The reduction then goes as follows. For every $\alpha, \beta \in \mathbb{F}^k$, we introduce a variable $x_{\alpha,\beta}$ which takes value in $\mathbb{F}^\ell$. In the yes-case of k-VectorSum, there exists $\vec{v}_1 \in V_1, \ldots, \vec{v}_k \in V_k$ such that $\sum_{i=1}^{k} \vec{v}_i = \vec{0}$, and we expect $x_{\alpha,\beta}$ to be $f(\alpha, \sum_{i=1}^{k} \beta_i \vec{v}_i)$, in other words, $\sum_{i=1}^{k} \sum_{j=1}^{k} \alpha_i \beta_j (A_1[i]\vec{v}_j, \ldots, A_\ell[i]\vec{v}_j)$ where $A_w[i]$ indicates the i-th row of the w-th matrix. Note that $f(\alpha, \sum_{i=1}^{k} \beta_i \vec{v}_i)$ is a degree-2 polynomial of α and β.

For simplicity of notation, we will use $e_i \in \mathbb{F}^k$ to denote the i-th unit vector, and use $\mathbf{1} \in \mathbb{F}^k$ to denote the all-one vector.

We want to apply four types of tests on those variables:

1. Check whether $x : \mathbb{F}^{2k} \to \mathbb{F}^\ell$ is a vector-valued degree-2 polynomial. This can be done by the low-degree test described in Lemma 6. For each $\vec{\alpha}, \vec{\beta}, \vec{t}_1, \vec{t}_2 \in \mathbb{F}^k$, check whether $\{x_{\vec{\alpha}+i\cdot\vec{t}_1, \vec{\beta}+i\cdot\vec{t}_2} | 0 \leq i \leq 3\}$ are point values of a degree-2 polynomial. Each test is applied on 4 variables, and we say the arity of each such test is 4 in shorthand.
2. Check whether x which maps (α, β) to $x_{\alpha,\beta}$ is linear in both α and β, i.e., whether $x_{\alpha+\alpha',\beta} = x_{\alpha,\beta} + x_{\alpha',\beta}, \forall \alpha, \alpha', \beta \in \mathbb{F}^k$, and $x_{\alpha,\beta+\beta'} = x_{\alpha,\beta} + x_{\alpha,\beta'}, \forall \alpha, \beta, \beta' \in \mathbb{F}^k$. The arity of each such test is 3.
3. For each $u \in [k], \alpha, \beta \in \mathbb{F}^k$, check whether $x_{\alpha,\beta+e_u} - x_{\alpha,\beta} = f(\alpha, \vec{v}) \in \mathbb{F}^\ell$ for some $\vec{v} \in V_u$. The arity of each such test is 2.
4. For each $\alpha, \beta \in \mathbb{F}^k$, check whether $x_{\alpha,\beta+\mathbf{1}} - x_{\alpha,\beta} = \vec{0}$. The arity of each such test is 2.

Construction of the Graph. The vertices are divided into three types. Vertices in each type are further partitioned into groups, and each group forms an independent set:

type-1 There are $(|\mathbb{F}|^{2k})^2$ groups, each of which indicates a test of type 1, and consists of $\leq |\mathbb{F}|^{4\ell}$ vertices corresponding to all satisfying assignments of the 4 variables in the test.

type-2 There are $2(|\mathbb{F}|^k)^3$ groups, each of which indicates a test of type 2, and consists of $\leq |\mathbb{F}|^{2\ell}$ vertices corresponding to all satisfying assignments of the 3 variables in the test.

type-3 There are $|\mathbb{F}|^{2k}$ groups indexed by $(\alpha, \beta) \in \mathbb{F}^{2k}$, each consisting of $\mathbb{F}^\ell$ vertices which correspond to $\mathbb{F}^\ell$ possible assignments for variable $x_{\alpha,\beta}$.

We make copies of vertices, so that the numbers of type-1 groups and type-2 groups are the same, and their sum equals to the number of type-3 groups. Specifically, the three types of vertices are made into $2, |\mathbb{F}|^k, 4\mathbb{F}^{2k}$ copies, respectively. The total number of groups is therefore $k' = 8|\mathbb{F}|^{4k}$, while the total number of vertices is at most $2|\mathbb{F}|^{4k+4\ell} + 2|\mathbb{F}|^{4k+2\ell} + 4|\mathbb{F}|^{4k+\ell} = |\mathbb{F}|^{O(k+\log n)}$.

The edges are specified as follows:

1. A variable (type-3) vertex and a test (type-1/2) vertex are linked if and only if they specify the same assignment for the variable, or the test is irrelevant of that variable.
2. Two test vertices are linked if and only if they are consistent in all variables which appear in both tests.
3. Two variable vertices are linked if and only if the assignments specified by them can pass the above-mentioned third and fourth tests, or there is no such a test between them.

Two different copies of a same vertex are always linked.

Proof of Completeness. If Γ_0 is a yes-instance of k-VectorSum, i.e., there exists $\vec{v}_1 \in V_1, \ldots, \vec{v}_k \in V_k$ such that $\sum_{i=1}^k \vec{v}_i = \vec{0}$, by letting $x_{\alpha,\beta}$ take value $f(\alpha, \sum_{i=1}^k \beta_i \vec{v}_i)$, it's easy to see that such an assignment can pass all tests. Therefore, by picking a vertex from each group accordingly, one can obtain a clique of size k'.

Proof of Soundness. If Γ_0 is a no-instance of k-VectorSum, we will prove that there is no clique of size $\geq (1-\varepsilon)k'$ in G for some small constant ε.

Prove by contradiction. If there is a clique of size $\geq (1-\varepsilon)k'$, it must contain vertices from $\geq (1-2\varepsilon)$ fraction of type-3 groups which represent variables, vertices from $\geq (1-4\varepsilon)$ fraction of type-1 groups which represent low-degree tests, vertices from $\geq (1-8\varepsilon)$ fraction of type-2 groups which represent linearity tests $x_{\alpha+\alpha',\beta} = x_{\alpha,\beta} + x_{\alpha',\beta}$ and vertices from $\geq (1-8\varepsilon)$ fraction of type-2 groups which represent linearity tests $x_{\alpha,\beta+\beta'} = x_{\alpha,\beta} + x_{\alpha,\beta'}$.

In the following, we will denote by $\overline{x}_{\alpha,\beta}$ the assignment for $x_{\alpha,\beta}$ specified by the clique. If no assignment for $x_{\alpha,\beta}$ is specified, set $\overline{x}_{\alpha,\beta}$ arbitrarily as long as it is consistent with all selected test vertices (it is always possible since the selected test vertices are themselves consistent). As almost all low-degree tests and linearity tests are passed, we have:

▶ **Lemma 15.** *If $\varepsilon < \frac{c}{16}$ where c is the constant in Lemma 6, and there is a clique of size $\geq (1-\varepsilon)k'$, then the function $\pi(\alpha,\beta) = \overline{x}_{\alpha,\beta}$ $(\alpha, \beta \in \mathbb{F}^k)$ is 9ε-close to a function on α, β of the form*

$$\sum_{i=1}^{k}\sum_{j=1}^{k} \alpha_i \beta_j C_{i,j}$$

where $C_{i,j} \in \mathbb{F}^l$ denotes the coefficient of the term $\alpha_i\beta_j$.

Proof. Plugging $\delta = 9\varepsilon$ into Theorem 6, if $\pi(\alpha,\beta)$ is not δ-close to any degree-2 polynomial, at least $\min(\delta/2, cd^{-2}) > 4\varepsilon$ fraction of the degree-2 polynomial tests will not be passed. However, when there is a clique of size $\geq (1-\varepsilon)k'$, only $\leq 4\varepsilon$ fraction of degree-2 polynomial tests may fail. Therefore, π must be 9ε-close to a function of the form

$$\sum_{i=1}^{k}\sum_{j=1}^{k} \alpha_i\alpha_j A_{i,j} + \sum_{i=1}^{k}\sum_{j=1}^{k} \beta_i\beta_j B_{i,j} + \sum_{i=1}^{k}\sum_{j=1}^{k} \alpha_i\beta_j C_{i,j} + \sum_{i=1}^{k} D_i\alpha_i + \sum_{i=1}^{k} E_i\beta_i + F \tag{2}$$

where each coefficient is in $\mathbb{F}^l$. We only need to prove that if they also pass most of the linearity tests on α and on β, all coefficients except $C_{i,j}$ must be zeros.

Suppose $A_{i,j} \neq 0$ for some $i, j \in [k]$. Regarding $x_{\alpha+\alpha',\beta} - x_{\alpha,\beta} - x_{\alpha',\beta}$ as a function on $3k$ variables $\alpha_1 \dots \alpha_k, \alpha'_1 \dots \alpha'_k, \beta_1 \dots \beta_k$ and expand it by (2). There is a term $A_{i,j}(\alpha_i\alpha'_j + \alpha'_i\alpha_j)$ which can never be canceled. The function $x_{\alpha+\alpha',\beta} - x_{\alpha,\beta} - x_{\alpha',\beta}$ is not a zero function and by Schwartz-Zippel Lemma, only $\frac{2}{|\mathbb{F}|}$ fraction of α, α', β can make it equal to zero. However, by union bound, there are at least $1 - 8\varepsilon - 3 \cdot (9\varepsilon) > \frac{2}{|\mathbb{F}|}$ fraction of (α, α', β) such that $\overline{x}_{\alpha,\beta}, \overline{x}_{\alpha',\beta}, \overline{x}_{\alpha+\alpha',\beta}$ are all specified value according to the clique, consistent with equation (2), and satisfying $\overline{x}_{\alpha,\beta} + \overline{x}_{\alpha',\beta} = \overline{x}_{\alpha+\alpha',\beta}$, a contradiction. Therefore, $\forall i, j \in [k], A_{i,j} = 0$.

Similar arguments can be applied for the other coefficients and are omitted here. The only term remaining is $\sum_{i=1}^{k}\sum_{j=1}^{k} \alpha_i\beta_j C_{i,j}$ as desired. ◀

We call a variable $x_{\alpha,\beta}$ *good* if the clique consists of a variable vertex of it and it satisfies $\overline{x}_{\alpha,\beta} = \sum_{i=1}^{k}\sum_{j=1}^{k} \alpha_i\beta_j C_{i,j}$. Let $\varepsilon' = 2\varepsilon + 9\varepsilon$, from the above we know at least $(1 - \varepsilon')$ fraction of variables are good. Recall that from the construction of our graph and the property of clique, all arity-2 constraints between good variables are satisfied.

We call an $\alpha \in \mathbb{F}^k$ *excellent* if $\Pr_{\beta \in_R \mathbb{F}^k}[x_{\alpha,\beta} \text{ is good}] \geq \frac{2}{3}$. By Markov's Inequality, at least $1 - 3\varepsilon'$ fraction of α's are excellent.

▶ **Lemma 16.** *For each excellent α and for each $u \in [k]$, $\sum_{i=1}^{k} \alpha_i C_{i,u} = f(\alpha, \vec{v})$ for some unique $\vec{v} \in V_u$.*

Proof. For any fixed $u \in [k]$ and α, the set of edges between the vertex of $x_{\alpha,\beta}$ and the vertex of $x_{\alpha,\beta+e_u}$ for all β can be partitioned into disjoint length-5 cycles $\{x_{\alpha,\beta}, x_{\alpha,\beta+e_u}, \dots, x_{\alpha,\beta+4e_u}\}$ since the characteristic of $\mathbb{F}$ is 5. Observe that if at most two variables in a 5-cycle are not good, there still exist two adjacent vertices that are good.

For an excellent α, at most $\frac{1}{3} \leq \frac{2}{5}$ fraction of variables $x_{\alpha,\beta}$ are not good by definition, so there must exists a $\beta \in \mathbb{F}^k$ such that $x_{\alpha,\beta}$ and $x_{\alpha,\beta+e_u}$ are both good variables. According to the definition of good variables, we have

$$\overline{x}_{\alpha,\beta+e_u} - \overline{x}_{\alpha,\beta} = \sum_{i=1}^{k} \alpha_i C_{i,u}$$

and from the third type of constraints between them we can infer that

$$\overline{x}_{\alpha,\beta+e_u} - \overline{x}_{\alpha,\beta} = f(\alpha, \vec{v})$$

for some $\vec{v} \in V_u$.

Additionally, since for $\vec{v} \in V_u$, $f(\alpha, \vec{v})$ are all different (the second property in Lemma 14), for an excellent α and for all $u \in [k]$, we can deduce $\sum_{i=1}^{k} \alpha_i C_{i,u} = f(\alpha, \vec{v})$ for some unique $\vec{v} \in V_u$. ◀

In the following when $u \in [k]$ is fixed and omitted, we use $\vec{v}_\alpha$ to denote the unique vector in V_u specified by an excellent α. For an α which is not excellent, we also assign a unique vector $\vec{v}_\alpha \in V_u$ to it arbitrarily so that v_α is defined for all $\alpha \in \mathbb{F}^k$.

▶ **Lemma 17.** *If there is a clique of size $\geq (1 - \varepsilon)k'$, then for each $u \in [k]$,*

$$C_{i,u} = (A_1[i]\vec{v}, \dots, A_\ell[i]\vec{v})$$

for some unique $\vec{v} \in V_u$, where $A_w[i]$ indicates the i-th row of the w-th matrix.

Proof. Fix any $u \in [k]$, we first argue that at least $\geq \frac{3}{10}$ fraction of α specify the same $\vec{v} \in V_u$. It suffices to prove

$$\Pr_{\alpha,\alpha' \in_R \mathbb{F}^k}[\vec{v}_\alpha = \vec{v}_{\alpha'}] \geq \frac{3}{10}.$$

If this is not true, by union bound $3 \cdot \frac{3}{10} + 3(3\varepsilon') < 1$, there must exist α, α' such that the following two conditions hold:

1. $\alpha, \alpha', \alpha + \alpha'$ are all excellent.
2. $\vec{v}_\alpha, \vec{v}_{\alpha'}, \vec{v}_{\alpha+\alpha'}$ are all different.

Now that they are all excellent, we have

$$\begin{aligned} f(\alpha + \alpha', \vec{v}_{\alpha+\alpha'}) &= \sum_{i=1}^{k} (\alpha_i + \alpha'_i) C_{i,u} \\ &= f(\alpha, \vec{v}_\alpha) + f(\alpha', \vec{v}_{\alpha'}), \end{aligned}$$

contradicting with the third property in Lemma 14.

Therefore, at least $\frac{3}{10} - 3\varepsilon' > \frac{1}{|\mathbb{F}|}$ fraction of α are all excellent and specify the same $\vec{v} \in V_u$. Now suppose $C_{i,u} \neq (A_1[i]\vec{v}, \ldots, A_\ell[i]\vec{v})$, then there are at most $\frac{1}{|\mathbb{F}|}$ fraction of $\alpha \in \mathbb{F}^k$ making $\sum_{i=1}^{k} \alpha_i C_{i,u} = f(\alpha, \vec{v})$ by Schwartz-Zippel Lemma. However, we have $> \frac{1}{|\mathbb{F}|}$ fraction of such α, a contradiction. ◀

▶ **Lemma 18.** *If there is a clique of size $\geq (1-\varepsilon)k'$, then there exists $\vec{v}_1 \in V_1, ..., \vec{v}_k \in V_k$ such that $\sum_{i=1}^{k} \vec{v}_i = \vec{0}$.*

Proof. From Lemma 17 we know that for each $u \in [k]$, $C_{i,u} = (A_1[i]\vec{v}, \ldots, A_\ell[i]\vec{v})$ for some unique $\vec{v} \in V_u$. Thus $\overline{x}_{\alpha,\beta}$ indeed equals to $f(\alpha, \sum_{i=1}^{k} \beta_i \vec{v}_i)$ for every good variable $x_{\alpha,\beta}$.

The remaining proof is very similar to the proof of Lemma 16. Edges between the vertex of $x_{\alpha,\beta}$ and the vertex of $x_{\alpha,\beta+\mathbf{1}}$ for all $\beta \in \mathbb{F}^k$ can be divided into disjoint length-5 cycles $\{x_{\alpha,\beta}, x_{\alpha,\beta+\mathbf{1}}, \ldots, x_{\alpha,\beta+4\cdot\mathbf{1}}\}$ since the characteristic of $\mathbb{F}$ is 5.

For an excellent α, at most $\frac{1}{3} \leq \frac{2}{5}$ fraction of variables $x_{\alpha,\beta}$ are not good, so there must be two variables $x_{\alpha,\beta}$ and $x_{\alpha,\beta+\mathbf{1}}$ which are both good. According to the definition of good variables, we have

$$\overline{x}_{\alpha,\beta+s} - \overline{x}_{\alpha,\beta} = f\left(\alpha, \sum_{i=1}^{k} \vec{v}_i\right)$$

and from the fourth type of constraints between them we can infer that

$$\overline{x}_{\alpha,\beta+\mathbf{1}} - \overline{x}_{\alpha,\beta} = \vec{0}.$$

Therefore, $f(\alpha, \sum_{i=1}^{k} \vec{v}_i) = \vec{0}$ for every excellent α.

Suppose $\sum_{i=1}^{k} \vec{v}_i \neq \vec{0}$, then there exists $i \in [\ell]$ such that $A_i(\sum_{i=1}^{k} \vec{v}_i) \neq \vec{0}$ by the first property in Lemma 14. There are at most $\frac{1}{|\mathbb{F}|}$ fraction of α such that $f(\alpha, \sum_{i=1}^{k} \vec{v}_i) = \vec{0}$ by Schwartz-Zippel Lemma, but we have $\geq 1 - 3\varepsilon'$ fraction of excellent α, a contradiction. ◀

3.3 Putting Things Together

Combing Theorem 11 with Theorem 13, we obtain an improved lower bound for constant gap k-Clique under ETH as follows.

▶ **Theorem 1.** *Assuming* ETH*, for any constant $c > 1$ and any computable function f, no algorithm can find a clique of size k/c in the k-Clique problem in $f(k)n^{o(\log k)}$ time.*

Proof. Without loss of generality assume f is non-decreasing and unbounded. Given a 3SAT formula φ with n variables, each appearing in at most 3 clauses, we first run the reduction in Theorem 11 to produce a k-VectorSum instance of size $2^{O(n/k)}$, then run the reduction

in Theorem 13 to produce a constant gap c^k-Clique instance of size at most $c^k 2^{O(n/k)}$. Using the graph product method, we can amplify the gap to any constant, while keeping the parameter $k' = c^{O(k)}$ and instance size $n' \leq c^{O(k)} 2^{O(n/k)}$. Therefore, an $f(k')n^{o(\log k')}$ time algorithm for constant gap k'-Clique would lead to an algorithm for 3SAT in

$$f(k')(n')^{o(\log k')} \leq f(c^{O(k)})(c^{O(k)}2^{O(n/k)})^{o(k)} \leq 2^{o(n)}$$

time, contradicting ETH. The last inequality holds because n can be sufficiently large compared to k. ◀

Below we present two remarks about possible extensions of our results on ETH lower bounds of gap k-Clique.

▶ Remark 19 (On higher degree Reed-Muller Codes). It is natural to extend our idea to obtain a reduction from k-VectorSum to a CSP problem with $< 2^{o(k)}$ variables using Reed–Muller code with larger degree polynomials. However, the reduction from CSP to k-Clique has such an important property: when there is a clique of size εk for some constant ε, the following two conditions hold:

1. A constant fraction of arity-d constraints ($d > 2$) are satisfied.
2. All arity-2 constraints between a constant fraction of variables are satisfied.

The second condition holds because an arity-2 constraint between two variables can be directly transformed into an edge between two vertices. If there is a large clique, it means all arity-2 constraints between the involved variables are simultaneously satisfied. However, if we use larger degree polynomials, the arity of constraints has to be larger, too. It cannot directly fit into the framework of k-Clique. If this barrier can be broken, it may be possible to obtain reductions with an even smaller parameter blow-up using larger degree polynomials.

▶ Remark 20 (On locally decodable codes). Our reduction implicitly depends on the property of 2-query locally decodable code, that we could decode $f(\alpha, \vec{v_i})$ for some fixed α by querying only 2 positions. As pointed out in [13], 2-query locally decodable code has at least an exponential blow up. Hence our method is optimal in this sense. We could also consider how to remove this dependence.

4 $k^{o(1)}$-Ratio FPT Inapproximability of k-Clique under ETH

In this section, we show how to use expander graphs to amplify the gap efficiently, and how it leads to an improved inapproximability ratio of k-Clique in FPT time under ETH. The idea comes from the classical technique used to amplify gap in the non-parameterized version of Clique problem, which was proposed by Alon et al. [3].

▶ **Theorem 21.** *For some constants $d \in \mathbb{N}, 0 < \lambda < 1$ and for any $t \in \mathbb{N}$, there is an algorithm which runs in $O(k^2 d^{2t} |V|^{2t})$ time, on input an instance $\Gamma = (V, E)$ of k-Clique problem, outputs an instance Γ' of k'-Clique problem such that*

- *$k' = kd^{t-1}$.*
- *(Completeness.) If Γ has a k-clique, then Γ' has a k'-clique.*
- *(Soundness.) If Γ has no εk-clique, then Γ' has no clique of size $k'((1-\lambda)\sqrt{\varepsilon} + \lambda)^{t-1}$.*

Proof. Let H be an (k, λ, d)-expander constructed from Lemma 8. We construct Γ' as follows. Each of the $k' = kd^{t-1}$ groups in Γ' is associated with a unique path of length-t random walk on H. We use $(c_1, \ldots, c_t)$ to name a group in Γ', where each $c_i \in [k]$ indicates a group in Γ.

A vertex in Γ' is a length-t sequence of vertices in Γ. Namely, there is a vertex $(u_1, \ldots, u_t)$ in the $(c_1, \ldots, c_t)$-th group in Γ' if and only if each u_i is belongs to group c_i in Γ. Therefore, the total number of vertices is at most $kd^{t-1}|V|^t$ in Γ'.

A vertex $(u_1, \ldots, u_t)$ in group $(c_1, \ldots, c_t)$ is linked to a vertex $(v_1, \ldots, v_t)$ in group $(d_1, \ldots, d_t)$ if and only if

- $(c_1, \ldots, c_t) \neq (d_1, \ldots, d_t)$,
- and the vertices $\{v_1, \ldots, v_t, u_1, \ldots, u_t\}$ form a clique in Γ.

The reduction runs in $O(k^2 d^{2t}|V|^{2t})$ time by simply enumerating every pair of vertices in Γ' and checking if there is an edge between them.

Completeness. Let $\{v_1, \ldots, v_k\}$ be an k-clique in Γ. Then in group $(c_1, \ldots, c_t)$ in Γ', we can pick the vertex $(v_{c_1}, \ldots, v_{c_t})$. It's easy to see those vertices form an kd^{t-1}-clique.

Soundness. For any clique V in Γ', let U be the collection of vertices in Γ which appear as part of the name of a vertex in V. Since V is a clique in Γ', it follows by construction that U is also a clique in Γ and thus $|U| \leq \varepsilon k$. Recall that each $(c_1, \ldots, c_t)$ represents a length-t random walk on H, and all those c_i's lie in a set of size $\leq \varepsilon k$ (which corresponds to the collection of groups that vertices in U belong to). By plugging $n = k, |\mathcal{B}| \leq \varepsilon k$ into Lemma 7, the number of different groups that vertices in V belong to is bounded by $kd^{t-1}((1-\lambda)\sqrt{\varepsilon} + \lambda)^{t-1}$, and so is $|V|$. ◀

For any function $\delta(k) = o(1)$, by setting t to be as large as some $o(\log k)$, we can make $\varepsilon' = ((1-\lambda)\sqrt{\varepsilon} + \lambda)^{t-1}$ smaller than $k^{-\delta(k)}$ while keeping $k' = kd^{t-1} \leq k^{O(1)}$. Thus, by combining Theorem 1 and Theorem 21, we have the following corollary.

▶ **Corollary 2.** *Assuming* ETH*, for any $g(k) = k^{o(1)}$, the k-*Clique *problem has no $g(k)$-FPT-approximation algorithm.*

5 From Constant Gap k-Clique to PIH

In this section we will show that strong lower bound of constant gap k-Clique implies PIH. For simplicity of notation, we additionally define problems Gap-clique(k, ℓ) and Gap-biclique(k, ℓ) $(k > \ell)$, whose definitions are almost the same as k-Clique and k-Biclique, except that the soundness parameter is ℓ. We have the following theorem:

▶ **Theorem 3.** *If* Gap-clique$(k, \varepsilon k)$ *does not admit $f(k) \cdot n^{O(\frac{k}{\log k})}$-time algorithms for some $0 < \varepsilon < 1$, then* PIH *is true.*

The proof is relatively elementary and consists of three steps: first reduce constant gap k-Clique to constant gap k-Biclique, then use a *disperser* to compress the soundness parameter to $\frac{\log k}{k}$, finally use the Kővári-Sós-Turán Theorem to show that in the soundness case, the density of every $2k$-vertex bipartite subgraph is low.

▶ **Lemma 22.** *If* Gap-clique$(k, \varepsilon k)$ *does not admit $f(k) \cdot n^{O(\frac{k}{\log k})}$-time algorithms for some $0 < \varepsilon < 1$, then neither does* Gap-biclique$(k, \frac{1+\varepsilon}{2}k)$.

Proof. We reduce a Gap-clique$(k, \varepsilon k)$ instance $G = (V_1 \dot\cup \ldots \dot\cup V_k, E)$ to a Gap-biclique$(k, \frac{1+\varepsilon}{2}k)$ instance $G' = (U_1 \dot\cup \ldots \dot\cup U_k, W_1 \dot\cup \ldots \dot\cup W_k, E)$ as follows.

The vertex sets in each side are just copies of V, i.e., $U_i = W_i = V_i, \forall i \in [k]$. Two vertices $u \in U_i, w \in W_j$ where $i \neq j$ are linked if and only if their corresponding vertices are linked in G, while two vertices $u \in U_i, w \in W_i$ are linked iff they correspond to the same vertex in G.

The completeness case is obvious. In the soundness case, suppose we can pick $\frac{1+\varepsilon}{2}k$ vertices from different parts of U and $\frac{1+\varepsilon}{2}k$ vertices from different parts of W such that they form a biclique. Let the collection of picked vertices be S. Then there must be an index set $\mathcal{I}$ of size εk such that $\forall i \in \mathcal{I}$, $(S \cap U_i \neq \emptyset) \wedge (S \cap W_i \neq \emptyset)$. Moreover, $|S \cap U_i| = |S \cap W_i| = 1$ by our construction of edges between U_i and W_i. Then consider the set $\bigcup_{i \in \mathcal{I}}(S \cap U_i)$ which is of size at least εk. The vertices in it must form a clique of size $|\mathcal{I}|$ in the original graph G. ◀

▶ **Lemma 23.** *If* Gap-Biclique$(k, \varepsilon k)$ *does not admit* $f(k) \cdot n^{O(\frac{k}{\log k})}$*-time algorithms for some constant* $0 < \varepsilon < 1$*, then for any constant* $0 < c < 1$*, no algorithm can solve* Gap-Biclique$(k, c \log k)$ *in* $f(k) \cdot n^{O(1)}$ *time.*

Proof. Given a Gap-Biclique$(k, \varepsilon k)$ instance $G = (U_1 \dot\cup \ldots \dot\cup U_k, W_1 \dot\cup \ldots \dot\cup W_k, E)$, let $\ell = \lceil \frac{3k}{\varepsilon c \log k} \rceil$ and let $\mathcal{I} = (I_1, \ldots, I_k)$ be a $(k, k, \ell, c \log k, 1-\varepsilon)$-disperser. Since the size of $\mathcal{I}$ is independent of n, we can deterministically enumerate all possible $\mathcal{I}$ to find a valid one in $f(k)$ time. The existence of such a disperser is guaranteed by Lemma 10. We construct a new Gap-Biclique$(k, c \log k)$ instance $G' = (U'_1 \dot\cup \ldots \dot\cup U'_k, W'_1 \dot\cup \ldots \dot\cup W'_k, E)$ as follows.

The groups of vertices in G' correspond to the combination of groups in G according to the disperser. Specifically, for $1 \leq i \leq k$, let $I_i = \{i_1, \ldots, i_\ell\}$, then each vertex in U'_i will correspond to a tuple of vertices $(u_{i_1}, \ldots, u_{i_\ell})$ where u_{i_j} comes from U_{i_j} in G for all $1 \leq j \leq \ell$. The construction of right vertices $W'_1, \ldots W'_k$ is similar. The size of the new instance is therefore at most $n^\ell = n^{O(\frac{k}{\log k})}$.

An edge between a left vertex $(u_{i_1}, \ldots, u_{i_\ell})$ and a right vertex $(w_{j_1}, \ldots, w_{j_\ell})$ exists if and only if the vertices $\{u_{i_1}, \ldots, u_{i_\ell}, w_{j_1}, \ldots, w_{j_\ell}\}$ form a biclique $K_{\ell,\ell}$ in G.

The completeness case is still obvious, and we focus on the soundness case. Prove by contradiction, if there exists $c \log k$ vertices from different groups of U' and $c \log k$ vertices from different groups of W' which form a biclique $K_{c \log k, c \log k}$, let S be the collection of vertices which appear as part of one of the $2c \log k$ tuples. For $1 \leq i \leq k$, arbitrarily pick one vertex from each $S \cap U_i$, $S \cap W_i$ if not empty, then we claim that the resulting collection must be a biclique of size $\geq \varepsilon k$ on both sides. The promise of biclique is from our construction, while the size is guaranteed by properties of the disperser.

Therefore, an $f(k) \cdot n^{O(1)}$ time algorithm for the Gap-Biclique$(k, c \log k)$ problem would lead to an $f(k) \cdot \left(n^{O(\frac{k}{\log k})}\right)^{O(1)} = f(k) \cdot n^{O(\frac{k}{\log k})}$ time algorithm for Gap-Biclique$(k, \varepsilon k)$ problem. This completes the proof. ◀

▶ **Theorem 24** (Kővári-Sós-Turán, [19])**.** *For any graph* G *on* n *vertices, if* G *does not contain* $K_{a,a}$ *as a subgraph, then* G *has at most* $O(n^{2-1/a})$ *edges.*

Proof of Theorem 3. By plugging in $a = c \log k$ for some sufficiently small constant $0 < c < 1$ such that the $O(k^{2-1/(c \log k)})$ in Theorem 24 is no more than $\varepsilon' k^2$ for some constant $0 < \varepsilon' < 1$, Theorem 24 and Lemma 23 imply that if Gap-Biclique$(k, \varepsilon k)$ does not admit $f(k) \cdot n^{O(\frac{k}{\log k})}$-time algorithms, then no FPT algorithm can distinguish the following cases for a k-Biclique instance $G = (U, W, E)$ with

- *(Completeness.)* there exists $u_1 \in U_1, \ldots, u_k \in U_k, w_1 \in W_1, \ldots w_k \in W_k$ such that they form a biclique $K_{k,k}$.
- *(Soundness.)* for all $u_1 \in U_1, \ldots, u_k \in U_k, w_1 \in W_1, \ldots w_k \in W_k$, the vertex set $\{u_1, \ldots, u_k, v_1, \ldots, v_k\}$ induce a subgraph with at most $O(k^{2-1/(c \log k)}) \leq \varepsilon' k^2$ edges for some constant $0 < \varepsilon' < 1$.

We link all pairs of vertices which are on the same side but not in the same group. In the completeness case, we can find $2k$ vertices from distinct groups such that they form a clique and thus the number of edges induced is $\binom{2k}{2}$. In the soundness case, the number of edges induced by $2k$ vertices from distinct groups is at most $\varepsilon' k^2 + 2\binom{k}{2} < \varepsilon''\binom{2k}{2}$ for some $0 < \varepsilon'' < 1$.

At last, by Lemma 22, if Gap-clique$(k,\ \varepsilon k)$ does not admit $f(k) \cdot n^{O(\frac{k}{\log k})}$-time algorithms for some $0 < \varepsilon < 1$, then neither does Gap-biclique$(k,\ \frac{1+\varepsilon}{2}k)$, hence no FPT-algorithm can approximate Densest k-Subgraph to an ε'' factor. ◀

6 Conclusion

In this paper, we provide a tighter ETH-lower bound for constant gap k-Clique by replacing the Hardamard code used in [20] by the Reed-Muller Code with degree-2 polynomials. We use gap amplification techniques by expander graphs to rule out $k^{o(1)}$-ratio FPT-approximation algorithms for k-Clique under ETH. We also study the relationship between the constant gap k-Clique problem and PIH. We show that almost tight lower bounds for constant gap k-Clique can imply PIH.

A natural open question is whether we can derive such a lower bound for constant gap k-Clique under ETH. Formally, it is stated as follows:

Question 1. Assuming ETH, does constant gap k-Clique admit an algorithm in $f(k) \cdot n^{O(\frac{k}{\log k})}$ time?

It is also worth noting that assuming ETH, there is no $2^{o(n)}$-time algorithm for non-parameterized Max-Clique problem on n-vertex graphs. Hence, it is natural to ask whether our technique can be analogously applied to non-parameterized Max-Clique to obtain tight lower bounds:

Question 2. Assuming ETH, does constant gap Max-Clique admit an algorithm in $2^{o(n)}$ time?

Backdoor Sets on Nowhere Dense SAT

Abstract

For a satisfiable CNF formula ϕ and an integer t, a *weak backdoor set* to treewidth-t is a set of variables such that there is an assignment to this set that reduces ϕ to a *satisfiable* formula that has an incidence graph of treewidth at most t. A natural research program in the work on fixed-parameter algorithms (FPT algorithms) for SAT is to delineate the tractability borders for the problem of detecting a small weak backdoor set to treewidth-t formulas. In this line of research, Gaspers and Szeider (ICALP 2012) showed that detecting a weak backdoor set of size at most k to treewidth-1 is W[2]-hard parameterized by k if the input is an arbitrary CNF formula. Fomin, Lokshtanov, Misra, Ramanujan and Saurabh (SODA 2015), showed that if the input is d-CNF, then detecting a weak backdoor set of size at most k to treewidth-t is fixed-parameter tractable (parameterized by k, t, d). These two results indicate that sparsity of the input plays a role in determining the parameterized complexity of detecting weak backdoor sets to treewidth-t.

In this work, we take a major step towards characterizing the precise impact of sparsity on the parameterized complexity of this problem by obtaining algorithmic results for detecting small weak backdoor sets to treewidth-t for input formulas whose incidence graphs belong to a *nowhere-dense graph class*. Nowhere density provides a robust and well-understood notion of sparsity that is at the heart of several advances on model checking and structural graph theory. Moreover, nowhere-dense graph classes contain many well-studied graph classes such as *bounded treewidth graphs, graphs that exclude a fixed (topological) minor and graphs of bounded expansion*.

Our main contribution is an algorithm that, given a formula ϕ whose incidence graph belongs to a fixed nowhere-dense graph class and an integer k, in time $f(t,k)|\phi|^{\mathcal{O}(1)}$, either finds a satisfying assignment of ϕ, or concludes correctly that ϕ has no weak backdoor set of size at most k to treewidth-t.

To obtain this algorithm, we develop a strategy that only relies on the fact that nowhere-dense graph classes are biclique-free. That is, for every nowhere-dense graph class, there is a p such that it is contained in the class of graphs that exclude $K_{p,p}$ as a subgraph. This is a significant feature of our techniques since the class of biclique-free graphs also generalizes the class of graphs of bounded degeneracy, which are *incomparable* with nowhere-dense graph classes. As a result, our algorithm also generalizes the results of Fomin, Lokshtanov, Misra, Ramanujan and Saurabh (SODA 2015) for the special case of d-CNF formulas as input when d is fixed. This is because the incidence graphs of such formulas exclude $K_{d+1,d+1}$ as a subgraph.

1 Introduction

A central concept in the design of fixed-parameter algorithms for SAT is the notion of *backdoor sets* introduced by Williams et al. [41], which was also introduced under a different name by Crama et al. [9]. These are sets of variables in the input formula whose instantiation can lead to a dramatic simplification of the formula, moving the formula into a class where SAT is easy to solve, such as *Horn formulas*. Backdoor sets provide a natural way to express the deviation of a SAT instance from well-studied "islands of tractability" (i.e., tractable cases of SAT) and allow us to study the question -"could we easily solve SAT instances that do not necessarily fall neatly within a known tractable fragment, yet are 'close' to them?"

To formalize this idea, fix a class of CNF formulas, call it $\mathcal{C}$, which is also called the *base* class. Let ϕ be the input instance of SAT. If ϕ is satisfiable, then a nonempty subset B of the variables in ϕ is a *weak backdoor* of ϕ to the class $\mathcal{C}$ (or a weak $\mathcal{C}$-backdoor set) if there exists an assignment τ to the variables in B such that the reduced instance $\phi[\tau]$ is a satisfiable formula in the class $\mathcal{C}$. We say that B is a *strong backdoor* of ϕ to the class $\mathcal{C}$ (or strong $\mathcal{C}$-backdoor set) if, for every assignment τ to the variables in B, the reduced instance $\phi[\tau]$ is in $\mathcal{C}$. Clearly, if $\mathcal{C}$ is a class of formulas on which SAT can be efficiently solved and one knows a weak/strong $\mathcal{C}$-backdoor set of the input instance, then a straightforward way of checking satisfiability and computing a satisfying assignment of the input instance involves exploring all instantiations of the variables in the backdoor set and efficiently solving the simplified instances.

Over the last two decades, there has been an active theoretical research program on SAT – the design of algorithms for SAT by exploring the *parameterized complexity* of computing and utilizing small backdoor sets to an efficiently-solvable class of CNF formulas. The study of the parameterized complexity of the problem of finding small backdoor sets was formally initiated by Nishimura et al. [33] and over the past decade and a half, there has been an extensive study of backdoors for SAT in the realm of parameterized complexity (see [37, 39, 35, 26, 13, 21] for a partial list). We refer to the survey of Gaspers and Szeider [25] for an overview of many of these works. In recent years, the success brought to the parameterized complexity of SAT by the study of backdoor detection has been replicated for CSP [2, 4, 20, 17, 18] and Mixed-ILP [16]. We refer to the survey [22] for a more comprehensive picture of the state of the art on backdoors to CSPs.

A basic part of this research program exploring the parameterized complexity of SAT is to answer the question:

For which input formulas is the detection of small backdoors to the class of bounded-treewidth formulas fixed-parameter tractable?

Bounded-treewidth formulas are CNF formulas whose incidence graphs have bounded treewidth and it is well-known that SAT is efficiently solvable on these [10, 15, 38]. The study of computing small backdoors to bounded-treewidth formulas from the parameterized complexity perspective was initiated by Gaspers and Szeider in [23] and further studied in [24, 26]. Gaspers and Szeider [23] gave an FPT-approximation algorithm for the problem of computing a strong backdoor set to Acyclic formulas, which was later extended to bounded-treewidth formulas [26]. Specifically, they gave an algorithm that runs in time $f(k)|\phi|^{\mathcal{O}(1)}$, for some computable function f, and either detects a strong backdoor in ϕ of size at most 2^k to bounded-treewidth formulas or reports that there is no such strong backdoor of size at most k. Since approximate backdoor sets are also sufficient to solve SAT, they were able to conclude that SAT parameterized by the size of a smallest strong backdoor set to

bounded-treewidth formulas is fixed-parameter tractable *with no restrictions on the input*. On the other hand, the picture for weak backdoor sets is much less comprehensive and is the main motivation behind our work.

State of the art for detecting weak backdoors

In [23], Gaspers and Szeider studied the problem of detecting a weak backdoor of size at most k to Acyclic formulas, i.e, formulas with incidence graphs of treewidth at most 1. They showed that this problem is W[2]-hard in general but fixed-parameter tractable (FPT) on d-CNF formulas for every fixed d. This implies that d-SAT parameterized by the size of a smallest weak backdoor set to Acyclic formulas is fixed-parameter tractable. This result was subsequently improved by Fomin et al. [13], who showed that d-SAT parameterized by the size of a smallest weak backdoor set to bounded-treewidth formulas is fixed-parameter tractable. The lack of progress in this direction since then, means that the state of the art on detecting weak backdoors to bounded-treewidth formulas continues to experience a huge gap between instances for which we know parameterized hardness results (i.e., general CNF formulas) and instances for which we have FPT algorithms (i.e., d-CNF). Where exactly does the tractability border lie? This brings us to the overarching goal of identifying maximal classes of CNF formulas for which SAT is FPT when parameterized by the size of a smallest weak backdoor set to the class of bounded-treewidth formulas.

Our work

Since the incidence graphs of d-CNF formulas only have linearly-many edges in the number of clauses, a natural step towards the overarching goal outlined above is to first understand the effect that the "sparsity" of the input incidence graph has on the tractability of the problem. In particular, could one show that as long as the input has bounded degeneracy or is nowhere dense [32], then SAT is FPT parameterized by the size of a smallest weak backdoor set to bounded-treewidth formulas? Nowhere density yields a robust notion of a maximal sparse graph class and nowhere-dense graph classes have been at the heart of major developments in graph theory and model checking [31, 27, 29] in the last decade. Therefore, one could reasonably hope to harness the techniques developed in these efforts, towards our purpose. Starting from this point, in this paper, we obtain tractability results that take us simultaneously beyond the class of nowhere-dense graphs and graphs of bounded degeneracy. Towards this, we initiate the study of weak backdoor detection on *biclique-free formulas*. More precisely, we consider $K_{d,d}$-free formulas, which are CNF formulas where no set of d clauses contain literals from d variables in their common intersection. In graph-theoretic terms, the incidence graphs of $K_{d,d}$-free formulas exclude the complete bipartite graph $K_{d,d}$ as a subgraph. $K_{d,d}$-free graphs are very wide class of sparse graphs and include many well-studied graph classes such as *bounded treewidth graphs, graphs that exclude a fixed minor, graphs of bounded expansion, nowhere-dense graphs and graphs of bounded degeneracy*. That is, for any of the classes – bounded treewidth graphs, graphs that exclude a fixed minor, graphs of bounded expansion, nowhere-dense graphs and graphs of bounded degeneracy, there is a p such that the class is contained in the class of $K_{p,p}$-free graphs (see Figure 1 for an illustration of the inclusion relation between these classes).

1.1 Our results

In order to present our results in the most general terms possible, we consider weak backdoor sets not just to bounded treewidth formulas, but what we call $\mathcal{F}$-minor-free formulas. Let $\mathcal{F}$ be a finite set of graphs. For a CNF formula ϕ, a set S of variables is called *a weak*

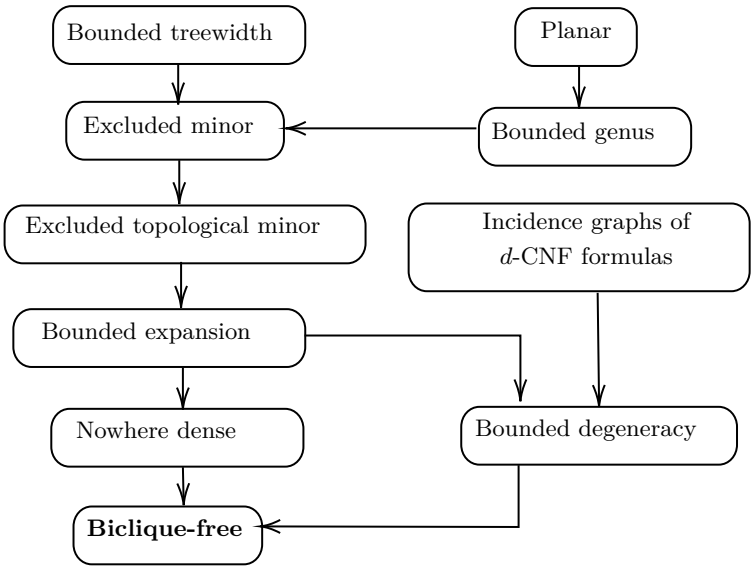

Figure 1 Inclusion relation between the class of biclique-free graphs considered in this paper and well-studied graph classes in the literature (figure based on [40]). If there in arrow of the form $A \to B$, then class A is a subclass of B.

$\mathcal{F}$-minor-free backdoor set of ϕ if it is a weak backdoor set of ϕ into the class of CNF formulas whose incidence graphs exclude every graph in $\mathcal{F}$ as a minor. Notice that a weak backdoor set of a formula into treewidth-t formulas is also a weak $\mathcal{F}$-minor-free backdoor set for some $\mathcal{F}$ – take $\mathcal{F}$ to be precisely the set of forbidden minors for graphs of treewidth at most t. Note that the size of $\mathcal{F}$ depends only on t. The reason for studying the problem in this more general setting is that it allows us to also obtain an additional result from the proof techniques used for our main result. Moreover, due to the extensive work in parameterized complexity on connections between vertex-deletion problems to bounded treewidth graphs and vertex-deletion problems to minor-free graphs, there is a rich collection of powerful algorithmic techniques that we are able to draw from (see, for example, [14, 19, 13]).

We now state our central result formally and discuss our corollaries and further context.

▶ **Theorem 1.** *For every $d \in \mathbb{N}$, there is a computable function f_d and an algorithm $\mathcal{A}_d$ that satisfies the following:*

1. *$\mathcal{A}_d$ takes as input a $K_{d,d}$-free formula ϕ, a family $\mathcal{F}$ of graphs containing at least one planar graph, and an integer k.*
2. *$\mathcal{A}_d$ runs in time $f_d(\mathcal{F}, k) \cdot |\phi|^{\mathcal{O}(d)}$.*
3. *$\mathcal{A}_d$ either outputs a weak $\mathcal{F}$-minor-free-backdoor set of ϕ of size at most k, or concludes correctly that ϕ has no weak $\mathcal{F}$-minor-free-backdoor set of size at most k.*

Let us first make a few remarks regarding the time-complexity of the algorithm described in the above statement. First of all, in the running time of the above algorithm, the exponent in the term $|\phi|^{\mathcal{O}(d)}$ is independent of k and $\mathcal{F}$. Secondly, as our main goal is to obtain a fixed-parameter tractability classification result, and as we have proved our result in such general terms, we have not attempted to optimize the function f_d. Indeed, due to the standard step of invoking Courcelle's theorem as a subroutine when the input treewidth is already bounded (see, for example, [23, 26]) one should not expect this algorithm to be practical *as presented*. However, our result is an important proof of concept demonstrating

fixed-parameter tractability for such a general class of inputs. We believe that optimizing the function f_d is a more meaningful research question for specific subclasses of $K_{d,d}$-free formulas, e.g., formulas with incidence graphs that exclude a fixed graph as a minor.

We now describe the main consequences of our result. As discussed, it is well-known that satisfiability of a t-tw formula (i.e., a CNF formula whose incidence graph has treewidth at most t) can be tested in linear time for every fixed t and moreover, a satisfying assignment can be computed in the same time. Therefore, we can combine Theorem 1 with the fact that graphs of treewidth at most t have a finite and computable set of forbidden minors that include the $(t+1) \times (t+1)$-grid, which is a planar graph. This leads us to the first FPT algorithm for SAT on $K_{d,d}$-free formulas (for fixed d) parameterized by $t + \mathsf{wb}_t(\phi)$. Here, $\mathsf{wb}_t(\phi)$ denotes the size of a smallest weak t-tw-backdoor set of ϕ. The formal statement follows.

▶ **Theorem 2.** *For every $d \in \mathbb{N}$, there is a computable function f_d and an algorithm that, given $t \in \mathbb{N}$, a $K_{d,d}$-free formula ϕ and an integer k, runs in time $f_d(t,k)|\phi|^{\mathcal{O}(d)}$ and either finds a satisfying assignment of ϕ, or concludes correctly that ϕ has no weak t-tw-backdoor set of size at most k.*

An immediate corollary of the above theorem is that d-SAT is FPT parameterized by $t + \mathsf{wb}_t(\phi)$ for every fixed d. To obtain this, notice that a d-CNF formula is $K_{d+1,d+1}$-free.

A further consequence of the techniques used to prove Theorem 1 is in the case of weak backdoor sets to *nested formulas*. These form a subclass of $K_{3,3}$-free formulas and are known to have treewidth at most 3 (see preliminaries for the formal definition of nested formulas). However, this is not a precise characterization of these formulas, so we need a minor modification in the proof of Theorem 1 to obtain the following result.

▶ **Theorem 3.** *For every $d \in \mathbb{N}$, there is a computable function f_d and an algorithm that, given $t \in \mathbb{N}$, a $K_{d,d}$-free formula ϕ and an integer k, runs in time $f_d(t,k)|\phi|^{\mathcal{O}(d)}$ and either finds a satisfying assignment of ϕ, or concludes correctly that ϕ has no weak backdoor set of size at most k to the class of nested formulas.*

Hardness results for strong and weak backdoor detection

To complement our algorithmic results, we also show new hardness results that strengthen existing results. Towards this, we present a polynomial-time algorithm that, given a Set Cover instance $I = (U, \mathcal{S})$, numbers $d, d' \geq 2$ and a non-negative number k, outputs a CNF formula ϕ such that if I has a set cover of size k, then ϕ has a strong/weak backdoor set of size k to the class of empty formulas, which are formulas with no clauses. Conversely, if ϕ has a strong/weak backdoor set of size k to any subclass of $\mathcal{K}_{d,d'}$-free formulas, then I has a set cover of size k. This algorithm is effectively a reduction that implies that for any class $\mathcal{C}$ that is a superclass of empty formulas and a subclass of $\mathcal{K}_{d,d}$-free formulas for some $d \in \mathbb{N}$, the problem of detecting a strong/weak backdoor to $\mathcal{C}$ of size at most k is at least as hard as solving Set Cover parameterized by the solution size (i.e., it is W[2]-hard).

In particular, notice that for every $t \geq 0$, there exists a $d \geq 2$ such that t-tw-CNF is a subclass of $K_{d,d}$-free formulas. Moreover, nested formulas are subclasses of $K_{3,3}$-free formulas. Hence, we obtain the following consequences.

▶ **Theorem 4.** *For every $t \geq 0$, family $\mathcal{F}$ that contains a planar graph but does not contain an independent set, and for each class $\mathcal{C} \in \{t$-tw formulas, nested formulas, $\mathcal{F}$-minor-free formulas$\}$, the problem of detecting a strong/weak backdoor set to $\mathcal{C}$ of size at most k is $W[2]$-hard parameterized by k.*

Table 1 Our results for weak backdoor detection in relation to the state of the art. Each row corresponds to a base class into which we are finding a backdoor set. Each column corresponds to a possible class of inputs.

	Input: d-CNF	Input: $K_{d,d}$-free CNF	Input: CNF
Acyclic	FPT [23]	**FPT (Theorem 2)**	W[2]-hard [23]
Nested	**FPT**	**FPT (Theorem 3)**	W[2]-hard (**Theorem 4**)
tw-t (for every t)	FPT [13]	**FPT (Theorem 2)**	W[2]-hard (**Theorem 4**)
Planar-$\mathcal{F}$ minor-free	**FPT**	**FPT** (Theorem 1)	W[2]-hard (**Theorem 4**)

This theorem strengthens the hardness result of Gaspsers and Szeider [23] and shows that not only is it W[2]-hard to detect small weak backdoor sets (with no restriction on the input) to Acyclic formulas, but also to treewidth-t formulas for every fixed t.

2 Preliminaries

CNF Formulas

We consider propositional formulas in conjunctive normal form (CNF). In our algorithms to compute weak backdoor sets to bounded-treewidth formulas, we do not assume that the clauses exclude a pair of complementary literals. However, when the goal is to solve SAT, it can be assumed without loss of generality that the input formula does not contain a clause with a pair of complementary literals. For a CNF formula ϕ, we use $\mathsf{var}(\phi)$ and $\mathsf{cla}(\phi)$ to refer to the sets of variables and clauses in ϕ, respectively. We say that a variable x is positive (negative) in a clause C if $x \in C$ ($\overline{x} \in C$), and we write $\mathsf{var}(C)$ for the set of variables that are positive or negative in C, while we use $\mathsf{lit}(C)$ to denote the set of literals in C. For a set $\mathcal{C}$ of clauses, we use $\mathsf{var}(\mathcal{C})$ to denote $\bigcup_{C\in\mathcal{C}} \mathsf{var}(C)$ and call this set *the set of variables of* $\mathcal{C}$. Given a CNF formula ϕ and a truth assignment τ, $\phi[\tau]$ denotes the *truth assignment reduct* of ϕ under τ, which is the CNF formula obtained from ϕ by first removing all clauses that are satisfied by τ and second removing from the remaining clauses all literals $x, \overline{x}$ with $x \in \mathsf{var}(\tau)$. The assigned variables are also removed.

Incidence graphs

The *incidence graph* of a CNF formula ϕ, $\mathsf{inc}(\phi)$, is the bipartite graph whose vertices are the variables and clauses of ϕ, and where vertices corresponding to a variable x and a clause C are adjacent if and only if $x \in \mathsf{var}(C)$. Further, an edge between a vertex corresponding to $x \in \mathsf{var}(\phi)$ and $C \in \mathsf{cla}(\phi)$ has the *polarity* (or *label*) $+$ if $x \in \mathsf{lit}(C)$ and $\overline{x} \notin \mathsf{lit}(C)$ and is labeled $-$ if $\overline{x} \in \mathsf{lit}(C)$ and $x \notin \mathsf{lit}(C)$. If $x, \overline{x} \in \mathsf{lit}(C)$, then this edge is labeled $\mathfrak{b}$. For an incidence graph G, we abuse notation and use $\mathsf{var}(G)$ to refer to the vertices of G that correspond to variables in $\psi(G)$, and $\mathsf{cla}(G)$ to refer to the vertices of G that correspond to clauses in $\psi(G)$. Also, for a vertex subset $Y \subseteq V(G)$, we continue to use the notations $\mathsf{var}(Y)$ and $\mathsf{cla}(Y)$ to refer to the sets $\mathsf{var}(G) \cap Y$ and $\mathsf{cla}(G) \cap Y$, respectively. We say that a graph is $K_{d,d}$*-free* if it does not contain $K_{d,d}$ as a subgraph. Notice that the $K_{d,d}$-free incidence graphs correspond to CNF formulas where no set of d clauses contain literals from d distinct variables in their common intersection.

Nested formulas

A CNF formula ϕ is *nested* [28] precisely if the graph $\mathsf{inc}(\mathsf{univ}(\phi))$ is planar, where $\mathsf{univ}(\phi)$ is obtained from ϕ by adding any universal clause $c^\star$ containing a literal from each variable of ϕ. Moreover, $\mathsf{inc}(\phi)$ has treewidth at most 3 if ϕ is nested. Hence, one can determine satisfiability of nested formulas in polynomial time. Nested formulas are a subclass of planar CNF formulas and so, are also a subclass of $K_{3,3}$-free formulas.

Treewidth

Let G be a graph. A *tree decomposition* of G is a pair $(T, \mathcal{X} = \{X_t\}_{t \in V(T)})$ where T is a tree and $\mathcal{X}$ is a collection of subsets of $V(G)$ such that: (i) $\forall e = (u, v) \in E(G)$, there is $t \in V(T) : \{u, v\} \subseteq X_t$, and (ii) $\forall v \in V(G)$, $T[\{t \mid v \in X_t\}]$ is a non-empty connected subtree of T. We call the vertices of T *nodes* and the sets in $\mathcal{X}$ *bags* of the tree decomposition $(T, \mathcal{X})$. The *width* of $(T, \mathcal{X})$ is equal to $\max\{|X_t| - 1 \mid t \in V(T)\}$ and the *treewidth* of G is the minimum width over all tree decompositions of G. A *nice tree decomposition* is a pair $(T, \mathcal{X})$ where $(T, \mathcal{X})$ is a tree decomposition such that T is a rooted tree and the following conditions are satisfied: (i) Every node of the tree T has at most two children; (ii) if a node t has two children t_1 and t_2, then $X_t = X_{t_1} = X_{t_2}$; and (iii) if a node t has one child t_1, then either $|X_t| = |X_{t_1}| + 1$ and $X_{t_1} \subset X_t$ (in this case we call t_1 an *introduce node*) or $|X_t| = |X_{t_1}| - 1$ and $X_t \subset X_{t_1}$ (in this case we call t_1 a *forget node*). It is possible to transform a given tree decomposition $(T, \mathcal{X})$ into a nice tree decomposition $(T', \mathcal{X}')$ in time $O(|V| + |E|)$ [3]. A set $X \subseteq V(G)$ is a treewidth-t modulator for a graph G if the treewidth of $G - X$ is at most t.

Boundaried graphs

A t-boundaried graph is a triple (G, B, ℓ_G) where G is a graph, $B \subset V(G)$ of size t with each vertex $v \in B$ having a unique label $\ell_G(v) \in \{1, \ldots, t\}$. We refer to B as the *boundary* of G. We often refer to a t-boundaried graph simply as G with the function $\partial(G)$ returning the boundary of G and the function ℓ_G denoting the labeling function on the boundary. In other cases, it will be useful to mention the boundary explicitly, in which case we will use (G, B). When the size of the boundary is irrelevant to the discussion, we simply use "boundaried graph" instead of "t-boundaried graph".

Let $G = (X, C, E)$ be a boundaried incidence graph with boundary $\partial(G) = \{b_1, \ldots, b_{|\partial(G)|}\}$, where $\partial(G) \subseteq (X \cup C)$ and $b_i = \ell_G^{-1}(i)$. We use $\vartheta(G)$ to denote the $|\partial(G)|$-length binary word given as: $\vartheta(G)[i] = 0$ if $b_i \in X$ and $\vartheta(G)[i] = 1$ otherwise.

▶ **Definition 5** (Boundary types and mergeability). *We say that two boundaried incidence graphs $G_1 = (X_1, C_1, E_1)$ and $G_2 = (X_2, C_2, E_2)$ have the same* boundary type *if $\vartheta(G_1) = \vartheta(G_2)$. If G_1 and G_2 have the same boundary type, then we say that G_1 and G_2 are* mergeable *if for every u_1, $v_1 \in \partial(G_1)$ and u_2, $v_2 \in \partial(G_2)$ such that $\ell_{G_1}(u_1) = \ell_{G_2}(u_2)$ and $\ell_{G_1}(v_1) = \ell_{G_2}(v_2)$, at most one out of (u_1, v_1) and (u_2, v_2) is an edge in G_1 and G_2 respectively.*

Gluing operation and compatibility of boundaried graphs

A pair of boundaried incidence graphs G_1 and G_2 that are mergeable can be "glued" together along their boundaries to obtain a new incidence graph, which we denote by $G_1 \oplus G_2$. The gluing operation takes the disjoint union of G_1 and G_2 and identifies the vertices of $\partial(G_1)$ and $\partial(G_2)$ with the same label. If there are vertices u_1, $v_1 \in \partial(G_1)$ and u_2, $v_2 \in \partial(G_2)$ such that $\ell_{G_1}(u_1) = \ell_{G_2}(u_2)$ and $\ell_{G_1}(v_1) = \ell_{G_2}(v_2)$ then G has vertices u formed by unifying u_1 and u_2 and v formed by unifying v_1 and v_2. That is, u_1 and u_2 are merged to form the

supernode u and v_1 and v_2 are merged to form the supernode v. The new vertices u and v are adjacent if $(u_1, v_1) \in E(G_1)$ or $(u_2, v_2) \in E(G_2)$. The polarities of the edges in G_1 and G_2 are inherited in $G_1 \oplus G_2$ in the natural way.

▶ **Definition 6** (d-compatibility of boundaried graphs)**.** *Let G_1 and G_2 be two t-boundaried $K_{d,d}$-free incidence graphs. We say that G_1 and G_2 are* d-compatible *if they are mergeable and further, $G_1 \oplus G_2$ is also a $K_{d,d}$-free graph.*

Minors and nowhere-dense graph classes

Given an edge $e = (x, y)$ of a graph G, the graph G/e is obtained from G by contracting the edge e, that is, the endpoints x and y are replaced by a new vertex v_{xy} which is adjacent to the original neighbors of x and y (except x and y). A graph H obtained by a sequence of edge-contractions is said to be a *contraction* of G. We denote it by $H \leq_c G$. A graph H is a *minor* of a graph G if H is the contraction of some subgraph of G and we denote it by $H \leq_m G$. We say that a graph G is *H-minor-free* when it does not contain H as a minor. We also say that a graph class $\mathcal{G}$ is *H-minor-free* (or, excludes H as a minor) when all its members are H-minor-free. It is well-known [36] that if $H \leq_m G$ then $tw(H) \leq tw(G)$.

The notion of *shallow minors* is required to define nowhere-dense graph classes. The radius of a connected graph G is the minimum over all vertices v of G of the maximum distance between v and another vertex. For non-negative integer r, a graph H is a shallow minor at depth r of a graph G if there exists a subgraph X of G whose connected components have radius at most r, such that H is a simple graph obtained from G by contracting each component of X into a single vertex and then taking a subgraph.

We now recall the notion of *nowhere-dense* graph classes. Although the only property of a nowhere-dense graph class we require is that they are biclique-free, we give the formal definition here for the sake of completeness.

▶ **Definition 7.** *A class $\mathcal{C}$ of graphs is nowhere dense if there is a function $f : \mathbb{N} \to \mathbb{N}$ such that for every $r \geq 0$, $K_{f(r)}$ is* not *a shallow minor at depth r of the graph G, for every $G \in \mathcal{C}$.*

▶ **Proposition 8.** (see Fact 1, [40]) *Let $\mathcal{C}$ be a nowhere-dense class of graphs and let f be the corresponding function as described in the above definition. Then, there is a number t depending only on f such that for any $G \in \mathcal{C}$, G does not contain $K_{t,t}$ as a subgraph.*

Unbreakability

Roughly speaking, a graph is unbreakable if it is not possible to "break" it into two large parts by removing only a small number of vertices. We now give the formal definition. A pair (X, Y) where $X \cup Y = V(G)$ is a *separation* if there is no edge with one endpoint in $X \setminus Y$ and the other in $Y \setminus X$. The order of (X, Y) is $|X \cap Y|$. If there exists a separation (X, Y) of order at most c such that $|X \setminus Y| \geq s$ and $|Y \setminus X| \geq s$, called an *(s, c)-witnessing separation*, then G is *(s, c)-breakable*. Otherwise, G is *(s, c)-unbreakable*. The following lemma states that it is possible to determine (approximately) whether a graph is unbreakable or not using a fixed-parameter algorithm, and lemmas similar to it can be found in [5, 30].

▶ **Proposition 9** ([30])**.** *There exists an algorithm that, given $s, c \in \mathbb{N}$ and a graph G, runs in time $2^{O(c(s+c))} \cdot n^3 \log n$ and either returns an $(\frac{s}{2^c}, c)$-witnessing separation or correctly concludes that G is (s, c)-unbreakable.*

▶ **Observation 10.** *Let $t, \delta, \tau^\star \in \mathbb{N}$, where $t \leq 2\tau^\star$. Let (G, Z) be a t-boundaried graph and let (X, Y) be a $(\delta, \tau^\star)$-witnessing separation. Then, one of the pairs $(G[X], (X \cap Y) \cup (Z \cap X))$ or $(G[Y], (X \cap Y) \cup (Z \cap Y))$ is a t'-boundaried graph, where $t' \leq 2\tau^\star$.*

By repeatedly invoking the above observation, one can "zoom in" to a separation of small order in the graph such that one of the sides is large and induces an unbreakable subgraph.

▶ **Lemma 11.** *Let $\delta, \delta^\star, \tau^\star \in \mathbb{N}$ be such that $\delta^\star = 2^{\tau^\star} \cdot \delta$. Let (X, Y) be a separation of order at most $2\tau^\star$ in a graph G such that $|X| \geq \delta$. There is an algorithm that, given G, X, Y, runs in time $2^{\mathcal{O}(\tau^\star \cdot \delta^\star)} \cdot n^{\mathcal{O}(1)}$ and returns a separation $(\widetilde{X}, \widetilde{Y})$ of order at most $2\tau^\star$ in G such that $|\widetilde{X}| \geq \delta$ and $G[\widetilde{X}]$ is $(\delta^\star, \tau^\star)$-unbreakable.*

▶ Remark 12. Roughly speaking, the notions of boundaried incidence graphs, mergeability, and d-compatibility allows us to split our original input (formula's) incidence graph along a small balanced separator (of size at most some t) and treat the two sides of the separator as t-boundaried d-compatible graphs and focus our attention on one of these two graphs in order to make further progress. The notion of unbreakability plus Lemma 11 gives us a kind of "base case" where we are able to stop splitting our instance along such small separators and use the additional structure imposed by unbreakability to make progress.

3 Algorithm for Weak Planar-$\mathcal{F}$-minor-free-Backdoor Detection

In this section, we discuss the proof of Theorem 1. We begin with the following definitions and assumptions.

- Recall that d is fixed, i.e., it is a constant for us.
- We assume that $k > d$. Otherwise, we could simply guess (and verify) a weak-backdoor set of size at most k in time $|\phi|^{\mathcal{O}(d)}$. Here, k is the integer taken as input by the algorithm $\mathcal{A}$ described in Theorem 1.
- We assume that $\mathcal{F}$ is a family of graphs containing at least one planar graph and use η to denote a computable upper bound on the treewidth of $\mathcal{F}$-minor-free graphs.
- Define $\tau(k, d) = k^{d+1}$, $\tau'(\eta, k, d) = \tau(k, d) + 2\eta + 2$.
- We pick $\delta(\eta, k, d)$ to be a large enough function of $\tau'(\eta, k, d)$ to be decided later.
- Set $\delta'(\eta, k, d) = 2^{\tau'(\eta,k,d)} \cdot \delta(\eta, k, d)$.
- Let $\Delta(\eta, k, d) = \delta'(\eta, k, d) + 2\tau'(\eta, k, d)$.
- For ease of readability, we omit the arguments of these functions when they are clear from the context, e.g., we replace $\Delta(\eta, k, d)$ with Δ.

3.1 Overview of our algorithm

We first briefly describe the ideas used by Fomin et al. [13] in their randomized FPT algorithm to detect weak η-tw-backdoor sets when the input formula is d-CNF. We then outline the similarities and main differences with our algorithm.

Algorithm of Fomin et al [13]

Let G be the input incidence graph. Say that a set $X \subseteq V(G)$ is an η-modulator if $\mathsf{tw}(G - X) \leq \eta$. Fomin et al. observed that if X is a set of variables that form a weak η-tw-backdoor, then the set $N(X)$ of their neighbors in the incidence graph is an η-modulator. Note that $|N(X)|$ could be arbitrarily large compared to $|X|$. They then give a preprocessing procedure that ensures that for every η-tw-backdoor set X, the set $N(X)$ is incident to a large fraction of the edges in G. Therefore, if one picks an edge uniformly at random, then the clause endpoint of the edge belongs to $N(X)$ with constant probability. Further, since the clauses are of constant size d, we have that a randomly chosen variable from the clause belongs to X with a constant probability, some $f(d, \eta)$. The algorithm then simply branches

on the chosen variable x in the usual way – in one branch, the formula is simplified by setting x to 1 and recurse, and in the other branch, x is set to 0 and the residual instance is recursed upon.

The main obstacle in our setting is that simply obtaining a clause in $N(X)$ is not good enough since clauses can be arbitrarily large. This motivates us to look for a "domination core" within the incidence graph. That is, if we find sufficiently many clause vertices in $N(X)$, then it is possible to identify a small subset of variables that intersect X. However, being able to locate the required number of clause vertices in $N(X)$ is far from obvious even though we have access to the preprocessing rule of Fomin et al. For instance, each time we locate a vertex in $N(X)$ and remove it, the preprocessing rule could kick in again and even remove vertices of X. A similar issue arises in the recent work of Choudhary et al. [6] for Feedback Vertex Set on linear hypergraphs (whose incidence graphs are $K_{2,2}$-free). As a result, they needed to design problem specific preprocessing rules that heavily utilize the fact that they are dealing with deletion to graphs of treewidth 1. Moreover, their approach only works when the input incidence graph is $K_{2,2}$-free and extending it to our far more general setting appears to be a challenging task.

Our approach

To overcome the obstacle described above, we take a different route and use the notion of unbreakability [5] to argue that if we "zoom into" a subgraph that is large enough, has high treewidth, is separated from the rest of the graph by a small boundary and is unbreakable, then it is possible to identify sufficiently many vertices from $N(X)$ and a *domination core* can be extracted from this [34, 11, 12]. This is the main technical contribution of the paper and we believe that this approach can find further applications.

Our algorithm relies on Lemma 11 and Lemmas 13-16. Out of these, the next three lemmas correspond to the three main cases that we will encounter in our algorithm. In the following three lemmas, let $G^\star$ denote the input incidence graph, let G and H be $K_{d,d}$-free t-boundaried d-compatible incidence graphs ($t \leq 2\tau'$) with the same boundary type such that $G^\star = G \oplus H$. Moreover, suppose that $|\partial(G)| \leq 2\tau'$ and G is (δ', τ')-unbreakable. Recall that $\partial(G)$ and $\partial(H)$ denote the boundaries of G and H respectively. Moreover, we use n to denote the number of vertices in the incidence graph under consideration.

The first lemma states that if G has sufficiently high tree-width, then it is possible to compute a small family of clause-sets, each containing few clauses, such that if $G^\star$ contains a small variable set $S^\star$ such that deleting its neighborhood reduces the treewidth of G significantly, then in at least one of these clause-sets, every clause contains a variable of $S^\star$. In graph-theoretic terms, it shows that one can compute a small family of small clause-vertex sets, such that in at least one of these small clause-vertex sets, every vertex is adjacent to $S^\star$.

▶ **Lemma 13** (Case 1: High treewidth piece)**.** *Suppose* $\mathsf{tw}(G) > \Delta$*. Let* $S^\star \subseteq \mathsf{var}(G^\star)$ *be such that* $|S^\star| \leq k$ *and* $\mathsf{tw}(G^\star - N_{G^\star}[S^\star]) \leq \eta$*. There is an algorithm that, given* $G^\star$*,* G *and* H *as input, runs in time* $(\delta')^{\mathcal{O}(d\tau')}n^{\mathcal{O}(1)}$*, and outputs a family* $\mathscr{Q}$ *of subsets of* $\mathsf{cla}(G^\star)$ *of size* τ *each, with the following properties.*

1. $|\mathscr{Q}| = (\delta')^{\mathcal{O}(d\tau')}$*, and*
2. *there exists* $\mathcal{Q} \in \mathscr{Q}$ *such that each clause in* $\mathcal{Q}$ *contains a variable from* $S^\star$*.*

The following lemma is used to handle a situation similar to that above, with the only difference being that the treewidth of G is not too high. On the other hand, it is also high enough to ensure that any weak $\mathcal{F}$-minor-free-backdoor set of $G^\star$ intersects G in at least one vertex. The proof of this lemma uses Arnborg et al.'s extension [1] of Courcelle's Theorem and the fact that the existence of a small weak $\mathcal{F}$-minor-free-backdoor set is CMSO-expressible (see, for example, [23]). We refer the reader to [7, 1, 8] for a detailed introduction to CMSO.

▶ **Lemma 14** (Case 2: Moderately-high treewidth piece). *Suppose that* $\eta < \mathsf{tw}(G - \partial(G)) \leq \Delta$. *We can compute a set* $S \subseteq \mathsf{var}(G)$ *in time* $g(\eta, k, d) \cdot n^{\mathcal{O}(1)}$ *for some computable function* g, *such that the following hold.*

1. S *has size at most* $g(\eta, k, d)$, *and*
2. S *has a non-empty intersection with a weak* $\mathcal{F}$*-minor-free-backdoor set of size at most* k *for* $G \oplus H$ *(if one exists).*

The next lemma shows that if G has low-treewidth but has a large number of vertices, then one can obtain a strictly smaller, equivalent instance by closely following the graph-replacement arguments used by Fomin et al. [13], which in turn was inspired by ideas used in [19] for kernelization.

▶ **Lemma 15** (Case 3: Low treewidth piece). *Suppose that* $|V(G)| \geq \delta$ *and* $\mathsf{tw}(G - \partial(G)) \leq \eta$. *Then, there is a* $K_{d,d}$*-free incidence graph* G' *such that the following hold.*

1. $|V(G')| < |V(G^\star)|$.
2. *For every* $\gamma \leq k$, $\psi(G^\star)$ *has a weak* $\mathcal{F}$*-minor-free-backdoor set* S *of size at most* γ *if and only if* $\psi(G')$ *has a weak* $\mathcal{F}$*-minor-free-backdoor set* S' *of size at most* γ.
3. *Given* $G^\star, G$ *and* H, *one can obtain* G' *in time* $\widehat{g}(\mathcal{F}, k, d) \cdot n^{\mathcal{O}(1)}$ *for some computable function* $\widehat{g}$.

Having stated the three central lemmas that we will be using, we next demonstrate an immediate application of Lemma 13, following which we give the proof of Theorem 1 assuming the correctness of the three central lemmas.

Recall that Lemma 13 provides us a family of subsets of $\mathsf{cla}(G^\star)$ such that there is one subset where each clause contains a variable from S. In the following lemma we explain how to get a variable in S from such a family. The proof the lemma uses the concept of *domination core*, which is used in the study of parameterized complexity of dominating set on $K_{d,d}$-free graphs [34, 11, 12]. Recall that $k > d$.

▶ **Lemma 16** (Domination core). *There is an algorithm that, given a set* $Z_C \subseteq \mathsf{cla}(\phi)$ *of* τ *clauses of a* $K_{d,d}$*-free formula* ϕ, *each of whose variable set intersects some fixed variable set* $S \subseteq \mathsf{var}(\phi)$ *of size at most* k, *runs in polynomial time and outputs a set* Z_V *of at most* d *variables that intersects* S.

Proof. Let $Z_C^0 = Z_C$. We define $v_1, \ldots, v_r \in \mathsf{var}(\phi)$ and $\mathcal{C}_1, \ldots, \mathcal{C}_r \subseteq Z_C$ as follows. For every $i \in [r]$, we select v_i to be the lexicographically first variable disjoint from the previously selected variables, that occurs most frequently among the clauses in the set Z_C^{i-1}. We set $Z_C^i := N_{\mathsf{inc}(\phi)}(v_i) \cap Z_C^{i-1}$. We now observe that for every $i \in [d]$, either S intersects $\{v_1, \ldots, v_i\}$ or $|Z_C^i| \geq |Z_C^{i-1}|/k$. This is because S has size at most k and every clause in Z_C contains a variable of S. In particular, we have that either S intersects $Z_V = \{v_1, \ldots, v_d\}$ or it must be the case that $|Z_C^d| \geq k$ (since $|Z_C^0| \geq k^{d+1}$), implying the existence of a $K_{d,d}$ in $\mathsf{inc}(\phi)$, which is a contradiction. This completes the proof of the lemma. ◀

We are now ready to complete the proof of Theorem 1 assuming Lemmas 11-16. We restate it here for the reader's convenience.

▶ **Theorem 1.** *For every* $d \in \mathbb{N}$, *there is a computable function* f_d *and an algorithm* $\mathcal{A}_d$ *that satisfies the following:*

1. $\mathcal{A}_d$ *takes as input a* $K_{d,d}$*-free formula* ϕ, *a family* $\mathcal{F}$ *of graphs containing at least one planar graph, and an integer* k.
2. $\mathcal{A}_d$ *runs in time* $f_d(\mathcal{F}, k) \cdot |\phi|^{\mathcal{O}(d)}$.
3. $\mathcal{A}_d$ *either outputs a weak* $\mathcal{F}$*-minor-free-backdoor set of* ϕ *of size at most* k, *or concludes correctly that* ϕ *has no weak* $\mathcal{F}$*-minor-free-backdoor set of size at most* k.

Proof. We focus on solving the decision version of the problem. This is because, if the input is a yes-instance, then a weak $\mathcal{F}$-minor-free backdoor set of size at most k can be computed using self-reducibility. Let $I = (\phi, \mathcal{F}, k)$ denote the input instance and let G be the incidence graph of ϕ. Suppose that G has treewidth at most Δ. Then, one can use Courcelle's theorem to solve the problem (see, for example, [23, 26]). Hence, we may assume that G has treewidth $> \Delta$. In particular, $|V(G)| > \Delta$. Now, using Proposition 9, we either conclude that G is (δ', τ')-unbreakable or we compute a (δ, τ')-witnessing separation.

In the first case, we define $\partial(G) = \emptyset$ and H to be an edgeless graph with $\partial(H) = \emptyset$. We then invoke Lemma 13 to compute a set $\mathscr{Q}$ of size $\delta'^{\mathcal{O}(d\tau')}$ comprising sets of τ clauses each such that for some $\mathcal{Q} \in \mathscr{Q}$, each clause in $\mathcal{Q}$ contains a variable in some fixed weak backdoor set $S^\star$ (if one exists). Recall that $\mathsf{inc}(\phi) - N_{\mathsf{inc}(\phi)}[S^\star]$ has treewidth at most η, satisfying the premise of Lemma 13. We then invoke Lemma 16 on every $\mathcal{Q} \in \mathscr{Q}$ to compute a set Z_V of at most $d \cdot \delta'^{\mathcal{O}(d\tau')}$ variables that intersects $S^\star$. For every $x \in Z_V$ and $\alpha \in \{0,1\}$, we recursively solve the problem on the instance $I_{x,\alpha} = (\phi[x = \alpha], k-1)$. We conclude that I is a yes-instance if and only if there is an $x \in Z_V$ and $\alpha \in \{0,1\}$ such that $I_{x,\alpha}$ is a yes-instance.

Now, consider the second case, i.e., the case where we compute a (δ, τ')-witnessing separation (X, Y) for G. Notice that this separation satisfies the premises of Lemma 11 (by taking the same δ, taking $\delta^\star$ be δ' and $\tau^\star$ to be τ'). Hence, we execute the algorithm of this lemma to compute a separation $(\widetilde{X}, \widetilde{Y})$ of order at most $2\tau'$ in G such that $|\widetilde{X}| \geq \delta$ and $G[\widetilde{X}]$ is (δ', τ')-unbreakable. Let $\widetilde{G} = G[\widetilde{X}]$ and let $\widetilde{H} = G[\widetilde{Y}]$. At this point, we have that $|V(\widetilde{G})| \geq \delta$, $|\partial(\widetilde{G})| \leq 2\tau'$ and $\widetilde{G}$ is (δ', τ')-unbreakable.

Consider the following three cases depending on whether the "piece" $\widetilde{G} - \partial(\widetilde{G})$ has high treewidth or moderately-high treewidth or low treewidth. In each case, we will either strictly reduce the size of the instance or compute a bounded set of variables upon which to branch.

Case 1: $\mathsf{tw}(\widetilde{G} - \partial(\widetilde{G})) > \Delta$. We invoke Lemma 13 with $G := \widetilde{G}$ and $H := \widetilde{H}$ to compute $\mathscr{Q}$ and then Lemma 16 on the sets in $\mathscr{Q}$ as described above. This gives us a set Z_V of at most $d \cdot \delta'^{\mathcal{O}(d\tau')}$ variables that intersects a weak $\mathcal{F}$-minor-free-backdoor set $S^\star$ of ϕ of size at most k. Now, for every $x \in Z_V$ and $\alpha \in \{0,1\}$, we recursively solve the problem on the instance $I_{x,\alpha} = (\phi[x = \alpha], \mathcal{F}, k-1)$. We conclude that I is a yes-instance if and only if there is an $x \in Z_V$ and $\alpha \in \{0,1\}$ such that $I_{x,\alpha}$ is a yes-instance.

Case 2: $\eta < \mathsf{tw}(\widetilde{G} - \partial(\widetilde{G})) \leq \Delta$. We invoke Lemma 14 with $G := \widetilde{G}$ and $H := \widetilde{H}$ to compute a set $S \subseteq \mathsf{var}(G)$ of size at most $g(\eta, k, d)$ that has a non-empty intersection with a weak $\mathcal{F}$-minor-free-backdoor set of G of size at most k (if one exists). For every $x \in S$ and $\alpha \in \{0,1\}$, we recursively solve the problem on the instance $I_{x,\alpha} = (\phi[x = \alpha], \mathcal{F}, k-1)$. We conclude that I is a yes-instance if and only if there is an $x \in S$ and $\alpha \in \{0,1\}$ such that $I_{x,\alpha}$ is a yes-instance.

Case 3: $\mathsf{tw}(\widetilde{G} - \partial(\widetilde{G})) \leq \eta$. We invoke Lemma 15 with $G := \widetilde{G}$ and $H := \widetilde{H}$ to compute an equivalent instance $(\phi', \mathcal{F}, k)$ such that $|\phi'| < |\phi|$ and recurse on $(\phi', \mathcal{F}, k)$.

This completes the description of our algorithm. Each step of the algorithm has running time $\chi(\eta, d, k)$ for some computable function χ and at the end of each, we either make $2d \cdot \delta'^{\mathcal{O}(d\tau')}$ recursive calls with a strictly smaller budget k or strictly reduce the size of the instance. Hence, the running time follows. The correctness is derived from that of the three main lemmas (Lemmas 13, 14, 15) and the domination core lemma (Lemma 16). ◀

It remains to prove the three main lemmas. Lemma 13 captures the new technical insight at the heart of this work, and so we focus on that lemma in this extended abstract. We also give a proof sketch of Lemma 14 and as the proof of Lemma 15 closely mirrors the algorithm of Fomin et al. [13], we omit the details of this lemma in this extended abstract.

3.2 Handling unbreakable boundaried instances

Protrusions

For a graph G and $S \subseteq V(G)$, we define $\partial_G(S)$ as the set of vertices in S that have a neighbor in $V(G) \setminus S$. For a set $S \subseteq V(G)$ the *neighborhood* of S is $N_G(S) = \partial_G(V(G) \setminus S)$. When it is clear from the context, we omit the subscripts. An *r-protrusion* in a graph G is a set $X \subseteq V$ such that $|\partial(X)| \leq r$ and $\mathsf{tw}(G[X]) \leq r$. The *size* of a protrusion is the number of vertices in it. An α-cover in G is a set S such that $\sum_{v \in S} d(v)) \geq \alpha \cdot \sum_{v \in V(G)} d(v) = 2\alpha|E(G)|$. Here, $d(v)$ denotes the degree of the vertex v.

We begin with the following lemma that states that if a graph does not have large r-protrusions and there is a set Z of vertices whose deletion results in a graph of constant treewidth, then a constant fraction of the edge-set is incident on Z.

▶ **Lemma 17.** *Let $r = 2\eta + 2$, and $\alpha = \frac{1}{18(\eta+1)^2}$. Let J be a graph and $Z \subseteq V(J)$ such that $\mathsf{tw}(J - Z) \leq \eta$. If J has no r-protrusion of size at least r', then Z is an $\frac{\alpha}{r'}$-cover of J.*

Lemma 17 can be inferred directly from the proof of Lemma 3 in [14], although it does not state concrete values for the various parameters involved in the statement. The following lemma provides a procedure to extract, from a given $K_{d,d}$-free incidence graph with no *large* protrusions, a small set of clauses such that at least one of the clauses in this set contains a backdoor variable.

▶ **Lemma 18** (Protrusion-free instances)**.** *Let J be a $K_{d,d}$-free incidence graph and let $k, r' \in \mathbb{N}$. Let $S \subseteq \mathsf{var}(J)$ be a non-empty inclusion-wise minimal set such that $|S| \leq k$ and $\mathsf{tw}(J - N[S]) \leq \eta$. Moreover, suppose that J has no $(2\eta + 2)$-protrusion of size at least r'. There is an algorithm that, given J, runs in polynomial time, and outputs a subset $\mathcal{D}$ of $\mathsf{cla}(J)$ such that $|\mathcal{D}| = (k \cdot \eta \cdot r')^{\mathcal{O}(d)}$, and there exists a clause $C \in \mathcal{D}$ that contains a variable from S.*

Proof. Since J is an incidence graph, S is a variable set, and $\mathsf{tw}(J - N[S]) \leq \eta$, it follows that $\mathsf{tw}(J - N(S)) \leq \eta$. Invoking Lemma 17 with $Z = N(S)$, we infer that $N(S)$ is an $\frac{\alpha'}{r'}$-cover of J, where $\alpha' = \frac{1}{18(\eta+1)^2}$. Let $\alpha = \frac{\alpha'}{k \cdot r'}$, $g = \frac{\alpha}{2d}$, and $h = \prod_{i=0}^{d-1}(\alpha - ig)$. Let $X = \mathsf{var}(J)$ and $\mathcal{C} = \mathsf{cla}(J)$. Now we define a weight function w on $\mathcal{C}$ as follows. For every $C \in \mathcal{C}$, $w(C) = \frac{d(C)}{m}$, where m is the number of edges in J and $d(C)$ denotes the degree of the vertex C in J. Extending the weight function to sets in the natural way, we conclude that $w(\mathcal{C}) = \sum_{C \in \mathcal{C}} w(C) = 1$ by definition. It will be useful to keep in mind that picking an edge of J uniformly at random and picking the clause-vertex that appears as one of the endpoints of this edge corresponds to picking a vertex $C \in \mathcal{C}$ with probability $w(C)$.

Next, we identify sufficiently small sets $Y \subseteq X$ and $\mathcal{D}' \subseteq \mathcal{C}$ and prove that either $S \cap Y \neq \emptyset$ or $N_J(S) \cap \mathcal{D}' \neq \emptyset$. The sets $\mathcal{D}'$ and Y are defined as follows: $\mathcal{D}'$ is the set of vertices in $\mathcal{C}$ whose weight is greater than g and Y is the set of vertices in X such that it has no neighbor in $\mathcal{D}'$, and the sum of weights on its neighbors is at least α. Formally,

$$\mathcal{D}' = \{y \in \mathcal{C} \mid w(y) > g\}$$

$$Y = \{x \in X \setminus N(\mathcal{D}') \mid w(N(x)) \geq \alpha\}$$

Notice that for every $x \in Y$, $|N(x) \setminus \mathcal{D}'| \geq 2d$. This is because $w(N(x)) \geq \alpha = 2gd$ and every clause in $\mathcal{C} \setminus \mathcal{D}'$ has weight at most g.

▷ Claim 19. Either $N(S) \cap \mathcal{D}' \neq \emptyset$ or $S \cap Y \neq \emptyset$.

We next claim that the sets $\mathcal{D}'$ and Y are sufficiently small for our purposes.

▷ Claim 20. $|\mathcal{D}'| \leq 36(\eta+1)^2 d \cdot k \cdot r'$ and if $N(S) \cap \mathcal{D}' = \emptyset$, then $|Y| \leq d \cdot (36k \cdot r'(\eta+1)^2)^d$.

Given the above two claims, the algorithm is straightforward. We first construct $\mathcal{D}'$ and Y. If $|Y| \leq d \cdot (36k \cdot r'(\eta+1)^2)^d$, then we output a set $\mathcal{D}$ which is the union of $\mathcal{D}'$ and a set of clauses comprising one arbitrary neighbor of each vertex in Y. Otherwise, we simply output $\mathcal{D} = \mathcal{D}'$. From Claim 20, it follows that the size of $\mathcal{D}$ is bounded by $(k \cdot \eta \cdot r')^{\mathcal{O}(d)}$. Moreover, from both claims above, we conclude that some clause in $\mathcal{D}$ contains a variable in S. Since computing $\mathcal{D}'$ and Y can be done in polynomial time, this algorithm runs in polynomial time as required. This completes the proof of the lemma. ◀

In the following, let G and H be $K_{d,d}$-free t-boundaried d-compatible incidence graphs ($t \leq 2\tau'$) with the same boundary type, $|\partial(G)| \leq 2\tau'$ and G is (δ', τ')-unbreakable. Recall that $\partial(G)$ and $\partial(H)$ denote the boundaries of G and H respectively. Throughout this section, we denote by $G^\star$, the graph $G \oplus H$.

▶ **Lemma 13** (Case 1: High treewidth piece)**.** *Suppose* $\mathsf{tw}(G) > \Delta$. *Let* $S^\star \subseteq \mathsf{var}(G^\star)$ *be such that* $|S^\star| \leq k$ *and* $\mathsf{tw}(G^\star - N_{G^\star}[S^\star]) \leq \eta$. *There is an algorithm that, given* $G^\star$, G *and* H *as input, runs in time* $(\delta')^{\mathcal{O}(d\tau')} n^{\mathcal{O}(1)}$, *and outputs a family* $\mathscr{Q}$ *of subsets of* $\mathsf{cla}(G^\star)$ *of size* τ *each, with the following properties.*

1. $|\mathscr{Q}| = (\delta')^{\mathcal{O}(d\tau')}$, *and*
2. *there exists* $\mathcal{Q} \in \mathscr{Q}$ *such that each clause in* $\mathcal{Q}$ *contains a variable from* $S^\star$.

Proof. First we prove the following claim that will allow us to invoke Lemma 18 on certain subraphs of G.

▷ Claim 21. For every set $R \subseteq V(G)$ of size at most τ, $G - R$ does not contain a $(2\eta+2)$-protrusion of size at least $\delta' + 2\eta + 2$

Proof. For the sake of contradiction, suppose there exists $R \subseteq V(G)$ of size at most τ and $A \subseteq V(G-R)$ such that $G[A]$ is a $(2\eta+2)$-protrusion of size at least $\delta' + 2\eta + 2$. That is, $|\partial_{G-R}(A)| \leq 2\eta+2$ and $|A| \geq \delta'+2\eta+2$. Set $X = A \cup R$ and $Y = R \cup (V(G) \setminus (A \setminus \partial_{G-R}(A)))$ and observe that (X, Y) is a separation in G of order at most $|R|+|\partial_{G-R}(A)| \leq \tau+2\eta+2 = \tau'$, and $|X \setminus Y| = |A \setminus \partial_{G-R}(A)| \geq \delta'$. We now claim that $|Y \setminus X| = |V(G) \setminus (A \cup R)| \geq \delta'$. Suppose to the contrary that $|V(G) \setminus (A \cup R)| < \delta'$. Then, $\mathsf{tw}(G) \leq \mathsf{tw}(G[A]) + |V(G) \setminus (A \cup R)| + |R| \leq 2\eta + 2 + \delta' + \tau \leq \Delta$, which is a contradiction to the premise of the lemma. ◁

We next define a recursive procedure FindClauses. The input to FindClauses is G, a set $R \subseteq \mathsf{cla}(G)$ and an integer $q \in \{1, \ldots, \tau\}$ such that $|R| + q = \tau$. The output is a family $\mathscr{Q}'$ of subsets of $\mathsf{cla}(G) \setminus R$ of size q each, such that $|\mathscr{Q}'| \leq (k \cdot \eta \cdot \delta')^{c \cdot d \cdot q}$, for some constant $c > 0$. The following are the steps of the procedure FindClauses(G, R, q).

1: First we apply Lemma 18 where $J = G - R$ and $r' = \delta' + 2\eta + 2$ (the above claim guarantees that the premise of this lemma is satisfied by this choice of J and r'). Let $\mathcal{D}$ be the output of the algorithm of Lemma 18.
2: If $q = 1$, then we output $\{\{C\} \mid C \in \mathcal{D}\}$ and stop.
3: If $q > 1$, then for each $C \in \mathcal{D}$, we recursively call the procedure FindClauses with input G, $R \cup \{C\}$ and $q - 1$ to obtain a set $\mathscr{Q}_C$. Let $\mathscr{Q}'_C = \{Q \cup \{C\} \mid Q \in \mathscr{Q}_C\}$. We return $\mathscr{Q}' = \bigcup_{C \in \mathcal{D}} \mathscr{Q}'_C$ and stop.

Let c be a constant such that the output of Lemma 18 (i.e., $\mathcal{D}$) has cardinality bounded by $(k \cdot \eta \cdot r')^{c \cdot d}$. It can be proved that $|\mathscr{Q}'| \leq (k \cdot \eta \cdot \delta')^{c \cdot d \cdot q}$ by induction on q.

As the number of nodes in the recurrence tree is bounded by $|\mathscr{Q}'|$ and the algorithm in Lemma 18 runs in polynomial time, the running time of the procedure FindClauses is bounded by $|\mathscr{Q}'| \cdot n^{\mathcal{O}(1)}$.

Before moving to the description of the main algorithm of this lemma, we develop some additional notation. For every $Z \subseteq \partial(G)$, let $Z' = \mathsf{cla}(Z) \cup \{c \in \mathsf{cla}(G) \mid \exists v \in c : v \in \mathsf{var}(Z)\}$ and let Z'' be the subset of Z' comprising the (lexicographically) first $\min\{\tau, |Z'|\}$ elements. In other words, if Z' has at least τ elements, then we truncate it to size τ and obtain Z'' and otherwise, $Z'' = Z'$.

We are now ready to describe our main algorithm. We begin by setting $\mathscr{Q} := \emptyset$. We then compute Z'' for every $Z \subseteq \partial(G)$ and for every Z'' such that $|Z''| = \tau$, we set $\mathscr{Q} = \mathscr{Q} \cup \{Z''\}$. For every Z'' such that $|Z''| < \tau$, we set $\mathscr{Q}'_{Z''} \leftarrow \mathsf{FindClauses}(G, Z'', \tau - |Z''|)$ and we set $\mathscr{Q} = \mathscr{Q} \cup \{\{Q\} \cup Z'' \mid Q \in \mathscr{Q}'_{Z''}\}$. When we have completed iterating over all $Z \subseteq \partial(G)$ and updating $\mathscr{Q}$, we return it.

The correctness of the algorithm results from the following claim.

▷ Claim 22. There exists $\mathcal{Q} \in \mathscr{Q}$ such that each clause in $\mathcal{Q}$ contains a variable from $S^\star$.

It remains to argue the size bound on the output family and the running time of the algorithm. Since $q \leq \tau$ in every call to FindClauses and we have at most $2^{|\partial(G)|} \leq 2^{\tau'}$ such calls it follows that the cardinality of the output family is bounded by $(k \cdot \eta \cdot \delta')^{c \cdot d \cdot \tau} \cdot 2^{2\tau'}$ which is upper bounded by $(\delta')^{\mathcal{O}(d\tau')}$. By the same reasoning and from the upper bound on the running time of FindClauses, the running time of this algorithm is $(\delta')^{\mathcal{O}(d\tau')} n^{\mathcal{O}(1)}$. ◀

3.3 Handling boundaried instances with moderately high treewidth

▶ **Definition 23** (Label-wise isomorphism). *Let G_1 and G_2 be two graphs, and let t be a fixed positive integer. For $i \in \{1, 2\}$, let f_{G_i} be a function that associates with every vertex of $V(G_i)$ some subset of $[t]$. The image of a vertex $v \in G_i$ under f_{G_i} is called the label of that vertex. We say that that G_1 is* label-wise isomorphic *to G_2, and denote it by $G_1 \cong_t G_2$, if there is a map $h : V(G_1) \to V(G_2)$ such that (a) h is one to one and onto; (b) $(u, v) \in E(G_1)$ if and only if $(h(u), h(v)) \in E(G_2)$ and (c) $f_{G_1}(v) = f_{G_2}(h(v))$. We call h a* label-preserving isomorphism.

Notice that the first two conditions of Definition 23 simply indicate that G_1 and G_2 are isomorphic. Now, let G be a t-boundaried graph with t distinguished vertices, uniquely labeled from 1 to t. Given such a t-boundaried graph G, we define a canonical labeling function $\mu_G : V(G) \to 2^{[t]}$. The function μ_G maps every distinguished vertex v with label $\ell \in [t]$ to the set $\{\ell\}$, that is $\mu_G(v) = \{\ell\}$, and for all vertices $v \in V(G) \setminus \partial(G)$ we have that $\mu_G(v) = \emptyset$.

Next we define a notion of labeled edge contraction. Let H be a graph together with a function $f_H : V(H) \to 2^{[t]}$ and $(u, v) \in E(H)$. Furthermore, let H' be the graph obtained from H by identifying the vertices u and v into w_{uv}, removing all the parallel edges and removing all the loops. Then by *labeled edge contraction* of an edge (u, v) of a graph H, we mean obtaining a graph H' with the label function $f_{H'} : V(H') \to 2^{[t]}$. For $x \in V(H') \cap V(H)$ we have that $f_{H'}(x) = f_H(x)$ and for w_{uv} we define $f_{H'}(w_{uv}) = f_H(u) \cup f_H(v)$. Now we introduce a notion of labeled minors of a t-boundaried graph. Let H be a graph together with a function $f : V(H) \to 2^{[t]}$ and G be a t-boundaried graph with canonical labeling function μ_G. A graph H is called a labeled minor of G, if we can obtain a labeled isomorphic copy of H from G by performing edge deletion and labeled edge contraction. The *h-folio* of a t-boundaried graph G is the set $\mathcal{M}_h(G)$ of all t-labeled minors of G on at most h vertices.

▶ **Lemma 14** (Case 2: Moderately-high treewidth piece)**.** *Suppose that* $\eta < \mathsf{tw}(G - \partial(G)) \leq \Delta$. *We can compute a set* $S \subseteq \mathsf{var}(G)$ *in time* $g(\eta, k, d) \cdot n^{\mathcal{O}(1)}$ *for some computable function* g, *such that the following hold.*

1. S *has size at most* $g(\eta, k, d)$, *and*
2. S *has a non-empty intersection with a weak* $\mathcal{F}$*-minor-free-backdoor set of size at most* k *for* $G \oplus H$ *(if one exists).*

Proof. Fix a weak $\mathcal{F}$-minor-free-backdoor set $S^\star$ in $G^\star$. Since $G - \partial(G)$ has treewidth at least $\eta + 1$, it must be the case that $S^\star$ intersects $V(G)$. We ensure that the variables in $\partial(G)$ are added to the returned set S and so, we may assume henceforth that $S^\star$ is disjoint from $\partial(G)$.

Let $S_1^\star = S^\star \cap V(G)$. Let $\tau^\star : S^\star \to \{0,1\}$ be a partial assignment such that the incidence graph of $\phi[\tau^\star]$ is $\mathcal{F}$-minor free and let $\tau : \mathsf{var}(\phi) \to \{0,1\}$ be a satisfying assignment for ϕ that extends $\tau^\star$. Let $\tau_1^\star$ denote the restriction of $\tau^\star$ to $S_1^\star$. Let $Z_{kill} \subseteq \partial(G)$ denote those clauses in $\partial(G)$ that are satisfied by $\tau^\star$ and hence do not appear in $\phi[\tau^\star]$. Let $Z_{satext} \subseteq \partial(G)$ denote those clauses on the boundary that survive in $\phi[\tau^\star]$ and have at least one neighbor disjoint from $V(G)$ that satisfies it according to τ. Consider the t'-boundaried graph G_1' obtained from G by restricting the vertex set to those vertices that survive in $\mathsf{inc}(\phi[\tau^\star])$. Notice that the boundary of G' is precisely $\partial(G) \setminus Z_{kill}$. Finally, consider the h-folio $\mathcal{M}_h(G_1')$ where h is an upper bound on the largest graph in $\mathcal{F}$. The labels of the graphs in $\mathcal{M}_h(G_1')$ correspond to the vertices in $\partial(G) \setminus Z_{kill}$.

Now, let $S_2^\star \subseteq \mathsf{var}(G) \setminus \partial(G)$, $\tau_2^\star : S_2^\star \to \{0,1\}$ and $\widetilde{\tau} : \mathsf{var}(G) \to \{0,1\}$ such that the following hold:

- $|S_2^\star| \leq |S_1^\star|$,
- $\widetilde{\tau}$ extends $\tau_2^\star$, $\widetilde{\tau}$ coincides with τ on $\mathsf{var}(\partial(G))$ and $\widetilde{\tau}$ satisfies all clauses in $\mathsf{cla}(G) \setminus (Z_{satext} \cup Z_{kill})$,
- $\mathcal{M}_h(G_1') = \mathcal{M}_h(G_2')$ where G_2' is the graph obtained from G by deleting Z_{kill} and then restricting the vertex set to those vertices that survive after instantiating the vertices in $S_2^\star$ with $\tau_2^\star$.

▷ Claim 24. $\widehat{S} = (S^\star \setminus S_1^\star) \cup S_2^\star$ is also a weak backdoor set of ϕ of size at most k to $\mathcal{F}$-minor-free formulas.

In order to compute the required set S, it is sufficient to iterate over all $r \in [k]$ (guessing $|S_1^\star|$), assignments to the variables in $\partial(G)$ (guessing τ on the variables in the boundary), all possible (pairs) of disjoint subsets of $\mathsf{cla}(\partial(G))$ (guessing Z_{satext} and Z_{kill}) and all possible t'-labeled minors on at most h vertices (guessing $\mathcal{M}_h(G_1')$) and decide whether there exists a set $S_2^\star$ that satisfies the properties listed above and if yes, compute one. Finally, we return the union of all such sets. Notice that the number of such iterations is bounded by a function of η, k, d and hence the returned set has size at most $g(\eta, k, d)$ for some computable function g. Moreover, a set of the required kind in each iteration can be computed using Courcelle's theorem (see [23, 26] for MSO sentences capturing weak backdoors and minor exclusion). ◀

4 Hardness results for Backdoor Detection

Recall that an empty formula is a CNF formula with no clauses. Such formulas are trivially satisfiable.

▶ **Lemma 25.** *Let* $d, d' \geq 2$ *be two positive integers. There is a polynomial-time algorithm that takes as input* d, d', *an instance* $(U, \mathcal{S}, k)$ *of* Set Cover *and outputs a CNF formula* ϕ *with the following properties:*

1. *If* $(U, \mathcal{S}, k)$ *is a yes-instance of* Set Cover*, then* ϕ *has a strong/weak backdoor set of size at most* k *to the class of empty formulas.*
2. *If* ϕ *has strong/weak backdoor set of size at most* k *to any subclass of* $\mathcal{K}_{d,d'}$*-free formulas, then* $(U, \mathcal{S}, k)$ *is a yes-instance of* Set Cover*.*

Proof. Let $(U, \mathcal{S}, k)$ be the given instance of Set Cover. Now, we construct a CNF formula ϕ as follows. For each element $x \in U$, we have a set of $d'(k+1)$ variables $\{x_{i,j} \mid i \in [d'], j \in [k+1]\}$. For each $S \in \mathcal{S}$, we have a set of d variables $\{y_{S,i} \mid i \in [d]\}$. Thus,

$$\mathsf{var}(\phi) = \{x_{i,j} \mid x \in U, i \in [d'], j \in [k+1]\} \cup \{y_{S,i} \mid S \in \mathcal{S}, i \in [d]\}.$$

Next, we explain the construction of the set of clauses of ϕ. For each element $x \in U$, let $\mathcal{S}_x$ be the family of sets in $\mathcal{S}$ that contain x. For each $x \in U$, we make $d'(k+1)+1$ clauses as follows.

$$C_x = \{y_{S,i}, \overline{y}_{S,i} \mid S \in \mathcal{S}_x, i \in [d]\}, \text{ and}$$

$$\text{for all } i \in [d'] \text{ and } j \in [k+1], \quad T_x(i,j) = C_x \cup \{x_{i,j}, \overline{x}_{i,j}\}.$$

This completes the construction of ϕ. It is easy to verify that the construction can be done in polynomial time.

Next we prove the correctness of the algorithm. Consider the first statement. Let $\mathcal{P}$ be a solution for $(U, \mathcal{S}, k)$ of Set Cover. We claim that $Z = \{y_{S,1} \mid S \in \mathcal{P}\}$ is a strong backdoor set as well as a weak backdoor set of ϕ of size at most k to the class of empty formulas. Since $\mathcal{P}$ is a set cover, we have that for any $x \in U$, C_x contains a variable from Z, which appears both positively and negatively in C_x. Thus, for any assignment for the variables in Z, C_x is satisfied for all $x \in U$. This also implies that for any $x \in U, i \in [d']$, and $j \in [k+1]$, $T_x(i,j)$ is satisfied because $C_x \subseteq T_x(i,j)$. In other words, every clause is satisfied by every assignment to Z. This shows that Z is a strong backdoor set of ϕ of size at most k to the class of empty formulas. Since each such sub-formula is trivially satisfiable, we also conclude that every assignment to the variables in Z can be extended to a satisfying assignment of ϕ. This implies that Z is also a weak backdoor set of ϕ of size at most k to the class of empty formulas.

We now prove the second statement. Let Z be a strong or weak $\mathcal{C}$-backdoor set of size at most k for the CNF formula ϕ, where $\mathcal{C}$ is a subclass of $\mathcal{K}_{d,d'}$-free formulas. Let,

$$\mathcal{P} = \{S \in \mathcal{S} \mid \text{ there exists } j \in [d] \text{ such that } y_{S,j} \in Z\}.$$

We prove that $\mathcal{P}$ is indeed a solution for the Set Cover instance $(U, \mathcal{S}, k)$. Since $|Z| \leq k$, we have that $|\mathcal{P}| \leq k$. For the sake of contradiction assume that $\mathcal{P}$ is not a set cover of $(U, \mathcal{S})$. Then, there exists an element $x \in U$ that does not belong to any set in $\mathcal{P}$. This implies that none of the variables in C_x is present in Z. Consider the set of clauses $\mathcal{T} = \{T_x(i,j) \mid i \in [d'], j \in [k+1]\}$. C_x is a subset of every clause in $\mathcal{T}$. Moreover, the clauses in $\{T_x(i,j) \setminus C_x \mid i \in [d'], j \in [k+1]\}$ have pairwise disjoint variable sets. Since $\mathsf{var}(C_x) \cap Z = \emptyset$ and $|Z| \leq k$, there exists $j \in [k+1]$ such that the clauses $T_x(1,j), \ldots T_x(d',j)$ do not contain a variable from Z. Let Q be an arbitrary set in $\mathcal{S}$ containing x. Notice that $y_{Q,1}, \ldots, y_{Q,d} \notin Z$ because of our assumption that x is not covered by $\mathcal{P}$. As $y_{Q,1}, \ldots, y_{Q_d} \in \mathsf{var}(C_x)$, we have that $y_{Q,1}, \ldots, y_{Q,d} \in \mathsf{var}(T_x(i,j))$ for all $i \in [d']$. That is, the subgraph of $\mathsf{inc}(\phi)$ induced on $y_{Q,1}, \ldots, y_{Q,d}$ and $T_x(1,j), \ldots, T_x(d',j)$ forms a $K_{d,d'}$. Moreover this subgraph remains in the incidence graph of the formula obtained by simplifying ϕ based on any assignment to Z. This is a contradiction to the assumption that Z is a strong/weak $\mathcal{C}$-free backdoor set for ϕ. This completes the proof of the second statement. ◀

Lemma 25 implies Theorem 4 as argued in Section 1.

5 Conclusion

We have shown the fixed-parameter tractability of SAT parameterized by the size of a smallest weak backdoor to bounded-treewidth formulas, when the input belongs to the class of formulas whose incidence graphs are $K_{d,d}$-free. This implies the same result when the incidence graph of the input formula excludes a fixed (topological) minor or is from a class of bounded expansion or even from a nowhere-dense graph class. Thus, our main result advances our understanding of the parameterized complexity of SAT well beyond previously studied sparse inputs. In fact, we have shown that all nowhere-dense input formulas are tractable in this setting and moreover, by extending our result to biclique-free formulas, we have also identified natural classes of tractable formulas incomparable with nowhere-dense classes, i.e., formulas of bounded degeneracy.

We also reiterate that our main objective was to obtain a classification result and so, we have not attempted to optimize the running time and relied on invocations to Courcelle's theorem where it is standard in the literature on backdoor set detection. However, given the single-exponential (in k) running time of the algorithms in [13] that significantly improved upon similarly large exponential factors in [23, 26], it is not unreasonable to expect targeted research in this direction to yield similar speed-ups. A promising starting point towards this could be to consider subclasses of biclique-free graphs (e.g., graphs of bounded expansion) and identify those input classes where such a single-exponential dependence on k can be achieved.

Abstract

The classical coding theorem in Kolmogorov complexity states that if an n-bit string x is sampled with probability δ by an algorithm with prefix-free domain then $\mathsf{K}(x) \leq \log(1/\delta) + O(1)$. In a recent work, Lu and Oliveira [31] established an unconditional time-bounded version of this result, by showing that if x can be efficiently sampled with probability δ then $\mathsf{rKt}(x) = O(\log(1/\delta)) + O(\log n)$, where rKt denotes the randomized analogue of Levin's Kt complexity. Unfortunately, this result is often insufficient when transferring applications of the classical coding theorem to the time-bounded setting, as it achieves a $O(\log(1/\delta))$ bound instead of the information-theoretic optimal $\log(1/\delta)$.

Motivated by this discrepancy, we investigate optimal coding theorems in the time-bounded setting. Our main contributions can be summarised as follows.

• **Efficient coding theorem for rKt with a factor of 2.** Addressing a question from [31], we show that if x can be efficiently sampled with probability at least δ then $\mathsf{rKt}(x) \leq (2 + o(1)) \cdot \log(1/\delta) + O(\log n)$. As in previous work, our coding theorem is *efficient* in the sense that it provides a polynomial-time probabilistic algorithm that, when given x, the code of the sampler, and δ, it outputs, with probability ≥ 0.99, a probabilistic representation of x that certifies this rKt complexity bound.

• **Optimality under a cryptographic assumption.** Under a hypothesis about the security of cryptographic pseudorandom generators, we show that no efficient coding theorem can achieve a bound of the form $\mathsf{rKt}(x) \leq (2 - o(1)) \cdot \log(1/\delta) + \mathsf{poly}(\log n)$. Under a weaker assumption, we exhibit a gap between *efficient* coding theorems and *existential* coding theorems with near-optimal parameters.

• **Optimal coding theorem for pK^t and unconditional Antunes-Fortnow.** We consider pK^t complexity [17], a variant of rKt where the randomness is public and the time bound is fixed. We observe the existence of an optimal coding theorem for pK^t, and employ this result to establish an *unconditional* version of a theorem of Antunes and Fortnow [5] which characterizes the worst-case running times of languages that are in average polynomial-time over all P-samplable distributions.

1 Context and Background

A sampler is a probabilistic function that outputs Boolean strings. For any string $x \in \{0,1\}^*$ in its range, let $\mu(x)$ denote the probability with which x is generated. The Coding Theorem in Kolmogorov complexity states that if the sampler is computable and its domain is a prefix-free set, then for every x in its range

$$\mathsf{K}(x) \leq \log(1/\mu(x)) + O(1),$$

where $\mathsf{K}(\cdot)$ is the prefix-free Kolmogorov complexity. In other words, strings that are sampled with non-trivial probability have short representations. Note that the coding theorem achieves *optimal* expected length, since no uniquely decodable code can have expected length smaller than $\sum \mu(x) \log_2(1/\mu(x))$, the entropy of the sampler (the sum is over all x in the range of the sampler, assumed here to be finite).

The coding theorem is a central result in Kolmogorov complexity.[1] While it has found a number of applications in theoretical computer science (see, e.g., [28, 25, 1]), it comes with an important caveat: many aspects of the theory of Kolmogorov complexity are *non-constructive*. For instance, there is provably no algorithm that estimates $\mathsf{K}(x)$. Similarly, for arbitrary samplers, there is no effective compressor achieving the short representation provided by the coding theorem[2] and also no upper bound on the running time required to decompress x from it.

In order to translate results and techniques from Kolmogorov complexity to the setting of *efficient* algorithms and computations, several *time-bounded* variants of Kolmogorov complexity have been proposed. We refer to the book [29], thesis [25], and surveys [2, 3, 16, 4] for a comprehensive treatment of this area and its numerous applications to algorithms, complexity, cryptography, learning, and pseudorandomness, among other fields. We highlight that many exciting new results, which include worst-case to average-case reductions for NP problems [20, 21] and complexity-theoretic characterizations of one-way functions [30, 36], rely in a crucial way on time-bounded Kolmogorov complexity. These recent developments further motivate the investigation of key results from Kolmogorov complexity in the time-bounded setting.

In time-bounded Kolmogorov complexity we consider the minimum description length of a string x *with respect to machines that operate under a time constraint*. We informally review next two central notions in this area (see Section A for precise definitions). For a Turing machine $\mathcal{M}$, we let $|\mathcal{M}|$ denote its description length according to a fixed universal machine U. $\mathcal{M}(\varepsilon)$ denotes the computation of $\mathcal{M}$ over the empty string.

Kt Complexity. [26] This notion simultaneously considers description length and running time when measuring the complexity of a string x.

$$\mathsf{Kt}(x) \;=\; \min_{\text{TM } \mathcal{M},\, t \geq 1} \{|\mathcal{M}| + \log t \mid \mathcal{M}(\varepsilon) \text{ outputs } x \text{ in } t \text{ steps}\}\,.$$

K^t Complexity. [37] In contrast with Kt, here we fix the time bound $t\colon \mathbb{N} \to \mathbb{N}$, and consider the minimum description with respect to machines that run in time at most $t(|x|)$.

$$\mathsf{K}^t(x) \;=\; \min_{\text{TM } \mathcal{M}} \{|\mathcal{M}| \mid \mathcal{M}(\varepsilon) \text{ outputs } x \text{ in } t(|x|) \text{ steps}\}\,.$$

[1] For instance, [25] describes it as one of the four pillars of Kolmogorov complexity.

[2] However, there exists a probabilistic polynomial-time compressor that given x and an integer $m \geq \log(1/\mu(x))$ outputs a description of x of length m + small polylogarithmic overhead [6].

While Kt complexity is tightly related to optimal search algorithms (see [24] for a recent application), K^t is particularly useful in settings where maintaining a polynomial bound on the running time t is desired (see, e.g., [20]).

Antunes and Fortnow [5] introduced techniques that can be used to establish (conditional) coding theorems for K^t and Kt. In particular, if a sampler runs in *polynomial time* and outputs a string x with probability at least δ, then $\mathsf{Kt}(x) \leq \log(1/\delta) + O(\log n)$. Note that this coding theorem also achieves an optimal dependence on the probability parameter δ. However, the results of [5] rely on a strong derandomization assumption. For this reason, their application often lead to *conditional* results.

More recently, [31] established an *unconditional* coding theorem for a *randomized* analogue of Kt complexity. Before explaining their result, we review the definitions of rKt and rK^t.[3]

rKt Complexity. [35] In this definition, we consider randomized machines that output x with high probability.

$$\mathsf{rKt}(x) = \min_{\text{RTM } \mathcal{M},\, t \geq 1} \{|\mathcal{M}| + \log t \mid \mathcal{M}(\varepsilon) \text{ outputs } x \text{ in } t \text{ steps with probability} \geq 2/3\}.$$

rK^t Complexity. [10, 32][4] This is the randomized analogue of K^t, where the time bound t is fixed in advance.

$$\mathsf{rK}^t(x) = \min_{\text{RTM } \mathcal{M}} \{|\mathcal{M}| \mid \mathcal{M}(\varepsilon) \text{ outputs } x \text{ in } t(|x|) \text{ steps with probability} \geq 2/3\}.$$

In both cases, we can think of the randomized Turing machine $\mathcal{M}$ as a *probabilistic representation* of the input string x, in the sense that x can be recovered with high probability from its description. These measures allow us to employ methods from time-bounded Kolmogorov complexity in the setting of randomized computation, which is ubiquitous in modern computer science. For instance, [35, 32] employed rKt and rK^t to obtain bounds on the compressibility of prime numbers and other objects and to show that certain problems about time-bounded Kolmogorov complexity can be intractable. We note that, under derandomization assumptions (see [35]), for every string x, $\mathsf{rKt}(x) = \Theta(\mathsf{Kt}(x))$. Similarly, one can conditionally show that $\mathsf{K}^t(x)$ is essentially $\mathsf{rK}^t(x)$, up to a $O(\log |x|)$ additive term (see [17]). Consequently, insights obtained in the context of probabilistic notions of Kolmogorov complexity can often inform the study of more classical notions such as Kt and K^t.

Among other results, [31] established the following unconditional coding theorem in time-bounded Kolmogorov complexity: if a sampler runs in polynomial time and outputs a string x with probability at least δ, then $\mathsf{rKt}(x) = O(\log(1/\delta) + O(\log n)$. While this result can be used to port some applications of the coding theorem from Kolmogorov complexity to the time-bounded setting, in many cases it is still insufficient. This is because its dependence on the probability parameter δ is not optimal, which is often crucial in applications (see, e.g., [5, 1]).

2 Results

In this work, we investigate optimal coding theorems in time-bounded Kolmogorov complexity. We describe our results next.

[3] See Appendix A for a formal treatment.
[4] [10] refers to this notion as CBP^t complexity.

2.1 A Tighter Efficient Coding Theorem

Our first result addresses the question posed in [31, Problem 37].

▶ **Theorem 1.** *Suppose there is an efficient algorithm A for sampling strings such that $A(1^n)$ outputs a string $x \in \{0,1\}^n$ with probability at least δ. Then*

$$\mathsf{rKt}(x) \;\leq\; 2\log(1/\delta) + O\big(\log n + \log^2 \log(1/\delta)\big)\,,$$

where the constant behind the $O(\cdot)$ depends on A and is independent of the remaining parameters. Moreover, given x, the code of A, and δ, it is possible to compute in time $\mathsf{poly}(n, |A|)$, with probability ≥ 0.99, a probabilistic representation of x certifying this rKt-complexity bound.

In [9, Lemma 4], it was observed that by hashing modulo prime numbers one can obtain short descriptions of strings. As discussed in [31, Section A.2.1], for each efficient sampling algorithm, this technique implies that if some string x is produced with probability $\geq \delta$, then $\mathsf{rKt}(x) \leq 3\log(1/\delta) + O(\log n)$.[5] In contrast, Theorem 1 achieves a bound of the form $(2 + o(1)) \cdot \log(1/\delta) + O(\log n)$.

Theorem 1 readily improves some parameters in the applications of the coding theorem for rKt discussed in [31], such as the efficient instance-based search-to-decision reduction for rKt. We omit the details.

In [33, Section 3.1], we discuss extensions of this result. In particular, we describe precise bounds on the running time used in producing the corresponding probabilistic representation, and discuss computational aspects of the compression and decompression of x in detail. In [33, Appendix A], we discuss the computation of a probabilistic representation of the string x when one does not know a probability bound δ.

2.2 Matching Lower Bound Under a Cryptographic Assumption

It is possible to extend techniques from [5] to show the following conditional result (see [33, Section 3.2]).

▶ **Proposition 2.** *Assume there is a language $L \in \mathsf{BPTIME}\left[2^{O(n)}\right]$ that requires nondeterministic circuits of size $2^{\Omega(n)}$ for all but finitely many n. Suppose there is an efficient algorithm A for sampling strings such that $A(1^n)$ outputs a string $x \in \{0,1\}^n$ with probability at least $\delta > 0$. Then*

$$\mathsf{rKt}(x) \;\leq\; \log(1/\delta) + O(\log n).$$

While Proposition 2 provides a better bound than Theorem 1, the result is only *existential*, i.e., it does not provide an efficient algorithm that produces a probabilistic representation of x. In other words, Proposition 2 does not establish an *efficient* coding theorem. Our next result shows that the bound achieved by Theorem 1 is optimal for efficient coding theorems, under a cryptographic assumption.

[5] The bound from [31, Section A.2.1] is different because it does not take into account the running time, which incurs an additional overhead of $\log(1/\delta)$.

The Cryptographic Assumption. For a constant $\gamma \in (0,1)$, we introduce the γ-Crypto-ETH assumption, which can be seen as a cryptographic analogue of the well-known exponential time hypothesis about the complexity of k-CNF SAT [23]. Informally, we say that γ-Crypto-ETH holds if there is a pseudorandom generator $G\colon \{0,1\}^{\ell(n)} \to \{0,1\}^n$ computable in time $\mathrm{poly}(n)$ that fools *uniform algorithms* running in time $2^{\gamma \cdot \ell(n)}$. Any seed length $(\log n)^{\omega(1)} \leq \ell(n) \leq n/2$ is sufficient in our negative results.

In analogy with the well-known ETH and SETH hypotheses about the complexity of k-CNF SAT, we say that Crypto-ETH holds if γ-Crypto-ETH is true for some $\gamma > 0$, and that Crypto-SETH holds if γ-Crypto-ETH is true for every $\gamma \in (0,1)$. Since a candidate PRG of seed length $\ell(n)$ can be broken in time $2^{\ell(n)}\mathsf{poly}(n)$ by trying all possible seeds, these hypotheses postulate that for some PRGs one cannot have an attack that does sufficiently better than this naive brute-force approach.

We stress that these assumptions refer to uniform algorithms. In the case of non-uniform distinguishers, it is known that Crypto-SETH does not hold (see [15, 14, 13] and references therein). We provide a formal treatment of the cryptographic assumption in [33, Section 4].

▶ **Theorem 3** (Informal). *Let $\gamma \in (0,1)$ be any constant. If γ-Crypto-ETH holds, there is no efficient coding theorem for* rKt *that achieves bounds of the form* $(1+\gamma-o(1)) \cdot \log(1/\delta) + \mathsf{poly}(\log n)$.

Theorem 3 shows that if Crypto-ETH holds then the best parameter achieved by an *efficient* coding theorem for rKt is $(1+\Omega(1)) \cdot \log(1/\delta) + \mathsf{poly}(\log n)$. This exhibits an inherent gap in parameters between the efficient coding theorem (Theorem 1) and its existential analogue (Proposition 2). On the other hand, if the stronger Crypto-SETH hypothesis holds, then no efficient coding theorem for rKt achieves parameter $(2-o(1)) \cdot \log(1/\delta) + \mathsf{poly}(\log n)$. In this case, Theorem 1 is essentially optimal with respect to its dependence on δ.

Fine-grained complexity of coding algorithms for polynomial-time samplers. An rKt bound refers to the time necessary to *decompress* a string x from its probabilistic representation. On the other hand, an *efficient* coding theorem provides a routine that can *compress* x in polynomial time. More generally, a coding procedure for a sampler A consists of a pair of probabilistic algorithms (Compress, Decompress) that aim to produce a "good" codeword p for every string y sampled by A. The quality of p depends on three values: the length of p, the number of steps t_C used to produce p from y (the compression time), and the number of steps t_D used to produce y from p (the decompression time). It is interesting to understand the trade-off between these three values. Toward this goal, we aggregate them in a manner similar to rKt, by defining the 2-sided-rKt complexity of y to be, roughly, $|p| + \log(t_C + t_D)$ (the formal definition, see [33, Definition 25]), is more complicated because it takes into account that Compress and Decompress are probabilistic). Thus according to 2-sided-rKt, each bit gained by a shorter codeword is worth doubling the compression/decompression time. For instance, for simple samplers (say, having a finite range, or generating strings with the uniform distribution), there exist trivial polynomial time Compress and Decompress, which in case y is sampled with probability at least δ, produce a codeword p with $|p| = \log(1/\delta)$ (provided Compress and Decompress know δ). Such a coding procedure certifies for each sampled string a 2-sided-rKt complexity of $\log(1/\delta) + O(\log n)$. We say that the sampler admits coding with 2-sided-rKt complexity bounded by $\log(1/\delta) + O(\log n)$. In general, we have to include also the error probability of Compress and Decompress, which we omit in this informal discussion.

Similarly to Theorem 1 and Theorem 3 (and also with similar proofs), we establish the following theorem.

▶ **Theorem 4** (Informal). *The following results hold.*

(a) (Upper Bound) *Every polynomial-time sampler admits coding with* 2*-sided-*rKt *complexity* $2\log(1/\delta) + O(\log^2\log(1/\delta)) + O(\log n)$.

(b) (Conditional Lower Bound) *Let* $\gamma \in (0,1)$ *be any constant. If* γ*-*Crypto-ETH *holds, there exists a polynomial-time sampler that does not admit coding with* 2*-sided-*rKt *complexity bounded by* $(1+\gamma-o(1))\cdot\log(1/\delta) + \mathsf{poly}(\log n)$*, unless the error probability is greater than* $1/7$.

2.3 An Optimal Coding Theorem and Unconditional Antunes-Fortnow

While Theorem 1 improves the result from [31] to achieve a bound that is tight up to a factor of 2 and that is possibly optimal among efficient coding theorems, it is still insufficient in many applications. We consider next a variant of rKt that allows us to establish an *optimal* and *unconditional* coding theorem in time-bounded Kolmogorov complexity.

Fix a function $t\colon \mathbb{N}\to\mathbb{N}$. For a string $x\in\{0,1\}^*$, the probabilistic t-bounded Kolmogorov complexity of x (see [17]) is defined as

$$\mathsf{pK}^t(x) = \min\left\{ k \;\middle|\; \Pr_{w\sim\{0,1\}^{t(|x|)}}\left[\exists\,\mathcal{M}\in\{0,1\}^k,\ \mathcal{M}(w) \text{ outputs } x \text{ within } t(|x|) \text{ steps}\right] \geq \frac{2}{3}\right\}.$$

In other words, if $k = \mathsf{pK}^t(x)$, then with probability at least $2/3$ over the choice of the random string w, x admits a time-bounded encoding of length k. In particular, if two parties share a typical random string w, then x can be transmitted with k bits and decompressed in time $t = t(|x|)$. (Recall that here the time bound t is fixed, as opposed to rKt, where a $\log t$ term is added to the description length.)

It is possible to show that $\mathsf{K}^t(x)$, $\mathsf{rK}^t(x)$, and $\mathsf{pK}^t(x)$ correspond essentially to the same time-bounded measure, under standard derandomization assumptions [17].[6] One of the main benefits of pK^t is that it allows us to establish unconditional results that are currently unknown in the case of the other measures.[7]

▶ **Theorem 5.** *Suppose there is a randomized algorithm* A *for sampling strings such that* $A(1^n)$ *runs in time* $T(n)\geq n$ *and outputs a string* $x\in\{0,1\}^n$ *with probability at least* $\delta>0$. *Then*

$$\mathsf{pK}^t(x) \;=\; \log(1/\delta) + O(\log T(n))\,,$$

where $t(n) = \mathrm{poly}(T(n))$ *and the constant behind the* $O(\cdot)$ *depends on* $|A|$ *and is independent of the remaining parameters.*

Theorem 5 provides a time-bounded coding theorem that can be used in settings where the optimal dependence on δ is crucial. As an immediate application, it is possible to show an equivalence between efficiently sampling a fixed sequence $w_n\in\{0,1\}^n$ of objects (e.g., n-bit prime numbers) with probability at least $\delta_n/\mathsf{poly}(n)$ and the existence of bounds for the

---

[6] More precisely, under standard derandomization assumptions, $\mathsf{pK}^t(x)$ and $\mathsf{rK}^{t'}(x)$ coincide up to an additive term of $O(\log|x|)$, provided that $t' = \mathrm{poly}(t)$. A similar relation holds between K^t and rK^t.

[7] While in this work we focus on coding theorems, we stress that pK^t is a key notion introduced in [17] that enables the investigation of meta-complexity in the setting of probabilistic computations. It has applications in worst-case to average-case reductions and in learning theory.

corresponding objects of the form $\mathsf{pK}^{\mathrm{poly}}(w_n) = \log(1/\delta_n) + O(\log n)$.[8] This is the first tight equivalence of this form in time-bounded Kolmogorov complexity that does not rely on an unproven assumption.

As a more sophisticated application of Theorem 5, we establish an unconditional form of the main theorem from Antunes and Fortnow [5], which provides a characterization of the worst-case running times of languages that are in average polynomial-time over all P-samplable distributions.

We recall the following standard notion from average-case complexity (see, e.g., [8]). For an algorithm A that runs in time $T_A\colon \{0,1\}^* \to \mathbb{N}$ and for a distribution $\mathcal{D}$ supported over $\{0,1\}^*$, we say that A runs in polynomial-time on average with respect to $\mathcal{D}$ if there is some constant $\varepsilon > 0$ such that

$$\mathop{\mathbf{E}}_{x\sim\mathcal{D}}\left[\frac{T_A(x)^\varepsilon}{|x|}\right] < 1.$$

As usual, we say that a distribution $\mathcal{D}$ is P-samplable if it can be sampled in polynomial time.

▶ **Theorem 6.** *The following conditions are equivalent for any language $L \subseteq \{0,1\}^*$.*

(i) *For every P-samplable distribution $\mathcal{D}$, L can be solved in polynomial-time on average with respect to $\mathcal{D}$.*

(ii) *For every polynomial p, there exists a constant $b > 0$ such that the running time of some algorithm that computes L is bounded by $2^{O(\mathsf{pK}^p(x) - \mathsf{K}(x) + b\log(|x|))}$ for every input x.*

In contrast, [5] shows a *conditional* characterisation result that employs K^t complexity in the expression that appears in Item (*ii*).

3 Techniques

In this section, we provide an informal overview of our proofs and techniques.

Efficient Coding Theorem for rKt (Theorem 1). Breaking down the result into its components, Theorem 1 shows that for any polynomial-time sampler A, there exist a probabilistic polynomial-time algorithm Compress and an algorithm Decompress with the following properties: Compress on input an n-bit string x and δ (which estimates from below the probability with which A samples x), returns a codeword c_x of length $\log(1/\delta) + \mathrm{poly}(\log n)$ such that Decompress with probability ≥ 0.99 reconstructs x in time $1/\delta \cdot \exp(\mathrm{poly}(\log n))$. Note that the probabilistic representation of x certifying the rKt bound in Theorem 1 can be obtained from the codeword c_x and Decompress, and that obtaining a running time with a factor of $(1/\delta)^{1+o(1)}$ is crucial in order to get a final rKt bound of the form $(2 + o(1)) \cdot \log(1/\delta)$. (Actually, Compress does not have to depend on A, the 0.99 can be $1 - \varepsilon$ for arbitrary $\varepsilon > 0$, and the $\mathrm{poly}(\log n)$ term is $O(\log n + \log^2 \log(1/\delta))$, but we omit these details in our discussion). We explain what are the challenges in obtaining Compress and Decompress and how they are overcome. We remark that the construction is different from the approaches described in [31].

[8] An efficient sampler immediately implies the corresponding pK^t bounds via Theorem 5. On the other hand, objects of bounded pK^t complexity can be sampled by considering a random sequence of bits and a random program of appropriate length. We refer to [31, Theorem 6] for a weaker relation and its proof. Since the argument is essentially the same, we omit the precise details.

Decompress can run the sampler $K := O(1/\delta)$ times and obtain a list of elements S^* (the list of suspects) that with high probability contains x. Compress has to provide information that allows Decompress to prune S^* and find x. Since the algorithms do not share randomness, Compress does not know S^*, and so compression has to work for any $S \subseteq \{0,1\}^n$ of size K, only assuming that $x \in S$. Compress can use a bipartite lossless expander graph G, which is a graph with the property that any set S of left nodes with size $|S| \leq K$ has at least $(1-\varepsilon)D|S|$ neighbors, where D is the left degree. Such graphs are called $((1-\varepsilon)D, K)$ lossless expanders and they have numerous applications (see e.g., [11, 22]). An extension of Hall's matching theorem shows that for any set S of K left nodes, there is a matching that assigns to each $x \in S$, $(1-\varepsilon)D$ of its neighbors, so that no right node is assigned twice (i.e., the matching defines a subgraph with no collisions). Compress can just pick the codeword c_x to be one random neighbor of x. Then, Decompress can do the pruning of S^* as follows. Having S^* and c_x, it does the matching, and, since with probability $1-\varepsilon$, c_x is only assigned to x, Decompress can find x. There is one problem though. The algorithms for maximum matching in general bipartite graphs do not run in linear time (see [12, 34], and the references therein). Therefore, the decompression time would have a dependency on δ too large for us. Fortunately, lossless expanders can be used to do "almost" matching faster. [6] introduces *invertible functions* (see [33, Definition 12]) for the more demanding task in which the elements of S appear one-by-one and the matching has to be done in the online manner. We do not need online matching, but we take advantage of the construction in [6] to obtain a fast matching algorithm. It follows from [6], that in a lossless expander it is possible to do a greedy-type of "almost" matching, which means that every left node in S is matched to $(1-\varepsilon)D$ of its neighbors (exactly what we need), but with $\mathrm{poly}(\log n)$ collisions. The collisions can be eliminated with some additional standard hashing (see the discussion on [33, Page 14] for details). As we explain on [33, Page 14], this leads to decompression time $K \cdot D \cdot \mathrm{poly}(n)$ and the length of the codeword c_x is $\log |R| + |\text{hash-code}|$, where R is the right set of the lossless expander. To obtain our result, the degree D has to be $2^{\mathrm{poly}(\log n)}$ and $|R|$ has to be $K \cdot 2^{\mathrm{poly}(\log n)}$.

Building on results and techniques from [18], [6] constructs a $((1-\varepsilon)D, K)$ explicit lossless expander with left side $\{0,1\}^n$, degree $D = 2^d$ for $d = O(\log(n/\varepsilon) \cdot \log k)$, and right side R, with size verifying $\log |R| = k + \log(n/\varepsilon) \cdot \log k$ (where $k := \log K$). To obtain in Theorem 1 the dependency on n to be $O(\log n)$ (which is optimal up to the constant in $O(\cdot)$), we show the existence of a $((1-\varepsilon)D, K)$ explicit expander with $d = O(\log n + \log(k/\varepsilon) \cdot \log k)$ and $\log |R| = k + O(\log n + \log(k/\varepsilon) \cdot \log k)$. This lossless expander is constructed by a simple composition of the above lossless expander from [6] with a lossless expander from [18], with an appropriate choice of parameters (see [33, Section 3.1.1]).

Conditional Lower Bound for Efficient Coding Theorems (Theorem 3). Our goal is to show that there is no *efficient* coding theorem for rKt that achieves bounds of the form $(1+\gamma-o(1)) \cdot \log(1/\delta) + \mathrm{poly}(\log n)$, under the assumption that γ-Crypto-ETH holds for $\gamma \in (0,1)$. We build on an idea attributed to L. Levin (see e.g. [25, Section 5.3]). To provide an overview of the argument, let $G_n \colon \{0,1\}^{\ell(n)} \to \{0,1\}^n$ be a cryptographic generator of seed length $\ell(n) = n/2$ witnessing that γ-Crypto-ETH holds. In other words, G_n has security $2^{\gamma \cdot \ell(n)}$ against uniform adversaries. We define a sampler S_n as follows. On input $x \in \{0,1\}^n$, which we interpret as a random string, it outputs $G_n(x')$, where x' is the prefix of x of length $\ell(n)$. We argue that if an *efficient* algorithm F is able to compress every string y in the support of $\mathsf{Dist}(S_n)$, the distribution induced by the sampler S_n, to an rKt encoding of complexity $(1+\gamma-\varepsilon) \cdot \log(1/\delta'(y)) + C \cdot (\log n)^C$, where $\delta'(y)$ is a lower bound on $\delta(y)$ (the probability of y under $\mathsf{Dist}(S_n)$), we can use F to break G_n. (Note that F expects as input n, y, δ', and $\mathsf{code}(S)$.)

The (uniform) distinguisher D computes roughly as follows. Given a string $z \in \{0,1\}^n$, which might come from the uniform distribution U_n or from $G_n(U_{\ell(n)}) \equiv \mathsf{Dist}(S_n)$, D attempts to use F to *compress* z to a "succinct" representation, then checks if the computed representation *decompresses* to the original string z. If this is the case, it outputs 1, otherwise it outputs 0. (Note that we haven't specified what "succinct" means, and it is also not immediately clear how to run F, since it assumes knowledge of a probability bound δ'. For simplicity of the exposition, we omit this point here.) We need to argue that a test of this form can be implemented in time $2^{\gamma \cdot \ell(n)}$, and that it distinguishes the output of G from a random string.

To achieve these goals, first note that a typical random string cannot be compressed to representations of length, say, $n - \mathsf{poly}(\log n)$, even in the much stronger sense of (time-unbounded) Kolmogorov complexity. Therefore, with some flexibility with respect to our threshold for succinctness, the proposed distinguisher is likely to output 0 on a random string. On the other hand, if F implements an efficient coding theorem that achieves rKt encodings of complexity $(1+\gamma-\varepsilon)\cdot\log(1/\delta'(y))+\mathsf{poly}(\log n)$, the following must be true. Using that the expected *encoding length* of *any* (prefix-free) encoding scheme is at least $H(\mathsf{Dist}(S_n))$, where $\mathsf{Dist}(S_n)$ is the distribution of strings sampled by S_n and H is the entropy function, we get (via a slightly stronger version of this result) that a non-trivial measure of strings y in the support of $\mathsf{Dist}(S_n)$ have rKt *encoding length* at least $(1-\varepsilon/4)\cdot\log(1/\delta(y))$. Consequently, for such strings, an upper bound on rKt complexity of $(1+\gamma-\varepsilon)\cdot\log(1/\delta'(y))+\mathsf{poly}(\log n)$ when $\delta'(y)$ is sufficiently close to $\delta(y)$ implies that the running time t of the underlying machine satisfies $\log t \leq (\gamma-\varepsilon/2)\log(1/\delta(y))+\mathsf{poly}(\log n)$. Using that $\ell(n)=n/2$ and $\delta(y)\geq 2^{-\ell(n)}$ for any string y in the support of $\mathsf{Dist}(S_n)$, it is easy to check that (asymptotically) $t \leq 2^{(\gamma-\varepsilon/4)\cdot\ell(n)}$. For this reason, we can implement a (slightly modified) distinguisher D in time less than $2^{\gamma\cdot\ell(n)}$, by trying different approximations $\delta'(z)$ for an input string z and by running the decompressor on the produced representation for at most t steps on each guess for $\delta(z)$. By our previous discussion, a non-trivial measure of strings from $\mathsf{Dist}(S_n)$ will be accepted by D, while only a negligible fraction of the set of all strings (corresponding to the random case) will be accepted by D.

Implementing this strategy turns out to be more subtle than this. This happens because F is a *probabilistic* algorithm which does not need to commit to a *fixed* succinct encoding. We refer to the formal presentation in [33, Section 4] for details, where we also discuss the bound on the seed length $\ell(n)$.

Coding Theorem for pK^t (Theorem 5) and Unconditional [5] (Theorem 6). The proof of our optimal coding theorem for pK^t builds on that of the *conditional* coding theorem for K^t from [5], which can be viewed as a two-step argument. Roughly speaking, the first step is to show that if there is a polynomial-time sampler that outputs a string $x \in \{0,1\}^n$ with probability δ, then the polynomial-time-bounded Kolmogorov complexity of x is about $\log(1/\delta)+O(\log n)$ *if we are given a random string*. After this, they "derandomize" the use of random strings using a certain pseudorandom generator, which exists under a strong derandomization assumption. Our key observation is that the use of random strings arises naturally in probabilistic Kolmogorov complexity, and particularly in this case the random strings can be "embedded" into the definition of pK^t. As a result, we don't need to perform the afterward derandomization as in original proof of [5], and hence get rid of the derandomization assumption.

Next, we describe how to use Theorem 5, together with other useful properties of pK^t, to obtain an unconditional version of Antunes and Fortnow's main result. Let μ be a Kolmogorov complexity measure, such as $\mathsf{K}^{\mathsf{poly}}$, $\mathsf{rK}^{\mathsf{poly}}$ or $\mathsf{pK}^{\mathsf{poly}}$. The key notion in the proof

is the distribution (in fact, a class of semi-distributions) called m_μ, which is defined as $m_\mu(x) := 1/2^{\mu(x)}$. More specifically, following [5], it is not hard to show that, for every language L, L can be decided in polynomial-time on average with respect to m_μ if and only if its worst-case running time is $2^{O(\mu(x)-\mathsf{K}(x))}$ on input x (see [33, Lemma 25]). Then, essentially, to show our result we argue that L can be decided in polynomial time on average with respect to m_μ if and only if the same holds with respect to all P-samplable distributions.

Recall that if a distribution $\mathcal{D}$ *dominates* another distribution $\mathcal{D}'$ (i.e., $\mathcal{D}(x) \gtrsim \mathcal{D}'(x)$ for all x) and L is polynomial-time on average with respect to $\mathcal{D}$, then the same holds with respect to $\mathcal{D}'$ (see Definition 9 and Fact 10). Therefore, to replace m_μ above with P-samplable distributions, it suffices to show that m_μ is "universal" with respect to the class of P-samplable distributions, in the following sense.

1. m_μ dominates *every* P-samplable distribution. (This is essentially an optimal source coding theorem for the Kolmogorov measure μ.)
2. m_μ is dominated by *some* P-samplable distribution.

The above two conditions require two properties of the Kolmogorov measure μ that are somewhat conflicting: the first condition requires the notion of μ to be *general* enough so that m_μ can "simulate" *every* P-samplable distribution, while the second condition needs μ to be *restricted* enough so that m_μ can be "simulated" by *some* P-samplable (i.e., simple) distribution. For example, if μ is simply the time-unbounded Kolmogorov complexity K (or even the polynomial-space-bounded variant), then it is easy to establish an optimal source coding theorem for such a general Kolmogorov measure; however it is unclear how to sample in polynomial-time a string x with probability about $1/2^{\mathsf{K}(x)}$, so in this case μ does not satisfy the second condition. On the other hand, if μ is some restricted notion of time-bounded Kolmogrov complexity measure such as $\mathsf{K}^{\mathsf{poly}}$ or $\mathsf{rK}^{\mathsf{poly}}$, then one can obtain polynomial-time samplers that sample x with probability about $1/2^{\mathsf{K}^{\mathrm{poly}}(x)}$ or $1/2^{\mathsf{K}^{\mathrm{poly}}(x)}$ (up to a polynomial factor); however, as in [5], we only know how to show an *optimal* source coding theorem for $\mathsf{K}^{\mathsf{poly}}$ (or $\mathsf{rK}^{\mathsf{poly}}$) under a derandomization assumption. Therefore, in this case μ does not satisfies the first condition. Our key observation is that the notion $\mathsf{pK}^{\mathsf{poly}}$, which sits in between K and $\mathsf{K}^{\mathrm{poly}}$ (or $\mathsf{rK}^{\mathrm{poly}}$),[9] satisfies both conditions described above (see [33, Lemmas 36 and 37]).

4 Concluding Remarks and Open Problems

Our results indicate that Theorem 1 might be optimal among *efficient* coding theorems for rKt, i.e., those that efficiently produce representations matching the existential bounds. In the case of pK^t, the corresponding coding theorem (Theorem 5) is optimal. We have described a concrete application of Theorem 5 (Theorem 6). A second application appears in [17]. In both cases, achieving an optimal dependence on the probability parameter δ is critical, and for this reason, the result from [31] is not sufficient.

Naturally, we would like to understand the possibility of establishing an *unconditional* coding theorem for rKt with an optimal dependence on the probability parameter δ. While the validity of $\mathsf{Crypto\text{-}ETH}$ implies that no *efficient* coding theorem with this property exist, we have an *existential* coding theorem of this form under a derandomization assumption (Proposition 2). In the case of K^t complexity, it is known that an unconditional coding theorem with optimal dependence on δ implies that $\mathsf{EXP} \neq \mathsf{BPP}$ (see [25, Theorem 5.3.4]).

[9] We can show that for every $x \in \{0,1\}^*$ and every computable time bound $t\colon \mathbb{N} \to \mathbb{N}$, $\mathsf{K}(x) \lesssim \mathsf{pK}^t(x) \leq \mathsf{rK}^t(x) \leq \mathsf{K}^t(x)$.

However, the techniques behind this connection do not seem to lead to an interesting consequence in the case of rKt and rK^t. Consequently, an optimal coding theorem for rKt might be within the reach of existing techniques.

It would also be interesting to establish Theorem 3 under a weaker assumption, or to refute Crypto-SETH. A related question is the possibility of basing Crypto-ETH on the existence of one-way functions of exponential hardness. Existing reductions are not strong enough to provide an equivalence between one-way functions and cryptographic pseudorandomness in the exponential regime (see [38, 19]).

Finally, are there more applications of pK^t complexity and of Theorem 5? Since this coding theorem is both optimal and unconditional, we expect more applications to follow.

A Definitions and Basic Results

Time-bounded Kolmogorov complexity. For a function $t\colon \mathbb{N} \to \mathbb{N}$, a string x, and a universal Turing machine U, let the time-bounded Kolmogorov complexity be defined as

$$\mathsf{K}^t_U(x) = \min_{p\in\{0,1\}^*} \{|p| \mid U(p) \text{ outputs } x \text{ in at most } t(|x|) \text{ steps}\}.$$

A machine U is said to be *time-optimal* if for every machine M there exists a constant c such that for all $x \in \{0,1\}^n$ and $t\colon \mathbb{N} \to \mathbb{N}$ satisfying $t(n) \geq n$,

$$\mathsf{K}_U^{ct \log t}(x) \leq \mathsf{K}_M^t(x) + c,$$

where for simplicity we write $t = t(n)$. It is well known that there exist time-optimal machines [29, Th. 7.1.1]. In this paper, we fix such a machine U, and drop the index U when referring to time-bounded Kolmogorov complexity measures. It is also possible to consider prefix-free notions of Kolmogorov complexity. However, since all our results hold up to additive $O(\log |x|)$ terms, we will not make an explicit distinction.

Henceforth we will not distinguish between a Turing machine $\mathcal{M}$ and its encoding p according to U. If p is a probabilistic Turing machine, we define $t_p \in \mathbb{N} \cup \{\infty\}$ to be the maximum number steps it takes p to halt on input λ (the empty string), where the maximum is over all branches of the probabilistic computation.

rKt complexity and probabilistic representations. A probabilistic representation of a string x is a probabilistic Turing machine p that on input λ halts with x on the output tape with probability at least $2/3$. The rKt-complexity of a string x is the minimum, over all probabilistic representations p of x, of $p + \log t_p$. A *probabilistic representation* p of x *certifies* rKt*-complexity bounded by* Γ if $|p| + \log t_p \leq \Gamma$.

Distributions and semi-distributions. We consider distributions over the set $\{0,1\}^*$. We will identify a distribution with its underlying probability density function of the form $\mathcal{D}\colon \{0,1\}^* \to [0,1]$. A distribution $\mathcal{D}$ is a *semi-distribution* if $\sum_{x \in \{0,1\}^*} \mathcal{D}(x) \leq 1$, and is simply called a *distribution* if the sum is exactly 1. In this subsection, we will use the word "distribution" to refer to both distribution and semi-distribution.

Samplers. A *sampler* is a probabilistic algorithm A with inputs in $\{1\}^n$ such that $A(1^n)$ outputs a string $x \in \{0,1\}^n$.[10] It defines a family of distributions $\{\mu_{A,n}\}_{n \in \mathbb{N}}$, where $\mu_{A,n}$ is the distribution on $\{0,1\}^n$ defined by $\mu_{A,n}(x) = \mathbf{Pr}_A[A(1^n) = x]$.

Average-case complexity. We now review some standard definitions and facts from average-case complexity. We refer to the survey [8] for more details.

▶ **Definition 7** (Polynomial-time Samplable [7])**.** *A distribution $\mathcal{D}$ is called* P*-samplable if there exists a polynomial p and a probabilistic algorithm M such that for every $x \in \{0,1\}^*$, M outputs x with probability $\mathcal{D}(x)$ within $p(|x|)$ steps.*

▶ **Definition 8** (Polynomial Time on Average [27])**.** *Let A be an algorithm and $\mathcal{D}$ be a distribution. We say that A runs in polynomial-time on average with respect to $\mathcal{D}$ if there exist constants ε and c such that,*

$$\sum_{x \in \{0,1\}^*} \frac{t_A(x)^\varepsilon}{|x|} \mathcal{D}(x) \leq c,$$

[10] For simplicity, we assume that $A(1^n)$ samples a string of length n. Our coding theorems also hold for algorithms used to define P-samplable distributions, see Definition 7, with obvious changes in the proofs. Also, as in [31], our results can be easily generalised to samplers that on 1^n output strings of arbitrary length. In this case, while the length of x might be significantly smaller than n, an additive overhead of $\log n + O(1)$ is necessary in our coding theorems, as we need to encode 1^n.

where $t_A(x)$ denotes the running time of A on input x. For a language L we say that L can be solved in polynomial time on average with respect to $\mathcal{D}$ if there is an algorithm that computes L and runs in polynomial-time on average with respect to $\mathcal{D}$.

▶ **Definition 9** (Domination). *Let $\mathcal{D}$ and $\mathcal{D}'$ be two distributions. We say that $\mathcal{D}$* dominates *$\mathcal{D}'$ if there is a constant $c > 0$ such that for every $x \in \{0,1\}^*$,*

$$\mathcal{D}(x) \geq \frac{\mathcal{D}'(x)}{|x|^c}.$$

▶ **Fact 10** (See e.g., [5, Lemma 3.3]). *Let $\mathcal{D}, \mathcal{D}'$ be two distributions, and let A be an algorithm. If*

- *A runs in polynomial time on average with respect to $\mathcal{D}$, and*
- *$\mathcal{D}$ dominates $\mathcal{D}'$*

Then A also runs in polynomial time on average with respect to $\mathcal{D}'$.

Max Weight Independent Set in Graphs with No Long Claws: An Analog of the Gyárfás' Path Argument

Abstract

We revisit recent developments for the Maximum Weight Independent Set problem in graphs excluding a subdivided claw $S_{t,t,t}$ as an induced subgraph [Chudnovsky, Pilipczuk, Pilipczuk, Thomassé, SODA 2020] and provide a subexponential-time algorithm with improved running time $2^{\mathcal{O}(\sqrt{n}\log n)}$ and a quasipolynomial-time approximation scheme with improved running time $2^{\mathcal{O}(\varepsilon^{-1}\log^5 n)}$.

The Gyárfás' path argument, a powerful tool that is the main building block for many algorithms in P_t-free graphs, ensures that given an n-vertex P_t-free graph, in polynomial time we can find a set P of at most $t-1$ vertices, such that every connected component of $G-N[P]$ has at most $n/2$ vertices. Our main technical contribution is an analog of this result for $S_{t,t,t}$-free graphs: given an n-vertex $S_{t,t,t}$-free graph, in polynomial time we can find a set P of $\mathcal{O}(t\log n)$ vertices and an extended strip decomposition (an appropriate analog of the decomposition into connected components) of $G-N[P]$ such that every particle (an appropriate analog of a connected component to recurse on) of the said extended strip decomposition has at most $n/2$ vertices.

1 Introduction

The complexity of the Maximum Weight Independent Set problem (MWIS for short), one of the classic combinatorial optimization problems, varies depending on the restrictions imposed on the input graph from polynomial-time solvable (e.g., in bipartite or chordal graphs) through known to admit a quasipolynomial-time algorithm (graphs with bounded longest induced path [15]), a polynomial-time approximation scheme and a fixed-parameter algorithm (planar graphs [8]), a quasipolynomial-time approximation scheme (graphs excluding a fixed subdivided claw as an induced subgraph [10, 11]), to being NP-hard and hard to approximate within $n^{1-\varepsilon}$ factor in general graphs [20, 26]. A methodological study of this behavior leads to the following question:

> For which structures in the input graph, the assumption of their absence from the input graph makes MWIS easier and by how much?

The "absence of structures" notion can be made precise by specifying the forbidden structure and the containment relation, for example as a minor, topological minor, induced minor, subgraph, or induced subgraph. The last one – induced subgraph relation – is the weakest one, and thus the most expressible. This leads to the study of the complexity of MWIS in various hereditary graph classes, that is, graph classes closed under vertex deletion and thus definable by a (possibly infinite) list of forbidden induced subgraphs.

While a general classification of *all* hereditary graph classes with regards to the complexity of MWIS (or other classic graph problems) may be too complex, classifying graph classes with one forbidden induced subgraph looks more feasible. That is, we focus on H-free graphs, graphs excluding a fixed graph H as an induced subgraph. Furthermore, the complexity of a given problem (here, MWIS) in H-free graphs may indicate the impact of forbidding H as an induced subgraph on the complexity of MWIS in more general settings.

As observed by Alekseev [5, 6], the fact that MWIS remains NP-hard and APX-hard in subcubic graphs, together with the observation that subdividing every edge twice in a graph increases the size of the maximum independent set by exactly the number of edges of the original graph, leads to the conclusion that MWIS remains NP-hard and APX-hard in H-free graphs unless every connected component of H is a path or a tree with three leaves.

In what follows, for integers $t, a, b, c > 0$, by P_t we denote the path on t vertices, and by $S_{a,b,c}$ we denote the tree with three leaves within distance a, b, and c from the unique vertex of degree 3 of the tree. Since 1980s, it has been known that MWIS is polynomial-time solvable in P_4-free graphs (because of their strong structural properties) and in $S_{1,1,1}$-free graphs [23, 25] (because the notion of an augmenting path from the matching problem generalizes to MWIS in $S_{1,1,1}$-free, i.e., claw-free graphs). For many years, only partial results in subclasses were obtained until the area started to develop rapidly around 2014.

Lokshtanov, Vatshelle, and Villanger [21] adapted the framework of potential maximal cliques [9] to show a polynomial-time algorithm for MWIS in P_5-free graphs; this was later generalized to P_6-free graphs [17] and other related graph classes [3, 4]. More importantly for this work, Bacsó et al. [7] observed that the classic Gyárfás' path argument, developed to

show that for every fixed t the class of P_t-free graphs is χ-bounded [18, 19], also easily gives a subexponential-time algorithm for MWIS in P_t-free graphs. The crucial corollary of the Gyárfás' path argument lies in the following.

▶ **Theorem 1.** *Given an n-vertex graph G, one can in polynomial time find an induced path Q in G such that every connected component of $G - N[V(Q)]$ has at most $n/2$ vertices.*

For P_t-free graphs the said path Q has at most $t-1$ vertices. Bacsó et al. [7] observed that branching either on the highest degree vertex (if this degree is larger than $\sqrt{n}$) or on the whole set $N[V(Q)]$ for the path Q coming from Theorem 1 (otherwise) gives an algorithm with running time bound exponential in $\sqrt{n} \cdot \mathrm{poly}(t, \log n)$.

Chudnovsky, Pilipczuk, Pilipczuk, and Thomassé [10, 11] added to the mix an observation that a simple branching algorithm is able to get rid of *heavy* vertices: vertices of the input graph whose neighborhood contains a large fraction of the sought independent set. Once this branching is executed and the graph does not have heavy vertices, the set $N[Q]$ from Theorem 1 contains only a small fraction of the sought solution and, if one aims for an approximation algorithm, can be just sacrificed, yielding a quasipolynomial-time approximation scheme (QPTAS) for MWIS in P_t-free graphs. Using this as a starting point and leveraging on the celebrated *three-in-a-tree* theorem of Chudnovsky and Seymour [13], they developed a much more involved QPTAS and a subexponential algorithm (with running time bound $2^{n^{8/9}\mathrm{poly}(\log n, t)}$) for MWIS in $S_{t,t,t}$-free graphs.

Consider the following simple template for a branching algorithm for MWIS: if the current graph is disconnected, solve independently every connected component; otherwise, pick a vertex (*pivot*) v and branch whether v is in the sought independent set (recursing on $G - N[v]$) or not (recursing on $G - v$). The performance of such an algorithm highly depends on how we choose the pivot v. Theorem 1 suggests that in P_t-free graphs the vertices of Q may be good choices: there is only a bounded number of them, and the deletion of *the whole* neighborhood $N[V(Q)]$ splits G into multiplicatively smaller pieces. In a breakthrough result, Gartland and Lokshtanov [15] showed how to choose the pivot and measure the progress of the algorithm, obtaining a quasipolynomial-time algorithm for MWIS in P_t-free graphs. Later, Pilipczuk, Pilipczuk, and Rzążewski [24] provided an arguably simpler measure, leading to an improved (but still quasipolynomial) running time bound. These developments have been subsequently generalized to a larger class of problems beyond MWIS and to $C_{>t}$-free graphs (graphs without induced cycle of length more than t) [16].

This progress suggests that MWIS may be actually solvable in polynomial time in H-free graphs for all open cases, that is, whenever H is a forest whose every connected component has at most three leaves. However, we seem still far from proving it: not only we do not know how to improve the quasipolynomial bounds of [15, 24] to polynomial ones, but also it remains unclear how to merge the approach of [15, 24] with the way how [10, 11] used the three-in-a-tree theorem [13].

In this work, we make a step in this direction, providing an analog of Theorem 1 for $S_{t,t,t}$-free graphs. Before we state it, let us briefly discuss what we can hope for in the class of $S_{t,t,t}$-free graphs.

Consider an example of a graph G being the line graph of a clique K. The graph G is $S_{1,1,1}$-free, but does not admit any (balanced in any useful sense) separator of the form $N[P]$ for a small set $P \subseteq V(G)$. The MWIS problem on G translates back to the maximum weight matching problem in the clique K; this problem is polynomial-time solvable, but with very different methods than branching. In particular, we are not aware of any way of solving maximum weight matching in a clique in quasipolynomial time by simple branching.

Thus, we expect that an algorithm for MWIS in $S_{t,t,t}$-free graphs, given such a graph G, will discover that it is actually working with the line graph of a clique and apply maximum weight matching techniques to the preimage graph K.

Chudnovsky and Seymour, in their project to understand claw-free graphs [12], developed a good way of describing that a graph "looks like a line graph" by the notion of an *extended strip decomposition*. The formal definition can be found in Section 2. Here, we remark that in an extended strip decomposition of a graph, one can distinguish *particles* being induced subgraphs of the graph; an algorithm for MWIS can recurse on individual particles, compute the maximum weight independent sets there, and combine the results into a maximum weight independent set in the whole graph using a maximum weight matching algorithm on an auxiliary graph (cf. [10, 11]). Thus, an extended strip decomposition of a graph with particles of multiplicatively smaller size is very useful for recursion; it can be seen as an analog of splitting into connected components of multiplicatively smaller size, as it is in the case of the components of $G - N[V(Q)]$ in Theorem 1.

With the above discussion in mind, we can now state our main technical result.

▶ **Theorem 2.** *Given an n-vertex graph G and $t \geqslant 1$, one can in polynomial time either:*

- *output an induced copy of $S_{t,t,t}$ in G, or*
- *output a set $\mathcal{P}$ consisting of at most $11 \log n + 6$ induced paths in G, each of length at most $t+1$, and a rigid extended strip decomposition of $G - N[\bigcup_{P \in \mathcal{P}} V(P)]$ whose every particle has at most $n/2$ vertices.*

Combining Theorem 2 with previously known algorithmic techniques, we derive two algorithms for MWIS in $S_{t,t,t}$-free graphs. Actually, our algorithms work in a slightly more general setting. For integers $s, t \geqslant 1$, by $sS_{t,t,t}$ we denote the graph with s connected components, each isomorphic to $S_{t,t,t}$. Recall that by the observation of Alekseev [5, 6] the only graphs H, for which we can hope for tractability results for MWIS in H-free graphs, are forests whose every component has at most three leaves. We observe that each such H is contained in $sS_{t,t,t}$, for some s and t depending on H. Thus algorithms for $sS_{t,t,t}$-free graphs, for every s and t, cover *all* potential positive cases.

First, we observe that the statement of Theorem 2 seamlessly combines with the method how [7] obtained a subexponential-time algorithm for MWIS in P_t-free graphs. As a result, we obtain a subexponential-time algorithm for MWIS in $sS_{t,t,t}$-free graphs with improved running time as compared to [10, 11].

▶ **Theorem 3.** *Let $s, t \geqslant 1$ be constants. Given an n-vertex $sS_{t,t,t}$-free graph G with weights on vertices, one can in time exponential in $\mathcal{O}(\sqrt{n} \log n)$ compute an independent set in G of maximum possible weight.*

Second, we observe that the statement of Theorem 2 again seamlessly combines with the method how [10, 11] obtained a QPTAS for MWIS in P_t-free graphs, obtaining an arguably simpler QPTAS for MWIS in $sS_{t,t,t}$-free graphs with improved running time (compared to [10, 11]).

▶ **Theorem 4.** *Let $s, t \geqslant 1$ be constants. Given an n-vertex $sS_{t,t,t}$-free graph G with weights on vertices, and a real $\varepsilon > 0$, one can in time exponential in $\mathcal{O}(\varepsilon^{-1} \log^5 n)$ compute an independent set in G that is within a factor of $(1-\varepsilon)$ of the maximum possible weight.*

After preliminaries in Section 2, we prove Theorem 2 in Section 3. Proofs of Theorems 3 and 4 are provided in Section 4. Finally, we discuss future steps in Section 5.

2 Preliminaries

Notation. For a family $\mathcal{Q}$ of sets, by $\bigcup \mathcal{Q}$ we denote $\bigcup_{Q \in \mathcal{Q}} Q$. If the base of a logarithmic function is not specified, we mean the logarithm of base 2, i.e., $\log n := \log_2 n$. For a function $\mathfrak{w} : V \to \mathbb{Z}_{\geqslant 0}$ and subset $V' \subseteq V$, we denote $\mathfrak{w}(V') := \sum_{v \in V'} \mathfrak{w}(v)$.

Let G be a graph. For $X \subseteq V(G)$, by $G[X]$ we denote the subgraph of G induced by X, i.e., $(X, \{uv \in E(G) : u, v \in X\})$. If the graph G is clear from the context, we will often identify induced subgraphs with their vertex sets. The sets $X, Y \subseteq V(G)$ are *complete* to each other if for every $x \in X$ and $y \in Y$ the edge xy is present in G. Note that this, in particular, implies that X and Y are disjoint. We say that two sets X, Y *touch* if $X \cap Y \neq \emptyset$ or there is an edge with one end in X and another in Y.

For a vertex v, by $N_G(v)$ we denote the set of neighbors of v, and by $N_G[v]$ we denote the set $N_G(v) \cup \{v\}$. For a set $X \subseteq V(G)$, we also define $N_G(X) := \bigcup_{v \in X} N_G(v) - X$, and $N_G[X] = N_G(X) \cup X$. If it does not lead to confusion, we omit the subscript and write simply $N(\cdot)$ and $N[\cdot]$.

By $T(G)$, we denote the set of all triangles in G. Similarly to writing $xy \in E(G)$, we will write $xyz \in T(G)$ to indicate that $G[\{x, y, z\}] \simeq K_3$.

Extended strip decompositions. Now let us define a certain graph decomposition which will play an important role in the paper. An *extended strip decomposition* of a graph G is a pair (H, η) that consists of:

- a simple graph H,
- a set $\eta(x) \subseteq V(G)$ for every $x \in V(H)$,
- a set $\eta(xy) \subseteq V(G)$ for every $xy \in E(H)$, and its subsets $\eta(xy, x), \eta(xy, y) \subseteq \eta(xy)$,
- a set $\eta(xyz) \subseteq V(G)$ for every $xyz \in T(H)$,

which satisfy the following properties (also see Figure 1):

1. $\{\eta(o) \mid o \in V(H) \cup E(H) \cup T(H)\}$ is a partition of $V(G)$,
2. for every $x \in V(H)$ and every distinct $y, z \in N_H(x)$, the set $\eta(xy, x)$ is complete to $\eta(xz, x)$,
3. every $uv \in E(G)$ is contained in one of the sets $\eta(o)$ for $o \in V(H) \cup E(H) \cup T(H)$, or is as follows:
   - $u \in \eta(xy, x), v \in \eta(xz, x)$ for some $x \in V(H)$ and $y, z \in N_H(x)$, or
   - $u \in \eta(xy, x), v \in \eta(x)$ for some $xy \in E(H)$, or
   - $u \in \eta(xyz)$ and $v \in \eta(xy, x) \cap \eta(xy, y)$ for some $xyz \in T(H)$.

Note that for an extended strip decomposition (H, η) of a graph G, the number of vertices of H can be much larger than the number of vertices of G. However, in such case many sets $\eta(\cdot)$ are empty and thus H is "unnecessarily complicated." An extended strip decomposition (H, η) is *rigid* if (i) for every $xy \in E(H)$ it holds that $\eta(xy, x) \neq \emptyset$, and (ii) for every $x \in V(H)$ such that x is an isolated vertex it holds that $\eta(x) \neq \emptyset$. Observe that if we *restrict* η to $V' \subset V(G)$, i.e. we keep in η only vertices of V', (H, η) after the restriction remains an extended strip decomposition, but it might not be rigid any more.

▶ **Observation 5.** *Let (H, η) be a rigid extended strip decomposition of an n-vertex graph G. Then $|E(H)| \leqslant n$ and $|V(H)| \leqslant 2n$.*

Proof. Recall that since (H, η) is rigid, for every $xy \in E(H)$ we have that $\emptyset \neq \eta(xy, x) \subseteq \eta(xy)$, and for every isolated vertex x of H we have $\eta(x) \neq \emptyset$.

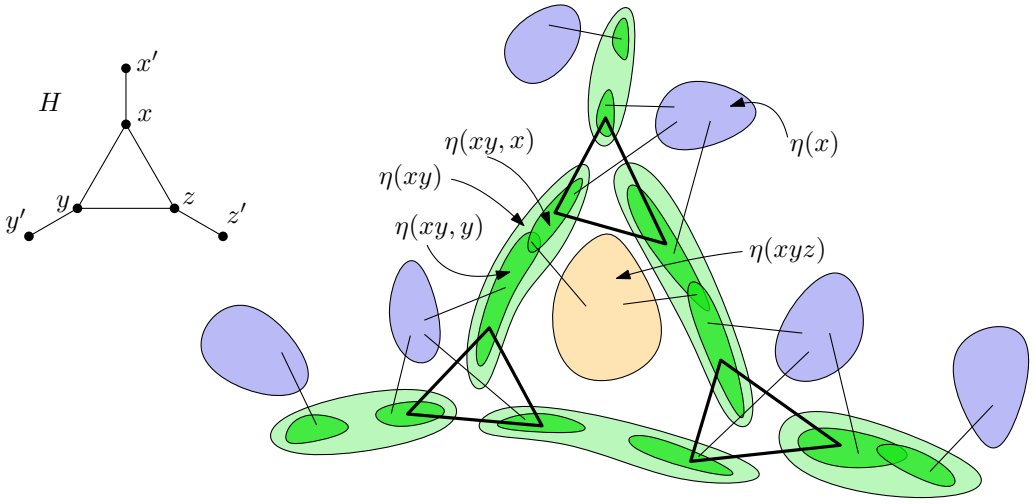

Figure 1 A graph H and an extended strip decomposition (H, η) of a graph G. Sets $\eta(\cdot)$ corresponding to vertices, edges, and the triangle of H are marked green, blue, and orange, respectively. The edges between distinct sets are drawn thick if they must exist, and thin if they may exist.

Let V_0 and V_+ denote, respectively, the sets of vertices of H with degree 0 and more than 0. As the family $\{\eta(xy) \mid xy \in E(H)\} \cup \{\eta(x) \mid x \in V_0\}$ consists of pairwise disjoint nonempty subsets of $V(G)$, we conclude that $|E(H)| + |V_0| \leqslant n$ and therefore $|E(H)| \leqslant n$.

Note that by the handshaking lemma we have $|E(H)| \geqslant |V_+|/2$, and so $|V(H)| = |V_0| + |V_+| \leqslant |V_0| + 2|E(H)| \leqslant 2n$ by the previous argument. ◀

We say that a vertex $v \in V(G)$ is *peripheral* in (H, η) if there is a degree-one vertex x of H, such that $\eta(xy, x) = \{v\}$, where y is the (unique) neighbor of x in H. For a set $Z \subseteq V(G)$, we say that (H, η) is an *extended strip decomposition of* (G, Z) if H has $|Z|$ degree-one vertices and each vertex of Z is peripheral in (H, η).

The following theorem by Chudnovsky and Seymour [13] is a slight strengthening of their celebrated solution of the famous *three-in-a-tree* problem. We will use it as a black-box to build extended strip decompositions.

▶ **Theorem 6** (Chudnovsky, Seymour [13, Section 6]). *Let G be an n-vertex graph and consider $Z \subseteq V(G)$ with $|Z| \geqslant 2$. There is an algorithm that runs in time $\mathcal{O}(n^5)$ and returns one of the following:*

- *an induced subtree of G containing at least three elements of Z,*
- *a rigid extended strip decomposition (H, η) of (G, Z).*

Let us point out that actually, an extended strip decomposition produced by Theorem 6 satisfies more structural properties, but of our purpose, we will only use the fact that it is rigid.

Particles of extended strip decompositions. Let (H, η) be an extended strip decomposition of a graph G. We introduce some special subsets of $V(G)$ called *particles*, divided into five *types*.

$$\begin{aligned}
\text{vertex particle:} &\quad A_x := \eta(x) \text{ for each } x \in V(H),\\
\text{edge interior particle:} &\quad A^{\perp}_{xy} := \eta(xy) - (\eta(xy,x) \cup \eta(xy,y)) \text{ for each } xy \in E(H),\\
\text{half-edge particle:} &\quad A^{x}_{xy} := \eta(x) \cup \eta(xy) - \eta(xy,y) \text{ for each } xy \in E(H),\\
\text{full edge particle:} &\quad A^{xy}_{xy} := \eta(x) \cup \eta(y) \cup \eta(xy) \cup \bigcup_{z\,:\,xyz \in T(H)} \eta(xyz) \text{ for each } xy \in E(H),\\
\text{triangle particle:} &\quad A_{xyz} := \eta(xyz) \text{ for each } xyz \in T(H).
\end{aligned}$$

Observe that the number of all particles of (H,η) is at most $\mathcal{O}(|V(H)|^3)$. However, the number of nonempty particles is linear in the number of vertices of G.

▶ **Observation 7.** *Let (H,η) be an extended strip decomposition of an n-vertex graph. Then the number of nonempty particles of (H,η) is bounded by $4n$.*

Proof. Let V', E', T', respectively, be the subsets consisting of those elements o of $V(H)$, $E(H)$, or $T(H)$, for which $\eta(o) \neq \emptyset$. Observe that each $o \in V' \cup T'$ gives rise to one nonempty particle A_o, and each $xy \in E'$ gives rise to at most four nonempty particles: $A^{\perp}_{xy}, A^{x}_{xy}, A^{y}_{xy}, A^{xy}_{xy}$. Moreover, since $\{\eta(o) \mid o \in V' \cup E' \cup T'\}$ are pairwise disjoint subsets of $V(G)$, we have that $|V'| + |E'| + |T'| \leqslant n$. Hence, the number of nonempty particles is bounded by $|V'| + |T'| + 4|E'| = (|V'| + |T'| + |E'|) + 3|E'| \leqslant 4n$. ◀

A vertex particle A_x is *trivial* if x is an isolated vertex in H. Similarly, an extended strip decomposition (H,η) is *trivial* if H is an edgeless graph. The following observation follows immediately from the definitions of an extended strip decomposition and particles.

▶ **Observation 8.** *Let (H,η) be an extended strip decomposition of a graph G. For each $xy \in E(H)$ the following hold:*

1. $A^{\perp}_{xy} \subseteq A^{x}_{xy} \subseteq A^{xy}_{xy}$,
2. *for any $v_x \in \eta(xy,x)$ and $v_y \in \eta(xy,y)$ we have $N(A^{xy}_{xy}) = N(v_x) \cup N(v_y) - A^{xy}_{xy}$.*

We conclude this section by recalling an important property of particles of extended strip decompositions, observed by Chudnovsky et al. [10].

▶ **Theorem 9** (Chudnovsky et al. [10, Lemma 6.8])**.** *Let (H,η) be an extended strip decomposition of G. Suppose P_1, P_2, P_3 are three induced paths in G that do not touch each other, and moreover each of P_1, P_2, P_3 has an endvertex that is peripheral in (H,η). Then in (H,η) there is no particle that touches each of P_1, P_2, P_3.*

3 Main result

In this section, we prove our main result, i.e., Theorem 2. Let us first give an overview of our approach. We present a recursive algorithm that, for a given graph G, will return one of the outcomes of Theorem 2. Let $n := |V(G)|$ be the number of vertices in the input graph; the value of n will not change throughout the recursive steps of the algorithm. We start with finding a Gyárfás path Q navigating towards the largest component in G. That is, by Theorem 1, we find Q such that each connected component of $G - N[Q]$ is of size at most $\frac{n}{2}$. Finding such a small connected component is a great outcome as we can readily include it as a small trivial vertex particle of an extended strip decomposition we are constructing. We say that a particle is *small* if its size is at most $\frac{n}{2}$, and an extended strip decomposition is *refined* if all its particles are small. Observe that if $|Q| \leq 3t+1$, we immediately get the

desired refined extended strip decomposition of G. Otherwise, we proceed to the main part of the algorithm. At each step, we will remove some vertices from Q, and will measure the progress of our algorithm in the number of the remaining vertices of Q.

Formally, we create a set $\mathcal{Q}$ of at most two non-touching induced paths such that $\bigcup \mathcal{Q} \subseteq Q$. At each step of recursion we obtain a set $\hat{\mathcal{Q}}$ with $|\bigcup \hat{\mathcal{Q}}| \leq \frac{2}{3}|\bigcup \mathcal{Q}|$ that represents $\mathcal{Q}$ for the next step. Hence, in $11 \log n$ recursive steps, $|\bigcup \mathcal{Q}|$ drops below $3t+1$. In the base case of the recursion, when $|\bigcup \mathcal{Q}| \leq 3t+1$, we return the refined trivial extended strip decomposition ensured by maintaining the property that $G - N[\bigcup \mathcal{Q}]$ has connected components of size at most $\frac{n}{2}$ throughout the recursive steps. In each step of recursion, we further split the induced path(s) in $\mathcal{Q}$ so we are able to use Theorem 6 to obtain an extended strip decomposition (H, η). If (H, η) is already refined, then we are done. Otherwise, it contains a particle A that is not small. We use Theorem 9 to select at most two paths touching A. Then it is easy to separate A with the respective touching paths from the rest of the graph. The graph induced by A and the touching paths form a smaller instance, i.e., an instance where $|\bigcup \mathcal{Q}|$ drops by a factor of $\frac{2}{3}$. We need to ensure that at every recursive step, we include only a constant number of paths of length $t+1$ into $\mathcal{P}$ (i.e., the set of paths in the second outcome of Theorem 2). We now prove the core recursive formulation of the algorithm formally.

▶ **Lemma 10** (Recursion). *Given a graph G and a set $\mathcal{Q}$ of at most two induced paths (vertex disjoint non-adjacent), and a refined extended strip decomposition of $G - N[\bigcup \mathcal{Q}]$. In polynomial time, we can output one of the following:*

- *an induced copy of $S_{t,t,t}$ in G, or*
- *$\mathcal{P}$, $X \subseteq N[\bigcup \mathcal{P}]$, and a refined extended strip decomposition (H, η) of $G - X$, so that $|\mathcal{P}| \leq 6 \log_{3/2}(|\bigcup \mathcal{Q}|) + 6$ and the longest path in $\mathcal{P}$ has at most $t+1$ vertices.*

Proof. If the longest path of $\mathcal{Q}$ has at most $3t+1$ vertices, return $\mathcal{P} \coloneqq \mathcal{Q}$ where each path in $\mathcal{P}$ may be further split in at most three paths on at most $t+1$ vertices, and $X \coloneqq N[\bigcup \mathcal{P}]$. Hence, we output the extended strip decomposition we were given by the assumptions of the lemma.

Otherwise, let Q_1 be the longest path in $\mathcal{Q}$. Let u_1 and u_2 be the $\left(\left\lfloor \frac{|Q_1|}{3} \right\rfloor + 1\right)$-th and the $\left(2\left\lfloor \frac{|Q_1|}{3} \right\rfloor + 2\right)$-th vertex of Q_1, respectively. The removal of u_1 and u_2 from Q_1 divides the path into three induced non-touching subpaths Q_1^1, Q_1^2, and Q_1^3, each of length at least t. Let Q_2 be the remaining path of $\mathcal{Q}$, should it exist. We define $\mathcal{S} \coloneqq \{Q_1^1, Q_1^2, Q_1^3, Q_2\}$ if Q_2 exists, or $\mathcal{S} \coloneqq \{Q_1^1, Q_1^2, Q_1^3\}$, otherwise. Consult Figure 2 to see an overview of the definitions described in this paragraph. For each path $P \in \mathcal{S}$ we define $\mathrm{pref}(P)$ as the set comprising:

- first $t-1$ vertices of P (or all vertices of P if $|P| < t-1$), and
- the separating vertex of Q_1 directly preceding P if $P \in \{Q_1^2, Q_1^3\}$.

It can be easily seen that the set of vertices $\mathrm{pref}(P)$ forms an induced path of length at most t. We finally define *shells* of paths in $\mathcal{S}$. Given a path $P \in \mathcal{S}$, we set $\mathrm{shell}(P) \coloneqq N[\mathrm{pref}(P)] - \bigcup \mathcal{S}$ if $|P| \geq t$ and $\mathrm{shell}(P) \coloneqq N[\mathrm{pref}(P)]$ otherwise. Intuitively, if $|P| < t$, the shell of P takes the whole neighborhood as we do not have a use for a short path in the next stage of our algorithm. For a long enough path P ($|P| > t$), the shell of P intersects all short paths (shorter than t) connecting the first vertex of P with the rest of the graph. In other words, each path from the first vertex of P to any vertex of $G - \mathrm{shell}(P)$ outside of P will have length at least t. To ease the notation, we define $\mathcal{S}_{\geq t} \coloneqq \{P \in \mathcal{S} \mid |P| \geq t\}$, $\mathrm{shell}(\mathcal{S}) \coloneqq \bigcup_{P \in \mathcal{S}} \mathrm{shell}(P)$, and $\mathrm{pref}(\mathcal{S}) \coloneqq \bigcup_{P \in \mathcal{S}} \mathrm{pref}(P)$.

Now, we use the algorithm from Theorem 6 on Z being the set of the first vertices of paths in $\mathcal{S}_{\geq t}$ and the graph defined as $G - \mathrm{shell}(\mathcal{S})$. If Theorem 6 produced an induced tree with three leaves among Z, it contains an induced $S_{t,t,t}$, since those must have been

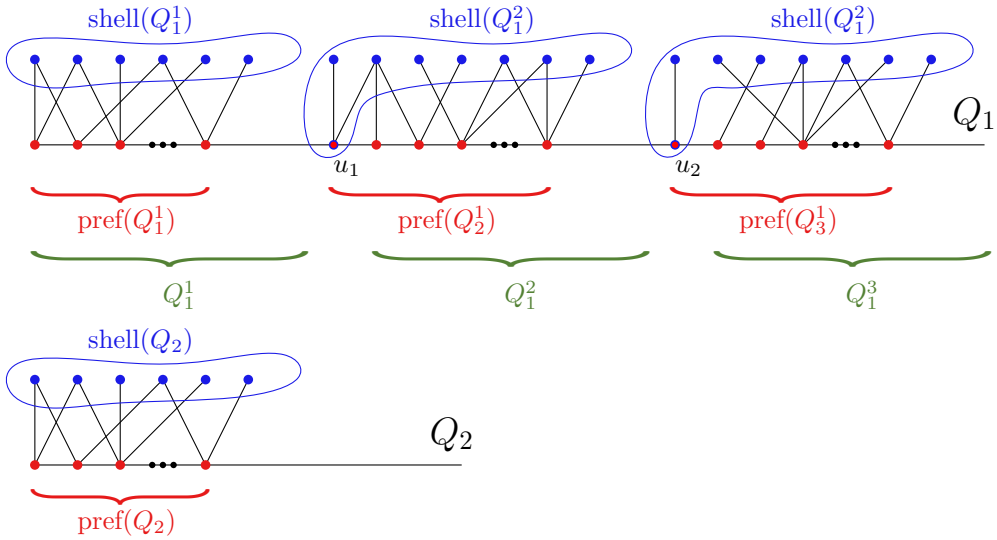

Figure 2 Definitions of pref($\mathcal{S}$) and shell($\mathcal{S}$) in case of $|Q_2| \geq t$.

induced branches at least t vertices long in $G - \text{shell}(\mathcal{S})$. Hence, we obtained an extended strip decomposition (H', η') of $G - \text{shell}(\mathcal{S})$. If the obtained decomposition is refined, we return $\mathcal{P} \coloneqq \text{pref}(\mathcal{S})$, $X \coloneqq \text{shell}(\mathcal{S})$, and the extended strip decomposition $(H \coloneqq H', \eta \coloneqq \eta')$.

Therefore, the obtained extended strip decomposition (H', η') of $G - \text{shell}(\mathcal{S})$ contains a particle A which is not small, i.e., A is composed of at least $\frac{n}{2}$ vertices. As every vertex in Z is peripheral in (H', η'), we know that no three paths in $\mathcal{S}_{\geq t}$ touch one particle by Theorem 9. Therefore, we take the set $\hat{\mathcal{Q}}$ of at most two paths, say P_1 and P_2, touching A (for convenience, let P_1 or P_2 be an empty set if it does not exist). We now compute the maximum proportion of $\bigcup \mathcal{Q}$ put to $\hat{\mathcal{Q}}$. If both $P_1, P_2 \subseteq Q_1$, then this fraction is at most $\frac{2}{3}$ as by the definition $|Q_1^i| \leq \frac{|Q_1|}{3}$, for $i \in \{1, 2, 3\}$. If one is Q_2 and the other comes from Q_1, then we estimate $a + \frac{1-a}{3} = \frac{2a+1}{3} \leq \frac{2}{3}$ for $a = |Q_2|/|\bigcup \mathcal{Q}| \leq \frac{1}{2}$. Hence, we know that $|\bigcup \hat{\mathcal{Q}}| \leq \frac{2}{3}|\bigcup \mathcal{Q}|$. We define $\hat{G} \coloneqq A \cup P_1 \cup P_2$ to use Lemma 10 on a smaller instance. Now, we need to verify that the assumption of the lemma holds. We claim the following:

▷ Claim 11. $\hat{G} - N[\bigcup \hat{\mathcal{Q}}]$ has a refined extended strip decomposition.

Proof. As $\hat{G}$ is an induced subgraph of G and $G - N[\bigcup \mathcal{Q}]$ has a refined extended strip decomposition, we know that $\hat{G} - N[\bigcup \mathcal{Q}]$ has a refined extended strip decomposition. First, recall that $N[u_1] - (Q_1^1 \cup Q_1^2) \subseteq \text{shell}(Q_1^2)$, which is disjoint with $V(\hat{G})$. Analogously $N[u_2] - (Q_1^2 \cup Q_1^3)$ is disjoint with $V(\hat{G})$. Also, if $|Q_2| < t$ then Q_2 is disjoint with $V(\hat{G})$ as well. Hence, $\hat{G} - N[\bigcup \mathcal{Q}] \simeq \hat{G} - N[\bigcup \mathcal{S}_{\geq t}]$. Also, recall that the only paths among $\mathcal{S}_{\geq t}$ that touch A are in $\hat{\mathcal{Q}}$. Hence, observe that $\hat{G} - N[\bigcup \mathcal{S}_{\geq t}] \simeq \hat{G} - N[\bigcup \hat{\mathcal{Q}}]$. ◁

Therefore, we can apply Lemma 10 inductively on $\hat{G}$ and $\hat{\mathcal{Q}}$, obtaining $\hat{\mathcal{P}}$ and $\hat{X}$, and a refined extended strip decomposition $(\hat{H}, \hat{\eta})$ of $\hat{G} - \hat{X}$. We need to combine the extended strip decomposition obtained from the recursion with the extended strip decomposition (H', η') we obtained earlier.

We can always suppose that particle A is of type A_{xy}^{xy} for some edge $xy \in E(H')$, unless A is of type A_x for an isolated vertex $x \in V(H')$. That is because A_{xy}^{xy} is the superset of all possible particle types. As Theorem 6 gives us that both $\eta'(xy, x)$ and $\eta'(xy, y)$ are nonempty, we can select $v_x \in \eta'(xy, x)$ and $v_y \in \eta'(xy, y)$ (possibly $v_x = v_y$). By Observation 8, the set

$$X' \coloneqq (N(v_y) \cup N(v_x)) - V(A)$$

separates A from the rest of G. Set $\mathcal{P}' \coloneqq \{\{v_x\}, \{v_y\}\}$. In the case of A_x such that $x \in V(H)$ is an isolated vertex, we set $\mathcal{P}' \coloneqq \emptyset$ and $X' \coloneqq \emptyset$ and still such A is separated from the rest of G by X'. We return:

- $\mathcal{P} \coloneqq \hat{\mathcal{P}} \cup \mathcal{P}' \cup \operatorname{pref}(\mathcal{S})$,
- $X \coloneqq \hat{X} \cup X' \cup \operatorname{shell}(\mathcal{S})$,
- an extended strip decomposition (H, η) of $G - X$, where H is $\hat{H}$ with an additional isolated vertex w, and η is $\hat{\eta}$ restricted only to vertices in $A - X$ with an additional trivial vertex particle $\eta(w)$ containing all vertices of $G - X - A$.

Recall that during the recursion, we do not require rigidity, therefore, we do not mind restricting η only to a subset of vertices. Note that indeed, $G - X - A$ may contain parts of P_1 or P_2, however, $\eta(w)$ does not touch any vertices contained in $\hat{\eta}$ restricted to $A - X$ as $X' \subseteq X$ completely separated $A - X$ from $G - X - A$.

We compute that $|\mathcal{P}| \leq 6 + 6\log_{3/2}\left(\left|\bigcup \hat{\mathcal{Q}}\right|\right) + 6 \leq 6\log_{3/2}(|\bigcup \mathcal{Q}|) + 6$ as we added at most six new paths into $\mathcal{P}$. Observe that the described algorithm runs in polynomial time as we just computed that the depth of recurrence is logarithmic in $|\bigcup(\mathcal{Q})| \leq |V(G)|$ and each recursive call takes polynomial time in the size of G. ◀

Proof of Theorem 2. Using Theorem 1 we find a Gyárfás path Q. We get the desired outcome by Lemma 10 on G with $\mathcal{Q} \coloneqq \{Q\}$. The extended strip decomposition needed by the lemma's assumption is trivial. That is, each connected component of $G - Q$ is represented by a vertex particle of small size. Note that Lemma 10 provides an extended strip decomposition of $G - X$, where $X \subseteq \bigcup \mathcal{P}$ and Theorem 2 only requires an extended strip decomposition of $G - \bigcup \mathcal{P}$, so we can restrict the obtained extended strip decomposition to $V(G) - \bigcup \mathcal{P}$. We conclude the proof of Theorem 2 by the following calculation:

$$6\log_{3/2} n + 6 \leq 11 \log n + 6.$$

Note that for any extended strip decomposition (H, η) we can easily add the assumption that sets $\eta(xy, x) \neq \emptyset$ for any edge $xy \in E(H)$. As suppose $\eta(xy, x) = \emptyset$; then we can update (H, η) by adding $\eta(xy)$ to $\eta(y)$ and removing xy from H. Moreover, we can simply remove any empty trivial vertex particle form η and the corresponding isolated vertex from H. Therefore, we may suppose that the obtained extended strip decomposition is rigid. ◀

In the following simple corollary we apply Theorem 2 to $sS_{t,t,t}$-free graphs, for some $s, t \geq 1$.

▶ **Corollary 12.** *Let $s \geqslant 1, t \geqslant 1$ be constants. Let G be an $sS_{t,t,t}$-free graph on n vertices. Then in polynomial time we can find a set X consisting of at most*

$$(s-1)(3t+1) + (11\log n + 6)(t+1)$$

vertices and a rigid extended strip decomposition of $G - N[X]$ whose every particle has at most $n/2$ vertices.

Proof. Induction on s. If $s = 1$, then we obtain the result immediately by Theorem 2. Thus let us assume that $s \geqslant 2$ and the theorem holds for $(s-1)S_{t,t,t}$-free graphs.

We exhaustively check if there is some $Y \subseteq V(G)$ with $|Y| = 3t+1$, such that $G[Y] \simeq S_{t,t,t}$; we can do it in time $n^{3(t+1)+\mathcal{O}(1)} = n^{\mathcal{O}(1)}$. If such Y does not exist, then we can immediately apply Theorem 2, and the proof is complete. Thus suppose that Y exists.

We observe that the graph $G' \coloneqq G - N[Y]$ is $(s-1)S_{t,t,t}$-free. Denote $n' \coloneqq |V(G')|$. By the inductive assumption, in time $(n')^{\mathcal{O}(1)} = n^{\mathcal{O}(1)}$ we can obtain a set $X' \subseteq V(G')$ of size at most $(s-2)(3t+1) + (11\log n' + 6)(t+1)$ and a rigid extended strip decomposition (H, η) of $G' - N[X']$ whose every particle is of size at most $n'/2$.

We set $X = Y \cup X'$. Now X and (H, η) satisfy the statement of the theorem, as $G' - N[X'] = G - N[X]$ and $n' \leqslant n$. The total running time is polynomial in n as the depth of the recursion is $s - 1$. ◀

4 Algorithmic applications

In this section we will show how to combine Theorem 2 with the approach of Chudnovsky et al. [10, 11] in order to obtain a QPTAS and a subexponential-time algorithm for MWIS in $S_{t,t,t}$-free graphs, i.e., we prove Theorems 3 and 4.

Both algorithms follow the same general outline; let us sketch it before we get into the details of each particular case. Each algorithm is a recursive procedure, which consists of two phases. In the first one, we deal with the vertices of G that are *heavy*, which means that their neighborhood is "large", where the exact meaning of "large" depends on the particular algorithm.

Once there are no heavy vertices, i.e., the neighborhood of each vertex is "small", we proceed to the second phase. We call Corollary 12 for the current instance G, obtaining a small-sized set X and a rigid extended strip decomposition (H, η) of $G - N[X]$, whose every particle is of small size. The crux is that since we are in the second phase, all vertices in X are not heavy, and since X is of small size, the whole set $N[X]$ is "small". We treat $N[X]$ separately in a way that depends on the particular algorithm.

Next, for each particle A of (H, η), we call the algorithm recursively for $G[A]$, obtaining (a good approximation of) a maximum-weight independent set in $G[A]$. Finally, we combine the obtained results to derive (a good approximation of) a maximum-weight independent set in G. This last step is based on the idea of Chudnovsky et al. [10, 11] to reduce the problem to finding a maximum-weight matching in a graph obtained by a simple modification of H. Since the size of H is linear in $|V(G)|$ (by Observation 5), this problem can be solved in time polynomial in $|V(G)|$ using, e.g., the classic algorithm of Edmonds [14]. The last step is encapsulated in the following lemma, whose exact statement comes from Abrishami et al. [1].

▶ **Lemma 13** (Chudnovsky et al. [10, 11]). *Let $\varsigma \in [0, 1]$ be a real number. Let G be an n-vertex graph equipped with a weight function $\mathfrak{w} : V(G) \to \mathbb{Z}_{\geqslant 0}$. Suppose that G is given along with an extended strip decomposition (H, η), where H has N vertices.*
Let $I_0 \subseteq V(G)$ be a fixed independent set in G. Furthermore, assume that for each particle A of (H, η) we are given an independent set $I(A)$ in $G[A]$ such that $\mathfrak{w}(I(A)) \geqslant \varsigma \cdot \mathfrak{w}(I_0 \cap A)$. Then in time polynomial in $n + N$ we can compute an independent set I in G such that $\mathfrak{w}(I) \geqslant \varsigma \cdot \mathfrak{w}(I_0)$.

Let us stress out that the algorithm from Lemma 13 does not need to know the value of ς or the independent set I_0.

The main difference between our approach and the one of Chudnovsky et al. [11] is that we use Theorem 2 and its consequence, i.e., Corollary 12. The previous algorithms used a similar statement but with a worse (and much more involved) guarantee on the size of X and each particle. Furthermore, the way we obtain our set X is significantly simpler.

4.1 Proof of Theorem 3

Before we proceed to the proof, let us first explain the meaning of "small", and how to deal with $N[X]$ in this particular case. Here the neighborhood of a vertex is "small" if it has few vertices (more specifically, at most $\sqrt{n/t}$). In the first phase, we deal with heavy vertices v (i.e., of large degree) with simple branching: we guess whether v is included in our optimum solution or not. Since the degree of v is large, in the first branch, we obtain significant progress, which is enough to obtain a subexponential running time.

In the second phase, since $N[X]$ is the neighborhood of $\mathcal{O}(\log n)$ vertices, each of degree $\mathcal{O}(\sqrt{n})$, the total size of $N[X]$ is $\mathcal{O}(\sqrt{n}\log n)$. Thus we can afford to exhaustively guess the intersection of our optimum solution with $N[X]$.

Proof of Theorem 3. Let $s,t \geqslant 1$ be constants and let $(G,\mathfrak{w})$ be an instance of MWIS, where G is $sS_{t,t,t}$-free and has n vertices. We observe that if n is small, i.e., bounded by a constant, then we can solve the problem by brute force. Thus we assume that $n \geqslant n_0$, where n_0 is a constant (depending on s and t) whose exact value follows from the reasoning below.

First, consider the case that there exists $v \in V(G)$ such that $\deg v \geqslant \sqrt{n/t}$. We branch on including v in the final solution: we either delete v from G, or we delete $N[v]$ and add v to the solution returned by the recursive call. Then we output the one of these two solutions that has a larger weight. The correctness of this step of the algorithm is straightforward.

Hence, we can assume that for every $v \in V(G)$ it holds that $\deg v \leqslant \sqrt{n/t}$. By Corollary 12, since G is $sS_{t,t,t}$-free, we obtain a set X of size $(s-1)(3t+1)+(11\log n+6)(t+1) \leqslant 12(t+1)\log n$ (here we use that n is large), and a rigid extended strip decomposition (H,η) of $G' = G - N[X]$ whose every particle has at most $n/2$ vertices.

We exhaustively guess an independent set $J \subseteq N[X]$; think of it as an intersection of the intended optimum solution with $N[X]$. Consider the graph $G'' := G' - N[J]$. We modify (H,η) by removing the vertices from $N[J]$ from the sets $\eta(\cdot)$. Let us call the obtained strip decomposition (H,η'); note that it might not be rigid. We call the algorithm recursively for the subgraph $G''[A]$ for every nonempty particle A of (H,η'). Let $I(A)$ be the solution. If $A = \emptyset$, then $I(A) = \emptyset$. By the inductive assumption $I(A)$ is a maximum-weight independent set in $G''[A]$. Then we use Lemma 13 for $\varsigma = 1$ to combine the solutions into a maximum-weight independent set I_J of G''. Finally, we return the independent set $J \cup I_J$ whose weight is maximum over all choices of J. Note that the correctness of this step is guaranteed by the exhaustive guessing of J and Lemma 13.

Running time. Let $F(n)$ denote the running time of our algorithm for n-vertex instances. We prove that $F(n) = 2^{\mathcal{O}(\sqrt{tn}\log n)}$. If $n < n_0$, then the claim clearly holds. So let us assume that $n \geqslant n_0$.

In the first case we call the algorithm for two instances, one of size $n-1$ and one of size at most $n - \sqrt{n/t}$. Hence,

$$F(n) \leqslant F(n-1) + F(n-\sqrt{n/t}) = 2^{\mathcal{O}\left(\frac{n\log n}{\sqrt{n/t}}\right)} \leqslant 2^{\mathcal{O}(\sqrt{tn}\log n)}.$$

Here we skip the description how this recursion is solved, as it is pretty standard. For a formal proof we refer the reader to Bacsó et al. [7, Lemma 1].

It remains to analyze the running time of the step in which the maximum degree of vertices in G is bounded by $\sqrt{n/t}$. Corollary 12 asserts that we obtain X and the rigid extended strip decomposition (H,η) of $G' = G - N[X]$ in time polynomial in n. There are $2^{\mathcal{O}(\sqrt{n/t}\cdot t\log n)} = 2^{\mathcal{O}(\sqrt{nt}\log n)}$ ways of choosing the set J. In polynomial time we modify (H,η) into (H,η').

Observe that while (H,η') might not be rigid, it was obtained from a rigid extended strip decomposition (H,η) by deleting some vertices from the sets $\eta(\cdot)$. In particular, both decompositions have the same sets of particles, and every nonempty particle of (H,η') is also a nonempty particle of (H,η). Thus by Observation 7 we call the algorithm recursively for at most $4n$ nonempty particles, each of size at most $n/2$. By Observation 5, the total number of particles of (H,η') is polynomial in n. Finally, having computed a maximum-weight

independent set contained in each particle, by Lemma 13, we can compute the final solution in time polynomial in n. Hence, there are constants c, c_1, c_2, where $c \gg c_1, c_2$, such that total running time of this step is bounded by:

$$F(n) \leqslant 2^{c_1 \cdot \sqrt{nt} \log n} \left(n^{c_2} + 4n \cdot 2^{c \cdot \sqrt{tn/2} \log (n/2)} \right) \overset{c \gg c_1, c_2}{\leqslant} 2^{c \cdot \sqrt{tn} \log n}, \tag{1}$$

and so is the total complexity of the algorithm. ◀

4.2 Proof of Theorem 4

Again let us start with explaining the algorithm-specific details of the outline presented at the start of Section 4.

We will use the notion of β-heavy vertices from [10, 11]. Consider a graph G, a weight function $\mathfrak{w} : V(G) \to \mathbb{Z}_{\geqslant 0}$, and an independent set $I \subseteq V(G)$. Let $\beta \in (0, 1/2]$ be a real. We say that a vertex $v \in V(G)$ is *β-heavy* (with respect to I) if $\mathfrak{w}(N[v] \cap I) > \beta \cdot \mathfrak{w}(I)$. A set J is *good for I* if $J \subseteq I$ and $N[J]$ contains all vertices that are β-heavy with respect to I.

▶ **Lemma 14** (Chudnovsky et al. [10, 11]). *Let G be an n-vertex graph for $n > 2$, $\mathfrak{w} : V(G) \to \mathbb{Z}_{\geqslant 0}$ be a weight function, $I \subseteq V(G)$ be an independent set, and $\beta \in (0, 1/2]$ be a real. Then there exists a set J of size at most $\lceil \beta^{-1} \log n \rceil$ which is good for I.*

Now the vertex is heavy if it is β-heavy for some carefully chosen parameter β. This means that a neighborhood of a vertex is "large" if it contains a significant ($\geqslant \beta$) fraction of the weight of I_{OPT}. In the first phase, we exhaustively guess the set J that is good for a fixed optimum solution I_{OPT}. Note that J is of small size and since $J \subseteq I_{\mathsf{OPT}}$, we know that $N(J)$ contains no vertices from I_{OPT} and thus can be safely removed from the graph.

Since J is good for I_{OPT}, we know that $G - N[J]$ contains no heavy vertices, and for this graph we call Corollary 12. Now, as $N[X]$ is a neighborhood of few non-heavy vertices, we know that the total weight of $I_{\mathsf{OPT}} \cap N[X]$ is small and thus can be sacrificed, as we aim for an approximation.

Proof of Theorem 4. Let $s, t \geqslant 1$ be constants and let $(G, \mathfrak{w})$ be an instance of MWIS, where G is $sS_{t,t,t}$-free and has n vertices. Let $\varepsilon \in (0, 1)$ be fixed. Fix a maximum-weight independent set I_{OPT} in G with respect to $\mathfrak{w}$. We describe a procedure that finds in G an independent set I of weight at least $(1 - \varepsilon) \cdot \mathfrak{w}(I_{\mathsf{OPT}})$.

Let N be the minimum power of two greater than or equal to the size of our initial instance. Note that $n \leqslant N < 2n$. The value of N will not change throughout the execution of the algorithm.

The algorithm itself is a recursive procedure. The arguments of each call are a graph G', which is an induced subgraph of G, the weight function on $V(G')$ obtained by restricting the domain of $\mathfrak{w}$, and an integer h, which can be intuitively understood as the depth of the current call in the recursion tree. Since it does not lead to confusion, we will always denote the weight function by $\mathfrak{w}$. We will keep the invariant that for each call $(G', \mathfrak{w}, h)$ it holds that $|V(G')| \leqslant N/2^h$. The initial call, corresponding to the root of the recursion tree, is for $(G, \mathfrak{w}, 0)$.

Consider a call for the instance $(G', \mathfrak{w}, h)$. If $|V(G')| < n_0$, where n_0 is a constant (depending on s and t) that follows from the reasoning below, then we can solve the problem by brute force. Thus let us assume that $n \geqslant n_0$. In particular, $N > 1$.

We set

$$\beta(h,\varepsilon) := \frac{\varepsilon}{12(t+1)\log(N/2^h)\cdot((1-\varepsilon)\log N + \varepsilon(h+1))}. \tag{2}$$

It is straightforward to verify that for $h < \log N$ we have $\beta(h,\varepsilon) \in (0, 1/2]$. On the other hand, if $h \geqslant \log N$, then G' is of constant size and thus $\beta(h,\varepsilon)$ is not computed for such h.

Let $\mathcal{J}$ be the family of all independent sets in G' of size at most $\lceil \beta(h,\varepsilon)^{-1} \log(N/2^h)\rceil$. For each $J \in \mathcal{J}$ we proceed as follows. If $|V(G'-N[J])| < n_0$, then we compute a maximum-weight independent set I_J in $G'-N[J]$ by brute force. Otherwise, we use Corollary 12, to obtain a set $X_J \subseteq V(G'-N[J])$ and a rigid extended strip decomposition (H,η) of $G'-N[J]-N[X_J]$ such that each particle of (H,η) is of size at most $|V(G'-N[J])|/2$. By Corollary 12, we obtain

$$\begin{aligned} |X_J| &\leqslant (s-1)(3t+1) + (11\log|V(G'-N[J])| + 6)(t+1) \\ &\leqslant 12(t+1)\log|V(G')| \leqslant 12(t+1)\log(N/2^h). \end{aligned} \tag{3}$$

Let $Y_J := N(J) \cup N[X_J]$. We modify (H,η) into an extended strip decomposition of $G'-Y_J$ as follows. For each $v \in J$, we add to H an isolated vertex x_v, and set $\eta(x_v) = \{v\}$.[1] Let us call this extended strip decomposition (H',η'). Observe that each particle of (H',η') is of size at most $|V(G'-N[J])|/2 \leqslant |V(G')|/2$. Furthermore, since (H,η) is rigid, so is (H',η').

For each nonempty particle A of (H',η') we call the algorithm recursively on an instance $(G'[A], \mathfrak{w}, h+1)$. Let $I(A)$ be the value returned by the algorithm. For each empty particle A we set $I(A) := \emptyset$. Finally, we apply the algorithm from Lemma 13, in order to obtain an independent set I_J of $G'-Y_J$ and thus of G'. Recall that the value of ς is not needed to apply Lemma 13; we will define it in the next paragraph when we discuss the approximation guarantee. As the solution, we return the set I_J of maximum weight, over all choices of $J \in \mathcal{J}$.

Approximation guarantee. Consider the recursion tree of our algorithm. We mark some nodes of the recursion tree. First, we mark the root. Now consider some marked node z corresponding to a call $(G',\mathfrak{w},h)$, such that z is not a leaf node. Observe that by Lemma 14, there is some $J \in \mathcal{J}$ (for this particular instance) which is good for $I_{\mathsf{OPT}} \cap V(G')$. Fix such J. If there is more than one, we choose one arbitrarily. We mark the children of z that correspond to the calls on the particles of the extended strip decomposition of $G'-Y_J$.

Let $\mathcal{T}$ be the subtree of the recursion tree induced by the marked nodes. Note that each leaf of $\mathcal{T}$ is a leaf of the whole recursion tree, i.e., it corresponds to an instance of constant size. Since at each level of the recursion, the size of the instance drops by at least half, we observe that each instance at level h (where the root is at level 0) is of size at most $N/2^h$. Consequently, the depth of $\mathcal{T}$ is at most $\log N$.

Consider a call for an instance $(G',\mathfrak{w},h)$ and let J be good for I_{OPT}. Let us estimate $\mathfrak{w}(I_{\mathsf{OPT}} \cap Y_J)$. First, observe that since $J \subseteq I_{\mathsf{OPT}}$, we have that $\mathfrak{w}(I_{\mathsf{OPT}} \cap N(J)) = 0$. Moreover, since J was chosen to be good, there are no $\beta(h,\varepsilon)$-heavy vertices in $V(G'-N[J])$, and in particular, in $N[X_J]$. Hence,

$$\begin{aligned} \mathfrak{w}(I_{\mathsf{OPT}} \cap Y_J) = \mathfrak{w}(I_{\mathsf{OPT}} \cap N[X_J]) &\leqslant |X_J| \cdot \beta(h,\varepsilon) \cdot \mathfrak{w}(I_{\mathsf{OPT}} \cap V(G')) \\ &\overset{(2) \text{ and } (3)}{\leqslant} \frac{\varepsilon}{(1-\varepsilon)\log N + \varepsilon(h+1)} \cdot \mathfrak{w}(I_{\mathsf{OPT}} \cap V(G')). \end{aligned} \tag{4}$$

[1] Another possible way of dealing with the set J would be to add it directly in the computed solution. However, we decided to restore J to the graph, so that these vertices are handled by Lemma 13 and do not require any special treatment.

The following claim shows that the solution computed for the instance $(G', \mathfrak{w}, h)$ at each node of $\mathcal{T}$ is a reasonable approximation of $I_{\mathsf{OPT}} \cap V(G')$.

▷ Claim 15. Let z be a node of $\mathcal{T}$, and let $(G', \mathfrak{w}, h)$ be the instance corresponding to z. Let I be the independent set returned by the algorithm for the call at z. Then $\mathfrak{w}(I) \geqslant \left(1 - \varepsilon + \frac{\varepsilon h}{\log N}\right) \cdot \mathfrak{w}\left(I_{\mathsf{OPT}} \cap V(G')\right)$.

Proof. First, observe that if z is a leaf of $\mathcal{T}$, then the statement of the claim is satisfied. Indeed, in this case I is computed by brute force, and hence $\mathfrak{w}(I) = \mathfrak{w}(I_{\mathsf{OPT}} \cap V(G'))$.

Recall that the algorithm returns the solution of maximum weight among all choices of $J \in \mathcal{J}$, so clearly we have $\mathfrak{w}(I) \geqslant \mathfrak{w}(I_J)$, where J is good for $I_{\mathsf{OPT}} \cap V(G')$.

We proceed by induction on h. First, consider a node z at the level $h = \log N$. As the depth of $\mathcal{T}$ is at most $\log N$, we observe that z must be a leaf, so the claim follows by the observation above.

Assume that the claim holds for $h+1 \in [\log N]$ and consider a node z at level h. If z is a leaf, then again, we are done. Otherwise, let $\mathcal{A}$ be the set of nonempty particles of the extended strip decomposition of $G' - Y_J$. For every such particle A, we recursively computed an independent set $I(A)$. By the inductive assumption, we have that $\mathfrak{w}(I(A)) \geqslant \left(1 - \varepsilon + \frac{\varepsilon(h+1)}{\log N}\right) \mathfrak{w}(I_{\mathsf{OPT}} \cap V(G'[A]))$; note that these recursive calls are at level $h+1$. Clearly, the same holds for empty particles because $\emptyset$ is there an optimum solution.

Thus, by Lemma 13 applied to I_{OPT} and $\varsigma = 1 - \varepsilon + \frac{\varepsilon(h+1)}{\log N}$, we obtain an independent set I_J in $G' - Y_J$, such that

$$\begin{aligned} \mathfrak{w}(I_J) &\geqslant \left(1 - \varepsilon + \frac{\varepsilon(h+1)}{\log N}\right) \mathfrak{w}(I_{\mathsf{OPT}} \cap V(G' - Y_J)) \\ &= \left(1 - \varepsilon + \frac{\varepsilon(h+1)}{\log N}\right) \left(\mathfrak{w}(I_{\mathsf{OPT}} \cap V(G')) - \mathfrak{w}(I_{\mathsf{OPT}} \cap Y_J)\right). \end{aligned} \tag{5}$$

Combining (5) with (4) and simplifying the formula, we obtain

$$\mathfrak{w}(I_J) \geqslant \left(1 - \varepsilon + \frac{\varepsilon h}{\log N}\right) \mathfrak{w}(I_{\mathsf{OPT}} \cap V(G')),$$

which concludes the proof of the claim. ◁

Since the root of the recursion tree belongs to $\mathcal{T}$, the final result I returned for the call at the root (i.e., for $(G, \mathfrak{w}, 0)$) satisfies

$$\mathfrak{w}(I) \geqslant (1 - \varepsilon) \cdot \mathfrak{w}\left(I_{\mathsf{OPT}} \cap V(G)\right) = (1 - \varepsilon) \cdot \mathfrak{w}(I_{\mathsf{OPT}}).$$

This concludes the discussion of the approximation guarantee.

Running time. Recall that the recursion tree has depth at most $\log N$. Let us show the following claim concerning the running time.

▷ Claim 16. Let z be a node of the recursion tree, and let $(G', \mathfrak{w}, h)$ be the instance corresponding to z. Then the algorithm solves this instance in time $2^{\mathcal{O}\left(\varepsilon^{-1} \log^4 N \log\left(N/2^{h-1}\right)\right)}$.

Proof. Let $F(h)$ denote the upper bound for the running time of our algorithm, depending on the level of the call in the recursion tree. We aim to show that there is an absolute constant c, such that for N sufficiently large we have

$$F(h) \leqslant 2^{c \cdot \varepsilon^{-1} \log^4 N \log\left(N/2^{h-1}\right)}.$$

Recall that $|V(G')| \leqslant N/2^h$. If z is a leaf, then the instance is of constant size, and thus the claim holds (assuming that c is sufficiently large). In particular this happens if $h = \log N$. So let us assume that the claim holds for the calls at level $h+1$ and that $h < \log N$.

Recall that we first enumerate the family $\mathcal{J}$ of all independent sets of size at most $\lceil \beta(h,\varepsilon)^{-1} \log(N/2^h) \rceil$. Observe that

$$|\mathcal{J}| \leqslant |V(G')|^{\lceil \beta(h,\varepsilon)^{-1} \log(N/2^h) \rceil} \leqslant 2^{\log(N/2^h) \lceil \beta(h,\varepsilon)^{-1} \log(N/2^h) \rceil},$$

and the family $\mathcal{J}$ can be enumerated in time polynomial in its size.

For each $J \in \mathcal{J}$, using Corollary 12 and modifying its outcome, in polynomial time we obtain a set X_J and a rigid extended strip decomposition (H', η') of $G - Y_J$, where $Y_J = N[X_J] \cup N(J)$.

Next, we call the algorithm recursively for at most $4 \cdot |V(G')| \leqslant 4 \cdot N/2^h$ instances, each at depth $h+1$. Finally, use use Lemma 13 to obtain our solution in time polynomial in $|V(G')|$ and thus in $N/2^h$.

Thus the running time is bounded by the following expression (here c_1, c_2, c_3 are absolute constants, such that c_1 and c_2 are much smaller than c_3, and $c_3 = c/12(t+1)$):

$$\begin{aligned}
F(h) &\leqslant 2^{c_1 \cdot \beta(h,\varepsilon)^{-1} \log^2(N/2^h)} \cdot \left((N/2^h)^{c_2} + 4 \cdot (N/2^h) \cdot F(h+1) \right) \\
&\overset{c_3 \gg c_1, c_2}{\leqslant} 2^{c_3 \cdot \beta(h,\varepsilon)^{-1} \log^2(N/2^h)} \cdot 2^{c \cdot \varepsilon^{-1} \log^4 N \log(N/2^h)} \\
&= \exp\left\{ c_3 \cdot \beta(h,\varepsilon)^{-1} \log^2(N/2^h) + c \cdot \varepsilon^{-1} \log^4 N \log(N/2^h) \right\} \\
&\leqslant \exp\left\{ c_3 \cdot 12(t+1) \cdot \left(\frac{1-\varepsilon}{\varepsilon} \log N + (h+1) \right) \log^3(N/2^h) + c \cdot \varepsilon^{-1} \log^4 N \log(N/2^h) \right\} \\
&\overset{h < \log N}{\leqslant} \exp\left\{ c \cdot \varepsilon^{-1} \log^4 N + c \cdot \varepsilon^{-1} \log^4 N \log(N/2^h) \right\} \\
&= \exp\left\{ c \cdot \varepsilon^{-1} \log^4 N (\log(N/2^h) + 1) \right\} = \exp\left\{ c \cdot \varepsilon^{-1} \log^4 N \log(N/2^{h-1}) \right\}.
\end{aligned}$$

This completes the proof of the claim. ◁

Now we apply Claim 16 to the initial call $(G, \mathfrak{w}, 0)$ and obtain that the overall running time is

$$2^{\mathcal{O}(\varepsilon^{-1} \log^5 N)} = 2^{\mathcal{O}(\varepsilon^{-1} \log^5 n)},$$

as $N < 2n$. This completes the proof. ◀

5 Conclusion

In the QPTAS of Chudnovsky, Pilipczuk, Pilipczuk, and Thomassé [10, 11] it was more convenient to measure the weight of parts of the graph not by the number of vertices, but by the weight of the intersection of the sought solution with the part in question. We observe that we can adapt Theorem 2 to this setting of unknown weight function.

▶ **Theorem 17.** *Given an n-vertex graph G and an integer t, one can in time $n^{\mathcal{O}(t \log n)}$ either:*

- *output an induced copy of $S_{t,t,t}$ in G, or*
- *output a family $\mathcal{F}$ satisfying the following:*
  1. *every element of $\mathcal{F}$ is a pair of a set $\mathcal{P}$ consisting of at most $11 \log n + 6$ induced paths in G, each of length at most $t+1$, and an extended strip decomposition of $G - N[\bigcup \mathcal{P}]$;*

2. *for every weight function* $\mathfrak{w} : V(G) \to \mathbb{Z}_{\geqslant 0}$ *there exists a pair in* $\mathcal{F}$ *such that every particle in the extended strip decomposition of the pair has weight at most half of the total weight of* G*;*
3. *the size of* $\mathcal{F}$ *is bounded by* $n^{\mathcal{O}(\log n)}$*.*

Proof sketch. As observed in [10, 11], in G one can identify at most n^2 induced paths such that for every weight function $\mathfrak{w} : V(G) \to \mathbb{Z}_{\geqslant 0}$, at least one of the identified path is a Gyárfás' path for $\mathfrak{w}$, that is, a path Q such that every connected component of $G - N[Q]$ is of weight at most half of the weight of G. Thus, we can guess the path Q as in the proof in Theorem 2 out of at most n^2 candidates.

Then, in the recursive step in the proof of Theorem 2, instead of choosing the heavy particle to recurse on, we guess which particle is heavy (or that none exists). It is easy to see that any extended strip decomposition in the process will have fewer than n inclusion-wise maximal particles; thus, this gives $n^{\mathcal{O}(\log n)}$ possible outputs to enumerate. ◀

We think the $\log n$ factor in Theorem 2 is an artifact of our technique, and is not necessary. Therefore, we pose the following conjecture.

▶ **Conjecture 18.** *For every integer* $t \geqslant 1$ *there exists a constant* $\varepsilon > 0$ *and an integer* s *such that every* $S_{t,t,t}$*-free graph* G *admits a set* $P \subseteq V(G)$ *of size at most* s *such that* $G - N[P]$ *admits a rigid extended strip decomposition whose every particle has at most* $(1-\varepsilon)|V(G)|$ *vertices.*

Abrishami, Chudnovsky, Dibek, and Rzążewski [2] very recently announced a polynomial-time algorithm for MWIS in $S_{t,t,t}$-free graphs of bounded degree. Their argument is quite involved and revisits the proof of the three-in-a-tree theorem [13].

Confirming Conjecture 18 would imply the same result almost immediately, possibly with a better running time. Indeed, one needs to branch on $N[P]$ and recurse on the remainder of every particle of (H, η). The maximum degree of H is bounded by a function of the maximum degree of G (i.e., is a constant), which ensures that the sum of sizes of all particles is linear in $|V(G)|$. This in turns implies that the total complexity of the algorithm can be bounded by a polynomial function. Note that the same approach using Theorem 2 yields quasipolynomial running time bound.

We see Theorem 2 as the analog of Theorem 1 in the classes of $S_{t,t,t}$-free graphs: with its help, obtaining a QPTAS or a subexponential algorithm was relatively simple, following the ideas of [7, 10, 11]. We expect it is a first step to get a quasipolynomial-time algorithm for MWIS in $S_{t,t,t}$-free graphs, similarly as Theorem 1 is an essential ingredient of the algorithms for P_t-free graphs [15, 24]. However, there is a lot of work to be done: the way how [15, 24] measure the progress of the branching algorithm is quite intricate; furthermore, for the class of $C_{>t}$-free graphs (graphs excluding all cycles of length more than t as induced subgraphs, a proper superclass of P_t-free graphs) while an analog of Theorem 1 is known, the corresponding measure of the progress of the branching algorithm is much more involved [16].

Abstract

The AP-LCA problem asks, given an n-node directed acyclic graph (DAG), to compute for every pair of vertices u and v in the DAG a lowest common ancestor (LCA) of u and v if one exists, i.e. a node that is an ancestor of both u and v but no proper descendent of it is their common ancestor. Recently [Grandoni et al. SODA'21] obtained the first sub-$n^{2.5}$ time algorithm for AP-LCA running in $O(n^{2.447})$ time. Meanwhile, the only known conditional lower bound for AP-LCA is that the problem requires $n^{\omega-o(1)}$ time where ω is the matrix multiplication exponent.

In this paper we study several interesting variants of AP-LCA, providing both algorithms and fine-grained lower bounds for them. The lower bounds we obtain are the first conditional lower bounds for LCA problems higher than $n^{\omega-o(1)}$. Some of our results include:

- In any DAG, we can detect all vertex pairs that have at most two LCAs and list all of their LCAs in $O(n^{\omega})$ time. This algorithm extends a result of [Kowaluk and Lingas ESA'07] which showed an $\tilde{O}(n^{\omega})$ time algorithm that detects all pairs with a unique LCA in a DAG and outputs their corresponding LCAs.
- Listing 7 LCAs per vertex pair in DAGs requires $n^{3-o(1)}$ time under the popular assumption that 3-uniform 5-hyperclique detection requires $n^{5-o(1)}$ time. This is surprising since essentially cubic time is sufficient to list all LCAs (if $\omega = 2$).
- Counting the number of LCAs for every vertex pair in a DAG requires $n^{3-o(1)}$ time under the Strong Exponential Time Hypothesis, and $n^{\omega(1,2,1)-o(1)}$ time under the 4-Clique hypothesis. This shows that the algorithm of [Echkardt, Mühling and Nowak ESA'07] for listing all LCAs for every pair of vertices is likely optimal.
- Given a DAG and a vertex $w_{u,v}$ for every vertex pair u, v, verifying whether all $w_{u,v}$ are valid LCAs requires $n^{2.5-o(1)}$ time assuming 3-uniform 4-hyperclique requires $n^{4-o(1)}$ time. This defies the common intuition that verification is easier than computation since returning some LCA per vertex pair can be solved in $O(n^{2.447})$ time.

1 Introduction

A lowest common ancestor (LCA) of two nodes u and v in a directed acyclic graph (DAG) is a common ancestor c of u and v such that no proper descendent of c is a common ancestor of u and v. The AP-LCA problem asks to compute for every pair of nodes in a given DAG, some LCA, provided a common ancestor exists.

Computing LCAs is an important problem with a wide range of applications. For instance, LCA computation is a key ingredient in verification of the correctness of distributed computation (e.g. [10]), object inheritance in object oriented programming languages such as C++ and Java (e.g. [2, 19, 26]), and computational biology for finding the closest ancestor of species in rooted phylogenetic networks (e.g. [22]).

Computing LCAs is very well-understood in trees [7, 8, 17, 24, 27, 37, 38, 40]. Aït-Kaci, Boyer, Lincoln and Nasr [2] were one of the first to consider LCAs in DAGs, focusing on lattices and lower semilattices with object inheritance in mind. Nykänen and Ukkonen [36] obtained efficient algorithms for directed trees and asked if there is a subcubic time algorithm for AP-LCA in DAGs.

Bender, Martin Farach-Colton, Pemmasani, Skiena and Sumazin [6] gave the first subcubic, $O(n^{(3+\omega)/2}) \leq O(n^{2.687})$, time algorithm for AP-LCA in DAGs, where $\omega < 2.37286$ is the matrix multiplication exponent [4]. They also showed that AP-LCA is equivalent to the so-called All-Pairs Shortest LCA Distance problem. Czumaj, Kowaluk and Lingas [30, 18] improved the AP-LCA running time to $O(n^{2.575})$ using a reduction to the Max-Witness Product problem. With the current best bounds for rectangular matrix multiplication [33], their algorithm runs in $O(n^{2.529})$ time.

Notice that all subcubic algorithms above would run in $\tilde{O}(n^{2.5})$ time[1] if $\omega = 2$. For more than a decade, this running time remained unchallenged. It seemed that AP-LCA might actually require $n^{2.5-o(1)}$ time, similar to several other $n^{2.5}$ time problems such as computing the Max-Witness product (see e.g. [34]).

Recently, Grandoni, Italiano, Lukasiewicz, Parotsidis and Uznanski [25] showed that this is not the case, giving an algorithm that runs in $O(n^{2.447})$ time, or in $\tilde{O}(n^{7/3})$ time if $\omega = 2$.

It is not hard to show (see [6, 18]) that any algorithm for AP-LCA can be used to solve Boolean Matrix Multiplication (BMM), and hence beating $O(n^\omega)$ time for AP-LCA would likely be difficult. No higher conditional lower bounds are known for the problem. It is still open whether $O(n^\omega)$ time can actually be achieved for AP-LCA.

Partial progresses have been made for DAGs with special structures or for variants of AP-LCA. Czumaj, Kowaluk and Lingas [18] showed that AP-LCA is in $O(n^\omega)$ time for low-depth DAGs. Kowaluk and Lingas [31] showed that in $O(n^\omega \log n)$ time one can return an LCA for every vertex pair that has a unique LCA. Eckhardt, Mühling and Nowak [20] showed that one can solve the AP-All-LCA problem, which asks to output all LCAs for every pair of vertices, in $O(n^{\omega(1,2,1)})$ time. Here $\omega(1,2,1) \leq 3.252$ is the exponent of multiplying an $n \times n^2$ by an $n^2 \times n$ matrix. AP-LCA was also studied in the weighted setting [5], the dynamic setting [20] and the space-efficient setting [32].

This paper considers the following questions:

1. Can we return all LCAs for every pair of nodes that has at most 2 LCAs, in $\tilde{O}(n^\omega)$ time, extending Kowaluk and Lingas's algorithm [31]?
2. The AP-LCA problem asks us to exhibit a single LCA for each vertex pair. What if we want to list 2, 3, ..., k LCAs? How fast can we do it?

[1] $\tilde{O}$ hides poly-logarithmic factors.

So far two variants of LCA are studied: list a single LCA per pair and list all LCAs per pair. What about listing numbers in between? This is just as natural. In phylogenetic networks for instance, there can be multiple LCAs per species pair, but typically not too many. Then listing a constant number of LCAs fast can give a better picture than listing a single representative. Other applications of AP-LCA would similarly make more sense for listing multiple LCAs.

3. How fast can we count the number of LCAs each vertex pair has?
4. Suppose that for every pair of nodes u, v in a DAG we are given a node $w_{u,v}$. Can we efficiently determine whether $w_{u,v}$ is an LCA of u and v, for each u, v? One would think that if AP-LCA can be solved faster than $O(n^{2.5})$ time, then this verification version of the problem should also be solvable faster.

We provide algorithms and fine-grained conditional lower bounds to address the above questions. Our lower bounds are the first conditional lower bounds higher than $n^{\omega-o(1)}$ for LCA problems.

1.1 Our results

Detecting and listing $O(1)$ LCAs. Our results for this part are summarized in Table 1.

Table 1 A summary of our results for detecting and listing LCAs. In the second and third columns, we give the best known runtime exponents for AP-AtLeast$k$-LCA and AP-List-k-LCA respectively. An exponent of 3 above corresponds to the trivial brute-force algorithm. In the fourth and fifth columns, we give the best conditional lower bounds for the exponent of AP-AtLeast$k$-LCA, and the corresponding hardness sources for the lower bounds. The exponents and lower bounds in the last row are for AP-All-LCA problem. All values in parentheses are the corresponding values when $\omega = 2$.

k	AP-AtLeast$k$-LCA Exponent		AP-List-k-LCA Exponent		Best Lower Bound		Source of LB

Let us define AP-Exact$k$-LCA, AP-AtLeast$k$-LCA and AP-AtMost$k$-LCA as the problems of deciding for every pair of vertices in a given DAG, whether they have exactly, greater than or equal to, and less than or equal to k LCAs, respectively.

We study how fast AP-Exact$k$-LCA, AP-AtLeast$k$-LCA and AP-AtMost$k$-LCA can be solved for constant k. More generally, we study the problem of returning k LCAs per vertex pair if it has at least k LCAs, or all LCAs if it has fewer. We call the latter problem AP-List-k-LCA.

For any constant k, one can return up to k LCAs for every vertex pair in a DAG in cubic time using a trivial brute-force algorithm[2]. More generally, if $\omega = 2$, the $O(n^{\omega(1,2,1)})$ time AP-All-LCA algorithm in [20] would also run in essentially cubic time.

[2] We first compute a topological ordering of the graph in $O(n^2)$ time and the transitive closure in $O(n^\omega)$ time using [23]. For each vertex pair (u, v), we scan the vertices in the reverse order of the topological ordering, and declare the current vertex w a new LCA if w can reach both u and v and w cannot reach any LCAs found so far. We stop the scan as soon as we find k LCAs or reach the end of the topological ordering. Given the transitive closure, each reachability check can be finished in $O(1)$ time, so the overall running time of the algorithm is $O(kn^3)$.

It is thus interesting to study *for what values of k,* AP-Exact$k$-LCA*,* AP-AtLeast$k$-LCA*,* AP-AtMost$k$-LCA *and* AP-List-k-LCA *are solvable in truly subcubic, $O(n^{3-\varepsilon})$ for $\varepsilon > 0$, time.*

We show that for every constant k, the listing problem AP-List-k-LCA and the decision problem AP-AtLeast$k$-LCA are subcubically equivalent. This statement appears as Theorem 28 in the main text. Thus, the values k for which one problem is in subcubic time are exactly the same for the other problem.

We also prove a convenient equivalence between AP-Exact$k$-LCA, AP-AtLeast$k$-LCA and AP-AtMost$k$-LCA:

▶ **Theorem 1.** *For any constant $k \geq 0$, the running times of* AP-Exact$k$-LCA*,* AP-AtMost$k$-LCA *and* AP-AtLeast$(k+1)$-LCA *are the same up to constant factors.*

Now we can focus on AP-Exact$k$-LCA, and due to the above equivalence, we also obtain results for the other variants.

Next, we extend the result of Kowaluk and Lingas [31] for pairs with unique LCAs to pairs with two LCAs by showing that AP-Exact$k$-LCA can be solved in $O(n^\omega)$ time for both $k = 1, 2$. Moreover, the corresponding witness LCAs can be listed in the same time.

▶ **Theorem 2.** AP-Exact1-LCA *and* AP-Exact2-LCA *can be solved in $O(n^\omega)$ time with high probability by Las Vegas algorithms. Moreover, finding the LCAs for vertex pairs (u, v) that have exactly 1 or 2 LCAs can also be solved in $O(n^\omega)$ time with high probability.*

This theorem appears as Theorems 26 and 27 in the main text. By our equivalence theorem, the same result applies to AP-AtLeast$(k+1)$-LCA and AP-AtMost$k$-LCA for $k = 1, 2$.

Our algorithm for AP-Exact1-LCA is different from that of [31]. The algorithm of [31] is deterministic while ours is randomized, so it is seemingly weaker. We nevertheless include our approach to AP-Exact1-LCA as it is simple and saves a factor of $\log n$. Additionally, our approach generalizes to AP-Exact2-LCA.

As our techniques no longer seem to work for the case of deciding if there are exactly 3 LCAs, we turn to conditional lower bounds. We prove that under popular fine-grained hypotheses, the following hold in the word-RAM model with $O(\log n)$ bit words (Theorem 30): AP-Exact$k$-LCA requires time $n^{2.5-o(1)}$ for $k = 3$, $n^{8/3-o(1)}$ for $k = 4$, $n^{2.8-o(1)}$ for $k = 5$ and $n^{3-o(1)}$ for $k = 6$.

With our earlier equivalence theorem in mind, our conditional lower bound for AP-Exact3-LCA means that detecting for each pair whether it has at least 4 LCAs, or listing 4 LCAs per vertex pair also requires $n^{2.5-o(1)}$ time. In particular, this shows that listing 4 LCAs is more difficult than listing just one LCA per vertex pair, as the latter has an $O(n^{2.447})$ time algorithm [25].

Furthermore, our conditional lower bound for AP-Exact6-LCA also implies that AP-AtLeast7-LCA requires $n^{3-o(1)}$ time, and hence the clearly even harder problem of listing 7 LCAs per vertex pair requires $n^{3-o(1)}$ time. This is intriguing since as we mentioned earlier, we can list all LCAs per pair in essentially cubic time if $\omega = 2$.

We also show the following algorithmic results for AP-List-2-LCA and AP-List-3-LCA.

▶ **Theorem 3.** *For $k = 2$ and $k = 3$, the* AP-List-k-LCA *problem can be deterministically solved in $\tilde{O}(n^{2+\lambda})$ time, where λ satisfies the equation $\omega(1, \lambda, 1) = 1 + 2\lambda$. Here, $\omega(1, \lambda, 1)$ is the exponent of multiplying an $n \times n^\lambda$ by an $n^\lambda \times n$ matrix.*

The running time for AP-List-k-LCA above matches the best known running time for Max-Witness product [18]. Using the current best bounds for rectangular matrix multiplication [33], the runtime we get for AP-List-k-LCA is $O(n^{2.529})$ for $k = 2$ and 3.

Counting LCAs. We now turn our attention to computing the number of LCAs for every pair of vertices in a DAG. We call this problem AP-#LCA. As shown in [20], we can list all LCAs for every pair of vertices in $O(n^{\omega(1,2,1)})$ time, which is essentially cubic time if $\omega = 2$. Thus in particular, we can also count all the LCAs in the same amount of time.

One might wonder, can the counts be computed faster, in truly subcubic time? We show that under the Strong Exponential Time (SETH) Hypothesis [29, 13, 14], this is impossible, even if we are only required to return the count for a vertex pair if it is smaller than some superconstant function $g(n)$. Notice that we can solve this restrained case in $O(n^3 g(n))$ time using the brute-force algorithm, so the following theorem is tight up to $n^{o(1)}$ factors when $g(n)$ is $\tilde{O}(1)$.

▶ **Theorem 4.** *Assuming SETH,* AP-#LCA *requires* $n^{3-o(1)}$ *time, even if we only need to return the minimum between the count and* $g(n)$ *for any* $g(n) = \omega(1)$.

The current best running time $O(n^{\omega(1,2,1)})$ for listing LCAs and also for AP-#LCA is actually supercubic, however. For the current best bounds on $\omega(1,2,1)$, it is $O(n^{3.252})$ [33]. In fact, there are serious limitations of the known matrix multiplication techniques [3, 15, 16] that show that current techniques cannot be used to prove that $\omega(1,2,1) < 3.05$.

In this case, the cubic lower bound for AP-#LCA under SETH would not be entirely satisfactory. We thus present a tight conditional lower bound from the 4-Clique problem.

The 4-Clique problem asks, does a given n-node graph contain a clique on 4 nodes? The fastest known algorithm for 4-Clique runs in $\tilde{O}(n^{\omega(1,2,1)})$ time [21], which has remained unchallenged for almost two decades. We show that an improvement over the $O(n^{\omega(1,2,1)})$ time for AP-#LCA would also solve 4-Clique faster.

▶ **Theorem 5.** *If the* AP-#LCA *problem can be solved in* $T(n)$ *time, then* 4-Clique *can be computed in* $O(T(n) + n^{\omega})$ *time.*

Verifying LCAs. Oftentimes in algorithms, one is also concerned with the problem of verifying an answer besides computing an answer. In many cases, verification is an easier problem than computation. For instance, even though computing the product of two $n \times n$ matrices A and B currently is only known to be possible in $O(n^{2.373})$ time, verifying whether the product of A and B is a matrix C can be done in randomized $\tilde{O}(n^2)$ time. This was the basis of the Blum-Luby-Rubinfeld linearity test [9].

We consider the following two verification variants of AP-LCA which we call Ver-LCA and AP-Ver-LCA. In both variants, we are given an n-node DAG, and for every pair of nodes u, v in the DAG, we are also given a node $w_{u,v}$. In Ver-LCA, we want to determine whether all $w_{u,v}$ are LCAs for their respective pair u, v, i.e. that the matrix w of candidate LCAs is all correct (or conversely, that there is *some* pair that has an incorrect entry). In the AP-Ver-LCA variant we want to know for every u, v whether $w_{u,v}$ is an LCA of u and v, so this variant is potentially more difficult. After we compute the transitive closure of the graph, it takes $O(n)$ time to verify whether a vertex $w_{u,v}$ is indeed an LCA of u and v. Thus, both Ver-LCA and AP-Ver-LCA can be solved in $O(n^3)$ time. No faster algorithm is known to the best of our knowledge.

Kowaluk and Lingas [31] solved a variant of AP-Ver-LCA concerning vertex pairs that have at most 2 LCAs. Specifically, given one or two nodes per pair they showed how to verify that those nodes are all the LCAs for the pair, in $O(n^{\omega})$ time. However, their algorithm is not able to compute 2 LCAs for vertex pairs that have exactly 2 LCAs in $O(n^{\omega})$ time.

Surprisingly, we provide strong evidence that Ver-LCA and AP-Ver-LCA are actually *harder* than AP-LCA, as AP-LCA can be solved in $O(n^{2.5-\varepsilon})$ time for $\varepsilon > 0$, while under popular fine-grained hypotheses, Ver-LCA and AP-Ver-LCA require $n^{2.5-o(1)}$ time.

Our first hardness result is that the running time of AP-Ver-LCA is at least as high as that of the Max-Witness problem, whose current best running time is $O(n^{2.529})$ [30, 33]. If $\omega = 2$, then Max-Witness would be solvable in $\tilde{O}(n^{2.5})$ time, and it is hypothesized [34] that no $n^{2.5-o(1)}$ time algorithms exist for it.

▶ **Theorem 6.** *If the* AP-Ver-LCA *problem can be solved in* $T(n)$ *time, then the* Max-Witness *problem can be solved in* $\tilde{O}(T(n))$ *time.*

Note that Czumaj, Kowaluk and Lingas's algorithm [18] for AP-LCA is essentially a reduction from AP-LCA to Max-Witness. Combined with their algorithm, the above theorem says that we can solve AP-Ver-LCA in $T(n)$ time, then we can solve AP-LCA in $\tilde{O}(T(n))$ time.

Our second result is the hardness of Ver-LCA based on the hardness of the $(4,3)$-Hyperclique problem: given a 3-uniform hypergraph on n nodes, return whether it contains a 4-hyperclique. This problem is hypothesized to require $n^{4-o(1)}$ time [35], and solving it in $O(n^{4-\varepsilon})$ time for $\varepsilon > 0$ would imply improved algorithms for Max-3-SAT and other problems (see [35] and the discussion therein).

▶ **Theorem 7.** *Assuming the* $(4,3)$-Hyperclique *hypothesis,* Ver-LCA *requires* $n^{2.5-o(1)}$ *time.*

Thus, verifying candidate LCAs is most likely harder than finding LCAs, defying the common intuition that verification should be easier than computation.

1.2 Paper Organization

In Section 2, we give necessary definitions. In Section 3, we list basic relationships among AP-Exact$k$-LCA, AP-AtMost$k$-LCA and AP-AtLeast$k$-LCA, including Theorem 1. In Section 4, we show $O(n^{\omega})$ time algorithms for AP-Exact1-LCA and AP-Exact2-LCA, proving Theorem 2. In Section 5, we consider the AP-List-k-LCA problem. In Section 6, we prove several conditional lower bounds for AP-Exact$k$-LCA and AP-#LCA, including Theorem 4 and Theorem 5. In Section 7, we show conditional lower bounds for AP-Ver-LCA, proving Theorem 6 and Theorem 7. Finally, in Section 8, we conclude with several open problems.

2 Preliminaries

2.1 Notation

Let $G = (V, E)$ be a DAG. For every $u, v \in V$, we use $\mathsf{LCA}(u, v)$ to denote the set of vertices that are LCAs for vertex pair u and v. We use $u \rightsquigarrow v$ to denote that u can reach v via zero or more edges and use $u \not\rightsquigarrow v$ to denote that u cannot reach v. In particular, $u \rightsquigarrow u$ for every $u \in V$. We also use $\mathsf{Anc}(u)$ to denote the set of vertices that can reach u. For any $V' \subseteq V$, we use $G[V']$ to denote the subgraph in G induced by the vertex set V'.

We use $\omega < 2.37286$ to denote the matrix multiplication exponent [4]. For any constants $a, b, c \geq 0$, we use $\omega(a, b, c)$ to denote the exponent of multiplying an $n^a \times n^b$ matrix by an $n^b \times n^c$ matrix, in the arithmetic circuit model. Note that the fastest known algorithms for square [4] and rectangular [33] matrix multiplication all work in the arithmetic circuit model.

It is well-known that $\omega(a, b, c) = \omega(b, c, a)$ (see e.g. [12]).

2.2 Variants of AP-LCA

Given a DAG $G = (V, E)$, we study the following variants of AP-LCA.

▶ **Definition 8** (AP-Exact$k$-LCA)**.** *Decide if* $|\mathsf{LCA}(u, v)| = k$ *for every pair* $u, v \in V$*.*

▶ **Definition 9** (AP-AtMost$k$-LCA). *Decide if* $|\mathsf{LCA}(u,v)| \leq k$ *for every pair* $u, v \in V$.

▶ **Definition 10** (AP-AtLeast$k$-LCA). *Decide if* $|\mathsf{LCA}(u,v)| \geq k$ *for every pair* $u, v \in V$.

▶ **Definition 11** (AP-#LCA). *Compute* $|\mathsf{LCA}(u,v)|$ *for every pair* $u, v \in V$.

▶ **Definition 12** (AP-List-k-LCA). *Compute for every pair* $u, v \in V$ *a list of* k *distinct LCAs. If any pair* $u, v \in V$ *has fewer than* k *LCAs, output all of their LCAs.*

▶ **Definition 13** (AP-All-LCA). *For every pair* $u, v \in V$, *output* $\mathsf{LCA}(u,v)$.

▶ **Definition 14** (AP-Ver-LCA). *Given a candidate vertex* $w_{u,v}$ *for each pair* $u, v \in V$, *decide if* $w_{u,v} \in \mathsf{LCA}(u,v)$ *for every pair* $u, v \in V$.

▶ **Definition 15** (Ver-LCA). *Given a candidate vertex* $w_{u,v}$ *for each pair* $u, v \in V$, *decide if there exists* $u, v \in V$ *such that* $w_{u,v}$ *is not an LCA for* u *and* v.

2.3 Fine-Grained Hypotheses

In this section, we list the hypotheses we use in this paper.

Eisenbrand et al. [21] gave the current best algorithm for 4-Clique that runs in $O(n^{\omega(1,2,1)})$ time. The 4-Clique hypothesis states that we cannot improve this algorithm much.

▶ **Hypothesis 16** (4-Clique Hypothesis [11, 1]). *On a Word-RAM with* $O(\log n)$ *bit words, detecting a 4-clique in an* n*-node graph requires* $n^{\omega(1,2,1)-o(1)}$ *time.*

▶ **Hypothesis 17** ((ℓ,k)-Hyperclique Hypothesis, [35]). *Let* $\ell > k > 2$ *be constant integers. On a Word-RAM with* $O(\log n)$ *bit words, detecting whether an* n*-node* k*-uniform hypergraph contains an* ℓ*-hyperclique requires* $n^{\ell-o(1)}$ *time.*

Using common techniques (see e.g. [39]), the (ℓ,k)-Hyperclique hypothesis actually implies the hardness of the following unbalanced version of (ℓ,k)-Hyperclique.

▶ **Fact 18.** *Assuming the* (ℓ,k)-Hyperclique *hypothesis, on a Word-RAM with* $O(\log n)$ *bit words, detecting whether a* k*-uniform* ℓ*-partite hypergraph with* $n^{a_1}, \ldots, n^{a_\ell}$ *vertices on each part for* $a_1, \ldots, a_\ell > 0$ *requires* $n^{a_1+\cdots+a_\ell-o(1)}$ *time.*

▶ **Hypothesis 19** (Max-k-SAT Hypothesis, [35]). *On a Word-RAM with* $O(\log n)$ *bit words, for any* $k \geq 3$, *given a* k*-CNF formula on* n *variables and* $\mathrm{poly}(n)$ *clauses, determining the maximum number of clauses that can be satisfied by a Boolean assignment of the variables requires* $2^{n-o(n)}$ *time.*

▶ **Hypothesis 20** (Strong Exponential Time Hypothesis (SETH), [28, 13, 14]). *On a Word-RAM with* $O(\log n)$ *bit words, for every* $\epsilon > 0$, *there exists* k *such that* k-SAT *on* n *variables cannot be solved in* $O(2^{(1-\epsilon)n})$ *time.*

▶ **Definition 21.** *The* Max-Witness *product* C *of two* $n \times n$ *Boolean matrices* A *and* B *is defined as*

$$C[i,j] = \max\{k \mid A[i,k] = B[k,j] = 1\}$$

where the maximum is defined to be $-\infty$ *if no such witness exists.*

The best running time to compute the Max-Witness product is $O(n^{2+\lambda})$ where λ satisfies the equation $\omega(1,\lambda,1) = 1 + 2\lambda$ [18]. This running time is $\tilde{O}(n^{2.5})$ if $\omega = 2$. It is used as a hypothesis that this running time cannot be improved much.

▶ **Hypothesis 22** (Max-Witness Hypothesis, [34]). *On a Word-RAM with* $O(\log n)$ *bit words, computing the* Max-Witness *product of two* $n \times n$ *matrices requires* $n^{2.5-o(1)}$ *time.*

3 Relationships among AP-Exact$k$-LCA, AP-AtMost$k$-LCA and AP-AtLeast$k$-LCA

In this section, we consider the relationships between AP-Exact$k$-LCA, AP-AtMost$k$-LCA and AP-AtLeast$k$-LCA. Our results are depicted in Figure 1 and are proven in the full version of the paper.

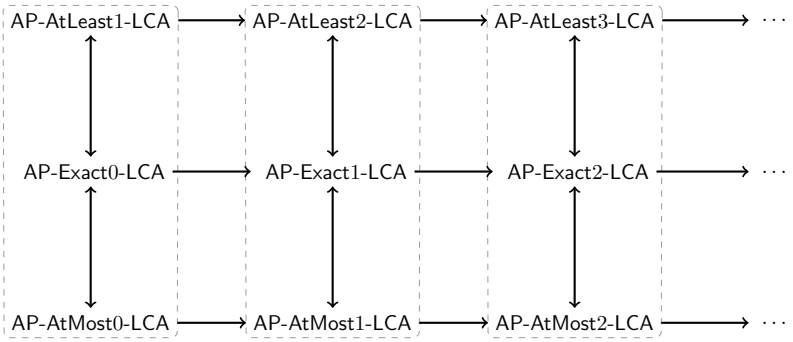

Figure 1 Reductions between AP-AtMost$k$-LCA, AP-Exact$k$-LCA and AP-AtLeast$k$-LCA. All arrows in this figure represent $O(n^2)$ time reductions from an instance to another instance with the same input sizes up to constant factors.

We first show the following lemma (whose proof is deferred to the full version) which then allows us to show that AP-Exact$(k+1)$-LCA (resp. AP-AtMost$(k+1)$-LCA, AP-AtLeast$(k+1)$-LCA) is harder than AP-Exact$k$-LCA (resp. AP-AtMost$k$-LCA, AP-AtLeast$k$-LCA) for $k \geq 0$.

▶ **Lemma 23.** *Given a DAG G with n vertices, we can create another DAG G' with $2n+1$ vertices and a map $\rho : V(G) \to V(G')$ in $O(n^2)$ time such that for every $u, v \in V(G)$, the number of LCAs of u and v in G is exactly one fewer than the number of LCAs of $\rho(u)$ and $\rho(v)$ in G'.*

▶ **Corollary 24.** *For any $k \geq 0$, an instance of* AP-Exact$k$-LCA *(resp.* AP-AtMost$k$-LCA, AP-AtLeast$k$-LCA*) with n vertices reduces to an instance of* AP-Exact$(k+1)$-LCA *(resp.* AP-AtMost$(k+1)$-LCA, AP-AtLeast$(k+1)$-LCA*) with $O(n)$ vertices in $O(n^2)$ time.*

Finally, we recall the relationship among AP-Exact$k$-LCA, AP-AtMost$k$-LCA and AP-AtLeast$k$-LCA.

▶ **Theorem 1.** *For any constant $k \geq 0$, the running times of* AP-Exact$k$-LCA, AP-AtMost$k$-LCA *and* AP-AtLeast$(k+1)$-LCA *are the same up to constant factors.*

4 Algorithms for AP-Exact$k$-LCA

As noted in the introduction, AP-Exact$k$-LCA can be solved in $O(n^3)$ time for any constant k. Interestingly, an algorithm by Kowaluk and Lingas [31] that finds and verifies the LCAs for vertex pairs with a unique LCA implies that AP-Exact1-LCA can be solved in $\tilde{O}(n^\omega)$ time deterministically. In this section, we present an alternative randomized algorithm for AP-Exact1-LCA, and also extend the algorithm for AP-Exact2-LCA.

The following claim is essential to our AP-Exact1-LCA algorithm. We defer its proof to the full version fo the paper.

▷ Claim 25. Given a DAG $G = (V, E)$, for every pair of vertices $u, v \in V$, we have that

$$\mathsf{Anc}(u) \cap \mathsf{Anc}(v) = \bigcup_{w \in \mathsf{LCA}(u,v)} \mathsf{Anc}(w). \tag{1}$$

Moreover, if $\mathsf{Anc}(u) \cap \mathsf{Anc}(v) = \bigcup_{w \in S} \mathsf{Anc}(w)$ for some $S \subseteq V$, it must be the case that $\mathsf{LCA}(u, v) \subseteq S$.

▶ **Theorem 26.** *There exists an $O(n^\omega)$ time Las Vegas algorithm for* AP-Exact1-LCA *that succeeds with high probability. Additionally, this algorithm can find the unique LCA for all pairs of vertices that have exactly* 1 *LCA.*

Proof. For every pair of vertices u and v with a unique LCA w, we rewrite Equation (1) as $\mathsf{Anc}(u) \cap \mathsf{Anc}(v) = \mathsf{Anc}(w)$. In fact, Claim 25 gives us that this holds if and only if w is a unique LCA of the pair u and v.

Let $f : V \to \mathbb{Z}_p$ be a random function for some $p = \Theta(n^{10})$. For every $S \subseteq V$, we will use $f(S)$ to denote $\sum_{x \in S} f(x)$. Then with high probability, for any $u, v, x \in V$,

$$\mathsf{Anc}(u) \cap \mathsf{Anc}(v) = \mathsf{Anc}(x) \quad \text{if and only if} \quad f(\mathsf{Anc}(u) \cap \mathsf{Anc}(v)) = f(\mathsf{Anc}(x)).$$

To see this, note that for $S, S' \subseteq V$, if $S \neq S'$, then $f(S) - f(S')$ is a sum of a nonzero number of independent uniform random variables from $\mathbb{Z}_p$. Thus if $S \neq S'$, then $\Pr[f(S) = f(S')] = \frac{1}{p}$. Since we are comparing $O(n^2)$ such sets of the form $f(\mathsf{Anc}(x))$ and $f(\mathsf{Anc}(u) \cap \mathsf{Anc}(v))$, by a union bound, the probability that two distinct sets collide is $O(n^4/p)$.

Therefore, it suffices to compute $f(\mathsf{Anc}(x))$ and $f(\mathsf{Anc}(u) \cap \mathsf{Anc}(v))$ for all $u, v, x \in V$. For each $x \in V(G)$, it is easy to compute $f(\mathsf{Anc}(x)) = \sum_{v \in \mathsf{Anc}(x)} f(v)$ in $O(n)$ time. To compute $F(u, v) = f(\mathsf{Anc}(u) \cap \mathsf{Anc}(v))$ for all $u, v \in V$, we construct the following matrices. Let A be the transitive closure of G and let $B[x, v] = f(x) \cdot A[x, v]$. Now, note that the (u, v)-th entry of $C = A^T B$ gives us $C[u, v] = \sum_{x \in \mathsf{Anc}(u) \cap \mathsf{Anc}(v)} f(x) = F(u, v)$, as desired. Therefore, we can compute all $F(u, v)$ in $O(n^\omega)$ time.

Now, we sort the list $L = \{f(v) \mid v \in V(G)\}$ in $\tilde{O}(n)$ time. For each $u, v \in V$, we can find an arbitrary $w_{u,v}$ such that $F(u, v) = f(w_{u,v})$ in $\tilde{O}(1)$ time. Assuming none of the $O(n^2)$ sets we are interested in collide, which happens with probability at least $1 - O(n^4/p) = 1 - O(1/n^6)$, we find such a $w_{u,v}$ if and only if it is the unique LCA of $u, v \in V$.

To make this algorithm Las Vegas, we first notice that if our algorithm does not report a $w_{u,v}$, then u and v does not have a unique LCA. For the vertex pairs that our algorithm does find a $w_{u,v}$, we run [31]'s verification algorithm (Theorem 2 in [31]) to verify if each $w_{u,v}$ is in fact the unique LCA of u, v in $O(n^\omega)$ time. If we find any errors, we can simply repeat the algorithm. ◀

Now we show how to extend our AP-Exact1-LCA algorithm to AP-Exact2-LCA.

▶ **Theorem 27.** *There exists an $O(n^\omega)$ time Las Vegas algorithm for* AP-Exact2-LCA *that succeeds with high probability. Additionally, this algorithm can find the two LCAs for all pairs of vertices with exactly 2 LCAs.*

Proof. For all pair of vertices u and v with exactly two LCAs, say a and b, we rewrite (1) as $\mathsf{Anc}(u) \cap \mathsf{Anc}(v) = \mathsf{Anc}(a) \cup \mathsf{Anc}(b)$. Moreover, for any u, v, a, b such that the above equation holds, it must be the case that either both a and b are the only LCAs of u and v, or exactly one of them is the unique LCA (and the other is a common ancestor). We can detect the latter case with high probability by performing the algorithm as described in Theorem 26.

Let $f : V(G) \to \mathbb{Z}_p$ be a random function for some $p = \Theta(n^{10})$. By the same argument as Theorem 26, with high probability, for any $u, v, a, b \in V$,

$$\mathsf{Anc}(u) \cap \mathsf{Anc}(v) = \mathsf{Anc}(a) \cup \mathsf{Anc}(b) \quad \text{if and only if} \quad f(\mathsf{Anc}(u) \cap \mathsf{Anc}(v)) = f(\mathsf{Anc}(a) \cup \mathsf{Anc}(b)).$$

Let $F(u, v) = f(\mathsf{Anc}(u) \cap \mathsf{Anc}(v))$ and $H(a, b) = f(\mathsf{Anc}(a) \cup \mathsf{Anc}(b))$. As we saw in Theorem 26, we can compute $F(u, v)$ in $O(n^\omega)$ time.

To compute $H(a, b)$, note that $\mathsf{Anc}(a) \cup \mathsf{Anc}(b) = \overline{\overline{\mathsf{Anc}(a)} \cap \overline{\mathsf{Anc}(b)}}$. First, we compute the transitive closure A of G in $O(n^\omega)$ time. Then, we construct an $n \times n$ matrix M by setting $M[x, a] = 1 - A[x, a]$. Now, construct another matrix N by setting $N[x, b] = f(x) \cdot M[x, b]$. Then, it is easy to see that

$$(M^T N)[a, b] = \sum_{x \in \overline{\mathsf{Anc}(a)} \cap \overline{\mathsf{Anc}(b)}} f(x) = f(\overline{\mathsf{Anc}(a)} \cap \overline{\mathsf{Anc}(b)}).$$

Therefore, one can compute

$$H(a, b) = f(\mathsf{Anc}(a) \cup \mathsf{Anc}(b)) = f(V) - f(\overline{\mathsf{Anc}(a)} \cap \overline{\mathsf{Anc}(b)}) = f(V) - (M^T N)[a, b]$$

for all $a, b \in V$ in $O(n^\omega)$ time.

Now, sort $L = \{H(a, b) \mid a, b \in V\}$. For each u, v which does not have a unique LCA, search for an arbitrary pair $a_{u,v}, b_{u,v}$ (if one exists) such that $F(u, v) = H(a_{u,v}, b_{u,v})$ in $\tilde{O}(1)$ time. With probability $1 - O(1/n^6)$, we find such a pair for each u, v if and only if $a_{u,v}$ and $b_{u,v}$ are the only two LCAs of u and v.

To make this algorithm Las Vegas, we first notice that if our algorithm does not report a pair $a_{u,v}, b_{u,v}$, then u and v does not have exactly two LCAs. For vertex pairs for which our algorithm does find two LCA candidates, we run [31]'s verification algorithm (it is described in a remark in [31]) to verify that $a_{u,v}$ and $b_{u,v}$ are the only two LCAs of u and v in $O(n^\omega)$ time. If we find any errors, we can simply repeat the algorithm from the beginning. ◀

Note that our technique for AP-Exact1-LCA and AP-Exact2-LCA does not extend to AP-Exact3-LCA because it would require us to list $f(\mathsf{Anc}(x) \cup \mathsf{Anc}(y) \cup \mathsf{Anc}(z))$ for all $x, y, z \in V$, which easily exceeds n^ω time. In fact, in Section 6, we show it is unlikely to obtain an $\tilde{O}(n^\omega)$ time algorithm for AP-Exact3-LCA by proving that any $O(n^{2.5-\epsilon})$ time algorithm for $\epsilon > 0$ for AP-Exact3-LCA would refute the $(4, 3)$-Hyperclique hypothesis. Thus, AP-Exact3-LCA is indeed (conditionally) harder than AP-Exact1-LCA and AP-Exact2-LCA.

5 AP-LCA Listing Algorithms

In this section, we consider the AP-List-k-LCA problem. First, we show that AP-AtLeast$k$-LCA and AP-List-k-LCA are *subcubically equivalent*, i.e. either both or neither have a truly subcubic time algorithm.

▶ **Theorem 28.** *Suppose* AP-AtLeast$k$-LCA *can be computed in $T(n)$ time for a constant k. Then,* AP-List-k-LCA *can be computed in $O(\sqrt{n^3 \cdot T(n)})$ time. In particular,* AP-AtLeast$k$-LCA *and* AP-List-k-LCA *are subcubically equivalent.*

Proof. Suppose we are given a DAG $G = (V, E)$. First compute a topological ordering π of the vertices in $O(n^2)$ time, and the transitive closure D in $O(n^\omega)$ time. Now, for every pair of vertices u and v, we inductively find their k topologically latest (with respect to π) LCAs.

Suppose we have found the set $S(u, v)$ of the topologically latest $\ell - 1$ LCAs for every pair of vertices u, v, for some $1 \leq \ell \leq k$ with respect to π. Now, partition the vertices into sets $V = V_1 \sqcup V_2 \sqcup \cdots \sqcup V_{n/L}$, where V_1 contains the first L vertices in the topological ordering, V_2 contains the next L and so on for a parameter L that we will set later.

Let $\mathsf{LCA}_{G[W]}(u,v)$ denote the set of LCAs of u and v in the subgraph induced by W (note the distinction between $\mathsf{LCA}_{G[W]}(u,v)$ and $\mathsf{LCA}(u,v) \cap W$). Consider the vertex set $U_i = V_i \sqcup V_{i+1} \sqcup \cdots \sqcup V_{n/L}$ and the induced subgraph $G_i = G[U_i]$. We will prove the following claim in the full version of the paper.

▷ Claim 29. For $u, v \in U_i$, it must be the case that $\mathsf{LCA}_{G_i}(u,v) = \mathsf{LCA}(u,v) \cap U_i$.

Now we describe our algorithm. For $i = n/L, n/L-1, \ldots, 1$, run AP-AtLeast$\ell$-LCA on each G_i. For each $(u,v) \in V \times V$, keep track of the largest index $i_{u,v}$ where AP-AtLeastℓ-LCA outputs 1, i.e. largest index such that $|\mathsf{LCA}_{G_i}(u,v)| \geq \ell$. By Claim 29, this must mean that $|\mathsf{LCA}(u,v) \cap U_{i_{u,v}}| \geq \ell$ whereas $|\mathsf{LCA}(u,v) \cap U_{i_{u,v}-1}| < \ell$. In other words, the ℓth LCA lies in $V_{i_{u,v}}$. By Corollary 24, we can compute AP-AtLeastℓ-LCA in time $O(T(n))$. Therefore, this step takes $O\left(\frac{n}{L} \cdot T(n)\right)$ time in total.

Next, for each $u, v \in V$, note that the topologically ℓth LCA must lie in the vertex partition $V_{i_{u,v}}$, if $i_{u,v}$ exists. Therefore, it suffices to find the latest vertex $x \in V_{i_{u,v}}$ such that $x \in \mathsf{Anc}(u) \cap \mathsf{Anc}(v)$ and no $y \in S(u,v)$ is a descendent of x. Such an x must in fact be the ℓth LCA. Note that these checks can be done in $O(1)$ time for each $x \in V_{i_{u,v}}$ using the transitive closure D. If there is no $i_{u,v}$ such that AP-AtLeastℓ-LCA outputs 1, then u and v have fewer than ℓ LCAs. This step takes $O(\ell \cdot L) = O(L)$ time for each pair $u, v \in V$.

Since we have to iteratively find up to k LCAs per vertex pair, the overall runtime of the algorithm is $O(n^\omega + k(\frac{n}{L} \cdot T(n) + n^2 \cdot L))$. Choosing $L = \sqrt{T(n)/n}$, we have a runtime of $O(\sqrt{n^3 \cdot T(n)})$.

Moreover, it is clear that if there is a subcubic algorithm for AP-List-k-LCA, we can use the same algorithm to solve AP-AtLeast$k$-LCA with an $\tilde{O}(n^2)$ additional cost. Therefore the two problems are in fact subcubically equivalent. ◀

In Theorem 26 and Theorem 27, we showed $O(n^\omega)$ time algorithms for AP-Exact1-LCA and AP-Exact2-LCA. By their equivalences with AP-AtLeast2-LCA and AP-AtLeast3-LCA respectively, we can also solve AP-AtLeast2-LCA and AP-AtLeast3-LCA in $O(n^\omega)$ time. By Theorem 28, these imply $O(n^{(\omega+3)/2})$ time algorithms for AP-List-2-LCA and AP-List-3-LCA.

In the following theorem, we show that we can further improve the $O(n^{(3+\omega)/2})$ running time for AP-List-2-LCA and AP-List-3-LCA to $\tilde{O}(n^{2+\lambda})$ time where $\omega(1,\lambda,1) = 1 + 2\lambda$. Interestingly this running time matches the current best running time of the Max-Witness problem [18]. For these algorithms, we use an idea from [31] about comparing the sizes of two sets for verifying whether a set of one or two vertices are all the LCAs.

▶ **Theorem 3.** *For $k = 2$ and $k = 3$, the* AP-List-k-LCA *problem can be deterministically solved in $\tilde{O}(n^{2+\lambda})$ time, where λ satisfies the equation $\omega(1,\lambda,1) = 1 + 2\lambda$. Here, $\omega(1,\lambda,1)$ is the exponent of multiplying an $n \times n^\lambda$ by an $n^\lambda \times n$ matrix.*

We defer the proof of Theorem 3 to the full version of the paper.

6 Lower Bounds

In this section, we show our conditional lower bounds for AP-Exact$k$-LCA and AP-#LCA. These lower bounds are the first conditional lower bounds for LCA problems that are higher than $n^{\omega - o(1)}$.

6.1 Lower Bounds for AP-Exact$k$-LCA

First, we show lower bounds for the AP-Exact$k$-LCA problem by reducing from 3-uniform hypercliques. Combined with Corollary 24, the following theorem also shows that, for all constant $k \geq 6$, AP-Exact$k$-LCA requires $n^{3-o(1)}$ time.

▶ **Theorem 30.** *Assuming the* $(4,3)$-Hyperclique *hypothesis,* AP-Exact3-LCA *requires* $n^{2.5-o(1)}$ *time. Assuming the* $(5,3)$-Hyperclique *hypothesis,* AP-Exact4-LCA *and* AP-Exact6-LCA *require* $n^{8/3-o(1)}$ *and* $n^{3-o(1)}$ *time respectively. Also, assuming the* $(6,3)$-Hyperclique *hypothesis,* AP-Exact5-LCA *requires* $n^{14/5-o(1)}$ *time.*

Proof. All four reductions share the same underlying ideas. Thus, we only give full details for the first reduction. The remaining reductions are deferred to the full version of the paper.

$(4,3)$-Hyperclique $\rightarrow$ AP-Exact**3**-LCA. Suppose we are given a 3-uniform 4-partite hypergraph G on vertex sets A, B, C, U, where $|A| = |B| = |C| = \sqrt{n}$, and $|U| = n$. By Fact 18, the $(4,3)$-Hyperclique hypothesis implies that it requires $(|A||B||C||U|)^{1-o(1)} = n^{2.5-o(1)}$ time to determine whether G contains a 4-hyperclique.

We construct the following instance of AP-Exact3-LCA as depicted in Figure 2. The graph G' contains 3 layers of vertices V_1, V_2, V_3. Vertex set V_1 is a copy of U, vertex set V_2 equals $(A \times B) \sqcup (B \times C) \sqcup (C \times A)$ and vertex set V_3 equals $(A \times B) \sqcup C$. To distinguish vertices from V_2 and V_3, we use subscript 2 and 3, e.g. $(a,b)_2$ and $(a,b)_3$, to denote vertices from V_2 and V_3 respectively.

We also add the following edges to the graph G':

- Add a directed edge from every vertex in V_1 to every vertex in V_3.
- Add a directed edge from any vertex in V_2 to any vertex in V_3 as long as they do not have *inconsistent* labels. For instance, for every $a \in A, b \in B, c \in C$, we add an edge from $(a,b)_2$ to $(a,b)_3$ and to c_3, but we do not add an edge from $(a,b)_2$ to $(a,b')_3$ if $b \neq b'$.
- For every $u \in V_1$ and every $(x,y)_2 \in V_2$, add a directed edge from u to (x,y) if and only if there is *not* a 3-hyperedge among u, x and y.

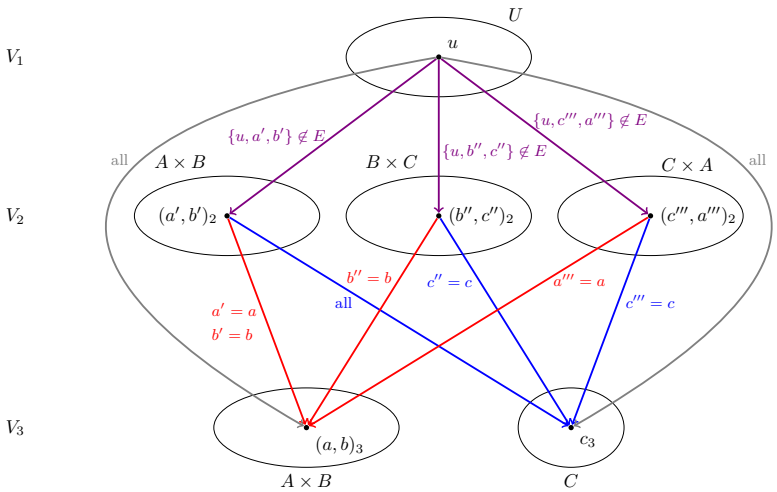

Figure 2 Construction of G' in Theorem 30 from the 3-uniform 4-hyperclique instance. Between the parts where we mark "all", we add all possible edges. Between the parts where we mark a condition, we only add an edge when the corresponding condition holds.

We consider the set of LCAs for every pair of $(a,b)_3, c_3 \in V_3$.

First, since G' is a three layered graph, all common ancestors of $(a,b)_3$ and c_3 in V_2 are their LCAs. Since we only add edges from V_2 to V_3 when the labels are consistent, it is easy to verify that the set of LCAs in V_2 is $\{(a,b)_2, (b,c)_2, (c,a)_2\}$.

Now we claim that a,b,c are in a 4-hyperclique in G if and only if $(a,b)_3$ and c_3 have an LCA in V_1 and there is a 3-hyperedge among a,b,c in G.

Suppose a,b,c are in a 4-hyperclique with a vertex $u \in V(G)$. Since G is 4-partite, we must have $u \in U$. The copy of u in G' is clearly a common ancestor of $(a,b)_3$ and c_3, since we add all possible edges from V_1 to V_3. Because a,b,c,u is in a 4-hyperclique, $\{a,b,u\}, \{b,c,u\}, \{c,a,u\} \in E(G)$. Therefore, in G' we do not add edges from u to any of $(a,b)_2, (b,c)_2$ and $(c,a)_2$. Since these are the only common ancestors of $(a,b)_3$ and c_3 in V_2, u in fact cannot reach any other vertex that can reach both $(a,b)_3$ and c_3, which makes u an LCA. Clearly, there is a 3-hyperedge among a,b,c in G.

To prove the converse, suppose $u \in V_1$ is an LCA of $(a,b)_3$ and c_3 and there is a 3-hyperedge among a,b,c in G. In that case, u cannot reach any vertex that can reach both $(a,b)_3$ and c_3. In particular, u cannot reach any of $(a,b)_2, (b,c)_2, (c,a)_2$. When we add edges from V_1 to V_2, we have that $\{a,b,u\}, \{b,c,u\}, \{c,a,u\}$ are all 3-hyperedges in G. Also, since $\{a,b,c\}$ is a 3-hyperedge, there is indeed a 4-hyperclique with vertices a,b,c,u.

Thus, a,b,c are in a 4-hyperclique in G if and only if the number of LCAs of $(a,b)_3$ and c_3 is not 3 and there is a 3-hyperedge among a,b,c in G. Thus, given the result of an AP-Exact3-LCA computation of G', we can easily determine if G has a 4-hyperclique. Therefore, assuming the $(4,3)$-Hyperclique hypothesis, AP-Exact3-LCA requires $n^{2.5-o(1)}$ time. ◀

▶ Remark 31. Note that in all our reductions to AP-Exact$k$-LCA for $3 \leq k \leq 5$, we only need to output the results for $o(n^2)$ pairs of u and v. For instance, in the reduction from $(4,3)$-Hyperclique to AP-Exact3-LCA, we only need to output whether (u,v) has exactly 3 LCAs for $u \in A \times B$ and $v \in C$. The total number of such pairs is only $O(n^{1.5})$. This is the main reason why we do not get $n^{3-o(1)}$ conditional lower bounds for AP-Exact$k$-LCA for $3 \leq k \leq 5$. On the other hand, in the reduction to AP-Exact6-LCA, we do have $\Theta(n^2)$ queries.

Williams [41] showed that Max-3-SAT reduces to 3-uniform hypercliques. Lincoln, Vassilevska Williams and Williams [35] further generalized this reduction to a reduction from Constraint Satisfaction Problem (CSP) on degree-3 formulas to 3-uniform hypercliques. Therefore, Theorem 30 also works assuming the Max-3-SAT hypothesis or the hardness of maximizing the number of satisfying clauses in degree-3 CSP formulas.

▶ **Corollary 32.** *Assuming* Max-3-SAT *(or even max degree* 3 *CSP formulas) on* N *variables and* $\text{poly}(n)$ *clauses requires* $2^{N-o(N)}$ *time,* AP-Exact3-LCA*,* AP-Exact4-LCA*,* AP-Exact5-LCA *and* AP-Exact6-LCA *requires* $n^{2.5-o(1)}$*,* $n^{8/3-o(1)}$*,* $n^{14/5-o(1)}$ *and* $n^{3-o(1)}$ *time respectively.*

6.2 Lower Bounds for Counting LCAs

In this section, we show two conditional lower bounds for AP-#LCA, one based on SETH and one based on the 4-Clique hypothesis.

The next lemma is a crucial tool for the SETH lower bound. It is a generalization of our previous reduction from $(5,3)$-Hyperclique to AP-Exact6-LCA.

▶ **Lemma 33.** *If there exists a* $T(N)$ *time algorithm for* AP-Exact$\binom{2(k-1)}{k-1}$-LCA *for graphs with* N *vertices, then there exists an* $O(f(k)\,\text{poly}(n)^{f(k)}T(2^{n/3}))$ *time algorithm for* Max-k-SAT *with* n *variables and* $\text{poly}(n)$ *clauses for some function* f*.*

To prove the lemma, we first reduce Max-k-SAT to k-uniform $(2k-1)$-hyperclique, which is a straightforward generalization of Williams' Max-2-SAT algorithm [41]. Then we reduce k-uniform $(2k-1)$-hyperclique to AP-Exact$\binom{2(k-1)}{k-1}$-LCA, building on ideas similar to the proof of Theorem 30. The full proof can be found in the full version of the paper.

▶ Remark 34. Lemma 33 implies that if we assume the Max-k-SAT hypothesis, then AP-Exact$\binom{2(k-1)}{k-1}$-LCA requires $n^{3-o(1)}$ time. Since our reduction uses $(2k-1,k)$-Hyperclique as an intermediate problem, the same lower bound also holds assuming the $(2k-1,k)$-Hyperclique hypothesis.

Now we show our SETH lower bound using Lemma 33.

▶ **Theorem 4.** *Assuming SETH,* AP-#LCA *requires $n^{3-o(1)}$ time, even if we only need to return the minimum between the count and $g(n)$ for any $g(n)=\omega(1)$.*

Proof. For the sake of contradiction, assume AP-#LCA has an $O(n^{3-\epsilon})$ time algorithm for $\epsilon>0$ when the algorithm only needs to return the minimum between the count and $g(n)$. For any fixed k, when n is large enough, we have $\binom{2(k-1)}{k-1}<g(n)$, so we can solve AP-Exact$\binom{2(k-1)}{k-1}$-LCA in $O(n^{3-\epsilon})$ time. Thus, by Lemma 33, we can solve Max-k-SAT (and thus k-SAT) with n variables and $\mathrm{poly}(n)$ clauses in time

$$O(f(k)\,\mathrm{poly}(n)^{f(k)}(2^{n/3})^{3-\epsilon})=O(f(k)\,\mathrm{poly}(n)^{f(k)}2^{(1-\epsilon/3)n})=O(\mathrm{poly}(n)\cdot 2^{(1-\epsilon/3)n}),$$

which would refute SETH. ◀

Finally, we present our reduction from 4-Clique to AP-#LCA, showing an $n^{\omega(1,2,1)-o(1)}$ lower bound for AP-#LCA assuming the current algorithm for 4-Clique is optimal.

▶ **Theorem 5.** *If the* AP-#LCA *problem can be solved in $T(n)$ time, then* 4-Clique *can be computed in $O(T(n)+n^{\omega})$ time.*

Proof. Suppose we are given a 4-Clique instance $G=(V,E)$. Without loss of generality, we assume G is a 4-partite graph with four vertex parts $V=A\sqcup B\sqcup C\sqcup D$ of size n each.

First, make a copy $G'=(V',E')$ of G, and modify the edge set of G' as follows:

- Remove all edges between A and B.
- Direct all edges from D to A and B.
- Direct all edges from C to A,B and D.

Then we add two additional vertex sets A' and B' to G', where A' is a copy of A and B' is a copy of B. We use a' to denote the copy of $a\in A$ in A' and use b' to denote the copy of $b\in B$ in B'. We also add the following edges:

- For every $a\in A$, add an edge (a',a).
- For every $b\in B$, add an edge (b',b).
- For every $a\in A,b\in B$, add two edges (a',b) and (b',a).
- For every $a\in A,c\in C$, add an edge (c,a') if $\{c,a\}\notin E$.
- For every $b\in B,c\in C$, add an edge (c,b') if $\{c,b\}\notin E$.

This construction of the graph is also depicted in Figure 3. From there, it is clear that G' is a 3-layered graph.

▷ Claim 35. For every $a\in A,b\in B,c\in C$, c is an LCA of a and b in G' if and only if $\{c,a\},\{c,b\}\in E$ and there doesn't exist any $d\in D$ such that $\{c,d\},\{d,a\},\{d,b\}\in E$.

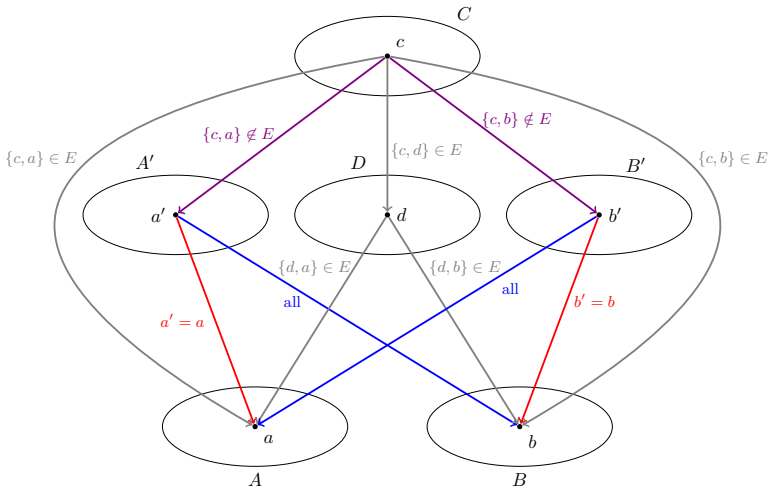

Figure 3 Construction of G' in Theorem 5 given a 4-partite 4-Clique instance. Between parts where we mark "all", we add all possible edges. Between parts where we mark a condition, we only add an edge when the corresponding condition holds.

Proof. First, suppose c is an LCA of a and b. For the sake of contradiction, suppose $\{c, a\} \notin E$. Then by the construction of G', $(c, a') \in E'$. Also, $(a', a), (a', b) \in E'$, so c cannot be an LCA. This leads to a contradiction, so we must have $\{c, a\} \in E$. Similarly, we must have $\{c, b\} \in E$. Finally, suppose for the sake of contradiction that there exists a $d \in D$ such that $\{c, d\}, \{d, a\}, \{d, b\} \in E$, then by construction, $(c, d), (d, a), (d, b) \in E'$, so c cannot be an LCA. Thus, there doesn't exist any $d \in D$ such that $\{c, d\}, \{d, a\}, \{d, b\} \in E$.

Now we prove the converse direction. Suppose $\{c, a\}, \{c, b\} \in E$ and there doesn't exist any $d \in D$ such that $\{c, d\}, \{d, a\}, \{d, b\} \in E$. By our construction, $(c, a), (c, b) \in E'$, so c is at least a common ancestor of a and b. Since G' is a 3-layered graph, it suffices to show that there isn't any vertex u in the middle layer such that $(c, u), (u, a), (u, b) \in E'$. First, for any $u \in A'$, if $u \neq a'$, then $(u, a) \notin E'$; if $u = a'$, then $(c, u) \notin E'$ because $\{c, a\} \in E$. Therefore, there isn't any $u \in A'$ such that $(c, u), (u, a), (u, b) \in E'$. Similarly, there isn't any $u \in B'$ such that $(c, u), (u, a), (u, b) \in E'$. For any $d \in D$, we already have the condition that at least one of $\{c, d\}, \{d, a\}, \{d, b\}$ is not in E, so at least one of $(c, d), (d, a), (d, b)$ is not in E'. Therefore, c is an LCA. ◁

Using this claim, we describe our algorithm below.

First, run AP-#LCA to compute $|\mathsf{LCA}(a, b)|$ for all $(a, b) \in A \times B$. Since G' is a three-layered graph, the set of LCAs of a and b in the middle layer is exactly the set of their common neighbors in the middle layer. Therefore, we can easily compute $|\mathsf{LCA}(a, b) \cap (A' \cup B' \cup D)|$ in $O(n^\omega)$ time by using matrix multiplication to count the number of their common neighbors in the middle layer. Also, clearly, there isn't any LCA of a and b in A or B. Thus, we can compute the number of $c \in C$ that is an LCA of a and b by

$$|\mathsf{LCA}(a, b) \cap C| = |\mathsf{LCA}(a, b)| - |\mathsf{LCA}(a, b) \cap (A' \cup B' \cup D)|.$$

By Claim 35, $|\mathsf{LCA}(a, b) \cap C|$ is exactly the number of $c \in C$ such that $\{c, a\}, \{c, b\} \in E$ and there doesn't exist any $d \in D$ such that $\{c, d\}, \{d, a\}, \{d, b\} \in E$.

Next, in $O(n^\omega)$ we can use matrix multiplication again to compute $Q(a, b)$ for every (a, b) where $Q(a, b)$ is defined as the number of $c \in C$ such that $\{c, a\}, \{c, b\} \in E$.

Note that $Q(a,b) - |\mathsf{LCA}(a,b) \cap C|$ is exactly the number of $c \in C$ such that $\{c,a\}, \{c,b\} \in E$ and there *exists* $d \in D$ such that $\{c,d\}, \{d,a\}, \{d,b\} \in E$. Thus, a and b are in a 4-clique if and only if $\{a,b\} \in E$ and $Q(a,b) - |\mathsf{LCA}(a,b) \cap C| > 0$.

Overall, if we can compute AP-#LCA in $T(n)$ time, then we can solve the 4-partite 4-Clique instance in $O(T(n) + n^\omega)$ time. ◀

Since AP-#LCA is easier than AP-All-LCA, this lower bound shows that the AP-All-LCA algorithm in [20] is in fact conditionally optimal.

7 AP-Ver-LCA

In this section, we show two conditional lower bounds for AP-Ver-LCA, based on the Max-Witness hypothesis and the $(4,3)$-Hyperclique hypothesis. First, recall the following theorem:

▶ **Theorem 6.** *If the* AP-Ver-LCA *problem can be solved in $T(n)$ time, then the* Max-Witness *problem can be solved in $\tilde{O}(T(n))$ time.*

At the high level, we reduce the MaxWitness problem to $O(\log n)$ calls of the AP-Ver-LCA problem using a parallel binary search technique.

Proof. Without loss of generality, suppose $n = 2^\ell$ for some integer ℓ. Suppose we have two $n \times n$ Boolean matrices A and B, each already padded with a column and row of ones to ensure that there always exists a Boolean witness. Now, we will describe an algorithm to compute $C = \mathsf{Max\text{-}Witness}(A,B)$ using an AP-Ver-LCA algorithm $\ell = \log n$ times. At the high level, we will be using a parallel binary search to find the maximum witness corresponding to each entry of C.

Construct a tripartite graph G on vertices $V = I \sqcup J \sqcup K$, where $|I| = |J| = |K|$ and identify each of the sets with $[n]$. Add a directed edge from $k \in K$ to $i \in I$ if $A[i,k] = 1$ and an edge from $k \in K$ to $j \in J$ if $B[k,j] = 1$. Then, computing $C[i,j]$ is the same as determining the largest $k \in K$ that is a common ancestor of both $i \in I$ and $j \in J$. Now, we will iteratively find the tth bit in the binary representation of each $C[i,j]$ for $t = 1, \ldots, \ell$ (the first bit is the highest order bit, and the last bit is the lowest order bit). In the first iteration, we do the following.

Phase 1: Construct a graph G_1 by first making a copy of G and adding a vertex w. Then, we add a directed edge from w to every vertex in $I \cup J$. Now, add a directed edge from w to all vertices $k \in K$ whose binary representation starts with 1. Finally, run AP-Ver-LCA where we guess w is an LCA for all pairs $(i,j) \in I \times J$. If w is in fact an LCA, set $c_{i,j}^{(1)} = 0$, and otherwise, set $c_{i,j}^{(1)} = 1$.

More generally, at the tth iteration of the algorithm, we do the following.

Phase t: At the tth iteration of the algorithm for $1 \le t \le \ell$, construct the graph G_t as follows. First, make a copy of G. Then, for each string $b = b_1 b_2 \ldots b_{t-1} \in \{0,1\}^{t-1}$, create a vertex w_b. Now, add an edge from w_b to all vertices in K whose binary representation starts with $b_1 b_2 \ldots b_{t-1} || 1$. Then, add an edge from every w_b to every vertex in $I \cup J$. If $c_{i,j}^{(t-1)} = b$, guess that w_b is an LCA for $(i,j) \in I \times J$. Run AP-Ver-LCA with all of these guesses. If the algorithm outputs YES for (i,j), set $c_{i,j}^{(t)} = b||0$. Otherwise, set $c_{i,j}^{(t)} = b||1$.

We show by induction that at Phase t, $c_{i,j}^{(t)}$ is the first t bits of $C[i,j]$. In Phase 1, note that w is an LCA for $(i,j) \in I \times J$ exactly when none of its children are common ancestors of (i,j). In other words, (i,j) has no common ancestor (and hence no witness) $k \in K$ whose first bit is 1.

Suppose at iteration $t-1$, this claim is true. In other words, for each i, j, $d_{i,j} = c_{i,j}^{(t-1)}$ corresponds to the first $t-1$ bits of $C[i,j]$. Then, at iteration t, we guessed that $w_{d_{i,j}}$ is an ancestor. Since $w_{d_{i,j}}$ only has children whose first t bits are $d_{i,j}||1$, it is an LCA of (i,j) exactly when none of these children are common ancestors, i.e. the largest common ancestor of (i,j) has binary representation starting with $d_{i,j}||0$. Otherwise, it starts with $d_{i,j}||1$, as desired.

Therefore, after ℓ iterations, we have that $C[i,j] = c_{i,j}^{(\ell)}$ (where we interpret $c_{i,j}$ as an ℓ-bit binary integer). The algorithm does $O(n^2)$ work at each phase to construct G_t, and then invokes an AP-Ver-LCA algorithm. Hence the overall runtime is $\tilde{O}(n^2 + T(n)) = \tilde{O}(T(n))$, as desired. ◀

▶ **Theorem 7.** *Assuming the* $(4,3)$-Hyperclique *hypothesis,* Ver-LCA *requires* $n^{2.5-o(1)}$ *time.*

Proof. Suppose we are given a 3-uniform 4-partite hypergraph G on vertex sets A, B, C, U, where $|A| = |B| = |C| = \sqrt{n}$, and $|U| = n$. The $(4,3)$-Hyperclique hypothesis implies that it requires $n^{2.5-o(1)}$ time to determine whether G contains a 4-hyperclique by Fact 18.

We construct the following Ver-LCA instance G' on $O(n)$ vertices.

The graph G' contains 3 layers of vertices V_1, V_2, V_3 with an additional vertex s. We set V_1 to be $A \times B$, set V_2 to be a copy of U and set V_3 to be $(B \times C) \sqcup (C \times A)$.

We also add the following edges to the graph G'.

- Add a directed edge from every $v_1 \in V_1$ to every $v_3 \in V_3$.
- Add a directed edge from $(a,b) \in V_1$ to $u \in V_2$ if and only if $\{u,a,b\} \in E(G)$.
- Add a directed edge from $u \in V_2$ to $(b,c) \in V_3$ if and only if $\{u,b,c\} \in E(G)$. Similarly, add a directed edge from $u \in V_2$ to $(c,a) \in V_3$ if and only if $\{u,c,a\} \in E(G)$.
- Add a directed edge from s to every other vertex in G'. This ensures that every pair of vertices has some common ancestors, and thus has at least one LCA.

We claim that for every $a \in A, b \in B, c \in C$, a, b, c are in a 4-hyperclique in G if and only if $\{a,b,c\} \in E(G)$ and (a,b) is *not* an LCA of (b,c) and (c,a) in G.

First, if a, b, c are in a 4-hyperclique with u, then clearly $\{a,b,c\} \in E(G)$. Also, by the construction of G', $((a,b),u), (u,(b,c)), (u,(c,a))$ are all edges in G'. Thus, (a,b) can reach a vertex u which can reach both (b,c) and (c,a), so (a,b) is not an LCA of (b,c) and (c,a).

Conversely, if $\{a,b,c\} \in E(G)$ and (a,b) is *not* an LCA of (b,c) and (c,a), then since (a,b) can reach both (b,c) and (c,a) via edges added from V_1 to V_3, (a,b) must be able to reach some vertex that can reach both (b,c) and (c,a). Such a vertex must belong to V_2. Say the vertex is u, then by the construction of G', we must have $\{a,b,u\}, \{b,c,u\}, \{c,a,u\} \in E(G)$. Together with the hyperedge $\{a,b,c\}$, a, b, c is in a 4-hyperclique.

Therefore, we can run Ver-LCA on G' with the following set of LCA candidates:

- For every $a \in A, b \in B, c \in C$ such that $\{a,b,c\} \in E(G)$, let $w_{(b,c),(c,a)} = (a,b)$.
- For every other pair of vertices $u, v \in V(G')$, we use Grandoni et al.'s algorithm [25] to find an actual LCA $\ell_{u,v}$ for them in $O(n^{2.447})$ time and set $w_{u,v} = \ell_{u,v}$.

If some LCA candidate is incorrect, it must be that (a,b) is not an LCA for (b,c) and (c,a) for some $a \in A, b \in B, c \in C$ such that $\{a,b,c\} \in E(G)$ and thus by previous discussion, the hypergraph G has a 4-hyperclique. On the other hand, if all LCA candidates are correct, then the hypergraph G does not have a 4-hyperclique.

Therefore, assuming the $(4,3)$-Hyperclique hypothesis, Ver-LCA requires $n^{2.5-o(1)}$ time. ◀

Our conditional lower bounds for AP-Ver-LCA and Ver-LCA are surprising because they suggest that AP-Ver-LCA and Ver-LCA require $n^{2.5-o(1)}$ time, while AP-LCA can be computed in $O(n^{2.447})$ time [25]. This defies the common intuition that verification should be easier than computation.

8 Open problems

We conclude this work by pointing out some potential future directions.

1. Does there exist a subcubic time algorithm for AP-Exact$k$-LCA for any $3 \leq k \leq 5$? Or, can we show an $n^{3-o(1)}$ conditional lower bound for AP-Exact$k$-LCA for any such k? How about AP-Ver-LCA?
2. Is it possible to show conditional lower bounds for AP-List-k-LCA without using AP-AtLeast$k$-LCA as an intermediate problem? For instance, since AP-AtLeast$k$-LCA has $O(n^\omega)$ time algorithms for $k \leq 3$, we cannot hope to get a higher than n^ω lower bound for AP-List-k-LCA for $k \leq 3$ using AP-AtLeast$k$-LCA as an intermediate problem. However, the current best algorithm for AP-List-1-LCA runs in $O(n^{2.447})$ and the best algorithm for AP-List-2-LCA and AP-List-3-LCA runs in $O(n^{2.529})$ time.
3. All our reductions reduce to instances of LCA variants in graphs with $O(1)$ layers. In such graphs, some variants could have faster algorithms. In particular, AP-LCA has an $\tilde{O}(n^\omega)$ time algorithm [18] for graphs with $O(1)$ layers, and thus we cannot hope to show a higher conditional lower bound using our techniques. In order to overcome this, we need to find reductions that show hardness for LCA variants in graphs with many layers.
4. Are there any other related problems whose verification version is easier than the computation version? Can we reduce these problems to or from AP-LCA?

A PTAS for Capacitated Vehicle Routing on Trees

Claire Mathieu
CNRS Paris, France

Hang Zhou
École Polytechnique, Institut Polytechnique de Paris, France

Abstract

We give a polynomial time approximation scheme (PTAS) for the unit demand capacitated vehicle routing problem (CVRP) on trees, for the entire range of the tour capacity. The result extends to the splittable CVRP.

2012 ACM Subject Classification Theory of computation → Routing and network design problems

1 Introduction

Given an edge-weighted graph with a vertex called *depot*, a subset of vertices with demands, called *terminals*, and an integer *tour capacity* k, the *capacitated vehicle routing problem (CVRP)* asks for a minimum length collection of tours starting and ending at the depot such that those tours together cover all the demand and the total demand covered by each tour is at most k. In the *unit demand* version, each terminal has unit demand, which is covered by a single tour;[1] in the *splittable* version, each terminal has a positive integer demand and the demand at a terminal may be covered by multiple tours.

The CVRP was introduced by Dantzig and Ramser in 1959 [15] and is arguably one of the most important problems in Operations Research. Books have been dedicated to vehicle routing problems, e.g., [26, 18, 14, 3]. Yet, these problems remain challenging, both from a practical and a theoretical perspective.

Here we focus on the special case when the underlying metric is a tree. That case has been the object of much research. The splittable tree CVRP was proved NP-hard in 1991 [24], so researchers turned to approximation algorithms. Hamaguchi and Katoh [21] gave a simple lower bound: every edge must be traversed by enough tours to cover all terminals whose shortest paths to the depot contain that edge. Based on this lower bound, they designed a 1.5-approximation in polynomial time [21]. The approximation ratio was improved to $(\sqrt{41}-1)/4$ by Asano, Katoh, and Kawashima [4] and further to 4/3 by Becker [6], both results again based on the lower bound from [21]. On the other hand, it was shown in [4] that using this lower bound one cannot achieve an approximation ratio better than 4/3. More recently, researchers tried to go beyond a constant factor so as to get a $(1+\epsilon)$-approximation, at the cost of relaxing some of the constraints. When the tour capacity is allowed to be

[1] Thus we may identify the demand coverd with the number of terminals covered.

violated by an ϵ fraction, there is a bicriteria PTAS for the unit demand tree CVRP due to Becker and Paul [10]. When the running time is allowed to be quasi-polynomial, Jayaprakash and Salavatipour [22] very recently gave a *quasi-polynomial time approximation scheme (QPTAS)* for the unit demand and the splittable versions of the tree CVRP. In this paper, we close this line of research by obtaining a $(1+\epsilon)$-approximation without relaxing any of the constraints – in other words, a *polynomial-time approximation scheme (PTAS)*.

▶ **Theorem 1.** *There is an approximation scheme for the unit demand capacitated vehicle routing problem (CVRP) on trees with polynomial running time.*

▶ **Corollary 2.** *There is an approximation scheme for the splittable capacitated vehicle routing problem (CVRP) on trees with running time polynomial in the number of vertices n and the tour capacity k.*

To the best of our knowledge, this is the first PTAS for the CVRP in a non-trivial metric and for the entire range of the tour capacity. Previously, PTASs for small capacity as well as QPTASs were given for the CVRP in several metrics, see Section 1.1.3.

1.1 Related Work

Our algorithms build on [22] and [10] but with the addition of significant new ideas, as we now explain.

1.1.1 Comparison with the QPTAS in [22]

Jayaprakash and Salavatipour noted in [22] that

"*it is not clear if it (the QPTAS) can be turned into a PTAS without significant new ideas.*"

The running time in [22] is $n^{O_\epsilon(\log^4 n)}$. Where do those four $\log n$ factors in the exponent come from? At a high level, the QPTAS in [22] consists of three parts: (1) reducing the height of the tree; (2) designing a bicriteria QPTAS; (3) going from the bicriteria QPTAS to a true QPTAS. Our approach builds on [22] but differs from it in each of the three parts, so that in the end we get rid of all of four $\log n$ factors, hence a PTAS.

(1) Jayaprakash and Salavatipour [22] reduce the input tree height from $O(n)$ to $O_\epsilon(\log^2 n)$; whereas instead of the input tree, we consider a *tree of components* (Lemma 9) and reduce its height to $O_\epsilon(1)$, see Figure 1. Pleasingly, the height reduction (Section 4) is much simpler than in [22]. The analysis differs from [22] and uses the structure of a near-optimal solution established in Section 3 and the *bounded distance* property (Definition 3 and Theorem 5).

(2) In the *adaptive rounding* used in [22], they consider the entire range $[1, k]$ of the demands of subtours and partition the subtour demands into *buckets*, resulting in $\Omega_\epsilon(\log k)$ different subtour demands after rounding. In our approach, we define *large* and *small* subtours inside components, depending on whether their demands are $\Omega_\epsilon(k)$ (Definition 14). Then we transform the solution structure to eliminate small subtours (Section 3), hence only $O_\epsilon(1)$ different subtour demands after rounding. This elimination requires a delicate handling of small subtours. Thanks to the additional structure, our analysis of the adaptive rounding is simpler than in [22], and in particular, we do not need the concept of buckets.

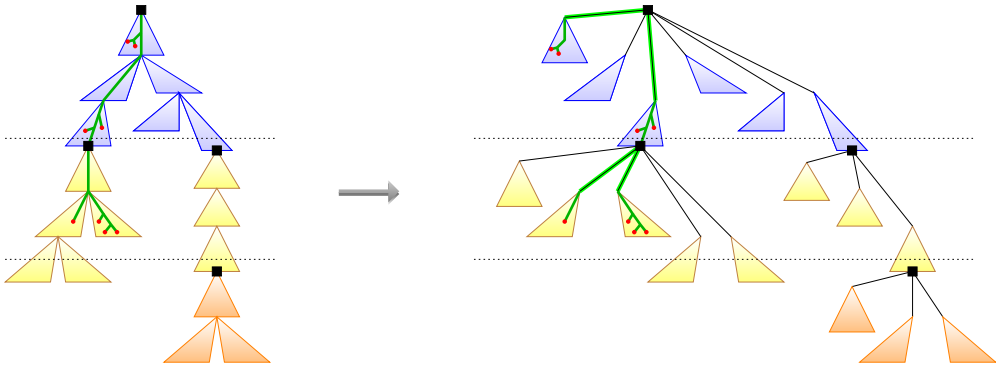

Figure 1 Height reduction for a tree of components. The left figure represents the initial tree of components, where each triangle represents a component. We partition the components into classes (indicated by blue, yellow, and orange), according to the distances from the roots of the components to the root of the tree, and we reduce the height within each class to 1 (right figure), see Section 4. The thick green path in the left figure represents a tour in an optimal solution. The red circular nodes are the terminals visited by that tour. The corresponding tour in the new tree (right figure) spans the same set of terminals.

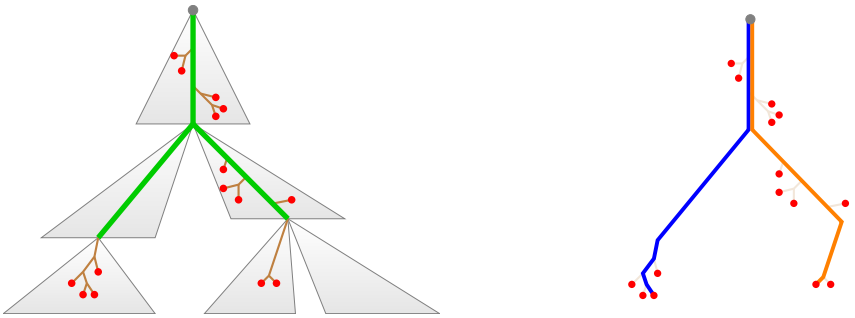
(3) Jayaprakash and Salavatipour show that the *orphan tokens*, which are removed from the tours exceeding capacity, can probably be covered by duplicating a small random set of tours in the optimal solution. Their approach requires remembering the demands of $\Omega(\log n)$ subtours passing through each edge. To avoid this $\Omega(\log n)$ factor, our approach to cover the orphan tokens (Section 3.1) is different, see Figure 2. The analysis of our approach (Sections 3.2 and 3.3) contains several novelties of this paper.

1.1.2 Comparison with the Bicriteria PTAS in [10]

Why is the algorithm in [10] a bicriteria PTAS, but not a PTAS?

Becker and Paul [10] start by decomposing the tree into *clusters*. (1) They require that each *leaf* cluster is visited by a single tour. When the violation of the tour capacity is not allowed, this requirement does not preserve a $(1+\epsilon)$-approximate solution. (2) They also require that each *small* internal cluster is visited by a single tour. To that end, they modify the optimal solution by reassigning all terminals of a small cluster to some existing tour at the cost of possibly violating the tour capacity. Such modifications do not seem achievable in the design of a PTAS.

In this paper, we start by defining *components* (Lemma 9), inspired by *clusters* in [10]. Unlike [10], we allow terminals in any component to be visited by multiple tours. However, allowing many subtours inside a component could result in an exponential running time for a dynamic program. To prevent that, we modify the solution structure inside a component so that the number of subtours becomes bounded (Theorem 13). Instead of considering all subtours simultaneously as in [10], we distinguish *small* subtours from *large* subtours (Definition 14). Inspired by [10], we combine small subtours and reallocate them to existing tours such that the violation of the tour capacity is an $O(\epsilon)$ fraction, see Steps 1 to 3 of the construction in Section 3.1. Next, we use the *iterated tour partitioning (ITP)* and its postprocessing to reduce the demand of the tours exceeding capacity (Figure 2), which is a novelty in this paper, see Steps 4 to 6 of the construction in Section 3.1. The ITP algorithm and its postprocessing are analyzed in Sections 3.2 and 3.3. In particular, we bound the cost due to the ITP algorithm thanks to the *bounded distance* property (Theorem 5) and to



(a) Constructing a traveling salesman tour. **(b)** Adding connections to the depot.

Figure 2 Covering the *orphan tokens* (in red). In Figure 2a, the orphan tokens are contained in the small pieces (in brown) that are removed from the tours exceeding capacity. We add the thick paths (in green) to connect all of the small pieces to the root of the tree. The cost of the thick paths is an $O(\epsilon)$ fraction of the optimal cost (Lemma 17 and Corollary 18), thanks to the bounded distance property. The induced traveling salesman tour is a double cover of the tree spanning the orphan tokens. Next, we apply the *iterated tour partitioning (ITP)* algorithm on that tour. In Figure 2b, the two paths (in blue and in orange) represent the connections to the depot added by the ITP algorithm. Their cost is again an $O(\epsilon)$ fraction of the optimal cost (Lemma 19), thanks to the bound on the number of orphan tokens and the bounded distance property.

the parameters in our component decomposition that are different from those in [10], see Remark 10. Besides the above novelties in our approach, the height reduction (Figure 1, see also Section 4), the adaptive rounding (Section 5), the reduction to bounded distances, as well as part of the dynamic program are new compared with [10]. These additional techniques are essential in the design of our PTAS, because of the more complicated solution structure inside components in our approach compared with the solution structure inside clusters in [10].

1.1.3 Other Related Work

Constant-factor approximations in general metric spaces

The CVRP is a generalization of the *traveling salesman problem (TSP)*. In general metric spaces, Haimovich and Rinnooy Kan [20] introduced a simple heuristics, called *iterated tour partitioning (ITP)*. Altinkemer and Gavish [2] showed that the approximation ratio of the ITP algorithm for the unit demand and the splittable CVRP is at most $1 + \left(1 - \frac{1}{k}\right) C_{\text{TSP}}$, where $C_{\text{TSP}} \geq 1$ is the approximation ratio of a TSP algorithm. Bompadre, Dror, and Orlin [12] improved this bound to $1 + \left(1 - \frac{1}{k}\right) C_{\text{TSP}} - \Omega\left(\frac{1}{k^3}\right)$. The ratio for the unit demand and the splittable CVRP on general metric spaces was recently improved by Blauth, Traub, and Vygen [11] to $1 + C_{\text{TSP}} - \epsilon$, for some small constant $\epsilon > 0$.

QPTASs

Das and Mathieu [16] designed a QPTAS for the CVRP in the Euclidean space; Jayaprakash and Salavatipour [22] designed a QPTAS for the CVRP in trees and extended that algorithm to QPTASs in graphs of bounded treewidth, bounded doubling or highway dimension. When the tour capacity is fixed, Becker, Klein, and Saulpic [7] gave a QPTAS for planar graphs and bounded-genus graphs.

PTASs for small capacity

In the Euclidean space, there have been PTAS algorithms for the CVRP with small capacity k: work by Haimovich and Rinnooy Kan [20], when k is constant; by Asano et al. [5] extending techniques in [20], for $k = O(\log n / \log\log n)$; and by Adamaszek, Czumaj, and Lingas [1], when $k \leq 2^{\log^{f(\epsilon)}(n)}$. For higher dimensional Euclidean metrics, Khachay and Dubinin [23] gave a PTAS for fixed dimension ℓ and $k = O(\log^{\frac{1}{\ell}}(n))$. Again when the capacity is bounded, Becker, Klein and Schild [9] gave a PTAS for planar graphs; Becker, Klein, and Saulpic [8] gave a PTAS for graphs of bounded highway dimension; and Cohen-Addad et al. [13] gave PTASs for bounded genus graphs and bounded treewidth graphs.

Unsplittable CVRP

In the *unsplittable* version of the CVRP, every terminal has a positive integer demand, and the entire demand at a terminal should be served by a single tour. On general metric spaces, the best-to-date approximation ratio for the unsplittable CVRP is roughly 3.194 due to the recent work of Friggstad et al. [17]. For tree metrics, the unsplittable CVRP is APX-hard: indeed, it is NP-hard to approximate the unsplittable tree CVRP to better than a 1.5 factor [19] using a reduction from the bin packing problem. Labbé, Laporte and Mercure [24] gave a 2-approximation for the unsplittable tree CVRP. The approximation ratio for the unsplittable tree CVRP was improved to $(1.5 + \epsilon)$ very recently by Mathieu and Zhou [25], building upon several techniques in the current paper.

1.2 Overview of Our Techniques

The main part of our work focuses on the unit demand tree CVRP, and we extend our results to the splittable tree CVRP in the end of this work.

▶ **Definition 3** (bounded distances). *Let $D_{\min}$ (resp. $D_{\max}$) denote the minimum (resp. maximum) distance between the depot and any terminal in the tree. We say that an instance has* bounded distances *if $D_{\max} < \left(\frac{1}{\epsilon}\right)^{\frac{1}{\epsilon}-1} \cdot D_{\min}$.*

Theorem 1 follows directly from Theorems 4 and 5.

▶ **Theorem 4.** *There is a polynomial time $(1 + 4\epsilon)$-approximation algorithm for the unit demand CVRP on the tree T with bounded distances.*

▶ **Theorem 5.** *For any $\rho \geq 1$, if there is a polynomial time ρ-approximation algorithm for the unit demand (resp. splittable, or unsplittable) CVRP on trees with* bounded distances*, then there is a polynomial time $(1 + 5\epsilon)\rho$-approximation algorithm for the unit demand (resp. splittable, or unsplittable) CVRP on trees with* general distances*.*

Theorem 5 may be of independent interest for the splittable and the unsplittable versions of the tree CVRP.

Outline for unit demand instances with bounded distances (Theorem 4)

First, we show that there exists a near-optimal solution with a simple structure, and afterwards, we use a dynamic program to compute the best solution with that structure.

In Section 3, we consider the *components* of the tree T (Lemma 9) and we show that there exists a near-optimal solution such that terminals within each component are visited by a constant $O_\epsilon(1)$ number of tours and that each of those tours visits $\Omega_\epsilon(k)$ terminals in that component (Theorem 13). The proof of Theorem 13 contains several novelties in our

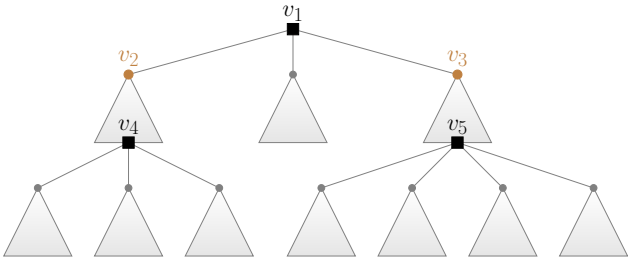


Figure 3 At each vertex of the tree, the dynamic program memorizes the capacities used by the subtours in the subtree and their total cost. Terminals within each component are visited by $O_\epsilon(1)$ tours and each of those tours visits $\Omega_\epsilon(k)$ terminals in that component. Here is an example of the flow of execution in the dynamic program. First, independent computation in each component. Next, computation in the subtrees rooted at vertices v_4 and v_5. Then computation for the subtrees rooted at vertices v_2 and v_3. Finally, computation for the subtree rooted at vertex v_1. The output is the best solution in the subtree rooted at v_1. Vertices v_1, v_4, and v_5, whose degrees may be arbitrarily large, are where adaptive rounding of the subtour demands is needed to maintain polynomial time. The cost due to the rounding is small thanks to the way components are defined and the bounded distance property, and does not accumulate excessively because the height is bounded (Section 4).

work. We start by defining *large* and *small* subtours inside a component, depending on the number of terminals visited by the subtours. To construct a near-optimal solution with that structure, first, we detach small subtours from their initial tours, combine small subtours in the same component, and reallocate the combined subtours to existing tours. Then we remove subtours from tours exceeding capacity. To connect the removed subtours to the root of the tree, we include the *spines subtours* (Definition 12) of all *internal components*, and we obtain a traveling salesman tour. Next, we apply the *iterated tour partitioning (ITP)* algorithm on that tour, see Figure 2. Finally, in a postprocessing step, we eliminate the small subtours created due to the ITP algorithm. The complete construction is in Section 3.1; the feasibility of the construction is in Section 3.2; and the analysis on the constructed solution is in Section 3.3, which in particular uses the bounded distance property.

In Section 4, we transform the tree T into a tree $\hat{T}$ that has $O_\epsilon(1)$ levels of components (Figure 1) and satisfies the following property.

▶ **Fact 6.** *The tree $\hat{T}$ defined in Section 4 can be computed in polynomial time. The components in the tree $\hat{T}$ are the same as those in the tree T. Any solution for the unit demand CVRP on the tree $\hat{T}$ can be transformed in polynomial time into a solution for the unit demand CVRP on the tree T without increasing the cost.*

Thanks to the structure of the near-optimal solution on T (Section 3) and to the bounded distance property, the optimal cost for $\hat{T}$ is increased by an $O(\epsilon)$ fraction compared with the optimal cost for T (Theorem 23).

In Section 5, we apply the *adaptive rounding* on the demands of the subtours in a near-optimal solution on $\hat{T}$. Recall that in the design of the QPTAS by Jayaprakash and Salavatipour [22], the main technique is to show the existence of a near-optimal solution in which the demand of a subtour can be rounded to the nearest value from a set of only *poly-logarithmic* threshold values. In our work, we reduce the number of threshold values to *a constant* $O_\epsilon(1)$ (Theorem 26). To analyze the adaptive rounding, observe that an extra cost occurs whenever we detach a subtour and complete it into a separate tour by connecting it to the depot. We bound the extra cost thanks to the structure of a near-optimal solution inside components (Section 3), the reduced height of the components (Section 4), as well as the bounded distance property.

In the full version of the paper, we design a *polynomial-time dynamic program* that computes the best solution on the tree $\hat{T}$ that satisfies the constraints on the solution structure imposed by previous sections. The algorithm combines a dynamic program inside components and two dynamic programs in subtrees, see Figure 3. Thus we obtain the following Theorem 7.

▶ **Theorem 7.** *Consider the unit demand CVRP on the tree $\hat{T}$. There is a dynamic program that computes in polynomial time a solution with cost at most $(1+4\epsilon)\cdot \mathrm{opt}$, where* opt *denotes the optimal cost for the unit demand CVRP on the tree T.*

Theorem 4 follows directly from Theorem 7 and Fact 6.

Reduction from general distances to bounded distances (Theorem 5)

In the full version of the paper, we prove Theorem 5. We use Baker's technique to split tours into pieces such that each piece covers terminals that are within a certain range of distances from the depot. This requires duplicating some parts of the tours so that each piece of the tour is connected to the depot.

Extension to the splittable setting (Corollary 2)

In the full version of the paper, we extend the result in Theorem 1 to the splittable setting, thus obtaining Corollary 2.

Open questions

Previously, Jayaprakash and Salavatipour [22] extended their QPTAS on trees to QPTASs on graphs of bounded treewidth and beyond, including Euclidean spaces. While some of our techniques extend to those settings, others do not seem to carry over without significant additional ideas, so it is an interesting open question whether the techniques in our paper could be used in the design of PTAS algorithms for other metrics, such as graphs of bounded treewidth, planar graphs, and Euclidean spaces.

2 Preliminaries

Let T be a rooted tree (V, E) with root $r \in V$ and edge weights $w(u, v) \geq 0$ for all $(u, v) \in E$. The root r represents the *depot* of the tours. Let n denote the number of vertices in V. Let $V' \subseteq V$ denote the set of *terminals*, such that a *token* is placed on each terminal $v \in V'$. Let $k \in [1, n]$ be an integer *capacity* of the tours. The *cost* of a tour t, denoted by $\mathrm{cost}(t)$, is the overall weight of the edges on that tour. We say that a tour *visits* a terminal $v \in V'$ if the tour picks up the token at v.[2]

▶ **Definition 8** (unit demand tree CVRP)**.** *An instance of the* unit demand *version of the* capacitated vehicle routing problem (CVRP) *on* trees *consists of*

- *an edge weighted* tree $T = (V, E)$ *with* $n = |V|$ *and with* root $r \in V$ *representing the* depot*,*
- *a set* $V' \subseteq V$ *of* terminals*,*
- *a positive integer* tour capacity k *such that* $k \leq n$*.*

[2] Note that a tour might go through a terminal v without picking up the token at v.

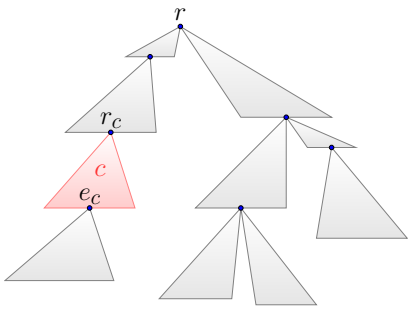

Figure 4 Decomposition into components. In this example, the tree is decomposed into four *leaf* components and six *internal* components. An internal component c has a *root* vertex r_c and an *exit* vertex e_c.

A feasible solution is a set of tours such that

- *each tour starts and ends at r,*
- *each tour visits at most k terminals,*
- *each terminal is visited by one tour.*

The goal is to find a feasible solution such that the total cost of the tours is minimum.

Let OPT (resp. OPT_1, OPT_2, or OPT_3) denote an optimal (resp. near-optimal) solution to the unit demand CVRP, and let opt (resp. opt_1, opt_2, or opt_3) denote the value of that solution.

Without loss of generality, we assume that every vertex in the input tree T has exactly two children, and that the terminals are the same as the leaf vertices of the tree. Indeed, general instances can be reduced to instances with these properties by inserting edges of weight 0, removing leaf vertices that are not terminals, and slicing out internal vertices of degree two, see, e.g. [10] for details.

For any vertex $v \in V$, a *subtour at the vertex v* is a path that starts and ends at v and only visits vertices in the subtree rooted at v. The *demand* of a subtour is the number of terminals visited by that subtour. For each vertex $v \in V$, let $\mathrm{dist}(v)$ denote the distance between v and the depot in the tree T. For technical reasons, we allow *dummy* terminals to be included in the solution at internal vertices of the tree.

Throughout the paper, we define several constants depending on ϵ: Γ (Lemma 9), α (Theorem 13), H_ϵ (Lemma 21), and β (Theorem 26). They satisfy the relation that $H_\epsilon \gg \Gamma \gg 1 \gg \epsilon \gg \alpha \gg \beta$.

Decomposition of the Tree into Components

The component decomposition (Lemma 9) is inspired by the cluster decomposition by Becker and Paul [10]. The proof of Lemma 9 is similar to arguments in [10]; we give its proof in the full version of the paper for completeness.

▶ **Lemma 9.** *Let $\Gamma = \frac{12}{\epsilon}$. There is a polynomial time algorithm to compute a partition of the edges of the tree T into a set $\mathcal{C}$ of* components *(see Figure 4), such that all of the following properties are satisfied:*

- *Every component $c \in \mathcal{C}$ is a connected subgraph of T; the* root *vertex of the component c, denoted by r_c, is the vertex in c that is closest to the depot.*
- *We say that a component $c \in \mathcal{C}$ is a* leaf *component if all descendants of r_c in tree T are in c, and is an* internal *component otherwise. A leaf component c interacts with other components at vertex r_c only. An internal component c interacts with other components at two vertices only: at vertex r_c, and at another vertex, called the* exit *vertex of the component c, and denoted by e_c.*

- *Every component $c \in \mathcal{C}$ contains at most $2\Gamma \cdot k$ terminals. We say that a component is* big *if it contains at least $\Gamma \cdot k$ terminals. Each leaf component is big.*
- *If the number of components in $\mathcal{C}$ is strictly greater than one, then we have: (1) there exists a map from all components to big components, such that the image of a component is among its descendants (including itself), and each big component has at most three pre-images; and (2) the number of components in $\mathcal{C}$ is at most $3/\Gamma$ times the total demand in the tree T.*

▶ Remark 10. The root and the exit vertices of components are a rough analog of *portals* used in approximation schemes for other problems: they are places where the dynamic program will gather and synthesize information about partial solutions before passing it on.

Compared with [10], the decomposition in Lemma 9 uses different parameters: the number of terminals inside a *leaf component* is $\Theta(k/\epsilon)$, whereas in [10] the number of terminals inside a *leaf cluster* is $\Theta(\epsilon \cdot k)$; the threshold demand to define *big components* is $\Theta(k/\epsilon)$, whereas in [10] the threshold demand to define *small clusters* is $\Theta(\epsilon^2 \cdot k)$.

▶ **Definition 11** (subtours in components and subtour types)**.** *Let c be any component. A* subtour in the component c *is a path that starts and ends at the root r_c of the component, and such that every vertex on the path is in c. The* type *of a subtour is "*passing*" if c is an internal component and the exit vertex e_c belongs to that subtour; and is "*ending*" otherwise.*

A passing subtour in c is to be combined with a subtour at e_c. In a leaf component, there is no passing subtour.

▶ **Definition 12** (spine subtour)**.** *For an internal component c, we define the* spine subtour *in the component c, denoted by spine_c, to be the connection (in both directions) between the root vertex r_c and the exit vertex e_c of the component c, without visiting any terminal.*

From the definition, a spine subtour in a component is also a passing subtour in that component.

Without loss of generality, we assume that any subtour in a component c either visits at least one terminal in c or is a spine subtour; that any tour traverses each edge of the tree at most twice (once in each direction); and that any tour contains at most one subtour in any component.[3]

3 Solutions Inside Components

In this section, we prove Theorem 13, which is a main novelty in this paper.

▶ **Theorem 13.** *Let $\alpha = \epsilon^{(\frac{1}{\epsilon}+1)}$. Consider the unit demand CVRP on the tree T with bounded distances. There exist dummy terminals and a solution OPT_1 visiting all of the real and the dummy terminals, such that all of the following holds:*

1. *For each component c, there are at most $\frac{2\Gamma}{\alpha} + 1$ tours visiting terminals in c;*
2. *For each component c and each tour t visiting terminals in c, the number of the terminals in c visited by t is at least $\alpha \cdot k$;*
3. *We have $\text{opt}_1 \leq (1+\epsilon) \cdot \text{opt}$.*

[3] If a tour contains several subtours in a component c, we may combine those subtours into a single subtour in c without increasing the cost of the tour.

3.1 Construction of OPT_1

▶ **Definition 14** (large and small subtours). *We say that a subtour is* large *if its demand is at least $\alpha \cdot k$, and* small *otherwise.*

The construction of OPT_1, starting from an optimal solution OPT, is in several steps.

Step 1: Detaching small subtours

Prune each tour of OPT so that it only visits the terminals that do *not* belong to a small subtour in any component, and is minimal. In other words, if a tour t in OPT contains a small ending subtour t_e in a component c, then we remove t_e from t; and if a tour t in OPT contains a non-spine small passing subtour t_p in a component c, then we remove t_p from t, except for the spine subtour of c.

Let A denote the set of the resulting tours. Note that each tour in A is connected. The removed pieces of a non-spine small passing subtour t_p may be disconnected from one another.

The parts of OPT that have been pruned consist of the set $\mathcal{E}$, each element being a small ending subtours in a component, and of the set $\mathcal{P}$, each element being a group of pieces in a component obtained from a non-spine small passing subtour by removing the corresponding spine subtour. The *demand* of a group of pieces in $\mathcal{P}$ is the number of terminals in all of the pieces in that group.

Step 2: Combining small subtours within components

- For each component c, repeatedly concatenate subtours in c from the set $\mathcal{E}$ so that in the end, all resulting subtours in c from the set $\mathcal{E}$ have demands between $\alpha \cdot k$ and $2\alpha \cdot k$ except for at most one subtour.
- For each component c, repeatedly merge groups in c from the set $\mathcal{P}$ so that in the end, all resulting groups in c from the set $\mathcal{P}$ have demands between $\alpha \cdot k$ and $2\alpha \cdot k$ except for at most one group.

Let $\mathcal{E}'$ and $\mathcal{P}'$ denote the corresponding sets after the modifications for all components c. Let $B = \mathcal{E}' \cup \mathcal{P}'$. An *element* of B is either a *subtour* or a *group of pieces* in a component c. For each component c, all elements of B in the component c have demands between $\alpha \cdot k$ and $2\alpha \cdot k$ except for at most two elements with smaller demands.

Step 3: Reassigning small subtours

Construct a bipartite graph with vertex sets A and B and with edge set E. Let a be any tour in A, and let a_0 denote the corresponding tour in OPT. Let b be any element in B. The set E contains an edge between a and b if and only if the element b contains terminals from a_0; the weight of the edge (a, b) is the number of terminals in both b and a_0. By Lemma 1 from [10], there exists an assignment $f : B \to A$ such that each element $b \in B$ is assigned to a tour $a \in A$ with $(a, b) \in E$ and that, for each tour $a \in A$, the demand of a plus the overall demand of the elements $b \in B$ that are assigned to a is at most the demand of the corresponding tour a_0 plus the maximum demand of any element in B.

Let A_1 denote the set of *pseudo-tours* induced by the assignment f. Each pseudo-tour in A_1 is the union of a tour $a \in A$ and the elements $b \in B$ that are assigned to a.

Step 4: Correcting tour capacities

For each pseudo-tour a_1 in A_1, if the demand of a_1 exceeds k, we repeatedly remove an element $b \in B$ from a_1, until the demand of a_1 is at most k.

Let A_2 denote the resulting set of pseudo-tours. Every pseudo-tour in A_2 is a connected tour of demand at most k (Lemma 15). Let $B^* \subseteq B$ denote the set of the removed elements $b \in B$. The elements in B^* are represented by the small pieces in Figure 2a (Page 4).

Step 5: Creating additional tours

We connect the elements of B^* to the depot by creating additional tours as follows.

- Let Q denote the union of the spine subtours for all internal components. Q is represented by the green thick paths in Figure 2a. Let X denote a multi-subgraph of T that is the union of the elements in B^* and the edges in Q. Observe that each element in B^* is connected to the depot through edges in Q. Thus X is connected, and induces a traveling salesman tour t_{TSP} visiting all terminals in B^*. Without loss of generality, we assume that, for any component c, if t_{TSP} visits terminals in c, then those terminals belong to a single subpath p_c of t_{TSP}, such that p_c does not visit any terminal from other components.
- If the traveling salesman tour t_{TSP} is within the tour capacity, then let A_3 denote the set consisting of a single tour t_{TSP}. Otherwise, we apply the *iterated tour partitioning (ITP)* algorithm [20] on t_{TSP}: we partition t_{TSP} into segments with exactly k terminals each, except possibly the last segments containing less than k terminals. For each segment, we connect its endpoints to the depot so as to make a tour, see Figure 2b. Let A_3 denote the resulting set of tours.

Let $A_4 = A_2 \cup A_3$.

Step 6: Postprocessing

For each component c, we rearrange the small subtours in A_4 as follows.

- For each tour t in A_4 that contains a small subtour in c, letting t_c denote this small subtour, if t_c is an ending subtour, we remove t_c from t; if t_c is a passing subtour, we remove t_c from t, except for the spine subtour in c. The total demand of all of the removed small subtours in c is at most k (Lemma 16).
- We create an additional tour t_c^* from the depot that connects all of the removed small subtours in c. If the demand of t_c^* is less than $\alpha \cdot k$, then we include dummy terminals at r_c into the tour t_c^* so that its demand is exactly k.

Let A_5 denote the resulting set of tours after removing small subtours from A_4. Let A_6 denote the set of newly created tours $\{t_c^*\}_{c \in \mathcal{C}}$.

Finally, let $\text{OPT}_1 = A_5 \cup A_6$.

In Section 3.2, we show that OPT_1 is a feasible solution to the unit demand tree CVRP; in Section 3.3, we prove the three properties of OPT_1 in the claim of Theorem 13.

3.2 Feasibility of the Construction

▶ **Lemma 15.** *Every pseudo-tour in A_2 is a connected tour of demand at most k.*

Proof. Let a_2 be any pseudo-tour in A_2. By the construction in Step 4, the demand of a_2 is at most k. It suffices to show that a_2 is a connected tour.

Observe that a_2 is the union of a tour $a \in A$ and some elements $b_1, \ldots, b_q$ from B, for $q \geq 0$. From the construction, any tour $a \in A$ is connected. Consider any b_i for $i \in [1, q]$. Observe that $f(b_i) = a$, so the edge (a, b_i) belongs to the bipartite graph (A, B). If b_i is a

subtour at r_c for some component c, then r_c must belong to the tour a; and if b_i is a group of pieces in some component c, then the spine subtour of c must belong to the tour a. So the union of a and b_i is connected. Thus $a_2 = a \cup b_1 \cup \cdots \cup b_q$ is a connected tour. ◀

▶ **Lemma 16.** *In any component c, the total demand of all of the removed small subtours in c at the beginning of Step 6 is at most k.*

Proof. Let c be any component. The key is to show that the number of non-spine small subtours in c that are contained in tours in A_4 is at most 4. Since $A_4 = A_2 \cup A_3$, we analyze the number of non-spine small subtours in c that are contained in tours in A_2 and in A_3, respectively.

The tours in A_2 contain at most two non-spine small subtours in c, since at most two elements of B in component c have demands less than $\alpha \cdot k$.

We claim that the tours in A_3 contain at most two non-spine small subtours in c. If A_3 consists of a single tour t_{TSP}, the claim follows trivially since any tour contains at most one subtour in c from our assumption. Next, we consider the case when A_3 is generated by the ITP algorithm. From our assumption, if t_{TSP} visits terminals in c, then those terminals belong to a single subpath p_c of t_{TSP}, such that p_c does not visit any terminal from other components. By applying the ITP algorithm on t_{TSP}, we obtain a collection of segments. All segments that intersect p_c visit exactly k terminals in c, except for possibly the first and the last of those segments visiting less than k terminals in c. Hence at most two non-spine small subtours in c among the tours in A_3.

Therefore, the number of non-spine small subtours in c in the solution A_4 is at most 4. Since each small subtour has demand at most $\alpha \cdot k$, the total demand of the removed small subtours is at most $4 \cdot \alpha \cdot k < k$. ◀

3.3 Analysis of $\mathbf{OPT_1}$

Let $c \in \mathcal{C}$ be any component. From Lemma 9, c contains at most $2\Gamma \cdot k$ real terminals. Each tour in A_5 visiting terminals in c visits at least $\alpha \cdot k$ real terminals in c, so there are at most $\frac{2\Gamma}{\alpha}$ tours in A_5 visiting terminals in c. There is a single tour in A_6, the tour t_c^*, that visits terminals in c. Hence the first property of the claim. From the construction of t_c^*, the second property of the claim follows.

It remains to analyze the cost of OPT_1. Compared with OPT, the extra cost in OPT_1 is due to Step 5 and Step 6 of the construction. This extra cost consists of the cost of the edges in Q (Step 5), the cost in the ITP algorithm to connect the endpoints of all segments to the depot (Step 5), and the cost of the postprocessing (Step 6), which we bound in Corollary 18 and Lemmas 19 and 20, respectively. Both Corollary 18 and Lemma 20 are based on Lemma 17.

▶ **Lemma 17.** *We have* $\displaystyle\sum_{\text{component } c} \text{dist}(r_c) \le \frac{\epsilon}{8} \cdot \text{opt}.$

Proof. For any edge e in T, let u and v denote the two endpoints of e such that u is the parent of v. Let T_e denote the subtree of T rooted at v. Let n_e denote the number of terminals in T_e. From the lower bound in [21], we have

$$\text{opt} \ge \sum_{e \in T} 2 \cdot w(e) \cdot \frac{n_e}{k}.$$

Since each big component contains at least $\Gamma \cdot k$ terminals, we have

$$n_e \ge \sum_{\text{big component } c \subseteq T_e} \Gamma \cdot k.$$

Thus

$$\begin{aligned}\text{opt} &\geq \sum_{e\in T} 2\cdot w(e)\cdot \sum_{\text{big component } c\subseteq T_e} \Gamma \\ &= \sum_{\text{big component } c} \Gamma\cdot \sum_{e\in T \text{ such that } c\subseteq T_e} 2\cdot w(e) \\ &= \sum_{\text{big component } c} \Gamma\cdot 2\cdot \text{dist}(r_c).\end{aligned}$$

From Lemma 9, there exists a map from all components to big components such that the image of a component is among its descendants (including itself) and each big component has at most three pre-images. Thus

$$3\cdot \sum_{\text{big component } c} \text{dist}(r_c) \geq \sum_{\text{component } c} \text{dist}(r_c).$$

Therefore,

$$\text{opt} \geq \frac{2\cdot\Gamma}{3}\cdot \sum_{\text{component } c} \text{dist}(r_c).$$

The claim follows since $\Gamma = \frac{12}{\epsilon}$. ◀

▶ **Corollary 18.** *We have* $\text{cost}(Q) \leq \frac{\epsilon}{4}\cdot \text{opt}$.

Proof. Observe that every edge in Q belongs to the connection (in both directions) between the depot and the root of some component c. By Lemma 17, we have

$$\text{cost}(Q) \leq 2\cdot \sum_{\text{component } c} \text{dist}(r_c) \leq \frac{\epsilon}{4}\cdot \text{opt}.$$ ◀

▶ **Lemma 19.** *Let* Δ_1 *denote the cost in the ITP algorithm to connect the endpoints of all segments to the depot in Step 5. We have* $\Delta_1 \leq \frac{\epsilon}{4}\cdot \text{opt}$.

Proof. Let n' denote the number of terminals in the tree T. First, we show that the number of terminals on t_{TSP} is at most $4\alpha\cdot n'$. Observe that the number of terminals on t_{TSP} is the overall removed demand in Step 4. Consider any pseudo-tour $a_1 \in A_1$ whose demand exceeds k. Let a_0 denote the corresponding tour in OPT. By the construction, the demand of a_1 is at most the demand of a_0 plus the maximum demand of any element in B. Since the demand of a_0 is at most k and the demand of any element in B is at most $2\alpha\cdot k$, the demand of a_1 is at most $k + 2\alpha\cdot k$. Let a_2 denote the corresponding tour after the correction of capacity in Step 4. Since any element in B has demand at most $2\alpha\cdot k$, the demand of a_2 is at least $k - 2\alpha\cdot k$. So the total removed demand from a_1 in Step 4 is at most $4\alpha\cdot k$. There are at most $\frac{n'}{k}$ pseudo-tours $a_1 \in A_1$ whose demands exceed k. Summing over all those pseudo-tours, the overall removed demand in Step 4 is at most $\frac{n'}{k}\cdot 4\alpha\cdot k = 4\alpha\cdot n'$. Hence the number of terminals on t_{TSP} is at most $4\alpha\cdot n'$.

If $4\alpha\cdot n' \leq k$, then t_{TSP} is within the tour capacity, so the ITP algorithm is not applied and $\Delta_1 = 0$. It remains to consider the case in which $4\alpha\cdot n' > k$. By the construction in the ITP algorithm, every segment visits exactly k terminals except possibly the last segment. Thus the number ℓ_{ITP} of resulting tours in the ITP algorithm is

$$\ell_{\text{IPT}} \leq \frac{4\alpha\cdot n'}{k} + 1. \tag{1}$$

Since $4\alpha \cdot n' > k$, we have $\ell_{\mathrm{IPT}} < \frac{8\alpha \cdot n'}{k}$. Since $\Delta_1 \le \ell_{\mathrm{ITP}} \cdot 2 \cdot D_{\max}$ and using Definition 3 and the definition of α in the claim of Theorem 13, we have

$$\Delta_1 < \frac{8\alpha \cdot n'}{k} \cdot 2 \cdot \left(\frac{1}{\epsilon}\right)^{\frac{1}{\epsilon}-1} \cdot D_{\min} < \frac{\epsilon}{2} \cdot \frac{n'}{k} \cdot D_{\min}.$$

On the other hand, the solution OPT consists of at least $\frac{n'}{k}$ tours, so $\mathrm{opt} \ge \frac{2n'}{k} \cdot D_{\min}$. Therefore, $\Delta_1 \le \frac{\epsilon}{4} \cdot \mathrm{opt}$. ◀

▶ **Lemma 20.** *Let Δ_2 denote the cost of the postprocessing (Step 6). Then $\Delta_2 \le \frac{\epsilon}{2} \cdot \mathrm{opt}$.*

Proof. For each leaf component c, the cost to connect the small subtours in c to the depot in Step 6 is at most $2 \cdot \mathrm{dist}(r_c)$; and for each internal component c, the cost to connect the small subtours in c to the depot is at most $2 \cdot \mathrm{dist}(r_c) + \mathrm{cost}(\mathrm{spine}_c)$. Summing over all components, we have

$$\Delta_2 \le \sum_{\text{component } c} 2 \cdot \mathrm{dist}(r_c) + \sum_{\text{internal component } c} \mathrm{cost}(\mathrm{spine}_c).$$

By Lemma 17, we have

$$\sum_{\text{component } c} 2 \cdot \mathrm{dist}(r_c) \le \frac{\epsilon}{4} \cdot \mathrm{opt}$$

and

$$\sum_{\text{internal component } c} \mathrm{cost}(\mathrm{spine}_c) = \mathrm{cost}(Q) \le \frac{\epsilon}{4} \cdot \mathrm{opt}.$$

Thus $\Delta_2 \le \frac{\epsilon}{2} \cdot \mathrm{opt}$. ◀

From Corollary 18 and Lemmas 19 and 20, we have $\mathrm{opt}_1 \le \mathrm{opt} + \mathrm{cost}(Q) + \Delta_1 + \Delta_2 \le (1+\epsilon) \cdot \mathrm{opt}$. This completes the proof for Theorem 13.

4 Height Reduction

In this section, we transform the tree T into a tree $\hat{T}$ so that $\hat{T}$ has $O_\epsilon(1)$ levels of components, see Figure 1. We assume that the tree T has bounded distances. To begin with, we partition the components according to the distances from their roots to the depot.

▶ **Lemma 21.** *Let $\tilde{D} = \alpha \cdot \epsilon \cdot D_{\min}$. Let $H_\epsilon = (\frac{1}{\epsilon})^{\frac{2}{\epsilon}+1}$. For each $i \in [1, H_\epsilon]$, let $\mathcal{C}_i \subseteq \mathcal{C}$ denote the set of components $c \in \mathcal{C}$ such that $\mathrm{dist}(r_c) \in \big[(i-1) \cdot \tilde{D}, i \cdot \tilde{D}\big)$. Then any component $c \in \mathcal{C}$ belongs to a set $\mathcal{C}_i$ for some $i \in [1, H_\epsilon]$.*

Proof. Let $c \in \mathcal{C}$ be any component. We have

$$\mathrm{dist}(r_c) \le D_{\max} < \left(\frac{1}{\epsilon}\right)^{\frac{1}{\epsilon}-1} \cdot D_{\min} = H_\epsilon \cdot \tilde{D},$$

where the second inequality follows from Definition 3, and the equality follows from the definition of α in Theorem 13 and the definitions of $\tilde{D}$ and H_ϵ. Thus there exists $i \in [1, H_\epsilon]$ such that $c \in \mathcal{C}_i$. ◀

▶ **Definition 22** (maximally connected sets and critical vertices). *We say that a set of components $\tilde{\mathcal{C}} \subseteq \mathcal{C}_i$ is* maximally connected *if the components in $\tilde{\mathcal{C}}$ are connected to each other and $\tilde{\mathcal{C}}$ is maximal within $\mathcal{C}_i$. For a maximally connected set of components $\tilde{\mathcal{C}} \subseteq \mathcal{C}_i$, we define the* critical vertex *of $\tilde{\mathcal{C}}$ to be the root vertex of the component $c \in \tilde{\mathcal{C}}$ that is closest to the depot.*

Figure 1 (Page 3) is an example with three levels of components: $\mathcal{C}_1$, $\mathcal{C}_2$, and $\mathcal{C}_3$, indicated by different colors. There are four maximally connected sets of components. The critical vertices are represented by rectangular nodes.

Algorithm 1 Construction of the tree $\hat{T}$ (see Figure 1).

```
for each i ∈ [1, H_ε] do
    for each maximally connected set of components C̃ ⊆ C_i do
        z ← critical vertex of C̃
        for each component c ∈ C̃ do
            δ ← r_c-to-z distance in T
            Split the tree T at the root vertex r_c of the component c    ▷ r_c is duplicated
            Add an edge between the root of the component c and z with weight δ
T̂ ←the resulting tree
```

Let $\hat{T}$ be the tree constructed in Algorithm 1. We observe that Algorithm 1 is in polynomial time, and Fact 6 follows from the construction. We show in Theorem 23 that the optimal cost for $\hat{T}$ is increased by an $O(\epsilon)$ fraction compared with the optimal cost for T.

▶ **Theorem 23.** *Consider the unit demand CVRP on the tree $\hat{T}$. There exist dummy terminals and a solution* OPT_2 *visiting all of the real and the dummy terminals, such that all of the following holds:*

1. *For each component c, there are at most $\frac{2\Gamma}{\alpha} + 1$ tours visiting terminals in c;*
2. *For each component c and each tour t visiting terminals in c, the number of the terminals in c visited by t is at least $\alpha \cdot k$;*
3. *We have* $\mathrm{opt}_2 < (1 + 3\epsilon) \cdot \mathrm{opt}$, *where* opt *denotes the optimal cost for the unit demand CVRP on the tree T.*

In the rest of the section, we prove Theorem 23.

4.1 Construction of OPT_2

Consider any tour t in OPT_1. Let U denote the set of terminals visited by t.[4] We define the tour $\hat{t}$ as the minimal tour in the tree $\hat{T}$ that spans all terminals in U, see Figure 1. Let OPT_2 denote the set of the resulting tours on the tree $\hat{T}$ constructed from every tour t in OPT_1. Then OPT_2 is a feasible solution to the unit demand CVRP on $\hat{T}$.

4.2 Analysis of OPT_2

The first two properties in Theorem 23 follow from the construction and Theorem 13.

In the rest of the section, we analyze the cost of OPT_2.

▶ **Lemma 24.** *Let t denote any tour in* OPT_1. *Let $\hat{t}$ denote the corresponding tour in* OPT_2. *Then* $\mathrm{cost}(\hat{t}) \leq (1 + \epsilon) \cdot \mathrm{cost}(t)$.

[4] We assume that t is a minimal tour in T spanning all terminals in U.

Proof. We follow the notation on U from Section 4.1. Let $\mathcal{C}(U)$ denote the set of components $c \in \mathcal{C}$ that contains a (possibly spine) subtour of $\hat{t}$. Observe that the cost of $\hat{t}$ consists of the following two parts:

1. for each component $c \in \mathcal{C}(U)$, the cost of the subtour in c from the tour t; we *charge* that cost to the subtour in t;
2. for each component $c \in \mathcal{C}(U)$, the cost of the edge (r_c, z), where z denotes the father vertex of r_c in $\hat{T}$. Note that z is a critical vertex on $\hat{t}$. We analyze that cost over all components $c \in \mathcal{C}(U)$ as follows.

Let $Z \subseteq V$ denote the set of critical vertices $z \in V$ on $\hat{t}$. For any critical vertex $z \in Z$, let $Y(z)$ denote the set of edges (z, v) in the tree $\hat{T}$ such that v is a child of z and that the edge (z, v) belongs to the tour $\hat{t}$. The overall cost of the second part is the total cost of the edges in $Y(z)$ for all $z \in Z$.

Fix a critical vertex $z \in Z$. Let (z, v_1) denote the edge in $Y(z)$ such that $\mathrm{dist}(v_1)$ is minimized, breaking ties arbitrarily. From the minimality of $\mathrm{dist}(v_1)$, the z-to-v_1 path in T does not go through any component in $\mathcal{C}(U)$. From the construction, the cost of the edge (z, v_1) in $\hat{T}$ equals the cost of the z-to-v_1 path in T. It is easy to see that the z-to-v_1 path in T belongs to the tour t. Indeed, tour $\hat{t}$ traverses the edge (z, v_1) on its way to visit some terminals of U in the subtree rooted at v_1. In order to visit the corresponding terminals in T, tour t must traverse the z-to-v_1 path. We *charge* the cost of the edge (z, v_1) in $\hat{T}$ to the z-to-v_1 path in T. Next, we analyze the cost due to the other edges in $Y(z)$. Consider one such edge (z, v). From the construction, there exists $i \in [1, H_\epsilon]$, such that both $\mathrm{dist}(z)$ and $\mathrm{dist}(v)$ belong to $\big[(i-1) \cdot \tilde{D}, i \cdot \tilde{D}\big)$. Thus the cost of the z-to-v path in T equals $\mathrm{dist}(v) - \mathrm{dist}(z) < \tilde{D}$, so the extra cost in $\hat{t}$ due to the edge (z, v) is at most $2 \cdot \tilde{D}$ (for both directions). Therefore, the extra cost in $\hat{t}$ due to those $|Y(z)| - 1$ edges in $Y(z)$ is at most $2 \cdot \tilde{D} \cdot (|Y(z)| - 1)$.

Summing over all vertices $z \in Z$, and observing that all charges are to disjoint parts of t, we have

$$\mathrm{cost}(\hat{t}) \leq \mathrm{cost}(t) + 2 \cdot \tilde{D} \cdot \sum_{z \in Z} (|Y(z)| - 1). \tag{2}$$

It remains to bound $\sum_{z \in Z} (|Y(z)| - 1)$. The analysis uses the following basic fact in trees.

▶ **Fact 25.** *Let H be a tree with L leaves. For each vertex u in H, let $m(u)$ denote the number of children of u in H. Then*

$$\sum_{u \in H} (m(u) - 1) \leq L - 1.$$

We construct a tree H as follows. Starting from the tree spanning U in $\hat{T}$, we contract vertices in each component $c \in \mathcal{C}(U)$ into a single vertex; let H denote the resulting tree. It is easy to see that each leaf in H corresponds to a component $c \in \mathcal{C}(U)$ that contains at least one terminal in U (using the definition of $\mathcal{C}(U)$ and the fact that any descending component of c do not belong to $\mathcal{C}(U)$). From the second property of Theorem 23 (which follows from Theorem 13), terminals in U belong to at most $1/\alpha$ components. Thus, by Fact 25 we have

$$\sum_{z \in Z} (|Y(z)| - 1) \leq (1/\alpha) - 1.$$

Combined with Equation (2), we have

$$\mathrm{cost}(\hat{t}) - \mathrm{cost}(t) < 2 \cdot \tilde{D} \cdot (1/\alpha) = 2 \cdot \alpha \cdot \epsilon \cdot D_{\min} \cdot (1/\alpha) = 2\epsilon \cdot D_{\min},$$

using the definition of $\tilde{D}$ in Lemma 21. Since $\mathrm{cost}(t) \geq 2 \cdot D_{\min}$, the claim follows. ◀

Applying Lemma 24 on each tour t in OPT_1 and summing, we have $\mathrm{opt}_2 \leq (1+\epsilon)\cdot \mathrm{opt}_1$. By Theorem 13, $\mathrm{opt}_1 \leq (1+\epsilon)\cdot \mathrm{opt}$, thus $\mathrm{opt}_2 \leq (1+3\epsilon)\cdot \mathrm{opt}$. This completes the proof of Theorem 23.

5 Adaptive Rounding on the Subtour Demands

In this section, we prove Theorem 26. We use the adaptive rounding to show that, in a near-optimal solution, the demands of the subtours at any critical vertex are from a set of $O_\epsilon(1)$ values. This property enables us to later guess those values in polynomial time by a dynamic program.

▶ **Theorem 26.** *Let $\beta = \frac{1}{4}\cdot\epsilon^{(\frac{4}{\epsilon}+1)}$. Consider the unit demand CVRP on the tree $\hat{T}$. There exist dummy terminals and a solution OPT_3 visiting all of the real and the dummy terminals, such that all of the following holds:*

1. *For each component c, there are at most $\frac{2\Gamma}{\alpha}+1$ tours visiting terminals in c;*
2. *For each critical vertex z, there exist $\frac{1}{\beta}$ integer values in $[\alpha\cdot k, k]$ such that the demands of the subtours at the children of z are among these values;*
3. *We have $\mathrm{opt}_3 < (1+4\epsilon)\cdot \mathrm{opt}$, where opt denotes the optimal cost for the unit demand CVRP on the tree T.*

5.1 Construction of OPT_3

We construct the solution OPT_3 by modifying the solution OPT_2.

Let $I \subseteq V$ denote the set of vertices $v \in V$ that is either the root of a component or a critical vertex. Consider any vertex $v \in I$ in the bottom up order. Let $\mathrm{OPT}_2(v)$ denote the set of subtours at v in OPT_2. We construct a set $A(v)$ of subtours at v satisfying the following invariants:

- the subtours in $A(v)$ have a one-to-one correspondence with the subtours in $\mathrm{OPT}_2(v)$; and
- the demand of each subtour of $A(v)$ is at most that of the corresponding subtour in $\mathrm{OPT}_2(v)$.

The construction of $A(v)$ is according to one of the following three cases on v.

Case 1: v is the root vertex r_c of a leaf component c in $\hat{T}$

Let $A(v) = \mathrm{OPT}_2(v)$.

Case 2: v is the root vertex r_c of an internal component c in $\hat{T}$

For each subtour $a \in \mathrm{OPT}_2(v)$, if a contains a subtour at the exit vertex e_c of component c, letting t denote this subtour and t' denote the subtour in $A(e_c)$ corresponding to t, we replace the subtour t in a by the subtour t'. Let $A(v)$ be the resulting set of subtours at v.

Case 3: v is a critical vertex in $\hat{T}$

We apply the technique of the *adaptive rounding*, previously used by Jayaprakash and Salavatipour [22] in their design of a QPTAS the tree CVRP. The idea is to *round up* the demands of the subtours at the children of v so that the resulting demands are among $\frac{1}{\beta}$ values.

Let $r_1, \ldots, r_m$ be the children of v in $\hat{T}$. For each subtour $a \in \mathrm{OPT}_2(v)$ and for each $i \in [1, m]$, if a contains a subtour at r_i, letting t denote this subtour and t' denote the subtour

in $A(r_i)$ corresponding to t, we replace t in a by t'. Let $A_1(v)$ denote the resulting set of subtours at v.

Let W_v denote the set of the subtours at the children of v in $A_1(v)$, i.e., $W_v = A(r_1) \cup \cdots \cup A(r_m)$. If $|W_v| \leq \frac{1}{\beta}$, let $A(v) = A_1(v)$. In the following, we consider the non-trivial case when $|W_v| > \frac{1}{\beta}$. We sort the subtours in W_v in non-decreasing order of their demands, and partition these subtours into $\frac{1}{\beta}$ groups of equal cardinality.[5] We *round* the demands of the subtours in each group to the maximum demand in that group. The demand of a subtour is increased to the rounded value by adding *dummy* terminals at the children of v. We rearrange the subtours in W_v as follows.

- Each subtour $t \in W_v$ in the last group is discarded, i.e., detached from the subtour in $A_1(v)$ to which it belongs.
- Each subtour $t \in W_v$ in other groups is associated in a one-to-one manner to a subtour $t' \in W_v$ in the next group. Letting a (resp. a') denote the subtour in $A_1(v)$ to which t (resp. t') belongs, we detach t from a and reattach t to a'.

Let $A(v)$ be the set of the resulting subtours at v after the rearrangement for all $t \in W_v$.

For each subtour t that is discarded in the construction, we complete t into a separate tour by adding the connection (in both directions) to the depot. Let B denote the set of these newly created tours. Let $\mathrm{OPT}_3 = A(r) \cup B$.

It is easy to see that OPT_3 is a feasible solution to the unit demand CVRP, i.e., each tour in OPT_3 is connected and visits at most k terminals, and each terminal is covered by some tour in OPT_3.

5.2 Analysis of OPT_3

From the construction, in any component $c \in \mathcal{C}$, the non-spine subtours in OPT_3 are the same as those in OPT_2. From Theorem 23, we obtain the first property in Theorem 26, and in addition, each subtour at a child of a critical vertex in OPT_2 has demand at least $\alpha \cdot k$. The second property of the claim follows from the construction of OPT_3.

It remains to analyze the cost of OPT_3. Let $\Delta = \mathrm{opt}_3 - \mathrm{opt}_2$. Observe that Δ is due to adding connections to the depot to create the tours in the set B.

Fix any $i \in [1, H_\epsilon]$. Let $Z \subseteq V$ denote the set of vertices $v \in V$ such that v is the critical vertex of a maximally connected component $\tilde{\mathcal{C}} \subseteq \mathcal{C}_i$. For any $v \in Z$, we analyze the number of discarded subtours in the set W_v defined in Section 5.1. If $|W_v| \leq \frac{1}{\beta}$, there is no discarded subtour in W_v; if $|W_v| > \frac{1}{\beta}$, the number of discarded subtours in W_v is $\lceil \beta \cdot |W_v| \rceil < \beta \cdot |W_v| + 1 < 2\beta \cdot |W_v|$. Let W denote the disjoint union of W_v for all vertices $v \in Z$. Thus W contains at most $2\beta \cdot |W|$ discarded subtours. Let Δ_i denote the cost to connect the discarded subtours in W to the depot. We have

$$\Delta_i \leq 2\beta \cdot |W| \cdot 2 \cdot D_{\max} < \frac{1}{2} \cdot \epsilon^{(\frac{4}{\epsilon}+1)} \cdot |W| \cdot 2 \cdot \left(\frac{1}{\epsilon}\right)^{\frac{1}{\epsilon}-1} \cdot D_{\min} = \frac{\epsilon}{H_\epsilon} \cdot \alpha \cdot |W| \cdot D_{\min}, \quad (3)$$

where the second inequality follows from the definition of β (Theorem 26) and Definition 3, and the equality follows from the definitions of α (Theorem 13) and of H_ϵ (Lemma 21). From the second property of the claim, each subtour in W has demand at least $\alpha \cdot k$, so there are at least $\alpha \cdot |W|$ tours in OPT_3. Any tour in OPT_3 has cost at least $2 \cdot D_{\min}$, so we have

$$\mathrm{opt}_3 \geq 2 \cdot \alpha \cdot |W| \cdot D_{\min}. \quad (4)$$

[5] We add empty subtours to the first groups if needed in order to achieve equal cardinality among all groups.

From Equations (3) and (4), we have

$$\Delta_i < \frac{\epsilon}{2 \cdot H_\epsilon} \cdot \mathrm{opt}_3.$$

Summing over all integers $i \in [1, H_\epsilon]$, we have $\Delta = \sum_i \Delta_i \leq \frac{\epsilon}{2} \cdot \mathrm{opt}_3$. Thus

$$\mathrm{opt}_3 \leq \frac{2}{2-\epsilon} \cdot \mathrm{opt}_2.$$

By Theorem 23, $\mathrm{opt}_2 \leq (1+3\epsilon) \cdot \mathrm{opt}$. Therefore, $\mathrm{opt}_3 \leq (1+4\epsilon) \cdot \mathrm{opt}$. This completes the proof of Theorem 26.

Abstract

We consider the problem of reconstructing a graph G in two natural sampling models: 1) each sample corresponds to a random induced subgraph and 2) for a fixed adjacency matrix A_G for G, each sample corresponds to a random principal submatrix (i.e., a submatrix formed by deleting the same set of rows and columns) of A_G. We refer to these models as the "unordered" and "ordered" models respectively. The two models are motivated by work on the *reconstruction conjecture* in combinatorics and *trace reconstruction* in theoretical computer science. Despite the superficial similarities between the models, we show that the sample complexity of reconstruction can be exponentially different. Our main results are as follows:

- In the unordered model, we show that almost all graphs can be reconstructed with $\Theta(p^{-2}\log n)$ samples if each node is included in the random subgraph with *any* constant probability p; this is optimal. We show our upper bound extends to smaller values of p as well. In contrast, for arbitrary graphs, we show that $\exp(\Omega(n))$ samples are required for reconstruction even for 2-regular graphs. One of the key technical steps in the first result is showing that, with high probability, any subgraph isomorphism in a random graph has at most $O(\log n)$ non-fixed points.
- In the ordered model, we show that any graph with constant arboricity or degeneracy (i.e., every induced subgraph has constant average degree) can be reconstructed with $\exp(\widetilde{O}(n^{1/3}))$ samples and that arbitrary graphs can be reconstructed with $\exp(\widetilde{O}(n^{1/2}))$ samples. The results about almost all graphs in the first model carry over to the second. One of the key technical steps in the first result is showing that reconstruction of low degeneracy graphs can be reduced to learning a small number of moments of sets of the form $\{i-j : j < i, (i,j) \in E\}$ and $\{j-i : i < j, (i,j) \in E\}$ where $G = ([n], E)$ is the unknown graph.

1 Introduction

We consider the problem of reconstructing an undirected graph G on n nodes in the following two natural sampling models:

- **Unordered Model**: Each node is sampled independently with probability p. The returned sample is the induced subgraph $G[A]$ where A is the set of sampled nodes. We wish to reconstruct G *up to isomorphism*.
- **Ordered Model**: Let A_G be a fixed adjacency matrix for G. Each node is sampled independently with probability p. For each node not sampled, the corresponding row and column of A_G are deleted and the returned sample corresponds to the resulting submatrix. We wish to reconstruct A_G.

We are interested in the sample complexity of reconstruction in each model, i.e., the number of samples required to reconstruct the original graph with high probability. When $p = 1/2$, the problem in the unordered model is how many uniformly random induced subgraphs are required to reconstruct a graph. The problem in the ordered model is how many random principal submatrices (i.e., submatrices formed by symmetric row/column deletions) are required to reconstruct a symmetric binary matrix with 0s on the diagonal. We will be interested in reconstructing both arbitrary graphs and random graphs (i.e., *almost all* graphs). In the ordered model, we are also interested in reconstructing low-degeneracy graphs. Degeneracy is perhaps the most natural notion of sparsity in graphs and sparsity has played an important role in other reconstruction problems such as compressed sensing [12] and trace reconstruction [20].

Unordered Model and Reconstruction from k-Decks. Reconstruction in the unordered model is closely connected to the problem of reconstruction from k-decks. Given an undirected graph G, its *k-deck* is the multiset of all $\binom{n}{k}$ induced subgraphs on k of the vertices of G. The $(n-1)$-deck is typically referred to as just the *deck*. The Reconstruction Conjecture, due to Kelly [17] and Ulam [31], asks whether there exist two different graphs with at least three nodes, that have the same deck. Bollobas [3] proved that almost all graphs can be reconstructed by taking three graphs from its deck. Furthermore, almost all sets of three graphs from the deck of G suffice to reconstruct it. Recently, Spinoza and West [30] generalized this result to the following. Let $\varepsilon > 0$ be an arbitrarily small constant and let $\ell \leq (1-\varepsilon)n/2$. Then, almost all graphs can be reconstructed from some subset of $\binom{\ell+2}{2}$ induced subgraphs from the $(n-\ell)$-deck. Note that if a k-deck is sufficient to reconstruct a graph, then one approach to bounding the sample complexity in our problem is to analyze the sample complexity of reconstructing the k-deck; this could be done by repeatedly sampling subgraphs of the appropriate size and estimating the number of copies of each such subgraph in the graph. However, the results above suggest it might be possible to reconstruct random graphs more efficiently. Many of the above results rely on showing that for almost all graphs G, any two "large" subgraphs of G are not isomorphic. In our problem we need to consider subgraphs of G that are significantly smaller and have to bound the number of isomorphisms rather than ensuring there are none.

Ordered Model and Trace Reconstruction. There is also a natural variant of the k-deck problem for matrices where now the k-deck corresponds to the multiset of all submatrices or principal submatrices. For example, reconstruction from such k-decks was studied by Kós et al. [18] and they showed that the $O(n^{2/3})$-deck was sufficient for reconstruction. Our problem in the ordered model can be thought of a stochastic variant of this problem.

Our problem is also closely related to the *trace reconstruction* problem. In this problem the goal is to reconstruct an unknown binary string $x \in \{0,1\}^n$ from independent random subsequences, or "traces", where each subsequence is formed by deleting each bit with probability $q = 1 - p$ and then concatenating the remaining bits. The trace reconstruction problem was first proposed by Batu et al. [2]. Since then, the problem attracted a lot of attention and ended up branching out into several directions and variants [4, 10, 10, 11, 13–16, 20–22, 26, 27, 29, 32]. The best upper and lower bounds known for this problem are $\exp(\widetilde{O}(n^{1/5}))$ and $\widetilde{\Omega}(n^{2/3})$ traces respectively, and were both proved recently by Chase [6, 7]. Our approach for reconstructing arbitrary graphs is very similar to the approach in [20, 27], but the result on reconstructing low-degenerary graphs requires combining those ideas with a "peeling" approach that iteratively reconstructs the neighborhood of low degree nodes, removes these nodes, and recurses on the remaining graph.

There is a natural variant of the classical string trace reconstruction problem where we have an unknown $n \times n$ binary matrix, and each trace is a sub-matrix obtained by deleting each row and column independently with probability q. The best known upper bound for this variant is $\exp(\widetilde{O}(n^{1/2}))$ traces [20]. The matrix variant is different from the string version because there are now dependencies between the bits that are deleted. The matrix variant is very closely related to the ordered model we consider; the only slight difference is that in the ordered model there is the symmetric constraint when deleting rows and columns of the adjacency matrix. There has also recently been work on tree reconstruction [4, 10, 21] that, although related somewhat to our work, primarily deals with different models of deletion channels that are only defined for rooted trees. There have been recent advances in a "smoothed" variant of the problem where each bit of the string is replaced by a uniform random bit with some probability [8]. Another variant, *coded* trace reconstruction, involving efficiently encodable codes that can be recovered despite some constant probability of edit errors, has also been studied extensively [5, 9, 10]. A generalized formulation of the problem where instead of a single unknown string, we draw a string at random from some distribution over strings and pass it through a deletion channel, has also garnered some recent interest [1, 25]. Note that in both the ordered and unordered model, the main challenge to reconstruction is that the nodes are not labelled. However, we note that are also other interesting reconstruction problems arising in the context of labelled graph, see e.g., Mossel and Ross [23], but these consider very different models from those considered here.

1.1 Our Results

1. **Unordered Model:** We show that for almost all graphs, $\Theta(p^{-2} \log n \log(1/\delta))$ traces (where in this model a trace is a randomly induced subgraph) suffice for reconstruction with probability at least $1 - \delta$, as long as the retention probability p is $\widetilde{\Omega}(1/n^{1/6})$. Note that this is optimal for the range of p considered since $\Theta(p^{-2} \log n)$ traces are required to ensure every edge appears in at least one trace.[1] In contrast, we show that reconstructing arbitrary graphs is hard: even distinguishing between a pair of 2-regular graphs may require $\exp(\Omega(n))$ traces. We show, however, that if the maximum degree of G is at most one, then it can be reconstructed with $\Theta(n)$ traces. One of the key technical steps in the first result is showing that, with high probability, any subgraph isomorphism in a random graph has at most $O(\log n)$ non-fixed points. This contrasts with a classic result by Müller [31] that shows that there are isomorphic subgraphs (where the isomorphism may contain an unbounded number of non-fixed points) of size $n/2$ but no isomorphic subgraphs of size $n(1 + \varepsilon)/2$ for any constant $\varepsilon > 0$.
2. **Ordered Model:** Our main result in the ordered model is that $\exp(\widetilde{O}(n^{1/3}))$ samples (i.e., a random principal submatrix of the adjacency matrix) suffice to reconstruct graphs of constant degeneracy, as long as the retention probability p is a constant. Recall that the *degeneracy* of a graph is the smallest $k \in \mathbb{N}$ such that every induced subgraph has a vertex of degree at most k.[2] One of the key technical steps in the first result is showing

[1] This follows by considering a graph that consists of $n/2$ vertex-disjoint edges. The edges of such a graph appear in a trace independently of one another. Hence, the probability that every edge appears in at least one of t traces is $(1 - (1 - p^2)^t)^{n/2}$ and this is at most $(1 - 2/n)^{n/2} \leq 1/e$ if $t < \log_{1-p^2}(2/n) = \Omega(\log(n)/p^2)$.

[2] Note that the degeneracy of a graph is constant factor related to the arboricity of the graph. It is a robust notion of the sparsity of a graph in that it ensures that the induced subgraph on any r nodes

that reconstruction of low degeneracy graphs can be reduced to learning a small number of moments of sets of the form $\{i-j : j < i, (i,j) \in E\}$ and $\{j-i : i < j, (i,j) \in E\}$. These moments can then be learned via an extension of methods from complex analysis that have been developed for the trace reconstruction problem. Our results represents a strong separation between sample complexity of reconstruction in the ordered and unordered models since 2-regular graphs are a special case of low degeneracy graphs. Finally, we show that any graph can be reconstructed with $\exp(\widetilde{O}(n^{1/2}))$ traces. The upper bound is established via a slight modification of a result by Krishnamurthy et al. [20]; they considered independent row/column deletions and the modification is required to deal with the fact that in our setting a row is deleted iff the corresponding column is deleted.

2 Reconstruction of Almost All Graphs in the Unordered Model

For reconstructing almost all graphs in the unordered model, the high level approach is:

1. Determine a *consistent* labeling of all nodes in the traces such that two nodes receive the same label iff they correspond to the same node in the unknown graph G. Determining this labelling will be the main technical challenge in our approach and it is especially challenging in the unordered model (compared to the ordered model) because there is no apparent ordering of the nodes that are observed in a trace.
2. If each pair of nodes of G appears together in some trace, we know whether or not there exists an edge between these two nodes. Note that

   $$T := 3p^{-2} \log n$$

   traces are sufficient to ensure this second condition with high probability.[3]

The natural question is how to determine a consistent labeling. We do this by considering all pairs of traces and for each node in the first trace of the pair we determine which node, if any, it corresponds to in the second trace. If we do this for all pairs of traces and every node of G appears in at least one trace, then for each node of G we identify all of its occurrences amongst the traces. Hence, the problem of finding a consistent labeling reduces to the problem of finding corresponding nodes in two traces.

How do we find and label corresponding nodes between two traces? Suppose one trace is the induced subgraph on a set of nodes A and the second trace is the induced subgraph on a set of nodes B. To find the corresponding nodes, a possible approach is the find the largest subgraph in $G[A]$ that is isomorphic to a subgraph in $G[B]$. If this subgraph were $G[A \cap B]$ *and* $G[A \cap B]$ were asymmetric, i.e., had no non-trivial automorphisms, then this would allow us to identify corresponding nodes. If G is random, there is indeed reason to hope that $G[A \cap B]$ is the largest common subgraph. In fact, if the probability p used in the generation of the traces is strictly greater than $1/\sqrt{2}$ we can show that this approach works exactly as stated, via a classic graph theory result by Müller [24]. His result establishes that for any constant $\varepsilon > 0$, for almost every graph G, the induced subgraphs with at least $(1+\varepsilon)n/2$ vertices have no nontrivial automorphisms and are pairwise non-isomorphic. We omit the details as we will instead prove a more general result that applies even when $p < 1/\sqrt{2}$. To

has $O(r)$ edges.

[3] Throughout this paper, we will mean a "high probability" bound to be one that holds with probability $1 - 1/\text{poly}(n)$. In this case, the high probability bound follows because the probability that there exists a pairs of nodes that does not appear up in the same trace is at most $\binom{n}{2}(1-p^2)^T \leq n^2 e^{-p^2 T}$.

prove the more general result, in the next section we will define a family of graphs called *distinctive graphs* and prove that a random graph is distinctive with high probability. In the following section, we show that it is possible to find corresponding nodes between two traces with high probability if the graph G is distinctive. This will require more than just finding the largest pair of isomorphic subgraphs, as described below.

2.1 Active Isomorphisms and Distinctive Graphs

Strengthening Müller's result to apply to subgraphs of size less than $n/2$ would give a possible approach to finding corresponding nodes when $p < 1/\sqrt{2}$. Unfortunately this is not possible: a random graph contains two isomorphic subgraphs on $n/2$ nodes with probability at least $1/2$. For example, for any pair of nodes u and v, $G[C \cup \{u\}] \cong G[C \cup \{v\}]$ where C consists of nodes that are neighbors of both u and v or neighbors of neither, and the expected size of $C \cup \{u\}$ is $n/2$. However, note that the isomorphism in this example will consist almost entirely of fixed points. And indeed, this turns out to be a constraint that we can leverage to our benefit: if we disallow isomorphisms with many fixed points, we can break the $n/2$ barrier in Müller's result.

▶ **Definition 1** (Active Isomorphisms). *Given a graph G and two subsets A, B of vertices, say A and B have an* active isomorphism *if there exists an isomorphism between $G[A]$ and $G[B]$ with no fixed points. Say G has an* active subgraph isomorphism of size M *if there exist vertex subsets A and B with $|A| = |B| = M$ with an active isomorphism.*

We next show that a random graph drawn from $\mathcal{G}(n, 1/2)$ is unlikely to have large active subgraph isomorphisms.

▶ **Theorem 2.** *For all sufficiently large n, with high probability, a random graph on n vertices has no active subgraph isomorphisms of size $M = 20 \log n$.*

Proof. Let G be a random graph drawn from $\mathcal{G}(n, 1/2)$, and let $A, B \subseteq V(G)$ be subsets of size M and let $\varphi : A \to B$ be a bijection that has no fixed points. Consider the pairs $\mathcal{A} := \{\{a_1, a_2\} : a_1, a_2 \in A, a_1 \neq a_2\}$ and $\mathcal{B} := \{\{b_1, b_2\} : b_1, b_2 \in B, b_1 \neq b_2\}$. Note that φ naturally induces a bijection φ' from $\mathcal{A}$ to $\mathcal{B}$. Each vertex pair $\mathcal{A}$ is either an edge or a non-edge; we think of these as the two *types* of pairs. The map φ is an isomorphism precisely when φ' preserves types. Note that while φ has no fixed points, φ' may have fixed points. In particular, $\{u, v\}$ is a fixed point of φ' iff $\varphi(u) = v$ and $\varphi(v) = u$. Hence, if t is the number of non-fixed points of φ', it follows that $t \geq \binom{M}{2} - M/2$. Define a directed graph $\mathcal{G}$ on the vertex set $\mathcal{A} \sqcup \mathcal{B}$ with:

- An arc from $\{u, u'\} \in \mathcal{A}$ to $\{v, v'\} \in \mathcal{B}$ if $\varphi'(\{u, u'\}) = \{v, v'\}$.
- An arc from $\{v, v'\} \in \mathcal{B}$ to $\{w, w'\} \in \mathcal{A}$ if $\{v, v'\} = \{w, w'\}$.

See Figure 1 for an example. Since each node has out-degree and in-degree at most 1 (where every node in $\mathcal{A}$ has out-degree exactly 1), $\mathcal{G}$ is a disjoint union of even cycles and odd paths that start in $\mathcal{A}$ and end in $\mathcal{B}$. For φ to be an isomorphism, all nodes in the same connected component of $\mathcal{G}$ must have the same type. If the component is a path with k nodes in $\mathcal{B}$, the probability all nodes of the component have the same type is $1/2^k$. If the component is a cycle with k nodes in $\mathcal{B}$, the probability is $1/2^{k-1}$. Hence, the probability of φ being an isomorphism is $1/2^{|\mathcal{B}|-c}$ where c is the number of cycles. Note that there are at most $|\mathcal{B}| - t$ cycles with exactly one node in $\mathcal{B}$ and the rest have at least two nodes in $\mathcal{B}$. Hence, $(|\mathcal{B}| - t) + 2(c - |\mathcal{B}| + t) \leq |\mathcal{B}|$ and this implies $|\mathcal{B}| - c \geq t/2$. Hence, the probability φ is an isomorphism is at most $1/2^{t/2}$.

The probability of A and B having an active isomorphism is bounded above by the total number of bijections from A to B with all points non-fixed, times the probability of such a bijection being an isomorphism, which is bounded above by $M! \cdot 2^{-t/2} \leq 2^{M \log M - t/2} \leq 2^{M \log M - \frac{1}{2}\binom{M}{2} + M/4}$. Taking the union bound over all subgraphs of size M still gives $\binom{n}{M}^2 \cdot 2^{M \log M - \frac{1}{2}\binom{M}{2} + M/4} \leq 2^{3M \log n + M/4 - \frac{1}{2}\binom{M}{2}} = 2^{-40 \log^2 n + 10 \log n} \leq 2^{-30 \log^2 n} = n^{-\Omega(\log n)}$. ◀

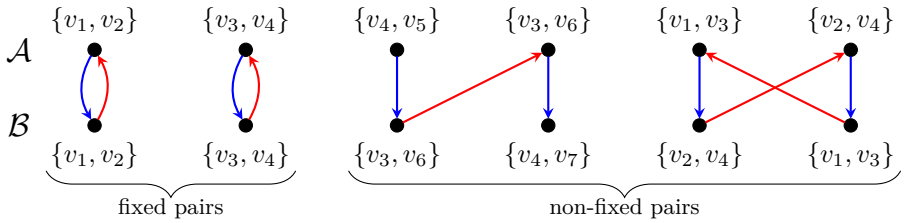

Figure 1 A construction from the proof of Theorem 2. Here, the blue arcs represent the isomorphism φ' between pairs in $\mathcal{A}$ and pairs in $\mathcal{B}$, while red arcs represent the *same* pair of vertices.

▶ **Corollary 3** (Extension to Müller). *For all sufficiently large n, with high probability, there are no two isomorphic subgraphs of a random n-vertex graph G for which the isomorphism has $20 \log n$ or more non-fixed points.*

Proof. Theorem 2 immediately implies there does not exist a subgraph isomorphism with more than M non-fixed points because a subgraph isomorphism with M non-fixed points implies the existence of a size M active subgraph isomorphism. ◀

Suppose a graph G has a subgraph H that has no nontrivial automorphisms. We can now fix a *canonical* ordering τ of $V(H)$, and define the *signature* of a vertex $v \in V(G)$ with respect to H as the length-$|V(H)|$ binary vector whose ith entry is 1 if and only if v is adjacent to the ith vertex of H in the ordering τ. For a fixed asymmetric subgraph H, we say vertices $u, v \in V(G)$ are *distinguishable with respect to H* if and only if they have distinct signatures with respect to H.

▶ **Definition 4** (Distinctive Graphs). *We say that a graph G on n vertices is* distinctive *if the following conditions are met:*

1. *Any subgraph of G on $200 \log n$ or more vertices is asymmetric.*
2. *For any two subsets $A, B \subseteq V(G)$ satisfying $G[A] \cong G[B]$, there are at most $200 \log n$ non-fixed points in the isomorphism between them.*
3. *For all but a $1/n$ fraction of subgraphs H of G with $|V(H)| \geq 200 \log n$, the vertices in $V(G)$ are pairwise distinguishable with respect to H.*

Note that the isomorphism in the second condition in the definition is well-defined and unique, because $G[A]$ and $G[B]$ of size more than $200 \log n$ are asymmetric by the first condition; similarly, the third condition is well-defined, because H is asymmetric, also by the first condition.

▶ **Theorem 5.** *Almost all graphs are distinctive.*

Proof. Consider a random graph G. The probability that any particular k-node random subgraph has a non-identity isomorphism is at most $2^{k \log k - k^2/100}$ (see e.g. Theorem 3.1 in [28]). Taking the union bound over all $\binom{n}{k}$ subgraphs of G and all possible sizes of the subgraph from k to n, the probability of G having a non-asymmetric subgraph on k or more vertices is at most $2^{\log n(1+2k)+k-k^2/100}$, which is $1/\text{poly}(n)$ for $k \geq 200 \log n$. The second follows directly from Corollary 3 above. The third is due to the following counting argument. Fix a random subgraph H of G of size at least $200 \log n$. For a fixed $v \in V(G)$, the probability of there being an edge to any given vertex of H is $1/2$, and these are independent for different vertices v. Therefore, the signature of a vertex v with respect to a fixed H corresponds to a uniformly random binary string if $v \notin H$. If $v \in H$, the string is uniformly random aside from the index corresponding to v, which is deterministically 0. The probability that two of these signatures match is at most $2^{-|V(H)|+1} \leq 2^{-200 \log n+1} \leq n^{-199}$. Therefore, by the union bound, the probability that two vertices in G have the same signature with respect to H is at most $\binom{n}{2}/n^{199} \leq 1/n^{197}$. Therefore, the expected fraction of random subgraphs H of size at least $200 \log n$ with the property that there are two distinct vertices that are indistinguishable with respect to H is at most $1/n^{197}$. The probability this fraction exceeds $1/n$ is at most $1/n^{196}$ by an application of the Markov bound. ◀

2.2 Reconstruction of Distinctive Graphs

Let G be a distinctive graph on n vertices. In this section, we will show an upper bound on the sample complexity of reconstructing G from uniformly random induced subgraphs, obtained by retaining each vertex independently with probability $p \geq 12n^{-1/6} \log^{2/3} n$. Recall that if we take $T := 3p^{-2} \log n$ samples uniformly at random, then we see each pair of vertices appear together in *some* trace.

Consider first just two such random induced subgraphs $G[A]$ and $G[B]$ where A and B are subsets of the nodes formed independently by sampling each node in G with probability p. Let H be the largest graph that appears as an induced subgraph of both $G[A]$ and $G[B]$. Let $A' \subseteq A$ and $B' \subseteq B$ be the nodes in A and B that induce H. Note that it could be that $A' = B' = A \cap B$, but while $G[A \cap B]$ is a subgraph of both $G[A]$ and $G[B]$, we do not know if it is the largest subgraph that appears in both. However, since $|A'| = |B'| \geq |A \cap B|$ and $\mathbb{E}[|A \cap B|] = p^2 n \gg 200 \log n$ by our choice of p we know $|A'| = |B'| \geq 200 \log n$ with high probability. Then, by Distinctive Property 1, we can assume that $G[A']$ and $G[B']$ are asymmetric and that there is a unique isomorphism φ between the copy of H in $G[A]$ and the copy of H in $G[B]$.

Let us now subsample the vertices in $G[A']$ with probability

$$\alpha := \frac{1}{1200T^2 \log n},$$

and call the resulting set of vertices $C' \subset A'$. Observe that the number of vertices not fixed by φ is at most $200 \log n$ by Distinctive Property 2. So by Markov's inequality, the probability that we subsample such a non-fixed point is at most $200\alpha \log n$. So with probability at least $1 - 200\alpha \log n$, the set C' consists entirely of fixed points in φ and is therefore entirely in the intersection $A \cap B$.

Let $\mathcal{D}_{C'}$ be the distribution of C', i.e., we sample A, find H, and then subsample the nodes of H. For the sake of analysis, suppose we can identify the nodes in $A \cap B$ and let C be the set formed by sampling from $A \cap B$ with probability α. Let $\mathcal{D}_C$ be the distribution of C. Both the definition of $\mathcal{D}_{C'}$ and $\mathcal{D}_C$ is with respect to some fixed A and B.

▶ **Theorem 6.** *The variational distance between $\mathcal{D}_C$ and $\mathcal{D}_{C'}$ is at most $200\alpha \log n$.*

Proof. Let $x, y \in \{0,1\}^{|(A\cap B)\cup A'|}$ be the characteristic vectors of C and C' respectively, where we have padded each of their domains up with zeros if necessary, for notational convenience. Let $\gamma_i(b) := \mathbb{P}(x_i = b)$ and $\beta_i(b) := \mathbb{P}(y_i = b)$ where $b \in \{0,1\}$. Define $S_1 := A \cap B$, and $S_2 := A'$. Then, $\ell_1(\mathcal{D}_C, \mathcal{D}_{C'})$ is

$$\begin{aligned}
&\sum_{z\in\{0,1\}^{|(A\cap B)\cup A'|}} \left|\prod_i \gamma_i(z_i) - \prod_i \beta_i(z_i)\right| \\
&\leq \sum_i \sum_{b\in\{0,1\}} \left|\gamma_i(b) - \beta_i(b)\right| \\
&= \sum_{i\in S_1\cap S_2} \sum_{b\in\{0,1\}} \left|\gamma_i(b) - \beta_i(b)\right| + \sum_{i\in S_1\setminus S_2} \sum_{b\in\{0,1\}} \left|\gamma_i(b) - \beta_i(b)\right| \\
&\quad + \sum_{i\in S_2\setminus S_1} \sum_{b\in\{0,1\}} \left|\gamma_i(b) - \beta_i(b)\right|.
\end{aligned}$$

where the first inequality follows from the fact the ℓ_1-distance between two product distributions is at most the sum of the ℓ_1 distance between the marginals.[4]

Of these, the first term vanishes, as the inner difference is zero, whereas the two other terms are bounded by 2α for each term, giving us $\ell_1(X, Y) \leq 2\alpha(|S_1 \setminus S_2| + |S_2 \setminus S_1|) \leq 2\alpha \cdot 200 \log n$. Since the variational distance is half the ℓ_1-distance, the stated result follows. ◀

▶ **Corollary 7.** *If $p \geq 12n^{-1/6}\log^{2/3} n$, then with probability at least $1 - 400\alpha \log n$ (where the probability is taken over the choice of A, B and the subsampling of A), C' satisfies the condition in distinctive property 3.*

Proof. Let S be the event that the graph we draw satisfies Distinctive Property 3. Then, by Theorem 6, we know $\mathbb{P}_{\mathcal{D}_C}(S) - \mathbb{P}_{\mathcal{D}_{C'}}(S) \leq \|\mathcal{D}_C - \mathcal{D}_{C'}\|_{TV} \leq 200\alpha \log n$. Recall that $T = 3p^{-2}\log n$ and $\alpha = 1/(1200T^2 \log n)$. Therefore,

$$\mathbb{E}[|C|] = p^2 n\alpha = \frac{p^2 n}{1200T^2 \log n} = \frac{p^2 n \cdot p^4}{1200 \cdot 9\log^2 n \cdot \log n} > 250 \log n$$

for $p \geq 12n^{-1/6}\log^{2/3} n$. By an application of the Chernoff bound, $|C| \geq 200 \log n$ with high probability. Because G is distinctive, this implies that C satisfies the condition in Distinctive Property 3. Note that for $p = \widetilde{\Omega}(n^{-1/6})$, we have $200\alpha \log n = \widetilde{\Omega}(n^{-2/3}) \gg 1/n$, and so it follows that $P_{\mathcal{D}_{C'}}(S)$ is at least $1 - 1/n - 200\alpha \log n \gg 1 - 400\alpha \log n$. So, with the stated probability, C' satisfies the property of condition 3. ◀

This gives rise to our main result, the following algorithm for reconstructing G.

▶ **Theorem 8.** *Let G be a distinctive graph on n vertices and $\delta > 0$. We can reconstruct G with probability at least $1 - \delta$ from $\Theta(p^{-2} \cdot \log n \cdot \log(1/\delta))$ traces, when the retention probability p satisfies $p = \widetilde{\Omega}(n^{-1/6})$.*

---

[4] This can be verified via induction of the number of marginals since by the triangle inequality:

$$\left|\prod_{i\geq 1}\gamma_i(z_i) - \prod_{i\geq 1}\beta_i(z_i)\right| \leq \left|\prod_{i\geq 1}\gamma_i(z_i) - \alpha_1(z_1)\prod_{i\geq 2}\beta_i(z_i)\right| + \left|\alpha_1(z_1)\prod_{i\geq 2}\beta_i(z_i) - \prod_{i\geq 1}\beta_i(z_i)\right|.$$

where the second term when summed over z equals the ℓ_1 distance between the first marginal and we apply the induction hypothesis to the first term.

Proof. The proof relies on the following observation. Suppose that for *any* two traces G_1 and G_2, and any vertices $x \in G_1$ and $y \in G_2$, we can identify whether or not x and y are the "same" in the sense of corresponding to the same original vertex in G. Now, if we have enough traces so that each vertex in the original graph G appears in at least one of them, then we can *consistently* cluster all the vertices in all the traces into n clusters, with the vertices in each cluster corresponding to the same vertex in G. These clusters give rise to a "labeling" of the nodes in the traces with labels 1 through n. If now, in addition, each *pair* of vertices in G appear together in some trace, we have a way of identifying whether there is an edge between the pair of nodes in G, and therefore we can recover the isomorphism class of G, which is equivalent to reconstructing G in the unordered setting. This corresponds to the approach highlighted in the high level description at the start of this section.

Formally, we have the following algorithm for reconstructing G given $T = 3p^{-2}\log n$ random induced subgraphs of G. For any two of these subgraphs, we can find the largest common subgraph to both of them, and then subsample from it with probability α as defined above. By Corollary 7, this subsampled subgraph satisfies the third distinctive property with high probability, and so we can use it to obtain the signatures of all vertices in $A \cup B$, enabling us to label the two sampled subgraphs consistently with respect to each other. With high probability, every pair of vertices will appear together in one of the sampled subgraphs. Therefore, as long as we have a consistent labeling of all vertices in these subgraphs with respect to each other, we will have a consistent labeling of the entire graph G, and therefore be able to reconstruct it.

The probability of this happening, by union bounding over the at most T^2 pairs of random subgraphs we generated, is at least $1 - 400T^2\alpha\log n = 1 - 400T^2\log n \cdot \frac{1}{1200T^2\log n} = 1 - \frac{1}{3} = 2/3$. We can now reduce the failure probability to δ by repeating the process $O(\log 1/\delta)$ times and taking the most commonly reconstructed graph. This requires an additional factor of $O(\log 1/\delta)$ in the number of traces. ◀

▶ **Corollary 9.** *Let n be a sufficiently large integer and $p = \widetilde{\Omega}(n^{-1/6})$. For almost all n-node graphs, $\Theta(p^{-2} \cdot \log n \cdot \log(1/\delta))$ traces suffice for reconstruction with probability at least $1 - \delta$.*

3 Reconstruction of Arbitrary Graphs in the Unordered Model

We next consider reconstructing arbitrary graphs and show that even distinguishing two fixed graphs may require $2^{\Omega(n)}$ random induced subgraphs, highlighting the vast gap between random graphs and arbitrary graphs. In fact the lower bound even applies to distinguishing between two graphs with maximum degree 2. This immediately implies a lower bound for reconstruction. Note that for any constant p, the entire graph is selected as a random subgraph with probability p^n and therefore $O(1/p^n) = 2^{O(n)}$ is a trivial upper bound on the sample complexity for full reconstruction. So the following lower bound establishes that this trivial upper bound is optimal.

▶ **Theorem 10.** *Distinguishing the cycle C_{2n} with high probability from two disjoint copies of the cycle C_n requires $2^{\Omega(n)}$ traces in the unordered model.*

Proof. Let D_1 be the distribution over subgraphs generated when the original graph is C_{2n}. Let D_1' be the distribution conditioned on the event A that we now define. Partition the vertices of C_{2n} into n pairs of "opposite" nodes (i.e. pairs of nodes at a distance exactly n from each other). Let A be the event that there exists an opposite pair in which both nodes are deleted. Note that $\Pr(A) = 1 - (1-q^2)^n$ where q is the deletion probability.

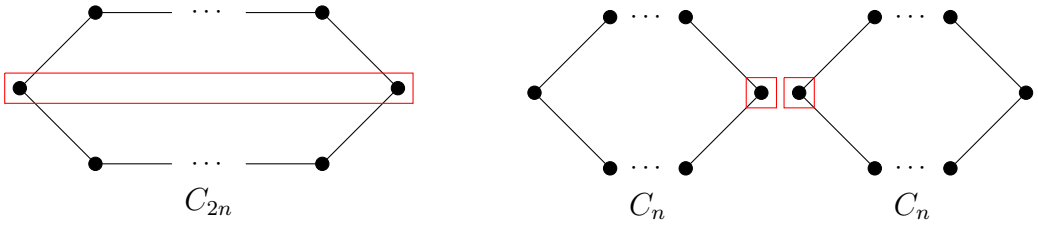

Figure 2 The construction for the proof of Theorem 10. The event A is the deletion of a pair of "opposite" nodes, such as the pair shown in red on the left; the even B is the deletion of a pair of nodes, one from each of the cycles, such as the pair shown in red on the right. Observe that these two events leave us with the same graph.

Now suppose the input graph is two copies of C_n. Let D_2 be the distribution over subgraphs generated. Let D_2' be the distribution conditioned on the following event B. Partition the vertices into pairs of nodes where each pair consists of exactly one node from each C_n. Let B be the event that there exists a pair in which both nodes are deleted. Note that $\Pr(B) = 1 - (1-q^2)^n$. Therefore, by the triangle inequality, we can bound the total variational distance between D_1 and D_2 as follows:

$$\|D_1 - D_2\|_{TV} \leq \|D_1 - D_1'\|_{TV} + \|D_1' - D_2'\|_{TV} + \|D_2' - D_2\|_{TV} = O(\Pr(\overline{A}) + \Pr(\overline{B})) = 2^{-\Omega(n)}$$

where we used the fact that $D_1' = D_2'$ and substituted $q = 1/2$. Hence, we need at least $2^{\Omega(n)}$ samples to distinguish between D_1 and D_2. ◀

It is worth remarking here that we needed degree-2 graphs for the example in Theorem 10, as evidenced by the following observation, which we state as a theorem.

▶ **Theorem 11.** *For any $\delta > 0$, a graph with maximum degree one can be reconstructed with probability at least $1 - \delta$ in $\Theta(n \log(1/\delta))$ samples.*

Proof. A graph with maximum degree one is a matching and some isolated vertices. It suffices, therefore, to learn the size $k \leq n/2$ of the matching. This size in the random subgraph is distributed as $\mathrm{Bin}(k, 1/4)$. But the unknown value k can be determined by taking the average matching observed over $t = O(n)$ traces. Specifically, let X be defined to be the average matching size. Then, because k is an integer, if we have $|X - k/4| < 1/8$, then $4X$ rounded to the nearest integer is exactly k. We have $\mathbb{E}[X] = k/4$ and $\mathbb{V}[X] \leq k/(4t)$. Hence, by Chebyshev's inequality, we have $\Pr[|X - k/4| \geq 1/8] \leq \frac{k/(4t)}{1/8^2} \leq 1/10$, where $t = cn$ for some sufficiently large constant c. We can boost the probability up as before for an additional $\log(1/\delta)$ factor. ◀

4 Reconstruction of Low Degeneracy Graphs in the Ordered Model

In this section, we turn our attention to the *ordered* model. We show that the sample complexity of reconstructing graphs with constant degeneracy is $\exp(\widetilde{O}(n^{1/3}))$, as long as the retention probability p is a constant. Recall that the *degeneracy* of an undirected graph is the smallest value d such that every induced subgraph has a node of degree at most d. Note that the degeneracy is within a factor 2 of the *arboricity*, i.e., the minimum number of forests into which its edges can be partitioned. Hence, the result applies to a natural and large class of graphs, that includes all trees, planar graphs, and indeed, all graphs of bounded treewidth.

4.1 Discussion of Challenges

Given a graph G and its adjacency matrix A, let us first consider what happens structurally to the matrix A when we pass it through a deletion channel. For instance, consider the degree sequence, viewed as the sequence of row weights of the matrix A. Of course, the number of terms in the degree sequence in general decreases (and we would expect about pn terms to survive in expectation), but observe that the terms that do survive may also change in *value*. In fact, each surviving vertex v now contributes a term to the degree sequence that is drawn from the distribution $\mathrm{Bin}(\deg(v), p)$. However, the *value* of a particular element of the degree sequence in the trace is not in general independent of its *position* within that trace. This is because the decrease in its value is not independent of the total number of neighbors that are deleted in the channel. The *shift* in position, on the other hand, is only dependent on the number of neighbors that appear *before* the corresponding row that are deleted. This is the main difficulty that our approach circumvents.

4.2 The Offset Method

We assume that we have a fixed n-vertex graph G with a fixed adjacency matrix A. For any vertex $i \in [n]$, we define the *backward* and *forward offsets*.

$$A_{\leftarrow}(i) = \{i - j : j < i, (i,j) \in E\} \qquad A_{\rightarrow}(i) = \{j - i : i < j, (i,j) \in E\}$$

For example, if

$$A = \begin{pmatrix} 0 & 1 & 0 & 0 \\ 1 & 0 & 1 & 1 \\ 0 & 1 & 0 & 1 \\ 0 & 1 & 1 & 0 \end{pmatrix}$$

then we have backward offsets $A_{\leftarrow}(1) = \varnothing$, $A_{\leftarrow}(2) = \{1\}$, $A_{\leftarrow}(3) = \{1\}$, and $A_{\leftarrow}(4) = \{1, 2\}$, and forward offsets $A_{\rightarrow}(1) = \{1\}$, $A_{\rightarrow}(2) = \{1, 2\}$, $A_{\rightarrow}(3) = \{1\}$, and $A_{\rightarrow}(4) = \varnothing$. Of course, $A_{\leftarrow}(1) = A_{\rightarrow}(n) = \varnothing$ for any adjacency matrix.

Let $a_{i,k} = \sum_{x \in A_{\leftarrow}(i)} x^k$ and $b_{i,k} = \sum_{x \in A_{\rightarrow}(i)} x^k$, where by convention we set $0^0 = 0$ and $1^0 = 1$. These are the *offset moments of order* k for vertex i. Note that $a_{i,0} + b_{i,0}$ is the degree of vertex i.

We need the following result due to Krasikov and Roddity, whose proof follows from Corollaries 2.4 and 2.5 in [19].

▶ **Theorem 12** (Krasikov-Roddity, 1997). *Let $S = \{u_1, \ldots, u_d\}$ be any subset of $\{0, 1, \ldots, n-1\}$ of size d. Then, S is uniquely determined by the system*

$$u_1^r + \ldots + u_d^r = n_r, \quad r = 1, \ldots, d.$$

Now we state the core idea of our proof, which relies on the following observation about the quantities $\{a_{i,k}\}$ and $\{b_{i,k}\}$ that we just defined.

▶ **Theorem 13.** *Let G have degeneracy d. Then, the values $\{a_{i,k}\}_{i \in [n]}$ and $\{b_{i,k}\}_{i \in [n]}$ for $k = 0, \ldots, d$ uniquely determine G. In other words, reconstructing $\{a_{i,k}\}$ and $\{b_{i,k}\}$ with high probability suffices to reconstruct G with high probability.*

Proof. We use induction on the number of non-isolated nodes. The base case when the number of non-isolated nodes is 0 is trivial. Suppose the Theorem is true when there are up to t non-isolated nodes. Let G be a d-degenerate graph with $t + 1$ non-isolated nodes. There

exists a node i with degree at most d, with backward and forward offsets $A_{\leftarrow}(i)$ and $A_{\rightarrow}(i)$ respectively, and offset moments $a_{i,k}$ and $b_{i,k}$ for $k = 0, \ldots, d$. By Theorem 12, given $a_{i,k}$ and $b_{i,k}$ we can reconstruct $A_{\leftarrow}(i)$ and $A_{\rightarrow}(i)$.

The idea is to identify this vertex i and reconstruct its neighbors, and induct on the remaining graph with these edges between node i and its neighbors removed. Clearly, i is identifiable from the zeroth moment. Let G' be the graph formed by removing all edges incident to i. For all remaining vertices j, let $a'_{j,k}$ and $b'_{j,k}$ be the corresponding offset moments. Observe that $a'_{j,k}$ and $b'_{j,k}$ can be computed from i, $a_{j,k}$, $b_{j,k}$, $A_{\leftarrow}(i)$, and $A_{\rightarrow}(i)$; furthermore, G' itself is a d-degenerate graph with at most $t-1$ non-isolated nodes, and so by induction, there is no other such graph with $t-1$ non-isolated nodes with the same offset moments. We can now reconstruct G' precisely by induction, and add in the missing edges from vertex i using $A_{\leftarrow}(i)$ and $A_{\rightarrow}(i)$. ◀

▶ Remark 14. Note that the quantities $a_{i,k}$ and $b_{i,k}$ for $k = 0, 1, \ldots, d$ would suffice to learn the neighborhood of node i directly (given Theorem 12) if the degree of node i were at most d, and we could bypass induction altogether. But if the degree is strictly bigger than d, we would have to first reconstruct other parts of the graph so that, after doing so, there are at most d unknown edges incident to i. This is where the inductive argument becomes necessary.

We now state the main result of this section. We relegate the somewhat technical proof to the next subsection. This proof uses similar complex analytic techniques as in [27], which are now standard in the literature, which involve bounding the values of Littlewood polynomials on the unit circle in the complex plane. In our case, crucially, we need to understand how the moments behave, which requires additional work.

▶ **Theorem 15.** *$\{a_{i,k}\}_{i\in[n]}$ and $\{b_{i,k}\}_{i\in[n]}$ can be reconstructed with high probability using $\exp(\widetilde{O}(d^{2/3}n^{1/3}))$ traces.*

4.3 Computing Offset Moments: Proof of Theorem 15

Recall that p and q are the retention and deletion probability respectively, so that $p + q = 1$. In this subsection, we make a simplification: if $p \in (1/m, 1/(m-1)]$ for some integer m, we assume, without loss of generality, that $p = 1/m$. This makes the analysis easier. Of course, given a deletion channel corresponding to retention probability p, we can always manually simulate one with any lower retention probability, so this is a valid assumption.

Recall that the object of interest in this subsection is the kth moment, where k can go up to the degeneracy d, which suffices by Theorem 13. We denote by $\widetilde{a}_{j,k}$ and $\widetilde{b}_{j,k}$ the *observed* (i.e., sampled) values of $a_{j,k}$ and $b_{j,k}$ respectively from our traces. Consider the polynomial $\sum_{i\geq 1} b_{i,k}w^{i-1}$, and consider its expected value when we look at the trace from the deletion channel. We have, by linearity of expectation,

$$\mathbb{E}\left[\sum_{i\geq 1}\widetilde{b}_{i,k}w^{i-1}\right] = \sum_{i\geq 1} w^{i-1}\mathbb{E}[\widetilde{b}_{i,k}]. \tag{1}$$

Consider the event that the ith row of the trace comes from the jth row of the original adjacency matrix A, for some $i \leq j \leq n$. This happens precisely when exactly $i-1$ of the first $j-1$ rows are retained, and the jth row is also retained, which happens with probability $\binom{j-1}{i-1}p^i q^{j-i}$. However, the *value* of $b_{j,k}$ changes as well, which we need to account for.

To analyze this change, the first key thing to observe is that the shift in the eventual position of $b_{j,k}$ is independent of the change in its value; the former is a function of the rows *before* j that are deleted, while the latter is a function of the rows *after* j that are deleted, and we assert independence in the deletion probability of each row.

It remains to analyze the expected value of $b_{j,k}$ after A is passed through the deletion channel. Recall that $b_{j,k} = \sum_{x \in A_{\rightarrow}(j)} x^k$, the sum of kth powers of the forward offsets in row j. Now, for a given offset x in the row under consideration, it survives with probability p, and if so, ends up as the offset $1+y$, where y is a random variable that follows a $\mathrm{Bin}(x-1,p)$ distribution, since each of the $x-1$ columns between the diagonal and the original offset can be deleted with probability p. Therefore, the value of $b_{j,k}$ is

$$\sum_{x \in A_{\rightarrow}(j)} p(1+y)^k, \tag{2}$$

where $y \sim \mathrm{Bin}(x-1,p)$. Since each offset is bounded above by n, and there are at most n of them, this expression is bounded above by $O(n^{k+1})$.

We also need a lower bound: ignoring the extra factor of p, each of the $k+1$ terms in the expansion of (2) is an integer multiple of a power of y, and so the expected value of each such term is an integer multiple of m^{-k} (since the terms less than 1 are all products of the form $p^r q^s$, where $r+s \leq k$). Therefore, each nonzero term in the expectation is bounded away in absolute value from 0 by m^{-k-1}.

An exactly symmetric argument holds for the expected value of $a_{j,k}$ as well, by "indexing" in the opposite direction to $b_{j,k}$. Denote by $\Phi_a(j,k)$ and $\Phi_b(j,k)$ these expected values of $a_{j,k}$ and $b_{j,k}$ respectively, where $\Phi_a(j,k)$ and $\Phi_b(j,k)$ are between $\Omega(m^{-k-1})$ and $O(n^{k+1})$. The lower bound is necessary, as we do not want these expected values to be (exponentially) close to zero.

It follows from the arguments above that (1) reduces to (using backward offsets instead of forward ones, by a symmetric argument):

$$\begin{aligned}\mathbb{E}\left[\sum_{i\geq 1} \widetilde{a}_{i,k} w^{i-1}\right] &= \sum_{i\geq 1} w^{i-1} \sum_{j=i}^{n} \binom{j-1}{i-1} p^i q^{j-i} \Phi_a(j,k) \\ &= \sum_{j\geq 1} \Phi_a(j,k) \sum_{i=1}^{j} \binom{j-1}{i-1} p^i w^{i-1} q^{j-i}.\end{aligned}$$

With a change of variables, this becomes

$$\sum_{j\geq 1} \Phi_a(j,k) p \sum_{i'=0}^{j-1} \binom{j-1}{i'} (pw)^{i'} q^{j-1-i'} = \sum_{j\geq 1} \Phi_a(j,k) p (pw+q)^{j-1}$$

We write $pw+q=z$. To obtain a lower bound on the variational distance between two distributions coming from two different matrices, say A and A' with $\widetilde{a}_{i,k}$ and $\widetilde{a}'_{i,k}$ denoting the distribution of backward offsets from them respectively, we obtain

$$\mathbb{E}\left[\sum_{i\geq 1} (\widetilde{a}_{i,k} - \widetilde{a}'_{i,k}) w^{i-1}\right] = \sum_{j=1}^{n} (\Phi_a(j,k) - \Phi'_a(j,k)) p z^{j-1}. \tag{3}$$

The right side of equation (3) is a polynomial in z of degree less than n, where by the triangle inequality, each nonzero coefficient is upper bounded in absolute value by $O(n^{k+1})$, and lower bounded by $\Omega(m^{-k-1})$.

We now need a technical and non-trivial lemma. This is a generalization of Theorem 7 in [20], which in turns adapts a lemma in [27]. The arguments in those papers can be extended in a straightforward way to apply the same results to powers higher than 2, which is the core idea of this lemma. We use a localized lower bound on a generalized version of Littlewood polynomials, where the coefficients can be (up to) polynomially large instead of being in $\{-1, 0, 1\}$. We omit the proof here.

▶ **Lemma 16** (Generalized Littlewood polynomial bound)**.** *Let $G(z)$ be a nonzero complex polynomial in z with its degree bounded by n, integer coefficients, and each coefficient bounded in absolute value by $O(n^r)$. Then, for any fixed positive L, there is some $z^\star \in \{e^{i\theta} : -\pi/L \leq \theta \leq \pi/L\}$ such that $|G(z^\star)| \geq n^{(1-L)(r+1)}$.*

This lemma enables us to conclude the following.

▶ **Lemma 17.** *We have,*

$$\sum_{i\geq 1} \left|\mathbb{E}\left[\widetilde{a}_{i,k} - \widetilde{a}'_{i,k}\right]\right| \geq \exp\left(-\widetilde{\Omega}(k + k^{2/3}n^{1/3})\right).$$

Proof. Multiplying both sides of (3) by m^{k+1} yields a polynomial precisely of the kind described in Lemma 16 on the right hand side. Therefore, applying Lemma 16, we conclude that for some $z^\star \in \{e^{i\theta} : -\pi/L \leq \theta \leq \pi/L\}$,

$$\begin{aligned} m^{k+1}\sum_{i\geq 1} \left|\mathbb{E}\left[\widetilde{a}_{i,k} - \widetilde{a}'_{i,k}\right]\right| \cdot |(z^\star)^{i-1}| &\geq \left|\mathbb{E}\Big[\sum_{i\geq 1} m^{k+1}(\widetilde{a}_{i,k} - \widetilde{a}'_{i,k})(z^\star)^{i-1}\Big]\right| \\ &\geq n^{(1-L)(k+2+\frac{\log m}{\log n}(k+1))}. \end{aligned}$$

Noting that $|z^\star| < \exp(C_1/L^2)$ for some finite constant C_1, we now obtain

$$\begin{aligned} m^{k+1}\sum_{i\geq 1} \left|\mathbb{E}\left[\widetilde{a}_{i,k} - \widetilde{a}'_{i,k}\right]\right| &\geq n^{(1-L)(k+2+\frac{\log m}{\log n}(k+1))}\exp(-C_1 n/L^2) \\ &= \exp\left(-C_2 kL\log n - C_1 n/L^2\right) \end{aligned}$$

for some constant C_2. Here, C_2 is dependent on $\log m$, which is constant when the retention probability p is a constant. The right hand side of this equation is maximized when L is $\widetilde{O}(n^{1/3}/k^{1/3})$. We then conclude

$$\sum_{i\geq 1} \left|\mathbb{E}\left[\widetilde{a}_{i,k} - \widetilde{a}'_{i,k}\right]\right| \geq m^{-k-1}\cdot\exp\left(-\widetilde{\Omega}(k^{2/3}n^{1/3})\right) = \exp\left(-\widetilde{\Omega}(k + k^{2/3}n^{1/3})\right),$$

where $k = O(n)$ can be absorbed into the second term. ◀

To finish the proof of Theorem 15, we just need a standard union bound argument.

▶ **Theorem 18** (Folklore)**.** *Let $\mathcal{F}$ be a family of distributions where any two distributions $A, B \in \mathcal{F}$ have variational distance at least ε, for some $\varepsilon > 0$. Then, we can distinguish any member of $\mathcal{F}$ using $O(\log(|\mathcal{F}|)/\varepsilon^2)$ samples.*

Using Theorem 18 directly on the distributions defined in the proof of Theorem 15 proves that we can recover $\{a_{i,k}\}_{i\in[n]}$ in $\exp(\widetilde{O}(k^{2/3}n^{1/3}))$ traces. This holds for $\{b_{i,k}\}_{i\in[n]}$ as well, proving Theorem 15.

5 Reconstructing Arbitrary Graphs in the Ordered Model

In this section, we prove that arbitrary adjacency matrices can be reconstructed with high probability using $\exp(\widetilde{O}(n^{1/2}))$ samples in the ordered model. This is in contrast to the unordered model where we showed, in Theorem 10, that $\exp(\Omega(n))$ samples were necessary. The proof is a small modification of an existing result by Krishnamurthy et al. [20] on the problem on reconstructing arbitrary binary matrices when rows and columns are deleted independently.

▶ **Theorem 19.** *For graph reconstruction,* $\exp(O(n^{1/2}\sqrt{q\log n}/p))$ *traces suffice with high probability to recover an arbitrary adjacency matrix* $A \in \{0,1\}^{n\times n}$*, where* p *is the retention probability and* $q = 1-p$*.*

Proof Sketch. In our problem, the ith row is deleted iff the ith column is deleted, while the proof in [20] breaks when there are such dependencies. However, it is possible to make a small modification in the existing proof to handle this. The idea is to re-index the entries of the matrices such that the probability the entry in position (i',j') of the original matrix ends up in position (i,j) can be expressed conveniently in terms of two independent random variables. Let us formalize the change and sketch the rest of the approach.

For a matrix $A \in \{0,1\}^{n\times n}$, let $\widetilde{A}$ denote a matrix trace. Let us denote the (i,j)th entry of the matrix as $A_{i,j}$, for $i,j = 0,1,\ldots,n-1$, an indexing protocol we adhere to for every matrix. We restrict our attention to the entries above the diagonal, which suffices for reconstruction. For complex numbers $w_1, w_2 \in \mathbb{C}$, similar to the proof of Theorem 15, observe that

$$\begin{aligned}\mathbb{E}\left[\sum_{i,j=0}^{n-1}\widetilde{A}_{i,i+j}w_1^i w_2^j\right] &= p^2\sum_{i,j}w_1^i w_2^j \sum_{k_i\geq i,k_j\geq j} A_{k_i,k_i+k_j}\binom{k_i}{i}\binom{k_j-1}{j-1}p^i q^{k_i-i}p^{j-1}q^{k_j-j}\\ &= p^2\sum_{k_1=0,k_2=1}^{n-1} A_{k_1,k_1+k_2}(pw_1+q)^{k_1}(pw_2+q)^{k_2}\end{aligned}$$

Thus, for two adjacency matrices A, B, we have

$$\begin{aligned}\frac{1}{p^2}\mathbb{E}\left[\sum_{i,j=0}^{n-1}(\widetilde{A}_{i,i+j}-\widetilde{B}_{i,i+j})w_1^i w_2^j\right] &= \sum_{\substack{k_1=0\\k_2=1}}^{n-1}(A_{k_1,k_1+k_2}-B_{k_1,k_1+k_2})(pw_1+q)^{k_1}(pw_2+q)^{k_2}\\ &\triangleq f(z_1,z_2),\end{aligned}$$

where $z_1 = pw_1+q$ and $z_2 = pw_2+q$. The rest of the argument is identical to the proof of Krishnamurthy et al. [20]. Specifically, since all the coefficients of $f(z_1,z_2)$ are in $\{-1,0,1\}$, and the degree is $n-1$ in each variable it can be shown that for any $L>0$ there exist $z_1^\star, z_2^\star \in \{e^{i\theta} : |\theta| \leq \pi/L\}$ such that $|f(z_1^\star,z_2^\star)| \geq \exp(-C_1L^2\log n)$ for some constant C_1. If $z_1^\star = pw_1^\star+q$ and $z_2^\star = pw_2^\star+q$ then $|w_1^\star|, |w_2^\star| \leq \exp(C_2q/(Lp)^2)$ for some constant C_2.

Substituting these bounds and applying the triangle inequality gives,

$$\begin{aligned}\frac{1}{p^2}\sum_{i,j}\left|\mathbb{E}[\widetilde{A}_{i,i+j}-\widetilde{B}_{i,i+j}]\right| &\geq \frac{f(z_1^\star,z_2^\star)}{|w_1^\star|^n|w_2^\star|^n}\\ &\geq \exp\left(-C_1L^2\log n - \frac{2C_2qn}{L^2p^2}\right)\\ &\geq \exp\left(-C\frac{\sqrt{nq\log n}}{p}\right) \triangleq \varepsilon\end{aligned}$$

where the second inequality follows by optimizing for L, similar to our approach in the previous section. So if we estimate each $\mathbb{E}[\widetilde{A}_{i,i+j}]$ and $\mathbb{E}[\widetilde{B}_{i,i+j}]$ up to additive error bounded above by $p^2\varepsilon/(2n^2)$, we can distinguish between A and B. This immediately leads to the claimed bound via a union bound over all possible pairs and adjacency matrices. ◀

It seems difficult to construct lower bounds the sample complexity of reconstruction in the ordered model, beyond an obvious reduction from string trace reconstruction as follows. Given a binary string $\sigma = (x_1, \ldots, x_n)$, we can create the ordered graph G_σ on $n+1$ vertices $v_1, \ldots, v_{n+1}$ by adding edges of the form (v_i, v_{n+1}) if and only if $x_i = 1$. Clearly, there is an injective map from length-n binary strings to $(n+1)$-vertex ordered graphs. Furthermore, taking a trace of a binary string by passing it through a deletion channel with probability q of deletion corresponds exactly to taking a trace from the ordered subgraph conditioned on the vertex $n+1$ being preserved. This automatically implies a lower bound of $\widetilde{\Omega}(n^{3/2})$ samples for graph reconstruction in the ordered model due to [6]. On the surface, the ordered graph reconstruction problem seems to be fundamentally harder than the string trace reconstruction problem as well, but it is significantly harder to improve the lower bound.

6 Conclusion and Open Problems

We considered two natural graph reconstruction problems: reconstructing a graph from random induced subgraphs (the unordered model) and reconstructing an graph adjacency matrix via random symmetric submatrices (the ordered model). We showed that for almost all graphs G on n nodes, $\Theta(p^{-2}\log n)$ random induced subgraphs are necessary and sufficient to reconstruct G with high probability if each subgraph is formed by deleting each node with probability $1-p$. In contrast, we showed that there exist pairs of graphs that require $2^{\Omega(n)}$ random induced subgraphs to distinguish even when $p = 1/2$. We showed that $\exp(\widetilde{O}(n^{1/3})$ random symmetric submatrices are sufficient to construct sparse graphs (specifically, graphs with constant degeneracy or arboricity) and observed that $\exp(\widetilde{O}(n^{1/2}))$ random symmetric submatrices are sufficient to reconstruct arbitrary graphs.

Some Open Questions. In a fairly general sense, our results resolve the sample complexity of graph reconstruction in the unordered model. However, it may interesting to also consider time complexity. For example, the current approach requires isomorphism testing for an exponential number of pairs of subgraphs and it seems plausible that a more efficient approach could exist. For the ordered model, it is natural to ask whether the sample complexity of our upper bounds can be improved. Proving lower bounds for trace construction type problems is notoriously difficult and there is currently an exponential gap between the best lower and upper bounds. However, more tractable open questions include whether our results are optimal for mean-based algorithms [27], i.e., algorithms that only use the expected value of each bit in the trace. Another potential direction is whether it is possible to adapt ideas from Chase's recent work [7] to improve the exponential dependence on n or the degeneracy d. This may require substantial work in finding the two-dimensional extensions to several results. Of course, while d-degenerate graphs are a robust class of structures in themselves, it would be a natural next step to try to relax that condition altogether. Removing this constraint means denser rows of the adjacency matrix, which seems to require many more samples to effectively reconstruct, as well as novel ideas that go beyond the Krasikov-Roddity methods of set reconstruction from [19]. However, there may well be other classes of graphs that our current approach is suitable for and easily generalizable to. For instance, graphs with high girth are a natural candidate for trying to reconstruct using the techniques of this paper, as

small-diameter neighborhoods in an arbitrary high-girth graph are acyclic, and therefore the high-girth condition is akin to a "local" bounded-degeneracy condition. It seems natural to try and extend our approach to this class of graphs as well. Yet another direction to explore would be to consider lower values of p in the unordered model. Our current bounds are good enough for $p = \widetilde{\Omega}(1/n^{1/6})$, but we suspect this bound is an artifact of our approach rather than being inherent to the problem. While the majority of the related literature on similar problems typically concern themselves with constant p, which are covered by our work, exploring e.g., $p = O(\text{poly}\log n)/n$ may require new techniques.

Abstract

We consider a very wide class of models for sparse random Boolean 2CSPs; equivalently, degree-2 optimization problems over $\{\pm 1\}^n$. For each model $\mathcal{M}$, we identify the "high-probability value" $s^*_{\mathcal{M}}$ of the natural SDP relaxation (equivalently, the quantum value). That is, for all $\epsilon > 0$ we show that the SDP optimum of a random n-variable instance is (when normalized by n) in the range $(s^*_{\mathcal{M}} - \epsilon, s^*_{\mathcal{M}} + \epsilon)$ with high probability. Our class of models includes non-regular CSPs, and ones where the SDP relaxation value is strictly smaller than the spectral relaxation value.

1 Introduction

A large number of important algorithmic tasks can be construed as constraint satisfaction problems (CSPs): finding an assignment to Boolean variables to optimize the number of satisfied constraints. Almost every form of constraint optimization is NP-complete; thus one is led to questions of efficiently finding near-optimal solutions, or understanding the complexity of average-case rather than worst-case instances. Indeed, understanding the complexity of random sparse CSPs is of major importance not just in traditional algorithms theory, but also in, e.g., cryptography [25], statistical physics [27], and learning theory [14].

Suppose we fix the model $\mathcal{M}$ for a random sparse CSP on n variables (e.g., random k-SAT with a certain clause density). Then it is widely believed that there should be a constant $c^*_{\mathcal{M}}$ such that the optimal value of a random instance is $c^*_{\mathcal{M}} \pm o_{n\to\infty}(1)$ with high probability (whp). (Here we define the optimal value to mean the maximum number of simultaneously satisfiable constraints, divided by the number of variables.) Unfortunately, it is extremely difficult to prove this sort of result; indeed, it was considered a major breakthrough when Bayati, Gamarnik, and Tetali [6] established it for one of the simplest possible cases: Max-Cut on random d-regular graphs (which we will denote by $\mathcal{MC}_d$). Actually "identifying" the value $c^*_{\mathcal{M}}$ (beyond just proving its existence) is even more challenging. It is generally possible to estimate $c^*_{\mathcal{M}}$ using heuristic methods from statistical physics, but making these estimates

rigorous is beyond the reach of current methods. Taking again the example of Max-Cut on d-regular random graphs, it was only recently [16] that the value $c^*_{\mathcal{MC}_d}$ was determined up to a factor of $1 \pm o_{d\to\infty}(1)$. The value for any particular d, e.g. $c^*_{\mathcal{MC}_3}$, has yet to be established.

Returning to algorithmic questions, we can ask about the *computational feasibility* of optimally solving sparse random CSPs. There are two complementary questions to ask: given a random instance from model $\mathcal{M}$ (with presumed optimal value $c^*_{\mathcal{M}} \pm o_{n\to\infty}(1)$), can one efficiently *find* a solution achieving value $\gtrapprox c^*_{\mathcal{M}}$, and can one efficiently *certify* that every solution achieves value $\lessapprox c^*_{\mathcal{M}}$? The former question is seemingly a bit more tractable; for example, a very recent breakthrough of Montanari [29] gives an efficient algorithm for (whp) finding a cut in a random graph $\mathcal{G}(n,p)$ graph of value at least $(1-\epsilon)c^*_{\mathcal{G}(n,p)}$. On the other hand, we do not know any algorithm for efficiently certifying (whp) that a random instance has value at most $(1+\epsilon)c^*_{\mathcal{G}(n,p)}$. Indeed, it reasonable to conjecture that no such algorithm exists, leading to an example of a so-called "information-computation gap".

To bring evidence for this we can consider *semidefinite programming* (SDP), which provides efficient algorithms for certifying an upper bound on the optimal value of a CSP [20]. Indeed, it is known [35] that, under the Unique Games Conjecture, the basic SDP relaxation provides essentially optimal certificates for CSPs in the *worst case*. In this paper we in particular consider Boolean 2CSPs – more generally, optimizing a homogeneous degree-2 polynomial over the hypercube – as this is the setting where semidefinite programming is most natural. Again, for a fixed model $\mathcal{M}$ of random sparse Boolean 2CSPs, one expects there should exist a constant $s^*_{\mathcal{M}}$ such that the optimal SDP-value of an instance from $\mathcal{M}$ is whp $s^*_{\mathcal{M}} \pm o_{n\to\infty}(1)$. Philosophically, since semidefinite programming is doable in polynomial time, one may be more optimistic about proving this and explicitly identifying $s^*_{\mathcal{M}}$. Indeed, some results in this direction have recently been established.

1.1 Prior work on identifying high-probability SDP values

Let us consider the most basic case: $\mathcal{MC}_d$, Max-Cut on random d-regular graphs. For ease of notation, we will consider the equivalent problem of maximizing $\frac{1}{n}x^{\mathsf{T}}(-\boldsymbol{A})x$ over $x \in \{\pm 1\}^n$, where $\boldsymbol{A}$ is the adjacency matrix of a random n-vertex d-regular graph.[1] Although $s^*_{\mathcal{MC}_d}$, the high-probability SDP relaxation value, was pursued as early as 1987 [8] (see also [18]), it was not until 2015 that Montanari and Sen [30] established the precise result $s^*_{\mathcal{MC}_d} = 2\sqrt{d-1}$. That is, in a random d-regular graph, whp the basic SDP relaxation value [8, 37, 15, 34] for the size of the maximum cut is $(\frac{d}{4} + \sqrt{d-1} \pm o_{n\to\infty}(1))n$. Here the special number $2\sqrt{d-1}$ is the maximum eigenvalue of the d-regular infinite tree.

The proof of this result has two components: showing $\textsc{Sdp}(-\boldsymbol{A}) \geq 2\sqrt{d-1} - \epsilon$ whp, and showing $\textsc{Sdp-Dual}(-\boldsymbol{A}) \leq 2\sqrt{d-1} + \epsilon$ whp. Here $\textsc{Sdp}(A) = \max\{\langle \rho, A\rangle : \rho \succeq 0,\ \rho_{ii} = \frac{1}{n}\ \forall i\}$ denotes the "primal" SDP value on matrix A (commonly associated with the Goemans–Williamson rounding algorithm [23]), and $\textsc{Sdp-Dual}(A) = \min\{\lambda_{\max}(A+\mathrm{diag}(\zeta)) : \mathrm{avg}_i(\zeta_i) = 0\}$ denotes the (equal) "dual" SDP value on A. To show the latter bound, it is sufficient to observe that $\textsc{Sdp-Dual}(-\boldsymbol{A}) \leq \lambda_{\max}(-\boldsymbol{A})$, the "eigenvalue bound", and $\lambda_{\max}(-\boldsymbol{A}) \leq 2\sqrt{d-1} + o_n(1)$ whp by Friedman's Theorem [21]. As for lower-bounding $\textsc{Sdp}(-\boldsymbol{A})$, Montanari and Sen used the "Gaussian wave" method [19, 13, 24] to construct primal SDP solutions achieving at least $2\sqrt{d-1} - \epsilon$ (whp). The idea here is essentially to build the SDP solutions using an approximate eigenvector (of finite support) of the infinite d-regular tree achieving eigenvalue $2\sqrt{d-1} - \epsilon$; the fact that SDP constraint "$\rho_{ii} = \frac{1}{n}\ \forall i$" can be satisfied relies heavily on the regularity of the graph.

[1] Throughout this work, **boldface** is used to denote random variables.

▶ Remark 1. The Montanari–Sen result in passing establishes that the (high-probability) eigenvalue and SDP bounds coincide for random regular graphs. This is consistent with a known theme, that the two bounds tend to be the same (or nearly so) for graphs where "every vertex looks similar" (in particular, for regular graphs). This theme dates back to Delorme and Poljak [15], who showed that $\textsc{Sdp-Dual}(-A) = \lambda_{\max}(-A)$ whenever A is the adjacency matrix of a vertex-transitive graph.

Subsequently, the high-probability SDP value $s^*_{\mathcal{M}}$ was established for a few other models of random regular 2CSPs. Deshpande, Montanari, O'Donnell, Schramm, and Sen [17] showed that for $\mathcal{M} = \mathcal{NAE}3_c$ – meaning random regular instances of NAE-3SAT (not-all-equals 3Sat) with each variable participating in c clauses – we have $s^*_{\mathcal{M}} = \frac{9}{8} - \frac{3}{8} \cdot \frac{\sqrt{c-1}-\sqrt{2}}{c}$. We remark that NAE-3SAT is effectively a 2CSP, as the predicate $\mathrm{NAE}_3 : \{\pm 1\}^3 \to \{0,1\}$ may be expressed as $\frac{3}{4} - \frac{1}{4}(xy + yz + zx)$, supported on the "triangle" formed by variables x, y, z. The analysis in this paper is somewhat similar to that in [30], but with the infinite graph $\mathfrak{X} = K_3 \star K_3 \star \cdots \star K_3$ (c times) replacing the d-regular infinite tree. This $\mathfrak{X}$ is the $2c$-regular infinite "tree of triangles" depicted (partly, in the case $c = 3$) in Figure 1. More generally, [17] established the high-probability SDP value for large random (edge-signed) graphs that locally resemble $K_r \star K_r \star \cdots \star K_r$, the $(r-1)c$-regular infinite "tree of cliques K_r". (The $r = 2$ case essentially generalizes [30].) As in [30], $s^*_{\mathcal{M}}$ coincides with the (high-probability) eigenvalue bound. The upper bound on $s^*_{\mathcal{M}}$ is shown by using Bordenave's proof [9] of Friedman's Theorem for random (c, r)-biregular graphs. The lower bound on $s^*_{\mathcal{M}}$ is shown using the Gaussian wave technique, relying on the distance-regularity of the graphs $K_r \star K_r \star \cdots \star K_r$ (indeed, it is known that every infinite distance-regular graph is of this form).

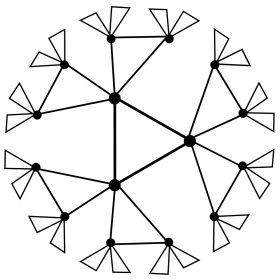

Figure 1 The 6-regular infinite graph $K_3 \star K_3 \star K_3$, modeling random 3-regular NAE3-SAT.

Mohanty, O'Donnell, and Paredes [28] generalized the preceding two results to the case of "two-eigenvalue" 2CSPs. Roughly speaking, these are 2CSPs formed by placing copies of a small weighted "constraint graph" $\mathcal{H}$ – required to have just two distinct eigenvalues – in a random regular fashion onto n vertices/variables. (This is indeed a generalization [17], as cliques have just two distinct eigenvalues.) As two-eigenvalue examples, [28] considered CSPs with the "CHSH constraint" – and its generalizations, the "Forrelation$_k$" constraints – which are important in quantum information theory [11, 1]. Here the SDP value of an instance is particularly relevant as it is precisely the optimal "quantum entangled value" of the 2CSP [12]. Once again, it is shown in [28] that the high-probability SDP and eigenvalue bounds coincide for these types of CSPs. The two-eigenvalue condition is used at a technical level in both the variant of Bordenave's theorem proven for the eigenvalue upper bound, and in the Gaussian wave construction in the SDP lower bound.

Most recently, O'Donnell and Wu [33] used the results of Bordenave and Collins [10] (a substantial generalization of [9]) to establish the high-probability *eigenvalue relaxation bound* for very wide range of random 2CSPs, encompassing all those previously mentioned: namely, any quadratic optimization problem defined by random "matrix polynomial lifts" over literals.

1.2 Our work

In this work, we establish the high-probability SDP value $s^*_{\mathcal{M}}$ for random instances of any 2CSP model $\mathcal{M}$ arising from lifting matrix polynomials (as in [33]). This generalizes all previously described work on SDP values, and covers many more cases, including random lifts of any base 2CSP (as used in certain community detection models) and random graphs modeled on any free/additive/amalgamated product. Such graphs have seen numerous applications within theoretical computer science, for example the zig-zag product in derandomization (e.g. [36]) and lifts of 2CSPs in the study of the stochastic block model (e.g [2]). At the end of this section we derive a corollary of our main theorem with applications to the latter. See Section 2 for more details and definitions, and see [33] for a thorough description of the kinds of random graph/2CSP models that can arise from matrix polynomials.

Very briefly, a matrix polynomial p is a small, explicit "recipe" for producing random n-vertex edge-weighted graphs, each of which "locally resembles" an associated *infinite* graph $\mathfrak{X}_p$. For example, $p_3(Y_1, Y_2, Y_3) \coloneqq Y_1 + Y_2 + Y_3$ is a recipe for random (edge-signed) 3-regular n-vertex graphs, and here $\mathfrak{X}_{p_3}$ is the infinite 3-regular tree. As another example, if $p_{333}(Z_{1,1}, \dots, Z_{3,3})$ denotes the following matrix polynomial –

$$\begin{pmatrix} 0 & Z_{1,1}Z^*_{1,2} + Z_{2,1}Z^*_{2,2} + Z_{3,1}Z^*_{3,2} & Z_{1,1}Z^*_{1,3} + Z_{2,1}Z^*_{2,3} + Z_{3,1}Z^*_{3,3} \\ Z_{1,2}Z^*_{1,1} + Z_{2,2}Z^*_{2,1} + Z_{3,2}Z^*_{3,1} & 0 & Z_{1,2}Z^*_{1,3} + Z_{2,2}Z^*_{2,3} + Z_{3,2}Z^*_{3,3} \\ Z_{1,3}Z^*_{1,1} + Z_{2,3}Z^*_{2,1} + Z_{3,3}Z^*_{3,1} & Z_{1,3}Z^*_{1,2} + Z_{2,3}Z^*_{2,2} + Z_{3,3}Z^*_{3,2} & 0 \end{pmatrix} \tag{1}$$

– then p_{333} is a recipe for random (edge-signed) 6-regular n-vertex graphs where every vertex participates in 3 triangles. In this case, $\mathfrak{X}_{p_{333}}$ is the infinite graph (partly) depicted in Figure 1. The Bordenave–Collins theorem [10] shows that if $\boldsymbol{A}$ is the adjacency matrix of a random *unsigned* n-vertex graph produced from a matrix polynomial p, then whp the "nontrivial" spectrum of $\boldsymbol{A}$ will be within ϵ (in Hausdorff distance) of the spectrum of $\mathfrak{X}_p$. In the course of derandomizing this theorem, O'Donnell and Wu [33] established that for random *edge-signed* graphs, the modifier "nontrivial" should be dropped. As a consequence, in the signed case one gets $\lambda_{\max}(\boldsymbol{A}) \approx \lambda_{\max}(\mathfrak{X}_p)$ up to an additive ϵ, whp; i.e., the high-probability eigenvalue bound for CSPs derived from p is precisely $\lambda_{\max}(\mathfrak{X}_p)$. We remark that for simple enough p there are formulas for $\lambda_{\max}(\mathfrak{X}_p)$; regarding our two example above, it is $2\sqrt{2}$ for $p = p_3$, and it is 5 for $p = p_{333}$. In particular, if p is a linear matrix polynomial, $\lambda_{\max}(\mathfrak{X}_p)$ may be determined numerically with the assistance of a formula of Lehner [26] (see also [22] for the case of standard random lifts of a fixed base graph).

In this paper we investigate the high-probability *SDP* value – denote it s^*_p – of a large random 2CSP (Boolean quadratic optimization problem) produced by a matrix polynomial p. Critically, our level of generality lets us consider *non-regular* random graph models, in contrast to all previous work. Because of this, we see cases in contrast to Remark 1, where (whp) the SDP value is strictly smaller than the eigenvalue relaxation bound. As a simple example, for random edge-signed $(2, 3)$-biregular graphs, the high-probability eigenvalue bound is $\sqrt{2-1} + \sqrt{3-1} = 1 + \sqrt{2} \approx 2.414$, but our work establishes that the high-probability SDP value is $\sqrt{\frac{13}{4} + 2\sqrt{2}} - \frac{1}{10} \approx 2.365$.

An essential part of our work is establishing the appropriate notion of the "SDP value" of an infinite graph $\mathfrak{X}_p$, with adjacency operator A_∞. While the eigenvalue bound $\lambda_{\max}(A_\infty)$ makes sense for the infinite-dimensional operator A_∞, the SDP relaxation does not. The definition $\textsc{Sdp}(A_\infty) = \max\{\langle \rho, A_\infty \rangle : \rho \succeq 0,\ \rho_{ii} = \frac{1}{n}\ \forall i\}$ does not make sense, since "n" is ∞. Alternatively, if one tries the normalization $\rho_{ii} = 1$, any such ρ will have infinite trace, and hence $\langle \rho, A_\infty \rangle$ may be ∞. Indeed, since the only control we have on A_∞'s "size" will be an operator norm ("∞-norm") bound, the expression $\langle \rho, A_\infty \rangle$ is only guaranteed to make sense if ρ is restricted to be trace-class (i.e., have finite "1-norm").

On the other hand, we know that the eigenvalue bound $\lambda_{\max}(A_\infty)$ is too weak, intuitively because it does not properly "rebalance" graphs $\mathfrak{X}_p$ that are not regular/vertex-transitive. The key to obtaining the correct bound is introducing a new notion, intermediate between the eigenvalue and SDP bounds, that is appropriate for graphs $\mathfrak{X}_p$ arising from matrix polynomial recipes. Although these graphs may be irregular, their definition also allows them to be viewed as *vertex-transitive* infinite graphs with $r \times r$ *matrix* edge-weights. In light of their vertex-transitivity, Remark 1 suggests that a "maximum eigenvalue"-type quantity – suitably defined for matrix-edge-weighted graphs – might serve as the sharp replacement for SDP value. We introduce such a quantity, calling it the *partitioned SDP* bound. Let G be an n-vertex graph with $r \times r$ matrices as edge-weights, and let A be its adjacency matrix, thought of as a Hermitian $n \times n$ matrix whose entries are $r \times r$ matrices. We will define

$$\textsc{PartSdp}(A) = \sup\{\langle \rho, A \rangle : \rho \succeq 0,\ \operatorname{tr}(\rho)_{ii} = \tfrac{1}{r}\}, \tag{2}$$

where here $\operatorname{tr}(\rho)$ refers to the $r \times r$ matrix obtained by summing the entries on A's main diagonal (themselves $r \times r$ matrices), and $\operatorname{tr}(\rho)_{ii}$ denotes the scalar in the (i,i)-position of $\operatorname{tr}(\rho)$. This partitioned SDP bound may indeed be regarded as intermediate between the maximum eigenvalue and the SDP value. On one hand, given a scalar-edge-weighted n-vertex graph with adjacency matrix A, we may take $r = 1$ and then it is easily seen that $\textsc{PartSdp}(A)$ coincides with $\lambda_{\max}(A)$. On the other hand, if we regard A as a 1×1 matrix and take $r = n$ (so that we a have single vertex with a self-loop weighted by all of A), then $\textsc{PartSdp}(A) = \textsc{Sdp}(A)$.

In the full version, we define $\textsc{PartSdp}(A)$ even for bounded-degree infinite graphs with $r \times r$ edge-weights. Furthermore, it has the following SDP dual:

$$\textsc{PartSdp-Dual}(A) = \inf\{\lambda_{\max}(A + \mathbb{1}_{n\times n} \otimes \operatorname{diag}(\zeta)) : \operatorname{avg}(\zeta_1, \ldots, \zeta_r) = 0\}.$$

We show in the full version that there is no SDP duality gap between $\textsc{PartSdp}(A)$ and $\textsc{PartSdp-Dual}(A)$, even in the case of infinite graphs. It is precisely the common value of $\textsc{PartSdp}(\mathfrak{X}_p)$ and $\textsc{PartSdp-Dual}(\mathfrak{X}_p)$ that is the high-probability SDP value of large random 2CSPs produced from p; our main theorem is the following:

▶ **Theorem 2.** *Let p be a matrix polynomial with $r \times r$ coefficients. Let A_∞ be the adjacency operator (with $r \times r$ entries) of the associated infinite lift $\mathfrak{X}_p$, and write $s_p^* = \textsc{PartSdp}(A_\infty) = \textsc{PartSdp-Dual}(A_\infty)$. Then for any $\epsilon, \beta > 0$ and sufficiently large n, if $\boldsymbol{A}_n$ is the adjacency matrix of a random edge-signed n-lift of p, it holds that $s_p^* - \epsilon \le \textsc{Sdp}(\boldsymbol{A}_n) \le s_p^* + \epsilon$ except with probability at most β.*

Note that $\textsc{PartSdp}(A_\infty)$ is a fixed value only dependent on the polynomial p, a finitary object.

The upper bound $\textsc{Sdp}(\boldsymbol{A}_n) \le \textsc{PartSdp-Dual}(A_\infty) + \epsilon$ in this theorem can be derived from the results of [10, 33]. Our main work is to prove the lower bound $\textsc{Sdp}(\boldsymbol{A}_n) \ge \textsc{PartSdp}(A_\infty) - \epsilon$. For this, our approach is inspired by the Gaussian Wave construction

of [30, 17] for d-regular graphs (in the random lifts model), which can be viewed as constructing a feasible $\textsc{Sdp}(\boldsymbol{A}_n)$ solution of value $\lambda_{\max}(A_\infty) - \epsilon$ using a truncated eigenfunction of A_∞. Since local neighborhoods in A_∞ look like local neighborhoods in $\boldsymbol{A}_n$ with high probability, the eigenfunction can be "pasted" almost everywhere into the graph $\boldsymbol{G}_n$, which gives an SDP solution of value near $\lambda_{\max}(A_\infty)$.

This approach runs into clear obstacles in our setting. Indeed, the raw eigenfunctions are of no use to us, as *the SDP value may be smaller than the spectral relaxation value.* Instead, we first show that there is a ρ_0 with only finitely many nonzero entries that achieves the sup in Equation (2) up to ϵ. This is effectively a finite $r \times r$ matrix-edge-weighted graph. We then show that this ρ_0 can (just as in the regular case) whp be "pasted" almost everywhere into the graph $\boldsymbol{G}_n$ defined by $\boldsymbol{A}_n$, which gives an SDP solution of value close to $\textsc{PartSdp}(A_\infty)$. The fact that $\mathfrak{X}_p$ and $\boldsymbol{G}_n$ are regarded as regular tree-like graphs with matrix edge-weights (rather than as irregular graphs with scalar edges-weights) is crucially used to show that the "pasted solution" satisfies the finite SDP's constraints "$\rho_{ii} = \frac{1}{n}\ \forall i$".

1.2.1 Application to hypothesis testing in block models

Montanari and Sen's aforementioned work [30] was motivated in part by the following question: can the basic SDP value serve as a *hypothesis test* for distinguishing Erdős-Rényi block models from random graphs with a planted partition/max-cut structure? Though polynomial-time hypothesis tests are known to exist whenever the task is information-theoretically possible [31] (even for the robust version of the problem, using a non-basic SDP [4]), the question of whether the canonical basic (Goemans–Williamson) SDP value can be used to hypothesis test is still interesting. Montanari and Sen show that the answer is affirmative for average degree $d = \Theta(1)$ large enough, but for small constant d their question remains open.

Using our results, we resolve the analogue of the question of Montanari and Sen in the large-planted-cut regime of the random-lift version of the block model, the so-called "equitable block model" [2]. The n-vertex equitable 2-community block model with internal degree a and external degree b is the distribution $\textsc{Block}(n, a, b)$ defined as a random $n/2$-lift of the 2-vertex graph with b parallel edges and a self-loops on each vertex.

▶ **Corollary 3.** *For any $\epsilon, \beta > 0$ and sufficiently large n, if $\boldsymbol{G}_n \sim \textsc{Block}(n, a, b)$ and $\boldsymbol{A}_n$ is the adjacency matrix of $\boldsymbol{G}_n$, then*

$$\left|\textsc{Sdp}(-\boldsymbol{A}_n) - \max(b - a,\ 2\sqrt{a + b - 1})\right| \leq \epsilon$$

except with probability at most β.

The bound $b - a$ is achieved by the integral cut which partitions the vertices according to their preimage in the 2-vertex graph. The upper bound $\textsc{Sdp}(-\boldsymbol{A}_n) \leq \max(b - a, 2\sqrt{a + b - 1}) + \epsilon$ follows from the eigenvalue bound on $-\boldsymbol{A}_n$. As above, what is new is our lower bound which shows that $\textsc{Sdp}(-\boldsymbol{A}_n) \geq 2\sqrt{a + b - 1} - \epsilon$.

In an $(a + b)$-regular random graph, the result of Montanari and Sen [30] (see also [3]) implies that $\textsc{Sdp}(-\boldsymbol{A}_n) = 2\sqrt{a + b - 1} \pm \epsilon$ with high probability. Hence, Corollary 3 proves that the basic (Goemans–Williamson) SDP value is the same in both models and so does not furnish a hypothesis testing algorithm when $b - a < 2\sqrt{a + b - 1}$. This is consistent with the prediction of [2], who conjecture that when $b - a < 2\sqrt{a + b - 1}$, no polynomial-time algorithm can robustly (under the addition of random noise) hypothesis test between random regular graphs and the equitable block model.[2] In [2], the authors give a lower bound for a different SDP relaxation, but they do not characterize the basic SDP value.

[2] We remark that in the Erdős-Rényi version of the 2-community block model, the threshold for information-

2 Preliminaries

To preface the following definitions and concepts, we remark that our "real" interest is in graphs/2CSPs with real scalar weights. The introduction of matrix edge-weights facilitates two things: helping us define a wide variety of interesting scalar-weighted graphs via matrix polynomial lifts; and, facilitating the definition of PartSdp$(\cdot)$, which we use to bound the SDP relaxation value of the associated 2CSPs. Our use of potentially complex matrices is also not really essential; we kept them because prior work that we utilize ([10], the tools in Section 3) is stated in terms of complex matrices. However the reader will not lose anything by assuming that all Hermitian matrices are in fact symmetric real matrices.

2.1 Matrix-weighted graphs

In the following definitions, we'll restrict attention to graphs with at-most-countable vertex sets V and bounded degree. We also often use bra-ket notation, with $(|v\rangle)_{v\in V}$ denoting the standard orthonormal basis for the complex vector space $\ell_2(V)$.

▶ **Definition 4** (Matrix-weighted graph). *Fix any $r \in \mathbb{N}^+$. A* matrix-weighted graph *will refer to a directed simple graph $G = (V, E)$ with self-loops allowed, in which each directed edge e has an associated* weight $a_e \in \mathbb{C}^{r\times r}$. *If $(v, w) \in E \implies (w, v) \in E$ and $a_{(w,v)} = a^*_{(v,w)}$, we say that G is an* undirected *matrix-weighted graph. The* adjacency matrix *of G is the operator A, acting on $\ell_2(V) \otimes \mathbb{C}^r$, given by*

$$\sum_{(v,w)\in E} |w\rangle\langle v| \otimes a_{(v,w)}.$$

It can be helpful to think to think of A in matrix form, as a $|V| \times |V|$ matrix whose entries are themselves $r \times r$ edge-weight matrices. Note that if G is undirected if and only if A is self-adjoint, $A = A^*$.

▶ **Definition 5** (Extension of a matrix-weighted adjacency matrix). *Given a $|V| \times |V|$ matrix A with $r \times r$ entries, we may also view it as a $|V|r \times |V|r$ matrix with scalar entries. When we wish to explicitly call attention to the distinction, we will call the latter matrix the* extension *of A, and denote it by $\widetilde{A}$.*

2.2 Matrix polynomials

▶ **Definition 6** (Matrix polynomial). *Let $Y_1, \dots, Y_d$ be formal indeterminates that are their own inverses, and let $Z_1, \dots, Z_e$ be formal indeterminates with formal inverses $Z_1^*, \dots, Z_e^*$. For a fixed r, we define a* matrix polynomial *to be a formal noncommutative polynomial p over the indeterminates $Y_1, \dots, Z_e^*$, with coefficients in $\mathbb{C}^{r\times r}$. In particular, we may write*

$$p = \sum_w a_w w,$$

where the sum is over words w on the alphabet of indeterminates, each a_w is in $\mathbb{C}^{r\times r}$, and only finitely many a_w are nonzero. Here we call a word reduced *if it has no adjacent Y_iY_i or $Z_iZ_i^*$ pairs. We will denote the empty word by $\mathbb{1}$.*

theoretic and computational distinguishability coincide. However, in the equitable case, the models are always information-theoretically distinguishable, since in Block(n, a, b) there is always an integral solution of value exactly $b - a$, and this will not occur in the d-regular case with high probability.

As we will shortly describe, we will always be considering substituting unitary operators for the Z_i's, and unitary involution operators for the Y_i's. Thus we can think of Z_i^* as both the inverse *and* the "adjoint" of indeterminate Z_i, and similarly we think of $Y_i^* = Y_i$.

▶ **Definition 7** (Adjoint of a polynomial)**.** *Given a matrix polynomial $p = \sum_w a_w w$ as above, we define its* adjoint *to be*

$$p^* = \sum_w a_w^* w^*,$$

where a^* is the usual adjoint of $a \in \mathbb{C}^{r\times r}$, and w^* is the adjointed reverse of w. That is, if $w = w_1 \cdots w_k$ then $w^* = w_k^* \cdots w_1^*$, where $\mathbb{1}^* = \mathbb{1}$, $Y_i^* = Y_i$, and $Z_i^{**} = Z_i$. We say p is self-adjoint *if $p^* = p$ formally.*

Note that in any self-adjoint polynomial, some terms will be self-adjoint, and others will come in self-adjoint pairs. In this work, we will only be considering self-adjoint polynomials.

2.3 Lifts of matrix polynomials

▶ **Definition 8** (n-lift)**.** *Given a matrix polynomial over the indeterminates $Y_1, \ldots, Z_e^*$, we define an n-*lift *to be a sequence $\mathcal{L} = (M_1, \ldots, M_d, P_1, \ldots, P_e)$ of $n \times n$ matrices, where each P_i is a signed permutation matrix and each M_i is a signed matching matrix.*[3] *A* random n-lift $\boldsymbol{\mathcal{L}} = (\boldsymbol{M}_1, \ldots, \boldsymbol{M}_d, \boldsymbol{P}_1, \ldots, \boldsymbol{P}_e)$ *is one where the matrices are chosen independently and uniformly at random. A* random unsigned n-lift $\boldsymbol{\mathcal{L}} = (\boldsymbol{M}_1, \ldots, \boldsymbol{M}_d, \boldsymbol{P}_1, \ldots, \boldsymbol{P}_e)$ *is one where the permutation and matching matrices are chosen independently and uniformly at random, and all the signs are $+1$.*

▶ **Definition 9** (Evaluation/substitution of lifts.)**.** *Given an n-lift $\mathcal{L}$ and a word w, we define $\mathcal{L}^w$ to be the $n \times n$ operator obtained by substituting appropriately into w: namely, $Y_i = M_i$, $Z_i = P_i$, and $Z_i^* = P_i^*$ for each i (and substituting the empty word with the $n \times n$ identity operator). Given also a matrix polynomial $p = \sum_w a_w w$, we define the* evaluation of p at $\mathcal{L}$ *to be the following operator on $\mathbb{C}^n \otimes \mathbb{C}^r$:*[4]

$$p(\mathcal{L}) = \sum_w \mathcal{L}^w \otimes a_w.$$

▶ Remark 10. Note that each P_i is unitary and each M_i a unitary involution (as promised), so $p^*(\mathcal{L}) = p(\mathcal{L})^*$. Thus $p(\mathcal{L})$ is a self-adjoint operator whenever p^* is a self-adjoint polynomial. In this case we also have that $p(\mathcal{L})$ may be viewed as the adjacency matrix of an undirected graph on vertex set $[n]$ with $r \times r$ edge-weights.

Note that the evaluation $p(\mathcal{L})$ of a matrix polynomial may be viewed as the adjacency matrix of a undirected graph on $[n]$ with $r \times r$ edge-weights; or, its extension may be viewed as the adjacency matrix of an undirected graph on $[n] \times [r]$ with scalar edge-weights. In this way, each fixed matrix polynomial p, when applied to a random lift, gives rise to a random (undirected, scalar-weighted) graph model.

---

[3] A signed matching matrix is the adjacency matrix of a perfect matching with ± 1 edge-signs. If $d > 0$ then we must restrict to even n.

[4] Note that coefficients a_w are written on the left in p, as is conventional, but we take the tensor/Kronecker product on the right so that the matrix form of $p(\mathcal{L})$ may be more naturally regarded as an $n \times n$ matrix with $r \times r$ entries.

▶ **Example 11.** *A simple example is the matrix polynomial*

$$p(Y_1, Y_2, Y_3) = Y_1 + Y_2 + Y_3.$$

Here $r = 1$ and each coefficient is just the scalar 1. This p gives rise to a model of random edge-signed 3-regular graphs on $[n]$.

By moving to actual matrix coefficients with $r > 1$, one can get the random (signed) graph model given by randomly n-lifting any base r-vertex graph H.

▶ **Example 12.** *As a simple example,*

$$p(Z_1, Z_2, Z_3) = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} Z_1 + \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix} Z_1^* + \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} Z_2 + \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix} Z_2^* + \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} Z_3 + \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix} Z_3^*$$

is the recipe for random 3-regular (edge-signed) $(n + n)$-vertex bipartite graphs. The reader may like to view this as a 2×2 matrix of polynomials,

$$p(Z_1, Z_2, Z_3) = \begin{pmatrix} 0 & Z_1 + Z_2 + Z_3 \\ Z_1^* + Z_2^* + Z_3^* & 0 \end{pmatrix},$$

but recall that we actually Kronecker-product the coefficient matrices "on the other side". So rather than as a 2×2 block-matrix with $n \times n$ blocks, we think of the resulting adjacency matrix as an $n \times n$ block-matrix with 2×2 blocks; equivalently, an n-vertex graph with 2×2 matrix edge-weights.

▶ **Example 13.** *The matrix polynomial p_{333} mentioned in (1) gives an example of a* nonlinear *polynomial with matrix coefficients. Again, we wrote it there as a 3×3 matrix of polynomials for compactness, but for analysis purposes we will view it as a degree-2 polynomial with 3×3 coefficients.*

▶ **Definition 14** (∞-lift)**.** *Formally, we extend Definition 8 to the case of $n = \infty$ as follows. Let V_∞ denote the free product of groups $\mathbb{Z}_2^{\star d} \star \mathbb{Z}^{\star e}$, with its components generated by $g_1, \dots, g_d$, $h_1, h_1^{-1}, \dots, h_e, h_e^{-1}$. Thus the elements of V_∞ are in one-to-one correspondence with the reduced words over indeterminates $Y_1, \dots, Z_e^*$. The generators $g_1, \dots, g_d, h_1, \dots, h_e$ act as permutations on V_∞ by left-multiplication, with the first d in fact being matchings. We write $\sigma_1, \dots, \sigma_{d+e}$ for these permutations, and we also identify them with their associated permutation operators on $\ell_2(V_\infty)$. Finally, we write $\mathfrak{L}_\infty = (\sigma_0, \dots, \sigma_{d+2e})$ for* "the" ∞-lift *associated to p. (Note that this lift is "unsigned".)*

▶ **Definition 15** (Evaluation at the ∞-lift, and $\mathfrak{X}_p$.)**.** *The evaluation of a matrix polynomial p at the infinity lift $\mathcal{L}_\infty$ is now defined just as in Definition 9; the resulting operator $p(\mathcal{L}_\infty)$ operates on $\ell_2(V_\infty) \otimes \mathbb{C}^r$. We may think of the result as a matrix-weighted graph on vertex set V_∞, and we will sometimes denote this graph by $\mathfrak{X}_p$. When p is understood, we often write $A_\infty = p(\mathcal{L}_\infty)$ for the adjacency operator of $\mathfrak{X}_p$, which can be thought of as an infinite matrix with rows/columns indexed by V_∞ and entries from $\mathbb{C}^{r \times r}$, or as its "extension" $\widetilde{A}_\infty$, an infinite matrix with rows/columns indexed by $V_\infty \times [r]$ and scalar entries.*

▶ **Example 16.** *For the polynomial $p = Y_1 + \cdots + Y_d$, the corresponding graph $\mathfrak{X}_p$ is the infinite (unweighted) d-regular tree.*

We may now state a theorem which is essentially the main result ("Theorem 2") of [10]. The small difference is that our notion of random n-lifts, which includes ± 1 *signs* on the matchings/permutations, lets one eliminate mention of "trivial" eigenvalues (see [33, Thms. 1.9, 10.10]).

▶ **Theorem 17.** *Let p be a self-adjoint matrix polynomial with coefficients from $\mathbb{C}^{r\times r}$ on indeterminates $Y_1, \dots, Z_e^*$. Then for all $\epsilon, \beta > 0$ and sufficiently large n, the following holds:*

Let $\boldsymbol{A}_n = p(\boldsymbol{\mathcal{L}}_n)$, where $\boldsymbol{\mathcal{L}}_n$ is a random n-lift, and let $A_\infty = p(\mathcal{L}_\infty)$. Then except with probability at most β, the spectra $\operatorname{spec}(\boldsymbol{A}_n)$ and $\operatorname{spec}(A_\infty)$ are at Hausdorff distance at most ϵ

2.4 Random lifts as optimization problems

Given a Hermitian (i.e., self-adjoint) matrix $A \in \mathbb{C}^{n\times n}$, we are interested in the task of maximizing $x^\top Ax$ over all Boolean vectors $x \in \{\pm 1\}^n$. (Since A is Hermitian, the quantity $x^\top Ax$ is always real, so this maximization problem makes sense.) This is the same as maximizing the homogeneous degree-2 (commutative) polynomial $\sum_{i,j} A_{ij}x_ix_j$ over $x \in \{\pm 1\}^n$, and it is also essentially the same task as the Max-Cut problem on (scalar-)weighted undirected graphs. More precisely, if G is a weighted graph on vertex set $[n]$ with adjacency matrix A, then G's maximum cut is indicated by the $x \in \{\pm 1\}^n$ that maximizes $x^\top(-A)x$. For the sake of scaling we will also include a factor of $\frac{1}{n}$ in this optimization problem, leading to the following definition:

▶ **Definition 18** (Optimal value)**.** *Given a Hermitian matrix $A \in \mathbb{C}^{n\times n}$, we define*

$$\textsc{Opt}(A) = \sup_{x\in\{\pm1\}^n} \left\{\tfrac{1}{n} x^{\mathsf{T}} Ax\right\} = \sup_{x\in\left\{\pm\frac{1}{\sqrt{n}}\right\}^n} \left\{x^{\mathsf{T}} Ax\right\}.$$

(For finite-dimensional A, the sup*s and* inf*s mentioned in this section are all achieved.)*

We remark that

$$x^{\mathsf{T}} Ax = \operatorname{tr}(x^{\mathsf{T}} Ax) = \operatorname{tr}(xx^\top A) = \langle xx^\top, A\rangle,$$

where we use the notation $\langle B, C\rangle = \operatorname{tr}(BC)$. Thus we also have

$$\textsc{Opt}(A) = \sup_{\rho\in \mathrm{Cut}_n} \left\{\tfrac{1}{n}\langle \rho, A\rangle\right\},$$

where Cut_n is the "cut polytope", the convex hull of all matrices of the form xx^{T} for $x \in \{\pm 1\}^n$. (Since $\langle \rho, A\rangle$ is linear in ρ, maximizing over the convex hull is the same as maximizing over the extreme points, which are just those matrices of the form xx^{T}.)

The above optimization problem has a natural relaxation: maximizing $\frac{1}{n}x^{\mathsf{T}} Ax$ over all *unit* vectors x. This leads to the following efficiently computable upper bound on $\textsc{Opt}(A)$:

▶ **Definition 19** (Eigenvalue bound)**.** *Given a Hermitian matrix $A \in \mathbb{C}^{n\times n}$, we define the* eigenvalue bound *to be*

$$\textsc{Eig}(A) = \sup\{\langle \rho, A\rangle : \rho \succeq 0,\ \operatorname{tr}(\rho) = 1\},$$

where here $\rho \succeq 0$ denotes that ρ is (Hermitian and) positive semidefinite.

The matrices ρ being optimized over in $\textsc{Eig}(A)$ are known as *density matrices*; i.e., $\textsc{Eig}(A)$ is the maximal inner product between A and any density matrix. Note that if $\varrho \in \mathrm{Cut}_n$, then $\rho = \frac{1}{n}\varrho$ is a density matrix. Thus, $\textsc{Eig}(A)$ is a relaxation of $\textsc{Opt}(A)$, or in other words, $\textsc{Opt}(A) \le \textsc{Eig}(A)$.

The set of density matrices is convex, and it's well known that its extreme points are all the rank-1 density matrices; i.e., those ρ of the form xx^{T} for $x \in \mathbb{C}^n$ with $\|x\|_2^2 = 1$. Thus in $\textsc{Eig}(A)$ it is equivalent to just maximize over these extreme points:

$$\textsc{Eig}(A) = \sup_{\substack{x\in\mathbb{C}^n\\ \|x\|_2^2=1}} \left\{\langle xx^{\mathsf{T}}, A\rangle\right\} = \sup_{\substack{x\in\mathbb{C}^n\\ \|x\|_2^2=1}} \left\{x^{\mathsf{T}} Ax\right\}.$$

From this formula we see that $\textsc{Eig}(A)$ is also equal to $\lambda_{\max}(A)$, the maximum eigenvalue of A; hence the terminology "eigenvalue bound". One may also think of $\textsc{Eig}(A)$ and $\lambda_{\max}(A)$ as SDP duals of one another.

We now mention another well known, tighter, upper bound on $\textsc{Opt}(A)$.

▶ **Definition 20** (Basic SDP bound)**.** *Given a Hermitian matrix $A \in \mathbb{C}^{n\times n}$, the* basic SDP bound *is defined to be*

$$\textsc{Sdp}(A) = \sup\{\langle \rho, A\rangle : \rho \succeq 0,\ \rho_{ii} = \tfrac{1}{n}, \forall i\}.$$

Recall that an $n \times n$ matrix ϱ is a *correlation matrix* [38] if it is PSD and has all diagonal entries equal to 1. Thus $\textsc{Sdp}(A)$ is equivalently maximizing $\frac{1}{n}\langle \varrho, A\rangle$ over all correlation matrices ϱ. We also note that any cut matrix is a correlation matrix, and any correlation matrix is a density matrix, hence so

$$\textsc{Opt}(A) \le \textsc{Sdp}(A) \le \textsc{Eig}(A).$$

▶ **Definition 21** (Dual SDP bound)**.** *The semidefinite dual of $\textsc{Sdp}(A)$ is the following [15]:*

$$\textsc{Sdp-Dual}(A) = \inf_{\substack{\zeta\in\mathbb{R}^n \\ \mathrm{avg}(\zeta_1,\dots,\zeta_n)=0}} \{\lambda_{\max}(A + \mathrm{diag}(\zeta))\}.$$

Despite the fact that the usual "Slater condition" for strong SDP duality fails in this case (because the set of correlation matrices isn't full-dimensional), one can still show [34] that $\textsc{Sdp}(A) = \textsc{Sdp-Dual}(A)$ indeed holds for finite-dimensional A.

▶ Remark 22. In this work we frequently consider matrix-weighted graphs with adjacency matrices A, thought of as $n\times n$ matrices with entries from $\mathbb{C}^{r\times r}$. For such matrices, whenever we write $\textsc{Opt}(A)$, we mean $\textsc{Opt}(\widetilde{A})$ for the $nr \times nr$ "extension" matrix $\widetilde{A}$ (see Definition 5), and similarly for $\textsc{Eig}(A)$, $\lambda_{\max}(A)$, $\textsc{Sdp}(A)$, $\textsc{Sdp-Dual}(A)$.

As mentioned in Section 1, the eigenvalue bound $\lambda_{\max}(A)$ makes sense when A is the adjacency matrix of an infinite graph (with bounded degree). However $\textsc{Sdp}(A)$ does not extend to the infinite case, as the number "n" appearing in its definition is not finite. On the other hand, we now introduce a new, intermediate, "maximum eigenvalue-like" bound that is appropriate for matrix-weighted graphs. This is the "partitioned SDP bound" appearing in the statement of our main Theorem 2. In the following Section 3, we will show that it generalizes well to the case of infinite graphs.

▶ **Definition 23** (Partitioned SDP bound)**.** *Let A be an $n \times n$ Hermitian matrix with entries from $\mathbb{C}^{r\times r}$. We define its* partitioned SDP bound *to be*

$$\textsc{PartSdp}(A) = \sup\{\langle \rho, A\rangle : \rho \succeq 0,\ \mathrm{tr}(\rho) \in \tfrac{1}{r}\mathrm{Corr}_r\},$$

where:

- *the matrices ρ are also thought of as $n \times n$ matrices with entries from $\mathbb{C}^{r\times r}$;*
- *$\langle \rho, A\rangle$ is interpreted as $\langle \widetilde{\rho}, \widetilde{A}\rangle$;*
- *$\mathrm{tr}(\rho)$ denotes the sum of the diagonal entries of ρ, which is an $r \times r$ matrix;*
- *Corr_r is the set of $r \times r$ correlation matrices;*
- *in other words, the final condition is that $\mathrm{tr}(\rho)_{ii} = \frac{1}{r}$ for all $i \in [r]$.*

▶ Remark 24. As mentioned, the partitioned SDP bound can be viewed as "intermediate" between the eigenvalue bound and the SDP bound. To explain this, suppose A is an $n \times n$ Hermitian matrix. On one hand, we can regard A as an $n \times n$ matrix with 1×1 matrix entries ($r = 1$); in this viewpoint, $\textsc{PartSdp}(A) = \textsc{Eig}(A)$. On the other hand, we can regard A as a 1×1 matrix with a single $n \times n$ matrix entry ($r = n$); in this viewpoint, $\textsc{PartSdp}(A) = \textsc{Sdp}(A)$.

It is easy to see that the partitioned SDP bound indeed has an SDP formulation, and we now state its SDP dual:

▶ **Definition 25.** *The SDP dual of* $\textsc{PartSdp}(A)$ *is the following:*

$$\textsc{PartSdp-Dual}(A) = \inf_{\substack{\zeta \in \mathbb{R}^r \\ \mathrm{avg}(\zeta_1,\ldots,\zeta_r)=0}} \{\lambda_{\max}(A + \mathbb{1}_{n\times n} \otimes \mathrm{diag}(\zeta))\}.$$

Weak SDP duality, $\textsc{PartSdp}(A) \le \textsc{PartSdp-Dual}(A)$, holds as always, but again it is not obvious that strong SDP duality holds. In fact, not only does strong duality hold, it even holds in the case of *infinite* matrices A. This fact is crucial for our work, and proving it the subject of the upcoming technical section.

3 The infinite SDPs

This technical section is deferred to the full version and we only state some results here. First, we show that strong duality $\textsc{PartSdp}(A) = \textsc{PartSdp-Dual}(A)$ holds, even for infinite matrices A with $r \times r$ entries. Even in the finite case this is not trivial, as the feasible region for the SDP $\textsc{PartSdp}(A)$ is not full-dimensional, and hence the Slater condition ensuring strong duality does not apply. The infinite case involves some additional technical considerations, needed so that we may eventually apply the strong duality theorem for conic linear programming of Bonnans and Shapiro [7, Thm. 2.187]. Second, we show that in the optimization problem $\textsc{PartSdp}(A)$, values arbitrarily close to the optimum can be achieved by matrices ρ of finite support (i.e., with only finitely many nonzero entries). Indeed (though we don't need this fact), these finite-rank ρ need only have rank at most r. This fact is familiar from the case of $r = 1$, where the optimizer in the eigenvalue bound Definition 19 is achieved by a ρ of rank 1 (namely $|\psi\rangle\langle\psi|$ for any maximum eigenvector $|\psi\rangle$). Finally, we consolidate all these results into a theorem statement suitable for use with graphs produced by infinite lifts of matrix polynomials.

3.1 SDP duality for matrix edge-weighted graphs

Let V_∞ be a countable set of nodes and let G_∞ be a bounded-degree graph on V_∞ with matrix edge-weights from $\mathbb{C}^{r\times r}$. Let A_∞ be the adjacency operator for G_∞, acting on $\ell_2(V_\infty) \otimes \mathbb{C}^r$ and assumed self-adjoint; we may think of it as an infinite matrix with rows and columns indexed by V_∞, and with entries from $\mathbb{C}^{r\times r}$.

For any $\epsilon > 0$, there exists:

- $\hat{\zeta} \in \mathbb{R}^r$ with $\mathrm{avg}_j(\hat{\zeta}_j) = 0$;
- a finite subset $F \subset V_\infty$;
- a PSD matrix ρ with rows/columns indexed by V_∞ and entries from $\mathbb{C}^{r\times r}$, supported on the rows/columns F, with

$$\mathrm{tr}(\rho)_{jj} = \tfrac{1}{r}, \quad j = 1 \ldots r;$$

such that for

$$\hat{A} = \widetilde{A}_\infty + \mathbb{1}_{V_\infty} \otimes \mathrm{diag}(\hat{\zeta}),$$

we have

$$s^* := \lambda_{\max}(\hat{A}) = \textsc{PartSdp-Dual}(A_\infty) = \textsc{PartSdp}(A_\infty) \ge \langle \rho, A_\infty \rangle = \langle \rho_F, A_F \rangle \ge s^* - \epsilon, \tag{3}$$

where ρ_F, A_F denote ρ, A_∞ (respectively) restricted to the rows/columns F.

4 The SDP value of random matrix polynomial lifts

In this section we prove our main Theorem 2. To that end, let p be any self-adjoint matrix polynomial over indeterminates $Y_1, \dots, Y_d, Z_1, \dots, Z_e^*$ with $r \times r$ coefficients. Let $A_\infty = p(\mathcal{L}_\infty)$ denote the adjacency operator of the infinite lift $\mathfrak{X}_p$, and write $s^* = \textsc{PartSdp}(A_\infty) = \textsc{PartSdp-Dual}(A_\infty)$ as in Equation (3). Fix any $\epsilon, \beta > 0$, and let $\boldsymbol{A}_n = p(\boldsymbol{\mathcal{L}})$ denote the adjacency matrix of a corresponding n-lift, formed from $\boldsymbol{\mathcal{L}} = (\boldsymbol{M}_1, \dots, \boldsymbol{M}_d, \boldsymbol{P}_1, \dots, \boldsymbol{P}_e)$. Our goal is to show that except with probability at most β (assuming n is sufficiently large),

$$s^* - \epsilon \le \textsc{Sdp}(\boldsymbol{A}_n) = \textsc{Sdp-Dual}(\boldsymbol{A}_n) \le s^* + \epsilon.$$

Given our setup, the upper bound follows easily from prior work, namely Theorem 17. Let $\hat{\zeta}$ and $\hat{A}$ be as in Section 3.1, and consider the matrix polynomial p' defined by

$$p' = p + \mathrm{diag}(\hat{\zeta})\mathbb{1}.$$

Then on one hand, the ∞-lift of p' has adjacency operator precisely $\hat{A}$; on the other hand,

$$\boldsymbol{A}'_n \coloneqq p'(\boldsymbol{\mathcal{L}}) = \boldsymbol{A}_n + \mathbb{1}_{n\times n} \otimes \mathrm{diag}(\hat{\zeta}).$$

Thus Theorem 17 tells us that except with probability $\beta/2$ (provided n is large enough), the spectra $\mathrm{spec}(\boldsymbol{A}'_n)$ and $\mathrm{spec}(\hat{A})$ are at Hausdorff distance at most ϵ, from which it follows that

$$\lambda_{\max}(\boldsymbol{A}'_n) \le \lambda_{\max}(\hat{A}) + \epsilon = s^* + \epsilon.$$

But this indeed proves $\textsc{Sdp-Dual}(\boldsymbol{A}_n) \le s^* + \epsilon$, because $\hat{\zeta}$ has $\mathrm{avg}(\hat{\zeta}) = 0$ and hence is feasible for $\textsc{Sdp-Dual}(\boldsymbol{A}_n)$.

It therefore remains to prove $\textsc{Sdp}(\boldsymbol{A}_n) \ge s^* - \epsilon$.

4.1 A lower bound on the basic SDP value

In this section we complete the proof of our main theorem by showing that $\textsc{Sdp}(\boldsymbol{A}_n) \ge s^* - \epsilon$ except with probability at most $o(1) = o_{n\to\infty}(1)$ (which is at most $\beta/2$ as needed, provided n is large enough).

Let F, ρ, ρ_F, A_F be as in Section 3.1, except with that section's "ϵ" replaced by $\epsilon/2$, so that $\langle \rho_F, A_F \rangle \ge s^* - \epsilon/2$. Adding finitely many vertices to F if necessary, we may assume that it consists of all reduced words over $Y_1, \dots, Y_d, Z_1, \dots, Z_e^*$ of length at most some finite f_0. We also make the following definition:

▶ **Definition 26** (Cycle in a lift). *Given an n-lift $\mathcal{L}$, a* cycle of length $\ell > 0$ *is a pair (i, w), where $i \in [n]$ and w is a reduced word of length ℓ such that $\mathcal{L}^w |i\rangle = \pm |i\rangle$, and $\langle i|\mathcal{L}^{w'}|i\rangle = 0$ (i.e., $\mathcal{L}^{w'}|i\rangle \neq \pm|i\rangle$) for all proper prefixes w' of w.*

We will employ the following basic random graph result, [10, Lem. 23], stated in our language:

▶ **Lemma 27.** *For the random n-lift $\boldsymbol{\mathcal{L}}$, the expected number of cycles of length ℓ is $O(\ell(d + 2e - 1)^\ell)$.*

Applying this for all $\ell \le f \coloneqq 2f_0 + \deg(p)$ and using Markov's inequality, we conclude:

▶ **Corollary 28.** *Except with probability at most $n^{-.99}$, the random n-lift $\boldsymbol{\mathcal{L}}$ has at most $O(n^{.99})$ cycles of length at most f. In this case, we can exclude a set of "bad" vertices $B \subseteq [n]$ with $|B|/n \le O(n^{-.01}) = o(1)$ so that:*

$$\forall i \notin B, \quad \forall \text{ reduced words } w \text{ with } 0 < |w| \le 2f_0 + \deg(p), \qquad \langle i|\boldsymbol{\mathcal{L}}^w|i\rangle = 0.$$

We henceforth fix an outcome $\boldsymbol{\mathcal{L}} = \mathcal{L}$ (and hence $\boldsymbol{A}_n = A_n$) such that the conclusion of Corollary 28 holds, accruing our $o(1)$ probability of failure. Under this assumption, we will show $\textsc{Sdp}(A_n) \geq s^* - \epsilon/2 - o(1)$, which is sufficient to complete the proof.

▶ Remark 29. Note that our choice of $\boldsymbol{\mathcal{L}}$ depends only on the structure (i.e. the non-zero entries of A_n), not the signs. Therefore, we can take the signs in $\boldsymbol{\mathcal{L}}$ to be arbitrary; in particular, $\boldsymbol{\mathcal{L}}$ can be unsigned.

Our plan will be to first construct a "provisional" near-feasible PSD solution σ for $\textsc{Sdp}(A_n)$, with rows/columns indexed by $[n]$ and with $r \times r$ entries, such that:

- $|\langle \sigma, A_n \rangle - \langle \rho_F, A_F \rangle| \leq o(1)$, and hence $\langle \sigma, A_n \rangle \geq s^* - \epsilon/2 - o(1)$;
- for $i \notin B$, the $r \times r$ matrix σ_{ii} has diagonal entries $\frac{1}{nr}$.

Then, we will show how to "fix" σ to a some σ' that is truly feasible for $\textsc{Sdp}(A_n)$, while still having $\langle \sigma', A_n \rangle \geq \langle \sigma, A_n \rangle - o(1) \geq s^* - \epsilon/2 - o(1)$.

4.1.1 Constructing a near-feasible solution

▶ **Definition 30.** *For each $i \in [n]$, we define a linear operator $\Phi_i : \mathbb{C}^F \to \mathbb{C}^n$ by*

$$\Phi_i = \sum_{v \in F} \mathcal{L}^v \, |i\rangle\langle v| \,,$$

and also $\widetilde{\Phi}_i = \Phi_i \otimes \mathbb{1}_{r \times r}$. We furthermore define σ_i to be the $n \times n$ matrix with $r \times r$ entries whose extension $\widetilde{\sigma}_i$ is

$$\widetilde{\sigma}_i = \widetilde{\Phi}_i \cdot \widetilde{\rho}_F \cdot \widetilde{\Phi}_i^\mathsf{T}.$$

▶ Remark 31. $\widetilde{\sigma}_i$ is PSD, being the conjugation by $\widetilde{\Phi}_i$ of the PSD operator $\widetilde{\rho}_F$.

▶ **Proposition 32.** *If $i \notin B$, then $\widetilde{\Phi}_i^\mathsf{T} \widetilde{A}_n \widetilde{\Phi}_i = \widetilde{A}_F$.*

Proof. Thinking of $\widetilde{\Phi}_i^\mathsf{T} \widetilde{A}_n \widetilde{\Phi}_i$ as an $F \times F$ matrix of $r \times r$ matrices, it follows that its (u, v) entry is given by

$$\sum_{\text{term } a_w w \text{ in } p} \langle i | \mathcal{L}^{v^* w u} | i \rangle \, a_w.$$

On the other hand, the (u, v) entry of A_F is by definition

$$\sum_{\text{term } a_w w \text{ in } p} 1[v^* w u = \mathbb{1}] a_w,$$

where "$v^* w u = \mathbb{1}$" denotes that the reduced form of word $v^* w u$ is the empty word. We therefore have equality for all u, v provided $\langle i | \mathcal{L}^{v^* w u} | i \rangle = 0$ whenever $v^* w u \neq \emptyset$. But Corollary 28 tells us this indeed holds for $i \notin B$, because $|v^* w u| \leq 2 f_0 + \deg(p)$. ◀

▶ **Corollary 33.** *For $i \notin B$ we have $\langle \sigma_i, A_n \rangle = \langle \rho_F, A_F \rangle$.*

Proof. When $i \notin B$,

$$\langle \sigma_i, A_n \rangle = \operatorname{tr}(\widetilde{\sigma}_i \widetilde{A}_n) = \operatorname{tr}(\widetilde{\Phi}_i \widetilde{\rho}_F \widetilde{\Phi}_i^\mathsf{T} \widetilde{A}_n) = \operatorname{tr}(\widetilde{\rho}_F \widetilde{\Phi}_i^\mathsf{T} \widetilde{A}_n \widetilde{\Phi}_i) = \operatorname{tr}(\widetilde{\rho}_F \widetilde{A}_F) = \langle \rho_F, A_F \rangle,$$

where the last equality used Proposition 32 ◀

We now define our "provisional" SDP solution σ via

$$\sigma = \operatorname*{avg}_{i\in[n]}\{\sigma_i\};$$

this is indeed PSD, being the average of PSD operators. Using Corollary 33, $|B|/n = o(1)$, and the fact that $|\langle\sigma_i, A_n\rangle| \le O(1)$ for every i (since σ_i only has $O(1)$ nonzero entries, each bounded in magnitude by $O(1)$), we conclude:

▶ **Proposition 34.** *$|\langle\sigma, A_n\rangle - \langle\rho_F, A_F\rangle| \le o(1)$, and hence $\langle\sigma, A_n\rangle \ge s^* - \epsilon/2 - o(1)$.*

Now similar to Proposition 35 we have the following:

▶ **Proposition 35.** *If $j \notin B$, then the (j,j) entry of σ is $\frac{1}{n}\operatorname{tr}(\rho_F)$ (and hence is an $r \times r$ matrix with diagonal entries equal to $\frac{1}{nr}$).*

Proof. By definition, the (j,j) entry of σ is

$$\begin{aligned}
&= \operatorname*{avg}_{i\in[n]} \sum_{u,v\in F} \langle j|\mathcal{L}^u|i\rangle \langle u|\rho_F|v\rangle \langle i|\mathcal{L}^{v^*}|j\rangle \\
&= \tfrac{1}{n} \sum_{u,v\in F} \langle u|\rho_F|v\rangle \cdot \sum_{i\in[n]} \langle j|\mathcal{L}^u|i\rangle \langle i|\mathcal{L}^{v^*}|j\rangle \\
&= \tfrac{1}{n} \sum_{u,v\in F} \langle u|\rho_F|v\rangle \cdot \langle j|\mathcal{L}^{uv^*}|j\rangle \qquad \text{(since } \textstyle\sum_i |i\rangle\langle i| = \mathbb{1}\text{)}
\end{aligned}$$

where we are writing $\langle u|\rho_F|v\rangle$ for the $r \times r$ matrix at the (u,v) entry of ρ_F. Now when $j \notin B$, we have that $\langle j|\mathcal{L}^{vw^*}|j\rangle = 1[vw^* = \emptyset]$ by Corollary 28, since $|vw^*| \le 2f_0$. Thus all summands above drop out, except for the ones with $u = v$; this indeed gives $\frac{1}{n}\operatorname{tr}(\rho_F)$. ◀

4.1.2 Fixing σ

Finally, we slightly fix σ to make it truly feasible for $\textsc{Sdp}(A)$. Let σ' be the $n \times n$ matrix, with entries from $\mathbb{C}^{r\times r}$, defined as follows:

$$\sigma'_{ij} = \begin{cases} \sigma_{ij} & \text{if } i,j \notin B, \\ \frac{1}{nr}\mathbb{1}_{r\times r} & \text{if } i = j \in B, \\ 0 & \text{else.} \end{cases}$$

This σ' is easily seen to be PSD, being a principal submatrix of the PSD matrix σ, direct-summed with the PSD matrix $\frac{1}{nr}\mathbb{1}_{r\times r}$. As well, the $nr \times nr$ extension matrix $\widetilde{\sigma}'$ has all diagonal entries equal to $\frac{1}{nr}$, by Proposition 35. Thus $\widetilde{\sigma}'$ is feasible for $\textsc{Sdp}(A_n) = \textsc{Sdp}(\widetilde{A}_n)$, and it remains for us to show that

$$\langle\sigma, A_n\rangle - \langle\sigma', A_n\rangle \le o(1); \tag{4}$$

this will imply $\langle\sigma', A_n\rangle \ge s^* - \epsilon/2 - o(1)$ by Proposition 34, and hence $\textsc{Sdp}(A_n) \ge s^* - \epsilon$ (for sufficiently large n), as desired.

We have

$$\langle\sigma, A_n\rangle - \langle\sigma', A_n\rangle = \langle\sigma - \sigma', A_n\rangle \le \|\widetilde{\sigma} - \widetilde{\sigma}'\|_1 \|\widetilde{A}_n\|_\infty.$$

Next,

$$\|\widetilde{A}_n\|_\infty = \|p(\mathcal{L})\|_\infty = \|\sum_w \mathcal{L}^w \otimes a_w\|_\infty \le \sum_w \|\mathcal{L}^w\|_\infty \cdot \|a_w\|_\infty = \sum_w \|a_w\|_\infty \le O(1).$$

Here the final equality is because each $\mathcal{L}^w$ is a signed permutation matrix (hence has $\|\mathcal{L}^w\|_\infty = 1$), and the final inequality is because p has only constantly many coefficients, of constant size. Thus to establish Inequality (4), it remains to show $\|\widetilde{\sigma} - \widetilde{\sigma}'\|_1 \leq o(1)$.

Define the orthogonal projection matrices $\Pi_B = \sum_{i \in B} |i\rangle\langle i| \otimes \mathbb{1}_{r \times r}$ and similarly $\Pi_{\overline{B}}$, where $\overline{B} = [n] \setminus B$. Observe that

$$\sigma' = \tfrac{1}{nr}\Pi_B + \Pi_{\overline{B}}\sigma\Pi_{\overline{B}},$$

and thus

$$\|\widetilde{\sigma} - \widetilde{\sigma}'\|_1 = \|\widetilde{\sigma} - \widetilde{\Pi}_{\overline{B}}\widetilde{\sigma}\widetilde{\Pi}_{\overline{B}} - \tfrac{1}{nr}\widetilde{\Pi}_B\|_1 \leq \|\widetilde{\sigma} - \widetilde{\Pi}_{\overline{B}}\widetilde{\sigma}\widetilde{\Pi}_{\overline{B}}\|_1 + \tfrac{1}{nr}\|\widetilde{\Pi}_B\|_1.$$

But $\frac{1}{nr}\|\widetilde{\Pi}_B\|_1 = \frac{|B|}{n} = o(1)$, so it remains to show

$$\|\widetilde{\sigma} - \widetilde{\Pi}_{\overline{B}}\widetilde{\sigma}\widetilde{\Pi}_{\overline{B}}\|_1 \leq o(1).$$

Note that $\widetilde{\sigma} \in \mathbb{C}^{nr \times nr}$ is nearly a density matrix: it is PSD, and all but a $1 - o(1)$ fraction of its diagonal entries are $\frac{1}{nr}$, with the remaining ones being bounded in magnitude by $O(\frac{1}{n})$. Thus $\mathrm{tr}(\widetilde{\sigma}) = 1 \pm o(1)$, and we can therefore scale $\widetilde{\sigma}$ by a $1 \pm o(1)$ factor to produce a true density matrix $\hat{\sigma}$. Clearly it now suffices to show

$$\|\hat{\sigma} - \widetilde{\Pi}_{\overline{B}}\hat{\sigma}\widetilde{\Pi}_{\overline{B}}\|_1 \leq o(1).$$

But this follows from Winter's Gentle Measurement Lemma [39, Lem. 9], which bounds the quantity on the left by $\sqrt{8\lambda}$, where $\lambda = 1 - \mathrm{tr}(\hat{\sigma}\widetilde{\Pi}_{\overline{B}}) = o(1)$. This completes the proof.

5 Application to block models

In this section we will describe the application of our results to the hypothesis testing problem in block models; that is, using the (Goemans–Williamson) SDP value of the negated adjacency matrix $\textsc{Sdp}(-A)$ to distinguish between uniformly regular d-regular graphs and the "equitable stochastic block model" described by Bandeira et al and others [32, 5, 2].

In the n-vertex equitable 2-community block model, the n vertices are divided into two groups, and each vertex has a edges to vertices of the same group, and b edges to vertices of the other group (and $a + b = d$). A random graph of this form is generated by taking a random unsigned $n/2$-lift of the 2-vertex graph which has b parallel edges, and a self-loops on each vertex. The corresponding polynomial which describes the lift is

$$\begin{aligned} p(Y_1, \ldots, Y_{2a}, Z_1, \ldots, Z_b) = &\begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \left(\sum_{i=1}^{a} Y_i \right) + \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} \left(\sum_{i=a+1}^{2a} Y_i \right) \\ &+ \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} \left(\sum_{i=1}^{b} Z_i \right) + \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix} \left(\sum_{i=1}^{a} Z_i^* \right). \end{aligned} \tag{5}$$

By evaluating p at a random unsigned $n/2$-lift $\boldsymbol{\mathcal{L}} = (\boldsymbol{M}_1, \ldots, \boldsymbol{M}_{2a}, \boldsymbol{P}_1, \ldots, \boldsymbol{P}_b)$ we obtain (the adjacency matrix of) a random graph $\boldsymbol{A}_n$ in the n-vertex equitable 2-community block model. We note that the infinite lift $p(\mathcal{L}_\infty)$ is (multiple copies of) the infinite d-regular graph; thus in particular we have $\mathrm{spec}(A_\infty) = [-2\sqrt{d-1}, 2\sqrt{d-1}]$.

To upper bound $\textsc{Sdp}(-\boldsymbol{A}_n)$, we use the eigenvalue bound $\textsc{Sdp}(-\boldsymbol{A}_n) \leq \lambda_{\max}(-\boldsymbol{A}_n)$. In contrast to the previous sections of our paper, the finite random lift here is unsigned, hence we need to take some care with the "trivial eigenvalues" of the resulting lift.

▶ **Definition 36** (Trivial eigenvalues). *Given a matrix polynomial p with coefficients from $\mathbb{C}^{r\times r}$, the associated* trivial eigenvalues *are simply the (multiset of) eigenvalues of $p(1,\dots,1) \in \mathbb{C}^{r\times r}$.*

Note that the trivial eigenvalues of our polynomial in Equation (5) are those of $\begin{pmatrix} a & b \\ b & a \end{pmatrix}$, namely $a+b$ and $a-b$. In the case of unsigned matrix polynomial lifts, Bordenave and Collins [10] show the following:

▶ **Theorem 37.** *Let p be a self-adjoint matrix polynomial with coefficients from $\mathbb{C}^{r\times r}$ on indeterminates $Y_1,\dots,Z_e^*$. Write T for the trivial eigenvalues of p. Then for all $\epsilon,\beta>0$ and sufficiently large n, the following holds:*

Let $\boldsymbol{A}_n = p(\boldsymbol{\mathcal{L}}_n)$, where $\boldsymbol{\mathcal{L}}_n$ is a random unsigned n-lift, and let $A_\infty = p(\mathcal{L}_\infty)$. Then except with probability at most β, the spectra $\operatorname{spec}(\boldsymbol{A}_{n,\perp}) \setminus T$ and $\operatorname{spec}(A_\infty)$ are at Hausdorff distance at most ϵ.

Applying this to the equitable stochastic block model, it means that the nontrivial eigenvalues of graphs in the model are between $-2\sqrt{d-1}-\epsilon$ and $2\sqrt{d-1}+\epsilon$ with high probability (i.e., the same range as for random d-regular graphs). Recalling that the trivial eigenvalues of $-\boldsymbol{A}_n$ are $-(a+b)$ and $-(a-b)$, we indeed get $\lambda_{\max}(\boldsymbol{A}_n) \le \max(b-a,\ 2\sqrt{a+b-1})+\epsilon$ with high probability, implying the upper bound in Corollary 3

As for the lower bound in Corollary 3, we refer to Remark 29 to see that the proof in Section 4.1 holds regardless of signs on the lift used to construct the SDP solution. Thus Section 4.1 also establishes a lower bound of $\textsc{Sdp}(-\boldsymbol{A}_n) \ge 2\sqrt{a+b-1}-\epsilon$. Meanwhile, in the $\textsc{Block}(n,a,b)$ we can always take an integral solution that is the ±1-indicator for the two communities in the partition; this will have value exactly $b-a$ and hence we also always have $\textsc{Sdp}(-\boldsymbol{A}_n) \ge b-a$. This completes the proof of the lower bound in Corollary 3.

Abstract

For a permutation $\pi : [k] \to [k]$, a function $f : [n] \to \mathbb{R}$ contains a π-appearance if there exists $1 \leq i_1 < i_2 < \cdots < i_k \leq n$ such that for all $s, t \in [k]$, $f(i_s) < f(i_t)$ if and only if $\pi(s) < \pi(t)$. The function is π-free if it has no π-appearances. In this paper, we investigate the problem of testing whether an input function f is π-free or whether f differs on at least εn values from every π-free function. This is a generalization of the well-studied monotonicity testing and was first studied by Newman, Rabinovich, Rajendraprasad and Sohler [28]. We show that for all constants $k \in \mathbb{N}$, $\varepsilon \in (0, 1)$, and permutation $\pi : [k] \to [k]$, there is a one-sided error ε-testing algorithm for π-freeness of functions $f : [n] \to \mathbb{R}$ that makes $\tilde{O}(n^{o(1)})$ queries. We improve significantly upon the previous best upper bound $O(n^{1-1/(k-1)})$ by Ben-Eliezer and Canonne [7]. Our algorithm is adaptive, while the earlier best upper bound is known to be tight for nonadaptive algorithms.

1 Introduction

Given a permutation $\pi : [k] \to [k]$, a function $f : [n] \to \mathbb{R}$ contains a π-appearance if there exists $1 \leq i_1 < i_2 < \cdots < i_k \leq n$ such that for all $s, t \in [k]$ it holds that $f(i_s) < f(i_t)$ if and only if $\pi(s) < \pi(t)$. In other words, the function restricted to the indices $\{i_1, \ldots, i_k\}$ respects the ordering in π. The function is π-free if it has no π-appearance. For instance, the set of all real-valued monotone non-decreasing functions over $[n]$ is $(2, 1)$-free. The notion of π-freeness is well-studied in combinatorics, where the famous Stanley-Wilf conjecture about the bound on the number of π-free permutations $f : [n] \to [n]$ has spawned a lot of work [13, 14, 5, 25, 3], ultimately culminating in a proof by Marcus and Tardos [26]. The problem of designing algorithms to determine whether a given permutation $f : [n] \to [n]$ is π-free is an active area of research [2, 1, 10], with linear time algorithms for constant k [23, 20]. Apart from the theoretical interest, practical motivations to study π-freeness include the study of motifs and patterns in time series analysis [11, 32, 24].

In this paper, we study property testing of π-freeness, first studied by Newman, Rabinovich, Rajendraprasad and Sohler [28]. Specifically, given $\varepsilon \in (0, 1)$, an ε-testing algorithm for π-freeness accepts an input function f that is π-free, and rejects if at least εn values of

f need to be changed for it to become π-free[1]. This problem is a generalization of the well-studied monotonicity testing on the line ($(2,1)$-freeness), which was one of the first works in combinatorial property testing, and is still being studied actively [17, 18, 12, 15, 6, 16, 31].

Newman, Rabinovich, Rajendraprasad and Sohler [28] showed that for a general permutation π of length k, the problem of π-freeness can be ε-tested using a nonadaptive[2] algorithm of query complexity $O_{k,\varepsilon}(n^{1-1/k})$.[3] Additionally, they showed that, for nonadaptive algorithms, one cannot obtain a significant improvement on this upper bound for $k \geq 4$. In a subsequent work, Ben-Eliezer and Canonne [7] improved this upper bound to $O_{k,\varepsilon}(n^{1-1/(k-1)})$, which they showed to be tight for nonadaptive algorithms. For monotone permutations π of length k, namely, either $(1, 2, \ldots, k)$ or $(k, k-1, \ldots, 1)$, [28] presented an algorithm with query complexity $(\varepsilon^{-1} \log n)^{O(k^2)}$ to ε-test π-freeness. This was improved, in a sequence of works [8, 9], to $O_{k,\varepsilon}(\log n)$, which is optimal for constant ε even for the special case of testing $(2,1)$-freeness [19].

Despite the extensive study and advances in testing freeness of monotone permutations, improving the complexity of testing freeness of arbitrary permutations has remained open all this while. For arbitrary permutations of length at most 3, [28] gave an adaptive algorithm for testing freeness with query complexity $(\varepsilon^{-1} \log n)^{O(1)}$. However, the case of general $k > 3$ has remained elusive. In particular, the techniques of [28] for $k = 3$ do not seem to generalize even for $k = 4$.

As remarked above, optimal *nonadaptive* algorithms are known for any k [7], but, their complexity tends to be linear in the input length as k grows. For the special case of $(2,1)$-freeness, it is well-known that adaptivity does not help at all in improving the complexity of testing [18, 19]. Adaptivity is known to help somewhat for the case of testing freeness of monotone permutations of length k, where, every nonadaptive algorithm has query complexity $\Omega((\log n)^{\log k})$ [8], and the $O_{k,\varepsilon}(\log n)$-query algorithm of Ben-Eliezer, Letzter, and Waingarten [9] is adaptive. Adaptivity significantly helps in testing freeness of arbitrary permutations of length 3 as shown by [28] and [7].

Our results. In this work, we give adaptive ε-testing algorithms for π-freeness of permutations π of arbitrary constant length k with complexity $\tilde{O}_{k,\varepsilon}(n^{o(1)})$. Hence, testing π-freeness has quite efficient sublinear algorithms even for relatively large patterns. Our result shows a strong separation between adaptive and nonadaptive algorithms for testing pattern freeness.

▶ **Theorem 1.1.** *Let $\varepsilon \in (0,1)$, $k \in \mathbb{N}$ and $\pi : [k] \to [k]$ be a permutation. There exists an ε-tester for π-freeness of functions $f : [n] \to \mathbb{R}$ with query complexity $\tilde{O}_{k,\varepsilon}(n^{O(1/\log\log\log n)})$.*

Discussion of our techniques. The algorithm that we design has one-sided error and rejects only if it finds a π-appearance in the input function $f : [n] \to \mathbb{R}$. In the following paragraphs, we present some ideas behind a $\tilde{O}(\sqrt{n})$-query algorithm for detecting a π-appearance in a function f that is ε-far from π-free, for a permutation π of length 4. The case of length-4 permutations is not much different from the general case (where, we additionally recurse on problems of smaller length patterns). The $\tilde{O}(\sqrt{n})$ queries algorithm, however, is much

[1] Algorithms in this area are typically randomized, and the decisions to accept and reject are with high constant probability. See [33, 22] for definitions of property testing.

[2] An algorithm whose queries do not depend on the answers to previous queries is a nonadaptive algorithm. It is adaptive otherwise.

[3] Throughout this work, we are interested in the parameter regime of constant $\varepsilon \in (0,1)$ and k. The notation $O_{k,\varepsilon}(\cdot)$ hides a factor that is an arbitrary function of these parameters.

simpler than the general one, but it outlines many of the ideas involved in the latter one. A more detailed description appears in Section 3. The formal description of the general algorithm is given in Section 4. The correctness proof and query complexity analysis of the general algorithm can be found in the full version [30].

For a parameter $\varepsilon \in (0,1)$, a function f is ε-far from π-free if at least an εn of its values needs to be changed in order to make it π-free. In other words, the Hamming distance of f from the closest π-free real-valued function over $[n]$ is at least εn. A folklore fact is that the Hamming distance and the deletion distance of f to π-freeness are equal, where the deletion distance of f to π-freeness is the cardinality of the smallest set $S \subseteq [n]$ such that f restricted to $[n] \setminus S$ is π-free. By virtue of this equality, a function that is ε-far from π-free has a matching of π-appearances of cardinality at least $\varepsilon n/4$. This observation facilitates our algorithm and all previous algorithms on testing π-freeness, including monotonicity testers.

The basic ingredient in our algorithms is the use of a natural representation of $f : [n] \to \mathbb{R}$ by a Boolean function over a grid $[n] \times R(f)$, where $R(f)$ denotes the range of f. Specifically, we visualize the function as a grid of n points in $\mathbb{R}^2$, such that for each $i \in [n]$, the point $(i, f(i))$ is a marked point of the grid. We denote this grid with marked points as G_n. This view has been useful in the design of approximation algorithms for the related and fundamental problem of estimating the length of Longest Increasing Subsequence (LIS) in a real-valued array [35, 34, 27, 29]. Adopting this view, for any permutation π, a π-appearance at places $(i_1, \ldots, i_k)$ in f corresponds naturally to a k-tuple of points $\{i_j, f(i_j)\},\ j = 1 \ldots k$ in G_n, for which their relative order (in G_n) forms a π-appearance. The converse is also true: every π-appearance in the Boolean grid G_n corresponds to a π-appearance in f.

We note that the grid G_n is neither known to nor directly accessible by the algorithm, and in particular, $R(f)$ is not assumed to be known. A main first step in our algorithm is to approximate the grid G_n by a coarser $m \times m$ grid of boxes, $G_{m,m}$, for $m << n$, a parameter that will determine the query complexity. The grid $G_{m,m}$ is defined as follows. Suppose that we have a partition of $R(f)$ into m disjoint contiguous intervals of increasing values, referred here as "layers", $I_1, \ldots, I_m$, and let $S_1, \ldots, S_m$ be a partition of $[n]$ into m contiguous intervals of equal length, referred to as "stripes". These two partitions decompose G_n and the f-points in it into m^2 boxes which form the grid of cells $G_{m,m}$. The (i,j)-th cell of this grid is the Cartesian product $S_i \times I_j$, and is denoted $\mathsf{box}(S_i, I_j)$. We view the non-empty cells in $G_{m,m}$ as a coarse approximation of G_n (and of the input function, equivalently). The grid $G_{m,m}$ has a natural order on its boxes (viewed as points in $[m] \times [m]$).

While $G_{m,m}$ is also not directly accessible to the algorithm, it can be well-approximated very efficiently. Fixing m, we use sampling by $\tilde{O}(m)$ queries to identify and *mark* the boxes in $G_{m,m}$ that contain a non-negligible density of points of G_n. This provides a good enough approximation of the grid $G_{m,m}$. For the rest of this top-level explanation, assume that we have fixed $m << n$, and we know $G_{m,m}$; that is, we know the the number of points of G_n belonging to each box in $G_{m,m}$, but not necessarily the points themselves.

If we find k nonempty boxes in $G_{m,m}$ that form a π-appearance when viewed as points in the $[m] \times [m]$ grid, then G_n (and hence f) contains a π-appearance for any set of k points that is formed by selecting one point from each of the corresponding boxes. See Figure 1(A) for such a situation, for $\pi = (3,2,1,4)$. We first detect such π-appearances by our knowledge of $G_{m,m}$. However, the converse is not true: it could be that G_n contains many π-appearances, where the corresponding points, called "legs", are in boxes that share layers or stripes, and hence do not form π-appearances in $G_{m,m}$. See e.g., Figure 1(B) for such an appearance for $\pi = (3,2,1,4)$. Thus, assuming that the function is far from being π-free, and no π-appearances are detected in $G_{m,m}$, there must be many π-appearances in

which some legs share a layer or a stripe in $G_{m,m}$. In this case, the seminal result of Marcus and Tardos [26], implies that only $O(m)$ of the boxes in $G_{m,m}$ are non-empty. An averaging argument implies that if f is ε-far from being π-free, then after deleting layers or stripes in $G_{m,m}$ with $\omega(1)$ dense boxes, we are still left with a partial function (on the undeleted points) that is ε'-far from being π-free, for a large enough ε'.

Now, to be specific, consider $\pi = (3, 2, 1, 4)$ although all the following ideas work for any specific 4-length permutation. Any π-appearance has its four legs spread over at most 4 marked boxes. This implies that there are only constantly many non-isomorphic ways of arranging the marked boxes containing any particular π-appearance (in terms of the order relation among the marked boxes, and the way the legs of the π-appearance are included in them). These constantly many ways are called "configurations" in the sequel. Thus any π-appearance is consistent with a certain configuration. Additionally, in case multiple points in a π-appearance share some marked boxes, this appearance induces the appearances of permutations of length smaller than 4 in each box (which are sub-permutations ν of π). If a constant fraction of the π-appearances are spread across multiple marked boxes, there will be many such ν-appearances in the marked boxes in the coarse grid. Hence, one phase of our algorithm will run tests for ν-appearances for smaller patterns ν (which can be done in $\operatorname{polylog} n$ queries using known testers for patterns of length at most 3) on each marked box, and combine these ν-appearances to detect a π-appearance, if any. This phase, while seemingly simple will require extra care, as combining sub-patterns appearances into a global π-appearance is not always possible. This is a major issue in the general case for $k > 4$.

The simpler case is when there is a constant fraction of π-appearances such that all 4 points of each such appearance belong to a single marked box. This can be solved by randomly sampling a few marked boxes and querying all the points in them to see if there are any π-appearances. A special treatment has to be made in the case a constant fraction of the π-appearances have their legs belonging to the same layer or the same stripe. But this will be an easy extension of the "one-box" case.

To obtain the desired query complexity, consider first setting $m = \tilde{O}(\sqrt{n})$. Getting a good enough estimate of $G_{m,m}$ as described above take $\tilde{O}(m) = \tilde{O}(\sqrt{n})$ queries. Then, testing each box for ν-freeness, for smaller permutations ν takes $\operatorname{polylog} n$ per test, but since this is done for all marked boxes, this step also takes $\tilde{O}(m) = \tilde{O}(\sqrt{n})$. Finally, in the last simpler case, we may just query all indices in a sampled box that contains at most $n/m = \sqrt{n}$ indices, by our setting of m. This results in a $\tilde{O}(\sqrt{n})$-query tester for π-freeness.

To obtain a better complexity, we reduce the value of m, and, in the last step, we randomly sample a few marked boxes and run the algorithm recursively. This is so, since, in the last step, we are in the case that for a constant fraction of the π-appearances, all four legs of each π-appearance belong to a single marked box (or a constant number of marked boxes sharing a layer or stripe). The depth of recursion depends monotonically on n/m and the larger it is the smaller is the query complexity. The bound we describe in this article is $n^{O(1/\log\log n \log n)}$ which is due to the exponential deterioration of the distance parameter ε in each recursive call. Our algorithm for permutations of length $k > 4$ uses, in addition to the self-recursion, a recursion on k too.

Finally, even though it was not explicitly mentioned, we call ν-freeness or π-freeness algorithms on marked boxes (or a collection of constantly many marked boxes sharing a layer or stripe) and not the entire grid. Since we do not know which points belong to the marked boxes, but only know that their density is significant, we can access points in them only via sampling and treating points that fall outside the desired box as being *erased*. This necessitates the use of erasure-resilient testers [16]. Such testers are known for all permutation patterns of length at most 3 [16, 29, 28]. In addition, the basic tester we design is also erasure-resilient, which makes it possible for it to be called recursively.

Some additional complications we had to overcome. In the recursive algorithm for k-length permutation freeness, $k \geq 4$, we need to find ν-appearances that are restricted to appear in specific configurations, for smaller length permutations ν. To exemplify this notion, consider testing $\nu = (1, 3, 2)$-freeness. In the usual (unrestricted) case, $f : [n] \mapsto \mathbb{R}$ has a ν-appearance if the values at any three indices have a ν-consistent order. In a restricted case, we may ask ourselves whether f is free of ν-appearances where the indices corresponding to the $1, 3$-legs of a ν-appearance are at most $n/2$ (that is in the first half of $[n]$), while the index corresponding to the 2-leg is larger than $n/2$. This latter property seems at least as hard to test as the unrestricted one. In particular, for the ν-appearance as described above, it could be that while f is far from being ν-free in the usual sense, it is still free of having restricted ν-appearances. In our algorithm, we need to test (at lower recursion levels) freeness from such restricted appearances. The extra restriction is discussed in Section 3 and Section 4.

Open questions. The major open question is to determine the exact (asymptotic) complexity of testing π-freeness of arbitrary permutations $\pi : [k] \to [k]$, $k \geq 3$. While the gaps for $k = 3$ are relatively small (within polylog n range), the gaps are yet much larger for $k \geq 4$. We do not have any reason to think that the upper bound obtained in this draft is tight. We did not try to optimize the exponent of n in the $\tilde{O}(n^{o(1)})$ expression, but the current methods do not seem to bring down the query complexity to polylog n. We conjecture, however, that the query complexity is polylog n for all constant k. Another open question is whether the complexity of a two-sided error testing might be lower than of one-sided error testing.

Finally, Newman and Varma [29] used lower bounds on testing pattern freeness of monotone patterns of length $k \geq 3$ (for nonadaptive algorithms), to obtain lower bounds on the query complexity of nonadaptive algorithms for LIS estimation. Proving any lower bound better than $\Omega(\log n)$ for adaptively testing freeness, for arbitrary permutations of length k for $k \geq 3$, may translate in a similar way to lower bounds on adaptive algorithms for LIS estimation.

Other definitions of π-freeness. In the definition of π-freeness, we required strict inequalities on function values to have an occurrence of the pattern. A natural variant is to allow weak inequalities, that is – for a set indices $1 \leq i_1 < i_2 \cdots < i_k \leq n$ a *weak*-π appearance is when for all $s, t \in [k]$ it holds that $f(i_s) \leq f(i_t)$ if and only if $\pi(s) < \pi(t)$. Such a relaxed requirement would mean that having a collection of k or more equal values is already a π-appearance for any pattern π. For monotone patterns of length k, the deletion distance equals to the Hamming distance, for any k, for this relaxed definition as well. We do not know if this is true for larger k for non-monotone patterns in general, although we suspect that the Hamming distance is never larger than the deletion distance by more than a constant factor. Proving this will be enough to make our results true for testing freeness of any constant size forbidden permutation, even with the relaxed definition. We show that the Hamming distance is equal to the deletion distance for patterns of length at most 4. Hence, Theorem 1.1 also holds for weak-π-freeness for $k \leq 4$.

Another variant that may seem related is when the forbidden order pattern is not necessarily a permutation (that is, arbitrary function from $[k]$ to $[k]$ which is not one-to-one). For example, for the 4-pattern $\alpha = (1, 2, 3, 1)$, an α-appearance in f at indices $i_1 < i_2 < i_3 < i_4$ is when $f(i_1) < f(i_2) < f(i_3)$ and $f(i_4) = f(i_1)$, as dictated by the order in α. For testing freeness of such patterns, $\Omega(\sqrt{n})$ adaptive lower bounds exist (due to a simple probabilistic argument) even for the very simple case of $(1, 1)$-freeness, which corresponds to the property of being a one-to-one function.

An interesting point to mention, in this context, is that for testing freeness of forbidden permutations, a major tool that we use is the Marcus-Tardos bound. Namely, that the number of 1's in an $m \times m$ Boolean matrix that does not contain a specific permutation matrix of order k is $O(m)$. For non-permutation patterns, similar bounds are not true in general anymore, but do hold in many cases (or hold in a weak sense, e.g., only slightly more than linear). In such cases, the Marcus-Tardos bound could have allowed relatively efficient testing. However, the lower bounds hinted above for the $(1,1)$-pattern makes the testing problem completely different from that of testing forbidden permutation patterns.

Another area where we have significant gaps in our knowledge is about testing for pattern freeness for functions of bounded or restricted range (for the special case of $(2,1)$-freeness, such a study was initiated by Pallavoor, Raskhodnikova and Varma [31] and followed upon by others [6, 29]). We do know that in the very extreme case, that is, for functions from the line $[n]$ to a constant-sized range, pattern freeness is testable in constant time even for much more general class of forbidden patterns [4].

Lastly, if we restrict our attention to functions $f : [n] \to [n]$ that are themselves permutations, Fox and Wei [21] argued that for some special types of distance measures such as the rectangular-distance and Kendall's tau distance, testing π-freeness can be done in constant query complexity. Testing π-freeness w.r.t. the Hamming or deletion distances is very different, and still remains open for this setting.

Organization. Section 2 contains the notation, important definitions, and a discussion of some key concepts related to testing π-freeness. Section 3 contains a high level overview of an $\tilde{O}(\sqrt{n})$-query algorithm for patterns of length 4. The formal description of our π-freeness tester for permutations π of length $k \geq 4$ and the proof ideas for a special case appear in Section 4. All the missing proofs can be found in the full version [30].

2 Preliminaries and discussion

For a function $f : [n] \to \mathbb{R}$, we denote by $R(f)$ the image of f. We often refer to the elements of the domain $[n]$ as *indices*, and the elements of $R(f)$ as *values*. For $S \subseteq [n]$, $f|_S$ denotes the restriction of f to S. Throughout, n will denote the domain size of the function f.

We often refer to events in a probability space. For ease of representation, we will say that an event E occurs with high probability, denoted "w.h.p.", if $\Pr(E) > 1 - n^{-\log n}$, to avoid specifying accurate constants.

Let $\mathcal{S}_k$ denote the set of all permutations of length k. We view $\pi = (a_1, \ldots, a_k) \in \mathcal{S}_k$ as a function (and not as a cyclus), that is, where $\pi(i) = a_i,\ i \in [k]$. We refer to a_i as the ith value in π, and as the a_i-leg of π. Thus e.g., for $\pi = (4,1,2,3)$, the first value is 4, and the third is 2, while the 4-leg of π is at the first place and its 1-leg is at the second place. We often refer to $\pi \in \mathcal{S}_k$ as a k-pattern.

2.1 Deletion distance vs. Hamming distance

Let $f : [n] \to \mathbb{R}$. The deletion distance of f from being π-free is $\mathrm{Ddist}_\pi(f) = \min\{|S| :\ S \subseteq [n],\ f|_{[n]\setminus S}$ is π-free$\}$. Namely, it is the cardinality of the smallest set $S \subseteq [n]$ that intersects each π-appearance in f. The Hamming distance of f from being π-free, $\mathrm{Hdist}_\pi(f)$ is the minimum of $\mathrm{dist}(f, f') = |\{i :\ i \in [n],\ f(i) \neq f(i')\}|$ over all functions $f' : [n] \to \mathbb{R}$ that are π-free. For $0 \leq \varepsilon < 1$ we say that f is ε-far from π-freeness in deletion distance, or Hamming distance, if $dist_\pi(f) \geq \varepsilon n$, and otherwise we say that f is ε-close to π-freeness, where $dist_\pi(f)$ is the corresponding distance.

▷ Claim 2.1. $\text{Ddist}_\pi(f) = \text{Hdist}_\pi(f)$

Claim 2.1 is extremely important for testing π-freeness, and is what gives rise to *all* testers of monotonicity, as well as π-freeness that are known. This is due to the fact that the tests are really designed for the deletion distance, rather then the Hamming distance. The folklore observation made in Claim 2.2 facilitates such tests, and Claim 2.1 makes the tests work also for the Hamming distance. Due to Claim 2.1, we say that a function f is ε-far from π-free without specifying the distance measure.

Let $\pi \in \mathcal{S}_k$ and $f : [n] \to \mathbb{R}$. A matching of π-appearances in f is a collection of π-appearances that are pairwise disjoint as sets of indices in $[n]$. The following claim is folklore and immediate from the fact that the size of a minimum vertex cover of a k-uniform hypergraph is at most k times the cardinality of a maximal matching.

▷ Claim 2.2. Let $\pi \in \mathcal{S}_k$. If $f : [n] \to \mathbb{R}$ is ε-far from being π-free, then there exists a matching of π-tuples of size at least $\varepsilon n/k$.

All our algorithms have one-sided error, i.e., they always accept functions that are π-free. For functions that are far from being π-free, using Claim 2.2, our algorithms aim to detect some π-appearance, providing a witness for the function to not be π-free. Hence, in the description below, and throughout the analysis of the algorithms, the input function is assumed to be ε-far from π-free.

2.2 Viewing a function as a grid of points

Let $f : [n] \to \mathbb{R}$. We view f as points in an $n \times |R(f)|$ grid G_n. The horizontal axis of G_n is labeled with the indices in $[n]$. The vertical axis of G_n represents the image $R(f)$ and is labeled with the distinct values in $R(f)$ in increasing order, $r_1 < r_2 < \ldots < r_{n'}$, where $|R(f)| = n' \leq n$. We refer to an index-value pair $(i, f(i)), i \in [n]$ in the grid as a *point*. The grid has n points, to which our algorithms do not have direct access. In particular, we do not assume that $R(f)$ is known. The function is one-to-one if $|R(f)| = n$.

Note that if M is a matching of π-appearances in f, then M defines a corresponding matching of π-appearances in G_n. We will always consider this alternative view, where the matching M is a set of disjoint π-appearances in the grid G_n.

2.2.1 Coarse grid of boxes

For a pair of subsets (S, I), where $S \subseteq [n]$ and $I \subseteq R(f)$, we denote by $\mathsf{box}(S, I)$, the subgrid $S \times I$ of G_n with the set of points in G_n (corresponding to f) in this subgrid. In most cases, S and I will be intervals in $[n]$ and $R(f)$, respectively, and hence the name *box*. The *length* of $\mathsf{box}(S, I)$ is defined to be $|S|$. A box is *nonempty* if it contains at least one point and is *empty* otherwise.

Consider an arbitrary collection of pairwise disjoint contiguous value intervals $\mathcal{L} = \{I_1, \ldots I_m\}$, such that $I \subseteq \cup_{i\in[m]} I_i$. The set $\mathcal{L}$ naturally defines a partition of the points in $\mathsf{box}(S, I)$ into m horizontal *layers*, $L_i = \{(j, f(j)) : j \in S, f(j) \in I_i\},\ i \in [m]$. A layer is *multi-valued* if it has two points with different values. It is said to be *single-valued* otherwise.

Assume that, in addition to a set of layers $\mathcal{L}$, we have a partition of S into disjoint intervals $S = \cup_1^m S_i$ where $S_i = [a_i, b_i]$, and $b_i < a_{i+1},\ i = 1, \ldots m-1$, then $\mathcal{S} = (S_1, \ldots S_m)$ partitions $\mathsf{box}(S, I)$ and the points in it, into m vertical *stripes* $\{\text{St}(S)\}_{S\in\mathcal{S}}$ where $\text{St}(S) = \mathsf{box}(S, I)$ contains the points $\{(i, f(i)) : i \in S\}$. The layering $\mathcal{L}$ together with the stripes $\mathcal{S}$ partition $\mathsf{box}(S, I)$ into a coarse grid $G_{m,m}$ of boxes $\{\mathsf{box}(S_i, I_j)\}_{i,j\in[m]}$ that is isomorphic to the

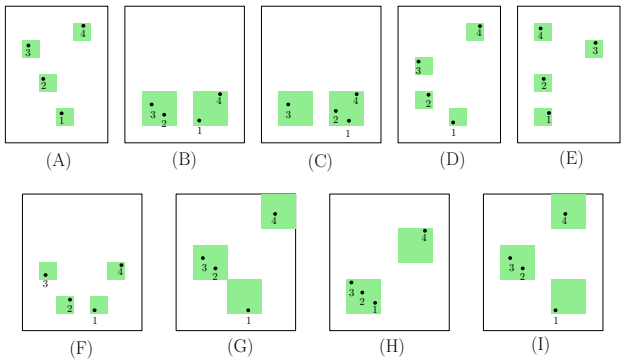

Figure 1 Each rectangle represents a different grid G_n, where the green shaded boxes correspond to some nonempty boxes in those grids. Each figure represents a different configuration type with respect to the appearance of some 4-length pattern. The dots and the numbers indicate possible splittings of the 4 legs of π. *Figure (E) represents the pattern* $(4, 2, 1, 3)$ *and all others represent the pattern* $(3, 2, 1, 4)$.

grid $[m] \times [m]$. Note that $\mathsf{box}(S, I)$ could even be the entire grid G_n. Given such a grid $G_{m,m}$, the layer of $\mathsf{box}(S_i, I_j)$, denoted $L(\mathsf{box}(S_i, I_j))$, is $\mathsf{box}(S, I_j)$ and its stripe, denoted $\mathrm{St}(\mathsf{box}(S_i, I_j))$, is $\mathsf{box}(S_i, I)$.

We say that *layer L is below layer L'*, and write $L < L'$, if the largest value of a point in L is less than the smallest value of a point in L'. For stripes $\mathrm{St}(S), \mathrm{St}(S')$, we write $\mathrm{St}(S) < \mathrm{St}(S')$ if the largest index in S is smaller than the smallest index in S'. For the grid $G_{m,m}$ and two boxes B_1, B_2 in it, $B_1 < B_2$ if $L(B_1) < L(B_2)$ and $\mathrm{St}(B_1) < \mathrm{St}(B_2)$.

2.2.2 Patterns among and within nonempty boxes

Consider a coarse grid of boxes, $G_{m,m}$, defined as above on the grid of points G_n. There is a natural homomorphism from the points in G_n to the nonempty boxes in $G_{m,m}$ where those points fall. For f and a grid of boxes $G_{m,m}$ as above, we refer to this homomorphism implicitly. This homomorphism defines when $G_{m,m}$ contains a π-appearance in a natural way. For example, consider the permutation $\pi = (3, 2, 1, 4) \in \mathcal{S}_4$. We say that $G_{m,m}$ *contains* π if there are nonempty boxes B_1, B_2, B_3, B_4 such that $\mathrm{St}(B_1) < \mathrm{St}(B_2) < \mathrm{St}(B_3) < \mathrm{St}(B_4)$ and $L(B_3) < L(B_2) < L(B_1) < L(B_4)$ (see Figure 1(A)).

▶ **Observation 2.3.** *Let $\mathcal{L}, \mathcal{S}$ be a partition of G_n into layers and stripes as above, with $|\mathcal{L}| = m$, $|\mathcal{S}| = m$ then if $G_{m,m}$ contains π then G_n (and equivalently f) has a π-appearance.*

The converse of Observation 2.3 is not true; G_n may contain a π-appearance while $G_{m,m}$ does not. This happens when some of the boxes that contain the π-appearance share a layer or a stripe. Two boxes are *directly-connected* if they share a layer or a stripe. The transitive closure of the relation *directly-connected* is called *connected*. An arrangement of boxes where every two boxes are connected is called a *connected component*, or simply, a component. The size of a connected component is the number of boxes in it.

For $\pi \in \mathcal{S}_k$, a π-appearance in G_n implies that the k points corresponding to such a π-appearance are in $i \leq k$ distinct components in $G_{m,m}$, where the jth component C_j may contain b_j boxes each containing at least one point of the corresponding π-appearance. We refer to the π-values in the corresponding boxes of the components as *legs*. For example, for $\pi = (3, 2, 1, 4)$, the π-appearance shown in Figure 1(B) is contained in two boxes that share the same layer, and hence form one component. The left box contains the $3, 2$ legs of the π-appearance and other contains the $1, 4$ legs. A different 1-component 2-boxed appearance in the same two boxes has 3 appearing in B_1 and all the other legs in B_2 as in Figure 1(C).

Examples for $\pi = (3, 2, 1, 4)$-appearances with two components C_1, C_2 are illustrated in Figure 1(F) and Figure 1(H). In the first, C_1, C_2 contain 2 boxes each, where C_1 contains the $(3, 4)$ legs of the appearance, each in one box, and C_2 contains the $(1, 2)$ legs. In the second, each component is 1-boxed, where the first contains the $(3, 2, 1)$-legs and the other contains the 4-leg of the appearance. Figure 1(A) contains a $(3, 2, 1, 4)$-appearance in 4 components. Some other possible appearances with 1 component and 3 components are illustrated in Figure 1(B), Figure 1(C), Figure 1(D) and Figure 1(G).

To sum up, each π-appearance in G_n defines an arrangement of nonempty boxes in $G_{m,m}$ that contain the legs of that appearance. This arrangement is defined by the relative order of the layers and stripes among the boxes, and has at most k components. Such a box-arrangement that can contain the legs of a π-appearance is called a *configuration*. Note that there may be many different π-appearances in distinct boxes, all having the same configuration $\mathcal{C}$. Namely, in which, the arrangements of the boxes in terms of the relative order of layers and stripes are identical. So, a configuration is just a set of boxes (or points) in the $k \times k$ grid. An actual set of boxes in $G_{m,m}$ forming a specific type of configuration is referred to as a *copy* of that configuration.

Let $c(k)$ be the number of all possible configurations that are consistent with a π-appearance, for $\pi \in \mathcal{S}_k$. For any fixed π, the number $c(k)$ of distinct types of configurations is constant as shown in the following observation.

▶ **Observation 2.4.** $c(k) \leq 2^{O(k \log k)}$

A configuration $\mathcal{C}$ does not fully specify the way in which a π-appearance can be present. It is necessary to also specify the way the k legs of the π-appearance are partitioned among the boxes in a copy of $\mathcal{C}$. Let $\mathcal{B}$ denote a set of boxes forming the configuration $\mathcal{C}$. Let $\phi : [k] \to \mathcal{B}$ denote the mapping of the legs of the π-appearance to boxes in $\mathcal{B}$, where $\phi(j), j \in [k]$ denotes the box in $\mathcal{B}$ containing the j-th leg of the π-appearance. We say that the copy of $\mathcal{C}$ formed by the boxes in $\mathcal{B}$ contains a ϕ-legged π-appearance.

A configuration $\mathcal{C}$ in which the boxes form $p \geq 2$ components, and that is consistent with a π-appearance, defines $\nu_1, \ldots, \nu_p$ -appearances, respectively, in the p components of $\mathcal{C}$, where ν_j for $j \in [p]$ is the subpermutation of π that is defined by the restriction of π to the j-th component. In addition, $\mathcal{C}$ defines the corresponding mappings $\phi_j, j = 1, \ldots p$, of the corresponding legs of each ν_j to the corresponding boxes in the jth component. For example, consider $\pi = (3, 2, 1, 4)$ and the box arrangement shown in Figure 1(F). That arrangement has two connected components: one that contains B_1, B_4 and the other that contains B_2, B_3, where we number the boxes from left to right (by increasing stripe order). Further, the (only) consistent partition of the legs of π into these boxes is $\pi(i) \in B_i,\ i \in [4]$. In particular, it means that the component formed by B_1, B_4 contains the $3, 4$ legs of π and the component formed by B_2, B_3 contains the $2, 1$ legs of π. Thus, in terms of the discussion above, the component formed by B_1, B_4 has a $\nu_1 = (1, 2)$-appearance (corresponding to the $3, 4$ legs of π), with leg mapping ϕ_1 mapping the 1-leg into B_1 and the 2-leg into B_4. Similarly, the component formed by B_2, B_3 has a $\nu_2 = (2, 1)$-appearance (corresponding to the $2, 1$ legs of π) with corresponding leg mapping ϕ_2 that maps the 2-leg into B_2 and the 1-leg into B_3. Note that the converse is also true: every ν_1 appearance in the component $B_1 \cup B_4$, with a leg-mapping ϕ_1 (that is, in which the $1, 2$ legs are in B_1, B_4 respectively), in addition to a ν_2 appearance in $B_2 \cup B_3$ with the leg-mapping ϕ_2, results in a π-appearance in $G_{m,m}$.

This latter comment leads to the crucial observation that if π defines the corresponding $\nu_1, \ldots, \nu_p$ appearances in the p components of the configuration $\mathcal{C}$, then, *any* $\nu_1, \ldots, \nu_p$-appearances in the p components of any copy of $\mathcal{C}$ with consistent leg-mappings is a π-appearance in $\mathcal{C}$. This is formally stated below.

▶ **Definition 2.5.** *Let $\nu \in \mathcal{S}_r$. Let $B_1, \ldots, B_p$ be a set of boxes forming* one *component C and $\phi : [r] \mapsto \{B_1, \ldots, B_p\}$ be an arbitrary mapping of the legs of a ν-appearance to boxes. We say that C has a ϕ-legged ν-appearance if there is a ν-appearance in $\cup_{j=1}^{p} B_j$ in which for each $i \in [r]$, the i-th leg of ν appears in the box $B_{\phi(i)}$.*

▶ **Observation 2.6.** *Let $\pi \in \mathcal{S}_k$ and assume that there exists a π-appearance in G_n that in the grid of boxes $G_{m,m}$ forms a configuration $\mathcal{C}$ that contains t components $C_1, \ldots, C_t$, with C_j having r_j boxes, $j = 1, \ldots, t$ respectively. Let the restriction of this π-appearance to $C_1, \ldots, C_t$ define the permutation patterns $\nu_1, \ldots \nu_t$ in $C_1, \ldots, C_t$, with leg mappings $\phi_1, \ldots \phi_t$, respectively.*

Then, any collection of configuration copies of C_j, $j = 1, \ldots t$, for which $\cup_1^t C_j$ is a copy of $\mathcal{C}$, and ϕ_j-legged ν_j-appearances in C_i, $i = 1, \ldots, t$, defines a π-appearance in $\cup_1^t C_j$. ⌟

2.3 Erasure-resilient testing

Erasure-resilient (ER) testing, introduced by Dixit, Raskhodnikova, Thakurta and Varma [16], is a generalization of property testing. In this model, algorithms get oracle access to functions for which the values of at most α fraction of the points in the domain are erased by an adversary, for $\alpha \in [0, 1)$. As part of our algorithm for testing π-freeness for $\pi \in \mathcal{S}_k$ for $k \geq 4$, we call testers for smaller subpatterns on sub-regions of the grid G_n which may be defined by, say, $\mathsf{box}(S, I)$ for some $S \subseteq [n], I \subseteq R(f)$. In this case, the only access to points in $\mathsf{box}(S, I)$ is by sampling indices from S and checking whether their values fall in I. If the values do not fall in I, we can treat them as erasures. Given the assurance that the number of points falling in $\mathsf{box}(S, I)$ is a constant fraction of $|S|$, we can simply run ER testers on $f|_S$ to test for these smaller subpatterns.

3 High level description of the basic algorithm for $\pi \in \mathcal{S}_4$

Many of the high level ideas in the design of our π-freeness tester of complexity $\tilde{O}(n^{o(1)})$ are described in this section. For simplicity, we describe first the ideas behind a $\tilde{O}(\sqrt{n})$-query tester for π-freeness of $\pi \in \mathcal{S}_4$. Towards the end of this section, we briefly describe how to generalize these ideas to obtain the query complexity of $\tilde{O}(n^{o(1)})$ and for longer constant-length permutations. For simplicity, we assume in what follows that the input function $f : [n] \to \mathbb{R}$ is one-to-one. The algorithm for functions that are not one-to-one differs in a few places and these are explained in Section 4.1.

For the purposes of this high level description, we fix the forbidden permutation $\pi = (3, 2, 1, 4)$. The same algorithm works for any $\pi \in \mathcal{S}_4$. We view f as an (implicitly given) $n \times |R(f)|$ grid G_n consisting of points $(i, f(i))$ for $i \in [n]$, where, in particular, $R(f)$ is neither known nor bounded. Our first goal is to approximate G_n by a coarse grid of boxes $G_{m,m}$, as described above, for $m = \sqrt{n}$. This is done by querying f on $\tilde{\Theta}(m)$ random indices, after which we obtain a partition $\mathcal{L}$ of $R(f)$ into $m' = \Theta(m)$ horizontal layers (value intervals). Then we partition the index set $[n]$ into m' contiguous intervals $\{S_i\}_{i=1}^{m'}$ of equal length. This results in a grid $G_{m',m'}$ in which we estimate the density of each box as the number of sampled points falling in that box, normalized by n/m'. A box $\mathsf{box}(S_i, I_j), i, j \in [m']$ will be tagged as *dense* if it contains $\Omega(1)$ fraction of sampled points. All of the above takes $\tilde{O}(m) = \tilde{O}(\sqrt{n})$ queries, for the above choice of m. It satisfies the following properties with high probability:

- Each layer, that is $\mathsf{box}([n], I_j)$, $j \in [m']$, has approximately the same number of points.
- It is either the case that the dense boxes contain all but an insignificant fraction of the points in G_n, or the total number of marked boxes is larger than $m' \log n$.

Next, we use the following lemma of Marcus and Tardos.

▶ **Lemma 3.1** ([26]). *For any $\pi \in \mathcal{S}_k$, $k \in \mathbb{N}$, there is a constant $\kappa(k) \in \mathbb{N}$ such that for any $r \in \mathbb{N}$, if a grid $G_{r,r}$ contains at least $\kappa(k) \cdot r$ marked points, then it contains a π-appearance among the marked points.*

Let $\kappa = \kappa(4)$. Using Lemma 3.1, we may assume that there are at most $\kappa \cdot m'$ non-empty boxes in $G_{m',m'}$, as otherwise, we already would have found a π-appearance in $G_{m',m'}$, which by Observation 2.3, implies a π-appearance in G_n and in f as well. Hence, as a result of the gridding, if we do not see a π-appearance among the sampled points, the second item above implies that there are $\Theta(m')$ dense boxes in $G_{m',m'}$ and that these boxes cover a large fraction of the points of G_n.

An averaging argument implies that, for an appropriate constant $d = d(\varepsilon)$, only a small constant fraction of layers (or stripes) contain more than d nonempty boxes. Therefore, since the grid G_n is ε-far from being π-free, the restriction of G_n to the layers and stripes that contain at most d boxes each, is also ε'-far from π-free for a large enough constant $\varepsilon' < \varepsilon$. This implies that G_n restricted to the points in dense boxes that belong to layers and stripes containing at most d dense boxes each, has a matching M of π-appearances of size at least $\varepsilon' n/4$. We assume in what follows that this is indeed the situation.

An important note at this point, is that every dense box B is contained in $O(d^3)$ (that is, constantly many) 1-component configurations with at most 4 dense boxes. This implies that there are $O(m)$ such copies of 1-component configurations in $G_{m',m'}$.

Recall that every π-appearance in M defines a configuration of at most 4 components in $G_{m',m'}$. Hence, the matching M of size $|M| = \Omega(n)$ can be partitioned into 4 sub-matchings $M = M_1 \cup M_2 \cup M_3 \cup M_4$, where M_i, $i = 1, \ldots, 4$ consists of the π-appearances participating in configurations having exactly i components. Since $|M| = \Omega(n)$ it follows that at least one of M_i, $i = 1, 2, 3, 4$ is of linear size. Now, any π-appearance in M_4 is an appearance in 4 distinct dense boxes in $G_{m',m'}$, where no two share a layer or a stripe. In that case, such an appearance can be directly detected from the tagged $G_{m',m'}$ with no further queries.

The description of the rest of the algorithm can be viewed as a treatment of several independent cases regarding which of the constantly many configuration types contributes the larger mass out of the $\Omega(n)$ π-appearances in $M_1 \cup M_2 \cup M_3$. There are only two significant cases, but to ease the reader, we split these two cases into the more natural larger number of cases, and observe at the end that most cases can be treated conceptually in the same way.

Case 1: Assume that $|M_1| \geq \varepsilon' n/3$, and further, for simplicity, that a constant fraction of the π-appearances in M_1 are in a single-box component. Then, on average, a dense box, out of the $\Theta(m')$ dense boxes, is expected to contain at least $\Theta(n/m') = \Theta(m') = \Theta(\sqrt{n})$ many π-appearances. Thus a random dense box B is likely to have $\Theta(\sqrt{n})$ many π-appearances, and hence, making queries to all points of such a box will enable us to find one such π-appearance. This takes an additional $n/m' = \Theta(\sqrt{n})$ queries, which is within the query budget.

Next, consider the case that a constant fraction of the π-appearances in M_1 belong to a configuration $\mathcal{C}$ that has more than one dense box (but only one connected component). By a similar argument, a random dense box is expected to participate in at least $\Theta(n/m')$ many π-appearances of copies of configuration-type $\mathcal{C}$. Since each dense box is part of at most $O(d^3)$ (constantly many) connected components of at most 4 dense boxes, sampling a random dense box B and querying all the indices in each of the components that contain at most 4 dense boxes and involve B, is likely to find a π-appearance with high probability. Each connected component is over at most $4n/m'$ indices, resulting in $O(n/m')$ queries.

Case 2: $|M_3| \geq \varepsilon' n/3$, and assume first that a constant fraction of the members in M_3 belong to copies of a configuration $\mathcal{C}$ of 3 components B_1, B_2, B_3, where each one is a single box. For our current working example, $\pi = (3,2,1,4)$, assume further that B_1 contains the $3,2$ legs of a π-appearance and B_2, B_3 contain its 1 and 4 legs, respectively (see Figure 1(G) for an example). In this case B_1 is not $(2,1)$-free (as B_1 contains the $(3,2)$-subpattern of π).

By an averaging argument, it follows that there is a dense box B for which: (a) B is far from $(2,1)$-free, and (b) there are corresponding dense boxes B_2, B_3 that, together with B, form a copy of the configuration $\mathcal{C}$. Now, a test follows easily. We test every dense box for $(2,1)$-freeness, which can be done in $O(\log n)$ queries per box, and hence in $\tilde{O}(m)$ in total. Then, by the guarantee above we will find the corresponding B and B_2, B_3 and a π-appearance in it (by Observation 2.6 with the trivial mapping).

A similar argument holds for a 3-component configuration $\mathcal{C}'$ in which one component contains more than one box, and for any configuration of 3 components.

Case 3: Assume now that $|M_2| \geq \varepsilon' n/3$, and that the corresponding configurations of the π-appearances in M_2 contain two single-box components B_1, B_2, where B_1 holds the first 3 legs of π and B_2 holds the 4-th leg. E.g., For $\pi = (3,2,1,4)$, the configuration $\mathcal{C}$ contains two boxes B_1, B_2 where B_1 contains the subpattern $(3,2,1)$ and B_2 is any nonempty box such that $B_1 < B_2$, (see Figure 1(H) for an illustration). An averaging argument, as made in Case 2, shows that there is a dense box B_1 for which (a) B_1 is far from $(3,2,1)$-free, and (b) there is a corresponding dense box B_2 that, together with B_1, forms a copy of the configuration $\mathcal{C}$. This suggests a test that is conceptually similar to the test in Cases 1 and 2. We test each box for being $(3,2,1)$-free. This can be done in $\operatorname{polylog} n$ queries (e.g., [8]). Then once finding a $(3,2,1)$ in B_1 for which (a) and (b) hold, $B_1 \cup B_2$ contains a π-appearance.

We note here that for the example above, we ended by testing for $(3,2,1)$-freeness which is relatively easy. For a different configuration or π, we might need to test B_1 for a different $\nu \in \mathcal{S}_3$, but this can be done for any $\nu \in \mathcal{S}_3$ using $O(\operatorname{polylog} n)$ queries [28]. Hence the same argument and complexity guarantee hold for any 2-component configuration $\mathcal{C}$ as above.

Case 4: A more complicated situation arises when $|M_2| \geq \varepsilon' n/3$, and the corresponding configurations of the π-appearances in M_2 are formed of two components D, B, with D holding 3 legs of π in 2 or 3 boxes (rather than in one box as in Case 3). E.g., $\pi = (4,2,1,3)$, and the configuration $\mathcal{C}$ as illustrated in Figure 1(E).

By a similar averaging argument to that made in Case 2, it follows that there is a dense box B_1 for which (a) there are dense boxes B_2, B_3 forming a copy D' of D with B_1, and a dense box B such that the configuration formed by D', B is a copy of $\mathcal{C}$, and (b) there are $\Omega(n/m) = \Omega(\sqrt{n})$ ϕ-legged $(3,2,1)$-appearances in D', where ϕ is consistent with the leg mapping that is induced by the configuration $\mathcal{C}$. This implies a conceptually similar test to that of the simpler Case 3 above - we test each of the $O(m)$ components D for $(3,2,1)$-freeness, and then with the existence of the corresponding box B we find a π-appearance. However, this is not perfectly accurate: the algorithm for finding $\nu = (3,2,1)$ in D', although efficient, might find a $(3,2,1)$-appearance where the 3 legs appear in B_1 or in $B_1 \cup B_2$. But this does not extend with B to form a π-appearance, as the leg mapping is not consistent with the one that is induced by $\mathcal{C}$. Namely, unlike before, we do not only need to find a ν-appearance in D but rather a ϕ-legged ν-appearance with respect to a fixed mapping ϕ (that in this case maps each leg to a different box in the component D').

To resolve the problem we need to efficiently test ϕ-legged ν-appearances in multi-boxed components. This, however, we currently do not know how to do. Instead, we design a test that either finds a ϕ-legged ν-appearance, or finds the original π-appearance. This is done using the procedure $\mathsf{AlgTest}_\pi(\nu, \phi, D, m, \varepsilon)$ that will be described in Section 4.

Case 5: The last case that we did not consider yet is when most of the π-appearances are in a configuration containing more than one component, with at least two components containing two (or more) legs each. For $\pi \in \mathcal{S}_4$ the only such case is when the configuration $\mathcal{C}$ contains exactly two components, each containing exactly two legs of π. Returning to our working example with $\pi = (3, 2, 1, 4)$, such examples are depicted e.g., in Figure 1(B) or 1(F). For the explanation below, we will discuss the case that the configuration $\mathcal{C}$ is as in Figure 1(F). Namely, it contains components D_1 that is above D_2, with two boxes each $D_1 = \{B_1, B_4\}$ and $D_2 = \{B_2, B_3\}$, and so that every box contains exactly one leg of π (boxes are numbered by order from left to right in $G_{m',m'}$). Our goal is to find two copies D'_1, D'_2 of the components D_1, D_2 respectively, that form a copy of $\mathcal{C}$, and to find a ϕ_1-legged appearance of $(1, 2)$ in D'_1, and a ϕ_2-legged appearance of $(2, 1)$ in D'_2, so that Observation 2.6 will implies that these two appearances form together a π appearance. Indeed, an averaging argument shows that there are D'_1, D'_2 as above, with D'_i containing $\Omega(n/m)$ ϕ_i-legged appearances of ν_i for $i = 1, 2$. However, we do not know that sampling a pair D'_1, D'_2 in some way, will result in such a good pair. Rather, we are only assured of the existence of only one such pair! Hence, in this case we need to test *every* component D', and for every $\nu \in \mathcal{S}_2$, and for every leg mapping ϕ, for a ϕ-legged ν-appearance in D' in order to find such an asserted pair of components. Such restricted ν-appearances can be tested in $O(\log n)$ queries per component. Therefore, this takes $\tilde{O}(m)$ queries in total. The same argument holds for any $\pi \in \mathcal{S}_4$, and for every configuration that is consistent with Case 5.

Concluding remarks

- At some places in the algorithm above, we had to test for ν-appearances (or restricted ν-appearances) in "dense" subgrids of G_n. For this, we need that all our algorithms are ER, which will be implicitly clear from the description. We also need to take care of reducing the total error when we do non-constant number of by tests, or want to guarantee a large success probability for a large number of events - this is done by trivial amplification that results in a multiplicative $\operatorname{polylog} n$ factor.
- In Case 1, we reduced the problem of finding a π-appearance in G_n, that is assumed to be ε-far from π-free, to the same problem on a subrange of the indices (formed by a small component) of size $\Theta(n/m)$ (with a smaller but constant distance parameter $\varepsilon' < \varepsilon$). For the setting of $m = \sqrt{n}$, solving the problem on the reduced domain was trivially done by querying all indices in the subrange. In the general algorithm, where our goal is a query complexity of $n^{o(1)}$, we set $m = n^\delta$ for an appropriately small δ and apply self-recursion in Case 1.
- In Cases 2, 3, 4 we end up testing ν-freeness for $\nu \in \mathcal{S}_2 \cup \mathcal{S}_3$ in dense boxes, or ϕ-legged ν-freeness of such ν in components of multiple dense boxes. An average argument shows that this can simply be done by sampling one box or component, and making queries to all indices therein. This however, is true only for $\pi \in \mathcal{S}_4$.
  Case 5 is different: here sampling a small number of components does not guarantee an expected large number of the corresponding appearances. This is the reason that we need to test *all* components with at most 2 dense boxes, for ϕ-legged ν-freeness, and for every $\nu \in \mathcal{S}_2$ and leg mapping ϕ. Algorithm $\mathsf{AlgTest}_\pi(\nu, \phi, D, m, \varepsilon)$ can do this for any

$\nu \in \mathcal{S}_2 \cup \mathcal{S}_3$ in n^δ queries for an arbitrary small constant δ. Since we have to do it in Case 5, we may do the same in cases 2, 3, 4 as well! As a result, the algorithm above will contain only two cases: Case 1 where we reduce the problem to the same problem but on a smaller domain, and the new Case 2 where we test *every* small component for ϕ-legged ν-appearance for every $\nu \in \mathcal{S}_2 \cup \mathcal{S}_3$ and every leg mapping ϕ – namely a case in which we reduce the problem to testing (restricted appearances) for smaller patterns.

- In view of the comment above, the idea behind improving the complexity to n^δ for constant $0 < \delta < 1$ is obvious: Choosing $m = n^{\delta/2}$ will result in an $m \times m$ grid, where Layering can be done in $\tilde{O}(n^{\delta/2})$ queries. Then, Case 2 will be done in an additional n^δ queries by setting a query complexity for $\mathsf{AlgTest}_\pi(\nu, \phi, D, m, \varepsilon)$ to be $n^{\delta/2}$ per component. The self-recursion in Case 1 will result in the same problem over a range of n/m. For the fixed $m = n^{\delta/2}$, this will result in a recursion depth of $2/\delta$, after which the domain size will drop down to m and allow making queries to all corresponding indices. This results in a total of $\tilde{O}(n^\delta)$ queries, including the amplification needed to account for the accumulation of errors and deterioration of the distance parameter at lower recursion levels.
- **Generalized testing and testing beyond $k = 4$.** Applying the same ideas to $\pi \in \mathcal{S}_k$, $k \geq 5$ works essentially the same way, provided we can test for ϕ-legged ν-freeness of $\nu \in \mathcal{S}_r$ for $r < k$. This we know how to do for $\nu \in \mathcal{S}_3$ but not beyond. In particular, one difficulty is that after gridding, a superlinear number of non-empty boxes do not guarantee such appearance, as Lemma 3.1 does not apply. However, for our goal of testing π-freeness for $\pi \in \mathcal{S}_k$, we can relax the task of finding ϕ-legged ν-freeness of $\nu \in \mathcal{S}_r, r \leq k$ to the following problem which we call "generalized-testing ν w.r.t. π", denoted $\mathsf{GeneralizedTesting}_\pi(\nu, D, \phi)$: The inputs are a permutation $\nu \in \mathcal{S}_r$, a component D, and a leg mapping ϕ. Our goal is to find either a ϕ-legged ν-appearance **OR** a π-appearance in D. The way we solve this generalized problem is very similar, conceptually, to the way we solve the unrestricted problem. This will be defined formally in the next section.

4 Generalized testing of forbidden patterns

In this section, we formally define the problem of testing (or deciding) freeness from ν-appearances with a certain leg-mapping. We then provide an algorithm for a relaxation of this testing problem, which we call $\mathsf{GeneralizedTesting}_\pi(\nu, \phi, D)$. This will imply, in turn, our algorithm for testing π-freeness.

Recall that G_n denotes the $n \times n$ grid that represents the input function $f : [n] \to \mathbb{R}$. Let $G_{\ell,\ell}$ be a partition of G_n into a grid of boxes for arbitrary $\ell \geq 1$, and D be a connected component in $G_{\ell,\ell}$ containing t boxes $B_1, \ldots, B_t$. Let $\nu \in \mathcal{S}_r$, and let $\phi : [r] \mapsto [t]$ be an arbitrary mapping of the legs of ν into the boxes of D, where $t \leq r$. We say that $1 \leq i_1 \leq \ldots \leq i_r \leq n$ is a ϕ-legged ν-appearance if $(i_1, \ldots, i_r)$ forms a ν-appearance in G_n such that $(i_j, f(i_j)) \in B_x$ for $x = \phi(j)$, $j = 1, \ldots, r$. That is, the corresponding legs of the ν-appearance are mapped into the boxes given by ϕ. For example, consider Figure 1(B), $\nu = (3, 2, 1, 4)$, and D the component formed by the two boxes in the same layer. The function ϕ maps the 3 and 2-legs of the appearance to the left box and the 1 and 4-legs to the right box.

For ϕ, ν as above, the property of containing a ϕ-legged ν-appearance is a generalization of the problem of pattern-freeness; taking $\ell = 1$, $G_{\ell,\ell}$ is just G_n itself viewed as one single box D. Any ν-appearance in G_n is a ϕ-legged ν-appearance for the constant function $\phi \equiv D$.

The complexity of testing ϕ-legged ν-freeness is not clear and was not previously explicitly studied. For permutations of length 2 as well as for longer monotone permutations, its complexity is identical to unrestricted testing and can be done in $\text{polylog}\, n$ queries. For length 3 non-monotone permutations it can be done in $\text{polylog}\, n$ queries using similar ideas as in [28]. For larger $k \geq 4$ the complexity is open.

While testing ϕ-legged ν-freeness is interesting in its own, we encounter it only as a sub-problem in the testing of standard π-freeness. This motivates the following definition.

Let $\pi \in \mathcal{S}_k$, G_n be fixed. Further let $G_{\ell,\ell}$ be a decomposition of G_n into boxes and D be a t-boxed *one component* over boxes $(B_1, \ldots, B_t)$, $t \leq r$, in $G_{\ell,\ell}$. For inputs $\nu \in \mathcal{S}_r$, and $\phi : [r] \mapsto \{B_1, \ldots, B_t\}$, the problem $\mathsf{GeneralizedTesting}_\pi(\nu, \phi, D)$, is to find a ϕ-legged ν-appearance in D **OR** to find any (unrestricted) π-appearance. The distance of D from being ϕ-legged ν-free is defined naturally. The distance for the generalized testing w.r.t π, $\mathsf{GeneralizedTesting}_\pi(\nu, \phi, D)$, is defined as the distance from being free of ϕ-legged ν-appearance regardless of the π-appearances.

Our algorithm for $\mathsf{GeneralizedTesting}_\pi(\nu, \phi, D)$ is called $\mathsf{AlgTest}_\pi(\nu, \phi, D, m, \varepsilon)$ (presented in Algorithm 1), where $\pi \in \mathcal{S}_k$ is fixed. The algorithm has inputs: $\nu \in \mathcal{S}_r$, $r \leq k$, a component D in a decomposition $G_{\ell,\ell}$ of G_n that contain boxes $B_1, \ldots, B_t$, $t \leq r$, and a function $\phi : [r] \to \{B_1, \ldots B_t\}$. In addition, it gets a distance parameter ε, and a free parameter m that that is used to control the query complexity which will be $\tilde{O}(m^r)$ for $m \geq n^{\Omega(1/\log\log\log n)}$. With high probability, the algorithm either finds a π-appearance or a ϕ-legged ν-appearance in D, if D is ε-far from being free of ϕ-legged ν-appearances.

The algorithm is recursive. A recursion is done by reducing ν to smaller length patterns, and/or self-reduction to the same ν but on a smaller length box D'. The base cases are when the length of D is small enough to allow queries to all indices in D, or when $\nu \in \mathcal{S}_2$, in which case the algorithm is reduced to testing monotonicity.

The permutation $\pi \in \mathcal{S}_k$ is fixed and hardwired into the algorithm. G_n is assumed to fixed and not part of the recursion. The actual input is the t-boxed component D in a grid of boxes $G_{\ell,\ell}$ over G_n (that is, a sub-function of the original function f).

In general, the complexity of testing ϕ-legged ν-appearances may depend on ϕ and ν. Our algorithm does not use any structure of π. The only role of π in the algorithm is to ensure that after gridding D, the resulting grid $D_{m,m}$ contains only a linear in m number of marked boxes (as otherwise, by Lemma 3.1, a π-appearance is guaranteed).

Finally, and as we already pointed out, the algorithm for $\mathsf{GeneralizedTesting}_\pi(\nu, \phi, D)$ will allow us to test for π-freeness in G_n by calling $\mathsf{AlgTest}_\pi(\pi, \phi, G_n, m, \varepsilon)$, where ϕ is the constant function that maps each of the k legs to the single box G_n.

The following theorem asserts the correctness of $\mathsf{AlgTest}_\pi(\pi, \phi, G_n, m, \varepsilon)$ and the corresponding query complexity. We assume that ℓ and a corresponding component D in the grid of boxes $G_{\ell,\ell}$, inside G_n, is given.

▶ **Theorem 4.1.** *Let $\varepsilon \in (0,1)$ and $\nu \in \mathcal{S}_r$, $r \leq k$. Let $D = \mathsf{box}(S, I)$ be a connected component in $G_{\ell,\ell}$, composed of boxes $B_1, \ldots, B_t$, $t \leq r$ and $\phi : [r] \to \{B_1, \ldots B_t\}$. If D is ε-far from being free of ϕ-legged ν-appearances, then $\mathsf{AlgTest}_\pi(\nu, \phi, D, m, \varepsilon)$ finds, either a ϕ-legged ν-appearance or a π-appearance, with probability at least $1 - o(1)$. Its query complexity is $\tilde{O}(n^{\eta r})$, for $\eta \in (0,1)$ and $m = n^\eta$.*

We note that since $\mathsf{AlgTest}_\pi(\nu, \phi, D, m, \varepsilon)$ either finds π or a ϕ-legged ν-appearance in D, then if D is free of ϕ-legged ν-appearance, the algorithm will never return such an appearance. As a result, the corollary below follows by calling $\mathsf{AlgTest}_\pi(\pi, \phi, G_n, m, \varepsilon)$.

Algorithm 1 $\mathsf{AlgTest}_{\pi}(\nu, \phi, D, m, \varepsilon)$.

Input: pattern $\nu \in \mathcal{S}_r$; D is a component in $G_{\ell,\ell}$ containing boxes $B_1, \ldots, B_t$ for $1 \leq t \leq r$; the function $\phi : [r] \mapsto \{B_1, \ldots, B_t\}$ is a leg-mapping of ν into the boxes of D.

Goal: Find a ϕ-legged ν-appearance **or** an unrestricted π-appearance, in D.

Let $S = \cup_{i\in[r]} \mathrm{St}(B_{\phi(i)})$ and $I = \cup_{i\in[r]} L(B_{\phi(i)})$ define $\mathsf{box}(S, I)$ in $G_{\ell,\ell}$ that contains D (or the subcomponent of D where a ν-appearance should be found).

Base cases:

1. If $|S| \leq m$ query all indices in S. **Output** "π-appearance is found" or "ϕ-legged ν-appearance is found" if one of these is found, otherwise **output** "not found".
2. If $r \leq 2$, use the test for restricted appearance of 2-patterns. This is easy and will not be described in this manuscript. If $r = 1$, **output** "ϕ-legged ν-appearance is found" if $\phi(1)$ contains a point. If $k = 1$, **output** "π is found" if D contains a point.
3. If the sampled points in D already contains a ϕ-legged ν-appearance, or contains a π-appearance then **output**: "found ϕ-legged ν-appearance" or "found π-appearance" respectively.

Gridding D: We set $\beta = \frac{\varepsilon}{200k\kappa(k)}$. Call Gridding on $\mathsf{box}(S, I)$ with parameters: (S, I, m, β). The details on the procedure Gridding can be found in the full version [30]. As a result, we obtain a decomposition of $\mathsf{box}(S, I)$ (and D) into an $m' \times m'$ grid of sub-boxes $D_{m',m'}$, $m \leq m' \leq 2m$, where a subset of boxes are *marked* and a subset of the marked boxes are *dense*.

Simple case: If $D_{m',m'}$ contains more than $\kappa(k) \cdot m'$ marked sub-boxes then **output** "found π-appearance".

Sparsification: Delete every stripe and layer in $D_{m',m'}$ that contains more than $d = 100k\kappa(k)/\varepsilon$ marked sub-boxes. Delete all non-dense sub-boxes.

Multi-component configurations: For every possible configuration $\mathcal{C}$ of sub-boxes that is consistent with ϕ such that $\mathcal{C}$ forms components $\mathcal{C}_1, \ldots \mathcal{C}_p$, $p > 1$, the pair (ν, ϕ) define sub-permutations of ν : $\nu_1, \ldots, \nu_p$ and subfunctions of ϕ : $\phi_1, \ldots, \phi_p$ on $\mathcal{C}_1, \ldots \mathcal{C}_p$ respectively.

Let c denote the number of distinct configurations with at most r components.

Recursively **call** $\mathsf{AlgTest}_{\pi}(\nu_i, \phi_i, D_i, m, \varepsilon')$ with distance parameter $\varepsilon' = \frac{9\varepsilon}{10kcr^2 \cdot r! \cdot (2d)^r}$ for *every* component D_i, where D_i is a copy of $\mathcal{C}_i$ in $D_{m',m'}$, and is contained in D. Note that the recursive call is done for smaller length patterns ν_is.

Output "found ϕ-legged ν-appearance" if for a copy $(D_1, \ldots, D_p)$ of $(\mathcal{C}_1, \ldots, \mathcal{C}_p)$, the region D_i contains a ϕ_i-legged ν_i-appearance for each $i = 1, \ldots, p$. Or **output** "found π-appearance" if a π-appearance is found among the sampled points.

One component configurations: Let $\mathcal{A}$ be the set of all possible copies of configurations $\mathcal{C}$ in $D_{m',m'}$ for which $\mathcal{C}$ forms *one* component, and that are contained in D. Note that $\mathcal{A}$ contains $O(m)$ such copies.

loop $\frac{\log^3 n}{\varepsilon^r}$ times:

Sample a member D' from $\mathcal{A}$. For each ϕ-consistent mapping ϕ', recursively **call** $\mathsf{AlgTest}_{\pi}(\nu, \phi', D', m, \varepsilon'')$ with $\varepsilon'' = \frac{9\varepsilon}{20k \cdot (2d)^r \cdot (r-1)! \cdot r^r}$.

▷ A mapping ϕ' from the legs of a ν-appearance to the sub-boxes in $D_{m',m'}$, is ϕ-consistent if for each i-leg, $i = 1, \ldots, r$, the sub-box $\phi'(i)$ is contained in the box $\phi(i)$.

end loop

If no output is declared in any of the previous steps, **output** "not-found".

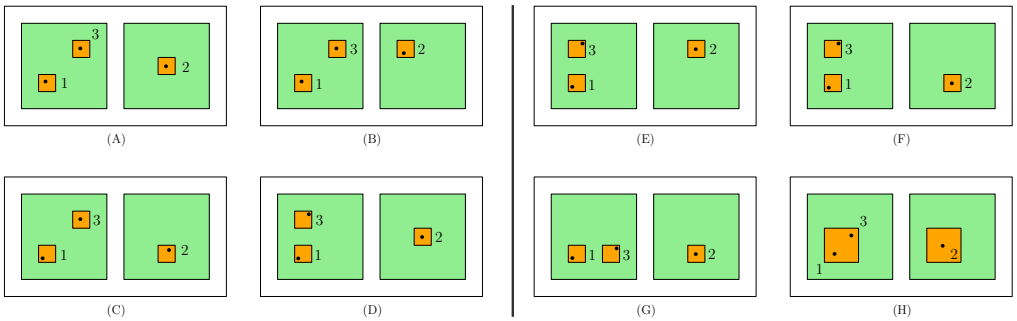

Figure 2 Different configurations for (1,3,2)-appearances.

▶ **Corollary 4.2.** *There is a 1-sided error test for π-freeness, for every $\pi \in \mathcal{S}_k$ of query-complexity $\tilde{O}(n^{\delta k})$ for arbitrary $\delta > 1/\log\log\log n$.*

4.1 Proof of Correctness

In this section, we give a description of the algorithm and the proof sketch for the first non-base case of testing ϕ-legged ν-freeness of $\nu \in \mathcal{S}_r$, $r = 3$, with respect to an arbitrary $\pi \in \mathcal{S}_k$ and for some fixed $k \geq 4$. The full proof of Theorem 4.1 can be found in the full version [30].

4.1.1 An example for $\nu \in \mathcal{S}_3$

For this exposition, we fix $\nu = (1, 3, 2)$, and D being composed of 2 boxes B_1 B_2, in the same layer, where B_1 is to the left of B_2, and ϕ maps the $1, 3$ legs of ν to B_1, and the 2-leg to B_2. See Figure 2(D) for illustration of one such case. In the figure, the green boxes represent B_1 and B_2. The orange boxes indicate the subboxes in the finer grid formed when gridding is called on the green boxes.

We note that Figure 2(D) illustrates the hardest case for $\nu \in \mathcal{S}_3$. There are additional one-component configurations in which the boxes are in the same stripe or layer, but these turn out to be much easier. We will set $m = m(n)$ to be defined later and express the complexity as a function of m. We do not specify π since, as explained above, π is only needed at Step 4 when the number of marked boxes is superlinear in m' in some recursive call. The same argument holds for any $\pi \in \mathcal{S}_k$, $k \geq 4$.

Algorithm for $\nu = (1, 3, 2)$ and B_1, B_2 as above:

1. We assume that B_1, B_2 have at most $s \leq n$ indices each, and that the distance of $B_1 \cup B_2$ from being free from ϕ-legged ν-appearance is at least $\varepsilon = \Omega(1)$. In particular B_1, B_2 are dense. We start in Step 3 of Algorithm 1 where we do gridding of the union of B_1 and B_2 into a $m' \times m'$ grid, $D_{m',m'}$, of sub-boxes (each having roughly at most s/m' indices), where $m \leq m' \leq 2m$. We either find a π-appearance among the sampled points or we may assume, after Steps 4, 5 that there are $O(m')$ dense sub-boxes in $B_1 \cup B_2$ and that each layer and each stripe contains $O(1)$ dense boxes. This is obtained by an averaging argument and is described in the formal proof in the full version. It shows that if $B_1 \cup B_2$ contains a large matching of ϕ-legged ν-appearances, then so does the restricted domain after deleting points from non-dense boxes, and deleting layers and stripes that contain too many dense boxes. This steps takes $\tilde{O}(m)$ queries (the complexity of gridding).
2. A ϕ-legged ν-appearance in $B_1 \cup B_2$ can be in 8 possible configurations in the grid $D_{m',m'}$, as depicted in Figure 2. Consider first $\mathcal{C}_1, \ldots, \mathcal{C}_4$ as in Figure 2(A)-(D), that form 2 or 3 components each. For these, a ϕ-legged ν-appearance in $B_1 \cup B_2$ decomposes into two

or three subpatterns, and for which any restricted appearances in the corresponding components results in a ϕ-legged ν-appearance. E.g., in Figure 2(B) the configuration $\mathcal{C}_2$ contains one component $D_1 = (B_{1,3}, B_{2,2})$, where $B_{1,3} \in B_1, B_{2,2} \in B_2$, and another single boxed component $B_{1,1} \in B_1$, where $B_{i,j}$ is the orange subbox contained within the green box B_i and such that the j-th leg belongs to $B_{i,j}$ for $i \in [2], j \in [3]$.

In Step 6, we test each of the $O(m)$ many copies of D_1 for a ϕ'-legged $(2,1)$-appearance for which $\phi'(2) = B_{1,3}$ and $\phi'(1) = B_{2,2}$. Then for any such D_1-copy in which a such ϕ'-legged $(2,1)$-appearance is found, any nonempty dense box $B_{1,1}$ forming with D_1 a copy of $\mathcal{C}_2$ results in a ϕ-legged ν-appearance.

Since this is a reduction to generalized 2-pattern appearance, the recursion stops here with $O(\log n)$-complexity per copy of D_1. Hence, altogether this will contribute a total of $\tilde{O}(m)$ queries. The same argument holds for any of $\mathcal{C}_i,\ i = 1,2,3,4$.

If a desired appearance is found, then clearly a correct output is produced.

Finally, if indeed (B_1, B_2) contains $\Omega(s)$ (that is, linear in the length of $B_1 \cup B_2$) many ϕ-legged ν-appearances that are consistent with one of the configurations $\mathcal{C}_i, i = 1,2,3,4$, then there will be such a D_1 and corresponding $B_{1,1}$ that together contribute $\Omega(s/m)$ (that is – linear in the domain size of D_1) such subpattern appearances by an averaging argument.

We note that for the more general case of $r > 3$, the reduction will be done in higher complexity per component (that is dependent on m rather than just $O(\log n)$).

3. Consider now $\mathcal{C}_i, i = 5,6,7,8$ that form 1-component each (with 2 or 3 orange subboxes). In these cases, if such appearances contribute ε' to the total distance, then a simple averaging argument shows that for a uniformly sampled component, its distance will be linear from being free from ϕ-legged ν-appearances. Hence in Step 9, sampling such a component will enable us to recursively find a ϕ-legged ν-appearance with high probability. Since the length of a component on which the recursive call is made is $\Theta(s/m)$, the complexity of this step is $\tilde{O}(q(s/m))$, where $q(*)$ is the complexity of the algorithm, for the case of $\nu \in \mathcal{S}_3$, in terms of the length of D.

The correctness of the algorithm follows from the fact that if D is indeed far from being ϕ-legged ν-free, then it must be that there are linearly many ϕ-legged ν-appearances in at least one of the 8 configurations discussed above, and for each case, either a π-appearance or a ϕ-legged ν-appearance is found, by induction.

The base case is for $m = n$ for which the trivial algorithm that queries all indices is obviously correct, and has complexity n. To understand the query complexity for general m, let a be the smallest integer for which $m^a \geq n$. We express the query complexity for functions over a domain of length n, and parameter m as $q(m,a)$ for a as defined above. We get that, omitting polylogarithmic factors, $q(m,1) = m = s$ (that is the base case above), and $q(m,a) = m + m + q(m, a-1)$ where the first summand is the number of queries made by the gridding, the second is the number of queries made by Step 2 above (corresponding to Step 6 in AlgTest), and the last is the query complexity of the recursive call on subbox of length s/m with the same m, for which the corresponding $a' = a - 1$.

The recursion equation implies that $q(a,m) = \tilde{O}(am)$, which implies a query complexity n^δ by choosing $m = n^\delta$. We note that this is true as long as m (and hence δ) is large enough, as the recursion depth is a and there is an exponential deterioration of the distance parameter at each recursive call in Steps 2 and 3 above (corresponding to Steps 6 and 9 in AlgTest). However, for arbitrary constant $\delta < 1$ we can achieve complexity n^δ and this is true even for $\delta = 1/\log\log\log n$ for which the complexity becomes $n^{o(1)}$.

A final note that is due here, is that for $\nu \in \mathcal{S}_r$ with $r \geq 4$, the complexity of Step 2 above is not $O(\log n)$, and thus the complexity dependence on m becomes important.

Abstract

The compression of highly repetitive strings (i.e., strings with many repetitions) has been a central research topic in string processing, and quite a few compression methods for these strings have been proposed thus far. Among them, an efficient compression format gathering increasing attention is the run-length Burrows–Wheeler transform (RLBWT), which is a run-length encoded BWT as a reversible permutation of an input string on the lexicographical order of suffixes. State-of-the-art construction algorithms of RLBWT have a serious issue with respect to (i) non-optimal computation time or (ii) a working space that is linearly proportional to the length of an input string. In this paper, we present *r-comp*, the first optimal-time construction algorithm of RLBWT in BWT-runs bounded space. That is, the computational complexity of r-comp is $O(n + r \log r)$ time and $O(r \log n)$ bits of working space for the length n of an input string and the number r of equal-letter runs in BWT. The computation time is optimal (i.e., $O(n)$) for strings with the property $r = O(n/\log n)$, which holds for most highly repetitive strings. Experiments using a real-world dataset of highly repetitive strings show the effectiveness of r-comp with respect to computation time and space.

1 Introduction

Highly repetitive strings (i.e., strings including many repetitions) have become common in research and industry. For instance, the 1000 Genomes Project [32] was established for the purpose of building a detailed catalogue of human genetic variation, and it has sequenced a large number of human genomes. Nowadays, approximately 60 billion pages are said to exist on the Internet, and large sections of those pages (e.g., version-controlled documents) are highly repetitive. There is therefore a growing demand to develop scalable data compression for efficiently storing, processing, and analyzing a gigantic number of highly repetitive strings.

To fulfill this demand, quite a few data compression methods for highly repetitive strings have been developed. Examples are LZ77 [34], grammar compression [19, 12, 31, 14], block trees [2], and many others [25, 22, 10]. Among them, an efficient compression format gathering increased attention is the *run-length Burrows–Wheeler transform* (RLBWT), which is a run-length encoded BWT [6] as a reversible permutation of an input string on the lexicographical order of suffixes. Recently, researchers have focused on developing string

Table 1 Summary of state-of-the-art RLBWT construction algorithms. The update time in the rightmost column is the time needed to construct a new RLBWT from the current RLBWT for a character newly added to the string. The update time of r-comp is amortized. T is an input string of alphabet size σ and length n; $|\mathsf{PFP}|$ is the size of the dictionary and factorization created by the prefix-free parsing of T [5].

Method	Type	Running time	Working space (bits)	Update time
D. Belazzougui+ [4]	indirect	$O(n)$	$O(n \log \sigma)$	Unsupported
J. Munro+ [20]	indirect	$O(n)$	$O(n \log \sigma)$	Unsupported

KK method [17, 23]	direct	$O(n(\log \log n)^2 + r \log^8 n)$	$O(r \operatorname{polylog} n)$	Unsupported
PP method [30]	direct	$O(n \log r)$	$O(r \log n)$	$O(\log r)$
Faster-PP method [28]	direct	$O(n \log r)$	$O(r \log n)$	$O(\log r)$
r-comp (this study)	direct	$O(n + r \log r)$	$O(r \log n)$	$O(1 + (r \log r)/n)$

processing methods such as locate query [13, 1, 3, 26], document listing [7], and substring enumeration [27] on RLBWT. Although several algorithms for constructing the RLBWT from an input string have been proposed thus far, there is no prior work that achieves the computational complexity of optimal time (i.e., time linearly proportional to the length of the input string) and BWT-runs bounded space (i.e., a working space linearly proportional to the number of equal-letter runs in the BWT and logarithmically proportional to the length of the input string).

Contribution. We present *r-comp*, the first construction algorithm of RLBWT that achieves optimal time and BWT-runs bounded space. R-comp directly constructs the RLBWT of an input string. It reads one character of an input string at a time from the reversed string and gradually builds the RLBWT corresponding to the suffixes read so far. The state-of-the-art online construction methods [30, 28] use inefficient data structures such as dynamic wavelet trees and B-trees for inserting each character into the current RLBWT at an insertion position, which is the most time-consuming part in an RLBWT construction. We present a new *divided BWT (DBWT)* representation of BWT and a new bipartite graph representation on DBWT called *LF-interval graph* to speed up the construction of RLBWT. The DBWT and LF-interval graph are efficiently built while reading each character one by one, and they enable us to quickly compute an appropriate position for inserting each character into the current RLBWT of the string. Another remarkable property of r-comp is the ability to extend the RLBWT for a newly added character without rebuilding the data structures used in r-comp from the beginning.

As a result, the computational complexity of r-comp is $O(n + r \log r)$ time and $O(r \log n)$ bits of working space for the length n of an input string and the number r of equal-letter runs in BWT. In particular, the computational complexity is optimal (i.e., $O(n)$) for strings with the property $r = O(n/\log n)$, which holds for most highly repetitive strings. We experimentally tested the ability of r-comp to compress various highly repetitive strings, and we show that r-comp performs better than other methods with respect to computation time and space.

2 Related work

There are two types of methods for indirectly or directly constructing the RLBWT of a string (see Table 1 for a summary of state-of-the-art construction algorithms of RLBWT). In the indirect constructions of RLBWT, the BWT of an input string is first built and then the

BWT is encoded into the RLBWT by run-length encoding. Several efficient algorithms for constructing the BWT of a given string have been proposed [4, 16, 21, 8, 16, 20]. Let T be a string of length n with an alphabet of size σ, and let r be the number of equal-letter runs in its BWT. Kempa [15] proposed a RAM-optimal time construction of the BWT of string T with compression ratio $n/r = \Omega(\mathrm{polylog}\, n)$. The algorithm runs in $O(n/\log_\sigma n)$ time with $O(n \log \sigma)$ bits of working space. Kempa and Kociumaka also proposed a BWT construction in $O(n \log \sigma)$ bits of working space [16]. This algorithm runs in $O(n \log \sigma / \sqrt{\log n})$ time, which is bounded by $o(n)$ time for a string with $\log \sigma = o(\sqrt{\log n})$. These algorithms are not space efficient for highly repetitive strings in that their working space is linearly proportional to the length of the input string.

Big-BWT [5] is a practical algorithm for constructing the BWT of a huge string using *prefix-free parsing*, which constructs a dictionary of strings and a factorization from string T. Although Big-BWT runs in optimal time (i.e., $O(n)$) with $O(|\mathsf{PFP}| \log n)$ bits of working space for the sum $|\mathsf{PFP}|$ of (i) the lengths of all the strings in the dictionary and (ii) the number of strings in the factorization, Big-BWT is not space efficient for highly repetitive strings in the worst case, because $|\mathsf{PFP}|$ can be $\sqrt{n}$ times larger than r, resulting in $\Omega(r\sqrt{n} \log n)$ bits of working space (see the full version of the paper [24] for the proof). Even worse, several data structures used in these indirect constructions cannot be updated. Thus, one needs to rebuild the data structures from scratch for a newly added character, which reduces the usability of indirect constructions of RLBWT.

In the direct constructions of RLBWT, Policriti and Prezza [30] proposed an algorithm for the construction of RLBWT, which we call *PP method*. The PP method reads an input string in reverse by one character, and it gradually builds the RLBWT corresponding to the suffix that was just read, where an inefficient dynamic wavelet tree is used for inserting a character into the RLBWT at an appropriate position, limiting the scalability of the PP method in practice. Ohno et al. [28] proposed a faster method, which we call *Faster-PP method*, by replacing the dynamic wavelet tree used in the PP method by a B-tree. Whereas both the PP method and Faster-PP method run with the same time and space complexities – $O(n \log r)$ time and $O(r \log n)$ bits of working space – the time complexity is not the optimal time for most highly repetitive strings.

Kempa and Kociumaka [17] proposed a conversion algorithm, which is referred to as *KK method*, from the LZ77 parsing [34] of T to the RLBWT in $O(z \log^7 n)$ time with $O(z\, \mathrm{polylog}\, n)$ bits of space, where z is the number of phrases in the parsing. Theoretically, we can compute the RLBWT of an input string by combining the KK method with an algorithm for computing the LZ77 parsing (e.g., [23]), and the working space of their conversion is bounded by $O(r\, \mathrm{polylog}\, n)$ bits because $z = O(r \log n)$ [22]. Kempa and Langmead [18] proposed a practical algorithm for constructing a compressed grammar from an input string in $\Omega(n)$ time using an approximate LZ77 parsing. Because these methods use several static data structures that cannot be updated, the data structures must be rebuilt from scratch when a new character is added.

Although there are several algorithms for indirectly or directly constructing the RLBWT, no previous work has been able to achieve optimal time (i.e., $O(n)$ time) with BWT-runs bounded space (i.e., $O(r \log n)$ bits). We present *r-comp*, the first direct construction of RLBWT that achieves optimal time with BWT-runs bounded space for most highly repetitive strings. Details of r-comp are presented in the following sections.

This paper is organized as follows. Section 3 introduces basic notions used in this paper, and a DBWT representation of BWT is presented in Section 4. Section 5 presents an LF-interval graph representation of DBWT and a fast update operation on LF-interval

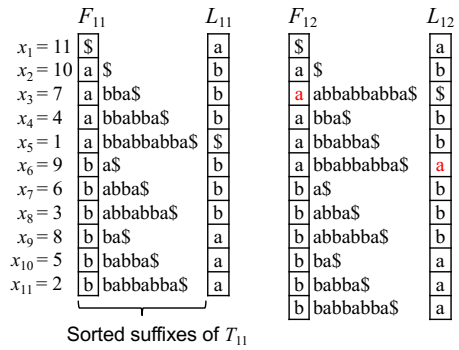

Figure 1 (Left) Sorted suffixes of $T_{11} = abbabbabba\$$, F_{11}, and L_{11}. (Right) Sorted suffixes of $T_{12} = aabbabbabba\$$, F_{12}, and L_{12}.

graphs. The r-comp algorithm is presented in Section 6. Section 7 presents the experimental results using the r-comp algorithm on benchmark and real-world datasets of highly repetitive strings.

3 Preliminaries

Basic notation. An *interval* $[b, e]$ for two integers b and e ($b \leq e$) represents the set $\{b, b+1, \ldots, e\}$. Let T be a string of length n over an alphabet $\Sigma = \{1, 2, \ldots, n^{O(1)}\}$ of size σ, and $|T|$ be the length of T (i.e., $|T| = n$). Let $T[i]$ be the i-th character of T (i.e., $T = T[1], T[2], \ldots, T[n]$) and $T[i..j]$ be the substring of T that begins at position i and ends at position j. Let T_δ be the suffix of T of length δ ($1 \leq \delta \leq n$), i.e., $T_\delta = T[(n-\delta+1)..n]$. A *rank query* $\mathsf{rank}(T, c, i)$ on a string T returns the number of occurrences of character c in $T[1..i]$, i.e., $\mathsf{rank}(T, c, i) = |\{j \mid T[j] = c, 1 \leq j \leq i\}|$.

For a string P, $P[i] < P[j]$ means that the i-th character of P is smaller than the j-th character of P. Moreover, $T \prec P$ means that T is lexicographically smaller than P. Formally, $T \prec P$ if and only if either of the following two conditions holds: (i) there exists an integer i such that $T[1..i-1] = P[1..i-1]$ and $T[i] < P[i]$; (ii) T is a prefix of P (i.e., $T = P[1..|T|]$) and $|T| < |P|$. Here, $\mathsf{occ}_<(T, c)$ denotes the number of characters smaller than character c in string T (i.e., $\mathsf{occ}_<(T, c) = |\{j \mid j \in \{1, 2, \ldots, n\} \text{ s.t. } T[j] < c\}|$). Special character \$ is the smallest character in Σ. Throughout this paper, we assume that special character \$ only appears at the end of T (i.e., $T[n] = \$$ and $T[i] \neq \$$ for all $\{1, 2, \ldots, n-1\}$).

A *run* is defined as the maximal repetition of the same character. Formally, a substring $T[i..j]$ of T is a *run* of the same character c if it satisfies the following three conditions: (i) $T[i..j]$ is a repetition of the same character c (i.e., $T[i] = T[i+1] = \cdots = T[j] = c$); (ii) $i = 1$ or $T[i-1] \neq c$; (iii) $j = n$ or $T[j+1] \neq c$.

We use base-2 logarithm throughout this paper. Our computation model is a unit-cost word RAM with a machine word size of $\Theta(\log n)$ bits. We evaluate the space complexity in terms of the number of machine words. A bitwise evaluation of space complexity can be obtained with a $\log n$ multiplicative factor.

BWT, LF function, and RLBWT. The BWT [6] of a suffix T_δ is a permuted string L_δ of T_δ, and it is constructed as follows: all the suffixes of T_δ are sorted in the lexicographical order and the character preceding each suffix is taken. Formally, let $x_1, x_2, \ldots, x_\delta$ be the starting positions of the sorted suffixes of T_δ (i.e., $x_1, x_2, \ldots, x_\delta$ are a permutation

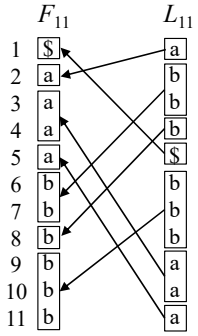

Figure 2 DBWT-repetitions and their corresponding F-intervals on F_{11} for a DBWT $D_{11} = a, bb, b, \$, bbb, aa, a$ of BWT L_{11} in Figure 1. Each rectangle on L_{11} represents a DBWT-repetition, and each rectangle on F_{11} represents an F-interval on F_{11}. Each directed arrow indicates the F-interval corresponding to the DBWT-repetition on L_{11}.

of sequence $1, 2, \ldots, \delta$ such that $T_\delta[x_1..\delta] \prec T_\delta[x_2..\delta] \prec \cdots \prec T_\delta[x_n..\delta]$). Then, $L_\delta = T_\delta[x_1 - 1], T_\delta[x_2 - 1], \ldots, T_\delta[x_\delta - 1])$, where $T_\delta[0]$ is defined as the last character of T_δ (i.e., $T_\delta[0] = T_\delta[\delta] = \$$). Similarly, the permuted string F_δ of suffix T_δ consists of the first characters of the sorted suffixes of T_δ, i.e., $F_\delta = T_\delta[x_1], T_\delta[x_2], \ldots, T_\delta[x_\delta]$.

Figure 1 illustrates the sorted suffixes of T_{11} and T_{12} for $T = aabbabbabba\$$. Here, $x_1, x_2, \ldots, x_{11}$ are the starting positions of the sorted suffixes of T_{11}. Moreover, $L_{11} = abbb\$bbbaaa$ and $F_{11} = \$aaaabbbbbb$. The BWT of T is $L_{12} = ab\$bbabbbaaa$.

There is a one-to-one correspondence between L_δ and F_δ because the two strings are permutations of T_δ. Formally, for two integers $i, j \in \{1, 2, \ldots, \delta\}$, $L_\delta[i]$ corresponds to $F_\delta[j]$ if and only if either of the following two conditions holds: (i) $x_i - 1 = x_j$ or (ii) $x_i = 1$ and $x_j = \delta$. *LF function* LF_δ is a bijective function from L_δ to F_δ [11]. Function $\mathsf{LF}_\delta(i) = j$ for two integers $i, j \in \{1, 2, \ldots, \delta\}$ if and only if $L_\delta[i]$ corresponds to $F_\delta[j]$. *LF formula* [11] is a well-known property of LF function, and it enables us to compute the corresponding position in F_δ from a position in L_δ. Namely, $\mathsf{LF}_\delta(i)$ is equal to the summation of (i) the number of characters in L_δ smaller than $L_\delta[i]$ and (ii) the number of $L_\delta[i]$ in the prefix $L_\delta[1..i]$, i.e., $\mathsf{LF}_\delta(i) = \mathsf{occ}_<(L_\delta, L_\delta[i]) + \mathsf{rank}(L_\delta, i, L_\delta[i])$.

BWT can be separated into all the runs of the same character. We call each run BWT-run. For BWT L_δ, r BWT-runs $P_1, P_2, \ldots, P_r$ satisfy (i) $L_\delta = P_1, P_2, \ldots, P_r$ and (ii) each P_i $(i = 1, 2, \ldots, r)$ is a run of the same character in L_δ. The RLBWT of a suffix T_δ is defined as a sequence of r pairs $(P_1[1], |P_1|)$, $(P_2[1], |P_2|)$, …, $(P_r[1], |P_r|)$. The RLBWT can be stored in $r(\log n + \log \sigma)$ bits, and we can recover T_δ from the RLBWT using LF function (e.g., [26]). Throughout this paper, r denotes the number of BWT-runs in the BWT of T.

In Figure 1, the BWT-runs in the BWT L_{11} of T_{11} are $a, bbb, \$, bbb$, and aaa. The RLBWT of T_{11} is $(a, 1)$, $(b, 3)$, $(\$, 1)$, $(b, 3)$, and $(a, 3)$.

4 DBWT

The divided BWT (DBWT) is a general concept in the RLBWT and is the foundation of the LF-interval graph. Formally, the DBWT D_δ of BWT L_δ is defined as a sequence $L_\delta[p_1..(p_2 - 1)], L_\delta[p_2..(p_3 - 1)], \ldots, L_\delta[p_k..(p_{k+1} - 1)]$ for $p_1 = 1 < p_2 < \cdots < p_k < p_{k+1} = n + 1$, where $L_\delta[p_i..(p_{i+1} - 1)]$ for each $i = 1, 2, \ldots, k$ is a repetition of the same character. We call each repetition of the same character in the DBWT *DBWT-repetition*. A DBWT-repetition is not necessarily a run. DBWT D_δ is equal to the RLBWT of T_δ if and only if $L_\delta[p_i..(p_i - 1)]$ for each $i \in \{1, 2, \ldots, k\}$ is a run.

In Figure 2, sequence $D_{11} = a, bb, b, \$, bbb, aa, a$ of equal-letter repetitions is a DBWT for BWT L_{11} of string T_{11}. The DBWT-repetitions in D_{11} are the strings enclosed by the rectangles on L_{11}.

The DBWT of a BWT is not unique because a BWT can be divided by various criteria. We present a criterion for DBWT in the following in order to efficiently build RLBWT. The LF function maps each DBWT-repetition $L_\delta[p_i..(p_{i+1}-1)]$ into the consecutive characters on interval $[\mathsf{LF}_\delta(p_i), \mathsf{LF}_\delta(p_{i+1}-1)]$, which is called an *F-interval* on F_δ. The LF formula enables us to compute $\mathsf{LF}_\delta(j)$ for each position $j \in [p_i, (p_{i+1}-1)]$ on the i-th DBWT-repetition in $O(1)$ time using the starting position p_i of the DBWT-repetition and the F-interval $[\mathsf{LF}_\delta(p_i), \mathsf{LF}_\delta(p_{i+1}-1)]$ corresponding to the DBWT-repetition as follows: $\mathsf{LF}_\delta(j) = \mathsf{LF}_\delta(p_i) + j - p_i$.

In Figure 2, each F-interval on F_{11} corresponding to a DBWT-repetition on L_{11} is enclosed by a rectangle. The F-intervals on F_{11} are $[1,1]$, $[2,2]$, $[3,4]$, $[5,5]$, $[6,7]$, $[8,8]$, and $[9,11]$. The F-interval corresponding to the second DBWT-repetition bb is $[6,7]$.

Let α be a user-defined parameter no less than 2 (i.e., $\alpha \geq 2$). DBWT-repetition $L_\delta[p_i..(p_{i+1}-1)]$ is said to *cover* the starting position $\mathsf{LF}_\delta(p_j)$ of an F-interval $[\mathsf{LF}_\delta(p_j), \mathsf{LF}_\delta(p_{j+1})]$ on F_δ if interval $[p_i, (p_{i+1}-1)]$ on F_δ contains the position $\mathsf{LF}_\delta(p_j)$ (i.e., $\mathsf{LF}_\delta(p_j) \in [p_i, (p_{i+1}-1)]$). The DBWT-repetition is said to be α-*heavy* if it covers at least α starting positions of the F-intervals on F_δ for parameter $\alpha \geq 2$. Similarly, F-interval $[\mathsf{LF}_\delta(p_i), \mathsf{LF}_\delta(p_{i+1}-1)]$ on F_δ is said to cover the starting position p_j of a DBWT-repetition $L_\delta[p_j..(p_{j+1}-1)]$ if interval $[\mathsf{LF}_\delta(p_i), \mathsf{LF}_\delta(p_{i+1}-1)]$ on L_δ contains the position p_j (i.e., $p_j \in [\mathsf{LF}_\delta(p_i), \mathsf{LF}_\delta(p_{i+1}-1)]$). An F-interval is said to be α-heavy if it covers at least α starting positions of DBWT-repetitions for parameter $\alpha \geq 2$. A DBWT is said to be α-*balanced* if the DBWT includes neither α-heavy DBWT-repetitions nor F-intervals, and D_δ^α denotes an α-balanced DBWT of BWT L_δ.

In Figure 2 with $\alpha = 3$, the fifth DBWT-repetition bbb of D_{11} covers two starting positions of F-intervals $[6,7]$ and $[8,8]$ on F_{11}, and the DBWT-repetition is not 3-heavy. The F-interval $[9,11]$ of the fifth DBWT-repetition covers the starting positions of two DBWT-repetitions aa and a. Moreover, the F-interval of the fifth DBWT-repetition is not 3-heavy. Thus, D_{11} is 3-balanced because D_{11} includes neither 3-heavy DBWT-repetitions nor F-intervals.

In the next section, the α-balanced DBWT is used to derive the time needed to update an LF-interval graph.

5 LF-interval graph

An LF-interval graph is a bipartite graph that represents both (i) the correspondence between each pair of elements in L_δ and F_δ according to the LF function and (ii) a covering relationship between DBWT-repetitions and F-intervals on a DBWT. The LF-interval graph $\mathsf{Grp}(D_\delta)$ for DBWT D_δ of k DBWT-repetitions $L_\delta[p_1..(p_2-1)], L_\delta[p_2..(p_3-1)], \ldots, L_\delta[p_k..(p_{k+1}-1)]$ is defined as 4-tuple $(U \cup V,\ E_{LF} \cup E_L \cup E_F,\ B_U \cup B_V,\ B_L \cup B_F)$, as detailed in the following.

Set $U = \{u_1, u_2, \ldots, u_k\}$ is a set of nodes, and u_i for each $i \in \{1, 2, \ldots, k\}$ represents the i-th DBWT-repetition $L_\delta[p_i..(p_{i+1}-1)]$ on DBWT D_δ. Moreover, set $V = \{v_1, v_2, \ldots, v_k\}$ is a set of nodes, and v_i for each $i \in \{1, 2, \ldots, k\}$ represents the F-interval $[\mathsf{LF}_\delta(p_i), \mathsf{LF}_\delta(p_{i+1}-1)]$ mapped from the i-th DBWT-repetition represented as u_i on DBWT D_δ by the LF function.

The set E_{LF} of undirected edges in LF-interval graph $\mathsf{Grp}(D_\delta)$ represents the correspondence between DBWT-repetitions on DBWT D_δ and F-intervals on F_δ according to the LF function. Formally, $E_{LF} \subseteq (U \times V)$ is a set of undirected edges between U and V, and $(u_i, v_j) \in E_{LF}$ holds if and only if the i-th DBWT-repetition $L_\delta[p_i..(p_{i+1}-1)]$ represented as u_i is mapped to the j-th F-interval $[\mathsf{LF}_\delta(p_j), \mathsf{LF}_\delta(p_{j+1}-1)]$ represented as v_j. Namely, $E_{LF} = \{(u_1, v_1), (u_2, v_2), \ldots, (u_k, v_k)\}$.

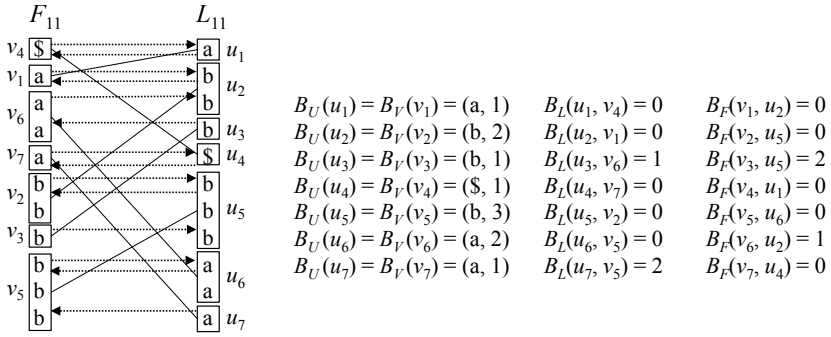

Figure 3 LF-interval graph $\mathsf{Grp}(D_{11})$ for DBWT D_{11} in Figure 2.

Two sets E_L and E_F of directed edges represent the covering relationship between DBWT-repetitions and F-intervals on DBWT D_δ. Set $E_L \subseteq (U \times V)$ is a set of directed edges from U to V, and $(u_i, v_j) \in E_L$ holds if and only if F-interval $[\mathsf{LF}_\delta(p_j), \mathsf{LF}_\delta(p_{j+1} - 1)]$, represented as v_j, covers the starting position p_i of DBWT-repetition $L_\delta[p_i..(p_{i+1} - 1)]$, represented as u_i. Formally, $E_L = \{(u_i, v_j) \mid 1 \leq i, j \leq k \text{ s.t. } p_i \in [\mathsf{LF}_\delta(p_j), \mathsf{LF}_\delta(p_{j+1} - 1)]\}$. Similarly, $E_F \subseteq (V \times U)$ is a set of directed edges from V to U, and $(v_j, u_i) \in E_F$ holds if and only if DBWT-repetition $L_\delta[p_i..(p_{i+1} - 1)]$, represented as u_i, covers the starting position $\mathsf{LF}_\delta(p_j)$ of F-interval $[\mathsf{LF}_\delta(p_j), \mathsf{LF}_\delta(p_{j+1} - 1)]$, represented as v_j. Formally, $E_F = \{(v_j, u_i) \mid 1 \leq i, j \leq k \text{ s.t. } \mathsf{LF}_\delta(p_j) \in [p_i, (p_{i+1} - 1)]\}$.

Function $B_U : U \to (\Sigma, \mathbb{N})$ is a label function for the set U of nodes, and it maps each node $u_i \in U$ to a pair consisting of the character in Σ and the length in $\mathbb{N} = \{1, 2, \ldots\}$ for the i-th DBWT-repetition represented by u_i. Namely, $B_U(u_i) = (L_\delta[p_i], p_{i+1} - p_i)$. Similarly, $B_V : V \to (\Sigma, \mathbb{N})$ is a label function for the set V of nodes, and it maps each node $v_i \in V$ to a pair consisting of the character in Σ and the length in $\mathbb{N}$ for the repetition $F_\delta[\mathsf{LF}_\delta(p_i)..\mathsf{LF}_\delta(p_{i+1} - 1)]$ of the same character on the F-interval represented by v_i. Namely, $B_V(v_i) = (F_\delta[\mathsf{LF}_\delta(p_i)], \mathsf{LF}_\delta(p_{i+1} - 1) - \mathsf{LF}_\delta(p_i) + 1)$. For all $i \in \{1, 2, \ldots, k\}$, $B_U(u_i) = B_V(v_i)$ holds by the LF formula.

Function $B_L : E_L \to \mathbb{N}$ is a label function for the set E_L of directed edges, and it maps each edge $(u_i, v_j) \in E_L$ to an integer value representing the difference between the starting position p_i of DBWT-repetition $L_\delta[p_i..(p_{i+1} - 1)]$, represented as u_i, and the starting position $\mathsf{LF}_\delta(p_j)$ of F-interval $[\mathsf{LF}_\delta(p_j), \mathsf{LF}_\delta(p_{j+1} - 1)]$, represented as v_j. Namely, $B_L(u_i, v_j) = p_i - \mathsf{LF}_\delta(p_j)$.

Similarly, $B_F : E_F \to \mathbb{N}$ is a label function for the set E_F of directed edges, and it maps each edge $(v_j, u_i) \in E_F$ to an integer value representing the difference between the starting position $\mathsf{LF}_\delta(p_j)$ of F-interval $[\mathsf{LF}_\delta(p_j), \mathsf{LF}_\delta(p_{j+1} - 1)]$, represented as v_j, and the starting position p_i of DBWT-repetition $L_\delta[p_i..(p_{i+1} - 1)]$, represented as u_i. Namely, $B_F(v_j, u_i) = \mathsf{LF}_\delta(p_j) - p_i$.

Figure 3 illustrates LF-interval graph $\mathsf{Grp}(D_{11})$ for DBWT D_{11} in Figure 2. For $U = \{u_1, u_2, \ldots, u_7\}$ and $V = \{v_1, v_2, \ldots, v_7\}$, each node $u_i \in U$ (respectively, $v_j \in V$) is enclosed by a rectangle on L_{11} (respectively, F_{11}). We have $E_{LF} = \{(u_1, v_1), (u_2, v_2), (u_3, v_3), (u_4, v_4), (u_5, v_5), (u_6, v_6), (u_7, v_7)\}$. We depict each undirected edge in set E_{LF} by solid lines. Moreover, $E_L = \{(u_1, v_4), (u_2, v_1), (u_3, v_6), (u_4, v_7), (u_5, v_2), (u_6, v_5), (u_7, v_5)\}$, and $E_F = \{(v_1, u_2), (v_2, u_5), (v_3, u_5), (v_4, u_1), (v_5, u_6), (v_6, u_2), (v_7, u_4)\}$. Each directed edge in the two sets E_L and E_F is depicted by a dotted arrow. The four label functions B_U, B_V, B_L, and B_F are listed in Figure 3.

5.1 Dynamic data structures for the LF-interval graph

Several dynamic data structures are used for efficiently updating LF-interval graph $\mathsf{Grp}(D_\delta)$. Two doubly linked lists are used for supporting the insertions and deletions of nodes in U and V. The nodes in U should be totally ordered with respect to the starting position of the DBWT-repetition, which is represented as a node in U. Namely, $u_1 < u_2 < \cdots < u_k$. The nodes in set U are stored in a doubly linked list, where each node $u_i \in U$ has previous and next pointers connecting to the previous and next nodes, respectively, in the total order of nodes in U. Similarly, the nodes in V should be totally ordered with respect to the starting position of the F-interval, which is represented as a node in V. Namely, $v_{\pi_1} < v_{\pi_2} < \ldots < v_{\pi_k}$ holds for permutation $\pi_1, \pi_2, \ldots, \pi_k$ of sequence $1, 2, \ldots, k$ such that $\mathsf{LF}_\delta(p_{\pi_1}) < \mathsf{LF}_\delta(p_{\pi_2}) < \ldots < \mathsf{LF}_\delta(p_{\pi_k})$. The nodes in V are stored in another doubly linked list, where each node $v_i \in V$ has previous and next pointers connecting to the previous and next nodes in the increasing order of nodes in V, respectively. The space of two doubly linked lists storing nodes in U and V is $O(k \log n)$ bits.

All the nodes corresponding to α-heavy DBWT-repetitions in U are stored in an array data structure in any order. Similarly, all the nodes corresponding to α-heavy F-intervals in V are stored in another array data structure in any order. The two arrays take $O(k \log n)$ bits of space. Each array stores nothing if D_δ is α-balanced.

An *order maintenance data structure* [9] is used for comparing two nodes in U with the total order of U, and the data structure supports the following three operations: (i) the order operation determines whether or not node $u_i \in U$ precedes node $u_j \in U$ in the total order of U; (ii) the insertion operation inserts node $u_i \in U$ right after node $u_j \in U$ in the total order of U; (iii) the deletion operation deletes node $u_i \in U$ from U. The data structure supports these three operations in $O(1)$ time with $O(k \log n)$ bits of space, and it is used with a B-tree that stores the nodes in V, as explained below.

A B-tree (a type of self-balancing search tree) is built on the set V of nodes using the combination of the order maintenance data structure, where each node v_i in V is totally ordered with respect to (i) the total order of the node u_i in U that is connected to v_i by an edge in E_{LF} (i.e., $(u_i, v_i) \in E_{LF}$) and (ii) the first character $L_\delta[p_i]$ of the DBWT-repetition is represented as u_i. For a node $v_i \in V$, the B-tree stores a pair $(u_i, L_\delta[p_i])$ as the key of the node v_i. Nodes in V are totally ordered using the key, and $v_i \in V$ precedes $v_j \in V$ if and only if either of the following conditions holds: (i) $L_\delta[p_i] < L_\delta[p_j]$ or (ii) $L_\delta[p_i] = L_\delta[p_j]$ and u_i precedes u_j in the total order of U (i.e., $i < j$). Condition (ii) is efficiently computed in $O(1)$ time by the order maintenance data structure of U. According to the following lemma, the order of keys in the B-tree is the same as that of the nodes stored in the doubly linked list of V (i.e., the order of the nodes in the B-tree is $v_{\pi_1} < v_{\pi_2} < \ldots < v_{\pi_k}$).

▶ **Lemma 1.** *For two distinct nodes $v_i, v_j \in V$, the key of v_i precedes that of v_j in the B-tree of V if and only if v_i precedes v_j in the doubly linked list of V (i.e., $\mathsf{LF}_\delta(p_i) < \mathsf{LF}_\delta(p_j)$).*

Proof. See the full version of the paper [24]. ◀

The B-tree with the order maintenance data structure supports the three operations of search, insertion, and deletion for any node in V in $O(\log k)$ time with $O(k \log n)$ bits of space.

5.2 Extension of BWT ([30, 28])

The BWT of a suffix can be extended from the BWT of a shorter suffix [30, 28]. In this section, we review the extension of BWT, which is used for updating the LF-interval graph. The BWT $L_{\delta+1}$ of a suffix $T_{\delta+1}$ of length $\delta + 1$ can be computed from the BWT L_δ of the

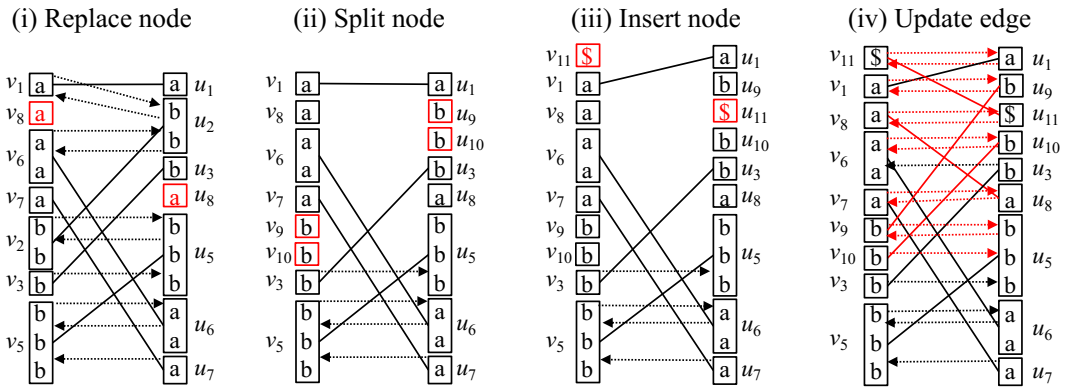

Figure 4 Each step in the update operation for the LF-interval graph in Figure 3. New nodes and edges created in each step are colored in red.

suffix T_δ of length δ using the following two steps: (i) special character \$ in L_δ is replaced with the first character c of $T_{\delta+1}$ (i.e., $c = T[n-\delta]$); (ii) special character \$ is inserted into L_δ at a position ins. Here, ins is computed by the LF formula as follows: for the position rep of special character \$ in L_δ (i.e., $L_\delta[\mathsf{rep}] = \$$), $\mathsf{ins} = \mathsf{occ}_<(L_\delta, c) + \mathsf{rank}(L_\delta, \mathsf{rep}, c) + 1$.

In Figure 1, BWT L_{12} of suffix T_{12} can be extended from L_{11} of suffix T_{11}. The first character c of T_{12} is a, and special character \$ is replaced with a at $\mathsf{rep} = 5$ on L_{11}. The insertion position ins for L_{11} is 3 because $\mathsf{occ}_<(L_{11}, a) + \mathsf{rank}(L_{11}, \mathsf{rep}, a) + 1 = 3$.

5.3 Foundation of updates of the LF-interval graph

Given the first character c in suffix $T_{\delta+1}$ of length $\delta+1$, an update operation of LF-interval graph $\mathsf{Grp}(D^\alpha_\delta)$ for an α-balanced DBWT $D^\alpha_\delta = L_\delta[p_1..(p_2-1)], L_\delta[p_2..(p_3-1)], \ldots, L_\delta[p_k..(p_{k+1}-1)]$ of T_δ updates $\mathsf{Grp}(D^\alpha_\delta)$ to $\mathsf{Grp}(D^{2\alpha+1}_{\delta+1})$ for a $(2\alpha+1)$-balanced DBWT $D^{2\alpha+1}_{\delta+1}$ of $T_{\delta+1}$. The update operation updates the given LF-interval graph according to the extension of BWT. This operation consists of four main steps: (I) *replace node*, (II) *split node*, (III) *insert node*, and (IV) *update edge*. Note that the update operation presented in this section is a foundation for the ones presented in the following two subsections, where several modifications are made to the foundation for faster operation.

(I) Replace node. This step replaces the node $u_i \in U$ labeled $(\$, 1)$ with a new one $u_{i'}$ labeled $(c, 1)$, and it updates V according to the replacement of the node in U. Node u_i can be found in $O(1)$ time by keeping track of it on U. The doubly linked list of U is updated according to the replacement. The node $v_i \in V$ connected to u_i by edge $(u_i, v_i) \in E_{LF}$ is removed from V, and a new node $v_{i'}$ labeled $(c, 1)$ is inserted into V at the position next to the most backward node v_g of the nodes whose keys are smaller than key (u_i, c). Node v_g can be found in $O(\log k)$ time using the B-tree of V. This step takes $O(\log k)$ time in total.

Figure 4-(I) shows an example of the replace-node step for the LF-interval graph $\mathsf{Grp}(D_{11})$ in Figure 3. Node $u_4 \in U$ labeled $(\$, 1)$ on $\mathsf{Grp}(D_{11})$ is replaced with node u_8 labeled $(a, 1)$. Node $v_4 \in V$, which is connected to u_4 by edge $(v_4, u_4) \in E_{LF}$, is removed from V, and edge (v_4, u_4) is removed from E_{LF}. A new node v_8 with label $(a, 1)$ is inserted into V. This node is inserted into the doubly linked list of V at the position next to v_1 (i.e., $v_g = v_1$).

(II) Split node. The insert-node step (as the next step) inserts a new node representing special character \$ into U. However, before the insert-node step, the split-node step splits a node $u_j \in U$ into two new nodes at an appropriate position on the doubly linked list of

U. This step is executed for inserting the new node representing special character \$ into U at a appropriate position in the insert-node step. Following the extension of BWT in Section 5.2, node $u_j \in U$ has label $(L_\delta[p_j], p_{j+1} - p_j)$ for the two starting positions p_j and p_{j+1} satisfying $p_j < \mathsf{ins} < p_{j+1}$ for the insertion position ins of special character \$. Such a node u_j exists if and only if (i) the BWT $L_{\delta+1}$ of $T_{\delta+1}$ does not have special character \$ as the last character (i.e., $\mathsf{ins} \neq \delta + 1$) and (ii) $p_i \neq \mathsf{ins}$ for all $i \in \{1, 2, \ldots, k\}$. This is because $p_1 < p_2 < \ldots < p_{k+1}$ and $p_{k+1} = \delta + 1$ hold.

If node u_j does not exist in U, this step does not split nodes. Otherwise, u_j is replaced with two new nodes $u_{j'}$ and $u_{j'+1}$ in the doubly linked list of U, where $u_{j'}$ is previous to $u_{j'+1}$. The new nodes $u_{j'}$ and $u_{j'+1}$ are labeled as $(L_\delta[p_j], \mathsf{ins} - p_j)$ and $(L_\delta[p_j], p_{j+1} - \mathsf{ins})$ using insertion position ins, respectively.

Although we do not know position ins in the split-node step, we can find node u_j. This is because (i) set V contains node v_{gnext} representing the F-interval starting at position ins unless $\mathsf{ins} = \delta + 1$, and (ii) v_{gnext} is next to v_g in the doubly linked list of V for the node v_g searched for in the replace-node step. The following lemma ensures that we can find u_j and compute the labels of the new nodes in $O(1)$ time.

▶ **Lemma 2.** *The following two statements hold after executing the replace-node step: (i) we can check whether u_j exists or not in $O(1)$ time; (ii) we can find u_j and compute the labels of two nodes $u_{j'}$ and $u_{j'+1}$ in $O(1)$ time.*

Proof. See the full version of the paper [24]. ◀

Next, set V is updated according to the replacement of nodes in U, i.e., for undirected edge $(u_j, v_j) \in E_{LF}$, node v_j is replaced with two new nodes $v_{j'}$ and $v_{j'+1}$ in the doubly linked list of V, where $v_{j'}$ is previous to $v_{j'+1}$. Nodes $v_{j'}$ and $v_{j'+1}$ have the same labels of $u_{j'}$ and $u_{j'+1}$, respectively. Therefore, this step takes $O(1)$ time.

Figure 4-(II) illustrates an example of the split-node step. In this example, $\mathsf{ins} = 3$, $v_{\mathsf{gnext}} = v_6$, $v_j = v_2$, $v_{j'} = v_9$, and $v_{j'+1} = v_{10}$ hold. In Figure 3, the directed edge starting at node v_6 is labeled as integer 1 by function $B_F(v_6, u_2)$, and the directed edge points to node u_2 with label $(b, 2)$. Hence, node u_2 is replaced with two nodes u_9 and u_{10}. Two nodes u_9 and u_{10} are labeled with pairs $(b, 1)$ and $(b, 1)$, respectively. Node v_2 is connected to u_2 by edge $(v_2, u_2) \in E_{LF}$, and v_2 is replaced with two nodes v_9 and v_{10}. Here, v_9 and v_{10} are labeled with pairs $(b, 1)$ and $(b, 1)$, respectively.

(III) Insert node. This step inserts a new node $u_{x'}$ labeled $(\$, 1)$ into U, and it updates V according to the insertion of U. Analogous to the extension of BWT described in Section 5.2, the position for inserting the new node in the doubly linked list of U is determined according to the following three cases: (i) Node $u_j \in U$ was found and it was split into two nodes $u_{j'}$ and $u_{j'+1}$ in the split-node step. In this case, node $u_{x'}$ is inserted at the position next to $u_{j'} \in U$ on the doubly linked list of U. (ii) Node u_j was not found, and new node $v_{i'}$ is inserted at the position next to the last element on the doubly linked list of V in the replace-node step. In this case, $u_{x'}$ is inserted at the position next to the last element on the doubly linked list of U. (iii) Node u_j was not found, and $v_{i'}$ is inserted at the position previous to a node $v_{\mathsf{gnext}} \in V$ on the doubly linked list of V. In this case, v_{gnext} is connected to a node $u_x \in U$ by a directed edge in E_F, and $u_{x'}$ is inserted into the doubly linked list of U at the position previous to u_x.

Next, this step creates a new node $v_{x'}$ labeled $(\$, 1)$, and it is inserted into the doubly linked list of V. The new node is inserted at the top of the list, because the new label includes special character \$. This step takes $O(1)$ time.

Figure 4-(III) illustrates an example of the insert-node step. Because the split-node step replaced node u_2 with two nodes u_9 and u_{10}, the insert-node step inserts node u_{11} labeled $(\$, 1)$ at the position next to u_9 on the doubly linked list of U. On the other hand, the step inserts node v_{11} labeled $(\$, 1)$ in the doubly linked list of V at the position previous to node v_1.

(IV) Update edge. This step updates the set E_{LF} of undirected edges and two sets E_L and E_F of directed edges according to the two sets U and V, which were updated in the previous steps. This step consists of two phases: (i) for the nodes of u_i, v_i, u_j, and v_j removed in the replace-node and split-node steps, the edges connected to these nodes are removed from E_{LF}, E_L, and E_F; (ii) new edges connecting new nodes (i.e., $u_{j'}$, $u_{j'+1}$, $v_{i'}$, and $v_{j'+1}$) are added to E_{LF}, E_L, and E_F. The labels of new directed edges are computed at the second phase. The number of removed edges and new edges can be bounded by $O(\alpha)$ because (i) every node in the LF-interval graph for an $O(\alpha)$-balanced DBWT is connected to $O(\alpha)$ edges, (ii) the DBWT represented by the given LF-interval graph $\mathsf{Grp}(D_\delta^\alpha)$ is α-balanced, and (iii) the LF-interval graph $\mathsf{Grp}(D_{\delta+1}^{2\alpha+1})$ outputted by this update operation represents a $(2\alpha+1)$-balanced DBWT. Because the number of updated edges is small, this step can be performed in $O(\alpha)$ time. See the full version of the paper [24] for the details of the update-edge step. Formally, we obtain the following lemma.

▶ **Lemma 3.** *The update-edge step takes $O(\alpha)$ time.*

Proof. See the full version of the paper [24]. ◀

In Figure 4-(IV), four edges (u_8, v_8), (u_9, v_9), (u_{10}, v_{10}), and (u_{11}, v_{11}) connecting new nodes are added to E_{LF}. Six directed edges (u_1, v_{11}), (u_9, v_1), (u_{11}, v_8), (u_{10}, v_6), (u_8, v_7), and (u_5, v_9) are added to E_L. Similarly, seven directed edges (v_{11}, u_1), (v_1, u_9), (v_8, u_{11}), (v_6, u_{10}), (v_7, u_8), (v_9, u_5), and (v_{10}, u_5) are added to E_F.

Update of the data structures. Similar to the update-edge step, the four data structures in the LF-interval graph (i.e., the order maintenance data structure, the B-tree of set V, and two arrays that store nodes representing α-heavy DBWT-repetitions and F-intervals) are updated according to the removed nodes and new nodes.

See the full version of the paper [24] for the details of the algorithm updating the four data structures. The following lemma concerning the update time of the four data structures.

▶ **Lemma 4.** *Updating the four data structures takes $O(\alpha + \log k)$ time.*

Proof. See the full version of the paper [24]. ◀

The update operation takes $O(\alpha + \log k)$ time in total. The following lemma concerning the theoretical results on this update operation holds.

▶ **Theorem 5.** *The following two statements hold: (i) the update operation takes $O(\alpha + \log k)$ time; (ii) the update operation takes as input the LF-interval graph for an α-balanced DBWT D_δ^α of BWT L_δ, and it outputs the LF-interval graph for a $(2\alpha+1)$-balanced DBWT $D_{\delta+1}^{2\alpha+1}$ of BWT $L_{\delta+1}$ with at most two α-heavy DBWT-repetitions and at most two α-heavy F-intervals.*

Proof. See the full version of the paper [24]. ◀

From Theorem 5, the update operation outputs the LF-interval graph for a $(2\alpha+1)$-balanced DBWT $D_{\delta+1}^{2\alpha+1}$ of BWT $L_{\delta+1}$, which is not α-balanced. The output DBWT $D_{\delta+1}^{2\alpha+1}$ is balanced into an α-balanced DBWT $D_{\delta+1}^{\alpha}$ by the balancing operation presented in Section 5.6. The update of the LF-interval graph presented in this section takes $O(\alpha + \log k)$ time, which results in an $O(\alpha n + n \log k)$-time construction of the RLBWT from an input string of length n. The following two sections (Section 5.4 and Section 5.5) present two modified updates of the LF-interval graph in $O(\alpha + \log k)$-time and $O(\alpha)$-time, respectively, in order to achieve the $O(\alpha n + r \log r)$-time construction of an RLBWT with $O(r \log n)$ bits of working space.

5.4 $O(\alpha + \log k)$-time update of LF-interval graph

This section presents the update operation $\mathsf{update}(\mathsf{Grp}(D_\delta^\alpha), c)$ taking an LF-interval graph $\mathsf{Grp}(D_\delta^\alpha)$ and the first character c of suffix $T_{\delta+1}$ as input and running in $O(\alpha + \log k)$ time by modifying the foundation of the update operation presented in Section 5.3. For the node u_{i-1} previous to the node u_i representing special character \$ in the doubly linked list of U and the node u_{i+1} next to u_i, update operation $\mathsf{update}(\mathsf{Grp}(D_\delta^\alpha), c)$ is applied if neither u_{i-1} nor u_{i+1} has labels including character c.

We first present a modified update of the B-tree of V in $O(\log k)$ time. This update replaces the original update of the B-tree. The following lemma holds with respect to nodes searched for using the B-tree of V in the replace-node step of this update operation.

▶ **Lemma 6.** *For the node $v_g \in V$ searched for using the B-tree of V in the replace-node step of the update operation $\mathsf{update}(\mathsf{Grp}(D_\delta^\alpha), c)$, v_g satisfies any one of the following three properties: (i) for undirected edge $(u_g, v_g) \in E_{LF}$ and node $u_{g+1} \in U$ next to u_g in the doubly linked list of U, the two consecutive nodes u_g and u_{g+1} have labels including different characters, and the label of u_{g+1} does not include special character \$; (ii) for the node $u_{g+2} \in U$ next to u_{g+1} in the doubly linked list of U, the two nodes u_g and u_{g+2} have labels including different characters, and the label of u_{g+1} includes special character \$; (iii) the label of u_g includes special character \$.*

Proof. See the full version of the paper [24]. ◀

Thus, the B-tree of V stores only the nodes in V satisfying one of the three conditions of Lemma 6, because Lemma 6 ensures only such nodes are searched for in the replace-node step of this update operation.

The target nodes inserted into the B-tree of V (respectively, the target nodes deleted from the B-tree of V) are limited to four (respectively, three) according to the following lemma.

▶ **Lemma 7.** *Nodes $u_i \in U$ and $v_i \in V$ are the nodes removed from U and V by the replace-node steps, respectively. Node $u_{i-1} \in U$ is the node previous to node u_i in the doubly linked list of U, and $v_{i-1} \in V$ is the node connected to u_{i-1} by undirected edge $(u_{i-1}, v_{i-1}) \in E_{LF}$. Node $v_j \in V$ is the node removed from V by the split-node step, and $v_{j'}, v_{j'+1} \in V$ are the nodes newly created by the same step. Similarly, $v_{i'} \in V$ and $v_{x'} \in V$ are the nodes created by the replace-node and insert-node steps, respectively. Then, the following two statements hold for the update operation $\mathsf{update}(\mathsf{Grp}(D_\delta^\alpha), c)$: (i) targets inserted into the B-tree of V can be limited to only four nodes $v_{i-1}, v_{i'}, v_{x'}$, and $v_{j'+1}$; (ii) the targets deleted from the B-tree of V can be limited to only three nodes, v_{i-1}, v_i, and v_j.*

Proof. See the full version of the paper [24]. ◀

Thus, all the nodes inserted into the B-tree of V can be found by searching for only four nodes $v_{i-1}, v_{i'}, v_{x'}$, and $v_{j'+1}$ and checking whether or not each one, $v_{i-1}, v_{i'}, v_{x'}$, and $v_{j'+1}$, satisfies one of the three conditions presented in Lemma 6. Similarly, all the nodes deleted from the B-tree of V can be found by searching for only three nodes v_{i-1}, v_i, and v_j and checking whether or not each of these nodes satisfies one of the three conditions. This modified update of the B-tree takes $O(\log k)$ time in total.

The algorithm of update operation $\mathsf{update}(\mathsf{Grp}(D_\delta^\alpha), c)$ is the same as that of the original update operation presented in Section 5.3 except for the algorithm updating the B-tree of V. Hence, update operation $\mathsf{update}(\mathsf{Grp}(D_\delta^\alpha), c)$ takes $O(\alpha + \log k)$ time in total. The following lemma concerning the theoretical results on this update operation holds.

▶ **Lemma 8.** *Assume that the B-tree of V in LF-interval graph $\mathsf{Grp}(D_\delta^\alpha)$ contains only nodes satisfying one of the three conditions of Lemma 6: (i) update operation $\mathsf{update}(\mathsf{Grp}(D_\delta^\alpha), c)$ runs in $O(\alpha+\log k)$ time; (ii) the update operation outputs the LF-interval graph $\mathsf{Grp}(D_{\delta+1}^{2\alpha+1})$ for a $(2\alpha+1)$-balanced DBWT $D_{\delta+1}^{2\alpha+1}$ of BWT $L_{\delta+1}$ with at most two α-heavy DBWT-repetitions and at most two α-heavy F-intervals; (iii) the B-tree of V in the outputted LF-interval graph contains only nodes satisfying one of the three conditions of Lemma 6.*

In the next subsection, the second modified update operation of LF-interval graph achieves $O(\alpha)$ time using the B-tree of V containing only nodes satisfying one of the three conditions of Lemma 6.

5.5 $O(\alpha)$-time update of LF-interval graph

This section presents fast update operation $\mathsf{fastUpdate}(\mathsf{Grp}(D_\delta^\alpha), c)$, which takes an LF-interval graph $\mathsf{Grp}(D_\delta^\alpha)$ and the first character c of suffix $T_{\delta+1}$ as input and runs in $O(\alpha)$ time. This time is achieved by modifying the foundation of the update operation presented in Section 5.3, and the B-tree of V needs to contain only nodes of satisfying one of the three conditions of Lemma 6 in the input and output LF-interval graphs, similar to the update operation in Section 5.4 (Lemma 8).

For node $u_{i-1} \in U$ previous to node $u_i \in U$ that represents special character \$ in the doubly linked list of U and node $u_{i+1} \in U$ next to u_i, the fast update operation is applied if either or both u_{i-1} and u_{i+1} have a label including character c; the update operation in Section 5.4 is applied otherwise. The large computational demand of the update operation on LF-interval graphs presented in Section 5.3 derives from the access and update of the B-tree of V in $O(\log k)$ time, resulting in an $O(\alpha + \log k)$ time update of LF-interval graphs. We present two improvements to the foundation of the update operation: (i) deletion and insertion operations of the B-tree of V in $O(1)$ time and (ii) the replace-node step in $O(1)$ time without using the B-tree of V. The details of the fast operation are presented in the full version of the paper [24].

Deletion and insertion operations of B-tree in constant time. Generally, inserting/deleting a key into/from the B-tree of V takes $O(\log k)$ time. We present $O(1)$-time deletion and insertion operations of a specific node in the B-tree of V without the need for heavyweight operations to maintain the balance of the B-tree.

Recall that (i) $u_{i'} \in U$ and $v_{i'} \in V$ are the nodes created by the replace-node step, (ii) $v_j \in V$ is the node removed from V by the split-node step, and (iii) $u_{x'} \in U$ and $v_{x'} \in V$ are the nodes created by the insert-node step. Let $u_{i'-1} \in U$ (respectively, $u_{i'+1} \in U$) be the node previous to node $u_{i'}$ (respectively, the node next to node $u_{i'}$) in the doubly linked list of U after the insert-node step has been executed. Then, there exist two nodes $v_{i'-1}$ and $v_{i'+1} \in V$ such that $(u_{i'-1}, v_{i'-1}), (u_{i'+1}, v_{i'+1}) \in E_{LF}$.

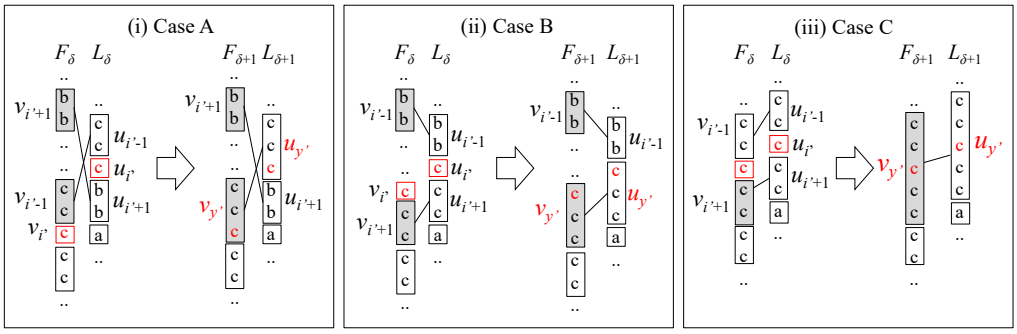

Figure 5 Three cases A, B, and C for preprocessing deletions/insertions in the B-tree. Gray nodes are stored in the B-tree.

In the fast update operation, the target nodes deleted from the B-tree are limited to at most four nodes $v_i, v_j, v_{i'-1}$, and $v_{i'+1}$, which is similar to Lemma 7-(ii). In the doubly linked list of V, node v_i is replaced with the new node $v_{x'}$ created in the insert-node step of the update operation. Because the two nodes v_i and $v_{x'}$ represent special character \$, both satisfy the third condition of Lemma 6. Thus, both nodes v_i and $v_{x'}$ are placed on the root of the B-tree. Hence, v_i can be deleted and $v_{x'}$ can be inserted into the B-tree in $O(1)$ time without balancing the B-tree.

Next, in the doubly linked list of V, node v_j is replaced with the two nodes $v_{j'}$ and $v_{j'+1} \in V$ that were created in the split-node step of the update operation. Node $v_{j'}$ satisfies none of the three conditions of Lemma 6. Thus, v_j is deleted from the B-tree of V, and $v_{j'+1}$ (that is, not $v_{j'}$) is only inserted into the B-tree of V if v_j is contained in the B-tree of V because of the next lemma.

▶ **Lemma 9.** *The following two statements hold: (i) $v_{j'}$ satisfies none of the three conditions of Lemma 6; (ii) for the node $u_j (\neq u_{i-1})$ connected to v_j by undirected edge $(u_j, v_j) \in E_{LF}$, $v_{j'+1}$ satisfies any one of the three conditions of Lemma 6 if and only if v_j satisfies any one of the three conditions.*

Proof. See the full version of the paper [24]. ◀

Because v_j is replaced with $v_{j'+1}$ in the doubly linked list of V, the element representing v_j can be replaced with the element representing $v_{j'+1}$ in the B-tree from Lemma 1. Hence, v_j is deleted from the B-tree of V and $v_{j'+1}$ is inserted into the B-tree of V in $O(1)$ time without balancing the B-tree. Illustrations of the replacement of two nodes v_i and v_j in the doubly linked list of V can be found in the full version of the paper [24].

The above procedure inserts $v_{j'+1}$ into the B-tree of V even if the node satisfies none of the three conditions of Lemma 6. This is because Lemma 9-(ii) assumes that $u_j \neq u_{i-1}$ holds, but $u_j \neq u_{i-1}$ is not always true. If the assumption holds, $v_{j'+1}$ is appropriately inserted into the B-tree of V. Otherwise (i.e., $v_{j'+1} = v_{i'-1}$ holds), node $v_{j'+1}$ is appropriately deleted from the B-tree of V in $O(1)$ time, which is explained next.

Two nodes $v_{i'-1}$ and $v_{i'+1}$ are appropriately deleted from the B-tree of V, and new nodes are inserted into the B-tree of V in the update operation of the LF-interval graph. For updating the B-tree of V in $O(1)$ time, we merge at most three nodes $v_{i'}$, $v_{i'-1}$, and $v_{i'+1}$ into a new node in a prepossessing step. The merging of nodes and update of the B-tree are performed according to the following three cases.

Case A: $v_{i'-1}$ has a label including character c and $v_{i'+1}$ does not have a label including character c (Figure 5-(i)). First, the two consecutive nodes $u_{i'-1}$ with label (c, ℓ) and $u_{i'}$ with label $(c, 1)$ are merged into a new one $u_{y'}$ with label $(c, \ell + 1)$ in the doubly linked list of U. Then, set V is updated according to the merge of the two nodes in U, i.e., the two consecutive nodes $v_{i'-1}$ and $v_{i'}$ are merged into a new one $v_{y'}$ with label $(c, \ell + 1)$ in the doubly linked list of V.

Node $v_{i'+1}$ is kept in the B-tree of V (if the node is contained in the B-tree). Node $v_{i'-1}$ is deleted from the B-tree of V and new node $v_{y'}$ is inserted only if $v_{i'-1}$ is contained in the B-tree of V. Because $v_{i'-1}$ is replaced by $v_{y'}$ in the doubly linked list of V, $v_{i'-1}$ can be deleted from the B-tree of V and $v_{y'}$ can be inserted in $O(1)$ time from Lemma 1.

Case B: $v_{i'-1}$ does not have a label including character c, and $v_{i'+1}$ has a label including character c (Figure 5-(ii)). First, the two consecutive nodes $u_{i'}$ and $u_{i'+1}$ with label (c, ℓ') are merged into a new node $u_{y'}$ with label $(c, \ell' + 1)$ in the doubly linked list of U. Then, set V is updated according to the merge of the two nodes in U.

In this case, $v_{i'-1}$ is contained in the B-tree of V, and the node is kept. Node $v_{i'+1}$ is deleted from the B-tree of V and new node $v_{y'}$ is inserted only if $v_{i'+1}$ is contained in the B-tree of V. Because $v_{i'+1}$ is replaced with $v_{y'}$ in the doubly linked list of V, $v_{i'+1}$ is deleted from the B-tree of V and $v_{y'}$ is inserted in $O(1)$ time from Lemma 1.

Case C: both $v_{i'-1}$ and $v_{i'+1}$ have labels including the same character c (Figure 5-(iii)). First, the three consecutive nodes $u_{i'-1}$, $u_{i'}$ and $u_{i'+1}$ are merged into a new node $u_{y'}$ with label $(c, \ell + \ell' + 1)$ including the same character c in the doubly linked list of U. Then, set V is updated according to the merge of the three nodes in U.

In this case, $v_{i'-1}$ is not contained in the B-tree of V. Node $v_{i'+1}$ is deleted from the B-tree and the new node $v_{y'}$ is inserted if $v_{i'+1}$ is contained in the tree; otherwise, $v_{y'}$ is not inserted into the tree. Because $v_{i'+1}$ is replaced by $v_{y'}$ in the doubly linked list of V, $v_{i'+1}$ is deleted and $v_{y'}$ is inserted into the B-tree of V in $O(1)$ time from Lemma 1.

One of the three cases always holds (see the full version of the paper [24]). The preprocessing of the B-tree of V (i.e., the merging of nodes) does not affect Lemma 9. Hence, updating the B-tree takes $O(1)$ time.

Replace-node step in constant time. The replace-node step is performed in $O(1)$ time by finding the position for inserting a new node $v_{i'}$ with label $(c, 1)$ into the doubly linked list of V without accessing the B-tree of set V. This is made possible if either or both u_{i-1} and u_{i+1} have labels including the same character c. The following lemma holds.

▶ **Lemma 10.** *If either or both u_{i-1} and u_{i+1} have labels including the same character c, the position for inserting the new node $v_{i'}$ into the doubly linked list of V can be found in $O(1)$ time.*

Proof. See the full version of the paper [24]. ◀

The following lemma concerning the conclusion of the fast update operation holds.

▶ **Lemma 11.** *Assume that the B-tree of V in LF-interval graph $\mathsf{Grp}(D^{\alpha}_{\delta})$ contains only the nodes that satisfy one of the three conditions of Lemma 6: (i) fast update operation $\mathsf{fastUpdate}(\mathsf{Grp}(D^{\alpha}_{\delta}), c)$ runs in $O(\alpha)$ time; (ii) the fast update operation outputs the LF-interval graph for a $(2\alpha+1)$-balanced DBWT $D^{2\alpha+1}_{\delta+1}$ of BWT $L_{\delta+1}$ with at most two α-heavy DBWT-repetitions and at most two α-heavy F-intervals; (iii) the B-tree of V in the outputted LF-interval graph contains only nodes satisfying one of the three conditions of Lemma 6.*

Proof. See the full version of the paper [24]. ◀

Both update operation $\mathsf{update}(\mathsf{Grp}(D_\delta^\alpha), c)$ and fast update operation $\mathsf{fastUpdate}(\mathsf{Grp}(D_\delta^\alpha), c)$ output the LF-interval graph for a $(2\alpha+1)$-balanced DBWT $D_{\delta+1}^{2\alpha+1}$ of BWT $L_{\delta+1}$ with at most two α-heavy DBWT-repetitions and at most two α-heavy F-intervals. The outputs are balanced by the balancing operation presented in the next subsection such that the LF-interval graph represents an α-balanced DBWT $D_{\delta+1}^\alpha$ of BWT $L_{\delta+1}$.

5.6 Balancing operation of the LF-interval graph

Balancing operation $\mathsf{balance}(\mathsf{Grp}(D_\delta))$ takes the LF-interval graph $\mathsf{Grp}(D_\delta)$ for a DBWT D_δ of BWT L_δ as input, and it outputs the LF-interval graph $\mathsf{Grp}(D_\delta^\alpha)$ for an α-balanced DBWT D_δ^α of the same BWT. The basic idea behind the balancing operation is to iteratively remove each of nodes representing α-heavy DBWT repetitions and α-heavy F-intervals from the given LF-interval graph by splitting the chosen node into two nodes. The balancing operation repeats this process until it obtains the LF-interval graph for an α-balanced DBWT.

We explain the algorithm of the balancing operation. At each iteration, the balancing operation processes the LF-interval graph for an $O(\alpha)$-balanced DBWT with $O(\alpha)$ α-heavy DBWT-repetitions and $O(\alpha)$ α-heavy F-intervals. Let $(u_i, v_i) \in E_{LF}$ be an undirected edge such that node $u_i \in U$ represents an α-heavy DBWT-repetition, or node $v_i \in V$ represents an α-heavy F-interval. At the iteration, node u_i is split into two nodes, and v_i is split into two nodes according to the splitting of u_i. The LF-interval graph $\mathsf{Grp}(D_\delta^{O(\alpha)})$ is updated according to the splitting of u_i and v_i. One iteration of the balancing operation takes $O(\alpha)$ time. See the full version of the paper [24] for the details of the balancing operation.

The following lemma concerning the theoretical results on the balancing operation holds.

▶ **Lemma 12.** *For the LF-interval graph $\mathsf{Grp}(D_\delta^{2\alpha+1})$ for a $(2\alpha+1)$-balanced DBWT including at most two α-heavy DBWT-repetitions and at most two α-heavy F-intervals, we assume that the B-tree of V in the LF-interval graph contains only nodes satisfying one of the three conditions of Lemma 6. Then, balancing operation $\mathsf{balance}(\mathsf{Grp}(D_\delta^{2\alpha+1}))$ takes $O(\alpha)$ time per iteration for all $\alpha \geq 4$, and the B-tree of V in the outputted LF-interval graph contains only nodes satisfying one of the three conditions of Lemma 6.*

Proof. See the full version of the paper [24]. ◀

6 R-comp algorithm

In this section, we present the r-comp algorithm, and we also present its space and time complexities. The r-comp algorithm takes input string T and parameter $\alpha \geq 2$, and it outputs the RLBWT of T. The pseudo-code of r-comp is given in Algorithm 1.

The algorithm reads T from its end to its beginning (i.e., $T[n], T[n-1], \ldots, T[1]$), and it gradually builds the LF-interval graph $\mathsf{Grp}(D_n^\alpha)$ for an α-balanced DBWT D_n^α of BWT L_n of T. At each $\delta \in \{1, 2, \ldots, n-1\}$, LF-interval graph $\mathsf{Grp}(D_\delta^\alpha)$ for an α-balanced DBWT D_δ^α of BWT L_δ of $T[(n-\delta+1)..n]$ (i.e., suffix T_δ) is built. For the node $u_i \in U$ representing special character \$ in the doubly linked list of set U of nodes in LF-interval graph $\mathsf{Grp}(D_\delta^\alpha)$, two nodes $u_{i-1} \in U$ and $u_{i+1} \in U$ are previous and next to node u_i, respectively, in the list. If neither the label of u_{i-1} nor the label of u_{i+1} includes the $(n-\delta)$-th character c of T (i.e., the first character c of $T_{\delta+1}$), the update operation $\mathsf{update}(\mathsf{Grp}(D_\delta^\alpha), c)$ described in Section 5.4 is applied; otherwise the fast update operation $\mathsf{fastUpdate}(\mathsf{Grp}(D_\delta^\alpha), c)$ described in Section 5.5

Algorithm 1 R-comp algorithm. The algorithm takes string T and parameter $\alpha \geq 2$ as input, and it outputs the RLBWT of T. n : length of T; D_δ^α : α-balanced DBWT of BWT L_δ of $T[(n-\delta+1)..n]$; $\mathsf{Grp}(D_\delta^\alpha)$: the LF-interval graph of α-balanced DBWT D_δ^α.

```
1: function R-COMP(T, α)
2:     D_1^α ← $                                  ▷ Initialize D_1^α as special character $
3:     build Grp(D_1^α)
4:     for δ = 1, 2, ..., n − 1 do
5:         c ← T[n − δ]                           ▷ Read character c from T[n − δ]
6:         if neither the label of u_{i−1} nor the label of u_{i+1} includes character c then
7:             Grp(D_{δ+1}^{2α+1}) ← update(Grp(D_δ^α), c)      ▷ The update operation in Sec. 5.4
8:         else
9:             Grp(D_{δ+1}^{2α+1}) ← fastUpdate(Grp(D_δ^α), c) ▷ The fast update operation in Sec. 5.5
10:        end if
11:        Grp(D_{δ+1}^α) ← balance(Grp(D_{δ+1}^{2α+1}))      ▷ The balancing operation in Sec. 5.6
12:    end for
13:    Recover D_n^α from Grp(D_n^α)
14:    Convert D_n^α into the RLBWT of T
15:    Return the RLBWT
16: end function
```

is applied. Both the update operation and the fast update operation output an LF-interval graph $\mathsf{Grp}(D_{\delta+1}^{2\alpha+1})$ for DBWT $D_{\delta+1}^{2\alpha+1}$ of BWT $L_{\delta+1}$ that is not α-balanced. Thus, the r-comp algorithm balances the LF-interval graph such that it represents an α-balanced DBWT $D_{\delta+1}^\alpha$ using the balancing operation in Section 5.6 as $\mathsf{Grp}(D_{\delta+1}^\alpha)$. After $(n-1)$ iterations of those steps, the LF-interval graph $\mathsf{Grp}(D_n^\alpha)$ for α-balanced DBWT D_n^α of BWT L_n is obtained; it is then converted into D_n^α using the doubly linked list of U. Finally, D_n^α is converted into the RLBWT of T.

6.1 Space and time complexities

Space complexity. The r-comp algorithm requires $O(k \log n)$ bits of space for k DBWT-repetitions in the DBWT D_n^α because the LF-interval graph $\mathsf{Grp}(D_n^\alpha)$ for the DBWT requires $O(k \log n)$ bits of space. The value of k depends on the number of executions of update, fast update, and balancing operations executed by the r-comp algorithm. The following lemma ensures that k can be bounded by $O(r)$.

▶ **Lemma 13.** *We modify the fast update operation. Then, the following three statements hold: (i) this modification does not affect Lemma 11; (ii)* $k \leq r + k_{\mathsf{split}}$*; (iii)* $k_{\mathsf{split}} \leq \frac{2r}{\lceil \alpha/2 \rceil - 7}$ *holds for any constant* $\alpha \geq 16$*.*

Proof. See the full version of the paper [24]. ◀

Because $k = O(r)$ by Lemma 13, the following theorem is obtained.

▶ **Theorem 14.** *The r-comp algorithm takes* $O(r \log n)$ *bits of working space for* $\alpha \geq 16$*.*

Time complexity. The bottleneck of r-comp is the update operation of LF-interval graph with $O(\alpha + \log k)$ time in Section 5.4. The number of executions of the update operation can be bounded by $O(r)$. This fact indicates that we can bound the running time of r-comp by $O(\alpha n + r \log k)$, i.e., $O(\alpha n + r \log r)$. Finally, we obtain the following theorem.

▶ **Theorem 15.** *R-comp runs in $O(\alpha n + r \log r)$ time for $\alpha \geq 16$.*

Proof. See the full version of the paper [24]. ◀

7 Experiments

Setup. We empirically tested the performance of the r-comp algorithm on strings from four datasets with different types of highly repetitive strings: (i) nine strings from the Pizza&Chili repetitive corpus [29]; (ii) three strings (boost, samtools, and sdsl) of the latest revisions of Git repositories, each of which is 1GB in size; (iii) a 37GB string (enwiki) of English Wikipedia articles with a complete edit history [33]; and (iv) a 59GB string (chr19.1000) obtained by concatenating chromosome 19 from 1,000 human genomes in the 1000 Genomes Project [32]. See the full version of the paper [24] for the relevant statistics in the datasets. The ratio n/r of string length n to the number r of BWT-runs in BWT is the compression ratio of each string. The strings with high compression ratios are versions of Wikipedia articles (einstein.de.txt and einstein.en.txt), revisions of Git repositories (boost, samtools, and sdsl), and 1000 human genomes (chr19.1000).

We implemented two versions of the r-comp algorithm (i.e., r-comp and r-comp$_{\text{saving}}$). Here, r-comp is the straightforward implementation of the r-comp algorithm presented in Section 6; r-comp$_{\text{saving}}$ is a space-saving implementation of the r-comp algorithm. This version is more space efficient than r-comp because it uses a grouping technique with parameter $g = 16$. We compared r-comp and r-comp$_{\text{saving}}$ with three state-of-the-art algorithms, one indirect construction algorithm of RLBWT (Big-BWT) and two direct construction algorithms of RLBWT (the PP and Faster-PP methods), which were reviewed in Section 2 and summarized in Table 1. The comparisons were performed using a single thread on one core of a CPU. The source code of the r-comp algorithm is available at `https://github.com/kampersanda/rcomp`. See the full version of the paper [24] for the details of the setup.

Results. A comparison of the r-comp variants (r-comp and r-comp$_{\text{saving}}$) shows that the working space of r-comp$_{\text{saving}}$ was 3.8–4.4 times smaller than that of r-comp, whereas the construction time of r-comp$_{\text{saving}}$ was at most only 2.0 times slower and at most 2.0 times faster on world_leaders and samtools. These results show r-comp$_{\text{saving}}$ has a high compression performance when compared with r-comp. Comparisons of the experimental results of r-comp$_{\text{saving}}$ and the other methods are presented below.

r-comp$_{\text{saving}}$ was the fastest in the comparison to the direct RLBWT constructions of the PP and Faster-PP methods. Especially for strings with a large ratio n/r, r-comp$_{\text{saving}}$ was 81–118 times faster than the PP method and 3.8–5.1 times faster than the Faster-PP method; the working space of r-comp$_{\text{saving}}$ was 2.4–6.1 times larger than that of the PP method and 2.8–2.9 times larger than that of the Faster-PP method, which shows that the working space of r-comp$_{\text{saving}}$ is reasonable considering its construction time. For the large dataset enwiki, r-comp$_{\text{saving}}$ finished the construction in 6.8 hours, whereas the Faster-PP method took 15.4 hours. In addition, the PP method did not finish within 24 hours. For the 1000 human genomes chr19.1000, r-comp$_{\text{saving}}$ finished the construction in 11 hours, whereas the PP and Faster-PP methods did not finish within 24 hours.

In the comparison between r-comp and Big-BWT, r-comp was more space efficient than Big-BWT on most strings. Because r was much smaller than $|\mathsf{PFP}|$, the results are consistent with the theoretical bound $O(r \log n)$ of the working space of the r-comp algorithm (Theorem 14). On strings with large values of $|\mathsf{PFP}|/r$, whereas r-comp$_{\text{saving}}$ was slower

than Big-BWT, the difference in the construction times between r-comp$_{\text{saving}}$ and Big-BWT were reasonable if one considers the space efficiency of r-comp$_{\text{saving}}$. For example, for boost, r-comp was 26 times more space efficient and only 2.7 times slower; for world_leaders, r-comp was 3.9 times more space efficient and only 1.5 times slower.

On the large datasets (i.e., enwiki and chr19.1000), r-comp was more space-efficient but slower than Big-BWT; r-comp was 2.3 times space-efficient but 10 times slower than Big-BWT on enwiki; r-comp was 2.5 times space-efficient but 11 times slower than Big-BWT on chr19.1000.

Overall, r-comp$_{\text{saving}}$ was the fastest RLBWT construction in $O(r \log n)$ bits of space. Although Big-BWT was faster than r-comp$_{\text{saving}}$, it was not space efficient for several strings (e.g., boost). On most datasets, r-comp$_{\text{saving}}$ achieved a better tradeoff between construction time and working space. Furthermore, r-comp has a huge advantage in that it supports the insertion of a new character into RLBWT, while BigBWT does not support such an insertion operation.

8 Conclusion

We presented r-comp, the first optimal-time construction algorithm of RLBWT in $O(n)$ time with $O(r \log n)$ bits of working space for highly repetitive strings with $r = O(n/\log n)$. Experimental results using benchmark and real-world datasets of highly repetitive strings demonstrated the superior performance of the r-comp algorithm.

The idea behind the DBWT presented in this paper has a wide variety of applications, and it is applicable to the construction of various types of data structures. Therefore, a future task is to develop optimal-time constructions of various data structures for fast queries.

Abstract

We identify two new big clusters of proof complexity measures equivalent up to polynomial and $\log n$ factors. The first cluster contains, among others, the logarithm of tree-like resolution size, regularized (that is, multiplied by the logarithm of proof length) clause and monomial space, and clause space, both ordinary and regularized, in regular and tree-like resolution. As a consequence, separating clause or monomial space from the (logarithm of) tree-like resolution size is the same as showing a strong trade-off between clause or monomial space and proof length, and is the same as showing a super-critical trade-off between clause space and depth. The second cluster contains width, Σ_2 space (a generalization of clause space to depth 2 Frege systems), both ordinary and regularized, as well as the logarithm of tree-like size in the system $R(\log)$. As an application of some of these simulations, we improve a known size-space trade-off for polynomial calculus with resolution. In terms of lower bounds, we show a quadratic lower bound on tree-like resolution size for formulas refutable in clause space 4. We introduce on our way yet another proof complexity measure intermediate between depth and the logarithm of tree-like size that might be of independent interest.

1 Introduction

With the rise of computer science, questions like "can we solve a problem?" got a quantitative counterpart: "how hard is it to solve a problem?". Proof complexity deals with the quantitative version of "can we prove a theorem?", namely, the question "how hard is it to prove a theorem?". The systematic study of the latter question for propositional proof systems started with Cook and Reckhow [13], where its fundamental role in complexity theory was identified.

The most natural, arguably also the most important, measure of the complexity of a proof is its size, and indeed, much of the research in propositional proof complexity has concentrated on proof size lower bounds. But given in particular their role in proof systems of practical significance, several other natural complexity measures have been considered, and that has led to a considerable line of study about relations between them (*simulations*), lack of relations thereof (*separations*) and the inherent impossibility of optimizing two different measures at once (*trade-offs*). To aid further discussion, let us review those measures and previous results that are most pertinent to this work.

A measure that directly emerged from the study of proof size lower bounds is width; the width of a resolution proof is the number of literals in the largest clause occurring in the proof. Its importance was accentuated by Ben-Sasson and Wigderson [8], who, building on the earlier works of Clegg et al. [12] and Impagliazzo et al. [23] showing an analogous result for polynomial calculus, showed that a short resolution proof can be transformed into a narrow one. Namely, we have

$$W(F \vdash \bot) \leq \log S_T(F \vdash \bot) + W(F), \tag{1}$$

$$W(F \vdash \bot) \leq O\left(\sqrt{n \log S_R(F \vdash \bot)}\right) + W(F). \tag{2}$$

Here $W(F \vdash \bot)$, $S_T(F \vdash \bot)$ and $S_R(F \vdash \bot)$ stand for the minimum width, tree-like size and DAG-like size respectively of refuting an unsatisfiable CNF F in resolution; similar notation is employed throughout the paper. $W(F)$ is the maximum width of a clause in F.

Space complexity for propositional proofs was introduced in [16, 1]. Esteban and Torán [16] showed that a short tree-like resolution proof can be transformed into a resolution proof of small clause space:

$$\mathrm{CSpace}(F \vdash \bot) \leq \log S_T(F \vdash \bot). \tag{3}$$

Atserias and Dalmau [2] demonstrated the first instance of the relationship between space and width, showing that a resolution proof having small clause space can be transformed into a narrow one:

$$W(F \vdash \bot) \leq \mathrm{CSpace}(F \vdash \bot) + W(F). \tag{4}$$

Constructive versions of their result were given by Filmus et al. [18] and Razborov (unpublished), see also Krajíček [26, Theorem 5.5.5]. It is worth noting that (3) and (4) taken together provide a refinement of (1) and that, viewed this way, we relate two *sequential* measures (tree-like size and width) with a *space* measure as an intermediate. We will see more examples of such an interplay in this paper.

More recently, Bonacina [9] showed that for total space in resolution (measured as the sum of widths of clauses in a configuration) we have

$$W(F \vdash \bot) \leq O\left(\sqrt{\mathrm{TSpace}(F \vdash \bot)}\right) + W(F), \tag{5}$$

and Galesi et al. [19] showed a weakened version of (4), but for the analogue of clause space in stronger proof systems operating with polynomials (or in fact even arbitrary Boolean functions of monomials):

$$W(F \vdash \bot) \leq O\left(\left(\mathrm{MSpace}(F \vdash \bot)\right)^2\right) + W(F). \tag{6}$$

Regularized[1] versions μ^* of space complexity measures are defined by multiplying the measure in question μ by the logarithm of the proof length; these were considered e.g. by Ben-Sasson [4] and Razborov [37]. The latter paper also contains a suggestion that the "right" level of precision when comparing measures of this kind are up to polynomial and $\log n$ factors;[2] we will henceforth call two measures *equivalent* if they simulate each other

[1] The paper [37] used the word "amortized" but Sam Buss pointed out to us that it is somewhat misleading in this context.

[2] Note that the size/length measures appear in this set-up under a logarithm. Hence this corresponds to *quasi*-polynomial simulations in the Cook-Reckhow framework.

in this sense. The paper [37] identified a big cluster of ordinary and regularized space complexity measures, including total and variable space, that are all equivalent to proof depth in resolution. One notable measure that defied this classification was (regularized) clause space.[3]

Our contributions

In this paper we identify two other big clusters of equivalent complexity measures not covered by the results in [37]. The cumulative picture combining both previously known and new results is summarized in Figure 1. There, arrows are to be interpreted as inequalities, and $\approx$

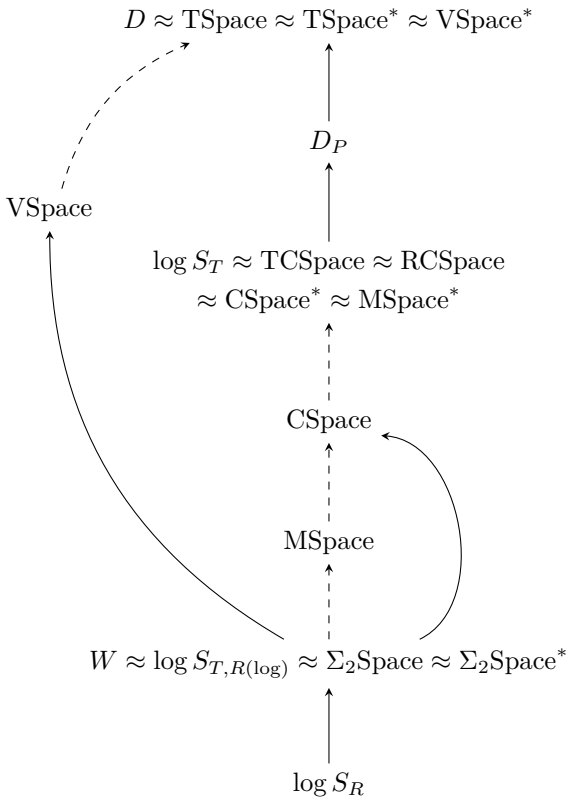

Figure 1 Simulations.

as equality, both up to polynomial and $\log n$ factors. A solid arrow from μ_1 to μ_2 indicates that a separation between μ_1 and μ_2 is known, that is, it additionally indicates that there exists a sequence $\{F_n\}$ of unsatisfiable CNFs such that $\mu_2(F_n \vdash \bot) \geq (\mu_1(F_n \vdash \bot)+\log n)^{\omega(1)}$. To improve readability, we have omitted from Figure 1 the argument $F \vdash \bot$.

Let us briefly explain this picture. The first new cluster is centered around the logarithm of tree-like resolution size. Given the proof method of the simulation (3) in [16], it can be obviously strengthened in two directions: by replacing the left-hand side with clause space in *tree-like* resolution or by replacing it with *regularized* clause space. Tree-like clause space in resolution was shown to be equivalent to the logarithm of tree-like size in the same paper [16, Corollary 5.1]; in other words, after this replacement in the left-hand side, the bound (3) becomes tight, within the precision we are tolerating.

[3] A technical remark: [37, Theorem 3.2] does not apply to clause space as it is not bounded from below by the number of variables.

We show that the second variant, that is *regularized* clause space, is also equivalent to the logarithm of tree-like resolution size, and this result extends to also include regularized *monomial* space to the same cluster. Given that [16, Corollary 5.1] also holds for (ordinary) clause space in *regular* resolution [16, Corollary 4.2], this means that all these space measures turn out to be equivalent to each other and to the log of tree-like resolution size. We also remark (given the results above, this readily follows from definitions) that *regularized* versions of the clause space in tree-like or regular resolution are also in this cluster.

The question of whether (ordinary) clause space also belongs here is what we consider to be a major, and most likely very difficult, open problem. But since it has turned out to be closely related to several other threads in proof complexity, we prefer to keep the momentum and defer further discussion to the concluding Section 5.

Our second cluster is presided by resolution width. First, we introduce a natural analogue of clause space in DNF resolution that we call Σ_2 *space*. This can be seen as an extension of clause space to depth 2 Frege systems; indeed, the restriction of Σ_2 space to depth 1 Frege is precisely clause space, and its restriction to k-DNF resolution, for constant k, coincides, up to a constant factor, with the concept of space that has been studied before for such systems (see e.g. [15, 7]). In our model, configurations are *arbitrary* sets of DNFs, and we charge k for every individual k-DNF in the memory. Clearly, $\Sigma_2\mathrm{Space} \leq \mathrm{CSpace}$ and $\Sigma_2\mathrm{Space}^* \leq \mathrm{CSpace}^*$. Then we strengthen the Atserias-Dalmau bound (4) by replacing CSpace with Σ_2Space and continue to show that *both* ordinary and regularized versions of Σ_2 space are actually equivalent to resolution width.

Thus, remarkably, the difficult open question on whether we have a strong trade-off between space and length for clause space gets a relatively easy negative solution for a stronger proof system. We have also been able to locate in this cluster another interesting size measure: the size of tree-like proofs in the system $R(\log)$, which gives a somewhat unexpected generalization of (1). We have not been able to retrieve the equivalence of width and tree-like size in $R(\log)$ from the literature in exactly this form but it is implicit in Lauria [27] and, with a bit of effort, can be traced back as far as Krajíček [24].

It is worth noting that some of the simulations in this cluster work only in the syntactical setting. This comes in contrast with what happens with the other two clusters: all simulations involving clause, monomial, variable and total space, also work in a purely semantic setting. For example, in case of monomial space we can allow arbitrary Boolean functions of monomials as memory configurations and allow any number of sound inferences to be performed at once in each step.

We use (some of) these simulations to prove:

1. *There are unsatisfiable CNFs F of size $O(n)$ with $S(F \vdash \bot) \leq O(n)$, $W(F \vdash \bot) \leq O(1)$ and* $\mathrm{MSpace}^*(F \vdash \bot) \geq \Omega(n/\log n)$ (Theorem 4.1).
   This is an improvement on the previously known bounds $\mathrm{MSpace}^*(F \vdash \bot) \geq \Omega(n^{2/11})$ [3], $\mathrm{MSpace}^*(F \vdash \bot) \geq \Omega(n^{1/4})$ [22] and $\mathrm{MSpace}^*(F \vdash \bot) \geq n^{1/2}/(\log n)^{O(1)}$ [21]. Unlike these previous results, our proof is remarkably simple.
2. *There are unsatisfiable CNFs F of size $O(n)$ with* $\mathrm{CSpace}(F \vdash \bot) = 4$ *and* $S_T(F \vdash \bot) \geq \Omega(n^2/\log n)$ (Theorem 4.7).
   This is a first, admittedly modest, step toward separating clause space and, say, tree-like size; as we already said, we will discuss this question in more details in Section 5. It is for this proof that we need the last unexplained entry D_P on Figure 1: it stands for *positive depth*, and it is a one-sided version of depth. We also remark that the space bound in this result is optimal. More precisely, we make a relatively simple observation (Theorem 4.2) that $\mathrm{CSpace}(F \vdash \bot) \leq 3$ if and only if F is "essentially Horn" in which case it will possess a linear size tree-like resolution refutation.

Finally, let us briefly summarize what is known (to the best of our knowledge) in terms of separating the measures in Figure 1. Let us start with "true" separations, i.e. separations that work modulo polynomial overheads and $\log n$ factors. From now on, for proof complexity measures μ_1, μ_2 we will use the notation $\mu_1 \preceq \mu_2$ to stand for $\mu_1(F \vdash \bot) \leq (\mu_2(F \vdash \bot) \log n)^{O(1)}$ for any CNF F in n variables; $\mu_1 \approx \mu_2$ is the same as $\mu_1 \preceq \mu_2 \wedge \mu_2 \preceq \mu_1$. Clearly $\preceq$ is transitive, and this implies that $\approx$ is an equivalence relation and $\preceq$ imposes a partial order on its equivalence classes.

Bonet and Galesi [10] proved that $W \not\preceq \log S_R$. More precisely, there are constant width formulas F of size $O(n^3)$ such that $S_R(F \vdash \bot) \leq O(n^3)$ and $W(F \vdash \bot) \geq \Omega(n)$. Ben-Sasson [4] proved that VSpace $\not\preceq$ CSpace, and after negating the variables in his formulas, this works two more levels up on Figure 1. Namely, there are constant-width formulas F of size $O(n)$ such that VSpace$(F \vdash \bot) \geq \Omega(n/\log n)$ while $D_P(F \vdash \bot) \leq O(1)$. This also provides a separation between D_P and D that, though, is much easier to prove directly [38, Theorem 4.6]. Without negating the variables, it is easy to see that Ben-Sasson's proof actually gives $D_P(F \vdash \bot) \geq \Omega(n/\log n)$, thus separating D_P from $\log S_T$ and hence from the whole middle cluster. Again, it is also easy to see this directly. Ben-Sasson, Håstad and Nordström [31, 6] separated clause space from width; while it is believed that their formulas should also have large monomial space complexity, the questions of separating clause space from monomial space, as well as monomial space from width are widely open.

Separating space complexity measures from their own regularized versions appear to be a very daunting task in general. As follows from Figure 1, for variable space this is equivalent to separating it from depth [38]. A quadratic separation between VSpace and VSpace* was proved in [37, Section 6], with a disappointingly elaborate proof. Nothing is known in terms of separating CSpace from (the cluster of) CSpace*: Theorem 4.7 makes a progress in that direction, but it is admittedly rather modest. Nothing seems to be known for CSpace vs. MSpace, and our structural picture provides a good heuristic explanation of the difficulty of this question: it would also separate MSpace from MSpace*. Finally, in [32] a quadratic separation between width and monomial space has been established using methods very different from those in [6].

The paper is organized as follows. After giving the necessary definitions in Section 2, in Section 3 we refine (many simulations do not actually involve a polynomial overhead or extra $\log n$ factors) and prove the relations of Figure 1. In Section 4 we prove items 1 and 2 above. The paper is concluded with a few remarks and open problems in Section 5.

2 Preliminaries

A *literal* is a propositional variable x or its negation $\overline{x}$. We let $\overline{\overline{x}} \stackrel{\text{def}}{=} x$. A *clause* is a disjunction (possibly empty) of literals over distinct variables, and a *term* is a conjunction (possibly empty) of such literals. For a clause $C = \ell_1 \vee \cdots \vee \ell_w$, we define the term $\overline{C} \stackrel{\text{def}}{=} \overline{\ell_1} \wedge \cdots \wedge \overline{\ell_w}$; similarly for a term $t = \ell_1 \wedge \cdots \wedge \ell_w$, $\overline{t} \stackrel{\text{def}}{=} \overline{\ell_1} \vee \cdots \vee \overline{\ell_w}$. The *width* of a clause or a term is the number of literals it contains. A *CNF formula* is a conjunction of clauses, and a *DNF formula* is a disjunction of terms. The *width*, $W(F)$, of a CNF or DNF formula F is the width of the largest clause or term it contains. A CNF or DNF formula of width at most w is called *w-CNF* or *w-DNF* respectively. Clauses may be alternatively viewed as 1-DNFs, but the latter class is slightly larger as tautological 1-DNFs like $x \vee \overline{x}$ *are* allowed.

A *partial (truth) assignment* (often called *restriction*) is a mapping from a subset V of all propositional variables to $\{0, 1\}$; it is naturally extended to the negations of the variables in V by $\alpha(\overline{x}) \stackrel{\text{def}}{=} \overline{\alpha(x)}$. The result of applying a partial assignment α to a CNF formula F is

another CNF formula $F|_\alpha$, obtained by deleting from F all literals ℓ such that $\alpha(\ell) = 0$ and deleting all clauses containing a literal ℓ such that $\alpha(\ell) = 1$. Similarly for DNF formulas. $F|_\alpha$ is called the *restriction* of F to α. For a formula F, we write $\alpha \models F$ if every total extension of α satisfies F or, in other words, if $F|_\alpha$ is *semantically* equal to 1. For a set of formulas S, $\alpha \models S$ means $\alpha \models \bigwedge_{F \in S} F$, and for two sets of formulas S and T, we write $S \models T$ if all total assignments satisfying every formula in S also satisfy every formula in T. For a clause C, we denote by α_C the minimal partial assignment such that $\alpha_C \models \overline{C}$.

Resolution is a proof system operating with clauses. Its inference rules are:

$$\frac{C}{C \vee D}, \quad \frac{C \vee x \qquad D \vee \overline{x}}{C \vee D}. \tag{7}$$

The leftmost one is called the *weakening rule*; the rightmost one is called the *resolution rule*. We refer to the variable x in an application of the resolution rule as the variable being *resolved*. One of the reasons to include the (redundant) weakening rule is that it makes resolution proofs closed under restricting by a partial assignment.

The *width* $W(\pi)$ of a resolution proof π is defined as the maximum width of a clause in it, and the width $W(F \vdash \bot)$ is usually defined as the minimum width $W(\pi)$ of a resolution refutation π of F. This definition, however, is ill-suited for those CNFs that themselves have large width, like the pigeonhole principle. We have found it way more natural and convenient to work with its slightly modified version used in [20] that we will denote by $W(\vdash_F \bot)$. It is defined as follows.

Instead of just allowing the clauses C of F as axioms, we allow them to participate in the form of the following more general *F-cut rule*:

$$\frac{D \vee \overline{\ell_1} \qquad \dots \qquad D \vee \overline{\ell_r}}{D}, \tag{8}$$

where $\ell_1 \vee \ldots \vee \ell_r$ is a clause of F. In case some $D \vee \overline{\ell_j}$ contains contradictory literals, it is removed from the premises. In particular, when $D = C$, the list of premises becomes empty so the clauses of F are still available as axioms.

It is easy to see that $W(\vdash_F \bot) \le W(F \vdash \bot) \le W(\vdash_F \bot) + W(F) - 1$, hence the difference between the standard definition and ours becomes immaterial when $W(F)$ is small, and it does not have any noticeable impact on the *size* of a refutation.

One immediate advantage of this definition is that if we replace $W(F \vdash \bot)$ with $W(\vdash_F \bot)$ in (1), (2), (4), (5) or (6), we need not keep the annoying terms $W(F)$ any more, they just disappear. Simulations on Figure 1 will work without any restrictions on the width of the refuted CNF. More advantages of a similar flavor will become clear later, see Theorems 3.4 and 4.2 in particular.

Let us also remark that resolution with the F-cut rule is nothing else but Gentzen's sequent calculus with only atomic cuts, restricted to proving sequents of the form $C_1, \ldots, C_m \to$, where $C_1, \ldots, C_m$ are clauses (see [32]).

DNF resolution, or depth 2 Frege, is the straightforward extension of resolution where we allow, apart from variables in the resolution rule, also formulas of depth 1[4] to be resolved. DNF resolution operates with DNF formulas. Its axioms and inference rules are:

$$\frac{}{x \vee \overline{x}}, \quad \frac{G}{G \vee H}, \quad \frac{G \vee t_1 \qquad H \vee t_2}{G \vee H \vee (t_1 \wedge t_2)}, \quad \frac{G \vee t \qquad H \vee \overline{t}}{G \vee H},$$

[4] For this reason, some authors use the term "depth 1 Frege" for DNF resolution; we prefer to stick to the convention under which depth refers to *lines* in a Hilbert-style proof.

where G and H are DNF formulas and t, t_1, t_2 and $t_1 \wedge t_2$ are terms. The leftmost rule is the weakening rule in this context, and the rightmost rule is called the *cut rule*. The remaining rule allows us to deal with $\wedge$ connectives, and is called $\wedge$*-introduction*.

For a non-decreasing function $f : \mathbb{N} \to \mathbb{N}$, $R(f)$ is the subsystem of DNF resolution where each DNF in a proof of size s is required to have width at most $f(s)$. $R(k)$ for k a constant is usually denoted by $\mathrm{Res}(k)$ (thus, resolution is $\mathrm{Res}(1)$). DNF resolution and $R(f)$ were first introduced in [25].

Next, we would like to consider systems for manipulating terms. The syntactic details of such systems will not matter for our results, but for concreteness, let us present a prominent system of algebraic flavor originally introduced in [12]. We will actually use an extension, proposed in [1], called *polynomial calculus with resolution* and abbreviated as *PCR*. PCR works with a fixed field $\mathbb{F}$. Clauses/terms are represented as *monomials*. The syntactic objects PCR operates with are *polynomials* in $\mathbb{F}[x_1, \ldots, x_n, \overline{x_1}, \ldots, \overline{x_n}]$, represented as linear combinations over $\mathbb{F}$ of monomials, and a proof line P is to be interpreted as asserting that $P = 0$. The axioms and inference rules of the system are:

$$\frac{}{\ell^2 - \ell}, \quad \frac{}{\ell + \overline{\ell} - 1}, \quad \frac{P \qquad Q}{\alpha P + \beta Q}, \quad \frac{P}{\ell P},$$

where $\ell \in \{x_1, \ldots, x_n, \overline{x_1}, \ldots, \overline{x_n}\}$, $P, Q \in \mathbb{F}[x_1, \ldots, x_n, \overline{x_1}, \ldots, \overline{x_n}]$ and $\alpha, \beta \in \mathbb{F}$.

In each of the above systems, non-logical axioms are given as a set of clauses S, viewed as a CNF formula F (in PCR, a clause $C = \ell_1 \vee \cdots \vee \ell_k \in S$ is represented as the monomial $\overline{\ell_1} \ldots \overline{\ell_k}$). A proof of the unsatisfiability of F, or a *refutation* of F, is a derivation of a syntactic contradiction, denoted by $\perp$, from the clauses of F. In resolution and DNF resolution $\perp$ is the empty clause; in PCR, it is the polynomial 1.

We can view proofs as DAGs, by drawing edges from premises to conclusions in applications of the inference rules. If a proof DAG is a tree, that is every formula or polynomial in it is used as a premise at most once, then we say that the proof is *tree-like*. The *size* of a tree-like proof is the number of its leaves, and its *depth* is the length of its longest root-to-leaf path. We will also consider a one-sided version of depth, which we call *positive depth*. (The analogue of this notion in the context of computational complexity was recently defined in [29].) The positive depth of a tree-like resolution proof is the maximum number of *negative* literals introduced along a root-to-leaf path. We denote tree-like size, depth and positive depth by S_T, D and D_P respectively.

To define space complexity measures, we need to consider a different topology, namely view a proof as a sequence of *memory configurations* [16, 1]. A memory configuration will be a set of clauses in resolution, a set of DNF formulas in DNF resolution, or a set of polynomials in PCR. In a proof from a CNF F then, to go from a memory configuration to the next we may do one of the following:

Axiom Download: add a clause of the formula F, or a logical axiom of the system we are working with;

Erasure: delete a clause/DNF formula/polynomial, or

Inference: add the result of applying an inference rule to formulas in the current configuration.

A proof in configurational form is said to be *tree-like* if, whenever a formula is used as a premise in an inference rule, it is immediately erased from the memory.

The *clause space* of a configuration in resolution is the number of clauses it contains, its *variable space* the number of *distinct* variables it contains, and its *total space* the total number of literals, counting repetitions, it contains. For DNF resolution, we will be interested in what we call Σ_2 *space* of a configuration. The Σ_2 space of a configuration $\mathcal{M} = \{G_1, \ldots, G_s\}$ is defined as the sum of widths: $\Sigma_2\mathrm{Space}(\mathcal{M}) \stackrel{\mathrm{def}}{=} W(G_1) + \ldots + W(G_s)$. For PCR, we will consider the *monomial space*, which is the number of *distinct* monomials in a configuration.

For a space measure μ on configurations and a proof $\pi = \mathcal{M}_1, \ldots, \mathcal{M}_t$, we naturally let $\mu(\pi) \stackrel{\text{def}}{=} \max\{\mu(\mathcal{M}_i) \mid 1 \leq i \leq t\}$. As in [37], we will also consider *regularized* versions μ^* defined as $\mu^*(\pi) \stackrel{\text{def}}{=} \mu(\pi) \cdot \log|\pi|$, where $|\pi| \stackrel{\text{def}}{=} t$ is the *length* of π. All logarithms in this paper have base 2.

Finally, for a complexity measure μ on proofs, we write $\mu(F \vdash G)$ for the minimum value of $\mu(\pi)$, taken over all proofs of G from F; if such a proof does not exist, we set $\mu(F \vdash G)$ to be ∞. In most cases, the measure μ clearly suggests what the underlying proof system should be. For example, $W(F \vdash \bot)$ is the minimum width of a resolution refutation of F, and $\text{MSpace}^*(F \vdash \bot)$ is the minimum regularized monomial space of a PCR refutation (in configurational form) of F. $S_T(F \vdash \bot)$ shall mean the minimum size of a tree-like resolution refutation of F. We shall use the notation $S_{T,R(f)}(F \vdash \bot)$ to mean the minimum size of a tree-like $R(f)$-refutation of F. $\text{TCSpace}(F \vdash \bot)$ is the minimum clause space taken over all tree-like configurational refutations of F in resolution. Likewise, $\text{RCSpace}(F \vdash \bot)$ stands for the clause space in *regular* resolution, i.e. the subsystem of resolution where we require that a variable cannot be resolved more than once on any path in (the DAG resulting from the expansion of) the configurational proof π.

3 Simulations

3.1 Tree-like resolution size and regularized monomial space

First we show that $\log S_T$ in resolution, TCSpace, RCSpace, CSpace^* and MSpace^*, are all equivalent. Our main new contribution is the following simulation.

▶ **Theorem 3.1.** *For any unsatisfiable CNF formula F over n variables,*

$$\log S_T(F \vdash \bot) \leq 2\text{MSpace}^*(F \vdash \bot)\log(n+1),$$
$$\text{TCSpace}(F \vdash \bot) \leq 2\left(\text{MSpace}^*(F \vdash \bot) + 1\right).$$

Proof. The proof is analogous to the construction in [37] showing that depth is upper bounded by regularized variable space. Let $\mathcal{M}_1, \ldots, \mathcal{M}_t$ be a refutation of F in configurational form, of monomial space s. We show, by induction on d, that for every interval $[i..j] \subseteq [1..t]$ with $j > i$, $j - i \leq 2^d$, and for every clause D such that $\alpha_D \models \mathcal{M}_i$ and $\alpha_D \models \neg\mathcal{M}_j$, it holds that $S_T(F \vdash D) \leq (n+1)^{ds}$ and, moreover, the assumed tree-like resolution proof can be carried out in clause space at most $ds + 2$. The theorem follows by taking $[i..j] \coloneqq [1..t]$, $d \coloneqq \lceil \log t \rceil$ and $D \coloneqq \bot$.

Suppose that $d = 0$, so that $j = i + 1$. The statement is vacuously true except when the step consists in downloading an axiom C from F, simply because in all other cases we have $\mathcal{M}_i \models \mathcal{M}_{i+1}$ and hence D with the specified properties does not even exist. Let D be a clause for which $\alpha_D \models \mathcal{M}_i$ and $\alpha_D \models \neg(\mathcal{M}_i \cup \{C\})$. Then we necessarily must have $\alpha_D \models \neg C$, which is equivalent to saying that D is a weakening of C.

For the inductive step, suppose that $d > 0$, let $[i..j] \subseteq [1..t]$ be any interval with $j - i \leq 2^d$, $j > i + 1$, and let D be a clause such that $\alpha_D \models \mathcal{M}_i$ and $\alpha_D \models \neg\mathcal{M}_j$. Set $k \coloneqq i + \lceil (j-i)/2 \rceil$, so that $k - i \leq 2^{d-1}$ and $j - k \leq 2^{d-1}$. Let the list $m_1, \ldots, m_s$ contain all monomials occurring in $\mathcal{M}_k$. For a clause A and a monomial $m = \ell_1 \ldots \ell_r$, consider the following derivation of A:

$$\dfrac{\dfrac{A \vee \ell_1 \qquad \dfrac{\dfrac{A \vee \ell_r \qquad A \vee \overline{\ell_1} \vee \ldots \vee \overline{\ell_r}}{A \vee \overline{\ell_1} \vee \ldots \vee \overline{\ell_{r-1}}}}{\vdots}}{A \vee \overline{\ell_1} \vee \overline{\ell_2}} \qquad \dfrac{A \vee \ell_2}{A \vee \overline{\ell_1}}}{A}$$

Call this derivation tree $\mathbf{T}_{A;m}$. For the required tree-like resolution proof of D, start with $\mathbf{T}_{D;m_1}$. To every leaf of $\mathbf{T}_{D;m_1}$ labelled by a clause D', append the tree $\mathbf{T}_{D';m_2}$. Continue this process for all $m_1, \ldots, m_s$. If at any point during this construction, a forbidden disjunction containing a variable and its negation occurs, then we delete that node and contract at its parent. The resulting tree $\mathbf{T}$ has at most $(n+1)^s$ leaves, and each of its leaves is labelled by a clause E such that $\alpha_E \models \mathcal{M}_k$ or $\alpha_E \models \neg\mathcal{M}_k$. From the induction hypothesis, there are tree-like resolution proofs of all those clauses from F, of size $(n+1)^{(d-1)s}$. Therefore, there is a tree-like resolution proof of D from F of size $(n+1)^{ds}$.

To see that this proof can be carried out in clause space at most $ds+2$, notice that the proof designated by $\mathbf{T}$ can be carried out in clause space $s+2$. Proceed with this proof, and whenever a clause at its leaves is downloaded, keep all current clauses in memory (there are at most s of them – the maximum clause space is hit when the parent of two leaves is brought to memory), and derive it in clause space at most $(d-1)s+2$. The fact that such a derivation exists is guaranteed by the induction hypothesis. The resulting proof has clause space at most $s+(d-1)s+2 = ds+2$. ◀

For the rest of the relations, we claim that for an unstatisfiable CNF F in n variables,

$$\begin{aligned}&\mathrm{RCSpace}(F \vdash \bot) \le \mathrm{TCSpace}(F \vdash \bot) \le \log S_T(F \vdash \bot) + 2\\ &\le 2\mathrm{MSpace}^*(F \vdash \bot)\log(n+1) + 2 \le 2\mathrm{CSpace}^*(F \vdash \bot)\log(n+1) + 2\\ &\le 2\mathrm{RCSpace}^*(F \vdash \bot)\log(n+1) + 2 \le 2\left(\mathrm{RCSpace}(F \vdash \bot)\right)^2 \log(n+1)\log(2n) + 2.\end{aligned}$$

The first inequality follows from the observation that every tree-like refutation can be pruned to the regular form, and this operation does not increase its space. The second inequality is [16, Theorem 2.1], and the third is Theorem 3.1. The fourth and the fifth inequalities are obvious. Finally, the last inequality follows from [16, Corollary 4.2].

As a byproduct, we get that TCSpace $\approx$ RCSpace. This comes in sharp contrast with the situation for size, where there is an exponential separation between tree-like and regular resolution [5].

We also see from [16, Corollary 4.2] that, somewhat surprisingly, instead of regularizing clause space by multiplying it by the logarithm of *size*, we could have as well used a much weaker regularization multiplying by the logarithm (!) of depth, and the resulting measure would still be in this cluster. This allows us to re-cast the main open problem of whether CSpace $\approx$ CSpace* in terms of the existence of a *super-critical* (in the sense of [36]) trade-off between clause space and depth.

The remaining (non-trivial) simulation on Figure 1 involving this cluster is:

▶ **Theorem 3.2.** *For any unsatisfiable CNF formula F,* $\mathrm{TCSpace}(F \vdash \bot) \le D_P(F \vdash \bot) + 2$.

Proof. The argument is a refinement of the argument in [16] showing that tree-like clause space is bounded by depth. We show, by induction on $\mathbf{T}$, that if $\mathbf{T}$ is a tree-like resolution proof of a clause E from F of positive depth d, then there is a tree-like resolution proof, in configurational form, of E from F of clause space at most $d+2$.

If $\mathbf{T}$ has size at most 2, then $d \leq 1$, and $\mathrm{TCSpace}(F \vdash \bot) \leq 3$. Otherwise, let $\mathbf{T}_1$ and $\mathbf{T}_2$ be the subproofs of $\mathbf{T}$ proving the two clauses E_1 and E_2 respectively from which E is derived via an application of the resolution rule and possibly applications of the weakening rule. One of $\mathbf{T}_1$ and $\mathbf{T}_2$, say $\mathbf{T}_1$, must have positive depth at most $d-1$. From the induction hypothesis, there is a tree-like proof π_1 of E_1 of clause space at most $d+1$, and a tree-like proof π_2 of E_2 of clause space at most $d+2$. Deriving first E_2 using π_2, and then, keeping E_2 in memory, deriving E_1 using π_1, we get a proof of E of clause space at most $d+2$. ◀

3.2 Resolution width and Σ_2 space

The simulations for our second cluster will depend upon the following "locality" property of DNF resolution.

▶ **Lemma 3.3.** *Let α be a partial assignment. For each of the inference rules of DNF resolution, if both premises contain a term satisfied by α, then α satisfies some term in the conclusion.*

The main theorem of this section says that as long as we transition from depth 1 Frege to depth 2 Frege, then not only width continues to be smaller than space, but in fact it becomes (almost) equal to it. As a historical remark, an extension of the Atserias-Dalmau bound (4) for the case of $\mathrm{Res}(k)$ is sketched in [18], and, although it is not stated explicitly, it is also apparent in [15].

▶ **Theorem 3.4.** *For any unsatisfiable CNF formula F,*

$$\frac{1}{5}\Sigma_2\mathrm{Space}(F \vdash \bot) \leq W(\vdash_F \bot) \leq \Sigma_2\mathrm{Space}(F \vdash \bot).$$

Proof. Let $\mathcal{M}_1, \ldots, \mathcal{M}_t$ be a DNF resolution refutation of F, of Σ_2 space s. We will construct a sequence $\mathbf{T}_1, \ldots, \mathbf{T}_t$ of derivations in the system "resolution plus the F-cut rule (8)". The property we are going to maintain is that for every clause D labelling a leaf of $\mathbf{T}_i$, either D is a weakening of a clause C in F (call such a leaf an *axiom leaf*) or the following hold:

1. for every $G \in \mathcal{M}_i$, α_D satisfies some term of G;
2. $W(D) \leq \Sigma_2\mathrm{Space}(\mathcal{M}_i)$.

$\mathbf{T}_1$ has one vertex labelled by the empty clause. Now suppose we have constructed $\mathbf{T}_{i-1}$ such that 1 and 2 hold for all non-axiom leaves. For every such leaf v labelled by a clause D, do the following.

- *Axiom Download*: Suppose that $\mathcal{M}_i = \mathcal{M}_{i-1} \cup \{C\}$, where $C = \ell_1 \vee \cdots \vee \ell_r$ is either a clause of F (viewed as a 1-DNF) or a logical axiom $x \vee \overline{x}$. If C and D contain conflicting literals, then item 1 is automatically satisfied and we do nothing at this leaf. Next, $C \subseteq D$ would have implied that C is a clause of F which is impossible since we have assumed that the leaf is non-axiom. Thus, there exists at least one $j \in [r]$ such that $\ell_j \notin D$, and for any such j we add to v a child labelled by $D \vee \overline{\ell_j}$. This will be an application of the F-cut rule if C is a clause or of the resolution rule if C is $x \vee \overline{x}$.
- *Erasure*: Suppose that $\mathcal{M}_i \subseteq \mathcal{M}_{i-1}$. Add to v a single child labelled by a clause $E \subseteq D$ such that $W(E) \leq \Sigma_2\mathrm{Space}(\mathcal{M}_i)$ and for every $G \in \mathcal{M}_i$, α_E satisfies some term of G.
- The case of an *inference* is immediately taken care of by Lemma 3.3, D does not change.

Since $\bot \in \mathcal{M}_t$, $\mathbf{T}_t$ may not contain any non-axiom leaves and hence defines a refutation. Also, it is clear from the construction and property 2 above that any clause D appearing in it must satisfy $W(D) \leq \max_{1 \leq i \leq t} \Sigma_2\mathrm{Space}(\mathcal{M}_i) = s$. Hence $W(\vdash_F \bot) \leq s$.

For the converse inequality, suppose that $C_1, \ldots, C_t$ is a refutation in the system "resolution plus the F-cut rule", of width w. For every $i \in [t]$, set $G_i := \bigvee_{j=1}^{i} \overline{C_j}$. Each G_i is a w-DNF. For our small space refutation, we will first derive G_t and $G_{t-1} \vee C_t$, then cutting on C_t derive from these formulas G_{t-1}, then derive $G_{t-2} \vee C_{t-1}$, and continue this way until we get the empty clause. Notice that $G_{i-1} \vee C_i$ is either a tautology with an obvious derivation in DNF resolution, or C_i is a clause of F. In the latter case, we can immediately derive $G_{i-1} \vee C_i$. Otherwise, C_i will be the result of applying either the resolution rule or the weakening rule or F-cut rule to some clauses among $C_1, \ldots, C_{i-1}$. In either case, it can be checked that $G_{i-1} \vee C_i$ has a tree-like proof of Σ_2 space at most $3w$, and therefore the proof above can be carried in Σ_2 space at most $5w$. ◀

▶ Remark 3.5. The second part of this proof implies that *a posteriori*, DNF resolution will retain its power in terms of space even if we restrict the *formula space* (the maximum number of DNFs in a configuration) to a constant. This in turn immediately implies, also a posteriori, that we can balance our definition of Σ_2 space replacing in it $W(G_1) + \ldots + W(G_s)$ with $s \cdot \max(W(G_1), \ldots, W(G_s))$, and the resulting measure will still be equivalent to Σ_2 space. We are not aware of a direct proof of this simulation by-passing width.

We get from Theorem 3.4 that strong length-space trade-offs conjectured for variable, clause and monomial space, are ruled out for DNF resolution. In particular, we get:

▶ **Corollary 3.6.** *For any unsatisfiable CNF formula F with n variables,*

$$\Sigma_2\mathrm{Space}^*(F \vdash \bot) \leq O\left((\Sigma_2\mathrm{Space}(F \vdash \bot))^2 \log n\right).$$

Proof. Let $s := \Sigma_2\mathrm{Space}(F \vdash \bot)$. By the first part of Theorem 3.4, F has a width $O(s)$ resolution refutation with the additional F-cut rule. We apply to this refutation the construction from the second part of Theorem 3.4 in which we can clearly assume $t \leq n^{O(s)}$ (since all clauses in the sequence can be assumed to be different). By an easy inspection, the length of the resulting refutation will still be $n^{O(s)}$. Therefore,

$$\Sigma_2\mathrm{Space}^*(F \vdash \bot) \leq O(s^2 \log n).$$ ◀

▶ **Corollary 3.7.** *If F has a constant Σ_2 space refutation, then it has a refutation of constant Σ_2 space and polynomial length.*

Proof. The refutation constructed in the proof of Corollary 3.6 will in our case also have constant Σ_2 space. ◀

Let us finally deal with the remaining measure, tree-like proofs in $R(\log)$.

▶ **Theorem 3.8.** *Let F be an unsatisfiable CNF formula over n variables. Then*

$$\Sigma_2\mathrm{Space}(F \vdash \bot)^{1/2} \leq \log S_{T,R(\log)}(F \vdash \bot) \leq O(W(\vdash_F \bot) \log n).$$

Proof. For the upper bound, let π be a resolution refutation of F of width $w := W(\vdash_F \bot)$. Apply to it the construction in the second part of the proof of Theorem 3.4 once again. By inspection (cf. the proof of Corollary 3.6), this refutation is tree-like, has size $n^{O(w)}$ and every term occurring in it has width at most w. Padding it with dummy formulas if necessary, we can assume that it has size $\geq 2^w$ which makes it into a tree-like $R(\log)$ refutation of the required size.

For the lower bound, the argument is an adaptation of the argument in [16] showing (3). Namely, by pebbling, a tree-like proof $\mathbf{T}$ of size $s > 1$ can be turned into a proof in configurational form, where each configuration contains at most $\log s$ formulas occurring in $\mathbf{T}$. If $\mathbf{T}$ is a refutation in $R(\log)$, then all terms occuring in $\mathbf{T}$ have width at most $\log s$, so the resulting refutation has Σ_2 space $(\log s)^2$. ◀

▶ Remark 3.9. For the more conventional system Res($\log n$), the subsystem of DNF resolution where each DNF in a refutation of F is required to have width $O(\log n)$, n the number of variables of F, the second inequality in Theorem 3.8 is false (see Figure 2). This follows from an easy adaptation of the proof of [15, Corollary 14].

4 Size-space trade-offs and tree-like size lower bounds

4.1 A lower bound on regularized monomial space

One application of the results of the previous section is that they easily allow us to show trade-offs[5] between regularized clause or monomial space and size.

It is known [22, 21] that there are formulas F of size $\Theta(n)$ that have a resolution refutation of size $O(n)$ (and thus a $O(n)$ refutation in the stronger system PCR), but $\mathrm{MSpace}^*(F \vdash \bot) \geq n^{1/2}/(\log n)^{O(1)}$. Theorem 3.1, combined with the lower bounds of [5] and [17] on $\log S_T$ and TCSpace immediately gives the following improvement.

▶ **Theorem 4.1.** *For every $n \geq 0$, there is a formula F of size $\Theta(n)$ that has a resolution refutation of size $O(n)$, width $O(1)$, and such that* $\mathrm{MSpace}^*(F \vdash \bot) \geq \Omega\left(n/\log n\right)$.

Proof. [5] demonstrates the existence of an $O(1)$-CNF F that has resolution refutations of size $O(n)$, width $O(1)$, and such that $\log S_T(F \vdash \bot) \geq \Omega(n/\log n)$. In fact, [5] shows that $\Omega(n/\log n)$ is also the lower bound on the number of points the Delayer can score in the Prover-Delayer game of [35] played on F. Now, it is proved in [17] that this number of points is precisely equal to $\mathrm{TCSpace}(F \vdash \bot)$ and then the result immediately follows from the second inequality in Theorem 3.1. ◀

4.2 Trade-offs between positive depth and tree-like size for Horn formulas and tree-like size lower bounds

We would like next to focus on tree-like size lower bounds for resolution attained for formulas with small clause space. We will show that a tree-like resolution refutation of a Horn formula actually describes a pebbling strategy, the space and time of the strategy being the positive depth and size respectively of the proof. This gives a more transparent version of the result of [5] used in the proof of Theorem 4.1, which moreover has a natural generalization allowing us to prove some tree-like lower bounds for formulas of small clause space.

[5] We would like to stress that, following the (perhaps, unfortunate) convention established in the previous papers, we mean *potential* trade-offs. In other words, we prove lower bounds on the regularized space and we only know that *our method fails* to extend them to the ordinary monomial space. As we explained in Section 1 and will further elaborate in Section 5, proving *actual* trade-offs in this setting is a major and difficult open problem.

4.2.1 Horn formulas – basics

Horn formulas, that include pebbling formulas, have seen a plethora of applications in proof complexity over the past two decades, including separating resolution size from tree-like resolution size [5], separating width from variable space and clause space [4, 6, 7], separating depth from tree-like clause space [38], and giving trade-offs [4, 7, 22, 3], to name a few.

A CNF formula is called *Horn* if every clause in it has at most one non-negated variable. Equivalently, a Horn formula is a set of implications involving variables, with at most one variable at the right hand side of the implication. An implication of the form $x_1, \dots, x_k \to y$ is asserting that if all the x_i's are true, then y is true; $x_1, \dots, x_k \to$ is asserting that one of the x_i's is false, $\to y$ is asserting that y is true, and $\to$ is a contradiction.

The following result states that Horn formulas make up, in a certain sense, the easiest class of formulas for proof complexity. For its purposes, it is convenient to define a slightly modified version $\mathrm{CSpace}(\vdash_F \bot)$ of the clause space, in the same vein we defined $W(\vdash_F \bot)$ above. Namely, we replace the three standard rules with the following

Three-in-one rule: from a configuration $\mathcal{M}$, infer any configuration $\mathcal{M}^* \subseteq \mathcal{M} \cup F \cup \{C\}$, where C is obtained from clauses in $\mathcal{M}, F$ via the resolution or weakening rule.

▶ **Theorem 4.2.** *Let F be a CNF formula. The following are equivalent:*

1. *F contains an unsatisfiable CNF sub-formula resulting from a Horn formula by negating some of its variables;*
2. $\mathrm{CSpace}(F \vdash \bot) \le 3$*;*
3. $\mathrm{CSpace}(\vdash_F \bot) \le 1$*;*
4. $W(\vdash_F \bot) \le 1$.

Proof. For $1 \implies 2$, we can w.l.o.g. assume that F itself is an unsatisfiable Horn formula. We show, by induction on the number of variables n, that it can be refuted in clause space 3. The base case is trivial. Now, suppose that $n > 0$, and let y be a variable such that F contains the clause $\to y$. Such a clause must exist, for if every clause contained a negated variable, then we could satisfy F by setting every variable to false. Setting $y := 1$, we get an unsatisfiable Horn formula $F|_{y:=1}$ with $n-1$ variables. From the induction hypothesis, there is a clause space 3 refutation of $F|_{y=1}$. Weakening every clause in it by $\overline{y}$ gives us a space 3 proof of $\overline{y}$ from F. Now we only have to download y and infer $\bot$.

For $2 \implies 3$, let $\mathcal{M}_1, \dots, \mathcal{M}_t$ be a space 3 refutation of the formula F; we can assume w.l.o.g. that it does not contain weakening rules. Consider a path in the corresponding refutation tree of *maximum* possible length, say $C_i \in \mathcal{M}_{t_i}$ $(0 \le i \le h)$ are such that $t_0 < \dots < t_h = t$, C_0 is an axiom, $C_h = \bot$ and for $i \ge 1$, C_i is obtained by resolving C_{i-1} with some $D_{i-1} \in \mathcal{M}_{t_i-1}$. It remains to show that D_{i-1} is actually an axiom for any $i \ge 1$. For $i = 1$ this follows from the maximality of the chosen path. For $i \ge 2$, we have $\mathcal{M}_{t_{i-1}} = \{C_{i-2}, D_{i-2}, C_{i-1}\}$. Therefore C_{i-1} is consistent (and hence not resolvable) with the two other clauses in $\mathcal{M}_{t_{i-1}}$. All clauses that may have been inferred in $\mathcal{M}_{t_{i-1}+1}, \dots, \mathcal{M}_{t_i}$ must have C_{i-1} as one of their premises and, as a consequence, are also not resolvable with C_{i-1}. Hence the only clauses in those configurations that may be resolvable with C_{i-1} (in particular, D_{i-2}) are the axioms.

The implication $3 \implies 4$ is proven by an argument similar to the first part of the proof of Theorem 3.4. Namely, a space 1 refutation of minimum length in the three-in-one model must necessarily be a sequence $\{C_1\}, \dots, \{C_t\}$, where C_{i+1} is obtained by resolving C_i with a clause in F. The non-axiom leaves of the tree $\mathbf{T}_i$ will simply be all those literals among $\overline{\ell_{i,1}}, \dots, \overline{\ell_{i,r_i}}$, where $C_i = \ell_{i,1} \vee \dots \vee \ell_{i,r_i}$, that are not axioms of F. It can routinely be

checked that, as in the proof of Theorem 3.4, $\mathbf{T}_i$ will be a resolution derivation using only the F-cut rule (notice that to keep the width 1, the weakening rule has to be incorporated into the F-cut rule).

Finally, for $4 \implies 1$, we again proceed by induction on the number of variables n of F. The base case is trivial. Suppose that $n > 0$. The fact that there is a width 1 refutation of F, forces F to have a one literal clause (since the refutation must start somewhere), say ℓ. Setting $\ell := 1$, we get a width 1 refutation of $F|_{\ell:=1}$. From the induction hypothesis, a sub-formula G of $F|_{\ell:=1}$ is unsatisfiable Horn up to negating some variables. Let $\widehat{G}$ be the corresponding sub-formula of F; $\widehat{G}$ is obtained from G by restoring $\overline{\ell}$ to some of its clauses. Then $\widehat{G} \wedge \ell$ is an unsatisfiable Horn sub-formula of F. ◀

4.2.2 Tree-like resolution proofs as pebbling strategies

The paper [4] shows that a configurational resolution refutation π of the so-called *pebbling contradiction* Peb_G on a graph G defines a pebbling strategy on G, of time at most $|\pi|$ and space equal to the variable space $\mathrm{VSpace}(\pi)$. These are strategies in the so-called black-white game of [14]. We shall show that a tree-like resolution proof $\mathbf{T}$ of any Horn formula H defines a pebbling strategy of time equal to the size of $\mathbf{T}$ and space essentially equal to the *positive* depth of $\mathbf{T}$. These are strategies in the more basic black-only pebbling game that in the case $H = \mathrm{Peb}_G$ corresponds to the black-only pebbling game on G. Urquhart [38] showed how to relate them to ordinary depth. In a sense, our Proposition 4.3 below can be viewed as a (far-reaching) refinement of his result.

The rules of the black-only pebbling game, played on a Horn formula H, are as follows. There is a limited amount of pebbles. Pebbles are placed on the variables of H according to the rules:

1. A pebble can be placed on a variable y if $x_1, \ldots, x_k \to y$ is a clause of H, and all $x_1, \ldots, x_k$ have pebbles on them. In particular, a pebble can be always placed on any variable y such that $\to y$ is a clause of H.
2. A pebble can be removed from a variable at any time.

A *configuration* of the pebbling game is a set of the variables of H. A *pebbling strategy* is a sequence of configurations, each resulting from the previous one by one of the rules above. We say that a pebbling strategy *refutes* H if it ends with a configuration where for some clause $x_1, \ldots, x_k \to$ of H, all variables $x_1, \ldots, x_k$ are pebbled. Note that if H is unsatisfiable, then such a clause must exist.

▶ **Proposition 4.3.** *Let H be an unsatisfiable Horn formula. A tree-like resolution refutation $\mathbf{T}$ of H of size s and positive depth d can be converted into a pebbling strategy that, starting with the empty configuration, refutes H in at most s steps and using at most $d + 1$ pebbles.*

Proof. We begin with a slight modification of our refutation. Namely, viewing $\mathbf{T}$ as a decision tree, its nodes naturally correspond to partial assignments, and for the clause C sitting at the node α, we have $\alpha \models \neg C$. Let us replace C with the *maximal* clause satisfying this property. This will give us a refutation, of the same size and positive depth, in which the resolution rule (7) is reduced to

$$\frac{C \vee x \qquad C \vee \overline{x}}{C} \tag{9}$$

and leaves are labelled by weakenings of axioms in H.

This refutation need not necessarily consist of Horn formulas even if the original one did so. Nonetheless we will still represent clauses in the sequential form $S \to T$, where S, T are disjoint sets of variables, like at the beginning of Section 4.2.1. Note that $|S| \leq d$ for any clause $S \to T$ appearing in $\mathbf{T}$.

We shall now show by induction that every subtree of $\mathbf{T}$ deriving a clause $S \to T$, leads to a pebbling strategy that, starting with pebbles on all variables of S and using at most $d+1$ pebbles, either refutes H, or ends with a configuration which has pebbles on all variables of S and on one variable of T. Thus, if T is empty then the former must occur and, in particular, the strategy corresponding to the empty sequent $\to$ will start with no pebbles on the variables of H and will refute H.

Suppose that $S \to T$ is at a leaf. If there are variables $x_1, \ldots, x_k$ in S such that $x_1, \ldots, x_k \to$ is a clause of H, then that leaf describes a strategy that, starting with pebbles on all variables in S, immediately refutes H. Otherwise, there must be variables $x_1, \ldots, x_k$ in S and a variable y in T such that $x_1, \ldots, x_k \to y$ is a clause of H. Then the strategy of that leaf is to put a pebble on y. Since $|S| \leq d$, the number of pebbles used is at most $d+1$, as required.

If $S \to T$ is not at a leaf, then consider its left and right subtrees $\mathbf{T}_1$ and $\mathbf{T}_2$ proving $S, x \to T$ and $S \to T, x$ respectively (cf. (9)). The strategy corresponding to $S \to T$ is defined as follows. First follow $\mathbf{T}_2$'s strategy. If that strategy either refutes H or places a pebble on one of T's variables, then we are done. Otherwise, when the strategy of $\mathbf{T}_2$ is concluded, there are pebbles on S and x. Remove all other pebbles and follow the strategy of $\mathbf{T}_1$. The bound $d+1$ on the number of pebbles used at any moment follows from the same bound for $\mathbf{T}_1$ and $\mathbf{T}_2$.

Clearly, the number of steps of the pebbling strategy corresponding to $\to$ is at most the size of $\mathbf{T}$, and the required bound on the number of pebbles was already noticed. ◀

▶ Remark 4.4. The proof of Proposition 4.3 relies on an intuitionistic interpretation of the resolution rule. In the intuitionistic tradition, the denotational view of assigning truth values is, philosophically, nonsense. A proposition is "true" if it is provable, and a proof of e.g. a formula $S \to T$ is a construction that given proofs of all the elements of S produces a proof of some element in T. What Proposition 4.3 says is that a tree-like resolution derivation of $S \to T$ precisely describes such a construction, assuming that proofs of all the clauses of H are known. Moreover this construction will be economical in the number of steps and memory if the size and the positive depth respectively of the proof are small. Let us further notice, that although Proposition 4.3 is stated for Horn formulas, it really is general; it could be stated, with minimal modifications, for arbitrary CNFs.

4.2.3 Tree-like size lower bounds

The following theorem turns pebbling time-space trade-offs for a Horn formula H into tree-like size lower bounds for its substituted version $H[\vee_2]$. We formulate it in a somewhat general form, to account for various kinds of pebbling trade-offs in the literature. The substituted version $F[\vee_2]$ of a CNF $F(x_1, \ldots, x_n)$ is defined by replacing x_i with $y_i \vee z_i$ for mutually distinct variables $\{y_1, z_1, \ldots, y_n, z_n\}$, followed by converting the result back to the CNF form in the straightforward way.

▶ **Theorem 4.5.** *Let H be an unsatisfiable Horn formula on n variables. Suppose that every pebbling strategy that refutes H in s steps and using d pebbles, starting with no pebbles on its variables, satisfies $(d-1) \cdot f(s) \geq g(n)$ for non-decreasing positive functions f, g. Then $f(t) \log t \geq g(n)$, where $t \stackrel{\text{def}}{=} S_T(H[\vee_2] \vdash 0)$.*

Proof. Create a probability space of partial assignments by choosing independently for every variable x of H, which was substituted by $y \vee z$, one of y and z with probability $1/2$ and setting it to zero. Note that for any α from this space, $H[\vee_2]|_\alpha$ is identical to H up to

renaming its variables and hence $\mathbf{T}|_\alpha$ is a refutation of H, again up to renaming variables. Let $\mathbf{T}$ be an arbitrary tree-like resolution refutation of $H[\vee_2]$ of size t represented as in the proof of Proposition 4.3. That is weakenings are omitted from the resolution rule, and appear at the leaves only. Let $D_1, \ldots, D_k$ be all clauses of positive depth $g(n)/f(t)$ occurring in $\mathbf{T}$. We have that

$$P\left[\bigvee_{i=1}^{k}(D_i|_\alpha \neq 1)\right] \leq \sum_{i=1}^{k} P[D_i|_\alpha \neq 1] \leq k2^{-g(n)/f(t)} \leq t2^{-g(n)/f(t)}.$$

If $f(t)\log t < g(n)$, then the above probability is smaller than 1, which means that there is a point α in our sample space such that $\mathbf{T}|_\alpha$ is a tree-like resolution refutation of size at most t and positive depth $\leq g(n)/f(t)$. This, from Proposition 4.3, gives a pebbling strategy that refutes H in t steps using d pebbles, where $(d-1)\cdot f(t) < g(n)$. ◀

Recall that for a DAG G, the pebbling contradiction Peb_G is defined as the Horn formula consisting of all clauses $S \to x$, where $x \in V(G)$ and S is the set of all its immediate predecessors, as well as the clauses $x \to$ for any sink x. Plugging into Theorem 4.5 various DAGs from the literature with known bounds on their pebbling complexity and various functions f, we can get several corollaries. The first is a simplified proof of the separation by Ben-Sasson et al.

▶ **Corollary 4.6** [5]. *There are formulas of size $O(n)$ having DAG-like resolution refutations of size $O(n)$, every tree-like resolution refutation of which requires size* $\exp(\Omega(n/\log n))$.

Proof. This is by setting $f := 1$ in Theorem 4.5, and using the graphs of [34] having constant in-degree and requiring $\Omega(n/\log n)$ pebbles to pebble. ◀

The next result was promised in the introduction. It should be compared with Theorem 4.2.

▶ **Theorem 4.7.** *There are formulas of size $O(n)$ having tree-like resolution refutations of clause space 4, every tree-like resolution refutation of which has size $\Omega(n^2/\log n)$.*

Proof sketch. This is by setting $f(t) := t$ in Theorem 4.5, and using the graphs of [28, Theorem 2.3.2] having linear size and exhibiting a $dt \geq \Omega(n^2)$ trade-off. These graphs can be pebbled using 3 pebbles, and that immediately gives that $\mathrm{CSpace}(\mathrm{Peb}_{G_n}[\vee_2] \vdash \bot) \leq O(1)$. By being more careful, it is possible to bring the space down to the minimum possible value, namely 4, for which a super-linear lower bound on tree-like resolution size is possible. ◀

By using the construction from [28, Theorem 4.2.6], Theorem 4.7 can be further generalized to a lower bound $(n/\log n)^{\Omega(k)}$ on the tree-like resolution size of refuting formulas with clause space k. Let us further notice that the fact that the space 4 refutation in Theorem 4.7 is tree-like might be interesting, as typically tree-like resolution size lower bounds have been proven in the literature based on the prover-delayer game of [35], which also gives a lower bound for the clause space of tree-like resolution refutations (cf. Theorem 4.1).

5 Concluding remarks

We showed that $\log S_T$, CSpace^* and MSpace^* are equivalent up to polynomial and $\log n$ factors, demonstrating a picture perfectly analogous to the picture involving D, VSpace^* and TSpace^* in [37]. The most important question remains (widely) open:

▶ Problem 5.1. Is it true that $\mathrm{CSpace} \approx \log S_T$ or $\mathrm{MSpace} \approx \log S_T$? Recall for comparison that $\log S_T \approx \mathrm{CSpace}^* \approx \mathrm{MSpace}^*$.

Equivalently, do there exist strong trade-offs between clause (or monomial) space and length? It should be contrasted with trade-offs results in e.g. [7, 3], and it is a perfect analogue of Urquhart's question [38] about variable space vs. depth studied in [37, Section 6]. Let us make a few more remarks about this problem.

Firstly, for very small space essentially this question was already asked in the literature before. Namely (see e.g. [30, Open Problem 16]), are there formulas having constant clause space refutations and with the property that any such refutation must necessarily have super-polynomial length? Suitably adjusting it to our framework:

▶ Problem 5.2 (small space variant). Are there formulas that have $(\log n)^{O(1)}$ clause or monomial space refutations and with the property that any such refutation must be of super-quasi-polynomial length $\exp((\log n)^{\omega(1)})$? Equivalently, any tree-like resolution refutation must have super-quasi-polynomial length.

In terms of the perceived difficulty, we do not discern too much of a difference between Problems 5.1, 5.2 and Nordström's question. In fact, we would like to cautiously conjecture that there are formulas F with $\mathrm{CSpace}(F \vdash \bot) \leq 5$ and $\mathrm{CSpace}^*(F \vdash \bot) \geq \exp\left(n^{\Omega(1)}\right)$. But the only result we were able to prove in that direction is the rather weak Theorem 4.7.

Secondly, as suggested by Figure 1, any strong separation between monomial space and clause space would immediately solve Problem 5.1 for monomial space. As we consider the latter to be most likely very difficult, we take it as a good heuristic explanation of why we have not seen any progress on the former problem as well. But let us ask this, and one obviously relevant question, explicitly anyway:

▶ Problem 5.3. Is it true that $\mathrm{CSpace} \approx \mathrm{MSpace}$? Is it true that $\mathrm{MSpace} \approx W$?

We note that by the result from [31, 6], at least one of these must be false. A quadratic separation between width and monomial space has been recently proved by the first author (manuscript in preparation). For a discussion on related topics, see also [11, Section 7.5.5].

Finally, while all these conjectured trade-offs are very strong, they are still not super-critical in the sense of [36] (the required lower bound on length never exceeds 2^n). However, as we pointed out in Section 3.1 in all these questions refutation length can be replaced with depth. Since the depth, as a stand-alone measure, is always bounded by n, these actually *are* questions about the existence of a *super-critical* trade-off between clause space and *depth*.

We have (somewhat surprisingly) proved that DNF resolution behaves very differently from resolution with respect to space. Intermediate systems based on $\mathrm{Res}(k)$ for a constant k were studied in a similar context before, and it is very natural to wonder what is the situation for those systems.

Let us first remark that for $\mathrm{Res}(k)$-refutations, the definition of space from [15, 7] (formula space) coincides with ours up to a factor of k so we need not distinguish between the two. Then Theorem 3.1 readily generalizes to this regime and gives $\log S_{T,\mathrm{Res}(k)} \approx \mathrm{Res}(k)\mathrm{Space}^*$, extending the bottom half of Figure 1 as shown in Figure 2. The proof of Corollary 3.6, however, fails for a constant k as badly as it fails for $k = 1$. Hence we have one more question to ask:

▶ Problem 5.4 (Res(k)-variant). Is there a constant $k > 0$ such that $\log S_{T,\mathrm{Res}(k)} \approx \mathrm{Res}(k)\mathrm{Space}$ or at least $\log S_{T,\mathrm{Res}(k)} \preceq \mathrm{CSpace}$?

Let us also mention that as k increases, both hierarchies, $\log S_{T,\mathrm{Res}(k)}$ (and, hence, also $\mathrm{Res}(k)\mathrm{Space}^*$) and $\mathrm{Res}(k)\mathrm{Space}$ are proper ([15] and [7] respectively). This excludes the dual version of Remark 3.5: while the formula space of DNF resolution refutations can be reduced to constant, this is not true for the widths of individual formulas in the memory.

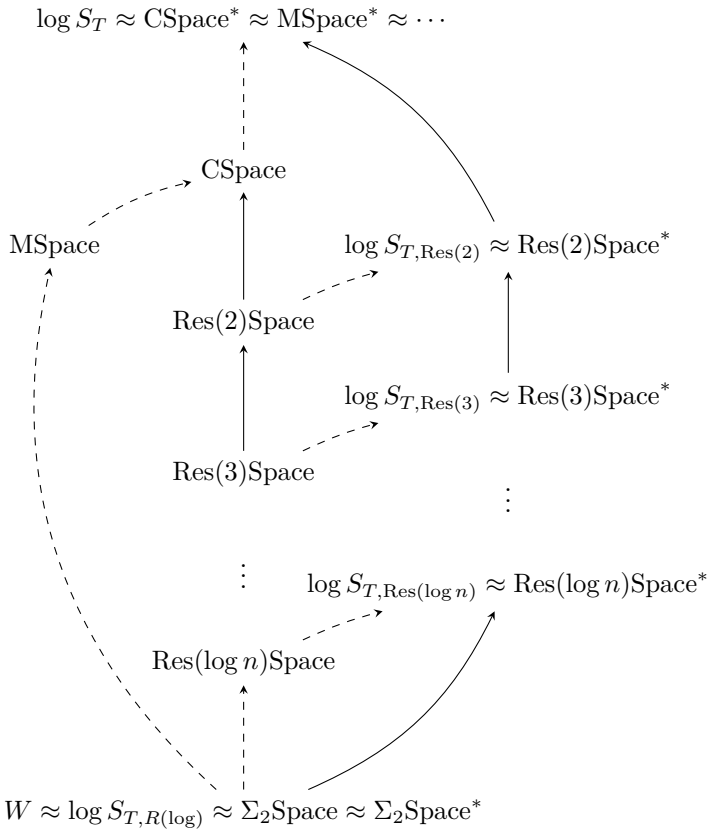

Figure 2 Σ_2 space and tree-like size for subsystems of DNF resolution.

The relation between VSpace and CSpace is also unknown in one direction (the opposite one is taken care of by [4]). Let us re-iterate the problem posed e.g. in [37]:

▶ Problem 5.5. Is it true that CSpace $\preceq$ VSpace?

Just as with the questions of similar nature discussed above, a negative answer would also imply a separation between VSpace and VSpace*, hence we can expect it to be very difficult.

Learning Algorithms Versus Automatability of Frege Systems

Ján Pich
University of Oxford, UK

Rahul Santhanam
University of Oxford, UK

Abstract

We connect learning algorithms and algorithms automating proof search in propositional proof systems: for every sufficiently strong, well-behaved propositional proof system P, we prove that the following statements are equivalent,

- **Provable learning.** P proves efficiently that p-size circuits are learnable by subexponential-size circuits over the uniform distribution with membership queries.
- **Provable automatability.** P proves efficiently that P is automatable by non-uniform circuits on propositional formulas expressing p-size circuit lower bounds.

Here, P is sufficiently strong and well-behaved if I.-III. holds: I. P p-simulates Jeřábek's system WF (which strengthens the Extended Frege system EF by a surjective weak pigeonhole principle); II. P satisfies some basic properties of standard proof systems which p-simulate WF; III. P proves efficiently for some Boolean function h that h is hard on average for circuits of subexponential size. For example, if III. holds for $P = \mathsf{WF}$, then Items 1 and 2 are equivalent for $P = \mathsf{WF}$. The notion of automatability in Item 2 is slightly modified so that the automating algorithm outputs a proof of a given formula (expressing a p-size circuit lower bound) in p-time in the length of the shortest proof of a closely related but different formula (expressing an average-case subexponential-size circuit lower bound).

If there is a function $h \in \mathsf{NE} \cap \mathsf{coNE}$ which is hard on average for circuits of size $2^{n/4}$, for each sufficiently big n, then there is an explicit propositional proof system P satisfying properties I.-III., i.e. the equivalence of Items 1 and 2 holds for P.

1 Introduction

Learning algorithms and automatability algorithms searching for proofs in propositional proof systems are central concepts in complexity theory, but a priori they appear rather unrelated.

Learning algorithms. In the PAC model of learning introduced by Valiant [34], a circuit class $\mathcal{C}$ is learnable by a randomized algorithm L over the uniform distribution, up to error ϵ, with confidence δ and membership queries, if for every Boolean function f computable by a circuit from $\mathcal{C}$, when given oracle access to f, L outputs with probability $\geq \delta$ over the uniform distribution a circuit computing f on $\geq (1-\epsilon)$ inputs. An important task of learning theory is to find out if standard circuit classes such as $\mathsf{P/poly}$ are learnable by efficient circuits. A way to approach the question is to connect the existence of efficient learning algorithms to other standard conjectures in complexity theory. For example, we can try to prove that efficient learning of $\mathsf{P/poly}$ is equivalent to $\mathsf{P} = \mathsf{NP}$ or to the non-existence of strong pseudorandom generators. In both cases one implication is known: $\mathsf{P} = \mathsf{NP}$ implies efficient learning of $\mathsf{P/poly}$ (with small error and high confidence) which in turn breaks pseudorandom generators. However, while some progress on the opposite implications has been made, they remain open, cf. [2, 33].

Automatability. The notion of automatability was introduced in the work of Bonet, Pitassi and Raz [6]. A propositional proof system P is automatable if there is an algorithm A such that for every tautology ϕ, A finds a P-proof of ϕ in p-time in the size of the shortest P-proof of ϕ. That is, even if P does not prove all tautologies efficiently, it can still be automatable. Establishing (non-)automatability results for concrete proof systems is one of the main tasks of proof complexity. This led to many attempts to link the notion of automatability to other standard complexity-theoretic conjectures. For example, recently Atserias and Müller [3] proved that automating Resolution is NP-hard and their work has been extended to other weak proof systems, e.g. [12, 13, 14]. For stronger systems, it is known that automating Extended Frege system EF, Frege or even constant-depth Frege would break specific cryptographic assumptions such as the security of RSA or Diffie-Hellman scheme, cf. [23, 6, 5]. It remains, however, open to obtain non-automatability of strong systems like Frege under a generic assumption such as the existence of strong pseudorandom generators, let alone to prove the equivalence between such notions.

In the present paper we derive a conditional equivalence between learning algorithms for p-size circuits and automatability of proof systems on tautologies encoding circuit lower bounds.

1.1 Our result

An ideal connection between learning and automatability would say that for standard proof systems P,

"P is automatable if and only if $\mathsf{P/poly}$ is learnable efficiently".

We establish this modulo some provability conditions and a change of parameters. Additionally, we need to consider automatability only w.r.t. formulas encoding circuit lower bounds. More precisely, denote by $\mathsf{tt}(f,s)$ a propositional formula which expresses that boolean function f represented by its truth-table is not computable by a boolean circuit of size s represented by free variables, see Section 3. So $\mathsf{tt}(f,s)$ is a tautology if and only if f is hard for circuits of size s. Note that f is represented by 2^n bits, if n is the number of inputs of f, so the size of $\mathsf{tt}(f,s)$ is $2^{O(n)}$. Similarly, let $\mathsf{tt}(f,s,t)$ be a formula expressing that circuits of size s fail to compute f on $\geq t$-fraction of inputs. In our main result (Theorem 1)

we use a slightly modified notion of automatability where the automating algorithm for a proof system P is non-uniform and outputs a P-proof of a given formula $\mathsf{tt}(f, n^{O(1)})$ in p-time in the size of the shortest P-proof of $\mathsf{tt}(f, 2^{n^{o(1)}}, 1/2 - 1/2^{n^{o(1)}})$, see Section 3.[1]

▶ **Theorem 1** (Informal, cf. Theorem 18)**.** *Let P be any propositional proof system which APC_1-provably p-simulates WF and satisfies some basic properties, e.g. $P = \mathsf{WF}$. Moreover, assume that P proves efficiently $\mathsf{tt}(h, 2^{n/4}, 1/2 - 1/2^{n/4})$ for some boolean function h. Then, the following statements are equivalent:*

1. **Provable learning.** *P proves efficiently that p-size circuits are learnable by $2^{n^{o(1)}}$-size circuits, over the uniform distribution, up to error $1/2 - 1/2^{n^{o(1)}}$, with membership queries and confidence $1/2^{n^{o(1)}}$.*
2. **Provable automatability.** *P proves efficiently that P is automatable by non-uniform circuits on formulas $\mathsf{tt}(f, n^{O(1)})$.*

WF is an elegant strengthening of EF introduced by Jeřábek [15], which corresponds to the theory of approximate counting APC_1, a theory formalizing probabilistic p-time reasoning, see Section 2.2. Concrete proof systems which APC_1-provably p-simulate WF and satisfy the basic properties from Theorem 1 include WF itself or even much stronger systems such as set theory ZFC (if we interpret ZFC as a suitable system for proving tautologies, see Section 5). We emphasize that the conditional equivalence from Theorem 1 holds for any sufficiently strong proof system satisfying some basic properties. The error and confidence of learning algorithms can be amplified "for free", see Section 2.1, but we did not make the attempts to prove that the amplification is efficiently provable already in WF.

Perhaps the most unusual aspect of Theorem 1 is its usage of metamathematics: we do not prove the equivalence between automatability and learning but between *provable* automatability and *provable* learning. We believe that the usage of metamathematics is not a substantial deviation. It would be very surprising if, e.g., an efficient learning algorithm existed but not provably (in some natural proof system).

Plausibility of the assumption. The main assumption in Theorem 1 is the provability of a circuit lower bound $\mathsf{tt}(h, 2^{n/4}, 1/2 - 1/2^{n/4})$. This assumption has an interesting status. Razborov's conjecture about hardness of Nisan-Wigderson generators implies a conditional hardness of formulas $\mathsf{tt}(h, n^{O(1)})$ for Frege (for every h), cf. [31], and it is possible to consider extensions of the conjecture to all standard proof systems, even set theory ZFC. On the other hand, all major circuit lower bounds for weak circuit classes and explicit boolean functions are known to be effciently provable in EF [2], cf. [29, 25]. If we believe that explicit circuit lower bounds such as $\mathsf{tt}(h, 2^{n/4}, 1/2 - 1/2^{n/4})$, for some $h \in \mathsf{EXP}$, are true, it is also perfectly plausible that they are efficiently provable in a standard proof system such as ZFC [3] or EF. Notably, if EF proves efficiently $\mathsf{tt}(h, 2^{n/4})$ for some boolean function h, then EF simulates WF, cf. [22, Lemma 19.5.4]. If there is a p-time algorithm which given a string of length 2^n (specifying the size of $\mathsf{tt}(h, 2^{n/4})$) generates an EF-proof of $\mathsf{tt}(h, 2^{n/4})$, then EF is p-equivalent to WF. To see that, combine Lemma 12 with the fact (proved in [15]) that APC_1 proves the reflection principle for WF.

---

[1] We believe that the gap between $\mathsf{tt}(f, n^{O(1)})$ and $\mathsf{tt}(f, 2^{n^{o(1)}}, 1/2 - 1/2^{n^{o(1)}})$ can be almost closed, if one uses learning of subexponential-size circuits instead of p-size circuits in Item 1 of Theorem 1 and tt-formulas expressing subexponential-size circuit lower bounds in Item 2.

[2] This has not been verified for lower bounds obtained via the algorithmic method of Williams [35].

[3] Efficient provability of $\mathsf{tt}(h, 2^{n/4}, 1/2 - 1/2^{n/4})$ in ZFC, for some $h \in \mathsf{EXP}$, would follow from the standard provability of this lower bound in ZFC.

As a corollary of Theorem 1 we show that, under a standard hardness assumption, there is an explicit proof system P for which the equivalence holds. This, follows, essentially, by "hard-wiring" tautologies $\mathsf{tt}(h, 2^{n/4}, 1/2 - 1/2^{n/4})$ to WF.

▶ **Corollary 2** (cf. Corollary 22). *Assume there is a* $\mathsf{NE} \cap \mathsf{coNE}$*-function* $h_n : \{0,1\}^n \mapsto \{0,1\}$ *such that for each sufficiently big* n*,* h_n *is not* $(1/2 + 1/2^{n/4})$*-approximable by* $2^{n/4}$*-size circuits.*[4] *Then there is a proof system* P *(which can be described explicitly given the definition of* h_n*) such that Items 1 and 2 from Theorem 1 are equivalent.*

The proof of Theorem 1 reveals also a proof complexity collapse which we discuss in the arXiv version of the paper.

1.2 Outline of the proof

Our starting point for the derivation of Theorem 1 is a relation between natural proofs and automatability which goes back to a work of Razborov and Krajíček. Razborov [30, 28] proved that certain theories of bounded arithmetic cannot prove explicit circuit lower bounds assuming strong pseudorandom generators exist. Krajíček [19, 21] developed the concept of feasible interpolation (a weaker version of automatability, cf. [22]) and reformulated Razborov's unprovability result in this language, see [22, Section 17.9] for more historical remarks.

▶ **Theorem 3** (Razborov-Krajíček [30, 28, 19] - informal version). *Let* P *be a proof system which simulates* EF *and satisfies some basic properties. If* P *is automatable and* P *proves efficiently* $\mathsf{tt}(h, n^{O(1)})$ *for some function* h*, then there are* $\mathsf{P/poly}$*-natural proofs useful against* $\mathsf{P/poly}$*.*

The second crucial ingredient we will use is a result of Carmosino, Impagliazzo, Kabanets and Kolokolova, who showed that natural proofs can be turned into learning algorithms [8]. This allows us to conclude the following.

▶ **Theorem 4** (Informal). *Let* P *be a proof system simulating* EF *and satisfying some basic properties. If* P *proves efficiently* $\mathsf{tt}(h, n^{O(1)})$ *for some function* h*, then automatability of* P *implies the existence of subexponential-size circuits learning p-size circuits over the uniform distribution, with membership queries.*

Theorem 4 directly implies that if strong pseudorandom generators exist and EF proves efficiently $\mathsf{tt}(h, n^{O(1)})$ for some h, then EF is automatable if and only if there are subexponential-size circuits learning p-size circuits over the uniform distribution, with membership queries. The disadvantage of this observation is that, unlike in Theorem 1, its assumptions are known to imply that both sides of the desired equivalence are false.

We note that the proof of Theorem 4 can be used to show also that optimal and automatable proof systems imply learning algorithms. In fact, it is possible to prove, unconditionally, that there is some propositional proof system P such that automatability of P is equivalent to the existence of subexponential-size circuits infnitely often learning $\mathsf{P/poly}$ over the uniform distribution. The proof is, however, non-constructive so (unlike in Corollary 2) we do not know which system P satisfies the equivalence. We discuss these results in more detail in the arXiv version of the paper.

[4] A circuit C with n inputs γ-approximates function $f : \{0,1\}^n \mapsto \{0,1\}$ if $\Pr_{x \in \{0,1\}^n}[C(x) = f(x)] \geq \gamma$.

The entrance of metamathematics. Unfortunately, it is unclear how to derive the opposite implication in Theorem 4. We do not know how to automate, say, EF assuming just the existence of efficient learning algorithms. In order to get the reverse, we need to assume that an efficient learning algorithm is provably correct in a proof system P, which p-simulates WF. For simplicity, let $P = \mathsf{WF}$. If we assume that WF proves efficiently for some small circuits that they can learn p-size circuits, we can show that there are small circuits such that WF proves efficiently that these circuits automate WF on formulas $\mathsf{tt}(f, n^{O(1)})$. In more detail, we first formalize in APC_1 the implication that WF-provable learning yields automatability of WF on $\mathsf{tt}(f, n^{O(1)})$ - if a learning circuit A does not find a small circuit for a given function f, the automating circuit uses WF-proof of the correctness of A to produce a short WF-proof of $\mathsf{tt}(f, n^{O(1)})$. Then, we translate the APC_1-proof to WF and conclude that WF proves that WF-provable learning implies automatability of WF. This allows us to show that if we have WF-provable learning, then WF is WF-provably automatable on $\mathsf{tt}(f, n^{O(1)})$.

It is important that assuming WF-provable learning, we are able to derive WF-provable automatability of WF, and not just automatability of WF. This makes it possible to obtain the opposite direction and establish the desired equivalence: If we know that WF proves that WF is automatable, we can formalize the proof of Theorem 4 in WF and conclude the existence of WF-provable learning algorithms.

Benefits of bounded arithmetic. The proof of Theorem 1 relies heavily on formalizations. Among other things we need to formalize the result of Carmosino, Impagliazzo, Kabanets and Kolokolova in APC_1[5], and use an elaborated way of expressing complex statements about metacomplexity by propositional formulas: existential quantifiers often need to be witnessed before translating them to propositional setting. The framework of bounded arithmetic allows us to deal with these complications in an elegant way: we often reason in bounded arithmetic, possibly using statements of higher quantifier complexity, and only subsequently translate the outcomes to propositional logic, if the resulting (proved) statement has coNP form. Notably, already propositional formulas expressing probabilities in the definition of learning algorithms require more advanced tools - the probabilities are encoded using suitable Nisan-Wigderson generators which come out of the notion of approximate counting in APC_1, cf. Section 3.2.

1.3 Related results

Learning algorithms and automatability have been linked already in the work of Alekhnovich, Braverman, Feldman, Klivans and Pitassi [1], who showed an informal connection between learning of weak circuit classes and automatability of some weak systems such as tree-like Resolution. As already mentioned, Atserias and Müller [3] proved that automating Resolution is NP-hard and their work has been extended to other weak proof systems, see e.g. [12, 13, 14]. A direct consequence of these results is that efficient algorithms automating the respective proof systems can be used to learn efficiently classes like P/poly. A major difference between these results and ours is that for our results to apply, the proof system needs to be sufficiently strong, while for the other results, the proof system needs to be weak (in the sense that lower bounds for the system are already known).

[5] We will actually formalize "CIKK" just conditionally, in order to avoid the formalization of Bertrand's postulate.

1.4 Open problems

Unconditional equivalence between learning and automatability. Is it possible to avoid the assumption on the provability of a circuit lower bound in Theorem 1 and establish an unconditional equivalence between learning and automatability?

Complexity theory from the perspective of metamathematics. Our results demonstrate that in the context of metamathematics it is possible to establish some complexity-theoretic connections which we are not able to establish otherwise. We exploit the metamathematical nature of the notion of automatability: efficient P-provability of the correctness of an algorithm implies efficient P-provability of automatability of P. Is it possible to take advantage of metamathematics in other contexts and resolve other important open problems in this setting? For example, could we get a version of the desired equivalence between the existence of efficient learning algorithms and the non-existence of cryptographic pseudorandom generators, cf. [26, 33, 27]? The question of basing cryptography on a worst-case assumption such as $\mathsf{P} \neq \mathsf{NP}$ could be addressed in this setting by showing that if a sufficiently strong proof system P proves efficiently that there is no strong pseudorandom generator[6], then P is p-bounded.

Circuit lower bound tautologies. How essential are circuit lower bound tautologies in our results? Consider fundamental questions of proof complexity (p-boundness, optimality, automatability) w.r.t. formulas $\mathsf{tt}(f, s)$. Do they coincide with the original ones? Are formulas $\mathsf{tt}(f, s)$ the hardest ones, do they admit optimal proof systems, or can we turn automatability on formulas $\mathsf{tt}(f, s)$ into automatability on all formulas?

2 Preliminaries

2.1 Natural proofs and learning algorithms

$[n]$ denotes $\{1, \ldots, n\}$. $\mathsf{Circuit}[s]$ denotes fan-in two Boolean circuits of size at most s. The size of a circuit is the number of gates.

▶ **Definition 5** (Natural property [32]). *Let $m = 2^n$ and $s, d : \mathbb{N} \mapsto \mathbb{N}$. A sequence of circuits $\{C_{2^n}\}_{n=1}^{\infty}$ is a $\mathsf{Circuit}[s(m)]$-natural property useful against $\mathsf{Circuit}[d(n)]$ if*

1. Constructivity. *C_m has m inputs and size $s(m)$,*
2. Largeness. *$\Pr_x[C_m(x) = 1] \geq 1/m^{O(1)}$,*
3. Usefulness. *For each sufficiently big m, $C_m(x) = 1$ implies that x is a truth-table of a function on n inputs which is not computable by circuits of size $d(n)$.*

▶ **Definition 6** (PAC learning). *A circuit class $\mathcal{C}$ is learnable over the uniform distribution by a circuit class $\mathcal{D}$ up to error ϵ with confidence δ, if there are randomized oracle circuits L^f from $\mathcal{D}$ such that for every Boolean function $f : \{0,1\}^n \mapsto \{0,1\}$ computable by a circuit from $\mathcal{C}$, when given oracle access to f, input 1^n and the internal randomness $w \in \{0,1\}^*$, L^f outputs the description of a circuit satisfying*

$$\Pr_w[L^f(1^n, w) \text{ } (1-\epsilon)\text{-approximates } f] \geq \delta.$$

[6] The formalization of this statement would assume the existence of a p-size circuit which for any p-size circuit defining a potential pseudorandom generator outputs its distinguisher.

L^f uses non-adaptive membership queries if the set of queries which L^f makes to the oracle does not depend on the answers to previous queries. L^f uses random examples if the set of queries which L^f makes to the oracle is chosen uniformly at random.

In this paper, PAC learning always refers to learning over the uniform distribution. While, a priori, learning over the uniform distribution might not reflect real-world scenarios very well (and on the opposite end, learning over all distributions is perhaps overly restrictive), as far as we can tell it is possible that PAC learning of p-size circuits over the uniform distribution implies PAC learning of p-size circuits over all p-samplable distributions. Binnendyk, Carmosino, Kolokolova, Ramyaa and Sabin [4] proved the implication, if the learning algorithm in the conclusion is allowed to depend on the p-samplable distribution.

Boosting confidence and reducing error. The confidence of the learner and its error can be improved generically, see the arXiv version of the paper. We can thus often ignore the optimisation of these parameters.

Natural proofs vs learning algorithms. Natural proofs are actually equivalent to efficient learning algorithms with suitable parameters. In this paper we need just one implication.

▶ **Theorem 7** (Carmosino-Impagliazzo-Kabanets-Kolokolova [8]). *Let R be a* P/poly*-natural property useful against* Circuit$[n^k]$ *for $k \geq 1$. Then, for each $\gamma \in (0,1)$,* Circuit$[n^{k\gamma/a}]$ *is learnable by* Circuit$[2^{O(n^\gamma)}]$ *over the uniform distribution with non-adaptive membership queries, confidence 1, up to error $1/n^{k\gamma/a}$, where a is an absolute constant.*

2.2 Bounded arithmetic and propositional logic

Theories of bounded arithmetic capture various levels of feasible reasoning and present a uniform counterpart to propositional proof systems.

The first theory of bounded arithmetic formalizing p-time reasoning was introduced by Cook [10] as an equational theory PV. We work with its first-order conservative extension PV_1 from [24]. The language of PV_1, denoted PV as well, consists of symbols for all p-time algorithms given by Cobham's characterization of p-time functions, cf. [9]. A PV-formula is a first-order formula in the language PV. Σ^b_0 ($=\Pi^b_0$) denotes PV-formulas with only sharply bounded quantifiers $\exists x, x \leq |t|$, $\forall x, x \leq |t|$, where $|t|$ is "the length of the binary representation of t". Inductively, Σ^b_{i+1} resp. Π^b_{i+1} is the closure of Π^b_i resp. Σ^b_i under positive Boolean combinations, sharply bounded quantifiers, and bounded quantifiers $\exists x, x \leq t$ resp. $\forall x, x \leq t$. Predicates definable by Σ^b_i resp. Π^b_i formulas are in the Σ^p_i resp. Π^p_i level of the polynomial hierarchy, and vice versa. PV_1 is known to prove Σ^b_0(PV)-induction:

$$A(0) \wedge \forall x\ (A(x) \to A(x+1)) \to \forall x A(x),$$

for Σ^b_0-formulas A, cf. Krajíček [18].

Buss [7] introduced the theory S^1_2 extending PV_1 with the Σ^b_1-length induction:

$$A(0) \wedge \forall x < |a|, (A(x) \to A(x+1)) \to A(|a|),$$

for $A \in \Sigma^b_1$. S^1_2 proves the sharply bounded collection scheme $BB(\Sigma^b_1)$:

$$\forall i < |a|\ \exists x < a, A(i,x) \to \exists w\ \forall i < |a|, A(i, [w]_i),$$

for $A \in \Sigma^b_1$ ($[w]_i$ is the ith element of the sequence coded by w), which is unprovable in PV_1 under a cryptographic assumption, cf. [11]. On the other hand, S^1_2 is $\forall\Sigma^b_1$-conservative over PV_1. This is a consequence of Buss's witnessing theorem stating that $\mathsf{S}^1_2 \vdash \exists y, A(x,y)$ for $A \in \Sigma^b_1$ implies $\mathsf{PV}_1 \vdash A(x, f(x))$ for some PV-function f.

Following a work by Krajíček [20], Jeřábek [15, 16, 17] systematically developed a theory APC_1 capturing probabilistic p-time reasoning by means of approximate counting.[7] The theory APC_1 is defined as $\mathsf{PV}_1 + dWPHP(\mathsf{PV})$ where $dWPHP(\mathsf{PV})$ stands for the dual (surjective) pigeonhole principle for PV-functions, i.e. for the set of all formulas

$$x > 0 \to \exists v < x(|y|+1)\forall u < x|y|,\ f(u) \neq v,$$

where f is a PV-function which might involve other parameters not explicitly shown. We devote Section 2.3 to a more detailed description of the machinery of approximate counting in APC_1.

Any Π^b_1-formula ϕ provable in PV_1 can be expressed as a sequence of tautologies $||\phi||_n$ with proofs in the Extended Frege system EF which are constructible in p-time (given a string of the length n), cf. [10]. Similarly, Π^b_1-formulas provable in APC_1 translate to tautologies with p-time constructible proofs in WF, an extension of EF introduced by Jeřábek [15]. We describe the translation and system WF in more detail below.

As it is often easier to present a proof in a theory of bounded arithmetic than in the corresponding propositional system, bounded arithmetic functions, so to speak, as a uniform language for propositional logic.

We refer to Krajíček [22] for basic notions in proof complexity.

▶ **Definition 8** (WF (WPHP Frege), cf. Jeřábek [15])**.** *Let L be a finite and complete language for propositional logic, i.e. L consists of finitely many boolean connectives of constant arity such that each boolean function of every arity can be expressed by an L-formula, and let $\mathcal{R}$ be a finite, sound and implicationally complete set of Frege rules (in the langauge L). A* WF*-proof of a (L-)circuit A is a sequence of circuits $A_0, \dots, A_k$ such that $A_k = A$, and each A_i is derived from some $A_{j_1}, \dots, A_{j_\ell}$, $j_1, \dots, j_\ell < i$ by a Frege rule from $\mathcal{R}$, or it is similar to some A_j, $j < i$, or it is the dWPHP axiom,*

$$\bigvee_{\ell=1}^{m} (r_\ell \neq C_{i,\ell}(D_{i,1}, \dots, D_{i,n})),$$

where $n < m$ and r_ℓ are pairwise distinct variables which do not occur in circuits A, $C_{i,\ell'}$, or A_j for $j < i$, but may occur in circuits $D_{i,1}, \dots, D_{i,n}$.

The similarity rule in Definition 8 is verified by a specific p-time algorithm which checks that circuits A_i and A_j can be "unfolded" to the same (possible huge) formula, cf. [15, Lemma 2.2.]. Intuitively, the NLOG ($\subseteq$ P) algorithm recognizes if two circuits are not similar by guessing a partial path through them, going from the output to the inputs, where on at least one instruction the circuits disagree. As defined WF depends on the choice of Frege rules and language L, but for each choice the resulting systems are p-equivalent, so we can identify them. The dWPHP axiom refers to "dual weak pigeonhole principle" postulating the existence of an element $r_1, \dots, r_m$ outside the range of a p-size map $C_{i,1}, \dots, C_{i,m} : \{0,1\}^n \mapsto \{0,1\}^m$.

[7] Krajíček [20] introduced a theory BT defined as $\mathsf{S}^1_2 + dWPHP(\mathsf{PV})$ and proposed it as a theory for probabilistic p-time reasoning.

The dWPHP axiom comes with a specification of circuits $C_{i,1},\dots,C_{i,m},D_{i,1},\dots,D_{i,n}$ so that we can recognize the axiom efficiently. The role of circuits $D_{i,1},\dots,D_{i,n}$ in the dWPHP axiom is to allow WF to postulate not only that $r_1,\dots,r_m$ is not the output of $C_{i,1},\dots,C_{i,m}$ on a specific input $x_1,\dots x_n$ but to postulate that $r_1,\dots,r_m$ is not the output of $C_{i,1},\dots,C_{i,m}$ on other inputs (which could depend on $r_1,\dots,r_m$) either.

The translation of a Π^b_1 formula ϕ into a sequence of propositional formulas $||\phi||_{\overline{n}}$ works as follows. For each PV-function $f(x_1,\dots,x_k)$ and numbers $n_1,\dots,n_k$ we have a p-size circuit C_f computing the restriction $f:2^{n_1}\times\cdots\times 2^{n_k}\mapsto 2^{b(n_1,\dots,n_k)}$, where b is a suitable "bounding" polynomial for f. The formula $||f||_{\overline{n}}(p,q,r)$ expresses that C_f outputs r on input p, with q being the auxiliary variables corresponding to the nodes of C_f. The formula $||\phi(x)||_{\overline{n}}(p,q)$ is defined as $||\phi'(x)||_{\overline{n}}(p,q)$, where ϕ' is the negation normal form of ϕ, i.e. negations in ϕ' are only in front of atomic formulas. The formula $||\phi'(x)||_{\overline{n}}(p,q)$ is defined inductively in a straightforward way so that $||\dots||$ commutes with $\vee,\wedge$. The atoms p correspond to variables x, atoms q correspond to the universally quantified variables of ϕ and to the outputs and auxiliary variables of circuits C_f for functions f appearing in ϕ. Sharply bounded quantifiers are replaced by polynomially big conjuctions resp. disjunctions. For the atomic formulas we have,

$$||f(x)=g(x)||_{\overline{n}} :=||f(x)||_{\overline{n}}(p,q,r)\wedge||g(x)||_{\overline{n}}(p,q',r')\to\bigwedge_i r_i=r'_i,$$

$$||\neg f(x)=g(x)||_{\overline{n}} :=||f(x)||_{\overline{n}}(p,q,r)\wedge||g(x)||_{\overline{n}}(p,q',r')\to\neg\bigwedge_i r_i=r'_i,$$

$$||f(x)\le g(x)||_{\overline{n}} :=||f(x)||_{\overline{n}}(p,q,r)\wedge||g(x)||_{\overline{n}}(p,q',r')\to\bigwedge_i(r_i\wedge\bigwedge_{j>i}(r_j=r'_j)\to r'_i),$$

$$||\neg f(x)\le g(x)||_{\overline{n}} :=||f(x)||_{\overline{n}}(p,q,r)\wedge||g(x)||_{\overline{n}}(p,q',r')\to\neg\bigwedge_i(r_i\wedge\bigwedge_{j>i}(r_j=r'_j)\to r'_i).$$

2.3 Approximate counting

In order to prove our results we will need to use Jeřábek's theory of approximate counting. This section recalls the properties of APC_1 we will need.

By a definable set we mean a collection of numbers satisfying some formula, possibly with parameters. When a number a is used in a context which asks for a set it is assumed to represent the integer interval $[0,a)$, e.g. $X\subseteq a$ means that all elements of set X are less than a. If $X\subseteq a$, $Y\subseteq b$, then $X\times Y:=\{bx+y\mid x\in X,y\in Y\}\subseteq ab$ and $X\dot\cup Y:=X\cup\{y+a\mid y\in Y\}\subseteq a+b$. Rational numbers are assumed to be represented by pairs of integers in the natural way. We use the notation $x\in Log\leftrightarrow\exists y,\ x=|y|$ and $x\in LogLog\leftrightarrow\exists y,\ x=||y||$.

Let $C:2^n\to 2^m$ be a circuit and $X\subseteq 2^n, Y\subseteq 2^m$ definable sets. We write $C:X\twoheadrightarrow Y$ if $\forall y\in Y\exists x\in X,\ C(x)=y$. Jeřábek [17] gives the following definitions in APC_1 (but they can be considered in weaker theories as well).

▶ **Definition 9.** *Let $X,Y\subseteq 2^n$ be definable sets, and $\epsilon\le 1$. The size of X is approximately less than the size of Y with error ϵ, written as $X\preceq_\epsilon Y$, if there exists a circuit C, and $v\neq 0$ such that*

$$C:v\times(Y\dot\cup\epsilon 2^n)\twoheadrightarrow v\times X.$$

$X\approx_\epsilon Y$ stands for $X\preceq_\epsilon Y$ and $Y\preceq_\epsilon X$.

Since a number s is identified with the interval $[0, s)$, $X \preceq_\epsilon s$ means that the size of X is at most s with error ϵ.

The definition of $X \preceq_\epsilon Y$ is an unbounded $\exists\Pi^b_2$-formula even if X, Y are defined by circuits so it cannot be used freely in bounded induction. Jeřábek [17] solved this problem by working in HARD^A, a conservative extension of APC_1, defined as a relativized theory $\mathsf{PV}_1(\alpha) + dWPHP(\mathsf{PV}(\alpha))$ extended with axioms postulating that $\alpha(x)$ is a truth-table of a function on $||x||$ variables hard on average for circuits of size $2^{||x||/4}$, see Section 3.2. In HARD^A there is a $\mathsf{PV}_1(\alpha)$ function $Size$ approximating the size of any set $X \subseteq 2^n$ defined by a circuit C so that $X \approx_\epsilon Size(C, 2^n, 2^{\epsilon^{-1}})$ for $\epsilon^{-1} \in Log$, cf. [17, Lemma 2.14]. If $X \cap t \subseteq 2^{|t|}$ is defined by a circuit C and $\epsilon^{-1} \in Log$, we can define

$$\Pr_{x<t}[x \in X]_\epsilon := \frac{1}{t} Size(C, 2^{|t|}, 2^{\epsilon^{-1}}).$$

The presented definitions of approximate counting are well-behaved:

▶ **Proposition 10** (Jeřábek [17]). *(in PV_1) Let $X, X', Y, Y', Z \subseteq 2^n$ and $W, W' \subseteq 2^m$ be definable sets, and $\epsilon, \delta < 1$. Then*

- **i)** $X \subseteq Y \Rightarrow X \preceq_0 Y$,
- **ii)** $X \preceq_\epsilon Y \wedge Y \preceq_\delta Z \Rightarrow X \preceq_{\epsilon+\delta} Z$,
- **iii)** $X \preceq_\epsilon X' \wedge W \preceq_\delta W' \Rightarrow X \times W \preceq_{\epsilon+\delta+\epsilon\delta} X' \times W'$.
- **iv)** $X \preceq_\epsilon X' \wedge Y \preceq_\delta Y'$ *and* X', Y' *are separable by a circuit, then* $X \cup Y \preceq_{\epsilon+\delta} X' \cup Y'$.

▶ **Proposition 11** (Jeřábek [17]). *(in APC_1)*

1. *Let $X, Y \subseteq 2^n$ be definable by circuits, $s, t, u \leq 2^n$, $\epsilon, \delta, \theta, \gamma < 1, \gamma^{-1} \in Log$. Then*
   - **(i)** $X \preceq_\gamma Y$ *or* $Y \preceq_\gamma X$,
   - **(ii)** $s \preceq_\epsilon X \preceq_\delta t \Rightarrow s < t + (\epsilon + \delta + \gamma)2^n$,
   - **(iii)** $X \preceq_\epsilon Y \Rightarrow 2^n \backslash Y \preceq_{\epsilon+\gamma} 2^n \backslash X$,
   - **(iv)** $X \approx_\epsilon s \wedge Y \approx_\delta t \wedge X \cap Y \approx_\theta u \Rightarrow X \cup Y \approx_{\epsilon+\delta+\theta+\gamma} s + t - u$.
2. *(Disjoint union) Let $X_i \subseteq 2^n$, $i < m$ be defined by a sequence of circuits and $\epsilon, \delta \leq 1$, $\delta^{-1} \in Log$. If $X_i \preceq_\epsilon s_i$ for every $i < m$, then $\bigcup_{i<m}(X_i \times \{i\}) \preceq_{\epsilon+\delta} \sum_{i<m} s_i$.*
3. *(Averaging) Let $X \subseteq 2^n \times 2^m$ and $Y \subseteq 2^m$ be definable by circuits, $Y \preceq_\epsilon t$ and $X_y \preceq_\delta s$ for every $y \in Y$, where $X_y := \{x | \langle x, y\rangle \in X\}$. Then for any $\gamma^{-1} \in Log$,*

   $$X \cap (2^n \times Y) \preceq_{\epsilon+\delta+\epsilon\delta+\gamma} st.$$

When proving Σ^b_1 statements in APC_1 we can afford to work in $\mathsf{S}^1_2 + dWPHP(\mathsf{PV}) + BB(\Sigma^b_2)$ and, in fact, assuming the existence of a single hard function in PV_1 gives us the full power of APC_1. Here, $BB(\Sigma^b_2)$ is defined as $BB(\Sigma^b_1)$ but with $A \in \Sigma^b_2$.

▶ **Lemma 12** ([25]). *Suppose $\mathsf{S}^1_2 + dWPHP(\mathsf{PV}) + BB(\Sigma^b_2) \vdash \exists y A(x, y)$ for $A \in \Sigma^b_1$. Then, for every $\epsilon < 1$, there is k and PV-functions g, h such that PV_1 proves*

$$|f| \geq |x|^k \wedge \exists y, |y| = ||f||, C_h(y) \neq f(y) \to A(x, g(x, f))$$

where $f(y)$ is the yth bit of f, $f(y) = 0$ for $y > |f|$, and C_h is a circuit of size $\leq 2^{\epsilon||f||}$ generated by h on f, x. Moreover, $\mathsf{APC}_1 \vdash \exists y A(x, y)$.

3 Formalizing complexity-theoretic statements

3.1 Circuit lower bounds

An "almost everywhere" formulation of a circuit lower bound for circuits of size s and a function f says that for every sufficiently big n, for each circuit C with n inputs and size s, there exists an input y on which the circuit C fails to compute $f(y)$.

If $f : \{0,1\}^n \to \{0,1\}$ is an NP function and $s = n^k$ for a constant k, this can be written down as a $\forall\Sigma^b_2$ formula $\mathsf{LB}(f, n^k)$,

$$\forall n,\ n > n_0\ \forall \text{ circuit } C \text{ of size } \leq n^k\ \exists y,\ |y| = n,\ C(y) \neq f(y),$$

where n_0 is a constant and $C(y) \neq f(y)$ is a Σ^b_2 formula stating that a circuit C on input y outputs the opposite value of $f(y)$.

If we want to express $s(n)$-size lower bounds for $s(n)$ as big as $2^{O(n)}$, we add an extra assumption on n stating that $\exists x,\ n = ||x||$. That is, the resulting formula $\mathsf{LB}_{\mathsf{tt}}(f, s(n))$ has form "$\forall x, n; n = ||x|| \to \dots$". Treating x, n as free variables, $\mathsf{LB}_{\mathsf{tt}}(f, s(n))$ is Π^b_1 if f is, for instance, SAT because $n = ||x||$ implies that the quantifiers bounded by $2^{O(n)}$ are sharply bounded. Moreover, allowing $f \in \mathsf{NE}$ lifts the complexity of $\mathsf{LB}_{\mathsf{tt}}(f, s(n))$ just to $\forall\Sigma^b_1$. The function $s(n)$ in $\mathsf{LB}_{\mathsf{tt}}(f, s(n))$ is assumed to be a PV-function with input x (satisfying $||x|| = n$).

In terms of the *Log*-notation, $\mathsf{LB}(f, n^k)$ implicitly assumes $n \in Log$ while $\mathsf{LB}_{\mathsf{tt}}(f, n^k)$ assumes $n \in LogLog$. By chosing the scale of n we are determining how big objects are going to be "feasible" for theories reasoning about the statement. In the case $n \in LogLog$, the truth-table of f (and everything polynomial in it) is feasible. Assuming just $n \in Log$ means that only the objects of polynomial-size in the size of the circuit are feasible. Likewise, the theory reasoning about the circuit lower bound is less powerful when working with $\mathsf{LB}(f, n^k)$ than with $\mathsf{LB}_{\mathsf{tt}}(f, n^k)$. (The scaling in $\mathsf{LB}_{\mathsf{tt}}(f, s)$ corresponds to the choice of parameters in natural proofs and in the formalizations by Razborov [29].)

We can analogously define formulas $\mathsf{LB}_{\mathsf{tt}}(f, s(n), t(n))$ expressing an average-case lower bound for f, where f is a free variable (with $f(y)$ being the yth bit of f and $f(y) = 0$ for $y > |f|$). More precisely, $\mathsf{LB}_{\mathsf{tt}}(f, s(n), t(n))$ generalizes $\mathsf{LB}_{\mathsf{tt}}(f, s(n))$ by saying that each circuit of size $s(n)$ fails to compute f on at least $t(n)$ inputs, for PV-functions $s(n), t(n)$. Since $n \in LogLog$, $\mathsf{LB}_{\mathsf{tt}}(f, s(n), t(n))$ is Π^b_1.

Propositional version. An $s(n)$-size circuit lower bound for a function $f : \{0,1\}^n \to \{0,1\}$ can be expressed by a $2^{O(n)}$-size propositional formula $\mathsf{tt}(f, s)$,

$$\bigvee_{y \in \{0,1\}^n} f(y) \neq C(y)$$

where the formula $f(y) \neq C(y)$ says that an $s(n)$-size circuit C represented by $poly(s)$ variables does not output $f(y)$ on input y. The values $f(y)$ are fixed bits. That is, the whole truth-table of f is hard-wired in $\mathsf{tt}(f, s)$.

The details of the encoding of the formula $\mathsf{tt}(f, s)$ are not important for us as long as the encoding is natural because systems like EF considered in this paper can reason efficiently about them. We will assume that $\mathsf{tt}(f, s)$ is the formula resulting from the translation of Π^b_1 formula $\mathsf{LB}_{\mathsf{tt}}(h, s)$, where $n_0 = 0$, n, x are substituted after the translation by fixed constants so that $x = 2^{2^n}$, and h is a free variable (with $h(y)$ being the yth bit of h and $h(y) = 0$ for $y > |h|$) which is substituted after the translation by constants defining f.

Analogously, we can express average-case lower bounds by propositional formulas $\mathsf{tt}(f, s(n), t(n))$ obtained by translating $\mathsf{LB}_{\mathsf{tt}}(h, s(n), t(n)2^n)$, with $n_0 = 0$, fixed $x = 2^{2^n}$ and h substituted after the translation by f.

3.2 Learning algorithms

A circuit class $\mathcal{C}$ is defined by a PV-formula if there is a PV-formula defining the predicate $C \in \mathcal{C}$. Definition 6 can be formulated in the language of HARD^A: A circuit class $\mathcal{C}$ (defined by a PV-formula) is learnable over the uniform disribution by a circuit class $\mathcal{D}$ (defined by a PV-formula) up to error ϵ with confidence δ, if there are randomized oracle circuits L^f from $\mathcal{D}$ such that for every Boolean function $f : \{0,1\}^n \mapsto \{0,1\}$ (represented by its truth-table) computable by a circuit from $\mathcal{C}$, for each $\gamma^{-1} \in Log$, when given oracle access to f, input 1^n and the internal randomness $w \in \{0,1\}^*$, L^f outputs the description of a circuit satisfying

$$\Pr_w[L^f(1^n, w) \ (1-\epsilon)\text{-approximates } f]_\gamma \geq \delta.$$

The inner probability of approximability of f by $L^f(1^n, w)$ is counted exactly. This is possible because f is represented by its truth-table, which implies that $2^n \in Log$.[8]

Propositional version. In order, to translate the definition of learning algorithms to propositional formulas we need to look more closely at the definition of HARD^A.

PV_1 can be relativized to $\mathsf{PV}_1(\alpha)$. The new function symbol α is then allowed in the inductive clauses for introduction of new function symbols. This means that the language of $\mathsf{PV}_1(\alpha)$, denoted also $\mathsf{PV}(\alpha)$, contains symbols for all p-time oracle algorithms.

▶ **Proposition 13** (Jeřábek [15]). *For every constant $\epsilon < 1/3$ there exists a constant n_0 such that APC_1 proves: for every $n \in LogLog$ such that $n > n_0$, there exist a function $f : 2^n \to 2$ such that no circuit of size $2^{\epsilon n}$ computes f on $\geq (1/2 + 1/2^{\epsilon n})2^n$ inputs.*

▶ **Definition 14** (Jeřábek [15]). *The theory HARD^A is an extension of the theory $\mathsf{PV}_1(\alpha) + dWPHP(\mathsf{PV}(\alpha))$ by the axioms*

1. *$\alpha(x)$ is a truth-table of a Boolean function in $||x||$ variables,*
2. *$\mathsf{LB}_{\mathsf{tt}}(\alpha(x), 2^{||x||/4}, 2^{||x||}(1/2 - 1/2^{||x||/4}))$, for constant n_0 from Proposition 13,*
3. *$||x|| = ||y|| \to \alpha(x) = \alpha(y)$.*

By inspecting the proof of Lemma 2.14 in [17], we can observe that on each input $C, 2^n, 2^{\epsilon^{-1}}$ the $\mathsf{PV}_1(\alpha)$-function $Size$ calls α just once (to get the truth-table of a hard function which is then used as the base function of the Nisan-Wgiderson generator). In fact, $Size$ calls α on input x which depends only on $|C|$, the number of inputs of C and w.l.o.g. also just on $|\epsilon^{-1}|$ (since decreasing ϵ leads only to a better approximation). In combination with the fact that the approximation $Size(C, 2^n, 2^{\epsilon^{-1}}) \approx_\epsilon X$, for $X \subseteq 2^n$ defined by C, is not affected by a particular choice of the hard boolean function generated by α, we get that APC_1 proves

$$\mathsf{LB}_{\mathsf{tt}}(y, 2^{||y||/4}, 2^{||y||}(1/2 - 1/2^{||y||/4})) \wedge ||y|| = S(C, 2^n, 2^{\epsilon^{-1}}) \to \ Sz(C, 2^n, 2^{\epsilon^{-1}}, y) \approx_\epsilon X,$$

where Sz is defined as $Size$ with the only difference that the call to $\alpha(x)$ on $C, 2^n, 2^{\epsilon^{-1}}$ is replaced by y and $S(C, 2^n, 2^{\epsilon^{-1}}) = ||x||$ for a PV-function S.

[8] It could be interesting to develop systematically a standard theory of learning algorithms in APC_1 and WF, but it is not our goal here. Note, for example, that when we are learning small circuits it is not clear how to boost the confidence to 1 in APC_1, because we don't have counting with exponential precision.

This allows us to express $\Pr_{x<t}[x \in X]_\epsilon = a$, where $\epsilon^{-1} \in Log$ and $X \cap t \subseteq 2^{|t|}$ is defined by a circuit C, without a $\mathsf{PV}_1(\alpha)$ function, by formula

$$\forall y\,(\mathsf{LB}_{\mathsf{tt}}(y, 2^{||y||/4}, 2^{||y||}(1/2{-}1/2^{||y||/4}))\wedge||y|| = S(C, 2^{|t|}, 2^{\epsilon^{-1}}) \to Sz(C, 2^{|t|}, 2^{\epsilon^{-1}}, y)/t = a).$$

We denote the resulting formula by $\Pr^y_{x<t}[x \in X]_\epsilon = a$. We will use the notation $\Pr^y_{x<t}[x \in X]_\epsilon$ in equations with the intended meaning that the equation holds for the value $Sz(\cdot,\cdot,\cdot,\cdot)/t$ under corresponding assumptions. For example, $t \cdot \Pr^y_{x<t}[x \in X]_\epsilon \preceq_\delta a$ stands for "$\forall y, \exists v, \exists$ circuit $\hat{C}$ (defining a surjection) which witnesses that $\mathsf{LB}_{\mathsf{tt}}(y, 2^{||y||/4}, 2^{||y||}(1/2 - 1/2^{||y||/4})) \wedge ||y|| = S(C, 2^{|t|}, 2^{\epsilon^{-1}})$ implies $Sz(C, 2^{|t|}, 2^{\epsilon^{-1}}, y) \preceq_\delta a$".

The definition of learning can be now expressed without a $\mathsf{PV}_1(\alpha)$ function: If circuit class $\mathcal{C}$ is defined by a PV-function, the statement that a given oracle algorithm L (given by a PV-function with oracle queries) learns a circuit class $\mathcal{C}$ over the uniform distribution up to error ϵ with confidence δ can be expressed as before with the only difference that we replace $\Pr_w[L^f(1^n, w)\ (1-\epsilon)\text{-approximates } f]_\gamma \geq \delta$ by

$$\Pr^y_w[L^f(1^n, w)\ (1-\epsilon)\text{-approximates } f]_\gamma \geq \delta.$$

Since the resulting formula A defining learning is not Π^b_1 (because of the assumption $\mathsf{LB}_{\mathsf{tt}}$) we cannot translate it to propositional logic. We will sidestep the issue by translating only the formula B obtained from A by deleting subformula $\mathsf{LB}_{\mathsf{tt}}$ (but leaving $||y|| = S(\cdot,\cdot,\cdot)$ intact) and replacing the variables y by fixed bits representing a hard boolean function. In more detail, Π^b_1 formula B can be translated into a sequence of propositional formulas $\mathsf{lear}^y_\gamma(L, \mathcal{C}, \epsilon, \delta)$ expressing that "if $C \in \mathcal{C}$ is a circuit computing f, then L querying f generates a circuit D such that $\Pr[D(x) = f(x)] \geq 1 - \epsilon$ with probability $\geq \delta$, which is counted approximately with precision γ". Note that C, f are represented by free variables and that there are also free variables for error γ from approximate counting and for boolean functions y. As in the case of tt-formulas, we fix $|f| = 2^n$, so n is not a free variable. Importantly, $\mathsf{lear}^y_\gamma(L, \mathcal{C}, \epsilon, \delta)$ does not postulate that y is a truth-table of a hard boolean function. Nevertheless, for any fixed (possibly non-uniform) bits representing a sequence of boolean functions $h = \{h_m\}_{m>n_0}$ such that h_m is not $(1/2 + 1/2^{m/4})$-approximable by any circuit of size $2^{m/4}$, we can obtain formulas $\mathsf{lear}^h_\gamma(L, \mathcal{C}, \epsilon, \delta)$ by substituting bits h for y.

Using a single function h in $\mathsf{lear}^h_\gamma(L, \mathcal{C}, \epsilon, \delta)$ does not ruin the fact that (the translation of function) Sz approximates the respective probability with accuracy γ because Sz queries a boolean function y which depends just on the number of atoms representing γ^{-1} and on the size of the circuit D defining the predicate we count together with the number of inputs of D. The size of D and the number of its inputs are w.l.o.g. determined by the number of inputs of f.

If we are working with formulas $\mathsf{lear}^h_\gamma(L, \mathcal{C}, \epsilon, \delta)$, where h is a sequence of bits representing a hard boolean function, in a proof system which cannot prove efficiently that h is hard, our proof system might not be able to show that the definition is well-behaved - it might not be able to derive some standard properties of the function Sz used inside the formula. Nevertheless, in our theorems this will never be the case: our proof systems will always know that h is hard.

In formulas $\mathsf{lear}^y_\gamma(L, \mathcal{C}, \epsilon, \delta)$ we can allow L to be a sequence of nonuniform circuits, with a different advice string for each input length. One way to see that is to use additional input to L in Π^b_1 formula B, then translate the formula to propositional logic and substitute the right bits of advice for the additional input. Again, the precise encoding of the formula $\mathsf{lear}^y_\gamma(L, \mathcal{C}, \epsilon, \delta)$ does not matter very much to us but in order to simplify proofs we will

assume that $\mathsf{lear}^y_\gamma(L, \mathsf{Circuit}[n^k], \epsilon, \delta)$ has the from $\neg\mathsf{tt}(f, n^k) \to R$, where n, k are fixed, f is represented by free variables and R is the remaining part of the formula expressing that L generates a suitable circuit with high probability.

3.3 Automatability

Let Φ be a class of propositional formulas. We say that a proof system P is automatable w.r.t. Φ up to proofs of size s, where $s : \Phi \mapsto \mathbb{N}$ is a function, if there is a PV-function A such that for each $\phi \in \Phi$ and each t-size P-proof of ϕ with $t \leq s$, $A(\phi, 1^t)$ is a P-proof of ϕ.

In our main theorem we will need a slightly modified notion of automatability where the automating algorithm outputs a proof of a given tautology ϕ which is not much longer than a proof of an associated tautology ψ. (Formula ψ will be closely related to ϕ: while ϕ will express a worst-case lower bound, ψ will express an average-case lower bound for the same function.)

Let Φ be a class of pairs of propositional formulas. We say that a proof system P is automatable w.r.t. Φ up to proofs of size s if there is a PV-function A such that for each pair $\langle \psi, \phi \rangle \in \Phi$ and each t-size P-proof of ψ with $t \leq s$, $A(\phi, 1^t)$ is a P-proof of ϕ.

Propositional version. If Φ is defined by a PV-function and $s \in Log$ is a PV-function, the statement that an algorithm A (given by a PV-function) automates system P w.r.t. Φ up to proofs of size s is Π^b_1. Therefore, it can be translated into a sequence of propositional formulas $\mathsf{aut}_P(A, \Phi, s)$. Again, in formulas $\mathsf{aut}_P(A, \Phi, s)$ we can allow A to be a sequence of nonuniform circuits and s to be arbitrary possibly nonuniform parameter.

4 Learning algorithms from natural proofs in APC_1

The formalization of the transformation of natural proofs into learning algorithms follows from a straightforward inspection of the original proof. The proof can be found in the arXiv version of the paper.

▶ **Theorem 15.** *There is a* PV*-function L such that* APC_1 *proves: For $k \geq 1$, $d \geq 2$, $2^{n^d}, n^{dk}, \delta^{-1} \in Log$, $\delta < 1/N^3$ and a prime $n^d \leq p \leq 2n^d$, let R_N be a circuit with $N = 2^n$ inputs such that for sufficiently big N,*

1. *$R_N(x) = 1$ implies that x is a truth-table of a boolean function with n inputs hard for* $\mathsf{Circuit}[n^{10dk}]$,
2. *$\{x \mid R_N(x) = 1\} \succeq_\delta 2^N/N$.*

Then, circuits with n^d inputs and size n^{dk} are learnable by circuit $L(R_N, p)$ over the uniform distribution with membership queries, confidence $1/N^4$, up to error $1/2 - 1/N^3$. Here, the confidence is counted approximately with error δ using PV*-function Sz and the corresponding assumptions* $\mathsf{LB}_{\mathsf{tt}}$ *expressing hardness of a boolean function y, i.e. using formulas* $\Pr^y[\cdot]_\delta$.

5 Main theorem

Our main theorem holds for any "decent" proof system p-simulating WF, which is well-behaved in the sense that it APC_1-provably satisfies some basic properties.

▶ **Definition 16** (APC_1-decent proof system)**.** *A propositional proof system P is* APC_1*-decent if the language L of P is finite and complete, i.e. L consists of connectives of constant arity such that each boolean function of every arity can be expressed by an L-formula, P proves efficiently its own reflection principle, i.e. formulas stating that if π is a P-proof of ϕ then ϕ holds, cf. [22], and there is a* PV*-function F such that* APC_1 *proves:*

1. *P p-simulates* WF*, i.e. F maps each* WF*-proof of ϕ to a P-proof of ϕ.*
2. *P admits substitution property: F maps each triple $\langle \phi, \rho, \pi \rangle$ to a P-proof of $\phi|_\rho$, where π is a P-proof of ϕ and $\phi|_\rho$ is formula ϕ after applying substitution ρ which replaces atoms of ϕ by formulas.*
3. *F maps each pair $\langle \pi, \pi' \rangle$, where π is a P-proof of ϕ and π' is a P-proof of $\phi \to \psi$, to a P-proof of ψ.*

In Definition 16, WF refers to some fixed system from the set of all WF systems. It follows from the proof of Lemma 17 that if APC_1 proves that P p-simulates a WF-system Q, then for every WF-system R, APC_1 proves that P p-simulates R, so the particular choice of the WF-system does not matter. When we use connectives $\wedge, \vee, \neg, \to$ in an APC_1-decent system P, we assume that these are expressed in the language of P.

▶ **Lemma 17.** *Each* WF *system is APC_1-decent. Moreover, for each APC_1-decent proof system P the following holds.*

1. *For every Frege rule which derives ϕ from $\phi_1, \ldots, \phi_k$, there is a* PV*-function F such that APC_1 proves that F maps each $(k+1)$-tuple $\langle \pi_1, \ldots, \pi_k, \rho \rangle$ to a P-proof of $\phi|_\rho$, where π_i is a P-proof of $\phi_i|_\rho$ for a substitution ρ replacing each atom of $\phi, \phi_1, \ldots, \phi_k$ by a formula.*
2. *There is a* PV*-function F such that APC_1 proves that F maps each pair $\langle \phi, b \rangle$, for assignment b satisfying formula ϕ, to a P-proof of $\phi(b)$.*
3. *Let π be a P-proof of $E \to \phi$, where E defines a computation of a circuit which is allowed to use atoms from ϕ as inputs but other atoms of E do not appear in ϕ, i.e. E is the conjunction of extension axioms of* EF *built on atoms from ϕ. Then, there is a $poly(|\pi|)$-size P-proof of ϕ.*

Proof. WF is known to prove efficiently its own reflection principle, cf. [15]. In order to show that it is APC_1-decent, it thus suffices to prove that it satisfies Items 1-3 from Definition 16.

Item 2 is established already in PV_1 by Σ^b_1-induction on the length of the proof π (which can be used because of $\forall\Sigma^b_1$-conservativity of S^1_2 over PV_1): F replaces each circuit C from π by $C|_\rho$ and preserves all WF-derivation rules.

Item 1 holds trivially if the given WF-system P is the WF-system P' from Definition 16. Otherwise, we use implicational completeness of P and the completeness of the language of P to simulate all $O(1)$ Frege rules of P' by $O(1)$ steps in P. (This does not require that the implicational completeness of P is provable in APC_1 because we need to simulate only $O(1)$ Frege rules of finite size). Similarly, by Σ^b_1-induction and the completeness of the language of P, we simulate each circuit in the language of P' by a circuit in the language of P and show that this simulation preserves the similarity rule. Then, given an s-size P'-proof of ϕ, we obtain a $poly(s)$-size P-proof of ϕ using the simulation of Frege rules of P', the similarity rule and dWPHP axiom, together with substituting the right circuits in Frege rules. This is done again in PV_1 by Σ^b_1-induction on the length of the P'-proof.

Item 3 follows by simulating modus ponens as in the proof of Item 1.

For the "moreover" part, see the arXiv version of the paper. ◀

APC_1-decent proof systems can be much stronger than WF. For example, consider ZFC as a propositional proof system: a ZFC-proof of propositional formula ϕ is a ZFC-proof of the statement encoding that ϕ is a tautology. We can add the reflection of ZFC to WF, i.e. we will allow WF to derive (substitutional instances of) formulas stating that "If π is a ZFC-proof of ϕ, then ϕ holds." The new system is as strong as ZFC w.r.t. tautologies and it is easy to see that it is APC_1-decent. (The reflection of the system can be proved in APC_1 extended with an axiom postulating the reflection for ZFC.)

▶ **Theorem 18** (Learning versus automatability). *Let P be an APC_1-decent proof system and assume there is a sequence of boolean functions $h = \{h_n\}_{n>n_1}$, for a constant n_1, such that P proves efficiently $\mathsf{tt}(h_n, 2^{n/4}, 1/2 - 1/2^{n/4})$. Then, for each constant K and constant $\gamma < 1$, the following statements are equivalent.*

1. **Provable learning.** *For each $k \geq 1$ and $\ell \geq K + 1$, there are 2^{Kn^γ}-size circuits A such that for each sufficiently big n, P proves efficiently*

   $$\mathsf{lear}^h_{1/2^{\ell n^\gamma}}(A, \mathsf{Circuit}[n^k], 1/2 - 1/2^{Kn^\gamma}, 1/2^{Kn^\gamma}).$$

2. **Provable automatability.** *For each $k \geq 1$, for each function $s(n) \geq 2^n$, there is a constant K' and $s^{K'}$-size circuits B such that P proves efficiently*

   $$\mathsf{aut}_P(B, \Phi, s),$$

   where Φ is the set of pairs $\langle \mathsf{tt}(f, 2^{Kn^\gamma}, 1/2 - 1/2^{Kn^\gamma}), \mathsf{tt}(f, n^k)\rangle$ for all boolean functions f with n inputs.

Proof. (**1.** $\to$ **2.**) We first prove the following statement in APC_1.

▷ Claim 19 (in APC_1). Assume that π is a P-proof of $\mathsf{lear}^y_{1/2^{\ell n^\gamma}}(A, \mathsf{Circuit}[n^k], 1/2 - 1/2^{Kn^\gamma}, \delta)$ for a circuit A and a boolean function y represented by fixed bits in formula $\mathsf{lear}^y_{1/2^{\ell n^\gamma}}(\cdot, \cdot, \cdot, \cdot)$. Further, assume that the probability that A on queries to f outputs a circuit D such that $\Pr[D(x) = f(x)] \geq 1/2 + 1/2^{Kn^\gamma}$ is $< \delta$, where the outermost probability is counted approximately with error $1/2^{\ell n^\gamma}$ using PV-function Sz and the corresponding assumptions $\mathsf{LB}_{\mathsf{tt}}$ expressing hardness of y, i.e. using formulas $\Pr^y[\cdot]_{1/2^{\ell n^\gamma}}$ for the same y as above - we treat y as a free variable here. Then there is a $poly(|\pi|)$-size P-proof of $\mathsf{tt}(f, n^k)$ or y does not satisfy the assumptions of $\Pr^y[\cdot]_{1/2^{\ell n^\gamma}}$.

To see that the claim holds, we reason in APC_1 as follows. Assume π is a P-proof of $\mathsf{lear}^y_{1/2^{\ell n^\gamma}}(A, \mathsf{Circuit}[n^k], 1/2 - 1/2^{Kn^\gamma}, \delta)$ but A on queries to f outputs a circuit $(1/2 + 1/2^{Kn^\gamma})$-approximating f with probability $< \delta$. Then, either y does not satisfy the assumptions of $\Pr^y[\cdot]_{1/2^{\ell n^\gamma}}$ or there is a trivial $2^{O(n)}$-size P-proof of $\neg\mathsf{tt}(f, n^k) \to \neg R(b)$, for predicate R from the definition of $\mathsf{lear}^y_{1/2^{\ell n^\gamma}}(A, \mathsf{Circuit}[n^k], 1/2 - 1/2^{Kn^\gamma}, \delta)$ and a complete assignment b. The P-proof is obtained by evaluating function Sz which counts the confidence of A - note that functions f, y and algorithm A are represented inside P by fixed bits so the P-proof just evaluates a $2^{O(n)}$-size circuit on some input, which is possible by Lemma 17, Item 2. (We use here also the fact that APC_1 knows that the probability statement expressed by function Sz translates to $\neg R$ in the negation normal form.) The formula $\neg\mathsf{tt}(f, n^k) \to \neg R(b)$ is obtained from $\neg R(b)$ by an instantiation of a single Frege rule, which is available by Lemma 17, Item 1. Applying again Lemma 17, Item 1, from a P-proof of $\mathsf{lear}^y_{1/2^{\ell n^\gamma}}(A, \mathsf{Circuit}[n^k], 1/2 - 1/2^{Kn^\gamma}, \delta)$ and a P-proof of $\neg\mathsf{tt}(f, n^k) \to \neg R(b)$, we construct a $poly(|\pi|)$-size P-proof of $\mathsf{tt}(f, n^k)$. This proves the claim.

Next, observe that APC_1 proves that "If for a sufficiently big n and $\ell \geq K + 1$ the probability that a circuit A on queries to f outputs a circuit $(1/2 + 1/2^{Kn^\gamma})$-approximating f is $\geq 1/2^{Kn^\gamma}$, where the probability is counted approximately with error $1/2^{\ell n^\gamma}$ using PV-function Sz and the corresponding assumptions $\mathsf{LB}_{\mathsf{tt}}$, then there is a circuit of size $|A|$ $(1/2 + 1/2^{Kn^\gamma})$-approximating f or y does not satisfy the assumptions of $\Pr^y[\cdot]_{1/2^{\ell n^\gamma}}$." This is because, if such a circuit did not exist, a trivial surjection would witness that 2^m times the probability that A outputs a circuit $(1/2 + 1/2^{Kn^\gamma})$-approximating f, counted approximately with error $1/2^{\ell n^\gamma}$ using function Sz, is $\preceq_{1/2^{\ell n^\gamma}} 0$. Here, 2^m is the domain of the surjection. By Proposition 11 1.*ii*), this would imply $2^m/2^{Kn^\gamma} < 2^{m+1}/2^{\ell n^\gamma}$, which is a contradiction for $\ell \geq K + 1$ and sufficiently big n.

Therefore, Claim 19 implies that APC_1 proves that "For sufficiently big n and $\ell \geq K+1$, if π is a P-proof of $\mathsf{lear}^{y}_{1/2^{\ell n^\gamma}}(A, \mathsf{Circuit}[n^k], 1/2 - 1/2^{Kn^\gamma}, 1/2^{Kn^\gamma})$ for circuits A of size 2^{Kn^γ}, then there is a P-proof of $\mathsf{tt}(f, n^k)$ or there is a 2^{Kn^γ}-size circuit $(1/2 + 1/2^{Kn^\gamma})$-approximating f or there is a $2^{||y||/4}$-size circuit $(1/2+1/2^{||y||/4})$-approximating y or $||y|| \leq n_0$ or $||y|| \neq S(\cdot, 2^m, 2^{2^{\ell n^\gamma}})$;" for n_0 from Definition 14. Since this is a Σ^b_1-statement, by Lemma 12, PV_1 proves the same statement with the existential quantifiers witnessed by PV-functions assuming they are given a boolean function h' which is hard for circuits of size $2^{||h'||/4}$, for sufficiently big $|h'|$.

The last statement provable in PV_1 is Π^b_1 so we can translate it to EF. This gives us $poly(|\pi|, 2^n)$-size circuits B_0 such that for sufficiently big n, EF proves efficiently

"If $\ell \geq K+1$,
h' is not computable by a particular circuit of size $2^{||h'||/4}$, $|h'|$ is sufficiently big,
y is not $(1/2 + 1/2^{||y||/4})$-approximable by a particular circuit of size $2^{||y||/4}$, $||y|| > n_0$,
$||y|| = S(\cdot, 2^m, 2^{2^{\ell n^\gamma}})$
and π is a P-proof of $\mathsf{lear}^{y}_{1/2^{\ell n^\gamma}}(A, \mathsf{Circuit}[n^k], 1/2 - 1/2^{Kn^\gamma}, 1/2^{Kn^\gamma})$ for 2^{Kn^γ}-size A,
then B_0 (given π, h' and formula $\mathsf{tt}(f, n^k)$) outputs a P-proof of $\mathsf{tt}(f, n^k)$
or B_0 outputs a 2^{Kn^γ}-size circuit $(1/2 + 1/2^{Kn^\gamma})$-approximating f.".[9]

If we now assume that P proves efficiently $\mathsf{tt}(h_n, 2^{n/4}, 1/2 - 1/2^{n/4})$ and that Item 1 holds, then by Definition 16, Items 1-3, for each k, there are p-size circuits B_1 such that for each sufficiently big n, P proves efficiently "B_1 (given just formula $\mathsf{tt}(f, n^k)$) outputs a P-proof of $\mathsf{tt}(f, n^k)$ or B_1 outputs a 2^{Kn^γ}-size circuit $(1/2 + 1/2^{Kn^\gamma})$-approximating f." (We use here also the fact that PV_1 knows that $S(\cdot, 2^m, 2^{2^{\ell n^\gamma}})$ depends just on n.) Consequently, since P proves efficiently its own reflection, for each sufficiently big n, P proves efficiently that "if π is a P-proof of $\mathsf{tt}(f, 2^{Kn^\gamma}, 1/2 - 1/2^{Kn^\gamma})$ then B_1 outputs a P-proof of $\mathsf{tt}(f, n^k)$".[10] Finally, we make the P-proofs work for all n by increasing the size of B_1 by a constant. This finishes the proof of case $(1. \to 2.)$.

$(\mathbf{2.} \to \mathbf{1.})$ The opposite implication can be obtained from Lemma 20 and 21 which formalize Theorem 4.

▶ **Lemma 20.** *For each $d \geq 2$, each $k \geq 10d$ and each sufficiently big c, there is a PV-function L such that for each PV-function B the theory APC_1 proves: Assume the reflection principle for P holds, π is a P-proof of*

$$\mathsf{tt}(h_n \oplus g, 2^{Kn^\gamma}, 1/2 - 1/2^{Kn^\gamma}) \vee \mathsf{tt}(g, 2^{Kn^\gamma}), \tag{1}$$

where g is represented by free variables, and that B automates P on Φ up to size $|\pi|^c$. Then, for prime $n^d \leq p \leq 2n^d$, where $2^{n^d} \in Log$, for $\delta^{-1} \in Log$ such that $\delta < 1/N^3 = 2^{3n}$, $L(B, \pi, p)$ is a $poly(2^n, |\pi|)$-size circuit learning circuits with $m = n^d$ inputs and size $m^{k/10d}$,

[9] Formally, the statement "If a particular assignment a satisfies formula ϕ, then formula ψ holds" means that "If a is the output of a computation of a specific circuit W (where W is allowed to use as inputs atoms from ψ, but other atoms of W do not appear in ψ), and a satisfies ϕ, then ψ". By Lemma 17, Item 3, if we assume that the statement is efficiently provable in P and that P proves efficiently ϕ, then P proves efficiently ψ. Note also that for $A, B \in \Sigma^b_0$, the translation $||A \to B||$ is $\neg||\neg A|| \to ||B||$, which might not be the same formula as $||A|| \to ||B||$. Nevertheless, EF proves efficiently that $E \to (||A|| \leftrightarrow \neg||\neg A||)$, where E postulates that auxiliary variables of $||A||$ encode the computation of a suitable circuit. Therefore, in systems like EF or P, if we have a proof of $||A||$ and $||A \to B||$, we can remove the assumption E after proving $E \to ||B||$, assuming "non-input" variables of E do not occur in $||B||$, and ignore the difference between $||A||$ and $\neg||\neg A||$.

[10] It is assumed that the encoding of the statement coincides with the encoding of aut_P.

with confidence $1/N^4$*, up to error* $1/2 - 1/N^3$*, where the confidence is counted approximately with error* δ *using* PV*-function* Sz *and the corresponding assumptions* $\mathsf{LB}_{\mathsf{tt}}$ *expressing hardness of a boolean function* y*, i.e. using formulas* $\Pr^y[\cdot]_\delta$*.*

▶ **Lemma 21** ("XOR trick")**.** PV_1 *proves that for all boolean functions* g, h'' *with* n *inputs, for sufficiently big* n*,* $\mathsf{LB}_{\mathsf{tt}}{}'(h'', 3 \cdot 2^{Kn^\gamma}, 2^n(1/2 - 1/2^{Kn^\gamma}))$ *implies* $\mathsf{LB}_{\mathsf{tt}}{}'(h'' \oplus g, 2^{Kn^\gamma}, 2^n(1/2 - 1/2^{Kn^\gamma})) \vee \mathsf{LB}_{\mathsf{tt}}{}'(g, 2^{Kn^\gamma})$*, where* $\mathsf{LB}_{\mathsf{tt}}{}'$ *is obtained from* $\mathsf{LB}_{\mathsf{tt}}$ *by setting* $n_0 = 0$ *and skipping the universal quantifier on* n*, i.e. all formulas* $\mathsf{LB}_{\mathsf{tt}}{}'$ *refer to the same* n*.*

The proof of Lemma 21 is almost immediate: By Σ^b_1-induction, a 2^{Kn^γ}-size circuit C_1 computing g and a 2^{Kn^γ}-size circuit C_2 $(1/2+1/2^{Kn^\gamma})$-approximating $h'' \oplus g$ can be combined into a circuit $C_1 \oplus C_2$ of size $3 \cdot 2^{Kn^\gamma}$ which $(1/2 + 1/2^{Kn^\gamma})$-approximates h''.

The implication (2. $\to$ 1.) can be derived from Lemma 20 and 21 as follows. Since the APC_1-provable statement from Lemma 20 is Σ^b_1, similarly as above, we can witness it and translate to EF at the expense of introducing an additional assumption about the hardness of a boolean function h'. That is, for each p-size circuit B there are $poly(|\pi|, 2^{n^d})$-size circuits A and $poly(|\pi|, 2^{n^d})$-size EF-proofs of

"If the reflection principle for P is satisfied by a particular assignment,
π is a P-proof of (1),
h' is not computable by a particular circuit of size $2^{||h'||/4}$, $|h'|$ is sufficiently big,
y is not $(1/2 + 1/2^{||y||/4})$-approximable by a particular circuit of size $2^{||y||/4}$, $||y|| > n_0$,
$||y|| = S(\cdot, \cdot, 2^{|\delta^{-1}|})$
and $n^d \le p \le 2n^d$ is a prime,
then, for $\delta < 1/N^3$, $\mathsf{lear}^y_\delta(L(B, \pi, p), \mathsf{Circuit}(m^{k/10d}), 1/2 - 1/N^3, 1/N^4)$
or $A(B, \pi, h')$ outputs a falsifying assignment of $\mathsf{aut}_P(B, \Phi, |\pi|^c)$.".

Analogously, PV_1-proof from Lemma 21 yields p-size EF-proofs of the implication "$\mathsf{tt}(h_n, 3 \cdot 2^{Kn^\gamma}, 1/2 - 1/2^{Kn^\gamma})$ is falsified by a particular assignment or (1) holds". By the assumption of the theorem, there are p-size P-proofs of $\mathsf{tt}(h_n, 3 \cdot 2^{Kn^\gamma}, 1/2 - 1/2^{Kn^\gamma})$ for sufficiently big n. Hence, by Definition 16, Items 1-3, there are p-size P-proofs of (1) for sufficiently big n. As P proves efficiently also its own reflection, this yields $poly(2^{n^d})$-size P-proofs of

"If h' is not computable by a particular circuit of size $2^{||h'||/4}$, $|h'|$ is sufficiently big,
y is not $(1/2 + 1/2^{||y||/4})$-approximable by a particular circuit of size $2^{||y||/4}$, $||y|| > n_0$,
$||y|| = S(\cdot, \cdot, 2^{|\delta^{-1}|})$
and $n^d \le p \le 2n^d$ is a prime,
then, for $\delta < 1/N^3$, $\mathsf{lear}^y_\delta(L(B, \pi, p), \mathsf{Circuit}(m^{k/10d}), 1/2 - 1/N^3, 1/N^4)$
or $A(B, \pi, h')$ outputs a falsifying assignment of $\mathsf{aut}_P(B, \Phi, |\pi|^c)$.".

By Bertrand's postulate there is a prime $n^d \le p \le 2n^d$, so EF proves that p is a prime by a trivial $2^{O(n^d)}$-size proof which verifies all possible divisors. Therefore, choosing $d > 1/\gamma$, Item 2 and p-size P-proofs of $\mathsf{tt}(h_n, 2^{n/4}, 1/2 - 1/2^{n/4})$ imply Item 1.

It remains to prove Lemma 20.

Suppose π is a P-proof of (1). Assuming that B automates P on Φ, we want to obtain a $\mathsf{P/poly}$-natural property useful against $\mathsf{Circuit}[n^k]$. To do so, observe (first, without formalizing it in APC_1) that for each g, B can be used to find a proof of $\mathsf{tt}(h_n \oplus g, n^k)$ or to recognize that $\mathsf{tt}(g, 2^{Kn^\gamma})$ holds - if $\mathsf{tt}(g, 2^{Kn^\gamma})$ was falsifiable, there would exist a $poly(|\pi|)$-size P-proof of $\mathsf{tt}(h_n \oplus g, 2^{Kn^\gamma}, 1/2 - 1/2^{Kn^\gamma})$ obtained by substituting the falsifying assignment to the proof of (1) and thus B would find a short proof of $\mathsf{tt}(h_n \oplus g, n^k)$, for

sufficiently big c. Since for random g, both $h_n \oplus g$ and g are random functions, we know that with probability $\geq 1/2$ B finds a proof of $\mathsf{tt}(h_n \oplus g, n^k)$ or with probability $\geq 1/2$ it recognizes that $\mathsf{tt}(g, 2^{Kn^\gamma})$ holds. In both cases, B yields a $\mathsf{P/poly}$-natural property useful against $\mathsf{Circuit}[n^k]$.

Let us formalize reasoning from the previous paragraph in $\mathsf{APC_1}$. Let $N = 2^n$ and B' be the algorithm which uses B to search for P-proofs of $\mathsf{tt}(h_n \oplus g, n^k)$ or to recognize that $\mathsf{tt}(g, 2^{Kn^\gamma})$ holds. B' uses π to know how long it needs to run B. Assume for the sake of contradiction that

$$G_0 := \{g \oplus h_n \mid B'(g) \text{ outputs a } P\text{-proof of } \mathsf{tt}(h_n \oplus g, n^k)\} \preceq_0 2^N/3$$

$$G_1 := \{g \mid B'(g) \text{ recognizes that } \mathsf{tt}(g, 2^{Kn^\gamma}) \text{ holds}\} \preceq_0 2^N/3.$$

It is easy to construct a surjection S witnessing that $2^N \preceq_0 G_0 \cup G_1$: S maps $g \in G_1$ to g and $g \in G_0$ to $g \oplus h_n$. Following the argument above we conclude that S is a surjection: for each g, either $g \in G_1$ (and $S(g) = g$) or $g \oplus h_n \in G_0$ (and $S(g \oplus h_n) = g$). Here, we use the assumption that $\mathsf{APC_1}$ knows that P admits the substitution property and simulates Frege rules. Thus, by Proposition 10 *iv*), $2^N \preceq_0 2 \cdot 2^N/3$, which yields a contradiction by Proposition 11 1.*ii*). Consequently, by Proposition 11 1.*i*), $G_0 \succeq_\delta 2^N/3$ or $G_1 \succeq_\delta 2^N/3$ for $\delta^{-1} \in \mathit{Log}$. Since $g \in G_0$ and $g \in G_1$ are decidable by p-size circuits and we assume the reflection principle for P (which implies that G_0 is useful), this means that either G_0 or G_1 defines a $\mathsf{P/poly}$-natural property useful against $\mathsf{Circuit}[n^k]$.

Finally, by the $\mathsf{APC_1}$-formalization of [8], Theorem 15, we obtain $\mathit{poly}(2^n, |\pi|)$-size circuit $L(B, \pi, p)$ learning circuits with $m = n^d$ inputs and size $n^{k/10}$, over the uniform distribution, with membership queries, confidence $1/N^4$, up to error $1/2 - 1/N^3$. ◀

▶ **Corollary 22.** *Assume there is a* $\mathsf{NE} \cap \mathsf{coNE}$*-function* $h_n : \{0,1\}^n \mapsto \{0,1\}$ *such that for each sufficiently big* n*,* h_n *is not* $(1/2 + 1/2^{n/4})$*-approximable by* $2^{n/4}$*-size circuits. Then there is a proof system* P *(which can be described explicitly*[11] *given the definition of* h_n*) such that for each constant* K *and* $\gamma < 1$*, Items 1 and 2 from Theorem 18 are equivalent. Moreover, the equivalence holds for each* $\mathsf{APC_1}$*-decent system simulating* P*.*

Abstract

We introduce a new data structure for answering connectivity queries in undirected graphs subject to batched vertex failures. Precisely, given any graph G and integer parameter k, we can in fixed-parameter time construct a data structure that can later be used to answer queries of the form: "are vertices s and t connected via a path that avoids vertices $u_1, \ldots, u_k$?" in time $2^{\mathcal{O}(k)}$. In the terminology of the literature on data structures, this gives the first deterministic data structure for connectivity under vertex failures where for every fixed number of failures, all operations can be performed in constant time.

With the aim to understand the power and the limitations of our new techniques, we prove an algorithmic meta theorem for the recently introduced *separator logic*, which extends first-order logic with atoms for connectivity under vertex failures. We prove that the model-checking problem for separator logic is fixed-parameter tractable on every class of graphs that exclude a fixed topological minor. We also show a weak converse. This implies that from the point of view of parameterized complexity, under standard complexity theoretical assumptions, the frontier of tractability of separator logic is almost exactly delimited by classes excluding a fixed topological minor.

The backbone of our proof relies on a decomposition theorem of Cygan, Lokshtanov, Pilipczuk, Pilipczuk, and Saurabh [SICOMP '19], which provides a tree decomposition of a given graph into bags that are unbreakable. Crucially, unbreakability allows to reduce separator logic to plain first-order logic within each bag individually. Guided by this observation, we design our model-checking algorithm using dynamic programming over the tree decomposition, where the transition at each bag amounts to running a suitable model-checking subprocedure for plain first-order logic. This approach is robust enough to provide also an extension to efficient enumeration of answers to a query expressed in separator logic.

1 Introduction

1.1 Connectivity under vertex failures

In many applications, we do not need to answer a query once but rather need to repeatedly answer queries over dynamically changing data. A prime example are databases, where a database is repeatedly modified and queried by the users. In most cases, the modifications to the database can be expected to be small compared to its size, which suggests that in a preprocessing step, we can set up a data structure that is efficiently updated after each modification and that allows for efficient querying. In 1997, Frigioni and Italiano introduced the *dynamic subgraph model* [22], which allows to conveniently model such dynamic situations in the particular case of connectivity in network infrastructures that are subject to node or link failures. This model, which has been studied intensively in the data structures community under the name of *connectivity oracles under vertex failures*, is as follows. We are given a graph G and an integer k. We imagine that G is a network in which at every moment, at most k vertices (or edges) are inactive (are subject to *failures*). The goal is to construct a data structure that supports the following two operations. First, one can *update* G by resetting the set of failed vertices to a given set of size at most k. Second, one can *query* G by asking, for a given pair of vertices s and t, whether s and t can be connected by a path that avoids the failed vertices.

Following the introduction of the problem by Frigioni and Italiano [22] and the more general problem of batched vertex or edge failures by Pătraşcu and Thorup [37][1], there has been a long line of work on data structures for connectivity oracles under vertex and edge failures. We refer to a remarkably comprehensive literature overview in the work of Duan and Pettie [17], which also provides the currently best bounds for the problem as far as combinatorial and deterministic data structures are concerned. Their data structure can be initialized in time $\mathcal{O}(|G|\|G\| \cdot \log|G|)$, takes $\mathcal{O}(k\|G\| \log|G|)$ space, and supports updates in $\mathcal{O}(k^3 \log^3|G|)$ time and queries in $\mathcal{O}(k)$ time. Here $|G|$ is the vertex count of G and $\|G\|$ is the joint number of edges and vertices in G. These bounds can be slightly improved at the cost of allowing randomization, however, the polylogarithmic dependency on the size of the graph in the update time persists. As noted in [17], from known results it is possible to derive data structures with constant time complexity of operations for $k \leqslant 3$ (or $k \leqslant 4$ for edge failures), but, citing their words, "scaling these solutions up, even to an arbitrarily large constant k, becomes prohibitively complex, even in the simpler case of edge failures."

Recently, van den Brand and Saranurak [42] proposed a very different approach to the problem, using which they obtained a randomized data structure that can be initialized in time $\mathcal{O}(|G|^\omega)$, takes $\mathcal{O}(|G|^2 \log|G|)$ space, and supports updates in $\mathcal{O}(k^\omega)$ time and queries in $\mathcal{O}(k^2)$ time (where ω is the exponent for the boolean matrix multiplication).

In particular, the update and the query time are constant for constant k; to the best of our knowledge, this is the only data structure that has this property known so far. The approach is algebraic and, simplifying it substantially, boils down to storing a matrix of

[1] Strictly speaking, in [37] Pătraşcu and Thorup considered only edge failures. To the best of our knowledge, (batched) vertex failures on general graphs were first investigated by Duan and Pettie [16].

counts of walks between pairs of vertices and extracting answers to queries using algebraic operations on those counts. To manipulate the counts efficiently, one needs to work on their short hashes, for instance in the form of elements from a fixed finite field. This introduces randomization and avoiding it within this methodology seems difficult. We remark that the data structure of van den Brand and Saranurak [42] works even for the more general problem of reachability in directed graphs under vertex failures, and can handle arc insertions.

As the first main contribution of this paper, we prove the following theorem. Note that querying whether two vertices are connected by a path avoiding failed vertices is equivalent to an update followed by a connectivity query in the terminology of previous works [42, 16, 17, 37].

▶ **Theorem 1.1.** *Given a graph G and an integer k, one can in time $2^{2^{\mathcal{O}(k)}} \cdot |G|^2\|G\|$ construct a data structure that may answer the following queries in time $2^{\mathcal{O}(k)}$: given $s,t \in V(G)$ and k vertices $u_1,\ldots,u_k$ of G, are s and t connected in G by a path that avoids the vertices $u_1,\ldots,u_k$? The space usage of the data structure is $2^{2^{\mathcal{O}(k)}} \cdot \|G\|$.*

Note that in Theorem 1.1, for every fixed k, all operations are supported in constant time (which is exponential in k). Also, the data structure is entirely deterministic and purely combinatorial. To the best of our knowledge, this is the first deterministic (non-randomized) data structure with constant time queries. Note also that for a fixed k, the space usage of our data structure is linear in the size of the graph, as opposed to the quadratic dependency in the result of van den Brand and Saranurak [42].

We remark that in the first version of this paper [36], the query time in Theorem 1.1 is stated as $2^{2^{\mathcal{O}(k)}}$ instead of $2^{\mathcal{O}(k)}$. The improved query time is due to an improvement in one of the ingredients of our proof (see Theorem 2.4 below), provided by Wojciech Przybyszewski.

The doubly-exponential dependencies on k may seem high, however we also derive two variants of our data structure that achieve the following tradeoffs:

- The space usage and the query time can be reduced to $2^{\mathcal{O}(k^2)} \cdot \|G\|$ and $k^{\mathcal{O}(1)}$, respectively, while the construction time becomes $2^{\mathcal{O}(k^2)} \cdot |G|^{\mathcal{O}(1)}$.
- The space usage and the query time can be replaced with $k^{\mathcal{O}(1)} \cdot |G|^2$ and $k^{\mathcal{O}(1)}$, respectively, while the construction time becomes $2^{\mathcal{O}(k \log k)} \cdot |G|^{\mathcal{O}(1)}$.

Note the first statement offers both more efficient queries (the query time is even polynomial in k), and smaller space usage. The slight drawback is that the polynomial factor in the construction time becomes unspecified, but it is still of the form $|G|^{\mathcal{O}(1)}$. In the second statement, the space usage becomes polynomial in k at the expense of making it quadratic in $|G|$. The tradeoffs are obtained by a non-trivial replacement of particular components in the proof of Theorem 1.1; see the discussion in Section 6 of the full version. We consider the statement provided in Theorem 1.1 to be the cleanest formulation, hence we put a primary focus on it.

As for the proof of Theorem 1.1, our approach is completely new compared to the previous approaches [42, 16, 17, 37]. Our key combinatorial observation is that connectivity queries over a constant number k of vertex failures can be evaluated in constant time provided the underlying graph G is sufficiently well-connected. The requirement on the well-connectedness of G depends on the number k. Obviously, there is no guarantee that the input graph G satisfies this property. We therefore use a decomposition theorem of Cygan, Lokshtanov, Pilipczuk, Pilipczuk, and Saurabh [15] that (roughly) states the following (see Theorem 2.1). For every graph G and fixed number k, there is a tree decomposition where every intersection of adjacent bags has bounded size and every bag is well-connected for parameter k. Moreover, such a tree decomposition can be computed in time $2^{\mathcal{O}(k^2)}|G|^2\|G\|$. The data structure of

Theorem 1.1 is constructed around the tree decomposition $\mathcal{T}$ provided by the theorem of Cygan et al. [15]. Intuitively speaking, whether s and t are connected via a path that avoids the vertices $u_1, \ldots, u_k$ can be decided using dynamic programming over $\mathcal{T}$. We employ known techniques developed for answering queries on trees in constant time, for instance a deterministic variant of Simon's factorization [12], to be able to compute the outcome of this dynamic programming efficiently for any query given on input.

We provide a more detailed overview of the proof of Theorem 1.1 in Section 2. All proofs are provided in the full version [36] (numbers referring to `https://arxiv.org/abs/2111.03725v1`).

1.2 Algorithmic meta theorems

Once an algorithmic technique has been applied to solve a specific problem, it is very desirable to understand the power and the limitations of that technique, that is, to understand which other problems can be solved with that technique and which problems cannot. An approach to this very general goal is to prove an *algorithmic meta theorem*: a theorem that establishes tractability for a whole class of problems, possibly on certain restricted input instances. As logic allows to conveniently define classes of algorithmic problems, namely, the class of all problems that can be expressed in the logic under consideration, algorithmic meta theorems are often formulated as model-checking problems for a logic. In the *model-checking problem* for a logic $\mathcal{L}$ on a class of graphs $\mathscr{C}$ we are given a graph $G \in \mathscr{C}$ and a sentence $\varphi \in \mathcal{L}$, and the task is to decide whether φ holds in G. The archetypal result of this form is a result of Courcelle stating that every formula of monadic-second order logic (MSO_2) can be evaluated in linear time on all graphs whose treewidth is bounded by some fixed constant [13]. This result has been extended to various other logics $\mathcal{L}$ and graph classes $\mathscr{C}$.

This approach to algorithmic meta theorems can be made precise in the language of parameterized complexity, as follows. Say that $\mathcal{L}$ is *tractable* on $\mathscr{C}$ if the model-checking problem for $\mathscr{C}$ and $\mathcal{L}$ is *fixed-parameter tractable (fpt)*: it can be solved in time $f(\varphi) \cdot \|G\|^c$, for some computable function f and a constant c, both depending only on $\mathscr{C}$. Results about tractability of a logic $\mathcal{L}$ on a class $\mathscr{C}$ imply the tractability of a vast array of problems – namely all problems that can be expressed in the logic $\mathcal{L}$ – on a given class of graphs. For instance, if model-checking *first-order logic* (FO) is fpt on a class of graphs $\mathscr{C}$, then in particular the dominating set problem is fpt on $\mathscr{C}$, since the existence of a dominating set of size k can be expressed by a first-order sentence with $k+1$ quantifiers that range over the vertices of the graph. Similarly, the independent set problem is then also fpt on $\mathscr{C}$. On the other hand, if the more powerful logic MSO_2 is tractable on a class of graphs $\mathscr{C}$, then the 3-colorability problem, or the hamiltonicity problem are polynomial-time solvable on $\mathscr{C}$, since both those problems can be expressed using an MSO_2 sentence, whose quantifiers that range over *sets* of vertices and edges of the graph.

There has been a long line of work on fixed-parameter tractability of model-checking FO, as it is arguably the most fundamental logic. This culminated in the work of Grohe, Kreutzer and Siebertz [24], who proved that this problem is fixed-parameter tractable on every class that is *nowhere dense*. Those classes include for example the class of planar graphs, or every class with bounded maximum degree, or of bounded genus. Without going into details, nowhere denseness is a general notion of uniform sparseness in graphs, and it is broader than most well-studied concepts of sparseness considered in structural graph theory, such as excluding a fixed (topological) minor. As observed by Dvořák et al. [19], the result of Grohe et al. is tight in the following sense: whenever $\mathscr{C}$ is not nowhere dense and is closed under taking subgraphs, then FO model-checking on $\mathscr{C}$ is as hard as on general graphs, that

is, AW[⋆]-hard. This means that as far as subgraph-closed classes are concerned, sparsity – described formally through the notion of nowhere denseness – exactly delimits the area of tractability of FO and the limits of the locality method for FO model-checking.

The aforementioned classic theorem of Courcelle [13] states that the model-checking problem for MSO_2 is fixed-parameter tractable on a class $\mathscr{C}$ if $\mathscr{C}$ has bounded treewidth. The proof translates the given sentence into a suitable tree automaton working on a tree decomposition of the input graph; this approach brings a wide range of automata-based tools to the study of MSO_2 on graphs. Again, as shown by Kreutzer and Tazari [31] and Ganian et al. [23], under certain complexity assumptions this is (almost) the most one could hope for: on subgraph-closed classes whose treewidth is poly-logarithmically unbounded, model-checking of MSO_2 becomes intractable from the parameterized perspective. So for MSO_2, bounded treewidth (almost) delimits the frontier of tractability, at least for subgraph-closed classes, and automata-based techniques exactly explain what can be done algorithmically.

With the aim to provide a meta theorem that captures the essence of the techniques developed to answer connectivity under vertex failures, we search for a logic that can express these queries. It is easy to see that MSO_2 is strong enough, but in fact, MSO_2 is much stronger and as explained above, it is intractable beyond graphs of bounded treewidth. On the other hand, FO can only express local properties and in particular, it cannot even express the very simple query of whether two vertices are in the same connected component. This naturally leads to an extension of FO that may use connectivity under vertex failures as atomic formulas. Such a logic was very recently introduced independently by Bojańczyk [6] and by Schirrmacher et al. [39] under the name *separator logic*, and denoted $\mathsf{FO}+\mathsf{conn}$. This logic extends FO by predicates $\mathsf{conn}_k(s,t,u_1,\ldots,u_k)$ (one for each $k \geqslant 0$) with the following semantics: if $s,t,u_1,\ldots,u_k$ are vertices of a graph G, then $\mathsf{conn}_k(s,t,u_1,\ldots,u_k)$ holds if and only if there is a path that connects s with t and does not pass through any of the vertices $u_1,\ldots,u_k$. Thus, separator logic involves very basic connectivity queries that have a global character, unlike plain FO, which is local. As a consequence, separator logic can express many interesting algorithmic properties, such as acyclicity, k-connectivity, the feedback vertex set problem parameterized by solution size and many recently studied elimination distance problems [9]. On the other hand, while $\mathsf{conn}_k(s,t,u_1,\ldots,u_k)$ predicates are expressible in MSO_2, it is no surprise that the expressive power of $\mathsf{FO}+\mathsf{conn}$ is strictly weaker than that of MSO_2. For example, MSO_2 can express bipartiteness, while $\mathsf{FO}+\mathsf{conn}$ cannot [39, Theorem 3.11]. Separator logic is also incomparable with the recently introduced compound logic [20]. While compound logic can express the atomic connectivity predicates under vertex failures, it is not closed under negation. On the other hand, compound logic can express the exclusion of minors, a property not expressible in separator logic.

As the second main result of the paper, we prove an algorithmic meta theorem for separator logic. We show that the frontier of tractability of $\mathsf{FO}+\mathsf{conn}$ is almost exactly delimited by classes of graphs that exclude a fixed topological minor. More precisely, we prove the following complementary results.

▶ **Theorem 1.2.** *Let $\mathscr{C}$ be a class of graphs that exclude a fixed graph as a topological minor. Then given $G \in \mathscr{C}$ and an $\mathsf{FO}+\mathsf{conn}$ sentence φ, one can decide whether φ holds in G in time $f(\varphi)\cdot\|G\|^3$, where f is a computable function depending on $\mathscr{C}$.*

Our result implies e.g. the recent result about elimination distance to bounded degree [3], but it is much more general as it unifies in particular all elimination distance problems to classes definable in separator logic on classes that exclude a topological minor. Note that it does not subsume the result of [27] as e.g. the elimination distance to bipartite graphs and vertex planarization cannot be expressed by separator logic.

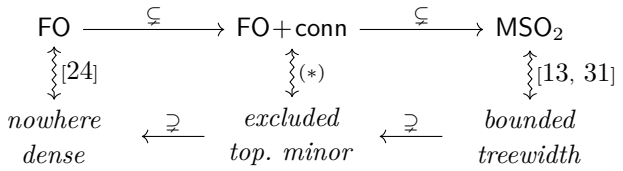

Figure 1 Correspondences between logics and properties of graph classes. An arrow $\mathcal{L} \rightsquigarrow \mathcal{P}$ between a logic $\mathcal{L}$ and a property $\mathcal{P}$ of graph classes denotes a correspondence: the logic $\mathcal{L}$ is tractable on a graph class $\mathscr{C}$ if and, under additional assumptions, only if, the class $\mathscr{C}$ has the property $\mathcal{P}$. Our result is the central correspondence $(*)$.

For the lower bound, we will need a technical assumption. We say that a class $\mathscr{C}$ admits *efficient encoding of topological minors* if for every graph H there exists $G \in \mathscr{C}$ such that H is a topological minor of G, and, given H, such G together with a suitable topological minor model can be computed in time polynomial in $|H|$. Note that in particular such G can be only polynomially larger than H.

▶ **Theorem 1.3.** *Let $\mathscr{C}$ be a subgraph-closed class of graphs that admits efficient encoding of topological minors. Then the model-checking of* $\mathsf{FO}{+}\mathsf{conn}$ *on $\mathscr{C}$ is* $\mathsf{AW}[\star]$*-hard, even for the fragment that uses only* conn_k *predicates with $k \leqslant 2$.*

On the one hand, these results show that separator logic is a natural logic whose expressive power lies strictly between FO and MSO_2, and which corresponds, in the sense described above, to a natural property of classes of graphs that lies between bounded treewidth and nowhere denseness, see Figure 1. On the other hand, the proof of Theorem 1.2 provides a general meta-explanation of the technique of dynamic programming over tree decompositions with unbreakable parts. In particular, the tractability result provided by Theorem 1.2 generalizes several recent algorithmic results for concrete problems expressible in separator logic [3, 10, 32]. However, there are some concrete problems where the general methodology non-trivially applies and which seem not to be captured by our meta-theorem [1, 27].

The proof of Theorem 1.3 is easy (see Section 3), so we focus on sketching the proof of Theorem 1.2, which is the main technical contribution of the second part of the paper. Let us fix an $\mathsf{FO}{+}\mathsf{conn}$ sentence φ, and let $k+2$ be the maximum arity of connectivity predicates appearing in φ. Again, the key observation is that conn_k predicates can be rewritten to plain FO provided the graph is well-connected, and the reason for this is the same combinatorial observations that underlies the proof of Theorem 1.1. Coming back to our dynamic programming on the tree decomposition, we choose to present it using a new framework based on automata, as this brings us closer to the classic understanding of logic on tree-decomposable graphs. Intuitively, the automaton processes a given tree in a bottom-up manner, but we assume that on the children of every node there is an additional structure of a graph. We say that such trees are *augmented* with graphs. When the automaton processes a node x, it chooses a transition based on an FO query executed on the graph on the children of x, where each child is labeled with the state computed for it before in the run. Then testing whether a formula $\varphi \in \mathsf{FO}{+}\mathsf{conn}$ holds on a graph G is reduced to deciding whether an automaton constructed from φ accepts such an *augmented tree*, constructed from the tree decomposition provided by the theorem of Cygan et al. [15]. The run of the automaton can be computed efficiently when the graphs augmenting the tree admit efficient FO model-checking, which is the case when the input graph excludes a fixed topological minor.

The benefit of this approach is that other questions related to the logic FO+conn can be reduced in the same way to questions about tree automata over augmented trees. We showcase this by proving that given an FO+conn query $\varphi(\bar{x})$ with free variables and a graph G from a fixed topological-minor-free class $\mathscr{C}$, the answers to $\varphi(\bar{x})$ on G can be enumerated with constant delay after fpt preprocessing (see Theorem 8.2 of the full version for a precise statement). Similarly, the formula $\varphi(\bar{x})$ can be queried in constant time after fpt preprocessing (see Theorem 8.1 of the full version). In general, we believe that the framework of automata over augmented trees may be of independent interest, as it seems to be a convenient model for understanding dynamic programming procedures over tree-decomposable structures.

Similar fpt query-answering and enumeration algorithms for plain FO have been obtained for classes with bounded expansion [30, 41], low degree [18], and nowhere dense classes [40] and for MSO_2 on trees and graphs of bounded treewidth [5, 29, 4]. Our general approach based on augmented trees allows us to generalize those results to trees that are augmented with graphs coming from a nowhere dense class, and to a certain logic combining the power of MSO on trees and FO on graphs.

Let us comment on the novelty of using the decomposition theorem of Cygan et al. [15]. The result of Cygan et al. [15] has been used several times for various graph problems [14, 15, 35, 33, 38]. Our application is the most similar to (and in fact, draws inspiration from) the work of Lokshtanov et al. [34], who proved the following statement: for every CMSO_2 sentence φ and $k \in \mathbb{N}$, model-checking φ on general graphs can be reduced to model-checking φ on (q,k)-unbreakable graphs, where q is a constant depending on φ and k. As FO+conn is subsumed by CMSO_2, this result can be almost applied to establish Theorem 1.2. The caveat is that the unbreakable graph output by the reduction needs to admit efficient FO model-checking so that the considered FO+conn sentence can be decided in fpt time after rewriting it to plain FO. In essence, we show that it is possible to guarantee this provided the input graph excludes a fixed topological minor. We remark that the work of Lokshtanov et al. [34] does not use the decomposition theorem of Cygan et al. [15] directly, but relies on its conceptual predecessor, the *recursive understanding* technique [11, 28].

Organization. In the extended abstract we give a detailed overview over the proofs of our main results: Theorem 1.1, Theorem 1.2, and Theorem 1.3. We provide all formal definitions and proofs in the full version [36]. The theorem numbers for references in the full version are provided in parenthesis.

2 Connectivity under vertex failures: overview of Theorem 1.1

In this section we provide an overview of the proofs of Theorem 1.1. This proof exposes all main ideas in a purely algorithmic setting. Then we discuss how the same methodology can be used for Theorem 1.2. In this introduction we assume familiarity with basic terminology of tree decompositions.

Unbreakability. As mentioned in Section 1, the central idea of this work is to tackle problems involving connectivity predicates using a decomposition into well-connected – or, more formally, *unbreakable* – parts. We first need to recall a few definitions.

A *separation* in a graph G is a pair (A,B) of vertex subsets such that $A \cup B = V(G)$ and there are no edges in G between $A - B$ and $B - A$. The *order* of the separation is the cardinality of the *separator* $A \cap B$. A vertex subset X is (q,k)-*unbreakable* in a graph G if for every separation (A,B) in G of order at most k in G, either $|A \cap X| \leqslant q$ or $|B \cap X| \leqslant q$.

So intuitively speaking, a separation of order k cannot break X in a balanced way: one of the sides must contain at most q vertices of X. For example, cliques and $k+1$-connected graphs are (k,k)-unbreakable, and square grids are $(\mathcal{O}(k^2),k)$-unbreakable.

The notion of unbreakability has been implicitly introduced in the context of parameterized algorithms by Kawarabayashi and Thorup in their work on the k-Way Cut problem [28]. This work has brought about the method of *recursive understanding*, which was then made explicit by Chitnis, Cygan, Hajiaghayi, Pilipczuk, and Pilipczuk in the technique of *randomized contractions* [11]. Intuitively, recursive understanding is a Divide&Conquer scheme using which one can reduce problems on general graphs to problems on suitably unbreakable graphs, provided certain technical conditions are satisfied. The technique was also applied in the context of model-checking: Lokshtanov, Ramanujan, Saurabh, and Zehavi [34] proved that the problem of deciding a property expressed in CMSO_2 in fpt time on general graphs can be reduced to the same problem on suitably unbreakable graphs. This result was used to provide algorithms for computing elimination distance to certain graph classes [2, 21, 26], which is very much related to separator logic (see [39, Example 3.5]).

In this work, we will not use recursive understanding or randomized contractions *per se*, but their conceptual successor: the decomposition into unbreakable parts. Precisely, the following theorem was proved by Cygan, Lokshtanov, Pilipczuk, Pilipczuk, and Saurabh [15].

▶ **Theorem 2.1** ([15]). *There is a function $q(k) \in 2^{\mathcal{O}(k)}$ such that given a graph G and $k \in \mathbb{N}$, one can in time $2^{\mathcal{O}(k^2)} \cdot |G|^2\|G\|$ construct a (rooted) tree decomposition $\mathcal{T} = (T, \mathsf{bag})$ of G satisfying the following.*

- *All adhesions in $\mathcal{T}$ are of size at most $q(k)$; and*
- *every bag of $\mathcal{T}$, say at node x, is $(q(k),k)$-unbreakable in the subgraph of G induced by the union of bags at all descendants[2] of x.*

We remark that a different variant of Theorem 2.1 was later proved by Cygan, Komosa, Lokshtanov, Pilipczuk, Pilipczuk, and Wahlström [14]. This variant provides much stronger unbreakability guarantees – $q(k) = k$ – at the cost of relaxing the unbreakability to hold only in the whole graph G. See Section 3 of the full version for a discussion. The variant of [14] can be also used in our context and this leads to improving some quantitative bounds, however for simplicity, we focus on Theorem 2.1 in this overview.

A typical usage of Theorem 2.1 is to apply bottom-up dynamic programming on the obtained tree decomposition $\mathcal{T} = (T, \mathsf{bag})$. The subproblem for a node x of T corresponds to finding partial solutions in the subgraph of G induced by the union of bags at descendants of x, for every possible behavior of such a partial solution on the adhesion connecting x with its parent. That this adhesion has size at most $q(k)$ gives an upper bound on the number of different behaviors. To solve such a subproblem one needs to aggregate the solutions computed for the children of x by solving an auxiliary problem on the subgraph induced by the bag of x. In various problems of interest, the unbreakability of the bag becomes helpful in solving the auxiliary problem. This general methodology has been successfully used to give multiple fpt algorithms for cut problems [15, 14, 38], most prominently for Minimum Bisection [15]. More recent uses include a parameterized approximation scheme for the Min k-Cut problem [35] and a fixed-parameter algorithm for Graph Isomorphism parameterized by the size of the excluded minor [33]. On a high level, we apply the same methodology here.

[2] We follow the convention that every node is its own ancestor and descendant.

The case of totally unbreakable graphs. Let us come back to the problem of evaluating connectivity queries: we are given a graph G and after some preprocessing of G, we would like to be able to quickly evaluate for given vertices $s, t, u_1, \ldots, u_k$ whether $\mathsf{conn}_k(s, t, u_1, \ldots, u_k)$ holds. Consider first the following special case: the whole G is (q, k)-unbreakable for some parameter q (or more formally, $V(G)$ is (q, k)-unbreakable in G). The key observation is that then, whether $\mathsf{conn}_k(s, t, u_1, \ldots, u_k)$ holds can be easily decided in time polynomial in q and k as follows.

Run a breadth-first search from s in $G - \{u_1, \ldots, u_k\}$, but terminate the search once $q+1$ different vertices have been reached. If the search reached t, then for sure $\mathsf{conn}_k(s, t, u_1, \ldots, u_k)$ holds. If the search finished before reaching $q+1$ different vertices and it did not reach t, then for sure $\mathsf{conn}_k(s, t, u_1, \ldots, u_k)$ does not hold. In the remaining case, perform a symmetric procedure starting from t. The key observation is that if both breadth-first searches – from s and from t – got terminated after reaching $q+1$ different vertices, then the (q, k)-unbreakability of G implies that $\{u_1, \ldots, u_k\}$ do not separate s from t. So then $\mathsf{conn}_k(s, t, u_1, \ldots, u_k)$ holds. It is straightforward to implement this procedure in time polynomial in q and k given the standard encoding of G through adjacency lists.

In the general case, we cannot expect the given graph G to be (q, k)-unbreakable for any parameter q bounded in terms of k. However, we can use Theorem 2.1 to compute a tree decomposition $\mathcal{T}$ of G into parts that are (q, k)-unbreakable for $q \in 2^{\mathcal{O}(k)}$. The idea is that then, a query $\mathsf{conn}_k(s, t, u_1, \ldots, u_k)$ can be evaluated by bottom-up dynamic programming on $\mathcal{T}$. By suitably precomputing enough auxiliary information about $\mathcal{T}$, this evaluation can be performed in time depending only on q and k.

Evaluating a query on the decomposition. Consider then the following setting: we are given the decomposition $\mathcal{T} = (T, \mathsf{bag})$ provided by Theorem 2.1, and for given $s, t, u_1, \ldots, u_k$ we would like to decide whether $\mathsf{conn}_k(s, t, u_1, \ldots, u_k)$ holds. So far let us not optimize the complexity: the goal is only to design a general algorithmic mechanism which will be later implemented efficiently using appropriate data structures.

For every node x of T, let $\mathsf{adh}(x)$ be the adhesion between x and its parent (or $\emptyset$ if x is the root), let $\mathsf{cone}(x)$ be the union of the bags at the descendants of x, and let $\mathsf{comp}(x) = \mathsf{cone}(x) - \mathsf{adh}(x)$. Call a node x *affected* if $\mathsf{comp}(x)$ contains a vertex of $\{s, t, u_1, \ldots, u_k\}$, and *unaffected* otherwise. Further, let $D(x) = \mathsf{adh}(x) \cup (\mathsf{comp}(x) \cap \{s, t\})$; note that $|D(x)| \leqslant q + 2$. Our goal is to compute the following *(connectivity) profile* for every node x of T:

$$\mathsf{profile}(x) = \left\{ \{a, b\} \in \binom{D(x)}{2} \;\middle|\; a \text{ and } b \text{ are connected in } G[\mathsf{cone}(x) - \{u_1, \ldots, u_k\}] \right\}.$$

We remark that the tree decomposition $\mathcal{T}$ can be chosen so that it satisfies the following basic connectivity property: for every node x and vertices $a, b \in \mathsf{adh}(x)$, there is a path connecting a and b whose all internal vertices belong to $\mathsf{comp}(x)$. Thus, for every unaffected node x, we have that $\mathsf{profile}(x) = \binom{D(x) - \{u_1, \ldots, u_k\}}{2}$.

It is easy to see that the profile of x is uniquely determined by the profiles of the children of x and the subgraph induced by the bag of x. The following lemma shows that this can be done efficiently.

▶ **Lemma 2.2** (informal statement, Lemma 4.4 in the full version). *Let x be a node of T. Suppose that for each affected child z of x we are given* $\mathsf{profile}(z)$*. Then, subject to suitable preprocessing of G, one can compute* $\mathsf{profile}(x)$ *in time polynomial in q.*

Note that every node has at most $k+2$ affected children, hence the input to the algorithm of Lemma 2.2 is of size polynomial in q.

Let us sketch the proof of Lemma 2.2. In essence, we apply the same strategy as the one from the case when the whole graph G is unbreakable. We define the *bag graph of* x, denoted $\mathsf{bgraph}(x)$, as the graph[3] obtained from $G[\mathsf{bag}(x)]$ by turning the adhesion $\mathsf{adh}(z)$ into a clique, for every child z of x. Note that $\mathsf{bgraph}(x)$ does not depend on the query, and thus can be precomputed upon initialization. As $\mathsf{bag}(x)$ is (q,k)-unbreakable in $G[\mathsf{cone}(x)]$, to test whether two vertices $a, b \in \mathsf{bag}(x)$ are connected in $G[\mathsf{cone}(x) - \{u_1, \ldots, u_k\}]$ it suffices to apply breadth-first searches from a and b in $\mathsf{bgraph}(x)$ that are terminated after reaching $q+1$ different vertices, except that these searches are forbidden to use vertices from $\{u_1, \ldots, u_k\} \cap \mathsf{bag}(x)$ as well as those edges originating from contracting the adhesion of affected children into cliques that are not in respective profiles. Provided $\mathsf{bgraph}(x)$ is precomputed and a list of affected children together with their profiles is given on input, it is easy to implement this algorithm so that it runs in time polynomial in q. Thus we can decide for every pair $\{a,b\} \in \binom{\mathsf{adh}(x)}{2}$ whether it should be included in $\mathsf{profile}(x)$. A similar reasoning can be applied to pairs in $\binom{D(x)}{2}$ that include s or t.

By applying Lemma 2.2 bottom-up, we can compute all the profiles in time $q^{\mathcal{O}(1)} \cdot |T| \leqslant q^{\mathcal{O}(1)} \cdot |G|$. Then we can read whether $\mathsf{conn}_k(s,t,u_1,\ldots,u_k)$ holds by checking whether $\{s,t\}$ belongs to the profile of the root of T. Hence, the query $\mathsf{conn}_k(s,t,u_1,\ldots,u_k)$ can be evaluated in time $q^{\mathcal{O}(1)} \cdot |G|$.

Data structure. Our final goal is to enrich the decomposition $\mathcal{T}$ with some additional information so that the mechanism presented above can be executed in time depending only on q.

For a vertex v of G, let $\mathsf{top}(v)$ be the unique top-most node of T whose bag contains v. Let $\widehat{S} := \{s,t,u_1,\ldots,u_k\}$ and let $X = \{\mathsf{top}(v) \colon v \in \widehat{S}\}$.

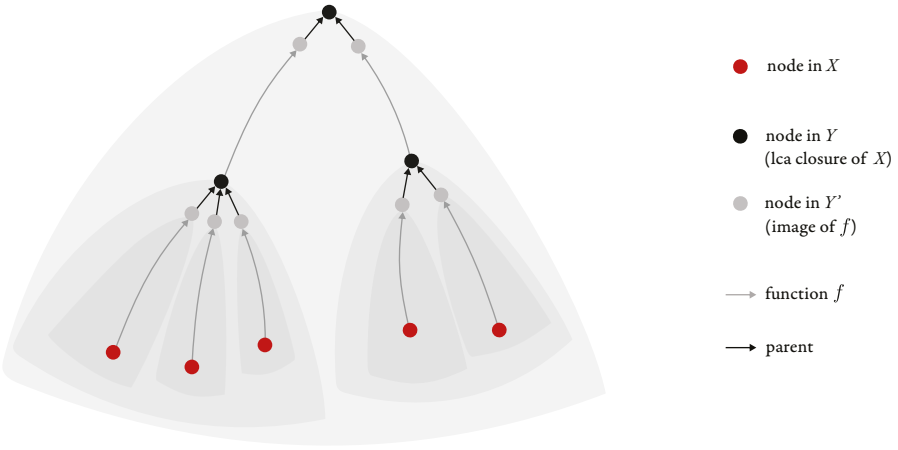

Figure 2 The sets X, Y and Y'. Only the nodes from $Y \cup Y'$ are marked in the figure, wheras the shaded areas indicate subtrees consisting of nodes which are not marked in the figure. Every affected node lies on a path from some $y \in Y$ to $f(y) \in Y'$.

[3] The bag graph $\mathsf{bgraph}(x)$ is actually defined slightly differently for technical reasons, as the graph obtained from $G[\mathsf{cone}(x)]$ by contracting, for each $y \in \mathsf{children}(x)$, the set $\mathsf{comp}(y)$ into a single vertex, identified with y. See the full version for the details.

Note that $|X| \leqslant |\widehat{S}| \leqslant k+2$ and that a node of T is affected if and only if it is an ancestor of a node from X. Let now Y be the *lowest common ancestor closure* of X: the set comprising X and all lowest common ancestors of pairs of vertices of X. It is well-known that then $|Y| \leqslant 2|X| - 1 \leqslant 2k+3$. We also add the root of T to Y in case it is not already present; thus $|Y| \leqslant 2k+4$. Observe that if for every vertex v we store a pointer to $\mathsf{top}(v)$, and we set up the data structure for lowest common ancestor queries of Harel and Tarjan [25] on T, then for given $s, t, u_1, \ldots, u_k$ the set Y can be computed in time polynomial in k. For every node y in Y let $f(y)$ denote the closest ancestor of y whose parent belongs to Y, or y if no such ancestor exists (see Figure 2). Note that every affected node lies on a path joining y with $f(y)$, for some $y \in Y$. Let $Y' = \{f(y) \mid y \in Y\}$. Then Y' is the set of all nodes that are affected children of a node in Y. Note that every element in Y' has exactly one preimage under f, that is, there is an function $f^{-1}\colon Y' \to Y$ such that $f(f^{-1}(y')) = y'$ for all $y' \in Y'$. In particular, $|Y'| \leqslant |Y|$. Using a slight modification of the data structure of Harel and Tarjan [25], we can compute Y' as well as the function $f^{-1}\colon Y' \to Y$ in time polynomial in k.

The idea is that when evaluating query $\mathsf{conn}_k(s, t, u_1, \ldots, u_k)$, we can compute the profiles only for the nodes of $Y \cup Y'$, instead of all affected nodes of T. Note that the root of T was explicitly added to Y, so we will still be able to read the answer to $\mathsf{conn}_k(s, t, u_1, \ldots, u_k)$ from the profile of the root.

We process the nodes of $Y \cup Y'$ in a bottom-up manner. Consider then any element $x \in Y \cup Y'$; our task is to compute its profile based on the profiles of its strict descendants belonging to $Y \cup Y'$. We distinguish two cases. In the first case, $x \in Y$, so we may compute $\mathsf{profile}(x)$ using the algorithm of Lemma 2.2. The second case is of an element $x \in Y'$; then $x = f(y)$ where $y = f^{-1}(x)$. Observe that the path from y to x consists of affected nodes, whose siblings are unaffected nodes. We now show how $\mathsf{profile}(x)$ can be computed from $\mathsf{profile}(y)$.

For two nodes c, d of T, where c is an ancestor of d, let $\mathsf{torso}(c, d)$ be the set of all pairs $\{a, b\} \in \binom{\mathsf{adh}(c) \cup \mathsf{adh}(d)}{2}$ such that in G there is a path from a to b whose all internal vertices belong to $\mathsf{comp}(c) - \mathsf{cone}(d)$. Then to compute $\mathsf{profile}(x)$ from $\mathsf{profile}(y)$, construct an auxiliary graph with vertices $(\mathsf{adh}(x) \cup \mathsf{adh}(y)$ and edges $\mathsf{profile}(y) \cup \mathsf{torso}(x, y)$. Now observe that $\mathsf{profile}(x)$ is the reachability relation in this graph restricted to $\mathsf{adh}(x) - \{u_1, \ldots, u_k\}$. The key point implying the correctness of this observation is that there are no vertices from X in $\mathsf{comp}(x) - \mathsf{comp}(y)$.

Observe now that the values of $\mathsf{torso}(c, d)$ for (c, d) ranging over ancestor/descendants pairs in T are independent of the query. Therefore, upon initialization we can compute a data structure that can be queried for those valued efficiently. The statement below describes two possible implementations.

▶ **Lemma 2.3** (Lemmas 4.2 and 6.2 of the full version, combined and improved). *Given $\mathcal{T}$, one can set up data structures that can answer $\mathsf{torso}(c, d)$ queries with the following specifications:*

1. *initialization time $q^{\mathcal{O}(1)} \cdot |G|^2\|G\|$, memory usage $q^{\mathcal{O}(1)} \cdot |G|^2$, query time $q^{\mathcal{O}(1)}$; or*
2. *initialization time $2^{\mathcal{O}(q^2)} \cdot |G|$, memory usage $2^{\mathcal{O}(q^2)} \cdot |G|$, query time $q^{\mathcal{O}(1)}$.*

The first point of Lemma 2.3 is actually straightforward: just compute and store all the $\mathcal{O}(|T|^2) = \mathcal{O}(|G|^2)$ answers to the torso queries, each in time $q^{\mathcal{O}(1)} \cdot \|G\|$ using $q^{\mathcal{O}(1)}$ applications of breadth-first search. The second point, which trades exponential dependency on q for obtaining linear memory usage and initialization time, is more interesting. Before we discuss it, let us observe that we may now complete the proof of Theorem 1.1. Indeed, using the data structure from the second point of Lemma 2.3, we can compute $\mathsf{profile}(x)$

from $\mathsf{profile}(y)$ for each $x \in Y'$ and $y = f^{-1}(x)$. By performing this procedure for all the at most $2(2k+4)$ nodes of $Y \cup Y'$ in a bottom-up manner, we eventually compute the profile of the root of T, from which the answer to the query can be read. The running time is dominated by $q^{\mathcal{O}(1)}$ calls to the data structure of the second point of Lemma 2.2, each taking $2^{\mathcal{O}(q^2)} = 2^{2^{\mathcal{O}(k)}}$ time.

Finally, let us discuss the proof of the second point of Lemma 2.3. We reduce this problem to the problem of evaluating *product queries* in a semigroup-labeled tree, defined as follows. Suppose T is a rooted tree whose edges are labeled with elements of a finite semigroup S. The task is to set up a data structure that for given nodes x, y, where x is an ancestor of y, outputs the product of the elements of S on the path in T from x to y. The problem of evaluating torso queries can be reduced to this abstract setting by considering a suitable semigroup of *bi-interface graphs*, which represent connectivity between corresponding adhesions; see [7, 8] for the origins of this concept. This semigroup has size $2^{\mathcal{O}(q^2)}$. So it then suffices to use the following result.

▶ **Theorem 2.4** (Przybyszewski). *There is a data structure for the problem of evaluating product queries in a tree T labeled with elements of a finite semigroup S that achieves query time $\log(|S|)^{\mathcal{O}(1)}$, memory usage $|S|^{\mathcal{O}(1)} \cdot |T|$, and initialization time $|S|^{\mathcal{O}(1)} \cdot |T|$.*

Note that this formulation is an improvement over Theorem 5.1 in the first version of our paper [36], as the query time $|S|^{\mathcal{O}(1)}$ is replaced by $\log(|S|)^{\mathcal{O}(1)}$. This improvement is due to Wojciech Przybyszewski.

This finishes the proof of Theorem 1.1. Note that in the argumentation there are two modules that can be replaced with other solutions:

- The decomposition of Theorem 2.1 can be replaced with the more recent variant from [14]. This allows us to have $q = k$, implying that all the $2^{2^{\mathcal{O}(k)}}$ factors are replaced with $2^{\mathcal{O}(k^2)}$. The cost is increasing the polynomial factor of the initialization time to an unspecified term $|G|^{\mathcal{O}(1)}$ and several technical complications in the analysis, which nevertheless can be overcome.
- Instead of using the data structure of the second point of Lemma 2.3, we can use the first point. This allows us to have polynomial dependency on q in the query time and space usage at the cost of quadratic dependence on $|G|$ in the memory usage.

In particular, if only the first replacement is performed, then we obtain a data structure with initialization time $2^{\mathcal{O}(k^2)} \cdot |G|^{\mathcal{O}(1)}$, memory usage $2^{\mathcal{O}(k^2)} \cdot \|G\|$, and query time $k^{\mathcal{O}(1)}$, and if both are performed, then we obtain a data structure with initialization time $2^{\mathcal{O}(k \log k)} \cdot |G|^{\mathcal{O}(1)}$, memory usage $k^{\mathcal{O}(1)} \cdot |G|^2$, and query time $k^{\mathcal{O}(1)}$.

3 Model-checking FO+conn: Theorems 1.2 and 1.3

We now turn to the proofs of Theorem 1.2 and Theorem 1.3. In those theorems, we fix a class $\mathscr{C}$ and consider the model-checking problem for the logic $\mathsf{FO}{+}\mathsf{conn}$, that is, the problem of deciding whether a given $\mathsf{FO}{+}\mathsf{conn}$ sentence holds in a given graph $G \in \mathscr{C}$.

Lower bound. First let us explain why we require $\mathscr{C}$ to exclude a fixed topological minor in Theorem 1.2. Clearly, the model-checking problem for $\mathsf{FO}{+}\mathsf{conn}$ generalizes the model-checking problem for FO, so $\mathscr{C}$ should be in particular a class for which it is known that FO model-checking is FPT. This is the case not only for classes that exclude a topological minor but also for all nowhere dense classes [24]. So let us see why it is not enough to merely assume that $\mathscr{C}$ is nowhere dense.

For a graph G and $k \in \mathbb{N}$, the *k-subdivision* $G^{(k)}$ of G is obtained from G by replacing each edge by a path of length $k+1$. It follows from the definition of nowhere denseness that the class $\mathscr{C}$ of all graphs of the form $G^{(n)}$, where G is an arbitrary graph on n vertices, is nowhere dense. However, a formula of $\mathsf{FO}+\mathsf{conn}$ can easily recover G from $G^{(n)}$, at least when G has no vertices of degree 2. Indeed, the original vertices of G are precisely the vertices of $G^{(n)}$ that have degree at least 3, which can be expressed by an FO formula $\varphi_V(x)$. Furthermore, two such vertices u, v are adjacent in G if and only if there is some vertex z of degree 2 in $G^{(n)}$ such that for every vertex w of $G^{(n)}$, $\mathsf{conn}_2(z, w, u, v)$ holds only if w has degree 2 in $G^{(n)}$. This condition can be written using an $\mathsf{FO}+\mathsf{conn}$ formula $\varphi_E(u, v)$. Using this observation, any FO sentence φ can be replaced by an $\mathsf{FO}+\mathsf{conn}$ sentence φ', so that for every graph G as above, φ holds in G if and only if φ' holds in $G^{(n)}$. Essentially, φ' is obtained from φ by replacing every atomic formula $E(x, y)$ (denoting adjacency) by $\varphi_E(x, y)$, and guarding all quantifiers by $\varphi_V(x)$. Therefore, if we could efficiently model-check φ' on the nowhere dense class $\mathscr{C}$, we could as well model-check φ on the class of all graphs (of size at least 3 and minimum degree at least 3), as follows: given an arbitrary graph G, first construct the graph $G^{(n)} \in \mathscr{C}$ (in time polynomial in $n = |V(G)|$) and then test φ' on $G^{(n)}$. Hence, if $\mathsf{FO}+\mathsf{conn}$ model-checking was fpt on $\mathscr{C}$, then FO model-checking would be fpt on the class of all graphs, implying $\mathsf{FPT} = \mathsf{AW}[\star]$. So nowhere dense graph classes are too general for the statement of Theorem 1.2 to hold. Intuitively, the notion of nowhere denseness is not preserved under contracting long paths, which can be simulated in the logic $\mathsf{FO}+\mathsf{conn}$.

The same simple argument proves Theorem 1.3. Indeed, the argument works not only for the graph $G^{(n)}$ obtained as the n-subdivision of G but also for any subdivision G' (obtained by replacing each edge independently by any number of vertices) of G, as long as G' can be computed from G in polynomial time. The condition that $\mathscr{C}$ is subgraph-closed and admits efficient encoding of topological minors guarantees precisely that for any given graph G we can construct, in polynomial time, a graph G' which is a subdivision of G and belongs to $\mathscr{C}$. This yields Theorem 1.3 (see Section 9 of the full version for details).

Upper bound. We now give some details concerning the proof of Theorem 1.2, which is the second main contribution of the paper.

The starting observation is that for a (q, k)-unbreakable graph G, the query $\mathsf{conn}_k(u, v, x_1, \ldots, x_k)$ can be expressed in plain FO. Indeed, this query fails if and only if there is a set A of at most q vertices which contains exactly one of the vertices u and v, and such that all neighbors of vertices of A outside of A are contained in $\{x_1, \ldots, x_k\}$. The existence of such a set of q vertices can be expressed using q existential quantifiers followed by a universal quantifier. So $\mathsf{FO}+\mathsf{conn}$ with connectivity queries of arity at most $k+2$ is equally expressive as plain FO on (q, k)-unbreakable graphs, as long as q is a constant.

Now, if the graph G is not (q, k)-unbreakable, we work with the tree decomposition into (q, k)-unbreakable parts given by Theorem 2.1, where $q = q(k)$ is a constant depending on k. The next observation is that the constant-time querying algorithm used in the proof of Theorem 1.1 and explained above, can be seen as a formula on a suitably defined logical structure. Indeed, if we look into the data structure answering the queries $\mathsf{conn}_k(u, v, x_1, \ldots, x_k)$, we notice that each such query triggers a constant number of operations asking about the least common ancestor of two nodes in the tree decomposition, or asking about the membership of a vertex to a bag. Additionally, the algorithm may ask, for two vertices u, v belonging to a bag x, whether u and v are adjacent in the original graph, or whether they are adjacent in the bag graph $\mathsf{bgraph}(x)$. Finally, the algorithm also performs torso queries. We may therefore construct a logical structure, corresponding to the data structure, such that this

basic functionality is expressible by a first-order formula in this structure. Then the query $\mathsf{conn}_k(u, v, x_1, \ldots, x_k)$ becomes expressible using a plain FO formula in the logical structure. It will then remain to show that we can model check FO formulas in fpt on the resulting logical structure.

It is convenient to abstract away the details of our logical structure, and represent it in the following form: It is a tree T (possibly vertex-labeled), together with additional edges (possibly labeled) between some nodes which are siblings in the tree. We call such a structure an *augmented tree*. In such a tree, the set of children of any node v carries a structure of a graph. In the particular case of our construction, those graphs will precisely correspond to bag graphs. Recall that a bag graph is obtained from the subgraph induced by a bag by turning all adhesions towards children into cliques. It is not difficult to show (see Lemma 3.4 of the full version) that if the original graph G is H-topological-minor free, then the resulting bag graphs are H'-topological-minor-free for some H' depending on H and on k.[4] Hence, we obtain a tree augmented with H'-topological-minor-free graphs. And the original query $\mathsf{conn}_k(u, v, x_1, \ldots, x_k)$ can be now represented as an FO formula in the augmented tree, where the FO formula may use the ancestor relation $\leqslant$ on the tree nodes, as well as the adjacency relation between the siblings. Showing this basically amounts to revisiting the proof of Lemma 2.2 and arguing that the atomic algorithmic operations can now be simulated by FO formulas in the augmented tree.

Let us note here that the remainder of the argument would go through even if we assumed that the resulting tree is augmented with graphs from a fixed nowhere dense class $\mathscr{C}'$ which is not necessarily topological-minor-free. However, if the original graph G merely belongs to a nowhere dense class $\mathscr{C}$, then the bag graphs, and hence the graphs in the augmented tree, no longer need to belong to any fixed nowhere dense class. In fact, they may contain arbitrarily large cliques.

Continuing with the proof, now it remains to show that we can solve FO model-checking on trees augmented with H'-topological-minor-free graphs in fixed-parameter time, where the FO formulas may use the ancestor relation in the tree as well as the edge relation among the siblings. For this, we lift the usual, automata-based techniques for model-checking on trees, to the case of augmented trees. We define automata that process augmented trees in a bottom-up fashion, labeling the nodes of the tree with states from a finite set of states, starting from the leaves and proceeding towards the root. At any node x, to determine the state of the automaton at x, we consider the graph induced on the children of x in the augmented tree, vertex-labeled by the states computed earlier. Then the state at x is determined by evaluating a fixed collection of first-order sentences on this labeled graph. In this way, all nodes of the tree are labeled by states, and the automaton accepts the augmented tree depending on the state at the root.

By construction, it can be decided in fpt time whether or not a given such automaton accepts a given tree that is augmented with graphs that come from, say, a nowhere dense class. Additionally, using standard techniques, we show that for every first-order sentence φ on augmented trees there is such an automaton that determines whether φ holds in a given augmented tree. Therefore, FO model-checking is fpt on trees augmented with graphs from a nowhere dense class; this in particular applies to classes with excluded topological minors.

[4] Here we refer to the bgraph as defined in Footnote 3.

To summarize, to model-check a sentence φ of $\mathsf{FO}+\mathsf{conn}$ on a H-topological-minor-free graph G, we perform the following reasoning:

1. Using Theorem 2.1, compute a tree decomposition $\mathcal{T}$ of G with (q,k)-unbreakable bags, where $k+2$ is the maximal arity of the connectivity predicates in φ, and $q = q(k)$.
2. Turn $\mathcal{T}$ into a tree $\mathcal{T}'$ augmented with H'-topological-minor free graphs, where H' depends on H and k.
3. In the augmented tree $\mathcal{T}'$, the connectivity predicate $\mathsf{conn}_k(u,v,x_1,\ldots,x_k)$ can be expressed using a plain FO formula. This follows by analyzing how connectivity predicates are evaluated in constant time, and observing that the atomic operations can be performed using FO formulas in the augmented trees.
4. Therefore, also φ can be expressed as a plain FO formula φ', which is evaluated in $\mathcal{T}'$.
5. Convert φ' into an automaton $\mathcal{A}$ processing augmented trees, using standard automata-based techniques.
6. Run $\mathcal{A}$ on $\mathcal{T}'$ in a bottom-up fashion. This involves performing FO queries on the graphs induced on the children of any given node, and uses one of the known algorithms for FO model-checking on H'-topological-minor-free graphs.

In Section 7 of the full version we describe the basic toolbox of automata on augmented trees, explaining in detail the last two steps above, abstracting away from the specific application, and providing further results on augmented trees, e.g. concerning query enumeration. In fact, with the same methods we can show that not only FO model-checking is fpt on trees augmented with graphs from a nowhere dense class, but also a more general logic $\mathsf{FO}(\mathsf{MSO}(\preccurlyeq, A) \cup \Sigma)$ combining the power of FO on the augmenting graphs with MSO on trees can be solved in fpt on augmented trees. We then show in Section 8 (of the full version) how to express the predicates conn_k on augmented trees using this more general logic $\mathsf{FO}(\mathsf{MSO}(\preccurlyeq, A) \cup \Sigma)$.

4 Discussion

In this work we have added computational problems related to conn queries in graphs and the logic $\mathsf{FO}+\mathsf{conn}$ to the growing list of applications of the decomposition theorem of Cygan et al. [15]. Several questions can be asked about possible improvements of the obtained complexity bounds, especially regarding the data structure of Theorem 1.1.

First, in both the model-checking algorithm of Theorem 1.2 and the construction algorithm of the data structure of Theorem 1.1, the main bottleneck for the polynomial factor is the running time of the algorithm to compute the tree decomposition of Cygan et al. (see Theorem 2.1). This running time is cubic in the size of the graph, while in both applications presented in this work, the remainder of the construction takes fpt time with at most quadratic dependence on the graph size. Therefore, it seems imperative to revisit Theorem 2.1 with the purpose of improving the time complexity of the construction algorithm.

Second, in Section 6 of the full version we showed how to improve the time complexity of queries to polynomial in k by using the weakly unbreakable tree decomposition provided by [14]. The drawback is that the space usage of the data structure becomes $k^{\mathcal{O}(1)} \cdot |G|^2$. However, the quadratic dependence on $|G|$ is caused only by the brute-force implementation of the data structure for torso queries provided by Lemma 6.2 of the full version. So now we have two implementations of this data structure:

- Theorem 2.4 and Lemma 4.2 (of the full version) offers query time $q^{\mathcal{O}(1)}$ and space usage $2^{\mathcal{O}(q^2)} \cdot |T|$.
- Lemma 6.2 (of the full version) offers query time $q^{\mathcal{O}(1)}$ and space usage $q^{\mathcal{O}(1)} \cdot |T|^2$.

Is it possible to design a data structure that would offer query time $q^{\mathcal{O}(1)}$ while keeping the space usage at $q^{\mathcal{O}(1)} \cdot |T|$?

A Perfect Sampler for Hypergraph Independent Sets

Abstract

The problem of uniformly sampling hypergraph independent sets is revisited. We design an efficient *perfect* sampler for the problem under a similar condition of the asymmetric Lovász local lemma. When specialized to d-regular k-uniform hypergraphs on n vertices, our sampler terminates in expected $O(n \log n)$ time provided $d \leq c \cdot 2^{\frac{k}{2}}$ where $c > 0$ is a constant, matching the rapid mixing condition for Glauber dynamics in Hermon, Sly and Zhang [10]. The analysis of our algorithm is simple and clean.

1 Introduction

The problem of uniformly sampling hypergraph independent sets, or equivalently the solutions of monotone CNF formulas, has been well-studied in recent years. Consider a hypergraph $\Phi = (V, \mathcal{C})$ on $|V| = n$ vertices. A set $S \subseteq V$ is an independent set if $C \cap S \neq C$ for all $C \in \mathcal{C}$. Assuming the hypergraph is d-regular and k-uniform, [10] showed that the natural Glauber dynamics mixes in $O(n \log n)$ time when $d \leq c \cdot 2^{\frac{k}{2}}$ for some constant $c > 0$. The sampler implies a fully polynomial-time randomized approximation scheme (FPRAS) for counting hypergraph independent sets [13]. On the other hand, it was shown in [1] that there is no FPRAS for the problem when $d \geq 5 \cdot 2^{\frac{k}{2}}$, unless **NP** = **RP**. Therefore, the result of [10] is tight up to a multiplicative constant.

The proof in [10] analyzes the continuous-time Glauber dynamics under the framework of *information percolation* developed in [14] for studying the cutoff phenomenon of the Ising model. In this framework, one can view the coupling history of a Markov chain as time-space slabs, and the failure of the coupling at time t as a discrepancy path percolating from t back to the beginning. The analysis of this structure can result in (almost) optimal bounds in many interesting settings.

The percolation analysis in [10] is technically complicated due to the *continuous* nature of the chain which leads to involved dependencies in both time and space. Recently, discrete analogs of the time-space slabs have been introduced in sampling solutions of general CNF

[1] Part of the work was done while the author was an undergraduate student at Shanghai Jiao Tong University.

formulas in the Lovász local lemma regime [11, 8]. Notably in [8], an elegant discrete time-space structure, tailored to *systematic scan*, was introduced to support the analysis of *coupling from the past* (CFTP) paradigm [17]. In contrast to simulating Glauber dynamics, the method of CFTP allows to produce *perfect samples* (i.e. without approximation error) from stationary distribution.

In this article, we refine the discrete time-space structure in [8], which we call the *witness graph*, and apply it to the problem of sampling hypergraph independent sets. This leads to an efficient CFTP sampler that (1) outputs perfect samples; (2) matches the bound in [10] and operates also in the asymmetric case under Lovász local lemma-like condition; and (3) has significantly simpler analysis. More specifically, we study a natural grand coupling of the systematic scan for sampling hypergraph independent sets. To apply the method of CFTP, one needs to detect the coalescence of the grand coupling efficiently at each stage of the algorithm. The monotone property of hypergraph independent sets allows us to reduce the detection to arguing about percolation on the witness graph. This observation provides sufficient flexibility for us to carefully bound related probabilities. We first show that, under a condition similar to the *asymmetric* Lovász local lemma, a perfect sampler exists.

▶ **Theorem 1.** *Let $\mathcal{G}$ collects all hypergraphs $\Phi = (V, \mathcal{C})$ such that*

$$\forall C \in \mathcal{C} : 2|C| \cdot 2^{-|C|} \leq (1-\varepsilon) \cdot x(C) \cdot \prod_{C' \in \Gamma_{\Phi^2}(C)} (1 - x(C')),$$

for some constant $\varepsilon \in (0,1)$ and function $x : \mathcal{C} \to (0,1)$. Here $\Gamma_{\Phi^2}(C)$ denotes the set of hyperedges within distance 2 to C in Φ (excluding C itself).

There exists an algorithm that inputs a hypergraph $\Phi \in \mathcal{G}$ and outputs an independent set of Φ uniformly at random, in expected time

$$O\left(-\frac{1}{\log(1-\varepsilon)} \cdot \log\left(\sum_{C \in \mathcal{C}} \frac{x(C)}{1-x(C)}\right) \cdot \sum_{C \in \mathcal{C}} \sum_{v \in C} d_v |C|\right),$$

where d_v is number of hyperedges in Φ that contains v.

In the proof of Theorem 1, we view a discrepancy path of the coupling percolating from time t back to the beginning as an object similar to the *witness tree* in [16] for certifying the non-termination of a randomized algorithm. This is an interesting analogy between an algorithm that *samples* the solutions of CNF formulas and an algorithm that *finds* them. We map the discrepancy paths in the witness graph to connected trees generated by *multi-type Galton-Watson process* in the hypergraph. As a result, a certain spatial mixing property implies the rapid mixing of the chain.

For k-uniform d-regular hypergraphs, the result in Theorem 1 translates to the condition $d \leq \frac{c \cdot 2^{k/2}}{k^{1.5}}$ for some constant $c > 0$ by choosing $x(C) = \frac{1}{d^2 k^2}$. We give a refined analysis for this symmetric case to remove the denominator:

▶ **Theorem 2.** *Let $\mathcal{G}$ collects all k-uniform d-regular hypergraphs $\Phi = (V, \mathcal{C})$ such that*

$$d \leq \left(\frac{1}{4}\sqrt{\frac{9-\varepsilon}{2}} - \frac{1}{2}\right) \cdot 2^{k/2}.$$

for some constant $\varepsilon \in (0,1)$. There exists an algorithm that inputs a hypergraph $\Phi \in \mathcal{G}$ and outputs a hypergraph independent set of Φ uniformly at random, in expected time $O\left(-\frac{1}{\log(1-\varepsilon)} \cdot k^2 d^2 n \cdot (\log n + \log d)\right)$ where $n := |V|$.

Compared to the result in [10], our sampler has the advantage of being perfect. Our analysis inductively enumerates discrepancy paths, taking into account the structure of the overlapping between hyperedges. Thanks to the clean structure of the witness graph, our proof is much simpler than the one in [10].

Relation to sampling solutions of general CNF formulas

The problem of sampling hypergraph independent sets is a special case of sampling the solutions of general CNF formulas or CSP instances which draw a lot of recent attention [15, 3, 11, 8, 12, 7, 6, 5, 4, 2, 9]. For general k-CNF formulas where each variable is of degree d (corresponding to the k-uniform d-regular hypergraphs here), the best condition needed for an efficient sampler is $d < \frac{1}{\mathrm{poly}(k)} \cdot 2^{\frac{k}{40/7}}$ [11, 8] which is much worse than the condition $d < c \cdot 2^{\frac{k}{2}}$ for hypergraph independent sets. A main reason is that for general CNF formulas, the state space of the local Markov chain is no longer connected, and therefore one needs to project the chain onto a sub-instance induced by some special set of variables. The loss of the projection step, however, is not well-understood. On the other hand, this is not an issue for hypergraph independent sets and therefore (almost) optimal bounds can be obtained.

We remark that the technique developed here for non-uniform graphs can also be applied to general CNF formulas to analyze the projection chain.

2 Preliminaries

2.1 Hypergraph independent sets

Recall in the introduction we mentioned that a set $S \subseteq V$ is an independent set of a hypergraph $\Phi = (V, \mathcal{C})$ if $S \cap C \neq C$ for every $C \in \mathcal{C}$. Sometimes we represent it as a (binary) coloring $\sigma \in \{0,1\}^V$, which is the indicator for S. That is, we say σ is an hypergraph independent set if $\forall C \in \mathcal{C}, \exists v \in C : \sigma(v) = 0$. Denoting by Ω_Φ the collection of all independent sets of Φ, our goal is to efficiently produce a sample from the uniform measure μ on Ω_Φ.

Let us fix some notations used throughout our discussion:

- We assume $V := [n]$ and $m := |\mathcal{C}|$. We denote the degree of a vertex $v \in V$ as $d_v := |\{C \in \mathcal{C} : v \in C\}|$ and the maximum degree as $d := \max_{v \in V} d_v$. A hypergraph is d-regular if every vertex is of degree d and is k-uniform if every hyperedge is of size k.
- For any $C \in \mathcal{C}$, we use $\Gamma^+_{\Phi^2}(C)$ to denote the set of hyperedges C' such that either $C \cap C' \neq \varnothing$ or there exists C^* such that $C \cap C^* \neq \varnothing$ and $C^* \cap C' \neq \varnothing$. Furthermore, let $\Gamma_{\Phi^2}(C) := \Gamma^+_{\Phi^2}(C) \setminus \{C\}$.
- For any coloring $\sigma \in \{0,1\}^V$, we use $\sigma^{v \leftarrow r}$ to denote the coloring obtained after recoloring $v \in V$ by $r \in \{0,1\}$ in σ.

2.2 Systematic scan and coupling from the past

Fix a hypergraph $\Phi = (V, \mathcal{C})$ and the uniform distribution μ over Ω_Φ. We use the so-called *systematic scan* Markov chain to sample independent sets from μ.

Let us define a transition map $f : \Omega_\Phi \times V \times \{0,1\} \to \Omega_\Phi$ by

$$f(\sigma; v, r) := \begin{cases} \sigma^{v \leftarrow r} & \text{if } \sigma^{v \leftarrow r} \in \Omega_\Phi; \\ \sigma & \text{otherwise.} \end{cases}$$

It takes the given coloring $\sigma \in \Omega_\Phi$ and tries to recolor vertex v with the proposed r. Next, we fix a deterministic *scan sequence* $v_1, v_2, \ldots$ where $v_i := (i \bmod n) + 1$ and write

$$F(\sigma; r_1, \ldots, r_t) := f(f(\cdots f(\sigma; v_1, r_1) \cdots); v_t, r_t).$$

Basically, it begins with the given coloring $\sigma \in \Omega_\Phi$ and runs f for t steps to update vertex colors. The vertices are updated periodically as specified by the scan sequence; the proposed colors for every steps are provided by the arguments $r_1, \ldots, r_t$. For a collection of initial states $S \subseteq \Omega_\Phi$, we use $F(S; r_1, \ldots, r_t)$ to denote the set $\{F(\sigma; r_1, \ldots, r_t) : \sigma \in S\}$.

▶ **Definition 3.** *The* systematic scan *is a Markov chain* (X_t) *defined by*

$$X_t := F(\sigma; R_1, \ldots, R_t) \quad \forall t$$

for some $\sigma \in \Omega_\Phi$ *and some independent* $\texttt{Bernoulli}(1/2)$ *variables* $R_1, R_2, \ldots$.

The systematic scan is not a time-homogeneous Markov chain. However, we can (and will) bundle every n steps into an atomic round so that the bundled version – denoting its transition matrix P_Φ – is homogeneous. It is easy to check that P_Φ is irreducible and aperiodic with stationary distribution μ.

Given a Markov chain with stationary μ, in the usual Markov chain Monte Carlo method, one obtains a sampler for μ as follows: Starting from some initial X_0, simulate the chain for t steps with sufficiently large t and output X_t. The fundamental theorem of Markov chains says that if the chain is finite, irreducible and aperiodic, then the distribution of X_t converges to μ when t approaches infinity. However, since we always terminate the simulation after some fixed finite steps, the sampler obtained is always an "approximate" sampler instead of a "perfect" one.

The work of [17] proposed an ingenious method called *coupling from the past* (CFTP) to simulate the given chain in a reverse way with a random stopping time. A perfect sampler for μ can be obtained in this way. Roughly speaking, it essentially simulates an infinite long chain using only finitely many steps. To achieve this, it relies upon a routine to detect whether the (finite) simulation coalesces with the virtual infinite chain. Once the coalescence happens, one can output the result of the simulation – which is also the result of the infinite chain and thus follows the stationary distribution perfectly.

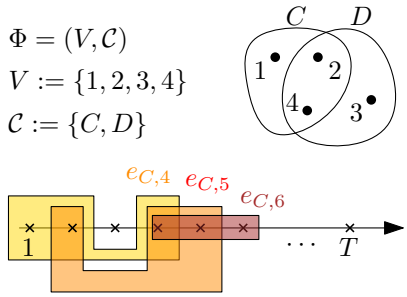
We use CFTP to simulate our systematic scan and obtain a desired perfect sampler for hypergraph independent sets. The key ingredient to apply CFTP is how to detect the coalescence. We describe and analyze our algorithm in Section 3.

3 Perfect Sampler via Information Percolation

In this section, we describe our perfect sampler for hypergraph independent sets. With the help of a data structure introduced in [8], we apply the argument of information percolation to analyze the algorithm. We utilize the monotonicity of the hypergraph independent sets and establish a sufficient condition for the algorithm to terminate.

3.1 The witness graph

In this section, we introduce the notion of witness graph $H_T = (V_T, E_T)$ for the systematic scan up to some time $T \in \mathbb{N}$. A similar structure was used in [8] for sampling general CNF formulas.



$e_{C,1} = \{1\}$	
$e_{C,2} = \{1, 2\}$	$e_{D,2} = \{2\}$
	$e_{D,3} = \{2, 3\}$
$e_{C,4} = \{1, 2, 4\}$	$e_{D,4} = \{2, 3, 4\}$
$e_{C,5} = \{5, 2, 4\}$	
$e_{C,6} = \{5, 6, 4\}$	$e_{D,6} = \{6, 3, 4\}$
	$e_{D,7} = \{6, 7, 4\}$
$e_{C,8} = \{5, 6, 8\}$	$e_{D,8} = \{6, 7, 8\}$
...	...

Figure 1 An illustration of the witness graph. In this example, the hypergraph Φ has four vertices and two hyperedges. We list the vertices of the witness graph in the table on the right. The lower left picture visualizes three vertices in H_T; all of them have label C.

Given a vertex $v \in V$, we denote its last update time up to moment t as

$$\texttt{UpdTime}(v, t) = \max\{t^* \le t : v_{t^*} = v\}.$$

Clearly $\texttt{UpdTime}(v, t) \in (t - n, t]$ is a deterministic number.

For $C \in \mathcal{C}$ and $t \in [T]$, let $e_{C,t} := \{\texttt{UpdTime}(v, t) : v \in C\}$ be timestamps when the elements in C got their latest updates up to time t. Conversely, we say $e_{C,t}$ has *label* C and denote it by $C(e_{C,t}) := C$.

The vertex set of witness graph is given by

$$V_T := \{e_{C,t} : t \in [T], v_t \in C \in \mathcal{C}\}.$$

We put a directed edge $e_{C,t} \to e_{C',t'}$ into E_T if and only if $t' \in (e_{C,t} \cap e_{C',t'}) \setminus \{t\}$. Note that H_T is acyclic, since $\max e > \max e'$ for any directed edge $e \to e'$. We remark that the witness graph is a deterministic object which by itself does not incorporate any randomness.

The following lemma measures the number of vertices labelled by a certain $C \in \mathcal{C}$ that are 2-distant from a given vertex in the witness graph. It is useful throughout the enumeration in later discussions.

▶ **Lemma 4.** *For any $e_{C,t} \in V_T$ and $C' \in \mathcal{C}$, we have $|e_{C',t'} \in V_T : \texttt{dist}(e_{C,t}, e_{C',t'}) = 2| \le 2|C'|$.*

Proof. If $C' \notin \Gamma^+_{\Phi^2}(C)$ then $|e_{C',t'} \in V_T : \texttt{dist}(e_{C,t}, e_{C',t'}) = 2| = 0$. Otherwise, $t' \in [t - 2n + 2, t)$, and there are at most $2|C'|$ timestamps $e_{C',t'}$ satisfying $t' \in [t - 2n + 2, t)$. ◀

3.2 Coalescence and percolation

For any $L \in \mathbb{N}$ we fix $T = T(L) := n(L + 1)$. On top of the witness graph H_T we define a probability space as follows. We tie an independent $\texttt{Bernoulli}(1/2)$ variable B_t to each time point $t \in [T]$. We say a vertex $e \in V_T$ is *open* if $B_t = 1$ for all $t \in e$, and call a set of vertices $P \subseteq V$ *open* if all $e \in P$ are open. The event $\mathcal{B}_L$ is defined as

> "H_T contains an induced open path $P = (e_1, \ldots, e_L) \subseteq V_T$ of length L where $e_1 \cap (T - n, T] \neq \varnothing$".

For the coming few pages, the notation $\mathcal{B}_L(R_1, \ldots, R_T)$ indicates that we are using (external) random variables $R_1, \ldots, R_T$ as *concrete realizations* of our abstract variables $B_1, \ldots, B_T$. Needless to say, $R_1, \ldots, R_T$ themselves should be independent $\texttt{Bernoulli}(1/2)$ for such notation to make sense.

Starting from Section 4, however, we will switch back to the abstract setting and sweep the concrete realization under the rug.

Recall F is the transition map for our systematic scan.

▶ **Lemma 5.** *Assume $L \in \mathbb{N}$, $T := n(L+1)$ and $R_1, \ldots, R_T$ are independent* `Bernoulli`$(1/2)$ *variables. If $|F(\Omega_\Phi; R_1, \ldots, R_T)| > 1$ then $\mathcal{B}_L = \mathcal{B}_L(R_1, \ldots, R_T)$ happens.*

To prove Lemma 5 we specify a *grand coupling*, namely a family of Markov chains that share the same random sequence $R_1, \ldots, R_T$ provided by the lemma.

For every $\sigma \in \Omega_\Phi$, define a copy of systematic scan $(X_{\sigma,t})_{0 \le t \le T}$ by

$$X_{\sigma,t} := F(\sigma, R_1, \ldots, R_t) \quad \forall 0 \le t \le T.$$

In addition, we define an auxiliary Markov chain $(Y_t)_{0 \le t \le T}$ by

$$Y_0 := \{1\}^V, \qquad Y_t := Y_{t-1}^{v_t \leftarrow R_t} \quad \forall 1 \le t \le T.$$

The chain $(Y_t)_{0 \le t \le T}$ dominates the execution of $(X_{\sigma,t})_{0 \le t \le T}$ by monotonicity:

▶ **Proposition 6.** *For all $\sigma \in \Omega_\Phi$ and $0 \le t \le T$, we have $X_{\sigma,t} \le Y_t$.*

Proof. Initially, $X_{\sigma,0} = \sigma \le \{1\}^V = Y_0$ for all $\sigma \in \Omega_\Phi$. At any time $t \ge 1$, all the chains update the same vertex v_t and (i) if $R_t = 0$ then $X_{\sigma,t}(v_t) = 0$; (ii) if $R_t = 1$ then $Y_t(v_t) = 1$. So the ordering $X_{\sigma,t} \le Y_t$ is preserved throughout. ◀

▶ **Proposition 7.** *Let $0 \le t \le T$ be a time point. If there exist $\sigma, \tau : X_{\sigma,t}(v_t) \ne X_{\tau,t}(v_t)$, then there is a hyperedge $C \in \mathcal{C}$ containing v_t such that $C \setminus \{v_t\}$ was fully colored by "1" in exactly one of $X_{\sigma,t}$ and $X_{\tau,t}$. Furthermore, $Y_t(C) = \{1\}^C$.*

Proof. Since $X_{\sigma,t}(v_t) \ne X_{\tau,t}(v_t)$, we know that $R_t = 1$ and thus $Y_t(v_t) = 1$. According to the definition of transition map f, one of the two chains failed to recolor v_t by "1" because there exists a hyperedge C such that $C \setminus \{v_t\}$ was fully colored "1" in that chain just before time t. Hence $Y_t(C \setminus \{v_t\}) = \{1\}^{C \setminus \{v_t\}}$ by Proposition 6. Putting together we have $Y_t(C) = \{1\}^C$. ◀

We are now ready to prove Lemma 5.

Proof of Lemma 5. Assume $|F(\Omega_\Phi; R_1, \ldots, R_T)| > 1$; that is, there exist $\sigma, \tau \in \Omega_\Phi$ and $v \in V$ such that $X_{\sigma,T}(v) \ne X_{\tau,T}(v)$. We inductively construct a path in H_T as follows:

1. Set $i \leftarrow 1$. Let $t_1 := \texttt{UpdTime}(v, T) \in (T-n, T]$.
2. While $t_i \ge n$ do the following. Regarding Proposition 7 and the fact $X_{\sigma,t_i}(v_{t_i}) \ne X_{\tau,t_i}(v_{t_i})$, there is a hyperedge $C_i \in \mathcal{C}$ containing v_{t_i} such that $C_i \setminus \{v_{t_i}\}$ was fully colored by "1" in exactly one of X_{σ,t_i} and X_{τ,t_i}. So we may find an earliest time $t_{i+1} \in e_i := e_{C_i,t_i}$ such that $X_{\sigma,t_{i+1}}(v_{t_{i+1}}) \ne X_{\tau,t_{i+1}}(v_{t_{i+1}})$ and $t_{i+1} < t_i$. Moreover, $Y_{t_i}(C_i) = \{1\}^{C_i}$ implies that e_i is open. Let $i \leftarrow i+1$ and repeat.

Note that $t_{i+1} \in e_i$ by definition. On the other hand $t_{i+1} \in e_{i+1} = e_{C_{i+1},t_{i+1}}$ since $v_{t_{i+1}} \in C_{i+1}$. Combining with the condition $t_{i+1} < t_i$, we see $t_{i+1} \in (e_i \cap e_{i+1}) \setminus \{t_i\}$ and consequently $e_i \to e_{i+1}$ is indeed an edge in H_T. Therefore the above procedure returns an open (not necessarily induced) path $P^\circ = (e_1, \ldots, e_r) \subseteq V_T$ where r is the number of rounds. It starts at vertex e_1 that intersects $(T-n, T]$, and ends at vertex e_r that intersects $[1, n)$.

Let $P \subseteq P^\circ$ be a *shortest path* from e_1 to e_r in $H_T[P^\circ]$. It must be an induced path in H_T since H_T is acyclic. It is open since $P \subseteq P^\circ$. Finally, every vertex $e \in P$ "spans" a time interval of at most n, so the length of P is at least $T/n - 1 = L$. ◀

3.3 The perfect sampler

We are ready to introduce our perfect sampler for hypergraph independent sets. Let $L \in \mathbb{N}$ be a parameter to be fixed later (roughly in the order of $O(\log m)$) and $T = T(L) := n(L+1)$ as usual. The algorithm follows the standard framework of CFTP.

Algorithm 1 The CFTP sampler of hypergraph independent sets.

Input: A hypergraph $\Phi = (V, \mathcal{C})$.
Output: An independent set of Φ sampled uniformly from μ.

$j \leftarrow 0$;
repeat
  $j \leftarrow j + 1$;
  generate independent $\texttt{Bernoulli}(1/2)$ variables $R_{-jT+1}, \ldots, R_{-(j-1)T}$;
until *not* $\texttt{Detect}(\Phi, R_{-jT+1}, \ldots, R_{-(j-1)T})$;
return $F\left(\{0\}^V; R_{-jT+1}, \ldots, R_0\right)$.

Algorithm 2 The Detect subroutine.

Input: A hypergraph $\Phi = (V, \mathcal{C})$ and a sequence $R_1, \ldots, R_T$.
Output: Whether $\mathcal{B}_L(R_1, \ldots, R_T)$ happens.

foreach $C \in \mathcal{C}$ **do**
  foreach $t \in [T] : v_t \in C$ **do**
    foreach $v \in C \setminus \{v_t\}$ **do**
      foreach $C' \in \mathcal{C} : v \in C' \neq C$ **do**
        $t' \leftarrow \texttt{UpdTime}(v, t)$;
        connect $e_{C,t} \to e_{C',t'}$ if both of them are open with regard to $R_1, \ldots, R_T$;
breadth-first search from all $e_{C,t} : C \in \mathcal{C}, t \in (T-n, T]$ until the current vertex intersects $[1, n)$;
return *if the path has length* $\geq L$.

▶ **Theorem 8.** *Suppose there exist constant $\varepsilon \in (0,1)$ and β such that $\mathbf{Pr}[\mathcal{B}_L] \leq \beta \cdot (1-\varepsilon)^L$ for all L. With the concrete choice $L := \left\lceil \frac{\log(2\beta)}{-\log(1-\varepsilon)} \right\rceil$, Algorithm 1 terminates with probability 1 and has expected running time $O\left(\frac{\log(2\beta)}{-\log(1-\varepsilon)} \cdot \sum_{C \in \mathcal{C}} \sum_{v \in C} d_v |C|\right)$. Moreover, its output distribution ν is exactly μ upon termination.*

Proof. The `Detect` subroutine (Algorithm 2) essentially constructs the witness graph H_T and decides if $\mathcal{B}_L(R_1, \ldots, R_T)$ happens. Since the inputs fed by Algorithm 1 are always independent $\texttt{Bernoulli}(1/2)$ variables as required, we have

$$p := \mathbf{Pr}\left[\texttt{Detect}(\Phi, R_{-jT+1}, \ldots, R_{(-j-1)T})\right] = \mathbf{Pr}[\mathcal{B}_L] \leq \beta \cdot (1-\varepsilon)^L = \frac{1}{2}.$$

where the inequality follows from the assumption of the theorem.

Note that Algorithm 1 feeds disjoint (hence independent) sequences into Algorithm 2 in different rounds, so the corresponding return values are independent. Therefore, the total number of rounds J follows geometric distribution $\texttt{Geom}(1-p)$. In particular $\mathbf{Pr}[J < \infty] = 1$ and $\mathbf{E}[J] = \frac{1}{1-p} \leq 2$. So the algorithm terminates with probability 1.

Next we analyze the running time of a single call to Algorithm 2. Each iteration of the nested loop can be implemented in constant time: We index each vertex $e_{C,t}$ by the pair (C,t) to allow random access; the test of openness can be computed and stored beforehand to facilitate fast lookup. So the nested loop takes

$$O\left(\sum_{C\in\mathcal{C}}|C|\cdot L\cdot\sum_{v\in C}d_v\right)$$

time to finish. The standard breadth-first search consumes time proportional to the number of edges in the witness graph, which is bounded by the same quantity.

Finally, recall that Algorithm 1 calls Algorithm 2 J times. But $\mathbf{E}[J]\le 2$, so the expected running time of our sampler is $O\left(L\cdot\sum_{C\in\mathcal{C}}\sum_{v\in C}d_v|C|\right)$.

We could now turn to show $\nu=\mu$ as advertised. Upon termination, the percolation event $\mathcal{B}_L(R_{-JT+1},\dots,R_{-(J-1)T})$ does not happen and hence $\left|F(\Omega_\Phi;R_{-JT+1},\dots,R_{-(J-1)T})\right|=1$ by Lemma 5. But this in particular means

$$|F(\Omega_\Phi;R_{-JT+1},\dots,R_0)|=1. \tag{1}$$

For each integer $s\ge 0$, we define a (virtual) copy $(Z_t^s)_{-sn\le t\le 0}$ of systematic scan which starts from $\{0\}^V$ at time $-sn$:

$$Z_t^s:=F\left(\{0\}^V;R_{-sn+1},\dots,R_t\right).$$

Let ν^s denote the distribution of Z_0^s. Then $\lim_{s\to\infty}\nu^s=\mu$ by convergence theorem. On the other hand,

$$\begin{aligned}\|\nu^s-\nu\|&\le\mathbf{Pr}\left[F\left(\{0\}^V;R_{-sn+1},\dots,R_0\right)\ne F\left(\{0\}^V;R_{-JT+1},\dots,R_0\right)\right] && \text{(coupling)}\\ &\le\mathbf{Pr}[sn<JT] && \text{(by (1))}\\ &\to 0. && \text{(as } s\to\infty)\end{aligned}$$

Hence $\nu=\lim_{s\to\infty}\nu^s=\mu$. ◀

3.4 Proofs of Theorem 1 and Theorem 2

Armed with Theorem 8, we only need to bound $\mathbf{Pr}[\mathcal{B}_L]$ under various conditions. We bound the quantity in Section 4. As a result, Theorem 1 follows from Lemma 9 and Theorem 2 follows from Lemma 13.

4 Percolation on Witness Graphs

Let $\Phi=(V,\mathcal{C})$ be a hypergraph with $|V|=n$ and let H_T be its witness graph for any $T=(L+1)n$, $L\in\mathbb{N}$. We will analyze the probability $\mathbf{Pr}[\mathcal{B}_L]$ in the abstract probability space, where each time point $t\in[T]$ is associated with an independent $\texttt{Bernoulli}(1/2)$ variable.

4.1 General hypergraphs

▶ **Lemma 9.** *If there exists a constant $\varepsilon\in(0,1)$ and a function $x:\mathcal{C}\to(0,1)$ satisfying*

$$\forall C\in\mathcal{C}:2|C|\cdot 2^{-|C|}\le(1-\varepsilon)\cdot x(C)\cdot\prod_{C'\in\Gamma_{\Phi^2}(C)}(1-x(C')),$$

then $\mathbf{Pr}[\mathcal{B}_L]\le\sum_{C\in\mathcal{C}}\frac{x(C)}{1-x(C)}\cdot(1-\varepsilon)^{\lfloor\frac{L+1}{2}\rfloor}$ for all $L\in\mathbb{N}$.

For every $C \in \mathcal{C}$, we use $\mathcal{P}_{C,L}$ to denote the collection of induced paths $(e_1, e_2, \ldots, e_L)$ in H_T where $e_1 \cap (T-n, T] \neq \varnothing$ and the label of e_1 is C (namely $C(e_1) = C$). Let

$$\mathcal{P}^2_{C,\lfloor \frac{L+1}{2} \rfloor} := \left\{ (e_1, e_3, e_5 \ldots, e_{2\lfloor \frac{L-1}{2} \rfloor + 1}) \,:\, (e_1, e_2, e_3 \ldots, e_L) \in \mathcal{P}_C \right\}.$$

Then by the union bound, we have

$$\begin{aligned} \mathbf{Pr}\left[\mathcal{B}_L\right] &\leq \sum_{C \in \mathcal{C}} \sum_{P \in \mathcal{P}_{C,L}} \mathbf{Pr}\left[P \text{ is open}\right] \leq \sum_{C \in \mathcal{C}} \sum_{P \in \mathcal{P}^2_{C,\lfloor \frac{L+1}{2} \rfloor}} \mathbf{Pr}\left[P \text{ is open}\right] \\ &= \sum_{C \in \mathcal{C}} \sum_{(e_1, \ldots, e_{\lfloor \frac{L+1}{2} \rfloor}) \in \mathcal{P}^2_{C,\lfloor \frac{L+1}{2} \rfloor}} \prod_{i=1}^{\lfloor \frac{L+1}{2} \rfloor} 2^{-|C(e_i)|}, \end{aligned} \tag{2}$$

where the last equality follows from the fact that $e_i \cap e_{i+1} = \varnothing$ holds for every pair of consecutive vertices of a path in $\mathcal{P}^2_{C,\lfloor \frac{L+1}{2} \rfloor}$.

▶ **Lemma 10.** *If there exists a function $x : \mathcal{C} \to (0,1)$ satisfying*

$$\forall C \in \mathcal{C} : 2|C| \cdot 2^{-|C|} \leq (1-\varepsilon) \cdot x(C) \cdot \prod_{C' \in \Gamma^+_{\Phi^2}(C)} (1 - x(C')),$$

then

$$\sum_{C \in \mathcal{C}} \sum_{(e_1, \ldots, e_{\lfloor \frac{L+1}{2} \rfloor}) \in \mathcal{P}^2_{C,\lfloor \frac{L+1}{2} \rfloor}} \prod_{i=1}^{\lfloor \frac{L+1}{2} \rfloor} 2^{-|C(e_i)|} \leq \sum_{C \in \mathcal{C}} \frac{x(C)}{1 - x(C)} \cdot (1-\varepsilon)^{\lfloor \frac{L+1}{2} \rfloor}.$$

Lemma 9 is clearly a consequence of Lemma 10. We prove the latter by analyzing a *multi-type Galton-Watson branching process*.

4.1.1 Multi-type Galton-Watson branching process

Recall $\Phi = (V, \mathcal{C})$ is a fixed hypergraph and we assume that there exists a function $x : \mathcal{C} \to (0,1)$ assigning each $C \in \mathcal{C}$ a number in $(0,1)$. A $\mathcal{C}$-labelled tree is a tuple $\tau = (V_\tau, E_\tau, \mathcal{L})$ where $\mathcal{L} : V_\tau \to \mathcal{C}$ labels each vertex in V_τ with a hyperedge in $\mathcal{C}$.

Let $C \in \mathcal{C}$ be a hyperedge. Consider the following process which generates a random $\mathcal{C}$-labelled tree with the root labelled with C:

- First produce a root vertex u with label C. Initialize the active set A as $\{u\}$.
- Repeat the following until A is empty:
  - Pick some $u \in A$.
  - For every $C' \in \Gamma^+_{\Phi^2}(\mathcal{L}(u))$: create a new child for u labelled with C' *with probability* $x(C')$ independently; Add the new child to A.
  - Remove u from A.

We let $\mathcal{T}_C$ be the set of all labelled trees that can be generated by the above process and let $\mu_{\mathcal{T}_C}$ be the distribution over $\mathcal{T}_C$ induced by the process.

▶ **Lemma 11.** *For every labelled tree $\tau = (V_\tau, E_\tau, \mathcal{L}) \in \mathcal{T}_C$, it holds that*

$$\mu_{\mathcal{T}_C}(\tau) = \frac{1 - x(C)}{x(C)} \cdot \prod_{v \in V_\tau} x(\mathcal{L}(v)) \cdot \prod_{C' \in \Gamma^+_{\Phi^2}(\mathcal{L}(v))} (1 - x(C')).$$

Proof. For a vertex $v \in V_\tau$ we use $W_v \subseteq \Gamma^+_{\Phi^2}(\mathcal{L}(v))$ to denote the set of labels that do not occur as a label of some child nodes of v. Then clearly, the probability that the Galton-Watson branching process produces exactly the tree τ is given by

$$\mu_{\mathcal{T}_C}(\tau) = \frac{1}{x(C)} \prod_{v \in V_\tau} x(\mathcal{L}(v)) \prod_{C' \in W_v} (1 - x(C')).$$

In order to get rid of the W_v, we can rewrite the expression as

$$\begin{aligned}\mu_{\mathcal{T}_C}(\tau) &= \frac{1 - x(C)}{x(C)} \prod_{v \in V_\tau} \frac{x(\mathcal{L}(v))}{1 - x(\mathcal{L}(v))} \prod_{C' \in \Gamma^+_{\Phi^2}(\mathcal{L}(v))} (1 - x(C')) \\ &= \frac{1 - x(C)}{x(C)} \prod_{v \in V_\tau} x(\mathcal{L}(v)) \prod_{C' \in \Gamma_{\Phi^2}(\mathcal{L}(v))} (1 - x(C')).\end{aligned}$$

◀

For every $\ell \geq 1$, we also use $\mathcal{T}_{C,\ell}$ to denote the set of labelled trees in $\mathcal{T}_C$ containing exactly ℓ vertices. In the following, we slightly abuse notation and say that a labelled tree $\tau = (V_\tau, E_\tau, \mathcal{L}) \in \mathcal{T}_C$ (or $\mathcal{T}_{C,\ell}$) if there exists some $\tau' \in \mathcal{T}_C$ (or $\mathcal{T}_{C,\ell}$) such that τ and τ' are isomorphic.

4.1.2 Proof of Lemma 10

Let $\ell = \lfloor \frac{L+1}{2} \rfloor$. It follows from the assumption that for every $C \in \mathcal{C}$,

$$\begin{aligned}&\sum_{P=(e_1,e_2,\ldots,e_\ell) \in \mathcal{P}^2_{C,\ell}} \prod_{i=1}^{\ell} 2^{-|C(e_i)|} \\ &\leq (1-\varepsilon)^\ell \cdot \sum_{P=(e_1,e_2,\ldots,e_\ell) \in \mathcal{P}^2_{C,\ell}} \prod_{i=1}^{\ell} \frac{1}{2|C(e_i)|} \cdot x(C(e_i)) \prod_{C' \in \Gamma_{\Phi^2}(C(e_i))} (1 - x(C')). \qquad (3)\end{aligned}$$

We now define a mapping $\Psi : \mathcal{P}^2_{C,\ell} \to \mathcal{T}_{C,\ell}$ that maps each $P = (e_1, e_2, \ldots, e_\ell)$ to a labelled directed path $\tau = (V_\tau, E_\tau, \mathcal{L})$ where

- $V_\tau = \{u_1, u_2, \ldots, u_\ell\}$;
- $E_\tau = \{(u_i, u_{i+1}) : i \in [\ell - 1]\}$; and
- for every $i \in [\ell]$, $\mathcal{L}(u_i) = C(e_i)$.

The mapping Ψ is not necessarily an injection, but we can bound its multiplicity.

▶ **Lemma 12.** *For every labelled tree $\tau = (V_\tau, E_\tau, \mathcal{L}) \in \mathcal{T}_{C,\ell}$ with $V_\tau = \{u_1, \ldots, u_\ell\}$ and $E_\tau = \{(u_i, u_{i+1}) : i \in [\ell - 1]\}$, it holds that*

$$\left|\Psi^{-1}(\tau)\right| \leq 2^{\ell-1} \cdot \prod_{i=1}^{\ell} |\mathcal{L}(u_i)|.$$

Proof. We prove it by induction:

1. When $\ell = 1$, the lemma holds because there are at most $|C|$ timestamps e with label C such that $e \cap (T - n + 1, T] \neq \varnothing$;
2. We assume the statement holds for $\ell \geq 1$. Let $V_\tau = \{u_1, u_2, \ldots, u_\ell, u_{\ell+1}\}$ and $V_{\tau'} = \{u_1, u_2, \ldots, u_\ell\}$. According to the definition of Ψ, we know that for all $P \in \Psi^{-1}(\tau)$, it was extended from some $P' \in \Psi^{-1}(\tau')$. Therefore, it suffices to analyze the possible extension from P' to $P \in \Psi^{-1}(\tau)$. Assuming $P' = (e_1, e_2, \ldots, e_\ell)$ and $P = \{e_1, e_2, \ldots, e_\ell, e_{\ell+1}\}$, if P

was extended from P', then $\texttt{dist}(e_\ell, e_{\ell+1}) = 2$ and $C(e_{\ell+1}) = \mathcal{L}(u_{\ell+1})$. Therefore, there are at most $2|\mathcal{L}(u_{\ell+1})|$ timestamps $e_{\ell+1}$ satisfying $P \in \Psi^{-1}(\tau)$ according to Lemma 4. Combining with the induction hypothesis, the statement holds for $\ell + 1$. ◀

Clearly for those $\tau \in \mathcal{T}_{C,\ell}$ which are not directed paths, its pre-image $\Psi^{-1}(\tau) = \varnothing$. Therefore, it follows from Lemma 11 and Lemma 12 that

$$\begin{aligned}
&\sum_{P=(e_1,e_2,\ldots,e_\ell)\in\mathcal{P}^2_{C,\ell}} \prod_{i=1}^{\ell} \frac{1}{2|C(e_i)|} \cdot x(C(e_i)) \prod_{C'\in\Gamma_{\Phi^2}(C(e_i))} (1 - x(C')) \\
&\leq \sum_{\substack{\tau=(V_\tau,E_\tau,\mathcal{L})\in\mathcal{T}_{C,\ell}:\\ V_\tau=\{u_1,\ldots,u_\ell\}}} \prod_{i=1}^{\ell} x(\mathcal{L}(u_i)) \prod_{C'\in\Gamma_{\Phi^2}(\mathcal{L}(u_i))} (1 - x(C')) \\
&= \frac{x(C)}{1 - x(C)} \sum_{\tau\in\mathcal{T}_{C,\ell}} \mu_{\mathcal{T}_C}(\tau) \\
&< \frac{x(C)}{1 - x(C)}.
\end{aligned}$$

4.2 Refined analysis for uniform hypergraphs

If the instance $\Phi = (V, \mathcal{C})$ is a d-regular k-uniform hypergraph, we can choose $x(C) = \frac{1}{d^2k^2}$ in Lemma 9 and the condition becomes $d \leq \frac{c\cdot 2^{k/2}}{k^{1.5}}$ for some constant $c > 0$. In this section, we present a refined analysis for this case which removes the denominator $k^{1.5}$.

▶ **Lemma 13.** *For all $\varepsilon \in (0, 1)$ and $k \geq 2$, if*

$$d \leq \left(\frac{1}{4}\sqrt{\frac{9-\varepsilon}{2}} - \frac{1}{2}\right) \cdot 2^{k/2}$$

then $\mathbf{Pr}[\mathcal{B}_L] \leq \frac{k}{2^k} \cdot m \cdot (1-\varepsilon)^{\lfloor \frac{L}{2}-1 \rfloor}$ for all $L \in \mathbb{N}$.

For every induced path $(u_1, \ldots, u_\ell)$ in H_T, and $L > 0$, we use $\mathcal{P}_{(u_1,\ldots,u_\ell),L}$ to denote the collection of induced paths in H_T of length L with prefix $(u_1, \ldots, u_\ell)$[2].

▶ **Lemma 14.** *For all $\varepsilon \in (0, 1)$ and $k \geq 2$, if*

$$d \leq \left(\frac{1}{4}\sqrt{\frac{9-\varepsilon}{2}} - \frac{1}{2}\right) \cdot 2^{k/2}$$

then for every $u \in V_{H_T}$ and every $L \in \mathbb{N}$,

$$\mathbf{Pr}\left[\exists \text{ open } P \in \mathcal{P}_{(u),L} \;\middle|\; u \text{ is open}\right] \leq (1-\varepsilon)^{\lfloor \frac{L}{2}-1 \rfloor}.$$

We first show that Lemma 13 follows from Lemma 14.

Proof of Lemma 13. By the union bound, we have

$$\begin{aligned}
\mathbf{Pr}[\mathcal{B}_L] &\leq \sum_{C\in\mathcal{C}} \sum_{e_{C,t}:t\in(T-n,T]} \mathbf{Pr}\left[\exists \text{ open } P \in \mathcal{P}_{(e_{C,t}),L}\right] \\
&= \sum_{C\in\mathcal{C}} \sum_{e_{C,t}:t\in(T-n,T]} \mathbf{Pr}\left[\exists \text{ open } P \in \mathcal{P}_{(e_{C,t}),L} \;\middle|\; e_{C,t} \text{ is open}\right] \cdot \mathbf{Pr}\left[e_{C,t} \text{ is open}\right] \\
&\leq km(1-\varepsilon)^{\lfloor \frac{L}{2}-1 \rfloor} \cdot 2^{-k}.
\end{aligned}$$

◀

[2] Unlike the notation $\mathcal{P}_{C,L}$ defined in Section 4.1, we do not require $u_1 \cap \{T - n + 1, \ldots, T\} \neq \varnothing$ here.

The remaining part of the section is devoted to a proof of Lemma 14. We apply induction on L. The base case is that $L = 1$ and $L = 2$, in which the lemma trivially holds. For larger L and every path $P = (u_1, u_2, u_3 \dots, u_L) \in \mathcal{P}_{(u_1),L}$, we discuss how the vertices u_1, u_2 and u_3 overlap.

Recall for every $u = e_{C,t} \in V_T$, $C(u) = C$ is its label. Similar to [10], we classify the tuple (u_1, u_2, u_3) into three categories.

- We say u_2 is *good* if $|C(u_2) \cap C(u_1)| \leq \alpha \cdot k$ where $\alpha \in [0, 1]$ is a parameter to be set;
- If u_2 is not good, we say (u_2, u_3) is of *type I* if $C(u_3) \cap C(u_1) \neq \varnothing$;
- If u_2 is not good, we say (u_2, u_3) is of *type II* if $C(u_3) \cap C(u_1) = \varnothing$.

Then we can write

$$\begin{aligned}
&\mathbf{Pr}\left[\exists \text{ open } P \in \mathcal{P}_{(u_1),L} \;\middle|\; u_1 \text{ is open}\right] \qquad (4)\\
\leq\ &\mathbf{Pr}\left[\exists \text{ open } P = (u_1, u_2, u_3, \dots) \in \mathcal{P}_{(u_1),L} \text{ where } u_2 \text{ is good} \;\middle|\; u_1 \text{ is open}\right]\\
&+ \mathbf{Pr}\left[\exists \text{ open } P = (u_1, u_2, u_3, \dots) \in \mathcal{P}_{(u_1),L} \text{ where } (u_2, u_3) \text{ is of type I} \;\middle|\; u_1 \text{ is open}\right]\\
&+ \mathbf{Pr}\left[\exists \text{ open } P = (u_1, u_2, u_3, \dots) \in \mathcal{P}_{(u_1),L} \text{ where } (u_2, u_3) \text{ is of type II} \;\middle|\; u_1 \text{ is open}\right]
\end{aligned}$$

In the following, we bound the probabilities in the three cases respectively.

u_2 is good

In this case, we have $|C(u_2) \cap C(u_1)| \leq \alpha \cdot k$. Therefore, conditioned on u_1 being open, at least $(1 - \alpha) \cdot k$ variables in u_2 are free (i.e. independent of those variables related to u_1). The number of choices of $C(u_2)$ is at most $k \cdot d$ and the number of choices of u_2 with fixed $C = C(u_2)$ is at most k. Combining this with the induction hypothesis, we have

$$\begin{aligned}
&\mathbf{Pr}\left[\exists \text{ open } P = (u_1, u_2, u_3, \dots) \in \mathcal{P}_{(u_1),L} \text{ where } u_2 \text{ is good} \;\middle|\; u_1 \text{ is open}\right]\\
=\ &\mathbf{Pr}\left[\bigcup_{\text{good } u_2^*} \left[\exists \text{ open } P \in \mathcal{P}_{(u_1,u_2^*),L}\right] \;\middle|\; u_1 \text{ is open}\right]\\
\leq\ &\sum_{\text{good } u_2^*} \mathbf{Pr}\left[\exists \text{ open } P \in \mathcal{P}_{(u_1,u_2^*),L} \;\middle|\; u_1 \text{ is open}\right]\\
=\ &\sum_{\text{good } u_2^*} \mathbf{Pr}\left[u_2^* \text{ is open} \mid u_1 \text{ is open}\right] \cdot \mathbf{Pr}\left[\exists \text{ open } P \in \mathcal{P}_{(u_1,u_2^*),L} \;\middle|\; (u_1, u_2^*) \text{ is open}\right]\\
=\ &\sum_{\text{good } u_2^*} \mathbf{Pr}\left[u_2^* \text{ is open} \mid u_1 \text{ is open}\right] \cdot \mathbf{Pr}\left[\exists \text{ open } P' \in \mathcal{P}_{(u_2^*),L-1} \;\middle|\; u_2^* \text{ is open}\right]\\
\leq\ &k^2 d \cdot 2^{-(1-\alpha)k} \cdot (1 - \varepsilon)^{\lfloor \frac{L-3}{2} \rfloor}. \qquad (5)
\end{aligned}$$

(u_2, u_3) is of type I

In this case, we know $C(u_3)$ is adjacent to $C(u_1)$ in Φ and therefore the number of the choices of $C(u_3)$ is at most kd. The choice of u_3 with fixed $C = C(u_3)$ is at most $2k$ by Lemma 4. On the other hand, since P is an induced path, $u_1 \cap u_3 = \varnothing$ and $\mathbf{Pr}\left[u_3 \text{ is open} \mid u_1 \text{ is open}\right] = 2^{-k}$. Combining these facts with the induction hypothesis, we have

$$
\begin{aligned}
&\mathbf{Pr}\left[\exists \text{ open } P=(u_1,u_2,u_3,\dots)\in\mathcal{P}_{(u_1),L} \text{ where } (u_2,u_3) \text{ is of type I} \;\middle|\; u_1 \text{ is open}\right]\\
\le\ &\mathbf{Pr}\left[\bigcup_{u_3^*:\exists u_2,\ (u_2,u_3^*) \text{ type I}} \left[\exists \text{ open } P'\in\mathcal{P}_{(u_3^*),L-2}\right] \;\middle|\; u_1 \text{ is open}\right]\\
\le\ &\sum_{u_3^*:\exists u_2,\ (u_2,u_3^*) \text{ type I}} \mathbf{Pr}\left[\exists \text{ open } P'\in\mathcal{P}_{(u_3^*),L-2} \;\middle|\; u_1 \text{ is open}\right]\\
=\ &\sum_{u_3^*:\exists u_2,\ (u_2,u_3^*) \text{ type I}} \mathbf{Pr}\left[u_3^* \text{ is open} \;\middle|\; u_1 \text{ is open}\right]\cdot\mathbf{Pr}\left[\exists \text{ open } P'\in\mathcal{P}_{(u_3^*),L-2} \;\middle|\; (u_1,u_3^*) \text{ is open}\right]\\
=\ &\sum_{u_3^*:\exists u_2,\ (u_2,u_3^*) \text{ type I}} \mathbf{Pr}\left[u_3^* \text{ is open} \;\middle|\; u_1 \text{ is open}\right]\cdot\mathbf{Pr}\left[\exists \text{ open } P'\in\mathcal{P}_{(u_3^*),L-2} \;\middle|\; u_3^* \text{ is open}\right]\\
\le\ &2k^2d\cdot 2^{-k}\cdot(1-\varepsilon)^{\lfloor\frac{L-4}{2}\rfloor}. \qquad (6)
\end{aligned}
$$

(u_2, u_3) is of type II

This case is more complicated. We will enumerate all type II pairs (u_2, u_3) and bound the sum of probabilities that some path in $\mathcal{P}_{(u_2,u_3),L-1}$ is open conditioned on u_1 being open. To this end, we first enumerate all pairs $(C_2, C_3) \in \mathcal{C}^2$ and then consider all pairs (u_2, u_3) with $C(u_2) = C_2$ and $C(u_3) = C_3$.

For a fixed pair (C_2, C_3), we aim to bound the probability

$$
\sum_{\substack{(u_2,u_3) \text{ is of type II,}\\ C(u_2)=C_2, C(u_3)=C_3}} \mathbf{Pr}\left[\exists \text{ open } P\in\mathcal{P}_{(u_1,u_2,u_3),L} \;\middle|\; u_1 \text{ is open}\right]. \qquad (7)
$$

To ease the notation, we let $C_1 := C(u_1)$. In order for the above sum to be nonzero, we must have $|C_2 \cap C_1| > \alpha \cdot k$ and $C_3 \cap C_1 = \varnothing$. Let $a := |C_2 \cap C_1|$ and $b := |C_3 \cap C_2|$. Recall the notations in Section 3.1. For those (u_2, u_3) with $C(u_2) = C_2$ and $C(u_3) = C_3$, we can write them as $u_2 = e_{C_2,t_2}$ and $u_3 = e_{C_3,t_3}$ respectively. In the following, all pairs (u_2, u_3) discussed are of type II.

Note that $e_{C_2,t_2} =: u_2 \neq u_2' := e_{C_2,t_2'}$ if and only if $t_2 \neq t_2'$. Similarly $e_{C_2,t_2} =: u_3' \neq u_3' := e_{C_2,t_2'}$ if and only if $t_3 \neq t_3'$. Moreover, if $u_2 \neq u_2'$, then $|u_2 \cap u_1| \neq |u_2' \cap u_1|$ and similarly if $u_3 \neq u_3'$, then $|u_3 \cap u_2| \neq |u_3' \cap u_2|$. As a result, we can enumerate type II pairs (u_2, u_3) by enumerating the sizes of $u_2 \cap u_1$ and $u_3 \cap u_2$ respectively. On the other hand, if we know that $|u_2 \cap u_1| = i$ and $|u_3 \cap u_2| = j$, then,

$$
\begin{aligned}
&\mathbf{Pr}\left[\exists \text{ open } P\in\mathcal{P}_{(u_1,u_2,u_3),L} \;\middle|\; u_1 \text{ is open}\right]\\
=\ &\mathbf{Pr}\left[u_2 \text{ is open} \mid u_1 \text{ is open}\right]\cdot\mathbf{Pr}\left[u_3 \text{ is open} \mid (u_1,u_2) \text{ is open}\right]\\
&\cdot\mathbf{Pr}\left[\exists \text{ open } P\in\mathcal{P}_{(u_1,u_2,u_3),L} \;\middle|\; (u_1,u_2,u_3) \text{ is open}\right]\\
\le\ &\mathbf{Pr}\left[u_2 \text{ is open} \mid u_1 \text{ is open}\right]\cdot\mathbf{Pr}\left[u_3 \text{ is open} \mid u_2 \text{ is open}\right]\\
&\cdot\mathbf{Pr}\left[\exists \text{ open } P'\in\mathcal{P}_{(u_3),L-2} \;\middle|\; u_3 \text{ is open}\right]\\
=\ &2^{-(k-i)}\cdot 2^{-(k-j)}\cdot\mathbf{Pr}\left[\exists \text{ open } P'\in\mathcal{P}_{(u_3),L-2} \;\middle|\; u_3 \text{ is open}\right].
\end{aligned}
$$

These facts together with the induction hypothesis give

$$\begin{aligned}
&\sum_{\substack{(u_2,u_3) \text{ is of type II:}\\ C(u_2)=C_2, C(u_3)=C_3}} \mathbf{Pr}\left[\exists \text{ open } P \in \mathcal{P}_{(u_1,u_2,u_3),L} \;\middle|\; u_1 \text{ is open}\right] \\
&\le \sum_{i=1}^{a}\sum_{j=1}^{b} 2^{-(k-i)} \cdot 2^{-(k-j)} \cdot (1-\varepsilon)^{\lfloor \frac{L-4}{2} \rfloor} \\
&\le 2^{a+b-2k} \cdot 4(1-\varepsilon)^{\lfloor \frac{L-4}{2} \rfloor}.
\end{aligned}$$

It remains to enumerate (C_2, C_3) pairs. Since we know that $|C_2 \cap C_1| > \alpha \cdot k$, the number of choices of C_2 is at most $\frac{d \cdot k}{\alpha \cdot k} = \frac{d}{\alpha}$[3]. For every fixed C_2, we let $\mathcal{C} = \left\{C_3^{(1)}, C_3^{(2)}, \ldots, C_3^{(m)}\right\}$ be the collection of all possible C_3. Denote $a := |C_2 \cap C_1|$ as before and for every $i \in [m]$ let $b_i := \left|C_3^{(i)} \cap C_2\right|$. The probability of interest can therefore be written as

$$\begin{aligned}
&\mathbf{Pr}\left[\exists \text{ open } (u_1,u_2,u_3,\ldots) \in \mathcal{P}_{(u_1),L} \text{ where } (u_2,u_3) \text{ is of type II and } C(u_2)=C_2 \;\middle|\; u_1 \text{ is open}\right] \\
&\le \sum_{\substack{(u_1,u_2,u_3,\ldots)\in\mathcal{P}_{(u_1),L}:\\ (u_2,u_3) \text{ is of type II,}\\ C(u_2)=C_2}} \mathbf{Pr}\left[\exists \text{ open } P \in \mathcal{P}_{(u_1,u_2,u_3),L} \;\middle|\; u_1 \text{ is open}\right] \\
&\le \left(\sum_{i=1}^{m} 2^{a+b_i-2k}\right) \cdot 4(1-\varepsilon)^{\lfloor \frac{L-4}{2} \rfloor}.
\end{aligned}$$

To bound the term $\sum_{i=1}^{m} 2^{a+b_i-2k}$, let us list some properties of the numbers involved:

- $a \le k$ and $1 \le m \le (k-a)d$;
- $1 \le b_i \le k-a$ for all $i \in [m]$;
- $\sum_{i=1}^{m} b_i \le (k-a)d$. (This can be seen by an argument similar to the last footnote and the fact that $C_3 \cap C_1 = \varnothing$.)

Roughly the numbers are acting against each other: If a and m are large then the b_i's are small. So it is possible to control $\sum_{i=1}^{m} 2^{a+b_i-2k}$ reasonably:

▶ **Lemma 15.** *Suppose $a \le k$ and $1 \le m \le (k-a)d$. Then for any integers $b_1, \ldots, b_m \in [k-a]$ such that $\sum_{i=1}^{m} b_i \le (k-a)d$, we have the inequality $\sum_{i=1}^{m} 2^{a+b_i-2k} \le d \cdot 2^{-k}$.*

We arrange the proof in Appendix A. Returning to previous discussion, we derive

$$\begin{aligned}
&\mathbf{Pr}\left[\exists \text{ open } P = (u_1,u_2,u_3,\ldots) \in \mathcal{P}_{(u_1),L} \text{ where } (u_2,u_3) \text{ is of type II} \;\middle|\; u_1 \text{ is open}\right] \\
&\le \frac{4d^2}{\alpha} \cdot 2^{-k} \cdot (1-\varepsilon)^{\lfloor \frac{L-4}{2} \rfloor}. \qquad (8)
\end{aligned}$$

Putting all together

Plugging Equations (5), (6) and (8) into Equation (4), we have

$$\begin{aligned}
&\mathbf{Pr}\left[\exists \text{ open } P \in \mathcal{P}_{(u_1),L} \;\middle|\; u_1 \text{ is open}\right] \\
&\le \left(k^2 d \cdot 2^{-(1-\alpha)k} + 2k^2 d \cdot 2^{-k} + \frac{4d^2}{\alpha} \cdot 2^{-k}\right) \cdot (1-\varepsilon)^{\lfloor \frac{L-4}{2} \rfloor} \\
&< \left(2^{\alpha k+2} k^2 d + \frac{4}{\alpha} d^2\right) 2^{-k} \cdot (1-\varepsilon)^{\lfloor \frac{L-4}{2} \rfloor}
\end{aligned}$$

[3] To see this, consider the following way to enumerate all C_2 incident to C_1 in Φ: First pick a vertex in C_1 and then pick one of its incident hyperedges. This way we enumerated (with repetitions) $k \cdot d$ hyperedges in total, and every hyperedge $C_2 : |C_2 \cap C_1| > \alpha \cdot k$ is enumerated at least $\alpha \cdot k$ times.

where we used a very crude inequality $2^{\alpha k}+2 < 2^{\alpha k+2}$. Let us take $\alpha = \alpha(k) := \frac{1}{2} + \frac{3-2\log k}{k} \in [0,1]$ for any $k \geq 2$. Note that $2^{\alpha k+2}k^2 = 2^{5+k/2}$ by definition. On the other hand, from basic calculus one may find that $\alpha(k) : k \in \mathbb{N}$ attains minimum value $1/8$ at $k = 8$, thus $4/\alpha \leq 32 = 2^5$. Hence the above bound continues as:

$$\begin{aligned}\cdots &\leq \left(2^{k/2}d + d^2\right) 2^{5-k} \cdot (1-\varepsilon)^{\lfloor \frac{L-4}{2} \rfloor} \\ &\leq (1-\varepsilon) \cdot (1-\varepsilon)^{\lfloor \frac{L-4}{2} \rfloor} \\ &\leq (1-\varepsilon)^{\lfloor \frac{L-2}{2} \rfloor}\end{aligned}$$

where the second line is due to our assumption $d \leq \left(\frac{1}{4}\sqrt{\frac{9-\varepsilon}{2}} - \frac{1}{2}\right) \cdot 2^{k/2} =: d^*$. To see this, observe that the function $g(d) := 2^{k/2}d + d^2$ is monotonically increasing when $d \geq 0$, and that $g(d^*) = (1-\varepsilon) \cdot 2^{k-5}$.

▶ Remark 16. When $\varepsilon := 0.1$, say, the condition becomes (approximately) $d \leq 0.027 \cdot 2^{k/2}$. Taking smaller ε will allow larger applicable range of d, but it comes at the price of slowing down the sampler (by a multiplicative log-factor; see Theorem 8).

If k is sufficiently large we can further improve our bound to $d \lesssim \frac{\sqrt{33-\varepsilon}-1}{16} \cdot 2^{k/2}$.

A Proof of Lemma 15

For each $j \in [k-a]$ we introduce a counter $x_j := |\{i : b_i = j\}|$ that counts the number of b_i's taking a specific value j. Then the constraint of the lemma translates to

$$\sum_{j=1}^{k-a} j \cdot x_j \leq (k-a)d,$$

and we want to show

$$\sum_{j=1}^{k-a} 2^{a+j-2k} \cdot x_j \leq d \cdot 2^{-k}.$$

To this end, we consider a (relaxed) linear program with variables $x_1, \ldots, x_{k-a}$:

$$\begin{aligned} \max \quad & \sum_{j=1}^{k-a} 2^{a+j-2k} \cdot x_j \\ \text{s.t} \quad & \sum_{j=1}^{k-a} j \cdot x_j \leq (k-a)d \\ & x_j \geq 0 \quad (\forall j \in [k-a]). \end{aligned}$$

By the *strong duality theorem of linear programming*, its maximum value equals the minimum value of the dual program

$$\begin{aligned} \min \quad & (k-a)d \cdot y \\ \text{s.t} \quad & j \cdot y \geq 2^{a+j-2k} \quad (\forall j \in [k-a]) \\ & y \geq 0. \end{aligned}$$

Clearly the minimum value is obtained when y is as small as possible. It is clear that the sequence $h_j := \frac{2^j}{j}$ is monotonically increasing for integers $j \geq 1$, so the minimum possible y is given by the $(k-a)$-th constraint, namely

$$y^* := \frac{2^{a+(k-a)-2k}}{k-a} = \frac{2^{-k}}{k-a}.$$

Therefore, the minimum value of the dual – also the maximum value of the primal – is exactly $d \cdot 2^{-k}$, as desired.

Threshold Rates of Code Ensembles: Linear Is Best

Abstract

In this work, we prove new results concerning the combinatorial properties of random linear codes. By applying the thresholds framework from Mosheiff et al. (FOCS 2020) we derive fine-grained results concerning the list-decodability and -recoverability of random linear codes.

Firstly, we prove a lower bound on the list-size required for random linear codes over $\mathbb{F}_q$ ε-close to capacity to list-recover with error radius ρ and input lists of size ℓ. We show that the list-size L must be at least $\frac{\log_q \binom{q}{\ell} - R}{\varepsilon}$, where R is the rate of the random linear code. This is analogous to a lower bound for list-decoding that was recently obtained by Guruswami et al. (IEEE TIT 2021B). As a comparison, we also pin down the list size of random codes which is $\frac{\log_q \binom{q}{\ell}}{\varepsilon}$. This result almost closes the $O(\frac{q \log L}{L})$ gap left by Guruswami et al. (IEEE TIT 2021A). This leaves open the possibility (that we consider likely) that random linear codes perform better than the random codes for list-recoverability, which is in contrast to a recent gap shown for the case of list-recovery from erasures (Guruswami et al., IEEE TIT 2021B).

Next, we consider list-decoding with constant list-sizes. Specifically, we obtain new lower bounds on the rate required for:

- List-of-3 decodability of random linear codes over $\mathbb{F}_2$;
- List-of-2 decodability of random linear codes over $\mathbb{F}_q$ (for any q).

This expands upon Guruswami et al. (IEEE TIT 2021A) which only studied list-of-2 decodability of random linear codes over $\mathbb{F}_2$. Further, in both cases we are able to show that the rate is larger than that which is possible for uniformly random codes.

A conclusion that we draw from our work is that, for many combinatorial properties of interest, random linear codes actually perform *better* than uniformly random codes, in contrast to the apparently standard intuition that uniformly random codes are best.

1 Introduction

Coding theory is concerned with developing efficient means to makes data robust to noise. The mathematical objects used for this purpose are *(error-correcting) codes*, which are just subsets $\mathcal{C} \subseteq \Sigma^n$, where Σ is a finite alphabet of size q. It is often convenient to set $\Sigma = \mathbb{F}_q$,

where $\mathbb{F}_q$ is the finite field of order q,[1] in which case we can insist that $\mathcal{C}$ be a subspace of $\mathbb{F}_q^n$. We call such a code *linear* and denote it $\mathcal{C} \leq \mathbb{F}_q^n$. As we are mostly concerned with linear codes in the sequel we will always set $\Sigma = \mathbb{F}_q$.[2]

In order for a code to be useful for information transmission in noisy environments, we require $\mathcal{C}$ to satisfy noise-resilience properties, which amounts to insisting that the codewords are "difficult to confuse." A basic way to do this is to define a distance metric on $\mathbb{F}_q^n$ and then insist that the codewords are not too clustered. The standard choice is the (relative) *Hamming distance* which is defined as $d(\vec{x}, \vec{y}) = \frac{1}{n}|\{i \in [n] : x_i \neq y_i\}|$ for $\vec{x}, \vec{y} \in \mathbb{F}_q^n$: in words, it is the fraction of coordinates on which the vectors $\vec{x}$ and $\vec{y}$ differ. The *minimum distance* of a code is then the minimum distance between two distinct codewords, i.e., $\delta := \min\{d(\vec{c}, \vec{d}) : \vec{c}, \vec{d} \in \mathcal{C}, \vec{c} \neq \vec{d}\}$.

Beyond the minimum distance, there are other proxies for a code's noise-resilience that are widely studied. First and foremost, a popular relaxed notion of noise-resilience is provided by *list-decodability*, which informally asks that the code not be "too" clustered around any one point. More precisely, a code is said to be (ρ, L)-list-decodable if there are never L or more codewords that are all within distance ρ of some vector $z \in \mathbb{F}_q^n$, i.e.,

$$\forall \vec{z} \in \mathbb{F}_q^n,\ |\{\vec{x} \in \mathcal{C} : d(\vec{x}, \vec{z}) \leq \rho\}| < L\ .$$

The integer L is called the *list-size*. This notion, originally introduced by Elias and Wozencraft [6, 35], finds uses within coding theory and beyond in, e.g., complexity theory [27, 2, 33], cryptography [25], and learning theory [8].

We will also investigate another relaxation of list-decoding: *list-recovery*. Here, we are given a collection of input lists $S_1, \ldots, S_n \subseteq \mathbb{F}_q$ of bounded size, and the requirement is that there are not too many codewords that agree too much with these input lists. More precisely, for an integer $\ell \leq q$ we require that

$$\forall \vec{S} = (S_1, \ldots, S_n) \in \binom{\mathbb{F}_q}{\ell}^n,\ |\{\vec{x} \in \mathcal{C} : d(\vec{x}, \vec{S}) \leq \rho\}| < L\ .$$

In the above, we are denoting by $\binom{\mathbb{F}_q}{\ell}$ the family of all ℓ-element subsets of $\mathbb{F}_q$, and we are extending the Hamming distance notation $d(\cdot, \cdot)$ via

$$d(\vec{x}, \vec{S}) = \frac{1}{n}|\{i \in [n] : x_i \notin S_i\}|\ .$$

Note that $(\rho, 1, L)$-list-recovery is equivalent to list-decoding, demonstrating that list-recoverability is indeed a generalization of list-decodability. While list-recovery was initially introduced as a stepping stone towards list-decoding [11, 12, 13, 14] it has since found many new uses in theoretical computer science more broadly [20, 24, 29, 7, 22, 23].

In order for a code to provide for efficient information transmission, we would like for the code's *rate* to be as large as possible, which is a measure of the amount of information transmitted per symbol of a codeword. More precisely, the code's rate R is defined as $\frac{\log_q |\mathcal{C}|}{n}$; when the code is linear, this is simply $\frac{\dim(\mathcal{C})}{n}$.

At its core, coding theory is concerned with determining the achievable tradeoffs between a code's rate and its noise-resilience for various noise models. In this work, we focus upon the list-decodability and list-recoverability of codes. An important question we ask is how

[1] In this case, we will of course insist that q be a prime power.

[2] For nonlinear codes this does potentially lose some generality, as the alphabet size in that case could be any integer. We do remark that our results concerning arbitrary codes hold for all integer q, but emphasizing this point is not relevant to our purposes.

large the list-size L must be for these tasks. This is useful in practice, as the main constraint on the run time of most list-decoding/recovery algorithms is due to the need to process the list. Further, in applications of list-recoverable codes to constructions of expanders [20] the quality of the expansion is directly governed by the list-size.

Random Ensembles of Codes. As a stepping-stone towards a thorough understanding of the achievable tradeoffs (which is believed to be a very challenging problem), we take cues from much of the literature and study the behaviour of "typical" codes. That is, we sample codes of a prescribed rate according to natural distributions and investigate their list-decodability/-recoverability. In particular, we consider random *linear* codes, which are uniformaly sampled subspaces of $\mathbb{F}_q^n$ of the prescribed dimension. We also study uniformly random subsets of $\mathbb{F}_q^n$ of the prescribed size, which we call *random codes*.

In our work, we endeavour to provide a more fine-grained understanding of the combinatorial properties of these code ensembles. In this way, we help to uncover the landscape of achievable parameters for various code properties of interest. Beyond its theoretical interest, many code constructions [14, 19, 22, 23] use (small) linear codes as a component, and better list-decodability/recoverability of these inner codes improves these constructions.

In our results, we highlight a (perhaps surprising) fact: for list-decoding/recovery, random linear codes seem to perform *better* than uniformly random codes. On the one hand, even for the basic property of minimum distance it has already been observed that random linear codes (which achieve the Gilbert-Varshamov bound) outperform uniformly random codes. On the other hand, for problems such as list-decoding and list-recovery much of the literature appears to be focused on showing that random linear codes are "not too much worse" than uniformly random codes. We hope our work encourages the coding theory community to change perspective and endeavour to prove that random linear codes are in fact better.

1.1 Our Results

List-Recoverability of Random Linear Codes. As a first result, we provide a new lower bound on the list-size of random linear codes for list-recoverability. For context, we recall the list-recoverability capacity theorem, which gives us some coarse-grained information regarding achievable tradeoffs. For an integer $1 \leq \ell < q$, error-radius $\rho \in (1 - \ell/q)$ and $\varepsilon > 0$ it states the following:

- If $R \leq 1 - h_{q,\ell}(\rho) - \varepsilon$, there exist (ρ, ℓ, L)-list-recoverable codes with $L = O(\ell/\varepsilon)$.
- If $R \geq 1 - h_{q,\ell}(\rho) + \varepsilon$, there *do not* exist (ρ, ℓ, L)-list-recoverable codes with $L = o(q^{\varepsilon n})$.

In the above, the function $h_{q,\ell}(\cdot)$ is the (q, ℓ)-entropy function; its precise definition is not important at the moment so we defer it to Section 2. Informally, when studying codes of rate ε below the capacity for a small $\varepsilon > 0$ we refer to them as *capacity-approaching* and call ε as the *gap-to-capacity*.

This already tells us that the capacity for (ρ, ℓ, L)-list-recovery is $1 - h_{q,\ell}(\rho)$ if we insist that L be subexponential in n. However, we can ask for more fine-grained information: in particular, exactly how large must the list-size L be as a function of ε and the other parameters?

For random linear codes, we prove the following lower bound.

▶ **Theorem 1** (List-Recoverability Lower Bound for Random Linear Codes). *Let $1 \leq \ell \leq q$ be integers with q a prime power and fix $\rho \in (0, 1 - \ell/q)$. Fix $\delta > 0$. For sufficiently small $\varepsilon > 0$, a random linear code in $\mathbb{F}_q^n$ of rate $1 - h_{q,\ell}(\rho) - \varepsilon$ is whp not $\left(\rho, \ell, \lfloor \frac{\log_q \binom{q}{\ell} - (1 - h_{q,\ell}(\rho))}{\varepsilon} - \delta \rfloor\right)$-list-recoverable.*

Table 1 This table summarizes much of the work on the list-recoverability of random linear codes (RLC) and random codes (RC). The lower bound of [15] only applies when $q = p^{\Omega(1/\varepsilon)}$ for a prime p, and in [32] $\eta > 0$ is viewed as a small constant. [15] also offers a similar lower bound for the case of list-recovery from erasures.

Source	Model	Radius	Rate	List-size bound
Folklore	RC	$\rho > 0$	$1 - h_{q,\ell}(\rho) - \varepsilon$	$\leq O(\ell/\varepsilon)$
[37]	RLC	$\rho > 0$	$1 - h_{q,\ell}(\rho) - \varepsilon$	$\leq q^{O(\ell/\varepsilon)}$
[32]	RLC	$\rho = 1 - \frac{\ell}{q} - \eta$	$0.99(1 - h_{q/\ell}(\alpha) - \log_q(\ell))$	$\leq q^{O(\ln^2(\ell/\eta))}$
[15]	RLC	$\rho = 0$	$1 - \log_q(\ell) - \varepsilon$	$\geq \ell^{\Omega(1/\varepsilon)}$
Theorem 1	RLC	$\rho > 0$	$1 - h_{q,\ell}(\rho) - \varepsilon$	$> \frac{\log_q \binom{q}{\ell} - (1 - h_{q,\ell}(\rho))}{\varepsilon}$
Theorem 2	RC	$\rho > 0$	$1 - h_{q,\ell}(\rho) - \varepsilon$	$\approx \frac{\log_q \binom{q}{\ell}}{\varepsilon}$

For context, we consider the case of uniformly random codes. In this case, we obtain a tight result.

▶ **Theorem 2** (List-Recoverability for Random Codes). *Let $1 \leq \ell \leq q$ be integers with q a prime power and fix $\rho \in (0, 1 - \ell/q)$. Fix $\delta > 0$. For sufficiently small $\varepsilon > 0$, a random code in $\mathbb{F}_q^n$ of rate $1 - h_{q,\ell}(\rho) - \varepsilon$ is whp* not *$\left(\rho, \ell, \lfloor \frac{\log_q \binom{q}{\ell}}{\varepsilon} - \delta \rfloor\right)$-list-recoverable.*

On the other hand, for any $\varepsilon > 0$ and n sufficiently large, a random code in $\mathbb{F}_q^n$ of rate $1 - h_{q,\ell}(\rho) - \varepsilon$ is whp $\left(\rho, \ell, \lceil \frac{\log_q \binom{q}{\ell}}{\varepsilon} \rceil + 1\right)$-list-recoverable.

In this way, we pin down the list-recoverability for random codes to one of two or three possible values: $\lfloor \frac{\log_q \binom{q}{\ell}}{\varepsilon} + 0.99 \rfloor$, $\lceil \frac{\log_q \binom{q}{\ell}}{\varepsilon} \rceil$ (if it's different) or $\lceil \frac{\log_q \binom{q}{\ell}}{\varepsilon} \rceil + 1$.

Comparing Theorems 1 and 2 we see that our lower bound on random linear codes is less than the precise bound we have on random codes. One could potentially draw the conclusion that Theorem 1 should be improved. However, we believe that it is in fact tight. For the case of list-decoding binary codes it has already been shown that random linear performs better than uniformly random, and the bounds we obtain are the natural generalizations of the (tight) results for that case. We therefore conjecture that Theorem 1 is indeed tight. This stands in stark contrast to *erasure* list-recovery:[3] for this model, it is known that random linear codes can require lists of size $\ell^{\Omega(1/\varepsilon)}$ [15] (at least, if the field has large characteristic), whereas the lists for random codes can be just $O(\ell/\varepsilon)$. A summary of the state-of-the-art for list-recovery of RLCs and RCs is provided in Table 1.

▶ Remark 3. It might appear that our conjecture that random linear codes outperform random codes for list-recovery is contradicted by the result of [15]. However, we emphasize that the capacity for erasure list-recovery is larger, so if a code is ε-close to capacity for list-recovery from erasures for small $\varepsilon > 0$ it is above capacity for list-recovery from errors, the model we study. Hence, this lower bound does not contradict our conjecture. One can also consider the model where ρ approaches the limit $1 - \ell/q$ as is done in [32]; in this case we still suspect that random linear codes outperform uniformly random codes, but this is just speculation and further investigation is required.

[3] Here, the requirement is that for all subsets $S_1, \ldots, S_n \subseteq \mathbb{F}_q$ where at least $(1 - \rho)n$ of the S_i's satisfy $|S_i| \leq \ell$ (and the others may be all of $\mathbb{F}_q$), the number of codewords in $S_1 \times \cdots \times S_n$ is less than L.

List-decoding with small lists. Next, we turn our attention to the challenge of list-decoding when the output list-size L is a (small) constant. Thus, we are no longer in the regime where we can expect to approach the list-decoding capacity, and we are interested to know by how much we are required to back off if, say, $L = 3, 4$.

First, we consider the case where $L = 4$ for the binary field, which we also refer to as *list-of-*3 decoding. Here and throughout, we also use the following notation (which is slightly abusive): for $q \geq 2$ and nonnegative reals $x_1, \ldots, x_t$ with $x_1 + \cdots + x_t \leq 1$, $H_q(x_1, \ldots, x_t) = \sum_{i=1}^{t} x_i \log_q \frac{1}{x_i} + (1 - x_1 - \cdots - x_t) \log_q \frac{1}{1-x_1-\cdots-x_t}$.

We first prove the following possibility result for random linear codes. In the following,

$$\mathcal{B}_\rho = \left\{(x_1, x_2) \in \mathbb{R}^2 : x_1 + 2x_2 \leq 4\rho, x_1 + x_2 \leq 1, x_1, x_2 \geq 0\right\} .$$

▶ **Theorem 4** (List-of-3 decoding Random Linear Binary Codes). *Let $\rho \in (0, 5/16)$[4] and suppose*

$$R < 1 - \max_{(x_1,x_2)\in\mathcal{B}_\rho} \frac{H_2(x_1, x_2) + 2x_1 + x_2 \log_2 3}{3} .$$

Then a random linear code over $\mathbb{F}_q$ of rate R is whp $(\rho, 4)$-list-decodable.

For context, we also study the list-of-3 decodability of random codes over the binary alphabet. In this case, we can prove the following:

▶ **Theorem 5** (List-of-3 decoding Random Binary Codes). *Let $\rho \in (0, 5/16)$ and suppose*

$$R > 1 - \max_{(x_1,x_2)\in\mathcal{B}_\rho} \frac{1 + H_2(x_1, x_2) + 2x_1 + x_2 \log_2 3}{4} .$$

Then a random code over $\{0, 1\}$ of rate R is whp not *$(\rho, 4)$-list-decodable.*

On the other hand, if

$$R < 1 - \max_{(x_1,x_2)\in\mathcal{B}_\rho} \frac{1 + H_2(x_1, x_2) + 2x_1 + x_2 \log_2 3}{4} ,$$

then a random code over $\{0, 1\}$ is whp $(\rho, 4)$-list-decodable.

As $\frac{1+F}{4} \geq \frac{F}{3}$ whenever $F \leq 3$, we see that the bound in Theorem 4 is greater than the bound from Theorem 5. Using terminology that we later make precise, we see that the *threshold rate* for list-of-3 decoding binary random linear codes strictly exceeds that of binary random codes.

Next, we study list-of-2 decoding over alphabets of size $q > 2$. And again, our theorems demonstrate that random linear codes strictly outperform random codes. Define

$$\mathcal{D}_\rho := \{(x_1, x_2) \in \mathbb{R}^2 : x_1 + x_2 \leq 3\rho, x_1 + x_2 \leq 1, x_1, x_2 \geq 0\}.$$

▶ **Theorem 6** (List-of-2 decoding Random Linear q-ary Codes). *Let $\rho \in (0, 1/3)$ and suppose*

$$R < 1 - \max_{(x_1,x_2)\in\mathcal{D}_\rho} \frac{H_q(x_1, x_2) + x_1 \log_q 3(q-1) + x_2 \log_q (q-1)(q-2)}{2} .$$

Then a random linear code over $\mathbb{F}_q$ of rate R is whp $(\rho, 3)$-list-decodable.

[4] If $\rho \geq 5/16$ it is known that there are no $(\rho, 4)$-list-decodable codes with postive rate [1].

▶ **Theorem 7** (List-of-2 decoding Random q-ary Codes). *Let $\mathbb{F}_q$ be an alphabet of size q. Let $\rho \in (0, 1/3)$ and suppose*

$$R > 1 - \max_{(x_1,x_2)\in\mathcal{D}_\rho} \frac{1 + H_q(x_1, x_2) + x_1 \log_q 3(q-1) + x_2 \log_q (q-1)(q-2)}{3} .$$

Then a random code over $\mathbb{F}_q$ of rate R is whp not $(\rho, 3)$*-list-decodable.*

On the other hand, if

$$R < 1 - \max_{(x_1,x_2)\in\mathcal{D}_\rho} \frac{1 + H_q(x_1, x_2) + x_1 \log_q 3(q-1) + x_2 \log_q (q-1)(q-2)}{3} ,$$

then a random code over $\mathbb{F}_q$ is whp $(\rho, 3)$-list-decodable.

Again, we can see that the bound from Theorem 6 is greater than the bound from Theorem 7. We therefore conjecture that this phenomenon of random linear codes outperforming random codes extends to more values of L. To provide more evidence for this conjecture, we extend an argument for binary random linear codes of [10, 26] to larger values of L, and by comparing it to a computation of the threshold rate for random binary codes, show that for many parameter regimes of interest we do indeed have random linear codes outperforming random codes.

1.2 Techniques

In order to obtain our results, we rely on a recently developed toolkit for proving threshold rates for combinatorial properties of random (linear) codes. This toolkit was developed by Mosheiff et al. [28] on the way to proving that LDPC codes achieve list-decoding capacity; recent works [15, 16] have found further uses for the techniques in investing combinatorial properties of random linear codes. An analogous threshold toolkit for *random codes* was provided in [17].

Broadly speaking, the techniques of [28, 17] apply when considering a property of codes defined by forbidding a family of "bad" subsets, each of which have constant cardinality (independent of n). For example, the property of (ρ, L)-list-decodability is defined by forbidding all L-element subsets $B = \{x_1, \ldots, x_L\}$ of a Hamming ball $B(z, \rho) = \{x \in \mathbb{F}_q^n : d(x, z) \leq \rho\}$ from appearing in the code. In [28], it is proved that for any such local property there is a *threshold* rate R^* such that:

- If $R < R^*$, a random linear code satisfies the property with high probability;
- If $R > R^*$, a random linear code fails to satisfy the property with high probability.

The theorem furthermore characterizes the threshold rate R^* as the solution to a certain optimization problem. In this work, we endeavour to compute new bounds on the threshold rate R^* for various properties of interest.

In the remainder, we provide intuition for the characterization of the threshold rate from [28]. First, we identify subsets $B \subseteq \mathbb{F}_q^n$ of size L with the matrix in $\mathbb{F}_q^{n\times L}$ whose columns are given by B (the choice of ordering is immaterial), and we say that a matrix M is contained in a code $\mathcal{C}$ if $\mathcal{C}$ contains all of M's columns. For a collection of matrices $\mathcal{M} \subseteq \mathbb{F}_q^{n\times L}$, we would like to compute the threshold rate R^* for "$\mathcal{M}$-freeness," i.e., the code property of not containing a matrix in $\mathcal{M}$.

As we are interested in list-decoding/recovery, we define a set of matrices $\mathcal{M}$ such that if $\mathcal{C}$ contains a matrix from $\mathcal{M}$ then $\mathcal{C}$ is not list-decodable/recoverable. We say that the collection $\mathcal{M}$ is "bad" for list-decoding/recovery. As intuition, for list-decoding we can just take the set of matrices where each column lies in some ball $B(z, \rho)$. Next, we would like

to show that $\mathcal{M}$ is "abundant" in the sense that it is very likely that $\mathcal{C}$ contains a matrix $M \in \mathcal{M}$. In other words, if X_M denotes the indicator random variable for the event $M \subseteq \mathcal{C}$, then we should expect $X_{\mathcal{M}} := \sum_{M \in \mathcal{M}} X_M \geq 1$.

It is relatively easy to compute $\mathbb{E}[X_{\mathcal{M}}]$ and see when it exceeds 1; however, to conclude that $X_{\mathcal{M}}$ is likely to be large one needs a concentration bound. Such a bound is often provided by estimating the variance of $X_{\mathcal{M}}$. Broadly construed, [28] applies the second moment method to demonstrate that there is really only one reason that $X_{\mathcal{M}}$ would fail to be concentrated: it is because for some compressing matrix $A \in \mathbb{F}_q^{L \times L'}$ with $L' \leq L$ the set $\{MA : M \in \mathcal{M}\}$ is too small.

List-Recovery. First, we endeavour to prove a lower bound on the list-size for list-recovery. This means that we need to say that if the list-size is too small then the random linear code quite likely contains a matrix from a set $\mathcal{M}$ of bad matrices for list-recovery. In light of the above, to conclude our argument we need to show that for any compressing matrix A, the set $\{MA : M \in \mathcal{M}\}$ remains large.

To do this, we use information-theoretic techniques: we identify each of our bad matrices $M \in \mathcal{M}$ with an appropriate *type*, which is a distribution $\tau \sim \mathbb{F}_q^L$ defined as the empirical distribution of M's rows. A lower bound on $\{MA : M \in \mathcal{M}\}$ is then implied by a lower bound on the entropy of the random variable $A\vec{\boldsymbol{u}}$ for $\vec{\boldsymbol{u}} \sim \tau$. We are also free to choose the type τ which is "bad" for a certain property, in the sense that if a code contains a matrix of type τ then it fails to satisfy the property.

For the case of (ρ, ℓ, L)-list-recovery, the following type is bad: one samples uniformly $\boldsymbol{S} \in \binom{\mathbb{F}_q}{\ell}$ and then outputs $\vec{\boldsymbol{u}} = (\boldsymbol{u}_1, \ldots, \boldsymbol{u}_L) \in \mathbb{F}_q^L$, where each $\boldsymbol{u}_i$ is independently uniform over $\boldsymbol{S}$ with probability $1 - \rho$ and uniform over $\mathbb{F}_q \setminus \boldsymbol{S}$ otherwise. It thus follows that a lower bound on $\{AM : M \in \mathcal{M}\}$ is implied by a lower bound on the entropy of the random variable $A\vec{\boldsymbol{u}}$ for $\vec{\boldsymbol{u}} \sim \tau$.

Obtaining this lower bound requires a rather lengthy argument; we overview the main ideas now. We begin by partitioning the coordinates of $A\vec{\boldsymbol{u}}$ into subsets $J_1, \ldots, J_k \subseteq [L']$, where each J_i depends on at least 2 "fresh" coordinates from $\vec{\boldsymbol{u}}$, along with (perhaps) a set of leftover coordinates J_{k+1}. We then provide two arguments depending on the maximum size of a part. If, say, $|J_1|$ is large, then we can show that $(A\vec{\boldsymbol{u}})_{J_1}$ already experiences a large entropy increase. This is shown by demonstrating that these coordinates alone already allow us to nontrivially guess the subset $\boldsymbol{S}$. Otherwise, we argue that all the parts provide a nontrivial increase in the entropy, and since there must be a large number of parts in this case, by summing over all the parts we provide an adequate lower bound.

This result generalizes the list-decoding lower bound that was provided in [15, Theorem IV.1]. The argument in that paper exploited the fact that a sample from the bad type for list-decoding has a simpler structure: it looks like $\vec{\boldsymbol{v}} + \boldsymbol{\alpha}\vec{1}$, where $\vec{\boldsymbol{v}}$ is a q-ary Bernoulli random variable and $\boldsymbol{\alpha} \in \mathbb{F}_q$ is uniformly random. In our case, we do not have this nice linear structure,[5] making the analysis more intricate.

List-Decoding with Small Lists. For our results concerning list-decoding with small lists, we again use the thresholds framework. In this case, we need to consider *any* type that is bad for $(\rho, 3)$ or $(\rho, 4)$-list-decoding. For these small values of L, we are able to identify the linear map A which leads to the maximum relative entropy $\frac{H_q(A\tau)}{\dim(A\tau)}$: in each case, it is given by the map sending $(x_1, \ldots, x_L) \mapsto (x_1 - x_L, \ldots, x_{L-1} - x_L)$.

[5] One might be tempted to look at $\vec{\boldsymbol{v}} + \vec{\boldsymbol{w}}$ where $\vec{\boldsymbol{v}}$ is q-ary Bernoulli and $\vec{\boldsymbol{w}}$ is uniform over $\boldsymbol{S}$, but note that for $\ell - 1$ choices for $\boldsymbol{v}_i \in \mathbb{F}_q^*$ the sum $\boldsymbol{v}_i + \boldsymbol{w}_i$ still lies in $\boldsymbol{S}$.

To provide the proof, we break up the vector spaces based on the number of distinct coordinates of the entries, and observe that a type which is bad for list-decodability can only put so much probability mass on each of these parts. To conclude, we rely on the concavity of the entropy function as well as some combinatorial reasoning concerning the subspaces of $\mathbb{F}_2^4$ and $\mathbb{F}_q^3$. Even for these small values of L we need to be quite careful to avoid a massive explosion in the number of cases to consider, as we must look at all compressing linear maps A.

Random Codes. For the case of random codes, we can compute the threshold rates for all the properties of interest in a relatively straightforward way, as the characterization from [17] does not require us to consider any sort of compressing mapping on the types. Quite notably, in all cases we see that random linear codes appear to perform better than random codes. This is perhaps in contrast to commonly held beliefs: in this sense, a main goal of our work is to disseminate this counterintuitive phenomenon.

1.3 Related Work

In Section 1.2 we outlined the works [28, 15, 17] which developed and studied the thresholds toolkit that we apply. In this section, we provide more context for the study of random linear codes and their list-decodability/-recoverability. In what follows, q always denotes the alphabet size and ε the "gap-to-capacity" for a capacity-approaching code.

List Size Lower Bounds for Random (Linear) Codes. As we provide lower bounds for list-recovery of random linear codes, we briefly survey the known lower bounds for list-decoding. First, Guruswami and Narayanan [21] showed that capacity-approaching random (linear) codes require lists of size $\Omega_{\rho,q}(1/\varepsilon)$: by inspecting the proof one can note that the implied constant tends to 0 as $\rho \to 1 - 1/q$, or if $q \to \infty$. While on the surface their approach appears very different to ours, their use of a second-moment method is akin to the proofs underlying the thresholds framework from [28], so the approaches are in fact somewhat similar. Later, Li and Wootters [26] gave a $\sim 1/\varepsilon$ list-size lower bound for capacity-approaching random codes. Again, the argument relies on the second-moment method.

In [15], a lower bound for the list-decodability of capacity-approaching random linear codes is given, showing that lists of size $\sim \frac{h_q(\rho)}{\varepsilon}$ are required: our list-recovery list-size lower bound is a generalization of this result. Lastly, in [17] the threshold rate for $(\rho, 2)$-list-decodability is computed, providing a lower bound and an upper bound: this segues us nicely into a discussion of the work on computing upper bounds on list-sizes.

List Size Upper Bounds for Random Linear Codes. There has been a long line of work [37, 10, 9, 5, 34, 31, 32, 26, 17] studying the list-decodability of capacity-approaching random linear codes, and we now highlight some relevant results. First, Zyablov and Pinkser [37] demonstrated that capacity-approaching RLCs are indeed (ρ, L)-list-decodable, albeit with $L = q^{\Omega(1/\varepsilon)}$. Subsequent work has endeavoured to prove list-decodability with $L = O(1/\varepsilon)$. The existence of such linear codes over $\mathbb{F}_2$ was first demonstrated by [10]; later, [26] showed that this holds with high probability for randomly sampled linear codes, and subsequently [15] showed this is true for *average-radius*[6] list-decoding.

[6] In this model, it is required that the code does not contain L points whose average distance from a centre is less than ρ. Thus, it is a stricter requirement than standard list-decoding.

As for larger alphabets, [9] showed that lists of size $O_{\rho,q}(1/\varepsilon)$ do indeed suffice for random linear codes. We further remark that their argument uses a certain Ramsey-theoretic concept called a 2-increasing sequence to choose the order in which to reveal coordinates, which is vaguely reminiscent of the "fresh" coordinates that we have defined by the J_i's in our list-recovery lower bound argument. A drawback of this work is that the implied constant in the $O_{\rho,q}(\cdot)$ notation degrades as $\rho \to 1-1/q$ or if q grows too large. In light of this restriction, a line of works [5, 34, 31] has studied the "high noise regime," where $\rho = 1-1/q-\eta$ and one endeavours to show that lists of size $O(1/\eta^2)$ suffice for codes of rate $\Omega(\eta^2)$. These results are still not quite optimal in the sense that the implied constants (even for the rate) lag behind the parameters achievable by random codes. Lastly, for list-recoverability with input list-size ℓ it appears that the best upper bound on the list-size is due to [32], where it is shown that lists of size $(q\ell)^{O(\log(\ell)/\varepsilon)}$ suffice.

Lower Bounds for List Sizes of Arbitrary Codes. While we exclusively study random (linear) codes, we view these as a proxy for determining the actual achievable tradeoffs. As lists of size $\Theta(1/\varepsilon)$ are required for random codes, it is natural to wonder if all capacity-approaching (ρ, L)-list-decodable codes require lists of size $\Omega(1/\varepsilon)$. Blinovsky [4, 3] has shown a lower bound of $\Omega_\rho(\log(1/\varepsilon))$. In the high noise regime, viz., $\rho = 1-1/q-\eta$, Guruswami and Vadhan [21] provided a $\Omega_q(1/\eta^2)$ lower bound on the list size. Lastly, for *average-radius* list-decoding Guruswami and Narayanan [18] proved a $\Omega_\rho(1/\sqrt{\varepsilon})$ lower bound.

1.4 Open Problems

In this work, we have progressed our understanding of combinatorial properties of random (linear) codes. A main conclusion of our work is that for list-decoding/recovery, random linear codes perform better.[7]

There are many open problems which remain to be studied and we list some below.

- Provide the corresponding upper bounds on the threshold rate for $(\rho, 4)$-list-decoding binary random linear codes, and the threshold rate for $(\rho, 3)$-list-decoding q-ary random linear codes.
- Provide the corresponding lower bound on the threshold rate for (ρ, ℓ, L)-list-recovery in the capacity-approaching regime. In fact, for $q > 2$, the threshold rate for (ρ, L)-list-decoding is still open. This is quite likely a very challenging problem; the only tight argument we have is due to [10, 26] (see also [15]) which only applies to list-decoding over the binary field, and this argument appears too "rigid" to apply in more generality.
- Get a better understanding for *worst-case* codes. In particular, to the best of our knowledge the *Plotkin points* for (ρ, L)-list-decoding for $q > 2$ are not known. That is, compute the minimum value ρ^* such that for all $\rho > \rho^*$, there are no q-ary (ρ, L)-list-decodable code families with positive rate. (Recent work [36] expresses the Plotkin point as a solution to a certain optimization problem, but we do not see how to extract a simple expression from this.)

1.5 Organization

In the subequent section, we introduce the necessary notations and definitions that we will use in this work, along with the tools from [28, 17] that we apply. In Section 3, we provide our lower bound on the list-size for the list-recoverability of random linear codes which

[7] For list-recovery, we admittedly only provide some evidence in this direction.

approach capacity. In Section 4, we lower bound the threshold rate for list-of-2 decoding (for general q) and list-of-3 decoding (in the binary case). We also compare random linear codes to random codes over the binary alphabet for more values of L. For space reasons, most of the technical proofs are deferred to the full version.

2 Preliminaries

Miscellaneous Notations. For an integer $n \geq 1$, we denote $[n] := \{1, 2, \ldots, n\}$. For a set X we denote by $\binom{X}{\ell}$ the family of all subsets of X with ℓ elements, and similarly $\binom{X}{\leq \ell}$ denotes the family of all subsets of X with $\leq \ell$ elements. Throughout, $\mathbb{F}_q$ denotes the finite field with q elements, for q a prime power.

For clarity, vectors are typically denoted with an arrow overtop. Given a vector $\vec{x} \in \mathbb{F}_q^n$ and a subset $I \subseteq [n]$ we denote by $\vec{x}_I$ the length $|I|$ vector $(x_i : i \in I) \in \mathbb{F}_q^{|I|}$. We reserve $\vec{1}$ for the all-1's vector; if we wish to emphasize its length we subscript it, i.e., $\vec{1}_D$ is the all-1's vector of length D. Random variables are typically written in boldface, e.g., $\boldsymbol{x}, \boldsymbol{y}$, etc. In particular, random vectors are denoted, e.g., $\vec{\boldsymbol{u}}$.

Coding Theory Terminology. A *code* $\mathcal{C}$ is a subset of $\mathbb{F}_q^n$ for $\mathbb{F}_q$ the finite field of order q, a prime power. Elements $\vec{c} \in \mathcal{C}$ are called *codewords*, the integer n is the *block-length*, and the integer q is the *alphabet size*; such a code is also called *q-ary*. When $q = 2$ the code is deemed *binary*. We are typically interested in *linear* codes, which are $\mathcal{C} \leq \mathbb{F}_q^n$, i.e., they are subspaces. The *rate* of a code $\mathcal{C}$ is $R = R(\mathcal{C}) := \frac{\log_q |\mathcal{C}|}{n}$ and its minimum distance is $\delta = \delta(\mathcal{C}) := \min\{d(\vec{c}, \vec{d}) : \vec{c} \neq \vec{d}, \vec{c}, \vec{d} \in \mathcal{C}\}$, where $d(\vec{x}, \vec{y}) = \frac{1}{n}|\{i \in [n] : x_i \neq y_i\}|$ is the (relative) Hamming distance from $\vec{x}$ to $\vec{y}$. We also slightly extend this notation as follows: for a vector $\vec{x} \in \mathbb{F}_q^n$ and a tuple of subsets $\vec{S} = (S_1, \ldots, S_n)$, $S_i \subseteq \mathbb{F}_q$, we define $d(\vec{x}, \vec{S}) := \frac{1}{n}|\{i \in [n] : x_i \notin S_i\}|$, i.e., the fraction of coordinates i for which $\vec{x}$ "disagrees" with the corresponding subset of $\vec{S}$.

A *random linear code* of rate R is a uniformly random subspace of $\mathbb{F}_q^n$ of dimension Rn.[8] As this concept will arise regularly in this work, we occasionally use the abbreviation *RLC*. A *random code* of rate R is a random subset of $\mathbb{F}_q^n$ obtained by including each element independently with probability $q^{(R-1)n}$.[9] For this concept, we use the abbreviation *RC*.

2.1 List-decodability and List-recoverability

In this work, we study combinatorial properties of linear codes. Of primary interest to us are list-decodability and list-recoverability, which we now define.

▶ **Definition 8** (List-decodability). *Let $\rho \in (0, 1 - 1/q)$ and $L \geq 1$. A code $\mathcal{C} \subseteq \mathbb{F}_q^n$ is called* (ρ, L)-list-decodable *if for all $\vec{z} \in \mathbb{F}_q^n$,*

$$|\{\vec{c} \in \mathcal{C} : d(\vec{c}, \vec{z}) \leq \rho\}| < L \ .$$

[8] In fact, there are different ways to sample linear codes. For concreteness, we typically implicitly use the model where a random parity check matrix $\boldsymbol{H} \in \mathbb{F}_q^{(1-R)n \times n}$ is sampled and we output $\boldsymbol{\mathcal{C}} = \ker(\boldsymbol{H})$. Of course, there is a small chance $\boldsymbol{\mathcal{C}}$ has rate larger than R, but as this probability is exponentially small in n it is immaterial to our conclusions. We also briefly use the model where a random $\boldsymbol{G} \in \mathbb{F}_q^{Rn \times n}$ is sampled and we output $\boldsymbol{\mathcal{C}} = \mathrm{im}(\boldsymbol{G})$.

[9] By Chernoff bounds, such a code as rate $R \pm o(1)$ with high probability.

We also use the terminology "list-of-L-decoding" for $(\rho, L+1)$-list-decoding, e.g., list-of-2-decoding corresponds to $(\rho, 3)$-list-decoding.

The list-decoding *capacity* is the value $R^*(\rho)$ such that for any $R < R^*(\rho)$ there exists $L > 1$ such that infinite families of (ρ, L)-list-decodable codes of rate at least R exist, but for any $R > R^*(\rho)$ such an infinite family does not exist. It is known that

$$R^*(\rho) = 1 - h_q(\rho) \ ,$$

where

$$h_q(\rho) = \rho \log_q \frac{q-1}{\rho} + \log_q \frac{1}{1-\rho}$$

is the q-ary entropy function.

▶ **Definition 9** (List-recoverability). *Let $\rho \in (0, 1-1/q)$, $1 \le \ell \le q$ and $L \ge 1$. A code $\mathcal{C} \subseteq \mathbb{F}_q^n$ is called* (ρ, ℓ, L)-list-recoverable *if for all tuples of subsets $\vec{S} = (S_1, \ldots, S_n) \in \binom{\mathbb{F}_q}{\le \ell}^n$,*

$$|\{\vec{c} \in \mathcal{C} : d(\vec{c}, \vec{S}) \le \rho\}| < L \ .$$

In analogy to the list-decoding capacity, the *list-recovery capacity* is the value $R^*(\rho, \ell)$ such that for any $R < R^*(\rho, \ell)$ there exists $L > 1$ such that infinite families of (ρ, ℓ, L)-list-recoverable codes of rate at least R exist, but for any $R > R^*(\rho, \ell)$ such an infinite family does not exist. It is known that

$$R^*(\rho, \ell) = 1 - h_{q,\ell}(\rho) \ ,$$

where

$$h_{q,\ell}(\rho) = \rho \log_q \frac{q-\ell}{\rho} + (1-\rho) \log_q \frac{\ell}{1-\rho}$$

is the (q, ℓ)-entropy function.

2.2 Information-Theoretic Concepts

For a random variable $\boldsymbol{x}$ over a domain $\mathcal{X}$ we denote its entropy by

$$H(\boldsymbol{x}) = \sum_{x \in \mathcal{X}} \Pr[\boldsymbol{x} = x] \log \frac{1}{\Pr[\boldsymbol{x} = x]} \ ,$$

where we use the convention $0 \log \frac{1}{0} = 0$. If τ is a distribution then we define $H(\tau)$ to be the entropy of a random variable distributed according to τ.

Given another random variable $\boldsymbol{y}$ supported on a set $\mathcal{Y}$, the *conditional entropy* of $\boldsymbol{x}$ given $\boldsymbol{y}$ is

$$H(\boldsymbol{x}|\boldsymbol{y}) = \mathop{\mathbb{E}}_{y \sim \boldsymbol{y}} [H(\boldsymbol{x}|\boldsymbol{y} = y)] = \sum_{x \in \mathcal{X}, y \in \mathcal{Y}} \Pr[\boldsymbol{x} = x, \boldsymbol{y} = y] \log \frac{\Pr[\boldsymbol{x} = x]}{\Pr[\boldsymbol{x} = x, \boldsymbol{y} = y]} \ .$$

Intuitively, this is the expected amount of entropy remaining in $\boldsymbol{x}$ after revealing $\boldsymbol{y}$. Conditional entropy satisfies the *chain rule* $H(\boldsymbol{x}, \boldsymbol{y}) = H(\boldsymbol{x}|\boldsymbol{y}) + H(\boldsymbol{y})$, which can be extended by induction to larger collections of random variables.

We also use the notion of *mutual information*, which is a measure of the amount of information one random variable gives about another and is defined as follows:

$$I(\boldsymbol{x}; \boldsymbol{y}) = H(\boldsymbol{x}) - H(\boldsymbol{x}|\boldsymbol{y}) = H(\boldsymbol{y}) - H(\boldsymbol{y}|\boldsymbol{x}) = H(\boldsymbol{x}, \boldsymbol{y}) - H(\boldsymbol{x}) - H(\boldsymbol{y}) \ .$$

(The equalities are justified by the chain rule.) We also consider the *conditional mutual information*, defined as follows:

$$I(\boldsymbol{x};\boldsymbol{y}|\boldsymbol{z}) = H(\boldsymbol{x}|\boldsymbol{z}) - H(\boldsymbol{x}|\boldsymbol{y},\boldsymbol{y}) = H(\boldsymbol{y}|\boldsymbol{z}) - H(\boldsymbol{y}|\boldsymbol{x},\boldsymbol{z}) = H(\boldsymbol{x},\boldsymbol{y}|\boldsymbol{z}) - H(\boldsymbol{x}|\boldsymbol{z}) - H(\boldsymbol{y}|\boldsymbol{z}) \ ,$$

where $\boldsymbol{z}$ is another random variable.

Conditional entropy, mutual information and conditional mutual information all satisfy the *data-processing inequality*: for any function f supported on $\mathcal{Y}$ (the domain of Y), we have

$$H(\boldsymbol{x}|f(\boldsymbol{y})) \geq H(\boldsymbol{x}|\boldsymbol{y}) \ , I(\boldsymbol{x};\boldsymbol{y}) \geq I(\boldsymbol{x};f(\boldsymbol{y})) \ , I(\boldsymbol{x};\boldsymbol{y}|\boldsymbol{z}) \geq I(\boldsymbol{x};f(\boldsymbol{y})|\boldsymbol{z}) \ .$$

We will also use *Fano's inequality*.

▶ **Theorem 10** (Fano's Inequality.). *Let $\boldsymbol{x}$ be a random variable supported on $\mathcal{X}$, $\boldsymbol{y}$ a random variable supported on $\mathcal{Y}$ and $f : \mathcal{Y} \to \mathcal{X}$. Define $p_{\mathrm{err}} := \Pr[f(\boldsymbol{y}) \neq \boldsymbol{x}]$. Then,*

$$H(\boldsymbol{x}|\boldsymbol{y}) \leq h(p_{\mathrm{err}}) + p_{\mathrm{err}} \cdot \log(|\mathcal{X}| - 1) \ .$$

When we wish to change the base of the logarithm with which the entropy or mutual information, the desired base is subscripted. That is,

$$H_q(\boldsymbol{x}) := \frac{H(\boldsymbol{x})}{\log q} \ , \qquad I_q(\boldsymbol{x};\boldsymbol{y}) := \frac{I(\boldsymbol{x};\boldsymbol{y})}{\log q} \ ,$$

and similarly for the conditional versions of these quantities. Finally, as a slight abuse of notation, we also write

$$H_q(x_1,\ldots,x_t) = \sum_{i=1}^{t} x_i \log_q \frac{1}{x_i} + (1 - x_1 - \cdots - x_t) \log_q \frac{1}{1 - x_1 - \cdots - x_t}$$

if $x_1,\ldots,x_t$ are positive numbers satisfying $\sum_{i=1}^{t} x_i \leq 1$. (We caution that for $q > 2$, $H_q(x) \neq h_q(x)$.)

2.3 Thresholds

We now introduce the specialized notations and tools that we will need in order to apply the machinery of [28]. First, for a distribution $\tau \sim \mathbb{F}_q^b$ and a linear map $A : \mathbb{F}_q^b \to \mathbb{F}_q^c$, we let $A\tau$ denote the distribution of the random vector $A\vec{\boldsymbol{u}}$ for $\vec{\boldsymbol{u}} \sim \tau$. In more detail, $A\tau$ has the following probability mass function:

$$\Pr_{\vec{\boldsymbol{v}} \sim A\tau}[\vec{\boldsymbol{v}} = \vec{y}] = \sum_{\vec{x} \in A^{-1}(\vec{y})} \Pr_{\vec{\boldsymbol{u}} \sim \tau}[\vec{\boldsymbol{u}} = \vec{x}] \ .$$

While we are generally concerned with understanding the probability that certain "bad sets" lie in our code, it is in fact more convenient to work with matrices. For a matrix $M \in \mathbb{F}_q^{n \times b}$ and a code $\mathcal{C} \subseteq \mathbb{F}_q^n$ we say that $\mathcal{C}$ contains M if the columns of M are contained in $\mathcal{C}$.

Every matrix is assigned a *type*, and the type of a matrix is determined by the matrix's empirical row distribution as follows:

▶ **Definition 11** ($\tau_M, \dim(\tau), \mathcal{M}_{n,\tau}$). *For a matrix $M \in \mathbb{F}_q^{n \times b}$, we define its* type τ_M *to be the distribution given by the empirical distribution of M's rows. That is, for all $\vec{v} \in \mathbb{F}_q^b$ we have*

$$\tau_M(\vec{v}) := \frac{|\{i \in [n] : i\text{th row of } M \text{ equals } \vec{v}\}|}{n} \ .$$

For a distribution τ on $\mathbb{F}_q^b$, $\dim(\tau)$ denotes the dimension of the span of τ's support, i.e.,

$$\dim(\tau) := \dim(\mathrm{span}(\mathrm{supp}(\tau))).$$

*We denote by $\mathcal{M}_{n,\tau}$ the set of all matrices in $\mathbb{F}_q^{b\times n}$ with empirical row distribution τ. We call a type τ b-*local *if $\tau \sim \mathbb{F}_q^b$; note that a b-local type has $\dim(\tau) \le b$.*

▶ Remark 12. Technically, for a distribution $\tau \sim \mathbb{F}_q^b$ it could be the case that $\mathcal{M}_{n,\tau}$ is empty just because, for some $\vec{v} \in \mathbb{F}_q^b$, $\tau(\vec{v}) \notin \{0, 1/n, 2/n, \dots, (n-1)/n, 1\}$. For such τ, we can define $\mathcal{M}_{n,\tau}$ to consist of those matrices which contain either $\lfloor n \cdot \tau(\vec{v})\rfloor$ or $\lceil n \cdot \tau(\vec{v})\rceil$ copies of $\vec{v}$. As we are always dealing with the setting where n is assumed to be sufficiently large compared to all other parameters, this does not affect the analysis. Hence, we may safely ignore this technicality, which we do for the clarity of exposition.

Our target is an understanding of the threshold rate for a combinatorial property of random linear codes. The combinatorial properties that we will study are those that are defined by excluding a set of types, as follows.

▶ **Definition 13** (τ-freeness, local properties)**.** *Given a code $\mathcal{C}$ and a type τ, we say that $\mathcal{C}$ is* τ-free *if $\mathcal{C}$ does not contain any matrix $M \in \mathcal{M}_{n,\tau}$, i.e., no matrix M of type τ.*

For a set $\mathcal{T}$ of types, where each $\tau \sim \mathbb{F}_q^b$ for some $b \in \mathbb{N}$, we say that $\mathcal{C}$ is $\mathcal{T}$-free *if it is τ-free for all $\tau \in \mathcal{T}$. We refer to $\mathcal{T}$-freeness as a* b-local property *of codes.*

For a more in-depth discussion of the definition, we refer the reader to, [28, Section 2] or [30, Chapter 3]. To provide some intuition, we demonstrate how (ρ, ℓ, L)-list-recoverability may be described as an L-local property. We define $\mathcal{T}$ to be the set of all types $\tau \sim \mathbb{F}_q^L$ such that for some (correlated) distribution $\nu \sim \binom{\mathbb{F}_q}{\ell}$,

$$\forall i \in [L], \quad \Pr_{(\vec{\boldsymbol{u}},\boldsymbol{S})\sim(\tau,\nu)}[\boldsymbol{u}_i \notin \boldsymbol{S}] \le \rho \tag{1}$$

and furthemore we require

$$\forall 1 \le i < j \le L, \quad \Pr_{\vec{\boldsymbol{u}}\sim\tau}[\boldsymbol{u}_i \neq \boldsymbol{u}_j] > 0 \ .$$

(This second condition amounts to requiring that any matrix of type τ has distinct columns.) We refer to the collection of all these types as $\mathcal{T}_{\rho,\ell,L}$.

We now characterize (up to $o(1)$ terms) the threshold rate of a property.

▶ **Theorem 14** ([30], Theorem 3.3.9: Thresholds for Random Linear Codes)**.** *Fix $b \in \mathbb{N}$ and let $\mathcal{T}$ be a set of b-local types. Then the threshold rate for $\mathcal{T}$-freeness is*

$$1 - \max_{\tau\in\mathcal{T}} \min_{A} \left\{ \frac{H_q(A\tau)}{\dim(A\tau)} \right\} \pm o_{n\to\infty}(1) \ , \tag{2}$$

where the minimum is taken over all surjective linear maps $A : \mathbb{F}_q^b \to \mathbb{F}_q^c$ with $c \le b$.

Let us specialize to the case of τ-freeness for a single type τ. Suppose that $R > 1 - \min_A \left\{ \frac{H_q(A\tau)}{\dim(A\tau)} \right\}$. Theorem 14 tells us that it is unlikely that a RLC of rate R is τ-free. Stated differently, we can expect that there is at least one matrix of type τ contained in such an RLC. In fact, while we do not prove this, it is in fact likely that there will be *many* such matrices. For this reason, we use the following terminology for types τ satisfying $R > 1 - \min_A \left\{ \frac{H_q(A\tau)}{\dim(A\tau)} \right\}$: we call them *abundant*.

In proving an upper bound R_{upper} on the threshold rate for a property of interest (e.g., (ρ, ℓ, L)-list-recovery), we will follow the following steps. First, we define an appropriate set type τ and prove that a code satisfies the property of interest only if it is τ-free. Informally, we refer to this as a proof that τ is *bad* for the property of interest. Next, we show that for RLCs of rate R_{upper}, the type τ is abundant. This is the more challenging part of the theorem, as the minimization over the set of all linear maps A is quite challenging to control. Nonetheless, we are able to carry out this program for (ρ, ℓ, L)-list-recovery, as advertised.

In proving a lower bound on R_{low} on the threshold rate for a property of interest (e.g., $(\rho, 3)$-list-decoding), we need to consider *any* type that is bad for list-decoding, and then show that it is *implicitly rare*: that is, for some matrix A, there are relatively few matrices of type $A\tau$, and hence it is likely no matrix of that type lies in the RLC. That is, we must upper bound the ratio of the entropy of $A\tau$ with the dimension of $A\tau$. Here, we have the freedom to choose A, but the argument must apply to all types τ. This is especially tricky when given a type τ whose support is contained in a strict subspace, as then the bound on the entropy must be commensurately smaller. It is for this reason that we only consider small values of L, as one suffers from a combinatorial explosion in the number of possible support spaces for the types.

Thresholds for Random Codes. For thresholds of random codes, the characterization theorem is simpler in the sense that we do not have to minimize over compressive mappings, at least if the property satisfies certain technical conditions. Fortunately, the characterization applies to list-recoverability, and hence also list-decodability.

▶ **Theorem 15** ([17], Theorem 2: Thresholds for Random Codes)**.** *Let $b \in \mathbb{N}$ and let $\mathcal{T}$ be a set of b-local types. Let T be a convex approximation for $\mathcal{T}$. Then the threshold rate for $\mathcal{T}$-freeness is*

$$1 - \frac{\max_{\tau \in T} H_q(\tau)}{b} \ .$$

▶ **Proposition 16** ([17], Lemma 1)**.** *$\mathcal{T}_{\rho,\ell,L}$ is a convex approximation for the property of (ρ, ℓ, L)-list-recoverability.*

3 Lower Bound on List-Size for List-Recovery

Througout this section, the following notations are fixed:

- $q \in \mathbb{N}$ is a (fixed) prime power;[10]
- $\ell \in \mathbb{N}$ satisfies $1 \leq \ell < q$;
- $\rho \in \mathbb{R}$ satisfies $0 < \rho < 1 - \frac{\ell}{q}$; and
- $\delta > 0$ is a small constant.

All these parameters are constants, independent of the growing parameter n. Our main result in this section is the following theorem.

▶ **Theorem 17.** *There exists $\varepsilon_{q,\ell,\rho,\delta} > 0$ such that for all $0 < \varepsilon < \varepsilon_{q,\ell,\rho,\delta}$ and n sufficiently large, a random linear code in $\mathbb{F}_q^n$ of rate $1 - h_{q,\ell}(\rho) - \varepsilon$ is not $\left(\rho, \ell, \lfloor \frac{\log_q \binom{q}{\ell} - (1 - h_{q,\ell}(\rho))}{\varepsilon} - \delta \rfloor\right)$-list-recoverable with probability $1 - o(1)$.*

[10] When we discuss random codes, q may be any positive integer.

The proof of this theorem follows the same outline as has been used in, e.g., [15]. Namely, we begin by defining a L-local type which we show is *bad* for (ρ, ℓ, L)-list-recovery. Later, we prove that the type is indeed *abundant*, which is the more challenging part of the theorem.

The bad L-local type is defined as follows.

▶ **Definition 18** (The bad type for (ρ, ℓ, L)-list-recoverability)**.** *Fix $L \in \mathbb{N}$. Define the distribution $\tau \sim \mathbb{F}_q^L$ via the following procedure for sampling a random vector $\vec{\boldsymbol{u}} = (\boldsymbol{u}_1, \ldots, \boldsymbol{u}_L)$:*

- *First, $\boldsymbol{S} \sim \binom{\mathbb{F}_q}{\ell}$ is sampled uniformly at random;*
- *Second, for $i = 1, \ldots, L$, we sample $\boldsymbol{u}_i \sim \mathbb{F}_q$ as*

$$\Pr[\boldsymbol{u}_i = x | \boldsymbol{S} = S] = \begin{cases} \frac{1-\rho}{\ell} & \text{if } x \in S \\ \frac{\rho}{q-\ell} & \text{if } x \notin S \end{cases} ,$$

and conditioned on $\boldsymbol{S} = S$, the coordinates $\boldsymbol{u}_1, \ldots, \boldsymbol{u}_L$ are independent*.*

Note that such a type does indeed lie in the set $\mathcal{T}_{\rho,\ell,L}$. Indeed, if $\nu \sim \boldsymbol{S}$ we clearly have

$$\forall i \in [L], \quad \Pr_{(\vec{\boldsymbol{u}}, \boldsymbol{S}) \sim (\tau, \nu)} [\boldsymbol{u}_i \notin \boldsymbol{S}] = \rho$$

and we also readily have $\Pr_{\vec{\boldsymbol{u}} \sim \tau}[\boldsymbol{u}_i \neq \boldsymbol{u}_j] > 0$. From [17], we conclude that τ is bad for (ρ, ℓ, L)-list-recovery.

We now claim that the type τ is indeed abundant, i.e., that it has sufficiently large (relative) entropy. This is the more technical part of the proof, and its proof is deferred to the full version.

▶ **Lemma 19.** *There exists an integer $L_{\rho,q,\ell,\delta}$ such that for all integers $L \geq L_{\rho,q,\ell,\delta}$, the following holds. Let $\vec{\boldsymbol{u}} \sim \tau$, and let $A \in \mathbb{F}_q^{L' \times L}$ with $L' \leq L$ and $\operatorname{rank}(A) = L'$. Then*

$$H_q(A\vec{\boldsymbol{u}}) \geq L' \cdot h_{q,\ell}(\rho) + \log_q \binom{q}{\ell} - 1 + h_{q,\ell}(\rho) - \delta \geq L' \cdot \left(h_{q,\ell}(\rho) + \frac{\log_q \binom{q}{\ell} - 1 + h_{q,\ell}(\rho) - \delta}{L} \right) .$$

Assuming Lemma 19, we now show that this does indeed yield our target Theorem 17.

Proof of Theorem 17. Let $L_{\rho,q,\ell,\delta/2}$ be the promised constant from Lemma 19, and choose $\varepsilon_{q,\ell,\rho,\delta} := \frac{\log_q \binom{q}{\ell} - 1 + h_{q,\ell}(\rho)}{L_{\rho,q,\ell,\delta/2}+1}$. Let $\varepsilon < \varepsilon_{q,\ell,\rho,\delta}$. Let $L = \left\lfloor \frac{\log_q \binom{q}{\ell} - 1 + h_{q,\ell}(\rho)}{\varepsilon} - \delta \right\rfloor$, and define τ as in Definition 18 with this choice of L.

By Lemma 19, as $L \geq L_{\rho,q,\ell,\delta/2}$ we have that for all surjective linear maps $A : \mathbb{F}_q^L \to \mathbb{F}_q^{L'}$

$$\frac{H_q(A\tau)}{L'} \geq h_{q,\ell}(\rho) + \frac{\log_q \binom{q}{\ell} - 1 + h_{q,\ell}(\rho) - \delta/2}{L} .$$

We note further that as τ has full support the same is true for $A\tau$, i.e., $\dim(A\tau) = L'$. Thus, by Theorem 14 we have that the threshold rate for τ-freeness is at most

$$1 - h_{q,\ell}(\rho) - \frac{\log_q \binom{q}{\ell} - 1 + h_{q,\ell}(\rho) - \delta/2}{L} - o_{n\to\infty} < 1 - h_{q,\ell}(\rho) - \varepsilon ,$$

where the last inequality holds for large enough n. In other words, a random linear code of rate $1 - h_{q,\ell}(\rho) - \varepsilon$ contains a matrix $M \in \mathcal{M}_{n,\tau}$ with probability $1 - o(1)$. As we know that a code $\mathcal{C}$ which contains a matrix of type τ is not (ρ, ℓ, L)-list-recoverable, our theorem is proved. ◀

3.1 List-recoverability lower bound for random codes

For context, we provide nearly matching upper and lower bounds for list-recovery for *uniformly* random codes. There is a similar result for list-recovery provided in [17], but it is not optimized for the case of capacity-approaching codes.

▶ **Theorem 20.** *There exists $\varepsilon_{q,\ell,\rho,\delta}$ such that for all $0 < \varepsilon < \varepsilon_{q,\ell,\rho,\delta}$ and n sufficiently large, a random code in $\mathbb{F}_q^n$ of rate $1 - h_{q,\ell}(\rho) - \varepsilon$ is not $\left(\rho, \ell, \lfloor \frac{\log_q \binom{q}{\ell}}{\varepsilon} - \delta \rfloor\right)$-list-recoverable.*

On the other hand, for any $\varepsilon > 0$ and n sufficiently large, a random code in $\mathbb{F}_q^n$ of rate $1 - h_{q,\ell}(\rho) - \varepsilon$ is $\left(\rho, \ell, \lceil \frac{\log_q \binom{q}{\ell}}{\varepsilon} + 1 \rceil\right)$-list-recoverable.

In this way, we can essentially pin-down the list size of a rate $1 - h_{q,\ell}(\rho) - \varepsilon$ random code to one of three possible values. This is similar to the result on the list-decodability of binary random linear codes from [15]. Again, the proof is deferred to the full version.

4 List-Decoding with Small Lists

In this section, we investigate the list-decodability of random codes and random linear codes with constant list size. Specifically, for list-of-3 decoding over the binary field, we can show that the threshold rate for list-decoding of random linear codes is strictly better than that for list-decoding uniformly random codes. Further, for larger field sizes we are able to show that the threshold rate for list-of-2 decoding over $\mathbb{F}_q$ is strictly better for random linear codes than for uniformly random codes. This extends the result of [17] which only applies to list-of-2 decoding for binary codes.

For our lower bound on the threshold rates for RLCs, we follow the following procedure. First, we consider any type that is bad for, e.g., $(\rho, 3)$-list-decoding, i.e., a type from $\mathcal{T}_{\rho,1,3}$. For any such type τ, we upper bound $\frac{H_q(A\tau)}{\dim(A\tau)}$ for the linear map A sending $(x_1, x_2, x_3) \mapsto (x_1 - x_3, x_2 - x_3)$. This is straightforward when the $\dim(A\tau)$ is full (requiring essentially only the concavity of the entropy function); when it is smaller, more careful reasoning is required. For space reasons, all the proofs of this section are deferred to the full version.

As a final contribution, we recall that in [15] it is shown that over the binary field the threshold rate for random linear codes is strictly better than random codes in the capacity-approaching regime. We observe that their techniques can be extended to show that such a trend holds for any constant list size L (assuming the decoding radius ρ is not too large). To do this, we first prove a lower bound on the threshold rate of binary random linear codes by applying the argument in [26] and an upper bound on the threshold rate of binary random codes following the argument in [15]. Although our proof resorts to known techniques, such results were not stated before and greatly strengthen our belief that random linear codes perform better than random codes. In light of the available evidence, a reasonable conjecture would be that the for all alphabet sizes, the threshold rate of random linear codes is strictly better than that of random codes.

4.1 List-of-3 Decoding for Binary Alphabet

In this section, we study the threshold rate for list-of-3 decoding binary codes. We recall that the Plotkin point for list-of-3 decoding binary codes, i.e., the maximum value of ρ for which $(\rho, 4)$-list-decoding with positive rate is possible, is $5/16$ [1]. Our main theorem is the following:

▶ **Theorem 21.** *Let $\rho \in (0, 5/16)$. The threshold rate for $(\rho, 4)$-list-decoding a random linear code over $\mathbb{F}_2$ is at least*

$$1 - \max\left\{ \frac{H_2(x_1, x_2) + 2x_1 + x_2 \log_2 3}{3} : x_1 + 2x_2 \leq 4\rho, x_1 + x_2 \leq 1, x_1, x_2 \geq 0 \right\}.$$

Next, for context, we consider the threshold rate for $(\rho, 4)$-list-decoding uniformly random codes.

▶ **Theorem 22.** *Let $\rho \in (0, 5/16)$. The threshold rate for $(\rho, 4)$-list decoding random code over $\{0, 1\}$ is*

$$1 - \max\left\{ \frac{1 + H_2(x_1, x_2) + 2x_1 + x_2 \log_2 3}{4} : x_1 + 2x_2 \leq 4\rho, x_1 + x_2 \leq 1, x_1, x_2 \geq 0 \right\}.$$

As $\frac{1+F}{4} \geq \frac{F}{3}$ for all $F \leq 3$, the lower bound on the threshold rate provided by Theorem 21 is greater than the exact value from Theorem 22. This demonstrates that random linear codes do indeed perform better.

4.2 List-of-2 Decoding for Arbitrary Alphabets

We now study list-of-2 decoding over $\mathbb{F}_q$ for $q \geq 3$. Here, the Plotkin point is to the best of our knowledge unknown, and we just prove our result for $\rho < 1/3$.

▶ **Theorem 23.** *Let $\rho \in (0, 1/3)$. The threshold rate for $(\rho, 3)$-list decoding random linear code over $\mathbb{F}_q$ with $q \geq 3$ is at least*

$$1 - \max\left\{ \frac{H_q(x_1, x_2) + x_1 \log_q 3(q-1) + x_2 \log_q (q-1)(q-2)}{2} : x_1 + 2x_2 \leq 3\rho, x_1 + x_2 \leq 1, x_1, x_2 \geq 0 \right\}.$$

For context, we again consider random codes.

▶ **Theorem 24.** *Let $\rho \in (0, 1/3)$. The threshold rate for $(\rho, 3)$-list decoding random code over $\mathbb{F}_q$ is*

$$1 - \max\left\{ \frac{1 + H_q(x_1, x_2) + x_1 \log_q 3(q-1) + x_2 \log_q (q-1)(q-2)}{3} : x_1 + 2x_2 \leq 3\rho, x_1 + x_2 \leq 1, x_1, x_2 \geq 0 \right\}.$$

Again, by noting $\frac{1+F}{3} \geq \frac{F}{2}$ for all $F \leq 2$, we conclude that random linear codes do indeed perform better: the lower bound on the threshold rate furnished by Theorem 23 is strictly greater than the exact threshold rate of Theorem 24.

4.3 List Decoding for Binary Alphabets with Larger Lists

In this subsection, we observe that the list-decodability of random linear codes is better than random codes over the binary field for any list size L.

We begin by stating our possibility result for random linear codes. The proof is an adaptation of the argument from [10, 26] which we omit due to the space limit.

▶ **Theorem 25.** *For any fixed list size L and $\delta > 0$, a random linear code over the binary field of rate $1 - h_2(\rho) - \frac{h_2(\rho)}{L-1-2\delta} - \delta$ is (ρ, L)-list decodable with probability $1 - 2^{-\Omega_{\delta,L}(n)}$.*

Next, we provide an upper bound on the list size of a random code. The proof, which appears in the full version, uses the threshold framework.

▶ **Theorem 26.** *Let L be a fixed constant list size and δ be any positive constant. With high probability, a random code with rate $\frac{L-1}{L}(1-h_2(\rho)) - \frac{h_2(2\rho-2\rho^2)-h_2(\rho)}{L} + \delta$ is not (ρ, L)-list decodable.*

From these two theorems, we note the following. If we let δ tend to 0, the upper bound provided by Theorem 26 is smaller than that provided by Theorem 25 as $(3+\frac{1}{L-1})h_2(\rho) - h_2(2\rho-2\rho^2) < 1$, assuming ρ is not too large.

Explicit and Efficient Construction of Nearly Optimal Rate Codes for the Binary Deletion Channel and the Poisson Repeat Channel

Ittai Rubinstein
Blavatnik School of Computer Science, Tel-Aviv University, Israel
QEDMA Quantum Computing, Tel-Aviv, Israel

Abstract

Two of the most common models for channels with synchronisation errors are the Binary Deletion Channel with parameter p (BDC_p) – a channel where every bit of the codeword is deleted i.i.d with probability p, and the Poisson Repeat Channel with parameter λ (PRC_λ) – a channel where every bit of the codeword is repeated Poisson(λ) times.

Previous constructions based on synchronisation strings yielded codes with rates far lower than the capacities of these channels [6, 9], and the only efficient construction to achieve capacity on the BDC at the time of writing this paper is based on the far more advanced methods of polar codes [23].

In this work, we present a new method for concatenating synchronisation codes and use it to construct simple and efficient encoding and decoding algorithms for both channels with nearly optimal rates.

1 Introduction

The theory of error-correcting–codes deals with methods for encoding messages to be sent over noisy media in such a manner that they can be correctly decoded afterwards. Initially introduced by Shannon [22], this field has proven to be instrumental in understanding the theory of computation, and has had a wide variety of applications in other fields, such as communications, and computational biology [24].

The most commonly considered models are "Synchronous Models" - models where the message may be altered or erased, but every letter that was received can be traced back to its original position in the transmitted message. This category includes models such as the Binary Symmetry Channel (BSC) where some of the bits in the transmitted message are flipped (i.e. changed from 1 to 0 or vice versa), and the Binary Erasure Channels (BEC) where some of the bits of the transmitted message are replaced with a question mark (but are not removed, thus preserving the alignment between the transmitted message and the received message). These models can be adversarial (such as [14]), where the code must correct any error the channel may produce, or average-case (such as [22]), where the effect of the channel is random and decoding only needs to succeed w.h.p.

Synchronous models are very well researched, and have a variety of efficient encoding and decoding algorithms [24]. The main method used for such channels are linear error-correcting–codes and they rely heavily on the fact that the letters of the received messages can be mapped back into letters of the transmitted messages.

However, in many real world applications, deletions and insertions can cause the received codewords to be misaligned and the decoder must also deal with synchronisation errors [18, 17]. Perhaps the most intuitive asynchronous channel is the Binary Deletion Channel. This is a channel where every transmitted bit is deleted i.i.d with probability p (where $1 > p > 0$ is a parameter of the channel).

Here, unlike with the binary erasure channel, deleted bits are not replaced with a question mark, but are completely removed from the sequence, shifting the rest of the received codeword. For instance, when transmitting the codeword $w = (1, 0, 0, 0, 1, 1)$, the BEC may result in the received codeword $r_{\text{BEC}} = (1, 0, ?, ?, 1, ?)$ while a similar pattern of deletions would result in the received codeword $r_{\text{BDC}} = (1, 0, 1)$.

This channel represents a simple model for many real-life systems in which there is a loss of information due to synchronisation errors. Moreover, the tools developed for this channel have been instrumental in a variety of other fields [18, 17].

A slightly more complex model which we will also consider, is the Poisson Repeat Channel with parameter $\lambda > 0$ (PRC_λ). This is a channel where every transmitted bit is received Poisson(λ) times. While originally used to help prove lower bounds on the capacity of binary deletion channels, Poisson repeat channels are interesting in their own right. Indeed, Poisson repeats can model every-day examples like a sticky key in a keyboard, as well as deeper technological issues such as errors in single photon generation (a crucial step in light-based quantum computing) [2].

However, the PRC also presents a slightly greater challenge. This is because bits can now be received more than once, resulting in several new types of synchronisation errors. Continuing with our previous example where the codeword $w = (1, 0, 0, 0, 1, 1)$ was transmitted, the received codeword in the BDC model will always start with at most a single 1 bit, unless all three 0s were deleted. In the Poisson repeat channel, this is not the case and the received codeword $r_{\text{PRC}} = (1, 1, 0, 1)$ is a possible outcome.

Several previous results have shown an interesting connection between these two noise models. For instance, Mitzenmacher and Drinea's lower bound for the capacity of the BDC channel [19] is based on their previous lower bound for the capacity of the PRC channel, and Con and Shpilka's constructive codes for the BDC channel [6] are also applicable to the PRC channel.

In this paper we will focus our attention on these two channels, but we believe our tools and approaches can be applicable to other asynchronous channels as well.

1.1 Previous Work

Asynchronous channels present us with a varied field of research, and we will not be able to cover all of its results here. The excellent surveys by Mitzenmacher, Cheraghchi et al and Mercier et al [18, 17, 5] give a more detailed background.

Determining the capacity of the BDC_p channel, remains an open problem, and so far it has been answered only for some extremal cases. When $p \to 0$, the capacity of this channel is $1 - h(p)$ [15] (where $h(\cdot)$ is the binary entropy function), when $p \to 1$, the capacity is $\mu(1-p)$ where $\frac{1}{9} < \mu \leq 0.4143 - o(1)$ [19, 8] (where $o(1)$ is w.r.t the block size n), and [25] give lower bounds for some of the intermediate values of p.

However, the lower bound on the capacity by Mitzenmacher and Drinea [19] is not based on an efficient construction. Recently, Con and Shpilka constructed a family of error-correcting-codes with rate $r \geq \frac{1-p}{16}$ for the BDC_p channel and $r \geq \frac{\lambda}{17}$ for the PRC_λ (when $\lambda < \frac{1}{2}$) [6], improving upon the results of Guruswami and Li who presented the first explicit codes with rate $\Theta(1-p)$ in [9]. This was improved upon by, Tal et al and by Pfister and Tal who showed that polar codes can be used to construct efficiently decodable codes with optimal rates for the BDC channel [23, 20].

Haeupler and Shahrasbi [13] construct a family of efficient codes for InsDel channels with a sufficiently large alphabet, and Haeupler, Rubinstein and Shahrasbi improve the decoder in [12], reaching quasi-linear complexity.

In the adversarial model, Guruswami and Wang [10] showed that there are codes with rate $1 - \widetilde{O}\left(\sqrt{\delta}\right)$ that can correct up to δn errors. This rate was improved by Cheng et al. [3] and further by Haeupler [11]. More recently it was shown by Con, Shpilka and Tamo [7] that, surprisingly, linear error correcting codes are also effective for adversarial InsDel channels.

1.2 Main Contribution

In this work we will construct a family of codes, with efficient encoding and decoding algorithms, whose rates are arbitrarily close to the capacities of the BDC and PRC channels. Unlike the previous results of Tal et al. and of Pfister and Tal [23, 20], this construction does not require the more advanced machinery of polar codes. Furthermore, the construction presented has a decoding error probability of $\exp\left(-\Theta\left(n^{\frac{1}{6}}\right)\right)$ (where n is the block length) with a quasi-linear complexity decoder, while Pfister and Tal's code requires $n^{\frac{3}{2}+\varepsilon}$ time for the same error probability.

Both our code and Pfister and Tal's construction assume that we are given some inner code which achieves a high rate on the channel but which does not necessarily have efficient encoding and decoding algorithms, and both methods produce a new version of this code with efficient encoding and decoding. However, Pfister and Tal's construction requires this code to be generated by a hidden-Markov distribution, while the construction presented here can be used with any inner code. Li et al. proved that there exists a finite hidden-Markov distribution code that achieves capacity for this channel [16] and this model can clearly be found in $O(1)$ time using an enumeration technique similar to the one described in Section 4.1, but such a code has not been found yet.

▶ **Theorem 1** (Main Result (informal)). *Any (possibly inefficient) family of codes for either the BDC or the PRC channel can be converted into a family of codes for the same channel with an arbitrarily close rate, that has encoding and decoding algorithms with a quasi-linear complexity.*

It should be noted that while this complexity is asymptotically very good, it hides within it a very large constant factor, and while we do not have an exact bound on it, we expect it to grow as the rate of the code approaches the capacity of the channel.

Nonetheless, this allows us to construct to construct a family of efficient codes which achieve rates of $\frac{1-p}{9}$ for the BDC_p channel, thus completing the line of works started by Guruswami and Li [9] and continued by Con and Shpilka [6].

Our construction is based on a new technique for tracking inner codewords in a concatenation of synchronisation codes, which we hope may be useful in other cases as well:

Most previous constructions use buffers of 0s as the delimiters between inner codewords. Then, by bounding the probability that the channel would transform any substring of the inner codeword into a sufficiently long sequence of 0s, they can ensure that long sequences of

0s in the received codeword mostly correspond to delimiters. In other words, when separating the received codeword into inner codewords, one searches the entire string for patterns that may have come from a delimiter.

In our construction, we will use delimiters in a very different manner. Instead of searching the entire codeword for the delimiters, we will use our knowledge of the length of the inner codeword and the average expansion of the channel to produce a prior estimate for the distance between consecutive delimiters. Using this prior estimate, we are able to find the delimiters one after another, without looking at the entire codeword.

This new method allows us to drastically reduce the probability that even a single inner delimiter will be missed, while reducing the overhead of the delimiters to a negligible fraction of the codeword. The ability to decode under the assumption that all delimiters will be found simplifies the outer code in our construction, and the fact that we will not search for a delimiter within an inner codeword allows us to use a general inner code, resulting in a nearly optimal rate.

1.3 An Overview of Con and Shpilka's Construction

Since our approach will be similar to that of [6], we will begin with a short overview of their construction, which is based on a concatenation of codes.

Initially, the message is divided into segments of length $\sigma = O(1)$. These are thought of as members of an alphabet Σ of size $|\Sigma| = 2^\sigma$ and can be encoded using [13]. Each letter in the encoded message is then converted back to a string of σ binary symbols and is encoded using an inner code. Since the inner code is only applied to strings of length $\sigma = O(1)$, it can be inefficient without affecting the asymptotic complexity of the encoding / decoding algorithms. The encoded strings are appended and separated by delimiters - in this case buffers of 0s.

Con and Shpilka's construction has a quasi-linear encoding algorithm and a quadratic decoding algorithm, where the computational bottleneck of the decoding algorithm comes from decoding the outer code. The improved decoding algorithm for Haupler and Shahrasbi's code [12] can be used with Con and Shpilka's code to reduce the complexity of their decoding algorithm to a quasi-linear time as well.

1.4 Sketch of the Proof

Our construction will be based on a similar strategy, but with a few key differences. Firstly, we note that most of the overhead of this code is caused by the fact that the inner code is designed to preserve a certain structure.

By removing this structure we are able to significantly increase the rate of our code. However, this comes at a cost - separating unstructured codewords from the delimiters is made far more difficult. We overcome this using a slightly more complex construction of delimiters and a careful analysis.

In addition, the delimiters themselves account for another constant fraction of the overhead of Con and Shpilka's code. By using a recursive concatenation, we are able to reduce the cost of these delimiters to a negligible fraction of the overhead.

At each step of this recursion, we will assume that there exists a BDC/PRC code with message length k and block length n, and we will construct a code with message length k^2 and block length $n' = (1 + o(1))\, nk$.

We will do this by separating the k^2 bit message into k strings of k bits each. We will think of each of these k-bit strings as a member of an alphabet of size $|\Sigma| = 2^k$ and use a ReedSolomon $[k + 2t, k, t]_{2^k}$ code to give it some redundancy (i.e. a Reed-Solomon code over a field of size 2^k, message length k and block length $k + 2t$ with distance $t = o(k)$).

If we were constructing a code for a discrete memoryless channel (DMC) such as the BEC, this step might not be very surprising, because without synchronisation errors we could map the received codeword back into the letters of the Reed-Solomon codeword. However, in our case this might seem somewhat counter-intuitive, since Reed Solomon codes offer no protection against the synchronisation errors we are trying to correct. This step works for asynchronous channels as well because our delimiters are designed to fully preserve the synchronisation *between* inner codewords and the Reed Solomon code will only need to compensate for a small number of local decoding failures of inner codewords.

We will encode each of the $k + 2t$ letters of the Reed Solomon codeword using our inner code. This will output a list of $k + 2t$ strings of length n bits each. Finally, we will append these strings after inserting a delimiter between each two.

The delimiters will be made up of two parts: a positioning string which will help us find the delimiter and two partitioning strings which will help us separate between the delimiters and the inner codewords themselves. The reason that we need partitioning strings, is that we make no assumptions about the structure of the inner code. Therefore, any sequence of bits that originated from the delimiter could have originated from the inner codeword.

For instance, suppose we had used buffers of 0s as our delimiters. Since we make no assumptions about the structure of the inner code, we have no way of knowing whether or not the inner codeword begins with a sequence of 0s, so we can't tell where the delimiter ends and the inner codeword begins.

This makes separating the two a very difficult task and will be at the heart of our construction. Our separation between inner codewords and delimiters will not be completely accurate, but we will be able to bound the effect this has on the decoding failure probability by using the fact that the inner code is designed to deal with (some) deletions.

Both parts of the delimiter will be based on an idea we call "valleys". Similar to the markers defined by Cheraghchi et al [4], we will define valleys to be a long sequence of 0s followed by a long sequence of 1s (when looking at the cumulative sum of the string minus $\frac{1}{2}$, these translate to local minima - see Figure 1). Unless one of these two sequences is completely deleted by the channel, a valley in the transmitted message will result in a valley in the received message.

We will use this observation to align indices within the received message to their source in the transmitted message. We will start with an estimate of where the center of some valley from the transmitted message should be in the received message, and then we will go downhill to the nearest local minima (see Algorithm 1). By bounding both the probability that one of these sequences was removed and the probability that our initial estimate was outside the bounds of the received valley, we can correlate the center of the received valley to the center of the transmitted valley with high probability.

Each positioning string will be a long valley, and each partitioning string will be a short valley. We set the positioning string to be long, because we need to be able to find its center, given only a very rough estimate. On the other hand, setting the partitioning strings this long would reduce the accuracy of its separation from the inner codewords.

The decoding algorithm will be similar to the encoding algorithm, but in a reversed order. First, we will align the received message by locating the centers of the positioning strings. Then we will use the partitioning strings to separate the delimiters from the inner codewords, and apply the inner code decoding to obtain the inner codewords. Finally, we use the Reed Solomon decoding to correct up to t errors that may have occurred.

1.5 Organization

In Section 2 we will define basic notations, show some well-known inequalities that we will use in our analysis and present the basic building block of our construction. Section 3 contains the construction of our recursive step and in Section 4 we will prove the basis of the recursion and show how we can connect it to the recursive step. In Section 5 we will extend our results to the Poisson repeat channel. Finally, in Section 6 we will discuss the implications and limitations of these results, as well as potential avenues for future research. We leave the slightly more technical proof that of our bound for the decoding failure probabilities to the full version (see Section 6 of the full version [21]).

2 Preliminaries

2.1 Average-case Codes

▶ **Definition 2.** *Let Σ be a finite set and let $k, n \in \mathbb{N}$ be positive integers.*

We will say that C is a random channel *acting on the* alphabet Σ *and* block-length n *if it maps any member of Σ^n to a distribution on some set $\mathcal{Y}$.*

Furthermore, we will say that encoding and decoding algorithms $E : \Sigma^k \to \Sigma^n, D : \mathcal{Y} \to \Sigma^k$ *for this channel with* message length k *have* rate $\rho = \frac{k}{n}$ *and a* decoding falure probability (DFP) *of*

$$\delta = \max_{m \in \{0,1\}^k} \{\Pr[D(C(E(m))) \neq m]\}.$$

In other words, the DFP of a code is the probability that a message will be decoded incorrectly if the message was chosen adversarially, but the effects of the channel were random.

▶ **Definition 3.** *Let C be a random channel. We will say that $\mathcal{F} = \{(E_i, D_i)\}_{i \in \mathbb{N}}$ is a family of codes for C if:*

- *The message lengths k_i of E_i, D_i are unbounded ($k_i \xrightarrow[i \to \infty]{} \infty$).*
- *The DFPs δ_i of E_i, D_i in C are vanishing ($\delta_i \xrightarrow[i \to \infty]{} 0$).*

Throughout the decoding process we will often attempt to align the received message with the transmitted codeword.

▶ **Definition 4.** *When the channel acts independently on each letter of the input (i.e. when $C(b_1, \ldots, b_n) = C(b_1) \ldots C(b_n)$), we will say that the ith coordinate of a message transmitted over some asynchronous channel and the jth coordinate of the received message are* aligned, *if the first $i-1$ letters of the transmitted message were mapped to a string of length at most j by the channel and the first i letters of message were mapped to at least j letters by the channel.*

2.2 Probability Inequalities

Throughout this paper we will bound the probability that several parts of our construction will fail. This will require several bounds on the tails of Poisson and binomial distributions, which we will present in this section. Perhaps the most important tool at our disposal will be the Chernoff bound.

▶ **Theorem 5** (Chernoff Bound for Binomial and Poisson Distributions). *For all* $\frac{1}{2} > \varepsilon, p > 0$, $n \in \mathbb{N}$ *and* $\lambda > 0$*:*

$$\Pr\left[|Bin(p,n) - pn| > \varepsilon pn\right] \leq 2\exp\left(-\frac{1}{4}\varepsilon^2 pn\right)$$

$$\Pr\left[|Poisson(\lambda) - \lambda| > \varepsilon\lambda\right] \leq 2\exp\left(-\frac{1}{4}\varepsilon^2\lambda\right).$$

This theorem is based on the Chernoff bound (see Section 2.2 of [1]) and an analysis of entropy functions. We leave its slightly technical proof to the full version (see Appendix 8.1 of [21]).

Another special case of the Chernoff bound (see Appendix 8.2 of [21]) is

▶ **Theorem 6** (Binomial Tail). *For all* $\alpha > e^2$, $\frac{1}{\alpha+1} > p > 0$ *and* $n \in \mathbb{N}$*:*

$$\Pr\left[Bin(p,n) > (\alpha+1)pn\right] \leq \exp\left(-\frac{1}{2}\log(\alpha)\,\alpha pn\right).$$

2.3 Aligning Valleys

Our main tool in aligning the messages will be an idea we call valleys.

▶ **Definition 7.** *We will define a* valley *with* faces *of length* x *and* y *to be a string of* x *0s followed by* y *1s.*

In other words $Valley(x,y) = 0^x 1^y$.

We will define the center *of a valley to be the index where it transitions from* 0*s to* 1*s (i.e. the index of the last* 0 *bit).*

Suppose the codeword contains some valley $V = \text{Valley}(x,y)$. This is encoded by the channel into a valley whose face lengths are i.i.d $\text{Bin}(1-p,x)$ and $\text{Bin}(1-p,y)$ (or $\text{Pois}(\lambda,x)$ and $\text{Pois}(\lambda,y)$ for the PRC channel). Assuming neither side of the valley was completely deleted, the center of the received valley and the center of the transmitted valley should be aligned.

Our definition of valleys is similar to the markers considered in [4], but we will view our valleys very differently. Cheraghchi et al construct their inner code so that is is unlikely to contain a long sequence of 0s. This allows them to find the delimiters by searching for the next sequence of 0s and then use the marker to zero in on the center of the delimiter.

In our decoding algorithm, we will produce an approximate estimate for where the center of a certain valley should be, and by finding its actual center we will be able to align that index to a position within the transmitted message. We will do so using Algorithm 1.

Intuitively, this algorithm works by using the observation that if the valley was not distorted by the channel too much and our initial estimate for its center was not off by too much, then we known whether or not our guess was to the right or to the left (since the left face of the valley has 0s and the right face has 1s). We can then correct our position. If we are on the left face, go right until we reach the center and vice versa.

In order to clarify this approach we will consider a simple example. Suppose we are building a code for the BDC_p channel with parameter $p = \frac{1}{2}$ and we decide to use a valley of length 32 on either side to align some index.

That is, our transmitted message would be as follows (where the bold digit signifies the center of the valley).

$$m = [\ldots]00000000000000000000000000000000\mathbf{0}11111111111111111111111111111111[\ldots]$$

Algorithm 1 Align Valley.

Input : a received codeword $w \in \{0,1\}^*$, estimated center of valley j
Output : the center of the valley j'
$j' \leftarrow j$;
if $w[j] = 0$ **then**
  while $w[j'] \neq 1$ **do**
    $i \leftarrow i + 1$;
  end
  return $j' - 1$;
else
  while $w[j'] \neq 0$ **do**
    $i \leftarrow i - 1$;
  end
  return j' ;
end

Suppose the channel made the following deletions:

$$d = [\ldots] \cdots 0 \cdot \cdot \cdot \cdot \cdot \cdot 000 \cdot 0 \cdot \cdot 00 \cdot \cdot \cdot \cdot 0 \cdot 0 \cdot 0 \cdot \cdot 0 \cdot \cdot 1 \cdot 1 \cdot 11 \cdot 11 \cdot 1 \cdots 111 \cdot 1111111 \cdot \cdot \cdot \cdot \cdot 1[\ldots]$$

Furthermore, assume that we have some prior estimate that the center of the received valley should be 5 bits from its actual position.

Then the received codeword would be as follows, where the underlined digit signifies our prior estimate for the center of the valley.

$$w = [\ldots]00000000000111111\underline{1}111111111111[\ldots]$$

Algorithm 1 would start from this initial estimate and advance to the left, returning the correct center of the valley.

$$w = [\ldots]00000000000\mathbf{0}11111111111111111[\ldots]$$

In Figure 1 we show a geometric representation of this algorithm.

3 Recursive Step

In this section we will define the recursive step in our construction, explain the rationale behind it and begin to prove its correctness. Intuitively, the main theorem we will prove here is that any error correcting code for the BDC with message length k can be transformed into a code with message length k^2 and that the DFP, rate and complexity of the new code "scale well". More formally we will show that:

▶ **Theorem 8** (Recursive Step). *For some constants $c_1, c_2, c_3, k_0, \delta_0 > 0$ and for all $k > k_0$, $d > 0$, $2^{k-1} - k > t > 0$, $\delta_0 > \delta > 0$, $1 > p > 0$ and any error correcting code C for the BDC_p channel with message length k, block length n and DFP δ, there exists an error correcting code C' for the BDC_p with message length k^2, block length $n' \leq (k + 2t)(n + \frac{d}{1-p})$ and DFP:*

$$\delta' \leq \Pr\left[Bin\left(\delta^{c_1}, k + 2t\right) > t\right] + c_3\left(k + 2t\right) \exp\left(-c_2 \min\left\{d, \frac{d^2}{k}\right\}\right).$$

Furthermore, there exist an encoder and decoder for C' with time complexity $\widetilde{O}\left(n'\right)$ using up to $k + 2t$ calls to the encoder and decoder of C.

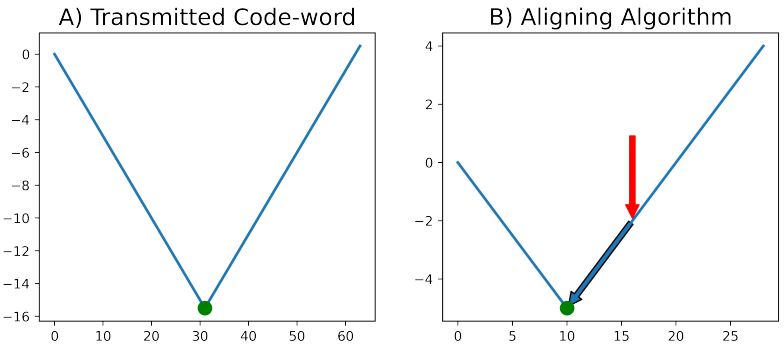

Figure 1 A visual representation of the algorithm for aligning valley centers on a specific example of a valley with parameters $(32, 32)$, being sent over a BDC_p channel with parameter $p = \frac{1}{2}$. The plots go up by $\frac{1}{2}$ whenever the relevant string has a 1 and down by $\frac{1}{2}$ whenever it has a 0. **A**) The transmitted message, with the green dot representing the center of the valley. **B**) First, the channel deletes some of the bits resulting in a skewed valley. We are given some prior estimate for the center of the valley (red arrow). The algorithm goes down the valley (blue arrow), until it terminates at the center (green dot).

We will use this construction in two scenarios: to improve the base of the recursion and for the steps of the recursion. In Table 1, we present the parameters of Theorem 8 and the asymptotic values for both use cases.

Table 1 The parameters of Theorem 8, and their asymptotic values in the two use cases.

Parameter	Description	Recursion Base | Step
k	Message Length	
n	Block Length	$\Theta\left(\frac{k}{1-p}\right)$
d	Delimiter Length	$\Theta\left(k^{\frac{2}{3}}\right)$
t	Reed Solomon Redundancy	$o(k) \mid \Theta\left(k^{\frac{2}{3}}\right)$
δ	Inner Code DFP	$o(1) \mid \exp\left(-\frac{c_2}{2}k^{\frac{1}{6}}\right)$
c_1, c_2, c_3	Constants	$\frac{1}{34}$, $\frac{1}{256}$, 6

The first set of values is used for improving of the base of the recursion. In this case, our only bound on δ will be that it is an arbitrarily small constant, but its relation to k will not be exactly known. Our goal in this step of the construction will be to reduce the error probability at the cost of an arbitrarily small but non-negligible cost to the rate of the code, and we will accomplish this by setting t to be of the order of $\Theta\left(\delta^{\frac{c_1}{2}}k\right)$.

The second scenario is that of a step in our recursion. We will construct our recursion in such a manner that the DFP of the inner code will be bounded by $\delta < \exp\left(-\frac{c_2}{2}k^{\frac{1}{6}}\right)$. By setting $t = d = \Theta\left(k^{\frac{2}{3}}\right)$ we will be able ensure that on the one hand, the DFP of the final code will be $\delta' \ll \exp\left(-\frac{c_2}{2}\left(k^2\right)^{\frac{1}{6}}\right)$ while on the other, the rate of the code will be reduced by only a factor of $1 - O\left(\frac{t+d}{k}\right) = 1 - O\left(k^{\frac{1}{3}}\right) = 1 - o(1)$.

The construction of the code $C' : \{0,1\}^{k^2} \to \{0,1\}^{n'}$ is as described in the introduction. First, the input string is split into k parts of length k each. These are considered as elements in an alphabet of size 2^k and a Reed Solomon encoding with parameters $[k+2t, k, t]_{2^k}$ is applied to them. Each of these is encoded using the encoder of C, a delimiter is appended to each codeword and the concatenation of all of these strings is outputted.

Similarly, the decoding algorithm works by locating the delimiters, separating them from the inner codewords and then decoding each inner codeword using the decoder of C. The decoded inner codewords are once again viewed as letters in an alphabet of size 2^k and the Reed Solomon decoding is applied.

We will define a delimiter with parameters α, β to be a valley of length β surrounded by two valleys of length α. In other words

$$\text{Delimiter}\,(\alpha,\beta) = \text{Valley}\,(\alpha)\,\text{Valley}\,(\beta)\,\text{Valley}\,(\alpha) = 0^\alpha 1^\alpha 0^\beta 1^\beta 0^\alpha 1^\alpha$$

The exact values of α and β are presented in the full version (see Section 6 of [21]), but they will be of the order of $\alpha = \Theta\left(\frac{\log\left(\frac{1}{\delta}\right)}{1-p}\right)$ and $\beta = \frac{d}{2(1-p)} - 2\alpha = \Theta\left(\frac{k^{\frac{2}{3}}}{1-p}\right)$.

In order to complete the construction, we still need to provide methods of locating the delimiters in the received codeword and separating them from the inner codewords. These steps will be explained in the following subsections.

3.1 Positioning Strings

We will use the positioning strings to locate the delimiters one at a time.

Let us denote by L_i the location of the center of the ith positioning string in the received codeword. We can estimate the location of the center of the first positioning string as being around $\mathbb{E}[L_1] = (1-p)(n+2\alpha+\beta)$ bits from the beginning of the received codeword. However, this is only a rough estimate and in reality $L_1 \sim \text{Bin}\,(n+2\alpha+\beta, 1-p)$. We want to find the exact center.

This is where the valleys come into play. With high probability, $|L_1 - \mathbb{E}[L_1]|$ will not be much larger than $\sigma_{L_1} = \sqrt{p(1-p)(n+2\alpha+\beta)}$ (where σ_{L_1} is the standard deviation of L_1), and at least $\frac{1-p}{2}\beta$ of the bits on either side of the valley will survive the channel. Therefore, so long as $\sqrt{p(1-p)(n+2\alpha+\beta)} \ll \frac{1-p}{2}\beta$, we can expect Algorithm 1 to find the value of L_1 w.h.p.

Once we have found the ith delimiter, we go on to search for the $i+1$-th. At each step we use the aligned center of the previous positioning string L_i to obtain an estimate for $L_{i+1} \sim L_i + \text{Bin}\,(n+4\alpha+2\beta, 1-p)$, and use its valley to correct our estimate. In the full version we show that the probability that even a single positioning string will not be correctly found is at most $(k+2t)\exp\left(-c_2 \min\left\{d, \frac{d^2}{k}\right\}\right)$ (see Section 6 of [21]).

3.2 Partitioning Strings

Once we have located the centers of all of the delimiters, we still need to separate them from the inner codewords. This step is surprisingly difficult, because, unlike Con and Shpilka [6] who designed their inner code to preserve a certain structure that would help them differentiate it from the delimiters, we reduce our overhead precisely by making no assumptions about the structure of the inner code.

For instance, if we were to use buffers of 0s as our delimiters and the inner codewords surrounding the delimiter happened to start / end with sequences of 0s, then we would have had a hard time telling which of the 0s belonged to the delimiter and which belonged to the inner codeword. The same applies for any choice of the delimiters.

Our solution to this problem will be based on two ideas. First, we will attempt to approximate the correct separation as accurately as possible. However, this will not yield a perfect separation and we will need to mitigate the effects of this inaccuracy.

The first step will be accomplished by surrounding the positioning string with two valleys. When decoding we can find the centers of these valleys by going from the positioning string until the ends of its valley and then proceeding to the bottom of the next/previous valleys.

Once we have found the center of a partitioning string, we can estimate the length of the faces of its valley. Each of those will be i.i.d distributed according to $F \sim \text{Bin}\,(1-p,\alpha)$. By guessing $f = (1-p)\alpha$ we will get a good approximation of F (to within an error of $\Theta\left(\sqrt{p(1-p)\alpha}\right)$).

If we were to use this estimate as the separation between the delimiter and the inner codeword we would have a two sided error probability, either due to overshooting (attributing some bits of the inner codeword to the delimiter) or due to undershooting.

In the former case, this would cause us to delete some additional bits from the inner codeword. Since the inner code is designed to deal with deletions, it stands to reason that it might also be able to decode received messages if they were also subject to a small amount of additional deletions. This claim is not straightforward, since the inner code deals with random deletions and we will be subjecting it to a very structured set of deletions. However, with a careful analysis we can bound the effect these deletions can have on the DFP of the inner code.

However, in the latter case we would end up erroneously inserting part of the delimiter to one end of the inner codeword. Since the inner code is for a deletion channel, it might not be able to correctly decode the inner codeword, even after a small number of insertions. Therefore, we have no way of bounding the effect this could have on its DFP.

That is why we want to reduce the probability of undershooting significantly more than the probability of overshooting. To do this, instead of taking the estimate $f = \mathbb{E}F$, we will use the estimate $f = \mathbb{E}\left[F\right] + \eta\sigma_F$ for some parameter η (where σ_F is the standard deviation of F).

If F was at most η standard deviations from its expectancy, then we would have $f - F \in [0, 2\eta\sigma_F]$. The lower bound means that no bits from the delimiter would ever trickle into the inner codeword, and the upper bound limits the number of bits from the inner codeword we will delete by accidentally attributing them to the delimiter.

In the full version of the paper we bound both the probability that $f - F \notin [0, 2\eta\sigma_F]$ and the effect these deletions could have on the DFP of the inner code (see Section 6 of [21]).

4 The Recursive Construction

In the previous section we defined the manner in which we recursively concatenate our code to increase the message length at a negligible cost to the rate of the code and the complexity of its encoder and decoder. In this section we will construct the base of this recursion and set the parameters for the recursive steps.

4.1 The Base of the Recursion

When choosing the base of the recursion we are in essence transforming a lower bound on the capacity of the channel to an actual error correcting code. We will do this in a very inefficient manner, but as with Con and Shpilka's inner code, since this code will have message and block length of $O(1)$, this does not affect the asymptotic complexity of our construction.

In order to begin our recursion, we will need a base code with sufficiently low DFP and sufficiently large message length. By definition, a lower bound on the capacity of the channel is a proof that there exists a family of codes for the channel with $r \geq \text{capacity} - \varepsilon$ for any $\varepsilon > 0$. Therefore for any $k_0, \delta_0 > 0$ there are some codes in that family with message length $k > k_0$ and DFP $\delta < \delta_0$. Let κ be the smallest such block length. Since κ is determined by k_0 and δ_0, and since k_0 and δ_0 are constant parameters of our construction, $\kappa = f(k_0, \delta_0) = O(1)$ must also be constant.

We will enumerate over values of $k > k_0$ and for each of them we will attempt to construct a base code. This process will terminate when $k = \kappa$, so it will require only a finite number of iterations.

Since we are looking for an encoding map from some finite set of messages $\{0,1\}^k$ (where k is the message length) to some finite set of codewords $\{0,1\}^n$ (where $n < \frac{9}{1-p}k = O(1)$ is the block length), and a decoding map from $\{0,1\}^{\leq n} \to \{0,1\}^k$, there are only finitely many pairs of this form. By enumerating over all of these pairs and evaluating their DFP, we will be able to find a base code with message length k if one exists.

Since all of the steps in this process had a constant complexity, our construction of the inner code had a constant $O(1)$ complexity. It should be noted that this algorithm is extremely inefficient and that we do not even know how to bound its complexity (except that it is $O(1)$). We hope that future research will address this issue.

4.2 Connecting the Recursive Steps

All that remains now is to combine the recursive step shown in Section 3 with the base case constructed in the previous subsection.

Throughout most of the recursion we will use the recursive step defined in Theorem 8 in the following setting:

$$\begin{aligned} \delta_k &< \exp\left(-\frac{c_2}{2}k^{\frac{1}{6}}\right) \\ d_k &= k^{\frac{2}{3}} \\ t_k &= k^{\frac{2}{3}}. \end{aligned} \tag{1}$$

Applying the recursion Theorem 8, for sufficiently large k, we have:

$$\delta_{k^2} \leq \Pr\left[\text{Bin}\left(\delta^{c_1}, k+2t\right) > t\right] + c_3\left(k+2t\right)\exp\left(-c_2 \min\left\{d, \frac{d^2}{k}\right\}\right). \tag{2}$$

We use Theorem 6 to bound the first term in the new decoding failure probability for sufficiently small δ, by

$$\Pr\left[\mathrm{Bin}\left(\delta^{c_1}, k+2t\right) > t\right] \leq \exp\left(-\frac{c_1}{4}\log\left(\frac{1}{\delta}\right)t\right) \leq \frac{1}{2}\exp\left(-\frac{c_2}{2}t\right)$$

and the second term for sufficiently large k by

$$(k+2t)\exp\left(-c_2\min\left\{d, \frac{d^2}{k}\right\}\right) = \exp\left(-c_2 k^{\frac{1}{3}} + O\left(\log\left(k\right)\right)\right) \leq \frac{1}{2}\exp\left(-\frac{c_2}{2}k^{\frac{1}{3}}\right).$$

Combining these inequality gives us a bound on the new DFP:

$$\delta_{k^2} \leq \exp\left(-\frac{c_2}{2}k^{\frac{1}{3}}\right). \tag{3}$$

The overhead of the code can also be easily bounded. From the recursion theorem, we know that $n_{k^2} \leq \left(n_k + \frac{d_k}{1-p}\right)(k+2t_k)$. Since $n_k \geq \frac{k}{1-p}$ (from the upper bounds on the capacity of these channels) and $d_k = t_k = k^{\frac{2}{3}}$, we have:

$$\begin{aligned} n_{k^2} &\leq \left(1+k^{-\frac{1}{3}}\right)^2 \frac{k^2}{k} n_k \leq \left[\left(1+k^{-\frac{1}{3}}\right)\cdot\left(1+k^{-\frac{1}{6}}\right)\right]^2 \frac{k^2}{\sqrt{k}} n_{\sqrt{k}} = \\ &= \underbrace{\left[\left(1+k^{-\frac{1}{3}}\right)\cdot\left(1+k^{-\frac{1}{6}}\right)\cdot\ldots\cdot\left(1+\left(k_{\mathrm{base}}\right)^{-\frac{1}{3}}\right)\right]^2}_{=:X} \frac{k^2}{k_{\mathrm{base}}} n_{k_{\mathrm{base}}}. \end{aligned} \tag{4}$$

Since $n_{k_{\mathrm{base}}} = \frac{1}{r_{\mathrm{base}}}k_{\mathrm{base}}$ (where r_{base} is the rate of the base code), it is easy to see that $r_{k^2} = \frac{k^2}{n_{k^2}} = \frac{1}{X}r_{\mathrm{base}}$. By bounding the value of X, we can bound the increase in the overhead of the code due to the recursion.

$$\begin{aligned} X &= \left[\left(1+k^{-\frac{1}{3}}\right)\cdot\left(1+k^{-\frac{1}{6}}\right)\cdot\cdots\cdot\left(1+\left(k_{\mathrm{base}}\right)^{-\frac{1}{3}}\right)\right]^2 \\ &\leq \exp\left(2k^{-\frac{1}{3}} + 2k^{-\frac{1}{6}} + \cdots + 2\left(k_{\mathrm{base}}\right)^{-\frac{1}{3}}\right) \leq \exp\left(2\frac{\left(k_{\mathrm{base}}\right)^{-\frac{1}{3}}}{1-\left(k_{\mathrm{base}}\right)^{-\frac{1}{3}}}\right). \end{aligned} \tag{5}$$

For a sufficiently large k_{base}, it is clear that this value can be set arbitrarily close to 1, giving our code a nearly optimal rate.

However, this does not conclude our construction, since in each step of the recursion we assumed that $\delta_k \leq \exp\left(-\frac{c_2}{2}k^{\frac{1}{3}}\right)$, but our base construction only produced a code with an arbitrarily small δ_{base} and its relationship to k_{base} is unknown.

4.3 Completing the Construction

In order to bridge this gap, we apply the recursive step to the base code one more time, with slightly different parameters. We will denote by $k_0, \delta_0, d_0, t_0, n_0$ the parameters of the first application of the recursive step and by $k_{\mathrm{base}} = {k_0}^2, n_{\mathrm{base}}, \delta_{\mathrm{base}}$ the parameters of the resulting code.

As before, we will set $d = k^{\frac{2}{3}}$, but unlike the previous setting, since δ_0 is not necessarily as small as we would want it to be, we will need to set the value of t to be somewhat larger.

In particular, we will set $t_0 = \lceil {\delta_0}^{\frac{c_1}{2}} k_0 \rceil$. Theorem 6 shows that, for sufficiently small δ_0, the probability that a binomial variable with parameters $[\delta_0, k_0 + 2t_0]$ will be greater than t_0 is of the order of $\exp\left(-\Theta(k_0)\right)$. Therefore, for sufficiently large k_0, the DFP after the first step of the recursion would be:

$$\delta_{\mathrm{base}} < \exp\left(-\Theta(k_0)\right) + \exp\left(-c_2 {k_0}^{\frac{1}{3}} + o\left({k_0}^{\frac{1}{3}}\right)\right) < \exp\left(-\frac{c_2}{2}{k_{\mathrm{base}}}^{\frac{1}{6}}\right). \tag{6}$$

Finally, we need to bound the rate of the entire code. Using Equations (4) and (5), we are able to bound the rate:

$$\begin{aligned} r_{k^2} < X r_{\text{base}} &\leq \exp\left(2\frac{(k_{\text{base}})^{-\frac{1}{3}}}{1-(k_{\text{base}})^{-\frac{1}{3}}}\right) r_{\text{base}} \\ &\leq \exp\left(2\frac{{k_0}^{-\frac{1}{3}}}{1-{k_0}^{-\frac{1}{3}}}\right)\left(1+{\delta_0}^{\frac{c_1}{2}}\right) r_0. \end{aligned} \tag{7}$$

For sufficiently large k_0 and sufficiently small δ_0, this can be arbitrarily close to r_0 which in turn can be arbitrarily close to the capacity of the channel, obtaining an arbitrarily close to optimal rate for our code.

4.4 Decoding Complexity

The recursive step promises at most $k + 2t$ calls to the lower level of the construction and $\widetilde{O}(n')$ other operations. Let T_{base} be the encoding / decoding complexity of the base scenario, let T_k be the total complexity of the operation for our code with message length k and I_k be the complexity due to operations which are not part of the lower levels of the recursion (i.e. finding the delimiters, separating them from the inner codewords and decoding the Reed Solomon encoding).

Similar to our bound on the rate of the code, we can bound the decoding / encoding complexities by:

$$\begin{aligned} T_{k^2} &= (k+2t)T_k + I_{k^2} = I_{k^2} + \left(k + 2k^{\frac{2}{3}}\right) T_k \\ &= I_{k^2} + \left(k + 2k^{\frac{2}{3}}\right) I_k + \left(k + 2k^{\frac{2}{3}}\right)\left(\sqrt{k} + 2k^{\frac{1}{3}}\right) T_{\sqrt{k}} \\ &\leq I_{k^2} + \exp\left(2\frac{{k_0}^{-\frac{1}{3}}}{1-{k_0}^{-\frac{1}{3}}}\right)\frac{k^2}{k} I_k + \left(k + 2k^{\frac{2}{3}}\right)\left(\sqrt{k} + 2k^{\frac{1}{3}}\right) T_{\sqrt{k}} \leq \dots \\ \cdots &\leq \exp\left(2\frac{{k_0}^{-\frac{1}{3}}}{1-{k_0}^{-\frac{1}{3}}}\right)\left(\frac{k^2}{k} I_k + \frac{k^2}{\sqrt{k}} I_{\sqrt{k}} + \cdots + \frac{k^2}{k_{\text{base}}} I_{k_{\text{base}}} + \frac{k^2}{k_{\text{base}}} T_{\text{base}}\right). \end{aligned} \tag{8}$$

The recursive step can have at most a quasi-linear complexity on top of its calls to the inner code (see Theorem 8). Therefore, $I_k = \widetilde{O}(n)$. Inserting this into Equation (8), we are can see that $T_{k^2} = \widetilde{O}(n')$.

5 Adaptation to the Poisson Repeat Channel

In this section we will adapt the construction of our code for the BDC channel detailed in the last two sections, to the PRC channel. Adapting the recursive step will be fairly straightforward. However, adapting the base step will be a bit more tricky.

When working with the BDC, we used the fact that the received message could not be longer than the transmitted one. This allowed us to build a decoding table that can return some value for any of the possible received messages. However, the PRC could (with very low probability) expand a transmitted message to an arbitrarily long received message, and we will need to adapt our construction to address this issue.

5.1 Adapting the Recursive Step

▶ **Theorem 9** (Recursive-Step for the PRC). *There exist some constants $c_1, c_2, k_0, \delta_0 > 0$, such that for any $k > k_0$, $d > 0$, $2^{k-1} - k > t > 0$, $\delta_0 > \delta > 0$, $\lambda > 0$ and any error correcting code C for the PRC_λ channel with block length k, message length n and DFP δ, there exists an error correcting code C' for the PRC_λ with block length k^2, message length $n' \leq (k+2t)(n+\frac{d}{\lambda})$ and DFP $\delta' \leq \Pr\left[Bin\left(\delta^{c_1}, k+2t\right) > t\right] + (k+2t)\exp\left(-c_2 \min\left\{d, \frac{d^2}{k}\right\}\right)$.*

Furthermore, there exist an encoder and decoder for C' with time complexity $\widetilde{O}\left(n'\right)$ using up to $k+2t$ calls to the encoder and decoder of C.

We will construct the recursive step almost exactly as in Section 3, only changing $1-p$ to λ in our conversion of lengths of bits over the channel.

5.2 Adapting the Base of the Recursion

In this section, we will adapt our construction of the base of our recursion from Section 4 to the PRC. It is easy to see that for any $\lambda > 0$, there exists a family of codes for this channel with some non-negligible rate $\rho = \Theta(1)$ w.r.t the message length (for instance, by applying the jigsaw construction of [19] with the Morse code distribution). We will set k_0, δ_0 to be the minimal value of the message length k and DFP δ for which there exists such a base code that will suffice for our construction.

Unlike the previous construction, here we will only be able to approximate the DFP of our base code, so we will need to set two bounds. Let $\kappa_1 \geq k_0$ be the minimal message length for which there is a code in the family of codes such that it has a DFP of at most δ_0, and let $\kappa_2 \geq k_0$ be the minimal message length for which there is a code in the family of codes such that it has a DFP of at most $\frac{\delta_0}{2}$. Similar to the construction in Section 4.1, we do not have an explicit bound on κ_1, κ_2, but we know that they are bounded by some $O(1)$ constant.

As in Section 4.1, we will enumerate over values of $k \geq k_0$, but this time we only promise that our enumeration will end somewhere between κ_1 and κ_2. For each such k, we enumerate over all $n \leq \rho k$, encoders $C : \{0,1\}^k \to \{0,1\}^n$ and decoders $D : \{0,1\}^m \to \{0,1\}^k$, where m is the smallest integer for which:

$$\Pr\left[\text{Poisson}(\lambda n) \geq m\right] \leq \frac{\delta}{2}.$$

For each of these encoder-decoder pairs, we enumerate over all messages in $\{0,1\}^k$ and encode them using the encoder. For each codeword, we enumerate over all possible results of applying the channel to the codeword that have output length at most m.

We sum the probabilities of the eventualities where this process would result in a decoding failure (cases where the channel outputted more than m bits are counted as failures), and take the message with the highest DFP. This gives us an approximation of

$$\text{DFP}_{\text{actual}} \leq \text{DFP}_{\text{estimate}} \leq \text{DFP}_{\text{actual}} + \frac{\delta}{2}.$$

If the estimated DFP is at most δ, then we output the pair of encoder-decoder tables. It is easy to see that if the actual DFP is at most $\frac{\delta}{2}$ then the estimate DFP is at most δ and we will output it. Therefore our process either terminates before κ_2 or at κ_2 and must have a constant complexity.

6 Discussion

In this paper we presented several new techniques for constructing error-correcting–codes for asynchronous channels, and used them to prove a method of transforming lower bounds on the capacities of the BDC and PRC channels to efficient encoding and decoding algorithms. This answers the main question considered [6] and [9].

However, this construction is far from practical. For instance, the inner code at the basis of our recursion is constructed in a doubly exponential time in the size of the inner codes message length. Even our bound on the decoding failure of the inner code is $\delta^{\frac{1}{34}} = \exp\left(\frac{k^{\frac{1}{6}}}{34}\right)$ which is technically $o(1)$ but converges extremely slowly.

Furthermore, this work deals only with BDC and PRC channels. While these channels offer us a chance to model the behaviour of asynchronous channels, they do not represent the more realistic channels which contain both synchronisation errors and bit-flipping errors. To this end, the binary InsDel channel offers a more comprehensive model and it remains an open question whether the methods described here can be used to construct efficient codes for it as well.

Finally, now that we have a framework for efficient encoding and decoding for the BDC and PRC channels, we can return to the question of the capacity of these channels. We know that when $p \to 1$ this capacity scales proportionally to $1-p$, but the factor of this conversion is still unknown. Mitzenmacher and Drinea [19] showed that these capacities are at least $\frac{1-p}{9}$, and [8] gave an upper bound of $0.4143(1-p) \pm o_n(1)$, but this gap is far from closed.

Maximizing Non-Monotone Submodular Functions over Small Subsets: Beyond 1/2-Approximation

Aviad Rubinstein
Computer Science Department, Stanford University, CA, USA

Junyao Zhao
Computer Science Department, Stanford University, CA, USA

Abstract

In this work we give two new algorithms that use similar techniques for (non-monotone) submodular function maximization subject to a cardinality constraint. The first is an offline fixed-parameter tractable algorithm that guarantees a 0.539-approximation for all non-negative submodular functions. The second algorithm works in the random-order streaming model. It guarantees a $(1/2 + c)$-approximation for *symmetric* functions, and we complement it by showing that no space-efficient algorithm can beat 1/2 for asymmetric functions. To the best of our knowledge this is the first provable separation between symmetric and asymmetric submodular function maximization.

1 Introduction

We study the algorithmic problem of selecting a small subset of k elements out of a (very) large ground set of n elements. In particular, we want the small subset to consist of k elements that are valuable *together*, as is captured by an objective function $f : 2^E \to \mathbb{R}_{\geq 0}$. Without any assumptions on f it is hopeless to get efficient algorithms; we make the assumption that f is *submodular*[1], one of the most fundamental and well-studied assumptions in combinatorial optimization.

Alas, even for submodular functions, strong impossibility results are known. Two of the most important frameworks we have for circumventing impossibility results are (i) approximation algorithms – look for solutions that are only approximately optimal; and (ii) paramerterized complexity – look for algorithms of which the runtime is efficient as a function of the large ground set n, but may have a worse dependence[2] on the smaller parameter

[1] I.e., functions where the marginal value of an element is decreasing as the set grows.

[2] Formally, an algorithm is said to be fixed-parameter tractable if it runs in time $h(k) \cdot \text{poly}(n)$ for *any* function h. Here h could be arbitrarily fast growing, e.g. doubly-exponential or Ackermann – this is asymptotically faster than the naive n^k. In this work we will be more ambitious (and closer to practice) and present algorithms that run in time $2^{\tilde{O}(k)} \cdot n$.

k. To appreciate the relevance of parameterized complexity in practice, it's important to note that in many applications of submodular maximization k is indeed quite small, e.g. in data summarization [4], we want an algorithm that, given a large image dataset chooses a representative subset of images that must be small enough to fit our screen.

Submodular optimization has been thoroughly studied under the lens of approximation algorithms; much less work has been done about its parameterized complexity (with the exception of [27], see discussion of related works). In either case, strong, tight hardness results are known. In this work we show that combining both approaches gives surprisingly powerful algorithms.

On the technical level, we develop novel insights to design and analyze fixed-parameter tractable (FPT) algorithms for (non-monotone) submodular function maximization. We instantiate these ideas to give new results in two settings: offline ("classical") algorithms for which we are interested in the running time and query complexity[3], and random-order streaming algorithms for which we mostly care about the memory cost.

Main result I: offline algorithms

Our first result is an (offline) FPT algorithm that guarantees an improved approximation ratio for submodular function maximization.

To compare our result with the approximation factors achievable by polynomial-time algorithms, we first briefly survey the existing algorithmic and hardness results.

On the algorithmic side, the current state-of-art polynomial-time algorithm for general non-monotone submodular functions achieves 0.385-approximation [5]. For sub-classes of submodular functions, better polynomial-time approximation algorithms are known: notable examples include monotone functions (the greedy algorithm achieves $(1 - 1/e)$-approximation [25]), and symmetric functions[4] (the state-of-the-art approximation factor is 0.432 [11]).

From the hardness perspective, known results rule out *polynomial* query complexity algorithms with approximation factors better than 1/2 or 0.491 for symmetric [10, 28] or asymmetric functions [14], respectively. It is also known that even FPT algorithms cannot beat $(1 - 1/e)$-approximation, and this holds even for monotone submodular functions [24].

In FPT time, the streaming algorithm of [2] implies a 1/2-approximation algorithm for general non-monotone functions (although it is not explicitly stated as an FPT algorithm in their paper), which slightly beats the aforementioned 0.491 bound for asymmetric functions. However, this result does not tell us whether FPT algorithms can beat the 1/2 bound for symmetric functions. A-priori, it was plausible that 1/2-approximation is the best achievable approximation by FPT algorithms for symmetric functions and hence general non-monotone functions. (In fact, prior to discovering our new algorithms, we had expected that the 1/2-approximation would indeed be the best that FPT algorithms can achieve.)

We are thus excited to report that we were able to design an FPT algorithm (Algorithm 4) that not only outperforms all the previous algorithms but also surpasses all the upper limits on the approximation factor in the existing hardness results, *by a significant margin, regardless of whether the function is symmetric or not*:

[3] I.e., the function f is given as a value oracle. The query complexity is number of queries made by the algorithm, which is clearly a lower bound of the runtime.

[4] I.e. functions that assign the same value to a set and its complement, which capture some of the most important applications of non-monotone submodular functions, including mutual information and cuts in (undirected) graphs and hypergraphs.

▶ **Theorem 1** (FPT algorithm). *There is a* 0.539*-approximation algorithm for cardinality constrained submodular maximization that has runtime and query complexity* $2^{\widetilde{O}(k)} \cdot n$.

Main result II: random-order streaming

Our FPT algorithm (Algorithm 4) uses a subroutine (Algorithm 1) which can be interpreted as a *random-order streaming algorithm*, and thus, in addition to our FPT result, we also hope to understand the power and the limit of Algorithm 1 in the random-order streaming model. In this model (see the detailed setup in Section 2), a streaming algorithm makes a single pass over a stream of elements arriving in a uniformly random order. An algorithm keeps a carefully chosen subset of the elements it has seen in a buffer of bounded size. At any point in the stream, the algorithm can make unlimited queries of the function values on subsets of the elements in the buffer. The goal is to obtain a good approximation of the offline optimum while keeping the buffer small (ideally, polynomial in k and independent of n).

We show that Algorithm 1 achieves 1/2-approximation for general non-monotone submodular functions[5] and beats 1/2-approximation for symmetric functions using $\widetilde{O}(k^2)$-size buffer[6]:

▶ **Theorem 2** (Random-order streaming algorithm). *For cardinality constrained submodular function maximization in the random-order streaming model, there is an algorithm using* $\widetilde{O}(k^2)$*-size buffer that achieves* 1/2*-approximation for general non-monotone submodular functions and* 0.5029*-approximation for symmetric submodular functions.*

We complement the algorithmic result with a tight 1/2-hardness result in the random-order streaming setting:

▶ **Theorem 3** (1/2-hardness for random-order streaming). *If* $n = 2^{o(k)}$*, any* $(1/2 + \varepsilon)$*-approximation algorithm for cardinality-constrained non-monotone submodular maximization in the random-order streaming model must use an* $\Omega(n/k^2)$*-size buffer. In fact, this hardness result holds against stronger algorithms that are not captured by the standard random-order streaming model for submodular maximization (see Remark 9).*

This hardness result is quite surprising because it shows in contrast to monotone submodular maximization, non-monotone submodular maximization in the random-order setting is *not any easier than* that in the worst-order setting where the elements arrive in the worst-case order – for worst-order streaming model, it is known that $\Omega(n/k^3)$-size buffer is required to beat 1/2-approximation even if the submodular function is monotone [13], but for random-order model, recent work by [1] gives a $(1-1/e-\varepsilon)$-approximate algorithm using $O(k/2^{\mathrm{poly}(\varepsilon)})$-size buffer, which is improved to $O(k/\varepsilon)$ by a simpler algorithm of [20].

Furthermore, notice that our algorithmic result and hardness result together exhibit a separation between symmetric and asymmetric submodular functions in the random-order streaming setting. This separation is interesting because in the literature, tight hardness result for general non-monotone functions often continues to hold for symmetric functions. For example, for unconstrained non-monotone submodular maximization, there is a family of symmetric functions for which $(1/2 + \varepsilon)$-approximation requires $2^{\Omega(n)}$ queries [10, 28], and there are efficient matching 1/2-approximation algorithms even for asymmetric functions [6].

[5] The 1/2-approximation of Algorithm 1 for general non-monotone functions is not interesting by itself – 1/2-approximation was achieved even if the elements arrive in the worst-case order [2]. However, Algorithm 1, which takes advantage of the random order, led us to the discovery of the 1/2-hardness in the random-order setting.

[6] These algorithmic results also hold for the (similar but incomparable) secretary with shortlists model [1].

To the best of our knowledge, our result is the *first provable separation of symmetric and asymmetric submodular maximization in any setting*, let alone a natural setting that gains a lot of interests recently. Although admittedly we would be more excited to see such separation in the more classic offline setting of constrained non-monotone submodular maximization, currently we are still far from figuring out whether there is a separation in this setting (because of the gap between the current best 0.432-approximation algorithm for symmetric functions and the current best 0.491-hardness for general asymmetric functions we mentioned earlier), and we hope our result can provide some insights on how to resolve this problem.

Future directions

Our FPT algorithm achieves significantly better-than-1/2 approximation for general non-monotone submodular functions in the offline setting, and its subrountine Algorithm 1 breaks the 1/2 hardness for symmetric submodular functions in the random-order streaming setting – but what is the best possible approximation ratio in those respective settings? We leave this as an open problem for future work.

We remark that no FPT (small-buffer resp.) algorithm can break the $1 - 1/e$ barrier for symmetric functions in the offline (random-order streaming resp.) setting. For asymmetric functions, this follows from the classic work of [24] for monotone submodular functions which we mentioned earlier. For symmetric submodular maximization, the monotone functions exhibiting $(1-1/e)$-hardness are obviously not symmetric; but in appendix of the full version, we are able to give a simple black-box approximation-preserving reduction from symmetric non-monotone to asymmetric monotone submodular function maximization that works in both the offline and random-order streaming settings:

▶ **Proposition 4.** *For cardinality-constrained symmetric submodular function maximization, any algorithm guaranteeing a $(1 - 1/e + \varepsilon)$-approximation must:*
Offline *use $n^{\Omega(k)}$ queries; or*
Random-order streaming *use $\Omega(n)$-buffer size.*

1.1 Additional related work

FPT submodular optimization

The study of parameterized complexity of submodular maximization was initiated by [27] who focused on monotone submodular functions. [27] gives an FPT approximation scheme for monotone submodular functions that are either p-separable or have a bounded ratio of total singleton contribution ($\sum_{e \in E} f(\{e\})$) to total value ($f(E)$). However, for general monotone submodular functions even FPT algorithms (in terms of query complexity) cannot break the classic $1 - 1/e$ barrier [24]. Furthermore, even for the special case of max-k-cover, no FPT algorithms can beat $1 - 1/e$ assuming gap-ETH [8, 21].

Streaming submodular optimization

Our work is related to recent works on maximizing submodular functions in random order streams [1, 20, 26], but all the latter focus on monotone functions. Submodular optimization in worst-order streaming models has also been extensively studied in recent years, e.g. [4, 7, 19, 9, 12, 23, 3, 17, 18, 22, 2, 15, 16, 13]. In the worst-order literature, most relevant to our work is [2] who gave a 1/2-approximation for general (non-monotone) submodular functions, and [13] who proved a matching inapproximability.

2 Preliminaries

▶ **Definition 5.** *Given a ground set of elements E, a function $f : 2^E \to \mathbb{R}_{\geq 0}$ is submodular if for all $S \subseteq T \subseteq E$ and $i \in E \setminus T$, $f(S \cup \{i\}) - f(S) \geq f(T \cup \{i\}) - f(T)$. Moreover, we denote the marginal gain by $f(X|S) := f(X \cup S) - f(S)$.*

▶ **Definition 6.** *A function $f : 2^E \to \mathbb{R}_{\geq 0}$ is symmetric if for all $S \subseteq E$, $f(S) = f(E \setminus S)$.*

In this paper, we **always consider maximizing non-negative submodular functions** over n elements under a cardinality constraint k, i.e., $\max_{X \in E, |X| \leq k} f(X)$. The following lemma [10] for non-negative submodular functions will be useful.

▶ **Lemma 7.** *Let $f : 2^E \to \mathbb{R}_{\geq 0}$ be a submodular function. Further, let R be a random subset of $T \subseteq E$ in which every element occurs with probability at least p (not necessarily independently). Then, $\mathbf{E}[f(R)] \geq pf(T) + (1-p)f(\emptyset)$.*

Moreover, we are interested in the fixed-parameter tractable algorithms.

▶ **Definition 8.** *For submodular maximization over n elements with cardinality constraint k, we say an algorithm is fixed-parameter tractable (FPT) if it has runtime $h(k) \cdot poly(n)$, where h can be any finite function.*

Besides, we are also interested in studying low-memory algorithms for submodular maximization in the random-order streaming model, and in this setting, we only care about the memory cost but not the runtime. We follow the standard setup of streaming model for submodular maximization in the literature (see e.g., the model in the original work [4, Section 3] and more recent works [2, 16, 20]), and the only additional assumption we make is that the elements arrive in uniformly random order (which was studied in e.g., [1, 20]).

Random-order streaming model

In the random-order streaming model, an algorithm is given a single pass over a dataset in a streaming fashion, where the stream is a uniformly random permutation of the input dataset and each element is seen once. The algorithm is allowed to store the elements or any information in a memory buffer with certain size. To be precise, at any point during the runtime of the algorithm,

$$\text{memory cost} = \text{number of stored elements} + \text{number of bits of stored information}.$$

Note that the elements and information are treated separately. One can think of the elements as physical tokens[7], and the algorithm has a limited number of special slots to store the tokens. Besides these special slots, the algorithm has other limited space to store arbitrary information. The total memory cost should not exceed the algorithm's memory size.

Every time when a new element arrives, the algorithm can decide how to update its memory buffer, i.e., whether to store the new element or remove other elements in its memory, and what information to add or remove. At any time, the algorithm can make any number

[7] The standard streaming model for submodular maximization assumes the elements are stored like physical tokens rather than using arbitrary encoding, because the model eventually wants to restrict the algorithm's access to the value oracle. If we store elements using arbitrary encoding, it is not clear how to restrict oracle access for general submodular functions (although it is possible to define such model for some special applications). There is another model that allows elements to be stored in arbitrary encoding [13, Appendix B] - this model does not restrict oracle access at all, but instead it assumes that the elements appearing in the stream are a small part of the ground set.

of queries to the value oracle of the objective submodular function, but it is only allowed to query the value of any subset of the elements that are stored in its memory. For example, at some point during the stream, suppose the algorithm stores an element e, and it makes a query of the value of set $\{e\}$ and writes the result of the query in its memory in any format it prefers (e.g., "the value of $\{e\}$ is..."), and then it removes element e. After removing e, it will never be allowed to query the value of any set that contains e in the future, but it can still keep the information "the value of $\{e\}$ is...", which it wrote before, in its memory, as long as it wants.

At the end of the stream, the algorithm outputs a subset of elements that are stored in its memory as the solution set.

▶ Remark 9. Our streaming algorithm falls into the above model and has low memory cost (specifically, $\tilde{O}(k^2)$). Our hardness result in fact holds against stronger algorithms that are allowed to (i) store infinite bits of information (i.e., only the number of stored elements counts as memory cost) and (ii) output any size-($\leq k$) subset of elements as the solution set (i.e., during the stream, the algorithm is still only allowed to query any subset of elements stored in its memory, but at the end of the stream, it can output any size-($\leq k$) subset of the ground set as it wants[8]).

Finally, we note that all the missing proofs of this extended abstract can be found in the full version of our paper on arXiv (the URL is provided on the title page).

3 The core algorithm

In this section, we present the core algorithm of this work (Algorithm 1), which is actually our streaming algorithm. Our FPT algorithm will use this core algorithm as a subroutine. The goal of this section is to establish the common setup for the analysis of our FPT algorithm for general submodular functions and the analysis of the streaming algorithm for symmetric submodular functions. In this process, we will also do a warm-up that shows a 1/2-approximation for the core algorithm on general submodular functions.

Algorithm 1 SymmetricStream(f, E, k, ε).

Partition the first ε fraction of the random stream E into windows $w_1, \ldots, w_{3k}$ of equal size.
$S_0 \leftarrow \emptyset$
$H \leftarrow \emptyset$
for $i \leftarrow 1$ to $3k$ **do**
    $e_i \leftarrow \arg\max_{e \in w_i} f(e|S_{i-1})$
    $S_i \leftarrow S_{i-1} \cup \{e_i\}$
for $e \in E \setminus \{w_1, w_2, \ldots, w_{3k}\}$ **do**
    for $i = 1, 2, \ldots, 3k$ **do**
        if $f(e|S_{i-1}) > f(e_i|S_{i-1})$ and $|H| < 18k^2 \log k/\varepsilon$ **then**
            $H \leftarrow H \cup \{e\}$
return $\arg\max_{X \subseteq S_{3k} \cup H, |X| \leq k} f(X)$

[8] I.e., it can output something like "My solution set is {1,3,11,...}" even if elements $1, 3, 11$ are not in its memory.

At a high level, Algorithm 1 divides the first ε fraction of the stream into $3k$ windows[9] and greedily selects the element e_i with the best marginal gain in each window i. (Although we use the notation S_i in the pseudocode for clarity, we only need to keep track of one ordered solution set in the first for loop.) Then it freezes the solution set, and for the rest of the stream, it only selects the first $18k^2 \log k/\varepsilon$ elements that have better marginal gain than e_i conditioned on the $(i-1)$-th partial solution for some $0 \leq i \leq 3k-1$. Finally, it finds the best size-k solution from all the selected elements by brute force. Due to line 9, the memory usage is $O(k^2 \log k/\varepsilon)$. The runtime before the final brute-force search is $O(nk)$ because of the for loops, and the brute-force search takes time $k\binom{|S_{3k} \cup H|}{k} = 2^{\widetilde{O}(k)}$ as $|S_{3k}| = 3k$ and $|H| = O(k^2 \log k/\varepsilon)$, and hence, the total runtime is $O(nk) + 2^{\widetilde{O}(k)}$ (which is not polynomial in k, but in this paper, we focus on the memory bound for streaming setting and FPT algorithms for offline setting).

3.1 Warm-up

As a warm-up, we show the 1/2-approximation of our core algorithm for general submodular functions, which also helps set up the proof of our main algorithmic results. Before getting to the technical proof, we provide the intuition for Algorithm 1 in the following. First, we want to make sure that with high probability $|H|$ never meets the size threshold in the if condition at line 9, and thus the size threshold essentially does not affect our analysis. This follows by a standard argument (see Lemma 11).

Because the stream is in random order, most optimal elements will be visited during the for loop at line 7. A part of them O_H will be picked by the algorithm, and the other part O_L will not be selected. Consider the set $S_{|O_L|}$ defined in the algorithm. Because of the if condition at line 9, the elements in $S_{|O_L|}$ have better marginal contribution than O_L, and we can show that $f(S_{|O_L|}) \geq f(O_L|S_{|O_L|})$, which is somewhat similar to the classic greedy algorithm for monotone submodular maximization. Since $O_H \cup S_{|O_L|}$ and $S_{|O_L|}$ are two candidate solutions under the radar of the algorithm's final brute-force search, the algorithm achieves at least

$$\frac{f(O_H \cup S_{|O_L|}) + f(S_{|O_L|})}{2} \geq \frac{f(O_H \cup S_{|O_L|}) + f(O_L|S_{|O_L|})}{2} \geq \frac{f(O_H \cup O_L \cup S_{|O_L|})}{2}, \quad (1)$$

where the last inequality is by submodularity.

To complete the analysis, we observe that $f(O_H \cup O_L \cup S_{|O_L|})$ is not significantly worse than $f(O_H \cup O_L)$, and hence 1/2-approximation follows from (1). Indeed, because $S_{|O_L|}$ is chosen from a random ε fraction of E, it cannot hurt $O_H \cup O_L$ significantly – otherwise, there should be many other elements similar to $S_{|O_L|}$, and together they would hurt $O_H \cup O_L$ so much that would eventually contradict non-negativity. This is formally shown in Lemma 10. Using Lemma 10 and Lemma 11, we can prove the 1/2-approximation. The proof of Lemma 10 and Lemma 11 can be found in the full version.

▶ **Lemma 10.** *Let O denote the optimal size-k solution. Then, for any constants $\varepsilon \in (0, 1]$ and $\varepsilon' > 0$,*

- *with probability at least $1 - \varepsilon/\varepsilon'$, there does not exist a set Y of elements in the first ε fraction of the stream such that $f(Y|O) \leq -\varepsilon' f(O)$,*
- *and moreover, with probability at least $1 - 3\varepsilon/(\varepsilon')^2$, for all $\ell \in \{\varepsilon' k, 2\varepsilon' k, \ldots, k\}$, for any $S \subseteq S_{3\ell} \setminus S_{2\ell}$, $f(S|O \cup S_{2\ell}) \geq -\varepsilon' f(O)$.*

[9] The choice of $3k$ suffices to beat 1/2 approximation for symmetric submodular function, but it is conceivable that a larger budget might improve the final constant. For our FPT algorithm, dividing into k windows would also work, but that does not improve the runtime asymptotically.

▶ **Lemma 11.** *With probability* $1 - 3/k$, $|H| < 18k^2 \log k/\varepsilon$, *namely, Algorithm 1 never ignores any elements due to the memory threshold (line 9).*

▶ **Theorem 12.** *Algorithm 1 achieves* $(1/2 - O(\sqrt{\varepsilon}) - O(1/k))$*-approximation for non-negative non-monotone submodular functions in the random-order streaming model.*

Proof. Let O be the size-k optimal set, and let $O' \subseteq O$ be the subset of optimal elements that appear in the last $1 - \varepsilon$ fraction of the stream. We partition O' into O_L and O_H, where O_L are the optimal elements that are not selected by the algorithm, and O_H are those selected. Let S_L be short for solution $S_{|O_L|}$ in the algorithm. If the good event in the first bullet point of Lemma 10 with $\varepsilon' = \sqrt{\varepsilon}$ happens (which we denote by A_1), then $f(S_L|O_L \cup O_H) \geq f(S_L|O) \geq -\sqrt{\varepsilon} f(O)$, where the first inequality is by submodularity. If A_1 happens, we have that

$$\begin{aligned} f(O_H \cup S_L) + f(O_L|S_L) &= f(O_H|S_L) + f(S_L \cup O_L) \\ &\geq f(O_H|S_L \cup O_L) + f(S_L \cup O_L) \quad \text{(By submodularity)} \\ &= f(O_L \cup O_H \cup S_L) \\ &= f(O_L \cup O_H) + f(S_L|O_L \cup O_H) \\ &\geq f(O_L \cup O_H) - \sqrt{\varepsilon} f(O). \end{aligned} \tag{2}$$

Let $O_L = \{o_1, o_2, \ldots, o_{|L|}\}$. If the good event in Lemma 11, denoted by A_2, happens, then, we have the following simple observation by design of the algorithm.

▶ **Observation 13.** *If* A_2 *happens, then for any* $o \in O_L$, $f(o|S_{i-1}) \leq f(e_i|S_{i-1})$, *for all* $i \in [3k]$, *because* o *is skipped by the algorithm.*

Given A_2, using the above observation, we have that

$$\begin{aligned} f(O_L|S_L) &\leq \sum_{o \in O_L} f(o|S_L) && \text{(By submodularity)} \\ &\leq \sum_{i=1}^{|O_L|} f(o_i|S_{i-1}) && \text{(By submodularity)} \\ &\leq \sum_{i=1}^{|O_L|} f(e_i|S_{i-1}) && \text{(By Observation 13)} \\ &= f(S_L). && \text{(By telescoping sum)} \end{aligned} \tag{3}$$

Combining Eq. (2) and (3), we get

$$f(O_H \cup S_L) + f(S_L) \geq f(O_L \cup O_H) - \sqrt{\varepsilon} f(O). \tag{4}$$

By Lemma 7, $\mathbf{E}[f(O')] \geq (1 - \varepsilon) f(O)$. By a Markov argument,

$$\mathbf{E}[f(O') \mid A_1, A_2] \geq (1 - \varepsilon - \sqrt{\varepsilon} - 3/k) f(O), \tag{5}$$

and hence, by taking expectation for both sides of Eq. (4), we have that

$$\begin{aligned} \mathbf{E}[f(O_H \cup S_L) + f(S_L) \mid A_1, A_2] &\geq \mathbf{E}[f(O_L \cup O_H) \mid A_1, A_2] - \sqrt{\varepsilon} f(O) \\ &\geq (1 - \varepsilon - 2\sqrt{\varepsilon} - 3/k) f(O). \end{aligned}$$

Finally, $\mathbf{E}[f(O_H \cup S_L) + f(S_L)] \geq \Pr(A_1, A_2) \cdot \mathbf{E}[f(O_H \cup S_L) + f(S_L) \mid A_1, A_2] \geq (1 - \sqrt{\varepsilon} - 3/k)(1 - \varepsilon - 2\sqrt{\varepsilon} - 3/k) f(O) = (1 - O(\sqrt{\varepsilon} + 1/k)) f(O)$. The proof finishes because $O_H \cup S_L$ and S_L are both subsets of $S_{3k} \cup H$, so one of them must achieve at least half of $(1 - O(\sqrt{\varepsilon} + 1/k)) f(O)$. ◀

3.2 Our plan for the algorithmic results

The proof of our main algorithmic results (Theorem 17, Theorem 14 and Theorem 15) is based on factor-revealing convex programs[10]. We know that factor-revealing programs are not intuitive and hence not easy to understand, although they are effective tools for formalizing the proof. Therefore, in the future sections of this extended abstract, instead of formally proving the main results, we will provide the intuition and interpretable (but less formal) analysis for our algorithmic results. **We recommend the readers read the intuition and informal interpretable analysis in this extended abstract, and then check the formal proofs that involve factor-revealing programs starting from Section 3.2 in the full version.**

For convenience, in the informal interpretable analysis in this extended abstract, we will **continue using the notations** O, O_L, O_H that have appeared in this section.

4 FPT algorithms for non-monotone submodular functions

In this section, building on Algorithm 1, we give FPT algorithms that achieves better-than-1/2 approximation for general non-monotone submodular functions. We first present a basic FPT algorithm that achieves 0.512-approximation to show the main ideas, then we discuss how to improve the basic algorithm to get 0.539-approximation.

4.1 The basic FPT algorithm

Essentially, after running Algorithm 1, our basic FPT algorithm (Algorithm 2) searches for O_H by brute force, and then starting with O_H as the initial solution set, it runs classic greedy algorithm to construct a size-k solution set, and it repeats this step many times without replacement, i.e., each time the elements selected by greedy algorithm are removed from ground set, and finally it returns the best size-k solution set among all the repetitions. The pseudocode is given in Algorithm 2.

Algorithm 2 FPT$(f, E, k, \varepsilon, T)$.

Initialize an empty set X^*.
Run Algorithm 1 on the input[11] (f, E, k, ε) and keep S_{3k} and the final version of H in Algorithm 1.
for each size-$(\leq k)$ subset $O_H^{\text{guess}} \subseteq H$ **do**
    Initialize an empty set of elements I.
    for $i = 1, 2, \ldots, T$ **do**
        Run greedy algorithm with O_H^{guess} as the initial solution set[12] to build a size-k solution set $O_H^{\text{guess}} \cup X_i$. Add X_i to I and remove X_i from E.
    Let $X' = \arg\max_{X \subseteq S_{3k} \cup H \cup I, |X| \leq k} f(X)$ and let $X^* = X'$ if $f(X') > f(X^*)$.
    Add I back to E.
return X^*

[10] The certificates for these convex programs can be found in the full version.
[11] Randomly permute E if it is not in random order.
[12] Specifically, the greedy algorithm starts with solution set $X = O_H^{\text{guess}}$ and runs in $k - |X|$ iterations. In each iteration, it selects the element e in E that maximizes $f(e|X)$ and add e to X. (**We assume without loss of generality** that the maximal $f(e|X)$ is always non-negative. Otherwise, we can add dummy elements to E.)

Algorithm 2 runs in fixed-parameter polynomial time. Indeed, because $|H| = \widetilde{O}(k^2)$ by design of Algorithm 1, the outer loop has less than $k\binom{\widetilde{O}(k^2)}{k} = 2^{\widetilde{O}(k)}$ iterations, and for the inner loop, we will only need T to be an arbitrarily large constant. Greedy algorithm runs in $O(kn)$ time. Moreover, since $|I| \leq Tk$ and $|S_{3k} \cup H| = \widetilde{O}(k^2)$ with high probability, the brute-force step (Line 7) in Algorithm 2 takes time $k\binom{\widetilde{O}(k^2)}{k} = 2^{\widetilde{O}(k)}$. Furthermore, the runtime of Algorithm 1 excluding the exhaustive search in its last step is polynomial. Hence, the total runtime is $n \cdot 2^{\widetilde{O}(k)}$.

Instead of formally proving the approximation ratio for Algorithm 2 (which we will do in the full version), we give an interpretable analysis for the better-than-1/2 approximation. At very high level, the intuition is that if Algorithm 1 only gets 1/2 approximation, then it must be the case that $f(O_H) = \frac{f(O_H \cup O_L)}{2}$. Now we consider the candidate solution $O_H \cup X_i$ for $i \in \{1, 2, 3\}$, and we can argue that if $f(X_i|O_H) = 0$, i.e., the candidate solution does not beat 1/2, then X_i must hurt $O_H \cup O_L$ a lot. Moreover, By submodularity, $X_1 \cup X_2 \cup X_3$ hurts $O_H \cup O_L$ by at least the sum of how much each X_i ($i \in \{1, 2, 3\}$) hurts. Together, we show that this would contradict non-negativity of the function. Now we explain this intuition in more details.

Informal interpretable analysis

The starting point is the analysis of Theorem 12. We can show that for the instance to be hard, in the sense that Algorithm 1 is only able to get 1/2 approximation, then it requires $f(O_H) = \frac{f(O_H \cup O_L)}{2}$ (this will be explained with more details in the interpretable analysis provided before Theorem 17, but for now, let us take this as given). Because O_H is selected by Algorithm 1, in the outer iteration when Algorithm 2 guesses O_H correctly, it runs classic greedy algorithm many times based on O_H without replacement. Consider the set X_1 selected in the first run of greedy algorithm. By standard analysis of greedy algorithm, we can derive that $f(X_1|O_H) \geq f(O_L|O_H \cup X_1)$. If $f(X_1|O_H) = 0$ (otherwise $X_1 \cup O_H$ beats 1/2), then $f(O_L|O_H \cup X_1) \leq 0$, which implies $f(O_L \cup O_H \cup X_1) \leq f(O_H \cup X_1) = f(O_H) = \frac{f(O_H \cup O_L)}{2}$. Hence $f(X_1|O_L \cup O_H) \leq -\frac{f(O_H \cup O_L)}{2}$. WLOG, the first run of greedy did not select most of O_L, because otherwise $f(X_1|O_H)$ should be significantly large. Therefore, similarly, we can derive that if $f(X_2|O_H) = 0$, where X_2 is selected in the second run of greedy, then $f(X_2|O_L \cup O_H) \leq -\frac{f(O_H \cup O_L)}{2}$. By submodularity, $f(X_1 \cup X_2|O_L \cup O_H) \leq f(X_1|O_L \cup O_H) + f(X_2|O_L \cup O_H) \leq -f(O_H \cup O_L)$. Notice that this implies $f(X_1 \cup X_2 \cup O_L \cup O_H) \leq 0$. Hence, the third run of greedy algorithm must obtain very large $f(X_3|O_H)$ (and hence $X_3 \cup O_H$ beats 1/2), because otherwise we can repeat above argument and show that $f(X_1 \cup X_2 \cup X_3 \cup O_L \cup O_H) < 0$, which violates non-negativity of the function f. Furthermore, by running greedy many times, we are able to extract even more value from O_L, which is formally formulated by the factor-revealing programs in the proof in the full version.

▶ **Theorem 14.** *For sufficiently large constant T and sufficiently small constant ε, Algorithm 2 achieves* 0.512*-approximation for non-negative non-monotone submodular maximization with a cardinality constraint.*

4.2 Improved FPT algorithm

Algorithm 2 can be improved to achieve better approximation ratio. In this subsection, we present the improved algorithm, the pseudocode of which is given in Algorithm 4. In the full version, we will provide the intuition behind this algorithm (which involves the formal proof of Theorem 14) and the formal proof for the improved approximation factor.

Algorithm 3 RECURSIVE(f, E, k, I, t, T).

Initialize empty sets I' and X^*.
for each size-($\leq k$) subset $O_t^{\text{guess}} \subseteq I$ **do**
  for $i = 1, 2, \ldots, T$ **do**
    Run greedy algorithm on E with O_t^{guess} as the initial solution set to build a size-k solution set $O_t^{\text{guess}} \cup X_i$.
    Add X_i to I' and remove X_i from E.
  Add I' back to E.
  if $t \leq T$ **then**
    Run Algorithm 3 on input $(f, E, k, I \cup I', t+1, T)$, which returns solution set X'.
    Let $X^* = X'$ if $f(X') > f(X^*)$.
  else
    Let $X^* = \arg\max_{X \subseteq I, |X| \leq k} f(X)$.
return X^*

Algorithm 4 FPT$^+$(f, E, k, ε, T).

Initialize an empty set of elements I.
Run Algorithm 1 on input (f, E, k, ε) and keep S_{3k} and the final version of H in Algorithm 1.
Run Algorithm 3 on input $(f, E, k, S_{3k} \cup H, 1, T)$, which returns X^*.
return X^*

▶ **Theorem 15.** *For sufficiently large constant T and sufficiently small constant ε, Algorithm 4 achieves 0.539-approximation for non-negative non-monotone submodular maximization with a cardinality constraint.*

5 $(1/2 + c)$-approximation for random-order streaming symmetric submodular maximization

In this section, we show that Algorithm 1 *beats* 1/2-approximation for symmetric non-monotone submodular functions using $\widetilde{O}(k^2)$ memory. Together with our lower bound result (Theorem 18), this separates the symmetric non-monotone submodular functions from general non-monotone submodular functions in the random-order streaming model. To our best knowledge, this is first such separation.

The following lemma is the key feature of symmetric submodular functions which we will take advantage of, and it basically says for symmetric submodular function, a set can not hurt another set by more than its own value.

▶ **Lemma 16.** *For any non-negative symmetric submodular function $f : V \to \mathbb{R}_{\geq 0}$, for any disjoint $X, Y \subseteq V$, $f(X|Y) \geq -f(X)$.*

Proof. By submodularity, $f(X|Y) \geq f(X|V \setminus X) = f(V) - f(V \setminus X)$, and by symmetry and non-negativity, $f(V) - f(V \setminus X) = f(\emptyset) - f(X) \geq -f(X)$. ◀

Instead of showing the technical proof of the better-than-1/2 approximation (which is provided in the full version), we give the interpretable analysis for why Algorithm 1 can beat 1/2 for symmetric submodular functions. The interpretable analysis is still a little lengthy and technical. At very high level, the idea is if none of $S_{|O_L|}$ and $O_H \cup S_{|O_L|}$ and

$O_H \cup (S_{2|O_L|} \setminus S_{|O_L|})$ beats 1/2, then we can show that (i) $f(O_H) = f(O_L) = \frac{f(O_H \cup O_L)}{2}$, (ii) $f(O_H|S_{2|O_L|}) = -f(O_H)$, and (iii) $f(S_{3|O_L|} \setminus S_{2|O_L|}|S_{2|O_L|}) \geq (1 - 1/e)f(O_L)$. The punchline is that using (ii), we can further show that (iv) $f(S_{3|O_L|} \setminus S_{2|O_L|}|O_H) \geq f(S_{3|O_L|} \setminus S_{2|O_L|}|S_{2|O_L|})$ (basically, the argument is if O_H hurts $S_{2|O_L|}$ a lot, then by Lemma 16, which is due to symmetry, one can argue O_H can not hurt $S_{3|O_L|}$ more than how much it hurts $S_{2|O_L|}$). Therefore, by (i) and (iii) and (iv), we know that $O_H \cup (S_{3|O_L|} \setminus S_{2|O_L|})$ beats 1/2 approximation. Now we explain this idea in more details.

Informal interpretable analysis

The starting point is the analysis for Theorem 12. The reader can first review the intuition given in the beginning of the subsection of Theorem 12. There we argued that the algorithm achieves half of $f(O_H \cup S_{|O_L|}) + f(S_{|O_L|}) \geq f(O_H \cup O_L)$, and hence for the instance to be hard (in the sense that the algorithm only gets 1/2 approximation), it requires $f(O_H \cup S_{|O_L|}) = f(S_{|O_L|}) = \frac{f(O_H \cup O_L)}{2}$. This implies $f(O_H|S_{|O_L|}) = 0$, and by submodularity $f(O_H|O_L \cup S_{|O_L|}) \leq 0$, and hence $f(O_H \cup O_L \cup S_{|O_L|}) \leq f(O_L \cup S_{|O_L|})$. Recall that we argued $S_{|O_L|}$ can not hurt $O_H \cup O_L$ significantly, and thus, $f(O_H \cup O_L) \leq f(O_H \cup O_L \cup S_{|O_L|}) \leq f(O_L \cup S_{|O_L|})$, but since $f(S_{|O_L|}) = \frac{f(O_H \cup O_L)}{2}$, we have that $f(O_L|S_{|O_L|}) = f(S_{|O_L|})$, which implies[13] $f(S_{|O_L|}) \geq f(O_L)$. Moreover, since $f(S_{|O_L|}) = \frac{f(O_H \cup O_L)}{2}$, we have $f(O_L) \leq \frac{f(O_H \cup O_L)}{2}$ and hence $f(O_H) \geq \frac{f(O_H \cup O_L)}{2}$, but we also have $f(O_H) \leq \frac{f(O_H \cup O_L)}{2}$ because otherwise $O_H \cup S_{|O_L|}$ should have beaten 1/2-approximation as $S_{|O_L|}$ does not hurt O_H significantly, and therefore it holds that $f(O_H) = f(O_L) = \frac{f(O_H \cup O_L)}{2}$.

Now consider the set $S_{2|O_L|} \setminus S_{|O_L|}$. If $f(S_{2|O_L|} \setminus S_{|O_L|}|O_H) = 0$ (otherwise $S_{2|O_L|} \setminus S_{|O_L|} \cup O_H$ beats 1/2), then by submodularity and the fact that $S_{2|O_L|} \setminus S_{|O_L|}$ does not hurt anything significantly (which is yet another application of Lemma 10), we have $f(S_{2|O_L|} \setminus S_{|O_L|}|O_H \cup S_{|O_L|}) = 0$ and hence $f(O_H \cup S_{2|O_L|}) = f(O_H \cup S_{|O_L|}) = \frac{f(O_H \cup O_L)}{2}$. Notice that $f(O_L|O_H \cup S_{2|O_L|}) = f(O_L \cup O_H \cup S_{2|O_L|}) - f(O_H \cup S_{2|O_L|}) \geq f(O_L \cup O_H) - f(O_H \cup S_{2|O_L|}) = \frac{f(O_H \cup O_L)}{2}$, where the inequality is again due to the fact that $S_{2|O_L|}$ does not hurt. Therefore, similar to how we argued $f(S_{|O_L|}) \geq f(O_L)$, we can show that $f(S_{2|O_L|} \setminus S_{|O_L|}|S_{|O_L|}) \geq f(O_L)$. Since $f(S_{2|O_L|}) \geq f(S_{2|O_L|} \setminus S_{|O_L|}|S_{|O_L|}) + f(S_{|O_L|}) \geq 2f(O_L) = 2f(O_H)$ and $f(O_H \cup S_{2|O_L|}) = \frac{f(O_H \cup O_L)}{2} = f(O_H)$, we have that $f(O_H|S_{2|O_L|}) \leq -f(O_H)$, and together with Lemma 16, we have that $f(O_H|S_{2|O_L|}) = -f(O_H)$.

Here comes the final punchline – If $S_{3|O_L|}/S_{2|O_L|}$ has significant marginal contribution to $S_{2|O_L|}$, then $S_{3|O_L|}/S_{2|O_L|}$ must have at least the same marginal contribution to O_H (and therefore, $O_H \cup S_{3|O_L|}/S_{2|O_L|}$ will beat 1/2). Specifically, this follows from

$$
\begin{aligned}
f(S_{3|O_L|}/S_{2|O_L|}|O_H) &\geq f(S_{3|O_L|}/S_{2|O_L|}|O_H \cup S_{2|O_L|}) \\
&\qquad \text{(By submodularity)} \\
&= f(O_H|S_{3|O_L|}) - f(O_H|S_{2|O_L|}) + f(S_{3|O_L|}/S_{2|O_L|}|S_{2|O_L|}) \\
&\geq -f(O_H) - f(O_H|S_{2|O_L|}) + f(S_{3|O_L|}/S_{2|O_L|}|S_{2|O_L|}) \\
&\qquad \text{(By Lemma 16)} \\
&= f(S_{3|O_L|}/S_{2|O_L|}|S_{2|O_L|}) \\
&\qquad \text{(By } f(O_H|S_{2|O_L|}) = -f(O_H)\text{)}
\end{aligned}
$$

[13] Intuitively, by the if condition at line 9 of Algorithm 1, we can show that the marginal contribution of each iterate of $S_{|O_L|}$ is at least $\frac{f(O_L|S_{|O_L|})}{|O_L|}$, but because $f(O_L|S_{|O_L|}) = f(S_{|O_L|})$, each iterate actually makes the same marginal contribution. Notice that the first iterate should make contribution more than any element in O_L by the if condition.

(One can check the first equality is true by expanding both sides of the equality.) It remains to show $f(S_{3|O_L|}/S_{2|O_L|}|S_{2|O_L|})$ is indeed significantly large. This is essentially due to $f(O_L|O_H \cup S_{2|O_L|}) \geq \frac{f(O_H \cup O_L)}{2}$, which we argued earlier, and the if condition at line 9. In particular, we can show $f(S_{3|O_L|}/S_{2|O_L|}|S_{2|O_L|})$ is at least $1-1/e$ fraction of $f(O_L|S_{2|O_L|})$ by the standard analysis of the classic greedy algorithm for monotone submodular maximization.

In the full version, we will formally prove the better-than-1/2 approximation of Algorithm 1 using the factor-revealing programs.

▶ **Theorem 17.** *For sufficiently small ε and large k, Algorithm 1 achieves strictly better-than-1/2 approximation for non-negative non-monotone symmetric submodular functions in the random-order streaming model.*

On a side note, the constant we get here is by no means tight. (Indeed, we have an improvement, which may also improve the constant for our FPT algorithm, but it requires numerically solving non-convex programs rather than the convex programs in our proofs.) What is interesting is the separation between symmetric and general submodular functions in the random-order streaming model. Also, it is tempting to conjecture that Algorithm 1 achieves optimal $1-1/e$ approximation for monotone submodular functions, given its success in the non-monotone regime. Nonetheless, we have a hard instance that refutes this conjecture. The details would be made available to the interested reader upon request.

6 Tight 1/2 hardness for random-order streaming non-monotone submodular maximization

In this section, we present the lower bound result for non-monotone submodular maximization in the random-order streaming model (described in Section 2). The approximation factor in the lower bound result is tight because of the upper bound in Theorem 12 for example.

▶ **Theorem 18.** *Assuming $n = 2^{o(k)}$, any $(1/2+\varepsilon)$-approximation algorithm for non-monotone submodular maximization in the random-order streaming model must use $\Omega(n/k^2)$ memory. In fact, this hardness result holds against even stronger algorithms (see Remark 9) that are beyond the scope of the standard random-order streaming model for submodular maximization.*

The formal proof is provided in the full version. Here we give the construction of the hard instance and explain the main idea.

Construction of the hard instance

The function f we construct here is essentially a cut function on an unweighted bipartite directed hypergraph[14] plus a modular function. The ground set $V := A_1 \cup A_2$ for f is the set of n vertices of the graph, where A_1 and A_2 denote the two parts respectively. Specifically, $A_2 := \{u_1, \ldots, u_{\varepsilon k}\}$, and A_1 is partitioned into $\ell := (n-\varepsilon k)/b$ buckets of vertices $B_1, \ldots, B_\ell$, each of size $b := k - \varepsilon k$. Now we describe a random generating procedure that generates the hyperedges in the graph:

1. First, for each $i \in [\ell]$, we sample a random subset of vertices $N_i \subset A_2$ of size $|N_i| = \varepsilon^2 k$, and for each $u_j \in N_i$, we create a directed hyperedge from B_i to u_j.

[14] A directed hyperedge in a directed hypergraph is represented by some (U, v), where U is a subset of vertices, and $v \notin U$ is a vertex. For any subset of vertices S, a hyperedge (U, v) is cut by S iff $|U \cap S| > 0$ and $v \notin S$. It is well-known that such cut function is submodular.

2. Then, we slightly modify the graph generated in step 1 as follows: We sample a uniformly random $g \in [\ell]$. For each $u_j \in N_g$, we remove the hyperedge from B_g to u_j, and instead, for each $v \in B_g$, we create a directed hyperedge from $\{v\}$ to u_j. (That is, for each $u_j \in N_g$, we replace the hyperedge from B_g to u_j with individual edges from each $v \in B_g$ to u_j.)

The final submodular function $f : V \to \mathbb{R}_{\geq 0}$ is the sum of the cut function on the above generated hypergraph plus the modular function $c(S) := (\varepsilon^2 k^2) \cdot \frac{|S \cap A_2|}{|A_2|}$. See Figure 1 for an illustration.

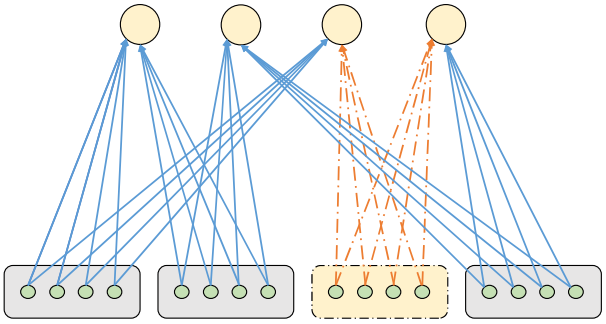

Figure 1 An illustration of our hard instance: At the top we have all εk vertices of A_2, each of which has value εk. At the bottom we have all $(n - \varepsilon k)$ vertices of A_1 that are separated into $\ell = (n - \varepsilon k)/b$ buckets, each of which has $b = k - \varepsilon k$ vertices. We choose a bucket B_g (with yellow filling and dashed outline) uniformly at random. There are εk individual edges (orange and dashed) from each vertex in bucket B_g to B_g's neighborhood N_g, and there are εk hyperedges (blue and solid) from every other bucket B_i (with gray filling and solid outline) to its neighborhood N_i.

Basically, in the above hard instance, we constructed a single good bucket B_g (which is incident to independent individual edges and hence can contribute high value in a cut) and lots of bad buckets B_i (which is incident to hyperedges and hence can only contribute low value in a cut) for all $i \in [\ell] \setminus \{g\}$.

The optimal solution for this hard instance is $B_g \cup (A_2 \setminus N_g)$, i.e., the union of the vertices in the good bucket B_g and the vertices in A_2 except B_g's neighborhood N_g, and specifically, the edges incident to B_g contribute half of the optimal value due to the cut function, and $A_2 \setminus N_g$ contributes the other half due to the modular function c.

However, it is hard for an $o(n/k^2)$-memory algorithm to find out which bucket is the good bucket. Intuitively, to tell whether a bucket B_i is the good bucket, the algorithm needs to query the value of a set that contains at least two vertices of B_i, because otherwise, the value of the set does not depend on whether B_i is incident to individual edges or hyperedges. In order to query the value of a set that contains at least two vertices of B_i, the algorithm has to store at least two vertices of B_i in its memory, because of the restriction in the random-order streaming model (see Section 2). Since the algorithm has low memory, it cannot store two elements for many B_i's at the same time. Using this observation, we can prove w.h.p. the algorithm cannot find the good bucket B_g during the entire stream. Furthermore, we can show by standard concentration inequality that w.h.p. any size-$(\leq k)$ solution set that does not contain enough vertices of B_g has at most half of the optimal value.

Although it was easy to describe the basic idea above, formalizing it requires nontrivial efforts, and we believe that the techniques in our formal proof, which we provide in the full version, are interesting and could be applied for proving hardness of other problems in the random-order streaming setting.

Approximate Triangle Counting via Sampling and Fast Matrix Multiplication

Jakub Tětek
Basic Algorithms Research Copenhagen, University of Copenhagen, Denmark

Abstract

There is a simple $O(\frac{n^3}{\epsilon^2 T})$ time algorithm for $1\pm\epsilon$-approximate triangle counting where T is the number of triangles in the graph and n the number of vertices. At the same time, one may count triangles exactly using fast matrix multiplication in time $\tilde{O}(n^\omega)$. Is it possible to get a negative dependency on the number of triangles T while retaining the state-of-the-art n^ω dependency on n? We answer this question positively by providing an algorithm which runs in time $O\left(\frac{n^\omega}{T^{\omega-2}}\right) \cdot \text{poly}(n^{o(1)}/\epsilon)$. This is optimal in the sense that as long as the exponent of T is independent of n, T, it cannot be improved while retaining the dependency on n. Our algorithm improves upon the state of the art when $T \gg 1$ and $T \ll n$.

We also consider the problem of approximate triangle counting in sparse graphs, parameterized by the number of edges m. The best known algorithm runs in time $\tilde{O}_\epsilon\left(\frac{m^{3/2}}{T}\right)$ [Eden et al., SIAM Journal on Computing, 2017]. An algorithm by Alon et al. [JACM, 1995] for exact triangle counting that runs in time $\tilde{O}(m^{2\omega/(\omega+1)})$. We again get an algorithm whose complexity has a state-of-the-art dependency on m while having negative dependency on T. Specifically, our algorithm runs in time $O\left(\frac{m^{2\omega/(\omega+1)}}{T^{2(\omega-1)/(\omega+1)}}\right) \cdot \text{poly}(n^{o(1)}/\epsilon)$. This is again optimal in the sense that no better constant exponent of T is possible without worsening the dependency on m. This algorithm improves upon the state of the art when $T \gg 1$ and $T \ll \sqrt{m}$.

In both cases, algorithms with *time* complexity matching *query* complexity lower bounds were known on some range of parameters. While those algorithms have optimal *query* complexity for the whole range of T, the time complexity departs from the query complexity and is no longer optimal (as we show) for $T \ll n$ and $T \ll \sqrt{m}$, respectively. We focus on the time complexity in this range of T. To the best of our knowledge, this is the first paper considering the discrepancy between query and time complexity in graph parameter estimation.

1 Introduction

The problem of counting triangles in a graph is both a fundamental problem in graph algorithms and a problem with many applications, for example in network science [5], biology [8, 19, 21] or sociology [25, 15]. Triangle counting is, also for these reasons, one of the basic procedures in graph mining. Consequently, triangle counting has received a lot of attention both in the theoretical and applied communities.

There are algorithms for *exact* triangle counting that have time complexity $\tilde{O}(n^\omega)$ [1] and $\tilde{O}(m^{2\omega/(\omega+1)})$ [3] where ω is the smallest constant such that two $n \times n$ matrices can be multiplied in time $n^{\omega+o(1)}$.

A natural variant of this problem is *approximate triangle counting*. In this problem, we are given a graph with T triangles and want to output $\hat{T} = (1 \pm \epsilon)T$ with probability 2/3. Several algorithms are known for approximate triangle counting that have *negative dependence* on the number of triangles T. Assuming the algorithm may sample random vertices and edges, there are algorithms that run in time $O_\epsilon(\frac{n^3}{T})$ [2] and $\tilde{O}_\epsilon(\frac{m^{3/2}}{T})$ [9][3]. However, no algorithm is known that would get the best of both worlds – algorithms with state-of-the-art dependency on n or m while being negatively dependent on T. We show two such algorithms in this paper. Moreover, our algorithms are optimal in the following sense: the dependence on T in the time complexity of our algorithms cannot be improved without worsening the dependency on n or m as long as the exponent of T is constant (i.e., is independent of n, m, T). This optimality follows from the lower bound shown by Eden, Levi, Ron, and Seshadhri [9], as we show in the full version of this paper.

The main contribution of our paper is an algorithm for approximate triangle counting that runs in time $\tilde{O}_\epsilon\left(\frac{n^\omega}{T^{\omega-2}}\right)$. We then use it to give an algorithm for the same problem running in time $\tilde{O}_\epsilon\left(\frac{m^{2\omega/(\omega+1)}}{T^{2(\omega-1)/(\omega+1)}}\right)$. This improves upon our first algorithm for sparse graphs. Note that both time complexities are sublinear for sufficiently large values of T. To the best of our knowledge, this is the first work that uses fast matrix multiplication in sublinear-time algorithms. Assuming constant ϵ, our algorithms improve upon the state-of-the-art when $T \ll n$, and $T \gg 1$ or $T \ll \sqrt{m}$ and $T \gg 1$ (for Algorithm 4 and Algorithm 5, respectively). In other words, our algorithms improve upon the state of the art when the time complexity (of both our and the state-of-the-art algorithms) is $\gg n^2$ and $\gg m$, respectively. Figure 1 shows a plot of the complexity of our algorithms, in comparison to other algorithms for approximate triangle counting.

The basic approach we use is to sample vertices, recursively count triangles in the subgraph induced by these sampled vertices, and estimate the total number of triangles based on this count. The main hurdle in this approach is that when a vertex is contained in many triangles (we call such a vertex triangle-heavy, and triangle-light otherwise), this results in a poor concentration of the number of triangles in the induced subgraph as the inclusion of one vertex can make a large difference in the number of triangles. We get around this by introducing a procedure based on fast matrix multiplication which finds all vertices contained in many triangles, and a procedure for approximately counting triangles that contain at least one such vertex. We count triangles that consist of light vertices separately. The fact that the vertices are light helps us ensure concentration of our estimate. These triangles are counted using a recursive approach. An obstacle to overcome is that in some cases the time spent in each successive level of recursion may grow exponentially.

---

[1] We use $\tilde{O}(f(x))$ with the meaning that it ignores an $f(x)^{o(1)}$ factor; this is necessary as ω only determines the time complexity up to $n^{o(1)}$. This differs from the usual use in which $\tilde{O}(f(x)) = \cup_{c>0} O(f(x)\log^c f(x))$. $\tilde{O}_\epsilon$ in addition ignores $\text{poly}(\frac{1}{\epsilon})$.

[2] This algorithm follows from a paper of Lipton, Naughton, Schneider, and Seshadhri [20]. In this paper, the authors show an algorithm that gives a relative approximation to the bias of a Bernoulli trial. One may reduce approximate triangle counting to this problem by picking at random three vertices and checking whether they form a triangle. See also the presentation of Watanabe [24].

[3] The main result of the paper is an algorithm and lower bound in a slightly different setting. This algorithm is only mentioned in the paper briefly.

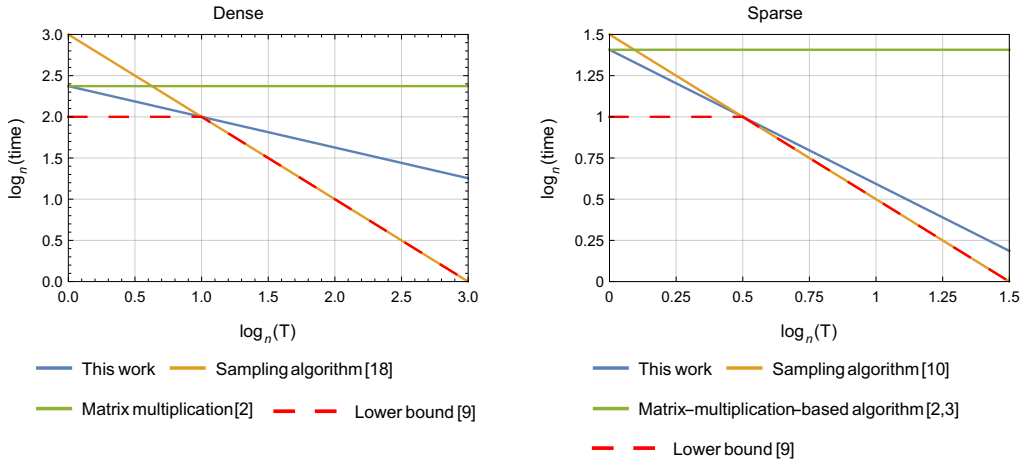

Figure 1 Comparison of the time complexities, assuming ϵ is constant. This plot assumes the best currently known bound $\omega < 2.3728596$ from [2]. For more detail, see Table 1.

We find it surprising that it is sufficient to use matrix multiplication to find the vertices contained in many triangles. That is, the matrix multiplication is only used to decide which triangles are going to be counted by which subroutine, while the counting itself is done without the help of matrix multiplication.

The setting. When an algorithm runs in sublinear time, it is of importance how the algorithm is allowed to access the graph. This is because the algorithm does not have the time to pre-process the whole graph. We assume the following standard setting: the algorithm may in constant time (1) get the i-th vertex, (2) get the j-th neighbor of a given vertex, (3) query the degree of a given vertex, and (4) given two vertices, tell whether they are adjacent or not (this is called the pair query). In the second part of this paper, we assume a setting where instead of the query (1), we can in constant time (1') get the i-th edge. This setting is also standard in the area of sublinear algorithms. As the main contribution of this paper is in the superlinear regime (as this is where we improve upon the state of the art), we do not describe the settings in more detail. See, for example, [13] for a more detailed description.

Time complexity vs. query complexity. In the area of sublinear algorithms, it is customary to focus on the *query complexity* (that is the number of queries, in the above sense, performed) of an algorithm, as opposed to the time complexity. The time complexity is then usually (near-)linear in the query complexity. However, this is the case only in the sublinear regime, and it breaks down when the time complexity is superlinear[4]. In this case, one may always read the whole graph in $O(n+m)$ queries. The time complexity is then usually significantly larger than the query complexity. This regime is our main focus.

Specifically, an algorithm is described in [9] that uses the edge access query (1') and has query complexity $\tilde{O}_\epsilon(\min(n+m, m^{3/2}/T))$. This is known to be near-optimal[5] [11]. In the sublinear regime (that is, for T large enough), the asymptotic time complexity is the same

[4] It may seem confusing talking about a sublinear-time algorithm having superlinear time complexity. The reason is that an algorithm is usually said to be sublinear time if its complexity is sublinear for some setting of the parameters (but not necessarily for all).

[5] Whenever we talk about optimality, we consider the case of ϵ being constant.

as the query complexity and it is, therefore, also near-optimal. However, in the superlinear regime, the time complexity is polynomially larger than the query complexity. Up until now, nothing was known about whether the time complexity can be improved in this case. We answer this question positively. In doing this, we give, to the best of our knowledge, the first algorithm answering a question of this type (that is, a question regarding the discrepancy between the time and query complexities in the superlinear regime).

1.1 Our results

The main contributions of this paper are the following two algorithms for approximate triangle counting. The first algorithm (Algorithm 4) is suitable for dense graphs and its time complexity is parameterized by n, T, and ϵ. The second algorithm (Algorithm 5) is suitable for sparse graphs and its time complexity is parameterized by m and T. Both of our algorithms have a state-of-the-art dependency on n, m while being negatively dependent on T. Our algorithms improve upon the existing algorithms when $1 \ll T \ll n$ and $1 \ll T \ll \sqrt{m}$, respectively.

We compare these results to the previous work in the following table. These time complexities are also plotted in Figure 1.

Table 1 Algorithms for approximate triangle counting. Algorithms with complexity independent of ϵ in fact solve exact triangle counting. (Note that algorithms with dependency on ϵ have the dependency hidden in O_ϵ in this table.)

1.2 Related work

Algorithms. The number of triangles in a graph can be trivially counted in time $O(n^3)$. Itai and Rodeh [16] obtained an algorithm that runs in time $O(m^{3/2})$, a significant improvement for sparse graphs. A simpler algorithm with the same complexity, based on bounds on arboricity has been given by Chiba and Nishizeki [7]. A more efficient algorithm for *approximate* triangle counting has been obtained by Kolountzakis, Miller, Peng, and Tsourakakis [18]. In their paper, the authors presented an algorithm that runs in time $\tilde{O}_\epsilon(m + \frac{m^{3/2}}{T})$. This has been later improved by Eden et. al. [9] to $\tilde{O}_\epsilon(\frac{n}{T^{1/3}} + \frac{m^{3/2}}{T})$ when having vertex queries and not edge queries (having query (1) but not (1′)) and to $\tilde{O}_\epsilon(\frac{m^{3/2}}{T})$ when having edge queries (query (1′)).

While fast matrix multiplication gives a $\tilde{O}(n^\omega)$ algorithm for exact triangle counting, it is not immediately clear an improvement can be achieved in sparse graphs. In their paper, Alon, Yuster, and Zwick [3] show an algorithm for exact triangle counting that runs in time $\tilde{O}(m^{2\omega/(\omega+1)})$. This algorithm works by counting triangles whose all vertices have high degree using matrix multiplication while using a naïve algorithm for the rest of the graph. We use a variant of this approach for approximate triangle counting in sparse graphs in Section 3.

Sampling from graphs in order to estimate the number of triangles has been considered many times [23, 22, 17, 6]; for more details, see the introduction of [17]. The bounds then often depend on an upper bound on the number of triangles containing any single edge or similar parameters, for example in [22] or [23]. In this paper, we go further in the sense that we use a similar sampling approach (in fact, we use the same sampling scheme that was used in [6] but use a finer analysis) but explicitly ensure the bound on the number of triangles containing any single vertex. In other papers using similar sampling schemes, it is just assumed that this or a similar bound is already satisfied for the input instance.

Lower bounds. From the side of lower bounds, Eden et. al. [9] have proven a lower bound on the query complexity, thus also implying a lower bound on the time complexity. This lower bound is presented for the setting when random edge queries are not allowed, but the lower bound of $\Omega(\min(m, m^{3/2}/T))$ also holds in the setting when they are. This was made explicit by Eden and Rosenbaum [12] who presented a significantly simpler proof based on communication complexity.

▶ **Theorem 1** (Theorem 4.7 of [12]). *For any $n, m \in O(n^2), T \in O(m^{3/2})$, it holds that any multiplicative-approximation algorithm for the number of triangles in a graph must perform $\Omega\left(\min\left(m, \frac{m^{3/2}}{T}\right)\right)$ queries, where the allowed queries are degree queries, pair queries, random neighbor queries, random vertex queries, and random edge queries.*

We use this lower bound to prove the claim that the exponent of T in Theorem 12 is optimal, out of all algorithms running in time $\tilde{O}(n^\omega/T^c)$ for some constant c and similarly the exponent in Theorem 15 is optimal out of all algorithms running in time $\tilde{O}(m^{2\omega/(\omega+1)}/T^c)$.

By choosing $m = \Theta(n^2)$ in the above theorem, it follows that

▶ **Corollary 2.** *For any n and $T \in O(n^3)$, it holds that any multiplicative-approximation algorithm for the number of triangles in a graph must perform $\Omega\left(\min\left(n^2, \frac{n^3}{T}\right)\right)$ queries, where the allowed queries are degree queries, pair queries, neighbor queries, random vertex queries, and random edge queries.*

Fast matrix multiplication. There is a large literature on fast matrix multiplication. We only mention here the asymptotically most efficient matrix multiplication algorithm which is currently the algorithm by Alman and Williams [2] which runs in time $\tilde{O}(n^\omega)$ for some $\omega < 2.3728596$.

1.3 Technical overview

1.3.1 Triangle counting in dense graphs

Sampling and (lack of) concentration. Suppose we sample each vertex independently with some probability p. The expected number of triangles in the subgraph induced by the sampled vertices is then p^3T. If we were able to show concentration around the expected value, we could count the number of triangles in this subgraph and based on that, estimate the number of triangles in the original graph.

Unfortunately, the number of triangles is not concentrated; for example, in the case when there is one vertex that is contained in all triangles. We show that we get concentration if we limit the number of triangles containing any single vertex. We, therefore, have some threshold τ and call all vertices that are contained in more than τ triangles triangle-heavy. Assume that the graph does not have any triangle-heavy vertices. By choosing τ sufficiently

small and by choosing p sufficiently large, we may get a good estimate of the number of triangles in the original graph, based on the number of triangles in the subgraph induced by the sampled vertices.

In the final algorithm, we separately count triangles that contain at least one triangle-heavy vertex and triangles that do not. For this, we need to be able to find all triangle-heavy vertices in the graph and then estimate the number of triangles that contain at least one triangle-heavy vertex. We efficiently count triangles with no triangle-heavy vertex by reducing the problem to one on a smaller graph by the sampling procedure we just described.

Finding triangle-heavy vertices by matrix multiplication. We now sketch how to find the set of vertices that are contained in many triangles. We sample each vertex with some small probability p'. This gives a subset of vertices of size $\approx p'n$. We find all vertices that are contained in a triangle in the subgraph induced by the sampled vertices in time $O\big((p'n)^\omega\big)$ by using matrix multiplication. We repeat this experiment an appropriate number of times. We report vertices that were contained in at least one triangle in at least one repetition of the experiment. If a vertex is contained in few triangles, the probability that it is reported can be bounded by using union bound over all triangles it is contained in and over all iterations. The intuition for why vertices contained in many triangles are reported with good probability is the following. We bound the variance of the total number of triangles that the vertex will be in over all repetitions. The repetitions are independent, but there are correlations between triangles within one repetition. If we set the probability p' to be small enough, we can show that these correlations are small. This allows us to show concentration of the number of triangles containing any single vertex that are observed in the sampled subgraphs.

Counting triangles with triangle-heavy vertices. Suppose we are given a subset of vertices such that each of those vertices is contained in many triangles. We now sketch how to give a factor $3+\epsilon$ approximation to the number of triangles that contain at least one of these vertices. In the body of the paper, we then give a $(1+\epsilon)$-approximation by a more careful argument.

We estimate separately for each vertex the number of triangles it is contained in. The fact that each vertex individually is in many triangles allows us to employ a concentration argument separately for each vertex. We then use union bound over all vertices. Specifically, for each vertex v from the set of vertices that is given to us, we perform the following experiment many times: we sample two vertices and we check whether they form a triangle with v. We use the proportion of the experiments that ended up with a triangle to estimate the number of triangles v is contained in. We add together the estimates for all vertices in the set. This is where the factor 3 comes from – a triangle may be counted from all its 3 vertices.

Recursive algorithm. The last trick we introduce is that we use recursion to approximately count the triangles in the sampled subgraph. Doing this in such a way to give a correct algorithm with the desired complexity is the technically most challenging part of our paper. An obstacle is that we need the precision to be increasing in the depth of recursion. Specifically, in our algorithm, the allowed error decreases at an exponential rate in the depth of recursion. Moreover, we need to use probability amplification, meaning that the number of recursive calls also grows exponentially with the depth of recursion. This leads, in some situations, to the time complexity of the k-th level of recursion increasing exponentially in k; we bound this time.

1.3.2 Triangle counting in sparse graphs

We set a parameter θ and say a vertex is degree-heavy if its degree is at least θ and degree-light otherwise. We count separately *(a)* triangles on the subgraph induced by the degree-heavy vertices and *(b)* triangles that contain at least one degree-light vertex. This is basically the idea used by Alon, Yester, and Zwick [3] for their exact triangle-counting algorithm. We use our algorithm for approximate triangle counting in dense graphs to count the triangles from case *(a)* and sampling to count the triangles *(b)*. The sampling-based estimation is based on ideas from [7, 9]. Specifically, we assign each triangle to its vertex with the lowest degree (breaking ties arbitrarily). We then repeatedly perform the following experiment: pick an edge uniformly at random; consider its endpoint v with the lower degree; pick one of its neighbors at random; check whether it forms a triangle together with the edge we have sampled and whether the triangle is assigned to v. If so, return $d(v)$, otherwise return 0. We estimate the number of triangles based on the average of the returned values of the experiments.

1.4 Notation

Throughout the paper, we denote the number of vertices and edges of a graph by n and m, respectively. We use T to denote the number of triangles. We define $a \pm b = [a - b, a + b]$. This can be used for example in $(1 \pm \epsilon)a$ which is then equal to $[(1 - \epsilon)a, (1 + \epsilon)a]$. We call $(1 \pm \epsilon)$-approximation to a number a any number b such that $b \in (1 \pm \epsilon)a$. Similarly, we call *additive* $\pm c$ approximation to a number a any number b such that $b \in a \pm c$. We call *diamond* a graph isomorphic to  and *butterfly* a graph isomorphic to  . By "the number of diamonds in G" we mean the number of, not necessarily induced, subgraphs of G isomorphic to a diamond. We similarly talk about "the number of butterflies in a graph". We denote the subgraph of G induced by $V' \subseteq V$ by $G[V']$.

2 Triangle counting in dense graphs

In this section, we present the main result of our paper – an algorithm for approximate triangle counting, parameterized by n and the number of triangles T. In the lemmas that follow, we prove, among other things, bounds on the expectation of the estimators. We do this because our algorithm requires some "advice" and having a bound on the expectation will allow us to remove the need for this advice, as we describe in Section 2.5. We now define some notation that we will need.

We call a vertex *triangle-dense* for a parameter τ if there are at least τ triangles that contain the vertex and *triangle-light* if at most $\tau/20$ triangles contain it (there can thus be vertices that are neither triangle-light nor triangle-heavy). We define T_v to be the number of triangles containing the vertex v. We abuse notation and also denote by T_v the set of all triangles containing v. We use $T_v(G)$ instead when we want to explicitly specify the graph. T denotes the number of triangles in G but we again abuse notation and use this to also denote the set of triangles. Again, if we want to specify the graph, we use $T(G)$.

We now prove a simple lemma on fractional moments of the binomial distribution. We will use this to bound the time complexity of matrix multiplication executed on a random subgraph of some given graph. Specifically, we will use it on a subgraph obtained by keeping each vertex with some appropriately chosen probability and removing the other vertices. The lemma also holds for other exponents than ω, but fixing the exponent allows for a simpler proof.

▶ **Lemma 3.** *Assume $p \geq 1/n$. It holds that $E(Bin(n,p)^\omega) = O(n^\omega p^\omega)$.*

Proof. $Bin(n,p)$ has its third moment equal to

$$(n(n-1)(n-2)p^3) + 3(n(n-1)p^2) + np = O(n^3p^3)$$

where the equality holds because $p \geq 1/n$. Since $\omega < 3$, the function $x^{\omega/3}$ is concave. By the Jensen's inequality, we then get $E(Bin(n,p)^\omega) \leq \big(E(Bin(n,p)^3)\big)^{\omega/3} = O(n^\omega p^\omega)$. ◀

2.1 Triangle-light subgraph

We show a reduction from the problem of approximately counting triangles in a graph with no triangle-heavy vertices to the problem of approximately counting triangles in a smaller graph. Before that, we need to prove the following lemma.

▶ **Lemma 4.** *Let G be a graph with T triangles such that any vertex is contained in at most τ triangles and let D, B be the number of diamonds and butterflies in G, respectively. Then $D + B \leq \frac{3}{2}\tau T$.*

Proof. Let S be the number of pairs $(\triangle_1, \triangle_2)$ of triangles in G such that $\triangle_1$ and $\triangle_2$ share at least one vertex. It holds $D + B \leq S/2$ (the factor of 2 is there because the pairs are ordered). Consider a fixed triangle $\triangle_1 = uvw$. How many triangles are there that share a vertex with $\triangle_1$? Each of the vertices u, v, w can be contained in at most $\tau - 1$ other triangles. There can be, therefore, at most $3(\tau - 1)$ incidences between $\triangle_1$ and other triangles containing at least one of the vertices u, v, w. Therefore $D + B \leq S/2 \leq 3T(\tau - 1)/2$. ◀

We are now ready to prove the following lemma. Note that to use it (in order to set the probability p), one has to have a lower bound on the number of triangles. We resolve this issue later.

▶ **Lemma 5.** *Let $G' = (V', E')$ be the induced subgraph of G resulting from keeping each vertex with probability $p \geq \max(5\frac{1}{\sqrt[3]{\epsilon^2 T}}, 10\frac{1}{\epsilon\sqrt{T/\tau}})$ and removing it otherwise. Let $\hat{T} = |T(G')|/p^3$. Then $\hat{T}$ is an unbiased estimate of T. Moreover if any vertex $v \in G$ is contained in at most τ triangles, then $\hat{T} \in (1 \pm \epsilon)T$ with probability at least $19/20$.*

Proof. Let $\triangle$ be a triangle in G. Let $X_\triangle = 1$ if $\triangle \in T(G')$ and 0 otherwise. Let $T' = T(G')$. It holds that

$$E(\hat{T}) = E(T'/p^3) = \sum_{\triangle \in T} E(X_\triangle)/p^3 = T$$

and the estimate is, therefore, unbiased.

We now bound $Var(T')$. Recall that $T(G)$ is the set of triangles in G. Let $D(G)$ the set of diamonds in G, $B(G)$ the set of butterflies in G, and $\ddot{T}(G)$ the set of disjoint (unordered) pairs of triangles in G. Let $D = |D(G)|$, $B = |B(G)|$, and $\ddot{T} = |\ddot{T}(G)|$. By $\{\triangle_1, \triangle_2\} \in D(G)$ we mean that $\triangle_1 \cup \triangle_2 = A$ for some $A \in D(G)$ and analogously for $B(G)$ and $\ddot{T}(G)$.

We first bound the second moment of T'

$$\begin{aligned} E(T'^2) =& E\left(\Big(\sum_{\triangle \in T(G)} X_\triangle\Big)^2\right) \\ =& E\Big(\sum_{\triangle \in T(G)} X_\triangle^2\Big) + E\Big(\sum_{\substack{\triangle_1, \triangle_2 \in T(G) \\ \triangle_1 \neq \triangle_2}} X_{\triangle_1} X_{\triangle_2}\Big) \end{aligned}$$

$$
\begin{aligned}
&= E\Big(\sum_{\triangle \in T(G)} X_{\triangle}^2\Big) + E\Big(2 \sum_{\{\triangle_1,\triangle_2\} \in D(G)} X_{\triangle_1} X_{\triangle_2}\Big) \\
&\quad + E\Big(2 \sum_{\{\triangle_1,\triangle_2\} \in B(G)} X_{\triangle_1} X_{\triangle_2}\Big) + E\Big(2 \sum_{\{\triangle_1,\triangle_2\} \in \ddot{T}(G)} X_{\triangle_1} X_{\triangle_2}\Big) \\
&= p^3 T + 2p^4 D + 2p^5 B + 2p^6 \ddot{T} \\
&\leq p^3 T + 2(D+B)p^4 + p^6 T^2 \\
&\leq p^3 T + 3p^4 \tau T + p^6 T^2
\end{aligned}
$$

where we have used that $D + B \leq \frac{3}{2}\tau T$ (by Lemma 4) and $2\ddot{T} \leq T^2$. At the same time, $E(T') = p^3 T$. Therefore,

$$Var(T') = E(T'^2) - E(T')^2 \leq p^3 T + 3p^4 \tau T.$$

This means that $E(\hat{T}) = T$ and $Var(\hat{T}) = Var(\frac{1}{p^3}T') = \frac{1}{p^3}T + \frac{3}{p^2}\tau T$. Since $p \geq \max(5\frac{1}{\sqrt[3]{\epsilon^2 T}}, 10\frac{1}{\epsilon\sqrt{T/\tau}})$, it holds $Var(\hat{T}) \leq (1/5^3 + 3/10^2)\epsilon^2 T^2 < \frac{1}{20}\epsilon^2 T^2$. It, therefore holds by the Chebyshev inequality that $P(|\hat{T} - T| \geq \epsilon T) \leq 1/20$. ◀

2.2 Triangle-heavy subgraph

We now show an algorithm that approximately counts triangles that contain at least one vertex from set V_H where V_H is some given set that does not contain any triangle-light vertices.

Algorithm 1 Count $(1 \pm \epsilon)$-approximately triangles in G containing a vertex from V_H.

```
for v ∈ V_H do
    T̂_v ← 0
    repeat 360 n² log n / (ε²τ) times
        Sample u, w ∈ V
        Let ℓ = |{u, v, w} ∩ V_H|
        If uvw forms a triangle, increment T̂_v by ε²τ / (360ℓ log n)
return Σ_{v∈V_H} T̂_v
```

▶ **Lemma 6.** *Given a set V_H, Algorithm 1 returns an unbiased estimate of the number of triangles containing at least one vertex from V_H.*

Assume V_H contains all triangle-heavy vertices of G and no triangle-light vertices. Then Algorithm 1 returns $(1 \pm \epsilon)$-approximation of the number of triangles that contain at least one triangle-heavy vertex with probability at least $1 - O(\frac{1}{n})$. It runs in time $O(\frac{Tn^2 \log n}{\epsilon^2 \tau^2})$.

Proof. We introduce charges on vertices. For any triangle $\triangle$ that contains at least one vertex that is in V_H, we divide and charge single unit to the vertices in $\triangle \cap V_H$, dividing it fairly (if there are, e.g., two vertices from V_H in the triangle, they are both charged 1/2). Let χ_v be the charge on vertex v. The total amount charged (that is, $\sum_{v \in V_H} \chi_v$) is equal to the number of triangles that contain at least one vertex from V_H. Note that this is the quantity we want to estimate.

The algorithm considers $v \in V_H$ and samples one pair of vertices u, w. Consider the amount charged by uvw to v; call it χ'_v. It holds that $E(\chi'_v) = \chi_v/n^2$. When uvw form a triangle, the algorithm increments $\hat{T}_v$ by $\frac{\epsilon^2\tau}{360\ell \log n} = \frac{\chi'_v \epsilon^2 \tau}{360 \log n}$. Therefore, the increment is, in expectation, equal to $\frac{\chi_v \epsilon^2 \tau}{360 n^2 \log n}$. Since there are $\frac{n^2 \log n}{360\epsilon^2\tau}$ repetitions, it holds

$$E(\hat{T}_v) = \frac{360n^2 \log n}{\epsilon^2\tau} \cdot \frac{\chi_v \epsilon^2 \tau}{360 n^2 \log n} = \chi_v.$$

By the linearity of expectation, we have $E(\sum_{v \in V_H} \hat{T}_v) = \sum_{v \in V_H} \chi_v$ which we said above is equal to the number of triangles with empty intersection with V_H.

We now prove concentration around mean. For each vertex, we have $\frac{360n^2 \log n}{\epsilon^2\tau}$ independent random variables corresponding to the increments in $\hat{T}$. These random variables have values between 0 and $\frac{\epsilon^2\tau}{360 \log n}$ and their sum has expectation $\chi_v \geq \frac{T_v}{3} \geq \frac{\tau}{60}$ where the second inequality holds from the assumption that V_H contains no triangle-light vertices. By the Chernoff bound,

$$P(|\hat{T}_v - T_v| \geq \epsilon T_v) \leq 2 \exp\Big(- \frac{\epsilon^2\tau/60}{3\epsilon^2\tau/(360 \log n)} \Big) \leq \frac{2}{n^2}.$$

By the union bound, it holds for all v that $\hat{T}_v$ is an $(1 \pm \epsilon)$-approximate of T_v, with probability at least $1 - \frac{2}{n}$. On this event, the algorithm correctly gives a $(1 \pm \epsilon)$-approximation of the number of triangles containing at least one triangle-heavy vertex. ◀

2.3 Finding the triangle-heavy subgraph

In this section, we show how to find a set of vertices that contains each triangle-heavy vertex with probability at least 2/3 and each triangle-light vertex with probability at most 1/3. This guarantee may be strengthened by probability amplification (applying the probability amplification separately to each vertex) to make sure that, with high probability, all triangle-heavy vertices are reported, and none of the triangle-light vertices are. This only adds a $O(\log n)$ factor to the time complexity of this subroutine.

We solve separately the case $\tau \leq n$ and $\tau \geq n$. On the range $\tau \leq n$, we get an algorithm running in time $\tilde{O}(\frac{n^\omega}{\tau^{\omega-2}})$. On the range $\tau \geq n$, we get time complexity $O(\frac{n^3}{\tau}) \subseteq \tilde{O}(\frac{n^\omega}{\tau^{\omega-2}})$ (the inclusion holds on this range of τ). This means that on this range, our bound is not tight. However, this is the case only on the range of T for which a near-optimal algorithm was already known, and we only show this for completeness; the reader may wish to skip the case of $\tau \geq n$. Putting the guarantees for the two ranges together, it follows that

▶ **Corollary 7.** *There is an algorithm that with probability at least $1 - O(\frac{1}{n})$ reports all triangle-heavy vertices and no triangle-light vertices while having time complexity $\tilde{O}(\frac{n^\omega}{\tau^{\omega-2}})$.*

2.3.1 The case $\tau \leq n$

▶ **Lemma 8.** *Assuming $\tau \leq n$, Algorithm 2 lists any triangle-heavy vertex with probability at least 2/3 and any triangle-light vertex with probability at most 1/3. It has expected time complexity $\tilde{O}(\frac{n^\omega}{\tau^{\omega-2}})$.*

---

[6] This may be done as follows. Raise the adjacency matrix of $G[V_i]$ to the third power. Each diagonal element in this matrix corresponds to a vertex (as rows and columns correspond to vertices and diagonal vertices have both the row and column corresponding to the same vertex). Consider the vertices that have a non-zero value on the corresponding diagonal position. These are exactly the vertices contained in some triangle by standard equivalence between taking powers of adjacency matrices and between counting walks in graphs.

Algorithm 2 Distinguish triangle-heavy vertices from triangle-light vertices.

$\mathcal{M} \leftarrow \emptyset$
for $i \in [k = 6\tau^2]$ **do**
  $V_i \leftarrow$ sample each vertex $v \in V$ independently with probability $p = \tau^{-1}$
  $V_i' \leftarrow$ find all vertices contained in a triangle in $G[V_i]$ in time $\tilde{O}(|V_i|^\omega)$ [6]
  $\mathcal{M} \leftarrow \mathcal{M} \cup V_i'$
return $\mathcal{M}$

Proof. Consider a triangle-light vertex v. That is, there are at most $\tau/20$ triangles in G containing v. The probability that a triangle is discovered in one iteration is, by the union bound, at most $\tau p^3/20$. Taking a union bound over the k iterations, the probability that a triangle containing v is found (and thus v reported) is at most $k\tau p^3/20 < 1/3$.

Consider a triangle-heavy vertex v. Let X_i for $i \in [k]$ be the number of triangles containing v discovered in the i-th iteration. For $\triangle \in T$, let $X_{\triangle,i}$ be an indicator that triangle $\triangle$ is discovered in i-th iteration. It now holds $X_i = \sum_{\triangle \in T, v \in \triangle} X_{\triangle,i}$. Let $X = \sum_{i=1}^{k} X_i$.

By the linearity of expectation, it holds that

$$E(X) = E\Big(\sum_{i=1}^{k} X_i\Big) = kp^3 T_v = 6T_v/\tau.$$

We now bound the variance of X. We first bound

$$Var(X_i) \leq E(X_i^2) = E\Bigg(\sum_{\triangle_1, \triangle_2 \in T_v} X_{\triangle_1,i} X_{\triangle_2,i}\Bigg) \leq p^3 T_v + p^4 T_v^2$$

where the last inequality holds because there are $\leq T_v^2$ terms (i.e. pairs of triangles containing v) that are 1 with probability $\leq p^4$ (such pairs have at least 4 vertices) and there are T_v terms (i.e. pairs of triangles containing v) that are 1 with probability p^3 (these are pairs that have $\triangle_1 = \triangle_2$ and the pair thus has 3 vertices). Since the iterations are independent, it holds that

$$Var(X) = Var\Big(\sum_{i=1}^{k} X_i\Big) = kVar(X_i) \leq 6\tau^2(p^3 T_v + p^4 T_v^2) = \frac{6}{\tau} T_v + \frac{6}{\tau^2} T_v^2 \leq \frac{12 T_v^2}{\tau^2}$$

where the last inequality holds because $T_v \geq \tau$. It, therefore, holds by the Chebyshev inequality that

$$P(X = 0) \leq \frac{Var(X)}{E(X)^2} \leq \frac{12T_v^2/\tau^2}{(6T_v/\tau)^2} = 1/3.$$

We now argue the time complexity. It holds that $|V_i| \sim Bin(n, p)$. By Lemma 3, each iteration has expected time complexity $\tilde{O}(n^\omega p^\omega)$ because of the assumption $p = 1/\tau \geq 1/n$. There are $O(p^{-2})$ iterations. The total time complexity is thus $\tilde{O}(p^{-2} p^\omega n^\omega) = \tilde{O}\Big(\frac{n^\omega}{\tau^{\omega-2}}\Big)$. ◀

2.3.2 The case $\tau > n$

We repeat that this case only applies to the range where an optimal algorithm is already known (see the beginning of Section 2.3) and we only show this for completeness; the reader may wish to skip this part.

Algorithm 3 Distinguish triangle-heavy vertices from triangle-light vertices.

```
1 M ← ∅
2 for v ∈ V do
3     repeat k = 2n²/τ times
4         Sample u, w ∈ V
5         if uvw ∈ T then
6             M ← M ∪ {v}
7 return M
```

▶ **Lemma 9.** *Algorithm 3 lists any triangle-heavy vertex with probability at least* $2/3$ *and any triangle-light vertex with probability at most* $1/3$*. It runs in time* $\tilde{O}(\frac{n^3}{\tau})$*.*

Proof. Consider the probability that a triangle-light vertex v is reported. Similarly to the case $\tau \leq n$, it holds by the union bound over all incident triangles and over the k iterations that this probability is at most $\tau/20 \cdot k \cdot 1/n^2 \leq 1/3$.

Consider now the probability a triangle-heavy vertex v is reported. In each iteration, the probability that we find an incident triangle is $T_v/n^2 \geq \tau/n^2$. The probability that we report v is now at least $1 - (1 - \tau/n^2)^{2n^2/\tau} \geq 1 - 1/e^2 \geq 2/3$. ◀

2.4 Recursive algorithm

We now take the subroutines presented above and put them together into one recursive algorithm. Our proof of correctness works by induction on the depth of recursion. For this reason, the statement assumes the input graph can be random, as we use the inductive hypothesis on a sampled subgraph of the input graph. This algorithm requires advice $\tilde{T}$ such that $\tilde{T} \leq E(T)$ (note that T is a random variable as the input graph may be random); we will remove the need for advice later. As we already mentioned, for the advice removal, we will need to prove a bound on the expectation of the estimate.

We show an algorithm that gives additive approximation. The reason is that this is better suited for performing recursive calls. Specifically, the time complexity of getting relative approximation is worse when T is small. If it happened that most triangles contained a triangle-heavy vertex, we would recurse on a subgraph with few triangles, making it more costly to get the relative approximation. We then show how this algorithm can be turned into an algorithm that gives relative approximation.

Note that line 11 can be efficiently implemented as follows: We pick $X \sim Bin(n, p)$, then sample X vertices without replacement, keep only the vertices from $V \setminus V_H$.

▶ **Lemma 10.** *Suppose* G *is a (possibly random) graph. Given parameters* A*,* $\tilde{T}$*, Algorithm 4 returns* $\hat{T}$ *such that* $E(\hat{T}) \leq E(T)$ [7]*. Moreover, if* $\tilde{T} \geq E(T)$*, Algorithm 4 returns* $\hat{T} \in T \pm A$ *with probability at least* $4/5$*. It runs in expected time* $\tilde{O}\big(\frac{n^\omega}{(A^2/\tilde{T})^{\omega-2}} + \frac{\tilde{T}^{4+1/3}Tn^2}{A^6}\big)$*.*

Proof. The structure of the proof is as follows. We first prove that $E(\hat{T}) \leq E(T)$. We prove this by induction. We then go on to prove correctness (that is, that the returned answer is $(1 \pm \epsilon)$-approximation with probability $4/5$), also by induction. In both cases, the induction is on the depth of recursion. Note that, while the instances on which the algorithm

[7] Since the graph can be random, T is a random variable

Algorithm 4 Estimate the number of triangles in G, advice $\tilde{T}$, and error parameter A.

1 $q \leftarrow 1/\log(nT/A)$
2 **if** $A^2 \leq \frac{10^7}{q}\tilde{T}$ **then**
3 **return** *number of triangles in G, computed using matrix multiplication*
4 **if** $\tilde{T} < 1/5$ **then**
5 **return** 0
6 $q \leftarrow 1/\log\left(\frac{nT}{A}\right)$
7 $\tilde{T}' = 20\tilde{T}$
8 $\tau \leftarrow \frac{A^2q^2}{40000\tilde{T}'}$
9 $V_H \leftarrow$ triangle-heavy vertices w.r.t. τ using Corollary 7
10 $\hat{T}_H \leftarrow$ estimate number of triangles with non-empty intersection with V_H using Algorithm 1 with $\epsilon = qA/(2\tilde{T}')$
11 $V' \leftarrow$ sample each vertex from $V \setminus V_H$ independently with probability $p = \frac{20\sqrt{\tau\tilde{T}'}}{qA} = 1/10$
12 $\hat{T}_{V'} \leftarrow$ estimate number of triangles in $G[V']$ by a recursive call with $A = (1-q)p^3A$ and with $\tilde{T} = \tilde{T}p^3$; amplify success probability to 19/20 by taking median of 7 independent executions
13 **return** $\hat{T}_H + \hat{T}_{V'}/p^3$

is called in the recursive calls are random, the recursion tree is deterministic. This means that performing induction on the depth of recursion is formally correct. Finally, we prove the time complexity; in this part, we analyze the whole recursion tree instead of using induction.

Estimate's expected value. We now prove $E(\hat{T}|G) \leq E(T|G)$. We prove this by induction on the depth of recursion. If the condition on line 2 is satisfied, then $\hat{T} = T$ and the inequality thus holds. If the condition on line 4 is satisfied, then $\hat{T} = 0$ and the inequality also holds. Consider now the case when neither of these conditions are satisfied. By the inductive hypothesis, $E(\hat{T}_{V'}|V', G) \leq E(T_{V'}|V', G)$. Moreover, by Lemma 5, $E(T_{V'}/p^3|V_H, G) = E(T(G[V \setminus V_H])|V_H, G)$ and therefore

$$\begin{aligned} E(\hat{T}_{V'}/p^3|V_H, G) &= E(E(\hat{T}_{V'}/p^3|V', G)|V_H, G) \\ &\leq E(E(T_{V'}/p^3|V', G)|V_H, G) \\ &= E(T_{V'}/p^3|V_H, G) = E(T(G[V \setminus V_H])|V_H, G). \end{aligned}$$

It follows from Lemma 6 that $E(\hat{T}_H|V_H, G)$ is an unbiased estimate of the number of triangles in G containing at least one vertex from V_H. This implies that $E(\hat{T}_H|G) = T - T(G[V \setminus V_H])$. We now put this all together:

$$\begin{aligned} E(\hat{T}) &= E\big(E(\hat{T}_H|V_H, G) + E(\hat{T}_{V'}/p^3|V_H, G)\big) \\ &\leq E\big(E(\hat{T}_H|V_H, G)\big) + E\big(E(T(G[V \setminus V_H])|V_H, G)\big) \\ &= E(T - T(G[V \setminus V_H])) + E(T(G[V \setminus V_H])) = E(T). \end{aligned}$$

Note that this bound on the expectation is not using in any way that V_H contains all triangle-heavy vertices and no triangle-light vertices.

Correctness. We first focus on the base case. Consider the case $A^2 \leq \tilde{T}$. In this case, the condition on line 2 is satisfied. The algorithm is then clearly correct.

We now focus on the case when the condition on line 4 is satisfied. Consider one call of the algorithm in the tree of recursion where this is the case. Let k be the depth of this call in the tree. We denote by $G, T, n, A, \tilde{T}, \epsilon$ the respective values in this specific call. We use the subscript $_0$ to denote the respective values in the original call. For example, T_0 would be the number of triangles in the whole graph on which the algorithm was executed.

It holds that $E(T) \leq 1/10^{3k} T_0 \leq 1/10^{3k} \tilde{T}_0 = \tilde{T}$. It holds by the Markov's inequality that $P(5\tilde{T} \geq T) \geq 4/5$. When $\tilde{T} < 1/5$ (this is the condition on line 4), this means that $P(T = 0) \geq 4/5$, meaning that the algorithm is correct in this case and runs in time $O(1)$.

We now prove the inductive step. Consider one recursive call, regardless of the level of recursion. Again, we use $G, T, n, A, \tilde{T}, \epsilon$ to denote the respective values. We assume that $\tilde{T}' \geq T$ in this call. This holds with probability at least 19/20 by the Markov inequality as $\tilde{T}' = 20\tilde{T} \geq 20E(T)$. We now bound the error probability by 3/20. Together with the fact that $P(\tilde{T}' \geq T) \geq 19/20$, this gives a bound on the probability of the call returning an invalid answer of 4/20. Let $\epsilon = \frac{qA}{2\tilde{T}'}$. It then holds $\epsilon \leq \frac{qA}{2T}$. We have $p = 1/10$. We show that $p \geq \max(5\frac{1}{\sqrt[3]{\epsilon^2 T}}, 10\frac{1}{\epsilon\sqrt{T/\tau}})$ (this is the assumption of Lemma 5). It holds $\frac{1}{10} \geq 10\frac{1}{\epsilon\sqrt{T/\tau}}$ from the way we set τ. Because $A^2 \geq \frac{10^7}{q}\tilde{T}$, it also holds

$$5\frac{1}{\sqrt[3]{\epsilon^2 T}} \leq \frac{5}{\sqrt[3]{qA^2/(4\tilde{T}')}} \leq \frac{5}{\sqrt[3]{q\frac{10^7}{q}\tilde{T}/(4\tilde{T}')}} = \frac{1}{10}.$$

By Lemma 5, it holds with probability at least 19/20 that

$$T(G[V']) / p^3 \in (1 \pm \epsilon) T(G[V \setminus V_H]) \subseteq T(G[V \setminus V_H]) \pm qA/2.$$

By the induction hypothesis, it holds that with probability at least 19/20, $\hat{T}_{V'} = T(G[V']) \pm (1-q)p^3 A$. Note that $E(T_{k+1}) = E(E(T_{V'}|G)) \leq E(T/10^3) \leq \tilde{T}/10^3 = \tilde{T}_{k+1}$, where the subscript $_{k+1}$ refers to the respective values at a call on recursion depth $k+1$. This means that the assumption on $\tilde{T}$ is satisfied. Also note that to get success probability 19/20, it does suffice to take the median of 7 independent executions (as can be easily checked, $P(Bin(7, 1/5) \geq g) < 1/20$). Putting this together, with probability at least 18/20, it holds that

$$\hat{T}_{V'}/p^3 \in T(G[V'])/p^3 \pm (1-q)A \subseteq T(G[V \setminus V_H]) \pm (1 - q/2)A.$$

Moreover, with probability at least 19/20, $\hat{T}_H = T(V_H) \pm \epsilon T(V_H) \subseteq T(V_H) \pm qA/2$ by Lemma 6 where the inclusion holds because we have set $\epsilon = qA/(2\tilde{T}') \leq qA/(2T) \leq qA/(2T(V_H))$. By the union bound, with probability at least 17/20, $|\hat{T}_H - T(V_H)| \leq qA/2$ and $|T(V')/p^3 - T(V \setminus V_H)| \leq (1 - q/2)A$, in which case $\hat{T}_H + \hat{T}_L/p^3 = T \pm A$ – the resulting answer is correct. Including the probability that $\tilde{T}' \leq T$ (we assumed in the analysis that this is not the case), we get that the answer is correct with probability at least 16/20.

Time complexity. We again consider one recursive call and use $G, T, n, A, \tilde{T}, \epsilon$ to denote the respective values in this one call, and the subscript $_0$ is used to refer to the respective values in the original call. We first show that we may ignore in the analysis the time spent on line 3. Counting triangles exactly by using fast matrix multiplication takes $\tilde{O}(n^\omega) \subseteq \tilde{O}\big(\frac{n^\omega}{\tau^{\omega-2}} + \frac{\tilde{T}^4 T n^2}{A^6}\big)$ time (the inclusion holds thanks to the assumption $A^2 \leq \tilde{T}$ which is satisfied on line 3). This is equal to the bound on the time complexity of the call that we use below. In the rest of the proof, we therefore ignore the time spent on line 3.

The time complexity of line 9 is $\tilde{O}(\frac{n^\omega}{\tau^{\omega-2}})$ and complexity of line 10 is $\tilde{O}(\frac{Tn^2}{\epsilon^2\tau^2}) = \tilde{O}(\frac{\tilde{T}'^4Tn^2}{q^2A^6})$ by Corollary 7 and Lemma 6, respectively (note that ϵ is defined on line 10). Since $p = 1/10$, the number of vertices in a depth k recursive call is stochastically dominated by $Bin(n, 1/10^k)$ [8] while the value of A is in a depth k recursive call multiplied by factor of $\big((1-q)p^3\big)^k = \big((1-q)/10^3\big)^k$ and $\tilde{T}' = 1/10^{3k}\tilde{T}'_0$. In each recursive call, we make 7 recursive calls for the probability amplification. The number of calls at recursion depth k is then 7^k. The expected time spent in the depth k recursive calls on line 9 is

$$E\Big(7^k\frac{n^\omega\log n}{\tau^{\omega-2}}\Big) \le \tilde{O}\Big(7^k\frac{n_0^\omega/10^{\omega k}}{(q^2\epsilon_0^2(1-q)^k * \tilde{T}'_0/10^{3k})^{\omega-2}}\Big) = \tilde{O}\Big(q^{4-2\omega}\Big(\frac{7\cdot 10^{3(\omega-2)}}{(1-q)^{\omega-2}10^\omega}\Big)^k\cdot\frac{n_0^\omega}{\epsilon_0^2T_0^{\omega-2}}\Big).$$

This decreases exponentially since $\omega \le 2.5$ [9]and, therefore, the time on line 9 is dominated by the first call. (By changing constants in the algorithm, this argument can be made to work even for asymptotically slower sub-cubic matrix multiplication algorithms.) However, the time spent on line 10 is

$$E\Big(7^k\frac{\tilde{T}'^4Tn^2}{q^2A^6}\Big) = 7^k\frac{\tilde{T}'^4E(T)n^2}{q^2A^6} \le 7^k\frac{\tilde{T}'^4_0/10^{4\cdot3k}\cdot T_0/10^{3k}\cdot n^2/10^{2k}}{q^2A_0^6(1-q)^{6k}/10^{6\cdot3k}} = \Big(\frac{10}{1-q}\Big)^k\cdot\frac{\tilde{T}'^4_0T_0n_0^2}{q^2A_0^6}$$

which increases at an exponential rate. We now upper bound the number of recursive calls (in other words, we upper bound k). In each subsequent recursive call, $\tilde{T}$ decreases by a factor of $1/p^3 = 10^3$. This means that after $\log_{1000}\tilde{T} + O(1)$ recursive calls, it will hold that $\tilde{T} \le 1/20$, in which case the algorithm finishes on line 4 in time $O(1)$ with no additional recursive calls. Therefore $k \le \log_{1000}\tilde{T} + O(1)$. Since the amount of work at each level of recursion increases exponentially, the work is dominated by the last level of recursion. Thanks to our bound on k, the amount of time spent on line 8 is

$$\begin{aligned}O\Big(\Big(\frac{10}{1-q}\Big)^{\log_{1000}\tilde{T}_0+O(1)}\cdot\frac{\tilde{T}_0^4T_0n^2}{q^2A_0^6}\Big) &= O\Big((1-q)^{-\log_{1000}\tilde{T}_0}\frac{\tilde{T}_0^{4+1/3}T_0n^2}{q^2A_0^6}\Big)\\ &= O\Big(\frac{\tilde{T}_0^{4+1/3+\log_{1000}(1/(1-q))}T_0n^2}{q^2A_0^6}\Big)\end{aligned}$$

and substituting $q = 1/\log(nT/A)$, we get that the total time complexity is

$$\tilde{O}\left(\frac{q^{4-2\omega}n^\omega}{\epsilon^2T^{\omega-2}} + \frac{\tilde{T}^{4+1/3+\log_{1000}(1/(1-q))}Tn^2}{q^2A^6}\right) = \tilde{O}\left(\frac{n^\omega}{\epsilon^2T^{\omega-2}} + \frac{\tilde{T}^{4+1/3}Tn^2}{A^6}\right). \quad ◀$$

We now get the following claim, which guarantees relative approximation, unlike Lemma 10.

▶ **Proposition 11.** *There is an algorithm that, given $\epsilon > 0$ and $\tilde{T}$ returns an estimate $\hat{T}$ of T, such that $E(\hat{T}) \le E(T)$ of T and if, moreover, $T \le \tilde{T} \le 2T$, it holds $\hat{T} \in (1\pm\epsilon)T$ with probability at least $4/5$. It runs in expected time $\tilde{O}(\frac{n^\omega}{(\epsilon^2T)^{\omega-2}} + \frac{n^2}{\epsilon^6T^{2/3}})$.*

Proof. By substituting $A = \epsilon\tilde{T}/2$, it is sufficient to calculate approximation with additive error A. This can be done by Lemma 10, giving us the desired bounds. ◀

[8] This is the case as in each level of recursion, we keep each triangle-light vertex with probability $p = 1/10$ while removing all other vertices with high probability.

[9] The argument works for $\omega > 2.5$ if some constants in the algorithms are modified.

2.5 Removing advice

We remove the dependency on $\tilde{T}$ by performing a geometric search. This method has been used many times before, for example in [9, 14, 1, 10, 4, 11]. In our case, it is slightly more complicated in that our algorithm requires both a lower and an upper bound on T. For this reason, we describe the method in completeness. We also prove a variant that gives a guarantee of absolute approximation. We will need this for triangle counting in sparse graphs.

▶ **Theorem 12.** *There is an algorithm that, given $\epsilon > 0$ (respectively A) returns $\hat{T} \in (1 \pm \epsilon)T$ (respectively $\hat{T} \in T \pm A$) with probability at least $2/3$. It runs in expected time $\tilde{O}(\frac{n^\omega}{(\epsilon^2 T)^{\omega-2}} + \frac{n^2}{\epsilon^6 T^{2/3}})$ (respectively $\tilde{O}(\frac{n^\omega}{(A^2/\tilde{T})^{\omega-2}} + \frac{T^{5+1/3}n^2}{A^6})$).*

Proof. We present the argument for the relative approximation. The exact same argument gives the absolute approximation by using Lemma 10 in place of Proposition 11.

We start with $\tilde{T} = \binom{n}{3}$ and, in each step, divide $\tilde{T}$ by a factor of two. When it holds that $\hat{T} \geq \tilde{T}$ where $\hat{T}$ is the estimate returned by the algorithm, we return $\hat{T}$ as the final estimate of T.

We now argue correctness. The estimate $\hat{T}$ given by the algorithm is always non-negative and it holds $E(\hat{T}) \leq T$. By Markov's inequality, $P(\hat{T} \geq 2T) \leq 1/2$, regardless of the choice of $\tilde{T}$. We amplify this probability to $\Theta(1/\log n)$ by taking the median of $\Theta(\log\log n)$ independent executions. When $\hat{T} \geq \tilde{T}$ (this is when we return $\hat{T}$ as the final estimate), it holds with probability at least $1 - O(1/\log n)$ that $\tilde{T} \leq 2T$ as otherwise, it would be the case that $\hat{T} \geq \tilde{T} \geq 2T$ which holds with probability $O(1/\log n)$. Conditioned on $\tilde{T} \leq 2T$, the algorithm gives a $(1 \pm \epsilon)$-approximate estimate (respectively additive $\pm A$ estimate) by Proposition 11 (respectively Lemma 10). By the union bound, the failure probability is then arbitrarily small if we make the constants in Θ sufficiently small.

We now argue the time complexity. The probability amplification only increases the time complexity by a $O(\log\log n)$ factor. When $\tilde{T} \leq T$, with probability $1 - O(1/\log n)$ we return the estimate and quit. We now consider the calls of the algorithm with $\tilde{T} \leq T$. The time complexity increases exponentially (as T is decreasing exponentially) while the probability of performing a call is decreasing at a rate faster than exponential. Therefore, the time complexity is dominated by the first call when $\tilde{T} \leq T$. This time complexity is as claimed by Proposition 11 (respectively Lemma 10). ◀

2.6 Optimality

The lower bound of Eden et. al. [9] implies that our algorithm is in certain sense optimal. Specifically, the exponent in the dependency on T cannot be improved without worsening the dependency on n, as long as the exponent of T is constant. That still leaves open the possibility of improving the dependency on n and getting an algorithm with a non-constant exponent of T.

▶ **Proposition 13.** *Suppose there is an algorithm which runs in time $\tilde{O}\left(\frac{n^\omega}{T^\delta}\right)$ for some constant δ, and returns a constant-factor approximation of T with probability at least $2/3$. Then $\delta \leq \omega - 2$.*

Proof. Suppose $\delta > \omega - 2$. Then, for $T = \Theta(n)$, the algorithm runs in time $o(n)$. This is in contradiction to the lower bound of from [9] which states that any such algorithm has to run in time $\Omega(n)$. ◀

3 Triangle counting in sparse graphs

We now show how Algorithm 4 can be used to get an efficient algorithm for counting triangles in a sparse graph. The algorithm finds all vertices with degree at least some parameter θ, then it uses Algorithm 4 to count triangles in the subgraph induced by these vertices and uses sampling in the rest of the graph. We set $\theta = \frac{m^{(\omega-1)/(\omega+1)}}{T^{(\omega-3)/(\omega+1)}\epsilon^{(2\omega-6)/(\omega+1)}}$.

For sake of simplicity, we show an algorithm with an additional $O(m)$ term in its complexity. As the time complexity of the algorithm from [4] is lower in the sublinear regime than what we claim, we may obtain an algorithm with the desired complexity by running the two algorithms in parallel and terminating when one of them finishes. In this section, we use a total order $\prec$ defined as $u \prec v$ if $d(u) \leq d(v)$ and ties broken arbitrarily in a consistent way.

Algorithm 5 Estimate the number of triangles in G and advice $\tilde{T}$.

1 $\theta \leftarrow \frac{m^{(\omega-1)/(\omega+1)}}{\tilde{T}^{(\omega-3)/(\omega+1)}\epsilon^{(2\omega-6)/(\omega+1)}}$
2 $V_H \leftarrow$ find all vertices v with $d(v) \geq \theta$
3 $\hat{T}_H \leftarrow$ count triangles in $G[V_H]$ using Algorithm 4 with error $\pm\epsilon\tilde{T}/2$; amplify success probability to $\frac{5}{6}$
4 $M \leftarrow 0$
5 **repeat** $k = 12\frac{\theta m}{\epsilon^2\tilde{T}}$ **times**
6 $\quad e \leftarrow$ pick an edge uniformly at random
7 $\quad uv \leftarrow e$, such that $u \succ v$
8 $\quad w \leftarrow$ pick a random neighbor of v
9 $\quad$ **if** $v \notin V_H$ *and* $w \succ v$ *and* $uvw \in T$ **then**
10 $\quad\quad M \leftarrow M + d(v)$
11 $\hat{T}_L = \frac{m}{2k}M$
12 **return** $\hat{T}_H + \hat{T}_L$

We now prove the main theorem for triangle counting in sparse graphs. The last part in the following theorem is there to enable us to remove advice like we did in Section 2.5.

▶ **Lemma 14.** *Let us have a graph G. Given parameters $1 > \epsilon > 0$ and advice $\tilde{T}$, Algorithm 5 returns $\hat{T}$ such that $P(\hat{T} \geq 2T) \leq 2/3$. Moreover, if $\tilde{T} \leq T$, Algorithm 5 returns $\hat{T} \in (1 \pm \epsilon)T$ with probability at least $4/5$. It runs in expected time*

$$\tilde{O}\Big(\frac{m^{2\omega/(\omega+1)}}{\epsilon^{4(\omega-1)/(\omega+1)}\tilde{T}^{2(\omega-1)/(\omega+1)}} + \frac{m^{4/(\omega+1)}}{\epsilon^{2(9+\omega)/(\omega+1)}T^{4(5-\omega)/(3(\omega+1))}} + m\Big).$$

With the current best bound on ω, we get running time of $\tilde{O}(\frac{m^{1.408}}{\epsilon^{1.628}T^{0.814}} + \frac{m^{1.186}}{\epsilon^{6.744}T^{1.038}})$. For constant ϵ, the second term is significantly smaller than the first one.

Proof. Let T_L be the set of triangles that are not contained in $G[V_H]$ – or equivalently, that have their $\prec$-minimal vertex outside of V_H – and, by an abuse of notation, also the number of such triangles. Let T_H be the number of triangles contained in $G[V_H]$.

Let X_i be the increment in M in the i-th iteration of the loop on line line 5. We now calculate the expectation of M after all k iterations. Let us fix a triangle $\triangle \in T$ and define $X_i' = X_i$ if $uvw = \triangle$ in the i-th iteration and $X_i' = 0$ otherwise (note that u, v, w are defined in the algorithm). If a is the vertex of $\triangle$ minimal w.r.t. $\prec$, it now holds that

$E(X_i') = d(a)P(X_i' = d(a))$. It holds that $X_i' = d(a)$ if and only if $v = a$ and $uvw = \triangle$. For this to happen, the algorithm has to sample in the i-th iteration the edge uv or wv. This happens with probability $2/m$. Then, it has to be the case that the random neighbor sampled on line 7 is the single vertex of $\triangle$ not in e. This happens with probability $1/d(a)$. This gives us that $E(X_i') = \frac{d(a)}{md(a)} = 2/m$. By summing over all triangles in T_L and by linearity of expectation, it holds that $E(X_i) = 2T_L/m$. Therefore, the estimate $\hat{T}_L = \frac{m}{2k}M = \frac{m}{2k}\sum_{i=1}^{k} X_i$ is an unbiased estimate of T_L.

We now bound the variance. We use the inequality[10] $Var(X) \leq \sup(X)E(X)$ to get $Var(X_i) \leq \theta E(X_i) = 2\theta T_L/m$. Therefore $Var(mX_i/2) = \frac{1}{2}\theta m T_L$. Taking average of $12\frac{\theta m}{\epsilon^2 \tilde{T}}$ independent trials, we get variance $\frac{1}{24}\epsilon^2 \tilde{T} T_L \leq \frac{1}{24}\epsilon^2 T^2$. By the Chebyshev's inequality, it therefore holds that

$$P(|\hat{T}_L - T_L| \geq \epsilon T/2) \leq \frac{Var(\hat{T}_L)}{(\epsilon T/2)^2} \leq 1/6.$$

At the same time, by Lemma 10, it holds that $\hat{T}_H \in T_H \pm \epsilon\tilde{T}/2 \subseteq T_H \pm \epsilon T/2$ with probability at least $5/6$ (note that we have amplified the success probability). By the union bound, with probability at least $2/3$, it holds that both $|\hat{T}_L - T_L| \leq \epsilon T/2$ and $|\hat{T}_H - T_H| \leq \epsilon T/2$. Therefore, the algorithm returns a $(1 \pm \epsilon)$-approximate answer with probability at least $2/3$.

We now argue the time complexity. We spend $O(n)$ time on line 2. There are no more than m/θ vertices with degree at least θ. Triangles in $G[V_H]$ are therefore counted, by Theorem 12, in time

$$\tilde{O}\Big(\frac{(m/\theta)^\omega}{(A^2/\tilde{T})^{\omega-2}} + \frac{T_H^{5+1/3}(m/\theta)^2}{A^6}\Big) \leq \tilde{O}\Big(\frac{(m/\theta)^\omega}{(\epsilon^2\tilde{T})^{\omega-2}} + \frac{(m/\theta)^2}{\epsilon^6 T^{2/3}}\Big)$$
$$= \tilde{O}\Big(\frac{m^{2\omega/(\omega+1)}}{\epsilon^{4(\omega-1)/(\omega+1)}\tilde{T}^{2(\omega-1)/(\omega+1)}} + \frac{m^{4/(\omega+1)}}{\epsilon^{2(\omega+1)/(\omega+1)}T^{(7-\omega)/(\omega+1)}}\Big).$$

The time spent in each iteration of the loop on line 5 is $O(1)$. The total time spent in the loop is therefore

$$O\Big(\frac{\theta m}{A^2/\tilde{T}}\Big) = O\Big(\frac{\theta m}{\epsilon^2\tilde{T}}\Big) = O\Big(\frac{m^{2\omega/(\omega+1)}}{\epsilon^{4(\omega-1)/(\omega+1)}\tilde{T}^{2(\omega-1)/(\omega+1)}}\Big).$$

Putting these two time complexities together, we get the desired running time.

We now prove that $P(\hat{T} \geq 2T) \leq 2/3$ [11]. Since $\epsilon < 1$, it holds that $P(\hat{T}_H \geq 2T_H) \leq P(\hat{T}_H \geq (1+\epsilon)T_H) \leq 1/6$ as we have amplified the success probability of Algorithm 4 to $\frac{5}{6}$. Moreover, as we have shown, $E(\hat{T}_L) = T_L$ and, therefore, $P(\hat{T}_L \geq 2T_L) \leq 1/2$ ◀

By the same argument as in Section 2.5, we may remove the need for advice [12]. We run the algorithm in parallel with the algorithm from [4], resulting in an algorithm with its time complexity being the minimum of the complexities of the two respective algorithms. This gives us the following claim.

---

[10] $\sup(X)$ is the smallest x such that $P(X > x) = 0$.

[11] We cannot use the Markov's inequality in a straightforward way. The reason is that it is not clear how to bound the expectation of the estimate coming from Theorem 12. While we do have a bound on the expectation of the estimate given by, Algorithm 4 it is not clear a bound of this type carries over when we perform the advice removal.

[12] Instead of directly using the Markov inequality in the argument, we may use the last part of Lemma 14 to get the same guarantee.

▶ **Theorem 15.** *There is an algorithm that returns a* $(1 \pm \epsilon)$*-approximation of the number of triangles with probability at least* $2/3$*. It runs in time*

$$\tilde{O}\Big(\frac{m^{2\omega/(\omega+1)}}{\epsilon^{4(\omega-1)/(\omega+1)}\tilde{T}^{2(\omega-1)/(\omega+1)}} + \frac{m^{4/(\omega+1)}}{\epsilon^{2(9+\omega)/(\omega+1)}T^{4(5-\omega)/(3(\omega+1))}}\Big).$$

3.1 Optimality

Like in the case of dense graphs, we show that our algorithm is in certain sense optimal.

▶ **Proposition 16.** *Suppose there is an algorithm that uses both random vertex and random edge queries, which runs in time* $\tilde{O}(\frac{m^{2\omega/(\omega+1)}}{T^\delta})$ *for some constant* δ*, and returns a constant-factor approximation of* T *with probability at least* $2/3$*. Then* $\delta \leq 2(\omega-1)/(\omega+1)$*.*

Proof. Suppose $\delta > 2(\omega-1)/(\omega+1)$. Then, for $T = \Theta(\sqrt{m})$, the algorithm runs in time $o(m)$. This is in contradiction to the lower bound from [9] which states that any such algorithms has to run in time $\Omega(m)$. ◀

Abstract

Zero-free based algorithms are a major technique for deterministic approximate counting. In Barvinok's original framework [4], by calculating truncated Taylor expansions, a quasi-polynomial time algorithm was given for estimating zero-free partition functions. Patel and Regts [29] later gave a refinement of Barvinok's framework, which gave a polynomial-time algorithm for a class of zero-free graph polynomials that can be expressed as counting induced subgraphs in bounded-degree graphs.

In this paper, we give a polynomial-time algorithm for estimating classical and quantum partition functions specified by local Hamiltonians with bounded maximum degree, assuming a zero-free property for the temperature. Consequently, when the inverse temperature is close enough to zero by a constant gap, we have a polynomial-time approximation algorithm for all such partition functions. Our result is based on a new abstract framework that extends and generalizes the approach of Patel and Regts.

1 Introduction

Let $\Omega = [q]^V$ be a finite space of configurations, where V is a set of n variables. Let $H_1, \ldots, H_m$ be a collection of local constraints, where each $H_j : \Omega \to \mathbb{C}$ is independent of all but a small subset of variables, and let $H = \sum_{j=1}^{m} H_j$. The *partition function* of the given system is defined by

$$Z_H(\beta) = \sum_{\sigma \in \Omega} \exp(-\beta \cdot H(\sigma)), \tag{1}$$

where the parameter β is usually called the *inverse temperature*.

The computational complexity of partition functions is one of the central topics in theoretical computer science, which has been found wide applications in computational counting, combinatorics, and statistical physics. To date, numerous algorithms as well as hardnesses of approximation for the partition functions of various systems have been established, to list a few [20, 32, 15, 21, 39, 37, 35, 36, 25, 34, 13, 26, 6, 10, 7]. The most important question here is, what property captures the approximability of partition functions.

It is widely believed that for various classes of partition functions of interests, the hardness of approximation is captured by the locus of complex zeros. The study of the locus of complex zeros has a rich history in statistical physics, for example, in the famous Lee-Yang theorem [24]. In computer science, the absence of complex zeros may imply efficient approximation algorithms for partition functions [4, 29, 31, 19, 27, 26, 30, 12, 17, 16, 18, 33, 9, 11]. This line of research was initiated by Barvinok's pioneering works [1, 2, 3, 4, 5], which used truncated Taylor expansions to approximate non-vanishing polynomials and established quasi-polynomial time approximations of partition functions with no complex zeros within a region. Later in a seminal work of Patel and Regts [29], this quasi-polynomial running time was improved to polynomial time for a class of graph polynomials which can be expressed as induced subgraph sums in graphs of constant maximum degree. And this polynomial-time framework was further extended by Liu, Sinclair and Srivastava [27] to hypergraph 2-spin systems with no complex-zeros for the external field.

For the quantum version, several (classical) algorithms have been proposed, including [23, 18, 28], to estimate the quantum generalization of the partition function defined as in (1) where H is the *Hamiltonian*. Yet, an important question remains to answer is the polynomial-time approximability of the quantum or classic partition function in the form of (1) assuming its zero-freeness.

1.1 Our results

We show the polynomial-time approximability of partition functions assuming zero-freeness, for both classical and quantum partition functions.

Let V be a set of n *sites* (also called *vertices* or *particles*). Let $q \geq 2$ be an integer. Throughout the paper, we assume that each site $u \in V$ is associated with a q-dimensional Hilbert space $\mathcal{V}_u$, and let $\mathcal{V} = \bigotimes_{u \in V} \mathcal{V}_u$. A *Hamiltonian* H is a Hermitian matrix in $\mathcal{V}$. The support of a Hamiltonian H, denoted by $\mathrm{supp}(H)$, is the minimal set of sites on which H acts non-trivially. Given a Hamiltonian H, $\exp(H)$ is defined by $\exp(H) = \sum_{\ell=1}^{\infty} \frac{1}{\ell!} H^{\ell}$, and the *partition function* $Z_H : \mathbb{C} \to \mathbb{C}$ induced by H is defined as follows:

$$\forall \beta \in \mathbb{C}, \quad Z_H(\beta) \triangleq \mathbf{Tr}\left[\exp(-\beta H)\right]. \tag{2}$$

We are interested in partition functions induced by local Hamiltonians with bounded maximum degrees.

▶ **Definition 1** (local Hamiltonian). *A Hamiltonian $H \in \mathcal{V}$ is said to be* k-local *if H can be expressed as*

$$H = \sum_{j=1}^{m} H_j,$$

where each H_j acts non-trivially on at most k sites, i.e. $|\mathrm{supp}(H_j)| \leq k$. A Hamiltonian $H \in \mathcal{V}$ called a (k, d)-Hamiltonian *if H is k-local and for every $v \in V$, $\deg(v) \triangleq |\{j \mid v \in \mathrm{supp}(H_j)\}| \leq d$.*

Notice that if all H_j's are diagonal, then H is diagonal as well. The quantum partition function $Z_H(\beta)$ then degenerates to the classical partition function defined in (1). Indeed, in such diagonal case we have

$$Z_H(\beta) = \sum_{\sigma \in [q]^V} \exp(-\beta \cdot H(\sigma)),$$

where $H(\sigma) = \sum_{j=1}^{m} H_j(\sigma)$ and $H_j(\sigma)$ represents the σ-th diagonal entry of H_j. Since each H_j is diagonal and acts non-trivially on subset $\mathrm{supp}(H_j)$ of at most k sites, the value of $H_j(\sigma)$ is determined by the variables in $\mathrm{supp}(H_j)$. Hence the $Z_H(\beta)$ above is precisely the classical partition function defined in (1).

The quantum partition functions encode rich information about quantum systems, e.g. the free energy and ground state energy. Meanwhile, the non-diagonal property, especially the non-commutativity of multiplication for non-diagonal matrices, imposes great challenges for the computation of partition functions.

We prove the following zero-free based approximability of quantum partition functions.

▶ **Theorem 2** (Theorem 15, informal). *Let $\Omega \subseteq \mathbb{C}$ be a "well-shaped" complex region (formalized by Definition 12) and $k, d \geq 1$ be constants. There is a deterministic algorithm which takes a (k, d)-Hamiltonian H on n sites and a β from interior of Ω as input, and outputs an estimation of the quantum partition function $Z_H(\beta)$ in polynomial time in n, if Z_H satisfies the zero-free property such that $|\log Z_H| \leq \mathrm{poly}(n)$ on Ω.*

The formal statement (Theorem 15) is more general: it further takes into account the measurement of the quantum system. Such generalization may encode broader classes of partition functions, e.g. the ones with external fields, and also enable sampling from Gibbs state. Following a recent major advance for quantum zero-freeness of Harrow et al. [18], we give concrete applications (in Section 5), namely, polynomial-time algorithms for approximating the quantum partition function (Theorem 21) and sampling from the Gibbs state (Theorem 25) in a high-temperature regime (where β is close to zero by a constant gap), improving the quasi-polynomial-time algorithms in [18]. A polynomial-time approximation of the quantum partition functions in a slightly bigger high-temperature regime was obtained in [28] using the cluster expansion technique [19], by transforming the quantum partition function to a polymer model and showing the convergence of the cluster expansion assuming high temperature.

We prove polynomial-time approximability of the quantum partition function directly from a black-box property of zero-freeness, without further restricting the parameters of the model. Moreover, our result is proved in a new abstract framework, namely, functions specified by abstract neighborhood structures called *dependency graphs*. We prove the following general result.

▶ **Theorem 3** (Theorem 14, informal). *Suppose that functions $\{f_G\}$ specified by dependency graphs G satisfies certain boundedness property of its Taylor coefficients (formalized in Definition 10). Let $\Omega \subseteq \mathbb{C}$ be a "well-shaped" complex region. There is a deterministic algorithm which takes a dependency graph G of $O(1)$ max-degree and x from the interior of Ω as input, and outputs an estimation of $f_G(x)$ in polynomial time in size n of G, if $f_G(0)$ is easy to compute and f_G satisfies the zero-free property such that $|\log f_G| \leq \mathrm{poly}(n)$ on Ω.*

The abstract framework is described in Definition 10. As verified in Section 3, our framework subsumes previous polynomial-time frameworks for zero-free based algorithms ([29] and [27]) as special cases, and more importantly, it extends the previous frameworks to become compatible with infinite-degree polynomials and non-commutative systems, which are crucial for quantum partition functions.

2 Preliminaries

2.1 Local Hamiltonians

Given a Hamiltonian H in $\mathcal{V}$, we use $\mathrm{supp}(H)$ to denote the *support* of H, the minimal set of sites on which H acts non-trivially. Formally, if S is the support of H, then S is the minimal subset of V satisfying that $H = H_S \otimes I_{V\setminus S}$, where H_S is a Hamiltonian in the space $\bigotimes_{v\in S}\mathcal{V}_v$ and $I_{V\setminus S}$ is the identity matrix in the space $\bigotimes_{v\in V\setminus S}\mathcal{V}_v$. Readers may refer to [14, 22] for a thorough treatment.

2.2 Basic facts about complex functions

A complex-valued function $f : \Omega \to \mathbb{C}$ defined on a complex domain $\Omega \subseteq \mathbb{C}$ is called *holomorphic* if for every point $z \in \Omega$, the complex derivative exists in a neighborhood of z. A holomorphic function $f : \Omega \to \mathbb{C}$ is infinitely differentiable and equals locally to its Taylor series. A *biholomorphic* function is a bijective holomorphic function whose inverse is also holomorphic Furthermore, a function $f : \mathbb{C} \to \mathbb{C}$ is called an *entire* function if it is holomorphic on $\mathbb{C}$. A region $\Omega \subseteq \mathbb{C}$ is simply connected if $\overline{\mathbb{C}} \setminus \Omega$ is connected, where $\overline{\mathbb{C}} = \mathbb{C} \cup \{\infty\}$ denotes the extended complex plane.

The logarithm of a complex-valued function f, denoted by $g = \log f$, is a function such that $f(z) = \mathrm{e}^{g(z)}$. For holomorphic function $f : \Omega \to \mathbb{C} \setminus \{0\}$ on simply connected region $\Omega \subseteq \mathbb{C}$, such $\log f$ always exists (see e.g. [38]). Specifically, for an arbitrarily fixed pair $z_0, c_0 \in \mathbb{C}$ satisfying that $f(z_0) = \mathrm{e}^{c_0}$, we have

$$\forall z \in \Omega, \quad \log f(z) = \int_P \frac{f'(w)}{f(w)}\, dw \; + c_0, \tag{3}$$

where P is an arbitrary path in Ω connecting z and z_0. Throughout the paper, we mainly deal with such holomorphic f on simply connected Ω that $0 \in \Omega$ and $f(0) \in \mathbb{R}^+$. For such case, the definition of $\log f$ is uniquely determined by $z_0 = 0$ and the real $c_0 = \ln(f(0))$.

2.3 Approximation of non-vanishing function

We now recap the polynomial interpolation technique of Barvinok [4] to estimate values of non-vanishing holomorphic functions.

For $b \in \mathbb{R}^+$, we use $\mathbb{D}_b$ to denote the complex disc of radius b centered at the origin. Formally,

$$\mathbb{D}_b = \{z \in \mathbb{C} | \, |z| < b\}\,.$$

In particular, let $\mathbb{D} = \mathbb{D}_1$ denote the unit disc.

For $\beta \in \mathbb{C}$ and $\delta \in \mathbb{R}^+$, we use $S_{\beta,\delta}$ to denote δ-strip of interval $[0, \beta] = \{t\beta \mid t \in [0, 1]\}$. Formally,

$$S_{\beta,\delta} = \{z \in \mathbb{C} \mid \mathrm{dist}(z, [0, \beta]) < \delta\}\,.$$

where $\mathrm{dist}(\cdot, \cdot)$ denotes Euclidean distance. It is clear that both $\mathbb{D}_b$ and $S_{\beta,\delta}$ are simply connected.

The following is the key property of zero-freeness for complex-valued functions.

▶ **Definition 4** (zero-freeness). *Let $M > 0$ be finite positive real. A holomorphic function f on a simply connected region $\Omega \subseteq \mathbb{C}$ is* M-zero-free *on Ω if $|\log f(z)| \le M$ for all $z \in \Omega$.*

Notice that the zero-freeness of f on Ω implies that f is non-vanishing on the same region. A definition of $\log f$ is assumed in the context when this concept is used.

For any polynomial $p \in \mathbb{C}[z]$ that does not vanish on $\mathbb{D}$, the polynomial p automatically exhibits the above zero-freeness property with a bounded gap on $\mathbb{D}_b$ for any $b \in (0,1)$.

▶ **Lemma 5.** *Let $p \in \mathbb{C}[z]$ be a polynomial of degree d, and let $b \in (0,1)$. If $p(z) \neq 0$ for all $z \in \mathbb{D}$, then p is M-zero-free on $\mathbb{D}_b$ for $M = d \ln \frac{1}{1-b} + |\log p(0)|$.*

Proof. Let $\zeta_1, \zeta_2, \ldots, \zeta_d \in \mathbb{C}$ denote the roots of polynomial p. For any $z \in \mathbb{D}_b$,

$$\begin{aligned} |\log p(z)| &= \left| \log p(0) + \sum_{j=1}^{d} \log\left(1 - \frac{z}{\zeta_j}\right) \right| \\ &\leq |\log p(0)| - \sum_{j=1}^{d} \ln\left(1 - \left|\frac{z}{\zeta_j}\right|\right) \\ &\leq |\log p(0)| + d \ln \frac{1}{1-b}. \end{aligned}$$

The inequalities are due to that all $|\zeta_j| > 1$ since $p(z) \neq 0$ for all $z \in \mathbb{D}$. ◀

The following lemma of Barvinok says that any holomorphic function on $\mathbb{D}$ can be approximated by its truncated Taylor expansion if it is zero-free on $\mathbb{D}$.

▶ **Lemma 6** (Barvinok [4])**.** *Let $g : \mathbb{D} \to \mathbb{C}$ be holomorphic and $M > 0$. If $|g(z)| \leq M$ for all $z \in \mathbb{D}$, then for any $z \in \mathbb{D}$ and any $m \in \mathbb{N}^+$,*

$$\left| g(z) - \sum_{k=0}^{m} \frac{g^{(k)}(0)}{k!} z^k \right| \leq \frac{M}{\delta} (1-\delta)^{m+1},$$

where $\delta = \operatorname{dist}(z, \partial\mathbb{D})$ denotes the Euclidean distance between z and boundary of unit disc.

When Lemma 6 is applied to $g = \log f$ for some holomorphic $f : \mathbb{D} \to \mathbb{C} \setminus \{0\}$, one can obtain a multiplicative approximation of f on $\mathbb{D}$ assuming zero-freeness of f on $\mathbb{D}$. To make such approximation effective, we should be able to compute the Taylor coefficients of $g = \log f$.

The following *Newton's identity* relates the Taylor coefficients of $g = \log f$ to those of f.

▶ **Lemma 7** (Newton's identity)**.** *Let $f(z) = \sum_{k=0}^{+\infty} f_k z^k$ be an entire function such that $f(z) \neq 0$ for all $z \in \mathbb{D}$. Then $g(z) = \log f(z) = \sum_{k=0}^{+\infty} g_k z^k$ is well-defined on $\mathbb{D}$, and*

$$n g_n = n f_n - \sum_{k=1}^{n-1} k g_k f_{n-k}.$$

Proof. By the definition of $g = \log f$, we have $f' = g' f$. Therefore,

$$\begin{aligned} n f_n = \frac{1}{(n-1)!} f^{(n)}(0) &= \frac{1}{(n-1)!} \sum_{k=0}^{n-1} \binom{n-1}{k} f^{(k)}(0) g^{(n-k)}(0) \\ &= \sum_{k=0}^{n-1} (n-k) g_{n-k} f_k \\ &= \sum_{k=1}^{n} k g_k f_{n-k}. \end{aligned}$$

◀

When the zero-free region is not unit disc, some preprocessing is needed. The following polynomial transformation from $\mathbb{D}$ to any $S_{\beta,\delta}$ is a consequence of [4, Lemma 2.2.3].

▶ **Lemma 8.** *For any $\beta \in \mathbb{C}$, $\delta \in (0,1)$, there is an explicitly constructed polynomial $p_{\beta,\delta}$ of degree $d = d(\beta,\delta)$ satisfying*

- *$p_{\beta,\delta}(0) = 0$ and $p_{\beta,\delta}(1-\delta_0) = \beta$ for some $\delta_0 \in (0,1)$;*
- *$p_{\beta,\delta}(\mathbb{D}) \subseteq S_{\beta,\delta}$;*

The following proposition was proved in [4, Lemma 2.2.3], which explicitly gave a polynomial mapping a disk with radius slightly larger than 1 to a strip.

▶ **Proposition 9.** *Let $\delta \in (0,1)$ be a constant, and let $q_\delta \in \mathbb{C}[z]$ be defined as follows:*

$$q_\delta(z) = \frac{1}{\sum_{k=1}^{n} \frac{C^k}{k}} \sum_{k=1}^{n} \frac{(Cz)^k}{k},$$

where $C = 1 - \exp\left(-\frac{1}{\delta}\right)$, $n = \left\lfloor \left(1+\frac{1}{\delta}\right)\exp(1+\frac{1}{\delta}) \right\rfloor$.

Then for all $|z| < \rho$, where $\rho = \frac{1-\exp\left(-1-\frac{1}{\delta}\right)}{1-\exp\left(-\frac{1}{\delta}\right)} > 1$,

1. *$q_\delta(0) = 0$, $q_\delta(1) = 1$,*
2. *$\mathbf{Re}\left(q_\delta(z)\right) \in [-\delta, 1+2\delta]$ and $|\mathbf{Im}\left(q_\delta(z)\right)| \le 2\delta$.*

Proof of Lemma 8. We now prove Lemma 8 using Proposition 9. Without loss of generality, we assume that $\beta \neq 0$. Note that the polynomial q_δ defined in Proposition 9 satisfies $q_\delta(0) = 0$, $q_\delta(1) = 1$, and $q_\delta(\mathbb{D}_\rho) \subseteq S_{1,4\delta}$.

Therefore, we can set $p_{\beta,\delta}(z) = \beta q_{\delta'}(\rho' z)$, where $\delta_0 = \frac{\delta}{4|\beta|}$ and $\rho' = \frac{1-\exp\left(-1-\frac{1}{\delta'}\right)}{1-\exp\left(-\frac{1}{\delta'}\right)}$. We conclude our proof by observing that $p_{\beta,\delta}(\mathbb{D}) \subseteq S_{\beta,\delta}$ and $p_{\beta,\delta}(0) = 0$, $p_{\beta,\delta}\left(\frac{1}{\rho'}\right) = \beta$. ◀

3 Approximation of Zero-Free Holomorphic Function

We now introduce an abstraction for partition functions, namely, multiplicative holomorphic functions specified by a class of abstract structures called dependency graphs.

A *dependency graph* is a vertex-labeled graph $G = (V, E, \mathcal{L})$, where (V, E) is an undirected simple graph, and $\mathcal{L} = (L_v)_{v \in V}$ assigns each vertex $v \in V$ a label L_v. Two labeled graphs $G = (V, E, \mathcal{L})$ and $G' = (V', E', \mathcal{L}')$ are isomorphic if there is a bijection $\phi : V \to V'$ such that the two simple graphs (V, E) and (V', E') are isomorphic under ϕ and $L_v = L'_{\phi(v)}$ for all $v \in V$. Furthermore, we say that two labeled graphs $G = (V, E, \mathcal{L})$ and $G' = (V', E', \mathcal{L}')$ are disjoint if $V \cap V' = \varnothing$. A family $\mathcal{G}$ of dependency graphs is called *downward-closed* if for any $G = (V, E, \mathcal{L}) \in \mathcal{G}$ and any $S \subseteq V$ we have $G[S] \in \mathcal{G}$, where $G[S]$ stands for the subgraph of G induced by subset $S \subseteq V$ preserving labels.

We use $f.$ to denote an operator that maps each dependency graph G in $\mathcal{G}$ to an entire function $f_G : \mathbb{C} \to \mathbb{C}$ (i.e. f_G is holomorphic on $\mathbb{C}$), such that f_G gives the same entire function for isomorphic dependency graphs G. Such an $f.$ is *multiplicative* if for any G that is disjoint union of G_1, G_2, we have $f_G = f_{G_1} f_{G_2}$.

▶ **Definition 10** (boundedness). *Let $\mathcal{G}$ be a downward-closed family of dependency graphs. Let $\alpha, \beta \ge 1$. A multiplicative $f.$ is called (α,β)-*bounded *on $\mathcal{G}$ if for any $G = (V, E, \mathcal{L}) \in \mathcal{G}$, we have $f_G(0) \in \mathbb{R}^+$ and*

$$f_G(z) = f_G(0) + \sum_{\ell=1}^{+\infty} \left(\sum_{S \subseteq V} \lambda_{G[S],\ell} \right) z^\ell,$$

where the complex coefficients $(\lambda_{H,\ell})_{H\in\mathcal{G},\ell\in\mathbb{N}^+}$ *are invariant for isomorphic dependency graphs* H*, and satisfy that* $\lambda_{H,\ell}\neq 0$ *only if* $|V_H|\leq\alpha\ell$*, and each* $\lambda_{H,\ell}$ *can be calculated within* $\beta^\ell\cdot\mathrm{poly}(\ell)$ *time.*

For (α,β)-bounded $f.$, it always holds that $f_G(0)\in\mathbb{R}^+$. Then we always fix the definition of $\log f$ to be the one uniquely defined by Eq.(3) with $z_0=0$ and $c_0=\ln(f(0))$ being real. Such $\log f$ is well defined within a neighborhood of the origin.

As we will formally verify in Section 3.2, this notion of bounded holomorphic functions specified by dependency graphs generalizes the bounded induced graph counting polynomials (BIGCPs) of Patel and Regts [29]. A major difference here is that f_G may not be a polynomial of finite degree.

We show that for (α,β)-bounded $f.$, the approach of Patel and Regts [29] based on Newton's identity and local enumeration of connected subgraphs can efficiently compute Taylor coefficients of $\log f_G$, even though the function f_G can now encode problems far beyond counting subgraphs.

▶ **Theorem 11** (efficient coefficient computing)**.** *Let* $\mathcal{G}$ *be a downward-closed family of dependency graphs, and* $f.$ *be* (α,β)*-bounded on* $\mathcal{G}$ *for* $\alpha,\beta\geq 1$*. There exists a deterministic algorithm which given any* $G\in\mathcal{G}$ *and* $\ell\in\mathbb{N}^+$ *as input, outputs the* ℓ*-th coefficient of the Taylor series of* $\log f_G$ *at the origin in time* $\widetilde{O}\left(n(8\mathrm{e}\beta\Delta)^{\alpha\ell}\right)$*, where* n *is the number of vertices,* Δ *is the maximum degree of* G*, and* $\widetilde{O}(\cdot)$ *hides* $\mathrm{poly}(\Delta,\ell,\log(n))$*.*

The theorem will be proved in Section 4.

Due to Riemann mapping theorem in complex analysis, for any proper and simply connected region $\Omega\subset\mathbb{C}$ and any point $z_0\in\Omega$, there is a biholomorphic function h from $\mathbb{D}$ to Ω such that $h(0)=z_0$. We are interested in those good regions $\Omega\subseteq\mathbb{C}$ such that a transformation h from $\mathbb{D}$ to Ω does not only exist but also has efficiently computable Taylor coefficients.

▶ **Definition 12** (good region)**.** *Let* $\gamma\geq 1$*. A simply connected region* $\Omega\subseteq\mathbb{C}$ *is* γ-good *if* $0\in\Omega$ *and given any* $x\in\Omega$*, there exists a holomorphic function* h_x *on* $\mathbb{D}$ *along with a* $z_x\in\mathbb{D}$ *such that:*

1. $h_x(\mathbb{D})\subseteq\Omega$*,* $h_x(0)=0$ *and* $h_x(z_x)=x$*;*
2. *for every* $\ell\in\mathbb{N}^+$*, the* ℓ*-th Taylor coefficient* $h_{x,\ell}$ *of* h_x *at 0 can be determined in* $\gamma^\ell\mathrm{poly}(\ell)$ *time.*

Given a γ*-good region* $\Omega\subseteq\mathbb{C}$ *and* $\delta\in(0,1)$*, we use* Ω_δ *to denote the set of all* $x\in\Omega$ *with* $z_x\in\mathbb{D}_{1-\delta}$*.*

Any convex region is 1-good, given access to an oracle that determines the distance to its boundary.

▶ **Fact 13.** *Let* $\Omega\subseteq\mathbb{C}$ *be a convex region. Suppose that for any* $z\in\Omega$*,* $\mathrm{dist}(z,\partial\Omega)$ *can be determined in* $O(1)$ *time. Then* Ω *is* 1*-good.*

Proof of Fact 13. The convexity of Ω implies that $\mathrm{dist}([z_l,z_r],\partial\Omega)=\min(\mathrm{dist}(z_l),\mathrm{dist}(z_r))$ for arbitrary complex values $z_l,z_r\in\Omega$, where $[z_l,z_r]=\{z_l+t(z_r-z_l)\mid t\in[0,1]\}$. Hence, for each $x\in\Omega$, we set $f_x=p_{x,\delta}$, a polynomial defined in Proposition 9. We conclude the proof by observing that the k-th coefficient of $p_{x,\delta}$ can be determined in $O(k)$ time. ◀

Applying our Theorem 11 to $\log f_G$, combining with Barvinok's approximation (Lemma 6) and our notion of good region, we obtain the following theorem for multiplicative approximation of zero-free f_G's.

▶ **Theorem 14** (efficient ε-approximation). *Let $\alpha, \beta, \gamma \geq 1$. Let $\mathcal{G}$ be a downward-closed family of dependency graphs, and $f_\cdot$ be (α, β)-bounded on $\mathcal{G}$. Let $\Omega \subset \mathbb{C}$ be a γ-good region.*

For any $\delta \in (0,1)$, there is a deterministic algorithm which takes $G \in \mathcal{G}$, $x \in \Omega_\delta$ and an error bound $\varepsilon \in (0,1)$ as input, and outputs an estimation $\widehat{f_G(x)}$ of $f_G(x)$ within ε-multiplicative error:

$$1 - \varepsilon \leq \frac{\left|\widehat{f_G(x)}\right|}{|f_G(x)|} \leq 1 + \varepsilon,$$

in $\widetilde{O}\left(n \left(\frac{M}{\delta\varepsilon}\right)^C\right)$ time with $C = \frac{\alpha}{\delta}\ln(8\mathrm{e}\Delta(\beta+\gamma))$, where Δ is the maximum degree of G, if provided that f_G is M-zero-free on $\Omega \subset \mathbb{C}$ and the value of $f_G(0)$ is also provided to the algorithm.

Note that in above theorem, the zero-freeness property can be verified on any particular class of dependency graphs, although the boundedness property should be guaranteed on a downward-closed family. When applying this theorem, the value of $f_G(0)$ is usually trivial to compute (e.g. $f_G(0) = 1$), and the M-zero-freeness is usually established for some $M = \mathrm{poly}(n)$ (e.g. $M = O(n)$) on n-vertex dependency graphs. In such typical cases, the running time in Theorem 14 is bounded as $\left(\frac{n}{\delta\varepsilon}\right)^{O\left(\frac{1}{\delta}\log\Delta\right)}$.

Proof of Theorem 14. Let $h = h_x$ be a holomorphic function that transforms $\mathbb{D}$ to the γ-good region Ω with $h(z_x) = x$, where $z_x \in \mathbb{D}_{1-\delta}$ since $x \in \Omega_\delta$. And let $f_G^h = f_G \circ h$.

First, observe that f_G^h is M-zero-free on $\mathbb{D}$, because $\left|\log f_G^h(z)\right| = \left|\log f_G(h(z))\right| \leq M$ holds for all $z \in \mathbb{D}$ since $h(\mathbb{D}) \subseteq \Omega$ and f_G is M-zero-free on Ω. Then by Lemma 6, for any $z \in \mathbb{D}$, the difference between $\log f_G^h(z)$ and the truncated Taylor expansion at 0 is bounded by

$$\left|\log f_G^h(z) - \sum_{k=0}^{m} \frac{\left(\log f_G^h\right)^{(k)}(0)}{k!} z^k\right| \leq \frac{M}{\delta}(1-\delta)^{m+1} < \varepsilon, \tag{4}$$

for $m = \lceil \frac{1}{\delta}\ln\frac{M}{\delta\varepsilon} \rceil$.

It remains to verify that $f_\cdot^h$ is $(\alpha, \beta+\gamma)$-bounded on $\mathcal{G}$. By Theorem 11, this will prove the theorem.

For $\ell \in \mathbb{N}^+$, let $h_k^{(\ell)}$ denote the k-th Taylor coefficient of $h(z)^\ell$ at $z = 0$. Since $h(0) = 0$, we have

$$h(z)^\ell = \left(\sum_{k=1}^{+\infty} h_k z\right)^\ell = \sum_{k=\ell}^{+\infty} h_k^{(\ell)} z^k$$

Since f_G is (α, β)-bounded and $h(0) = 0$, we have

$$\begin{aligned}
f_G^h(z) &= f_G(0) + \sum_{\ell=1}^{+\infty}\left(\sum_{S\subseteq V}\lambda_{G[S],\ell}\right) h(z)^\ell \\
&= f_G(0) + \sum_{\ell=1}^{+\infty}\left(\sum_{S\subseteq V}\lambda_{G[S],\ell}\right)\left(\sum_{k=\ell}^{+\infty} h_k^{(\ell)} z^k\right) \\
&= f_G(0) + \sum_{k=1}^{+\infty}\sum_{S\subseteq V}\left(\sum_{\ell=1}^{k} h_k^{(\ell)}\lambda_{G[S],\ell}\right) z^k \\
&= f_G(0) + \sum_{k=1}^{+\infty}\left(\sum_{S\subseteq V}\lambda_{G[S],k}^h\right) z^k,
\end{aligned}$$

where $\lambda^h_{H,k}$ for any $H \in \mathcal{G}$ and $k \in \mathbb{N}^+$ is defined as

$$\lambda^h_{H,k} \triangleq \sum_{\ell=1}^{k} h_k^{(\ell)} \lambda_{H,\ell}.$$

Clearly, $\lambda^h_{H,k} = 0$ if $|V_H| > \alpha k$, where V_H denotes the vertex set of H, since $\lambda_{H,\ell} = 0$ if $|V_H| > \alpha\ell$. And it can be verified that any $\lambda^h_{H,k}$ can be determined within $(\beta+\gamma)^k \mathrm{poly}(k)$ time. This is because within $\beta^k \mathrm{poly}(k)$ time, one can list all $\lambda_{H,1}, \ldots, \lambda_{H,k}$, and for each $1 \le \ell \le k$, $h_k^{(\ell)}$ is just the coefficient of z^k in $\left(h_1 z + h_2 z^2 + \cdots + h_k z^k\right)^\ell$, which can be calculated in $\mathrm{poly}(k)$ time given all $h_1, \ldots, h_k$, which can be listed beforehand in $\gamma^k \mathrm{poly}(k)$ time. Overall, this takes at most $(\beta+\gamma)^k \mathrm{poly}(k)$ time.

Therefore, $f^h_\cdot$ is $(\alpha, \beta+\gamma)$-bounded. ◀

3.1 Quantum partition functions

We formally prove Theorem 2. Recall the definition of quantum partition function Z_H in (2). We extend this definition by considering measurement.

Recall that $\mathcal{V} = \bigotimes_{u \in V} \mathcal{V}_u$ where V is the set of n sites and each $\mathcal{V}_u$ is a q-dimensional Hilbert space. A *measurement* $\mathcal{O}$ is a positive operator in $\mathcal{V}$. The quantum partition function induced by Hamiltonian H under measurement $\mathcal{O}$, both in $\mathcal{V}$, is defined by

$$Z_{H,\mathcal{O}}(\beta) \triangleq \mathbf{Tr}\left[\exp(\beta H)\mathcal{O}\right]. \tag{5}$$

Furthermore, a measurement $\mathcal{O}$ is *tensorized* if $\mathcal{O} = \bigotimes_{v \in V} \mathcal{O}_v$ where $\mathrm{supp}(\mathcal{O}_v) = \{v\}$.

We show that under tensorized measurement $\mathcal{O}$, the quantum partition functions $Z_{H,\mathcal{O}}$ defined by local Hamiltonians with $O(1)$ maximum degree are $(1, O(1))$-bounded. Together with Theorem 14 we obtain the following theorem.

▶ **Theorem 15.** *Let $\Omega \subset \mathbb{C}$ be a γ-good region for $\gamma \ge 1$. For any $\delta \in (0,1)$, there is a deterministic algorithm such that given any (k,d)-Hamiltonian H and tensorized measurement $\mathcal{O}$, provided that $\frac{1}{\mathbf{Tr}[\mathcal{O}]} Z_{H,\mathcal{O}}$ is M-zero-free on Ω, for any temperature $\beta \in \Omega_\delta$ and error bound $\varepsilon \in (0,1)$, the algorithm outputs an estimation of $Z_{H,\mathcal{O}}(\beta)$ within ε-multiplicative error in $\widetilde{O}\left(n \left(\frac{M}{\delta\varepsilon}\right)^C\right)$ time with $C = \frac{1}{\delta} \ln\left(8ed\left(2q^{3k}+\gamma\right)\right)$.*

Note that when the measurement $\mathcal{O}$ is the identity, $Z_{H,\mathcal{O}}$ is precisely the partition function Z_H, which implies Theorem 2. As discussed in the introduction, Theorem 15 covers all classical partition functions (with or without external field) when temperature is the complex variable.

Following a recent work of Harrow, Mehraban and Soleimanifar [18], Theorem 15 gives polynomial-time approximations of quantum partition functions defined by local Hamiltonians with $O(1)$ maximum degree when the inverse temperature β is close to zero. And following a standard routine of self-reduction, in the same regime, we have a polynomial-time approximate sampler from the quantum Gibbs state after the measurement in the computational basis. These applications are given in Section 5.

Proof of Theorem 15. Given a (k,d)-Hamiltonian $H = \sum_{j=1}^m H_j$, we can construct a dependency graph $G_H = (U, E, \mathcal{L})$ as follows:

1. $U = [m]$ is the vertex set;
2. $E = \left\{\{x,y\} \in \binom{U}{2} \mid \mathrm{supp}(H_x) \cap \mathrm{supp}(H_y) \neq \varnothing\right\}$;
3. for any $x \in U$, its label is given by $L_x = H_x$.

Let $\mathcal{G}_k$ denote the family of all such G_H where H is a k-local Hamiltonian. It is obvious that such $\mathcal{G}_k$ is downward-closed.

Let $\mathcal{O} = \bigotimes_{v\in V} \mathcal{O}_v$ be a tensorized measurement. For any $G = G_H \in \mathcal{G}_k$, where $H = \sum_{j=1}^{m} H_j$, define:

$$f_G(z) = \frac{1}{\mathbf{Tr}\left[\mathcal{O}\right]} Z_{H,\mathcal{O}}(z) = \frac{1}{\mathbf{Tr}\left[\mathcal{O}\right]} \mathbf{Tr}\left[\exp\left(-z\sum_{j=1}^{m} H_j\right)\mathcal{O}\right].$$

The rest of the proof verifies that such $f_\cdot$ is $(1, 2q^{3k})$-bounded on $\mathcal{G}_k$, which is sufficient to prove the theorem by Theorem 14.

We first verify that such $f_\cdot$ is multiplicative. For any $G = (U, E, \mathcal{L}) \in \mathcal{G}_k$ that is the disjoint union of $G_1 = (U_1, E_1, \mathcal{L}_1)$ and $G_2 = (U_2, E_2, \mathcal{L}_2)$, there exists a bipartition $V = V_1 \uplus V_2$ such that $\mathrm{supp}(H_x) \subseteq V_1$ for all $x \in U_1$ and $\mathrm{supp}(H_y) \subset V_2$ for all $y \in U_2$. Let $H_{U_i} = \sum_{x\in U_i} H_x$ for $i = 1, 2$. We have,

$$\begin{aligned}
f_G(z) &= \frac{1}{\mathbf{Tr}[\mathcal{O}]} \mathbf{Tr}\left[\exp\left(-z(H_{U_1} + H_{U_2})\right)\mathcal{O}\right] \\
&= \frac{1}{\mathbf{Tr}[\mathcal{O}]} \mathbf{Tr}[\exp(-zH_{U_1})\exp(-zH_{U_2})\mathcal{O}] \\
&= \frac{1}{\mathbf{Tr}[\mathcal{O}]} \mathbf{Tr}_{V_1}\left[\exp(-zH_{U_1})\bigotimes_{v\in V_1}\mathcal{O}_v\right] \mathbf{Tr}_{V_2}\left[\exp(-zH_{U_2})\bigotimes_{v\in V_2}\mathcal{O}_v\right] \\
&= \frac{1}{\mathbf{Tr}^2[\mathcal{O}]} \mathbf{Tr}[\exp(-zH_{U_1})\mathcal{O}]\mathbf{Tr}[\exp(-zH_{U_2})\mathcal{O}] \\
&= f_{G_1}(z) f_{G_2}(z)
\end{aligned}$$

Here the subscripts V_1, V_2 in $\mathbf{Tr}_{V_1}, \mathbf{Tr}_{V_2}$ indicates the sets of sites that the operators act on. Therefore, $f_\cdot$ is multiplicative.

For any $G = (U, E, \mathcal{L}) \in \mathcal{G}_k$ and any $\ell \in \mathbb{N}^+$, define

$$\lambda_{G,\ell} = \frac{1}{\ell!}\frac{1}{\mathbf{Tr}[\mathcal{O}]} \sum_{f:[\ell]\overset{\text{onto}}{\to} U} \mathbf{Tr}\left[\left(\prod_{j=1}^{\ell} H_{f(j)}\right)\mathcal{O}\right]. \tag{6}$$

Observe that $\lambda_{G,\ell} = 0$ if $|U| > \ell$ as there is no surjection from $[\ell]$ to U. Moreover, for $H = \sum_{x\in U} H_x$,

$$\begin{aligned}
f_G(z) = 1 + \sum_{\ell=1}^{+\infty} \frac{\beta^\ell}{\ell!}\mathbf{Tr}\left[H^\ell\mathcal{O}\right] &= 1 + \sum_{\ell=1}^{+\infty} \frac{z^\ell}{\ell!} \sum_{x_1,x_2,\ldots,x_\ell\in U} \mathbf{Tr}\left[\left(\prod_{j=1}^{\ell} H_{x_j}\right)\mathcal{O}\right] \\
&= 1 + \sum_{\ell=1}^{+\infty}\left(\sum_{S\subseteq U}\lambda_{G[S],\ell}\right) z^\ell.
\end{aligned}$$

It remains to show that $\lambda_{G,\ell}$ can be determined within $(2q^{3k})^\ell \mathrm{poly}(\ell)$ time.

Fix a $G = (U, E, \mathcal{L}) \in \mathcal{G}_k$. For any $S \subseteq U$, define

$$H_{S,\ell} \triangleq \sum_{f:[\ell]\overset{\text{onto}}{\to} S} \prod_{j=1}^{\ell} H_{f(j)}.$$

Clearly, $\lambda_{G,\ell} = \frac{1}{\ell!}\frac{1}{\mathbf{Tr}[\mathcal{O}]}\mathbf{Tr}\left[H_{U,\ell}\mathcal{O}\right]$. Moreover, the following recurrence holds for $H_{S,\ell}$:

$$H_{S,\ell} = \sum_{j\in S} H_j \left(H_{S,\ell-1} + H_{S\setminus\{j\},\ell-1}\right), \tag{7}$$

where the boundary cases are given by $H_{\varnothing,0} = I$, and $H_{S,\ell} = \mathbf{0}$ (the 0-matrix) if $\ell < |S|$, or $S = \varnothing$ but $\ell > 0$. Note that $H_{S,\ell}$ acts non-trivially on at most $k\,|S|$ sites, where each site corresponds to a q-dimensional Hilbert space, thus $H_{S,\ell}$ can be represented as a matrix of size at most $q^{k|S|} \times q^{k|S|}$ and the recursion step (7) can be evaluated in time $O(|S|q^{3k|S|})$. Therefore, for any $S \subseteq U$ that $1 \le |S| \le \ell$, $H_{S,\ell}$ can be computed in time $O(2^{|S|}\ell|S|q^{3k|S|}) = O(\ell^2 2^\ell q^{3k\ell})$ by a dynamic programming that constructs a $2^S \times [\ell]$ table according to the recurrence (7). And finally, $\lambda_{G,\ell} = \frac{1}{\ell!}\frac{1}{\mathbf{Tr}[\mathcal{O}]}\mathbf{Tr}\left[H_{U,\ell}\mathcal{O}\right]$ can be computed from $H_{U,\ell}$ in $O(q^{3k\ell})$ time because $H_{U,\ell}$ acts non-trivially on at most $k|U| \le k\ell$ sites and $\mathcal{O}$ is tensorized. ◀

3.2 Induced subgraph counting

Our framework (Definition 10) subsumes bounded induced graph counting polynomials (BIGCP) defined by Patel and Regts [29].

A BIGCP $p.$ defines multiplicative graph polynomials p_G for all graphs $G = (V, E)$. Moreover, there exists integer $\alpha \ge 1$ and sequence $\lambda_{H,\ell}$ of complex values such that the following conditions are satisfied.

1. For any graph $G = (V, E)$, p_G can be expressed as

$$p_G(z) = 1 + \sum_{\ell=1}^{m(G)} \left(\sum_{\substack{H=(V_H,E_H)\\ |V_H|\le\alpha\ell}} \lambda_{H,\ell}\cdot \mathrm{ind}(H,G) \right) z^\ell,$$

   where $\mathrm{ind}(H, G)$ represents the number of induced subgraphs $G[S]$, $S \subseteq V$, isomorphic to H.
2. $\lambda_{H,\ell}$ can be determined in $O(\beta^\ell)$ time for some constant $\beta \ge 1$.

For any $G = (V, E)$, we define a dependency graph $G^* = (V, E, \mathcal{L})$ where $\mathcal{L}$ labels every $v \in V$ with a trivial symbol $*$. Let $\mathcal{G}$ denote the family of all G^*, which is clearly downward-closed. We define $f_{G^*} = p_G$.

Note that

$$\sum_{\substack{H=(V_H,E_H)\\ |V_H|\le\alpha\ell}} \lambda_{H,\ell}\mathrm{ind}(H,G) = \sum_{\substack{S\subseteq V\\ |S|\le\alpha\ell}} \lambda_{G[S],\ell}.$$

Therefore, any BIGCP $p.$ corresponds to an $f.$ that is (α, β)-bounded on $\mathcal{G}^*$.

3.3 Boolean CSP with external field

A Boolean-variate constraint satisfaction problem (Boolean CSP) is specified by a $\Phi = (V, E, \boldsymbol{\phi})$, where $H = (V, E)$ is a hypergraph and $\boldsymbol{\phi} = (\phi_e)_{e\in E}$ such that each $\phi_e : \{0,1\}^e \to \mathbb{C}$ is a Boolean-variate complex-valued constraint function. Furthermore, $\Phi = (V, E, \boldsymbol{\phi})$ is a (k, d)-formula if $|e| \le k$ for every $e \in E$ and $\deg(v) = |\{e \in E \mid v \in e\}| \le d$ for every $v \in V$.

The partition function for a Boolean CSP $\Phi = (V, E, \boldsymbol{\phi})$ of external field λ is defined as:

$$Z_\Phi(\lambda) = \sum_{\sigma\in\{0,1\}^V} \left(\prod_{e\in E} \phi_e(\sigma|_e)\right) \lambda^{\|\sigma\|_1}.$$

In [27], Liu, Sinclair and Srivastava formulated the above partition function as counting hypergraph insects and gave a polynomial-time algorithm for such a partition function assuming its zero-freeness. Such partition functions are also subsumed in our framework.

Given a Boolean CSP $\Phi = (V, E, \boldsymbol{\phi})$, a dependency graph $G_\Phi = (V_\Phi, E_\Phi, \mathcal{L}_\Phi)$ can be constructed as follows:

1. $V_\Phi = V$;
2. for any distinct $u, v \in V_\Phi = V$, $\{u, v\} \in E_\Phi$ iff $\{u, v\} \subseteq e$ for some $e \in E$;
3. for any $v \in V_\Phi = V$, its label $L_v = (\phi_e)_{e\in E, v\in e}$.

Note that each constraint ϕ_e appears in labels of all $v \in e$, and the maximum degree of G_Φ is bounded by $\Delta \le (k-1)d$ for a (k, d)-formula Φ.

Let $\mathcal{G}_{k,d}$ denote the family of all such dependency graphs G_Φ, where $\Phi = (V, E, \boldsymbol{\phi})$ is a (k, d)-formula, and all their induced subgraphs. Obviously, such $\mathcal{G}_{k,d}$ is downward-closed.

Let $G \in \mathcal{G}_{k,d}$. Without loss of generality, suppose that $G = G_\Phi[U]$ is the subgraph of the dependency graph G_Φ induced by $U \subseteq V$, where $\Phi = (V, E, \boldsymbol{\phi})$ is a Boolean CSP.

We define

$$f_G(\lambda) = \sum_{\sigma\in\{0,1\}^U} \prod_{\substack{e\in E\\ e\cap U\neq\varnothing}} \phi_e^U(\sigma|_{U\cap e})\lambda^{\|\sigma\|_1},$$

where $\phi_e^U : U \cap e \to \mathbb{C}$ is defined as that for any $\tau \in \{0, 1\}^{U\cap e}$,

$$\phi_e^U(\tau) = \phi_e(\tau^*),$$

where $\tau^* \in \{0, 1\}^e$ extends τ and assigns all $v \in e \setminus U$ with 0. It is easy to verify that such definition f_G uses only the information stored in the dependency graph G, thus it is well defined. Meanwhile, it is also easy to verify that $f_\cdot$ is multiplicative and $f_G(\lambda) = Z_\Phi(\lambda)$ if $G = G_\Phi$.

For $G = G_\Phi[U]$ where $\Phi = (V, E, \boldsymbol{\phi})$ and $U \subseteq V$, define $\lambda_{G,\ell}$, as

$$\lambda_{G,\ell} = \begin{cases} \prod_{\substack{e\in E\\ e\cap U\neq\varnothing}} \phi_e^U(\mathbf{1}_{U\cap e}), & |U| = \ell \\ 0, & o.w. \end{cases}$$

Each $\lambda_{G,\ell}$ can be determined in $\mathrm{poly}(k, d, \ell)$ time.

Observe that,

$$f_G(\lambda) = 1 + \sum_{\ell=1}^{|U|} \sum_{\substack{\sigma\in\{0,1\}^U\\ \|\sigma\|_1=\ell}} \prod_{\substack{e\in E\\ e\cap U\neq\varnothing}} \phi_e^U(\sigma|_{U\cap e})\lambda^\ell = 1 + \sum_{\ell=1}^{|U|} \sum_{\substack{S\subseteq U\\ |S|=\ell}} \prod_{\substack{e\in E\\ e\cap S\neq\varnothing}} \phi_e^S(\mathbf{1}_{S\cap e})\lambda^\ell$$
$$= 1 + \sum_{\ell=1}^{+\infty} \left(\sum_{S\subseteq U} \lambda_{G[S],\ell}\right) \lambda^\ell.$$

Therefore, $f_\cdot$ is a $(1, 1)$-bounded on $\mathcal{G}_{k,d}$.

Applying Theorem 14, we immediately obtain the following corollary. Similar bound has been proved in [27], but here we only need to encode the problem in our framework.

▶ **Corollary 16.** *Let $\Omega \subseteq \mathbb{C}$ be a γ-good region for $\gamma \geq 1$. For any $\delta \in (0,1)$, there is a deterministic algorithm such that given any (k,d)-formula Φ for Boolean CSP, provided that Z_Φ is M-zero-free on Ω, for any external field $\lambda \in \Omega_\delta$ and error bound $\varepsilon \in (0,1)$, the algorithm outputs an estimation of $Z_\Phi(\lambda)$ within ε-multiplicative error in $\widetilde{O}\left(n\left(\frac{M}{\delta\varepsilon}\right)^C\right)$ time with $C = \frac{1}{\delta}\ln(8ekd(1+\gamma))$.*

Since such $Z_\Phi(\lambda)$ is a polynomial with finite degree, by Fact 13 and Lemma 5, if $\Omega \subseteq \mathbb{C}$ is a convex region and Z_Φ does not vanish on a slightly larger region $\Omega' = \{(1+\delta)z \mid z \in \Omega\}$ for some constant gap $\delta \in \mathbb{R}^+$, then $M = O_\delta(n)$ and hence the algorithm in Corollary 16 runs in $\left(\frac{n}{\varepsilon}\right)^{O(\ln(kd))}$ time.

3.4 A barrier to non-multiplicative functions

Our framework based on functions f_G induced by dependency graphs G is fairly expressive. However, the current technique crucially relies on the multiplicative property of f_G. The current method would meet a barrier when dealing with systems lacking such property.

We explain this using a concrete example. Consider the following generalization of (1):

$$\forall \beta \in \mathbb{C}, \quad Z_{H,H'}(\beta) \triangleq \mathbf{Tr}\left[\exp(-\beta H + H')\right]. \tag{8}$$

Here, H and H' are two Hamiltonians in $\mathcal{V}$. It encompasses the transverse Ising model and XXZ model. Unfortunately, this partition function fails to fit in our framework due to its non-multiplicative nature, even when H' is a tensorized operator. For Hamiltonians H_1, H_2 such that $\mathrm{supp}(H_1) \cap \mathrm{supp}(H_2) = \varnothing$ and a tensorized operator $H' = \bigotimes_{v\in V} H'_v$, the following equality fails to hold in general: $Z_{H_1+H_2,H'}(\beta) = \frac{1}{\mathbf{Tr}[\exp(H')]} Z_{H_1,H'}(\beta) Z_{H_2,H'}(\beta)$.

For example, let

$$H_1 = I \bigotimes \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix},\ H_2 = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \bigotimes I,\ H' = -\begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} \bigotimes \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}.$$

For $\beta = 1$, it holds that $Z_{H_1+H_2,H'}(\beta) = \mathbf{Tr}\left[\exp(-H_1 - H_2 + H')\right] = 3\mathrm{e}^{-1} + \mathrm{e}^{-2}$ but $\mathbf{Tr}\left[\exp(H')\right] = \mathrm{e}^{-1} + 3$ and $Z_{H_i,H'}(\beta) = \mathbf{Tr}\left[\exp(-H_i + H')\right] = 3\mathrm{e}^{-1} + 1$ for $i \in \{1,2\}$.

The main obstacle comes from the non-commutativity of Hamiltonians and it remains open to design a polynomial-time algorithm for such partition function assuming only zero-freeness.

4 Efficient Coefficient Computing

In this section we prove Theorem 11. First we need to establish the following lemma.

▶ **Lemma 17.** *Let $\mathcal{G}$ be a downward-closed family of dependency graphs, and f be (α,β)-bounded on $\mathcal{G}$ for $\alpha, \beta \geq 1$. Recursively define the sequence $(\zeta_{H,i})_{H\in\mathcal{G},\ell\in\mathbb{N}^+}$ of complex numbers as follows: for any $H = (V_H, E_H, \mathcal{L}_H) \in \mathcal{G}$ and any $\ell \in \mathbb{N}^+$,*

$$\zeta_{H,\ell} = \lambda_{H,\ell} - \sum_{s=1}^{\ell-1} \frac{s}{\ell} \sum_{\substack{S,T\subseteq V_H \\ S\cup T = V_H}} \zeta_{H[S],s}\lambda_{H[T],\ell-s}. \tag{9}$$

It holds that $\zeta_{H,\ell} \neq 0$ only if H is connected and $|V_H| \leq \alpha\ell$. Moreover, for any $G = (V,E,\mathcal{L}) \in \mathcal{G}$,

$$\log f_G(z) = \log f_G(0) + \sum_{\ell=1}^{+\infty} \left(\sum_{S\subseteq V} \zeta_{G[S],\ell}\right) z^\ell. \tag{10}$$

As in [29, 27], the following result of Borgs et al. [8] is used.

▶ **Fact 18** (Lemma 2.1 (c) in [8]). *Let $G = (V, E)$ be a graph with maximum degree Δ, $v \in V$ be a vertex and $\ell \in \mathbb{N}_{\geq 1}$. Then the number of connected subgraphs of size ℓ containing v is at most $\frac{(\mathrm{e}\Delta)^{\ell-1}}{2}$.*

With this fact, we can enumerate all connected induced subgraphs $G[S]$ of $|S| \leq \ell$ vertices efficiently.

▶ **Lemma 19.** *There exists a deterministic algorithm which takes a dependency graph $G = (V, E, \mathcal{L})$ on $n = |V|$ vertices with maximum degree Δ and a positive integer $\ell \in \mathbb{N}^+$ as input, and outputs*

$$\mathcal{C}_{\leq \ell} = \{S \subseteq V \mid |S| \leq \ell, G[S] \text{ is connected}\}, \tag{11}$$

in time $\widetilde{O}(n(\mathrm{e}\Delta)^{\ell})$, where $\widetilde{O}(\cdot)$ hides $\mathrm{poly}(\Delta, \ell, \log(n))$.

Proof. Let $\mathcal{C}^v_{=\ell}$ denote the collection of such $S \subseteq V$ containing $v \in V$ that $|S| = \ell$ and $G[S]$ is connected. Clearly $\mathcal{C}_{\leq \ell} = \bigcup_{\substack{v \in V \\ j \leq \ell}} \mathcal{C}^v_{=j}$. Now construct each $\mathcal{C}^v_{=\ell}$ inductively. When $\ell = 1$, $\mathcal{C}^v_{=1} = \{\{v\}\}$. For $\ell \geq 2$, we enumerate all $S \in \mathcal{C}^v_{=\ell-1}$ and $u \in V \setminus S$ such that $G[S \cup \{u\}]$ is connected, and include $S \cup \{u\}$ into $\mathcal{C}^v_{=\ell}$. It is easy to see that this correctly constructs $\mathcal{C}^v_{=\ell}$. By Fact 18, $|\mathcal{C}^v_{=\ell}| \leq (\mathrm{e}\Delta)^{\ell-1}/2$. Representing each set S as a string of vertices in S sorted in increasing order of vertices, the set $\mathcal{C}^v_{=\ell}$ can be stored by a standard dynamic data structure such as prefix trees, so that it takes $O(\Delta\ell(\mathrm{e}\Delta)^{\ell-1})$ time to iterate over all $(S, u) \in \mathcal{C}^v_{=\ell-1} \times V$ such that $G[S \cup \{u\}]$ may be connected, and for each such (S, u) pair it takes $\mathrm{poly}(\Delta, \ell, \log n)$ time to check weather $G[S \cup \{u\}]$ is connected or $S \cup \{u\}$ is already in $\mathcal{C}^v_{=\ell}$, and insert S into $\mathcal{C}^v_{=\ell}$ if necessary. Overall, it takes $\widetilde{O}(n(\mathrm{e}\Delta)^{\ell})$ time to construct $\mathcal{C}_{\leq \ell}$. ◀

Combining the above algorithm with (9), we can compute coefficients $\zeta_{H,\ell}$ for $\log f_G$ efficiently.

▶ **Lemma 20.** *Let $\mathcal{G}$ be a downward-closed family of dependency graphs, and f. be (α, β)-bounded on $\mathcal{G}$ for $\alpha, \beta \geq 1$. There exists a deterministic algorithm which takes a dependency graph $G = (V, E, \mathcal{L}) \in \mathcal{G}$ on $n = |V|$ vertices with maximum degree Δ and a positive integer $\ell \in \mathbb{N}^+$ as input, and outputs $(\zeta_{G[S],\ell})_{S \in \mathcal{C}_{\leq \alpha\ell}}$ within $\widetilde{O}\left(n(8\mathrm{e}\beta\Delta)^{\alpha\ell}\right)$ time, where $\mathcal{C}_{\leq \alpha\ell}$ is defined in Eq.* (11)*.*

The lemma follows by first enumerating all $S \in \mathcal{C}_{\leq \alpha\ell}$, which takes $\widetilde{O}\left(n(\mathrm{e}\Delta)^{\alpha\ell}\right)$ time according to Lemma 19, and second for every $S \in \mathcal{C}_{\leq \alpha\ell}$, taking $H = G[S]$ and computing $\zeta_{H,\ell}$ using a dynamic programming given by Eq. (9), which takes $\widetilde{O}(8^{\alpha\ell}\beta^{\ell})$ time.

Let $\log f_G(z) = \log f_G(0) + \sum_{\ell=1}^{+\infty} g_{G,\ell} z^{\ell}$. Due to Lemma 17, $\zeta_{G[S],\ell} = 0$ if $G[S]$ is disconnected or $|S| > \alpha\ell$, thus due to Eq. (9), the ℓ-th Taylor coefficient of $\log f_G$ is given by

$$g_{G,\ell} = \sum_{S \subseteq V} \zeta_{G[S],\ell} = \sum_{S \in \mathcal{C}_{\leq \alpha\ell}} \zeta_{G[S],\ell}.$$

Therefore, Theorem 11 is proved. It only remains to prove Lemma 17.

Proof of Lemma 17. Fix an arbitrary $G \in \mathcal{G}$, and consider f_G. Let $\log f_G = \log f_G(0) + \sum_{\ell=1}^{+\infty} g_{G,\ell} z^{\ell}$ denote the Taylor's expansion of $\log f_G$ at the origin, and $f_G(z) = f_G(0) + \sum_{\ell=1}^{+\infty} f_{G,\ell} z^{\ell}$ denote the Taylor's expansion of f_G at the origin. We prove by induction on $\ell \geq 1$ that

$$g_{G,\ell} = \sum_{S \subseteq V} \zeta_{G[S],\ell}, \tag{12}$$

which implies (10).

For the induction basis, when $\ell = 1$, by Lemma 7 we have $g_{G,1} = f_{G,1}$. by the definition of bounded graph function in Definition 10, $f_{G,1} = \sum_{S\subseteq V} \lambda_{G[S],1}$; and it follows from (9) that $\lambda_{G[S],1} = \zeta_{G[S],1}$. Altogether, we have

$$g_{G,1} = f_{G,1} = \sum_{S\subseteq V} \lambda_{G[S],1} = \sum_{S\subseteq V} \zeta_{G[S],1}.$$

Now suppose that the induction hypothesis (12) holds for all $\ell' < \ell$. We have

$$\begin{aligned}
\sum_{S\subseteq V} \zeta_{G[S],\ell} &= \sum_{S\subseteq V} \left(\lambda_{G[S],\ell} - \sum_{s=1}^{\ell-1} \frac{s}{\ell} \sum_{\substack{L,R\subseteq V \\ L\cup R = S}} \zeta_{G[L],s} \cdot \lambda_{G[R],\ell-s} \right) \\
&= \sum_{S\subseteq V} \lambda_{G[S],\ell} - \sum_{s=1}^{\ell-1} \frac{s}{\ell} \left(\sum_{L\subseteq V} \zeta_{G[L],s} \right) \left(\sum_{R\subseteq V} \lambda_{G[R],\ell-s} \right) \\
&= f_{G,\ell} - \sum_{s=1}^{\ell-1} \frac{s}{\ell} g_{G,s} f_{G,\ell-s} && \text{(I.H.)} \\
&= g_{G,\ell}. && \text{(Lemma 7)}
\end{aligned}$$

This finishes the inductive proof of (12).

Next, we prove that $\zeta_{H,\ell} = 0$ if $H = (V_H, E_H, \mathcal{L}_H) \in \mathcal{G}$ is disconnected or $|V_H| > \alpha\ell$. Recall that $f.$ is (α, β)-bounded, we have $\lambda_{H,\ell} = 0$ for $|V_H| > \alpha\ell$. Then the fact that $\zeta_{H,\ell} = 0$ for $|V_H| > \alpha\ell$ can be verified by induction on $\ell \geq 1$. Specifically, by Eq. (9),

$$\zeta_{H,\ell} = \lambda_{H,\ell} - \sum_{s=1}^{\ell-1} \frac{s}{\ell} \sum_{\substack{S,T\subseteq V_H \\ S\cup T = V_H}} \zeta_{H[S],s} \lambda_{H[T],\ell-s}.$$

For the basis, $\zeta_{H,1} = \lambda_{H,1} = 0$ when $|V_H| > \alpha$. In general, observe that assuming $|V_H| > \alpha\ell$, for any $S \cup T = V_H$, it must hold that either $|S| > \alpha s$ or $|T| > \alpha(\ell - s)$. Therefore, assuming $|V_H| > \alpha\ell$, $\zeta_{H,\ell} = 0$ follows from the induction hypothesis.

Finally, it remains to verify that $\zeta_{H,\ell} = 0$ if H is disconnected, which follows from the multiplicative property of $f.$. By contradiction, assume that $\zeta_{H,\ell} \neq 0$ for some disconnected $H \in \mathcal{G}$. Let $S^* \subseteq V_H$ be a minimal subset of V such that $H[S^*]$ is disconnected and $\zeta_{H[S^*],\ell} \neq 0$. Since $H[S^*]$ is disconnected, there exist nonempty $L, R \subseteq S^*$ such that $L \cup R = S^*$ and L, R are disconnected in $H[S^*]$. Due to the multiplicative property of $f.$, we have $f_{G[S^*]} = f_{G[L]} \cdot f_{G[R]}$. Therefore,

$$g_{G[S^*],\ell} = g_{G[L],\ell} + g_{G[R],\ell} = \sum_{S\subseteq L} \zeta_{G[S],\ell} + \sum_{S\subseteq R} \zeta_{G[S],\ell}, \tag{13}$$

where the first equation can be formally verified for any disjoint dependency graphs $G_1, G_2 \in \mathcal{G}$ and any z in the neighborhood of the origin, such that for an arbitrary path P in Ω connecting z and the origin,

$$\begin{aligned}
\log f_{G_1\cup G_2}(z) &= \log f_{G_1\cup G_2}(0) + \int_P \frac{f'_{G_1\cup G_2}(z)}{f_{G_1\cup G_2}(z)}\, dz \\
&= \log f_{G_1}(0) + \log f_{G_2}(0) + \int_P \left(\frac{f'_{G_1}(z)}{f_{G_1}(z)} + \frac{f'_{G_2}(z)}{f_{G_2}(z)} \right) dz \\
&= \log f_{G_1}(z) + \log f_{G_2}(z).
\end{aligned}$$

On the other hand,

$$g_{G[S^*],\ell} = \sum_{S \subseteq S^*} \zeta_{G[S],\ell} = \zeta_{G[S^*],\ell} + \sum_{S \subset S^*} \zeta_{G[S],\ell} = \zeta_{G[S^*],\ell} + \sum_{S \subseteq L} \zeta_{G[S],\ell} + \sum_{S \subseteq R} \zeta_{G[S],\ell}, \quad (14)$$

where the last equation is due to the minimality of S^*. Combining (13) and (14), we have $\zeta_{G[S^*],\ell} = 0$, a contradiction. ◀

5 Applications

In this section, we prove that any zero-free partition function of local Hamiltonians with bounded maximum degree is polynomial-time approximable if the inverse temperature is close enough to 0. This is formally stated by the following theorem. Recall the definition of the partition function $Z_{H,\mathcal{O}}$ induced by Hamiltonian H under measurement $\mathcal{O}$ in (5).

▶ **Theorem 21.** *Let $k, d \in \mathbb{N}^+$, $h > 0$, $\delta \in (0,1)$ and $\beta_0 = \frac{1}{5ekdh}$. There is a deterministic algorithm such that given any (k,d)-Hamiltonian $H = \sum_{j=1}^m H_j$ on n sites satisfying $\|H_j\| \le h$ and tensorized measurement $\mathcal{O}$, for any temperature $\beta \in \mathbb{D}_{(1-\delta)\beta_0}$ and error bound $\varepsilon \in (0,1)$, the algorithm outputs an estimation of $Z_{H,\mathcal{O}}(\beta)$ within ε-multiplicative error in $\widetilde{O}\left(\left(\frac{n}{\delta\varepsilon}\right)^C\right)$ time with $C = \frac{1}{\delta}\left(\ln 8ed + 3k \ln q\right) + 1$.*

It was established in [18] that any partition function $Z_H(\beta)$ exhibits zero-freeness property in a high-temperature regime (when the inverse temperature β is close to 0). A similar lemma holds for partition functions $Z_{H,\mathcal{O}}(\beta)$ under tensorized measurement $\mathcal{O}$.

▶ **Lemma 22** (high temperature zero-freeness)**.** *Let $h \in \mathbb{R}^+$, $H = \sum_{j=1}^m H_j$ be a (k,d)-Hamiltonian on n sites, and $\mathcal{O}$ be a tensorized measurement. If $\|H_j\| \le h$ for all $1 \le j \le m$, then for any $\beta \in \mathbb{D}_{\beta_0}$ where $\beta_0 = \frac{1}{5edkh}$, it holds that $\left|\log \frac{Z_{H,\mathcal{O}}(\beta)}{\mathbf{Tr}[\mathcal{O}]}\right| \le n$.*

Theorem 21 follows directly from Lemma 22 and Theorem 15.

The proof of Lemma 22 extends the zero-freeness analysis in [18] to the case where a tensorized measurement $\mathcal{O}$ is present. We will see that the same inductive proof based on cluster expansion works for this more general case.

Define H_X the Hamiltonian H restricted on X by

$$H_X = \sum_{\substack{i \in [m] \\ \mathrm{supp}(H_i) \subseteq X}} H_i,$$

and define the partition function $Z_{H,\mathcal{O}}$ restricted on X by $Z^X_{H,\mathcal{O}}(\beta) = \mathbf{Tr}_X[\exp(-\beta H_X)\mathcal{O}_X]$, where $O_X = \bigotimes_{v \in X} \mathcal{O}_v$, and $Z^{\varnothing}_{H,\mathcal{O}} = 1$ by convention. Here the subscript X in $\mathbf{Tr}_X$ indicates that the operators act on the sites in X.

Moreover, recall the dependency graph $G_H = (U, E, \mathcal{L})$ defined in the proof of Theorem 15:

1. $U = [m]$;
2. $E = \{(x,y) \in U \times U \mid x \ne y, \mathrm{supp}(H_x) \cap \mathrm{supp}(H_y) \ne \varnothing\}$;
3. $L_x = H_x$ for any $x \in U$.

We are now ready to introduce the cluster expansions of partition functions. The following lemma was an extension of [18, Lemma 26] with tensorized measurement $\mathcal{O}$.

▶ **Lemma 23** (high temperature expansion [18, Lemma 26]). *Let $h \in \mathbb{R}^+$, $H = \sum_{i=1}^m H_i$ be a (k,d)-Hamiltonian, $\mathcal{O}$ be a tensorized measurement and $\beta_0 = \frac{1}{\mathrm{e}(\mathrm{e}-1)dh}$. If $\|H_i\| \le h$, then the following holds for all $\Lambda \subseteq V$, $x \in \Lambda$ and $\beta \in \mathbb{D}_{\beta_0}$.*

$$Z^{\Lambda}_{H,\mathcal{O}}(\beta) = \mathbf{Tr}[\mathcal{O}_x] Z^{\Lambda\setminus\{x\}}_{H,\mathcal{O}}(\beta) + \sum_{\substack{S\subseteq[m]\\ \exists j\in S, x\in \mathrm{supp}(H_j)\\ G_H[S] \text{ is connected}}} W_S(\beta) Z^{\Lambda\setminus R_S}_{H,\mathcal{O}}(\beta),$$

where $W_S(\beta) = \sum_{l=|S|}^{+\infty} \frac{(-\beta)^l}{l!} \sum_{\substack{(i_1,\ldots,i_l)\in S^l\\ \cup_{j=1}^l \{i_j\}=S}} \mathbf{Tr}_{R_S}\left[\prod_{j=1}^l H_{i_j} \mathcal{O}_{R_S}\right]$, *and* $R_S = \bigcup_{j\in S} \mathrm{supp}(H_j)$.

We also need the following technical lemma from [18].

▶ **Lemma 24** (Harrow, Mehraban and Soleimanifar [18, Lemma 27]). *Let $H = \sum_{i=1}^m H_i$ be a (k,d)-Hamiltonian, and $\beta_0 = \frac{1}{5\mathrm{e}dkh}$, then for $|\beta| < \beta_0$*

$$\sum_{\substack{S\subseteq[m]\\ \exists j\in S, x\in \mathrm{supp}(H_j)\\ G_H[S] \text{ is connected}}} \left(\mathrm{e}^{|\beta|h} - 1\right)^{|S|} \exp(dh\mathrm{e}^2 |\beta| |R_S|) \le \mathrm{e}(\mathrm{e}-1)dh|\beta|.$$

Proof Sketch of Lemma 22. Fix an arbitrary $\Lambda \subseteq V$. As observed in [18], it suffices to prove that removal of any single site $x \in \Lambda$ can only produce a bounded additive overhead to $\log Z^{\Lambda}_{H,\mathcal{O}}(\beta)$. Formally, we are going to prove that when $|\beta| < \beta_0$, for any $x \in \Lambda$,

$$\left|\log\left|\frac{1}{\mathbf{Tr}[\mathcal{O}_x]} \frac{Z^{\Lambda}_{H,\mathcal{O}}(\beta)}{Z^{\Lambda\setminus\{x\}}_{H,\mathcal{O}}(\beta)}\right|\right| \le \mathrm{e}^2 dh|\beta|. \tag{15}$$

The proof is by induction on $|\Lambda|$. The induction basis with $|\Lambda| = 1$ is easy to establish. Now suppose that (15) holds for all smaller Λ. By Lemma 23 and Lemma 24, we have

$$\begin{aligned}
\left|\log\left|\frac{1}{\mathbf{Tr}[\mathcal{O}_x]} \frac{Z^{\Lambda}_{H,\mathcal{O}}(\beta)}{Z^{\Lambda\setminus\{x\}}_{H,\mathcal{O}}(\beta)}\right|\right| &= \left|\log\left|1 + \sum_{\substack{S\subseteq[m]\\ \exists j\in S, x\in \mathrm{supp}(H_j)\\ G_H[S] \text{ is connected}}} W_S(\beta) \left(\frac{1}{\mathbf{Tr}[\mathcal{O}_x]} \frac{Z^{\Lambda\setminus R_S}_{H,\mathcal{O}}(\beta)}{Z^{\Lambda\setminus\{x\}}_{H,\mathcal{O}}(\beta)}\right)\right|\right| \\
&\overset{(*)}{\le} -\log\left(1 - \sum_{\substack{S\subseteq[m]\\ \exists j\in S, x\in \mathrm{supp}(H_j)\\ G_H[S] \text{ is connected}}} |W_S(\beta)| \left(\frac{\exp\left(-\mathrm{e}^2 dh|\beta|\right)}{\mathbf{Tr}[\mathcal{O}_{R_S}]}\right)\right) \\
&\le -\log\left(1 - \sum_{\substack{S\subseteq[m]\\ \exists j\in S, x\in \mathrm{supp}(H_j)\\ G_H[S] \text{ is connected}}} \frac{(\exp(|\beta|h) - 1)^{|S|}}{\exp(\mathrm{e}^2 dh|\beta|)}\right) \\
&\le -\log(1 - \mathrm{e}(\mathrm{e}-1)dh|\beta|) \le \mathrm{e}^2 dh|\beta|,
\end{aligned}$$

where $(*)$ follows from the induction hypothesis and the last inequality follows from the fact that $-\log\left(1 - \frac{\mathrm{e}-1}{\mathrm{e}} y\right) \le y$ for all $y \in [0,1]$. ◀

Besides estimation of partition function, another related important computational problem is to sample according to the Gibbs state.

The quantum Gibbs state specified by Hamiltonian $H \in \mathcal{V}$ and inverse temperature $\beta \in \mathbb{R}^+$ is:

$$\rho_H(\beta) = \frac{\exp(-\beta H)}{Z_H(\beta)}.$$

The classical distribution $\mu_{H,\beta}$ over $[q]^V$ is the quantum Gibbs state $\rho_H(\beta)$ after measurement in the computational basis, i.e.

$$\forall \sigma \in [q]^V, \quad \mu_{H,\beta}(\sigma) = \frac{Z_{H,\mathcal{O}_\sigma}(\beta)}{Z_H(\beta)},$$

where $\mathcal{O}_\sigma = |\sigma\rangle\langle\sigma|$. Note that $\mu_{H,\beta}$ is a well-defined distribution over $[q]^V$. To see this, first note that $\sum_\sigma \mathcal{O}_\sigma = I$ is the identity matrix in $\mathcal{V}$, and hence $\sum_\sigma Z_{H,\mathcal{O}_\sigma}(\beta) = Z_H(\beta)$; and second, both $\mathcal{O}_\sigma$ and $\exp(\beta H)$ are positive semidefinite since H is Hermitian and $\beta \in \mathbb{R}^+$, and hence $Z_{H,\mathcal{O}_\sigma}(\beta) = \mathbf{Tr}\left[\exp(\beta H)\mathcal{O}_\sigma\right] \geq 0$.

In the same regime as Theorem 21, we have a polynomial-time approximate sampler from $\mu_{H,\beta}$, the classical distribution obtained after measurement of the quantum Gibbs state in the computational basis.

▶ **Theorem 25.** *Let $k, d \in \mathbb{N}^+$, $h > 0$, $\delta \in (0,1)$ and $\beta_0 = \frac{1}{5ekdh}$. There is a randomized algorithm such that given any (k,d)-Hamiltonian $H = \sum_{j=1}^m H_j$ on n sites satisfying $\|H_j\| \leq h$, for any temperature $\beta \in \mathbb{D}_{(1-\delta)\beta_0}$ and error bound $\varepsilon \in (0,1)$, the algorithm outputs an approximate sample $\sigma \in [q]^V$ within ε total variation distance from the distribution $\mu_{H,\beta}$, in $\widetilde{O}\left(\left(\frac{n}{\delta\varepsilon}\right)^C\right)$ time with $C = \frac{1}{\delta}\left(2\ln 8ed + 6k\ln q\right) + 3$.*

Proof. We leverage the algorithm in Theorem 21 as a subroutine, and give the following classical algorithm for approximate sampling from $\mu_{H,\beta}$.

Without loss of generality, we may assume that $V = [n]$. Let $\mathcal{M}_j = |j\rangle\langle j|$ for $1 \leq j \leq q$, and $\mathcal{M}_{v,j} = \left(\bigotimes_{\ell=1}^{v-1} I\right) \otimes \mathcal{M}_j \otimes \left(\bigotimes_{\ell=v+1}^{n} I\right)$. Our procedure for sampling $\sigma \in [q]^V$ is as follows.

1. Initialize $\mathcal{O}$ with the identity operator on Hilbert space $\mathcal{H}$;
2. Iterate v from 1 to n;
3. For each j from 1 to n, estimate $z_{v,j} = Z_{H,\mathcal{O}_{v-1}\mathcal{M}_{v,j}}(\beta)$ within $\varepsilon_0 = \frac{\varepsilon}{10n}$-multiplicative error.
4. samples $j \in [q]$ proportional to $\tilde{z}_{v,j}$, the estimation of $z_{v,j}$, updates $\mathcal{O}$ with $\mathcal{O}\mathcal{M}_{v,j}$, and assigns $\sigma(v)$ with j.

Note that $\mathcal{O}$ is a tensorized measurement during the process. Hence, Theorem 21 guarantees an estimation of $z_{v,j}$ within ε_0-multiplicative error in $\widetilde{O}(\left(\frac{n}{\varepsilon\delta}\right)^C)$ time with $C = \frac{1}{\delta}\left(2\ln 8ed + 6k\ln q\right) + 2$. Furthermore, note that for each configuration $\sigma \in [q]^V$,

$$\frac{\mathbf{Pr}[\sigma \text{ is generated}]}{\mu_{H,\mathcal{O}}(\sigma)} = \prod_{v=1}^{n} \frac{z_{v,\sigma(v)}}{\sum_{j\in[q]} z_{v,j}} \frac{\sum_{j=1}^q \tilde{z}_{v,j}}{\tilde{z}_{v,\sigma(v)}},$$

and for each $v \in V$ and $j \in [q]$,

$$1 - \varepsilon_0 \leq \frac{\tilde{z}_{v,j}}{z_{v,j}} \leq 1 + \varepsilon_0.$$

Hence,

$$1-\varepsilon \overset{(*)}{<} \left(\frac{1-\varepsilon}{1+\varepsilon}\right)^n \leq \frac{\mathbf{Pr}[\sigma \text{ is generated}]}{\mu_{H,\mathcal{O}}(\sigma)} \leq \left(\frac{1+\varepsilon_0}{1-\varepsilon_0}\right)^n \overset{(\star)}{<} 1+\varepsilon,$$

where $(\star)$ follows from $\left(\frac{1+\varepsilon_0}{1-\varepsilon_0}\right) \leq (1+3\varepsilon_0)^n < \exp(\frac{3}{10}\varepsilon) < 1+\varepsilon$, and $(*)$ follows from $(\star)$ and $\frac{1}{1+\varepsilon} > 1-\varepsilon$. Therefore, the total varaince distance between $\mu_{H,\mathcal{O}}$ and the output from our sampler will differ at most ε.

We conclude the proof by observing that our algorithm calls the subrountine $O(nq)$ times with parameter $\varepsilon_0 = \frac{\varepsilon}{10n}$, which takes $\widetilde{O}\left(\left(\frac{n}{\varepsilon}\right)^C\right)$ time with $C = \frac{1}{\delta}\left(2\ln 8ed + 6k\ln q\right) + 3$ in total. ◀

Faster Cut-Equivalent Trees in Simple Graphs

Tianyi Zhang
Tel Aviv University, Israel

Abstract

Let $G = (V, E)$ be an undirected connected simple graph on n vertices. A cut-equivalent tree of G is an edge-weighted tree on the same vertex set V, such that for any pair of vertices $s, t \in V$, the minimum (s, t)-cut in the tree is also a minimum (s, t)-cut in G, and these two cuts have the same cut value. In a recent paper [Abboud, Krauthgamer and Trabelsi, STOC 2021], the authors propose the first subcubic time algorithm for constructing a cut-equivalent tree. More specifically, their algorithm has [1]$\widetilde{O}(n^{2.5})$ running time. Later on, this running time was significantly improved to $n^{2+o(1)}$ by two independent works [Abboud, Krauthgamer and Trabelsi, FOCS 2021] and [Li, Panigrahi, Saranurak, FOCS 2021], and then to $(m + n^{1.9})^{1+o(1)}$ by [Abboud, Krauthgamer and Trabelsi, SODA 2022].

In this paper, we improve the running time to $\widetilde{O}(n^2)$ graphs if near-linear time max-flow algorithms exist, or $\widetilde{O}(n^{17/8})$ using the currently fastest max-flow algorithm. Although our algorithm is slower than previous works, the runtime bound becomes better by a sub-polynomial factor in dense simple graphs when assuming near-linear time max-flow algorithms.

1 Introduction

It is well known from Gomory and Hu [10] that any undirected graph can be compressed into a single tree while all pairwise minimum cuts are preserved exactly. More specifically, given any undirected graph $G = (V, E)$ on n vertices and m edges, there exists an edge weighted tree T on the same set of vertices V, such that: for any pair of vertices $s, t \in V$, the minimum (s, t)-cut in T is also a minimum (s, t)-cut in G, and their cut values are equal. Such trees are called Gomory-Hu trees or cut-equivalent trees. In the original paper [10], Gomory and Hu showed an algorithm that reduces the task of building a cut-equivalent tree to $n - 1$ max-flow instances. Gusfield [13] modified the original algorithm Gomory and Hu so that no graph contractions are needed when applying max-flow subroutines. So far, in weighted graphs, faster algorithms for building cut-equivalent trees were only byproducts of faster max-flow algorithms. In the recent decade, there has been a sequence of improvements on max-flows using the interior point method [16, 20, 19, 15, 6], and the current best running time is $\widetilde{O}(m + n^{1.5})$ by [6], so computing a cut-equivalent tree takes time $\widetilde{O}(mn + n^{2.5})$.

[1] $\widetilde{O}$ hides poly-logarithmic factors.

When G is a simple graph, several improvements have been made over the years. Bhalgat et al. [14] designed an $\widetilde{O}(mn)$ time algorithm for cut-equivalent trees using a tree packing approach based on [9, 7]. Recent advances include an upper bound of $O(m^{3/2}n^{1/6})$ by Abboud, Krauthgamer and Trabelsi [2], and in a subsequent work [3] by the same set of authors, they proposed the first subcubic time algorithm that constructs cut-equivalent trees in simple graphs, and their running time is $n^{2.5+o(1)}$. Recently, by two independent works [4, 18], this running time was improved to $n^{2+o(1)}$ which is almost-optimal in dense graphs, and further to a subquadratic time $(m+n^{1.9})^{1+o(1)}$ by [5].

All of these upper bounds rely on the current fastest max-flow algorithm with runtime $\widetilde{O}(m+n^{1.5})$. However, even if we assume the existence of a $\widetilde{O}(m)$-time max-flow algorithm, the above algorithms still have $n^{2+o(1)}$ running time in dense graphs which contains an extra sub-polynomial factor.

1.1 Our results

Let $\mathsf{MF}(m_0, n_0)$ be the running time complexity of max-flow computation in unweighted multi-graphs with m_0 edges and n_0 vertices, and let $\mathsf{MF}(m_0) = \mathsf{MF}(m_0, m_0)$ for convenience.

The main result of this paper is a near-quadratic time algorithm assuming existence of quasi-linear time max-flow algorithms. For a detailed comparison with recent published works, please refer to the table below where conditional runtime refers to the assumption of near-linear time max-flow algorithms.

▶ **Hypothesis 1.** $\mathsf{MF}(m_0, n_0) = \widetilde{O}(m_0 + n_0)$.

▶ **Theorem 2.** *Let $G = (V, E)$ be a simple on n vertices. Under Hypothesis 1, there is a randomized algorithm that constructs a cut-equivalent tree of G in $\widetilde{O}(n^2)$ time with high probability. Using the current fastest max-flow algorithm [6], the running time becomes $\widetilde{O}(n^{17/8})$.*

reference	conditional runtime	unconditional runtime
[3]	$\widetilde{O}(n^{2.5})$	$n^{2.5+o(1)}$
[4]	$n^{2+o(1)}$	$n^{2+o(1)}$
[18]	$n^{2+o(1)}$	$n^{2+o(1)}$
[5]	$(m+n^{1.75})^{1+o(1)}$	$(m+n^{1.9})^{1+o(1)}$
new	$\widetilde{O}(n^2)$	$\widetilde{O}(n^{17/8})$

Comparison with subsequent works. In a very recent but unpublished online preprint [1] (see also a note by [21]), significant progress has been made where an unconditional $\widetilde{O}(n^2)$ runtime has been achieved for cut-equivalent trees in general weighted graphs, which completely subsumes our result.

1.2 Technical overview

Our algorithm is largely based on the framework of [3]. In this subsection, we will discuss the running time bottlenecks of [3] and how to bypass them. For simplification, consider the following task. Let $\mathcal{T}$ be a partition tree which is an intermediate tree of the Gomory-Hu algorithm. Take an arbitrary node $N \subseteq V$ of $\mathcal{T}$ which represents a vertex subset of V. Let $G_{\mathcal{T}}[N] = (V_{\mathcal{T}}[N], E_{\mathcal{T}}[N])$ be the auxiliary graph obtained by contracting each component of $\mathcal{T} \setminus \{N\}$ into a single vertex in the original graph G.

Fix a pivot vertex $p \in N$, we want to find a sequence of vertices $v_1, v_2, \cdots, v_l \in N$, and compute a sequence of latest minimum cuts $(L_i, V_{\mathcal{T}}[N] \setminus L_i), 1 \leq i \leq l$ in $G_{\mathcal{T}}[N]$ for $(v_i, p), 1 \leq i \leq l$, where $v_i \in K_i, p \notin K_i$, such that:

(1) $l \geq \Omega(|N|)$.

(2) For each $1 \leq i \leq l$, $|L_i| \leq |N|/2$.

If we cut all sides $L_i \cap N$ off of N and form tree nodes, then by the above two properties all tree nodes are vertex subsets of N of size at most $|N|/2$. So, if we can recursively repeat this procedure on smaller subsets, then it would produce a cut-equivalent tree in logarithmically many rounds.

For this task, the basic idea of [3] is to apply expander decompositions. Suppose the original graph G is decomposed into disjoint clusters $V = C_1 \cup C_2 \cup \cdots$ such that each $G[C_i]$ is a ϕ-expander, and the total number of inter-cluster edges is bounded by $\widetilde{O}(\phi n^2)$. For simplicity let us assume G is a roughly regular graph and each vertex $v \in V$ has degree $\deg_G(v) \in [n/2, n)$. For each v, suppose $(L_v, V \setminus L_v)$ is the latest min-cut for (v, p), and let C_v be the ϕ-expander of the expander decomposition that contains v. Vertices of N are divided into three types.

1. Vertices in clusters whose size is less than $n/4$, namely $|C_v| < n/4$.
2. Vertices in clusters whose size is at least $n/4$, namely $|C_v| \geq n/4$, plus that $|C_v \cap L_v| \leq 10/\phi$. Note that there are only a constant number of such clusters.
3. $|C_v| \geq n/4$, plus that $|C_v \setminus L_v| \leq 10/\phi$.

The first bottleneck

To compute L_v for type-1 vertices, we simply go over all such v's, and compute the max-flow from v to p in $G_{\mathcal{T}}[N]$. Since each type-1 vertex must contribute $n/2 - n/4 = n/4$ inter-cluster edges as the input graph G is simple, the total number of type-1 vertices does not exceed $\widetilde{O}(\phi n)$, summing over all tree nodes N of $\mathcal{T}$.

For type-2 vertices, using the isolating cut lemma devised in [3, 17], we can compute all the sides L_v in $\widetilde{O}(\mathsf{MF}(\mathsf{vol}_G(N))/\phi)$ time, which sum to $\widetilde{O}(\mathsf{MF}(n^2)/\phi)$ over all nodes N of $\mathcal{T}$. So, under Hypothesis 1, the total time cost of type-1 and type-2 vertices is $\widetilde{O}(\phi n^3 + n^2/\phi)$, which is always larger than $n^{2.5}$. So in their algorithm [3], parameter ϕ is equal to $1/\sqrt{n}$.

Our observation is that applying max-flow for each type-1 vertex is too costly. To overcome this bottleneck, we simply avoid computing cuts $(L_v, V_{\mathcal{T}}[N] \setminus L_v)$ for both type-1 and type-2 vertices. If the total number of type-2&3 vertices is larger than the total number of type-1 vertices, then we can skip all type-1 vertices. However, if the number of type-1 vertices dominates in N, then the number of type-2&3 vertices is at most $\widetilde{O}(\phi n)$ over all such kind of N. In this case, the total degree $\mathsf{vol}_G(N)$ is at most $\widetilde{O}(\phi n^2)$, and therefore, when summing over all nodes N of $\mathcal{T}$, computing all type-1 vertices takes time at most $\widetilde{O}(\phi^2 n^3)$, instead of $\widetilde{O}(\phi n^3)$, and so the new balance would be $\widetilde{O}(\phi^2 n^3 + n^2/\phi)$. Therefore, if we choose $\phi = n^{-1/3}$, it becomes $n^{7/3}$ which is already better than $n^{2.5}$. In the final algorithm, we will classify expander sizes using $\log n$ many different thresholds, instead of just one threshold (which is n/4 here), and so in the end we can set $\phi = 1/\log^{O(1)} n$. In general cases where graph G has various vertex degrees, we need to apply boundary-linked expander decomposition from a recent work [11]; especially we need to make use of property (3) in Definition 4.2 of [11].

The second bottleneck

In the work [3], in order to compute latest min-cuts $(L_v, V_{\mathcal{T}}[N] \setminus L_v)$ for type-3 vertices, they consider the laminar family formed by all sides L_v. If the laminar family has tree depth at most k, then their algorithm can compute cuts $(L_v, V_{\mathcal{T}}[N] \setminus L_v)$ by applying $k + 10/\phi$ max-flows in $G_{\mathcal{T}}[N]$. To ensure that the depth is bounded by k, they need a first randomly refine node N into $|N|/k$ sub-nodes which takes $|N|/k$ Gomory-Hu steps. Hence, in total, it requires at least $k + |N|/k > \sqrt{|N|}$ max-flow invocations, which leads to a $n^{2.5}$ running time under Hypothesis 1.

To bypass this barrier, the observation is that the depth of the laminar family in each ϕ-expander is already small, so actually we do not need the help from the refinement step. More precisely, instead of looking at the entire laminar family formed by sets $\{L_v\}_{v\in N}$, we only look at the laminar family formed by sets $\{C_v \cap L_v\}_{v\in N}$ for each cluster C. It can be proved that the depth of this smaller laminar family is always bounded by $O(1/\phi)$. In the end, to compute latest min-cuts $(L_v, V_{\mathcal{T}}[N] \setminus L_v)$ for all type-2&3 vertices, we will only use $O(1/\phi)$ max-flow instances in total.

2 Preliminaries

Let $G = (V, E)$ be an arbitrary simple graph on n vertices and m edges with unit-capacities. For any $v \in V$, let $\deg_G(v)$ be the number of its neighbors in V. For any subset $S \subseteq V$, define $\mathsf{vol}_G(S) = \sum_{v\in S} \deg_G(v)$, and let $\mathsf{out}_G(S)$ count the number of edges in $E \cap (S \times (V \setminus S))$, and define $G[S]$ to be the induced subgraph of S on G.

Introduced in [8], the latest minimum (s, t)-cut is a minimum (s, t)-cut such that the side containing s has minimum size as well. It is proved that latest minimum cuts are unique, and can be computed by any max-flow algorithm for (s, t).

Here are some basic facts about min-cuts.

▶ **Lemma 3** (Lemma 2.8 in [3]). *For any vertices $a, b, p \in V$, assume $(A, V\setminus A)$ and $(B, V\setminus B)$ are min-cuts for $(a, p), (b, p)$ respectively. If $b \in A$, then $(A \cup B, V \setminus (A \cup B))$ is a min-cut for (a, p) as well.*

▶ **Lemma 4** (Lemma 2.9 in [3]). *For any vertices $a, b, p \in V$, assume $(A, V\setminus A)$ and $(B, V\setminus B)$ are min-cuts for $(a, p), (b, p)$ respectively. If $a \notin B$ and $b \notin A$, then $(A \setminus B, V \setminus (A \setminus B))$ is a min-cut for (a, p).*

2.1 Cut-equivalent trees

A cut-equivalent tree is a tree $\mathcal{T}$ on V with weighted edges, such that for any pair $s, t \in V$, there is a minimum cut $(S, V \setminus S)$ in G such that it is also a minimum cut in $\mathcal{T}$ with the same cut value. Now let us turn to define some terminologies for cut-equivalent trees.

Partition trees

A partition tree $\mathcal{T}$ of graph G is a tree whose nodes $U_1, U_2, \cdots, U_l$ represent disjoint subsets of V such that $V = U_1 \cup U_2 \cup \cdots \cup U_l$. For each node U of $\mathcal{T}$, the auxiliary graph $G_{\mathcal{T}}[U] = (V_{\mathcal{T}}[U], E_{\mathcal{T}}[U])$ of U is built by contracting each component of $\mathcal{T} \setminus \{U\}$ into a single vertex in the original graph G.

Gomory-Hu algorithm

Gomory-Hu algorithm provides a flexible framework for constructing a cut-equivalent tree. The algorithm begins with a partition tree $\mathcal{T}$ which is the single node that subsumes the entire vertex set V, and creates more nodes iteratively by refining its nodes. In each iteration, the algorithm picks an arbitrary node that represent a non-singleton subset $U \subseteq V$, and selects two arbitrary vertex $s, t \in U$. Then, compute the minimum cut $(S, V_{\mathcal{T}}[U] \setminus S)$ between s, t in the auxiliary graph $G_{\mathcal{T}}[U]$. Finally, split node U into two nodes that correspond to subsets $S \cap U$ and $(V_{\mathcal{T}}[U] \setminus S) \cap U$ respectively, connected by an edge with weight equal to the value of the cut $(S, V_{\mathcal{T}}[U] \setminus S)$ in $G_{\mathcal{T}}[U]$. For each node W that was U's neighbor on $\mathcal{T}$, reconnect W to node $S \cap U$ if S contains the contracted node that subsumes W; otherwise reconnect W to node $(V_{\mathcal{T}}[U] \setminus S) \cap U$.

A tree is called **GH-equivalent**, if it is a partition tree that can be constructed during Gomory-Hu algorithm by certain choice of nodes U to split and pairs of vertices $s, t \in U$.

Refinement with respect to subsets

Consider a partition tree $\mathcal{T}$ which is GH-equivalent. Let U be one of $\mathcal{T}$'s node and let $R \subseteq U$ be a subset. A refinement of $\mathcal{T}$ with respect to R is to repeatedly execute a sequence of Gomory-Hu iterations by always picking two different vertices from $s, t \in R$ that are currently in the same node of $\mathcal{T}$ and refine $\mathcal{T}$ using a minimum (s, t)-cut. So after the refinement of $\mathcal{T}$ with respect to R, $\mathcal{T}$ is still GH-equivalent.

▶ **Lemma 5** ([12]). *For any node U of $\mathcal{T}$ and any subset $R \subseteq U$, a refinement of $\mathcal{T}$ with respect to R can be computed in time $\widetilde{O}(|R| \cdot \mathsf{MF}(\mathsf{vol}_G(U)))$.*

▶ **Lemma 6** (see definition of partial trees in [3]). *After the refinement on a GH-equivalent tree $\mathcal{T}$ with respect to R, for any $a, b \in R$, let $N_a \ni a$ and $N_b \ni b$ be nodes of $\mathcal{T}$. Then, the min-cut of (N_a, N_b) in $\mathcal{T}$ is a min-cut in G for (a, b) as well.*

k-partial trees

A k-partial tree $\mathcal{T}$ is a GH-equivalent partition tree such that all vertices $u \in V$ such that $\deg_G(u) \leq k$ are singletons of $\mathcal{T}$. The following lemma states that k-partial trees always exist and can be computed efficiently for small k's.

▶ **Lemma 7** ([14]). *There is an algorithm that, given an undirected graph with unit edge capacities and parameter k on n vertices, computes a k-partial tree in time $\min\{\widetilde{O}(nk^2), \widetilde{O}(mk)\}$.*

2.2 Expander decomposition

For any pair of disjoint sets $S, T \subseteq V$, let $E_G(S, T)$ be the set of edges between S, T in G. The conductance of a cut $(S, V \setminus S)$ is $\Phi_G(S) = |E_G(S, V \setminus S)| / \min\{\mathsf{vol}_G(S), \mathsf{vol}_G(V \setminus S)\}$, and the conductance of a graph G is defined as $\Phi_G = \min_S \Phi_G(S)$. A graph G is a ϕ-expander if $\Phi_G \geq \phi$.

For any vertex subset $S \subseteq V$ and positive value $x > 0$, let $G[S]^x$ be the subgraph induced on S where we add $\lceil x \rceil$ self-loops to each vertex $v \in S$ for every boundary edge $(v, w), w \notin S$. As an example, in graph $G[S]^1$ the degrees of all vertices are the same as in the original graph G.

We need a strong expander decomposition algorithm from a recent work [11].

▶ **Definition 8** (boundary-linked expander decomposition [11]). *Let $G = (V, E)$ be a graph on n vertices and m edges, and $\alpha, \phi \in (0, 1)$ be parameters. An (α, ϕ)-expander decomposition of V consists of a partition $\mathcal{C} = \{C_1, C_2, \cdots, C_k\}$ of V such that the following holds.*
(1) $\sum_{i=1}^{k} \mathsf{out}_G(C_i) \leq \log^4 n \cdot \phi m$.
(2) *For any i, $G[U_i]^{\alpha/\phi}$ is a ϕ-expander.*
(3) *For any i, $\mathsf{out}_G(C_i) \leq \log^7 n \cdot \phi \mathsf{vol}_G(C_i)$.*
In the original paper [11], the upper bounds are stated with $O(\cdot)$ notations that hide constant factors; here we simply raise the exponent of log-factors to simplify the notations.

▶ **Lemma 9** ([11]). *Given any unweighted graph $G = (V, E)$ on n vertices and m edges, for any $\alpha, \phi \in (0, 1)$ such that $\alpha \leq 1/\log^{\mathsf{c}} m$ where c is a certain constant, a (α, ϕ)-expander decomposition can be computed in $\widetilde{O}(m/\phi)$ with high probability.*

2.3 Isolating cuts

▶ **Lemma 10** (isolating cuts [3]). *Given an undirected edge-weighted graph $H = (X, F, \omega)$, a pivot vertex $p \in X$, and a set of terminal vertices $T \subseteq X$. For each $u \in T$, let $(K_u, X \setminus K_u)$ be the latest minimum (u, p)-cut for each $u \in T$. Then, in time $\widetilde{O}(\mathsf{MF}(|F|, |X|))$ we can compute $|T|$ disjoint sets $\{K'_u\}_{u \in T}$ such that for each $u \in T$, if $K_u \cap T = \{u\}$ then $K'_u = K_u$.*

3 Quadratic time Gomory-Hu tree under Hypothesis 1

3.1 The main algorithm

In this section we try to prove the first half of Theorem 2. Let $G = (V, E)$ denote the simple graph as our input data. Define some parameters: $\phi = \frac{1}{10 \log^{\mathsf{c}+10} n}$ is a global conductance parameter that is used to construct expander decompositions, and $r = 10 \log^5 n$ is a sampling parameter which is needed when choosing pivots; here c is the same constant as in Definition 8. Without loss of generality, assume $\sqrt{n}$ is an integral power of 2. Define a degree set $\mathcal{D} = \{\sqrt{n}, 2\sqrt{n}, 2^2\sqrt{n}, \cdots, n\}$.

Preparation

Throughout the algorithm, $\mathcal{T}$ will be the cut-equivalent tree under construction, where each of $\mathcal{T}$'s node will represent a subset of vertices of V. As a preparation step, compute a (ϕ, ϕ)-expander decomposition on G and obtain a partitioning $\mathcal{C} = \{C_1, C_2, \cdots, C_k\}$ of V. Categorize clusters in $\mathcal{C}$ according to their sizes: for each 2^i, define $\mathcal{C}_i$ to be the set of clusters whose sizes are within interval $[2^i, 2^{i+1})$.

At the beginning, initialize $\mathcal{T}$ to be a $\sqrt{n}$-partial tree by applying the algorithm from [14] that takes running time $\widetilde{O}(n^2)$.

Iteration

In each round, we will divide simultaneously all nodes of $\mathcal{T}$ which contains at least $20r$ vertices in V. In the end, the total number of rounds will be bounded by $\widetilde{O}(1)$. To describe our algorithm, let us focus on any single node $N \subseteq V$ of $\mathcal{T}$ whose size $|N|$ is at least $20r$. The first step is to refine the partition of N by a set of random pivots. More specifically, sample a pivot subset $R \subseteq N$ of size $10r$ by picking each vertex with probability proportional to its degree in G; more precisely, repeatedly sample for $10r$ times a vertex from N where each vertex $v \in N$ is selected with probability $\deg_G(v)/\mathsf{vol}_G(N)$.

Then, refine the node N of $\mathcal{T}$ by computing a partial tree with respect to R using Lemma 5, which further divides N into several subsets each containing a distinct vertex from R. After applying this pivot-sampling & refining step to each of the original node of $\mathcal{T}$, $\mathcal{T}$ has undergone one pass of partition, and now each node U of $\mathcal{T}$ is associated with a unique pivot vertex $p \in U \cap R$.

For the rest, let us focus on each node U of the current $\mathcal{T}$ as well as its pivot p, such that $U \subseteq N$ is a subdivision of the previous node N but $\mathsf{vol}_G(U) \geq 0.5\mathsf{vol}_G(N)$. For each $k \in \mathcal{D}$, define $U_k = \{u \in U \mid \deg_G(u) \in [k, 2k)\}$, so $U = \bigcup_{k\in\mathcal{D}} U_k$. Take a parameter $d \in \mathcal{D}$ such that $d|U_d|$ is maximized, namely $d \in \arg\max_{k\in\mathcal{D}} k|U_k|$. Therefore, $2d|U_d| \geq \mathsf{vol}_G(U)/\log n$. Next, for each index i, define $\mathsf{cnt}[i]$ to be the number of vertices from U_d that lie within clusters from $\mathcal{C}_i$. Take $s = 2^{i_U}$ such that $\mathsf{cnt}[i_U]$ is maximized.

For each cluster $C \in \mathcal{C}_{i_U}$ such that $C \cap U_d$ is nonempty, conduct the expander search routine described in the next subsection (Algorithm 2) to compute cuts $(K_u, V_{\mathcal{T}}[U] \setminus K_u)$ in the auxiliary graph $G_{\mathcal{T}}[U]$ for a set W_C of vertices $u \in W_C \subseteq C \cap U_d$ with respect to pivot p; so $u \in K_u, p \in V_{\mathcal{T}}[U] \setminus K_u$. It will be guaranteed that for each $u \in W_C$, we have $\mathsf{vol}_G(K_u \cap U) \leq 0.5\mathsf{vol}_G(N)$. In the end, define $W = \bigcup_{C\in\mathcal{C}_{i_U}} W_C$.

We will prove that all $(K_u, V_{\mathcal{T}}[U] \setminus K_u)$ are latest min-cuts for (u, p). Since all latest minimum cuts $(K_u, V_{\mathcal{T}}[U] \setminus K_u)$ are with respect to p, they should form a laminar family. Then, for each $u \in W$ such that K_u is maximal in the laminar family, split $K_u \cap U$ off the node U and create a new node for vertex set $K_u \cap U$. Since we always take maximal K_u's, all of these sets are disjoint in $V_{\mathcal{T}}[U]$, so the creation of new nodes on $\mathcal{T}$ is well-defined. Pseudo-code CondGomoryHu summarizes our algorithm.

Algorithm 1 CondGomoryHu$(G = (V, E))$.

3.2 Finding latest min-cuts in expanders

Our algorithm is similar to the one from [3]. The input to this procedure is a node $U \subseteq V$ of the current partition tree $\mathcal{T}$ under construction, together with parameters s, d defined previously, as well as an expander $C \in \mathcal{C}_{i_U}$ that intersects U_d. The output of this procedure will be a subset $W_C \subseteq C \cap U_d$, and their cuts $(K_u, V_{\mathcal{T}}[U] \setminus K_u)$ for all $u \in W_C$ in the auxiliary graph $G_{\mathcal{T}}[U]$, with the extra property that $\mathsf{vol}_G(K_u \cap U) \leq 0.5\mathsf{vol}_G(N)$. In the end, we will show that with high probability, all these cuts are latest min-cuts in $G_{\mathcal{T}}[U]$.

To describe our algorithm, consider all vertices $u \in C \cap U_d$ and their latest minimum cuts $(L_u, V_{\mathcal{T}}[U] \setminus L_u)$ with respect to pivot $p \in U$. Let λ_u be the cut value of $(L_u, V_{\mathcal{T}}[U] \setminus L_u)$ in $G_{\mathcal{T}}[U]$. All of the sets $L_u \cap C \cap U_d$ should form a laminar family, which corresponds to a tree structure $\mathcal{T}_p^d[C]$, where each tree node M of $\mathcal{T}_p^d[C]$ packs a subset of $C \cap U_d$, such that for all $u \in M$ the set $L_u \cap C \cap U_d$ are the same. More specifically, $\mathcal{T}_p^d[C]$ is constructed as follows: first arrange the laminar family $\{L_u \cap C \cap U_d\}_{u \in C \cap U_d}$ as a tree, and then for each node $L_u \cap C \cap U_d$ on this tree, associate with this node the set $M = \{v \in C \cap U_d \mid L_v \cap C \cap U_d = L_u \cap C \cap U_d\} \subseteq L_u \cap C \cap U_d$.

We need to emphasize that our algorithm does not know $\mathcal{T}_p^d[C]$ at the beginning, but it will gradually explore part of $\mathcal{T}_p^d[C]$ during the process.

Preparation

Initialize $W_C = \emptyset$. Assume $|C \cap U_d| \geq 10/\phi^2$; otherwise we could simply reset $W_C = C \cap U_d$ and run $|C \cap U_d|$ instances of max-flow to compute all latest cuts. As a preparatory step, the algorithm repeatedly takes a random subset $T \subseteq C \cap U_d$ by selecting each vertex independently with probability ϕ. Then apply Lemma 10 on graph $G_{\mathcal{T}}[U]$ to compute isolating cuts of terminal vertices from T with respect to pivot p. This procedure goes on for $10 \log n/\phi$ iterations, and for each $u \in C \cap U_d$, let $(A_u^i, V_{\mathcal{T}}[U] \setminus A_u^i)$ be the isolating cut computed for u in the i-th iteration; if u was not selected by T in the i-th iteration, simply set $A_u^i = \{u\}$. Finally, let A_u be the set among $\{A_u^i\}_{1 \leq i \leq 10 \log n/\phi}$ such that the cut value of $(A_u, V_{\mathcal{T}}[U] \setminus A_u)$ in the auxiliary graph $G_{\mathcal{T}}[U]$ is minimized; to break ties, we select A_u^i that minimizes $|A_u^i|$. Let κ_u be the cut value of $(A_u, V_{\mathcal{T}}[U] \setminus A_u)$ for $u \in C \cap U_d$.

If one of $|A_u \cap C \cap U_d| > 2/\phi$, then the algorithm fails and aborts; we will prove that the failure probability is small.

Exploring $\mathcal{T}_p^d[C]$

A node M of $\mathcal{T}_p^d[C]$ is called **large** if $|C \cap U_d \setminus L_u| \leq 2/\phi$ for any $u \in M$, and if $|L_u \cap C \cap U_d| \leq 2/\phi$ it is called **small**. Similarly, a vertex $u \in C \cap U_d$ is called large, if $|C \cap U_d \setminus L_u| \leq 2/\phi$; otherwise if $|L_u \cap C \cap U_d| \leq 2/\phi$, it is called small.

▶ **Lemma 11.** *All large nodes on $\mathcal{T}_p^d[C]$ should lie on a single path ended at root.*

Proof. Suppose otherwise there exists two different large nodes M_1, M_2 of $\mathcal{T}_p^d[C]$ such that $M_1 \cap M_2 = \emptyset$. Take any $u_1 \in M_1, u_2 \in M_2$. Since M_1, M_2 are large nodes, we know $|C \cap U_d \setminus L_{u_1}| \leq 2/\phi$, $|C \cap U_d \setminus L_{u_2}| \leq 2/\phi$. As $C \cap U_d \cap L_{u_1}$ and $C \cap U_d \cap L_{u_2}$ are disjoint, we have $|C \cap U_d| \leq |C \cap U_d \setminus L_{u_1}| + |C \cap U_d \setminus L_{u_2}| \leq 4/\phi$, which contradicts that $|C \cap U_d| \geq 10/\phi^2$. ◀

The main idea of our algorithm is to find the lowest large node on $\mathcal{T}_p^d[C]$; to clarify a bit more, here "lowest" means farthest from root. Initialize a set $S \leftarrow C \cap U_d$ and maintain an ordering of vertices in S according to the cut value of κ_u, also initialize variable $Q \leftarrow \emptyset$.

Repeat the following procedure: take $u \in S \setminus Q$ such that κ_u is maximized. Apply max-flow in graph $G_{\mathcal{T}}[U]$ to compute the latest min-cut L_u for (u, p). Consider two possibilities.

- L_u is small. Then assign $S \leftarrow S \setminus (Q \cup L_u)$, and $Q \leftarrow \emptyset$.
- L_u is large. If $L_u \cap C \cap U_d = S$, then add u to Q; otherwise if $L_u \cap C \cap U_d \neq S$, reset $S \leftarrow L_u \cap C \cap U_d$ and $Q \leftarrow \{u\}$.

The repetition terminates if either (1) $|C \cap U_d \setminus S| > 2/\phi$ or (2) $|Q| > 2/\phi$. In the first case, assign $W_C \leftarrow \{u \in S \mid \mathsf{vol}_G(A_u \cap U) \leq 0.5\mathsf{vol}_G(N)\}, K_u \leftarrow A_u$ and terminate. Note that this notation $\mathsf{vol}_G(A_u \cap U)$ is well-defined, since all vertices in U are also vertices in V, not contracted vertices in $V_{\mathcal{T}}[U]$.

Now suppose we are in the second case. Let $L = L_v$ for an arbitrary $v \in Q$. We will prove afterwards that $(L, V_{\mathcal{T}}[U] \setminus L)$ is the latest min-cut corresponding to the lowest large node. Let κ be the cut value of $(L, V_{\mathcal{T}}[U] \setminus L)$, and define $B = \{u \in S \mid \kappa_u > \kappa\}$. Assign $W_C \leftarrow \{u \in S \setminus B \mid \mathsf{vol}_G(A_u \cap U) \leq 0.5\mathsf{vol}_G(N)\}, K_u \leftarrow A_u$ and for each $u \in W_C$.

After that, take an arbitrary $v \in Q$. If it satisfies that $\mathsf{vol}_G(L \cap U) \leq 0.5\mathsf{vol}_G(N)$, then update $W_C = W_C \cup \{v\}$ and $K_v \leftarrow L$. The whole exploration procedure is summarized as pseudo-code ExploreTree.

Algorithm 2 ExploreTree(U, p, d, C).

```
prepare A_u and κ_u for all u ∈ C ∩ U_d;
initialize S ← C ∩ U_d, Q ← ∅;
while max{|C ∩ U_d \ S|, |Q|} ≤ 2/φ do
    take u ∈ arg max_{v∈S\Q}{κ_v};
    apply max-flow to compute L_u;
    if u is small then
        S ← S \ (Q ∪ L_u), and Q ← ∅;
    else
        if L_u ∩ C ∩ U_d = S then
            Q ← Q ∪ {u};
        else
            S ← L_u ∩ C ∩ U_d, Q ← {u};
if |C ∩ U_d \ S| > 2/φ then
    return W_C ← {u ∈ S | vol_G(A_u ∩ U) ≤ 0.5vol_G(N)}, K_u ← A_u, ∀u ∈ W_C;
else
    define B = {u ∈ S | κ_u > κ} where κ is the cut value of (S, V_T[U] \ S);
    W_C ← {u ∈ S \ B | vol_G(A_u ∩ U) ≤ 0.5vol_G(N)}, K_u ← A_u, ∀u ∈ W_C;
    draw an arbitrary vertex v ∈ Q and set L = L_v;
    if vol_G(L ∩ U) ≤ 0.5vol_G(N) then
        assign W_C ← W_C ∪ {v} and K_v ← L;
    return W_C;
```

3.3 Proof of correctness

First we prove a basic property of isolating cuts, which is also used in [3].

▶ **Lemma 12** ([3]). *For each $u \in C \cap U_d$, either $|L_u \cap C \cap U_d| \leq 2/\phi$ or $|C \cap U_d \setminus L_u| \leq 2/\phi$; namely each vertex is either large or small. Furthermore, with high probability, when u is small, $A_u = L_u$.*

Proof. Since $\deg_G(u) < 2d$, the cut value of $(L_u, V_{\mathcal{T}}[U] \setminus L_u)$ is smaller than $2d$. Unpack all contracted vertices of $V_{\mathcal{T}}[U]$, and let $L'_u \subseteq V$ be the set of vertices belonging to L_u or contracted in L_u. Therefore, since $G_{\mathcal{T}}[U]$ is a contracted graph of G, the cut value of $(L_u, V_{\mathcal{T}}[U] \setminus L_u)$ is equal to the cut value of $(L'_u, V \setminus L'_u)$.

Suppose otherwise that $|L'_u \cap C \cap U_d| > 2/\phi$ and $|C \cap U_d \setminus L'_u| > 2/\phi$. Then, by property (2) of the (ϕ, ϕ)-expander decomposition, $G[C]^1$ is a ϕ-expander, and so the number of edges between $L'_u \cap C$ and $C \setminus L'_u$ is at least $\phi \cdot \min\{\mathsf{vol}_G(L'_u \cap C), \mathsf{vol}_G(C \setminus L'_u)\} > 2d$, which is a contradiction.

Let us turn to the second half of the statement. Suppose u is small, and so $|L_u \cap C \cap U_d| \leq 2/\phi$. Then, since T selects each vertex in $C \cap U_d$ with probability ϕ, with probability $\phi \cdot (1-\phi)^l > \phi/8$, $T \cap L_u \cap C = \{u\}$ is a singleton. In this case, by Lemma 10, $A^i_u = L_u$. As T is sampled for $10 \log n/\phi$ times, with high probability $A_u = L_u$. ◀

Here is a basic fact regarding large vertices.

▶ **Lemma 13.** *For any large vertex u, $\lambda_u < \kappa_u$.*

Proof. If $\lambda_u = \kappa_u$, then the latest min-cut should be contained in A_u, which contains at most $2/\phi$ vertices from $C \cap U_d$, and so u cannot be large. ◀

Next we analyze the behavior of the while-loop in ExploreTree.

▶ **Lemma 14.** *If $Q \neq \emptyset$, then for each $u \in Q$, $L_u \cap C \cap U_d = S$.*

Proof. Each time S is updated, either Q adds a vertex u on line-10 such that $L_u \cap C \cap U_d = S$, or Q is updated to $\{u\}$ on line-12. So the equality always holds. ◀

▶ **Lemma 15.** *At the beginning of any iteration of the while-loop, $\forall v \in S$, if v is large, then we have $L_v \cap C \cap U_d \subseteq S$.*

Proof. We prove this statement by induction on the number of iterations. Initially, this holds as $S = C \cap U_d$. For any intermediate iteration, consider two cases.

- u is small. We claim that before updating S, for all large vertices $v \in S \setminus (Q \cup L_u)$, L_v and $L_u \cup Q$ are disjoint; if this can be proved, then we conclude $L_v \cap C \cap U_d \subseteq S \setminus (Q \cup L_u)$, as $L_v \cap C \cap U_d \subseteq S$ holds before.
  Suppose that $L_v \cap L_u \neq \emptyset$. Then as all latest minimum cuts form a laminar family and that $v \notin L_u$, it must be $L_u \subseteq L_v$. As v is large, $L_v \cap C \cap U_d$ contains more vertices than $A_v \cap C \cap U_d$, and so by Lemma 13, we have $\lambda_v < \kappa_v$. Now, by line-4, since κ_u is the largest among all vertices in $S \setminus Q$, $\kappa_v \leq \kappa_u$. Finally, using Lemma 12, we know $\kappa_u = \lambda_u$ as u is small. Concatenating all the inequalities we have:

  $$\lambda_v < \kappa_v \leq \kappa_u = \lambda_u$$

  which contradicts the fact that $(L_u, V_{\mathcal{T}}[U] \setminus L_u)$ is a min-cut for (u, p) as $L_u \subseteq L_v$.
  Now suppose that $L_v \cap Q \neq \emptyset$, say $w \in L_v \cap Q$. Then by Lemma 14, $v \in S \subseteq L_w$, and so both w, v are in $L_v \cap L_w$, which means $L_v = L_w$, and so $L_v \cap L_u = L_w \cap L_u = L_u \neq \emptyset$, which is a contradiction as discussed just before.

- u is large. In this case, the algorithm would reassign $S \leftarrow L_u \cap C \cap U_d$. Then, for all $v \in S$, as $(L_v, V_{\mathcal{T}}[U] \setminus L_v)$ is the latest minimum cut, it must be $L_v \subseteq L_u$, irrespective of whether v is large or not. ◀

Next we prove that when the while-loop ends, either all vertices in S are small, or S corresponds to the cut of the lowest large node on $\mathcal{T}_p^d[C]$.

▶ **Lemma 16.** *If $|C \cap U_d \setminus S| > 2/\phi$, then all vertices in S are small.*

Proof. Consider any vertex $u \in S$. If u is large, then by Lemma 15, $L_u \cap C \cap U_d \subseteq S$, and so $|C \cap U_d \setminus L_u| \geq |C \cap U_d \setminus S| > 2/\phi$, which contradicts the definition of being large. ◀

▶ **Lemma 17.** *After the while-loop ends, if $|C \cap U_d \setminus S| \leq 2/\phi$ and $|Q| > 2/\phi$, then $(L, V_{\mathcal{T}}[U] \setminus L)$ is the latest min-cut of the lowest large node on $\mathcal{T}_p^d[C]$. Moreover, $B = \{u \in S \mid \kappa_u > \kappa\}$ is the set of all vertices u such that $L_u \cap C \cap U_d = S$, and consequently all $L_u, \forall u \in B$ are equal.*

Proof. As the while-loop ends with $|Q| > 2/\phi$, the last iteration must have ended on line-10. Therefore, $(L, V_{\mathcal{T}}[U] \setminus L)$ is the latest min-cut of some $u \in Q$. Suppose otherwise $(L, V_{\mathcal{T}}[U] \setminus L)$ is not the latest min-cut of the lowest large node on the imaginary tree $\mathcal{T}_p^d[C]$. Then, there exists a large vertex $v \in L \cap C \cap U_d$ such that $L_v \cap C \cap U_d \subsetneq S$ but $|C \cap U_d \setminus L_v| \leq 2/\phi$. As $|Q| > 2/\phi$, there must exist $w \in L_v \cap Q$. By Lemma 14, $v \in L \cap C \cap U_d = S = L_w \cap C \cap U_d$, so both v, w are in $L_v \cap L_w$, and consequently $L_v = L_w$, $L_v \cap C \cap U_d = S$, contradiction.

Now let us turn to the second half of the statement. Consider any $u \in B$. $(A_u, V_{\mathcal{T}}[U] \setminus A_u)$ cannot be a min-cut as $\kappa_u > \kappa$. By Lemma 12, u must be a large vertex. On the one hand, by Lemma 15, $L_u \cap C \cap U_d \subseteq S$, and on the other hand, $L_u \cap C \cap U_d$ cannot be strictly smaller than S as S is the lowest already. Hence $L_u \cap C \cap U_d = S$.

For any $u \notin B$, by definition $\kappa_u \leq \kappa$. If u is large, then $\lambda_u < \kappa_u \leq \kappa$, so $L_u \cap C \cap U_d \subsetneq S$, which also contradicts that S corresponds to the lowest large node on $\mathcal{T}_p^d[C]$. ◀

Finally, we prove that all cuts $(K_u, V_{\mathcal{T}}[U] \setminus K_u)$ output by the algorithm are latest min-cuts with high probability.

▶ **Lemma 18.** *All cuts $(K_u, V_{\mathcal{T}}[U] \setminus K_u)$ output by the algorithm are latest min-cuts with high probability.*

Proof. If the algorithm terminates on line-14, then by Lemma 16, all vertices in W_C are small. So by Lemma 12, $L_u = A_u = K_u, \forall u \in W_C$. Otherwise, if the algorithm terminates on line-21, then by Lemma 17, all vertices in W_C are small. Hence, by Lemma 12, $L_u = A_u = K_u, \forall u \in W_C \setminus B$; also, for any $u \in W_C \cap B$, we have $L_u = L = K_u$. ◀

3.4 Running time analysis

First we analyze the running time of each call of expander search.

▶ **Lemma 19.** *The total running time of the expander search in graph $G_{\mathcal{T}}[U]$ is bounded by $\widetilde{O}(\mathsf{MF}(\mathsf{vol}_G(U), |V_{\mathcal{T}}[U]|)/\phi)$.*

Proof. During the preparation step, each invocation of Lemma 10 induces a set of max-flow instances whose total size is bounded by $\widetilde{O}(|E_{\mathcal{T}}[U]|) = \widetilde{O}(\mathsf{vol}_G(U))$. Since it is repeated for $O(\log n/\phi)$ times, the total time is at most $\widetilde{O}(\mathsf{MF}(\mathsf{vol}_G(U), |V_{\mathcal{T}}[U]|)/\phi)$.

Next, let us analyze the cost of ExploreTree.

▷ Claim 20. After each iteration of the while-loop, the value of $|C \cap U_d \setminus S| + |Q|$ always increases by at least 1, so the total number of max-flow instances during the loop is bounded by $O(1/\phi)$.

Proof of claim. If an iteration ends on line-10, Q increases by one while S does not change. If an iteration of the while-loop ends on line-7, then on the one hand, by Lemma 14 we have $Q \subseteq S$; on the other hand, by the pseudo-code, $u \notin Q$ before updating S, Q. Hence, after line-7, $|C \cap U_d \setminus S| + |Q|$ increases by at least 1.

If an iteration ends on line-12, we claim that before updating S, Q, we have $L_u \cap Q = \emptyset$. In fact, by Lemma 14, for any $w \in Q$, $L_w \cap C \cap U_d = S$. By Lemma 15, as $L_u \cap C \cap U_d \neq S$, it must be $L_u \cap C \cap U_d \subsetneq S = L_w \cap C \cap U_d$. Hence, $w \notin L_u$. As w is arbitrary, we know $Q \cap L_u = \emptyset$. Therefore, after updating $S \leftarrow L_u \cap C \cap U_d$, $|C \cap U_d \setminus S|$ has increased by $|Q|$. Notice that after updating Q, $|Q| = 1$. So $|C \cap U_d \setminus S| + |Q|$ has increased by one. ◁

Since each while-loop conducts one max-flow in graph $G_{\mathcal{T}}[U]$, by the above claim, the total cost of the while-loop involves max-flow instances of total size $\widetilde{O}(\mathsf{vol}_G(U)/\phi)$, and the reduction time is dominated by the same amount. After the while-loop, the running time is linear in the size of output, so it is not the bottleneck. ◀

Next we analyze the running time during refinement of U.

▶ **Lemma 21.** *The total running time of cutting vertices (the for-loop on line-6 of CondGomoryHu) from U takes total time of $\widetilde{O}(\frac{n}{s} \cdot \mathsf{MF}(2d \cdot \mathsf{cnt}[i_U] \log^2 n, |V_{\mathcal{T}}[U]|))$.*

Proof. On the one hand, the number of clusters in $\mathcal{C}_{i_U}$ is at most n/s since each cluster has size at least s. So, by Lemma 19, the total time of expander search is $\widetilde{O}(\frac{n}{s} \cdot \mathsf{MF}(\mathsf{vol}_G(U)))$. By maximality of $d|U_d|$ and $\mathsf{cnt}[i_U]$, we have that:

$$\mathsf{vol}_G(U) \leq 2d|U_d| \log n \leq 2d \cdot \mathsf{cnt}[i_U] \log^2 n$$

Since the number of edges in $G_{\mathcal{T}}[U]$ is $\mathsf{vol}_G(U)$, the overall time complexity would be $\widetilde{O}(\frac{n}{s} \cdot \mathsf{MF}(2d \cdot \mathsf{cnt}[i_U] \log^2 n, |V_{\mathcal{T}}[U]|))$. ◀

To bound the total time across all different nodes of $\mathcal{T}$ that correspond to the same choice of (s, d), we need the following lemma.

▶ **Lemma 22.** *In any single iteration of the while-loop on line-2 of CondGomoryHu, over all different nodes U of $\mathcal{T}$ that correspond to the same choice of (s, d), we have $\sum_U \mathsf{cnt}[i_U] \leq 4sn/d$.*

Proof. If $s \geq d/4$, then since all such nodes U are packing disjoint subsets of vertices of V, $\sum_U \mathsf{cnt}[i_U] \leq n \leq 4sn/d$. So next we only consider the case where $s < d/4$.

When $s < d/4$, we can upper bound the total number of vertices in clusters in $\mathcal{C}_{i_U}$ whose degrees in G are within the interval $[d, 2d)$. Take any cluster $C \in \mathcal{C}_{i_U}$ and any vertex $u \in C \cap U_d$. Since $|C| < 2s = d/2$ and G is a simple graph, at least $d/2$ of u's neighbors in G are outside of C. So the crossing edges contributed by u is at least $d/2$. By property (3) of the Definition 8, the total number of crossing edges should be bounded as:

$$\begin{aligned}\sum_{C \in \mathcal{C}_{i_U}} \mathsf{out}_G(C) &\leq \log^7 n \cdot \phi \cdot \sum_{C \in \mathcal{C}_{i_U}} \mathsf{vol}_G(C) \leq \log^7 n \cdot \phi \cdot \sum_{C \in \mathcal{C}_{i_U}} (4s^2 + \mathsf{out}_G(C)) \\ &\leq 4 \log^7 n \cdot \phi sn + \log^7 n \cdot \phi \sum_{C \in \mathcal{C}_{i_U}} \mathsf{out}_G(C)\end{aligned}$$

As $\phi = \frac{1}{10\log^{c+10} n}$, we have $\sum_{C\in\mathcal{C}_{i_U}} \mathsf{out}_G(C) \le 8\log^7 n \cdot \phi sn < sn$. As each vertex in $C \cap U_d$ contributes $d/2$ to the above summation, the total number of vertices from U_d in $\mathcal{C}_{i_U}$ is bounded by $2sn/d$. ◀

Combining the above two lemmas gives the following corollary.

▶ **Corollary 23.** *Under Hypothesis 1, the time of dividing all nodes of $\mathcal{T}$ for a single iteration of the while-loop on line-2 in* CondGomoryHu *is bounded by $\widetilde{O}(n^2)$.*

The next thing would be analyzing the total number of rounds of the while-loop. Similar to [3], we first need to prove that with high probability, the number of $u \in C \cup U_d$ such that $\mathsf{vol}_G(K_u) > 0.5\mathsf{vol}_G(U)$ is roughly at most $|U_d|/r$.

▶ **Lemma 24.** *With high probability over the choice of $R \subseteq N$, the total number of $u \in U_d$ such that $\mathsf{vol}_G(L_u \cap U) > 0.5\mathsf{vol}_G(N)$ is at most $\frac{4|U_d|\log^2 n}{r}$.*

Proof. The proof is similar to the one in [3]. To avoid confusion, let $\mathcal{T}^{\text{old}}$ be the version of $\mathcal{T}$ before refining with respect to R, and let $\mathcal{T}$ refer to the tree after refinement. For each pair of vertices in the super node $x, q \in N$, define $(\Gamma^q_x, V_{\mathcal{T}^{\text{old}}}[N] \setminus \Gamma^q_x)$ to be the latest minimum cut of (x, q) in $G_{\mathcal{T}^{\text{old}}}[N]$. Define M^q_x to be the set of all vertices $y \in N$ such that $x \in \Gamma^q_y$. Basic concentration inequalities show that for any q, x, if $\mathsf{vol}_G(M^q_x) \ge \frac{\log n}{r}\mathsf{vol}_G(N)$, then with high probability, $M^q_x \cap R \neq \emptyset$.

The following claim is a crucial relationship between Γ^p_u and L_u.

▷ Claim 25 (Observation 4.3 in [3]). $\Gamma^p_u \cap U = L_u \cap U$.

Proof of claim. As $(L_u, V_{\mathcal{T}}[U] \setminus L_u)$ is the latest minimum cut in $G_{\mathcal{T}}[U]$ which is a contracted graph of $G_{\mathcal{T}^{\text{old}}}[N]$ following standard Gomory-Hu steps, $(L_u, V_{\mathcal{T}}[U] \setminus L_u)$ is a min-cut for (u, p) in $G_{\mathcal{T}^{\text{old}}}[N]$. Since $(\Gamma^p_u, V_{\mathcal{T}^{\text{old}}}[N] \setminus \Gamma^p_u)$ is the latest minimum cut in $G_{\mathcal{T}^{\text{old}}}[N]$, we have $\Gamma^p_u \cap U \subseteq L_u \cap U$. Next we only focus on the other direction.

Let $W_1, W_2, \cdots, W_l \subseteq V_{\mathcal{T}^{\text{old}}}[N]$ be all contracted vertices of $V_{\mathcal{T}}[U]$ which are crossed by Γ^p_u; in other words, $\Gamma^p_u \cap W_i \neq \emptyset$ and $W_i \setminus \Gamma^p_u \neq \emptyset$ for all $1 \le i \le l$. Since N is refined using pivots from R, according to Lemma 6, we know that for each i there exists a pivot $q_i \in R \cap W_i$ such that $(W_i, V_{\mathcal{T}^{\text{old}}}[N] \setminus W_i)$ is a minimum cut for (q_i, p); in fact, $q_i \in R \cap W_i$ are in the neighboring nodes of U in $\mathcal{T}$.

We claim that $q_i \in \Gamma^p_u$; otherwise if $q_i \notin \Gamma^p_u$, as $u \notin W_i$, by Lemma 4, the cut $(X, V_{\mathcal{T}^{\text{old}}}[N] \setminus X)$ where $X = \Gamma^p_u \setminus W_i$ is also a minimum cut for (u, p), which contradicts that $(\Gamma^p_u, V_{\mathcal{T}^{\text{old}}}[N] \setminus \Gamma^p_u)$ is the latest min-cut.

Construct a new cut $(Y, V_{\mathcal{T}^{\text{old}}}[N] \setminus Y)$ where $Y = \Gamma^p_u \cup \bigcup_{i=1}^{l} W_i$. On the one hand, as $q_i \in \Gamma^p_u, \forall i$, by repeatedly applying Lemma 3 we know $(Y, V_{\mathcal{T}^{\text{old}}}[N] \setminus Y)$ is a minimum cut for (u, p) as well; On the other hand, Y does not cross any contracted nodes in $G_{\mathcal{T}}[U]$, so $(Y, V_{\mathcal{T}}[U] \setminus Y)$ is a valid cut in $G_{\mathcal{T}}[U]$ as well. As $(L_u, V_{\mathcal{T}}[U] \setminus L_u)$ is the latest cut in $G_{\mathcal{T}}[U]$, we know $L_u \cap U \subseteq Y \cap U = \Gamma^p_u \cap U$. This concludes our proof. ◁

Consider the set of all $u \in U_d$ such that $\mathsf{vol}_G(L_u \cap U) > 0.5\mathsf{vol}_G(N)$; let them be $u_1, u_2, \cdots, u_l$. By the above claim, it must be $\mathsf{vol}_G(\Gamma^p_{u_i} \cap N) \ge \mathsf{vol}_G(\Gamma^p_{u_i} \cap U) = \mathsf{vol}_G(L_{u_i} \cap U) > 0.5\mathsf{vol}_G(N)$ as well. Therefore, any two sets $\Gamma^p_{u_i}, \Gamma^p_{u_j}$ must intersect. Since $(\Gamma^p_{u_i}, V_{\mathcal{T}^{\text{old}}}[N] \setminus \Gamma^p_{u_i})$ are latest cuts with respect to the same pivot p, they should form a total order, say $\Gamma^p_{u_1} \subseteq \Gamma^p_{u_2} \subseteq \cdots \Gamma^p_{u_l}$, and so by definition $u_2, u_3, \cdots, u_l \in M^p_{u_1}$.

▷ Claim 26. $M^p_{u_1} \cap R = \emptyset$.

Proof of claim. If $\exists w \in M^p_{u_1} \cap R$, then by definition, $u \in \Gamma^p_w$. As $(\Gamma^p_w, V_{\mathcal{T}^{\text{old}}}[N] \setminus \Gamma^p_w)$ is the latest min-cut for (w,p) in $G_{\mathcal{T}^{\text{old}}}[N]$, any min-cut for (w,p) in $G_{\mathcal{T}^{\text{old}}}[N]$ should contain u on the same side as w. By Lemma 6, u should belong to the part which contains w after the refinement with respect to R, which makes a contradiction as u stays with p in the same part. ◁

By the above lemma, we know $\mathsf{vol}_G(M^p_{u_1}) < \frac{\log n}{r}\mathsf{vol}_G(N)$, and hence we have:

$$d(l-1) \le \mathsf{vol}_G(M^p_{u_1}) < \frac{\log n}{r}\mathsf{vol}_G(N) \le \frac{2\log n}{r}\mathsf{vol}_G(U) \le \frac{4\log^2 n}{r}d|U_d|$$

So $l \le \frac{4|U_d|\log^2 n}{r}$. ◀

Finally we need to bound the total number of rounds in the while-loop. Call a cluster $C \in \mathcal{C}_{i_U}$ **bad**, if the total number of vertices $u \in C \cap U_d$ such that $\mathsf{vol}_G(L_u \cap U) > 0.5\mathsf{vol}_G(N)$ is more than $0.1|C \cap U_d|$; otherwise it is called **good**.

▶ **Lemma 27.** *Consider any invocation of ExploreTree with input parameters U, p, d, C. Suppose cluster C is good, then $|W_C| > 0.8|C \cap U_d|$.*

Proof. First consider the case where ExploreTree terminated on line-14. The while-loop must have terminated on line-7. Then as u is small, $|S| \ge |C \cap U_d| - 2/\phi - |Q| - |C \cap L_u \cap U_d| \ge |C \cap U_d| - 6/\phi$. Therefore, $|W_C| \ge |C \cap U_d| - 6/\phi - 0.1|C \cap U_d| > 0.8|C \cap U_d|$.

Now suppose ExploreTree terminated on line-21. In this case, $C \cap U_d \setminus W_C$ only includes vertices in $C \cap U_d \setminus S$, plus vertices $v \in C \cap U_d$ such that $\mathsf{vol}_G(L_v \cap U) > 0.5\mathsf{vol}_G(N)$. Since C is good, we know $|W_C| \ge |C \cap U_d| - 2/\phi - 0.1|C \cap U_d| > 0.8|C \cap U_d|$. ◀

▶ **Lemma 28.** $\sum_{C \in \mathcal{C}_{i_U} \text{ is bad}} |C \cap U_d| \le \frac{40|U_d|\log^2 n}{r}$.

Proof. By Lemma 24, the total number of vertices u such that $\mathsf{vol}_G(L_u \cap U) > 0.5\mathsf{vol}_G(N)$ is at most $\frac{4|U_d|\log^2 n}{r}$. By definition of badness, we have $\sum_{C \in \mathcal{C}_{i_U} \text{ is bad}} |C \cap U_d| \le \frac{40|U_d|\log^2 n}{r}$. ◀

▶ **Lemma 29.** *For each node U such that $\mathsf{vol}_G(U) > 0.5\mathsf{vol}_G(N)$, and for each set $K_u = L_u$ which is cut off by our algorithm, we have $\mathsf{vol}_G(K_u \cap U) \le 0.5\mathsf{vol}_G(N)$. Furthermore, let P be the rest of U after cutting all K_u's. Then $\mathsf{vol}_G(P) \le (1 - \frac{1}{2\log^2 n})\mathsf{vol}_G(U)$.*

Proof. The first half of the claim is automatically guaranteed by the algorithm. Let us only consider the second half.

By Lemma 27, the total volume that has been cut off from U is at least

$$\begin{aligned}\sum_{C \in \mathcal{C}_{i_U} \text{ is good}} d|W_C| &\ge \sum_{C \in C_{i_U} \text{ is good}} 0.8d|C \cap U_d| \ge \frac{0.8d}{\log n}|U_d| - 0.8d \sum_{C \in \mathcal{C}_{i_U} \text{ is bad}} |C \cap U_d| \\ &\ge \frac{0.8d}{\log n}|U_d| - \frac{32d\log^2 n}{r}|U_d| \ge \frac{0.8}{\log^2 n}\mathsf{vol}_G(U) - \frac{32}{\log^3 n}\mathsf{vol}_G(U) \\ &\ge \frac{1}{2\log^2 n}\mathsf{vol}_G(U)\end{aligned}$$

Hence, the volume of $\mathsf{vol}_G(P)$ is reduced by a factor of at most $1 - \frac{1}{2\log^2 n}$. ◀

By Lemma 29, after each round of the while-loop, for each node $U \subseteq N$, either we already have $\mathsf{vol}_G(U) \le 0.5\mathsf{vol}_G(N)$ after the refinement with respect to random set R, or U is further divided into sub-nodes whose volume are at most $\max\{0.5\mathsf{vol}_G(N), (1 - \frac{1}{2\log^2 n})\mathsf{vol}_G(U)\}$. Therefore the number of rounds is at most $\log^3 n$. So the total running time should be $\widetilde{O}(n^2)$ as well under Hypothesis 1.

4 Unconditional cut-equivalent trees

4.1 The main algorithm

In this section we will prove the second half of Theorem 2 using existing max-flow algorithms. The algorithm is mostly the same as the previous algorithm conditioning on Hypothesis 1, and the extra work is to deal with the additive $n^{1.5}$ term that appears in the running time of max-flow algorithm from [6]. Similar to the previous algorithm, we will also use the same set of parameters ϕ, r, and use degree set $\mathcal{D} = \{\sqrt{n}, 2\sqrt{n}, 2^2\sqrt{n}, \cdots, n\}$.

Preparation

Throughout the algorithm, $\mathcal{T}$ will be the cut-equivalent tree under construction, where each of $\mathcal{T}$'s node will represent a subset of vertices of V. As a preparation step, compute a (ϕ, ϕ)-expander decomposition on G and obtain a partitioning $\mathcal{C} = \{C_1, C_2, \cdots, C_k\}$ of V. Categorize clusters in $\mathcal{C}$ according to their sizes: for each 2^i, define $\mathcal{C}_i$ to be the set of clusters whose sizes are within interval $[2^i, 2^{i+1})$.

Iteration

In each round, the algorithm tries to simultaneously subdivide all nodes of $\mathcal{T}$ which contains at least $20r$ vertices in V. Following the same procedure as in the previous algorithm, for each node N of $\mathcal{T}$, further refine N into a set of smaller sub-nodes. Then, for each such sub-node U, define variables d, U_d and $s = 2^{i_U}$ accordingly. If (1) $d \geq n^{3/4}$ or (2) $s > n^{3/4}/\sqrt{d}$, we would continue to the do same as in algorithm CondGomoryHu which invokes the expander search procedure.

The unconditional algorithm diverges from the conditional algorithm in Theorem 2 from here if $d < n^{3/4}$ and $s \leq n^{3/4}/\sqrt{d}$. Intuitively, when s is relatively small, the number of expanders whose sizes are roughly s would be large, and so expander searches would be costly because of the additive term $n^{1.5}$ in the running time of computing max-flow. What we would do is to directly apply Lemma 7 on graph $G_{\mathcal{T}}[U]$ to isolate all vertices in U_d on the tree $\mathcal{T}$ once and for all. The pseudo-code is summarized as GomoryHu.

4.2 Running time analysis

▶ **Lemma 30.** *Each round of the while-loop in GomoryHu takes time* $\widetilde{O}(n^{17/8})$.

Proof. Let us study an arbitrary iteration. Suppose the condition on line-6 holds, namely $d \geq n^{3/4}$ or $s > n^{3/4}/\sqrt{d}$. Then in this case we would do exactly the same as in the conditional algorithm, and the only difference we are invoking the max-flow algorithm from [6]. According to Lemma 21, we could upper bound the running time as

$$\widetilde{O}(\frac{n}{s} \cdot \mathsf{MF}(2d \cdot \mathsf{cnt}[i_U] \log^2 n, |V_{\mathcal{T}}[U]|)) = \widetilde{O}(\frac{nd}{s}\mathsf{cnt}[i_U] + \frac{n}{s} \cdot |V_{\mathcal{T}}[U]|^{1.5})$$

for each node U. Since all tree nodes U are disjoint vertex subsets of V, $\sum_{U \in \mathcal{T}} |V_{\mathcal{T}}[U]|^{1.5} \leq n^{1.5}$. Therefore, by Lemma 22, this sums to $\widetilde{O}(n^2 + \frac{n^{2.5}}{s})$.

Algorithm 3 GomoryHu($G = (V, E)$).

```
1  initialize a partition tree 𝒯, as well as parameters φ, r;
2  while ∃N ⊆ V, U a node of 𝒯, |N| ≥ 20r do
3      for node N of 𝒯 with |N| ≥ 20r do
4          repeat for 10r times: each time we sample a vertex u ∈ N with probability
             deg_G(u) / vol_G(N), and let the sampled set be R;
5          call Lemma 5 on node N with respect to R;
6          for node U ⊆ N of 𝒯 such that vol_G(U) > 0.5 vol_G(N) do
7              take d such that d|U_d| is maximized;
8              take s = 2^{i_U} such that cnt[i_U] is maximized;
9              if d ≥ n^{3/4} or s > n^{3/4}/√d then
10                 for each C ∈ 𝒞_{i_U} do
11                     run expander search on C within node U to compute a subset
                         W_C ⊆ C ∩ U_d, and the latest min-cuts (K_u, V_𝒯[U] \ K_u) for each
                         u ∈ W_C;
12                 define W = ⋃_{C∈𝒞_{i_U}} W_C;
13                 for each u ∈ W such that K_u is maximal, split K_u ∩ U off of U and
                     create a new node on 𝒯;
14             else
15                 apply Lemma 7 on the auxiliary graph G_𝒯[U] with input parameter
                     k = 2d, so that all vertices in U_d become singletons in 𝒯;
16 for node U of 𝒯 such that |U| < 20r do
17     repeatedly refine U using the generic Gomory-Hu steps until all nodes are
         singletons;
18 return 𝒯 as a cut-equivalent tree;
```

We first claim that $s \geq \sqrt{2d}$. In fact, by maximality of $\mathsf{cnt}[i_U]$, there exists at least one cluster $C \in \mathcal{C}_{i_U}$ that intersects U_d. Take any $u \in C \cap U_d$. Then since G is a simple graph, more than $d - s$ neighbors of u are outside of C, thus $\mathsf{out}_G(C) > d - s$. By property (3) of Definition 8, we have:

$$\mathsf{out}_G(C) \leq \log^7 n \cdot \phi \mathsf{vol}_G(C) \leq \log^7 n \cdot \phi(4s^2 + \mathsf{out}_G(C))$$

As $\phi = \frac{1}{10 \log^{c+10}}$, we have $\mathsf{out}_G(C) \leq 0.4s^2 + 0.1\mathsf{out}_G(C)$, and so $\mathsf{out}_G(C) < 0.5s^2$. As $\mathsf{out}_G(C) > d - s$, we have $s > \sqrt{2d}$.

When $d \geq n^{3/4}$, as $s \geq \sqrt{2d} > n^{3/8}$ we have $\widetilde{O}(n^2 + \frac{n^{2.5}}{s}) = \widetilde{O}(n^{17/8})$. If $d < n^{3/4}$ and $s > n^{3/4}/\sqrt{d}$, then we also bound the total running time as $\widetilde{O}(n^2 + \frac{n}{s\phi} \cdot n^{1.5}) = \widetilde{O}(n^{17/8})$.

Now suppose the condition on line-6 does not hold, then $d < n^{3/4}$ and $s \leq n^{3/4}/\sqrt{d}$. In this case, similar to Lemma 22, we can prove that the total volume $\mathsf{vol}_G(U)$ over all different U's is bounded by $\widetilde{O}(ns)$. So applying Lemma 7 in this round takes time at most $\widetilde{O}(nsd) = \widetilde{O}(n^{17/8})$. ◀

▶ **Lemma 31.** *The total number of rounds of the while-loop in GomoryHu is bounded by* $O(\log^3 n)$.

Proof. If each round of the while-loop, if $d \geq n^{3/4}$ or $s > n^{3/4}/\sqrt{d}$ for node U, then according to the proof of Lemma 29, the volume of each subdivision is bounded by $\max\{0.5\mathsf{vol}_G(N), (1-\frac{1}{2\log^2 n})\mathsf{vol}_G(U)\}$. If $d < n^{3/4}$ and $s \leq n^{3/4}/\sqrt{d}$, then all vertices in U_d become singletons on $\mathcal{T}$; also, and for the same reason, all subdivision of U should be at most $(1-\frac{1}{2\log^2 n})\mathsf{vol}_G(U)$. Therefore, the number of while-loop iterations is at most $O(\log^3 n)$. ◀

Abstract

We develop value iteration-based algorithms to solve in a unified manner different classes of combinatorial zero-sum games with mean-payoff type rewards. These algorithms rely on an oracle, evaluating the dynamic programming operator up to a given precision. We show that the number of calls to the oracle needed to determine exact optimal (positional) strategies is, up to a factor polynomial in the dimension, of order R/sep, where the "separation" sep is defined as the minimal difference between distinct values arising from strategies, and R is a metric estimate, involving the norm of approximate sub and super-eigenvectors of the dynamic programming operator. We illustrate this method by two applications. The first one is a new proof, leading to improved complexity estimates, of a theorem of Boros, Elbassioni, Gurvich and Makino, showing that turn-based mean payoff games with a fixed number of random positions can be solved in pseudo-polynomial time. The second one concerns entropy games, a model introduced by Asarin, Cervelle, Degorre, Dima, Horn and Kozyakin. The *rank* of an entropy game is defined as the maximal rank among all the ambiguity matrices determined by strategies of the two players. We show that entropy games with a fixed rank, in their original formulation, can be solved in polynomial time, and that an extension of entropy games incorporating weights can be solved in pseudo-polynomial time under the same fixed rank condition.

1 Introduction

1.1 Motivation

Deterministic and turn-based stochastic Mean Payoff games are fundamental classes of games with an unsettled complexity. They belong to the complexity class NP ∩ coNP [21, 47] but they are not known to be polynomial-time solvable. Various algorithms have been developed and analyzed. The pumping algorithm is a pseudo-polynomial iterative scheme introduced by

Gurvich, Karzanov and Khachyan [25] to solve the optimality equation of deterministic mean payoff games. Zwick and Paterson [47] derived peudo-polynomial bounds for the same games by analyzing value iteration. Friedmann showed that policy iteration, originally introduced by Hoffman and Karp in the setting of zero-sum games [26], and albeit being experimentally fast on typical instances, is generally exponential [22]. We refer to the survey of [9] for more information and additional references.

Entropy games have been introduced by Asarin et al. [10]. They are combinatorial games, in which one player, called Tribune, wants to maximize a topological entropy, whereas its opponent, called Despot, wishes to minimize it. This topological entropy quantifies the freedom of a half-player, called People. Although the formalization of entropy game is recent, specific classes or variants of entropy games appeared earlier in several fields, including the control of branching processes, population dynamics and growth maximization [42, 38, 37, 46], risk sensitive control [27, 8], mathematical finance [5], or matrix multiplication games [10]. Asarin et al. showed that entropy games also belong to the class NP $\cap$ coNP. Akian et al. showed in [1] that entropy games reduce to ordinary stochastic mean payoff games with infinite action spaces (actions consist of probability measures and the payments are given by relative entropies), and deduced that the subclass of entropy games in which Despot has a fixed number of significant positions (positions with a non-trivial choice) can be solved in polynomial time. The complexity of entropy games without restrictions on the number of (significant) Despot positions is an open problem.

1.2 Main Results

We develop value iteration-based algorithms to solve in a unified manner different classes of combinatorial zero-sum games with mean-payoff type rewards. These algorithms rely on an oracle, evaluating approximately the dynamic programming operator of the game. Our main results include universal estimates, providing explicit bounds for the error of approximation of the value, as a function of two characteristic quantities, of a metric nature. The first one is the *separation* sep, defined as the minimal difference between distinct values induced by (positional) strategies. The second one, R, is defined in terms the norm of approximate sub and super-optimality certificates. These certificates are vectors, defined as sub or super-solutions of non-linear eigenproblems. For games such that the mean payoff is independent of the initial state, we show that (exact) optimal strategies can be found in a number of calls to the oracle bounded by the ratio R/sep, up to a factor polynomial in the number of states, see Theorems 10 and 18. We also obtain a similar complexity bound for games in which the mean payoff does depend on the initial state, under additional assumptions.

We provide two applications of this method.

The first application is a new proof of an essential part of the theorem of Boros, Elbassioni, Gurvich and Makino [16], showing that turn-based stochastic mean payoff games with a fixed number of random positions can be solved in pseudo-polynomial time. The original proof relies on a deep analysis of a generalization to the stochastic case of the "pumping algorithm" of [25]. Our analysis of value iteration leads to improved complexity estimates. Indeed, we bound the characteristic numbers R and sep in a tight way, by exploiting bit-complexity estimates for the solutions of Fokker–Planck and Poisson-type equations of discrete Markov chains.

The second application concerns entropy games. Let us recall that in such a game, the value of a pair of (positional) strategies of the two players is given by the Perron root of a certain principal submatrix of a nonnegative matrix, which we call the *ambiguity matrix*,

as it measures the number of nondeterministic choices of People. We show that entropy games with a fixed rank, and in particular, entropy games with a fixed number of People's states, can be solved in pseudo-polynomial time; see Corollary 32. These results concern the extended model of entropy games introduced in [1], taking into account weights. Then, entropy games in the sense of [10] (implying a unary encoding of weights) that have a fixed rank can be solved in polynomial time. These results rely on separation bounds for algebraic numbers arising as the eigenvalues of integer matrices with a fixed rank.

1.3 Related Work

The idea of applying value iteration to analyze the complexity of deterministic mean-payoff games goes back to the classical work of Zwick and Paterson [47]. In some sense, the present approach extends this idea to more general classes of games. When specialized to stochastic mean payoff games with perfect information, our bounds should be compared with the ones of Boros, Elbassioni, Gurvich, and Makino [16, 15]. The authors of [16] generalize the "pumping" algorithm, developed for deterministic games by Gurvich, Karzanov, and Khachiyan [25], to the case of stochastic games. The resulting algorithm is also pseudopolynomial if the number of random positions is fixed, see Remark 26 for a detailed comparison. The algorithm of Ibsen-Jensen and Miltersen [28] yields a stronger bound in the case of simple stochastic games, still assuming that the number of random positions is fixed. A different approach, based on an analysis of strategy iteration, was developed by Gimbert and Horn [24] and more recently by Auger, Badin de Montjoye and Strozecki [11]. The value iteration algorithm for concurrent mean payoff games, under an ergodicity condition, has been studied by Chatterjee and Ibsen-Jensen [19]. Theorem 18 there bounds the number of iterations needed to get an ϵ-approximation of the mean-payoff. When specialized to this case, Theorem 13 below improves this bound by a factor of $|\log \epsilon|$.

We build on the operator approach for zero-sum games, see [13, 34, 36]. Our study of entropy games is inspired by the works of Asarin et al. [10] and Akian et al. [1]. We rely on the existence of optimal positional strategies for entropy games, established in [1] by an o-minimal geometry approach [14] and also, on results of non-linear Perron–Frobenius theory, especially the Collatz–Wielandt variational formulation of the escape rate of an order preserving and additively homogeneous mapping [35, 23, 2, 4].

The present work, providing complexity bounds based on value iteration, grew out from an effort to understand the surprising speed of value iteration on random stochastic games examples arising from tropical geometry [7], by investigating suitable notions of condition numbers [6]. An initial version of some of the present results (concerning turn based stochastic games) appeared in the PhD thesis of one of the authors [40].

1.4 Organization of the Paper

In Section 2 we recall the definitions and basic properties of turn-based stochastic mean payoff games and entropy games, and also key notions in the "operator approach" of zero-sum games, including the Collatz–Wielandt optimality certificates.

The universal complexity bounds based on value iteration are presented in Section 3. First, we deal with games whose value is independent of the initial state, and then, we extend these results to determine the set of initial states with a maximal value.

The applications to turn-based stochastic mean payoff games and to entropy games are provided in Section 4 and Section 5. The detailed proofs can be found in the extended version of the present paper.

2 Preliminaries on Dynamic Programming Operators and Games

2.1 Introducing Shapley Operators: The Example of Stochastic Turn-Based Zero-Sum Games

Shapley operators are the two-player version of the Bellman operators (a.k.a. dynamic programming or one-day operators) which are classically used to study Markov decision processes. In this section, we introduce the simplest example of Shapley operator, arising from stochastic turn-based zero-sum games.

A *stochastic turn-based zero-sum game* is a game played on a digraph $(\mathscr{V}, \mathscr{E})$ in which the set of vertices $\mathscr{V}$ has a non-trivial partition $\mathscr{V} = \mathscr{V}_{\mathrm{Min}} \uplus \mathscr{V}_{\mathrm{Max}} \uplus \mathscr{V}_{\mathrm{Nat}}$. There are two players, called *Min* and *Max*, and a half-player, *Nature*. The sets $\mathscr{V}_{\mathrm{Min}}$, $\mathscr{V}_{\mathrm{Max}}$ and $\mathscr{V}_{\mathrm{Nat}}$ represent the sets of states at which Min, Max, and Nature respectively play. The set of edges $\mathscr{E}$ represents the allowed moves. We assume $\mathscr{E} \subset \mathscr{V}_{\mathrm{Min}} \times \mathscr{V}_{\mathrm{Max}} \cup \mathscr{V}_{\mathrm{Max}} \times \mathscr{V}_{\mathrm{Nat}} \cup \mathscr{V}_{\mathrm{Nat}} \times \mathscr{V}_{\mathrm{Min}}$, meaning that Min, Max, and Nature alternate their moves. More precisely, a turn consists of three successive moves: when the current state is $j \in \mathscr{V}_{\mathrm{Min}}$, Min selects and edge (j, i) in $\mathscr{E}$ and the next state is $i \in \mathscr{V}_{\mathrm{Max}}$. Then, Max selects an edge (i, k) in $\mathscr{E}$ and the next state is $k \in \mathscr{V}_{\mathrm{Nat}}$. Next, Nature chooses an edge $(k, j') \in \mathscr{E}$ and the next state is $j' \in \mathscr{V}_{\mathrm{Min}}$. This process can be repeated, alternating moves of Min, Max, and Nature.

We make the following assumption.

▶ **Assumption 1.** *Each player has at least one available action in each state in which he has to play, i.e., for all $j \in \mathscr{V}_{\mathrm{Min}}, i \in \mathscr{V}_{\mathrm{Max}}$, and $k \in \mathscr{V}_{\mathrm{Nat}}$, the sets $\{i' \colon (j, i') \in \mathscr{E}\}$, $\{k' \colon (i, k') \in \mathscr{E}\}$ and $\{j' \colon (k, j') \in \mathscr{E}\}$ are non-empty.*

Furthermore, every state $k \in \mathscr{V}_{\mathrm{Nat}}$ controlled by Nature is equipped with a probability distribution on its outgoing edges, i.e., we are given a vector $(P_{kj})_{j \in \mathscr{V}_{\mathrm{Min}}}$ with rational entries such that $P_{kj} \geqslant 0$ for all i and $\sum_{(k,j) \in \mathscr{E}} P_{kj} = 1$. We suppose that Nature makes its decisions according to this probability distribution, i.e., it chooses an edge (k, j) with probability P_{kj}. Moreover, we are given two integer matrices $A, B \in \mathbb{Z}^{\mathscr{V}_{\mathrm{Max}} \times \mathscr{V}_{\mathrm{Min}}}$. These matrices encode the payoffs of the game in the following way: if the current state of the game is $j \in \mathscr{V}_{\mathrm{Min}}$ and Min selects an edge (j, i), then Player Min pays to Max the amount $-A_{ij}$. Similarly, if the current state of the game is $i \in \mathscr{V}_{\mathrm{Max}}$ and Max selects an edge (i, k), then Max receives from Min the payment B_{ik}.

We first consider the *game in horizon N*, in which each of the two players Min and Max makes N moves, starting from a known initial state, which by convention we require to be controlled by Min. In this setting, a *history* of the game consists of the sequence of states visited up to a given stage. A *strategy* of a player is a function which assigns to a history of the game a decision of this player. A pair of strategies (σ, τ) of players Min and Max induces a probability measure on the set of finite sequences of states. Then, the expected reward of Max, starting from the initial position j_0, is defined by

$$R_{j_0}(\sigma, \tau) \coloneqq \mathbb{E}_{\sigma\tau}\Big(\sum_{p=0}^{N-1} (-A_{i_p j_p} + B_{i_p k_p})\Big)\,,$$

in which the expectation $\mathbb{E}_{\sigma,\tau}$ refers to the probability measure induced by (σ, τ), and $j_0, i_0, k_0, j_1, i_1, k_1, \dots$ is the random sequence of states visited when applying this pair of strategies. The objective of Max is to maximize this reward, while Min wants to minimize it. The game in horizon N starting from state j is known to have a *value* v_j^N and optimal strategies σ^* and τ^*, meaning that

$$R_j(\sigma^*, \tau) \leqslant v_j^N \coloneqq R_j(\sigma^*, \tau^*) \leqslant R_j(\sigma, \tau^*)\,,$$

for all strategies σ of Min and τ of Max. The *value vector* $v^N := (v^N_j)_{j\in\mathscr{V}_{\mathrm{Min}}}$ keeps track of the values of all initial states. A classical dynamic programming argument, see e.g. [33, Th. IV.3.2], shows that

$$v^0 = 0, \qquad v^N = F(v^{N-1}),$$

where the *Shapley operator* F is the map from $\mathbb{R}^{\mathscr{V}_{\mathrm{Min}}}$ to $\mathbb{R}^{\mathscr{V}_{\mathrm{Min}}}$ defined by

$$F_j(x) := \min_{(j,i)\in\mathscr{E}} \Big(-A_{ij} + \max_{(i,k)\in\mathscr{E}} \big(B_{ik} + \sum_{(k,l)\in\mathscr{E}} P_{kl}x_k\big)\Big), \text{ for all } j \in \mathscr{V}_{\mathrm{Min}}. \tag{1}$$

Assumption 1 guarantees that F is well defined. One can also consider the *mean-payoff* stochastic game, in which the payment $g_{j_0}(\sigma,\tau)$ received by Player Max becomes the limiting average of the sum of instantaneous payments, i.e.,

$$g_{j_0}(\sigma,\tau) := \liminf_{N\to+\infty} \mathbb{E}_{\sigma\tau}\Big(\frac{1}{N}\sum_{p=0}^{N-1}(-A_{i_pj_p} + B_{i_pk_p})\Big). \tag{2}$$

We say that a strategy is *positional* if the decision of the player depends only of the current state. A result of Liggett and Lippman [31] entails that a mean payoff game has a value χ_j and that there exists a pair of optimal positional strategies (σ^*,τ^*), meaning that

$$g_j(\sigma^*,\tau) \leqslant \chi_j := g_j(\sigma^*,\tau^*) \leqslant g_j(\sigma,\tau^*),$$

for every initial state $j \in \mathscr{V}_{\mathrm{Min}}$ and pair of non-necessarily positional strategies (σ,τ) of players Min and Max. A result of Mertens and Neyman [32] entails in particular that the value of the mean-payoff game coincides with the limit of the normalized value of the games in horizon N, i.e.,

$$\chi = \lim_{N\to\infty} \frac{v^N}{N} = \lim_{N\to\infty} \frac{F^N(0)}{N},$$

where $F^N = F\circ\cdots\circ F$ denotes the Nth iterate of F and 0 the vector that has all entries equal to 0.

▶ Remark 1. In our model, players Min, Max, and Nature play successively, so that a turn decomposes in three stages, resulting in a Shapley operator of the form (1). Alternative models, like the one of [16], in which a turn consists of a single move, reduce to our model by adding linearly many dummy states, and rescaling the mean payoff by a factor 3.

2.2 The Operator Approach to Zero-Sum Games

We shall develop a general approach, which applies to various classes of zero-sum games with a mean-payoff type payment. To do so, it is convenient to introduce an abstract version of Shapley operators, following the "operator approach" of stochastic games [36, 34]. This will allow us to apply notions from nonlinear Perron–Frobenius theory, especially sub and super eigenvectors, and Collatz-Wielandt numbers, which play a key role in our analysis.

Recall that the sup-norm is defined by $\|x\|_\infty := \max_{i\in[n]} |x_i|$. We also use the *Hilbert's seminorm* [23], which is defined by $\|x\|_{\mathrm{H}} := \mathbf{t}(x) - \mathbf{b}(x)$, where $\mathbf{t}(x) := \max_{i\in[n]} x_i$ (read "top") and $\mathbf{b}(x) := \min_{i\in[n]} x_i$ (read "bottom"). We endow $\mathbb{R}$ with the standard order $\leqslant$, which is extended to vectors entrywise.

A self-map F of $\mathbb{R}^n$ is said to be *order-preserving* when

$$x \leqslant y \implies F(x) \leqslant F(y) \text{ for all } x,y \in \mathbb{R}^n, \tag{3}$$

and *additively homogeneous* when

$$F(\lambda + x) = \lambda + F(x) \text{ for all } \lambda \in \mathbb{R} \text{ and } x \in \mathbb{R}^n\,, \tag{4}$$

where, for any $z \in \mathbb{R}^n$, $\lambda + z$ stands for the vector with entries $\lambda + z_i$.

▶ **Definition 2.** *A self-map F of $\mathbb{R}^n$ is an* (abstract) Shapley operator *if it is order-preserving and additively homogeneous.*

A basic example is provided by the Shapley operator of a turn-based stochastic mean-payoff game (1). Here, the additive homogeneity axiom captures the absence of discount. We shall see in the next section a different example, arising from entropy games.

We point out that any order-preserving and additively homogeneous self-map F of $\mathbb{R}^n$ is nonexpansive in the sup-norm, meaning that

$$\|F(x) - F(y)\|_\infty \leqslant \|x - y\|_\infty \text{ for all } x, y \in \mathbb{R}^n\,.$$

Using the nonexpansiveness property, we get that the existence and the value of the limit $\lim_{N\to\infty}(F^N(x)/N)$ are independent of the choice of $x \in \mathbb{R}^N$. We call this limit the *escape rate* of F, and denote it by $\chi(F)$. When F is the Shapley operator of a turn-based stochastic mean-payoff game, fixing $x = 0$, we see that $F^N(x)$ coincides with the value vector in horizon N, and so $\chi_j(F)$ yields the mean-payoff when the initial state is j, consistently with our notation χ_j in Section 2.1.

The escape rate is known to exist under some "rigidity" assumptions. The case of semialgebraic maps is treated in [34], whereas the generalization to o-minimal structures (see [43] for background), which is needed in the application to entropy games, is established in [14].

▶ **Theorem 3** ([34] and [14])**.** *Suppose that the function $F\colon \mathbb{R}^n \to \mathbb{R}^n$ is nonexpansive in any norm and that it is semialgebraic, or, more generally, defined in an o-minimal structure. Then, the escape rate $\chi(F)$ does exist.*

This applies in particular to Shapley operators of turn-based mean-payoff games, since in this case the operator F, given by (1), is piecewise affine, and a fortiori semialgebraic. In the case of entropy games, we shall see in the next section that the relevant Shapley operator is defined by a finite expression involving the maps log, exp, as well as the arithmetic operations, and so that it is definable in a richer stucture, which is still o-minimal. We emphasize that no knowledge of o-minimal techniques is needed to follow the present paper, it suffices to admit that the escape rate does exist for all the classes of maps considered here, and this follows from Theorem 3.

When the map F is piecewise-affine, a result finer than Theorem 3 holds:

▶ **Theorem 4** ([30])**.** *A piecewise affine self-map F of $\mathbb{R}^n$ that is nonexpansive in any norm admits an* invariant half-line*, meaning that there exist $z, w \in \mathbb{R}^n$ such that*

$$F(z + \beta w) = z + (\beta + 1)w$$

for any $\beta \in \mathbb{R}$ large enough. In particular, the escape rate $\chi(F)$ exists, and is given by the vector w.

This entails that $F^k(z + \beta w) = z + (\beta + k)w$, and so, by nonexpansiveness of F, for all $x \in \mathbb{R}^n$, $F^k(x) = k\chi(F) + O(1)$ as $k \to \infty$. This expansion is more precise than Theorem 3, which only states that $F^k(x) = k\chi(F) + o(k)$.

For a general order-preserving and additively homogeneous self-map of $\mathbb{R}^n$, and in particular, for the Shapley operators of the entropy games considered below, an invariant half-line may not exist. However, we can still recover information about the sequences $(F^k(x)/k)_k$ through non-linear spectral theory methods. Assuming that F is an order-preserving and additively homogeneous self-map of $\mathbb{R}^n$, the *upper Collatz–Wielandt number* of F is defined by:

$$\overline{\mathrm{cw}}(F) \coloneqq \inf\{\mu \in \mathbb{R} \colon \exists z \in \mathbb{R}^n, F(z) \leqslant \mu + z\}\,, \tag{5}$$

and the *lower Collatz–Wielandt number* of F by:

$$\underline{\mathrm{cw}}(F) \coloneqq \sup\{\mu \in \mathbb{R} \colon \exists z \in \mathbb{R}^n, F(z) \geqslant \mu + z\}\,. \tag{6}$$

It follows from Fekete's subadditive lemma that the two limits $\lim_{k\to\infty} \mathbf{t}(F^k(0)/k)$ and $\lim_{k\to\infty} \mathbf{b}(F^k(0)/k)$, which may be thought of as upper and lower regularizations of the escape rate, always exist, see [23]. In the examples of interest to us, the escape rate $\chi(F)$ does exist, it represents the mean-payoff vector, and then $\lim_{k\to\infty} \mathbf{t}(F^k(0)/k) = \mathbf{t}(\chi(F)) = \max_j \chi_j(F)$ is the maximum of the mean payoff among all the initial states. Similarly, $\lim_{k\to\infty} \mathbf{b}(F^k(0)/k) = \mathbf{b}(\chi(F))$ is the minimum of these mean payoffs.

The interest of the vectors z arising in the definition of Collatz-Wielandt numbers is to provide *approximate optimality certificates*, allowing us to bound mean payoffs from above and from below. Indeed, if $F(z) \leqslant \mu + z$, using the order-preserving property and additively homogeneity of F, we get that $F^k(z) \leqslant k\mu + z$ for all $k \in \mathbb{N}$, and, by nonexpansiveness of F, $\lim_{k\to\infty} \mathbf{t}(F^k(0)/k) = \lim_{k\to\infty} \mathbf{t}(F^k(z)/k) \leqslant \mu$. Similarly, if $F(z) \geqslant \mu + z$, we deduce that $\lim_{k\to\infty} \mathbf{b}(F^k(0)/k) \geqslant \mu$. The following result of [23], which can also be obtained as a corollary of a minimax result of Nussbaum [35], see [2], shows that these bounds are optimal.

▶ **Theorem 5** ([23, Prop. 2.1], [2, Lemma 2.8 and Rk. 2.10])**.** *Let F be an order-preserving and additively homogeneous self-map of $\mathbb{R}^n$. Then, $\lim_{k\to\infty} \mathbf{t}(F^k(x)/k) = \overline{\mathrm{cw}}(F)$ and $\lim_{k\to\infty} \mathbf{b}(F^k(x)/k) = \underline{\mathrm{cw}}(F)$ for any $x \in \mathbb{R}^n$.*

Thus, when F is the Shapley operator of a game, the quantities $\overline{\mathrm{cw}}(F)$ and $\underline{\mathrm{cw}}(F)$ respectively correspond to the greatest and smallest mean payoff among all the initial states.

A simpler situation arises when there is a vector $v \in \mathbb{R}^n$ and a scalar $\lambda \in \mathbb{R}$ such that

$$F(v) = \lambda + v\,. \tag{7}$$

The scalar λ, which is unique, is known as the *ergodic constant*, and (7) is referred to as the *ergodic equation*. Then, $\underline{\mathrm{cw}}(F) = \overline{\mathrm{cw}}(F) = \lambda$. The vector v is known as a *bias* or *potential*. It will be convenient to have a specific notation for the ergodic constant λ when the ergodic equation is solvable, then, we set $\mathrm{erg}(F) := \lambda$. The existence of a solution (λ, v) of (7) is guaranteed by certain "ergodicity" assumptions [3]. When the Shapley operator F is piecewise affine, it follows form Kohlberg's theorem (Theorem 4) that the ergodic equation (7) is solvable if and only if the mean payoff is independent of the initial state.

Denote $\bar{\mathbb{R}} \coloneqq \mathbb{R} \cup \{-\infty\}$. Properties (3) and (4) also make sense for self-maps of $\bar{\mathbb{R}}^n$, by requiring them to hold for all $x, y \in \bar{\mathbb{R}}^n$ and $\lambda \in \bar{\mathbb{R}}$. Any order-preserving and additively homogeneous self-map F of $\mathbb{R}^n$ admits a unique continuous extension $\bar{F}$ to $\bar{\mathbb{R}}^n$, obtained by setting, for $x \in \bar{\mathbb{R}}^n$,

$$\bar{F}(x) \coloneqq \inf\{F(y) \colon y \in \mathbb{R}^n, y \geqslant x\}\ . \tag{8}$$

Moreover, $\bar{F}$ is still order-preserving and additively homogeneous, see [18] for details. Hence, in the sequel, we assume that any order-preserving and additively homogeneous self-map F of $\mathbb{R}^n$ is canonically extended to $\bar{\mathbb{R}}^n$, and we will not distinguish between F and $\bar{F}$.

2.3 Entropy Games

Entropy games were introduced in [10]. We follow the presentation of [1] since it extends the original model, see Remark 9 for a comparison.

Similarly to stochastic turn-based zero-sum games, an *entropy game* is played on a digraph $(\mathscr{V}, \mathscr{E})$ in which the set of vertices $(\mathscr{V}, \mathscr{E})$ has a non-trivial partition $\mathscr{V} = \mathscr{V}_{\mathrm{Min}} \uplus \mathscr{V}_{\mathrm{Max}} \uplus \mathscr{V}_{\mathrm{Nat}}$. As in the case of stochastic turn-based games, players Min, Max, and Nature control the states $\mathscr{V}_{\mathrm{Min}}$, $\mathscr{V}_{\mathrm{Max}}$, $\mathscr{V}_{\mathrm{Nat}}$ respectively and they alternate their moves, i.e., $\mathscr{E} \subset \mathscr{V}_{\mathrm{Min}} \times \mathscr{V}_{\mathrm{Max}} \cup \mathscr{V}_{\mathrm{Max}} \times \mathscr{V}_{\mathrm{Nat}} \cup \mathscr{V}_{\mathrm{Nat}} \times \mathscr{V}_{\mathrm{Min}}$. We also suppose that the underlying graph satisfies Assumption 1. In the context of entropy games, player Min is called *Despot*, player Max is called *Tribune*, and Nature is called *People*. For this reason, we denote $\mathscr{V}_D \coloneqq \mathscr{V}_{\mathrm{Min}}$, $\mathscr{V}_T \coloneqq \mathscr{V}_{\mathrm{Min}}$, and $\mathscr{V}_P \coloneqq \mathscr{V}_{\mathrm{Nat}}$. The name "Tribune" coined in [10], refers to the magistrates interceding on behalf of the plebeians in ancient Rome.

The first difference between stochastic turn-based games and entropy games lies in the behavior of Nature: while in stochastic games Nature makes its decisions according to some fixed probability distribution, in entropy games People is a *nondeterministic* player, i.e., nothing is assumed about the behavior of People. The second difference lies in the definition of the payoffs received by Tribune. We suppose that every edge $(p, d) \in \mathscr{E}$ with $p \in \mathscr{V}_P$ and $d \in \mathscr{V}_D$ is equipped with a *multiplicity* m_{pd} which is a (positive) natural number. The *weight* of a path is defined to be the product of the weights of the arcs arising on this path. For instance, the path $(d_0, t_0, p_0, d_1, t_1, p_1, d_2, t_2)$ where $d_i \in \mathscr{V}_D$, $t_i \in \mathscr{V}_T$ and $p_i \in \mathscr{V}_P$, makes 2 and 1/3 turn, and its weight is $m_{p_0 d_1} m_{p_1 d_2}$. A *game in horizon* N is then defined as follows: if (σ, τ) is a pair of strategies of Despot and Tribune, then we denote by $R_d^N(\sigma, \tau)$ the sum of the weights of paths with initial state d that make N turns and that are consistent with the choice of (σ, τ). Tribune wants to maximize this quantity, while Despot wants to minimize it. As for stochastic turn-based games, a dynamic programming argument given in [1] shows that the value $V^N \in \mathbb{R}_{>0}^{\mathscr{V}_D}$ of this game does exist, and that it satisfies the recurrence

$$V^0 = \mathbf{1}, \qquad V^N = T(V^{N-1}),$$

where $\mathbf{1}$ is the vector whose entries are identically one and the operator $T \colon \mathbb{R}_{>0}^{\mathscr{V}_D} \to \mathbb{R}_{>0}^{\mathscr{V}_D}$ is defined by

$$T_d(x) \coloneqq \min_{(d,t)\in\mathscr{E}} \max_{(t,p)\in\mathscr{E}} \sum_{(p,l)\in\mathscr{E}} m_{pl} x_l, \text{ for all } d \in \mathscr{V}_D . \tag{9}$$

To define a game that lasts for an infinite number of turns, we consider the limit

$$V_d^\infty(\sigma, \tau) \coloneqq \limsup_{N\to+\infty} (R_d^N(\sigma, \tau))^{1/N},$$

which may be thought of as a measure of the freedom of People. The logarithm of this limit is known as a *topological entropy* in symbolic dynamics. The following result shows that the value of the entropy game V_d^∞ does exist and that it coincides with the limit of the renormalized value $(V_d^N)^{1/N} = [T^N(\mathbf{1})]_d^{1/N}$ of the finite horizon entropy game, so that the situation is similar to the case of stochastic turn-based games, albeit the renormalization now involves a Nth geometric mean owing to the multiplicative nature of the payment.

▶ **Theorem 6** ([1]). *The entropy game with initial state d has a value V_d^∞. Moreover, there are (positional) strategies σ^* and τ^* of Despot and Tribune, such that, for all $d \in \mathscr{V}_D$,*

$$V_d^\infty(\sigma^*, \tau) \leqslant V_d^\infty = V_d^\infty(\sigma^*, \tau^*) \leqslant V_d^\infty(\sigma, \tau^*),$$

for all strategies σ and τ of the two players. In addition, the value vector $V^\infty := (V_d^\infty)_{d\in\mathscr{V}_D}$ coincides with the vector

$$\lim_{N\to\infty} \big(T^N(\mathbf{1})\big)^{1/N} \in \mathbb{R}^{\mathscr{V}_D}_{>0} \ ,$$

in which the operation $\cdot^{1/N}$ is understood entrywise.

Entropy games can be cast in the general operator setting of Section 2.2, by introducing the conjugate operator $F\colon \mathbb{R}^{\mathscr{V}_D} \to \mathbb{R}^{\mathscr{V}_D}$,

$$F := \log \circ T \circ \exp \tag{10}$$

in which $\exp\colon \mathbb{R}^{\mathscr{V}_D} \mapsto \mathbb{R}^{\mathscr{V}_D}_{>0}$ is the map which applies the exponential entrywise, and $\log := \exp^{-1}$. Since the maps log and exp are order preserving, and since the weights m_{pl} appearing in the expression of $T(x)$ in (9) are nonnegative, the operator F is order preserving. Moreover, using the morphism property of the map log and exp with respect to multiplication and addition, we see that F is also additively homogeneous, hence, it is an abstract Shapley operator in the sense of Definition 2. Moreover, it is definable in the real exponential field, which was shown to be an o-minimal structure by Wilkie [45], and this is precisely how Theorem 6 is derived in [1] from Theorem 3. Actually, entropy games are studied in [1] in a more general setting, allowing history dependent strategies and showing that positional strategies are optimal. It is also shown there that the game has a uniform value in the sense of Mertens and Neyman [32].

When the (positional) strategies σ, τ are fixed, the value can be characterized by a classical result of Perron–Frobenius theory.

▶ **Definition 7.** *Given a pair of strategies (σ,τ) of Despot and Tribune, we define the* ambiguity matrix $M^{\sigma,\tau} \in \mathbb{R}^{\mathscr{V}_D\times\mathscr{V}_D}_{\geqslant 0}$*, with entries $(M^{\sigma,\tau})_{k,l} = m_{\tau(\sigma(k)),l}$ if $\big(\tau(\sigma(k)),l\big) \in \mathscr{E}$ and $(M^{\sigma,\tau})_{k,l} = 0$ otherwise, i.e., this is the weighted transition matrix of the subgraph $\mathscr{G}^{\sigma,\tau}$ obtained by keeping only the arcs $\mathscr{V}_D \to \mathscr{V}_T$ and $\mathscr{V}_T \to \mathscr{V}_P$ determined by the two strategies.*

The digraph $\mathscr{G}^{\sigma,\tau}$ can generally be decomposed in strongly connected components $\mathscr{C}_1,\dots,\mathscr{C}_s$, and each of these components, $\mathscr{C}_i$, determines a principal submatrix of $M^{\sigma,\tau}$, denoted by $M^{\sigma,\tau}[\mathscr{C}_i]$, obtained by keeping only the rows and columns in $\mathscr{C}_i \cap \mathscr{V}_D$. We denote by $\rho(\cdot)$ the spectral radius of a matrix, which is also known as the *Perron root* when the matrix is nonnegative and irreducible, see [12] for background.

▶ **Proposition 8** ([38], [46, Th. 5.1])**.** *The value of the subgame with initial state d, induced by a pair of strategies σ,τ, coincides with*

$$\max\{\rho(M^{\sigma,\tau}[\mathscr{C}_i])\colon \textit{there is a dipath } d\to\mathscr{C}_i \textit{ in } \mathscr{G}^{\sigma,\tau}\} \ .$$

▶ Remark 9. In the original model of Asarin et al. [10], an entropy game is specified by finite sets of states of Depot and Tribune, D and T, respectively, by a finite alphabet Σ representing actions, and by a transition relation $\Delta \subset T\times\Sigma\times D \cup D\times\Sigma\times T$. A turn consists of four successive moves by Despot, People, Tribune, and People: in state $d\in D$, Despot selects an action $a\in\Sigma$, then, People moves to one state $t\in P$ such that $(d,a,t)\in\Delta$. Then, Tribune selects an action $b\in\Sigma$, and People moves to one state $d'\in D$ such that $(t,b,d')\in\Delta$. This reduces to the model of [1] by introducing dummy states, identifying a turn in the game of [10] to a succession of two turns in the game of [1]. Another difference is that the payment, in [10], corresponds to $\max_{d\in D} \limsup_{N\to\infty}(R_d^N)^{1/N}$, and this is equivalent

Algorithm 1 Basic value iteration algorithm.

```
1: procedure ValueIteration(F)
2:   ▷ F a Shapley operator from ℝ^n to ℝ^n
3:   u := 0 ∈ ℝ^n
4:   repeat u := F(u)   ▷ At iteration ℓ, u = F^ℓ(0) is the value vector of the game in finite horizon ℓ
5:   until t(u) ⩽ 0 or b(u) ⩾ 0
6:   if t(u) ⩽ 0 then return "cw̄(F) ⩽ 0"   ▷ Player Min wins for all initial states
7:   else return "cw(F) ⩾ 0"   ▷ Player Max wins for all initial states
8:   end
9: end
```

to letting Tribune choose the initial state before playing the game. Then, the value of the game in [10] coincides with the maximum of the values of the initial states, $\max_d V_d^\infty$, see [1, Prop. 11]. Finally in [10], the arcs have multiplicity one, whereas we allow integer multiplicies (coded in binary), as in [1].

3 Bounding the Complexity of Value Iteration

In this section, F is an (abstract) Shapley operator, i.e., an order-preserving and additively homogeneous self-map of $\mathbb{R}^n$.

3.1 A Universal Complexity Bound for Value Iteration

The most straightforward idea to solve a mean-payoff game is probably value iteration: we infer whether or not the mean-payoff game is winning by solving the finite horizon game, for a large enough horizon. This is formalized in Algorithm 1.

When the non-linear eigenproblem $F(w) = \operatorname{erg}(F) + w$ is solvable, we shall use the following metric estimate, which represents the minimal Hilbert's seminorm of a bias vector

$$R(F) := \inf \{ \|w\|_{\mathrm{H}} \colon w \in \mathbb{R}^n,\ F(w) = \operatorname{erg}(F) + w \} \ .$$

In general, however, this non-linear eigenproblem may not be solvable. Then, we consider, for $\lambda \in \mathbb{R}$,

$$S_\lambda(F) = \{ v \in \mathbb{R}^n \colon \lambda + v \leqslant F(v) \}, \qquad S^\lambda(F) = \{ v \in \mathbb{R}^n \colon \lambda + v \geqslant F(v) \} \ .$$

▶ **Theorem 10.** *Procedure* ValueIteration *(Algorithm 1) is correct as soon as* $\underline{\mathrm{cw}}(F) > 0$ *or* $\overline{\mathrm{cw}}(F) < 0$*, and it terminates in a number of iterations* N_{vi} *bounded by*

$$\inf \left\{ \frac{\|v\|_{\mathrm{H}}}{\lambda} \colon \lambda > 0\,,\ v \in S_\lambda(F) \cup S^{-\lambda}(F) \right\} \ . \tag{11}$$

In particular, if F *has a bias vector and* $\operatorname{erg}(F) \neq 0$*, we have* $N_{vi} \leqslant \frac{R(F)}{|\operatorname{erg}(F)|}$.

We prove this theorem by using the Collatz-Wielandt variational characterization of the limits $\lim_{k\to\infty} \mathbf{t}(F^k(x)/k)$ and $\lim_{k\to\infty} \mathbf{b}(F^k(x)/k)$, see Theorem 5. A special case of Theorem 10 in which the existence of a bias vector is assumed appeared in [6] (without proof).

▶ Remark 11. The infimum in (11) is generally not attained. Consider for instance $F : \mathbb{R}^2 \to \mathbb{R}^2$ given by $F(x) = (\log(\exp(x_1) + \exp(x_2)), x_2) - \alpha$, where $\alpha > 0$. Then, since $F_2(x) = x_2 - \alpha < x_2$, we have $S_\lambda(F) = \emptyset$ for $\lambda > 0$. Besides, since $x - \lambda \geqslant F(x)$ if and only if $x_1 - \lambda \geqslant \log(\exp(x_1) + \exp(x_2)) - \alpha$ and $x_2 - \lambda \geqslant x_2 - \alpha$, it follows that $S^{-\lambda}(F) \neq \emptyset$

Algorithm 2 Value iteration in finite precision arithmetics.

procedure FPValueIteration($\tilde{F}$)
  $u \coloneqq 0 \in \mathbb{R}^n$, $\ell \coloneqq 0 \in \mathbb{N}$, $\epsilon \in \mathbb{R}_{>0}$
  repeat $u \coloneqq \tilde{F}(u)$; $\ell \coloneqq \ell + 1$ ▷ *We suppose that the operator F is evaluated in approximate arithmetics, so that $\tilde{F}(u)$ is at most at distance ϵ in the sup-norm from its true value $F(u)$.*
  until $\ell\epsilon + \mathbf{t}(u) \leqslant 0$ or $-\ell\epsilon + \mathbf{b}(u) \geqslant 0$
  if $\ell\epsilon + \mathbf{t}(u) \leqslant 0$ **then return** "$\overline{\mathrm{cw}}(F) \leqslant 0$" ▷ *Player Min wins for all initial states*
  end
  if $-\ell\epsilon + \mathbf{b}(u) \geqslant 0$ **then return** "$\underline{\mathrm{cw}}(F) \geqslant 0$" ▷ *Player Max wins for all initial states*
  end
end

Algorithm 3 Approximating the value of a mean-payoff game when it is independent of the initial state, and computing approximate optimality certificates, working in finite precision arithmetic.

procedure ApproximateConstantMeanPayoff(F)
  $u, x, y \coloneqq 0 \in \mathbb{R}^n$, $\ell \coloneqq 0 \in \mathbb{N}$, $\delta \in \mathbb{R}_{>0}$ ▷ *The number δ is the desired precision of approximation.*
  repeat $u \coloneqq \tilde{F}(u)$; $\ell \coloneqq \ell + 1$ ▷ *The operator F is evaluated in approximate arithmetic, so that $\tilde{F}(u)$ is at most at distance $\epsilon \coloneqq \delta/8$ in the sup-norm from its true value $F(u)$.*
  until $\mathbf{t}(u) - \mathbf{b}(u) \leqslant (3/4)\delta\ell$
$\kappa \coloneqq \mathbf{b}(u)/\ell$; $\lambda \coloneqq \mathbf{t}(u)/\ell$
$u \coloneqq 0$
  for $i = 1, 2, \dots, \ell - 1$ **do** $u \coloneqq \tilde{F}(u)$; $x \coloneqq \max\{x, -i\kappa + u\}$; $y \coloneqq \min\{y, -i\lambda + u\}$
  done
return "$[\underline{\mathrm{cw}}(F), \overline{\mathrm{cw}}(F)]$ is included in the interval $[\kappa - \delta/8, \lambda + \delta/8]$, which is of width at most δ. Furthermore, we have $\kappa - \delta/8 + x \leqslant F(x)$ and $\lambda + \delta/8 + y \geqslant F(y)$." ▷ *All initial states have a value in $[\kappa - \delta/8, \lambda + \delta/8]$.*
end

if and only if $\lambda < \alpha$. Now let $v \in S^{-\lambda}(F)$ for some $\lambda < \alpha$. Without loss of generality, we may assume $\mathbf{b}(v) = 0$. Then, we have $v_1 - \lambda \geqslant \log(\exp(v_1) + \exp(v_2)) - \alpha \geqslant \log 2 - \alpha$ and so $\frac{\|v\|_{\mathrm{H}}}{\lambda} \geqslant 1 + \frac{\log 2 - \alpha}{\lambda}$. We conclude that the infimum in (11) is equal to $\frac{\log 2}{\alpha}$ but it is not attained.

3.2 Value Iteration in Finite Precision Arithmetics

Algorithm 1 can be adapted to work in finite precision arithmetic. Consider the variant given in Algorithm 2. We assume that each evaluation of the Shapley operator F is performed with an error of at most $\epsilon > 0$ in the sup-norm. In this section, we denote by $\tilde{F} \colon \mathbb{R}^n \to \mathbb{R}^n$ the operator which approximates F, as in Procedure FPValueIteration, so it satisfies

$$\|\tilde{F}(x) - F(x)\|_\infty \leqslant \epsilon \text{ for all } x \in \mathbb{R}^n. \tag{12}$$

The following result is established by exploiting nonexpansiveness properties of Shapley operators.

▶ **Theorem 12.** *Procedure FPValueIteration (Algorithm 2) is correct as soon as $\underline{\mathrm{cw}}(F) > 2\epsilon$ or $\overline{\mathrm{cw}}(F) < -2\epsilon$, and it terminates in a number of iterations N^ϵ_{vi} bounded by*

$$\inf \left\{ \frac{\|v\|_{\mathrm{H}}}{\lambda - 2\epsilon} \colon \lambda > 2\epsilon\,,\ v \in S_\lambda(F) \cup S^{-\lambda}(F) \right\}\,. \tag{13}$$

In particular, if F has a bias vector and $|\operatorname{erg}(F)| > 2\epsilon$, we have $N^\epsilon_{vi} \leqslant \frac{R(F)}{|\operatorname{erg}(F)| - 2\epsilon}$.

Procedure ApproximateConstantMeanPayoff returns sub and super-eigenvectors x and y, satisfying $\kappa - \delta/8 + x \leqslant F(x)$ and $\lambda + \delta/8 + y \geqslant F(y)$, which, by Theorem 5, entails

that $[\underline{\mathrm{cw}}(F), \overline{\mathrm{cw}}(F)]$ is included in the interval $[\kappa - \delta/8, \lambda + \delta/8]$. The construction of these sub and sup-eigenvectors, by taking infima and suprema of normalized orbits of F, is inspired by [23, Proof of Lemma 2].

▶ **Theorem 13.** *Suppose that $\overline{\mathrm{cw}}(F) = \underline{\mathrm{cw}}(F)$, and let ρ denote this common value. Then, Procedure* ApproximateConstantMeanPayoff *(Algorithm 3) halts and is correct for any given desired precision of approximation $\delta \in \mathbb{R}_{>0}$. Furthermore, if $R \coloneqq \max\{\|v\|_{\mathrm{H}}, \|w\|_{\mathrm{H}}\}$, where $v, w \in \mathbb{R}^n$ are any two vectors that satisfy $\rho - \delta/8 + v \leqslant F(v)$ and $\rho + \delta/8 + w \geqslant F(w)$, then this procedure stops after at most $\lceil 8R/\delta \rceil$ iterations of the first loop.*

3.3 Finding the States of Maximal Value

In this section, we will show how the value iteration algorithm can be adapted to decide whether or not a given game has constant value, and to find the set of states that have the maximal value. Our analysis is based on an abstract notion of dominion. As previously, we suppose that $F\colon \mathbb{R}^n \to \mathbb{R}^n$ is an order-preserving and additively homogeneous operator. Recall that thanks to (8), F is canonically extended to define a self-map of $\bar{\mathbb{R}}^n$. Furthermore, given a nonempty set $\mathscr{S} \subset [n]$, we define the operator $F^{\mathscr{S}}\colon \bar{\mathbb{R}}^{\mathscr{S}} \to \bar{\mathbb{R}}^{\mathscr{S}}$ as $F^{\mathscr{S}} \coloneqq \mathbf{p}^{\mathscr{S}} \circ F \circ \mathbf{i}^{\mathscr{S}}$, where $\mathbf{p}^{\mathscr{S}}\colon \bar{\mathbb{R}}^n \to \bar{\mathbb{R}}^{\mathscr{S}}$ is the projection on the coordinates in $\mathscr{S}$ which is defined as usual by $\mathbf{p}^{\mathscr{S}}_j(x) = x_j$ for $j \in \mathscr{S}$, and $\mathbf{i}^{\mathscr{S}}\colon \bar{\mathbb{R}}^{\mathscr{S}} \to \bar{\mathbb{R}}^n$ is defined by $\mathbf{i}^{\mathscr{S}}_j(x) = x_j$ if $j \in \mathscr{S}$ and $\mathbf{i}^{\mathscr{S}}_j(x) = -\infty$ otherwise.

▶ **Definition 14.** *A* dominion (of Player Max) *is a nonempty set $\mathscr{D} \subset [n]$ such that $F^{\mathscr{D}}$ preserves $\mathbb{R}^{\mathscr{D}}$, i.e., such that $F^{\mathscr{D}}(x) \in \mathbb{R}^{\mathscr{D}}$ for all $x \in \mathbb{R}^{\mathscr{D}}$.*

As discussed in [7, 3], for stochastic mean-payoff games (with finite action spaces), a dominion of a player can be interpreted as a set of states such that the player can force the game to stay in this set if the initial state belongs to it. This terminology differs from the one of [29], in which a dominion is required in addition to consist only of initial states that are winning for this player. The algorithms that we discuss in this section require an additional assumption on the structure of the Shapley operator F.

▶ **Assumption 2.** *We assume that the limit $\chi^{\mathscr{D}} \coloneqq \lim_{\ell\to\infty} \frac{(F^{\mathscr{D}})^\ell(0)}{\ell} \in \mathbb{R}^{\mathscr{D}}$ exists for every dominion $\mathscr{D} \subset [n]$. Furthermore, we assume that the set $\mathscr{D}_{\max} \coloneqq \{j \in [n]\colon \chi^{[n]}_j = \overline{\mathrm{cw}}(F)\}$ is a dominion and that it satisfies $\underline{\mathrm{cw}}(F^{\mathscr{D}_{\max}}) = \overline{\mathrm{cw}}(F^{\mathscr{D}_{\max}}) = \overline{\mathrm{cw}}(F)$.*

▶ Remark 15. We note that the first part of Assumption 2 holds automatically when the Shapley operator $F\colon \mathbb{R}^n \to \mathbb{R}^n$ is definable in an o-minimal structure. Indeed, in this case the relation (8) implies that $F^{\mathscr{D}}$ is definable in the same structure for every dominion $\mathscr{D}$, so $\chi^{\mathscr{D}}$ exists by Theorem 3. We will see that the second part of the assumption applies to the games considered in this paper.

▶ Remark 16. Assumption 2 will allow us to make an induction on the number states, by a reduction to a simpler game with a reduced state space $\mathscr{D}$. In particular, the assumption that the limit $\chi^{\mathscr{D}} = \lim_{\ell\to\infty} \frac{(F^{\mathscr{D}})^\ell(0)}{\ell}$ exists will allow us to apply value iteration to the Shapley operator of the reduced game, $F^{\mathscr{D}}$.

From now on, we denote $\chi \coloneqq \chi^{[n]}$ and $\mathscr{D}_{\max} \coloneqq \{j \in [n]\colon \chi_j = \overline{\mathrm{cw}}(F)\}$. The following theorem applies to Shapley operators for which an a priori separation bound is known: if $\overline{\mathrm{cw}}(F) > \underline{\mathrm{cw}}(F)$, it requires an apriori bound $\delta > 0$ such that $\overline{\mathrm{cw}}(F) - \underline{\mathrm{cw}}(F) > \delta$. We note that the existence of the approximate sub and super-eigenvectors v and w used in this theorem follows from Theorem 5 and from Assumption 2.

Algorithm 4 Deciding if the value is constant.

```
1: procedure DecideConstantValue(F, δ, R)
2:     u := 0 ∈ R^n, ℓ := 0 ∈ N.
3:     F̃ := any map such that F̃(u) is at most at distance ϵ := δ/8 in the sup-norm from F(u).
4:     repeat u := F̃(u); ℓ := ℓ + 1
5:     until t(u) − b(u) ⩽ (3/4)δℓ or ℓ = 1 + ⌈8R/δ⌉
6:     if ℓ = 1 + ⌈8R/δ⌉ then
7:         S := {i : u_i = b(u)}
8:         return S    ▷ The value of the game depends on the initial state. We have χ_i < cw̄(F) for all i ∈ S.
9:     else
10:        return ∅    ▷ The value of the game is independent of the initial state.
11:    end
12: end
```

▶ **Theorem 17.** *Suppose that F is such that either $\overline{\mathrm{cw}}(F) = \underline{\mathrm{cw}}(F)$ or $\overline{\mathrm{cw}}(F) - \underline{\mathrm{cw}}(F) > \delta$ for some $\delta > 0$. Let $\mathscr{D}_{\max}$ be the set of states of maximal value and $R := \max\{\|v\|_{\mathrm{H}}, \|w\|_{\mathrm{H}}\}$, where $v, w \in \mathbb{R}^{\mathscr{D}_{\max}}$ are any two vectors that satisfy $\overline{\mathrm{cw}}(F) - \delta/8 + v \leqslant F^{\mathscr{D}_{\max}}(v)$ and $\overline{\mathrm{cw}}(F) + \delta/8 + w \geqslant F^{\mathscr{D}_{\max}}(w)$. Then, Procedure DecideConstantValue (Algorithm 4) is correct.*

Let

$$\mathrm{sep}(F) := \inf_{\mathscr{D}} \left(\overline{\mathrm{cw}}(F^{\mathscr{D}}) - \underline{\mathrm{cw}}(F^{\mathscr{D}})\right)$$

where the infimum is taken over all the dominions $\mathscr{D}$ of F which contain all the states of maximal value and satisfy $\overline{\mathrm{cw}}(F^{\mathscr{D}}) - \underline{\mathrm{cw}}(F^{\mathscr{D}}) > 0$.

To state the final result of this section, we will suppose that we have an access to an oracle that approximates F to a given precision $\epsilon > 0$. More precisely, given a point $x \in \bar{\mathbb{R}}^n$, the oracle is supposed to output a point $y \in \bar{\mathbb{R}}^n$ that satisfies $y_j = -\infty$ for all $j \in [n]$ such that $F_j(x) = -\infty$ and $|F_j(x) - y_j| \leqslant \epsilon$ for all j such that $F_j(x) \neq -\infty$. We have

▶ **Theorem 18.** *Let $\delta > 0$ be such that $\delta < \mathrm{sep}(F)$, $\mathscr{D}_{\max}$ be the set of states of maximal value and $R := \max\{\|v\|_{\mathrm{H}}, \|w\|_{\mathrm{H}}\}$, where $v, w \in \mathbb{R}^{\mathscr{D}_{\max}}$ are any two vectors that satisfy $\overline{\mathrm{cw}}(F) - \delta/8 + v \leqslant F^{\mathscr{D}_{\max}}(v)$ and $\overline{\mathrm{cw}}(F) + \delta/8 + w \geqslant F^{\mathscr{D}_{\max}}(w)$. Then, the set of initial states of maximal value can be found by making at most $n^2 + n\lceil 8R/\delta \rceil$ calls to oracle that approximates F to precision $\epsilon := \delta/8$.*

4 Application to Stochastic Mean-Payoff Games

In this section, we apply our results to stochastic mean-payoff games. We start by bounding the separation sep and the metric estimate $R(F)$, when F is the Shapley operator of a stochastic turn-based zero-sum game as in (1). We recall that the entries of A and B are integers. This is not more special than assuming that the entries of A and B are rational numbers (we may always rescale rational payments so that they become integers). We set

$$W := \max\{|A_{ij} - B_{ik}| : i \in \mathscr{V}_{\mathrm{Max}}, j \in \mathscr{V}_{\mathrm{Min}}, k \in \mathscr{V}_{\mathrm{Nat}}\} . \tag{14}$$

We also assume that the probabilities P_{kj} are rational, and that they have a common denominator $M \in \mathbb{N}_{>0}$, $P_{kj} = Q_{kj}/M$, where $Q_{kj} \in [M]$ for all $k \in \mathscr{V}_{\mathrm{Nat}}$ and $j \in \mathscr{V}_{\mathrm{Min}}$. We say that a state $k \in \mathscr{V}_{\mathrm{Nat}}$ is a *significant random state* if there are at least two indices $j, j' \in \mathscr{V}_{\mathrm{Min}}$ such that $P_{kj} > 0$ and $P_{kj'} > 0$. We denote by s the number of significant random states and by $n := |\mathscr{V}_{\mathrm{Min}}|$ the number of states controlled by Min. The following estimates follow from optimal bit-complexity results for Markov chains, established in [41]. These improve an estimate in [16].

▶ **Lemma 19.** *We have* $\operatorname{sep}(F) > 1/(nM^{\min\{s,n-1\}})^2$.

▶ **Lemma 20.** *Suppose that* $\underline{\mathrm{cw}}(F) = \overline{\mathrm{cw}}(F)$. *Then, there exists a vector* $u \in \mathbb{R}^{\mathcal{V}_{\mathrm{Min}}}$ *such that* $F(u) = \overline{\mathrm{cw}}(F) + u$ *and*

$$R(F) \leqslant \|u\|_{\mathrm{H}} \leqslant 8nWM^{\min\{s,n-1\}} \ .$$

The existence of the bias vector follows from Kohlberg's theorem (Theorem 4). The bias is generally not unique (even up to an additive constant) and the main difficulty then is to find a "short" bias. The one which is constructed in the proof of this lemma relies on the notion of Blackwell optimality. This notion requires to consider the *discounted* version of the game, in which the payment (2) is replaced by $\mathbb{E}_{\sigma\tau}\sum_{p=0}^{\infty}(1-\alpha)^p(-A_{i_pj_p}+B_{i_pk_p})$, where $0<\alpha<1$ and $1-\alpha$ is the discount factor. The discounted game with initial state i has a value, $x_i(\alpha)$, and the value vector, $x(\alpha)=(x_i(\alpha))\in\mathbb{R}^n$ is the unique solution of the fixed point problem $x(\alpha)=F((1-\alpha)x(\alpha))$. Then, a strategy of a player is *Blackwell optimal* if it is optimal in all the discounted games with a discount factor sufficiently close to 1. It can be obtained by selecting minimizing or maximizing actions when evaluating the expression $F((1-\alpha)x(\alpha))$, for $\alpha>0$ close enough to 0. Moreover, it follows from Kohlberg's proof that $x(\alpha)$ admits an expansion $x(\alpha)=\chi(F)/\alpha+u+o(\alpha)$ when $\alpha\to 0^+$, where u is a bias vector. If Q is the stochastic matrix determined by a pair of Blackwell optimal strategies of the two players, and if r is the associated one-stage payment vector, then, the bias vector u satisfies a Poisson-type equation $\chi(F)+u=r+Qu$. Moreover, this special bias vector has the remarkable property of having a zero expectation with respect to all invariant measures of Q, and together with the bit-complexity estimate of [41, Th. 1.5] for the solution of Poisson-type equations, this leads to the proof of Lemma 20.

Thanks to these estimates, we arrive at the following corollaries.

▶ **Corollary 21.** *Let* F *be a Shapley operator as above, supposing that* F *has a bias vector and that* $\operatorname{erg}(F)$ *is nonzero. Then, procedure* ValueIteration *stops after*

$$N_{vi} \leqslant 8n^2WM^{2\min\{s,n-1\}} \tag{15}$$

iterations and correctly decides which of the two players is winning.

▶ Remark 22. When specialized to deterministic mean-payoff games, i.e., when $s=0$, Corollary 21 yields $N_{\mathrm{vi}}=O(n^2W)$ which is precisely the bound that follows from the analysis of value iteration by Zwick and Paterson [47].

▶ **Corollary 23.** *Suppose that* F *has a bias vector and let* $\mu \coloneqq nM^{\min\{s,n-1\}}$. *Then, Procedure* ApproximateConstantMeanPayoff, *applied to* F *and to* $\delta \coloneqq \mu^{-2}$, *terminates in at most*

$$128n^3WM^{3\min\{s,n-1\}}$$

calls to the oracle. Moreover the interval returned by this procedure contains a unique rational number of denominator at most μ, *which coincides with the value, and optimal policies can be obtained from the approximate optimality certificates generated by the procedure.*

Let us explain how the optimal strategies are obtained from the output of Procedure ApproximateConstantMeanPayoff. This procedure returns sub and super-eigenvectors x and y that satisfy $\kappa-\delta/8+x\leqslant F(x)$ and $\lambda+\delta/8+y\geqslant F(y)$ where $\lambda=\operatorname{erg}(F)$. By selecting, for each state $j\in\mathcal{V}_{\mathrm{Min}}$, a minimizing action in the expression

$$F_j(y)=\min_{(j,i)\in\mathcal{E}}\Big(-A_{ij}+\max_{(i,k)\in\mathcal{E}}\big(B_{ik}+\sum_{(k,l)\in\mathcal{E}}P_{kl}y_k\big)\Big),$$

one gets a positional strategy which guarantees to Min a value at most $\lambda + \delta/8$. A similar method is used to construct a positional strategy of Max. Then, since $\delta = \mu^{-2}$ is smaller than the separation bound between values of different strategies, we deduce these policies guarantee a value of λ to each of the players, and so, they are optimal.

▶ **Corollary 24.** *Let $\mu \coloneqq nM^{\min\{s,n-1\}}$. Then, we can find the set of states with maximal value of a stochastic mean-payoff game by performing at most $65n^4WM^{3\min\{s,n-1\}}$ calls to the oracle approximating F with precision $\delta \coloneqq 1/\mu^2$.*

▶ Remark 25. If we are given the matrices A, B, P explicitly, then the operator F can be evaluated exactly in $O(E)$ complexity, where E is the number of edges of the graph representing a stochastic mean-payoff game. In particular, there is no need to construct an approximation oracle in order to apply the results of this section. Nevertheless, even in this case it may be beneficial to use an approximation oracle. Indeed, if we evaluate F exactly, then each value iteration $u \coloneqq F(u)$ increases the number of bits needed to encode u. As a result, value iteration would require exponential memory. In order to avoid this problem, one can replace F with an approximation oracle $\tilde{F}$ obtained as follows. Let $\mu \coloneqq nM^{\min\{s,n-1\}}$ and $\epsilon \coloneqq 1/(8\mu^2)$. Given $x \in \bar{\mathbb{R}}^{\mathcal{V}_{\mathrm{Min}}}$, we first compute $y \coloneqq F(x)$ exactly and then round the finite coordinates of y in such a way that the rounded vector $\tilde{y}$ satisfies $|y_j - \tilde{y}_j| \leqslant \epsilon$ whenever $y_j \neq -\infty$ and $\tilde{y}_j$ is a rational number with denominator at most $8\mu^2$. One can check that if we use $\tilde{F}$ obtained in this way as an approximation oracle, then all algorithms presented in this section require $O\big(nE\log(nMW)\big)$ memory, which is polynomial in the size of the input.

▶ Remark 26. Since a single call to the oracle approximating F can be done in $O(E)$ arithmetic operations, by combining Corollary 24 with Corollary 23 we see that the set of states with maximal value, and a pair of optimal strategies within this set can be found in $O(n^4EWM^{3\min\{s,n-1\}})$ complexity. This should be compared with the algorithm BWR-FindTop from [16] which achieves the same aim using a pumping algorithm instead of value iteration. If we combine the estimate from [41] with the complexity bound presented in [16] for the pumping algorithm, then we get that BWR-FindTop has $O(V^6EWs2^sM^{4s} + V^3EW\log W)$ complexity, where V is the number of vertices of the graph. In particular, our result gives a better complexity bound. Furthermore, the authors of [16] show that, given an oracle access to BWR-FindTop and to another oracle that solves deterministic mean-payoff games, one can completely solve stochastic mean-payoff games with pseudopolynomial number of calls to these oracles, provided that s is fixed. Hence, we can speed-up this algorithm by replacing the oracle BWR-FindTop with our algorithms.

5 Solving Entropy Games With Bounded Rank

Recall that the dynamic programming operator T of an entropy game, as well as its conjugate F, which we call the Shapley operator of an entropy game, were defined in (9),(10). As in the last section, we denote $n \coloneqq |\mathcal{V}_D|$ and we put $W \coloneqq \max_{(p,k)\in\mathcal{E}} m_{pk}$.

We define the *rank* of the entropy game to be the maximum of the ranks of the ambiguity matrices, see Definition 7. The following result is established by combining a separation bound of Rump [39] for algebraic numbers, with bounds on determinants of nonnegative matrices with entries in an interval, building on the study of Hadamard's maximal determinant problem for matrices with entries in $\{0,1\}$ [20].

▶ **Theorem 27.** *Suppose two pairs of strategies yield distinct values in an entropy game of rank r, with n Despot's states. Then, these values differ at least by $\nu_{n,r}^{-1}$ where*

$$\nu_{n,r} \coloneqq 2^r(r+1)^{8r}r^{-2r^2+r+1}(ne)^{4r^2}\big(1 \vee \frac{W}{2}\big)^{4r^2} \quad .$$

We show that the value of an entropy game is always in the interval $[1, nW]$. Then, a separation bound for values of different pairs of strategies entails a separation bound for their logarithm, differing only by a nW factor:

▶ **Corollary 28.** *Suppose two pairs of strategies yield distinct values in an entropy game of rank r, with n Despot's states. Then, the logarithms of these values differ at least by $\hat{\nu}_{n,r}^{-1}$ where*

$$\hat{\nu}_{n,r} \coloneqq nW\nu_{n,r} \ .$$

▶ **Proposition 29.** *Let $0 < \delta < 1$. Then, there exist vectors $w, z \in \mathbb{R}_{>0}^{\mathscr{V}_D}$ such that $e^{-\delta}\mathbf{b}(V^\infty)w \leqslant T(w)$, $e^{\delta}\mathbf{t}(V^\infty)z \geqslant T(z)$, and $\max\{\|\log w\|_{\mathrm{H}}, \|\log z\|_{\mathrm{H}}\} \leqslant 1200(n^3 \log W + n^2 \log \delta^{-1})$.*

This proposition is established by observing that for a given value of δ, w and z are defined by semi-linear constraints, and by using bitlength estimates on the generators and vertices of polyhedra defined by inequalities.

By applying Theorem 18 to the Shapley operator $F = \log \circ T \circ \exp$, and by using the bounds Corollary 28 and Proposition 29, we get:

▶ **Theorem 30.** *In an entropy game of rank at most r, we can find the set of initial states with maximal value by performing $O(nR_{n,r}\hat{\nu}_{n,r})$ calls to an oracle approximating F with precision $\delta/8$ where $\delta = (\hat{\nu}_{n,r})^{-1}$.*

The following decomposition property for entropy games extends a classical property of deterministic mean payoff games. Once the set of Despot's states with maximal value is known, it allows one to determine the value of the other states by reduction to an entropy game induced by the other states of Despot. To state this property formally, we denote by $\mathscr{D}_{\max} \subset \mathscr{V}_D$ the states of Despot of maximal value, and we put ${\mathscr{V}_P}^{\mathscr{D}_{\max}} \coloneqq \{p \in \mathscr{V}_P \colon \exists k \in \mathscr{D}_{\max}, (p,k) \in \mathscr{E}\}$ and ${\mathscr{V}_T}^{\mathscr{D}_{\max}} \coloneqq \{t \in \mathscr{V}_T \colon \exists p \in {\mathscr{V}_P}^{\mathscr{D}_{\max}}, (t,p) \in \mathscr{E}\}$.

▶ **Lemma 31** (Decomposition property)**.** *Let $\mathscr{S}_1 \coloneqq \mathscr{D}_{\max} \uplus {\mathscr{V}_T}^{\mathscr{D}_{\max}} \uplus {\mathscr{V}_P}^{\mathscr{D}_{\max}}$ and $\mathscr{S}_2 \coloneqq \mathscr{V} \setminus \mathscr{S}_1$. Furthermore, suppose that $\mathscr{S}_2$ is nonempty. Consider the induced digraphs $\mathscr{G}[\mathscr{S}_1]$ and $\mathscr{G}[\mathscr{S}_2]$ of the original graph $\mathscr{G} = (\mathscr{V}, \mathscr{E})$. Then, the entropy games arising by restricting the graph to $\mathscr{G}[\mathscr{S}_1]$ and $\mathscr{G}[\mathscr{S}_2]$ satisfy Assumption 1. Furthermore, if (σ_1, τ_1) are optimal strategies of Despot an Tribune in the induced entropy game on $\mathscr{G}[\mathscr{S}_1]$ and (σ_2, τ_2) are optimal strategies of Despot and Tribune in the induced entropy game on $\mathscr{G}[\mathscr{S}_2]$, then the joint strategies*

$$\forall k \in \mathscr{V}_D,\ \sigma(k) = \begin{cases} \sigma_1(k) & \text{if } k \in \mathscr{D}_{\max}, \\ \sigma_2(k) & \text{otherwise,} \end{cases} \quad \forall t \in \mathscr{V}_T,\ \tau(t) = \begin{cases} \tau_1(t) & \text{if } t \in {\mathscr{V}_T}^{\mathscr{D}_{\max}}, \\ \tau_2(t) & \text{otherwise.} \end{cases} \tag{16}$$

are optimal in the original game.

We also note that the Shapley operator of an entropy game can be approximated in polynomial time, this follows by using a result of Borwein and Borwein [17] on the approximation of the log and exp maps, together with a scaling argument, see [1, Lemma 27]. Then, by combining Theorem 30 and Lemma 31, we get:

▶ **Corollary 32.** *A pair of optimal policies of an entropy game of rank r can be found in $O(n^2 R_{n,r}\hat{\nu}_{n,r})$ calls to an oracle that return F with a precision of $1/(16\hat{\nu}_{n,r})$. Then, entropy games in the original model of Asarin et al. [10] and with a fixed rank are polynomial-time solvable, whereas entropy games with weights, in the model of Akian et al. [1], and with a fixed rank, are pseudo-polynomial time solvable.*

▶ **Corollary 33.** *Entropy games with weights and with a fixed number of People's positions are pseudo-polynomial time solvable.*

We say that a state of a game is *significant* if there are several options in this state, in particular, a state p of People is significant if there are at least two distinct arcs (p,k) and (p,l) in $\mathscr{E}$. We may ask whether the statement of Corollary 33 carries over to entropy games with a fixed number of significant People's states. The following result shows that this can not be derived from the universal value iteration bounds, since value iteration needs $\Omega(W^{n-1})$ iterations to recognize the optimal strategy.

▶ **Theorem 34.** *There is a family of $G_n(W)$ of Despot-free entropy games, and a constant $C > 0$, with the following properties:*

1. *$G_n(W)$ has arc weights $\leqslant W$, only one significant Tribune's position, with two actions, and $2n+1$ People's positions among which there are only 4 significant positions;*
2. *The action of Tribune that is optimal in the mean-payoff entropy game is never played, if Tribune plays optimally in the entropy game of finite horizon k, for all $k \leqslant CW^{n-1}$.*

Let us explain how the game $G_n(W)$ is constructed. We start by estimating the positive root of a special polynomial p_n.

▶ **Proposition 35.** *Consider the polynomial $p_n(x) = x^n - W(x^{n-1} + \cdots + 1)$, where $W > 0$. Then, p_n has a unique positive root, $x_n(W)$, which satisfies*

$$x_n(W) = W + 1 - 1/W^{n-1} + o(1/W^{n-1}) \ , \qquad \text{as } W \to \infty \ .$$

This is established by applying the Newton-Puiseux algorithm [44] to the equation $p_n(x) = 0$ parameterized by W. Then, we define the companion matrix of p_n, $A_n = A_n(W)$, together with the sequence $(z(k))_{k\in\mathbb{N}}$,

$$A_n(W) := \left(\begin{array}{ccc|c} W & \cdots & W & W \\ \hline & I_{n-1} & & 0 \end{array}\right) \ , \ z(k) = \max(\mathbf{1}_n^\top A_n^k \mathbf{1}_n, \alpha \mathbf{1}_{n-1}^\top A_{n-1}^k \mathbf{1}_{n-1}) \ , \tag{17}$$

where for all $k \geqslant 1$, $\mathbf{1}_k$ is the vector of dimension k with unit entries, I_k the identity matrix of dimension k, and $\alpha > 1$. We note that A_n is an irreducible nonnegative matrix, so, the unique positive root of p_n is actually the Perron root of A_n. Using Proposition 35, as well as explicit bounds for the left Perron eigenvector of A_n, we can show that the maximum in (17) is achieved by the rightmost term for $k \leqslant k^*$ and by the leftmost term for $k > k^*$ where $k^* = (\log 2)W^{n-1} + o(W^{n-1})$. Moreover, $z(k)$ can be interpreted as the value in horizon $k+1$ of an entropy game satisfying the conditions of the theorem. Indeed, the leftmost term $\mathbf{1}_n^\top A_n^k \mathbf{1}_n$ can be interpreted as the value in horizon $k+1$ of a Despot-free and Tribune-free entropy game, with $n+1$ People's states, among which there are only two significant states: one encoding the first row of A_n, and another one encoding the row vector $\mathbf{1}_n^\top$. The term $\alpha \mathbf{1}_{n-1}^\top A_{n-1}^k \mathbf{1}_{n-1}$ also admits an interpretation as the value of a similar game. We finally construct the entropy game $G_n(W)$ by allowing Tribune to choose whichever of these elementary games is played. This can be implemented by taking the disjoint union of the graphs of the two elementary games, and adding one significant state of Tribune, with only two actions. One action gives rise to the left term of the maximum in (17), whereas the other action gives rise to the right term, so that the value of the corresponding entropy game in horizon k is precisely $z(k-1)$. Since $\lambda_n > \lambda_{n-1}$, in the mean-payoff entropy game, the optimal action for Tribune is to choose the term with the highest geometric growth, i.e., to play "left", which guarantees a geometric growth of λ_n. However, for $k \leqslant k^* + 1$, the optimal action of Tribune in the game of horizon k is always to play "right". This shows Theorem 34.

6 Concluding Remarks

We developed generic value iteration algorithms, which apply to various classes of zero-sum games with mean payoffs. These algorithms admit universal complexity bounds, in an approximate oracle model – we only need an oracle evaluating approximately the Shapley operator. These bounds involve three fundamental ingredients: the number of states, a separation bound between the values induced by different strategies, and a bound on the norms of Collatz-Wielandt vectors. We showed that entropy games with a fixed rank (and in particular, entropy games with a fixed number of People's states) are pseudo-polynomial time solvable. This should be compared with the result of [1], showing that entropy games with a fixed number of Despot positions are polynomial-time solvable. Since fixing the number of states of Despot or People leads to improved complexity bounds, one may ask whether entropy games with a fixed number of significant Tribune states are polynomial or at least pseudo-polynomial, this is still an open question.

Abstract

The topological properties of a set have a strong impact on its computability properties. A striking illustration of this idea is given by spheres and closed manifolds: if a set X is homeomorphic to a sphere or a closed manifold, then any algorithm that semicomputes X in some sense can be converted into an algorithm that fully computes X. In other words, the topological properties of X enable one to derive full information about X from partial information about X. In that case, we say that X has computable type. Those results have been obtained by Miller, Iljazović, Sušić and others in the recent years. A similar notion of computable type was also defined for pairs (X, A) in order to cover more spaces, such as compact manifolds with boundary and finite graphs with endpoints.

We investigate the higher dimensional analog of graphs, namely the pairs (X, A) where X is a finite simplicial complex and A is a subcomplex of X. We give two topological characterizations of the pairs having computable type. The first one uses a global property of the pair, that we call the ϵ-surjection property. The second one uses a local property of neighborhoods of vertices, called the surjection property. We give a further characterization for 2-dimensional simplicial complexes, by identifying which local neighborhoods have the surjection property.

Using these characterizations, we give non-trivial applications to two famous sets: we prove that the dunce hat does not have computable type whereas Bing's house does. Important concepts from topology, such as absolute neighborhood retracts and topological cones, play a key role in our proofs.

1 Introduction

Computable analysis is a theory formalizing computations on real numbers using finite but arbitrary precision, and allowing to investigate the theoretical possibility of solving problems on real numbers. The computable aspects of topology are an important research topic in computable analysis. Computability of homology groups was investigated in [10], computability of planar continua in [18], computability of the Brouwer fixed-point theorem was studied in [20] and [3], and computability of Polish spaces is addressed in [11].

A particularly rich topic is the computability of subsets of the plane and of Euclidean spaces. For instance, the computability of Julia sets has thoroughly been studied [4], the computability of the Mandelbrot set is still an open problem [13] and the computability of the set of solutions of a computable equation is generally a non-trivial problem [21].

These studies reveal that many natural definitions of sets induce a *semi-algorithm*, and finding a proper *algorithm* computing the set can be challenging. Informally, a compact subset of the plane is *semicomputable* if there is an algorithm that for each pixel, semidecides whether the pixel is disjoint from the set, i.e. halts exactly in that case. A compact subset of the plane is *computable* if there is an algorithm that decides, for each pixel, whether it intersects the set. This idea can be generalized to higher dimensions, and to subsets of many mathematical spaces.

Although semicomputability of compact sets is strictly weaker than computability in general, it turns out that they are equivalent for many natural sets, and that this phenomenon comes from the topological properties of these sets. For instance, it was prove by Miller [19] that semicomputability and computability are equivalent for spheres, and for every set that is homeomorphic to a sphere. This result leads to the following definition: say that a compact space X has **computable type** if any semicomputable set Y that is homeomorphic to X is actually computable. This property has been intensively studied by Miller [19] and more recently by Iljazović and his co-authors [5, 17, 9, 15, 6, 7] in the recent years. A striking aspect of this property is that it builds a bridge between computability theory and topology. The following results were obtained:

- The n-dimensional sphere $\mathbb{S}_n$ (which is the higher dimensional analog of the circle) has computable type [19],
- Every closed n-manifold (these are compact spaces which are locally homeomorphic to $\mathbb{R}^n$, e.g. the n-dimensional sphere and the n-dimensional torus) has computable type [17].

A line segment or a disk fails to have this property: it is not difficult to build a semicomputable disk which is not computable. However, a similar result can be proved if one requires in addition that the boundary of the set is semicomputable. It leads to the following generalization from compact spaces X to pairs (X, A) where X and $A \subseteq X$ are compact: a pair (X, A) has **computable type** if for any semicomputable pair (Y, B) that is homeomorphic to (X, A), Y is computable. The following results have been obtained for pairs:

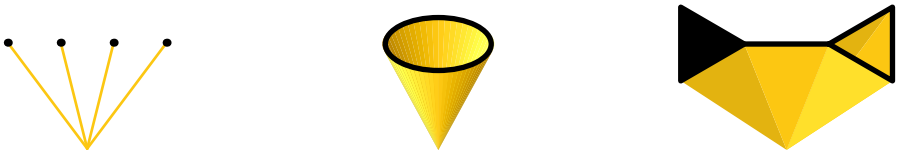
- The n-dimensional ball (which is the higher dimensional analog of the disk) with its bounding sphere $(\mathbb{B}_n, \mathbb{S}_{n-1})$ has computable type [19],
- Every compact manifold with boundary $(M, \partial M)$ has computable type [17],
- Every finite (topological) graph (G, V_1), where V_1 is the set of vertices of degree 1, has computable type [15].

Our goal in this paper is to study the property of having computable type for a broader class of spaces, to characterize the pairs having computable type and to develop a unifying argument for the known examples. Our first observation is that graphs and manifolds have the common property that they are locally topological cones as follows (see Figure 1 for an illustration of this idea):

- A finite graph is locally a cone of a finite set,
- A 2-dimensional manifold is locally a disk, which is the cone of a circle, and more generally an n-dimensional manifold is locally an n-ball, which is the cone of an $(n-1)$-sphere.

In this article, we study the class of finite simplicial complexes which is a large class of spaces that are also locally topological cones, as illustrated in Figure 1c.

Finite simplicial complexes are the higher dimensional analogs of finite graphs. They are made of simplices that are attached together along their faces. This class of compact topological spaces is large enough to include many examples (e.g., most common compact manifolds, geometrical models from computer graphics) and can be easily described using finite combinatorial information, so we can hope to obtain a full characterization of computable type for them. We do not consider infinite simplicial complexes because the usual topologies make them non-compact.



(a) A local cone in a graph.

(b) A local cone in a 2-manifold.

(c) A local cone in a simplicial complex.

Figure 1 Examples of local cones in 3 types of spaces.

Let (X, A) be a pair consisting of a finite simplicial complex X and a subcomplex A. We call such a pair a **simplicial pair**. Our main problem is to understand which simplicial pairs (X, A) have computable type. We give a thorough answer, by giving two topological characterizations of the simplicial pairs (X, A) having computable type. One of them is global whereas the other one is local. The local characterization makes it very easy to check whether a simplicial pair (X, A) has computable type, by inspecting the neighborhoods of each vertex separately. Those neighborhoods are called **local cones**, because they are topological cones with the vertex as the tip (precise definitions will be given in the article). We then use the local characterization to prove or disprove that specific sets, such as **Bing's house** and the **dunce hat**, have computable type. The previous techniques developed in the literature were too specific to be applied to these sets. Our techniques not only make it possible to treat any simplicial complex, but also provide a simple and visual way to settle the question for many sets.

The proofs are non-trivial but the statements are elegant and easy to apply. For instance it is very easy to apply our results to show that the dunce hat does not have computable type. However, the internals of the proofs of the theorems are rather involved and we are not aware of any simpler, more direct argument. Therefore our results provide significant progress in the understanding of the computable type property. Moreover, our approach in this article is new in the sense that the proofs are very different from the arguments developed in the literature on the computable type property.

It turns out that the computability property we are studying is intimately related to topology, so we need to use topology in our investigation. However, we only assume familiarity with basic topology (e.g., continuity and compactness). When we use more advanced topological notions, we give the necessary background (e.g. cones, simplicial complexes).

The results. Let us summarize the main results of this paper. We will be working with pairs (X, A) consisting of a compact metric space X and a compact subset A, to be informally thought as the boundary of X. A typical example is given by the pair $(\mathbb{B}_{n+1}, \mathbb{S}_n)$ consisting of the $(n+1)$-dimensional ball and the n-dimensional sphere:

$$\mathbb{B}_{n+1} = \{x \in \mathbb{R}^{n+1} : \|x\| \leq 1\},$$
$$\mathbb{S}_n = \{x \in \mathbb{R}^{n+1} : \|x\| = 1\},$$

where $\|\cdot\|$ is the Euclidean norm or any equivalent norm. We introduce two important properties of pairs, given in Definition 3.1 and restated here.

▶ **Definition.** A pair (X, A) has the **surjection property** if every continuous function $f : X \to X$ satisfying $f|_A = \mathrm{id}_A$ is surjective.

Let $\epsilon > 0$. A pair (X, A) has the **ϵ-surjection property** if every continuous function $f : X \to X$ satisfying $f|_A = \mathrm{id}_A$ and $d(f, \mathrm{id}_X) < \epsilon$ is surjective.

For instance, a consequence of Brouwer's fixed-point theorem is that the pair $(\mathbb{B}_{n+1}, \mathbb{S}_n)$ has the surjection property.

The main result of the paper is Theorem 3.4, which relates computable type with these two properties. We restate it here. We recall that a **simplicial pair** (X, A) consists of a finite simplicial complex X and a subcomplex $A \subseteq X$.

▶ **Theorem.** *Let (X, A) be a simplicial pair such that A has empty interior in X. The following conditions are equivalent:*

1. *(X, A) has computable type,*
2. *There exists $\epsilon > 0$ such that (X, A) has the ϵ-surjection property,*
3. *Every local cone pair of (X, A) has the surjection property.*

Condition 2. is the global property mentioned above and condition 3. is the local one. This theorem reduces a computability-theoretic property to purely topological ones. We develop further techniques to determine whether a pair has computable type, by applying this theorem or by analyzing when the topological properties are satisfied. The first one is stability under finite unions (Theorem 4.1 and Corollary 4.2).

▶ **Theorem** (Finite union)**.** *Let (X, A) be a simplicial pair and $(X_i, A_i)_{i \leq n}$ be pairs of subcomplexes such that $X = \bigcup_{i \leq n} X_i$ and $A = \bigcup_{i \leq n} A_i$. If each (X_i, A_i) has computable type, then (X, A) has computable type.*

The second one is a further characterization of the 2-dimensional simplicial pairs having computable type, by reducing the surjection property for local cone pairs to a simple property of graphs (Theorem 4.4). We demonstrate the strength of that result by giving non-trivial applications to two famous sets: the dunce hat (Figure 4a) and Bing's house (Figure 5).

In order to make the paper understandable to a larger audience, we give informal proofs of the main results. The detailed proofs can be found in the full version [14].

The paper is organized as follows. In Section 2, we give the needed background on computability of sets, simplicial complexes and cone spaces. In Section 3, we define the surjection property and the ϵ-surjection property, state and prove our main result. In Section 4, we present techniques to prove or disprove the (ϵ-)surjection property. As an application, we prove that the dunce hat does not have computable type whereas the Bing's house does, by studying the local cones of each of the two sets. In Section 5, we briefly discuss the possible notions of boundary ∂X of a simplicial complex X that make the pair $(X, \partial X)$ have computable type. We finally formulate open questions and discuss a generalization of our results in Section 6.

2 Preliminaries

We give here some necessary preliminaries in computability theory and topology. We start with this central definition.

▶ **Definition 2.1.** *A **pair** (X, A) consists of a compact metrizable space X and a compact subset $A \subseteq X$. A **copy** of a pair (X, A) in a topological space Z is a pair (Y, B) such that $Y \subseteq Z$ is homeomorphic to X and A is sent to B by the homeomorphism.*

2.1 Computability of sets

We recall definitions and results about the Hilbert cube and computable type. We will mainly use the following notion from computability theory: a set $A \subseteq \mathbb{N}$ is **computably enumerable (c.e.)** if there exists a Turing machine that, on input $n \in \mathbb{N}$, halts if and only if $n \in A$. This notion immediately extends to subsets of countable sets, whose elements can be encoded by natural numbers.

Computability in the Hilbert cube. We work in the Hilbert cube because it is universal among the separable metrizable spaces, in particular every compact metrizable space embeds in the Hilbert cube.

▶ **Definition 2.2.** *The **Hilbert cube** is the space $Q = [0,1]^{\mathbb{N}}$ endowed with the metric $d(x,y) = \sum_i 2^{-i}|x_i - y_i|$. We let $(B_i)_{i\in\mathbb{N}}$ be a computable enumeration of the open balls $B(x,r)$ where $x \in Q$ has finitely many non-zero rational coordinates and $r > 0$ is rational; these B_is are called **rational balls**.*

▶ Notation 1. If $X \subseteq Q$ and $f, g : X \to Q$, then let $d_X(f,g) = \sup_{x\in X} d(f(x), g(x))$.

We recall definitions of computability of compact subsets of the Hilbert cube. The reader can find more details about computability of sets in [2, 16].

▶ **Definition 2.3** (Computability of sets). *A compact set $X \subseteq Q$ is:*
- ***Semicomputable** if there exists a c.e. set $E \subseteq \mathbb{N}$ such that $Q \setminus X = \bigcup_{i\in E} B_i$,*
- ***Computable** if it is semicomputable and $\{i \in \mathbb{N} : X \cap B_i \neq \emptyset\}$ is c.e.*

*A pair (X, A) in Q is **semicomputable** if both X and A are semicomputable.*

Intuitively, X is semicomputable if there is an algorithm that takes any rational cube as input (a voxel) and semidecides whether that cube is disjoint from X, i.e. halts exactly in this case. X is computable if there is an algorithm that *decides* whether a cube intersects the set.

For instance, the Mandelbrot set is semicomputable because its definition gives an algorithm that can eventually detect that a point is outside this set; whether it is computable is an open problem, see [13].

▶ **Example 2.4.** The line segment $I = [0,1]$, embedded in the simplest way as $[0,1] \times \{q\} \subseteq Q$ where $q = (0, 0, \ldots)$, is computable. However, if $A \subseteq \mathbb{N}$ is the halting set (a non-computable c.e. set) and $x_A = \sum_{n\in A} 2^{-n}$, then $[x_A, 1] \times \{q\}$ is a copy of I which is semicomputable but not computable.

The Hilbert cube itself is a computable subset of itself. A compact set $X \subseteq Q$ is semicomputable if and only if the set $\{(i_1, \ldots, i_n) \in \mathbb{N}^* : X \subseteq B_{i_1} \cup \ldots \cup B_{i_n}\}$ is c.e., and it is computable if and only if in addition it contains a dense computable sequence. A function $f : Q \to Q$ is **computable** if there exists a c.e. set $E \subseteq \mathbb{N}^2$ such that $f^{-1}(B_i) = \bigcup_{(i,j)\in E} B_j$. The image of a (semi)computable set under a computable function is a (semi)computable set. Semicomputable sets have very useful properties: if $X \subseteq Q$ is semicomputable and $f, g : X \to Q$ are computable, then $\{q \in \mathbb{Q} : d_X(f,g) < q\}$ is c.e.

Computable type. The next definition is the main notion of this article (see [17]).

▶ **Definition 2.5.** *A pair (X, A) has **computable type** if for every semicomputable copy (Y, B) of the pair in the Hilbert cube, Y is computable.*

A compact space X has computable type if the pair $(X, \emptyset)$ has.

▶ Remark 2.6. In fact, in [17] computable type was defined separately for copies in computable metric spaces and computably Haudorff spaces. In a forthcoming article, we show that taking the copies in computably Hausdorff spaces, computable metric spaces or the Hilbert cube are all equivalent using the fact that computable metric spaces embed effectively in the Hilbert cube, as well as Schröder's computable metrization theorem [22].

2.2 Topology

We recall some notions which will be used, like simplicial complexes and cone spaces. We will work with compact metrizable spaces only, and may omit this assumption in the statements.

▶ **Definition 2.7.** *Let (X, A) be a pair. A **retraction** $r : X \to A$ is a continuous function such that $r|_A = \mathrm{id}_A$. If a retraction exists, then we say that A is a **retract** of X.*

Simplicial complex. Let $V = \{0, \dots, n\}$ and $P_+(V)$ be the set of non-empty subsets of V. An **abstract finite simplicial complex** is a set $S \subseteq P_+(V)$ such that if $\sigma \in S$ and $\emptyset \neq \sigma' \subset \sigma$, then $\sigma' \in S$. Its elements $\sigma \in S$ are called the **simplices** of S. If $\sigma \in S$ has $n+1$ elements, then σ is an ***n*-simplex**. The **vertices** of S are the singletons $\{i\} \in S$. $\sigma \in S$ is **free** if there exists exactly one $\sigma' \in S$ with $\sigma \subsetneq \sigma'$. A **subcomplex** of S is an abstract simplicial complex contained in S.

The **support** of a vector $x = (x_0, \dots, x_n) \in [0,1]^{n+1}$ is $\mathrm{supp}(x) = \{i : x_i \neq 0\}$. The **standard realization** of an abstract simplicial complex S is the set

$$|S| = \Big\{x = (x_0, \dots, x_n) \in [0,1]^{n+1} : \sum_i x_i = 1, \mathrm{supp}(x) \in S\Big\}.$$

Any space homeomorphic to the standard realization of an abstract finite simplicial complex is called a **finite simplicial complex**. We often identify an abstract simplicial complex and its standard realization.

A **simplicial pair** (X, A) consists of a finite simplicial complex X and a subcomplex A.

▶ Remark 2.8. For technical reasons, we will implicitly assume that A contains all the free vertices of X (those are the points x having a neighborhood homeomorphic to $[0, 1)$ with a homeomorphism sending x to 0).

In a simplicial complex, each vertex has a neighborhood which is usually called a star and is topologically a cone. Our main result will relate the computable type property with a property of these local cones. Because we are dealing with pairs, we need to define local cone pairs, as follows.

▶ **Definition 2.9.** *Let (X, A) be the standard realization of a simplicial pair and $v_i = (0, \dots, 0, 1, 0, \dots, 0)$ be a vertex. The **local cone pair** at v_i is (K_i, M_i) defined by:*

$$K_i = \{x \in X : x_i \geq 1/2\},$$
$$M_i = \{x \in X : x_i = 1/2\} \cup (K_i \cap A).$$

Note that the coefficient $1/2$ is arbitrary and could be replaced by any number in $(0, 1)$.

▶ Remark 2.10. We call (K_i, M_i) a cone pair because K is a topological cone: let $L_i = \{x \in X : x_i = 1/2\}$, K_i is a copy of the cone of L_i, obtained from $L_i \times [0, 1]$ by identifying all the points $(l, 0)$ together. The point obtained by this identification is the tip of the cone and corresponds to the vertex v_i. If $N_i = \{x \in A : x_i = 1/2\}$, then M_i is the union of L_i and of the cone of N_i.

In the language of simplicial complexes, K_i corresponds to the *star* of v_i and L_i to the *link* of v_i. K_i is homeomorphic to the union of simplices containing v_i. Each such simplex has a face that does not contain v_i, and L_i is the union of these faces.

3 The (ϵ-)surjection property and computable type for simplicial pairs

We now present the main result of this paper, that identifies which simplicial pairs have computable type, using the following topological properties.

▶ **Definition 3.1.** *A pair (X, A) has the **surjection property** if every continuous function $f : X \to X$ satisfying $f|_A = \mathrm{id}_A$ is surjective.*

*A pair (X, A) in Q has the **ϵ-surjection property** for some $\epsilon > 0$, if every continuous function $f : X \to X$ satisfying $f|_A = \mathrm{id}_A$ and $d_X(f, \mathrm{id}_X) < \epsilon$ is surjective.*

▶ **Example 3.2.**

- For every $n \in \mathbb{N}$, the $(n+1)$-dimensional ball and its bounding n-dimensional sphere form a pair $(\mathbb{B}_{n+1}, \mathbb{S}_n)$ that has the surjection property. It is a consequence of an equivalent formulation of Brouwer's fixed-point theorem that $\mathbb{S}_n$ is not a retract of $\mathbb{B}_{n+1}$ (Corollary 2.15 in [12]).
- The pair $(\mathbb{S}_n, \emptyset)$ does not have the surjection property (take a constant function $f : \mathbb{S}_n \to \mathbb{S}_n$), but has the ϵ-surjection property if ϵ is sufficiently small. It can be proved using classical results in topology, or as a consequence of Theorem 3.4 below.
- If $A \subsetneq X$ is a retract of X, then the pair (X, A) does not have the surjection property, as witnessed by the retraction.

Although the ϵ-surjection property depends on the particular copy of a pair (X, A), quantifying over ϵ yields a topological invariant, i.e. a property of the pair that is satisfied either by all copies or by none of them.

▶ **Proposition 3.3.** *Whether there exists $\epsilon > 0$ such that (X, A) has the ϵ-surjection property does not depend on the copy of (X, A) in Q.*

Proof. If (Y, B) is a copy of (X, A), then let $\phi : X \to Y$ be a homeomorphism such that $\phi(A) = B$. By compactness of X, ϕ is uniformly continuous so given $\epsilon > 0$, there exists $\delta > 0$ such that if $d(x, x') < \delta$ then $d(\phi(x), \phi(x')) < \epsilon$. If (Y, B) has the ϵ-surjection property, then we show that (X, A) has the δ-surjection property. Let $f : X \to X$ be continuous, satisfying $f|_A = \mathrm{id}_A$ and $d_X(f, \mathrm{id}_X) < \delta$. Define $g = \phi \circ f \circ \phi^{-1} : Y \to Y$: one has $g|_B = \mathrm{id}_B$ and $d_Y(g, \mathrm{id}_Y) < \epsilon$ by choice of δ so g is surjective, hence f is surjective. ◀

We now state the main result of this paper.

▶ **Theorem 3.4** (The main theorem)**.** *Let (X, A) be a simplicial pair such that A has empty interior in X. The following statements are equivalent:*

1. *(X, A) has computable type,*
2. *(X, A) has the ϵ-surjection property for some $\epsilon > 0$,*
3. *All the local cone pairs (K_i, M_i) have the surjection property.*

We separate the proof into several independent parts.

▶ Remark 3.5. A single topological space X has many different simplicial decompositions, i.e. many abstract simplicial complexes whose realizations are homeomorphic to X. For instance, a triangle can be decomposed into many smaller triangles. At first sight, the third condition in Theorem 3.4 depends on the choice of the decomposition, because the local

cone pairs are taken at the vertices of the decomposition. However, the theorem implies that the choice of the simplicial decomposition is irrelevant, because conditions 1. and 2. do not depend on the decomposition: if all the cone pairs in a simplicial decomposition have the surjection property, then it is still true for all other simplicial decompositions of the space.

For a simplicial pair that is itself homeomorphic to a cone pair, we obtain a further equivalence, which is a consequence of Theorem 3.4.

Let (L, N) be a simplicial pair. The **simplicial cone pair** induced by (L, N) is the pair (K, M) defined by $K = \mathrm{Cone}(L)$ and $N = L \cup \mathrm{Cone}(N)$, as in Remark 2.10.

▶ **Corollary 3.6.** *Let (K, M) be a simplicial cone pair such that M has empty interior in K. The following statements are equivalent:*

1. *(K, M) has computable type,*
2. *(K, M) has the ϵ-surjection property for some $\epsilon > 0$,*
3. *(K, M) has the surjection property.*

Proof. The surjection property implies the ϵ-surjection property for any pair. Conversely, if the pair (K, M) has the ϵ-surjection property then each local cone pair has the surjection property, but (K, M) is itself homeomorphic to one of its local cone pairs. ◀

The rest of this section is devoted to the proof of this result. We will give several applications in the next section.

3.1 The ϵ-surjection property implies computable type

In this section we give an informal idea of the proof of 2. $\Rightarrow$ 1. in Theorem 3.4. The idea of the proof is that if A has empty interior in X and (X, A) has the ϵ-surjection property, then for an open set U the following conditions are equivalent:

- U intersects X,
- There exists a continuous non-surjective function $g : (X \setminus U) \cup A \to X$ such that $g|_A = \mathrm{id}_A$ and $d_X(g, \mathrm{id}_X) < \epsilon$.

This equivalence is straightforward. If U intersects X, then let g be the inclusion map. Conversely, if such a g exists then $(X \setminus U) \cup A$ must differ from X by the ϵ-surjection property for (X, A), so U intersects X.

The finite simplicial complex X has good topological properties because it is a compact Absolute Neighborhood Retract (ANR), which means that any copy of X in Q is a retract of some neighborhood of that copy. The detailed proof consists in showing how to use these properties to prove that the existence of such a function g can be detected by an algorithm if (X, A) is semicomputable. The main idea is that one does not need to search for an arbitrary continuous function g, but for a computable one. Therefore, one can test whether an open set U intersects X, which makes X computable.

3.2 The ϵ-surjection property is equivalent to the local surjection property

In this section we give an informal proof of the equivalence 2. $\Leftrightarrow$ 3. in Theorem 3.4

The ϵ-surjection property implies the local surjection property. It is easy to see that if a local cone pair does not have the surjection property, then for any $\epsilon > 0$, the pair (X, A) does not have the ϵ-surjection property. It relies on the particular property of a cone that it contains arbitrarily small copies of itself, obtained by scaling it down: for any $\lambda \in (0, 1)$,

the set $K_i(\lambda) = \{x \in X : x_i \geq \lambda\}$ is a copy of K_i and it has arbitrarily small diameter as λ approaches 1. Given $\epsilon > 0$, consider λ such that $K_i(\lambda)$ has diameter less than ϵ. Take a non-surjective function f from $K_i(\lambda)$ to itself which is the identity on the corresponding set $M_i(\lambda)$, and extend it to a non-surjective function $g : X \to X$ by simply defining $g(x) = x$ for x outside $K_i(\lambda)$. One has $d(g, \mathrm{id}_X) < \epsilon$, showing that (X, A) does not have the ϵ-surjection property.

The local surjection property implies the ϵ-surjection property. Now, assume that for every $\epsilon > 0$, (X, A) does not have the ϵ-surjection property. We show that some local cone pair does not have the surjection property. The idea is to start from a sufficiently small $\epsilon > 0$, to be defined later, and a non-surjective function $h : X \to X$ such that $h|_A = \mathrm{id}_A$ and $d(h, \mathrm{id}_X) < \epsilon$ and consider its restriction h_0 to a local cone K which is not contained in the image of h. This function h_0 does not immediately disprove the surjection property for the local cone pair (K, M) because $h_0(K)$ may not be contained in K and h_0 may not be the identity on M. However, h_0 almost satisfies these properties: $h_0(K)$ is at distance ϵ from K and h_0 is ϵ-close to the identity on M. Again, using the fact that K is a compact Absolute Neighborhood Retract (ANR) and the properties derived from that, if one takes ϵ sufficiently small, then one can transform h_0 into a continuous function G that sends K to itself, is the identity on M and is still non-surjective. Therefore, (K, M) does not have the surjection property.

3.3 Computable type implies the ϵ-surjection property

We prove 1. $\Rightarrow$ 2. in Theorem 3.4. We show that if a simplicial pair (X, A) does not have the ϵ-surjection property for any $\epsilon > 0$, then it has a semicomputable copy in Q that is not computable. In order to build that semicomputable copy, we show that the pair fails in a computable way to have the ϵ-surjection property, which is expressed by Definition 3.7.

For two non-empty compact sets $A, B \subseteq Q$, their Hausdorff distance is

$$d_H(A, B) = \max(\max_{a \in A} d(a, B), \max_{b \in B} d(b, A)).$$

▶ **Definition 3.7.** *Let $\epsilon > 0$ and $(X, A) \subseteq Q$ fail to have the ϵ-surjection property. Say that $\delta > 0$ is an **ϵ-witness** if there exists a continuous function $f : X \to X$ such that $f|_A = \mathrm{id}_A$, $d_X(f, \mathrm{id}_X) < \epsilon$ and $d_H(f(X), X) > \delta$.*

*Say that (X, A) has **computable witnesses** if there is a computable function $\epsilon \mapsto \delta(\epsilon)$ such that for every $\epsilon > 0$, $\delta(\epsilon)$ is an ϵ-witness.*

For a compact pair (X, A) (not necessarily simplicial), having computable witnesses is sufficient to build a semicomputable copy which is not computable.

▶ **Theorem 3.8.** *Let $(X, A) \subseteq Q$ be a computable pair having computable witnesses. (X, A) does not have computable type.*

Informal proof. In order to give some intuition, let us show precisely another but related result: if we only assume that (X, A) does not have the surjection property, then one can encode the halting problem for *one* program p in a copy of (X, A), in the following sense. Given p, one can produce an algorithm that semicomputes a copy (X_p, A_p) of (X, A); any algorithm computing X_p could be used to decide whether p halts.

Let $(X_0, A_0) \subseteq Q$ be a semicomputable copy of (X, A) and $\delta > 0$ be such that there exists a non-surjective continuous function $f : X_0 \to X_0$ such that $f|_{A_0} = \mathrm{id}_{A_0}$ and $d_H(X_0, f(X_0)) > \delta$.

Given a program p, we define a copy (X_p, A_p). If p does not halt, then $(X_p, A_p) = (X_0, A_0)$. If p halts, then (X_p, A_p) is another copy (X_1, A_1) defined by the following algorithm.

Start enumerating the complements of X_0 and A_0. If p eventually halts then consider a copy (X_1, A_1) of (X_0, A_0) with the following properties:

- (X_1, A_1) is compatible with (i.e. disjoint from) the current enumeration of the complements of X_0 and A_0,
- $d_H(X_1, X_0) > \delta$.

The existence of f implies the existence of (X_1, A_1), which can be effectively found. We then continue enumerating the complements of X_1 and A_1.

We have just given an algorithm that semicomputes a copy (X_p, A_p) of (X, A), be it (X_0, A_0) or (X_1, A_1). Any algorithm that computes X_p could be used to know whether p halts: p halts if and only if $d_H(X_p, X_0) > \delta$, which can be decided from the computable information about X_p.

Now, assuming that (X, A) does not have the ϵ-surjection property for any ϵ, and using the assumption that a witness $\delta(\epsilon)$ can be computed from any ϵ, we apply this strategy against all the programs in parallel and at infinitely many scales. The idea is simple but the details are rather technical. ◀

Note that the standard realization of a simplicial pair is computable. We now show that if it has witnesses, then it always have *computable* witnesses, which together with Theorem 3.8 concludes the proof of 1. ⇒ 2. in Theorem 3.4.

▶ **Proposition 3.9.** *If a simplicial pair (X, A) does not have the ϵ-surjection property for any $\epsilon > 0$, then its standard realization has computable witnesses.*

Proof. By 3. ⇒ 2. in Theorem 3.4, there exists a local cone pair (K_i, M_i) which does not have the surjection property, so there exists a non-surjective function $f_0 : K_i \to K_i$ such that $f_0|_{M_i} = \mathrm{id}_{M_i}$. One can assume w.l.o.g. that $d_X(f_0, \mathrm{id}_X) < 1$. Let $\delta_0 > 0$ be such that $d_H(f_0(X), X) > \delta_0$. Given $\epsilon > 0$, the number $\delta = \delta_0\epsilon$ can be computed from ϵ and is an ϵ-witness. Indeed, the function f obtained by applying f_0 to a version of K_i scaled by a factor ϵ and extended as the identity elsewhere satisfies all the conditions. ◀

4 Techniques for the (ϵ-)surjection property

Theorem 3.4 enables one to reduce the computable type property to topological properties, namely the ϵ-surjection property and the surjection property for local cone pairs. Proving or disproving these properties may not be straightforward, so we develop a few techniques that help in many cases.

4.1 Finite union

The first result is a way to prove that a simplicial pair has the ϵ-surjection property by decomposing it as a finite union of pairs that all have the ϵ-surjection property.

▶ **Theorem 4.1** (Finite union). *Let (X, A) be a finite simplicial pair and $(X_i, A_i)_{i \leq n}$ be pairs of subcomplexes such that $X = \bigcup_{i \leq n} X_i$ and $A = \bigcup_{i \leq n} A_i$. If every pair (X_i, A_i) has the ϵ-surjection property for some $\epsilon > 0$, then (X, A) has the δ-surjection property for some $\delta > 0$.*

Informal proof. We are using good topological properties of finite simplicial complexes. For each i, there exists a neighborhood U_i of X_i and a retraction $r_i : U_i \to X_i$ with a special property: if x belongs to the topological interior of X_i, then the only preimage of x by r_i is x.

Let δ be sufficiently small and assume that (X, A) does not have the δ-surjection property. Let $f : X \to X$ be continuous, non-surjective and satisfy $f|_A = \mathrm{id}_A$ and $d_X(f, \mathrm{id}_X) < \delta$. There must be $i \leq n$ and x in the interior of X_i that is not in the image of f. We can then create a function $f_i : X_i \to X_i$ as follows: f_i is the restriction of $r_i \circ f$ to X_i (it is possible if δ is sufficiently small, so that $f(X_i) \subseteq U_i$).

The special property of r_i implies that x is not in the image of f_i. Moreover, f_i is continuous, is the identity on A_i and is ϵ-close to id_{X_i} if δ is sufficiently small. ◀

▶ **Corollary 4.2.** *Let (X, A) be a simplicial pair and $(X_i, A_i)_{i\leq n}$ be pairs of subcomplexes such that $X = \bigcup_{i\leq n} X_i$ and $A = \bigcup_{i\leq n} A_i$. If every pair (X_i, A_i) has computable type, then (X, A) has computable type.*

For instance, if a finite simplicial complex X is a finite union of subcomplexes that are homeomorphic to spheres, then X has computable type. More generally, if a finite simplicial pair (X, A) is a finite union of pairs of subcomplexes (X_i, A_i) that are homeomorphic to pairs $(\mathbb{S}_n, \emptyset)$ or $(\mathbb{B}_{n+1}, \mathbb{S}_n)$, then (X, A) has computable type.

4.2 Cone of a graph

In a 2-dimensional simplicial pair, the local cones are cones of graphs. We obtain a characterization of the surjection property for such cones. In order to state the result, we need to define the cone pair induced by a pair, already informally discussed in Remark 2.10. Let (L, N) be a pair. We define the cone pair $(K, M) := \mathrm{Cone}(L, N)$ as follows:

- $K = \mathrm{Cone}(L)$ is the quotient of $L \times [0, 1]$ by the equivalence relation $(x, 0) \sim (y, 0)$,
- $M = L \cup \mathrm{Cone}(N)$, where L is embedded in K as $L \times \{1\}$.

The space L is called the **base** of the cone $K = \mathrm{Cone}(L)$, and the equivalence class $L \times \{0\}$ is called the **tip** of K.

▶ **Example 4.3.** Let us illustrate this notion on the usual example of balls and spheres:

- $\mathrm{Cone}(\mathbb{S}_n, \emptyset) = (\mathbb{B}_{n+1}, \mathbb{S}_n)$ with the tip at the center of $\mathbb{B}_{n+1}$,
- $\mathrm{Cone}(\mathbb{B}_n, \mathbb{S}_{n-1}) = (\mathbb{B}_{n+1}, \mathbb{S}_n)$ with the tip in $\mathbb{S}_n$.

Here is the main result of this section.

▶ **Theorem 4.4.** *Let (L, N) be a pair such that L is a finite graph and N is a subset of its vertices. The following statements are equivalent:*

1. $\mathrm{Cone}(L, N)$ *has the surjection property,*
2. *Every edge is in a cycle or a path starting and ending in N.*

We follow the usual convention that in a graph, a path and a cycle do not visit a vertex twice, i.e. they are topologically a line segment and a circle respectively. In particular, a path connects two different points.

▶ **Example 4.5** (Star pair)**.** Fix some $n \geq 1$ and let X be the star with n branches and A be the n endpoints of these branches (see Figure 2), with a special case for $n = 1$: $\mathrm{Cone}(\{v\}, \emptyset) = (\mathbb{B}_1, \mathbb{S}_0)$. The pair (X, A) is precisely $\mathrm{Cone}(A, \emptyset)$. As A has no edge, it satisfies the conditions of Theorem 4.4, therefore (X, A) has the surjection property. One can then obtain Iljazović's result that every finite graph has computable type [15], because the local cones of a finite graph are stars, which have the surjection property.

(a) Star with 5 branches. **(b)** Star with 1 branch.

Figure 2 The star pairs (X, A) have the surjection property (Example 4.5) (X in yellow, A in black).

▶ **Example 4.6** (n squares)**.** Fix some $n \geq 2$ and let X be the union of n squares which all meet in one common edge and A be the union of all the other edges (see Figure 3). The pair (X, A) has the surjection property. Indeed, $(X, A) = \mathrm{Cone}(A, \emptyset)$ and A is a graph which is a union of circles (each circle is the boundary of the union of two squares). Therefore, $\mathrm{Cone}(A, \emptyset)$ has the surjection property by Theorem 4.4. Finally, (X, A) has computable type by Corollary 3.6.

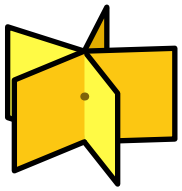


Figure 3 A union of 5 squares is the cone of a graph; the tip is at the center, the graph is in black (Example 4.6).

We expect a generalization of Theorem 4.4 to cones of arbitrary simplicial complexes, by using the notions of n-cycles and relative n-cycles from homology, generalizing cycles and paths respectively [12].

In the next section we apply Theorem 4.4, giving an example of a cone pair of a graph which does not have the surjection property.

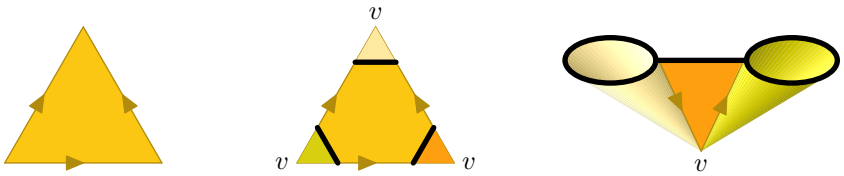
4.3 The dunce hat

The **dunce hat** D is the space obtained from a solid triangle by gluing its three sides together, with the orientation of one side reversed (see Figure 4a). It is a classical example, introduced by Zeeman [23], of a space that is contractible but not intuitively so. It is a 2-dimensional simplicial complex with no free edge, i.e. no edge that belongs to one triangle only.

▶ **Theorem 4.7.** *The dunce hat does not have computable type.*

Proof. First, it is possible to turn the dunce hat into a simplicial complex, so we can apply our results. The vertices of the triangle are identified to a point v, and we show that the local cone pair at that point does not have the surjection property. Indeed, in Figure 4c one can see that the local cone pair at v is $\mathrm{Cone}(L, \emptyset) = (\mathrm{Cone}(L), L)$ where L is the graph consisting of two circles joined by a line segment.

We apply Theorem 4.4: L is a finite graph containing an edge which is neither in a cycle nor in a path from N to N (N is empty), therefore $\mathrm{Cone}(L, N)$ does not have the surjection property. Theorem 3.4 then implies that the dunce hat does not have computable type. ◀



(a) Dunce hat. **(b)** Local cone pair. **(c)** Local cone pair.

Figure 4 (a) The dunce hat is obtained by gluing the edges with the indicated orientations; (b) and (c) a local cone pair $(\mathrm{Cone}(L), L) = \mathrm{Cone}(L, \emptyset)$ with tip at v, with L in black.

As far as we know, there is no simple and visual way of building a semicomputable copy of the dunce hat that is not computable, i.e. the involved construction carried out in the proof of Theorem 3.4 cannot be avoided. The same remark applies to the pair $(\mathrm{Cone}(L), L)$ depicted in Figure 4c.

If A is the identified edges of the triangle, then it can be proved, by analyzing its local cone pairs, that the pair (D, A) has computable type. In particular, the local cone pair at v is $\mathrm{Cone}(L, N)$ where N consists of the two endpoints of the middle interval, so L is the union of two circles and a line segment between two points of N, hence $\mathrm{Cone}(L, N)$ has the surjection property by Theorem 4.4.

▶ Remark 4.8 (Quotient vs pair). It is proved in [8] that for any compact pair (X, A) where A has empty interior, if the quotient space X/A has computable type then the pair (X, A) has computable type. It is also proved that the converse implication fails, the counter-example is given by the circle X and a subset A consisting of a converging sequence together with its limit. The pair (X, A) has computable type, simply because X itself has computable type. However, X/A is homeomorphic to the Hawaiian earring which does not have computable type. This quotient is not a finite simplicial complex.

We give another counter-example of a quotient space which is a finite simplicial complex. Let $L = C_1 \vee I \vee C_2$, X be the cylinder of L and A the two bases of the cylinder. Inspecting the local cones one can show that (X, A) has computable type but X/A does not.

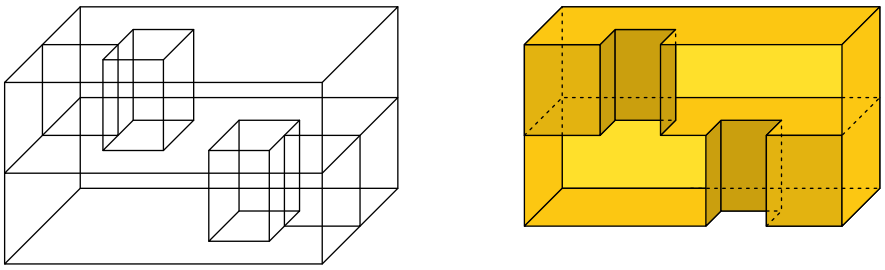
4.4 Bing's house, or the house with two rooms

All the known examples of sets having computable type are non-contractible (note that we are not considering pairs, but single sets), and one might conjecture that no contractible set has computable type. We give a counter-example, which is a famous space that was defined as a counter-example for other properties. It was invented by Bing [1] and is now called **Bing's house**, or the house with two rooms. The set is depicted in Figure 5, together with a half-cut to help visualizing it. It is an example of a space which is contractible but not intuitively so. It can be endowed with a simplicial complex structure (by triangulating each flat surface). It is then a 2-dimensional simplicial complex with no free edge, which means that every edge belongs to at least two triangles.

Using our results we easily show that this set has computable type as a single set, i.e. without adjoining a boundary to it.

▶ **Theorem 4.9.** *Bing's house has computable type.*

It is worth noticing that thanks to our results, it can be proved by looking at pictures only, although the argument can be formalized.



(a) Bing's house. **(b)** Half-cut.

Figure 5 Bing's house with two rooms and a half-cut of it (the full house is obtained by adding the symmetric reflection of the half-cut through the front vertical plane). It consists of two rooms, each of which can be accessed from outside through a tunnel crossing the other room. Each tunnel is linked by an internal wall to a side wall.

Proof. Using Theorem 3.4, it is sufficient to inspect the possible local cones. One easily sees that there are three types of possible cones, depicted in Figure 6. The basis of each cone is a graph which is a union of 1, 2 or 3 cycles, so by Theorem 4.4 each cone pair has the surjection property, therefore Bing's house has computable type by Theorem 3.4.

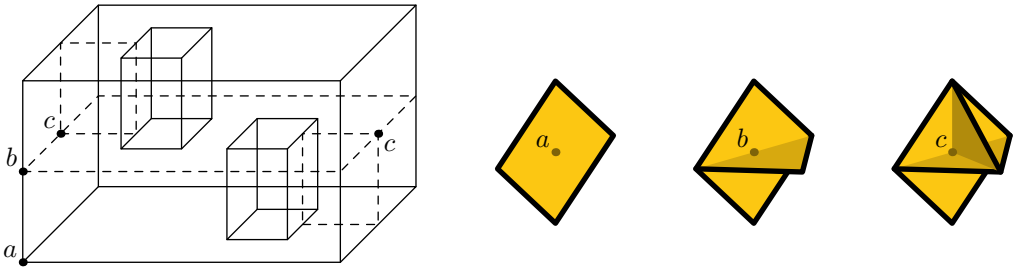


Figure 6 The local cones in Bing's house: their bases (in black) are graphs that are unions of cycles. Each point of Bing's house is the tip of one of these three cones: two points are tips of the third cone, all the other points on the dashed lines are tips of the second cone, all the other points are tips of the first cone. ◀

5 Boundary

Given a simplicial complex X, a natural problem is to understand whether there is a minimal notion of boundary ∂X such that the pair $(X, \partial X)$ has computable type. We make a few observations about three possible candidates. Let

- $\partial_1 X$ be the union of simplices that are contained in *exactly* one simplex of the next dimension, i.e. $\partial_1 X$ is the union of the free simplices of X,
- $\partial_+ X$ be the union of simplices that are contained in *at least* one simplex of the next dimension,
- $\partial_{\text{odd}} X$ be the union of simplices that are contained in *an odd number* of simplices of the next dimension.

In the proofs of the next results, we say that a simplex M in X is **maximal** if it is not contained in a higher-dimensional simplex of X.

▶ **Proposition 5.1.** *Every simplicial pair $(X, \partial_+ X)$ has computable type.*

Proof. Let $(M_i)_{i\leq n}$ be an enumeration of the maximal simplices of X. M_i is a ball, let ∂M_i be its bounding sphere, which is a subcomplex of M_i. One has $X = \bigcup_{i\leq n} M_i$ and $\partial_+ X = \bigcup_{i\leq n} \partial M_i$. Each pair $(M_i, \partial M_i)$ has the surjection property (Example 3.2), so $(X, \partial_+ X)$ has the ϵ-surjection property for some ϵ by Theorem 4.1. As a result, $(X, \partial_+ X)$ has computable type by Theorem 3.4. ◀

▶ **Proposition 5.2.** *Let X be a finite simplicial complex and A a subcomplex. If (X, A) has computable type, then A contains $\partial_1 X$.*

Proof. Assume that some simplex Δ belongs to $\partial_1 X$ but not to A. We show that for every $\epsilon > 0$, (X, A) does not have the ϵ-surjection property, implying that (X, A) does not have computable type by Theorem 3.4. Let $\epsilon > 0$. Let Δ' be the unique maximal simplex having Δ as a face (Δ' has one more vertex than Δ). There is a non-surjective function $f : \Delta' \to \Delta'$ which is ϵ-close to the identity and is the identity on the other faces of Δ': f slightly pushes points of Δ' away from Δ. We extend f as the identity on the rest of X, which gives a continuous function because Δ is free. As Δ is not in A, f is the identity on A. ◀

The following observations can be made:

- Although $(X, \partial_1 X)$ has computable type when X is a 1-dimensional complex (i.e., a graph), it is no more true for 2-dimensional complexes. For the dunce hat D, one has $\partial_1 D = \emptyset$ but we saw in Theorem 4.7 that $(D, \emptyset)$ does not have computable type.
- While $(X, \partial_+ X)$ always has computable type by Proposition 5.1, $\partial_+ X$ is far from optimal. For instance, it is always non-empty (unless X is a single point), but for any sphere $\mathbb{S}_n$, the pair $(\mathbb{S}_n, \emptyset)$ already has computable type.
- In a subsequent paper we prove that $(X, \partial_{\text{odd}} X)$ always has computable type, using homology. Observe that $\partial_{\text{odd}} X$ is in general not optimal, as the example of graphs shows: $(X, \partial_1 X)$ has computable type and $\partial_1 X$ is usually smaller than $\partial_{\text{odd}} X$, which contains all the vertices of odd degrees.

6 Open questions and generalization

We leave two open questions.

▶ **Question 1.** *Is there a canonical notion of boundary ∂X for a simplicial complex X, such that $(X, \partial X)$ always has computable type, and ∂X is minimal in some sense?*

▶ **Question 2.** *For simplicial pairs (L, N), is it possible to characterize the surjection property for $\text{Cone}(L, N)$ in terms of the homology of (L, N)?*

We finally mention that the proof of the main result actually applies to more general spaces. For instance one can prove that if $(M, \partial M)$ is a compact manifold with boundary, then $\text{Cone}(M, \partial M)$ has computable type because it satisfies the surjection property, although it is not always a simplicial complex. These results will appear in a forthcoming article.

Unboundedness for Recursion Schemes: A Simpler Type System

David Barozzini

Jan Wróblewski
Institute of Informatics, University of Warsaw, Poland

Abstract

Decidability of the problems of unboundedness and simultaneous unboundedness (aka. the diagonal problem) for higher-order recursion schemes was established by Clemente, Parys, Salvati, and Walukiewicz (2016). Then a procedure of optimal complexity was presented by Parys (2017); this procedure used a complicated type system, involving multiple flags and markers. We present here a simpler and much more intuitive type system serving the same purpose. We prove that this type system allows to solve the unboundedness problem for a widely considered subclass of recursion schemes, called safe schemes. For unsafe recursion schemes we only have soundness of the type system: if one can establish a type derivation claiming that a recursion scheme is unbounded then it is indeed unbounded. Completeness of the type system for unsafe recursion schemes is left as an open question. Going further, we discuss an extension of the type system that allows to handle the simultaneous unboundedness problem.

We also design and implement an algorithm that fully automatically checks unboundedness of a given recursion scheme, completing in a short time for a wide variety of inputs.

1 Introduction

Higher-order recursion schemes (*recursion schemes* for short) proved to be useful in model-checking programs using higher-order functions, see e.g. Kobayashi [13] (recursion schemes are algorithmically manageable abstractions of such programs, faithfully representing the control flow). Higher-order functions are widely used in functional programming languages, like Haskell, OCaml, and Lisp; additionally, higher-order features are now present in most mainstream languages like Java, JavaScript, Python, or C++.

The formalism of recursion schemes is equivalent via direct translations to simply-typed λY-calculus [27] and to higher-order OI grammars [9, 16]. Collapsible pushdown systems [11] and ordered tree-pushdown systems [6] are other equivalent formalisms. Recursion schemes cover some other models such as indexed grammars [1] and ordered multi-pushdown automata [3].

The usefulness of recursion schemes follows from the fact that trees generated by them have decidable MSO theory [20]. When the property to be verified is given by a parity automaton (a formalism equivalent to the MSO logic), and when the recursion scheme is of order m, the model-checking problem is m-EXPTIME-complete; already for reachability properties the problem is $(m-1)$-EXPTIME-complete [14]. Although this high complexity may be threatening, there exist algorithms that behave well in practice. They make use of appropriate systems of intersection types. Namely, a Japanese group created model-checkers TRecS [13] and HorSat [4], and prototype verification tools, MoCHi [15] and EHMTT verifier [28], on top of them. A group hosted in Oxford created model-checkers HORSC [19] and TravMC2 [18]. Necessarily these model-checkers are very slow on some worst-case examples, but on schemes generated from some real life higher-order programs they usually work in a reasonable time (while in the worst-case a huge type derivation may be required, it is often the case that there exists a small type derivation that can be found quickly).

In recent years, interest has arisen in model checking recursion schemes against properties that are not regular (i.e., not expressible in the MSO logic). This primarily concerns the *unboundedness problem* for word languages recognized by recursion schemes [22], and its generalization – the *simultaneous unboundedness problem* (aka. the diagonal problem) [10, 7, 26]. Decidability of the latter problem implied computability of downward closures (with respect to the subsequence relation) for these languages [29], and decidability of their separability by piecewise testable languages [8]. It was also possible to establish decidability of the WMSO+U logic (an extension of MSO with a quantifier U, talking about unboundedness) over trees generated by recursion schemes [25].

Moreover, there is also a link to asynchronous shared-memory programs, being a common way to manage concurrent requests in a system. In asynchronous programming, each asynchronous function is a sequential program. When run, it can change the global shared state of the program and run other asynchronous functions. A scheduler repeatedly and non-deterministically executes pending asynchronous functions. Majumdar, Thinniyam and Zetzsche [17] have proven that when asynchronous functions are modeled as recursion schemes, the question whether there is an a priori upper bound on the number of pending executions of asynchronous functions can be reduced to the problem we consider here, namely the unboundedness problem for a single recursion scheme.

In this paper we revisit the (simultaneous) unboundedness problem for word languages recognized by recursion schemes. This problem asks, for a set of letters Σ_{a} and a language of words L (recognized by a recursion scheme), whether for every $n \in \mathbb{N}$ there is a word in L where every letter from Σ_{a} occurs at least n times. Equivalently, one can consider a recursion scheme generating an infinite tree t and ask whether for every $n \in \mathbb{N}$ there is a finite branch in t where every letter from Σ_{a} occurs at least n times. The problem is already interesting when $|\Sigma_{\mathsf{a}}| = 1$; then we talk about the unboundedness problem. Decidability of the simultaneous unboundedness problem was first established by Hague, Kochems, and Ong [10], for a well-recognized subclass of recursion schemes, called *safe* schemes [9, 12, 2, 5, 27]. The solution was then generalized to all recursion schemes by Clemente, Parys, Salvati, and Walukiewicz [7]. These two algorithms are useless in practice, not only because their complexity is much higher than the optimal one, but mainly because they perform some transformations of recursion

schemes that are extremely costly in every case, not only in the worst case. The complexity of the problem for recursion schemes (namely, $(m-1)$-EXPTIME-completeness for schemes of order m) was settled by Parys [26]; moreover, his solution uses intersection types, and thus it is potentially suitable for implementation (by analogy to the regular model-checking case, where algorithms using type systems led to reasonable implementations). In the single-letter case ($|\Sigma_{\mathsf{a}}| = 1$) the problem is still $(m-1)$-EXPTIME-complete; a slightly simpler type system for this case was presented by Parys [22]. Unfortunately, the type systems of Parys [22, 26] have two drawbacks. First, they are quite complicated: type judgments can be labeled by different kinds of flags and markers, which influence type derivations in a convoluted way. Second (and related to first), it seems that the number of choices for these flags and markers is quite large, and thus finding type derivations even for quite simple recursions schemes may be very costly. Having these drawbacks in mind, we leave experimental evaluation of these algorithms for future work.

In this paper we rather consider a much simpler type system, proposed by Parys in his survey [24], based on an earlier work concerning lambda-terms representing functions on numerals [21]. This type system is much easier than the previous one: every type is labeled only by a single "productivity flag" having an intuitive meaning. Namely, the flag says whether the lambda-term under consideration is responsible for creating occurrences of the letter from Σ_{a}. It was only conjectured that this type system may be used to solve the unboundedness problem.

Our contributions are as follows:

- We prove that the type system allows to solve the unboundedness problem for all safe recursion schemes.
- We show that the algorithm using the type system solves the unboundedness problem for safe recursion schemes of order m in $(m-1)$-EXPTIME (being optimal).
- We prove soundness of the type system for all (i.e., also unsafe) recursion schemes, saying that if one has found a type derivation claiming that a recursion schemes is unbounded then it is indeed unbounded. Completeness of the type system for unsafe recursion schemes is left as an open problem.
- We implement an algorithm solving the unboundedness problem by means of the proposed type system, and we present results of our experiments. The outcome of the algorithm is always correct if the recursion scheme given on input is safe. When the recursion scheme is not safe, proofs of its unboundedness found by the algorithm are still guaranteed to be correct. However, our theorems do not guarantee that the algorithm will find a proof of unboundedness in the unsafe case, so if the algorithm fails to find such a proof, it does not mean that the unsafe recursive scheme is necessarily bounded.
- We then generalize the type system to the simultaneous unboundedness problem (i.e., the multiletter case), obtaining the same properties: algorithm in $(m-1)$-EXPTIME for safe recursion schemes of order m, and soundness for all recursion schemes.
- We implement an optimized version of our algorithm, InfSat, which is fast for a wide variety of inputs. We build upon the implementation of HorSat [4]. We modify HorSat benchmarks to conform to InfSat input format, and present their results to show that InfSat is able to handle inputs described by Broadbent and Kobayashi [4] as "practical" as well as additional benchmarks crafted to measure the speed of InfSat.

2 Preliminaries

The set of *sorts* is constructed from a unique basic sort o using a binary operation $\to$. Thus o is a sort and if α, β are sorts, so is $(\alpha \to \beta)$. The order of a sort is defined by: $ord(\mathsf{o}) = 0$, and $ord(\alpha \to \beta) = \max(1 + ord(\alpha), ord(\beta))$.

A *signature* Σ is a set of typed constants, that is, symbols with associated sorts. We assume that sorts of all constants in the signature are of order at most 1, that is, of the form $\underbrace{\mathsf{o} \to \cdots \to \mathsf{o} \to}_{r} \mathsf{o}$; for a constant of such a sort, r is called its *arity*. We fix a distinguished constant $\omega \in \Sigma$ of arity 0 (it will be used in places where a computation diverges).

The set of *infinitary simply-typed lambda-terms* is defined coinductively as follows. A constant $a \in \Sigma$ of sort α is a lambda-term of sort α. For each sort α there is a countable set of variables $x^\alpha, y^\alpha, \ldots$ that are also lambda-terms of sort α. If M is a lambda-term of sort β and x^α a variable of sort α then $\lambda x^\alpha.M$ is a lambda-term of sort $\alpha \to \beta$. Finally, if M is a lambda-term of sort $\alpha \to \beta$ and N is a lambda-term of sort α then $M\,N$ is a lambda-term of sort β. As usual, we identify lambda-terms up to alpha-conversion. We often omit the sort annotation of variables, but formally every variable has a sort. We use the standard notions of free variables, substitution, and beta-reduction (of course during substitution and beta-reduction we rename bound variables to avoid name conflicts). A lambda-term is called *closed* when it does not have free variables. For a lambda-term M of sort α, the order of M, denoted $ord(M)$, is defined as $ord(\alpha)$.

The *complexity* of a lambda-term M is the maximum of orders of those subterms of M that are not of the form $a\,M_1\,\ldots\,M_k$, where a is a constant and $k \geq 0$ (or 0 if there are no such subterms). Note that for most lambda-terms M the complexity is just the maximum of orders of all subterms of M; the difference is only at complexity 0 and 1: we want lambda-terms built entirely from constants to have complexity 0, not 1.

A closed lambda-term of sort o and complexity 0 is called a *tree*. Equivalently, a lambda-term is a tree if it is of the form $a\,M_1\,\ldots\,M_r$, where $M_1, \ldots, M_r$ are trees, and r is the arity of a. While talking about a *branch* of a tree, we mean a finite branch that ends in a leaf not being ω-labeled. Formally, a *(finite) branch* of a tree $T = a\,T_1\,\ldots\,T_r$ is a sequence of constants $a_1, a_2, \ldots, a_k$ such that $a_1 = a \neq \omega$, and either $a_2, \ldots, a_k$ (with $k \geq 2$) is a finite branch of some T_i, or $r = 0$ and $k = 1$.

We consider Böhm trees only for closed lambda-terms of sort o. For such a lambda-term M, its *Böhm tree* is constructed by coinduction, as follows: if there is a sequence of beta-reductions from M to a lambda-term of the form $a\,M_1\,\ldots\,M_r$, and $T_1, \ldots, T_r$ are Böhm trees of $M_1, \ldots, M_r$, respectively, then $a\,T_1\,\ldots\,T_r$ is a Böhm tree of M; if there is no such a sequence of beta-reductions from M, then the constant ω is a Böhm tree of M. It is folklore that every closed lambda-term of sort o has exactly one Böhm tree (the order in which beta-reductions are performed does not matter); this tree is denoted by $BT(M)$. Notice that a Böhm tree is indeed a tree, and that if M is finite then its Böhm tree equals the beta-normal form of M.

A *recursion scheme* $\mathcal{G}$ is a finite representation of a closed lambda-term $\Lambda(\mathcal{G})$ that is of sort o and regular, that is, has finitely many different subterms. We postpone the definition of a recursion scheme until Section 6. As the *order* of $\mathcal{G}$ we understand the complexity of $\Lambda(\mathcal{G})$. We do not claim that every regular lambda-term of sort o can be directly represented by a recursion scheme, however we remark that every regular lambda-term of sort o is equivalent (in the sense of having the same Böhm tree) to some lambda-term represented by a recursion scheme.

Simultaneous unboundedness problem. Fix a set of *important constants* Σ_{a}. We say that a closed lambda-term M of sort o is *unbounded* (with respect to Σ_{a}) if for every $n \in \mathbb{N}$ there exists a finite branch of $BT(M)$ with at least n occurrences of every constant from Σ_{a}. The *simultaneous unboundedness problem* (SUP) is to decide, given a recursion scheme $\mathcal{G}$, whether $\Lambda(\mathcal{G})$ is unbounded.

In the special case of $|\Sigma_{\mathsf{a}}| = 1$ we talk about the *unboundedness problem*.

3 Type system

In this section we present a type system that allows us to solve the (single-letter) unboundedness problem. The type system was first proposed in Parys' survey [24], without any correctness proofs.

In the remaining part of the paper, except for Section 7, we assume that the signature Σ consists of four constants: a of arity 1, b of arity 2, and c and ω of arity 0, where only a is important, that is $\Sigma_{\mathsf{a}} = \{\mathsf{a}\}$. This is without loss of generality, since we can replace a constant of arbitrary arity by a combination of these four constants, without changing the answer to the unboundedness problem.

Before defining the type system (and safety), let us state a theorem describing its desired properties:

▶ **Theorem 3.1.** *The following two statements are equivalent for every safe closed lambda-term M of sort o:*

(1) *M is unbounded (i.e., for every $n \in \mathbb{N}$ there exists a finite branch of $BT(M)$ with at least n occurrences of the constant a);*

(2) *for every $n \in \mathbb{N}$ there exists $v \geq n$ such that one can derive $\emptyset \vdash M : (v, \mathsf{r})$.*

In this theorem, type judgments contain a natural number v, called a *productivity value*. The goal of this value is to approximately count the number of occurrences of the important constant a on a selected branch of $BT(M)$.

Types in the type system differ from sorts in that on the left side of $\to$, instead of a single type, we have a set of so-called *type pairs* (f, τ), where τ is a *type*, and $f \in \{\mathsf{pr}, \mathsf{np}\}$ is a *productivity flag* (where pr stands for productive, and np for nonproductive). The unique atomic type is denoted r. More precisely, for each sort α we define the set $\mathcal{T}^\alpha$ of types of sort α as follows:

$$\mathcal{T}^{\mathsf{o}} = \{\mathsf{r}\}, \qquad \mathcal{T}^{\alpha\to\beta} = \mathcal{P}(\{\mathsf{pr}, \mathsf{np}\} \times \mathcal{T}^\alpha) \times \mathcal{T}^\beta,$$

where $\mathcal{P}$ denotes the powerset. A type $(T, \tau) \in \mathcal{T}^{\alpha\to\beta}$ is denoted as $\bigwedge T \to \tau$, or $\bigwedge_{i\in I}(f_i, \tau_i) \to \tau$ when $T = \{(f_i, \tau_i) \mid i \in I\}$. In this notation we implicitly assume that all the pairs (f_i, τ_i) are different. The empty intersection is denoted by $\top$. Moreover, to our terms we will not only assign a type τ, but also a productivity flag $f \in \{\mathsf{pr}, \mathsf{np}\}$ (which together form a pair (f, τ)). Let us emphasize that for every sort α the set $\mathcal{T}^\alpha$ is finite.

Intuitively, a lambda-term has type $\bigwedge T \to \tau$ when it can return τ, while taking an argument for which we can derive all type pairs from T; simultaneously, while having such a type, the lambda-term is obligated to use its arguments in all ways described by type pairs from T. For example, the lambda-term $\lambda x.\mathsf{c}$ does not use its argument, and hence it is necessarily of type $\top \to \mathsf{r}$ (i.e., $\bigwedge T \to \tau$ with $T = \emptyset$).

To determine the productivity flag f assigned to a lambda-term M, we should imagine that M is a subterm of a closed term K of sort o, and we should select some finite branch in $BT(K)$ (with the intuition that different choices of the branch correspond to different type derivations). Then, we assign to M the flag pr (productive) when the subterm M is responsible for increasing the number of occurrences of the constant a on the selected branch. To be more precise, a lambda-term is responsible for producing occurrences of a constant a in two cases. First, when it explicitly contains the constant a – assuming that this a will be placed on the selected branch. Second, when it takes a productive argument (i.e., an argument responsible for producing a) and uses it at least twice. The first possibility occurs for example in the lambda-term $M_1 = \lambda x.\mathsf{a}\,x$; the constant a is explicitly produced. In order to see

the second possibility, consider the lambda-term $M_2 = \lambda y.\lambda x.y\,(y\,x)$, and suppose that the argument received for y is the aforementioned productive lambda-term $\lambda x.\mathsf{a}\,x$, which outputs the constant a. Then, the lambda-term M_2 is itself responsible for increasing the number of occurrences of a in the resulting tree, compared to the number of occurrences produced by the argument. Notice that the same lambda-term M_2 has also another type: the argument received for y may be nonproductive (say $\lambda x.x$), and then M_2 becomes nonproductive as well. Next, let us compare M_2 with the lambda-term $M_2' = \lambda y.\lambda x.y\,x$, when used with the argument $\lambda x.\mathsf{a}\,x$. Although the argument is used, and one a is output, the lambda-term M_2' has nothing to do with increasing the number of occurrences of a; it is nonproductive.

A *type judgment* is of the form $\Gamma \vdash M : (v, \tau)$, where we require that the type τ and the lambda-term M are of the same sort. The *type environment* Γ is a set of bindings of variables of the form $x^\alpha : (g, \tau)$, where $g \in \{\mathsf{pr}, \mathsf{np}\}$ and $\tau \in \mathcal{T}^\alpha$. In Γ we may have multiple bindings for the same variable. By $dom(\Gamma)$ we denote the set of variables x which are bound by Γ, and by $\Gamma{\restriction_{\mathsf{pr}}}$ we denote the set of only those bindings $x : (g, \tau)$ from Γ in which $g = \mathsf{pr}$. We are not only interested in whether some type can be derived, but we also want to assign a value to every derivation; to this end, a type judgment contains a number $v \in \mathbb{N}$, which is called a *productivity value*. Having $v = 0$ corresponds to the np flag, while positive values correspond to the pr flag. Thus, while a productivity flag says only whether any occurrence of the important constant a is produced, the productivity value approximates (is a lower bound on) the number of produced occurrences of this constant. Note that in type judgments we store the productivity value, coming from the infinite set $\mathbb{N}$, while in types we abstract this value to the productivity flag, which allows us to have finitely many types.

We now present rules of the type system, starting from rules for constants:

$$\emptyset \vdash \mathsf{a} : (1, (f, \mathsf{r}) \to \mathsf{r}) \qquad \emptyset \vdash \mathsf{c} : (0, \mathsf{r})$$

$$\emptyset \vdash \mathsf{b} : (0, (f, \mathsf{r}) \to \top \to \mathsf{r}) \qquad \emptyset \vdash \mathsf{b} : (0, \top \to (f, \mathsf{r}) \to \mathsf{r})$$

Notice that in the rule for b we have a type (f, r) (with an arbitrary flag f) only for one of the two arguments; this corresponds to the fact that we are interested in a single branch of the Böhm tree, so we want to descend only to a single child. Moreover, we do not have a rule for the constant ω, because by definition a branch cannot contain occurrences of this constant.

While typing a variable x, we take its type from the type environment, and we use 0 as the productivity value. The lambda-term x itself is not responsible for producing any constants, no matter whether the lambda-term substituted for x will produce any constants or not. A lambda-term becomes productive when a productive variable x is used twice; we account for that in the application typing rule (@).

$$x : (f, \tau) \vdash x : (0, \tau)$$

When we pass through a lambda-binder, we simply move some type pairs between the argument and the type environment:

$$\frac{\Gamma \cup \{x : (f_i, \tau_i) \mid i \in I\} \vdash K : (v, \tau) \qquad x \notin dom(\Gamma)}{\Gamma \vdash \lambda x.K : (v, \bigwedge_{i \in I} (f_i, \tau_i) \to \tau)}\ (\lambda)$$

Before giving the last rule, we need one more definition. Given a family of type environments $(\Gamma_i)_{i \in J}$, a *duplication factor*, denoted $dupl((\Gamma_i)_{i \in J})$, equals $\sum_{i \in J} \left|\Gamma_i{\restriction_{\mathsf{pr}}}\right| - \left|\bigcup_{i \in J} \Gamma_i{\restriction_{\mathsf{pr}}}\right|$. It counts the number of repetitions ("duplications") of productive type bindings in the type environments: a productive type binding belonging to one type environment does not add anything, a productive type binding belonging to two type environments adds 1, and so on.

$$\frac{0 \notin I \qquad \forall i \in I.\ (f_i = \mathsf{pr}) \Leftrightarrow (v_i > 0 \vee \Gamma_i{\restriction_{\mathsf{pr}}} \neq \emptyset) \qquad \Gamma_0 \vdash K : (v_0, \bigwedge_{i\in I}(f_i,\tau_i) \to \tau) \qquad \Gamma_i \vdash L : (v_i,\tau_i) \text{ for each } i \in I}{\bigcup_{i\in\{0\}\cup I} \Gamma_i \vdash K\, L : (\mathit{dupl}((\Gamma_i)_{i\in\{0\}\cup I}) + \sum_{i\in\{0\}\cup I} v_i, \tau)}\ (@)$$

Here, by using the notation $\bigwedge_{i\in I}(f_i,\tau_i)$, we assume that the pairs (f_i,τ_i) are all different.

In the rule above, the condition $(f_i = \mathsf{pr}) \Leftrightarrow (v_i > 0 \vee \Gamma_i{\restriction_{\mathsf{pr}}} \neq \emptyset)$ means that when K requires a "productive" argument, then either we can apply an argument L that is itself productive, or we can apply a nonproductive L that uses a productive variable (the argument obtained after substituting something for this variable will become productive).

Using the *dupl* function we realize the intuition that when a variable responsible for creating occurrences of a (i.e., productive) is used at least twice, then the lambda-term is itself responsible for increasing the number of occurrences of a; thus we add *dupl* to the productivity value.

Because we are interested in counting duplications of type bindings, it was necessary to require that every type binding from the type environment is actually used somewhere (in particular $\Gamma \vdash M : (f,\tau)$ does not necessarily imply $\Gamma, x : (g,\sigma) \vdash M : (f,\tau)$). On the other hand, a type environment is a set: a repeated usage of a type binding is counted in the productivity value, but is not reflected in the type environment.

Let us underline that although we consider infinite lambda-terms, all type derivations are required to be finite. This may look suspicious, but note that when a lambda-term has type $\top \to \tau$ (like, e.g., the constant b), then we need no derivation for its argument.

▶ **Example 3.2.** Let us give an example of a derivation for a lambda-term $\lambda y.\lambda z.y\,(y\,(\mathsf{a}\,z))$ of sort $(\mathsf{o}\to\mathsf{o})\to\mathsf{o}\to\mathsf{o}$. In this particular derivation, we will assume that y and z are both productive.

$$\frac{\vdash \mathsf{a} : (1,(\mathsf{pr},\mathsf{r})\to\mathsf{r}) \qquad z : (\mathsf{pr},\mathsf{r}) \vdash z : (0,\mathsf{r})}{z : (\mathsf{pr},\mathsf{r}) \vdash \mathsf{a}\,z : (1,\mathsf{r})}\ (@)$$

In the innermost application, we have an important constant a and a productive variable z. The important constant has value 1. The value of z is 0 because, even though it is productive, any important constants it produces will be just moved from the argument substituted for z. No important constant will be lost or produced during this process. There are no duplicates of variables in the application $\mathsf{a}\,z$, so the value of the application is equal to sum of values, that is, 1.

$$\frac{y : (\mathsf{pr},(\mathsf{pr},\mathsf{r})\to\mathsf{r}) \vdash y : (0,(\mathsf{pr},\mathsf{r})\to\mathsf{r}) \qquad z : (\mathsf{pr},\mathsf{r}) \vdash \mathsf{a}\,z : (1,\mathsf{r})}{z : (\mathsf{pr},\mathsf{r}),\ y : (\mathsf{pr},(\mathsf{pr},\mathsf{r})\to\mathsf{r}) \vdash y\,(\mathsf{a}\,z) : (1,\mathsf{r})}\ (@)$$

We apply y to $\mathsf{a}\,z$. Variable y is productive and takes a productive argument, which means that it incorporates its argument into the tree it produces and somehow increases the number of important constants in the process. However, this increase is computed in the lambda-term that is substituted for y, not here, hence it has value 0.

$$\frac{y : (\mathsf{pr},(\mathsf{pr},\mathsf{r})\to\mathsf{r}) \vdash y : (0,(\mathsf{pr},\mathsf{r})\to\mathsf{r}) \qquad z : (\mathsf{pr},\mathsf{r}),\ y : (\mathsf{pr},(\mathsf{pr},\mathsf{r})\to\mathsf{r}) \vdash y\,(\mathsf{a}\,z) : (1,\mathsf{r})}{z : (\mathsf{pr},\mathsf{r}),\ y : (\mathsf{pr},(\mathsf{pr},\mathsf{r})\to\mathsf{r}) \vdash y\,(y\,(\mathsf{a}\,z)) : (2,\mathsf{r})}\ (@)$$

Both sides have y in the environment here, so the duplication factor in $y\,(y\,(\mathsf{a}\,z))$ is 1. We add it to the sum of values from both sides of the application, obtaining 2.

$$\dfrac{\dfrac{z : (\mathsf{pr},\mathsf{r}),\ y : (\mathsf{pr},(\mathsf{pr},\mathsf{r})\to\mathsf{r}) \vdash y\,(y\,(\mathsf{a}\,z)) : (2,\mathsf{r})}{y : (\mathsf{pr},(\mathsf{pr},\mathsf{r})\to\mathsf{r}) \vdash \lambda z.y\,(y\,(\mathsf{a}\,z)) : (2,(\mathsf{pr},\mathsf{r})\to\mathsf{r})}\,(\lambda)}{\vdash \lambda y.\lambda z.y\,(y\,(\mathsf{a}\,z)) : (2,(\mathsf{pr},(\mathsf{pr},\mathsf{r})\to\mathsf{r})\to(\mathsf{pr},\mathsf{r})\to\mathsf{r})}\,(\lambda)$$

The lambda-binders move z and y from the environment into the type without changing the value. The final value for this closed lambda-term is 2, as it always adds one important constant to the Böhm tree and, when something that increases the number of important constants is substituted for y, it applies that twice, causing at least one extra important constant to be added compared to what just one instance of y would do.

Note that it is possible to derive other type judgments for the lambda-term $y\,(y\,(\mathsf{a}\,z))$. For example, the value would be equal to one if y was not productive, even if z was productive:

$$y : (\mathsf{np},(\mathsf{pr},\mathsf{r})\to\mathsf{r}),\ z : (\mathsf{pr},\mathsf{r}) \vdash y\,(y\,(\mathsf{a}\,z)) : (1,\mathsf{r}).$$

The rationale is that while y takes productive arguments, it uses them exactly once and does not add an important constant to the Böhm tree either, so applying it any number of times will not change the number of important constants.

4 Soundness

In this section we prove the soundness of the type system, as described by following lemma, from which the (2) ⇒ (1) implication of Theorem 3.1 follows immediately:

▶ **Lemma 4.1.** *If we can derive $\emptyset \vdash M : (v,\mathsf{r})$, where M is a closed lambda-term of sort o, then $BT(M)$ has a finite branch containing at least v occurrences of a.*

We prove Lemma 4.1 as follows. First, as in work of Parys [26, 24] we observe that instead of working directly with infinite lambda-terms M, we can "cut off" parts of M not involved in the finite derivation of $\emptyset \vdash M : (v,\mathsf{r})$, (i.e., subterms used as arguments for which no type pair is required). Formally, by cutting off we mean replacing by lambda-terms of the form $\lambda x_1.\cdots.\lambda x_k.\omega$, where the variables $x_1,\ldots,x_k$ are chosen so that the sort of the lambda-term is appropriate. In consequence, it is enough to prove Lemma 4.1 for finite lambda-terms.

Second, we repeatedly use Lemma 4.2 below, reducing M to its beta-normal form N, and never decreasing the productivity value. Finally, we observe that the beta-normal form N is simply a tree; a derivation of $\emptyset \vdash N : (v',\mathsf{r})$, using only the rules for constants and application, describes some branch of this tree containing exactly v' occurrences of the important constant a. It remains to justify the following lemma, which describes a single beta-reduction:

▶ **Lemma 4.2.** *If we can derive $\emptyset \vdash M : (v,\mathsf{r})$, where M is a finite closed lambda-term of sort o, and M is not in the beta-normal form, then we can derive $\emptyset \vdash N : (v',\mathsf{r})$ for a lambda-term N such that $M \to_\beta N$, and for some v' satisfying $v \le v'$.*

While proving this lemma, we consider the leftmost outermost redex, $(\lambda x.K)\,L$. Thanks to this choice, L is necessarily a closed subterm. This simplifies the situation: it is enough to consider empty type environments (we remark, however, that Lemma 4.2 can be shown in a similar way for every reduction, not only for the leftmost outermost reduction). We want to replace every subderivation D for a type judgment $\emptyset \vdash (\lambda x.K)\,L : (w,\tau)$ concerning

this redex with a derivation D' for $\Gamma \vdash K[L/x] : (w', \tau)$. We obtain D' by appropriately reorganizing subderivations of D: we take the subderivation of D concerning K, we replace every leaf deriving a type σ for x by the subderivation of D deriving this type σ for L, and we update type environments and productivity values appropriately.

Notice that every subderivation concerning L is moved to at least one leaf concerning x (nothing can disappear). The only reason why the value of the derivation can decrease is that potentially a productive type binding $x : (\mathsf{pr}, \sigma)$ was duplicated (say, n times) in the derivation concerning K. In D' this binding is no longer present (in $K[L/x]$ there is no x) so the value decreases by n, but in this situation the subderivation deriving σ for L becomes inserted in $n+1$ leaves. This subderivation is productive, so by creating n additional copies of this subderivation we increase the value at least by n, compensating the loss caused by elimination of x. This implies that $w \leq w'$, and consequently $v \leq v'$. Check Appendix A of the full version for more details.

5 Completeness for safe lambda-terms

In this section we prove completeness for a subclass of lambda-terms called safe lambda-terms. The question whether completeness holds for general lambda-terms is left open.

A lambda-term M is *superficially safe* when for every free variable x of M it holds that $ord(M) \leq ord(x)$. A lambda-term M is *safe* if it is superficially safe, and if for its every subterm of the form $K\, L_1 \ldots L_k$, where K is not an application and $k \geq 1$, all subterms $K, L_1, \ldots, L_k$ are superficially safe. This definition of safety coincides with the definitions from Salvati and Walukiewicz [27], and from Blum and Ong [2].

Completeness for safe lambda-terms is given by the following lemma.

▶ **Lemma 5.1.** *For every $m \in \mathbb{N}$ there exists a function $H_m \colon \mathbb{N} \to \mathbb{N}$ such that if M is a closed safe lambda-term of sort o and complexity at most m, and in $BT(M)$ there is a finite branch having at least n occurrences of a, then we can derive $\emptyset \vdash M : (v, \mathsf{r})$ for some v such that $n \leq H_m(v)$.*

While proving this lemma, it is convenient to split the productivity value into two parts. Given some fixed $\ell \in \mathbb{N}$, instead of type judgments of the form $\Gamma \vdash N : (v, \tau)$ we consider extended type judgments of the form $\Gamma \vdash N : (u \oplus_\ell w, \tau)$, where $u + w = v$. On u we accumulate only duplication factors concerning variables of order at least ℓ, and on w the remaining part of the value (i.e., duplication factors concerning variables of order smaller than ℓ, plus the number of rules for the constant a). Having this definition, we can state a counterpart of Lemma 4.2:

▶ **Lemma 5.2.** *Suppose that we can derive $\Gamma \vdash K[L/x] : (u \oplus_\ell w, \tau)$, where L is closed, has order ℓ, and does not use any variables of order at least ℓ. Then we can derive $\Gamma \vdash (\lambda x.K)\, L : (u' \oplus_\ell w', \tau)$ for some u', w' such that $2^u \cdot w \leq 2^{u'} \cdot w'$ and $u + w = 0 \Rightarrow u' + w' = 0$.*

Similarly to Lemma 4.2, the derivation concerning $(\lambda x.K)\, L$ in the above lemma is obtained by appropriately reorganizing subderivations of the derivation concerning $K[L/x]$. In the type derivation concerning $K[L/x]$, there are some (zero or more) subderivations concerning L. A difficulty is caused by the fact that the same type pair (f, σ) may be derived for multiple copies of L in $K[L/x]$, using different subderivations. For every such (f, σ) derived for L we should choose just one subderivation, so that we can use it for the only copy of L in $(\lambda x.K)\, L$. We choose the subderivation that provides the largest second component of the value; the other subderivations are removed. The value of the new derivation decreases, because some subderivations are removed, and increases, because we have a new variable x, that may cause some duplications.

It remains to see that the value $u' \oplus_\ell w'$ of the new derivation satisfies the inequality $2^u \cdot w \leq 2^{u'} \cdot w'$. Consider some type pair (f, σ) derived for L. If $f = \mathsf{np}$, the value of the removed subderivations is 0, and the duplications of $x : (f, \sigma)$ in the type environment are not counted, so such a type pair does not cause any change of the value. Suppose that $f = \mathsf{pr}$, and that we have removed n subderivations proving the type pair (f, σ) for L; this may decrease the second component of the value at most $n + 1$ times (the n removed subderivations have values not greater than the one that remains). Simultaneously, in K we use $n + 1$ times the variable x with this type pair (f, σ), which increases the value (the total duplication factor) by n. The key point is that L does not use any variables of order at least ℓ, and thus the first component (concerning variables of order at least ℓ) of the value of subderivations for L is 0. Thus, we decrease the second component of the value at most $n + 1$ times, and we increase the first component of the value by at least n. Since $2^n \geq n + 1$, we obtain the required inequality between values.

It is also important that L is closed so that after removing some subderivations concerning L, the type environment of the whole derivation remains unchanged. This finishes the proof of Lemma 5.2 (a more formal proof, containing all details, can be found in Appendix B.1 of the full version).

We now come back to the proof of Lemma 5.1. First, as in the previous section, we can assume that M is finite by "cutting off" (i.e., replacing with $\lambda x_1.\cdots\lambda x_k.\omega$) its parts not needed for producing the selected finite branch of $BT(M)$.

Second, it is convenient to assume here that M is homogeneous. A sort $\alpha_1 \to \cdots \to \alpha_k \to \mathsf{o}$ is *homogeneous* if $ord(\alpha_1) \geq \cdots \geq ord(\alpha_k)$ and all $\alpha_1, \ldots, \alpha_k$ are homogeneous. A lambda-term is homogeneous if its every subterm has a homogeneous sort. It is known that every finite closed safe lambda-term M of sort o can be converted into a lambda-term M' that is additionally homogeneous [23], but has the same beta-normal form. Analyzing how M is transformed into M' (in [23]), it is tedious but straightforward to check that we can derive $\emptyset \vdash M : (v, \mathsf{r})$ if and only if we can derive $\emptyset \vdash M' : (v, \mathsf{r})$; this is done in Appendix B.2 of the full version.

It is thus enough to prove Lemma 5.1 assuming that M is finite and homogeneous. To this end, we consider a particular sequence of reductions leading from M to its beta-normal form $BT(M)$. Namely, whenever a lambda-term N reached so far (i.e., after some number of reductions) from M is of complexity $\ell + 1$, then we reduce in N a redex $(\lambda x.K)\, L$ such that $ord(\lambda x.K) = \ell + 1$, and no variables of order at least ℓ occur in L, both as free variables and as bound variables; we call such a redex *ℓ-good*. Such a redex always exists: among redexes with $ord(\lambda x.K) = \ell + 1$ it is enough to choose the rightmost one. The complexity of a lambda-term cannot increase during a beta-reduction, thus in the sequence of reductions we can find lambda-terms $M_m, M_{m-1}, \ldots, M_0$, where $M_m = M$, and $M_0 = BT(M)$, and the complexity of every $M_{\ell+1}$ is at most $\ell + 1$, and M_ℓ can be reached from $M_{\ell+1}$ by a sequence of ℓ-good reductions.

Homogeneity is preserved during beta-reductions. Moreover, ℓ-good beta-reductions preserve safety (while this is not true for arbitrary beta-reductions). Indeed, homogeneity for an ℓ-good redex $(\lambda x.K)\, L$ implies that $ord(L) = \ell$ (the first argument is of the highest order, i.e., of order ℓ), thus safety implies that all free variables of L are of order at least ℓ. But, by the definition of an ℓ-good redex, no variables of order at least ℓ occur in L. It follows that L is closed. While substituting a closed lambda-term L for x, all superficially safe subterms of K remain superficially safe (no new free variables appear). Thus the lambda-term after the ℓ-good beta-reduction remains safe.

Recall the sequence of lambda-terms $M_m, M_{m-1}, \ldots, M_0$ defined above. Assuming that in $BT(M) = M_0$ there is a finite branch having exactly n occurrences of a, we can derive $\emptyset \vdash M_0 : (n, \mathsf{r})$ using only the rules for application and constants. Suppose now that we can derive $\emptyset \vdash M_\ell : (v_\ell, \mathsf{r})$ for some $\ell \in \{0, \ldots, m-1\}$. We want to find a derivation of $\emptyset \vdash M_{\ell+1} : (v_{\ell+1}, \mathsf{r})$, where for arbitrarily large values v_ℓ, the values $v_{\ell+1}$ are also arbitrarily large (more precisely, we obtain the inequality $v_\ell \leq 2^{v_{\ell+1}}$). Notice that between $M_{\ell+1}$ and M_ℓ there may be arbitrarily many (ℓ-good) reductions. Consider thus some ℓ-good redex $(\lambda x.K)\, L$ that is reduced at some moment between $M_{\ell+1}$ and M_ℓ. By definition, L does not use any variables of order at least ℓ and, as already observed, L is closed; thus, Lemma 5.2 can be applied. We start with $\emptyset \vdash M_\ell : (0 \oplus_\ell v_\ell, \mathsf{r})$ (notice that in M_ℓ there are no variables of order ℓ or higher, so the first component of the value is 0). Then, we use Lemma 5.2 for every ℓ-good beta-reduction between $M_{\ell+1}$ and M_ℓ. This leads to $\emptyset \vdash M_{\ell+1} : (u_{\ell+1} \oplus_\ell w_{\ell+1}, \mathsf{r})$, where $v_\ell \leq 2^{u_{\ell+1}} \cdot w_{\ell+1} \leq 2^{v_{\ell+1}}$ (taking $v_{\ell+1} = u_{\ell+1} + w_{\ell+1}$), as required.

The function H_m, appearing in the statement of Lemma 5.1, can be defined as a tower of powers of 2 of height m: $H_0(v) = v$ and $H_{\ell+1}(v) = H_\ell(2^v)$. Then from $n \leq H_\ell(v_\ell)$ it follows that $n \leq H_{\ell+1}(v_{\ell+1})$; since $n = H_0(v_0)$, we thus obtain the desired inequality $n \leq H_m(v_m)$.

6 The algorithm

Both design and implementation of our algorithm is based on the HorSat algorithm, a saturation-based algorithm for model checking recursion schemes against alternating automata by Broadbent and Kobayashi [4].

Our type system was described in previous sections to work with any infinitary lambda-term. The algorithm, in turn, inputs infinitary lambda-terms represented in a finite way, in the form of a recursion scheme. To be concrete, we make this representation explicit now: A recursion scheme $\mathcal{G} = (\Sigma, \mathcal{N}, \mathcal{R}, X_{\mathsf{st}})$ consists of

- a signature Σ (i.e., a set of constants with assigned arities),
- a set $\mathcal{N}$ of nonterminals with assigned sorts (formally, nonterminals are just distinguished variables),
- a mapping $\mathcal{R}$ from nonterminals in $\mathcal{N}$ to finite lambda-terms such that $\mathcal{R}(X)$ is of the same sort as X, has no free variables other than nonterminals from $\mathcal{N}$, and is of the form $\lambda x_1.\cdots.\lambda x_n.K$, where the subterm K does not contain any lambda-binders, and
- a starting nonterminal $X_{\mathsf{st}} \in \mathcal{N}$ of sort o.

We assume that elements of $\mathcal{N}$ are not used as bound variables, and that $\mathcal{R}(X)$ is not a nonterminal. Furthermore, as in previous sections, we assume for simplicity that $\Sigma = \{\mathsf{a}, \mathsf{b}, \mathsf{c}\}$, where the constants $\mathsf{a}, \mathsf{b}, \mathsf{c}$ have arity $1, 2, 0$, respectively (the implementation, however, accepts arbitrary signatures).

Given a recursion scheme $\mathcal{G}$, and a lambda-term M (possibly containing some nonterminals from $\mathcal{N}$), let $\Lambda_{\mathcal{G}}(M)$ be the lambda-term obtained as a limit of applying repeatedly the following operation to M: take an occurrence of some nonterminal X, and replace it by $\mathcal{R}(X)$ (the nonterminals should be chosen so that every nonterminal is eventually replaced). We remark that while substituting $\mathcal{R}(X)$ for a nonterminal X, there is no need for any renaming of variables (capture-avoiding substitution), since $\mathcal{R}(X)$ does not have free variables other than nonterminals. The infinitary lambda-term *represented by* $\mathcal{G}$ is defined as $\Lambda_{\mathcal{G}}(X_{\mathsf{st}})$, and denoted $\Lambda(\mathcal{G})$. Observe that $\Lambda(\mathcal{G})$ is a closed lambda-term of sort o. We say that $\mathcal{G}$ is *safe* if $\mathcal{R}(X)$ is safe for every $X \in \mathcal{N}$; then $\Lambda(\mathcal{G})$ is safe as well.

The goal of the algorithm is to determine whether $\Lambda(\mathcal{G})$ for a given recursion scheme $\mathcal{G}$ is unbounded or not. In the light of Theorem 3.1, this boils down to checking whether one can derive $\emptyset \vdash \Lambda(\mathcal{G}) : (v, \mathsf{r})$ for arbitrarily large values of v. The idea is to find a single derivation with a productive "loop"; by repeating this loop, one can increase the productivity value arbitrarily. We make this more precise now.

First, we determine type pairs that can be derived for non-terminals. Namely, for $v \in \mathbb{N}$ let $\mathfrak{p}(v) = \mathsf{pr}$ if $v > 0$ and $\mathsf{pr}(v) = \mathsf{np}$ otherwise. Let $\mathcal{T}_{\mathcal{G}}$ be the smallest set containing all bindings $X : (\mathfrak{p}(v), \tau)$ (with $X \in \mathcal{G}$) such that we can derive $\emptyset \vdash \mathcal{R}(X) : (v, \tau)$, potentially using $\emptyset \vdash Y : (w, \sigma)$ for $(Y : (\mathfrak{p}(w), \sigma)) \in \mathcal{T}_{\mathcal{G}}$ as assumptions (i.e., as additional typing rules).

Note that productivity values in derivations may be shifted (i.e., increased/decreased by a constant): we can derive $\emptyset \vdash \mathcal{R}(X) : (v, \tau)$ out of an assumption $\emptyset \vdash Y : (w, \sigma)$ if and only if we can derive $\emptyset \vdash \mathcal{R}(X) : (v + (w' - w), \tau)$ out of an assumption $\emptyset \vdash Y : (w', \sigma)$ with $\mathfrak{p}(w) = \mathfrak{p}(w')$. It is thus enough to try assumptions $\emptyset \vdash Y : (w, \sigma)$ with $w = 0$ and $w = 1$ only.

We have only finitely many bindings that may be potentially added to $\mathcal{T}_{\mathcal{G}}$, as there are finitely many possible types per sort and each nonterminal of $\mathcal{G}$ has a fixed sort. Moreover, taking into account the above, there are only finitely many derivations that may be potentially created for lambda-terms $\mathcal{R}(X)$. It follows that $\mathcal{T}_{\mathcal{G}}$ may be computed using saturation (i.e., as the least fixed point). The following lemma is immediate:

▶ **Lemma 6.1.** *For any nonterminal $X \in \mathcal{N}$ and any type pair (f, τ) one can derive $\Lambda_{\mathcal{G}}(X) : (v, \tau)$ for some v with $\mathfrak{p}(v) = f$ if and only if $(X : (f, \tau)) \in \mathcal{T}_{\mathcal{G}}$.*

Next, knowing which type judgments may be derived, we want to detect a productive cycle. To this end, we create a graph with bindings from $\mathcal{T}_{\mathcal{G}}$ as nodes, called a *derivation graph*. We draw an edge from $X : (\mathfrak{p}(v), \tau)$ to $Y : (\mathfrak{p}(w), \sigma)$ if one can derive $\emptyset \vdash \mathcal{R}(X) : (v, \tau)$ using $\emptyset \vdash Y : (w, \sigma)$ as an assumption, and potentially using some other assumptions $\emptyset \vdash Z : (u, \rho)$ with $(Z : (\mathfrak{p}(u), \rho)) \in \mathcal{T}_{\mathcal{G}}$ (the assumption $\emptyset \vdash Y : (w, \sigma)$ necessarily has to be used, at least once). Such an edge is called *productive* if $v > w$. Note that this may happen for three reasons: 1) in the derivation there is some positive duplication factor or an important constant, 2) some other assumption $\emptyset \vdash Z : (u, \rho)$ with $u > 0$ is used, or 3) the assumption $\emptyset \vdash Y : (w, \sigma)$ is used more than once and $w > 0$. Note that edges of the derivation graphs can be incrementally computed at the time of computing $\mathcal{T}_{\mathcal{G}}$. We now obtain the main theorem, adding Point (3) equivalent to Point (2) from Theorem 3.1:

▶ **Theorem 6.2.** *The following two statements are equivalent for every recursion scheme $\mathcal{G} = (\Sigma, \mathcal{N}, \mathcal{R}, X_{\mathsf{st}})$:*

(2) *one can derive $\emptyset \vdash \Lambda(\mathcal{G}) : (v, \mathsf{r})$ for arbitrarily large values of v,*

(3) *$(X_{\mathsf{st}} : (\mathsf{pr}, \mathsf{r})) \in \mathcal{T}_{\mathcal{G}}$ and the derivation graph contains a cycle with a productive edge, reachable from $X_{\mathsf{st}} : (\mathsf{pr}, \mathsf{r})$.*

By Theorem 3.1, assuming additionally that $\mathcal{G}$ is safe, Point (2) (and hence Point (3) as well) is also equivalent to the property we want to check:

(1) $\Lambda(\mathcal{G})$ is unbounded.

Proof. Point (2) follows from Point (3) quite directly. Indeed, an edge from $X : (\mathsf{pr}, \tau)$ to $Y : (\mathsf{pr}, \sigma)$ means that any derivation of $\emptyset \vdash \Lambda_{\mathcal{G}}(Y) : (w, \sigma)$ can be extended to a derivation of $\emptyset \vdash \Lambda_{\mathcal{G}}(X) : (v, \tau)$ for some $v \geq w$ (in the sense that the latter contains the former as a subderivation), where $v > w$ if the edge is productive. Following edges on the cycle with a

productive edge we can thus extend a derivation of $\emptyset \vdash \Lambda_{\mathcal{G}}(X) : (v, \tau)$ into a larger derivation of $\emptyset \vdash \Lambda_{\mathcal{G}}(X) : (v', \tau)$, where $v' > v$; doing this repeatedly increases the productivity value arbitrarily. Finally, we can use the path from $X_{\mathsf{st}} : (\mathsf{pr}, \mathsf{r})$ to the cycle, making the created derivation a part of a derivation concerning $\Lambda(\mathcal{G}) = \Lambda_{\mathcal{G}}(X_{\mathsf{st}})$.

Let us move on to the implication from Point (2) to Point (3). First, consider all possible derivations of $\emptyset \vdash \mathcal{R}(X) : (v, \tau)$ (with arbitrary $X \in \mathcal{N}$, v, τ) that may use assumptions (additional typing rules) $\emptyset \vdash Y : (v', \tau')$ for nonterminals Y, as in the definition of $\mathcal{T}_{\mathcal{G}}$. Because $\mathcal{R}(X)$ for every $X \in \mathcal{N}$ is a finite lambda-term, and $|\mathcal{N}|$ is finite as well, there exists a bound B such that any derivation as above uses assumptions for nonterminals in at most B leaves, and simultaneously the growth of productivity value caused by duplication factor or important constants in the derivation is at most B.

Next, we prove (by induction on the size of a derivation) that if we can derive $\emptyset \vdash \Lambda_{\mathcal{G}}(X) : (v, \tau)$ with $v \geq (2B)^k$ for some $k \in \mathbb{N}$, then $(X : (\mathfrak{p}(v), \tau)) \in \mathcal{T}_{\mathcal{G}}$ and in the derivation graph there is a path from this node having at least k productive edges. Indeed, out of a derivation of $\emptyset \vdash \Lambda_{\mathcal{G}}(X) : (v, \tau)$ we can reconstruct a derivation of $\emptyset \vdash \mathcal{R}(X) : (v, \tau)$; whenever the former derivation contains a (strictly smaller) subderivation concerning $\Lambda_{\mathcal{G}}(Y)$ for some nonterminal Y, in the latter we use an assumption concerning Y, which is in $\mathcal{T}_{\mathcal{G}}$ by the induction hypothesis. This already shows that $(X : (\mathfrak{p}(v), \tau)) \in \mathcal{T}_{\mathcal{G}}$. If $k = 0$, we are done. Suppose that $k \geq 1$. By properties of the bound B, in the derivation of $\emptyset \vdash \mathcal{R}(X) : (v, \tau)$ there has to be an assumption $\emptyset \vdash Y : (v', \tau')$ with $v' \geq \frac{v-B}{B} \geq \frac{v}{2B}$ (from v we subtract B for duplication factors and important constants inside the derivation of $\emptyset \vdash \mathcal{R}(X) : (v, \tau)$, and we divide the remaining part of the productivity value into at most B assumptions), that is, we can derive $\emptyset \vdash \Lambda_{\mathcal{G}}(Y) : (v', \tau')$. If $v' = v \geq (2B)^k$, then we have an edge to a node from which there is a path having at least k productive edges, by the induction hypothesis. Otherwise $v > v' \geq (2B)^{k-1}$, so we have a productive edge to a node, from which there is a path having at least $k - 1$ productive edges, by the induction hypothesis.

Starting with $X = X_{\mathsf{st}}$ and $k > |\mathcal{T}_{\mathcal{G}}|$ we obtain a path from $(X_{\mathsf{st}} : (\mathsf{pr}, \mathsf{r}))$ containing more than $|\mathcal{T}_{\mathcal{G}}|$ productive edges; this path has to reach a cycle with a productive edge, as needed for Point (3). ◀

6.1 Implementation

Our implementation is based on the implementation of HorSat [4] (more precisely: of HorSat2, a revised version of the HorSat algorithm, due to Kobayashi and Terao). The main reason behind the efficiency of our (and HorSat's) implementation is that we do not compute all possible bindings in $\mathcal{T}_{\mathcal{G}}$. We derive only types which may be useful in a derivation of a type of the starting nonterminal X_{st}.

To this end, we first perform a 0-CFA analysis of the input to compute which lambda-terms may flow into particular nonterminal parameters. For example, if we have a nonterminal X with a parameter x, we find all applications in the form $M_X\, N$, where M_X is a lambda-term where the head is X or may eventually be substituted by X; then the lambda-term N is flowing into the parameter x. Note that 0-CFA analysis gives an overestimation. For example, for a nonterminal Y with two parameters x and y it is possible to write two applications, $Y\, M\, N$ and $Y\, M'\, N'$, transformed in such a way that, according to 0-CFA output, M may flow into x at the same time as N' into y. This behavior can exponentially (with respect to the number of arguments) increase the number of possible typings of Y that the algorithm has to check.

Thanks to 0-CFA analysis, we have a complete list of lambda-terms which may be substituted for parameters of nonterminals, which limits the set of computed types of nonterminals while still retaining all types required to type X_{st}. This is sufficient to start a

loop where new types are found. In this loop, nonterminals (more precisely: the lambda-terms $\mathcal{R}(X)$ for nonterminals X) are typed using information about types flowing into their parameters. New types of nonterminals enable finding new types of lambda-terms in which these nonterminals occur. These lambda-terms again flow into parameters of some nonterminals, so the new types enable finding additional typings of these nonterminals, returning to the beginning of the loop. This loop continues until a fixpoint, that is, until no new typings of nonterminals or lambda-terms flowing into their parameters can be computed. As there is a finite number of possible typings of nonterminals and lambda-terms in any given recursion scheme, this fixpoint will be reached after finitely many steps. During this loop, each time we type a nonterminal, we take note of typings of nonterminals that were used in the derivation (i.e., are subtrees in the final derivation tree), and incrementally construct the derivation graph described earlier in this section. This way we find all parts of the derivation graph that are reachable from $X_{\mathsf{st}} : (\mathsf{pr}, \mathsf{r})$; the optimizations made by 0-CFA only remove unreachable parts.

We perform typing of terms without lambda-bindings in a top-down manner, that is, we iterate over all possible types an application may have, find compatible types for its left-hand side, and then type-check its right-hand side under each possible environment with its desired, already known type. The top-down approach is particularly efficient when the constant b is present in the term, since its argument with type $\top$ does not have to be type-checked. This is also the case for nonterminals with arguments of type $\top$.

We also include three optimizations similar to the ones present in HorSat:

- After a new type of a nonterminal is found, we type all lambda-terms that contain it in a way where the new typing is used at least once. This optimization can be turned off with a flag `-nofntty`.
- After a new type of a lambda-term flowing into a parameter x of a nonterminal X is found, we search for new typings of $\mathcal{R}(X)$ (or its subterms that flow into parameters of other nonterminals) in a way where at least one instance of the parameter x has the new type. This optimization can be turned off with a flag `-noftty`.
- When no parameter of a nonterminal X is used as a left-hand side of an application in $\mathcal{R}(X)$, we infer types of parameters of X from left-hand sides of applications instead of using types of lambda-terms flowing into these parameters. Then $\mathcal{R}(X)$ does not have to be typed whenever a new type is computed for lambda-terms flowing into its parameters. This optimization can be turned off with a flag `-nohvo`.

6.2 Benchmarks

We prepared benchmarks for the implementation of our algorithm by modifying benchmarks presented in the HorSat paper [4]. HorSat is an algorithm that efficiently checks whether an alternating tree automaton (ATA) accepts the Böhm tree of the lambda-term defined by a recursion scheme. This problem is different from ours, however, it also performs an analysis on the same trees and is also m-EXPTIME-complete, where the difficulty depends on the order m of the lambda-term. Hence, we use benchmark results presented in the HorSat paper [4] as an indication that the terms used there are difficult to analyze.

The details on the original benchmarks and their origin can be found in the HorSat paper [4]. According to authors of the aforementioned paper, these benchmarks contain practical data. Indeed, some of them model analysis of an XHTML document or a short computer program. Analysis of many of them was not completed in a reasonable time by other model checking algorithms similar to HorSat, while HorSat only failed to analyze benchmark `fibstring` in a reasonable time.

Table 1 InfSat benchmark results in all combinations of optimization flags.

TO means timeout (10 minutes), OOM means out of memory error.

Let us describe how we modified the benchmarks to fit our analysis. We left the original recursion scheme intact and selected a few important constants that are present close to leaves of generated trees to increase the difficulty. The result was a decision problem whether the operations described by important constants in modelled programs could be executed unbounded number of times, assuming the program halted. Additionally, we added four benchmarks specific to InfSat that answer mathematical questions such as whether there exist arbitrarily large odd numbers defined as Church numerals.

We present results of our benchmarks in Table 1. They were performed on a laptop with Intel Core i5-7600K, 16GB RAM. We consider these results a success, as only two benchmarks on practical data failed to compute within ten minutes. As InfSat is the first efficient algorithm solving the simultaneous unboundedness problem, we do not have any data to which we could compare our benchmark results. At this stage, we can assess effectiveness of our optimizations. We can see that using all optimization flags produced good results consistently, however, each optimization happened to slow down some benchmarks. The reason is that optimizations turned off by `-noftty` and `-nofntty` add substantial polynomial overhead when generating list of possible environments and optimization turned off by `-nohvo` changes the way types of some terms are computed. However, all of them can exponentially reduce the computation time in many cases which is why they are turned on by default.

7 Multi-letter case

It is not difficult to modify the type system to handle simultaneous unboundedness. In this part, instead of a single important constant a of arity 1, we consider important constants $\mathsf{a}_1, \ldots, \mathsf{a}_s$, all of arity 1 ($\Sigma_{\mathsf{a}}$ is the set containing them all). Besides them, in the signature Σ we have a constant b of arity 2, and constants c and ω of arity 0.

In the type system instead of a single productivity flag in $\{\mathsf{pr}, \mathsf{np}\}$, we have a productivity set, being a subset of Σ_{a}, and saying which important letters are produced. Likewise, instead of a productivity value in $\mathbb{N}$, we have a productivity function $v\colon \Sigma_{\mathsf{a}} \to \mathbb{N}$, specifying a value separately for every letter. The rules of the type system are adopted in the expected way: $v(\mathsf{a}_i)$ increases when we use constant a_i, and when we duplicate a type binding for a type pair (A, σ) with $\mathsf{a}_i \in A$.

One more change is, however, necessary. Indeed, while proving Lemma 5.2 in the multi-letter case, we cannot choose a single subderivation concerning L that has the greatest value, since now a value is not a number, but rather a function. Instead, for every constant a_i we can choose a subderivation concerning L for which the i-th coordinate of the value is the greatest. We thus need to allow s (i.e., $|\Sigma_{\mathsf{a}}|$) subderivations for every type pair.

To this end, on the left of the arrow in a type, we do not have a set of types, but rather a multiset of types, where we allow to have at most s copies of every type. Likewise, in the type environment we have at most s copies of every type binding.

Formally, an *s-multiset* is a multiset that contains at most s copies of every element. The set of s-multisets of elements of X is denoted $\mathcal{P}_{\leq s}(X)$. Notice that 1-multisets are just sets, hence $\mathcal{P}_{\leq 1}(X) = \mathcal{P}(X)$. A union of s-multisets U, V, denoted $U \cup V$, is defined as follows: if U and V contain, respectively, n and m copies of an element x, then $U \cup V$ contains $\min(n+m, s)$ copies of this element. We use the notation $\{x_i \mid i \in I\}$ for $\bigcup_{i\in I}\{x_i\}$, where $\{x_i\}$ is the multiset containing x_i once.

For each sort α we define the set $\mathcal{T}_s^\alpha$ of types of sort α as follows:

$$\mathcal{T}_s^\circ = \{\mathsf{r}\}, \qquad \mathcal{T}_s^{\alpha\to\beta} = \mathcal{P}_{\leq s}(\mathcal{P}(\Sigma_{\mathsf{a}}) \times \mathcal{T}_s^\alpha) \times \mathcal{T}_s^\beta.$$

We again use the notation with $\to$ and $\bigwedge$, but this time while writing $\bigwedge_{i\in I}(f_i, \tau_i) \to \tau$, we assume that any pair occurs as (f_i, τ_i) at most s times.

A *type judgment* is of the form $\Gamma \vdash M : (v, \tau)$, where $v\colon \Sigma_{\mathsf{a}} \to \mathbb{N}$, and where we require that the type τ and the lambda-term M are of the same sort. The *type environment* Γ is an s-multiset of bindings of variables of the form $x^\alpha : (A, \tau)$, where $A \subseteq \Sigma_{\mathsf{a}}$ is a *productivity set* and $\tau \in \mathcal{T}_s^\alpha$ is a type. For $a \in \Sigma_{\mathsf{a}}$ by $\Gamma\restriction_a$ we denote the s-multiset of those binding from Γ that have a in their productivity set.

By $\mathbf{0}$ we denote the function from Σ_{a} to $\mathbb{N}$ that maps every a_i to 0, and by χ_i the function that maps a_i to 1 and all other a_j to 0. The type system consists of the following rules:

$$\emptyset \vdash \mathsf{a}_i : (\chi_i, (A, \mathsf{r}) \to \mathsf{r}) \qquad \emptyset \vdash \mathsf{c} : (\mathbf{0}, \mathsf{r})$$

$$\emptyset \vdash \mathsf{b} : (\mathbf{0}, (A, \mathsf{r}) \to \top \to \mathsf{r}) \qquad \emptyset \vdash \mathsf{b} : (\mathbf{0}, \top \to (A, \mathsf{r}) \to \mathsf{r}) \qquad x : (A, \tau) \vdash x : (\mathbf{0}, \tau)$$

$$\frac{\Gamma \cup \{x : (A_i, \tau_i) \mid i \in I\} \vdash K : (v, \tau) \qquad x \notin \mathit{dom}(\Gamma)}{\Gamma \vdash \lambda x.K : (v, \bigwedge_{i\in I}(A_i, \tau_i) \to \tau)}\ (\lambda)$$

We define the duplication factor $dupl((\Gamma_j)_{j\in J})$, as the function (from Σ_{a} to $\mathbb{N}$) that maps every important constant $a \in \Sigma_{\mathsf{a}}$ to $\sum_{j\in J} |\Gamma_j\restriction_a| - \left|\bigcup_{j\in J} \Gamma_j\restriction_a\right|$.

$$\frac{\begin{array}{cc} 0 \notin I & \forall i \in I.\ A_i = \{a \in \Sigma_{\mathsf{a}} \mid v_i(a) > 0 \vee \Gamma_i\restriction_a \neq \emptyset\} \\ \Gamma_0 \vdash K : (v_0, \bigwedge_{i\in I}(A_i, \tau_i) \to \tau) & \Gamma_i \vdash L : (v_i, \tau_i) \text{ for each } i \in I \end{array}}{\bigcup_{i\in\{0\}\cup I} \Gamma_i \vdash K\ L : (dupl((\Gamma_i)_{i\in\{0\}\cup I}) + \sum_{i\in\{0\}\cup I} v_i, \tau)}\ (@)$$

Recall that this time any pair may occur as (f_i, τ_i) at most s times.

Abstract

We consider the parameterized verification problem for distributed algorithms where the goal is to develop techniques to prove the correctness of a given algorithm regardless of the number of participating processes. Motivated by an asynchronous binary consensus algorithm [3], we consider round-based distributed algorithms communicating with shared memory. A particular challenge in these systems is that 1) the number of processes is unbounded, and, more importantly, 2) there is a fresh set of registers at each round. A verification algorithm thus needs to manage both sources of infinity. In this setting, we prove that the safety verification problem, which consists in deciding whether all possible executions avoid a given error state, is PSPACE-complete. For negative instances of the safety verification problem, we also provide exponential lower and upper bounds on the minimal number of processes needed for an error execution and on the minimal round on which the error state can be covered.

1 Introduction

Distributed algorithms received in the last decade a lot of attention from the automated verification community. Parameterized verification emerged as a subfield that specifically addresses the verification of distributed algorithms. The main challenge is that distributed algorithms should be proven correct for any number or participating processes. Parameterized models are thus infinite by nature and parameterized verification is in general unfeasible [2]. However, one can recover decidability by considering specific classes of parameterized models, as in the seminal work by German and Sistla where identical finite state machines interact via rendezvous communications [14]. Since then, various models have been proposed to handle various communication means (see [11, 7] for surveys).

Shared memory is one possible communication means. This paper makes first steps towards the parameterized verification of *round-based* distributed algorithms in the shared-memory model; examples of such algorithms can be found in [4, 3, 16]. In particular, our approach covers Aspnes' consensus algorithm [3] which we take as a motivating example. Shared-memory models *without rounds* have been considered in the literature: the verification

of safety properties for systems with a leader and many anonymous contributors interacting via a single shared register is coNP-complete [12, 13]; and for Büchi properties, it is NP-complete [10]. Randomized schedulers have also been considered for shared-memory models without leaders; the verification of almost-sure coverability is in EXPSPACE, and is PSPACE-hard [9]. Finally, safety verification is PSPACE-complete for so-called distributed memory automata, that combine local and global memory [8].

Round-based algorithms make verification particularly challenging since they use fresh copies of the registers at each round, and an unbounded number of asynchronous processes means that verification must handle a system with an unbounded number of registers. This is why existing verification techniques fall short at analyzing such algorithms combining two sources of infinity: an unbounded number of processes, and an unbounded number of rounds (hence of registers).

Algorithm 1 Aspnes' consensus algorithm [3].

```
1  int k := 0, bool p ∈ {0,1}, (rg_b[r])_{b∈{b0,b1},r∈ℕ} all initialized to ⊥;
2  while true do
3      read from rg_{b0}[k] and rg_{b1}[k];
4      if rg_{b0}[k] = ⊤ and rg_{b1}[k] = ⊥ then p := 0;
5      else if rg_{b0}[k] = ⊥ and rg_{b1}[k] = ⊤ then p := 1;
6      write ⊤ to rg_{bp}[k];
7      if k > 0 then
8          read from rg_{b1−p}[k−1];
9          if rg_{b1−p}[k−1] = ⊥ then return p;
10     k := k+1;
```

Algorithm 1 gives the pseudocode of the binary consensus algorithm proposed by Aspnes [3], in which the processes communicate through shared registers. The algorithm proceeds in asynchronous rounds, which means that there is no *a priori* bound on the round difference between pairs of processes. Furthermore, reading from and writing to registers are separate operations, and a sequence of a read and a write cannot be performed atomically. Each round r has two shared registers $\mathsf{rg}_{b_i}[r]$ for $i \in \{0,1\}$; notation b_i is used in register indices to avoid confusion with other occurrences of digits 0 and 1. All registers are initialized to a default value $\bot$, and within an execution, their value may only be updated to $\top$. Intuitively, $\mathsf{rg}_{b_i}[r] = \top$ if i is the proposed consensus value at round r.

As usual in distributed consensus algorithms, each process starts with a preference value p. At each round, a process starts by reading the value of the shared registers of that round (**Line 3**). If exactly one of them is set to $\top$, the process updates its preference p to the corresponding value (**Lines 4** and **5**). In all cases, it writes $\top$ to the current-round register that corresponds to its preference p (**Line 6**). Then, it reads the register of the previous round corresponding to the opposite preference $1-p$ (**Line 8**), and if it is $\bot$, the process decides its preference p as return value for the consensus (**Line 9**). To be able to decide its current preference value, a process thus has to win a race against others, writing to a register of its current round k while no other process has written to the register of round $k-1$ for the opposite value. Note that a process can read from and write to the registers of its current round, whereas the registers of the previous rounds are read-only.

The expected properties of such a distributed consensus algorithm are *validity*, *agreement* and *termination*. Validity expresses that if all processes start with the same preference p, then no process can return a value different from p. Agreement expresses that no two processes

can return different values. Finally, termination expresses that eventually all processes should return a value. The termination of Aspnes' algorithm is only guaranteed under some fairness constraints on the adversary that schedules the moves of processes [3]. Its validity and agreement properties hold unconditionally. Our objective is to develop automated verification techniques for safety properties, which include validity and agreement.

For a single round –corresponding to one iteration of the while loop– safety properties can be proved applying techniques from [12, 13]. The additional difficulty here lies in the presence of unboundedly many rounds and thus of unboundedly many shared registers. Other settings of parameterized verification exist for round-based distributed algorithms, but none of them apply to asynchronous shared-memory distributed algorithms: they either concern fault-tolerant threshold-based algorithms [5, 6], or synchronous distributed algorithms [15, 1].

Contributions

In this paper, we introduce round-based register protocols, a formalism that models round-based algorithms in which processes communicate via shared memory. Figure 1 depicts a representation of Aspnes' algorithm in this formalism.

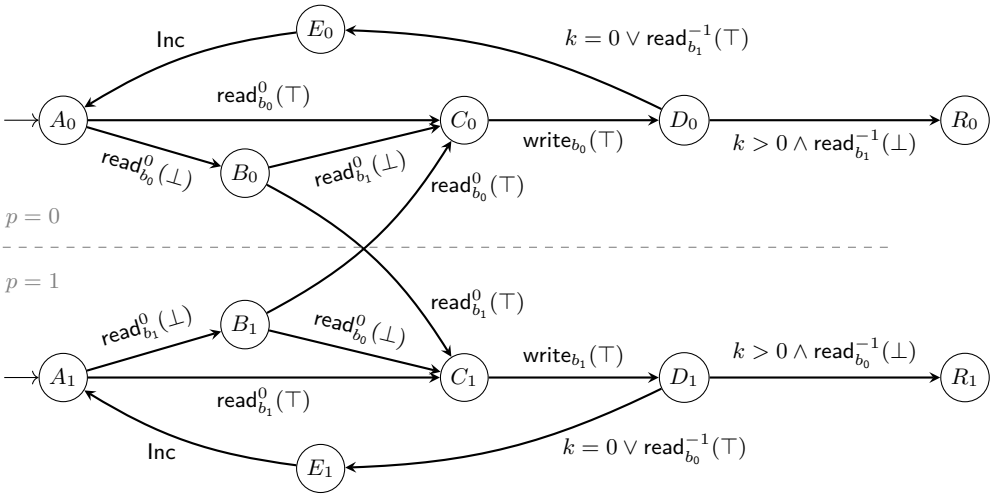

Figure 1 A round-based register protocol for Aspnes' noisy consensus algorithm. Since the first round ($k = 0$) slightly differs from the others, to avoid duplication of the state space, we allow for guards on round number k in the transition labels.

Round-based register protocols form a class of models inspired by register protocols [12, 9, 13], which were introduced to represent shared-memory distributed algorithms *without rounds*. In register protocols, states typically represent the control point of each process as well as the value of its private variables. For instance, the preference p of the process is encoded in the state space: in the top part, $p = 0$ and in the bottom part $p = 1$, as reflected by the states indices. To allow for multiple rounds and round increments, as in Line **10**, we extend register protocols with a new action Inc that labels the transitions from state E_p to state A_p, for each preference $p \in \{0, 1\}$. The processes may read from the registers of the current round but also from those of previous rounds, so reads must specify not only the register identifier but also the lookback distance to the current round: for a process in round k, $\mathsf{read}_{b_p}^{-d}(x)$ represents reading value x from register $\mathsf{rg}_{b_p}[k-d]$.

The validity and agreement properties translate as follows on the register protocols. For validity, one needs to check two properties, one for each common preference $p \in \{0, 1\}$. Namely, if all processes start in state A_0 (resp. A_1), then no processes can enter state R_0

(resp. R_1). Agreement requires that, independently from the initial state of each process in $\{A_0, A_1\}$, no executions reach a configuration with at least one process in R_0 and at least one process in R_1. Both validity and agreement are safety properties.

After introducing round-based register protocols, we study the parameterized verification of safety properties, with the objective of automatically checking whether a configuration involving an error state can be covered for arbitrarily many processes. Our main result is the PSPACE-completeness of this verification problem. We develop an algorithm exploiting the fact that the processes may only read the values of registers within a bounded window on rounds. However, a naive algorithm focusing on the v latest rounds only is hopeless: perhaps surprisingly, we show that the number of *active* rounds (i.e., rounds where a non-idle process is in) may need to be as large as exponential to find an execution covering an error state. The cutoff i.e., the minimal number of processes needed to cover an error state, may also be exponential. The design of our polynomial space algorithm addresses these difficulties by carefully tracking *first-write orders*, that is, the order in which registers are written to for the first time. One of the main technical difficulties of the algorithm is making sure that enough information is stored in this way, allowing the algorithm to solve the verification problem, while also staying in polynomial space.

The rest of the paper is structured as follows. To address the verification of safety properties for round-based register protocols, after introducing their syntax and semantics (Section 2.1), we first observe that they enjoy a monotonicity property (Section 2.2), which justifies the definition of a sound and complete abstract semantics (Section 2.3). We then highlight difficulties of coming up with a polynomial space decision procedure (Section 3.1). Namely, we provide exponential lower bounds on (1) the minimal round number, (2) the minimal number of processes, and (3) the minimal number of active rounds in error executions. We then introduce the central notion of *first-write orders* and its properties (Section 3.2). Section 3.3 details our polynomial-space algorithm, and Section 3.4 presents the complexity-matching lower bound.

2 Round-based shared-memory systems

2.1 Register protocols with rounds

▶ **Definition 1** (Round-based register protocols). *A* round-based register protocol *is a tuple* $\mathcal{P} = \langle Q, q_0, \mathsf{d}, \mathrm{D}, \mathsf{v}, \Delta \rangle$ *where*

- Q *is a finite set of states with a distinguished initial state* q_0*;*
- $\mathsf{d} \in \mathbb{N}$ *is the number of shared registers per round;*
- D *is a finite data alphabet containing* d_0 *the initial value and* $\mathrm{D} \setminus \{d_0\}$ *the values that can be written to the registers;*
- v *is the visibility range (a process on round* k *may read only from rounds in* $[k - \mathsf{v}, k]$*);*
- $\Delta \subseteq Q \times \mathcal{A} \times Q$ *is the set of transitions, where* $\mathcal{A} = \{\mathsf{Inc}\} \cup \{\mathsf{read}_\alpha^{-i}(x) \mid i \in [0, \mathsf{v}], \alpha \in [1, \mathsf{d}], x \in \mathrm{D}\} \cup \{\mathsf{write}_\alpha(x) \mid \alpha \in [1, \mathsf{d}], x \in \mathrm{D} \setminus \{d_0\}\}$ *is the set of actions.*

Intuitively, in a round-based register protocol, the behavior of a process is described by a finite-state machine with a local variable k representing its current round number; note that each process has its own round number, as processes are asynchronous and can be on different rounds. Moreover, there are d registers per round, and the transitions can read and modify these registers. Transitions in round-based register protocols can be labeled with three different types of actions: the Inc action simply increments the current round number

of the process; action $\mathsf{read}_\alpha^{-i}(x)$ can be performed by a process at round k when the value of register α of round $k-i$ is x; finally, with the action $\mathsf{write}_\alpha(x)$, a process at round k writes value x to the register α of round k. Note that all actions $\mathsf{read}_\alpha^{-i}(x)$ must satisfy $i \leq \mathsf{v}$; in other words, processes of round k can only read values of registers of rounds $k - \mathsf{v}$ to k.

For complexity purposes, we define the size of the protocol $\mathcal{P} = \langle Q, q_0, \mathsf{d}, \mathrm{D}, \mathsf{v}, \Delta\rangle$ as $|\mathcal{P}| = |Q| + |\mathrm{D}| + |\Delta| + \mathsf{v} + \mathsf{d}$ (thus implicitly assuming that v is given in unary).

Before defining the semantics of round-based register protocols, let us introduce some useful notations. For round number k, we write $\mathsf{rg}_\alpha[k]$ the register α of round k, we let $\mathsf{Reg}_k = \{\mathsf{rg}_\alpha[k] \mid \alpha \in [1, \mathsf{d}]\}$ denote the set of registers of round k, and $\mathsf{Reg} = \bigcup_{k\in\mathbb{N}} \mathsf{Reg}_k$ the set of all registers.

Round-based register protocols execute on several processes asynchronously. The processes communicate via the shared registers, and they progress in a fully asynchronous way through the rounds. A *location* $(q, k) \in Q \times \mathbb{N}$ describes the current state q and round number k of a process, and $\mathsf{Loc} = Q \times \mathbb{N}$ is the set of all locations. A configuration intuitively describes the location of each process, as well as the value of each register. Since processes are anonymous and indistinguishable, the locations of all processes can be represented by maps $\mathsf{Loc} \to \mathbb{N}$ describing how many processes populate each location. Formally, a *concrete configuration* is a pair $\gamma = (\mu, d) \in \mathbb{N}^{\mathsf{Loc}} \times \mathrm{D}^{\mathsf{Reg}}$ such that $\sum_{(q,k)\in\mathsf{Loc}} \mu(q, k) < \infty$. We write $\Gamma = \mathbb{N}^{\mathsf{Loc}} \times \mathrm{D}^{\mathsf{Reg}}$ for the set of all concrete configurations. For a concrete configuration $\gamma = (\mu, d)$, the location multiset μ is denoted $\mathsf{loc}(\gamma)$ and the value $d(k)(\alpha)$ of register α at round k in γ is written $\mathsf{data}_{\mathsf{rg}_\alpha[k]}(\gamma)$. The *size* of γ corresponds to the number of involved processes: $|\gamma| = \sum_{(q,k)\in\mathsf{Loc}} \mu(q, k)$. Configuration γ is *initial* if for every $(q, k) \neq (q_0, 0)$, $\mathsf{loc}(\gamma)(q, k) = 0$, and for every register ξ, $\mathsf{data}_\xi(\gamma) = d_0$. The set of initial concrete configurations therefore consists of all $\mathsf{init}_n = ((q_0, 0)^n, d_0^{\mathsf{Reg}})$. A register is *blank* when it still has initial value d_0. The *support* of the multiset $\mathsf{loc}(\gamma)$ is $\mathsf{supp}(\gamma) = \{(q, k) \mid \mathsf{loc}(\gamma)(q, k) > 0\}$. Finally, for $\gamma, \gamma' \in \Gamma$, we write $\mathsf{data}(\gamma) = \mathsf{data}(\gamma')$ whenever for all $\xi \in \mathsf{Reg}$, $\mathsf{data}_\xi(\gamma) = \mathsf{data}_\xi(\gamma')$.

The evolution from a concrete configuration to another reflects the effect of a process taking a transition in the register protocol. A *move* is thus an element $\theta = (\delta, k)$ consisting of a transition $\delta \in \Delta$ and a round number k; $\mathsf{Moves} = \Delta \times \mathbb{N}$ is the set of all moves. For two concrete configurations γ, γ', we say that γ' is a *successor* of γ if there is a move $((q, a, q'), k) \in \mathsf{Moves}$ satisfying one of the following conditions, depending on the action type:

- **(i)** $a = \mathsf{Inc}$, $\mathsf{loc}(\gamma)(q, k) > 0$, $\mathsf{loc}(\gamma') = \mathsf{loc}(\gamma) \ominus (q, k) \oplus (q', k{+}1)$, and $\mathsf{data}(\gamma') = \mathsf{data}(\gamma)$;
- **(ii)** $a = \mathsf{read}_\alpha^{-i}(x)$ with $x \in \mathrm{D}$, $\mathsf{data}_{\mathsf{rg}_\alpha[k-i]}(\gamma) = x$, $\mathsf{loc}(\gamma)(q, k) > 0$, $\mathsf{loc}(\gamma') = \mathsf{loc}(\gamma) \ominus (q, k) \oplus (q', k)$ and $\mathsf{data}(\gamma') = \mathsf{data}(\gamma)$;
- **(iii)** $a = \mathsf{write}_\alpha(x)$ with $x \in \mathrm{D} \setminus \{d_0\}$, $\mathsf{data}_{\mathsf{rg}_\alpha[k]}(\gamma') = x$, $\mathsf{loc}(\gamma)(q, k) > 0$, $\mathsf{loc}(\gamma') = \mathsf{loc}(\gamma) \ominus (q, k) \oplus (q', k)$ and for all $\xi \in \mathsf{Reg} \setminus \{\mathsf{rg}_\alpha[k]\}$, $\mathsf{data}_\xi(\gamma') = \mathsf{data}_\xi(\gamma)$.

Here, $\oplus$ and $\ominus$ are operations on multisets, respectively adding and removing elements. The first case represents round increment for a process and the register values are unchanged. The second case represents a read: it requires that the correct value is stored in the corresponding register, that the involved process moves, and that the register values are unchanged. By convention, here, if $k - i < 0$, i.e., for registers with negative round numbers, we let $\mathsf{data}_{\mathsf{rg}_\alpha[k-i]}(\gamma) = d_0$. Finally, the last case represents a write action; it only affects the corresponding register, and the state of the involved process. Note that in all cases, $|\gamma| = |\gamma'|$: the number of processes is constant. If γ' is a successor of γ by move θ, we write $\gamma \xrightarrow{\theta} \gamma'$. A *concrete execution* is an alternating sequence $\gamma_0, \theta_1, \gamma_1, \ldots, \gamma_{\ell-1}, \theta_\ell, \gamma_\ell$ of concrete configurations and moves such that for all i, $\gamma_i \xrightarrow{\theta_{i+1}} \gamma_{i+1}$. In such a case, we write $\gamma_0 \xrightarrow{*} \gamma_\ell$, and we say that γ_ℓ is reachable from γ_0. A location (q, k) is *coverable from* γ_0 when there exists $\gamma \in \mathsf{Reach}(\gamma_0)$ such that $(q, k) \in \mathsf{loc}(\gamma_0)$, and similarly a state q is *coverable from* γ_0 when there exist $k \in \mathbb{N}$ such that (q, k) is coverable from γ_0.

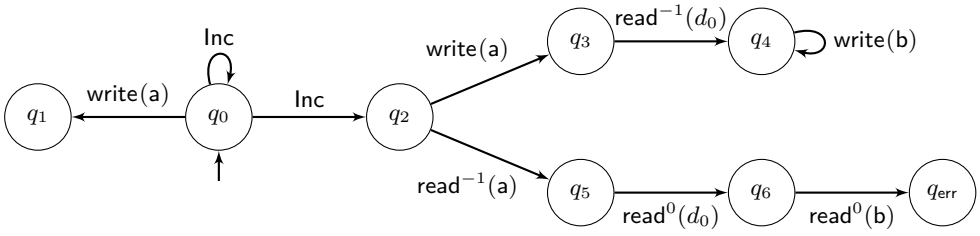

Figure 2 A simple round-based register protocol.

Given a concrete configuration $\gamma \in \Gamma$, $\mathsf{Reach}_{\mathsf{c}}(\gamma)$ denotes the set of all configurations that can be reached from γ: $\mathsf{Reach}_{\mathsf{c}}(\gamma) = \{\gamma' \mid \gamma \xrightarrow{*} \gamma'\}$.

We are now in a position to define our problem of interest:

SAFETY PROBLEM FOR ROUND-BASED REGISTER PROTOCOLS
Input: A round-based register protocol $\mathcal{P} = \langle Q, q_0, \mathsf{d}, \mathrm{D}, \mathsf{v}, \Delta\rangle$ and a state $q_{\mathsf{err}} \in Q$
Question: Is it the case that for every $n \in \mathbb{N}$, for every $\gamma \in \mathsf{Reach}_{\mathsf{c}}(\mathsf{init}_n)$ and for every round number k, $\mathsf{loc}(\gamma)(q_{\mathsf{err}}, k) = 0$?

The state q_{err} is referred to as an *error state* that all executions should avoid. An *error configuration* is a configuration in which the error state q_{err} appears, and an *error execution* is an execution containing an error configuration. Given a protocol $\mathcal{P}$ and a state q_{err}, in order to check whether $(\mathcal{P}, q_{\mathsf{err}})$ is a positive instance of the safety problem, we will look for an error execution, and therefore check the dual problem: whether there exist a size n and a configuration $\gamma \in \mathsf{Reach}_{\mathsf{c}}(\mathsf{init}_n)$ such that for some round number k, $\mathsf{loc}(\gamma)(q_{\mathsf{err}}, k) > 0$.

▶ **Example 2.** We illustrate round-based register protocols and their safety problem on the model depicted in Figure 2. This protocol has a single register per round ($\mathsf{d} = 1$, and the register identifier is thus omitted), and set of symbols $\mathrm{D} = \{d_0, a, b\}$. Let us give two examples of concrete executions. State q_4 is coverable from init_1 with the sequence of moves:

$$\pi_1 = \big(\langle(q_0,0)\rangle, \substack{\mathsf{rg}[0]=d_0\\ \mathsf{rg}[1]=d_0}\big) \xrightarrow{\langle q_0,\mathsf{Inc},q_2\rangle,0} \big(\langle(q_2,1)\rangle, \substack{\mathsf{rg}[0]=d_0\\ \mathsf{rg}[1]=d_0}\big) \xrightarrow{\langle q_2,\mathsf{write}(a),q_3\rangle,1} \big(\langle(q_3,1)\rangle, \substack{\mathsf{rg}[0]=d_0\\ \mathsf{rg}[1]=a}\big)$$
$$\xrightarrow{\langle q_3,\mathsf{read}^{-1}(d_0),q_4\rangle,1} \big(\langle(q_4,1)\rangle, \substack{\mathsf{rg}[0]=d_0\\ \mathsf{rg}[1]=a}\big).$$

State q_6 is coverable from init_2 as witnessed by the concrete execution:

$$\pi_2 = \big(\langle(q_0,0),(q_0,0)\rangle, \substack{\mathsf{rg}[0]=d_0\\ \mathsf{rg}[1]=d_0}\big) \xrightarrow{\langle q_0,\mathsf{write}(a),q_1\rangle,0} \big(\langle(q_0,0),(q_1,0)\rangle, \substack{\mathsf{rg}[0]=a\\ \mathsf{rg}[1]=d_0}\big) \xrightarrow{\langle q_0,\mathsf{Inc},q_2\rangle,0}$$
$$\big(\langle(q_2,1),(q_1,0)\rangle, \substack{\mathsf{rg}[0]=a\\ \mathsf{rg}[1]=d_0}\big) \xrightarrow{\langle q_2,\mathsf{read}^{-1}(a),q_5\rangle,1} \big(\langle(q_5,1),(q_1,0)\rangle, \substack{\mathsf{rg}[0]=a\\ \mathsf{rg}[1]=d_0}\big) \xrightarrow{\langle q_5,\mathsf{read}^{0}(d_0),q_6\rangle,1}$$
$$\big(\langle(q_6,1),(q_1,0)\rangle, \substack{\mathsf{rg}[0]=a\\ \mathsf{rg}[1]=d_0}\big).$$

However, it can be observed that no concrete execution can cover both states *at the same round* whatever the number of processes, thus preventing from covering q_{err}. We justify this observation in Subsection 3.2. This example is a positive instance of the safety problem. ⌟

▶ **Example 3.** The validity of Aspnes' algorithm can be expressed as two safety properties, with A_0 (resp. A_1) as initial state, and R_1 (resp. R_0) as error state. Let us argue that the protocol of Figure 1 is safe for $q_0 = A_0$ and $q_{\mathsf{err}} = R_1$; the other case is symmetric. Towards a contradiction, suppose there exists an execution $\pi : \mathsf{init}_n \xrightarrow{*} \gamma_1 \xrightarrow{\theta} \gamma_2 \xrightarrow{*} \gamma$ where

γ_2 contains a process in the bottom part, and γ_2 is the first such configuration along π. Then $\theta = ((B_0, \mathsf{read}^0_{b_1}(\top), C_1), k)$ for some k, thus implying that $\mathsf{data}_{\mathsf{rg}_{b_1}[k]}(\gamma_1) = \top$. However, b_1 can only be written to $\mathsf{rg}_{b_1}[k]$ by a process already in the bottom part, which contradicts the minimality of γ_2.

To formally encode agreement of Aspnes' algorithm as a safety property, we make two slight modifications to the protocol from Figure 1. We add an extra initial state q_0 with silent outgoing transitions to A_0 and to A_1; we also add an error state q_{err} that can be covered only if R_0 and R_1 are covered in a same execution. To do so, one can mimick the gadget at q_4 and q_6 in Figure 2, using an extra letter $b \in \mathrm{D}$ and adding Inc loops on both R_0 and R_1, allowing processes to synchronize on the same round, before writing and reading b.

Checking validity and agreement automatically for Aspnes' algorithm requires the machinery that we develop in the rest of the paper. ⌟

2.2 Monotonicity

Similarly to other parameterized models, and specifically shared-memory systems [13, 9], round-based register protocols enjoy a monotonicity property called the copycat property. Intuitively, this property states that if a location can be populated with one process, then, increasing the size of the initial configuration, it can be populated by an arbitrary number of them without affecting the behaviour of the other processes. Formally:

▶ **Lemma 4** (Copycat property). *Let $q \in Q$, $k, n, N \in \mathbb{N}$ and $\gamma_{\mathsf{i}}, \gamma_{\mathsf{f}} \in \Gamma$ such that $\gamma_{\mathsf{f}} \in \mathsf{Reach}_{\mathsf{c}}(\gamma_{\mathsf{i}})$ and $(q, k) \in \mathsf{supp}(\gamma_{\mathsf{f}})$. Then there exist $\gamma'_{\mathsf{i}}, \gamma'_{\mathsf{f}} \in \Gamma$ such that $\gamma'_{\mathsf{f}} \in \mathsf{Reach}_{\mathsf{c}}(\gamma'_{\mathsf{i}})$ and:*

- $|\gamma'_{\mathsf{i}}| = |\gamma_{\mathsf{i}}| + N$, $\mathsf{supp}(\gamma'_{\mathsf{i}}) = \mathsf{supp}(\gamma_{\mathsf{i}})$, *and* $\mathsf{data}(\gamma'_{\mathsf{i}}) = \mathsf{data}(\gamma_{\mathsf{i}})$;
- $\mathsf{loc}(\gamma'_{\mathsf{f}}) = \mathsf{loc}(\gamma_{\mathsf{f}}) \oplus (q, k)^N$ *and* $\mathsf{data}(\gamma'_{\mathsf{f}}) = \mathsf{data}(\gamma_{\mathsf{f}})$.

The copycat property strongly relies on the fact that operations on the registers are non-atomic. In particular it is crucial that processes cannot atomically read and write to a given register, since that could prevent another process from copycating its behaviour.

By the copycat property, the existence of an execution covering the error state q_{err} implies the existence of similar executions for any larger number of processes, which motivates the notion of cutoff. Formally, given $(\mathcal{P}, q_{\mathsf{err}})$ a negative instance of the safety problem, the *cutoff* is the least $n_0 \in \mathbb{N}$ such that for every $n \geq n_0$ there exist $\gamma_n \in \mathsf{Reach}_{\mathsf{c}}(\mathsf{init}_n)$ and $k_n \in \mathbb{N}$ with $\mathsf{loc}(\gamma_n)(q_{\mathsf{err}}, k_n) > 0$.

Another consequence is that any value that has been written to a register can be rewritten, at the cost of increasing the number of involved processes.

▶ **Corollary 5.** *Let $n \in \mathbb{N}$, $\pi : \mathsf{init}_n \xrightarrow{*} \gamma_1 \xrightarrow{*} \gamma$ a concrete execution and $\xi \in \mathsf{Reg}$ a register such that $\mathsf{data}_\xi(\gamma_1) \neq d_0$. There exist $n' \geq n$ and a concrete execution $\pi' : \mathsf{init}_{n'} \xrightarrow{*} \gamma'$ such that $\mathsf{loc}(\gamma) \subseteq \mathsf{loc}(\gamma')$, $\mathsf{data}_\xi(\gamma') = \mathsf{data}_\xi(\gamma_1)$ and for all $\xi' \neq \xi$, $\mathsf{data}_{\xi'}(\gamma') = \mathsf{data}_{\xi'}(\gamma)$.*

2.3 Abstract semantics

The copycat property suggests that, for existential coverability properties, the precise number of processes populating a location is not relevant, only the support of the location multiset matters. As for registers, the only important information to remember is whether they still contain the initial value, or they have been written to (the support then suffices to deduce which values can be written and read). In this section, we therefore define an abstract semantics for round-based register protocols, and we prove it to be sound and complete for the safety problem.

Formally, an *abstract configuration*, or simply a *configuration*, is a pair $\sigma \in 2^{\mathsf{Loc}} \times 2^{\mathsf{Reg}}$, with location support $\mathsf{loc}(\sigma) \in 2^{\mathsf{Loc}}$ and set of written registers $\mathsf{FW}(\sigma) \in 2^{\mathsf{Reg}}$. We write Σ for the set $2^{\mathsf{Loc}} \times 2^{\mathsf{Reg}}$ of all configurations. The (unique) *initial* configuration is $\sigma_{\mathsf{init}} = (\{(q_0, 0)\}, \emptyset)$. Configuration σ' is a successor of configuration σ if there exists a move $\theta = ((q, a, q'), k) \in \mathsf{Moves}$ such that one of the following conditions holds:

- **(i)** $a = \mathsf{Inc}$, $(q, k) \in \mathsf{loc}(\sigma)$, $\mathsf{loc}(\sigma') = \mathsf{loc}(\sigma) \cup \{(q', k{+}1)\}$, and $\mathsf{FW}(\sigma') = \mathsf{FW}(\sigma)$;
- **(ii)** $a = \mathsf{read}_\alpha^{-i}(x)$ with $x \neq d_0$, $(q, k) \in \mathsf{loc}(\sigma)$, $\mathsf{rg}_\alpha[k{-}i] \in \mathsf{FW}(\sigma)$, $\mathsf{loc}(\sigma') = \mathsf{loc}(\sigma) \cup \{(q', k)\}$, $\mathsf{FW}(\sigma') = \mathsf{FW}(\sigma)$ and there is a transition $(q_1, \mathsf{write}_\alpha(x), q_2) \in \Delta$ with $(q_1, k{-}i), (q_2, k{-}i) \in \mathsf{loc}(\sigma)$;
- **(iii)** $a = \mathsf{read}_\alpha^{-i}(d_0)$, $(q, k) \in \mathsf{loc}(\sigma)$, $\mathsf{rg}_\alpha[k{-}i] \notin \mathsf{FW}(\sigma)$, $\mathsf{loc}(\sigma') = \mathsf{loc}(\sigma) \cup \{(q', k)\}$ and $\mathsf{FW}(\sigma') = \mathsf{FW}(\sigma)$;
- **(iv)** $a = \mathsf{write}_\alpha(x)$ with $x \neq d_0$, $(q, k) \in \mathsf{loc}(\sigma)$, $\mathsf{loc}(\sigma') = \mathsf{loc}(\sigma) \cup \{(q', k)\}$ and $\mathsf{FW}(\sigma') = \mathsf{FW}(\sigma) \cup \{\mathsf{rg}_\alpha[k]\}$.

In this case, we write $\sigma \xrightarrow{\theta} \sigma'$. An (abstract) *execution* is an alternating sequence of configurations and moves $\rho = \sigma_0, \theta_1, \sigma_1, \ldots, \sigma_{\ell-1}, \theta_\ell, \sigma_\ell$ such that for all i, $\sigma_i \xrightarrow{\theta_{i+1}} \sigma_{i+1}$, and we write $\sigma \xrightarrow{*} \sigma_\ell$. Similarly to the concrete semantics, $\mathsf{Reach}(\sigma) = \{\sigma' \mid \sigma \xrightarrow{*} \sigma'\}$ denotes the set of *reachable configurations from* σ. Again, a location (q, k) is *coverable from* σ when there exists $\sigma' \in \mathsf{Reach}(\sigma)$ such that $(q, k) \in \mathsf{loc}(\sigma')$, and similarly a state q is *coverable from* σ when there exist $\sigma' \in \mathsf{Reach}(\sigma)$ and $k \in \mathbb{N}$ such that $(q, k) \in \mathsf{loc}(\sigma')$. We simply say that a configuration is *reachable* if it is reachable from the initial configuration σ_{init}, and that a location (resp. a state) is *coverable* if it is coverable from the initial configuration σ_{init}.

▶ **Example 6.** Consider again the protocol of Example 2. The (abstract) execution associated with the concrete execution π_1 in this example is

$$\rho_1 = \big(\{(q_0,0)\},\emptyset\big) \xrightarrow{\langle q_0,\mathsf{Inc},q_2\rangle,0} \big(\{(q_0,0),(q_2,1)\},\emptyset\big) \xrightarrow{\langle q_2,\mathsf{write}(a),q_3\rangle,1}$$
$$\big(\{(q_0,0),(q_2,1),(q_3,1)\},\{\mathsf{rg}[1]\}\big) \xrightarrow{\langle q_3,\mathsf{read}^{-1}(d_0),q_4\rangle,1} \big(\{(q_0,0),(q_2,1),(q_3,1),(q_4,1)\},\{\mathsf{rg}[1]\}\big).$$

Similarly, the execution associated with π_2 is

$$\rho_2 = \big(\{(q_0,0)\},\emptyset\big) \xrightarrow{\langle q_0,\mathsf{write}(a),q_1\rangle,0} \big(\{(q_0,0),(q_1,0)\},\{\mathsf{rg}[0]\}\big) \xrightarrow{\langle q_0,\mathsf{Inc},q_2\rangle,0}$$
$$\big(\{(q_0,0),(q_1,0),(q_2,1)\},\{\mathsf{rg}[0]\}\big) \xrightarrow{\langle q_2,\mathsf{read}^{-1}(a),q_5\rangle,1} \big(\langle(q_0,0),(q_1,0),(q_2,1),(q_5,1)\rangle,\{\mathsf{rg}[0]\}\big)$$
$$\xrightarrow{\langle q_5,\mathsf{read}^{0}(d_0),q_6\rangle,1} \big(\langle(q_0,0),(q_1,0),(q_2,1),(q_5,1),(q_6,1)\rangle,\{\mathsf{rg}[0]\}\big).$$ ⌟

Note that, in contrast to the concrete semantics, the location support of configurations cannot decrease along an abstract execution. One can easily be convinced that any concrete execution can be lifted to an abstract one, by possibly increasing the support, which is not a problem as long as one is interested in the verification of safety properties. Conversely, from an abstract execution, for a large enough number of processes, using the copycat property one can build a concrete execution with the same final location support. Altogether, the abstract semantics is therefore sound and complete to decide the safety problem on round-based register protocols.

▶ **Theorem 7.** *Let $\mathcal{P}$ be a round-based register protocol, q_{err} a state and $k \in \mathbb{N}$. Then:*

$$\exists n \in \mathbb{N}, \exists \gamma \in \mathsf{Reach}_{\mathsf{c}}(\mathsf{init}_n) : (q_{\mathsf{err}}, k) \in \mathsf{loc}(\gamma) \iff \exists \sigma \in \mathsf{Reach}(\sigma_{\mathsf{init}}) : (q_{\mathsf{err}}, k) \in \mathsf{loc}(\sigma).$$

Moreover, for negative instances of the safety problem, the proof of Theorem 7 yields an upper bound on the cutoff, which is linear in the round number at which q_{err} is covered.

▶ **Corollary 8.** *If there exists $k \in \mathbb{N}$ such that (q_{err}, k) is coverable, then, letting $N = 2|Q|(k{+}1){+}1$, there exists $\pi : \mathsf{init}_N \xrightarrow{*} \gamma$ such that $(q_{\mathsf{err}}, k) \in \mathsf{loc}(\gamma)$.*

3 Decidability and complexity of the safety problem

3.1 Exponential lower bounds everywhere!

To highlight the challenges in coming up with a polynomial space algorithm, we first state three exponential lower bounds when considering safety verification of round-based register protocols. Namely, we prove that (1) the minimal round are which the error state is covered, (2) the minimal number of processes needed for an error execution, and (3) the minimal number of simultaneously active rounds within an error execution, all may need to be exponential in the size of the protocol.

Exponential minimal round

▶ **Proposition 9.** *There exists a family* $(\mathcal{BC}_m)_{m\geq 1}$ *of round-based register protocols with* q_{err} *an error state, visibility range* $\mathsf{v} = 0$ *and number of registers per round* $\mathsf{d} = 1$*, such that* $|\mathcal{BC}_m| = O(m)$ *and the minimum round at which* q_{err} *can be covered is in* $\Omega(2^m)$*.*

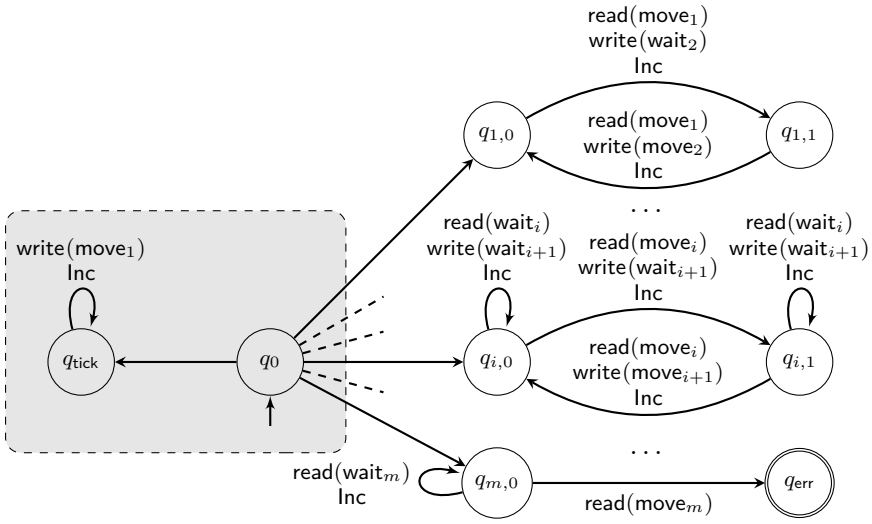

Figure 3 Protocol $\mathcal{BC}_m$ for which an exponential number of rounds is needed to cover q_{err}. For the sake of readability, transitions may be labelled by a sequence of actions: *e.g.*, the transition from $q_{i,0}$ to $q_{i,1}$ is labelled by $\mathsf{read}(\mathsf{move}_1)$, $\mathsf{write}(\mathsf{wait}_2)$, Inc. Such sequences of actions are not performed atomically: one should in principle add intermediate states to split the transition into several consecutive transitions, with one action each. We also use silent transitions (with no action label) that do not perform any action. The tick gadget in grey will be modified in subsequent figures.

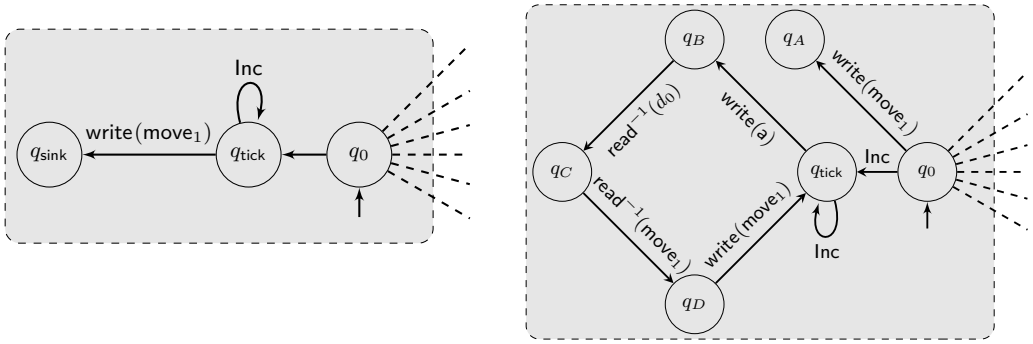
The protocol $\mathcal{BC}_m$, depicted in Figure 3, encodes a binary counter on m bits. The high-level idea of this protocol is that the counter value starts with 0 and is incremented at each round; setting the most significant bit to 1 puts a process in q_{err}. In order to cover q_{err}, any concrete execution needs at least $m+1$ processes: one in q_{tick} ticking every round, and one per bit, in states $\{q_{i,0}, q_{i,1}\}$ to represent the value of the counter's i-th bit. At round k, the value of the i-th least significant bit is 0 if at least one process is at $(q_{i,0}, k)$, and 1 if at least one process is at $(q_{i,1}, k)$. Finally, at round 2^{m-1}, setting the m-th least significant bit –of weight 2^{m-1}– to 1 corresponds to $(q_{\mathsf{err}}, 2^{m-1})$ being covered.

The following proposition is useful for the analysis of $\mathcal{BC}_m$. It states that, in register protocols where $\mathsf{v} = 0$ and $\mathsf{d} = 1$, coverable locations can be covered with a common execution.

▶ **Proposition 10.** *In a register protocol $\mathcal{P}$ with $\mathsf{v} = 0$ and $\mathsf{d} = 1$, for any finite set L of coverable locations, there exists $n \in \mathbb{N}$ and an execution $\rho : \sigma_{\mathsf{init}} \xrightarrow{*} \sigma$ such that, for all $(q, k) \in L$, $(q, k) \in \mathsf{loc}(\sigma)$.*

Our protocol $\mathcal{BC}_m$ satisfies the following property, that entails Proposition 9.

▶ **Proposition 11.** *Let $k \in [0, 2^{m-1}]$. Location (q_{err}, k) is coverable in $\mathcal{BC}_m$ iff $k = 2^{m-1}$.*



(a) An exponential number of processes is needed to cover q_{err}.

(b) An exponential number of active rounds is needed to cover q_{err}.

Figure 4 Two modifications of the tick mechanism of $(\mathcal{BC}_m)_{m\geq 1}$ yielding protocols that need respectively an exponential number of processes and an exponential number of active rounds.

Exponential cutoff

▶ **Proposition 12.** *There exists a family $(\mathcal{P}_m)_{m\geq 1}$ of round-based register protocols with q_{err} an error state, $\mathsf{v} = 0$ and $\mathsf{d} = 1$, such that $|\mathcal{P}_m| = O(m)$ and the minimal number of processes to cover an error configuration is in $\Omega(2^m)$.*

The protocol $\mathcal{P}_m$ is easily obtained from $\mathcal{BC}_m$ by modifying the tick mechanism so that each tick must be performed by a different process, as illustrated in Figure 4a. Since exponentially many ticks are needed to cover q_{err}, the cutoff is also exponential.

Exponential number of simultaneously active rounds

We have seen that the minimal round at which the error state can be covered may be exponential. Perhaps more surprisingly, we now show that the processes may need to spread over exponentially many different rounds. We formalise this with the notion of active rounds. At a configuration along a given execution, round k is *active* when some process is at round k and not idle, i.e., it performs a move later in the execution. The *number of active rounds* of an execution is the maximum number of active rounds at each configuration along the execution.

Towards a polynomial space algorithm for the safety problem, a polynomial bound on the number of active rounds would allow one to guess on-the-fly an error execution by storing only non-idle processes for the current configuration. However, such a polynomial bound does not exist:

▶ **Proposition 13.** *There exists a family $(\mathcal{P}'_m)_{m\geq 1}$ of round-based register protocols with q_{err} an error state, $\mathsf{v} = 1$ and $\mathsf{d} = 1$, such that $|\mathcal{P}'_m| = O(m)$ and the minimal number of active rounds for any error execution is in $\Omega(2^m)$.*

The protocol $\mathcal{P}'_m$ is again obtained from $\mathcal{BC}_m$ by modifying the tick mechanism, as illustrated in Figure 4b. The transitions from q_{tick} to q_B and from q_B to q_C ensure that, for all $k \in [0, 2^{m-1}]$, a must be written to $\mathsf{rg}[k]$ before it is written to $\mathsf{rg}[k-1]$. The transitions from q_C to q_D and from q_D to q_{tick}, on the contrary, ensure that, for all $k \in [1, 2^{m-1}]$, move_1 must be written to $\mathsf{rg}[k-1]$ before it is written to $\mathsf{rg}[k]$. Hence, in an error execution, when move_1 is first written to $\mathsf{rg}[0]$, all rounds from 1 to 2^{m-1} must be active, and the number of active rounds is at least 2^{m-1}.

Note that Proposition 13 requires $\mathsf{v} > 0$. Generally for round-based register protocols with $\mathsf{v} = 0$, processes in different rounds do not interact and an error execution can be reordered: all moves on round 0 first, then all moves on round 1, and so on, so that the number of active rounds is at most 2. Therefore, when $\mathsf{v} = 0$, a naive polynomial-space algorithm for the safety problem consists in computing all coverable states round after round.

3.2 Compatibility and first-write orders

The *compatibility* of coverable locations expresses that they can be covered in a common execution. Formally, two locations (q_1, k_1) and (q_2, k_2) are *compatible* when there exists $\rho : \sigma_{\mathsf{init}} \xrightarrow{*} \sigma$ such that $(q_1, k_1), (q_2, k_2) \in \mathsf{loc}(\sigma)$. In contrast to several other classes of parameterized models (such as broadcast protocols for instance), for round-based register protocols, not all coverable locations are compatible, which makes the safety problem trickier.

▶ **Example 14.** The importance of compatibility can be illustrated on the protocol of Figure 2, whose safety relies on the fact that, for all $k \geq 1$, locations (q_4, k) and (q_6, k) –although both coverable– are *not* compatible. Intuitively, in order to cover (q_4, k), one must write a to $\mathsf{rg}[k]$ and then read d_0 from $\mathsf{rg}[k-1]$, while in order to cover (q_6, k), one must read a from $\mathsf{rg}[k-1]$ and then read d_0 from $\mathsf{rg}[k]$. Since d_0 cannot be written, covering (q_4, k) requires a write to $\mathsf{rg}[k]$ while $\mathsf{rg}[k-1]$ is still blank, and covering (q_6, k) requires the opposite. ⌟

More generally, the order in which registers are first written to appears to be crucial for compatibility. We thus define in the sequel the *first-write order* associated with an execution, and use it to give sufficient conditions for compatibility of locations, that we express as being able to combine executions covering these locations.

▶ **Definition 15.** *For $\rho = \sigma_0, \theta_1, \cdots \theta_\ell, \sigma_\ell$ an execution, move θ_i is a* first write *(to $\mathsf{rg}_\alpha[k]$) if $\theta_i = ((q, \mathsf{write}_\alpha(x), q'), k)$ and $\mathsf{rg}_\alpha[k] \notin \mathsf{FW}(\sigma_{i-1})$. The* first-write order *of ρ is the sequence of registers $\mathsf{fwo}(\rho) = \xi_1 : \ldots : \xi_m$ such that the j-th first write along ρ writes to ξ_j.*

Following Example 6, $\mathsf{fwo}(\rho_1) = \mathsf{rg}[1]$ and $\mathsf{fwo}(\rho_2) = \mathsf{rg}[0]$. Two executions with same first-write order can be combined into a "larger" one with same first-write order.

▶ **Lemma 16.** *Let $\rho_1 : \sigma_{\mathsf{init}} \xrightarrow{*} \sigma_1$ and $\rho_2 : \sigma_{\mathsf{init}} \xrightarrow{*} \sigma_2$ be two executions such that $\mathsf{fwo}(\rho_1) = \mathsf{fwo}(\rho_2)$. Then, there exists $\rho : \sigma_{\mathsf{init}} \xrightarrow{*} \sigma$ such that $\mathsf{loc}(\sigma) = \mathsf{loc}(\sigma_1) \cup \mathsf{loc}(\sigma_2)$, $\mathsf{FW}(\sigma) = \mathsf{FW}(\sigma_1) = \mathsf{FW}(\sigma_2)$, and $\mathsf{fwo}(\rho) = \mathsf{fwo}(\rho_1) = \mathsf{fwo}(\rho_2)$.*

It follows that, for any fixed first-write order, there is a *maximal support* that can be covered by executions having that first-write order.

To extend the previous result, we exploit the fact that executions do not read registers arbitrarily far back. It is sufficient to require the first-write orders to have the same projections on all round windows of size v. Formally, for a first-write order f, and two round numbers $k, k' \in \mathbb{N}$ with $k \leq k'$, $\mathsf{proj}_{[k,k']}(\mathsf{f})$ denotes the restriction of f to registers from rounds k to k'.

▶ **Lemma 17.** *Let* $\rho_1 \colon \sigma_{\mathsf{init}} \xrightarrow{*} \sigma_1$ *and* $\rho_2 \colon \sigma_{\mathsf{init}} \xrightarrow{*} \sigma_2$ *be two executions of a register protocol with visibility range* v*, such that, for all* $k \in \mathbb{N}$*,* $\mathsf{proj}_{[k-\mathsf{v},k]}(\mathsf{fwo}(\rho_1)) = \mathsf{proj}_{[k-\mathsf{v},k]}(\mathsf{fwo}(\rho_2))$*. Then, there exists* $\rho \colon \sigma_{\mathsf{init}} \xrightarrow{*} \sigma$ *such that* $\mathsf{loc}(\sigma) = \mathsf{loc}(\sigma_1) \cup \mathsf{loc}(\sigma_2)$*,* $\mathsf{FW}(\sigma) = \mathsf{FW}(\sigma_1) = \mathsf{FW}(\sigma_2)$*, and, for all* $k \in \mathbb{N}$*,* $\mathsf{proj}_{[k-\mathsf{v},k]}(\mathsf{fwo}(\rho)) = \mathsf{proj}_{[k-\mathsf{v},k]}(\mathsf{fwo}(\rho_1)) = \mathsf{proj}_{[k-\mathsf{v},k]}(\mathsf{fwo}(\rho_2))$*.*

▶ **Example 18.** Agreement of Aspnes' algorithm is closely related to the notion of location (in)compatibility. Intuitively, one requires that no pair of locations (R_0, k_0) and (R_1, k_1) are compatible. Their incompatibility is a consequence of a difference between the first-write orders of the executions that respectively cover them. First, for every $k \geq 1$ and every execution $\rho : \sigma_{\mathsf{init}} \xrightarrow{*} \sigma \xrightarrow{*} \sigma'$, if $\mathsf{rg}_{b_i}[k] \in \mathsf{FW}(\sigma)$ and $\mathsf{rg}_{b_{1-i}}[k-1] \notin \mathsf{FW}(\sigma)$, then $\mathsf{rg}_{b_{1-i}}[k] \notin \mathsf{FW}(\sigma')$; indeed, since $\mathsf{rg}_{b_{1-i}}[k] \notin \mathsf{FW}(\sigma)$, all locations in $\mathsf{loc}(\sigma)$ whose states correspond to $p = 1 - i$ are either on round $\leq k-1$ or on round k not on state E_{1-i}, and $\perp$ can no longer be read from $\mathsf{rg}_{b_{1-i}}[k]$; by induction, for all $k' \geq k$, $\mathsf{rg}_{b_{1-i}}[k'] \notin \mathsf{FW}(\sigma')$. Let $\rho_0 : \sigma_{\mathsf{init}} \xrightarrow{*} \sigma_0$ and $\rho_1 : \sigma_{\mathsf{init}} \xrightarrow{*} \sigma_1$ such that, for all $i \in \{0,1\}$, $(R_i, k_i) \in \mathsf{loc}(\sigma_i)$. For all $i \in \{0,1\}$, moves $\theta_i := ((C_i, \mathsf{write}_{b_i}(\top), D_i), k_i)$ and $\theta'_i := ((D_i, \mathsf{read}^{-1}_{b_{1-i}}(\perp), R_i), k_i)$ are in ρ_i, and θ_i appears before θ'_i in ρ_i. Therefore, by letting i such that $k_i \leq k_{1-i}$, ρ_i requires that $\mathsf{rg}_{b_i}[k_i]$ is first-written while $\mathsf{rg}_{b_{1-i}}[k_i - 1]$ is still blank, and therefore that $\mathsf{rg}_{b_i}[k_{1-i}]$ is left blank, while ρ_{1-i} requires a first write on $\mathsf{rg}_{b_i}[k_{1-i}]$, which proves that (R_0, k_0) and (R_1, k_1) are incompatible. Note that $\mathsf{fwo}(\rho_0)$ and $\mathsf{fwo}(\rho_1)$ do not have the same projection on $[k_{1-i} - 1, k_{1-i}]$, which justifies that Lemma 17 does not apply. ⌟

3.3 Polynomial-space algorithm

We now present the main contribution of this paper.

▶ **Theorem 19.** *The safety problem for round-based register protocols is in PSPACE.*

To establish Theorem 19, because PSPACE is closed under complement and thanks to Savitch's theorem, it suffices to provide a nondeterministic procedure that finds an error execution (if one exists) within polynomial space. We do this in two steps: first, we give a nondeterministic procedure that iteratively guesses projections of a first-write order and computes the set of coverable locations under those projections, but does not terminate; second, we justify how to run this procedure in polynomial space and that it can be stopped after an exponential number of iterations (thus encodable by a polynomial space binary counter).

The high-level idea of the nondeterministic procedure is to iteratively guess a first-write order f, and to simultaneously compute the set of coverable locations under f. Thanks to Lemma 17, rather than considering a precise first-write order, the algorithm guesses its projections on windows of size v. Concretely, at iteration k, the algorithm guesses $F_k = \mathsf{proj}_{[k-\mathsf{v},k]}(\mathsf{f})$ and computes the set $S_k(F_k)$ of states that can be covered at round k under f. These sets are computed incrementally along the prefixes of F_k, called *progressions*, which are considered in increasing order. For each prefix, we check whether a first write to the last register is *feasible*, that is, whether some coverable location is the source of such a write; we reject the computation otherwise.

Algorithm 2 provides the skeleton of this procedure. In **Line 3** of Algorithm 2, the sequence of registers F_k is constructed from F_{k-1} by removing the registers at round $(k-\mathsf{v}-1)$ and non-deterministically inserting some registers at round k. By convention, in the special case where $k = 0$, F_0 is set to a sequence of registers of round 0. From **Line 4** on, one considers the successive progressions of F_k, i.e., prefixes of increasing length, **Line 5** setting f to the prefix of F_k of length i. At **Line 7**, the set of coverable states at round k for progression $f = g{:}\xi$ is inherited from the one for progression g.

Algorithm 2 Non-deterministic polynomial space algorithm to compute the set of coverable states round by round.

Variables computed : $\mathcal{F} = (F_k)_{k\in\mathbb{N}}$, $(S_k(f))_{k\in\mathbb{N}, f\in\mathsf{Prefixes}(F_k)}$

1 **Initialisation**: $S_0(\varepsilon) := \{q_0\}$; $\forall (k,f) \neq (0,\varepsilon)$, $S_k(f) := \emptyset$; ;
2 **for** k *from* 0 *to* $+\infty$ **do**
3 non-deterministically choose F_k from F_{k-1} ;
4 **for** i *from* 0 *to* $\mathsf{length}(F_k)$ **do**
5 $f := \mathsf{prefix}_i(F_k)$;
6 **if** $f \neq \epsilon$ **then**
7 Let $f = g{:}\xi$, and set $S_k(f) := S_k(f) \cup S_k(g)$;
8 add to $S_k(f)$ the states that can be covered from round $k{-}1$ by Inc moves;
9 **if** *first write to* $\mathsf{last}(f)$ *is feasible* **then**
10 saturate $S_k(f)$ by read and write moves;
11 **else**
12 Reject;

The next line requires an extra definition. For every $k \in \mathbb{N}$ and every prefix f of F_k, the *synchronisation* $\phi^k_{k-1}(f)$ is the longest prefix of F_{k-1} that coincides with f on rounds $k{-}\mathsf{v}$ to $k{-}1$, i.e. such that $\mathsf{proj}_{[k-\mathsf{v},k-1]}(\phi^k_{k-1}(f)) = \mathsf{proj}_{[k-\mathsf{v},k-1]}(f)$. This is always well defined since F_k is obtained from F_{k-1} by removing registers of round $k{-}\mathsf{v}{-}1$, and inserting registers of round k. So $\phi^k_{k-1}(f)$ can be obtained from f by removing registers of round k, and inserting back those of round $k{-}\mathsf{v}{-}1$ that, in F_{k-1}, are before the first register of round in $[k-\mathsf{v}, k-1]$ that is not in f. Similarly, we define the prefixes of f corresponding to previous rounds. For every $r < k{-}1$ and every prefix f of F_k, the *synchronisation* $\phi^k_r(f)$ is defined inductively by $\phi^k_r(f) := \phi^{r+1}_r(\phi^k_{r+1}(f))$, so that $\phi^k_r(f) := \phi^{r+1}_r(\phi^{r+2}_{r+1}(\dots(\phi^{k-1}_{k-2}(\phi^k_{k-1}(f)))\dots))$. Last, by convention, $\phi^k_k(f) := f$.

▶ **Example 20.** We illustrate the notion of synchronisation function on a toy example. Consider the sequence of registers $F_1 = \alpha_1 : \beta_1 : \gamma_0 : \delta_0 : \epsilon_1 : \zeta_0$, where the subscripts denote the rounds, and assume that $\mathsf{v} = 1$. The sequence F_2 is obtained from F_1 by removing the round 0 registers $\gamma_0, \delta_0, \zeta_0$, and by inserting some registers of round 2. For instance, one nondeterministically construct $F_2 = \alpha_1 : \eta_2 : \beta_1 : \theta_2 : \epsilon_1$. In that case, for instance $\phi^2_1(\alpha_1 : \eta_2 : \beta_1) = \alpha_1 : \beta_1 : \gamma_0 : \delta_0$; in words, when we are at iteration 2 with progression $\alpha_1 : \eta_2 : \beta_1$, the corresponding progression at iteration 1 is $\alpha_1 : \beta_1 : \gamma_0 : \delta_0$. Also, $\phi^2_1(\alpha_1 : \eta_2) = \alpha_1$ and $\phi^2_1(\alpha_1 : \eta_2 : \beta_1 : \theta_2) = \alpha_1 : \beta_1 : \gamma_0 : \delta_0 : \epsilon_1 : \zeta_0$.

On iteration further, one could have $F_3 = \eta_2 : \kappa_3 : \theta_2$ and thus $\phi^3_1(\eta_2 : \kappa_3) = \phi^2_1(\phi^3_2(\eta_2 : \kappa_3)) = \phi^2_1(\alpha_1 : \eta_2 : \beta_1) = \alpha_1 : \beta_1 : \gamma_0 : \delta_0$. ⌟

Now, $S_k(f)$ is defined in two steps. First, **Line 8** adds to $S_k(f)$ the states that can be immediately obtained by an Inc move from states coverable at round $k{-}1$. Formally, $S_k(f) := S_k(f) \cup \{q' \in Q \mid \exists q \in S_{k-1}(\phi^k_{k-1}(f)), (q, \mathsf{Inc}, q') \in \Delta\}$. **Line 9** then checks that a first write to the last register in f is feasible; that is, if $f = g : \mathsf{rg}_\alpha[k]$, then, one checks whether there exists a write transition $(q, \mathsf{write}_\alpha(x), q') \in \Delta$ with $x \neq d_0$ and $q \in S_k(g)$. Second, in **Line 10**, we saturate $S_k(f)$ by all possible moves at round k. Formally, we add every state $q' \in Q \setminus S_k(f)$ such that there exist $q \in S_k(f)$ and $(q, a, q') \in \Delta$ where action a satisfies one of the following conditions:

- $a = \mathsf{read}^{-j}_\alpha(d_0)$ and $\mathsf{rg}_\alpha[k{-}j]$ does not appear in f;
- $a = \mathsf{read}^{-j}_\alpha(x)$ with $x \neq d_0$, $\mathsf{rg}_\alpha[k{-}j]$ appears in f and there exist $q_1, q_2 \in S_{k-j}(\phi^k_{k-j}(f))$ such that $(q_1, \mathsf{write}_\alpha(x), q_2) \in \Delta$;
- $a = \mathsf{write}_\alpha(x)$ and $\mathsf{rg}_\alpha[k]$ appears in f.

In **Line 12**, the computation is rejected since the guessed first-write order is not feasible.

Characterisation of the sets $S_k(F_k)$ computed in Algorithm 2

For a family of first-write order projections $\mathcal{F} = (F_k)_{k\in\mathbb{N}}$ and a round k, we define $Q\mathsf{cover}(\mathcal{F}, k) = \{q \mid \exists \rho\colon \sigma_{\mathsf{init}} \xrightarrow{*} \sigma \text{ s.t. } (q,k) \in \mathsf{loc}(\sigma) \text{ and } \forall r \leq k, \mathsf{proj}_{[r-\mathsf{v},r]}(\mathsf{fwo}(\rho)) = F_r\}$. In words, $Q\mathsf{cover}(\mathcal{F}, k)$ is the set of states that can be covered at round k by an execution whose first-write order projects to the family $\mathcal{F}$ on windows of size v.

Observe that the only non-deterministic choice in Algorithm 2 is the choice of the sequences F_k; hence, for a given $\mathcal{F} = (F_k)_{k\in\mathbb{N}}$, there is at most one non-rejecting computation whose first-write order projections agrees with family $\mathcal{F}$. In that case, we say that the $\mathcal{F}$-computation of Algorithm 2 is non-rejecting.

▶ **Theorem 21.** *For $\mathcal{F} = (F_k)_{k\in\mathbb{N}}$ a family of projections, if the $\mathcal{F}$-computation of Algorithm 2 is non-rejecting, then the computed sets $(S_k(F_k))_{k\in\mathbb{N}}$ satisfy, for all $k \in \mathbb{N}$, $S_k(F_k) = Q\mathsf{cover}(\mathcal{F}, k)$. Also, for any execution ρ from σ_{init}, letting $\mathcal{F} = (\mathsf{proj}_{[k-\mathsf{v},k]}(\mathsf{fwo}(\rho)))_{k\geq 0}$, the $\mathcal{F}$-computation of Algorithm 2 is non-rejecting.*

Building on Algorithm 2, our objective it to design a polynomial space algorithm to decide the safety problem for round-based register protocols. Theorem 21 shows the correctness of the nondeterministic procedure in the following sense: a non-rejecting computation computes all coverable states for the guessed first-write order, and any possible first-write order admits a corresponding non-rejecting computation. To conclude however, the space complexity should be polynomial in the size of the protocol, and termination must be guaranteed by some stopping criterion.

Staying within space budget. As presented, Algorithm 2 needs unbounded space to execute since it stores all sequences of first-write orders F_k and all sets $S_k(f)$. To justify that polynomial space is sufficient, we first observe that some computed values can be ignored after each iteration. Precisely, iteration k only uses variables of iteration $k-1$ for increments and of iterations $k-\mathsf{v}$ to $k-1$ for read/write moves. Thus, at the end of iteration k, all variables indexed with round $k-\mathsf{v}$ can be forgotten. It is thus sufficient to store the variables of $\mathsf{v}+1$ consecutive rounds.

To conclude, observe also that the maximum length of any sequence F_k is $\mathsf{d}(\mathsf{v}+1)$. Therefore each F_k has at most $\mathsf{d}(\mathsf{v}+1)+1$ prefixes, and there are at most $(\mathsf{d}(\mathsf{v}+1)+1)(\mathsf{v}+1)$ sets $S_r(f)$ with $r \in [k-\mathsf{v}, k]$ for a fixed round number k. We also do not need to store the value of k. All in all, the algorithm can be implemented in space complexity $O(Q \cdot \mathsf{d} \cdot \mathsf{v}^2)$.

Ensuring termination. To exhibit a stopping criterion, we apply the pigeonhole principle to conclude that after a number of iterations at most exponential in $Q \cdot \mathsf{d} \cdot \mathsf{v}^2$, the elements stored in memory repeat from a previous iteration, so that the algorithm starts looping. If q_{err} was not covered at that point, it cannot be covered in further iterations. One can thus use an iteration counter, encoded in polynomial space in the size of the protocol, to count iterations and return a decision when the counter reaches its largest value.

Note that, for negative instances of the safety problem, this gives an exponential upper bound on the round number at which q_{err} is covered. Combined with Corollary 8, it yields an exponential upper bound on the cutoff too. Both match the lower bounds established in Propositions 9 and 12.

▶ **Corollary 22.** *Let $\mathcal{P}$ be a round-based register protocol, and q_{err} an error state. If $(\mathcal{P}, q_{\mathsf{err}})$ is a negative instance of the safety problem, then there exist $K, N \in \mathbb{N}$ both exponential in $|\mathcal{P}|$ such that there exist $k \leq K$ and a concrete execution $\pi : \mathsf{init}_N \xrightarrow{*} \gamma$ such that $(q_{\mathsf{err}}, k) \in \mathsf{loc}(\gamma)$.*

With the space constraints and stopping criterion discussed above, the nondeterministic algorithm decides the safety problem for round-based register protocols. Indeed, it suffices to execute Algorithm 2 up until iteration K and check whether q_{err} appears in one the sets $S_k(F_k)$. If q_{err} is found in some $S_k(F_k)$ with $k \leq K$, then $q_{\mathsf{err}} \in Q\mathsf{cover}(\mathcal{F}, k)$, where $(\mathcal{F}_r)_{r \leq k}$ is the family of projections picked by the computation of the algorithm. Thus, the protocol is unsafe. Conversely, if the protocol is unsafe, then there exist $k \leq K$ and $\rho : \sigma_{\mathsf{init}} \xrightarrow{*} \sigma$ such that $(q_{\mathsf{err}}, k) \in \mathsf{loc}(\sigma)$. Letting $\mathcal{F} = (\mathsf{proj}_{[r-\mathsf{v},r]}(\mathsf{fwo}(\rho)))_{r \in \mathbb{N}}$, the $\mathcal{F}$-computation of the algorithm is non-rejecting, and since $q_{\mathsf{err}} \in Q\mathsf{cover}(\mathcal{F}, k)$, one has $q_{\mathsf{err}} \in S_k(F_k)$.

3.4 PSPACE lower bound

▶ **Theorem 23.** *The safety problem for round-based register protocols is PSPACE-hard, even for fixed* $\mathsf{v} = 0$ *and fixed* $\mathsf{d} = 1$.

Proof. The proof is by reduction from the validity of QBF.

From a 3-QBF instance, we define a round-based register protocol $\mathcal{P}_{\mathsf{QBF}}$ with an error state q_{err} so that the answer to the safety problem is no if and only if the answer to QBF-validity is yes, i.e., state q_{err} is coverable if, and only if, the QBF instance is valid. This proves that the safety problem is coPSPACE-hard, and therefore that it is PSPACE-hard since PSPACE = coPSPACE.

The protocol $\mathcal{P}_{\mathsf{QBF}}$ that we construct from a QBF instance is partly inspired by the binary counter from Figure 3. Recall that in $\mathcal{BC}_m$, each bit is represented by a subprotocol, and every round corresponds to an increment of the counter value. In $\mathcal{P}_{\mathsf{QBF}}$, each variable is represented by a subprotocol, and every round corresponds to considering a different valuation and evaluating whether it makes the inner SAT formula true. $\mathcal{P}_{\mathsf{QBF}}$ uses a single register per round ($\mathsf{d} = 1$), and the subprotocol corresponding to variable x writes at each round the truth value of x in the considered valuation. The protocol is designed to enumerate all relevant valuations, and take the appropriate decision about the validity.

We fix an instance ϕ of 3-QBF over the $2m$ variables $\{x_0, \cdots, x_{2m-1}\}$

$$\phi = \forall x_{2m-1} \exists x_{2m-2} \forall x_{2m-3} \exists x_{2m-4} \dots \forall x_1 \exists x_0 \bigwedge_{1 \leq j \leq p} a_j \vee b_j \vee c_j \ ,$$

with for every $j \in [1, p]$, $a_j, b_j, c_j \in \{x_i, \neg x_i \mid i \in [0, 2m-1]\}$ are the literals and write ψ for the inner 3-SAT formula.

From ϕ we construct a round-based register protocol on the data alphabet

$$\mathrm{D} := \{\mathsf{wait}_i, \mathsf{yes}_i, \mathsf{no}_i \mid i \in [0, 2m]\} \cup \{\mathtt{x_i}, \neg\mathtt{x_i} \mid i \in [0, 2m-1]\} \cup \{d_0\} \ ,$$

that in particular contains two symbols $\mathtt{x_i}$ and $\neg\mathtt{x_i}$ for each variable x_i. Moreover, we let $\mathsf{v} = 0$ and $\mathsf{d} = 1$.

Thanks to Proposition 10, when $\mathsf{v} = 0$ and $\mathsf{d} = 1$, all coverable locations are compatible, for every finite number of coverable locations, there exists an execution that covers all these locations. We therefore do not have to worry about with which execution a location is coverable, and we will simply write that a location *is coverable* or *is not coverable* and that a symbol *can be written* or *cannot be written* to a given register.

The protocol we construct is represented in Figure 5; it contains several gadgets that we detail in the sequel. Before that we provide a high-level view of $\mathcal{P}_{\mathsf{QBF}}$. In $\mathcal{P}_{\mathsf{QBF}}$, each variable x_i is represented by a subprotocol $\mathcal{G}_i$, and every round corresponds to considering a different valuation and evaluating whether it makes the inner SAT formula true with the gadget $\mathcal{P}_{\mathsf{check}}(\psi)$. The gadget $\mathcal{G}_i$ writes at each round the truth value of x_i in the considered evaluation. The protocol enumerates all valuations: a given round k will correspond to one

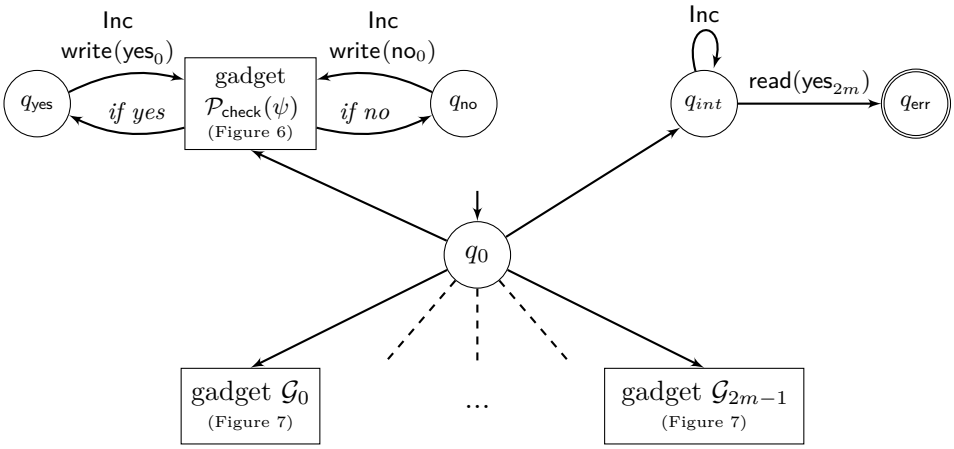


Figure 5 Overview of the protocol $\mathcal{P}_{\mathsf{QBF}}$. All transitions to gadgets go to their initial states.

valuation of the variables of ψ, in which variable x is true if $\mathtt{x}$ can be written to $\mathsf{rg}[k]$, and false if $\neg\mathtt{x}$ can be written to $\mathsf{rg}[k]$. The enumeration of the valuations and corresponding evaluations of ψ are performed so as to take the appropriate decision about the validity of the global formula ϕ.

We start by describing the gadget $\mathcal{P}_{\mathsf{check}}(\psi)$, depicted in Figure 6, that checks whether ψ is satisfied by the valuation under consideration. State q_{yes} corresponds to ψ evaluated to

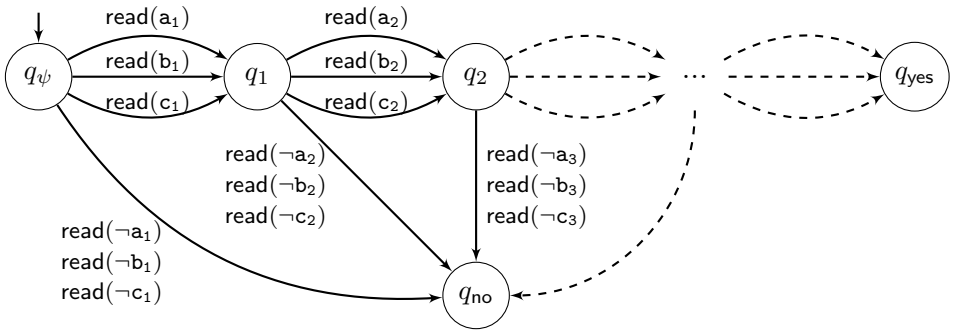

Figure 6 Gadget $\mathcal{P}_{\mathsf{check}}(\psi)$ that checks whether ψ is satisfied by the current valuation.

true and q_{no} corresponding to ψ evaluated to false. Note that we allow transitions labelled by sequences of actions; for instance the transition from state q_ψ to state q_{no} consists of three consecutive reads. The following lemma proves that the gadget $\mathcal{P}_{\mathsf{check}}(\psi)$ indeed checks how ψ evaluates for the current valuation.

▶ **Lemma 24.** *Let $k \in \mathbb{N}$. Suppose that (q_ψ, k) is coverable and that we have a valuation ν of the variables of ψ such that, for every $i \in [0, 2m-1]$:*

- *if $\nu(x_i) = 1$, then $\mathtt{x_i}$ can be written to $\mathsf{rg}[k]$, and $\neg\mathtt{x_i}$ cannot,*
- *if $\nu(x_i) = 0$, then $\neg\mathtt{x_i}$ can be written to $\mathsf{rg}[k]$, and $\mathtt{x_i}$ cannot.*

Then (q_{yes}, k) is coverable if and only if $\nu \models \psi$, and (q_{no}, k) is coverable if and only if $\nu \models \neg\psi$.

We now explain how valuations are enumerated, and how the different quantifiers are handled. The procedure next, given valuation ν, computes the next valuation $\mathsf{next}(\nu)$ that needs to be checked. Eventually, the validity of the formula will be determined by checking whether $\nu_0 \models \psi$ (where ν_0 assigns 0 to all variables) and $\mathsf{next}^k(\nu_0) \models \psi$ for increasing values of $k \geq 1$.

Let ν a valuation of all variables, and define the valuation $\mathsf{next}(\nu)$. Let ϕ_i denote the subformula $Qx_i \dots \forall x_1 \exists x_0 \psi$ where $Q = \exists$ if i is even, and $Q = \forall$ otherwise. We write $\nu \models \phi_i$ when ϕ_i is true when its free variables $x_{2m-1}, \dots, x_{i+1}$ are set to their values in ν. The procedure next uses variables $b_i \in \{\mathsf{yes}, \mathsf{no}, \mathsf{wait}\}$ for each $i \in [0, 2m]$, whose role is the following. We will set $b_0 = \mathsf{yes}$ if $\nu \models \psi$, and $b_0 = \mathsf{no}$ otherwise. For any $1 \leq i \leq 2m-1$, $b_i = \mathsf{yes}$ means $\nu \models \phi_i$; $b_i = \mathsf{no}$ means $\nu \not\models \phi_i$; while $b_i = \mathsf{wait}$ means that more valuations need to be checked to determine whether $\nu \models \phi_i$ or not. Given a valuation ν, the procedure next computes, at each iteration i, the truth value of x_i in valuation $\mathsf{next}(\nu)$ and the value of b_{i+1}. After $2m$ iterations, this provides the new valuation $\mathsf{next}(\nu)$ against which ψ must be checked. Formally, $b_0 = \mathsf{yes}$ if $\nu \models \psi$, and $b_0 = \mathsf{no}$ otherwise, and for all $i \in [0, 2m-1]$:

- If $b_i = \mathsf{wait}$, then $\mathsf{next}(\nu)(x_i) := \nu(x_i)$ and $b_{i+1} := \mathsf{wait}$.
- Otherwise
  - If i is even (existential quantifier).
    - if $b_i = \mathsf{yes}$, then $\mathsf{next}(\nu)(x_i) := 0$ and $b_{i+1} := \mathsf{yes}$,
    - if $b_i = \mathsf{no}$ and $\nu(x_i) = 0$, then $\mathsf{next}(\nu)(x_i) := 1$ and $b_{i+1} := \mathsf{wait}$,
    - if $b_i = \mathsf{no}$ and $\nu(x_i) = 1$, then $\mathsf{next}(\nu)(x_i) := 0$ and $b_{i+1} := \mathsf{no}$.
  - if i is odd (universal quantifier),
    - if $b_i = \mathsf{no}$, then $\mathsf{next}(\nu)(x_i) := 0$ and $b_{i+1} := \mathsf{no}$,
    - if $b_i = \mathsf{yes}$ and $\nu(x_i) = 0$, then $\mathsf{next}(\nu)(x_i) := 1$ and $b_{i+1} := \mathsf{wait}$,
    - if $b_i = \mathsf{yes}$ and $\nu(x_i) = 1$, then $\mathsf{next}(\nu)(x_i) := 0$ and $b_{i+1} := \mathsf{yes}$.

Note that variable b_{2m} is computed but not used in the computation. Its value will play the role of a result, e.g., in Lemma 25.

The following lemma formalizes how validity can be checked using next. It is easily proven by induction on m.

▶ **Lemma 25.** *ϕ is valid if and only if, when iterating* next *from valuation ν_0, one eventually obtains a computation of* next *that sets b_{2m} to* yes*. Otherwise, one eventually obtains a computation of* next *that sets b_{2m} to* no*.*

▶ **Example 26.** Let us illustrate the next operator and Lemma 25 on a small example. Assume

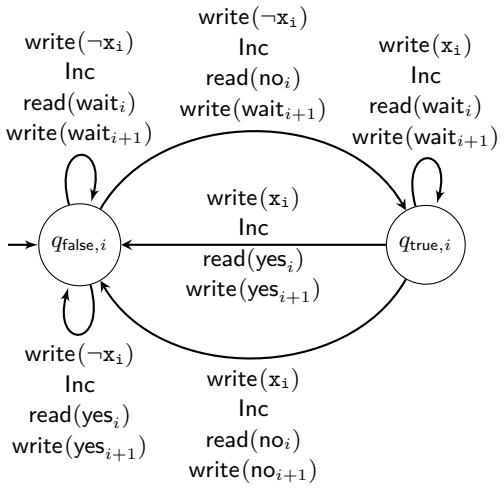
$$\phi = \exists x_2 \forall x_1 \exists x_0 \; \neg x_2 \wedge \neg x_1 \wedge (x_1 \vee \neg x_0),$$

which is not a valid formula. To determine that ϕ is not valid, we start by checking the valuation $\nu_0 = (0, 0, 0)$, writing ν_0 as the tuple $(\nu_0(x_0), \nu_0(x_1), \nu_0(x_2))$. Let $\nu = \mathsf{next}(\nu_0)$. ν_0 satisfies the inner formula, hence we set $b_0 = \mathsf{yes}$. By following the procedure of next, we obtain $\nu(x_0) = 0$, $b_1 = \mathsf{yes}$ in the first iteration (in fact, $\nu_0 \models \phi_0$); and $\nu(x_1) = 1$, $b_2 = \mathsf{wait}$ in the second iteration. In fact, even though $\nu_0 \models \psi$, because x_1 is quantified universally, we cannot yet conclude: we must also check whether ψ holds by setting x_1 to 1. This is what $b_2 = \mathsf{wait}$ means, and this is why $\nu(x_1)$ is set to 1. Lastly, we obtain $\nu(x_2) = 0$ and $b_3 = \mathsf{wait}$, therefore $\nu = (0, 1, 0)$.

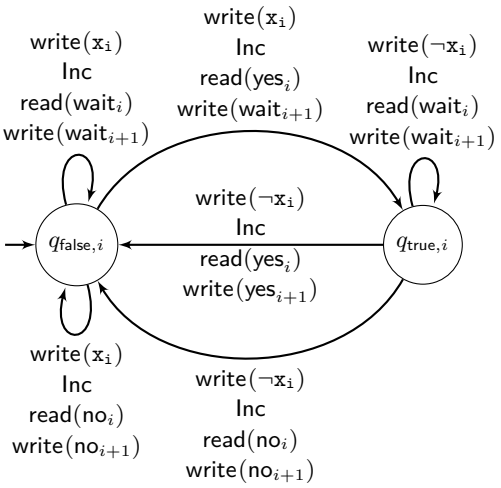
Let $\nu' = \mathsf{next}(\nu) = \mathsf{next}^2(\nu_0)$. We observe that $\nu \not\models \psi$ and set $b_0 = \mathsf{no}$. We then have $\nu'(x_0) = 1$, $b_1 = \mathsf{wait}$, and therefore $\nu'(x_1) = 1$ and $\nu'(x_2) = 0$. In the end, $\nu' = (0, 1, 1)$.

The computation of $\mathsf{next}^3(\nu_0)$ then sets x_2 to 1 because no valuation with $x_2 = 0$ satisfied the formula. We obtain $\mathsf{next}^3(\nu_0) = (1, 0, 0)$ and $\mathsf{next}^4(\nu_0) = (1, 0, 1)$. The computation of $\mathsf{next}^5(\nu_0)$ sets b_{2m} to no, establishing that ϕ is not valid. ⌟

Now, we define, for all $i \in [0, 2m-1]$, a gadget $\mathcal{G}_i$ that will play the role of variable x_i. At each round, gadget $\mathcal{G}_i$ receives from gadget $\mathcal{G}_{i-1}$ a value in $\{\mathsf{wait}_i, \mathsf{yes}_i, \mathsf{no}_i\}$ (except for gadget $\mathcal{G}_0$ which receives this value from $\mathcal{P}_{\mathsf{check}}(\psi)$). It transmits a value in $\{\mathsf{wait}_{i+1}, \mathsf{yes}_{i+1}, \mathsf{no}_{i+1}\}$ to $\mathcal{G}_{i+1}$, and modifies the value of variable x_i accordingly, writing either $\mathtt{x_i}$ or $\neg\mathtt{x_i}$ to the register. These gadgets $\mathcal{G}_i$ are given in Figure 7a if x_i is existentially quantified (i.e., i even),



(a) Gadget $\mathcal{G}_i$ for existentially quantified variable x_i (i.e., i even).



(b) Gadget $\mathcal{G}_i$ for universally quantified variable x_i (i.e., i odd).

Figure 7 Illustration of the gadgets $\mathcal{G}_i$.

and Figure 7b if x_i is universally quantified (i.e., i odd). Using those gadgets $\mathcal{G}_i$ and $\mathcal{P}_{\mathsf{check}}(\psi)$ together with the earlier described gadget $\mathcal{P}_{\mathsf{check}}(\psi)$, we define the protocol $\mathcal{P}_{\mathsf{QBF}}$ represented in Figure 5.

Finally, the following lemma justifies the correctness of our construction by formalising the relation between next and $\mathcal{P}_{\mathsf{QBF}}$.

▶ **Lemma 27.** *Let $k \in \mathbb{N}$ and $\nu_k := \mathsf{next}^k(\nu_0)$, the valuation obtained by applying next k times from $\nu_0 := 0^{2m}$. For all $i \in [0, 2m-1]$:*

- *$(q_{\mathsf{false},i}, k)$ is coverable if and only if $\nu_k(x_i) = 0$,*
- *$(q_{\mathsf{true},i}, k)$ is coverable if and only if $\nu_k(x_i) = 1$,*
- *$\neg\mathtt{x_i}$ can be written to $\mathsf{rg}[k]$ if and only if $\nu_k(x_i) = 0$,*
- *$\mathtt{x_i}$ can be written to $\mathsf{rg}[k]$ if and only if $\nu_k(x_i) = 1$.*

Moreover, if $k > 0$, then for all $j \in [0, 2m]$:

- *yes_j can be written to $\mathsf{rg}[k]$ if and only if computation $\nu_k = \mathsf{next}(\nu_{k-1})$ sets b_j to yes,*
- *no_j can be written to $\mathsf{rg}[k]$ if and only if computation $\nu_k = \mathsf{next}(\nu_{k-1})$ sets b_j to no,*
- *wait_j can be written to $\mathsf{rg}[k]$ if and only if computation $\nu_k = \mathsf{next}(\nu_{k-1})$ sets b_j to wait.*

Combining Lemma 27 with Lemma 25 proves that there exists a register to which yes_{2m} can be written if and only if ϕ is valid. Also, q_{err} is coverable in $\mathcal{P}_{\mathsf{QBF}}$ if and only if there exists a register to which yes_{2m} can be written, concluding the proof of Theorem 23. ◀

It may seem surprising that the safety problem is PSPACE-hard already for $\mathsf{d} = 1$ and $\mathsf{v} = 0$, i.e., with a single register and no visibility on previous rounds. For single register protocols without rounds, safety properties can be verified in polynomial time with a simple saturation algorithm. This complexity blowup highlights the expressive power of rounds, independently of the visibility on previous rounds.

Theorems 19 and 23 yield the precise complexity of the safety problem.

▶ **Corollary 28.** *The safety problem for round-based register protocols is PSPACE-complete.*

4 Conclusion

This paper makes a first step towards the automated verification of round-based shared-memory distributed algorithms. We introduce the model of round-based register protocols and solves its parameterized safety verification problem. Precisely, we prove that this problem is PSPACE-complete, providing in particular a non-trivial polynomial space decision algorithm. We also establish exponential lower and upper bounds on the cutoff and on the minimal round at which an error is reached.

Many interesting extensions could be considered, such as assuming the presence of a leader as in [13], or considering other properties than safety. In particular, for algorithms such as Aspnes', beyond validity and agreement that are safety properties, one would need to be able to handle liveness properties (possibly under a fairness assumption) to prove termination.

Passive Learning of Deterministic Büchi Automata by Combinations of DFAs

León Bohn

Christof Löding
RWTH Aachen University, Germany

Abstract

We present an algorithm that constructs a deterministic Büchi automaton in polynomial time from given sets of positive and negative example words. This learner constructs multiple DFAs using a polynomial-time active learning algorithm on finite words as black box using an oracle that we implement based on the given sample of ω-words, and combines these DFAs into a single DBA. We prove that the resulting algorithm can learn a DBA for each DBA-recognizable language in the limit by providing a characteristic sample for each DBA-recognizable language. We can only guarantee completeness of our algorithm for the full class of DBAs through characteristic samples that are, in general, exponential in the size of a minimal DBA for the target language. But we show that for each fixed k these characteristic samples are of polynomial size for the class of DBAs in which each subset of pairwise language-equivalent states has size at most k.

1 Introduction

The problem of constructing finite automata from example words (also referred to as passive learning of automata) has been investigated since the 1970ies [8, 26, 14], see [17] for a survey. The task is to develop an algorithm that infers a finite automaton from a given sample $S = (S_+, S_-)$ such that all words from the finite set S_+ of positive examples are accepted, and all words from the finite set S_- are rejected. Such an algorithm can be viewed as a way of learning an automaton from a given set of examples, and we therefore refer to such algorithms as learners in the following.

Besides the running time of a learner, it is also of interest for which languages it can learn a finite automaton. In order to characterize learners that are robust and generalize from the sample, Gold proposed the notion of "learning in the limit" [13]. Given a class $\mathcal{C}$ of regular languages, a learner is said to learn every language in $\mathcal{C}$ in the limit, if for each language $L \in \mathcal{C}$ there is a characteristic sample S^L that is consistent with L and such that the learner returns a DFA for L for each sample that is consistent with L and contains all examples from S^L. In this case, we also say that the learner is complete for the class $\mathcal{C}$.

In [14] Gold presents a learner that constructs in polynomial time a DFA for a given sample and that can learn every regular language in the limit. Moreover, for each regular language L there is a characteristic sample of size polynomial in the minimal DFA for L. Such a learner is said to learn every regular language in the limit from polynomial data.

The key property that is used in most learning algorithms for regular languages is the characterization of regular languages by the Myhill/Nerode congruence: For a language L, two words u, v are equivalent if they cannot be distinguished by the language, that is, if for each word w, either both uw, vw are in L, or both are not in L. It is a basic result from automata theory that L is regular iff the Myhill/Nerode congruence has finitely many classes, and that these classes can be used as state set of the minimal DFA for L (see basic textbooks on automata theory, e.g. [15]). The idea for Gold's algorithm is to infer the Myhill/Nerode congruence from the sample $S = (S_+, S_-)$ based on the following idea. Two words u, v cannot be equivalent for any language that is consistent with S, if there is a word w such that $uw \in S_+$ iff $vw \in S_-$. Roughly speaking, Gold's algorithm uses such "obviously distinguishable" words as states for a DFA. If the sample does not contain enough information, it can happen that the resulting DFA is not consistent with the sample, and then the algorithm simply defaults to returning a DFA for S_+. The algorithm RPNI [21] avoids this problem by starting from a tree-shaped DFA for S_+, and then trying to merge states of this DFA in a specific order. If a merge leads to a DFA that is inconsistent with the sample, then the merge is discarded. Otherwise, the two states are merged, and the algorithm continues with this smaller DFA. This algorithm runs in polynomial time and learns every regular language in the limit from polynomial data [21]. Since then, many variations of such state merging techniques have been proposed and implemented, e.g., in the framework learnlib [16] and the library flexfringe [27]

While there is a lot of work on construction of DFAs from samples, very little is known about this problem for automata on infinite words, so called ω-automata. These have been studied since the early 1960s as a tool for solving decision problems in logic [11] (see also [24]), and are nowadays used in procedures for formal verification and synthesis of reactive systems (see, e.g., [6, 25, 19] for surveys and recent work). Syntactically, ω-automata are very similar to NFA resp. DFA (standard nondeterministic resp. deterministic finite automata on finite words), and they also share many closure and algorithmic properties. However, while the definition of the Myhill/Nerode congruence can easily be lifted to ω-languages, it does not give a characterization of the regular ω-languages. In particular, deterministic ω-automata may need several different language equivalent states in order to accept some regular ω-languages (as opposed to DFAs). As a consequence, deterministic ω-automata do not share the good properties of DFAs, e.g., minimization of deterministic Büchi automata is NP-hard [23], and also the methods for learning DFAs cannot be directly transferred to ω-automata. In fact, the current algorithms for constructing deterministic ω-automata from examples are adaptions of the algorithm of Gold [5] and of RPNI [9], and they are only known to learn ω-languages with informative right congruence (IRC) in the limit. The class IRC [4] consists of those languages that can be accepted by deterministic ω-automata without different language equivalent states, and thus can be handled by an adaption of the methods from finite words.

In this paper we propose a passive learning algorithm that is complete for the class of ω-languages that can be accepted by deterministic Büchi automata (DBA) (meaning that it can learn every language form that class in the limit). To the best of our knowledge, this is the first learning algorithm that is complete for a relevant class of ω-languages beyond languages with IRC. While DBA languages still form a strict subclass of the regular ω-languages, each regular ω-language is a finite Boolean combination of DBA languages [24], and therefore the DBA languages form an important class for understanding learning problems for ω-automata.

Our algorithm uses a learning algorithm for DFAs as sub-procedure, but interestingly an active learning algorithm. Such algorithms have to infer the DFA of a target language based on queries that are answered by an oracle. Angluin proposed an algorithm that learns the minimal DFA for a target language L based on membership and equivalence queries

in polynomial time [1]. A membership query asks for a specific word if it is in the target language, and the oracle answers "yes" or "no". An equivalence query asks if a hypothesis DFA accepts the target language, and the oracle provides a word as counterexample if it does not. We make use of such an active learning algorithm as black box in order to infer a set of DFAs that are then used to build the DBA. Roughly, our algorithm works as follows for a given ω-sample $S = (S_+, S_-)$ consisting of ultimately periodic ω-words (the use of ultimately periodic words is standard in learning of ω-automata [18, 3, 5, 9]):

- Infer a right congruence $\sim$ that is consistent with S. This can be done using the same methods as for finite words.
- For each class of $\sim$ learn a DFA using an active learning algorithm as black box, answering the queries of this algorithm based on the information in S.
- Combine the DFAs into a DBA: Start in the DFA for the initial class of $\sim$. Whenever a DFA reaches an accepting state, redirect the transition into the initial state of the DFA for the current class, and make this transition accepting for the Büchi condition.[1]

This algorithm runs in polynomial time and can learn every DBA language in the limit. The characteristic sample for a DBA language L that we use for showing the learning in the limit result can be of size exponential in a smallest DBA for L. But we also show that it is polynomial if we fix the size of sets of pairwise language equivalent states in the DBAs. This generalizes known results for learning in the limit from polynomial data for languages with IRC [5, 9].

Besides the work on passive learning, there are also some papers on active learning of ω-languages from queries. In general, it seems that efficient active learning of deterministic omega-automata is more difficult than efficient passive learning. This is witnessed by the fact that a polynomial time active learner (with membership and equivalence queries) yields an efficient passive learner, and that polytime active learning IRC ω-languages is not easier than polytime active learning general omega-languages (see [9] for both results). For this reason, the currently known active learning algorithms either learn different representations for ω-languages, as for example families of DFAs in [3], or include syntactic information on the target automaton in the form of loop index queries [20].

The remainder of the paper is structured as follows. In Section 2 we introduce basic terminology and definitions used in the paper. Subsequently, in Section 3 we present our learning algorithm and prove that it is a consistent polynomial time DBA-learner. In Section 4 we prove the completeness result that our algorithm can learn every DBA language in the limit. In Section 5 we analyze the size of the characteristic samples from the completeness proofs, and we conclude in Section 6.

2 Preliminaries

For a finite alphabet Σ we denote by Σ^* and Σ^ω the set of all finite and infinite words over Σ, respectively and define $\Sigma^+ = \Sigma^* \setminus \{\varepsilon\}$, where ε denotes the empty word. A language is a subset of Σ^* and an ω-language a subset of Σ^ω. We sometimes simply write language instead of ω-language, the meaning should always be clear from the context. We use $\preceq$ to denote the canonical or length-lexicographic order on finite words over Σ, in which words are first ordered by length, and words of same length are ordered lexicographically for some underlying linear order of the alphabet. For a finite word u and a finite or infinite word v,

[1] We use Büchi acceptance on transitions, i.e., a run is accepting if it passes infinitely many accepting transitions.

we write $u \sqsubseteq v$ if $ux = v$ for some $x \in \Sigma^*$ or $x \in \Sigma^\omega$, respectively, and call u a *prefix* of v. We use $\mathsf{Prf}(w)$ to denote the set of all prefixes of a finite or infinite word w and extend this notation to a set X of words in the natural way, i.e. $\mathsf{Prf}(X) = \bigcup_{w \in X} \mathsf{Prf}(w)$.

We say that $(u, v) \in \Sigma^* \times \Sigma^+$ is a *representation of* $w \in \Sigma^\omega$ if $uv^\omega = w$. If an ω-word w has such a representation, we call w *ultimately periodic*, and we denote the set of all possible representations $\Sigma^* \times \Sigma^+$ with $\mathbb{UP}$. For a finite word u and a (ω)-language L, we define $u^{-1}L = \{w \mid uw \in L\}$. Note that if L is an ω-language, then $u^{-1}L$ is an ω-language as well. For a word w, we use $w[i, j]$ to denote the infix of w from position i to position j and set $w[i, j] = \varepsilon$ if $i > j$. We write $(u, v) \preceq (u', v')$ if $u \preceq u'$ or $u = u'$ and $v \preceq v'$. For a set $X \subseteq \mathbb{UP}$ of representations, we define $[\![X]\!]_\omega = \{uv^\omega \mid (u, v) \in X\}$.

A *deterministic transition system* (TS) is given as a tuple $\mathcal{T} = (Q, \Sigma, \iota, \delta)$, where Q is a finite, non-empty set of states, Σ is the finite alphabet, $\iota \in Q$ is the initial state and $\delta : Q \times \Sigma \to Q$ is the transition function. We use $|\mathcal{T}|$ to refer to the size of $\mathcal{T}$, which is the number of states in Q. The run of $\mathcal{T}$ on some word $w = w_0 w_1 \ldots \in \Sigma^* \cup \Sigma^\omega$ is the unique (possibly infinite) sequence $\rho = \mathsf{run}(\mathcal{T}, w) = q_0 w_0 q_1 w_1 \ldots$ with $q_0 = \iota$ and $q_{i+1} = \delta(q_i, w_i)$ for $i < |w|$. For a finite word w, we use $\mathcal{T}(w)$ to denote the last state of $\mathsf{run}(\mathcal{T}, w)$. We define the *infinity set*, referred to as $\mathsf{inf}(\rho)$, of a run $\rho = q_0 w_0 q_1 w_1 \ldots$, as the set containing all pairs (q, a) such that there exist infinitely many positions i with $q_i = q$ and $w_i = a$. For a finite run $\rho = q_0 w_0 \ldots w_{n-1} q_n$ and a set $X \subseteq Q \times \Sigma$, we use $\rho \cap X$ to denote the transitions of ρ that are in X, i.e. $\rho \cap X = \{(q_i, w_i) \in X \mid i < n\}$.

By equipping $\mathcal{T}$ with a set of *final states* $F \subseteq Q$, we obtain a *deterministic finite automaton* (DFA) $\mathcal{A} = (Q, \Sigma, \iota, \delta, F)$. The language accepted by $\mathcal{A}$ is denoted as $L(\mathcal{A})$ and contains all words $w \in \Sigma^*$ such that $\mathcal{T}(w) \in F$. By combining a transition system $\mathcal{T}$ with a *Büchi condition* (on transitions), which is a set $\beta \subseteq Q \times \Sigma$, we obtain a *deterministic Büchi automaton* (DBA) $\mathcal{A} = (Q, \Sigma, \iota, \delta, \beta)$. Its accepted language $L(\mathcal{A})$ contains all infinite words w such that $\mathsf{inf}(\mathsf{run}(\mathcal{T}, w)) \cap \beta \neq \emptyset$. When we depict a DBA with acceptance condition β in a figure, we underline the label a of a transition leaving the state q, if $(q, a) \in \beta$. We can use the terminology for transition systems also for automata by simply ignoring the acceptance component. Similarly, the size of an automaton is equal to the size of the underlying transition system.

The class of DBA-recognizable languages is a strict subclass of the class of the regular ω-languages, which are defined in terms of nondeterministic Büchi automata. We do not detail the definition here because it is not relevant for our paper (see [24] for a survey of the topic). It is well known that two regular ω-languages, and hence also two DBA-recognizable languages, are equal iff they coincide on the ultimately periodic words [11] (see also [12]).

We call a relation $\sim \subseteq \Sigma^* \times \Sigma^*$ a *right congruence* if $u \sim w$ implies $ua \sim wa$ for all $a \in \Sigma$. For $u \in \Sigma^*$ we write $[u]_\sim$ for the set of all $v \in \Sigma^*$ with $u \sim v$, also referred to as the *equivalence class* of u. For a language $L \subseteq \Sigma^*$ or $L \subseteq \Sigma^\omega$, we define the right congruence of L, denoted by $\sim_L$, as $u \sim_L v$ iff $u^{-1}L = v^{-1}L$.

A right congruence $\sim$ defines the canonical TS $\mathcal{T}_\sim = (Q_\sim, \Sigma, [\varepsilon]_\sim, \delta_\sim)$ where $Q_\sim$ is the set of classes in $\sim$ and $\delta([u]_\sim, a) = [ua]_\sim$. Due to this correspondence, we write $c \in Q_\sim$ to denote that c is a class of $\sim$. Similarly, we can associate with every TS $\mathcal{T}$ a congruence $\sim_\mathcal{T} \subseteq \Sigma^* \times \Sigma^*$, where $u \sim_\mathcal{T} v$ iff $\mathcal{T}(u) = \mathcal{T}(v)$. Let p, q be states of some automaton $\mathcal{A}$ that accepts the language L, and let c be a class of $\sim_L$. By abuse of notation, we use $q \in c$ if $\mathcal{A}$ reaches q on some word $u \in c$. Further, we write $p \sim q$ if $p \in c$ and $q \in c$ for some class c. We use L_c for a class c of $\sim_L$ to denote the language $u^{-1}L$ for a $u \in c$.

An *ω-sample* is a pair $S = (S_+, S_-)$ with $S_+, S_- \subseteq \mathbb{UP}$ and $[\![S_+]\!]_\omega \cap [\![S_-]\!]_\omega = \emptyset$. We refer to words in S_+ as *positive*, while those in S_- are called negative. Since we only use ω-samples in our algorithm, we often simply write sample instead of ω-sample. We only consider finite samples, and the size of S, denoted as $|S|$, is defined as the sum of all $|u| + |v|$ for $(u, v) \in S_+ \cup S_-$. Furthermore, we call a sample $S = (S_+, S_-)$ consistent with a language L, if $L \cap [\![S_-]\!]_\omega = \emptyset$ and $[\![S_+]\!]_\omega \subseteq L$. Similarly, an automaton $\mathcal{A}$ is called *consistent* with S if $L(\mathcal{A})$ is consistent with S. We say that $u, v \in \Sigma^*$ are *separated by* S if there exists a word $w \in \Sigma^\omega$ such that $uw, vw \in \big([\![S_+]\!]_\omega \cup [\![S_-]\!]_\omega\big)$ and $\big(uw \in [\![S_+]\!]_\omega \Leftrightarrow vw \in [\![S_-]\!]_\omega\big)$. A DFA $\mathcal{D}$ is called *prefix-consistent* with the ω-sample $S = (S_+, S_-)$ if for all $w \in [\![S_+]\!]_\omega$ we have that $\mathsf{Prf}(w) \cap L(\mathcal{D}) \neq \emptyset$ and $\mathsf{Prf}([\![S_-]\!]_\omega) \cap L(\mathcal{D}) = \emptyset$.

A right congruence $\sim$ is consistent with S if $u \not\sim v$ for all $u, v \in \Sigma^*$ that are separated by S. In a *partial* TS $\mathcal{T}$, the transition function δ can have undefined values. While the definition of run also applies to partial TS, it is possible that the run of a partial TS on some words is undefined. A partial TS $\mathcal{T}$ has a conflict with a sample S if there are $u, v \in \Sigma^*$ that are separated by S but lead to the same state in $\mathcal{T}$ (which in particular means that the runs of $\mathcal{T}$ on u and v must exist). Note that $\sim$ is consistent with S iff the corresponding TS $\mathcal{T}_\sim$ has no conflict with S.

A passive learner (for DBAs) is a function f that maps ω-samples to DBAs. f is called a polynomial-time learner if f can be computed in polynomial time. A learner f is *consistent* if it constructs from each ω-sample $S = (S_+, S_-)$ a DBA $\mathcal{A}$ such that S is consistent with $L(\mathcal{A})$. We say that f can learn every DBA language in the limit if for each DBA language L there is a *characteristic sample* S^L such that $L(f(S^L)) = L$ and $f(S^L) = f(S)$ for each sample S that is consistent with L and contains S^L (so f produces the same DBA for L for all samples containing S^L). For a class $\mathcal{C}$ of DBA languages we say that f can learn every language in $\mathcal{C}$ in the limit *from polynomial data* if the characteristic samples for the languages in $\mathcal{C}$ are of polynomial size (in the smallest DBA for the corresponding language).

We also consider the standard active learning scenario for DFAs, in which the learning algorithm can obtain information on the target language L by posing membership and equivalence queries to an oracle [1]. In the following let L be a regular language. An oracle T for L answers a membership query $\mathsf{mem}(w)$ with either "yes" or "no", depending on whether the w is in the target language L or not. In an equivalence query $\mathsf{equiv}(\mathcal{A}_H)$, the active learner proposes a hypothesis $\mathcal{A}_H$ to T. If $\mathcal{A}_H$ accepts precisely the target language L, the oracle returns "yes". Otherwise, T answers "no" and additionally provides the learner with a word from the symmetric difference of $L(\mathcal{A}_H)$ and L, which serves as a counterexample. We make use of the following result.

▶ **Theorem 1** ([1], Theorem 6). *Let L be a regular language and T be an oracle for L. There exists an active learner* AL *that returns the minimal DFA $\mathcal{A}_L$ for L. Moreover, the runtime of* AL *is polynomial in the size of the minimal DFA and the length of the longest counterexample provided by T, and the size of all hypotheses used in equivalence queries is polynomial in the size of $\mathcal{A}_L$.*

3 A Learner for DBAs

In this section we introduce DBAInf (for DBA inference), a passive learner for deterministic Büchi automata, and describe how it constructs a DBA from a finite ω-sample. We start with an informal description of the underlying idea, then provide a formal description of the learning algorithm, and finally show that DBAInf is a consistent polynomial time learner for the class of DBAs.

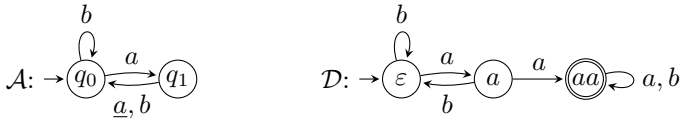

Figure 1 Illustrations for the high-level description of DBAInf. On the left a DBA $\mathcal{A}$ accepting the words in which the infix aa appears infinitely often. The DFA $\mathcal{D}$ on the right is constructed in an intermediate step of DBAInf from the ω-sample given in Example 2.

High-Level Description of the Idea

DFA-learners for languages of finite words are based on the fact that for the minimal DFA of a regular language, there is a one-to-one correspondence between states and equivalence classes of the right congruence of the language. DFA-learners basically extract a right congruence from the sample (consisting of finite words) that is then used for defining the transition system for the resulting DFA. The central obstacle in passive learning for ω-automata is the lack of such a one-to-one correspondence between states and equivalence classes. For example, the language L over the alphabet $\{a, b\}$ consisting of all words in which the infix aa occurs infinitely often cannot be recognized by a DBA with only one state. However, L has only one equivalence class, since for all $u \in \Sigma^*, w \in \Sigma^\omega$ we have $uw \in L$ if and only if $w \in L$. Thus, given an ω-sample that is consistent with L, the extracted right congruence will only have one class since the ω-sample does not separate any words.

We explain the idea underlying DBAInf for languages with only one equivalence class such as L, that is, if the sample does not separate any two words. The formal description then also covers the general case.

Basically, DBAInf attempts to identify specific subwords, also referred to as the *positive patterns of* L in the following description, that appear infinitely often precisely in words belonging to L. Consider, for example, the DBA $\mathcal{A}$ depicted in Figure 1 on the left, which accepts L. Regardless of which state $\mathcal{A}$ is in, reading the pattern aa makes $\mathcal{A}$ use an accepting transition, which means aa is a positive pattern of L. On the right-hand side of Figure 1 a DFA $\mathcal{D}$ that accepts all positive patterns of L is depicted. From $\mathcal{D}$ we can now obtain a DBA for L, which we refer to as $\mathsf{DBA}(\mathcal{D})$, by replacing each transition leading into a final state (state aa in the example) with an accepting transition that leads to the initial state (state ε in the example). In the example in Figure 1, the operation $\mathsf{DBA}(\mathcal{D})$ returns a DBA isomorphic to $\mathcal{A}$.

The core idea of DBAInf is to learn such a DFA for the positive patterns. For this purpose, given some ω-sample $S = (S_+, S_-)$, DBAInf uses an active learning algorithm AL for DFAs as black-box, and answers the queries of this algorithm based on S. To ensure that $\mathsf{DBA}(\mathcal{D})$ is consistent with S, we require that the active learning algorithm learns a DFA $\mathcal{D}$ that does not accept any infix of a loop of a negative example, and that for any position in a positive example an infix starting at this position is accepted. So whenever AL asks an equivalence query for a hypothesis $\mathcal{D}$, DBAInf checks whether $\mathcal{D}$ satisfies this condition and stops if yes. Otherwise, a positive or negative example is found on which $\mathcal{D}$ violates the condition and a corresponding finite word is returned.

▶ **Example 2.** Consider an ω-sample $S = (S_+, S_-)$ with $[\![S_+]\!]_\omega = \{(aba)^\omega\}$ and $[\![S_-]\!]_\omega = \{b^\omega, (ab)^\omega\}$. Recall that $[\![S_+]\!]_\omega$ refers to the ω-words, while S_+ itself is specified by pairs (u, v) of finite words representing uv^ω. The precise representation of the ultimately periodic words in $[\![S_+]\!]_\omega$ and $[\![S_-]\!]_\omega$ does not play any role. In the first step, DBAInf infers a right congruence that is consistent with S. Since S does not separate any finite words, this

Input: An ω-sample $S = (S_+, S_-)$.
Output: The deterministic Büchi automaton $\mathcal{A}$.
1. Extract a right congruence $\sim$ from S by constructing a TS $\mathcal{T}_\sim$
2. Build a sample $S^{(c)}$ for each $\sim$-class c
3. Compute a DFA $\mathcal{D}_c = \mathsf{PrfCons}(S^{(c)})$ for each class c of $\sim$
4. Return the DBA $\mathcal{A} := \mathsf{DBA}(\mathcal{T}_\sim, (\mathcal{D}_c)_{c \in \sim})$

Figure 2 An overview of the algorithm DBAInf. The individual steps are explained in the text.

right congruence has only one class $c = [\varepsilon]_\sim$. For this class, DBAInf now uses an active learning algorithm AL for DFAs. In order to answer the queries of AL, DBAInf constructs an ω-sample $S^{(c)}$ with $S^{(c)}_+ = \{(\varepsilon, aab), (\varepsilon, aba), (\varepsilon, baa)\}$, representing all the suffixes of $[\![S_+]\!]_\omega$, and $S^{(c)}_- = \{(\varepsilon, b), (\varepsilon, ab), (\varepsilon, ba)\}$, representing all the suffixes of $[\![S_-]\!]_\omega$ starting at a position in a loop (which is the same in this example as all suffixes of $[\![S_-]\!]_\omega$). The precise execution of DBAInf now depends on the active learning algorithm AL that is used. We do not detail a precise active learner here but simply explain how queries would be answered. The queries that we use in this example correspond to a version of Angluin's algorithm by Rivest and Schapire [22], see also [7, Section 19.4].

AL starts by asking membership queries for ε, a, b, which are all answered negatively because these are all prefixes of $[\![S^{(c)}_-]\!]_\omega$ (and hence infixes of loops of negative examples from S). Then AL asks an equivalence query for the DFA that rejects all words. Since this DFA does not accept prefixes of all words in $[\![S^{(c)}_+]\!]_\omega$, DBAInf selects the smallest $(u, v) \in S^{(c)}_+$ such that no prefix of uv^ω is accepted by the DFA. In this example this is (ε, aab). The counterexample that is given to AL is the shortest prefix of $[\![(\varepsilon, aab)]\!]_\omega = (aab)^\omega$ that is not a prefix of $[\![S^{(c)}_-]\!]_\omega$, in this case aa. After this counterexample, AL asks a few more membership queries, namely for $ba, aaa, ab, aba, aaaa, aaba$ which are answered negatively for prefixes of $[\![S^{(c)}_-]\!]_\omega$ (that is, ba, ab, aba), and positively for all other words. With this information, AL asks an equivalence query for the DFA $\mathcal{D}$ shown in Figure 1. Since $\mathcal{D}$ accepts a prefix for each word in $[\![S^{(c)}_+]\!]_\omega$ and rejects all prefixes of words in $[\![S^{(c)}_-]\!]_\omega$, the execution of AL ends. Then DBAInf returns the DBA obtained by the operation $\mathsf{DBA}(\mathcal{D})$, which is isomorphic to $\mathcal{A}$ in Figure 1. ◀

This idea can be generalized to more than one equivalence class by first extracting a right congruence $\sim$ from S that is consistent with S, and then learning one DFA for each equivalence class c of $\sim$ with a more refined definition of the samples $S^{(c)}$ that is illustrated for a single class in Example 2. These DFAs are combined into a DBA by taking the product of $\mathcal{T}_\sim$ with the union of the $\mathcal{D}_c$, and redirecting transitions of the DFAs that lead to an accepting state into the initial state of the $\mathcal{D}_c$ for the current class c given by $\mathcal{T}_\sim$. The details are given in the formal description of the algorithm.

Formal Description of the Learner

The overall structure of the algorithm DBAInf in shown in Figure 2. The individual steps are described in more detail below. In the description, $S = (S_+, S_-)$ always refers to the ω-sample that is the input for DBAInf. After the description, we illustrate the steps with an example.

Step 1. The algorithm DBAInf starts by constructing a right congruence $\sim$ that is consistent with S, represented by a TS $\mathcal{T}_\sim = (Q_\sim, \Sigma, [\varepsilon]_\sim, \delta_\sim)$. For obtaining an algorithm that can learn every DBA language in the limit, it is important to use a method that can infer the right

congruence $\sim_L$ of any DBA language L in the limit. This is possible by slightly modifying one of the algorithms described in [5, 10], which learn ω-automata with an acceptance condition, while we are only interested in a right congruence in this step. Because of this different setting, we briefly describe a possible construction for $\mathcal{T}_\sim$ similar to the algorithm in [10]. The transition system $\mathcal{T}_\sim$ is built incrementally by considering prefixes of positive examples in $[\![S_+]\!]_\omega$ that exit the transition system (via an undefined transition). In order to guarantee termination in polynomial time, only prefixes up the length $k \cdot \ell^2$ are considered, with $k = \max\{|u| \mid (u, v) \in S_+\}$ and $\ell = \max\{|v| \mid (u, v) \in S_+\}$. The construction of $\mathcal{T}_\sim$ proceeds as follows:

- Start with only the initial state $\varepsilon \in Q_\sim$ and no transitions. Then repeat:
  - Pick the smallest u and a in canonical order such that ua is a prefix of a positive example word, $|ua| \leq k \cdot \ell^2$, and $\delta_\sim(u, a)$ is not yet defined. If no such ua exists, exit the loop.
  - If there is $v \in Q_\sim$ such that setting $\delta_\sim(u, a) = v$ does not lead to a conflict of $\mathcal{T}_\sim$ with S, then define $\delta_\sim(u, a) = v$ for the least such v in canonical order. Otherwise, add ua to $Q_\sim$ and let $\delta_\sim(u, a) = ua$.
- If there remain positive examples in $[\![S_+]\!]_\omega$ for which the run in $\mathcal{T}_\sim$ is not defined (because of missing transitions), complete $\mathcal{T}_\sim$ by adding appropriate paths to disjoint loops for all such elements of $[\![S_+]\!]_\omega$.
- Finally, add a sink state as target for all remaining undefined transitions.

This construction runs in polynomial time (because of the limit on the length of the considered ua, and since all tests can be carried out in polynomial time). By construction, $\mathcal{T}_\sim$ has no conflict with S, and hence the associated right congruence $\sim$ is consistent with S, as required. In the following, we identify states in $Q_\sim$ with the corresponding equivalence classes of $\sim$.

Step 2. For each equivalence class $c \in Q_\sim$, we define a sample $S^{(c)} = (S_+^{(c)}, S_-^{(c)})$ based on the infixes of example words starting in positions i such that $\mathcal{T}_\sim(w[1, i-1]) = c$. Formally, we have that $S_+^{(c)}$ contains for each $xw \in [\![S_+]\!]_\omega$ with $\mathcal{T}_\sim(x) = c$ the minimal $(u, v) \in \mathbb{UP}$ such that $w = uv^\omega$. We define $S_-^{(c)}$ to contain for each $xw \in [\![S_-]\!]_\omega$ with $\mathcal{T}_\sim(x) = c$ the minimal (ε, v) such that $w = v^\omega$ and $\mathcal{T}_\sim(xv) = c$, if such a word v exists.

Note that this definition formally ranges over infinitely many x, but for each (u, v) in S it suffices to consider the prefixes x of length at most $|u| + |v||Q_\sim|$ because the run of uv^ω in $\mathcal{T}_\sim$ has an initial part of length at most u followed by a period of length at most $|v||Q_\sim|$. This observation gives a polynomial bound on the number of elements in $S^{(c)}$ and also on their size.

Step 3. In the third step, DBAInf constructs for each class c of $\sim$ a DFA $\mathcal{D}_c$ that is prefix-consistent with $S^{(c)}$. This construction is achieved by passing $S^{(c)}$ to the algorithm PrfCons, which is depicted in Algorithm 1. Given an ω-sample $R = (R_+, R_-)$, PrfCons uses a polynomial-time active learning algorithm AL for DFAs, and answers the queries of AL based on R. We assume that R_- only contains periodic words, which is satisfied by the samples $S^{(c)}$ on which PrfCons is applied.

▶ **Lemma 3.** *For every ω-sample $R = (R_+, R_-)$ with $R_- \subseteq \{\varepsilon\} \times \Sigma^+$, PrfCons terminates in polynomial time and returns a DFA that is prefix-consistent with R.*

Proof. We first show that all answers given to AL during the execution of PrfCons are consistent with the language $P = \Sigma^* \setminus \mathsf{Prf}([\![R_-]\!]_\omega)$: If a membership query $\mathsf{mem}(x)$ is answered positively, then $x \notin \mathsf{Prf}([\![R_-]\!]_\omega)$ and hence $x \in P$. Analogously, a negative answer

Algorithm 1 PrfCons.

Input: An ω-sample $R = (R_+, R_-)$ with $R_- \subseteq (\{\varepsilon\} \times \Sigma^+)$.
Output: A DFA $\mathcal{D}$ that is prefix-consistent with R.
Simulate an active learning algorithm AL for DFAs that satisfies the properties of Theorem 1, and answer its queries as follows:

Query `mem`(x)
  if $x \in \mathsf{Prf}([\![R_-]\!]_\omega)$ **then**
    answer "no"
  else
    answer "yes"
Query `equiv`$(\mathcal{D})$
  if $\mathcal{D}$ *is prefix-consistent with* R **then**
    stop simulation and output $\mathcal{D}$
  else if *there exists a* $w \in [\![R_+]\!]_\omega$ *with* $\mathsf{Prf}(w) \cap L(\mathcal{D}) = \emptyset$ **then**
    pick the minimal $(u, v) \in R_+$ such that $uv^\omega \cap L(\mathcal{D}) = \emptyset$
    return *shortest* $x \sqsubseteq uv^\omega$ *with* $x \notin \mathsf{Prf}([\![R_-]\!]_\omega)$ *as counterexample*
  else
    let $(\varepsilon, v) \in R_-$ be minimal such that $\mathsf{Prf}(v^\omega) \cap L(\mathcal{D}) \neq \emptyset$
    return *shortest prefix* x *of* v^ω *with* $x \in L(\mathcal{D})$ *as counterexample*

to $\mathsf{mem}(x)$ implies $x \in \mathsf{Prf}([\![R_-]\!]_\omega)$, meaning $x \notin P$. For an equivalence query $\mathsf{equiv}(\mathcal{D})$, we distinguish the two cases in PrfCons. In the first case, the returned counterexample x is not accepted by $\mathcal{D}$ and is not in $\mathsf{Prf}([\![R_-]\!]_\omega)$. So $x \in P$ and giving x as counterexample means that it should be accepted. In the other case, the query is answered with a prefix $x \in \mathsf{Prf}(v^\omega) \cap L(\mathcal{D})$ for some $(\varepsilon, v) \in R_-$ such that x is accepted by $\mathcal{D}$. So $x \notin P$ and should be accepted. Hence, all answers provided to AL are consistent with the language P.

Since a DFA that accepts P is prefix-consistent with R, the execution of AL either terminates with a DFA for P, or it terminates earlier if a prefix-consistent DFA $\mathcal{D}$ is used in an equivalence query. Therefore, all hypotheses $\mathcal{D}$ used by AL are of size polynomial in the size of a minimal DFA for P (see Theorem 1). It is not hard to verify that P can be accepted by a DFA whose size is polynomial in $|R|$ using the prefixes of $[\![R_-]\!]_\omega$ as non-accepting states, and introducing a loop on v for each $(\varepsilon, v) \in R_-$ when reaching a prefix of v^ω that is not a prefix of any other word in $[\![R_-]\!]_\omega$. Adding an accepting sink for all missing transitions results in a DFA for P. (A similar construction is described in more detail in [5] for the construction of the "table look-up DPA".)

To conclude that the execution of AL terminates in polynomial time, it remains to verify that the lengths of the provided counterexamples are indeed polynomial in $|R|$. The counterexample for an equivalence query on $\mathcal{D}$ is a shortest word that is prefix of an example from R and is accepted/rejected by $\mathcal{D}$ (depending on the case). These words are clearly polynomial in the size of R and $\mathcal{D}$, and hence polynomial in the size of R. ◀

Step 4. The constructed DFAs are combined into a DBA by taking the product of $\mathcal{T}_\sim$ with the union of the $\mathcal{D}_c$, and redirecting transitions of the DFAs that lead to an accepting state into the initial state of the $\mathcal{D}_c$ for the current class c given by $\mathcal{T}_\sim$.

Formally, we assume that the state sets of the $\mathcal{D}_c$ are pairwise disjoint, and define $\mathsf{DBA}(\mathcal{T}_\sim, (\mathcal{D}_c)_{c \in Q_\sim}) = (Q, \Sigma, \iota, \delta, \beta)$ as follows:

- $Q := Q_\sim \times \bigcup_{c \in Q_\sim} Q_c$
- $\iota := ([\varepsilon]_\sim, \iota_{[\varepsilon]_\sim})$ (note that $\iota_{[\varepsilon]_\sim}$ is the initial state of $\mathcal{D}_{[\varepsilon]_\sim}$)

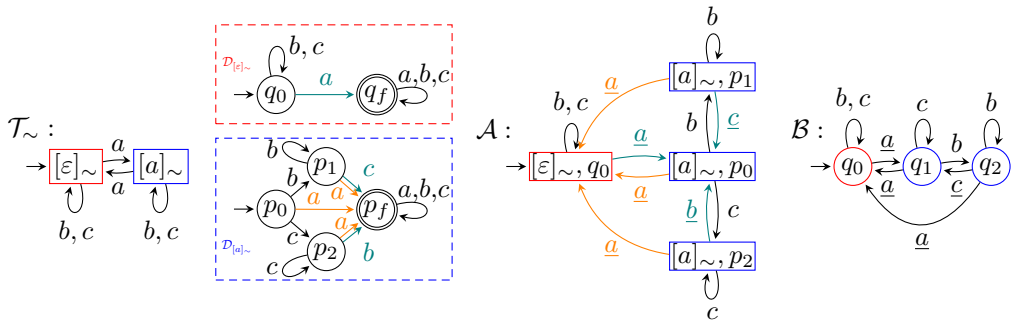

Figure 3 Illustrations for the execution of DBAInf on the sample S given in Example 4.

- For $(c, q) \in Q$ and $a \in \Sigma$ let $q' = \delta_{\hat{c}}(q, a)$ for the unique $\hat{c} \in Q_\sim$ with $q \in Q_{\hat{c}}$, and let $c' = \delta_\sim(c, a)$. Then
  - $\delta((c, q), a) = \begin{cases} (c', q') & \text{if } q' \notin F_{\hat{c}} \\ (c', \iota_{c'}) & \text{if } q' \in F_{\hat{c}} \end{cases}$
  - $((c, q), a) \in \beta$ if $q' \in F_{\hat{c}}$.

This DBA is returned by the algorithm DBAInf. Note that syntactically, a tuple of the form $(\mathcal{T}_\sim, (\mathcal{D}_c)_{c \in Q_\sim})$ is the same as a family of DFAs, which are considered for active learning of ω-languages in [3]. The semantics is, however, very different. Families of DFAs can represent all regular ω-languages but turning them into a deterministic ω-automaton for the represented language involves an exponential blow-up, in general [2]. So the way we use these tuples of DFAs here is not related to these families of DFAs. Before we prove that DBAInf is a consistent polynomial time DBA-learner, we illustrate it with an example.

▶ **Example 4.** As an example for the execution of DBAInf, consider $S = (S_+, S_-)$ with

$[\![S_+]\!]_\omega = \{a^\omega, (ba)^\omega, (ca)^\omega, a(bc)^\omega, a(bcb)^\omega, a(cbc)^\omega\}$ and
$[\![S_-]\!]_\omega = \{b^\omega, c^\omega, (bc)^\omega, aa(bc)^\omega, ab^\omega, ac^\omega\}$.

DBAInf first extracts a right congruence $\sim$ consisting of two equivalence classes. The corresponding transition system $\mathcal{T}_\sim$ is shown in Figure 3 on the left. The words ε and a are separated by S, since $a(bc)^\omega \in S_+$ and $(bc)^\omega \in S_-$. The b, c-loops on $[\varepsilon]_\sim$ do not introduce a conflict, as well as the a-transition from $[a]_\sim$ to $[\varepsilon]_\sim$. The b-transition from $[a]_\sim$ cannot go back to $[\varepsilon]_\sim$ because this would introduce a conflict for the words b and ab, which are separated by S, again because of $a(bc)^\omega \in S_+$ and $(bc)^\omega \in S_-$. Hence, there is a b-loop on $[a]_\sim$. Similarly, for the c-transition from $[a]_\sim$. The resulting transition system is complete, so no further states have to be added.

In the second step, the samples $S^{[\varepsilon]_\sim}$ and $S^{[a]_\sim}$ are computed. The positive components of these samples are $S_+^{[\varepsilon]_\sim} = \{(\varepsilon, a), (\varepsilon, ba), (\varepsilon, ab), (\varepsilon, ca), (\varepsilon, ac), (a, bc), (a, bcb), (a, cbc)\}$ and $S_+^{[a]_\sim} = \{\varepsilon\} \times \{a, ba, ab, ca, ac, bc, cb, bcb, bbc, cbb, cbc, bcc, ccb\}$.

To illustrate how these samples are constructed, consider $(ba)^\omega \in S_+$. It induces the sequence of classes $([\varepsilon]_\sim[\varepsilon]_\sim[a]_\sim[a]_\sim)^\omega$ in $\mathcal{T}_\sim$ and thus contributes (ε, ba) and (ε, ab) to both $S_+^{[\varepsilon]_\sim}$ and $S_+^{[a]_\sim}$. The example $a(bcb)^\omega$ induces the sequence $[\varepsilon]_\sim([a]_\sim)^\omega$, and hence contributes (a, bcb) to $S_+^{[\varepsilon]_\sim}$, and $\{\varepsilon\} \times \{bcb, cbb, bbc\}$ to $S_+^{[a]_\sim}$. Similarly, for the other positive examples.

The negative components are $S_-^{[\varepsilon]_\sim} = \{\varepsilon\} \times \{b, c, bc, cb\}$ and $S_-^{[a]_\sim} = \{\varepsilon\} \times \{b, c\}$. For example, $aa(bc)^\omega$ induces the class sequence $[\varepsilon]_\sim[a]_\sim([\varepsilon]_\sim)^\omega$. This adds (ϵ, bc) and (ε, cb) to $S_-^{[\varepsilon]_\sim}$ and nothing to $S_-^{[a]_\sim}$ because the only position with class $[a]_\sim$ after the first a is not in the periodic part, and hence there is no v such that $av^\omega = aa(bc)^\omega$. Similarly, for the other negative examples.

Executing PrfCons on these samples gives rise to two DFAs $\mathcal{D}_{[\varepsilon]_\sim}$ and $\mathcal{D}_{[a]_\sim}$ with 2 and 4 states, respectively, which are depicted in the middle of Figure 3. Next to that (on the right) in Figure 3, the DBA $\mathcal{A}$ that is the result of $\mathsf{DBA}(\mathcal{T}_\sim, \mathcal{D}_{[\varepsilon]_\sim}, \mathcal{D}_{[a]_\sim})$ is shown. The states of $\mathcal{A}$ are pairs of states of $\mathcal{T}_\sim$ and of the union of $\mathcal{D}_{[\varepsilon]_\sim}$ and $\mathcal{D}_{[a]_\sim}$. Accepting transitions that reset into $\mathcal{D}_{[\varepsilon]_\sim}$ are depicted in orange and those that reset into $\mathcal{D}_{[a]_\sim}$ are colored teal. On the very right of Figure 3, a minimal DBA $\mathcal{B}$ that accepts the same language as $\mathcal{A}$ is depicted. The states of $\mathcal{B}$ are colored according to the class of $\sim$ that they belong to.

Consistency

We now prove that DBAInf always infers a DBA that is consistent with the given ω-sample.

▶ **Theorem 5.** DBAInf *is a consistent polynomial time DBA-learner.*

Proof. Let $S = (S_+, S_-)$ be an ω-sample and $\sim$ be a right congruence that is consistent with S, as constructed by DBAInf in the first step (represented by $\mathcal{T}_\sim = (Q_\sim, \Sigma, [\varepsilon]_\sim, \delta_\sim)$). As in Figure 2, let $\mathcal{D}_c$ be the DFA constructed from $S^{(c)}$ for each class c of $\sim$. Further, let $\mathcal{A} = \mathsf{DBA}(\mathcal{T}_\sim, (\mathcal{D}_c)_{c \in Q_\sim})$ be the DBA returned by DBAInf. The extraction of $\mathcal{T}_\sim$ and the construction of the samples $S^{(c)}$ can be done in polynomial time. By Lemma 3 PrfCons runs in polynomial time for each class c and returns a DFA $\mathcal{D}_c$ whose size is polynomial in $|S|$. Hence, the construction of $\mathsf{DBA}(\mathcal{T}_\sim, (\mathcal{D}_c)_{c \in Q_\sim})$ and thus the overall procedure DBAInf can be completed in polynomial time.

For consistency, first note that in the construction of $\mathcal{A}$, the first component of the states is always updated according to $\delta_\sim$. Therefore, for each $u \in \Sigma^*$, the state (c, q) reached by $\mathcal{A}$ after reading u is such that c is the class of u, i.e., $\mathcal{T}_\sim$ reaches c when reading u.

We start by showing that $\mathcal{A}$ rejects all words in S_-. Let $w = uv^\omega$ for a $(u, v) \in S_-$. As w is ultimately periodic, we can write the run of $\mathcal{A}$ on w as $\rho\pi^\omega$. Pick a position $i \geq \max\{|u|, |\rho|\}$ such that $\mathcal{A}$ uses an accepting transition when reaching position i in w. If no such position exists, then $\mathcal{A}$ uses only finitely many accepting transitions and hence rejects w. It is easily verified that if such a position i exists, we can write $uv^\omega = xy^\omega$ and $\rho\pi^\omega = \hat{\rho}(\hat{\pi})^\omega$ such that $|x| = |\hat{\rho}| = i$ and $|y| = |\hat{\pi}|$. Let c be the class reached after reading x, meaning $\mathcal{T}_\sim(x) = c$ and $\mathcal{A}$ is in state (c, ι_c) after reading x. This means $\hat{\pi}$ starts and ends in (c, ι_c) and thus $\delta_\sim(c, y) = c$. Since $xy^\omega = uv^\omega \in [\![S_-]\!]_\omega$, we have $(\varepsilon, y) \in S_-^{(c)}$ by the definition of $S^{(c)}$. Because the DFA $\mathcal{D}_c$ is prefix-consistent with $S^{(c)}$ by Lemma 3, it does not accept any prefix of y^ω. Thus, $\mathcal{D}_c$ will never reach a final state when reading the suffix of w starting at position i. By definition this means $\mathcal{A}$ uses no accepting transitions after position i in w, and hence rejects w.

Now let us show that $\mathcal{A}$ accepts all words in S_+. Let $w = uv^\omega \in [\![S_+]\!]_\omega$ and let ρ be the run of $\mathcal{A}$ on w. Let i be a position such that ρ is in a state of the form (c, ι_c) at position i. Then $\mathcal{A}$ uses an accepting transition after position i: If ρ is in state (c, ι_c) at position i, this means that also $\mathcal{T}_\sim(w[1, i-1]) = c$, and we can find words $u \in \Sigma^*, w' \in \Sigma^\omega$ such that $|u| = i$ and $w = uw'$. By definition of $S_+^{(c)}$, we have that $w' \in [\![S_+^{(c)}]\!]_\omega$. Since $\mathcal{D}_c$ is prefix-consistent with $S^{(c)}$, there exists a prefix $x \sqsubseteq w'$ that is accepted by $\mathcal{D}_c$. Hence, $\mathcal{A}$ uses an accepting transition on the prefix x of w'. From that we can conclude that ρ uses infinitely many accepting transitions since ρ starts in $([\varepsilon]_\sim, \iota_{[\varepsilon]_\sim})$ and each accepting transition ends in a state of the form (c, ι_c) for a class c of $\sim$. ◀

4 Completeness of the Learning Algorithm

In this section we establish that the class of DBA languages can be learned in the limit by DBAInf. For obtaining this completeness result, we show how to construct a sample S^L for a DBA language L such that DBAInf constructs a DBA for L from each sample S that

contains S^L and is consistent with L. We separate the construction of S^L in two parts. The first part ensures that DBAInf infers the right congruence $\sim_L$ in the first step. The second part ensures that, based on the correct right congruence $\sim_L$, a DBA for L is constructed. We keep the first part short as the idea for this is the same as for RPNI on finite words [21] and the passive learner for ω-automata from [9]. Roughly, the sample has to cover all transitions and states of $\mathcal{T}_{\sim_L}$ and provide examples that separate all different states. This has to be done in a specific way using minimal words reaching the states and transitions of $\mathcal{T}_{\sim_L}$.

▶ **Lemma 6.** *For every DBA language L there exists an ω-sample $S^{\sim_L}$ such that $|S^{\sim_L}|$ is polynomial in the size of L and* DBAInf *extracts $\sim_L$ from every sample that is consistent with L and contains $S^{\sim_L}$.*

The remainder of this section is about the second part of the construction of S^L: DBAInf returns a DBA that consists of smaller DFAs $\mathcal{D}_c$ for each class c of the extracted congruence $\sim$. We want to ensure that these DFAs satisfy certain conditions that are captured in the definition of "safe" below.

▶ **Definition 7.** *Let L be a DBA language and*

$$\mathcal{K}(L) = \{u \in \Sigma^+ \mid \text{for all } y \in \Sigma^* \text{ if } (uy)^{-1}L = L \text{ then } (uy)^\omega \in L\}.$$

We call a DFA $\mathcal{D}$ safe for *L, if*
1. *for each word $w \in L$, $\mathcal{D}$ accepts some prefix of w, and*
2. *$L(\mathcal{D}) \subseteq \mathcal{K}(L)$.*

Our goal is to build the sample S^L in such a way that the samples $S^{(c)}$ constructed in the second step of DBAInf ensure that AL learns a DFA that is safe for L_c according to Definition 7 above. Then Lemma 10 further below shows that the DBA returned by DBAInf accepts L. For this purpose, we consider for each class c an execution of AL in which the answers given to the queries of AL are consistent with $\mathcal{K}(L_c)$. The answers used in this run of AL are used to define the part of the sample that ensures that $\mathsf{PrfCons}(S^{(c)})$ returns a DFA that is safe for L_c (see Algorithm 2, Lemma 11, and Lemma 12). In order to ensure that the execution of AL terminates, we need to show that $\mathcal{K}(L_c)$ is regular, which we do first in Lemma 8 and Lemma 9. For this we assume that $\mathcal{A} = (Q, \Sigma, \iota, \delta, \beta)$ is some DBA that accepts L. Let

$$\mathcal{K}_q(\mathcal{A}) = \{u \in \Sigma^* \mid \text{ for all } v \in \Sigma^* : \text{ if } q \xrightarrow{uv} q \text{ then } \mathsf{run}(\mathcal{A}, uv) \cap \beta \neq \emptyset\}$$

be the set of all words u, that do not lie on a rejecting loop starting in the state q. As an example consider the DBA $\mathcal{B}$ on the right of Figure 3. We have $\mathcal{K}_{q_0}(\mathcal{B}) = \Sigma^* a \Sigma^*$, $\mathcal{K}_{q_1}(\mathcal{B}) = \Sigma^*(a+b)\Sigma^*$, and $\mathcal{K}_{q_2}(\mathcal{B}) = \Sigma^*(a+c)\Sigma^*$. In general, a DFA for $\mathcal{K}_q(\mathcal{A})$ can be constructed by using $\mathcal{A}$ with initial state q, and one new accepting sink state to which all accepting transitions of $\mathcal{A}$ are redirected, and all transitions from states p such that each path from p to q contains an accepting transition.

▶ **Lemma 8.** *For every DBA $\mathcal{A}$ and each state $q \in Q$, the language $\mathcal{K}_q(\mathcal{A})$ is regular and can be recognized by a DFA of size at most $|\mathcal{A}| + 1$.*

Proof. To construct a DFA that recognizes $\mathcal{K}_q(\mathcal{A})$, we first extract the transition system $\mathcal{T}$ underlying $\mathcal{A}$. Then we remove from $\mathcal{T}$ all transitions which are accepting in $\mathcal{A}$. Subsequently, we build the set G consisting of all transitions $q \xrightarrow{a} p$ such that p and q lie in different SCCs of $\mathcal{T}$. This allows us to finally define the DFA $\mathcal{B} = (Q \cup \{\top\}, \Sigma, q, \delta', \{\top\})$ with

$$\delta'(q,a) = \begin{cases} p & \text{if } (q \xrightarrow{a} p) \notin (\beta \cup G) \\ \top & \text{otherwise.} \end{cases}$$

It is easily verified that the size of $\mathcal{B}$ is indeed linear in $|Q|$ as only one state is added. Further, we can show that $\mathcal{B}$ accepts $\mathcal{K}_q(\mathcal{A})$ by considering both directions of the mutual inclusion:

- Let $w \in L(\mathcal{B})$, then the run of $\mathcal{B}$ on w must end in the only final state, $\top$. This state can clearly only be reached if a transition $\tau \in beta \cup G$ is used. If $\tau \in \beta$, then $\mathcal{A}$ must use the accepting transition τ on w and hence any extension of w leading back to q is also guaranteed to use an accepting transition. Otherwise, $\tau \in G$ and thus from q the word w reaches a state $p \in \mathcal{T}$, which lies in a different SCC. This either happens if p and q lie in different SCCs in $\mathcal{A}$ or if all paths leading from p to q use at least one accepting transition in G. Clearly in both cases we have $w \in \mathcal{K}_q(\mathcal{A})$.
- On any word $w \in \mathcal{K}_q(\mathcal{A})$, the DBA $\mathcal{A}$ reaches from q some state p such that either p is in a different SCC or every path returning to q uses an accepting transition. In the former case the two states also lie in different SCCs and hence there exists some transition τ connecting the SCCs. By construction, however, we know that $\tau \in G$ and hence it is redirected to the final state $\top$ in $\mathcal{B}$. On the other hand if both states lie in the same SCC, then removing all accepting transitions guarantees that q can no longer be reached from p, as every path uses an accepting transition. Thus, p and q are in different SCCs in $\mathcal{T}$ and thus by an analogous argument, $\mathcal{B}$ accepts w. ◀

We can now express $\mathcal{K}(L_c)$ as intersection of the languages $\mathcal{K}_q(\mathcal{A})$ for states q in class c. As example, consider again the DBA $\mathcal{B}$ on the right of Figure 3. The states q_1 and q_2 belong to the class $[a]_\sim$. The intersection $\mathcal{K}_{q_1}(\mathcal{B}) \cap \mathcal{K}_{q_2}(\mathcal{B})$ consists of all words that contain a or contain both b and c. This is the language $\mathcal{K}(L(\mathcal{B})_{[a]_\sim})$.

▶ **Lemma 9.** *Let $\mathcal{A}$ be a DBA, $L = L(\mathcal{A})$ and c be a class of $\sim_L$. Then $\mathcal{K}(L_c) = \bigcap_{q \in c} \mathcal{K}_q(\mathcal{A})$, and in particular $\mathcal{K}(L_c)$ is regular.*

Proof. For the first inclusion of the equality, let $u \in \mathcal{K}(L_c)$. Assume to the contrary that there is some $q \in c$ with $u \notin \mathcal{K}_q(\mathcal{A})$. Then there is $v \in \Sigma^*$ such that in $\mathcal{A}$ we have $q \xrightarrow{uv} q$ without using an accepting transition. Note that $q \in c$ implies that $\mathcal{A}$ with initial state q accepts L_c. But then $(uv)^{-1}L_c = L_c$ and $(uv)^\omega \notin L_c$, which is a contradiction to $u \in \mathcal{K}(L_c)$.

For the inclusion from right to left, let $u \in \mathcal{K}_q(\mathcal{A})$ for all states q with $q \in c$. Consider an arbitrary $v \in \Sigma^*$ with $(uv)^{-1}L_c = L_c$. We need to show that $(uv)^\omega \in L_c$ because then $u \in \mathcal{K}(L_c)$. We pick some state $q_0 \in c$ and consider the run $\rho = q_0 \xrightarrow{uv} q_1 \xrightarrow{uv} q_2 \xrightarrow{uv} \dots$ of $\mathcal{A}$ on $(uv)^\omega$ from q_0. For all i, we have $q_i \in c$ since $(uv)^{-1}L_c = L_c$. There is some state q such that the set of indices $I = \{i \in \mathbb{N} \mid q = q_i\}$ is infinite. But then for any $i, j \in I$ with $i < j$ there must be an accepting transition between q_i and q_j in ρ by definition of $\mathcal{K}_q(\mathcal{A})$, and hence $(uv)^\omega \in \mathcal{K}_c(L)$.

Regularity of $\mathcal{K}(L_c)$ follows as it is a finite intersection of languages that are regular by Lemma 8. ◀

In the following Lemma, we show that if each constructed DFA $\mathcal{D}_c$ for a class c satisfies the conditions of Definition 7 with respect to the language L_c, then the resulting DBA accepts precisely L.

▶ **Lemma 10.** *Let $L \subseteq \Sigma^\omega$ be a DBA-recognizable language, and for each $c \in Q_{\sim_L}$ let $\mathcal{D}_c$ be a DFA that is safe for L_c. Then $\mathsf{DBA}(\mathcal{T}_{\sim_L}, (\mathcal{D}_c)_{c \in Q_{\sim_L}})$ accepts L.*

Proof. In the following let $\mathcal{A} = \mathsf{DBA}(\mathcal{T}_{\sim_L}, (\mathcal{D}_c)_{c \in Q_{\sim_L}})$. For the first inclusion consider a word $w \in L$. The run of $\mathcal{A}$ on w begins in (c_0, ι_{c_0}), where $c_0 = [\varepsilon]_{\sim_L}$ and ι_{c_0} refers to the initial state of $\mathcal{D}_{c_0}$. As $w \in L$, we clearly also have that $w \in L_{c_0}$, which by the first condition in the definition of "safe" (Definition 7) implies that $v_0 \in L(\mathcal{D}_{c_0})$ for some prefix v_0 of w. Thus, on the prefix v_0, $\mathcal{A}$ uses an accepting transition and reaches some state (c_1, ι_{c_1}) for

$c_1 = \mathcal{T}_{\sim_L}(v_0)$. Now let w_1 be the infinite word such that $w = v_0 w_1$. Since $\mathcal{T}_{\sim_L}$ reaches c_1 on v_0, we have that $w_1 \in L_{c_1}$ and thus by the first condition there exists a prefix $v_1 \sqsubseteq w_1$ such that $v_1 \in L(\mathcal{D}_{c_1})$. Thus, the run of $\mathcal{A}$ from (c_1, ι_{c_1}) on v_1 uses an accepting transition and reaches the state (c_2, ι_{c_2}) for some class c_2 with $\mathcal{T}_{\sim_L}(v_0 v_1) = c_2$. Repeated application of this argument yields a factorization $w = v_0 v_1 \dots$ and an infinite sequence $(c_i)_{i \in \mathbb{N}}$ with $c_0 = [\varepsilon]_{\sim_L}$, such that $c_{i+1} = \delta^*_{\sim_L}(c_i, v_i)$ and $v_i \in L(\mathcal{D}_{c_i})$ for all $i \in \mathbb{N}$. The run ρ of $\mathcal{A}$ on $w = v_0 v_1 \dots$ can similarly be factorized into $\rho = \rho_0 \rho_1 \dots$, such that ρ_i begins in (c_i, ι_{c_i}) and ends in $(c_{i+1}, \iota_{c_{i+1}})$. Additionally, each of these factors ρ_i uses an accepting transition. This means that the run of $\mathcal{A}$ on w uses infinitely many accepting transitions and thus $w \in L(\mathcal{A})$.

For the other inclusion, let $w \in L(\mathcal{A})$ and ρ be the run of $\mathcal{A}$ on w. Since ρ uses infinitely many accepting transitions, there exists a factorization $w = v_0 v_1 \dots$ and a sequence $(c_i)_{i \in \mathbb{N}}$ with $c_0 = [\varepsilon]_{\sim_L}$ such that $(c_0, \iota_{c_0}) \xrightarrow{v_0} (c_1, \iota_{c_1}) \xrightarrow{v_1} \dots$ in $\mathcal{A}$ and on each v_i the last transition is accepting and all the other transitions are non-accepting. By construction of $\mathcal{A}$, each v_i is accepted by the DFA $\mathcal{D}_{c_i}$ and hence by the second condition of "safe" (Definition 7) also $v_i \in \mathcal{K}(L_c)$. Consider now any DBA $\mathcal{B}$ that accepts L. By Lemma 9 we know that $\mathcal{K}(L_c) = \bigcap_{q \in c} \mathcal{K}_q(\mathcal{B})$ for all classes $c \in Q_{\sim_L}$. Let π be the unique run of $\mathcal{B}$ on $w = v_0 v_1 \dots$, then π can be written as $\iota_B = q_0 \xrightarrow{v_0} q_1 \xrightarrow{v_1} \cdots$. As $\mathcal{B}$ has a finite number of states, we know that there exists an infinite set I of indices such that $q_i = q_j$ for all $i, j \in I$. Note that because $\mathcal{B}$ accepts L, we have $q_i \in c_i$ for all $i \in \mathbb{N}$. But then since $v_i \in \mathcal{K}_{c_i}(L)$ and $\mathcal{K}_{c_i}(L) \subseteq \mathcal{K}_{q_i}(\mathcal{B})$ (by Lemma 9) for all $i \in I$, between any two visits to a state q_i with $i \in I$, $\mathcal{B}$ uses an accepting transition. As I is an infinite set, this guarantees that the run of $\mathcal{B}$ on w uses infinitely many accepting transitions and hence $w \in L(\mathcal{B}) = L$. ◀

In the following, we describe how a sample can be constructed to guarantee that PrfCons yields a DFA that is safe for some DBA language L. For this we use a specific execution of the active learning algorithm AL, shown in Algorithm 2. We refer to this specific execution as the L-run of AL and denote the sample that it produces with $S^{\mathsf{AL},L}$. We present the L-run in form of an algorithm, but we are only interested in the definition of the sample $S^{\mathsf{AL},L}$ and not its computation. Therefore, we do not go into further detail regarding the computation of each individual operation. Note that the L-run of AL is defined along the same lines as the algorithm PrfCons shown in Algorithm 1, but now the queries are answered based on the language L and not based on a sample. The ω-words added to the sample $S^{\mathsf{AL},L}$ ensure that PrfCons will give the same answers to the queries of AL for any sample that includes $S^{\mathsf{AL},L}$ and is consistent with L.

▶ **Lemma 11.** *For a DBA-recognizable language L, the size of $S^{\mathsf{AL},L}$ is polynomial in the size of a minimal DFA for $\mathcal{K}(L)$. Furthermore, the DFA $\mathcal{D}$ returned by the L-run of* AL *is safe for L.*

Proof. We first explain why all the answers of the L-run to the queries of AL are consistent with $\mathcal{K}(L)$. For the membership queries this is obvious from the definition of $\mathcal{K}(L)$. For equivalence queries, consider the first case. The word x that is given as counterexample satisfies the definition of $\mathcal{K}(L)$ and is not accepted by the current hypothesis $\mathcal{D}$, so giving this counterexample is consistent with $\mathcal{K}(L)$. Let us argue that such a word x always exists. Let $\mathcal{A} = (Q, \Sigma, \iota, \delta, \beta)$ be a DBA with $L(\mathcal{A}) = L$. Since $uv^\omega \in L$, it is accepted from all states that are equivalent to the initial state. So there is a prefix $z \sqsubseteq uv^\omega$ such that for every q that is equivalent to ι, the run from q on uv^ω uses an accepting transition on the prefix z. Now assume that y is such that $(zy)^{-1}L = L$. Then the run of $\mathcal{A}$ on $(zy)^\omega$ is accepting

Algorithm 2 Definition of $S^{\mathsf{AL},L}$ by a specific execution of AL, called L-run of AL.

Input: A DBA accepting $L \subseteq \Sigma^\omega$.
Output: The ω-sample $S^{\mathsf{AL},L} = (S_+^{\mathsf{AL},L}, S_-^{\mathsf{AL},L})$ and the DFA $\mathcal{D}$
$S_+^{\mathsf{AL},L} \leftarrow \emptyset, S_-^{\mathsf{AL},L} \leftarrow \emptyset$
Simulate an active learning algorithm AL that satisfies the properties of Theorem 1, and answer its queries as follows:
Query `mem(`x`)`
  if $(xy)^\omega \notin L$ *for some* $y \in \Sigma^*$ *with* $(xy)^{-1}L = L$ **then**
    $S_-^{\mathsf{AL},L} \leftarrow S_-^{\mathsf{AL},L} \cup \{(\varepsilon, xy)\}$ for the shortest such y and answer "no"
  else
    answer "yes"
Query `equiv(`$\mathcal{D}$`)`
  if *there exists a word* $w \in L$ *with* $\mathsf{Prf}(w) \cap L(\mathcal{D}) = \emptyset$ **then**
    pick the minimal (u, v) such that $uv^\omega \in L$ and $\mathsf{Prf}(uv^\omega) \cap L(\mathcal{D}) = \emptyset$
    $S_+^{\mathsf{AL},L} \leftarrow S_+^{\mathsf{AL},L} \cup \{(u, v)\}$
    choose minimal $x \sqsubseteq uv^\omega$ with $(xy)^{-1}L = L \Rightarrow (xy)^\omega \in L$ for all $y \in \Sigma^*$
    forall $x' \sqsubseteq x$ *with* $x' \neq x$ **do**
      choose the minimal y' such that $(x'y')^\omega \notin L$ and $(x'y')^{-1}L = L$
      $S_-^{\mathsf{AL},L} \leftarrow S_-^{\mathsf{AL},L} \cup \{(\varepsilon, x'y')\}$
    return x *as counterexample*
  else if *there is some* $v \in \Sigma^+$ *with* $v^\omega \notin L, v^{-1}L = L$ *and* $\mathsf{Prf}(v^\omega) \cap L(\mathcal{D}) \neq \emptyset$ **then**
    pick v to be the minimal word with this property
    $S_-^{\mathsf{AL},L} \leftarrow S_-^{\mathsf{AL},L} \cup \{(\varepsilon, v)\}$
    return *minimal* $x \sqsubseteq v^\omega$ *such that* $x \in L(\mathcal{D})$ *as counterexample*
  else
    terminate the execution of AL and output $S^{\mathsf{AL},L}$, $\mathcal{D}$

because it uses an accepting transition on each z-segment. Hence, z is in $\mathcal{K}(L)$ and there exists a minimal prefix x of uv^ω with this property that can be given as counterexample. In the second case of an equivalence query, the selected $x \sqsubseteq v^\omega$ is accepted by $\mathcal{D}$, but it is not in $\mathcal{K}(L)$ because there is a y such that $xy = v^k$ for some k.

Thus, all answers to AL are consistent with $\mathcal{K}(L)$, and therefore all hypothesis DFAs $\mathcal{D}$ are of polynomial size in $\mathcal{A}_{\mathcal{K}(L)}$ (since AL satisfies the conditions of Theorem 1). From that one can derive that the counterexamples given to AL, and also the examples added to $S^{\mathsf{AL},L}$ for equivalence queries are of polynomial size in $\mathcal{A}_{\mathcal{K}(L)}$. Hence, the computation time taken by AL is also polynomial in $\mathcal{A}_{\mathcal{K}(L)}$, and the size of the words in membership queries is polynomial in $\mathcal{A}_{\mathcal{K}(L)}$. This implies that also the size of the examples added to $S^{\mathsf{AL},L}$ for the answers of membership queries is polynomial in $\mathcal{A}_{\mathcal{K}(L)}$.

It remains to show that the DFA $\mathcal{D}$ computed by the L-run of AL is safe for L (see Definition 7). The first case of an equivalence query guarantees that for each $w \in L$, some prefix $x \sqsubseteq w$ is accepted by $\mathcal{D}$. To verify that the second condition of Definition 7 is satisfied, let $u \in L(\mathcal{D})$. If $u \notin \mathcal{K}(L)$, then there exists a word $y \in \Sigma^*$ such that $(uy)^{-1}L = L$ and $(uy)^\omega \notin L$. This means that the second case of the equivalence query matches with $v = uy$, and hence the simulation of $\mathcal{D}$ will not stop as long as $\mathcal{D}$ accepts a word outside $\mathcal{K}(L)$. ◀

For a DBA-recognizable language L, we now define the sample

$$S^L = S^{\sim_L} \cup \Big(\bigcup_{c \in Q_{\sim_L}} r_c \cdot S^{\mathsf{AL},L_c} \Big) \text{ for the smallest } r_c \in \Sigma^* \text{ such that } \mathcal{T}_{\sim_L}(r_c) = c$$

where the union and concatenation operation on samples is done component wise, and "smallest" refers to the length-lexicographic ordering. The next lemma establishes that each DFA $\mathcal{D}_c$ for a class c that DBAInf constructs from a consistent sample containing S^L is safe for L_c.

▶ **Lemma 12.** *Let L be a DBA language with right congruence $\sim$. If $S = (S_+, S_-)$ is consistent with L and contains S^L, then for each class c, $\mathsf{PrfCons}(S^{(c)})$ returns a DFA $\mathcal{D}_c$ that is safe for L_c.*

Proof. Since S is consistent with L, we know that $[\![S_+^{(c)}]\!]_\omega \subseteq L_c$ and $[\![S_-^{(c)}]\!]_\omega \cap L_c = \emptyset$. We show that $\mathsf{PrfCons}(S^{(c)})$ gives the same answers to AL as the L_c-run.

- For a membership query $\mathsf{mem}(x)$:
  - If "no" is answered during the L_c-run of AL, then there exists some $(\varepsilon, xy) \in S_-^{\mathsf{AL},L_c}$ with $(xy)^\omega \notin L_c$ and $(xy)^{-1}L_c = L_c$. By definition, we have $r_c(xy)^\omega \in [\![S_-^L]\!]_\omega$ for some $r_c \in \Sigma^*$ with $\mathcal{T}_\sim(r_c) = c$. Because $(xy)^{-1}L_c = L_c$, it further holds that also $\mathcal{T}_\sim(r_c xy) = c$. This means $(xy)^\omega \in [\![S_-^{(c)}]\!]_\omega$ and thus $\mathsf{PrfCons}(S^{(c)})$ also answers "no".
  - If the L_c-run of AL answers "yes", then $(xy)^\omega \in L_c$ for all $y \in \Sigma^*$ with $(xy)^{-1}L_c = L_c$. But then x cannot be a prefix of $[\![S_-^{(c)}]\!]_\omega$ because $S_-^{(c)}$ contains only periodic words and $[\![S_-^{(c)}]\!]_\omega \cap L_c = \emptyset$.
- Consider an equivalence query $\mathsf{equiv}(\mathcal{D})$:
  - Whenever the L_c-run goes to the first case, the minimal (u, v) with $uv^\omega \in L_c$ and $\mathsf{Prf}(uv^\omega) \cap L(\mathcal{D}) = \emptyset$ is in S_+^{AL,L_c}. By definition, this means $(r_c u, v) \in S_+^L \subseteq S_+$ and thus $\mathsf{PrfCons}(S^{(c)})$ also goes to the first case. Note that there cannot be a $(\hat{u}, \hat{v}) \in S_+^{(c)}$ with $\mathsf{Prf}(\hat{u}\hat{v}^\omega) \cap L(\mathcal{D}) = \emptyset$ and $(\hat{u}, \hat{v}) \prec (u, v)$, as otherwise $(\hat{u}, \hat{v})$ would have been selected by the L_c-run. Further, $\mathsf{PrfCons}(S^{(c)})$ picks the same prefix $x \sqsubseteq uv^\omega$: For all strict prefixes $x' \sqsubset x$, we have $(r_c, x'y') \in S_-^{\mathsf{AL},L}$ for the minimal $y' \in \Sigma^*$ such that $(x'y')^{-1}L_c = L_c$ and some $r_c \in \Sigma^*$ with $\mathcal{T}_\sim(r_c) = c$. But then $x' \in \mathsf{Prf}([\![S_-^{(c)}]\!]_\omega)$ and thus $\mathsf{PrfCons}(S^{(c)})$ cannot return x' as a counterexample.
  - If the L_c-run goes to the second case, then $\mathcal{D}$ accepts a prefix of all words in L_c and hence for each $w \in [\![S_+^{(c)}]\!]_\omega$ we have $\mathsf{Prf}(w) \cap L(\mathcal{D}) \neq \emptyset$. Thus, $\mathsf{PrfCons}(S^{(c)})$ also goes to the second case. By construction, we have that $(\varepsilon, v) \in S_-^{\mathsf{AL},L}$ for the minimal v with $v^\omega \notin L_c, v^{-1}L_c = L_c$ and $\mathsf{Prf}(v^\omega) \cap L(\mathcal{D}) \neq \emptyset$. Thus, $(r_c, v) \in S_-^L \subseteq S_-$, which guarantees that $(\varepsilon, v) \in S_-^{(c)}$. There can be no $(\varepsilon, \hat{v}) \in S_-^{(c)}$ with $\hat{v} \prec v$ and $\mathsf{Prf}(\hat{v}^\omega) \cap L(\mathcal{D}) \neq \emptyset$, since $(\varepsilon, \hat{v}) \in S_-^{(c)}$ implies $\hat{v}^\omega \notin L_c$ and $\hat{v}^{-1}L_c = L_c$, which would contradict the minimality of v. Therefore, $\mathsf{PrfCons}(S^{(c)})$ returns the same counterexamples as the L_c-run.

So $\mathsf{PrfCons}(S^{(c)})$ computes the same DFA as the L_c-run and therefore this DFA is safe for L_c by Lemma 11. ◀

By combining the previous results, we are now able to establish that DBAInf can learn all DBA-recognizable languages in the limit.

▶ **Theorem 13.** DBAInf *is a polynomial-time DBA-learner that learns every DBA-recognizable language in the limit.*

Proof. Let L be a DBA-recognizable language and $S = (S_+, S_-)$ be a sample that is consistent with L and contains S^L. Polynomial runtime of DBAInf was already established in Theorem 5, so it remains to show that DBAInf constructs a DBA for L from the sample S. By Lemma 6, we know that DBAInf extracts $\sim_L$ from S. In the third step, DBAInf constructs a DFA $\mathcal{D}_c$ from $S^{(c)}$ for each $\sim_L$-class c. It is guaranteed by Lemma 12 that each $\mathcal{D}_c$ is safe for L_c. Thus, we can conclude from Lemma 10 that $L(\mathsf{DBA}(\mathcal{T}_{\sim_L}, (\mathcal{D}_c)_{c \in Q_{\sim_L}})) = L$ and hence DBAInf returns a DBA which accepts precisely L. ◀

5 Sample Size

As stated in Theorem 13, DBAInf can learn every DBA language in the limit, i.e., for each DBA language L there is a characteristic ω-sample S^L such that DBAInf constructs a DBA for L when executed on an ω-sample S that is consistent with L and contains S^L. In this section, we analyze the size of this sample in terms of the size of L, which is the size of a smallest DBA for L. The characteristic sample S^L that is constructed in Section 4 consists of the following components:

- The sample $S^{\sim_L}$ whose size is polynomial in the size of L, see Lemma 6.
- The samples S^{AL,L_c} (prefixed by a word r_c) that ensure that the DFAs $\mathcal{D}_c$ satisfy the properties of Lemma 10. The size of these samples is polynomial in the size of a minimal DFA for $\mathcal{K}(L_c)$ according to Lemma 11.

This raises the question on the size of the minimal DFA for $\mathcal{K}(L_c)$ compared to the size of L. It turns out that this size can be exponential in the size of L.

▶ **Proposition 14.**

1. *Let L be recognizable by a DBA $\mathcal{A}$ with n states, and let c be a class of $\sim_L$. The number of states of the minimal DFA for $\mathcal{K}(L_c)$ is in $O((n+1)^k)$ where k is the number of states of $\mathcal{A}$ that are in class c.*
2. *There is a family $(L^{(k)})_{k \geq 1}$ of DBA languages such that $\sim_{L^{(k)}}$ has only one class, L_k can be accepted by a DBA with k states, and the minimal DFA for $\mathcal{K}(L^{(k)})$ has 2^k many states for each $k \geq 1$.*

Proof (sketch). The first claim directly follows from $\mathcal{K}(L_c) = \bigcap_{q \in c} \mathcal{K}_q(\mathcal{A})$ (see Lemma 9) and Lemma 8. For the second claim, let $\Sigma_k = \{1, \ldots, k\}$ for $k > 0$, and define the language $L^{(k)} \subseteq \Sigma_k^\omega$ as the set of all ω-words that contain infinitely many occurrences of each symbol from Σ_k. Since membership in $L^{(k)}$ does not depend on any finite prefix, each $\sim_{L^{(k)}}$ has only one class. Each $L^{(k)}$ can be accepted by a DBA $\mathcal{A}^{(k)}$ with k states that repeatedly verifies the occurrence of each symbol from Σ_k in ascending order. The language $\mathcal{K}(L^{(k)})$ consists of all u that contain all letters from Σ_k. It is not difficult to check that the minimal DFA for $\mathcal{K}(L^{(k)})$ has 2^k states. ◀

This means that the size of the characteristic sample for L that we construct in our completeness proof can be of size exponential in the size of L. But if we fix the number of states in each equivalence class, then we obtain a class of DBA languages that can be learned in the limit from polynomial data by DBAInf. For this purpose, we say that a DBA language L has a k-informative right congruence if it can be accepted by a DBA with at most k different states per $\sim_L$ equivalence class. By k-IRC(DBA) we denote the corresponding class of languages. The DBA languages with informative right congruence from [4] correspond to the class 1-IRC(DBA). As a direct consequence of Proposition 14 and the fact that the characteristic sample for L is polynomial in the size of L and $\mathcal{K}(L)$, we obtain:

▶ **Theorem 15.** *For every fixed k,* DBAInf *can learn every language in k-IRC(DBA) in the limit from polynomial data (the degree of the polynomial depends on k).*

The existing polynomial time learners for deterministic ω-automata used with a Büchi condition are known to learn every language in 1-IRC(DBA) from polynomial data [5, 9]. The algorithm in [5] cannot learn any DBA language outside of 1-IRC(DBA), and while the algorithm in [9] can learn DBA languages outside 1-IRC(DBA), there are very simple DBA languages that it cannot learn.

For understanding the worst-case exponential size of the characteristic sample for L, we take a closer look at the operation $\mathsf{DBA}(\mathcal{T}_\sim, (\mathcal{D}_c)_{c\in Q_\sim})$ that is used for constructing the DBA $\mathcal{A}$ from the DFAs $(\mathcal{D}_c)_{c\in Q_\sim}$ computed in Step 3. (see Figure 2). Lemma 10 asserts that $\mathcal{A}$ accepts L if each $\mathcal{D}_c$ is safe for L_c (see Definition 7). In the completeness proof we use DFAs $\mathcal{D}_c$ for the languages $\mathcal{K}(L_c)$, which are safe of L_c but can be of exponential size in $\mathcal{A}$ as shown in Proposition 14. This raises the question whether DFAs that are safe for L_c need to be, in general, of exponential size. We show that this is not the case, formally stated in Lemma 17 further below. For the proof of Lemma 17 we use the following lemma.

▶ **Lemma 16.** *Let $\mathcal{A}$ be a DBA with n states and $w \in \Sigma^*$ be word. If $\mathcal{A}$ uses n^2+1 accepting transitions on the run on w starting in a state q, then $\mathcal{A}$ uses at least one accepting transition on its run on w from each state p with $p \sim_{L(\mathcal{A})} q$.*

Proof (sketch). If this is not the case, one can find two language equivalent states p, q and a word $u \in \Sigma^*$ such that u loops on p without an accepting transition, and u loops on q with an accepting transition in the loop, contradicting the language equivalence of p and q. ◀

▶ **Lemma 17.** *Let $\mathcal{A}$ be a DBA with n states, $L = L(\mathcal{A})$ and $\sim$ be the right congruence of L. For each class c of $\sim$ there is a DFA D_c of size polynomial in $|\mathcal{A}|$ such that $\mathcal{D}_c$ is safe for L_c, and thus $\mathsf{DBA}(\mathcal{T}_\sim, (\mathcal{D}_c)_{c\in Q_\sim})$ accepts L.*

Proof (sketch). For a class c of $\sim$ pick a state $q_c \in c$ as initial state of $\mathcal{D}_c$, and simulate $\mathcal{A}$ while incrementing a counter each time $\mathcal{A}$ uses an accepting transition. If this counter exceeds n^2+1, then go to an accepting sink. From Lemma 16 and Lemma 9 it follows that $\mathcal{D}_c$ is safe for L_c. ◀

This shows that the way how we compose a DBA from DFAs can, in principle, produce polynomial size DBAs for each DBA language L. So the reason for the exponential size of the characteristic sample of L in the completeness proof is not enforced by the operation that is used to build the DBA from the DFAs, but is rather coming from the way how we extract information from that sample to obtain the DFAs.

6 Conclusion

We have presented a passive learning algorithm DBAInf for DBAs that constructs a consistent DBA in polynomial time for a given ω-sample, and can learn every DBA language in the limit. Previously, the only known class of ω-languages learnable in the limit was the class of languages with informative right congruence [5, 9], whose definition eliminates one of the most difficult properties of ω-automata, namely that deterministic ω-automata often need several language equivalent states for accepting a language. While the characteristic samples for DBAInf that are used in the completeness proof are of exponential size in the worst-case, we obtain learnability in the limit from polynomial data for the class of DBAs that have no more than k states that are all pairwise language equivalent, for each fixed k. This includes the class of DBA languages with informative right congruence for $k = 1$.

Our algorithm uses an active learning algorithm for DFAs as black-box. Our first attempts to build a DBA learner, following the same basic idea but using a passive learner for DFAs instead of an active one, failed. The reason for this seems to be that one carefully needs to select the information from the ω-sample that used for building the DFAs, in order to obtain a robust DBA learner with the learning in the limit property. An active learning algorithm selects this information with its queries. In future work we plan to investigate whether these ideas can be extended to deal with all regular ω-languages by learning deterministic parity automata. It is also an open question whether our approach can be improved in order to obtain learnability in the limit from polynomial data for all DBA languages.

Abstract

Given a Markov decision process (MDP) M and a formula Φ, the strategy synthesis problem asks if there exists a strategy σ s.t. the resulting Markov chain $M[\sigma]$ satisfies Φ. This problem is known to be undecidable for the probabilistic temporal logic PCTL. We study a class of formulae that can be seen as a fragment of PCTL where a local, bounded horizon property is enforced all along an execution. Moreover, we allow for linear expressions in the probabilistic inequalities. This logic is at the frontier of decidability, depending on the type of strategies considered. In particular, strategy synthesis is decidable when strategies are deterministic while the general problem is undecidable.

1 Introduction

Given an MDP M and a probabilistic temporal logic formula Φ, the strategy synthesis problem is to determine if there exists a strategy σ to resolve the nondeterminism in M such that the resulting Markov chain (MC) $M[\sigma]$ satisfies Φ, and if so, to construct one such strategy. The probabilistic temporal logic that we study in this paper allows us to express rich probabilistic global temporal constraints over a *bounded* horizon that must be enforced along all computations. Let us illustrate our logic with a few examples. The formula $\mathrm{A}\,\mathrm{G}(\mathbb{P}(\mathrm{F}^5\,\mathsf{Good}) \geq 0.95)$ expresses that it must always be the case, under the strategy σ, that along all computations, the probability to reach a good state within 5 steps is at least 0.95. This is a quantitative bounded horizon Büchi property. In addition, our logic allows for comparing the probability of different events: $\mathrm{A}\,\mathrm{G}\,\mathbb{P}(\mathrm{F}^5\,\mathsf{Good}) \geq 2 \times \mathbb{P}(\mathrm{F}^{10}\,\mathsf{Bad}))$ expresses that under the strategy σ, along all computations, it is always the case that the probability to reach a good state within 5 steps is at least twice the probability of reaching a bad state within 10 steps. The ability to compare probabilities of different events, while not present in classical

logics like PCTL, is necessary to express properties like probabilistic noninterference [13]. This feature has been introduced and studied in probabilistic hyperlogics, e.g. [2], where the ability to compare probabilities plays a central role in describing applications. While hyperlogics are very expressive and highly undecidable, we study here the ability to compare probabilities in a weaker logical setting in order to understand more finely the decidability border that probabilistic comparisons, and more generally linear expressions, induce.

While the model-checking problem for PCTL and MDPs is decidable [6], the synthesis problem is in general undecidable [15].[1] Synthesis for PCTL [15], HyperPCTL [2], and as well as for our logic (as shown in Theorem 37) is undecidable. To recover decidability, we explore two options. First, we consider subclasses of strategies: memoryless deterministic strategies (MD), memoryless randomized strategies (MR), and history-dependant deterministic strategies (HD) are important classes to be considered. Second, we identify syntactically defined sublogics with better decidability properties. For instance, while for PCTL objectives the synthesis problem for HD strategies is highly undecidable (Σ_1^1-complete) [15], it has been shown that the problem is decidable for the cases of MD and MR strategies [15]. The synthesis problem for the qualitative fragment of PCTL, where probabilistic operator can only be compared to constant 0 and 1, is decidable for HD strategies. An important contribution of this paper is to show that the synthesis problem for our sublogics is decidable for HD strategies. To the best of our knowledge, this is the first decidability result for a class of unbounded memory strategies (here HD) and quantitative probabilistic temporal properties.

Main technical contributions. We introduce the logic L-PCTL and two sublogics. L-PCTL extends PCTL with linear constraints over probability subformulae. We first study the window L-PCTL fragment that only allows bounded until or bounded weak until operators in the path formulae. The results for this fragment are presented in Table 1(a) where columns distinguish between memoryless (M) and history-dependent strategies (H), and rows between deterministic (D) and randomized strategies (R). Second, we study the *global* window L-PCTL extension of this logic in which window formulae appear in the scope of an A G operator that imposes the window formula to hold on every state of every computation. The results for this fragment are presented in Table 1(b). Third, we adapt results from the literature to the full logic as summarized in Table 1(c). An L-PCTL formula is *flat* if it does not have nested probabilistic operators, while it is *non-strict* if it does not contain strict comparison operators ($>$ or $<$) for comparing probability expressions.

Our two main technical contributions are focused on the synthesis problem for the global window L-PCTL logic. First, we introduce a fixpoint characterization of the set of strategies that enforces an L-PCTL window property globally. This characterization is effective for HD strategies, leads to a 2EXPTIME algorithm, and we provide an EXPTIME lower bound. Furthermore, the fixpoint characterization allows us to prove that the synthesis problem is in coRE for the class of history-dependent randomized (HR) strategies for the flat and non-strict fragment of global window L-PCTL. Second, we prove that the synthesis problem for HR strategies is undecidable with an original technique that reduces the halting problem of 2-counter Minsky machines (2CM) to our synthesis problem. We believe that the fixpoint characterization and the 2CM encoding are of independent interest.

[1] The difference between the two problems is essentially as follows: in the model-checking problem, each probabilistic operator in the formula is associated with one strategy (or scheduler) while in the synthesis problem, a *unique* strategy is fixed and used for all the probabilistic operators.

Table 1 A summary of our results for the synthesis problem on MDPs for L-PCTL formulae.

Finally, the satisfiability problem [7] for PCTL (and its variants) can be reduced to the synthesis problem. The decidability of the satisfiability problem for PCTL is a long standing open problem. Our decidability result for the synthesis problem for HD strategies and global window PCTL formulae can be transferred to the following version of the satisfiability problem: given a granularity g for the probabilities, and a global window PCTL formula Φ, does there exist an MC with granularity g that satisfies Φ? (Theorem 31). This gives a new positive decidability result for the satisfiability problem with an unbounded horizon fragment of PCTL and unbounded MCs.

Related work. The model-checking problem for PCTL is decidable [6] and should not be confused with the synthesis problem. In [15], the authors study the synthesis problem for PCTL on MDPs and stochastic games. In [5] it is shown that both randomization and memory in strategies are necessary even for flat window PCTL formulae. Further, [5] shows that the synthesis of MD strategies for PCTL objectives is NP-complete, and [16] shows that MR synthesis is in EXPTIME.[2] For the qualitative fragment of PCTL, deciding the existence of MR and HD strategies have been shown to be NP-complete and EXPTIME-complete, respectively [15]. As previously mentioned, the synthesis problems for HD and HR strategies in the general case of (quantitative) PCTL objectives are highly undecidable [15].

In [11], a probabilistic hyperlogic (PHL) has been introduced to study hyperproperties of MDPs. PHL allows quantification over strategies, and includes PCTL* and temporal logics for hyperproperties such as HYPERCTL* [10]. Hence the model-checking problem in PHL can ask for the existence of a strategy for hyperproperties, and has been shown to be

[2] For the existence of MR strategies for PCTL objectives, in the introduction of [15], it is claimed that the problem is in PSPACE, with a reference to [16]. However, in [16] only an EXPTIME upper bound is proven, for the more general problem of stochastic games. The proof encodes the problem as a polynomial-size formula in the first-order theory of the reals with a fixed alternation of quantifiers so that deciding it is in EXPTIME. The claim seems to be that the complexity of their approach drops to PSPACE when all states are controllable. There is no convincing argument there for that claim, in particular their formula still contains universal quantifiers.

undecidable [11]. Another related work is [1], where HyperPCTL [2] has been extended with strategy quantifiers, and studies hyperproperties over MDPs. The model-checking problem for this logic is also undecidable. In both of these undecidability proofs, the constructed formula contains unbounded finally (F) properties that cannot be expressed in the global window fragment of PCTL that we study here. In both [11] and [1], the model-checking problem is decidable when restricted to MD strategies but is undecidable for HD strategies.

The PCTL satisfiability problem is open for decades. In [14], decidability of finite and infinite satisfiability has been considered for several fragments of PCTL using unbounded finally (F) and unbounded always (G) operators. In [9], satisfiability for bounded PCTL has been considered where the number of steps or horizon used in the operators is restricted by a bound. In [4], a problem related to the satisfiability problem called the feasibility problem has been studied. Given a PCTL formula φ, and a family of Markov chains defined using a set of parameters and with a fixed number of states, the feasibility problem is to identify a valuation for the parameters such that the realized Markov chain satisfies φ. In the satisfiability problem that we study here, the number of states is however not fixed a priori and can be arbitrarily large.

2 Preliminaries

A *probability distribution* on a finite set S is a function $d : S \to [0, 1]$ such that $\sum_{s \in S} d(s) = 1$. We denote the set of all probability distributions on set S by $\mathsf{Dist}(S)$.

▶ **Definition 1.** *A* Markov chain *(MC) is a tuple* $M = \langle S, s_{\mathsf{init}}, \mathbb{P}, \mathsf{AP}, L\rangle$ *where* S *is a countable set of states,* $s_{\mathsf{init}} \in S$ *is an initial state,* $\mathbb{P} : S \to \mathsf{Dist}(S)$ *is a transition function,* AP *is a non-empty finite set of atomic propositions, and* $L : S \to 2^{\mathsf{AP}}$ *is a labelling function.*

If $\mathbb{P}$ maps a state s to a distribution d so that $d(s') > 0$, we write $s \xrightarrow{d(s')} s'$ or simply $s \to s'$, and we denote $\mathbb{P}(s, s')$ the probability $d(s')$. We say that the atomic proposition p holds on a state s if $p \in L(s)$.

A *finite path* $\rho = s_0 s_1 \cdots s_i$ in an MC M is a sequence of consecutive states, so that for all $j \in [0, i-1]$, $s_j \to s_{j+1}$. We denote $|\rho| = i$ the length of ρ, $\mathsf{last}(\rho) = s_i$ and $\mathsf{first}(\rho) = s_0$. We also consider states to be paths of length 0. Similarly, an *infinite path* is an infinite sequence $\rho = s_0 s_1 \cdots$ so that for all $j \in \mathbb{N}$, $s_j \to s_{j+1}$. If ρ is a finite (resp. infinite) path $s_0 s_1 \cdots$, we let $\rho[i]$ denote s_i, $\rho[:i]$ denote the finite prefix $s_0 \cdots s_i$, and $\rho[i:]$ denote the finite (resp. infinite) suffix $s_i s_{i+1} \cdots$.

We denote the set of all finite paths in M by FPaths_M. We introduce notations for the subsets FPaths^{i}_{M} (resp. $\mathsf{FPaths}^{\leq i}_{M}$, $\mathsf{FPaths}^{<i}_{M}$) of paths of length i (resp. of length at most or less than i). Let $\mathsf{FPaths}_M(s)$ denote the set of paths ρ in FPaths_M such that $\mathsf{first}(\rho) = s$. More generally, $\mathsf{FPaths}_M(\rho)$ denotes the set of paths which admit ρ as a prefix. Similarly, we let Paths_M be the set of infinite paths of M, and extend the previous notations for fixing an initial state or a shared prefix. In particular, $\mathsf{Paths}_M(\rho)$ is called the cylinder of ρ.

If $\rho = s_0 \dots s_i$ is a finite path and $\rho' = s_i s_{i+1} \dots$ is a finite or infinite path so that $\mathsf{first}(\rho') = \mathsf{last}(\rho)$, let $\rho \cdot \rho' = s_0 \dots s_i s_{i+1} \dots$ denote their concatenation.

▶ **Definition 2.** *Let* s *be a state of an MC* M*. The MC* M *naturally defines a* probability measure μ^s_M *on* $(\mathsf{Paths}_M(s), \Omega^s_M)$*, where* Ω^s_M *is the* σ*-algebra of cylinders, i.e. the sets* $\mathsf{Paths}_M(\rho)$ *with* $\rho \in \mathsf{FPaths}_M(s)$*, their complements and countable unions.*

The measure of a cylinder $\mathsf{Paths}_M(\rho)$ is the product of the probabilities of each transition in the finite path ρ, and by Carathéodory's extension theorem we get a measure μ^s_M over Ω^s_M. As s is always obvious from context (first state of the paths being considered), we omit it

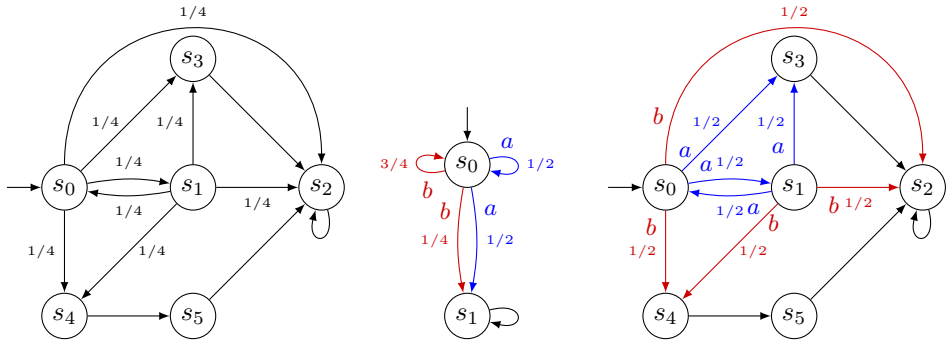

Figure 1 An MC and two MDPs, with states s_i and actions $\{a, b\}$. In MCs, transitions are labelled by their probability, and the probability is 1 if unspecified. In MDPs, transitions are labelled by their action and probability. If the action is unspecified (black transitions), then every action allows this transition. The initial state is s_0. In our examples, the set of atomic propositions is the set of states, so that the proposition s_i holds on state s_i only.

from the measure notation, in favour of μ_M. We note that $\mathsf{FPaths}_M(s)$ is a set of finite words over a countable alphabet, and as such is countable. In particular, if $\mathcal{C} \subseteq \mathsf{FPaths}_M(s)$ is a set of prefixes forming disjoint cylinders,[3] then $\mu_M(\bigcup_{\rho\in\mathcal{C}} \mathsf{Paths}_M(\rho)) = \sum_{\rho\in\mathcal{C}} \mu_M(\mathsf{Paths}_M(\rho))$. Moreover, if $\Pi \subseteq \mathsf{Paths}_M(s)$ is the complement of a measurable set Π', $\mu_M(\Pi) = 1 - \mu_M(\Pi')$.

▶ **Definition 3.** *A* Markov decision process *(MDP) is a tuple* $\mathcal{M} = \langle S, A, s_{\mathsf{init}}, \mathbb{P}, \mathsf{AP}, L\rangle$, *where* S *is a finite set of states,* A *is a finite set of actions,* $s_{\mathsf{init}} \in S$ *is an initial state,* $\mathbb{P} : S \times A \to \mathsf{Dist}(S)$ *is a transition function*[4], AP *is a non-empty finite set of atomic propositions, and* $L : S \to 2^{\mathsf{AP}}$ *is a labelling function.*

If $\mathbb{P}$ maps a state s and an action a to a distribution d so that $d(s') > 0$, we write $s \xrightarrow{a,d(s')} s'$ or simply $s \xrightarrow{a} s'$, and we denote $\mathbb{P}(s, a, s')$ the probability $d(s')$. We extend from MCs to MDPs the definitions and notations of finite and infinite paths, now labelled by actions and denoted $\rho = s_0 \xrightarrow{a_0} s_1 \xrightarrow{a_1} \cdots$. Moreover, for a finite path ρ, we denote by $\rho \cdot as$ (resp. $sa \cdot \rho$) the concatenation of ρ with $\mathsf{last}(\rho) \xrightarrow{a} s$ (resp. of $s \xrightarrow{a} \mathsf{first}(\rho)$ with ρ).

We say that $\mathcal{M}$ is stored in size $|\mathcal{M}|$ if the number of states $|S|$, the number of actions $|A|$ and the number of transitions $s \xrightarrow{a} s'$ in $\mathcal{M}$ are bounded by $|\mathcal{M}|$. Then, $|\mathsf{FPaths}^{\leq i}_{\mathcal{M}}|$, the number of paths of horizon at most i, is in $|\mathcal{M}|^{\mathcal{O}(i)}$. Moreover, the probabilities in $\mathbb{P}$ are assumed to be rational numbers stored as pairs of integers $\frac{a}{b}$ in binary, so that $a, b \leq 2^{|\mathcal{M}|}$.

A (probabilistic) *strategy* is a function $\sigma : \mathsf{FPaths}_{\mathcal{M}} \to \mathsf{Dist}(A)$ that maps finite paths ρ to distributions on actions. A strategy σ is *deterministic* if the support of the distribution $\sigma(\rho)$ has size 1 for every ρ, it is *memoryless* if $\sigma(\rho)$ depends only on the last state of ρ, *i.e.* if σ satisfies that for all $\rho, \rho' \in \mathsf{FPaths}_{\mathcal{M}}$, $\mathsf{last}(\rho) = \mathsf{last}(\rho')$ implies $\sigma(\rho) = \sigma(\rho')$. We denote by $\sigma(\rho, a)$ the probability of the action a in the distribution $\sigma(\rho)$.

An MDP $\mathcal{M} = \langle S, A, s_{\mathsf{init}}, \mathbb{P}, \mathsf{AP}, L\rangle$ equipped with a strategy σ defines an MC, denoted $\mathcal{M}[\sigma]$, obtained intuitively by unfolding $\mathcal{M}$ and using σ to define the transition probabilities. Formally $\mathcal{M}[\sigma] = \langle \mathsf{FPaths}_{\mathcal{M}}, s_{\mathsf{init}}, \mathbb{P}_\sigma, \mathsf{AP}, L'\rangle$, with finite paths of $\mathcal{M}$ as states, transitions defined for all $\rho \in \mathsf{FPaths}_{\mathcal{M}}$, $a \in A$ and $s \in S$ by $\mathbb{P}_\sigma(\rho, \rho \cdot as) = \sigma(\rho, a)\mathbb{P}(\mathsf{last}(\rho), a, s')$, and

[3] $\mathsf{Paths}_M(\rho)$ and $\mathsf{Paths}_M(\rho')$ share a path if and only if either ρ is a prefix of ρ' or ρ' is a prefix of ρ.
[4] This formalism implies that every action is available from every state. This is w.l.o.g., as one can model illegal actions by sending them to a special state.

atomic propositions assigned by $L'(\rho) = L(\mathsf{last}(\rho))$. In particular, note that since S is finite $\mathsf{FPaths}_{\mathcal{M}}$ is infinite but countable. We say that a finite path ρ in $\mathcal{M}$ *matches* a finite path ρ' in $\mathcal{M}[\sigma]$ if $\mathsf{last}(\rho') = \rho$, so that they follow the same sequence of states and actions. We say that a path $\rho \in \mathsf{FPaths}_{\mathcal{M}}$ has probability m in $\mathcal{M}[\sigma]$ if ρ matches $\rho' \in \mathsf{FPaths}_{\mathcal{M}[\sigma]}$ and m is the measure of $\mathsf{Paths}_{\mathcal{M}[\sigma]}(\rho')$. It corresponds to the likelihood of having ρ as a prefix when following σ and starting from $\mathsf{first}(\rho)$.

We may omit M or $\mathcal{M}$ from all previous notations when they are clear from the context. MC notations may use σ as shorthand for $\mathcal{M}[\sigma]$, *e.g.* μ_σ is the probability measure induced by $\mathcal{M}[\sigma]$, and FPaths_σ refers to finite paths of non-zero probability under σ.

▶ **Example 4.** Consider the MC on the left of Figure 1, and the property asking to reach the state s_2 in at most two steps. Consider the set of paths of length at most two from s_0 to s_2. Let $\Pi = \mathsf{Paths}(s_0 s_2) \uplus \mathsf{Paths}(s_0 s_1 s_2) \uplus \mathsf{Paths}(s_0 s_3 s_2)$ be the infinite paths obtained from their cylinders. Then, the probability of reaching s_2 in two steps when starting from s_0 is $\mu(\Pi) = \frac{1}{4} + \frac{1}{16} + \frac{1}{4} = \frac{9}{16}$. Note that the probability of reaching s_2 in two steps when starting from s_1 is also $\frac{9}{16}$. Every other state reaches s_2 with probability 1 in two steps. Consider now the MDP in the middle of Figure 1, and the property asking that the state reached after the first transition is s_1. For every strategy σ, the probability that this property holds in $\mathcal{M}[\sigma]$ is equal to $\sigma(s_0, a)\frac{1}{2} + \sigma(s_0, b)\frac{1}{4} = \sigma(s_0, a)\frac{1}{2} + (1 - \sigma(s_0, a))\frac{1}{4} = \sigma(s_0, a)\frac{1}{4} + \frac{1}{4}$.

Probabilistic CTL with Linear expressions. A formula of L-PCTL is generated by the nonterminal Φ in the following grammar:

▶ **Definition 5** (L-PCTL in normal form, syntax)**.**

$$\Phi := p \mid \neg p \mid \Phi_1 \wedge \Phi_2 \mid \Phi_1 \vee \Phi_2 \mid \sum_{i=1}^{n} c_i \mathbb{P}\left[\varphi_i\right] \succcurlyeq c_0$$
$$\varphi := \mathrm{X}^{\ell}\, \Phi \mid \Phi_1\, \mathrm{U}^{\ell}\, \Phi_2 \mid \Phi_1\, \mathrm{W}^{\ell}\, \Phi_2 \mid \Phi_1\, \mathrm{U}^{\infty}\, \Phi_2 \mid \Phi_1\, \mathrm{W}^{\infty}\, \Phi_2$$

where p ranges over the atomic propositions in AP, ℓ ranges over $\mathbb{N}$, and $n \in \mathbb{N}_{>0}$, $(c_0, \cdots, c_n) \in \mathbb{Z}^n$, $\succcurlyeq \in \{\geq, >\}$ define linear inequalities.

We call a formula generated by Φ a *state formula*, and a formula generated by φ a *path formula*. The *horizon label* of a path formula is the label of its root operator, *i.e.* either ℓ or ∞. Intuitively, the Next operator $\mathrm{X}^{\ell}\, \Phi$ means that Φ holds in exactly ℓ steps, the (unbounded) Until and Weak until operators U^{∞} and W^{∞} are defined as usual in CTL, and their bounded version $\Phi_1\, \mathrm{U}^{\ell}\, \Phi_2$ and $\Phi_1\, \mathrm{W}^{\ell}\, \Phi_2$ impose a horizon on the reachability of Φ_2. We will use the standard notations X, U and W, defined by X^1, U^{∞} and W^{∞}, respectively.

▶ **Definition 6** (L-PCTL in normal form, semantics)**.** *For a fixed MC M of states S, we inductively define $[\![\Phi]\!]_M$ as a set of states, and for each state s we define $[\![\varphi]\!]^s_M$ as a measurable set of infinite paths starting from s:*

$$[\![p]\!]_M = \{s \in S \mid p \in L(s)\} \qquad [\![\neg p]\!]_M = \{s \in S \mid p \notin L(s)\}$$
$$[\![\Phi_1 \wedge \Phi_2]\!]_M = [\![\Phi_1]\!]_M \cap [\![\Phi_2]\!]_M \qquad [\![\Phi_1 \vee \Phi_2]\!]_M = [\![\Phi_1]\!]_M \cup [\![\Phi_2]\!]_M$$
$$\left[\!\!\left[\sum_{i=1}^{n} c_i \mathbb{P}\left[\varphi_i\right] \succcurlyeq c_0\right]\!\!\right]_M = \{s \in S \mid \sum_{i=1}^{n} c_i\ \mu_M([\![\varphi_i]\!]^s_M) \succcurlyeq c_0\}$$
$$\left[\!\!\left[\mathrm{X}^{\ell}\, \Phi\right]\!\!\right]^s_M = \{\rho \in \mathsf{Paths}(s) \mid \rho[\ell] \in [\![\Phi]\!]_M\}$$
$$\left[\!\!\left[\Phi_1\, \mathrm{U}^{\ell}\, \Phi_2\right]\!\!\right]^s_M = \{\rho \in \mathsf{Paths}(s) \mid \exists j \leq \ell, \rho[j] \in [\![\Phi_2]\!]_M \wedge \forall i < j, \rho[i] \in [\![\Phi_1]\!]_M\}$$

$$\begin{aligned}
\left[\!\left[\Phi_1 \,\mathrm{W}^{\ell}\, \Phi_2\right]\!\right]^{s}_{M} &= \{\rho \in \mathsf{Paths}(s) \mid \forall j \leq \ell, (\rho[j] \in [\![\Phi_1]\!]_M \vee \rho[j] \in [\![\Phi_2]\!]_M) \\
&\qquad \vee \exists i < j, \rho[i] \in [\![\Phi_2]\!]_M\} \\
[\![\Phi_1 \,\mathrm{U}\, \Phi_2]\!]^{s}_{M} &= \{\rho \in \mathsf{Paths}(s) \mid \exists j \in \mathbb{N}, \rho[j] \in [\![\Phi_2]\!]_M \wedge \forall i < j, \rho[i] \in [\![\Phi_1]\!]_M\} \\
[\![\Phi_1 \,\mathrm{W}\, \Phi_2]\!]^{s}_{M} &= \{\rho \in \mathsf{Paths}(s) \mid \forall j \in \mathbb{N}, (\rho[j] \in [\![\Phi_1]\!]_M \vee \rho[j] \in [\![\Phi_2]\!]_M) \\
&\qquad \vee \exists i < j, \rho[i] \in [\![\Phi_2]\!]_M\}
\end{aligned}$$

Then, we write $s \models_M \Phi$ (resp. $\rho \models_M \varphi$) if $s \in [\![\Phi]\!]_M$ (resp. $\rho \in [\![\varphi]\!]_M^{\mathsf{first}(\rho)}$), and say that s satisfies Φ (resp. ρ satisfies φ). We denote by $\equiv$ the semantic equivalence of state or path formulae (that holds on all MCs). Finally, we write $M \models \Phi$ if $s_{\mathsf{init}} \models_M \Phi$. Note that by restricting the linear inequalities to $n = 1$ and $\ell = 1$ in X^{ℓ}, we recover the standard definition of PCTL (see *e.g.* [6]).

We define usual notions as syntactic sugar, so that state formulae allow for $\bot := p \wedge \neg p$ and $\top := p \vee \neg p$ (for any $p \in \mathsf{AP}$). We allow rational constants c_1 and all comparison symbols in $\{\leq, <, =, \neq, >, \geq\}$ in linear expressions, with $\sum_{i=1}^{n} c_i \mathbb{P}[\varphi_i] \preccurlyeq c_0 := \sum_{i=1}^{n} (-c_i)\mathbb{P}[\varphi_i] \succcurlyeq -c_0$ and $=, \neq$ defined as conjunctions or disjunctions. Moreover, path formulae allow for $\mathrm{F}^{\ell}\,\Phi := \top \,\mathrm{U}^{\ell}\, \Phi$ and $\mathrm{G}^{\ell}\,\Phi := \Phi \,\mathrm{W}^{\ell}\, \bot$. We allow the negation operation $\neg$ in state and path formulae, and recover a formula in normal form using De Morgan's laws, the negation of inequalities ($\geq$ becomes $<$ and $>$ becomes $\leq$), and the duality rule $\neg(\Phi_1 \,\mathrm{W}^{\ell}\, \Phi_2) \equiv (\neg\Phi_1 \wedge \neg\Phi_2) \,\mathrm{U}^{\ell}\, \neg\Phi_1$. Finally, boolean implication and equivalence are defined as usual. A notable property is $\Phi_1 \,\mathrm{W}^{\ell}\, \Phi_2 \equiv (\Phi_1 \,\mathrm{U}^{\ell}\, \Phi_2) \vee \mathrm{G}^{\ell}\, \Phi_1$.

We encode L-PCTL formulae as trees, whose internal nodes are labelled by state or path operators and whose leaves are labelled by atomic propositions. Let $\ell_{\max} \geq 1$ denote an upper bound on horizon labels ℓ of subformula of Φ where ℓ is finite. The constants c_i in linear expressions are encoded in binary, and *the horizon labels ℓ are encoded in unary*, so that if the overall encoding of Φ is of size $|\Phi|$, we shall have $\ell_{\max} \leq |\Phi|$. We argue that this choice is justified from a larger point of view that extends PCTL to PCTL* by allowing boolean operations in path formulae, as the bounded horizon operators $\mathrm{X}^{\ell}, \mathrm{U}^{\ell}, \mathrm{W}^{\ell}$ can be seen as syntactic sugar for a disjunction of nested X operators of size $\mathcal{O}(\ell)$.

▶ **Definition 7.** *An L-PCTL formula Φ (in normal form) is a* window formula *if the horizon label ℓ of every path operator in Φ is finite, so that the unbounded* U *and* W *are not used. It is a* non-strict *formula if $\succcurlyeq$ is always $\geq$ in its linear inequalities. It is a* flat *formula if the measure operator $\mathbb{P}$ is never nested, so that if Φ is seen as a tree, every branch has at most one node labelled by a linear inequality $\sum_{i=1}^{n} c_i \mathbb{P}[\varphi_i] \succcurlyeq c_0$.*

▶ **Definition 8.** *A* global window *formula is a formula of the shape $\mathrm{A}\,\mathrm{G}\,\Phi$, with Φ a window L-PCTL formula. It is satisfied by a state s of M if every infinite path in $\mathsf{Paths}_M(s)$ satisfies the path formula $\mathrm{G}\,\Phi$, or equivalently if every state reachable from s satisfies Φ.*

▶ **Lemma 9.** *The* global window *formula $\mathrm{A}\,\mathrm{G}\,\Phi$ is satisfied on a state s of M if and only if s satisfies the L-PCTL formula $\mathbb{P}[\mathrm{G}\,\Phi] = 1$.*

Proof. If $\mathrm{A}\,\mathrm{G}\,\Phi$ holds on s, then $\mu_M([\![\mathrm{G}\,\Phi]\!]^s_M) = \mu_M(\mathsf{Paths}_M(s)) = 1$. If $\mathrm{A}\,\mathrm{G}\,\Phi$ is not satisfied on s, then there exists a finite path ρ leading to a state that violates Φ, so that the entire cylinder $\mathsf{Paths}_M(\rho)$ satisfies the path formula $\mathrm{F}\,\neg\Phi$. It follows that $\mu_M([\![\mathrm{G}\,\Phi]\!]^s_M) = 1 - \mu_M([\![\mathrm{F}\,\neg\Phi]\!]^s_M) \leq 1 - \mu_M(\mathsf{Paths}_M(\rho)) < 1$. ◀

▶ **Example 10.** Consider the MC M to the left of Figure 1. Let Φ be the L-PCTL formula $\mathbb{P}\left[\mathrm{F}^2\, s_2\right] \geq \frac{9}{16}$. It is a window formula, that is flat and non-strict. As detailed in Example 4, every state of M satisfies Φ. Therefore, M satisfies the global window formula $\mathrm{A}\,\mathrm{G}\,\Phi$.

Consider now the MDP $\mathcal{M}$ to the right of Figure 1. Let σ denote the memoryless strategy that chooses, in s_0 and s_1, action a with probability $\frac{1}{2}$ and action b with probability $\frac{1}{2}$. While $\mathcal{M}[\sigma]$ is an infinite MC by definition, it is bisimilar to the MC on the left of Figure 1 and must satisfy the same PCTL formulae, so that $\mathcal{M}[\sigma] \models \mathrm{A}\,\mathrm{G}\,\Phi$. In Section 3, we will show that σ is the only strategy on $\mathcal{M}$ that satisfies $\mathrm{A}\,\mathrm{G}\,\Phi$.

Model checking and synthesis problems. The *model-checking problem* of an L-PCTL formula Φ and of a finite MC M is the decision problem asking if $M \models \Phi$. The *synthesis problem* of an L-PCTL formula Φ and of an MDP $\mathcal{M}$ asks if there exists a strategy σ so that $\mathcal{M}[\sigma] \models \Phi$. We also consider the sub-problems that restrict the set of strategies to subsets defined by constraints on the memory or on determinism. For example, the memoryless (resp. deterministic) synthesis problem asks for a memoryless (resp. deterministic) strategy satisfying the formula. They are indeed distinct problems:

▶ **Example 11.** Consider the MDP in the middle of Figure 1. Let Φ be the window formula $(\mathbb{P}\left[\mathrm{F}^2\, s_1\right] = \frac{5}{8}) \wedge (\mathbb{P}\left[\mathrm{X}\, s_1\right] \geq \frac{1}{2} \vee \mathbb{P}\left[\mathrm{X}\, s_1\right] \leq \frac{1}{4})$. First, $s_0 \models \mathbb{P}\left[\mathrm{X}\, s_1\right] \geq \frac{1}{2} \Leftrightarrow \sigma(s_0, a) = 1$ and $s_0 \models \mathbb{P}\left[\mathrm{X}\, s_1\right] \leq \frac{1}{4} \Leftrightarrow \sigma(s_0, a) = 0$, so that the first move must be deterministic. If the first action is a, and the transition $s_0 \xrightarrow{a} s_0$ is chosen, then the next choice must be b to ensure $\mathbb{P}\left[\mathrm{F}^2\, s_1\right] = \frac{5}{8}$. Similarly, if the first action is b, the next choice on s_0 must be a. Moreover, $s_1 \models \Phi$ under any strategy. Thus, the only strategies that satisfy $\mathrm{A}\,\mathrm{G}\,\Phi$ are the strategies that alternate between a and b as long as we are in s_0, while no memoryless strategy satisfies $\mathrm{A}\,\mathrm{G}\,\Phi$. On the other hand, in Example 10 randomisation is needed. An example that require both randomisation and memory can be constructed by combining both examples.

▶ **Proposition 12.** *The* model-checking *problem for L-PCTL formulae and finite MCs can be solved in* PTIME. *This comes at no extra cost when compared to standard PCTL [6].*

Proof. This problem is detailed in [6, Thm. 10.40] for a PCTL definition that only allows expressions of the shape $c_1\mathbb{P}\left[\varphi\right] \succcurlyeq c_0$ to quantify over path formulae. Extending to $\sum_{i=1}^{n} c_i\mathbb{P}\left[\varphi_i\right] \succcurlyeq c_0$ is straight-forward, as their algorithm computes the measure of $\mathbb{P}\left[\varphi\right]$, and then checks if the comparison holds. The intuition is that the measure of bounded operators X^ℓ, U^ℓ and W^ℓ are obtained by $\mathcal{O}(\ell)$ vector-matrix multiplications, while unbounded U and W are seen as linear equation systems. Overall, the complexity is in $|M|^{\mathcal{O}(1)}|\Phi|\ell_{\max}$. ◀

3 Synthesis for global window PCTL

In this section, we detail complexity results on the synthesis problem for global window L-PCTL formulae. We fix a Markov decision process $\mathcal{M}$, a formula $\mathrm{A}\,\mathrm{G}\,\Phi$ where Φ is a window L-PCTL formula, and ask if there exists a strategy σ so that $\mathcal{M}[\sigma] \models \mathrm{A}\,\mathrm{G}\,\Phi$. We also address the sub-problems concerning deterministic or memoryless strategies.

Solving window formulae. We start by constructing a strategy σ so that $\mathcal{M}[\sigma] \models \Phi$. The formula Φ can be seen syntactically as a tree with state or path operators on internal nodes and atomic propositions on leaves. The window length of a branch of this tree is the sum of the horizon labels ℓ of path operators in the branch. The *window length* of the formula Φ is an integer $\mathcal{L}$ obtained as the maximum over every branch of Φ of their respective window lengths. In particular, $\mathcal{L} \leq |\Phi|\ell_{\max}$. For example, if $\Phi = \mathbb{P}\left[\mathrm{X}\,\mathbb{P}\left[\mathrm{X}^2\, p_1\right] \geq \frac{1}{2}\right] \leq \frac{1}{2} \vee \mathbb{P}\left[\mathrm{F}^2\, p_3\right] > 0$, then $\ell_{\max} = 2$ and $\mathcal{L} = \max(1+2, 2) = 3$.

▶ **Definition 13.** *Let s be a state of $\mathcal{M}$ and Φ be a window L-PCTL formula of window length $\mathcal{L}$. A* window strategy *for s of horizon $\mathcal{L}$ is a mapping $\partial : \mathsf{FPaths}_{\mathcal{M}}^{\leq \mathcal{L}}(s) \to \mathsf{Dist}(A)$.*

A window strategy ∂ for state s can be seen as a partial strategy, only defined on paths of length under $\mathcal{L}$ that start from s. Formally, ∂ defines a set of strategies $\sigma : \mathsf{FPaths}_{\mathcal{M}} \to \mathsf{Dist}(A)$, where the first $\mathcal{L}$ steps from s are specified by ∂, and the subsequent steps are not. This set of strategies is called the *cylinder* of the window strategy ∂. In particular, if two strategies σ and σ' are in the cylinder of the window strategy ∂, then the MCs $\mathcal{M}[\sigma]$ and $\mathcal{M}[\sigma']$ coincide for the first $\mathcal{L}$ steps from s, in the sense that every path $\rho \in \mathsf{FPaths}^{\leq\mathcal{L}}_{\mathcal{M}}(s)$ has the same probability m in $\mathcal{M}[\sigma]$ and in $\mathcal{M}[\sigma']$. In this case, we say that m is the probability of ρ under ∂.

We may conflate a window strategy ∂ with an arbitrary strategy σ in its cylinder, so that $\mathsf{FPaths}^{\leq\mathcal{L}}_{\partial}(s)$ is a set of paths in $\mathcal{M}[\sigma]$. Then, we say that the window strategy ∂ for state s satisfies Φ, noted $s \models_{\partial} \Phi$, if $s \models_{\sigma} \Phi$ for all σ in the cylinder of ∂. Conversely, a strategy $\sigma : \mathsf{FPaths}_{\mathcal{M}} \to \mathsf{Dist}(A)$ naturally defines a window strategy ∂_ρ for every fixed prefix ρ, so that for all $\rho' \in \mathsf{FPaths}^{\leq\mathcal{L}}_{\mathcal{M}}(\mathsf{last}(\rho))$, $\partial_\rho(\rho') = \sigma(\rho \cdot \rho')$.

▶ **Lemma 14.** *Let Φ be a window L-PCTL formula of window length $\mathcal{L}$, σ be a strategy for $\mathcal{M}$, and let ∂_s be the window strategy defined by σ on state s and horizon $\mathcal{L}$ (the fixed prefix is s). Then, it holds that $s \models_{\sigma} \Phi \Leftrightarrow s \models_{\partial_s} \Phi$.*

Thus, the synthesis problem on window formulae reduces to finding a window strategy ∂ for s_{init} so that $s_{\mathsf{init}} \models_{\partial} \Phi$. Let ∂ be a window strategy for state s and horizon $\mathcal{L}$. Let $\mathcal{X}_s$ denote a finite set of variables $x_{\rho,a}$, with $\rho \in \mathsf{FPaths}^{\leq\mathcal{L}}_{\mathcal{M}}(s)$, and $a \in A$. The window strategy ∂ can be seen as a point in the real number space $\mathbb{R}^{\mathcal{X}_s}$, where $x_{\rho,a}$ encodes $\partial(\rho, a)$. Conversely, every point in $\mathbb{R}^{\mathcal{X}_s}$ so that $\forall x \in \mathcal{X}_s$, we have $x \in [0, 1]$, and $\forall \rho \in \mathsf{FPaths}^{\leq\mathcal{L}}_{\mathcal{M}}(s)$, we have $\sum_{a\in A} x_{\rho,a} = 1$ represents a window strategy. Therefore, the points of $\mathbb{R}^{\mathcal{X}_s}$ that encode a window strategy can be described by a finite conjunction of linear inequalities $x \geq 0$, $x \leq 1$ and $x_{\rho,a_1} + \cdots + x_{\rho,a_k} = 1$ over the variables $\mathcal{X}_s$.

We want to similarly characterise the set of window strategies satisfying a given window L-PCTL formula. As will become apparent later on, we will need polynomial inequalities.

▶ **Definition 15.** *The* first-order theory of the reals *(FO-$\mathbb{R}$) is the set of all well-formed sentences of first-order logic that involve universal and existential quantifiers and logical combinations of equalities and inequalities of real polynomials.*[5]

We allow the use of strict comparison operators $\{<, \neq, >\}$ as the negation of their non-strict versions. We also assume that the formula is written in *prenex normal form* (PNF), *i.e.* as a sequence of alternating blocks of quantifiers followed by a quantifier-free formula. Finally, if $\mathcal{S} = \{x_1, \cdots, x_k\}$ is a finite set of variables, we use the notation $\exists\, \mathcal{S}$ as shorthand for the quantifier sequence $\exists x_1 \cdots \exists x_k$.

This theory is decidable, and admits a doubly-exponential quantifier elimination procedure [18]. Of particular interest is the existential fragment of FO-$\mathbb{R}$, denoted $\exists$-$\mathbb{R}$, where only $\exists$ is allowed. It is decidable in PSPACE [8].

We say that an FO-$\mathbb{R}$ formula of free variables $\mathcal{X}$ is *non-strict* if it is satisfied by a closed set of points in $\mathbb{R}^{\mathcal{X}}$. In particular, an FO-$\mathbb{R}$ formula that only uses non-strict comparison symbols $\{\leq, =, \geq\}$ and that is negation-free[6] is non-strict.

▶ **Proposition 16.** *Let s be a state of $\mathcal{M}$ and Φ be a window L-PCTL formula. The set of window strategies ∂ such that $s \models_{\partial} \Phi$ can be represented in $\exists$-$\mathbb{R}$ as a PNF formula of free variables $\mathcal{X}_s$. This formula is of size $|\Phi||\mathcal{M}|^{\mathcal{O}(\mathcal{L})}$, and can be computed in* EXPTIME*. If Φ is flat and non-strict then the $\exists$-$\mathbb{R}$ formula is non-strict.*

[5] The primitives operations are multiplication and addition, the comparison symbols are $\{\leq, =, \geq\}$.
[6] A formula is negation-free if the Boolean negation operator $\neg$ is not used.

Proof sketch. We encode the problem in the theory of the reals, by using free variables $x_{\rho,a} \in [0,1]$ that have the value of $\partial(\rho, a)$, existential variables $y_{\rho,\Phi'} \in \{0,1\}$ that are true if the state subformula Φ' is satisfied when one follows ∂ after a fixed history of ρ, and existential variables $z_{\rho,\varphi} \in [0,1]$ having the probability that the path subformula φ is satisfied when one follows ∂ after a fixed history of ρ. The z variables use "local consistency equations" that equate the probability of a path formula on the current state as a linear combination of its probability on the successor states. For the $\mathrm{X}^\ell\,\Phi'$ formula this translates into $z_{\rho,\mathrm{X}^\ell\,\Phi'} = \sum_{s \xrightarrow{a} s'} x_{\rho,a}\mathbb{P}(s,a,s') z_{\rho\cdot a s',\mathrm{X}^{\ell-1}\,\Phi'}$ for example. The y variables can then be defined, so that $y_{\rho,(\sum_{i=1}^n c_i\mathbb{P}[\varphi_i] \succcurlyeq c_0)} = 1$ if and only if $\sum_{i=1}^n c_i z_{\rho,\varphi_i} \succcurlyeq c_0$. Lastly we ask that $y_{s,\Phi} = 1$. To maintain the non-strict property, some subtlety is needed in the way nested probabilistic operators are dealt with. ◀

If we use a PSPACE decision procedure for $\exists$-$\mathbb{R}$ on the formula of Proposition 16, we get:

▶ **Theorem 17.** *The synthesis problem for* window *L-PCTL formulae is in* EXPSPACE.

▶ **Example 18.** Consider the MDP $\mathcal{M}$ to the right of Figure 1, and $\Phi = \mathbb{P}\left[\mathrm{F}^2\, s_2\right] \geq \frac{9}{16}$. Let us describe the formula obtained by Proposition 16. $s_0 \models_\partial \Phi$ can be encoded schematically as the formula $\exists z_{s_0,\mathrm{F}^2\, s_2} \exists z_{s_0 a s_1,\mathrm{F}^1\, s_2}$, s.t. $z_{s_0,\mathrm{F}^2\, s_2} = \frac{x_{s_0,a}}{2} z_{s_0 a s_1,\mathrm{F}^1\, s_2} + \frac{x_{s_0,a}}{2} + \frac{x_{s_0,b}}{2} \wedge z_{s_0 a s_1,\mathrm{F}^1\, s_2} = \frac{x_{s_0 a s_1,b}}{2} \wedge z_{s_0,\mathrm{F}^2\, s_2} \geq \frac{9}{16}$. For readability reasons, we simplified boolean expressions involving $\top$ or $\bot$ when appropriate, and we omitted the variables that can be simplified out immediately, as well as the constraints making sure that the variables x encode probabilities.

After quantifier elimination, and using $x_{s_0,a} + x_{s_0,b} = 1$, we get $x_{s_0,a}\, x_{s_0 a s_1,b} \geq \frac{1}{4}$. Observe that, as mentioned in Example 10, a window strategy ∂ that sets $x_{s_0,a} = x_{s_0 a s_1,b} = \frac{1}{2}$ satisfies Φ. Similarly, $s_1 \models_\partial \Phi$ can be encoded as $x_{s_1,a}\, x_{s_1 a s_0,b} \geq \frac{1}{4}$.

Fixed point characterisation of global window formulae. Let Φ be a window L-PCTL formula of window length $\mathcal{L}$. In this subsection, we describe a fixed point characterisation of the synthesis problem for the global window formula $\mathrm{A}\,\mathrm{G}\,\Phi$.

A *window strategy portfolio* Π of horizon $\mathcal{L}$ (in short, a portfolio Π) maps each state s to a set Π_s of window strategies for s of horizon $\mathcal{L}$. A window strategy portfolio can be seen as a set of points in $\mathbb{R}^{\mathcal{X}_s}$ for every state s. Given two window strategy portfolios Π and Π' of horizon $\mathcal{L}$, we write $\Pi \subseteq \Pi'$ if for all $s \in S$, it holds that $\Pi_s \subseteq \Pi'_s$. Then, the set of all window strategy portfolios of horizon $\mathcal{L}$ is a complete lattice w.r.t. $\subseteq$, where for a set $\mathcal{S}$ of portfolios, the meet $\bigsqcap \mathcal{S}$ (resp. the join $\bigsqcup \mathcal{S}$) maps s to $\bigcap_{\Pi\in\mathcal{S}} \Pi_s$ (resp. $\bigcup_{\Pi\in\mathcal{S}} \Pi_s$).

Let $s \xrightarrow{a} s'$ be a transition in $\mathcal{M}$, and let ∂, ∂' be window strategies for s and s', respectively, of horizon $\mathcal{L}$. We say that ∂ and ∂' are *compatible* w.r.t. $s \xrightarrow{a} s'$ if they make the same decisions on shared paths, *i.e.* for all $\rho \in \mathsf{FPaths}_{\mathcal{M}}^{<\mathcal{L}}(s')$ the probability of $sa\cdot\rho$ under ∂ equals the probability of ρ under ∂' multiplied by $\partial(s,a)\mathbb{P}(s,a,s')$. In particular, whenever $sa\cdot\rho$ has non-zero probability under ∂ and $|\rho| < \mathcal{L} - 1$, we have $\partial(sa\cdot\rho) = \partial'(\rho)$. Similarly, we say that ∂ and a set $\Pi_{s'}$ of window strategies for s' are compatible w.r.t. $s \xrightarrow{a} s'$ if either $\partial(s,a) = 0$ or there exists a window strategy ∂' in $\Pi_{s'}$ so that ∂ and ∂' are compatible w.r.t. $s \xrightarrow{a} s'$.

Let f map portfolios to portfolios, so that $\mathsf{f}(\Pi)$ maps $s \in S$ to the set $\mathsf{f}(\Pi)_s$ of window strategies $\partial \in \Pi_s$ so that for each $s \xrightarrow{a} s'$ in $\mathcal{M}$, we have that ∂ and $\Pi_{s'}$ are compatible w.r.t. $s \xrightarrow{a} s'$. Intuitively, f removes from Π_s the window strategies ∂ that are not compatible with any continuation after a transition $s \xrightarrow{a} s'$ for some action a. Then, f is expressible in the theory of the reals:

▶ **Lemma 19.** *Let* Π *be a portfolio, encoded as an* $\exists$-$\mathbb{R}$ *formula* R^s*, of free variables* $\mathcal{X}_s$*, for every state* s*. Assume that each* R^s *is a PNF formula of size* F*. Then,* $\mathsf{f}(\Pi)_s$ *can also be encoded as a PNF formula, of size in* $\mathcal{O}(|\mathcal{M}|F) + |\mathcal{M}|^{\mathcal{O}(\mathcal{L})}$*. Moreover, if the formulae associated with* Π *are non-strict, so are the formulae of* $\mathsf{f}(\Pi)$*.*

Proof. Let $s \xrightarrow{a} s'$ be a transition in $\mathcal{M}$, and let ∂, ∂' be window strategies for s and s', encoded as points in $\mathbb{R}^{\mathcal{X}_s}$ and $\mathbb{R}^{\mathcal{X}_{s'}}$, respectively. If $\rho \in \mathsf{FPaths}_{\mathcal{M}}^{\leq \mathcal{L}}(s')$, then let $\mathrm{POLY}(\rho)$ denote the polynomial $\prod_{0 \leq i < |\rho|} x_{\rho[:i],a_i} \mathbb{P}(s_i, a_i, s_{i+1})$. Then, the strategies ∂ and ∂' are compatible w.r.t. $s \xrightarrow{a} s'$ if for all $\rho \in \mathsf{FPaths}_{\mathcal{M}}^{\leq \mathcal{L}-1}(s')$ so that $\mathrm{POLY}(\rho) > 0$, for all $a' \in A$ we have $x_{sa\cdot\rho,a'} = x_{\rho,a'}$. Then, if $\Pi_{s'}$ is encoded as the formula $R^{s'}$, we get that ∂ and $\Pi_{s'}$ are compatible w.r.t. $s \xrightarrow{a} s'$ if there exists a valuation of $\mathcal{X}_{s'}$ that encodes a window strategy ∂' so that ∂ and ∂' are compatible w.r.t. $s \xrightarrow{a} s'$. This property corresponds to the formula defined by

$$\mathcal{F}(s,a,s') := \exists \mathcal{X}_{s'}, R^{s'} \wedge \bigwedge_{\rho \in \mathsf{FPaths}_{\mathcal{M}}^{\leq \mathcal{L}-1}(s')} \mathrm{POLY}(\rho) = 0 \vee \bigwedge_{a' \in A} x_{sa\cdot\rho,a'} = x_{\rho,a'}$$

Therefore, if Π_s is encoded as R^s then the formula $R^s \wedge \bigwedge_{s \xrightarrow{a} s'} x_{s,a} = 0 \vee \mathcal{F}(s,a,s')$ encodes $\mathsf{f}(\Pi)_s$. Observe that it introduces non-strict comparisons, existential quantifiers, and no negation operations, and is of size in $F + |\mathcal{M}|(F + |\mathcal{M}|^{\mathcal{O}(\mathcal{L})})$. ◀

▶ **Example 20.** Consider again the MDP $\mathcal{M}$ to the right of Figure 1. Let Π be the portfolio where Π_{s_0} is defined by $x_{s_0,a}\ x_{s_0as_1,b} \geq \frac{1}{4} \wedge x_{s_0as_1,b} \leq c$ with $c \in \left[\frac{1}{2}, 1\right]$, Π_{s_1} is defined by $x_{s_1,a}\ x_{s_1as_0,b} \geq \frac{1}{4} \wedge x_{s_1as_0,b} \leq c$, and Π is $\top$ on every other state of $\mathcal{M}$.[7] Then, using Lemma 19 yields that a formula equivalent to $x_{s_0,a}\ x_{s_0as_1,b} \geq \frac{1}{4} \wedge x_{s_0as_1,b} \leq 1 - \frac{1}{4c}$ encodes $\mathsf{f}(\Pi)_{s_0}$. Symmetrically, $\mathsf{f}(\Pi)_{s_1}$ can be encoded as $x_{s_1,a}\ x_{s_1as_0,b} \geq \frac{1}{4} \wedge x_{s_1as_0,b} \leq 1 - \frac{1}{4c}$.

▶ **Lemma 21** (Knaster-Tarski, Kleene)**.** *The operator* f *is Scott-continuous (upwards and downwards), and is thus monotone. Let* Q *be a set of window strategy portfolios of horizon* $\mathcal{L}$ *that forms a complete lattice w.r.t.* $\subseteq$*. Then, the set of fixed points of* f *in* Q *forms a complete lattice w.r.t.* $\subseteq$*. Moreover,* f *has a greatest fixed point in* Q *equal to* $\bigsqcap\{\mathsf{f}^n(\bigsqcup Q) \mid n \in \mathbb{N}\}$*.*

Let Φ be a window L-PCTL formula of window length $\mathcal{L}$. Let $Q^\Phi = \{\Pi \mid \forall s \in S, \forall \partial \in \Pi_s, s \models_\partial \Phi\}$ be the set of portfolios containing window strategies of horizon $\mathcal{L}$ that ensure Φ. It is closed by $\bigsqcap$ and $\bigsqcup$, and therefore forms a complete lattice. The greatest element $\bigsqcup Q^\Phi$ is the full portfolio mapping every s to all window strategies ∂ so that $s \models_\partial \Phi$. We denote Π^Φ the greatest fixed point of f in Q^Φ, that must exist by Lemma 21.

▶ **Proposition 22.** *Let* s_0 *be a state, and let* Φ *be a window L-PCTL formula. Then,* $\Pi^\Phi_{s_0} \neq \emptyset$ *if and only if there exists a strategy* σ *so that* $s_0 \models_\sigma \mathrm{A\,G}\,\Phi$*.*

Proof sketch. On the one hand, we show that if σ is a strategy so that $s_0 \models_\sigma \mathrm{A\,G}\,\Phi$, and if $\Pi^{s_0,\sigma}$ is the set of window strategies obtained for state s and horizon $\mathcal{L}$ from fixed prefixes of non-zero probability in σ, then $\Pi^{s_0,\sigma}$ is a fixed point of f in Q^Φ so that $\Pi^{s_0,\sigma}_{s_0} \neq \emptyset$. On the other hand, we show that from every fixed point Π of f in Q^Φ that is non-empty on a state s_0, we can inductively construct a strategy σ so that $s_0 \models_\sigma \mathrm{A\,G}\,\Phi$, that intuitively consists in picking successive window strategies from Π that are compatible with each other. ◀

[7] We omitted the constraints that ensure that all variables encode probabilities.

Therefore, computing Π^Φ solves the synthesis problem for global window L-PCTL formulae. By Lemma 21, we have that Π^Φ is the limit of the non-increasing sequence $(\mathsf{f}^i(\bigsqcup Q^\Phi))_{i\in\mathbb{N}}$, with $\bigsqcup Q^\Phi$ being the full portfolio that can be obtained as an $\exists$-$\mathbb{R}$ formula by Proposition 16, so that $\mathsf{f}^i(\bigsqcup Q^\Phi)$ is computable by Lemma 19 as an $\exists$-$\mathbb{R}$ formula of size in $|\Phi||\mathcal{M}|^{\mathcal{O}(\mathcal{L}+i)}$.

▶ **Example 23.** Let $\mathcal{M}$ be the MDP to the right of Figure 1, and $\Phi = \mathbb{P}\left[\mathrm{F}^2\, s_2\right] \geq \frac{9}{16}$. As detailed in Example 18, the set of strategies $(\bigsqcup Q^\Phi)_{s_0}$ is described by $x_{s_0,a}x_{s_0as_1,b} \geq \frac{1}{4}$, the set of strategies $(\bigsqcup Q^\Phi)_{s_1}$ is described by $x_{s_1,a}x_{s_1as_0,b} \geq \frac{1}{4}$, and the set $\bigsqcup Q^\Phi$ is described by $\top$ on all other states.[8] By Example 20, $\mathsf{f}^i(\bigsqcup Q^\Phi)_{s_0}$ is described by $x_{s_0,a}x_{s_0as_1,b} \geq \frac{1}{4} \wedge x_{s_0as_1,b} \leq c_i$, where the constant c_i is defined by $c_0 = 1$ and $c_{i+1} = 1 - \frac{1}{4c_i}$. Similarly, $\mathsf{f}^i(\bigsqcup Q^\Phi)_{s_1}$ is described by $x_{s_1,a}x_{s_1as_0,b} \geq \frac{1}{4} \wedge x_{s_1as_0,b} \leq c_i$, and $\mathsf{f}^i(\bigsqcup Q^\Phi)$ is $\top$ on all other states. The sequence $(c_i)_{i\in\mathbb{N}}$ is a decreasing sequence that converges towards $\frac{1}{2}$ (but never reaches it).

The limit of this sequence is the greatest fixpoint $\Pi^\Phi_{s_0}$, described by $x_{s_0,a}x_{s_0as_1,b} \geq \frac{1}{4} \wedge x_{s_0as_1,b} \leq \frac{1}{2}$ on s_0, $x_{s_1,a}x_{s_1as_0,b} \geq \frac{1}{4} \wedge x_{s_1as_0,b} \leq \frac{1}{2}$ on s_1, $\top$ everywhere else. If we follow the proof of Proposition 22, we can recover the only choice on s_0 and s_1 that ensures $\mathrm{A\,G}\,\Phi$: play a and b with probability $\frac{1}{2}$.

We note that this fixed point computation is not an algorithm: as we have seen in Example 23 the fixed point may not be reachable in finitely many steps. In this case, we do not know if the limit will be empty or not. Nonetheless, this characterisation yields multiple corollary results, that we detail in the remainder of this section.

Flat, non-strict formulae. If Φ is flat and non-strict then $\mathsf{f}^i(\bigsqcup Q^\Phi)$ maps every state to a compact set.[9] The limit of an infinite decreasing sequence of non-empty compact sets in $\mathbb{R}^{\mathcal{X}_s}$ is non-empty. Therefore, if the limit of a decreasing sequence of compact sets is the empty set, it must be reached after finitely many steps. Thus, if $\Pi^\Phi_s = \emptyset$, then there exists $i \in \mathbb{N}$ so that $\mathsf{f}^i(\bigsqcup Q^\Phi)_s = \emptyset$.

▶ **Theorem 24.** *The synthesis problem for flat, non-strict* global window *L-PCTL formulae is in* coRE.

As we will detail in Section 4, the synthesis problem for flat, non-strict global window formulae is undecidable (coRE-hard), and therefore coRE-complete.

▶ Remark 25. From the proof of Proposition 16, it follows that if Φ is non-flat, that is, it contains nested probabilistic operators, then the set of window strategies ∂ such that $s \models_\partial \Phi$ may not be closed and hence $\bigsqcup Q^\Phi$ is not necessarily a compact set.

▶ Remark 26. Note that in Example 23 we were able to compute by hand the limit of the sequence of $\exists$-$\mathbb{R}$ formulae describing $\mathsf{f}^i(\bigsqcup Q^\Phi)$, and obtained an $\exists$-$\mathbb{R}$ formula for the greatest fixed point Π^Φ_s. This is not always possible: there exists an MDP $\mathcal{M}$ and a flat, non-strict global window formula $\mathrm{A\,G}\,\Phi$ so that Π^Φ_s cannot be expressed in FO-$\mathbb{R}$. Indeed, FO-$\mathbb{R}$ formulae can be seen as finite words over a countable alphabet, so that there are countably many of them. If by contradiction Π^Φ_s was always expressible in FO-$\mathbb{R}$, we could enumerate all FO-$\mathbb{R}$ formulae and check for each of them if it describes a fixed-point of f where s_{init} is mapped to a non-empty set, two properties also expressible in FO-$\mathbb{R}$ by using Lemma 19. This would show that the synthesis problem is recursively enumerable, therefore in $\mathsf{RE} \cap \mathsf{coRE}$ *i.e.* decidable, which is absurd as it is coRE-complete as we will see in Section 4.

[8] Once again, we omit the constraints that ensure that all variables encode probabilities.
[9] Non-strict formulae describe closed sets, and all variables are in $[0, 1]$ as they encode probabilities.

Deterministic strategies. In this paragraph, we study the synthesis problem for deterministic strategies. First, note that the window strategy defined by a deterministic strategy for a given prefix and horizon is also deterministic. Conversely, if ∂ is a deterministic window strategy then there exists a deterministic strategy in its cylinder. Therefore, Lemma 14 carries over, and finding a deterministic strategy satisfying a window formula reduces to finding a deterministic window strategy for it. Then, note that for a fixed state s, each deterministic window strategy can be seen as a boolean assignment over the set $\mathcal{X}_s$ of variables, and we have that $|\mathcal{X}_s| = |\mathcal{M}|^{\mathcal{O}(\mathcal{L})}$. Therefore, the set of deterministic window strategies is finite, of doubly-exponential size $2^{|\mathcal{M}|^{\mathcal{O}(\mathcal{L})}}$. We denote by W the number of deterministic window strategies. By guessing a window strategy and verifying it in EXPTIME, we get a NEXPTIME upper bound on the synthesis problem for window formulae. By guessing a strategy in an online manner we can lower this complexity, and show that the problem is in fact PSPACE-complete.

▶ **Proposition 27.** *The synthesis problem for* window *L-PCTL formulae is* PSPACE*-complete when restricted to* deterministic *strategies.*

Proof. We present a non-deterministic algorithm, running in polynomial space, that accepts all positive instances of the synthesis problem with deterministic strategies. We will guess a deterministic window strategy ∂ and check that Φ holds on the resulting MC. In order to avoid guessing an exponential certificate (the entire strategy ∂), we will perform a depth-first search (DFS) traversal of the MDP, starting from s_{init} and of horizon $\mathcal{L}$, where we guess every decision of ∂ in an online manner ($\partial(\rho)$ is guessed when the search path, that is the path from s_{init} to the current state, is ρ for the first time). We will compute along the way information that ultimately lets us evaluate if Φ holds on the root node of the search. At any point in the DFS, when the current path traversed from s_{init} is ρ, this information represents partial evaluations of subformulae of Φ on states along ρ, according to the strategy ∂. Formally, we equip each state in the DFS with a set of formulae to be evaluated. For each path formula φ in the set, we store the probability of satisfying the formula according to paths previously visited by the DFS. Once all of the subtree below a state has been seen by the search, this value matches the probability $\mathbb{P}[\varphi]$, and we can then use this value to evaluate the state formulae that needs to know $\mathbb{P}[\varphi]$ on the current state. In order to define the sets of subformulae to evaluate, we can use the same induction rules as in the proof of Proposition 16, that reduce the evaluation of a formula such as $\mathrm{X}^{\ell}\,\Phi_1$ or $\Phi_1\,\mathrm{U}^{\ell}\,\Phi_2$ on a given state to the evaluation of Φ_1, Φ_2, $\mathrm{X}^{\ell-1}\,\Phi_1$ or $\Phi_1\,\mathrm{U}^{\ell-1}\,\Phi_2$ on the current or the next state. Overall, we need to remember a path of length at most $\mathcal{L}$, a set of subformulae of Φ on each state in this path, and a probability for each such path formula. Assuming that the probabilities can be stored in polynomial space, this is indeed a PSPACE algorithm.

We argue that these probabilities can always be stored in polynomial space. Indeed, they correspond to the measure, in the MC defined by ∂, of a finite union of cylinders defined by prefixes of length at most $\mathcal{L}$. Since ∂ is deterministic, these measures are finite sums of real numbers obtained as the product of at most $\mathcal{L}$ constants appearing as transition probabilities on $\mathcal{M}$. Using a standard binary representation of rational numbers as irreducible fractions, we get that since $\mathcal{L}$ is polynomial in $|\Phi|$ these probabilities are always rational and of polynomial size.

We show a reduction from the synthesis problem with a generalized reachability objective in a two-player game. Given an arena with a set V of vertices that are partitioned into vertices belonging to Player 1 and Player 2, given an initial vertex v_0, and reachability sets $F_1, \ldots, F_k$, the problem asks for a (deterministic) Player 1 strategy that ensures reaching each of the sets against any Player 2 strategies. The generalized reachability problem is PSPACE-complete [12].

We construct an MDP $\mathcal{M}$ with $Q = V$ set of states and transitions which are the same as the edges of the two-player game arena. A Player 1 vertex corresponds to a state in the MDP such that for every outgoing edge (v, v_i) from v, we have an action a_i labelling the transition (v, v_i) in $\mathcal{M}$. For a Player 2 vertex v, all the outgoing edges (v, v_i) correspond to transitions for the same action to vertices v_i with equal probability. Also a state $v \in Q$ in $\mathcal{M}$ is labelled x_i for $i \leq i \leq k$ if and only if the corresponding vertex $v \in F_i$ in the two-player game. Further, if Player 1 has a wining strategy in the generalized reachability game, then she can visit all the reachability sets within a total of nk steps with a deterministic strategy.

Now consider the property Φ defined as $\bigwedge_{i=1}^{k} \mathbb{P}\left[\mathrm{F}^{nk}\, x_i\right] = 1$. There exists a deterministic strategy from v_0 in $\mathcal{M}$ satisfying Φ if and only if Player 1 has a winning strategy for the generalized reachability objective. ◀

As there are finitely many deterministic window strategies of horizon $\mathcal{L}$, the fixed point computation always terminates and thus provides decidability. We also reduce the problem asking if an alternating Turing machine running in polynomial space accepts a given word to deterministic strategy synthesis.

▶ **Proposition 28.** *The synthesis problem for* global window *L-PCTL formulae is in* 2EXPTIME *when restricted to* deterministic *strategies. Moreover, it is* EXPTIME*-hard.*

Proof. For global window formulae, we need to change the set Q^Φ, defined in Section 3, to only contain deterministic window strategies. It is still a complete lattice, and Proposition 22 carries over for deterministic strategies. Moreover, for every portfolio Π, there are finitely many strictly smaller portfolios, at most $|\mathcal{M}|W$. As the sequence $(\mathsf{f}^i(\bigsqcup Q^\Phi))_{i\in\mathbb{N}}$ is non-increasing, the fixed point is reached in at most $|\mathcal{M}|W$ steps. Each step can be performed without relying on the theory of the reals, by representing the window strategies explicitly as trees of depth $\mathcal{L}$. Applying the operator f on a portfolio amounts to checking if a tree is a prefix of another. Overall, the fixed point computation is doubly-exponential.

Note that if we rely on computing $\exists$-$\mathbb{R}$ formulae for $(\mathsf{f}^i(\bigsqcup Q^\Phi))_{i\in\mathbb{N}}$ instead of these explicit sets of strategies, the formulae could a priori grow to sizes in $|\Phi||\mathcal{M}|^{\mathcal{O}(\mathcal{L}+|\mathcal{M}|W)}$, so that we end up with a triply-exponential upper bound.

For the EXPTIME-hardness, we use APSPACE = EXPTIME and present a polynomial reduction from alternating polynomial-space Turing machines. We consider a Turing machine of states Q and tape alphabet Σ, so that each state q is equipped with a label $L(q) \in \{\forall, \exists\}$, except for the accepting and rejecting states $q_\top$ and $q_\bot$, where $L(q) = q$. Let $w \in \Sigma^*$ be an input word, and let $n \in \mathbb{N}$ be a bound on the length of the tape used when running w on the machine. Since we considered a polynomial space machine, n is polynomial. W.l.o.g., we assume that for every input, the Turing machine we consider above halts, and the input is accepted if and only if it halts in $q_\top$.

Let $\mathcal{M}$ be the MDP from Figure 2, where each named state is assigned an identical label. We describe a window formula Φ that ensures that controller only makes choices that faithfully represent an execution of the alternating Turing machine. Let $N = 2n + 5$ be the number of steps needed to follow a cycle from s to s in $\mathcal{M}$. If l is a label in $\mathcal{M}$, we shorten the L-PCTL formula $\mathbb{P}\left[\mathrm{F}^N\, l\right] = 1$ as $\mathrm{F}_1^N\, l$. It means that every path of length N must reach l. Intuitively, a run of the Turing machine can be described as a path in this MDP, where one full loop around s describes a configuration of the Turing machine: visiting a_i means that cell number i contains a, visiting a_i^H means that additionally the reading head is in position i, and entering the gadget q^a means that we are in state q and will read an a. Either controller or the environment gets to pick the next transition, and then we go back to s.

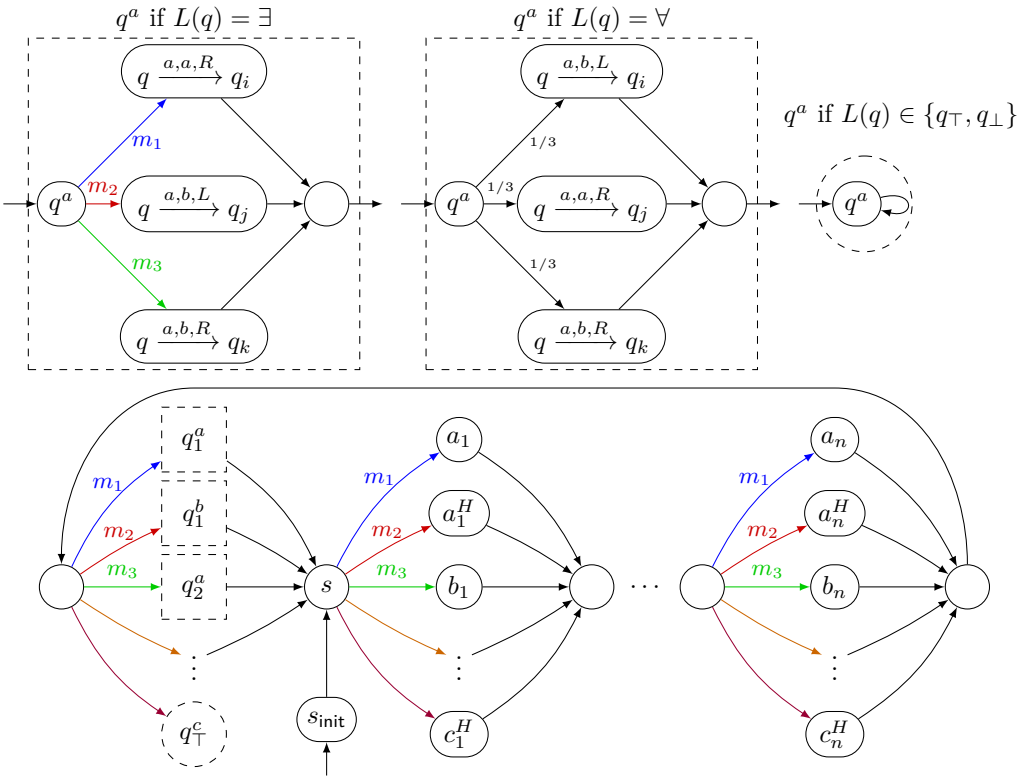

Figure 2 The MDP used in the reduction from APSPACE to deterministic synthesis for global window formulae. The colored transitions m_1, m_2, ... represent different actions, black transitions are available for every action, and the probability of a transition is 1 if unspecified. The letters a, b, c enumerate the tape alphabet Σ, while q_1, q_2, ... enumerate the states in Q, with $q_\top$ the accepting state. The only randomized transition is in the universal gadget q^a, and uses a uniform distribution over reachable states.

The formula Φ is obtained as the conjunction of the following constraints:

In order to ensure that the tape is initialized appropriately, we ask for every letter $a \in \Sigma$ in position $i > 1$ in the input word w that $s_{\mathsf{init}} \Rightarrow \mathrm{F}_1^N\, a_i$. If the first letter in w is a and the initial state of the Turing machine is q_1, we also ask $s_{\mathsf{init}} \Rightarrow \mathrm{F}_1^N\, a_1^H \wedge \mathrm{F}_1^N\, q_1^a$.

In order to simulate the transitions on the tape cells correctly, we ask for every $1 \leq i < n$, $a, c \in \Sigma$ and transition $q \xrightarrow{a,b,L} q'$ that

$$(s \wedge \mathrm{F}_1^N\, c_i \wedge \mathrm{F}_1^N\, a_{i+1}^H) \Rightarrow \mathbb{P}\Big[\mathrm{X}^{N-2}((q \xrightarrow{a,b,L} q') \Rightarrow \mathrm{F}_1^N\, c_i^H \wedge \mathrm{F}_1^N\, b_{i+1})\Big] = 1\,.$$

We similarly ask for every $1 \leq i < n$, $a, c \in \Sigma$ and transition $q \xrightarrow{a,b,R} q'$ that

$$(s \wedge \mathrm{F}_1^N\, a_i^H \wedge \mathrm{F}_1^N\, c_{i+1}) \Rightarrow \mathbb{P}\Big[\mathrm{X}^{N-2}((q \xrightarrow{a,b,R} q') \Rightarrow \mathrm{F}_1^N\, b_i \wedge \mathrm{F}_1^N\, c_{i+1}^H)\Big] = 1\,.$$

The other tape cells should be left untouched, so that for every $1 \leq i < n$, $a, b \in \Sigma$ and transition $q \xrightarrow{c,d,L} q'$, we ask that

$$(s \wedge \mathrm{F}_1^N\, a_i \wedge \mathrm{F}_1^N\, b_{i+1}) \Rightarrow \mathbb{P}\Big[\mathrm{X}^{N-2}((q \xrightarrow{c,d,L} q') \Rightarrow \mathrm{F}_1^N\, a_i)\Big] = 1\,.$$

Similarly for every transition transition $q \xrightarrow{c,d,R} q'$, we ask that

$$(s \wedge \mathrm{F}_1^N\, a_i \wedge \mathrm{F}_1^N\, b_{i+1}) \Rightarrow \mathbb{P}\Big[\mathrm{X}^{N-2}((q \xrightarrow{c,d,R} q') \Rightarrow \mathrm{F}_1^N\, b_{i+1})\Big] = 1\,.$$

Finally, in order to update the state, we ask for every transition $q \xrightarrow{a,b,D} q'$ with $D \in \{L, R\}$ and every $1 \leq i \leq n$, $c \in \Sigma$ that $(q \xrightarrow{a,b,D} q') \wedge \mathrm{F}_1^N\, c_i^H \Rightarrow \mathrm{F}_1^N\, q'^c$.

Then, we let $q_\top$ and $q_\bot$ be the labels that hold on all states $q_\top^a$ and $q_\bot^a$, respectively, for all $a \in \Sigma$. We consider the global window formula $\mathrm{A}\,\mathrm{G}[(\Phi \vee q_\top) \wedge \neg q_\bot]$, and show that there is a winning strategy for this formula in $\mathcal{M}$ if and only if the alternating Turing machine accepts the input word w. Indeed, an alternating Turing machine equipped with an initial word can be seen as a turn-based two-player zero-sum reachability game played on the execution tree of the machine, where we ask if there exists a strategy for player $\exists$ that ensures against every strategy of $\forall$ the state $q_\top$ is reached. ◀

Memoryless strategies. We study the synthesis of memoryless strategies. The window strategy defined by a memoryless strategy for a given prefix and a horizon is also memoryless. Conversely, a memoryless window strategy has a memoryless strategy in its cylinders. By Lemma 14, finding a memoryless strategy satisfying a window formula reduces to finding a memoryless window strategy for it. Let s be a state. As usual, a window strategy ∂ for state s can be seen as an assignment in $[0, 1]$ for variables $\mathcal{X}_s$. However, the memoryless property asks that $\partial(\rho) = \partial(\rho')$ for all ρ, ρ' that share the same last state s', or equivalently $x_{\rho,a} = x_{\mathsf{last}(\rho),a}$ for all ρ. Thus, we can replace every instance of $x_{\rho,a}$ by $x_{\mathsf{last}(\rho),a}$ in the $\exists$-$\mathbb{R}$ formula of Proposition 16, so that the set of free variables used to represent a memoryless window strategy for s is $\mathcal{X}_s = \{x_{s',a} \mid \exists \rho \in \mathsf{FPaths}_{\mathcal{M}}^{\leq \mathcal{L}}(s), s' = \mathsf{last}(\rho)\}$. Similarly, the variables $y_{\rho,\Phi}$ and $z_{\rho,\varphi}$ can be replaced by by $y_{\mathsf{last}(\rho),\Phi}$ and $z_{\mathsf{last}(\rho),\varphi}$ respectively, as the satisfaction of a state formula, or the probability of satisfying a path formula, only depend on the current state. The formula is now of polynomial size, so that we obtain as a corollary:

▶ **Proposition 29.** *The synthesis problem for* window *L-PCTL formulae is in* PSPACE *when restricted to* memoryless *strategies.*

Further, following a reduction in [15], it can be shown that the MR synthesis problem for window L-PCTL objectives is at least as hard as the Square-Root-Sum problem which is known to be in PSPACE, but whose exact complexity is a longstanding open problem.

We now study the memoryless synthesis problem for global window formulae. For each state s, let R^s denote the $\exists$-$\mathbb{R}$ formula encoding the window formula Φ for state s, as per Proposition 29. The free variables are the variables in $\mathcal{X}_s \subseteq \mathcal{X} = \{x_{s',a} \mid s' \in S, a \in A\}$. A memoryless strategy σ can be seen as a point in $\mathbb{R}^{\mathcal{X}}$, so that $\sigma(s, a)$ is assigned to $x_{s,a}$. For all states s and s', we define a variable $r_{s,s'} \in \{0, 1\}$ quantified existentially, and construct a formula ensuring that if $r_{s,s'} = 0$ then s' is not reachable from s under the strategy σ. This formula states $r_{s,s} = 1$ for all states s, and asks that the variables r are a solution to the system of equations asking, for all s, s', s'' and a, that if $r_{s,s'} = 1$ and $x_{s',a}\mathbb{P}(s', a, s'') > 0$ then $r_{s,s''} = 1$. Therefore, the set of states s' so that $r_{s,s'} = 1$ is an over-approximation.[10]

Then, the formula asking that there exists a value for each variable r so that $R^{s'}$ holds whenever $r_{s,s'} = 1$ represents the memoryless strategies that satisfy Φ on an over-approximation of the states reachable from s, which is equivalent to satisfying $\mathrm{A}\,\mathrm{G}\,\Phi$ when

[10] For example, the formula is satisfied if $r_{s,s'}$ is 1 for all s, s', which represents an over-approximation of the set of states reachable from s where every state is reachable.

starting from state s. Note that since the variables $r_{s,s'}$ are existentially quantified, and Φ is only required to be satisfied on states reachable from s, then there always exists a valuation for these r variables that sets $r_{s,s'}$ to 1 if and only if s' is reachable from s. It follows that:

▶ **Proposition 30.** *The synthesis problem for* global window *L-PCTL formulae is in* PSPACE *when restricted to* memoryless *strategies.*

PCTL satisfiability. We now consider the satisfiability problem, that asks, given a formula Φ, if there a exists an MC M so that $M \models \Phi$. This is a longstanding open problem for PCTL formulae. One can also consider variants of the problem, that either restrict Φ to a sublogic of PCTL or limit M to MCs that belong to a particular set, such as finite MCs or MCs where all probabilities are rational numbers. The decidability of these variants is also open and, as noted in [7], some PCTL formulae are only satisfiable by infinite MCs. In particular, we say that an MC M has granularity bounded by $N \in \mathbb{N}$ if every probability in the transition function $\mathbb{P}$ is equal to a rational $\frac{a}{b}$ with $b \leq N$. The *bounded granularity satisfiability problem* asks, given Φ and N, if there exists an MC of granularity bounded by N that satisfies Φ. The bounded granularity satisfiability problem for global window L-PCTL formulae can be reduced to the HD strategy synthesis problem for global window L-PCTL formulae. Therefore, we obtain the following result as a corollary of Proposition 28:

▶ **Theorem 31.** *The bounded granularity satisfiability problem for global window L-PCTL formulae is decidable in complexity doubly-exponential in* $|\Phi|$ *and* N*. Moreover, finite MCs are sufficient, in the sense that for every formula* $\mathrm{A}\,\mathrm{G}\,\Phi$ *that admits a model* M *of granularity bounded by* N*, there exists a finite MC* M' *of granularity bounded by* N *so that* $M' \models \mathrm{A}\,\mathrm{G}\,\Phi$*.*

Proof sketch. Given a formula with atomic propositions AP, and a granularity bound N, we intuitively consider an MC of states 2^{AP} with an action for every distribution over 2^{AP} whose granularity is bounded by N, so that this action describes the next states and their probabilities. Then, every MC of granularity bounded by N can be seen as a deterministic strategy in this MDP, so that strategy synthesis and MC satisfiability are equivalent. We can then apply Proposition 28. Moreover, finite MCs are sufficient as finite-memory strategies are sufficient for global window PCTL when restricted to deterministic strategies. ◀

4 Undecidability

In Section 3, we have shown that the synthesis problem for flat, non-strict global window L-PCTL formulae is in coRE. In this section, we argue that it is coRE-hard and that it becomes Σ^1_1-hard when relaxing the hypothesis that the formulae considered are non-strict.

When considering flat non-strict formulae, we proceed via a reduction from the non-halting problem of a two-counter Minsky machine. A two-counter Minsky machine consists of a list of instructions $l_1 : \mathsf{ins}_1, \ldots, l_n : \mathsf{ins}_n$ and two counters c_2 and c_3 (the indices 2 and 3 are chosen to ease the notations) where, for all $i \leq n$, we have ins_i an instruction in one the following types, for $j \in \{2, 3\}$ and $1 \leq k, m \leq n$: $\mathsf{Inc}_j(k)$: $c_j := c_j + 1$; goto k; $\mathsf{Branch}_j(k, m)$: if $c_j = 0$ then goto k; else $c_j := c_j - 1$, goto m; H: halt. The semantics of these instructions is straightforward. The non-halting problem for Minsky machine, denoted MinskyNotStop, is to decide, given a machine Msk, if its execution is infinite. This problem is undecidable, as stated in the theorem below.

▶ **Theorem 32** ([17])**.** *MinskyNotStop is* coRE*-complete.*

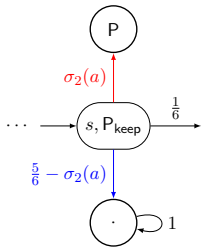

Figure 3 The end of a gadget.

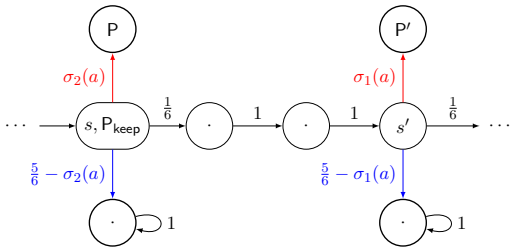

Figure 4 The end of a gadget on the left, and the beginning of another one on the right.

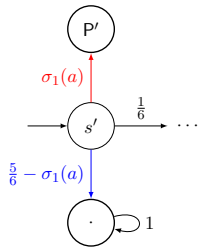

Figure 5 The beginning of a gadget.

Given $\mathsf{Msk} = l_1 : \mathsf{ins}_1, \ldots, l_n : \mathsf{ins}_n$ on two counters c_2 and c_3, we build an MDP $\mathcal{M}$ and an L-PCTL formula Φ such that there exists a strategy σ for $\mathcal{M}$ s.t. $\mathcal{M}[\sigma] \models \Phi$ if and only if $\mathsf{Msk} \in \mathsf{MinskyNotStop}$. The crucial point of the reduction is to encode the values of the counters that may take unbounded values. It is done in $\mathcal{M}$ by encoding these values in the probability (chosen by the strategy σ) to see a given predicate in the next few steps. More specifically, in the situation where the counters are such that $\{c_2 \mapsto x_2; c_3 \mapsto x_3\}$, we consider the probability $p(x_2, x_3) = \frac{5}{6} \times \frac{1}{2^{x_2}} \times \frac{1}{3^{x_3}}$. We then associate to each different instruction a gadget, i.e. an MDP, and a formula encoding the update of probability $p(x_2, x_3)$ according to how the counters are changed by the corresponding instruction. Inside a gadget, one can find predicates of the shape $(\mathsf{P}.)$. They are used to define the formulae specifying the expected behavior of the strategy. Furthermore, there is also an entering and an exiting probability which correspond to the encoding of the counters respectively before and after the effect of the instructions. We define below formally the notion of well-placed gadgets.

▶ **Definition 33** (Gadgets). *A gadget* Gd *is an MDP with an* entering probability *and an* exiting probability. *Consider Figure 3 that represents how every gadget* Gd *ends. The exiting probability* $p^{\mathsf{ex}}_{\mathsf{Gd}}$ *is the probability* $\sigma_2(a)$ *to visit the state on the top. It is equal to* $p^{\mathsf{ex}}_{\mathsf{Gd}} = \mathbb{P}_s(\mathrm{F}^1\, \mathsf{P})$, i.e. *the probability that* $\mathrm{F}^1\, \mathsf{P}$ *holds on state* s. *Consider Figure 5. All gadgets begin as in this figure: a state* s' *with a successor satisfying the predicate* P'. *The* entering probability $p^{\mathsf{en}}_{\mathsf{Gd}}$ *is the probability* $\sigma_1(a)$ *to see* P', *that is:* $p^{\mathsf{en}}_{\mathsf{Gd}} = \mathbb{P}_{s'}(\mathrm{F}^1\, \mathsf{P}')$. *A gadget is* well-placed *if, as for the gadget on the right of Figure 4, it is preceded by two dummy states, themselves immediately preceded by a gadget.*

Before looking at how specific instructions are encoded in the counters and the formula, we have to ensure that the exiting probability of a gadget is equal to the entering probability of the following well-placed gadget. This is done with the formula: $\Phi_{\mathsf{keep}} := \mathsf{P}_{\mathsf{keep}} \Rightarrow (\mathbb{P}(\mathrm{F}^1\, \mathsf{P}) = 6 \cdot \mathbb{P}(\mathrm{F}^4\, \mathsf{P}'))$. These definitions ensure the following proposition:

▶ **Proposition 34** (Entering probability of a well-placed gadget). *Assume that a well-placed gadget* Gd' *follows a gadget* Gd. *Then, for a strategy* σ *s.t. the formula* $\mathrm{A}\, \mathrm{G}\, \Phi_{\mathsf{keep}}$ *is satisfied, the exiting probability of gadget* Gd *is equal to the entering probability of gadget* Gd'*:* $p^{\mathsf{ex}}_{\mathsf{Gd}} = p^{\mathsf{en}}_{\mathsf{Gd}'}$.

Due to lack of space, we only exhibit the gadgets encoding the increment of a counter and for testing if a counter value is 0. Consider the increment of counter c_2. By definition of $p(x_2, x_3)$, incrementing that counter is simulated by multiplying the probability by $\frac{1}{2}$.We define the gadget $\mathsf{Gd}_{c_2{+}{+}}$ and the formula $\Phi_{c_2{+}{+}}$ ensuring that the probability is indeed multiplied by $\frac{1}{2}$. The gadget $\mathsf{Gd}_{c_2{+}{+}}$ is depicted in Figure 6.In addition, we define the L-PCTL formula $\Phi_{c_2{+}{+}}$ such that $\Phi_{c_2{+}{+}} := \mathsf{P}_{c_2{+}{+}} \Rightarrow (\mathbb{P}(\mathrm{F}^2\, \mathsf{P}_{c_2}) = 6 \cdot 2 \cdot \mathbb{P}(\mathrm{F}^3\, \mathsf{P}_+))$. The interest of these definitions lies in the proposition below.

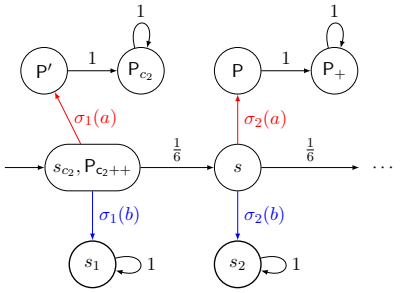

Figure 6 The gadget Gd_{c_2++} for the operation $c_2 := c_2 + 1$.

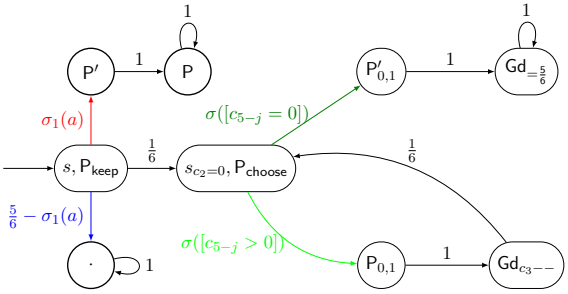

Figure 7 The gadget $\mathsf{Gd}_{c_2=0}$ for testing that the counter $c_2 = 0$.

▶ **Proposition 35** (Incrementing Gadget Specification). *If the entering probability* $p^{\mathsf{en}}_{\mathsf{Gd}_{c_2++}}$ *of the gadget* Gd_{c_2++} *is equal to* $p(x_2, x_3)$ *with* $x_2, x_3 \in \mathbb{N}$*, then whenever the formula* $\mathrm{A\,G}\,\Phi_{c_2++}$ *is satisfied, the exiting probability* $p^{\mathsf{ex}}_{\mathsf{Gd}_{c_2++}}$ *of this gadget is equal to* $p^{\mathsf{ex}}_{\mathsf{Gd}_{c_2++}} = p(x_2 + 1, x_3)$.

We now consider the gadget that tests if a counter value is 0, let us exemplify it with counter c_2 in gadget $\mathsf{Gd}_{c_2=0}$ depicted in Figure 7. The gadget $\mathsf{Gd}_{=5/6}$ used on the right tests that both counters have value 0 (i.e. the entering probability is equal to 5/6).Then, the idea is as follows: as long as counter c_3 has a positive value, the strategy σ has to take the bottom branch to decrement it and once this counter has reached 0, it can take the top branch to check that the probability is indeed equal to 5/6. Note that one cannot decrement counter c_2 in this gadget, hence if its value is positive, there is no way to pass the test of the comparison to 5/6. To ensure that the choice at state $s_{c_2=0}$ is deterministic, we consider the formula $\Phi_{0,1} := \mathsf{P}_{\mathsf{choose}} \Rightarrow (\mathbb{P}(\mathrm{X}\,\mathsf{P}_{0,1}) = 1 \vee \mathbb{P}(\mathrm{X}\,\mathsf{P}'_{0,1}) = 1)$. We have the proposition below:

▶ **Proposition 36** (Testing Gadget Specification). *Assume that the entering probability* $p^{\mathsf{en}}_{\mathsf{Gd}_{c_2=0}}$ *of the gadget* $\mathsf{Gd}_{c_2=0}$ *is equal to* $p(x_2, x_3)$ *for some* $x_2, x_3 \in \mathbb{N}$*. Then, there is a strategy* σ *such that the formula* $\mathrm{A\,G}[\Phi_{\mathsf{keep}} \wedge \Phi_{0,1} \wedge \Phi_{c_3--} \wedge \Phi_{=5/6}]$ *is satisfied if and only if* $x_2 = 0$.

We can similarly test that a counter is different from 0. A gadget corresponding to a branching instruction can then be defined by using these gadgets.Finally, a gadget corresponding to the Halt instruction only consists of a gadget where no strategy σ can satisfy the formula considered. Overall, we can combine all these gadgets to encode all the instructions of the Minsky machine Msk.We obtain the theorem below.

▶ **Theorem 37.** *The synthesis problem for flat, non-strict global window L-PCTL formulae is* coRE*-hard.*

When considering arbitrary flat formulae without the non-strict constraint, we can adapt the proof to reduce from the problem asking if there is an execution of a Minsky Machine that visits infinitely often the first instruction [3], so that the strategy synthesis problem becomes highly undecidable.

▶ **Theorem 38.** *The synthesis problem for flat global window L-PCTL formulae is* Σ^1_1*-hard.*

The construction here is similar to the case with the non-strict constraint, except that whenever the first instruction is seen, a choice is given to the strategy which can set in how many number of steps n the first instruction will be seen again (note that this number may be arbitrarily large). This choice is encoded by resetting a new counter c_5 to value n, which is then decremented each time the first instruction is not seen, and a problem arises if this

counter ever reaches 0. In terms of probability, the value $p(x_2, x_3)$ is initially multiplied by $\frac{1}{5^n}$ and then multiplied by 5 each time the first instruction is not seen. Hence, the probabilities chose by σ may be arbitrarily close to 0, but cannot be equal to 0. This is where we need the non-strict comparison with 0.

Abstract

We establish that the subgame perfect equilibrium (SPE) threshold problem for mean-payoff games is **NP**-complete. While the SPE threshold problem was recently shown to be decidable (in doubly exponential time) and **NP**-hard, its exact worst case complexity was left open.

1 Introduction

Nash equilibria (NEs), a fundamental solution concept in game theory, are defined as strategy profiles such that no player can improve their payoff by changing unilaterally their strategy. So NEs can be interpreted as self-inforcing contracts from which there is no incentive to deviate unilaterally. Unfortunately, NEs are known to suffer, in sequential games like infinite duration games played on graphs, from the issue of *non-credible threats*: to enforce a NE, some players may threaten other players to play irrationally in order to punish deviations. This is allowed by the definition of NEs, as in case of deviation from one player, the other players are not bound to rational behaviors anymore and they can therefore play irrationally w.r.t. their own objectives in order to sanction the deviating player. This drawback of NEs has triggered the introduction of the notion of *subgame-perfect equilibria* (SPEs) [22], a more complex but more natural solution concept for sequential games. A strategy profile is an SPE if after every history, i.e. in every *subgame*, the strategies of the players still form an NE. Thus, SPEs impose rationality even after a deviation and only rational behaviors can be used to coerce the behavior of other players.

In this paper, we study the complexity of SPE problems in infinite-duration sequential games played on graphs with mean-payoff objectives. While NEs always exist in those games, as proved in [8], SPEs do not always exist as shown in [23, 7]. The *SPE threshold problem*, i.e. the problem of deciding whether a given mean-payoff game admits an SPE satisfying some constraints on the payoffs it grants to the players, has recently been proved to be decidable

in [3]. However, its worst-case computational complexity is open: [3] provides only an **NP** lower bound and a 2**ExpTime** upper bound. In this paper, we close this complexity gap and prove that the problem is actually **NP**-complete.

Contributions. The starting point of our algorithm is the characterization of SPEs recently presented in [3], based on the notions of *requirement* and *negotiation function*. A requirement on a game G is a function $\lambda : V \to \mathbb{R} \cup \{\pm\infty\}$, where V is the state space of G. For a given state v, the value $\lambda(v)$ should be understood as the minimal payoff that the player controlling the state v will require in a play traversing v in order to avoid deviating. A requirement captures, therefore, some level of *rationality* of the players. The negotiation function transforms each requirement λ into a (possibly stronger) requirement $\mathsf{nego}(\lambda)$, such that $\mathsf{nego}(\lambda)(v)$ is the best payoff that the player controlling v can ensure, while playing against a coalition of the other players that play rationally with regards to the requirement λ. A play is the outcome of an SPE if and only if it satisfies the requirement λ^*, the least fixed point of the negotiation function – or equivalently, one of its fixed points. We recall that result in Lemma 29. In order to obtain our nondeterministic polynomial time algorithm, the rest of the paper constructs a notion of witness recognizing the positive instances of the SPE threshold problem. Such witnesses admit three pieces. First, we show that the size of λ^* can be bounded by a polynomial function of the size of the game (Theorem 37). This result is obtained by showing that the set of fixed points of the negotiation function can be characterized by a finite union of polyhedra that in turn can be represented by linear inequations. While the number of inequations that are needed for that characterization may be large (it cannot be bounded polynomially), we show that each of those inequations have coefficients and constants whose binary representations can be bounded polynomially. As the least fixed point is the minimal value in this set, it is represented by a vertex of one of those polyhedra. Then this guarantees, using results that bounds the solutions of linear equalities, that the least fixed point has a binary representation that is polynomial and so it can be guessed in polynomial time by a nondeterministic algorithm: it will be the first piece of our notion of witness, in the non-deterministice algorithm we design to solve the SPE threshold problem. Second, we define a witness of polynomial size for the existence of a play, consistent with a given requirement, which generates a payoff vector between the desired thresholds (Theorem 38). This play is not guaranteed to be regular. Third, we define a witness of polynomial size to prove that a requirement is indeed a fixed point of the negotiation function. This notion of certificate relies on a new and more compact game characterization of the negotiation function called the *reduced negotiation game* (Definition 41, Theorem 44). These results are far from trivial as we also show that SPEs may rely on strategy profiles that are not regular and require infinite memory. As both the least fixed point and its two certificates can be guessed and verified in polynomial time, we obtain **NP** membership for the threshold problem, closing the complexity gap left open in [3] (Theorem 48).

Additionally, all the previous results do also apply to ε-SPEs, a quantitative relaxation of SPEs. In particular, Theorem 48 does also apply to the ε-SPE threshold problem.

Related works. Non-zero sum infinite duration games have attracted a large attention in recent years, with applications targeting reactive synthesis problems, see e.g. [1, 9, 10, 14, 19] and their references. We now detail other works more closely related to our contributions.

In [7], Brihaye et al. introduce and study the notion of weak SPE, which is a weakening of the classical notion of SPE. This weakening is equivalent to the original SPE concept on reward functions that are *continuous*. This is the case for example for the quantitative

reachability reward function, on which Brihaye et al. solve the SPE threshold problem in [6]. The mean-payoff cost function is not continuous and the techniques used in [7], and generalized in [11], cannot be used to characterize SPEs for the mean-payoff reward function.

In [21], Meunier develops a method based on Prover-Challenger games to solve the problem of the existence of SPEs on games with a finite number of possible payoffs. In mean-payoff games, the number of possible payoffs is uncountably infinite.

In [15], Flesch and Predtetchinski present another characterization of SPEs on games with finitely many possible payoffs, based on a game structure with infinite state space. In [3], Brice et al. define the notions of requirements and negotiation function. They prove that the negotiation function is characterized by a zero-sum two-player game called *abstract negotiation game*, which is similar to the game introduced in the characterization of Flesch and Predtetchinski. As a starting point for algorithms, they also provide an effective representation of this game, called *concrete negotiation game*, which turns out to be a zero-sum finite state multi-mean-payoff games [24]. Finally, they use those tools to prove that the SPE threshold problem is decidable for mean-payoff games. They left open the question of its precise complexity: they provide a **NP** lower bound and a 2**ExpTime** upper bound. In [5], the same authors use those tools to close the complexity gap for the SPE threshold problem in parity games, which had been proved to be **ExpTime**-easy and **NP**-hard by Ummels and Grädel in [16]. They prove that the problem is actually **NP**-complete. The techniques used in that paper heavily rely on the fact that parity objectives are ω-regular, which is not the case of mean-payoff games in general.

In [13], Chatterjee et al. study mean-payoff *automata*, and give a result that can be translated into an expression of all the possible payoff vectors in a mean-payoff game. In [2], Brenguier and Raskin give an algorithm to build the Pareto curve of a multi-dimensional two-player zero-sum mean-payoff game. To do so, they study systems of equations and of inequations, and they prove that they always admit simple solutions (with polynomial size). Those technical results will be used along this paper.

Structure of the paper. In Section 2, we introduce the necessary background. Section 3 recalls the notions of requirement and negotiation function, and link them to NEs and SPEs. Section 4 recalls results about the size of solutions of systems of equations or inequations, and use them to bound the size of the least fixed point of the negotiation function. Section 5 defines a witness for the existence of a λ-consistent play between two given thresholds. Section 6 introduces the reduced negotiation game that is a new compact characterization of the negotiation function. Finally, Section 7 applies those results to prove the **NP**-completeness of the SPE threshold problem on mean-payoff games. The proofs that are not presented here can be found in appendices of [4], the full version of this paper.

2 Background

Games, strategies, equilibria. In all what follows, we study infinite duration turn-based quantitative games on finite graphs with complete information.

▶ **Definition 1** (Game). A *non-initialized game* is a tuple $G = (\Pi, V, (V_i)_{i\in\Pi}, E, \mu)$, where:

- Π is a finite set of *players*;
- (V, E) is a directed graph, called the *underlying graph* of G, whose vertices are sometimes called *states* and whose edges are sometimes called *transitions*, and in which every state has at least one outgoing transition. For the simplicity of writing, a transition $(v, w) \in E$ will often be written vw;

- $(V_i)_{i\in\Pi}$ is a partition of V, in which V_i is the set of states *controlled* by player i;
- $\mu : V^\omega \to \mathbb{R}^\Pi$ is an *payoff function*, that maps each infinite word ρ to the tuple $\mu(\rho) = (\mu_i(\rho))_{i\in\Pi}$ of the players' *payoffs*.

An *initialized game* is a tuple (G, v_0), often written $G_{\restriction v_0}$, where G is a non-initialized game and $v_0 \in V$ is a state called *initial state*. We often use the word *game*, alone, for both initialized and non-initialized games.

▶ **Definition 2** (Play, history). A *play* (resp. history) in the game G is an infinite (resp. finite) path in the graph (V, E). It is also a play (resp. history) in the initialized game $G_{\restriction v_0}$, when v_0 is its first vertex. The set of plays (resp. histories) in the game G (resp. the initialized game $G_{\restriction v_0}$) is denoted by $\mathsf{Plays}G$ (resp. $\mathsf{Plays}G_{\restriction v_0}, \mathsf{Hist}G, \mathsf{Hist}G_{\restriction v_0}$). We write Hist_iG (resp. $\mathsf{Hist}_iG_{\restriction v_0}$) for the set of histories in G (resp. $G_{\restriction v_0}$) of the form hv, where v is a vertex controlled by player i.

Given a play ρ (resp. a history h), we write $\mathsf{Occ}(\rho)$ (resp. $\mathsf{Occ}(h)$) the set of vertices that appear in ρ (resp. h), and $\mathsf{Inf}(\rho)$ the set of vertices that appear infinitely often in ρ. For a given index k, we write $\rho_{\leq k}$ (resp. $h_{\leq k}$), or $\rho_{<k+1}$ (resp. $h_{<k+1}$), the finite prefix $\rho_0 \dots \rho_k$ (resp. $h_0 \dots h_k$), and $\rho_{\geq k}$ (resp. $h_{\geq k}$), or $\rho_{>k-1}$ (resp. $h_{>k-1}$), the infinite (resp. finite) suffix $\rho_k\rho_{k+1}\dots$ (resp. $h_kh_{k+1}\dots h_{|h|-1}$). Finally, we write $\mathsf{first}(\rho)$ (resp. $\mathsf{first}(h)$) the first vertex of ρ (and $\mathsf{last}(h)$ the last vertex of h).

▶ **Definition 3** (Strategy, strategy profile). A *strategy* for player i in the initialized game $G_{\restriction v_0}$ is a function $\sigma_i : \mathsf{Hist}_iG_{\restriction v_0} \to V$, such that $v\sigma_i(hv)$ is an edge of (V, E) for every hv. A history h is *compatible* with a strategy σ_i if and only if $h_{k+1} = \sigma_i(h_0 \dots h_k)$ for all k such that $h_k \in V_i$. A play ρ is compatible with σ_i if all its prefixes are.

A *strategy profile* for $P \subseteq \Pi$ is a tuple $\bar\sigma_P = (\sigma_i)_{i\in P}$, where each σ_i is a strategy for player i in $G_{\restriction v_0}$. A play or a history is *compatible* with $\bar\sigma_P$ if it is compatible with every σ_i for $i \in P$. A *complete* strategy profile, usually written $\bar\sigma$, is a strategy profile for Π. Exactly one play is compatible with a complete strategy profile: we write it $\langle\bar\sigma\rangle$, and call it the *outcome* of $\bar\sigma$.

When i is a player and when the context is clear, we will often write $-i$ for the set $\Pi \setminus \{i\}$. When $\bar\tau_P$ and $\bar\tau'_Q$ are two strategy profiles with $P \cap Q = \emptyset$, we write $(\bar\tau_P, \bar\tau'_Q)$ the strategy profile $\bar\sigma_{P\cup Q}$ such that $\sigma_i = \tau_i$ for $i \in P$, and $\sigma_i = \tau'_i$ for $i \in Q$.

Before moving on to SPEs, let us recall that an NE is a strategy profile such that no player has an incentive to deviate unilaterally.

▶ **Definition 4** (Nash equilibrium). Let $G_{\restriction v_0}$ be a game. The strategy profile $\bar\sigma$ is a *Nash equilibrium* – or *NE* for short – in $G_{\restriction v_0}$ if and only if for each player i and for every strategy σ'_i, called *deviation of* σ_i, we have the inequality $\mu_i\left(\langle\sigma'_i, \bar\sigma_{-i}\rangle\right) \leq \mu_i\left(\langle\bar\sigma\rangle\right)$.

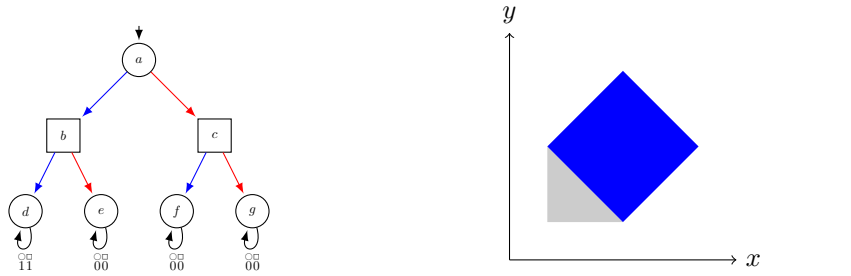
An SPE is a strategy profile whose all substrategy profiles are NEs.

▶ **Definition 5** (Subgame, substrategy). Let hv be a history in the game G. The *subgame* of G after hv is the game $\left(\Pi, V, (V_i)_i, E, \mu_{\restriction hv}\right)_{\restriction v}$, where $\mu_{\restriction hv}$ maps each play to its payoff in G, assuming that the history hv has already been played: formally, for every $\rho \in \mathsf{Plays}G_{\restriction hv}$, we have $\mu_{\restriction hv}(\rho) = \mu(h\rho)$. If σ_i is a strategy in $G_{\restriction v_0}$, its *substrategy* after hv is the strategy $\sigma_{i\restriction hv}$ in $G_{\restriction hv}$, defined by $\sigma_{i\restriction hv}(h') = \sigma_i(hh')$ for every $h' \in \mathsf{Hist}_iG_{\restriction hv}$.

▶ Remark. The initialized game $G_{\restriction v_0}$ is also the subgame of G after the one-state history v_0.

▶ **Definition 6** (Subgame-perfect equilibrium). Let $G_{\restriction v_0}$ be a game. The strategy profile $\bar\sigma$ is a *subgame-perfect equilibrium* – or *SPE* for short – in $G_{\restriction v_0}$ if and only if for every history h in $G_{\restriction v_0}$, the strategy profile $\bar\sigma_{\restriction h}$ is a Nash equilibrium in the subgame $G_{\restriction h}$.

The notion of subgame-perfect equilibrium refines the notion of Nash equilibrium and excludes coercion by non-credible threats.



(a) Two Nash equilibria. **(b)** An example for the operator $\llcorner$.

Figure 1 Illustration for preliminary notions.

▶ Example 7. Consider the game pictured in Figure 1a. It is initialized with initial state a, and has two players, player ○ and player □, who own respectively the circle and the square vertices. The payoff function assigns to each player a payoff of 1 for the play abd^ω, and 0 for all the other plays. Two different strategy profiles are represented here, one by the blue colored transitions, which has outcome abd^ω, one by the red colored ones, which has outcome acg^ω. Both are NEs: clearly, no player can increase their payoff by deviating from the blue choices, and in the case of the red profile, a deviation of player □ can only lead to the play acf^ω, and a deviation of player ○ to abe^ω – both plays give to both player the payoff 0. However, for player □, going from b to e is not a rational choice, hence the red profile is not an SPE, while the blue profile is one.

An ε-SPE is a strategy profile which is *almost* an SPE: if a player deviates after some history, they will not be able to improve their payoff by more than a quantity $\varepsilon \geq 0$. Note that a 0-SPE is an SPE, and conversely.

▶ **Definition 8** (ε-SPE)**.** Let $G_{\restriction v_0}$ be a game, and $\varepsilon \geq 0$. A strategy profile $\bar{\sigma}$ from v_0 is an ε-SPE if and only if for every history h, for every player i and every strategy σ'_i, we have $\mu_i(\langle \bar{\sigma}_{-i\restriction h}, \sigma'_{i\restriction h}\rangle) \leq \mu_i(\langle \bar{\sigma}_{\restriction h}\rangle) + \varepsilon$.

Mean-payoff games. We now turn to the definition of mean-payoff objectives.

▶ **Definition 9** (Mean-payoff, mean-payoff game)**.** In a graph (V, E), we associate to each mapping $r : E \to \mathbb{Q}$ the *mean-payoff function*:

$$\mathsf{MP}_r : h_0 \dots h_n \mapsto \frac{1}{n}\sum_{k=0}^{n-1} r_i\left(h_k h_{k+1}\right).$$

A game $G = (\Pi, V, (V_i)_i, E, \mu)$ is a *mean-payoff game* if its underlying graph is finite, and if there exists a tuple $(r_i)_{i\in\Pi}$ of reward functions, such that for each player i and every play ρ:

$$\mu_i(\rho) = \liminf_{n\to\infty} \mathsf{MP}_{r_i}(\rho_{\leq n}).$$

The mapping r_i is called *reward function* of player i: it represents the immediate reward that each action grants to player i. The final payoff of player i is their average payoff along the play, classically defined as the limit inferior[1] over n (since the limit may not be defined) of the average payoff after n steps. When the context is clear, we liberally write $\mathsf{MP}_i(h)$ for $\mathsf{MP}_{r_i}(h)$, and $\mathsf{MP}(h)$ for the tuple $(\mathsf{MP}_i(h))_i$, as well as $r(uv)$ for the tuple $(r_i(uv))_i$.

[1] An alternative definition of mean-payoff games exists, with a limit superior instead of inferior. While in zero-sum one dimensional games, the two definitions lead to the same notion of optimality, this is not the case when considering multiple dimensions, see e.g. [24]. All the results presented in this paper apply only on mean-payoff games defined with a limit inferior.

In the sequel, we develop a worst-case optimal algorithm to solve the *ε-SPE threshold problem*, which is a generalization of the *SPE threshold problem*, defined as follows.

▶ **Definition 10** (ε-SPE threshold problem)**.** Given a rational number $\varepsilon \geq 0$, a mean-payoff game $G_{\restriction v_0}$ and two thresholds $\bar{x}, \bar{y} \in \mathbb{Q}^\Pi$, does there exist an ε-SPE $\bar{\sigma}$ in $G_{\restriction v_0}$ such that $\bar{x} \leq \mu(\langle\bar{\sigma}\rangle) \leq \bar{y}$?

That problem is already known, by [3], to be 2**ExpTime** and **NP**-hard. The proof given in that paper does also show that **NP**-hardness still holds when ε is fixed to 0. Let us also add that the existence of an SPE in a given mean-payoff game, i.e. the same problem with no thresholds and with $\varepsilon = 0$, is itself **NP**-hard.

▶ **Definition 11** (SPE existence problem)**.** Given a mean-payoff game $G_{\restriction v_0}$, does there exist an SPE in $G_{\restriction v_0}$?

▶ **Lemma 12.** *The SPE existence problem is* **NP***-hard.*

Set of possible payoffs. A first important result that we need is the characterization of the set of possible payoffs in a mean-payoff game, which has been introduced in [13]. Given a graph (V, E), we write $\mathsf{SC}(V, E)$ the set of simple cycles it contains. Given a finite set D of dimensions and a set $X \subseteq \mathbb{R}^D$, we write $\mathsf{Conv}X$ the convex hull of X. We will often use the subscript notation $\mathsf{Conv}_{x \in X} f(x)$ for the set $\mathsf{Conv} f(X)$.

▶ **Definition 13** (Downward sealing)**.** Given a set $Y \subseteq \mathbb{R}^D$, the *downward sealing* of Y is the set $\llcorner Y = \left\{ (\min_{\bar{z} \in Z} z_d)_{d \in D} \;\middle|\; Z \text{ is a finite subset of } Y \right\}$.

▶ Example 14. In $\mathbb{R}^2$, if Y is the blue area in Figure 1b, then $\llcorner Y$ is the union of the blue area and the gray area.

▶ **Lemma 15** ([13])**.** *Let G be a mean-payoff game, whose underlying graph is strongly connected. The set of the payoffs $\mu(\rho)$, where ρ is a play in G, is exactly the set:*

$$\llcorner \left(\mathop{\mathsf{Conv}}_{c \in \mathsf{SC}(V,E)} \mathsf{MP}(c) \right).$$

Two-player zero-sum games. We now recall several definitions and two classical results about two-player zero-sum games.

▶ **Definition 16** (Two-player zero-sum game)**.** A *two-player zero sum game* is a game G with $\Pi = \{1, 2\}$ and $\mu_2 = -\mu_1$.

▶ **Definition 17** (Borel game)**.** A game G is *Borel* if the function μ, from the set V^ω equipped with the product topology to the Euclidian space $\mathbb{R}^\Pi$, is Borel, i.e. if, for every Borel set $B \subseteq \mathbb{R}^\Pi$, the set $\mu^{-1}(B)$ is Borel.

▶ Remark. Mean-payoff games are Borel (see [12]).

▶ **Lemma 18** (Determinacy of Borel games, [20])**.** *Let $G_{\restriction v_0}$ be a zero-sum Borel game, with $\Pi = \{1, 2\}$. Then, we have the following equality:*

$$\sup_{\sigma_1} \inf_{\sigma_2} \mu_1(\langle\bar{\sigma}\rangle) = \inf_{\sigma_2} \sup_{\sigma_1} \mu_1(\langle\bar{\sigma}\rangle).$$

That quantity is called *value* of $G_{\restriction v_0}$, denoted by $\mathsf{val}_1(G_{\restriction v_0})$.

▶ **Definition 19** (Optimal strategy). Let $G_{\restriction v_0}$ be a zero-sum Borel game, with $\Pi = \{1, 2\}$. The strategy σ_1 is *optimal* in $G_{\restriction v_0}$ if $\inf_{\sigma_2} \mu_1(\langle \sigma_1, \sigma_2 \rangle) = \mathsf{val}_1(G_{\restriction v_0})$.

Let us now define memoryless strategies, and a condition under which they can be optimal.

▶ **Definition 20** (Memoryless strategy). A strategy σ_i in a game $G_{\restriction v_0}$ is *memoryless* if for every vertex $v \in V_i$ and for all histories h and h', we have $\sigma_i(hv) = \sigma_i(h'v)$.

We usually write $\sigma_i(\cdot v)$ for the state $\sigma_i(hv)$ for every h. For every game $G_{\restriction v_0}$, we write $\mathsf{ML}(G_{\restriction v_0})$ for the set of memoryless strategies in $G_{\restriction v_0}$.

▶ **Definition 21** (Shuffling). Let ρ, η and θ be three plays in a game G. The play θ is a *shuffling* of ρ and η if there exist two sequences of indices $k_0 < k_1 < \dots$ and $\ell_0 < \ell_1 < \dots$ such that $\eta_0 = \rho_{k_0} = \eta_{\ell_0} = \rho_{k_1} = \eta_{\ell_1} = \dots$, and:

$$\theta = \rho_0 \dots \rho_{k_0-1} \eta_0 \dots \eta_{\ell_0-1} \rho_{k_0} \dots \rho_{k_1-1} \eta_{\ell_0} \dots \eta_{\ell_1-1} \dots .$$

▶ **Definition 22** (Convexity, concavity). A function $f : \mathsf{Plays} G \to \mathbb{R}$ is *convex* if every shuffling θ of two plays ρ and η satisfies $f(\theta) \geq \min\{f(\rho), f(\eta)\}$. It is *concave* if $-f$ is convex.

▶ Remark. Mean-payoff functions, defined with a limit inferior, are convex.

▶ **Lemma 23.** *In a two-player zero-sum game played on a finite graph, every player whose payoff function is concave has an optimal strategy that is memoryless.*

Proof. According to [18], this result is true for qualitative objectives, i.e. when μ can only take the values 0 and 1. It follows that for every $\alpha \in \mathbb{R}$, if a player i, whose payoff function is concave, has a strategy that ensures $\mu_i(\rho) \geq \alpha$ (understood as a qualitative objective), then they have a memoryless one. Hence the equality:

$$\mathsf{val}_1(G_{\restriction v_0}) = \sup_{\sigma_1 \in \mathsf{ML}(G_{\restriction v_0})} \inf_{\sigma_2} \mu_1(\langle \bar{\sigma} \rangle).$$

Since the underlying graph (V, E) is finite, memoryless strategies exist in finite number, hence the supremum above is realized by a memoryless strategy σ_1 that is, therefore, optimal. ◀

3 Requirements and negotiation

We now recall some notions and results from [3], which are the starting point of our algorithm.

Requirements. In the sequel, we write $\overline{\mathbb{R}}$ the set $\mathbb{R} \cup \{\pm\infty\}$.

▶ **Definition 24** (Requirement). A *requirement* on the game G is a mapping $\lambda : V \to \overline{\mathbb{R}}$.

For a given state v, the quantity $\lambda(v)$ represents the minimal payoff that the player controlling v will require in a play traversing the state v.

▶ **Definition 25** (λ-consistency). Let λ be a requirement on a game G. A play ρ in G is λ-*consistent* if and only if, for all $i \in \Pi$ and $n \in \mathbb{N}$ with $\rho_n \in V_i$, we have $\mu_i(\rho_{\geq n}) \geq \lambda(\rho_n)$. The set of λ-consistent plays from a state v is denoted by $\lambda\mathsf{Cons}(v)$.

▶ Remark. The set $\lambda\mathsf{Cons}(v)$ can be empty, and is not regular in general.

▶ **Definition 26** (λ-rationality). Let λ be a requirement on a mean-payoff game G. Let $i \in \Pi$. A strategy profile $\bar{\sigma}_{-i}$ is λ-*rational* if and only if there exists a strategy σ_i such that, for every history hv compatible with $\bar{\sigma}_{-i}$, the play $\langle \bar{\sigma}_{\restriction hv} \rangle$ is λ-consistent. We then say that the strategy profile $\bar{\sigma}_{-i}$ is λ-rational *assuming* σ_i. The set of λ-rational strategy profiles in $G_{\restriction v}$ is denoted by $\lambda\mathsf{Rat}(v)$.

Negotiation. In mean-payoff games, as well as in a wider class of games (see [3] and [15]), SPEs are characterized by the fixed points of the *negotiation function*, a function from the set of requirements into itself. We always use the convention $\inf \emptyset = +\infty$.

▶ **Definition 27** (Negotiation function)**.** Let G be a game. The *negotiation function* is the function that transforms each requirement λ on G into a requirement $\mathsf{nego}(\lambda)$ on G defined, for each $i \in \Pi$ and $v \in V_i$, by:

$$\mathsf{nego}(\lambda)(v) = \inf_{\bar{\sigma}_{-i} \in \lambda\mathsf{Rat}(v)} \sup_{\sigma_i} \mu_i(\langle \bar{\sigma} \rangle).$$

The quantity $\mathsf{nego}(\lambda)(v)$ is the best payoff the player controlling the state v can enforce if the other players play rationally with regards to the requirement λ.

▶ Remark. The negotiation function satisfies the following properties.

- It is monotone: if $\lambda \leq \lambda'$ (for the pointwise order), then $\mathsf{nego}(\lambda) \leq \mathsf{nego}(\lambda')$.
- It is also non-decreasing: for every λ, we have $\lambda \leq \mathsf{nego}(\lambda)$.
- There exists a λ-rational strategy profile from v against the player controlling v if and only if $\mathsf{nego}(\lambda)(v) \neq +\infty$.

Link with SPEs. The SPE outcomes in a mean-payoff game are characterized by the fixed points of the negotiation function, or equivalently by its least fixed point. That result can be extended to ε-SPEs. To that end, we recall the notion of ε-fixed points of a function.

▶ **Definition 28** (ε-fixed point)**.** Let $\varepsilon \geq 0$, let D be a finite set and let $f : \overline{\mathbb{R}}^D \to \overline{\mathbb{R}}^D$ be a mapping. A tuple $\bar{x} \in \mathbb{R}^D$ is a *ε-fixed point* of f if for each $d \in D$, for $\bar{y} = f(\bar{x})$, we have $y_d \in [x_d - \varepsilon, x_d + \varepsilon]$.

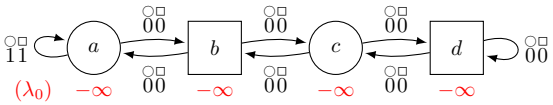
▶ Remark. A 0-fixed point is a fixed point, and conversely.

▶ **Lemma 29** ([3])**.** *Let $G_{\restriction v_0}$ be a mean-payoff game, and let $\varepsilon \geq 0$. The negotiation function on G has a least ε-fixed point λ^*, and given a play ρ in $G_{\restriction v_0}$, the three following assertions are equivalent: (1) the play ρ is an ε-SPE outcome; (2) the play ρ is λ-consistent for some ε-fixed point λ of the negotiation function; (3) the play ρ is λ^*-consistent.*

The abstract negotiation game. Given λ and $u \in V$, the quantity $\mathsf{nego}(\lambda)(u)$ can be characterized as the value of a *negotiation game*, a two-player zero-sum game opposing the player *Prover*, who simulates a λ-rational strategy profile and wants to minimize player i's payoff, and the player *Challenger*, who simulates player i's reaction by accepting or refusing Prover's proposals. Two negotiation games were defined in [3]. Conceptually simpler, the *abstract negotiation game* $\mathsf{Abs}_{\lambda i}(G)_{\restriction u}$ unfolds as follows:

- from the state v, Prover chooses a λ-consistent play ρ from the state v and proposes it to Challenger. If Prover has no play to propose, the game is over and Challenger gets the payoff $+\infty$.
- Once a play ρ has been proposed, Challenger can accept it. Or he can *deviate*, and choose a prefix $\rho_{\leq k}$ with $\rho_k \in V_i$ and a new transition $\rho_k w \in E$.
- In the former case, the game is over. In the latter, it starts again from the state w.

If Challenger finally accepts a proposal ρ, then his payoff is $\mu_i(\rho)$. If he deviates infinitely often, then Prover's proposals and his deviations construct a play $\dot{\pi} = \rho^{(0)}_{\leq k_0} \rho^{(1)}_{\leq k_1} \rho^{(2)}_{\leq k_2} \cdots$. Then, Challenger's payoff is $\mu_i(\dot{\pi})$. It has been proved in [3] that the equality $\mathsf{nego}(\lambda)(u) = \mathsf{val}_{\mathbb{C}}(\mathsf{Abs}_{\lambda i}(G)_{\restriction u})$ holds. Thus, the abstract negotiation game captures a first intuition on how the negotiation function can be computed.



(λ_0)	$-\infty$	$-\infty$	$-\infty$	$-\infty$
(λ_1)	1	0	0	0
(λ_2)	1	1	0	0
(λ_3)	1	1	1	0
(λ_4)	1	1	1	1

Figure 2 Iterations of the negotiation function.

▶ Example 30. Let G be the game of Figure 2, where each edge is labelled by the rewards $r_{\bigcirc}$ and $r_{\square}$. Below the states, we present the requirements $\lambda_0 : v \mapsto -\infty$, $\lambda_1 = \mathsf{nego}(\lambda_0)$, $\lambda_2 = \mathsf{nego}(\lambda_1)$, $\lambda_3 = \mathsf{nego}(\lambda_2)$, and $\lambda_4 = \mathsf{nego}(\lambda_3)$. Let us explicate those computations, using the abstract negotiation game. From λ_0 to λ_1: since every play is λ_0-consistent, Prover can always propose whatever she wants. From the state a, whatever she (trying to minimize player $\bigcirc$'s payoff) proposes, Challenger can always make player $\bigcirc$ deviate in order to loop on the state a. Then, in the game G, player $\bigcirc$ gets the payoff 1, hence $\lambda_1(a) = 1$. From the state b, Prover (trying to minimize player $\square$'s payoff) can propose the play $(bc)^\omega$. If Challenger makes player $\square$ deviate to go to the state a, then Prover can propose the play $a(bc)^\omega$. Even if Challenger makes player $\square$ deviate infinitely often, he cannot give him more than the payoff 0, hence $\lambda_1(b) = 0$. Similar situations happen from the states c and d, hence $\lambda_1(c) = \lambda_1(d) = 0$. From λ_1 to λ_2: now, from the state b, whatever Prover proposes at first, Challenger can make player $\square$ deviate and go to the state a. From there, since we have $\lambda_1(a) = 1$, Prover has to propose a play in which player $\bigcirc$ gets the payoff 1. The only such plays do also give the payoff 1 to player $\square$, hence $\lambda_2(b) = 1$. Similar situations explain $\lambda_3(c) = 1$, and $\lambda_4(c) = 1$. Finally, plays ending with the loop a^ω are all λ_4-consistent, hence Prover can always propose them, hence the requirement λ_4 is a fixed point of the negotiation function – and therefore the least. By Lemma 29, the SPE plays in G are exactly the plays in which both player $\bigcirc$ and player $\square$ get the payoff 1.

The concrete negotiation game. The abstract negotiation game cannot be directly used for an algorithmic purpose, since it has an infinite state space. However, it can be turned into a game on a finite graph if Prover does not propose plays as a whole, but edge by edge. In the *concrete negotiation game* $\mathsf{Conc}_{\lambda i}(G)_{\restriction (u,\{u\})}$, the states controlled by Prover have the form (v, M), where $M \subseteq V$ memorizes the states seen since the last time Challenger did deviate, in order to control that the play Prover is constructing since that moment is effectively λ-consistent: for each $u \in M$, Prover has to give to the player controlling u at least the payoff $\lambda(u)$. Similarly, the states controlled by Challenger are of the form (vv', M), where $vv' \in E$ is an edge proposed by Prover. The game unfolds as follows:

- from the state (v, M), Prover chooses a transition vv' and proposes it to Challenger.
- Once a transition vv' has been proposed, Challenger can accept it. Or, if $v \in V_i$, he can *deviate*, and choose a new transition vw.
- If the former case, the game starts again from the state $(v', M \cup \{v'\})$. In the latter, it starts from the state $(w, \{w\})$.

For every play $\pi = (\rho_0, M_0)(\rho_0\rho'_0, M_0)(\rho_1, M_1)(\rho_1\rho'_1, M_1)\dots$ in $\mathsf{Conc}_{\lambda i}(G)$, we write $\dot{\pi} = \rho_0\rho_1\dots$ the play in G constructed by Prover's proposals and Challenger's deviations. Then, Challenger's payoff in the play π is either $+\infty$ if there exists an index k such that the suffix $\pi_{\geq 2k}$ contains no deviation and $\dot{\pi}_{\geq k}$ is not λ-consistent, and $\mu_i(\dot{\pi})$ otherwise.

In [3], a first algorithm was proposed to solve the ε-SPE threshold problem, using the fact that in the concrete negotiation game, Challenger has a memoryless optimal strategy, to design a complete representation of the negotiation function, and to compute its least ε-fixed point. However, that algorithm requires doubly exponential time, because it needs to enumerate all the memoryless strategies available for Challenger, whose number is exponential in the size of the concrete game, itself exponential in the size of G. Here, we make use of the concrete negotiation game only to bound the size of the least ε-fixed point: our algorithm will use a third negotiation game, the *reduced negotiation game*.

4 Size of the least ε-fixed point

In this section, after having recalled some results about the sizes of solutions to linear equations and inequations, we prove that the least ε-fixed point of the negotiation function in a game G has a size that is polynomial in the size of G and ε. The first piece of the witnesses identifying positive instances of the ε-SPE threshold problem will then be an ε-fixed point of the negotiation function of polynomial size.

About size, equations and inequations. We define here the notion of size that we use.

▶ **Definition 31** (Size)**.** The *size* of a rational number $r = \frac{p}{q}$, where $p, q \in \mathbb{Z}$ are co-prime, is the quantity $\|r\| = 1 + \lceil \log_2(|p| + 1) \rceil + \lceil \log_2(|q| + 1) \rceil$. The size of an irrational number is $+\infty$. The size of the infinite numbers is $\|+\infty\| = \|-\infty\| = 1$. The size of a tuple $\bar{x} \in O^D$, where D is a set and O is a set of objects for which the notion of size has been defined, is the quantity $\mathsf{card} D + \sum_{d \in D} \|x_d\|$. Similarly, the size of a function $f : D \to X$ is the quantity $\mathsf{card} D + \sum_{d \in D} \|f(d)\|$, and the size of a set $X \subseteq O$ is the quantity $\mathsf{card} X + \sum_{x \in X} \|x\|$.

The proof of Theorem 37 below requires the manipulation of *polytopes*, e.g. downward sealings of convex hulls (from Lemma 15), expressed as solution sets of *systems of linear inequations*.

▶ **Definition 32** (Linear equations, inequations, systems)**.** Let D be a finite set. A *linear equation* in $\mathbb{R}^D$ is a pair $(\bar{a}, b) \in \left(\mathbb{R}^D \setminus \{\bar{0}\}\right) \times \mathbb{R}$. The *solution set* of the equation $(\bar{a}, b)$ is the set $\mathsf{Sol}_=(\bar{a}, b) = \{\bar{x} \in \mathbb{R}^D \mid \bar{a} \cdot \bar{x} = b\}$, where $\cdot$ denotes the canonical scalar product on the euclidian space $\mathbb{R}^D$. A set $X \subseteq \mathbb{R}^D$ is a *hyperplane* of $\mathbb{R}^D$ if it is the solution set of some linear equation. A *system of linear equations* is a finite set Σ of linear equations. The *solution set* of the system Σ is the set $\mathsf{Sol}_=\Sigma = \bigcap_{(\bar{a},b) \in \Sigma} \mathsf{Sol}_=(\bar{a}, b)$. A set $X \subseteq \mathbb{R}^D$ is a *linear subspace* of $\mathbb{R}^D$ if it is the solution set of some system of linear equations.

A *linear inequation* in $\mathbb{R}^D$ is a pair $(\bar{a}, b) \in \left(\mathbb{R}^D \setminus \{\bar{0}\}\right) \times \mathbb{R}$. The *solution set* of the inequation $(\bar{a}, b)$ is the set $\mathsf{Sol}_\geq(\bar{a}, b) = \{\bar{x} \in \mathbb{R}^D \mid \bar{a} \cdot \bar{x} \geq b\}$. A set $X \subseteq \mathbb{R}^D$ is a *half-space* of $\mathbb{R}^D$ if it is the solution set of some linear inequation. A *system of linear inequations* is a finite set Σ of linear inequations. The *solution set* of the system Σ is the set $\mathsf{Sol}_\geq\Sigma = \bigcap_{(\bar{a},b) \in \Sigma} \mathsf{Sol}_\geq(\bar{a}, b)$. A set $X \subseteq \mathbb{R}^D$ is a *polyhedron* of $\mathbb{R}^D$ if it is the solution set of some system of linear inequations Σ. A *vertex* of X is a point $\bar{x} \in \mathbb{R}^D$ such that $\{\bar{x}\} = \mathsf{Sol}_=(\Sigma')$ for some subset $\Sigma' \subseteq \Sigma$. A *polytope* is a bounded polyhedron.

▶ Remark. Polyhedra are closed sets. The polytopes of $\mathbb{R}^D$ are exactly the sets of the form $\mathsf{Conv}(S)$, where S is a finite subset of $\mathbb{R}^D$.

▶ **Lemma 33** ([13])**.** *Let Σ be a system of inequations, and let $X = \mathsf{Sol}_\geq(\Sigma)$. The set $\llcorner X$ is itself a polyhedron, and there exists a system of inequations Σ' such that $\llcorner X = \mathsf{Sol}_\geq(\Sigma')$ and that for every $(\bar{a}', b') \in \Sigma'$, there exists $(\bar{a}, b) \in \Sigma$ with $\|(\bar{a}', b')\| \leq \|(\bar{a}, b)\|$.*

▶ **Lemma 34** ([2], Theorem 1). *There exists a polynomial P_1 such that, for every system of equations Σ, there exists a point $\bar{x} \in \mathsf{Sol}_{=}\Sigma$, such that $\|\bar{x}\| \leq P_1\left(\max_{(\bar{a},b)\in\Sigma}\|(\bar{a},b)\|\right)$.*

▶ **Corollary 35.** *For every system of inequations Σ, each vertex $\bar{x}$ of the polyhedron $\mathsf{Sol}_{\geq}(\Sigma)$ has size $\|x\| \leq P_1\left(\max_{(\bar{a},b)\in\Sigma}\|(\bar{a},b)\|\right)$.*

Note that in Lemma 33, in Lemma 34 and in Corollary 35, the number of equations or inequations has no influence. A consequence of Lemma 34 is the following result.

▶ **Lemma 36.** *There exists a polynomial P_2 such that, for each finite set D and every finite subset $X \subseteq \mathbb{R}^D$, there exists a system of linear inequations Σ, such that $\mathsf{Sol}_{\geq}(\Sigma) = \mathsf{Conv}(X)$ and $\|(\bar{a},b)\| \leq P_2(\|X\|)$ for every $(\bar{a},b) \in \Sigma$.*

Size of the least ε-fixed point. The following theorem bounds the size of the least fixed point of the negotiation function. As we used the notation $\bar{x}$ for tuples so far, we use the notation $\bar{\bar{x}}$ for tuples of tuples.

▶ **Theorem 37.** *There exists a polynomial P_3 such that for every mean-payoff game G, the least ε-fixed point λ^* of the negotiation function has size $\|\lambda^*\| \leq P_3(\|G\| + \|\varepsilon\|)$.*

Proof sketch. It has been proved in [3] that Challenger has a memoryless optimal strategy in every concrete negotiation game. Given a requirement λ, a player i, a state $v \in V_i$ and a memoryless strategy $\tau_{\mathbb{C}}$, we can construct the set of payoff vectors $\mu(\dot{\pi})$, where π is a play in $\mathsf{Conc}_{\lambda i}(G)_{\restriction(v,\{v\})}$ compatible with $\tau_{\mathbb{C}}$, as a union of polytopes defined using Lemma 15. If we intersect the upward closures of those sets, then $\mathsf{nego}(\lambda)(v)$ is equal to the least value x_i, where $\bar{x}$ belongs to that intersection. Therefore, if $X_\lambda \subseteq \mathbb{R}^{V\times\Pi}$ is the product of those intersections, then for each i and $v \in V_i$, we have $\mathsf{nego}(\lambda) = \inf\{x_{vi} \mid \bar{\bar{x}} \in X_\lambda\}$.

To each tuple of tuples $\bar{\bar{x}} \in \mathbb{R}^{V\times\Pi}$, we associate the requirement $\lambda_{\bar{\bar{x}}}$ defined by $\lambda_{\bar{\bar{x}}}(v) = x_{vi} - \varepsilon$ for each $i \in \Pi$ and $v \in V_i$. Then, we define $X = \left\{\bar{\bar{x}} \;\middle|\; \bar{\bar{x}} \in X_{\lambda_{\bar{\bar{x}}}}\right\}$, and we show that any requirement λ is an ε-fixed point of the negotiation function if and only $\lambda = \lambda_{\bar{\bar{x}}}$ for some $\bar{\bar{x}} \in X$. Then, the set X is itself a union of polyhedra, hence the linear mapping $\bar{\bar{x}} \mapsto \sum_v \lambda_{\bar{\bar{x}}}(v)$ has its minimum over X on some vertex $\bar{\bar{x}}$ of one of those polyhedra. The requirement λ^* is equal to $\lambda_{\bar{\bar{x}}}$, hence its size can be bounded using Corollary 35. ◀

5 Constrained existence of a λ-consistent play

We claim that a non-deterministic algorithm can recognize the positive instances of the ε-SPE threshold problem by guessing an ε-fixed point λ of the negotiation function. Once λ has been guessed, according to Lemma 29, two assertions must be proved: on the one hand, that there exists a λ-consistent play between the two desired thresholds, and on the other hand, that λ is actually an ε-fixed point of the negotiation function. The latter will be handled later through the concept of *reduced negotiation game*. Now, we tackle the former, and provide the second piece of our notion of witness: to prove the existence of a λ-consistent play ρ with $\bar{x} \leq \mu(\rho) \leq \bar{y}$, we need to guess the sets $W = \mathsf{Inf}(\rho)$ and $W' = \mathsf{Occ}(\rho)$, and a tuple of tuples $\bar{\bar{\alpha}} \in [0,1]^{\Pi\times\mathsf{SC}(W)}$ indicating how ρ combines the cycles of W, i.e. such that:

$$\mu(\rho) = \left(\min_{j\in\Pi} \sum_{c\in\mathsf{SC}(W)} \alpha_{jc}\mathsf{MP}_i(c)\right)_i.$$

▶ **Theorem 38.** *There exists a polynomial P_4 such that for every mean-payoff game $G_{\restriction v_0}$, for every $\bar{x},\bar{y} \in \mathbb{R}^V$, and for every requirement λ on G, there exists a λ-consistent play ρ in $G_{\restriction v_0}$ satisfying $\bar{x} \leq \mu(\rho) \leq \bar{y}$ if and only if there exist two sets $W \subseteq W' \subseteq V$ and a tuple of tuples $\bar{\bar{\alpha}} \in [0,1]^{\Pi\times\mathsf{SC}(W)}$ such that:*

- *the set W is strongly connected in (V, E), and accessible from the state v_0 using only and all the states of W';*
- *for each player i, we have $\sum_c \alpha_{ic} = 1$, and:*

$$x_i \leq \min_{j\in\Pi} \sum_{c\in\mathsf{SC}(W)} \alpha_{jc}\mathsf{MP}_i(c) \leq y_i;$$

- *for each player i and $v \in W \cap V_i$, we have:*

$$\min_{j\in\Pi} \sum_{c\in\mathsf{SC}(W)} \alpha_{jc}\mathsf{MP}_i(c) \geq \lambda(v);$$

- $\|\bar{\bar{\alpha}}\| \leq P_4(\|G, \bar{x}, \bar{y}, \lambda\|)$.

Proof. Let us first notice that given a set $X \subseteq \mathbb{R}^\Pi$, the elements of the set $\llcorner(\mathsf{Conv}X)$ are exactly the tuples of the form:

$$\left(\min_{j\in\Pi} \sum_{x\in X} \alpha_{jx} x\right)_{i\in\Pi}$$

for some tuple $\bar{\bar{\alpha}} \in \mathbb{R}^{\Pi\times X}$ satisfying $\sum_x \alpha_{ix} = 1$ for each x.

Now, let us assume that W, W' and $\bar{\bar{\alpha}}$ exist. Then, there exists a play η with $\mathsf{Occ}(\eta) = \mathsf{Inf}(\eta) = W$ with payoff vector:

$$\mu(\eta) = \left(\min_{j\in\Pi} \sum_{x\in X} \alpha_{jx} x\right)_{i\in\Pi}.$$

Moreover, since W is accessible from v_0 using all and only the vertices of W', there exists a history $h\eta_0$ from v_0 to η_0 with $\mathsf{Occ}(h) = W'$. Then, the play $\rho = h\eta$ is λ-consistent and satisfies $\bar{x} \leq \mu(\rho) \leq \bar{y}$.

Conversely, if the play ρ exists: let $W = \mathsf{Inf}(\rho)$ and $W' = \mathsf{Occ}(\rho)$. The polytope:

$$Z = \left\{ \mu(\eta) \;\middle|\; \begin{array}{c} \eta \in \lambda\mathsf{Cons}(G_{\restriction v_0}), \\ \mathsf{Inf}(\eta) = W, \\ \mathsf{Occ}(\eta) = W', \\ \text{and } \bar{x} \leq \mu(\eta) \leq \bar{y} \end{array} \right\} = \left\{ \bar{z} \in \llcorner \left(\underset{c\in\mathsf{SC}(W)}{\mathsf{Conv}} \mathsf{MP}(c) \right) \;\middle|\; \begin{array}{c} \bar{x} \leq \bar{z} \leq \bar{y}, \text{ and} \\ \forall i, \forall v \in W' \cap V_i, z_i \geq \lambda(v) \end{array} \right\}$$

(the equality holds by Lemma 15) is nonempty (it contains at least $\mu(\rho)$). By Lemma 36, the set $\mathsf{Conv}_{c\in SC(W)}\mathsf{MP}(c)$ is defined by a system of inequations which all have size $\|(\bar{a}, b)\| \leq P_2\left(\max_c \|\mathsf{MP}(c)\|\right)$. Since by Lemma 33, the inequations defining $\llcorner\left(\mathsf{Conv}_{c\in SC(W)}\mathsf{MP}(c)\right)$ are not larger, there exists a polynomial P_6, independent of $G, \bar{x}, \bar{y}$ and λ, such that Z is defined by a system of inequations Σ such that for every $(\bar{a}, b) \in \Sigma$, we have $\|(\bar{a}, b)\| \leq P_6(\|(G, \bar{x}, \bar{y}, \lambda)\|)$. Therefore, by Corollary 35, the polytope Z admits a vertex $\bar{z}$ of size $\|\bar{z}\| \leq P_1(P_6(\|(G, \bar{x}, \bar{y}, \lambda)\|))$.

Then, since we have $\bar{z} \in \llcorner\left(\underset{c\in\mathsf{SC}(W)}{\mathsf{Conv}} \mathsf{MP}(c)\right)$, that vertex is, according to Definition 13, of the form:

$$\bar{z} = \left(\min_j \sum_c \alpha_{jc}\mathsf{MP}_j(c)\right)_i$$

for some tuple of tuples $\bar{\bar{\alpha}} \in [0,1]^{\Pi\times\mathsf{SC}(W)}$ with $\sum_c \alpha_{ic} = 1$ and having, by Corollary 35 again, size $\|\bar{\bar{\alpha}}\| \leq P_1\left(\max_{i\in\Pi} \sum_{c\in\mathsf{SC}(W)} \|\mathsf{MP}_i(c)\| + \|z_i\|\right)$, i.e. $\|\bar{\bar{\alpha}}\| \leq P_4(\|(G, \bar{x}, \bar{y}, \lambda)\|)$ for some polynomial P_4 independent of $G, \bar{x}, \bar{y}$ and λ. ◀

Now, we need the third piece of our witness, which will be evidence of the fact that the requirement λ is an ε-fixed point of the negotiation function.

6 The reduced negotiation game

The abstract negotiation game has an infinite (and uncountable) state space in general, and the concrete negotiation game has an exponential one. In [5], the infiniteness of the abstract negotiation game has been handled in the case of parity games, by proving that Prover has an optimal strategy that is memoryless, and that proposes only simple plays with a finite representation. Unfortunately, this result does not apply to mean-payoff games, where Prover needs infinite memory in general. That fact is illustrated in the next example.

▶ Example 39. In the game of Figure 3a, the requirement λ defined by $\lambda(a) = \lambda(b) = 1$ is a fixed point of the negotiation function (it is actually the least fixed point). Indeed, from the state a (the situation is symmetrical from the state b), consider the strategy for Prover that proposes always, from the state v, the play $vb^{|h|^2}(a^3b^3)^\omega$, where h is the history that has already been constructed by her proposals and Challenger's deviations. If Challenger accepts such a play, then he gets the payoff 1. If he deviates infinitely often, then Prover loops longer and longer on the state b, and he also gets the payoff 1. The loop on b corresponds to what we will call later a *punishing cycle*. Now, if Prover uses only finite memory, Challenger can get a payoff better than 1 by always deviating and go to b as soon as he can: then, edges giving to player ○ the reward 2 will occur with a nonzero frequency.

However, the plays proposed by Prover in the previous example are very similar: only the number of repetitions of the loop b does increase. More generally, one observes that Prover can play optimally while always proposing a play of the form $hc^n\rho$, where h, c and ρ are constant, and only the number n increases, quadratically with the time – so that Challenger's payoff is dominated by the mean-payoff $\mathsf{MP}_i(c)$ if he deviates infinitely often.

▶ **Definition 40** (Punishment family)**.** A *punishment family* is a set of plays of the form:

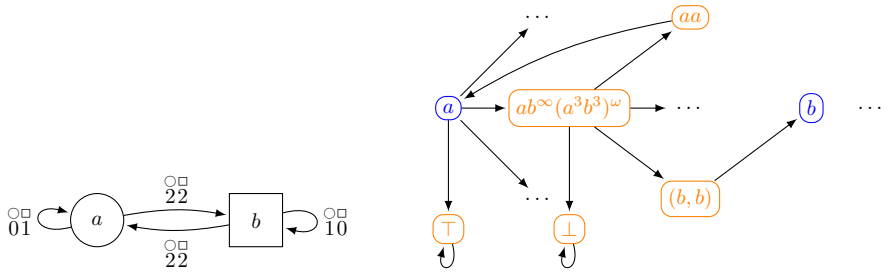
$$\{hc^n\rho \mid n > 0, \mu(\rho) = \bar{x}, \mathsf{Occ}(\rho) = W\}$$

where h is a simple history, c is a nonempty simple cycle, and where $W \subseteq V$ and $\bar{x} \in \mathbb{R}^\Pi$. The cycle c is called its *punishing cycle*. For every $\beta \in \mathbb{N}$, a *β-punishment family* is a punishment family with $\|\bar{x}\| \leq \beta$. A β-punishment family is represented by the data h, c, $\mu(\rho)$ and $\mathsf{Occ}(\rho)$, and that representation has a size smaller than or equal to the quantity $3\mathsf{card}V\lceil\log_2(\mathsf{card}V + 1)\rceil + \beta$.

We write $hc^\infty\rho$ for the punishment family $\{hc^n\rho' \mid n > 0, \mu(\rho') = \mu(\rho), \mathsf{Occ}(\rho') = \mathsf{Occ}(\rho)\}$. Beware that the play ρ matters only for its payoff vector and the vertices it traverses: if $\mathsf{Occ}(\rho) = \mathsf{Occ}(\rho')$ and $\mu(\rho) = \mu(\rho')$, then $hc^\infty\rho = hc^\infty\rho'$. We write $\mu(hc^\infty\rho)$ for the common payoff vector of all elements of $hc^\infty\rho$, and we will say that $hc^\infty\rho$ is λ-consistent if all its elements are (or equivalently, if one of its elements is). Let us clarify that a punishment family is not an equivalence class: for example, in the game of Figure 3a, the play ab^ω belongs to both $a^\infty b^\omega$ and $ab^\infty b^\omega$, which are distinct. We can now define the *reduced negotiation game*, where Prover proposes β-punishment families instead of plays.

▶ **Definition 41** (Reduced negotiation game)**.** Let G be a mean-payoff game, let λ be a requirement, let i be a player, let $v_0 \in V_i$ and let β be a natural integer. The corresponding *reduced negotiation game* is the game $\mathsf{Red}^\beta_{\lambda i}(G)_{\restriction v_0} = (\{\mathbb{P}, \mathbb{C}\}, S, (S_\mathbb{P}, S_\mathbb{C}), \Delta, \nu)_{\restriction v_0}$, where:

- the player $\mathbb{P}$ is called *Prover*, and the player $\mathbb{C}$ *Challenger*;
- the states controlled by Prover are the states of G, i.e. $S_\mathbb{P} = V$;
- the states controlled by Challenger are the states of the form $[hc^\infty\rho]$, (c, u) or $[h'v]$, where:



(a) The game G.

(b) The reduced negotiation game.

Figure 3 A game on which Prover needs infinite memory.

- $hc^\infty\rho$ is a λ-consistent β-punishment family,
- there exists a state $\rho_k \in V_i$ along the play ρ such that $\rho_k u \in E$,
- and $h'v$ is a history such that h' is a prefix of the history hc, and $\mathsf{last}(h') \in V_i$;

plus two additional states, written $\top$ and $\bot$;

- with the same notations, the set Δ contains the transitions of the form:
  - $v[hc^\infty\rho]$ (Prover proposes a punishment family);
  - $v\bot$ (Prover gives up);
  - $[hc^\infty\rho]\top$ (Challenger accepts Prover's proposal);
  - $[hc^\infty\rho][h'v]$ (Challenger deviates before the punishing cycle – *pre-cycle deviation*);
  - $[hc^\infty\rho](c,u)$ (Challenger deviates after the punishing cycle – *post-cycle deviation*);
  - $[h'v]v$ and $(c,u)u$ (Prover has now to propose a new play);
  - $\top\top$ and $\bot\bot$ (the play is over);
- given a history $H = H_0 \dots H_n \in \mathsf{HistRed}^\beta_{\lambda i}(G)$ that does not reach the state $\bot$, we write $\dot{H} = h^{(1)} \dots h^{(n)}$ the history or play in G defined by, for each k:
  - if $H_{k-1}H_k = v[hc^\infty\rho]$, then $h^{(k)}$ is empty;
  - if $H_{k-1}H_k = [hc^\infty\rho]\top$, then $h^{(k)} \dots h^{(n)} = hc^{\left|h^{(1)}\dots h^{(k-1)}h\right|^2}\rho$ (the number of times the cycle c is repeated depends quadratically on the time);
  - if $H_{k-1}H_k = [hc^\infty\rho][h'v]$, then $h^{(k)} = h'$;
  - if $H_{k-1}H_k = [hc^\infty\rho](c,v)$, then $h^{(k)} = hc^{\left|h^{(1)}\dots h^{(k-1)}h\right|^2}h'$, where h' is among the shortest histories such that $\mathsf{Occ}(h') \subseteq \mathsf{Occ}(\rho)$, $\mathsf{last}(h') \in V_i$ and $\mathsf{last}(h')v \in E$;
  - if $H_{k-1}H_k = [h'v]v$ or $(c,v)v$, then $h^{(k)}$ is empty;

  and that definition is naturally extended to plays: for example, if G is the game of Figure 3a and if $\pi = a[ab^\infty a^\omega][aa]a[ab^\infty a^\omega](b,b)b[b^\infty a^\omega]\top^\omega$, then $\dot{\pi} = a \cdot ab^{2^2} \cdot ab^{7^2}a^\omega = a^2b^4ab^{49}a^\omega$;
- the payoff function ν is defined, for each play π, by $\nu_{\mathbb{C}}(\pi) = -\nu_{\mathbb{P}}(\pi) = +\infty$ if π reaches the state $\bot$, and $\nu_{\mathbb{C}}(\pi) = -\nu_{\mathbb{P}}(\pi) = \mu_i(\dot{\pi})$ otherwise.

▶ Example 42. Figure 3b illustrates a (small) part of the game $\mathsf{Red}^2_{\lambda\bigcirc}(G)_{\restriction a}$, where G is the game of Figure 3a, and $\lambda(a) = \lambda(b) = 1$. Blue states are owned by Prover, orange ones by Challenger. When Prover proposes the punishment family $ab^\infty(a^3b^3)^\omega$, the function $\nu_{\mathbb{C}}$ interprets it as the play $ab^{|h|^2}(a^3b^3)^\omega$, where h is the history that has already been constructed so far.

▶ Remark. Reduced negotiation games are Borel, and are played on a finite graph.

Link with the negotiation function. We will now prove that the reduced negotiation game captures the negotiation function, as do the abstract and concrete ones. For that purpose, we first need the following key result.

▶ **Lemma 43.** *In a reduced negotiation game, Prover has a memoryless optimal strategy.*

Proof. This lemma is a consequence of Lemma 23: the payoff function $\nu_{\mathbb{C}}$ is concave. Indeed, let ξ be a shuffling of two plays π and χ. If either π or χ reaches the state $\bot$ (in which case both do), then we immediately have $\nu_{\mathbb{C}}(\dot{\xi}) \leq \max\{\nu_{\mathbb{C}}(\dot{\pi}), \nu_{\mathbb{C}}(\dot{\chi})\} = +\infty$. Otherwise, the play $\dot{\xi}$ is a shuffling of $\dot{\pi}$ and $\dot{\chi}$, and since mean-payoff objectives defined with a limit inferior are convex, we have $\nu_{\mathbb{C}}(\dot{\xi}) \leq \max\{\nu_{\mathbb{C}}(\dot{\pi}), \nu_{\mathbb{C}}(\dot{\chi})\}$. ◀

This lemma enables us to prove that the reduced negotiation game is equivalent to the other negotiation games.

▶ **Theorem 44.** *There exists a polynomial P_4 such that for every mean-payoff game G, every requirement λ with rational values, each player i and each $v_0 \in V_i$, for every $\beta \geq P_4(\|G\| + \|\lambda\|)$, we have* $\mathsf{nego}(\lambda)(v_0) = \mathsf{val}_{\mathbb{C}}\left(\mathsf{Red}^{\beta}_{\lambda_i}(G)_{\restriction v_0}\right)$.

Proof. For every mean-payoff game G and every requirement λ, we assume:

$$\beta \geq P_1\left(P_2\left(\|\{\mathsf{MP}(c) \mid c \in \mathsf{SC}(G)\}\|\right)\right)$$

and for each $v \in V$:

$$\beta \geq \|\lambda(v)\| + 3,$$

which are indeed quantities that are bounded by a polynomial of $\|G\| + \|\lambda\|$.

- *First direction:* $\mathsf{nego}(\lambda)(v_0) \geq \mathsf{val}_{\mathbb{C}}\left(\mathsf{Red}^{\beta}_{\lambda_i}(G)_{\restriction v_0}\right)$.
  Let $\bar{\sigma}_{-i}$ be a strategy profile in G that is λ-rational assuming a strategy σ_i, and let $x = \sup_{\sigma'_i} \mu_i(\langle \bar{\sigma}_{-i}, \sigma'_i \rangle)$. We wish to prove that there exists a strategy $\tau_{\mathbb{P}}$ in the reduced negotiation game such that $\sup_{\tau_{\mathbb{C}}} \nu_{\mathbb{C}}(\langle \bar{\tau} \rangle) \leq x$. Thus, we will have proved that the quantity $\mathsf{val}_{\mathbb{C}}\left(\mathsf{Red}^{\beta}_{\lambda_i}(G)_{\restriction v_0}\right)$ is smaller than or equal to every such x, and therefore smaller than or equal to $\mathsf{nego}(\lambda)(v_0)$.
  Let us define simultaneously the strategy $\tau_{\mathbb{P}}$ and a mapping $\varphi : \mathsf{Hist}_{\mathbb{P}}\mathsf{Red}^{\beta}_{\lambda_i}(G)_{\restriction v_0} \to \mathsf{Hist}G_{\restriction v_0}$, such that for each history H, the punishment family $\tau_{\mathbb{P}}(H)$ will be defined from the play $\langle \bar{\sigma}_{\restriction \varphi(H)} \rangle$. We guarantee inductively that if $H \in \mathsf{Hist}_{\mathbb{P}}\mathsf{Red}^{\beta}_{\lambda_i}(G)_{\restriction v_0}$ is compatible with $\tau_{\mathbb{P}}$, then $\varphi(H) \in \mathsf{Hist}G_{\restriction v_0}$ is compatible with $\bar{\sigma}_{-i}$. First, let us define $\varphi(v_0) = v_0$.
  Let $H \in \mathsf{Hist}_{\mathbb{P}}\mathsf{Red}^{\beta}_{\lambda_i}(G)_{\restriction v_0}$ be a history compatible with $\tau_{\mathbb{P}}$ as it has been defined so far, and such that $\varphi(H)$ has already been defined. Let $\eta^0 = \langle \bar{\sigma}_{\restriction \varphi(H)} \rangle$. By induction hypothesis, the history $\varphi(H)$ is compatible with $\bar{\sigma}_{-i}$, hence the play η^0 is λ-consistent, and satisfies $\mu_i(\eta^0) \leq x$.
  Let $\eta^0_{\leq \ell}$ be the shortest prefix of η^0 that is not simple, i.e. such that there exists $k < \ell$ with $\eta^0_k = \eta^0_\ell$. If $\mathsf{MP}_i\left(\eta^0_{k+1} \dots \eta^0_\ell\right) \leq x$, then we define $\tau_{\mathbb{P}}(H) = \left[\eta^0_{\leq k}\left(\eta^0_{k+1} \dots \eta^0_\ell\right)^{\infty} \rho\right]$, where ρ is a play such that $\mathsf{Occ}(\rho) = \mathsf{Occ}\left(\eta^0_{>\ell}\right)$, that $\mu_i(\rho) \leq x$, and that $\|\mu(\rho)\| \leq \beta$. Such a play exists, because the polytope:

$$Z = \left\{ \mu(\rho) \;\middle|\; \begin{array}{c} \forall j, \forall v \in V_j \cap \mathsf{Occ}(\eta^0), \mu_j(\rho) \geq \lambda(v), \\ \text{and } \mathsf{Occ}(\rho) = \mathsf{Occ}\left(\eta^0_{>\ell}\right) \end{array} \right\}$$

  is nonempty (it contains $\eta^0_{>\ell}$), and has at least one vertex $\bar{z}$ with $z_i \leq x$ (because $\mu_i(\eta^0_{>\ell}) \leq x$), which by Lemma 36 and Corollary 35 has size $\|\bar{z}\| \leq \beta$.

Otherwise, if $\mathsf{MP}_i\left(\eta^0_{k+1}\dots\eta^0_\ell\right) > x$, we define $\eta^1 = \eta^0_{\leq k}\eta^0_{>\ell}$, and we iterate the process, which does necessarily terminate – because $\mu_i(\eta^0) \leq x$. As a consequence, it effectively defines the proposal $\tau_{\mathbb{P}}(H) = \left[\eta^n_{\leq k}\left(\eta^n_{k+1}\dots\eta^n_\ell\right)^\infty\rho\right]$, for some n. Then, for each prefix hv, we define $\varphi\left(H\left[\eta^n_{\leq k}\left(\eta^n_{k+1}\dots\eta^n_\ell\right)^\infty\rho\right][hv]v\right) = \varphi(H)\eta^0_{\leq m}$, where $\eta^0_{\leq m}$ is the prefix of η^0 of which n simple cycles have been pulled out to obtain the prefix h of η^n; and similarly, for each pair (c,v), we define $\varphi\left(H\left[\eta^n_{\leq k}\left(\eta^n_{k+1}\dots\eta^n_\ell\right)^\infty\rho\right](c,v)v\right) = \varphi(H)\eta^0_{\leq m}$, where $\eta^0_{\leq m}$ is the prefix of η^0 from which n simple cycles have been pulled out to obtain the shortest prefix $\eta^n_{\leq p}$ of η^n such that $\eta^n_p \in V_i$ and $\eta^n_p v \in E$.

Thus, the mapping φ is defined on every history compatible with $\tau_{\mathbb{P}}$, and the image of such a history is always a history compatible with $\bar\sigma_{-i}$. We define it arbitrarily on other histories. Note that for each history H, the history $\dot H$ can be obtained from $\varphi(H)$ by pulling out cycles c satisfying $\mathsf{MP}_i(c) > x$, and adding cycles d with $\mathsf{MP}_i(d) \leq x$. As a consequence, if $\mathsf{MP}_i(\varphi(H)) \leq x$, then $\mathsf{MP}_i(\dot H) \leq x$ – and the same result is true when we naturally extend the mapping φ to plays.

Let us now prove that $\sup_{\tau_{\mathbb{C}}}\nu_{\mathbb{C}}(\langle\bar\tau\rangle) \leq \sup_{\sigma'_i}\mu_i(\langle\bar\sigma_{-i},\sigma'_i\rangle)$. Let π be a play compatible with $\tau_{\mathbb{P}}$:

- the state $\bot$ does not appear in π, because Prover's strategy does never use a transition to it.
- If π has the form $\pi = H[hc^\infty\rho]\top^\omega$: then, we have $\nu_{\mathbb{C}}(\pi) = \mu_i(\rho) \leq x$.
- If π is made of infinitely many deviations: the play $\varphi(\pi)$ is compatible with $\bar\sigma_{-i}$, hence $\mu_i(\varphi(\pi)) \leq x$; which implies $\mu_i(\dot\pi) \leq x$, i.e. $\nu_{\mathbb{C}}(\pi) \leq x$.

- *Second direction:* $\mathsf{nego}(\lambda)(v_0) \leq \mathsf{val}_{\mathbb{C}}\left(\mathsf{Red}^\beta_{\lambda i}(G)_{\restriction v_0}\right)$.

Let $\tau_{\mathbb{P}}$ be a memoryless strategy for Prover in the reduced negotiation game, and let $y = \sup_{\tau_{\mathbb{C}}}\nu_{\mathbb{C}}(\langle\bar\tau\rangle)$. We want to show that $\mathsf{nego}(\lambda)(v_0) \leq y$: by Lemma 43, it will be enough to conclude. If $y = +\infty$, it is clear. Let us assume that $y \neq +\infty$. Then, we will define a strategy profile $\bar\sigma$, where $\bar\sigma_{-i}$ is λ-rational assuming σ_i, such that $\sup_{\sigma'_i}\mu_i(\langle\bar\sigma_{-i},\sigma'_i\rangle) \leq y$: we proceed inductively by defining the play $\langle\bar\sigma_{\restriction hv}\rangle$ for each history hv compatible with $\bar\sigma_{-i}$ such that h is empty, or $\mathsf{last}(h) \in V_i$ and $v \neq \sigma_i(h)$. Such a history is called a *bud history*. After other histories, the strategy profile can be defined arbitrarily. To that end, we construct a mapping ψ which maps each bud history to a history $\psi(hv) \in \mathsf{Hist}_{\mathbb{P}}\mathsf{Red}^\beta_{\lambda i}(G)_{\restriction v_0}$ that is compatible with $\tau_{\mathbb{P}}$. This mapping will induce a definition of $\bar\sigma$: since $y \neq +\infty$, we have $\tau_{\mathbb{P}}(\psi(hv)) \neq \bot$: let then $[h'c^\infty\rho] = \tau_{\mathbb{P}}(\psi(hv))$. We then define $\langle\bar\sigma_{\restriction hv}\rangle = h'c^{|hh'|^2}\rho$, which is a λ-consistent play since $h'c^\infty\rho$ is a λ-consistent punishment family, by definition of the reduced negotiation game.

Let now h_0v be a bud history: we assume that $\bar\sigma$ has been defined on every prefix of h_0, but not on h_0v itself. If h_0 is empty, that is if $h_0v = v_0$, then we define $\psi(h_0v) = v_0$. Otherwise, let us write $h_0 = h_1wh_2$, where h_1w is the longest prefix of h_0 that is a bud history – that is, its longest prefix such that $\psi(h_1w)$ has been defined, or its shortest prefix such that wh_2 is compatible with $\bar\sigma_{\restriction h_1w}$. Let $H = \psi(h_1w)$, and let $[hc^\infty\rho] = \tau_{\mathbb{P}}(H)$. We have defined $\langle\bar\sigma_{\restriction h_1w}\rangle = hc^{|h_1h|^2}\rho$, and consequently, the history wh_2 is a prefix of that play. If it is a prefix of the history hc, then we define $\psi(h_0v) = H[hc^\infty\rho][wh_2v]v$. Otherwise, we define $\psi(h_0v) = H[hc^\infty\rho](c,v)v$.

Now, the strategy profile $\bar\sigma$ has been defined, and since all the punishment families proposed by Prover are λ-consistent, the strategy profile $\bar\sigma_{-i}$ is λ-rational assuming σ_i. Let η be a play compatible with $\bar\sigma_{-i}$, and let us prove that $\mu_i(\eta) \leq y$. If η has finitely many prefixes that are bud histories, then let $\eta_{\leq n}$ be the longest one: we have $\eta_{\geq n} = hc^{n+|h|}\rho$, where $[hc^\infty\rho] = \tau_{\mathbb{P}}(\psi(\eta_{\leq n}))$. Then, we have $\mu_i(\eta) = \mu_i(\rho) \leq y$.

Now, if η has infinitely many such prefixes, then there exists a unique play π in the reduced negotiation game such that for any prefix $\eta_{\leq n}$ of η that is a bud history, the history $\psi(\eta_{\leq n})$ is a prefix of π. Then, if π contains finitely many post-cycle deviations, then there exist two indices m and n such that $\eta_{\geq m} = \dot{\pi}_{\geq n}$, hence $\mu_i(\eta) = \mu_i(\dot{\pi}) \leq y$. Finally, if π contains infinitely many post-cycle deviations, i.e. infinitely many occurrences of a state of the form (c, v), then let us choose such state that minimizes the quantity $\mathsf{MP}_i(c)$. The play η has the form:

$$\eta = h_0 c^{k_0^2} h_1 c^{k_1^2} h_2 \dots,$$

where for each n, we have $k_n = \left| h_0 c^{k_0^2} \dots c^{k_{n-1}^2} h_n \right|$. Then, if we write $M = \max r_i$, we have:

$$\mathsf{MP}_i\left(h_0 c^{k_0^2} \dots h_n c^{k_n^2}\right) \leq \frac{1}{k_n + k_n^2|c| - 1}\left(k_n M + \left(k_n^2|c| - 1\right)\mathsf{MP}_i(c)\right),$$

which converges to $\mathsf{MP}_i(c)$ when n tends to $+\infty$, hence $\mu_i(\eta) \leq \mathsf{MP}_i(c)$. Now, since $\tau_{\mathbb{P}}$ is memoryless, there exists a play of the form HC^ω that is compatible with it, and such that $(c, v) \in \mathsf{Occ}(C) \subseteq \mathsf{Inf}(\pi)$; and by definition of y, we have $\mathsf{MP}_i(\dot{C}) = \nu_{\mathbb{C}}(HC^\omega) \leq y$. By minimality of $\mathsf{MP}_i(c)$, we have $\mathsf{MP}_i(\dot{C}) = \mathsf{MP}_i(c)$, hence $\mathsf{MP}_i(c) \leq y$, and therefore $\mu_i(\eta) \leq y$. ◀

Thus, a given requirement λ is an ε-fixed point of nego if and only if for each i and $v \in V_i$, there exists a memoryless strategy $\tau_{\mathbb{P}}$ in the game $\mathsf{Red}^\beta_{\lambda i}$, with $\beta = P_4(\|G\| + \|\lambda\|)$, such that $\sup_{\tau_{\mathbb{C}}} \nu_{\mathbb{C}}(\langle\bar{\tau}\rangle) \leq \lambda(v) + \varepsilon$. The reduced negotiation game has an exponential size, but it contains only $\mathsf{card} V$ states that are controlled by Prover: memoryless strategies for Prover are therefore objects of polynomial size. Thus, such memoryless strategies constitute the third and last piece of our notion of witness.

7 Algorithm and complexity

We are now in a position to define formally our notion of witness.

▶ **Definition 45** (Witness). Let $I = (G_{\restriction v_0}, \bar{x}, \bar{y}, \varepsilon)$ be an instance of the ε-SPE threshold problem. A *witness* for I is a tuple $\left(W, W', \bar{\bar{\alpha}}, \lambda, (\tau_{\mathbb{P}}^v)_v\right)$, where $W \subseteq W' \subseteq V$; $\bar{\bar{\alpha}} \in [0,1]^{\Pi \times \mathsf{SC}(W)}$; λ is a requirement; and each $\tau_{\mathbb{P}}^v$ is a memoryless strategy in the game $\mathsf{Red}^\beta_{\lambda i}(G)_{\restriction v}$, where $\beta = P_4(\|G\| + \|\lambda\|)$. A witness is *valid* if:

- each strategy $\tau_{\mathbb{P}}^v$ satisfies the inequality $\sup_{\tau_{\mathbb{C}}} \nu_{\mathbb{C}}(\langle \tau_{\mathbb{P}}^v, \tau_{\mathbb{C}}\rangle) \leq \lambda(v) + \varepsilon$;
- the sets W and W' and the tuple of tuples $\bar{\bar{\alpha}}$ satisfy the hypotheses of Theorem 38.

▶ Remark. The sets W and W', as well as the tuple of strategies $(\tau_{\mathbb{P}}^v)_v$, have polynomial size. In order to bound the size of witnesses by a polynomial, we only have to bound $\|\lambda\|$ and $\left\|\bar{\bar{\alpha}}\right\|$.

The ε-SPE threshold problem will be **NP**-easy if we show, first, that there exists a valid witness of polynomial size if and only if the instance is positive, and second, that the validity of a witness can be decided in polynomial time. The former is a consequence of Lemma 29, Theorem 37, Theorem 38, Theorem 44, and Lemma 43:

▶ **Lemma 46.** *There exists a polynomial P_5 such that an instance I of the ε-SPE threshold problem admits a valid witness of size $P_5(\|I\|)$ if and only if it is a positive instance.*

Let us now tackle the latter.

▶ **Lemma 47.** *Given an instance of the ε-SPE threshold problem and a witness for it, deciding whether that witness is valid is* **P***-easy.*

Proof. The validity of a witness is defined by two conditions. As regards the second one, all the hypotheses of Theorem 38 can be checked in polynomial time with classical algorithms. Let us now show how the first condition can also be checked in polynomial time.

Let $n = \mathsf{card} V$. Given a memoryless strategy $\tau_{\mathbb{P}}^v$ of Prover in a reduced negotiation game, one can construct in a time polynomial in $\|\tau_{\mathbb{P}}^v\|$ the graph $\mathsf{Red}_{\lambda i}^{\beta}(G)[\tau_{\mathbb{P}}^v]$, defined as the underlying graph of $\mathsf{Red}_{\lambda i}^{\beta}(G)$ where all the transitions that are not compatible with $\tau_{\mathbb{P}}^v$ have been omitted, as well as all the states that are, then, no longer accessible from the state v. That graph has indeed a polynomial size, because it is composed only of:

- at most n vertices of the form $w \in V$;
- at most n vertices of the form $\tau_{\mathbb{P}}(\cdot w)$ (either equal to $\bot$ or of the form $[hc^\infty\rho]$);
- at most n^2 vertices of the form (c, w);
- at most $2n^2$ vertices of the form $[h'w']$, where h' is a prefix of the history hc for some punishment family $[hc^\infty\rho] = \tau_{\mathbb{P}}(\cdot w)$;
- possibly the state $\top$.

We call this connected graph the *deviation graph*. Note that if among those vertices, there is the vertex $\bot$, then since the vertices that are not accessible have been removed, we have $\sup_{\tau_{\mathbb{C}}} \nu_{\mathbb{C}}(\langle\bar{\tau}\rangle) = +\infty$ and the problem can be solved immediately. In what follows, we assume that it is not the case, i.e. that for each w, the state $\tau_{\mathbb{P}}(\cdot w)$ has the form $[hc^\infty\rho]$. Deciding whether $\sup_{\tau_{\mathbb{C}}} \nu_{\mathbb{C}}(\langle\bar{\tau}\rangle) \leq \alpha$ is then equivalent to deciding whether there exists a path π, in that graph, such that $\nu_{\mathbb{C}}(\pi) > \alpha$. Such a play can have three forms.

- It can end in the state $\top$, i.e. with Challenger accepting Prover's proposal. The existence of such a play can be decided immediately, by checking whether in the deviation graph, there exists a vertex of the form $[hc^\infty\rho]$ with $\mu_i(hc^\infty\rho) > \alpha$.
- It can avoid the state $\top$, and comprise finitely many post-cycle deviations. This is the case if and only if there exists a cycle C in the deviation graph, without post-cycle deviations, such that $\mathsf{MP}_i(\dot{C}) > \alpha$. The existence of such a cycle can be decided in polynomial time with Karp's algorithm (see [17]).
- It can avoid the state $\top$, and comprise infinitely many post-cycle deviations. In that case, we have $\nu_{\mathbb{C}}(\pi) \leq \mathsf{MP}_i(c)$ for each state of the form (c, w) appearing infinitely often along π; then, there exists a cycle C in the deviation graph, such that every state of the form (c, w) along C satisfies $\mathsf{MP}_i(c) > \alpha$. Conversely, if such a cycle exists, then π exists. The existence of such a cycle can be decided in polynomial time with Karp's algorithm.

Therefore, the existence of such a play is decidable in polynomial time. ◀

Thus, given an instance of the ε-SPE threshold problem, a valid witness can be guessed and checked in polynomial time. Since the ε-SPE threshold problem has been proved to be **NP**-hard in [3], we finally obtain the following theorem:

▶ **Theorem 48.** *The ε-SPE threshold problem in mean-payoff games is* **NP***-complete.*

Abstract

In this paper, we look at good-for-games Rabin automata that recognise a Muller language (a language that is entirely characterised by the set of letters that appear infinitely often in each word). We establish that minimal such automata are exactly of the same size as the minimal memory required for winning Muller games that have this language as their winning condition. We show how to effectively construct such minimal automata. Finally, we establish that these automata can be exponentially more succinct than equivalent deterministic ones, thus proving as a consequence that chromatic memory for winning a Muller game can be exponentially larger than unconstrained memory.

1 Introduction

Games. Games, as considered in this work, are played by two antagonistic players, called the existential and universal players, who move a token around finite edge-coloured directed graphs. When the token lands on a position belonging to one of the players, this player moves it along an outgoing edge onto a new position. At the end of the day, the players have constructed an infinite path, called a play, and the winner is determined based on some language $\mathbb{W}$ of winning infinite sequences of colours, called the winning condition (we call $\mathbb{W}$-games the games which use the winning condition $\mathbb{W}$). Solving such games consists of deciding whether the existential player has a winning strategy, i.e. a way to guarantee, whatever the moves of the opponent are, that the play will end up in the winning condition. Solving infinite duration games is at the crux of many algorithms used in verification, synthesis, and automata theory [9, 19, 38, 30]. Difficulties in solving them are both theoretical and practical, and many questions pertaining to game resolution still remain unanswered.

Memory. Several parameters are relevant for solving a game: its size, of course, but also its winning condition and the complexity of winning strategies. A measure of this complexity is the memory used by a strategy. The simplest strategies are those that use no memory (positional strategies): decisions depend exclusively on the current position, and not on the past of the game. A strategy uses a finite amount of memory if the information that we need to retain from the past can be summarized by a finite state machine that processes the sequence of moves played in the game. In this case, the amount of memory used by the strategy is the number of states of this machine. Given a winning condition $\mathbb{W}$, a fundamental question is what is the minimal quantity m such that if the existential player wins a $\mathbb{W}$-game, there is a winning strategy using a memory of size m (we call m the memory requirements of $\mathbb{W}$). In addition to its size, a memory also has structure, which further elucidates the game dynamics. Understanding both the size and the structure of memories for $\mathbb{W}$ is a crucial step to design algorithms for solving $\mathbb{W}$-games.

Question A: Give a structural description of the optimal memory in $\mathbb{W}$-games.

Muller conditions. While there is a large zoo of winning conditions in the literature, here we are interested in ω-regular ones (described by finite state automata over infinite words), and, in particular, so called Muller conditions, for which the winner depends only on the colours that are seen infinitely often in the play. Memory requirements for Muller conditions have been studied in depth by Dziembowski, Jurdziński and Walukiewicz [15]. They provide a "formula" for computing the size of the minimal memory sufficient for winning in all games with a given Muller winning condition, based on the Zielonka tree [43], which describes the structure of a Muller condition. The Zielonka tree has also been used to characterise the memory requirements of Muller conditions when randomised strategies are allowed [21] and to provide minimal parity automata recognising a Muller condition [11]. This fundamental structure is also at the heart of our contribution.

Game reductions and good-for-gameness. When confronted with a $\mathbb{W}$-game, a standard solution is to reduce it to a game with a larger underlying graph, but a simpler winning condition. The typical way to do this (but not the only one) is to perform the composition of the game with a suitable automaton with another acceptance condition $\mathbb{W}'$ that accepts the language $\mathbb{W}$. The result is an $\mathbb{W}'$-game which has as size the product of the size of the original game and the size of the automaton. There is a subtlety here: not all automata can be used for this operation. For a non-deterministic automaton, this is in general incorrect, while using a deterministic automaton is always correct. So here, finding a minimal deterministic automaton for a given language improves the complexity of game resolution, and there is a large body of research in this direction (see [11, 26, 31] for Muller conditions, [1, 10, 41, 42] for minimisation of automata, and [32, 39, 36, 37, 40, 34, 31, 14, 29] for determinisation). However, some non-deterministic automata can also be used to perform this reduction. These are called good-for-games automata (GFG) [20, 12].

Some languages are known to be recognised by good-for-games automata that are exponentially more succinct than any equivalent deterministic automaton [27], and several lines of research concerning good-for-games automata are under study (how to decide "good-for-gameness" [3, 27, 4, 6], how expressive is "good-for-gameness" for pushdown automata [28, 18] what are good-for-games quantitative automata [5], etc). However, one key question that has not yet been addressed concerning good-for-games automata is how to design techniques as general as possible for building them. To the best of our knowledge, the only existing result in this direction is a polynomial-time algorithm to minimise co-Büchi GFG automata [1].

Question B: Provide general tools for constructing good-for-games automata.

In this paper, in the context of Muller conditions, we relate these two lines of study, and in particular give partial answers to the general questions A and B. Indeed, we show that the memory needed to win in L-games for a Muller language L coincides with the size of minimal GFG Rabin automata for L, and, in this sense, we give a structural description of the memory for Muller games, thus giving a refined answer to question A in this case. We also provide an optimal way to construct these minimal good-for-games automata, thus answering question B in the context of Muller conditions.

Contributions

1. We show that for all ω-regular languages L, the size (number of states) of a good-for-games Rabin-automaton for L is an upper bound on the memory that the existential player needs to implement winning strategies for L-games. This inequality is straightforward, but had not been stated explicitly prior to this work.
2. We establish that when L is a Muller language, the following two quantities are equal: the least size of a good-for-games Rabin-automaton for L and the least memory required for the existential player in all L-games in which she wins. Furthermore, we provide an efficient way to construct such a minimal automaton from the Zielonka tree of the condition [43]. This automaton can be seen, in a certain way, as a quotient of the minimal deterministic parity automaton for this language, as described in [11].
   Let us note that the least amount of memory needed to win a Muller game was described precisely by Dziembowski, Jurdziński and Walukiewicz [15]. We show here that the optimal strategy described in [15] can be implemented in a good-for-games Rabin-automaton. In combination with Item 1, this provides another proof of the upper bound in [15].
3. Finally, we provide a family of Muller languages such that the smallest GFG Rabin automata recognising it are of linear size in the number of letters, while equivalent deterministic Rabin automata grow exponentially. Note that the least size of a deterministic Rabin automaton for a Muller language L is known to coincide with the chromatic memory needed for winning L-games [10] (i.e. a memory that is updated based only on the letters seen, independently of the position in the game). The question of equivalence between chromatic memory and memory was asked by Kopcyński [23, 24], and an arbitrary difference between these two notions was established only recently by Casares [10]. Our new result, which is incomparable, shows that the chromatic memory can grow exponentially in the size of the alphabet, even when the general memory remains linear.

Together these three points develop techniques to solve Muller games in an optimal way by means of good-for-games Rabin automata reductions. The last point shows that an exponential gain can be achieved compared to using classical deterministic Rabin automata. Overall, our contribution supplements our understanding of Muller languages and highlights the – so far unexplored – fundamental role of GFG automata in the equation. Indeed, up to now GFG automata had mainly been studied for their succinctness, expressivity or algorithmic properties. Here, we shed light on a novel dimension of this automata class.

Related work. There is vast amount of literature on the memory requirements of different games. The first results in this direction where the proofs of the positionality of parity conditions and half-positionality of Rabin conditions [16, 22] and the finite-memory determinacy of Muller games [19]. The exact memory requirements of Muller conditions where characterised in [15]. In his PhD Thesis [23, 24], Kopczyński characterises several classes of

conditions that are half-positional, introduces the concept of chromatic memories (memories that are updated based only on colours seen) and provides an algorithm to decide the chromatic memory requirements of a winning condition. Conditions that are positional for both players over all graphs where characterised in [13] and those that are positional over finite graphs in [17]. More recently, these two results have been generalized to finite-memory conditions [8, 7]. The memory requirements have been proved to be different to the chromatic memory requirements in general [10], but conditions that are finite-memory determined are also chromatic-finite-memory determined [25].

Structure of this document. In Section 2, we describe the classical definitions related to our work such as games, automata and good-for-gamesness. In Section 3, we show why good-for-games Rabin automaton can be used as a memory structure for the existential player, the optimality of the construction for Muller conditions, and how to construct the least such automaton. In Section 4, we establish that this construction can be exponentially more succinct than deterministic Rabin automata. Section 5 concludes the paper.

2 Definitions

Notations. $|A|$ denotes the cardinality of a set A, $\mathcal{P}(A)$ its power set and $\mathcal{P}_+(A) = \mathcal{P}(A)\backslash\{\emptyset\}$. For a finite non-empty alphabet Σ, we write Σ^* and Σ^ω for the sets of finite and *infinite words* over Σ, respectively. The empty word is denoted by ε. Given $w = w_0w_1w_2\cdots \in \Sigma^\omega$, we denote $Inf(w) \subseteq \Sigma$ the set of letters that appear infinitely often in w. We let $w[i..j]$ be the finite word $w_iw_{i+1}...w_j$ if $i \leq j$, and ε if $j < i$.

We extend maps $\sigma : A \to B$ to A^* and A^ω component-wise and we denote these extensions by σ whenever no confusion arises. For a positive rational number $q \in \mathbb{Q}$ we denote by $\lfloor q \rfloor$ the greatest integer $n \in \mathbb{N}$ such that $n \leq q$.

2.1 Games and their memory

Games. We consider turn-based infinite duration games played between the existential and the universal player (referred to as *Exist* and *Univ*) over a directed graph. Formally, a Γ-coloured *game* is a tuple $\mathcal{G} = (V = V_E \uplus V_A, E, x_0, \mathbb{W})$, which consists of a set of vertices V partitioned into Exist's positions V_E and Univ's ones, V_A; a set of *transitions* (also called edges or moves) $E \subseteq V \times (\Gamma \cup \{\varepsilon\}) \times V$; an initial vertex $x_0 \in V$ and a subset $\mathbb{W} \subseteq \Gamma^\omega$ of winning sequences. We make the assumptions that there is at least one move from every position and that no cycle is labelled exclusively by ε. We will denote by $\gamma : E \to \Gamma \cup \{\varepsilon\}$ the function that assigns to each edge its colour. We write $Out(x)$ for the set of outgoing moves from x, that is, $Out(x) = \{e \in E \ : \ e = (x, c, x') \text{ for some } x' \in V, c \in \Gamma \cup \{\varepsilon\}\}$. If Γ is a game using the winning condition $\mathbb{W}$ we call it a $\mathbb{W}$-*game*.

Each player moves a pebble along an outgoing edge whenever it lands on a position belonging to that player, forming an infinite path $\pi \in E^\omega$ starting in x_0 called a *play*.

We denote $\gamma(\pi)$ sequence of colours labelling π omitting the ε labels (we remark that $\gamma(\pi) \in \Gamma^\omega$, since there are no cycles entirely labelled by ε). The play is *winning* for the existential player if $\gamma(\pi) \in \mathbb{W}$. A *partial play* is a finite path $\pi \in E^*$ in $\mathcal{G}$ starting in x_0. A *strategy for the existential player* is a function $\sigma\colon E^* \to E$ such that if a partial play π ends in a position $x \in V_E$, then $\sigma(\pi) \in Out(x)$. We say that a play π is *consistent with* the strategy σ if for every partial play π' that is a prefix of π ending in a position controlled by Exist, the next edge in π is $\sigma(\pi')$. The strategy σ is *winning* if every play consistent with σ is winning for the existential player. We say that the game $\mathcal{G}$ is *won by* the existential player

if that player has a winning strategy in $\mathcal{G}$. A strategy is *positional* if it can be represented by a function $\sigma\colon V_E \to E$ (that is, the choice of the next transition only depends on the current position, and not on the history of the path).

Winning conditions. We fix an alphabet Γ.

Muller. A *Muller condition* over the alphabet Γ is given by a family $\mathcal{F} \subseteq \mathcal{P}_+(\Gamma)$. A word $w \in \Gamma^\omega$ *satisfies the Muller condition* $\mathcal{F}$ if $Inf(w) \in \mathcal{F}$. The *language of the Muller condition* $\mathcal{L}_\mathcal{F} \subseteq \Gamma^\omega$ contains the ω-words that satisfy $\mathcal{F}$.

Rabin. A *Rabin condition* over the alphabet Γ is represented by a family of *Rabin pairs* $R = \{(G_1, R_1), \dots, (G_r, R_r)\}$, where $G_i, R_i \subseteq \Gamma$ and $G_i \cap R_i = \emptyset$. The Rabin pair j is said to be *green in* c if $c \in G_j$, to be *red in* c if $c \in R_j$, or to be *orange in* c if none of the previous occur. A word $w \in \Gamma^\omega$ *satisfies the Rabin condition* R if $Inf(w) \cap G_j \neq \emptyset$ and $Inf(w) \cap R_j = \emptyset$ for some index $j \in \{1, \dots, r\}$. Said differently, there is a Rabin pair j which is red in finitely many letters from w, and green for infinitely many letters of w. The *language of the Rabin condition* $\mathcal{L}_\mathcal{R} \subseteq \Gamma^\omega$ contains the ω-words that satisfy $\mathcal{R}$.

Parity. To define a *parity condition* we suppose that $\Gamma \subseteq \mathbb{N}$. A word $w \in \Gamma^\omega$ *satisfies the parity condition* if the maximum in $Inf(w)$ is even. The *language of the parity condition* contains the ω-words that satisfy it.

We say that a language $L \subseteq \Gamma^\omega$ is a *Muller language* if it is the language of some Muller condition $\mathcal{F}$. Equivalently, L is a Muller language if it can be described as a boolean combination of atomic propositions of the form "the letter "a" appears infinitely often" and their negations. Note that languages of Rabin conditions are languages of Muller conditions, and that languages of parity conditions are languages of Rabin conditions, but the converses do not hold. Given a Muller condition $\mathcal{F} \subseteq \mathcal{P}_+(\Gamma)$ and a subset $C \subseteq \Gamma$, we define the *restriction of* $\mathcal{F}$ *to* C as the Muller condition over C given by $\mathcal{F}|_C = \{A \subseteq C \,:\, A \in \mathcal{F}\}$.

Memory structures. A *memory structure for the game* $\mathcal{G}$ of moves E is a tuple $\mathcal{M} = (M, m_0, \mu, \sigma)$ where M is a *set of memory states*, $m_0 \in M$ is an *initial memory state*, $\mu : M \times E \to M$ is an *update function*, and $\sigma : M \times V_E \to E$ maps each position x owned by the existential player to a move from x. The *size* of $\mathcal{M}$ is the cardinal of M. We extend the function μ to paths by induction: $\mu(m, \varepsilon) = m$, and $\mu(m, \pi e) = \mu(\mu(m, \pi), e)$ for a path $\pi \cdot e \in E^*$. The memory structure $\mathcal{M}$ *induces a strategy* $\sigma_\mathcal{M}\colon E^* \to V_E$ given by $\sigma_\mathcal{M}(\pi) = \sigma(\mu(m_0, \pi), Last(\pi))$, where $Last(\pi)$ is the last position of the partial play π.

We say that $\mathcal{M}$ is a *chromatic memory structure* if there is a function $\mu_c\colon M \times (\Gamma \cup \{\varepsilon\}) \to M$ such that $\mu_c(m, \varepsilon) = m$ for every $m \in M$ and $\mu(m, e) = \mu_c(m, \gamma(e))$ for all edges $e \in E$.

The *memory requirements* of a winning condition $\mathbb{W}$ are defined as the least integer n such that if $\mathcal{G}$ is an $\mathbb{W}$-game won by the existential player, then she has a winning strategy given by a memory of size at most n. We denote this quantity by $\mathrm{mem}(\mathbb{W})$.

We say that a winning condition $\mathbb{W}$ is *exist-positional* (also called *half-positional*) if $\mathrm{mem}(\mathbb{W}) = 1$. Equivalently, $\mathbb{W}$ is exist-positional if Exist has a winning positional strategy whenever Exist has a winning strategy at all.

2.2 Automata and good-for-gameness

Automata. A *non-deterministic automaton* $\mathcal{A} = (Q, \Sigma, Q_0, \Delta, \Gamma, \mathbb{W})$ (or simply an *automaton*) consists of a finite set of *states* Q, an input alphabet Σ, a non-empty set of *initial states* $Q_0 \subseteq Q$, a *transition relation* $\Delta \subseteq Q \times \Sigma \times \Gamma \times Q$ and an *acceptance condition* $\mathbb{W} \subseteq \Gamma^\omega$. We will

write $\delta\colon Q \times \Sigma \to \mathcal{P}(Q)$ for the function $\delta(q,a) = \{q' \in Q \,:\, (q,a,c,q') \in \Delta \text{ for some } c \in \Gamma\}$. The *size* of the automaton, $|\mathcal{A}|$, is the number of its states. A *run of the automaton* over a word $a_0a_1a_2\cdots \in \Sigma^\omega$ is a sequence of transitions of the form:

$$\rho = (q_0,a_0,c_0,q_1)(q_1,a_1,c_1,q_2)\cdots \in \Delta^\omega, \text{ such that } q_0 \in Q_0 \text{ is an initial state.}$$

A run is *accepting* if $c_0c_1c_2\cdots \in \mathbb{W}$. If an accepting run over a word $w \in \Sigma^\omega$ exists, the automaton *accepts* w. The set of accepted words is the *language accepted by the automaton*, written $L(\mathcal{A})$. The automaton is *deterministic* if Q_0 is a singleton and Δ is such that for all states q and letter $a \in \Sigma$, there exists exactly one transition of the form (q,a,c,q'). In this case, for all words $w \in \Sigma^\omega$ there exists one and exactly one run of the automaton over w.

An automaton using an acceptance condition $\mathbb{W}$ (resp. an acceptance condition of type $X \in \{\text{Muller, Rabin, parity}\}$) is called an $\mathbb{W}$-*automaton* (resp. X-automaton).

Good-for-gameness. The automaton $\mathcal{A}$ is *good-for-games* (GFG) if there is a resolver for it, consisting of a choice of an initial state $r_0 \in Q_0$ and a function $r : \Sigma^* \times \Sigma \to \Delta$ such that for all words $w \in L(\mathcal{A})$, the run $t_0t_1... \in \Delta^\omega$, called the *run induced by* r and defined by $t_i = r(w[0..i-1], w[i])$, starts in r_0 and is an accepting run over w. In other words, r should be able to construct an accepting run in $\mathcal{A}$ letter-by-letter with only the knowledge of the word so far, for all words in $L(\mathcal{A})$.

2.3 The Zielonka tree of a Muller condition

A *tree* $T = (N, \sqsubseteq)$ is a nonempty finite set of *nodes* N equipped with an order relation $\sqsubseteq$ called the *ancestor relation* (x is an ancestor of y if $x \sqsubseteq y$), such that (1) there is a minimal node for $\sqsubseteq$, called *the root*, and (2) the ancestors of an element are totally ordered by $\sqsubseteq$. The converse relation is the *descendant* relation. Maximal nodes are called *leaves*, and the set of leaves of T is denoted by $Leaves(T)$. Given a node n of a tree T, the *subtree of* T *rooted at* n is the tree T restricted to the nodes that have n as ancestor. A node n' is a *child* of n if it is a minimal strict descendant of it. The set of children of n is written $Children_T(n)$. The *height* of a tree T is the maximal length of a chain for the ancestor relation. An A-*labelled tree* is a tree T together with a labelling function $\nu\colon N \to A$.

▶ **Definition 1** ([43]). *Let $\mathcal{F} \subseteq \mathcal{P}_+(\Gamma)$ be a Muller condition. A* Zielonka tree *for $\mathcal{F}$, denoted $\mathcal{Z}_\mathcal{F} = (N, \sqsubseteq, \nu : N \to \mathcal{P}_+(\Gamma))$ is a $\mathcal{P}_+(\Gamma)$-labelled tree with nodes partitioned into* round nodes *and* square nodes*, $N = N_\bigcirc \uplus N_\square$ such that:*

- *The root is labelled Γ.*
- *If a node is labelled $X \subseteq \Gamma$, with $X \in \mathcal{F}$, then it is a round node, and its children are labelled exactly with the maximal subsets $Y \subseteq X$ such that $Y \notin \mathcal{F}$.*
- *If a node is labelled $X \subseteq \Gamma$, with $X \notin \mathcal{F}$, then it is a square node, and its children are labelled exactly with the maximal subsets $Y \subseteq X$ such that $Y \in \mathcal{F}$.*

We remark that if n is a node of $\mathcal{Z}_\mathcal{F}$, then the subtree of $\mathcal{Z}_\mathcal{F}$ rooted at n is a Zielonka tree for $\mathcal{F}|_{\nu(n)}$, (the restriction of $\mathcal{F}$ to the label of n).

We equip trees with an order in order to navigate in them. An *ordered Zielonka tree* is a Zielonka tree for which the set of children of each node is equipped with a total order("from left to right"). The function $Next_n$ maps each child of n to its successor for this order, in a cyclic way. For each node $n \in N$ and each leaf l below n we define the set $Jump_n(l)$ containing a leaf l' if there are two children n_1, n_2 of n such that $n_1 \sqsubseteq l$, $n_2 \sqsubseteq l'$ and $n_2 = Next_n(n_1)$ (we remark that $n_1 = n_2$ if n has only one child). For $n = l$ we define $Jump_n(l) = \{l\}$. That

is, $l' \in Jump_n(l)$ if we can reach l' by the following procedure: we start at l, we go up the tree until finding the node n, we change to the next branch below n (in a cyclic way) and we re-descend to l'. From now on, we will suppose that all Zielonka trees are ordered, without explicitly mentionning it.

▶ **Example 2.** We will use the following Muller condition as a running example throughout the paper. Let $\Gamma = \{a, b, c\}$ and let $\mathcal{F}$ be the Muller condition defined by:

$$\mathcal{F} = \{\{a, b\}, \{a, c\}, \{b\}\}.$$

In Figure 1 we show the Zielonka tree for $\mathcal{F}$. We use Greek letters to name the nodes of the tree, N. We have that $Jump_\alpha(\delta) = \{\varepsilon, \zeta\}$ and $Jump_\gamma(\zeta) = \{\varepsilon\}$. The numbering of the branches will be used in Section 3.2.

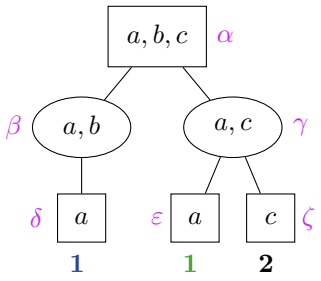

Figure 1 Zielonka tree $\mathcal{Z}_\mathcal{F}$ for $\mathcal{F} = \{\{a, b\}, \{a, c\}, \{b\}\}$.

▶ **Definition 3** ([15]). *Let T be a tree with nodes partitioned into round and square nodes, its* memory for the existential player *(*memory *for short), denoted* mem-tree(T)*, is defined inductively as:*

- 1 *if T has exactly one node.*
- *The sum of the memories of the subtrees of T rooted at the children of the root, if the root is round.*
- *The maximum of the memories of the subtrees of T rooted at the children of the root, if the root is square.*

For instance, for the Zielonka tree from Example 2, mem-tree$(\mathcal{Z}_\mathcal{F}) = 2$.

The key result justifying the introduction of this notion is that it characterises precisely the quantity of memory required for winning an $\mathcal{F}$-game, as shown by the next proposition.

▶ **Proposition 4** ([15]). *For all Muller conditions $\mathcal{F}$,* mem$(\mathcal{F})$ = mem-tree$(\mathcal{Z}_\mathcal{F})$.

3 GFG Rabin automata correspond to memory structures for Muller games

In this section, we prove the following result:

▶ **Theorem 5.** *Let L be a Muller language. The memory requirements for L coincide with the size of a minimal GFG Rabin automaton recognising L.*

In Section 3.1 we show the first direction: the size of a GFG Rabin automaton for a Muller language L is always an upper bound on the memory required by the existential player on L-games. In Section 3.2, we show how to construct a GFG Rabin automaton from

the Zielonka tree of a Muller condition of size mem-tree($\mathcal{Z}_L$) = mem(L), completing the equivalence. Moreover, we can build this minimal GFG Rabin automaton in polynomial time given the Zielonka tree of the Muller condition.

3.1 A GFG Rabin automaton induces a memory structure for any game

In this section, we establish Corollary 10 which states that the size of a GFG Rabin automaton $\mathcal{A}$ accepting a Muller language L is an upper bound on the memory required for winning all L-games. Concretely, given an L-game won by the existential player, we are able to construct a memory structure inducing a winning strategy based on $\mathcal{A}$. The argument is standard: we construct the product game of $\mathcal{A}$ and the L-game, which is a Rabin game in which the existential player enjoys a positional winning strategy; then we use the $\mathcal{A}$-component of this product as a memory structure for a strategy in the original L-game.

▶ **Lemma 6.** *Let $\mathcal{A} = (Q, \Sigma, Q_0, \Delta, \Gamma, \mathbb{W})$ be a GFG $\mathbb{W}$-automaton recognising a language $L \subseteq \Sigma^\omega$, with $\mathbb{W}$ exist-positional. Then if $\mathcal{G}$ is an L-game won by Exist, she can win it using a strategy given by a memory structure $\mathcal{M} = (Q, r_0, \mu, \sigma)$.*

Proof. Let $\mathcal{G} = (V = V_E \uplus V_A, E, x_0, L)$ and $\mathcal{A} = (Q, \Sigma, r_0, \Delta, \Gamma, \mathbb{W})$, where $r_0 \in Q_0$ is the initial state chosen by some resolver. We consider the product $\mathbb{W}$-game $\mathcal{G}'$ in which:

- Positions are elements in $V' = (V \times Q) \cup (V \times \Gamma \times \mathcal{P}(Q))$. The initial position is (x_0, r_0).
- Exist's positions are $V'_E = (V_E \times Q) \cup (V \times \Gamma \times \mathcal{P}(Q))$.
- There is an ε-coloured edge from (x, q) to $(x', c, \delta(q, c))$ if $(x, c, x') \in E$, $c \neq \varepsilon$, and to (x', q) if $(x, \varepsilon, x') \in E$.
- There is a c-labelled edge from (x, c, S) to (x, q') for all $q' \in S \subseteq Q$.
- The winning condition is $\mathbb{W}$.

In short, in this game the players still negotiate a play in G, but in addition, the existential player must simultaneously build an accepting run on the labelling of this play in $\mathcal{A}$.

If $\mathcal{A}$ is GFG then whenever the existential player wins in $\mathcal{G}$, she also wins in $\mathcal{G}'$ [20, Theorem 3] by playing a winning strategy on the $\mathcal{G}$ component of $\mathcal{G}'$ and using the resolver for $\mathcal{A}$ to choose the successor state in the $\mathcal{A}$ component.

This strategy is not necessarily positional. However, since $\mathbb{W}$ is exist-positional, the existential player also has a positional strategy $s : V'_E \to E'$. We can now build a memory structure $\mathcal{M}_s = (Q, r_0, \mu, \sigma)$ that projects the strategy s onto $\mathcal{G}$ (and updates itself with the projection of s onto $\mathcal{A}$):

- $\mu(q, e) = q$ if e is an ε-coloured move of $\mathcal{G}$ and
- $\mu(q, (x, c, x')) = q'$ where $q' = s(x', c, \delta(q, c))$ otherwise;
- $\sigma(q, x) = s(x, q)$.

Since s is a winning strategy in $\mathcal{G}'$, its projection onto $\mathcal{G}$ is a strategy that only agrees with plays with labels in $L(\mathcal{A})$, that is, winning plays. ◀

▶ Remark 7. Note that there is a slight subtlety here: the resolver, which induces a winning strategy in the product game, does not need to be positional. In fact, it might require exponential memory [27, Theorem 1]. Yet, for each L-game, a memory based on $\mathcal{A}$ suffices.

▶ **Lemma 8** ([22, 43])**.** *Rabin conditions are exist-positional.*

As a direct consequence we obtain the following Proposition.

▶ **Proposition 9.** *Let L be a Muller language accepted by a GFG Rabin automaton $\mathcal{A}$. Then, in every L-game $\mathcal{G}$ won by the existential player, she can win using a strategy given by a memory structure of size $|\mathcal{A}|$.*

▶ **Corollary 10.** *If $\mathcal{A}$ is a GFG Rabin automaton accepting a Muller language L, then* $\mathrm{mem}(L) \leqslant |\mathcal{A}|$.

3.2 An optimal construction of a GFG Rabin automaton

So far, we have seen that given a GFG Rabin automaton, it can serve as a memory structure for the games of which it accepts the winning condition. In this section we do the converse: we build a minimal GFG Rabin automaton for a Muller language L of the same size as the minimal memory required to win in L-games.

3.2.1 The construction

▶ **Proposition 11.** *Let $\mathcal{F} \subseteq \mathcal{P}_+(\Gamma)$ be a Muller condition. There exists a GFG Rabin automaton recognising $\mathcal{L}_\mathcal{F}$ of size* $\mathrm{mem}(\mathcal{F})$.

To prove Propositon 11, we build a GFG Rabin automaton $\mathcal{R}_\mathcal{F} = (Q, \Gamma, q_0, \Delta, \Gamma', R)$ for $\mathcal{L}_\mathcal{F}$ based on the Zielonka tree $\mathcal{Z}_\mathcal{F}$, as illustrated in Figure 2. We use a mapping from the leaves of $\mathcal{Z}_\mathcal{F}$ to the states of the automaton that guarantees that two leaves of which the last common ancestor is a round node cannot map to the same state. The number of states required to satisfy this condition ($\star$ below) coincides with mem-tree($\mathcal{Z}_\mathcal{F}$). Then, for each leaf of $\mathcal{Z}_\mathcal{F}$ and letter $c \in \Gamma$, we identify its last ancestor n in $\mathcal{Z}_\mathcal{F}$ containing c, and, using the $Jump_n$ function (defined in Section 2.3), pick a leaf below the next child of n. We add a c-transition with label n between the states mapped to from these leaves. This way, we can identify a run in the automaton with a promenade through the nodes of the Zielonka tree. If during this promenade a unique minimal node (for $\sqsubseteq$) is visited infinitely often, it is not difficult to see that the sequence of input colours belongs to $\mathcal{F}$ if and only if the label of this minimal node is an accepting set (it is a round node). We devise a Rabin condition over the set of nodes of the Zielonka tree accepting exactly these sequences of nodes.

We now describe the construction of the automaton $\mathcal{R}_\mathcal{F} = (Q, \Gamma, q_0, \Delta, N, R)$ formally, starting from the Zielonka tree $\mathcal{Z}_\mathcal{F} = (N, \sqsubseteq, \nu : N \to \mathcal{P}_+(\Gamma))$, and then proceed to prove its correctness.

States. First, we set $Q = \{1, 2, \ldots, \text{mem-tree}(\mathcal{Z}_\mathcal{F})\}$ and we label the leaves of $\mathcal{Z}_\mathcal{F}$ by a mapping $\eta : \mathit{Leaves}(\mathcal{Z}_\mathcal{F}) \to \{1, 2, \ldots, \text{mem-tree}(\mathcal{Z}_\mathcal{F})\}$ verifying the property:

> If $n \in \mathcal{Z}_\mathcal{F}$ is a round node with children $n_1 \neq n_2$, for any pair of leaves l_1 and l_2 below n_1 and n_2, respectively, $\eta(l_1) \neq \eta(l_2)$. ($\star$)

▶ **Lemma 12.** *For every Zielonka tree $\mathcal{Z}_\mathcal{F}$ there is a mapping verifying Property $\star$ of the form $\eta : \mathit{Leaves}(\mathcal{Z}_\mathcal{F}) \to \{1, 2, \ldots, \text{mem-tree}(\mathcal{Z}_\mathcal{F})\}$.*

Proof. We prove it by induction in the height of $\mathcal{Z}_\mathcal{F}$. Let $n_1, \ldots, n_k$ be the children of the root of $\mathcal{Z}_\mathcal{F}$. We write $\mathcal{F}_i$ to denote the Muller condition restricted to $\nu(n_i)$ and $\eta_i : \mathit{Leaves}(\mathcal{Z}_{\mathcal{F}_i}) \to \{1, 2, \ldots, \text{mem-tree}(\mathcal{Z}_{\mathcal{F}_i})\}$ be a labelling verifying Property $\star$, for $1 \leq i \leq k$. We distinguish two cases according to the shape of the root.

If the root of $\mathcal{Z}_\mathcal{F}$ is a square node ($\Gamma \notin \mathcal{F}$), then the mapping $\eta(l) = \eta_i(l)$ if the leaf l belongs to the subtree $\mathcal{Z}_{\mathcal{F}_i}$ verifies Property $\star$.

If the root of $\mathcal{Z}_\mathcal{F}$ is a round node ($\Gamma \in \mathcal{F}$), then mem-tree$(\mathcal{Z}_\mathcal{F}) = \sum_{i=1}^{k}$ mem-tree$(\mathcal{Z}_{\mathcal{F}_i})$, and we can partition $\{1, 2, \ldots,$ mem-tree$(\mathcal{Z}_\mathcal{F})\}$ into disjoint sets $C_1, \ldots, C_k$ of size $|C_i| =$ mem-tree$(\mathcal{Z}_{\mathcal{F}_i})$. We write σ_i for a bijection from $\{1, \ldots,$ mem-tree$(\mathcal{Z}_{\mathcal{F}_i})\}$ to C_i. Then, the mapping $\eta(l) = \sigma_i(\eta_i(l))$, if the leaf l belongs to the subtree $\mathcal{Z}_{\mathcal{F}_i}$ verifies Property $\star$. ◀

We suppose that the image of the leftmost leaf under η is 1 and choose the initial state q_0 to be 1. In Example 2, the labelling $\eta(\delta) = \eta(\varepsilon) = 1$, $\eta(\zeta) = 2$ verifies Property $\star$.

Transitions. For each leaf $l \in \mathit{Leaves}(\mathcal{Z}_\mathcal{F})$ and each letter $c \in \Gamma$, we define a c-transition from $\eta(l)$, with an output label from $\Gamma' = N$, as follows: let n be the maximal ancestor of l that contains the letter c in its label and let l' be the leftmost leaf in $\mathit{Jump}_n(l)$[1]. Then, $(\eta(l), c, n, \eta(l')) \in \Delta$. That is, if we are in a state $\eta(l)$, when we read the letter $c \in \Gamma$ we can choose to go up in the Zielonka tree from l until visiting a node n with c in its label. We produce the letter n as output, then we change to the next child of n (in a cyclic way) and we descend to the leftmost leaf below it. The destination is the η-label of this leaf[2].

Following the above definition, we obtain a mapping from transitions in the automaton to $\mathit{Leaves}(\mathcal{Z}_\mathcal{F}) \times \Gamma \times N \times \mathit{Leaves}(\mathcal{Z}_\mathcal{F})$. We say that l and l' are the leaves *corresponding to* the transition (q, a, n, q') if this transition is sent to (l, a, n, l') by this mapping. The node n produced as output is the last common ancestor of l and l'. The automaton obtained in this way might present multiple transitions labelled by the same input letter between two states. We will show in Proposition 18 that duplicated transitions can be removed.

Acceptance condition. We define a Rabin condition over the alphabet $\Gamma' = N$, that is the set of nodes of the Zielonka tree. We define a Rabin pair for each round node of $\mathcal{Z}_\mathcal{F}$ (that is, nodes whose label is an accepting set of letters for $\mathcal{F}$): $R = \{(G_n, R_n)\}_{n \in N_\bigcirc}$. Let n be a round node and n' be a general node of $\mathcal{Z}_\mathcal{F}$:

$$\begin{cases} n' \in G_n & \text{if } n' = n, \\ n' \in R_n & \text{if } n' \neq n \text{ and } n \text{ is not an ancestor of } n'. \end{cases}$$

That is, for the letter n', the Rabin pairs corresponding to round ancestors of n' are not affected by it (they are "orange in n'"). If this node n' is round, then it belongs to $G_{n'}$ (this pair is "green in n'"). For any other node $n \in N_\bigcirc$, we have $n' \in R_n$ (the pair is "red in n'").

▶ Remark 13. The construction presented depends on the order of the nodes of the Zielonka tree. However, the size of the resulting automaton is independent of this order.

▶ **Example 14.** Let $\mathcal{F} = \{\{a, b\}, \{a, c\}, \{b\}\}$ be the Muller condition from Example 2. The labelling of the leaves of the Zielonka tree given by $\eta(\delta) = \eta(\varepsilon) = 1$, $\eta(\zeta) = 2$ verifies Property $\star$. Figure 2 shows the GFG Rabin automaton obtained by following this procedure.

The Rabin condition of this automaton is given by two Rabin pairs (corresponding to the round nodes of the Zielonka tree in Figure 1):

$$G_\beta = \{\beta\}, \quad R_\beta = \{\alpha, \gamma, \varepsilon, \zeta\},$$
$$G_\gamma = \{\gamma\}, \quad R_\gamma = \{\alpha, \beta, \delta\}.$$

[1] We could add all transitions $\{(\eta(l), n, \eta(l')) : l' \in \mathit{Jump}_n(l)\}$ to Δ. However, a resolver for the GFG automaton just needs to make use of one of these transitions, so in order to simplify the automaton we make an arbitrary choice (the leftmost leaf).

[2] We remark that l' is the target of the transition of the Zielonka tree parity automaton from l reading letter "c" [11]. See also Section 3.2.3.

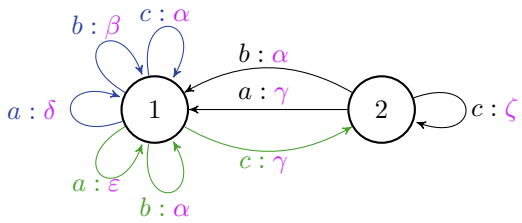

Figure 2 The GFG Rabin automaton obtained from the Zielonka tree $\mathcal{Z}_{\mathcal{F}}$.

3.2.2 Proof of correctness

▶ **Lemma 15.** *Let $w = n_0 n_1 n_2 \cdots \in N^\omega$ be an infinite sequence of nodes of the Zielonka tree. The word w satisfies the Rabin condition defined above if and only if there is a unique minimal node for the ancestor relation in $Inf(w)$ and this minimal node is round (recall that the root is the minimal element in $\mathcal{Z}_{\mathcal{F}}$).*

Proof. Suppose that there is a unique minimal node in $Inf(w)$, called n, and that n is round. We claim that w is accepted by the Rabin pair (G_n, R_n). It is clear that $Inf(w) \cap G_n \neq \emptyset$, because $n \in G_n$. It suffices to show that $Inf(w) \cap R_n = \emptyset$: By minimality, any other node $n' \in Inf(w)$ is a descendant of n (equivalently, n is an ancestor of n'), so $n' \notin R_n$.

Conversely, suppose that $w \in N^\omega$ satisfies the Rabin condition. Then, there is some round node $n \in N_\bigcirc$ such that $Inf(w) \cap G_n \neq \emptyset$ and $Inf(w) \cap R_n = \emptyset$. Since $G_n = \{n\}$, we deduce that $n \in Inf(w)$. Moreover, as $Inf(w) \cap R_n = \emptyset$, all nodes in $Inf(w)$ are descendants of n. We conclude that n is the unique minimal node in $Inf(w)$, and it is round. ◀

▶ **Lemma 16.** *The automaton $\mathcal{R}_{\mathcal{F}}$ recognises the language $\mathcal{L}_{\mathcal{F}}$ and is good-for-games.*

Proof. $\mathcal{L}(\mathcal{R}_{\mathcal{F}}) \subseteq \mathcal{L}_{\mathcal{F}}$: Let $u \in \mathcal{L}(\mathcal{R}_{\mathcal{F}})$ and let $w \in N^\omega$ be the sequence of nodes produced as output of an accepting run over u in $\mathcal{R}_{\mathcal{F}}$. By Lemma 15, there is a unique minimal node n for $\sqsubseteq$ appearing infinitely often in w and moreover n is round. Let $n_1, \ldots, n_k$ be an enumeration of the children of n (from left to right), with labels $\nu(n_i) \subseteq \Gamma$ (we remark that $\nu(n_i) \notin \mathcal{F}$, for $1 \leq i \leq k$). We will prove that $Inf(u) \subseteq \nu(n)$ and $Inf(u) \not\subseteq \nu(n_i)$ for $1 \leq i \leq k$. By definition of the Zielonka tree, as n is round, this implies that $Inf(u) \in \mathcal{F}$.

Since eventually all nodes produced as output are descendants of n (by minimality), $Inf(u)$ must be contained in $\nu(n)$ (by definition of the transitions of $\mathcal{R}_{\mathcal{F}}$).

We suppose, towards a contradiction, that $Inf(u) \subseteq \nu(n_j)$ for some $1 \leq j \leq k$. Let $Q_i = \{\eta(l) \,:\, l \text{ is a leaf below } n_i\}$ be the set of states corresponding to leaves under n_i, for $1 \leq i \leq k$. We can suppose that the leaves corresponding to transitions of an accepting run over u are all below n, and therefore, transitions of such a run only visit states in $\bigcup_{i=1}^{k} Q_i$. Indeed, eventually this is going to be the case, because if some of the leaves l, l' corresponding to a transition (q, a, n', q') are not below n, then n' would not be a descendant of n (since n' is the least common ancestor of l and l'). Also, by Property $\star$, we have $Q_i \cap Q_j = \emptyset$, for all $i \neq j$. By definition of the transitions of $\mathcal{R}_{\mathcal{F}}$, if $c \in \Gamma$ is a colour in $\nu(n)$ but not in $\nu(n_i)$, all transitions from some state in Q_i reading the colour c go to Q_{i+1}, for $1 \leq i \leq k-1$ (and to Q_1 if $i = k$). Also, if $c \in \nu(n_i)$, transitions from states in Q_i reading c stay in Q_i. We deduce that a run over u will eventually only visit states in Q_j, for some j such that $Inf(u) \subseteq \nu(n_j)$. However, the only transitions from Q_j that would produce n as output are those corresponding to a colour $c \notin \nu(n_j)$, so the node n is not produced infinitely often, a contradiction.

$\mathcal{L}_\mathcal{F} \subseteq \mathcal{L}(\mathcal{R}_\mathcal{F})$ and good-for-gameness: We will describe a strategy for a resolver in $\mathcal{R}_\mathcal{F}$ using as memory the set of leaves of the Zielonka tree[3]. It will verify at every step that if the memory is on the leaf l, then $\mathcal{R}_\mathcal{F}$ is on the state $\eta(l)$. The initial state of the memory is the leftmost leaf of $\mathcal{Z}_\mathcal{F}$. If we are on the memory state l and the letter $c \in \Gamma$ is read, we take the transition $(\eta(l), c, n, \eta(l')) \in \Delta$, where n is the maximal ancestor of l such that $c \in \nu(n)$ and l' is the leftmost leaf in $Jump_n(l)$; the memory state is updated to l'. Let us suppose that a word $u \in \mathcal{L}_\mathcal{F}$ is given as input to the automaton. We will see that the run produced by this strategy is accepting. We can suppose that the only colours appearing in u are those of $Inf(u)$. Let n be the leftmost $\sqsubseteq$-maximal node such that $Inf(u) \subseteq \nu(n)$. Since $Inf(u) \in \mathcal{F}$, n is a round node. We will prove that the run produced by the resolver above only produces nodes that are descendants of n (including n) infinitely often and that it produces n infinitely often and is therefore accepting. Let $n_1, \dots, n_k$ be the children of n from left to right, and let $L_1, \dots, L_k$ be the (disjoint) sets of leaves below them, respectively. By the definition of the transitions and the strategy, the memory will eventually only consider leaves in $\bigcup_{i=1}^{k} L_i$, and will produced as output nodes that are descendants of n (including n itself). Also, each time that the memory is in some state in L_i and a colour not in $\nu(n_i)$ is given, a transition leading to some state in $\eta(L_{i+1})$ ($\eta(L_1)$ if $i = k$) producing the node n as output is taken. Since $Inf(u)$ is not contained in $\nu(n_i)$ for $1 \leq i \leq k$ (by the maximality assumption), this occurs infinitely often. ◀

▶ Remark 17. We have shown that given as input the Zielonka tree of a Muller condition $\mathcal{F}$ we can build in polynomial time a minimal GFG Rabin automaton for $\mathcal{L}_\mathcal{F}$. On the other hand, with the same input, it is NP-complete to decide whether there is a deterministic Rabin automaton of size k recognising $\mathcal{L}_\mathcal{F}$ [10, Theorem 31]. Therefore, unless P = NP, there are Muller languages for which minimal deterministic Rabin automata are strictly greater than minimal GFG Rabin automata. We will explicitly show some of these languages in Section 4.

3.2.3 Relation with the Zielonka-tree parity automaton

The Zielonka tree has been previously used to provide a minimal deterministic parity automaton for a Muller condition [11, 33]. The automata states are the leaves of the Zielonka tree, and the transition from a leaf l reading colour c goes to the leftmost leave in $Jump_n(l)$, where n is the last ancestor of l containing colour c. For example, Figure 3 shows a parity automaton recognising the Muller condition $\mathcal{F} = \{\{a, b\}, \{a, c\}, \{b\}\}$ from Example 2.

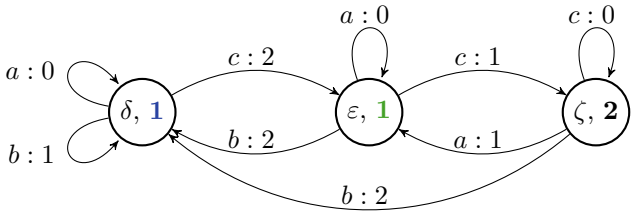

Figure 3 Parity automaton $\mathcal{P}_\mathcal{F}$ obtained from the Zielonka tree from Figure 1.

[3] This strategy is given by the (deterministic) Zielonka tree parity automaton $\mathcal{P}_\mathcal{F}$. It suffices to note that there is a morphism from $\mathcal{P}_\mathcal{F}$ to $\mathcal{R}_\mathcal{F}$ preserving all edges and the acceptance of loops.

This minimal parity automaton $\mathcal{P}_\mathcal{F}$ is closely related to the GFG Rabin automaton $\mathcal{R}_\mathcal{F}$ presented in Section 3.2. More precisely, the automaton $\mathcal{R}_\mathcal{F}$ can be regarded as a quotient of $\mathcal{P}_\mathcal{F}$ given by the numbering $\eta\colon \mathit{Leaves}(\mathcal{Z}_\mathcal{F}) \to \{1,\dots,\text{mem-tree}(\mathcal{Z}_\mathcal{F})\}$. That is, to obtain $\mathcal{R}_\mathcal{F}$ we merge the states $\eta^{-1}(i)$ for $1 \le i \le \text{mem-tree}(\mathcal{Z}_\mathcal{F})$ and we keep all transitions. Moreover, the strategy for a resolver for $\mathcal{R}_\mathcal{F}$ as presented in the proof of Lemma 16 is exactly given by the deterministic automaton $\mathcal{P}_\mathcal{F}$. However, we note that in general a parity condition is not sufficient in $\mathcal{R}_\mathcal{F}$ to accept $\mathcal{L}_\mathcal{F}$ and we need to replace it by a Rabin one.

We observe that the GFG Rabin automaton from Figure 2 is obtained as a quotient of the deterministic parity automaton in Figure 3.

3.2.4 Simplifications and optimisations

Given an automaton $\mathcal{A} = (Q, \Sigma, Q_0, \Delta, \Gamma, \mathbb{W})$ we say that it has *duplicated edges* if there are some pair of states $q, q' \in Q$ and two different transitions between them labelled with the same input letter: $(q, a, \alpha, q'), (q, a, \beta, q') \in \Delta$.

As remarked previously, the construction we have presented provides an automaton potentially having duplicated edges, which can be seen as an undesirable property (even if some automata models such as the HOA format [2] allow them). We show next that we can always derive an equivalent automaton without duplicated edges. Intuitively, in the Rabin case, if we want to merge two transitions having as output letters α and β, we add a fresh letter $(\alpha\beta)$ to label the new transition. For each Rabin pair, this new letter will simulate the best of either α or β depending upon the situation.

▶ **Proposition 18** (Simplification of automata). *Let $\mathcal{A}$ be a Muller (resp. Rabin) automaton presenting duplicated edges. There exists an equivalent Muller (resp. Rabin) automaton $\mathcal{A}'$ on the same set of states without duplicated edges. Moreover, if $\mathcal{A}$ is GFG, $\mathcal{A}'$ can be chosen GFG. In the Rabin case, the number of Rabin pairs is also preserved.*

Proof. For the Rabin case, let $\mathcal{A}'$ be an automaton that is otherwise as $\mathcal{A}$ except that instead of the transitions Δ of $\mathcal{A}$ it only has one a-transition $q \xrightarrow{a:x} q' \in \Delta'$ (with a fresh colour x per transition) per state-pair q, q' and letter $a \in \Sigma$. That is, $\Delta' = \{(q, a, x_j, q') : (q, a, y, q') \in \Delta \text{ for some } y\}$. The new Rabin condition $\{(G'_1, R'_1), \dots, (G'_r, R'_r)\}$ is defined as follows. For each transition $q \xrightarrow{a:x} q'$:

- $x \in G'_i$ if $q \xrightarrow{a:y} q' \in \Delta$ for some $y \in G_i$ (there is a green transition for the i^{th} pair)
- $x \in R'_i$ if for all $q \xrightarrow{a:y} q' \in \Delta$, $y \in R_i$ (there is no green or orange transition for the i^{th} pair).

We claim that $L(\mathcal{A}') = L(\mathcal{A})$. Indeed, if $u \in L(\mathcal{A})$, as witnessed by some run ρ and a Rabin pair (G_i, R_i), then the corresponding run ρ' in $\mathcal{A}'$ over u is also accepting with Rabin pair (G'_i, R'_i): the transitions of $\mathit{Inf}(\rho) \cap G_i$ induce transitions of $\mathit{Inf}(\rho') \cap G'_i$ and the fact that $\mathit{Inf}(\rho) \cap R_i = \emptyset$ guarantees that $\mathit{Inf}(\rho') \cap R'_i = \emptyset$.

Conversely, if $u \in L(\mathcal{A}')$ as witnessed by a run ρ' and Rabin pair (G'_i, R'_i), then there is an accepting run ρ over u in $\mathcal{A}$: such a run can be obtained by choosing for each transition $q \xrightarrow{a:x} q'$ of ρ' where $x \in G'_i$ a transition $q \xrightarrow{a:y} q' \in \Delta$ such that $y \in G_i$, which exists by definition of $\mathcal{A}'$, for each transition $q \xrightarrow{a:x} q'$ where $x \notin G_i \cup R_i$ a transition $q \xrightarrow{q,y} q' \in \Delta$ such that $y \notin R_i$, which also exists by definition of $\mathcal{A}'$, and for other transitions $q \xrightarrow{a:x} q'$ (that is, those for which $x \in R'_i$) an arbitrary transition $q \xrightarrow{a:y} q' \in \Delta$. Since ρ' is accepting, we have $\mathit{Inf}(\rho') \cap G_i \neq \emptyset$ and $\mathit{Inf}(\rho) \cap R_i = \emptyset$, that is, ρ is also accepting.

For the Muller case, the argument is even simpler. As above, we consider $\mathcal{A}'$ that is otherwise like $\mathcal{A}$ except that instead of the transitions Δ of $\mathcal{A}$, it only has one a-transition $q \xrightarrow{a:x} q' \in \Delta'$ (with a fresh colour per transition) per state-pair q, q' and the accepting

condition is defined as follows. A set of transitions T is accepting if and only if for each $t = q \xrightarrow{a:x} q' \in T$ there is a non-empty set $S_t \subseteq \{q \xrightarrow{a:y} q' \in \Delta\}$ such that $\bigcup_{t \in T} S_t$ is accepting in $\mathcal{A}$. In other words, a set of transitions in $\mathcal{A}'$ is accepting if for each transition we can choose a non-empty subset of the original transitions in $\mathcal{A}$ that form an accepting run in $\mathcal{A}$.

We claim that $L(\mathcal{A}') = L(\mathcal{A})$. Indeed if $u \in L(\mathcal{A})$, as witnessed by some run ρ, the run ρ' that visits the same sequence of states in $\mathcal{A}'$ is accepting as witnessed by the transitions that occur infinitely often in ρ.

Conversely, assume $u \in L(\mathcal{A}')$, as witnessed by a run ρ' and a non-empty subset S_t for each transitions t that occurs infinitely often in ρ' such that $\bigcup_{t \in Inf(\rho)} S_t$ is accepting in $\mathcal{A}$. Then there is an accepting run ρ over u in $\mathcal{A}$ that visits the same sequence of states as ρ' and chooses instead of a transition $t \in Inf(\rho)$ each transition in S_t infinitely often, and otherwise takes an arbitrary transition. The set of transitions ρ visits infinitely often is exactly $\bigcup_{t \in Inf(\rho)} S_t$, and is therefore accepting.

Finally, observe that in both cases, if $\mathcal{A}$ if GFG, then the automaton $\mathcal{A}'$ without duplicate edges is also GFG since $\mathcal{A}'$ is obtained from $\mathcal{A}$ by merging transitions. Indeed, the resolver r of $\mathcal{A}$ induces a resolver r' for $\mathcal{A}'$ by outputting the unique transition with the same letter and state-pair as r. By the same argument as above, the run induced by r' is accepting if and only if the run induced by r is. ◀

▶ **Example 19.** The GFG Rabin automaton from Figure 2 has duplicated transitions. In Figure 4 we present an equivalent GFG Rabin automaton without duplicates. For this, we have merged the self-loops in state 1 labelled with a and b respectively. We have added the output letters $(\alpha\beta)$ and $(\delta\varepsilon)$. The new Rabin pairs are given by:

$$G'_\beta = \{\beta, (\alpha\beta)\}, \quad R'_\beta = \{\alpha, \gamma, \varepsilon, \zeta\},$$
$$G'_\gamma = \{\gamma\}, \quad R'_\gamma = \{\alpha, \beta, (\alpha\beta), \delta\}.$$

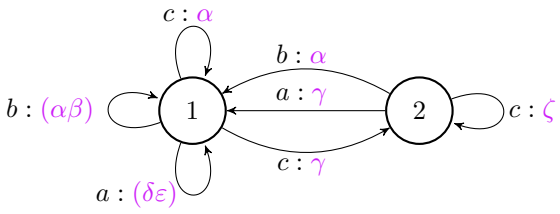

Figure 4 The simplified GFG Rabin automaton.

▶ Remark 20 (Optimisation on the number of Rabin pairs). An important parameter in the study of Rabin automata is the number of Rabin pairs used. The automaton presented in this Section uses a number of Rabin pairs that equals the number of round nodes in the Zielonka tree. This can be improved by using only the round nodes in the Zielonka directed acyclic graph (obtained from the tree by merging nodes with the same labels). However, even this latter option is not always optimal and we conjecture that minimising the number of Rabin pairs without increasing the size of the automaton is NP-complete.

4 GFG Rabin automata recognising Muller conditions can be exponentially more succinct than deterministic ones in number of states

On his PhD Thesis [23, 24], Kopczyński raised the question of whether the general and the chromatic memory requirements of winning conditions always coincide. By Theorem 5 and [10, Theorem 28], in the case of Muller conditions, this question is equivalent to the following:

> Is there a Muller language L such that minimal GFG Rabin automata recognising L are strictly smaller than deterministic Rabin automata for L?

In [10] this question is answered positively. It is shown that for every $n \in \mathbb{N}$ there is a Muller language L_n over an alphabet Γ_n such that a minimal GFG Rabin automaton for it has size 2, but a minimal deterministic Rabin automaton for it has size n. However, the size of the alphabet Γ_n in that example also has size n. A natural question is whether GFG Rabin automata recognising Muller conditions can be exponentially more succinct than deterministic ones, when also taking into account the alphabet size. This is indeed the case:

▶ **Theorem 21.** *There exists a constant $\alpha > 1$, a sequence of natural numbers $n_1 < n_2 < n_3 \dots$ and a sequence of Muller conditions $\mathcal{F}_{n_i}$ over $\Gamma_{n_i} = \{1, \dots, n_i\}$ such that*
- *a minimal GFG Rabin automaton for $\mathcal{L}_{\mathcal{F}_{n_i}}$ has size $\lfloor n_i/2 \rfloor$,*
- *a minimal deterministic Rabin automaton for $\mathcal{L}_{\mathcal{F}_{n_i}}$ has size at least α^{n_i}.*

A lower bound for such a constant is $\alpha = 1.116$.

We devote the rest of this Section to proving Theorem 21. In brief, the Muller conditions in question require half the colours to be seen infinitely often. The construction of the small GFG Rabin automaton follows from constructing the Zielonka tree of the condition. For the lower bound on the deterministic Rabin automaton, we reduce the problem to finding a lower bound on the chromatic number of a certain graph, which we finally show to be sufficiently large for a family of our Muller conditions.

Let $n \in \mathbb{N}$. We define the following Muller condition over $\Gamma_n = \{1, \dots, n\}$:

$$\mathcal{F}_n = \{C \subseteq \Gamma_n \,:\, |C| = \lfloor n/2 \rfloor\}.$$

The Zielonka tree of $\mathcal{F}_n$ is depicted in Figure 5 (for n even).

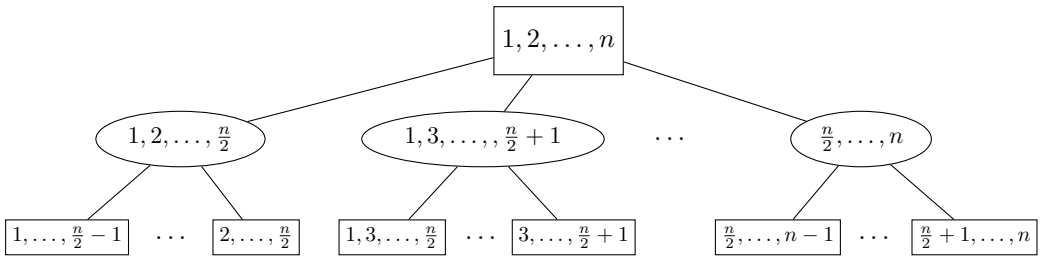

Figure 5 Zielonka tree $\mathcal{Z}_{\mathcal{F}_n}$ for $\mathcal{F}_n = \{C \subseteq \Gamma_n \,:\, |C| = \lfloor n/2 \rfloor\}$.

Each round node in $\mathcal{Z}_{\mathcal{F}_n}$ has exactly $\lfloor n/2 \rfloor$ children, and therefore mem-tree$(\mathcal{Z}_{\mathcal{F}_{n_i}}) = \lfloor n/2 \rfloor$. Thus, a minimal GFG Rabin automaton recognising $\mathcal{L}_{\mathcal{F}_n}$ has size $\lfloor n/2 \rfloor$ (by Proposition 4 and Theorem 5).

We now give a lower bound for deterministic Rabin automata recognising $\mathcal{L}_{\mathcal{F}_n}$. Our main tool will be Lemma 22, which uses the notion of *cycles*. A *cycle* of an automaton $\mathcal{A}$ is a set of transitions forming a closed path (not necessarily simple). The set of states of a cycle consists

of those states that are the source of some transition in it. If $\mathcal{A}$ is a Rabin automaton, we say that a cycle is accepting (resp. rejecting) if the colours $c_1, \dots, c_k$ appearing in its transitions form a word $(c_1 c_2 \dots c_k)^\omega$ that satisfies (resp. does not satisfy) the Rabin condition.

▶ **Lemma 22** ([11]). *Let $\mathcal{A}$ be a deterministic Rabin automaton. If ℓ_1 and ℓ_2 are two rejecting cycles in $\mathcal{A}$ with some state in common, then the union of ℓ_1 and ℓ_2 is also a rejecting cycle.*

For the following, let $\mathcal{A}$ be a deterministic Rabin automaton recognising $\mathcal{L}_{\mathcal{F}_n}$. For each subset of letters $C \subseteq \Gamma_n$, we define a *final C-Strongly Connected Component* (C-*FSCC* for short) as a set of states P of $\mathcal{A}$ such that:

- For every pair of states $p, q \in P$, there is a word $w \in C^*$ labelling a path from p to q.
- For every $p \in P$ and $w \in C^*$, the run over w starting in p remains in P.

It is easy to see that for every $C \subseteq \Gamma_n$ there exists some C-FSCC in $\mathcal{A}$.

▶ **Lemma 23.** *Let $C_1, C_2 \subseteq \Gamma_n$ such that $|C_i| < \lfloor n/2 \rfloor$, for $i = 1, 2$ and such that $|C_1 \cup C_2| = \lfloor n/2 \rfloor$. If P_1 and P_2 are two C_1 and C_2-FSCC, respectively, then $P_1 \cap P_2 = \emptyset$.*

Proof. For $i = 1, 2$, let ℓ_i be a cycle visiting all states of P_i and reading exactly the set of letters C_i. By definition of $\mathcal{L}_{\mathcal{F}_n}$, ℓ_i is a rejecting cycle. If P_1 and P_2 had some state in common, we could take the union of the cycles ℓ_1 and ℓ_2, producing an accepting cycle, which is impossible by Lemma 22. ◀

We associate the following (undirected) graph $\mathcal{G}_{\mathcal{F}_n} = (V_{\mathcal{F}_n}, E_{\mathcal{F}_n})$ to the Muller condition $\mathcal{F}_n$:

- $V_{\mathcal{F}_n} = \mathcal{P}(\Gamma_n)$.
- There is an edge between two subsets $C_1, C_2 \subseteq \Gamma_n$ if and only if $|C_i| < \lfloor n/2 \rfloor$, for $i = 1, 2$, and $|C_1 \cup C_2| = \lfloor n/2 \rfloor$.

That is, we connect two vertices if they correspond to rejecting sets but taking their union we obtain an accepting set.

We reduce finding lower bounds in the size of deterministic Rabin automata to giving lower bounds for the chromatic number of $\mathcal{G}_{\mathcal{F}_n}$. A *colouring* of an undirected graph $G = (V, E \subseteq V \times V)$ is a mapping $c : V \to \Lambda$ such that $c(v) = c(v') \Rightarrow (v, v') \notin E$ for every pair of nodes $v, v' \in V$. We say that such a colouring has size $|\Lambda|$. The *chromatic number* of G is the minimal number k such that G has a colouring of size k. We denote it $\chi(G)$.

▶ **Lemma 24.** *A lower bound for the size of a minimal deterministic Rabin automaton recognising $\mathcal{L}_{\mathcal{F}_n}$ is given by $\chi(\mathcal{G}_{\mathcal{F}_n})$.*

Proof. Let $\mathcal{A}$ be a deterministic Rabin automaton recognising $\mathcal{L}_{\mathcal{F}_n}$ with states Q. We define a colouring c of $\mathcal{G}_{\mathcal{F}_n}$ using Q as colours. For each $C \subseteq \Gamma_n$, we let P_C be a C-FSCC and we pick a state $q_C \in P_C$. We define $c(C) = q_C$. We prove that this is a correct colouring. Suppose that C_1 and C_2 are two vertices in $\mathcal{G}_{\mathcal{F}_n}$ connected by some edge, that is, $|C_i| < \lfloor n/2 \rfloor$ and $|C_1 \cup C_2| = \lfloor n/2 \rfloor$. If $q_{C_1} = q_{C_2}$, it means that $P_{C_1} \cap P_{C_2} \neq \emptyset$, contradicting Lemma 23. ◀

▶ Remark 25. The definition of $\mathcal{G}_{\mathcal{F}_n}$ is not specific to this Muller condition. It can be defined analogously for any other Muller condition and Lemma 24 holds by the same argument.

▶ **Proposition 26.** *There exists a constant $\alpha > 1$ and a sequence of natural numbers $n_1 < n_2 < n_3 \dots$ such that $\alpha^{n_i} \leq \chi(\mathcal{G}_{\mathcal{F}_{n_i}})$.*

In order to prove Proposition 26 we introduce some further graph-theoretic notions. Let $\mathcal{G} = (V, E)$ be an undirected graph. An *independent set* of $\mathcal{G}$ is a set $S \subseteq V$ such that $(v, v') \notin E$ for every pair of vertices $v, v' \in S$.

▶ **Lemma 27.** *Let $R \subseteq V$, and let $\mathcal{G}_R = (R, E|_{R\times R})$ be the subgraph of $\mathcal{G}$ induced by R. Then, $\chi(\mathcal{G}) \geq \chi(\mathcal{G}_R)$.*

▶ **Lemma 28.** *Let m be an upper bound on the size of the independent sets in $\mathcal{G}$. Then*

$$\chi(\mathcal{G}) \geq \frac{|V|}{m}.$$

Proof. Let $c\colon V \to \Lambda$ be a colouring of $\mathcal{G}$ with $|\Lambda| = \chi(\mathcal{G})$. Then, by definition of a colouring, for each $x \in \Lambda$, $c^{-1}(x)$ is an independent set in $\mathcal{G}$, so $|c^{-1}(x)| \leq m$. Also, $V = \bigcup_{x\in\Lambda} c^{-1}(x)$, so

$$|V| = \sum_{x\in\Lambda} |c^{-1}(x)| \leq \chi(\mathcal{G}) \cdot m. \qquad \blacktriangleleft$$

We will find a subgraph of $\mathcal{G}_{\mathcal{F}_n}$ for which we can provide an upper bound on the size of its independent sets. The upper bound is provided by the following theorem (adapted from [35, Theorem 15]).

▶ **Theorem 29** ([35], Theorem 15)**.** *Let $n > k > 2t$ such that $k - t$ is a prime number. Suppose that $\mathcal{B}$ is a family of subsets of size k of Γ_n such that $|A \cap B| \neq t$ for any pair of subsets $A, B \in \mathcal{B}$. Then,*

$$|\mathcal{B}| \leq \binom{n}{k-t-1}.$$

We conclude this section with the proof of Proposition 26.

Proof of Proposition 26. Let p be a prime number and let $n = 5p$. We will study the subgraph of $\mathcal{G}_{\mathcal{F}_n}$ formed by the subsets of size exactly $k = \lfloor 3n/10 \rfloor$. We denote this subgraph by $H_{n,k}$. Two subsets $A, B \subseteq \Gamma_n$ of size k verify that $|A \cup B| = \lfloor n/2 \rfloor$ if and only if $|A \cap B| = \lfloor n/10 \rfloor$. We set $t = \lfloor n/10 \rfloor$. We get $k - t = p$ so we can apply Theorem 29 and we obtain that any independent set in $H_{n,k}$ has size at most $\binom{n}{\frac{1}{5}n-1}$. By Lemma 28, $\chi(H_{n,k}) \geq \binom{n}{\lfloor \frac{3}{10}n \rfloor} / \binom{n}{\frac{1}{5}n-1}$. By Lemma 27 we know that this lower bound also holds for $\mathcal{G}_{\mathcal{F}_n}$. Using Stirling's approximation we obtain that

$$\chi(\mathcal{G}_{\mathcal{F}_n}) \geq \binom{n}{\lfloor \frac{3}{10}n \rfloor} \Big/ \binom{n}{\frac{1}{5}n-1} = \Omega\left(\left(\frac{(1/5)^{1/5}(4/5)^{4/5}}{(3/10)^{3/10}(7/10)^{7/10}}\right)^n\right) = \Omega(1.116^n).$$

To conclude, we take an enumeration of prime numbers, $p_1 < p_2 < \dots$ and we set $n_i = 5p_i$. $\blacktriangleleft$

▶ Remark 30 (Choices of k and t). The choice of $k = \lfloor 3n/10 \rfloor$ and $t = \lfloor n/10 \rfloor$ in the previous proof might appear quite enigmatic. We try to explain them now.

We want to find a number k such that there is not a big family of sets $\{A_i \subseteq \Gamma_n\}$ of size $|A_i| = k$ such that $|A_i \cup A_j| \neq n/2$, and express this fact in terms of $|A_i \cap A_j|$. Since $|A \cup B| = 2k - |A \cap B|$, if we define $t = 2k - n/2$, then $|A \cup B| \neq n/2$ if and only if $|A \cap B| \neq t$, so the value of t will be completely determined by the choice of k. Our objective is to minimise the upper bound given in Theorem 29 (what we do by minimising $k - t$) while making sure that the hypothesis $k > 2t$ is verified. In the boundary of this condition ($k = 2t$) we obtain $k = n/3$, so we express our choices as $k = (1/3 - \varepsilon)n$ and $t = (1/6 - 2\varepsilon)n$. Moreover, $k - t = (1/6 + \varepsilon)n$ has to be a prime number (for infinite n). If $1/6 + \varepsilon = 1/q$ for some $q \in \mathbb{N}$, we would succeed by considering n of the form $q \cdot p$, for p a prime number. We will therefore take $\varepsilon = \frac{6-q}{6q}$, for some q, $1 \leq q \leq 5$. With the optimal choice, $q = 5$, we obtain $k = 3n/10$, $t = n/10$ and $k - t = n/5$. Since k and t will not be integers for n of the form $5p$ (p a prime number) we are forced to take the integer part in the proof of Proposition 26.

5 Conclusion

We believe that our work is a significative advance in the understanding of the memory needed for winning ω-regular games. In combination with the literature, we can describe the current understanding of Muller languages as follows:

- The least memory necessary for winning all won L-games equals the least number of states of a GFG Rabin automaton for L.
- Computing this quantity can be done in polynomial time for L given by its Zielonka tree.
- The least chromatic memory necessary for winning all won L-games equals the least number of states of a deterministic Rabin automaton for L.
- Computing this quantity is NP-complete for L given by its Zielonka tree.
- The chromatic memory can be arbitrarily larger than the memory. It can be exponential in the size the alphabet, even while the memory remains linear.

This description shows that GFG automata play a key, and, up till now, unexplored role in understanding the complexity of Muller languages and that this role is – in some respect – even more important than that of the more classical deterministic automata.

Abstract

Reachability, distance, and matching are some of the most fundamental graph problems that have been of particular interest in dynamic complexity theory in recent years [8, 13, 11]. Reachability can be maintained with first-order update formulas, or equivalently in DynFO in general graphs with n nodes [8], even under $O(\frac{\log n}{\log \log n})$ changes per step [13]. In the context of how large the number of changes can be handled, it has recently been shown [11] that under a polylogarithmic number of changes, reachability is in DynFO$[\oplus](\leq, +, \times)$ in planar, bounded treewidth, and related graph classes – in fact in any graph where small *non-zero circulation weights* can be computed in NC.

We continue this line of investigation and extend the meta-theorem for reachability to distance and bipartite maximum matching with the same bounds. These are amongst the most general classes of graphs known where we can maintain these problems deterministically without using a majority quantifier and even maintain witnesses. For the bipartite matching result, modifying the approach from [15], we convert the static non-zero circulation weights to dynamic matching-isolating weights.

While reachability is in DynFO$(\leq, +, \times)$ under $O(\frac{\log n}{\log \log n})$ changes, no such bound is known for either distance or matching in any non-trivial class of graphs under non-constant changes. We show that, in the same classes of graphs as before, bipartite maximum matching is in DynFO$(\leq, +, \times)$ under $O(\frac{\log n}{\log \log n})$ changes per step. En route to showing this we prove that the rank of a matrix can be maintained in DynFO$(\leq, +, \times)$, also under $O(\frac{\log n}{\log \log n})$ entry changes, improving upon the previous $O(1)$ bound [8]. This implies a similar extension for the non-uniform DynFO bound for maximum matching in general graphs and an alternate algorithm for maintaining reachability under $O(\frac{\log n}{\log \log n})$ changes [13].

1 Introduction

In traditional complexity theory it is assumed that the given input remains fixed throughout the computation. However in real-life scenarios, many situations involve an evolving input where parts of the data change frequently. Recomputing everything from scratch for these large datasets after every change is not an efficient option. Therefore, the goal is to dynamically maintain some auxiliary data structure to help us recompute the results quickly.

The dynamic complexity framework of Patnaik and Immerman [28] is one such approach that has its roots in descriptive complexity [23] and is closely related to the setting of Dong, Su, and Topor [14]. Here we would like to make the updates and queries by first-order logic formulas. For example, by maintaining some auxiliary relations, the reachability relation can be updated after every single edge modification in FO [8] i.e., the reachability query is contained in the dynamic complexity class DynFO [28]. The motivation to use first-order logic as the update method has connections to other areas. From the circuit complexity perspective, this implies that such queries are highly parallelizable, i.e., can be updated by polynomial-size circuits in constant-time due to the correspondence between FO and uniform AC^0 circuits [2]. From the perspective of database theory, such a program can be translated into equivalent SQL queries.

The area has seen renewed interest in proving further upper bounds results, partly after the resolution of the long-standing conjecture [28] that reachability is in DynFO under single edge modifications [8]. A natural direction to extend this result is to see which other fundamental graph problems also admit such efficient dynamic programs. The closely related problems of maintaining distance and matching are two such examples, though a DynFO bound for these problems in general graphs has been elusive so far. The best known bound for distance is DynTC^0 [20] and non-uniform $\mathsf{DynAC}^0[\oplus]$ [5]. Here, the updates are computed in FO formulas with majority quantifiers (uniform TC^0 circuits) and non-uniform FO formulas with parity quantifiers ($\mathsf{AC}^0[\oplus]$ circuits), respectively. For matching, we have a non-uniform DynFO bound for maintaining the size of the maximum matching [8]. The only non-trivial class of graphs where both these problems are in DynFO is bounded treewidth graphs [12].

At the same time progress has been made to understand how large a modification to the input can be handled by similar dynamic programs. It is of particular interest since, in applications, changes to a graph often come as a bulk set of edges. It was shown that reachability can be maintained in $\mathsf{DynFO}(\leq, +, \times)$ under changes of size $O(\log n / \log \log n)$ [13] in graphs with n nodes. Here, the class $\mathsf{DynFO}(\leq, +, \times)$ extends DynFO by access to built-in arithmetic, which is more natural for bulk changes. To handle larger changes, it is known that even for reachability, changes of size larger than polylogarithmic cannot be handled in DynFO [11]. And for changes of polylogarithmic size, the previous techniques seem to require extending DynFO by majority quantifiers [13]. Under bulk changes of polylog(n) size, we can even maintain distance and the size of a maximum matching in the uniform and the non-uniform version of $\mathsf{DynFO}[\mathsf{MAJ}](\leq, +, \times)$, respectively [13, 26].

Making further progress in this direction, recently it has been shown in [11] that reachability is in DynFO[$\oplus$]($\leq, +, \times$) (i.e., update formulas may use parity quantifiers) under polylog(n) changes in the class of graphs where polynomially bounded *non-zero circulation weights* can be computed statically in the parallel complexity class NC. A weight function for the edges of a graph has non-zero circulation if the (alternate) sum of the weights of the edges of every directed cycle is non-zero (see Section 2 for more details). Planar [29], bounded genus [10], bounded treewidth [11], single crossing minor-free [4] are some of the well-studied graph classes for which non-zero circulation weights can be computed in NC.

In this work, we first extend this result to prove similar meta-theorems for maintaining distance (including a shortest path witness) and the *search* version of minimum weight bipartite maximum matching (MinWtBMMSearch) in the same classes of graphs.

▶ **Theorem 1.** Distance *and* MinWtBMMSearch *are in* DynFO[$\oplus$]($\leq, +, \times$) *under polylog*(n) *edge changes on classes of graphs where non-zero circulation weights can be computed in* NC.

Note that these are the only classes of graphs known where we can maintain both these problems *deterministically* without using a majority quantifier and even maintain a witness to the solution (in other words, maintain a solution to the search problem).

While reachability can be maintained in DynFO($\leq, +, \times$) under bulk changes in general graphs, no such bound is known for either distance or matching in any non-trivial class of graphs under a non-constant number of changes. Since maintaining the size of maximum matching reduces to maintaining the rank of a matrix via bounded expansion first-order truth-table (bfo-tt) reduction [8], the following gives a non-uniform DynFO($\leq, +, \times$) bound for maintaining the size of maximum matching in *general* graphs to $O(\frac{\log n}{\log \log n})$ changes.

▶ **Theorem 2.** *Rank of a matrix from* $\mathbb{Z}_p^{n \times n}$ *is in* DynFO($\leq, +, \times$) *under* $O(\frac{\log n}{\log \log n})$ *entry changes.*

Earlier it was known that the rank of a matrix with small integer entries can be maintained in DynFO under changes that affect a single entry [8]. As reachability reduces to matrix rank via bfo-reduction [8], Theorem 2 also gives an alternative algorithm for maintaining reachability in DynFO($\leq, +, \times$) under $O(\frac{\log n}{\log \log n})$ changes. This is interesting in its own right as it generalizes the *rank-method* for maintaining reachability [8] even under bulk changes without going via the Sherman-Morrison-Woodbury identity [13].

Finally, building on Theorem 2, we show another meta theorem for maintaining the size of a maximum matching in bipartite graphs (BMMSize) in DynFO($\leq, +, \times$) under slightly sublogarithmic bulk changes, in the same class of graphs as in Theorem 1. Previously, no DynFO($\leq, +, \times$) bound was known even in planar graphs under single edge changes.

▶ **Theorem 3.** BMMSize *is in* DynFO($\leq, +, \times$) *under* $O(\frac{\log n}{\log \log n})$ *edge changes on classes of graphs for which non-zero circulation weights can be computed in* NC.

Main Technical Contributions. There are two major technical contributions of this work:

- *Converting the statically computed non-zero circulation weights for bipartite matchings to dynamically isolating weights for bipartite matchings.* Our main approach (described in detail in Section 3) is to assign polynomially bounded *isolating* weights to the edges of an evolving graph so that the minimum weight solution under these weights is *unique*. While static non-zero circulation weights guarantee this under deletions, for insertions, the dynamization is based on the seminal work of [15]. They construct isolating weights for perfect matching for arbitrary bipartite graphs, but which are quasipolynomially

Table 1 Previously known and new results in graphs with non-zero circulation weights in NC.

Problem	#changes		
	$O(1)$	$O(\frac{\log n}{\log \log n})$	$\log^{O(1)} n$
Reach	DynFO [8]	DynFO [13]	DynFO[⊕] [11]
Distance	DynFO[⊕]	DynFO[⊕]	DynFO[⊕]
BMMSize	DynFO	DynFO	DynFO[⊕]
BMMSearch	DynFO[⊕]	DynFO[⊕]	DynFO[⊕]

large in the size of the graphs. By assigning such weights only to the changed part of the graph and carefully combining with the previously assigned weights, we make sure the edge weights remain small as well as isolating throughout, using the Muddling Lemma (see Section 2). Our construction parallels that of [11] where dynamic isolating weights for reachability in non-zero circulation graphs were constructed based on the static construction from [24]. In addition to extending the reachability result (Theorem 1) this also enables us to prove a DynFO$(\leq, +, \times)$ bound (Theorem 3) for bipartite maximum matching (previously, a rather straightforward application of non-zero circulation weights in planar graphs could only achieve a DynFO[⊕] bound under single edge changes [26]).

- *Maintaining rank of a matrix under sublogarithmically many changes.* This involves non-trivially extending the technique from [8], which maintains rank under single entry changes, and combining it with [13] which shows how to compute the determinant of a small matrix of dimension $O(\frac{\log n}{\log \log n})$ in FO$(\leq, +, \times)$.

Organization. After some preliminaries in Section 2, in Section 3 we discuss the connection between dynamic isolation and static non-zero circulation and show its applications for matching and distance in Section 4 and Section 6, respectively. In Section 5, we describe the DynFO$(\leq, +, \times)$ algorithm for maximum matching, which is built on the rank algorithm under bulk changes from Section 7. Finally, we conclude with Section 8.

2 Preliminaries and Notations

Dynamic Complexity. The goal of a dynamic program is to answer a given query on an *input structure* subjected to insertion or deletion of tuples. The program may use an *auxiliary data structure* over the same domain. Initially, both input and auxiliary structures are empty; and the domain is fixed during each run of the program.

For a (relational) structure $\mathcal{I}$ over domain D and schema σ, a change $\Delta\mathcal{I}$ consists of sets R^+ and R^- of tuples for each relation symbol $R \in \sigma$. The result $\mathcal{I} + \Delta\mathcal{I}$ is the input structure where $R^{\mathcal{I}}$ is changed to $(R^{\mathcal{I}} \cup R^+) \setminus R^-$. The set of affected elements is the (active) domain of tuples in $\Delta\mathcal{I}$. A dynamic program $\mathcal{P}$ is a set of first-order formulas specifying how auxiliary relations are updated after a change. For a state $\mathcal{S} = (\mathcal{I}, \mathcal{A})$ with input structure $\mathcal{I}$ and auxiliary structure $\mathcal{A}$ we denote the state of the program after applying a change sequence α and updating the auxiliary relations accordingly by $\mathcal{P}_\alpha(\mathcal{S})$.

The dynamic program maintains a q-ary query Q under changes that affect k elements if it has a q-ary auxiliary relation ANS that at each point stores the result of Q applied to the current input structure. I.e., for each non-empty sequence α of changes affecting k elements, the relation ANS in $\mathcal{P}_\alpha(\mathcal{S}_\emptyset)$ and the relation $Q(\alpha(\mathcal{I}_\emptyset))$ coincide, where the state $\mathcal{S}_\emptyset = (\mathcal{I}_\emptyset, \mathcal{A}_\emptyset)$ consists of an input structure $\mathcal{I}_\emptyset$ and an auxiliary structure $\mathcal{A}_\emptyset$ over some common domain that both have empty relations, and $\alpha(\mathcal{I}_\emptyset)$ is the input structure after applying α.

If a dynamic program maintains a query, we say that the query is in DynFO. Similar to DynFO, one can define the class of queries DynFO$(\leq, +, \times)$ that allows for auxiliary relations initialized as a linear order, and the corresponding addition and multiplication relations. One can further extend this class by allowing parity quantifiers to yield the class DynFO$[\oplus](\leq, +, \times)$ and majority quantifiers to yield the class DynFO[MAJ]$(\leq, +, \times)$. The parity and majority functions of n bits $a_1, \ldots, a_n$ are true if $\sum_{i=1}^{n} a_i = 1 \pmod 2$ and $\sum_{i=1}^{n} a_i \geq n/2$, respectively. As we focus on changes of non-constant size, we include arithmetic in our setting. See [13, 11] for more details.

The *Muddling Lemma* [11] states that to maintain many natural queries, it is enough to maintain the query for a bounded number of steps, that we crucially use in this paper. In the following, we first recall the necessary notions before stating the lemma.

A query Q is *almost domain-independent* if there is a $c \in \mathbb{N}$ such that $Q(\mathcal{A})[(\text{adom}(\mathcal{A}) \cup B)] = Q(\mathcal{A}[(\text{adom}(\mathcal{A}) \cup B)])$ for all structures $\mathcal{A}$ and sets $B \subseteq A \setminus \text{adom}(\mathcal{A})$ with $|B| \geq c$. Here, adom$(\mathcal{A})$ denotes the *active domain*, the set of elements that are used in some tuple of $\mathcal{A}$. A query Q is $(\mathcal{C}, f)$*-maintainable*, for some complexity class $\mathcal{C}$ and some function $f : \mathbb{N} \to \mathbb{R}$, if there is a dynamic program $\mathcal{P}$ and a $\mathcal{C}$-algorithm $\mathbb{A}$ such that for each input structure $\mathcal{I}$ over a domain of size n, each linear order $\leq$ on the domain, and each change sequence α of length $|\alpha| \leq f(n)$, the relation Q in $\mathcal{P}_\alpha(\mathcal{S})$ and $Q(\alpha(\mathcal{I}))$ coincide, where $\mathcal{S} = (\mathcal{I}, \mathbb{A}(\mathcal{I}, \leq))$. AC^i is the class of problems that can be solved using polynomial-size circuit of $O(\log^i n)$ depth and $\mathsf{NC} = \cup_i \mathsf{AC}^i$.

▶ **Lemma 4** (Muddling Lemma [11]). *Let Q be an almost domain independent query, and let $c \in \mathbb{N}$ be arbitrary. If the query Q is $(\mathsf{AC}^d, 1)$-maintainable under changes of size $\log^{c+d} n$ for some $d \in \mathbb{N}$, then Q is in* DynFO$(\leq, +, \times)$ *under changes of size $\log^c n$.*

There are several roughly equivalent ways to view the complexity class DynFO as capturing:

- The dynamic complexity of maintaining a Pure SQL database under fixed (first-order) updates and queries (the original formulation from [28]).
- The circuit dynamic complexity of maintaining a property where the updates and queries use uniform AC^0 circuits (see [2] for the equivalence of uniform AC^0 and FO).
- The parallel dynamic complexity of maintaining a property where the updates and queries use constant time on a CRCW PRAM (for the definition of Concurrent RAM, see [23]).

The first characterization is popular in the Logic and Database community, while the second is common in more complexity-theoretic contexts. The third one is useful to compare and contrast this class with dynamic algorithms, which essentially classify dynamic problems in terms of the sequential time for updates and queries. Operationally, our procedure is easiest to view in terms of the second or even the third viewpoint. We would like to emphasize that modulo finer variations based on built-in predicates (like arithmetic and order) in the first variation, uniformity in the second one and built-in predicates (like shift) in the third one, the three viewpoints are entirely equivalent.

We refer the readers to [8, 13, 11] for more discussion on the basics of the dynamic complexity framework.

Weight function and Circulation. Let $G = (V, E)$ be an undirected graph with vertex set V and edge set E. By $G = (V, \vec{E})$ denote the corresponding graph where each of its edges is replaced by two directed edges, pointing in opposite directions. Let $|V| = n$ and we use the natural interpretation of the universe i.e., the set of vertices as the natural numbers from $[n]$.

A set system $\mathcal{M}$ on a universe U is a family of subsets of U i.e. $\mathcal{M} \subseteq 2^U$. Examples include the family of s, t-shortest paths and perfect matchings in a graph. A weight function $w : U \to \mathbb{Z}_{\geq 0}$ (the set of non-negative integers) induces a weight of $w(M) = \sum_{e \in M} w(e)$ on

an element $M \in \mathcal{M}$. Such a weight function is said to be *isolating* for $\mathcal{M}$ if there is at most one element $M_0 \in \mathcal{M}$ with the minimum weight. The notion of isolation can be extended to a collection of families of graphs such as the collection of families of s,t-shortest paths for all $s,t \in V$. The weight function $w(e) = 2^{(n+1)u+v}$ for $e = \{u,v\}$, $u < v$, is a trivial isolating function – instead we want to give weights polynomially bounded in the size of the universe. A randomized construction of such a weight function is known for arbitrary set systems [27].

A function $w : \vec{E} \to \mathbb{Z}$ is called *skew-symmetric* if for all $e \in \vec{E}$, $w(e) = -w(e^r)$ (where e^r represent the edge with its direction reversed). The *circulation* of a directed cycle under a skew symmetric weight function is the absolute value of the sum of weights of the directed edges in the cycle. The skew-symmetric weight function w induces a *non-zero circulation* on the graph if every directed cycle in the graph gets a non-zero circulation under w.

We know from [3] that if w assigns non-zero circulation to every cycle that consists of edges of $\vec{E}$, then it isolates a directed path between each pair of vertices in $G = (V, \vec{E})$. Also, if G is a bipartite graph, then the weight function w can be used to construct a weight function $w' : E \to \mathbb{Z}$ that isolates a perfect matching in G [29]. For planar [29], bounded genus [10], bounded treewidth [11], and for any single crossing minor-free graph [4] non-zero circulation weights can be computed *deterministically* in Logspace, which is a subclass of NC.

Our convention represents by $\langle w_1, \ldots, w_k \rangle$ the weight function that on edge e takes weight $\sum_{i=1}^{k} w_i(e) B^{k-i}$, where $w_1, \ldots, w_k$ are weight functions such that $\max_{i=1}^{k} (n \cdot w_i(e)) \leq B$.

Maintaining Witnesses. The proof of [27] for the construction of a perfect matching witness carries over to the dynamic setting also and allow us to maintain a witness to the solution in $\mathsf{DynFO}[\oplus](\leq, +, \times)$. Since the perfect matching is isolated, from its weight one can infer the edges in the matching by deleting the edges one a time in parallel and see if the weight remains unchanged and accordingly place the edge in the matching. This is doable in $\mathsf{FO}[\oplus](\leq, +, \times)$. The extraction procedure for shortest path and maximum cardinality matching is similar.

3 Dynamic Isolation from Static Non-Zero Circulation

We know (from Section 2) that non-zero circulation weights are isolating weights. Thus, statically (when the given graph does not change over time) we can use them to obtain efficient parallel algorithm for distance and matching. However maintaining these weights seems to be hard in an evolving graph. This is because even for planar graphs where static non-zero circulation weights are easy to construct [3, 9, 29] maintaining them dynamically seems to need a dynamic planar embedding algorithm. And that alone doesn't seem to suffice since even small changes in the input can lead to large changes in the embedding and that will require us to change the weights of many edges (since weight of the edges are determined by the embedding [3, 29]). This induces us to side-step maintaining non-zero circulation weights.

In this paper, we circumvent this problem by modifying the approach of [15] to convert the given static nonzero-circulation weights to dynamic isolating weights. Notice that [15] yields a black box recipe to produce isolating weights of quasipolynomial magnitude for bipartite graphs, which we label as *FGT-weights* in the following way. Let $e_1, e_2, \ldots$ be the edges of a bipartite graph. Consider a non-zero circulation of exponential magnitude viz. $w_0(e_i) = 2^i$. Next, consider a list of $\ell = O(\log n)$ primes $\vec{p} = (p_1, \ldots, p_\ell)$, each of $O(\log n)$ bits, which yield a weight function $w_{\vec{p}}(e_i)$. This is defined by taking the ℓ weight functions $w_0 \bmod p_j$ for $j \in \{1, \ldots, \ell\}$ and concatenating them with *shifting* the weights to the higher-order bits appropriately, that is: $w_{\vec{p}}(e) = \langle w_0(e) \bmod p_1, \ldots, w_0(e) \bmod p_\ell \rangle$. This

is so that there is no overflow from the j-th to the $(j-1)$-th weight for any $j \in \{2, \ldots, \ell\}$. In [15], it was proved that for every graph there exist some set of ℓ primes such that the respective weight function $w_{\vec{p}}$ isolates a perfect matching in the graph.

Suppose we start with a graph with static polynomially bounded weights ensuring non-zero circulation. In a step, some edges are inserted or deleted. The graph after deletion is a subgraph of the original graph; hence the non-zero circulation remains non-zero after a deletion[1], but we have to do more in the case of insertions. We aim to give the newly inserted edges FGT-weights in the higher-order bits while giving weight 0 to all the original edges in G again in the higher-order bits. Thus the weight of all perfect matchings that survive the deletions in a step remains unchanged. Moreover, if none such survive but new perfect matchings are introduced (due to insertion of edges) the lightest of them is determined solely by the weights of the newly introduced edges. In this case, our modification of the existential proof from [15] ensures that the minimum weight perfect matching is unique.

In order to handle bulk insertion of $N = \log^{O(1)} n$ edges, we need to apply the FGT-recipe described above to a set system with a universe of N elements. This yields quasipolynomial ($N^{\log^{O(1)} N}$) weights in N which are therefore still subpolynomial in n ($2^{(\log\log n)^{O(1)}} = 2^{o(\log n)} = n^{o(1)}$). Further, the number of primes is polyloglog ($\log^{O(1)} N = (\log\log n)^{O(1)}$) and so sublogarithmic ($\log^{o(1)} n$). Hence, the number of possible different weights is subpolynomial, which allows us to derandomize our algorithm by going over all possible FGT-weight functions defined above. We point out that in [11] a similar scheme is used for reachability and bears the same relation to [24] as this section does to [15]. We have the following lemma, which we prove in Section 3.1. Our proof of the lemma is crucially based on [15] but our proof is self contained except for Lemma 9 which we assume as a black box.

▶ **Lemma 5.** *Let G be a bipartite graph with non-zero circulation w^{old}. Suppose $N = \log^{O(1)} n$ edges are inserted into G to yield G^{new}. Then we can compute polynomially many weight functions in $\mathsf{FO}(\leq, +, \times)$ that have $O(\log n)$ bit weights, and at least one of them, w^{new} is isolating. Furthermore, the weights of the original edges remain unchanged under w^{new}.*

3.1 Details of Maintaining Dynamic Isolating Weights

We divide the edges of the graph into *real* and *fictitious*, where the former represents the newly inserted edges and the latter original undeleted edges[2].

Next, we follow the proof idea of [15] but focus on assigning weights to only real edges which are $N = \log^{O(1)} n$ in number. We do this in $\log N$ stages starting with a graph $G_0 = G$ and ending with an acyclic graph G_ℓ that contains a unique perfect matching if and only if G contains a perfect matching, where $\ell = \log N$. At each step, we maintain the following.

▶ **Invariant 6.** For $i \geq 1$, G_i contains no cycles with at most 2^{i+1} real edges.

Assuming this invariant we complete the proof of Lemma 5:

Proof of Lemma 5. From the invariant above G_ℓ does not contain any cycle that consists of real edges. From the construction of G_ℓ, if G has a perfect matching, then so does G_ℓ and hence it is a perfect matching. Notice that W_ℓ is obtained from $p_1, \ldots, p_\ell$ that include $O((\log\log n)^2) = o(\log n)$ many bits. Thus there are (sub)polynomially many such weighting functions W_ℓ, depending on the primes $\vec{p}$. Let $w = B \cdot W_\ell + w^{old}$ where we recall that $W_\ell(e)$

[1] If we merely had isolating weights, this would not necessarily preserve isolation.
[2] We use the terms old $\leftrightarrow$ fictitious and new $\leftrightarrow$ real interchangeably in this section.

is non-zero only for the new (real) edges and w^{old} is non-zero only for the old (fictitious) edges. Thus, any perfect matching that consists of only old edges is lighter than any perfect matching containing at least one new edge. Moreover, if the real edges in two matchings differ, then, from the construction of W_ℓ (for some choice of $\vec{p}$) both matchings cannot be the lightest as W_ℓ real isolates a matching. Thus the only remaining case is that we have two distinct lightest perfect matchings, which differ only in the old edges. But the symmetric difference of any two such perfect matchings is a collection of cycles consisting of old edges. But each cycle has a non-zero circulation in the old graph and so we can obtain a matching of even lesser weight by replacing the edges of one of the matchings in one cycle by the edges of the other one. This contradicts that both matchings were of least weight. ◀

Next we show how Invariant 6 is maintained. Notice that the case $i = 0$ follows from the above discussion and the induction starts at $i > 0$.

We first show how to construct G_{i+1} from G_i such that if G_i satisfies the inductive invariant 6, then so does G_{i+1}. In the i-th step, let $\mathcal{C}_{i+1}$ be the set of cycles that contain at most 2^{i+2} real edges, for $i > 1$. For each such cycle $C = f_0, f_1, \ldots$ containing $k \leq 2^{i+2}$ real edges (with f_0 being the least numbered real edge in the cycle), edge-partition the cycle into 4 consecutive paths $P_j(C)$ for $j \in \{0, 1, 2, 3\}$ such that the first three paths contain exactly $\lfloor \frac{k}{4} \rfloor$ real edges and the last path contains the rest. In addition ensure that the first edge in each path is a real edge. Let the first edge of the 4-paths be respectively $f'_0 (= f_0), f'_1, f'_2, f'_3$. We identify each cycle in $\mathcal{C}_{i+1}$ with these 4-tuples $\langle f'_0, f'_1, f'_2, f'_3 \rangle$.

For a cycle $C \in \mathcal{C}_{i+1}$, we define a set C' which consists of only real edges of C. Similarly, $\mathcal{C}'_{i+1} = \{C' \mid C \in \mathcal{C}_{i+1} \wedge C' \neq \emptyset\}$. Note that there can be many cycles in $\mathcal{C}_{i+1}$ corresponding to a single set in $\mathcal{C}'_{i+1}$ (i.e., those cycles that contain the same set of real edges). We fix a particular $C \in \mathcal{C}_{i+1}$ for every $C' \in \mathcal{C}'_{i+1}$ with which it is associated. The 4-tuple associated with the cycle C is also associated with the corresponding set C'. We have the following which shows that the associated 4-tuples $\langle f'_0, f'_1, f'_2, f'_3 \rangle$ uniquely characterise sets in $\mathcal{C}'_{i+1}$.

▷ Claim 7. There is at most one set in $\mathcal{C}'_{i+1}$ that has a given 4-tuple $\langle f'_0, f'_1, f'_2, f'_3 \rangle$ associated with it.

Proof. Suppose two distinct sets $C'_1, C'_2 \in \mathcal{C}'_{i+1}$ have a common 4-tuple $\langle f'_0, f'_1, f'_2, f'_3 \rangle$ associated with them. Let C_1, C_2 be two cycles corresponding to C'_1 and C'_2, respectively. Then for at least one $j \in \{0, 1, 2, 3\}$, $P_j(C_1) \neq P_j(C_2)$. Hence, $P_j(C_1) \cup P_j(C_2)$ is a closed walk in G_i containing at most $2 \times \lceil \frac{2^{i+2}}{4} \rceil = 2^{i+1}$ real edges, contradicting the assumption on G_i. ◁

This shows that there are at most N^4 elements in $\mathcal{C}'_{i+1}$ because that is the maximum number of distinct 4-tuples of real edges. We define circulation for the sets in $\mathcal{C}'_{i+1}$ via the circulation for those in $\mathcal{C}_{i+1}$. We know that for every $C' \in \mathcal{C}'_{i+1}$ there is at least one $C \in \mathcal{C}_{i+1}$ corresponding to it. Let w be a weight function that gives non-zero weights to only real edges of the graph. Circulation of $C' \in \mathcal{C}'_{i+1}$ with respect to w is defined as $c_w(C') = c_w(C) = |w(e_1) - w(e_2) + w(e_3) - \ldots|$, where $e_i \in C$. This is well-defined since in bipartite graphs the parity of the length of any two paths between the same pair of vertices is the same. Thus, all C such that they have C' associated with it, have the same circulation since the sign associated with a real edge does not change for any such C. Now we will use the following lemma to ensure non-zero circulations to sets in $\mathcal{C}'_{i+1}$.

▶ **Lemma 8** (Based on Lemma 2 in [16]). *For every constant $k > 0$ there is a constant $k_0 > 0$ such that for every set S of m-bit integers with $|S| \leq m^k$, the following holds: There is a $k_0 \log m$-bit prime number p such that for any $x, y \in S$, if $x \neq y$ then $x \not\equiv y \bmod p$.*

We apply the above lemma to the set $c_{w_0}(\mathcal{C}'_{i+1}) = \{c_{w_0}(C') : C' \in \mathcal{C}'_{i+1}\}$. Here, the weight function w_0 assigns weights $w_0(e_j) = 2^j$ to the real edges which are $e_1, e_2, \ldots, e_N$ in an arbitrary but fixed order. Notice that from the above claim, the size of this set is $|\mathcal{C}'_{i+1}| \leq N^4$. Since $w_0(e_j)$ is j-bits long hence $c_{w_0}(C)$ for any cycle $C \in \mathcal{C}_i$ that has less than 2^{i+2} real edges is at most $i + j + 2 < 4N$-bits long. Thus, we obtain a prime p_{i+1} of length at most $k_0 \log(4N)$ by picking $k = 4$. We define $w_{i+1}(e_j) = w_0(e_j) \bmod p_{i+1}$. By Lemma 8 we know that circulation of each set in $\mathcal{C}'_{i+1}$ is non-zero with respect to w_{i+1}. Therefore, circulation of all the cycles in $\mathcal{C}_{i+1}$ is nonzero with respect to w_{i+1} (remember that w_{i+1} assign nonzero weights to only real edges).

Now consider the following crucial lemma from [15]:

▶ **Lemma 9** ([15]). *Let $G = (V, E)$ be a bipartite graph with a weight function w. Let C be a cycle in G such that $c_w(C) \neq 0$. Let E_1 be the union of all minimum weight perfect matchings in G. Then the graph $G_1 = (V, E_1)$ does not contain the cycle C. Moreover, all the perfect matchings in G_1 have the same weight.*

Let B be a large enough constant (though bounded by a polynomial in N) to be specified later. We shift the original accumulated weight function W_i and add the new weight function w_{i+1} to obtain: $W_{i+1}(e) = W_i(e)B + w_{i+1}(e)$. Apply W_{i+1} on the graph G_i to obtain the graph G_{i+1}. Inductively suppose we have the invariant 6 that the graph G_i did not have any cycles containing at most 2^{i+1} real edges. This property is preserved when we take all the perfect matchings in G_i and apply W_{i+1} yielding G_{i+1}. Moreover, from Lemma 9 and the construction of w_{i+1}, the cycles of $\mathcal{C}_i$ disappear from G_{i+1} restoring the invariant. This yields a weight function W_ℓ using that $\ell = \log n$ (see the discussion before Invariant 6).

Notice that it suffices to take B greater than the number of real edges times the maximum of $w_i(e)$ over i, e. Showing that G_1 contains no cycle with at most 4 real edges mimics the above more general proof, and we skip it here. We say that a weight function that gives non-zero weights to the real edges, *real isolates* $\mathcal{M}$ for a set system $\mathcal{M}$ if the minimum weight set in $\mathcal{M}$ is unique with respect to that weight function. In our context, $\mathcal{M}$ will refer to the set of perfect/maximum matchings.

4 Maximum Cardinality Matching Search in DynFO$[\oplus](\leq, +, \times)$

In this section, we convert the static algorithm for maximum matching search in bipartite graphs into a dynamic algorithm with the help of the isolating weights from the previous section. In the static setting [6] the problem reduces to determining non-singularity of an associated matrix given a non-zero circulation for the graph.

The algorithm extracts what is called a min-weight *generalized* perfect matching (min-weight GPM), that is, a matching along with some self-loops. The construction proceeds by adding a distinct edge (v, t_v) on every vertex $v \in V(G)$ with a self-loop on the new vertex t_v to yield the graph G'. The idea is to match as many vertices as possible in G' using the actual edges of G while reserving the pendant edges (v, t_v) to match vertices that are unmatched by the maximum matching. If a vertex v is matched in a maximum matching of G then the vertex t_v is "matched" using a self-loop.

Given a non-zero circulation weight w''' for G the weight function for G' is $w = \langle w', w'', w''' \rangle$. Here we represent by w' the function that is identically 0 for all the self loops and is 1 for all the other edges. $w''(e)$ is zero except for pendant edges $e = (v, t_v)$, for $v \in V(G)$, which have $w''(e) = v$ (where v is interpreted as a number in $\{1, \ldots, |V(G)|\}$) such that all vertices get distinct numbers. The paper [6] considers the weighted Tutte matrix

T where for an edge (u, v) the entry $T(u, v) = \pm x^{w(u,v)}$ (say, with a positive sign iff $u < v$) and is zero otherwise. It shows that in the univariate determinant polynomial $det(T)$ the least degree term x^W with a non-zero coefficient must have this coefficient equal to ± 1 and the exponent W is the weight of the minimum weight generalized perfect matching in G'. Further this min-weight GPM consists of a maximum cardinality matching in G along with the edges (v, t_v) for all the vertices v unmatched in the maximum matching. The edges in the maximum matching can then be obtained by checking if, on removing the edge (u, v), the weight of the min-weight maximum matching increases.

The idea behind the proof is as follows:

1. The most significant weight function w' ensures that the cardinality of the actual edges (i.e. edges from G) picked in the min-wight GPM in G' equals the cardinality of the maximum matching in G. This is because the GPM would cover as many of the t_v vertices with self-loops as possible to minimize the weight that ensures the corresponding v must be covered by an actual edge.
2. The next most significant weight function w'' is used to ensure that all the min-weight GPMs use the same set of pendant edges. This is because, otherwise, there is an alternating path in the symmetric difference of the two GPMs that starts and ends at self-loops t_u, t_v. Then, the difference in the weights w'' of the two matchings restricted to the path is $u - v \neq 0$ and we can find a GPM of strictly smaller weight by replacing the edges of one matching with the edges of the other matching restricted to the path, contradicting that both matchings were the lightest GPMs.
3. The least significant weight function w''' then isolates the GPM since all min-weight GPMs are essentially perfect matchings restricted to the same set S of vertices, namely those that are not matched by the corresponding pendant edges and the non-zero circulation weights on G ensures that these are isolating weights on the induced graph $G[S]$.

We claim that we just need *isolating* weights w''' instead of non-zero circulation weights to ensure that the above technique works. Replacing non-zero circulations with isolating weights does not affect the first two steps. It would seem, the third step does not work since isolating weights for G might not be isolating weights for the subgraph $G[S]$. However, Lemma 5 can be applied to the graph $G[S]$ directly – notice that in the above proof sketch S is determined by the first two weight functions w', w'' and does not depend on the third w'''.

As described above, we need to maintain the determinant of a certain matrix A related to the Tutte matrix in order to find the size of the maximum cardinality matching. For a small change matrix B, the Matrix Determinant Lemma [30, 17]

$$\det(A + UBV) = \det(I + BVA^{-1}U)\det(A)$$

allows us to maintain the determinant by reducing it to maintaining the inverse of the matrix. To maintain the inverse, the Sherman-Morrison-Woodbury formula [19]

$$(A + UBV)^{-1} = A^{-1} - A^{-1}U(I + BVA^{-1}U)^{-1}BVA^{-1}$$

tells us how the task of recomputing the inverse of a non-singular matrix A under small changes B reduces to that of computing the inverse of a small matrix $(I+BVA^{-1}U)$ statically. So we need to ensure that the matrix remains invertible throughout which is what we achieve below by tinkering with the definition of the Tutte matrix. We have the following definition:

▶ **Definition 10.** *The generalized Tutte matrix is a matrix with rows and columns indexed by $V(G') = V(G) \cup \{t_v : v \in V(G)\}$ and with the following weights on edges: $T(t_v, t_v) = 1$, $T(v, v) = x^{w_\infty}$ and $T(a, b) = \pm x^{\langle w', w'', w''' \rangle (a,b)}$ whenever $a, b \in V(G'), a \neq b$. It is ensured in the above that $T(a, b) = -T(b, a)$. Here w_∞ is a polynomially bounded number larger than the largest of the weights $\langle w', w'', w''' \rangle (a, b)$.*

Note that the generalized Tutte matrix is not unique. We now have the following:

▶ **Lemma 11.** *Let T be a generalized Tutte matrix defined above, then the highest exponent w such that x^w divides $det(T)$ is twice the weight of the min-weight GPM in G'. Further, the matrix T is invertible.*

Proof. From the properties of the weight function $\langle w', w'', w''' \rangle$ we see that the minimum weight generalized perfect matching is unique see [6, Lemma 9]. The exponent of the least degree monomial is twice the weight of the min-weight GPM when we take superposition of the unique min-weight GPM with itself [6, Observation 14]. The self loops on the vertices t_v appear only once in a monomial and twice in the superposition, but because their weight is zero under $\langle w', w'', w''' \rangle$ it will not affect the exponent.

In order to guarantee invertibility of T we just need to prove that the product of the diagonal terms yields a monomial of much higher degree than any other monomial and of coefficient one, since this implies that the matrix is non-singular because this monomial cannot be canceled out by the rest of the monomials. Consider the product of the diagonal entries viz. $x^{\frac{|V(G')|}{2} w_\infty} = x^{|V(G)| w_\infty}$. Any monomial with less than $|V(G)|$ diagonal entries $T(v, v)$ is bound to be of much smaller exponent. Now the monomials which use an off-diagonal entry $T(v, u)$ or $T(v, t_v)$ must miss out on the diagonal entry in the v-th row, making the exponent much smaller. ◀

4.1 Maintaining the Determinant and Inverse of a Matrix

We need the following definitions and results about univariate polynomials, matrices of univariate polynomials and operations therein over a finite field of characteristic 2. Let $\mathbb{F}_2$ be the field of characteristic 2 containing 2 elements. For (potentially infinite) power series $f, g \in \mathbb{F}_2[[x]]$, we say f *m-approximates* g (denoted by $f \approx_m g$) if the first m terms of f and g are the same. We will extend this notation to matrices and write $F \approx_m G$ where $F, G \in \mathbb{F}_2[[x]]^{\ell \times \ell}$ are matrices of power series. We will have occasion to use this notation only when one of F, G is a matrix of polynomials, that is, a matrix of finite power series.

Notice that if $A \in \mathbb{F}_2[x]^{n \times n}$ with the degree of entries bounded by w_∞, then there exists $A^{-1} \in \mathbb{F}_2[[x]]^{n \times n}$. For us, only the monomials with degrees at most w_∞ are relevant. Thus we will assume that we truncate A^{-1} at w_∞ many terms to yield matrix $A' \approx_{w_\infty} A^{-1}$. Then we have the following:

▶ **Lemma 12** (Lemma 10 in [11]). *Suppose $A \in \mathbb{F}_2[x]^{n \times n}$ is invertible over $\mathbb{F}_2[[x]]$, and $C \in \mathbb{F}_2[x]^{n \times n}$ is an m-approximation of A^{-1}. If $A + UBV$ is invertible over $\mathbb{F}_2[[x]]$ with $U \in \mathbb{F}_2[x]^{n \times \ell}, B \in \mathbb{F}_2[x]^{\ell \times \ell}$, and $V \in \mathbb{F}_2[x]^{\ell \times n}$, then $(A + UBV)^{-1} \approx_m C - CU(I + BVCU)^{-1}BVC$. Furthermore, if $\ell \leq \log^c n$ for some fixed c and all involved polynomials have polynomial degree in n, then the right-hand side can be computed in $\mathsf{FO}[\oplus](\leq, +, \times)$ from C and ΔA.*

Similar to the above (using the closure of m-approximation under product), we get an approximate version of the Matrix Determinant Lemma, that is:

▶ **Proposition 13.** *Suppose $A \in \mathbb{F}_2[x]^{n \times n}$ is invertible over $\mathbb{F}_2[[x]]$, and $C \in \mathbb{F}_2[x]^{n \times n}$ is an m-approximation of A^{-1} and polynomial $d(x) \approx_m det(A)$ then $d \cdot \det(I + BVCU) \approx_m \det(A + UBV)$.*

We can now proceed to prove Theorem 1:

Proof of Theorem 1. By putting $m = w_\infty$ and applying Lemma 12 and Propositions 13 to the generalized Tutte matrix from Lemma 11 and using the (Muddling) Lemma 4, we complete the matching part of Theorem 1 (see Section 6 for the proof involving distance). ◀

5 Maximum Cardinality Matching in DynFO$(\leq, +, \times)$

In this section we prove Theorem 3 by giving a DynFO$(\leq, +, \times)$ algorithm for maintaining the size of a maximum matching under $O(\frac{\log n}{\log\log n})$ changes. Notice that the approach in the previous section has the limitation that it only gives a DynFO$[\oplus](\leq, +, \times)$ bound as we need to maintain polynomials of large (polynomial in n) degree. Instead, the main ingredient here is a new algorithm for maintaining the rank of a matrix in DynFO$(\leq, +, \times)$ under $O(\frac{\log n}{\log\log n})$ changes (Section 7). Our matching algorithm follows the basic approach of the non-uniform DynFO algorithm of [8]. Here, since we use deterministic isolation weights (as opposed to the randomized isolation weights of [27]), with some more work, we obtain a *uniform* DynFO$(\leq, +, \times)$ bound under bulk changes.

The algorithm of [8] builds on the well-known correspondence between the size of maximum matching and the rank of the Tutte matrix of the corresponding graph – if a graph contains a maximum matching of size m then the associated Tutte matrix is of rank $2m$ [25]. The dynamic rank algorithm from Section 7 cannot be applied directly since the entries of the Tutte matrix are indeterminates. However, the rank can be determined by replacing each x_{ij} by $2^{w(i,j)}$. Here w assigns a positive integer weight to every edge (i, j) under which the maximum matching gets unique minimal weight, i.e., it is matching-isolating. Using the Isolation Lemma [27], it can be shown that the correspondence between the rank and the size of the maximum matching does not change after such a weight transformation [22, 8].

Our algorithm diverges from [8] as we need to deterministically compute these isolating weights and also, to somehow maintain those. Since we do not know how to maintain such weights directly, as in Section 4, we convert the static non-zero circulation weights to dynamic isolating weights using the Muddling Lemma 4. Given a graph G, let B_w be its weighted Tutte matrix with each x_{ij} replaced by $2^{w(i,j)}$ for an isolating weight function w. Initially, the static non-zero circulation weights provide such weights. Since we are only interested in computing the rank of B_w, we do not need to make the initial modifications of adding pendant edges or self-loops to G as before. So the weight function w is just the non-zero circulation weight $\langle w''' \rangle$ here. In the dynamic process, similar to Section 4, we use the FGT-weights w_{new} on top for the newly inserted edges. We have the following:

▶ **Lemma 14.** *Given a dynamic algorithm for maintaining the rank of an integer matrix under $k = O(\log^c n)$ changes at each step for some fixed constant c, we can maintain the size of the maximum matching in the same complexity class under $O(k)$ changes for the class of graphs where non-zero circulation weights can be computed in* NC.

Proof. Given a graph G, assume we have an algorithm for computing the non-zero circulation weight function w in $\mathsf{NC}^i \subseteq \mathsf{AC}[\frac{\log^i n}{\log\log n}]$ for some fixed integer i. Once these weights w are available, rank(B_w) can be found in NC^2 [1] which is contained in $\mathsf{AC}[\frac{\log^2 n}{\log\log n}]$. Since $O(k)$ changes can occur at each step, during this time, total of $O(k \cdot (\frac{\log^i n}{\log\log n} + \frac{\log^2 n}{\log\log n}))$ many new changes accumulate. As w assigns non-zero circulation weights to the edges of G, we can assign weight 0 to the deleted edges and the weights remain isolating. For the newly inserted edges, which are only polylog(n) many, we compute the polynomially bounded FGT-weights in AC^0 using Lemma 9. Thanks to Lemma 4, in $O(\frac{\log^i n}{\log\log n} + \frac{\log^2 n}{\log\log n}))$ many steps we can take care of all the insertions by adding k new edges at each step along with k old ones in double

the speed using our rank algorithm. Note that, during the static rank computation phase, we do not restart the static algorithm for computing the weight w. Instead, we recompute these weights once the rank computation using them finishes. More precisely, we can think of a combined static procedure that computes the non-zero circulation weights followed by the rank of the weighted Tutte matrix B_w in NC^b for b=max$(i, 2)$. And on this combined procedure, we apply our Muddling Lemma 4. ◀

We can now prove Theorem 3:

Proof of Theorem 3. Similar to [8, Theorem 16] this implies a *uniform* bounded expansion first-order truth-table (bfo-tt) reduction from maximum matching to rank in this special case.[3] Since $\mathsf{DynFO}(\leq, +, \times)$ is closed under bfo-tt reductions [8, Proposition 4] and dynamic rank maintenance is in $\mathsf{DynFO}(\leq, +, \times)$ under $O(\frac{\log n}{\log \log n})$ changes (Theorem 2), in classes of graphs where non-zero circulation weights can be computed in NC we have the result. ◀

6 Maintaining Distance under Bulk Changes

In this section, extending the reachability result of [11], we show that distances can be maintained in $\mathsf{DynFO}[\oplus](\leq, +, \times)$ under polylog(n) changes in classes of graphs where non-zero circulation can be computed in NC. We start with describing the reachability algorithm of [11] followed by the necessary modifications needed for maintaining distance information.

6.1 Outline of the Approach for Reachability

Let $G = (V, E)$ be the given n-node graph with an isolating weight assignment w. For a formal variable x, let the corresponding weighted adjacency matrix $A = A_{(G,w)}(x)$ be defined as follows: if $(u, v) \in E$, then $A[u, v] = x^{w(u,v)}$, and 0 otherwise. Consider the matrix $D = (I - A)^{-1}$, where I is the identity matrix. Notice that the matrix $(I - A)$ is invertible over the ring of formal power series (see [13]). Here $D = \sum_{i=0}^{\infty}(A)^i$ is a matrix of formal power series in x and in the (s, t)-entry, the coefficient of the i-th terms gives the number of walks from s to t of weight i.

As w isolates the minimal weight paths in G, it is enough to compute these coefficients modulo 2 for all i up to some polynomial in n since there is a unique path with the minimal weight if one exists. So, it is enough to compute and update the inverse of the matrix $I - A$. Though to do it effectively, we compute the *n-approximation* C of D, which is a matrix of formal polynomials that agrees with the entries of D up to degree $i \leq n$ terms. This precision is preserved by the matrix operations we use, see [13, Proposition 14].

When applying a change ΔG to G that affects k nodes, the associated matrix A is updated by adding a suitable change matrix ΔA with at most k non-zero rows and columns, and can therefore be decomposed into a product UBV of suitable matrices U, B, and V, where B is a $k \times k$ matrix. To update the inverse, we employ the Sherman-Morrison-Woodbury identity (cf. [19]), which gives a way to update the inverse when A is changed to $A + \Delta A$ as follows:

$$(A + \Delta A)^{-1} = (A + UBV)^{-1} = A^{-1} - A^{-1}U(I + BVA^{-1}U)^{-1}BVA^{-1}.$$

[3] Intuitively, bounded expansion first-order (bfo) reductions are first-order reductions such that each tuple in a relation and each constant of the input structure affects at most a constant number of tuples and constants in the output structure. A bfo-tt reduction bears the same relation to a bfo-reduction as a truth-table reduction bears to a many-one reduction. For a formal definition see [8, Section 3.2] where it was first formalized.

The right-hand side can be computed in $\mathsf{FO}[\oplus](\leq, +, \times)$ for $k = \log^{O(1)} n$ since modulo 2 computation of (1) multiplication and iterated addition of polynomials over $\mathbb{Z}$ and (2) computation of the inverse of $I + BVA^{-1}U$ which is also a $k \times k$ matrix is possible in $\mathsf{FO}[\oplus](\leq, +, \times)$ for (matrices of) polynomials with polynomial degree [18]. Finally, we need to assign weights to the changed edges as well so that the resulting weight assignment remains isolating. We show how to achieve this starting with non-zero circulation weights. Using [11, Theorem 5] we can assume that such a weight assignment is given, and that we only need to update the weights once.

Let u be skew-symmetric non-zero circulation weights for G and let n^k be the polynomial bound on the weights. Further, let w be the isolating weight assignment that gives weight $n^{k+2} + u(e)$ to each edge $e \in E$. During the AC^d initialization, we compute the weights u and w and an n^b-approximation matrix C of $(I - A_{(G,w)}(x))^{-1}$ mod 2 for some constant b.

When changing G via a change ΔE with deletions E^- and insertions E^+, the algorithm proceeds as follows: To compute the isolating weights w^-, the non-zero circulation weights u^- for G^- are obtained from u by setting the weight of deleted edges $e \in E^-$ to 0. As u^- gives the same weight to all simple cycles in G^- as u gives to these cycles in G, it has non-zero circulation. To handle E^+ it can be shown that [11, Lemma 11] there is a FO-computable (from w, E^+ and the reachability information in G) family W' of polynomially many weight assignments such that $\exists w' \in W'$ isolating for $(V, E \setminus E^- \cup E^+)$.

Hence we need to maintain polynomially many different instances of the graph with different weight functions from W' such that in at least one of them the paths are isolated. The idea is that if there is an s-t-path using at least one inserted edge from E^+, then there is a unique minimal path among all s-t-paths that use at least one such edge, while ignoring the weight of the paths that is contributed by edges from E. The edge weights from E^+ are multiplied by a large polynomial to ensure that the combined weight assignment with the existing weights for edges in E remains isolating. Since the weights are constructed only for a graph with $N = \log^{O(1)} n$ many nodes, and although they are not polynomially bounded in N, they *are* in n. Please refer to [11, Section 6] for more details.

From the above discussion, to prove a similar bound for distances, it suffices to show that (1) after every polylog(n) changes, we can ensure the edge weights remain "shortest path-isolating" and (2) under such weights the distance can be updated in $\mathsf{FO}[\oplus](\leq, +, \times)$.

6.2 Dynamic Isolation of Shortest Paths

In the following, we first describe how the isolating weights for reachability can be modified to give weights for isolating shortest paths. Similar to maintaining reachability, our algorithm handles deletions and insertions differently. In case of deletion, we set the weight of the deleted edges $e \in E^-$ to 0 and due to the non-zero circulation weights, the weights remain isolating. For insertions, the idea is to do a *weight refinement* by shifting the original edge weights $w(e)$ (1 in case of unweighted graphs) to the highest order bits in the bit-representation, in the presence of other newly assigned weights to the edges.

We define a new weight functions $w^* = \langle w, w', u \rangle$ and assign these weights to the inserted edges $e \in E^+$. The existing edges E are not assigned any w' weight and all those bits remain zeroes. So we get a family of weight functions W^*. Here w is the polynomially-bounded original edge weights, w' is one of the (polynomially many) isolating weights from the family W' assigned to the newly added edges E^+ during the dynamic process, and u are the non-zero circulation weights that are computed statically. The combined weights w^* is FO-constructible from the weights w, w' and u as all involving numbers are $O(\log n)$ bits long (see [21, Theorem 5.1]). The correctness of the fact that these weights are indeed shortest

path isolating follows from [11, Lemma 11] with the observation that since the original edge weights are shifted to the highest-order bits, the minimum weight path with these combined weights corresponds to the shortest path in the original graph.

The update algorithm for maintaining reachability can be extended to maintaining distances also [13]. Here, instead of checking only the non-zeroness of the (s,t)-entry in the polynomial matrix C, we compute the minimum degree term as well (with coefficient 1), which can be done in $\mathsf{FO}[\oplus](\leq,+,\times)$. By construction, the degree of a term in this polynomial is same as the weight of the corresponding walk under the dynamic isolating weights and applying an easy transformation gives us back the original weights, that is, the weight of the shortest path from s to t in G'. This proves the distance part of Theorem 1.

7 Maintaining Rank under Bulk Changes

In this section we prove Theorem 2. For ease of exposition, we build upon the algorithm as described in [7, Section 3.1]. Before going into the details of the proof, we start with defining some important notation, followed by our overall proof strategy. Let A be a $n \times n$ matrix over $\mathbb{Z}_p$, where $p = O(n^3)$ is a prime. Let K be the kernel of A. For a vector $v \in \mathbb{Z}_p^n$, we define $S(v) = \{i \in n \mid (Av)_i \neq 0\}$, where $(Av)_i$ denotes the ith coordinate of the vector Av. Let B be a basis of Z_p^n. A vector $v \in B$ is called *i-unique* with respect to A and B if $(Av)_i \neq 0$ and $(Aw)_i = 0$ for all other $w \in B$. A basis B is called *A-good* if all the vectors in $B - K$ are i-unique with respect to A and B. For a vector $v \in B - K$, the minimum i for which it is i-unique is called the principal component of v, denoted as $\mathrm{pc}(v)$.

Starting with an A-good basis B, and introducing a small number of changes to yield A' may lead to B losing its A-goodness. To restore this, we alter the matrix B in two phases to obtain an A'-good basis B'. The first phase involves identifying a full rank submatrix in A' corresponding to the changed entries, inverting it, and restoring the pc's of the columns of that full rank submatrix. In the second phase, we restore the pc's of the rest of vectors, which had lost the pc's either because of the changes or during Phase 1. The rough outline is similar to that of [7] but in order to handle non-constant changes we have to make non-trivial alterations and use efficient small matrix inversion from [13]. We have Theorem 2 from the following lemma, whose proof is provided in Section 7.1:

▶ **Lemma 15.** *Let $A, A' \in \mathbb{Z}_p^{n\times n}$ be two matrices such that A' differs from A in $O(\frac{\log n}{\log\log n})$ places. If B is an A-good basis then we can compute an A'-good basis B' in $\mathsf{FO}(\leq,+,\times)$.*

▶ **Proposition 16** ([8])**.** *Let $A \in \mathbb{Z}_p^{n\times n}$ and B an A-good basis of $\mathbb{Z}_p^n$. Then $rank(A) = n - |B \cap K|$ is the number of vectors in the basis that have a pc.*

▷ Claim 17. If the rank of an $n \times n$ matrix A is r then there exists a prime $p = O(max(n, \log N)^3)$ such that the rank of A over $\mathbb{Z}_p$ is also r, where N is the maximum absolute value the entries of the matrix A contain.

Proof. We know that if the rank of A is r then there exists a $r \times r$ submatrix A_s of A such that its determinant is nonzero. The value of this determinant is at most $n!N^n$, which can be represented by $O(n(\log n + \log N))$ many bits. Therefore, this determinant is divisible by at most $O(n(\log n + \log N))$ many primes. Thus by the prime number theorem, we can say that for a large enough n there exists a prime p of magnitude $O(max(n, \log N)^3)$ such that determinant of A_s is not divisible by p. ◁

Hence, to compute the rank of A, it is sufficient to compute the rank of the matrices (A mod p) for all primes p of size $O(max(n, \log N)^3)$ and take the maximum among them. Below we show how to maintain the rank of the matrix A mod p for a fixed prime p. We replicate the same procedure for all the primes in parallel.

A' is the matrix that is obtained by changing k many entries of A. Notice that if B is not A'-good basis, that means there are some vectors in $B - K'$ which are not i-unique with respect to B and A', where K' is the kernel of A'. A vector $w \in B - K'$ which was i-unique ($i \in [n]$) with respect to A and B may no longer be i-unique with respect to A' and B for the following two reasons, (i) $i \notin S'(w)$, (ii) there may be more than one vector w' such that $i \in S'(w')$. For a vector v, $S'(v)$ denotes the set of non-zero coordinates of the vector $A'v$. Below we give an AC^0 algorithm to construct an A'-good basis.

In several places we make use of the fact that sum and product of polylog(n) many numbers each with of polylog(n) bits can be computed in AC^0 [21, Theorem 5.1].

7.1 Construction of an A'-good basis

Let $k = O(\frac{\log n}{\log \log n})$ and $M = (A'B)_{R,C}$ be the $n \times n$ matrix where R is the set of rows and C is the set of columns of M. We know that $A'B$ differs from AB in a set R_0 of at most k many rows. Let $M_{R_0,*}$ be the matrix M restricted to the rows in the set R_0.

▷ Claim 18. There exists a prime $q = O(\log^3 n)$ such that the rank of $(M_{R_0,*} \bmod q)$ is equal to the rank of $(M_{R_0,*} \bmod p)$.

Proof. The proof follows from the proof of Claim 17. ◁

From the above claim, it follows that a row basis of $(M_{R_0,*} \bmod p)$ remains a row basis of $(M_{R_0,*} \bmod q)$ for some $O(\log \log n)$-bit prime q. Next, we have two constructive claims:

▷ Claim 19. A row basis R_1 of $(M_{R_0,*} \bmod q)$ can be found in AC^0.

Proof. Note that number of rows in R_0 are $O(\frac{\log n}{\log \log n})$; thus, the number of the subsets of the rows of R_1 are polynomially many (in n), and each row in the set R_0 can be indexed by $O(\log \log n)$ many bits. An element of $\mathbb{Z}_q$ can also be represented by $O(\log \log n)$ many bits. Therefore, for a fixed subset S of R_0, all the linear combinations of the rows of S can be represented by $O(\log n)$ many bits. We try all the linear combinations in parallel. Also, we do this for all the subsets in parallel. The subset with the maximum cardinality in which all the linear combinations result in non-zero values will be the maximum set of linearly independent rows in $(M_{R_0,*} \bmod q)$. ◁

▷ Claim 20. A column basis C_1 of $(M_{R_1,*} \bmod q)$ can be found in AC^0.

Proof. To find the maximum set of linearly independent columns in the matrix $M_{R_1,*}$ we just check in parallel if the rank of $M_{R_1,i}$ is greater than the rank of $M_{R_1,i-1}$ for all $i \in [m]$. Let $c_1, c_2 \dots c_m$ be the columns in the matrix $M_{R_1,*}$. Note that the set of columns c_i such that the rank of $M_{R_1,i}$ is more than the rank of $M_{R_1,i-1}$, form a maximum set of linearly independent columns in $M_{R_1,i}$. We can check this in AC^0. ◁

We are going to construct four matrices $D^{(1)}, E^{(1)}, D^{(2)}, E^{(2)}$ successively such that the product $B' = B \times D^{(1)} \times E^{(1)} \times D^{(2)} \times E^{(2)}$ is an A'-good basis. For this, we need to show that each column c_i of $A'B'$ is either an all zero-column or there exists a unique j such that the j-th entry of the column is non-zero. In other words, each column of B' is either i-unique or it is in the kernel of A'. We will show how to obtain each of the four matrices above as well as take their product in AC^0. We need a technical lemma before we start.

Combining Matrices. Here we state a lemma about constructing matrices from smaller matrices that we we will use several times. Let $X \in \mathbb{Z}_p^{n\times n}$ be a matrix and let $X^{1,1} \in \mathbb{Z}_p^{\ell\times\ell}$, $X^{1,2} \in \mathbb{Z}_p^{\ell\times(n-\ell)}$, $X^{2,1} \in \mathbb{Z}_p^{(n-\ell)\times\ell}$, $X^{2,2} \in \mathbb{Z}_p^{(n-\ell)\times(n-\ell)}$ be 4 matrices and let $R, C \subseteq [n]$ be two subsets of indices of cardinality ℓ each. Let $\bar{R} = [n] \setminus R, \bar{C} = [n] \setminus C$. Then we have:

▶ **Lemma 21.** *Given the matrices $X^{i,j}$ for $I, J \in [2]$ and the sets R, C explicitly for $|R| = |C| = \ell = (\log n)^{O(1)}$, we can construct, in AC^0, the matrix Y such that $Y_{R,C} = X^{1,1}$, $Y_{R,\bar{C}} = X^{1,2}$, $Y_{\bar{R},C} = X^{2,1}$ and $Y_{\bar{R},\bar{C}} = X^{2,2}$.*

Proof. Notice that the sets R, C can be sorted in AC^0 because computing the position $pos_R(r)$ of an element $r \in R$ (i.e., the number of elements not larger than r) is equivalent to finding the sum of at most ℓ bits (which are zero for elements of R larger than r and one otherwise).

The position $pos_{\bar{R}}(r')$ of an element $r' \in \bar{R}$ (i.e. the number of elements of $\bar{R}$ not larger than r') can also be found in AC^0. This is because we can first find the set $R(r') = \{r_i \in R : r_i < r'\}$ in AC^0. Then $pos_{\bar{R}}(r') = r' - |R(r')|$ because there are r' rows with indices at most r' and out of these all but $|R(r')|$ are in $\bar{R}$ and thus can be computed in AC^0. We can similarly compute $pos_C(c), pos_{\bar{C}}(c')$ for $c \in C$ and $c' \in \bar{C}$.

Finally given $i, j \in [n]$ the element $Y_{i,j}$ is $X^{1,1}_{pos_R(i),pos_C(j)}$ if $i \in R, j \in C$. Similarly if $i \in \bar{R}, j \in C$ then it is $X^{2,1}_{pos_{\bar{R}}(i),pos_C(j)}$, if $i \in R, j \in \bar{C}$ then it is $X^{1,2}_{pos_R(i),pos_{\bar{C}}(j)}$ and if $i \in \bar{R}, j \in \bar{C}$ then it is $X^{2,2}_{pos_{\bar{R}}(i),pos_{\bar{C}}(j)}$. This completes the proof. ◀

Phase 1. First, we restore the i-uniqueness of the columns indexed by the set C_1. Let R_{C_1} be the set of rows in R indexed by the same set of indices as C_1 in C. We right multiply M with another matrix $D^{(1)} \in \mathbb{Z}_p^{n\times n}$ such that $D^{(1)}_{R_{C_1},C_1}$ is the inverse of M_{R_1,C_1} and $D^{(1)}_{R-R_{C_1},C-C_1}$ is the identity matrix and all the other entries of $D^{(1)}$ are zero. Since the inverse of a $k \times k$ matrix can be computed in AC^0 [11], matrix $D^{(1)}$ can be obtained in AC^0 via Lemma 21.

Let $M^{(1)} = M \times D^{(1)}$, note that ${M^{(1)}}_{R_1,C_1}$ is an identity matrix. Since $M = A' \times B$, we have $M^{(1)} = M \times D^{(1)} = A' \times B \times D^{(1)}$. Note that since ${M^{(1)}}_{R_1,C_1}$ is an identity matrix, the vectors corresponding to the columns in C_1 in the matrix $B \times D^{(1)}$ can now easily be made i-unique. Since ${M^{(1)}}_{R_1,C_1}$ is an identity matrix, all columns in the matrix ${M^{(1)}}_{R_1,C-C_1}$ can be written as the linear combinations of columns of ${M^{(1)}}_{R_1,C_1}$. Let $\tilde{M}^{(1)}$ be a matrix defined as $\tilde{M}^{(1)} = M^{(1)} \times E^{(1)}$, where $E^{(1)} \in \mathbb{Z}_p^{n\times n}$ is constructed as follows. (i) $E^{(1)}_{R_{C_1},*}$ is same as $M^{(1)}_{R_1,*}$. (ii) $E^{(1)}_{R-R_{C_1},C_1}$ is the zero matrix. (iii) $E^{(1)}_{R-R_{C_1},C-C_1}$ is the negative identity matrix. Using Lemma 21, we can construct $E^{(1)}$ in AC^0. Note that $\tilde{M}^{(1)}_{R_1,C_1}$ is an identity matrix and $\tilde{M}^{(1)}_{R_1,C-C_1}$ is a zero matrix. Thus we can say that vectors corresponding to columns in C_1 in the matrix $B \times D^{(1)} \times E^{(1)}$ are i-unique for some $i \in R_1$.

Next, we perform a procedure similar to Phase 1 for those vectors which lost their pc's when we changed the matrix from A to A', i.e. those vectors w which were i-unique for some i, but $i \notin S'(w)$.

Phase 2. There can be at most k vectors which lost their pc's while changing the matrix from A to A'. Some of these vectors might get their pc's set in Phase 1. Let $\tilde{C}_2$ be the remaining set of vectors in B. Notice $C_1 \cap \tilde{C}_2$ is empty. To set the pc's of these vectors, we repeat the above procedure for the matrix $\tilde{M}^{(1)}_{*,\tilde{C}_2}$ as follows.

Find the column basis C_2 of $\tilde{M}^{(1)}_{*,\tilde{C}_2}$ in AC^0 recalling that $|\tilde{C}_2| \leq k$ and using Claim 19 on the transpose of $\tilde{M}^{(1)}_{*,\tilde{C}_2}$. By considering the transpose of $\tilde{M}^{(1)}_{*,C_2}$ and applying Claim 20 we can get a row basis R_2 of $\tilde{M}^{(1)}_{*,C_2}$. Notice that $R_1 \cap R_2$ is empty. We construct a matrix $D^{(2)} \in \mathbb{Z}_p^{n\times n}$ in AC^0 using Lemma 21 such that $D^{(2)}_{R_{C_2},C_2}$ contains the inverse of $\tilde{M}^{(1)}_{R_2,C_2}$, $D^{(2)}_{R-R_{C_2},C-C_2}$ is an identity matrix and the rest of the entries of $D^{(2)}$ are zero. Here R_{C_2} is the set of rows indexed by the same indices as in the set C_2 of columns. Let $\tilde{M}^{(2)} = \tilde{M}^{(1)} \times D^{(2)} \times E^{(2)}$, where $E^{(2)}$ is constructed in AC^0 (using Lemma 21) so that: (i) $\tilde{M}^{(2)}_{R_1\cup R_2,C_1\cup C_2}$ is the identity matrix. (ii) $\tilde{M}^{(2)}_{R_1,C-C_1}$ and $\tilde{M}^{(2)}_{R-R_1,\tilde{C}_2-C_2}$ are zero matrices. Finally, we have $B' = B \times D^{(1)} \times E^{(1)} \times D^{(2)} \times E^{(2)}$. Since each column of the newly constructed matrices contains at most $(k+1)$ non-zero entries, we can obtain B' in AC^0.

▷ Claim 22. B' is an A'-good basis.

Proof. First, we prove that the vectors which lost their pc's, either get new pc's or they are modified to be in the kernel of A'. Let $w \in B$ be a vector that lost its pc and it is not captured in both Phase 1 or Phase 2. Assume it is not captured in Phase 1, i.e. the vector $A'w$ does not belong to the column set indexed by C_1. Then it will be captured in Phase 2. If it is not captured in Phase 2 as well, then we can say that $A'w$ does not belong to the columns indexed by the set C_2. Therefore it can be written as a linear combination of the vectors in C_2. In Phase 2, we modify such vectors in a way that $A'w$ becomes a zero vector, i.e. w goes into the kernel of A'. Also, note that the vector which did not lose their pc's and are not captured in Phase 1 and Phase 2, do not lose their pc's in the procedure. ◁

We prove that we can maintain the number of pc's in B in AC^0 using the next claim. However, we need to set up some notation first. Let $P^{\text{old}}, P^{\text{new}}$ be respectively, the number of pc's before and after the phases. Let $V^{\text{new}}_{R_1}$ and $V^{\text{new}}_{R_2}$ denote the set of vectors that have their pc's in the rows R_1 and R_2, after the phases. Let $V^{\text{old}}_{R_0}$ denote the set of vectors that have their pc's in the rows R_0 before starting of Phase 1 and V_1 denotes the set of vectors which have their pc's in the rows $R - R_0$ before the Phase 1 and attain pc's in the rows R_1 after Phase 2. Note that all the cardinalities of all the sets of vectors mentioned above are $O(\frac{\log n}{\log\log n})$. Therefore, we can compute their cardinalities in AC^0.

▷ Claim 23. $P^{\text{new}} = P^{\text{old}} - |V^{\text{old}}_{R_0}| + |V^{\text{new}}_{R_1}| + |V^{\text{new}}_{R_2}| - |V_1|$.

Proof. First, we assume that all the vectors in the set $V^{\text{old}}_{R_0}$ lose their pc's after the phases therefore we subtract $|V^{\text{old}}_{R_0}|$ from P. But some of these vectors get their pc's in Phase 1 and Phase 2. Therefore, we add $|V^{\text{new}}_{R_1}|$ and $|V^{\text{new}}_{R_2}|$ back to the sum. Notice that $V^{\text{new}}_{R_1}$ may contain those vectors as well that had their pc's in the rows indexed by $R - R_0$ before Phase 1. That means these vectors had a pc before and after the two phases, but we added their number $|V^{\text{new}}_{R_1}|$. Therefore, we subtract the number of such vectors by subtracting $|V_1|$ from the total sum. ◁

This brings us to the proof of Lemma 15.

Proof of Lemma 15. The proof is complete from the above claims because the number of pc's is precisely the rank of the matrix as a consequence of Proposition 16. ◀

8 Conclusion

In this work, we prove two meta-theorems for distance and maximum matching, which provide the best known dynamic bounds in graphs where non-zero circulation weights can be computed in parallel. This includes important graph classes like planar, bounded genus, bounded treewidth graphs. We show how to non-trivially modify two known techniques and combine them with existing tools to yield the best known dynamic bounds for more general classes of graphs, and at the same time allow for bulk updates of larger cardinality. While for bipartite matching we are able to show a $\mathsf{DynFO}(\leq, +, \times)$ bound it would be interesting to achieve this also for maintaining distances, even in planar graphs under single edge changes.
