+1)\rceil$ and κ_0 depends on d and e only. ◀

5 Dual tree-depth, circuit complexity and Graver basis

In this section, we link minimum dual tree-depth of a matrix to its circuit complexity. Due to space constraints, details of some of the arguments used in the proof are omitted.

▶ **Theorem 12.** *There exists a polynomial-time algorithm that for a given matrix A whose rank is smaller than the number of its columns outputs an equivalent matrix A' such that $\mathrm{td}_D(A') \leq c_1(A)^2$ and $\mathrm{ec}(A') \leq 2\lceil\log_2 c_1(A)\rceil$.*

Proof. We start with the description of the algorithm from the statement of the theorem. Let A be the input matrix. We apply the algorithm from Theorem 9 to the matroid $M(A)$ given by the columns of the matrix A. Let T be the contraction*-decomposition tree output by the algorithm, let d be its depth and let X be the set of columns of A that are the labels of the edges of T, i.e., the elements of $M(A)$ used in the contractions. Since the columns contained in X form a base of the column space of A, we can perform row-operations on the matrix A in a way that the submatrix formed by the columns of X is an identity matrix; let A' be the resulting matrix. The algorithm outputs the matrix A'.

We now analyze the matrix A' that is output by the algorithm. Since the rank of A is smaller than the number of its columns, the matrix A has at least one circuit and so $c_1(A) \geq 2$. Observe that every circuit of $M(A)$ contains at most $c_1(A)$ elements and so it holds that $d \leq c_1(A)^2$, i.e., the depth of T is at most $c_1(A)^2$. Let F be a rooted forest obtained from T by removing the root and for each edge e, associating the vertex of e farther from the root of T with the (unique) row of A' that is non-zero in the column that is the label of e. Hence, the vertex set of F is formed by the rows of A'. Since it can be shown that the dual graph of A' is a subgraph of $\mathrm{cl}(F)$, it follows that that $\mathrm{td}_D(A') \leq c_1(A)^2$ (note that the height of F is at most $c_1(A)^2$).

It remains to analyze the entry complexity of A'. The entries of A' in the columns of X are zero or one. Every column z of A' that is not contained in X forms a circuit with some of the columns of X. The entries of A' in the column z are equal to $-c_x/c_z$ where c_x, $x \in X$, and c_z are the corresponding integer entries of this circuit of A' (and so of A). We conclude that the entry complexity of A' is at most $2\lceil\log_2 c_1(A)\rceil$. ◀

Theorem 12 implies that $g_1(A) \leq f_D\left(c_1(A)^2, 2\lceil \log_2 c_1(A)\rceil\right)$ for every matrix A with $\mathcal{C}(A) \neq \emptyset$, where f_D is the function from Theorem 1. Note that the condition $\mathcal{C}(A) \neq \emptyset$ is necessary as otherwise A has no circuit and so $c_1(A)$ is not defined. We state this bound as a corollary.

▶ **Corollary 13.** *There exists a function $f : \mathbb{N} \to \mathbb{N}$ such that $g_1(A) \leq f(c_1(A))$ for every matrix A with $\mathcal{C}(A) \neq \emptyset$.*

We next combine the algorithms from Theorems 2 and 12.

▶ **Corollary 14.** *There exists a function $f : \mathbb{N} \to \mathbb{N}$ and an FPT algorithm for the parameterization by k that for a given rational matrix A:*

- *either outputs that $c_1(A) > k$, or*
- *outputs a matrix A' that is equivalent to A, its dual tree-depth is $\mathrm{td}^*_D(A)$ and its entry complexity is at most $f(k)$.*

Proof of Corollary14. For an input matrix A, we apply the algorithm from Theorem 12 to get a matrix A' equivalent to A. If the dual tree-depth of A' is larger than k^2 or the entry complexity of A' is larger than $2\lceil \log_2 k\rceil$, then $c_1(A) > k$ and we arrive at the first conclusion. Otherwise, we apply the algorithm from Theorem 2 with parameters $d = k^2$ and $e = 2\lceil \log_2 k\rceil$ to compute a matrix A'' equivalent to A' and so to A such that the dual tree-depth of A'' is $\mathrm{td}^*_D(A)$ and the entry complexity of A'' is $O(k^4 2^{2k^2} \log k)$. ◀

Finally, the previous corollary together with Theorem 1 yields the parameterized algorithm for testing whether an input matrix is equivalent to a matrix with small dual tree-depth and small entry complexity as given in Theorem 8.

Proof of Theorem 8. Let f_D be the function from the statement of Theorem 1 and set $k = f_D(d, e)$. Apply the algorithm from Corollary 14 with the parameter k to an input matrix A. If the algorithm reports that $c_1(A) > k$, then A is not equivalent to a matrix with dual tree-depth at most d and entry complexity at most e. If the algorithm outputs a matrix A' and $\mathrm{td}_D(A') > d$, then $\mathrm{td}^*_D(A) > d$ and so the matrix A is not equivalent to a matrix with dual tree-depth at most d. Otherwise, the dual tree-depth of A' is at most d and its entry complexity is $2^{O(k^2)} = 2^{O\left(f_D(d,e)^2\right)}$, i.e., it is bounded by a function of d and e only as required. ◀

6 Computational hardness of depth parameters

In this section, we complement our algorithmic results by establishing computational hardness of matroid depth parameters that we discussed in this paper. The hardness results apply even when the input matroid is given by its representation over a fixed (finite or infinite) field.

We start with defining a matroid $M_{\mathbb{F}}(G)$ derived from a graph G. Fix a field $\mathbb{F}$. For a graph G, we define an $\mathbb{F}$-represented matroid $M_{\mathbb{F}}(G)$ as follows. The matroid $M_{\mathbb{F}}(G)$ contains $|G| + \|G\|$ elements, which correspond to the vertices and the edges of G. We next associate each element of $M_{\mathbb{F}}(G)$ with a vector of $\mathbb{F}^{V(G)}$. An element of $M_{\mathbb{F}}(G)$ corresponding to a vertex w of G is represented by e_w and an element of $M_{\mathbb{F}}(G)$ corresponding to an edge ww' of G is represented by $e_w - e_{w'}$.

We next define a graph G/A for a graph G and a linear subspace A of $\mathbb{F}^{V(G)}$. Let W be the subset of vertices of $V(G)$ such that $e_w \in A$ for $w \in W$, and let F be a maximal subset of edges $ww' \in E(G)$ such that

- A contains a vector $e_w + \alpha e_{w'}$ for a non-zero element $\alpha \in \mathbb{F}$, and
- the set containing all vectors e_w, $w \in W$, and all vectors $e_w - e_{w'}$, $ww' \in F$, is linearly independent.

The graph G/A is obtained by deleting all vertices of W and then contracting all edges contained in F. The next lemma asserts that G/A is well-defined. We remark that the proof of the next lemma as well as the proofs of Lemmas 16 and 17 are omitted due to space constraints.

▶ **Lemma 15.** *Let G be a graph, $\mathbb{F}$ a field and A a linear subspace of $\mathbb{F}^{V(G)}$. The graph G/A is well-defined, i.e., the graph G/A does not depend on the choice of the set F in its definition.*

The next lemma relates the number of components of the matroid $M_{\mathbb{F}}(G)/A$ and the number of components of the graph G/A for a graph G and a linear subspace A of $\mathbb{F}^{V(G)}$.

▶ **Lemma 16.** *Let G be a graph, $\mathbb{F}$ a field and A a linear subspace of $\mathbb{F}^{V(G)}$. The number of components of $M_{\mathbb{F}}(G)/A$ is at most the number of components of the graph G/A.*

We next link the existence of a balanced independent set in a bipartite graph to the contraction*-depth of a suitably defined matroid. We remark that the idea of using a bipartite graph with cliques added between the vertices of its parts was used in [43] to establish that computing tree-depth of a graph is NP-complete.

▶ **Lemma 17.** *Let G be a bipartite graph with parts X and Y, let $\mathbb{F}$ be a field, and let k be an integer. Let G' be the graph obtained from G by adding all edges between the vertices of X and between the vertices of Y. The following three statements are equivalent.*

- *There exists an independent set containing k elements of X and k elements of Y.*
- *The contraction*-depth of $M_{\mathbb{F}}(G')$ is at most $|X| + |Y| - k$.*
- *The contraction-depth of the matroid $2M_{\mathbb{F}}(G')$ is at most $|X| + |Y| - k + 1$.*

We are now ready to state and prove our hardness result.

▶ **Theorem 18.** *For every field $\mathbb{F}$, each of the following five decision problems, whose input is an $\mathbb{F}$-represented matroid M and an integer d, is NP-complete:*

- *Is the contraction-depth of M at most d?*
- *Is the contraction*-depth of M at most d?*
- *Is the contraction-deletion-depth of M at most d?*
- *Is the contraction*-deletion-depth of M at most d?*
- *Is the deletion-depth of M at most d?*

Proof. It is NP-complete to decide for a bipartite graph G with parts X and Y and an integer k whether there exist k-element subsets $X' \subseteq X$ and $Y' \subseteq Y$ such that $X' \cup Y'$ is independent [43]. For an input bipartite graph G, let G' be the graph obtained from G by adding all edges between the vertices of X and between the vertices of Y. We claim that the existence of such subsets X' and Y' is equivalent to each of the following four statements:

- The matroid $2M_{\mathbb{F}}(G')$ has contraction-depth at most $|X| + |Y| - k + 1$.
- The matroid $M_{\mathbb{F}}(G')$ has contraction*-depth at most $|X| + |Y| - k$.
- The matroid $(|G'| + 1)M_{\mathbb{F}}(G')$ has contraction-deletion-depth at most $|X| + |Y| - k + 1$.
- The matroid $(|G'| + 1)M_{\mathbb{F}}(G')$ has contraction*-deletion-depth at most $|X| + |Y| - k$.

The equivalence of the first and second statements follow directly from Lemma 17. Since the rank of the matroid $(|G'|+1)M_{\mathbb{F}}(G')$ is $|G'|$, its contraction-deletion-depth is at most $|G'|+1$ and its contraction*-deletion-depth is at most $|G'|$. As each element of the matroid $(|G'|+1)M_{\mathbb{F}}(G')$ is parallel to (at least) $|G'|$ elements of the matroid, it follows that the contraction-deletion-depth of $M_{\mathbb{F}}(G')$ is the same as its contraction-depth and its contraction*-deletion-depth is the same as its contraction*-depth. Lemma 17 now implies the equivalence of the third and fourth statements. As the matroids $2M_{\mathbb{F}}(G')$, $M_{\mathbb{F}}(G')$ and $(|G'|+1)M_{\mathbb{F}}(G')$ can be easily constructed from the input graph G in time polynomial in $|G|$, the NP-completeness of the first four problems listed in the statement of the theorem follows.

For an $\mathbb{F}$-represented matroid M, it is easy to construct an $\mathbb{F}$-represented matroid M^* that is dual to M in time polynomial in the number of the elements of M [42, Chapter 2]. Since the contraction-depth of M is equal to the deletion-depth of M^*, it follows that the fifth problem listed in the statement of the theorem is also NP-complete. ◀

Abstract

An extensive research effort targets optimal (in)approximability results for various NP-hard optimization problems. Notably, the works of (Creignou'95) as well as (Khanna, Sudan, Trevisan, Williamson'00) establish a tight characterization of a large subclass of MaxSNP, namely Boolean MaxCSPs and further variants, in terms of their polynomial-time approximability. Can we obtain similarly encompassing characterizations for classes of *polynomial-time optimization problems*?

To this end, we initiate the systematic study of a recently introduced polynomial-time analogue of MaxSNP, which includes a large number of well-studied problems (including Nearest and Furthest Neighbor in the Hamming metric, Maximum Inner Product, optimization variants of k-XOR and Maximum k-Cover). Specifically, for each k, MaxSP_k denotes the class of $O(m^k)$-time problems of the form $\max_{x_1,\dots,x_k} \#\{y : \phi(x_1,\dots,x_k,y)\}$ where ϕ is a quantifier-free first-order property and m denotes the size of the relational structure. Assuming central hypotheses about clique detection in hypergraphs and exact Max-3-SAT, we show that for any MaxSP_k problem definable by a quantifier-free m-edge *graph* formula ϕ, the *best possible* approximation guarantee in faster-than-exhaustive-search time $O(m^{k-\delta})$ falls into one of four categories:

- optimizable to exactness in time $O(m^{k-\delta})$,
- an (inefficient) approximation scheme, i.e., a $(1+\varepsilon)$-approximation in time $O(m^{k-f(\varepsilon)})$,
- a (fixed) constant-factor approximation in time $O(m^{k-\delta})$, or
- an m^{ε}-approximation in time $O(m^{k-f(\varepsilon)})$.

We obtain an almost complete characterization of these regimes, for MaxSP_k as well as for an analogously defined minimization class MinSP_k. As our main technical contribution, we show how to rule out the existence of *approximation schemes* for a large class of problems admitting constant-factor approximations, under a hypothesis for *exact* Sparse Max-3-SAT algorithms posed by (Alman, Vassilevska Williams'20). As general trends for the problems we consider, we observe: (1) Exact optimizability has a simple algebraic characterization, (2) only few maximization problems do not admit a constant-factor approximation; these do not even have a subpolynomial-factor approximation, and (3) constant-factor approximation of minimization problems is *equivalent* to deciding whether the optimum is equal to 0.

1 Introduction

For many optimization problems, the best known exact algorithms essentially explore the complete search space, up to low-order improvements. While this holds true in particular for NP-hard optimization problems such as maximum satisfiability, also common polynomial-time optimization problems like Nearest Neighbor search are no exception. When facing such a problem, the perhaps most common approach is to relax the optimization goal and ask for *approximations* rather than optimal solutions. Can we obtain an approximate value significantly faster than exhaustive search, and if so, what is the best approximation guarantee we can achieve?

Even considering polynomial-time problems only, the study of such questions has led to significant algorithmic breakthroughs, such as locality-sensitive hashing (LSH) [49, 41, 11], subquadratic-time approximation algorithms for Edit Distance [56, 18, 17, 19, 14, 12, 26, 55, 21, 43, 13], scaling algorithms for graph problems [37, 70, 34], and fast approximation algorithms via the polynomial method [5, 6] (which lead to the currently fastest known exponential-time approximation schemes for MaxSAT).

These algorithmic breakthroughs have recently been complemented by exciting tools for proving hardness of approximation in P: Most notably, the distributed PCP framework [4] has lead to strong conditional lower bounds, including fundamental limits for Nearest Neighbor search [62], as well as tight approximability results for the Maximum Inner Product problem [28]. Other technical advances include evidence against deterministic approximation schemes for Longest Common Subsequence [1, 3, 29], strong (at times even tight) problem-specific hardness results such as [61, 22, 16, 25, 52], the first fine-grained equivalences of approximation in P results [30, 29], and related works on parameterized inapproximability [27, 51, 59], see [36] for a survey.

These strong advances from both sides shift the algorithmic frontier and the frontier of conditional hardness towards each other. Consequently, it becomes increasingly important to generalize isolated results – both algorithms and reductions – towards making these frontiers explicit: A more comprehensive description of current techniques might enable us to understand general trends underlying these works and to highlight the most pressing limitations of current methods. In fact, we view this as one of the fundamental tasks and uses of fine-grained algorithm design & complexity.

Optimization Classes in P. To study (hardness of) approximation in P in a general way, we study a class MaxSP_k recently introduced in [23] (see the full version of this paper for a comparison to the classic class MaxSNP, which motivated the definition of MaxSP_k). This class consists of polynomial-time optimization problems of the form:

$$\max_{x_1,\dots,x_k} \#\{y : \phi(x_1,\dots,x_k,y)\},$$

where ϕ is a quantifier-free first-order property.[1] One obtains an analogous minimization class MinSP$_k$ by replacing maximization by minimization. A large number of natural and well-studied problems can be expressed this way: In particular, we may think of each x_i ranging over a set X_i of n vectors in $\{0,1\}^d$, and the task is to maximize (or minimize) the number of coordinates y satisfying an arbitrary Boolean function over the coordinate values $x_1[y], \dots, x_k[y]$ (here, ϕ is defined using a binary relation $R \subseteq (X_1 \cup \dots \cup X_k) \times Y$ that expresses whether the y-th coordinate of x_i is 0 or 1; see Section 2 for details). In particular, this class of problems includes:

- (Offline) Furthest/Nearest Neighbor search in the Hamming metric ($\max_{x_1,x_2} / \min_{x_1,x_2} d_H(x_1,x_2)$),
- Maximum/Minimum Inner Product; the latter is the optimization formulation of the Most-Orthogonal Vectors problem [2] ($\max_{x_1,x_2} / \min_{x_1,x_2} \langle x_1, x_2 \rangle$),
- A natural similarity search problem that we call Maximum k-Agreement ($\max_{x_1,\dots,x_k} \#\{y : x_1[y] = \dots = x_k[y]\}$),
- Maximum k-Cover [35, 31, 59] and its variation Maximum Exact-k-Cover [54] ($\max_{x_1,\dots,x_k} \#\{y : x_i[y] = 1 \text{ for some } i\}$, $\max_{x_1,\dots,x_k} \#\{y : x_i[y] = 1 \text{ for exactly one } i\}$)[2],
- The canonical optimization variants of the k-XOR problem [50, 33] ($\max_{x_1,\dots,x_k} / \min_{x_1,\dots,x_k} \#\{y : x_1[y] \oplus \dots \oplus x_k[y] = 0\}$).

  By the standard split-and-list technique [66], it is easy to see that any c-approximation for Maximum k-XOR or Minimum k-XOR in time $O(n^{k-\delta}\operatorname{poly}(d))$ gives a c-approximation for Max-LIN (maximize the number of satisfied constraints of a linear system over $\mathbb{F}_2$, see [45, 66, 6]) or the Minimum Distance Problem[3] (finding the minimum weight of a non-zero code word of a linear code over $\mathbb{F}_2$, see [63]), respectively, in time $O(2^{n(1-\delta')})$.

By a simple baseline algorithm, all of these problems can be solved in time $O(m^k)$, where m denotes the input size (for the above setting of k sets of n vectors in $\{0,1\}^d$ we have $m = O(nd)$). A large body of work addresses problems with $k = 2$, typically inventing or adapting strong techniques to each specific problem as needed:

- Abboud, Rubinstein, and Williams introduced the distributed PCP in P framework and ruled out almost-polynomial approximations for the Maximum Inner Product problem assuming the Strong Exponential Time Hypothesis (SETH). Subsequently, Chen [28] strengthened the lower bound and gave an approximation algorithm resulting in tight bounds on the approximability in strongly subquadratic time, assuming SETH. Corresponding inapproximability results for its natural generalization to k-Maximum Inner Product have been obtained in [51].
- In contrast, strong approximation algorithms have a rich history for the Nearest Neighbor search problem: Using LSH, we can obtain an $(1+\varepsilon)$-approximation in time $O(n^{2-\Theta(\varepsilon)})$ [44, 9, 10, 15]. Using further techniques, the dependence on ε has been improved to $O(n^{2-\Omega(\sqrt{\varepsilon})})$ [64] and $O(n^{2-\tilde{\Omega}(\sqrt[3]{\varepsilon})})$ [5, 6]. On the hardness side, Rubinstein [62] shows that the dependence on ε cannot be improved indefinitely, by proving that for every δ, there exists an ε such that $(1+\varepsilon)$-approximate Nearest Neighbor search requires time $\Omega(n^{2-\delta})$ assuming SETH. In particular, this rules out $\operatorname{poly}(1/\varepsilon)n^{2-\delta}$-time algorithms with $\delta > 0$.

[1] Note that [23] more generally defines classes MaxSP$_{k,\ell}$ for $\ell \geq 1$. We focus on MaxSP$_k$ = MaxSP$_{k,1}$, as it was determined as computationally harder than MaxSP$_{k,\ell}$ with $\ell \geq 2$, and contains many natural problems (see below).

[2] These problems are typically studied in the setting where k is part of the input, while we consider them for a fixed constant k.

[3] In fact, even for the Nearest Codeword Problem over $\mathbb{F}_2$.

- For the dual problem of Furthest Neighbor search (i.e., diameter in the Hamming metric), [20] gives a $O(n^{2-\Theta(\varepsilon^2)})$-time algorithm, which was improved to $O(n^{2-\Theta(\varepsilon)})$ via reduction to Nearest Neighbor search in [47]. Following further improvements [42, 48], also here [5, 6] give an $O(n^{2-\tilde{\Omega}(\sqrt[3]{\varepsilon})})$-time algorithm. Analogous inapproximability to Rubinstein's result are given in [30].
- For Minimum Inner Product, the well-known Orthogonal Vectors hypothesis [65] (which is implied by SETH [66]) is precisely the assumption that already distinguishing whether the optimal value is 0 or at least 1 cannot be done in strongly subquadratic time. Interestingly, Chen and Williams [30] show a converse: a refutation of the Orthogonal Vectors hypothesis would give a subquadratic-time constant-factor approximation for Minimum Inner Product.

In the above list, we focus on the difficult case of moderate dimension $d = n^{o(1)}$ (when measuring the time complexity with respect to the input size). Lower-dimensional settings such as $d = \Theta(\log n)$, $d = \Theta(\log \log n)$ or even lower are addressed in other works [69, 30].

While the above collection of results gives a detailed understanding of isolated problems, we know little about general phenomena of (in)approximability in MaxSP_k and MinSP_k using faster-than-exhaustive-search algorithms: Are there problems for which constant-factor approximations are best possible? Is maximizing (or minimizing) Inner Product the only problem without a constant-factor approximation? Which problems can we optimize exactly?

There are precursors to our work that show fine-grained *equivalence classes* of approximation problems in P [29, 30]. However, establishing membership of a problem in these classes requires a problem-specific proof, while we are interested in *syntactically* defined classes, where class membership can be immediately read off from the definition of a problem. Our aim is to understand the approximability landscape of such classes fully. Finally, the previous works either focus on lower-dimensional settings [30][4], or target more powerful problems than we consider, such as Closest-LCS-Pair [29].

MaxSP_k as Polynomial-Time Analogue of MaxSNP. Investigating NP-hard optimization problems, Papadimitriou and Yannakakis [60] introduced the class MaxSNP, which motivates the definition of MaxSP_k as a natural polynomial-time analogue (see [23] and the full version of this paper for details). As a general class containing prominent, constant-factor approximable optimization problems, MaxSNP was introduced to give the first evidence that Max-3-SAT does not admit a PTAS, by proving that Max-3-SAT belongs to the hardest-to-approximate problems in MaxSNP.

Ideally, one would like to understand the approximability landscape in MaxSNP fully and give tight approximability results for each such problem. Major advances towards this goal have been achieved by Creignou [32] and Khanna, Sudan, Trevisan, and Williamson [53] who gave a complete classification of a large subclass of MaxSNP, namely, maximum Boolean Constraint Satisfaction Problems (MaxCSP): Each Boolean MaxCSP either is polynomial-time optimizable or it does not admit a PTAS unless P = NP, rendering a polynomial-time constant-factor approximation best possible. For minimization analogues, including Boolean MinCSPs, the situation is more diverse with several equivalence classes needed to describe the result [53].

We initiate the study of the same type of questions in the polynomial-time regime. Our aim is to achieve a detailed understanding of MaxSP_k and MinSP_k akin to the classification theorems achieved for MaxCSPs and MinCSPs [32, 53].

[4] Chen and Williams also give some results for the moderate-dimensional case; we discuss these in Section 3.

1.1 Our Results

We approach the classification of MaxSP$_k$ and MinSP$_k$ by considering the simplest, yet expressive case of a *single, binary relation* involved in the first-order formula; this route was also taken in earlier classification work for first-order properties [24]. We may thus view the relational structure as a graph, and call such a formula a *graph formula*. Note that despite its naming, this includes problems not usually viewed as graph problems, such as all examples given in the introduction, which are natural problems on sets of *vectors* in $\{0,1\}^d$.

We obtain a classification of each graph formula into one of four regimes, assuming central fine-grained hardness hypotheses whose plausibility we detail in the full version of this paper. All of our hardness results are implied by the Sparse Max-3-SAT hypothesis [7], which states that for all $\delta > 0$ there is some $c > 0$ such that Max-3-SAT on n variables and cn clauses has no $O(2^{n(1-\delta)})$-time algorithm.[5] (Actually, most of our hardness results already follow from weaker assumptions.)

▶ **Theorem 1.** *Let ψ be a MaxSP$_k$ or MinSP$_k$ graph formula. Assuming the Sparse Max-3-SAT hypothesis, ψ belongs to precisely one of the following regimes:*

R1 Efficiently optimizable:
There is some $\delta > 0$ such that ψ can be solved exactly in time $O(m^{k-\delta})$.

R2 Admits an approximation scheme, but not an efficient one:
For all $\varepsilon > 0$, there is some $\delta > 0$ such that ψ can be $(1+\varepsilon)$-approximated in time $O(m^{k-\delta})$. However, for all $\delta > 0$, there is some $\varepsilon > 0$ such that ψ cannot be $(1+\varepsilon)$-approximated in time $O(m^{k-\delta})$.

R3 Admits a constant-factor approximation, but no approximation scheme:
There are $\varepsilon, \delta > 0$ such that ψ can be $(1+\varepsilon)$-approximated in time $O(m^{k-\delta})$. However, there also exists an $\varepsilon > 0$ such that for all $\delta > 0$, ψ cannot be $(1+\varepsilon)$-approximated in time $O(m^{k-\delta})$.

R4 Arbitrary polynomial-factor approximation is best possible (maximization):
For every $\varepsilon > 0$, there is some $\delta > 0$ such that ψ can be $O(m^{\varepsilon})$-approximated in time $O(m^{k-\delta})$. However, for every $\delta > 0$, there exists some $\varepsilon > 0$ such that ψ cannot be $O(m^{\varepsilon})$-approximated in time $O(m^{k-\delta})$.

No approximation at all (minimization):
For all $\delta > 0$, we cannot decide whether the optimum value of ψ is 0 or at least 1 in time $O(m^{k-\delta})$.

Note that the characteristics of the fourth (i.e., hardest) regime differ between the maximization and the minimization case.

This theorem has immediate consequences for the approximability landscape in MaxSP$_k$ and MinSP$_k$, based on fine-grained assumptions: In particular, while any MaxSP$_k$ graph formula can be approximated within a subpolynomial factor $O(m^{\varepsilon})$, we can rule out optimal approximation ratios that *grow with m but are strictly subpolynomial* (i.e., there are *no* graph formulas whose optimal approximability within $O(m^{k-\Omega(1)})$ time is $\Theta(\log\log m)$, $\Theta(\log^2 m)$ or $2^{\Theta(\sqrt{\log m})}$). Furthermore, there are no graph formulas with an $f(1/\varepsilon)m^{k-\Omega(1)}$ approximation scheme that cannot already be optimized to exactness in time $m^{k-\Omega(1)}$.

In fact, beyond Theorem 1 we even give an almost complete characterization of each regime: Specifically, we introduce integer-valued hardness parameters $0 \le H_{\text{and}}(\psi) \le H_{\text{deg}}(\psi) \le k$ (defined in Section 3). As illustrated in Figure 1, we show how to place any graph formula ψ

[5] This hypothesis is a stronger version of the Max-3-SAT hypothesis [58].

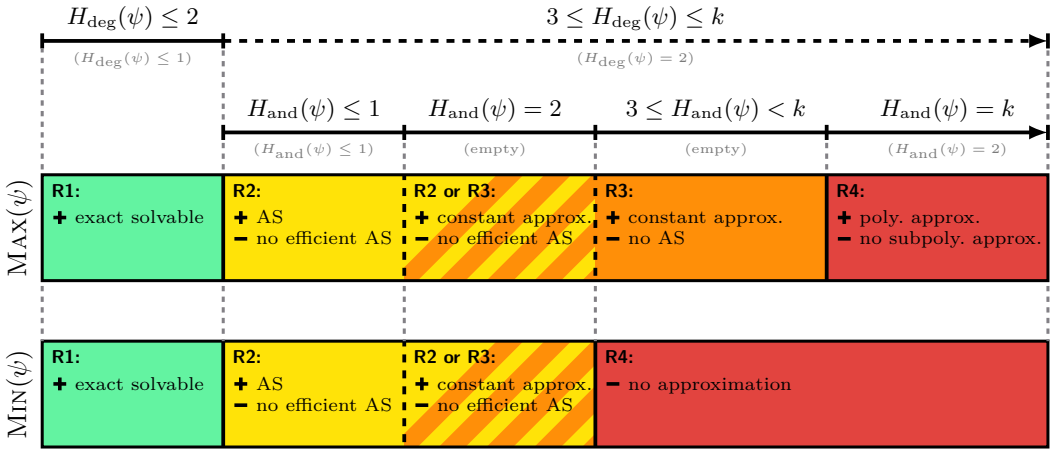

Figure 1 Visualizes our classification of first-order optimization problems $\textsc{Max}(\psi)$ and $\textsc{Min}(\psi)$ for all $k \geq 3$, in terms of the hardness parameters H_{and} and $H_{\deg}$ (as defined in Definitions 4 and 6). See Definition 10 for the precise definition of an (efficient) approximation scheme (AS). The pale labels indicate how to change the conditions to obtain the picture for $k = 2$.

Table 1 Some interesting examples classified according to Figure 1. For each problem ψ, an instance consists of k sets of n vectors $X_1, \ldots, X_k \subseteq \{0,1\}^d$. We write $\psi = \max_{x_1,\ldots,x_k} / \min_{x_1,\ldots,x_k} \phi$ and only list the inner formulas ϕ in the table.

Problem ψ	ϕ	$H_{\deg}(\psi)$	$H_{\text{and}}(\psi)$	Hardness regime
Maximum/Minimum 2-Agreement	$\#\{y : x_1[y] = x_2[y]\}$	2	1	R2
Maximum/Minimum 3-Agreement	$\#\{y : x_1[y] = x_2[y] = x_3[y]\}$	2	2	R1
Maximum k-Agreement, $k \geq 4$	$\#\{y : x_1[y] = \cdots = x_k[y]\}$	$2\lfloor \frac{k}{2} \rfloor$	$k-1$	R3
Minimum k-Agreement, $k \geq 4$	$\#\{y : x_1[y] = \cdots = x_k[y]\}$	$2\lfloor \frac{k}{2} \rfloor$	$k-1$	R4
Maximum/Minimum k-XOR	$\#\{y : x_1[y] \oplus \cdots \oplus x_k[y]\}$	k	1	R2
Maximum k-Inner Product	$\#\{y : x_1[y] \wedge \cdots \wedge x_k[y]\}$	k	k	R4
Minimum k-Inner Product	$\#\{y : x_1[y] \wedge \cdots \wedge x_k[y]\}$	k	k	R4

into its corresponding regime depending solely on $H_{\text{and}}(\psi)$ and $H_{\deg}(\psi)$ – with the *single exception* of formulas ψ with $H_{\text{and}}(\psi) = 2$ and $H_{\deg}(\psi) \geq 3$. For these formulas (e.g., Maximum Exact-3-Cover), it remains open whether they belong to Regime 2 or 3, i.e., whether or not they admit an approximation scheme (see Open Problem 1).

In the full version we give natural problems for each regime (showing in particular that each regime is indeed non-empty). A particular highlight is that we can prove existence of *constant-factor approximable formulas that do not admit an approximation scheme*, such as Maximum-4-Agreement (see Section 3, Theorem 11 for a technical discussion of the lower bound). In the full version of this paper, we give the details on how to calculate the hardness parameters $H_{\text{and}}(\psi)$ and $H_{\deg}(\psi)$ for each example in Table 1.

While the approximability of problems in the third and fourth regime seem rather unsatisfactory, we also consider the setting of additive approximation, and show that for every MaxSP_k and MinSP_k graph formula, there is an additive approximation scheme; however, assuming the Sparse MAX-3-SAT hypothesis it cannot be an efficient one unless we can optimize the problem exactly.

▶ **Theorem 2** (Additive Approximation). *For every ψ, we give an additive approximation scheme, i.e., for every $\varepsilon > 0$, there is a $\delta > 0$ such that we compute the optimum value up to an additive $\varepsilon|Y|$ error in time $O(m^{k-\delta})$.*

If ψ does not belong to Regime 1, we show that unless the Sparse Max-3-SAT hypothesis fails, for every $\delta > 0$, there is some $\varepsilon > 0$ such that we cannot compute the optimum value up to an additive $\varepsilon|Y|$ error in time $O(m^{k-\delta})$.

Finally, we remark that our classification identifies general trends in MaxSP_k and MinSP_k, including that exact optimizability is described by a simple algebraic criterion, and that constant-factor approximation for minimization problems is equivalent to testing whether the optimum is 0. We address these trends in Section 3.

On Plausibility of the Hypotheses. As tight unconditional lower bounds for polynomial-time problems are barely existent, we give *conditional* lower bounds, based on established assumptions in fine-grained complexity theory, such as SETH (see [65] for an excellent survey). The essentially only exception is the only recently introduced *Sparse* Max-3-SAT hypothesis [7]; we use this hypothesis only for giving evidence against approximation schemes and for ruling out certain additive approximation schemes. While it is possible that this hypothesis could ultimately be refuted, our classification describes the frontier of the current state of the art. At the very least, our conditional lower bound for approximation schemes reveals a rather surprising connection: To obtain an *approximation scheme* for *polynomial-time problems* such as Maximum 4-Agreement, we need to give an *exponential*-time improvement for *exact* solutions for Sparse Max-3-SAT!

1.2 Further Related Work

Parameterized Inapproximability. The problem settings we consider are related to a recent and strong line of research on parameterized inapproximability, including [27, 51, 31, 59, 57] (see [36] for a recent survey). In these contexts, one seeks to determine optimal approximation guarantees within some running time of the form $f(k)n^{g(k)}$ (such as FPT running time $f(k)\,\text{poly}(n)$ or running time $n^{o(k)}$) for some parameter k (such as the solution size). Unfortunately, many of these results do not immediately establish hardness for specific values of k. An important exception is work by Karthik, Laekhanukit, and Manurangsi [51], which among other results establishes inapproximability of k-Dominating Set and the Maximum k-Inner Product within running time $O(n^{k-\varepsilon})$, assuming SETH. We give a detailed comparison of our setting to notions used in Karthik et al.'s work in the full version of this work.

Fine-Grained Complexity of First-Order Properties. Studying the fine-grained complexity of polynomial-time problem classes defined by first-order properties has been initiated in [68, 40], with different settings considered in [39, 38]. In particular, for model-checking first-order properties, [40] provides a completeness result (a fine-grained analogue of the Cook-Levin Theorem) and [24] provides a classification theorem (a fine-grained analogue of Schaefer's Theorem, see also Section 3.1).

For *optimization* in P, [23] provides completeness theorems for MaxSP$_k$ (a fine-grained analogue of MaxSNP-completeness of Max-3-SAT [60]). In contrast, the present paper gives a classification theorem (building a fine-grained analogue of the approximability classifications of optimization variants of CSPs [32, 53]).

2 Preliminaries

For an integer $k \geq 0$, we set $[k] = \{1, \ldots, k\}$. For a set A and integer $k \geq 0$ we denote by $\binom{A}{k}$ the set of all size-k subsets of A. Let $\phi(z_1, \ldots, z_k)$ a Boolean function, and let $S \subseteq [k]$. Any function obtained by instantiating all variables z_i ($i \notin S$) in ϕ by constant values is called an *S-restriction* of ϕ. Finally, we write $\tilde{O}(\cdot)$ to hide poly-logarithmic factors and denote by $\omega < 2.373$ the exponent of square matrix multiplication [8].

2.1 First-Order Model-Checking

A *relational structure* consists of n objects and relations $R_1, \ldots, R_\ell$ (of arbitrary arities) between these objects. A *first-order formula* is a quantified formula of the form

$$\psi = (Q_1 x_1) \ldots (Q_{k+1} x_{k+1})\, \phi(x_1, \ldots, x_{k+1}),$$

where ϕ is a Boolean formula over the predicates $R(x_{i_1}, \ldots, x_{i_\ell})$ and each Q_i is either a universal or existential quantifier. Given a $(k+1)$-partite structure on objects $X_1 \cup \cdots \cup X_{k+1}$, the *model-checking problem* (or *query evaluation problem*) is to check whether ψ holds on the given structure, that is, for x_i ranging over X_i and by instantiating the predicates $R(x_{i_1}, \ldots, x_{i_\ell})$ in ϕ according to the structure, ψ is valid.

Following previous work in this line of research [40, 24], we usually assume that the input is represented sparsely – that is, we assume that the relational structure is written down as an exhaustive enumeration of all records in all relations; let m denote the total number of such entries[6]. The convention is reasonable as this data format is common in the context of database theory and also for the representation of graphs (where it is called the *adjacency list* representation), see Section 4 for a further discussion.

A first-order formula ψ is called a *graph formula* if it is defined over a single binary predicate $E(x_i, x_j)$. Many natural problems fall into this category; see [24] for a detailed discussion on the subject.

2.2 MaxSP$_k$ and MinSP$_k$

In analogy to first-order properties with quantifier structure $\exists^k \forall$ (with maximization instead of $\exists$ and counting instead of $\forall$) and following the definition in [23], we now introduce the class of optimization problems. Let MaxSP$_k$ be the class containing all formulas of the form

[6] By ignoring objects not occurring in any relation, we may always assume that $n \leq O(m)$.

$$\psi = \max_{x_1,\dots,x_k} \#_{y}\, \phi(x_1,\dots,x_k,y), \tag{1}$$

where, as before, ϕ is a Boolean formula over some predicates $R(x_{i_1},\dots,x_{i_\ell})$. We similarly define MinSP$_k$ with "min" in place of "max". Occasionally, we write OptSP$_k$ to refer to both of these classes simultaneously, and we write "opt" as a placeholder for either "max" or "min". In analogy to the model-checking problem for first-order properties, we associate to each formula $\psi \in$ OptSP$_k$ an algorithmic problem:

▶ **Definition 3** (Max(ψ) and Min(ψ)). *Let $\psi \in$ MaxSP$_k$ be as in (1). Given a $(k+1)$-partite structure on objects $X_1 \cup \dots \cup X_k \cup Y$, the Max($\psi$) problem is to compute*

$$\mathrm{OPT} = \max_{x_1\in X_1,\dots,x_k\in X_k} \#_{y\in Y}\, \phi(x_1,\dots,x_k,y).$$

We similarly define Min(ψ) for $\psi \in$ MinSP$_k$. Occasionally, for $\psi \in$ OptSP$_k$, we write Opt(ψ) to refer to both problems simultaneously.

For convenience, we introduce some further notation: For objects $x_1 \in X_1,\dots,x_k \in X_k$, we denote by $\mathrm{Val}(x_1,\dots,x_k) = \#_{y\in Y}\,\phi(x_1,\dots,x_k,y)$ the *value* of $(x_1,\dots,x_k)$.

The problem Opt(ψ) can be solved in time $O(m^k)$ for all OptSP$_k$ formulas ψ, by a straightforward extension of the model-checking baseline algorithm; see [23] for details. As this is clearly optimal for $k = 1$, we will often implicitly assume that $k \geq 2$ in the following.

For a clean analogy between model-checking and the optimization classes MaxSP$_k$ and MinSP$_k$, we will from now view model-checking as "testing for zero". More precisely, the model-checking problem of $\exists x_1 \dots \exists x_k \forall y \neg\phi(x_1,\dots,x_k,y)$ is equivalent to testing whether Min(ψ) has optimal solution OPT $= 0$, where $\psi = \min_{x_1,\dots,x_k} \#_y\, \phi(x_1,\dots,x_k,y)$. We refer to the latter problem as Zero(ψ).

Definition 3 introduces Max(ψ) and Min(ψ) as *exact* optimization problems (i.e., OPT is required to be computed exactly). We say that an algorithm computes a *(multiplicative) c-approximation* for Max(ψ) if it computes any value in the interval $[c^{-1}\cdot \mathrm{OPT}, \mathrm{OPT}]$. Similarly, a (multiplicative) c-approximation for Min(ψ) computes a value in $[\mathrm{OPT}, c\cdot\mathrm{OPT}]$.

3 Technical Overview

This section serves the purpose of stating our results formally, to provide the main proof ideas and techniques, and to convey some intuition whenever possible. Due to space constraints, we omit precise definitions of the fine-grained hypotheses here and instead refer to the full version of this paper.

We first introduce our hardness parameters: the and-hardness $H_{\mathrm{and}}(\psi)$ borrowed from previous work [24] (reviewed below), as well as a novel algebraic parameter that we call degree-hardness $H_{\deg}(\psi)$. In the subsequent sections, we give an overview over our various algorithmic and hardness results based on the values $H_{\deg}(\psi), H_{\mathrm{and}}(\psi)$ (see Figure 1), with the formal proof of Theorem 1 given at the end of this section.

3.1 Bringmann et al.'s Model-Checking Dichotomy

Bringmann, Fischer and Künnemann [24] established a fine-grained classification of all $\exists^k\forall$-quantified graph properties into computationally easy and hard model-checking problems. As our work extends that classification (and also since our results are of a similar flavor), we briefly summarize their results. The hardness parameter presented in Definition 4 forms the basis for the dichotomy.

Here, and for the remainder of this section, we write ψ_0 to denote the Boolean function obtained from ψ in the following way: Let $\psi = \mathrm{opt}_{x_1,\dots,x_k} \#_y \phi(x_1,\dots,x_k,y)$ be any graph formula, where ϕ is a propositional formula over the atoms $E(x_i,x_j)$ $(i,j \in [k])$ and $E(x_i,y)$ $(i \in [k])$. Consider the Boolean function obtained from ϕ by replacing every atom $E(x_i,x_j)$ $(i,j \in [k])$ by *false*. What remains is a Boolean function over the k atoms $E(x_i,y)$ $(i \in [k])$ and we denote this formula by ψ_0. For example, if $\psi = \max_{x_1,x_2} \#_y(\neg E(x_1,x_2) \wedge E(x_1,y) \wedge E(x_2,y))$ then we define $\psi_0 : \{0,1\}^2 \to \{0,1\}$ by $\psi_0(a_1,a_2) = a_1 \wedge a_2$.

As apparent in Definition 4, the core difficulty of a formula ψ is captured by ψ_0 and thus not affected by the predicates $E(x_i,x_j)$. In the full version we elaborate on this phenomenon.

▶ **Definition 4** (And-Hardness). *Let ϕ be a Boolean function on k inputs. The* and-hardness $H_{\mathrm{and}}(\phi)$ *of ϕ is the largest integer $0 \le h \le k$ such that, for any index set $S \in \binom{[k]}{h}$, there exists some S-restriction of ϕ with exactly one satisfying assignment. (Set $H_{\mathrm{and}}(\phi) = 0$ for constant-valued ϕ.) For an OptSP_k graph formula ψ, we define $H_{\mathrm{and}}(\psi) = H_{\mathrm{and}}(\psi_0)$.*

This hardness parameter essentially specifies the computational hardness of the model-checking problems $\textsc{Zero}(\phi)$; here, $H_{\mathrm{and}}(\psi) \le 2$ is the critical threshold:

▶ **Theorem 5** (Model-Checking, [24]). *Let ψ be a MinSP_k graph formula.*

- *If $H_{\mathrm{and}}(\psi) \le 2$ and $H_{\mathrm{and}}(\psi) < k$, then $\textsc{Zero}(\psi)$ can be solved in time $O(m^{k-\delta})$ for some $\delta > 0$.*
- *If $3 \le H_{\mathrm{and}}(\psi)$ or $H_{\mathrm{and}}(\psi) = k$, then $\textsc{Zero}(\psi)$ cannot be solved in time $O(m^{k-\delta})$ for any $\delta > 0$ unless the Max-3-SAT hypothesis fails.*

3.2 Exact Optimization

We are now ready to detail our results. Our main contribution is a dichotomy for the exact solvability and approximability of $\textsc{Max}(\psi)$ and $\textsc{Min}(\psi)$ for all MaxSP_k and MinSP_k graph formulas ψ. For the exact case, the decisive criterion for the hardness of some formula ψ can be read off the polynomial *extension* of the function ψ_0. Specifically, for any Boolean function ϕ there exists a (unique) multilinear polynomial with real coefficients that computes ϕ on binary inputs. By abuse of notation, we refer to that polynomial by writing ϕ as well. The *degree* $\deg(\phi)$ of ϕ is the degree of its polynomial extension.

As an example, consider the Exact-3-Cover property: $\phi(z_1,z_2,z_3)$ is true if and only if exactly one of its inputs z_1, z_2 or z_3 is true. Then its unique multilinear polynomial extension is

$$\phi(z_1,z_2,z_3) = 3z_1z_2z_3 - 2(z_1z_2 + z_2z_3 + z_3z_1) + (z_1 + z_2 + z_3),$$

and therefore $\deg(\phi) = 3$.

▶ **Definition 6** (Degree Hardness). *Let ϕ be a Boolean function on k inputs. The* degree hardness $H_{\deg}(\phi)$ *of ϕ is the largest integer $0 \le h \le k$ such that, for any index set $S \in \binom{[k]}{h}$, there exists some S-restriction of ϕ of degree h. For an OptSP_k graph formula ψ, we define $H_{\deg}(\psi) = H_{\deg}(\psi_0)$.*

It always holds that $H_{\mathrm{and}}(\psi) \le H_{\deg}(\psi)$, but in general these parameters behave very differently. With $H_{\deg}$ in place of H_{and}, we are able to recover the same classification as Theorem 5 for both exact maximization and minimization:

▶ **Theorem 7** (Exact Optimization). *Let ψ be an OptSP_k graph formula.*

- *If $H_{\deg}(\psi) \leq 2$ and $H_{\deg}(\psi) < k$, then $\text{Opt}(\psi)$ can be solved in time $O(m^{k-\delta})$ for some $\delta > 0$.*
- *If $3 \leq H_{\deg}(\psi)$ or $H_{\deg}(\psi) = k$, then $\text{Opt}(\psi)$ cannot be solved in time $O(m^{k-\delta})$ for any $\delta > 0$ unless the Max-3-SAT hypothesis fails.*

The algorithmic part is proven along the same lines as [24]: We first brute-force over all but $k = 3$ quantifiers, and solve the remaining problem by a reduction to maximum-weight triangle detection with small edge weights. Intuitively, since the degree of the resulting 3-variable problem is at most 2, we can express the objective as a sum of three parts depending on two variables each (this approach is also used in a similar context in [67, Chapter 6.5]). This allows us to label the edges of a triangle instance with corresponding parts, which can be shown to yield average edge weight $O(1)$.

The conditional lower bound is more interesting. Our reduction is inspired by a standard argument proving quadratic-time hardness of the Maximum Inner Product problem (MaxIP). That lower bound is based on the OV hypothesis, so it consists of a reduction from an OV instance $X_1, X_2 \subseteq \{0,1\}^d$ to an instance of MaxIP. The idea is to use a *gadget* that maps every entry in $x_i \in X_i$ to a constant number of new entries;[7] let $x_i' \in \{0,1\}^{O(d)}$ denote the vector after applying the gadget coordinate-wise. The crucial property is that $\langle x_1', x_2' \rangle = d - \langle x_1, x_2 \rangle$, and thus a pair of orthogonal vectors x_1, x_2 corresponds to a pair of vectors x_1', x_2' of maximum inner product.

To mimic the reduction for all problems which are hard in the sense of Theorem 7, we settle for the weaker but sufficient property that the value of (x_1', x_2') equals $\beta_1 d - \beta_2 \langle x_1, x_2 \rangle$, for some positive integers β_1, β_2. It follows from our algebraic characterization of hard functions that a gadget with such guarantees always exists. Ultimately, our hardness proof makes use of that gadget in a similar way as for MaxIP.

The hardness part of Theorem 7 can in fact be stated in a more fine-grained way: If some problem $\text{Opt}(\psi)$ has degree hardness $h = H_{\deg}(\psi) \geq 3$, then the hardness proof can be conditioned on the weaker h-Uniform HyperClique assumption. That connection can be complemented by a partial converse, thus revealing a certain *equivalence* between exact optimization and hyperclique detection. An analogous equivalence for model-checking graph formulas could not be proved and was left as an open problem in [24].

▶ **Theorem 8** (Equivalence of $\text{Opt}(\psi)$ and HyperClique). *Let ψ be an OptSP_k graph formula of degree hardness $h = H_{\deg}(\psi) \geq 2$.*

- *If $\text{Opt}(\psi)$ can be solved in time $O(m^{k-\delta})$ for some $\delta > 0$, then, for some (large) $k' = k'(k, h, \delta)$, h-Uniform k'-HyperClique can be solved in time $O(n^{k'-\delta'})$ for some $\delta' > 0$.*
- *If h-Uniform $(h+1)$-HyperClique can be solved in time $O(n^{h+1-\delta})$ for some $\delta > 0$, then $\text{Opt}(\psi)$ can be solved in time $O(m^{k-\delta'})$ for some $\delta' > 0$.*

3.3 Approximation

Since Theorem 7 gives a complete classification for the exact solvability of $\text{Opt}(\psi)$, the next natural question is to study the approximability of properties which are hard to compute exactly. Unlike the exact case, we use different techniques and tools to give our classification for maximization and minimization problems.

[7] Every entry a in x_1 is replaced by three new coordinates $(a, 1-a, 1-a)$ and every entry b in x_2 is replaced by $(1-b, b, 1-b)$. The contribution to the inner product of the new vectors is equal to $a(1-b) + (1-a)b + (1-a)(1-b) = 1 - ab$.

3.3.1 Maximization

We obtain a simple classification of all constant-factor approximable maximization problems, conditioned on the Strong Exponential Time Hypothesis (SETH).

▶ **Theorem 9** (Constant Approximation – Maximization). *Let ψ be a MaxSP$_k$ graph formula.*
- *If $H_{\text{and}}(\psi) < k$ (or equivalently, if ψ_0 does not have exactly one satisfying assignment), then there exists a constant-factor approximation for Max(ψ) in time $O(m^{k-\delta})$ for some $\delta > 0$.*
- *Otherwise, if $H_{\text{and}}(\psi) = k$ (or equivalently, ψ_0 has exactly one satisfying assignment), then there exists no constant-factor approximation for Max(ψ) in time $O(m^{k-\delta})$ for any $\delta > 0$, unless SETH fails.*

We give a high-level explanation of our proof by focusing on two representative problems: On the one hand, strong conditional hardness results have been shown for the MaxIP problem [4, 28]. When ψ_0 has a single satisfying assignment, Max(ψ) is equivalent (up to complementation) to MaxIP, so we adapt the hardness results for our setting.

On the other hand, consider the Furthest Neighbor problem: Given two sets of bit-vectors $X_1, X_2 \subseteq \{0,1\}^d$, compute the maximum Hamming distance between vectors $x_1 \in X_1$ and $x_2 \in X_2$. There exists a simple linear-time 3-approximation for this problem: Fix some $x_1 \in X_1$ and compute its furthest neighbor $x_2 \in X_2$. Then compute the furthest neighbor $x_1' \in X_1$ of x_2 and return the distance between x_1' and x_2 as the answer. By applying the triangle inequality twice, it is easy to see that this indeed yields a 3-approximation. That argument generalizes for approximating Max(ϕ) whenever ψ_0 satisfies the following property: If α is a satisfying assignment of ψ_0, then the component-wise negation of α is also satisfying. Finally, if ψ_0 has at least two satisfying assignments, then Max(ψ) can be reduced to this special case via a reduction which worsens the approximation ratio by at most a constant factor. The essential insight for that last step is that we can always "cover" all satisfying assignments by only two satisfying assignments, as there always exists one satisfying assignment which contributes a constant fraction (depending on k) to the optimal value.

We give a finer-grained view of the classification in Theorem 9 in two ways. First, we want to isolate properties which admit *arbitrarily good* constant-factor approximations. We make that notion precise in the following definition:

▶ **Definition 10** (Approximation Scheme). *Let ψ be an OptSP$_k$ formula. We say that Opt(ψ) admits an* approximation scheme *if for any $\varepsilon > 0$ there exists some $\delta > 0$ and an algorithm computing a $(1+\varepsilon)$-approximation of Opt(ψ) in time $O(m^{k-\delta})$.*[8]

In the following theorem, we identify some formulas which admit such an approximation scheme, and some formulas for which this is unlikely:

▶ **Theorem 11** (Approximation Scheme – Maximization). *Let ψ be a MaxSP$_k$ graph formula.*
- *If $H_{\text{and}}(\psi) \leq 1$, then there exists a randomized approximation scheme for Max(ψ).*
- *If $3 \leq H_{\text{and}}(\psi)$ or $H_{\text{and}}(\psi) = k$, then there exists no approximation scheme for Max(ψ) unless the Sparse Max-3-SAT hypothesis fails.*

Unfortunately, we were not able to close the gap in Theorem 11, and it remains open whether problems with $H_{\text{and}}(\phi) = 2$ admit approximation schemes. In Section 4, we give a specific example falling into this category.

[8] We stress that in our work, ε is always a constant and cannot depend on m.

For the first item, we give approximation schemes for any $\textsc{Max}(\psi)$ with $H_{\text{and}}(\psi) = 1$ via a reduction to Furthest Neighbor, which, as mentioned in the introduction, admits an approximation scheme.

The lower bound is more interesting: By Theorem 9 we know that if ψ has and-hardness $H_{\text{and}}(\psi) < k$, then it admits a constant-factor approximation. Nevertheless, the lower bound in Theorem 9 only addresses formulas of and-hardness $H_{\text{and}}(\psi) = k$. In particular, Theorem 11 identifies a class of problems for which some (fixed) constant-factor approximation is *best-possible in terms of approximation.*

At a technical level, we make use of interesting machinery to obtain the lower bound. The starting point is the *distributed PCP* framework, which was introduced in [4] and further strengthened in [62, 28] to give hardness of approximation for Maximum k-Inner Product (k-MaxIP). In this case, we cannot use this tool directly, since it crucially relies on the fact that the *target* problem $\textsc{Max}(\psi)$ has full hardness $H_{\text{and}}(\psi) = k$.[9] Instead, we first show Max-3-SAT-hardness of the following intermediate problem:

▶ **Problem 12** ($(k,3)$-OV). *Given sets of n vectors $X_1, \ldots, X_k \subseteq \{0,1\}^d$, where each coordinate $y \in [d]$ is associated to three* active *indices $a, b, c \in [k]$, detect if there are vectors $x_1 \in X_1, \ldots, x_k \in X_k$ such that for all $y \in [d]$, it holds that $x_a[y] \cdot x_b[y] \cdot x_c[y] = 0$ where a, b, c are the active indices at y.*

We then provide a gap introducing reduction from $(k,3)$-OV to $\textsc{Max}(\psi)$, in the same spirit as the PCP reduction gives such a reduction from k-OV to k-MaxIP. This involves several technical steps as outlined in Figure 2. At a high level, we decompose a $(k,3)$-OV instance into a combination of multiple 3-OV instances and use the PCP reduction as a black box on each of these. After combining the outputs of the reduction, we obtain instances of $\textsc{Max}(\psi)$ with the desired gap. The issue with this approach is that the PCP reduction blows up the dimension of the input vectors exponentially,[10] which makes the reduction inapplicable to our case if we start from a moderate-dimensional $(k,3)$-OV instance. To show that $(k,3)$-OV does not even have a $O(m^{k-\delta})$-time algorithm when the dimension is $d = O(\log n)$, we use the stronger *Sparse* Max-3-SAT hypothesis.[11] See the full version of this paper for further discussion of this hypothesis.

The second way in which we get a closer look at Theorem 9 is by inspecting the hardest regime, i.e., when $H_{\text{and}}(\psi) = k$:

▶ **Theorem 13** (Polynomial-Factor Approximation). *Let ψ be a $\textsc{MaxSP}_k$ graph formula of full and-hardness $H_{\text{and}}(\psi) = k$.*

- *For every $\varepsilon > 0$, there exists some $\delta > 0$ such that an m^{ε}-approximation for $\textsc{Max}(\psi)$ can be computed in time $O(m^{k-\delta})$.*
- *For every $\delta > 0$, there exists an $\varepsilon > 0$ such that there exists no m^{ε}-approximation for $\textsc{Max}(\psi)$ in time $O(m^{k-\delta})$ unless SETH fails.*

The lower bound is obtained by applying the subsequent improvements on the distributed PCP framework by [62, 28, 51], which improve the parameters of the reduction via algebraic geometry codes and expander graphs. For the upper bound, we give a simple algorithm which exploits the sparsity of the instances.

[9] More precisely, the reduction exploits the fact that ψ_0 has a unique satisfying assignment to encode the communication protocol used in the reduction.

[10] An instance of k-OV on dimension $d = c \log n$ is reduced to multiple instances of k-MaxIP on dimension $\exp(c) \log n$.

[11] Morally, just as SETH implies the hardness of low-dimensional OV, the *Sparse* Max-3-SAT Hypothesis implies the hardness of *low-dimensional* $(k,3)$*-OV*.

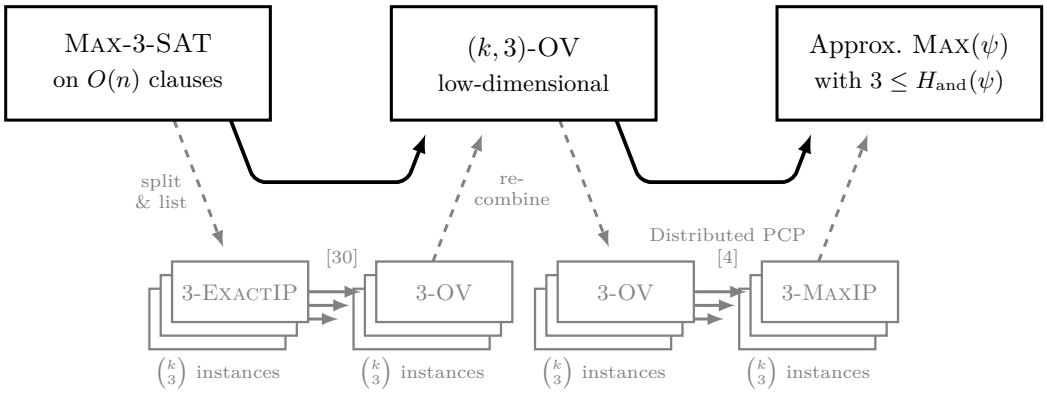

Figure 2 The chain of reductions from Sparse Max-3-SAT to VMax(ψ) involving two main steps. Both proofs involve several intermediate steps as illustrated in the gray parts.

3.3.2 Minimization

There is an easier criterion for the hardness of approximating minimization problems. Namely, observe that giving a multiplicative approximation to a minimization problem Min(ψ) is at least as hard as testing if the optimal value is zero (recall that we refer to this problem as Zero(ψ)). More precisely, suppose that we are given an instance with OPT $= 0$. Then any multiplicative approximation must return an optimal solution.

It turns out that this is the only source of hardness for Min(ψ) problems. We show a fine-grained equivalence of deciding Zero(ψ) and approximating Min(ψ) within a constant factor:

▶ **Theorem 14** (Constant Approximation is Equivalent to Testing Zero). *Let ψ be a MinSP$_k$ graph formula. Via a randomized reduction, there exists a constant-factor approximation algorithm for Min(ψ) in time $O(m^{k-\delta})$ for some $\delta > 0$ if and only if Zero(ψ) can be solved in time $O(m^{k-\delta'})$ for some $\delta' > 0$.*

To reduce approximating Min(ψ) to Zero(ψ), we make use of *locality-sensitive hashing* (LSH). This technique was for instance used to solve the Approximate Nearest Neighbors problem in Hamming spaces [44], and was recently adapted by Chen and Williams to show that Minimum Inner Product can be reduced to OV [30]. The latter result constitutes a singular known case for the general trend in MinSP$_k$ revealed by Theorem 14. In comparison, our reduction is simpler and more general, but gives weaker guarantees on the constant factor.

We specifically use LSH for a reduction from approximating Min(ψ) to the intermediate problem of *listing* solutions to Zero(ψ) – the better the listing algorithm performs, the better the approximation guarantee. For instance, an algorithm listing L solutions in time $O(m^{k-\delta} \cdot L^{\delta/k})$ for some $\delta > 0$ results in a constant-factor approximation, while a listing algorithm in time $\tilde{O}(m^{k-\delta} + L)$ leads to an approximation scheme. To finish the proof of Theorem 14, we show that any Zero(ψ) problem with an $O(m^{k-\delta})$-time decider, for some $\delta > 0$, also admits a listing algorithm in time $O(m^{k-\delta} \cdot L^{\delta/k})$.

Since the hardness of Zero(ψ) is completely classified [24], we obtain the following dichotomy as a consequence of Theorem 14:

▶ **Corollary 15** (Constant Approximation – Minimization). *Let ψ be a $\textsc{MinSP}_k$ graph formula.*

- *If $H_{\text{and}}(\psi) \leq 2$ and $H_{\text{and}}(\psi) < k$, then there exists a randomized constant-factor approximation algorithm for $\textsc{Min}(\psi)$ in time $O(m^{k-\delta})$ for some $\delta > 0$.*
- *If $3 \leq H_{\text{and}}(\psi)$ or $H_{\text{and}}(\psi) = k$, then computing any approximation for $\textsc{Min}(\psi)$ in time $O(m^{k-\delta})$ for any $\delta > 0$ is not possible unless the Max-3-SAT hypothesis fails.*

Similar to the maximization case, let us next consider approximation schemes for minimization problems. We can reuse the general framework outlined in the previous paragraphs to obtain an approximation scheme by giving an output-linear listing algorithm in time $\tilde{O}(m^{k-\delta} + L)$, for all formulas with and-hardness at most $H_{\text{and}}(\psi) \leq 1$.

▶ **Theorem 16** (Approximation Scheme – Minimization). *Let ψ be a $\textsc{MinSP}_k$ graph formula. If $H_{\text{and}}(\psi) \leq 1$, then there exists a randomized approximation scheme for $\textsc{Min}(\psi)$.*

3.4 Efficient (Multiplicative) Approximation Schemes

Theorems 11 and 16 show that if $H_{\text{and}}(\psi) \leq 1$, then we can give approximation schemes for $\textsc{Opt}(\psi)$. In the full version, we complement this result by ruling out the existence of *efficient* approximation schemes for most regimes. We say that $\textsc{Opt}(\psi)$ admits an efficient (multiplicative) approximation scheme if there is some fixed constant $\delta > 0$ such that for any $\varepsilon > 0$, a multiplicative $(1+\varepsilon)$-approximation for $\textsc{Opt}(\psi)$ can be computed in time $O(m^{k-\delta})$.

▶ **Theorem 17.** *Let ψ be an $\textsc{OptSP}_k$ graph formula. If $3 \leq H_{\text{deg}}(\psi)$ or $H_{\text{deg}}(\psi) = k$, then there exists no efficient approximation scheme for $\textsc{Opt}(\psi)$ assuming the Sparse Max-3-SAT Hypothesis.*

3.5 Proving the Main Theorem

We can now put things together to prove Theorem 1.

Proof of Theorem 1. We only sketch the proof for a maximization problem ψ with $k \geq 3$; the other cases are similar. We show how to classify ψ into one of the four stated regimes with a case distinction based on the hardness parameters $H_{\text{and}}(\psi)$ and $H_{\text{deg}}(\psi)$. This case distinction can also be read off Figure 1.

- If $H_{\text{deg}}(\psi) \leq 2$: By Theorem 7, ψ is efficiently optimizable, so it lies in R1.
- Otherwise, it holds that $3 \leq H_{\text{deg}}(\psi) \leq k$. In this case, we make a further distinction:
  - $H_{\text{and}}(\psi) \leq 1$: By Theorem 11, ψ admits an approximation scheme but by Theorem 17 not an efficient one, so it lies in R2.
  - $H_{\text{and}}(\psi) = 2$: By Theorem 9, ψ admits an efficient constant-factor approximation but by Theorem 17, it does not admit an efficient approximation scheme. Thus, depending on whether ψ admits an approximation scheme or not, it lies in R2 or R3. (As mentioned below Theorem 1, this is the single case where we cannot place the formula in its precise regime, see also Open Problem 1.)
  - $3 \leq H_{\text{and}}(\psi) < k$: By Theorem 9, ψ admits an efficient constant factor approximation but by Theorem 11 it has no approximation scheme, so it lies in R3.
  - $H_{\text{and}}(\psi) = k$: By Theorem 13, ψ admits an efficient polynomial-factor approximation, and this is best possible, so it lies in R4. ◀

4 Discussion and Open Problems

Our investigation reveals all possible approximability types (in better-than-exhaustive-search time) for general classes of polynomial-time optimization problems, namely graph formulas in MaxSP_k and MinSP_k. Our results, which give an almost complete characterization, open up the following questions:

- Can we extend our classification beyond graph formulas, i.e., when we allow more binary relations, or even higher-arity relations? Such settings include, e.g., generalizations of Max k-XOR from $\mathbb{F}_2$ to $\mathbb{F}_q$, or variants of the densest subgraph problem on hypergraphs.
- In our setting, each variable x_i ranges over a separate set X_i, also known as a *multichromatic* setting. We leave it open to transfer our results to the *monochromatic* setting (see e.g. [52]).
- While we consider running times expressed in the input size (as usual in database contexts), it would also be natural to consider parameterization in the number n of objects in the relational structure, see [68].

Besides these extensions, we ask whether one can close the remaining gap in our classification: Do formulas ψ with $H_{\text{and}}(\psi) = 2$ and $H_{\text{deg}}(\psi) \geq 3$ admit an approximation scheme? As a specific challenge, we give the following open problem:

▶ **Open Problem 1.** *Is there an approximation scheme for Maximum Exact-3-Cover (or its minimization variant)? Specifically, can we prove or rule out that for every $\varepsilon > 0$, there is some $\delta > 0$ such that we can $(1+\varepsilon)$-approximate Maximum Exact-3-Cover in time $O(m^{3-\delta})$?*

It appears likely that showing existence of an approximation scheme for Maximum Exact-3-Cover would lead to a full characterization of MaxSP_k.

Finally, while we focused on the qualitative question whether or not exhaustive search can be beaten, a follow-up question is to determine precise *approximability-time tradeoffs*. In this vein, consider the well-studied Maximum k-Cover problem: A simple linear-time greedy approach is known to establish a $(1-1/e)^{-1}$-approximation [46]. Subsequent lower bounds show that this is conditionally best possible in polynomial-time [35] and even $f(k)m^{o(k)}$-time (under Gap-ETH) [31, 59]. On the other hand, for every fixed k, we show (1) existence of an approximation scheme, but (2) rule out an efficient one assuming SETH, i.e., for every $\delta > 0$, there is some $\varepsilon > 0$ such that an $(1+\varepsilon)$-approximation requires time $\Omega(m^{k-\delta})$.

▶ **Open Problem 2.** *Let $k \geq 2$. Can we determine, for every $1 \leq \gamma \leq (1-1/e)^{-1}$, the optimal exponent α of the fastest γ-approximation for Maximum k-Cover running in time $O(m^{\alpha \pm o(1)})$, assuming plausible fine-grained hardness assumptions?*

Note that the extreme cases for $\gamma = 1$ and $\gamma = (1-1/e)^{-1}$ are already settled and that [59] shows that for all immediate cases, α must have a linear dependence on k, assuming Gap-ETH.

Abstract

We present new exact and approximation algorithms for 0-1-Knapsack and Unbounded Knapsack:

- *Exact Algorithm for 0-1-Knapsack:* 0-1-Knapsack has known algorithms running in time $\widetilde{O}(n + \min\{n \cdot \mathrm{OPT}, n \cdot W, \mathrm{OPT}^2, W^2\})$ [Bellman '57], where n is the number of items, W is the weight budget, and OPT is the optimal profit. We present an algorithm running in time $\widetilde{O}(n + (W + \mathrm{OPT})^{1.5})$. This improves the running time in case n, W, OPT are roughly equal.
- *Exact Algorithm for Unbounded Knapsack:* Unbounded Knapsack has known algorithms running in time $\widetilde{O}(n + \min\{n \cdot p_{\max}, n \cdot w_{\max}, p_{\max}^2, w_{\max}^2\})$ [Axiotis, Tzamos '19, Jansen, Rohwedder '19, Chan, He '22], where n is the number of items, $w_{\max}$ is the largest weight of any item, and $p_{\max}$ is the largest profit of any item. We present an algorithm running in time $\widetilde{O}(n + (p_{\max} + w_{\max})^{1.5})$, giving a similar improvement as for 0-1-Knapsack.
- *Approximating Unbounded Knapsack with Resource Augmentation:* Unbounded Knapsack has a known FPTAS with running time $\widetilde{O}(\min\{n/\varepsilon, n + 1/\varepsilon^2\})$ [Jansen, Kraft '18]. We study *weak* approximation algorithms, which approximate the optimal profit but are allowed to overshoot the weight constraint (i.e. resource augmentation). We present the first approximation scheme for Unbounded Knapsack in this setting, achieving running time $\widetilde{O}(n + 1/\varepsilon^{1.5})$. Along the way, we also give a simpler FPTAS with lower order improvement in the standard setting.

For all of these problem settings the previously known results had matching conditional lower bounds. We avoid these lower bounds in the approximation setting by allowing resource augmentation, and in the exact setting by analyzing the time complexity in terms of weight and profit parameters (instead of only weight or only profit parameters).

Our algorithms can be seen as reductions to Min-Plus-Convolution on monotone sequences with bounded entries. These structured instances of Min-Plus-Convolution can be solved in time $\widetilde{O}(n^{1.5})$ [Chi, Duan, Xie, Zhang '22] (in contrast to the conjectured $n^{2-o(1)}$ lower bound for the general case). We complement our results by showing reductions in the opposite direction, that is, we show that achieving our results with the constant 1.5 replaced by any constant < 2 implies subquadratic algorithms for Min-Plus-Convolution on monotone sequences with bounded entries.

1 Introduction

In this paper we present new exact and approximation algorithms for Knapsack problems.

Exact Pseudopolynomial Algorithms for Unbounded Knapsack. In the Unbounded Knapsack problem we are given a set of n items, where each item has a weight w_i and a profit p_i, along with a knapsack capacity W. The goal is to find a *multiset* of items which maximizes the total profit and has total weight at most W. The textbook dynamic programming algorithm for Unbounded Knapsack due to Bellman [6] runs in time $O(nW)$ or in time $O(n \cdot \mathrm{OPT})$, where OPT is the value of the optimal solution. Recent literature on Unbounded Knapsack studies alternative parameters: Axiotis and Tzamos [3] and Jansen and Rohwedder [25] independently presented algorithms running in time $\widetilde{O}(w_{\max}^2)$ and $\widetilde{O}(p_{\max}^2)$,[1] where $w_{\max}$ is the largest weight of any item and $p_{\max}$ the largest profit of any item – in general $w_{\max}$ could be much smaller than W and $p_{\max}$ much smaller than OPT, so these algorithms improve upon Bellman's algorithm for some parameter settings. Chan and He [15] presented further improvements[2] achieving time $\widetilde{O}(n\, w_{\max})$ and $\widetilde{O}(n\, p_{\max})$ Note that when $w_{\max} \approx p_{\max} \approx n$ all mentioned algorithms require at least quadratic time $\Omega(n^2)$. Can we overcome this quadratic barrier? In this paper we answer this positively by considering the combined parameter $w_{\max} + p_{\max}$.

▶ **Theorem 1.** *Unbounded Knapsack can be solved in expected time* $\widetilde{O}(n + (p_{\max} + w_{\max})^{1.5})$.

This result is particularly interesting in light of recent fine-grained lower bounds for Unbounded Knapsack. Indeed, for each previous result that we have mentioned above, a matching conditional lower bound is known [19, 28]. For example, Unbounded Knapsack cannot be solved in time $O((n+W)^{2-\delta})$ for any constant $\delta > 0$ under a plausible hypothesis. Inspecting these conditional lower bounds, we observe that they construct hard instances where only the profit parameters or only the weight parameters are under control; one of the two must be very large to obtain a hardness reduction. We thus avoid these conditional lower bounds by considering the combined profit and weight parameter $w_{\max} + p_{\max}$.

Exact Pseudopolynomial Algorithms for 0-1 Knapsack. The 0-1 Knapsack problem is the variant of Unbounded Knapsack where every input item can appear at most once in any solution. Bellman's algorithm also solves 0-1 Knapsack in time $O(nW)$ or $O(n \cdot \mathrm{OPT})$. However, the landscape is more diverse when considering other parameters. In particular, it is open whether 0-1 Knapsack can be solved in time $\widetilde{O}(n + w_{\max}^2)$ or $\widetilde{O}(n + p_{\max}^2)$.[3] Table 1 shows a non-exhaustive list of pseudopolynomial-time algorithms for 0-1 Knapsack using different combinations of the parameters $n, w_{\max}, p_{\max}, W, \mathrm{OPT}$. Note that when all

[1] We use the notation $\widetilde{O}(T) = \cup_{c>0} O(T \log^c T)$ to supress polylogarithmic factors

[2] Note that we can assume that $n \leq w_{\max}$ without loss of generality since if there are multiple items with the same weight, we can keep only the one with the largest profit. Similarly, $n \leq p_{\max}$.

[3] This gap is analogous to the case of Subset Sum where we are given a set of numbers X and a target number t. For the unbounded case, where the goal is to find whether a multiset of items in X sums to t, Jansen and Rohwedder [25] gave an algorithm in time $\widetilde{O}(n+u)$ where u is the largest number in the input. For the more standard "0-1" case where we ask for a subset of X summing to t, the best known running times are $\widetilde{O}(n+t)$ [8, 26], $O(nu)$ [33], $\widetilde{O}(n+u^2/n)$ by combining [21] and [8, 26], and $\widetilde{O}(n+u^{3/2})$ by combining [21] and [8, 26] and [33]; see also [11, 34] for generalizations to X being a multiset and related results.

Table 1 Non-exhaustive list of pseudopolynomial-time algorithms for 0-1 Knapsack.

Running Time	Reference
$O(n \cdot \min\{W, \mathrm{OPT}\})$	[6]
$O(n \cdot p_{\max} \cdot w_{\max})$	[33]
$\widetilde{O}(n + w_{\max} \cdot W)$	[27, 5, 3]
$\widetilde{O}(n + p_{\max} \cdot W)$	[5]
$\widetilde{O}(n \cdot \min\{w_{\max}^2, p_{\max}^2\})$	[3]
$\widetilde{O}((n+W) \cdot \min\{w_{\max}, p_{\max}\})$	[5]
$O(n + \min\{w_{\max}^3, p_{\max}^3\})$	[34]
$\widetilde{O}(n + (W + \mathrm{OPT})^{1.5})$	**Theorem 2**

these parameters are bounded by $O(n)$, all existing algorithms require at least quadratic time $\Omega(n^2)$. In this paper we show that by considering the combined weight and profit parameter $W + \mathrm{OPT}$ we can overcome this quadratic barrier.

▶ **Theorem 2.** *There is a randomized algorithm for 0-1 Knapsack that runs in time $\widetilde{O}(n + (W + \mathrm{OPT})^{1.5})$ and succeeds with high probability.*

Similar to the unbounded case, matching conditional lower bounds ruling out time $O((n+W)^{2-\delta})$ and $O((n+\mathrm{OPT})^{2-\delta})$ for any $\delta > 0$ are known [19, 28]. These lower bounds construct hard instances where only one of W, OPT is under control, the other needs to be very large. We thus avoid these lower bounds by considering the combined weight and profit parameter $W + \mathrm{OPT}$.

Approximation Schemes for Unbounded Knapsack. Since Unbounded Knapsack is well known to be NP-hard, it is natural to study approximation algorithms. In particular, a *fully polynomial-time approximation scheme* (FPTAS) given $0 < \varepsilon < 1$ computes a solution x with total weight $w(x) \leq W$ and total profit $p(x) \geq (1-\varepsilon)\mathrm{OPT}$ in time $\mathrm{poly}(n, 1/\varepsilon)$. The first FPTAS for Unbounded Knapsack was designed by Ibarra and Kim in 1975 [23] and runs in time $\widetilde{O}(n + (1/\varepsilon)^4)$. In 1979 Lawler [30] improved the running time to $\widetilde{O}(n + (1/\varepsilon)^3)$. This was the best known until Jansen and Kraft in 2018 [24] presented an FPTAS running in time $\widetilde{O}(n + (1/\varepsilon)^2)$. This algorithm has a matching conditional lower ruling out time $O((n + 1/\varepsilon)^{2-\delta})$ for any $\delta > 0$ [19, 28, 32].

We present a new FPTAS for Unbounded Knapsack which is (as we believe) simpler than Jansen and Kraft's, and has a lower order improvement in the running time:

▶ **Theorem 3.** *Unbounded Knapsack has an FPTAS with running time $\widetilde{O}\left(n + \frac{(1/\varepsilon)^2}{2^{\Omega(\sqrt{\log(1/\varepsilon)})}}\right)$.*

Bringmann and Nakos [10] recently gave an FPTAS for the related Subset Sum problem which achieves the same running time.

Weak Approximation for Unbounded Knapsack. Motivated by the matching upper and conditional lower bounds for FPTASs for Unbounded Knapsack, we study the relaxed notion of *weak approximation* as coined in [32]: we relax the weight constraint and seek a solution x with total weight $w(x) \leq (1+\varepsilon) \cdot W$ and total profit $p(x) \geq (1-\varepsilon)\mathrm{OPT}$. Note that OPT is still the optimal value of any solution with weight at most W. This can be

interpreted as bicriteria approximation (approximating both the weight and profit constraint) or as resource augmentation (the optimal algorithm is allowed weight W while our algorithm is allowed a slightly larger weight of $(1+\varepsilon)\cdot W$). All of these are well-established relaxations of the standard (=strong[4]) notion of approximation. Such weaker notions of approximation are typically studied when a PTAS for the strong notion of approximation is not known. More generally, studying these weaker notions is justified whenever there are certain limits for strong approximations, to see whether these limits can be overcome by relaxing the notion of approximation. In particular, we want to understand whether this relaxation can overcome the conditional lower bound ruling out time $O((n+1/\varepsilon)^{2-\delta})$. For the related Subset Sum problem this question has been resolved positively: Bringmann and Nakos [10] conditionally ruled out strong approximation algorithms in time $O((n+1/\varepsilon)^{2-\delta})$ for any $\delta > 0$, but Mucha, Węgrzycki and Włodarczyk [32] designed a weak FPTAS in time $\widetilde{O}(n+(1/\varepsilon)^{5/3})$.

In this paper, we give a positive answer for Unbounded Knapsack:

▶ **Theorem 4.** *Unbounded Knapsack has a weak approximation scheme running in expected time* $\widetilde{O}(n+(\frac{1}{\varepsilon})^{1.5})$.

Our theorem gives reason to believe that resource augmentation indeed makes the problem easier. Specifically, obtaining a strong approximation scheme with the same running time as our weak one would refute the existing conditional lower bound for strong approximation.

Min-Plus-Convolution. All conditional lower bounds mentioned above are based on a hypothesis about the MinConv problem: Given sequences $A, B \in \mathbb{Z}^n$ compute their $(\min,+)$-convolution, which is the sequence $C \in \mathbb{Z}^{2n}$ with $C[k] = \min_{i+j=k} A[i]+B[j]$.[5] The MinConv problem can be trivially solved in time $O(n^2)$. This can be improved to time $n^2/2^{\Omega(\sqrt{\log n})}$ via a reduction to $(\min,+)$-matrix product due to Bremner et al. [7], and using Williams' algorithm for the latter [37] (which was derandomized later by Chan and Williams [17]). The lack of truly subquadratic algorithms despite considerable effort has led researchers to postulate the MinConv hypothesis, namely that MinConv cannot be solved in time $O(n^{2-\delta})$ for any constant $\delta > 0$ [19, 28]. Many problems are known to have conditional lower bounds from the MinConv hypothesis, see, e.g., [4, 14, 19, 25, 28, 29].

Central to our work is a reduction from MinConv to Unbounded Knapsack shown independently by Cygan et al. [19] and Künnemann et al. [28]. In particular, they showed that if Unbounded Knapsack on n items and $W = O(n)$ can be solved in subquadratic time, then MinConv can be solved in subquadratic time. This reduction immediately implies matching conditional lower bounds for the previously known exact algorithms with running times $O(n\cdot W)$, $\widetilde{O}(w_{\max}^2)$ and $\widetilde{O}(n\cdot w_{\max})$, as mentioned earlier.

A small modification of this reduction extends to the dual case, i.e., an exact subquadratic-time algorithm for Unbounded Knapsack with $\mathrm{OPT} = O(n)$ would result in a subquadratic-time algorithm for MinConv. This establishes matching conditional lower bounds for the algorithms in time $O(n\cdot\mathrm{OPT})$, $\widetilde{O}(p_{\max}^2)$ and $\widetilde{O}(n\cdot p_{\max})$. Moreover, by setting $\varepsilon = \Theta(1/\mathrm{OPT})$, an FPTAS for Unbounded Knapsack would yield an exact algorithm for MinConv, establishing that the $\widetilde{O}(n+(1/\varepsilon)^2)$-time FPTAS is conditionally optimal. This last observation was pointed out in [32].

[4] From now on, by "strong" approximation we mean the standard (non-weak) notion of approximation.
[5] If we replace the min by a max, we obtain the MaxConv problem, which is equivalent to MinConv after negating the sequences. Therefore, we will sometimes use these two names interchangeably.

In fact, the reduction due to Cygan et al. [19] is even an equivalence, showing that Unbounded Knapsack is intimately connected to MinConv. The same reduction is also known for 0-1 Knapsack [19, 28], so a similar discussion applies to 0-1 Knapsack.

Bounded Monotone Min-Plus-Convolution. Despite its postulated hardness, there are restricted families of instances of MinConv for which subquadratic algorithms are known, see e.g. [9, 12, 16, 18]. Central to this paper is the case when the input sequences $A, B \in \mathbb{Z}^n$ are monotone non-decreasing and have entries bounded by $O(n)$; we call this task BMMinConv.

In a celebrated result, Chan and Lewenstein gave an algorithm for BMMinConv that runs in expected time $O(n^{1.859})$ [16]. As a big hammer, their algorithm uses the famous Balog-Szemerédi-Gowers theorem from additive combinatorics. Very recently, Chi, Duan, Xie and Zhang showed how to avoid this big hammer and improved the running time to expected $\widetilde{O}(n^{1.5})$ [18].

All of our results mentioned so far use this BMMinConv algorithm as a subroutine. That is, our algorithms are reductions from various Knapsack problems to BMMinConv.

Equivalence with Bounded Monotone Min-Plus-Convolution. We complement our results by showing reductions in the opposite direction: Following the same chain of reductions as in [19, 28] but starting from bounded monotone instances of $(\min,+)$-convolution, we reduce BMMinConv to $O(n)$ instances of Unbounded Knapsack with $O(\sqrt{n})$ items each, where it holds that $w_{\max}, p_{\max}, W$ and OPT are all bounded by $O(\sqrt{n})$. Instantiating this reduction for the exact and approximate setting, we show the following theorem.

▶ **Theorem 5** (Equivalence). *For any problems A and B from the following list, if A can be solved in time $\widetilde{O}(n^{2-\delta})$ for some $\delta > 0$, then B can be solved in randomized time $\widetilde{O}(n^{2-\delta/2})$:*

1. *BMMaxConv on sequences of length n*
2. *Unbounded Knapsack on n items and $W, \mathrm{OPT} = O(n)$*
3. *0-1 Knapsack on n items and $W, \mathrm{OPT} = O(n)$*
4. *Weak $(1+\varepsilon)$-approximation for Unbounded Knapsack on n items and $\varepsilon = \Theta(1/n)$*

On the one hand, Theorem 1 solves Unbounded Knapsack in time $\widetilde{O}(n + (p_{\max} + w_{\max})^{1.5})$ by using Chi, Duan, Xie and Zhang's subquadratic BMMinConv algorithm [18]. On the other hand, Theorem 5 shows that any algorithm solving Unbounded Knapsack in time $\widetilde{O}(n + (p_{\max} + w_{\max})^{2-\delta})$ can be transformed into a subquadratic BMMinConv algorithm. This shows that both our exact and approximation algorithms take essentially *the only possible route* to obtain subquadratic algorithms, by invoking a BMMinConv algorithm.

Is randomness necessary? The algorithms given by Theorems 1, 2 and 4 are all randomized. If we insist on deterministic algorithms, we note that by applying Chan and Lewenstein's deterministic $\widetilde{O}(n^{1.864})$-time algorithm for BMMaxConv [16], we can obtain deterministic versions of Theorem 1 and Theorem 4 with exponent 1.864 instead of 1.5 (i.e. the only part where we use randomness is in applying Chi, Duan, Xie and Zhang's algorithm [18]). On the other hand, we do not know[6] how to derandomize Theorem 2.

[6] Our algorithm closely follows Bringmann's algorithm for Subset Sum [8] whose derandomization is an open problem.

Organization of the extended abstract. Due to space constraints, we only include the details of our exact algorithm for Unbounded Knapsack and 0-1 Knapsack in the main part of this manuscript. We defer our approximation schemes and the equivalence between BMMinConv and knapsack problems to the full version.

1.1 Technical Overview

Exact algorithm for Unbounded Knapsack. In Section 3 we present our exact algorithm for Unbounded Knapsack. Let $(\mathcal{I}, W)$ be an instance of Unbounded Knapsack. We denote by $\mathcal{P}_i[0, \dots, W]$ the array where $\mathcal{P}_i[j]$ is the maximum profit of a solution of weight at most j using at most 2^i items. Since each item has weight at least 1, any feasible solution consists of at most W items. Thus, our goal is to compute the value $\mathcal{P}_{\lceil \log W \rceil}[W] = \mathrm{OPT}$.

The natural approach is to use dynamic programming: since $\mathcal{P}_0$ consists of solution of at most one item, it can be computed in time $O(n)$. For $i > 0$ we can compute $\mathcal{P}_i[0, \dots, W]$ by taking the $(\max, +)$-convolution of $\mathcal{P}_{i-1}[0, \dots, W]$ with itself. This gives an algorithm in time $O(W^2 \log W)$.

Jansen and Rohwedder [25] and Axiotis and Tzamos [3] showed that instead of convolving sequences of length W, it suffices to convolve only $O(w_{\max})$ entries of $\mathcal{P}_{i-1}$ in each iteration. This improves the running time to $O(w_{\max}^2 \log W)$ by using the naive algorithm for $(\max, +)$-convolution. The approach of Jansen and Rohwedder [25] is as follows. Suppose x is the optimal solution for a target value $\mathcal{P}_i[j]$. They showed that x can be split into two solutions x_1, x_2 such that (i) the number of items in each part is at most 2^{i-1} and (ii) the difference between the weights of both parts is at most $O(w_{\max})$. Thus, (i) guarantees that both x_1 and x_2 are optimal solutions for two entries of $\mathcal{P}_{i-1}$, and (ii) implies that these entries lie in an interval in $\mathcal{P}_{i-1}$ of length $O(w_{\max})$. In this way, they can afford to perform the $(\max, +)$-convolution of only $O(w_{\max})$ entries in $\mathcal{P}_{i-1}$.

To show the existence of such a partitioning of x they make use of Steinitz' Lemma [36], which shows that any collection of m vectors in $\mathbb{R}^d$ with infinity norm at most 1, whose sum is 0, can be permuted such that every prefix sum has norm at most $O(d)$ (see Lemma 11 for the precise statement). The partitioning of x follows from Steinitz' Lemma by taking the weights of the items picked by x as 1-dimensional vectors. The usage of Steinitz' Lemma to reduce the number of states in dynamic programs was pioneered by Eisenbrand and Weismantel [20], and further refined by Jansen and Rohwedder [25].

In our algorithm, we use Steinitz' Lemma in a similar way to split the number of items and the weight of x, but additionally we use it to ensure that the profits of the solutions x_1, x_2 differ by at most $O(p_{\max})$ (see Lemma 12). In this way, by carefully handling the subproblems $\mathcal{P}_{i-1}$ we can enforce that the values of the $O(w_{\max})$ entries that need to be convolved have values in a range of size $O(p_{\max})$. Since the arrays $\mathcal{P}_i$ are monotone non-decreasing, we can then apply the algorithm for BMMaxConv, and thus handle each subproblem in time $\widetilde{O}((p_{\max} + w_{\max})^{1.5})$.

Exact algorithm for 0-1 Knapsack. Cygan et al. [19] showed that there is a reduction from 0-1 Knapsack to MaxConv. More precisely, they showed that if MaxConv can be solved in time $T(n)$, then 0-1 Knapsack can be solved in randomized time $\widetilde{O}(T(W))$. Their reduction is a generalization of Bringmann's Subset Sum algorithm [8], which can be seen as a reduction from Subset Sum to Boolean convolution. Cygan et al. showed that the reduction for 0-1 Knapsack can be obtained by essentially replacing the Boolean convolutions by $(\max, +)$-convolutions in Bringmann's algorithm.

In Section 4 we observe that this reduction produces instances of MaxConv which are monotone non-decreasing and have entries bounded by OPT. That is, we obtain BMMaxConv instances of size $O(W + \mathrm{OPT})$, and following the analysis of [19] we obtain an algorithm for 0-1 Knapsack in time $\widetilde{O}(n + (W + \mathrm{OPT})^{1.5})$, which yields Theorem 2.

Approximating Unbounded Knapsack. Let $(\mathcal{I}, W)$ be an instance of Unbounded Knapsack. Consider the array $\mathcal{P}[0, \ldots, W]$ where $\mathcal{P}[j]$ is the maximum profit of a solution with weight at most j. In particular, $\mathcal{P}[W] = \mathrm{OPT}$ is the optimal value of the instance. We will use that the sequence $\mathcal{P}[0, \ldots, W]$ is monotone.

We present the following simple algorithm to compute $\mathcal{P}[0, \ldots, W]$, which is based on an algorithm for (unbounded) Subset Sum from Bringmann [8]. Fix an optimal solution x for an entry $\mathcal{P}[j]$. We can split x into three smaller solutions x_1, x_2, x_3 such that the total weight of both x_1 and x_2 is at most $j/2$, and x_3 is consists of at most one item. It follows that if we know $\mathcal{P}[0, \ldots, j/2]$, then we can compute $\mathcal{P}[0, \ldots, j]$ by taking the $(\max, +)$-convolution of $\mathcal{P}[0, \ldots, j/2]$ with itself and possibly adding one extra item from $\mathcal{I}$. In particular, if we compute all entries $\mathcal{P}[0, \ldots, W/n]$ as a base case using dynamic programming in time $O(W)$, then we can compute the entire sequence $\mathcal{P}[0, \ldots, W]$ by applying $O(\log n)$ $(\max, +)$-convolutions on sequences of length at most W. The overall running time is $O(W^2 \log n)$.

Although this exact algorithm is not particularly exciting or new, it can be nicely extended to the approximate setting. We show that by replacing the exact $(\max, +)$-convolutions with approximate ones, we obtain an FPTAS for Unbounded Knapsack in time $\widetilde{O}(n+1/\varepsilon^2)$. To this end, we preprocess the item set to get rid of *light* items with weight smaller than $\varepsilon \cdot W$, and *cheap* items with profit smaller than $\varepsilon \cdot \mathrm{OPT}$, while decreasing the optimal value by only $O(\varepsilon \cdot \mathrm{OPT})$. We now proceed as in the exact case, starting with the base case $\mathcal{P}[0, \ldots, \varepsilon \cdot W]$, which is all-zeroes since there are no more light items. Then we can build up $\mathcal{P}[0, \ldots, 2^j \varepsilon W]$ for increasing values of j by performing approximate $(\max, +)$-convolutions, until we have computed $\mathcal{P}[0, \ldots, W]$. For approximating $(\max, +)$-convolutions we use an algorithm due to Chan [13], which in our setting without cheap items runs in time $\widetilde{O}(1/\varepsilon^2)$. Thus, after applying the preprocessing in time $O(n)$, we compute a $(1+\varepsilon)$-approximation of $\mathcal{P}[0, \ldots, W]$ by applying $O(\log 1/\varepsilon)$ approximate $(\max, +)$-convolutions in overall time $\widetilde{O}(n + (1/\varepsilon)^2)$.

Then, we treat the case of weak approximation. The main steps of the algorithm are virtually the same as before. The crucial difference is that now we can afford to round weights. In this way, we can adapt Chan's algorithm and construct MaxConv instances which are monotone non-decreasing and have bounded entries. This yields BMMaxConv instances, and by using Chi, Duan, Xie and Zhang's algorithm for this special case [18], we can compute a weak approximation of $(\max, +)$-convolution in time $\widetilde{O}((1/\varepsilon)^{1.5})$. By similar arguments as for the strong approximation, this yields a weak approximation scheme running in time $\widetilde{O}(n + (1/\varepsilon)^{1.5})$.

Equivalence between BMMinConv and Knapsack problems. As mentioned earlier in the introduction, Cygan et al. [19] and Künnemann et al. [28] independently showed a reduction from MinConv to Unbounded Knapsack. In the full version of the paper, we show that following the same chain of reductions from MaxConv to Unbounded Knapsack but instead starting from BMMaxConv, with minor adaptations we can produce instances of Unbounded Knapsack with $W, \mathrm{OPT} = O(n)$. Together with our exact algorithm for Unbounded Knapsack, which we can phrase as a reduction to BMMaxConv, we obtain an equivalence of BMMaxConv and Unbounded Knapsack with $W, \mathrm{OPT} = O(n)$ – if one of these problems can be solved in subquadratic time, then both can.

Note that for Unbounded Knapsack with $W, \mathrm{OPT} = O(n)$ a weak $(1+\varepsilon)$-approximation for $\varepsilon = \Theta(1/n)$ already computes an exact optimal solution. This yields the reduction from BMMaxConv to the approximate version of Unbounded Knapsack. We similarly obtain a reduction to 0-1 Knapsack with $W, \mathrm{OPT} = O(n)$. This yields our equivalences from Theorem 5.

2 Preliminaries

We write $\mathbb{N} = \{0, 1, 2, \dots\}$. For $t \in \mathbb{N}$ we let $[t] = \{0, 1, \dots, t\}$. For reals $a \le b$ we write $[a, b]$ for the interval from a to b, and for reals a, b with $b \ge 0$ we write $[a \pm b]$ for the interval $[a - b, a + b]$.

We formally define the Unbounded Knapsack problem. We are given a set of items $\mathcal{I} = \{(p_1, w_1), \dots, (p_n, w_n)\}$, where each item i has a profit $p_i \in \mathbb{N}$ and a weight $w_i \in \mathbb{N}$, and a knapsack capacity $W \in \mathbb{N}$. The task is to maximize $\sum_{i=1}^{n} p_i \cdot x_i$ subject to the constraints $\sum_{i=1}^{n} w_i \cdot x_i \le W$ and $x \in \mathbb{N}^n$. The more standard 0-1 Knapsack problem is defined in the same way, but the solution x is constrained to $x \in \{0, 1\}^n$.

Given an instance $(\mathcal{I}, W)$, we denote by $x \in \mathbb{N}^n$ a multiset of items, where x_i is the number of copies of the i-th item. We sometimes refer to x as a *solution*. We write $p_{\mathcal{I}}(x)$ for the total profit of x, i.e., $p_{\mathcal{I}}(x) := \sum_i x_i \cdot p_i$. Similarly, we write $w_{\mathcal{I}}(x) := \sum_i x_i \cdot w_i$ for the weight of x. When the item set $\mathcal{I}$ is clear from context, we drop the subscript and simply write $p(x)$ and $w(x)$. We denote the number of items contained in a solution x by $\|x\|_1 := \sum_i x_i$. A solution x is *feasible* if it satisfies the constraint $w(x) \le W$. We denote by OPT the maximum profit $p(x)$ of any feasible solution x. We denote by $p_{\max} := \max_{(p,w)\in\mathcal{I}} p$ the maximum profit of any input item and by $w_{\max} := \max_{(p,w)\in\mathcal{I}} w$ the maximum weight of any input item.

Notions of Approximation. We say that an algorithm gives a *strong* $(1+\varepsilon)$-approximation for Unbounded Knapsack if it returns a solution $x \in \mathbb{N}^n$ with weight $w(x) \le W$ and profit $p(x) \ge (1-\varepsilon) \cdot \mathrm{OPT}$. We say that an algorithm gives a *weak* $(1+\varepsilon)$-approximation for Unbounded Knapsack if it returns a solution $x \in \mathbb{N}^n$ with profit $p(x) \ge (1-\varepsilon) \cdot \mathrm{OPT}$ and weight $w(x) \le (1+\varepsilon) \cdot W$. We stress that here OPT still denotes the optimum value with weight at most W, i.e., $\mathrm{OPT} = \max\{p(x) \mid x \in \mathbb{N}^n, w(x) \le W\}$.

Profit Sequences. Given an item set $\mathcal{I}$ and capacity W, we define the array $\mathcal{P}_{\mathcal{I}}[0, \dots, W]$, where $\mathcal{P}_{\mathcal{I}}[j]$ is the maximum profit achievable with capacity j, i.e.,

$$\mathcal{P}_{\mathcal{I}}[j] := \max\{p_{\mathcal{I}}(x) \colon x \in \mathbb{N}^n, w_{\mathcal{I}}(x) \le j\}.$$

Note that $\mathcal{P}_{\mathcal{I}}[0] = 0$. A textbook way to compute $\mathcal{P}_{\mathcal{I}}[0, \dots, W]$ is by dynamic programming:

▶ **Fact 6.** *$\mathcal{P}_{\mathcal{I}}[0, \dots, W]$ can be computed using dynamic programming in time $O(n \cdot W)$.*

We will also consider the array $\mathcal{P}_{\mathcal{I},k}[0, \dots, W]$, where we restrict to solutions with at most 2^k items, for any non-negative integer k, i.e., for any $j \in [W]$ we set

$$\mathcal{P}_{\mathcal{I},k}[j] := \max\{p_{\mathcal{I}}(x) \colon x \in \mathbb{N}^n, w(x) \le j, \|x\|_1 \le 2^k\}.$$

When $\mathcal{I}$ is clear from context, we will drop the subscript and write $\mathcal{P}[0, \dots, W]$ and $\mathcal{P}_k[0, \dots, W]$. When we work with 0-1 Knapsack instead of Unbounded Knapsack, we will use the same notation $\mathcal{P}_{\mathcal{I}}$ and $\mathcal{P}_{\mathcal{I},k}$, where we restrict to $x \in \{0, 1\}^n$ instead of $x \in \mathbb{N}^n$.

MaxConv. The $(\max,+)$-convolution $A \oplus B$ of two sequences $A[0,\dots,n], B[0,\dots,n] \in \mathbb{Z}^{n+1}$ is a sequence of length $2n+1$ where $(A \oplus B)[k] := \max_{i+j=k} A[i] + B[j]$. We call MaxConv the task of computing the $(\max,+)$-convolution of two given sequences.

We will use the following handy notation: Given sequences $A[0,\dots,n], B[0,\dots,n]$ and intervals $I, J \subseteq [n]$ and $K \subseteq [2n]$, we denote by $C[K] := A[I] \oplus B[J]$ the computation of $C[k] := \max\{A[i] + B[j] \colon i \in I, j \in J, i+j=k\}$ for each $k \in K$. The following proposition shows that this can be computed efficiently. We defer the proof to Appendix A.

▶ **Proposition 7.** *If MaxConv can be solved in time $T(n)$, then $C[K] = A[I] \oplus B[J]$ can be computed in time $O(T(|I|+|J|)+|K|)$.*

Sometimes we will refer to the $(\min,+)$-convolution, where we replace max by a min. The two problems MinConv and MaxConv are equivalent after negating the sequences.

BMMaxConv. In the BMMaxConv problem, we compute the $(\max,+)$-convolution of sequences of length n which are monotone non-decreasing and have bounded values. For this setting Chan and Lewenstein [16] gave the first subquadratic algorithm, and recently Chi, Duan, Xie and Zhang gave the following remarkable result:

▶ **Theorem 8** (BMMaxConv [18]). *Given monotone non-decreasing sequences $A[0,\dots,n]$ and $B[0,\dots,n]$ with entries $A[i], B[i] \in [O(n)] \cup \{-\infty\}$ for all $i \in [n]$, their $(\max,+)$-convolution $A \oplus B$ can be computed in expected time $\widetilde{O}(n^{1.5})$.*

Note that Chi, Duan, Xie and Zhang phrase their result for $(\min,+)$-convolution of monotone increasing sequences with entries in $[O(n)]$. We prove in Appendix A that both statements are equivalent, so their result also works for $(\max,+)$-convolution with entries in $[O(n)] \cup \{-\infty\}$.

Witnesses. Let $A[0,\dots,n], B[0,\dots,n]$ be an instance of MaxConv. Let $C := A \oplus B$. Given $k \in [2n]$, we say that $i \in [n]$ is a *witness* for $C[k]$ if $C[k] = A[i] + B[k-i]$. We say that an array $M[0\dots,2n]$ is a *witness array*, if each entry $M[k]$ contains some witness for $C[k]$.

For the general case of MaxConv it is well known (e.g. [35, 1]) that computing the witness array has the same time complexity as $(\max,+)$-convolution, up to a polylog(n) overhead. This reduction does not immediately apply to BMMaxConv because the sequences might not remain monotone. However, we make it work with some extra care, see Appendix B for the proof.

▶ **Lemma 9** (Witness Finding). *If BMMaxConv can be computed in time $T(n)$, then a witness array $M[0,\dots,2n]$ can be computed in time $\widetilde{O}(T(n))$.*

Niceness asumptions on time bounds. For all time bounds $T(n)$ in this paper, we make the following niceness assumptions: (1) $T(\widetilde{O}(n)) \le \widetilde{O}(T(n))$, and (2) $k \cdot T(n) \le O(T(kn))$ for any $k, n \ge 1$. This is satisfied for all natural time bounds of polynomial-time or pseudopolynomial-time algorithms, in particular it holds for all functions of the form $T(n) = \Theta(n^\alpha \log^\beta n)$ for any constants $\alpha \ge 1, \beta \ge 0$.

3 Exact algorithm for Unbounded Knapsack

In this section we prove the following Theorem:

▶ **Theorem 10.** *If BMMaxConv on length-n sequences can be solved in time $T(n)$, then Unbounded Knapsack can be solved in time $\widetilde{O}(n + T(p_{\max} + w_{\max}))$, where $p_{\max}$ is the largest profit of any item and $w_{\max}$ is the largest weight of any item.*

Note that Theorem 1 follows as an immediate corollary of Theorem 10 by plugging in Chi, Duan, Xie and Zhang's algorithm (Theorem 8).

For the entire section, fix an instance $(\mathcal{I}, W)$ of the Unbounded Knapsack problem. Recall that $\mathcal{P}_i[0, \dots, W]$ is defined as $\mathcal{P}_i[j] := \max\{p(x) \colon w(x) \leq j, \|x\|_1 \leq 2^i\}$, and set $\Delta := p_{\max} + w_{\max}$. Suppose we know that the optimal solution consists of at most 2^k items. Then, our goal is to compute the value $\mathcal{P}_k[W]$. The natural approach is to use dynamic programming: if we have computed $\mathcal{P}_{i-1}$, then $\mathcal{P}_i = \mathcal{P}_{i-1} \oplus \mathcal{P}_{i-1}$. To get our desired running time, we will show that we only need to convolve $O(\Delta)$ entries of $\mathcal{P}_{i-1}$ and that we can enforce that all of these fall in a range of $O(\Delta)$ values. By monotonicity of $\mathcal{P}_{i-1}$, we end up with a BMMaxConv instance, which can be solved in time $O(T(\Delta))$. The resulting total time to compute $\mathcal{P}_i[W]$ is $O(n + k \cdot T(\Delta))$. With additional preprocessing we ensure that $k = O(\log \Delta)$, turning the running time into $\widetilde{O}(n + T(\Delta))$.

3.1 Preparations

We need to show that when computing the optimal answer for some entry $\mathcal{P}_i[j]$, we can split it in such a way that both its total profit and its total weight are roughly halved. Our main tool to show this is the Steinitz Lemma [22, 36]. A beautiful proof for it can be found in [31].

▶ **Lemma 11** ([22, 36, Steinitz Lemma])**.** *Let $\|.\|$ be a norm in $\mathbb{R}^m$ and let M be an arbitrary collection of t vectors in $\mathbb{R}^m$ such that $\|v\| \leq 1$ for every $v \in M$ and $\sum_{v \in M} v = 0$. Then, it is possible to permute the vectors in M into a sequence $(v_1, \dots, v_t)$ such that $\|v_1 + \cdots + v_k\| \leq m$ holds for every $k \in [t]$.*

We use the Steinitz Lemma to argue that the items in a solution can be split in two parts in such a way that both the total profit and the total weight are roughly halved:

▶ **Lemma 12** (Splitting Lemma)**.** *Let $i \geq 1$ and consider a solution $x \in \mathbb{N}^n$ with $\|x\|_1 \leq 2^i$. Then there is a partition of x into two solutions $x_1, x_2 \in \mathbb{N}^n$ with the following properties:*

1. *(Splitting of Items) $\|x_1\|_1, \|x_2\|_1 \leq 2^{i-1}$ and $x = x_1 + x_2$,*
2. *(Approximate Splitting of Weight) $|w(x_1) - \frac{1}{2}w(x)| \leq 2\Delta$ and $|w(x_2) - \frac{1}{2}w(x)| \leq 2\Delta$,*
3. *(Approximate Splitting of Value) $|p(x_1) - \frac{1}{2}p(x)]| \leq 2\Delta$ and $|p(x_2) - \frac{1}{2}p(x)]| \leq 2\Delta$.*

Proof. Let $t := \|x\|_1 \leq 2^i$. First assume that t is even; we will remove this assumption later. Write $x = \sum_{j=1}^{t} x^{(j)}$ where each $x^{(j)}$ corresponds to one copy of some item, i.e. $\|x^{(j)}\|_1 = 1$, and set $v^{(j)} = \begin{pmatrix} w(x^{(j)}) \\ p(x^{(j)}) \end{pmatrix}$. Note that $\|v^{(j)}\|_\infty \leq \Delta$. By applying the Steinitz Lemma on the vectors $v^{(j)} - \frac{1}{t}\begin{pmatrix} w(x) \\ p(x) \end{pmatrix}$ (after normalizing by Δ), we can assume that the $v^{(j)}$'s are ordered such that

$$\left\| \sum_{j=1}^{t/2} v^{(j)} - \frac{1}{2}\begin{pmatrix} w(x) \\ p(x) \end{pmatrix} \right\|_\infty \leq 2\Delta. \tag{1}$$

Fix this ordering, and let $x_1 = x^{(1)} + \ldots + x^{(t/2)}$, corresponding to $v^{(1)}, \ldots, v^{(t/2)}$, and let $x_2 = x^{(t/2+1)} + \ldots + x^{(t)}$, corresponding to the remaining vectors $v^{(t/2+1)}, \ldots, v^{(t)}$. We now check that x_1, x_2 satisfy the properties of the lemma:

- Property 1 is clearly satisfied by construction.
- For property 2, note that (1) implies $|w(x_1) - \frac{1}{2}w(x)| \leq 2\Delta$. Since $w(x_2) = w(x) - w(x_1)$, we have that $|w(x_2) - \frac{1}{2}w(x)| = |\frac{1}{2}w(x) - w(x_1)| \leq 2\Delta$.
- Property 3 follows in the same way as property 2.

If t is odd, then $t + 1 \leq 2^i$, so we can add a dummy vector $x^{(t+1)} = 0$ with corresponding $v^{(t+1)} := \binom{0}{0}$ and repeat the same argument with $t := t + 1$. ◀

When we apply Lemma 12 to an optimal solution corresponding to an entry of the array $\mathcal{P}_i$, we obtain the following lemma.

▶ **Lemma 13.** *Let $\beta > 0$. For any index $j \in [\beta \pm 8\Delta] \cap [W]$ there are indices $j_1, j_2 \in [\frac{\beta}{2} \pm 8\Delta] \cap [W]$ with the following properties:*

(i) $j_1 + j_2 = j$,
(ii) $\mathcal{P}_i[j] = \mathcal{P}_{i-1}[j_1] + \mathcal{P}_{i-1}[j_2]$,
(iii) $|\mathcal{P}_{i-1}[j_1] - \frac{1}{2}\mathcal{P}_i[j]| \leq 2\Delta$ *and* $|\mathcal{P}_{i-1}[j_2] - \frac{1}{2}\mathcal{P}_i[j]| \leq 2\Delta$.

Proof. Let $x \in \mathbb{N}^n$ be an optimal solution for $\mathcal{P}_i[j]$, that is, we have $p(x) = \mathcal{P}_i[j]$, $w(x) \leq j$, and $\|x\|_1 \leq 2^i$. We apply Lemma 12 to x and obtain $x_1, x_2 \in \mathbb{N}^n$ such that $x_1 + x_2 = x$. We do a case distinction based on $w(x_1), w(x_2)$:

- $w(x_1), w(x_2) \in [\frac{j}{2} \pm 4\Delta]$: Let $j_1 := w(x_1)$ and $j_2 := j - j_1$; note that $j_1, j_2 \in [\frac{j}{2} \pm 4\Delta] \subseteq [\frac{\beta}{2} \pm 8\Delta]$. We argue that $p(x_1) = \mathcal{P}_{i-1}[j_1]$ and $p(x_2) = \mathcal{P}_{i-1}[j_2]$. Indeed, since $w(x_1) = j_1$ the solution x_1 is feasible for weight j_1, so $p(x_1) \leq \mathcal{P}_{i-1}[j_1]$. Similarly, since $w(x_2) = w(x) - w(x_1) \leq j - w(x_1) = j_2$ the solution x_2 is feasible for weight j_2, so $p(x_2) \leq \mathcal{P}_{i-1}[j_2]$. Moreover, by optimality of x we have $p(x_1) + p(x_2) = p(x) = \mathcal{P}_i[j] \geq \mathcal{P}_{i-1}[j_1] + \mathcal{P}_{i-1}[j_2]$, so we obtain $p(x_1) = \mathcal{P}_{i-1}[j_1]$ and $p(x_2) = \mathcal{P}_{i-1}[j_2]$. Using these equations together with $p(x) = \mathcal{P}_i[j]$, property (ii) follows from $p(x) = p(x_1) + p(x_2)$, property (iii) follows from Property 3 of Lemma 12, and property (i) holds by definition of j_2.
- $w(x_1) < \frac{j}{2} - 4\Delta$: Property 2 of Lemma 12 implies that $|w(x_1) - w(x_2)| \leq 4\Delta$, and thus $w(x_2) \leq \frac{j}{2}$. Therefore, x_1 and x_2 are feasible for weights $j_1 := \lfloor \frac{j}{2} \rfloor$ and $j_2 := \lceil \frac{j}{2} \rceil$, respectively. Note that $j_1, j_2 \in [\frac{\beta}{2} \pm (4\Delta + 1)] \subseteq [\frac{\beta}{2} \pm 8\Delta]$. Property (i) is obvious, and properties (ii) and (iii) now follow as in the first case.
- $w(x_1) > \frac{j}{2} + 4\Delta$: Similarly as the previous case, property 2 of Lemma 12 implies that $w(x_2) \geq \frac{j}{2}$. Therefore, we have $w(x) = w(x_1) + w(x_2) > j + 4\Delta$, which contradicts the assumption $w(x) \leq j$.
- $w(x_2) < \frac{j}{2} - 4\Delta$ or $w(x_2) > \frac{j}{2} + 4\Delta$: Symmetric to the previous two cases. ◀

3.2 The algorithm

We are now ready to present our algorithm. The idea is to use the Splitting Lemma 12 to convolve smaller sequences which are bounded and monotone.

Let $\mathcal{I} = \{(w_i, p_i)\}_{i=1}^n$ with capacity constraint W be an instance of Unbounded Knapsack. Since any item has $w_i \geq 1$, we know that any solution $x \in \mathbb{N}^n$ consists of at most W items. Thus, to compute the value of the optimal solution it suffices to compute $\mathcal{P}_k[W]$ where $k := \lceil \log W \rceil$.

Our approach is as follows. We do binary search for OPT in the range $[p_{\max} \cdot W]$. Suppose we have the current guess α. Instead of computing the arrays $\mathcal{P}_i$, we compute *clipped versions*, i.e., C_i which has the property that $C_i[j] \geq \alpha$ if and only if $\mathcal{P}_i[j] \geq \alpha$.

We compute C_i as follows: At every step, we only compute the values for $O(\Delta)$ weights $C_i[W \cdot 2^{i-k} \pm 8\Delta]$. For the base case $i = 0$, we simply set $C_0[0, \dots, 8\Delta] := \mathcal{P}_0[0, \dots, 8\Delta]$. Note that this can be done in time $O(n + \Delta)$ by doing one pass over the item set, since $\mathcal{P}_0$ only considers solutions with at most one item. Moreover, observe that $C_0[0, \dots, 8\Delta]$ is monotone non-decreasing by definition of $\mathcal{P}_0$.

For the general case $i > 0$ we first compute an array $A_i[W \cdot 2^{i-k} \pm 8\Delta]$ by taking the $(\max, +)$-convolution of $C_{i-1}[W \cdot 2^{i-1-k} \pm 8\Delta]$ with itself. To obtain $C_i[W \cdot 2^{i-k} \pm 8\Delta]$, we clip the values in A_i which are too large, and set to $-\infty$ the values which are to small. This ensures that all values in C_i lie within a range of $O(\Delta)$, except for values that are $-\infty$. Algorithm 1 contains the pseudocode.

Algorithm 1 Given an instance $(\mathcal{I}, W)$ of Unbounded Knapsack and a guess $\alpha \in [p_{\max} \cdot W]$, the algorithm computes a value $C_k[W]$ satisfying the guarantee in Lemma 15.

1: $k := \lceil \log W \rceil$
2: Initialize $C_0[0, \dots, 8\Delta] := \mathcal{P}_0[0, \dots, 8\Delta]$ by iterating over the item set $\mathcal{I}$ once
3: **for** $i = 1, \dots, k$ **do**
4: $\quad A_i[W \cdot 2^{i-k} \pm 8\Delta] := C_{i-1}[W \cdot 2^{i-1-k} \pm 8\Delta] \oplus C_{i-1}[W \cdot 2^{i-1-k} \pm 8\Delta]$
5: $\quad C_i[j] := \begin{cases} \lceil \alpha \cdot 2^{i-k} \rceil + 24\Delta & \text{if } A_i[j] > \alpha \cdot 2^{i-k} + 24\Delta \\ -\infty & \text{if } A_i[j] < \alpha \cdot 2^{i-k} - 40\Delta \\ A_i[j] & \text{otherwise} \end{cases}$
return $C_k[W]$

Due to the clipping, at every step we compute a $(\max, +)$-convolution of sequences of length $O(\Delta)$ and values in $[O(\Delta)] \cup \{-\infty\}$ (after shifting the indices and values appropriately). Furthermore, note that all convolutions involve monotone non-decreasing sequences. Indeed, as noted above the starting sequence C_0 is monotone non-decreasing. Convolving it with itself produces a monotone non-decreasing sequence again, and the clipping in line 5 of Algorithm 1 preserves monotonicity. The same argument applies for further iterations. Thus, the running time of Algorithm 1 is $O(n + T(\Delta) \log W)$, where $T(\Delta)$ is the running time to compute BMMaxConv on sequences of length Δ.

Regarding correctness, we claim the following:

▷ Claim 14. For every $i \in [k]$ and every index $j \in [W \cdot 2^{i-k} \pm 8\Delta] \cap [W]$ the following holds:
- If $\mathcal{P}_i[j] \in [\alpha \cdot 2^{i-k} - 40\Delta, \alpha \cdot 2^{i-k} + 24\Delta]$, then $C_i[j] = \mathcal{P}_i[j]$.
- If $\mathcal{P}_i[j] > \alpha \cdot 2^{i-k} + 24\Delta$, then $C_i[j] = \lceil \alpha \cdot 2^{i-k} \rceil + 24\Delta$.
- If $\mathcal{P}_i[j] < \alpha \cdot 2^{i-k} - 40\Delta$, then $C_i[j] = -\infty$.

Intuitively, the claim says that entries "close" to the (scaled) guess $\alpha \cdot 2^{i-k}$ get computed exactly, while entries below and above get clipped appropriately.

Proof. We prove the claim by induction on i. In the base case $i = 0$, note that since $\alpha \in [p_{\max} \cdot W]$ and $k = \lceil \log W \rceil$ we have $\alpha \cdot 2^{-k} \leq p_{\max} \leq \Delta$. Thus, $[\alpha \cdot 2^{-k} - 40\Delta, \alpha \cdot 2^{-k} + 24\Delta]$ contains the whole interval $[0, \Delta]$ of possible values of $\mathcal{P}_0[j] = C_0[j]$ (for any $0 \leq j \leq 8\Delta$).

Now we show that the claim holds for any $1 \leq i \leq k$ assuming it holds for $i - 1$. Fix any $j \in [W \cdot 2^{i-k} \pm 8\Delta]$. Note that the thresholding in line 4 of Algorithm 1 does not increasy any of the entries in A_i, so $C_i[j] \leq A_i[j]$. Moreover, since inductively $C_{i-1}[j'] \leq \mathcal{P}_{i-1}[j']$ for all j', by definition of A_i we have $A_i[j] \leq \mathcal{P}_i[j]$. Hence, we obtain $C_i[j] \leq \mathcal{P}_i[j]$. We use this observation to obtain the claim, by showing an appropriate lower bound for $C_i[j]$ in the following.

Pick indices j_1, j_2 as guaranteed by Lemma 13. Property (i) of Lemma 13 guarantees that the computation of $A_i[j]$ in line 3 of Algorithm 1 looks at the entries j_1, j_2 in C_{i-1}. Hence, $A_i[j] \geq C_{i-1}[j_1] + C_{i-1}[j_2]$.

We proceed by a case distinction on the values of the entries $\mathcal{P}_{i-1}[j_1]$ and $\mathcal{P}_{i-1}[j_2]$:

Case 1: $\mathcal{P}_{i-1}[j_1], \mathcal{P}_{i-1}[j_2] \in [\alpha \cdot 2^{i-1-k} - 40\Delta, \alpha \cdot 2^{i-1-k} + 24\Delta]$. By the induction hypothesis, both values are computed exactly, that is, $C_{i-1}[j_1] = \mathcal{P}_{i-1}[j_1]$ and $C_{i-1}[j_2] = \mathcal{P}_{i-1}[j_2]$. Thus, $A_i[j] \geq C_{i-1}[j_1] + C_{i-1}[j_2] = \mathcal{P}_{i-1}[j_1] + \mathcal{P}_{i-1}[j_2] = \mathcal{P}_i[j]$, using property (ii) of Lemma 13. Since we observed above that $A_i[j] \leq \mathcal{P}_i[j]$, we obtain $A_i[j] = \mathcal{P}_i[j]$. The thresholding in line 4 of Algorithm 1 now yields the claim for this case.

Case 2: $\mathcal{P}_{i-1}[j_1] > \alpha \cdot 2^{i-1-k} + 24\Delta$. Property (iii) of Lemma 13 implies that $|\mathcal{P}_{i-1}[j_1] - \mathcal{P}_{i-1}[j_2]| \leq 4\Delta$, and hence $\mathcal{P}_{i-1}[j_2] \geq \alpha \cdot 2^{i-1-k} + 20\Delta$. Thus, property (ii) of Lemma 13 implies $\mathcal{P}_i[j] = \mathcal{P}_{i-1}[j_1] + \mathcal{P}_{i-1}[j_2] > \alpha \cdot 2^{i-k} + 24\Delta$. Therefore, we want to show that $C_i[j] = \lceil \alpha \cdot 2^{i-k} \rceil + 24\Delta$.

By the induction hypothesis, we have $C_{i-1}[j_1] = \lceil \alpha \cdot 2^{i-1-k} \rceil + 24\Delta$ and $C_{i-1}[j_2] \geq \alpha \cdot 2^{i-1-k} + 20\Delta$. Hence, $A_i[j] \geq C_{i-1}[j_1] + C_{i-1}[j_2] > \alpha \cdot 2^{i-k} + 40\Delta$. Due to the thresholding, we conclude that $C_i[j] = \lceil \alpha \cdot 2^{i-k} \rceil + 24\Delta$, as desired.

Case 3: $\mathcal{P}_{i-1}[j_1] < \alpha \cdot 2^{i-k} - 40\Delta$. Similarly as in case 2, property (iii) of Lemma 13 implies that $\mathcal{P}_{i-1}[j_2] \leq \alpha \cdot 2^{i-1-k} - 36\Delta$. Thus, $\mathcal{P}_i[j] = \mathcal{P}_{i-1}[j_1] + \mathcal{P}_{i-1}[j_2] < \alpha \cdot 2^{i-k} - 76\Delta$. Since $C_i[j] \leq \mathcal{P}_i[j]$, but $C_i[j]$ takes values in $\{-\infty\} \cup [\alpha \cdot 2^{i-k} \pm 40\Delta]$ it follows that $C_i[j] = -\infty$. ◁

Given the claim, it is easy to see that $C_k[W] \geq \alpha$ if and only if $\mathcal{P}_k[W] \geq \alpha$. Along with the running time analysis argued earlier, we obtain the following lemma.

▶ **Lemma 15.** *Algorithm 1 runs in time $O(n + T(\Delta) \log W)$, where $T(\Delta)$ is the time complexity of BMMaxConv on sequences of length Δ, and computes a value $C_k[W]$ which satisfies $C_k[W] \geq \alpha$ if and only if $\mathrm{OPT} = \mathcal{P}_k[W] \geq \alpha$.*

Given Lemma 15, we can do binary search to find the optimal value. This gives an algorithm for Unbounded Knapsack in time $O((n + T(\Delta)) \log W \log \mathrm{OPT})$. To shave the polylog$(W, \mathrm{OPT})$ factors and obtain the running time $\widetilde{O}(n + T(\Delta))$ claimed in Theorem 10, we make use of the following lemma. It allows us to reduce the capacity of the instance by repeatedly adding copies of the item with maximum profit-to-weight ratio. Similar results have been shown for general ILPs [20], for Unbounded Knapsack [5] and for the Coin Change problem [15]. For completeness, we include the proof by Chan and He [15, Lemma 4.1].[7]

▶ **Lemma 16.** *Let $(p_{i^*}, w_{i^*}) := \mathrm{argmax}_{(p,w) \in \mathcal{I}} \frac{p}{w}$. If $W \geq 2w_{\max}^3$, then there exists an optimal solution containing (p_{i^*}, w_{i^*}).*

Proof. Consider an optimal solution x that does not contain item (p_{i^*}, w_{i^*}). If there is an item (p_j, w_j) that appears at least w_{i^*} times in x, then we can replace w_{i^*} of the copies of item (p_j, w_j) by w_j copies of item (p_{i^*}, w_{i^*}). By definition of (p_{i^*}, w_{i^*}), this does not decrease the total profit of the solution, so by optimality of x the new solution x' is also optimal. Therefore, some optimal solution contains (p_{i^*}, w_{i^*}).

[7] Both Chan and He [15] and Bateni et al. [5] show that the same conclusion of the lemma holds if $W > w_{i^*}^2$, with a slightly more involved argument. For our purposes, this simple variant is enough.

It remains to consider the case that x contains less than w_{i^*} copies of every item, so its total weight is at most $n \cdot w_{i^*} \cdot w_{\max}$. Note that $n \leq w_{\max}$, because without loss of generality there is at most one item per distinct weight (otherwise we can keep only the item with the largest profit for each weight). Thus, the total weight of x is at most $w_{\max}^3$. It follows that $W < w_{\max}^3 + w_{i^*} \leq 2w_{\max}^3$, since otherwise we could add at least one copy of (p_{i^*}, w_{i^*}) to x, contradicting its optimality. ◀

We now put all pieces together: As a preprocessing step we repeatedly add the item (p_{i^*}, w_{i^*}) and decrease W by w_{i^*}, as long as $W > 2w_{\max}^3$. After this preprocessing, we have $W = O(w_{\max}^3) = O(\Delta^3)$, and thus $\mathrm{OPT} \leq W \cdot p_{\max} = O(\Delta^4)$. The we do binary search for OPT, using Algorithm 1 as a decision procedure. By Lemma 15, the overall running time is $O((n + T(\Delta)) \log^2 \Delta) = \widetilde{O}(n + T(\Delta))$. This completes the proof of Theorem 10.

3.3 Solution Reconstruction

The algorithm we described gives us the value OPT of the optimal solution. In this section we will describe how to use witness arrays (Lemma 9) to reconstruct a feasible solution $x \in \mathbb{N}^n$ such that $p(x) = \mathrm{OPT}$ with only a polylogarithmic overhead in the overall running time.

▶ **Lemma 17.** *A optimal solution x can be reconstructed in time $\widetilde{O}(n + T(p_{\max} + w_{\max}))$.*

Proof Sketch. Let $k = \lceil \log W \rceil$ be as in Algorithm 1. After determining the value of OPT, run Algorithm 1 again with the guess $\alpha = \mathrm{OPT}$. For every BMMaxConv in line 4 compute the witness array M_i corresponding to A_i via Lemma 9. This takes time $\widetilde{O}(n+T(p_{\max}+w_{\max}))$. Now, the idea is to start from $C_k[W]$ and traverse the *computation tree* of Algorithm 1 backwards. That is, we look at the pair of entries $C_{k-1}[M_k[W]], C_{k-1}[W - M_k[W]]$ which define the value of $C_k[W]$ and recursively obtain the pair of entries in C_{k-2} determining the value of $C_{k-1}[M_k[W]]$, etc. By proceeding in this way, we eventually hit the leaves, i.e., the entries of $C_0[0, \ldots, 8\Delta] = \mathcal{P}_0[0, \ldots, 8\Delta]$, which correspond to the items in an optimal solution. A naive implementation of this idea takes time $O(\sum_{i \leq k} 2^i) = O(2^k) = O(W)$, which is too slow.

Now we describe an efficient implementation of the same idea. For each $i \in [k]$ construct an array $Z_i[W \cdot 2^{i-k} \pm 8\Delta]$ initialized to zeros. Set $Z_k[W] := 1$. We will maintain the invariant that $Z_i[j]$ stores the number of times we arrive at $C_i[j]$ by traversing the computation tree starting at $C_k[W]$. This clearly holds for $Z_k[W] = 1$ by definition. Now we describe how to fill the entries for the levels below. Iterate over $i = k, k-1, \ldots, 1$. For each entry $j \in [W \cdot 2^{i-k} \pm 8\Delta] \cap [W]$ add $Z_i[j]$ to its witness entries in the level below, i.e., increase $Z_{i-1}[M_i[j]]$ by $Z_i[j]$ and $Z_{i-1}[j - M_i[j]]$ by $Z_i[j]$. The invariant is maintained by definition of the witnesses, and because Algorithm 1 guarantees that $M_i[j], j - M_i[j] \in [2 \cdot 2^{i-1-k} \pm 8\Delta] \cap [W]$. Note that this procedure takes time $O(k\Delta) = \widetilde{O}(\Delta)$.

Finally, note that for the base case we have that each $Z_0[j]$ for $j \in [8\Delta]$ counts the number of times that we hit the entry $C_0[j] = \mathcal{P}_0[j]$ in the computation tree starting from $C_k[W]$. Recall that by definition, $\mathcal{P}_0[j]$ is the maximum profit of an item in $\mathcal{I}$ with weight at most j. Hence, every entry $\mathcal{P}_0[j]$ corresponds to a unique item in $\mathcal{I}$. Therefore, we can read off from $Z_0[0, \ldots, 8\Delta]$ the multiplicity of each item included in an optimal solution. The overall time of the procedure is $\widetilde{O}(n + T(p_{\max} + w_{\max}))$, as claimed. ◀

4 Exact Algorithm for 0-1 Knapsack

Cygan et al. [19] showed the following reduction from 0-1 Knapsack to BMMaxConv:

▶ **Theorem 18** ([19, Theorem 13]). *If MaxConv on length-n sequences can be solved in time $T(n)$, then 0-1 Knapsack can be solved in time $O(T(W\log W)\log^3(n/\delta)\log n)$ with probability at least $1-\delta$.*

Their reduction is a generalization of Bringmann's algorithm for Subset Sum [8], replacing Boolean convolutions by $(\max,+)$-convolutions. We observe that essentially the same reduction yields sequences of length $O(W)$ which are monotone and have entries bounded by OPT. In particular, these are BMMaxConv instances. This yields the following:

▶ **Theorem 19** (0-1 Knapsack $\to$ BMMaxConv). *If BMMaxConv on length-n sequences can be solved in time $T(n)$, then 0-1 Knapsack can be solved in time $\widetilde{O}(n+T(W+\mathrm{OPT}))$ with high probability.*

Proof. The proof is virtually the same as [19, Theorem 13], so we omit some details. In particular, we emphasize how the constructed instances can be seen to be monotone and bounded, but we omit some details of the correctness argument. The idea of the algorithm is the following: split the item set $\mathcal{I}$ into groups $G_{(a,b)}\subseteq\mathcal{I}$ such that all items $(p,w)\in\mathcal{I}$ with $p\in[2^{a-1},2^a)$ and $w\in[2^{b-1},2^b)$ are in group $G_{(a,b)}$. That is, all items within each group have weights and profits within a factor of 2 of each other, and thus there are $O(\log W\log\mathrm{OPT})$ many groups. We will describe how to compute $\mathcal{P}_{G_{(a,b)}}[0,\dots,W]$ for each $G_{(a,b)}$. Having that, we simply combine all the profit arrays into $\mathcal{P}_{\mathcal{I}}[0,\dots,W]$ using $(\max,+)$-convolutions. Since we have $O(\log W\log\mathrm{OPT})$ groups, and each profit array is a monotone non-decreasing sequence of length W with entries bounded by OPT, the combination step takes time $\widetilde{O}(T(W+\mathrm{OPT}))$.

Fix some group $G_{(a,b)}$. Since every $(p,w)\in G_{(a,b)}$ has $w\in[2^{a-1},2^a)$ and $p\in[2^{b-1},2^b)$, any feasible solution from $G_{(a,b)}$ consists of at most $z:=\lceil\min\{W/2^{a-1},\mathrm{OPT}/2^{b-1}\}\rceil$ items. Thus, by splitting the items in $G_{(a,b)}$ randomly into z subgroups $G_{(a,b),1},\dots,G_{(a,b),z}$, any fixed feasible solution has at most $O(\log z)$ items in each subgroup $G_{(a,b),k}$ with high probability. To see this, fix a solution x and note that,

$$\mathbf{Pr}[\text{at least } r \text{ items from } x \text{ fall in } G_{(a,b),k}]\le\binom{z}{r}\left(\frac{1}{z}\right)^r\le\left(\frac{e\cdot z}{r}\right)^r\left(\frac{1}{z}\right)^r=\left(\frac{e}{r}\right)^r,$$

where the first inequality follows due to a union bound over all subsets of items of size r. By setting $r=O(\log z)$, we can bound this probability by z^{-c} for any constant c. So by a union bound, none of the z groups $G_{(a,b),1},\dots,G_{(a,b),z}$ has more than $\kappa:=O(\log z)$ elements from the fixed solution x with probability at least $1-1/\operatorname{poly}(z)$.

Therefore, to obtain the value of any fixed solution it suffices to compute the optimal solution consisting of at most κ items from $G_{(a,b),k}$ for every target weight $\le O(2^a\kappa)$, and then merge the results. More precisely, for every $1\le i\le z$ we compute the array $\mathcal{P}_{G_{(a,b),i},\log(\kappa)}[0,\dots,O(2^a\kappa)]$. Recall that this is defined as

$$\mathcal{P}_{G_{(a,b),i},\log(\kappa)}[j]:=\max\{p(x)\colon x \text{ is a solution from } G_{(a,b),i} \text{ with } w(x)\le j,\|x\|_1\le\kappa\}$$

for each $j\in[O(2^a\kappa)]$. For ease of notation, we denote the array by $\mathcal{P}_{G_i,\kappa}:=\mathcal{P}_{G_{(a,b),i},\log\kappa}$.

Then, we merge the $\mathcal{P}_{G_i,\kappa}$'s using $(\max,+)$-convolutions. Now we describe these two steps in more detail:

Computing $\mathcal{P}_{G_i,\kappa}[0,\dots,O(2^a\kappa)]$. Since we only care about solutions with at most κ items, we use randomization again[8]: split the items in $G_{(a,b),i}$ into κ^2 buckets $A_1,\dots,A_{\kappa^2}$. By the birthday paradox, with constant probability it holds that any fixed solution is shattered among the buckets, i.e., each bucket contains at most 1 item of the solution. Thus, for each bucket A_k we construct the array $\mathcal{P}_{A_k,0}[0,\dots,2^a]$. Recall that this is defined as

$$\mathcal{P}_{A_k,0}[j] := \max\{p(x)\colon x \text{ is a solution from } A_k \text{ with } w(x)\le j, \|x\|_1\le 1\}$$

for each entry $j\in[2^a]$. To combine the results, we compute $\mathcal{P}_{A_1,0}\oplus\mathcal{P}_{A_2,0}\oplus\cdots\oplus\mathcal{P}_{A_{\kappa^2},0}$. By definition, every $\mathcal{P}_{A_i,0}$ is a monotone non-decreasing sequence of length 2^a with entries bounded by 2^b. Thus, the merging step takes time $O(T((2^a+2^b)\cdot\kappa^2)\cdot\kappa^2)$.

Each entry of the resulting array has the correct value $\mathcal{P}_{i,\kappa}[j]$ with constant probability, since a corresponding optimal solution is shattered with constant probability. By repeating this process $O(\log z)$ times and keeping the entrywise maximum among all repetitions, we boost the success probability to $1-1/\operatorname{poly}(z)$. Thus, by a union bound over the z subgroups $G_{(a,b),1},\dots,G_{(a,b),z}$, we get that any z fixed entries $\mathcal{P}_{G_1,\kappa}[j_1],\dots,\mathcal{P}_{G_z,\kappa}[j_z]$ corresponding to a solution which is partitioned among the z subgroups get computed correctly with probability at least $1-1/\operatorname{poly}(z)$. This adds an extra $O(\log z)=O(\kappa)$ factor to the running time.

Merging $\mathcal{P}_{G_1,\kappa}\oplus\cdots\oplus\mathcal{P}_{G_z,\kappa}$. This computation is done in a binary tree-like fashion. That is, in the first level we compute $(\mathcal{P}_{G_1,\kappa}\oplus\mathcal{P}_{G_2,\kappa}),(\mathcal{P}_{G_3,\kappa}\oplus\mathcal{P}_{G_4,\kappa}),\dots,(\mathcal{P}_{G_{z-1},\kappa}\oplus\mathcal{P}_{G_z,\kappa})$. In the second level we merge the results from the first level in a similar way. We proceed in the same way with further levels. Since we merge z sequences, we have $\lceil\log z\rceil$ levels of computation. In the j-th level, we compute the $(\max,+)$-convolution of $z/2^j$ many monotone non-decreasing sequences of length $O(2^j\cdot 2^a\cdot\kappa)$ with entries bounded by $O(2^j\cdot 2^b\cdot\kappa)$. Therefore, overall the merging takes time

$$O\Big(\sum_{j=1}^{\lceil\log z\rceil}\frac{z}{2^j}\cdot T((2^a+2^b)\cdot 2^j\cdot\kappa)\Big)\le\widetilde{O}(T((2^a+2^b)\cdot z)),$$

where we used both of our niceness assumptions $k\cdot T(n)\le O(T(k\cdot n))$ for any $k>1$ and $T(\widetilde{O}(n))\le\widetilde{O}(T(n))$. Since $z=\lceil\min\{W/2^{a-1},\mathrm{OPT}/2^{b-1}\}\rceil$, we have $\widetilde{O}(T((2^a+2^b)\cdot z)=\widetilde{O}(T(W+\mathrm{OPT}))$.

Wrapping up. To recap, the algorithm does the following steps:

1. Split the items into $O(\log W\log\mathrm{OPT})$ groups $G_{(a,b)}$. This takes time $O(n)$.
2. Randomly split each group $G_{(a,b)}$ into $z:=\lceil\min\{W/2^{a-1},\mathrm{OPT}/2^{b-1}\}\rceil$ subgroups $G_{(a,b),i}$ for $i\in[z]$.
3. For each $G_{(a,b),i}$ compute the array $\mathcal{P}_{G_i,\kappa}[0,\dots,O(2^a\kappa)]$ in time $O(T((2^a+2^b)\kappa^2)\cdot\kappa^3)$. Since $\kappa=O(\log z)$, the total time over all $i\in[z]$ is

   $$O(z\cdot T((2^a+2^b)\kappa^2)\cdot\kappa^3)\le O(T((2^a+2^b)\cdot z\cdot\kappa^2)\kappa^3)\le\widetilde{O}(T((2^a+2^b)\cdot z))\le\widetilde{O}(T(W+\mathrm{OPT})).$$

   Note that here we use the niceness assumptions on $T(n)$. In particular, first we used that $k\cdot T(n)\le O(T(k\cdot n))$ for any $k>1$, and then that $T(\widetilde{O}(n))\le\widetilde{O}(T(n))$.
4. Merge the arrays $\mathcal{P}_{G_1,\kappa}\oplus\cdots\oplus\mathcal{P}_{G_z,\kappa}$ in time $\widetilde{O}(T(W+\mathrm{OPT}))$ to obtain $\mathcal{P}_{G_{(a,b)}}[0,\dots,W]$.
5. Merge the arrays $\mathcal{P}_{G_{(a,b)}}$ using $O(\log W\log\mathrm{OPT})$ convolutions in total time $\widetilde{O}(T(W+\mathrm{OPT}))$.

[8] This step is called "Color Coding" in [8, 19].

Thus, the overall time of the algorithm is $\widetilde{O}(n+T(W+\mathrm{OPT}))$. Note that as mentioned earlier in the proof, the algorithm succeeds in computing any *fixed* entry $\mathcal{P}_{\mathcal{I}}[j]$ with probability at least $1-1/\operatorname{poly}(z)$. In particular, this is sufficient to compute the optimal solution $\mathcal{P}_{\mathcal{I}}[W]$ with good probability. As described, the algorithm only returns the value of the optimal solution. In the full version of the paper, we show how to reconstruct an optimal solution. ◀

A Missing Proofs from Section 2

Proof of Proposition 7. By shifting the indices, we can assume that $A[I]$ and $B[J]$ are sequences $A'[0,\dots,|I|-1]$ and $B'[0,\dots,|J|-1]$. Compute $C' := A' \oplus B'$ in time $T(|A|+|B|)$. By shifting the indices back, we can infer the values of the entries $C[I+J] = A[I] \oplus B[J]$. Thus, we can simply read off the entries in $C[K]$ from the array C'. ◀

Equivalence between variants of BMMaxConv

As stated in Section 2, the algorithm of Chi, Duan, Xie and Zhang [18] computes the $(\min,+)$-convolution of sequences which are monotone increasing and have values in $[O(n)]$. The following proposition shows that this is equivalent to solving MaxConv on monotone non-decreasing sequences with values in $[O(n)] \cup \{-\infty\}$, which justifies Theorem 8.

▶ **Proposition 20.** *MaxConv on monotone non-decreasing sequences of length n and values in $[O(n)] \cup \{-\infty\}$ is equivalent to MinConv on monotone increasing sequences of length n and values in $[O(n)]$, in the sense that if one can be solved in time $T(n)$ then the other can be solved in time $O(T(n))$.*

Proof. We first describe how to reduce MaxConv on monotone non-decreasing sequences and values in $[O(n)] \cup \{-\infty\}$ to MinConv on monotone increasing sequences and values in $[O(n)]$ via a simple chain of reductions:

- *Removing $-\infty$:* Let $A[0,\dots,n], B[0,\dots,n]$ be an instance of MaxConv where A, B are monotone non-decreasing and $A[i], B[i] \in [O(n)] \cup \{-\infty\}$. We start by reducing it to an equivalent instance of MaxConv on monotone non-decreasing sequences and values in $[O(n)]$ (i.e. we remove the $-\infty$ entries). Let Δ be the maximum entry of A and B. Construct a new sequence $A'[0,\dots,n]$ where $A'[i] := 0$ if $A[i] = -\infty$, and $A'[i] := A[i] + 2\Delta$ otherwise. Construct $B'[0,\dots,n]$ from B in the same way. Note that A' and B' are monotone non-decreasing and have values in $[O(n)]$. Moreover, we can infer the values of any entry $(A \oplus B)[k]$ from C': if $C'[k] \le 3\Delta$ then $(A \oplus B)[k] = -\infty$ and otherwise $(A \oplus B)[k] = C'[k] - 4\Delta$.
- *Reducing to MaxConv on non-increasing sequences:* Now we reduce an instance $A[0,\dots,n]$, $B[0,\dots,n]$ of MaxConv on monotone non-decreasing sequences and values in $[O(n)]$ to an instance of MinConv on monotone non-increasing sequences and values in $[O(n)]$. Let Δ be the maximum entry of A and B. Construct two new sequences A' and B' by setting $A'[i] := \Delta - A[i]$ and $B'[i] := \Delta - B[i]$. Then A' and B' are monotone non-increasing and given their $(\min,+)$-convolution we can easily infer the $(\max,+)$-convolution of A and B.
- *Reducing to MinConv on increasing sequences:* Next, we reduce an instance $A[0,\dots,n]$, $B[0,\dots,n]$ of MinConv on monotone non-increasing sequences and values in $[O(n)]$ to an instance of MinConv on increasing sequences and values in $[O(n)]$. Construct two new sequences A' and B' by reversing and adding a linear function to A and B, i.e., set $A'[i] := A[n-i] + i$ and $B'[i] := B[n-i] + i$ for every $i \in [n]$. Note that A' and B' are monotone increasing sequences, and given their $(\min,+)$-convolution we can infer the $(\min,+)$-convolution of A and B.

Combining the reductions above, we conclude that MaxConv on monotone non-decreasing sequences with values in $[O(n)] \cup \{-\infty\}$ can be reduced in linear time to MinConv on monotone increasing sequences with values in $[O(n)]$. To show the reduction in the other direction, we can apply the same ideas: we first negate the entries and shift them to make them non-negative, then reverse the resulting sequences. We omit the details. ◀

B Witnesses for BMMaxConv

In this section we give the proof of Lemma 9. For the remainder of this section, fix an instance $A[0,\dots,n], B[0,\dots,n]$ of BMMaxConv and let $C := A \oplus B$. To compute the witness array $M[0,\dots,2n]$, we first show that if an entry $C[k]$ has a unique witness then

we can easily find it. Then we reduce to the unique witness case with randomization. This approach is well known [35, 1], but some extra care is needed to ensure that the instances remain monotone and bounded. The standard derandomization for this approach [2] also works in our setting.

▶ **Lemma 21.** *If BMMaxConv on length-n sequences can be computed in time $T(n)$, then in time $\widetilde{O}(T(n))$ we can compute an array $U[0,\dots,2n]$ such that for every $k \in [2n]$ if $C[k]$ has a unique witness $M[k]$ then $U[k] = M[k]$. The output $U[k]$ is undefined otherwise.*

Proof. We will describe how to compute the unique witnesses bit by bit. For each bit position $b \in [\lceil \log n \rceil]$ let $i_b \in \{0,1\}$ be the b-th bit of i. Construct sequences A_b, B_b defined as $A_b[i] := 2A[i] + i + i_b$ and $B_b[i] := 2B[i] + i$ for $i \in [n]$. Note that A_b, B_b are still monotone non-decreasing and have entries bounded by $O(n)$. Compute $C_b := A_b \oplus B_b$. For each $k \in [2n]$, we set the b-th bit of $U[k]$ to $C_b[k] \bmod 2$. It is not hard to see that for those entries $C[k]$ which have unique witnesses $U[k]$, this procedure indeed gives the b-th bit of $U[k]$. Indeed, note that because we double every entry in A_b, B_b and add a linear function, adding i_b does not change the maximizer. Therefore, if $C[k]$ has a unique witness then $C'[k]$ has a unique witness whose b-th bit can be read from the least significant bit of $C'[k]$. Thus, by repeating this over all bit positions $b \in [\lceil \log n \rceil]$, we compute the entire array of unique witnesses U using $O(\log n)$ invocations to BMMaxConv, as desired. ◀

Proof of Lemma 9. Fix a set $S \subseteq [n]$. We say that an entry $C[k]$ gets *isolated* by S if the number of witnesses of $C[k]$ in S is exactly one. We will now describe how to find the witnesses of all entries isolated by S (the idea and argument is similar as in the proof of Lemma 21). Construct sequences A', B' where for each $i \in [n]$ we set

$$A'[i] := \begin{cases} 2A[i] + i + 1 & \text{if } i \in S \\ 2A[i] + i & \text{otherwise} \end{cases}$$

and $B'[i] := 2B[i] + i$. Note that these sequences are monotone non-decreasing and have entries bounded by $O(n)$. Let $C' := A' \oplus B'$. We claim that if an entry $C[k]$ is isolated by S, then $C'[k]$ has a unique witness. To see this, note that if no witness of $C[k]$ gets included in S, then we have that $C'[k] = 2C[k] + k$. If at least one witness gets included in S, then $C'[k] = 2C[k] + k + 1$. In particular, if a witness gets isolated then $C'[k]$ will have a unique witness, as claimed. Thus, by Lemma 21 we can compute in time $\widetilde{O}(T(n))$ an array $U[0,\dots,2n]$ which contains the witnesses of all entries that are isolated by S. Note that some entries of U might be undefined, but we can simply check in time $O(n)$ which entries of U are true witnesses, by iterating over $k \in [2n]$ and checking whether the equality $C[k] = A[U[k]] + B[k - U[k]]$ holds.

Now we show how to select appropriate sets S. Fix an entry $C[k]$ and denote by $R \in [n]$ its number of witnesses. We sample $S \subseteq [n]$ by including each element $i \in [n]$ independently with probability $p := 2^{-\alpha}$ where $\alpha \in \mathbb{N}$ is chosen such that $2^{\alpha-2} \le R \le 2^{\alpha-1}$. Let X be the random variable counting the number of witnesses of $C[k]$ that get sampled in S. By keeping the first two terms in the inclusion-exclusion formula we have that $\mathbf{Pr}[X \ge 1] \ge p \cdot R - \binom{R}{2} p^2$, and by a union bound $\mathbf{Pr}[X \ge 2] \le \binom{R}{2} p^2$. Thus,

$$\mathbf{Pr}[X = 1] = \mathbf{Pr}[X \ge 1] - \mathbf{Pr}[X \ge 2] \ge p \cdot R(1 - p \cdot R) \ge 1/8$$

where the last inequality holds because $1/8 \le p \cdot R \le 1/4$ due to the choice of α. In particular, S isolates $C[k]$ with probability at least $1/8$.

We now put the pieces together. Iterate over the $O(\log n)$ possible values for α. Sample a set S and find all witnesses of entries isolated by S as described earlier in time $\widetilde{O}(T(n))$. As we argued above, if $C[k]$ has R witnesses and $2^{\alpha-2} \leq R \leq 2^{\alpha-1}$, then $C[k]$ gets isolated with constant probability. Thus, by repeating this step with the same α for $O(\log n)$ freshly sampled sets S we find a witness for all such entries $C[k]$ with probability at least $1-1/\operatorname{poly}(n)$. Combining the results across iterations we obtain the array of witnesses $M[0,\ldots,2n]$ in time $\widetilde{O}(T(n))$, as desired.

Finally, we note that this procedure can be derandomized with standard techniques [2]. ◀

Improved Sublinear-Time Edit Distance for Preprocessed Strings

Abstract

We study the problem of approximating the edit distance of two strings in sublinear time, in a setting where one or both string(s) are preprocessed, as initiated by Goldenberg, Rubinstein, Saha (STOC '20). Specifically, in the (k, K)-*gap edit distance* problem, the goal is to distinguish whether the edit distance of two strings is at most k or at least K. We obtain the following results:

- After preprocessing *one* string in time $n^{1+o(1)}$, we can solve $(k, k \cdot n^{o(1)})$-gap edit distance in time $(n/k + k) \cdot n^{o(1)}$.
- After preprocessing *both* strings separately in time $n^{1+o(1)}$, we can solve $(k, k \cdot n^{o(1)})$-gap edit distance in time $kn^{o(1)}$.

Both results improve upon some previously best known result, with respect to either the gap or the query time or the preprocessing time.

Our algorithms build on the framework by Andoni, Krauthgamer and Onak (FOCS '10) and the recent sublinear-time algorithm by Bringmann, Cassis, Fischer and Nakos (STOC '22). We replace many complicated parts in their algorithm by faster and simpler solutions which exploit the preprocessing.

1 Introduction

The *edit distance* (also known as *Levenshtein distance*) is a fundamental measure of similarity between strings. It has numerous applications in several fields such as information retrieval, computational biology and text processing. Given strings X and Y, their edit distance denoted by $\mathsf{ED}(X, Y)$ is defined as the minimum number of character insertions, deletions and substitutions needed to transform X into Y.

Table 1 A comparison of sublinear-time algorithms for the $(k, k \cdot g)$-gap edit distance problem for different gap parameters g. All algorithms in this table are randomized and succeed with high probability. Note that some of these results are subsumed by others.

A textbook dynamic programming algorithm computes the edit distance of two strings of length n in time $O(n^2)$. Popular conjectures such as the *Strong Exponential Time Hypothesis* imply that that this algorithm is essentially optimal, as there is no strongly subquadratic-time algorithm [8, 1, 16, 2]. As for some applications involving enormous strings (such as DNA sequences) quadratic-time algorithms are impractical, a long line of research developed progressively better and faster *approximation* algorithms [9, 11, 26, 7, 4, 17, 25, 14]. The current best approximation guarantee in near-linear time is an algorithm by Andoni and Nosatzki [6] computing an $f(1/\varepsilon)$-approximation in time $O(n^{1+\varepsilon})$.

Another more recent line of research studies edit distance in the *sublinear-time* setting. Here the goal is to approximate the edit distance without reading the entire input strings. More formally, in the (k, K)-gap edit distance problem the goal is to distinguish whether the edit distance between X and Y is at most k or greater than K. The performance of gap algorithms is typically measured in terms of the string length n and the gap parameters k and K. This problem has been studied in several works [10, 7, 20, 13, 24] most of which focus on the (k, k^2)-gap problem. Currently, there are two incomparable best known results: A recent result by Goldenberg, Kociumaka, Krauthgamer and Saha [19] established a non-adaptive algorithm for the (k, k^2)-gap problem in time $\widetilde{O}(n/k^{3/2})$.[1] Another recent result by Bringmann, Cassis, Fischer and Nakos [15] reduces the gap to $O^*(1)$ and solves the $(k, O^*(k))$-gap problem in time $O^*(n/k+k^4)$.[2] See Table 1 for a more detailed comparison.

Our starting point is the work by Goldenberg, Rubinstein and Saha [21] which studies sublinear algorithms for edit distance in the *preprocessing model*. Here, we are allowed to preprocess one or both input strings X and Y *separately*, and then use the precomputed

[1] We write $\widetilde{O}(\cdot)$ to hide polylogarithmic factors $(\log n)^{O(1)}$.
[2] We write $O^*(\cdot)$ to hide subpolynomial factors $n^{o(1)}$ in n.

information to solve the (k, K)-gap edit distance problem. This model is motivated by applications where many long strings are compared against each other. For example, the *string similarity join* problem is to find all pairs of strings in a database (containing e.g. DNA sequences) which are close in edit distance; see [27] for a survey on practically relevant algorithms. Note that in these applications, if we have an algorithm with almost-linear preprocessing time (which is the case for all the algorithms we present in this paper), then the overhead incurred by preprocessing is comparable to the time necessary to read and store the strings in the first place. In [21], the authors pose and investigate the following open question:

> *"What is the complexity of approximate edit distance with preprocessing when $k \ll n$?" [21]*

This question has spawned significant interest in the community [18, 21, 13], and with this paper we also make progress towards this question. We give an overview of results in Table 1. Note that most results are hard to compare to each other (one-sided versus two-sided preprocessing, exact versus $O(1)$-approximate versus $O(k)$-approximate).

In the two-sided model, all known algorithms (with almost-linear preprocessing time[3] and, say, subpolynomial gap $g = n^{o(1)}$) share the common barrier that the query time is $\Omega(k^2)$. Due to this barrier, Goldenberg et al. [21] specifically ask whether there exists an approximation algorithm with sub-k^2 query time. One of our contributions is that we answer this question in the affirmative.

Our Results. We develop sublinear-time algorithms for the $(k, O^*(k))$-gap edit distance problem, in the one-sided and two-sided preprocessing model, respectively.

▶ **Theorem 1** (One-Sided Preprocessing). *Let X, Y be length-n strings. After preprocessing Y in time $O^*(n)$, we can solve the $(k, k \cdot n^{o(1)})$-gap edit distance problem for X and Y in time $O^*(n/k + k)$ with high probability.*

In comparison to the (k, k^2)-gap algorithms from [21, 13] with best query time[4] $\widetilde{O}(n/k+k)$, we contribute the following improvement: Ignoring lower-order factors, we reduce the gap from k to $O^*(1)$ while achieving the same query time $O^*(n/k+k)$ and the same preprocessing time $O^*(n)$. In comparison to the $(k, O^*(k))$-gap algorithm in time $O^*(n/k + k^4)$ from [15], we achieve the same gap but an improved query time for large k, at the cost of preprocessing one of the strings.

In the two-sided model, we obtain an analogous result, where the query time no longer depends on n/k.

▶ **Theorem 2** (Two-Sided Preprocessing). *Let X, Y be length-n strings. After preprocessing both X and Y (separately) in time $O^*(n)$, we can solve the $(k, k \cdot n^{o(1)})$-gap edit distance problem for X and Y in time $O^*(k)$ with high probability.*

We remark that all hidden factors in both theorems are $2^{\widetilde{O}(\sqrt{\log n})}$. For a detailed comparison of this algorithm to the previously known results, see Table 1. We point out that Theorem 2 settles the open question from [21] whether there exists an edit distance approximation algorithm with small gap and sub-k^2 query time.

[3] Here we insist on almost-linear preprocessing time since the celebrated embedding of edit distance into the ℓ_1-metric with distortion $n^{o(1)}$ due to Ostrovsky and Rabani [26] achieves query time $O(\log n)$ but requires preprocessing time $\Omega(n^2)$.

[4] For the (k, k^2)-gap problem, the running time bounds $\widetilde{O}(n/k + k)$ and $\widetilde{O}(n/k)$ can be considered equal, as for $k \geq \sqrt{n}$ the algorithm may return a trivial answer.

Our Techniques. To achieve our results we build on the recent sublinear-time algorithm by Bringmann, Cassis, Fischer and Nakos [15], which itself builds on an almost-linear-time algorithm by Andoni, Krauthgamer and Onak [4]. The basic idea of the original algorithm is to split the strings into several smaller parts and recur on these parts with non-uniform precisions. The idea of [15] is to prune branches in the recursion tree, by detecting and analyzing periodic substructures. Towards that, they designed appropriate property testers to efficiently detect these structures. In our setting, we observe that having preprocessed the string(s), we can prune the computation tree much more easily. Thus, our algorithm proceeds in the same recursive fashion as [15] and uses a similar set of techniques, but due to the preprocessing it turns out to be simpler and faster.

Further Related Work. In the previous comparison about sublinear-time algorithms, we left out streaming and sketching algorithms [12, 18, 9] and document exchange protocols [23, 12, 22].

Future Directions. There are several interesting directions for future work. We specifically mention two open problems.

1. *Constant gap?* As Table 1 shows, so far no constant-gap sublinear-time algorithm is known. Maybe the one-sided preprocessing setting is more approachable for this challenge. We believe that our approach is hopeless to achieve a constant gap, since we borrow from the recursive decomposition introduced in [4] which inherently incurs a polylogarithmic overhead in the approximation factor.
2. *Improving the query time?* The well-known $\Omega(n/K)$ lower bound against the (k, K)-gap *Hamming distance* problem (and therefore against edit distance) continues to hold in the one-sided preprocessing setting. In particular, the most optimistic hope is an algorithm with query time $O^*(n/k)$ for the $(k, O^*(k))$-gap edit distance problem. Can this be achieved or is the extra $+k$ in the query time of Theorem 1 necessary? For two-sided preprocessing, to the best of our knowledge no lower bound is known.

2 Preliminaries

We set $[\,i\,..\,j\,] = \{\,i, i+1, \ldots, j-1\,\}$ (in particular, $[\,i\,..\,i\,] = \emptyset$) and $[\,j\,] = [\,0\,..\,j\,]$. We say that an event happens *with high probability* if it happens with probability at least $1 - 1/\operatorname{poly}(n)$, where the degree of the polynomial can be an arbitrary constant. We write $\operatorname{poly}(n) = n^{O(1)}$ and $\widetilde{O}(n) = n(\log n)^{O(1)}$.

Let X, Y be strings over an alphabet Σ with polynomial size. We denote by $|X|$ the length of X. We denote by $X \circ Y$ the *concatenation* of X and Y. We denote by $X[\,i\,]$ the i-th character in X starting with index zero. We denote by $X[\,i\,..\,j\,]$ the substring of X with indices in $[\,i\,..\,j\,]$, that is, including i and excluding j. For out-of-bounds indices we set $X[\,i\,..\,j\,] = X[\,\max(i,0)\,..\,\min(j,|X|)\,]$. If X and Y have the same length, we define their *Hamming distance* $\mathsf{HD}(X,Y)$ as the number of non-matching characters $\mathsf{HD}(X,Y) = |\{\,i : X[\,i\,] \neq Y[\,i\,]\,\}|$. For two strings X, Y with possibly different lengths, we define their *edit distance* $\mathsf{ED}(X,Y)$ as the smallest number of character *insertions*, *deletions* and *substitutions* necessary to transform X into Y. An *optimal alignment* between X and Y is a monotonically non-decreasing function $A : \{\,0, \ldots, |X|\,\} \to \{\,0, \ldots, |Y|\,\}$ such that $A(0) = 0$, $A(|X|) = |Y|$ and

$$\mathsf{ED}(X,Y) = \sum_{i=0}^{|X|-1} \mathsf{ED}(X[\,i\,], Y[\,A(i)\,..\,A(i+1)\,]).$$

It is easy to see that there is an optimal alignment between any two strings X, Y: Trace an optimal path through the standard dynamic program for edit distance and assign $A(i)$ to the smallest j for which the path crosses (i, j).

Let T be a rooted tree, and let v be a node in T. We denote by $\mathsf{root}(T)$ the root node in T. We denote by $\mathsf{parent}(v)$ the parent node of v. We denote by $\mathsf{depth}(v)$ the length of the root-to-v path, and by $\mathsf{height}(v)$ the length of the longest v-to-leaf path.

3 Overview

3.1 A Linear-Time Algorithm à la Andoni-Krauthgamer-Onak

We start to outline an almost-linear-time algorithm to approximate the edit distance of two strings X, Y following the framework of the Andoni-Krauthgamer-Onak algorithm [4], with some changes as in [15] and some additional modifications (see the novel trick outlined at the end of this subsection).

First Ingredient: A Divide-and-Conquer Scheme. The basic idea of the algorithm is to apply a divide-and-conquer scheme to reduce the approximation of the global edit distance to approximating the edit distance of several smaller strings. The straightforward idea of partitioning both strings X, Y into parts $X_1, \dots, X_m, Y_1, \dots, Y_m$ and computing the edit distances $\mathsf{ED}(X_i, Y_i)$ does not immediately work; instead we need to consider *several shifts* of the string Y_i. We remark that this concept of recurring on smaller strings for several shifts is quite standard in previous work. The following lemma uses the same ideas as the "$\mathcal{E}$-distance" defined in [4]. We give a proof in Appendix A.

▶ **Lemma 3** (Divide and Conquer). *Let X, Y be length-n strings, and let $0 = j_0 < \cdots < j_B = n$. We write $X_i = X[\, j_{i-1} \,..\, j_i \,]$ and $Y_{i,s} = Y[\, j_{i-1} + s \,..\, j_i + s \,]$.*

- *For all shifts $s_1, \dots, s_B$ we have that $\mathsf{ED}(X, Y) \le \sum_i \mathsf{ED}(X_i, Y_{i,s_i}) + 2|s_i|$.*
- *There are shifts $s_1, \dots, s_B$ with $\sum_i \mathsf{ED}(X_i, Y_{i,s}) \le 2\mathsf{ED}(X, Y)$ and $2|s_i| \le \mathsf{ED}(X, Y)$ for all i.*

To explain how to apply Lemma 3, we first specify on which substrings our algorithm is supposed to recur. To this end, let T be a balanced B-ary tree with n leaves. T will act as the "recursion tree" of the algorithm. For a string X of length n, we define a substring X_v for every node v in T as follows: If the subtree below X_v spans from the i-th to the j-th leaf (ordered from left to right), then we set $X_v = X[\, i \,..\, j+1 \,]$. In particular, X_v is a single character for each leaf v, and $X_{\mathsf{root}(T)} = X$. We further define $X_{v,s} = X[\, i+s \,..\, j+s+1 \,]$. For concreteness, we set $B = 2^{\sqrt{\log n \log\log n}} = n^{o(1)}$ throughout the paper.

A Simple Algorithm. Based on Lemma 3, we next present a simple (yet slow) algorithm. Our goal is to compute, for each node v in the tree T, an approximation $\widetilde{\mathsf{ED}}(X_v, Y_{v,s})$ of $\mathsf{ED}(X_v, Y_{v,s})$ for all shifts s. The result at the root node is returned as the desired approximation of $\mathsf{ED}(X, Y)$. The algorithm works as follows: For each leaf we can cheaply compute $\mathsf{ED}(X_v, Y_{v,s})$ exactly by comparing the single characters X_v and $Y_{v,s}$. For each internal node with children $v_1, \dots, v_B$ we compute

$$\widetilde{\mathsf{ED}}(X_v, Y_{v,s}) = \sum_{i=1}^{B} \min_{s_i \in \mathbf{Z}} \widetilde{\mathsf{ED}}(X_{v_i}, Y_{v_i,s_i}) + 2|s - s_i|. \tag{1}$$

A careful application of Lemma 3 shows that if the recursive approximations $\mathsf{ED}(X_{v_i}, Y_{v_i,s_i})$ have multiplicative error at most α, then by approximating $\mathsf{ED}(X_v, Y_{v,s})$ as in (1) the multiplicative error becomes $2\alpha + B$. Since we repeat this argument recursively up to depth $\mathsf{depth}(T) \leq \log_B(n)$, the multiplicative error accumulates to $B \cdot \exp(O(\log_B(n))) = n^{o(1)}$.

This simple algorithm achieves the desired approximation quality, however, it is not fast enough: For every node v we have to compute $\widetilde{\mathsf{ED}}(X_v, Y_{v,s})$ for too many shifts s (naively speaking, for up to n shifts). As a first step towards dealing with this issue, we first show that at every node v we can in fact tolerate a certain *additive* error (in addition to the multiplicative error discussed before) using a technique called *Precision Sampling*. Then we exploit the freedom of additive errors to run this algorithm for a *restricted* set of shifts s.

Second Ingredient: Precision Sampling. It ultimately suffices to compute an approximation of $\mathsf{ED}(X, Y)$ with *additive* error k in order to solve the constant-gap edit distance problem. We leverage this freedom to also solve the recursive subproblems up to some additive error. Specifically, we will work with the following data structure:

▶ **Definition 4** (Precision Tree). *Let T be a balanced B-ary tree with n leaves. For $t \in \mathbf{N}$, we randomly associate a* tolerance t_v *to every node v in T as follows:*

- *If v is the root, then set $t_v = t$;*
- *otherwise set $t_v = t_{\mathsf{parent}(v)} \cdot u_v/3$, where we sample $u_v \sim \mathrm{Exp}(O(\log n))$ (the exponential distribution with parameter $O(\log n)$).*

We refer to T as a precision tree with initial tolerance t.

The tolerance t_v at a node v determines the additive error which we can tolerate at v. That is, our goal is to approximate $\mathsf{ED}(X_v, Y_{v,s})$ with additive error t_v (and the same multiplicative error as before). The initial tolerance is set to $t = k$. The critical step is how to combine the recursive approximations with additive error $t_{v_1}, \ldots, t_{v_B}$ to an approximation with additive error t_v. The naive solution would incur error $\sum_i t_{v_i} \gg t_v$. Instead, we employ the *Precision Sampling Lemma* [4, 5, 3, 15] (see Lemma 15 in Section 4) to recombine the recursive approximation and avoid this blow-up in the additive error.

An Improved Algorithm. We can now improve the simple algorithm to a near-linear-time algorithm. In the original Andoni-Krauthgamer-Onak algorithm this was achieved by pruning most recursive subproblems (depending on their tolerances t_v). We will follow a different avenue: Our algorithm recurs on every node in the precision tree, and we obtain a linear-time algorithm by bounding the expected running time per node by $n^{o(1)}$.

We achieve this by the following novel trick: We restrict the set of feasible shifts s at each node v with respect to the tolerance t_v. In fact, we require two constraints: First, we restrict s to values smaller than $\approx k$ in absolute value. This first restriction is correct since we only want to maintain edit distances bounded by k; this idea was also used in previous works. Second, we restrict the feasible shifts s at any node v to multiples of $\lfloor t_v/2 \rfloor$. Then, in order to approximate $\mathsf{ED}(X_v, Y_{v,s})$ for any shift s we let $\tilde{s}$ denote the closest multiple of $\lfloor t_v/2 \rfloor$ to s, and approximate $\mathsf{ED}(X_v, Y_{v,s})$ by $\mathsf{ED}(X_v, Y_{v,\tilde{s}})$. Since $|s - \tilde{s}| \leq t_v/2$, both edit distances differ by at most t_v. Recall that we can tolerate this error using the Precision Sampling technique. Let $S_v = \{ -k \cdot n^{o(1)}, \ldots, k \cdot n^{o(1)} \} \cap \lfloor t_v/2 \rfloor \mathbf{Z}$ denote the set of shifts respecting these restrictions (the precise lower-order term $n^{o(1)}$ will be fixed later).

In terms of efficiency, we have improved as follows: At every node the running time is essentially dominated by the number of feasible shifts s. Using our discretization trick, there are only $|S_v| = k \cdot n^{o(1)}/t_v$ such shifts. By the following Lemma 5, we can bound this number in expectation by $k \cdot n^{o(1)}/t_{\mathsf{root}(T)} = n^{o(1)}$.

▶ **Lemma 5** (Expected Precision). *Let T be a B-ary precision tree with initial tolerance t and $B = \exp(\widetilde{\Theta}(\sqrt{\log n}))$, and let v be a node in T. Then, conditioned on a high-probability event E, it holds that*

$$\mathbf{E}\left(\frac{1}{t_v}\,\middle|\,E\right) \leq \frac{(\log n)^{O(\mathsf{depth}(v))}}{t} \leq \frac{n^{o(1)}}{t}.$$

We include a proof in Appendix A. For technical reasons, the lemma is only true conditioned on some high-probability event E. For the remainder of this paper, we implicitly condition on this event E.

3.2 How to Go Sublinear?

Following the idea of [15], our strategy is to turn this algorithm into a sublinear-time algorithm by not exploring the whole precision tree recursively, and instead only exploring a smaller fragment. To achieve this, the goal is to approximate $\mathsf{ED}(X_v, Y_{v,s})$ for many nodes v directly, without the need to explore their children – we say that we *prune* v. The algorithm by [15] uses several structural insights on periodic versus non-periodic strings to implement pruning rules. We can avoid the complicated treatment and follow a much simpler avenue, exploiting that we can preprocess the strings.

In the following, we will assume that we have access to an oracle answering the following two queries. In the next section we will argue how to efficiently implement data structures to answer these queries.

- $\textsc{Matching}(X, Y, v)$: Returns either $\textsc{Close}(s^*)$ where s^* satisfies $|s^*| \leq k \cdot n^{o(1)}$ and $\mathsf{HD}(X_v, Y_{v,s^*}) \leq t_v/2$, or $\textsc{Far}$ in case that there is no shift s^* with $X_v = Y_{v,s^*}$, see Definition 8. (Note that if $1 \leq \min_{s^*} \mathsf{HD}(X_v, Y_{v,s^*}) \leq t_v/2$, the query can return either $\textsc{Close}(s^*)$ or $\textsc{Far}$.)
- $\textsc{ShiftedDistance}(Y, v, s, s')$: For shifts $|s|, |s'| \leq k \cdot n^{o(1)}$, returns an approximation of $\mathsf{ED}(Y_{v,s}, Y_{v,s'})$ with additive error $t_v/2$ (and $n^{o(1)}$-multiplicative error, see Definition 9).

Suppose for the moment that both queries can be answered in constant time. Then we can reduce the running time of the previous linear-time algorithm to time $k \cdot n^{o(1)}$ as follows: We try to prune each node v by querying $\textsc{Matching}(X, Y, v)$. If the $\textsc{Matching}$ query reports $\textsc{Far}$, we simply continue recursively as before (i.e., no pruning takes place). However, if the matching query reports $\textsc{Close}(s^*)$, then we can prune v as follows: Query $\textsc{ShiftedDistance}(Y, v, s^*, s)$ for all shifts $s \in S_v$ and return the outcome as an approximation of $\mathsf{ED}(X_v, Y_{v,s})$ for all shifts s. For the correctness we apply the triangle inequality and argue that the additive error is bounded by $t_v/2 + t_v/2 = t_v$.

It remains to argue that the number of recursive computations is bounded by $k \cdot n^{o(1)}$. The intuitive argument is as follows: Assume that $\mathsf{ED}(X, Y) \leq k$ (i.e., we are in the "close" case) and consider an optimal alignment between X and Y, which contains at most k mismatches. Recall that each level of the precision tree induces a partition of X into consecutive substrings X_v. Thus, there are at most k substrings X_v which contain a mismatch in the optimal alignment. For all *other* substrings, there are no mismatches and hence $X_v = Y_{v,s^*}$ for some shift s^*. It follows that on every level there are at most k nodes for which the $\textsc{Matching}$ test fails, and in total there are only $k \cdot \mathsf{height}(T) = O(k \log n)$ such nodes.

3.3 How to Answer Matching and Shifted-Distance Queries?

It remains to find data structures which answer these queries efficiently. We assume that the precision tree T has been generated in advance and is shared across all precomputations. In particular, this requires "public randomness" for the otherwise independent precomputations.

Matching Queries. The idea is to precompute and store fingerprints (i.e. hashes) of the substrings $Y_{v,s}$ for every node v in the partition tree and all shifts $s \in \{-k \cdot n^{o(1)}, \dots, k \cdot n^{o(1)}\}$. Then, to answer a query we simply compute the fingerprint of X_v and lookup whether it equals one of the precomputed fingerprints. Alas, a naive implementation of this idea is too slow since upon query we might need to read the whole string X. To obtain the desired sublinear query time, we instead subsample the strings X_v and $Y_{v,s}$ with rate $\approx 1/t_v$. In this way we incur additive Hamming error at most $t_v/2$, as desired. Formally, we show the following lemma in Section 4.1:

▶ **Lemma 6** (Matching Queries). *We can preprocess Y in expected time $n^{1+o(1)}$ to answer $\textsc{Matching}(X, Y, v)$ queries in time $\widetilde{O}(|X_v|/t_v)$ with high probability. Moreover, we can separately preprocess both X and Y in expected time $n^{1+o(1)}$ to answer $\textsc{Matching}(X, Y, v)$ queries in time $O(1)$ with high probability.*

The key difference between the one-sided and the two-sided preprocessing is that in the former we need to compute the fingerprint for X_v, which takes time $O(|X_v|/t_v)$ (we shave the factor t_v due to the subsampling), while in the latter we can afford to precompute these fingerprints and answer the queries faster.
