Shifted-Distance Queries. We give two ways to answer ShiftedDistance queries. The first one relies in a black-box manner on any almost-linear-time algorithm to compute an edit distance approximation with multiplicative error $n^{o(1)}$ [4, 7, 6]. Using the same trick as before to restrict the set of feasible shifts, it suffices to approximate $\mathsf{ED}(Y_{v,s}, Y_{v,s'})$ for all shifts $s \in S_v$ and $s' \in \{-k \cdot n^{o(1)}, \dots, k \cdot n^{o(1)}\}$. (We could also discretize the range of s', but this does not improve the performance here.) In this way, we incur an additive error of at most $O(t_v)$. The computation per node v takes time $|Y_v| \cdot k \cdot k \cdot n^{o(1)}/t_v$, which becomes $kn^{1+o(1)}$ in expectation by Lemma 5 and by summing over all nodes v.

We then show that we can improve the preprocessing time to $n^{1+o(1)}$ by applying the non-oblivious embedding of edit distance into ℓ_1 by Andoni and Onak [7]. Formally we obtain the following lemma, which we prove in Section 4.3.

▶ **Lemma 7** (Shifted-Distance Queries). *We can preprocess Y in time $n^{1+o(1)}$ to answer $\textsc{ShiftedDistance}(Y, v, s, s')$ queries in time $n^{o(1)}$ with high probability.*

4 Our Algorithm in Detail

In this section we give a detailed proof of our main theorems by analyzing Algorithms 1 and 2 (see Sections 4.4 and 4.5). Algorithm 2 is the previously discussed reformulation of the Andoni-Krauthgamer-Onak algorithm, with the improvement that the recursive computation can be avoided whenever Algorithm 1 succeeds. Algorithm 1 implements the pruning rule which, as we will argue, triggers often enough to improve the running time.

Throughout we fix the initial tolerance of the precision tree T to $t = t_{\mathsf{root}(T)} = k$. Moreover, we set $S = \{-k \cdot 3^{\log_B(n)}, \dots, k \cdot 3^{\log_B(n)}\}$ and $S_v = S \cap \lfloor t_v/2 \rfloor \mathbf{Z}$. Observe that $|S| = k \cdot 3^{\log_B(n)} = k \cdot n^{o(1)}$ for our choice of $B = \exp(\widetilde{O}(\sqrt{\log n}))$.

Outline. Compared to the technical overview, we present the details in the reverse order: Starting with the implementation of the data structures for MATCHING and SHIFTED-DISTANCE queries (in Section 4.1), we first analyze Algorithm 1 (in Section 4.4). Then we analyze Algorithm 2 (in Section 4.5) and put the pieces together for our main theorems (in Section 4.6).

4.1 Matching Queries

In this section we show to implement data structures that answer MATCHING queries. We start with a formal definition.

▶ **Definition 8** (Matching Queries). *Let X, Y be strings of length n, and let v be a node in the precision tree. A* MATCHING(X, Y, v) *query is correctly answered by one of two outputs:*

- CLOSE(s^*) *for some shift $s^* \in S$ satisfying $\mathsf{HD}(X_v, Y_{v,s^*}) \leq t_v/2$, or*
- FAR *if there exists no shift $s^* \in S$ with $X_v = Y_{v,s^*}$.*

▶ **Lemma 6** (Matching Queries). *We can preprocess Y in expected time $n^{1+o(1)}$ to answer* MATCHING(X, Y, v) *queries in time $\widetilde{O}(|X_v|/t_v)$ with high probability. Moreover, we can separately preprocess both X and Y in expected time $n^{1+o(1)}$ to answer* MATCHING(X, Y, v) *queries in time $O(1)$ with high probability.*

Proof. We first explain the general idea behind the data structure and then point out the specifics for the one-sided and two-sided preprocessing. For each node v in the precision tree, we subsample a set $H_v \subseteq [\,|Y_v|\,]$ with rate $\Theta(\log n/t_v)$ and sample a hash function $h : \Sigma^{|H_v|} \to [\,\mathrm{poly}(n)\,]$ from any universal family of hash functions. (Take for instance the function $h(\sigma_1, \ldots, \sigma_{|H_v|}) = \sum_i a_i\sigma_i \bmod p$ for some prime $p = \mathrm{poly}(n)$ and random a_i's).

We associate to a string $A \in \Sigma^{|Y_v|}$ the *fingerprint* $h(A[\,H_v\,])$, where we write $A[\,H_v\,]$ for the subsequence of A with indices in H_v. We claim that these fingerprints can distinguish any two strings A, B with $\mathsf{HD}(A, B) > t_v/2$ with high probability. Indeed, the probability that H_v contains an index i with $A[\,i\,] \neq B[\,i\,]$ is at least

$$1 - \left(1 - \frac{\Omega(\log n)}{t_v}\right)^{\mathsf{HD}(A,B)} \geq 1 - \exp(-\Omega(\log n)) = 1 - \frac{1}{\mathrm{poly}(n)}.$$

Hence, with high probability we have that $A[\,H_v\,] \neq B[\,H_v\,]$. Moreover, since h is sampled from a universal family of hash functions, we also have that $h(A[\,H_v\,]) \neq h(B[\,H_v\,])$ with high probability. On the other hand, if $A = B$ then clearly $h(A[\,H_v\,]) = h(B[\,H_v\,])$. We now turn to the implementation details for one-sided and two-sided preprocessing.

One-Sided Preprocessing. In the preprocessing phase, we prepare for every node v the fingerprints of $Y_{v,s}$ for all shifts $s \in S$, and store these fingerprints in a lookup table. In the query phase, given some string X we compute the fingerprint of X_v and check whether it appears in the lookup table. If so, we return CLOSE(s^*) for the shift s^* corresponding to the precomputed fingerprint. Otherwise, we return FAR. The correctness follows from the previous paragraph.

The expected running time of the preprocessing phase is bounded by $\sum_v \widetilde{O}(|Y_v|/t_v \cdot |S|)$ (for every node we have to prepare $|S|$ fingerprints, each taking time $\widetilde{O}(|Y_v|/t_v)$). This becomes $\sum_v O(|Y_v| \cdot n^{o(1)}/t_{\mathsf{root}(T)} \cdot k) = \sum_v O(|Y_v| \cdot n^{o(1)}) = n^{1+o(1)}$ in expectation over the tolerances t_v; see Lemma 5. The query time is dominated by computing the fingerprint of X_v which takes expected time $\widetilde{O}(|X_v|/t_v)$ (even with high probability by an application of the Chernoff bound).

Two-Sided Preprocessing. For two-sided preprocessing, we can also prepare the fingerprints of X_v for all nodes v in the preprocessing phase. The expected preprocessing time is still $n^{1+o(1)}$, but for queries it only takes constant time to perform the lookup. ◀

4.2 Simple Shifted-Distance Queries

We next demonstrate how to deal with ShiftedDistance queries, formally defined as follows:

▶ **Definition 9** (Shifted-Distance Queries). *Let Y be a string of length n, let v be a node in the precision tree and let $s, s' \in S$. A ShiftedDistance(Y, v, s, s') query computes a number satisfying:*

$$\mathsf{ED}(Y_{v,s}, Y_{v,s'}) - t_v/2 \leq \textsc{ShiftedDistance}(Y, v, s, s') \leq n^{o(1)} \cdot (\mathsf{ED}(Y_{v,s}, Y_{v,s'}) + t_v/2).$$

We will first show how to implement a simpler version of Lemma 7 at the cost of worsening the preprocessing time to $kn^{1+o(1)}$ instead of $n^{1+o(1)}$. The benefit of this weaker version is that it is a black-box reduction to any almost-linear time $n^{o(1)}$-approximation algorithm for edit distance, while the improved version crucially relies on the properties of the particular algorithm by Andoni and Onak [7]. In the next section we show how to obtain the speed-up.

▶ **Lemma 10** (Slower Shifted-Distance Queries). *We can preprocess Y in time $kn^{1+o(1)}$ to answer ShiftedDistance(Y, v, s, s') queries in time $n^{o(1)}$ with high probability.*

Proof. We will use the result that an $n^{o(1)}$-approximation for the edit distance of two length-n strings can be computed in time $n^{1+o(1)}$ [4, 7, 6]. In the preprocessing phase, we compute $n^{o(1)}$-factor approximations $\widetilde{\mathsf{ED}}(Y_{v,\tilde{s}}, Y_{v,s'})$ for all nodes v, all $\tilde{s} \in S_v$ and all $s' \in S$. Then, to answer a query ShiftedDistance(Y, v, s, s') we let

$$\tilde{s} := \operatorname*{argmin}_{\tilde{s} \in S_v} |s - \tilde{s}|$$

and output $\widetilde{\mathsf{ED}}(Y_{v,\tilde{s}}, Y_{v,s'})$.

First we argue that this gives a good approximation. Indeed, we have that $|s - \tilde{s}| \leq t_v/4$ by the definition of S_v. Therefore:

$$\begin{aligned}\widetilde{\mathsf{ED}}(Y_{v,\tilde{s}}, Y_{v,s'}) &\leq n^{o(1)} \cdot \mathsf{ED}(Y_{v,\tilde{s}}, Y_{v,s'}) \\ &\leq n^{o(1)} \cdot (\mathsf{ED}(Y_{v,s}, Y_{v,s'}) + \mathsf{ED}(Y_{v,s}, Y_{v,\tilde{s}})) \\ &\leq n^{o(1)} \cdot (\mathsf{ED}(Y_{v,s}, Y_{v,s'}) + t_v/2),\end{aligned}$$

where second inequality is an application of the triangle inequality, and the last inequality follows since we can transform $Y_{v,\tilde{s}}$ into $Y_{v,s}$ by adding and removing $t_v/4$ symbols. A symmetric argument shows the claimed lower bound $\widetilde{\mathsf{ED}}(Y_{v,\tilde{s}}, Y_{v,s'}) \geq \mathsf{ED}(Y_{v,s}, Y_{v,s'}) - t_v/2$.

Next we analyze the running time. For the preprocessing, we compute $|S_v| \cdot |S| = O^*(k^2/t_v)$ many approximations for each node v, each in time $|Y_v|^{1+o(1)}$. We can bound $\mathbf{E}(1/t_v) = n^{o(1)}/k$ by Lemma 5, so the expected total time is $\sum_v |Y_v|^{1+o(1)} n^{o(1)} \cdot k = kn^{1+o(1)}$. Answering a query takes constant time since we only need to compute s^* as stated above and perform a constant-time lookup. ◀

4.3 Faster Shifted-Distance Queries

In this section we show how to improve the preprocessing time for ShiftedDistance queries to $n^{1+o(1)}$. We thank the anonymous reviewer who suggested this improvement. The key technical tool to obtain this improvement is the following result by Andoni and Onak [7].

Algorithm 1 Approximates the edit distance of preprocessed strings, or fails.

Input: Strings X (un- or preprocessed) and Y (preprocessed), a node v in the precision tree
Output: An approximation $\widetilde{\mathsf{ED}}(X_v, Y_{v,s})$ of $\mathsf{ED}(X_v, Y_{v,s})$ for all $s \in S_v$, or FAIL

1: **if** MATCHING$(X, Y, v) =$ CLOSE(s^*) **then**
2: **return** $\widetilde{\mathsf{ED}}(X_v, Y_{v,s}) =$ SHIFTEDDISTANCE(Y, v, s^*, s) for all $s \in S_v$
3: **else**
4: **return** FAIL

▶ **Theorem 11** (Embedding Substrings into ℓ_1 [7]). *Let X be a string of length n. Then, for each integer m of the form $m = \lfloor n/B^i \rfloor$ for $0 \le i \le \log_B(n)$ and $B = 2^{\Theta(\sqrt{\log n \log\log n})}$, we can embed all length-m substrings $X_0, \dots, X_{n-m}$ of X into vectors $v_0^m, \dots, v_{n-m}^m$ of dimension $n^{o(1)}$ such that for every $j, j' \in [\, n - m + 1\,]$, with high probability it holds that*

$$\mathsf{ED}(X_j, X_{j'}) \le \|v_j^m - v_{j'}^m\|_1 \le n^{o(1)} \cdot \mathsf{ED}(X_j, X_{j'}).$$

The time to compute all vectors is $n^{1+o(1)}$.

The main application of this embedding in [7] is an $n^{o(1)}$-approximation for the edit distance of two length-n strings in time $n^{1+o(1)}$ (in [7], Theorem 11 is applied to the concatenation of two strings to compute the ℓ_1-distance between their corresponding vectors). We remark that the guarantee of the embedding in Theorem 11 is *non-oblivious*, in the sense that the algorithm needs to have access to all the substrings it is embedding. In particular, this means that it cannot be directly applied in the two-sided preprocessing setting where we would like to embed the strings separately.

▶ **Lemma 7** (Shifted-Distance Queries). *We can preprocess Y in time $n^{1+o(1)}$ to answer SHIFTEDDISTANCE(Y, v, s, s') queries in time $n^{o(1)}$ with high probability.*

Proof. We assume without loss of generality that $n = |Y| = |X|$ is a power of B (we can pad both X and Y so that this holds, which has no impact on the running time or the approximation guarantee of our algorithms). We apply Theorem 11 to the string Y and store all the $n^{1+o(1)}$ embedded vectors. To answer a query SHIFTEDDISTANCE(Y, v, s, s'), note that $Y_{v,s}$ and $Y_{v,s'}$ are substrings of Y of length $m := n/B^{\mathsf{depth}(v)}$. Thus, the ℓ_1 distance between their corresponding vectors $v^m_{j(v,s)}, v^m_{j(v,s')}$ given by Theorem 11 gives the desired approximation (with no additive error). Since these vectors have dimension $n^{o(1)}$, the time to compute $\|v^m_{j(v,s)} - v^m_{j(v,s')}\|_1$ and answer the query is $n^{o(1)}$, as desired. ◀

4.4 Pruning Rule for Preprocessed Strings

In this section we analyze Algorithm 1. We always assume that either only Y or both X and Y have been preprocessed by Lemmas 6 and 7 to efficiently answer MATCHING and SHIFTEDDISTANCE queries.

▶ **Lemma 12** (Correctness of Algorithm 1). *Whenever Algorithm 1 does not return FAIL, it returns approximations $\widetilde{\mathsf{ED}}(X_v, Y_{v,s})$ satisfying with high probability*

$$\mathsf{ED}(X_v, Y_{v,s}) - t_v \le \widetilde{\mathsf{ED}}(X_v, Y_{v,s}) \le n^{o(1)} \cdot (\mathsf{ED}(X_v, Y_{v,s}) + t_v).$$

Proof. Algorithm 1 only succeeds if the MATCHING query in Algorithm 1 successfully identified some shift s^* with $\mathsf{HD}(X_v, Y_{v,s^*}) \leq t_v/2$ by Lemma 6. In this case, we report $\widetilde{\mathsf{ED}}(X_v, Y_{v,s}) := \textsc{ShiftedDistance}(Y, v, s^*, s)$. By Lemma 7, this is an approximation of $\mathsf{ED}(Y_{v,s^*}, Y_{v,s})$ with additive error $t_v/2$ and multiplicative error $n^{o(1)}$. Combining both facts, and using the triangle inequality we obtain that

$$\begin{aligned}\widetilde{\mathsf{ED}}(Y_{v,s^*}, Y_{v,s}) &\leq n^{o(1)} \cdot (\mathsf{ED}(Y_{v,s^*}, Y_{v,s}) + t_v/2)\\ &\leq n^{o(1)} \cdot (\mathsf{ED}(X_v, Y_{v,s}) + \mathsf{ED}(X_v, Y_{v,s^*}) + t_v/2)\\ &\leq n^{o(1)} \cdot (\mathsf{ED}(X_v, Y_{v,s}) + t_v),\end{aligned}$$

and

$$\begin{aligned}\widetilde{\mathsf{ED}}(Y_{v,s^*}, Y_{v,s}) &\geq \mathsf{ED}(Y_{v,s^*}, Y_{v,s}) - t_v/2\\ &\geq \mathsf{ED}(X_v, Y_{v,s}) - \mathsf{ED}(X_v, Y_{v,s^*}) - t_v/2\\ &\geq \mathsf{ED}(X_v, Y_{v,s}) - t_v.\end{aligned}$$

◀

▶ **Lemma 13** (Running Time of Algorithm 1)**.** *If only the string Y is preprocessed, then Algorithm 1 runs in expected time $O^*(|X_v|/t_v + k/t_v)$. If both strings X, Y are preprocessed, then Algorithm 1 runs in expected time $O^*(k/t_v)$.*

Proof. The expected running time of the MATCHING query is bounded by $\widetilde{O}(|X_v|/t_v)$ (for one-sided preprocessing) or by $O(1)$ (for two-sided preprocessing). The running time of a single SHIFTEDDISTANCE query is bounded by $n^{o(1)}$, and we make $|S_v| = \widetilde{O}(k/t_v)$ SHIFTEDDISTANCE queries. Hence, the total expected time is $O^*(|X_v|/t_v + k/t_v)$ (for one-sided preprocessing) or $O^*(k/t_v)$ (for two-sided preprocessing). ◀

▶ **Lemma 14** (Efficiency of Algorithm 1)**.** *For any two strings X, Y, there are at most $O(k \log n)$ many nodes v in the precision tree for which Algorithm 1 fails, assuming that $\mathsf{ED}(X, Y) \leq k$.*

Proof. It suffices to argue that there are at most $O(\mathsf{ED}(X, Y) \log n)$ nodes for which the MATCHING query in Algorithm 1 fails. We start with a fixed level in the precision tree, and enumerate all nodes on that level as $v_1, \ldots, v_m$. By definition we have that $X = \bigcirc_{i=1}^{m} X_{v_i}$, hence there exist indices $0 = j_0 < \cdots < j_m = n$ such that $X_{v_i} = X[\, j_i \,..\, j_{i+1}\,]$. Now consider an optimal alignment $A : \{\, 0, \ldots, n \,\} \to \{\, 0, \ldots, n \,\}$ between X and Y. In particular, A satisfies

$$\mathsf{ED}(X, Y) = \sum_{i=1}^{m} \mathsf{ED}(X[\, j_i \,..\, j_{i+1}\,], Y[\, A(j_i) \,..\, A(j_{i+1})\,]).$$

There can be at most $\mathsf{ED}(X, Y) \leq k$ many nonzero terms in the sum, and we claim that every zero term corresponds to a node v_i for which Algorithm 1 succeeds. Indeed, for any zero term we have $X[\, j_i \,..\, j_{i+1}\,] = Y[\, A(j_i) \,..\, A(j_{i+1})\,]$ and therefore $X_{v_i} = Y_{v_i,s^*}$ where $s^* = A(j_i) - j_i$. It remains to argue that $|s^*| \leq k$ (since otherwise the index s^* would be out-of-bounds and could not be detected by a MATCHING query). To see this, observe that

$$|s^*| \leq \mathsf{ED}(X[\, j_0 \,..\, j_i\,], Y[\, A(j_0) \,..\, A(j_i)\,]) \leq \mathsf{ED}(X, Y) \leq k,$$

exploiting again that A is an optimal alignment.

Finally, recall that there are only $\log_B(n) \leq \log n$ levels in the precision tree, hence the total number of nodes for which Algorithm 1 fails is bounded by $O(k \log n)$. ◀

Algorithm 2 Approximates the edit distance of preprocessed strings.

Input: Strings X (un- or preprocessed), Y (preprocessed), a node v in the precision tree
Output: An approximation $\widetilde{\mathsf{ED}}(X_v, Y_{v,s})$ of $\mathsf{ED}(X_v, Y_{v,s})$ for all $s \in S_v$

1: **if** Algorithm 1 succeeds and reports $\widetilde{\mathsf{ED}}(X_v, Y_{v,s})$ for all $s \in S_v$ **then**
2: **return** $\widetilde{\mathsf{ED}}(X_v, Y_{v,s})$ for all $s \in S_v$
3: **if** v is a leaf **then**
4: **return** $\mathsf{ED}(X_v, Y_{v,s})$ for all $s \in S_v$
5: **for** all children v_i of v **do**
6: Recursively compute $\widetilde{\mathsf{ED}}(X_{v_i}, Y_{v_i,s_i})$ for all $s_i \in S_{v_i}$
7: Compute $\widetilde{a}_{i,s} = \min_{s_i \in S_{v_i}} \widetilde{\mathsf{ED}}(X_{v_i}, Y_{v_i,s_i}) + 2 \cdot |s - s_i|$ for all $s \in S_v$
8: **return** $\textsc{Recover}(\widetilde{a}_{1,s}, \dots, \widetilde{a}_{B,s}, u_{v_1}, \dots, u_{v_B})$ for all $s \in S_v$

4.5 The Complete Algorithm

Our complete Algorithm 2 is essentially what we described in Section 4.5 with the additional pruning rule of applying Algorithm 1. We start with the correctness of Algorithm 2. We need the following lemma, which has previously been referred to as a *Precision Sampling Lemma* [4, 5, 3, 15]. The lemma was introduced by Andoni, Krauthgamer and Onak [4], and was refined in [5, 3].

Intuitively, the lemma serves the following purpose: For fixed numbers $a_1, \dots, a_B$, say that we have access to approximations $\widetilde{a}_1, \dots, \widetilde{a}_B$ with multiplicative error α and additive approximation error β. Then we can naively approximate $\sum_i a_i$ by $\sum_i \widetilde{a}_i$ with multiplicative error α and additive error $B \cdot \beta$. The Precision Sampling Lemma states that the blow-up in the additive error can be avoided if the approximations $\widetilde{a}_i$ instead have additive error $\beta \cdot u_i$ for some *non-uniformly sampled precisions* u_i.

▶ **Lemma 15** (Precision Sampling Lemma [3]). *Fix parameters $\delta > 0$, $\alpha \geq 1$ and $\beta \geq 0$. Let $a_1, \dots, a_B \geq 0$ be reals, and independently sample $u_1, \dots, u_B \sim \mathrm{Exp}(O(\log(\delta^{-1})))$ (for some sufficiently large hidden constant). There is an $O(B \log(\delta^{-1}))$-time algorithm $\textsc{Recover}$ satisfying for all $\widetilde{a}_1, \dots, \widetilde{a}_B$, with success probability at least $1 - \delta$:*

- *If $\widetilde{a}_i \geq \frac{1}{\alpha} \cdot a_i - \beta \cdot u_i$ for all i, then $\textsc{Recover}(\widetilde{a}_1, \dots, \widetilde{a}_B, u_1, \dots, u_B) \geq \frac{1}{2\alpha} \cdot \sum_i a_i - \beta$.*
- *If $\widetilde{a}_i \leq \alpha \cdot a_i + \beta \cdot u_i$ for all i, then $\textsc{Recover}(\widetilde{a}_1, \dots, \widetilde{a}_B, u_1, \dots, u_B) \leq 2\alpha \sum_i a_i + \beta$.*

▶ **Lemma 16** (Correctness of Algorithm 2). *Algorithm 2 computes values $\widetilde{\mathsf{ED}}(X_v, Y_{v,s})$ (for all $s \in S_v$) satisfying the following bounds with high probability:*

- $\widetilde{\mathsf{ED}}(X_v, Y_{v,s}) \geq n^{-o(1)} \cdot \mathsf{ED}(X_v, Y_{v,s}) - t_v$, *and*
- $\widetilde{\mathsf{ED}}(X_v, Y_{v,s}) \leq n^{o(1)} \cdot (\mathsf{ED}(X_v, Y_{v,s}) + t_v)$ *assuming that* $\mathsf{ED}(X_v, Y_{v,s}) \leq k$ *and* $2|s| \leq k$.

Proof. The recursion of Algorithm 2 terminates in one of three cases: If v is a leaf, then the output is exact and the claim is obvious. If v is directly solved by Algorithm 1, then by the guarantee of Lemma 12 the claim is true. It remains to analyze the case when the algorithm recurs, so assume that v is an internal node with children $v_1, \dots, v_B$. We prove the lower and upper bounds separately.

Lower Bound. Fix some shift $s \in S_v$, and let $s_1, \dots, s_B$ be the corresponding shifts selected in Algorithm 2 of the algorithm. We prove that $\widetilde{\mathsf{ED}}(X_v, Y_{v,s}) \geq \mathsf{ED}(X_v, Y_{v,s})/\alpha(\mathsf{height}(v)) - t_v$ by induction, where $\alpha(\mathsf{height}(v)) = 2^{\mathsf{height}(v)}$. To this end, we apply the Precision Sampling Lemma with $a_i = \mathsf{ED}(X_{v_i}, Y_{v_i,s_i}) + 2|s - s_i|$ and the following parameters:

- $\delta = 1/\operatorname{poly}(n)$,
- $\alpha = \alpha(\mathsf{height}(v) - 1)$,
- $\beta = t_v$.

Recall that the algorithm computes $\widetilde{a}_{i,s} = \widetilde{\mathsf{ED}}(X_{v_i}, Y_{v_i,s_i}) + 2|s - s_i|$, where the approximation $\widetilde{\mathsf{ED}}(X_{v_i}, Y_{v_i,s_i})$ is computed recursively. Hence, it satisfies $\widetilde{a}_{i,s} \geq a_i/\alpha - \beta \cdot u_{v_i}$ by the induction hypothesis (recall that $t_{v_i} \leq t_v \cdot u_{v_i}$). Then $\textsc{Recover}(\widetilde{a}_{1,s}, \ldots, \widetilde{a}_{B,s}, u_{v_1}, \ldots, u_{v_B})$ computes, with high probability, a number satisfying

$$\begin{aligned}
\textsc{Recover}(\cdot) &\geq \frac{1}{2\alpha(\mathsf{height}(v)-1)} \cdot \left(\sum_{i=1}^{B} a_i \right) - \beta \\
&= \frac{1}{2\alpha(\mathsf{height}(v)-1)} \cdot \left(\sum_{i=1}^{B} \mathsf{ED}(X_{v_i}, Y_{v_i,s_i}) + 2|s - s_i| \right) - t_v \\
&\geq \frac{1}{2\alpha(\mathsf{height}(v)-1)} \cdot \mathsf{ED}(X_v, Y_{v,s}) - t_v \\
&\geq \frac{1}{\alpha(\mathsf{height}(v))} \cdot \mathsf{ED}(X_v, Y_{v,s}) - t_v,
\end{aligned}$$

where in the third step, we applied the lower bound from Lemma 3 and in the last step we used the definition of $\alpha(\cdot)$. Finally, recall that $\mathsf{height}(T) \leq \log_B(n)$ and $B = \exp(\widetilde{\Theta}(\sqrt{\log n}))$. Hence the total multiplicative error is bounded by $\alpha(\log_B(n)) \leq 2^{\log_B(n)} = n^{o(1)}$.

Upper Bound. This proof is similar to the previous paragraph, but requires a more careful application of Lemma 3. We prove by induction the algorithm computes an approximation $\widetilde{\mathsf{ED}}(X_v, Y_{v,s}) \leq \alpha(\mathsf{height}(v)) \cdot (\mathsf{ED}(X_v, Y_{v,s}) + t_v)$ where this time the multiplicative error is bounded by $\alpha(\mathsf{height}(v)) \leq O(B) \cdot 2^{O(\mathsf{height}(v))}$, provided that $\mathsf{ED}(X_v, Y_{v,s}) \leq k \cdot 3^{\mathsf{depth}(v)}$ and $2|s| \leq k \cdot 3^{\mathsf{depth}(v)}$. Note that this implies the lemma statement.

Throughout, fix some shift $s \in S_v$. The idea is to first use Lemma 3 to find "optimal" shifts $s_1^*, \ldots, s_B^* \in \mathbf{Z}$, which we use for the recursive computation. Unfortunately these shifts s_i^* may not fall into the restricted set of feasible shifts S_{v_i}. We therefore argue that picking shifts $s_i \in S_{v_i}$ closest possible to s_i^* is sufficient to obtain the claimed guarantee. Formally, by Lemma 3 there exist shifts $s_1^*, \ldots, s_B^*$ satisfying the following two properties:

$$\sum_{i=1}^{B} \mathsf{ED}(X_{v_i}, Y_{v_i,s_i^*}) \leq 2\mathsf{ED}(X_v, Y_{v,s}), \tag{2}$$

$$2|s - s_i^*| \leq \mathsf{ED}(X_v, Y_{v,s}). \tag{3}$$

We now pick $s_1 \in S_{v_1}, \ldots, s_B \in S_{v_B}$ to be the closest values to the optimal shifts $s_1^*, \ldots, s_B^*$. As a first insight, observe that:

$$2|s_i^*| \leq 2|s - s_i^*| + 2|s| \leq \mathsf{ED}(X_v, Y_{v,s}) + 2|s| \leq 2k \cdot 3^{\mathsf{depth}(v)}.$$

Recall that we set $S = \{ -k \cdot 3^{\log_B(n)}, \ldots, k \cdot 3^{\log_B(n)} \}$ and we therefore have $s_i^* \in S$. It follows that $|s_i - s_i^*| \leq t_{v_i}/2$ and thus

$$2|s_i| \leq 2|s_i^*| + t_{v_i} \leq 2|s_i^*| + k \leq 2k \cdot 3^{\mathsf{depth}(v)} + k \leq k \cdot 3^{\mathsf{depth}(v_i)}.$$

Next, we claim that $\mathsf{ED}(X_{v_i}, Y_{v_i,s_i}) \leq k \cdot 3^{\mathsf{depth}(v_i)}$, which we will use to guarantee that the recursive calls of the algorithm succeed. Indeed, we have that

$$\mathsf{ED}(X_{v_i}, Y_{v_i,s_i}) \leq \mathsf{ED}(X_{v_i}, Y_{v_i,s_i^*}) + t_{v_i} \leq 2 \cdot \mathsf{ED}(X_v, Y_{v,s}) + k \leq k \cdot 3^{\mathsf{depth}(v_i)}.$$

We claim that if the algorithm was to choose the shifts s_i specified in the previous paragraph in Algorithm 2, then the output is bounded as claimed. (This is sufficient, since Algorithm 2 in fact minimizes over all possible shifts s_i.) In this case, we inductively have that

$$\begin{aligned}\widetilde{a}_{i,s} &\leq \widetilde{\mathsf{ED}}(X_{v_i}, Y_{v_i,s_i}) + 2|s - s_i| \\ &\leq \alpha(\mathsf{height}(v) - 1) \cdot (\mathsf{ED}(X_{v_i}, Y_{v_i,s_i}) + t_{v_i}) + 2|s - s_i| \\ &\leq \alpha(\mathsf{height}(v) - 1) \cdot (\mathsf{ED}(X_{v_i}, Y_{v_i,s_i^*}) + 3t_{v_i}) + 2|s - s_i^*|.\end{aligned}$$

In the last step we used that $\mathsf{ED}(X_{v_i}, Y_{v_i,s_i^*})$ differs from $\mathsf{ED}(X_{v_i}, Y_{v_i,s_i})$ by an additive error of t_{v_i}, and the same is true for $2|s - s_i^*|$ and $2|s - s_i|$. Next, we apply the Precision Sampling Lemma with $a_i = \mathsf{ED}(X_{v_i}, Y_{v_i,s_i^*}) + 2\alpha^{-1}|s - s_i^*|$ and parameters

- $\delta = 1/\operatorname{poly}(n)$,
- $\alpha = \alpha(\mathsf{height}(v) - 1)$,
- $\beta = \alpha t_v$.

Recall that $t_{v_i} = t_v \cdot u_{v_i}/3$, thus by definition we have that $\widetilde{a}_{i,s} \leq \alpha \cdot a_i + \beta \cdot u_{v_i}$. Therefore, the Precision Sampling Lemma states that with high probability the recovery algorithm returns

$$\begin{aligned}\textsc{Recover}(\cdot) &\leq 2\alpha \cdot \left(\sum_{i=1}^{B} a_i\right) + \beta \\ &\leq 2\alpha \left(\sum_{i=1}^{B} \mathsf{ED}(X_{v_i}, Y_{v_i,s_i^*})\right) + 2\left(\sum_{i=1}^{B} 2|s - s_i^*|\right) + \alpha t_v \\ &\leq 4\alpha \cdot \mathsf{ED}(X_v, Y_{v,s}) + 2B \cdot \mathsf{ED}(X_v, Y_{v,s}) + \alpha t_v \\ &\leq 4(\alpha + B) \cdot (\mathsf{ED}(X_v, Y_{v,s}) + t_v) \\ &\leq \alpha(\mathsf{height}(v)) \cdot (\mathsf{ED}(X_v, Y_{v,s}) + t_v),\end{aligned}$$

where for the third inequality we applied the bounds in (2) and (3) and in the last step we used the definition of $\alpha(\mathsf{height}(v)) = O(B) \cdot 2^{O(\mathsf{height}(v))}$ (for sufficiently large hidden constants). Since the tree has height $\log_B(n)$ and $B = \exp(\widetilde{\Theta}(\sqrt{\log n}))$, the overall approximation factor is bounded by $\alpha(\log_B(n)) = O(B) \cdot 2^{O(\log_B(n))} = n^{o(1)}$, as claimed. ◀

Next, we analyze the running time of Algorithm 2. It turns out that the bottleneck is the computation in Algorithm 2, and a naive implementation would be too slow for our purposes. For that reason, we use the following lemma for an improved implementation of Algorithm 2. The lemma is a generalization of [15, Lemma 10].

▶ **Lemma 17** (Range Minimum Problem). *Let T, T' be sets of integers (given in sorted order), and let $(b_{s'})_{s' \in T'}$ be given. There is an $O(|T| + |T'|)$-time algorithm to compute $(a_s)_{s \in T}$ defined by*

$$a_s = \min_{s' \in T'} b_{s'} + 2 \cdot |s - s'|.$$

Proof. The idea is to compute auxiliary values

$$a_s^{\leq} = \min_{\substack{s' \in T' \\ s' \leq s}} b_{s'} + 2s - 2s',$$

$$a_s^{\geq} = \min_{\substack{s' \in T' \\ s' \geq s}} b_{s'} - 2s + 2s',$$

as then returning $a_s = \min(a_s^{\leq}, a_s^{\geq})$ is correct. We show how to compute $a_s^{\leq}$ (for all s); the values $a_s^{\geq}$ are symmetric. Let $T = \{ s_1 < \cdots < s_{|T|} \}$. We evaluate the base case $a_{s_1}^{\leq}$ naively. We then compute $a_{s_i}^{\leq}$ for all $i = 2, \ldots, |T|$ as follows:

$$a_{s_i}^{\leq} = \min \left\{ a_{s_{i-1}}^{\leq} + 2s_i - 2s_{i-1}, \min_{s_{i-1} < s' \leq s_i} b_{s'} + 2s_i - 2s' \right\}.$$

For the correctness, we distinguish two cases. Let $s' \leq s_i$ be the index which attains the minimum in the definition of $a_{s_i}^{\leq}$. On the one hand, if $s' \leq s_{i-1}$, then $a_{s_i}^{\leq} = a_{s_{i-1}}^{\leq} + 2s_i - 2s_{i-1}$ and thus the first term in the minimum is correct. On the other hand, if $s' > s_{i-1}$, then the second term in the minimum is correct by definition. In order to compute $(a_s^{\leq})_s$ we sweep from left to right over all values in T and T' exactly once, hence the running time can be bounded by $O(|T| + |T'|)$. ◀

▶ **Lemma 18** (Running Time of Algorithm 2). *Assume that* $\mathsf{ED}(X, Y) \leq k$. *If only the string* Y *is preprocessed, then Algorithm 2 runs in expected time* $n^{1+o(1)}/k + kn^{o(1)}$. *If both strings* X, Y *are preprocessed, then Algorithm 2 runs in expected time* $kn^{o(1)}$.

Proof. We first bound the running time of a single execution of Algorithm 2 (ignoring the cost of recursive calls). The computation in Algorithm 2 merely compares single characters and therefore takes time $|S_v| = O^*(k/t_v)$. By Lemma 13, the call to Algorithm 1 takes expected time $O^*(|X_v|/t_v + k/t_v)$ (for one-sided preprocessing) or $O^*(k/t_v)$ (for two-sided preprocessing). Each iteration of the loop in Algorithms 2–2 is dominated by the computation in Algorithm 2 (ignoring the recursive calls in Algorithm 2). Using Lemma 17 with $T = S_v$ and $T' = S_{v_i}$, this step takes time $O(|S_v| + |S_{v_i}|)$, and thus the loop runs in time $O(B \cdot |S_v| + \sum_i |S_{v_i}|) = O^*(k/t_v + \sum_i k/t_{v_i})$. In all of these bounds we can bound $1/t_v$ by $n^{o(1)}/k$ in expectation, according to Lemma 5, so the total expected time per node becomes $n^{o(1)} \cdot (|X_v|/k + 1)$ (for one-sided preprocessing) or $n^{o(1)}$ (for two-sided preprocessing).

To account for the recursive calls, we first use Lemma 14 to bound the number of recursive calls by $O(k \log n)$. Let $v_1, \ldots, v_m$ (with $m = O(k \log n)$) denote all nodes for which Algorithm 2 is recursively called. Then the expected running time for one-sided preprocessing can be bounded by

$$\begin{aligned} n^{o(1)} \cdot \sum_{i=1}^{m} \left(\frac{|X_{v_i}|}{k} + 1 \right) &\leq kn^{o(1)} + n^{o(1)} \cdot \sum_{d=1}^{\log_B(n)} \sum_{\substack{i=1 \\ \mathsf{depth}(v_i)=d}}^{m} \frac{|X_{v_i}|}{k} \\ &\leq kn^{o(1)} + n^{o(1)} \cdot \sum_{d=1}^{\log_B(n)} \frac{n}{k} \\ &\leq kn^{o(1)} + \frac{n^{1+o(1)}}{k}. \end{aligned}$$

Here we used that across any level in the precision tree, the strings X_v form a partition of X into consecutive substrings. In the same way we can bound the running time for two-sided preprocessing by $kn^{o(1)}$. ◀

4.6 Proof of the Main Theorems

We are finally ready to prove our main theorems.

Proof of Theorems 1 and 2. We assume that either only Y (for Theorem 1) or both X and Y (for Theorem 2) are preprocessed by Lemmas 6 and 7. We will solve the (k, K)-gap edit distance problem, for some parameter K to be picked later, by running Algorithm 2 (with input $v = \mathsf{root}(T)$ and $s = 0$, so in particular $2|s| \leq k$). For the correctness proof, we apply Lemma 16 to the following two cases:

- If $\mathsf{ED}(X,Y) \le k$, then $\widetilde{\mathsf{ED}}(X,Y) \le n^{o(1)} \cdot (\mathsf{ED}(X,Y)+t) \le n^{o(1)} \cdot k$.
- If $\mathsf{ED}(X,Y) \ge K$, then $\widetilde{\mathsf{ED}}(X,Y) \ge n^{-o(1)} \cdot \mathsf{ED}(X,Y) - t \ge n^{-o(1)} \cdot K$.

By setting $K = k \cdot n^{o(1)}$ for a sufficiently large subpolynomial factor, we can distinguish the two cases based on the outcome $\widetilde{\mathsf{ED}}(X,Y)$.

Next, we analyze the running time. If $\mathsf{ED}(X,Y) \le k$, then the algorithm runs in expected time $n^{1+o(1)}/k + kn^{o(1)}$ or $kn^{o(1)}$, respectively; see Lemma 18. By Markov's inequality, the algorithm respects these time bounds with constant probability. We may therefore interrupt the algorithm after it exceeds its time budget and report "$\mathsf{ED}(X,Y) \ge K$" in case of an interruption. We can boost the success probability to $1 - 1/\operatorname{poly}(n)$ by running the algorithm $O(\log n)$ times in parallel and reporting the majority answer. (This also means that the preprocessing is repeated $O(\log n)$ times with independently sampled precision trees.) ◀

A Proofs of Lemmas 3 and 5

In this section we provide proofs of Lemmas 3 and 5.

▶ **Lemma 3** (Divide and Conquer). *Let X, Y be length-n strings, and let $0 = j_0 < \cdots < j_B = n$. We write $X_i = X[\, j_{i-1} \,..\, j_i \,]$ and $Y_{i,s} = Y[\, j_{i-1} + s \,..\, j_i + s \,]$.*

- *For all shifts $s_1, \ldots, s_B$ we have that $\mathsf{ED}(X,Y) \le \sum_i \mathsf{ED}(X_i, Y_{i,s_i}) + 2|s_i|$.*
- *There are shifts $s_1, \ldots, s_B$ with $\sum_i \mathsf{ED}(X_i, Y_{i,s}) \le 2\mathsf{ED}(X,Y)$ and $2|s_i| \le \mathsf{ED}(X,Y)$ for all i.*

Proof. Lower Bound. Let us write $Y_i = Y_{i,0} = Y[\, j_{i-1} \,..\, j_i \,]$ (in analogy to the notation X_i). It is clear that $\mathsf{ED}(Y_{i,s_i}, Y_i) \le 2|s_i|$ by deleting and inserting at most $|s_i|$ symbols. Therefore, by several applications of the triangle inequality we have

$$\begin{aligned}\sum_{i=1}^{B} \mathsf{ED}(X_i, Y_{i,s_i}) + 2|s_i| &\ge \sum_{i=1}^{B} \mathsf{ED}(X_i, Y_{i,s_i}) + \mathsf{ED}(Y_{i,s_i}, Y_i) \\ &\ge \sum_{i=1}^{B} \mathsf{ED}(X_i, Y_i) \\ &\ge \mathsf{ED}(X,Y).\end{aligned}$$

Upper Bound. For the upper bound, let $A : \{0, \ldots, n\} \to \{0, \ldots, n\}$ denote an optimal alignment between X and Y (as defined in Section 2). Then

$$\mathsf{ED}(X,Y) = \sum_{i=1}^{B} \mathsf{ED}(X[\, j_{i-1} \,..\, j_i \,], Y[\, A(j_{i-1}) \,..\, A(j_i) \,]). \tag{4}$$

We pick $s_i = A(j_{i-1}) - j_{i-1}$. The first step is to prove that $2|s_i| \le \mathsf{ED}(X,Y)$, thereby proving the second item of the upper bound. To see this, we first express $\mathsf{ED}(X,Y)$ as the sum of two edit distances $\mathsf{ED}(X[\, 0 \,..\, j_{i-1} \,], Y[\, 0 \,..\, A(j_{i-1}) \,])$ and $\mathsf{ED}(X[\, j_{i-1} \,..\, n \,], Y[\, A(j_{i-1}) \,..\, n \,])$, using that A is an optimal alignment. Now, since the edit distance of two strings A, B is always at least $|\,|A| - |B|\,|$, we conclude that $\mathsf{ED}(X,Y) \ge 2|s_i|$.

The next and final part is to prove that $\sum_i \mathsf{ED}(X_i, Y_{i,s_i}) \le 2\mathsf{ED}(X,Y)$.

$$\begin{aligned}\mathsf{ED}(X_i, Y_{i,s_i}) &= \mathsf{ED}(X[\, j_{i-1} \,..\, j_i \,], Y[\, A(j_{i-1}) \,..\, A(j_{i-1}) + j_i - j_{i-1} \,]) \\ &\le \mathsf{ED}(X[\, j_{i-1} \,..\, j_i \,], Y[\, A(j_{i-1}) \,..\, A(j_i) \,]) + |(A(j_i) - A(j_{i-1})) - (j_i - j_{i-1})| \\ &\le 2 \cdot \mathsf{ED}(X[\, i_{j-1} \,..\, i_j \,], Y[\, A(j_{i-1}) \,..\, A(j_i) \,]),\end{aligned}$$

where in the last step we again used that the edit distance between two strings is at least their length difference. It follows that

$$\sum_{i=1}^{B} \mathsf{ED}(X_i, Y_{i,s_i}) \le 2 \sum_{i=1}^{B} \mathsf{ED}(X[\, j_{i-1} \,..\, j_i \,], Y[\, A(j_{i-1}) \,..\, A(j_i) \,]) \le 2\mathsf{ED}(X,Y). \qquad \blacktriangleleft$$

▶ **Lemma 5** (Expected Precision). *Let T be a B-ary precision tree with initial tolerance t and $B = \exp(\widetilde{\Theta}(\sqrt{\log n}))$, and let v be a node in T. Then, conditioned on a high-probability event E, it holds that*

$$\mathbf{E}\left(\frac{1}{t_v} \,\middle|\, E \right) \le \frac{(\log n)^{O(\mathsf{depth}(v))}}{t} \le \frac{n^{o(1)}}{t}.$$

Proof. Recall that we assign $t_v = t_{\mathsf{parent}(v)} \cdot u_v/3$ for all non-root nodes in the precision tree, where the samples u_v are independent of each other and sampled from $\mathrm{Exp}(\lambda)$, the exponential distribution with parameter $\lambda = O(\log n)$. Recall that the exponential distribution has probability density function $f(x) = \lambda e^{-\lambda x}$, and thus

$$\mathop{\mathbf{P}}_{u\sim\mathrm{Exp}(\lambda)}(u \le x) = \int_{u=0}^{x} \lambda e^{-\lambda x} du = 1 - e^{-\lambda x} \le \lambda x.$$

We let E denote the event that $u_v \ge 1/\operatorname{poly}(n)$ for all nodes v. For any specific node v we have $u_v \ge 1/\operatorname{poly}(n)$ with high probability, and thus by a union bound E happens with high probability as well.

Next, we prove that conditioned on E, the expectation of $1/u$ for $u \sim \mathrm{Exp}(\lambda)$ is small:

$$\begin{aligned}
\mathop{\mathbf{E}}_{u\sim\mathrm{Exp}(\lambda)}(1/u \mid E) &\le \frac{1}{\mathbf{P}(E)} \cdot \int_{u=1/\operatorname{poly}(n)}^{\infty} \frac{1}{u} \cdot \lambda e^{-\lambda u} du \\
&\le \frac{1}{\mathbf{P}(E)} \cdot \left(\int_{u=1/\operatorname{poly}(n)}^{1} \frac{1}{u} \cdot \lambda e^{-\lambda u} du + \int_{u=1}^{\infty} \frac{1}{u} \cdot \lambda e^{-\lambda u} du \right) \\
&\le \frac{1}{\mathbf{P}(E)} \cdot O(\lambda \log n + 1) \\
&\le O(\log^2 n).
\end{aligned}$$

We now prove the claimed bound. Fix some node v and let $\mathsf{root}(T) = v_1, \ldots, v_{\mathsf{depth}(v)} = v$ denote the root-to-v path in the precision tree. Recall that $t_v = t \cdot (u_{v_1}/3) \cdots (u_{v_{\mathsf{depth}(v)}}/3)$. We have

$$\begin{aligned}
\mathbf{E}\left(\frac{1}{t_v} \,\middle|\, E\right) &= \frac{1}{t} \cdot \left(3 \cdot \mathop{\mathbf{E}}_{u\sim\mathrm{Exp}(\lambda)}\left(\frac{1}{u} \,\middle|\, E\right)\right)^{\mathsf{depth}(v)} \\
&\le \frac{(\log n)^{O(\mathsf{depth}(v))}}{t} \\
&\le \frac{n^{o(1)}}{t}.
\end{aligned}$$

For the last inequality, we used that $\mathsf{depth}(v) \le \log_B(n) = \widetilde{O}(\sqrt{\log n})$, and therefore the overhead becomes $\exp(\widetilde{O}(\sqrt{\log n})) = n^{o(1)}$. ◀

Polynomial Delay Algorithm for Minimal Chordal Completions

Abstract

Motivated by the problem of enumerating all tree decompositions of a graph, we consider in this article the problem of listing all the minimal chordal completions of a graph. In [8] (Pods 2017) Carmeli et al. proved that all minimal chordal completions or equivalently all proper tree decompositions of a graph can be listed in incremental polynomial time using exponential space. The total running time of their algorithm is quadratic in the number of solutions and the existence of an algorithm whose complexity depends only linearly on the number of solutions remained open. We close this question by providing a polynomial delay algorithm to solve this problem which, moreover, uses polynomial space.

Our algorithm relies on *Proximity Search*, a framework recently introduced by Conte and Uno [12] (Stoc 2019) which has been shown powerful to obtain polynomial delay algorithms, but generally requires exponential space. In order to obtain a polynomial space algorithm for our problem, we introduce a new general method called *canonical path reconstruction* to design polynomial delay and polynomial space algorithms based on proximity search.

1 Introduction

Since its introduction by Dirac [13], the class of chordal graphs received a lot of attention. The many interesting properties of chordal graphs (*e.g.* a linear number of maximal cliques and minimal separators, a useful intersection model, a specific elimination ordering to cite a few) lead to the design of efficient algorithms for problems that are usually difficult on general graphs. On top of that, chordal graphs are closely connected to an important graph parameter called *treewidth* and its associated *tree-decomposition* introduced independently by Halin [14] and Robertson and Seymour [22].

Treewidth has played an important role in algorithmics for the last forty years, since its introduction and popularization by Robertson and Seymour. This popularity is deserved: given a tree decomposition of small width, many problems that are usually hard become solvable in polynomial time.

From the structure of maximal cliques known for chordal graphs, it is well-known that an optimal tree-decomposition can be computed in linear time on this class. For general graphs, one way to define the treewidth is to find the smallest value k such that the graph is a subgraph of a k-tree, that is to say, a subgraph of a chordal graph with maximum clique size at most $k+1$. Unfortunately, it was shown by Arnborg, Corneil & Proskurowski [1] that determining whether a graph is a partial k-tree (*i.e.* a subgraph of a k-tree) is NP-complete. In a different direction, the *minimum fill-in* problem asks to find the minimum number of edges to add to the graph in order to turn it into a chordal graph. Yannakakis [27] proved that the minimum fill-in problem is NP-hard.

Since the aforementioned problems are intractable, relaxations of these problems have been considered. The problem of computing chordal completion that are *inclusion-wise minimal*, has been intensively studied, either to find an optimal tree decomposition with an exponential-time algorithm or to find one tree decomposition in polynomial-time. Over the past decades, numerous polynomial algorithms have been provided to compute one minimal chordal completion [3, 5, 24, 15, 19, 20, 23].

However, from an application point of view, computing only one tree decomposition might not be satisfactory. For that reason, Carmeli et al. [7, 8] considered the problem of listing all the minimal chordal completions of a graph, and hence obtaining all the minimal tree decompositions of a graph. In the same line of research, Ravid et al. [21] considered the same problem by adding a requirement on the order in which solutions are produced.

An enumeration algorithm lists every solution of a given problem exactly once. Since the considered problem can have exponentially (in the input size) many solutions, the traditional complexity measures are no longer relevant. Instead, the common approach called *output sensitive* analysis is to bound the time complexity by a function of the input and the output size. Johnson et al. adapted in [17] the notion of polynomial time algorithm for enumeration algorithms. An algorithm is said to be *output polynomial* if its complexity can be bounded by a polynomial function expressed in the size of both the input and the output. As the number of solutions might be huge, this notion is not fine enough to capture the efficiency of the algorithm. For that reason, Johnson et al. further refined this notion by introducing the *incremental polynomial time*, meaning that the time used to produce a new solution of the problem is bounded by a polynomial in the size of the input and the size of all the already produced solutions. They strengthened the concept with the notion of *polynomial delay*: the time between the generation of two consecutive solutions is bounded by a polynomial in the size of the input only. The total running time of a polynomial delay algorithm depends only linearly on the size of the output, and since all solutions have to be outputted, this dependency is optimal.

For the enumeration of minimal triangulations of a graph, Carmeli et al. in [7, 8] presented a highly non-trivial algorithm. Their algorithm runs in *incremental polynomial time*; its total complexity is quadratic in the number of solutions, and to avoid duplication of solutions, requires exponential space. The algorithm is based on a result by Parra & Scheffler [20], according to which there is a bijection between the minimal triangulations of a graph and the maximal independent sets of a special graph of minimal separators of the input graph. In [8], they proved under *Exponential Time Hypothesis* that their approach cannot be improved to achieve polynomial delay. This intractability result also holds for the exponential space.

In [7, 8] and at a Dagstuhl seminar [4], it was left as an open problem whether a polynomial delay and/or a polynomial space algorithm for this problem could be obtained. We answer this question by the affirmative. Our main result is the following theorem.

▶ **Theorem 1.** *The minimal chordal completions of a graph can be computed in polynomial delay and polynomial space.*

In addition, our algorithm is simple and can be easily implemented. Since it is a polynomial delay algorithm, its total complexity is linear in the number of solutions. It contrasts with the quadratic one of [7, 8].

The paper is organised as follows. In Section 2 we recall the results and techniques used in algorithmic enumeration. In Section 3, we present the concepts that will be used for minimal chordal completions, and we present a first polynomial delay and exponential space algorithm. Then in Section 4 we present our main result, namely a polynomial delay and polynomial space algorithm to list all the minimal chordal completions of a graph without duplication. Finally, in Section 5 we formalize the framework used in Section 4 by introducing a new general method called *canonical path reconstruction* to design polynomial space enumeration algorithms.

2 Definitions and preliminary results

Throughout the article, standard graph theory notations will be used. A graph, always assumed to be simple, finite and undirected, is denoted by $G = (V, E)$ where V is the set of vertices and E is the set of edges. When the context is ambiguous, notations $V(G)$ and $E(G)$ can be used. For any $k \geq 3$, C_k denotes a cycle of length k.

We denote by E^c the set of *non-edges* of G, that is, the complement of the set E in the larger set of all two-element subsets of V. Then, for a subset $F \subset E^c$ we denote by $\bar{F}$ the set $E^c \setminus F$.

A graph is *chordal*, or *triangulated*, if it does not contain any induced cycle of length 4 or more. In other words, every cycle of length more than 3 of a chordal graph has at least one chord (*i.e.* an edge that connects non-consecutive vertices of the cyle).

Given a graph G and a supergraph H of G on the same vertex set, H is called a *triangulation* of G if H is chordal, and the edges of H which are not edges of G are called *fill edges*. In the whole paper, triangulations, or chordal completions, will be identified with the set of fill edges they induce. This is why for a graph $G = (V, E)$, we call a set $F \subseteq E^c$ a *chordal completion of* G if the supergraph $G_F = (V, E \cup F)$ is chordal. Let us denote by $\mathcal{F}$ the set of all chordal completions of G and by $\mathcal{F}_{\min}$ the set of minimal chordal completions of G, with respect to inclusion. A characterisation of minimal chordal completions is given in [23, Theorem 2]: a chordal completion F of a graph G is minimal *if and only if* for any $f \in F$, the graph $G_F \setminus \{f\}$ has an induced C_4.

From now on, $G = (V, E)$ is considered to be an arbitrary input graph that has no particular property and is therefore not assumed to be chordal. In the whole article, notation n is used for the number of vertices of G, that is, $n = |V|$. Finally, as our goal is to enumerate all minimal chordal completions of G, we may simply refer to them as "minimal completions".

The enumeration of minimal chordal completion takes place in the more general task of enumerating the minimal or the maximal subsets of a set system. A *set system* is a couple $(\mathcal{U}, \mathcal{F})$ where $\mathcal{U}$ is called the ground set and $\mathcal{F} \subseteq 2^{\mathcal{U}}$ is a family of subsets of $\mathcal{U}$. For a set system $(\mathcal{U}, \mathcal{F})$ we denote by $\mathcal{F}_{\min}$ (resp. $\mathcal{F}_{\max}$) the inclusion-wise minimal (resp. maximal) sets in $\mathcal{F}$. Many enumeration problems consist in enumerating the set $\mathcal{F}_{\max}$ or $\mathcal{F}_{\min}$ of a set

system $(\mathcal{U}, \mathcal{F})$. Of course the set $\mathcal{F}$ is usually not part of the input and we simply assume that a polynomially computable oracle membership is given, *i.e.* one can check whether a subset $F \subseteq \mathcal{U}$ belongs to $\mathcal{F}$ in time polynomial in $\mathcal{U}$.

In [12], the authors describe a method called *Proximity Search* (by canonical reconstruction) to design polynomial delay algorithms to enumerate $\mathcal{F}_{\max}$ of a set system $(\mathcal{U}, \mathcal{F})$. Given a set family $\mathcal{F}$ on a ground set $\mathcal{U}$, an *ordering scheme* π is a function which associates for every $F \in \mathcal{F}$ a permutation $\pi(F) = f_1, ..., f_{|F|}$ of the elements of F such that for all $i < |F|$, the ith prefix $\{f_1, ..., f_i\}$ of $\pi(F)$ is in $\mathcal{F}$. Notice that a set system $(\mathcal{U}, \mathcal{F})$ has an ordering scheme if and only if for every $F \in \mathcal{F}$, there exists $f \in F$ such that $F \setminus \{f\} \in \mathcal{F}$. Set systems having this property are called *accessible*.

The method described in [12] is based on the *proximity* between 2 solutions. While this notion has been defined in a very general context, most of its use cases are based on an ordering scheme. Given an ordering scheme π, and given $F_1, F_2 \in \mathcal{F}$ with $\pi(F_2) = f_1, ..., f_{|F_2|}$, the *$\pi$-proximity* between F_1 and F_2, denoted by $F_1 \tilde{\cap} F_2$, is the largest $i \leq |F_2|$ such that $\{f_1, ..., f_i\} \subseteq F_1$. It is worth noticing that the proximity relation between two solutions is not necessarily symmetric.

A polynomial-time computable function $\textsc{Neighbours} : \mathcal{F}_{\max} \to 2^{\mathcal{F}_{\max}}$ is called *π-proximity searchable*, if for every $F_1, F_2 \in \mathcal{F}_{\max}$ there exists $F' \in \textsc{Neighbours}(F_1)$ such that $F' \tilde{\cap} F_2 > F_1 \tilde{\cap} F_2$. Finally, we say by extension that an ordering scheme π of a set system $(\mathcal{U}, \mathcal{F})$ is *proximity searchable* if there exists a π-proximity searchable function Neighbours.

One of the major results of [12] is the following theorem.

▶ **Theorem 2** ([12]). *Let $(\mathcal{U}, \mathcal{F})$ be a set system and assume that one can find in polynomial time a maximal set $F_0 \in \mathcal{F}_{max}$. If $\mathcal{F}$ has a proximity searchable ordering scheme, then $\mathcal{F}_{max}$ can be enumerated with polynomial delay.*

The proof of this theorem is based on the analysis of the *supergraph of solutions*. The supergraph of solutions is the directed graph having $\mathcal{F}_{\max}$ as vertex set and there is an arc from F_1 to F_2 if $F_2 \in \textsc{Neighbours}(F_1)$ (where Neighbours is the π-proximity searchable function). The proximity searchability of the ordering scheme implies that this supergraph of solutions is strongly connected. Then, the polynomial delay algorithm consists in starting from an arbitrary solution $F_0 \in \mathcal{F}_{\max}$ and performing a traversal of the supergraph of solutions, following at each step the arcs computed on the fly by Function Neighbours. The strong connectivity of the supergraph of solutions ensures that all solutions will be found. However, with this method, one needs to store in memory the solutions already visited, which in general results in the need of an exponential space.

One of the classical methods in enumeration to avoid the storage of the already outputted solutions is to define a parent-child relation over the set of solutions. It consists in associating to each $F \in \mathcal{F}_{\max} \setminus F_0$ a parent solution $\textsc{Parent}(F) \in \mathcal{F}_{\max}$ such that $F \in \textsc{Neighbours}(\textsc{Parent}(F))$. Given the Parent function, one can finally define the Children as $\textsc{Children}(F) := \{F' \in \textsc{Neighbours}(F) \mid \textsc{Parent}(F') = F\}$. The goal is to define the function Parent in such a way that the arcs of the supergraph of solutions defined by Function Children form a spanning arborescence of the supergraph of solutions, because in such a situation, one does not need to store the already visited solutions in a traversal of the supergraph of solutions. This method and the way to traverse the spanning arborescence of the supergraph is called *Reverse Search* [2] and has been used in many contexts.

Most applications of Reverse Search use a classical parent-child relation originally introduced in [25] for the enumeration of maximal independent sets of a graph. This specific parent-child relation has been used in general enumeration frameworks to obtain polynomial delay and polynomial space algorithms [18, 9]. Unfortunately, this method can only be used for hereditary set systems and it is not compatible with Proximity Search in general.

In [10] the authors show how to adapt this parent-child relation to commutable set systems (a class that strictly contains hereditary set systems) and in [11], it has been shown that the same method can be combined with Proximity Search to obtain polynomial delay and polynomial space algorithms for commutable set systems.

A set system is *commutable* if for any $X, Y \in \mathcal{F}$ with $X \subseteq Y$, the following two conditions hold:

- **Strong accessibility:**
  There exists $f \in Y \setminus X$ such that $X \cup \{f\} \in \mathcal{F}$
- **Commutability:**
  For any $a, b \in Y \setminus X$, if $X \cup \{a\} \in \mathcal{F}$ and $X \cup \{b\} \in \mathcal{F}$ then $X \cup \{a, b\} \in \mathcal{F}$

More formally, the authors introduce the notion of *prefix-closed* ordering schemes (*cf.* Section 5 for a definition) and they show the following theorem.

▶ **Theorem 3** ([11]). *Let $(\mathcal{U}, \mathcal{F})$ be a commutable set system and assume that one can find in polynomial time a maximal set $F_0 \in \mathcal{F}_{max}$. If $\mathcal{F}$ has a proximity searchable prefix-closed ordering scheme, then $\mathcal{F}_{max}$ can be enumerated with polynomial delay and polynomial space.*

The polynomial space complexity comes from the definition of a parent-child relation that strongly relies on the commutability property. In the current paper, we introduce a new way of defining parent-child relations called *canonical path reconstruction* that does not require the commutability property. Since the set of chordal completions is not a commutable set system, this new method will be used in Section 4 to obtain a polynomial delay algorithm. Then, in Section 5 we improve Theorem 3 by proving the following which applies to non-commutable set systems.

▶ **Theorem 4.** *Let $(\mathcal{U}, \mathcal{F})$ be a set system and assume that one can find in polynomial time a maximal set $F_0 \in \mathcal{F}_{max}$. If $\mathcal{F}$ has a proximity searchable prefix-closed ordering scheme, then $\mathcal{F}_{max}$ can be enumerated with polynomial delay and polynomial space.*

3 Enumeration of minimal chordal completions: polynomial delay

In this section we present a polynomial delay and exponential space algorithm to list all minimal chordal completions of a graph. In Section 3.1 we present all the concepts necessary to define an ordering scheme that will suit to minimal chordal completions. Then in Section 3.2, we present the neighbouring function and prove that this function is proximity searchable. As a consequence, together with Theorem 2, we obtain a polynomial delay algorithm.

3.1 Ordering scheme for chordal graphs

A class $\mathcal{C}$ of graphs is called *sandwich-monotone* [16] if for any two graphs H_1 and H_2 in $\mathcal{C}$ such that $E(H_1) \subsetneq E(H_2)$, there exists an edge $e \in E(H_2) \setminus E(H_1)$ such that $H_2 \setminus \{e\}$ is also in $\mathcal{C}$. This property is equivalent to being *strongly accessible* in terms of set systems (see for example [10]).

In [23, Lemma 2], the authors proved that the class of chordal graphs is sandwich-monotone. This immediately implies that if $F_1 \subsetneq F_2$ are two chordal completions of any graph, there exists $e \in F_2 \setminus F_1$ such that $F_2 \setminus \{e\}$ is a chordal completion, or equivalently there exists $e \in F_2 \setminus F_1$ such that $F_1 \cup \{e\}$ is a chordal completion. That rephrases as the following lemma.

▶ **Lemma 5.** *Chordal graphs are sandwich-monotone. In particular, chordal completions of G are sandwich-monotone.*

The general idea is then to use the sandwich-monotonicity of chordal completions to derive a suitable ordering scheme. The Proximity Search framework introduced in [10] has been designed to enumerate inclusion-wise maximal subsets of a set system. However, the same framework could be applied to the enumeration of inclusion-wise minimal subsets of a set system, by considering the complements of the solutions. To this effect, we will not work directly with the edge sets of the completions but rather with the sets of their *non-edges*. That is to say, we will consider for any completion F its complement $\bar{F} := E^c \setminus F$. The goal of this section is then to apply Proximity Search to the set $\bar{\mathcal{F}} := \{\bar{F} \mid F \in \mathcal{F}\}$ in order to enumerate the set $\bar{\mathcal{F}}_{\max} := \max(\bar{\mathcal{F}}) = \{\bar{F} \mid F \in \mathcal{F}_{min}\}$.

From now on, the elements of E^c (that is to say, the non-edges of G) are assumed to be arbitrarily ordered. The following definitions are similar to the ones given in [10] but are defined on $\mathcal{F}$ instead of $\bar{\mathcal{F}}$. Let F be a chordal completion of G and X be any subset of E^c. Consider the set X as the set from which we are allowed to remove elements. We define:

- $\textsc{Candidates}(F, X) := \{e \in X \cap F : F \setminus \{e\} \in \mathcal{F}\}$
- $\textsc{Candidates}(F) := \textsc{Candidates}(F, F)$
- $c(F, X) := \min(\textsc{Candidates}(F, X))$
- $c(F) := \min(\textsc{Candidates}(F))$

Now, given a chordal completion F and a set $X \subseteq E^c$, we denote by $\textsc{Del}(F, X)$ the chordal completion included in F by iteratively removing $c(F, X)$ from F at each step. Finally, we define $\textsc{Del}(F) := \textsc{Del}(F, F)$. Note that, for any F, X, computing $\textsc{Del}(F, X)$ corresponds to the following procedure.

Function Del(F, X).

while $\textsc{Candidates}(F, X) \neq \emptyset$ **do**
  remove $c(F, X)$ from F;
return F

▶ **Remark 6.** *By Lemma 5, if $F \in \mathcal{F}$, then $\textsc{Del}(F) \in \mathcal{F}_{min}$. That is to say, Del can be used to turn a chordal completion into a minimal one in a canonical way.*

Also, as E^c is a chordal completion (it corresponds to the clique completion) of G, the next lemma holds.

▶ **Lemma 7.** *If F is a minimal chordal completion of G, then $\textsc{Del}(E^c, \bar{F}) = F$.*

Proof. By Remark 6, it holds $\textsc{Del}(E^c, \bar{F}) \in \mathcal{F}_{\min}$, and $F \subset \textsc{Del}(E^c, \bar{F})$. As a result, since the only minimal solution containing F is F itself, then $\textsc{Del}(E^c, \bar{F}) = F$. ◀

The procedure followed to compute $\textsc{Del}(E^c, \bar{F})$ provides an ordering on the elements of $\bar{F}$ by considering the order in which the elements of $\bar{F}$ are removed to obtain F. From this ordering, we can define for any chordal completion F the canonical ordering $\textsc{Can}(\bar{F}) := s_1, ..., s_{|\bar{F}|}$ of $\bar{F}$ as follows:

- $s_1 := c(E^c, \bar{F})$;
- for all $1 \leq i < |\bar{F}|$, $s_{i+1} := c(E^c \setminus \{s_1, ..., s_i\}, \bar{F})$.

For a set $\bar{F}$ and its canonical ordering $\textsc{Can}(\bar{F}) := s_1, ..., s_{|\bar{F}|}$ we define $\bar{F}^i$ as the set of elements $\{s_1, ..., s_i\}$ of $\bar{F}$ and we define $F^i := E^c \setminus \bar{F}^i$. By definition of $\textsc{Candidates}(E^c, \bar{F})$, any prefix $\bar{F}^i$ of this ordering belongs to $\bar{\mathcal{F}}$. In other words, F^i denotes the chordal completion of G, not necessarily minimal, obtained by removing the ith prefix of $\textsc{Can}(\bar{F})$ from the clique completion. Thus, the canonical ordering Can is an ordering scheme of $\bar{\mathcal{F}}$.

This ordering will be used to measure the proximity between two solutions in order to call the Proximity Search algorithm for minimal chordal completions. Note that it can be computed in polynomial time for any solution, the complexity being essentially this of calling Function Del.

We now define the notion of proximity between two solutions that will be used in the sequel. For F_1 and F_2 two minimal completions of G, let $\textsc{Can}(\bar{F_2}) = f_1, ..., f_k$ be the canonical ordering of $\bar{F_2}$. The *proximity* $\bar{F_1} \tilde{\cap} \bar{F_2}$ between $\bar{F_1}$ and $\bar{F_2}$ is defined as the largest $i \leq k$ such that $\{f_1, ..., f_i\} \subseteq \bar{F_1}$. It is worth noticing that the proximity relation between two solutions is not necessarily symmetric. The notion defined here corresponds to the "standard" proximity measure that is usually adopted when using the Proximity Search framework [12, 10, 6]. Note that the proximity is defined here on the set of elements of E^c (that is to say, non-edges of G) which do *not* belong to the chordal completion. Since we are working on both the completions and their complement, by a slight abuse of language, when we speak about the proximity between two minimal completions, we actually mean the proximity between their complement sets.

3.2 Polynomial delay algorithm

We show in this section that the ordering scheme Can defined above is proximity searchable. Since the idea is to consider the complement sets of minimal completions rather than the completions themselves, we will seek to maximise the set of common *non-edges* between two minimal completions in order to increase the proximity. So, we actually show that Can is a proximity searchable ordering scheme of $\bar{\mathcal{F}}$.

The first goal is to define a suitable neighbouring function on the class of chordal graphs. Any solution must have a polynomial number of neighbours, each of them being computable in polynomial time in order to guarantee the polynomial delay when applying Proximity Search.

Given a chordal graph H and an edge $e = \{x, y\} \in E(H)$, the *flip operation* $\textsc{Flip}(H, e)$ consists in removing e from H, and turning the common neighbourhood of x and y into a clique. More formally, if $H' = \textsc{Flip}(H, e)$, then $V(H') = V(H)$ and $E(H') := (E(H) \setminus \{e\}) \cup \{uv \mid u, v \in N_H(x) \cap N_H(y)\}$. The flip operation is illustrated in Figure 1.

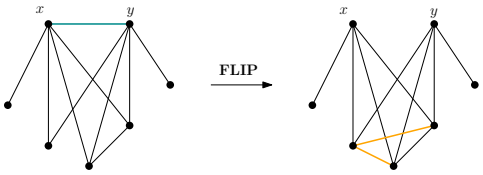

Figure 1 The flip operation on $e = \{x, y\}$. The common neighbourhood of x and y is turned into a clique.

Since H is chordal, the removal of e can create several chordless C_4s of which e was the only chord. We will see that completing the common neighbourhood of x and y into a clique adds the missing chords to all these C_4. In other words, the flip operation preserves the class of chordal graphs, as stated next.

▶ **Lemma 8.** *Let H be a chordal graph, and $e = \{x, y\}$ be an edge of H. Then the graph $H' := \textsc{Flip}(H, e)$ is also chordal.*

Proof. Assume (for contradiction) that H' contains a chordless cycle C of length $\ell > 3$.

Suppose C contains only edges of H. Since H is chordal, it does not contain long induced cycles. Then necessarily C is a C_4 of H of which e was the unique chord, otherwise there would be an induced cycle of length at least 4 (either C or a cycle made from e and edges of C) in the chordal graph H. By definition, the flip operation adds an edge between the other two vertices of C, meaning that C has a chord in H'. This cannot happen.

Therefore, C contains an edge $e' = \{z, t\}$ added by the flip operation (*i.e.* e' is an edge of H' but not of H). Since C contains the edge e', it does not contain any other fill edge added by the flip operation, otherwise a chord of C would also be added by the flip. Plus, we assumed that e' is added by the flip operation, so necessarily both z and t belong to $N_H(x) \cap N_H(y)$. Therefore, $P := C - \{e'\}$ is a $z - t$ path of H', disjoint from x and y. Remark that P is an induced path of H since it contains only edges of H, that is, z and t are in the same connected component of $H \setminus \{x, y\}$.

▷ Claim 9. Every vertex of P is in $N_H(x) \cap N_H(y)$.

Proof. Suppose that there exists a vertex s of P which is not a neighbour of x. We will show that there exists in H a chordless cycle containing s and x.

As s is not a neighbour of x, and z is by hypothesis, there exists $q \in N(x)$ a vertex of P that is between z and s, and closest to s on P. Similarly, let $r \in N(x)$ be a vertex of P that is between t and s, and closest to s.

The $q - r$ subpath of P induced by all vertices between q and r is therefore a chordless path of H of which all internal nodes are non-neighbours of x. It follows that adding x to this $q - r$ subpath creates a chordless cycle of length at least 4 in H. This is excluded, so all vertices of P are neighbours of x in H.

By symmetry in x and y, we also deduce that all vertices of P are neighbours of y.

The claim is proved: every vertex of P is in $N_H(x) \cap N_H(y)$. ◁

By the previous Claim, the flip operation turns the cycle C into a clique. Hence C has length 3, a contradiction. ◀

When dealing with chordal completions, the notation of the flip operation will be slightly adapted: for $F \in \mathcal{F}$, and $e \in F$ (e is always chosen among the fill edges of the completion), we write $\textsc{Flip}(F, e)$ instead of $\textsc{Flip}(G_F, e)$.

From Lemma 8, we are then able to deduce the following.

▶ **Lemma 10.** *Let F be a chordal completion of a graph G. If $F \in \mathcal{F}_{min}$, and $e \in F$, then $\textsc{Flip}(F, e) \in \mathcal{F}$.*

Proof. The only edge that is in F but not in $\textsc{Flip}(F, e)$ is e. Since $e \in F$, it implies that all edges of G are still in $\textsc{Flip}(F, e)$. As $\textsc{Flip}(F, e)$ is chordal by Lemma 8. ◀

Observe that $\textsc{Flip}(F, e)$ is a chordal completion of G that is not necessarily minimal.

We are now ready to explain the neighbouring function used to enumerate $\mathcal{F}_{\min}$. Given $F \in \mathcal{F}_{\min}$ and $e \in F$, we define the successor of F according to e as the minimal completion $\textsc{Succ}(F, e) := \textsc{Del}(\textsc{Flip}(F, e))$. We now define the neighbours of a solution F as $\textsc{Neighbours}(F) := \{\textsc{Succ}(F, f) | f \in F\}$. As a corollary of Remark 6 and Lemma 10, it is true that $\textsc{Succ}(F, e) \in \mathcal{F}_{\min}$. Observe also that each solution has a polynomial number of neighbours since $\textsc{Neighbours}(F) \leq |F|$.

Now the neighbouring function is properly defined, it is easy to notice that it can be computed in polynomial time. It remains to prove that the function NEIGHBOURS is CAN-proximity searchable. This will allow us to use Proximity Search on the set of minimal chordal completions of a graph G.

▶ **Lemma 11.** *Let F_1 and F_2 be two minimal chordal completions of a graph G. Let $f_1, \dots, f_k = \text{CAN}(\bar{F}_2)$ and let $i := \bar{F}_1 \tilde{\cap} \bar{F}_2$. Then the following statements hold:*
1. *$f_{i+1} \notin \bar{F}_1$;*
2. *$\overline{\text{SUCC}(F_1, f_{i+1})} \tilde{\cap} \bar{F}_2 > i$.*

Proof. 1. By definition of i as the length of the largest prefix of $\text{CAN}(\bar{F}_2)$ included in $\bar{F}_1$, it holds $f_{i+1} \notin \bar{F}_1$.

2. Let $F' := \text{FLIP}(F_1, f_{i+1})$, we will show that $\{f_1, ..., f_{i+1}\} \subseteq \bar{F'}$. Since $\text{SUCC}(F_1, f_{i+1}) \subseteq F'$, it will imply that $\{f_1, ..., f_{i+1}\} \subseteq \overline{\text{SUCC}(F_1, f_{i+1})}$, and finally $\overline{\text{SUCC}(F_1, f_{i+1})} \tilde{\cap} \bar{F}_2 \geq i+1$.

First, notice that by definition of FLIP, $f_{i+1} \notin F'$. Let x and y be the two endpoints of f_{i+1}. Assume for contradiction that an edge f_j, $j \leq i$ is added when completing $N_{G_{F_1}}(x) \cap N_{G_{F_1}}(y)$ into a clique. As stated earlier, the notation $\bar{F}_2^{\,i+1}$ is used to denote the set $\{f_1, ..., f_{i+1}\}$, which is included in $\bar{F}_2$, and F_2^{i+1} represents the associated chordal completion.

Let u and v be the two endpoints of f_j. Then x, u, y, v form a C_4 of which f_{i+1} was the unique chord in G_{F_1}. By definition of $\text{CAN}(\bar{F}_2)$, F_2^{i+1} is a chordal completion of G, and since neither the chords f_j nor f_{i+1} belong to it, at least one of the edges xu, uy, yv or vx does not belong to F_2^{i+1} since otherwise x, u, y, v would form a chordless C_4 in F_2^{i+1}. Assume without loss of generality that $xu \notin F_2^{i+1}$. Since $\bar{F}_2^{\,i+1} = \{f_1, ..., f_{i+1}\}$, there exists $\ell \leq i$ such that $xu = f_\ell$. But then we have found an edge $f_\ell \notin \bar{F}_1$ with $\ell \leq i$, which contradicts the assumption $\bar{F}_1 \tilde{\cap} \bar{F}_2 = i$.

Consequently, $\overline{\text{SUCC}(F_1, f_{i+1})} \tilde{\cap} \bar{F}_2 > i$. ◀

As a consequence, since the polynomial computable function SUCC is able to increase the proximity between 2 solutions, it proves that the ordering scheme defined by CAN is proximity searchable. More formally, the function $\text{NEIGHBOURS}(\bar{F}) := \{\bar{X} \mid X \in \text{NEIGHBOURS}(F)\}$ is a CAN-proximity searchable function and CAN is then a proximity searchable ordering scheme for $\bar{\mathcal{F}}_{max}$.

Therefore, by Theorem 2, $\bar{\mathcal{F}}_{max}$ or equivalently $\mathcal{F}_{\min}$ can be enumerated with polynomial delay. This is summarized in the following theorem.

▶ **Theorem 12.** *There exists a polynomial delay algorithm for the enumeration of minimal chordal completions of a graph.*

To prove that CAN is proximity searchable, we only used the fact that it is an ordering scheme of $\bar{\mathcal{F}}$. Thus any ordering scheme of $\bar{\mathcal{F}}$ is actually proximity searchable.

Yet, applying Proximity Search usually gives polynomial delay with exponential space: to avoid duplication it is necessary to store all the generated solutions in a lookup table. Each newly generated solution is then searched in the table in polynomial time.

4 Polynomial space

We would like to make the enumeration process work in polynomial space, since this could lead to an algorithm that is more usable in practice. As stated in Theorem 3, it is proven in [10] that if the ordering scheme is prefix-closed and $\mathcal{F}$ is a *commutable* set system, one can design a polynomial delay and polynomial space algorithm for the enumeration of $\mathcal{F}_{\max}$.

An ordering scheme π over $\mathcal{F}$ is called *prefix-closed*, if for all $F \in \mathcal{F}$, there exists an ordering $<_F$ of the elements of $\textsc{Candidates}(F)$ such that $\pi(\bar{F}) = f_1, ..., f_\ell$ *if and only if* for any $i < \ell$, it holds $f_{i+1} = \min_{<_{F^i}}(\textsc{Candidates}(F^i) \cap \bar{F})$. We know by definition of $\textsc{Can}$ that this ordering is prefix-closed (with the ordering of E^c). By Section 3, $\textsc{Can}$ is also proximity searchable. As stated earlier, chordal completions form a strongly accessible set system since they are sandwich-monotone, and so are their complements. However, the set of chordal completions is not a commutable set system, and neither is the set of their complements.

This section is devoted to the definition of a suitable parent-child relation over $\mathcal{F}_{\min}$ which does not require the system to be commutable, in order to obtain a polynomial space algorithm. In the supergraph of solutions, we identify a reference solution named F_0 and we manage to relate any other solution F to F_0. To uniquely determine the parent of a solution, we introduce a new concept called *canonical path reconstruction*. The idea is, for any solution F distinct from F_0, to identify a path in the supergraph of solutions from F_0 to F in a unique manner. Then the parent of solution F is defined as the immediate predecessor of F on this path. In addition, we are able to compute this path in polynomial time for any solution.

To ensure that such a path can be uniquely determined and computed in polynomial time we rely on the specific structure of chordal completions and more specifically on the fact that the canonical ordering we defined on chordal completions is prefix-closed. To the best of our knowledge, it is the first algorithm to define a parent-child relation in this manner.

The parent-child relation will define a spanning arborescence of the supergraph of solutions rooted at F_0. This way, the enumeration algorithm sums up in performing a traversal of the tree in a depth-first manner.

It is somehow counter-intuitive to observe that the canonical path of a solution is not necessarily part of the final arborescence rooted at F_0. This canonical path is only computed to find the last solution in the path before F to define it as the parent of F. We will prove that while the so defined parent-child relation does not exactly follow the canonical paths, it still forms a spanning arborescence of the solution set rooted at F_0.

Let us consider the total ordering $\prec$ over $\bar{\mathcal{F}}_{min}$ defined as $\bar{F}_1 \prec \bar{F}_2$ if $\textsc{Can}(\bar{F}_1)$ is lexicographically smaller than $\textsc{Can}(\bar{F}_2)$.

▶ **Lemma 13.** *Let $F_1, F_2 \in \mathcal{F}_{min}$ with $\textsc{Can}(\bar{F}_1) = f_1, ..., f_\ell$ and $\textsc{Can}(\bar{F}_2) = t_1, ..., t_k$. Assume furthermore that there exists $j \leq \ell$ such that $\{f_1, ..., f_j\} \subset \bar{F}_2$. Then one of the two possibilities holds:*

1. *$\bar{F}_2 \prec \bar{F}_1$;*
2. *$f_i = t_i$ for all $i \leq j$.*

Proof. Let i^* be the smallest index such that $t_{i^*} \neq f_{i^*}$. If $i^* > j$, then 2 holds. Else, $i^* \leq j$. In this case, we deduce from the minimality of i^* that

$$\bar{F_1}^{i^*-1} = \{f_1, ..., f_{i^*-1}\} = \{t_1, ..., t_{i^*-1}\} = \bar{F_2}^{i^*-1} .$$

Since $f_{i^*} \in \bar{F}_2$ and since $f_{i^*} \in \textsc{Candidates}(F_1^{i^*-1}, \bar{F}_1)$ by definition of $\textsc{Can}(\bar{F}_1)$, we deduce $f_{i^*} \in \textsc{Candidates}(F_2^{i^*-1}, \bar{F}_2)$. The canonical ordering $\textsc{Can}$ is prefix-closed, therefore we know that $t_{i^*} = \min(\textsc{Candidates}(F_2^{i^*-1}, \bar{F}_2))$. We deduce from it that $t_{i^*} \leq f_{i^*}$ and since $t_{i^*} \neq f_{i^*}$, we have $t_{i^*} < f_{i^*}$ which proves $\bar{F}_2 \prec \bar{F}_1$. ◀

The algorithm starts by computing $F_0 := \textsc{Del}(E^c)$ in polynomial time. This solution F_0 will be used as the reference solution. Note that we could start from any solution and the results would still be valid, but for simplicity we start from a solution that can easily be identified.

For a minimal chordal completion F with canonical ordering $\textsc{Can}(\bar{F}) := f_1, ..., f_\ell$, we define the *canonical path of* F as the sequence of minimal completions $F_0, ..., F_k = F$ starting at F_0 such that for all $1 \leq i \leq k$, $F_i = \textsc{Succ}(F_{i-1}, f_{(\bar{F}_{i-1} \tilde{\cap} \bar{F})+1})$. Remark that the edge $f_{(\bar{F}_{i-1} \tilde{\cap} \bar{F})+1}$ is part of F_{i-1} and the call to Succ is correct. Let us also note that by construction, the proximity strictly increases along the path. Then, $\textsc{Parent}(F)$ is defined for any $F \neq F_0$ as the last minimal completion F_{k-1} in the canonical path of F.

As remarked before, except F_{k-1}, the other ancestors of F may not be part of its canonical path. For instance F_{k-2} may not be the parent of F_{k-1}.

The detailled Parent function is presented 11.

Function Parent(F).

Compute $f_1, \ldots, f_\ell := \textsc{Can}(\bar{F})$;
Compute $F_{current} := \textsc{Del}(E^c)$;
while $F_{current} \neq F$ **do**
  $f := f_{(\overline{F_{current}} \tilde{\cap} \bar{F})+1}$;
  $F_{prec} := F_{current}$;
  $F_{current} := \textsc{Succ}(F_{prec}, f)$;
return F_{prec}

Then we define $\textsc{Children}(F) := \{F' \in \textsc{Neighbours}(F) \mid \textsc{Parent}(F') = F\} = \{\textsc{Succ}(F, e) \mid e \in F,\ \textsc{Parent}(\textsc{Succ}(F, e)) = F\}$.

▶ **Lemma 14.** *Let F be a minimal chordal completion of G, and let $F_0, \ldots, F_k = F$ be the canonical path of F. For all $j \leq k$, $\bar{F}_j \tilde{\cap} \bar{F} \geq j$.*

Proof. By construction of the canonical path of F, the proximity strictly increases at each step by at least one. ◀

By Lemma 14 the length of the canonical path of F is smaller than $|\bar{F}|$. Since the construction of the canonical path of F is done by applying at most $|\bar{F}|$ times Function Succ, $\textsc{Parent}(F)$ is computable in polynomial time for any $F \in \mathcal{F}_{\min}$.

Now, since the computation of $\textsc{Children}(F)$ is done by applying Function Succ followed by Function Parent at most $|F|$ times, it is also computable in polynomial time.

Once the Children function is defined, one just has to apply the classical algorithm to visit and output all solutions whose high-level description is presented in Algorithm 1. To prove the correctness of the algorithm, we just have to prove that the function Children defines a spanning arborescence on the set of solutions rooted at F_0.

Observe that the naive implementation of Algorithm 1 may use exponential space, since the height of the recursion tree might be exponential. Indeed the recursion tree corresponds to the arborescence defined by the parent-child relation and we are not able to guarantee that its height is polynomial. However, since the functions Parent and Children are computable in polynomial time we don't need to store the state of each recursion call. The classical trick introduced in [25] and formalized in [2] as part of the Reverse Search algorithm is to use Function Parent to perform the backtrack operation on the fly. Indeed this function is able to navigate backward in the tree, removing the need of keeping in memory all recursion calls. Thus, the algorithm only needs to keep in memory the current solution.

▶ **Theorem 15.** *Algorithm 1 outputs all minimal chordal completions of the input graph without duplication, with polynomial delay and using polynomial space.*

Algorithm 1 Efficient enumeration of minimal chordal completions.

input : A graph $G = (V, E)$
output : All minimal chordal completions of G

$F_0 := \textsc{Del}(E^c)$;
Call $\textsc{enum}(F_0)$;

Function `enum` *(F)*:
    `/* Output` F `if recursion depth is even */`;
    foreach $F' \in \textsc{Children}(F)$ **do**
        `enum`(F');
    `/* Output` F `if recursion depth is odd */`;

Proof. Assume that some solutions of $\mathcal{F}_{\min}$ are not outputted by the algorithm, and let F be the smallest one with respect to $\prec$ with $\textsc{Can}(\bar{F}) := f_1, ..., f_\ell$. Let $F_0, ..., F_k = F$ be the canonical path of F. We prove that all F_i, $i < k$ will be outputted by the algorithm. This way, $\textsc{Children}(F_{k-1})$ will be produced, contradicting the fact that F has not been outputted.

Let i be the smallest index such that F_i has not been processed by the algorithm. By minimality of $\bar{F}$ with respect to $\prec$, we know that $\bar{F} \prec \bar{F}_i$. Hence by Lemmas 13 and 14, $f_1, ..., f_i$ is a prefix of $\textsc{Can}(\bar{F}_i)$. So the canonical path of F_i is precisely $F_1, ..., F_i$ and $\textsc{Parent}(F_i) = F_{i-1}$. Now, by minimality of i, we know that F_{i-1} has been outputted by the algorithm, and $F_i \in \textsc{Children}(F_{i-1})$ will be outputted during the processing of F_i.

To obtain a polynomial delaya and polynomial space algorithm, we rely on the fact that the Parent and Childrenfunctions admit a polynomial time complexity. Then with this conditions fulfilled, it remains to show that Algorithm 1 can be implemented so that the delay required to produce a new solution is polynomial in the size of the input and that the memory space is polynomial. Algorithm 1 can be seen as a traversal of the tree of solutions defined by the Parent-Child relation. The time a solution is produced will depend of the height of the solution in the solution tree. It is either produced at the beginning of the call or at the end wheter the height is odd or even. This classic technique in enumeration grant the delay. For this same traversal of the solution tree, Uno [26] developped techniques, that provided the Parent and Children functions admit a polynomial time complexity, will be able to traverse the tree of solutions only using polynomial space. ◀

5 Canonical path reconstruction: a general approach

In fact, the result we proved for chordal completions is part of a more general framework. In this section, we show how to extend the algorithm obtained for chordal graphs, in order to apply it to other graph classes.

As stated in Theorem 3, the authors of [11] proved that if a proximity searchable ordering scheme is prefix-closed, then one can design a polynomial delay and polynomial space algorithm to enumerate $\mathcal{F}_{\max}$ whenever $\mathcal{F}$ is a commutable set system. We prove here that the same remains true even if the system is not commutable. To prove that, we adapt the concept of defined earlier *canonical path reconstruction* in a more general setting to define parent-child relations over $\mathcal{F}_{\max}$ which does not require the commutability condition.

Given $F \in \mathcal{F}$ we denote by F^+ the set $\{x \in \mathcal{U} : F \cup \{x\} \in \mathcal{F}\}$ of candidates for F. Assuming that an ordering scheme π is fixed, we denote by F^i the ith prefix of F according to π.

The notion of prefix-closed ordering has been introduced in [10] and it appears to be a key property to design parent-child relations. Intuitively assume that for each non maximal element of $F \in \mathcal{F}$ we have a preference given by a total ordering $<_F$ over the potential elements that can be added to F (i.e. a total ordering over F^+). This preference depends on the set F and the preference among two elements may vary from one F to another. Then an ordering scheme π is said to be prefix-closed if for each prefix F_i of F the next element f_{i+1} corresponds to the most preferred element that remains in F according to the preference relation $<_{F^i}$. More formally :

▶ **Definition 16.** *An ordering scheme π is* prefix-closed*, if there exists an ordering $<_F$ of the elements of F^+ for each $F \in \mathcal{F}$ that verify the following condition : For every $F \in \mathcal{F}$, $\pi(F) = f_1, ..., f_\ell$ if and only if $f_{i+1} = \min_{<_{F^i}}(F^{i^+} \cap F)$ for any $i < \ell$.*

The goal of this section is to prove the following theorem.

▶ **Theorem 17.** *If π is a polynomial time computable ordering scheme for $\mathcal{F}$ which is both proximity searchable and prefix-closed, then $\mathcal{F}_{max}$ can be enumerated with polynomial delay and polynomial space.*

Notice that any strongly accessible set system has a prefix-closed ordering scheme. Similarly as the one shown for chordal completions one can choose an arbitrary ordering on the elements of $\mathcal{U}$ and simply define $\pi(F) := f_1, ..., f_\ell$ with $f_{i+1} := \min(F^{i^+} \cap F)$. The strong accessibility ensures that this ordering is well defined.

To prove Theorem 17, we define the general parent-child relation over $\mathcal{F}_{\max}$ based on the *canonical path reconstruction method*. Let then π be a prefix-closed, proximity searchable ordering scheme on the set family $\mathcal{F}$.

Whenever an ordering scheme π is proximity searchable, the supergraph of solutions defined by the π-proximity searchable function Neighbours is strongly connected. The goal will be to choose a reference solution F_0 and to identify for each other solution F a canonical path from F_0 to F. The parent of F will be defined as the last solution of this path.

For a prefix-closed ordering scheme π, let us define a total ordering $\prec_\pi$ over $\mathcal{F}_{\max}$. Let $F_1, F_2 \in \mathcal{F}_{\max}$, $\pi(F_1) = t_1, ..., t_{|F_1|}$, $\pi(F_2) = f_1, ..., f_{|F_2|}$ and let $j \geq 0$ be the largest index such that $F_1^j = F_2^j$. Let us denote $F := F_1^j = F_2^j$. Then we have $F_1 \prec_\pi F_2$ if $t_{j+1} <_F f_{j+1}$.

We can now define what will be the canonical path of a solution $F \in \mathcal{F}_{\max}$. To this end, we need to define a function Next : $\mathcal{F}_{\max} \times \mathcal{F}_{\max} \to \mathcal{F}_{\max}$ such that given $F_1, F_2 \in \mathcal{F}_{\max}$ with $F_1 \tilde{\cap} F_2 = i$, $\textsc{Next}(F_1, F_2) \in \{F \in \textsc{Neighbours}(F_1) : F \tilde{\cap} F_2 > i\}$. Since we assumed that π is proximity searchable, we know that the set $\{F \in \textsc{Neighbours}(F_1) \mid F \tilde{\cap} F_2 > i\}$ is not empty. Hence, to define $\textsc{Next}(F_1, F_2)$, one just has to choose deterministically an element of the set $\{F \in \textsc{Neighbours}(F_1) : F \tilde{\cap} F_2 > i\}$. If the function Neighbours produces solutions in a deterministic order, then $\textsc{Next}(F_1, F_2)$ can be chosen as the first $F \in \textsc{Neighbours}(F_1)$ such that $F \tilde{\cap} F_2 > i$. Otherwise and to be as general as possible, let us define $\textsc{Next}(F_1, F_2) := \min_{Lex}\{F \in \textsc{Neighbours}(F_1) : F \tilde{\cap} F_2 > i\}$ as the lexicographically smallest set of $\{F \in \textsc{Neighbours}(F_1) : F \tilde{\cap} F_2 > i\}$.

Given a reference solution F_0, the *canonical path* of $F \in \mathcal{F}_{\max}$ is then defined as the sequence $F_0, ..., F_k$ of elements of $\mathcal{F}$ such that:

- $F_k = F$
- $F_{i+1} = \textsc{Next}(F_i, F)$ for all $i < k$

Each $F \in \mathcal{F}_{\max}$ has a canonical path. Indeed, applying Function Next increases the proximity with F, until F is eventually reached. We define the parent of a solution F of canonical path $F_0, ..., F_k$ as $\textsc{Parent}(F) := F_{k-1}$. The set of children of F is then defined as $\textsc{Children}(F) := \{F' \in \textsc{Neighbours}(F) \mid \textsc{Parent}(F') = F\}$.

▶ **Lemma 18.** *Let $F \in \mathcal{F}_{max}$ and let $F_0, ..., F_k$ be its canonical path. Then for all $i < j \leq k$, $F_j \tilde{\cap} F > F_i \tilde{\cap} F$.*

Proof. By construction of the canonical path of F the proximity increases at each step by at least 1. ◀

The immediate following Corollary ensures that canonical paths are of polynomial size.

▶ **Corollary 19.** *If $F \in \mathcal{F}_{max}$, then its canonical path is of size at most $|F| + 1$.*

▶ **Proposition 20.** *The function PARENT can be computed in time $O(\mathcal{P} + f^2\mathcal{N})$ where f is a maximum size of a solution in $\mathcal{F}_{max}$, $\mathcal{N}$ is the complexity of function NEIGHBOURS and $\mathcal{P}$ is the time needed to compute the function π.*

Proof. To compute the PARENT(F) we first need to compute $\pi(F)$ and then to compute the canonical path of F. By Corollary 19, the path is of length at most f, so we only need to call f times the function NEXT. To compute NEXT(T, F), we compute NEIGHBOURS(T) and for each $F' \in$ NEIGHBOURS(T) we compute the proximity between F' and F and check whether F' is lexicographically smaller than the current best candidate (notice that we don't need to compute $\pi(F')$). Since both operations can be done in $O(f)$, and since |NEIGHBOURS(T)| $< \mathcal{N}$ the function NEXT can be computed in time $O(f\mathcal{N})$. ◀

Since the computation of CHILDREN(F) is done by computing first the set NEIGHBOURS(F) and then filtering it according to the function PARENT, we obtain the following complexity for the function CHILDREN.

▶ **Corollary 21.** *The function CHILDREN can be computed in time $O(\mathcal{P} + f^2\mathcal{N}^2)$ where f is a maximum size of a solution in $\mathcal{F}_{max}$, $\mathcal{N}$ is the complexity of function NEIGHBOURS and $\mathcal{P}$ is the time needed to compute the function π.*

▶ **Lemma 22.** *Let $F \in \mathcal{F}_{max}$ with $\pi(F) = f_1, ..., f_\ell$, let $F_0, ..., F_k$ be its canonical path and let $i \leq k$. If $f_1, ..., f_{F_i \tilde{\cap} F}$ is a prefix of $\pi(F_i)$, then the canonical path of F_i is $F_0, ..., F_i$.*

Proof. Let $T_0, ..., T_h$ be the canonical path of F_i. By definition we have $T_0 = F_0$. Assume that $T_0, ..., T_j = F_0, ..., F_j$ for some $j < i$. By Lemma 18, we know $F_j \tilde{\cap} F < F_i \tilde{\cap} F$, so there exists $r < F_i \tilde{\cap} F$ such that $\{f_1, ..., f_r\} \subseteq F_j$ and $f_{r+1} \notin F_j$.

Hence, since $f_1, ..., f_{r+1}$ is a prefix of $\pi(F_i)$, we have $r = F_j \tilde{\cap} F = F_j \tilde{\cap} F_i < F_i \tilde{\cap} F$. Thus

$$\begin{aligned} F_{j+1} = \text{NEXT}(F_j, F) &= \min_{<_{Lex}} \{F' \in \text{NEIGHBOURS}(F_j) : \{j_1, ..., j_{r+1}\} \subseteq F'\} \\ &= \min_{<_{Lex}} \{F' \in \text{NEIGHBOURS}(T_j) : \{j_1, ..., j_{r+1}\} \subseteq F'\} = \text{NEXT}(T_j, F_i) = T_{j+1}. \end{aligned}$$

This concludes the proof. ◀

The following key lemma is the generalisation of Lemma 13 in the case of chordal completions.

▶ **Lemma 23.** *Let $F_1, F_2 \in \mathcal{F}$ with $\pi(F_1) = f_1, ..., f_\ell$ and $\pi(F_2) = t_1, ..., t_k$. Assume furthermore that there exists $j \leq \ell$ such that $\{f_1, ..., f_j\} \subseteq F_2$, then one of the two possibilities holds:*

1. *$F_2 \prec_\pi F_1$;*
2. *$f_i = t_i$ for all $i \leq j$.*

Proof. Let i be the smallest index such that $t_i \neq f_i$. If $i > j$, then 2 holds and we are done.

Assume that $i \leq j$. By minimality of i, we have $F_1^{i-1} = F_2^{i-1} =: L$. Since $f_i \in F_2$ and since $f_i \in F_1^{i-1^+}$, we know that $f_i \in L^+ \cap F_2$. Therefore, as $t_i = \min_{<_L}(L^+ \cap F_2)$, it holds $t_i \leq_L f_i$, and since $t_i \neq f_i$, we have $t_i <_L f_i$. It proves $F_2 \prec_\pi F_1$. ◀

The previous lemma is the one that makes the canonical path reconstruction method possible. Independently of the prefix-closed property, if one can find a total ordering $\prec$ over $\mathcal{F}_{\max}$ which satisfies Lemma 23, then the canonical path reconstruction method is applicable.

Finally, to prove Theorem 17, it remains to show that the polynomial time computable function Children defines a spanning arborescence on $\mathcal{F}_{\max}$. As already mentioned, the application of the Reverse Search algorithm in [2] would output all solutions without repetition with polynomial delay and polynomial space which will conclude the proof of Theorem 17.

▶ **Theorem 24.** *Children defines a spanning arborescence on $\mathcal{F}_{max}$ rooted at F_0.*

Proof. Recall that the supergraph of solution defined by Function Children is the directed graph on $\mathcal{F}_{\max}$ with arcs set $\{(F_i, F_j) \mid F_j \in \textsc{Children}(F_i)\}$.

Since each $F \in \mathcal{F}_{\max}$, $F \neq F_0$ has only one in-neighbour $\textsc{Parent}(F)$ it is sufficient to show that for all $F \in \mathcal{F}_{\max}$, there exists a path from F_0 to F. Let's denote by $\mathcal{R}(F_0) \subseteq \mathcal{F}_{\max}$ the sets $F \in \mathcal{F}_{\max}$ for which there exists a path from F_0 to F.

Assume for contradiction that $\mathcal{R}(F_0) \neq \mathcal{F}_{\max}$ and let $F := \min_{\prec_\pi}(\mathcal{F}_{\max} \setminus \mathcal{R}(F_0))$. Let $\pi(F) = f_1, ..., f_\ell$ and let $F_0, ..., F_k$ be the canonical path of F. Now, consider the the smallest index $i^* \leq k$ such that $F_{i^*} \notin \mathcal{R}(F_0)$. If $i^* = k$ then $F_{k-1} \in \mathcal{R}(F_0)$ and since $F_{k-1} = \textsc{Parent}(F)$, F would belong to $\textsc{Children}(F_{k-1})$ and then F would belong to $\mathcal{R}(F_0)$. So assume that $i^* < k$.

Let $j := F_{i^*} \tilde{\cap} F$. By minimality of F, we have $F \prec_\pi F_{i^*}$ and since $\{f_1, ..., f_j\} \subseteq F_{i^*}$, by Lemma 23, the $j^{(th)}$ prefix of $\pi(F_{i^*})$ is $f_1, ..., f_j$. Now by Lemma 22 the canonical path of F_{i^*} is $F_0, ..., F_{i^*}$, thus F_{i^*} has F_{i^*-1} as parent. By minimality of i^*, we know that $F_{i^*-1} \in \mathcal{R}(F_0)$ and since $F_{i^*} \in \textsc{Children}(F_{i^*-1})$, we deduce $F_i^* \in \mathcal{R}(F_0)$. ◀

Abstract

One of the most fundamental and well-studied problems in tile self-assembly is the Unique Assembly Verification (UAV) problem. This algorithmic problem asks whether a given tile system uniquely assembles a specific assembly. The complexity of this problem in the 2-Handed Assembly Model (2HAM) at a constant temperature is a long-standing open problem since the model was introduced. Previously, only membership in the class coNP was known and that the problem is in P if the temperature is one ($\tau = 1$). The problem is known to be hard for many generalizations of the model, such as allowing one step into the third dimension or allowing the temperature of the system to be a variable, but the most fundamental version has remained open.

In this paper, we prove the UAV problem in the 2HAM is hard even with a small constant temperature ($\tau = 2$), and finally answer the complexity of this problem (open since 2013). Further, this result proves that UAV in the staged self-assembly model is coNP-complete with a single bin and stage (open since 2007), and that UAV in the q-tile model is also coNP-complete (open since 2004). We reduce from Monotone Planar 3-SAT with Neighboring Variable Pairs, a special case of 3SAT recently proven to be NP-hard. We accompany this reduction with a positive result showing that UAV is solvable in polynomial time with the promise that the given target assembly will have a tree-shaped bond graph, i.e., contains no cycles. We provide a $\mathcal{O}(n^5)$ algorithm for UAV on tree-bonded assemblies when the temperature is fixed to 2, and a $\mathcal{O}(n^5 \log \tau)$ time algorithm when the temperature is part of the input.

1 Introduction

Since the inception of tile self-assembly [28], one of the most important algorithmic questions has been determining if a given tile system uniquely self-assembles into a specific assembly structure. This basic algorithmic question, termed the Unique Assembly Verification (UAV) problem, is fundamental for efficiently checking if a designed tile system acts as intended, and is tantamount to the design of an efficient simulator for a tile self-assembly model. Thus, UAV has been a central question for every self-assembly model.

Although many different self-assembly models have been proposed in order to simulate different laboratory or experimental setups, two premiere models have emerged as the primary foci of study. First, is the seeded Abstract Tile Assembly Model (aTAM) [28], in which singleton tiles attach one by one to a growing seed if sufficient bonding strength exists based on glue types of attaching tiles. This model has had many foundational results in recent years showing the limits related to intrinsic universality and program-size complexity [20, 21]. The second model is the hierarchical Two-Handed Tile Assembly Model (2HAM) [9], where any two producible assemblies may be combined (one in each of two hands) to create a new producible assembly provided there is sufficient bonding strength between the two pieces. Many foundational results that are known for the aTAM are still open for the 2HAM.

The 2HAM has been shown to be more powerful than the aTAM in its ability to build infinite fractal patterns [11, 18], its program-size efficiency for finite shapes [8], and its running-time efficiency for the self-assembly of finite shapes [12]. While the aTAM has a polynomial time solution to the UAV problem [2], allowing for the production of efficient simulators [17, 22, 29], the complexity of UAV in the 2HAM has remained a long-standing open problem in the field. The 2HAM appeared formally in 2013 [9], but was essentially defined in staged self-assembly [13] (2007), and a seeded version of the 2HAM appears as the *multiple tile* model in [4] (2004). UAV has been open for all of these models, and our coNP-complete result for UAV in the 2HAM proves that UAV with a single bin and single stage in the staged model is coNP-complete, and that UAV in the multiple tile model is also coNP-complete with polynomial-sized pieces, thus answering both of these long-standing open questions. See [15, 23, 30, 31] for surveys and applications of self-assembly theory.

Previous work on UAV. A number of results have pushed closer to resolving the complexity of UAV in the 2HAM. One of the first results showed that the simpler problem of determining if a given assembly was at least produced (i.e., built but possibly along with other different assemblies) is polynomial time solvable [16], which serves as a key step in showing that UAV resides within the class coNP. Another result augmented the basic 2HAM model to 3 dimensions and showed coNP-hardness for the 3D 2HAM [9]. A recent result focused on 2D, but allowed the temperature threshold, a parameter that determines how much glue strength is required for assemblies to stick together, to be a variable input to the UAV problem (as opposed to a fixed constant value), and showed coNP-completeness in this scenario [26].

Other approaches considered the allowance of initial assemblies consisting of small prebuilt assemblies, as opposed to only initial singleton tiles, and showed UAV becomes coNP^{NP}-complete with this extension [7]. Alternately, the inclusion of a negative force glue, even without detachments, has also been shown to imply coNP-completeness in the aTAM [10]. Another generalization of the 2HAM allows for up to k hands to create new assemblies, instead of just two, causing the problem to become either coNP-complete or PSPACE-complete, depending on the encoding of the variable k [5]. An even more powerful generalization of the 2HAM is the *staged* model [13], in which multiple distinct stages of self-assembly are considered. Within the staged model, UAV becomes coNP^{NP}-hard after 3 stages, and PSPACE-complete in general [6, 27]. Thus, for nearly every way in which the 2HAM has been extended, a corresponding hardness reduction has been found. Yet, the original question of UAV in the 2HAM has remained open.

Our Contributions. We show that UAV in the 2HAM is coNP-complete within the original model (2-dimensional, constant bounded temperature parameter, singleton tile initial assemblies), thus resolving the long-standing open problem of UAV in the 2HAM. Further, this

Table 1 Known Results for the Unique Assembly Verification Problem in the 2HAM and the results presented in this paper. $|A|$ is the size of the target assembly, τ is the temperature of the system, and $|T|$ is the number of tile types in the system. Under the **Temperature** column, τ indicates that the temperature may be included as part of the input.

Shape	Dimensions	Temperature	Complexity	Reference
General	2	1	$\mathcal{O}(\|A\|\|T\| \log \|T\|)$	[16]
General	3	2	coNP-complete	[9]
General	2	τ	coNP-complete	[26]

Tree	**2**	$\boldsymbol{\tau}$	$\mathcal{O}(\|A\|^5 \log \tau)$	**Thm. 12**

proves that UAV in the staged model with a single bin and stage is coNP-complete, and that UAV in the q-tile/multiple-tile model with polynomial-sized pieces is coNP-complete. We augment this result with a positive result for the special case of tree-shaped assemblies, providing a $\mathcal{O}(|A|^5 \log \tau)$ time solution for UAV in this case (where $|A|$ is the size of the assembly) even if τ is included as part of the input.

Our results are highlighted in Table 1 along with other known results for UAV in the 2HAM. To show coNP-hardness for UAV we construct an explicit polynomial-time reduction from Monotone Planar 3-SAT with Neighboring Variable Pairs (MP-3SAT-NVP). This reduction takes inspiration from the recent break-through proof that MP-3SAT-NVP is NP-hard and its use to prove that the connected-assembly-partitioning problem with unit squares is NP-hard [3]. For our tree UAV algorithm, we utilize a cycle decomposition approach over possible produced assemblies combined with dynamic programming.

Overview. The paper is structured as follows. Section 2 formally defines the model, the UAV problem, important definitions, and some small examples. Section 3 has the reduction proving UAV in the 2HAM is coNP-hard. Due to the numerous intricate details related to the proof, the section is broken up into several subsections explaining different aspects of the reduction. Section 4 then gives the algorithms for solving UAV for tree-bonded assemblies. Section 5 then concludes the paper with a summary and future work.

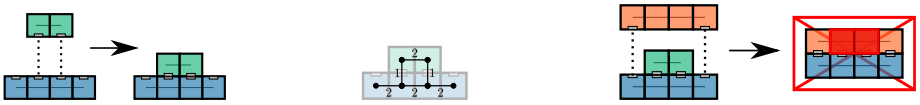
2 Definitions

In this section we overview the basic definitions related to the two-handed self-assembly model and the verification problems under consideration.

Tiles. A *tile* is a non-rotating unit square with each edge labeled with a *glue* from a set Σ. Each pair of glues $g_1, g_2 \in \Sigma$ has a non-negative integer *strength* $\text{str}(g_1, g_2)$.

Configurations. A *configuration* is a partial function $\tilde{A} : \mathbb{Z}^2 \to T$ for some set of tiles T, i.e. an arrangement of tiles on a square grid. For a configuration $\tilde{A}$ and vector $\vec{u} = \langle u_x, u_y \rangle$ with $u_x, u_y \in \mathbb{Z}^2$, $\tilde{A} + \vec{u}$ denotes the configuration $\tilde{A} \circ f$, where $f(x, y) = (x + u_x, y + u_y)$. For two configurations $\tilde{A}$ and $\tilde{B}$, $\tilde{B}$ is a *translation* of $\tilde{A}$, written $\tilde{B} \simeq \tilde{A}$, provided that $\tilde{B} = \tilde{A} + \vec{u}$ for some vector $\vec{u}$.

Bond graphs, and stability. For a given configuration $\tilde{A}$, define the *bond graph* $G_{\tilde{A}}$ to be the weighted grid graph in which each element of $\text{dom}(\tilde{A})$ is a vertex, and the weight of the edge between a pair of tiles is equal to the strength of the coincident glue pair. A



(a) Cooperative Binding. **(b)** Bond Graph. **(c)** Geometric Blocking.

Figure 1 (a) Example of an attachment that takes places using cooperative binding at $\tau = 2$. We denote a glue strength of 1 with a rectangle and a glue of strength 2 with a solid line through the two tiles. Dotted lines between glues indicate that these tiles may attach to each other with the respective strength. Assume assemblies shown are τ-stable unless stated otherwise. (b) The bond graph of the assembly showing that it is τ-stable. (c) These two assemblies are not τ-combinable since this would place two tiles at the same location. We say this is due to geometric blocking.

configuration is said to be *τ-stable* for a positive integer τ if $G_{\tilde{A}}$ is connected and if every edge cut of $G_{\tilde{A}}$ has a weight of at least τ. This means that the sum of the glue strengths along each cut is greater or equal to τ. A small example bond graph is shown in Figure 1b.

Assemblies. For a configuration $\tilde{A}$, the *assembly* of $\tilde{A}$ is the set $A = \{\tilde{B} : \tilde{B} \simeq \tilde{A}\}$. Informally an assembly A is a set containing all translations of a configuration $\tilde{A}$. An assembly A is a *subassembly* of an assembly B, denoted $A \sqsubseteq B$, provided that there exists an $\tilde{A} \in A$ and $\tilde{B} \in B$ such that $\tilde{A} \subseteq \tilde{B}$. We define $|A|$ to be the number of tiles in a configuration of A.

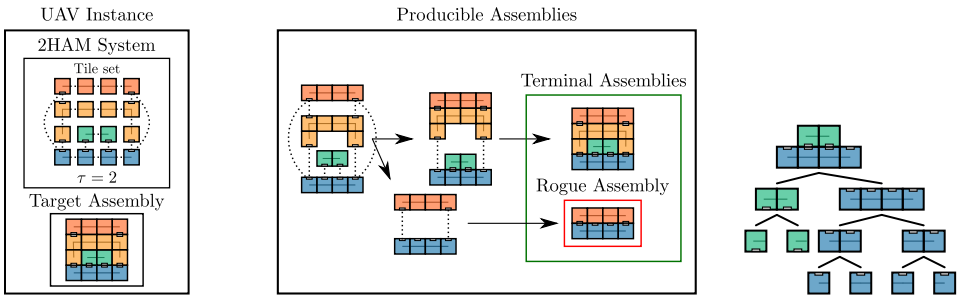
An assembly is *τ-stable* if the configurations it contains are τ-stable. Assemblies A and B are *τ-combinable* into an assembly C if there exist $\tilde{A} \in A$, $\tilde{B} \in B$, and $\tilde{C} \in C$ such that 1) $\tilde{A} \cup \tilde{B} = \tilde{C}$, 2) $\tilde{A} \cap \tilde{B} = \varnothing$, and 3) $\tilde{C}$ is τ-stable. Informally, two assemblies are τ-combinable if there exist two configurations of the assemblies that may be combined resulting in a τ-stable assembly without placing two tiles in the same location.

Two assemblies combining or binding together is called an attachment. An attachment takes place using *cooperative binding* if the two assemblies do not share a τ-strength glue and instead use multiple weaker glues summing to τ. An example of an attachment that takes place using cooperative binding can be seen in Figure 1a. If an attachment cannot take place because the two tiles would be placed in the same position, it is *geometrically blocked*. Two assemblies whose attachment is geometrically blocked is shown in Figure 1c.

Two-handed Assembly. A two-handed assembly system (2HAM) is an ordered tuple $\Gamma = (T, \tau)$ where T is a set of tiles and τ is a positive integer parameter called the *temperature*. For a system Γ, the set of *producible* assemblies P'_Γ is defined recursively as follows: 1) $T \subseteq P'_\Gamma$, and 2) If $A, B \in P'_\Gamma$ are τ-combinable into C, then $C \in P'_\Gamma$. We are naturally extending the concept of τ-combinable to single tiles by considering them assemblies of size 1.

A producible assembly is *terminal* provided it is not τ-combinable with any other producible assembly. Denote the set of all terminal assemblies of a system Γ as P_Γ. Intuitively, P'_Γ represents the set of all possible assemblies that can self-assemble from the initial set T, whereas P_Γ represents only the set of assemblies that cannot grow any further. Figure 2 shows a small 2HAM example.

An *Assembly Tree* for a 2HAM system $\Gamma = (T, \tau)$ is any rooted binary tree whose nodes are elements of P'_Γ, the leaves are single tiles from the set T, and the two children of any non-leaf node are τ-combinable into their parent. An assembly tree with root A is said to be an assembly tree for assembly A. A small example is shown in Figure 2c.



(a) UAV Instance. **(b)** Producible Assemblies. **(c)** Small Assembly Tree.

Figure 2 (a) An example instance of the Unique Assembly verification problem. The input is the 2HAM system (tile set and temperature) and the target assembly. (b) The main producible assemblies of the 2HAM system (for clarity, not all subassemblies are shown). The target assembly is producible and terminal. However, there is also a produced assembly that is a rogue assembly (highlighted) since it not a subassembly of our target and it is terminal. (c) A small example of an assembly tree for one of the producibles.

Unique Assembly. Intuitively, the unique assembly of A means that any produced assembly can continue to grow until it becomes A, thus making A the *uniquely produced* assembly if the process is provided sufficient time to assemble. This means A is the unique terminal assembly and all produced assemblies are subassemblies of A. Formally, we say a system Γ uniquely produces an assembly A if: 1) $P_\Gamma = \{A\}$, and 2) For all $B \in P'_\Gamma$, $|B| \leq |A|$.

▶ **Problem 1** (Unique Assembly Verification)**. Input:** A 2HAM system Γ, an assembly A. **Output:** Does Γ uniquely produce the assembly A?

The Unique Assembly Verification problem (UAV) is the computational problem that asks to verify if an assembly is uniquely produced. A key concept used throughout this paper is a *rogue assembly*, which is any producible assembly that breaks one of the conditions of unique assembly and serves as a proof that the instance of the UAV problem is false.

▶ **Definition 2** (Rogue Assembly)**.** *Given an instance of UAV (Γ, A), an assembly $R \sqsubseteq P'_\Gamma$ is a rogue assembly if $R \neq A$ and R is not a subassembly of A.*

We prove the following Lemma, which is used in the hardness reduction and the positive result. This lemma states that if the instance of UAV is false and all the tiles in Γ are used to build A, then any rogue assembly is made of combinable subassemblies of A.

▶ **Lemma 3.** *For an instance of UAV (Γ, A) that is false the following statement must be true: there exists two producible assemblies B, C such that $B, C \sqsubseteq A$ and B and C are τ-combinable into a rogue assembly R, or there exists a rogue assembly R that is composed of a single tile.*

Proof. First, since the instance of UAV is false, there must exist some rogue assembly R. If R is composed of a single tile, the Lemma is true. If R is not composed of a single tile, we walk through its assembly tree to find the assemblies B and C that are both subassemblies of our target A. Consider an assembly tree of R, Υ_R. Start at the root- if its two children are both subassemblies of A, then the rogue assembly R satisfies the Lemma. If either of the children is also a rogue assembly (not a subassembly of the target), then follow that node and do the same thing. If both are rogue assemblies, it does not matter which we follow.

Since this is an assembly tree all the leaves represent assemblies composed of one tile. Since we know none of the leaf assemblies are rogue assemblies (if it was the lemma would already be satisfied) we know at some point we must reach a node representing a rogue assembly that can be built from two subassemblies of our target A. ◀

3 Unique Assembly Verification Hardness

In this section, we show coNP-hardness of the Unique Assembly Verification problem in the 2HAM with constant temperature by a reduction from Monotone Planar 3-SAT with Neighboring Variable Pairs.

▶ **Problem 4** (Monotone Planar 3-SAT with Neighboring Variable Pairs (MP-3SAT-NVP)). **Input:** Boolean formula $\phi = C_1 \wedge \cdots \wedge C_m$ in 3-CNF form where each clause only contains positive or negated literals from $X = \{x_1, \ldots, x_n\}$. Further, any clause of ϕ with 3 variables is of the form (x_i, x_{i+1}, x_j) or $(\neg x_i \vee \neg x_{i+1} \vee \neg x_j)$, i.e., at least two of the literals are neighbors. **Output:** Does there exist a satisfying assignment to ϕ?

Monotone Planar 3-SAT with Neighboring Variable Pairs was recently shown to be NP-hard in [3]. We assume the instance of the problem is a rectilinear planar embedding where each variable is represented by a unit height rectangle arranged in the *variable row*. Any planar 3SAT formula has a rectilinear encoding [19]. We also assume that every clause is a unit-height rectangle with edges connecting the clauses and the contained variables. The monotone property ensures that each clause contains either only positive or only negative literals. Thus, the clauses may be separated with all positive clauses above the variable row, and all the negative clauses below. The final restriction is neighboring variable pairs, which states that for the three variables in each clause, at least two of the variables are neighbors in the variable row. An example instance is shown in Figure 3a.

3.1 Overview

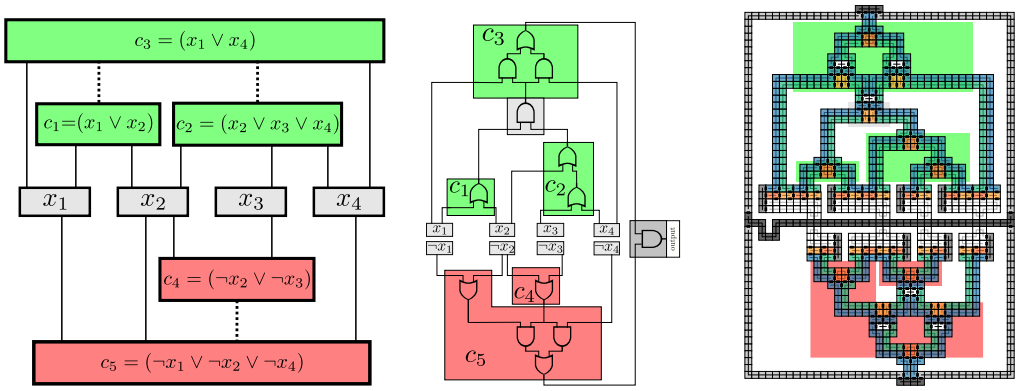
Given an instance of MP-3SAT-NVP ϕ, we build an assembly A and a 2HAM system Γ that uniquely assembles A if and only if ϕ does not have a satisfying assignment. An example instance is shown in Fig. 3a and 3c. Alternatively, Γ produces a rogue assembly if and only if there exists a satisfying assignment to ϕ.

The ability to place all positive clauses above the variables and negative clauses below, along with the neighboring variable pairs, allows the clauses to be built hierarchically from the variables up. These properties allow us to require all nested clauses be evaluated and built before the outer clause is built. Thus, we define *parent* and *child* clauses as well as *root* clauses. In Figure 3a, dotted lines connect child clauses c_1 and c_2 with their parent c_3. The root clauses are c_3 and c_5.[1]

▶ **Definition 5** (Parent/Child/Root Clause). *Given a rectilinear encoding of Monotone Planer 3-SAT, a clause C_p is a* parent *clause of* child *clause C_c, if C_p fully encloses C_c, and any other clause that encloses C_c also encloses C_p. A* root *clause is a clause without a parent.*

Since ϕ is monotone, the positive and negative clauses may be separated across the variable row. The assembly A is also separated by a horizontal bar that splits the assembly in two. This bar partially extends downward to prevent this assembly from attaching to itself. Above this bar is a subassembly that encodes the positive clauses and below the bar is a subassembly that encodes the negative clauses, which we call the positive and negative circuit, respectively.

[1] While a formula may have multiple clauses without a parent, the authors of [3] show that by adding additional variables, an instance may be constructed with only a single root clause. For MP-3SAT-NVP, we need at least two root clauses (one for the positive and negative sides).



(a) MP-3SAT-NVP Instance. **(b)** Target Assembly Circuit. **(c)** UAV Target Assembly.

Figure 3 (a) Example instance of Monotone Rectilinear 3SAT with Neighboring Variable Pairs. Dotted lines are drawn between parent and child clauses. In this example c_3 and c_5 are the positive and negative root clauses respectively. (b) A circuit view of our example instance with gates divided into the clauses they compute. We add AND gates (shown in grey) between child clauses that have the same variables. (c) Target assembly constructed from instance on left. Each tile in the assembly is a unique tile type. Each glue is unique except for the strength 1 glues connecting the horizontal bar and the arms of each circuit. The parts of the assembly that represent each clause are boxed in.

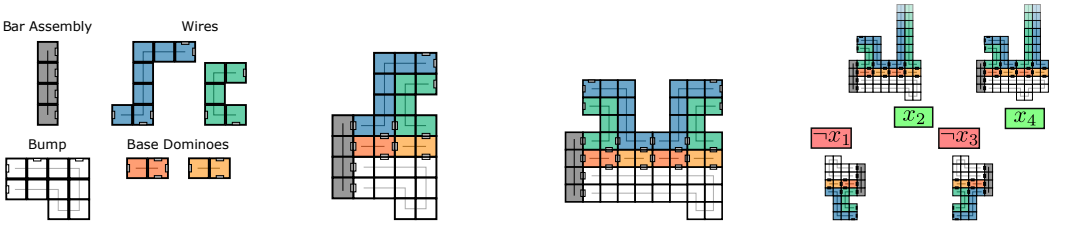
The target assembly is designed so that it must be built from the variables up to the clauses. The clause gadgets can only be built if they are satisfied. Thus, parent clauses require that their variables or child clauses be satisfied to build the gadget. We will ensure this by using AND and OR gadgets between the variable and clause gadgets. We cover the parts of the system and gadgets in the order they must assemble:

- Section 3.2: variable gadgets
- Section 3.3: OR gates and non-parent clause gadgets
- Section 3.4: AND gates and parent clauses
- Section 3.5: the root clauses and the horizontal bar
- Section 3.6: how a rogue assembly may form if and only if ϕ is satisfiable

3.2 Variable Gadget

For each variable gadget we use $(2 + 4d)$ subassemblies (Figure 4a) to build the variable gadget where d is the number of times the variable is used or its outdegree. An example is shown in Figure 4b where $d = 1$ and Figure 4c where $d = 2$. In the figures, the lines are strength-2 glues, and the rectangle glues are all strength-1, thus requiring cooperative binding for the subassemblies to attach in a specific build order. We draw our gadgets separated into subassemblies but we construct our tile set using the single tiles which will self-assemble into these subassemblies. Every variable gadget is built as follows.

- The **Bar Assembly** acts as a backbone (or separator) for the completed circuit subassemblies to connect to each other.
- The **Bump** is the first assembly to attach to the Bar Assembly. The Bump is a height 2 rectangle with an extra domino below it that is used for geometric blocking and encoding the assignment to that variable. The position of this domino is dependent on the position of the variable gadget on the opposite (negative) side.
- The **Base Dominoes** are used as part of the process of duplicating a variable path to multiple clauses. For each clause a variable is in, we use four subassemblies to connect to the next gadget. The first two gadgets are the Base dominoes. Once the Bump attaches



(a) Subassemblies of a variable gadget.

(b) A variable gadget with outdegree 1.

(c) A variable gadget with outdegree 2.

(d) Assignment to the example MP-3SAT-NVP instance.

Figure 4 (a) The smaller assemblies used for building a variable gadget. (b) A variable gadget for a variable that is used in a single clause. (c) A variable gadget with outdegree 2. For each additional output more base dominoes and wires are added. (d) A set of producible subassemblies representing variables that satisfy the example instance. We will walk through how these assemblies grow into a rogue assembly.

to the Bar Assembly, the Base Dominoes can attach cooperatively to both. Once the first Base Domino attaches the next can attach using the glue from the previous domino and the other from the Bump.[2]

- The **Wires** attach the variable gadgets to the clauses, and are the final two subassemblies for connecting to the next gadget. The first wire attaches cooperatively to the Bar Assembly and subsequent ones attach to the previous wire. The wires in our system are all built from two assemblies. When both halves of the wire are connected, the next gadget may attach. We call this a completed wire.

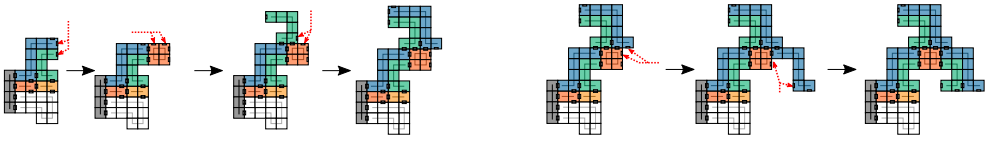
Variable gadgets in the negative circuit are built symmetrically rotated 180 degrees. We adjust the position of dominoes on the Bumps of the gadgets so that variable gadgets on opposite circuits that represent the same variable have their domino in the same column. We may generalize these gadgets to out degree d (the variable appears in d clauses) by increasing the width of the bump, and adding additional dominoes and wires.

3.3 OR Gates and Clause Gadgets

In CNF form, every variable in a clause is separated by a logical OR, thus, as part of our clause gadgets, we create OR gates to bring the variables together to ensure that the clause only forms if there is at least one variable assignment that satisfies the clause.

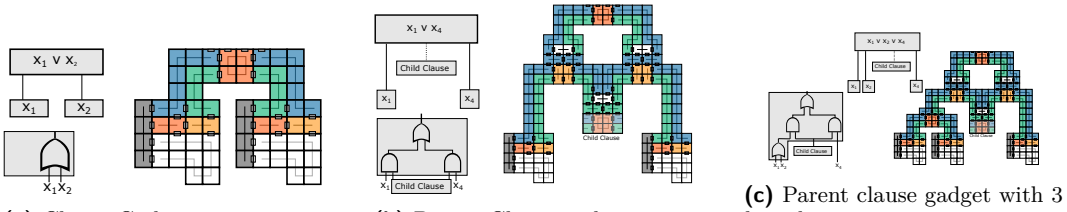
OR Gates. An example of how the OR gate grows off of a variable gadget is shown in Figure 5a. The OR gate consists of a single 2×2 square with strength-1 glues on the west, north, and east facing tile edges. The west and east glues each connect to the wires that input to the gate. The north glues are used cooperatively with glues on the incoming wire gadgets to attach another wire gadget going to the clause gadget. To complete the new wire gadget it must also cooperatively use the other incoming wire. Note the wires from the other input can backfill, but this does not cause an issue as the "backward" growth stops after building the wire. Figure 5b shows an example with only one variable used in the OR gate.

[2] Without these base dominoes, variable gadgets could build without the full Bump due to backfilling or backwards growth. The dominoes ensure this can not happen.



(a) Build OR gate. **(b)** Wire backing filling.

Figure 5 (a) The process of a variable gadget growing the OR gate used for clauses. Glues used for attachment in the next step are denoted by arrows. If one of the variable gadgets is constructed the 2×2 square assembly may attach. The output wires of the gate then attach cooperatively with the wire from the variable assembly and the square. Note that only one of the variable assemblies needs to be constructed for the OR gate to build its output wire. (b) Once the output wires of the OR gate have attached the wire for the other variable may "Backfill" or grow backwards.



(a) Clause Gadget. **(b)** Parent Clause gadget. **(c)** Parent clause gadget with 3 literals.

Figure 6 (a) A clause gadget with 2 neighboring variables. (b) A clause gadget with two variables and a child clause. (c) When a parent clause has 3 literals we know two of them must be neighbors. Using an additional OR gate we may use the same gadget as the clause with 2 literals.

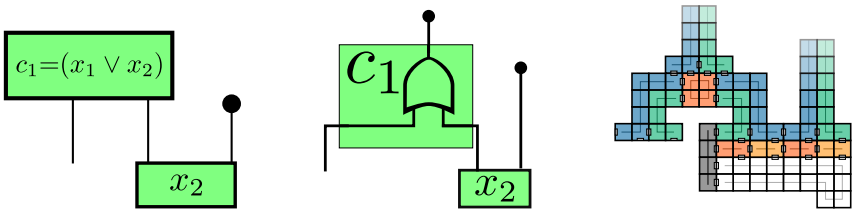
Non-parent Clauses. We first cover clauses without children, or clauses at the bottom of the circuit. The simplest type of this gadget are clauses with only 2 literals as in Figure 6a. This gadget is fairly straightforward to implement as we only need to use a single OR gate. An example of this type of clause is in Figure 7a, and its implementation is in Figure 7c. Note that both variables appear in other clauses so those variable gadgets have additional wires. For non-parent clauses with 3 literals (Figure 10a), we use 2 OR gates (Figure 8c).

3.4 AND Gates and Parent Clauses

Since every clause in CNF form is separated by a logical AND, we create AND gates that compare clauses. Thus, we need to know which clauses are parent clauses since they have child clauses underneath them with wires coming into the gates. We also build a FANOUT gate for connecting clauses.

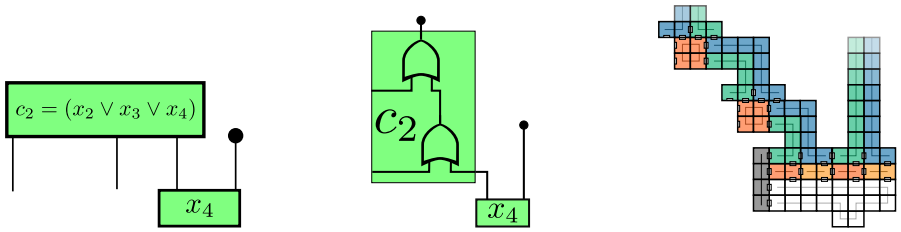
AND Gates. The AND gate uses 2 vertical dominoes that share a single strength-1 glue between them. Figure 9a shows an example AND gate being constructed. Once a wire that inputs to the gate is completed, one of the dominoes can cooperatively attach. The domino has another strength-1 glue on its north side that allows a horizontal domino to cooperatively attach using the glue exposed on the wire.

Using the glues from the newly attached dominoes, the two halves of the gate are able to attach to each other. This allows for the two glues on the horizontal dominoes to be used to cooperatively bind the white center domino. From here, the two halves of the wire that outputs from the AND gate can attach.



(a) Clause c_1. **(b)** Circuit for c_1. **(c)** Gadgets for c_1.

Figure 7 (a) The clause c_1 in Figure 3a is satisfied by $x_2 = 1$. (b) The OR gate grows off of x_2. The other wires on the variable gadget are used to connect to other clause gadgets. (c) The gadget constructed for the clause c_1. Note the other wire from the OR gate has backfilled.



(a) Clause c_2. **(b)** Circuit for c_2. **(c)** Gadgets c_3.

Figure 8 (a) c_2 from our example. This clause has 3 variables and no children. (b) The clause is computed using two OR gates. The gates are able to grow from x_4. (c) x_4 variable gadget allows for the two OR gates to attach.

FANOUT Gates. In order to build the parent clause, we also need a way to "fan-out" and copy the signal from an AND gate to two other gadgets. We do this by adding glues to the north side of the center domino and having two wires grow off of the gadget. This process is shown in Figure 9b.

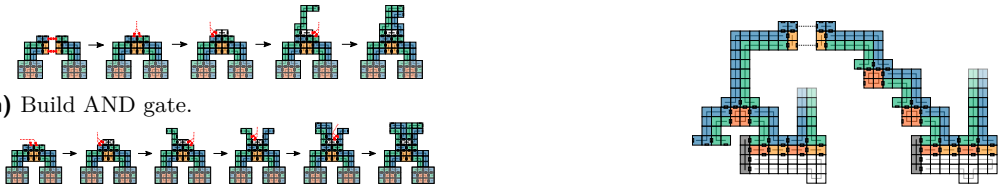
Parent Clauses. Consider a parent clause $C_p = (x_1 \vee x_4)$. Let C_c be the child clause. Since we want this gadget to build only if its own clause and its child are both satisfied, we can view this statement as $(x_1 \vee x_4) \wedge C_c$. However, we can modify the statement to be $(x_1 \wedge C_c) \vee (C_c \wedge X_4)$, which we can build since we have planar circuits. An example of the circuit and gadgets are shown in Figure 6b.

By the neighboring variable pairs restriction, we know that any clause with three variables has at least a pair of them being neighbors. This means that there cannot be any child clauses beneath that neighboring pair, so we may use an OR gate between those two variables and then build the rest of the gadget in the same way as the two literal version (Figure 6c).

In our example instance, the root clause of the positive circuit has two children. For these cases we may use the AND gadget to verify that both child clauses have been satisfied before allowing the parent clause to build. The root clause of the negative circuit in our example instance (Figure 11a) has three literals. The constructed gadget can be seen in Figure 11a.

3.5 Root Clauses and Horizontal Bar

Root Clauses and Arms. The root clause is the outermost clause on either side of the variables. Although it functions similar to the other clauses, instead of outputting a wire, a horizontal 4×1 rectangle can attach after it finishes assembling. The arms may then cooperatively bind to the rectangle and the wires of the root clause forming the top of the

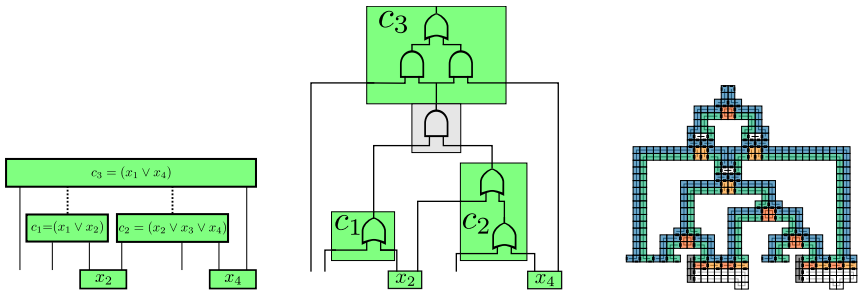


(a) Build AND gate.

(b) Build FANOUT.

(c) Attachment of an AND gate.

Figure 9 (a) The process of an AND gadget assembling. The output wires can only grow from the combined halves of the AND gate. (b) By modifying the center domino, two wires may be output from a single AND gate, which works as a FANOUT. (c) The two clauses c_1 and c_2 both have the same parent clause so they are joined by an AND gate. Once the dominoes attach to the output wire of the clauses the two assemblies may attach to each other.



(a) Clause c_3.

(b) Circuit for c_3.

(c) Gadget for c_3.

Figure 10 (a) The root clause of the example instance. This clause has two literals and two children. (b) Since the AND gate has built and x_4 satisfies c_3 the clause may grow. (c) The two child clause's output are connected by an AND gate and then used as the middle input to the gadget.

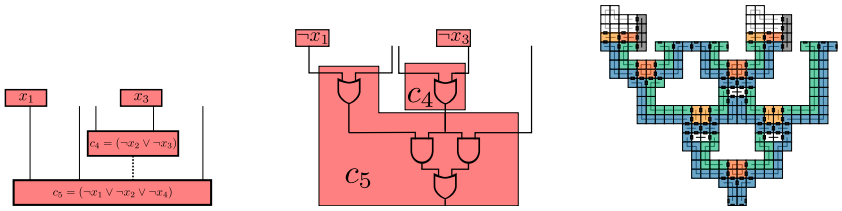
circuit. The glues on the ends of these arms allow for the circuit to attach to the horizontal bar. A high-level view of the root clauses and arms attached is shown in Figure 12a as well as a detail of the assembly process of the root clause in Figure 12b.

Horizontal Bar. The horizontal bar (Figure 12a) is a width-1 assembly that extends the width of both circuits with strength-1 glues on the north and south side of the outer tiles. Since the arms must also be able to attach to each other to form a rogue assembly the glues on the ends of the horizontal bar must be the same. In order to prevent the horizontal bar from attaching to another instance of itself, we extend the bar partially downward so it will geometrically block copies from attaching.

3.6 Rogue Assemblies

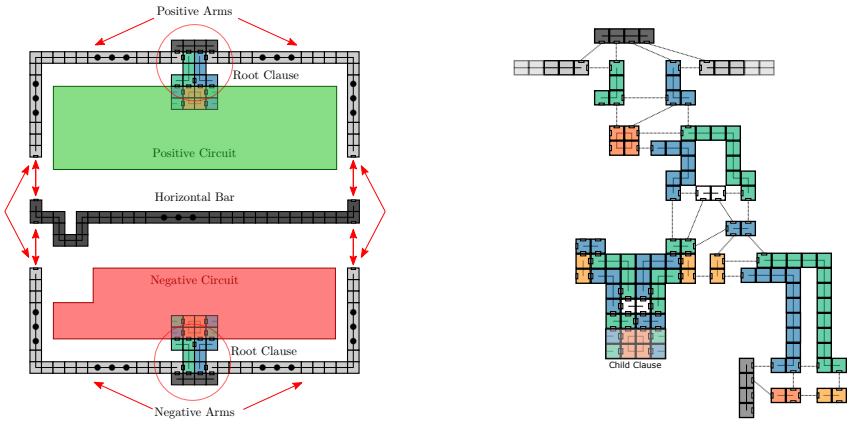
For the construction of the target assembly, each piece is built from the variables up to the root clause. However, the nondeterministic build order means that not all parts of each circuit need to be built in order for the root clause to be satisfied. For instance, if one of the variables in a clause attaches, the OR gates will still allow the wires to attach. Thus, using a variable constitutes setting it to true (and in the negative circuit using a variable is setting the negation to true).

With root clauses satisfied and the arms attaching, a rogue assembly may occur as shown in Figure 13c. The corresponding circuit is shown in Figure 13b. This can occur because the arms can attach to each other without the horizontal bar. Normally, the variable gadgets



(a) Clause c_5. **(b)** Circuit for c_5. **(c)** Gadget for c_5.

Figure 11 (a) In the example instance the negative circuit has c_5 which is a parent clause with 3 literals. (b) The negative circuit draw with gates. The variables x_1 and x_3 being false satisfies all the clauses. (c) The variable assemblies we selected at the beginning also grow into a circuit with the root clause built.



(a) Horizontal Bar and Completed Circuits. **(b)** Glues on root clause and variable gadgets.

Figure 12 (a) The root clauses and arms joining the positive and negative assemblies with the horizontal bar. The root clause allows a short wire to attach where the arms can then attach. Each arm has a strength-1 glue at the end. The horizontal bar separates the positive circuit from the negative circuit. The small bump is so the bar can not attach to other horizontal bars. (b) Each subassembly of the root clause cannot attach to each other without being satisfied from the child clauses since each subassembly only shares a strength-1 glue with adjacent assemblies.

would overlap and prevent this attachment if both the positive and the negative circuit used the same variable (which is setting a variable to both true and false). Thus, the positive and negative side each have their own set of variables that make all clauses on their respective sides true. This rogue assembly can only happen if there is a subset for each side that allows all clauses to be true, and thus satisfies the original MP-3SAT-NVP formula.

For an MP-3SAT-NVP instance ϕ and an assignment X_s to the variables in X, let A_p and A_n be the positive and negative circuit assemblies, respectively, created from ϕ. We say an assembly $A'_p \sqsubseteq A_p$ represents the assignment X_s if it has attached variable gadgets for the variables in X_s that equal 1, and has built its root clause. For negated circuits, it must have variable gadgets attached for variables set to 0 in X_s.

▶ **Lemma 6.** *For a rectilinear encoding of Monotone Planar 3SAT ϕ with neighboring variable pairs and 2HAM system Γ_ϕ as described above, there exist two producible assemblies $A'_p \sqsubseteq A_p$ and $A'_n \sqsubseteq A_n$ that both represent the same assignment X_s to the variables X, if and only if X_s satisfies ϕ.*

Proof. If there exists a satisfying assignment X_s to X, we may build A'_p by taking the variable gadgets for variables assigned to 1 and grow the circuit off of them. Since we know all the clauses are satisfied, each clause gadget (including the root clause) may grow resulting in an assembly A'_p that represents X_s. By the same argument we know A'_n is producible since X_s satisfies ϕ, which includes the negated clauses.

We prove these assemblies are producible only if X_s satisfies ϕ via contradiction. Assume X_s does not satisfy ϕ, but both assemblies A'_p and A'_n are producible. Since X_s does not satisfy ϕ, there must exist at least one unsatisfied clause c_i. W.L.O.G., assume c_i is a positive clause. We show the assembly A'_p cannot be produced.

If c_i is the root clause, assume all of the children of c_i are satisfied. The center input of the clause is a producible subassembly of A'_p since variable gadgets are allowed that satisfy the clauses below it. We can see in Figure 12b the other producible subassemblies of the gadgets only have a strength-1 glue between them. This means none of the subassemblies are able to attach to each other on their own. In order for the arms to attach to the output wire of the root clause, at least one of the AND gates must be fully constructed. The AND gate cannot assemble unless both halves of the gate have been constructed. The middle input is built, but the other half of the AND gadget must grow off a completed wire from the variable gadget. However, since c_i is not satisfied the variables gadgets which satisfy the formula have not attached so the assembly A'_p cannot build the clause gadget.

If c_i is another parent clause that is not the root. Let the clause c_j be the parent clause of c_i. If the clause gadget for c_i is not constructed then the gadget for c_j is not buildable. Since the gadgets used are the same as the root clause, the output wires of the clause gadget for c_i cannot be built without a variable gadget which satisfies the formula. The middle input of clause gadget representing c_j will not be buildable since this would be the output wire of c_i. The middle input goes to two AND gates that cannot construct unless both wires have been built. Thus, the output wire of c_j cannot be built without its children clauses satisfying it. In the case c_j has multiple children, the output wires of all its children are joined by AND gates that will not construct without both inputs.

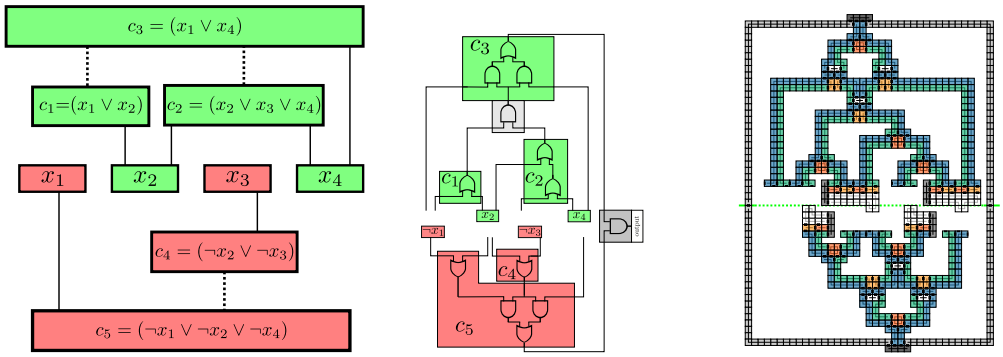
Finally, consider the case where c_i is a clause without children. In order for the clause's output wire to complete, it must be attached to an OR gadget and the outer wire of the variable gadget. The OR gadget may only attach to a completed wire from a variable gadget (or another OR). The variable gadget cannot be completed without placing the bump, so we cannot have built the outwire of c_i. By the same argument as the previous case, this clause not being built results in its parent not being built. If c_i is not satisfied, the clause gadget for c_i cannot be constructed, which means the assembly A'_p is not producible. ◀

▶ **Theorem 7.** *The Unique Assembly Verification problem in the 2HAM is coNP-Complete with $\tau = 2$.*

Proof. Given an instance of a rectilinear encoding of Monotone Planar 3SAT with neighboring variable pairs ϕ, we provide an explicit polynomial time reduction by creating a 2HAM system $\Gamma = (T, 2)$ and an assembly A such that Γ uniquely produces A if and only if there does not exist a satisfying assignment to ϕ. We create the assembly A by taking the rectilinear encoding of ϕ, arranging the rectangles on a grid graph, and replacing the rectangles with the given variable and clause gadgets. We also add the arms and horizontal bar.

Assume there exists a satisfying assignment X_s to the variables X, for ϕ. We know by Lemma 6, there exist two producible assemblies A'_p and A'_n that both contain the arms and have complementary bump positions[3]. These two assemblies can cooperatively bind to one another using the two glues on their arms, and thus produce a rogue assembly as in Figure 13c. This means a satisfying assignment to ϕ implies Γ does not uniquely construct A.

[3] Having complimentary bump positions is equivalent to both representing the same assignment.



(a) Satisfying Assignment. **(b)** Rogue Assembly Circuit. **(c)** Rogue Assembly.

Figure 13 (a) There exists a satisfying assignment for the example instance with green blocks representing variables which equal 1 and red blocks representing 0. (b) Rogue assembly drawn as a circuit with selected variables. (c) The 2HAM system will produce a Rogue Assembly from the two circuit assemblies which represent the satisfying assignment.

(a) Tree-bonded and Shaped. **(b)** Tree-bonded. **(c)** Not Tree-bonded.

Figure 14 (a) Both the shape and bond graph of this assembly are trees. (b) Even though the shape of this assembly is a square, its bond graph is acyclic, and thus this assembly is tree-bonded. (c) This assembly is not tree-bonded due to the cycle in its bond graph.

Now assume Γ does not uniquely produce A, so there exists some rogue assembly B. The only repeated glues in the tile set of Γ are the exposed glues on the arms. Any rogue assembly must use these two glues to assemble, and they must be assembled from two subassemblies of the target by Lemma 3. Let B be producible by combining two assemblies b and b'. Since both b and b' are producible assemblies with both their arms, and they can attach to each other, they are not geometrically blocked. This implies they must represent the same assignment and by Lemma 6, this can only be true if the assignment satisfies ϕ. By viewing which variable gadgets are included in the two assemblies, we can identify the satisfying assignment to ϕ. Thus, Γ will uniquely produce A if and only if there does not exist a satisfying assignment to ϕ. ◀

4 Verification of Tree-Bonded Assemblies

In this section, we investigate the problem of Unique Assembly Verification with the promise that the target assembly A is *tree-bonded*, meaning the bond graph of the target assembly forms a tree. Figures 14a and 14b show examples of tree-bonded assemblies. Figure 14c shows an assembly whose bond graph contains a cycle and thus is not a tree-bonded assembly. We first present a $\mathcal{O}(|A|^5)$ algorithm for temperature 2 systems, and then extend this method to provide a $\mathcal{O}(|A|^5 \log \tau)$ time dynamic programming algorithm for the case where the temperature τ of the system can be passed as a parameter. Before describing the algorithms, we first introduce some required definitions and the problem formulations.

Tree-Bonded Assemblies. An assembly A is a *tree-bonded assembly* if and only if the induced bond graph $\mathcal{G}_A$ is acyclic.

Binding Sites. For two configurations C_1 and C_2, we say a *binding site* $\mathcal{B}$ is a pair of points (p_a, p_b), such that their distance is $||p_a - p_b||_2 = 1$, and the tiles $C_1(p_a)$ and $C_2(p_b)$ have nonzero glue strength between each other. The set of binding sites for two configurations is the set of pairs of points that meet this requirement. We also define an *inner binding site*. For two configurations, C_1 and C_2, and a pair of binding sites $a = (a_1, a_2'), b = (b_1, b_2')$, let $I(a, b)$ be the set of binding sites that occur on the inside of the loop formed by a, b (inner binding sites). An example of the area enclosed by a loop is seen in Figure 15c.

Simple Loops. For two configurations, C_1 and C_2, and a pair of binding sites $a = (a_1, a_2'), b = (b_1, b_2')$, we say the loop formed by a, b is a *simple loop* if $|I(a, b)| = 0$.

Origin Configuration In discussing different configurations and assemblies, it is useful to anchor a configuration to a fixed point. For an assembly A, the *origin configuration* A_0 is the translation of $A's$ configuration such that the bottom left vertex of the bounding box of elements in $dom(A_0)$ is at the origin $(0, 0)$.

▶ **Problem 8** (Tree-UAV). **Input:** A 2HAM system Γ and a tree-bonded assembly A. **Output:** Does Γ uniquely produce the assembly A?

4.1 High-level Overview

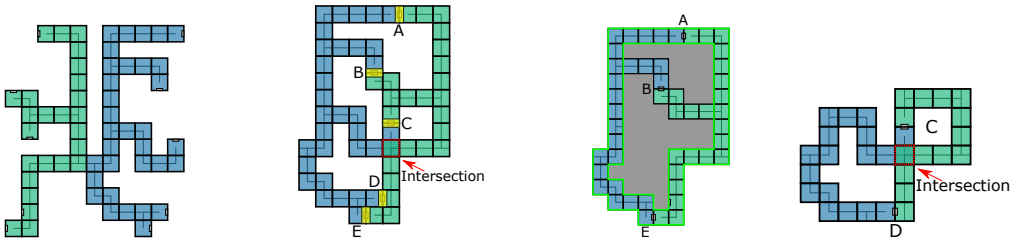
The high-level goal of this algorithm is to find a rogue assembly that acts as a witness that the instance of UAV is false. We note that a given instance, $P = (\Gamma, A)$, of Temp2-Tree-UAV, where $\Gamma = (T, 2)$, can be broken down into three possible cases. An example tree-bonded assembly is shown in Figure 15a.

1. The instance P is false, and Γ produces a tree-bonded rogue assembly.
2. The instance P is false, and the only rogue assemblies producible in Γ are non tree-bonded.
3. The instance P is true.

At a high level, the algorithm checks if either Case 1 or Case 2 as true, and f so, the algorithm rejects, otherwise it accepts. Case 1 can be checked efficiently by modifying Γ to function as a noncooperative system Γ' and utilizing the algorithm for temperature-1 UAV provided in [16]. To check the second case, Lemma 3 states that if the instance is false, it suffices to check pairs of subassemblies of the target assembly A in order to find a witness rogue assembly. Thus, we take two copies of the target assembly and attempt to find possible ways they may bond, even if the resulting assembly places two tiles at the same position. We call the pairs of tiles that contribute glue strength *binding sites* Tiles that are in the same position are called *intersections*. An example of both may be seen in Figure 15b.

We first analyze the case of temperature-2 systems where only two binding sites that do not intersect are needed. We then generalize this algorithm by using dynamic programming to find the set of binding sites to maximize the binding strength between the assemblies without any intersections.

▶ **Problem 9** (Temp2-Tree-UAV). **Input:** A $\tau = 2$ 2HAM system Γ and a tree-bonded assembly A. **Output:** Does Γ unique produce the assembly A?



(a) Tree-bonded Assembly. **(b)** Overlap Subassemblies. **(c)** Outer Loop. **(d)** Intersection loop.

Figure 15 (a) An example tree-bonded target assembly. (b) One possible overlap configuration formed by two subassemblies with 5 binding sites that are highlighted. (c) The loop formed by binding sites A and E is outlined in green. Any binding site that occurs in the grey shaded area, such as B, is in the set of inner binding sites for (A, E). (d) The loop formed using binding sites (C, D) intersects itself and cannot be used.

Algorithm 1 NonCoop-UAV(Γ, A). The runtime of Temp1-UAV is $\mathcal{O}(|A||T| \log |T|)$ [16].

Data: 2HAM System $\Gamma = (T, \tau)$, an assembly A
Result: Does Γ uniquely assembly A if it can only utilize strength $\geq \tau$ glues?
Modify T to create T' by removing all glues of strength less than τ, and setting the strength of all glues of strength $\geq \tau$ to 1;
if *Temp1-UAV*$(\Gamma' = (T', \tau = 1), A)$ **then** accept;
else reject;

4.2 Tree-Bonded Rogue Assemblies

The following algorithm checks if a system uniquely assembles a given shape provided the system is restricted to behaving in a noncooperative manner. This means that two assemblies can only attach if they share one or more strength-τ glues between them. This system functions equivalently to a temperature-1 system where all glues less than strength-τ are removed and all glues greater than strength-τ are set to strength-1. We modify the system in this way and then use the known polynomial time algorithm for temperature-1 UAV [16].

▶ **Lemma 10.** *For any 2HAM system $\Gamma = (\Sigma, \tau)$ and tree-bonded assembly A, if NonCoop-UAV(Γ, A) (Algorithm 1) is true, and Γ does not uniquely assemble A, then there exists assemblies B, B_1, B_2, s.t. $B \not\sqsubseteq A$, $B_1, B_2 \sqsubseteq A$, B_1 and B_2 combine to form B by utilizing cooperative binding.*

Proof. Since NonCoop-UAV(Γ, A) is true, but Γ does not uniquely assemble A, there must exist a rogue assembly $B' \not\sqsubseteq A$ since any subassembly of A would be tree-bonded. Consider an assembly tree Υ'_B for B'. Since NonCoop-UAV(Γ, A) is true, the singleton tile leaves of Υ'_B must be subassemblies of A. We will show there exists a node $B \in \Upsilon'_B$, with children B_1 and B_2, respectively, such that $B' \not\sqsubseteq A$, and $B_1, B_2 \sqsubseteq A$.

Let the root node of the tree Υ_B be the candidate node B, and let assemblies B_1 and B_2 be the two children of B. If B_1 and B_2 are both subassemblies of A, then the conditions are met. Otherwise, W.L.O.G. assume $B_1 \not\sqsubseteq A$. Now set the candidate node B to B_1 and repeat. Since all leaves of Υ_B represent subassemblies of A, there must be a point in which the candidate B node is some assembly $B \not\sqsubseteq A$, and its children are assemblies $B_1, B_2 \sqsubseteq A$. ◀

Algorithm 2 Algorithm to solve Temp2-Tree-UAV in $\mathcal{O}(|A|^5)$ time.

Data: 2HAM System $\Gamma = (\Sigma, 2)$, Tree-Bonded Assembly A of height h and width w
Result: Does Γ uniquely produce A?
if *NonCoop-UAV*(Γ, A) *rejects* **then** reject;
Let A_0 be the origin configuration of assembly A;
for $i \leftarrow -w$ **to** w **do**
  for $j \leftarrow -h$ **to** h **do**
    $A' \leftarrow A_0 + \langle i, j \rangle$;
    Let $\mathcal{B}$ be the set of binding sites between A_0 and A';
    for *each pair of binding sites* $a, b \in \mathcal{B}$ **do**
      if *The loop formed using* a, b *does not intersect itself* **then** reject;
accept;

4.3 Temperature-2

With respect to the given instance of Temp2-Tree-UAV P, if P is false, and the algorithm for NonCoop-UAV(Γ, A) returns "accept", then Lemma 10 implies there exist two subassemblies of the target, B_1 and B_2, that attach to each other using cooperative binding.

To find these two subassemblies, we take two "copies" of the target assembly and find all $|A|^2$ possible ways to combine them- even if it results in intersections. If any combination results in at least two binding sites, we attempt to find 2-combinable subassemblies. Since these subassemblies are also tree-bonded, there only exists one path between each pair of tiles- including the binding sites. So for each pair of binding sites, we take the loop formed by the two binding sites and check if it intersects itself. An example of a loop that intersects itself is shown in Figure 15d. If there ever exists a pair of binding sites whose paths do not intersect, then those two subassemblies will form a rogue assembly and we reject.

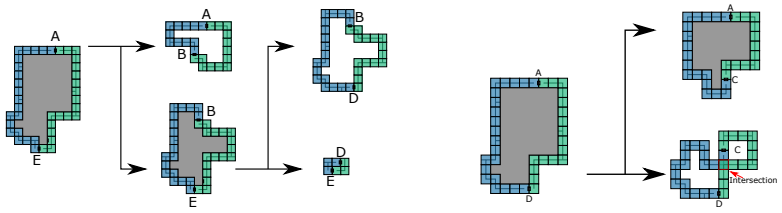
▶ **Theorem 11.** *There is a $\mathcal{O}(|A|^5)$ time algorithm that decides Temp2-Tree-UAV.*

Due to space constraints, the analysis of Alg. 2 and proof of Thm. 11 have been omitted.

4.4 Variable Temperature

We now present an algorithm for Tree-UAV as a generalization of the previous problem where the temperature of the system τ is given as input. The algorithm is similar except it does not suffice to only find a single loop since the temperature requirement attachment may be greater than 2. We must find multiple loops between binding sites that do not intersect. Once we find a way to combine the assemblies, we view binding sites and loops hierarchically using inner binding sites. An example of an inner binding site is in Figure 15c. We recursively calculate the max binding strength when taking each pair of binding sites as the outer loop. After calling NonCoop-UAV(Γ, A), we check each possible way to attach A to itself. For each of these ways, we build a $b \times b$ table where b is the total number of induced binding sites. For each pair of binding sites, we calculate the maximum value recursively augmented with the table. Thus, we only compute the maximum value once for each loop.

First, if the created loop intersects itself, we cannot use it, so the value is set to -1. Next, we check if the binding sites form a simple loop with no inner binding sites. Here, the max value is the sum of the glue strengths between the binding sites. For loops with inner binding sites, we do a *loop decomposition*, which is the process of breaking a loop into two smaller loops along one of the inner binding sites. An example is shown in Figure 16a.



(a) Loop Decomposition. **(b)** Invalid Loop Decomposition.

Figure 16 (a) One possible way to decompose loops into simple loops based on inner binding sites. (b) Decomposing the loop (A, D) along binding site C results in the loop (C, D) which intersects itself. This means we cannot decompose the loop (A, D) along C.

Algorithm 3 Algorithm to solve Tree-UAV in $\mathcal{O}(|A|^5 \log \tau)$ time.

Data: 2HAM System $\Gamma = (\Sigma, \tau)$, Tree-Bonded Assembly A of height h and width w
Result: Does Γ uniquely produce A?
if *NonCoop-UAV*(Γ, A) *rejects* **then** reject;
Let A_0 be the origin configuration of assembly A;
for $x \leftarrow -w$ **to** w **do**
  for $y \leftarrow -h$ **to** h **do**
    $A' \leftarrow A_0 + \langle x, y \rangle$;
    Let $\mathcal{B}$ be the set of binding sites between A_0 and A' and let $b = |\mathcal{B}|$;
    Create a $b \times b$ table $T_{\mathcal{B}}$ indexed by the elements of $\mathcal{B}$ with all cells empty;
    for *each pair of binding sites* $b_1, b_2 \in \mathcal{B}$ **do**
      if $maxStr(C = (A_0 \bigcup A'), T_{\mathcal{B}}, b_1, b_2) \geq \tau$ **then** reject;
accept;

To find the max binding strength of the outer loop, we break the loop up along each inner binding site and recursively get the max strength of the two resulting loops (subtracted by the glue strength of the inner binding site since it would be counted twice). If either of the smaller loops intersects itself, it returns -1 and we know not to use that inner binding site. The max binding strength of the outer loop is then the maximum of these computed values over all choices of inner binding sites. The recursive checks are implemented with a dynamic programming/memoization table to eliminate repeated recursive calls.

▶ **Theorem 12.** *There is a* $\mathcal{O}(|A|^5 \log \tau)$ *time algorithm that decides* Tree-UAV.

Due to space constraints, the analysis of Alg. 3 and proof of Thm. 12 have been omitted.

5 Conclusion

In this paper, we have addressed the long-standing open problem of the complexity of verifying unique assembly within the 2-handed tile self-assembly model and shown that the problem is coNP-complete even at temperature $\tau = 2$ and in two dimensions. These are the smallest possible values for which this problem can be hard, as both temperature-1 self-assembly and 1-dimensional self-assembly have established polynomial time verification solutions. Given this hardness, we explored a natural scenario where this problem might be more tractable, and showed that restricting the input assemblies to tree-bonded assemblies allows for an efficient $\mathcal{O}(|A|^5 \log \tau)$-time unique assembly verification algorithm.

Algorithm 4 $maxStr(C, T_{\mathcal{B}}, b_1, b_2)$. The subroutine that calculates the max strength when using two binding sites as the outer loop. The method $glueStr(b)$ takes in a binding site and returns the strength of the glue connecting the two tiles.

Data: Union of two assemblies C, Table T_B, and Binding sites b_1, b_2
Result: The maximum binding strength used to build a stable subassembly of C.
if $T_{\mathcal{B}}(b_1, b_2)$ *is empty* **then**
  if *The loop formed by* b_1, b_2 *intersects itself* **then** return -1;
  if $|I(b_1, b_2)| = 0$ **then** return $glueStr(b_1) + glueStr(b_2)$;
  Let $T_B(b_1, b_2) = 0$;
  for $b_i \in I(b_1, b_2)$ **do**
    if $maxStr(b_1, b_i) \neq -1$ *AND* $maxStr(b_i, b_2) \neq -1$) **then**
      $s \leftarrow maxStr(b_1, b_i) + maxStr(b_i, b_2) - glueStr(b_i)$;
      if $s > T_{\mathcal{B}}(b_1, b_2)$ **then** $T_{\mathcal{B}}(b_1, b_2) \leftarrow s$;
return $T_{\mathcal{B}}(b_1, b_2)$;

Future Work. While we have resolved the general question of unique assembly verification in the 2HAM, as well as addressed a natural restricted case of tree-bonded assemblies, there remain important directions for future research.

- Our hardness reduction utilizes a tile set that is roughly the size of the input assembly. All hardness results in the literature for the 2-handed self-assembly model have this property. Yet, the computational power of self-assembly allows for the assembly of large assemblies with small tile sets, as seen in the efficient self-assembly of squares [1, 24], or the implementation of "Busy Beaver" Turing machines [24]. How hard is UAV for large assemblies with substantially smaller tile sets. Does the hardness scale with assembly size or tile set size? Is there some form of fixed-parameter tractability for the UAV problem?
- We proved that UAV for the multiple tile (or q-tile) model is coNP-complete with polynomial-sized assemblies attaching. Is UAV polynomial in the multiple tile model and the 2HAM in the case where every producible assembly, except the one that grows into the terminal assembly, is bounded by a constant?
- A related question in the aTAM and the 2HAM is the number of two-handed operations actually required to make the problem hard. If all subassemblies can only grow by single tile attachments, how many two-handed operations to combine those subassemblies are needed for UAV to remain hard? The ability to more efficiently construct shapes by assembling parts separately has been studied in other models as well [25].
- Another direction initiated by our efficient tree assembly algorithm is the consideration of other natural restricted classes of the UAV problem. For example, how does UAV scale with respect to the genus of an assembly's connectivity graph? A related question involves verification for *fully connected* assemblies, a previously-studied concept [14] in which assemblies include positive bonds between all neighboring tiles.

Abstract

In this paper, we consider reachability oracles and reachability preservers for directed graphs/networks prone to edge/node failures. Let $G = (V, E)$ be a directed graph on n-nodes, and $\mathcal{P} \subseteq V \times V$ be a set of vertex pairs in G. We present the first non-trivial constructions of single and dual fault-tolerant pairwise reachability oracle with constant query time. Furthermore, we provide extremal bounds for sparse fault-tolerant reachability preservers, resilient to two or more failures. Prior to this work, such oracles and reachability preservers were widely studied for the special scenario of single-source and all-pairs settings. However, for the scenario of arbitrary pairs, no prior (non-trivial) results were known for dual (or more) failures, except those implied from the single-source setting. One of the main questions is whether it is possible to beat the $O(n|\mathcal{P}|)$ size bound (derived from the single-source setting) for reachability oracle and preserver for dual failures (or $O(2^k n|\mathcal{P}|)$ bound for k failures). We answer this question affirmatively. Below we summarize our contributions.

- For an n-vertex directed graph $G = (V, E)$ and $\mathcal{P} \subseteq V \times V$, we present a construction of $O(n\sqrt{|\mathcal{P}|})$ sized dual fault-tolerant pairwise reachability oracle with constant query time. We further provide a matching (up to the word size) lower bound of $\Omega(n\sqrt{|\mathcal{P}|})$ on the size (in bits) of the oracle for the dual fault setting, thereby proving that our oracle is (near-)optimal.
- Next, we provide a construction of $O(n + \min\{|\mathcal{P}|\sqrt{n},\ n\sqrt{|\mathcal{P}|}\})$ sized oracle with $O(1)$ query time, resilient to single node/edge failure. In particular, for $|\mathcal{P}|$ bounded by $O(\sqrt{n})$ this yields an oracle of just $O(n)$ size. We complement the upper bound with a lower bound of $\Omega(n^{2/3}|\mathcal{P}|^{1/2})$ (in bits), refuting the possibility of a linear-sized oracle for $\mathcal{P}$ of size $\omega(n^{2/3})$.
- We also present a construction of $O(n^{4/3}|\mathcal{P}|^{1/3})$ sized pairwise reachability preservers resilient to dual edge/vertex failures. Previously, such preservers were known to exist only under single failure and had $O(n + \min\{|\mathcal{P}|\sqrt{n},\ n\sqrt{|\mathcal{P}|}\})$ size [Chakraborty and Choudhary, ICALP'20]. We also show a lower bound of $\Omega(n\sqrt{|\mathcal{P}|})$ edges on the size of dual fault-tolerant reachability preservers, thereby providing a sharp gap between single and dual fault-tolerant reachability preservers for $|\mathcal{P}| = o(n)$.
- Finally, we provide a generic pairwise reachability preserver construction that provides a $o(2^k n|\mathcal{P}|)$ sized subgraph resilient to k failures, for any $k \geq 1$. Before this work, we only knew of an $O(2^k n|\mathcal{P}|)$ bound implied from the single-source setting [Baswana, Choudhary, and Roditty, STOC'16].

1 Introduction

Networks in most real-life applications are prone to failures. These failures, though unpredictable, are transient due to some simultaneous repair process that is undertaken in the application. This motivates the research on designing fault-tolerant structures for various graph problems. In the past few years, a lot of work has been done in designing fault-tolerant structures for various graph problems like connectivity [34, 32, 4, 26, 11], finding shortest paths [20], graph-structures preserving approximate distances [30, 19, 15, 22, 5, 6, 10, 3] etc. Reachability is one of the fundamental graph properties which is as ubiquitous as graphs themselves. In this paper, we study pairwise reachability structures under edge/node failures. In particular, given any set $\mathcal{P}$ of node-pairs, we provide design of graph sparsification structures, and sensitivity oracles for the reachability problem. We present our results in terms of edge failures. However, all our upper bound results also hold for node failures.[1]

1.1 Sensitivity Oracle

In the Sensitivity oracle, the goal is to design a data structure for a network prone to edge/vertex failures to efficiently answer queries pertaining to the graph structure (e.g., connectivity, reachability, distance, etc.). We first formally define the notion of Fault-Tolerant Reachability Oracle (FTRO).

▶ **Definition 1** (FTRO). *Let $\mathcal{P} \in V \times V$ be any set of pairs of vertices. For a graph G, a data structure $DS(G)$ is said to be a* k-Fault-Tolerant Reachability Oracle *of G for $\mathcal{P}$, denoted as k-FTRO$(G, \mathcal{P})$, if given a query with any pair $(s, t) \in \mathcal{P}$ and any subset $F \subseteq E$ of at most k edges, $DS(G)$ efficiently decides whether or not t is reachable from s in $G \setminus F$.*

To date, no non-trivial bounds were known for FT-pairwise reachability oracle. The only known results are for single-source setting (i.e., $\mathcal{P} = \{s\} \times V$) and all-pairs setting $\mathcal{P} = V \times V$.

For single-source setting, i.e., when $\mathcal{P} = \{s\} \times V$ for some source vertex $s \in V$, under (single and) dual failure, we have an $O(n)$ size oracle with $O(1)$ query time due to [29, 17]. As an immediate corollary, for arbitrary $\mathcal{P}$ pairs, we get an $O(n|\mathcal{P}|)$-sized single/dual failure pairwise FTRO with constant query time. The bound is extremely bad for a large-sized set $\mathcal{P}$. By storing a subgraph that preserves pairwise reachability (to be discussed in detail in Section 1.2) under single failure due to [11], we get an 1-FTRO of size $O(n + \min\{\sqrt{n}|\mathcal{P}|, n\sqrt{|\mathcal{P}|}\})$ but with $O(n)$ query time. The $O(n)$ query time is due to the fresh reachability computation over

[1] In the input graph, each vertex v can be replaced by an edge (v_{in}, v_{out}), where all the incoming and outgoing edges of v are directed into v_{in} and directed out of v_{out} respectively. Thus the failure of vertex v is equivalent to failure of edge (v_{in}, v_{out}).

the stored subgraph on each query, which is entirely undesirable in terms of the efficiency of a data structure. For the special setting of all-pairs, i.e., $\mathcal{P} = V \times V$, Brand and Saranurak [37] provided a $O(n^2)$ sized k-FTRO that has $O(k^\omega)$ query time, where ω is the constant of matrix-multiplication.

One of the main questions is the following: Does there exist a pairwise reachability oracle of size $o(n|\mathcal{P}|)$ and query time $o(n)$ even for a single failure? In this paper, we answer this question affirmatively. We provide an efficient construction of a $O(n\sqrt{|\mathcal{P}|})$ sized FTRO with constant query time that is resilient to dual failure (not just single failure).

▶ **Theorem 2** (Upper Bound on 2-FTRO). *A directed graph $G = (V, E)$ with n vertices can be processed in randomized polynomial time for a given set $\mathcal{P} \subseteq V \times V$ of vertex-pairs, to build a data structure of size $O(n\sqrt{|\mathcal{P}|})$, such that for any pair $(s, t) \in \mathcal{P}$ and any set F of (at most) two edge failure, it decides whether there is an s to t path in $G \setminus F$ in time $O(1)$.*

We further show that the above size bound cannot be improved further by providing a matching (up to the word size) lower bound for two failures. To date, no non-trivial (better than linear) size lower bound is known for any pairwise FTRO.

▶ **Theorem 3** (Lower Bound on 2-FTRO). *For any positive integers n, r ($r \leq n^2$), there exists an n-vertex directed graph with a vertex-pair set $\mathcal{P}$ of size r, such that any 2-FTRO$(G, \mathcal{P})$ must be of size $\Omega(n\sqrt{|\mathcal{P}|})$ (in bits).*

In case of source-wise 2-FTRO for a source set S (i.e, when $\mathcal{P} = S \times V$), our lower bound construction provides a lower bound of $\Omega(n|S|)$ (in bits). It is again a matching (up to the word size) lower bound because we know of an $O(n|S|)$-sized 2-FTRO for any source set S due to [17]. It is also worth noting that our lower bound holds irrespective of the query time and also for directed acyclic graphs.

The above lower bound does not hold for a single failure. So it is natural to ask whether we can design a smaller data structure, more specifically, $O(n)$-sized oracle that is resilient to a single failure. We provide a construction of $O(n + \min\{|\mathcal{P}|\sqrt{n}, n\sqrt{|\mathcal{P}|}\})$ sized 1-FTRO with constant $O(1)$ query time. In particular, we show that as long as the number of pairs is bounded by $O(\sqrt{n})$, we can achieve an oracle with $O(n)$ size and $O(1)$ query time. This result provides us a sharp separation in optimum size of a FTRO between single and dual failure. To the best of our knowledge, this is the first separation result between single and dual failure reachability oracle.

▶ **Theorem 4** (Upper Bound on 1-FTRO). *A directed graph $G = (V, E)$ with n vertices can be processed in polynomial time for a given set $\mathcal{P} \subseteq V \times V$ of vertex-pairs, to build a data structure of size $O(n + \min\{|\mathcal{P}|\sqrt{n}, n\sqrt{|\mathcal{P}|}\})$, such that for any pair $(s, t) \in \mathcal{P}$ and a failure edge f, it decides whether there is an s to t path in $G \setminus \{f\}$ in time $O(1)$.*

Note, the size bound of the above theorem matches the current best known bound for the pairwise reachability preserving subgraph for single failure [11].

The above upper bound gives $O(n)$ sized oracle only when the number of pairs is $O(\sqrt{n})$. Is it always possible to get a linear-sized pairwise 1-FTRO? More specifically, does any n-node graph G and a set $\mathcal{P}$ of node-pairs always possess a 1-FTRO$(G, \mathcal{P})$ of size $O(n + |\mathcal{P}|)$?[2] In this paper, we refute this possibility by showing the following.

[2] The presence of $|\mathcal{P}|$ term in the bound is justifiable by the fact that for non-failure case (i.e., the standard static setting), we can get a trivial $O(|\mathcal{P}|)$ sized oracle.

▶ **Theorem 5** (Lower Bound on 1-FTRO). *For any positive integers $n, d \geq 2$, any $p = p(n)$, there exists an n-vertex directed graph and a node-pair set $\mathcal{P}$ of size p, such that any 1-FTRO$(G, \mathcal{P})$ must be of size $\Omega\big(n^{2/(d+1)}p^{(d-1)/d}\big)$ (in bits).*

By setting $d = 2$ in the above theorem, we get a lower bound of $\Omega(n^{2/3}p^{1/2})$. This shows us that for $p = \omega(n^{2/3})$, there is an n-node graph G and a pair set $\mathcal{P}$ of size p, for which linear size 1-FTRO is not possible. Again, our lower bound holds irrespective of the query time and also for DAGs. We show the lower bound by establishing a connection between the optimal sized pairwise 1-FTRO and pairwise reachability preserving subgraph without any failure. In general, we show that the optimal size of any pairwise k-FTRO must be at least that of the reachability preserving subgraph with $k-1$ failures. Instead of just deciding the reachability between a pair of vertex, suppose the data structure is also asked to report a path between them (if exists). Then by a standard information-theoretic argument, the optimal size of any such data structure resilient to k failures must be of size at least that of reachability preserving subgraph with k failures. Unfortunately, such a direct argument does not work for a (Boolean) data structure that only decides the reachability. Ours is the first such connection. Readers may note that there is a gap between our upper and lower bound for pairwise 1-FTRO. We leave this as an interesting open question.

1.2 Reachability Preservers

In the context of graph sparsification, *reachability preserver* (or *reachability subgraph*) for a directed graph G and a set $\mathcal{P}$ of vertex-pairs is a sparse subgraph H with as few edges as possible so that for any pair $(s,t) \in \mathcal{P}$ there is a path from s to t in H if and only if there is such a path in G. In the standard static setting (with no failure), this object has been studied widely [18, 8, 1]. We study these objects in the presence of edge/node failures.

Let us formally define fault-tolerant reachability subgraph (FTRS) for a set of node-pairs.

▶ **Definition 6** (FTRS). *Let $\mathcal{P} \in V \times V$ be any set of pairs of vertices. A subgraph H of G is said to be a* k-Fault-Tolerant Reachability Subgraph *of G for $\mathcal{P}$, denoted as k-FTRS$(G, \mathcal{P})$, if for any pair $(s,t) \in \mathcal{P}$ and for any subset $F \subseteq E$ of at most k edges, t is reachable from s in $G \setminus F$ if and only if t is reachable from s in $H \setminus F$.*

For the particular case of single-source, i.e., $\mathcal{P} = \{s\} \times V$, Baswana, Choudhary, and Roditty [4] provided a polynomial-time algorithm that, given any n-node directed graph, constructs an $O(2^k n)$-sized k-FTRS. As a corollary, to preserve reachability between arbitrary $\mathcal{P}$ pairs, we get an $O(2^k n|\mathcal{P}|)$-sized k-fault-tolerant reachability preserver. For the general setting of arbitrary pairs, the only previously known non-trivial result was for single failure [11], wherein the authors gave an upper bound of $O(n + \min(|\mathcal{P}|\sqrt{n},\ n\sqrt{|\mathcal{P}|}))$ edges. It was left open whether for dual or more failures whether keeping fewer than $O(n|\mathcal{P}|)$ edges sufficient to preserve the pairwise reachability. In particular, does any n-node graph and a set $\mathcal{P}$ of node-pairs always admit a k-FTRS of size $o(2^k n|\mathcal{P}|)$?

In this work, we answer the above question affirmatively. For dual failures, we provide an upper bound of $O(n^{4/3}|\mathcal{P}|^{1/3})$ edges on the structure of 2-FTRS$(G, \mathcal{P})$.

▶ **Theorem 7** (Upper Bound on 2-FTRS). *For any directed graph $G = (V, E)$ with n vertices and a set $\mathcal{P} \subseteq V \times V$ of vertex-pairs, there exists a 2-FTRS$(G, \mathcal{P})$ having at most $O(n^{4/3}|\mathcal{P}|^{1/3})$ edges. Furthermore, we can find such a subgraph in polynomial time.*

Clearly, for $\mathcal{P}$ of size $\omega(\sqrt{n})$, the above result breaks below the $O(n|\mathcal{P}|)$ bound. We complement our upper bound result the following lower bound.

▶ **Theorem 8** (Lower Bound on 2-FTRS). *For every n, r ($r \leq n^2$), there exists an n-vertex directed graph G and a vertex-pair set $\mathcal{P}$ of size r such that any 2-FTRS$(G, \mathcal{P})$ requires $\Omega(n\sqrt{|\mathcal{P}|})$ edges.*

Again, we show a lower bound for source-wise 2-FTRS for a source set S (i.e, when $\mathcal{P} = S \times V$), of $\Omega(n|S|)$. This matches the $O(n|S|)$ upper bound [4] of 2-FTRS for any source set S. So for the source-wise preserver, we completely resolve the question regarding the size of an optimal preserver resilient to two or more failures. For general $k > 2$ failures, we provide a lower bound of $\Omega(2^{k/2}n\sqrt{|\mathcal{P}|})$ on the size of pairwise k-FTRS.

Previously, seemingly a much weaker lower bound was known [11], where the authors could only show a lower bound of $\Omega(n|\mathcal{P}|^{1/8})$, for $\mathcal{P}$ of size n^ϵ with $\epsilon \leq 2/3$. Our result provides a sharp separation between single and dual fault-tolerant reachability preservers for any $\mathcal{P}$ satisfying $\omega(1) \leq |\mathcal{P}| \leq o(n)$.

We also consider the question of beating $O(2^k n|\mathcal{P}|)$ bound for general k-FTRS. We show that for a certain regime of the size of $\mathcal{P}$, it is indeed possible to attain $o(2^k n|\mathcal{P}|)$ bound.

▶ **Theorem 9** (Upper Bound on k-FTRS). *For any $k \geq 1$, a directed graph $G = (V, E)$ with n vertices and a set $\mathcal{P} \subseteq V \times V$ of vertex-pairs satisfying $|\mathcal{P}| = \omega(kn^{1-\frac{1}{k}} \log n)$, there exists a k-FTRS$(G, \mathcal{P})$ having only $o(2^k n|\mathcal{P}|)$ edges.*

We summarize our results on single and dual failures in Table 1. Readers may note that there is a gap between the size of 2-FTRO and 2-FTRS in our results. We pose closing this embarrassing gap as an interesting open question.

Table 1 A comparison of size of FTRO and FTRS for single and dual failures.

Problem	Single Failure	Dual Failure
Reachability Oracle	$O(n + \min(\lvert\mathcal{P}\rvert\sqrt{n}, n\sqrt{\lvert\mathcal{P}\rvert}))$ $\Omega(n^{2/3}\lvert\mathcal{P}\rvert^{1/2})$ (in bits) (New)	$O(n\sqrt{\lvert\mathcal{P}\rvert})$ $\Omega(n\sqrt{\lvert\mathcal{P}\rvert})$ (in bits) (New)
Reachability Preserver	$O(n + \min(\lvert\mathcal{P}\rvert\sqrt{n}, n\sqrt{\lvert\mathcal{P}\rvert}))$ [11]	$O(n^{4/3}\lvert\mathcal{P}\rvert^{1/3})$ $\Omega(n\sqrt{\lvert\mathcal{P}\rvert})$ (New)

1.3 Related Work

A simple version of reachability preserver is when there is a single source vertex s, and we would like to preserve reachability from s to all other vertices. Baswana *et al.* [4] provided an efficient construction of a k-fault-tolerant single-source reachability preserver of size $O(2^k n)$. Further, they showed that this upper bound on the size of a preserver is tight up to some constant factor. As an immediate corollary, we get a k-FTRS of size $O(2^k n|\mathcal{P}|)$ (by applying the algorithm of [4] to find subgraph for each source vertex in pairs of $\mathcal{P}$ and then taking the union of all these subgraphs). We do not know whether this bound is tight for general k. However, for the standard static setting (with no faulty edges) much better bound is known. We know that even to preserve all the pairwise distances, not just reachability, there is a subgraph of size $O\big(n + \min(n^{2/3}|\mathcal{P}|, n\sqrt{|\mathcal{P}|})\big)$ [18, 8]. Later Abboud and Bodwin [1] showed that for any directed graph $G = (V, E)$ given a set S of

source vertices and a pair-set $\mathcal{P} \subseteq S \times V$ we can construct a pairwise reachability preserver of size $O\big(n + \min(\sqrt{n|\mathcal{P}||S|}, (n|\mathcal{P}|)^{2/3})\big)$. It is further shown that for any integer $d \geq 2$ there is an infinite family of n-node graphs and vertex-pair sets $\mathcal{P}$ for which any pairwise reachability preserver must be of size $\Omega\big(n^{2/(d+1)}|\mathcal{P}|^{(d-1)/d}\big)$. Note, for undirected graphs, storing spanning forests is sufficient to preserve pairwise reachability information, and thus we can always get a linear size reachability preserver for undirected graphs. We would like to emphasize that all our results in this paper hold for directed graphs.

By [4] we immediately get an oracle of size $O(2^k n)$ for k edge (or vertex) failures with query time $O(2^k n)$. For just dual failures, we have an $O(n)$ size oracle with $O(1)$ query time due to [17].

For undirected graphs, the optimal bound of $O(kn)$ edges for k-fault-tolerant connectivity preserver directly follows from k-edge (vertex) connectivity certificate constructions provided by Nagamochi and Ibaraki [31]. For connectivity oracle, Pătraşcu and Thorup [35] presented a data structure of $O(m)$ size that can handle any k edge failures in $O(k \log^2 n \log\log n)$ time to subsequently answer connectivity queries between any two vertices in $O(\log\log n)$ time. For small values of k, Duan and Pettie [24] improved the update time of [35] to $O(k^2 \log\log n)$ by presenting a data structure of $\widetilde{O}(m)$ size. For handling vertex failures, Duan and Pettie [25] provided a data structure of $O(mk \log n)$ size with $O(k^3 \log^3 n)$ update time and $O(k)$ query time.

Other closely related problems that have been studied in the fault-tolerant model include computing distance preservers [20, 33, 32, 12], depth-first-search tree [2], spanners [15, 22], approximate distance preservers [5, 34, 7], approximate distance oracles [23, 16], compact routing schemes [16, 14].

2 Preliminaries

For any integer n, we use $[n]$ to denote the set $\{1, 2, \cdots, n\}$. Given a directed graph $G = (V, E)$ on $n = |V|$ vertices and $m = |E|$ edges, the following notations will be used throughout the paper.

- $V(H)$: The set of vertices present in a graph H.
- $E(H)$: The set of edges present in a graph H.
- $H \setminus F$: For a set of edges F, the graph obtained by deleting the edges in F from graph H.
- $s - t$ path : A directed path from a vertex s to another vertex t.
- $P \circ Q$: The concatenation of two paths P and Q, i.e., a path that first follows P and then Q.
- $P[L]$: The subpath of the path P containing the first L vertices of P.
- $P[-L]$: The subpath of the path P containing the last L vertices of P.
- $P[u - v]$: The $u - v$ subpath of the path P.

Our algorithm for computing *pairwise-reachability* preservers (and oracles) in a fault tolerant environment employs the concept of a *single-source* FTRS which is a sparse subgraph that preserves reachability from a designated source vertex even after the failure of at most k edges in G. Baswana *et al.* [4] provide a construction of sparse k-FTRS for any general $k \geq 1$ when there is a designated source vertex.

▶ **Theorem 10** ([4]). *For any directed graph $G = (V, E)$, a designated source vertex $s \in V$, and an integer $k \geq 1$, there exists a (sparse) subgraph H of G which is a k-FTRS$(G, \{s\} \times V)$ and contains at most $2^k n$ edges. Moreover, such a subgraph is computable in $O(2^k mn)$ time, where n and m are respectively the number of vertices and edges in graph G.*

Note, in the FTRO definition we restrict ourselves to a data structure with constant query time. (The term *oracle* came from its ability to answer a query in constant time.) Unlike single-source k-FTRS, there is no non-trivial construction of single-source k-FTRO for $k \geq 3$. For $k = 2$, the following result by Choudhary [17] provides an $O(n)$ size oracle.

▶ **Theorem 11** ([17]). *There is a polynomial time algorithm that given any directed graph $G = (V, E)$, a designated source vertex $s \in V$, constructs a 2-FTRO$(G, \{s\} \times V)$ of size $O(n)$.*

Our constructions will require the knowledge of the vertices reachable from a vertex s as well as the vertices that can reach s. So we will use FTRS (and FTRO) defined with respect to a source vertex ($\{s\} \times V$ case), as well as FTRS (and FTRO) defined with respect to a destination vertex ($V \times \{s\}$ case).

In this paper, we consider fault-tolerant structures with respect to edge failures only. Vertex failures can be handled by simply splitting a vertex v into an edge (v_{in}, v_{out}), where the incoming and outgoing edges of v are respectively directed into v_{in} and directed out of v_{out}.

3 Technical Overview

Construction of a 2-FTRS for a single pair

Our starting point is a simple construction of a linear (in the number of vertices) sized 2-FTRS for a single pair. Recall, we already know of such a subgraph by [4]. However, this new alternate construction will shed more light on the specific structure of a 2-FTRS, which will play a pivotal role in our constructions of pairwise 2-FTRS and 2-FTRO. Given a directed graph G and a vertex-pair (s, t), we construct a subgraph $H_{(s,t)}$ as follows: First, consider two "maximally disjoint" $s-t$ paths $P^1_{(s,t)}$ and $P^2_{(s,t)}$ (that meet only at the cut-edges and cut-vertices). We refer to these two paths as *outer strands*. Next, we add several *coupling paths* between these two outer strands, which are edge-disjoint with the outer strands. For each vertex v on the outer strands, we check for the "earliest" vertex on the strand $P^1_{(s,t)}$ (and $P^2_{(s,t)}$), from which there is a path $Q^1_{(s,t),v}$ (and $Q^2_{(s,t),v}$) to v that is edge-disjoint with both the outer strands. We refer to these path $Q^i_{(s,t),v}$ as coupling paths. Roughly speaking, two outer strands together with the coupling paths constitute the subgraph $H_{(s,t)}$ (see Figure 1). The actual construction is slightly different. Let us first briefly discuss why the above subgraph is a 2-FTRS for the pair (s, t). Then we will comment on the issue with the above simple construction and how we overcome that.

Consider any two failure edges f_1, f_2. W.l.o.g. assume, they do not form an $s - t$ cut-set; otherwise, after the failure there won't be any $s - t$ path. Thus if both f_1, f_2 lie on one of the two outer strands (i.e., either on $P^1_{(s,t)}$ or $P^2_{(s,t)}$), then since these two strands are maximally disjoint, one of them will survive after the failures. So, let f_1, f_2 lie on the strand $P^1_{(s,t)}$, $P^2_{(s,t)}$ respectively. Then consider the subpaths of $P^1_{(s,t)}$, $P^2_{(s,t)}$ above f_1, f_2, and the subpaths of $P^1_{(s,t)}$, $P^2_{(s,t)}$ below f_1, f_2. Since by assumption f_1, f_2 does not form an $s - t$ cut-set, there must be a coupling path (edge-disjoint with $P^1_{(s,t)}$, $P^2_{(s,t)}$) from one of the top subpaths to one of the bottom subpaths in G. Since $H_{(s,t)}$ consists of all the coupling paths, we get a surviving path in $H_{(s,t)} \setminus \{f_1, f_2\}$. This shows that $H_{(s,t)}$ is a 2-FTRS$(G, (s, t))$. Moreover, one may observe from the above argument that, after failure of any two edges, one of the surviving paths in $H_{(s,t)}$ must be of the following form: It first follows one of the outer strand from s to some vertex u, then takes a coupling path till some vertex v on one of

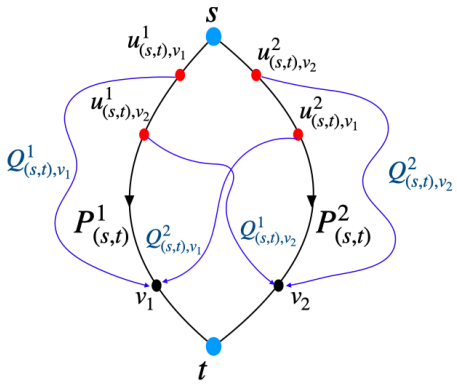

Figure 1 $H_{(s,t)}$=2-FTRS for a single pair (s,t). Two black paths are the outer strands and the purple paths are the coupling paths between them.

the outer strands, and finally follows the corresponding outer strand from v to t. We refer to such a path as *nice path*. The existence of such nice paths helps us in proving the correctness of our pairwise 2-FTRO and 2-FTRS construction in the subsequent sections.

As we mentioned earlier, our actual construction is slightly different. The main issue with the above simple construction is that the constituted subgraph could be of size $\omega(n)$ after adding all the coupling paths. To mitigate this issue, instead of adding all the coupling paths, we only add the "essential" coupling paths. (See the full version for the details.) It allows us to achieve $O(n)$ size bound without affecting the correctness of 2-FTRS. The guarantee of the existence of nice paths also remains unaffected. Of course, the correctness argument will become slightly more intricate.

Next, we use the above construction of a 2-FTRS of a single pair to study the pairwise dual fault-tolerant graph structures (reachability oracle and preserver). Our input is a directed graph $G = (V, E)$ with n nodes, and a node-pair set $\mathcal{P} \subseteq V \times V$.

Pairwise 2-FTRO: Upper bound

One of the main contributions of this work is a construction of a dual fault-tolerant pairwise reachability oracle (2-FTRO) of size $O(n\sqrt{|\mathcal{P}|})$. For simplicity, below, we briefly describe a construction that provides a slightly weaker bound, in particular, $O(n\sqrt{|\mathcal{P}|}\log n)$. Later we will comment on how to remove this extra $\log n$ factor.

We start with the 2-FTRS $H_{(s,t)}$, for each pair $(s,t) \in \mathcal{P}$. First, for all $(s,t) \in \mathcal{P}$, we consider the top and bottom $\Theta(n/\sqrt{|\mathcal{P}|})$ portion of the outer strands $(P^1_{(s,t)}, P^2_{(s,t)})$. We find a subset of vertices that intersects all these subpaths, i.e., acts as a "hitting set". Using a standard greedy algorithm we get a hitting set of size $O(\sqrt{|\mathcal{P}|}\log n)$. (Note, one may alternatively use random sampling to achieve the same bound for the hitting set with high probability.) Then we compute linear-sized single-source and single-destination 2-FTRO having query time $O(1)$, for each of the vertices in the hitting set using [17]. For each $(s,t) \in \mathcal{P}$, in a table $T_{(s,t)}$, we store one vertex from each of the top and bottom $\Theta(n/\sqrt{|\mathcal{P}|})$ length subpaths of $P^1_{(s,t)}$, $P^2_{(s,t)}$, that is also included in the hitting set. That constitutes the first part of our data structure.

Observe, for any two failure edges f_1, f_2 and a pair $(s,t) \in \mathcal{P}$, we know that there must be a surviving *nice* $s-t$ path in $H_{(s,t)} \setminus \{f_1, f_2\}$ (unless f_1, f_2 form an $s-t$ cut-set). Now, if that surviving path follows the bottom (or top) $\Theta(n/\sqrt{|\mathcal{P}|})$ length subpath of $P^j_{(s,t)}$ (for

some $j \in \{1, 2\}$), it must also pass through one of the stored vertices in $T_{(s,t)}$, say v (due to the hitting set property). In this scenario, we can easily check for presence of an $s - v$ and $v - t$ path after the failure of f_1, f_2 in G by trying with all the (at most four) stored vertices in $T_{(s,t)}$. For that, we only need $O(1)$ time during query.

Now, it only remains to consider the case when the surviving nice path in $H_{(s,t)} \setminus \{f_1, f_2\}$ passes though a coupling path $Q^i_{(s,t),v}$, for some vertex v lying on the bottom $\Theta(n/\sqrt{|\mathcal{P}|})$ length subpath of a outer strand, that starts from some vertex u lying on the top $\Theta(n/\sqrt{|\mathcal{P}|})$ length subpath of a outer strand. Informally, we only need to consider the scenario when both the outer strands are of length $O(n/\sqrt{|\mathcal{P}|})$. For simplicity, from now on we continue the description with this assumption. Intuitively, this enables us to look into a smaller graph (which need not be a subgraph of the original graph). We build an *auxiliary graph* $A_{(s,t)}$ (see Figure 2) from $H_{(s,t)}$. We define the auxiliary graph entirely on the vertex set of the outer strands ($P^1_{(s,t)}$, $P^2_{(s,t)}$). First, we add both the outer strands (i.e. all their edges) to the auxiliary graph. Next, we add *auxiliary edges* between the vertices if and only if there is a path between them in $H_{(s,t)}$ that is edge-disjoint with the outer strands. Then, We construct a 2-FTRO (having query time $O(1)$) for $A_{(s,t)}$ using [17]. We do this for all pair $(s, t) \in \mathcal{P}$. Since each auxiliary graph is defined over a set of $O(n/\sqrt{|\mathcal{P}|})$ sized vertex set, we need total $O(n\sqrt{|\mathcal{P}|})$ space. This finishes the description of our data structure. So, the final data structure consists of 2-FTROs of the vertices in the hitting set and 2-FTRO computed over $A_{(s,t)}$'s. Hence, the size of the whole data structure is $O(n\sqrt{|P|}\log n)$.

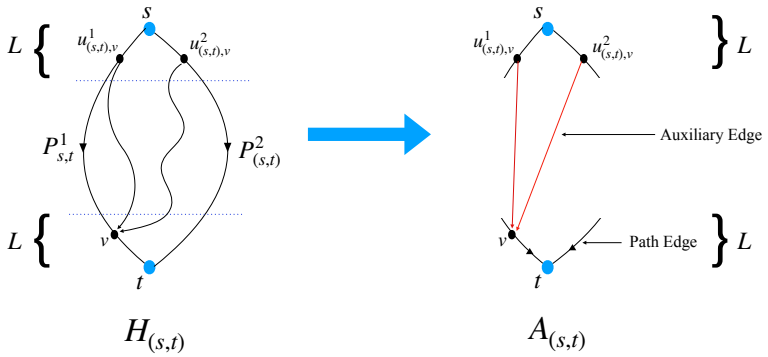

Figure 2 Auxiliary graph $A_{(s,t)}$ constructed from $H_{(s,t)}$.

It is not hard to see that any $s - t$ path of $H_{(s,t)}$ also leads to a valid $s - t$ path in $A_{(s,t)}$ and vice versa. However, it is not immediate that it will be the case even after the failure of f_1, f_2. The difficulty arises because many paths in $H_{(s,t)}$ now map to one path in $A_{(s,t)}$. We show that it is indeed the case that there is an $s - t$ path in $H_{(s,t)} \setminus \{f_1, f_2\}$ if and only if there is an $s - t$ path in the auxiliary graph $A_{(s,t)} \setminus \{f_1, f_2\}$ (given $P^1_{(s,t)}$, $P^2_{(s,t)}$ are of length at most $O(n/\sqrt{P})$). The actual description is slightly more involved because we cannot make any assumption on the length of $P^1_{(s,t)}$, $P^2_{(s,t)}$. Essentially, we need only to consider the top and bottom $O(n\sqrt{|\mathcal{P}|})$ portion of the outer strands and define the auxiliary graph over them. Then we prove the above claim without any assumption on the length of the outer strands. The guarantee on the existence of a nice $s - t$ path in $H_{(s,t)}$ after at most two failures comes handy in this case. Recall, in a nice path, there is at most one coupling sub-path. If both the endpoints of this coupling sub-path lie on the top and bottom $O(n\sqrt{|\mathcal{P}|})$ portion of the

outer strands, we get an auxiliary edge. As a result, we get an $s-t$ path in the auxiliary graph after the failures. We refer the readers to the full version for the details. Note, without the guarantee of a nice path, there could be many coupling sub-paths in a surviving $s-t$ path after failures. As a result, we may not get an auxiliary edge in our auxiliary graph.

During the query for a pair $(s,t) \in \mathcal{P}$, it suffices to either place $O(1)$ many reachability queries on the first part of our data structure or check the presence of an $s-t$ path in the auxiliary graph $A_{(s,t)}$. Hence, we get the overall query time to be only $O(1)$.

To remove the $O(\log n)$ factor from the size bound, we use the concept of *sparsifier with slack* [13, 27, 21, 9]. The extra $O(\log n)$ factor was coming due to the construction of the greedy hitting set. We show that if we prematurely terminate the same greedy hitting set algorithm, we get a *fractional hitting set* that hits a constant fraction of the input sets. As a consequence, we get a pairwise 2-FTRO with slack of size $O(n\sqrt{|\mathcal{P}|})$. Then we use an argument similar to that in [9] to get the same size bound for the (standard) pairwise 2-FTRO.

Optimality of pairwise dual fault-tolerant oracle

In this paper, we show that for pairwise 2-FTRO, our $O(n\sqrt{|\mathcal{P}|})$ bound is essentially tight up to the word size (Theorem 3). Actually, we show that for any source-wise 2-FTRO for a designated source set S, the trivial $O(n|S|)$ upper bound followed from [17], is tight. To do that, we first provide a $\Omega(n|S|)$ lower bound for source-wise 2-FTRS (leading to Theorem 8) by constructing a hard instance. Then we extend that lower bound to source-wise 2-FTRO using communication complexity.

We construct the hard instance for 2-FTRS as follows. Take any integer N, r. We consider two r-sized sets of vertex-disjoint (directed) paths each of length N. Then include a (directed) complete bipartite graph between the left set of r vertices and the right set of r vertices, for each level $k \in [N]$ (See Figure 3). The set S contains the start vertices of the paths in the left set and the terminal vertices of the paths in the right set. So, $|S| = 2r$. The number of vertices and the edges in this graph are $n = 2Nr$ and $\Theta(Nr^2)$ respectively. It is not difficult to observe that each edge in this graph must be present in any 2-FTRS for this graph with the pair set $\mathcal{P} = S \times S$ (See Figure 3). Consequently, we get a $\Omega(n|S|) = \Omega(n\sqrt{|\mathcal{P}|})$ lower bound.

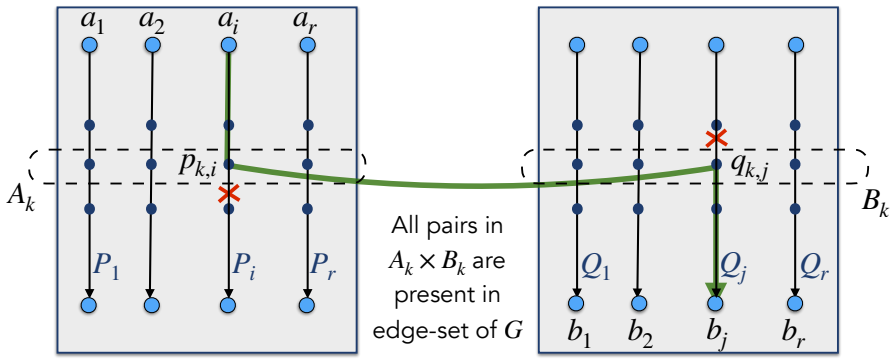

Figure 3 Dual fault-tolerant reachability preserver.

We then extend the above construction to 2-FTRO. Note, FTRO is a Boolean data structure that only decides reachability between a pair of vertices - does not report a path (if exists). If the data structure also reports a path (if exists), then using a standard information-

theoretic argument, it is possible to show that the data structure must be of a size equal to that of a FTRS. Such an argument does not work in general for FTRO. This is a general hurdle that we need to overcome to extend the lower of FTRS to FTRO. Fortunately, the hard instance we constructed for FTRS allows us to provide a reduction from (a close variant of) the *Index* problem. Then we use the randomized one-way communication complexity lower bound for the Index problem [28] to get a lower bound of $\Omega(n|S|)$ on the size (in bits) of any 2-FTRO. It is worth mentioning that our lower bound holds irrespective of the query time of 2-FTRO.

Pairwise 1-FTRO: Upper and lower bound

The above lower bound only holds for dual failures. So it remains open whether for single failure we can attain better than $O(n\sqrt{|\mathcal{P}|})$ size bound with $o(n)$ (ideally, constant) query time. In this section, we provide a construction of 1-FTRO of size $O(n + |\mathcal{P}|\sqrt{n})$ and query time $O(1)$. We show the construction by first designing a reachability oracle of size $O(n + |\mathcal{P}|\sqrt{n})$ resilient to single vertex failure. Then we extend that vertex fault-tolerant data structure to an edge fault-tolerant data structure of the same size.

One of the key ingredients of our construction is a clever data structure that could answer all-pairs reachability query under single vertex failure as long as all three vertices involved in the query belong to a cut-set. Formally, for a pair (s, t), let C be any subset of $s - t$ cut-vertices in the graph G. We build an $O(|C|)$ size data structure that, for any three vertices $x, y, z \in C$, decides the reachability between y, z upon failure of vertex x, in constant time. This data structure is inspired by the loop-nesting-forest [36]. We consider the ordering σ among the cut-vertices in C. Next, we build a predecessor forest and a successor forest with respect to this ordering σ. In the predecessor forest, the parent of any node w is the immediate predecessor u such that u, w are strongly connected even after the removal of all the predecessors of u from G. We symmetrically build the successor forest. Using constantly many Lowest Common Ancestor (LCA) and Level Ancestor (LA) queries on these forests, we can now decide the reachability between y, z upon failure of the vertex x (for any $x, y, z \in C$). By deploying any standard linear space LCA/LA data structure, we attain $O(|C|)$ space-bound and $O(1)$ query time. We refer the readers to the full version for the details.

Next, we use the above data structure to construct a pairwise fault-tolerant reachability oracle for single vertex failure. Observe, to decide the reachability between a pair upon failure, we need to check whether the failure vertex is a cut-vertex for that pair or not. At the high level, we need to keep the information about the cut-vertex-set for each pair. However, we cannot store them explicitly using small space. We first consider the cut-vertex-set for all the pairs in $\mathcal{P}$. Then we identify a *core pair-set* as follows: Take any pair in $\mathcal{P}$ with at least $\sqrt{n}$ cut-vertices, and add it into the core pair-set. Then iteratively add pairs from $\mathcal{P}$ with at least $\sqrt{n}$ new/uncovered (not part of the cut-vertex-set of any previously added pair) cut-vertices. For each pair added in the core pair-set, it *owns* the corresponding cut-vertices that were uncovered till then. Once we get the core pair-set, we are left with pairs each having at most $\sqrt{n}$ uncovered cut-vertices. Further note, the size of the core pair-set is at most $O(\sqrt{n})$. Consider the union of all the cut-vertices of the core pair-set, and build the previously mentioned data structure on it. For the remaining pairs, we store the uncovered cut-vertices associated with them using any static dictionary data structure. Note, each pair might have cut-vertices that are owned by some core pair. To keep track of them, for each pair and each core pair, we store the first and the last cut-vertex shared by them. These all constitute the final data structure. It is not hard to see that the size is $O(n + |\mathcal{P}|\sqrt{n})$. We

show that it suffices to either perform a query on the previously mentioned data structure or check whether the failure vertex is a cut-vertex in the dictionary structure during the query. (See the full version.)

Now, we extend the vertex fault-tolerant oracle to edge fault-tolerant oracle. We consider the set $\mathcal{C}$ of all the cut-edges for all the pairs in $\mathcal{P}$. Then we find the subset $\mathcal{C}_0$ that only contains the edges whose endpoints are strongly connected in G, but not after the failure of that edge. Observe, all the edges in $\mathcal{C}$ must be part of any strong-connectivity certificate, and all the edges in $\mathcal{C}_0$ must be part of any reachability preserver without any failure. Thus $|\mathcal{C}| = O(n)$ and $|\mathcal{C}_0| = O(n + \min\{|\mathcal{P}|\sqrt{n}, (n|\mathcal{P}|)^{2/3}\})$ by [1]. Next, we construct a new graph with $n + |\mathcal{C}_0|$ vertices such that checking the reachability upon an edge failure in the original graph reduces to checking the reachability (perhaps between a different pair) upon vertex failure in the new graph. As a consequence, we get an $O(n + |\mathcal{P}|\sqrt{n})$ sized 1-FTRO with constant query time.

We complement our upper bound result with a lower bound of $\Omega(n^{2/d+1}|\mathcal{P}|^{(d-1)/d})$ size (in bits) for any $d \geq 2$. We prove our lower bound by establishing a connection between the optimal size of a pairwise k-FTRO and that of a pairwise $(k-1)$-FTRS. In particular, we show that the optimal size of FTRO for any n-node graph and p-sized pair-set is at least that of $(k-1)$-FTRS for any $n/2$-node graph and p-sized pair-set. Such a connection between FTRO and FTRS is entirely new. To prove this relation, we use information-theoretic encoding-decoding argument. (See the full version.) Then the lower bound of 1-FTRO follows from the lower bound of reachability preserver without any failure by [1].

Pairwise 2-FTRS: Upper bound

We have already shown a lower bound of $\Omega(n\sqrt{|\mathcal{P}|})$ on the size of a pairwise 2-FTRS. However, so far we only known of $O(n|\mathcal{P}|)$ size 2-FTRS for any n-node graph G and pair set $\mathcal{P}$. In this work, we provide a deterministic polynomial time construction of a pairwise 2-FTRS of size $O(n^{4/3}|\mathcal{P}|^{1/3})$. For simplicity, below, we briefly describe a construction that provides a slightly weaker bound, in particular, $O(n\sqrt{|\mathcal{P}|}\log n)$. In the actual construction, we get rid of the $\log n$ factor by constructing a preserver with slack and then using the result of [9] - an idea similar to that used in pairwise 2-FTRO described earlier. Before proceeding further, let us emphasize that the main underlying idea behind our construction could be generalized to k-FTRS, for any $k \geq 1$, albeit with the help of randomization. We describe that generic construction later.

To get a sparse 2-FTRS for a node-pair set $\mathcal{P}$, we perform two-step sparsification. First, we apply our alternate construction of 2-FTRS for each of the pairs of $\mathcal{P}$. Then take a union of all of these subgraphs to get a $O(n|\mathcal{P}|)$ size intermediate subgraph H_{inter}, which is clearly a 2-FTRS for $\mathcal{P}$. Next, we further sparsify this intermediate subgraph. Similar to the technique used in oracle construction, we consider the top and bottom $\Theta(n^{2/3}|P|^{-1/3})$ portions of the outer strands ($P^1_{(s,t)}$, $P^2_{(s,t)}$) of $H_{s,t}$, for each $(s,t) \in \mathcal{P}$. Next, we construct a greedy hitting set containing $O(n^{1/3}|\mathcal{P}|^{1/3}\log n)$ vertices that intersects all these subpaths. We compute linear-sized single-source and single-destination 2-FTRS for each of these vertices in the hitting set using [4]. Let H_1 be the union of all these single-source and single-destination 2-FTRS. So, H_1 is of size $O(n^{4/3}|\mathcal{P}|^{1/3}\log n)$.

Consider any two failure edges f_1, f_2 and a pair $(s,t) \in \mathcal{P}$. If there is a surviving path in $G \setminus \{f_1, f_2\}$, we know that there is a *nice* $s-t$ path in $H_{(s,t)} \setminus \{f_1, f_2\}$. Using an argument similar to that in the oracle construction, if that nice path follows the top or bottom $\Theta(n^{2/3}|P|^{-1/3})$ portion of a outer strand, then there is also an $s-t$ path in $H_1 \setminus \{f_1, f_2\}$. So now on, it suffices to look into the case when the surviving nice path in

$H_{(s,t)} \setminus \{f_1, f_2\}$ passes though a coupling path $Q^i_{(s,t),v}$, for some vertex v lying on the bottom $\Theta(n^{2/3}|P|^{-1/3})$ length subpath of a outer strand, that starts from some vertex u lying on the top $\Theta(n^{2/3}|P|^{-1/3})$ length subpath of a outer strand.

If we could include the top and bottom $\Theta(n^{2/3}|P|^{-1/3})$ portion of the outer strands, and all the "essential" coupling path $Q^i_{(s,t),v}$'s with endpoints lying on the top and bottom $\Theta(n^{2/3}|P|^{-1/3})$ portions of the outer strands, we will be done. We indeed consider a union of the top and bottom $\Theta(n^{2/3}|P|^{-1/3})$ portion of the outer strands (for all $(s,t) \in \mathcal{P}$), and let us denote that by H_2. So, H_2 is of size $O(n^{2/3}|P|^{2/3})$. Unfortunately, we do not have a guarantee on the length of the coupling paths. Thus, if we include all the required coupling paths, we cannot argue about the sparsity of the final subgraph. (This portion of the construction differs significantly from that of our oracle construction.) We consider the subgraph obtained by taking a union of all the "essential" coupling paths with endpoints lying on the top and bottom $\Theta(n^{2/3}|P|^{-1/3})$ portions of the outer strands. (Let us denote this union by B.) Then we sparsify this subgraph further. For that purpose, we first isolate all the "high frequency" vertices (iteratively) and remove all the coupling paths containing them. Since total number of coupling paths in this subgraph is only $\Theta(n^{2/3}|P|^{2/3})$, we end up with "a few" ($O(n^{1/3}|P|^{1/3})$) high frequency vertices. Now, observe, in the remaining subgraph (denoted as H_4), degree of each vertex is "small" (at most $O(n^{1/3}|P|^{1/3})$). Next, for each of the high-frequency vertices, compute linear-sized single-source and single-destination 2-FTRS, and take a union of them to form a subgraph H_3. The union of H_1, H_2, H_3 and H_4 constitute the final subgraph.

It is not difficult to see that a surviving nice $s-t$ path in $H_{(s,t)} \setminus \{f_1, f_2\}$ either passes through one of the high frequency vertices, in which case we get an $s-t$ path in H_3; or is included in $H_2 \cup H_4$. Thus So, the union of all H_1, H_2, H_3 and H_4 will be a 2-FTRS for $\mathcal{P}$. It is worth mentioning that the correctness proof works only because of a guarantee of the existence of the nice path. Note, a nice path follows at most one coupling path as a subpath. Thus either that nice path follows the top or bottom $\Theta(n^{2/3}|P|^{-1/3})$ portion of the outer strands, or the coupling sub-path is part of B, which we further sparsify to get H_3 and H_4. Without the guarantee of a nice path, there could be many coupling sub-paths in a surviving $s-t$ path after failures. Endpoints of these coupling sub-paths may not lie on the top or bottom $\Theta(n^{2/3}|P|^{-1/3})$ portion of the outer strands. As a result, we miss them in B. As a consequence, $H_3 \cup H_4$ could not capture those coupling sub-paths.

Observe, each of the H_i's is of size at most $O(n^{4/3}|\mathcal{P}|^{1/3}\log n)$ (the $\log n$ factor is only there for H_1). So the total size is also $O(n^{4/3}|P|^{1/3}\log n)$.

Pairwise k-FTRS: Beating the $O(2^k n|\mathcal{P}|)$ bound

Currently, for any $k \geq 1$, we only know there always exists a pairwise k-FTRS of size $O(2^k n|\mathcal{P}|)$ for any pair set $\mathcal{P}$ [4]. Previously, we beat the above bound for $k = 2$. We cannot directly extend that bound for k-FTRS. The main obstacle is that for pairwise 2-FTRS, we have used a particular structure of a 2-FTRS for a single pair (i.e., the subgraph $H_{(s,t)}$). It is pretty difficult get such kind of structure for k-FTRS for any $k > 2$. However, the main underlying idea behind our pairwise 2-FTRS construction is to handle the "long" and "short" surviving paths separately. Informally, in the case of 2-FTRS, the hitting set helps us to look into only the short paths in $H_{(s,t)}$. We do a similar thing for k-FTRS using randomization.

Take a parameter ℓ, whose value we will fix later. We sample a uniformly random subset W of vertices of size $\tilde{O}(kn/\ell)$. Then we build a single-source and single-destination k-FTRS from those vertices. Let us denote the union of all these k-FTRSs as H_1. The size of H_1 is $O(k2^k n^2/\ell)$ by [4]. Suppose, for any failure edge-set F of size at most k, the length of any

shortest $s-t$ surviving path in $G \setminus F$ is at least ℓ. Consider an (arbitrarily chosen) shortest surviving $s-t$ path in $G \setminus F$ (which is of length at least ℓ). Then it is not hard to argue that W intersects that path with high probability. Thus we get an $s-t$ path in $H_1 \setminus F$. This part is similar to what we get in 2-FTRS using greedy hitting set.

So now on, we only need to handle the case when a shortest surviving path is of length at least ℓ. To do this, roughly speaking, we enumerate over all possible failure-set of size at most k and add a shortest surviving path in the subgraph. Trivially, we get a bound of only $O(n^k)$ on the number of possible failure edge-sets of size at most k. However, observe, we only need to handle the case when a surviving shortest path is of length at most ℓ. So before the failure also the length of a shortest path was at most ℓ. The initial shortest path (before any failure) will get destroyed only if one or more failure edges lie on that shortest path. This observation reduces the number of possible failure-set to $O(\ell^k)$. So, for each pair, we add $O(\ell^k)$ paths, each of length at most ℓ. For all the pairs, the total number of added edges is at most $O(\ell^{k+1}|\mathcal{P}|)$. We can further improve this bound to $O(\ell^k|\mathcal{P}|)$ by enumerating the failure-set of size up to $k-1$ and then adding two maximally edge-disjoint shortest paths. (See the full version for the details.) At the end, we get a subgraph of size $O(k2^k n^2/\ell + \ell^k|\mathcal{P}|)$. By optimizing the parameter ℓ, we get a size bound of $\widetilde{O}(k\ 2^k\ n^{\frac{2k}{k+1}}\ |\mathcal{P}|^{\frac{1}{k+1}})$. Note, this size bound beats the $O(2^k n|\mathcal{P}|)$ bound whenever $|\mathcal{P}| = \omega(kn^{\frac{k-1}{k}}\log n)$.

4 Conclusion

In this paper, we study compact oracle and sparse preservers for the problem of pairwise reachability under failures. For dual failures, we provide a construction of $O(n\sqrt{|\mathcal{P}|})$ sized reachability oracle that has constant query time, along with a matching (up to the word size) lower bound. It (almost) settles down the question on the optimal sized dual fault-tolerant pairwise reachability oracle. For single failure, we achieve a bound of $O(n + \min\{|\mathcal{P}|\sqrt{n}, n\sqrt{|\mathcal{P}|}\})$ on the size of oracle with constant query time. We complement our upper bound with a $\Omega(n^{2/3}|\mathcal{P}|^{1/2})$ size (in bits) lower bound, refuting the possibility of getting a linear-sized oracle for a single failure. We would like to pose the problem of closing the current gap between the upper and lower bound for a single fault-tolerant oracle as an open problem.

In the case of reachability preserver, we show an upper bound of $O(n^{4/3}|\mathcal{P}|^{1/3})$ edges for any n-node graph and a vertex-pair set $\mathcal{P}$, for dual failures setting. This improves the naive bound of $O(n|\mathcal{P}|)$ preserver (obtained from the result known for single-source setting). In addition, we obtain a lower bound of $\Omega(n\sqrt{|\mathcal{P}|})$ on the size of our reachability preserver under dual failures. Prior to our work it was known that for single failure, we can have preserver with $O(n + \min\{|\mathcal{P}|\sqrt{n},\ n\sqrt{|\mathcal{P}|}\})$ edges. Thus our lower bound provides a striking difference between the single and dual fault-tolerant setting as it gives a separation of $n^{1/4}$ factor for $|\mathcal{P}| = \Theta(\sqrt{n})$. One immediate open question after our work is whether a sparser pairwise reachability preserver exists for dual failures.

Next, we go beyond the dual failures and consider the question of getting sparse pairwise reachability preserver resilient up to k failures for any $k \geq 1$. Can there always exist a pairwise preserver of size $o(2^k n|\mathcal{P}|)$ for any k failures? We answer this question affirmatively by providing a randomized polynomial-time construction of a $o(2^k n|\mathcal{P}|)$ size preserver. We leave the question of finding an optimal k fault-tolerant pairwise preserver as an important open problem.

Abstract

The role of symmetry in Boolean functions $f : \{0,1\}^n \to \{0,1\}$ has been extensively studied in complexity theory. For example, symmetric functions, that is, functions that are invariant under the action of S_n, is an important class of functions in the study of Boolean functions. A function $f : \{0,1\}^n \to \{0,1\}$ is called transitive (or weakly-symmetric) if there exists a transitive group G of S_n such that f is invariant under the action of G. In other words, the value of the function remains unchanged even after the input bits of f are moved around according to some permutation $\sigma \in \mathsf{G}$. Understanding various complexity measures of transitive functions has been a rich area of research for the past few decades.

This work studies transitive functions in light of several combinatorial measures. The question that we try to address in this paper is what are the maximum separations between various pairs of combinatorial measures for transitive functions. Such study for general Boolean functions has been going on for many years. Aaronson et al. (STOC, 2021) have nicely compiled the current best-known results for general Boolean functions. But before this paper, no such systematic study had been done on the case of transitive functions.

Separations between a pair of combinatorial measures are shown by constructing interesting functions that demonstrate the separation. Over the past three decades, various interesting classes of functions have been designed for this purpose. In this context, one of the celebrated classes of functions is the "pointer functions". Ambainis et al. (JACM, 2017) constructed several functions, which are modifications of the pointer function in Göös et al. (SICOMP, 2018 / FOCS, 2015), to demonstrate the separation between various pairs of measures. In the last few years, pointer functions have been used to show separation between various other pairs of measures (Eg: Mukhopadhyay et al. (FSTTCS, 2015), Ben-David et al. (ITCS, 2017), Göös et al. (ToCT, 2018 / ICALP, 2017)).

However, the pointer functions themselves are not transitive. Based on the various kinds of pointer functions, we construct new transitive functions, which we use to demonstrate similar separations between various pairs of combinatorial measures as demonstrated by the original pointer functions. Our construction of transitive functions depends crucially on the construction of particular classes of transitive groups whose actions, though involved, help to preserve certain structural features of the input strings. The transitive groups we construct may be of independent interest in other areas of mathematics and theoretical computer science.

We summarize the current knowledge of relations between various combinatorial measures of transitive functions in a table similar to the table compiled by Aaronson et al. (STOC, 2021) for general functions.

1 Introduction

For a Boolean function $f : \{0,1\}^n \to \{0,1\}$ what is the relationship between its various combinatorial measures, like deterministic query complexity ($\mathsf{D}(f)$), bounded-error randomized and quantum query complexity ($\mathsf{R}(f)$ and $\mathsf{Q}(f)$ respectively), zero -randomized query complexity ($\mathsf{R}_0(f)$), exact quantum query complexity ($\mathsf{Q}_\mathsf{E}(f)$), sensitivity ($\mathsf{s}(f)$), block sensitivity ($\mathsf{bs}(f)$), certificate complexity ($\mathsf{C}(f)$), randomized certificate complexity ($\widetilde{\mathsf{RC}}(f)$), unambiguous certificate complexity ($\mathsf{UC}(f)$), degree ($\deg(f)$), approximate degree ($\widetilde{\deg}(f)$) and spectral sensitivity ($\lambda(f)$)[1]? For over three decades, understanding the relationships between these measures has been an active area of research in computational complexity theory. These combinatorial measures have applications in many other areas of theoretical computer science, and thus the above question takes a central position.

In the last couple of years, some of the more celebrated conjectures have been answered - like the quadratic relation between sensitivity and degree of Boolean functions [21]. We refer the reader to the survey [12] for an introduction to this area.

Understanding the relationship between various combinatorial measures involves two parts:

- Relationships – proving that one measure is upper bounded by a function of another measure. For example, for any Boolean function f, $\deg(f) \leq \mathsf{s}(f)^2$ and $\mathsf{D}(f) \leq \mathsf{R}(f)^2$.
- Separations – constructing functions that demonstrates separation between two measures. For example, there exists a Boolean function f with $\deg(f) \geq \mathsf{s}(f)^2$. Also there exists another Boolean function g with $\mathsf{D}(g) \geq \mathsf{R}(g)^2$.

Obtaining tight bounds between pairs of combinatorial measures - that is, when the relationship and the separation results match - is the holy grail of this area of research. The current best-known results for different pairs of functions have been nicely compiled in [2].

For special classes of Boolean functions the relationships and the separations might be different than that of general Boolean functions. For example, while it is known that there exists f such that $\mathsf{bs}(f) = \Theta(\mathsf{s}(f)^2)$ [26], for a symmetric function a more tighter result is known, $\mathsf{bs}(f) = \Theta(\mathsf{s}(f))$. The best-known relationship of $\mathsf{bs}(f)$ for a general Boolean functions is $\mathsf{s}(f)^4$ [21]. How the various measures behave for different classes of functions has been studied since the dawn of this area of research.

Transitive Functions. One of the most well-studied classes of Boolean functions is that of the transitive functions. A function $f : \{0,1\}^n \to \{0,1\}$ is transitive if there is a transitive group $G \leq \mathsf{S}_n$ such that the function value remains unchanged even after the indices of the input is acted upon by a permutation from G. Note that, when $G = \mathsf{S}_n$ then the function is symmetric. Transitive functions (also called "weakly symmetric" functions) has been studied extensively in the context of various complexity measure. This is because symmetry is a natural measure of the complexity of a Boolean function. It is expected that functions with more symmetry must have less variation among the various combinatorial measures. A recent work [7] has studied the functions under various types of symmetry in terms of quantum speedup. So, studying functions in terms of symmetry is important in various aspects.

For example, for symmetric functions, where the transitive group is S_n, most of the combinatorial measures become the same up to a constant [2]. Another example of transitive functions is the graph properties. The input is the adjacency matrix, and the transitive group

[1] For formal definitions of the various measures used in this paper please refer to the full version of this paper [15].

[2] There are still open problems on the tightness of the constants.

is the graph isomorphism group acting on the bits of the adjacency matrix. [31, 29, 23, 17] tried to obtain tight bounds on the relationship between sensitivity and block sensitivity for graph properties. They also tried to answer how low can sensitivity and block sensitivity go for graph properties?

In papers like [30, 14, 28, 16] it has been studied how low can the combinatorial measures go for transitive functions. The behavior of transitive functions can be very different from general Boolean functions. For example, while it is known that there are Boolean functions for which the sensitivity is as low as $\Theta(\log n)$ where n is the number of effective variables[3], it is known (from [28] and [21]) that if f is a transitive function on n effective variables then its sensitivity $s(f)$ is at least $\Omega(n^{1/12})$[4]. Similar behavior can be observed in other measures too. For example, it is easy to see that for a transitive function, the certificate complexity is $\Omega(\sqrt{n})$, while the certificate complexity for a general Boolean function can be as low as $O(\log n)$. Please see the full version of this paper [15] for a more detailed study.

A natural related question is:

What are tight relationships between various pairs of combinatorial measures for transitive functions?

By definition, the known relationship results for general functions hold for transitive functions. But tighter relationships may be obtained for transitive functions. On the other hand, the existing separations don't extend easily since the example used to demonstrate separation between certain pairs of measures may not be transitive. Some of the most celebrated examples are not transitive. For example some of the celebrated function construction like the pointer function in [4], used for demonstrating tight separations between various pairs like $\mathsf{D}(f)$ and $\mathsf{R}_0(f)$, are not transitive. Similarly, the functions constructed using the cheat sheet techniques [1] used for separation between quantum query complexity and degree, or approximate degree, are not transitive. Constructing transitive functions which demonstrate tight separations between various pairs of combinatorial measures is very challenging.

Our Results. We try to answer the above question for various pairs of measures. More precisely, our main contribution is to construct transitive functions that have similar complexity measures as the *pointer functions*. Hence for those pairs of measures where pointer functions can demonstrate separation for general functions, we prove that transitive functions can also demonstrate similar separation.

Our results and the current known relations between various pairs of complexity measures of transitive functions are compiled in Table 1. This table is along the lines of the table in [2] where the best-known relations between various complexity measures of general Boolean functions were presented.

Deterministic query complexity and zero-error randomized query complexity are two of the most basic measures and yet the tight relation between these measures was not known until recently. In [27] they showed that for the "balanced NAND-tree" function, $\widetilde{\wedge}$-tree, $\mathsf{D}(\widetilde{\wedge}\text{-tree}) \geq \mathsf{R}_0(\widetilde{\wedge}\text{-tree})^{1.33}$. Although the function $\widetilde{\wedge}$-tree is transitive, the best-known relationship was quadratic, that is for all Boolean function f, $\mathsf{D}(f) = O(\mathsf{R}_0(f)^2)$. In [4] a new function, A1, was constructed for which deterministic query complexity and zero-error randomized query complexity can have a quadratic separation between them, and this matched the known relationship results. The function in [4] was a variant of the pointer

[3] A variable is effective if the function is dependent on it.

[4] It is conjectured that the sensitivity of a transitive function is $\Omega(n^{1/3})$.

functions - a class of functions introduced by [20] that has found extensive usage in showing separations between various complexity measures of Boolean functions. The function, A1, also gave (the current best-known) separations between deterministic query complexity and other measures like quantum query complexity and degree. But the function A1 is not transitive. Using the A1 function we construct a transitive function that demonstrates a similar gap between deterministic query complexity and zero-error randomized query complexity, quantum query complexity, and degree.

▶ **Theorem 1.** *There exists a transitive function F_1 such that*

$$\mathsf{D}(F_1) = \widetilde{\Omega}(\mathsf{Q}(F_1)^4), \qquad \mathsf{D}(F_1) = \widetilde{\Omega}(\mathsf{R_0}(F_1)^2), \qquad \mathsf{D}(F_1) = \widetilde{\Omega}(\deg(F_1)^2).$$

The proof of Theorem 1 is presented in Section 4. In [4, 9] various variants of the pointer function have been used to show separation between other pairs of measures like $\mathsf{R_0}$ with R, $\mathsf{Q_E}$, deg, and Q, R with $\widetilde{\deg}$, deg, $\mathsf{Q_E}$ and sensitivity. Inspired by these functions, we construct transitive versions that demonstrate similar separation for transitive functions as general functions.

▶ **Theorem 2.** *There exists a transitive function F_2 such that*

$$\mathsf{R_0}(F_2) = \widetilde{\Omega}(\mathsf{R}(F_2)^2), \qquad \mathsf{R_0}(F_2) = \widetilde{\Omega}(\mathsf{Q_E}(F_2)^2), \qquad \mathsf{R_0}(F_2) = \widetilde{\Omega}(\deg(F_2)^2).$$

▶ **Theorem 3.** *There exists a transitive function F_3 such that*

$$\mathsf{R}(F_3) = \widetilde{\Omega}(\widetilde{\deg}(F_3)^4), \qquad \mathsf{R}(F_3) = \widetilde{\Omega}(\deg(F_3)^2).$$

The construction of these functions, though more complicated and involved, are similar in flavor to that of F_1. Due to lack of space, we skip the proofs of Theorem 2 and 3 in this conference version of this paper. The proofs are available in the full version of this paper [15]. Using standard techniques, we can also obtain the following theorems as corollaries to Theorem 3.

▶ **Theorem 4.** *There exists a transitive function F_4 such that $\mathsf{R_0}(F_4) = \widetilde{\Omega}(\mathsf{Q}(F_4)^3)$.*

▶ **Theorem 5.** *There exists a transitive function F_5 such that $\mathsf{R}(F_5) = \widetilde{\Omega}(\mathsf{Q_E}(F_5)^{1.5})$.*

▶ **Theorem 6.** *There exists transitive functions F_6 such that $\mathsf{R}(F_6) = \widetilde{\Omega}(\mathsf{s}(F_6)^3)$.*

Our proof techniques also help us make transitive versions of other functions like that used in[1] to demonstrate the gap between Q and certificate complexity.

▶ **Theorem 7.** *There exists a transitive function F_7 such that $\mathsf{Q}(F_7) = \widetilde{\Omega}(\mathsf{C}(F_7)^2)$.*

All our results are compiled (and marked in green) in Table 1.

One would naturally ask what stops us from constructing transitive functions analogous to the other functions, like cheat sheet-based functions. In fact, one could ask why to use ad-hoc techniques to construct transitive functions (as we have done in most of our proofs) and instead why not design a unifying technique for converting any function into a transitive function that would display similar properties in terms of combinatorial measures [5]. If one could do so, all the separation results for general functions (in terms of separation between pairs of measures) would translate to separation for transitive functions. In Section 5 we have discussed why such a task is challenging. We argue the challenges of making transitive versions of the cheat-sheet functions.

[5] In [7] they have demonstrated a technique that can be used for constructing a transitive partial function that demonstrates gaps (between certain combinatorial measures) similar to a given partial function that need not be transitive. But their construction need not construct a total function even when the given function is total.

Table 1 best-known separations between combinatorial measures for transitive functions.

(1) Entry $a; b$ in row A and column B represents: for any *transitive* function f, $A(f) = O(B(f))^{b+o(1)}$, and there exists a *transitive* function g such that $A(g) = \Omega(B(g))^a$.
(2) Cells with a green background are those for which we constructed new *transitive functions* to demonstrate separations that match the best-known separations for general functions. The previously known functions that gave the strongest separations were not transitive. The second row (in each cell) gives the reference to the Theorems where the separation result is proved. Although for these green cells, the bounds match that of the general functions, for some cells (with a light green color), there is a gap between the known relationships and best-known separations.
(3) In the cells with a white background, the best-known examples for the corresponding separation were already *transitive functions*. For these cells, the second row either contains the function that demonstrates the separation or a reference to the paper where the separation was proved. So for these cells, the separations for transitive functions matched the current best-known separations for general functions. Note that for some of these cells, the bounds are not tight for general functions.
(4) Cells with a yellow background are those where the best-known separations for transitive functions do not match the best-known separations for general functions.

2 Notations and Background

2.1 Notations and basic definitions

We use $[n]$ to denote the set $\{1, \ldots, n\}$. $\{0,1\}^n$ denotes the set of all n-bit binary strings. For any $X \in \{0,1\}^n$ the Hamming Weight of X (denoted $|X|$) will refer to the number of 1 in X. 0^n and 1^n denotes all 0's string of n-bit and all 1's string of n-bit, respectively.

We denote by S_n the set of all permutations on $[n]$. Given an element $\sigma \in \mathsf{S}_n$ and a n-bit string $x_1, \ldots, x_n \in \{0,1\}^n$ we denote by $\sigma[x_1, \ldots, x_n]$ the string obtained by permuting the indices according to σ. That is $\sigma[x_1, \ldots, x_n] = x_{\sigma(1)}, \ldots, x_{\sigma(n)}$. This is also called the action of σ on the $x_1, \ldots, x_n$.

Following are a couple of interesting elements of S_n that will be used in this paper.

▶ **Definition 8.** *For any $n = 2k$ the* flip *swaps $(2i-1)$ and $2i$ for all $1 \le i \le k$. The permutation* $\mathsf{Swap}_{\frac{1}{2}}$ *swaps i with $(k+i)$, for all $1 \le i \le k$. That is,*

$$\mathsf{flip} = (1,2)(3,4)\ldots(n-1,n) \qquad \& \qquad \mathsf{Swap}_{\frac{1}{2}}[x_1, \ldots, x_{2k}] = x_{k+1}, \ldots, x_{2k}, x_1 \ldots, x_k.$$

Every integer $\ell \in [n]$ has the canonical $\log n$ bit string representation. However the number of 1's and 0's in such a representation is not same for all $\ell \in [n]$. The following representation of $\ell \in [n]$ ensures that for all $\ell \in [n]$ the encoding has same Hamming weight.

▶ **Definition 9** (Balanced binary representation)**.** *For any $\ell \in [n]$, let $\ell_1, \ldots, \ell_{\log n}$ be the binary representation of the number ℓ where $\ell_i \in \{0,1\}$ for all i. Replacing* 1 *by* 10 *and* 0 *by* 01 *in the binary representation of ℓ, we get a $2\log n$-bit unique representation, which we call* Balanced binary representation *of ℓ and denote as $bb(\ell)$.*

In this paper all the functions considered are of form $F : \{0,1\}^n \to \{0,1\}^k$. By Boolean functions we would mean a Boolean valued function that is of the form $f : \{0,1\}^n \to \{0,1\}$.

An input to a function $F : \{0,1\}^n \to \{0,1\}^k$ is a n-bit string but also the input can be thought of as different objects. For example, if the $n = NM$ then the input may be thought of as a $(N \times M)$-matrix with Boolean values. It may also be thought of as a $(M \times N)$-matrix.

If $\Sigma = \{0,1\}^k$ then $\Sigma^{(n\times m)}$ denotes an $(n \times m)$-matrix with an element of Σ (that is, a k-bit string) stored in each cell of the matrix. Note that $\Sigma^{(n\times m)}$ is actually $\{0,1\}^{mnk}$. Thus, a function $F : \Sigma^{(n\times m)} \to \{0,1\}$ is actually a Boolean function from a $\{0,1\}^{nmk}$ to $\{0,1\}$, where we think of the input as an $(n \times m)$-matrix over the alphabet Σ.

One particular nomenclature that we use in this paper is that of 1-cell certificate.

▶ **Definition 10** (1-cell certificate)**.** *Given a function $f : \Sigma^{(n\times m)} \to \{0,1\}$ (where $\Sigma = \{0,1\}^k$) the 1-cell certificate is a partial assignments to the cells which forces the value of the function to* 1*. So a 1-cell certificate is of the form $(\Sigma \cup \{*\})^{(n\times m)}$. Note the here we assume that the contents in any cell is either empty or a proper element of Σ (and not a partial k-bit string).*

Another notation that is often used is the following:

▶ **Notation 11.** *If $A \leq \mathsf{S}_n$ and $B \leq \mathsf{S}_m$ are groups on $[n]$ and $[m]$ then the group $A \times B$ act on the cells on the matrix. Thus for any $(\sigma, \sigma') \in A \times B$ and a $M \in \Sigma^{(n\times m)}$ by $(\sigma, \sigma')[M]$ we would mean the permutation on the cell of M according to (σ, σ') and move the contains in the cells accordingly. Note that the relative position of bits within the contents in each cell is not touched.*

Next, we define the composition of two Boolean functions.

▶ **Definition 12** (Composition of functions)**.** *Let $f : \{0,1\}^{nk} \to \{0,1\}$ and $g : \{0,1\}^m \to \{0,1\}^k$ be two functions. The* composition of f and g*, denoted by $f \circ g : \{0,1\}^{nm} \to \{0,1\}$, is defined to be a function on nm bits such that on input $x = (x_1, \ldots, x_n) \in \{0,1\}^{nm}$, where each $x_i \in \{0,1\}^m$, $f \circ g(x_1, \ldots, x_n) = f(g(x_1), \ldots, g(x_n))$. We will refer f as* outer function *and g as* inner function*.*

2.2 Transitive Groups and Transitive Functions

The central objects in this paper are transitive Boolean function. We first define transitive groups.

▶ **Definition 13.** *A group $G \leq \mathsf{S}_n$ is transitive if for all $i, j \in [n]$ there exists a $\sigma \in G$ such that $\sigma(i) = j$.*

▶ **Definition 14.** *For $f : A^n \to \{0,1\}$ and $G \leq \mathsf{S}_n$ we say f is invariant under the action of G, if for all $\alpha_1, \ldots, \alpha_n \in A$.*

$$f(\alpha_1, \ldots, \alpha_n) = f(\alpha_{\sigma(1)}, \ldots, \alpha_{\sigma(n)}).$$

▶ **Observation 15.** *If $A \leq \mathsf{S}_n$ and $B \leq \mathsf{S}_m$ are transitive groups groups on $[n]$ and $[m]$ then the group $A \times B$ is a transitive group acting on the cells on the matrix.*

There are many interesting transitive groups. The symmetric group is indeed transitive. The graph isomorphism group (that acts on the adjacency matrix - minus the diagonal - of a graph by changing the ordering on the vertices) is transitive. The cyclic permutation over all the points in the set is a transitive group. The following is another non-trivial transitive group on $[k]$ that we will use extensively in this paper.

▶ **Definition 16.** *For any k that is a power of 2, the Binary-tree-transitive group Bt_k is a subgroup of S_k. To describe its generating set we think of group Bt_k acting on the elements $\{1, \ldots, k\}$ and the elements are placed in the leaves of a balanced binary tree of depth $\log k$ - one element in each leaf. Each internal node (including the root) corresponds to an element in the generating set of Bt_k. The element corresponding to an internal node in the binary tree swaps the left and right sub-tree of the node. The permutation element corresponding to the root node is called the Root-swap as it swaps the left and right sub-tree to the root of the binary tree.*

We now state two claims whose proofs we skip in this version of the paper but are available in the full version of the paper [15].

▷ Claim 17. The group Bt_k is a transitive group.

The following claim describes how the group Bt_k acts on various encoding of integers. Recall the balance-binary representation (Definition 9).

▷ Claim 18. For all $\widehat{\gamma} \in \mathsf{Bt}_{2\log n}$ there is a $\gamma \in \mathsf{S}_n$ such that for all $i, j \in [n]$, $\widehat{\gamma}[bb(i)] = bb(j)$ iff $\gamma(i) = j$.

Now let us consider another encoding that we will using for the set of rows and columns of a matrix.

▶ **Definition 19.** *Given a set R of n rows $r_1, \ldots, r_n$ and a set C of n columns $c_1, \ldots, c_n$ we define the balanced-pointer-encoding function $\mathcal{E} : (R \times \{0\}) \cup (\{0\} \times C) \to \{0,1\}^{4\log n}$, as follows:*

$$\mathcal{E}(r_i, 0) = bb(i) \cdot 0^{2\log n}, \text{ and, } \mathcal{E}(0, c_j) = 0^{2\log n} \cdot bb(j).$$

The following is a claim that is easy to verify.

▷ Claim 20. Let R be a set of n rows $r_1, \ldots, r_n$ and C be a set of n columns $c_1, \ldots, c_n$ and consider the *balanced-pointer-encoding function* $\mathcal{E} : (R \times \{0\}) \cup (\{0\} \times C) \to \{0,1\}^{4\log n}$. For any elementary permutation $\widehat{\sigma}$ in $\mathsf{Bt}_{4\log n}$ (other than the Root-swap) there is a $\sigma \in \mathsf{S}_n$ such that for any $(r_i, c_j) \in (R \times \{0\}) \cup (\{0\} \times C)$

$$\widehat{\sigma}[\mathcal{E}(r_i, c_j)] = \mathcal{E}(r_{\sigma(i)}, c_{\sigma(j)}),$$

where we assume $r_0 = c_0 = 0$ and any permutation of in S_n sends 0 to 0.

If $\widehat{\sigma}$ is the root-swap then for any $(r_i, c_j) \in (R \times \{0\}) \cup (\{0\} \times C)$

$$\widehat{\sigma}[\mathcal{E}(r_i, c_j)] = \mathsf{Swap}_{\frac{1}{2}}(\mathcal{E}(r_i, c_j)) = \mathcal{E}(c_j, r_i).$$

2.3 Pointer function

For the sake of completeness first we will describe the "pointer function" introduced in [4] that achieves separation between several complexity complexity measures like *Deterministic query complexity*, *Randomized query complexity*, *Quantum query complexity* etc. This function was originally motivated from a function in [20]. There are three three variants of the pointer function that have some special kind of non-Boolean domain, which we call *Pointer matrix*. Our function is a special "encoding" of that non-Boolean domain such that the resulting function becomes transitive and achieves the separation between complexity measures that matches the known separation between the general functions. Here we will define only the first variant of the pointer function.

▶ **Definition 21** (Pointer matrix over Σ)**.** *For $m, n \in \mathbb{N}$, let M be a $(m \times n)$ matrix with m rows and n columns. We refer to each of the $m \times n$ entries of M as* cells*. Each cell of the matrix is from a alphabet set Σ where $\Sigma = \{0,1\} \times \widetilde{P} \times \widetilde{P} \times \widetilde{P}$ and $\widetilde{P} = \{(i,j) | i \in [m], j \in [n]\} \cup \{\perp\}$. We call $\widetilde{P}$ as set of pointers where, pointers of the form $\{(i,j) | i \in [m], j \in [n]\}$ pointing to the cell (i,j) and $\perp$ is the null pointer. Hence,each entry $x_{(i,j)}$ of the matrix M is a 4-tuple from Σ. The elements of the 4-tuple we refer as* value*,* left pointer*,* right pointer *and* back pointer *respectively and denote by Value$(x_{(i,j)})$, LPointer$(x_{(i,j)})$, RPointer$(x_{(i,j)})$ and BPointer$(x_{(i,j)})$ respectively where Value $\in \{0,1\}$, LPointer, RPointer, BPointer $\in \widetilde{P}$. We call this type of matrix as* pointer matrix *and denote by $\Sigma^{n \times n}$.*

A special case of the pointer-matrix, which we call Type_1 pointer matrix over Σ*, is when for each cell of M, BPointer $\in \{[n] \cup \perp\}$ that is backpointers are pointing to the columns of the matrix.*

Also, in general when, BPointer $\in \{(i,j) | i \in [m], j \in [n]\} \cup \{\perp\}$, we call it a Type_2 pointer matrix over Σ.

Now we will define some additional properties of the domain that we need to define the pointer function.

▶ **Definition 22** (Pointer matrix with marked column)**.** *Let M be an $m \times n$* pointer-matrix *over Σ. A column $j \in [n]$ of M is defined to be a* marked column *if there exists exactly one cell (i,j), $i \in [m]$, in that column with entry $x_{(i,j)}$ such that $x_{(i,j)} \neq (1, \perp, \perp, \perp)$ and every other cell in that column is of the form $(1, \perp, \perp, \perp)$. The cell (i,j) is defined to be the* special element *of the* marked column *j.*

Let n be a power of 2. Let T be a rooted, directed and balanced binary tree with n-leaves and $(n-1)$ internal vertices. We will use the following notations that will be used in defining some functions formally.

▶ **Notation 23.** *Let n be a power of 2. Let T be a rooted, directed and balanced binary tree with n-leaves and $(n-1)$ internal vertices. Labels the edges of T as follows: the outgoing edges from each node are labeled by either $left$ or $right$. The leaves of the tree are labeled by the elements of $[n]$ from left to right, with each label used exactly once. For each leaf $j \in [n]$ of the tree, the path from the root to the leaf j defines a sequence of $left$ and $right$ of length $O(\log n)$, which we denote by $T(j)$.*

When n is not a power of 2, choose the largest $k \in \mathbb{N}$ such that $2^k \leq n$, consider a complete balanced tree with 2^k leaves and add a pair of child node to to each $n - 2^k$ leaves starting from left. Define $T(j)$ as before.

Now we are ready to describe the *Variant 1* of the pointer function.

▶ **Definition 24** (Variant 1 [4]). *Let* $\Sigma^{m\times n}$ *be a* Type_1 pointer matrix *where BPointer is a pointer of the form* $\{j|j \in [n]\}$ *that points to other column and LPointer, RPointer are as usual points to other cell. Define* $\mathsf{A1}_{(m,n)} : \Sigma^{m\times n} \to \{0,1\}$ *on a* Type_1 pointer matrix *such that for all* $x = (x_{i,j}) \in \Sigma^{m\times n}$*, the function* $\mathsf{A1}_{(m,n)}(x_{i,j})$ *evaluates to* 1 *if and only if it has a* 1- cell certificate *of the following form:*

1. *there exists exactly one* marked column $j^\star$ *in* M*,*
2. *There is a special cell, say* $(i^\star, j^\star)$ *which we call the special element in the the* marked column $j^\star$ *and there is a balanced binary tree* T *rooted at the special cell,*
3. *for each non-marked column* $j \in [n] \setminus \{j^\star\}$ *there exist a* cell l_j *such that* $Value(l_j) = 0$ *and* $BPointer(l_j) = j^\star$ *where* l_j *is the end of the path that starts at the* special element *and follows the pointers LPointer and RPointer as specified by the sequence* $T(j)$*.* l_j *exists for all* $j \in [n] \setminus \{j^\star\}$ *i.e. no pointer on the path is* $\perp$*. We refer* l_j *as the leaves of the tree.*

The above function achieves the separation between D vs. R_0 and D vs. Q for $m = 2n$. Here we will restate some of the results from [4] which we will use to prove the results for our function:

▶ **Theorem 25** ([4]). *The function* $\mathsf{A1}_{(m.n)}$ *in Definition 24 satisfies*

$\mathsf{D} = \Omega(n^2)$ *for* $m = 2n$ *where* $m, n \in \mathbb{N}$,

$\mathsf{R}_0 = \widetilde{O}(m+n)$ *for any* $m, n \in \mathbb{N}$,

$\mathsf{Q} = \widetilde{O}(\sqrt{m}+\sqrt{n})$ *for any* $m, n \in \mathbb{N}$.

Though [4] gives the deterministic lower bound for the function $\mathsf{A1}$ precisely for $2m \times m$ matrices following the same line of argument it can be proved that $\mathsf{D}(\Omega(n^2))$ holds for $n \times n$ matrices also. For sake of completeness we give a proof for $n \times n$ matrices in the full version of this paper [15].

▶ **Theorem 26.** $\mathsf{D}(\mathsf{A1}_{(n,n)}) = \Omega(n^2)$.

Also [20]'s function realises quadratic separation between D and deg and the proof goes via UC_{min} upper bound. But $\mathsf{A1}_{(n,n)}$ exhibits the same properties corresponding to UC_{min}. So, from the following observation it follows that $\mathsf{A1}_{(n,n)}$ also achieves quadratic separation between D and deg.

▶ **Observation 27.** $\deg(\mathsf{A1}_{(n,n)}) = O(n)$ *for any* $n \in \mathbb{N}$.

Another important observation that we need is the following:

▶ **Observation 28** ([4]). *For any input* $\Sigma^{n\times n}$ *to the function* $\mathsf{A1}_{(n,n)}$ *(in Definition 24) if we permute the rows of the matrix using a permutation* σ_r *and permute the columns of the matrix using a permutation* σ_c *and we update the pointers in each of the cells of the matrix accordingly then the function value does not change.*

3 High level description of our techniques

Pointer functions are defined over a special domain called *pointer matrix*, which is a $m \times n$ grid matrix. Each cell of the matrix contains some labels and some pointers that point either to some other cell or to a row or column [6]. As described in [20], the high level idea of pointer

[6] We naturally think of a pointer pointing to a cell as two pointers - one pointing to the row and the other to the column.

functions is the usage of pointers to make certificates unambiguous without increasing the input size significantly. This technique turns out to be very useful to give separations between various complexity measures as we see in [24], [19] and [4].

Now we want to produce a new function that possesses all the properties of pointer functions, along with the additional property of being transitive. To do so, first, we will encode the labels so that we can permute the bits (by a suitable transitive group) while keeping the structure of unambiguous certificates intact so that the function value remains invariant. One such natural technique would be to encode the contents of each cell in such a way that allows us to permute the bits of the contents of each cell using a transitive group and permute the cells among each other using another transitive group, and doing all of these while ensuring the unambiguous certificates remains intact [7]. This approach has a significant challenge: namely how to encode the pointers.

The information stored in each cell (other than the pointers) can be encoded using fixed logarithmic length strings of different Hamming weights - so that even if the strings are permuted and/or the bits in each string are permuted, the content can be "decoded". Unfortunately, this can only be done when the cell's contents have a constant amount of information - which is the case for pointer functions (except for the pointers). Since the pointers in the cell are strings of size $O(\log n)$ (as they are pointers to other columns or rows), if we want to use the similar Hamming weight trick, the size of the encoding string would need to be polynomial in $O(n)$. That would increase the size of the input compared to the unambiguous certificate. This would not give us tight separation results.

Also, there are three more issues concerning the encodings of pointers:

- As we permute the cells of the matrix according to some transitive group, the pointers within each cell need to be appropriately changed. In other words, when we move some cell's content to some other cell, the pointers pointing to the previous cell should point to the current cell now.
- If a pointer is encoded using a certain t-bit string, different permutations of bits of the encoded pointer can only generate a subset of all t-bit strings.
  For example: if we encode a pointer using a string of Hamming weight 10 then however we permute the bits of the string, the pointer can at most be modified to point to cells (or rows or columns) the encoding of whose pointers also have Hamming weight 10. (The issue is that permuting the bits of a string cannot change the Hamming weight of a string).
  The encoding of all the pointers should have the same Hamming weight.
- The encoding of the pointers has to be transitive. That is, we should be able to permute the bits of the encodings of the pointer using a transitive group in such a way that either the pointer value does not change or as soon as the pointer values changes, the cells gets permuted accordingly - kind of like an "entanglement".

The above three problems are somewhat connected. Our first innovative idea is to use *binary balance representation* (Definition 9) to represent the pointers. This way, we take care of the second issue. For the first and third issues, we define the transitive group – both the group acting on the contents of the cells (and hence on the encoding of the pointers) and the group acting on the cells itself – in a "entangled" manner. For this we induce a group action

[7] Here, we use the word "encode" since we can view the function defined only over codewords, and when the input is not a codeword, then it evaluates to 0. In our setting, since we are trying to preserve the one-certificates, the codewords are those strings where the unambiguous certificate is encoded correctly. At the same time, we must point out that the encoding of an unambiguous certificate is not necessarily unique.

acting on the nodes of a *balanced binary tree* and generate a transitive subgroup in S_n and $S_{2\log n}$ with the same action which will serve our purpose (Definition 16, Claim 18). This helps us to permute the rows (or columns) using a permutation while updating the encoding of the pointers accordingly.

By Claim 18, for every allowed permutation σ acting on the rows (or columns), there is a unique $\widehat{\sigma}$ acting on the encodings of the pointers in each of the cells such that the pointers are updated according to σ. This still has a delicate problem. Namely, each pointer is either pointing to a row or column. But the permutation $\widehat{\sigma}$ has no way to understand whether the encoding on which it is being applied points to a row or column. To tackle this problem, we think of the set of rows and columns as a single set. All of them are encoded by a string of size (say) $2t$, where for the rows, the second half of the encoding is all 0 while the columns have the first t bits all 0. This is the encoding described in Definition 19 using binary balanced representation. However, this adds another delicate issue about permuting between the first t bits of the encoding and the second t bits.

To tackle this problem, we modify the original function appropriately. We define a slightly modified version of existing pointer functions called $\mathsf{ModA1}$. This finally helps us obtain our "transitive pointer function," which has almost the same complexities as the original pointer function.

We have so far only described the high-level technique to make the 1st variation of pointer functions (Definition 24) transitive where there is the same number of rows and columns. The further variations need more delicate handling of the encoding and the transitive groups - though the central idea is similar.

4 Proof of Theorem 1

4.1 Transitive Pointer Function F_1 for Theorem 1

Our function $F_1 : \Gamma^{n\times n} \to \{0,1\}$ is a composition of two functions - an outer function $\mathsf{ModA1}_{(n,n)} : \bar{\Sigma}^{n\times n} \to \{0,1\}$ and an inner function $\mathsf{Dec} : \Gamma \to \bar{\Sigma}$. We will set Γ to be $\{0,1\}^{96\log n}$.

The outer function is a modified version of the $\mathsf{A1}_{(n,n)}$ - pointer function described in [4] (see Definition 24 for a description). The function $\mathsf{A1}_{(n,n)}$ takes as input a $(n\times n)$-matrix whose entries are from a set Σ and the function evaluates to 1 if a certain kind of 1-cell-certificate exists. Let us define a slightly modified function $\mathsf{ModA1}_{(n,n)} : \bar{\Sigma}^{n\times n} \to \{0,1\}$ where $\bar{\Sigma} = \Sigma \times \{\vdash, \dashv\}$. We can think of an input $A \in \bar{\Sigma}^{n\times n}$ as a pair of matrices $B \in \Sigma^{n\times n}$ and $C \in \{\vdash, \dashv\}^{n\times n}$. The function $\mathsf{ModA1}_{(n,n)}$ is defined as

$$\mathsf{ModA1}_{(n,n)}(A) = 1 \text{ iff } \begin{cases} \text{Either,} & \text{(i) } \mathsf{A1}_{(n,n)}(B) = 1, \text{ and, all the cells in the} \\ & \text{1-cell-certificate have } \vdash \text{ in the corresponding cells in } C \\ \text{Or,} & \text{(ii) } \mathsf{A1}_{(n,n)}(B^T) = 1, \text{ and, all the cells in the} \\ & \text{1-cell-certificate have } \dashv \text{ in the corresponding cells in } C^T \end{cases}$$

Note that both the two conditions (i) and (ii) cannot be satisfied simultaneously. From this it is easy to verify that the function $\mathsf{ModA1}_{(n,n)}$ has all the properties as $\mathsf{A1}_{(n,n)}$ as described in Theorem 25.

The inner function Dec (we call it a decoding function) is function from Γ to $\bar{\Sigma}$, where $\Gamma = 96\log n$. Thus our final function is

$$F_1 := \left(\mathsf{ModA1}_{(n,n)} \circ \mathsf{Dec}\right) : \Gamma^{n\times n} \to \{0,1\}.$$

4.1.1 Inner Function Dec

The input to $\mathsf{A1}_{(n,n)}$ is a Type_1 pointer matrix $\Sigma^{n\times n}$. Each cell of a Type_1 pointer matrix contains a 4-tuple of the form (Value, LPointer, RPointer, BPointer) where Value is either 0 or 1 and LPointer, RPointer are pointers to the other cells of the matrix and BPointer is a pointer to a column of the matrix (or can be a null pointer also). Hence, $\Sigma = \{0,1\} \times [n]^2 \times [n]^2 \times [n]$. For the function $\mathsf{A1}_{(n,n)}$ it was assumed (in [4]) that the elements of Σ is encoded as a k-length[8] binary string in a canonical way.

The main insight for our function $F_1 := \left(\mathsf{ModA1}_{(n,n)} \circ \mathsf{Dec}\right)$ is that we want to maintain the basic structure of the function $\mathsf{A1}_{(n,n)}$ (or rather of $\mathsf{ModA1}_{(n,n)}$) but at the same time we want to encode the $\bar{\Sigma} = \Sigma \times \{\vdash, \dashv\}$ in such a way that the resulting function becomes transitive. To achieve this, instead of having a unique way of encoding an element in $\bar{\Sigma}$ we produce a number of possible encodings[9] for any element in $\bar{\Sigma}$. The inner function Dec is therefore a decoding algorithm that given any proper encoding of an element in $\bar{\Sigma}$ will be able to decode it back.

For the ease of understanding we start by describing the possible "encodings" of $\bar{\Sigma}$, that is by describing the pre-images of any element of $\bar{\Sigma}$ in the function Dec.

"Encodings" of the content of a cell in $\bar{\Sigma}^{n\times n}$. We will encode any element of $\bar{\Sigma}$ using a string of size $96\log n$ bits. Recall that, an element in $\bar{\Sigma}$ is of the form $(V, (r_L, c_L), (r_R, c_R), (c_B), T)$, where V is the Boolean value, (r_L, c_L), (r_R, c_R) and c_B are the left pointer, right pointers and bottom pointer respectively and T take the value $\vdash$ or $\dashv$. The overall summary of the encoding is as follows:

- **Parts:** We will think of the tuple as 7 objects, namely V, r_L, c_L, r_R, c_R, c_B and T. We will use $16\log n$ bits to encode each of the first 6 objects. The value of T will be encoded in a clever way. So the encoding of any element of $\bar{\Sigma}$ contains 6 *parts* - each a binary string of length $16\log n$.
- **Blocks:** Each of 6 *parts* will be further broken into 4 *blocks* of equal length of $4\log n$. One of the blocks will be a special block called the "encoding block".

Now we explain, for a tuple $(V, (r_L, c_L), (r_R, c_R), (c_B), T)$ what is the 4 blocks in each part. We will start by describing a "standard-form" encoding of a tuple $(V, (r_L, c_L), (r_R, c_R), (c_B), T)$ when $T = \vdash$. Then, we will extend it to describe the standard for encoding the tuple when $T = \dashv$. And finally we will explain all other valid encoding of the tuple by describing all the allowed permutations on the bits of the encoding.

Standard-form encoding of $(V, (r_L, c_L), (r_R, c_R), (c_B), T)$ where $T = \vdash$. For the standard form of encoding we will assume that the information of $V, r_L, c_L, r_R, c_R, c_B$ are stored in parts $P1, P2, P3, P4, P5$ and $P6$ respectively. For all $i \in [6]$, the part P_i with have blocks B_1, B_2, B_3 and B_4, of which the block B_1 will be the encoding-block. The encoding will ensure that every parts within a cell will have distinct Hamming weight. The description is also compiled in the Table 2.

- For part $P1$ (that is the encoding of V) the encoding block B_1 will store $\ell_1 \cdot \ell_2$ where ℓ_1 be the $2\log n$ bit binary string with Hamming weight $2\log n$ and ℓ_2 is any $2\log n$ bit binary string with Hamming weight $2\log n - 1 - V$. The blocks B_2, B_3 and B_4 will store a $4\log n$ bit string that has Hamming weight $4\log n, 2\log n + 1$ and $2\log n + 2$ respectively. Any

[8] For the canonical encoding $k = (1 + 5\log n)$ was sufficient

[9] We use the term "encoding" a bit loosely in this context as technically an encoding means a unique encoding. What we actually mean is the pre-images of the function Dec.

Table 2 Standard form of encoding of element $(V,(r_L,c_L),(r_R,c_R),c_B,\vdash)$ by a $96\log n$ bit string that is broken into 6 parts $P_1,\ldots,P_6$ of equal size and each Part is further broken into 4 Blocks B_1,B_2,B_3 and B_4. So all total there are 24 blocks each containing a $4\log n$-bit string. For the standard form of encoding of element $(V,(r_L,c_L),(r_R,c_R),c_B,\dashv)$ we encode $(V,(r_L,c_L),(r_R,c_R),c_B,\vdash)$ in the standard form as described in the table and then apply the $\mathsf{Swap}_{\frac{1}{2}}$ on each block. The last column of the table indicates the Hamming weight of each Part.

...	B_1 "encoding"-block	B_2	B_3	B_4	Hamming weight
$P1$	$\ell_1\ell_2$, where $\lvert\ell_1\rvert = 2\log n$, and $\lvert\ell_2\rvert = 2\log n - 1 - V$	$4\log n$	$2\log n+1$	$2\log n+2$	$12\log n+2-V$
$P2$	$\mathcal{E}(r_L,0)$	$2\log n+3$	$2\log n+1$	$2\log n+2$	$7\log n+6$
$P3$	$\mathcal{E}(0,c_L)$	$2\log n+4$	$2\log n+1$	$2\log n+2$	$7\log n+7$
$P4$	$\mathcal{E}(r_R,0)$	$2\log n+5$	$2\log n+1$	$2\log n+2$	$7\log n+8$
$P5$	$\mathcal{E}(0,c_R)$	$2\log n+6$	$2\log n+1$	$2\log n+2$	$7\log n+9$
$P6$	$\mathcal{E}(0,c_B)$	$2\log n+7$	$2\log n+1$	$2\log n+2$	$7\log n+10$

fixed string with the correct Hamming weight will do. We are not fixing any particular string for the blocks B_2, B_3 and B_4 to emphasise the fact that we will be only interested in the Hamming weights of these strings.

- The encoding block $B1$ for parts $P2,P3,P4,P5$ and $P6$ will store the string $\mathcal{E}(r_L,0)$, $\mathcal{E}(0,c_L)$, $\mathcal{E}(r_R,0)$, $\mathcal{E}(0,c_r)$ and $\mathcal{E}(0,C_B)$ respectively, where $\mathcal{E}$ is the Balanced-pointer-encoding function (Definition 19). For part P_i (with $2\le i\le 6$) block B_2,B_3 and B_4 will store any $4\log n$ bit string with Hamming weight $2\log n+1+i$, $2\log n+1$ and $2\log n+2$ respectively.

Standard form encoding of $(V,(r_L,c_L),(r_R,c_R),(c_B),T)$ where $T=\dashv$. For obtaining a standard-form encoding of $(V,(r_L,c_L),(r_R,c_R),(c_B),T)$ where $T=\dashv$, first we encode $(V,(r_L,c_L),(r_R,c_R),(c_B),T)$ where $T=\vdash$ using the standard-form encoding. Let $(P1,P2,\ldots,P6)$ be the standard-form encoding of $(V,(r_L,c_L),(r_R,c_R),(c_B),T)$ where $T=\vdash$. Now for each of the block apply the $\mathsf{Swap}_{\frac{1}{2}}$ operator.

Valid permutation of the standard form. Now we will give a set of valid permutations to the bits of the encoding of any element of $\bar{\Sigma}$. The set of valid permutations are classified into into 3 categories:

1. Part-permutation: The 6 parts can be permuted using any permutation from S_6
2. Block-permutation: In each of the part, the 4 blocks (say B_1,B_2,B_3,B_4) can be permuted is two ways. (B_1,B_2,B_3,B_4) can be send to one of the following:

   (a) Simple Block Swap: (B_3,B_4,B_1,B_2) (b) Block Flip: $(B_2,B_1,\mathsf{flip}(B_3),\mathsf{flip}(B_4))$

The "decoding" function $\mathbf{Dec}:\{0,1\}^{96\log n}\to\bar{\Sigma}$.

- Identify the parts containing the encoding of V, r_L, c_L, r_R, c_R and c_B. This is possible because every part has a unique Hamming weight.
- For each part identify the blocks. This is also possible as in any part all the blocks have distinct Hamming weight. Recall, the valid Block-permutations, namely Simple Block Swap and Block Flip. By seeing the positions of the blocks one can understand if flip was applied and to what and using that one can revert the blocks back to the standard-form (recall Definition 9).

- In the part containing the encoding of V consider the encoding-block. If the block is of the form $\{(\ell_1\ell_2)$ such that $|\ell_1| = 2\log n, |\ell_2| \leq 2\log n - 1\}$ then $T = \{\vdash\}$. If the block is of the form $\{(\ell_2\ell_1)$ such that $|\ell_1| = 2\log n, |\ell_2| \leq 2\log n - 1\}$ then $T = \{\dashv\}$.
- By seeing the encoding block we can decipher the original values and the pointers.
- If the $96\log n$ bit string doesn't have the form of a valid encoding, then decode it as $(0, \perp, \perp, \perp)$.

4.2 Proof of Transitivity of the function

We start with describing the transitive group for which F_1 is transitive.

The Transitive Group. We start with describing a transitive group $\mathcal{T}$ acting on the cells of the matrix A. The matrix has rows $r_1, \ldots, r_n$ and columns $c_1, \ldots, c_n$. And we use the encoding function $\mathcal{E}$ to encode the rows and columns. So the index of the rows and columns are encoded using a $4\log n$ bit string. A permutation from $\mathsf{Bt}_{4\log n}$ (see Definition 16) on the indices of a $4\log n$ bit string will therefore induce a permutation on the set of rows and columns which will give us a permutation on the cells of the matrix. We will now describe the group $\mathcal{T}$ acting on the cells of the matrix by describing the permutation group $\widehat{\mathcal{T}}$ acting on the indices of a $4\log n$ bit string. The group $\widehat{\mathcal{T}}$ will be the group $\mathsf{Bt}_{4\log n}$ acting on the set $[4\log n]$. We will assume that $\log n$ is a power of 2. The group $\mathcal{T}$ with be the resulting group of permutations on the cells of the matrix induced by the group $\widehat{\mathcal{T}}$ acting on the indices on the balanced-pointer-encoding. Note that $\mathcal{T}$ is acting on the domain of $\mathcal{E}$ and $\widehat{\mathcal{T}}$ is acting on the image of $\mathcal{E}$. Also $\widehat{\mathcal{T}}$ is a transitive subgroup of $\mathsf{S}_{4\log n}$ from Claim 17.

▶ **Observation 29.** *For any $1 \leq i \leq 2\log n$ consider the permutation "ith-bit-flip" in $\widehat{\mathcal{T}}$ that applies the transposition $(2i-1, 2i)$ to the indices of the balanced-pointer-encoding. Since the $\mathcal{E}$-encoding of the row $(r_k, 0)$ uses the balanced binary representation of k in the first half and all zero sting in the second half, the jth bit in the binary representation of k is stored in the $2j-1$ and $2j$-th bit in the $\mathcal{E}$-encoding of r_i. So the j-th-bit-flip acts on the sets of rows by swapping all the rows with 1 in the j-th bit of their index with the corresponding rows with 0 in the j-th bit of their index. Also, if $i > \log n$ then there is no effect of the i-th-bit-flip operation on the set of rows. Similarly for the columns.*

Using Observation 29 we have the following claim.

▷ Claim 30. The group $\mathcal{T}$ acting on the cells of of the matrix is a transitive group. That is, for all $1 \leq i_1, j_1, i_2, j_2 \leq n$ there is a permutation $\widehat{\sigma} \in \widehat{\mathcal{T}}$ such that $\widehat{\sigma}[\mathcal{E}(i_1, 0)] = \mathcal{E}(i_2, 0)$ and $\widehat{\sigma}[\mathcal{E}(0, j_1)] = (0, j_2)$. Or in other words, there is a $\sigma \in \mathcal{T}$ acting on the cell of the matrix that would take the cell corresponding to row r_{i_1} and column c_{j_1} to the cell corresponding to row r_{i_2} and column c_{j_2}.

From the Claim 30 we see the group $\mathcal{T}$ acting on the cells of of the matrix is a transitive. But it does not touch the contents within the cells of the matrix. But the input to the function F_1 contains element of $\Gamma = \{0,1\}^{96\log n}$ in each cell. So we now need to extend the group $\mathcal{T}$ to a group G that acts on all the indices of the bits of the input to the function F_1.

Recall that the input to the function F_1 is a $(n \times n)$-matrix with each cell of matrix containing a binary string of length $96\log n$ which has 6 parts of size $16\log n$ each and each part has 4 blocks of size $4\log n$ each. We classify the generating elements of the group G into 4 categories:

1. Part-permutation: In each of the cells the 6 parts can be permuted using any permutation from S_6

2. Block-permutation: In each of the Parts the 4 blocks can be permuted in the following ways. (B_1, B_2, B_3, B_4) can be send to one of the following
   a. Simple Block Swap: (B_3, B_4, B_1, B_2)
   b. Block Flip (#1): $(B_2, B_1, \mathsf{flip}(B_3), \mathsf{flip}(B_4))$
   c. Block Flip (#2)[10]: $(\mathsf{flip}(B_1), \mathsf{flip}(B_2), B_4, B_3)$
3. Cell-permutation: for any $\sigma \in \mathcal{T}$ the following two action has to be done simultaneously:
   a. (Matrix-update) Permute the cells in the matrix according to the permutation σ. This keeps the contents within each cells untouched - it just changes the location of the cells.
   b. (Pointer-update) For each of blocks in each of the parts in each of the cells permute the indices of the $4 \log n$-bit strings according to σ, that is apply $\widehat{\sigma} \in \widehat{\mathcal{T}}$ corresponding to σ.

We now have the following theorems that would prove that the function F_1 is transitive.

▶ **Theorem 31.** *G is a transitive group and the function F_1 is invariant under the action of the G.*

Proof of Theorem 31. To prove that the group G is transitive we show that for any indices $p, q \in [96n^2 \log n]$ there is a permutation $\sigma \in \mathsf{G}$ that would take p to q. Recall that the string $\{0,1\}^{96n^2 \log n}$ is a matrix $\Gamma^{(n \times n)}$ with $\Gamma = \{0,1\}^{96 \log n}$ and every element in Γ is broken into 6 parts and each part being broken into 4 block of size $4 \log n$ each. So we can think of the index p as sitting in k_pth position $(1 \leq k_p \leq 4 \log n)$ in the block B_p of the part P_p in the (r_p, c_p)-th cell of the matrix. Similarly, we can think of q as sitting in k_qth position $(1 \leq k_q \leq 4 \log n)$ in the block B_q of the part P_q in the (r_q, c_q)-th cell of the matrix.

We will give a step by step technique in which permutations from G can be applied to move p to q.

- **Step 1: Get the positions in the block correct:** If $k_p \neq k_q$ then take a permutation $\widehat{\sigma}$ from $\widehat{\mathcal{T}}$ that takes k_p to k_q. Since $\widehat{\mathcal{T}}$ is a transitive so such a permutation exists. Apply the cell-permutation $\sigma \in \mathcal{T}$ corresponding to $\widehat{\sigma}$. As a result the index p can be moved to a different cell in the matrix but, by the choice of $\widehat{\sigma}$ its position in the block in which it is will be k_q. Without loss of generality, we assume the the cell location does not change.
- **Step 2: Get the cell correct:** Using a cell-permutation that corresponds to a series of "bit-flip" operations change r_p to r_q and c_p to c_q. Since one bit-flip operations basically changes one bit in the binary representation of the index of the row or column such a series of operations can be made.
  Since each bit-flip operation is executed by applying the bit-flips in each of the blocks so this might have once again changed the position of the index p in the block. But, even if the position in the block changes it must be a flip operation away. Or in other word, since in the beginning of this step $k_p = k_q$, so if k_q is even (or odd) then after the series bit-flip operations the position of p in the block is either k_q or $(k_q - 1)$ (or $(k_q + 1)$).
- **Step 3: Align the Part:** Apply a suitable permutation to ensure that the part P_p moves to part P_q. Note this does not change the cell or the block within the part or the position in the block.

[10] Actually this Block flip can be generated by a combination of Simple Block Swap and Block Flip (#1)

- **Step 4: Align the Block:** Using a suitable combination of Simple Block Swap and Block Flip ensures the Block number gets matched, that is B_p goes to B_q. In this case the cell or the Part does not change. But depending on whether the Block Flip operation is applied the position in the block can again change. But, the current position in the block k_p is at most one flip away from k_q.
- **Step 5: Apply the final flip:** It might so happen that already we a done after the last step. If not we know that the current position in the block k_p is at most one flip away from k_q. So we apply the suitable Block-flip operation. Thus will not change the cell position, Part number, Block number and the position in the block will match.

Hence we have proved that the group G is transitive. Now we show that the the function F_1 is invariant under the action of G, i.e., for any elementary operations π from the group G and for any input $\Gamma^{(n\times n)}$ the function value does not change even if after the input is acted upon by the permutation π.

Case 1: π is a Part-permutation: It is easy to see that the decoding algorithm Dec is invariant under Part-permutation. This was observed in description of the decoding algorithm Dec in Section 4.1.1. So clearly that the function F_1 is invariant under any Part-permutation.

Case 2: π is a Block-permutation: Here also it is easy to see that the decoding algorithm Dec is invariant under Block-permutation. This was observed in description of the decoding algorithm Dec in Section 4.1.1. Thus F_1 is also invariant under any Block-permutation.

Case 3: π is a Cell-permutation From Observation 28 it is enough to prove that when we permute the cells of the matrix we update the points in the cells accordingly.

Let $\pi \in \mathcal{T}$ be a permutation that permutes only the rows of the matrix. By Claim 20, we see that the contents of the cells will be updated accordingly. Similarly if π only permute the columns of the matrix we will be fine.

Finally, if π swaps the row set and the column set (that is if π makes a transpose of the matrix) then for all i row i is swapped with column i and it is easy to see that $\widehat{\pi}[\mathcal{E}(i,0)] = \mathcal{E}(0,i)$. In that case the encoding block of the value part in a cell also gets swapped. This will thus be encoding the T value as $\dashv$. And so the function value will not be affected as the $T = \dashv$ will ensure that one should apply the π that swaps the row set and the column set to the input before evaluating the function. ◀

4.3 Properties of the Function

▷ Claim 32. Deterministic query complexity of F_1 is $\Omega(n^2)$.

Proof. The function $\mathsf{ModA1}_{(n,n)}$ is a "harder" function than $\mathsf{A1}_{(n,n)}$. So $\mathsf{D}(\mathsf{ModA1}_{(n,n)})$ is at least that of $\mathsf{D}(\mathsf{A1}_{(n,n)})$. Now since, F_1 is $\left(\mathsf{ModA1}_{(n,n)} \circ \mathsf{Dec}\right)$ so clearly the $\mathsf{D}(F_1)$ is at least $\mathsf{D}(\mathsf{A1}_{(n,n)})$. Theorem 26 proves that $\mathsf{D}(\mathsf{A1}_{(n,n)})$ is $\Omega(n^2)$. Hence $\mathsf{D}(F_1) = \Omega(n^2)$. ◁

The following Claim 33 follows from the definition of the function $\mathsf{ModA1}_{(n,n)}$.

▷ Claim 33. The following are some properties of the function $\mathsf{ModA1}_{(n,n)}$

1. $\mathsf{R}_0(\mathsf{ModA1}_{(n,n)}) \leq 2\mathsf{R}_0(\mathsf{A1}_{(n,n)}) + O(n \log n)$
2. $\mathsf{Q}(\mathsf{ModA1}_{(n,n)}) \leq 2\mathsf{Q}(\mathsf{A1}_{(n,n)}) + O(n \log n)$
3. $\deg(\mathsf{ModA1}_{(n,n)}) \leq 2\deg(\mathsf{A1}_{(n,n)}) + O(n \log n)$

Finally, from "composition theorem" (formal proof of which is presented in the full version of the paper [15]) we see that the $\mathsf{R}_0(F_1)$, $\mathsf{Q}(F_1)$ and $\deg(F_1)$ are at most $O(\mathsf{R}_0(\mathsf{ModA1}_{(n,n)} \cdot \log n)$, $O(\mathsf{Q}(\mathsf{ModA1}_{(n,n)} \cdot \log n)$ and $O(\deg(\mathsf{ModA1}_{(n,n)} \cdot \log n)$, respectively. So combining this fact with Claim 32, Claim 33 and Theorem 25 (from [4]) we have Theorem 1.

5 Challenges in transitive versions of "cheat sheet" based functions

In this section we show that it is not possible to give a quadratic separation between degree and quantum query complexity for transitive functions by modifying the cheat sheet function using the techniques in [1] which go via unambiguous certificate complexity.

Let us start by recalling the cheat sheet framework from [1]. Let $f : \{0,1\}^n \to \{0,1\}$ be a total Boolean function. Let $C(f)$ be its certificate complexity and $Q(f)$ be its bounded-error quantum query complexity. We consider the following cheat sheet function, which we denote by $f_{CS,t} : \{0,1\}^{n\times\log t+t\times\log t\times C(f)\times\log n} \to \{0,1\}$:

- There are $\log t$ copies of f on disjoint sets on inputs denoted by $f_1, \ldots, f_{\log t}$.
- There are t cheat sheets: each cheat sheet is a block of $(\log t \times C(f) \times \log n)$ many bits
- Let $x_1, \ldots, x_{\log t} \in \{0,1\}^n$ denote the input to the $\log t$ copies of f and let $Y_1, \ldots, Y_t$ denote the t cheat sheets.
- Let $\ell = (f(x_1), \ldots, f(x_{\log t}))$. $f_{CS,t}$ evaluates to 1 if and only if Y_ℓ is a valid cheat sheet.

Separations between various complexity measures was shown in [1] using the cheat sheet framework. In [1], the separations that lower bound bounded-error quantum query complexity in terms of other complexity measures, for example degree, are obtained as follows:

1. Start with a total function $f : \{0,1\}^n \to \{0,1\}$ that has quadratic separation between quantum query complexity and certificate complexity: $Q(f) = \widetilde{\Omega}(n)$ and $C(f) = \widetilde{O}(\sqrt{n})$. Consider the cheat sheet version of this function $f_{CS,t}$, with $t = n^{10}$.
2. Lower bound $Q(f_{CS,t})$, for $t = n^{10}$, by $Q(f)$. This uses the hybrid method ([10]) and strong direct product theorem ([22]).
3. Upper bound degree of $f_{CS,t}$ by using the upper bound on the unambiguous certificate complexity of $f_{CS,t}$.

Instead of degree, one might use approximate degree in the third step above for a suitable choice of f (see [1] for details).

A natural approach to obtain a transitive function with gap between a pair of complexity measures is to modify the cheat sheet framework to make it transitive. One possible modification is to allow a poly-logarithmic blowup in the input size of the resulting transitive function while preserving complexity measures of the cheat sheet function that are of interest (upto poly-logarithmic factors).

We show, however, that it is not possible to obtain a quadratic separation between degree and quantum query complexity for transitive functions by modifying the cheat sheet function using the techniques in [1] which go via unambiguous certificate complexity. The reason for this is that the unambiguous certificate complexity of a transitive cheat sheet function on N-bits is $\Omega(\sqrt{N})$ (see Observation 34) whereas we show (see Lemma 35) that the quantum query complexity of such a function is $o(N)$.

Note that this does not mean that cheat sheet framework can not be made transitive to show such a quadratic gap. If the cheat sheet version of a function that is being made transitive has a better degree upper bound than that given by unambiguous certificate complexity then a better gap might be possible.

To formalize the above discussion we first need the following observation that lower bounds the certificate complexity of any transitive function.

▶ **Observation 34** ([30]). *Let $f : \{0,1\}^N \to \{0,1\}$ be a transitive function, then $C(f) \geq \sqrt{N}$.*

Next, we upper bound on quantum query complexity of cheat sheet function using quantum amplitude amplification ([11]). The details of proof of the following lemma can be found in the full version of this paper [15].

▶ **Lemma 35.** *The quantum query complexity of $f_{CS,t}$ is $O(\sqrt{t} \times \log t \times \sqrt{n} \times \log n)$.*

The cheat sheet version of f, $f_{CS,t}$, is a function on $\widetilde{\Theta}(n + C(f)t)$ many variables, where t is polynomial in n. From the cheat sheet property the unambiguous certificate complexity of $f_{CS,t}$, denoted by $\mathsf{UC}(f_{CS,t})$, is $\widetilde{\Theta}(C(f))$.

Let $\widetilde{f_{CS,t}}$ be a modified transitive version of $f_{CS,t}$ that preserves the quantum query complexity and certificate complexity of $f_{CS,t}$ upto poly-logarithmic factors, respectively. From Observation 34 it follows that $\mathsf{UC}(\widetilde{f_{CS,t}}) = \widetilde{\Omega}(\sqrt{n + C(f)t})$. On the other hand, since $\widetilde{f_{CS,t}}$ preserves the certificate complexity upto poly-logarithmic factors, $\mathsf{UC}(\widetilde{f_{CS,t}}) = \widetilde{O}(C(f))$. This implies that $t = \widetilde{O}(C(f))$. Lemma 35 that $Q(f_{CS,t})$ is at most $\widetilde{O}(C(f)\sqrt{t})$. Thus in order to achieve quadratic separation between UC and Q, t has to be $\widetilde{\Omega}(C(f)^2)$.

We end this section by giving a concrete approach towards showing separation between degree and quantum query complexity for a transitive functions using the cheat sheet method. We believe the it is possible to start with $f_{CS,t}$, for transitive function f and $t = \sqrt{n}$ and convert it to a transitive function that preserves the unambiguous certificate complexity and quantum query complexity upto poly-logarithmic factors, while incurring a poly-logarithmic blowup in the input size. However, we do not know how to prove quantum query complexity lower bound matching our upper bound from Lemma 35 for $t = \sqrt{n}$. We make the following conjecture towards this end, which, if true, implies that for a transitive function f, $Q(f) = \widetilde{\Omega}(\deg(f)^{4/3})$.

▶ **Conjecture 36.** *There exists a transitive function $f : \{0,1\}^n \to \{0,1\}$ with $C(f) = \widetilde{O}(\sqrt{n})$ and $Q(f) = \widetilde{\Omega}(n)$. Let $f_{CS,\sqrt{n}}$ be the cheat sheet version of f with $\sqrt{n}$ cheat sheets. Then $Q(f_{CS,\sqrt{n}}) = \Omega(n^{3/4})$.*

It was showed in [1] that the quantum query complexity of the cheat function $f_{CS,t}$, i.e. $Q(f_{CS,t})$, is lower bounded by $Q(f)$, when $t = n^{10}$. Their proof goes via he hybrid method ([10]) and strong direct product theorem ([22]). Is is interesting to find the the constant smallest c such that $Q(f_{CS,n^c}) = \Omega(Q(f))$. We know that such a c must be at least than 1 (from Lemma 35) and is at most 10 (from [1]). We state this formally below:

▶ **Question 37.** *Let $f : \{0,1\}^n \to \{0,1\}$ be a non-constant Boolean function and let f_{CS,n^c} be its cheat sheet version with n^c cheat sheets. What is the smallest c such that the following is true $Q(f_{CS,n^c}) = \Omega(Q(f))$.*

6 Conclusion

As far as we know, this is the first paper that presents a thorough investigation on the relationships between various pairs of complexity measures for transitive function.

The current best-known relationships and best-known separations between various pairs of measures for transitive functions are summarized in the Table 1. Unfortunately, a number of cells in the table are not tight. In this context, we would like to point out some important directions:

- For some of these cells, the separation results for transitive functions are weaker than that of the general functions. A natural question is the following: why can't we design a transitive version of the general functions that achieve the same separation? For some cases, like the cheat sheet-based functions, we discuss the difficulties and possible directions in Section 5. Thus following is a natural question.

  ▶ **Open Problem 38.** *For a pair of complexity measures for Boolean functions whose best-known separations are achieved via cheat sheets, obtain similar separations for transitive Boolean functions.*

- A total function was constructed in [13] that demonstrates quadratic separations between approximate degree with sensitivity and several other complexity measures. It is thus natural to investigate the following open problem.

  ▶ **Open Problem 39.** *Come up with transitive functions that achieve similar separations for those pair of measures whose best-known separations are shown by [13].*

- Recently [8], [5] and [6] came up with new classes of Boolean functions, starting with the HEX (see [8]) and EAH (see [6]) functions, that exhibit improved separations between certificate complexity and other complexity measures using the.
  In light of these recent developments is important to ask whether similar separations can be shown for transitive functions. Following open problem is a natural starting point.

  ▶ **Open Problem 40.** *Can the HEX and EAH functions be modified to a transitive functions, while preserving its desired complexity measures upto poly-logarithmic factors?*

- While we have been concerned only with lower bounds in this paper, it is an exciting research direction to bridge the gap between complexity measures of transitive Boolean functions by providing improved upper bounds.

  ▶ **Open Problem 41.** *Bridge the gaps in Table 1 by coming up with better upper bounds on complexity measures for transitive functions.*

In the full version of this paper, [15], we summarize the results on how low can individual complexity measures go for transitive function. Even with the recent results of [21] and [2], there are significant gaps between the best-known lower and upper bounds in this case which gives another set of open problems to investigate in the study of combinatorial measures of transitive Boolean functions.

Abstract

In the k-edge-connected spanning subgraph (kECSS) problem, our goal is to compute a minimum-cost sub-network that is resilient against up to k link failures: Given an n-node m-edge graph with a cost function on the edges, our goal is to compute a minimum-cost k-edge-connected spanning subgraph. This NP-hard problem generalizes the minimum spanning tree problem and is the "uniform case" of a much broader class of survival network design problems (SNDP). A factor of two has remained the best approximation ratio for polynomial-time algorithms for the whole class of SNDP, even for a special case of 2ECSS. The fastest 2-approximation algorithm is however rather slow, taking $O(mnk)$ time [Khuller, Vishkin, STOC'92]. A faster time complexity of $O(n^2)$ can be obtained, but with a higher approximation guarantee of $(2k-1)$ [Gabow, Goemans, Williamson, IPCO'93].

Our main contribution is an algorithm that $(1+\varepsilon)$-approximates the optimal fractional solution in $\tilde{O}(m/\varepsilon^2)$ time (independent of k), which can be turned into a $(2+\varepsilon)$ approximation algorithm that runs in time $\tilde{O}\left(\frac{m}{\varepsilon^2} + \frac{k^2 n^{1.5}}{\varepsilon^2}\right)$ for (integral) kECSS; this improves the running time of the aforementioned results while keeping the approximation ratio arbitrarily close to a factor of two.

1 Introduction

In the k-Edge-Connected Spanning Subgraph problem (kECSS), we are given an undirected n-node m-edge graph $G = (V, E)$ together with edge costs, and want to find a minimum-cost k-edge connected spanning subgraph.[1] For $k = 1$, this is simply the minimum spanning tree problem, and thus can be solved in $O(m)$ time [28]. For $k \geq 2$, the problem is a classical NP-hard problem whose first approximation algorithm was given almost four decades ago, where Frederickson and Jaja [19] gave a 3-approximation algorithm that runs in $O(n^2)$ time for the case of $k = 2$. The approximation ratio was later improved to 2 by an $\tilde{O}(mnk)$-time algorithm of Khuller and Vishkin [32].[2] This approximation factor of 2 has remained the best for more than 30 years, even for a special case of 2ECSS called the weighted tree augmentation problem. When the running time is of the main concern, the fastest known algorithm takes $O(n^2)$ time at the cost of a significantly higher $(2k - 1)$-approximation guarantee, due to Gabow, Goemans, and Williamson [22].

This above state-of-the-arts leave a big gap between algorithms achieving the best approximation ratio and the best time complexity. This gap exists even for $k = 2$. In this paper, we improve the running time of both aforementioned algorithms of [32, 22] while keeping the approximation ratio arbitrarily close to two. Our main contribution is a near-linear time algorithm that $(1 + \varepsilon)$-approximates the optimal *fractional* solution.

▶ **Theorem 1.** *For any $\varepsilon > 0$, there is a randomized $\widetilde{O}(m/\varepsilon^2)$-time algorithm that outputs a $(1 + \varepsilon)$-approximate* fractional *solution for kECSS.*

Following, in the high-level, the arguments of Chekuri and Quanrud [7] (i.e. solving the minimum-weight k disjoint arborescences in the style of [32] on the support of the sparsified fractional solution), the above fractional solution can be turned into a fast $(2 + \varepsilon)$-approximation algorithm for the integral version of kECSS.

▶ **Corollary 2.** *For any $\varepsilon > 0$, there exist*

- *a randomized $\widetilde{O}(m/\varepsilon^2)$-time algorithm that estimates the* value *of the optimal solution for kECSS to within a factor $(2 + \varepsilon)$, and*
- *a randomized $\tilde{O}\left(\frac{m}{\varepsilon^2} + \frac{k^2 n^{1.5}}{\varepsilon^2}\right)$-time algorithm that produces a feasible kECSS solution of cost at most $(2 + \varepsilon)$ times the optimal value.*

We remark that the term $\tilde{O}(k^2 n^{1.5})$ is in fact "tight" up to the state-of-the-art algorithm for finding minimum-weight k disjoint arborescences.[3]

Prior to our results, a sub-quadratic time algorithm was not known even for special cases of kECSS, called *k-Edge-Connected Augmentation* (kECA). In this problem, we are given a $(k - 1)$-edge-connected subgraph H of a graph G, and we want to minimize the total cost of adding edges in G to H so that H becomes k-edge connected. It is not hard to see that if we can α-approximates kECSS, then we can α-approximates kECA by assigning cost 0 to all

[1] Note that this problem should not be confused with a variant that allows to pick the same edge multiple time, which is sometimes also called kECSS (e.g., [6]). We follow the convention in [13] and call the latter variant minimum-cost k-edge connected spanning sub-multigraph (kECSSM) problem. (See also the work by Pritchard [39].)

[2] $\tilde{O}$ hides polylog(n) factor.

[3] More formally, if a minimum-weight union of k edge-disjoint arborescences can be found in time $T(k, m, n)$, then our algorithm would run in time $T(k, kn, n)$. The term $O(k^2 n^{1.5})$ came from Gabow's algorithm [20] that runs in time $O(km\sqrt{n}\log(nc_{\max}))$.

edges in H. This problem previously admits a $O(kn^2)$-time 2-approximation algorithm for any even integer k [31][4]. The approximation ratio of 2 remains the best even for 2ECA. Our result in Corollary 2 improves the previously best time complexity by a $\tilde{\Theta}(\sqrt{n})$ factor.

Perspective. The gap between algorithms with best approximation ratio and best time complexity in fact reflects a general lack of understanding on *fast approximation algorithms*. While polynomial-time algorithms were perceived by many as efficient, it is not a reality in the current era of large data, where it is nearly impossible to take $O(n^3)$ time to process a graph with millions or billions of nodes. Research along this line includes algorithms for sparsest cut [30, 29, 42, 35], multi-commodity flow [23, 17, 36], and travelling salesman problem [6, 7]. Some of these algorithms have led to exciting applications such as fast algorithms for max-flow [43], dynamic connectivity [38, 8, 40, 45, 37], vertex connectivity [34] and maximum matching [44].

The kECSS problem belongs to the class of survivable network design problems (SNDPs), where the goal is to find a subgraph ensuring that every pair of nodes (u, v) are $\kappa(u, v)$-edge-connected for a given function κ. (kECSS is the *uniform* version of SNDP where $\kappa(u, v) = k$ for every pair (u, v).) These problems typically focus on building a network that is resilient against device failures (e.g. links or nodes), and are arguably among the most fundamental problems in combinatorial optimization. Research in this area has generated a large number of beautiful algorithmic techniques during the 1990s, culminating in the result of Jain [26] which gives a 2-approximation algorithm for the whole class of SNDPs. Thus, achieving a *fast* 2-approximation algorithm for SNDPs is a very natural goal.

Towards this goal and towards developing fast approximation algorithms in general, there are two common difficulties:

1. Many approximation algorithms inherently rely on solving a *linear program (LP)* to find a fractional solution, before performing rounding steps. However, the state-of-the-art general-purpose linear program solvers are still quite slow, especially for kECSS and SNDP where the corresponding LPs are *implicit*.

   In the context of SNDP, the state-of-the-art (approximate) LP solvers still require at least quadratic time: Fleischer [18] designs an $\tilde{O}(mnk)$ for solving kECSS LP, and more generally for SNDP and its generalization [18, 14] with at least $\Theta(m \min\{n, k_{\max}\})$ iterations of minimum cost flow's computation are the best known running time where $k_{\max}$ is the maximum connectivity requirements.
2. Most existing techniques that round fractional solutions to integral ones are not "friendly" for the design of fast algorithms. For instance, Jain's celebrated iterative rounding [26] requires solving the LP $\Omega(m)$ times. Moreover, most LP-based network design algorithms are fine-tuned to optimize approximation factors, while designing near-linear time LP rounding algorithms requires limiting ourselves to a relatively small set of tools, about which we currently have very limited understanding.

This paper completely resolves the first challenge for kECSS and manages to identify a fundamental bottleneck of the second challenge.

[4] In Khuller and Vishkin [31], the kECA problem aims at augmenting the connectivity from k to $(k + 1)$ (but for us it is from $(k - 1)$ to k.)

Challenges for LP Solvers. Our main challenge is handling the so-called *box constraints* in the LPs. To be concrete, below is the LP relaxation of kECSS on graph $G = (V, E)$.

$$\min\{\sum_{e\in E} c_e x_e : \sum_{e\in\delta_G(S)} x_e \geq k \ (\forall S \subseteq V), x \in [0,1]^E\} \tag{1}$$

where $\delta_G(S)$ is the set of edges between nodes in S and $V \setminus S$. The box constraints refer to the constraints $x \in [0,1]^E$. Without these constraints, we can select the same edge multiple times in the solution; this problem is called kECSSM in [13] (see Footnote 1). Removing the box constraints often make the problem significantly easier. For example, the min-cost st-flow problem without the box constraints become computing the shortest st-path, which admits a much faster algorithm.

For kECSS, it can be shown that solving (1) without the box constraints can be reduced to solving (1) *with* $k = 1$ and multiplying all x_e with k. In other words, without the box constraints, fractional kECSS is equivalent to fractional 1ECSS.This *fractional* 1ECSS can be $(1+\varepsilon)$-approximated in near-linear time by plugging in the dynamic minimum cut data structure of Chekuri and Quanrud [6] to the multiplicative weight update framework (MWU).

However, with the presence of box constraints, to use the MWU framework we would need a dynamic data structure for a much more complicated cut problem, that we call, the *minimum normalized free cut* problem (roughly, this is a certain normalization of the minimum cut problem where the costs of up to k heaviest edges in the cut are ignored.) For our problem, the best algorithm in the static setting we are aware of (prior to this work) is to use Zenklusen's $\tilde{O}(mn^4)$-time algorithm [47] for the *connectivity interdiction* problem.[5] This results in an $\tilde{O}(kmn^4)$-time static algorithm. Speeding up and dynamizing this algorithm seems very challenging. Our main technical contribution is an efficient dynamic data structure (in the MWU framework) for the $(1+\varepsilon)$-approximate minimum normalized free cut problem. We explain the high-level overview of our techniques in Section 2.

Further Related Works. The kECSS and its special cases have been studied extensively. For all $k \geq 2$, the kECSS problem is known to be APX-hard [15] even on bounded-degree graphs [9] and when the edge costs are 0 or 1 [39]. Although a factor 2 approximation for kECSS has not been improved for almost 3 decades, various special cases of kECSS admit better approximation ratios (see for instance [25, 16, 1]). For instance, the unit-cost kECSS ($c_e = 1$ for all $e \in E$) behaves very differently, admitting a $(1 + O(1/k))$ approximation algorithm [21, 33]. For the 2ECA problem, one can get a better than 2 approximation when the edge costs are bounded [1, 16]. Otherwise, for general edge costs, the factor of 2 has remained the best known approximation ratio even for the 2ECA problem.

The kECSS problem in special graph classes have also received a lot of attention. In Euclidean setting, a series of papers by Czumaj and Lingas led to a near-linear time approximation schemes for constant k [12, 11]. The problem is solvable in near-linear time when k and treewidth are constant [3, 5]. In planar graphs, 2ECSS, 2ECSSM and 3ECSSM admit a PTAS [10, 4].

Organization. We provide a high-level overview of our proofs in Section 2. In Section 3, we explain the background on Multiplicative Weight Updates (MWU) for completeness (although this paper is written in a way that one can treat MWU as a black box). In Section 4, we

[5] In the connectivity interdiction problem, we are given $G = (V, E)$ and $k \in \mathbb{N}$, our goal is to compute $F \subseteq E$ to delete from G in order to minimize the minimum cut in the resulting graph.

prove our main technical component. In Section 5, we present our LP solver. In Section 6, we show how to round the fractional solution obtained from the LP solver. Due to space limitations, many proofs are deferred to Appendix.

2 Overview of Techniques

In this section, we give a high-level overview of our techniques in connection to the known results. Our work follows the standard Multiplicative Weight Update (MWU) framework together with the Knapsack Covering (KC) inequalities (see Section 3 for more background). Roughly, in this framework, in order to obtain a near-linear time LP solver for kECSS, it suffices to provide a fast dynamic algorithm for a certain optimization problem (often called the oracle problem in the MWU literature):

▶ **Definition 3** (Minimum Normalized Free Cuts). *We are given a graph $G = (V, E)$, weight function $\boldsymbol{w} : E \to \mathbb{R}_{\geq 0}$, integer k, and our goal is to compute a cut $S \subseteq V$ together with edges $F \subseteq \delta_G(S) : |F| \leq k - 1$ that minimizes the following objective[6]:*

$$\min_{S \subsetneq V, F \subseteq \delta_G(S) : |F| \leq (k-1)} \frac{\boldsymbol{w}(\delta_G(S) \setminus F)}{k - |F|},$$

where $\delta_G(S)$ denotes the set of edges that has exactly one end point in S. We call the minimizer (S, F) the minimum normalized free cut.

This is similar to the minimum cut problem, except that we are allowed to "remove" up to $(k-1)$ edges (called *free edges*) from each candidate cut $S \subseteq V$, and the cost would be "normalized" by a factor of $(k - |F|)$.[7] Notice that there are (apparently) two sources of complexity for this problem. First, we need to find the cut S and second, given S, to compute the optimal set $F \subseteq \delta_G(S)$ of free edges. To our best knowledge, a previously fastest algorithm for this problem takes $\tilde{O}(mn^4)$ time by reducing to the connectivity interdiction problem [47], while we require near-linear time. This is our first technical challenge.

Our second challenge is as follows. To actually speed up the whole MWU framework, in addition to solving the oracle problem statically efficiently, we further need to implement a dynamic version of the oracle with polylog(n) update time. In our case, the goal is to maintain a dynamic data structure on graph $G = (V, E)$, weight function $\mathbf{w}$, cost function c, that supports the following operation:

▶ **Definition 4.** *The* PunishMin *operation computes a $(1 + O(\varepsilon))$-approximate normalized free cut and multiply the weight of each edge $e \in \delta_G(S) \setminus F$ by a factor of at most e^{ε}.*[8]

We remark that invoking the PunishMin operation does not return the cut (S, F), and the only change is the weight function $\mathbf{w}$ being maintained by the data structure.

▶ **Proposition 5** (Informal). *Assume that we are given a dynamic algorithm that supports* PunishMin *with amortized* polylog(n) *cost per operations, then the kECSS LP can be solved in time $\tilde{O}(m)$.*

---

[6] For any function f, for any subset S of its domain, we define $f(S) = \sum_{s \in S} f(s)$.

[7] This is in fact a special case of a similar objective considered by Feldmann, Könemann, Pashkovich and Sanità [14], who considered applying the MWU framework for the generalized SNDP

[8] The actual weight $w(e)$ is updated for all $e \in \delta_G(S) \setminus F$: $w(e) \leftarrow w(e) \cdot \exp(\frac{\varepsilon c_{\min}}{c_e})$ where $c_{\min}$ is the minimum edge capacity in $\delta_G(S) \setminus F$.

Let us call such a dynamic algorithm a fast **dynamic punisher**. The fact that a fast dynamic punisher implies a fast LP solver is an almost direct consequence of MWU [23].

Therefore, we focus on designing a fast dynamic algorithm for solving (and punishing) the minimum normalized free cut problem. Our key idea is an efficient and dynamic implementation of the **weight truncation** idea.

> **Weight truncation**: Let $G = (V, E)$ and $\rho \in \mathbb{R}_{\geq 0}$ be a threshold. For any weight function $\mathbf{w}$ of G, denote by $\mathbf{w}_\rho$ the truncated weight defined by $\mathbf{w}_\rho(e) = \min\{\mathbf{w}(e), \rho\}$ for each $e \in E$. Call an edge e with $\mathbf{w}(e) \geq \rho$ a ρ-heavy edge.

Our main contribution is to show that, when allowing $(1+\varepsilon)$-approximation, we can use the weight truncation to reduce the minimum normalized free cut to minimum cut with $O(\text{polylog}(n))$ extra factors in the running time. Moreover, this reduction can be implemented efficiently in the dynamic setting. We present the ideas in two steps, addressing our two technical challenges mentioned above respectively. First, we show how to solve the static version of minimum normalized free cut in near-linear time. Second, we sketch the key ideas to implement them efficiently in the dynamic setting, which can be used in the MWU framework.

We remark that weight truncation technique has been used in different context. For instance, Zenklusen [47] used it for reducing the connectivity interdiction problem to $O(|E|)$ instances of the minimum budgeted cut problem.

2.1 Step 1: Static Algorithm

We show that the minimum normalized free cut problem can be solved efficiently in the static setting. For convenience, we often use the term cut to refer to a set of edges instead of a set of vertices.

Define the objective function of our problem as, for any cut C,

$$\mathsf{val}_{\mathbf{w}}(C) = \min_{F \subseteq C : |F| \leq k-1} \frac{\mathbf{w}(C \setminus F)}{k - |F|}.$$

For any weight function $\mathbf{w}$, denote by $\mathsf{OPT}_{\mathbf{w}} = \min_C \mathsf{val}_{\mathbf{w}}(C)$. In this paper, the graph G is always fixed, while $\mathbf{w}$ is updated dynamically by the algorithm (so we omit the dependence on G from the notation val and OPT). When $\mathbf{w}$ is clear from context, we sometimes omit the subscript $\mathbf{w}$.

We show that the truncation technique can be used to establish a connection between our problem and minimum cut.

▶ **Lemma 6.** *We are given a graph $G = (V, E)$, weight function $\boldsymbol{w}$, integer k, and $\varepsilon > 0$. For any threshold $\rho \in (\mathsf{OPT}_{\boldsymbol{w}}, (1+\varepsilon)\mathsf{OPT}_{\boldsymbol{w}}]$,*

- *any optimal normalized free cut in $(G, \boldsymbol{w})$ is a $(1+\varepsilon)$-approximate minimum cut in $(G, \boldsymbol{w}_\rho)$, and*
- *any minimum cut C^* in $(G, \boldsymbol{w}_\rho)$ is a $(1+\varepsilon)$-approximation for the minimum normalized free cut.*

Proof. First, consider any cut C with $\mathsf{val}(C) = \mathsf{OPT}$. Let $F \subseteq C$ be an optimal set of free edges for C, so we have $\mathbf{w}_\rho(C \setminus F) \leq \mathbf{w}(C \setminus F) = (k - |F|)\mathsf{OPT}$. Moreover, $\mathbf{w}_\rho(F) \leq |F|\rho$. This implies that

$$\mathbf{w}_\rho(C) = \mathbf{w}_\rho(C \setminus F) + \mathbf{w}_\rho(F) < k\rho \tag{2}$$

Next, we prove that any cut in $(G, \mathbf{w}_\rho)$ is of value at least $k\mathsf{OPT}$ (so the cut C is a $(1+\varepsilon)$ approximate minimum cut). Assume for contradiction that there is a cut C' such that $\mathbf{w}_\rho(C') < k\mathsf{OPT}$. Let $F' \subseteq C'$ be the set of ρ-heavy edges. Observe that $|F'| \leq k-1$ since otherwise the total weight $\mathbf{w}_\rho(C')$ would have already exceeded $k\mathsf{OPT}$. This implies that $\mathbf{w}(C' \setminus F') = \mathbf{w}_\rho(C' \setminus F') < (k - |F'|)\mathsf{OPT}$ and that

$$\mathsf{val}(C') \leq \frac{\mathbf{w}(C' \setminus F')}{(k - |F'|)} < \mathsf{OPT}$$

which is a contradiction. Altogether, we have proved the first part of the lemma.

To prove the second part of the lemma, consider a minimum cut C^* in $(G, \mathbf{w}_\rho)$, we have that $\mathbf{w}_\rho(C^*) < \mathbf{w}_\rho(C) < k\rho$ (from Equation (2)). Again, the set of heavy edges $F^* \subseteq C^*$ can contain at most $k-1$ edges, so we must have $\mathbf{w}(C^* \setminus F^*) < (k-|F^*|)\rho \leq (k-|F^*|)(1+\varepsilon)\mathsf{OPT}$, implying that $\mathsf{val}(C^*) < (1+\varepsilon)\mathsf{OPT}$. ◀

We remark that this reduction from the minimum normalized free cut problem to the minimum cut problem does not give an exact correspondence, in the sense that a minimum cut in $(G, \mathbf{w}_\rho)$ cannot be turned into a minimum normalized free cut in $(G, \mathbf{w})$. In other words, the approximation factor of $(1+\varepsilon)$ is unavoidable.

▶ **Theorem 7.** *Given a graph $G = (V, E)$ with weight function $\boldsymbol{w}$ and integer k, the minimum normalized free cut problem can be $(1+\varepsilon)$ approximated by using $O(\frac{1}{\varepsilon} \cdot \log n)$ calls to the exact minimum cut algorithm.*

Proof. We assume that the minimum normalized free cut of G is upper bounded by some value M which is polynomial in $n = |V(G)|$ (we show how to remove this assumption in the full version of the paper). For each i such that $(1+\varepsilon)^i \leq M$, we compute the minimum cut C_i in $(G, \mathbf{w}_{\rho_i})$ where $\rho_i = (1+\varepsilon)^i$ and return one with minimum value $\mathsf{val}(C_i)$. Notice that there must be some i^* such that $\rho_{i^*} \in (\mathsf{OPT}_{\mathbf{w}}, (1+\varepsilon)\mathsf{OPT}_{\mathbf{w}}]$ and by the lemma, we must have that C_{i^*} is a $(1+\varepsilon)$-approximate solution for the normalized free cut problem. ◀

By using any near-linear time minimum cut algorithm e.g., [27], the collorary follows.

▶ **Corollary 8.** *There exists a $(1+\varepsilon)$ approximation algorithm for the minimum normalized free cut problem that runs in time $\tilde{O}(|E|/\varepsilon)$.*

2.2 Step 2: Dynamic Algorithm

The next idea we use is from Chekuri and Quanrud [6]. One of the key concepts there is that it is sufficient to solve a "range punishing" problem in near-linear time; for completeness we prove this sufficiency in Appendix. In particular, the following proposition is a consequence of their work:

▶ **Definition 9.** *A **range punisher**[9] is an algorithm that, on any input graph G, initial weight function $\boldsymbol{w} = \boldsymbol{w}^{\text{init}}$, real numbers ε, and $\lambda \leq \mathsf{OPT}_{\boldsymbol{w}^{\text{init}}}$, iteratively applies* PunishMin *on $(G, \boldsymbol{w})$ until the optimal becomes at least $\mathsf{OPT}_{\boldsymbol{w}} \geq (1+\varepsilon)\lambda$.*

The following proposition connects a fast range punisher to a fast LP solver.

[9] Our range punisher corresponds to an algorithm of Chekuri and Quanrud [7] in one epoch.

▶ **Proposition 10.** *If there exists a range punisher running in time*

$$\widetilde{O}\left(|E| + K + \sum_{e\in E} \log(\frac{\boldsymbol{w}(e)}{\boldsymbol{w}^{\text{init}}(e)})\right)$$

where K is the number of cuts punished, then, there exists a fast dynamic punisher, and consequently the kECSS LP can be solved in near-linear time.

This proposition applies generally in the MWU framework independent of problems. That is, for our purpose of solving kECSS LP, we need a fast range punisher for the minimum normalized free cut problem. For Chekuri and Quanrud [6], they need such algorithm for the minimum cut problem (therefore a fast LP solver for the Held-Karp bound).

▶ **Theorem 11** ([6], informal)**.** *There exists a fast range punisher for the minimum cut problem.*

Our key technical tool in this paper is a more robust reduction from the range punishing of normalized free cuts to the one for minimum cuts. This reduction works for all edge weights and is suitable for the dynamic setting. That is, it is a strengthened version of Lemma 6 and is summarized below (see its proof in Section 4).

▶ **Theorem 12** (Range Mapping Theorem)**.** *Let $(G = (V, E), \boldsymbol{w})$ be a weighted graph. Let $\lambda > 0$ and $\rho = (1 + \gamma)\lambda$.*

1. *If the value of optimal normalized free cut is in $[\lambda, (1 + \gamma)\lambda)$, then the value of minimum cut in $(G, \boldsymbol{w}_\rho)$ lies in $[k\rho/(1 + \gamma), k\rho)$.*
2. *For any cut C where $\boldsymbol{w}_\rho(C) < k\rho$, then $\frac{\boldsymbol{w}(C\setminus F)}{k-|F|} < (1 + \gamma)\lambda$ where F contains all ρ-heavy edges in C. In particular, $\mathsf{val}(C) < (1 + \gamma)\lambda$.*

Given the above reduction, we can implement range punisher fast. We present its full proof in Section 5 and sketch the argument below.

▶ **Theorem 13.** *There exists a fast range punisher for the minimum normalized free cut problem.*

Proof (sketch). We are given λ and weighted graph $(G, \mathbf{w}) : \mathbf{w} = \mathbf{w}^{\text{init}}$ such that $\mathsf{OPT}_{\mathbf{w}^{\text{init}}} \geq \lambda$. Our goal is to punish the normalized free cuts until the optimal value in $(G, \mathbf{w})$ becomes at least $(1+\varepsilon)\lambda$. We first invoke Theorem 7 to get a $(1+\varepsilon)$-approximate cut, and if the solution is already greater than $(1 + \varepsilon)^2\lambda$, we are immediately done (this means $\mathsf{OPT} > (1 + \varepsilon)\lambda$).

Now, we know that $\mathsf{OPT} \leq (1 + \varepsilon)^2\lambda \leq (1 + 3\varepsilon)\lambda$. We invoke Lemma 12(1) with $\gamma = 3\varepsilon$. The minimum cut in $(G, \mathbf{w}_\rho)$ has size in the range $[k\rho/(1+3\varepsilon), k\rho)$. We invoke (one iteration of) Theorem 11 with $\lambda' = k\rho(1 + 3/\varepsilon)$ to obtain a cut C whose size is less than $k\rho$ and therefore, by Lemma 12(1), $\mathsf{val}(C) < (1 + 3\varepsilon)\lambda$. This is a cut that our algorithm can punish (we ignore the detail of how we actually punish it – we would need to do that implicitly since the cut itself may contain up to m edges). We repeat this process until all cuts whose values are relevant have been punished, that is, we continue this process until the returned cut C has size at least $k\rho$.

The running time of this algorithm is

$$\widetilde{O}\left(|E| + K + \sum_{e\in E} \log(\frac{\mathbf{w}_\rho(e)}{\mathbf{w}_\rho^{\text{init}}(e)})\right) \leq \widetilde{O}\left(|E| + K + \sum_{e\in E} \log(\frac{\mathbf{w}(e)}{\mathbf{w}^{\text{init}}(e)})\right)$$

Notice that we rely crucially on the property of our reduction using truncated weights. ◀

We remark that in the actual proof of Theorem 13, there are quite a few technical complications (e.g., how to find optimal free edges for a returned cut C?), and we cannot invoke Theorem 11 in a blackbox manner. We refer to Section 5 for the details.

2.3 LP Rounding for kECSS

Most known techniques for kECSS (e.g. [22, 33]) rely on iterative LP rounding, which is computationally expensive. We achieve fast running time by making use of the 2-approximation algorithm of Khuller and Vishkin [31].

Roughly speaking, this algorithm creates a directed graph H from the original graph G and then compute on H the minimum-weight k disjoint arboresences. The latter can be found by Gabow's algorithms, in either $\tilde{O}(|E||V|k)$ or $\tilde{O}(k|E|\sqrt{|V|}\log c_{\max})$ time.

To use their algorithm, we will construct H based on the support of the fractional solution x computed by the LP solver. By the integrality of the arborescence polytope [41], an integral solution is as good as the fractional solution. However, the support of x can be potentially large, which causes Gabow's algorithm to take longer time. Here our idea is a sparsification of the support, by extending the celebrated sparsification theorem of Benzcur and Karger [2] to handle our problem, i.e., we prove the following (see Section 6 for the proofs):

▶ **Theorem 14.** *Let G be a graph and c_G its capacities. There exists a capacitated graph (H, c_H) on the same set of vertices that can be computed in $\tilde{O}(m)$ such that (i) $|E(H)| = \tilde{O}(nk)$, and (ii) for every cut S and $F \subseteq S : |F| \leq (k-1)$, we have $c_G(S \setminus F) = (1 \pm \varepsilon)\, c_H(S \setminus F)$.*

Benzcur and Karger's theorem corresponds to this theorem when $k = 1$. We believe that this theorem might have further applications, e.g., for providing a fast algorithm for the connectivity interdiction problem. Our result implies the following (see Section 6 for the proof):

▶ **Theorem 15.** *Assume that there exists an algorithm that finds a minimum-weight k-arborescences in an m-edge n-node graph in time $T_k(m, n)$. Then there exists a $(2+\varepsilon)$ approximation algorithm for kECSS running in time $\tilde{O}(m/\varepsilon^2 + T_k(kn/\varepsilon^2, n))$*

Applying Theorem 15 with the Gabow's algorithm (see Theorem 35 in Section 6), we obtain Corollary 2.

3 Preliminaries

In this section, we review the multiplicative-weight update (MWU) framework for solving a (covering) LP relaxation of the form $\min\{c \cdot x : Ax \geq 1, x \geq 0\}$, where A is an m-by-n matrix with non-negative entries and $c \in \mathbb{R}^n_{\geq 0}$. Our presentation abstracts away the detail of MWU, so readers should feel free to skip this section.

Let $A_1, \ldots, A_m$ be the rows of matrix A. Here is a concrete example:

- **Held-Karp Bound:** The Held-Karp bound on input (G, c) aims at solving the LP:[10]

$$\min\{ \sum_{e \in E(G)} c_e x_e : \sum_{e \in S} x_e \geq 2 \text{ for any cut } S \subseteq E\}$$

[10] We refer the readers to [6] for more discussion about this LP and Held-Karp bound.

Matrix $A = A_G$ is a cut-edge incidence matrix of graph G where each row A_j corresponds to a cut $F_j \subseteq E(G)$, so there are exponentially many rows. Each column corresponds to an edge $e \in E(G)$. There are exactly $|E(G)|$ columns. The matrix is implicitly given as an input graph G.

We explain the MWU framework in terms of matrices. Some readers may find it more illustrative to work with concrete problems in mind.

MWU Framework for Covering LPs

In the MWU framework for solving covering linear programs, we are given as input an m-by-n matrix A and cost vectors c associated with the columns.[11] Let $\varepsilon > 0$ be a parameter; that is, we aim at computing a solution x that is $(1+\varepsilon)$ approximation of the optimal LP solution. Denote by $\textsc{MinRow}(A, w)$ the value $\min_{j\in[m]} A_j w$. We start with an initial weight vector $\mathbf{w}_i^{(0)} = 1/c_i$ for $i \in [n]$. On each day $t = 1, \ldots, T$, we compute an approximately "cheapest" row j^* such that $A_{j^*}\mathbf{w}^{(t-1)} \leq (1+\varepsilon)\textsc{MinRow}(A, \mathbf{w}^{(t-1)})$, and update the weight $\mathbf{w}_i^{(t)} \leftarrow \mathbf{w}_i^{(t-1)} \exp\left(\frac{\varepsilon A_{j^*,i} c_{\min}}{c_i}\right)$ where $c_{\min} = \min_{i\in[n]} \frac{c_i}{A_{j^*,i}}$.[12] After $T = O(n \log n/\varepsilon^2)$ many days, the solution can be found by taking the best scaled vectors; in particular, observe that, for any day t, the scaled vector $\bar{\mathbf{w}}^{(t)} = \mathbf{w}^{(t)}/\left(\min_{j\in[m]} A_j \mathbf{w}^{(t)}\right)$ is always feasible for the LP. The algorithm returns $\bar{\mathbf{w}}^{(t)}$ which has minimum cost. The following theorem shows that at least one such solution is near-optimal.

▶ **Theorem 16.** *For $T = O(\frac{n \log n}{\varepsilon^2})$, one of the solutions $\bar{\boldsymbol{w}}^{(t)}$ for $t \in [T]$ is a $(1 + O(\varepsilon))$ approximation of the optimal solution* $\min\{c \cdot x : Ax \geq 1, x \geq 0\}$.

Since we use slightly different language than the existing proofs in the literature, we provide a proof in the appendix.

KC Inequalities

Our LP is hard to work with mainly because of the mixed packing/covering constraints $x \in [0,1]^n$. There is a relatively standard way to get rid of the mixed packing/covering constraints by adding Knapsack covering (KC) inequalities into the LP. In particular, for each row (or constraint) $j \in [m]$, we introduce constraints:

$$(\forall F \subseteq \mathsf{supp}(A_j), |F| \leq (k-1)) : \sum_{i\in[n]\setminus F} A_{j,i}x_i \geq k - |F|, \text{ or } \sum_{i\in[n]\setminus F} \frac{A_{j,i}}{(k-|F|)} x_i \geq 1$$

Let A^{kc} be the new matrix after adding KC inequalities, that is, imagine the row indices of A^{kc} as (j, F) where $j \in [m]$ and $F \subseteq \mathsf{supp}(A_j)$; we define $A^{\mathsf{kc}}_{(j,F),i} = A_{j,i}/(k - |F|)$. The actual number of rows in A^{kc} can be as high as $m \cdot n^{O(k)}$, but our algorithm will not be working with this matrix explicitly.

The following lemma shows that we can now remove the packing constraints. We defer the proof to Appendix.

▶ **Lemma 17.** *Any solution to $\{x \in \mathbb{R}^n : A^{kc}x \geq 1, x \geq 0\}$ is feasible for $\{x \in \mathbb{R}^n : Ax \geq k, x \in [0,1]\}$. Conversely, for any point z in the latter polytope, there exists a point z' in the former such that $z' \leq z$.*

[11] There are several ways to explain such a framework. Chekuri and Quanrud [6] follow the continuous setting of Young [46]. We instead follow the combinatorial interpretation of Garg and Könemann [23].
[12] In the MWU literature, this is often referred to as an oracle problem.

▶ **Corollary 18.** *For any cost vector* $c \in \mathbb{R}^n_{\geq 0}$,

$$\min\{c^T x : A^{kc} x \geq 1, x \geq 0\} = \min\{c^T x : Ax \geq k, x \in [0,1]\}$$

4 Range Mapping Theorem

The goal of this section is to prove Theorem 12, a cornerstone of this paper. We emphasize that it works for *any* weight function $\mathbf{w}$. First, we introduce more notations for convenience. For any cut $C \in \mathcal{C}$, and any subset of edges $F \subseteq E$, we define $\mathsf{val}_{\mathbf{w}}(C,F) = \frac{\mathbf{w}(C \setminus F)}{k-|F|}$ if $F \subseteq C$ and $|F| < k$; otherwise, $\mathsf{val}_{\mathbf{w}}(C,F) = \infty$. Also, denote $\mathsf{val}_{\mathbf{w}}(C) = \min_{F \subseteq E} \mathsf{val}_{\mathbf{w}}(C,F)$. By definition, we have $\mathsf{val}_{\mathbf{w}}(C) = \min_{i \leq k-1} \mathsf{val}_{\mathbf{w}}(C, F_i)$ where F_i is the set of heaviest i edges in C with respect to weight function $\mathbf{w}$. We let $\mathsf{mincut}_{\mathbf{w}_\rho}$ be the value of a minimum cut with respect with weight $\mathbf{w}_\rho$. When it is clear from context, we sometimes omit the subscript $\mathbf{w}$. For any positive number ρ, let $H_{\mathbf{w},\rho} = \{e \in E \colon \mathbf{w}(e) \geq \rho\}$ be the set of ρ-heavy edges.[13] Define the weight truncation $\mathbf{w}_\rho(e) = \min\{\mathbf{w}(e), \rho\}$.

▶ **Theorem 19** (Restatement of Theorem 12)**.** *We are given a weighted graph* $(G, \boldsymbol{w})$, $\lambda > 0$ *be a parameter and* $\rho = (1+\gamma)\lambda$. *Then we have the following:*

1. *If* $\mathsf{OPT}_{\boldsymbol{w}} \in [\lambda, (1+\gamma)\lambda)$, *then* $\mathsf{mincut}_{\boldsymbol{w}_\rho} \in [k\rho/(1+\gamma), k\rho)$, *and*
2. *if a cut* C *satisfies* $\boldsymbol{w}_\rho(C) < k\rho$, *then* $\mathsf{val}_{\boldsymbol{w}}(C, H_{\boldsymbol{w},\rho} \cap C) < (1+\gamma)\lambda$.

Notice that the above theorem not only gives a mapping between solutions of the two problems but also that the heavy edges can be used as a set of free edges. We say that a cut C is *interesting* if it contains at most $k-1$ heavy edges, i.e., $|H_{\mathbf{w},\rho} \cap C| < k$.

▶ **Proposition 20.** *If cut* $C \subseteq E$ *is not interesting (i.e.,* $|H_{\boldsymbol{w},\rho} \cap C| \geq k$*), then* $\mathsf{val}_{\boldsymbol{w}}(C) \geq \rho$ *and* $\boldsymbol{w}_\rho(C) \geq k\rho$.

Proof. The fact that $\mathbf{w}_\rho(C) \geq k\rho$ follows immediately from the definition of heavy edges. Let F_i be the set heaviest i edges in C with respect to $\mathbf{w}$. Since C contains at least k heavy edges, we have that for all $i < k$, $C \setminus F_i$ contains at least $k-i$ heavy edges. Therefore, we have $\mathsf{val}_{\mathbf{w}}(C) = \min_{i \leq k-1} \frac{\mathbf{w}(C \setminus F_i)}{k-i} \geq \min_{i \leq k-1} \frac{(k-i)\rho}{k-i} = \rho$. ◀

Proposition 20 says that if a cut is not interesting it must be expensive as a normalized free cut (i.e., high $\mathsf{val}_{\mathbf{w}}(C)$) and as a graph cut (i.e., high $w_\rho(C)$). We next give a characterization that relates $\mathsf{val}_{\mathbf{w}}$ and the sizes of the cuts for interesting cuts.

▶ **Lemma 21.** *Let* C *be an interesting cut. Then* $\mathsf{val}_{\boldsymbol{w}}(C) \leq \mathsf{val}_{\boldsymbol{w}}(C, H_{\boldsymbol{w},\rho} \cap C) < \rho$ *if and only if* $\boldsymbol{w}_\rho(C) < k\rho$.

Proof. ($\rightarrow$) By definition of $\mathbf{w}_\rho$, we have

$$\mathbf{w}_\rho(C) = \mathbf{w}(C \setminus (H_{\mathbf{w},\rho} \cap C)) + \rho |H_{\mathbf{w},\rho} \cap C|. \tag{3}$$

If $\mathsf{val}_{\mathbf{w}}(C, H_{\mathbf{w},\rho} \cap C) < \rho$, then $\mathbf{w}(C \setminus H_{\mathbf{w},\rho} \cap C) < \rho(k - |H_{\mathbf{w},\rho} \cap C|)$. By Equation (3), we have $\mathbf{w}_\rho(C) < k\rho$.

($\leftarrow$) Denote $F = H_{\mathbf{w},\rho} \cap C$. By definition of val, we have

$$\mathsf{val}_{\mathbf{w}}(C) \leq \mathsf{val}_{\mathbf{w}}(C,F) = \frac{\mathbf{w}(C \setminus F)}{k-|F|} \overset{(3)}{=} \frac{\mathbf{w}_\rho(C) - \rho|F|}{k-|F|} < \frac{k\rho - \rho|F|}{k-|F|} = \rho.$$ ◀

[13] When it is clear from the context, for brevity, we might say that e is a *heavy edge* instead of *ρ-heavy edge*.

Proof of Theorem 19. For the first part, we begin by proving that $\mathsf{mincut}_{\mathbf{w}_\rho} < k\rho$. Let C^* be a cut such that $\mathsf{val}_{\mathbf{w}}(C^*) = \mathsf{OPT}_{\mathbf{w}}$. By Proposition 20, C^* must be interesting. Since $\mathsf{val}_{\mathbf{w}}(C^*) = \mathsf{OPT}_{\mathbf{w}} < (1+\gamma)\lambda = \rho$, Lemma 21 implies that we have $\mathbf{w}_\rho(C^*) < k\rho$. Therefore, $\mathsf{mincut}_{\mathbf{w}_\rho} < k\rho$.

Next, we prove that $\mathsf{mincut}_{\mathbf{w}_\rho} \geq k\rho/(1+\gamma)$. Let C be a cut, and denote $F = H_{\mathbf{w},\rho} \cap C$. If C is not interesting, then Proposition 20 implies that $\mathbf{w}_\rho(C) \geq k\rho \geq k\rho/(1+\gamma)$. If C is interesting, by definition of $\mathbf{w}_\rho$, we have

$$\mathbf{w}_\rho(C) = \mathbf{w}(C \setminus F) + \rho|F| \geq \mathsf{OPT}_{\mathbf{w}}(k - |F|) + \frac{\rho}{1+\gamma}|F| \geq \frac{\rho k}{1+\gamma}.$$

The last inequality follows since by assumption $\mathsf{OPT}_{\mathbf{w}} \geq \rho/(1+\gamma)$.

For the second part of the theorem, as $\mathbf{w}_\rho(C) < k\rho$, Proposition 20 implies that C is interesting. By Lemma 21, $\mathsf{val}_{\mathbf{w}}(C, H_{\mathbf{w},\rho} \cap C) < \rho = (1+\gamma)\lambda$. ◀

5 Fast Approximate LP Solver

In this section, we construct the fast range punisher for the normalized free cut problem. Our algorithm cannot afford to maintain the actual MWU weights, so it will instead keep track of *lazy weights*. From now on, we will use $\mathbf{w}^{\text{mwu}}$ to denote the actual MWU weights and $\mathbf{w}$ the weights that our data structure maintains.

▶ **Theorem 22** (Fast Range Punisher)**.** *Given graph G initial weight function $\boldsymbol{w}^{\text{init}}$ and two real values $\lambda, \varepsilon > 0$ such that $\lambda \leq \mathsf{OPT}_{\boldsymbol{w}^{\text{init}}}$, there is a randomized algorithm that iteratively applies* PunishMin *until the optimal with respect to the final weight function $\boldsymbol{w}^{\text{mwu}}$ becomes at least $\mathsf{OPT}_{\boldsymbol{w}^{\text{mwu}}} \geq (1+\varepsilon)\lambda$, in time $\widetilde{O}(|E| + K + \frac{1}{\varepsilon}\sum_{e\in E}\log(\cdot\frac{\boldsymbol{w}^{\text{mwu}}(e)}{\boldsymbol{w}^{\text{init}}(e)}))$, where K is the number of cuts punished.*

The following theorem is almost standard: the fast range punisher, together with a fast algorithm for approximating OPT_w for any weight $\mathbf{w}$, implies a fast approximate LP solver (e.g., see [6, 18]). For completeness, we provide the proof in the Appendix.

▶ **Theorem 23** (Fast LP Solver)**.** *Given a fast range punisher as described in Theorem 22, and a near-linear time algorithm for approximating OPT_w for any weight function w, there is an algorithm that output $(1+O(\varepsilon))$-approximate solution to kECSS LP in $\tilde{O}(m/\varepsilon^2)$ time.*

Notice that the above theorem implies our main result, Theorem 1. The rest of this section is devoted to proving Theorem 22. Following the high-level idea of [6], our data structure has two main components:

- **Range cut-listing data structure**: This data structure maintains dynamic (truncated) weighted graph $(G, \mathbf{w}_\rho)$ and is able to find a (short description of) $(1+O(\varepsilon))$-approximate cut whenever one exists, that is, it returns a cut of size between λ and $(1+O(\varepsilon))\lambda$ for some parameter λ. Since our weight function $\mathbf{w}$ changes over time, the data structure also has an interface that allows such changes to be implemented. The data structure can be taken and used directly in a blackbox manner, thanks to [6].
- **Lazy weight data structures**: Notice that a fast range punisher can only afford the running time of $\widetilde{O}\left(\sum_e \log \frac{\mathbf{w}^{\text{mwu}}(e)}{\mathbf{w}^{\text{init}}(e)}\right)$ for updating weights, while in the MWU framework, some edges would have to be updated much more often. We follow the idea of [6] to maintain approximate (lazy) weights that do not get updated too often but are still sufficiently close to the real weights. We remark that $\mathbf{w}^{\text{mwu}}$ only depends on the sequence of cuts, that PunishMin actually punishes. This lazy weight data structure is responsible for maintaining $\mathbf{w}$ that satisfies the following invariant:

▶ **Invariant 24.** *We have* $(1-\varepsilon)\boldsymbol{w}^{\mathrm{mwu}} \leq \boldsymbol{w} \leq \boldsymbol{w}^{\mathrm{mwu}}$.
That is, we allow $\mathbf{w}$ to underestimate weights, but they cannot deviate more than by a factor of $(1-\varepsilon)$. In this way, our data structure only needs to update the weight implicitly and output necessary increments to the cut listing data structure whenever the invariant is violated.

In sum, our range punisher data structures deal with three weight functions $\mathbf{w}$ (lazy weights), $\mathbf{w}_\rho$ (truncated lazy weights, used by the range cut listing data structure) and $\mathbf{w}^{\mathrm{mwu}}$ (actual MWU weights, maintained implicitly).

The rest of this section is organized as follows. In Section 5.1–Section 5.3, we explain the components that will be used in our data structure, and in Section 5.4, we prove Theorem 22 using these components.

5.1 Compact representation of cuts

This part serves as a "communication language" for various components in our data structure. Since a cut can have up to $\Omega(m)$ edges, the data structure cannot afford to describe it explicitly. We will use a compact representation of cuts [6], which allows us to describe any $(1+\varepsilon)$-approximate solution in a given weighted graph using $\tilde{O}(1)$ bits; notice that, in the MWU framework, we only care about (punishing) near-optimal solutions, so it is sufficient for us that we are able to concisely describe such cuts.

Formally, we say that a family $\mathcal{F}$ of subsets of edges is ε-canonical for $(G, \mathbf{w})$ if (i) $|\mathcal{F}| \leq \widetilde{O}(|E|)$, (ii) any $(1+\varepsilon)$-approximate minimum cut of $(G, \mathbf{w})$ is a disjoint union of at most $\tilde{O}(1)$ sets in $\mathcal{F}$, (iii) any set $S \in \mathcal{F}$ can be described concisely by $\tilde{O}(1)$ bits, and (iv) every edge in the graph belongs to $\tilde{O}(1)$ sets in $\mathcal{F}$. It follows that any $(1+\varepsilon)$-approximate cut admits a short description. Denote by $[[S]]$ a short description of cut $S \in \mathcal{F}$, and for each $(1+\varepsilon)$ approximate cut C, $[[C]]$ a short description of C.

▶ **Lemma 25** (implicit in [6]). *There exists a randomized data structure that, on input* $(G, \boldsymbol{w})$, *can be initialized in near-linear time, (w.h.p) constructs an* ε*-canonical family* $\mathcal{F} \subseteq 2^{E(G)}$, *and handles the following queries:*

- *Given a description* $[[C]]$ *of a* $(1+\varepsilon)$*-approximate cut, output a list of* $\tilde{O}(1)$ *subsets in* $\mathcal{F}$ *such that* C *is a disjoint union of those subsets in* $\tilde{O}(1)$ *time.*
- *Given a description of* $[[S]]$, $S \in \mathcal{F}$, *output a list of edges in* S *in* $\widetilde{O}(|S|)$ *time.*

5.2 Range Cut-listing Data Structure

The cut listing data structure is encapsulated in the following theorem.

▶ **Theorem 26** (Range Cut-listing Data Structure [6]). *The cut-listing data structure, denoted by* $\mathcal{D}$, *maintains dynamically changing weighted graph* $(G, \widehat{\boldsymbol{w}})$ *and supports the following operations.*

- $\mathcal{D}.\textsc{Init}(G, \boldsymbol{w}^{\mathrm{init}}, \lambda, \varepsilon)$ *where* G *is a graph,* $\widehat{\boldsymbol{w}}$ *is an initial weight function, and* $\mathsf{mincut}_{\widehat{\boldsymbol{w}}} \geq \lambda$*: initialize the data structure and the weight* $\widehat{\boldsymbol{w}} \leftarrow \boldsymbol{w}^{\mathrm{init}}$ *in* $\tilde{O}(m)$ *time.*
- $\mathcal{D}.\textsc{FindCut}()$: *output either a short description of a* $(1+O(\varepsilon))$*-approximate mincut* $[[C]]$ *or* $\emptyset$ *(when* $\mathsf{mincut}_{\widehat{\boldsymbol{w}}} > (1+\varepsilon)\lambda$*). The operation takes amortized* $\tilde{O}(1)$ *time.*
- $\mathcal{D}.\textsc{Increment}(\Delta)$ *where* $\Delta = \{(e, \delta_e)\}$ *is the set of increments (defined by a pair of an edge* $e \in E$ *and a value* $\delta_e \in \mathbb{R}_{\geq 0}$*): For each* $(e, \delta_e) \in \Delta$, $\widehat{\boldsymbol{w}}(e) \leftarrow \widehat{\boldsymbol{w}}(e) + \delta_e$. *The operation takes* $\tilde{O}(|\Delta|)$ *time (note that* $|\Delta|$ *corresponds to the number of increments).*

As outlined earlier, the cut listing data structure will be invoked with $\widehat{\mathbf{w}} = \mathbf{w}_\rho$.

5.3 Truncated Lazy MWU Increment

The data structure is formally summarized by the definition below.

▶ **Definition 27** (Truncated Lazy MWU Increment). *A truncated lazy MWU increment denoted by $\mathcal{L}$ maintains the approximate weight function $\boldsymbol{w}$ explicitly, and exact weight $\boldsymbol{w}^{\text{mwu}}$ implicitly and supports the following operations:*[14]

- $\mathcal{L}.\textsc{Init}(G, \boldsymbol{w}^{\text{init}}, \rho)$ *where G is a graph, $\boldsymbol{w}^{\text{init}}$ is the initial weight function, $\rho \in \mathbb{R}_{>0}$: Intialize the data structure, and set $\boldsymbol{w} \leftarrow \boldsymbol{w}^{\text{init}}$.*
- $\mathcal{L}.\textsc{Punish}([[C]])$ *where C is a cut: Internally punish the free cut (C, F) for some F (to be made precise later) and output a list of increment $\Delta = \{(e, \delta_e)\}$ so that for each $e \in E$, $\boldsymbol{w}^{\text{init}}(e)$ plus the total increment over e is $\boldsymbol{w}_\rho(e)$.*
- $\mathcal{L}.\textsc{Flush}()$*: Return the exact weight $\boldsymbol{w}^{\text{mwu}}$.*

Remark that the output list of increments returned by Punish is mainly for the purpose of syncing with the cut listing data structure (so it aims at maintaining $\mathbf{w}_\rho$ instead of $\mathbf{w}$). Also, in the Punish operation, the data structure must compute the set $F \subseteq C$ of free edges efficiently (these are the edges whose weights would not be increased). This is one of the reasons for which we cannot use the lazy update data structure in [6] as a blackbox.

▶ **Theorem 28.** *There exists a lazy MWU increment with the following time complexity: (i) init operation takes $\tilde{O}(m)$ time, (ii) Punish takes $\tilde{O}(K) + \widetilde{O}\left(\sum_e \log \frac{\boldsymbol{w}^{\text{mwu}}(e)}{\boldsymbol{w}^{\text{init}}(e)}\right)$ time in total where K is the number of calls to Punish and outputs at most $\widetilde{O}\left(\sum_e \log \frac{\boldsymbol{w}^{\text{mwu}}(e)}{\boldsymbol{w}^{\text{init}}(e)}\right)$ increments, and (iii) flush takes $\tilde{O}(m)$ time. Moreover, the Invariant 24 is maintained throughout the execution.*

For space reason, we prove Theorem 28 in the full version of the paper.

5.4 A Fast Range Punisher for Normalized Free Cut Problem

Now we have all necessary ingredients to prove Theorem 22. The algorithm is very simple and described in Algorithm 1. We initialize the cut-listing data structure $\mathcal{D}$ so that it maintains the truncated weight $\mathbf{w}_\rho$ and the lazy weight data structure $\mathcal{L}$. We iteratively use $\mathcal{D}$ to find a cheap cut in $(G, \mathbf{w}_\rho)$ until no such cut exists. Due to our mapping theorem, such a cut found can be used for our problem, and the data structure $\mathcal{L}$ is responsible for punishing the weights (Line 8) and returns the list of edges to be updated (this is for the cut-listing $\mathcal{D}$ to maintain its weight function $\mathbf{w}_\rho$).

[14] This is implicit in the sense that w is divided into parts and they are internally stored in different memory segments. Whenever needed, the real weight can be constructed from the memory content in near-linear time.

Algorithm

Algorithm 1 FastRangePunisher$(G, \mathbf{w}, \lambda)$.

Input: $G, \mathbf{w}^{\text{init}}, \lambda, \varepsilon$ such that $\mathsf{OPT}_{\mathbf{w}^{\text{init}}} \geq \lambda$.
Output: a correct weight function $\mathbf{w} = \mathbf{w}^{\text{mwu}}$ such that $\mathsf{OPT}_{\mathbf{w}} \geq (1+\varepsilon)\lambda$.

1 $\mathbf{w} \leftarrow \mathbf{w}^{\text{init}}$ and $\rho \leftarrow (1+\varepsilon)\lambda$
2 Let $\mathbf{w}_\rho$ be the truncated weight function of $\mathbf{w}$.
3 **if** $\mathsf{mincut}_{\mathbf{w}_\rho} \geq k\rho$ **then return** $\boldsymbol{w}$.
4 Let $\mathcal{D}$ and $\mathcal{L}$ be cut listing data structure, and truncated lazy MWU increment.
5 $\mathcal{D}$.Init$(G, \mathbf{w}_\rho, k\rho/(1+\varepsilon), \varepsilon)$
6 $\mathcal{L}$.Init$(G, \mathbf{w}, \rho, \varepsilon)$
7 **while** $\mathcal{D}$.FindCut() returns $[[C]]$ **do**
8 $\quad \Delta \leftarrow \mathcal{L}$.Punish$([[C]])$
9 $\quad \mathcal{D}$.Increment(Δ)
10 $\mathbf{w} \leftarrow \mathcal{L}$.Flush()
11 **return** $\boldsymbol{w}$.

Analysis

By input assumption, we have $\mathsf{OPT}_w \geq \lambda$. If $\mathbf{w}$ is returned at line 3, then $\mathsf{mincut}_{\mathbf{w}_\rho} \geq k\rho$. By Theorem 19(1), $\mathsf{OPT}_{\mathbf{w}^{\text{mwu}}} \geq \mathsf{OPT}_{\mathbf{w}} \geq \rho = (1+\varepsilon)\lambda$, and we are done (since minimum cut can be computed in near-linear time). Now, we assume that $\mathbf{w}$ is returned at the last line. The following three claims imply Theorem 22.

▷ Claim 29. For every cut $[[C]]$ returned by the range cut listing data structure during the execution of Algorithm 1, we have that $(C, H_{\mathbf{w},\rho} \cap C)$ is a $(1+O(\varepsilon))$-approximation to $\mathsf{OPT}_{\mathbf{w}^{\text{mwu}}}$ at the time $[[C]]$ is returned.

We remark that it is important that our cut punished must be approximately optimal w.r.t. the actual MWU weight.

Proof. By definition of $\mathcal{L}$.Flush() operation, we always have that the exact weight function and approximate weight function are identical at the beginning of the loop. By definition of $\mathcal{L}$.Punish$([[C]])$, the total increment plus the initial weight at the beginning of the loop for every edge e is $\mathbf{w}_\rho(e)$ and Invariant 24 holds. Therefore, by definition of $\mathcal{D}$.Increment(Δ), the range cut-listing data structure maintains the weight function $\mathbf{w}_\rho$ internally. We now bound the approximation of each cut $[[C]]$ that $\mathcal{D}$.FindCut() returned. Let $F = H_{\mathbf{w},\rho} \cap C$. By definition of FindCut(), we have that $\mathbf{w}_\rho(C) < k\rho$. By Theorem 19(2), $\mathsf{val}_{\mathbf{w}}(C, F) < (1+\varepsilon)\lambda$. By Invariant 24, we have that $\mathsf{val}_{\mathbf{w}^{\text{mwu}}}(C, \tilde{F}) < (1+O(\varepsilon))\lambda$. Since $\mathsf{OPT}_{\mathbf{w}^{\text{mwu}}} \geq \mathsf{OPT}_{w^{\text{init}}} \geq \lambda$, we have (C, F) is a $(1+O(\varepsilon))$-approximation to OPT_w. ◁

▷ Claim 30. At the end of Algorithm 1, we have $\mathsf{OPT}_{\mathbf{w}^{\text{mwu}}} \geq (1+\varepsilon)\lambda$.

Proof. Consider the time when $\mathcal{D}$.FindCut() outputs $\emptyset$. The fact that this procedure terminates means that $\mathsf{mincut}_{\mathbf{w}_\rho} \geq k\rho$. Therefore, Theorem 19(1) implies that $\mathsf{OPT}_{\mathbf{w}} \geq (1+\varepsilon)\lambda$. Let (C^*, F^*) be an optimal normalized free cut with respect to $\mathbf{w}^{\text{mwu}}$. We have

$$\begin{aligned}\mathsf{OPT}_{\mathbf{w}^{\text{mwu}}} &= \mathsf{val}_{\mathbf{w}^{\text{mwu}}}(C^*, F^*) \\ &\geq \mathsf{val}_{\mathbf{w}}(C^*, F^*) \\ &\geq \mathsf{OPT}_{\mathbf{w}} \\ &\geq (1+\varepsilon)\lambda\end{aligned}$$

where the first inequality follows from Invariant 24. ◁

▷ Claim 31. Algorithm 1 terminates in $\tilde{O}(m + K + \frac{1}{\varepsilon} \cdot \sum_{e \in E} \log(\frac{\mathbf{w}(e)}{\mathbf{w}^{\text{init}}(e)}))$ time where K is the number of PUNISH operations.

Proof. We first bound the running time due to truncated lazy MWU increment. By Theorem 28, the total running time due to $\mathcal{L}$ (i.e., $\mathcal{L}$.INIT, $\mathcal{L}$.PUNISH, $\mathcal{L}$.FLUSH) is $\tilde{O}(m + K + \frac{1}{\varepsilon} \cdot \sum_{e \in E} \log(\frac{\mathbf{w}(e)}{\mathbf{w}^{\text{init}}(e)}))$ time where K is the number of PUNISH operations. We bound the running time due to cut-listing data structure. Observe that the number of cuts listed equals the number of calls of PUNISH operations, and the total number of edge increments in $\mathcal{D}$ is $\widetilde{O}\left(\frac{1}{\varepsilon} \cdot \sum_{e \in E} \log(\frac{\mathbf{w}(e)}{\mathbf{w}^{\text{init}}(e)})\right)$. By Theorem 26, the total running time due to $\mathcal{D}$ (i.e, $\mathcal{D}$.INIT, $\mathcal{D}$.FINDCUT(), $\mathcal{D}$.INCREMENT(Δ)) is as desired. ◁

6 LP Rounding for kECSS (Proof of Theorem 15)

In this section, we show how to round the LP solution x found by invoking Theorem 1. The main idea is use a sampling technique to sparsify the support of x. On the subgraph $G' \subseteq G$ based on this sparsified support, we apply the 2-approximation algorithm of Khuller and Vishkin [32] to obtain a $(2+\varepsilon)$-approximation solution.

Let G be a graph with capacities c (we omit capacities whenever it is clear from the context). Our algorithm performs the following steps.

Step 1: Sparsification

We will be dealing with the following LP relaxation for kECSS.

$$\min\{\sum_{e \in E(G)} c(e)x_e : \sum_{e \in C \setminus S} x_e \geq k - |S|, \quad \forall C \in \mathcal{C}\ \forall S \in \{F : |F| \leq k-1 \wedge F \subseteq C\}, x \geq 0\}$$

Denote by $\mathsf{LP}_{kECSS}(G)$ the optimal LP value on input G. We prove the following lemma in the full version of the paper that will allow us to sparsify our graph without changing the optimal fractional value by too much:

▶ **Lemma 32.** *Given an instance (G, c), and in $\tilde{O}(m/\varepsilon^2)$ time, we can compute a subgraph G' having at most $\widetilde{O}(nk/\varepsilon^2)$ edges such that $\mathsf{LP}_{kECSS}(G') = (1 \pm O(\varepsilon))\mathsf{LP}_{kECSS}(G)$.*

The first step is simply to apply this lemma to obtain G' from G.

Step 2: Reduction to k-arborescences

Next, we reduce the kECSS problem to the minimum-cost k-arborescence problem which, on capacitated directed graph (H, c_H), can be described as the following IP:

$$\min\{\sum_{e \in E(H)} c_H(e)z_e : \sum_{e \in \delta^+(C)} z_e \geq k \text{ for } C \in \mathcal{C}; z \in \{0,1\}^{E(H)}\}$$

where $\mathcal{C}$ is the set of all cuts C such that $\{r\} \subseteq C \subsetneq V(G)$. Denote by $\mathsf{OPT}_{ar}(H)$ and $\mathsf{LP}_{ar}(H)$ the optimal integral and fractional values[15] of the minimum-cost k-arborescence problem respectively. We use the following integrality of its polytope:

▶ **Theorem 33** ([41], Corollary 53.6a)**.** *The minimum-cost k-arborescence's polytope is integral, so we have that $\mathsf{OPT}_{ar}(H) = \mathsf{LP}_{ar}(H)$ for every capacitated input graph H.*

[15] The relaxation is simply $\min\{\sum_{e \in E(H)} c_H(e)z_e : \sum_{e \in \delta^+(C)} z_e \geq k \text{ for } C \in \mathcal{C}; z \in [0,1]^{E(H)}\}$.

For any undirected graph G, denote by $D[G]$ the directed graph obtained by creating, for each (undirected) edge uv in G, two edges $(u \to v)$ and $(v \to u)$ in $D[G]$ whose capacities are just $c(uv)$. We will use the following theorem by Khuller and Vishkin (slightly modified) that relates the optimal values of the two optimization problems.

▶ **Theorem 34.** *For any graph (H, c), the following properties hold:*

- $\mathsf{LP}_{ar}(D[H]) \leq 2\mathsf{LP}_{kECSS}(H)$, *and*
- *Any feasible solution for k-arborescences in $D[H]$ induces a feasible kECSS solution in H of at most the same cost.*

Note that Theorem 33 and the algorithm by Khuller and Vishkin imply that the integrality gap of the kECSS LP is at most 2. While this result is immediate, it seems to be a folklore. To the best of our knowledge, it was not explicitly stated anywhere in the literature. This integrality gap allows us to obtain the first part of Corollary 2. We defer the proof of Theorem 34 to the full version of the paper. Our final tool to obtain Theorem 15 (and the second part of Corollary 2) is Gabow's algorithm:

▶ **Theorem 35** ([20])**.** *Given a graph $G = (V, E, c)$ with positive cost function c, a fixed root $r \in V$, and let $c_{\max}$ be the maximum cost on edges, there exists an algorithm that in $\tilde{O}(km\sqrt{n}\log(nc_{\max}))$ time outputs the integral minimum-cost k-arborescence.*

Algorithm of Theorem 15

Now, using the graph G' created in the first step, we create $D[G']$, and invoke Gabow's algorithm to compute an optimal k-arborescence in $D[G']$. Let $S \subseteq E(G)$ be the induced kECSS solution.

The cost of S is at most:

$$\begin{aligned}\mathsf{OPT}_{ar}(D[G']) &\leq \mathsf{LP}_{ar}(D[G']) \\ &\leq 2\mathsf{LP}_{kECSS}(G') \\ &\leq 2(1+O(\varepsilon))\mathsf{LP}_{kECSS}(G) \\ &\leq 2(1+O(\varepsilon))\mathsf{OPT}_{kECSS}(G)\end{aligned}$$

The first inequality is due to Theorem 33. The second one is due to Theorem 34 (first bullet). The third one is due to Lemma 32.

Analysis

Step 1 takes $\tilde{O}(m/\varepsilon^2)$ time, by Lemma 32. As the sparsified G' has $m' = \tilde{O}(\frac{nk}{\varepsilon^2})$ edges, for Step 2, by Theorem 35, we can compute the arborescence in $O(km'\sqrt{n}\log(nc_{\max})) = \tilde{O}(\frac{k^2 n^{1.5}}{\varepsilon^2}\log c_{\max})$ time. We show in the full version how to remove the term $\log c_{\max}$ in our case. In summary, the total running time is $\tilde{O}\left(\frac{m}{\varepsilon^2} + \frac{k^2 n^{1.5}}{\varepsilon^2}\right)$. Notice that the running time can be $\tilde{O}(\frac{m}{\varepsilon^2} + T_k(kn/\varepsilon^2, n))$ if we let the running time of Theorem 35 be $T_k(m, n)$, this complete the proof for Theorem 15.

Polylogarithmic Sketches for Clustering

Moses Charikar
Stanford University, CA, USA

Erik Waingarten
Stanford University, CA, USA

Abstract

Given n points in ℓ_p^d, we consider the problem of partitioning points into k clusters with associated centers. The cost of a clustering is the sum of p^{th} powers of distances of points to their cluster centers. For $p \in [1, 2]$, we design sketches of size $\text{poly}(\log(nd), k, 1/\epsilon)$ such that the cost of the optimal clustering can be estimated to within factor $1 + \epsilon$, despite the fact that the compressed representation does not contain enough information to recover the cluster centers or the partition into clusters. This leads to a streaming algorithm for estimating the clustering cost with space $\text{poly}(\log(nd), k, 1/\epsilon)$. We also obtain a distributed memory algorithm, where the n points are arbitrarily partitioned amongst m machines, each of which sends information to a central party who then computes an approximation of the clustering cost. Prior to this work, no such streaming or distributed-memory algorithm was known with sublinear dependence on d for $p \in [1, 2)$.

1 Introduction

Given a large number of high-dimensional points, is it possible to compress the raw representation into a very compact sketch so that we can understand how clusterable the data is from just this highly compressed representation? Given n points in d dimensions, we consider the problem of approximating the cost of clustering them into k clusters from a compressed representation whose size is polylogarithmic in both n and d.

For $n, d \in \mathbb{N}$, let $P = \{x_1, \ldots, x_n\} \in \mathbb{R}^d$ be any set of points with polynomially bounded entries (i.e., all coordinates may be represented with $O(\log(nd))$ bits). The (k, z)-clustering problem in ℓ_p^d, asks to partition P into at most k clusters $C_1, \ldots, C_k$ so as to minimize

$$\sum_{\ell=1}^{k} \min_{c_\ell \in \mathbb{R}^d} \sum_{x \in C_\ell} \|x - c_\ell\|_p^z. \tag{1}$$

The problem is a generalization of the k-means and k-median problem; in particular, in Euclidean space ($p = 2$), $z = 2$ corresponds to k-means, and $z = 1$ to k-median.

We note that the raw representation of the dataset uses $O(nd \log(nd))$ bits, and that any algorithm which outputs optimal cluster centers $c_1, \ldots, c_k \in \mathbb{R}^d$, or the optimal clustering $C_1, \ldots, C_k$ must utilize $\Omega(kd)$, or $\Omega(n \log k)$ bits of space, respectively. Hence, such algorithms cannot decrease the dependency on both n and d simultaneously. However, this does not rule out an exponential compression, from $O(nd \log(nd))$ bits to $\text{polylog}(nd)$ bits (for constant k and z), for algorithms which approximate the optimal clustering *cost*, which only needs $O(\log(nd))$ bits. In this work, we show that it is indeed possible to design sketches of size

poly$(\log(nd), 1/\epsilon)$ bits which ϵ-approximate the optimal clustering *cost*, despite the fact that we do not have enough information to compute the clusters nor the cluster centers which achieve such cost.

Our results fit into a line of prior work on approximating the cost of optimization problems without necessarily computing an optimal solution. These have been investigated before for various problems and in various contexts, including estimating minimum spanning tree [40, 31, 33], minimum cost matchings and Earth Mover's Distance [40, 5, 3, 13], minimum vertex cover and maximum matching [59, 56, 62, 57, 26, 47, 15] and model-fit [49, 48, 17]. Specifically for clustering problems, the value of the clustering cost is an important statistic; used, for example, in the "elbow method" for determining the number of clusters needed. We will show these sketches may be efficiently maintained on a stream as well as for distributed-memory models, implying polylog(nd)-bit algorithms for these models of computation.

We start by reviewing a set of techniques in the literature to either reduce the dependence on the data set size or the dependence on the dimension.

Coresets

The coreset technique is a "dataset compression" mechanism, aiming to reduce the dependency on n. From the n points $P \subset \mathbb{R}^d$, an algorithm computes a much smaller (weighted) set of points $S \subset \mathbb{R}^d$, $w\colon S \to \mathbb{R}_{\geq 0}$, such that the cost of clustering the weighted points S, w approximates that of P. Following a long line of work [11, 36, 1, 24, 52, 34, 35, 20, 61, 39, 29], the best coreset constructions for (k, z)-clustering in ℓ_p achieve sizes $\tilde{O}(k/\epsilon^4) \cdot \min\{1/\epsilon^{z-2}, k\}$ for a $(1 \pm \epsilon)$-approximation. The ensuing streaming and distributed-memory algorithms maintain a coreset of the input; these algorithms find (approximately) optimal centers $c_1, \ldots, c_k \in \mathbb{R}^d$ and use space complexity $d \cdot \tilde{O}(k/\epsilon^4) \cdot \min\{1/\epsilon^{z-2}, k\} \cdot \text{polylog}(n)$.[1]

Dimension Reduction and Sketching

In addition to constructing coresets, an algorithm may seek to optimize the dependence on d. There is a large body of work studying (oblivious) dimensionality reduction and sketching, where strong compression results are known for computing distances [2, 51, 60, 12, 23, 30, 42, 41, 44, 46, 7, 8, 18]. For example, for $p \in [1, 2]$ there exists a (randomized) sketch $\mathbf{sk}\colon \mathbb{R}^d \to \mathbb{R}^t$ with t much smaller than d such that, for any two vectors $x, y \in \mathbb{R}^d$, an algorithm can approximate $\|x - y\|_p$ from $\mathbf{sk}(x)$ and $\mathbf{sk}(y)$ with high probability. While these results are encouraging, leveraging such sketches for distance computation in order to compress entire optimization problems like (1) is highly nontrivial. The challenge is that (1) implicitly considers distances among infinitely many vectors, and we need to rule out the possibility of spurious low cost solutions in the "sketched" space which do not have an analog in the original space. In particular, prior to this work, no streaming or distributed-memory algorithm was known which could reduce the dependence on d for $p \in [1, 2)$.

There is one setting, of Euclidean space ($p = 2$), where one can sketch vectors while preserving (1). A sequence of works [19, 27, 14, 55] show that applying a Johnson-Lindenstrauss [45] map $\mathbf{\Pi}\colon \mathbb{R}^d \to \mathbb{R}^t$ with $t = O(z^4 \log(k/\epsilon)/\epsilon^2)$, sketches Euclidean vectors to $O(t \log(nd))$ bits and preserves (1) up to $1 \pm \epsilon$. We emphasize that Euclidean space $p = 2$ is special in this regard, because the Johnson-Lindenstrauss map achieves *dimension reduction*, a property known not to hold in ℓ_1 [22, 54, 4]. In particular, d-dimensional vectors $x \in \mathbb{R}^d$ in Euclidean space are sketched to vectors $\mathbf{\Pi}(x) \in \mathbb{R}^t$ in Euclidean space, i.e., one estimates

[1] The $\log n$-factors arise from utilizing the "merge-and-reduce" framework for maintaining coresets on a stream [16, 1], and the fact the coreset constructions are randomized.

$\|x-y\|_2$ by $\|\mathbf{\Pi}(x)-\mathbf{\Pi}(y)\|_2$. Thus the optimization problem (1) for d-dimensional Euclidean space reduces to the same optimization problem for a much smaller dimensional Euclidean space. This can therefore be composed with known coreset constructions. Importantly, the "sketched" space inherits all geometric properties of Euclidean spaces, a key aspect of prior works, and the reason they do not extend beyond Euclidean space. The technical challenge in applying sketches for ℓ_p when $p \neq 2$ is that the "sketched" space is non-geometric.[2]

1.1 Our results

We give a streaming and distributed-memory algorithm for (k,p)-clustering in ℓ_p with space complexity $\mathrm{poly}(\log(nd), k, 1/\epsilon)$ bits.

▶ **Theorem 1** (Streaming (k,p)-Clustering in ℓ_p). *For $p \in [1,2]$, there exists an insertion-only streaming algorithm which processes a set of n points $x_1,\ldots,x_n \in \mathbb{R}^d$ utilizing $\mathrm{poly}(\log(nd), k, 1/\epsilon)$ bits which outputs a parameter $\boldsymbol{\eta} \in \mathbb{R}$ satisfying*

$$(1-\epsilon)\min_{\substack{C_1,\ldots,C_k\\ \text{partition } [n]}}\sum_{\ell=1}^{k}\min_{c_\ell\in\mathbb{R}^d}\sum_{i\in C_\ell}\|x_i-c_\ell\|_p^p \le \boldsymbol{\eta} \le (1+\epsilon)\min_{\substack{C_1,\ldots,C_k\\ \text{partition } [n]}}\sum_{\ell=1}^{k}\min_{c_\ell\in\mathbb{R}^d}\sum_{i\in C_\ell}\|x_i-c_\ell\|_p^p$$

with probability at least 0.9.

▶ **Theorem 2** (Distributed-Memory (k,p)-Clustering in ℓ_p). *For $p \in [1,2]$, there exists a public-coin protocol where m machines receive an arbitrary partition of n points $x_1,\ldots,x_n \in \mathbb{R}^d$, each communicates $\mathrm{poly}(\log(md), k, 1/\epsilon)$ bits to a central authority who outputs a parameter $\boldsymbol{\eta} \in \mathbb{R}$ satisfying*

$$(1-\epsilon)\min_{\substack{C_1,\ldots,C_k\\ \text{partition } [n]}}\sum_{\ell=1}^{k}\min_{c_\ell\in\mathbb{R}^d}\sum_{i\in C_\ell}\|x_i-c_\ell\|_p^p \le \boldsymbol{\eta} \le (1+\epsilon)\min_{\substack{C_1,\ldots,C_k\\ \text{partition } [n]}}\sum_{\ell=1}^{k}\min_{c_\ell\in\mathbb{R}^d}\sum_{i\in C_\ell}\|x_i-c_\ell\|_p^p$$

with probability at least 0.9.

Both algorithms will follow from applying a coreset and compressing the representation of the coreset points into sketches to recover single-cluster cost. Specifically, the bottleneck for our algorithm will be estimating the cost of (k,p)-clustering in ℓ_p for $k=1$. We give a linear sketch such that given a set of points $x_1,\ldots,x_n \in \mathbb{R}^d$, one may approximate the ℓ_p^p-median cost:

$$\min_{y\in\mathbb{R}^d}\sum_{i=1}^{n}\|x_i-y\|_p^p.$$

Most of the technical work will be devoted to sketching this "ℓ_p^p-median cost" objective. Then, the streaming and distributed-memory algorithm will evaluate the sum of ℓ_p^p-median costs for all possible partitions of the coreset points into k parts. The following theorem gives a linear sketch for approximating the ℓ_p^p-median cost.[3]

[2] For example, the sketched space for ℓ_p with $p \neq 2$ does not satisfy the triangle inequality: it is not the case that for any $x,y,z \in \mathbb{R}^d$, the estimate of $(\mathbf{sk}(x),\mathbf{sk}(y))$ plus the estimate of $(\mathbf{sk}(y),\mathbf{sk}(z))$ is less than the estimate of $(\mathbf{sk}(x),\mathbf{sk}(z))$. On the other hand, for $p=2$, the estimates of $(\mathbf{sk}(x),\mathbf{sk}(y))$, $(\mathbf{sk}(y),\mathbf{sk}(z))$, and $(\mathbf{sk}(x),\mathbf{sk}(z))$ are $\|\mathbf{sk}(x)-\mathbf{sk}(y)\|_2$, $\|\mathbf{sk}(y)-\mathbf{sk}(z)\|_2$, and $\|\mathbf{sk}(x)-\mathbf{sk}(z)\|_2$, so the triangle inequality does hold in the sketched space.

[3] A related although different work is that of approximating the ℓ_p^p-median (for instance, see Appendix F of [10]). An ℓ_p^p-median is a vector in $\mathbb{R}^d$ which means the sketch outputs d numbers; however, we will sketch the ℓ_p^p-median cost, which is a real number. Hence, our sketch will use $\mathrm{poly}(\log(nd), 1/\epsilon)$ space, as opposed to $\Omega(d)$ space needed to describe an ℓ_p^p-median.

▶ **Theorem 3** (ℓ_p^p-Median Sketch)**.** *For $p \in [1,2]$, there exists a linear sketch which processes a set of n points $x_1, \ldots, x_n \in \mathbb{R}^d$ into a vector $\mathbb{R}^t$ with $t = \text{poly}(\log(nd), 1/\epsilon)$ and outputs a parameter $\boldsymbol{\eta} \in \mathbb{R}$ satsifying*

$$(1-\epsilon) \min_{y \in \mathbb{R}^d} \sum_{i=1}^{n} \|x_i - y\|_p^p \leq \boldsymbol{\eta} \leq (1+\epsilon) \min_{y \in \mathbb{R}^d} \sum_{i=1}^{n} \|x_i - y\|_p^p$$

with probability at least 0.9*.*

There are a few important remarks to make:

- The requirement that $p \leq 2$ is necessary for the exponential compression we desire. For $p > 2$, there are strong lower bounds for sketching distances which show that such sketches require $\Omega(d^{1-2/p})$ space [12]. For $p < 1$, we are not aware of small coresets.
- The focus of this work is on optimizing the space complexity of the sketch, and while we do not explicitly specify the running time of the sketching and streaming algorithms, a naive implementation runs in time $(k \log(nd)/\epsilon)^{(k \log n/\epsilon)^{O(1)}}$. The exponential factor is due to the fact that we evaluate the cost of all possible partitions of the $(k \log(n)/\epsilon)^{O(1)}$-coreset points into k clusters. One could alleviate the exponential dependence to $(k/\epsilon)^{O(1)}$ (as opposed to $(k \log n/\epsilon)^{O(1)}$) by running more sophisticated approximation algorithms [11, 50] on the sketched representation of the coreset.[4] We note that a super-polynomial dependence on k should is unavoidable, because $(1 \pm \epsilon)$-approximations for (k, z)-clustering problems, for *non-constant* k, are NP-hard [9, 53, 28].
- It would be interesting to generalize Theorem 1 to dynamic streams. The reason our algorithm works in the insertion-only model is that we utilize the coreset of [39] with the merge-and-reduce framework [16, 1] which do not support deletions. While there exist dynamic coreset constructions for the streaming model [21, 38], our use of coresets is not entirely black-box. Other dynamic coresets, like [37], focus on update time and do not optimize the space complexity. We must ensure that the algorithm for constructing the coreset does not utilize the d-dimensional representation of the dataset points. The coreset construction of [39] only consider distances between the dataset points, so it suffices for us to only maintain a sketch of the dataset points.
- The fact that $z = p$ in our theorems above is a consequence of our techniques. It is unclear to us whether this assumption is necessary, although our approach hinges on the fact ℓ_p^p is additive over the d coordinates. We leave this as a problem for future work.

A similar, yet importantly different notion of (k, z)-clustering considers *medoid* cost, where the centers of the k clusters $c_1, \ldots, c_k$ are restricted to be dataset points. While seemingly similar to the (k, z)-clustering objective where centers are unrestricted, these two are qualitatively very different from a sketching perspective. In the full version, we show that while a two-pass sketching algorithm may ϵ-approximate the medoid cost, ϵ-approximations for one-pass sketching algorithm require polynomial space.

1.2 Technical Overview

We give an overview of Theorem 3. Once that is established, combining the ℓ_p^p-median sketch with coresets, thereby establishing Theorems 1 and 2 is (relatively) straight-forward (for more details, we refer the reader to the full version). Recall that for $p \in [1,2]$, we will process n points $x_1, \ldots, x_n \in \mathbb{R}^d$, and aim to return an approximation to the ℓ_p^p-median cost:

[4] The one subtlety is that the algorithm should be implemented without explicitly considering the d-dimensional representation of the points. Instead, it should only use the sketches of Theorem 3.

$$\min_{c\in\mathbb{R}^d}\sum_{i=1}^{n}\|x_i-c\|_p^p. \tag{2}$$

It will be useful to assume that the points are centered, i.e., $\sum_{i=1}^n x_i = 0 \in \mathbb{R}^d$ (we can enforce this because our sketches will be linear). The approach will come from the fact that the above optimization problem decomposes into a sum of d independent optimizations, one for each coordinate, and (2) seeks to evaluate the sum. Specifically, we may write

$$\min_{c\in\mathbb{R}^d}\sum_{i=1}^{n}\|x_i-c\|_p^p = \sum_{j=1}^{d}\min_{c_j\in\mathbb{R}}\sum_{i=1}^{n}|x_{ij}-c_j|^p.$$

Furthermore, for any fixed $j\in[d]$, estimating

$$\min_{c_j\in\mathbb{R}}\sum_{i=1}^{n}|x_{ij}-c_j|^p \tag{3}$$

is much more amenable to ℓ_p-sketching. Specifically, we let $x_{\cdot,j}\in\mathbb{R}^n$ be the vector containing the j-th coordinates of all n points, and $\mathbf{1}\in\mathbb{R}^n$ be the all-1's vector. Then, the quantity $\sum_{i=1}^n |x_{ij}-c_j|^p = \|x_{\cdot,j}-c_j\mathbf{1}\|_p^p$, and since the ℓ_p-sketches are linear, an algorithm may maintain $\mathbf{sk}(x_{\cdot,j})\in\mathbb{R}^t$ (for $t=\mathrm{poly}(\log(nd))$) and after processing, could iterate through various values of $c_j\in\mathbb{R}$ to evaluate

$$\left(\sum_{i=1}^{n}|x_{ij}-c_j|^p\right)^{1/p} = \|x_{\cdot,j}-c_j\mathbf{1}\|_p \approx_{1\pm\epsilon} \text{ estimate of } (\mathbf{sk}(x_{\cdot,j}),\mathbf{sk}(c_j\mathbf{1})),$$

and output the smallest value of $c_j\in\mathbb{R}$ found. In order to guarantee an $(1\pm\epsilon)$-approximation of (3), only $\mathrm{poly}(1/\epsilon)$ values of c_j need to be tried (since first evaluating $c_j=0$ will specify the range where the optimal c_j may lie). A simple union bound implies that for any fixed $j\in[d]$, we can prepare a small sketch $\mathbf{sk}(x_{\cdot,j})$ from which we can approximate (3).

In summary, we want to estimate the sum of d minimization problems. Even though each of the d problems could be solved independently with a linear sketch, we do not want to process d linear sketches (as this increases space). In addition, we do not know which of the d minimizations will significantly affect the sum; hence, if we only (uniformly) sampled few $\boldsymbol{j}_1,\ldots,\boldsymbol{j}_t\sim[d]$ and only processed $t\ll d$ sketches along the sampled dimensions, the variance of the estimator may be too large, making it completely useless. The technique we will use was recently developed in [25], building on [6, 43], under the name "ℓ_p-sampling with meta-data." In this paper, we further develop the ideas, and apply them to sketches for clustering in a simple and modular way. We refer the reader to Remark 4 (following this technical overview), where we expand on the comparison to [25].

The goal is to approximate the sum of the d minimization problems by *importance sampling* (see Chapter 9 of [58]). While importance sampling is a well-known technique, it's use in (one-pass) linear sketching algorithms is counter-intuitive, and we are not aware of any linear sketches which use importance sampling in the literature, expect for this and the recent work of [25, 32]. Importance sampling will aim to estimate (2) by sampling with respect to an alternate distribution $\mathcal{D}$. In particular, (2) may be re-written as

$$d\cdot\mathop{\mathbf{E}}_{\boldsymbol{j}\sim[d]}\left[\min_{c_{\boldsymbol{j}}\in\mathbb{R}}\sum_{i=1}^{n}|x_{i\boldsymbol{j}}-c_{\boldsymbol{j}}|^p\right] = d\mathop{\mathbf{E}}_{\boldsymbol{j}\sim\mathcal{D}}[\mathbf{Y}_{\boldsymbol{j}}] \qquad \text{where}$$

$$\mathbf{Y}_{\boldsymbol{j}} \stackrel{\text{def}}{=} \min_{c_{\boldsymbol{j}}\in\mathbb{R}}\sum_{i=1}^{n}|x_{i\boldsymbol{j}}-c_{\boldsymbol{j}}|^p\cdot\frac{1}{\mathbf{Pr}_{\mathcal{D}}[\boldsymbol{j}]}, \tag{4}$$

where $\mathcal{D}$ is a distribution chosen so the variance of the random variable $\mathbf{Y}_{\boldsymbol{j}}$ for $\boldsymbol{j} \sim \mathcal{D}$ is bounded. Once the variance of the random variable is bounded, only a few samples are needed to estimate its expectation in (4). In general, the alternate distribution $\mathcal{D}$ depends on the data in order to decrease the variance; for instance, coordinates $j \in [d]$ whose value of (3) is higher should be sampled more often. Hence, importance sampling inherently interacts with the data in a two-stage process: 1) first, it samples $\boldsymbol{j} \sim \mathcal{D}$ (where the distribution is data-dependent), and 2) second, it evaluates $\mathbf{Y}_{\boldsymbol{j}}$ by using (3) and $\mathbf{Pr}_{\mathcal{D}}[\boldsymbol{j}]$ for the value $\boldsymbol{j} \in [d]$ specified in the first step.

In a two-pass algorithm, the two steps may be implemented sequentially. A *sampling* sketch, like that of [43], is used to sample $\boldsymbol{j} \sim \mathcal{D}$ in the first pass. In the second pass, the algorithm knows the value of the sampled $\boldsymbol{j}$, so it maintains a sketch $\mathbf{sk}(x_{\cdot,\boldsymbol{j}})$ of size t and a sketch $\mathbf{sk}'(\mathbf{Pr}_{\mathcal{D}}[\boldsymbol{j}])$ of size t' (to estimate $\mathbf{Pr}_{\mathcal{D}}[\boldsymbol{j}]$) from which it can evaluate the random variable $\mathbf{Y}_{\boldsymbol{j}}$. The counter-intuitive aspect is that, in this case, we will perform both steps in one-pass:

- We will use an ℓ_p-sampling sketch of [43] to sample from an importance sampling distribution $\mathcal{D}$, and
- Concurrently, we prepare $2d$ linear sketches: d sketches $\mathbf{sk}(x_{\cdot,j})$ to evaluate (3), one for each $j \in [d]$, and d sketches $\mathbf{sk}'(\mathbf{Pr}_{\mathcal{D}}[j])$ to evaluate $\mathbf{Pr}_{\mathcal{D}}[j]$, one for each $j \in [d]$. The non-trivial part is to *sketch the sketches*. by compressing the $2d$ linear sketches into a $O(\text{polylog}(nd))$-bit Count-Min data structure [30].

The guarantee will be that the ℓ_p-sampling sketch of [43] generates a sample $\boldsymbol{j} \sim \mathcal{D}$, and the Count-Min data structure can recover an approximation

$$\widehat{\mathbf{sk}_1} \approx \mathbf{sk}(x_{\cdot,\boldsymbol{j}}) \qquad \text{and} \qquad \widehat{\mathbf{sk}_2} \approx \mathbf{sk}'(\mathbf{Pr}_{\mathcal{D}}[\boldsymbol{j}]).$$

Furthermore, the sketch evaluation algorithm, which executes on the approximation $\widehat{\mathbf{sk}_1}$ and $\widehat{\mathbf{sk}_2}$, should be able to recover $(1 \pm \epsilon)$-approximations to (3) and $\mathbf{Pr}_{\mathcal{D}}[\boldsymbol{j}]$, so that the ratio of the two is a $(1 \pm 2\epsilon)$-approximation to $\mathbf{Y}_{\boldsymbol{j}}$.

While the above plan provides a general recipe for importance sampling, the idea of "sketching the sketches" may not be applied in a black-box manner. First, the alternate distribution $\mathcal{D}$ should admit a sampling sketch. Second, the sketch evaluation algorithm for $\mathbf{sk}(x_{\cdot,j})$ and $\mathbf{sk}'(\mathbf{Pr}_{\mathcal{D}}[j])$ should be robust to the errors introduced by the Count-Min compression. Bounding the errors introduced by the Count-Min data structure, and ensuring that the approximate sketches $\widehat{\mathbf{sk}_1}$ and $\widehat{\mathbf{sk}_2}$ constitutes the bulk of the technical work. Specifically for us, the plan is executed as follows: when $\sum_{i=1}^{n} x_i = 0 \in \mathbb{R}^d$, every j satisfies (we refer the reader to the full version for a thorough justification)

$$\frac{\min_{c_j \in \mathbb{R}} \sum_{i=1}^{n} |x_{ij} - c_j|^p}{\|x_{\cdot,j}\|_p^p} \in [2^{-p}, 1]. \tag{5}$$

Hence, we will let $\mathcal{D}$ be the distribution supported on $[d]$ given by setting, for each $j \in [d]$,

$$\Pr_{\boldsymbol{j} \sim \mathcal{D}}[\boldsymbol{j} = j] = \frac{\|x_{\cdot,j}\|_p^p}{Z} \qquad \text{where} \qquad Z = \sum_{j=1}^{d} \|x_{\cdot,j}\|_p^p = \sum_{i=1}^{n} \sum_{j=1}^{d} |x_{ij}|^p.$$

Note that (5) implies the variance of $\mathbf{Y}_{\boldsymbol{j}}$ for $\boldsymbol{j} \sim \mathcal{D}$ is appropriately bounded. Furthermore, since $\mathcal{D}$ is an ℓ_p-sampling distribution, the ℓ_p-sampling sketches of [43] are useful for sampling $\boldsymbol{j} \sim \mathcal{D}$. Finally, the approach of [43] is particularly suited for bounding the errors incurred by Count-Min on $\widehat{\mathbf{sk}_1}$ and $\widehat{\mathbf{sk}_2}$, which we overview below.

At a high level, the ℓ_p-sampling sketch of [43] generates a sample $\boldsymbol{j}$ from $[d]$ by identifying a *heavy hitter* in a random scaling of the vector specifying the sampling probabilities. In particular, the algorithm generates $\boldsymbol{u}_1, \ldots, \boldsymbol{u}_d \sim \text{Exp}(1)$ and identifies an entry $j \in [d]$ in the vector

$$\left(\frac{\|x_{\cdot,1}\|_p}{\boldsymbol{u}_1^{1/p}}, \frac{\|x_{\cdot,2}\|_p}{\boldsymbol{u}_2^{1/p}}, \ldots, \frac{\|x_{\cdot,d-1}\|_p}{\boldsymbol{u}_{d-1}^{1/p}}, \frac{\|x_{\cdot,d}\|_p}{\boldsymbol{u}_d^{1/p}} \right) \in \mathbb{R}^d,$$

whose value satisfies

$$\frac{\|x_{\cdot,j}\|_p}{\boldsymbol{u}_j^{1/p}} \gtrsim \left(\sum_{j'=1}^{d} \frac{\|x_{\cdot,j'}\|_p^p}{\boldsymbol{u}_{j'}} \right)^{1/p}, \tag{6}$$

and is the largest among those heavy hitters. For the coordinate $\boldsymbol{j} \in [d]$ recovered by the ℓ_p-sampling sketch [43], the inequality (6) gives a lower bound on how large $1/\boldsymbol{u}_{\boldsymbol{j}}^{1/p}$ will be. In particular, by applying the same transformation to the vector of *sketches*,

$$\left(\frac{\mathbf{sk}(x_{\cdot,1})}{\boldsymbol{u}_1^{1/p}}, \ldots, \frac{\mathbf{sk}(x_{\cdot,d})}{\boldsymbol{u}_d^{1/p}} \right) \in (\mathbb{R}^t)^d \qquad \text{and}$$
$$\left(\frac{\mathbf{sk}'(\mathbf{Pr}_{\mathcal{D}}[1])}{\boldsymbol{u}_1^{1/p}}, \ldots, \frac{\mathbf{sk}'(\mathbf{Pr}_{\mathcal{D}}[d])}{\boldsymbol{u}_d^{1/p}} \right) \in (\mathbb{R}^{t'})^d, \tag{7}$$

the t and t' coordinates corresponding to the sketches $\mathbf{sk}(x_{\cdot,\boldsymbol{j}}) \in \mathbb{R}^t$ and $\mathbf{sk}'(\mathbf{Pr}_{\mathcal{D}}[\boldsymbol{j}]) \in \mathbb{R}^{t'}$ will be heavy hitters of those vectors as well. Namely, with only $\text{poly}(\log(nd), 1/\epsilon)$-bits, the Count-Min data structure will recover the entries of $\mathbf{sk}(x_{\cdot,\boldsymbol{j}})$ and $\mathbf{sk}'(\mathbf{Pr}_{\mathcal{D}}[\boldsymbol{j}])$ up to a small additive error, proportional to the ℓ_1-norm of (7). We know the distribution of sketched vectors (7) (since these are simply ℓ_p-sketches [41]), so we will be able to bound the additive error and show that the sketch evaluation algorithms of $\widehat{\mathbf{sk}_1}$ and $\widehat{\mathbf{sk}_2}$ return the desired $(1 \pm \epsilon)$-approximations.

▶ Remark 4 (Comparison to [25]). The technique, "ℓ_p-sampling with meta-data", arises in [25] in the following context. They seek a linear sketch $\mathbf{sk}\colon \mathbb{R}^d \to \mathbb{R}^t$ which can process a vector $y \in \mathbb{R}^d$ and evaluate a weighted ℓ_1-norm, $\sum_{i=1}^d w_i(y) \cdot |y_i|$, where the weights $w_1(y), \ldots, w_d(y) \in \mathbb{R}_{\geq 0}$ are themselves dependent on the vector y. This arises as an algorithmic step in streaming algorithms for geometric minimum spanning tree and the earth-mover's distance. Mapping the above formulation to our setting, we want to evaluate a weighted ℓ_1-norm as well, where the i-th weight corresponds to $\mathbf{Pr}_{\boldsymbol{j} \sim \mathcal{D}}[\boldsymbol{j} = i]$, and the i-th value seek to sum is $\mathbf{Y}_i$ (as in (4)). The perspective of this technique as importance sampling (as presented in this work) is new. Indeed, the appropriate setting of weights is only apparent once one multiplies and divides the contribution of the j-th coordinate by $\|x_{\cdot,j}\|_p^p$ to define $\mathcal{D}$.

2 Sketching Median Costs

2.1 Statement of Main Lemma

▶ **Theorem 5.** *Fix $n, d \in \mathbb{N}$, as well as $p \in [1, 2]$ and $\epsilon, \delta \in (0, 1)$. There exists a linear sketch using $\text{poly}(\log d, 1/\epsilon, \log(1/\delta))$ space which processes a set of n points $x_1, \ldots, x_n \in \mathbb{R}^d$, and outputs a parameter $\boldsymbol{\eta} \in \mathbb{R}$ which satisfies*

$$\min_{y \in \mathbb{R}^d} \sum_{i=1}^{n} \|y - x_i\|_p^p \leq \boldsymbol{\eta} \leq (1+\epsilon) \min_{y \in \mathbb{R}^d} \sum_{i=1}^{n} \|y - x_i\|_p^p$$

with probability at least $1 - \delta$.

We work with the following representation of a linear sketch. The processed set of n points in $\mathbb{R}^d$ are stacked to form a vector $x \in \mathbb{R}^{nd}$. A linear sketch using space s is a distribution $\mathcal{M}$ supported on $s \times (nd)$ matrices. The theorem states that for any fixed $x_1, \ldots, x_n \in \mathbb{R}^d$, with probability $1 - \delta$ over the draw of $\mathbf{S} \sim \mathcal{M}$, an algorithm with access to the vector $\mathbf{S}x \in \mathbb{R}^s$ and $\mathbf{S}$ can output $\boldsymbol{\eta}$ satisfying the above guarantees.

Linear sketches of the above form imply efficient streaming algorithms, albeit with some subtleties. It is useful to first assume that the streaming algorithm can store its randomness for free (we will address this in the full version) so that it knows the matrix $\mathbf{S}$. In particular, since $\mathbf{S} \in \mathbb{R}^{s \times nd}$ acts on the vector $x \in \mathbb{R}^{nd}$ which vertically stacks $x_1, \ldots, x_n \in \mathbb{R}^d$, the columns of $\mathbf{S}$ may be broken up into n groups of size d, so

$$\mathbf{S} = \begin{bmatrix} \mathbf{S}_1 & \mathbf{S}_2 & \ldots & \mathbf{S}_n \end{bmatrix}, \qquad \text{and} \qquad \mathbf{S}x = \sum_{i=1}^{n} \mathbf{S}_i x_i.$$

In the *insertion-only* model, an algorithm would process the points one-at-a-time, and at time-step j, maintain $\sum_{i=1}^{j} \mathbf{S}_i x_i \in \mathbb{R}^s$. In the *turnstile* model of streaming, there is a subtlety in the implementation; namely, as the algorithm receives insertions and deletions of points in $\mathbb{R}^d$, it must know which index $i \in [n]$ it is considering. The reason is that the algorithm should know which of the sub-matrix $\mathbf{S}_i$ to update the point with.

For our application of the ℓ_p^p-median sketch to (k, p)-clustering in ℓ_p, we consider a weighted ℓ_p^p-median. Namely, for points $x_1, \ldots, x_n \in \mathbb{R}^d$ and weights $\lambda_1, \ldots, \lambda_n \in [0, 1]$ with $\sum_{i=1}^{n} \lambda_i = 1$, the ℓ_p^p-median cost with respect to weights $\lambda_1, \ldots, \lambda_n$ is

$$\min_{y \in \mathbb{R}^d} \sum_{i=1}^{n} \lambda_i \|y - x_i\|_p^p.$$

It is useful to first consider of $\lambda_1 = \cdots = \lambda_n = 1/n$. For general weights, the sketch will receive as input $\mathbf{S} = [\mathbf{S}_1, \ldots, \mathbf{S}_n] \in \mathbb{R}^{s \times (nd)}$, the vector $\sum_{i=1}^{n} \lambda_i^{1/p} \mathbf{S}_i x_i \in \mathbb{R}^s$, and the weights $\lambda_1, \ldots, \lambda_n$.

Centering Points

There is a straight-forward way to process the points so as to assume they are centered. Specifically, the average point may be subtracted from every point by applying a linear map, and since our sketch is linear, subtracting the average point may be incorporated into the sketch. For weights $\lambda_1, \ldots, \lambda_n \in [0, 1]$ satisfying $\sum_{i=1}^{n} \lambda_i = 1$, we consider the linear map

$$(x_1, \ldots, x_n) \mapsto \left(x_1 - \sum_{i=1}^{n} \lambda_i x_i, \ldots, x_n - \sum_{i=1}^{n} \lambda_i x_i \right) \in \mathbb{R}^{nd}.$$

Hence, we assume, without loss of generality, that the points $x_1, \ldots, x_n \in \mathbb{R}^d$ satisfy

$$\sum_{i=1}^{n} \lambda_i x_i = 0 \in \mathbb{R}^d. \tag{8}$$

The centering is useful for deriving the following set of inequalities, which will be useful for our sketching procedures. Suppose we denote $y \in \mathbb{R}^d$ as the point which minimizes $\sum_{i=1}^{n} \lambda_i \|y - x_i\|_p^p$. Then, for every $j \in [d]$,

$$\sum_{i=1}^{n} \lambda_i |y_j - x_{ij}|^p \leq \sum_{i=1}^{n} \lambda_i |x_{ij}|^p \leq 2^p \sum_{i=1}^{n} \lambda_i |y_j - x_{ij}|^p.$$

Importantly for us, every $j \in [d]$ satisfies

$$2^{-p} \leq \frac{\min_{y_j \in \mathbb{R}} \sum_{i=1}^n \lambda_i |y_j - x_{ij}|^p}{\sum_{i=1}^n \lambda_i |x_{ij}|^p} \leq 1. \tag{9}$$

We let $\mathcal{D}$ be the distribution supported on $[d]$ given by setting, for each $j \in [d]$,

$$\mathop{\mathbf{Pr}}_{\boldsymbol{j} \sim \mathcal{D}}[\boldsymbol{j} = j] = \frac{1}{Z} \sum_{i=1}^n \lambda_i |x_{ij}|^p \qquad \text{where} \qquad Z = \sum_{j'=1}^d \sum_{i=1}^n \lambda_i |x_{ij'}|^p = \sum_{i=1}^n \lambda_i \|x_i\|_p^p.$$

Then, the quantity we want to estimate may be equivalently re-written as:

$$\sum_{j=1}^d \min_{y_j \in \mathbb{R}} \sum_{i=1}^n \lambda_i |y_j - x_{ij}|^p = Z \cdot \mathop{\mathbf{E}}_{\boldsymbol{j} \sim \mathcal{D}} \left[\frac{\min_{y_{\boldsymbol{j}} \in \mathbb{R}} \sum_{i=1}^n \lambda_i |y_{\boldsymbol{j}} - x_{i\boldsymbol{j}}|^p}{\sum_{i=1}^n \lambda_i |x_{i\boldsymbol{j}}|^p} \right], \tag{10}$$

where the value within the expectation is bounded between 2^{-p} and 1. Furthermore, the quantity Z will be sketched with an ℓ_p-sketch, and a sample $\boldsymbol{j} \sim \mathcal{D}$ will be drawn with an ℓ_p-sampling sketch. Hence, the plan is to produce $t = O(1/\epsilon^2)$ samples of $\boldsymbol{j}_1, \ldots, \boldsymbol{j}_t \sim \mathcal{D}$, and produce a sketch to evaluate the numerator inside the expectation, and the denominator inside the expectation. Taking an empirical average of the samples to estimate the expectation, and multiplying it by the estimate of Z will give the desired estimator.

▶ **Lemma 6** (Main Lemma). *For any $n, d \in \mathbb{N}$, $p \in [1, 2]$ and $\epsilon, \delta \in (0, 1)$, let $s = \mathrm{poly}(\log d, 1/\epsilon, 1/\delta)$.*[5] *There exists a distribution $\mathcal{S}$ over $s \times (nd)$ matrices, and an algorithm such that for any n vectors $x_1, \ldots, x_n \in \mathbb{R}^d$ and any $\lambda_1, \ldots, \lambda_n \in [0, 1]$ with $\sum_{i=1}^n \lambda_i = 1$ and $\sum_{i=1}^n \lambda_i x_i = 0$, the following occurs:*

- *We sample $\mathbf{S} = [\mathbf{S}_1, \ldots, \mathbf{S}_n] \sim \mathcal{S}$, and we give the algorithm as input $\mathbf{S}$, $\sum_{i=1}^n \mathbf{S}_i(\lambda_i^{1/p} x_i)$, and $\lambda_1, \ldots, \lambda_n$.*
- *The algorithm outputs a tuple of three numbers $(\boldsymbol{j}, \boldsymbol{\alpha}, \boldsymbol{\beta}) \in [d] \times \mathbb{R}_{\geq 0} \times \mathbb{R}_{\geq 0}$. With probability at least $1 - \delta$ over the draw of $\mathbf{S} \sim \mathcal{S}$, we have the following two inequalities:*

$$(1-\epsilon) \left(\sum_{i=1}^n \lambda_i |x_{i\boldsymbol{j}}|^p \right)^{1/p} \leq \boldsymbol{\alpha} \leq (1+\epsilon) \left(\sum_{i=1}^n \lambda_i |x_{i\boldsymbol{j}}|^p \right)^{1/p},$$

$$(1-\epsilon) \min_{z \in \mathbb{R}} \left(\sum_{i=1}^n \lambda_i |x_{i\boldsymbol{j}} - z|^p \right)^{1/p} \leq \boldsymbol{\beta} \leq (1+\epsilon) \min_{z \in \mathbb{R}} \left(\sum_{i=1}^n \lambda_i |x_{i\boldsymbol{j}} - z|^p \right)^{1/p}.$$

- *Furthermore, the distribution of the random variable $\boldsymbol{j}$ is $\epsilon 2^{-p}$-close in total variation distance to $\mathcal{D}$.*

Proof of Theorem 5 assuming Lemma 6. Given Lemma 6, the proof of Theorem 5 is straight-forward. We fix $\lambda_1 = \cdots = \lambda_n = 1/n$, and we first handle the centering. We will utilize Lemma 6 which requires vectors $x_1, \ldots, x_n$ to satisfy $\sum_{i=1}^n \lambda_i x_i = 0$; hence, we sketch the vectors $x'_1, \ldots, x'_n$ given by $x'_i = x_i - \sum_{h=1}^n \lambda_h x_h$, which are now centered. By linearity, this is equivalent to maintaining the vector

$$\sum_{i=1}^n \lambda_i^{1/p} \mathbf{S}_i (x_i - \sum_{h=1}^n \lambda_h x_h) = \sum_{i=1}^n \left(\lambda_i^{1/p} \mathbf{S}_i - \lambda_i \sum_{h=1}^n \lambda_h^{1/p} \mathbf{S}_h \right) x_i \in \mathbb{R}^s.$$

[5] See the full version for the specific polynomial bounds.

We take $t = \omega(1/\epsilon^2)$ independent sketches from Lemma 6 with accuracy parameter $\epsilon/2$ and error probability $\delta = o(1/t)$. This, in turn, gives us t independent samples $(\boldsymbol{j}_1, \boldsymbol{\alpha}_1, \boldsymbol{\beta}_1)$, $\ldots$, $(\boldsymbol{j}_t, \boldsymbol{\alpha}_1, \boldsymbol{\beta}_t)$. By taking a union bound over the t executions of Lemma 6, with high probability, every $\boldsymbol{\alpha}_1, \ldots, \boldsymbol{\alpha}_t$ and $\boldsymbol{\beta}_1, \ldots, \boldsymbol{\beta}_t$ satisfy

$$\boldsymbol{\alpha}_\ell^p \approx_{(1+\epsilon p/2)} \sum_{i=1}^n \lambda_i |x_{i\boldsymbol{k}}|^p \qquad \text{and} \qquad \boldsymbol{\beta}_\ell^p \approx_{(1+\epsilon p/2)} \min_{z\in\mathbb{R}} \sum_{i=1}^n \lambda_i |x_{i\boldsymbol{k}} - z|^p,$$

and $\boldsymbol{j}_1, \ldots, \boldsymbol{j}_t$ are independent draws from a distribution $\mathcal{D}'$ which is $\epsilon 2^{-p}$-close to $\mathcal{D}$. For estimating Z, we use an ℓ_p-sketch to accuracy $\epsilon/2$ and failure probability $\delta = o(1)$. For example, the sketch for Z may proceed by applying an ℓ_p-sketch [41] to the stacked vector $x' \in \mathbb{R}^{nd}$ where

$$x'_{ij} = \lambda_i^{1/p} \cdot x_{ij},$$

so that the ℓ_p norm of x' is exactly $Z^{1/p}$. Let $\widehat{\mathbf{Z}}$ be the estimate for the Z. For our estimate $\boldsymbol{\eta}$ that we will output, we set

$$\boldsymbol{\eta} = \widehat{\mathbf{Z}} \cdot \frac{1}{t} \sum_{\ell=1}^t \operatorname{minmax}\left\{2^{-p}, \left(\frac{\boldsymbol{\beta}_\ell}{\boldsymbol{\alpha}_\ell}\right)^p, 1\right\},$$

where $\operatorname{minmax}(l, x, u)$ is l if $x \le l$, u if $u \ge x$, and x otherwise. To see why our estimator approximates (10), we have $\widehat{\mathbf{Z}}$ is a $(1 \pm \epsilon/2)$-approximation of Z. The latter quantity is the empirical average of t i.i.d random variables, each of which is bounded by 2^{-p} and 1. In particular, we have that with probability at least $1 - o(1)$, Chebyshev's inequality, and the conditions of $\boldsymbol{\beta}_\ell$ and $\boldsymbol{\alpha}_\ell$,

$$\mathop{\mathbf{E}}_{\boldsymbol{j}\sim\mathcal{D}'}\left[\frac{\min_{z\in\mathbb{R}} \sum_{i=1}^n \lambda_i |x_{i\boldsymbol{j}} - z|^p}{\sum_{i=1}^n \lambda_i |x_{i\boldsymbol{j}}|^p}\right] \approx_{(1+2\epsilon p)} \frac{1}{t}\sum_{\ell=1}^t \operatorname{minmax}\left\{2^{-p}, \left(\frac{\boldsymbol{\beta}_\ell}{\boldsymbol{\alpha}_\ell}\right)^p, 1\right\}.$$

It remains to show that

$$\mathop{\mathbf{E}}_{\boldsymbol{j}\sim\mathcal{D}'}\left[\frac{\min_{z\in\mathbb{R}} \sum_{i=1}^n \lambda_i |x_{i\boldsymbol{j}} - z|^p}{\sum_{i=1}^n \lambda_i |x_{i\boldsymbol{j}}|^p}\right] \approx_{(1\pm\epsilon)} \mathop{\mathbf{E}}_{\boldsymbol{j}\sim\mathcal{D}}\left[\frac{\min_{z\in\mathbb{R}} \sum_{i=1}^n \lambda_i |x_{i\boldsymbol{j}} - z|^p}{\sum_{i=1}^n \lambda_i |x_{i\boldsymbol{j}}|^p}\right].$$

This follows from two facts: (1) $\mathcal{D}'$ and $\mathcal{D}$ are $\epsilon 2^{-p}$ close, since the random variable is at most 1, the expectations are off by at most an additive $\epsilon 2^{-p}$-factor, and (2) both quantities above are the average of random variables which are at least 2^{-p}, so an additive $\epsilon 2^{-p}$ error is less than a multiplicative $(1 \pm \epsilon)$-error.

The above gives an estimate which is a $1 \pm \epsilon$-approximation with probability $1 - o(1)$, in order to boost the probability of success to $1 - \delta$, we simply repeat $O(\log(1/\delta))$ times and output the median estimate. ◀

The remainder of the section is organized as follows. We give in the (next) Subsection 2.2, the necessary sketches for obtaining $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ for a fixed coordinate j. Then, in the following Subsection 2.3, we show how we combine various sketches from Subsection 2.2 for different $j \in [d]$ to obtain $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ up to some additive error. Finally, the proof of Lemma 6 appears in the full version, where we apply a randomized transformation to the input so that the additive error from Subsection 2.3 is a multiplicative error for the specific sampled $\boldsymbol{j}$.

2.2 Sketch for Optimizing a Single Coordinate

In this subsection, we give linear sketches which are useful for optimizing over a single coordinate. Specifically, given the n vectors $x_1, \ldots, x_n \in \mathbb{R}^d$ and $j \in [d]$, we consider the k-th coordinate of the n vectors $x_{1j}, x_{2j}, \ldots, x_{nj} \in \mathbb{R}$. Hence, the linear sketches in this section will act on vectors in $\mathbb{R}^n$, corresponding to the j-th coordinates of the points, and will give approximations to

$$\sum_{i=1}^{n} \lambda_j |x_{ij}|^p \quad \text{(Corollary 8)} \quad \text{and} \quad \min_{y_j \in \mathbb{R}} \sum_{i=1}^{n} \lambda_j |y_j - x_{ij}|^p. \quad \text{(Lemma 9)}$$

The lemma statements also consider an additive error term, $\text{err} \in \mathbb{R}_{\geq 0}$, which will be necessary when combining these sketches in Subsection 2.3; however, it may be helpful to consider $\text{err} = 0$ on first reading.

▶ **Lemma 7.** *For any $n \in \mathbb{N}$, $p \in [1,2]$ and $\epsilon, \delta \in (0,1)$, let $s = O(\log(1/\delta)/\epsilon^2)$. There exists a distribution $\mathcal{M}$ over $s \times n$ matrices, and an algorithm such that for any $x \in \mathbb{R}^n$, $\lambda_1, \ldots, \lambda_n \in [0,1]$, and $y \in \mathbb{R}$, the following occurs:*

- *We sample $\mathbf{S} \sim \mathcal{M}$ as well as a random vector $\boldsymbol{\chi} = (\boldsymbol{\chi}_1, \ldots, \boldsymbol{\chi}_s) \in \mathbb{R}^s$ where each is an i.i.d p-stable random variable. For any $\text{err} \in \mathbb{R}_{\geq 0}$, we give the algorithm as input $\mathbf{S}$, $\mathbf{S}(\lambda^{1/p} \circ x) + \text{err} \cdot \boldsymbol{\chi}$, the parameters $\lambda_1, \ldots, \lambda_n$, and y.*[6]
- *The algorithm outputs a parameter $\widehat{\boldsymbol{\eta}} \in \mathbb{R}_{\geq 0}$, which depends on $\mathbf{S}, \mathbf{S}(\lambda^{1/p} \circ x) + \text{err} \cdot \boldsymbol{\chi}$, the parameters $\lambda_1, \ldots, \lambda_n$, and y which satisfies with probability at least $1 - \delta$ over $\mathbf{S}$ and $\boldsymbol{\chi}$,*

$$(1-\epsilon)\left(\sum_{i=1}^{n} \lambda_i |x_i - y|^p + \text{err}^p\right)^{1/p} \leq \widehat{\boldsymbol{\eta}} \leq (1+\epsilon)\left(\sum_{i=1}^{n} \lambda_i |x_i - y|^p + \text{err}^p\right)^{1/p}. \quad (11)$$

Furthermore, for every $j \in [s]$, the random variables $(\mathbf{S}(\lambda^{1/p} \circ x))_j \in \mathbb{R}$ are distributed as $\|\lambda^{1/p} \circ x\|_p \cdot \boldsymbol{\chi}_j$, where $\boldsymbol{\chi}_j$ are independent, p-stable random variables.

Proof. We notice that this simply corresponds to an ℓ_p-sketch of the vector $z \in \mathbb{R}^n$, which is given by letting each $z_i = \lambda^{1/p} \circ (x_i - y)$, so that the ℓ_p-sketch of [41] would accomplish this task. Since the algorithm receives $\mathbf{S}$, $\mathbf{S}(\lambda^{1/p} \circ x) + \text{err} \cdot \chi$ and $y \in \mathbb{R}$, the algorithm may compute $\mathbf{S}(\lambda^{1/p} \circ y \cdot \mathbf{1})$, where $\mathbf{1} \in \mathbb{R}^n$ is an all-1's vector, and evaluate the sketch

$$\mathbf{S}(\lambda^{1/p} \circ x) + \text{err} \cdot \boldsymbol{\chi} - \mathbf{S}(\lambda^{1/p} \circ y \cdot \mathbf{1}) = \mathbf{S}(\lambda^{1/p} \circ (x - y \cdot \mathbf{1})) + \text{err} \cdot \boldsymbol{\chi}$$

by linearity. Furthermore, note that the error simply corresponds to an ℓ_p-sketch of the vector $z' \in \mathbb{R}^{n+1}$ which sets $z'_i = z_i$ for $i \neq n+1$ and $z'_{n+1} = \text{err}$. ◀

▶ **Corollary 8.** *For any $n \in \mathbb{N}$, $p \in [1,2]$ and $\epsilon, \delta \in (0,1)$, let $s = O(\log(1/\delta)/\epsilon^2)$. There exists a distribution $\mathcal{M}$ over $s \times n$ matrices, and an algorithm such that for any $x \in \mathbb{R}^n$, and any $\lambda_1, \ldots, \lambda_n \in [0,1]$, the following occurs:*

- *We sample $\mathbf{S} \sim \mathcal{M}$ and a random vector $\boldsymbol{\chi} = (\boldsymbol{\chi}_1, \ldots, \boldsymbol{\chi}_s) \in \mathbb{R}^s$ of i.i.d p-stable random variables. For any $\text{err} \in \mathbb{R}_{\geq 0}$. We give the algorithm as input $\mathbf{S}$ and $\mathbf{S}(\lambda^{1/p} \circ x) + \text{err} \cdot \boldsymbol{\chi}$.*

[6] The notation $\lambda^{1/p} \circ x \in \mathbb{R}^n$ denotes the Hadamard product, where $(\lambda^{1/p} \circ x)_i = \lambda_i^{1/p} \cdot x_i$.

- *With probability at least* $1-\delta$ *over* $\mathbf{S}$ *and* $\boldsymbol{\chi}$*, the algorithm outputs a parameter* $\widehat{\boldsymbol{\gamma}} \in \mathbb{R}_{\geq 0}$*, which depends on* $\mathbf{S}$*, and* $\mathbf{S}(\lambda^{1/p} \circ x)$ *which satisfies*

$$(1-\epsilon)\left(\sum_{i=1}^{n} \lambda_i |x_i|^p + \mathrm{err}^p\right)^{1/p} \leq \widehat{\boldsymbol{\gamma}} \leq (1+\epsilon)\left(\sum_{i=1}^{n} \lambda_i |x_i|^p + \mathrm{err}^p\right)^{1/p}.$$

Furthermore, for every $j \in [s]$*, the random variables* $(\mathbf{S}(\lambda^{1/p} \circ x))_j \in \mathbb{R}$ *are independent and distributed as* $\|\lambda^{1/p} \circ x\|_p \cdot \boldsymbol{\chi}_j$*, where* $\boldsymbol{\chi}_j$ *are independent, p-stable random variables.*

Proof. We apply Lemma 7 to the vector $x \in \mathbb{R}^n$ with $y = 0$. ◀

▶ **Lemma 9.** *For any* $n \in \mathbb{N}$*,* $p \in [1,2]$ *and* $\epsilon, \delta \in (0,1)$*, let* $s = O(\log(1/(\epsilon\delta))/\epsilon^2)$*. There exists a distribution* $\mathcal{M}$ *over* $s \times n$ *matrices, and an algorithm such that for any* $x \in \mathbb{R}^n$ *and any* $\lambda_1, \ldots, \lambda_n \in [0,1]$ *with* $\sum_{i=1}^n \lambda_i = 1$*, whenever* $\sum_{i=1}^n \lambda_i x_i = 0$*, the following occurs:*

- *We sample* $\mathbf{S} \sim \mathcal{M}$ *and a random vector* $\boldsymbol{\chi} = (\boldsymbol{\chi}_1, \ldots, \boldsymbol{\chi}_s)$ *of i.i.d p-stable random variables. For any* $\mathrm{err} \in \mathbb{R}_{\geq 0}$*. We give the algorithm as input* $\mathbf{S}$*,* $\mathbf{S}(\lambda^{1/p} \circ x) + \mathrm{err} \cdot \boldsymbol{\chi}$*, the parameters* $\lambda_1, \ldots, \lambda_n$*, and a parameter* $\gamma \in \mathbb{R}_{\geq 0}$ *satisfying*

$$(1-\epsilon)\left(\sum_{i=1}^{n} \lambda_i |x_i|^p\right)^{1/p} \leq \gamma \leq (1+\epsilon)\left(\sum_{i=1}^{n} \lambda_i |x_i|^p\right)^{1/p}.$$

- *The algorithm outputs a parameter* $\widehat{\boldsymbol{\beta}} \in \mathbb{R}_{\geq 0}$ *which satisfies*

$$(1-\epsilon)\min_{z\in\mathbb{R}}\left(\sum_{i=1}^{n} \lambda_i |x_i - z|^p + \mathrm{err}^p\right)^{1/p} \leq \widehat{\boldsymbol{\beta}} \leq (1+\epsilon)\min_{z\in\mathbb{R}}\left(\sum_{i=1}^{n} \lambda_i |x_i - z|^p + \mathrm{err}^p\right)^{1/p}. \tag{12}$$

Furthermore, for every $j \in [s]$*, the random variables* $(\mathbf{S}(\lambda^{1/p} \circ x))_j$ *are independent and distributed as* $\|\lambda^{1/p} \circ x\|_p \cdot \boldsymbol{\chi}_j$*, where* $\boldsymbol{\chi}_j$ *are independent, p-stable random variables.*

Proof. We will utilize the sketch from Lemma 7, while varying the y's to find the minimum. Specifically, let $t = 16 \cdot 2^p/\epsilon$, and let the distribution $\mathcal{M}$ be the same as that of Lemma 7 instantiated with error probability $1 - t\delta$ and accuracy parameter $\epsilon/2$. We discretize the interval $[-4\gamma, 4\gamma]$ into t, evenly-spaced out points $y_1, \ldots, y_t \subset [-4\gamma, 4\gamma]$ such that $y_{\ell+1} - y_\ell = 8\gamma/t$. We utilize the algorithm in Lemma 7 to obtain estimates $\widehat{\boldsymbol{\eta}}_1, \ldots, \widehat{\boldsymbol{\eta}}_t$ satisfying (11) with $y_1, \ldots, y_t$, respectively. Then, we output

$$\widehat{\boldsymbol{\beta}} = \min_{\ell\in[t]} \widehat{\boldsymbol{\eta}}_\ell.$$

Since we amplified the error probability to less than $t\delta$, we may assume, by a union bound, that all estimates $\{\boldsymbol{\eta}_\ell\}_{\ell\in[t]}$ satisfy (11) with y_ℓ with probability at least $1-\delta$. First, for any $\ell \in [t]$,

$$\min_{z\in\mathbb{R}}\left(\sum_{i=1}^{n} \lambda_i |x_i - z|^p\right)^{1/p} \leq \left(\sum_{i=1}^{n} \lambda_i |x_i - y_\ell|^p\right)^{1/p},$$

and therefore, the lower bound in (12) is implied by (11). To prove the upper bound in (12), denote $z \in \mathbb{R}$ as the true minimizer of $(\sum_{i=1}^n \lambda_i |x_i - z|^p)^{1/p}$. By the fact $\sum_{i=1}^n \lambda_i = 1$ and the triangle inequality, we have

$$|z| = \left(\sum_{i=1}^n \lambda_i |z|^p\right)^{1/p} \leq \left(\sum_{i=1}^n \lambda_i |x_i - z|^p\right)^{1/p} + \left(\sum_{i=1}^n \lambda_i |x_i|^p\right)^{1/p} \leq 2\left(\sum_{i=1}^n \lambda_i |x_i|^p\right)^{1/p},$$

so $|z| \leq 2(1+\epsilon)\gamma \leq 4\gamma$, and thus $z \in [-4\gamma, 4\gamma]$. Let $\ell \in [t]$ be such that $|y_t - z| \leq 4\gamma/t$. Then, again by the triangle inequality and the fact $\sum_{i=1}^n \lambda_i x_i = 0$,

$$\begin{aligned}\left(\sum_{i=1}^n \lambda_i |x_i - y_t|^p\right)^{1/p} &\leq \left(\sum_{i=1}^n \lambda_i |x_i - z|^p\right)^{1/p} + 4\gamma/t \\ &\leq (1 + 4(1+\epsilon)2^p/t)\left(\sum_{i=1}^n \lambda_i |x_i - z|^p\right)^{1/p}.\end{aligned}$$

By the setting of t, $(\sum_{i=1}^n \lambda_i |x_i - y_t|^p)^{1/p} \leq (1+\epsilon/2)(\sum_{i=1}^n \lambda_i |x_i - z|^p)^{1/p}$, and by (11), we obtain the desired upper bound. ◀

2.3 Grouping Single Coordinate Sketches

In this subsection, we show how to compress d linear sketches (one for each coordinate) from Subsection 2.2. In the lemma that follows, the parameter $m \in \mathbb{N}$ should be considered the sketch size of the sketches in Subsection 2.2, and the linear sketch will take the d sketches from Subsection 2.2 (represented as a vector $\mathbb{R}^{dm}$). Each of the d linear sketches have each coordinate of $\mathbb{R}^m$ distributed as an i.i.d scaled p-stable random variable (specified by the last sentence in Corollary 8 and Lemma 9). Thus, we write the d sketches as $\boldsymbol{\Psi}_1 v_1, \ldots, \boldsymbol{\Psi}_d v_d \in \mathbb{R}^m$, where $v_j \in \mathbb{R}$ is a scaling, and $\boldsymbol{\Psi}_1, \ldots, \boldsymbol{\Psi}_d \in \mathbb{R}^{m \times n}$ are i.i.d p-stable matrices.

▶ **Lemma 10** (p-stable Sketch Compression via Count-Min)**.** *Let $d, m \in \mathbb{N}$, $\epsilon, \delta \in (0,1)$, and let $t = O(\log(d/\delta))$. There exists a distribution $\mathcal{C}$ over $(10tm/\epsilon^p) \times (dm)$ matrices, and an algorithm such that for any $v \in \mathbb{R}^d$, the following occurs:*

- *We sample $\mathbf{C} \sim \mathcal{C}$ and a $(dm) \times d$ matrix $\boldsymbol{\Psi}$, where $\boldsymbol{\Psi} = \mathrm{diag}(\boldsymbol{\Psi}_1, \ldots, \boldsymbol{\Psi}_d)$, and each $\boldsymbol{\Psi}_j = (\boldsymbol{\chi}_{j1}, \ldots, \boldsymbol{\chi}_{jm}) \in \mathbb{R}^m$ are independent p-stable random vectors.[7] The algorithm receives as input $\mathbf{C}$ and $\mathbf{C}\boldsymbol{\Psi}v$.*
- *The algorithm outputs, for each $j \in [d]$, a sequence of t vectors $\widehat{\boldsymbol{z}}_j^{(1)}, \ldots, \widehat{\boldsymbol{z}}_j^{(t)} \in \mathbb{R}^m$ which satisfy, for each $t' \in [t]$,*

$$\widehat{\boldsymbol{z}}_j^{(t')} = v_j \boldsymbol{\Psi}_j + \mathbf{err}_j^{(t')} \cdot \boldsymbol{\chi}_j^{(t')}. \tag{13}$$

where $\boldsymbol{\chi}_j^{(t')} \in \mathbb{R}^m$ is a vector of independent p-stable random variables, and $\mathbf{err}_j^{(t')} \in \mathbb{R}_{\geq 0}$ only depends on $\mathbf{C}$. With probability at least $1 - \delta$ over $\mathbf{C}$, for every $j \in [d]$

$$\left|\left\{t' \in [t] : \mathbf{err}_j^{(t')} \leq \epsilon \|v\|_p\right\}\right| \geq t/2. \tag{14}$$

[7] Hence, the vector $\boldsymbol{\Psi}v \in \mathbb{R}^{dm}$ is given by vertically stacking d vectors of the form $v_j \boldsymbol{\Psi}_j \in \mathbb{R}^m$.

Proof. The matrix $\mathbf{C}$ is a Count-Min matrix which given a vector $u \in \mathbb{R}^{dm}$ given by vertically stacking d vectors $u_1, \ldots, u_d \in \mathbb{R}^m$ repeats the following process: for each $t' \in [t]$, we sample a hash function $\boldsymbol{h}_{t'} : [d] \to [10/\epsilon^p]$, and for each $\ell \in [10/\epsilon^p]$ store the vector

$$\boldsymbol{b}_{t',\ell} \stackrel{\text{def}}{=} \sum_{j \in [d]} \mathbf{1}\{\boldsymbol{h}_{t'}(j) = \ell\} \cdot u_j \in \mathbb{R}^m.$$

In particular, the output $\mathbf{C}u$ consists of stacking $t \cdot 10/\epsilon^p$ vectors $(\boldsymbol{b}_{t',\ell} \in \mathbb{R}^m : t' \in [t], \ell \in [10/\epsilon^p])$, which gives the desired bound of $10mt/\epsilon^p$ on the output dimension of $\mathbf{C}$. For each $j \in [d]$ and $t' \in [t]$, the algorithm lets $\boldsymbol{\ell} = \boldsymbol{h}_{t'}(j)$ and sets

$$\widehat{\boldsymbol{z}}_j^{(t')} = \boldsymbol{b}_{t',\ell} = v_j \boldsymbol{\Psi}_j + \sum_{j' \in [d] \setminus \{j\}} \mathbf{1}\{\boldsymbol{h}_{t'}(j') = \boldsymbol{\ell}\} \cdot v_{j'} \cdot \boldsymbol{\Psi}_{j'}.$$

We now apply the p-stability property to the right-most summand, to notice that

$$\mathbf{err}_j^{(t')} = \left(\sum_{j' \in [d] \setminus \{j\}} \mathbf{1}\{\boldsymbol{h}_{t'}(j') = \boldsymbol{\ell}\} \cdot v_{j'}^p \right)^{1/p},$$

which only depends on $\mathbf{C}$. Furthermore, the inner most summand is at most $\epsilon^p/10 \sum_{j' \in [d] \setminus \{j\}} v_{j'}^p$ in expectation. By Markov's inequality, each $\mathbf{err}_j^{(t')} \leq \epsilon \|v\|_p$ with probability at least $9/10$. Since $t = O(\log(d/\delta))$, the probability that (14) is not satisfied for each $j \in [d]$ is at most δ/d by a Chernoff bound, so that a union bound gives the desired guarantees. ◀

The above lemma allows us to compress d many p-stable sketches into $O(\log(d/\delta)/\epsilon^p)$ many p-stable sketches, albeit with some error. Since the p-stable sketches that we will use (from Corollary 8 and Lemma 9) are exactly of the form $\boldsymbol{\Psi}v$ for some vector v, Lemma 10 will allow us to compress them. Namely, we will consider d sketches from Corollary 8 and Lemma 9 and utilize Lemma 10; for each $j \in [d]$, we will be able to recover t noisy versions of the sketch of Corollary 8 and Lemma 9 for coordinate j. Importantly, the noise is of the form an error times a p-stable random variable, and these are the kinds of errors that Corollary 8 and Lemma 9 can easily handle.

▶ **Lemma 11** (p-stable Sketch Recovery for Sample). *For $n, d \in \mathbb{N}$, $p \in [1, 2]$ and $\epsilon, \delta \in (0, 1)$, let $s = O(\log^2(d/\delta)/\epsilon^{2+p})$. There exists a distribution $\mathcal{R}$ over $s \times (nd)$ matrices, and an algorithm such that for any vectors $y_1, \ldots, y_n \in \mathbb{R}^d$ and weights $\lambda_1, \ldots, \lambda_n \in [0, 1]$ with $\sum_{i=1}^n \lambda_i = 1$, the following occurs with probability at least $1 - \delta$:*

- *We sample $\mathbf{S} = [\mathbf{S}_1, \ldots, \mathbf{S}_n] \sim \mathcal{R}$ and we give the algorithm as input $\mathbf{S}$, and the vector $\sum_{i=1}^n \mathbf{S}_i(\lambda_i^{1/p} y_i) \in \mathbb{R}^s$.*
- *The algorithm outputs d numbers $\boldsymbol{\alpha}_1, \ldots, \boldsymbol{\alpha}_d \in \mathbb{R}_{\geq 0}$ such that each $j \in [d]$ satisfies*

$$(1-\epsilon)\left(\sum_{i=1}^n \lambda_i |y_{ij}|^p\right)^{1/p} - \text{err} \leq \boldsymbol{\alpha}_j \leq (1+\epsilon)\left(\sum_{i=1}^n \lambda_i |y_{ij}|^p\right)^{1/p} + \text{err},$$

where $\text{err} \in \mathbb{R}_{\geq 0}$ is an additive error satisfying

$$\text{err} \leq \epsilon \left(\sum_{j=1}^d \sum_{i=1}^n \lambda_i |y_{ij}|^p\right)^{1/p}.$$

Proof. We combine Corollary 8 and Lemma 10. We describe the distribution $\mathcal{R}$ over $s \times (nd)$ matrices by giving a procedure for sampling $\mathbf{S} \sim \mathcal{R}$. $\mathbf{S}$ can be naturally expressed as a concatenation of matrices $\mathbf{S} = [\mathbf{S}_1, \ldots, \mathbf{S}_n]$.

- We let $\mathcal{M}$ be the distribution over $s_0 \times n$ matrices of Corollary 8 with error probability at most $\delta/(2dt)$ and accuracy ϵ (so that we may union bound over d sketches later) so that $s_0 = O(\log(dt/\delta)/\epsilon^2)$. We take d independent samples $\mathbf{S}'_1, \ldots, \mathbf{S}'_d \sim \mathcal{M}$.
- For each $j \in [d]$, we let P_j be the $n \times (nd)$ matrix where given the vector $y' \in \mathbb{R}^{nd}$ given by vertically stacking $\lambda_1^{1/p} y_1, \ldots, \lambda_n^{1/p} y_n \in \mathbb{R}^d$, sets $y'_{\cdot,j} = P_k j'$, where $y'_{\cdot,j} = \lambda^{1/p} \circ (y_{i,j})_{i \in [n]} \in \mathbb{R}^n$. Let P be the $(nd) \times (nd)$ matrix which stacks these matrices vertically.
- We sample $\mathbf{C} \sim \mathcal{C}$ as in Lemma 10 with $m = s_0$, where we set the accuracy parameter $\epsilon/2$ and the failure probability $\delta/2$. We let

$$\mathbf{S} = \mathbf{C} \cdot \mathrm{diag}(\mathbf{S}'_1, \ldots, \mathbf{S}'_d) \cdot P.$$

Intuitively, we will apply our sketch $\mathbf{S}$ on the vector the matrix $\mathbf{S}$ may be interpreted as first applying d sketches of Corollary 8 to the vectors $(\lambda^{1/p} \circ y_{\cdot,1}), \ldots, (\lambda^{1/p} \circ y_{\cdot,d}) \in \mathbb{R}^n$, and then applying $\mathbf{C}$ from Lemma 10. The algorithm for producing the estimates $\boldsymbol{\alpha}_1, \ldots, \boldsymbol{\alpha}_d$ proceeds by applying the algorithm of Lemma 10 to obtain, for each $j \in [d]$ a sequence of t vectors $\widehat{\boldsymbol{z}}_j^{(1)}, \ldots, \widehat{\boldsymbol{z}}_j^{(t)} \in \mathbb{R}^{s_0}$. We apply the algorithm of Corollary 8 to each of the t vectors to obtain estimates $\boldsymbol{\alpha}_j^{(1)}, \ldots, \boldsymbol{\alpha}_j^{(t)} \in \mathbb{R}_{\geq 0}$, and we let $\boldsymbol{\alpha}_j = \mathrm{median}\{\boldsymbol{\alpha}_j^{(t')} : t' \in [t]\}$.

To see why this works, consider the collection of d vectors

$$\boldsymbol{z}_j = \mathbf{S}'_j(\lambda^{1/p} \circ y_{\cdot,j}) \in \mathbb{R}^{s_0},$$

and notice that by Corollary 8, every $j \in [d]$ and $\ell \in [s]$, $\boldsymbol{z}_{j,\ell} \sim (\sum_{i=1}^n \lambda_i |y_{i,j}|^p)^{1/p} \cdot \boldsymbol{\chi}_{j,\ell}$, where $\boldsymbol{\chi}_{k,\ell}$ are independent, p-stable random variables. Indeed, if we write $v \in \mathbb{R}^d$ as the vector which sets

$$v_j = \left(\sum_{i=1}^n \lambda_i |y_{i,j}|^p \right)^{1/p},$$

then vertically stacking the vectors $\boldsymbol{z}_1, \ldots, \boldsymbol{z}_d \in \mathbb{R}^{s_0}$ gives a vector which is equivalently distributed as $\boldsymbol{\Psi} v$, where $\boldsymbol{\Psi}$ is the matrix from Lemma 10. In particular, with probability at least $1 - \delta/2$, the algorithm of Lemma 10 outputs dt vectors $(\widehat{\boldsymbol{z}}_j^{(t')} : j \in [d], t' \in [t])$ which satisfy

$$\widehat{\boldsymbol{z}}_j^{(t')} = \mathbf{S}'_k(\lambda^{1/p} \circ y_{\cdot,j}) + \mathbf{err}_j^{(t')} \cdot \boldsymbol{\chi}_{j,t'}. \tag{15}$$

Hence, with probability at least $1 - \delta/(2dt)$, the algorithm of Corollary 8 applied to $\widehat{\boldsymbol{z}}_j^{(t')}$ outputs an estimate $\boldsymbol{\alpha}_j^{(t')}$ satisfying $(1-\epsilon)(v_j^p + (\mathbf{err}_j^{(t')})^p)^{1/p} \leq \boldsymbol{\alpha}_j^{(t')} \leq (1+\epsilon)(v_j^p + (\mathbf{err}_j^{(t')})^p)^{1/p}$, and therefore, we have that each $\boldsymbol{\alpha}_j^{(t')}$ satisfies

$$(1-\epsilon)v_j - \mathbf{err}_j^{(t')} \leq \boldsymbol{\alpha}_j^{(t')} \leq (1+\epsilon)v_j + 2 \cdot \mathbf{err}_j^{(t')}.$$

Since at least $t/2$ of $t' \in [t]$ satisfies $\mathbf{err}_j^{(t')} \leq \epsilon/2 \cdot \|v\|_p$, the median $\boldsymbol{\alpha}_j^{(t')}$ satisfies the desired error guarantee. Applying a union bound over all dt applications of Corollary 8 and Lemma 10 gives the desired guarantees. ◀

▶ **Lemma 12** (p-stable Sketch Recovery for Optimizer)**.** *For $n, d \in \mathbb{N}$, $p \in [1,2]$ and $\epsilon, \delta \in (0,1)$, let $s = O(\log(d/\delta) \cdot \log(\log d/(\epsilon\delta))/\epsilon^{2+p})$. There exists a distribution $\mathcal{O}$ over $s \times (nd)$ matrices, and an algorithm such that for any vectors $y_1, \ldots, y_n \in \mathbb{R}^d$ and any set of weights $\lambda_1, \ldots, \lambda_n \in [0,1]$ where $\sum_{i=1}^n \lambda_i = 0$, whenever $\sum_{i=1}^n \lambda_i y_i = 0$, the following occurs with probability at least $1 - \delta$:*

- *We sample $\mathbf{S} = [\mathbf{S}_1, \ldots, \mathbf{S}_n] \sim \mathcal{O}$ and we give the algorithm as input $\mathbf{S}$, $\sum_{i=1}^n \mathbf{S}_i(\lambda_i^{1/p} y_i)$, the parameters $\lambda_1, \ldots, \lambda_n$, an index $j_0 \in [d]$, and a parameter $\gamma \in \mathbb{R}_{\geq 0}$ satisfying*

$$(1-\epsilon)\left(\sum_{i=1}^n \lambda_i |y_{ij_0}|^p\right)^{1/p} \leq \gamma \leq (1+\epsilon)\left(\sum_{i=1}^n \lambda_i |y_{ij_0}|^p\right)^{1/p}.$$

- *The algorithm outputs a parameter $\widehat{\boldsymbol{\beta}} \in \mathbb{R}_{\geq 0}$ which satisfies*

$$(1-\epsilon)\min_{z\in\mathbb{R}}\left(\sum_{i=1}^n \lambda_i |y_{ij_0} - z|^p\right)^{1/p} - \mathrm{err} \leq \widehat{\boldsymbol{\beta}} \leq (1+\epsilon)\min_{z\in\mathbb{R}}\left(\sum_{i=1}^n \lambda_i |y_{ij_0} - z|^p\right)^{1/p} + \mathrm{err},$$

where $\mathrm{err} \in \mathbb{R}_{\geq 0}$ is an additive error satisfying

$$\mathrm{err} \leq \epsilon\left(\sum_{j=1}^d \sum_{i=1}^n \lambda_i |y_{i,j}|^p\right)^{1/p}.$$

Proof. The proof follows similarly to that of Lemma 11; the only difference is that instead of using the sketch of Corollary 8, we use the sketch of Lemma 9. For completeness, we describe the distribution $\mathcal{O}$ over $s \times (nd)$ matrices by giving a procedure for sampling $\mathbf{S} \sim \mathcal{O}$:

- We let $\mathcal{M}$ be the distribution over $s_0 \times n$ matrices from Lemma 9 with accuracy ϵ and failure probability $\delta/(2t)$, where $s_0 = O(\log(t/(\epsilon\delta))/\epsilon^2)$. We take d independent samples $\mathbf{S}'_1, \ldots, \mathbf{S}'_d \sim \mathcal{M}$. Note that even though we take d independent samples, we will only require that the sketch t evaluations of the $\mathbf{S}_{j_0} \sim \mathcal{M}$ succeed (hence, we amplify the error probability to $\delta/(2t)$, as opposed to $\delta/(2td)$ as in Lemma 11).
- We sample $\mathbf{C} \sim \mathcal{C}$ as in Lemma 10 with $m = s_0$, where we set the accuracy parameter $\epsilon/2$ and failure probability $\delta/2$. Recalling the definition of P (see Item 2 in the proof of Lemma 11, we let

$$\mathbf{S} = \mathbf{C} \cdot \mathrm{diag}(\mathbf{S}'_1, \ldots, \mathbf{S}'_d) \cdot P.$$

Similarly to the proof of Lemma 11, $\mathbf{S}$ may be interpreted as applying the sketch of Lemma 10 to d vectors in $\mathbb{R}^{s_0}$, each $j \in [d]$ of which is an independent sketch $\mathbf{S}'_j(\lambda^{1/p} \circ y_{\cdot,j}) \in \mathbb{R}^{s_0}$, where $\mathbf{S}'_j \sim \mathcal{M}$ is the sketch of Lemma 9. Again, we consider the collection of d vectors $\boldsymbol{z}_j = \mathbf{S}'_j(\lambda^{1/p} \circ y_{\cdot,j}) \in \mathbb{R}^{s_0}$, for all $j \in [d]$, and by Lemma 9, every $j \in [d]$ has $\boldsymbol{z}_j \sim \|\lambda^{1/p} \circ y_{\cdot,j}\|_p \cdot \boldsymbol{\Psi}_j \in \mathbb{R}^{s_0}$, where $\boldsymbol{\Psi}_j$ is an independent, p-stable random vector. Writing $v \in \mathbb{R}^d$ by $v_j = \|\lambda^{1/p} \circ y_{\cdot,j}\|_p$, and we apply the algorithm of Lemma 10 and focus on the t vectors $\widehat{\boldsymbol{z}}_{j_0}^{(1)}, \ldots, \widehat{\boldsymbol{z}}_{j_0}^{(t)} \in \mathbb{R}^{s_0}$ which satisfy

$$\widehat{\boldsymbol{z}}_{j_0}^{(t')} = \mathbf{S}'_{j_0}(\lambda^{1/p} \circ y_{\cdot,j_0}) + \mathbf{err}_{j_0}^{(t')} \cdot \boldsymbol{\chi}_{j,t'}.$$

We apply the algorithm of Lemma 9 to each of the vectors $\widehat{\boldsymbol{z}}_{j_0} \in \mathbb{R}^s$, while giving as input the parameter γ to obtain the estimate $\widehat{\boldsymbol{\beta}}^{(1)}, \ldots, \widehat{\boldsymbol{\beta}}^{(t)}$. Then, we set $\widehat{\boldsymbol{\beta}} = \mathrm{median}\{\widehat{\boldsymbol{\beta}}^{(t')} : t' \in [t]\}$. Similarly to the proof of Lemma 11, $\widehat{\boldsymbol{\beta}}$ provides the desired approximation guarantees. ◀

Abstract

We study a bilevel optimization problem which is a zero-sum Stackelberg game. In this problem, there are two players, a leader and a follower, who pick items from a common set. Both the leader and the follower have their own (multi-dimensional) budgets, respectively. Each item is associated with a profit, which is the same to the leader and the follower, and will consume the leader's (follower's) budget if it is selected by the leader (follower). The leader and the follower will select items in a sequential way: First, the leader selects items within the leader's budget. Then the follower selects items from the remaining items within the follower's budget. The goal of the leader is to minimize the maximum profit that the follower can obtain. Let s_A and s_B be the dimension of the leader's and follower's budget, respectively. A special case of our problem is the bilevel knapsack problem studied by Caprara et al. [SIAM Journal on Optimization, 2014], where $s_A = s_B = 1$. We consider the general problem and obtain an $(s_B + \epsilon)$-approximation algorithm when s_A and s_B are both constant. In particular, if $s_B = 1$, our algorithm implies a PTAS for the bilevel knapsack problem, which is the first $\mathcal{O}(1)$-approximation algorithm. We also complement our result by showing that there does not exist any $(4/3 - \epsilon)$-approximation algorithm even if $s_A = 1$ and $s_B = 2$. We also consider a variant of our problem with resource augmentation when s_A and s_B are both part of the input. We obtain an $\mathcal{O}(1)$-approximation algorithm with $\mathcal{O}(1)$-resource augmentation, that is, we give an algorithm that returns a solution which exceeds the given leader's budget by $\mathcal{O}(1)$ times, and the objective value achieved by the solution is $\mathcal{O}(1)$ times the optimal objective value that respects the leader's budget.

1 Introduction

In recent years, there is an increasing interest in adopting the *Stackelberg competition model* [16] to address the critical security concern that arises in protecting our ports, airports, transportation, and other critical national infrastructures (see, e.g., [1, 29, 33]). In these

[1] Optional footnote, e.g. to mark corresponding author

problems, the attacker's target is to maximize the illicit gain, while the defender tries to mitigate the attack by minimizing the attacker's objective through deploying defending resources.

In this paper, we consider an abstract model for general defending problems called *interdiction with packing constraints* (IPC). In IPC, given are a set of items, together with a *leader* and a *follower*. Both the leader and the follower have their own (multi-dimensional) budgets, respectively. Each item is associated with a profit, which is the same to the leader and the follower, and will consume the leader's (follower's) budget if it is selected by the leader (follower). The leader and the follower will select items in a sequential way: First, the leader selects items within the leader's budget. Then the follower selects items from the remaining items within the follower's budget. The goal of the leader is to minimize the maximum profit that the follower can obtain. IPC captures the general setting where the follower is the attacker who gets profit by attacking items, and the leader is the defender who tries to minimize the attacker's gain by protecting a subset of items.

IPC can be formulated as a bilevel integer program (IP) as follows. Denote by $I = \{1, 2, \cdots, n\}$ the set of items. Each item $j \in I$ is associated with a *profit* $p_j \in \mathbb{Q}_{>0}$, an s_A-dimensional *cost vector* $\mathbf{A}_j \in \mathbb{Q}_{\geq 0}^{s_A}$ to the leader and an s_B-dimensional *weight vector* $\mathbf{B}_j \in \mathbb{Q}_{\geq 0}^{s_B}$ to the follower. The leader and the follower have their own *budget vectors*, denoted by $\mathbf{a} \in \mathbb{Q}_{\geq 0}^{s_A}$ and $\mathbf{b} \in \mathbb{Q}_{\geq 0}^{s_B}$, respectively. We introduce 0-1 variables x_j and y_j for each $j \in I$ as the decision variables for the leader and the follower. More precisely, if the leader chooses item j, then $x_j = 1$, otherwise $x_j = 0$. Similarly, $y_j = 1$ if the follower chooses item j and $y_j = 0$ otherwise. Denote by $\mathbf{x} = (x_1, x_2, \ldots, x_n)$, $\mathbf{y} = (y_1, y_2, \ldots, y_n)$, $\mathbf{p} = (p_1, p_2, \ldots, p_n)$ and $\mathbf{1} = (\underbrace{1, \ldots, 1}_{n})$. IPC can be formulated as a bilevel program $\mathbf{IPC}(I, \mathbf{a}, \mathbf{b})$ as follows:

$$\mathbf{IPC}(I, \mathbf{a}, \mathbf{b}) : \min_{\mathbf{x}} \ \mathbf{py} \tag{1a}$$

$$s.t.\ \mathbf{Ax} \leq \mathbf{a} \tag{1b}$$

$$\mathbf{x} \in \{0,1\}^n \tag{1c}$$

where $\mathbf{y}$ solves the following:

$$\max_{\mathbf{y}} \quad \mathbf{py} \tag{1d}$$

$$s.t. \quad \mathbf{By} \leq \mathbf{b} \tag{1e}$$

$$\mathbf{x} + \mathbf{y} \leq \mathbf{1} \tag{1f}$$

$$\mathbf{y} \in \{0,1\}^n \tag{1g}$$

where $\mathbf{A} = (\mathbf{A}_1, \cdots, \mathbf{A}_n)$ and $\mathbf{B} = (\mathbf{B}_1, \cdots, \mathbf{B}_n)$ are $s_A \times n$ and $s_B \times n$ non-negative rational matrices, respectively.

The most relevant prior work to our IPC model is the well-known knapsack interdiction problem introduced by DeNegre [14], which is the special case of IPC where $s_A = 1$ and $s_B = 1$. Very recently, Caprara et al. [4] proved that DeNegre's knapsack interdiction problem is $\sum_2^p$-complete and strongly NP-hard, which also implies the $\sum_2^p$-completeness and strongly NP-hardness for IPC. Caprara et al. showed a polynomial time approximation scheme (PTAS) for a special case of knapsack interdiction problem where the profit of an item is equal to its weight to the follower.

Except for the knapsack interdiction problem, we are not aware of any approximation algorithms for other special cases of IPC. However, if we relax the follower's problem by allowing $\mathbf{y}$ to take fractional value, then there are several research works in the literature. The most relevant work is the packing interdiction problem studied by Dinitz and Gupta [15],

where the follower's problem is given by $\max\{\sum_j p_j(1-x_j)y_j : B\mathbf{y} \leq \mathbf{b}, \mathbf{y} \geq \mathbf{0}\}$, while the leader's constraints are the same as Equation 1b and Equation 1c except that $s_A = 1$. Dinitz and Gupta provided an approximation algorithm whose ratio depends on the sparsity of the matrix B. Their techniques crucially rely on the fact that $\mathbf{y}$ can take fractional value, and therefore duality theory can be applied to the follower's problem, allowing the bilevel problem to be transformed to a single level problem. Besides the packing interdiction problem, quite a few graph interdiction problems have been studied in the literature, where the follower's problem is a standard graph optimization problem, and the leader can remove edges or vertices to minimize the follower's optimal objective value on the graph after edge-removal or vertex-removal. On planar graphs, polynomial time approximation schemes (PTASs) were obtained for network flow interdiction [32, 37] and matching interdiction [28]. On general graphs, approximation algorithms were also obtained for, e.g., connectivity interdiction [38], minimum spanning tree interdiction [26, 39], matching interdiction [15, 36], network flow interdiction [3, 9, 10], etc. All of these algorithms crucially rely on the follower's specific graph optimization problem and do not apply directly to IPC.

Our Contributions

The main contribution of this paper is an $(s_B + \epsilon)$-approximation polynomial time algorithm for IPC when s_A and s_B are both constant. In particular, when $s_B = 1$, our algorithm is a PTAS. Since the knapsack interdiction problem is a special case of IPC when $s_A = s_B = 1$, our result gives the first $\mathcal{O}(1)$-approximation algorithm for this problem. To complement our result, we also show that IPC does not admit any $(4/3 - \epsilon)$-approximation algorithm even if $s_B = 2$ and $s_A = 1$, assuming $P \neq NP$. This implies that the PTAS for $s_B = 1$ cannot be further extended to the case of $s_B \geq 2$.

We also consider a natural variant of IPC where the leader's budget can be violated. For this variant we obtain a $(\frac{\rho}{1-\alpha}, \frac{1}{\alpha})$-bicriteria approximation algorithm for any $\alpha \in (0, 1)$, which runs in polynomial time when s_A and s_B are arbitrary (not necessarily polynomial in the input size). More precisely, the algorithm takes as input two oracles, a ρ-approximation algorithm to the follower's optimization problem $\max\{\mathbf{py} : \mathbf{By} \leq \mathbf{b}, \mathbf{y} \in \{0,1\}^n\}$; and a separation oracle for the leader's problem that given any $\mathbf{x} = \mathbf{x}^0$, it either asserts that $\mathbf{Ax}^0 \leq \mathbf{a}$ or returns a violating constraint. Then in polynomial oracle time the algorithm returns a solution $\mathbf{x}^*$ for the leader such that $\mathbf{Ax}^* \leq \frac{1}{\alpha}\mathbf{a}$, and the objective value is at most $\frac{\rho T^*}{1-\alpha}$, where T^* is the optimal objective value with the leader's budget being $\mathbf{a}$. When we take, e.g., $\alpha = 1/2$, we achieve an objective of $2\rho T^*$ with the leader's budget augmented to $2\mathbf{a}$.

In terms of techniques, our main contribution is a general method for bilevel optimization problems where the leader's and follower's decision variables are both integral. Most prior works on bilevel optimization require follower's decision variables to take fractional values, which accommodates the application of LP duality to transform the bilevel optimization problem to a standard (single level) optimization, and are thus inapplicable when the follower's decision variables become integral. A common technique used in many single level optimization problems is to first classify items into large and small based on whether they can make a significant contribution to the objective value, then guess out large items via enumeration, and handle small items fractionally via LP (see, e.g., [5, 21, 22]. However, such a technique encounters a fundamental challenge in IPC: we can guess out all large items selected by the leader, however, the follower may still select arbitrarily from the remaining large items. In other word, the follower's choice on large items can never be guessed out, and therefore we cannot apply duality to the follower's problem. We overcome the challenge

based on the following two ideas: First, we show that given leader's choice on large items, there is a fixed number of "dominant choices" such that the follower's choice on remaining large items always belong to the dominant choices. Second, we show that there exists a subset of "critical items" such that the follower's choice on small items can be characterized through linear constraints given that these critical items are known. The two observations allow us to transform the bilevel program for IPC to an LP without utilizing duality.

The characterization of dominant choices and critical items become sophisticated in the general case when s_B is an arbitrary constant, but is much simpler in the special case $s_B = 1$. Hence, for ease of presentation, in the main part we present our algorithm for the special case to give an overview on the technical insights, and meanwhile provide a proof sketch towards generalizing the algorithm for the general case. Our techniques may be of separate interest to other bilevel optimization problems.

Related work

Our IPC problem lies generally in the area of *bilevel optimization*, which has received extensive research in the literature. Jeroslow [23] showed that in general, bilevel optimization problems are NP-hard even when the objectives and the constraints are linear. We refer readers to Colson et al. [11] for a comprehensive survey on bilevel optimization.

Within the area of bilevel optimization, *Mixed-Integer Bilevel Linear Problem* (MIBLP) is related to our IPC. MIBLP is a bilevel optimization problem where the objective functions and the constraints for the leader and follower are both linear. MIBLP has been studied extensively in the literature, see, e.g., [19, 20, 35]. We also refer the reader to [18, 25] for an overview on MIBLP solvers and related applications. Most of these algorithmic results are for finding exact solutions through, e.g., branch and bound based approach. For DeNegre's knapsack interdiction problem, an improved exact algorithm was derived by Federico Della Croce and Rosario Scatamacchia [12].

It is worth mentioning that besides DeNegre's knapsack interdiction problem (i.e., $s_A = s_B = 1$ in IPC), other variants of bilevel knapsack problems have also been studied in which the leader interferes the follower's program in a different way. One kind of bilevel knapsack problem was introduced by Dempe and Richter [13] where two players hold one knapsack, the leader determines the knapsack's capacity while the follower picks items into the knapsack to maximize his own total profit. The goal is to maximize the objective of the leader. Brotcorne et al. [2] gave a dynamic programming algorithm for both cases of this model. Chen and Zhang [8] proposed a bilevel knapsack variant where two players hold their own knapsacks and the leader can only influence the profit of the items. The follower is interested in his own revenue while the leader aims at maximizing the total profit of both players. The improved approximation results for this problem were derived by Xian Qiu and Walter Kern [34]. Another bilevel knapsack variant occurred in the work of Pferschy et al. [30] where the leader controls the weights of a subset of the follower's items and the follower aims at maximizing his own profit. The leader's payoff is the total weight of the items he controls and selected by the follower. Very recently, Pferschy et al. [31] tackled a "symmetrical" problem in which the leader can control the profits instead of item weights. In addition to these works, a matrix interdiction problem was studied by Kasiviswanathan and Pan [24].

It is also worth mentioning that the continuous version of DeNegre's knapsack interdiction problem, where the leader and the follower can both fractionally choose an item, has also been studied in recent years. Carvalho et al. [6] gave the first polynomial time optimal algorithm. Later on, a faster optimal algorithm was proposed by Woeginger and Fischer [17].

Some notations. We write column vectors in boldface, e.g. $\mathbf{x}, \mathbf{y}$, and their entries in normal font. For a vector $\mathbf{x}$, we either denote its entries by $\mathbf{x} = (x_1, x_2, \cdots, x_n)$, or by $\mathbf{x} = (\mathbf{x}[1], \mathbf{x}[2], \cdots, \mathbf{x}[n])$. Given two vectors $\mathbf{x}$ and $\mathbf{y}$ with the same dimension, we use $\mathbf{xy}$ to represent their dot product, i.e., $\mathbf{xy} = \sum_j x_j y_j$.

2 Hardness results

▶ **Theorem 1.** *Assuming $P \neq NP$, for arbitrary small $\epsilon > 0$, there does not exist a $(4/3 - \epsilon)$-approximation polynomial time algorithm for IPC when $s_A \geq 1$ and $s_B \geq 2$.*

Towards the proof, we need the 3 hitting set (3HS) problem.

Problem: 3 Hitting Set

Instance: A ground set $U = \{u_1, u_2, \cdots, u_n\}$; a collection C of m subsets $S_1, S_2, \cdots, S_m$ whose union is U, where each subset S_h contains exactly 3 elements; a positive integer k.

Question: Is there a hitting subset $S \subseteq U$ such that $|S| \leq k$, and S contains at least one element from each subset in C?

Proof. Recall that 3HS problem is a natural generalization of the well-known Vertex Cover problem, and both are NP-complete [27]. Our reduction is from the 3HS problem. Given an instance of the 3HS, we construct an instance of the IPC where $s_A = 1$, $s_B = 2$ as follows. Let $E = 10 \cdot \sum_{i=1}^{n} 10^i$, and Q be any sufficiently large integer, say, $Q = 10E$. Let $\mathbf{a} = k$ and $\mathbf{b} = (E, 4Q - E)$. The profit of every item constructed below is 1. For every element u_i, we construct an *element-item* (item i) whose interdiction cost is 1, and whose weight vector is $(10^i, Q - 10^i)$. For every subset $S_h = \{u_i, u_j, u_k\}$, we construct a *set-item* (item $n + h$) whose interdiction cost is $k + 1$ (that is, the leader cannot interdict a set-item), and whose weight vector is $(E - 10^i - 10^j - 10^k, Q - E + 10^i + 10^j + 10^k)$. In total we construct $n + m$ items.

We first claim that the objective value of any feasible solution for the IPC instance is at most 4. Suppose on the contrary the claim is false, then the follower is able to select at least 5 items under the budget $\mathbf{b} = (E, 4Q - E)$. Notice that for any $1 \leq i \leq n$, $Q - 10^i > Q - E \geq 0.9Q$, and for any $1 \leq i, j, k \leq n$ we have $Q - E + 10^i + 10^j + 10^k > 0.9Q$, if we sum up the weight vectors of any 5 items, then the second coordinate is at least $4.5Q$, which exceeds the budget $4Q - E$, hence the claim is true.

Suppose the 3HS instance admits hitting set S of size at most k, we show that the optimal objective value of the IPC instance is at most 3. Let $S = \{u_{\ell_1}, u_{\ell_2}, \cdots, u_{\ell_k}\}$ (if S contains less than k elements, we simply add arbitrary elements to make it contain exactly k items), then we consider the solution $\mathbf{x}$ where $x_{\ell_i} = 1$ for $1 \leq i \leq k$, and $x_j = 0$ otherwise. We claim that for any $\mathbf{y}$ satisfying $\mathbf{x} + \mathbf{y} \leq \mathbf{1}$, $\mathbf{py} = \sum_j y_j \leq 3$. Suppose on the contrary that the claim is false, then the follower can select at least 4, and hence exactly 4 items (given our claim in the above paragraph that shows the objective value cannot exceed 4). Notice that for every item, if we add the first and second coordinate of its weight vector, then the sum is exactly Q. Hence, if we add up the weight vector of the 4 items, it must be $(z, 4Q - z)$ for some z, and meanwhile, we have $(z, 4Q - z) \leq (E, 4Q - E)$, that is $z \leq E$ and $4Q - z \leq 4Q - E$. Hence, $z = E$, which means the sum of the first coordinate of the weight vectors of the 4 items is exactly $E = 10 \sum_i 10^i$. We first observe that it is impossible for the 4 items to be all element-items, this is because the first coordinate of the weight vector for any element-item is at most $10^n < 0.1E$. We then observe that there cannot be two set-items among the 4 items, because the first coordinate of the weight vector for any set-item is at least $E - 0.1E = 0.9E$. Hence, among the 4 items, there must be exactly 1 set-item and 3 element-items. Let the 3 element-items be those corresponding to u_i, u_j, u_k and the set-item be the one corresponding

to $\{u_{i'}, u_{j'}, u_{k'}\}$, then it follows that $10^i + 10^j + 10^k + E - 10^{i'} - 10^{j'} - 10^{k'} = E$, implying that $\{i, j, k\} = \{i', j', k'\}$. However, this is not possible because the hitting set S contains at least one element from $\{u_{i'}, u_{j'}, u_{k'}\} = \{u_i, u_j, u_k\}$, which implies that $x_i + x_j + x_k \geq 1$, and whereas y_i, y_j, y_k cannot be 1 simultaneously. Thus, the optimal objective value of the IPC instance is at most 3.

Suppose the optimal objective value of the IPC instance is at most 3, we show that the 3HS problem admits a hitting set of size at most k. Let $\mathbf{x}^*$ be the optimal solution for IPC. Consider the set $S^* = \{u_i : x_i^* = 1\}$. Given that $\sum_i x_i \leq k$, we know $|S^*| \leq k$. We claim that S^* is a hitting set. Suppose on the contrary that the claim is false, then there exists some subset $\{u_i, u_j, u_k\}$ such that $S^* \cap \{u_i, u_j, u_k\} = \emptyset$. Then we consider the 3 element-items whose weight vectors are $(10^i, Q - 10^i)$, $(10^j, Q - 10^j)$, $(10^k, Q - 10^k)$, and the set-item whose weight vector is $(E - 10^i - 10^j - 10^k, Q - E + 10^i + 10^j + 10^k)$. It is easy to see that the follower can select all the 4 items, leading to an objective value of 4, contradicting the fact that the optimal objective value is at most 3.

Now suppose there exists a $(4/3 - \epsilon)$-approximation polynomial time algorithm for the IPC. We apply the algorithm to the IPC instance constructed from the 3HS instance. If the 3HS instance admits a hitting set of size at most k, then the approximation algorithm returns a solution with objective value at most $4 - \epsilon < 4$, which means it must return a solution with objective value at most 3. If the 3HS instance does not admit a hitting set of size at most k, then the approximation algorithm returns a solution with objective value at least 4. Hence the polynomial time approximation algorithm can be used to determine whether 3HS problem admits a feasible solution, contradicting the NP-hardness of 3HS problem. ◀

3 A PTAS for IPC where $s_B = 1$ and s_A is a fixed constant

The goal of this section is to prove the following Theorem 2. Theorem 2 is a special case of our main result, however, its proof shares similar key ideas as the general case (where s_A and s_B are arbitrary fixed constants). Therefore, we provide a full presentation to demonstrate the technical insights, and in the next section we will show how to extend the techniques when $s_B \geq 2$.

▶ **Theorem 2.** *When $s_B = 1$ and s_A is an arbitrary fixed constant, there exists a polynomial time approximation scheme for IPC.*

The rest of this section is dedicated to proving the following Lemma 3, which implies Theorem 2 directly by scaling item profits (here we write $\mathbf{IPC}(I, \mathbf{a}, b)$ instead of $\mathbf{IPC}(I, \mathbf{a}, \mathbf{b})$ as $\mathbf{b}$ becomes 1-dimensional given that $s_B = 1$).

▶ **Lemma 3.** *Let OPT be the optimal objective value of $\boldsymbol{IPC}(I, \mathbf{a}, b)$. If $OPT \leq 1$, then for an arbitrarily small number $\epsilon > 0$, there exists a polynomial time algorithm that returns a feasible solution to $\boldsymbol{IPC}(I, \mathbf{a}, b)$ with an objective value of at most $1 + \mathcal{O}(\epsilon)$.*

3.1 Preprocessing

From now on we assume $OPT \leq 1$. Without loss of generality, we further assume that $\max_j p_j \leq 1$.

Scaling. We scale the matrix $\mathbf{A}$ and $\mathbf{B}$ such that $\mathbf{a} = \mathbf{1}$ and $b = 1$. From now on we denote this IPC instance as $\mathbf{IPC}(I, \mathbf{1}, 1)$. Without loss of generality, we further assume that $\max_j B_j \leq 1$.

Rounding down the profits. We apply the standard geometric rounding. Let $\delta > 0$ be some small parameter to be fixed later (in particular, we can choose $\delta = \epsilon^2$). Consider each item profit p_j. If $p_j \leq \delta^2$, we keep it as it is; otherwise $p_j > \delta^2$, we round the profit down to the largest value of the form $\delta^2(1+\delta)^h$. For profits whose values are at least δ^2, simple calculation shows there are at most $\tilde{\mathcal{O}}(1/\delta)$ distinct rounded profits. This rounding scheme introduces an additive loss of at most $\mathcal{O}(\delta)$ times the objective value. For simplicity, we still denote the rounded profits by p_j's.

Item classification. Recall that each item j is associated with a profit p_j and a weight vector $\mathbf{B}_j$. Since $s_B = 1$, we write B_j as its weight.

Classifying Weights: We say an item j has a *large* weight if $B_j > \delta$; otherwise, it has a *small* weight.

Classifying Profits: We say an item j has a *large* profit if $p_j > \delta$; a *medium* profit if $\delta^2 < p_j \leq \delta$; and a *small* profit if $p_j \leq \delta^2$.

We say an item is *large* if it has a large-profit, or a large-weight. Otherwise, the item is *small*. Large items and small items will be handled separately.

Denote by S^* the items selected by the leader in an optimal solution of $\mathbf{IPC}(I, \mathbf{1}, 1)$.

3.2 Handling Large Items

3.2.1 Determining the leader's choice on large items

The goal of this subsection is to guess large items in S^* in polynomial time.

Large-profit small-weight items. Notice that if there are at least $1/\delta$ such items for the follower to select, then selecting any $1/\delta$ of them gives a solution with an objective value strictly larger than 1, contradicting to the assumption that $OPT \leq 1$. Thus S^* must include all except at most $1/\delta - 1$ such items, which can be guessed out via $n^{\mathcal{O}(1/\delta)}$ enumerations. Hence, we have the following observation.

▶ **Observation 4.** *With $n^{\mathcal{O}(1/\delta)}$ enumerations, we can guess out all large-profit small-weight items in S^*.*

Small-profit large-weight items. Notice that the follower can select at most $1/\delta$ items from this subgroup and their total profit is at most $\delta^2 * \frac{1}{\delta} = \delta$. Hence, even if the leader does not select any such item, the objective value can increase by at most δ, which leads to the following observation.

▶ **Observation 5.** *With $\mathcal{O}(\delta)$ additive error, we may assume that S^* does not contain small-profit large-weight items.*

Large/medium-profit large-weight items. Notice that the follower can select at most $1/\delta$ items from this group. Since we are considering the case of $s_B = 1$, if there are two items that are not selected by the leader, and they have the same profit, then the follower always prefers the one with a smaller weight. Hence, we have the following lemma.

▶ **Lemma 6.** *With $n^{\tilde{\mathcal{O}}(1/\delta^2)}$ enumerations, we can guess out all large/medium-profit large-weight items in S^*.*

Proof. Recall that there are at most $\tilde{\mathcal{O}}(1/\delta)$ distinct large/medium profits. Let S_h be the set of large-weight items whose profits are all $\delta^2(1+\delta)^h$. We observe two facts: (i). Among items in $S_h \setminus S^*$, the follower always selects the ones with the smallest weights; (ii). The follower can select at most $1/\delta$ items from $S_h \setminus S^*$. We claim that, $S^* \cap S_h$ can be determined through guessing out the following $1/\delta$ key items in S_h: among items in $S_h \setminus S^*$, which is the item that has the k-th smallest weight for $k = 1, 2, \cdots, 1/\delta$?[2] To see the claim, let w_h^{max} be the weight of the item in $S_h \setminus S^*$ that has the $1/\delta$-th smallest weight. Consider any item in S_h: if its weight is smaller than w_h^{max}, and is not one of the key items, then this item must belong to S^* (by the definition of key items); if its weight is larger than or equal to w_h^{max}, and is not one of the key items, then it is not in S^* (there is no need for the leader to select such an item since the follower will never select this item even if it is available). Thus via $n^{\mathcal{O}(1/\delta)}$ enumerations, we can guess out all large/medium-profit large-weight items in $S^* \cap S_h$. Moreover, via total $n^{\tilde{\mathcal{O}}(1/\delta^2)}$ enumerations, we can guess out all large/medium-profit large-weight items in S^*. ◀

To summarize, our above analysis leads to the following lemma:

▶ **Lemma 7.** *With $\mathcal{O}(\delta)$ additive error, we can guess out all the large items in the optimal solution S^*, i.e., all items that either have a large profit or a large weight, by $n^{\tilde{\mathcal{O}}(\frac{1}{\delta^2})}$ enumerations.*

Let $\bar{I} \subseteq I = \{1, 2, \cdots, n\}$ be the set of small items, i.e., items of medium/small-profit and small-weight. Then $I \setminus \bar{I}$ is the set of large items. Denote by $\mathbf{x}^*$ the optimal solution to $\mathbf{IPC}(I, \mathbf{1}, 1)$, which is corresponding to S^*. In the following we assume a correct guess on large items. Hence, the values of $\{x_j^* : j \in I \setminus \bar{I}\}$ are known. We let $\mathbf{a}'$ be the total cost of these guessed-out large items.

3.2.2 Finding the follower's dominant choices on large items

Consider all the large items. Even if the leader's choice on large items is fixed, the follower may still have exponentially many different choices on the remaining large items. The goal of this subsection is to show that, among these choices of the follower, it suffices to restrict our attention to a few "dominant" choices that always outperform other choices.

For simplicity, we re-index items such that $\bar{I} = \{1, 2, \cdots, \bar{n}\}$, where $\bar{n} \leq n$.

We further assume that items in $\bar{I}$ are sorted in decreasing order of the profit-weight ratios p_j/B_j. For any $\bar{\mathbf{a}} \leq \mathbf{1}$ and $\bar{b} \leq 1$, denote by $\mathbf{IPC}(\bar{I}, \bar{\mathbf{a}}, \bar{b})$ the "residual instance" where the item set is $\bar{I}$, the budget vector of the leader is $\bar{\mathbf{a}}$ and the budget of the follower is $\bar{b}$.

Denote by $I' \subseteq I \setminus \bar{I}$ the subset of large items which are *not* selected by the leader. Note that due to the assumption $OPT \leq 1$ and that we have guessed out correct large items in S^*, the follower cannot select items from I' with total profit larger than 1. Hence, for each integer $k \in [1, 1 + 1/\epsilon]$, we can define the following sub-problem: among items in I', find out a subset of items with minimal total weight such that their total profit is within $[(k-1)\epsilon, k\epsilon)$. Denote by $SP(k)$ this sub-problem and by $KP(k\epsilon)$ its optimal solution, if it exists. We claim that the follower can select at most $\mathcal{O}(1/\delta)$ items from I', thus via $n^{\mathcal{O}(1/\delta)}$ enumerations, we can return $KP(k\epsilon)$ or assert there does not exist a feasible solution to $SP(k)$. The claim is guaranteed by the following two facts: (i). The total profit the follower could obtain from I' is at most 1; (ii). Items in I' either have a large-profit, or a large-weight.

[2] If there are less than $1/\delta$ items in S_h, we can simply guess out all items in $S_h \setminus S^*$ via $n^{\mathcal{O}(\frac{1}{\delta})}$ enumerations.

Let $\Theta = \{KP(k\epsilon) : k \in \{1, 2, \cdots, 1 + \frac{1}{\epsilon}\}\}$, which contains the follower's $\mathcal{O}(1/\epsilon)$ possible choices on I'. For $\ell \in \{1, 2, \cdots, 1 + \frac{1}{\epsilon}\}$, we let b_ℓ and P_ℓ be the total weight and the total profit of the items selected by the follower, respectively[3]. Then the follower has a residual budget of $1 - b_\ell$ for items in $\bar{I}$. Recall that the leader has a residual budget vector of $\mathbf{1} - \mathbf{a}'$ for items in $\bar{I}$.

Define $\mathbf{y}[\bar{I}] = (y_1, y_2 \cdots, y_{\bar{n}})$. Recall that by guessing we already know the value of x_j^* for $j \in I \setminus \bar{I}$. Consider the following bilevel program:

$$\textbf{Bi-IP}(I, \mathbf{1}, 1) : \min_{\mathbf{x}} P_\ell + \sum_{j=1}^{\bar{n}} p_j y_j$$

$$s.t. \sum_{j=1}^{\bar{n}} \mathbf{A}_j x_j \le \mathbf{1} - \mathbf{a}' \tag{2a}$$

$$x_j = x_j^*, \ \ \forall j \in I \setminus \bar{I} \tag{2b}$$

$$x_j \in \{0, 1\}, \ \ \forall j \in \bar{I} \tag{2c}$$

where integer $\ell, \mathbf{y}[\bar{I}]$ solves the following:

$$\max_{1 \le \ell \le 1 + \frac{1}{\epsilon}} \max_{\mathbf{y}[\bar{I}]} \ \ P_\ell + \sum_{j=1}^{\bar{n}} p_j y_j \tag{2d}$$

$$s.t. \qquad \sum_{j=1}^{\bar{n}} B_j y_j \le 1 - b_\ell \tag{2e}$$

$$y_j \le 1 - x_j, \ \ \forall j \in \bar{I} \tag{2f}$$

$$y_j \in \{0, 1\}, \ \ \forall j \in \bar{I} \tag{2g}$$

What is the difference between Bi-IP$(I, \mathbf{1}, 1)$ and IPC$(I, \mathbf{1}, 1)$, assuming the correct guess of x_j^* for $j \in I \setminus \bar{I}$? In **Bi-IP**$(I, \mathbf{1}, 1)$, the follower's choices on remaining large items are restricted to the $\mathcal{O}(1/\epsilon)$ choices in Θ, while in **IPC**$(I, \mathbf{1}, 1)$, the follower can choose any remaining large items. However, we observe that Θ contains all the follower's "dominant choices of remaining large items" in the sense that the follower uses the smallest budget to achieve a profit within $[(k-1)\epsilon, k\epsilon)$. Consequently, the objective value of **Bi-IP**$(I, \mathbf{1}, 1)$ differs by at most ϵ to that of **IPC**$(I, \mathbf{1}, 1)$. A formal description is given below.

▶ **Lemma 8.** *Let $\bar{\mathbf{x}}$ be any feasible solution to **Bi-IP**$(I, \mathbf{1}, 1)$. Then $\bar{\mathbf{x}}$ is also feasible to **IPC**$(I, \mathbf{1}, 1)$. Let $Obj_{Bi}(\bar{\mathbf{x}})$ and $Obj(\bar{\mathbf{x}})$ be the objective values of **Bi-IP**$(I, \mathbf{1}, 1)$ and **IPC**$(I, \mathbf{1}, 1)$ for $\mathbf{x} = \bar{\mathbf{x}}$, respectively. We have*

$$Obj_{Bi}(\bar{\mathbf{x}}) \le Obj(\bar{\mathbf{x}}) \le Obj_{Bi}(\bar{\mathbf{x}}) + \epsilon.$$

*Furthermore, let OPT_{Bi} and OPT be the optimal objective values of **Bi-IP**$(I, \mathbf{1}, 1)$ and **IPC**$(I, \mathbf{1}, 1)$, respectively, then we have*

$$OPT_{Bi} \le OPT \le OPT_{Bi} + \epsilon.$$

Proof. Compare the follower's possible choices in **Bi-IP**$(I, \mathbf{1}, 1)$ and **IPC**$(I, \mathbf{1}, 1)$ when the leader's solution is fixed to $\bar{\mathbf{x}}$. It is easy to see that in **IPC**$(I, \mathbf{1}, 1)$, the follower's feasible choices on the remaining large items contain Θ, it thus follows that $Obj_{Bi}(\bar{\mathbf{x}}) \le Obj(\bar{\mathbf{x}})$. Particularly, since the optimal solution $\mathbf{x}^*$ of **IPC**$(I, \mathbf{1}, 1)$ is a feasible solution of **Bi-IP**$(I, \mathbf{1}, 1)$ and the optimal solution of **Bi-IP**$(I, \mathbf{1}, 1)$ may achieve an even smaller value, it follows that $OPT_{Bi} \le OPT$. It remains to prove that $Obj(\bar{\mathbf{x}}) \le Obj_{Bi}(\bar{\mathbf{x}}) + \epsilon$ and $OPT \le OPT_{Bi} + \epsilon$.

[3] If there is no feasible solution to $SP(\ell)$, we let $b_\ell = 1$ and $P_\ell = 0$.

Note that $Obj(\bar{\mathbf{x}})$ is exactly the optimal objective value of the following integer program:

$$\begin{aligned}\mathbf{IP}(\bar{\mathbf{x}}): \max_{\mathbf{y}} \quad & \mathbf{py} \\ s.t. \quad & \sum_{j=1}^{n} B_j y_j \le 1 \\ & \mathbf{y} \le \mathbf{1} - \bar{\mathbf{x}} \\ & \mathbf{y} \in \{0,1\}^n\end{aligned}$$

Let $\bar{\mathbf{y}}$ be an optimal solution of $\mathbf{IP}(\bar{\mathbf{x}})$, then $Obj(\bar{\mathbf{x}}) = \sum_{j\in I\setminus\bar{I}} p_j\bar{y}_j + \sum_{j\in\bar{I}} p_j\bar{y}_j$. Recall that $\mathbf{x}^*$ is an optimal solution of $\mathbf{IPC}(I,\mathbf{1},1)$, and $\bar{\mathbf{x}}_j = \mathbf{x}^*_j$ for $j \in I\setminus\bar{I}$ by (2b). Consequently, if we compare the follower in $\mathbf{IPC}(I,\mathbf{1},1)$ and the follower in $\mathbf{Bi\text{-}IP}(I,\mathbf{1},1)$, the subset of items in $I\setminus\bar{I}$ available for the two followers to select is the same, and we let this subset be $R = \{j : x^*_j = 0, j \in I\setminus\bar{I}\}$. Given that we assume $OPT \le 1$, the maximal profit the follower could obtain from R is at most 1, thus there exists some integer $\bar{\ell} \in [1, 1+1/\epsilon]$ such that $\sum_{j\in I\setminus\bar{I}} p_j\bar{y}_j \in [(\bar{\ell}-1)\epsilon, \bar{\ell}\epsilon)$. By the definitions of $P_{\bar{\ell}}$ and $b_{\bar{\ell}}$, we have $\sum_{j\in I\setminus\bar{I}} p_j\bar{y}_j \le P_{\bar{\ell}} + \epsilon$ and $b_{\bar{\ell}} \le \sum_{j\in I\setminus\bar{I}} B_j\bar{y}_j$. Define $\mathbf{y}' \in \{0,1\}^n$ such that the $\mathbf{y}'$ is a combination of two partial solutions: in $I\setminus\bar{I}$, $\mathbf{y}'$ is the same as $KP(\bar{\ell}\epsilon)$; and in $\bar{I}$, $\mathbf{y}'$ is the same as $\bar{\mathbf{y}}$. Then $\mathbf{y}'$ is a feasible solution of the following program:

$$\begin{aligned}\overline{\mathbf{IP}}(\bar{\mathbf{x}}): \max_{\ell} \max_{\mathbf{y}[\bar{I}]} \quad & P_\ell + \sum_{j=1}^{\bar{n}} p_j y_j \\ s.t. \quad & \sum_{j=1}^{\bar{n}} B_j y_j \le 1 - b_\ell \\ & y_j \le 1 - \bar{x}_j, \ \ \forall j \in \bar{I} \\ & y_j \in \{0,1\}, \ \ \forall j \in \bar{I}\end{aligned}$$

Notice that the optimal objective value of $\overline{\mathbf{IP}}(\bar{\mathbf{x}})$ is $Obj_{Bi}(\bar{\mathbf{x}})$, thus $\mathbf{py}' = P_{\bar{\ell}} + \sum_{j=1}^{\bar{n}} p_j\bar{y}_j \le Obj_{Bi}(\bar{\mathbf{x}})$. To conclude, we have

$$Obj(\bar{\mathbf{x}}) = \sum_{j\in I\setminus\bar{I}} p_j\bar{y}_j + \sum_{j=1}^{\bar{n}} p_j\bar{y}_j \le P_{\bar{\ell}} + \epsilon + \sum_{j=1}^{\bar{n}} p_j\bar{y}_j \le Obj_{Bi}(\bar{\mathbf{x}}) + \epsilon$$

Particularly, given an optimal solution $\bar{\mathbf{x}}^*$ of $\mathbf{Bi\text{-}IP}(I,\mathbf{1},1)$, we have $Obj(\bar{\mathbf{x}}^*) \le OPT_{Bi} + \epsilon$. Since the optimal solution of $\mathbf{IPC}(I,\mathbf{1},1)$ may achieve an even smaller objective value, it follows that $OPT \le OPT_{Bi} + \epsilon$. Hence Lemma 8 is proved. ◀

3.3 Handling Small Items

According to Lemma 8, to solve $\mathbf{IPC}(I,\mathbf{1},1)$, it suffices to solve $\mathbf{Bi\text{-}IP}(I,\mathbf{1},1)$, which is the goal of this subsection. Towards this, we first obtain a linear relaxation of $\mathbf{Bi\text{-}IP}(I,\mathbf{1},1)$ where both the leader and the follower can select items fractionally. Then we reformulate this bilevel linear relaxation as a single level linear program and find an extreme point optimal fractional solution. Finally we round this fractional solution to obtain a feasible solution to $\mathbf{Bi\text{-}IP}(I,\mathbf{1},1)$ with an objective value of at most $1+\mathcal{O}(\epsilon)$, which is thus also a feasible solution to $\mathbf{IPC}(I,\mathbf{1},1)$ with an objective value of at most $1+\mathcal{O}(\epsilon)$.

Replace (2c) and (2g) in **Bi-IP**$(I, \mathbf{1}, 1)$ with $x_j \in [0,1](\forall j \in \bar{I})$ and $y_j \in [0,1](\forall j \in \bar{I})$, respectively, we obtain a relaxation of **Bi-IP**$(I, \mathbf{1}, 1)$ as follows.

$$\textbf{Bi-IP}_r(I, \mathbf{1}, 1): \min_{\mathbf{x}} P_\ell + \sum_{j=1}^{\bar{n}} p_j y_j$$

$$s.t. \sum_{j=1}^{\bar{n}} \mathbf{A}_j x_j \le \mathbf{1} - \mathbf{a}' \tag{3a}$$

$$x_j = x_j^*, \ \ \forall j \in I \setminus \bar{I} \tag{3b}$$

$$x_j \in [0,1], \ \ \forall j \in \bar{I} \tag{3c}$$

where integer $\ell, \mathbf{y}[\bar{I}]$ solves the following:

$$\max_{1 \le \ell \le 1+\frac{1}{\epsilon}} \max_{\mathbf{y}[\bar{I}]} \quad P_\ell + \sum_{j=1}^{\bar{n}} p_j y_j \tag{3d}$$

$$s.t. \quad \sum_{j=1}^{\bar{n}} B_j y_j \le 1 - b_\ell \tag{3e}$$

$$y_j \le 1 - x_j, \ \ \forall j \in \bar{I} \tag{3f}$$

$$y_j \in [0,1], \ \ \forall j \in \bar{I} \tag{3g}$$

Denote by OPT^r_{Bi} the optimal objective value of **Bi-IP**$_r(I, \mathbf{1}, 1)$. Note that items in $\bar{I}$ are sorted in decreasing order of the profit-weight ratios p_j/B_j. Consider any fixed leader's solution $\mathbf{x} \in [0,1]^n$ and any fixed ℓ, the follower is solving a knapsack problem in the remaining (fractional) items. The maximal objective value of the follower, given $\mathbf{x} \in [0,1]^n$ and ℓ, is obtained by a simple greedy algorithm that selects remaining fractional items in $\bar{I}$ in the natural order of indices (recall that items are re-indexed in non-increasing order of ratios), until the budget $1 - b_\ell$ is exhausted. Note that the greedy algorithm will stop at some (fractional) item when the budget $1 - b_\ell$ is exhausted[4]. We say this item is *critical* and let its index be c_ℓ. Given any fixed $\mathbf{x} \in [0,1]^n$ and ℓ, the maximal objective value of program (3d)-(3g) for $\mathbf{x}$ is

$$P_\ell + \sum_{j=1}^{c_\ell - 1} p_j(1 - x_j) + p_{c_\ell} \frac{1 - b_\ell - \sum_{j=1}^{c_\ell - 1} B_j(1 - x_j)}{B_{c_\ell}}, \tag{4a}$$

where c_ℓ is the critical item given $\mathbf{x}$ and ℓ. The following two formulas are directly given by the definition of critical.

$$\sum_{j=1}^{c_\ell - 1} B_j(1 - x_j) \le 1 - b_\ell \tag{5a}$$

$$B_{c_\ell} + \sum_{j=1}^{c_\ell - 1} B_j(1 - x_j) \ge 1 - b_\ell \tag{5b}$$

We first show that the optimal objective value of the **Bi-IP**$_r(I, \mathbf{1}, 1)$ is at most $OPT_{Bi} + \delta$.

[4] The greedy algorithm may pack all remaining (fractional) items without using up the budget $1 - b_\ell$. To patch this case, we add a dummy item whose profit is 0, cost vector is $\mathbf{0}$ and weight is sufficiently large. We assume the last item $\bar{n}$ is the dummy item.

▶ **Lemma 9.** *Let OPT_{Bi} and OPT^r_{Bi} be the optimal objective values of **Bi-IP**$(I, \mathbf{1}, 1)$ and **Bi-IP**$_r(I, \mathbf{1}, 1)$, respectively, then $OPT^r_{Bi} \leq OPT_{Bi} + \delta$.*

Proof. It is not straightforward if we compare **Bi-IP**$(I, \mathbf{1}, 1)$ with **Bi-IP**$_r(I, \mathbf{1}, 1)$ directly, as both the follower and the leader become stronger in the relaxation (in the sense they can pack items fractionally). Towards this, we introduce an intermediate bilevel program **Bi-IP**$_{in}(I, \mathbf{1}, 1)$, which is obtained by replacing (3c) in **Bi-IP**$_r(I, \mathbf{1}, 1)$ with $x_j \in \{0, 1\}(\forall j \in \bar{I})$, that is, we only allow the follower to select items fractionally but not the leader. Denote by OPT_{in} the optimal objective value of **Bi-IP**$_{in}(I, \mathbf{1}, 1)$.

First, we compare **Bi-IP**$_{in}(I, \mathbf{1}, 1)$ with **Bi-IP**$_r(I, \mathbf{1}, 1)$. We see that in **Bi-IP**$_r(I, \mathbf{1}, 1)$ the follower is facing a stronger leader who is allowed to fractionally pack items, and it thus follows that $OPT^r_{Bi} \leq OPT_{in}$.

Next, we compare **Bi-IP**$_{in}(I, \mathbf{1}, 1)$ and **Bi-IP**$(I, \mathbf{1}, 1)$. Note that the leader's solution must be integral in both programs. Any feasible solution of **Bi-IP**$_{in}(I, \mathbf{1}, 1)$ is a feasible solution of **Bi-IP**$(I, \mathbf{1}, 1)$, and vice versa. Let $\bar{\mathbf{x}}^*$ be an optimal solution of **Bi-IP**$(I, \mathbf{1}, 1)$, then $\bar{\mathbf{x}}^*$ is also a feasible solution of **Bi-IP**$_{in}(I, \mathbf{1}, 1)$. Once the leader fixes his solution as $\bar{\mathbf{x}}^*$ in **Bi-IP**$_{in}(I, \mathbf{1}, 1)$, there exist ℓ and $c_\ell \in \bar{I}$, such that the objective value of **Bi-IP**$_{in}(I, \mathbf{1}, 1)$ is

$$Obj_{in} = P_\ell + \sum_{j=1}^{c_\ell - 1} p_j(1 - \bar{x}^*_j) + p_{c_\ell} \frac{1 - b_\ell - \sum_{j=1}^{c_\ell - 1} B_j(1 - \bar{x}^*_j)}{B_{c_\ell}},$$

where c_ℓ is the critical item corresponding to $\bar{\mathbf{x}}^*$ and ℓ. We have the following two observations:

- $OPT_{Bi} \geq Obj_{in} - p_{c_\ell} \geq Obj_{in} - \delta$. This is because the follower in **Bi-IP**$(I, \mathbf{1}, 1)$ can guarantee an objective value of $P_\ell + \sum_{j=1}^{c_\ell - 1} p_j(1 - \bar{x}^*_j)$, and $p_j \leq \delta$ for $j \in \bar{I}$;
- $OPT_{in} \leq Obj_{in}$. This is because $\bar{\mathbf{x}}^*$ is just a feasible solution of **Bi-IP**$_{in}(I, \mathbf{1}, 1)$, while the optimal solution of the leader may achieve an even smaller objective value.

To summarize, we know $OPT^r_{Bi} \leq OPT_{in} \leq Obj_{in} \leq OPT_{Bi} + \delta$. Lemma 9 is proved. ◀

Given Lemma 9, we are still facing two questions: how can we solve **Bi-IP**$_r(I, \mathbf{1}, 1)$; and even if we obtain a fractional solution to **Bi-IP**$_r(I, \mathbf{1}, 1)$, how can we transform it to an integral solution without incurring a huge loss. Towards this, consider the optimal solution $\mathbf{x}^r$ to **Bi-IP**$_r(I, \mathbf{1}, 1)$. Note that leader's choice on large items is guessed out in **Bi-IP**$_r(I, \mathbf{1}, 1)$. Consider the scenario when the follower adopts the ℓ-th dominant choice on the remaining large items, and recall the definition of critical items (see Equation 4a). Given solution $\mathbf{x}^r$, for any $\ell \in \{1, 2, \cdots, 1 + \frac{1}{\epsilon}\}$ there must exist a critical item. Therefore, there are $1 + \frac{1}{\epsilon}$ critical items corresponding to $\mathbf{x}^r$. The crucial fact is that, while we cannot guess out $\mathbf{x}^r$ directly, we can guess out all the critical items corresponding to $\mathbf{x}^r$. More precisely, with $\bar{n}^{\mathcal{O}(1/\epsilon)}$ enumerations, we can guess out the critical item c^r_ℓ for $\mathbf{x}^r$ and each ℓ. Suppose we have guessed out the correct c^r_ℓ's corresponding to the optimal solution $\mathbf{x}^r$, we consider the following LP:

$$
\begin{aligned}
\mathbf{LP}_{\text{Bi-IP}}: \quad \min_{\mathbf{x},M} \quad & M \\
& \sum_{j=1}^{\bar{n}} \mathbf{A}_j x_j \le \mathbf{1} - \mathbf{a}' \\
& P_\ell + \sum_{j=1}^{c^r_\ell - 1} p_j(1-x_j) + p_{c^r_\ell} \frac{1 - b_\ell - \sum_{j=1}^{c^r_\ell - 1} B_j(1-x_j)}{B_{c^r_\ell}} \le M, \quad \forall\, \ell \in \{1, 2, \cdots, 1+\frac{1}{\epsilon}\} \\
& \sum_{j=1}^{c^r_\ell - 1} B_j(1-x_j) \le 1 - b_\ell, \quad \forall \quad \ell \in \{1, 2, \cdots, 1+\frac{1}{\epsilon}\} \\
& B_{c^r_\ell} + \sum_{j=1}^{c^r_\ell - 1} B_j(1-x_j) \ge 1 - b_\ell, \quad \forall \quad \ell \in \{1, 2, \cdots, 1+\frac{1}{\epsilon}\} \\
& x_j = x^*_j, \quad j \in I \setminus \bar{I} \\
& x_j \in [0,1], \quad j \in \bar{I}
\end{aligned}
$$

We have the following simple observation.

▶ **Observation 10.** *Let M^* and OPT^r_{Bi} be the optimal objective values of $\boldsymbol{LP}_{Bi\text{-}IP}$ and $\boldsymbol{Bi\text{-}IP}_r(I, \mathbf{1}, 1)$, respectively, then $M^* \le OPT^r_{Bi}$.*

Let $\mathbf{x}^r$ be an optimal solution to $\mathbf{Bi\text{-}IP}_r(I, \mathbf{1}, 1)$. The observation follows directly as $\mathbf{x}^r$ together with OPT^r_{Bi} form a feasible solution to $\mathbf{LP}_{\text{Bi-IP}}$.

In the meantime, we also have the following observation.

▶ **Observation 11.** *Let $\{\mathbf{x}^{ex}, M^*\}$ be an extreme point optimal solution to $\boldsymbol{LP}_{Bi\text{-}IP}$, then $\mathbf{x}^{ex}$ is also a feasible solution to $\boldsymbol{Bi\text{-}IP}_r(I, \mathbf{1}, 1)$ whose objective value is at most M^*.*

The observation follows since by the definition of critical, (4a) is the largest profit the follower can achieve. Hence, when $\mathbf{x} = \mathbf{x}^{ex}$ in $\mathbf{Bi\text{-}IP}_r(I, \mathbf{1}, 1)$, the objective value is bounded by M^*. Given the two observations above, we know $\mathbf{x}^{ex}$ is an optimal solution to $\mathbf{Bi\text{-}IP}_r(I, \mathbf{1}, 1)$ and we have $M^* = OPT^r_{Bi}$. Finally, a near-optimal solution to $\mathbf{IPC}(I, \mathbf{1}, 1)$ can be obtained through the optimal solution to $\mathbf{LP}_{\text{Bi-IP}}$, as implied by the following lemma.

▶ **Lemma 12.** *Let $\{\mathbf{x}^{ex}, M^*\}$ be an extreme point optimal solution to $\boldsymbol{LP}_{Bi\text{-}IP}$. Define $\tilde{\mathbf{x}}$ such that $\tilde{x}_j = 1$ if $x^{ex}_j = 1$, and $\tilde{x}_j = 0$ otherwise. Then $\tilde{\mathbf{x}}$ is a feasible solution of $\boldsymbol{IPC}(I, \mathbf{1}, 1)$ with an objective value of at most $OPT + \mathcal{O}(\epsilon)$, where OPT is the optimal objective value of $\boldsymbol{IPC}(I, \mathbf{1}, 1)$.*

Proof. The feasibility of $\tilde{\mathbf{x}}$ to $\mathbf{IPC}(I, \mathbf{1}, 1)$ is straightforward since

$$
\sum_{j=1}^{n} \mathbf{A}_j \tilde{x}_j = \sum_{j \in I \setminus \bar{I}} \mathbf{A}_j x^*_j + \sum_{j \in \bar{I}} \mathbf{A}_j \tilde{x}_j \le \mathbf{a}' + \sum_{j \in \bar{I}} \mathbf{A}_j x^{ex}_j \le \mathbf{a}' + \mathbf{1} - \mathbf{a}' \le \mathbf{1}.
$$

Notice that $\tilde{\mathbf{x}}$ is also feasible for $\mathbf{Bi\text{-}IP}(I, \mathbf{1}, 1)$ and $\mathbf{Bi\text{-}IP}_r(I, \mathbf{1}, 1)$. Let $Obj(\tilde{\mathbf{x}})$, $Obj_{Bi}(\tilde{\mathbf{x}})$ and $Obj^r_{Bi}(\tilde{\mathbf{x}})$ be the objective values of $\mathbf{IPC}(I, \mathbf{1}, 1)$, $\mathbf{Bi\text{-}IP}(I, \mathbf{1}, 1)$ and $\mathbf{Bi\text{-}IP}_r(I, \mathbf{1}, 1)$ by taking $\mathbf{x} = \tilde{\mathbf{x}}$, respectively. Since in $\mathbf{Bi\text{-}IP}_r(I, \mathbf{1}, 1)$, the leader is facing a stronger follower who can select fractional items in $\bar{I}$, it follows that $Obj_{Bi}(\tilde{\mathbf{x}}) \le Obj^r_{Bi}(\tilde{\mathbf{x}})$.

Now we compare the objective values of two solutions to $\mathbf{Bi\text{-}IP}_r(I, \mathbf{1}, 1)$, $\mathbf{x}^{ex}$ and $\tilde{\mathbf{x}}$. It is easy to see that in $\mathbf{x}^{ex}$, there are at most $(s_A + \frac{3(1+\epsilon)}{\epsilon})$ variables taking fractional values, and all these variables are in $\{x^{ex}_j : j \in \bar{I}\}$. So the leader in $\mathbf{x}^{ex}$ selects at most $(s_A + \frac{3(1+\epsilon)}{\epsilon})$

more items in $\bar{I}$, compared with the leader in $\tilde{\mathbf{x}}$. Consequently, the follower in $\mathbf{x}^{ex}$ may select at most $(s_A + \frac{3(1+\epsilon)}{\epsilon})$ less items in $\bar{I}$, compared with the follower in $\tilde{\mathbf{x}}$. Given that the objective value of $\mathbf{x}^{ex}$ is $OPT^r_{Bi} = M^*$, we have that

$$Obj^r_{Bi}(\tilde{\mathbf{x}}) \leq OPT^r_{Bi} + (s_A + \frac{3(1+\epsilon)}{\epsilon})\delta.$$

According to Lemma 8 and Lemma 9, we have $Obj(\tilde{\mathbf{x}}) \leq Obj_{Bi}(\tilde{\mathbf{x}}) + \epsilon$ and $OPT^r_{Bi} \leq OPT_{Bi} + \delta$. In conclusion, we have

$$Obj(\tilde{\mathbf{x}}) \leq OPT_{Bi} + (s_A + 1 + \frac{3(1+\epsilon)}{\epsilon})\delta + \epsilon.$$

Furthermore, $OPT_{Bi} \leq OPT$ by Lemma 8. By setting $\delta = \epsilon^2$, Lemma 12 is proved. ◀

Hence, if $OPT \leq 1$, then a feasible solution with objective value of at most $OPT + \mathcal{O}(\epsilon) \leq 1 + \mathcal{O}(\epsilon)$ is found, thus Lemma 3 is proved, and Theorem 2 follows.

4 Approximation algorithm for IPC where s_B and s_A are constant

In this section, we prove our main result – Theorem 13.

▶ **Theorem 13.** *When s_B and s_A are fixed constants, for an arbitrarily small number $\epsilon > 0$, there exists an $(s_B + \mathcal{O}(\epsilon))$-approximation polynomial time algorithm for IPC.*

Similar to the special case, by scaling item profits it suffices to show the following:

▶ **Lemma 14.** *Let OPT be the optimal objective value of $\boldsymbol{IPC}(I, \mathbf{a}, \mathbf{b})$. If $OPT \leq 1$, then for an arbitrarily small number $\epsilon > 0$, there exists a polynomial time algorithm that returns a feasible solution to $\boldsymbol{IPC}(I, \mathbf{a}, \mathbf{b})$ with an objective value of at most $s_B + \mathcal{O}(\epsilon)$.*

By further scaling the cost vectors and weight vectors, it suffices to find a near-optimal solution for $\mathbf{IPC}(I, \mathbf{1}, \mathbf{1})$.

Major technical challenge. Recall that the key to solving IPC for the special case of $s_B = 1$ is the establishment of $\mathbf{Bi\text{-}IP}(I, \mathbf{1}, 1)$, which is essentially equivalent to $\mathbf{IPC}(I, \mathbf{1}, 1)$. $\mathbf{Bi\text{-}IP}(I, \mathbf{1}, 1)$ is built upon the observation that the follower admits only $\mathcal{O}(\frac{1}{\epsilon})$ dominant choices on large items, where each dominant choice corresponds to the minimal budget needed by the follower to ensure a profit of $[(k-1)\epsilon, k\epsilon)$ where $k \in \{1, 2, \cdots, 1 + \frac{1}{\epsilon}\}$. Because the number of follower's choices on large items is small, its relaxation $\mathbf{Bi\text{-}IP}_r(I, \mathbf{1}, 1)$ has a small number of constraints (see Equation 3e), and therefore we can further transform $\mathbf{Bi\text{-}IP}_r(I, \mathbf{1}, 1)$ to $\mathbf{LP}_{\text{Bi-IP}}$ with a small number of constraints whose extreme point solution promises a good rounding. We aim to follow a similar method, however, when $s_B \geq 2$, we can no longer bound the follower's choices on large items. This is because to achieve a profit of $[(k-1)\epsilon, k\epsilon)$ where $k \in \{1, 2, \cdots, 1 + \frac{1}{\epsilon}\}$, the follower may have a huge number of different choices utilizing different budgets, where the budgets are now vectors instead of numbers, and are thus incomparable. To handle the problem, we use the idea of rounding: let $\mathbf{b} = (\mathbf{b}[1], \mathbf{b}[2], \cdots, \mathbf{b}[s_B])$ and $\mathbf{B}_j = (\mathbf{B}_j[1], \mathbf{B}[2], \cdots, \mathbf{B}[s_B])$. We call the first dimension ($\mathbf{b}[1]$ and $\mathbf{B}_j[1]$'s) the principal dimension. The principal dimension will be treated the same as the special case and will *not* be rounded. The coordinates of other dimensions ($\mathbf{b}[h]$ and $\mathbf{B}_j[h]$'s for $2 \leq h \leq s_B$) will be rounded. Then, we will be able to compare follower's different choices on large items: if there are two choices both achieving profit within $[(k-1)\epsilon, k\epsilon)$ for the same $k \in \mathcal{O}(\frac{1}{\epsilon})$, and furthermore, the summation of their weight vectors share the

same rounded value in each dimension $h \in [2, s_B]$, then the choice with smaller value in the principal dimension of the summed weight vectors dominates the other choice. By doing so, our argument for the special case can be carried over to the principal dimension.

There is one problem with the idea of rounding above, that is, if we round up weight vectors and meanwhile enlarge the follower's budget vector in dimension $h \in [2, s_B]$ (to accommodate the rounding up), the optimal objective value of IPC may increase. However, we are able to show that the optimal objective value only increases by a factor of s_B (see Lemma 15). This explains our approximation ratio of $s_B + \epsilon$.

Below we give a very brief walk through and the reader is referred to the full version [7] for details.

Step 1. We pick a small parameter δ as the rounding precision, keep the coordinates of weight vectors on principal dimension intact, and round the coordinates on other dimensions. We also round the profits. By doing so we obtain a rounded instance $\tilde{I}_\delta$. Then we pick another small parameter τ and enlarge the weight budget on dimension $h \in [2, s_B]$ by a factor of $1 + \tau$. By doing so we obtain:

$$
\begin{aligned}
\mathbf{IPC}_\tau(\tilde{I}_\delta, \mathbf{1}, \mathbf{1}) : \min_{\mathbf{x}} \ & \tilde{\mathbf{p}}\mathbf{y} \\
s.t. \ & \mathbf{A}\mathbf{x} \le \mathbf{1} \\
& \mathbf{x} \in \{0,1\}^n \\
& \text{where } \mathbf{y} \text{ solves the following:} \\
& \max_{\mathbf{y}} \quad \tilde{\mathbf{p}}\mathbf{y} \\
& s.t. \quad \sum_{j=1}^{n} \tilde{\mathbf{B}}_j[1] y_j \le 1 \\
& \qquad \sum_{j=1}^{n} \tilde{\mathbf{B}}_j[i] y_j \le 1 + \tau, \ \ \forall 2 \le i \le s_B \\
& \qquad \mathbf{x} + \mathbf{y} \le \mathbf{1} \\
& \qquad \mathbf{y} \in \{0,1\}^n
\end{aligned}
$$

where $\tilde{\mathbf{B}}_j[1] = \mathbf{B}_j[1]$, $\tilde{\mathbf{B}}_j[h]$, $2 \le h \le s_B$ and $\tilde{\mathbf{p}}$ are rounded weights and profits. We are able to prove the following lemma which ensures that solving $\mathbf{IPC}_\tau(\tilde{I}_\delta, \mathbf{1}, \mathbf{1})$ gives a good approximate solution to $\mathbf{IPC}(I, \mathbf{1}, \mathbf{1})$:

▶ **Lemma 15.** *Let $0 < \tau \le 1/2$. Let $\tilde{\mathbf{x}}$ be any feasible solution to $\boldsymbol{IPC}_\tau(\tilde{I}_\delta, \mathbf{1}, \mathbf{1})$. Then $\tilde{\mathbf{x}}$ is a feasible solution to $\boldsymbol{IPC}(I, \mathbf{1}, \mathbf{1})$. Let $\widetilde{Obj}_\tau(\tilde{\mathbf{x}})$ and $Obj(\tilde{\mathbf{x}})$ be the objective values of $\boldsymbol{IPC}_\tau(\tilde{I}_\delta, \mathbf{1}, \mathbf{1})$ and $\boldsymbol{IPC}(I, \mathbf{1}, \mathbf{1})$ for $\mathbf{x} = \tilde{\mathbf{x}}$, respectively. If $2\delta \le \tau \le 1/2$, we have*

$$Obj(\tilde{\mathbf{x}}) \le (1+\delta)\widetilde{Obj}_\tau(\tilde{\mathbf{x}}) \le s_B(1+\delta)Obj(\tilde{\mathbf{x}}).$$

Furthermore, let $\widetilde{OPT}_\tau$ and OPT be the optimal objective values of $\boldsymbol{IPC}_\tau(\tilde{I}_\delta, \mathbf{1}, \mathbf{1})$ and $\boldsymbol{IPC}(I, \mathbf{1}, \mathbf{1})$, respectively. We have

$$OPT \le (1+\delta)\widetilde{OPT}_\tau \le s_B(1+\delta)OPT.$$

Step 2. We handle large items. We first classify item profits into large, medium and small. We then classify item weights into large and small based on the largest coordinate in the weight vector, i.e., $\|\mathbf{B}_j\|_\infty$. We say an item is large if it has a large weight or a large profit, and small otherwise. Let S^* be the leader's optimal solution in $\mathbf{IPC}_\tau(\tilde{I}_\delta, \mathbf{1}, \mathbf{1})$. Using a similar argument as the special case, we can prove the following.

▶ **Lemma 16.** *With $\mathcal{O}(s_B\delta)$ additive error, we can guess out all items in S^* that have a large weight or a large profit by $n^{\tilde{\mathcal{O}}(s_B/\delta^{s_B+1})}$ enumerations.*

Utilizing the fact that coordinates in dimension $h \in [2, s_B]$ are all rounded, we can show that the follower only has a small number (i.e. $\tilde{\mathcal{O}}(s_B/\epsilon^{s_B})$) of dominant choices on large items, denoted as Θ. By restricting the follower's choices to Θ, we can obtain a new bilevel integer programming $\mathbf{MBi\text{-}IP}(\tilde{I}_\delta, \mathbf{1}, \mathbf{1})$. Similar to $\mathbf{Bi\text{-}IP}(I, \mathbf{1}, \mathbf{1})$ in the special case, $\mathbf{MBi\text{-}IP}(\tilde{I}_\delta, \mathbf{1}, \mathbf{1})$ has a small number of constraints.

Step 3. We handle small items. Since $\mathbf{MBi\text{-}IP}(\tilde{I}_\delta, \mathbf{1}, \mathbf{1})$ has a small number of constraints, we remove the integral constraint to obtain a relaxation $\mathbf{MBi\text{-}IP}_r(\tilde{I}_\delta, \mathbf{1}, \mathbf{1})$. Next, we transform this bilevel LP $\mathbf{MBi\text{-}IP}_r(\tilde{I}_\delta, \mathbf{1}, \mathbf{1})$ to a standard (single level) LP, denoted as $\mathbf{cen\text{-}LP}_\lambda$. Note that here the transformation is much more complicated than that in the special case: in the special case we know that if the follower can choose items fractionally, then its optimal fractional solution is always obtained greedily with respect to the ratio (i.e., profit to weight), whereas it suffices to guess one single critical item. In the general case, if the follower can choose items fractionally, we can only guarantee that among all items whose rounded weight vector are the same except for the principal dimension (i.e., $\mathbf{B}_j[h]$'s have the same rounded value for every $2 \le h \le s_B$), the follower selects items greedily with respect to the principal ratio (i.e., profit to weight coordinate in the principal dimension). Therefore, we need to guess a subset of critical items, and the subscript λ in $\mathbf{cen\text{-}LP}_\lambda$ corresponds to a set of parameters characterizing the subset of critical items. The most technical part is to show that the optimal solution to $\mathbf{cen\text{-}LP}_\lambda$ gives a good approximation to $\mathbf{MBi\text{-}IP}_r(\tilde{I}_\delta, \mathbf{1}, \mathbf{1})$ (see Lemma 31 in the full version [7]), where we need to create a sequence of "intermediate" LPs. Finally, we obtain an extreme point solution to $\mathbf{MBi\text{-}IP}_r(\tilde{I}_\delta, \mathbf{1}, \mathbf{1})$ by solving $\mathbf{cen\text{-}LP}_\lambda$, and round it to an integral solution. The rounding error can be bounded due to that $\mathbf{MBi\text{-}IP}_r(\tilde{I}_\delta, \mathbf{1}, \mathbf{1})$ contains a small number of constraints.

5 Approximation algorithm for IPC where s_B and s_A are arbitrary

We consider the most general setting of IPC where s_A and s_B are arbitrary (not necessarily polynomial in the input size).

We define $\max\{\mathbf{py} : \mathbf{By} \le \mathbf{b}, \mathbf{y} \in \{0,1\}^n\}$ as the *follower's problem*. A separation oracle for the *leader's problem* is an oracle such that given any $\mathbf{x} = \mathbf{x}^0 \in [0,1]^n$, it either asserts that $\mathbf{x}^0 \in \{\mathbf{x} : \mathbf{Ax} \le \mathbf{a}, \mathbf{x} \in [0,1]^n\}$, or returns a violating constraint. The goal of this section is to prove the following theorem.

▶ **Theorem 17.** *Given a separation oracle O_L for the leader's problem, and an oracle O_F for the follower's problem that returns a ρ-approximation solution, there exists a $(\frac{\rho}{1-\alpha}, \frac{1}{\alpha})$-bicriteria approximation algorithm for any $\alpha \in (0,1)$ that returns a solution $\mathbf{x}^* \in \{0,1\}^n$ such that $\mathbf{Ax}^* \le \frac{1}{\alpha} \cdot \mathbf{a}$, and*

$$\max\{\mathbf{py} : \mathbf{By} \le \mathbf{b}, \mathbf{y} \le \mathbf{1} - \mathbf{x}^*, \mathbf{y} \in \{0,1\}^n\} \le \frac{\rho T^*}{1-\alpha},$$

where T^* is the optimal objective value of $\boldsymbol{IPC}(I, \mathbf{a}, \mathbf{b})$. Furthermore, the algorithm runs in polynomial oracle time.

We omit the proof of Theorem 17 here, and refer the reader to the full version [7].

6 Conclusions

In this paper, we consider a general two-player zero-sum Stackelberg game in which the leader interdicts some items to minimize the total profit that the follower could obtain from the remaining items. We obtain an $(s_B + \epsilon)$-approximation algorithm when s_A and s_B are both constant, and show that there does not exist any $(4/3 - \epsilon)$-approximation algorithm when $s_B \geq 2$. Our algorithm is the best possible when $s_B = 1$, however, it is not clear whether it is the best possible when s_B is larger than or equal to 2. In particular, it is not clear whether an approximation algorithm with a ratio independent of s_B can be obtained. Furthermore, can we hope for a PTAS if $s_B \geq 2$ but the constraints of the leader or the follower are not given by general inequalities but follow from common optimization problems? For example, what if the follower's optimization problem is a bin packing problem? It would be interesting to investigate the bilevel generalization of well-known optimization problems, e.g., scheduling and bin packing.

Abstract

We study a generalization of the classic Online Joint Replenishment Problem (JRP) with Delays that we call the Online Weighted Cardinality JRP with Delays. The JRP is an extensively studied inventory management problem wherein requests for different item types arrive at various points in time. A request is served by ordering its corresponding item type. The cost of serving a set of requests depends on the item types ordered. Furthermore, each request incurs a delay penalty while it is left unserved. The objective is to minimise the total service and delay costs. In the Weighted Cardinality JRP, each item type has a positive weight and the cost of ordering is a non-decreasing, concave function of the total weight of the item types ordered. This problem was first considered in the offline setting by Cheung et al. (2015) but nothing is known in the online setting. Our main result is a deterministic, constant competitive algorithm for this problem.

1 Introduction

The Joint Replenishment Problem (JRP) is a class of optimisation problems that are fundamental to inventory management theory. The problem involves a sequence of requests on items that arrive at various times. Serving a set of requests incurs a cost that is determined by a given cost function that depends on the set of items the requests are on. The goal of the problem is to serve all requests whilst minimising the total cost incurred. There are two variants under which this problem is often studied. In the deadline variant, each request has an associated deadline that is must be served before whilst in the more general delay variant, each request incurs a delay penalty which must be paid. The delay is a non-decreasing, continuous function of the time the request was left unserved. Under the delay model, the goal is to minimise the total service and delay costs. We will be considering the JRP under a *make-to-order* mechanism [18], where items must be made to serve some request and cannot be held in inventory. In this paper, we consider the online setting. Here, requests arrive over time together with their deadline or delay functions and at any point in time, the algorithm may choose to serve some set of requests.

In the Classic JRP, each item type i has a corresponding *item ordering cost* K_i and there is a fixed *joint ordering cost* K_0. Whenever a set of items is served, the cost incurred is K_0 plus K_i for each item type i served. We note that regardless of the number of units of an item type i that gets served, only a fixed K_i is paid. This problem captures the well-known TCP Acknowledgement Problem. Buchbinder et al. [15] gave a 3-competitive algorithm for

Online Classic JRP with Delays and a lower bound of 2.64. Then, Bienkowski et al. [10] improved the lower bound to 2.754 and showed that the optimal competitive ratio for Online Classic JRP with Deadlines is 2.

With the competitive ratio of Online Classic JRP with Delays mostly settled, there has been a lot of interest in generalisations of the problem where different costs of serving requests are considered. One of these generalizations is Multi-Level Aggregation [9, 14] where we are given a rooted tree T with node costs and requests arrive at nodes of the tree. The cost of serving a set of requests is the cost of the subtree of T induced by the root and the nodes corresponding to the requests. Note that when T is depth 2, this captures JRP. The current best upper bounds for this problem depends on either the depth of T [14, 7], or are logarithmic in the number of vertices of T [8]. No super-constant lower bounds are known.

This problem was later generalized to Online Network Design with Delays [8] where we are given a graph G with edge/node costs and receive connectivity requests over time. The cost of serving a set of connectivity requests is the cost of the subgraph of G that satisfies the requests. This captures a wide class of problems such as Multi-Level Aggregation and Set Cover with Delay. Azar and Touitou [8] provided a framework to reduce a network design problem with delay or deadline to the classic offline variant without delay or deadline while incurring a logarithmic loss in the competitive ratio. Using this framework, they gave polylogarithmic-competitive algorithms for many network design problems with delays or deadlines. Recently, Touitou [30] recently showed that a sub-logarithmic competitive ratio is not possible for Online Network Design with Delays in its full generality. Thus, as powerful as this framework is, it cannot be used as is to improve the competitive ratios for problems such as Multi-Level Aggregation. For these problems, we will need to take advantage of the special structure of these problems to improve their competitive ratios.

In this paper, we introduce a natural generalisation of Online Classic JRP with Delays called the Online Weighted Cardinality JRP with Delays and show that the Azar-Touitou framework can be refined to give a constant competitive algorithm for the problem. In the Online Weighted Cardinality JRP with Delays, each item type i has an associated weight w_i and we are also given a non-negative, non-decreasing concave function f. The cost of serving a set of requests on a set λ of item types is $f(\sum_{i\in\lambda} w_i)$. The concave cost function captures a natural type of economies-of-scale in the real-world production of goods. It has also been considered in other optimization problems such as buy-at-bulk network design (see Section 1.2 for details). The special case of unit weights (called Cardinality JRP) was first studied by Cheung et al. [17] in the offline setting, and they gave a 5-approximation algorithm. We remark that this problem captures the Classic JRP by setting f to be the affine function $f(x) = K_0 + x$ and the weights $w_i = K_i$.

The main technical result of this paper is a constant-competitive algorithm for the case of unit weights.

▶ **Theorem 1.** *There is an $O(1)$-competitive, deterministic polynomial time algorithm for Online Cardinality JRP with Delay.*

For the weighted variant, we design a pseudo-polynomial time reduction from Weighted Cardinality JRP to Cardinality JRP to get the following result.

▶ **Theorem 2.** *There exists an $O(1)$-competitive, deterministic algorithm for Online Weighted Cardinality JRP with Delay.*

1.1 Our Techniques

We now outline the key ideas behind our algorithm for Online Cardinality JRP with Delay. First, as is common when dealing with concave functions, we focus on the special case where the function $f(x)$ is the minimum of n affine functions $g_i(x) = \sigma_i + \delta_i x$, and the σ_i's are geometrically increasing with i while the δ_i's are geometrically decreasing with i. Moreover, when we make a service, we specify which of these affine functions we use to pay for the service. When we make a service λ using g_i, we call it a *level* i service. The cost of the service is $g_l(\lambda) = \sigma_i + \delta_i|\lambda|$; we call σ_i the *shared cost* of the service and δ_i its *individual cost*. We call this the *Piecewise Cardinality JRP*. In the remainder of this section, we discuss our approach for Piecewise Cardinality JRP.

In Classic JRP, the main challenge is to balance the competing demands of aggregating requests into few orders to minimize the number of services and hence the total joint ordering costs incurred, and of aggregating requests on the same item types to minimize the total item ordering costs incurred. The additional challenge in Piecewise Cardinality JRP is deciding which level each service serves at. Since $2\sigma_i \leq \sigma_{i+1}$ and $\delta_i \geq 2\delta_{i+1}$ for all $i \in [1, n)$, a lower level service pays a lower shared cost but higher individual cost for each item type and is hence preferred for services with fewer items. On the other hand, a higher level service must pay a larger shared cost but can then serve items at a lower individual cost and should thus be used when serving more item types.

Our algorithm is inspired by the Azar-Touitou framework [8] and augmented with ideas from Gupta et al. [26] to decide which level we should make services at. In fact, we also show that applying the Azar-Touitou framework directly leads to a logarithmic competitive ratio at best (see full version). We first discuss how to handle the simpler deadline setting.

In the deadline setting, requests have levels which are initialised to 1 on arrival. When an unserved request of level j reaches a deadline, it triggers a level j service. We then upgrade its level to $j + 1$ if there are sufficient level j services made recently whose total individual cost can pay for the shared cost of the upgraded services. This makes sense because if there are too many level j services in a relatively small time period then the optimal solution could have aggregated the requests served by these requests into fewer higher-level services and incurred lower cost overall. While this seems to lead to a competitive ratio that depends on the number of levels, by making a careful choice of which level j services to charge to, we are able to achieve a constant competitive ratio. Once we have decided on the level of the service, say at level j', we set the budget of the service to its shared cost $\sigma_{j'}$ and serve unserved requests of level at most j' in ascending order of their deadline until the individual cost of the service reaches or exceeds the budget.

To generalise the algorithm to the delay setting, we adapt and extend the idea of investments used by [8]. Conceptually, instead of thinking of the delay penalty on requests being paid off continuously as time progresses, online algorithms with delay normally pay off the delay accumulated by requests when the request is served. However, with the notion of investments, services will pay off the delay accumulated by all requests, regardless of whether or not it serves it, and will also pay off and "invest" in the delay requests may accumulate in the future. This can be thought of as services investing in the delay requests accumulate and might accumulate in the future and incrementally paying it off as opposed to paying it all off in one go at service time. Our key innovation to extend upon the idea of investments used by [8] is to keep track of and utilise how much has been invested into each request. More specifically, we will invest in requests and once a sufficient amount has been invested into a set of requests of the same item type, we will serve the set of requests. To then generalise

the level updating condition used in the deadline variant, our algorithm will explicitly bound the amount invested in requests of a particular level by recent services and use this bound to determine when we update levels.

Our analysis uses similar ideas to [8] by defining service pointers to define different types of services and then breaking up our algorithm's cost into the costs of different types of services. Using our extended notion of investments, we introduce a novel charging argument. Previous works on online JRP and related problems often charge their algorithm's delay costs to the costs of its services which are then charged to the optimal solution. Our analysis differs by instead charging the algorithm's service costs to the delay costs we have invested in and then charging these costs to the optimal solution.

1.2 Related work

Multi-Level Aggregation was first studied by Bienkowski et al. [9] who gave an algorithm whose competitive ratio is exponential in the depth D of the tree T. This was later improved to $O(D)$ for the deadline setting by Buchbinder et al. [14] and then to $O(D^2)$ for the general delay model by Azar and Touitou [7]. The framework of Azar-Touitou [8] yields a competitive ratio that is logarithmic in the number of vertices of T.

Online Network Design with Delays was first studied by Azar and Touitou [8]. They proved polylogarithmic competitive ratios for many network design problems with delay and gave a $\Omega(\sqrt{log|V|})$ lower bound for the case of online node-weighted Steiner tree with delay and online directed Steiner tree with delay. This was recently improved to $\Omega(\log|V|/\log\log|V|)$ by Touitou [30].

A related problem is Set Cover with Delays where we are given a universe of elements and a collection of sets with costs, requests arrive on elements. The cost of serving a set of requests is the min-cost set cover for the corresponding set of elements. This problem was first studied by Carrasco et al. [16]. They gave a $O(\log N)$-competitive algorithm (where N is the number of requests) and proved a matching lower bound. Later, Azar et al. [3] gave an algorithm that is polylogarithmic in the number of sets and elements.

Two other online problems with delay that have received a lot of attention are matching [19, 1, 20, 12, 4, 13, 11, 6] and k-server [5, 13, 7, 24]. In Matching with Delays, requests arrive on points of a metric space and accumulate delay until they are matched. The objective is to minimize the length of the matching and the total delay cost. In the k-Server with Delays problem, we have k servers in a metric space and requests arrive on points of the metric space. A request is served by moving a server to its location. The goal is to minimize the total distance traveled by the servers and the delay incurred by the requests.

Concave cost functions have been widely-studied in the network design literature, both in the offline and online settings. The problem that is most closely relevant to our paper is Offline Single-Sink Buy-at-Bulk Network Design. We are given an undirected graph $G = (V, E)$ with edge lengths d_e, a concave cost function f, a sink t and a set of sources s_i. The cost of routing x_e units of flow on edge e is $f(x_e) \cdot d_e$. The total cost is the sum of the routing cost over all edges. The goal is to route one unit of flow between from each source s_i to the sink t with minimum total cost. The problem is known to be NP-hard and admits constant-factor approximation algorithms [28, 23, 21, 29, 25, 22, 27]. In the online setting, the sources arrive one-by-one. For the online problem, there is a tight deterministic $O(\log k)$-competitive algorithm [2, 31, 26].

2 Preliminaries

As mentioned in the Introduction, we will be mainly dealing with Piecewise Cardinality JRP with Delay. The Piecewise Cardinality JRP is a special case of Cardinality JRP where the cost function is a concave, piecewise function defined by taking the minimum of n affine functions, where n is arbitrary. More precisely, the cost of a service λ is $g(\lambda) = \min_i\{\sigma_i+\delta_i|\lambda| : i \in [1,n]\}$ where the cardinality $|\lambda|$ is the number of item types served in λ. The affine functions must also satisfy $2\sigma_i \leq \sigma_{i+1}$ and $\delta_i \geq 2\delta_{i+1}$ for all $i \in [1,n)$. We will also require that $\sigma_i \geq \delta_i$ for all i. Requests will then arrive over time and upon arrival, they have an associated deadline or delay function that is revealed.

When a service with cost $\sigma_i + \delta_i|\lambda|$ for some i is made, we will say that a *level i service* has been made and call the σ_i paid the *shared cost* of the service and the $\delta_i|\lambda|$ cost paid the *individual cost* of the service. Typically, a solution to Piecewise Cardinality JRP would specify when services are made and what requests are served by these services. The cost of this service would then be determined by taking the minimum of the piecewise affine functions. Equivalently, we can also require the solution to specify for each service not only the requests it serves but also the level it serves it in. This is a more useful formulation that we will be using in the sequel.

For the delay variant, which is the variant under which we are studying this problem, the delay penalty function $d_q(t)$ for a request q is a non-decreasing, continuous function of the time the request has been left unserved. We will also assume that the delay penalty for each request tends to infinity as the time tends to infinity which is a natural assumption also made by [8] to ensure that all requests must eventually be served.

Using standard techniques for dealing with concave functions we can reduce Cardinality JRP to Piecewise Cardinality JRP losing only a constant factor in the approximation ratio. We defer the details to the full version.

3 Piecewise Cardinality JRP with Delay

We now prove the following theorem. Omitted proofs can be found in the full version.

▶ **Theorem 3.** *There is a deterministic $O(1)$-competitive algorithm for Piecewise Cardinality JRP with Delay.*

3.1 Algorithm Intuition

We first introduce some terminology. We will say a request is *active* if it has arrived and is unserved. We will also assign each request a *request level* which is initially set to 1 upon arrival and is updated as the algorithm progresses. We say that an request is *eligible* for a level l service at time t if it is active and has level at most l at time t. Our algorithm allows services to incrementally pay off the delay that requests have accumulated in the past and may accumulate in the future; we call the latter an *investment cost*. In particular, we say that a service λ at time t *invests* an amount x into request q when λ pays off x amount of the delay cost that may be incurred by q after t. The *residual delay* of a request q at time t is defined as the amount of delay accumulated by the request up to time t that has not been paid for by some service.

When do we make a service? A level l service λ is *triggered* when the set of requests E eligible for a level l service accumulate a total residual delay of σ_l; we say that E are the eligible requests of λ. The intuition here is that our algorithm will make level l services whose total cost is $O(1) \cdot \sigma_l$ and hence waiting until σ_l unpaid delay accumulates means that our delay cost will be comparable to the service cost.

What level service should we make? When a level l service λ is triggered at time t, we first check if we can upgrade it to $l+1$. Roughly speaking, we upgrade to level $l+1$ if the amount invested by recent level l services so far is at least σ_{l+1}. This invariant allows us to bound our investment costs. We then proceed to the next step of deciding which requests to serve.

Which requests to serve? Next, the algorithm uses an investment process to decide which requests to serve. For each item type we add to our service, we incur an additional cost of δ_l. The investment process continually invests into the future delay of eligible requests. Once the total investment into requests of an item type i, from this service as well as prior services, reaches δ_l, we add i to the service, reset the counter to 0 and stop investing in requests of type i. The entire investment process stops once the total amount invested by the service reaches σ_l or the service contains the item types of all eligible requests, and we make the service. Intuitively, this investment process allows us to serve requests by order of urgency. Urgent requests can be interpreted as those that accumulate delay faster and hence will have investment counters that reach the required service threshold faster.

3.2 Algorithm Description

We now formally describe the algorithm. Our algorithm maintains the following information.

Service and request pointers. Each request and service will be assigned a pointer that points to some service. This will be specified in more detail later on. We classify services into the following types.

▶ **Definition 4** (Service types). *A service λ is:*

- *a* primary service *if it does not point to any service;*
- *an* upgrade service *if it is triggered initially at level l and the algorithm decided to upgrade it to level $l+1$;*
- *a* tail service *if it is neither a primary nor an upgrade service and no service points to λ;*
- *a* normal service *if it is not one of the above types, i.e. it is not a primary nor an upgrade service and there is a service pointing to it.*

Note that a tail service can become a normal service later on.

Investment counters. The algorithm maintains an investment counter $counter(l,i)$ for level l and each item type i. This counter keeps track of the amount invested into requests of type i since the last level l service containing type i or the beginning of time if there is no such service.

Investment intervals. To decide whether to upgrade service, the algorithm needs to keep track of the investments made by recent normal services. At the end of each service λ that is neither primary nor upgrade, for each eligible request q, the algorithm creates a *investment interval* $[t,\tau]$ on q with cost equal to the amount that λ invested in q. Here, t is the service time of λ. The interval also has a level, which is the level of the service. The details of the investment process and the definition of τ will be specified later.

Our algorithm consists of the following components:

Initialisation. Before any requests arrive, the investment counters $counter(l,i)$ are initialised to 0. When a request q arrives, we set its level to 1, its pointer to NULL.

Serving requests. A level l service λ is triggered when active requests of level at most l accumulate a total of σ_l residual delay. The algorithm then proceeds through the following four steps:

Step 1: Setting service pointer. The *triggering requests* for λ are the active level l requests with positive residual delay. The service pointer of λ will be determined by looking at its triggering requests. If all the triggering requests have a NULL pointer then the service pointer will be NULL. Otherwise, the service pointer will be set to be any of the non-NULL triggering request pointers. As will be shown later (Observation 8), all requests in the triggering requests set with a non-NULL pointer must in fact point to the same service so it does not matter which non-NULL triggering request pointer we choose.

Step 2: Determining the service level. When a level l service λ is triggered, if it is non-primary and not of the highest level n already then it is eligible for a level upgrade. To determine whether to upgrade the service, we use the following notion of witness sets.

▶ **Definition 5** (Witness sets). *Let λ be a level l service and a_q be the earliest arrival time among its eligible requests. The* witness set *of λ is the set W_λ of level l investment intervals that begin after a_q and were created by previous level l normal services. The cost of the witness set W_λ is the total cost of the investment intervals in it and is denoted by $c(W_\lambda)$.*

If $c(W_\lambda) \geq \sigma_{l+1}$, we upgrade λ's level to $l+1$; otherwise, it stays at level l. Note that upgrading the level of a service will not change its triggering requests or pointer but after upgrading, all requests of level $l+1$ will now also be eligible for λ and hence λ's set of eligible requests E_λ may increase. Algorithm 1 gives the pseudocode for Steps 1 and 2.

Step 3: Making the service. Our level l service λ at time t first pays off the residual delay that each eligible request $q \in E_\lambda$ has accumulated up to the service time t. Let $r_q(t_1, t_2)$ denote the residual delay accumulated by request q from times t_1 to t_2 then for each eligible request $q \in E_\lambda$, we pay off all residual delay since their arrival time, that is, $r_q(a_q, t)$.

Then the service begins the investment phase with an investment budget of σ_l where it invests in the future residual delay that the eligible requests accumulate from t. This begins with initializing the following variables: future time $\tau \leftarrow t$, the previous time $t' \leftarrow t$, the set of served requests $Q_\lambda \leftarrow \emptyset$ and the service investment counter to be 0. We then continuously increase τ. Each time τ increases, the residual delay incurred from time t' to τ by each request $q \in E_\lambda \setminus Q_\lambda$ is paid off and invested in. That is, we pay off $r_q(t', \tau)$ for each $q \in E_\lambda \setminus Q_\lambda$. This residual delay $r_q(t', \tau)$ invested in is added to the level l investment counter for q's corresponding item type as well as the service investment counter. We also add this amount to a variable $I_q(\lambda)$ which keeps track of how much λ has invested in the request q and will be used later to construct our investment intervals. If the investment counter for an item type i reaches δ_l then all eligible requests of item type i are added to the set Q_λ to be served and we stop investing in these requests. Finally, we set $t' \leftarrow \tau$ and iteratively continue the process. This process terminates if all eligible requests have been served and added to Q_λ or if the service investment counter equals σ_l which signifies a total of σ_l has been invested in future delay incurred by eligible requests. We note that at the end of this process, all eligible requests will have their delay paid off until time τ and hence can only accumulate residual delay beginning from time τ. To finish the service, we serve the requests in Q_λ, paying a fixed cost of σ_l as well as δ_l for each item type in Q_λ. This process is captured in Algorithm 2.

Note that it is possible for Q_λ to be empty.[1] In this case, we say that λ is an *empty service*. The delay costs paid off by the algorithm remains paid but it does not pay the shared or individual cost.

Step 4: Updating request pointers, levels, investment counters and investment intervals. At the end of the service, all eligible requests for λ left unserved have their pointers set to λ and levels set to l. If λ serves item type i then the level l investment counter for item i is reset to 0. If the service is not a primary or upgrade service then for each request that was eligible for λ, we construct the level l investment interval $[t, \tau]$ for this request with cost $I_q(\lambda)$ which is how much λ invested in the request. Note that all eligible requests for this service will have the same investment interval start and end times but the cost of each interval may differ. Pseudocode for these steps is given at the end of Algorithm 2.

Algorithm 1 Procedure to handle triggering and upgrading services.

Function *OnTrigger(level l)*
- Start a new service λ at current time t;
- `/* determine service pointer using triggering requests */`
- Let E_λ be all eligible requests;
- Let $Q_{trigger} \subseteq E_\lambda$ be those with positive residual delay and level l;
- $pointer(\lambda) \leftarrow pointer(q)$ for an arbitrary request $q \in Q_{trigger}$;
- `/* upgrade the service level if possible */`
- **if** $pointer(\lambda) \neq NULL$ *and* $l \neq n$ **then**
  - Let a_q be the earliest arrival time among requests in E_λ;
  - Let W_λ be the set of investment intervals created by level l normal services and begin after a_q;
  - **if** $\sum_{c \in W_\lambda} cost(c) \geq \sigma_{l+1}$ **then**
    - $l \leftarrow l + 1$;
    - Update E_λ to be the eligible requests for level $l + 1$;
- $level(\lambda) \leftarrow l$;
- **MakeService**(λ, t);

3.3 Analysis

We will bound the costs of the different types of services individually: primary services, normal services, upgrade services and tail services. By noting that every service must fall under one of these categories, this will enable us to bound the total cost of our algorithm. In the following, we abuse notation and use ALG to denote both the algorithm's solution and its cost, and OPT to denote both the optimal solution and its cost.

We first examine the structure and properties of our solution in Section 3.3.1. In particular, we will argue that the directed graph induced by the services and service pointers consist of node-disjoint directed paths and that all non-NULL pointers in a set of triggering requests must be the same.

Next, we look at the structure of our costs in Section 3.3.2. Most importantly, we will introduce the notion of *charged costs* which represent the costs of our services that need to be charged to OPT and show that the charged cost of a level l service is at most $3\sigma_l$.

[1] This can happen, for instance, if there are many eligible requests on many different item types so the service investment counter reaches σ_l before any of the $counter(l, i)$ reaches δ_l.

Algorithm 2 Procedure to handle serving requests and updating information post-service.

Function *MakeService(service λ, service time t)*
  `/* pay off all residual delay on eligible requests */`
  foreach $q \in E_\lambda$ **do**
    Pay off the residual delay $r_q(a_q, t)$;
    `/* set up counter to track how much` λ `invests in each request */`
    $I_q(\lambda) \leftarrow 0$;
  `/* Investment Phase */`
  $l \leftarrow level(\lambda)$; $\tau \leftarrow t$; $t' \leftarrow t$; $Q_\lambda \leftarrow \emptyset$; $invested \leftarrow 0$;
  Let $E_{\lambda,i}$ be the set of eligible requests of item type i;
  while $Q_\lambda \neq E_\lambda$ *and* $invested < \sigma_l$ **do**
    Continuously increment τ until either $invested + \sum_{q \in E_\lambda \setminus Q_\lambda} r_q(t', \tau) = \sigma_l$, or for some type i not in Q_λ, $counter(l, i) + \sum_{q \in E_{\lambda,i} \setminus Q_\lambda} r_q(t', \tau) = \delta_l$;
    `/* Update investment counters and` t' `*/`
    $invested \leftarrow invested + \sum_{q \in E_\lambda \setminus Q_\lambda} r_q(t', \tau)$;
    foreach *item type* i **do**
      $counter(l, i) \leftarrow counter(l, i) + \sum_{q \in E_{\lambda,i} \setminus Q_\lambda} r_q(t', \tau)$;
    foreach $q \in E_\lambda \setminus Q_\lambda$ **do**
      $I_q(\lambda) \leftarrow I_q(\lambda) + r_q(t', \tau)$;
      Pay off the residual delay $r_q(t', \tau)$;
    $t' \leftarrow \tau$;
    if *for some type* i *not in* Q_λ, $counter(l, i) = \delta_l$ **then**
      $Q_\lambda \leftarrow Q_\lambda \cup E_{\lambda,i}$;
      $counter(l, i) \leftarrow 0$;
  Serve Q_λ;
  `/* update pointers and levels of unserved eligible requests */`
  foreach $q \in E_\lambda \setminus Q_\lambda$ **do**
    $level(q) \leftarrow l$ and $pointer(q) \leftarrow \lambda$;
  `/* construct investment intervals */`
  if λ *is not a primary or upgrade service* **then**
    foreach $q \in E_\lambda$ **do**
      Construct a level l investment interval $[t, \tau]$ on q with cost $I_q(\lambda)$;

Section 3.3.3 will then begin our charging argument by showing that the charged cost of all services can be bounded by the charged costs of the primary and normal services. This is done by bounding the charged cost of the tail services by the charged cost of the primary and upgrade services and then charging the charged cost of the upgrade services to the charged cost of the normal services.

Finally, we finish our charging argument in Section 3.3.4 by charging the charged costs of the primary and normal services to OPT. This is the crux of our analysis. The charged cost of primary services is charged to OPT using a disjointness argument. The charged cost of the normal services is charged to the cost of our investment intervals. These investment intervals' costs are then charged to OPT by showing that for any service λ^* made by OPT and any request q served in λ^*, the total cost of q's investment intervals can be charged to the costs of λ^*.

To simplify our analysis, we assume that at most one service can be triggered at any given time. This is without loss of generality since the delay functions can be perturbed by an infinitesimal amount to ensure this holds.

3.3.1 Analysis: Solution Structure

We begin our analysis by proving properties of ALG's solution structure.

▶ **Observation 6.** ALG *serves all requests eventually. Moreover, when a request q is served at time t, the algorithm would have paid off its delay up till at least time t by the end of the service.*

Proof. We first argue that ALG serves all requests. This is because the delay on each request tends to infinity with time so each request will eventually accumulate enough delay to trigger a service and then have enough invested to trigger the service of the requests. This is because as the delay tends to infinity, ALG will never reach a scenario where it stops making services or stops investing in requests. The second part of the observation follows from the fact it was eligible for the service it was served in, and the service would have ensured that the delay of q up till time t has been paid off entirely. ◀

The following lemma implies that service pointers belonging to services of the same level are, in a sense, non-overlapping.

▶ **Lemma 7.** *Suppose a service λ' points to another service λ and their service times are $t' > t$, respectively. Let l be the level of λ. Then, there cannot be a service of level at least l made between t and t'.*

Proof. Suppose, towards a contradiction, that there is a level l service λ_0 made between t and t'. By definition of pointers, there exists a triggering request q for λ' that pointed to λ at the start of the service λ'; moreover, q is active and has level l between t and t'. Thus, q is eligible for λ_0. Since λ_0 did not serve q, it must have overwritten q's pointer and so q would not have pointed to λ at the start of λ', a contradiction. ◀

▶ **Observation 8.** *A service's set of triggering requests must be non-empty and all the triggering requests with a non-NULL pointer must have the same pointer.*

Proof. Consider any level l service λ. We first observe that the set of triggering requests must be non-empty. If this was not the case, then by definition there is no level l eligible request with positive residual delay when λ is triggered. Hence, all the requests whose residual delay contributed to triggering λ would have a level less than l and since $\sigma_{l-1} < \sigma_l$, a lower level service should have been triggered instead. Therefore, λ should never have been triggered in the first place.

Next we show that all triggering requests with a non-NULL pointer must point to the same service. Let q_1 be the triggering request whose pointer λ_1 was used as the service pointer for λ and let q_2 be another triggering request with pointer λ_2. Since q_1 and q_2 are level l requests, they must point to level l services. Moreover, the pointer of q_2 must have been set after λ_1 but before λ since otherwise it would have been eligible for λ_1 and been changed. Then, Lemma 7 implies that λ_2 must in fact be λ_1. ◀

From Observation 8, we know that a service pointer will always be uniquely defined and not dependent on which triggering request was chosen to determine the pointer as alluded to in the algorithm description. Next, we show that the directed graph induced by the services and service pointers consist of node-disjoint directed paths, which we call *service chains*.

▶ **Lemma 9.** *Every service can only point to at most one other service and be pointed at by at most one other service.*

Proof. By construction, a service pointer can only be one other service and hence every service can only point to at most one other service. Now we will argue that two services cannot point to the same service λ' of level l. Suppose there are two services λ_1 and λ_2 that point at λ'. By construction of service pointers, λ_1 and λ_2 must have been level l when they were triggered. By Lemma 7, we get that λ_1 and λ_2 must be the same service. Thus, each service can be pointed to by at most one other service. ◀

The following lemma implies that at any time, only the last service of a level can become normal in the future, all previous services of the level that are tail must remain tail. This ensures that our witness sets will not exclude any investment intervals that belong to tail services that later become normal services which is required later to prove Lemma 24.

▶ **Lemma 10.** *Let λ_1 and λ_2 be two level l services with service times $t_1 < t_2$, respectively. If λ_1 is tail at time t_2, then it will stay a tail service at all future times $t > t_2$.*

Proof. Suppose, towards a contradiction, that λ_1 became normal later on. Then, at some time $t_3 > t_2$, a level l service λ_3 was triggered and λ_3 pointed to λ_1. However, this contradicts Lemma 7 so λ_1 must stay a tail. ◀

3.3.2 Analysis: Cost Structure

We now analyse the properties of different costs incurred by our algorithm.

▶ **Definition 11** (Triggering, investment and charged costs). *For each level l service λ, we define the following three costs: (1) its* triggering delay cost *which is the residual delay on all eligible requests that is paid off at the beginning of the service; (2) its* investment cost *which are the delay costs invested in during the λ's investment phase; (3) its* charged cost *which is its shared cost plus its triggering delay cost plus its investment cost.*

Note that the algorithm may make an "empty service" in which no requests are served, in which case its charged cost is its triggering delay cost and its investment cost. We will first show that in order to bound the cost of ALG, it suffices to look at the charged costs.

▶ **Lemma 12.** *The total cost of* ALG *is at most twice the total charged cost of its services.*

Proof. The total cost of ALG is the total shared cost of its services plus the total individual cost of its services plus its delay cost. It suffices to bound the latter two costs in terms of total investment and triggering delay costs. A level l service only serves an item type i when the level l investment counter for i reaches δ_l and the counter is reset to 0 when it reaches δ_l. So, the total individual cost is at most the total investment cost. Observation 6 implies that the delay cost of ALG is at most the triggering delay cost plus investment cost. Putting the above bounds together gives the lemma. ◀

Next, we will bound the charged cost of any service which will later allow us to charge these costs to OPT.

▶ **Observation 13.** *The triggering delay costs incurred by a level l service is at most σ_l.*

Proof. Let λ be a level l service made by ALG. If λ is not an upgrade service, then its triggering delay cost is exactly σ_l, by construction. On the other hand, if λ is an upgrade service, then it was triggered because the active requests of level at most $l-1$ had a residual delay of σ_{l-1} but then its level was upgraded and its pool of eligible requests increased to include the level l requests. However, the fact that a level l service was not triggered at this time implies that the active requests of level at most l must have a residual delay less than σ_l. Therefore, in either case, the triggering delay is at most σ_l as required. ◀

▶ **Lemma 14.** *The charged cost of a level l service is at most $3\sigma_l$.*

Proof. The charged cost of a level l service as defined earlier is comprised of the triggering delay cost, the shared cost and the investment cost. By Observation 13, the triggering delay cost is at most σ_l. The shared cost is either σ_l or 0 in the case that no requests are served and hence the shared cost does not need to be paid. Lastly, by construction of the algorithm, the investment cost of the service is at most σ_l. Adding these three components up, the total charged cost is at most $3\sigma_l$ as required. ◀

The following lemma bounds the investment cost of normal services which will be used later to charge the costs of the normal services to OPT.

▶ **Lemma 15.** *Every normal service of level l has investment cost σ_l.*

Proof. The investment cost of a level l normal service λ is exactly σ_l. This is because by construction, the investment cost of a level l service is at most σ_l and can only be less if λ served all eligible requests. However, that would mean that λ is a tail service since there are no unserved requests pointing to it. ◀

3.3.3 Analysis: Bounding charged costs

We now begin our charging argument by showing that the charged costs of ALG can be bounded by the charged costs of the primary and normal services.

▶ **Lemma 16.** *The total charged costs of the tail services are at most 3 times the total charged costs of the primary and upgrade services.*

Proof. Consider any tail service λ of level l. By definition, it ends a chain that has reached level l and so the chain has an earlier service λ' that is a level l upgrade service or a primary service, in the case that $l = 1$. The service λ' has an investment cost of exactly σ_l as otherwise the service would have served all eligible requests and the chain would have ended already. Therefore, λ' has a charged cost of at least σ_l. By Lemma 14, λ's charged cost is at most 3 times that of λ'. Lastly, Lemma 9 implies that each primary or upgrade service is charged by at most one tail service. Summing up across all tail services, we get that their charged costs are at most 3 times the charged costs of the primary and upgrade services. ◀

We now bound the charged cost of the upgrade services by the charged cost of the normal services. In order to do so, we first show that the witness sets of our upgrade services must be pairwise disjoint.

▶ **Lemma 17.** *An investment interval cannot belong to the witness set of more than one upgrade service.*

Proof. Suppose towards a contradiction that there is a request q_c whose level l investment interval $[t, \tau]$ belongs to the witness sets of two upgrade services. Let the two level $l+1$ upgrade services be λ_1 and λ_2 with service times $t_1 < t_2$.

By construction, the interval $[t, \tau]$ was created by a service at time t. Since it belongs to the witness set of λ_1, it must have been created before t_1, and thus, $t < t_1$. Now consider λ_2. In order for $[t, \tau]$ to belong to its witness set, λ_2 must have an eligible request q_2 that arrived before t. The fact that q_2 is eligible for λ_2 at time t_2 implies that it is at most level l and active for all times prior to t_2. Moreover, the fact that q_2 arrives before t implies that it also arrives before $t_1 > t$. Therefore, at time t_1, q_2 has arrived, is active and of level at most l which makes it eligible for λ_1. After λ_1, q_2 would have its level set to $l+1$ and hence it would no longer be eligible for λ_2 when λ_2 is initially triggered (prior to upgrading). This contradicts the fact that q_2 is eligible for λ_2. See Figure 1 for an illustration of this proof. ◀

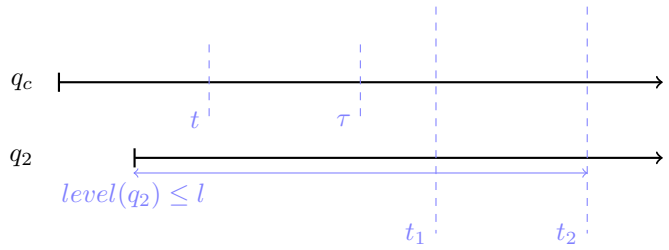

Figure 1 Illustration of the proof of Lemma 17.

▶ **Lemma 18.** *The total charged costs of the upgrade services is at most 3 times the total charged costs of the normal services.*

Proof. Let λ be a level l upgrade service at time t. By construction, the cost of its witness set W_λ is at least σ_l. By Lemma 14, λ has a charged cost of at most $3\sigma_l \leq 3cost(W_\lambda)$. Using Lemma 17, we get that the total charged costs of upgrade services is at most 3 times the total investment costs made by normal services. Since the investment costs of the normal services are at most the charged costs of the normal services, the lemma follows. ◀

3.3.4 Analysis: Charging to OPT

Having bounded the cost of ALG by the charged costs of the primary and normal services, it remains to charge these costs to OPT.

▶ **Lemma 19.** *The charged cost of the primary services is at most* 3 OPT.

Proof. Let Λ_1 be the set of primary services made by ALG. For each primary service $\lambda \in \Lambda_1$, let I_λ denote the interval $[a_\lambda, t_\lambda]$ where a_λ is the earliest arrival time among λ's triggering requests and t_λ is the service time of λ. By definition of primary services, the set of intervals $\mathcal{I} = \{I_\lambda\}_{\lambda \in \Lambda_1}$ are pairwise disjoint.

Consider an interval $I_\lambda \in \mathcal{I}$. If OPT made a service λ^* during I_λ, the shared cost of λ^* is at least σ_1. On the other hand, if OPT did not make a service during I_λ, then it must have incurred a total delay of at least σ_1 on the triggering requests of λ since they arrive no earlier than the start of I_λ. In both cases, OPT pays a cost of at least σ_1 during the interval I_λ.

Since the intervals $\mathcal{I}$ are disjoint, we have that OPT $\geq \sigma_1|\mathcal{I}|$. Thus, by Lemma 14, the charged cost of primary services is at most $3\sigma_1|\mathcal{I}| \leq 3$ OPT. ◀

▶ **Lemma 20.** *The charged cost of a normal service is at most 3 times its investment cost.*

Proof. This follows from Lemmas 15 and 14. ◀

Using Lemma 20, the charged cost of any normal service is at most 3 times its investment cost. Hence, to bound the charged costs of all normal services, it suffices to only look at the investment costs incurred by the normal services which, by definition is equal to the cost of the investment intervals made by normal services. Hence, we will show that the cost of every investment interval made by a normal service can be charged to some distinct cost incurred by OPT.

We will refer to investment intervals created by normal services as *normal investment intervals* and will now analyse the properties of these intervals.

▶ **Lemma 21.** *Let $[t, \tau]$ be a level l normal investment interval created by the normal service λ at time t. Then there cannot be a level $l' \geq l$ service triggered between times t and τ (inclusive) other than λ.*

Proof. Since λ is a normal service, there exists a later service λ_s at time t_s pointing to λ. Thus, there is a request q that is eligible for λ but is left unserved and later became a triggering request for λ_s. By definition of pointers and triggering requests, at time t_s, q points to λ and has positive residual delay. Since λ paid off the residual delay on eligible requests (which includes triggering requests) until time τ, λ_s occurred at time $t_s > \tau$.

Now we show that after t and before t_s, q is level l and there is no service for which q is eligible. Since q points to λ at time t_s, there cannot be a service between t (the service time of λ) and t_s for which q is eligible; otherwise, that service would have changed q's pointer and q would no longer be pointing to λ at time t_s. Thus, the level of q between times t and $\tau < t_s$ is l, the level of λ, and so there is no service of level at least l between t and τ. ◀

▶ **Lemma 22.** *For any request, its normal investment intervals are all disjoint.*

Proof. Assume towards a contradiction there is a request q with two non-disjoint normal investment intervals $[t_1, \tau_1]$ of level l_1 and $[t_2, \tau_2]$ of level l_2 where wlog $t_1 < t_2 < \tau_1$. We first notice that $l_2 \geq l_1$ since the level of a request can never decrease so after the service at time t_1, q is of level at least l_1. By Lemma 21, there is no service of level at least l_1 between times t_1 and τ_1 which contradicts our assumption. ◀

▶ **Lemma 23.** *Consider any two level l normal investment intervals that intersect. They must be created by the same level l normal service.*

Proof. Suppose this was not the case and that we have two intersecting level l investment intervals $[t_1, \tau_1]$, $[t_2, \tau_2]$ created by distinct normal services where wlog $t_1 \leq t_2 \leq \tau_1$. This would imply that we have a level l normal service at time t_1 and another normal level l service at time $t_2 \geq t_1$. However, Lemma 21 implies that there cannot be another level l service between times t_1 and τ_1 inclusive and hence the service at time t_2 should not have occurred, a contradiction. ◀

We now charge the cost of our normal investment intervals to OPT which will be the crux of our analysis. For this lemma, we will refer to "normal investment intervals" simply as "investment intervals" unless otherwise specified. The full proof of the lemma can be found in the Appendix.

▶ **Lemma 24.** *The total cost of normal investment intervals is at most* $6\,\mathrm{OPT}$.

Proof sketch. Consider a service λ^* made by OPT at level l^* and time t^* and let the set of requests served by λ^* be Q_{λ^*}.

For any request $q \in Q_{\lambda^*}$ we will first consider its investment intervals ending before t^*. These investment intervals ending before time t^* correspond to delay costs incurred prior to time t^* that had been invested in by a normal service and is hence at most the total delay accrued by the request up till time t^*. Since OPT pays the delay for the request q up till time t^*, the cost of the investment intervals ending before time t^* can be charged to the delay costs paid by OPT.

Next we consider the investment intervals belonging to requests in Q_{λ^*} that contain time t^*. There are two cases to consider: the intervals of level $l < l^*$ and the intervals of level $l \geq l^*$. For the intervals of a fixed level $l < l^*$ that intersect with time t^* we know by Lemma 23 that they must have all been created by the same normal service. Since a normal service can only invest a maximum amount of σ_l, the total cost of these intervals of level l must be at most σ_l. Summing up across all levels $l < l^*$ and noting that our σ values form a geometric series, we conclude that the cost of all the intervals with level $l < l^*$ is at most σ_{l^*} which is the shared cost that OPT must pay in serving λ^*. For the intervals of a fixed level $l \geq l^*$ we will consider a fixed item type i. Once again, by Lemma 23, these intervals must have been created by the same normal service and since a normal service can only invest at most δ_l in a particular item type before serving it, the total cost of the intervals at level l and for item i requests is at most δ_l. Summing up across all levels $l \geq l^*$ and noting that our δ values form a geometric series, we conclude that the cost of all item i intervals of level $l \geq l^*$ is at most $2\delta^*$ which is 2 times the individual cost paid by λ^* to serve the item type i. This argument applies to all item types served by λ^*.

Lastly, we consider the investment intervals belonging to requests in Q_{λ^*} that begin after time t^*. Once again we consider two cases: the intervals of level $l < l^*$ and the intervals of level $l \geq l^*$. For the intervals of level $l < l^*$, we consider a fixed level l and look at the latest starting interval at time t. There must have been a normal service at time t that created this interval and this implies that the witness set of this normal service cost less than σ_{l+1} since it was a normal service as opposed to an upgrade service. Since all requests in Q_{λ^*} must arrive before t^*, the witness set of the service at time t is a superset of the intervals of level l beginning after time t^*. Moreover, the intervals created by the service at time t must cost at most σ_l since the service can only invest at most σ_l. Overall, the intervals of level l that begin after time t^* cost at most $\sigma_{l+1} + \sigma_l < 2\sigma_{l+1}$. Summing up over all levels $l < l^*$ and using the geometric property of σ, we get a total investment interval cost of $4\sigma_l^*$ which is 4 times the shared cost paid by λ^*. For the intervals of level $l \geq l^*$ we once again fix a level $l \geq l^*$ and item type i. The cost of each of these item i, level l intervals must be added to the same investment counter without the counter being reset to 0. This is because all requests in Q_{λ^*} arrive before t^*, so if at any time after t^*, the level l investment counter for item i is reset to 0, all requests on item i and of level at most l must have been served and thus there is no way for a level l intervals to contribute to an investment counter after it has been reset. Since the investment counter by design has a maximum value of δ_l, this implies that the total cost of the level l, item i investment intervals is at most δ_l. Fixing the item i, summing up across all levels $l \geq l^*$ and utilising the geometric property of δ, we get that the investment intervals of item i and of level $l \geq l^*$ cost at most $2\delta_{l^*}$ which is 2 times what λ^* pays for the item i. We can once again apply this argument for all item types i served by λ^*.

Hence, it follows that for any service λ^*, the cost of the investment intervals in Q_{λ^*} can be charged to the cost of λ^* and by applying this argument across all services made by OPT, the lemma follows. ◀

▶ **Lemma 25.** *The charged cost of the normal services is at most* 18 OPT.

Proof. This follows from Lemmas 20 and 24. ◀

We conclude by combining the above ingredients to show that the algorithm is constant-competitive.Let P, U, T, N denote the charged service costs of primary services, upgrade services, tail services and normal services, respectively. Using Lemma 12 and the fact that the total charged service cost is $P + U + T + N$, we get

$$\begin{aligned}
\text{ALG} &\leq 2(P + U + T + N) \\
&\leq 2(4P + 4U + N) && \text{(Lemma 16)} \\
&\leq 2(4P + 13N) && \text{(Lemma 18)} \\
&\leq 24\,\text{OPT} + 26N && \text{(Lemma 19)} \\
&\leq 492\,\text{OPT} && \text{(Lemma 25)}
\end{aligned}$$

Hence, we get that $\text{ALG} \leq O(1) \times \text{OPT}$ as desired.

Abstract

We introduce a notion of *generic local algorithm*, which strictly generalizes existing frameworks of local algorithms such as *factors of i.i.d.* by capturing local *quantum* algorithms such as the Quantum Approximate Optimization Algorithm (QAOA).

Motivated by a question of Farhi et al. [arXiv:1910.08187, 2019], we then show limitations of generic local algorithms including QAOA on random instances of constraint satisfaction problems (CSPs). Specifically, we show that any generic local algorithm whose assignment to a vertex depends only on a local neighborhood with $o(n)$ other vertices (such as the QAOA at depth less than $\varepsilon \log(n)$) cannot arbitrarily-well approximate boolean CSPs if the problem satisfies a geometric property from statistical physics called the coupled overlap-gap property (OGP) [Chen et al., Annals of Probability, 47(3), 2019]. We show that the random MAX-k-XOR problem has this property when $k \geq 4$ is even by extending the corresponding result for diluted k-spin glasses.

Our concentration lemmas confirm a conjecture of Brandao et al. [arXiv:1812.04170, 2018] asserting that the landscape independence of QAOA extends to logarithmic depth – in other words, for every fixed choice of QAOA angle parameters, the algorithm at logarithmic depth performs almost equally well on almost all instances. One of these lemmas is a strengthening of McDiarmid's inequality, applicable when the random variables have a highly biased distribution, and may be of independent interest.

1 Introduction

Recent developments [3, 26, 16] of noisy intermediate-scale quantum (NISQ) devices [40] have brought us to the door of near-term quantum computation. As experimentalists can now build programmable quantum simulators up to 256 qubits [16], this motivates an important theoretical question: what computational advantage can such a NISQ device provide?

One of the constraints of NISQ devices is the inability to create high-fidelity global entanglement. This motivates the study of the power of quantum algorithms that are *local*. A leading candidate in this regime of quantum algorithms is the *Quantum Approximate Optimization Algorithm (QAOA)* [19] at shallow depths. While there have been some recent results [29, 5, 33] that formally examine the QAOA algorithm at depth $p = 1$ or 2, very few results exist for super-constant depth QAOA [17, 18].

Given the imminent quest of demonstrating quantum computational advantage, it is important to clarify for what optimization problems can near-term quantum algorithms (such as *local* quantum algorithms) reliably be expected to demonstrate computational advantage.

We show that local *quantum* algorithms, a large natural class of NISQ algorithms, are obstructed by a geometric property of the solution space known as the *coupled Overlap-Gap Property* [10]. We conjecture that this property is satisfied by most CSPs (Conjecture 5.1). Specific problems known to have this property include the diluted k-spin glass Hamiltonian (equivalent to a max-cut problem on random k-hypergraphs) [10], independent set on random graphs [17], planted clique [25], and many other problems that so far seem to elude efficient algorithms and be algorithmically hard [22]. In this manuscript, we also demonstrate that the random Max-k-XOR problem has this property (see subsection 2.4).

Our results lift the continuous coupled interpolation techniques of Chen et al. [10] to the generic quantum-inclusive setting, with stronger and more general concentration of measure statements about local quantum algorithms, extending the techniques of Farhi et al. [17].

Critical to our approach is a new definition of local algorithms we term *generic local algorithms* (See subsection 2.1). Previous work relating statistical-physics-derived OGPs to local algorithms leveraged the *factors of i.i.d.* framework for local algorithms, which fails to contain local quantum algorithms, as we demonstrate in Proposition 2.3. Our definition of *generic local algorithms* subsumes local quantum and classical algorithms (see Proposition 2.3 and Proposition 4.3) but still satisfies strong concentration properties (see Theorems 5.3 and 5.4 in the full version), allowing techniques for local classical algorithms [10] to apply to the quantum case. Two of our core technical contributions involve showing that the random MAX-k-XOR problem has a coupled Overlap Gap Property (see subsection 2.4) by extending the techniques of Chen et al. [10] and deriving a strengthened version of McDiarmid's inequality for highly-biased random variables using a martingale argument (see Lemma 2.7).

The rest of the paper is organized as follows: In subsection 1.1 we introduce the relevant spin glass literature, defining the notion of a diluted k-spin glass; in subsection 1.2 we introduce the relevant prior work; in subsection 1.3 we state our main theorems (informally); in subsection 1.4 we briefly explain the architecture of our proof and compare our techniques with those of Chen et al. [10] and Farhi et al. [17]; in subsection 1.5 we introduce the necessary mathematical preliminaries and notation, including the models of CSPs we work with and a rigorous defintion of local classical algorithms; in section 2 we state our separation of different

families of local algorithms and our main concentration lemmas; in section 5 we conclude by summarizing our results and mentioning many natural open problems closely related to and/or motivated by our work. Complete proofs and technical details are delegated to the appendices.

1.1 Diluted k-spin glasses, maximum cuts of sparse hypergraphs, and Max-k-XOR

Spin glass theory is a central theoretical framework in statistical physics. The Sherrington-Kirkpatrick model (SK model) [43] is one of the most well studied mathematical models in the theory and consists of two variables: spins $\{\sigma_i\}_{i\in[n]}$ and interactions $\{J_{i,j}\}_{i,j\in[n]}$. A spin σ_i takes values in $\{\pm 1\}$ and the interaction $J_{i,j}$ between two spins σ_i, σ_j is a real-valued variable that captures whether the physical system prefers the two spins to be the same ($J_{i,j} > 0$) or different ($J_{i,j} < 0$). The goal is to understand what spin configurations $\sigma \in \{-1, 1\}^n$ maximize the following quantity (a.k.a. Hamiltonian):

$$H(\sigma) = \sum_{i,j} J_{i,j}\sigma_i\sigma_j \,.$$

The setting is easily generalized to higher order interactions, i.e., $J_{i_1,\ldots,i_k}$ acting on k spins, and this is known as the k-spin model. See [35] for a comprehensive survey.

There is a natural correspondence between spin glass theory and combinatorial optimization problems. In a combinatorial optimization problem (e.g., MAX-CUT), a variable corresponds to a spin and a constraint corresponds to an interaction. Through this correspondence, the maximization of the above Hamiltonian $H(\sigma)$ serves as a proxy for maximizing the number of satisfied constraints in the combinatorial optimization problem.

A spin glass model additionally specifies a particular distribution on the interactions $\{J_{i,j}\}$ for all $i, j \in [n]$. The quantity of interest is the asymptotic maximum value

$$H^* := \lim_{n\to\infty} \frac{1}{n} \max_{\sigma} H(\sigma)\,,$$

(a.k.a. the ground state energy density), as well as spin configurations σ with $H(\sigma) \approx H^*$. There are many well-studied spin glass models in physics and various mathematical insights about these have been discovered over the years [12, 14, 42, 37]. For example, for the SK model [43], Parisi [38] proposed the infamous *Parisi Variational Principle* to capture the exact value of H^*. This was later rigorously proved by Talagrand [44] and again by Panchenko [36] in greater generality. These successes give hope to design local algorithms that simulate the physical system and output a final configuration as an approximation to the corresponding combinatorial optimization problem.

While traditional spin glass models consider the underlying non-trivial interactions as either lying on a certain physically-realistic graph (e.g., the non-zero $J_{i,j}$ form a 2D-grid) or being a *mean field approximation* (for example, where every $J_{i,j}$ is non-trivial), the applications in combinatorial optimization often require the underlying constraint graphs to be sparse and arbitrary. We use two methods of bridging the gap between the two settings:

- By studying the *diluted k-spin glass model* where one first samples a sparse hypergraph and then assigns non-trivial interactions on top of its hyperedges. Intuitively, approximating the H^* of the diluted k-spin glass corresponds to approximating the maximum cut over random sparse hypergraphs. This correspondence is made more precise in Definition 1.5.

- Using the techniques of *Gaussian interpolation* [27] and *Poisson interpolation* [21, 10] from statistical physics to relate the behavior of random dense spin glass models to random sparse CSPs. More specifically, we relate the random Max-k-XOR problem to mean-field p-spin glasses (Section 8 in the full version) by modifying the Guerra-Tonnineli interpolation used in Chen et al. [10].

Table 1 A dictionary between spin glass models and combinatorial optimization problems.

Spin glass models	Combinatorial optimization problems
Spins $\sigma \in \{-1,1\}^n$	An assignment to boolean variables
Interactions $\{J_{i_1,\ldots,i_k}\}_{i_1,\ldots,i_k\in[n]}$	Constraints (i.e., hyperedges)
Hamiltonian $H(\sigma)$	Value of an assignment (i.e., $\mathsf{val}_\Psi(\sigma)$)
Ground state energy H^*	Optimal value (i.e., val_Ψ)
Mean field model (e.g., SK model)	The underlying hypergraph *not* being a lattice
Diluted spin glass model	The underlying hypergraph being sparse

1.2 Prior Work

1.2.1 Constraint-satisfaction problems & hardness for classical algorithms

CSPs (described formally in Definition 1.4) are a natural class of combinatorial optimization problems that have been studied extensively in theoretical computer science [7, 32]. Many NP-Complete problems such as k-SAT, k-NAE-SAT, MAX-CUT and k-XOR, can be framed as CSPs. Consequently, unless $\mathcal{P} = \mathcal{NP}$, finding optimal solutions to these problems is infeasible. A natural question then is to understand how well can approximate answers to instances of these problems be constructed by efficient algorithms. Under the now widely believed *Unique Games Conjecture* [31], upper bounds on the approximability of CSPs are known [30, 41]. These bounds, however, are only worst-case and do not necessarily explicitly demonstrate a family of instances of a CSP that are hard to approximate. Additionally, they remain conditional on a positive resolution to the Unique Games Conjecture, which is still a difficult open problem in the field. In the average-case regime, the goal is to ask how well a *typical* instance of a CSP can be approximated, where the instance is chosen from a "natural" distribution over the set of instances. Perhaps surprisingly, great insight has been drawn about the algorithmic hardness (or lack thereof) about random instances of many CSPs based on work originating in the Statistical Physics community, particularly in Spin Glass Theory [34, 21, 39]. This was so because the problem of finding spin configurations of particles in many spin glass models that put a system in the ground state could naturally be interpreted as a CSP. Various iterative algorithms were proposed to study the problem of explicitly finding near-ground states of *typical* instances of various spin glass models [46, 9]. It was observed that these algorithms either consistently got better with the number of iterations, or hit a threshold which they could not exceed. To understand this, the work of Achlioptas et al. [1] studied the solution geometry of the k-SAT problem and found that most good solutions were in well separated clusters. Additionally, most variables in a good solution could only take a single value (i.e., they were "frozen"). This observation was stated as an intuitive reason for the failure of local algorithms on random instances of k-SAT. Gamarnik et al. [24] made this more formal and precise by showing that *no* classical local algorithm (described formally as *factors of i.i.d.*, see Definition 1.10) could approximate the

MAX-IND-SET problem arbitrarily well on sparse random graphs. Critical to their argument was the fact that *all* (not *most*) nearly-optimal solutions to the problem satisfied the *Overlap Gap Property* - they were in well separated clusters. In various works that followed up, many problems have been shown to have near-optimal solutions conform to this solution geometry and algorithmic hardness for various families of classical algorithms has been established [10, 23, 22].

1.2.2 The Overlap Gap Property & QAOA

A depth-p $QAOA$ algorithm, abbreviated as QAOA_p, applies a length-p sequence of unitaries to each hyperedge and outputs the measurement result of the final state. The goal of $QAOA$ is to approximate the optimal solutions on average-case (i.e., random) instances. For example, the work of Farhi et al. [19] showed that $QAOA_1$ achieved 0.6924-approximation for MAX-CUT on triangle-free 3-regular graphs while such an approximation ratio was not then known to be achievable by local classical algorithms.

Shortly after $QAOA_p$ (defined formally in Definition 2.2) was proposed as a way to solve hard optimization problems and possibly establish quantum computational advantage for MAX-CUT on 3-regular graphs [19], a local classical algorithm was designed that would outperform $QAOA_p$ on these graphs at depth 1 [29]. Consequently, because of a flurry of follow up results, QAOA has been shown to be outmatched by local classical algorithms up to depth 2 [33, 5] for the MAX-CUT problem on d-regular graphs with large girth. In fact, under the widely-believed conjecture in the Spin-Glass Theory community that the SK model does not satisfy the *Overlap Gap Property* [4], an AMP algorithm was recently proposed that outputs arbitrarily good cuts for large (but constant) degree random regular graphs [2]. To analyze the performance of $QAOA_p$ on a problem that possesses an OGP, Farhi et al. [17] was established that $QAOA_p$ with depth $p \leq \varepsilon \log(n)$ could not output independent sets of size better than .854 times the optimal for sparse random graphs. This work suggested that the OGP may broadly prove to be an obstacle for $QAOA_p$ while it is local as much as it does for various classical algorithms. However, MAX-IND-SET is not a (maximum) CSP and, additionally, the prior work [17] does not give an analysis that generalizes to CSPs. Our work establishes this generalization (see Theorem 1.1) and also immediately positively resolves the "landscape independence" conjecture of $QAOA_{\varepsilon \log(n)}$ (see Theorem 1.3) proposed by Brandao et al. [8]. This immediately suggests that quantum advantage is unlikely to be found up to this depth for CSPs with an OGP, and we conjecture that *almost all* CSPs will have an OGP (see subsection 5.1).

1.3 Our results

Our main result establishes that *any* local quantum algorithm, including $QAOA_p$ with $p \leq \varepsilon \log(n)$, is obstructed from arbitrarily approximating *any* CSP that satisfies a "coupled" *Overlap Gap Property* (described in subsubsection 1.5.3). The precise family of CSPs we will work over will be notated as (k, d)-$\mathsf{CSP}(f)$, where k denotes the number of variables in a single clause, d denotes the average number of clauses any variable appears in, and f denotes the predicate applied to each clause. For a formal definition, refer to Definition 1.4. We state the informal version of our results, the formal versions of which may be found in Theorems 4.2 and 4.3 in the full version of this paper.

▶ **Theorem 1.1** (Obstruction to $QAOA_p$ given coupled OGP, informal)**.** *Given a uniformly random instance Ψ of a (k,d)-CSP(f) that satisfies a coupled OGP, with high probability a depth-p $QAOA_p$ circuit with*

$$p \leq \frac{\log(n)}{2\log(d(k-1)/\ln(2))} - 1$$

cannot output a solution that is better than a $(1-\varepsilon_0)$-approximation for some $\varepsilon_0 > 0$.

In particular, this immediately implies an obstruction for approximating maximum cuts of random sparse hypergraphs, as a coupled OGP is known to exist for that problem [10]. Furthermore, though the obstruction in Theorem 1.1 is stated for $QAOA_p$, it will apply to any generic local algorithm, and will, therefore, also apply to any local quantum algorithm. This is stated more precisely in Theorem 2.8.

▶ **Theorem 1.2** (Obstruction to generic local algorithms on random Max-k-XOR, informal)**.** *For every even $k \geq 4$, there exists $d_0 \in \mathbb{N}$ and the following holds. There exists $\varepsilon_0 > 0$ such that if $QAOA_p$ outputs a solution $\sigma \in \{-1,1\}^n$ with $H(\sigma)$ being $(1-\varepsilon_0)$-close to the H^* of a random* Max-k-XOR *instance of average degree $d \geq d_0$ with probability at least* 0.99*, then $p = \Omega(\log n)$.*

This is stated formally in Corollary 4.4 in the full version, and answers a question of Farhi et al. [20], where the authors ask if $QAOA_p$ would perform well on k-spin generalizations of the SK model, citing Max-k-XOR in particular [10]. The above result is immediately implied by a proof of a coupled Overlap-Gap Property for the Max-k-XOR problem, stated in Lemma 2.9 and proved in Section 8 in the full version.

To prove Theorem 1.1, two key lemmas about the concentration of output of local quantum algorithms need to be proved (Theorems 5.3 and 5.4 in the full version). A corollary to these two lemmas is that the quality of solution output by $QAOA_p$ (with p as stated in Theorem 1.1) concentrates heavily around the expected value. More specifically, if we let $\mathsf{val}_\Psi(\sigma)$ denote the number of clauses of Ψ satisfied by an assignment $\sigma \in \{\pm 1\}^n$ to the variables, then this value has small deviation on almost all instances.

▶ **Theorem 1.3** (Landscape-independence of $QAOA_{\varepsilon\log(n)}$, informal)**.** *Given a random instance Ψ of a (k,d)-CSP(f) and a $QAOA_p$ circuit with depth p as stated in Theorem 1.1, the solution σ output by $QAOA_p$ with value $\mathsf{val}_\Psi(\sigma)$ concentrates as,*

$$\Pr\left[\left|\mathsf{val}_\Psi(\sigma) - \mathbb{E}[\mathsf{val}_\Psi(\sigma)]\right| \geq \delta n\right] \leq e^{O(n^\gamma)},$$

for every $\delta > 0$ and some $\gamma > 0$, and the probability taken over both the input distribution and internal randomness of the algorithm.

The theorem above immediately confirms a conjecture by Brandao et al. [8] about the "landscape independence" of $QAOA_p$ upto depth $\varepsilon\log(n)$. The "landscape independence" of $QAOA_p$ is a term which asserts that the algorithm performs almost equally well on almost all instances.

1.4 Technical overview

1.4.1 Chen et al. [10] analysis

Chen et al. [10] establish a coupled overlap-gap property (OGP) for the maximum cut of random hypergraphs. The property says that for two "coupled" random instances and any nearly optimal solutions $\sigma_1, \sigma_2 \in \{-1,1\}^n$ of these, the solutions either have large or small

overlap on the assignment values to the variables, i.e., there exists an interval $0 < a < b < 1$ such that $\langle \sigma_1, \sigma_2 \rangle / n \notin [a, b]$. The coupled OGP holds over an interpolation of a pair of hypergraphs $\{(G_1(t), G_2(t))\}_{t\in[0,1]}$ with the following three properties: for every $t \in [0, 1]$, denote $\sigma_1(t)$ and $\sigma_2(t)$ as the outputs of a factors i.i.d. algorithm on inputs $G_1(t)$ and $G_2(t)$ respectively. (i) when $t = 0$, $(G_1(0), G_2(0))$ are independent random hypergraphs and $\langle \sigma_1(0), \sigma_2(0) \rangle / n < a$ with high probability; (ii) when $t = 1$, $G_1(1) = G_2(1)$ are the same random hypergraph and $\langle \sigma_1(1), \sigma_2(1) \rangle / n = 1$ with high probability; (iii) for each $t \in [0, 1]$, the correlation $\langle \sigma_1(t), \sigma_2(t) \rangle / n$ between the two solutions is highly concentrated (with respect to the randomness of $G_1(t), G_2(t)$ and the algorithm) to a value $R(t)$, and $R(t)$ is a continuous function of t. By the intermediate value theorem, this contradicts the OGP if the solutions are nearly optimal and hence no such factors of i.i.d. algorithm can exist. Note that it is also important to assert that the hamming weight and the objective function values output by the algorithm also concentrate.

1.4.2 Our analysis

The key part of the proof in Chen et al. [10] that does not work for $QAOA_p$ is item (iii) of step 2. Specifically, local quantum algorithms are not factors of i.i.d. algorithms and hence their concentration analysis on the correlation between solutions to coupled instances does not apply. Intuitively, this is because local quantum circuits can induce entanglement between qubits in a local neighborhood which cannot be explained by a local hidden variable theory [6]. We overcome this issue by first generalizing the notion of factors of i.i.d. algorithms to what we call *generic local algorithms* (Definition 2.1).

To establish concentration of overlap for quantum local algorithms, the challenge lies in how to capture the local correlations of $G_1(t)$ and $G_2(t)$. We achieve this by defining a new notion of a random vector being *locally independent* (Definition 5.2 in the full version). This structure enables us to show concentration on a fixed instance over multiple runs of the generic local algorithm with respect to its internal randomness (Theorem 5.3 in the full version). Finally, to establish concentration between a pair of correlated instances ($G_1(t)$ and $G_2(t)$), we strengthen McDiarmid's inequality for biased distributions (Lemma 2.7) and this allows the concentration analysis of the correlation function $R(t)$ to pull through (Theorem 5.1 in the full version). We complete the analysis by showing that the hamming weight and objective function values output by a generic p-local algorithm also concentrate on any (k, d)-CSP(f), obtained as corollaries to the main concentration lemmas (Corollaries 5.10 and 5.13 in the full version).

1.4.3 Comparison with Chen et al. [10] and Farhi et al. [17]

We augment the techniques of Farhi et al. [17] to handle a coupled OGP over a continuous interpolation, as opposed to the coupled OGP in Farhi et al. [17] which is over a fixed discrete interpolation. The advantage of this is to enable the use of a broader family of coupled OGPs provable using statistical mechanics methods, whereas the coupled OGP of Farhi et al. [17] requires reasoning about explicit sequences of instances in a way that does not clearly generalize from their independent set analysis to the setting of CSPs.

Our statements additionally show stronger concentration than those of Chen et al. [10] which is necessary to demonstrate that polynomially many runs of the algorithm will (with high probability) not succeed. Lastly, we extend the coupled OGP from the setting of diluted k-spin glasses shown by Chen et al. [10] to the setting of random Max-k-XOR.

1.5 Preliminaries & notation

1.5.1 Constraint-satisfaction problems & hypergraphs

Constraint satisfaction problems are a class of optimization problems where a set of constraints on the underlying variables need to be satisfied in tandem. We restrict our attention to the setting where the variables are boolean valued and the number of constraints are *sparse*. Furthermore, every constraint involves k variables, where k is a constant independent of the number of variables.

▶ **Definition 1.4** (Random (k,d)-CSP(f))**.** *A (signed) random (k,d)-CSP(f) instance with a local constraint function $f : \{-1,1\}^k \to \{0,1\}$ is constructed as follows:*

1. *Choose $r \sim \text{Poisson}(dn/k)$.*
2. *Sample r clauses of size k by choosing each clause C_i independently as a collection of k variables uniformly at random from $\{x_1, \ldots, x_n\}^k$, and, in the case of a signed random CSP, random signs $s_{i,1}, \ldots, s_{i,k} \in \{\pm 1\}$.*

To each clause C_i there are k variables associated: $\{x_{i_1}, \ldots, x_{i_k}\}$. A clause is satisfied if there is some assignment to every $x_{i_j} \in \{-1,1\}$, such that, $f(x_{i_1}, \ldots, x_{x_k}) = 1$ (or $f(s_{i,1}x_{i_1}, \ldots, s_{i,k}x_{x_k}) = 1$ if signed). The value of an assignment $\sigma \in \{-1,1\}^n$ is defined as $\mathsf{val}_\Psi(\sigma) := \#\{C_i : f(\sigma_{i_1}, \ldots, \sigma_{i_k}) = 1\}$ (or $\#\{C_i : f(s_{i,1}\sigma_{i_1}, \ldots, s_{i,k}\sigma_{i_k}) = 1\}$ if signed). The optimal value of Ψ is defined as $\mathsf{val}(\Psi) := \max_\sigma \mathsf{val}_\Psi(\sigma)$.

When unspecified, we will be referring to unsigned CSPs. In a diluted k-spin glass, the underyling particles can be thought of as vertices of a hypergraph with $\frac{dn}{k}$ hyperedges. Each hyperedge is a tuple of k-vertices, and any interaction $J_{i_1,\ldots,i_k}$ over a tuple $(i_1, \ldots, i_k)$ is -1 if $(i_1, \ldots, i_k)$ is a hyperedge of G and 0 otherwise.

▶ **Definition 1.5** (Random k-uniform hypergraph)**.** *A* random *k-uniform hypergraph consists of choosing a number of edges $|E| \sim \text{Poisson}(\frac{dn}{k})$ and then choosing hyperedges $e_1, \ldots, e_{|E|}$ independently and uniformly at random from the set $\{1, \ldots, n\}^k$ of all vertex k-tuples.*

The underlying hamiltonian of a diluted k-spin glass then is,

$$H^G_{n,k,d}(\sigma) = -\sum_{e \in E} \sigma_{e_1} \ldots \sigma_{e_k}\,, \tag{1}$$

which on maximization corresponds to the MAX-CUT of a random k-uniform hypergraph. Observe that a (k,d)-CSP(f) can be encoded as a diluted k-spin glass by choosing the variables to be the set of vertices, the clauses to be the hyperedges, and the hamiltonian to be the same as in Equation 1 with the additional requirement that f acts on the variables in every hyperedge.

1.5.2 Vanishing Local Neighborhoods of Sparse Random Hypergraphs

We state a bound on sufficiently local neighborhoods of random sparse k-uniform hypergraphs. This bound is used in the obstruction result to precisely quantify the size of the neighborhood $p(n)$ up to which a $p(n)$-generic local algorithm does not "see the whole hypergraph" around any vertex.

▶ **Lemma 1.6** (Vanishing local neighborhoods of random sparse k-uniform hypergraphs). *Let $k \geq 2$ and $d \geq 2$ and $\tau \in (0,1)$. Then there exists $a > 0$ and $0 < A < 1$, such that, for n large enough and p satisfying*

$$2p + 1 \leq \frac{(1-\tau)\log n}{\log\left(\frac{d(k-1)}{\ln 2}\right)},$$

the following are true:

$$\Pr_{G\sim\mathcal{H}_{n,d,k}}[\max_i B_G(v_i, 2p) \geq n^A] \leq e^{-n^a}, \quad \text{and} \quad \Pr_{G\sim\mathcal{H}_{n,d,k}}[\max_i B_G(v_i, p) \geq n^{\frac{A}{2}}] \leq e^{-n^{\frac{a}{2}}}.$$

Intuitively, the above lemma says that the local neighborhood of each vertex is vanishingly small with high probability. To prove Lemma 1.6, we utilize a modified version of the proof of Farhi et al. [17, Neighborhood Size Theorem] to handle the case of sparse random hypergraphs and we defer the complete proof to Appendix B in the full version.

1.5.3 The Overlap Gap Property

We say that a (k,d)-CSP(f) (signed or unsigned) satisfies a *coupled overlap-gap property (OGP)* if, given two instances Ψ, Ψ' constructed so that they share a random t-fraction of clauses with the remaining $(1-t)$-fraction chosen independently, any two "good" solutions σ of Ψ and σ' of Ψ' are either very similar of dissimilar.

▶ **Definition 1.7** (Coupled OGP, informal). *A signed or unsigned (k,d)-CSP(f) satisfies a coupled OGP if there exists $\varepsilon_0 > 0$ and $0 < a < b < 1$ such that the following hold for every $t \in [0,1]$: Given two (k,d)-CSP(f) instances Ψ, Ψ' constructed so that they share a random t-fraction of their clauses and have the remaining $(1-t)$-fraction of clauses chosen independently and uniformly at random, then for every $0 < \varepsilon < \varepsilon_0$, the overlap between any $(1-\varepsilon)$-optimal solution σ of Ψ and σ' of Ψ' satisfies*

$$\frac{1}{n}\langle\sigma,\sigma'\rangle = \frac{1}{n}\left(\sum_{i=1}^{n}\sigma_i\sigma_i'\right) \notin [a,b]$$

with high probability.

A formal definition of the interpolation procedure described in Definition 1.7 and a complete and formal statement of a coupled OGP are provided in section 3.

1.5.4 Local classical algorithms

A local classical algorithm takes as input a hypergraph G and a label set S, runs a stochastic process $\{X^G(t)\}_t$ that associates to each vertex v a label $X_v^G(t) \in S$ at time t, and outputs an assignment σ_v to each vertex v according to its final label. While there is a huge design space for local classical algorithms, a *factors of i.i.d. algorithm* of radius p has the following restrictions:

1. The initial label for each vertex v is set to be one from an i.i.d. set of random variables $X_v^G(0)$.
2. For each vertex v, the assignment σ_v is a random variable that only depends on the labels from a p-neighborhood of v and is updated via a stochastic process.
3. The assignment function (also known as the *factor*) for each vertex is the same.
4. The label assignment of two vertices v, v' in hypergraphs G and G' are equivalent if the two vertices have *isomorphic* p-neighborhoods.

As we shall see, in subsection 2.1, we relax the first three conditions to include a larger class of local algorithms, which subsume local quantum algorithms. We now state the definition of the p-neighborhood of a vertex in a hypergraph, which generalizes the p-neighborhood of a graph by considering two vertices v and w to be adjacent if they belong to the same hyperedge e.

▶ **Definition 1.8** (p-neighborhood and hypergraphs with radius p)**.** *Let G be a hypergraph, $v \in V(G)$, and $p \in \mathbb{N}$. The p-neighborhood of v is defined as*

$$B_G(v,p) := \{w \in V(G) \,|\, w \text{ can be reached in } p \text{ steps from } v\}.$$

Let G be a hypergraph, $v \in V(G)$, and $p \in \mathbb{N}$. We say (G,v) has radius p if $B_p(G_v) = V(G)$. Further, let $k \in \mathbb{N}$, we define

$$\mathcal{G}_p := \{(G,v) \,|\, (G,v) \text{ has radius } p \text{ and } G \text{ is connected, finite, and } k\text{-uniform}\}$$

be the collections of hypergraphs with radius at most p.

To capture the fact that classical local algorithms assign the value of a vertex v by only looking at a stochastic process of the p-neighborhood, we define a factor f as a measurable function which gives a label $\sigma_v \in \{\pm 1\}$ to every vertex $v \in V(G)$. We restrict to the case where the label set $S = [0,1]$.

▶ **Definition 1.9** (Factor of radius p)**.** *Let $p \in \mathbb{N}$. We define the collection of all $[0,1]$-labelled hypergraphs of radius at most p as*

$$\Lambda_p := \left\{(G,v,X) \,|\, (G,v) \in \mathcal{G}_p \text{ and } X \in [0,1]^{V(G)}\right\}$$

We say $(G_1,v_1,X_1),(G_2,v_2,X_2) \in \Lambda_r$ are isomorphic if there exists a hypergraph isomorphism $\phi : V(G_1) \to V(G_2)$ such that (i) $\phi(v_1) = \phi(v_2)$ and (ii) $X_1 = X_2 \circ \phi$.

Finally, we say $f : \Lambda_p \to \{-1,1\}$ is a factor of radius p function if

1. *f is measurable.*
2. *$f(G_1,v_1,X_1) = f(G_2,v_2,X_2)$ for every isomorphic $(G_1,v_1,X_1),(G_2,v_2,X_2) \in \Lambda_r$.*

Intuitively, the output distribution of a factors of i.i.d. algorithm with radius p on a vertex v is determined by the p-neighborhood of v.

▶ **Definition 1.10** (Factors of i.i.d., [10, Section 2])**.** *Let $k,p \in \mathbb{N}$. A factors of i.i.d. algorithm A with radius p is associated with a factor of radius p function f with the following property. On input a k-uniform hyper graph G, the algorithm A samples a random labeling $X = \{X(v)\}_{v \in V(G)}$ where $X(v)$'s are i.i.d. uniform random variables on $[0,1]$. The output of A is $\sigma \in \{-1,1\}^{V(G)}$ where $\sigma_v := f(B_p(G,v), v, \{X(w)\}|_{w \in B_p(G,v)})$ for each $v \in V(G)$.*

Common local algorithms such as Glauber dynamics and Belief Propagation are examples of factors of i.i.d. algorithms.

2 Main Technical Theorems

The main results include showing that $QAOA_p$ is a generic p-local algorithm, a concept which subsumes *factors of i.i.d.* local algorithms and local quantum algorithms, and then establishing that this more general class of algorithms also have strong concentration properties. The concentration allows the original interpolation argument of Chen et al. [10] stated in subsubsection 1.4.1 to continue to pose an obstruction to generic p-local algorithms from outputting arbitrarily good solutions on almost all instances of a (k,d)-CSP(f) that has a coupled OGP.

2.1 Generic local algorithms

Generic local algorithms, including local quantum algorithms, can be defined from an information-based perspective. Specifically, given a parameter p that characterizes the locality of the information an algorithm has about the input, we can assert that a *generic* p-local algorithm makes independent decisions on appropriately far-away vertices and that all decisions for a vertex are sufficiently local.

▶ **Definition 2.1** (Generic local algorithms, informal). *Let $p \in \mathbb{N}$ and let S be a finite label set. We say an algorithm A (which takes a hypergraph G as an input) is generic p-local if the following hold:*

- **(Local distribution determination).** *For every set of vertices $L \subset V$, the joint marginal distribution of the labels $(A(G)_v)_{v\in L}$ depends only on the union of the p-neighborhoods of $v \in L$ in G.*
- **(Local independence).** *$A(G)_v$ is statistically independent of the joint distribution of $\{A(G)_{v'}\}$ for every v' that is farther than a distance of $2p$ from v.*

The definition makes no assumptions about how the randomness of the algorithm is instantiated, what sort of function is used to decide the label locally, or whether it is the same for every vertex. A formal defintion is provided in section 4, along with a procedure to partially sample from the run of the algorithm on correlated instances. We now briefly introduce the $QAOA_p$ circuit.

▶ **Definition 2.2** ($QAOA_p$ algorithm, [19]). *The $QAOA$ circuit parametrized by angle vectors $\hat{\gamma} = (\gamma_1, \ldots, \gamma_p)$ and $\hat{\beta} = (\beta_1, \ldots, \beta_p)$ looks as follows,*

$$U_p(\hat{\beta}, \hat{\gamma}) = \prod_{j=1}^{p} e^{-i\beta_j \sum_{k=1}^{n} X_k} e^{-i\gamma_j H_c(G)} .$$

In the circuit above, X_i is the Pauli-X matrix acting on the i-th qubit (with identity action everywhere else) and $H_C(G)$ is the hamiltonian that encodes the problem instance. For us, $H_C(G) = H^G_{n,k,d}$ where every k-spin interaction is replaced by a Pauli-Z interaction $Z_{e_1} \otimes \cdots \otimes Z_{e_k}$. Typically, the initial state on which the circuit is applied is a *symmetric product state*, most notably $|0\rangle^{\otimes n}$ or $|+\rangle^{\otimes n}$. The expected value that $QAOA$ outputs after applying the circuit on some initial state $|\psi_0\rangle$ is,

$$\langle\psi_0| U^\dagger H_c(G) U |\psi_0\rangle .$$

We will notate by $QAOA(\hat{\beta}, \hat{\gamma})$ a $QAOA$ circuit of depth $2p$ with angle parameters $\hat{\beta}$ and $\hat{\gamma}$. In our regime, we will work with *any* collection of *fixed* angles $(\hat{\beta}, \hat{\gamma})$.

As stated below, generic p-local algorithms strictly generalize the *factors of i.i.d.* framework as well as $QAOA_p$.

▶ **Proposition 2.3** (Generic local strictly generalizes factors of i.i.d.). *There exists a generic p-local algorithm as defined in Definition 2.1 that is not a p-local factors of i.i.d. algorithm as defined in Definition 1.10.*

▶ **Proposition 2.4** ($QAOA_p$ is generic p-local). *For every $p > 0$ and fixed angle vectors $\hat{\beta}$ and $\hat{\gamma}$, $QAOA_p(\hat{\beta}, \hat{\gamma})$ is generic p-local under Definition 2.1.*

The proofs for the two propositions above are provided in section 4.

2.2 Concentration of outputs of local quantum algorithms

Having shown that generic p-local algorithms capture classical & quantum local algorithms, we now first show that the outputs of these algorithms concentrate even when run on multiple fixed correlated instances. Additionally, the outputs concentrate over the input distribution from which the instances are drawn. The proof for the lemmas in this subsection are delegated to Section 5 in the full version.

2.2.1 Concentration over internal randomness of the algorithm

We first show that the output of generic p-local algorithms on sufficiently "local" functions of the underlying spins concentrates heavily, even when run on multiple correlated instances. We state an informal version of the lemma. For a formal and detailed version, please refer to Theorem 5.3 in the full version. "Spins" here refer to the assignment of a variable.

▶ **Lemma 2.5** (Concentration of local functions of spins, informal)**.** *Let $z,\ m \in \mathbb{N}$ and $A < 1$. Let σ be the output of a generic p-local algorithm on a fixed hypergraph G. Let $v_{j,i}$ denote the vertex corresponding to the i-th vertex (or variable) in the j-th hyperedge (or clause) with $j \in [m]$ and $i \in [z]$. Let $r = (r_1, \ldots, r_m)$ be a random vector of a correlated hypergraph G' with a certain joint independence structure (Definition 5.2 in the full version). Now, consider a sum $X = \sum_{j\in[m]} h(\sigma_{v_{j,1}}, \ldots, \sigma_{v_{j,z}})r_j$, where $|h| \leq 1$. Suppose that each vertex v occurs at most C times among the different $v_{j,i}$. Then, provided the p-neighborhood of every vertex in $G \cup G'$ has at most n^A vertices:*

$$\Pr_{\sigma,r}[|X - \mathop{\mathbb{E}}_{\sigma,r}[X]| \geq \delta n] \leq e^{-\Omega(\delta^2 m/(Czn^A))}\,.$$

The lemma above states that even when choosing two correlated instances G and G' that share, say t-fraction of their clauses, provided every vertex sees not too many vertices in the local neighborhood of the combined input $G \cup G'$, the value of sufficiently local functions h acting on the output of the algorithm concentrate. To get concentration of overlap between two solutions σ of G and σ' of G', we choose $h(\sigma_{v_{j,1}}, \ldots, \sigma_{v_{j,z}}) = \sigma_{v_j}$, $m = n$ and $r = \sigma'$. To get concentration for $\mathsf{val}_G(\sigma)$, we choose $h = f$ for the underlying (k,d)-$\mathsf{CSP}(f)$ and $m = \frac{dn}{k}$. When working to obtain concentration on a single instance, it suffices to set $G' = G$ and r to be the all 1s vector.

2.2.2 Concentration over instances

The prior lemma merely asserts that the output is concentrated for *fixed* correlated instances. However, this still doesn't imply that the output will be concentrated *across* random input instances. To do so, we need concentration over the distribution from which the inputs are sampled. This is accomplished by Theorem 5.4 in the full version, an informal version of which is stated below.

▶ **Lemma 2.6** (Concentration of differences of coupled hypergraphs, informal)**.** *Let f be a function of two hypergraphs over n vertices such that*

$$|f(G_1, G_2) - f(G_1', G_2')| \leq r(n)\,,$$

for some r whenever (G_1, G_2) differs from (G_1', G_2') by the addition and/or removal of a single hyperedge $e \in [n]^k$ from one or both hypergraphs. Furthermore, assume that the largest p-nieghborhood of G_1, G_2, G_1', G_2' has no more than $n^{\frac{A}{2}}$ vertices for some $A < 1$. Then $\exists\ a \in (0,1)$, such that

$$\Pr_{\substack{G_1,G_2\sim\\ \mathcal{H}_{n,k,d,t}}}\left[\left|f(G_1,G_2) - \mathop{\mathbb{E}}_{G_1,G_2} f(G_1,G_2)\right| \geq \delta n\, r(n)\right] \leq 2\exp\left(\frac{-3k\delta^2 n}{12(2-t)d + 2k\delta}\right) + 2\exp\left(-n^{a/2}\right).$$

The notation $G_1, G_2 \sim \mathcal{H}_{n,k,d,t}$ indicates that G_1 and G_2 are t-correlated *random* hypergraphs. This means that t-fraction of their hyperedges are chosen i.i.d. from $[n]^k$ and these are common. The remaining $(1-t)$ fraction of edges are chosen independently for each. For a formal definition of the coupled distribution, refer to Definition 3.3. The above lemma relies on two critical facts:

1. For $p \leq \varepsilon \log(n)$ (for an appropriately chosen ε), the p-neighborhood of a *random* k-uniform hypergraph has no more than $n^{\frac{A}{2}}$ vertices (Lemma 1.6).
2. A strengthening of *McDiarmid's Inequality* (Lemma 2.7) for biased distributions. This strengthening is proved via a martinagle argument.

2.2.3 Strengthened McDiarmid's Inequality

We end by stating the strengthened version of McDiarmid's Inequality (Lemma 2.7) for biased distributions, which is a generic concentration statement that may be of independent interest. The inequality adds a Bernstein-like variance term to the tail-bound that controls the likelihood of deviation, where the variance term depends on a precise quantification of how unlikely certain very rare events are.

▶ **Lemma 2.7** (McDiarmid's inequality for biased distributions). *Suppose that $X_1, \ldots, X_n$ are sampled i.i.d. from a distribution D over a finite set $\mathcal{X}$, such that D assigns probability $1-p$ to a particular outcome $\chi_0 \in \mathcal{X}$. Let $f : \mathcal{X}^n \to \mathbb{R}$ satisfy a bounded-differences inequality, so that*

$$|f(x_1, \ldots, x_{i-1}, x_i, x_{i+1}, \ldots x_n) - f(x_1, \ldots, x_{i-1}, x_i', x_{i+1}, \ldots x_n)| \leq c$$

for all $x_1, \ldots, x_n, x_i' \in \mathcal{X}$. Then

$$\Pr\left[|f(X_1, \ldots, X_n) - \mathbb{E}\, f(X_1, \ldots, X_n)| \geq \varepsilon\right] \leq 2 \exp\left(\frac{-\varepsilon^2}{2np(2-p)c^2 + 2c\varepsilon/3}\right).$$

The above inequality is robust in that if there are highly unlikely or likely (think $p = o_n(1)$) events that cause large deviations, then these deviations can be absorbed into the Bernstein-like variance term in the tail bound term. This means that one can get strong concentration bounds even in the presence of a vanishingly small set of events that cause large deviations. This property ends up being critical when showing concentration of outputs of generic local algorithms over the input distribution.

2.3 Obstruction of generic local algorithms by the Overlap Gap Property

We state our main theorem (informally) that obstructs all generic p-local algorithms on random instances Ψ of a (k,d)-CSP(f) that satisfies the coupled Overlap-Gap Property.

▶ **Theorem 2.8** (Obstruction to Generic p-Local Algorithms given coupled OGP, informal). *Let f be a boolean predicate defined on k variables and $p(n)$ be such that it satisfies the requirements of Lemma 2.5 and Lemma 2.6. Furthermore, assume that (k,d)-CSP(f) satisfies the coupled Overlap Gap Property. Then, given an instance $\Psi \sim (k,d)$-CSP(f) and a generic $p(n)$-local algorithm $\mathcal{A}$ that outputs a solution σ on input Ψ, with high probability, the solution will be no more than $(1-\varepsilon_0)$-optimal for some $\varepsilon_0 > 0$.*

The theorem above is stated in full precision and formality in Theorem 4.3 in the full version and proved formally in Section 6 of the full version. The theorem effectively obstructs any algorithm that makes assignments for variables by looking at $o(n)$ sized

local neighborhoods *irrespective* of how these decisions are made and what concrete model of randomness is used, provided the problem exhibits a coupled OGP. For instance, the obstruction would hold even for quantum algorithms that assign labels based on the local neighborhoods of qubits *and* start and end in a state that is moderately locally entangled - By this, we mean a state that exhibits entanglement only between any qubit i and $o(n)$ qubits in its $p(n)$-sized local neighborhood.

2.4 Overlap Gap Property for MAX-k-XOR

In Section 8 in the full version, we establish that the random Max-k-XOR problem obeys a coupled OGP, so that the obstruction implied by Theorem 2.8 holds for this problem.

▶ **Lemma 2.9** (Coupled OGP for random Max-k-XOR). *The random* Max-k-XOR *problem satisfies Definition 1.7.*

This is proven by means of a Guerra-Tonelli interpolation [28, 10], where a dense mean-field k-spin glass model is continuously transformed to the random Max-k-XOR model. Treated as a physical system, the thermodynamic equilibrium at each point in the interpolation is calculated at a low enough temperature so that the equilibrium states are approximately optimal. The change in equilibrium energy over the course of the interpolation is then shown to be small.

A coupled OGP is shown in this way by interpolating a pair of systems constrained so that the overlap between the two states of the systems is bounded.

3 Coupled Interpolation & Overlap-Gap Properties

We now state the OGP formally as it holds for the diluted k-spin glass model in both uncoupled and coupled form. To do so, we begin by introducing the notion of an overlap between two spin-configurations σ_1 and σ_2, which is equivalent to the number of spins that are the same in both configurations subtracted by the number of different spins, normalized by the number of particles in the system. Formally,

▶ **Definition 3.1** (Overlap between spin configuration vectors). *Given any two vectors $\sigma_1, \sigma_2 \in \{-1, 1\}^n$, the overlap between them is defined as,*

$$R(\sigma_1, \sigma_2) = \frac{1}{n}\langle \sigma_1, \sigma_2 \rangle = \frac{1}{n} \sum_{i \in [n]} (\sigma_1)_i (\sigma_2)_i \,.$$

We first state the OGP for diluted k-spin glasses about the overlap gaps in a *single instance.*

▶ **Theorem 3.2** (OGP for Diluted k-Spin Glasses, [10, Theorem 2]). *For every even $k \geq 4$, there exists an interval $0 < a < b < 1$ and parameters $d_0 > 0$, $0 < \eta_0 < P(k)$ and $n_0 > 1$, such that, for $d \geq d_0$, $n \geq n_0$ and $L = L(\eta_0, d)$, with probability at least $1 - Le^{-n/L}$ over the random hypergraph $G \sim \mathcal{H}_{n,d,k}$, whenever two spins σ_1, σ_2 satisfy*

$$\frac{H^G(\sigma_i)}{n} \geq M(k,d)\left(1 - \frac{\eta_0}{P(k)}\right),$$

then also, $|R(\sigma_1, \sigma_2)| \notin (a, b)$.

A more general version of the OGP excludes, with high probability, a certain range of overlaps between any two solutions of two different instances jointly drawn from a coupled random process. We first introduce this process, and then state the *coupled* version of the OGP as proven in Chen et al [10].

▶ **Definition 3.3** (Coupled Interpolation, [10, Section 3.2]). *The coupled interpolation $\mathcal{H}_{d,k,n,t}$ generates a coupled pair of hypergraphs $(G_1, G_2) \sim \mathcal{H}_{d,k,n,t}$ as follows:*

1. *First, a random number is sampled from* Poisson(tdn/k)*, and that number of random k-hyperedges are uniformly drawn from the set $[n]^k$ and put into a set E.*
2. *Then, two more random numbers are independently sampled from* Poisson$((1-t)dn/k)$*, and those numbers of random k-hyperedges are independently drawn from $[n]^k$ to form the sets E_1 and E_2 respectively.*
3. *Lastly, the two hypergraphs are constructed as $G_1 = (V, E \cup E_1)$ and $G_2 = (V, E \cup E_2)$.*

▶ **Theorem 3.4** (OGP for Coupled Diluted k-Spin Glasses, [10, Theorem 5]). *For every even $k \geq 4$, there exists an interval $0 < a < b < 1$ and parameters $d_0 > 0$, $0 < \eta_0 < P(k)$ and $n_0 > 1$, such that, for any $t \in [0,1]$, $d \geq d_0$, $n \geq n_0$ and constant $L = L(\eta_0, d)$, with probability at least $1 - Le^{-n/L}$ over the hypergraph pair $(G_1, G_2) \sim \mathcal{H}_{n,d,k,t}$, whenever two spins σ_1, σ_2 satisfy*

$$\frac{H^{G_i}(\sigma_i)}{n} \geq M(k,d)\left(1 - \frac{\eta_0}{P(k)}\right),$$

then their overlap satisfies $|R(\sigma_1, \sigma_2)| \notin [a, b]$.

We also provide a corresponding coupled OGP for random Max-k-XOR in Theorem 8.12 in the full version.

4 Locality and Shared Randomness

4.1 Generic p-local algorithms

We introduce a concept of "local random algorithm" which will allow for different runs of the same local algorithm to "share their randomness", even when run on mostly-different instances. Later we will demonstrate that QAOA is a local algorithm under this definition.

▶ **Definition 4.1** (Generic local algorithms). *We consider randomized algorithms on hypergraphs whose output $A(G) \in S^V$ assigns a label from some set S to each vertex in V. Such an algorithm is generic p-local if the following hold.*

- **(Local distribution determination).** *For every set of vertices $L \subset V$, the joint marginal distribution of its labels $(A(G)_v)_{v \in L}$ is identical to the joint marginal distribution of $(A(G')_v)_{v \in L}$ whenever $\bigcup_{v \in L} B_G(v,p) \cong_L \bigcup_{v \in L} B_{G'}(v,p)$, and,*
- **(Local independence).** *$A(G)_v$ is statistically independent of the joint distribution of $A(G)_{v'}$ over all $v' \notin B_G(v, 2p)$.*

Consequently, it will be possible to sample $A(G)_v$ without even knowing what the hypergraph looks like beyond a distance of p away from v.

This definition is more general than the factors of i.i.d. concept used in probability theory [24, 10]. Our definition, for instance, encompasses local quantum circuits whereas factors of i.i.d. algorithms satisfy Bell's inequalities and do not capture quantum mechanics.

▶ **Proposition 4.2** (Generic local strictly generalizes factors of i.i.d. (Restatement of Proposition 2.3)). *There exists a generic 1-local algorithm as defined in section 4 that is not a 1-local factors of i.i.d. algorithm as defined in Definition 1.10.*

A proof of this proposition is provided in Appendix A in the full version, and consists of setting up a Bell's inequality experiment within the framework of a generic 1-local algorithm.

4.2 Locality properties of QAOA for hypergraphs

We show that any QAOA circuit of depth p with some *fixed* angle parameters $(\hat{\beta}, \hat{\gamma})$ is a p-local algorithm. This allows us to describe a process to sample outputs of this circuit when it is run on two different input hypergraphs.

▶ **Proposition 4.3.** *For every $p > 0$, angle vectors $\hat{\beta}$ and $\hat{\gamma}$, $QAOA_p(\hat{\beta}, \hat{\gamma})$ is generic p-local under Definition 4.1.*

Proof. To see this, consider the structure of QAOA: we start with a product state $|\psi_0\rangle$ where each qubit corresponds to a vertex in the hypergraph, apply the unitary transformation $U = U_p(\hat{\beta}, \hat{\gamma})$ to the state, and then measure each vertex v in the computational basis with the Pauli-Z operator $\sigma_z(v)$. Equally valid and equivalent is the Heisenberg picture interpretation of this process, where we keep the product state $|\psi_0\rangle$ fixed but transform the measurements according to the reversed unitary transformation $U^\dagger$, so that we end up taking the measurements $U^\dagger \sigma_z(v) U$ on the fixed initial state.

Because the $\sigma_z(v)$ operators all commute with each other, their unitarily transformed versions $U^\dagger \sigma_z(v) U$ also mutually commute, and the measurements can be taken in any order without any change in results. Let $M(v) = U^\dagger \sigma_z(v) U$ and $M(L) = \{U^\dagger \sigma_z(u) U \mid u \in L\}$.

To show that QAOA satisfies the first property of generic p-local algorithms, we need to show that the marginal distribution of its assignments to any set $L' \subseteq V$ of vertices depends only on the union of the p-distance neighborhoods of L'. To show this, since we are allowed to take the measurements in any order, take the measurements in $M(L')$ before any other measurement. Then since the action of the unitary $U = U_p(\hat{\beta}, \hat{\gamma})$ on qubits in L' does not depend on any feature of the hypergraph outside of a radius of p around L', the operators $M(L')$ are fully determined by the p-local neighborhoods of L', and since we take them before every other measurement, the qubits are simply in their initial states when we make these measurements, thus the distribution of outputs is fully determined.

The same type of reasoning shows that the assignment to each $v \in V$ is statistically independent of the assignments to any set of vertices outside of a $2p$-distance neighborhood of v. Take $L'' \subset V \setminus B(v, 2p)$. Then $M(v)$ acts on a radius-p ball around v, and each measurement in $M(L'')$ acts on a radius-p ball around a vertex in L'', and by taking $\{M(v)\} \cup M(L'')$ before any of the measurements in $M(\{B(v, 2p) \setminus \{v\}\})$, we ensure that the qubits being measured by $M(v)$ are disjoint from and unentangled with those measured by anything in $M(L'')$. Hence the measurement $M(v)$ is independent of all measurements in $M(L'')$. We conclude that QAOA_p is a generic p-local algorithm. ◀

4.3 Shared randomness between runs of a generic local algorithm

We describe a process to sample the outputs of a generic local algorithm when run twice on two different hypergraphs, so that the two runs of the algorithm can share randomness when the hypergraphs have some hyperedges in common. This is not meant as a constructive algorithm, but a statistical process with no guarantee of feasible implementation.

The idea is to start with two t-coupled hypergraphs, which for large enough n, are likely to have some set of vertices L^+ whose p-neighborhoods are identical between the two hypergraphs. Since these vertices have identical p-neighborhoods, a generic p-local algorithm behaves identically on the vertices in L^+. We pick a random t^+ fraction of the elements of L^+, and assign the same labels to those vertices in the two coupled instances. Then the remaining labels on each hypergraph are assigned by generic p-local algorithms, conditioned on the output being consistent with the already assigned labels.

The formal definition may be found in the full version of this paper, where it is combined with the coupled OGP to demonstrate a contradiction if a generic local algorithm achieves a good approximation.

5 Conclusion & Future Work

The full version of this work conclusively establishes the coupled OGP as an obstruction to all local quantum algorithms on *any* (k, d)-CSP(f). In doing this, the work hints at and leaves open many interesting questions for future work in areas that are at the intersection of Quantum inapproximability, Statistical Physics, Random Graph Theory, Combinatorial Optimization and Average-Case Complexity.

5.1 Which CSPs have an OGP?

While various sparse CSPs such as k-SAT, unsigned max-k-XOR and k-NAE-SAT have been shown to exhibit clustering in their solution spaces at different clause-to-variable ratios [1, 15, 10], it is not known whether this property is pervasive to most CSPs or something that happens to a select few. Therefore, in order to understand the complexity landscape of CSPs on typical instances better, the following open question is interesting to investigate:

▶ **Conjecture 5.1** (Random Predicate CSPs and coupled OGP)**.** *Given a function f chosen uniformly at random from the set of functions $\mathcal{B}_k = \{g \mid g : \{\pm 1\}^k \to \{0, 1\}\}$, (k, d)-CSP(f) has a coupled-OGP for sufficiently large k and d with high probability (over the choice of f and instance $\Psi \sim (k, d)$-CSP(f)).*

Notice that the conjecture above is specifically interested in the solution geometry of a CSP in the *unsatisfiable* regime (large d). A positive resolution to the above conjecture will make the obstructions stated in Theorem 2.8 hold for *almost all* CSPs.
Another question of interest is which properties about a predicate f can be identified which would conclusively imply that a random instance Ψ of a (k, d)-CSP(f) will have an OGP.

▶ **Problem 5.1** (Properties of coupled-OGP predicates)**.** *Can we enumerate a set of necessary and sufficient conditions on f to be such that (k, d)-CSP(f) satisfies a coupled-OGP for sufficiently large k and d?*

5.2 Beyond log-depth obstructions for $QAOA_p$?

Work on obstructing $QAOA_p$ using an OGP heavily relies on the locality of the algorithm at shallow depths. It is interesting to investigate whether this obstruction can be extended beyond the $\varepsilon \log(n)$-depth regime to make this a non-local obstruction. Recent work [23, 45] suggests that the OGP may actually result in stronger obstructions than just local ones, and it would be interesting to see if these techniques can be generalized to the setting of $QAOA_p$ to yield obstructions that are non-local.

▶ **Problem 5.2** (Poylogarithmic obstructions to $QAOA_p$ in the OGP regime)**.** *Given a $QAOA_p$ circuit with depth $p \leq \varepsilon (\log(n))^c$ for some $c > 1$, does there exist $\varepsilon_0 > 0$, such that $QAOA_p$ is obstructed on a (k, d)-CSP(f) with a coupled OGP from outputting solutions that are better than (1 - ε_0) approximations to the optimal?*

5.3 A Quantum OGP and lifting "classical" obstructions

The idea of the OGP obstructing families of algorithms that are *stable* under small perturbations to the input [23] motivates the idea of a quantized version of the OGP, to apply to *quantum* CSPs. To define such a property over quantum states, however, there would need to be a metric that is very similar to the classical hamming distance over $\mathbb{F}_2$ and has the property that it is invariant over permutations of the canonical basis, while still quantifying entanglement in a desired way. One such possible metric is a *quantum* version of the Wasserstein distance of first order that was proposed by De-Palma et al. [13]. In particular, given a natural generalization of Definition 1.7 to a quantized setting using a quantum version of the Wasserstein distance of first order, it is interesting to investigate if a larger family of quantum circuits up to some depth $p(n)$ can be obstructed by a family of d-local hamiltonians $\{H_n\}_{n\geq n_0}$ that possess a qOGP (quantized Overlap-Gap Property). A result of this type could imply a way to generically "lift" classical obstructions for *stable* classical algorithms to a corresponding family of quantum algorithms.

5.4 Message-Passing algorithm for MAX-CUT of *all* d-regular graphs?

Finding an efficient classical algorithm that can output cuts that are arbitrary approximations of the optimal ones for d-regular graphs is a long-standing open problem in Random Graph Theory and Theoretical Computer Science. Recently, this problem was nearly completely solved by Alaoui et al. [2] as they constructed a Message-Passing algorithm for random regular graphs of very large degree under the widely believed no-OGP assumption about the SK model. However, the problem does not provide a complete solution as it needs the degree d to be larger than $O(\frac{1}{\varepsilon})$ in order to output a $(1-\varepsilon)$-optimal cut. A natural question is whether, under a no-OGP assumption, the result can be extended to output $(1-\varepsilon)$-optimal cuts for d-regular graphs for *any* $d \geq 3$.

▶ **Conjecture 5.2** (AMP algorithm for Random d-Regular Graphs). *There exists a poly$(n, \frac{1}{\varepsilon})$ time algorithm A that outputs a (1 - ε)-approximate cut of a random d-regular graph G with high probability under a "no-OGP" assumption for* any $d \geq 3$.

Note that the approach of Alaoui et al. [2] critically relies on the Guerra-Tonnineli interpolation between the $\mathcal{G}_{n,d}$ model and the SK-model which will *only* work for $d \geq O\left(\frac{1}{\varepsilon}\right)$. Consequently, a solution that works for *all* $d \geq 3$ will require a fundamentally different approach. A natural question that is motivated by the above conjecture is to then investigate if there is any range of degree for which the MAX-CUT problem over d-regular graphs possesses an OGP. Given the belief that the SK model does not exhibit an OGP, this would only be an interesting question in the relatively low-degree regime.

▶ **Problem 5.3** (Random d-Regular Graphs don't have an OGP). *Does the* MAX-CUT *problem on random d-regular graphs have an OGP for some $d \geq 3$? If so, for what $\{d_0, d_1\} \subset \mathbb{N}$ does the problem exhibit an OGP?*

The study of $QAOA_p$ was initiated on MAX-CUT for d-regular graphs: positive answers to the conjectures above would resolve the question of quantum advantage on the problem.

Fully-Dynamic $\alpha + 2$ Arboricity Decompositions and Implicit Colouring

Aleksander B. G. Christiansen

Eva Rotenberg
Technical University of Denmark, Lyngby, Denmark

Abstract

The arboricity α of a graph is the smallest number of forests necessary to cover its edges, and an arboricity decomposition of a graph is a decomposition of its edges into forests. The best near-linear time algorithm for arboricity decomposition guarantees at most $\alpha + 2$ forests if the graph has arboricity α (Blumenstock and Fischer [12]).

In this paper, we study arboricity decomposition for *dynamic graphs*, that is, graphs that are subject to insertions and deletions of edges. We give an algorithm that, provided the arboricity of the dynamic graph never exceeds α, maintains an $\alpha + 2$ arboricity decomposition of the graph in $\text{poly}(\log n, \alpha)$ update time, thus matching the number of forests currently obtainable in near-linear time for static (non-changing) graphs.

Our construction goes via dynamic bounded out-degree orientations, and we present a fully-dynamic algorithm that explicitly orients the edges of the dynamic graph, such that no vertex has an out-degree exceeding $\lfloor(1+\varepsilon)\alpha\rfloor + 2$. Our algorithm is deterministic and has a worst-case update time of $O(\varepsilon^{-6}\alpha^2 \log^3 n)$. The state-of-the-art explicit, deterministic, worst-case algorithm for bounded out-degree orientations maintains a $\beta \cdot \alpha + \log_\beta n$ out-orientation in $O(\beta^2\alpha^2 + \beta\alpha \log_\beta n)$ time [30].

As a consequence, we get an algorithm that maintains an implicit vertex colouring with $4 \cdot 2^\alpha$ colours, in amortised poly-$\log n$ update time, and with $O(\alpha \log n)$ worst-case query time. Thus, at the expense of $\log n$-factors in the update time, we improve on the number of colours from $2^{O(\alpha)}$ to $O(2^\alpha)$ compared to the state-of-the-art for implicit dynamic colouring [27].

1 Introduction

Graph colouring is a well-studied problem in computer science and discrete mathematics and has many applications such as planar routing and network optimization [17]. A proper colouring of a graph $G = (V, E)$ on n vertices is an assignment of colours to each vertex in $V(G)$ such that no neighbours receive the same colour. We are interested in minimising the number of colours used. The minimum number of colours that can be used to properly colour G, is called the *chromatic number* of G. It is NP-hard to even approximate the chromatic

number to within a factor of $n^{1-\varepsilon}$ for all $\varepsilon > 0$ [43, 29], but colourings with respect to certain parameters can be efficiently computed. For instance, it is well known that if a graph is uniformly sparse in the sense that we can decompose it into k forests, then we can efficiently compute a colouring: the sparsity of the graph ensures that every subgraph has a vertex of degree at most $2k - 1$, allowing us to compute a $2k$ colouring of the graph in linear time by colouring the vertices in a clever order. The minimum number of forests that the graph can be decomposed into is called the *arboricity* of G. In the past decades, much work has gone into the study of *dynamic algorithms* that are able to efficiently update a solution, as the problem undergoes updates. A general question about dynamic problems is: which (near-) linear-time solvable problems have polylogarithmic updatable solutions?

We study the problem of maintaining a proper colouring of a dynamic graph with bounded arboricity. This class of graphs encompasses, for instance, dynamic planar graphs where $\alpha \leq 3$. Here, the graph undergoes changes in the form of insertions and deletions of edges and one needs to maintain a proper colouring of the vertices with fast update times. We distinguish between two scenarios: one where, as is the case for dynamic planar graphs, we have access to an upper bound on the arboricity α_{max} throughout all updates, and one where we do not. Note that due to insights presented in [39], we can often turn an algorithm for the first scenario into an algorithm for the second by scheduling updates to $O(\log n)$ (partial) copies of the graph, thus incurring only an $O(\log n)$ overhead in the update time.

Barba et al. [6] showed that one cannot hope to maintain a proper, explicit vertex-colouring of a dynamic forest with a constant number of colours in poly-logarithmic update time. Consequently, we cannot maintain explicit colourings where the number of colours depend entirely on α with poly-logarithmic update time - even if we know an upper bound on α. This motivated Henzinger et al. [27] to initiate the study of *implicit* colourings. Here, instead of storing the colours of vertices explicitly in memory, a queryable data structure is provided which after some computations returns the colour of a vertex. If one queries the colours of two neighbouring vertices between updates, the returned colours must differ. Now, we can circumvent the lower bound by using known data structures for maintaining information in dynamic forest to 2-colour dynamic forests in poly-logarithmic update time. Henzinger et al. [27] use this to colour graphs via an *arboricity decomposition* i.e. a decomposition of the graph into forests. They present a dynamic algorithm that maintains an implicit proper $2^{O(\alpha)}$-colouring of a dynamic graph G with arboricity α. Their algorithm adapts to α, but in return it hides a constant (around 40) in the asymptotic notation. Even if one has an upper bound α_{max} on α, the currently best obtainable colouring uses $2^{4(\alpha_{max}+1)}$ colours by combining the arboricity decomposition algorithm from Henzinger et al. [27] with an algorithm of Brodal & Fagerberg [13] that maintains a $2(\alpha_{max} + 1)$ bounded out-degree orientation. Both of these algorithms use a lot of colours. Even for planar graphs with arboricity at most 3, $2^{16} > 60.000$ colours are used. This is quite far from 4 colours, which is always sufficient [3, 38], or the 5 colouring that can be computed in linear time [35, 14, 20].

Dynamic arboricity decompositions. Both colouring algorithms go via dynamic α'-bounded out-orientations. Here, the goal is to orient the edges of the graph while keeping out-degrees low. These are then turned into dynamic $2\alpha'$-arboricity decompositions. By 2-colouring each forest, such a decomposition yields a $2^{2\alpha'}$ colouring. Thus the lower α' is, the fewer colours we use. There has been a lot of work on maintaining dynamic low out-orientations [13, 8, 30, 26, 41], and much of this work aim to improve update complexity by relaxing the allowed out-degree. Motivated by implicit colourings, we provide a different trade-off, providing a lower α' value within polylog(n, α) update time. Specifically, a $\lfloor(1 + \varepsilon)\alpha\rfloor + 2$

dynamic out-orientation with $O(\log^3(n)\alpha^2/\varepsilon^6)$ update-time adaptive to α, and an $\alpha+2$ dynamic arboricity decomposition with $O(\text{poly}(\log n, \alpha_{max}))$ update time, when we have an upper bound α_{max} on the arboricity. Our algorithm maintaining the arboricity decomposition matches the number of forests obtained by the best static algorithm running in near-linear time [12].

These algorithms may also be interesting as they go below the 2α barrier on out-edges and forests respectively. In the static case there exist simple and elegant algorithms computing $2\alpha-1$ out-orientations and arboricity decompositions in linear time [4, 19]. For exact algorithms, the state-of-the-art algorithms spend time $\tilde{O}(m^{10/7})$ [34] or $\tilde{O}(m\sqrt{n})$ [33] for the out-orientation problem, and $\tilde{O}(m^{3/2})$ for the arboricity decomposition problem [21, 22]. Even statically computing an $\alpha+1$ out-orientation [31] resp. an $\alpha+2$ arboricity decomposition [12] takes $\tilde{O}(m)$ time. In the dynamic case, the out-orientation with the lowest bound on the out-degree with $O(\text{poly}(\log n, \alpha))$ update time seem to be the algorithm of Brodal & Fagerberg [13] that achieves $2(\alpha_{max}+1)$ out-degree. In [13] it is also noted that determining exactly the complexity of maintaining a d out-orientation for $d \in [\alpha, 2\alpha]$ is a 'theoretically interesting direction for further research'. We make some progress in this direction by showing how to maintain a $\lfloor(1+\varepsilon)\alpha\rfloor+2$ out-orientation with $\text{poly}(\log n, \alpha, \varepsilon^{-1})$ update time. Thus, if α is a constant, we may carefully choose ε to obtain a polylogarithmic $\alpha+2$ out-orientation.

1.1 Results

Let G be a dynamic graph with n vertices undergoing insertion and deletions of edges, and let α be the current arboricity of the graph; that is α might change, when edges are inserted and deleted. If we at all times have an upper bound α_{max} on α, we say that G is undergoing an α_{max} preserving sequence of updates. We have the following:

▶ **Theorem 1.** *For $1 > \varepsilon > 0$, there exists a fully-dynamic algorithm maintaining an explicit $((1+\varepsilon)\alpha+2)$-bounded out-degree orientation with worst-case insertion time $O(\log^3 n \cdot \alpha^2/\varepsilon^6)$ and worst-case deletion time $O(\log^3 n \cdot \alpha/\varepsilon^4)$*

Using pseudoforest decompositions, we obtain a fully dynamic, implicit colouring algorithm:

▶ **Corollary 2.** *Given a dynamic graph with n vertices, there exists a fully dynamic algorithm that maintains an implicit $2 \cdot 3^{(1+\varepsilon)\alpha}$ colouring with an amortized update time of $O(\log^4 n \cdot \alpha^2/\varepsilon^6)$ and a query time of $O(\alpha \log n)$.*

By moving edges between pseudoforests, we can turn the pseudoforest decomposition into a forest decomposition. This also gives a colouring algorithm using fewer colours.

▶ **Theorem 3.** *Given an initially empty and dynamic graph undergoing an arboricity α_{max} preserving sequence of updates, there exists an algorithm maintaining a $\lfloor(1+\varepsilon)\alpha\rfloor+2$ arboricity decomposition with amortized update time $O(\text{poly}(\log n, \alpha_{max}, \varepsilon^{-1}))$. In particular, setting $\varepsilon < \alpha_{max}^{-1}$ yields $\alpha+2$ forests with an amortized update time of $O(\text{poly}(\log n, \alpha_{max}))$.*

▶ **Corollary 4.** *Given a dynamic graph with n vertices, there exists a fully dynamic algorithm that maintains an implicit $4 \cdot 2^{\alpha}$ colouring with an amortized update of $O(\text{polylog}\, n)$ and a query time of $O(\alpha \log n)$.*

Finally, we modify an algorithm of Brodal & Fagerberg [13] so that it maintains an acyclic out-orientation.

▶ **Theorem 5.** *Given an initially empty and dynamic graph G undergoing an arboricity α_{max} preserving sequence of insertions and deletions, there exists an algorithm maintaining an acyclic $(2\alpha_{max}+1)$ out-degree orientation with an amortized insertion cost of $O(\alpha_{max}^2)$, and an amortized deletion cost of $O(\alpha_{max}^2 \log n)$.*

Table 1 Different dynamic algorithms for maintaining out-orientations. We state the bounds in terms of the arboricity α of the graphs, since many of the results referenced do the same.

1.2 Related Work

Dynamic colouring. Barba et al. [6] give algorithms for the dynamic recolouring problem, and show that c-colouring a dynamic forests incurs $\Omega(n^{\frac{1}{c(c-1)}})$ recolourings per update. Solomon & Wein give improved trade-offs between update time and recolourings and give a deterministic dynamic colouring algorithm parametrized by the arboricity α, using $O(\alpha^2 \log n)$ colours with $O(1)$ amortized update time [41]. Henzinger et al. [27] introduced the study of implicit colouring of sparse graphs in order to circumvent the explicit lower bound of Barba et al. [6]; they maintain an implicit colouring using $2^{O(\alpha)}$ colours, with $O(\log^3 n)$ update time and $O(\alpha \log n)$ query-time. Recently, there has also been a lot of work on the dynamic colouring problem parameterised by the maximum degree [9, 10, 28].

Bounded out-degree orientations. Much of the work with respect to bounded out-degree orientations has gone into either 1) statically computing bounded out-degree orientations with the minimum (or close to it) out-degree [21, 37, 11, 1], or 2) dynamically maintaining bounded out-degree orientations with efficient updates [13, 30, 41, 32, 8], but allowing weaker guarantees on the minimum out-degree (see Table 1). Note that the constant of 40 was extracted from an equation in the proof of Lemma 18 (on page 15) in [27]. The current state-of-the-art for exact, static algorithms have running time $\tilde{O}(m^{10/7})$ [34] and $\tilde{O}(m\sqrt{n})$ [33]. Kowalik [31] also gave an algorithm computing a $\lceil(1+\varepsilon)\alpha\rceil$ out-orientation in $\tilde{O}(m \cdot \varepsilon^{-1})$ time.

Arboricity decompositions. A lot of work has been put into producing efficient static algorithms for computing arboricity decompositions [21, 22, 18, 37] (see [12] for an overview). The fastest static algorithm runs in $\tilde{O}(m^{3/2})$ time [21, 22]. Also approximation algorithms have been studied in the static case. There exists a linear-time 2-approximation algorithm [4, 19]. Furthermore, Blumenstock & Fischer provide an algorithm computing a $\lceil(1+\varepsilon)\alpha\rceil+1$ arboricity decomposition in $\tilde{O}(m \cdot \varepsilon^{-1})$ time. Bannerjee et al. [5] provide an $\tilde{O}(m)$ dynamic algorithm maintaining the exact arboricity α of a dynamic graph, and show a lower bound of $\Omega(\log n)$ for dynamically maintaining arboricity. Henzinger et al. [27] provide a dynamic algorithm for maintaining a $2\alpha'$ arboricity decomposition, given access to any black box dynamic α' out-degree orientation algorithm. (See Table 2.)

Other related work. Motivated by the problem of finding a densest subgraph, Sawlani & Wang [39] gave an (implicit) dynamic approximation algorithm for maintaining a $(1+\varepsilon)\rho$ fractional out-degree orientation, where ρ is the maximum subgraph density. In order to tune the parameters in the algorithm, they use multiple (partial) copies of the same graph, where each copy has a different estimate of the maximum density of the graph.

Table 2 Overview of dynamic algorithms for maintaining arboricity decompositions. Note that applying Lemma 27 to Theorem 5 gives an arboricity decomposition, since the orientation is acyclic.

Reference	Forests	Update time	Uses Lemma from [27]	α
Bannerjee et al. [5]	α	$\tilde{O}(m)$	No	adaptive
Brodal & Fagerberg [13]	$4(\alpha+1)$	$O(\alpha+\log n)$ am.	Yes	fixed
Henzinger et al. [27]	80α	$O(\log^2 n)$ am.	Yes	adaptive
New (Thm. 5)	$2(\alpha+1)$	$O(\alpha^2 \log n)$ am.	Uses Lemma 27	fixed
New (Thm. 3)	$\alpha+2$	$O(\text{polylog}\, n)$ am.	No	adaptive

Computing near optimal out-orientations and arboricity decompositions has also been studied from a distributed point of view. Barenboim & Elkin gave a $(2+\varepsilon)$-approximation in [7]. This has since then been improved to $(1+\varepsilon)$-approximations [24, 25, 42, 23].

1.3 Summary of techniques

It is quite simple to compute 2-approximations of arboricity decompositions and bounded out-degree orientations in the static case: It follows from a Theorem of Nash-Williams [36] that a graph with arboricity α is $2\alpha-1$ *degenerate* i.e. every subgraph of the graph has a vertex of degree at most $2\alpha-1$. By continuously removing a vertex with minimum degree and assigning all remaining edges incident to it as out-edges, one obtains an acyclic $(2\alpha-1)$ out-orientation. By partitioning the edges into $2\alpha-1$ partitions s.t. no vertex has two out-edges in the same partition, one obtains a $(2\alpha-1)$-arboricity decomposition.

However, in order to get static algorithms computing close to optimal out-orientations and arboricity decompositions, one typically formulates the problems as combinatorial optimization problems. These can be difficult to approximate – even in the static case, and thus perhaps even more so dynamically. To achieve the low out-orientation algorithm, we build upon a technique of Sawlani & Wang [39]: if one allows edges to be partially assigned to both endpoints, one gets a relaxed version of the out-orientation problem which we will refer to as the *fractional out-orientation problem*. Here edges are assigned partially to both endpoints and one seeks to minimise the maximum *load* of a vertex, where a vertex's load is the sum of the loads contributed by each edge incident to the vertex.

A novelty in our approach lies in what we call *refinements* of fractional orientations: the edges that assign a substantial load to both endpoints form a subgraph – a refinement – of the original graph. We show how to remove cycles from the refinement without changing the loads of any vertices by reassigning edges along cycles. When the refinement is acyclic, the remaining edges have (almost) decided on which endpoint, they prefer. This ensures that we can naively 'round' all of the edges not in the refinement to become out-edges of the vertices they assign the most load. By 2-orienting the refinement, we obtain an algorithm for maintaining an out-orientation with close to the optimal number of out-edges.

Given an α' out-orientation, it is straighforward to split it into α' pseudoforests i.e. graphs where each component has at most one cycle: partition the edges into α' partitions such that no vertex has out-degree more than one in each partition. Every pseudoforest can be represented as a forest and a matching – simply put exactly one edge from each cycle into the matching. Blumenstock & Fischer [12] show that if one chooses the pseudoforests and the representation of the pseudoforsts in a clever way, then the union of all of the matchings form a forest. Thus by combining these techniques one can go from an α' orientation to an $\alpha'+1$ arboricity decomposition.

It is the same idea that underlies our dynamic arboricity decomposition algorithm: we maintain a refinement and a low out-orientation of the remaining edges as before. Then we partition the oriented edges into pseudoforests and finally we alter these pseudoforests and their representations to arrive at a low arboricity decomposition. The key challenge in making this process dynamic is that the altered pseudoforests must be obtainable by partitioning the current out-orientation; otherwise it is unclear how to maintain the pseudoforests as the graph is updated. In order to achieve this, we modify the approach of Blumenstock & Fischer such that the obtained pseudoforests stay faithful to the underlying orientation. However to do so, we have to alter the underlying orientation to accommodate our choice of pseudoforests. To be able to alter the orientation maintained by the out-orientation algorithm, we have to be careful to keep auxiliary datastructures updated and ensure that certain invariants are maintained. To achieve this, we show how to update the datastructures lazily, and we use a potential based argument to show that we can afford to maintain the required invariants.

Paper Outline. In Section 2, we first show how to 2-orient forests and then we recall the techniques of Sawlani & Wang [39] and Kopelowitz et al. [30]. In order to maintain the refinement, we need to represent some parts of the fractional out-orientation implicitly, hence in Section 2 we also make precise exactly how the fractional out-orientation can be accessed. In Section 3 we introduce refinements and show how to maintain them dynamically thus obtaining Theorem 1 and Corollary 2. In Section 4 we show Theorem 3 and Corollary 4. We begin by briefly discussing our approach, before we in Section 4.1 recall the techniques of Henzinger et al. [27] and Blumenstock & Fischer [12]. In Sections 4.2 to 4.7 we describe our new dynamic algorithm for maintaining an arboricity decomposition with close to the optimal number of forests. Finally, Section 5 is dedicated to Theorem 5. Due to space-constraints some proofs are left out (they can be found in the full-version [16]).

2 Preliminaries & Warm-up

Nash-Williams [36] showed that the arboricity α of a graph G satisfies $\alpha = \lceil \max_{J \subset G} \frac{|E(J)|}{|V(J)|-1} \rceil$. The *pseudoarboricity* α_p is the minimum number of pseudoforests that the edges of G can be partitioned into. The *maximum (subgraph) density* or the *fractional pseudoarboricity* ρ is defined as $\rho = \max_{J \subset G} \frac{|E(J)|}{|V(J)|}$. We have $\alpha_p = \lceil \rho \rceil$ [37]. Note that α and α_p are numerically very close, and that $\alpha_p(G)$ is the lowest maximum out-degree achievable when orienting the edges of an undirected graph G [31]. For an undirected graph G and a vertex $v \in V(G)$, we let $d(v)$ be the degree of v and $N(v)$ the neighbourhood of v. If G is directed, $d^+(v)$ denotes the out-degree of v and $N^+(v)$ the out-neighbourhood of v.

Explicit 2-out orientation of dynamic forests. We begin by considering the simpler problem of orienting the edges of dynamic forests so as to minimise the maximum out-degree of vertices. If we want an implicit out-orientation of a dynamic forest H, we can root each tree in H arbitrarily, and get an out-degree of 1 upon query-time using data structures for maintaining information in a dynamic forest (see for example [2, 40]). However, if we want the out-orientation to be explicit, there is a naive lower bound for maintaining a 1-out orientation: Take a path of length n. Deleting the edge between vertex $n/2$ and $n/2 + 1$, yields two sub-paths of length roughly $n/2$. No matter the 1-orientation of these paths, we can reconnect them so as to necessitate $\Omega(n)$ reorientations to restore a 1-orientation. This may be repeated to defy even the hope of an improved amortised analysis.

On the contrary, to obtain a 2-orientation, one can use dynamic heavy path decompositions to obtain an $O(\log(n))$ update time algorithm via orienting light edges towards the root, and heavy edges arbitrarily. For a rooted-tree T, we have the notion of parents and children of the vertices. The *parent* of v is the first vertex from v on the v-to-root path in T. The *children* of v are all neighbours of v that are not the parent of v. A *heavy child* w of v is then a child of v such that the sub-tree of T rooted at w contains more than half of the vertices of the sub-tree rooted at v. The heavy children in T induces *heavy edges* going from a vertex to its heavy child, and *light edges* going from a vertex to its non-heavy children. Every root-to-leaf path then contains at most $O(\log n)$ light edges. The heavy edges form the desired paths, and the light edges can be assigned to the endpoint that is a child of the other endpoint. Sleator and Tarjan [40] showed how to maintain such a heavy-light decomposition in $O(\log n)$ worst case update time, and with $O(1)$ overhead one can keep all light edges oriented towards the root. As such, we have:

▶ **Lemma 6.** *There exists a fully-dynamic algorithm maintaining an explicit 2-out orientation of an n-vertex dynamic forest with $O(\log n)$ worst-case update time.*

Fractional Out-degree Orientations. We will obtain a low-bounded out-degree orientation by deterministically rounding a *fractional out-degree orientation*. Here, the orientation problem is relaxed so that the edges are allowed to be assigned partially to each end-point, and the goal is to compute an orientation such that the maximum total load assigned to a vertex is minimized. A formal definition is as follows:

▶ **Definition 7.** *A* fractional α'-bounded out-degree orientation O *of a graph G is a pair of variables $X_e^u, X_e^v \in [0,1]$ for each edge $e = uv \in E(G)$ s.t. the following holds:*

1. $\forall e = uv \in E(G)$: $X_e^u + X_e^v = 1$
2. $\forall v \in V(G)$: $s(v) = \sum_{e:v\in e} X_e^v \leq \alpha'$

If furthermore $X_e^u, X_e^v \in \gamma^{-1} \cdot \mathbb{Z}$ for all $e \in E(G)$, we say that O is a (γ, α')-orientation.

In particular, an α'-bounded out-degree orientation is just a $(1, \alpha')$-orientation. We think of $s(v)$ as the load on vertex v, and α' as an upper bound on the allowed vertex load. The γ-parameter underlines the fact that we wish to discretise the fractional loads on edges to rational loads. If one does so in a symmetric manner for each edge, one can view a (γ, α')-orientation of a graph G as a $(1, \gamma\alpha')$-orientation of G^γ, where we define G^γ to be G, where every edge is replaced by γ copies. For an edge $e = uv \in E(G)$, we denote by B_e the bundle of γ edges representing e in G^γ. If G^γ is oriented, we denote by B_e^u the bundle of edges oriented $u \to v$. Since the copies of e in B_e are identical, we only care about the size of B_e^u, and not which copies of e it contains. Hence:

▶ **Observation 8.** *For a graph G, there is a natural bijection (up to symmetry) between $(1, \gamma \cdot \alpha')$ orientations of G^γ and (γ, α')-orientations of G.*

In light of this observation, we shall use these two descriptions interchangeably, and in some cases we shall refer to the same orientation as being both a $(1, \gamma\alpha')$-orientation of G^γ and a (γ, α')-orientation of G. We follow the approaches of Sawlani & Wang [39] and Kopelowitz et al. [30], so we repeat the following:

▶ **Definition 9** ([39])**.** *Given a $(1, \alpha')$-orientation of a graph G^γ, we say that an edge $u \to v \in E(G)$ is* η-valid *if $s(u) - s(v) \leq \eta$ and* η-invalid *otherwise. If also $s(v) - s(u) \leq \eta$, we say that $e = uv \in G$ is* doubly η-valid*. Furthermore, if $s(v) - s(u) \leq -\eta/2$ we say that e is an η-tight out-edge of u and an η-tight in-edge of v.*

Note that if $u \to v$ is η-invalid, then $s(u) - s(v) > \eta$ and so $-\eta > s(v) - s(u)$, so uv is η-tight. Note that typically $\eta = 1$.

▶ **Definition 10** ([39] Def. 3.5). *A* maximal η-tight chain from v *is a path of η-tight edges $v_0v_1, \dots v_{k-1}v_k$, such that $v_0 = v$ and v_k has no η-tight out-edges.*

A maximal η-tight chain to v *is a path of η-tight edges $v_0v_1, \dots v_{k-1}v_k$, such that $v_k = v$ and v_0 has no η-tight in-edges.*

▶ **Lemma 11** (Implicit in [39]). *Inserting an η-valid edge oriented $u \to v$ and reorienting a maximal η-tight chain from u will η-invalidate no η-valid edges.*

Deleting an edge oriented $u \to v$ and reorienting a maximal η-tight chain to u will η-invalidate no η-valid edges.

▶ Remark 12. Note that a maximal η-tight chain has length at most $\frac{2 \cdot \max_v s(v)}{\eta}$. Indeed, each time we follow an η-tight out-edge the load on the vertex increases by at least $\eta/2$.

If every edge is η-valid, Sawlani & Wang say that the orientation is *locally η-stable*. Kopelowitz et al. show the following guarantees for locally 1-stable orientations, where we, for ease of notation, define $\Delta^+ := (1+\varepsilon)\alpha\gamma + \log_{(1+\varepsilon)}(n)$:

▶ **Lemma 13** (Implicit in [30]). *If every edge in G^γ is 1-valid, then $\max_v s(v) \leq \Delta^+$.*

Implicit orientations. We are interested in maintaining a fractional out-degree orientation in which the fractional orientation of edges allow us to 'round' the fractional orientation to a low out-degree orientation. We are interested in two properties: first of all the maximum load of a vertex should be low, and second of all many of the edges should have either X_e^u or X_e^v close to 1, so that a naive rounding strategy does not increase the load of a vertex by much. By Lemma 13, if we ensure that the orientation is locally 1-stable, then we get an upper bound on the maximum vertex load. In order to ensure the second property, we redistribute load along cycles without breaking local stability. Our algorithm has two phases. A phase for inserting/deleting edges in a manner that η-invalidates no edges, thus ensuring the first property, and a second phase for redistributing load along edges in order to ensure that the orientation also has the second property. In order for these two phases to work (somewhat) independently, we think of each phase as having implicit access to the orientation; that is the insertion/deletion algorithm might have to pay a query cost in order to identify the precise fractional load of an edge or neighbourhood of a vertex.

▶ **Definition 14.** *An algorithm on an n vertex dynamic and oriented graph has implicit $(|L|, q(n))$ access to an orientation, if it has access to:*

1. *Operations for querying and changing fractional loads of edges in $O(\log n)$ time.*
2. *A query that returns a list containing a superset of all neighbours of a vertex that have changed status as in- or out-neighbour, since the last time the query was called on this vertex. The list should have length $\leq |L|$ and the query should run in $O(q(n))$ time.*

Implicitly Accessing Orientations. In this section, we outline how to modify the algorithm of Kopelowitz et al. [30] to run on G^γ and to support implicit access to the orientation. The ideas presented here are not new; they arise in [30] and [39], but we present them for completeness.

We think of the algorithm as being run on G^γ for some γ to be specified later. We think of each edge $e \in G$ as γ copies in G^γ, but in practice we only store e along with counters $|B_e^u|$, $|B_e^v|$ denoting the number of copies oriented in each direction. Now, we wish to run the

algorithm from [30] in order to insert/delete each copy of an edge one-by-one. This algorithm inserts/deletes a copy of an edge in G^γ using Lemma 11 with $\eta = 1$. We identify a tight chain from u by continuously looking at all out-neighbours and following tight out-edges, until the chain becomes maximal. We use max-heaps, stored at each vertex, to identify maximally tight chains to u. Since we only have implicit access to the orientation, we have to first process the list of possible changes to in- and out-neighbours before trying to identify the next tight edge. Furthermore, when we reorient said chains, we have to access the fractional load of each edge on the chain, before changing it. Hence, we have:

▶ **Theorem 15** (implicit in [30]). *Given implicit $(|L|, q(n))$ access to an orientation with $\max_v s(v) \leq \Delta^+$, there exists an algorithm that can insert and delete edges from the orientation without creating any new 1-invalid edges. The algorithm has worst-case insertion time of $O(\gamma \cdot \Delta^+(\Delta^+ + \log(n)(|L|+1) + q(n)))$ and a worst case deletion time of $O(\gamma \cdot \Delta^+(\log(n)(|L|+1) + q(n)))$.*

▶ Remark 16. Each insertion/deletion of a copy of an edge in G^γ with $\max_v s(v) \leq \Delta^+$ changes the load of at most $O(\Delta^+)$ edges. Indeed, we only change the load of edges on tight chains (and potentially one new edge), so the statement follows from Remark 12.

Scheduling Updates. Some of the algorithms rely on upper bounds on the arboricity. This is, however, not as limiting a factor as one might think, if we are willing to settle for implicit algorithms. In this section we describe how to use the algorithm of Sawlani & Wang [39] to schedule updates to $O(\log n)$ different copies of a graph such that each copy satisfies different density constraints. Here, we describe the main ideas behind the algorithm, and in the appendix of the full version [16], we paraphrase the ideas in more details.

Sawlani & Wang [39] maintain a fractional out-orientation of a graph G by using an algorithm similar to Theorem 15 to insert and delete edges in G^γ. By allowing η to scale with the maximum density ρ of G, they are able to make the update time independent of the actual value of ρ, provided that they have accurate estimates of ρ. By using $O(\log n)$ copies of G – each with different estimates ρ_{est} of ρ, they are able to at all times keep the copy where $\rho_{est} \leq \max_v s(v) < 2\rho_{est}$ fully updated. They call this copy the *active* copy. Similar to Remark 12 they observe that one can safely insert an edge uv in a copy where at least one of $s(u)$ or $s(v)$ is below $2\rho_{est}$. If, however, this is not the case, one cannot afford to update the copy. Sawlani & Wang resolve this issue by scheduling the updates so that they are only performed, when we can afford to do them. We can use this algorithm as a scheduler for our algorithms: We also run our algorithm on $O(\log n)$ copies of G. Whenever the algorithm from Theorem 1.1 in [39] has fully inserted or deleted an edge in a copy, we insert or delete the edge in our corresponding copy. Whenever our algorithm is queried, we then use the structure from the currently active copy to answer the query. Hence, we have:

▶ **Theorem 17** (Implicit in [39] as Theorem 1.1). *There exists a fully dynamic algorithm for scheduling updates that at all times maintains a pointer to a fully-updated copy with estimate ρ_{est} where $(1-\varepsilon)\rho_{est}/2 \leq \alpha(G) < 4\rho_{est}$. Furthermore, the updates are scheduled such that a copy G' with estimate ρ' satisfies $\alpha(G') \leq 4\rho'$. The algorithm has amortised $O(\log^4(n)/\varepsilon^6)$ update times.*

3 Dynamic Low Out-Orientations

In this section, we work towards the second goal: an orientation where many edges assign most of their load to one endpoint. To realise this, we introduce refinements of fractional orientations and show how to dynamically maintain them. The basic idea is to maintain

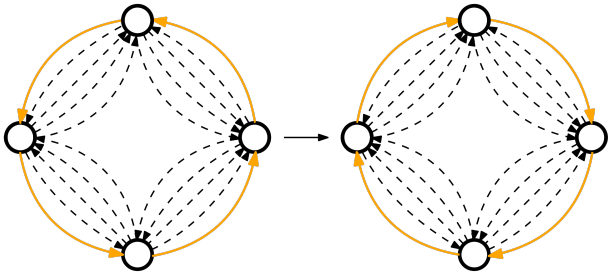

Figure 1 Inverting a cycle. We can reorient copies of edges forming a directed cycle without changing the load of any vertex. By reorienting edges in the refinement, at least one edge on the cycle becomes almost completely oriented towards one endpoint, and hence it can be expelled.

an orientation such that the fractional load of each vertex is small and such that the edges, that distribute their loads somewhat equally between both endpoints, form a forest. This property is nice, if we want to transform our orientation to a bounded out-degree orientation, since all edges outside of the forest almost already have decided on an orientation, and we can 2-orient trees using techniques from Section 2. Definition 18 formalises this idea:

▶ **Definition 18.** *Let O be a (γ, α')-orientation of a graph G. Then H is a (δ, μ)-refinement of G wrt. O if:*

1. $V(H) = V(G)$
2. *For all $e = uv \in E(G) : X_e^u, X_e^v \in (\delta, 1-\delta)$ implies that $e \in H$.*
3. *If $e \in H$, then $X_e^u, X_e^v \in [\delta - \mu, 1 - \delta + \mu]$*

The basic idea behind our algorithm is to maintain a refinement that is a forest. Whenever a cycle C occurs in the refinement, we can redistribute the fractional loads along the cycle so as to not change $s(v)$ for any $v \in C$, but such that an edge of C does not satisfy condition 2. in Definition 18 (see Figure 1). Thus we can remove this edge and again obtain an acyclic refinement with respect to this new orientation. Hence, we have the following observation:

▶ **Observation 19.** *Suppose $1 > \delta > \gamma^{-1} + \mu \geq 2\gamma^{-1} > 0$. Let H be (δ, μ)-refinement of a graph G wrt. some (γ, α')-orientation O of G. Then there exists a (δ, μ)-refinement of G, say H', wrt. some (γ, α')-orientation O' of G, such that H' is a forest.*

Note that if every edge of a graph G is η-valid, then an edge $e = uv \in G$ can only distribute its load somewhat evenly between u and v, if $s(u)$ and $s(v)$ are approximately the same. This implies that e is actually doubly η-valid:

▶ **Observation 20.** *If every edge in G^γ is η-valid, then every edge of a (δ, μ)-refinement H of G with $1 > \delta > \gamma^{-1} + \mu \geq 2\gamma^{-1}$ is doubly η-valid.*

Since the redistribution of fractional load of edges along a cycle does not change the load $s(v)$ of any vertex v, performing the redistribution from Observation 19 η-invalidates no edges.

3.1 The algorithm

As outlined earlier, our algorithm has two phases. In the first phase, we will insert and delete edges without η-invalidating any edges. We do this using the algorithm from Section 2. In the second phase, we examine all of the edges, whose fractional load was altered in phase 1. These edges might need to enter or exit H, depending on their new load. If such an insertion in H creates a unique cycle, we remove it as described in Observation 19. More precisely, the algorithm works as follows:

1. Insert (delete) γ copies of e into G^γ one at a time using a phase I algorithm from Section 2. Whenever a copy of an edge $f \in E(G)$ is reoriented in phase I, we push f onto a stack Q. If e is deleted in G, we also remove e from H.
2. When all γ copies of e are inserted, we set $g = uv = \texttt{pop}(Q)$ and update H as follows until Q is empty:
   - If $g \in H$ and $X_g^u \in (\delta, 1-\delta)$, we update the weight of g in H to match that of G^γ.
   - If $g \in H$ and $X_g^u \notin (\delta, 1-\delta)$, we remove g from H.
   - If $g \notin H$ and $X_g^u \in (\delta, 1-\delta)$, we push g onto a new stack S.
   - If $g \notin H$ and $X_g^u \notin (\delta, 1-\delta)$, we do nothing.
3. After processing all of Q, H together with the edges in S form a (δ, μ)-refinement of G. We now process each edge $h = uv \in S$ as follows:
   - If u, v are not in the same tree in H, we insert h into H.
   - Otherwise, u, v are in a unique cycle C in H. We update the weights along C, locate an edge wz along C with $X_{wz}^w, X_{wz}^z \notin (\delta, 1-\delta)$ and remove it from H. If $uv \neq wz$, we insert uv into H.
   - Finally, we update B_{wz}^w, B_{wz}^z in $G - H$ to match the weights wz had in H.

Since only edges from Q can enter S, we have the following Observation:

▶ **Observation 21.** *Let $S_{\max}$ and $Q_{\max}$ denote the maximum size of the stacks above during an insertion or a deletion. Then we have $S_{\max} \leq Q_{\max} \leq T$, where T is the total number of edges whose fractional orientation are altered during an insertion or a deletion.*

Furthermore, Observations 19 and 20 and Theorem 15 imply the invariants:

▶ **Invariant 22.** *Under the orientation induced by H for edges in $E(H)$ and by $G - H$ for edges in $E(G - H)$, every edge in $E(G)$ is η-valid.*

▶ **Invariant 23.** *H is both a (δ, μ)-refinement and a forest.*

3.2 Implementing updates

Since we maintain the invariant that H is a forest, we can use data structures for maintaining information in fully dynamic forests to store and update H:

▶ **Lemma 24** (Implicit in [2]). *Let F be a dynamic forest in which every edge $e = wz$ is assigned a pair of variables $X_e^w, X_e^z \in [0, 1]$ s.t. $X_e^w + X_e^z = 1$. Then there exists a data structure supporting the following operations, all in $O(\log |F|)$-time:*

- *link$(u, v, X_{uv}^u, X_{uv}^v)$: Add the edge uv to F and set $X_{uv}^u, X_{uv}^v = 1 - X_{uv}^u$ as indicated.*
- *cut(u, v): Remove the edge uv from F.*
- *connected(u, v): Return* true *if u, v are in the same tree, and* false *otherwise.*
- *add_weight(u, v, x): For all edges wz on the path $u \ldots wz \ldots v$ between u and v in F, set $X_{wz}^w = X_{wz}^w + x$ and $X_{wz}^z = X_{wz}^z - x$.*
- *min_weight(u, v): Return the minimum X_{wz}^w s.t. wz is on the path $u \ldots wz \ldots v$ in F.*
- *max_weight(u, v)): Return the maximum X_{wz}^w s.t. wz is on the path $u \ldots wz \ldots v$ in F.*

Note that using non-local search as described in [2], one can also locate the edges of minimum/maximum weight in $O(\log |F|)$-time. The lemma also shows that we can process an edge in Q in $O(\log n)$-time.

▶ **Observation 25.** *We can access and change the fractional load of $e \in H$ in time $O(\log n)$. We can do the same for $e \in G - H$ in $O(1)$ time, since these loads are not stored in top trees.*

To process an edge $uv \in S$ creating a cycle C in the (δ, μ) refinement H, we do as follows. Depending on the argument minimizing $l(C) = \mu + \min\{min\_weight(u,v) - \delta, 1 - \delta - max\_weight(u,v), X^u_{uv} - \delta, 1 - \delta - X^v_{uv}\}$, we either add or subtract $l(C)$ to every edge in C. We determine and remove the edge that minimized $l(C)$ from H. Thus we can process an edge in S in $O(\log n)$-time. Finally, if $\mu > \gamma^{-1}$ then every edge in $S \cup H$ has at least one copy in G^γ pointing in each direction both before and after the inversion of a cycle. Hence, no vertex receives any new in- nor out-neighbours. Since inverting a cycle does not change the load of any vertex, we need not update any priority queues for the insertion/deletion algorithm. Hence, we do not have to return any lists and so $|L| = q(n) = 0$.

3.3 Conclusions

▶ **Theorem 26.** *Suppose $1 > \delta > \gamma^{-1} + \mu > 2\gamma^{-1} > 0$, $\varepsilon > 0$. Then, there exists a dynamic algorithm that maintains a $(\gamma, (1+\varepsilon)\alpha + \gamma^{-1}\log_{(1+\varepsilon)} n)$-orientation of a dynamic graph G with arboricity α as well as a (δ, μ)-refinement H of G wrt. this orientation such that H is a forest. The fractional orientation of an edge can be computed in time $O(\log n)$, insertion takes worst-case $O(\gamma \cdot (\Delta^+)^2)$ time and deletion takes worst-case $O(\gamma \cdot \Delta^+ \cdot \log(n))$ time.*

Proof. Apply Theorem 15 for insertion/deletion. Note that $|L| = 0$ and $q(n) = 0$. The time spent repairing H after each insertion/deletion is in $O(\gamma\Delta^+ \log n)$ by Remark 16 and Observations 21 and 25, since we can process an edge from both Q and S in $O(\log n)$ time. Finally, Observation 20 and the Invariants 22 and 23 show correctness of the algorithm. ◀

Now tuning the parameters of Theorem 26, rounding edges in $G - H$ and 2-orienting H yields Theorem 1. By naively rounding $G - H$ in Theorem 26 and splitting the orientation using Lemma 27, we get an algorithm for dynamically maintaining a decomposition into $\lfloor(1+\varepsilon)\alpha'\rfloor$ pseudoforests and a single forest. Applying the colouring techniques from the full version yields Corollary 2.

4 Forests

We begin this section by outlining the main ideas for turning a dynamic low out-orientation into a dynamic low arboricity decomposition. Given a dynamic α'-bounded out-degree orientation, one can, with very little overhead, split it into α' 1-bounded out-degree orientations using a (slight modification) of an algorithm by Henzinger et al. [27]. Now, given this dynamic pseudoforest partition, we wish to apply the ideas of Blumenstock & Fischer [12] in order to turn the α' pseudoforests into $\alpha' + 1$ forests. The main technical challenge of making this process dynamic is the following: the algorithm from [27] relies heavily on each vertex having out-degree no more than 1 in each pseudoforest. However, the approach of Blumenstock & Fischer [12] is to move edges between pseudoforests, showing no regards as to why an edge was placed in a pseudoforest to begin with. Hence, if one naively applies this approach on top of the pseudoforest partition, one could potentially ruin the invariant that every vertex has out-degree no more than 1 in each pseudoforest, causing the algorithm of Henzinger et al. [27] to fail. We tackle this problem in steps. First, we show that if we were somehow able to invert the orientations of cycles, then we can make the moves of Blumenstock & Fischer's approach *faithful* to the degree condition of the pseudoforest algorithm of Henzinger et al. [27]. If we invert orientations along cycles in the pseudoforests, the out-degree of no vertex in the pseudoforests is changed. However, if we wish to perform these operations, we will have to do it in a manner that still allows us to maintain the underlying α'-bounded out-degree orientation. If the cycles are doubly η-valid, we invert the

cycles using Lemma 24. We do as in Section 3, but this time we add or subtract $1-\delta$ along the cycles. This ensures that every edge on the cycle now prefers the other endpoint, and so is naively rounded to the opposite direction without ending in H. The problem is that we have no guarantee that all edges are doubly η-valid. If an edge is only singly η-valid, then redistributing the load along a cycle containing this edge causes the edge to become invalid. However, by Lemma 11, we can delete such invalid edges and reinsert them again to restore the invariant that all edges are η-valid. We use a potential based argument to show that we can afford to perform these operations.

4.1 Ideas of Henzinger et al. and Blumenstock & Fischer

An α'-bounded out-degree orientation, can be split into α' pseudoforests by partitioning the edges such that each vertex has out-degree at most one in each partition. Then every connected component P_C in a partition is a pseudoforest. Indeed, $|E(P_C)| \leq |P_C|$ since every vertex has out-degree at most one. Hence, there can be at most one cycle in P_C. This idea is implicit in [27] by Henzinger et al. Note that we can store each pseudotree as a top tree with one extra edge with only $O(\log n)$ overhead per operation.

▶ **Lemma 27** (Implicit in [27]). *Given black box access to an algorithm maintaining an α'-bounded out-degree with update time $T(n)$, there exist an algorithm maintaining an α' pseudoforest decomposition with update time $O(T(n))$.*

Using the ideas of Blumenstock & Fischer [12], we can represent a pseudoforest P by a pair (F, M) s.t. F is a forest and M is matching, by adding exactly one edge from each cycle in P to M. Similarly, we can represent a partition of $E(G)$ into pseudoforests $(P_1, \ldots, P_k)$ by a pair (F, M) s.t. $F = \cup F_i$ and $M = \cup M_i$ and (F_i, M_i) represents P_i for all i.

In order to ensure the guarantees of Lemma 27, we need to maintain the invariant that every vertex has out-degree at most one in every pseudoforest. If this is the case, we say that the partition is *faithful* to the underlying orientation. Blumenstock & Fischer [12] perform operations on $G[M]$ in order to turn it into a forest. They call $G[M]$ the *surplus graph*. Some of the operations they perform, are described in the following lemma:

▶ **Lemma 28** (Implicit in [12]). *Let (F, M) be a faithful representation of a pseudoforest partition of a simple graph G equipped with an α'-bounded out-degree orientation. If $uv \in M_i$ and $vw \in M_j$ with $i \neq j$, then there exists an α'-bounded out-degree orientation with respect to which the partition gained by swapping $P_i \leftarrow P_i \cup \{vw\} - \{uv\}$ and $P_j \leftarrow P_j \cup \{uv\} - \{vw\}$ yields a faithful partition, and $uv \in M_j$ resp. $vw \in M_i$ iff. uv resp. vw are on the uni-cycle in their new pseudoforests.*

Furthermore, if $wx \in M_i$ for some x, then vw is not on a uni-cycle in P_i.

Proof. See [12] Lemma 2. To modify the orientation to accommodate the swaps, note that we can always reverse the direction of at most two cycles, without changing the out-degree of any vertex, such that both of the edges swapped are out-edges of v. Now swapping the two out-edges ensures that the partition stays faithful to the orientation (see Figure 2). ◀

Following Blumenstock & Fischer we note that if $e_1, \ldots, e_k$ is a path in a surplus graph $G[M]$ such that e_1 and e_k belong to the same matching M_i, then we can use the moves from Lemma 28 to restore colourfulness (see [12] Lemma 3). The key is that we can move the other edge in M_i towards e_1, and then after $O(k)$ switches, we are sure to end up in the furthermore part of Lemma 28. If a surplus graph contains no such paths, Blumenstock & Fischer say it is a *colourful* surplus graph. They show the following Lemma:

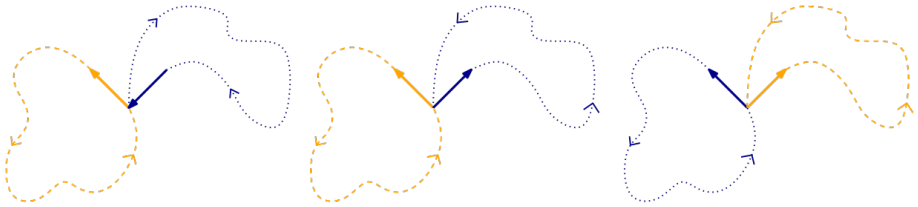

Figure 2 Moving edges between pseudoforests (represented by colour). Before performing the swap, we reorient a cycle so that the swapped edges are out-edges of their common endpoint. This ensures that every vertex has out-degree at most one in each pseudoforest.

▶ **Lemma 29** ([12]). *Suppose J is a colourful component of the surplus graph $G[M]$ of a graph G. Then for all $v \in J$ there exists an index i s.t. $N_{F_i}(v) \cap J = \emptyset$ and $J \cap M_i \neq \emptyset$.*

These Lemmas motivate the following approach: use Lemma 28 to ensure that the surplus graph is always colourful. Next use Lemma 28 to remove any cycles from the surplus graph.

4.2 Our algorithm for maintaining dynamic arboricity decompositions

Assume that we have an upper bound α_{max} on the arboricity throughout the entire update sequence. The algorithm works roughly as follows:

1. Run the algorithm from Theorem 26.
2. Naively round the orientation of each edge in $G - H$.
3. Split the rounded out-degree orientation on $G - H$ into pseudoforests.
4. Whenever an edge enters or moves between pseudoforests, we push it to a queue R.

We process each edge in $e \in R$ as follows: Put e into a pseudoforest. If e completes a cycle in a pseudoforest add it to $G[M]$. When e enters $G[M]$, we determine if it sits in a colourful component. If it doesn't, we apply Lemma 28 until all components in $G[M]$ are colourful. If a non-doubly valid cycle is reoriented in this process, we remove the singly-valid edges from the pseudoforests and add them to R. This ensures that the two edges from the same matching that we were trying to separate into two different components, are indeed separated. We will later bound the total number of edges pushed to R. If, on the other hand, the component is colourful, e may sit in a cyclic component. Then we apply Lemma 29 to remove the unique cycle. This may create a new non-colourful component, which we handle as before.

In the following, we describe the necessary data structures and sub-routines needed to perform these operations.

4.3 Operations on the surplus graph

In this section, we assume all cycles are doubly η-valid. In Section 4.5, we handle cases where this is not the case. Assuming that $G[M]$ is both colourful and acyclic, we can insert an edge in $G[M]$ and restore these invariants by performing switches according to Lemmas 28 and 29. Indeed, after inserting an edge, we can run, for example, a DFS on the component in $G[M]$ to determine if it is colourful. If it is not, we locate a path $e_1, \ldots, e_k$ such that $e_1, e_k \in M_i$. Then we apply Lemma 28 to e_{i-1} and e_i beginning with $i = k$, until an edge from M_i is removed from $G[M]$. Note that this is certain to happen when e_1 and e_3 belong to the same pseudoforest. We continue locating and handling paths until the component becomes colourful. If the component is colourful, but not acyclic, we choose a vertex v on the cycle and apply Lemma 29 to determine a pseudoforest represented in the component in which v is connected to no other vertex in the cyclic component. Then we determine a path

in the surplus graph between an edge in said pseudoforest and v. Now we move the edge in this pseudoforest to v using Lemma 28. If the edge is removed from $G[M]$ or the path is disconnected, we repeat the process. When such an edge is incident to v, we switch it with an edge on the cycle. Finally, we replace it in M with the unique neighbouring edge that is also incident to v in the cycle that put it in M. Now $G[M]$ is acyclic, but it may not be colourful. If this it the case, we repeat the arguments above until it becomes colourful. Note that these moves never create a cycle.

▶ **Lemma 30.** *After inserting an edge into $G[M]$, we can restore acyclicity and colourfulness in $O(\alpha^3 \log^2(n))$ time.*

4.4 Recovering neighbours

For each vertex, we will lazily maintain which of its out-edges belong to which pseudoforest. This costs only $O(1)$ overhead, when actually moving said edges. However, whenever we invert a cycle, these edges may change. Since the cycles can be long, we can only afford to update this information lazily, whenever the insertion/deletion algorithm determines the new out-neighbours of a vertex. When this happens, we say the vertex is *accessed*. Whenever an edge has its fractional load changed via a cycle inversion, it is always changed by the same amount. Hence, we make the following observation:

▶ **Observation 31.** *Between two accesses of a vertex v, the only possible new in-neighbours are the edges which were out-neighbours at the last access of v, and the only new out-neighbours are the vertices that are out-neighbours at the current access of v.*

Thus, we can recover exactly which incident edges might have changed in- and/or out-neighbour status from v, since the last time v was accessed by the insertion/deletion algorithm. To do so, we maintain that each top tree is rooted in the unique vertex, which has out-degree 0, when the underlying orientation is restricted to the tree. This ensures that we can recover v's unique out-edge in a pseudoforest by finding the first edge on the unique v-to-root path in the top tree. We maintain this information as follows:

- When we $link(u, v)$ with an edge oriented $u \to v$, we set the root of the new tree to be that of the tree containing v.
- When we $cut(u, v)$ with an edge oriented $u \to v$, we set the root of the tree containing u to be u and that containing v to be the same as the old tree.
- When we invert the orientation along a cycle originally oriented $u \to v \to \cdots \to u$, we change the root from v to u.
- When we perform a Lemma 29 swap, we also update the root accordingly.

Note that each update is accompanied by an operation costing $O(\log n)$ time, so the overhead for maintaining this information is only $O(1)$. With this information, we can recover the old out-neighbours as the stored out-neighbours, and the new out-neighbours by taking the first edge on the path from v to the root. Hence, we have shown:

▶ **Lemma 32.** *We can supply each vertex with a query returning a list L of neighbours which might have their status changed in time $O(\alpha \log n)$. Furthermore, $|L| = O(\alpha)$.*

4.5 Non doubly η-valid cycles

If a cycle is not doubly η-invalid, we still switch the orientation as before, but now we have to fix invalid edges. Assuming we know which edges have become η-invalidated, we fix them as follows: For every invalid edge, we first remove the edge from the pseudoforest it resides in.

This has two consequences. Firstly, the algorithm from Lemma 27 might move $O(1)$ edges between pseudoforests, and secondly, we also have to move an edge from the surplus graph back down as a normal edge in the pseudoforest it comes from. All of the (re)moved edges are pushed to the queue R. Then, we delete all invalid copies of edges in G^γ, and reinsert them. Now, all edges are valid again, and so we continue processing edges in R as described in Section 4.2. If an edge now belongs to H, we do not insert it into any pseudoforest.

It is important to note that the second consequence i.e. that we remove an edge from $G[M]$, either makes a Lemma 28 switch successful by removing one of the edges from M_i, or it removes an edge on one of the at most two paths between edges in M_i. In this case, we try to locate a second path, and handle it as before. This happens at most once: the component has at most one cycle, and hence at most two paths between two vertices. We ascribe the cost of deleting and reinserting invalid edges to the potential in Lemma 33 that bounds the total number of copies of edges that are inserted into G^γ. This cost is not ascribed to the algorithm maintaining $G[M]$. Set $\Delta^+_{max} = (1+\varepsilon)\alpha_{max}\gamma + \log_{(1+\varepsilon)} n$, we have:

▶ **Lemma 33.** *The total amount of insertions and deletions performed by the insertion / deletion algorithm over the entire update sequence is in* $O(\frac{\gamma\Delta^+_{max}}{\eta}(\Delta^+_{max} \cdot i + d))$

Lemma 33 allows us to bound the total number of edges moved between pseudoforests:

▶ **Lemma 34.** *We move at most* $O(\frac{\gamma(\Delta^+_{max})^3}{\eta}(i+d))$ *edges between pseudoforests.*

Note that this implies that the total no. of insertions into R is $O(\frac{\gamma(\Delta^+_{max})^3}{\eta}(i+d))$.

4.6 Locating singly η-valid edges

When we are accessing an edge, we can check if it is doubly η-valid or not (this information depends only on the load on the endpoints), and maintain this information in a dynamic forest using just 1 bit of information per edge. This allows us to later locate these edges using non-local searches in top trees. However, when edges go between being singly η-valid and doubly η-valid through operations not accessing said edge, we are not able to maintain this information. This can happen in two ways: either 1) a vertex has its load lowered causing an in-going edge to now become doubly η-valid or an outgoing edge to become singly η-valid or 2) a vertex has its load increased causing similar issues. We say an edge is *clean* if we updated the validity bit of an edge, the last time the out-degree of an endpoint of the edge was altered. Otherwise, we say it is *dirty*. Now if all edges on a cycle are clean, we can use top trees to direct searches for the edges that become invalidated by inverting the cycle.

We maintain a heavy-light decomposition of every forest using dynamic st-trees [40] to help us ensure that we can clean all edges in a cycle in time $O(\log^2 n)$. The idea is to maintain the invariant that all heavy edges are clean. Now we can clean a cycle by cleaning the at most $O(\log n)$ light edges on said cycle. In order to realise this invariant, whenever the degree of a vertex is changed, we need to update all of its incident heavy edges in all of the heavy-light decompositions. Since a vertex is incident to at most two heavy edges in each forest, we have to update $O(\alpha)$ heavy edges. The following holds:

▶ **Observation 35.** *We can locate singly η-valid edges on a clean cycle in time $O(\log n)$ per edge, if we spend $O(\log n)$ overhead updating the bit indicating double validity.*

▶ **Observation 36.** *We can insert and delete edges in the heavy-light decomposition in worst case $O(\log^2 n)$ time.*

▶ **Lemma 37.** *We can check if a cycle is doubly valid in time $O(\log^2 n)$.*

4.7 Conclusion

Theorem 3 and Corollary 4 follow from Lemma 38 (see full version for details).

▶ **Lemma 38.** *Consider a sequence of updates with i insertions and d deletions.*

1. *The insertion/deletion algorithm spends $O(\log^6(n) \cdot \alpha_{max}^4 \cdot \varepsilon^{-12}(i+d))$ time to update the fractional out-degree orientation and the refinement.*
2. *The algorithm maintaining the pseudoforests spends $O(\log^6(n) \cdot \alpha_{max}^3 \cdot \varepsilon^{-8}(i+d))$ time.*
3. *The algorithm maintaining the surplus graph spends $O(\log^6(n) \cdot \alpha_{max}^6 \cdot \varepsilon^{-8}(i+d))$ time.*

We have shown how to maintain an $\alpha+2$ arboricity decomposition of a fully dynamic graph as it undergoes an arboricity α preserving sequence of updates in $\text{poly}(\log n, \alpha)$ time per update. We have also shown how to maintain an $\lfloor(1+\varepsilon)\alpha\rfloor+2$ out-orientation of a fully dynamic graph in $\text{poly}(\log n, \alpha)$ time per update. These algorithms are the first dynamic algorithms to go below 2α forests and out-edges, respectively, and the number of forests matches the best near-linear static algorithm by Blumenstock and Fischer [12]. We apply these algorithms to get new trade-offs for implicit colouring algorithms for bounded arboricity graphs. In particular, we maintain $4 \cdot 2^\alpha$ and $2 \cdot 3^\alpha$ implicit colourings in $\text{poly}(\log n, \alpha)$ time per update. This improves upon the $2^{40\alpha}$ colours of the previous most colour-efficient algorithm maintaining $\text{poly}(\log n, \alpha)$ update time [27]. In particular, this reduces the number of colours for planar graphs from 2^{120} to 32. An interesting direction for future work is to see, if one can reduce the number of forests even further in the static case, while still achieving near-linear running time. Also, even though our algorithms use few colours and forests, the update times contain quite high polynomials in both $\log n$ and α. Is it possible to get more efficient update times without using more forests? Finally, for constant α, we get $\alpha+2$ out-edges. Brodal & Fagerberg [13] showed that one cannot get α out-edges with faster than $\Omega(n)$ update time (even amortised). The question remains, can one get $\alpha+1$?

5 Acyclic Orientations and Arboricity Decompositions

In this section, we briefly sketch the algorithm in Theorem 5 (Note that this section is partially based on the master's thesis by Christiansen [15, Chapter 9], see the full version for proofs). We modify an algorithm by Brodal & Fagerberg [13]. Specifically, we change how an edge is inserted. The algorithm maintains a list of out-edges $\text{out}(u)$ for each vertex $u \in G$. An edge e is in $\text{out}(u)$ if and only if $e \in E(G)$ and e is oriented away from u. As a result $d^+(u) = |\text{out}(u)|$. All of these lists are initialized to be empty. The algorithm ensures that the maximum out-degree of the vertices in G is d for some constant $d > 2\alpha$ to be specified later. The algorithm handles deletions and insertions in the following way:

Deletion: If e incident to x, y is deleted, we search $\text{out}(x)$ and $\text{out}(y)$ for e, and delete it.

Insertion: When an edge e is inserted, an arbitrary endpoint u of e is chosen, and e is added to $\text{out}(u)$. Now every edge in $\text{out}(u)$ is oriented in the other direction (also e) i.e. we delete $f = (u, v)$ from $\text{out}(u)$ and add f to $\text{out}(v)$ instead for all edges $f \in \text{out}(u)$. Now u has out-degree at most d, but the reorientations of an edge $f = (u, v)$ might increase $|\text{out}(v)|$ above d. The algorithm then proceeds by reorienting all out-edges out of v. It continues this process until all vertices have out-degree at most d.

Note that this process terminates: Since G has arboricity α, it has an orientation O such that the maximum out-degree in G is α. Call an edge in $E(G)$ *good*, if it is oriented the same way by both the algorithm and O and *bad* if it isn't. Now, inserting e could, in the worst case, make the algorithm change the orientation of α good edges. However from here on,

every vertex whose edges are reoriented will increase the total number of good edges by at least $d - 2\alpha \geq 1$, so the process terminates. The algorithm differs from the one presented in [13] in only one way. When an edge $e = uv$ is inserted, we always turn u into a sink. In [13], this only happens if u's out-degree increases above d. This small modification ensures no cycles are created: when an edge is inserted, one of its endpoints is turned into a sink, and so this edge is in no cycle. Also, turning a vertex into a sink does not create any cycles.

Abstract

Cohen, Peri and Ta-Shma [11] considered the following question: Assume the vertices of an expander graph are labelled by ± 1. What "test" functions $f : \{\pm 1\}^t \to \{\pm 1\}$ can or cannot distinguish t independent samples from those obtained by a random walk? [11] considered only balanced labellings, and proved that for all symmetric functions the distinguishability goes down to zero with the spectral gap λ of the expander G. In addition, [11] show that functions computable by AC^0 circuits are fooled by expanders with vanishing spectral expansion.

We continue the study of this question. We generalize the result to all labelling, not merely balanced ones. We also improve the upper bound on the error of symmetric functions. More importantly, we give a matching lower bound and show a symmetric function with distinguishability going down to zero with λ but not with t. Moreover, we prove a lower bound on the error of functions in AC^0 in particular, we prove that a random walk on expanders with constant spectral gap does not fool AC^0.

1 Introduction

Expanders are sparse undirected graphs that have many desirable pseudorandom properties. A formal definition can be given in several equivalent ways and here we consider the algebraic definition where an undirected graph $G = (V, E)$ is a λ-*spectral expander* if the second largest eigenvalue of its normalized adjacency matrix M is bounded above by λ. For simplicity, we only consider regular graphs, in which case M is also the random walk matrix of G. Expander graphs are among the most useful combinatorial objects in theoretical computer science, pivotal in derandomization [18, 29], complexity theory [37, 1, 12] and coding theory [32, 22, 33, 13] to name a few. Many works in the literature have studied explicit constructions of expander graphs (see, e.g., [24, 25, 7, 30, 6, 26]) and utilized their pseudorandom properties. We refer the reader to the excellent expositions [17, 35] and to Chapter 4 of [36].

Expanders can be thought of as spectral sparsifiers of the clique. Let $\mathbf{J}$ be the normalized adjacency matrix of the n-vertex complete graph with self-loops, i.e., the $n \times n$ matrix with all entries equal to $\frac{1}{n}$. One can express the normalized adjacency matrix M of G as $M = (1-\lambda)\mathbf{J} + \lambda E$ for some operator E with spectral norm bounded by 1. As such, one can hope to substitute a sample of two *independent* vertices with the "cheaper" process of sampling an edge from an expander and using its two (highly correlated) end-points. This is captured, e.g., by the expander mixing lemma [2]. This idea also appears in many derandomization results, [18, 3, 28, 29, 31, 9].

A useful generalization of the above is to consider not just an edge but rather a length $t-1$ random walk (where the length is measured in edges) on the expander as a replacement to t independent samples of vertices. For concreteness, consider a labelling $\mathsf{val} : V \to \{\pm 1\}$ of the vertices with mean $\mu = \mathbf{E}[\mathsf{val}(V)]$. Quite a lot is known about random walks on expanders. Next, we elaborate on the hitting property of expanders [1, 10, 19, 5] as well as the expander Chernoff bound [1, 10, 19, 14, 16].

The hitting property states that for every set $A \subset V$, a length $t-1$ random walk is contained in A with probability at most $(\mu + \lambda)^t$. For $\lambda \ll \mu$, this bound is close to μ^t - the probability of the event with respect to t independent samples. The expander hitting property corresponds to a random walk "fooling" the AND function, that is, for every λ-spectral expander and every labelling val as above, the AND function cannot distinguish with good probability labels obtained by t independent samples from labels obtained by taking a length $t-1$ random walk. The fundamental expander Chernoff bound states that the number of vertices in A visited by a random walk is highly concentrated around its measure $|A|/|V|$. The expander Chernoff bound corresponds to fooling functions indicating whether the normalized Hamming weight of the input is concentrated around some number μ. Perhaps surprisingly, it was shown that even the highly sensitive PARITY function is fooled by a random walk on expanders (this was noted independently by Alon in 1993 for arbitrarily long walks, Wigderson and Rozenman in 2004 for length 1 walks, and [33] where the result appears).

Sometimes a random walk *is not* a good replacement to independent samples. To see this, suppose G is a λ-spectral expander for some constant λ, that has a cut $A \subset V$ with $|A| = \frac{|V|}{2}$ and $|E(A, \overline{A})| \geqslant \mu|A|$ for $\mu \geqslant \frac{1}{2} + \widetilde{\Omega}(\lambda)$. Such graphs exist (see [15, Section 7]). If one samples t independent vertices $(v_1, \ldots, v_t)$ from the graph, we expect (v_i, v_{i+1}) to cross the cut about half the time, and by the Chernoff bound the actual number of cut crossings is highly concentrated around the mean. In contrast, when we take a random walk on the graph we expect to cross the cut a μ-fraction of the time, and intuitively the number of cut

crossings should be concentrated around μ.[1] Thus, the simple test function that counts the number of times we cross the cut and apply a threshold at $\frac{1}{2} + \tau$ for some $\tau = \widetilde{\Theta}(\lambda)$ should distinguish with probability close to 1 between a random walk and independent samples.

This brings to the forefront a natural question that was recently raised by [11] (see also the work of Guruswami and Kumar [15] who considered a related question).

What test functions does a random walk on an expander fool?

Formally, we compare two distributions on the set $\{\pm 1\}^t$. The first "ideal" distribution is obtained by sampling independently and uniformly at random t vertices $v_1, \ldots, v_t$ and returning $(\mathsf{val}(v_1), \ldots, \mathsf{val}(v_t))$. If we let $\mu = \mathbf{E}[\mathsf{val}(V)]$, the latter induces the distribution U_t^μ in which the t bits are independent and each has mean μ. The second distribution, denoted by $\mathrm{RW}_{G,\mathsf{val}}$, is obtained by taking a length $t-1$ random walk on the graph, namely, sample v_1 uniformly at random from V, and then for $i = 2, 3, \ldots, t$, sample v_i uniformly at random from the set of neighbors of v_{i-1}, and return $(\mathsf{val}(v_1), \ldots, \mathsf{val}(v_t))$. Denote

$$\mathcal{E}_{G,\mathsf{val}}(f) = \left|\mathbf{E}\, f(\mathrm{RW}_{G,\mathsf{val}}) - \mathbf{E}\, f(U_t^\mu)\right|.$$

Informally, $\mathcal{E}_{G,\mathsf{val}}(f)$ measures the distinguishability between these two distributions as observed by the test function f on the graph G with respect to the labelling val. We wish to have a discussion that holds uniformly on all λ-spectral expanders (on any number of vertices) and for every labelling. The bound, however, is expected to depend on the expectation μ of the labelling. We denote by $\mathcal{E}_{\lambda,\mu}(f)$ the supremum of $\mathcal{E}_{G,\mathsf{val}}(f)$ over all λ-spectral expanders G, on any number of vertices, and all labelling functions $\mathsf{val} : V \to \{\pm 1\}$ with $\mathbf{E}[\mathsf{val}(V)] = \mu$.

The work [11] focuses on the case $\mu = 0$. One result shows that

$$\mathcal{E}_{\lambda,0}(\mathsf{MAJ}) \leqslant O\left(\frac{\lambda^2}{\sqrt{t}}\right) \tag{1.1}$$

Their main result states that for each balanced labelling, for every symmetric function $f : \{\pm 1\}^t \to \{\pm 1\}$,

$$\mathcal{E}_{\lambda,0}(f) = O(\lambda \cdot \log^{3/2}(1/\lambda)). \tag{1.2}$$

This readily implies, for the specific case of balanced labelling, a central limit theorem with respect to the total variation distance, that vanishes as $\lambda \to 0$, thus strengthens previous results that considered the Kolmogorov distance [20, 23, 21] instead of the total variation distance.

To summarize the state of knowledge so far:

- Every symmetric function is fooled with error probability going down to zero with the spectral gap λ (see Equation (1.2)), where $\mu = 0$.
- The MAJ function is fooled with error probability going down to zero with t even when λ is fixed (see Equation (1.1)); and,
- The PARITY, AND, OR functions are fooled with error probability going down to zero *exponentially* fast with t even when λ is fixed.

Accordingly, let us say an error function vanishes with λ, if the error function is vanishing as $\lambda \to 0$. Similarly, we say an error function vanishes with t, if for some fixed $\lambda \geqslant 0$, it is going down to zero together with t.

[1] To show such a concentration one needs to invoke a Chernoff bound for a walk on the corresponding directed line graph.

[11] further considers non-symmetric functions. In particular, they analyze test functions that are computable by AC^0 circuits and prove that if f is computable by a size-s depth-d circuit then

$$\mathcal{E}_{\lambda,0}(f) = O(\sqrt{\lambda} \cdot (\log s)^{2(d-1)}). \tag{1.3}$$

Thus, for balanced labelling, every test function in AC^0 cannot distinguish t independent labels from those obtained by a random walk on a λ-spectral expander provided λ is taken sufficiently small. This result can be thought of as an analog of Braverman's celebrated result [8] (see also [34]) that studies the pseudorandomness of k-wise independent distributions with respect to AC^0 test functions. However, for it to be meaningful, the spectral gap λ should be small.

1.1 Our contribution

The work of [11] leaves several open problems. First, and foremost, while [11] show the error function of any symmetric function vanishes with λ, it leaves open the possibility that a better convegence exists and, perhaps, the error function of any symmetric function vanishes with t, i.e., for some fixed λ, the error function goes down to zero together with the walk length t. Indeed, this is the case with the AND, OR and PARITY functions, where the error vanishes exponentially fast with t, and the MAJ function where the error goes down polynomially in t (see Equation (1.1)). Similarly, one may ask whether the error of AC^0 functions decays faster than Equation (1.3) and allows for larger spectral gaps λ then dictated by the above bound.

Our first result is that there exists a symmetric function for which the error function does not vanish with t:

▶ **Theorem 1.** *There exists a family of symmetric functions $(f_t)_{t\in\mathbb{N}}$ where $f_t : \{\pm1\}^t \to \{\pm1\}$ such that for every λ there is a λ-spectral expander $G = (V, E)$, and a labelling $\mathsf{val} : V \to \{\pm1\}$ with $\mathbf{E}[\mathsf{val}(V)] = 0$, such that for all t, $\mathcal{E}_{G,\mathsf{val}}(f_t) = \Omega(\lambda)$.*

To explain how we obtain such a lower bound on a function f, we first review how [11] obtained their upper bound. The key idea in [11] is to expand the test function f under consideration in the Fourier basis. The question of fooling general test functions then reduces to the study of test functions that are Fourier characters. Now, let G denote the adjacency matrix of the graph (i.e, $M = \frac{1}{d}G$). Also, for a labelling $\ell : V \to \{\pm1\}$ let us denote by P the diagonal matrix with $\ell(i)$ in the i'th element on the diagonal. One can check that for the parity function $\chi_{[t]} : \{\pm1\}^t \to \{\pm1\}$, $\chi_{[t]}(x) = \prod_{i=1}^t x_i$, we get $\mathbf{E}[\chi_{[t]}(\mathrm{RW}_{G,\mathsf{val}})] = \mathbf{1}^T \left(\prod_{i=1}^t PG\right) \mathbf{1},$, where $\mathbf{1} = (\frac{1}{\sqrt{n}}, \ldots, \frac{1}{\sqrt{n}})$.

In general,

$$\mathbf{E}[\chi_S(\mathrm{RW}_{G,\mathsf{val}})] = \mathbf{1}^T \left(\prod_{i=1}^t P^{\delta_S(i)} G\right) \mathbf{1}, \tag{1.4}$$

where $\delta_S(i)$ is 1 if $i \in S$ an 0 otherwise. In [11] it is shown how to upper bound this expression for any λ-expander G and μ-biased function val.

For the proof of Theorem 1 we choose a λ-expander G and a labelling function val such that we can *exactly* express Equation (1.4) in terms of λ, S. To do so, we first choose G to be a Cayley graph over an Abelian group, and we use the fact that the eigenvectors of such a graph correspond to the characteristic functions of the underlying group, regardless of

the set of generators used. One disadvantage in choosing a Cayley graph over an Abelian group is that it cannot give constant degree exapnders, though this is not a concern to us because with logarithmic degree we can have vanishing second eigenvalue. Next, we choose the underlying group to be $\mathbb{Z}_2^n$. This guarantees that the characteristic functions of $\mathbb{Z}_2^n$, and therefore also all the entries in all eigenvectors, are Boolean, i.e., either 1 or -1. Finally, we choose the labelling function val to correspond to the entries of the eigenvalue with the second largest eigenvalue.

The above choices guarantee that $P\mathbf{1} = v_2$ and $Pv_2 = \mathbf{1}$ (because $P^2 = I$). Also $G\mathbf{1} = \mathbf{1}$ and $Gv_2 = \lambda v_2$. It follows that no matter what S is, $\left(\prod_{i=1}^{t} P^{\delta_S(i)} G\right)\mathbf{1}$ belongs to the two dimensional subspace $\mathrm{Span}\,(\mathbf{1}, v_2)$ and, furthermore, has a closed expression as a function of t, λ and S.

We finally choose a function f for which we can estimate the expression we get. We choose f to have high mass on its second Fourier level. It turns out that we can take f to be, e.g., the threshold function that returns one if the number of ones exceeds the mean by one standard deviation, and this function has error function that is of the order λ, and, therefore, in particular, vanishes with λ but not with t. It is interesting to note that, in contrast, the MAJ function, that has threshold at the mean, vanishes with t.

Next, using the same graph and labelling we also prove that constant spectral expansion does not suffice to fool AC^0 circuits. In fact, the bound obtained by [11] is tight up to a polynomial. Let $\mathsf{AC}(d)$ denote the class of all languages with polynomial size boolean circuit of depth at most d. Then:

▶ **Theorem 2.** *There exists a constant $\varepsilon > 0$ such that the following holds. For every integer $d \geqslant 3$ there exist $t_d, c_d \in \mathbb{N}$, and a family of functions $(h_t)_{t_d \leqslant t \in \mathbb{N}} \subset \mathsf{AC}(d)$ such that the following holds. For every $\lambda \geqslant \frac{c_d}{\log^{d-2} t}$ there is a λ-spectral expander $G = (V, E)$ and a labelling $\mathsf{val} : V \to \{\pm 1\}$ with $\mathbf{E}[\mathsf{val}(V)] = 0$ such that $\mathcal{E}_{G,\mathsf{val}}(h_t) \geqslant \varepsilon$.*

The choice of function f here is more complicated. The key idea is that two adjacent bits obtained by such a random walk are λ correlated. Thus, evaluating a function f on the parity of consecutive bits obtained by a random walk is the same as applying the noise operator $T_\lambda(f)$ (see Claim 17 for an exact statement). Having this key fact, we construct small depth functions that are highly sensitive to small noise. We first start with the Tribes function composed with XOR on two adjacent bits. This gives a function in $\mathsf{AC}(3)$ with large distinguishability. We then give a recursive construction of a family of functions $h_d \in \mathsf{AC}(d+1)$ for every d, where in each step we increase the depth by one and the noise sensitivity of h_d by a logarithmic factor. This gives the desired dependence of $\mathcal{E}_{G,\mathsf{val}}(h_d)$ on d.

Finally, we also tighten and simplify the upper bounds given in [11]. We prove:

▶ **Theorem 3.** *For every symmetric function $f : \{\pm 1\}^t \to \{\pm 1\}$, all $\mu \in (-1, 1)$ and $0 < \lambda < \frac{1-|\mu|}{128e}$ it holds that*

$$\mathcal{E}_{\lambda,\mu}(f) \leqslant \frac{124}{\sqrt{1-|\mu|}} \cdot \lambda.$$

Theorem 3 improves upon the corresponding theorem in [11] in two ways:

1. First, the results in [11] are obtained only for balanced test functions f. In contrast, Theorem 3 holds for every test function f with arbitrary bias μ.
2. Second, the bound stated in Theorem 3 improves upon the bound in Equation (1.2) by removing the $\log^{3/2}(1/\lambda)$ factor.

The extension of the results of [11] to arbitrary bias μ is obtained by modifying the Fourier basis we work with. For a given bias μ we choose a basis that consists of $\prod_{i \in S} \frac{x_i - \mu}{\sqrt{1-\mu^2}}$ for all $S \subseteq [t]$. The improvement of the poly-logarithmic factor is achieved by using a more direct Fourier analysis argument. The proof strategy of [11] is to bound the error of weight indicator functions, and use it to handle weights around the mean. Then the argument invokes the expander Chernoff bound for bounding the remaining weights. Our approach does not go through analyzing weight indicator functions nor it uses the expander Chernoff bound. Instead, we use a very simple bound on the Fourier mass of symmetric functions, which gives a simpler and better analysis.

1.2 Open problems

We conclude the introduction with several open problems that follow from our work.

1. Can one combine the distribution obtained by a random walk on an expander with another pseudorandom distribution to obtain stronger results for functions in AC^0. For example, does permuting the values of the random walk with a pairwise independent permutation yields a distribution that better fools AC^0?
2. As explained before, our lower bounds are obtained for a graph G that is a Cayley graph over an Abelian group. It is well-known that such a Cayley graph with constant expansion gap, has degree that depends on the number of vertices. Thus, a natural question is whether we can give similar lower bounds for constant degree graphs.
3. Continuing this line of thought, it is still possible that there is a family of graphs that fools all symmetric functions with error going down to zero with t. I.e., that while for some graphs (like Cayley graphs over $\mathbb{Z}_2^n$) there are bad labelling functions, for some other expander graphs, no such bad labellings exist. Similarly, it is possible that for some specific expanders better bounds exist for test functions in AC^0. Finding such graphs is a compelling goal that might require studying additional properties of graphs beyond expansion.
4. Finally, there is still a polynomial gap between the value of λ that fools functions in AC^0 and the corresponding lower bound we obtain. Any progress towards closing this gap will be interesting.

1.3 Paper organization

In Section 2 we give some background, mainly on Fourier Analysis. In Section 3 we recall the basic framework of [11], except that we do it for arbitrary bias μ rather than just bias $\mu = 0$. In Section 4 we choose the graph and labelling function that we use for the lower bounds, and for which we can compute exactly the error induced by characters. In Section 5 we prove Theorem 1 and show that threshold function at one standard deviation away from the mean has error that goes down to zero with λ but not with t. In Section 6 we prove a special case of Theorem 2 for the case of $d = 3$. The full proof of Theorem 2 appears in the full version of the paper. Then we turn to give a better upper bound on the error function and in show a better and tight upper bound with a simpler proof. Finally we show the threshold function about the mean (if $\mu = 0$ it is MAJ) and weight indicator functions do vanish with t. The last two results appear in the full version of the paper.

2 Preliminaries

We let $[n] = \{1, \ldots, n\}$, $\mathbb{1} \in \mathbb{R}^n$ denote the all 1s vector, i.e., $\mathbb{1} = (1, \ldots, 1)^T \in \mathbb{R}^n$. We let $\mathbf{1} \in \mathbb{R}^n$ denote the normalized vector of $\mathbb{1}$, i.e $\mathbf{1} = \frac{1}{\sqrt{n}} \cdot \mathbb{1}$, we also use $\mathbf{J} := \mathbf{1}\mathbf{1}^\mathsf{T}$. When we write $\|\cdot\|$ we always refer to the L_2-norm. Unless stated otherwise, $\log x = \log_2 x$. Throughout the paper, we make use of the following well known inequalities about binomial coefficients. Let $a \geqslant b \geqslant 1$ be integers. Then, $(\frac{a}{b})^b \leqslant \binom{a}{b} \leqslant (\frac{ea}{b})^b$.

2.1 Fourier analysis

Consider the space of functions $f : \{\pm 1\}^t \to \mathbb{R}$, along with the inner product

$$\langle f, g \rangle = 2^{-t} \sum_{x \in \{\pm 1\}^t} f(x)g(x).$$

It is a well-known fact that the set $\{\chi_S(x) \mid S \subseteq [t]\}$, where $\chi_S(x) = \prod_{i \in S} x_i$, forms an orthonormal basis with respect to this inner product, which is called the Fourier basis. Thus every function $f : \{\pm 1\}^t \to \mathbb{R}$ can be uniquely represented as $f(x) = \sum_{S \subseteq [t]} \widehat{f}(S)\chi_S(x)$, where $\widehat{f}(S) \in \mathbb{R}$.

In this work we consider other bases, with respect to a similar inner product. Let $\mu \in [-1, 1]$, and denote by U_t^μ the distribution over $\{\pm 1\}^t$ where each bit is chosen independently with expectation μ. Define $\langle f, g \rangle_\mu = \mathbf{E}_{x \sim U_t^\mu}[f(x)g(x)]$. Denote by $\sigma = \sqrt{1 - \mu^2}$, and let $\chi_S^\mu(x) = \prod_{i \in S} \frac{x_i - \mu}{\sigma}$. It is easy to see that the set $\{\chi_S^\mu(x) \mid S \subseteq [t]\}$, forms an orthonormal basis with respect to this new inner product, which is called the *μ-biased Fourier basis*. To see this, note that, by design, for $S \neq \emptyset$, $\mathbf{E}[\chi_S^\mu] = 0$ and $\mathbf{E}[(\chi_S^\mu)^2] = 1$. Similarly to the standard Fourier basis, every function $f : \{\pm 1\}^t \to \mathbb{R}$ can be uniquely represented as

$$f(x) = \sum_{S \subseteq [t]} \widehat{f_\mu}(S)\chi_S^\mu(x),$$

where $\widehat{f_\mu}(S) \in \mathbb{R}$.

We say that a function $f : \{\pm 1\}^t \to \mathbb{R}$ is symmetric if for every permutation $\sigma \in S_t$, $f(x_1, \ldots, x_t) = f(x_{\sigma(1)}, \ldots, x_{\sigma(t)})$. It is not hard to show that if f is symmetric, then for every $S_1, S_2 \subseteq [t]$, with $|S_1| = |S_2|$, $\widehat{f_\mu}(S_1) = \widehat{f_\mu}(S_2)$. This allows us to use the following definition for symmetric functions: $\widehat{f_\mu}(k) = \left|\widehat{f_\mu}([k])\right|$, which is the absolute value of the Fourier coefficients of any weight k character. For more details on biased Fourier analysis see Chapter 8 of [27].

3 The basic framework extended to arbitrary balanced tests

[11] reduced the analysis of the error function of a *balanced* test function f to the analysis of the error function of characters. In this section we restate this framework, but do it in a more general way that applies to any test function f, no matter how balanced it is.

Let $G = (V, E)$ be a regular λ-spectral expander, and let $\mathsf{val} : V \to \{\pm 1\}$ be a labelling of the vertices of G with $\mathbf{E}[\mathsf{val}(V)] = \mu$. Let $t \geqslant 1$ be an integer. We want to compare two distributions on $\{\pm 1\}^t$:

- The distribution obtained by sampling t vertices $v_1, \ldots, v_t$ uniformly and independently at random, and outputting the ordered tuple $(\mathsf{val}(v_1), \ldots, \mathsf{val}(v_t))$. Note that this is the same distribution as sampling a sequence of t elements in $\{\pm 1\}$ independently from a μ-biased distribution, that is a distribution with expectation μ. We denote this distribution by U_t^μ.

- $\mathrm{RW}_{G,\mathsf{val}}$ is the distribution obtained by sampling a random length $t-1$ path $v_1,\ldots,v_t$ in G and outputting the ordered tuple $(\mathsf{val}(v_1),\ldots,\mathsf{val}(v_t))$. Equivalently, sample v_1 uniformly at random from V. Then, for $i=2,3,\ldots,t$, sample v_i uniformly at random from the neighbours of v_{i-1}.

Let $f:\{\pm1\}^t\to\{\pm1\}$ be a test function. Expand f in the μ-biased Fourier basis,

$$f(x)=\sum_{S\subseteq[t]}\widehat{f_\mu}(S)\chi_S^\mu(x).$$

▶ **Lemma 4.** *Let $G=(V,E)$ be a regular λ-spectral expander, and let $\mathsf{val}:V\to\{\pm1\}$ be a labelling of the vertices of G with $\mathbf{E}[\mathsf{val}(V)]=\mu$. Then, for every function $f:\{\pm1\}^t\to\mathbb{R}$,*

$$\mathcal{E}_{G,\mathsf{val}}(f)\leqslant\sum_{\substack{S\subseteq T\\ S\neq\emptyset}}|\widehat{f_\mu}(S)|\mathcal{E}_{G,\mathsf{val}}(\chi_S^\mu).$$

Proof. Since $\mathbf{E}[\mathsf{val}]=\mu$, for $S\neq\emptyset$, $\mathbf{E}[\chi_S^\mu(U_t^\mu)]=0$ and thus $\mathbf{E}[f(U_t^\mu)]=\widehat{f_\mu}(\emptyset)$. Hence,

$$\mathcal{E}_{G,\mathsf{val}}(f)=|\mathbf{E}\,f(\mathrm{RW}_{G,\mathsf{val}})-\mathbf{E}\,f(U_t^\mu)|=\Big|\sum_{\substack{S\subseteq T\\ S\neq\emptyset}}\widehat{f_\mu}(S)\,\mathbf{E}[\chi_S^\mu(\mathrm{RW}_{G,\mathsf{val}})]\Big|.$$

For $S\neq\emptyset$, $\mathcal{E}_{G,\mathsf{val}}(\chi_S^\mu)=|\,\mathbf{E}[\chi_S^\mu(\mathrm{RW}_{G,\mathsf{val}})]|$. The proof follows by the triangle inequality. ◀

Lemma 4 motivates us to consider parity test functions which we do next. We start by introducing some notation. For an integer $k\geqslant 2$, we define the family $\mathcal{F}_k$ of subsets of $[k-1]$ that, informally, consists of all subsets for which at least one of every two consecutive elements participate in the set. We also require the "end points" $1,k-1$ to participate in the set. Formally, we define

$$\mathcal{F}_k=\{I\subseteq[k-1]\mid\{1,k-1\}\subseteq I\ \text{ and }\ \forall j\in[k-2]\ \ \{j,j+1\}\cap I\neq\emptyset\}\,. \tag{3.1}$$

So, for example, $\mathcal{F}_6$ consists of the elements $\{1,3,5\}$, $\{1,2,4,5\}$ as well as of all subsets of $[5]$ that have as a subset any one of these two elements, namely, $\{1,2,3,5\}$, $\{1,3,4,5\}$ and $\{1,2,3,4,5\}$. We extend the definition in the natural way to $k=0,1$ by setting $\mathcal{F}_0=\mathcal{F}_1=\emptyset$.

▶ **Definition 5.** *For integers $t\geqslant 1$, $2\leqslant k\leqslant t$ and $j\in[k-2]$ define the map*

$$\Delta_j:\binom{[t]}{k}\to\mathbb{N}$$

as follows. Let $S\subseteq[t]$ of size $k\geqslant 2$ and denote $S=\{s_1,\ldots,s_k\}$ where $s_1<\cdots<s_k$. For $i\in[k-1]$ write $\delta_i=s_{i+1}-s_i$. Define

$$\Delta_j(S)=\min(\delta_j,\delta_{j+1}).$$

▶ **Definition 6.** *For an integer $t\geqslant 1$ define the map $\Delta:\binom{[t]}{\geqslant 2}\to\mathbb{N}$ as follows. Let $S\subseteq[t]$ of size $k\geqslant 2$. For $k=2$ we define $\Delta(S)=\Delta_1(S)$, and for $k\geqslant 3$,*

$$\Delta(S)=\sum_{i=1}^{k-2}\Delta_i(S). \tag{3.2}$$

We prove:

▶ **Proposition 7.** *Let $G = (V, E)$ be a regular λ-spectral expander and $\mathsf{val} : V \to \{\pm 1\}$ a labelling of the vertices of G with $\mathbf{E}[\mathsf{val}(V)] = \mu$. Then, for every $1 \leqslant k \leqslant t$ and $S \subseteq [t]$ of size k,*

$$\mathcal{E}_{G,\mathsf{val}}(\chi_S^\mu) \leqslant \left(\frac{1+|\mu|}{1-|\mu|}\right)^{\frac{k-1}{2}} \cdot \sum_{I \in \mathcal{F}_k} \lambda^{\sum_{j\in I} \Delta_j(S)} \leqslant \left(\frac{1+|\mu|}{1-|\mu|}\right)^{\frac{k-1}{2}} 2^k \cdot \lambda^{\Delta(S)/2}.$$

We remark that for sets of size $|S| = 1$ the sum is taken over the empty index set $\mathcal{F}_1$ and so equals 0. We also note that when $|\mu| = 1$ the error is trivially zero, while our bound tends to infinity.

Proof. Consider any non-empty subset $S \subseteq [t]$ of size $|S| = k$. As $\mathbf{E}[\chi_S(U_t^\mu)] = 0$ we have that

$$\mathcal{E}_{G,\mathsf{val}}(\chi_S^\mu) = \left|\mathbf{E}[\chi_S^\mu(\mathrm{RW}_{G,\mathsf{val}})]\right|.$$

We wish to express the right hand side algebraically. Let $n = |V|$ and identify V with $[n]$ in an arbitrary way. Let P be the $n \times n$ diagonal matrix with

$$P_{v,v} = \frac{\mathsf{val}(v) - \mu}{\sqrt{1-\mu^2}}$$

for every $v \in [n]$. We slightly abuse notation and denote the random walk matrix (that is, the normalized adjacency matrix) of G also by G. Define $\delta_S(i) = 1$ if $i \in S$ and $\delta_S(i) = 0$ otherwise and observe that

$$\mathbf{E}[\chi_S^\mu(\mathrm{RW}_{G,\mathsf{val}})] = \mathbf{1}^T \left(\prod_{i=1}^{t} P^{\delta_S(i)} G\right) \mathbf{1},$$

where, recall, $\mathbf{1}$ is the all one vector normalized by $\frac{1}{\sqrt{n}}$. Indeed, informally, at the i'th step we take a random step using G and then, depending on i being an element of I or not, we multiply by P or by I, respectively. Thus, we can write

$$\mathbf{E}[\chi_S^\mu(\mathrm{RW}_{G,\mathsf{val}})] = \mathbf{1}^T G^{t-s_k} \left(\prod_{i=1}^{k-1} P G^{\Delta_i}\right) P G^{s_1} \mathbf{1} = \mathbf{1}^T \left(\prod_{i=1}^{k-1} P G^{\Delta_i}\right) P \mathbf{1}, \tag{3.3}$$

where we have used the regularity of G, namely, $G\mathbf{1} = \mathbf{1}$.

Next, we use the spectral decomposition of G. As G is a λ-spectral expander we know that $G = \mathbf{J} + \lambda E$ where $\|E\| \leqslant 1$. Similarly, As G^ℓ is a λ^ℓ-spectral expander we have that $G^\ell = \mathbf{J} + \lambda^\ell E_\ell$ for some operator E_ℓ with bounded norm $\|E_\ell\| \leqslant 1$. Thus,

$$\prod_{i=1}^{k-1} P G^{\Delta_i} = \sum_{I \subseteq [k-1]} \prod_{i=1}^{k-1} P B_i(I), \tag{3.4}$$

where

$$B_i(I) = \begin{cases} \lambda^{\Delta_i} E_{\Delta_i} & i \in I; \\ \mathbf{J} & \text{otherwise.} \end{cases}$$

For $I \subseteq [k-1]$ let

$$e_I = \mathbf{1}^T \left(\prod_{i=1}^{k-1} P B_i(I)\right) P \mathbf{1}.$$

Equations (3.3) and (3.4) imply that

$$\mathbf{E}[\chi_S(\mathrm{RW}_{G,\mathsf{val}})] = \sum_{I\subseteq[k-1]} e_I. \tag{3.5}$$

Not all subsets $I \subseteq [k-1]$ contribute non-zero values e_I to the sum. Indeed, if $k-1 \notin I$ then $B_{k-1}(I) = \mathbf{J}$ and so

$$\begin{aligned} e_I &= \mathbf{1}^T \left(\prod_{i=1}^{k-2} PB_i(I)\right)(P\mathbf{J})P\mathbf{1} \;= \mathbf{1}^T \left(\prod_{i=1}^{k-2} PB_i(I)\right)(P\mathbf{1}\mathbf{1}^T)P\mathbf{1} \\ &= \mathbf{1}^T \left(\prod_{i=1}^{k-2} PB_i(I)\right) P\mathbf{1}(\mathbf{1}^T P\mathbf{1}) = 0, \end{aligned}$$

because

$$\mathbf{1}^T P\mathbf{1} = \frac{1}{\sqrt{1-\mu^2}} \cdot \sum_{i\in[n]} \frac{\mathsf{val}(i)-\mu}{n} = \frac{\mathbf{E}[\mathsf{val}(V)]-\mu}{\sqrt{1-\mu^2}} = 0.$$

Similarly $e_I = 0$ for I not containing 1. Moreover, if $j, j+1$ are both not contained in I for some $j \in [k-2]$ then

$$\begin{aligned} e_I &= \mathbf{1}^T \left(\prod_{i=1}^{j-1} PB_i(I)\right)(PB_j(I))(PB_{j+1}(I)) \left(\prod_{i=j+2}^{k-2} PB_i(I)\right) P\mathbf{1} \\ &= \mathbf{1}^T \left(\prod_{i=1}^{j-1} PB_i(I)\right)(P\mathbf{J})(P\mathbf{J}) \left(\prod_{i=j+2}^{k-2} PB_i(I)\right) P\mathbf{1} = 0, \end{aligned}$$

Because

$$(P\mathbf{J})(P\mathbf{J}) = (P\mathbf{1}\mathbf{1}^T)(P\mathbf{1}\mathbf{1}^T) = P\mathbf{1}(\mathbf{1}^T P\mathbf{1})\mathbf{1}^T = 0.$$

Thus, any subset $I \subseteq [k-1]$ that may contribute to the sum in Equation (3.5) is contained in $\mathcal{F}_k$ as defined in Equation (3.1).

Next, we look at $I \in \mathcal{F}_k$. We have that

$$e_I = \mathbf{1}^T \left(\prod_{i=1}^{k-1} PB_i(I)\right) P\mathbf{1} \;\leqslant \prod_{i=1}^{k-1} \|PB_i(I)\| \;\leqslant \|P\|^{k-1} \prod_{i\in I} \|B_i(I)\|. \tag{3.6}$$

Recall that for every $i \in I$, $B_i(I) = \lambda^{\Delta_i} E_{\Delta_i}$ and that $\|E_{\Delta_i}\| \leqslant 1$. Thus, $\prod_{i\in I} \|B_i(I)\| \leqslant \prod_{i\in I} \lambda^{\Delta_i}$. Also, Let M be the $n \times n$ diagonal matrix defined by $M_{v,v} = \mathsf{val}(v)$ for all $v \in [n]$. Note that $P = \frac{1}{\sqrt{1-\mu^2}}(M - \mu I)$. As $\|M\| = 1$, using the triangle inequality we get

$$\|P\| \leqslant \frac{\|M\| + \|\mu I\|}{\sqrt{1-\mu^2}} \leqslant \frac{1+|\mu|}{\sqrt{1-\mu^2}} = \sqrt{\frac{1+|\mu|}{1-|\mu|}}. \tag{3.7}$$

Equation (3.6) and Equation (3.7) together imply that $e_I \leqslant \left(\frac{1+|\mu|}{1-|\mu|}\right)^{\frac{k-1}{2}} \prod_{i\in I} \lambda^{\Delta_i}$. This proves the first inequality in the proposition.

To prove the second inequality consider $I \in \mathcal{F}_k$, and notice that

$$2\sum_{i\in I} \Delta_i \geqslant \sum_{i=1}^{k-2} \delta_i\Delta_i + \delta_{i+1}\Delta_{i+1} \geqslant \sum_{i=1}^{k-2} \min(\Delta_i, \Delta_{i+1}),$$

because for every $i \in [k-2]$, at least one of $i, i+1$ is in I. To complete the proof of the second inequality notice also that $|\mathcal{F}_k| \leqslant 2^{k-1}$. ◀

4 Choosing the graph

In this section we choose an expander graph for which we obtain a precise analytic formula for the expectation of characters under the input distribution given by the random walk.

▷ Claim 8. Let $G = ([n], E)$ be a regular graph with second largest eigenvalue λ_2 and corresponding eigenvector v_2. Further assume all coordinates in v_2 have ± 1 values. Define $\mathsf{val}_2 : [n] \to \{\pm 1\}$ by $\mathsf{val}_2(i) = v_2(i)$. Let $S \subseteq [n]$, $|S| = k$. Let P be the diagonal matrix corresponding to val_2, that is, $P_{i,i} = \mathsf{val}_2(i) = v_2(i)$. Then,

$$\left(\prod_{i=1}^{k-1} PG^{\Delta_i}\right) P\mathbb{1} = \begin{cases} \lambda^{\sum_{i=1}^{(k-2)/2} \Delta_{2i+1}} \mathbb{1} & k \in \mathbb{N}_{even}, \\ \lambda^{\sum_{i=1}^{(k-1)/2} \Delta_{2i+1}} v_2 & k \in \mathbb{N}_{odd}. \end{cases}$$

Proof. We will prove the claim by induction. For the base case $k = 1$ it holds that $\prod_{i=1}^{k-1} PG^{\Delta_i} = I$, and the statement follows as $IP\mathbb{1} = v_2 = \lambda^0 v_2$. For the induction step, note that

$$\left(\prod_{i=1}^{k} PG^{\Delta_i}\right) P\mathbb{1} = PG^{\Delta_k} \left(\prod_{i=1}^{k-1} PG^{\Delta_i}\right) P\mathbb{1}.$$

If $k \in \mathbb{N}_{even}$ than $k-1 \in \mathbb{N}_{odd}$ and, using the induction hypothesis we get that

$$PG^{\Delta_k} \left(\prod_{i=1}^{k-1} PG^{\Delta_i}\right) P\mathbb{1} = PG^{\Delta_k} \lambda^{\sum_{i=1}^{(k-2)/2} \Delta_{2i+1}} v_2 \ = \lambda^{\sum_{i=1}^{k/2} \Delta_{2i+1}} \mathbb{1},$$

which is what we wanted to prove. The proof in the case that $k \in \mathbb{N}_{odd}$ is similar. ◁

▶ **Definition 9.** *For $S \subseteq [t]$ denote $\Delta_{odd}(S) = \sum_{i=1}^{\lfloor (|S|-1)/2 \rfloor} \Delta_{2i+1}(S)$.*

▶ **Corollary 10.** *Let $G = ([n], E)$ and $\mathsf{val}_2 : [n] \to \{\pm 1\}$ be as above. Then,*

$$\mathbf{E}[\chi_S(\mathrm{RW}_{G,\mathsf{val}_2})] = \begin{cases} \lambda^{\Delta_{odd}(S)} & |S| \in \mathbb{N}_{even}, \\ 0 & |S| \in \mathbb{N}_{odd}. \end{cases}$$

Proof. Note that $Pv_2 = \mathbb{1}$ and $P\mathbb{1} = v_2$. As before, it holds that

$$\mathbf{E}[\chi_S(\mathrm{RW}_{G,\mathsf{val}_2})] = \mathbf{1}^T \left(\prod_{i=1}^{k-1} PG^{\Delta_i}\right) P\mathbf{1} = \frac{1}{n} \mathbb{1}^{\mathsf{T}} \left(\prod_{i=1}^{k-1} PG^{\Delta_i}\right) P\mathbb{1}.$$

Using Claim 8, we conclude that,

$$\mathbf{E}[\chi_S(\mathrm{RW}_{G,\mathsf{val}_2})] = \begin{cases} \lambda^{\Delta_{odd}(S)} \cdot \frac{1}{n} \mathbb{1}^{\mathsf{T}} \mathbb{1} & k \in \mathbb{N}_{even}, \\ \lambda^{\sum_{i=1}^{k-1/2} \Delta_{2i+1}} \cdot \frac{1}{n} \mathbb{1}^{\mathsf{T}} v_2 & k \in \mathbb{N}_{odd}. \end{cases}$$

The fact that G is regular implies that $\mathbb{1}^{\mathsf{T}} v_2 = 0$, which finishes the case that k is odd; the case that k is even is handled similarly by noting that $\mathbb{1}^{\mathsf{T}} \mathbb{1} = n$. ◀

We now give an example to such a graph G. Cayley graphs over an Abelian group commute and share an orthonormal basis of eigenvectors, which is known to be the set of all characters of the group. If the group is $\mathbb{Z}_2^n$, the eigenvectors have entries that are 2nd roots of unity, i.e., have ± 1 entries as desired. The eigenvalues have a direct correspondence to the set of generators of the Cayley graph. Building on that, [4] proved that for every $0 < \lambda < 1$ of the form $\frac{1}{m}$ for $m \in \mathbb{N}$ and $m \leqslant n \in \mathbb{N}$, there is a Cayley graph on the n dimensional boolean cube, with $\lambda_2 = \lambda$. The degree of this graph depends both on n and λ.

From now on we let G be a regular expander with second largest eigenvalue λ and corresponding eigenvector with ± 1 entries, and we let val_2 reflect that eigenvector.

5 A lower bound for symmetric functions

In this section we prove the following theorem.

▶ **Theorem 11.** *Let $0 < c_0 \leqslant 1$, and let G, val_2 be as in the previous section, for $0 < \lambda < \frac{c_0^2}{12800 \cdot e}$. Let $f\colon \{\pm 1\}^t \to \{\pm 1\}$ be a symmetric function with $\left|\widehat{f}(2)\right| \geqslant \frac{c_0}{\sqrt{\binom{t}{2}}}$. Then,*

$$\mathcal{E}_{G,\mathsf{val}_2}(f) \geqslant 0.001 c_0 \lambda.$$

The idea behind the proof is to show that when choosing G, val_2 as in Section 4, the upper bound given by [11] is tight (up to the redundant poly logarithmic factor). We will use the following claim from [11].

▶ **Lemma 12** ([11], Lemma 4.4)**.** *Denote*

$$\beta_k = \sum_{\substack{S \subseteq [t] \\ |S|=k}} \mathbf{E}[\chi_S(\mathrm{RW}_{G,\mathsf{val}})]. \quad \textit{Then,} \quad \beta_k \leqslant 2^k \binom{t-1}{\lfloor \frac{k}{2} \rfloor} \left(\frac{\lambda}{1-\lambda}\right)^{\lceil \frac{k}{2} \rceil}. \tag{5.1}$$

Using these notations we are now ready to prove Theorem 11.

Proof of Theorem 11. Denote by $\mathcal{B}_2 = \{\{i, i+1\} \mid i \in [t-1]\}$, note that $|\mathcal{B}_2| = t-1$ and that for every $S \in \mathcal{B}_2$ it holds that $\Delta_{odd}(S) = 1$. Recall that $\mathcal{E}_{G,\mathsf{val}_2}(\chi_S) = 0$ if $|S| = 1$, therefore,

$$\mathcal{E}_{G,\mathsf{val}_2}(f) = \left| \sum_{S \subseteq [t], |S| \geqslant 2} \widehat{f}(|S|) \, \mathbf{E}[\chi_S(\mathrm{RW}_{G,\mathsf{val}})] \right| \tag{5.2}$$

$$\geqslant \left|\widehat{f}(2)\right| \left| \sum_{S \subseteq [t], |S|=2} \mathbf{E}[\chi_S(\mathrm{RW}_{G,\mathsf{val}})] \right| - \left| \sum_{S \subseteq [t], |S|>2} \widehat{f}(|S|) \mathcal{E}_{G,\mathsf{val}_2}(\chi_S) \right|. \tag{5.3}$$

However, by Corollary 10,

$$\left|\widehat{f}(2)\right| \left| \sum_{S \subseteq [t], |S|=2} \mathbf{E}[\chi_S(\mathrm{RW}_{G,\mathsf{val}})] \right| \geqslant \left|\widehat{f}(2)\right| \sum_{S \in \mathcal{B}_2} \lambda \; \geqslant c_0 \sqrt{2} \sqrt{\frac{t-1}{t}} \lambda \; \geqslant \frac{c_0}{\sqrt{2}} \lambda.$$

Furthermore,

$$\left| \sum_{S \subseteq [t], |S|>2} \widehat{f}(S) \mathcal{E}_{G,\mathsf{val}_2}(\chi_S) \right| \leqslant \sum_{k \geqslant 3} \left|\widehat{f}(k)\right| \beta_k \leqslant \sum_{k \geqslant 3} \frac{1}{\sqrt{\binom{t}{k}}} 2^k \binom{t-1}{\lfloor \frac{k}{2} \rfloor} \left(\frac{\lambda}{1-\lambda}\right)^{\lceil \frac{k}{2} \rceil},$$

where in the last inequality we used Lemma 12. The right hand side of the above equation is bounded above by

$$\sum_{k \geqslant 3} (16e)^{k/2} \lambda^{k/2} \leqslant 124 \lambda^{1.5}.$$

We omit the calculations. Assume that $\lambda \leqslant \frac{c_0^2}{128e \cdot 100}$. Then Equation (5.2) yields

$$\mathcal{E}_{G,\mathsf{val}_2}(f) \geqslant \frac{c_0}{\sqrt{2}} \lambda - 124 \lambda^{1.5} \geqslant 0.04 c_0 \lambda. \qquad \blacktriangleleft$$

In order to prove Theorem 1, we are left with providing a function f that satisfies the conditions of Theorem 11. Next, we show that the threshold function at one standard deviation distance from the mean has non-vanishing error in t.

We use the following definitions and claim. For integers t and $w \in \{0,1,\ldots,t\}$ let $\mathbf{1}_w : \{\pm 1\}^t \to \{0,1\}$ be the function indicating whether the weight of the input is w. That is, $\mathbf{1}_w(x_1,\ldots,x_t) = 1$ if $|\{i \in [t] \mid x_i = 1\}| = w$ and $\mathbf{1}_w(x_1,\ldots,x_t) = 0$ otherwise. We also define $\mathbf{1}_{>w} : \{\pm 1\}^{t+1} \to \{0,1\}$ be the function indicating whether the weight of the input is greater w. That is, $\mathbf{1}_w(x_1,\ldots,x_t) = 1$ if $\sum_i x_i > w$ and $\mathbf{1}_w(x_1,\ldots,x_t) = 0$ otherwise.

▷ Claim 13. For every $S \subseteq [t]$, it holds that

$$\widehat{(\mathbf{1}_w)_\mu}(S) = \frac{\widehat{(\mathbf{1}_{>w})_\mu}(S \cup \{0\})}{\sqrt{1-\mu^2}}.$$

Proof.

$$\begin{aligned}
\mathbf{1}_w(x_1,\ldots,x_t) &= \mathbf{1}_{>w}(1,x_1,\ldots,x_t) - \mathbf{1}_{>w}(0,x_1,\ldots,x_t) \\
&= \sum_{S\subseteq\{0,\ldots,t\}} \widehat{(\mathbf{1}_{>w})_\mu}(S)\chi^\mu_S(1,x_1,\ldots,x_t) - \sum_{S\subseteq\{0,\ldots,t\}} \widehat{(\mathbf{1}_{>w})_\mu}(S)\chi^\mu_S(0,x_1,\ldots,x_t) \\
&= \sum_{S\subseteq\{0,\ldots,t\}} \widehat{(\mathbf{1}_{>w})_\mu}(S)(\chi^\mu_S(1,x_1,\ldots,x_t) - \chi^\mu_S(0,x_1,\ldots,x_t)) \\
&\quad \sum_{\substack{S\subseteq\{0,\ldots,t\}\\ 0\in S}} \widehat{(\mathbf{1}_{>w})_\mu}(S)\frac{1}{\sqrt{1-\mu^2}}\chi^\mu_{S\setminus\{0\}}(x_1,\ldots,x_t),
\end{aligned}$$

and the claim follows. ◁

Proof of Theorem 1. Take $f = \mathbf{1}_{>w}$ for $w = \frac{t-\sqrt{t}}{2}$. We claim that $\left|\widehat{f}(2)\right| > \frac{c_0}{\sqrt{\binom{t}{2}}}$, for some absolute constant $c_0 > 0$ and therefore by Theorem 11, $\mathcal{E}_{G,\mathsf{val}}(f_t) \geqslant c \cdot \lambda$ for some constant c. Indeed, by Claim 13 we have $\widehat{f}(2) = \widehat{\mathbf{1}_w}(1)$ for $\mathbf{1}_w : \{\pm 1\}^{t-1} \to \{0,1\}$. To compute $\widehat{\mathbf{1}_w}(1)$ we apply [11, Claim 4.9] for $w = \frac{t-\sqrt{t}}{2}$ and get

$$\left|\widehat{\mathbf{1}_w}(1)\right| = \left|\frac{1}{2^{t-1}}\frac{\binom{t-1}{w}}{\binom{t-1}{1}}\sum_{\ell=0}^{\lfloor\frac{1}{2}\rfloor}(-1)^{1-\ell}\binom{w}{\ell}\binom{t-2w-1}{1-2\ell}\right| = \frac{1}{2^{t-1}}\frac{\binom{t-1}{w}}{t-1}(t-1-2w).$$

Substituting $w = \frac{t-\sqrt{t}}{2}$, together with the fact that $\binom{t-1}{\frac{t-\sqrt{t}}{2}} \geqslant \Omega\left(\frac{1}{\sqrt{t}}2^t\right)$, concludes the proof. ◀

6 A lower bound for AC^0 tests

In this section we use the noise operator. The following definitions and claims appear in [27].

▶ **Definition 14.** *Let $\rho \in [-1,1]$. For a fixed $x \in \{\pm 1\}^t$ we write $y \sim N_\rho(x)$ to denote the random string y that is drawn as follows: for each $i \in [t]$ independently,*

$$y_i = \begin{cases} x_i & \text{with probability } \frac{1+\rho}{2}, \\ -x_i & \text{with probability } \frac{1-\rho}{2}. \end{cases}$$

▶ **Definition 15.** *Let $\rho \in [-1,1]$. The noise operator T_ρ is the linear operator on functions $\{\pm 1\}^t \to \mathbb{R}$ defined by $T_\rho f(x) = \mathbf{E}_{y \sim N_\rho(x)} f(y)$. The fact that the operator is linear follows directly from the linearity of the expectation.*

Notice that $T_1(f) = f$ whereas $T_0(f)$ is the constant function $T_0(f) = \mathbf{E}\, f$. We make use of the following lemma.

▶ **Lemma 16.** *For every function $f : \{\pm 1\}^t \to \mathbb{R}$ it holds that: $\widehat{T_\rho f}(S) = \widehat{f}(S)\rho^{|S|}$.*

The starting point of this section is to connect the expectation of f under a random walk and the noise function $T_\lambda(f)$, we prove this claim in the full version of the paper.

▷ Claim 17. For $f\colon \{\pm 1\}^t \to \mathbb{R}$ define $\tilde{f}\colon \{\pm 1\}^{2t} \to \mathbb{R}$ by

$$\tilde{f}(x_1, x_2, \ldots, x_{2t-1}, x_{2t}) = f(x_1 \cdot x_2, \ldots, x_{2t-1} \cdot x_{2t}).$$

Then, $\mathbf{E}[\tilde{f}(\mathrm{RW}_{G,\mathsf{val}_2})] = (T_\lambda f)(\mathbb{1})$.

Proof. For $\{s_1, \ldots, s_k\} = S \subseteq [t]$ denote $2S\colon = \{2s_1 - 1, 2s_1, \ldots, 2s_k - 1, 2s_k\} \subseteq [2t]$. Note that $\Delta_{odd}(2S) = |S|$.

$$\begin{aligned}
\tilde{f}(x_1, x_2, \ldots, x_{2t-1}, x_{2t}) &= f(x_1 \cdot x_2, \ldots, x_{2t-1} \cdot x_{2t}) \\
&= \sum_{S \subseteq [t]} \widehat{f}(S) \chi_S(x_1 \cdot x_2, \ldots, x_{2t-1} \cdot x_{2t}) \\
&= \sum_{S \subseteq [t]} \widehat{f}(S) \chi_{2S}(x_1, x_2, \ldots, x_{2t-1}, x_{2t}).
\end{aligned}$$

Therefore,

$$\begin{aligned}
\mathbf{E}[\tilde{f}(\mathrm{RW}_{G,\mathsf{val}_2})] &= \sum_{S \subseteq [t]} \widehat{f}(S)\, \mathbf{E}[\chi_{2S}(\mathrm{RW}_{G,\mathsf{val}_2})] \\
&= \sum_{S \subseteq [t]} \widehat{f}(S) \lambda^{|S|} \\
&= \sum_{S \subseteq [t]} \widehat{f}(S) \lambda^{|S|} \chi_S(\mathbb{1}),
\end{aligned}$$

which is equal to $T_\lambda(f)(\mathbb{1})$ by Lemma 16. For the second equality we used Corollary 10. ◁

6.1 A lower bound for the Tribes function composed with IP

We now construct a function in $\mathsf{AC}(3)$, that satisfies Theorem 2. Later on we extend the construction inductively to obtain the general theorem. The idea behind the depth-3 construction is the following. We look for a function $f = f(x_1, \ldots, x_t) \in \mathsf{AC}(2)$ such that

$$|\, \mathbf{E}[f(U_t)] - T_\lambda(f)(\mathbb{1})| \geqslant \lambda \cdot \log t. \tag{6.1}$$

We then look at $\tilde{f}(y_1, \ldots, y_{2t}) = f(y_1 \cdot y_2, \ldots, y_{2t-1} \cdot y_{2t}) \in \mathsf{AC}(3)$ and note that:

- $\mathbf{E}[\tilde{f}(U_t)] = \mathbf{E}[f(U_t)]$ as the product of two uniform ± 1 bits is uniform; However,
- by Claim 17, $\mathbf{E}[\tilde{f}(\mathrm{RW}_{G,\mathsf{val}_2})] = T_\lambda(f)(\mathbb{1})$.

Together,

$$\mathcal{E}_\lambda(\tilde{f}) \geqslant \mathcal{E}_{G,\mathsf{val}_2}(\tilde{f}) = |\,\mathbf{E}[\tilde{f}(U_t)] - \mathbf{E}[\tilde{f}(\mathrm{RW}_{G,\mathsf{val}_2})]| = |\,\mathbf{E}[f(U_t)] - T_\lambda(f)(\mathbf{1})] \geqslant \lambda \cdot \log t,$$

which in turns implies Theorem 2, for $d = 3$.

We take f to be the Tribes function. Fix t; we choose parameters r, h such that $r \cdot h \leqslant t$ by taking $h = \log(t) - \log\log(t)$[2] and $r = \lfloor \frac{t}{\log t} \ln(2) \rfloor$. Partition $[t]$ into disjoint sets $I_1, \ldots, I_r$, each of size h. We define $f : \{\pm 1\}^t \to \{0,1\}$ to be the Tribes function on t bits and define g to be the related function

$$f(z_1, \ldots, z_t) = \bigvee_{i \in [r]} \bigwedge_{j \in I_i} z_j, \qquad g(z_1, \ldots, z_t) = \bigwedge_{i \in [r]} \bigvee_{j \in I_i} z_j.$$

Here, -1 is interpreted as "true", 1 is interpreted as "false". Note that $f, g \in \mathsf{AC}(2)$.

As before, we choose G to be a Cayley graph on the boolean hypercube with $\lambda_2 = \lambda$ and $\mathsf{val} = \mathsf{val}_2$.

▷ Claim 18. The functions f and g are almost balanced with respect to the uniform distribution. Quantitatively, $\mathbf{E}[f], \mathbf{E}[g] \in \left[\frac{1}{2} - O\left(\frac{\log t}{t}\right), \frac{1}{2} + O\left(\frac{\log t}{t}\right)\right]$.

Proof. From De Morgan's identity we have $g(x_1, \ldots, x_t) = 1 - f(\overline{x_1}, \ldots, \overline{x_t})$, so $\mathbf{E}[g] = 1 - \mathbf{E}[f]$ and so it is enough to prove the statement for f. To this end write

$$\begin{aligned}\mathbf{E}[f] = \mathbf{Pr}[f = 1] &= 1 - \prod_{i=1}^{r} \mathbf{Pr}\left[\bigwedge_{j \in I_i} z_j = 0\right] \\ &= 1 - \prod_{i=1}^{r} \left(1 - \mathbf{Pr}\left[\bigwedge_{j \in I_i} z_j = 1\right]\right) = 1 - \left(1 - \frac{1}{2^h}\right)^r.\end{aligned}$$

Using the fact that $1 - \varepsilon = e^{-\varepsilon + O(\varepsilon^2)}$ we obtain that

$$\begin{aligned}1 - \left(1 - \frac{1}{2^h}\right)^r &= 1 - e^{-2^{-h} r + O(2^{-2h} r)} \\ &= 1 - e^{-\ln 2 + O\left(\frac{\log t}{t}\right)} = \frac{1}{2} + \Theta\left(\frac{\log t}{t}\right),\end{aligned}$$

as desired. ◁

Denote by μ_p the product distribution over $\{\pm 1\}^t$, wherein for each $i \in [t]$ we have that $\mathbf{Pr}[z_i = -1] = p$. Abusing notation denote $\mu_p(f) = \mathbf{E}_{x \sim \mu_p}[f(x)]$.

▷ Claim 19. Let $p = \frac{1-\varepsilon}{2}$ and assume $\varepsilon \geqslant \frac{k}{\log(t)}$. Then,

$$\mu_p(f), \mu_p(g) \leqslant e^{-k/10}.$$

Proof. First, we analyze $\mu_p(f)$. By definition it is equal to

$$\begin{aligned}\mathop{\mathbf{Pr}}_{\mu_p}[f = 1] &= 1 - (1 - p^h)^r = 1 - (1 - 2^{-h}(1 - \varepsilon)^h)^r \\ &= 1 - \left(1 - 2^{-h}\left(1 - \frac{k}{\log t}\right)^h\right)^r \leqslant 1 - \left(1 - 2^{-h} e^{-k}\right)^r.\end{aligned}$$

[2] Recall that $\log t = \log_2 t$

Using $(1-\delta)^r \geqslant 1 - r\delta$, we get that the above expression is bounded by $r2^{-h}e^{-k} \leqslant e^{-k}$. Next, we upper bound $\mu_p(g)$. By definition, it is equal to

$$\mathop{\mathbf{Pr}}_{\mu_p}[g=1] \leqslant (1-(1-p)^h)^r = (1-2^{-h}(1+\varepsilon)^h)^r = \left(1-2^{-h}\left(1+\frac{k}{\log t}\right)^h\right)^r.$$

Using $(1+\delta)^r \geqslant \delta r$ for $\delta > 0$, we get that this is at most

$$(1-2^{-h}k)^r \leqslant e^{-r2^{-h}k} \leqslant e^{-k/10}. \qquad \lhd$$

We now prove Theorem 2 for $d=3$. We take $h(x_1, y_1, \ldots, x_t, y_t) = f(x_1 \cdot y_1, \ldots, x_t \cdot y_t)$. $h \in \mathsf{AC}(3)$ because $f \in \mathsf{AC}(2)$.

- On the one hand, by Claim 17, $\mathbf{E}[h(\mathrm{RW}_{G,\mathsf{val}_2})] = T_\lambda(f)(\mathbb{1}) = \mu_{\frac{1-\lambda}{2}}(f)$. By Claim 19, and using $\lambda \geqslant \frac{k}{\log t}$, we get that $\mathbf{E}[h(\mathrm{RW}_{G,\mathsf{val}_2})] < e^{-k/10}$.
- On the other hand, By Claim 18, $\mathbf{E}[h] = \mathbf{E}[f] \geqslant \frac{1}{2} - O(\frac{\log t}{t})$.

Together, h is as desired.

LCC and LDC: Tailor-Made Distance Amplification and a Refined Separation

Gil Cohen
Department of Computer Science, Tel Aviv University, Israel

Tal Yankovitz
Department of Computer Science, Tel Aviv University, Israel

Abstract

The Alon-Edmonds-Luby distance amplification procedure (FOCS 1995) is an algorithm that transforms a code with vanishing distance to a code with constant distance. AEL was invoked by Kopparty, Meir, Ron-Zewi, and Saraf (J. ACM 2017) for obtaining their state-of-the-art LDC, LCC and LTC. Cohen and Yankovitz (CCC 2021) devised a procedure that can amplify inverse-polynomial distances, exponentially extending the regime of distances that can be amplified by AEL. However, the improved procedure only works for LDC and assuming rate $1 - \frac{1}{\text{poly}\log n}$.

In this work we devise a distance amplification procedure for LCC with inverse-polynomial distances even for vanishing rate $\frac{1}{\text{poly}\log\log n}$. For LDC, we obtain a more modest improvement and require rate $1 - \frac{1}{\text{poly}\log\log n}$. Thus, the tables have turned and it is now LCC that can be better amplified. Our key idea for accomplishing this, deviating from prior work, is to tailor the distance amplification procedure to the code at hand.

Our second result concerns the relation between linear LDC and LCC. We prove the existence of linear LDC that are not LCC, qualitatively extending a separation by Kaufman and Viderman (RANDOM 2010).

1 Introduction

1.1 Distance amplification

It is a recurrent theme in coding theory that the construction of a code is done in two steps. In the first step, a code with weak parameters is constructed, and typically it is the distance of the code that is unsatisfactory. In the second step, one transforms the code obtained in the first step to a code with the desired parameters, where typically, in the process, the other parameters deteriorate only slightly. When the distance is the unsatisfactory parameter, the second step is referred to as a distance amplification step.

Examples that fall into this framework include the breakthrough constructions of near-optimal small-bias sets by Ta-Shma [19], and the state-of-the-art construction of locally decodable codes (LDC), locally correctable codes (LCC), and locally testable codes (LTC) by Kopparty, Meir, Ron-Zewi, and Saraf [17]. A prominent example from the (adjacent) PCP literature is Dinur's celebrated proof of the PCP Theorem by gap amplification [8]. It is interesting to note that in all the above cases the first step is done using algebraic machinery whereas the second step is based on combinatorial arguments.

1.2 LDC and LCC

Informally, a linear (q, δ) *locally decodable code (LDC)* is a code, given by an $\mathbb{F}$-linear encoding function $\mathsf{Enc} : \mathbb{F}^k \to \mathbb{F}^n$, where $\mathbb{F}$ is a finite field, that is also equipped with a "local decoder". The latter is a randomized algorithm, denoted by Dec, with the following guarantee. Given an oracle access to $z \in \mathbb{F}^n$ that is within relative Hamming distance δ from some codeword $\mathsf{Enc}(x)$, and given $i \in [k]$, $\mathsf{Dec}^z(i) = x_i$ with high probability. Moreover, Dec makes at most q queries to z. That is, every message symbol can be decoded, with high probability, by querying only few symbols of a corrupted codeword. A (q, δ) *locally correctable code (LCC)* is the variant in which one wishes to decode (or, more precisely, correct) the codeword symbols rather than the message symbols.

Locally decodable codes were defined by Katz and Trevisan [15] who proved that asymptotically good LDC require $q = \Omega(\log n)$ queries. Whether or not this bound is tight is a major open problem. An intensive research effort is devoted to the study and construction of LDC and LCC. Of particular interest is the study of asymptotically good LDC and LCC [18, 13, 14, 17, 12, 7] where the goal is to minimize the query complexity.

In their seminal work, Kopparty, Meir, Ron-Zewi and Saraf [17] constructed LDC and LCC with sub-polynomial query complexity. For the first step, a code with vanishing distance $\delta = \frac{1}{\mathrm{poly}(\log n)}$ was used [18], having the desired query complexity, namely, $q = 2^{\tilde{O}(\sqrt{\log n})}$. Then, in the second step the authors invoked a distance amplification procedure due to Alon, Edmonds and Luby [2, 1], which was originally introduced in the context of linear-time erasure codes, and observed that it converts an LDC (resp. LCC) with distance δ and query complexity q to an LDC (resp. LCC) with constant distance and query complexity $q_{\mathrm{new}} = q \cdot \mathrm{poly}(\frac{1}{\delta})$.

1.3 Improved distance amplification for LDC

Motivated by the key role that the distance amplification procedure plays in [17], Cohen and Yankovitz [7] asked whether much lower distances can be amplified. Indeed, AEL's procedure is mostly relevant in the regime $\delta = \frac{1}{\mathrm{poly}(\log n)}$. In [7], the authors devised an improved procedure that can amplify distances as low as $\frac{1}{n^\alpha}$ for any constant $\alpha < 1$ with a fairly low cost in query complexity, $q_{\mathrm{new}} = q^{O(\log \log n)}$ [1] (and even for $\alpha = 1 - o(1)$ at a small additional cost in query complexity). However, their improved distance amplification procedure has two drawbacks:

1. Unlike the AEL distance amplification procedure, the improved procedure was only shown to work for LDC (and it may or may not work for LCC).
2. Second, to amplify the distance, the original LDC must have rate close to one, more precisely, rate $1 - \frac{1}{\mathrm{poly}(\log n)}$.

2 Our contribution

We turn to present the two results of this work.

[1] $\mathrm{poly}(\log \log n)$ factors in the exponent of the query complexity can be safely ignored given that, at present, the lowest known query complexity is $2^{\tilde{\Theta}(\sqrt{\log n})}$. Such an overlook will matter only when (and if) the query complexity will go below quasi-poly-logarithmic.

2.1 Tailor-made distance amplification procedure

Our first contribution is a distance amplification procedure for LCC that can amplify distances as low as those handled by [7] (for LDC). Moreover, our procedure works even for vanishing rate LCC.

▶ **Theorem 1** (Distance amplification for LCC; informal). *Let $h \geqslant 1 \geqslant \alpha > 0$ be any constants. There exists a transformation that takes a q-query LCC with distance $\frac{1}{n^{\alpha}}$ and rate $\frac{1}{(\log\log n)^h}$ to an asymptotically good LCC with query complexity*

$$q_{\mathsf{new}} = q^{O((\log\log n)^{2h+2})}.$$

We chose to state our result in a somewhat informal manner. For the formal statement, see Corollary 37.

An example usage of Theorem 1 is given by the next corollary. The corollary shows the implication of a case that an LCC with query complexity meeting the Katz-Trevisan bound is shown to exist - only with a vanishing rate and distance.

▶ **Corollary 2** (Informal). *If there exists a q-query LCC for $q = \log n$, with distance $\frac{1}{\sqrt{n}}$ and rate $\frac{1}{\log\log n}$, then there exists an asymptotically good LCC with query complexity*

$$q_{\mathsf{new}} = (\log n)^{O((\log\log n)^4)}.$$

We now turn to give further details on the result.

Explicitness

In the statement of Theorem 1 we ignore the issue of explicitness. Indeed, understanding LDC and LCC is already interesting in the information-theoretic level. Having said that, our transformation is fairly explicit: It is a zero error randomized transformation that runs in polynomial-time. More precisely, for every "failure" parameter $\varepsilon > 0$, our transformation runs in time $\mathrm{poly}(n) \cdot \log \frac{1}{\varepsilon}$ and produces an LCC with probability at least $1 - \varepsilon$; otherwise, it declares failure. We find this aspect to be a minor issue as, recall, LCC are anyhow randomized in nature. Nonetheless, it will be interesting to obtain a deterministic transformation with matching parameters.

Codes vs. family of codes

A second issue that we chose to sweep under the rug in the statement of Theorem 1 is that the transformation operates on the level of family of codes rather than on the level of individual codes. That is, in order to produce an asymptotically good LCC of a given block-length n, our transformation requires as input a sufficiently dense family of codes. By that we mean that the consecutive block-lengths in the family are not too far apart. The density of the resulted family of codes is the same as that of the original family.

Amplifying lower distances

Like [7], we can even amplify sub-polynomial distances, in particular, distances of the form $1/n^{1-1/g(n)}$ for an increasing function g, and assuming a certain technical relation between g and the rate. In particular, for every constant $m \geqslant 1$ we can handle $g(n) = (\log\log n)^m$, and end up with query complexity

$$q_{\mathsf{new}} = q^{O((\log\log n)^{2h+2m+2})}.$$

We note that constructing a code for $g(n) = \log n$ is trivial.

Amplifying the distance of LDC

We also obtain an improvement for LDC by devising a distance amplification procedure that requires rate $1 - \frac{1}{\text{poly}(\log\log n)}$, modestly improving upon the $1 - \frac{1}{\text{poly}(\log n)}$ rate required by [7]. The reason that we can do much better for LCC is due to the rate amplification procedure of [7] that, informally, can amplify rate ρ LCC with q queries to constant rate LCC with query complexity $q_{\mathsf{new}} = q^{\text{poly}(\frac{1}{\rho})}$. Such a transformation is not known for LDC.

2.1.1 Proof idea

In this section we give a short and informal account on our proof technique, and start by contrasting our technique with prior work. Both the AEL distance amplification procedure, as was used in [17], and the one given by [7] are based on samplers and further involve a "small" code, that is, a code with logarithmic block-length. The latter improves upon the former by using unbalanced samplers (rather than balanced ones, or expander graphs as was used originally [1, 2]) and using a recursive construction. To obtain our result, we deviate from prior work and tailor the distance amplification procedure to the LCC at hand. That is, our procedure is "white box" - it produces a new code with improved distance by first examining the structure of the given code. To tailor the procedure to the LCC at hand, we do not work directly with the definition of LCC as it lacks sufficient structure to work with. Instead, we work with a more combinatorial characterization of LCC as was used in [7]. We turn to elaborate on this.

Let $C \subseteq \mathbb{F}^n$ be a linear (q, δ)-LCC. One can prove the following structural result. With every coordinate $i \in [n]$ one can associate a set, called a *query set*, $A_i = \{Q_1^i, \ldots, Q_m^i\}$ of $m = \delta n/q$ disjoint subsets of $[n]$, each of size at most q, such that the following holds: For every $c \in C$ and $t \in [m]$, c_i can be deduced from $c_{Q_t^i}$. Assume from here on, for simplicity, that $\delta = 1/\sqrt{n}$ and so $m = \sqrt{n}/q$. Denote $\bar{A}_i = \bigcup_{t=1}^m Q_t^i$ and note that $|\bar{A}_i| \leqslant \sqrt{n}$.

For our distance amplification procedure, we make use of a special partition π of $[n]$ into $\sqrt{n}$ parts $P_1, \ldots, P_{\sqrt{n}}$, each of size $\sqrt{n}$. We say that such a partition is a *d-splitter* for C (more precisely, a d-splitter for the query sets $A_1, \ldots, A_n$ obtained from C) if for every $s \in [\sqrt{n}]$ and $i \in [n]$, $|P_s \cap \bar{A}_i| \leqslant d$. We wish to minimize d and thus consider a max load balls into bins like problem: For every $i \in [n]$ we place a ball with color i at each of the coordinates in $\bar{A}_i$. Note that a coordinate $j \in [n]$ may contain many balls of different colors. Indeed, the average number of balls at coordinate $j \in [n]$ is $\sqrt{n}$. Our goal is to choose the partition π in such a way that every part P_t will contain at most d balls of the same color. It is easy to show that a d-splitter for C exists with $d = O(\frac{\log n}{\log\log n})$.

We construct a new code $C' \subseteq \mathbb{F}^n$ as follows. We take C' to be the code $C' \subseteq C$ with the property that for every part P_s of π, when C' is projected to the coordinate set P_s, the obtained vectors consist of codewords of a code $C_{\sqrt{n}}$ having block length $\sqrt{n}$, which is a q'-query LCC. That is to say, we require that for every $c \in C'$ and $s \in [\sqrt{n}]$, $c_{P_s} \in C_{\sqrt{n}}$. Observe that C' can be constructed by adjoining to the parity checks of C, the parity checks of $C_{\sqrt{n}}$ when restricted to each block in π.

We show that if $C_{\sqrt{n}}$ is a smooth LCC, which means that it queries each coordinate with roughly the same probability, then so is C'. Moreover, C' has query complexity qq'. Thus, C can be transformed into a smooth LCC of length n given that a smooth LCC of length $\sqrt{n}$ is at hand. This calls for a recursive construction which results with a smooth LCC with query complexity $q^{O(\log\log n)}$. After obtaining a smooth code, the final step is to invoke the AEL distance amplification to end up with a good LCC. This final step has a minor effect on the query complexity.

The above recursive construction must start with LCC of rate $1 - \frac{1}{\mathrm{poly}(\log\log n)}$. This is due to the rate deterioration throughout the $\log\log n$ recursive calls. For amplifying rate $\frac{1}{\mathrm{poly}(\log\log n)}$ LCC, as stated in Theorem 1, we invoke the rate amplification procedure of [7] before running the recursive construction described above. This has some effect on the density of the LCC family that the recursion has access to which requires some care.

2.2 Refined separation between LDC and LCC

Understanding the relation between LDC and LCC is fundamental. Currently the only regime in which the state of affairs is better understood is the 2-query regime [3, 4, 5]. In the constant-query regime for $q \geqslant 3$, q-LDC with sub-exponential length are known [20, 11, 9] whereas it is not known if this can be matched for q-LCC. Recall that in the constant-rate regime, the state of the art result of [17] achieves sub-polynomial query complexity and holds for LDC and LCC alike.

In the general case, clearly, a systematic LCC is an LDC. As every linear code can be made systematic (by applying Gaussian elimination to its generating matrix), a linear LCC induces a linear LDC with the same parameters. Thus, informally, LCC are stronger than LDC, at least for linear codes.

Are LDC and LCC "equivalent"?

As for the converse, Kaufman and Viderman [16] observed that an LDC is not necessarily an LCC. Their proof starts with an LDC. If it is not an LCC to begin with, we are done. If it is an LCC, the proof goes on by transforming it to a new code by appending to it one additional entry that does not involve low-weight constraints (namely, every vector in the dual code that does not vanish on the new entry is of large weight). In this way, one obtains an LDC with an entry that cannot be corrected with few queries. Such an entry can be shown to exist by a counting argument. This argument can be extended to produce many new bits that cannot be corrected.

While, formally, the argument above establishes the existence of LDC that are not LCC, it has a drawback which makes it somewhat less appealing. In the resulted code, the adjoined bits that cannot be corrected are not needed for decoding the original bits. This means that if one is given a code that is not an LCC because of the above transformation, with the task of taking such a code and "convert" it to an LCC, this could be done easily: simply by removing these coordinates, and this clearly would not harm the code's dimension. This raises the question: Can any linear LDC be so "easily" converted to an LCC of similar dimension and query complexity?

The thought that the answer to this question may turn out to be in the affirmative is not far fetched in the case of linear codes. Indeed, we know that the locality features of linear codes "come from" linear relations between different bits of the codeword and of the message. For example, if a linear code $\mathsf{Enc} : \mathbb{F}^k \to \mathbb{F}^n$ is a q-query LDC, and in particular the i-th bit of each message m can be deduced from a subset $Q \subseteq [n]$ that consists of at most q coordinates of $c = \mathsf{Enc}(m)$, then there exists a linear map $f_{i,Q}$ which satisfies $m_i = f_{i,Q}(c_Q)$ for any m. Likewise, if m_i can as well be deduced from another subset $Q' \subseteq [n]$, $|Q'| \leqslant q$ (as is expected due to the distance guarantee), then there is a linear map $f_{i,Q'}$ satisfying $m_i = f_{i,Q'}(c_{Q'})$ for every m. It follows that in such a case, for every codeword c, $f_{i,Q}(c_Q) = f_{i,Q'}(c_{Q'})$. Since $f_{i,Q}$ and $f_{i,Q'}$ are linear maps (that, we may assume, depend on all their parameters) this means that for every $j \in Q \triangle Q'$, there exists a linear map g_j satisfying $c_j = g_j(c_{Q_j})$ for every codeword c, where $Q_j = (Q \cup Q')\backslash\{j\}$.

Therefore, by the mere fact that $j \in [n]$ is sometimes used in the local decoding process of $i \in [k]$, it is implied that it is possible to "correct" the j-th coordinate by reading only a few locations of the codeword (at most $2q-1$). Thus, the question of whether local decoding implies local correction is in place, in the case of linear codes, and especially so in the setting where k is close to n.

In light of this, the fact that in the separating result of [16] between linear LDC and LCC, the coordinates which are shown to be uncorrectable are not used by the local decoding process, calls for the question of whether there exists a linear LDC with uncorrectable coordinates that are crucial for the decoding process.

Our result

The second contribution of this work is a proof for the existence of an LDC that is not an LCC in the following stronger sense: It contains entries that cannot be corrected which are crucial for the local decoder. This raises the question of what we mean by coordinates that are "crucial". The mere fact that it is possible for a set of coordinates to be queried by the local decoding process should not qualify them as such, as what allows for a code to be locally decodable or locally correctable is that there are many options to decode or correct each symbol. Thus, a more suitable interpretation for a "crucial" set of coordinates $J \subseteq [n]$ is the following: If every coordinate $j \in J$ is "zeroed out" from the code (i.e., for every codeword c we override c_j with zero) then the transformed code is no longer locally decodable. With this we are ready to present our separation.

▶ **Theorem 3** (Separation of LDC and LCC; Informal)**.** *Let $C : \mathbb{F}^k \to \mathbb{F}^n$ for $|\mathbb{F}| > 2$ and $k = \Theta(n)$ be a linear q-query LDC. Then, there exists a linear q^2-query LDC $\widehat{C} : \mathbb{F}^{k^2} \to \mathbb{F}^{n^2}$ with the following property. There exists a subset of coordinates $J \subseteq [n^2]$ in which every coordinate cannot be locally corrected with query complexity $\sqrt{n}$ and correction radius $1/\sqrt{n}$. Moreover, if every coordinate $j \in J$ is zeroed out from the code, then the relative distance of the obtained code is $\widetilde{O}(1/\sqrt{n})$ (and so it is certainly not an LDC).*

For the formal, more general, statement, see Theorem 46. Note that our result does not cover the binary field and it is an interesting question whether it can be extended to include that case.

Proof idea

The underlying idea of the proof of Theorem 3 is an operation on two codes to which we call *weighted tensoring*. The weighted tensoring of codes is similar to the standard tensoring of codes. In the case of standard tensoring, the encoding of the tensor of two codes is done by taking a matrix as input and applying the first code to each column and then applying the second code to each row in the resulted matrix. In the encoding of a weighted tesnor, before the second step, each entry of the matrix is multiplied by a non-zero field element, or weight.

We consider the case of weighted tensoring which is done with *random* weights. We show that while the code resulted from this is an LDC (assuming that the two input codes were so), with high probability there is a set of coordinates in the code that cannot be locally corrected, while being crucial for the decoding. The analysis showing that the set of coordinates cannot be locally corrected is done by considering the affect of the weights on the dual code. A probabilistic argument is then used to show that the argued codes exist.

Discussion

We end this section with a short discussion to clarify a potentially confusing point. While LCC are, in a sense, more powerful than LDC (indeed, our second contribution, Theorem 3, attempts to formalize that better), our first result, given by Theorem 1, transforms a vanishing rate LCC with polynomially-small distance to an asymptotically good LCC–a result that is not known for LDC. So, how can it be that we can do this for LCC and not for the weaker LDC?

Of course, this should cause no confusion as the latter is a *transformation* that works for LCC and not LDC, not a *construction* nor it is even a proof of existence. Put differently, although the transformation generates the stronger object, the transformation is also given it as its input.

3 Preliminaries

3.1 Notations and conventions

Unless stated otherwise, all logarithms are taken to the base 2. For $n \in \mathbb{N}$, we use $[n]$ to denote the set $\{1, \ldots, n\}$. For ease of readability, we sometimes avoid the use of floor and ceiling. This does not affect the stated results. We use $\mathbb{F}$ to denote a field, and any referenced field is assumed to be finite and of a constant size. When n and $\mathbb{F}$ are clear from context, we use $e_i \in \mathbb{F}^n$ to denote the i-th vector of the standard basis. For $q \in \mathbb{N}$, we use H_q to denote the q-ary entropy function, and H to denote the binary entropy function. For a vector $v \in \mathbb{F}^n$, we denote by $|v|$ the *hamming weight* of v, which is the number of its non-zero coordinates $|v| = |\{j \in [n] \mid v_j \neq 0\}|$, and the *support* of v is $\mathsf{supp}(v) = \{j \in [n] \mid v_j \neq 0\}$. For two vectors $u, v \in \mathbb{F}^n$, we denote their (absolute) hamming distance by $\mathsf{dist}(u, v)$. For a linear subspace $L \subseteq \mathbb{F}^n$, we denote by $L^{\leqslant q}$ the set of vectors of weight at most q. For two vector $u, v \in \mathbb{F}^n$, we use $\langle u, v \rangle$ to denote the inner product of u and v, $\sum_{i=1}^{n} u_i v_i \in \mathbb{F}$. For a vector $v \in \mathbb{F}^n$ and a sequence $I = (i_1, \ldots, i_m) \in [n]^m$, we denote by v_I the vector $(v_{i_1}, \ldots, v_{i_m}) \in \mathbb{F}^m$. For a linear subspace $L \subseteq \mathbb{F}^n$ and a sequence $I = (i_1, \ldots, i_m) \in [n]^m$, we denote by L_I the subspace $\{v_I \mid v \in L\}$. Note that L_I is indeed a subspace as it is given by a suitable projection.

A *partition* π of size k of $[n]$ is a set $\{P_1, \ldots, P_k\}$ of disjoint subsets of $[n]$, such that $P_1 \cup \cdots \cup P_k = [n]$. A partition $\{P_1, \ldots, P_k\}$ is *ordered* if each P_i is a sequence rather than a set (and the sequences, when viewed as sets, satisfy the same requirements). Throughout this paper, any partition of $[n]$ will be an ordered partition (though we may not state it explicitly) with the sequences defined by the natural increasing order of $\mathbb{N}$.

3.2 Error correcting codes

We start by recalling the definition of an error correcting code, and of a family of error correcting codes. In this work we only consider linear codes.

▶ **Definition 4.** *For $n \in \mathbb{N}$ and $\mathbb{F}$ a field, a* code *of length n over $\mathbb{F}$ is a linear subspace $C \subseteq \mathbb{F}^n$.*[2] *The dimension of the code, denoted by k, is the dimension of C over $\mathbb{F}$, $\dim_{\mathbb{F}} C$. The (non-local) distance of the code, denoted by d, is $\min_{c \in C, c \neq 0} |c|$. The rate of the code, denoted by ρ, is k/n. The (non-local) relative distance of the code, denoted by Δ, is d/n. The elements of C are called* codewords.

[2] We may omit the phrase "over $\mathbb{F}$" if the underlying field is clear from context.

We will also need to consider encodings of codes.

▶ **Definition 5.** *We call a function* $\mathsf{Enc} : \mathbb{F}^k \to \mathbb{F}^n$ *an* encoding *of a code* C *if it is an injective linear map and* $C = \mathsf{Im}(\mathsf{Enc})$.

▶ **Definition 6.** *For a field* $\mathbb{F}$*, a* code family *over* $\mathbb{F}$ *is a set of codes* $C = \{C^n\}$*, which contains at most one code* C^n *of length* n *over* $\mathbb{F}$*, for every possible length* $n \in \mathbb{N}$*. For every* $n \in \mathbb{N}$*, we denote by* $\lceil n \rceil^C$ *the minimal length of a code in the family* C *of length at least* n*, and by* $\lfloor n \rfloor^C$ *the maximal length of a code in the family of length at most* n*. For constants* $n_0 \in \mathbb{N}$*,* $c \geqslant 1$ *and* $d \leqslant 1$*, we say that the family is* (n_0, c, d)-dense *if for every* $n \geqslant n_0$*,* $\lceil n \rceil^C \leqslant cn$ *and* $\lfloor n \rfloor^C \geqslant dn$*.*

▶ **Definition 7.** *For a field* $\mathbb{F}$*, a* code-encoding family *over* $\mathbb{F}$ *is a set of pairs of codes and corresponding encodings* $C = \{(C^k, \mathsf{Enc}^k)\}$*, which contains at most one code* C^k *of dimension* k *over* $\mathbb{F}$*, for every possible dimension* $k \in \mathbb{N}$*. For every* $k \in \mathbb{N}$*, we denote by* $\lceil k \rceil^C$ *the minimal dimension of a code in the family* C *of dimension at least* k*, and by* $\lfloor k \rfloor^C$ *the maximal dimension of a code in the family of dimension at most* k*. For constants* $k_0 \in \mathbb{N}$*,* $c \geqslant 1$ *and* $d \leqslant 1$*, we say that the family is* (k_0, c, d)-dense *if for every* $k \geqslant k_0$*,* $\lceil k \rceil^C \leqslant ck$ *and* $\lfloor k \rfloor^C \geqslant dk$*.*

▶ **Definition 8.** *Let* C *be a code of length* n *over* $\mathbb{F}$*. The* dual code of C *is defined to be its orthogonal subspace* $C^\perp$*.*

▶ **Definition 9.** *Let* C *be a code of length* n *over* $\mathbb{F}$*, let* $i \in [n]$ *and* $B \subseteq [n]$*. We say that* B determines i in C *if there exists a function* $f : \mathbb{F}^{|B|} \to \mathbb{F}$ *such that for every* $c \in C$*,* $c_i = f(c_B)$*.*

We also need the following property of linear codes.

▶ **Fact 10.** *Let* C *be a code of length* n *over* $\mathbb{F}$*. Further let* $i \in [n]$*,* $Q \subseteq [n]$ *and* $x \in \mathbb{F}^{|Q|}$*. Then, one of the following cases must hold.*

1. *There is at most one* $\alpha \in \mathbb{F}$ *for which there exists some* $c \in C$ *satisfying* $c_Q = x$ *and* $c_i = \alpha$*.*
2. *For every* $\alpha \in \mathbb{F}$ *there is an equal number of* $c \in C$ *for which* $c_i = \alpha$*.*

In particular, either no function (even randomized) of c_Q *can predict* c_i *with probability larger than* $1/|\mathbb{F}|$*, when* $c \in C$ *is randomly chosen uniformly, or* c_Q *determines* c_i *for all* $c \in C$*.*

3.3 Locally decodable codes and locally correctable codes

▶ **Definition 11.** *For* $C \subseteq \mathbb{F}^n$*, we say that a procedure* $f : A \to B$ *is with* oracle access to $c \in C$ *if when* f *is run, it gets besides an input* $a \in A$*, access to* $c \in C$*:* f *can query* c_i *for indices* $i \in [n]$*. To describe a specific run of* f *with input* $a \in A$ *and oracle access to* $c \in C$*, we either say that* $f(a)$ is run with oracle access to c*, or write* $f^c(a)$ *for short. We say that* f *is* non-adaptive *if the queries it makes are independent of* $c \in C$*.*

▶ **Definition 12.** *For a code* C *of length* n *and dimension* k *over* $\mathbb{F}$*, and* Enc *and encoding of it,* (C, Enc) *is called a* (q, δ, ε)-LDC *(locally decodable code, abbreviated) if there exists a randomized procedure* $\mathsf{Dec} : [k] \to \mathbb{F}$ *that is given an oracle access to* $z \in \mathbb{F}^n$*, and has the following guarantee. For every* $i \in [k]$*,* $x \in \mathbb{F}^k$ *and* $z \in \mathbb{F}^n$ *satisfying* $\mathsf{dist}(z, \mathsf{Enc}(x)) \leqslant \delta n$*,* $\mathsf{Dec}^z(i) = x_i$ *with probability at least* $1 - \varepsilon$*. Furthermore,* $\mathsf{Dec}^z(i)$ *always makes at most* q *queries to* z*. We further require that* Dec *is non-adaptive. We call* Dec *a* local decoder *(or* decoder*) for* (C, Enc)*, and the parameter* q *is called the* query complexity *of* (C, Enc)*.*

▶ **Definition 13.** *A code-encoding family $C = \{(C^k, \mathsf{Enc}^k)\}$ of codes over $\mathbb{F}$ is called* a family of good $q(k)$-LDC*, or a* a family of good LDC with query complexity $q(k)$*, if every code C^k in the family is a code with rate at least $\rho(k)$, which is a $(q(k), \delta(k), \varepsilon(k))$-LDC, for $\rho(k) = \Omega(1)$, $\delta(k) = \Omega(1)$, and $\varepsilon(k) \leqslant 1/3$.*

We have the following easy fact.

▶ **Fact 14.** *If C is a code of length n and dimension $k > 0$ over $\mathbb{F}$ and Enc is an encoding of it, and if (C, Enc) is a (q, δ, ε)-LDC, then, provided that $\varepsilon < 1 - 1/|\mathbb{F}|$, the (non-local) relative distance of C, Δ, satisfies $\Delta > \delta$.*[3]

▶ **Definition 15.** *A code C of length n over $\mathbb{F}$ is called a* (q, δ, ε)-LCC *(locally correctable code, abbreviated) if there exists a randomized procedure $\mathsf{Cor} : [n] \to \mathbb{F}$ that is given an oracle access to $z \in \mathbb{F}^n$, and has the following guarantee. For every $i \in [n]$, $y \in C$ and $z \in \mathbb{F}^n$ satisfying $\mathsf{dist}(z, y) \leqslant \delta n$, $\mathsf{Cor}^z(i) = y_i$ with probability at least $1 - \varepsilon$. Furthermore, $\mathsf{Cor}^z(i)$ always makes at most q queries to z. We further require that Cor is non-adaptive and that $\mathsf{Cor}(i)$ never queries i*[4]*. We call Cor a* local corrector *(or* corrector*) for C, and the parameter q is called the* query complexity *of C.*

▶ **Definition 16.** *For a code C of length n over $\mathbb{F}$ (not necessarily a (q, δ, ε)-LCC), and $i \in [n]$, we say that i is a* (δ, q, ε)-correctable coordinate *in C if there exists a procedure $\mathsf{Cor} : [n] \to \mathbb{F}$ such that $\mathsf{Cor}(i)$ satisfies the requirements in Definition 15.*

▶ **Definition 17.** *A family $C = \{C^n\}$ of codes over $\mathbb{F}$ is called* a family of good $q(n)$-LCC*, or a* a family of good LCC with query complexity $q(n)$*, if every code C^n in the family is a code with rate at least $\rho(n)$, which is a $(q(n), \delta(n), \varepsilon(n))$-LCC, for $\rho(n) = \Omega(1)$, $\delta(n) = \Omega(1)$, and $\varepsilon(n) \leqslant 1/3$.*

The following well-known fact is an implication of the fact that every linear code has a systematic encoding[5].

▶ **Fact 18.** *If a code C is a (q, δ, ε)-LCC, then there exists an encoding Enc such that (C, Enc) is a (q, δ, ε)-LDC.*

4 Tailor made distance amplification

4.1 Characterization of LCC

In this section, we will need to use two characterizations of LCC, as was given by Definition 15. The first, given next in Definition 19, is of a (q, τ)-LCC, and resembles the definition of smooth codes given by [15] for LDC. A (q, τ)-LCC differs from a (q, δ, ε)-LCC in that its local correction is only required to succeed if it is given a codeword of the code, rather than a possible corrupted codeword. Accordingly, the correction of a (q, τ)-LCC has no "distance" guarantee, but instead it is required not to query any coordinate with too high probability, i.e., probability larger than τ. When we will construct an LCC, it will be easier to first argue that it is a (q, τ)-LCC and use that to show it can be made into a (q, δ, ε)-LCC for any ε and $\delta = \varepsilon/(\tau n)$.

[3] Note that in the case that $\varepsilon < 1/2$ a stronger bound $\Delta > 2\delta$ holds.

[4] The assumption that $\mathsf{Cor}(i)$ never queries i is only for simplicity. Any LCC which defies this assumption can be easily converted to one which does not, with a negligible effect on δ.

[5] An encoding Enc is a *systematic* encoding if for some $f : [k] \to [n]$, for all $x \in \mathbb{F}^k$ and $i \in [k]$, $\mathsf{Enc}(x)_{f(i)} = x_i$.

The second characterization, which will be given in Definition 23, is of what we call a (q,τ)-*query-set LCC*. Informally, a code is (q,τ)-*query-set LCC* if for every coordinate we have a large enough set of disjoint subsets of $[n]$, from which it can be decoded. The distance amplification procedure that we define utilizes these query sets and so the properties of the input code that we will use are that of its characterization as a (q,τ)-query-set LCC. This is, in a sense, a more "combinatorial" characterization of LCC which can be more conveniently used when a manipulation of these objects is needed.

The three characterizations of LCC all imply each other, but some of the transitions are at some cost to the parameters. Indeed, Claim 20 will show that a (q,τ)-LCC is a (q,δ,ε)-LCC for $\delta=\varepsilon/(\tau n)$, Claim 24 will show that a (q,τ)-query-set is a (q,τ)-LCC, and Claim 25 will complete the cycle and show that a (q,δ,ε)-LCC is a (q,τ)-query-set LCC for $\tau=q/(\delta n)$.

▶ **Definition 19.** *A code C of length n over $\mathbb{F}$ is called a (q,τ)-LCC if there exists a randomized procedure $\mathsf{Cor}:[n]\to\mathbb{F}$ that is given an oracle access to $c\in C$, and has the following guarantee. For every $i\in[n]$ and $c\in C$, $\mathsf{Cor}^c(i)=c_i$, with probability 1. Furthermore, $\mathsf{Cor}^c(i)$ always makes at most q queries to c, and for every $j\in[n]$, the probability that c_j is queried by $\mathsf{Cor}^c(i)$ is at most τ. We further require that Cor is non-adaptive and that $\mathsf{Cor}(i)$ never queries i. We call the parameter q* the query complexity *and the parameter τ the* smoothness *of the LCC.*

▷ Claim 20. Let C be a code of length n which is a (q,τ)-LCC. Then, for any $\varepsilon>0$, C is a (q,δ,ε)-LCC with $\delta=\varepsilon/(\tau n)$.

Proof. Let $\varepsilon>0$ and let Cor be a corrector of C. Let $c\in C$ and $z\in\mathbb{F}^n$ such that $\mathsf{dist}(c,z)\leqslant\delta n=\varepsilon/\tau$, and set $B=\{j\in[n]\mid z_j\neq c_j\}$. Fix $i\in[n]$. By the union bound over $j\in B$, except with probability ε, when $\mathsf{Cor}(i)$ is run with oracle access to $c\in C$, it does not make a query to an index in B. If this is the case, then if Cor was given access to z instead of c, it would successfully output c_i, as well. Thus, C is indeed a (q,δ,ε)-LCC as the same corrector Cor can be used with oracle access to strings $z\in\mathbb{F}^n$, and given that $\mathsf{dist}(c,z)\leqslant\delta n$, $\mathsf{Cor}(i)$ is promised to output c_i with probability at least $1-\varepsilon$. ◁

▶ **Definition 21.** *A set $\mathcal{A}=\{A_1,\ldots,A_n\}$ is called an* n-query-set *if for every $i\in[n]$, A_i is a set of disjoint subsets of $[n]\backslash\{i\}$. For every $i\in[n]$ we define $\overline{A_i}=\bigcup_{B\in A_i}B$.*

▶ **Definition 22.** *Let C be a code of length n and let $\mathcal{A}=\{A_1,\ldots,A_n\}$ be an n-query-set. $\mathcal{A}$ is said to be a* query-set for C *if for every $i\in[n]$ and $B\in A_i$, B determines i in C (see Definition 9).*

▶ **Definition 23.** *Let C be a code of length n. C is said to be a* (q,τ)-query-set-LCC *if there exists a set $\mathcal{A}=\{A_1,\ldots,A_n\}$ which is a query-set for C, such that for every $i\in[n]$, $|A_i|\geqslant 1/\tau$ and for every $B\in A_i$, $|B|\leqslant q$.*

▷ Claim 24. Let C be a code of length n over $\mathbb{F}$ which is a (q,τ)-query-set LCC. Then C is a (q,τ)-LCC.

Proof. Let $\mathcal{A}=\{A_1,\ldots,A_n\}$ be a query set that corresponds to C being a (q,τ)-query-set LCC. The following corrector Cor shows that C is a (q,τ)-LCC. Given $i\in[n]$, and oracle access to $c\in C$, $\mathsf{Cor}(i)$ samples uniformly at random some $B\in A_i$ and queries c_B. As B determines i in C, there exists a function f satisfying $f(c_B)=c_i$ for every $c\in C$, and so $\mathsf{Cor}(i)$ uses such a function and outputs its result. Thus, for every $c\in C$, the output of $\mathsf{Cor}(i)$ is always equal to c_i, and note that as any sampled $B\in A_i$ satisfies $|B|\leqslant q$, $\mathsf{Cor}(i)$ always makes at most q queries. Since A_i is of size at least $1/\tau$ and is composed of disjoint subsets of $[n]\backslash\{i\}$, any coordinate is queried by $\mathsf{Cor}(i)$ with probability at most τ, and $\mathsf{Cor}(i)$ never queries i. Thus, C is a (q,τ)-LCC. ◁

▷ Claim 25. Let C be a code of length n over $\mathbb{F}$ which is a (q, δ, ε)-LCC, for $\varepsilon < 1 - 1/|\mathbb{F}|$. Then, C is a (q, τ)-query-set-LCC for $\tau = q/(\delta n)$.

The proof for the claim is similar to the proof in [15] to their Theorem 1 and to the proof in [10] for Theorem 1.1.

Proof for Claim 25. To prove the claim, we need to show that there exists a set $\mathcal{A} = \{A_1, \ldots, A_n\}$ which is a query-set for C, such that for every $i \in [n]$, $|A_i| \geqslant 1/\tau = \delta n/q$ and for every $B \in A_i$, $|B| \leqslant q$. We construct $\mathcal{A}$ with the required properties by constructing each of the subsets separately. Let Cor denote a corrector promised by the fact that C is a (q, δ, ε)-LCC, and let $i \in [n]$. To construct A_i, we construct a sequence of disjoint sets $B^i_1, \ldots, B^i_{m_i} \subseteq [n] \backslash \{i\}$, in an iterative manner. We will eventually set $A_i = \{B^i_1, \ldots, B^i_{m_i}\}$. It will hold that for every j, B^i_j determines i in C, while satisfying $|B^i_j| \leqslant q$, and that $m_i \geqslant \delta n/q$, which will conclude the proof.

The construction of $B^i_1, \ldots, B^i_{m_i} \subseteq [n]$ is done by the following procedure. Start by setting $B^i_0 = \varnothing$. For $j = 1, 2, \ldots$, set $S^i_j = B^i_0 \cup \cdots \cup B^i_{j-1}$. If $|S^i_j| > \delta n$ halt and set $m_i = j - 1$ and $A_i = \{B^i_1, \ldots, B^i_{m_i}\}$. Otherwise, it holds that for every $c \in C$, for every modification of the coordinates in S^i_j to some erroneous values, $\mathsf{Cor}(i)$ correctly outputs c_i with probability at least $1 - \varepsilon$. An equivalent description of this case is the following: for every $c \in C$ and $z : S^i_j \to \mathbb{F}$, define $c^z \in \mathbb{F}^n$ such that for every $r \notin S^i_j$, $c^z_r = c_r$ and for $r \in S^i_j$, $c^z_r = z(r)$. The corrector Cor chooses a set of queries $Q \subseteq [n] \backslash \{i\}$, $|Q| \leqslant q$, according to some distribution[6] and applies some function f_Q on c^z_Q. We know that with probability at least $1 - \varepsilon$, $f_Q(c^z_Q) = c_i$. Since Q is sampled in a manner that is independent of c and z, by an averaging argument, there exists some fixed Q for which when $c \in C$ and $z : S^i_j \to \mathbb{F}$ are chosen randomly in a uniform manner, with probablity at least $1 - \varepsilon$ (this time over the choice of c and z), $f_Q(c^z_Q) = c_i$. Therefore, we can define another function f'_Q that only gets $c_{Q \backslash S^i_j}$, chooses z uniformly at random, and outputs $f_Q(c^z_Q)$. If $c \in C$ is chosen uniformly at random, $f'_Q(c_{Q \backslash S^i_j}) = c_i$ with probability at least $1 - \varepsilon > 1/|\mathbb{F}|$. By Fact 10, this implies that $Q \backslash S^i_j$ determines i in C. We therefore set $B^i_j = Q \backslash S^i_j$[7], and proceed to the next j.

As this process only halts when $|S^i_j| > \delta n$, and for every j, $|S^i_j| \leqslant q(j-1)$, we have that $m_i \geqslant \delta n/q$. Further note that by the choice of each B^i_j, the sets $B^i_1, \ldots, B^i_{m_i}$ are disjoint, and of size at most q, as required. This thus shows how each A_i can be constructed, and the claim follows. ◁

4.2 Splitters for query sets

Splitters for query sets, that are defined as follows, are key ingredients in our distance amplification procedure. Informally, a *c-splitter* for a query set $\mathcal{A} = \{A_1, \ldots, A_n\}$ is partition of $[n]$ which satisfies that for every i, the intersection between $\overline{A_i}$, the union all the sets in A_i that correspond to an index i, and each part of the partition, is not too large, i.e., of size at most c. In the distance amplification procedure, we will describe a corrector which samples a set $B \in A_i$, in some query set $\mathcal{A}$, and then makes queries according to which parts of the c-splitter intersect with B. For the resulted queries to be smooth, we will need the partition to "split" $A_1, \ldots, A_n$, meaning that no part of the partition is too common within any certain A_i.

[6] As the corrector in non-adaptive, $\mathsf{Cor}(i)$ naturally induces a distribution on subsets of $[n]$ which correspond to the possible query sets.

[7] Note that $i \notin B^i_j$, as $i \notin Q$, since $\mathsf{Cor}(i)$ by definition never queries i.

▶ **Definition 26.** *Let $n \in \mathbb{N}$, $\mathcal{A}$ an n-query-set and $c \in \mathbb{N}$. A partition π of $[n]$ is called a* c-splitter of $\mathcal{A}$ *if for every $i \in [n]$ and $P \in \pi$, $|P \cap \overline{A_i}| \leqslant c$.*

The next claim shows that if each A_i is of size at most k, then c-splitters with k parts exist, for c, the bound on the maximal intersection, being equal to roughly the minimal intersection that is possible, up to a constant factor.

▷ Claim 27. Let $n, k, q \in \mathbb{N}$ such that $k/n \leqslant 1$ and $q \geqslant \log n$. Further let $\mathcal{A} = \{A_1, \ldots, A_n\}$ be an n-query-set such that for every $i \in [n]$, $|A_i| \leqslant k$ and for every $B \in A_i$, $|B| \leqslant q$. Then, there exists a partition π of $[n]$ with k parts, each of size n/k, which is a c-splitter of $\mathcal{A}$ for $c = 2eq$.

Proof. The proof is by a probabilistic argument. We randomly choose a partition π with k equally-sized parts in a uniform manner among all such partitions. We bound the probability that π is not a c-splitter for $\mathcal{A}$: this is the case if $|\overline{A_i} \cap P| > c$ for some $i \in [n]$ and P a part of π. Towards this end, we first fix some $i \in [n]$ and $t \in [k]$, and let P_t denote the t-th part of π. We have that for every $j \in \overline{A_i}$ the probability that $j \in P_t$ is $1/k$, and for every fixed subset of $\overline{A_i}$ of size c, the probability that it is contained in P_t is at most $(1/k)^c$ (since for distinct $j, j' \in \overline{A_i}$, the events that $j \in P_t$ and $j' \in P_t$ are negatively correlated). By a union bound over the possible subsets of size c, the probability that $|\overline{A_i} \cap P_t| > c$ is at most

$$\begin{aligned}\binom{|\overline{A_i}|}{c}(1/k)^c &\leqslant \left(\frac{e|\overline{A_i}|}{ck}\right)^c \\ &\leqslant \left(\frac{eq}{c}\right)^c \\ &= \left(\frac{1}{2}\right)^{2eq}.\end{aligned}$$

By taking a union bound over all possible i, t, the probability that there exist $i \in [n]$ and $t \in [k]$ such that $|\overline{A_i} \cap P_t| > c$ is at most $nk\left(\frac{1}{2}\right)^{2eq} \leqslant n^2\left(\frac{1}{2}\right)^{2eq}$, which is less than 1 a $q \geqslant \log n$, and the claim follows. ◁

4.3 The distance amplification procedure

We now turn to define the basic operation behind our distance amplification procedure. This operation "composes"[8] two codes of different lengths, a big code and a small code, in a way that is parameterized by some partition of $[n]$. The result is a code of the same length as the big code, with an improved smoothness (if the partition satisfies certain requirements), as we will have in the claims that follow the definition. The distance amplification procedure (or perhaps, more directly, the smoothness amplification procedure) will be an iterative application of this composition.

▶ **Definition 28.** *Let C_1 be a code of length n_1, C_2 a code of length n_2, π a partition of $[n_1]$ into n_1/n_2 parts of size n_2. We define the* π-composition of C_1 and C_2, *which we denote by $C_1 \odot_\pi C_2$, to be the code $\{c \in C_1 \mid \forall P \in \pi \quad c_P \in C_2\}$.*

A bound on the rate of the composition of two codes is given in the following claim.

[8] Note that the term "composition" here is used in a different sense than the usual composition of two codes in coding theory, which is achieved from the composition of the encoding functions.

▷ Claim 29. If C_1, C_2 are codes with of lengths n_1, n_2 and rates ρ_1, ρ_2 respectively, then $C = C_1 \odot_\pi C_2$ is a code of length n_1 and rate at least $\rho_1 + \rho_2 - 1$.

Proof. That the length of C is n_1 follows from the definition. As for the rate, by inspecting the code dual to C, it can be seen that the dimension of $C^\perp$ is at most

$$d = (1-\rho_1)n_1 + \frac{n_1}{n_2}(1-\rho_2)n_2.$$

From that, the rate of C is at least $1 - d/n_1 = \rho_1 + \rho_2 - 1$. ◁

We now show that if the partition used in the composition is a c-splitter for a query set of the big code, the resulted code has smoothness roughly equal to the product of the two smoothnesses.

▷ Claim 30. Let C_1 be a code of length n_1 and C_2 a code of length n_2 which is a (q_2, τ_2)-LCC. Let $\mathcal{A} = \{A_1, \ldots, A_{n_1}\}$ be a query-set for C_1 such that for every i, $|A_i| \geqslant 1/\tau_1$ and for every $B \in A_i$, $|B| \leqslant q_1$. If π is a c-splitter for $\mathcal{A}$, then $C = C_1 \odot_\pi C_2$ is a (q, τ)-LCC for $q = q_1 q_2$ and $\tau = c\tau_1\tau_2$.

Proof. To show that C is a (q, τ)-LCC we need to show a corrector Cor for it. We first set up some notations. Let Cor_2 be a corrector promised by the fact that C_2 is a (q_2, τ_2)-LCC. For every $j \in [n]$, let P_j denote the part of π that contains j, and let $\bar{j}$ denote the index of j in P_j with respect to the natural order. For $i \in [n]$, and $B \in A_i$, let $f_{i,B} : \mathbb{F}^{|B|} \to \mathbb{F}$ denote a function satisfying $f_{i,B}(c_B) = c_i$ for every $c \in C_1$. Such $f_{i,B}$ is guaranteed to exists as $\mathcal{A}$ is a query-set for C_1.

For $i \in [n]$, $\mathsf{Cor}(i)$ with oracle access to $c \in C$ acts as follows: it first samples $B \in A_i$ uniformally at random. Secondly, for every $j \in B$, the procedure obtains c_j by invoking $\mathsf{Cor}_2(\bar{j})$ with oracle access to c_{P_j}. After obtaining c_j for every $j \in B$, $\mathsf{Cor}(i)$ outputs $f_{i,B}(c_B)$.

That $\mathsf{Cor}(i)$ successfully outputs c_i for every $c \in C$ is immediate, and follows from the fact that for every j, c_{P_j} is a codeword of C_2 and so $\mathsf{Cor}_2(\bar{j})$ with access to c_{P_j} correctly outputs c_j, and from the fact $c \in C_1$ and so $f_{i,B}(c_B) = c_i$. Moreover, $\mathsf{Cor}(i)$ makes at most $q_1 q_2$ queries to c, since $|B| \leqslant q_1$ by assumption, and Cor_2 makes at most q_2 queries.

It remains to bound the probability that a coordinate $r \in [n]$ is queried by $\mathsf{Cor}(i)$ for $i \in [n]$. Let p be the probability that $\mathsf{Cor}(i)$ queries r. Fix $B \in A_i$. Conditioned on the event that B was sampled by $\mathsf{Cor}(i)$ in the first step, r is queried by $\mathsf{Cor}(i)$ if one of the calls to $\mathsf{Cor}_2(\bar{j})$, with oracle access to c_{P_j}, queries c_r for some $j \in B$. That probability is at most $|B \cap P_r|\tau_2$. Indeed, this follows by taking the union bound over the different $j \in B$, noting that if $j \notin P_r$, c_r cannot be queried by $\mathsf{Cor}_2(\bar{j})$, and using that Cor_2 queries any coordinate with probability bounded above by τ_2. Therefore,

$$\begin{aligned}
p &\leqslant \sum_{B \in A_i} \mathbf{Pr}[B \text{ is sampled by } \mathsf{Cor}(i)] \cdot |B \cap P_r|\tau_2 \\
&= \sum_{B \in A_i} \frac{1}{|A_i|} \cdot |B \cap P_r|\tau_2 \\
&\leqslant \sum_{B \in A_i} \tau_1 \cdot |B \cap P_r|\tau_2 \\
&= \tau_1\tau_2 |P_r \cap \overline{A_i}| \\
&\leqslant c\tau_1\tau_2.
\end{aligned}$$

Note that we used the assumptions that $|A_i| \geqslant 1/\tau_1$, and that π is a c-splitter for $\mathcal{A}$. We thus have that $p \leqslant c\tau_1\tau_2$, which concludes the proof. ◁

The following lemma concludes the properties of the code that is achieved by the composition of two codes, when done with the c-splitter that is given by Claim 27.

▶ **Lemma 31.** *Let $n \in \mathbb{N}$. Assume there exists a code C_1 of length n over $\mathbb{F}$, with rate ρ_1, which is a (q_1, τ_1)-query-set-LCC for $q_1 \geqslant \log n$. Further assume that there exists a code C_2 of length $n\tau_1$ over $\mathbb{F}$, with rate ρ_2, which is a (q_2, τ_2)-LCC. Then, there exists a code C of length n, with rate $\rho_1 + \rho_2 - 1$, which is a $(q_1 q_2, 2eq_1\tau_1\tau_2)$-LCC.*

Proof. As C_1 is a (q_1, τ_1)-query-set-LCC, there exists an n-query-set $\mathcal{A} = \{A_1, \ldots, A_n\}$ in which for every i, $|A_i| \geqslant 1/\tau_1$ and for every $B \in A_i$, $|B| \leqslant q_1$. In particular, there exists a query set $\mathcal{A}' = \{A'_1, \ldots, A'_n\}$ in which every A'_i is of size exactly $1/\tau_1$ (which is achieved by, for each A_i, arbitrarily removing sets $B \in A_i$ until it is of size $1/\tau_1$). By Claim 27 invoked with $k = 1/\tau_1$, there exists a partition π of $[n]$, in which every part is of size $\tau_1 n$, which is a c-splitter for $\mathcal{A}'$, with $c = 2eq_1$. We take $C = C_1 \odot_\pi C_2$ to be the code with the claimed properties. Indeed, by Claim 29, C is of length n, and has rate at least $\rho_1 + \rho_2 - 1$. Furthermore, by applying Claim 30, and using that π is a c-splitter for $\mathcal{A}'$, we get that C is a (q, τ)-LCC for $q = q_1 q_2$ and $\tau = 2eq_1\tau_1\tau_2$, and the lemma follows. ◀

The following lemma, or more precisely, its proof, composes the distance amplification procedure. It assumes a family of codes which are LCC, and describes the properties of the code that is obtained by an iterative application of the composition, where at each iteration a code of the family is composed with the "current" code.

▶ **Lemma 32.** *Assume there exists a family of codes $C = \{C^n\}$ over $\mathbb{F}$, in which every code C^n of length n in the family is a code of rate $\rho(n) = 1 - r(n)$, which is a $(q(n), \tau(n))$-query-set-LCC for $q(n) \geqslant \log n$. Then, for every $t \in \mathbb{N}$, there exists a code family $C' = \{(C')^n\}$ over $\mathbb{F}$ which has a code $(C')^n$ of length n for every n which is a code length in C, and $(C')^n$ has the following properties. Define $n_1 = n$ and for $i = 2, \ldots, t+1$ let $n_i = \left\lceil \tau(n_{i-1}) n_{i-1} \right\rceil^C$. Then, $(C')^n$ has rate $\rho'(n) = 1 - \sum_{i=1}^{t} r(n_i)$, and is a $(q'(n), \tau'(n))$-LCC for $q'(n) = \prod_{i=1}^{t} q(n_i)$ and*

$$\tau'(n) = (2e)^{t-1} \frac{n_{t+1}}{n} \prod_{i=1}^{t-1} q(n_i).$$

Proof. To show the existence of a code family with the claimed properties, we describe how for every n that is a length of a code in the family C, a code of the same length, of the family C', can be constructed. Let C^n be a code of length n of the family C. Set $n_1 = n$ and for $i = 2, \ldots, t+1$, $n_i = \left\lceil \tau(n_{i-1}) n_{i-1} \right\rceil^C$, as defined in the claim. We construct a sequence of codes $C'_1, \ldots, C'_t$, where for each $i \in [t]$, C'_i is a code of length n_i and rate ρ'_i, which is a (q'_i, τ'_i)-LCC. We start by setting $C'_t = C^{n_t}$, and for $i = t-1, \ldots, 1$, we take C'_i to be a code which is the result of applying Lemma 31 on C^{n_i} and C'_{i+1}. Note that C^{n_i} is a $(q(n_i), \tau(n_i))$-query-set-LCC and C'_{i+1} is a code of length $n_{i+1} \geqslant \tau(n_i) n_i$, and so in particular C^{n_i} is indeed of smoothness n_{i+1}/n_i, as required for the lemma to be applicable. From Lemma 31 it follows that C'_i is a code of rate

$$\rho'_i = \rho(n_i) + \rho'_{i+1} - 1 = \rho'_{i+1} - r(n_i)$$

which is a (q'_i, τ'_i)-LCC for

$$q'_i = q(n_i) q'_{i+1},$$
$$\tau'_i = 2eq(n_i) \tau'_{i+1} \frac{n_{i+1}}{n_i}.$$

Recall that $C'_t = C^{n_t}$ and so $\rho'_t = 1 - r(n_t)$, $q'_t = q(n_t)$ and $\tau'_t = \tau(n_t)$. It follows inductively that for every $i \in [t]$,

$$\rho'_i = 1 - \sum_{j=i}^{t} r(n_j),$$

$$q'_i = \prod_{j=i}^{t} q(n_j),$$

and

$$\begin{aligned}\tau'_i &= (2e)^{t-i}\left(\prod_{j=i}^{t}\frac{n_{j+1}}{n_j}\right)\left(\prod_{j=i}^{t-1} q(n_j)\right)\\ &= (2e)^{t-i}\frac{n_{t+1}}{n_i}\left(\prod_{j=i}^{t-1} q(n_j)\right).\end{aligned}$$

We set C'_1, which is indeed a code of length n, to be the code $(C')^n$ of C', and from the account given above it follows that its rate, query complexity and smoothness are as stated, i.e., that $q'_1 = q'(n)$, $\rho'_1 = \rho'(n)$ and $\tau'_1 = \tau'(n)$. We thus have that C' is a family of codes with rate at least $\rho(n)$ that are $(q(n), \tau(n))$-LCC, and the lemma follows. ◀

4.4 Corollaries

In this part we present two corollaries of our distance amplification procedure that is given by Lemma 32. As a special case of the first corollary, Corollary 34, we will have that if one has a sufficiently dense code family of $(q(n), \delta(n), \varepsilon(n))$-LCC which is of high rate, meaning that each code has rate $\rho(n)$ that approaches 1 "fast enough", but with $\delta(n)$ that is only polynomially small in n, $\delta(n) = 1/n^{\alpha}$, for some constant $\alpha \in (0, 1)$, then there exists a good family of LCC with query complexity $q(n)^{O(\log\log n)}$. In the general case, a weaker guarantee on $\delta(n)$ can also be handled by Corollary 34, meaning that a sub-polynomial $\delta(n)$ can also be amplified. More precisely, Corollary 34 will state that if $\delta(n) = 1/n^{1-1/g(n)}$ for a (non-decreasing) function $g(n)$, then a family of good LCC can be constructed, with query complexity $q(n)^{O(g(n)\log\log n)}$. The requirement of the rate function $\rho(n)$, which we described as approaching 1 "fast enough", in more detail comes down to the requirement that $\rho(n) \geqslant 1 - 1/(g(n)(\ln\ln n)^2)$.

The second corollary, Corollary 37, addresses the case that the family of $(q(n), \delta(n), \varepsilon(n))$-LCC one starts with is of a much smaller rate, either of a constant rate or of a vanishing rate of $(1/\ln\ln n)^h$ for some constant h. In the case that $\delta(n) = 1/n^{\alpha}$ for some constant $\alpha \in (0, 1)$ and $\rho(n) \geqslant (1/\ln\ln n)^h$, as a special case Corollary 37 we will have that there exists a family of good LCC with query complexity $q(n)^{\mathrm{poly}(\log\log n)}$. Here too, sub-polynomial $\delta(n)$ can also handled by the corollary, as in a more general case, it is shown by Corollary 37 that if $\delta(n) = 1/n^{1-1/g(n)}$ for a non-decreasing $g(n) \leqslant \log n$, and if $\rho(n)$ is at least $(1/\ln\ln n)^h$ for some constant h, then a family of good LCC can be constructed, with query complexity $q(n)^{g(n)\mathrm{poly}(\log\log n)}$. The precise statement Corollary 37 is more generally stated and handles a few more cases that may be of interest.

We remark that while in any case that Corollary 34 can be applied so can Corollary 37 be used, the reason that we state both corollaries is that if one starts with an LCC that satisfies the requirement of Corollary 34 then using it, rather than using Corollary 37, would result in a better bound on the resulted query complexity. We further remark that the proof for

Corollary 37 builds on Corollary 34. Lastly, another reason that Corollary 34 is of interest is that it has an analogous corollary in the case of LDC (see Corollary 35), unlike Corollary 37 (whose proof relies on properties specific to LCC).

The proofs for the corollaries can be found in the full version of the paper (see [6]).

4.4.1 From high rate and low distance LCC to good LCC

The proof for the first corollary relies on the following lemma which states that any family of (q, τ)-LCC with constant rate can be converted to a family of good LCC by paying a multiplicative factor of $\text{poly}(\tau n)$ in query complexity. This lemma follows from the AEL distance amplification procedure [2, 1] and from the adaptation of it by [17] for LDC and LCC. To derive this lemma with certain parameters, some adaptations to these techniques are needed, and so we provide a full proof for Lemma 33 in the appendix of the full version.

▶ **Lemma 33.** *Let $C = \{C^n\}$ be a code family over $\mathbb{F}$ in which every code C^n is a $(q(n), \tau(n))$-LCC with rate $\rho(n) = \Omega(1)$. Then, there exists a code family $C' = \{(C')^n\}$ over $\mathbb{F}$ which has a code $(C')^n$ of length n for every C^n in C, such that $(C')^n$ is a $(q'(n), \delta'(n), \varepsilon)$-LCC for $q'(n) = O(q(n)(n\tau(n))^2)$, $\delta'(n) = \Omega(1)$ and $\varepsilon = 1/3$, with rate $\rho'(n) = \Omega(1)$.*

We now state our first corollary.

▶ **Corollary 34.** *Let $q(n) \geqslant \log n$[9] and $g(n) > 1$ be two non-decreasing functions. Assume there exists a family of codes $C = \{C^n\}$ over $\mathbb{F}$ that is (n_0, c, d)-dense, in which every code C^n of length n has rate*

$$\rho(n) \geqslant 1 - \frac{1}{g(n)(\ln \ln n)^2},$$

and either C^n is a $(q(n), \delta(n), \varepsilon(n))$-LCC, for $\varepsilon(n) < 1 - 1/|\mathbb{F}|$ and $\delta(n) = 1/n^{1-1/g(n)}$, or it is a $(q(n), \tau(n))$-query-set-LCC, for $\tau(n) = q(n)/n^{1/g(n)}$. Then, there exists a family of codes $C' = \{(C')^n\}$ over $\mathbb{F}$ that is (n_0, c, d)-dense, which is a family of good LCC with query complexity $q_{new}(n) = q(n)^{O(g(n) \ln \ln n)}$.

Note that Corollary 34 allows for the code family C in the hypothesis to be one of two types, either a family of (q, δ, ε)-LCC or a family of (q, τ)-query-set-LCC. For the proof, what we actually need is that C is of the second type. However, if one starts with a family C which is known to be of the first (more standard) type, with the specified $\delta(n)$, by Claim 25 it will follow that C is a family of query-set-LCC with the same smoothness $\tau(n)$ that is stated in the corollary in the second case. The corollary explicitly allows both of the types because it is also possible that the base code is already known to be a query-set-LCC, as would be the case in the proof of Corollary 37, which uses Corollary 34. It is preferable to avoid going back and forth between the types, as this has some cost in the resulted parameters.

We further state a corollary analogous to Corollary 34, that holds in the case of LDC. The proof for this corollary is straightforward given the result regarding LCC, and follows the same lines.

[9] We remark that while we assume for simplicity that $q(n) \geqslant \log n$, by the Katz-Trevisan bound (instantiated for the case of rate and distance as specified by the corollary), lifting this assumption would not yield an improvement in the obtained query complexity in any case.

▶ **Corollary 35.** *Let $n(k) > k$, $q(k) \geqslant \log n(k)$ and $g(k) > 1$ be non-decreasing functions. Assume there exists a code-encoding family $C = \{(C^k, \mathsf{Enc}^k)\}$ over $\mathbb{F}$ that is (k_0, c, d)-dense, in which every code C^k of dimension k has rate*

$$\rho(k) \geqslant 1 - \frac{1}{g(k)(\ln \ln k)^2} > \frac{1}{2},$$

and either (C^k, Enc^k) is a $(q(k), \delta(k), \varepsilon(k))$-LDC, for $\varepsilon(k) < 1 - 1/|\mathbb{F}|$ and $\delta(k) = 1/n(k)^{1-1/g(k)}$. Then, there exists a code-encoding family $C' = \{((C')^k, (\mathsf{Enc}')^k)\}$ over $\mathbb{F}$ that is (k_0, c, d)-dense, which is a family of good LDC with query complexity $q_{new}(k) = q(k)^{O(g(k) \ln \ln k)}$.

4.4.2 From low rate and low distance LCC to good LCC

The proof for our second corollary uses the following proposition from [7]. This proposition is basically Proposition 4.14 in [7] but for (q, τ)-query-set-LCC rather than for a different object[10]. That the proposition indeed applies to (q, τ)-query-set-LCC is quite immediate with the account given in [7].

▶ **Proposition 36** (Implicit in [7])**.** *Let C be a code of length n over $\mathbb{F}$ with rate ρ that is a (q, τ)-query-set-LCC. Then, for every $\ell \in \mathbb{N}$, there exists a code C' of length $n' = n^\ell$ with rate $1 - (1 - \rho)^\ell$, which is a (q', τ)-query-set-LCC for $q' = q^\ell$.*

We now state our second corollary.

▶ **Corollary 37.** *Let $h \geqslant 1$ be an arbitrary constant, $q(n) \geqslant \log n$ and $g(n) \in [1, \log n]$ non-decreasing functions, and $\rho(n)$ a non-increasing function, satisfying*

$$\frac{1}{(\ln \ln n)^h} \leqslant \rho(n) \leqslant 1 - \frac{1}{g(n)(\ln \ln n)^2}$$

for every n. Assume further that

$$\frac{1}{\rho(n+1)}(\ln g(n+1) + \ln \ln \ln(n+1)) - \frac{1}{\rho(n)}(\ln g(n) + \ln \ln \ln n) = O\left(\frac{1}{\log n}\right).$$

Assume there exists a family of codes $C = \{C^n\}$ over $\mathbb{F}$ that is $(n_0, 1, 1)$-dense[11], in which every code C^n of length n is a code of rate $\rho(n)$, which is a $(q(n), \delta(n), \varepsilon(n))$-LCC, for $\varepsilon(n) < 1 - 1/|\mathbb{F}|$ and

$$\delta(n) = \frac{1}{n^{1-1/g(n)}}.$$

Then, there exists a family of codes $C' = \{(C')^n\}$ over $\mathbb{F}$, which is a family of good LCC with query complexity $q_{new}(n) = q(n)^{e(n)}$ for

$$e(n) = O\left(\frac{1}{\rho(n)^2}(\ln g(n) + \ln \ln \ln n)^2 g(n) \ln \ln n\right).$$

[10] "dual SLR" in the terminology of [7].

[11] Note that if one starts with a code family C that is (n_0, c, d) for some constants c, d, then it can be easily converted to a $(n_0, 1, 1)$-dense family, with a constant multiplicative cost to the rate and with little affect to the obtained parameters.

5 LDC are not LCC via random weighted tensor codes

In this section we argue that there exist linear codes which are LDC but not LCC, in the following strong sense. Not only are these codes LDC while not being LCC even for a weak requirement of very high query complexity and very low correction radius, moreover, this negative property that local correction with such parameters is impossible is maintained in any puncturing of the code. We will be able to show this to be the case because in the codes that we construct the uncorrectable coordinates are crucial for the distance of the code, and in particular for the LDC feature of the code, thus any attempt to remove them while keeping these properties, fails. In this section here we state the main claims required for proving the result, the proofs for which can be found in the full version of the paper (see [6]).

We start with a few preliminaries for this section. In what follows we will sometimes need to conveniently convert a pair of indices $i_1 \in [m_1]$, $i_2 \in [m_2]$ to an index $i \in [m_1 m_2]$, and so we set the following convention. Where $m_1, m_2 \in \mathbb{N}$ are clear from context and $i_1 \in [m_1]$, $i_2 \in [m_2]$, we denote by $(i_1; i_2)$ the index $(i_2 - 1)m_1 + i_1 \in [m_1 m_2]$.

▶ **Definition 38** (Trivial coordinates). *For a code C of length n over $\mathbb{F}$, we say that a coordinate $j \in [n]$ is* trivial *(in C) if for every $c \in C$, $c_j = 0$.*

▶ **Definition 39** (Puncturing of codes). *Let C be a code of length n and dimension k over $\mathbb{F}$ and let $J \subseteq [n]$. For every codeword $c \in C$, we define the vector $(y_1, \ldots, y_n) \in \mathbb{F}^n$, where $y_j = c_j$ if $j \notin J$ and $y_j = 0$ otherwise, to be the J-*puncturing of c, *and we denote it by $c_{\setminus J}$. We define $\{c_{\setminus J} \mid c \in C\}$ to be the J-*punctured code C, and denote it by $C_{\setminus J}$. *Note that $C_{\setminus J}$ is indeed a code. Furthermore, given an encoding Enc of C, we define $\mathsf{Enc}_{\setminus J} : \mathbb{F}^k \to \mathbb{F}^n$ by $\mathsf{Enc}_{\setminus J}(x) = \mathsf{Enc}(x)_{\setminus J}$ for all $x \in \mathbb{F}^k$.*

5.1 Weighted tensors

We turn to define an operation to which we call the *weighted tensor* of two codes and state several of its properties. The codes of Theorem 3 will be constructed using a weighted tensor. This operation gets two input codes (more precisely, two codes and respective encodings), and a matrix of non-zero entries, and results in a new code. To define the result of the operation, we will define a new encoding function which depends on the encodings of the two input codes and on the weight matrix. We will then take the resulted code to be the image of that encoding. We begin by describing the encoding function of the *weighted tensor*.

Let $\mathsf{Enc}_1 : \mathbb{F}^{k_1} \to \mathbb{F}^{n_1}$ and $\mathsf{Enc}_2 : \mathbb{F}^{k_2} \to \mathbb{F}^{n_2}$ be a linear maps, and let $B \in \mathbb{F}^{n_1 \times k_2}$ be a matrix with non-zero entries. We define the following function $\mathsf{Enc} : \mathbb{F}^{k_1 k_2} \to \mathbb{F}^{n_1 n_2}$ that acts as follows on input $x \in \mathbb{F}^{k_1 k_2}$.

Action of Enc on x

1. Identify x with a matrix $X \in \mathbb{F}^{k_1 \times k_2}$ where for $i_1 \in [k_1]$, $i_2 \in [k_2]$, $X_{i_1, i_2} = x_{(i_1; i_2)}$.
2. Use Enc_1 to encode each column of X and set X' to be the resulted matrix, $X' \in \mathbb{F}^{n_1 \times k_2}$.
3. For each $j_1 \in [n_1], i_2 \in [k_2]$ multiply the element X'_{j_1, i_2} by B_{j_1, i_2} and set X'' to be the resulted matrix.
4. Use Enc_2 to encode each row of X'' and set X''' to be the resulted matrix, $X''' \in \mathbb{F}^{n_1 \times n_2}$.
5. Output $x' \in \mathbb{F}^{n_1 n_2}$ where for $j_1 \in [n_1], j_2 \in [n_2]$, $x'_{(j_1; j_2)} = X'''_{j_1, j_2}$.

▷ Claim 40. If Enc_1 and Enc_2 are injective then so is Enc.

▷ Claim 41. Let $A^1 \in \mathbb{F}^{n_1 \times k_1}$ and $A^2 \in \mathbb{F}^{n_2 \times k_2}$ be the generating matrices of Enc_1 and Enc_2, respectively. Then, for every $x \in \mathbb{F}^{k_1 k_2}$, $\mathsf{Enc}(x) = Ax$, where $A \in \mathbb{F}^{n_1 n_2 \times k_1 k_2}$ is the matrix where for $i_1 \in [k_1], i_2 \in [k_2], j_1 \in [n_1], j_2 \in [n_2]$ we have that $A_{(j_1;j_2),(i_1;i_2)} = A^1_{j_1,i_1} A^2_{j_2,i_2} B_{j_1,i_2}$. In particular, Enc is a linear map.

We can now define the weighted tensor operation.

▶ **Definition 42.** *Let Enc_1, Enc_2, B and Enc be as above. Let C_1 be a code of length n_1 and dimension k_1 over $\mathbb{F}$ such that Enc_1 is an encoding of it, and let C_2 be a code of length n_2 and dimension k_2 over $\mathbb{F}$ such that Enc_2 is an encoding of it. Let C be the image of Enc. We define the B-*weighted tensor of (C_1, Enc_1) and (C_2, Enc_2) *to be the pair (C, Enc), and denote $(C, \mathsf{Enc}) = (C_1, \mathsf{Enc}_1) \otimes_B (C_2, \mathsf{Enc}_2)$.*

▷ Claim 43. Let $(C, \mathsf{Enc}) = (C_1, \mathsf{Enc}_1) \otimes_B (C_2, \mathsf{Enc}_2)$. Then C is a code of length $n = n_1 n_2$ and dimension $k = k_1 k_2$ over $\mathbb{F}$, and Enc is an encoding of it.

5.2 Local decodability and correctablity of weighted tensors

The weighted tensor of two LDC is an LDC with comparable parameters, regardless of the weight matrix, as we have in the following claim.

▷ Claim 44. Let (C_1, Enc_1) be a $(q_1, \delta_1, \varepsilon_1)$-LDC, where C_1 is a code of length n_1 and dimension k_1 over $\mathbb{F}$. Let (C_2, Enc_2) be a $(q_2, \delta_2, \varepsilon_2)$-LDC, where C_2 is a code of length n_2 and dimension k_2 over $\mathbb{F}$, and let $B \in \mathbb{F}^{n_1 \times k_2}$ be a matrix with no zero entries. Then, $(C, \mathsf{Enc}) = (C_1, \mathsf{Enc}_1) \otimes_B (C_2, \mathsf{Enc}_2)$ is a $(q_1 q_2, \delta_1 \delta_2, 1 - (1 - \varepsilon_1)(1 - \varepsilon_2)^{q_1})$-LDC.

In the next claim we argue that the weighted tensor of two codes, when performed with a randomly chosen weight matrix is, with high probability, not locally correctable. In particular, there exists a subset of the coordinates which cannot be locally corrected even with a small correction radius guarantee, and cannot be removed from the code either if its decodablity is to be preserved.

▷ Claim 45. Let (C_1, Enc_1) be a $(q_1, \delta_1, \varepsilon_1)$-LDC of length n_1 and dimension k_1 over $\mathbb{F}$, and let (C_2, Enc_2) be a $(q_2, \delta_2, \varepsilon_2)$-LDC of length n_2 and dimension k_2 over $\mathbb{F}$. Assume that C_1 and C_2 have no non-trivial coordinates. Let $B \in \mathbb{F}^{n_1 \times k_2}$ be a random matrix of non-zero weights, chosen uniformly and independently, and let $(C, \mathsf{Enc}) = (C_1, \mathsf{Enc}_1) \otimes_B (C_2, \mathsf{Enc}_2)$. For every $t < k_2$ and $\tilde{q}, \tilde{\tilde{q}} \in \mathbb{N}$, $\delta \geqslant \tilde{q}/n_1$, $\delta' \geqslant t/k_2$ and $\varepsilon < 1 - 1/|\mathbb{F}|$, with probability at least $1 - n_1 n_2 \binom{n_1 n_2}{\tilde{q}} |\mathbb{F}|^{\tilde{q}} / (|\mathbb{F}| - 1)^t$ over the choice of B, C satisfies the following. There exists a set $\bar{J} \subseteq [n]$ such that every $j \in \bar{J}$ is not $(\tilde{q}, \delta, \varepsilon)$-locally correctable in C. Further, the relative (non-local) distance of $C_{\setminus \bar{J}}$ is less than t/k_2.

The main theorem of this part is an immediate consequence of Claim 45.

▶ **Theorem 46.** *Let (C_0, Enc_0) be a $(q_0, \delta_0, \varepsilon_0)$-LDC for a code C_0 of dimension k_0 and length n_0 over $\mathbb{F}$ for $|\mathbb{F}| > 2$, such that $\varepsilon_0 < 1 - 1/|\mathbb{F}|$, $k_0^{1/2} > 10 \log n_0$, and assume that C_0 has no trivial coordinates. Then, there exists a $(q_0^2, \delta_0^2, 1 - (1 - \varepsilon_0)^{q_0 + 1})$-LDC (C, Enc) for a code C of dimension $k = k_0^2$ and length $n = n_0^2$ over $\mathbb{F}$ satisfying the following property. There exists a set $J \subseteq [n]$ of coordinates such that every $j \in J$, j is not $(k^{1/4}, k^{1/4}/n^{1/2}, \varepsilon)$-locally correctable in C, for any $\varepsilon < 1 - 1/|\mathbb{F}|$. Moreover, the relative distance of $C_{\setminus J}$ is less than $5 \log(n)/k^{1/4}$ (in particular for any $\tilde{\tilde{q}} \in \mathbb{N}$ and $\varepsilon < 1 - 1/|\mathbb{F}|$, $C_{\setminus J}$ is not a $(\tilde{\tilde{q}}, 5 \log(n)/k^{1/4}, \varepsilon)$-LDC).*

Abstract

We study the performance of Markov chains for the q-state ferromagnetic Potts model on random regular graphs. While the cases of the grid and the complete graph are by now well-understood, the case of random regular graphs has resisted a detailed analysis and, in fact, even analysing the properties of the Potts distribution has remained elusive. It is conjectured that the performance of Markov chains is dictated by metastability phenomena, i.e., the presence of "phases" (clusters) in the sample space where Markov chains with local update rules, such as the Glauber dynamics, are bound to take exponential time to escape, and therefore cause slow mixing. The phases that are believed to drive these metastability phenomena in the case of the Potts model emerge as local, rather than global, maxima of the so-called Bethe functional, and previous approaches of analysing these phases based on optimisation arguments fall short of the task.

Our first contribution is to detail the emergence of the metastable phases for the q-state Potts model on the d-regular random graph for all integers $q, d \geq 3$, and establish that for an interval of temperatures, delineated by the uniqueness and a broadcasting threshold on the d-regular tree, the two phases coexist. The proofs are based on a conceptual connection between spatial properties and the structure of the Potts distribution on the random regular graph, rather than complicated moment calculations. This significantly refines earlier results by Helmuth, Jenssen, and Perkins who had established phase coexistence for a small interval around the so-called ordered-disordered threshold (via different arguments) that applied for large q and $d \geq 5$.

Based on our new structural understanding of the model, we obtain various algorithmic consequences. We first complement recent fast mixing results for Glauber dynamics by Blanca and Gheissari below the uniqueness threshold, showing an exponential lower bound on the mixing time above the uniqueness threshold. Then, we obtain tight results even for the non-local and more elaborate Swendsen-Wang chain, where we establish slow mixing/metastability for the whole interval of temperatures where the chain is conjectured to mix slowly on the random regular graph. The key is to bound the conductance of the chains using a random graph "planting" argument combined with delicate bounds on random-graph percolation.

1 Introduction

1.1 Motivation

Spin systems on random graphs have turned out to be a source of extremely challenging problems at the junction of mathematical physics and combinatorics [36, 37]. Beyond the initial motivation of modelling disordered systems, applications have sprung up in areas as diverse as computational complexity, coding theory, machine learning and even screening for infectious diseases; e.g. [1, 14, 22, 34, 38, 40, 41]. Progress has been inspired largely by techniques from statistical physics, which to a significant extent still await a rigorous justification. The physicists' sophisticated but largely heuristic tool is the Belief Propagation message passing scheme in combination with a functional called the Bethe free energy [35]. Roughly speaking, the fixed points of Belief Propagation are conjectured to correspond to the "pure states" of the underlying distribution, with the Bethe functional gauging the relative weight of the different pure states. Yet at closer inspection matters are actually rather complicated. For instance, the system typically possesses spurious Belief Propagation fixed points without any actual combinatorial meaning, while other fixed points need not correspond to metastable states that attract dynamics such as the Glauber Markov chain [11, 15]. Generally, the mathematical understanding of the connection between Belief Propagation and dynamics leaves much to be desired.

In this paper we investigate the ferromagnetic Potts model on the random regular graph. Recall, for an integer $q \geq 3$ and real $\beta > 0$, the Potts model on a graph $G = (V, E)$ corresponds to a probability distribution $\mu_{G,\beta}$ over all possible configurations $[q]^V$, commonly referred to as the Boltzmann/Gibbs distribution; the weight of a configuration σ in the distribution is defined as $\mu_{G,\beta}(\sigma) = \mathrm{e}^{\beta\mathcal{H}_G(\sigma)}/Z_\beta(G)$ where $\mathcal{H}_G(\sigma)$ is the number of edges that are monochromatic under σ, and $Z_\beta(G) = \sum_{\tau\in[q]^V} \mathrm{e}^{\beta\mathcal{H}_G(\tau)}$ is the normalising factor of the distribution. In physics jargon, β corresponds to the so-called inverse-temperature of the model, $\mathcal{H}_G(\,\cdot\,)$ is known as the Hamiltonian, and $Z_\beta(\,\cdot\,)$ is the partition function. Note, since $\beta > 0$, the Boltzmann distribution assigns greater weight to configurations σ where many edges join vertices of the same colour; thus, the pairwise interactions between vertices are ferromagnetic.

The Potts model on the d-regular random graph has two distinctive features. First, the local geometry of the random regular graph is essentially deterministic. For any fixed radius ℓ, the depth-ℓ neighbourhood of all but a tiny number of vertices is just a d-regular tree. Second, the ferromagnetic nature of the model precludes replica symmetry breaking, a complex type of long-range correlations [35]. Given these, it is conjectured that the model on the random regular graph has a similar behaviour to that on the clique (the so-called mean field case), and there has already been some preliminary evidence of this correspondence [4, 20, 19, 22, 29]. On the clique, the phase transitions are driven by a battle between two subsets of configurations (phases): (i) the paramagnetic/disordered phase, consisting of configurations where every colour appears roughly equal number of times, and (ii) the ferromagnetic/ordered phase, where one of the colours appears more frequently than

the others. It is widely believed that these two phases also mark (qualitatively) the same type of phase transitions for the Potts model on the random regular graph, yet this has remained largely elusive.

The main reason that this behaviour is harder to establish on the random regular graph is that it has a non-trivial global geometry which makes both the analysis of the distribution and Markov chains significantly more involved (to say the least). In particular, the emergence of the metastable states in the distribution, which can be established by way of calculus in the mean-field case, is out of reach with single-handed analytical approaches in the random regular graph and it is therefore not surprising that it has resisted a detailed analysis so far. Likewise, the analysis of Markov chains is a far more complicated task since their evolution needs to be considered in terms of the graph geometry and therefore much harder to keep track of.

Our main contribution is to detail the emergence of the metastable states, viewed as fixed points of Belief Propagation on this model, and their connection with the dynamic evolution of the two most popular Markov chains, the Glauber dynamics and the Swensen-Wang chain. We prove that these natural fixed points, whose emergence is directly connected with the phase transitions of the model, have the combinatorial meaning in terms of both the pure state decomposition of the distribution and the Glauber dynamics that physics intuition predicts they should. The proofs avoid the complicated moment calculations and the associated complex optimistion arguments that have become a hallmark of the study of spin systems on random graphs [2]. Instead, building upon and extending ideas from [3, 16], we exploit a connection between spatial mixing properties on the d-regular tree and the Boltzmann distribution. Our metastability results for the Potts model significantly refine those appearing in the literature, especially those in [22, 29] which are more relevant to this work, see Section 1.6 for a more detailed discussion.

We expect that this approach might carry over to other examples, particularly other ferromagnetic models. Let us begin by recapitulating Belief Propagation.

1.2 Belief Propagation

Suppose that $n, d \geq 3$ are integers such that dn is even and let $\mathbb{G} = \mathbb{G}(n, d)$ be the random d-regular graph on the vertex set $[n] = \{1, \ldots, n\}$. For an inverse temperature parameter $\beta > 0$ and an integer $q \geq 3$ we set out to investigate the Boltzmann distribution $\mu_{\mathbb{G},\beta}$; let us write $\boldsymbol{\sigma}_{\mathbb{G},\beta}$ for a configuration drawn from $\mu_{\mathbb{G},\beta}$.

A vital step toward understanding the Boltzmann distribution is to get a good handle on the partition function $Z_\beta(\mathbb{G})$. Indeed, according to the physicsts' cavity method, Belief Propagation actually solves both problems in one fell swoop [35]. To elaborate, with each edge $e = uv$ of $\mathbb{G}$, Belief Propagation associates two messages $\mu_{\mathbb{G},\beta,u\to v}, \mu_{\mathbb{G},\beta,v\to u}$, which are probability distributions on the set $[q]$ of colours. The message $\mu_{\mathbb{G},\beta,u\to v}(c)$ is defined as the marginal probability of v receiving colour c in a configuration drawn from the Potts model on the graph $\mathbb{G} - u$ obtained by removing u. The semantics of $\mu_{\mathbb{G},\beta,v\to u}$ is analogous.

Under the assumption that the colours of far apart vertices of $\mathbb{G}$ are asymptotically independent, one can heuristically derive a set of equations that links the various messages together. For a vertex v, let ∂v be the set of neighbours of v, and for an integer $\ell \geq 1$ let $\partial^\ell v$ be the set of vertices at distance precisely ℓ from v. The *Belief Propagation equations* read

$$\mu_{\mathbb{G},\beta,v\to u}(c) = \frac{\prod_{w\in\partial v\setminus\{u\}} 1 + (\mathrm{e}^\beta - 1)\mu_{\mathbb{G},\beta,w\to v}(c)}{\sum_{\chi\in[q]}\prod_{w\in\partial v\setminus\{u\}} 1 + (\mathrm{e}^\beta - 1)\mu_{\mathbb{G},\beta,w\to v}(\chi)} \qquad (uv \in E(\mathbb{G}),\ c \in [q]). \tag{1}$$

The insight behind (1) is that once we remove v from the graph, its neighbours $w \neq u$ are typically far apart from one another because $\mathbb{G}$ contains only a negligible number of short cycles. Hence, we expect that in $\mathbb{G} - v$ the spins assigned to $w \in \partial v \setminus \{u\}$ are asymptotically independent. From this assumption it is straightforward to derive the sum-product-formula (1).

A few obvious issues spring to mind. First, for large β it is not actually true that far apart vertices decorrelate. This is because at low temperature there occur q different ferromagnetic pure states, one for each choice of the dominant colour. To break the symmetry between them one could introduce a weak external field that slighly boosts a specific colour or, more bluntly, confine oneself to a conditional distribution on subspace where a specific colour dominates. In the definition of the messages and in (1) we should thus replace the Boltzmann distribution by the conditional distribution $\mu_{\mathbb{G},\beta}(\cdot \mid S)$ for a suitable $S \subseteq [q]^n$. Second, even for the conditional measure we do not actually expect (1) to hold precisely. This is because for any finite n minute correlations between far apart vertices are bound to remain.

Nonetheless, precise solutions $(\mu_{v\to u})_{uv\in E(\mathbb{G})}$ to (1) are still meaningful. They correspond to stationary points of a functional called the *Bethe free energy*, which connects Belief Propagation with the problem of approximating the partition function [44]. Given a collection $(\mu_{u\to v})_{uv\in E(\mathbb{G})}$ of probability distributions on $[q]$, the Bethe functional reads

$$\begin{aligned}\mathcal{B}_{\mathbb{G},\beta}\left((\mu_{u\to v})_{uv\in E(\mathbb{G})}\right) = \frac{1}{n}\sum_{v\in V(\mathbb{G})}\log\Bigg[\sum_{c\in[q]}\prod_{w\in\partial v}1+(\mathrm{e}^{\beta}-1)\mu_{w\to v}(c)\Bigg]\\ -\frac{1}{n}\sum_{vw\in E(\mathbb{G})}\log\Bigg[1+(\mathrm{e}^{\beta}-1)\sum_{c\in[q]}\mu_{v\to w}(c)\mu_{w\to v}(c)\Bigg].\end{aligned} \tag{2}$$

According to the cavity method the maximum of $\mathcal{B}_{\mathbb{G},\beta}\left((\mu_{u\to v})_{uv\in E(\mathbb{G})}\right)$ over all solutions $(\mu_{u\to v})_{uv\in E(\mathbb{G})}$ to (1) should be asymptotically equal to $\log Z_\beta(\mathbb{G})$ with high probability.

In summary, physics lore holds that the solutions $(\mu_{u\to v})_{uv\in E(\mathbb{G})}$ to (1) are meaningful because they correspond to a decomposition of the phase space $[q]^n$ into pieces where long-range correlations are absent. Indeed, these "pure states" are expected to exhibit metastability, i.e., they trap dynamics such as the Glauber Markov chain for an exponential amount of time. Moreover, the relative probabilities of the pure states are expected to be governed by their respective Bethe free energy. In the following we undertake to investigate these claims rigorously.

Before proceeding, let us mention that ferromagnetic spin systems on random graphs have been among the first models for which predictions based on the cavity method could be verified rigorously. Following seminal work by Dembo and Montanari on the Ising model [18] vindicating the "replica symmetric ansatz", Dembo, Montanari and Sun [20] studied, among other things, the Gibbs unique phase of the Potts ferromagnet on the random regular graph, and Dembo, Montanari, Sly and Sun [20] established the free energy of the model for all β (and d even). More generally, Ruozzi [39] pointed out how graph covers [43] can be used to investigate the partition function of supermodular models, of which the Ising ferromagnet is an example. In addition, Barbier, Chan and Macris [4] proved that ferromagnetic spin systems on random graphs are generally replica symmetric in the sense that the multi-overlaps of samples from the Boltzmann distribution concentrate on deterministic values.

1.3 The ferromagnetic and the paramagnetic states

An obvious attempt at constructing solutions to the Belief Propagation equations is to choose identical messages $\mu_{u\to v}$ for all edges $uv \in E(\mathbb{G})$. Clearly, any solution $(\mu(c))_{c\in[q]}$ to the system

$$\mu(c) = \frac{(1+(\mathrm{e}^\beta-1)\mu(c))^{d-1}}{\sum_{\chi\in[q]}(1+(\mathrm{e}^\beta-1)\mu(\chi))^{d-1}} \qquad (c\in[q]) \tag{3}$$

supplies such a "constant" solution to (1). Let $\mathcal{F}_{d,\beta}$ be the set of all solutions $(\mu(c))_{c\in[q]}$ to (3). The Bethe functional (2) then simplifies to

$$\mathcal{B}_{d,\beta}\big((\mu(c))_{c\in[q]}\big) = \log\Big[\sum_{c\in[q]}\big(1+(\mathrm{e}^\beta-1)\mu(c)\big)^d\Big] - \frac{d}{2}\log\Big[1+(\mathrm{e}^\beta-1)\sum_{c\in[q]}\mu(c)^2\Big]. \tag{4}$$

One obvious solution to (3) is the uniform distribution on $[q]$; we refer to that solution as paramagnetic/disordered and denote it by μ_{p}. Apart from μ_{p}, other solutions to (3) emerge as β increases for any $d \geq 3$. Specifically, let $\beta_u > 0$ be the supremum value of $\beta > 0$ where μ_{p} is the unique solution to (3).[1] Then, for $\beta = \beta_u$, one more solution μ_{f} emerges such that $\mu_{\mathrm{f}}(1) > \mu_{\mathrm{f}}(i) = \frac{1-\mu_{\mathrm{f}}(1)}{q-1}$ for $i = 2,\ldots,q$, portending the emergence of a metastable state and, ultimately, a phase transition. In particular, for any $\beta > \beta_u$, a bit of calculus reveals there exist either one or two distinct solutions μ with $\mu(1) > \mu(i) = \frac{1-\mu(1)}{q-1}$ for $i = 2,\ldots,q$; we denote by μ_{f} the solution of (3) which maximises the value $\mu(1)$ and refer to it as ferromagnetic/ordered. The value β_u is the so-called uniqueness threshold for the Potts model on the d-regular tree, see, e.g., [22] for a more detailed discussion and related pointers.

At the critical value

$$\beta_p = \max\{\beta \geq \beta_u : \mathcal{B}_{d,\beta}(\mu_{\mathrm{p}}) \geq \mathcal{B}_{d,\beta}(\mu_{\mathrm{f}})\} = \log\frac{q-2}{(q-1)^{1-2/d}-1}.$$

the ferromagnetic solution μ_{f} takes over from the paramagnetic solution μ_{p} as the global maximiser of the Bethe functional. For that reason, the threshold β_p is also known in the literature as the ordered-disordered threshold. Yet, up to the threshold

$$\beta_h = \log(1+q/(d-2))$$

the paramagnetic solution remains a local maximiser of the Bethe free energy; later, in Section 2.2 we will see that β_h has a natural interpretation as a tree-broadcasting threshold (and is also a conjectured threshold for uniqueness in the random-cluster representation for the Potts model, see [28] for details).

The relevance of these critical values has been demonstrated in [22] (see also [19] for d even, and [29] for q large), where it was shown that $\frac{1}{n}\log Z_\beta(\mathbb{G})$ is asymptotically equal to $\max_\mu \mathcal{B}_{d,\beta}(\mu)$, the maximum ranging over μ satisfying (3). In particular, at the maximum it holds that $\mu = \mu_{\mathrm{p}}$ when $\beta < \beta_p$, $\mu = \mu_{\mathrm{f}}$ when $\beta > \beta_p$ and $\mu \in \{\mu_{\mathrm{p}}, \mu_{\mathrm{f}}\}$ when $\beta = \beta_p$.

[1] The value does not have a closed-form expression, but there is an equivalent formulation of it given by the equality $\mathrm{e}^{\beta_u} = 1 + \inf_{y>1}\frac{(y-1)(y^{d-1}+q-1)}{y^{d-1}-y}$.

1.4 Slow mixing and metastability

To investigate the two BP solutions further and obtain connections to the dynamical evolution of the model, we need to look more closely how these two solutions $\mu_{\mathrm{p}}, \mu_{\mathrm{f}}$ manifest themselves in the random regular graph. To this end, we define for a given distribution μ on $[q]$ another distribution

$$\nu^{\mu}(c) = \frac{(1+(\mathrm{e}^{\beta}-1)\mu(c))^d}{\sum_{\chi\in[q]}(1+(\mathrm{e}^{\beta}-1)\mu(\chi))^d} \qquad (c\in[q]). \tag{5}$$

Let $\nu_{\mathrm{f}} = \nu^{\mu_{\mathrm{f}}}$ and $\nu_{\mathrm{p}} = \nu^{\mu_{\mathrm{p}}}$ for brevity; of course $\nu_{\mathrm{p}} = \mu_{\mathrm{p}}$ is just the uniform distribution. The distributions ν_{f} and ν_{p} represent the expected Boltzmann marginals within the pure states corresponding to μ_{f} and μ_{p}. Indeed, the r.h.s. of (5) resembles that of (3) except that the exponents read d rather than $d-1$. This means that we pass from messages, where we omit one specific endpoint of an edge from the graph, to actual marginals, where all d neighbours of a vertex are present. For small $\varepsilon > 0$, it will therefore be relevant to consider the sets of configurations

$$S_{\mathrm{f}}(\varepsilon) = \Big\{\sigma\in[q]^n : \sum_{c\in[q]}\Big|\big|\sigma^{-1}(c)\big| - n\nu_{\mathrm{f}}(c)\Big| < \varepsilon n\Big\},$$
$$S_{\mathrm{p}}(\varepsilon) = \Big\{\sigma\in[q]^n : \sum_{c\in[q]}\Big|\big|\sigma^{-1}(c)\big| - n\nu_{\mathrm{p}}(c)\Big| < \varepsilon n\Big\},$$

whose colour statistics are about $n\nu_{\mathrm{f}}$ and $n\nu_{\mathrm{p}}$, respectively; i.e., in S_{p}, all colours appear with roughly equal frequency, whereas in S_{f} colour 1 is favoured over the other $q-1$ colours (which appear with roughly equal frequency).

We are now in position to state our main result for Glauber dynamics. Recall that, for a graph $G=(V,E)$, Glauber is initialised at a configuration $\sigma_0\in[q]^V$; at each time step $t\geq 1$, Glauber draws a vertex uniformly at random and obtains a new configuration σ_t by updating the colour of the chosen vertex according to the conditional Boltzmann distribution given the colours of its neighbours. It is a well-known fact that Glauber converges in distribution to $\mu_{G,\beta}$; the mixing time of the chain is defined as the maximum number of steps t needed to get within total variation distance $\leq 1/4$ from $\mu_{G,\beta}$, where the maximum is over the choice of the initial configuration σ_0, i.e., the quantity $\max_{\sigma_0}\min\{t : d_{\mathrm{TV}}(\sigma_t,\mu_{G,\beta})\leq 1/4\}$.

For metastability, we will consider Glauber launched from a random configuration from a subset $S\subseteq[q]^V$ of the state space. More precisely, let us denote by $\mu_{G,\beta,S} = \mu_{G,\beta}(\cdot\mid S)$ the conditional Boltzmann distribution on S. We call S a *metastable state for Glauber dynamics* on G if there exists $\delta>0$ such that

$$\mathbb{P}\Big[\min\{t : \sigma_t\notin S\}\leq \mathrm{e}^{\delta|V|} \mid \sigma_0\sim\mu_{G,\beta,S}\Big] \leq \mathrm{e}^{-\delta|V|}.$$

Hence, it will most likely take Glauber an exponential amount of time to escape from a metastable state.

▶ **Theorem 1.1.** *Let $d,q\geq 3$ be integers and $\beta>0$ be real. Then, for all sufficiently small $\varepsilon>0$, the following hold w.h.p. over the choice of $\mathbb{G}=\mathbb{G}(n,d)$.*

(i) *If $\beta<\beta_h$, then $S_{\mathrm{p}}(\varepsilon)$ is a metastable state for Glauber dynamics on $\mathbb{G}$.*

(ii) *If $\beta>\beta_u$, then $S_{\mathrm{f}}(\varepsilon)$ is a metastable state for Glauber dynamics on $\mathbb{G}$.*

Further, for $\beta>\beta_u$, the mixing time of Glauber is $\mathrm{e}^{\Omega(n)}$.

Thus, we can summarise the evolution of the Potts model as follows. For $\beta<\beta_u$ there is no ferromagnetic state. As β passes β_u, the ferromagnetic state S_{f} emerges first as a metastable state. Hence, if we launch Glauber from S_{f}, the dynamics will most likely remain

trapped in the ferromagnetic state for an exponential amount of time, even though the Boltzmann weight of the paramagnetic state is exponentially larger (as we shall see in the next section). At the point β_p the ferromagnetic state then takes over as the one dominating the Boltzmann distribution, but the paramagnetic state remains as a metastable state up to β_h. Note in particular that the two states coexist as metastable states throughout the interval (β_u, β_h).

The metastability for the Potts model manifests also in the evolution of the Swendsen-Wang (SW) chain, which is another popular and substantially more elaborate chain that makes non-local moves, based on the random-cluster representation of the model. For a graph $G = (V, E)$ and a configuration $\sigma \in [q]^V$, a single iteration of SW starting from σ consists of two steps.

- *Percolation step:* Let $M = M(\sigma)$ be the random edge-set obtained by adding (independently) each monochromatic edge under σ with probability $p = 1 - \mathrm{e}^{-\beta}$.
- *Recolouring step:* Obtain the new $\sigma' \in [q]^V$ by assigning each component[2] of the graph (V, M) a uniformly random colour from $[q]$; for $v \in V$, we set σ'_v to be the colour assigned to v's component.

We define metastable states for SW dynamics analogously to above. The following theorem establishes the analogue of Theorem 1.1 for the non-local SW dynamics. Note here that SW might change the most-frequent colour due to recolouring step, so the metastability statement for the ferromagnetic phase needs to consider the set $S_{\mathrm{f}}(\varepsilon)$ with its $q-1$ permutations.

▶ **Theorem 1.2.** *Let $d, q \geq 3$ be integers and $\beta > 0$ be real. Then, for all sufficiently small $\varepsilon > 0$, the following hold w.h.p. over the choice of $\mathbb{G} = \mathbb{G}(n, d)$.*

(i) *If $\beta < \beta_h$, then $S_{\mathrm{p}}(\varepsilon)$ is a metastable state for SW dynamics on $\mathbb{G}$.*

(ii) *If $\beta > \beta_u$, then $S_{\mathrm{f}}(\varepsilon)$ together with its $q-1$ permutations is a metastable state for SW dynamics on $\mathbb{G}$.*

Further, for $\beta \in (\beta_u, \beta_h)$, the mixing time of SW is $\mathrm{e}^{\Omega(n)}$.

1.5 The relative weight of the metastable states

At the heart of obtaining the metastability results of the previous section is a refined understanding of the relative weight of the ferromagnetic and paramagnetic states. The following notion of non-reconstruction will be the key in our arguments; it captures the absence of long-range correlations within a set $S \subseteq [q]^n$, saying that, for any vertex v, a typical boundary configuration on $\boldsymbol{\sigma}_{\partial^\ell v}$ chosen according to the conditional distribution on S does not impose a discernible bias on the colour of v (for large ℓ, n; recall, $\partial^\ell v$ is the set of all vertices at distance precisely ℓ from v). More precisely, let $\mu = \mu_{\mathbb{G},\beta}$ and $\boldsymbol{\sigma} \sim \mu$; the Boltzmann distribution exhibits *non-reconstruction given a subset $S \subseteq [q]^n$* if for any vertex v it holds that

$$\lim_{\ell\to\infty} \limsup_{n\to\infty} \sum_{c\in[q]} \sum_{\tau\in S} \mathbb{E}\left[\mu(\tau \mid S) \times |\mu(\boldsymbol{\sigma}_v = c \mid \boldsymbol{\sigma}_{\partial^\ell v} = \tau_{\partial^\ell v}) - \mu(\boldsymbol{\sigma}_v = c \mid S)|\right] = 0,$$

where the expectation is over the choice of the graph $\mathbb{G}$.

[2] Note, isolated vertices count as connected components.

▶ **Theorem 1.3.** *Let $d, q \geq 3$ be integers and $\beta > 0$ be real. The following hold for all sufficiently small $\varepsilon > 0$ as $n \to \infty$.*

- **(i)** *For all $\beta < \beta_p$, $\mathbb{E}[\mu_{\mathbb{G},\beta}(S_{\mathrm{p}})] \to 1$ and, if $\beta > \beta_u$, then $\mathbb{E}\left[\frac{1}{n}\log \mu_{\mathbb{G},\beta}(S_{\mathrm{f}})\right] \to \mathcal{B}_{d,\beta}(\mu_{\mathrm{f}}) - \mathcal{B}_{d,\beta}(\mu_{\mathrm{p}})$.*
- **(ii)** *For all $\beta > \beta_p$, $\mathbb{E}[\mu_{\mathbb{G},\beta}(S_{\mathrm{f}})] \to 1/q$ and, if $\beta < \beta_h$, then $\mathbb{E}\left[\frac{1}{n}\log \mu_{\mathbb{G},\beta}(S_{\mathrm{p}})\right] \to \mathcal{B}_{d,\beta}(\mu_{\mathrm{p}}) - \mathcal{B}_{d,\beta}(\mu_{\mathrm{f}})$.*

Furthermore, the Boltzmann distribution given S_{p} exhibits non-reconstruction if $\beta < \beta_h$ and the Boltzmann distribution given S_{f} exhibits non-reconstruction if $\beta > \beta_u$.

Theorem 1.3 shows that for $\beta < \beta_p$ the Boltzmann distribution is dominated by the paramagnetic state S_{p} for $\beta < \beta_p$. Nonetheless, at β_u the ferromagnetic state S_{f} and its $q-1$ mirror images start to emerge. Their probability mass is determined by the Bethe free energy evaluated at μ_{f}. Further, as β passes β_p the ferromagnetic state takes over as the dominant state, with the paramagnetic state lingering on as a sub-dominant state up to β_h. Finally, both states S_{p} and S_{f} are free from long-range correlations both for the regime of β where they dominate and for those β where they are sub-dominant.

1.6 Discussion

Our slow mixing result for Glauber dynamics when $\beta > \beta_u$ (Theorem 1.1) significantly improves upon previous results of Bordewich, Greenhill and Patel [9] that applied to $\beta > \beta_u + \Theta_q(1)$. Similarly, our slow mixing result for Swendsen-Wang dynamics when $\beta \in (\beta_u, \beta_h)$ (Theorem 1.2) strengthens earlier results of Galanis, Štefankovič, Vigoda, Yang [22] which applied to $\beta = \beta_p$, and by Helmuth, Jenseen and Perkins [29] which applied for a small interval around β_p; both results applied only for q sufficiently large. To obtain our result for all integers $q, d \geq 3$, we need to carefully track how SW evolves on the random regular graph for configurations starting from the ferromagnetic and paramagnetic phases, by accounting for the percolation step via delicate arguments, whereas the approaches of [22, 29] side-stepped this analysis by considering the change in the number of monochromatic edges instead.

Our slow mixing results complement the recent fast mixing result of Blanca and Gheissari [6] for edge dynamics on the random d-regular graph that applies to all $\beta < \beta_u$. Roughly, edge dynamics is the analogue of Glauber dynamics for the random cluster representation of the Potts model (the random-cluster representation has nicer monotonicity properties). The result of [6] already implies a polynomial bound on the mixing time of SW when $\beta < \beta_u$ (due to comparison results by Ullrich that apply to general graphs [42]), and conversely our exponential lower bound on the mixing time of SW for $\beta \notin (\beta_u, \beta_h)$ implies an exponential lower bound on the mixing time of edge dynamics for $\beta \notin (\beta_u, \beta_h)$. The main open questions remaining are therefore showing whether Glauber dynamics for the Potts model mixes fast when $\beta \leq \beta_u$ and whether SW/edge-dynamics mixes fast when $\beta > \beta_h$. Extrapolating from the mean-field case (see discussion below), it is natural to conjecture that our slow mixing results are best-possible, i.e., for $\beta \leq \beta_u$, Glauber mixes rapidly and similarly, for $\beta \notin (\beta_u, \beta_h)$, SW mixes rapidly on the random regular graph.

Theorem 1.3, aside from being critical in establishing the aforementioned slow mixing and metastability results, is the first to establish for all $q, d \geq 3$ the coexistence of the ferromagnetic and paramagnetic phases for all β in the interval (β_u, β_h) and detail the logarithmic order of their relative weight in the same interval. Previous work in [22] showed coexistence for $\beta = \beta_p$ (for all $q, d \geq 3$) and [29] for β in a sub-interval of (β_u, β_h) around β_p (for large q and $d \geq 5$), see also footnote 3. We remark here that the approaches in [22, 29] establish more refined estimates on the deviations from the limiting value of the

log-partition function of the phases (in the corresponding regimes they apply), with [29] characterising in addition the limiting distribution using cluster-expansion methods. One can obtain analogous distributional characterisations for all $q, d \geq 3$ from our methods, once combined with the small subgraph conditioning method of [22]. It should be noted though the approach of [29] which goes through cluster expansion is more direct in that respect. We don't pursue such distributional results here since Theorem 1.3 is sufficient for our slow mixing results.

Together with Theorems 1.1 and 1.2, Theorem 1.3 delineates more firmly[3] the correspondence with the (simpler) mean-field case, the Potts model on the clique. In the mean-field case, there are qualitatively similar thresholds $\beta_u, \beta_p, \beta_h$ and the mixing time for Glauber and SW have been detailed for all β, even at criticality, see [7, 8, 25, 23, 17, 27, 31]. As mentioned earlier, the most tantalising question remaining open is to establish whether the fast mixing of SW for $\beta = \beta_u$ and $\beta \geq \beta_h$ in the mean-field case translates to the random regular graph as well. Another interesting direction is to extend our arguments to the random-cluster representation of the Potts model for all non-integer $q \geq 1$; note that the arguments of [5] and [29] do apply to non-integer q ($q \geq 1$ and q large, respectively). The proof of Theorem 1.3 relies on a truncated second moment computation, an argument that was applied to different models in [16, 13].

We further remark here that, from a worst-case perspective, it is known that sampling from the Potts model on d-regular graphs is #BIS-hard for $\beta > \beta_p$ [22], and we conjecture that the problem admits a poly-time approximation algorithm when $\beta < \beta_p$. However, even showing that Glauber mixes fast on any d-regular graph in the uniqueness regime $\beta < \beta_u$ is a major open problem, and Theorems 1.1 and 1.2 further demonstrate that getting an algorithm all the way to β_p will require using different techniques. On that front, progress has been made on the random regular graph: [29] obtained an algorithm for $d \geq 5$ and q large that applies to all β by sampling from each phase separately (using different tools), see also [10]. Moreover, for $\beta < \beta_p$, Efthymiou [21] gives an algorithm with weaker approximation guarantees but which applies to all $q, d \geq 3$ (see also [5]). In principle, and extrapolating again from the mean-field case, one could use Glauber/SW to sample from each phase on the random regular graph for all $q, d \geq 3$ and all β. Analysing such chains appears to be relatively far from the reach of current techniques even in the case of the random regular graph, let alone worst-case graphs. In the case of the Ising model however, the case $q = 2$, the analogue of this fast mixing question has recently been established for sufficiently large β in [26] on the random regular graph and the grid, exploiting certain monotonicity properties.

Finally, let us note that the case of the grid has qualitatively different behaviour than the mean-field and the random-regular case. There, the three critical points coincide and the behaviour at criticality depends on the value of q; the mixing time of Glauber and SW has largely been detailed, see [7, 33, 24].

[3] Note that the interval-behaviour on the random regular graph (and hence the correspondence with the mean-field case) is already implied to some extent by the interval-result of [29] (for q large and $d \geq 5$). Note however that the interval therein is contained strictly inside (β_u, β_h) and, in particular, its endpoints do not have the probabilistic interpretation of β_u, β_h. Nevertheless, [29] obtains various probabilistic properties of the metastable phases, including a stronger form of correlation decay than that of reconstruction that we consider here.

2 Overview

In this section we give an overview of the proofs of Theorems 1.1–1.3; for now, we will mostly work towards the proof of Theorem 1.3 which gives the main insights/tools that are needed to prove Theorems 1.1 and 1.2.

Fortunately, to prove Theorem 1.3, we do not need to start from first principles. Instead, we build upon the formula for the partition function $Z_\beta(\mathbb{G})$ and its proof via the second moment method from [22]. Additionally, we are going to seize upon facts about the non-reconstruction properties of the Potts model on the random d-regular tree, also from [22]. We will combine these tools with an auxiliary random graph model known as the planted model, which also plays a key role in the context of inference problems on random graphs [15].

Throughout most of the paper, instead of the simple random regular graph $\mathbb{G}$, we will work with the random d-regular multi-graph $\boldsymbol{G} = \boldsymbol{G}(n,d)$ drawn from the pairing model. Recall that $\boldsymbol{G}$ is obtained by creating d clones of each of the vertices from $[n]$, choosing a random perfect matching of the complete graph on $[n] \times [d]$ and subsequently contracting the vertices $\{i\} \times [d]$ into a single vertex i, for all $i \in [n]$. It is well-known that $\mathbb{G}$ is contiguous with respect to $\boldsymbol{G}$ [30], i.e., any property that holds w.h.p. for $\boldsymbol{G}$ also holds w.h.p. for $\mathbb{G}$.

The following notation will be handy. For a graph G and a configuration $\sigma \in [q]^{V(G)}$, define a probability distribution ν^σ on $[q]$ by letting

$$\nu^\sigma(s) = |\sigma^{-1}(s)|/n \qquad (s \in [q]).$$

In words, ν^σ is the empirical distribution of the colours under σ. Similarly, let $\rho^{G,\sigma} \in \mathcal{P}([q] \times [q])$ be the edge statistics of a given graph/colouring pair, i.e.,

$$\rho^{G,\sigma}(s,t) = \frac{1}{2|E(G)|} \sum_{u,v \in V(G)} \mathbf{1}\{uv \in E(G),\, \sigma_u = s,\, \sigma_v = t\}.$$

2.1 Moments and messages

The routine method for investigating the partition function and the Boltzmann distribution of random graphs is the method of moments [2]. The basic strategy is to calculate, one way or another, the first two moments $\mathbb{E}[Z_\beta(\boldsymbol{G})]$, $\mathbb{E}[Z_\beta(\boldsymbol{G})^2]$ of the partition function. Then we cross our fingers that the second moment is not much larger than the square of the first. It sometimes works. But potential pitfalls include a pronounced tendency of running into extremely challenging optimisation problems in the course of the second moment calculation and, worse, lottery effects that may foil the strategy altogether. While regular graphs in general and the Potts ferromagnet in particular are relatively tame specimens, these difficulties actually do arise once we set out to investigate metastable states. Drawing upon [3, 16] to sidestep these challenges, we develop a less computation-heavy proof strategy.

The starting point is the observation that the fixed points of (3) are intimately related to the moment calculation. This will not come as a surprise to experts, and indeed it was already noticed in [22]. To elaborate, let $\nu = (\nu(\sigma))_{\sigma \in [q]}$ be a probability distribution on the q colours. Moreover, let $\mathcal{R}(\nu)$ be the set of all symmetric matrices $(\rho(\sigma,\tau))_{\sigma,\tau \in [q]}$ with non-negative entries such that

$$\sum_{\tau \in [q]} \rho(\sigma,\tau) = \nu(\sigma) \qquad \text{for all } \sigma \in [q]. \tag{6}$$

Relatively standard arguments (e.g., [12, Lemma 2.7]) show that the first moment satisfies

$$\lim_{n\to\infty}\frac{1}{n}\log\mathbb{E}[Z_\beta(\boldsymbol{G})] = \max_{\nu\in\mathcal{P}([q]),\rho\in R(\nu)} F_{d,\beta}(\nu,\rho), \qquad \text{where}$$
$$F_{d,\beta}(\nu,\rho) = (d-1)\sum_{\sigma\in[q]}\nu(\sigma)\log\nu(\sigma) - d\sum_{1\le\sigma\le\tau\le q}\rho(\sigma,\tau)\log\rho(\sigma,\tau) + \frac{d\beta}{2}\sum_{\sigma\in[q]}\rho(\sigma,\sigma). \tag{7}$$

Thus, the first moment is governed by the maximum or maxima, as the case may be, of $F_{d,\beta}$. The function $F_{d,\beta}$ accounts for the contribution to $\mathbb{E}[Z_\beta(\boldsymbol{G})]$ coming from the set $\mathcal{Q}$ which consists of pairs (G,σ) with $\nu^\sigma = \nu + o(1)$ and $\rho^{G,\sigma} = \rho + o(1)$, i.e., the sum $\sum_{(G,\sigma)\in\mathcal{Q}}\mathbb{P}[\boldsymbol{G}=G]\mathrm{e}^{\beta\mathcal{H}_G(\sigma)}$ equals $\mathrm{e}^{nF_{d,\beta}(\nu,\rho)+o(n)}$.

We need to know that the maxima of $F_{d,b}$ are in one-to-one correspondence with the stable fixed points of (3). To be precise, a fixed point μ of (3) is *stable* if the Jacobian of (3) at μ has spectral radius strictly less than one. Let $\mathcal{F}^+_{d,\beta}$ be the set of all stable fixed points $\mu\in\mathcal{F}_{d,\beta}$. Moreover, let $\mathcal{F}^1_{d,\beta}$ be the set of all $\mu\in\mathcal{F}^+_{d,\beta}$ such that $\mu(1) = \max_{\sigma\in[q]}\mu(\sigma)$. In addition, let us call a local maximum (ν,ρ) of $F_{d,\beta}$ *stable* if there exist $\delta, c>0$ such that

$$F_{d,\beta}(\nu',\rho') \le F_{d,\beta}(\nu,\rho) - c\left(\|\nu-\nu'\|^2 + \|\rho-\rho'\|^2\right) \tag{8}$$

for all $\nu'\in\mathcal{P}([q])$ and $\rho'\in\mathcal{R}(\nu')$ such that $\|\nu-\nu'\| + \|\rho-\rho'\| < \delta$. Roughly, (8) provides that the Hessian of $F_{d,\beta}$ is negative definite on the subspace of all possible ν,ρ.

▶ **Lemma 2.2** ([22, Theorem 8]). *Suppose that $d,q\ge 3$ are integers and $\beta>0$ is a real. The map $\mu\in\mathcal{P}([q])\mapsto(\nu^\mu,\rho^\mu)$ defined by*

$$\nu^\mu(\sigma) = \frac{(1+(\mathrm{e}^\beta-1)\mu(\sigma))^d}{\sum_{\tau\in[q]}(1+(\mathrm{e}^\beta-1)\mu(\tau))^d}, \qquad \rho^\mu(\sigma,\tau) = \frac{\mathrm{e}^{\beta\mathbf{1}\{\sigma=\tau\}}\mu(\sigma)\mu(\tau)}{1+(\mathrm{e}^\beta-1)\sum_{s\in[q]}\mu(s)^2} \tag{9}$$

is a bijection from $\mathcal{F}^+_{d,\beta}$ to the set of stable local maxima of $F_{d,\beta}$. Moreover, for any fixed point μ we have $\mathcal{B}_{d,\beta}(\mu) = F_{d,\beta}(\nu^\mu,\rho^\mu)$.

For brevity, let $(\nu_\mathrm{p},\rho_\mathrm{p}) = (\nu^{\mu_\mathrm{p}},\rho^{\mu_\mathrm{p}})$ and $(\nu_\mathrm{f},\rho_\mathrm{f}) = (\nu^{\mu_\mathrm{f}},\rho^{\mu_\mathrm{f}})$. The following result characterises the stable fixed points $\mathcal{F}^1_{d,\beta}$.

▶ **Proposition 2.3** ([22, Theorem 4]). *Suppose that $d\ge 3, \beta>0$.*

- **(i)** *If $\beta<\beta_u$, then (3) has a unique fixed point, namely the paramagnetic distribution ν_p on $[q]$. This fixed point is stable and thus $F_{d,\beta}$ attains its global maximum at $(\nu_\mathrm{p},\rho_\mathrm{p})$.*
- **(ii)** *If $\beta_u<\beta<\beta_h$, then $\mathcal{F}^1_{d,\beta}$ contains two elements, namely the paramagnetic distribution ν_p and the ferromagnetic distribution ν_f; $(\nu_\mathrm{p},\rho_\mathrm{p})$ is a global maximum of $F_{d,\beta}$ iff $\beta\le\beta_p$, and $(\nu_\mathrm{f},\rho_\mathrm{f})$ iff $\beta\ge\beta_p$.*
- **(iii)** *If $\beta>\beta_h$, then $\mathcal{F}^1_{d,\beta}$ contains precisely one element, namely the ferromagnetic distribution ν_f, and $(\nu_\mathrm{f},\rho_\mathrm{f})$ is a global maximum of $F_{d,\beta}$.*

Like the first moment, the second moment boils down to an optimisation problem as well, albeit one of much higher dimension (q^2-1 rather than $q-1$). Indeed, it is not difficult to derive the following approximation (once again, e.g., via [12, Lemma 2.7]). For a probability distribution $\nu\in\mathcal{P}([q])$ and a symmetric matrix $\rho\in\mathcal{R}(\nu)$ let $\mathcal{R}^\otimes(\rho)$ be the set of all tensors $r=(r(\sigma,\sigma',\tau,\tau'))_{\sigma,\sigma',\tau,\tau'\in[q]}$ such that $r(\sigma,\sigma',\tau,\tau') = r(\tau,\tau',\sigma,\sigma')$ for $\tau,\tau',\sigma,\sigma'\in[q]$ and

$$\sum_{\sigma',\tau'} r(\sigma,\sigma',\tau,\tau') = \sum_{\sigma',\tau'} r(\sigma',\sigma,\tau',\tau) = \rho(\sigma,\tau) \quad \text{for all } \sigma,\tau\in[q]. \tag{10}$$

Then, with $H(\cdot)$ denoting the entropy function, we have

$$\lim_{n\to\infty}\frac{1}{n}\log\mathbb{E}[(Z_\beta(\boldsymbol{G}))^2] = \max_{\nu,\rho\in\mathcal{R}(\nu),r\in\mathcal{R}^\otimes(\rho)} F^\otimes_{d,\beta}(\rho,r),\ \text{where} \tag{11}$$

$$F^\otimes_{d,\beta}(\rho,r) = (d-1)H(\rho)+\frac{d}{2}H(r)+\frac{d\beta}{2}\sum_{\sigma,\sigma',\tau,\tau'\in[q]}\big(\mathbf{1}\{\sigma=\tau\}+\mathbf{1}\{\sigma'=\tau'\}\big)\,r(\sigma,\sigma',\tau,\tau').$$

A frontal assault on this optimisation problem is in general a daunting task due to the doubly-stochastic constraints in (10), i.e., the constraint $r\in\mathcal{R}^\otimes(\rho)$. But rather fortunately, to analyse the global maximum (over ν and ρ), these constraints can be relaxed, permitting an elegant translation of the problem to operator theory. In effect, the second moment computation can be reduced to a study of matrix norms. The result is summarised as follows.

▶ **Proposition 2.4** ([22, Theorem 7]). *For all $d,q\geq 3$ and $\beta>0$ we have*

$$\max_{\nu,\rho\in\mathcal{R}(\nu),r\in\mathcal{R}^\otimes(\rho)} F^\otimes_{d,\beta}(\rho,r) = 2\max_{\nu,\rho}F_{d,\beta}(\nu,\rho)$$

and thus $\mathbb{E}[Z_\beta(\boldsymbol{G})^2]=O(\mathbb{E}[Z_\beta(\boldsymbol{G})]^2)$.

Combining Lemma 2.2, Proposition 2.3 and Proposition 2.4, we obtain the following reformulation of [22, Theorem 7], which verifies that we obtain good approximations to the partition function by maximising the Bethe free energy on $\mathcal{F}_{d,\beta}$.

▶ **Theorem 2.5.** *For all integers $d,q\geq 3$ and real $\beta>0$, we have $\lim_{n\to\infty}n^{-1}\log Z_\beta(\mathbb{G}) = \max_{\mu\in\mathcal{F}_{d,\beta}}\mathcal{B}_{d,\beta}(\mu)$ in probability.*

While the *global* maximisation of the function $F^\otimes_{d,\beta}$ and thus the proof of Theorem 2.5 boils down to matrix norm analysis, in order to prove Theorems 1.3 and 1.1 via the method of moments we would in addition need to get a good handle on all the *local* maxima. Unfortunately, we do not see a way to reduce this more refined question to operator norms (and it seems unlikely that one exists). Hence, it would seem that we should have to perform a fine-grained analysis of $F^\otimes_{d,\beta}$ after all. But luckily another path is open to us. Instead of proceeding analytically, we resort to probabilistic ideas. and we harness "quiet-planting" arguments with the notion of non-reconstruction on the Potts model on the d-regular tree. We review the latter in the next section.

2.2 Non-reconstruction on the regular tree

Let $\mathbb{T}_d$ be the infinite d-regular tree with root o. For a probability distribution $\mu\in\{\mu_\mathrm{p},\mu_\mathrm{f}\}$ we define a broadcasting process $\boldsymbol{\sigma}=\boldsymbol{\sigma}_{d,\beta,\mu}$ on $\mathbb{T}_d$ as follows. Initially we draw the color $\boldsymbol{\sigma}_o$ of the root o from the distribution ν^μ. Subsequently, working our way down the levels of the tree, the color of a vertex v whose parent u has been coloured already is drawn from the distribution

$$\mathbb{P}\left[\boldsymbol{\sigma}_v=\sigma\mid\boldsymbol{\sigma}_u\right]=\frac{\mu(\sigma)\mathrm{e}^{\beta\mathbf{1}\{\sigma=\boldsymbol{\sigma}_u\}}}{\sum_{\tau\in[q]}\mu(\tau)\mathrm{e}^{\beta\mathbf{1}\{\tau=\boldsymbol{\sigma}_u\}}}.$$

Naturally, the colours of different vertices on the same level are pairwise independent, but not jointly since there is potentially some correlation with the root. Let $\partial^\ell o$ be the set of all vertices at distance precisely ℓ from o. We say that the broadcasting process has the *strong non-reconstruction property* if $\sum_{\tau\in[q]}\mathbb{E}\Big[\big|\mathbb{P}\left[\boldsymbol{\sigma}_o=\tau\mid\boldsymbol{\sigma}_{\partial^\ell o}\right]-\mathbb{P}\left[\boldsymbol{\sigma}_o=\tau\right]\big|\Big]=\mathrm{e}^{-\Omega(\ell)}$, where the expectation is over the random configuration $\boldsymbol{\sigma}_{\partial^\ell o}$ (distributed according to the broadcasting

process). In words, this says that the information about the spin of the root inferred from the spins of vertices at depth ℓ decays in the broadcasting process; the term "strong" refers that the decay is exponential with respect to the depth ℓ.

▶ **Proposition 2.6** ([22, Theorem 50]). *Let $d, q \geq 3$ be integers and $\beta > 0$ be real.*
(i) *For $\beta < \beta_h$, the broadcasting process $\boldsymbol{\sigma}_{d,\beta,\mu_{\mathrm{p}}}$ has the strong non-reconstruction property.*
(ii) *For $\beta > \beta_u$, the broadcasting process $\boldsymbol{\sigma}_{d,\beta,\mu_{\mathrm{f}}}$ has the strong non-reconstruction property.*

In order to prove Theorems 1.1–1.3 we will combine Proposition 2.6 with reweighted random graph models known as planted models. To be precise, we will consider two versions of planted models, a paramagnetic and a ferromagnetic one. Then we will deduce from Proposition 2.6 that the Boltzmann distribution of these planted models has the non-reconstruction property in a suitably defined sense. In combination with some general facts about Boltzmann distributions this will enable us to prove Theorems 1.1–1.3 without the need for complicated moment computations.

2.3 Second Moment via planting and non-reconstruction

We proceed to introduce the paramagnetic and the ferromagnetic version of the planted model. Roughly speaking, these are weighted versions of the common random regular graph $\mathbb{G}$ where the probability mass of a specific graph is proportional to the paramagnetic or ferromagnetic bit of the partition function. To be precise, for $\varepsilon > 0$, recall the subsets $S_{\mathrm{p}} = S_{\mathrm{p}}(\varepsilon), S_{\mathrm{f}} = S_{\mathrm{f}}(\varepsilon)$ of the configuration space $[q]^n$. Letting

$$Z_{\mathrm{f}}(G) = \sum_{\sigma \in S_{\mathrm{f}}} \mathrm{e}^{\beta \mathcal{H}_G(\sigma)} \text{ and } Z_{\mathrm{p}}(G) = \sum_{\sigma \in S_{\mathrm{p}}} \mathrm{e}^{\beta \mathcal{H}_{\boldsymbol{G}}(\sigma)}, \tag{12}$$

we define random graph models $\hat{\boldsymbol{G}}_{\mathrm{f}}, \hat{\boldsymbol{G}}_{\mathrm{p}}$ by

$$\mathbb{P}\left[\hat{\boldsymbol{G}}_{\mathrm{f}} = G\right] = \frac{Z_{\mathrm{f}}(G)\mathbb{P}\left[\boldsymbol{G} = G\right]}{\mathbb{E}[Z_{\mathrm{f}}(\boldsymbol{G})]}, \qquad \mathbb{P}\left[\hat{\boldsymbol{G}}_{\mathrm{p}} = G\right] = \frac{Z_{\mathrm{p}}(G)\mathbb{P}\left[\boldsymbol{G} = G\right]}{\mathbb{E}[Z_{\mathrm{p}}(\boldsymbol{G})]}. \tag{13}$$

Thus, $\hat{\boldsymbol{G}}_{\mathrm{f}}$ and $\hat{\boldsymbol{G}}_{\mathrm{p}}$ are d-regular random graphs on n vertices such that the probability that a specific graph G comes up is proportional to $Z_{\mathrm{f}}(G)$ and $Z_{\mathrm{p}}(G)$, respectively. Note, the expected value of $Z_{\mathrm{f}}(G)$ and $Z_{\mathrm{p}}(G)$ is captured by the function $F_{d,\beta}$, and we have (see Lemmas 3.2 and 3.3 in the full version)

$$\mathbb{E}[Z_{\mathrm{p}}(G)] = n^{O(1)} \exp(nF_{d,\beta}(\nu_{\mathrm{p}}, \rho_{\mathrm{p}})) \quad \text{and} \quad \mathbb{E}[Z_{\mathrm{f}}(G)] = n^{O(1)} \exp(nF_{d,\beta}(\nu_{\mathrm{f}}, \rho_{\mathrm{f}})). \tag{14}$$

The key ingredient to prove Theorem 1.3 is to quantify the overlap of two typical configurations in the conditional Boltzmann distributions (under S_{f} and S_{p}). To be precise, for a graph $G = (V, E)$, the overlap of two configurations $\sigma, \sigma' \in [q]^V$ is defined as the probability distribution $\nu(\sigma, \sigma') \in \mathcal{P}([q]^2)$ with

$$\nu_{c,c'}(\sigma, \sigma') = \frac{1}{n} \sum_{v \in V(G)} \mathbf{1}\{\sigma_v = c,\, \sigma'_v = c'\} \qquad (c, c' \in [q]).$$

For a graph G let $\boldsymbol{\sigma}_{G,\mathrm{f}}$ denote a sample from the conditional distribution $\mu_{G,\beta}(\cdot \mid S_{\mathrm{f}})$. and define $\boldsymbol{\sigma}_{G,\mathrm{p}}$ similarly for S_{p}. The following lemma studies the overlap for two configurations in the conditional distribution $\mu_{\hat{\boldsymbol{G}}_{\mathrm{p}},\beta}(\cdot \mid S_{\mathrm{p}})$, a similar lemma applies to the ferromagnetic phase S_{f}, see Lemma 3.9 in the full version.

▶ **Lemma 3.8.** *Let $d, q \geq 3$ be integers and $\beta < \beta_h$ be real. Let $\boldsymbol{\sigma}_{\hat{\boldsymbol{G}}_{\mathrm{p}},\mathrm{p}}, \boldsymbol{\sigma}'_{\hat{\boldsymbol{G}}_{\mathrm{p}},\mathrm{p}}$ be independent samples from $\mu_{\hat{\boldsymbol{G}}_{\mathrm{p}},\beta}(\cdot \mid S_{\mathrm{p}})$. Then $\mathbb{E}\big[d_{\mathrm{TV}}\big(\nu(\boldsymbol{\sigma}_{\hat{\boldsymbol{G}}_{\mathrm{p}},\mathrm{p}}, \boldsymbol{\sigma}'_{\hat{\boldsymbol{G}}_{\mathrm{p}},\mathrm{p}}), \nu_{\mathrm{p}} \otimes \nu_{\mathrm{p}}\big)\big] = o(1)$.*

To utilise Lemmas 3.8 and 3.9, we proceed to apply the second moment method to truncated versions of the paramagnetic and ferromagnetic partition functions $Z_{\mathrm{p}}, Z_{\mathrm{f}}$ where we expressly drop graphs that violate the overlap bounds from Lemmas 3.8. Thus, we introduce the events $\mathcal{E}_{\mathrm{p}} = \{G : \mathbb{E}\big[d_{\mathrm{TV}}(\nu(\boldsymbol{\sigma}_{G,\mathrm{p}}, \boldsymbol{\sigma}'_{G,\mathrm{p}}), \nu_{\mathrm{p}} \otimes \nu_{\mathrm{p}})\big] = o(1)\}$ and the analogous event $\mathcal{E}_{\mathrm{f}}$ for the ferromagnetic phase. Consider now the random variables

$$Y_{\mathrm{p}}(G) = Z_{\mathrm{p}}(G) \cdot \mathbf{1}\{G \in \mathcal{E}_{\mathrm{p}}\} \text{ and } Y_{\mathrm{f}}(G) = Z_{\mathrm{f}}(G) \cdot \mathbf{1}\{G \in \mathcal{E}_{\mathrm{f}}\}$$

Combining Lemma 3.8 with the Nishimori identity (17), we obtain

$$\frac{\mathbb{E}[Y_{\mathrm{p}}]}{\mathbb{E}[Z_{\mathrm{p}}]} = \mathbb{P}\left[\hat{\boldsymbol{G}}_{\mathrm{p}} \in \mathcal{E}_{\mathrm{p}}\right] \sim 1 \text{ and } \frac{\mathbb{E}[Y_{\mathrm{f}}]}{\mathbb{E}[Z_{\mathrm{f}}]} = \mathbb{P}\left[\hat{\boldsymbol{G}}_{\mathrm{f}} \in \mathcal{E}_{\mathrm{f}}\right] \sim 1$$

and thus $\mathbb{E}[Y_{\mathrm{p}}] \sim \mathbb{E}[Z_{\mathrm{p}}]$ and $\mathbb{E}[Y_{\mathrm{f}}] \sim \mathbb{E}[Z_{\mathrm{f}}]$. Crucially, estimating the second moments of these two random variables is a cinch because by construction we can avoid an explicit optimisation of the function $F^{\otimes}_{d,\beta}$ from (11). Indeed, because we drop graphs G whose overlaps stray far from the product measures $\nu_{\mathrm{p}} \otimes \nu_{\mathrm{p}}$ and $\nu_{\mathrm{f}} \otimes \nu_{\mathrm{f}}$, respectively, we basically just need to evaluate the function $F^{\otimes}_{d,\beta}$ at $\nu_{\mathrm{p}} \otimes \nu_{\mathrm{p}}$ and $\nu_{\mathrm{f}} \otimes \nu_{\mathrm{f}}$, which is a matter of relatively simple algebra (due to convexity arguments). We thus obtain the following.

▶ **Corollary 3.10.** *Let $d, q \geq 3$ be integers and $\beta > 0$ be real.*
(i) *If $\beta < \beta_h$, then $\mathbb{E}[Y_{\mathrm{p}}(\boldsymbol{G})] \sim \mathbb{E}[Z_{\mathrm{p}}(\boldsymbol{G})]$ and $\mathbb{E}[Y_{\mathrm{p}}(\boldsymbol{G})^2] \leq \exp(o(n))\mathbb{E}[Z_{\mathrm{p}}(\boldsymbol{G})]^2$.*
(ii) *If $\beta > \beta_u$, then $\mathbb{E}[Y_{\mathrm{f}}(\boldsymbol{G})] \sim \mathbb{E}[Z_{\mathrm{f}}(\boldsymbol{G})]$ and $\mathbb{E}[Y_{\mathrm{f}}(\boldsymbol{G})^2] \leq \exp(o(n))\mathbb{E}[Z_{\mathrm{f}}(\boldsymbol{G})]^2$.*

At this stage, one can combine Corollary 3.10 together with (14) to derive the first two parts of Theorem 1.3 (using also the results from Section 2.1).

3 Quiet planting and non-reconstruction

In this section we give an outline of the proof of Lemma 3.8, which was the main ingredient to carry out the second moment method of Section 2.3.

While the planted models defined in (13) are useful for the second-moment argument, working with them directly is rather unwieldy. Fortunately, there is a relatively simple way out using the so-called Nishimori identities; on the way, we will also introduce some of the ingredients that are used for the metastability/slow-mixing results.

To elaborate, we complement the definition (13) of the planted random graphs $\hat{\boldsymbol{G}}_{\mathrm{f}}, \hat{\boldsymbol{G}}_{\mathrm{p}}$ by also introducing a reweighted distribution on graphs for a specific configuration $\sigma \in [q]^n$. Specifically, we define a random graph $\hat{\boldsymbol{G}}(\sigma)$ by letting

$$\mathbb{P}\left[\hat{\boldsymbol{G}}(\sigma) = G\right] = \frac{\mathbb{P}\left[\boldsymbol{G} = G\right] \mathrm{e}^{\beta \mathcal{H}_G(\sigma)}}{\mathbb{E}[\mathrm{e}^{\beta \mathcal{H}_{\boldsymbol{G}}(\sigma)}]}. \tag{15}$$

Furthermore, recalling the truncated partition functions $Z_{\mathrm{f}}, Z_{\mathrm{p}}$ from (12), we introduce reweighted random configurations $\hat{\boldsymbol{\sigma}}_{\mathrm{f}} = \hat{\boldsymbol{\sigma}}_{\mathrm{f}}(\varepsilon) \in [q]^n$ and $\hat{\boldsymbol{\sigma}}_{\mathrm{p}} = \hat{\boldsymbol{\sigma}}_{\mathrm{p}}(\varepsilon) \in [q]^n$ with distributions

$$\mathbb{P}\left[\hat{\boldsymbol{\sigma}}_{\mathrm{f}} = \sigma\right] = \frac{\mathbf{1}\{\sigma \in S_{\mathrm{f}}\}\, \mathbb{E}[\mathrm{e}^{\beta \mathcal{H}_{\boldsymbol{G}}(\sigma)}]}{\mathbb{E}[Z_{\mathrm{f}}(\boldsymbol{G})]}, \qquad \mathbb{P}\left[\hat{\boldsymbol{\sigma}}_{\mathrm{p}} = \sigma\right] = \frac{\mathbf{1}\{\sigma \in S_{\mathrm{p}}\}\, \mathbb{E}[\mathrm{e}^{\beta \mathcal{H}_{\boldsymbol{G}}(\sigma)}]}{\mathbb{E}[Z_{\mathrm{p}}(\boldsymbol{G})]}. \tag{16}$$

We have the following paramagnetic and ferromagnetic *Nishimori identities*. Nishimori identities were derived in [15] for a broad family of planted models which, however, does not include the planted ferromagnetic models $\hat{\boldsymbol{G}}_{\mathrm{p}}, \hat{\boldsymbol{G}}_{\mathrm{f}}$. Nonetheless, the (simple) proof of Proposition 3.1 is practically identical to that in [15] (and is given in the full version).

▶ **Proposition 3.1.** *We have the distributional equalities*

$$(\hat{\boldsymbol{G}}_{\mathrm{p}}, \boldsymbol{\sigma}_{\hat{\boldsymbol{G}}_{\mathrm{p}},\mathrm{p}}) \stackrel{d}{=} (\hat{\boldsymbol{G}}(\hat{\boldsymbol{\sigma}}_{\mathrm{p}}), \hat{\boldsymbol{\sigma}}_{\mathrm{p}}), \qquad (\hat{\boldsymbol{G}}_{\mathrm{f}}, \boldsymbol{\sigma}_{\hat{\boldsymbol{G}}_{\mathrm{f}},\mathrm{f}}) \stackrel{d}{=} (\hat{\boldsymbol{G}}(\hat{\boldsymbol{\sigma}}_{\mathrm{f}}), \hat{\boldsymbol{\sigma}}_{\mathrm{f}}). \tag{17}$$

Proposition 3.1 paves the way for a more hands-on description of the planted models in (13). Indeed, the random graph models $(\hat{\boldsymbol{G}}(\hat{\boldsymbol{\sigma}}_{\mathrm{p}}), \hat{\boldsymbol{\sigma}}_{\mathrm{p}})$ and $(\hat{\boldsymbol{G}}(\hat{\boldsymbol{\sigma}}_{\mathrm{f}}), \hat{\boldsymbol{\sigma}}_{\mathrm{f}})$ are invariant under permutations of the vertices, so $\hat{\boldsymbol{\sigma}}_{\mathrm{p}}$ and $\hat{\boldsymbol{\sigma}}_{\mathrm{f}}$ are uniformly random given their colour statistics, and the random graphs $\hat{\boldsymbol{G}}(\hat{\boldsymbol{\sigma}}_{\mathrm{p}})$ and $\hat{\boldsymbol{G}}(\hat{\boldsymbol{\sigma}}_{\mathrm{f}})$ themselves are uniformly random and easy to sample given the planted assignment $\hat{\boldsymbol{\sigma}}_{\mathrm{p}}$ or $\hat{\boldsymbol{\sigma}}_{\mathrm{f}}$ and given the edge statistics $\rho^{\hat{\boldsymbol{G}}(\hat{\boldsymbol{\sigma}}_{\mathrm{p}}),\hat{\boldsymbol{\sigma}}_{\mathrm{p}}}$ and $\rho^{\hat{\boldsymbol{G}}(\hat{\boldsymbol{\sigma}}_{\mathrm{f}}),\hat{\boldsymbol{\sigma}}_{\mathrm{f}}}$. Moreover, because $(\nu_{\mathrm{p}}, \rho_{\mathrm{p}})$ and $(\nu_{\mathrm{f}}, \rho_{\mathrm{f}})$ are local maxima of the first moment function $F_{d,b}(\nu, \rho)$, a first moment argument based on (8) allows us to control the vertex-edge colour statistics very accurately, i.e., there exist $c, t_0 > 0$ such that for all $t \in [0, t_0]$

$$\mathbb{P}\left[d_{\mathrm{TV}}\left(\nu^{\hat{\boldsymbol{\sigma}}_{\mathrm{p}}}, \nu_{\mathrm{p}}\right) + d_{\mathrm{TV}}\left(\rho^{\hat{\boldsymbol{G}}(\hat{\boldsymbol{\sigma}}_{\mathrm{p}}),\hat{\boldsymbol{\sigma}}_{\mathrm{p}}}, \rho_{\mathrm{p}}\right) > t\right] \leq n^{O(1)}\mathrm{e}^{-ct^2 n}, \tag{18}$$

and similarly for the deviations from $(\nu_{\mathrm{f}}, \rho_{\mathrm{f}})$ in the ferromagnetic phase (see Lemmas 3.4 and 3.5 in the full version). At this point we have handy descriptions of the models $(\hat{\boldsymbol{G}}(\hat{\boldsymbol{\sigma}}_{\mathrm{p}}), \hat{\boldsymbol{\sigma}}_{\mathrm{p}})$ and $(\hat{\boldsymbol{G}}(\hat{\boldsymbol{\sigma}}_{\mathrm{f}}), \hat{\boldsymbol{\sigma}}_{\mathrm{f}})$, and therefore, via Proposition 3.1, $(\hat{\boldsymbol{G}}_{\mathrm{p}}, \boldsymbol{\sigma}_{\hat{\boldsymbol{G}}_{\mathrm{p}},\mathrm{p}})$ and $(\hat{\boldsymbol{G}}_{\mathrm{f}}, \boldsymbol{\sigma}_{\hat{\boldsymbol{G}}_{\mathrm{f}},\mathrm{f}})$.

We will next utilise the information on the distribution of $\hat{\boldsymbol{\sigma}}_{\mathrm{p}}, \rho^{\hat{\boldsymbol{G}}(\hat{\boldsymbol{\sigma}}_{\mathrm{p}}),\hat{\boldsymbol{\sigma}}_{\mathrm{p}}}$ to couple the distribution of the colouring produced by the tree broadcasting process and the colouring that $\hat{\boldsymbol{\sigma}}_{\mathrm{p}}$ induces on the neighbourhood of some particular vertex of $\hat{\boldsymbol{G}}(\hat{\boldsymbol{\sigma}}_{\mathrm{p}})$, say v. In particular, for $\ell = \lceil \log\log n \rceil$, the ℓ-neighbourhood of v is going to be tree-like, so conditional on the statistics $\nu^{\hat{\boldsymbol{\sigma}}_{\mathrm{p}}}, \rho^{\hat{\boldsymbol{G}}(\hat{\boldsymbol{\sigma}}_{\mathrm{p}}),\hat{\boldsymbol{\sigma}}_{\mathrm{p}}}$, an inductive coupling (see Lemma 3.6) shows that

$$d_{\mathrm{TV}}(\hat{\boldsymbol{\sigma}}_{\mathrm{p},\partial^\ell v}, \tau_{\partial^\ell o}) = d^\ell\left(d_{\mathrm{TV}}(\nu^{\hat{\boldsymbol{\sigma}}_{\mathrm{p}}}, \nu_{\mathrm{p}}) + d_{\mathrm{TV}}(\rho^{\hat{\boldsymbol{G}}(\hat{\boldsymbol{\sigma}}_{\mathrm{p}}),\hat{\boldsymbol{\sigma}}_{\mathrm{p}}}, \rho_{\mathrm{p}}) + n^{-0.99}\right).$$

From (18), it then follows that the last quantity is $o(n^{-1/5})$ with probability $1 - o(1/n)$. Hence, the colourings $\hat{\boldsymbol{\sigma}}_{\mathrm{p},\partial^\ell v}$ and $\tau_{\partial^\ell o}$ can be coupled such that both are identical with probability $1 - o(n^{-1/5})$. Consequently, from the tree broadcasting results of Proposition 2.6, we obtain that $\sum_{c\in[q]} \mathbb{E}\left|\nu_{\mathrm{p}}(c) - \mu_{\hat{\boldsymbol{G}}(\hat{\boldsymbol{\sigma}}_{\mathrm{p}}),\beta}(\boldsymbol{\sigma}_v = c \mid \boldsymbol{\sigma}_{\partial^\ell v} = \hat{\boldsymbol{\sigma}}_{\mathrm{p},\partial^\ell v})\right| < \ell^{-3}$ which translates via the Nishimori identity into

$$\sum_{c\in[q]} \mathbb{E}\left|\nu_{\mathrm{p}}(c) - \mu_{\hat{\boldsymbol{G}}_{\mathrm{p}},\beta}(\boldsymbol{\sigma}_v = c \mid \boldsymbol{\sigma}_{\partial^\ell v} = \boldsymbol{\sigma}_{\hat{\boldsymbol{G}}_{\mathrm{p}},\mathrm{p},\partial^\ell v})\right| < \ell^{-3}. \tag{19}$$

Proof Sketch of Lemma 3.8. Due to the Nishimori identity (17), it suffices to prove that for a sample $\boldsymbol{\sigma}_{\hat{\boldsymbol{G}}(\hat{\boldsymbol{\sigma}}_{\mathrm{p}}),\mathrm{p}}$ from $\mu_{\hat{\boldsymbol{G}}(\hat{\boldsymbol{\sigma}}_{\mathrm{p}}),\beta}(\cdot \mid S_{\mathrm{p}})$ that

$$d_{\mathrm{TV}}\big(\nu(\hat{\boldsymbol{\sigma}}_{\mathrm{p}}, \boldsymbol{\sigma}_{\hat{\boldsymbol{G}}(\hat{\boldsymbol{\sigma}}_{\mathrm{p}}),\mathrm{p}}), \nu_{\mathrm{p}} \otimes \nu_{\mathrm{p}}\big) = o(1). \tag{20}$$

To see (20), for colors $s, t \in [q]$, we consider the first and second moment of the number of vertices u with $\hat{\boldsymbol{\sigma}}_{\mathrm{p}}(u) = s$ and $\boldsymbol{\sigma}_{\hat{\boldsymbol{G}}(\hat{\boldsymbol{\sigma}}_{\mathrm{p}}),\mathrm{p}}(u) = t$. To facilitate the analysis of the second moment, it will be convenient to consider the following configuration $\boldsymbol{\sigma}'_{\hat{\boldsymbol{G}}(\hat{\boldsymbol{\sigma}}_{\mathrm{p}}),\mathrm{p}}$. Let $\boldsymbol{v}, \boldsymbol{w}$ be two random vertices such that $\hat{\boldsymbol{\sigma}}_{\mathrm{p}}(\boldsymbol{v}) = \hat{\boldsymbol{\sigma}}_{\mathrm{p}}(\boldsymbol{w}) = s$. Also let $\ell = \ell(n) = \lceil \log\log n \rceil$. Now, draw $\boldsymbol{\sigma}''_{\hat{\boldsymbol{G}}(\hat{\boldsymbol{\sigma}}_{\mathrm{p}}),\mathrm{p}}$ from $\mu_{\hat{\boldsymbol{G}}(\hat{\boldsymbol{\sigma}}_{\mathrm{p}}),\beta}(\cdot \mid S_{\mathrm{p}})$ and subsequently generate $\boldsymbol{\sigma}'_{\hat{\boldsymbol{G}}(\hat{\boldsymbol{\sigma}}_{\mathrm{p}}),\mathrm{p}}$ by re-sampling the colours of the vertices at distance less than ℓ from $\boldsymbol{v}, \boldsymbol{w}$ given the colours of the vertices at distance ℓ from $\boldsymbol{v}, \boldsymbol{w}$ and the event S_{p}. Then $\boldsymbol{\sigma}'_{\hat{\boldsymbol{G}}(\hat{\boldsymbol{\sigma}}_{\mathrm{p}}),\mathrm{p}}$ has distribution $\mu_{\hat{\boldsymbol{G}}(\hat{\boldsymbol{\sigma}}_{\mathrm{p}}),\beta}(\cdot \mid S_{\mathrm{p}})$. Moreover, since for two random vertices $\boldsymbol{v}, \boldsymbol{w}$ their ℓ-neighbourhoods are going to be disjoint w.h.p., the reconstruction property in (19) implies that w.h.p. for all $\chi, \chi' \in [q]$

$$\mathbb{P}\left[\boldsymbol{\sigma}'_{\hat{\boldsymbol{G}}_{\mathrm{p}},\mathrm{p}}(\boldsymbol{v}) = \chi, \boldsymbol{\sigma}'_{\hat{\boldsymbol{G}}_{\mathrm{p}},\mathrm{p}}(\boldsymbol{w}) = \chi' \mid \hat{\boldsymbol{\sigma}}_{\mathrm{p}}, \hat{\boldsymbol{G}}(\hat{\boldsymbol{\sigma}}_{\mathrm{p}}), \boldsymbol{v}, \boldsymbol{w}\right] = \nu_p(\chi)\nu_p(\chi') + o(1). \tag{21}$$

Hence, for a colour $t \in [q]$ let $\boldsymbol{X}(s,t)$ be the number of vertices u with $\hat{\boldsymbol{\sigma}}_{\mathrm{p}}(u) = s$ and $\boldsymbol{\sigma}'_{\hat{\boldsymbol{G}}_{\mathrm{p}},\mathrm{p}}(\boldsymbol{v}) = t$. Then (21) shows that w.h.p. $\mathbb{E}\left[\boldsymbol{X}(s,t) \mid \hat{\boldsymbol{\sigma}}_{\mathrm{p}}, \hat{\boldsymbol{G}}(\hat{\boldsymbol{\sigma}}_{\mathrm{p}})\right] \sim \frac{n}{q^2}$ and $\mathbb{E}\left[\boldsymbol{X}(s,t)^2 \mid \hat{\boldsymbol{\sigma}}_{\mathrm{p}}, \hat{\boldsymbol{G}}(\hat{\boldsymbol{\sigma}}_{\mathrm{p}})\right] \sim \frac{n^2}{q^4}$. Thus, (20) follows from Chebyshev's inequality. ◀

4 Metastability and Slow mixing

In this section, we prove Theorems 1.1 and 1.2. Recall from Section 1.3 the paramagnetic and ferromagnetic states $S_{\mathrm{p}}(\varepsilon)$ and $S_{\mathrm{f}}(\varepsilon)$ for $\varepsilon > 0$. For the purposes of this section we will need to be more systematic of keeping track the dependence of these phases on ε. In particular, we will use the more explicit notation $Z^{\varepsilon}_{\mathrm{p}}(G)$ and $Z^{\varepsilon}_{\mathrm{f}}(G)$ to denote the quantities $Z_{\mathrm{p}}(G)$ and $Z_{\mathrm{f}}(G)$, respectively, from (12). The following lemma, based on Theorem 1.3, reflects the fact that ν_{p} and ν_{f} are local maxima of the first-moment function $F_{d,\beta}$.

▶ **Lemma 4.1.** *Let $q, d \geq 3$ be integers and $\beta > 0$ be real. Then, for all sufficiently small constants $\varepsilon' > \varepsilon > 0$, there exists constant $\zeta > 0$ such that w.h.p. over $G \sim \boldsymbol{G}$, it holds that*

1. *If $\beta < \beta_h$, then $Z^{\varepsilon}_{\mathrm{p}}(G) \geq \mathrm{e}^{-n^{3/4}}\mathbb{E}[Z^{\varepsilon}_{\mathrm{p}}(\boldsymbol{G})]$ and $Z^{\varepsilon'}_{\mathrm{p}}(G) \leq (1+\mathrm{e}^{-\zeta n})Z^{\varepsilon}_{\mathrm{p}}(G)$.*
2. *If $\beta > \beta_u$, then $Z^{\varepsilon}_{\mathrm{f}}(G) \geq \mathrm{e}^{-n^{3/4}}\mathbb{E}[Z^{\varepsilon}_{\mathrm{f}}(\boldsymbol{G})]$ and $Z^{\varepsilon'}_{\mathrm{f}}(G) \leq (1+\mathrm{e}^{-\zeta n})Z^{\varepsilon}_{\mathrm{f}}(G)$.*

Theorem 1.1 will follow by way of a conductance argument. Let $G = (V, E)$ be a graph, and P be the transition matrix for the Glauber dynamics defined in Section 1.4. For a set $S \subseteq [q]^V$ define the *bottleneck ratio* of S to be $\Phi(S) = \frac{\sum_{\sigma\in S,\, \tau\notin S}\mu_{G,\beta}(\sigma)P(\sigma,\tau)}{\mu_{G,\beta}(S)}$. The following lemma provides a routine conductance bound (e.g., [32, Theorem 7.3]). For the sake of completeness the proof is included in the full version.

▶ **Lemma 4.2.** *Let $G = (V, E)$ be a graph. For any $S \subseteq [q]^V$ such that $\mu_G(S) > 0$ and any integer $t \geq 0$ we have $\|\mu_{G,S}P^t - \mu_{G,S}\|_{TV} \leq t\Phi(S)$.*

Proof of Theorem 1.1. We prove the statement for the pairing model $\boldsymbol{G}$, the result for $\mathbb{G}$ follows immediately by contiguity. Let $\varepsilon' > \varepsilon > 0$ and $\zeta > 0$ be small constants such that Lemma 4.1 applies, and let $G \sim \boldsymbol{G}$ be a graph satisfying the lemma. Set for convenience $\mu = \mu_{\boldsymbol{G},\beta}$; we consider first the metastability of $S_{\mathrm{f}}(\varepsilon)$ for $\beta > \beta_u$.

Since Glauber updates one vertex at a time it is impossible in one step to move from $\sigma \in S_{\mathrm{f}}(\varepsilon)$ to $\tau \in [q]^n \backslash S_{\mathrm{f}}(\varepsilon')$, i.e., $P(\sigma,\tau) = 0$, and therefore

$$\Phi\big(S_{\mathrm{f}}(\varepsilon)\big) = \frac{\sum_{\sigma\in S_{\mathrm{f}}(\varepsilon)}\sum_{\tau\notin S_{\mathrm{f}}(\varepsilon)}\mu(\sigma)P(\sigma,\tau)}{\mu\big(S_{\mathrm{f}}(\varepsilon)\big)} = \frac{\sum_{\sigma\in S_{\mathrm{f}}(\varepsilon)}\sum_{\tau\in S_{\mathrm{f}}(\varepsilon')\backslash S_{\mathrm{f}}(\varepsilon')}\mu(\sigma)P(\sigma,\tau)}{\mu\big(S_{\mathrm{f}}(\varepsilon)\big)}$$

By reversibility of Glauber, for any $\sigma, \tau \in [q]^n$ we have $\mu(\sigma)P(\sigma,\tau) = \mu(\tau)P(\tau,\sigma)$, and therefore the numerator is upper-bounded by $\mu\big(S_{\mathrm{f}}(\varepsilon')\backslash S_{\mathrm{f}}(\varepsilon)\big)$. Hence, $\Phi\big(S_{\mathrm{f}}(\varepsilon)\big) \leq \frac{\mu\left(S_{\mathrm{f}}(\varepsilon')\backslash S_{\mathrm{f}}(\varepsilon)\right)}{\mu\left(S_{\mathrm{f}}(\varepsilon)\right)} = \frac{Z^{\varepsilon'}_{\mathrm{f}}(G)-Z^{\varepsilon}_{\mathrm{f}}(G)}{Z^{\varepsilon}_{\mathrm{f}}(G)} \leq \mathrm{e}^{-\zeta n}$, where the last inequality follows from the fact that G satisfies Lemma 4.1. Lemma 4.2 now ensures that for all nonnegative integers $T \leq \mathrm{e}^{\zeta n/3}$

$$\big\|\mu\big(\cdot \mid S_{\mathrm{f}}(\varepsilon)\big)P^T - \mu\big(\cdot \mid S_{\mathrm{f}}(\varepsilon)\big)\big\|_{TV} \leq T \cdot \Phi(S_{\mathrm{f}}) \leq \mathrm{e}^{-2\zeta n/3}. \tag{22}$$

Now, consider the Glauber dynamics $(\sigma_t)_{t\geq 0}$ launched from σ_0 drawn from $\mu_{\mathbb{G},\beta,S_{\mathrm{f}}(\varepsilon)}$, and denote by $T_{\mathrm{f}} = \min\{t > 0 : \sigma_t \notin S_{\mathrm{f}}(\varepsilon)\}$ its escape time from $S_{\mathrm{f}}(\varepsilon)$. Observe that σ_t has the same distribution as $\mu(\cdot \mid S_{\mathrm{f}}(\varepsilon))P^t$, so (22) implies that for all nonnegative integers $T \leq \mathrm{e}^{\zeta n/3}$ it holds that $\big|\mathbb{P}[\sigma_T \in S_{\mathrm{f}}(\varepsilon)] - 1\big| < \mathrm{e}^{-2\zeta n/3}$, or equivalently $\mathbb{P}[\sigma_T \notin S_{\mathrm{f}}(\varepsilon)] \leq \mathrm{e}^{-2\zeta n/3}$. By a

union bound over the values of T, we therefore obtain that $\mathbb{P}[T_{\mathrm{f}} \leq \mathrm{e}^{\zeta n/3}] \leq \mathrm{e}^{-\zeta n/3}$, thus proving that $S_{\mathrm{f}}(\varepsilon)$ is a metastable state for $\beta > \beta_u$. Analogous arguments show that $S_{\mathrm{p}}(\varepsilon)$ is a metastable state for $\beta < \beta_h$.

The slow mixing of Glauber for $\beta > \beta_u$ follows from the metastability of $S_{\mathrm{f}}(\varepsilon)$. In particular, from Theorem 1.3 we have that $\big\|\mu\big(\cdot \mid S_{\mathrm{f}}(\varepsilon)\big) - \mu\big\| \geq 3/5$ and therefore, from (22), $\big\|\mu\big(\cdot \mid S_{\mathrm{f}}(\varepsilon)\big)P^T - \mu\big\| \geq 1/2$, yielding that the mixing time is $\mathrm{e}^{\Omega(n)}$. ◀

The key and much more challenging ingredient to establish Theorem 1.2 is to bound the probability that Swendsen-Wang escapes $S_{\mathrm{p}}(\varepsilon)$ and $S_{\mathrm{f}}(\varepsilon)$. More precisely, for a graph G, a configuration $\sigma \in [q]^n$, and $S \subseteq [q]^n$, let $P^G_{SW}(\sigma \to S)$ denote the probability that after one step of SW on G starting from σ, we end up in a configuration in S.

The following proposition shows that for almost all pairs (G, σ) from the ferromagnetic planted distribution $\big(\hat{\boldsymbol{G}}\big(\hat{\boldsymbol{\sigma}}_{\mathrm{f}}(\varepsilon)\big), \hat{\boldsymbol{\sigma}}_{\mathrm{f}}(\varepsilon)\big)$, the probability that SW leads to a configuration in the ferromagnetic phase, slightly enlarged, is $1-\mathrm{e}^{-\Omega(n)}$. Note here that SW might change the dominant colour due to recolouring step, so, for $\varepsilon > 0$, we consider the set of configurations $\tilde{S}_{\mathrm{f}}(\varepsilon)$ that consists of the ferromagnetic phase $S_{\mathrm{f}}(\varepsilon)$ together with its $q-1$ permutations, and the probability that SW escapes from it, starting from a ferromagnetic state.

▶ **Proposition 4.4.** *Let $q, d \geq 3$ be integers and $\beta \in (\beta_u, \beta_h)$. Then, for all sufficiently small constants $\varepsilon' > \varepsilon > 0$, there exists constant $\eta > 0$ such that with probability $1 - \mathrm{e}^{-\eta n}$ over the planted distribution $(G, \sigma) \sim \big(\hat{\boldsymbol{G}}\big(\hat{\boldsymbol{\sigma}}_{\mathrm{f}}(\varepsilon)\big), \hat{\boldsymbol{\sigma}}_{\mathrm{f}}(\varepsilon)\big)$, it holds that $P^G_{SW}\big(\sigma \to \tilde{S}_{\mathrm{f}}(\varepsilon')\big) \geq 1 - \mathrm{e}^{-\eta n}$.*

An analogous Proposition 4.3 applies for the paramagnetic distribution $\big(\hat{\boldsymbol{G}}\big(\hat{\boldsymbol{\sigma}}_{\mathrm{p}}(\varepsilon)\big), \hat{\boldsymbol{\sigma}}_{\mathrm{p}}(\varepsilon)\big)$. The proof of these Propositions requires a delicate analysis of the percolation step in SW since we need probability bounds that are exponentially close to 1. Especially for Proposition 4.4, the presence of a giant component (corresponding to the dominant colour) complicates the arguments significantly since we need to take into account the underlying vertex-edge colour statistics of $\big(\hat{\boldsymbol{G}}\big(\hat{\boldsymbol{\sigma}}_{\mathrm{f}}(\varepsilon)\big), \hat{\boldsymbol{\sigma}}_{\mathrm{f}}(\varepsilon)\big)\big)$ studied in Section 3. Even with Propositions 4.3 and 4.4 at hand, concluding Theorem 1.2 requires a bit of work based on the planting ideas.

Proof Sketch of Theorem 1.2. We consider first the metastability for the ferromagnetic phase when $\beta > \beta_u$. Let $\varepsilon' > \varepsilon > 0$ and $\eta, \zeta > 0$ be small constants such that Lemma 4.1 and Proposition 4.4 apply. Let $\theta = \frac{1}{10}\min\{\eta, \zeta\}$.

Let $\mathcal{Q}$ be the set of d-regular (multi)graphs that satisfy both items in Lemma 4.1. Moreover, let $\mathcal{Q}'$ be the set of d-regular (multi)graphs G such that the set of configurations where SW has conceivable probability of escaping $\tilde{S}_{\mathrm{f}}(\varepsilon')$ has small weight, i.e., the set

$$S_{\mathrm{Bad}}(G) = \big\{\sigma \in \tilde{S}_{\mathrm{f}}(\varepsilon) \,\big|\, P^G_{SW}\big(\sigma \to \tilde{S}_{\mathrm{f}}(\varepsilon')\big) < 1 - \mathrm{e}^{-\eta n}\big\}$$

has aggregate weight $Z_{\mathrm{Bad}}(G) = \sum_{\sigma \in S_{\mathrm{Bad}}(G)} \mathrm{e}^{\beta \mathcal{H}(G)}$ less than $\mathrm{e}^{-\theta n} Z^{\varepsilon}_{\mathrm{f}}(G)$. For a d-regular graph G such that $G \in \mathcal{Q} \cap \mathcal{Q}'$, using arguments analogous to those for Glauber, we have that $\Phi_{SW}\big(\tilde{S}_{\mathrm{f}}(\varepsilon)\big) \leq 10\mathrm{e}^{-\theta n}$. By arguments analogous to those in the proof of Theorem 1.1, we have that $\tilde{S}_{\mathrm{f}}(\varepsilon)$ is a metastable state for graphs $G \in \mathcal{Q} \cap \mathcal{Q}'$. Therefore, to finish the metastability proof for the random graph, it suffices to show that $\mathbb{P}(\boldsymbol{G} \in \mathcal{Q} \cap \mathcal{Q}') = 1 - o(1)$.

To do this, let $\mathcal{G}(n, d)$ be the set of all multigraphs that can be obtained in the pairing model and $\Lambda_{d,\beta}(n) = \big\{(G, \sigma) \,\big|\, G \in \mathcal{G}(n, d),\ \sigma \in \tilde{S}_{\mathrm{f}}(\varepsilon)\big\}$. Let $\mathcal{E}$ be the pairs $(G, \sigma) \in \Lambda_{d,\beta}(n)$ where one step of SW starting from G, σ stays within $\tilde{S}_{\mathrm{f}}(\varepsilon')$ with probability $1 - \mathrm{e}^{-\Omega(n)}$, more precisely $\mathcal{E} = \Big\{(G, \sigma) \in \Lambda_{d,\beta}(n) \,\Big|\, P^G_{SW}\big(\sigma \to \tilde{S}_{\mathrm{f}}(\varepsilon')\big) \geq 1 - \mathrm{e}^{-\eta n}\Big\}$. The aggregate weight corresponding to pairs $(G, \sigma) \notin \mathcal{E}$ can be lower-bounded by

$$\sum_{(G,\sigma) \in \Lambda_{d,\beta} \setminus \mathcal{E}} \mathrm{e}^{\beta \mathcal{H}_G(\sigma)} \geq \sum_{G \in \mathcal{Q} \setminus \mathcal{Q}'} \sum_{\sigma \in \Sigma_{\mathrm{Bad}}(G)} \mathrm{e}^{\beta \mathcal{H}_G(\sigma)} \geq \mathrm{e}^{-\theta n} \sum_{G \in \mathcal{Q} \setminus \mathcal{Q}'} Z^{\varepsilon}_{\mathrm{f}}(G).$$

For graphs $G \in \mathcal{Q}$ we have $Z^{\varepsilon}_{\mathrm{f}}(G) \geq \mathrm{e}^{-n^{3/4}}\mathbb{E}[Z^{\varepsilon}_{\mathrm{f}}(\boldsymbol{G})]$, and therefore

$$\sum_{(G,\sigma)\in\Lambda_{d,\beta}\setminus\mathcal{E}} \mathrm{e}^{\beta\mathcal{H}_G(\sigma)} \geq \mathrm{e}^{-(\theta n+n^{3/4})}\big|\mathcal{Q}\setminus\mathcal{Q}'\big|\ \mathbb{E}\big[Z^{\varepsilon}_{\mathrm{f}}(\boldsymbol{G})\big] = \mathrm{e}^{-(\theta n+n^{3/4})}\big|\mathcal{Q}\setminus\mathcal{Q}'\big|\ \frac{\sum_{(G,\sigma)\in\Lambda_{d,\beta}} \mathrm{e}^{\beta\mathcal{H}_G(\sigma)}}{\big|\mathcal{G}(n,d)\big|}$$

From the definition of $\big(\hat{\boldsymbol{G}}\big(\hat{\boldsymbol{\sigma}}_{\mathrm{f}}(\varepsilon)\big), \hat{\boldsymbol{\sigma}}_{\mathrm{f}}(\varepsilon)\big)$, cf. (15),(16), observe that

$$\frac{\sum_{(G,\sigma)\in\Lambda_{d,\beta}\setminus\mathcal{E}} \mathrm{e}^{\beta\mathcal{H}_G(\sigma)}}{\sum_{(G,\sigma)\in\Lambda_{d,\beta}} \mathrm{e}^{\beta\mathcal{H}_G(\sigma)}} = \mathbb{P}\big[\big(\hat{\boldsymbol{G}}(\hat{\boldsymbol{\sigma}}_{\mathrm{f}}(\varepsilon)), \hat{\boldsymbol{\sigma}}_{\mathrm{f}}(\varepsilon)\big) \in \Lambda_{d,\beta}\setminus\mathcal{E}\big] \leq \mathrm{e}^{-\eta n} \leq \mathrm{e}^{-10\theta n},$$

where the penultimate inequality follows from Proposition 4.4 and the last from the choice of θ. Combining the last two inequalities, we obtain $\mathbb{P}[\boldsymbol{G} \in \mathcal{Q}\setminus\mathcal{Q}'] = o(1)$. Since $\mathbb{P}[\boldsymbol{G} \in \mathcal{Q}] = 1-o(1)$ from Lemma 4.1, it follows that $\mathbb{P}[\boldsymbol{G} \in \mathcal{Q}\cap\mathcal{Q}'] \geq \mathbb{P}[\boldsymbol{G} \in \mathcal{Q}] - \mathbb{P}[\boldsymbol{G} \in \mathcal{Q}\setminus\mathcal{Q}'] \geq 1 - o(1)$. This concludes the proof for the metastability of the ferromagnetic phase $\tilde{S}_{\mathrm{f}}(\varepsilon)$ when $\beta > \beta_u$.

A similar bottleneck-ratio argument shows that $S_{\mathrm{p}}(\varepsilon)$ is a metastable state for $\beta < \beta_h$. The slow mixing of SW for $\beta \in (\beta_u, \beta_h)$ follows from the metastability of $\tilde{S}_{\mathrm{f}}(\varepsilon)$ when $\beta \in (\beta_u, \beta_p]$ and the metastability of $S_{\mathrm{p}}(\varepsilon)$ when $\beta \in [\beta_p, \beta_h)$. In particular, let $S \in \{\tilde{S}_{\mathrm{f}}(\varepsilon), S_{\mathrm{p}}(\varepsilon)\}$ be such that $\big\|\mu\big(\cdot \mid S\big) - \mu\big\| \geq 1/2$, then Lemma 4.2 gives that for $T = \mathrm{e}^{\Omega(n)}$, it holds that $\big\|\mu\big(\cdot \mid S\big)P^T_{SW} - \mu\big\| \geq 1/2 - 1/10$, yielding that the mixing time is $\mathrm{e}^{\Omega(n)}$. ◀

On Computing the k-Shortcut Fréchet Distance

Jacobus Conradi

Hausdorff Center for Mathematics, Universität Bonn, Germany

Abstract

The Fréchet distance is a popular measure of dissimilarity for polygonal curves. It is defined as a min-max formulation that considers all direction-preserving continuous bijections of the two curves. Because of its susceptibility to noise, Driemel and Har-Peled introduced the shortcut Fréchet distance in 2012, where one is allowed to take shortcuts along one of the curves, similar to the edit distance for sequences. We analyse the parameterized version of this problem, where the number of shortcuts is bounded by a parameter k. The corresponding decision problem can be stated as follows: Given two polygonal curves T and B of at most n vertices, a parameter k and a distance threshold δ, is it possible to introduce k shortcuts along B such that the Fréchet distance of the resulting curve and the curve T is at most δ? We study this problem for polygonal curves in the plane. We provide a complexity analysis for this problem with the following results: (i) assuming the exponential-time-hypothesis (ETH), there exists no algorithm with running time bounded by $n^{o(k)}$; (ii) there exists a decision algorithm with running time in $\mathcal{O}(kn^{2k+2}\log n)$. In contrast, we also show that efficient approximate decider algorithms are possible, even when k is large. We present a $(3+\varepsilon)$-approximate decider algorithm with running time in $\mathcal{O}(kn^2\log^2 n)$ for fixed ε. In addition, we can show that, if k is a constant and the two curves are c-packed for some constant c, then the approximate decider algorithm runs in near-linear time.

1 Introduction

With the prevalence of geographical data collection and usage, the need to process and compare polygonal curves stemming from this data arises. A popular versatile distance measure for polygonal curves is the Fréchet distance [27]. The distance measure is very similar to the well-known Hausdorff distance for geometric sets, except that it takes the ordering of points along the curves into account by minimizing over all possible direction-preserving continuous bijections between the two curves. Intuitively, the distance measure can be defined as follows. Imagine two agents independently traversing the two curves with varying speeds. Let δ be an upper bound on the (Euclidean) distance of the two agents that holds at any point in time during the traversal. The Fréchet distance corresponds to the minimum value of δ that can be attained over all possible traversals.

In practice, the distance measure may be distorted by outliers and measurement errors. As a remedy, partial similarity and distance measures have been introduced which are thought to be more robust. Buchin, Buchin and Wang define a *partial Fréchet distance* [14]

which maximizes the portions of the two curves matched to one-another within some given distance threshold. Driemel and Har-Peled suggested the *shortcut Fréchet distance* [21] in the spirit of the well-known edit distance for strings: a set of non-overlapping subcurves can be replaced by straight edges connecting the endpoints (so-called shortcuts) to minimize the Fréchet distance of the resulting curves. Akitaya, Buchin, Ryvkin and Urhausen [3] introduced a variant of the Fréchet distance, where a certain number of "jumps" (backwards and forwards) are allowed during the traversal of the two curves. We note that it has been acknowledged in the literature that partial dissimilarity measures generally do not satisfy metric properties [12, 25, 28].

It is conceivable that computing a partial dissimilarity based on the Fréchet distance should be more difficult than the standard Fréchet distance because of the structure of the optimization problems involved. We briefly discuss what is known for these problems. The continuous Fréchet distance can be computed in $\mathcal{O}(n^2\text{polylog}(n))$ time for two polygonal curves of n vertices [5, 13]. For the discrete Fréchet distance, slightly subquadratic time is possible, as it can be computed in $\mathcal{O}(\frac{n^2\log\log(n)}{\log(n)})$ time [2]. However, assuming the Strong-Exponential-Time-Hypothesis (SETH), there is no algorithm, in either the discrete or the continuous setting, for any $\varepsilon > 0$, with running time in $\mathcal{O}(n^{2-\varepsilon})$ [9, 11, 15]. Following these works, we know that the complexity of computing the standard Fréchet distance is roughly quadratic in the size of the input, both in the discrete and continuous setting, and this holds for any dimension $d \geq 1$. Strongly subquadratic approximation algorithms are possible for restricted classes of curves [6, 7, 10, 22] and for large approximation factors [17, 18].

Compared to the standard Fréchet distance, the overall picture of the computational complexity of the partial variants is much more heterogeneous. De Carufel et al. [20] showed that the problem of computing the partial Fréchet distance is not solvable by radicals over $\mathbb{Q}$ and that the degree of the polynomial equations involved is unbounded in general. On the other hand, some variants of the partial Fréchet distance can be computed exactly in polynomial time [14]. Computing the shortcut Fréchet distance was shown to be NP-hard [16] when shortcuts are allowed anywhere along the curve. On the other hand, the *discrete Fréchet distance with shortcuts* was shown to be computable in strictly subquadratic time by Avraham et al. [8], which is even faster than computing the standard variant without shortcuts. The variant defined by Akitaya et al. [3] turns out to be NP-hard, but allows for fixed-parameter tractable algorithms.

Our contribution. In this paper, we study the computational complexity of a parameterized version of the shortcut Fréchet distance, where the maximum number of shortcuts that may be introduced on the curve is restricted by a parameter k. We show that assuming the Exponential-Time-Hypothesis (ETH), no fixed-parameter tractable running time is possible with k being the parameter. For polygonal curves in the plane, we present an exponential-time exact algorithm and we show that near-linear time approximation algorithms are possible using certain realistic input assumptions on the two curves.

Previous work. Driemel and Har-Peled [21] introduced the shortcut Fréchet distance and described a near-linear time $(3+\varepsilon)$-approximation algorithm for the class of c-packed curves. However, they only allowed shortcuts that start and end at *vertices* of the base curve. Buchin, Driemel and Speckmann [16] showed that, if shortcuts are allowed *anywhere along the curve*, then the problem of computing the shortcut Fréchet distance exactly is NP-hard via reduction from SUBSET-SUM. They also describe a 3-approximation algorithm for the decision problem with running time in $\mathcal{O}(n^3 \log n)$ for the case that shortcuts may start and

end in the middle of edges. Prior to our work, there has been no study of exact algorithms for the shortcut Fréchet distance, with non-restricted shortcuts. Our analysis of the exact problem therefore closes an important gap in the literature. Obtaining the exact algorithm was surprisingly simple, once the relevant techniques were combined in the right way.

1.1 Basic definitions

▶ **Definition 1** (curve). *A curve T is a continuous map from $[0,1]$ to $\mathbb{R}^d$, where $T(t)$ denotes the point on the curve parameterized by $t \in [0,1]$. For $0 \leq s < t \leq 1$ we denote the subcurve of T from $T(s)$ to $T(t)$ by $T[s,t]$. A polygonal curve of complexity n is given by a sequence of n points in $\mathbb{R}^d$. The curve is then defined as the piecewise linear interpolation between consecutive points.*

▶ **Definition 2** (Fréchet distance). *Given two curves T and B in $\mathbb{R}^d$, their Fréchet distance is defined as*

$$d_{\mathcal{F}}(T,B) = \inf_{f,g:[0,1]\to[0,1]} \max_{t\in[0,1]} \|T(f(t)) - B(g(t))\|,$$

where f and g are monotone, continuous, non-decreasing and surjective. We call a pair of such functions (f,g) a traversal. Any such traversal has the cost $\max_{\alpha\in[0,1]} \|T(f(\alpha)) - B(g(\alpha))\|$ associated to it.

In our definition of the Fréchet distance given above, we follow Alt and Godau [4]. Strictly speaking, this definition does not use bijections as for the sake of convenience the strict monotonicity of f and g is relaxed.

▶ **Definition 3** (k-shortcut curve). *We call a line segment between two arbitrary points $B(s)$ and $B(t)$ of a curve B a shortcut on B, where $s < t$ and denote it by $\overline{B}[s,t]$. A k-shortcut curve of B is the result of replacing k subcurves $B[s_i,t_i]$ of B for $1 \leq i \leq k$ by shortcuts $\overline{B}[s_i,t_i]$ connecting their start and endpoint, with $t_i \leq s_{i+1}$ for $1 \leq i \leq k-1$.*

▶ **Definition 4** (k-shortcut Fréchet Distance). *Given two polygonal curves T and B, their k-shortcut Fréchet distance $d_{\mathcal{S}}^k(T,B)$ is defined as the minimum Fréchet distance between T and any k'-shortcut curve of B for some $0 \leq k' \leq k$. In this context, we call B the base curve (where we take shortcuts) and T the target curve (which we want to minimize the Fréchet distance to).*

1.2 Overview of this paper

In Section 3 we present an exact algorithm for deciding if the k-shortcut Fréchet distance is smaller than a given threshold δ. The algorithm can also be used for the non-parameterized variant by setting $k = n$. Our first main result is the following theorem.

▶ **Theorem 5.** *Let T and B be two polygonal curves in the plane with overall complexity n, together with a value $\delta > 0$. There exists an algorithm with running time in $\mathcal{O}\big(kn^{2k+2}\log n\big)$ and space in $\mathcal{O}\big(kn^{2k+2}\big)$ that decides whether $d_{\mathcal{S}}^k(T,B) \leq \delta$.*

Our algorithm for Theorem 5 iterates over the free space diagram by Alt and Godau [5] in k rounds. Within the free space diagram, a direction-preserving continuous bijection between two curves corresponds to a monotone path starting at $(0,0)$ and ending at $(1,1)$. In each round, we compute the set of points in the parametric space of the two curves that are reachable by using one additional shortcut. For computing the set of eligible shortcuts

spanning a fixed set of edges, we make use of the so-called line-stabbing wedge introduced by Guibas et al. [23]. Line-stabbing wedges were also used in the approximation algorithm by Buchin et al [16]. In our case, since we perform exact computations, the reachable space may be fragmented into a number of components, and this number may grow exponentially with the number of rounds.

In Section 5 we give some evidence that this high complexity due to fragmentation is not an artifact of our algorithm, but may be inherent in the problem itself. For this, we assume that the exponential time hypothesis (ETH) holds. The ETH states that 3-SAT in n variables cannot be solved in $2^{o(n)}$ time [24]. Our second main result is the following conditional lower bound.

▶ **Theorem 6.** *Unless ETH fails, there is no algorithm for the k-shortcut Fréchet distance decision problem in $\mathbb{R}^d$ for $d \geq 2$, with running time $n^{o(k)}$.*

Our conditional lower bound of Theorem 6 is obtained via reduction from a variant of the k-SUM problem, which is called k-Table-SUM. In particular, we construct a $(4k+2)$-shortcut Fréchet distance decision instance for a given k-Table-SUM instance. Our construction is based on the NP-hardness reduction by Buchin, Driemel and Speckmann [16]. Their reduction was from SUBSET-SUM and could not be directly applied to obtain our result. The construction implicitly encodes partial solutions for the SUBSET-SUM instance as reachable intervals on the edges of one of the curves. In this way, each shortcut taken by the optimal solution implements a choice for an element to be included in the sum. The previous reduction implemented this in the form of a binary choice, thereby leading to a number of shortcuts that is linear in n. In our case, the number of shortcuts taken should only depend on k and not n. Therefore, we give a new construction for a choice gadget, that allows to choose an element from a set to be included in a partial solution while using only a constant number of shortcuts for this choice. We remark that a tighter bound can be obtained when assuming the k-SUM hypothesis [1].

In light of the above results, it is interesting to consider approximation algorithms and realistic input assumptions for this problem. In Section 4 we show that there is an efficient approximation algorithm for this problem. If we can assume that the input curves are well-behaved, we even obtain a near-linear time algorithm for constant k. To formalize this, we consider the class of c-packed curves, see also [22].

▶ **Definition 7** (c-packed curves)**.** *For $c > 0$, a curve X is called c-packed if the total length of X inside any ball is bounded by c times the radius of the ball.*

The following is our third main result. Since any polygonal curve of complexity n is c-packed for some $c \leq 2n$, the theorem also implies a running time of $\mathcal{O}\big(kn^2\varepsilon^{-5}(\log^2(n\varepsilon^{-1})\big)$ for polygonal curves in the plane – without any input assumptions.

▶ **Theorem 8.** *Let T and B be two c-packed polygonal curves in the plane with overall complexity n, together with values $0 < \varepsilon \leq 1$ and $\delta > 0$. There exists an algorithm with running time in $\mathcal{O}\big(kcn\varepsilon^{-5}\log^2(n\varepsilon^{-1})\big)$ and space in $\mathcal{O}\big(kcn\varepsilon^{-4}\log^2(\varepsilon^{-1})\big)$ which outputs one of the following: (i) $d_{\mathcal{S}}^k(T,B) \leq (3+\varepsilon)\delta$ or (ii) $d_{\mathcal{S}}^k(T,B) > \delta$. In any case, the output is correct.*

The main ideas that go into the proof of Theorem 8 can be sketched as follows. The first observation is that a highly fragmented reachable space that leads to the high running time of the exact algorithm of Theorem 5 can be approximated by limiting the number of shortcuts that the algorithm may take. To show that the algorithm still takes the right

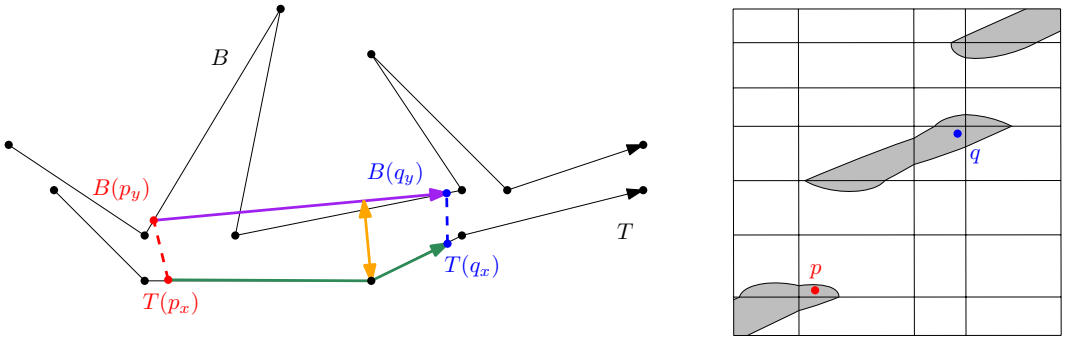

Figure 1 Free space diagram for a base curve B and a target curve T, with the δ-free space in gray. Marked are some grid lines with their corresponding vertex on each curve. The figure also shows a feasible proper tunnel $\tau(p, q)$. The shortcut $\overline{B}[p_y, q_y]$ is shown in purple, and the subcurve $T[p_x, p_y]$ in green. The price of $\tau(p, q)$ is the Fréchet distance of the shortcut and the subcurve.

decisions (within the approximation bounds), we make use of a property of shortcut prices that was first observed by Driemel and Har-Peled [21]. Namely, the price of a shortcut is approximately monotone and it suffices in each round to take the 'shortest' feasible shortcut among all shortcuts that are available. Now, the main challenge as compared to the algorithm in [21] is that this shortcut may still start in the middle of an edge. Thus, we would need to invoke the line-stabbing wedges, but this would be too expensive. Instead, we use a data structure by Driemel and Har-Peled [21] that allows to query the Fréchet distance of a line segment to a subcurve. We combine this with a scheme to simulate an approximation of the output of the line-stabbing wedge with queries to this data structure. In particular, we can approximate the line-stabbing wedge with a convex hull of a set of grid points. However, this is still not enough, as the free-space may have quadratic complexity. To obtain a near-linear running time for small c, we make use of the property of c-packed curves as observed by Driemel, Har-Peled and Wenk [22], that the complexity of the free space diagram of two c-packed curves is only linear in $c \cdot n$ when the curves are appropriately simplified.

2 Preliminaries

Our algorithm uses the free space diagram which was introduced by Alt and Godau [5] for computing the standard Fréchet distance.

▶ **Definition 9** (Free space diagram). *Let T and B be two polygonal curves in $\mathbb{R}^d$. The free space diagram of T and B is the joint parametric space $[0, 1]^2$ together with a not necessarily uniform grid, where each vertical line corresponds to a vertex of T and each horizontal line to a vertex of B (refer to Figure 1). We call the cell of the parametric space corresponding to the ith edge of the target curve and the jth edge of the base curve $C_{i,j}$. The δ-free space of T and B is defined as*

$$\mathcal{D}_\delta(T, B) = \{(x, y) \in [0, 1]^2 \mid \|T(x) - B(y)\| \leq \delta\}$$

This is the set of points in the parametric space whose corresponding points on B and T are at a distance at most δ. Denote by $\mathcal{D}_\delta^{(i,j)}(T, B) = \mathcal{D}_\delta(T, B) \cap C_{i,j}$ the δ-free space inside the cell $C_{i,j}$.

In the following T and B will often be fixed, thus we will simply write $\mathcal{D}_\delta$. It is known that $\mathcal{D}_\delta^{(i,j)}$ is convex and has constant complexity. More precisely, it is an ellipse intersected with the cell $C_{i,j}$. Furthermore the Fréchet distance between two curves is less than or equal

to δ if and only if there exists a monotone path (in x and y) in the free space that starts in the lower left corner $(0,0)$ and ends in the upper right corner $(1,1)$ cf. [5]. In the case of the k-shortcut Fréchet distance we need to also consider shortcuts when traversing the parametric space. When considering any k-shortcut curve B' of B and any traversal (f,g) of B' and T with associated cost δ, then (f,g) induces traversals (f',g') with associated cost at most δ on every shortcut $\overline{B}[s,t]$ and some corresponding subcurve $T[u,v]$ of T. To capture this, we use the notion of *tunnels* which was introduced in [21] and is defined as follows.

▶ **Definition 10** (Tunnel). *A tunnel $\tau(p,q)$ is a pair of points $p=(x_p,y_p)$ and $q=(x_q,y_q)$ in the parametric space of B and T, with $x_p \le x_q$ and $y_p \le y_q$. $\tau(p,q)$ is called feasible if p and q are in $\mathcal{D}_\delta$. We say that a tunnel is proper, if the endpoints of the shortcut do not lie on the same edge of B. We say a tunnel has a price* $\mathrm{prc}(\tau(p,q)) = d_{\mathcal{F}}(T[x_p,x_q],\overline{B}[y_p,y_q])$, *refer to Figure 1.*

▶ **Observation 11.** *Given line segments $\overline{ab}$ and $\overline{cd}$ in $\mathbb{R}^d$, then for the Fréchet distance we have $d_{\mathcal{F}}(\overline{ab},\overline{cd}) = \max(||a-c||, ||b-d||)$.*

▶ **Definition 12** (Reachable space). *We define the (δ,s)-reachable free space of T and B*

$$\mathcal{R}_{\delta,s}(T,B) = \{(x_p,y_p) \in [0,1]^2 \mid d^s_{\mathcal{S}}(T[0,x_p],B[0,y_p]) \le \delta\}$$

and again $\mathcal{R}^{(i,j)}_{\delta,s}(T,B) = \mathcal{R}_{\delta,s}(T,B) \cap C_{i,j}$. We call the intersection $\mathcal{R}^{(i,j)}_{\delta,s}(T,B) \cap C_{a,b}$ for any $(a,b) \in \{(i-1,j),(i,j-1),(i+1,j),(i,j+1)\}$ a reachability interval of the cell $C_{i,j}$. In particular for $(a,b) \in \{(i-1,j),(i,j-1)\}$ we call them incoming reachability intervals and for $(a,b) \in \{(i+1,j),(i,j+1)\}$ we call them outgoing reachability intervals.

Note that the reachability intervals for every cell $C_{i,j}$ and s are contained in $\partial C_{i,j}$, and each reachability interval is described by a (possibly empty) single interval, since any two points in the reachability interval can be connected via a monotone path that stays inside the δ-free space. We will simply write $\mathcal{R}_{\delta,s}$ and $\mathcal{R}^{(i,j)}_{\delta,s}$ whenever T and B are fixed. The k-shortcut Fréchet distance of T and B is at most δ if and only if $(1,1) \in \mathcal{R}_{\delta,k}$.

We want to reduce the problem of deciding the k-shortcut Fréchet distance to the problem of deciding on the existence of a monotone path in the free space diagram with k tunnels starting in $(0,0)$ and ending in $(1,1)$. Note that any tunnel $\tau(p,q)$ with $p=(x_p,y_p)$ and $q=(x_q,y_q)$, that is not proper, induces a traversal of $B[y_p,y_q] = \overline{B}[y_p,y_q]$ and $T[x_p,x_q]$. Thus we can omit the tunnel and replace it with a monotone path from p to q in $\mathcal{D}_\delta$. Therefore, in the following, we only consider monotone paths with proper tunnels.

▶ **Definition 13** (Monotone path with tunnels). *A monotone path with k proper tunnels in the δ-free space of two curves consists of $k+1$ monotone (in x and y) paths in the δ-free space from s_i to t_i for $1 \le i \le k+1$, with $s_1=(0,0)$, such that t_i lies to the left and below s_{i+1}, for $1 \le i \le k$. The k proper tunnels have the form $\tau(t_i,s_{i+1})$ for $1 \le i \le k$.*

▶ **Observation 14.** *Let T and B be two polygonal curves. The set $\mathcal{R}_{\delta,s}(T,B)$ is exactly the set of points $p \in \mathcal{D}_\delta(T,B)$ such that there exists a monotone path ending in p with at most s proper tunnels, each of price at most δ. (By definition, these paths have to start at $(0,0)$).*

To decide whether a cell is reachable by a tunnel, we need to check if there exists a shortcut edge that stabs through an ordered set of disks centered at a subset of the vertices of the other curve. To formalize this, we use the notion of ordered stabbers and line-stabbing wedges as defined by Guibas et al. [23].

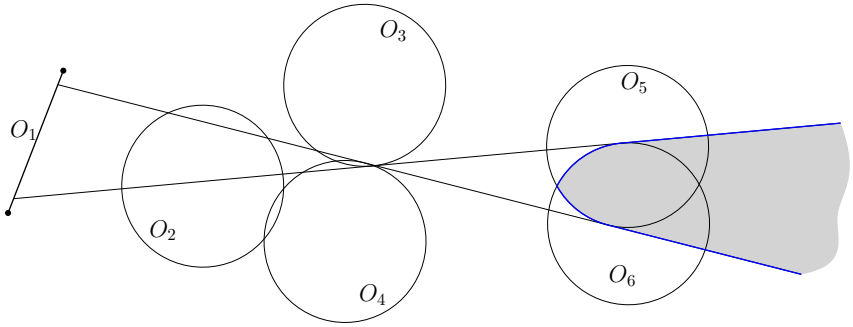

Figure 2 Example for the line-stabbing wedge for a line segment O_1 and disks $O_2, \ldots, O_6$. The line-stabbing wedge is shown in gray, with its boundary in blue.

▶ **Definition 15** (Line-stabbing wedge). *Given a sequence of n convex objects $O_1, \ldots, O_n$, an ordered stabber of this sequence is a line segment $l(x) = (1-x)s + xt$ from s to t, such that points $0 \leq x_1 \leq x_2 \leq \ldots \leq x_n \leq 1$ exist with $p_i = l(x_i) \in O_i$. We call p_i the realising points of l. We say that l stabs through $O_1, \ldots, O_n$. We call the set of points t that are endpoints of ordered stabbers of $O_1, \ldots, O_n$ the line-stabbing wedge of this sequence.*

In their paper, Guibas et al. give an algorithm to compute the line-stabbing wedge for a sequence of n unit disks as well as convex polygons of constant size, with running time $\mathcal{O}(n \log n)$. This line-stabbing wedge is described by $\mathcal{O}(n)$ circular arcs, and two tangents that go to infinity (see Figure 2). These instances can be scaled, such that we can use any sequence of disks $\{\mathrm{b}_\delta(p_1), \ldots, \mathrm{b}_\delta(p_n)\}$, where all disks have the same radius ($\mathrm{b}_\delta(p)$ denotes the closed disk of radius δ centered around p).

▶ **Observation 16.** *Let T, B and δ be given. Denote by v_k the vertices of T. For any feasible tunnel $\tau(p, q)$ with $p = (x_p, y_p) \in C_{a,b}$ and $q = (x_q, y_q) \in C_{i,j}$, it holds that $\overline{B}[y_p, y_q]$ stabs through the ordered set $\{\mathrm{b}_\delta(v_{a+1}), \ldots, \mathrm{b}_\delta(v_i)\}$, if and only if the price of $\tau(p, q)$ is at most δ.*

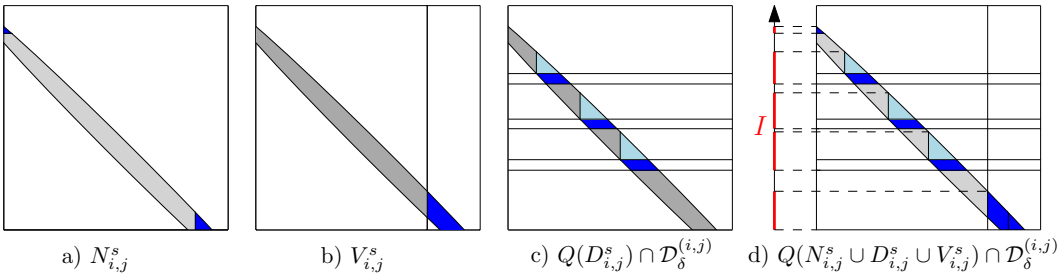
3 Exact decider algorithm

In this section we describe an exact decider algorithm for the k-shortcut Fréchet distance for two polygonal curves. The algorithm can also be used to solve the decision problem of the (unparameterized) shortcut Fréchet distance by setting $k = n$. We first describe the algorithm and then analyse its correctness and running time in Section 3.2. The full correctness proof can be found in [19].

3.1 The Algorithm

We are given a parameter k, a value δ and the two polygonal curves T and B in the plane. Our algorithm iterates over the δ-free space diagram of T and B in k rounds. In each round, based on the computation of the previous round, we compute the set of points that are reachable by using one additional shortcut. The goal is to compute the (δ, s)-reachable space $\mathcal{R}_{\delta,s}(T, B)$ in round s. In each round, we handle the cells of the free space diagram in a row-by-row order, and within each row from left to right. For every cell $C_{i,j}$ we consider three possible ways that a monotone path with proper tunnels can enter.

1. The monotone path could enter the cell $C_{i,j}$ from the neighboring cell $C_{i-1,j}$ to the left or from the neighboring cell $C_{i,j-1}$ below. This does not directly involve a tunnel.



a) $N^s_{i,j}$ b) $V^s_{i,j}$ c) $Q(D^s_{i,j}) \cap \mathcal{D}^{(i,j)}_\delta$ d) $Q(N^s_{i,j} \cup D^s_{i,j} \cup V^s_{i,j}) \cap \mathcal{D}^{(i,j)}_\delta$

Figure 3 Example of the composition of the reachable space within a single free-space cell. The lightblue sets in *c*) (resp. *d*)) contain all the points reachable via monotone paths inside the cell reachable from $D^s_{i,j}$ (resp. $N^s_{i,j} \cup D^s_{i,j} \cup V^s_{i,j}$) computed via $Q(\cdot) \cap \mathcal{D}^{(i,j)}_\delta$. The fragmentation of the reachable space in this cell $P^s_{i,j} = Q(N^s_{i,j} \cup D^s_{i,j} \cup V^s_{i,j}) \cap \mathcal{D}^{(i,j)}_\delta$ results in a large family of intervals I on the edge of B.

2. The monotone path could reach $C_{i,j}$ with a proper tunnel. We distinguish between vertical and diagonal tunnels (compare [16, 21] for a similar distinction).
   - **(i)** The tunnel may start in any cell $C_{a,b}$ with $a < i$ and $b < j$. We call this a diagonal tunnel.
   - **(ii)** The tunnel may start in any cell $C_{i,b}$ for $b < j$. We call this a vertical tunnel.

Using this distinction, we will describe how to compute the set of points reachable by a monotone path with s proper tunnels, for each cell of the diagram. We denote the set computed by the algorithm for cell $C_{i,j}$ in round s with $P^s_{i,j}$. The (δ, s)-reachable space is then obtained by taking the union of these sets over all rounds $\mathcal{R}^{(i,j)}_{\delta,s} = \bigcup_{0 \le s' \le s} P^{s'}_{i,j}$.

After k rounds, the algorithm tests whether the point $(1, 1)$ is contained in our computed set of reachable points. If this is the case, then the algorithm returns "$d^k_{\mathcal{S}}(T, B) \le \delta$", otherwise the algorithm returns "$d^k_{\mathcal{S}}(T, B) > \delta$".

Propagating reachability within a cell. To simplify the description of the algorithm, we use the following set function which receives a set $P \subseteq C_{i,j}$ for some cell $C_{i,j}$ and which extends P to all points above and to the right of it.

$$Q(P) = \{(x, y) \in [0, 1]^2 \mid \exists (a, b) \in P \text{ such that } a \le x \text{ and } b \le y\}$$

We will usually intersect this set with $\mathcal{D}^{(i,j)}_\delta$ to obtain all points that are reachable from a point of P by a monotone path that stays inside the δ-free space of this cell. Figure 3 c) shows an example of the resulting set. Note that the boundary of the resulting set can be described by pieces of the boundary of $\mathcal{D}^{(i,j)}_\delta$, pieces of the boundary of P, and horizontal and vertical line segments.

Step 1: Neighbouring cells. Since we traverse the cells of the diagram in a lexicographical order, we have already computed the (possibly empty) sets $P^s_{i-1,j}$ and $P^s_{i,j-1}$, by the time we handle cell $C_{i,j}$ in round s. Therefore, we can compute the incoming reachability intervals by intersecting $P^s_{i-1,j}$ and $P^s_{i,j-1}$ with $C_{i,j}$. Now we apply the function Q to these sets and denote the result with $N^s_{i,j}$ (refer to Figure 3 a):

$$N^s_{i,j} = \big(Q(P^s_{i-1,j} \cap C_{i,j}) \cup Q(P^s_{i,j-1} \cap C_{i,j})\big) \cap \mathcal{D}^{(i,j)}_\delta$$

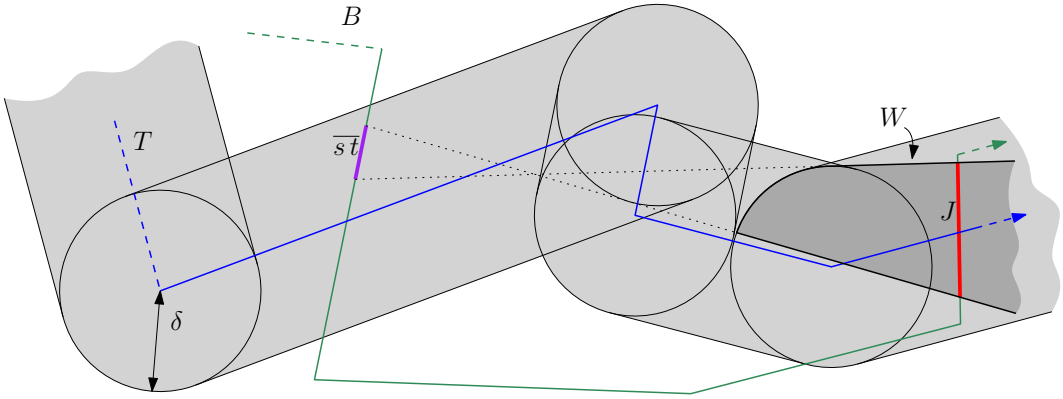


Figure 4 Example of the set J (in red) computed by the DIAGONALTUNNEL procedure.

Step 2 (i): Diagonal tunnels. We invoke the following procedure for every $a < i$ and $b < j$ with $P^{s-1}_{a,b}$. We denote the union of resulting sets of points in $\mathcal{D}^{(i,j)}_\delta$ computed in this step with $D^s_{i,j}$.

The procedure is given a set of points $P^{s-1}_{a,b}$ in the δ-free space $\mathcal{D}^{(a,b)}_\delta$ and computes all points in $\mathcal{D}^{(i,j)}_\delta$ that are endpoints of tunnels starting in $P^{s-1}_{a,b}$ with price at most δ. The procedure first projects $P^{s-1}_{a,b}$ onto the edge e_b of the base curve. The resulting set consists of disjoint line segments $I = \{\overline{s_1\,t_1}, \ldots\}$ along e_b (refer to Figure 3 d)). The procedure then computes the line-stabbing wedge W through $\overline{s_1\,t_1}$ and disks $\mathrm{b}_\delta(v_{a+1}), \ldots, \mathrm{b}_\delta(v_i)$ centered at vertices of T. W is then intersected with the edge e_j, resulting in a set J on e_j corresponding to a horizontal slab in $C_{i,j}$ (compare Figure 3 c) and Figure 4). This resulting set is then intersected with $\mathcal{D}^{(i,j)}_\delta$ to obtain all endpoints of feasible shortcuts with price at most δ starting in $\overline{s_1\,t_1}$. The procedure performs the above steps for every line segment $\overline{s\,t} \in I$ and returns the union of these sets. The resulting set may look as illustrated in Figure 3 c).

Step 2 (ii): Vertical tunnels. Let p denote a point in $\bigcup_{l \le j-1} P^{s-1}_{i,l}$ with minimal x-coordinate, i.e., a leftmost point in this set. A feasible vertical tunnel always has price at most δ, as the Fréchet distance of two line segments is bounded by the maximal euclidean distance of the start points or end points. Therefore, we simply take all points in the δ-free space to the right of p in the cell $C_{i,j}$. To do this, we compute the intersection of a halfplane that lies to the right of the vertical line at p with the δ-free space in $C_{i,j}$. We denote this set with $V^s_{i,j}$. Refer to Figure 3 b) for an example.

Putting things together. Finally, we compute the set $P^s_{i,j}$ by taking the union of the computed sets and extending this set by using the function Q defined above:

$$P^s_{i,j} = Q(N^s_{i,j} \cup D^s_{i,j} \cup V^s_{i,j}) \cap \mathcal{D}^{(i,j)}_\delta$$

It remains to specify the initialization: We define $P^0_{1,0} = P^0_{0,1} = \{(0,0)\}$, if $(0,0) \in \mathcal{D}_\delta$, and otherwise $P^0_{1,0} = P^0_{0,1} = \emptyset$. In addition we define $P^{-1}_{i,j} = \emptyset$ for all i, j.

3.2 Analysis

We argue that the structure of $P^s_{i,j}$ as computed by the algorithm is indeed as claimed. Namely for all i, j and s it holds that $\mathcal{R}^{(i,j)}_{\delta,s} = \bigcup_{0 \le s' \le s} P^{s'}_{i,j}$. The main argument of the proof consists of considering any monotone path with s proper tunnels ending in some cell.

Correctness then follows via induction over the lexicographical ordering of the cells in each round, and by induction over all rounds. The full proof of correctness can be found in [19]. Here, we provide an analysis of the running time of the algorithm.

▶ **Lemma 17.** *Let T and B be two polygonal curves in the plane with overall complexity n, together with a distance threshold $\delta > 0$. The algorithm described in Section 3.1 has running time in $\mathcal{O}(kn^{2k+2} \log n)$ and uses $\mathcal{O}(kn^{2k+2})$ space.*

Proof. Note that the sets $N^s_{i,j}$, $D^s_{i,j}$ and $V^s_{i,j}$ computed by the algorithm are described as intersections of $\mathcal{D}^{(i,j)}_\delta$ with halfplanes and horizontal slabs, and unions of these. For a fixed $P^s_{i,j}$ we define $n_{i,j,s}$ as the total number of such operations from which $P^s_{i,j}$ was obtained. As such, $\mathcal{O}(n_{i,j,s})$ bounds the complexity of this set.

The complexity of $N^s_{i,j}$ and $V^s_{i,j}$ is constant. The complexity of $D^s_{i,j}$ is bounded by the sum of the complexities of all cells to the lower left:

$$n_{i,j,s} \in \mathcal{O}\left(\sum_{0 \le a < i} \sum_{0 \le b < j} n_{a,b,s-1}\right).$$

As $i, j \le n$, and $s \le k$, and $n_{a,b,0} \in \mathcal{O}(1)$ for all a and b, it holds that $n_{i,j,s} \in \mathcal{O}(n^{2k})$.

Computing $D^s_{i,j}$ takes $\mathcal{O}(\sum_{a<i} \sum_{b<j} n_{a,b,s-1} \log n + n^2 \log n) = \mathcal{O}(n^{2k} \log n)$ time. This follows from the fact, that we compute $\mathcal{O}(n)$ line-stabbing wedges, and for every cell $C_{a,b}$ with $a < i$ and $b < j$ we handle $n_{a,b,s-1}$ line segments based on $P^{s-1}_{a,b}$. Computing $N^s_{i,j}$ takes $\mathcal{O}(n_{i-1,j,s} + n_{i,j-1,s}) = \mathcal{O}(n^{2k})$ time, as we need to compute the reachability intervals from neighbouring cells. Computing $V^s_{i,j}$ takes $\mathcal{O}(\sum_{b<j} n_{i,b,s-1}) = \mathcal{O}(n^{2k-1})$ time, as we need to compute the leftmost point $l^{s-1}_{i,j-1}$. The space required to store $P^s_{i,j}$ as required by latter iterations and cells is in $\mathcal{O}(n^{2k})$. Computing $Q(N^s_{i,j} \cup V^s_{i,j} \cup D^s_{i,j})$ takes linear time in the complexity of $N^s_{i,j} \cup V^s_{i,j} \cup D^s_{i,j}$, i.e. $\mathcal{O}(n^{2k})$. As we do this for every cell in every round, the running time overall is $\mathcal{O}(kn^{2k+2} \log n)$, and the space is bounded by $\mathcal{O}(kn^{2k+2})$. ◀

Lemma 17 together with the claimed correctness then imply Theorem 5. The algorithm can also be used for the (unparameterized) shortcut Fréchet distance by choosing $k = n$, since there can be at most n proper tunnels. We obtain the following corollary.

▶ **Corollary 18.** *Let T and B be polygonal curves in the plane with overall complexity n and let $\delta > 0$. There exists an algorithm with running time in $\mathcal{O}\big(n^{2n+3} \log n\big)$ and space in $\mathcal{O}\big(n^{2n+3}\big)$ that decides whether the shortcut Fréchet distance of T and B is at most δ.*

4 Approximate decision algorithm

In this section we describe a $(3+\varepsilon)$-approximation algorithm for the decision problem of the k-shortcut Fréchet distance of two polygonal curves in the plane. The algorithm has running time near-linear in n for c-packed curves. For general curves the running time is still polynomial in n and linear in k.

4.1 The modified algorithm

We describe how to modify the algorithm of Section 3 to circumvent the exponential complexity of the reachable space and obtain a polynomial-time approximation algorithm.

Let two polygonal curves T and B be given, together with a distance threshhold δ and approximation parameter ε. As before, the algorithm iterates over the cells of the free-space diagram and computes sets $N^s_{i,j}$, $V^s_{i,j}$, and $D^s_{i,j}$ for each cell $C_{i,j}$. The main difference is

now that, instead of computing the exact set of points that can be reached by a diagonal tunnel, we want to use an approximation for this set. For this, we define an approximate diagonal tunnel procedure, see further below. This procedure is called with the rightmost point $r^{s-1}_{i-1,j-1}$ in $\bigcup_{a<i;b<j} P^{s-1}_{a,b}$, ε and $\delta' = 3\delta$. Crucially, the set resulting from one call to the procedure has constant complexity and is sufficient to approximate the set $D^s_{i,j}$. We then compute $P^s_{i,j} = Q(N^s_{i,j} \cup D^s_{i,j} \cup V^s_{i,j}) \cap \mathcal{D}^{(i,j)}_\delta$, similarly to Section 3. From this we compute (i) the leftmost point $l^s_{i,j}$ in $\bigcup_{b\leq j} P^s_{i,b}$ based on $P^s_{i,j}$ and $l^s_{i,j-1}$, (ii) the rightmost point $r^s_{i,j}$ in $\bigcup_{a\leq i;b\leq j} P^s_{a,b}$ based on $P^s_{i,j}$, $r^s_{i-1,j}$ and $r^s_{i,j-1}$, and (iii) the outgoing reachability intervals of $P^s_{i,j}$. We store these variables to be used in the next round. Finally, after k rounds, we check if $(1,1)$ is contained in the computed set of reachable points.

Our approximate diagonal tunnel procedure makes use of a data structure by Driemel and Har-Peled, which is summarized in the following lemma. This data structure needs to be built once on T in the beginning and is then available throughout the algorithm.

▶ **Lemma 19** (distance oracle [21]). *Given a polygonal curve Z with n vertices in $\mathbb{R}^d$ and $\varepsilon > 0$, one can build a data structure $\mathcal{F}_\varepsilon$ in $\mathcal{O}\big(\chi^2 n \log^2 n\big)$ time, that uses $\mathcal{O}\big(n\chi^2\big)$ space such that given a query segment $\overline{p\,q}$ and any two points u and v on the curve, one can $(1+\varepsilon)$-approximate $d_{\mathcal{F}}(\overline{p\,q}, Z[u,v])$ in $\mathcal{O}\big(\varepsilon^{-2}\log n \log\log n\big)$ time, where $\chi = \varepsilon^{-d}\log\big(\varepsilon^{-1}\big)$.*

▶ **Definition 20** (Grid). *We define the scaled integer grid $\mathbb{G}_\delta = \big\{(\delta x, \delta y) \mid (x,y) \in \mathbb{Z}^2\big\}$.*

Approximate diagonal tunnel procedure. The procedure is described by Algorithm 1. The procedure is provided with parameters ε, δ, some $r' = (r_T, r_B)$ in cell $C_{a,b}$ and the edge e_j that is associated with a cell $C_{i,j}$. We want to compute a set of stabbers starting at $r = B(r_B)$ that contains every stabber through the disks $\mathrm{b}_\delta(v_{a+1}), \ldots, \mathrm{b}_\delta(v_i)$, and is contained in the set of all stabbers through disks of radius $(1+\varepsilon)^2\delta$ centered at the same vertices. We approximate this set of stabbers as follows.

We iterate over all grid points t of $\mathbb{G}_{\frac{\delta\varepsilon}{\sqrt{2}}}$ inside the disk $\mathrm{b}_{(1+\varepsilon)\delta}(v_i)$, and make queries to $\mathcal{F}_\varepsilon$ to determine if the Fréchet distance of the query segment $\overline{r\,t}$ to the subcurve of T from $T(r_T)$ to v_i is sufficiently small. We mark t if the approximate distance returned by the data structure is at most $(1+\varepsilon)^2\delta$. We then compute the convex hull H of all marked grid points, and the two tangents t_1 and t_2 of H through $B(r_B)$. The true set of endpoints of stabbers is approximated by the set H' of points that lie inside and 'behind' the convex hull H, from the perspective of r. Figure 5 illustrates this. We then intersect H' with the edge e_j resulting in a single horizontal slab in $C_{i,j}$, which is then intersected with $\mathcal{D}^{(i,j)}_\delta$ and returned.

4.2 Correctness of the approximate diagonal tunnel procedure

We denote with $\{\mathrm{b}_\delta(v_i)\}_i$ a sequence of disks $\{\mathrm{b}_\delta(v_1), \ldots, \mathrm{b}_\delta(v_m)\}$ for some m.

▶ **Lemma 21.** *Let $a, b_1, b_2 \in \mathbb{R}^d$ together with a sequence of vertices $v_1, \ldots, v_n$ be given. If $\overline{a\,b_1}$ stabs through disks $\{\mathrm{b}_\delta(v_i)\}_i$, and $\overline{a\,b_2}$ stabs through $\{\mathrm{b}_\delta(v_i)\}_i$, then for any $t \in [0,1]$ the line segment $\overline{a\,b(t)}$ stabs through $\{\mathrm{b}_\delta(v_i)\}_i$, where $b(t) = (1-t)b_1 + tb_2$.*

Proof. Refer to Figure 6. We can interpret the setting as a triangle with sides $(b_1 - a)$, $(b_2 - a)$, $(b_1 - b_2)$, where the first two sides correspond to the original stabbers and the last side to $b(t)$. Note that any line segment $\overline{a\,b(t)}$ lies completely within this triangle with $(b_1 - a)$ on the one and $(b_2 - a)$ on the other side. Hence, for every i and realising points p_i of $\overline{a\,b_1}$ and q_i of $\overline{a\,b_2}$, p_i lies on the one and q_i on the other side of $\overline{a\,b(t)}$. Since $\mathrm{b}_\delta(v_i)$ is convex and p_i and q_i are inside this disk, the intersection of $\overline{p_i\,q_i}$ and $\overline{a\,b(t)}$ is inside the disk

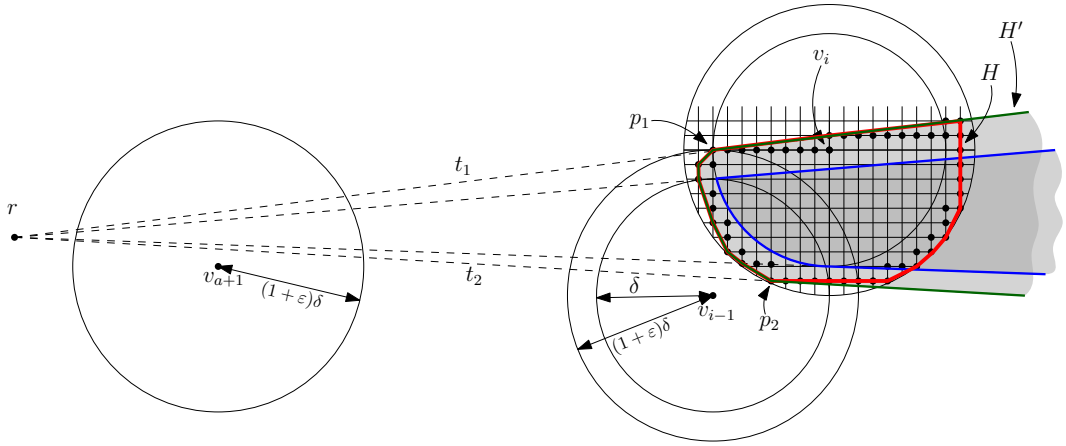

Figure 5 Illustration to the approximate diagonal tunnel procedure. The true line-stabbing wedge for disks with radius δ is shown in blue. The convex hull of eligible grid points is shown in red. The approximate line stabbing wedge is shown in green.

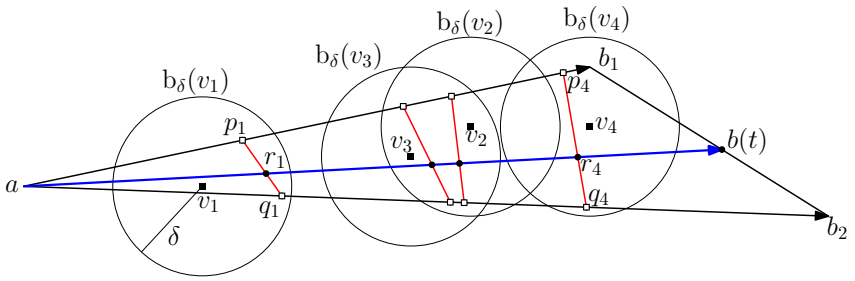

Figure 6 Linear interpolation between two δ-stabbers starting in a. Illustrations to the proof of Lemma 21. In blue $\overline{a\,b(t)}$, and in red $\overline{p_i\,q_i}$ is illustrated. Their intersections form the realising points r_i of $\overline{a\,b(t)}$.

as well. Call this intersection point r_i. The set $\{r_i\}_i$ are realising points for $\overline{a\,b(t)}$. This follows directly from the fact that $\{p_i\}_i$ and $\{q_i\}_i$ are ordered along their respective line segments, and thus $\overline{p_i\,q_i}$ never crosses another $\overline{p_j\,q_j}$. Thus for $i < j$, r_i appears before r_j along $\overline{a\,b(t)}$, implying the claim. ◀

▶ **Lemma 22.** *Let $a_1, a_2, b_1, b_2 \in \mathbb{R}^2$ together with a sequence of vertices $v_1, \ldots, v_n$ be given. If $\overline{a_1\,b_1}$ stabs through $\{\mathrm{b}_\delta(v_i)\}_i$, and $\|a_1 - b_1\| \leq \delta'$ and $\|a_2 - b_2\| \leq \delta'$, then $\overline{a_1\,b_1}$ stabs through $\{\mathrm{b}_{\delta+\delta'}(v_i)\}_i$.*

Proof. By Observation 11, $d_{\mathcal{F}}(\overline{a_1\,b_1}, \overline{a_2\,b_2}) \leq \delta'$, via the reparametrizaion (f, g) with $f(t) = (1-t)a_1 + ta_2$ and similarly $g(t) = (1-t)b_1 + tb_2$. As $p = \overline{a_1\,b_1}$ stabs through $\{\mathrm{b}_\delta(v_i)\}_i$, there exist realising points p_i along p, with p_i lying in the δ-disk centered at v_i. Then

$$\|g(f^{-1}(v_i)) - v_i\| \leq \|g(f^{-1}(v_i)) - p_i\| + \|p_i - v_i\| \leq \delta' + \delta.$$

Additionally, $q_i = g(f^{-1}(v_i))$ are ordered along $q = \overline{a_2\,b_2}$, proving the claim. ◀

▶ **Lemma 23.** *Given $r' = (r_T, r_B) \in C_{a,b}$, and edge e of B corresponding to the cell $C_{i,j}$, ε and δ like in the approximate diagonal tunnel procedure. Denote by S_δ the set of endpoints of all δ-stabbers (that is, stabbers through $\mathrm{b}_\delta(v_m)$ for $a+1 \leq m \leq i$) on the edge e_j starting at $r = B(r_B)$ and let C' be the point set computed by the algorithm. Then*

$$S_\delta \subseteq C' \subseteq S_{(1+\varepsilon)^2\delta}.$$

Algorithm 1 Approximate Diagonal Tunnel.

procedure apxDiagonalTunnel((r_T, r_B), (i, j), ε, δ)
  Let $r = B(r_B)$
  //r is the starting point of the shortcut
  for $t \in \left(\mathbb{G}_{\frac{\delta\varepsilon}{\sqrt{2}}} \cap \mathrm{b}_{3(1+\varepsilon)\delta}(v_i)\right)$ **do**
    Query $\mathcal{F}_\varepsilon$ for the distance $d_{\mathcal{F}_\varepsilon}(\overline{r\,t}, T[r_T, v_i])$ and store the answer in δ'
    if $\delta' \leq (1+\varepsilon)^2\delta$ **then**
      Mark t as eligible
      //t is an eligible endpoint of a shortcut
  Compute the convex hull H of eligible points
  if $r \in H$ **then**
    Return $C = \mathcal{D}_\delta^{(i,j)}$
  else
    Let U be the cone with apex r formed by tangents t_1 and t_2 from r to H
    Let $p_i \in H$ be a supporting point of the tangent t_i for $i \in \{1, 2\}$
    Let L be the subchain of ∂H with endpoints p_1 and p_2 which is facing r
    Let $H' \subset U$ be the set bounded by L and the rays supported by t_1 and t_2 facing away from r
    Let C' be the intersection of H' with e_j
    Return $C = (e_i \times C') \cap \mathcal{D}_\delta^{(i,j)}$

Proof. Let $y \in C'$. Then $q = B(y) \in H'$ where H' is set of points computed by the algorithm. Denote the intersection of $\overline{r\,q}$ and the boundary of H' by h. h is then a linear combination of at most two grid points whose stabbers from r have been marked as eligible i.e. who are $(1+\varepsilon)^2\delta$-stabber. Hence, Lemma 21 implies that $\overline{r\,q}$ is also a $(1+\varepsilon)^2\delta$-stabber, implying $C' \subseteq S_{(1+\varepsilon)^2\delta}$. Now let $q \in e$ be an arbitrary point such that $\overline{r\,q}$ is a δ-stabber. Let t be the last realising point of $\overline{r\,q}$. The line segment $\overline{r\,t}$ is a δ-stabber and t lies in $\mathrm{b}_\delta(v_i)$. We claim that t lies in H. Consider the set $G = \mathbb{G}_{\frac{\delta\varepsilon}{\sqrt{2}}} \cap \mathrm{b}_{\varepsilon\delta}(t)$. By the scale of the grid, t lies within the convex hull of G. Moreover $G \subset \mathrm{b}_{(1+\varepsilon)\delta}(v_i)$. Lemma 22 implies that $\overline{r\,t'}$ is a $((1+\varepsilon)\delta)$-stabber for any $t' \in G$. This in turn implies that for the first point s' of $\overline{r\,t'}$ inside $\mathrm{b}_{\delta(1+\varepsilon)}(v_a)$, $\overline{s'\,t'}$ is a $((1+\varepsilon)\delta)$-stabber, hence, t' would have been marked as an eligible endpoint of a $((1+\varepsilon)^2\delta)$-stabber. Since H is the convex hull of eligible points, it follows that $t \in \mathrm{conv}(G) \subset H$. Therefore $q \in H'$ and thus $q \in C'$. ◀

4.3 Result

We argue that the structure of $P_{i,j}^s$ as approximated by the algorithm is indeed as claimed. Namely for all i, j and s it holds that $\mathcal{R}_{\delta,s}^{(i,j)} \subset \bigcup_{0 \leq s' \leq s} P_{i,j}^{s'} \subset \mathcal{R}_{3(1+\varepsilon)^2\delta,s}^{(i,j)}$. The full proof can be found in [19]. We again consider any monotone path with s proper tunnels ending in some cell and show the set inclusion by induction. Indeed, it suffices to consider the tunnel starting in the rightmost reachable point in the lower left quadrant of the cell, if we call the approximate diagonal tunnel procedure with a distance threshold $\delta' = 3\delta$. This is implied by a lemma by Driemel and Har-Peled concerning the structure of prices of tunnels. The lemma states that if a feasible tunnel $\tau(r, q)$ costs more than 3δ then any feasible tunnel $\tau(p, q)$ with $x_p \leq x_r$ costs more than δ.

▶ **Lemma 24** (monotonicity of tunnels [21]). *Given a value $\delta > 0$ and two curves T_1 and T_2 such that T_2 is a subcurve of T_1, and given two line segments $\bar{B}_1$ and $\bar{B}_2$ such that $d_{\mathcal{F}}(T_1, \bar{B}_1) \leq \delta$ and the start (resp. end) point of T_2 is within distance δ to the start (resp. end) point of $\bar{B}_2$, then $d_{\mathcal{F}}(T_2, \bar{B}_2) \leq 3\delta$.*

The proof of the following theorem is very similar to the proof of Theorem 5. We invoke the algorithm of Section 4.1 with approximation parameter $\varepsilon' = \varepsilon/9$ and distance threshold δ, as $3(1+\varepsilon')^2 \leq (3+\varepsilon)\delta$. The main difference is the approximation of the set of points reachable by a diagonal tunnel.

▶ **Theorem 25.** *Let T and B be two polygonal curves in the plane with overall complexity n, together with values $0 < \varepsilon \leq 1$ and $\delta > 0$. There exists an algorithm with running time in $\mathcal{O}\big(kn^2\varepsilon^{-5}\log^2\big(n\varepsilon^{-1}\big)\big)$ and space in $\mathcal{O}\big(kn^2\varepsilon^{-4}\log^2\big(\varepsilon^{-1}\big)\big)$ which outputs one of the following: (i) $d_{\mathcal{S}}^k(T,B) \leq (3+\varepsilon)\delta$ or (ii) $d_{\mathcal{S}}^k(T,B) > \delta$. In any case, the output is correct.*

The running time of this algorithm can be improved even more for the special class of c-packed curves. For this, we use a known approximation scheme (see [22, 21, 7]) that uses μ-simplifications, which are a kind of approximation of the input curves. Crucially, the free-space diagram of two μ-simplifications of c-packed curves consists of only $\mathcal{O}(cn\varepsilon^{-1})$ many non-empty cells, if μ is chosen in the right way. These non-empty cells can be found using standard techniques in an output-sensitive manner.

Concretely, our algorithm first computes μ-simplifications of T and B, with $\mu = \varepsilon''\delta''$ where $\varepsilon'' = \varepsilon/20$ and $\delta'' = (1-2\varepsilon'')$, and then invokes the algorithm of Section 4.1 on the simplifications with distance threshold δ'' and approximation parameter ε''. From this, we obtain the following theorem. The detailed analysis can be found in [19].

▶ **Theorem 8.** *Let T and B be two c-packed polygonal curves in the plane with overall complexity n, together with values $0 < \varepsilon \leq 1$ and $\delta > 0$. There exists an algorithm with running time in $\mathcal{O}\big(kcn\varepsilon^{-5}\log^2\big(n\varepsilon^{-1}\big)\big)$ and space in $\mathcal{O}\big(kcn\varepsilon^{-4}\log^2\big(\varepsilon^{-1}\big)\big)$ which outputs one of the following: (i) $d_{\mathcal{S}}^k(T,B) \leq (3+\varepsilon)\delta$ or (ii) $d_{\mathcal{S}}^k(T,B) > \delta$. In any case, the output is correct.*

5 Hardness

We prove that the decision problem cannot be solved in $n^{o(k)}$ time, unless ETH fails. The full description can be found in [19]. We describe how to modify the NP-hardness reduction by Buchin, Driemel and Speckmann from [16] to suit our needs.

5.1 General idea

Our reduction from ETH works via the following intermediate problem. This link is facilitated by Pătraşcu and Williams [26].

▶ **Definition 26** (k-Table-SUM). *We are given k lists $S_1, \ldots, S_k$ of n non-negative integers $\{s_{i,1}, \ldots, s_{i,n}\}$ and a non-negative integer σ. We want to decide whether there are indices $\iota_1, \ldots, \iota_k$ such that $\sum_{i=1}^k s_{i,\iota_i} = \sigma$. We call $\sigma_j = \sum_{i=1}^j s_{i,\iota_i}$ the jth partial sum.*

Based on a k-Table-SUM instance we describe how to construct a $(4k+2)$-shortcut Fréchet distance instance consisting of the target curve T and the base curve B with the property, that they have a distance of 1 if and only if the underlying instance has a solution.

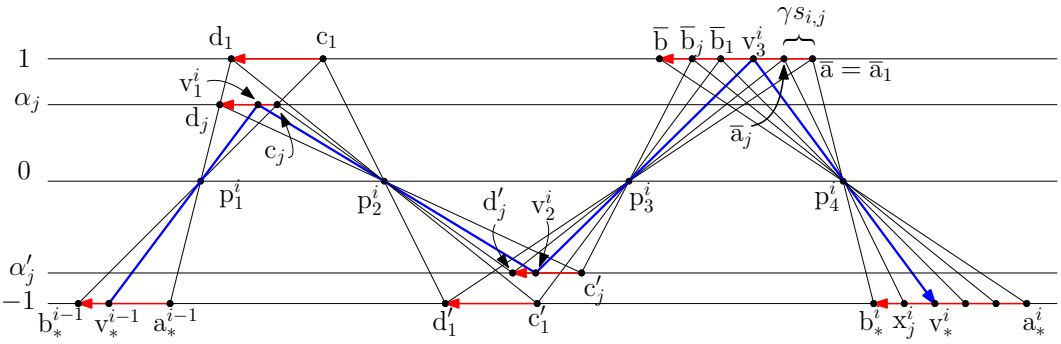

Figure 7 Schematic view of the path of a shortcut curve (in blue) through the gadget g_i in the case, where $s_{i,j}$ is selected from the ith list. Most top indices i are omitted. Furthermore, for presentation the mirror edges have horizontal overlap, while in the construction they do not.

The target curve T will lie on a horizontal line mostly going to the right. The only exceptions being so called *twists*. Twists force shortcuts traversing it to go through precisely one point, called its *focal point*. These twists are constructed by going a distance of 2 to the left, before continuing rightwards. Refer to Figure 8, points $p_1, \cdots, p_4$ and Figure 7, points $p_1^i, \cdots, p_4^i$.

The set of points in $\mathbb{R}^2$ which have a distance of at most 1 to the target curve we will call the *hippodrome*. The base curve will consist of several horizontal edges going to the left close to the boundary of the hippodrome. All other edges of the base curve will (essentially) lie outside the hippodrome. Exceptions have to be considered carefully. Any shortcut curve of B that has Fréchet distance of at most 1 to T we will call *feasible*. It is easy to see that any feasible shortcut curve must lie completely in the hippodrome. Since any edge of the base curve inside the hippodrome lies close to the boundary of it and is oriented in the opposite direction of the base curve, no feasible shortcut curve contains a large subcurve of the base curve. We will not place any edges of the base curve too close to twists, so that a shortcut must be taken to traverse these.

Intuitively we can think of the horizontal edges of the base curve as mirrors that disperse incoming light in all directions and focal points as a wall with a hole, like in a pinhole camera. A shortcut curve can be thought of as the path of a photon that tries to traverse this instance. It bounces from mirror to mirror, always passing through a focal point. A feasible shortcut curve exists if and only if it is possible to send a photon from the beginning of the base curve to the very end.

The instance as a whole can be segmented into gadgets, with a special gadget at the start and end, used to initialize and verify the solution (c.f. [16]). In between these, k gadgets will be placed, encoding one of the lists each from the k-Table-SUM instance.

5.2 Construction of the gadgets

In this section, we describe three gadgets: the encoding gadget g_i, the initialization gadget g_0 and the terminal gadget g_{k+1}. The base curve and the target curve pieces of these gadgets are then connected in the order of i. The encoding gadget is the heart-piece of our construction and constitutes the main difference to the NP-hardness reduction presented in [16].

Encoding gadget. The overall structure of a gadget g_i for some $1 \leq i \leq k$ is depicted in Figure 8. This gadget will encode the ith table $S_i = \{s_{i,1}, \ldots, s_{i,n}\}$ of the k-Table-SUM instance. As for the parameters, λ^i is the length of the entry edge, determined by the

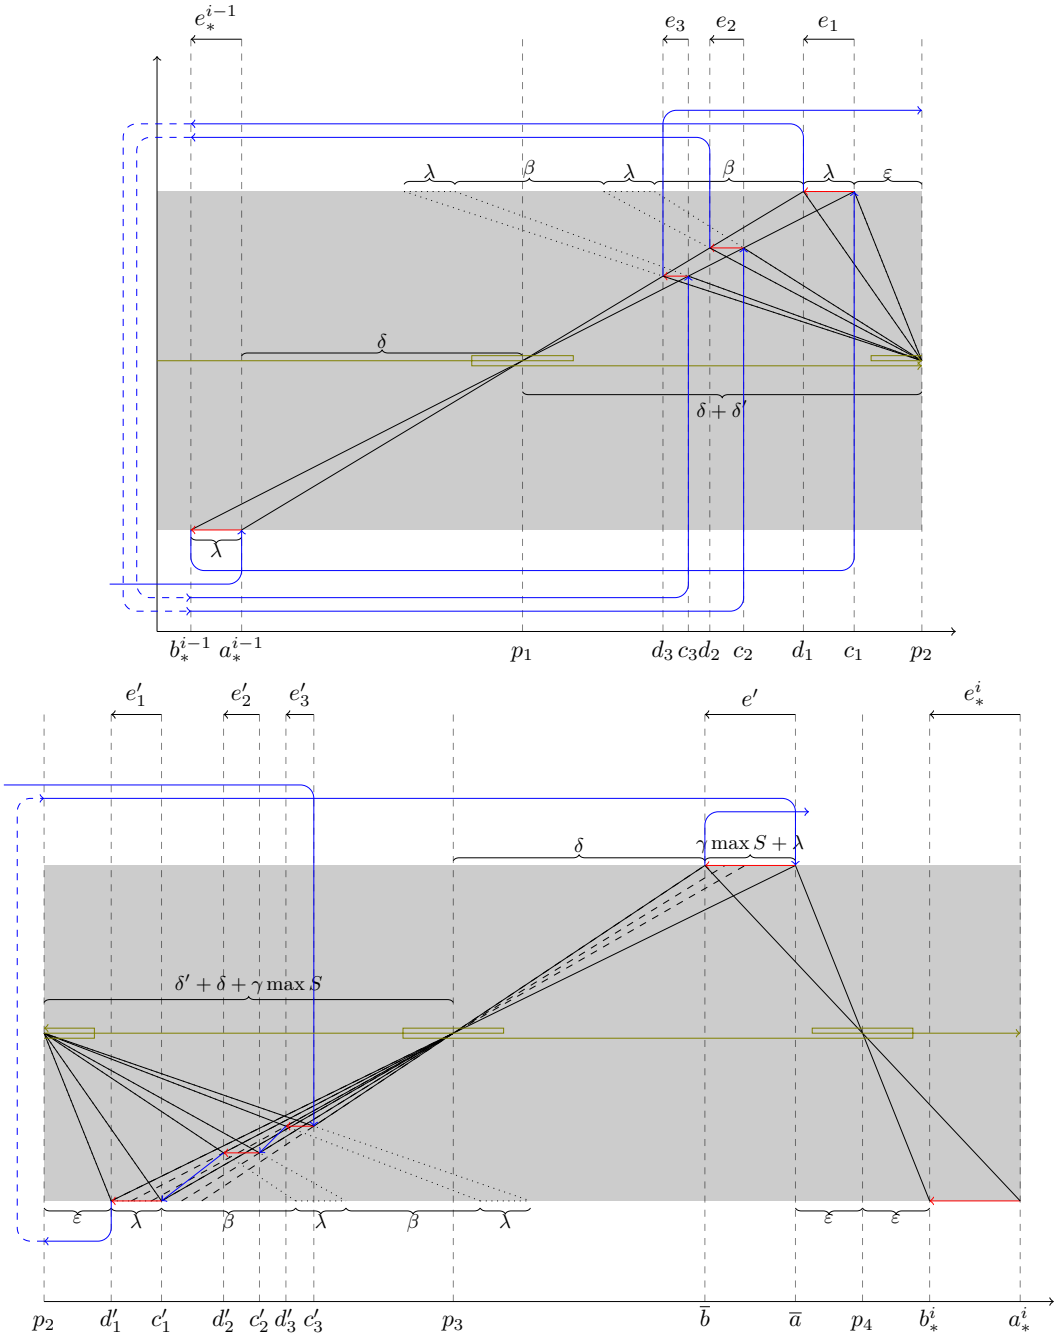

Figure 8 Detailed view of the construction of the encoding gadget. Mirror edges are red, connector edges blue and the target curve is green. Projection cones are black.

previous gadget g_{i-1}, and β is a global spacing parameter. The parameters δ^i and δ'^i are auxiliary parameters, with $\delta'^i = \lambda^i + \varepsilon$ and $\delta^i = \max(2\varepsilon + 1, (n-1)(\lambda^i + \beta) - \delta'^i)$ where ε is a globally fixed spacing parameter for twists. Excluding the entry edge of the base curve, B consists of $2n+2$ mirror edges and $\mathcal{O}(n)$ connector edges. For $1 \leq j \leq n$ the first n mirror edges e^i_j are defined by c^i_j and d^i_j, and the second n mirror edges e'^i_j are defined by c'^i_j and d'^i_j. The last two mirror edges are defined by $\bar{\mathrm{a}}^i$ and $\bar{\mathrm{b}}^i$, and a^i_* and b^i_*. The target curve T has four twists centred at $\mathrm{p}^i_1, \ldots, \mathrm{p}^i_4$. Since the index i will not change other than for the entry and exit edge, we will omit these indices in the construction of this gadget.

Intuition. The intuition behind the construction is as follows: We place the first projection point p_1 at a distance from the entry edge, such that n 'well-spaced' scaled copies of the entry edge fit 'behind' the projection point. These edges offer the choice, each edge corresponding to a single element in the table S_i. After this choice has been presented, we place another n copies of the entry edge behind the second projection point p_2. The two sets of copies correspond one-to-one, and any line starting at one copy going through p_2 only ever hits a single copy of the second set. The second set of copies is placed in such a way, such that passing through the third projection point p_3, any feasible shortcut curve receives an additional offset of $\gamma s_{i,j}$ on the edge e' corresponding to the choice of edge e_j. Lastly we define the entry edge to the next gadget.

How a solution is encoded. A shortcut curve traversing this gadget will look as follows. A shortcut curve reaches some point on the entry edge e^{i-1}_*. From here it takes a shortcut to some e^i_j, where the number j corresponds to a choice of edge to end on. The next shortcuts are forced to land on e'^i_j, then e'^i and finally e^i_*. The offset between the endpoint v^i_* of the last shortcut and b^i_* will be precisely the offset between v^{i-1}_* and b^i_* plus $\gamma s_{i,j}$ (refer to Figure 7), thus the choice of which edge to land on encodes picking an item. After k choices the offset will be approximately encoding the corresponding partial sum in the offset from b^k_*.

Initialization gadget. For the construction refer to Figure 9. Both the target curve T and the base curve B will start at x-coordinate 0 placing the start point for the base curve at $(0, 1)$, and the start point for the target curve at $(0, 0)$. The target curve will go rightwards, up to the first twist centred at $(\varepsilon + \gamma, 0)$ and continue rightwards after that. The base curve will immediately leave the hippodrome to the left and connect to the first mirror edge from $\mathrm{a}^0_* = (3\gamma + 2\varepsilon, -1)$ to $\mathrm{b}^0_* = (\gamma + 2\varepsilon, -1)$.

Terminal gadget. The terminal gadget g_{k+1} is the dual to the initialization gadget (refer to Figure 9). The entry edge from $(b^k_* + \lambda^k, -1)$ to $(b^k_*, -1)$ is defined by the previous gadget. The target curve T has a single twist at $(b^k_* + \lambda + \varepsilon, 0)$ and ends at $(b^k_* + 2\lambda + 2\varepsilon - \gamma(\sigma+1), 0)$. The base curve B connects the entry edge to $(b^k_* + 2\lambda + 2\varepsilon - \gamma(\sigma+1), 1)$ from outside the hippodrome. The final vertex $B(1)$ of the base curve is placed such that a shortcut from the entry edge e^k_* has to start precisely at x-coordinate $b^k_* + \gamma(\sigma+1)$ to hit the vertex.

5.3 Result

In the full version [19] of this paper we show that the curves can be constructed in $\mathcal{O}(kn)$ time. Furthermore, if we choose $\varepsilon = \frac{5}{2}$, $\beta = \max(32 + 4\lambda^k, \lambda^{k+1}) + 1$ and $\gamma = 16k + 6$, then the maximum numerical value of the coordinates constructed is in $\mathcal{O}(k^2 n \sum_{i=0}^{k} \max S_i)$. We then analyse the structure of a feasible solution under this choice of parameters and show that it properly encodes the partial sums, such that we can retain the solution to the k-Table-SUM instance. From this analysis, we obtain the following theorem.

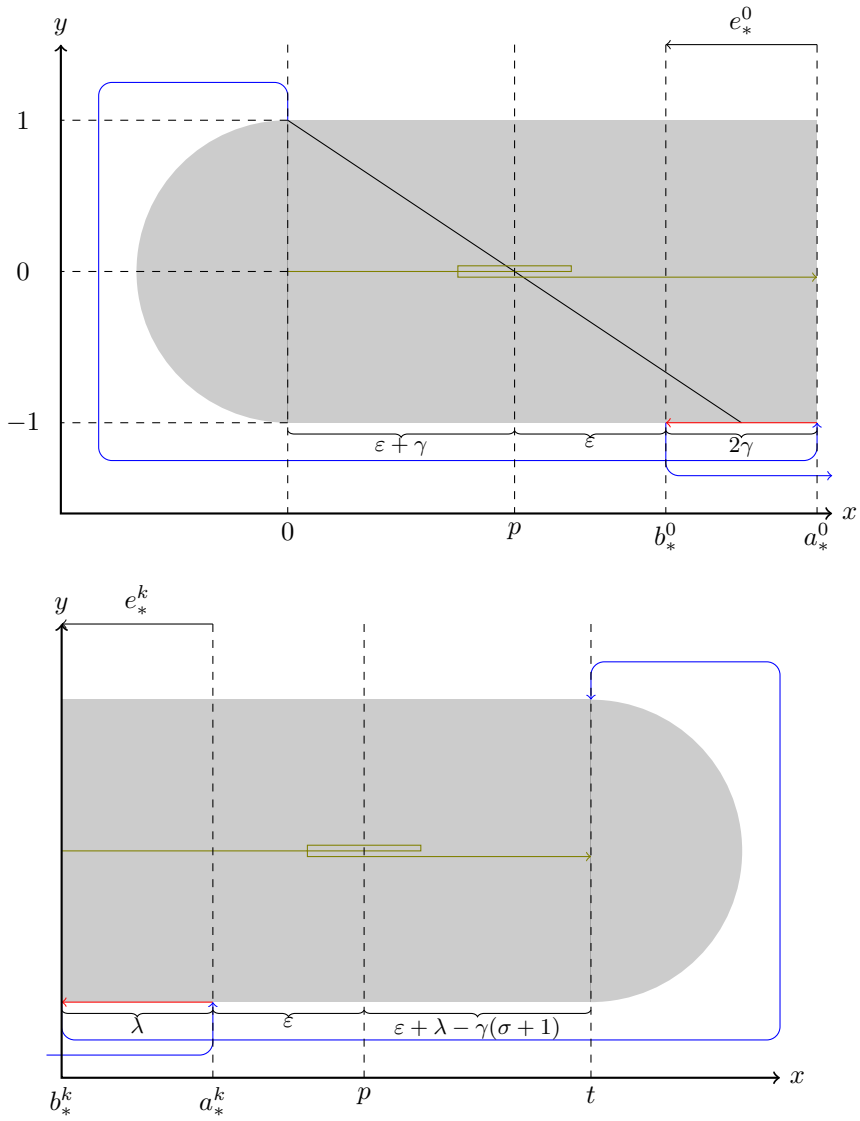

Figure 9 Construction of the Initialization and Terminal gadget. The first forced shortcut in the Initialization gadget is drawn in black. Mirror edges are red, connector edges are blue, and the target curve is green.

▶ **Theorem 6.** *Unless ETH fails, there is no algorithm for the k-shortcut Fréchet distance decision problem in $\mathbb{R}^d$ for $d \geq 2$, with running time $n^{o(k)}$.*

Abstract

We consider an important generalization of the Steiner tree problem, the *Steiner forest problem*, in the Euclidean plane: the input is a multiset $X \subseteq \mathbb{R}^2$, partitioned into k color classes $C_1, C_2, \ldots, C_k \subseteq X$. The goal is to find a minimum-cost Euclidean graph G such that every color class C_i is connected in G. We study this Steiner forest problem in the streaming setting, where the stream consists of insertions and deletions of points to X. Each input point $x \in X$ arrives with its color $\mathsf{color}(x) \in [k]$, and as usual for dynamic geometric streams, the input is restricted to the discrete grid $\{0, \ldots, \Delta\}^2$.

We design a single-pass streaming algorithm that uses $\mathrm{poly}(k \cdot \log \Delta)$ space and time, and estimates the cost of an optimal Steiner forest solution within ratio arbitrarily close to the famous Euclidean Steiner ratio α_2 (currently $1.1547 \leq \alpha_2 \leq 1.214$). This approximation guarantee matches the state of the art bound for streaming Steiner tree, i.e., when $k = 1$. Our approach relies on a novel combination of streaming techniques, like sampling and linear sketching, with the classical Arora-style dynamic-programming framework for geometric optimization problems, which usually requires large memory and has so far not been applied in the streaming setting.

We complement our streaming algorithm for the Steiner forest problem with simple arguments showing that any finite approximation requires $\Omega(k)$ bits of space.

1 Introduction

We study combinatorial optimization problems in dynamic geometric streams, in the classical framework introduced by Indyk [36]. In this setting, focusing on low dimension $d = 2$, the input point set is presented as a stream of insertions and deletions of points restricted to the discrete grid $[\Delta]^2 := \{0, \ldots, \Delta\}^2$. Geometric data is very common in applications and has been a central object of algorithmic study, from different computational paradigms (like data streams, property testing and distributed/parallel computing) to different application domains (like sensor networks and scientific computing). Research on geometric streaming algorithms has been very fruitful, and in particular, streaming algorithms achieving $(1 + \varepsilon)$-factor estimation (i.e., approximation of the optimal value) have been obtained for fundamental geometric problems, such as k-clustering [15, 28, 35], facility location [24, 43], and minimum spanning tree (MST) [27].

Despite this significant progress, some similarly looking problems are still largely open. Specifically, for the TSP and Steiner tree problems, which are the cornerstone of combinatorial optimization, it is a major outstanding question (see, e.g., [50]) whether a streaming algorithm can match the $(1+\varepsilon)$-approximation known for the offline setting [7, 46]. In fact, the currently best streaming algorithms known for TSP and Steiner tree only achieve $O(1)$-approximation, and follow by a trivial application of the MST streaming algorithm.

While MST is closely related to TSP and Steiner tree – their optimal values are within a constant factor of each other – it seems unlikely that techniques built around MST could achieve $(1 + \varepsilon)$-approximation for either problem. Indeed, even in the offline setting, the only approach known to achieve $(1 + \varepsilon)$-approximation for TSP and/or Steiner tree relies on a framework devised independently by Arora [7] and Mitchell [46], that combines geometric decomposition (e.g., a randomly shifted quad-tree) and dynamic programming. These two techniques have been used *separately* in the streaming setting in the past: quad-tree decomposition in [3, 4, 20, 24, 27, 28, 37, 43] and dynamic programming, mainly for string processing problems, in [13, 16, 22, 25, 31, 48, 51]. However, we are not aware of any successful application of the Arora/Mitchell framework, which combines these two approaches, for any geometric optimization problem whatsoever.

We make an important step towards better understanding of these challenges by developing new techniques that *successfully adapt the Arora/Mitchell framework to streaming*. To this end, we consider a generalization of Steiner tree, the classical **Steiner Forest Problem (SFP)**. In this problem (also called *Generalized Steiner tree*, see, e.g., [7]), the input is a multiset of n *terminal* points $X \subseteq [\Delta]^2$, partitioned into k *color classes* $X = C_1 \sqcup \cdots \sqcup C_k$, presented as a dynamic stream. In addition, apart from the coordinates of the point $x \in X$, its color $\mathsf{color}(x) \in [k]$ is also revealed upon its arrival in the stream[1]. The goal is to find a minimum-cost Euclidean graph G such that every color class C_i is connected in G. Observe that the Steiner tree problem is a special case of SFP in which all terminal points should be connected (i.e., $k = 1$). Similar to the Steiner tree problem, a solution to SFP may use points other than X; those points are called *Steiner points*.

▶ Remark. In the literature, the term SFP sometimes refers to the *special case* where *each color class contains only a pair of points*, i.e., each $C_i = \{s_i, t_i\}$ [11, 12, 14, 17, 33]. It is not difficult to see (see [49]) that one can reduce one problem into another in the standard setting of *offline algorithms*. The special case of pairs is often simpler to present and does

[1] The points are arriving and leaving in an arbitrary order; there is no requirement that each color arrives in a batch, i.e., that its points are inserted/deleted consecutively in the stream.

not restrict algorithmic generality for offline algorithms, even though the setting considered here is more natural for applications (see [45]). Nevertheless, the definition used here allows for better parameterization over the number of colors k.

Background. While one might hope for a streaming algorithm for SFP with $o(k)$ space, we observe that *this task is impossible*, even in the one-dimensional case. In Theorem 4.1, we present a reduction that creates instances of SFP in $\mathbb{R}$ such that every streaming algorithm achieving any finite approximation ratio for SFP must use $\Omega(k)$ bits of space. This holds even for insertion-only algorithms, and even if all color classes are of size at most 2.

Even for $k = 1$, which is the famous Steiner tree problem, the only known streaming algorithm is to estimate the cost of a minimum spanning tree (MST) and report it as an estimate for SFP. It is useful to recall here the *Steiner ratio* α_d, defined as the supremum over all point sets $X \subseteq \mathbb{R}^d$, of the ratio between the cost of an MST and that of an optimal Steiner tree. The famous Steiner ratio Gilbert-Pollak Conjecture [29] speculates that $\alpha_2 = \frac{2}{\sqrt{3}} \approx 1.1547$, but the best upper bound to date is only that $\alpha_2 \leq 1.214$ [23]. It follows that employing the streaming algorithm of Frahling, Indyk, and Sohler [27], which $(1+\varepsilon)$-approximates the MST cost using space $\mathrm{poly}(\varepsilon^{-1} \log \Delta)$, immediately yields a streaming algorithm that $(\alpha_2 + \varepsilon)$-approximates the Steiner tree cost, with the same space bound.

1.1 Our Contribution

Our main result is a *space and time* efficient, *single-pass* streaming algorithm that estimates the optimal *cost* OPT for SFP within $(\alpha_2 + \varepsilon)$ factor. Our space bound is nearly optimal in terms of the dependence in k, since any finite approximation for SFP requires space $\Omega(k)$ (Theorem 4.1), and our ratio matches the state of the art for Steiner tree (i.e., $k = 1$).

▶ **Theorem 1.1** (Informal Version of Theorem 3.1). *For any integers $k, \Delta \geq 1$ and any fixed $\varepsilon > 0$, one can with high probability $(\alpha_2 + \varepsilon)$-approximate the SFP cost of an input $X \subseteq [\Delta]^2$ presented as a dynamic stream, using space and query/update times bounded by* $\mathrm{poly}(k \cdot \log \Delta)$.

We notice that while the algorithm in Theorem 1.1 returns only an approximate cost of the optimal solution and it cannot return the entire approximate solution (since the output is of size $\Omega(n)$), an additional desirable feature of our algorithm in Theorem 1.1 is that it can return information about the colors in the trees in an approximate solution. That is, our algorithm can maintain a partition of the colors used in X into $I_1, \ldots, I_r \subseteq \{1, \ldots, k\}$, so that the sum of the costs of the minimum-cost Steiner trees for sets $\bigcup_{i \in I_j} C_i$ is an $(\alpha_2 + \varepsilon)$-approximation of SFP. It is worth noting that in estimating the optimal cost, our algorithm does use Steiner points. This means that the MST costs for sets $\bigcup_{i \in I_j} C_i$ of the aforementioned partition may be by an $O(1)$ factor larger than the estimate of the algorithm.

Comparison to a Simple Exponential-time Approach. As we shall discuss in Section 1.2, a simple brute force enumeration combined with linear sketching techniques yields a streaming algorithm also with near-optimal space, but significantly worse running time that is *exponential* in k. Technically, while this approach demonstrates the amazing power of linear sketching, its core is exhaustive search rather than an algorithmic insight, and thus it is quite limited, offering no path for improvements or extensions. Furthermore, the $\mathrm{poly}(k)$ running time in Theorem 1.1 is exponentially better than the exhaustive search, which seems to be a limit of what linear sketching could possibly achieve. Therefore even though the primary focus of streaming algorithms is on their space complexity, the improvement of the running

time is critical in terms of pursuing efficient algorithms and making our techniques broadly applicable. Indeed, similar exponential improvements of running time have been of key importance in the advances of various other fundamental streaming problems, for instance, for moment estimation the query time was improved from $\text{poly}(\varepsilon^{-1})$ to $\text{poly}\log(\varepsilon^{-1})$ [40], and for heavy hitters from $\text{poly}(n)$ to $\text{poly}\log(n)$ [44].

1.1.1 Technical Contribution: Adapting Arora's Framework to Streaming

We introduce a method for efficient streaming implementation of an offline Arora-style [7] dynamic-programming framework based on the quad-tree decomposition. This method, which is probably the first of its kind for geometric streams, is our main technical contribution.

In the offline setting, Borradaile, Klein, and Mathieu [14] and then Bateni and Hajiaghayi [11] extended the Arora's approach to obtain a polynomial-time approximation scheme (PTAS) for SFP. The key insight of these works is that one can tweak the optimal solution so that its cost remains nearly optimal, but it satisfies certain structural properties that allow for designing a suitable dynamic program. In Section 2, we review the structural theorem and the dynamic-programming approach for SFP from [11, 14] in more detail.

The main difficulty of using the Arora-style approach in low-space streaming is that in general, such approach requires access to all input points, that is, $\Omega(n)$ space to store $\Omega(n)$ leaves at the bottom of the quad-tree input decomposition that have to be considered as basic subproblems. In order to ensure a low-space implementation of the Arora-style framework in the streaming setting, we will use only $O(k \log \Delta)$ non-uniform leaf nodes of the quad-tree, each corresponding to a square. The definition of these leaf nodes is one of the novel ideas needed to make the dynamic-programming approach work in the streaming setting. Moreover, since each internal node in the quad-tree has degree 4, the total number of quad-tree squares to consider is thus $O(k \cdot \log \Delta)$.

The next challenge is that for the dynamic program to run, we need to find an $(\alpha_2 + \varepsilon)$-approximate estimation for each new leaf and each dynamic-programming subproblem associated with it. The definition of leaf squares will enable us to reduce it to estimating the MST cost for a certain subset of points inside the square. It would then be natural to just employ the MST sketch designed in [27] to estimate the MST cost, in a black box manner. However, the leaf squares are not known in advance as we can only find them after processing the stream and thus, it is impossible to build the MST sketch for each leaf square and each subproblem associated with it. To overcome this, we observe that in essence, the MST sketch consists of uniformly sampled points (with suitably rounded coordinates). We thus obtain the MST sketch for each color separately and only use the sampled points that are relevant for the subproblem to estimate the MST cost for the subproblem, in a way similar to [27].

However, due to restricting the attention to a single subproblem, the original analysis of the MST sketch in [27] has to be modified to deal with additional technical challenges. For instance, we may not sample any point relevant to a leaf square in case there are relatively few points in it. We need to account for the error arising from this case in a global way, by observing that then the MST cost inside the leaf square is a small fraction of the overall cost.

Further, to be able to accurately enumerate the subproblems for a leaf square, we need to know the set of color classes that intersect every leaf square, but unfortunately doing so exactly is impossible in the streaming setting. To this end, we employ a δ-net for a small-enough δ, so that the intersection test can be approximately done by only looking at the nearby net points. We show that this only introduces a small error for SFP, and that this δ-net can be constructed in a dynamic stream, using space by only a factor of $\text{poly}\log(\Delta)$ larger than the net. Finally, we apply the dynamic program using our leaf nodes as basic subproblems to obtain the estimation.

1.2 Could Other Approaches Work?

A Simple Exponential-time Streaming Algorithm Based on Linear Sketching. An obvious challenge in solving SFP is to determine the connected components of an optimal (or approximate) solution. Each color class must be connected, hence the crucial information is which *colors* are connected together (even though they do not have to be). Suppose momentarily that the algorithm receives an advice with this information, which can be represented as a partition of the color set $[k] = P_1 \sqcup \cdots \sqcup P_l$. Then a straightforward approach for SFP is to solve the Steiner tree problem separately on each part P_j (i.e., the union of some color classes), and report their total cost. In our streaming model, we could apply the aforementioned MST-based algorithm [27], using space $\mathrm{poly}(\varepsilon^{-1} \log \Delta)$, to achieve $(\alpha_2 + \varepsilon)$-approximation, and we would need $l \le k$ parallel executions of it (one for each P_j). An algorithm can bypass having such an advice by enumeration, i.e., by trying in parallel all the k^k partitions of $[k]$ and reporting the minimum of all their outcomes. This would still achieve $(\alpha_2 + \varepsilon)$-approximation, because each possible partition gives rise to a feasible SFP solution (in fact, this algorithm optimizes the sum-of-MST objective). However, this naive enumeration increases the space and time complexities by a factor of $O(k^k)$. We can drastically improve the space complexity by the powerful fact that the MST algorithm of [27] is based on a *linear sketch*, i.e., its memory contents is obtained by applying a (randomized) linear mapping to the input X. The huge advantage is that linear sketches of several point sets are mergeable. In our context, one can compute a linear sketch for each color class C_i, and then obtain a sketch for the union of some color classes, say some P_j, by simply adding up their linear sketches. These sketches are randomized, and hence, one has to make sure they use the same random coins (same linear mapping), and also to amplify the success probability of the sketches so as to withstand a union bound over all 2^k subsets $P_j \subseteq [k]$. This technique improves the space complexity and update time to be basically $\mathrm{poly}(k\varepsilon^{-1} \log \Delta)$, however the query time is still *exponential* in k. We state this result as follows, and its formal proof can be found in the full version.

▶ **Theorem 1.2.** *For any integers $k, \Delta \ge 1$ and any $0 < \varepsilon < 1/2$, one can with high probability $(\alpha_2 + \varepsilon)$-approximate SFP cost of an input $X \subseteq [\Delta]^2$ presented as a dynamic geometric stream, using space and update time of $O(k^2 \cdot \mathrm{poly}(\varepsilon^{-1} \cdot \log \Delta))$ and with query time $O(k^k) \cdot \mathrm{poly}(\varepsilon^{-1} \cdot \log \Delta)$.*

Tree Embedding. Indyk [36] incorporated the low-distortion tree embedding approach of Bartal [9] to obtain dynamic streaming algorithms with $O(\log \Delta)$ ratio for several geometric problems. This technique can be easily applied to SFP as well, but the approximation ratio is $O(\log \Delta)$ which is far from what we are aiming at.

Other $O(1)$-Approximate Offline Approaches. In the regime of $O(1)$-approximation, SFP has been extensively studied using various other techniques, not only dynamic programming. For example, in the offline setting there are several 2-approximation algorithms for SFP using the primal-dual approach and linear programming relaxations [1, 30, 38], and there is also a combinatorial (greedy-type) constant-factor algorithm called *gluttonous* [33]. Both of these approaches work in the general metric setting. While there are no known methods to turn the LP approach into low-space streaming algorithms, the gluttonous algorithm of [33] might seem amenable to streaming. Indeed, it works similarly to Kruskal's MST algorithm as it also builds components by considering edges in the sorted order by length, and the MST cost estimation in [27] is similar in flavor to Kruskal's algorithm. However, a crucial

difference is that the gluttonous algorithm stops growing a component once all terminals inside the component are satisfied, i.e., for each color i, the component either contains all points of C_i, or no point from C_i. This creates a difficulty that the algorithm must know for each component whether or not it is "active" (i.e., not satisfied), and there are up to n components, requiring overall $\Omega(n)$ bits of space. This information is crucial because "inactive" components do not have to be connected to anything else, but they may help to connect two still "active" components in a much cheaper way than by connecting them directly. Furthermore, we have a simple one-dimensional example showing that the approximation ratio of the gluttonous algorithm cannot be better than 2 (moreover, its approximation guarantee in [33] is significantly larger than 2). In comparison, our dynamic-programming approach gives a substantially better ratio of $\alpha_2 + \varepsilon$. Nevertheless, an interesting open question is whether the gluttonous algorithm admits a low-space streaming implementation.

1.3 Related Work

SFP has been extensively studied in operations research and algorithmic communities for several decades. This problem has been also frequently considered as a part of a more general network design problem (see, e.g., [1, 30, 38, 45]), where one could require for some subsets of vertices to maintain some higher inter-connectivity.

In the classical, offline setting, it is known that the Steiner tree problem is APX-hard in general graphs and in high-dimensional Euclidean spaces, and the same thus holds for SFP as it is more general. In general graphs, a 2-approximation algorithm is known due to Agrawal et al. [1] (see also [30, 38]). These 2-approximation algorithms rely on linear-programming relaxations, and the only two combinatorial constant-factor approximations for SFP were recently devised by Gupta and Kumar [33] and by Groß et al. [32]. For low-dimensional Euclidean space, which is the main focus of our paper, Borradaile et al. [14] and then Bateni and Hajiaghayi [11] obtained a $(1+\varepsilon)$-approximation by applying dynamic programming and geometric space decomposition, significantly extending the approach of Arora [7]. Further extensions of the dynamic-programming approach have led to a PTAS for metrics of bounded doubling dimension [17], planar graphs, and graphs of bounded treewidth [12].

There has been also extensive work for geometric optimization problems in the dynamic (turnstile) streaming setting, with low space. Indyk [36] designed $O(\log \Delta)$-approximate algorithms for several basic problems, like MST and matching. Follow-up papers presented a number of streaming algorithms achieving approximation ratio of $1+\varepsilon$ or $O(1)$ to the cost of Euclidean MST [27], various clustering problems [28, 34], geometric facility location [24, 43], earth-mover distance [3, 36], and various geometric primitives (see, e.g., [5, 18, 19, 26]). Some papers have studied geometric problems with superlogarithmic but still sublinear space and in the multipass setting (see, e.g., [6]). We are not aware of prior results for the (Euclidean) Steiner tree problem nor SFP in the streaming context, although $(1+\varepsilon)$-approximation of the MST cost [27] immediately gives a $(\alpha_2+\varepsilon)$-approximation of the Euclidean Steiner tree.

2 Preliminaries

For $x, y \in \mathbb{R}^2$, let $\operatorname{dist}(x,y) := \|x-y\|_2$. For $S, T \subseteq \mathbb{R}^2$, let $\operatorname{dist}(S,T) := \min_{x\in S, y\in T} \operatorname{dist}(x,y)$. For $S \subseteq \mathbb{R}^2$, let $\operatorname{diam}(S) := \max_{x,y\in S} \operatorname{dist}(x,y)$. A *$\rho$-packing* $S \subseteq \mathbb{R}^2$ is a point set such that $\forall x, y \in S$, $\operatorname{dist}(x,y) \geq \rho$. A *$\rho$-covering* of X is a subset $S \subseteq \mathbb{R}^2$ such that $\forall x \in X$, $\exists y \in S$, $\operatorname{dist}(x,y) \leq \rho$. We call $S \subseteq \mathbb{R}^2$ a *ρ-net* for X if it is both a ρ-packing and a ρ-covering for X.

▶ **Fact 2.1** (Packing Property, cf. [47]). *A ρ-packing $S \subseteq \mathbb{R}^d$ has size $|S| \leq \left(\frac{3\,\mathrm{diam}(S)}{\rho}\right)^d$.*

Metric Graphs. We call a weighted undirected graph $G = (X, E, w)$ a *metric graph* if for every edge $\{u, v\} \in E$, $w(u, v) = \mathrm{dist}(u, v)$, and we let $w(G)$ to be the sum of the weights of edges in G. A solution F of SFP may be interpreted as a metric graph. For a set of points S (e.g., S can be a square), let $F|_S$ be the subgraph of F formed by edges whose both endpoints belong to S. Note that we think of F as a *continuous* graph in which every point of an edge is itself a vertex, so $F|_S$ may be interpreted as a geometric intersection of F and S.

Randomly-Shifted Quad-trees [7]. Without loss of generality, let Δ be a power of 2, and let $L := 2\Delta$. A quad-tree sub-division is constructed on $[L]^2$. In the quad-tree, each node u corresponds to a square R_u and if it's not a leaf, it has four children, whose squares partition R_u. The squares in the quad-tree are of side-lengths that are powers of 2, and we say a square R is of level i if its side-length is 2^i (this is also the level of its corresponding node in the quad-tree, where leaves have level 0 and the root is at level $\log_2 L$). The whole quad-tree is shifted by a random vector in $[-\Delta, 0]^2$. Throughout, we assume a randomly-shifted quad-tree has been sampled from the very beginning. When we talk about a quad-tree square R, we interpret it as the point set that consists of both the boundary and the internal points. For $i = 0, \ldots \log_2 L$, let 2^i-*grid* $\mathcal{G}_i \subset \mathbb{R}^2$ be the set of centers of all level-i squares in the quad-tree.

2.1 Review of Dynamic Programming (DP) [11, 14]

The PTAS for geometric SFP in the offline setting [11, 14] is based on the quad-tree sub-division framework of Arora [7], with modifications tailored to SFP. For each square R in the (randomly-shifted) quad-tree,

- $O(\varepsilon^{-1} \log L)$ equally-spaced points on the boundary edges are designated as *portals*; and
- the $\gamma \times \gamma$ sub-squares of R are designated as *cells* of R, denoted $\mathsf{cell}(R)$, where $\gamma = \Theta(\varepsilon^{-1})$ is a power of 2.

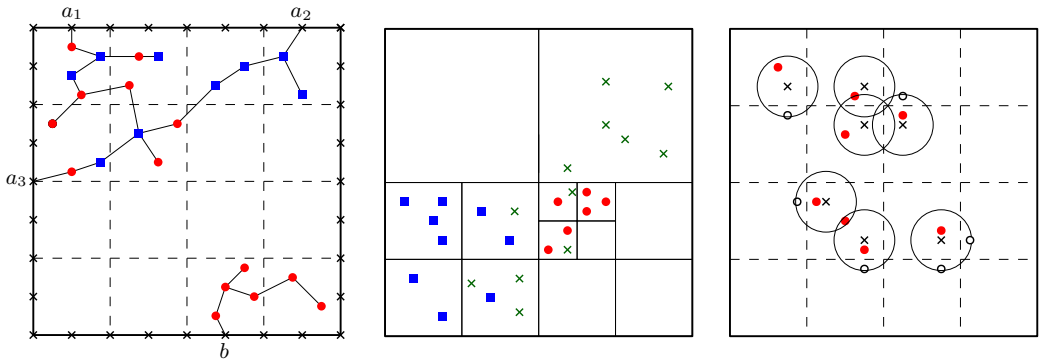
For each square R in the quad-tree, let ∂R be the boundary of R (which consists of four segments). The following is the main structural theorem from [11], and an illustration of it can be found in Figure 1a.

▶ **Theorem 2.2** ([11]). *For an optimal solution F of SFP, there is a solution F' (defined with respect to the randomly-shifted quad-tree), such that*

1. *$w(F') \leq (1+O(\varepsilon)) \cdot w(F)$ with constant probability (over the randomness of the quad-tree);*
2. *For each quad-tree square R, $F'|_{\partial R}$ has at most $O(\varepsilon^{-1})$ components, and each component of $F'|_{\partial R}$ contains a* portal *of R;*
3. *For each quad-tree square R and each cell P of R, if two points $x_1, x_2 \in X \cap P$ are connected to ∂R via F', then they are connected in $F'|_R$; this is called the* cell property.

It suffices to find the optimal solution that satisfies the structure defined in Theorem 2.2. This is implemented using dynamic programming (DP), where a subproblem of the DP is identified as a tuple (R, A, f, Π), specified as follows:

- R is a quad-tree square;
- A is a set of $O(\varepsilon^{-1})$ active portals through which the local solution enters/exits R;
- $f : \mathsf{cell}(R) \to 2^A$ s.t. for $S \in \mathsf{cell}(R)$, $f(S)$ represents the subset of A that S connects to;
- Π is a partition of A, where active portals in each part of Π have to be connected outside of R (in a larger subproblem).



(a) structural property. **(b)** simple squares. **(c)** compatibility checking.

Figure 1 Illustrations of the structural properties of Theorem 2.2 (Figure 1a), construction of simple squares by Algorithm 1 (Figure 1b) and the approximate compatibility checking idea in Section 3.2.2 (Figure 1c). Figure 1a shows a square R with portals (crosses) on ∂R, the 4×4 cells of R, and the part of solution $F'|_R$, such that $F'|_R$ passes ∂R through four portals a_1, a_2, a_3, b on the sides, and in each cell, points that are connected by F' to ∂R in the cell are connected in R. Figure 1b demonstrates the 13 simple squares constructed by Algorithm 1 for the three colors (noting that the 5 empty squares are also included as simple squares). In Figure 1c, red points are data points, cross points are the net points constructed from the data, and the black hollowed points are the added points for cells that are close-enough to a net point (for simplicity, not shown for cells containing a data point).

The use of R and A is immediate, and f is used to capture the connectivity between cells and portals (this suffices because we have the "cell property" in Theorem 2.2). Finally, Π is used to ensure feasibility, since a global connected component may be broken into several components in square R, and it is crucial to record whether or not these components still need to be connected from outside of R. An optimal solution for subproblem (R, A, f, Π) is defined as a minimum weight metric graph in R that satisfies the constraints A, f, Π. Standard combinatorial bounds show that the number of subproblems associated with each square is bounded by $(\varepsilon^{-1} \cdot \log \Delta)^{O(\varepsilon^{-2})}$ (see [11]).

▶ Remark 2.3. Strictly speaking, we use a simplified definition of DP subproblems, compared to [11]. Namely, one can additionally require that for any two cells $S, S' \in \mathsf{cell}(R)$, either $f(S) = f(S')$ or $f(S) \cap f(S') = \emptyset$ and that any active portal in A appears in $f(S)$ for some cell S. Then, f defines a partition of $\mathsf{cell}(R)$ and of A into local components inside R (taking into account only components connected to ∂R), and Π should encode which local components need be connected from the outside of R, implying that Π should be a partition of local components (instead of A). Thus, Π can also be thought of as a partition of the partition of A induced by f. We chose to give a more relaxed definition of DP subproblems as it is sufficient for describing how to implement the DP approach in the streaming setting.

3 Streaming Dynamic Programming: k^3-time-and-space Algorithm

In this section, we prove our main result, Theorem 1.1, restated with more precise bounds. Formally, we call the time for processing inserting/deleting one point as *update time*, and for reporting the estimate of OPT the *query time*.

▶ **Theorem 3.1.** *For any integers $k, \Delta \geq 1$ and any $0 < \varepsilon < 1/2$, one can with high probability $(\alpha_2 + \varepsilon)$-approximate the SFP cost of an input $X \subseteq [\Delta]^2$ presented as a dynamic geometric stream, using space and update time of $k^3 \cdot \mathrm{poly}(\log k \cdot \varepsilon^{-1} \cdot \log \Delta)$ and with query time bounded by $k^3 \cdot \mathrm{poly}(\log k) \cdot (\varepsilon^{-1} \cdot \log \Delta)^{O(\varepsilon^{-2})}$.*

Overview. Our approach for the streaming algorithm relies on a novel modification of the known PTAS for SFP in the offline setting [11, 14], which is based on dynamic programming (DP). One important reason why the DP requires $\Omega(n)$ space is that $\Omega(n)$ leaves in the quad-tree have to be considered as basic subproblems which correspond to singletons. To make the DP use only $\widetilde{O}(\mathrm{poly}(k))$ space, we will use only $\widetilde{O}(\mathrm{poly}(k))$ leaf nodes. Then, since each internal node in the quad-tree has degree 4, the total number of squares to consider is $\widetilde{O}(\mathrm{poly}(k))$. Furthermore, we design an algorithm that runs in time and space $\widetilde{O}(\mathrm{poly}(k))$ and finds an $(\alpha_2 + \varepsilon)$-approximate estimation for each new leaf and each DP subproblem associated with it. Finally, we apply the DP using such leaves as basic subproblems to obtain the estimation. We start in Section 3.1 with a description of this approach in the offline setting, and we make it streaming in Section 3.2. The proof of Theorem 3.1 is in Section 3.3.

3.1 Offline Algorithm

New Definition of Basic Subproblems. Each of our new leaves in the DP will be a *simple square* defined below. The idea behind the definition is also simple: If no color class is contained in R, then all points inside R must be connected to ∂R, so we can make better use of the cell property in Theorem 2.2.

▶ **Definition 3.2** (Simple Squares). *We call a square R* simple *if for every $1 \le i \le k$, $C_i \cap R \neq C_i$. In other words, there is no color class totally contained in R.*

We note that the number of all possible simple squares can still be large (in particular, any empty square is simple as well as any square containing a single point of color C_i with $|C_i| \ge 2$), and we use Lemma 3.3 below to show the existence of a small subset of simple squares that covers the whole instance and can be found efficiently. Our new leaves are naturally defined using such subset of squares.

▶ **Lemma 3.3.** *There is a subset $\mathcal{R}$ of disjoint simple squares, such that the union of the squares in $\mathcal{R}$ covers X, and $|\mathcal{R}| = O(k \cdot \log \Delta)$.*

Proof. Consider the recursive procedure specified in Algorithm 1 that takes as input a square R and returns a set of disjoint simple squares $\mathcal{R}$ that covers R; see Figure 1b for an illustration of the outcome of the procedure. For our proof, we apply the procedure with R being the root square covering the whole instance. Suppose the procedure returns $\mathcal{R}$.

Algorithm 1 Algorithm for finding simple squares.

```
1: procedure SIMP-SQUARE(R)
2:     if R is simple then return {R}
3:     else
4:         let {R_i}_i be the child squares of R in the quad-tree
5:         return ⋃_i SIMP-SQUARE(R_i)
```

We call a square R intermediate square if it is a square visited in the execution of the algorithm and it is not simple (i.e., R contains a color class). We observe that $|\mathcal{R}|$ is $O(1)$ times the number of intermediate squares. On the other hand, each color C_i can be totally contained in at most $O(\log \Delta)$ intermediate squares. Therefore, $|\mathcal{R}| = O(k \cdot \log \Delta)$. ◀

Approximation Algorithm for Subproblems on Simple Squares. Fix some simple square R. We now describe how each DP subproblem (R, A, f, Π) associated with R can be solved directly using an α_2-approximate algorithm that is amenable to the streaming setting.

Since R is a simple square, every point in R has to be connected to the outside of R, as otherwise the color connectivity constraint is violated. Hence, by the cell property of Theorem 2.2, for every cell $R' \in \mathsf{cell}(R)$, all points in R' are connected in R. Therefore, we enumerate all possible partitions of $\mathsf{cell}(R)$ that is consistent with the f constraint. For each partition, we further check whether it satisfies the constraint defined by Π. To do so, for each cell $R' \in \mathsf{cell}(R)$, we scan through all colors, and record the set of colors $\mathcal{C}_{R'} \subseteq \mathcal{C}$ that intersects R'. The $\mathcal{C}_{R'}$'s combined with the f constraint as well as the enumerated connectivity between cells suffice for checking the Π constraint.

Observe that every feasible solution of the subproblem corresponds to the above-mentioned partition of cells. Therefore, to evaluate the cost of the subproblem, we evaluate the sum of the MST costs of the parts in each partition and return the minimum one. The time complexity for evaluating each subproblem is bounded since $|A| = O(\varepsilon^{-1})$ and $|\mathsf{cell}(R)| = O(\varepsilon^{-2})$. The approximation ratio is α_2 because we use MST instead of Steiner tree for evaluating the cost. Using MST will enable us to implement this algorithm in the streaming setting.

3.2 Building Blocks for Streaming Algorithm

3.2.1 Constructing Simple Squares in the Streaming Setting

The first step is to construct a set of simple squares, as in Lemma 3.3, and an offline construction is outlined in Algorithm 1. For the streaming construction of simple squares, we observe that the key component of Algorithm 1 is a subroutine that tests whether a given square is simple or not. To implement the subroutine, we use a streaming algorithm to compute the bounding square for each color, and we test whether a given square contains any bounding square as a sub-square.

▶ **Lemma 3.4.** *Algorithm 1 can be implemented in the streaming setting, using space* $O(k \operatorname{poly}\log\Delta)$ *and in time* $O(k \operatorname{poly}\log\Delta)$ *per stream update, with success probability at least* $1 - \operatorname{poly}(\Delta^{-1})$.

Proof. The proof is ommited due to the space limit and can be found in the full version. ◀

3.2.2 Approximate Compatibility Checking

Suppose we applied Lemma 3.4 to obtain a set of simple squares $\mathcal{R}$. We proceed to evaluate the cost of subproblems associated with each simple square. Fix a simple square $R \in \mathcal{R}$. We next describe how to evaluate the cost for every subproblem associated with R, in streaming.

Suppose we are to evaluate the cost of a subproblem (R, A, f, Π). Since R is known, we have access to $\mathsf{cell}(R)$, and hence, we can enumerate the connectivity between the cells, which is a partition of $\mathsf{cell}(R)$, on-the-fly without maintaining other information about the input. Similarly, we can check the compatibility of the partition of cells with the f constraint, since the constraint only concerns the information about A and the partition. Then, when we check the compatibility of the partition of cells with Π, in the offline setting we need to compute the set of colors $\mathcal{C}_{R'} \subseteq \mathcal{C}$ that a cell R' intersects.

However, computing this set $\mathcal{C}_{R'}$ is difficult in the streaming setting, even if there is only one color C. Indeed, testing whether color C has an intersection with cell R' can be immediately reduced to the INDEX problem (see e.g. [42] for the definition), which implies an $\Omega(n)$ space bound, where n is the number of points of color C. Therefore, we need to modify the offline algorithm, and only test the intersection approximately.

To implement the approximate testing, for every color $C \in \mathcal{C}$, we impose a $\delta \cdot \operatorname{diam}(C)$-net N_C for C (see Section 2), where $\delta := O\left(\varepsilon^3 (k \log\Delta)^{-1}\right)$. A streaming algorithm in Lemma 3.5 is presented to compute this net. To be exact, the streaming algorithm in Lemma 3.5 returns

a set of points N_C such that for any point $x \in N_C$ at least one point in C is within distance $\delta \cdot \mathrm{diam}(C)$ from x (so N_C does not contain net points that are far away from C). Hence, take $D_C := \mathrm{diam}(N_C)$, and we have $D_C \in (1 \pm \delta) \cdot \mathrm{diam}(C)$. Then, for each cell $R' \in \mathsf{cell}(R)$ of each simple square R, we examine each point in N_C, and if $\mathrm{dist}(R', N_C) \le \delta \cdot D_C$, we add a new point $x \in R'$ such that $\mathrm{dist}(x, N_C) \le \delta \cdot D_C$ to the stream, and assign it color C. Furthermore, we declare C intersects R'. This idea is visually demonstrated in Figure 1c.

▶ **Lemma 3.5.** *There is an algorithm that for every $0 < \rho \le 1$ and every point set $S \subset \mathbb{R}^2$ provided as a dynamic geometric stream, computes a subset $N_S \subset \mathbb{R}^2$ that is a $\rho \cdot \mathrm{diam}(S)$-net for S such that for every $x \in N_S$ there exists $y \in S$ with $\mathrm{dist}(x, y) \le \rho \cdot \mathrm{diam}(S)$, with probability at least $1 - \mathrm{poly}(\Delta^{-1})$, using space $O(\rho)^{-2} \cdot \mathrm{poly}\log\Delta$, and running in time $O(\rho)^{-2} \cdot \mathrm{poly}\log\Delta$ per stream update.*

Proof. The proof is ommited due to the space limit and can be found in the full version. ◀

In fact, such procedure of adding points is oblivious to the subproblem, and should be done only once as a *pre-processing step* before evaluating any subproblems. Therefore, the subproblems are actually evaluated on a new instance $(X', \mathcal{C}')$ after the pre-processing. Since we apply Lemma 3.5 for every color i, and by the choice of δ, the space complexity for the pre-processing step is $O\left(k^3 \cdot \mathrm{poly}(\varepsilon^{-1}\log\Delta)\right)$, and the time complexity per update is bounded by this quantity. Next, we upper bound the error introduced by the new instance.

▶ **Lemma 3.6.** *Let* OPT *be the optimal SFP solution for the original instance $(X, \mathcal{C})$, and let* OPT′ *be that for $(X', \mathcal{C}')$. Then $w(\mathrm{OPT}) \le w(\mathrm{OPT}') \le (1+\varepsilon) \cdot w(\mathrm{OPT})$.*

Proof. Since OPT′ is a feasible solution for $(X, \mathcal{C})$, we obtain $w(\mathrm{OPT}) \le w(\mathrm{OPT}')$ by the optimality of OPT. It remains to prove the other side of the inequality.

Recall that for every color C, we use Lemma 3.5 to obtain a $\delta \cdot \mathrm{diam}(C)$-net N_C and estimate $\mathrm{diam}(C)$ using $D_C := \mathrm{diam}(N_C)$. Now, for every cell R' of every simple square, if $\mathrm{dist}(R', N_C) \le \delta \cdot D_C$ for some color C we add a point x to C satisfying $d(x, N_C) \le \delta \cdot D_C$, and for any other color $C' \ne C$ with $\mathrm{dist}(R', N_{C'}) \le \delta \cdot D_{C'}$, we add the same point x to C'. Note that we add at most one distinct point for each cell. Let $z \in N_C$ satisfy $d(x, z) \le \delta \cdot D_C$, then adding x increases OPT by at most $2\delta \cdot D_C \le 3\delta \cdot \mathrm{diam}(C)$, since one can connect x to $y \in C$ such that $\mathrm{dist}(y, z) \le \delta \cdot \mathrm{diam}(C)$ (such y must exist due to Lemma 3.5).

Since there are in total at most $O(k \log\Delta \cdot \varepsilon^{-2})$ cells in all simple squares by Lemma 3.3, the total increase of the cost is at most $O(\delta \cdot k \log\Delta \cdot \varepsilon^{-2}) \cdot \max_{C \in \mathcal{C}} \mathrm{diam}(C) \le \varepsilon \max_{C \in \mathcal{C}} \mathrm{diam}(C) \le \varepsilon w(\mathrm{OPT})$, using the definition of δ and $w(\mathrm{OPT}) \ge \max_{C \in \mathcal{C}}(\mathrm{diam}(C))$. We conclude that $w(\mathrm{OPT}') \le (1+\varepsilon) \cdot w(\mathrm{OPT})$. ◀

3.2.3 Evaluating Basic Subproblems in the Streaming Setting

After we obtain the new instance $(X', \mathcal{C}')$, we evaluate the cost for every subproblem (R, A, f, Π). Because of the modification of the instance, we know for sure the subset of colors $\mathcal{C}_{R'}$ for each cell R'. To evaluate the subproblem, recall that we start with enumerating a partition of $\mathsf{cell}(R)$ that is compatible with the subproblem, which can be tested efficiently using $\mathcal{C}_{R'}$'s. Suppose now $\{P_i := R_i \cup A_i\}_{i=1}^t$ is a partition of $\mathsf{cell}(R) \cup A$ that we enumerated (recalling that A is the set of active portals, which needs to be connected to cells in a way that is compatible to the constraint f). Then, as in the offline algorithm, we evaluate $\mathrm{MST}(P_i)$ of each part P_i, and compute the sum of them, i.e. $\sum_{i=1}^t \mathrm{MST}(P_i)$, however, we need to show how to do this in the streaming setting.

Frahling et al. [27] designed an algorithm that reports a $(1+\varepsilon)$-approximation for the value of the MST of a point set presented in a dynamic stream, using space $O(\varepsilon^{-1}\log\Delta)^{O(1)}$. Furthermore, as noted in Section 1, their algorithm maintains a linear sketch. Now, a natural idea is to apply this MST sketch, that is, create an MST sketch for each color, which only takes $k\cdot O(\varepsilon^{-1}\log\Delta)^{O(1)}$ space. Then, for each $P_i = R_i \cup A_i$, we compute the set of intersecting colors, and we create a new MST sketch $\mathcal{K}$ by first adding up the MST sketches of these colors (recalling that they are linear sketches), and then adding the active portals connected to P_i to the sketch. We wish to query the sketch $\mathcal{K}$ for the cost of $\mathrm{MST}(P_i)$.

However, this idea cannot directly work, since the algorithm by [27] only gives the MST value for *all* points represented by $\mathcal{K}$, instead of the MST value for a subset P_i. Therefore, we modify the MST sketch to answer the MST cost of a subset of points of interest.

Brief Review of the MST Sketch. We give a brief overview of the algorithm of [27] before we explain how we modify it. The first observation (already from [21]) is that the MST cost can be written as a weighted sum of the number of connected components in metric threshold graphs, which are obtained from the complete metric graph of the point set by removing edges of length larger than a threshold τ. Essentially, the idea is to count the number of MST edges of length larger than τ.

To estimate the number of components in a threshold graph, we round the points to a suitable grid and sample a small number of rounded points uniformly, using ℓ_0-samplers. An ℓ_0-sampler is a data structure that processes a dynamic stream (possibly containing duplicate items), succeeds with high probability, and conditioned on it succeeding, it returns a random item from the stream such that any item in the stream is chosen with the same probability $1/n$, where n is the ℓ_0 norm of the resulting frequency vector, i.e., the number of distinct items in the stream (see Lemma 3.7 for a more precise statement). For each sampled (rounded) point y, the algorithm in [27] runs a stochastic-stopping BFS from y and in particular, it checks if it explores the whole component of y within a random number of steps. We note that this requires an extended ℓ_0-sampler that also returns the neighboring points for each sampled point, as presented in [27] and stated in Lemma 3.7. The MST cost is estimated by a weighted sum of the number of completed BFS's, summed over all levels.

▶ **Lemma 3.7** (ℓ_0-Sampler with Neighborhood Information [27, Corollary 3]). *There is an algorithm that for $\delta > 0$, integer $\rho, \Delta \geq 1$, every set of points $S \subseteq [\Delta]^2$ presented as a dynamic geometric stream, succeeds with probability at least $1-\delta$ and, conditioned on it succeeding, returns a point $p \in S$ such that for every $s \in S$ it holds that $\Pr[p=s] = 1/|S|$. Moreover, if the algorithm succeeds, it also returns all points from $s \in S$ such that $\mathrm{dist}(p,s) \leq \rho$. The algorithm has space and both update and query times bounded by $\mathrm{poly}(\rho\cdot\varepsilon^{-1}\cdot\log\Delta\cdot\log\delta^{-1})$, and its memory contents is a linear sketch of S.*

Generalizing the MST Algorithm to Handle Subset Queries. Fix some part P_i. Recall that the P_i's always consist of at most $O(\varepsilon^{-2})$ cells (which are quad-tree squares), plus $O(\varepsilon^{-2})$ active portal points. Hence, a natural first attempt is to make the ℓ_0-samplers to sample only on these clipping squares defined by P_i. Unfortunately, this approach would not work, since the squares are not known in advance and may be very small (i.e., degenerate to a point), so sampling a point from them essentially solves the INDEX problem.

Therefore, to estimate $\mathrm{MST}(P_i)$, we still use the original ℓ_0-samplers, and we employ a careful sampling and estimation step. We sample from the whole point set maintained by the sketch $\mathcal{K}$ but we only keep the sampled points contained in P_i. We execute the stochastic BFS from these points that are kept, restricting the BFS to the points contained in P_i.

One outstanding problem of this sampling method is that if the number of points in P_i, or to be exact, the number of non-zero entries of level-i ℓ_0-samplers, is only a tiny portion of that of the full sketch, then with high probability, we do not sample any point from P_i at all. Hence, in this case, no stochastic BFS can be performed, and we inevitably answer 0 for the number of successful BFS's. This eventually leads to an additive error. We summarize the additive error and the whole idea of the above discussions in Lemma 3.8.

▶ **Lemma 3.8.** *There is an algorithm that for every $0 < \varepsilon < 1$, integer $k, \Delta \geq 1$, and every set of points $S \subseteq [\Delta]^2$ presented as a dynamic geometric stream, maintains a linear sketch of size $k^2 \cdot \mathrm{poly}(\log k \cdot \varepsilon^{-1} \log \Delta)$. For every query $(R, \{R_j\}_{j=1}^t, A)$ (provided after the stream ends) satisfying*

1. *R is a simple square, A is a subset of portals of R, and*
2. *$\{R_j\}_{j=1}^t \subseteq \mathsf{cell}(R)$,*

the algorithm computes from the linear sketch a real number E such that with probability at least $1 - \exp(-\log k \cdot \mathrm{poly}(\varepsilon^{-1} \log \Delta))$,

$$\mathrm{MST}(P) \leq E \leq (1+\varepsilon) \cdot \mathrm{MST}(P) + O\left(\frac{\mathrm{poly}(\varepsilon)}{k \log \Delta}\right) \cdot \mathrm{MST}(S)\,,$$

where $P = \left(\bigcup_{j=1}^t R_j\right) \cup A$. The algorithm runs in time $k^2 \cdot \mathrm{poly}(\log k \cdot \varepsilon^{-1} \log \Delta)$ per update and the query time is also $k^2 \cdot \mathrm{poly}(\log k \cdot \varepsilon^{-1} \log \Delta)$.

This lemma constitutes the main algorithm for the evaluation of the subproblem. Note that we only need to prove it for one point set S, since the sketch is linear. Indeed, when applying Lemma 3.8, we obtain the sketch for each color separately from the stream, and for every query, we first merge the sketches of colors relevant to the query and add query portals to the resulting sketch. By linearity, this is the same as if we obtain the sketch for all these colors and portals at once. Due to the space limit, the proof of Lemma 3.8 can be found in the full version.

3.3 Proof of Theorem 3.1

▶ **Theorem 3.1.** *For any integers $k, \Delta \geq 1$ and any $0 < \varepsilon < 1/2$, one can with high probability $(\alpha_2 + \varepsilon)$-approximate the SFP cost of an input $X \subseteq [\Delta]^2$ presented as a dynamic geometric stream, using space and update time of $k^3 \cdot \mathrm{poly}(\log k \cdot \varepsilon^{-1} \cdot \log \Delta)$ and with query time bounded by $k^3 \cdot \mathrm{poly}(\log k) \cdot (\varepsilon^{-1} \cdot \log \Delta)^{O(\varepsilon^{-2})}$.*

We combine the above building blocks to prove Theorem 3.1. See Algorithm 2 for a description of the complete algorithm. The space and update time follow immediately from Algorithm 2, Theorem 2.2 and Lemmas 3.4, 3.5, and 3.8.

The query time is bounded by $O(k \cdot \log \Delta) \cdot (\varepsilon^{-1} \cdot \log \Delta)^{O(\varepsilon^{-2})} \cdot \varepsilon^{-O(\varepsilon^{-1})} \cdot k^2 \cdot \mathrm{poly}(\log k \cdot \varepsilon^{-1} \log \Delta) \leq k^3 \cdot \mathrm{poly}(\log k) \cdot (\varepsilon^{-1} \log \Delta)^{O(\varepsilon^{-2})}$, where $O(k \cdot \log \Delta)$ is the number of simple squares (and thus, up to an $O(1)$ factor, the number of quad-tree squares for which we evaluate DP subproblems), $(\varepsilon^{-1} \cdot \log \Delta)^{O(\varepsilon^{-2})}$ is the number of subproblems associated with each square (see Section 2.1), $\varepsilon^{-O(\varepsilon^{-1})}$ is the number of MST queries evaluated for each subproblem, and each MST query takes $k^2 \cdot \mathrm{poly}(\log k \cdot \varepsilon^{-1} \log \Delta)$ time by Lemma 3.8.

[2] We need to use the same randomness for sketches $\{\mathcal{K}_C^{(3)}\}$ among all colors C so that they can be combined later.

Algorithm 2 Main streaming algorithm.

procedure SFPInitialization($\mathcal{C}$) ▷ $\mathcal{C}$ is the set of colors
  initialize a sketch $\mathcal{K}^{(1)}$ of Lemma 3.4, a set of sketches of Lemma 3.5 $\{\mathcal{K}^{(2)}_C\}_{C\in\mathcal{C}}$ for every color $C \in \mathcal{C}$ with parameter $\delta := \text{poly}(\varepsilon)(k \log \Delta)^{-1}$, and a set of (linear) sketches[2] of Lemma 3.8 $\{\mathcal{K}^{(3)}_C\}_{C\in\mathcal{C}}$ for every color $C \in \mathcal{C}$

procedure SFPUpdate(x, C, `insert/delete`) ▷ insert/delete point x of color C
  insert/delete point x in sketches $\mathcal{K}^{(1)}, \mathcal{K}^{(2)}_C, \mathcal{K}^{(3)}_C$

procedure SFPQuery ▷ the stream terminates
  use sketch $\mathcal{K}^{(1)}$ to compute a set of simple squares $\mathcal{R}$ ▷ see Section 3.2.1
  for each color $C \in \mathcal{C}$, use sketch $\mathcal{K}^{(2)}_C$ to compute a set of net points N_C, and let $D_C := \text{diam}(N_C)$ ▷ D_C is a $(1 \pm \varepsilon)$-approximation for $\text{diam}(C)$
  initialize a Boolean list $\mathcal{I}$ records whether a cell of a simple square and a color intersects ▷ This uses space at most $O(k \cdot \log \Delta \cdot \text{poly}(\varepsilon^{-1}))$
  for every $R \in \mathcal{R}$, $R' \in \mathsf{cell}(R)$ **do**
    if $\text{dist}(N_C, R') \le \rho \cdot D_C$ for some color C **then**
      let $x \in R'$ be a point such that $\text{dist}(x, N_C) \le \rho \cdot D_C$
      for every color C' with $\text{dist}(N_{C'}, R') \le \rho \cdot D_{C'}$ **do**
        add x to $\mathcal{K}^{(3)}_{C'}$ and record in $\mathcal{I}$ that R' intersects color C' ▷ see Section 3.2.2
  for each simple square R and an associated subproblem (R, A, f, Π) **do**
    for each partition of $\mathsf{cell}(R)$ **do**
      if the partition is compatible with the subproblem **then** ▷ see Section 3.2.2
        for each part R_j in the partition **do**
          let $A_j \subseteq A$ be the set of active portals that R_j connects to
          create linear sketch $\mathcal{K}'$, by adding up $\mathcal{K}^{(3)}_C$ for every C intersecting a cell in R_j ▷ the intersection information is recorded in $\mathcal{I}$
          add points in A_j to sketch $\mathcal{K}'$
          query sketch $\mathcal{K}'$ for the value of the MST of the part R_j and portals A_j (as in Lemma 3.8) ▷ see Section 3.2.3
        store the sum of the queried values of $\text{MST}(R_j, A_j)$ as the estimated cost for the subproblem
  invoke the DP (as in [11]) using the values of basic subproblem estimated as above
  return the DP value (for the root square with no active portals)

To bound the failure probability, we use a union bound over the failure probabilities of all applications and queries of the streaming algorithms as well as the error bound in Theorem 2.2. We observe that Theorem 2.2 incurs an $O(1)$ failure probability, and every other steps, except for the use of Lemma 3.8, have a failure probability of $\text{poly}(\Delta^{-1})$. Since we have $k \cdot (\varepsilon^{-1} \cdot \log \Delta)^{O(\varepsilon^{-2})}$ basic subproblems (see Section 2), and for each basic subproblem we need to evaluate at most $\varepsilon^{-O(\varepsilon^{-1})}$ MST queries, the total failure probability of evaluating the subproblems is at most

$$k \cdot (\varepsilon^{-1} \cdot \log \Delta)^{O(\varepsilon^{-2})} \cdot \varepsilon^{-O(\varepsilon^{-1})} \cdot \exp(-\log k \cdot \text{poly}(\varepsilon^{-1} \log \Delta)) \le \text{poly}(\Delta^{-1}),$$

by the guarantee of Lemma 3.8. Therefore, we conclude that the failure probability is then at most $\frac{2}{3}$. It remains to analyze the error.

Error Analysis. For the remaining part of the analysis, we condition on no failure of the sketches used in Algorithm 2 and on that the error bound in Theorem 2.2 holds. By Lemma 3.6, for the part of evaluating the basic subproblems (lines 14-22 of Algorithm 2), the actual instance that the linear sketches work on is $(1+O(\varepsilon))$-approximate. Hence, it suffices to show the DP value is accurate to that instance.

Our estimation is never an underestimate, by Lemma 3.8 and since all partitions that we enumerated are compatible with the subproblems; see Section 3.2.2. Hence, it remains to upper bound the estimation. Consider an optimal DP solution F, which we interpret as a metric graph (see Section 2). Then we create a new solution F' from F by modifying F using the following procedure. For each simple square R, we consider $F|_R$ which is the portion of F that is totally inside of R (see Section 2). For each component $S \subset R$ in $F|_R$, let S' be the point set formed by removing all Steiner points from S, except for portals of R (note that we remove portals of subsquares of R if they appear in S). Then, for each component S, we replace the subtree in F that spans S with the MST on S'. It is immediate that after the replacement, the new solution has the same connectivity of portals and terminal points as before. We define F' as the solution after doing this replacement for all simple squares.

F' is still a feasible solution. Furthermore, for every simple square R, if F is compatible with a subproblem (R, A, f, Π), then so does F'. By the construction of F', the definition of Steiner ratio α_2, and Theorem 2.2, we know that

$$w(F') \le \alpha_2 \cdot w(F) \le (1+O(\varepsilon)) \cdot \alpha_2 \cdot \mathrm{OPT}, \tag{1}$$

where the last inequality holds as we condition on that the error bound in Theorem 2.2 holds.

Now we relate the algorithm's cost to $w(F')$. Fix a simple square R, and suppose (R, A, f, Π) is the subproblem that is compatible with $F'|_R$. Then, the components in $F'|_R$ can be described by a partition of the cells plus their connectivity to active portals. Such a subproblem, together with the partition, must be examined by Algorithm 2 (in lines 14-22), and the MST value for each part is estimated in Algorithm 2. Since the algorithm runs a DP using the estimated values, the final DP value is no worse than the DP value that is only evaluated from the subproblems that are compatible to F'. Recall that our estimation for each subproblem not only has a multiplicative error of $(1+\varepsilon)$ but also an additive error by Lemma 3.8. Therefore, by the fact that F' always uses MST to connect points in components of basic subproblems, it suffices to bound the *total* additive error for the estimation of the MST cost of the components of F'.

Fix a connected (global) component Q of F', and let $\mathcal{C}_Q \subseteq \mathcal{C}$ be the subset of colors that belongs to Q. By Lemma 3.8, for every basic subproblem (R, f, A, Π) that is compatible with F', and every component P of $Q|_R$, the additive error is at most $O\left(\frac{\mathrm{poly}(\varepsilon)}{k \log \Delta}\right) \cdot \mathrm{MST}(S)$, where S is the union of color classes that intersect P plus the active portals A. Observe that $\mathcal{C}_S \subseteq \mathcal{C}_Q$ (where $\mathcal{C}_S$ is the set of colors used in S), so S is a subset of the point set of Q (note that Q contains all portals in A as F' is a portal-respecting solution and the subproblem is compatible with F') and thus $\mathrm{MST}(S) \le \mathrm{MST}(Q)$, which implies

$$O\left(\frac{\mathrm{poly}(\varepsilon)}{k \log \Delta}\right) \cdot \mathrm{MST}(S) \le O\left(\frac{\mathrm{poly}(\varepsilon)}{k \log \Delta}\right) \cdot \mathrm{MST}(Q) \le O\left(\frac{\mathrm{poly}(\varepsilon)}{k \log \Delta}\right) \cdot w(Q).$$

Observe that for each simple square R, $Q|_R$ has at most $O(\varepsilon^{-2})$ local components, hence, summing over all local components of $Q|_R$ and all simple squares R, the total additive error is bounded by $\mathrm{poly}(\varepsilon^{-1}) \cdot O(k \log \Delta) \cdot O\left(\mathrm{poly}(\varepsilon)/(k \log \Delta)\right) \cdot w(Q) \le \varepsilon \cdot w(Q)$, where use that there are at most $O(k \log \Delta)$ simple squares by Lemma 3.3. Finally, summing over all components Q of F', we conclude that the total additive error is $\varepsilon \cdot w(F')$. Combining with Equation (1), we conclude the error guarantee. This finishes the proof of Theorem 3.1.

4 Lower Bound: $\Omega(k)$ Bits are Necessary

In this section we demonstrate that any streaming algorithm for SFP achieving any finite approximation ratio for SFP requires $\Omega(k)$ bits of space.

▶ **Theorem 4.1.** *For every $k > 0$, every randomized streaming algorithm achieving a finite approximation ratio for SFP with k color classes of size at most 2 must require $\Omega(k)$ bits of space. This holds even for insertion-only algorithms and even when points are from the one-dimensional line $\mathbb{R}$.*

Proof. The proof is a reduction from the INDEX problem on k bits, where Alice holds a binary string $x \in \{0,1\}^k$, and Bob has an index $i \in [k]$. The goal of Bob is to compute the bit x_i in the one-way communication model, where only Alice can send a message to Bob and not vice versa. It is well-known that Alice needs to send $\Omega(k)$ bits for Bob to succeed with constant probability [41] (see also [42, 39]). Our reduction is from INDEX to SFP on the (discretized) one-dimensional line $[2k]$. Consider a randomized streaming algorithm ALG for SFP that approximates the optimal cost and in particular can distinguish whether the optimal cost is 0 or 1 with constant probability. We show that it can be used to solve the INDEX problem, implying that ALG needs to use $\Omega(k)$ bits of space.

Indeed, Alice applies ALG on the following stream: For each bit x_j, she adds to the stream a point of color j at location $2j + x_j$. So far $\mathrm{OPT} = 0$. She now sends the internal state of ALG to Bob. Then, Bob continues the execution of ALG (using the same random coins) by adding one more point to the stream: Given his index $i \in [k]$, he adds a point of color i at location $2i$. After that, $\mathrm{OPT} = 0 + x_i$, which is either 0 or 1. It follows that if ALG achieves a finite approximation with constant probability, then Bob can discover x_i and solve INDEX. ◀

5 Conclusions and Future Directions

Our paper makes a progress in the understanding of geometric streaming algorithms and of applicability of Arora's framework for low-space streaming algorithms for geometric optimization problems. Still, our work leaves a number of very interesting open problems.

Our approximation ratio $\alpha_2 + \varepsilon$ matches the current approximation ratio for the Steiner tree problem in geometric streams. Hence, any improvement to our approximation ratio would require to first improve the approximation for Steiner tree, even in insertion-only streams. This naturally leads to the main open problem of obtaining a $(1+\varepsilon)$-approximation for Steiner tree in geometric streams using only $\mathrm{poly}(\varepsilon^{-1} \log \Delta)$ space.

Our naïve algorithm for the Steiner forest problem given in Theorem 1.2 is also an $(\alpha_2 + \varepsilon)$-approximation with $\mathrm{poly}(k\varepsilon^{-1} \log \Delta)$ space, but its running time is exponential in k because it queries an (approximate) MST-value oracle on all possible subsets of color classes to find the minimum. We do not know if a smaller number of queries suffices here, but it is known that in a similar setup for coverage problems any oracle-based $O(1)$-approximation requires exponentially many queries to an approximate oracle [10]. Thus, it would not be surprising if a similar lower bound holds for our problem.

Our Theorem 4.1 shows that for SFP with color classes of size at most 2 one cannot achieve any bounded approximation ratio using space that is sublinear in $n \le 2k$. This strongly suggests that SFP with pairs of terminals (i.e., $C_i = \{s_i, t_i\}$) does not admit a constant-factor approximation in the streaming setting, although our lower bound construction does not extend to this case (as it requires having some size-1 color classes). We leave it as an open problem whether a constant-factor approximation in sublinear (in $n = 2k$) space is possible

for this version. We notice however that for the case where both points of each terminal pair are inserted/deleted together, it is possible to get an $O(\log n)$-approximation using the metric embedding technique of Indyk [36].

The main focus of this paper is on the study of SFP for the Euclidean plane, but in principle, our entire analysis can be extended to the Euclidean space $\mathbb{R}^d$, for any fixed $d \geq 2$. However, this would require extending the arguments of [11, 14], namely, the structural result restated in Theorem 2.2, and these details were not written explicitly in these papers.

The techniques developed in this paper seem to be general enough to be applicable to other problems/objectives with *connectivity constraints*, where the connectivity is specified by the colors and a solution is feasible if the points of the same color are connected. One such closely related problem is the sum-of-MST objective, i.e., the problem of minimizing the sum of the costs of trees such that points of the same color are in the same tree (see also [2, 53] for related problems). We hope that the approach developed in our paper can lead to a $(1+\varepsilon)$-approximation of the geometric version of this problem, using $\mathrm{poly}(k\varepsilon^{-1}\log\Delta)$ space and time (for space only, one can use similar techniques as in Theorem 1.2). Moreover, it may be possible to apply our approach to solve the connectivity-constrained variants of other classical problems, especially those where dynamic programming has been employed successfully, like r-MST and TSP [7]. For example, the TSP variant could be to find a collection of cycles of minimum total length with points of the same color in the same cycle.

At a higher level, the connectivity constraints may be more generally interpreted as grouping constraints. For instance, in the context of clustering, our color constraints may be viewed as *must-link* constraints, where points of the same color have to be placed in the same cluster. Such constrained clustering framework is of significant interest in data analysis (see, e.g., [52]). Our framework, combined with coreset techniques [28] and Arora's quad-tree methods (see [8]), may be used to design streaming algorithms for such clustering problems.

Finally, we believe that the framework of optimization problems with connectivity and grouping constraints is interesting on its own, going beyond the streaming setup. Such problems may be studied also in the setting of standard (offline) algorithms, as well as of online algorithms, approximation algorithms, fixed-parameter tractability, and heuristics.

Abstract

Embedding graphs in a geographical or latent space, i.e. inferring locations for vertices in Euclidean space or on a smooth manifold or submanifold, is a common task in network analysis, statistical inference, and graph visualization. We consider the classic model of random geometric graphs where n points are scattered uniformly in a square of area n, and two points have an edge between them if and only if their Euclidean distance is less than r. The reconstruction problem then consists of inferring the vertex positions, up to the symmetries of the square, given only the adjacency matrix of the resulting graph. We give an algorithm that, if $r = n^\alpha$ for $\alpha > 0$, with high probability reconstructs the vertex positions with a maximum error of $O(n^\beta)$ where $\beta = 1/2 - (4/3)\alpha$, until $\alpha \geq 3/8$ where $\beta = 0$ and the error becomes $O(\sqrt{\log n})$. This improves over earlier results, which were unable to reconstruct with error less than r. Our method estimates Euclidean distances using a hybrid of graph distances and short-range estimates based on the number of common neighbors. We extend our results to the surface of the sphere in $\mathbb{R}^3$ and to hypercubes in any constant dimension.

1 Introduction

Graph embedding is the art of assigning a position in some smooth space to each vertex, so that the graph's structure corresponds in some way to the metric structure of that space. If vertices with edges between them are geometrically close, this embedding can help us predict new or unobserved links, devise efficient routing strategies, and cluster vertices by similarity – not to mention (if the embedding is in two dimensions) give us a picture of the graph that we can look at and perhaps interpret. In social networks, this space might correspond literally to geography, or it might be a "latent space" whose coordinates measure

ideologies, affinities between individuals, or other continuous demographic variables (e.g. [15]). In some applications the underlying space is known; in others we wish to infer it, including the number of dimensions, whether it is flat or hyperbolic, and so on.

The literature on graph embedding is vast, and we apologize to the many authors who we will fail to cite. However, despite the broad utility of graph embedding in practice (see [27] for a recent experimental review) many popular heuristics lack rigorous guarantees. Here we pursue algorithms that reconstruct the position of every vertex with high accuracy, up to a symmetry of the underlying space.

Many versions of the reconstruction problem, including recognizing whether a graph has a realization as a geometric graph, are NP-complete [5, 8, 9] in the worst case. Thus we turn to distributions of random instances, and design algorithms that succeed with high probability in the instance. For many inference problems, there is a natural generative model where a ground truth structure is "planted," and the instance is then chosen from a simple distribution conditioned on its planted structure. For community detection a.k.a. the planted partition problem, for instance, we can consider graphs produced by the stochastic block model, a generative model where each vertex has a ground-truth label, and each edge (u, v) exists with a probability that depends on the labels of u and v. Reconstructing these labels from the adjacency matrix then becomes a well-defined problem in statistical inference, which may or may not be solvable depending on the parameters of the model (e.g. [1,19,20]). In the same spirit, a series of papers has asked to what extent we can reconstruct vertex positions from the adjacency matrix in random geometric graphs, where vertex positions are chosen independently from a simple distribution.

Random geometric graphs

Let n be an integer and let $r > 0$ be real. Let $V = \{v_i\}_{i=1}^n$ be a set of n points chosen uniformly at random in the square $[0, \sqrt{n}]^2$. The *random geometric graph* $G \in \mathcal{G}(n, r)$ has vertex set V and edge set $E = \{(u, v) : \|u - v\| \leq r\}$ where $\|u - v\|$ denotes the Euclidean distance. (We will often abuse notation by identifying a vertex with its position.)

This is a rescaling of the *unit disk model* where $r = 1$. We follow previous authors in varying the average degree of the graph by varying r rather than varying the density of points in the plane. Since the square has area n, the density is always 1: that is, the expected number of points in any measurable subset is equal to its area.

It is also natural to consider a Poisson model, where the points are generated by a Poisson point process with intensity 1. In that case the number of vertices fluctuates but is concentrated around n, and the local properties of the two models are asymptotically the same. The number of points in a region of area A is binomially distributed in the uniform model, and Poisson distributed with mean A in the Poisson model. In both cases, the probability that such a region of area is empty is at most e^{-A}; this is exact in the Poisson model, and is an upper bound on the probability $(1 - A/n)^n$ in the uniform model.

Random geometric graphs (RGGs) were first introduced by Gilbert in the early 1960s to model communications between radio stations [14]. Since then, RGGs have been widely used as models for wireless communication, in particular for wireless sensor networks. RGGs have also been extensively studied as mathematical objects, and much is known about their asymptotic properties [23, 26]. One well-known result is that $r_c = \sqrt{\log n/\pi}$ is a *sharp threshold* for connectivity for $G \in \mathcal{G}(n, r)$ in the square in both the uniform and Poisson models: that is, for any $\varepsilon > 0$, with high probability G is connected if $r > (1 + \varepsilon)r_c$ and disconnected if $r < (1 - \varepsilon)r_c$.

More generally, we can define RGGs on any compact Riemannian submanifold, by scattering n points uniformly according to the surface area or volume. We then define the edges as $E = \{(u, v) : \|u - v\|_g \leq r\}$ where $\|\cdot\|_g$ is the geodesic distance, i.e. the arc length of the shortest geodesic between u and v. On the sphere in particular this includes the cosine distance, since $\|u - v\|_g$ is a monotonic function of the angle between u and v.

The reconstruction problem

Given the adjacency matrix A of a random geometric graph defined on a smooth submanifold M, we want to find an embedding $\phi : V \to M$ which is as close as possible to the true positions of the vertices. As a measure of accuracy, we focus on the max distance $\max_v \|\phi(v) - v\|$ where we identify each vertex v with its true position.

However, if we are only given A, the most we can ask is for ϕ to be accurate up to M's symmetries. In the square, for instance, applying a rotation or reflection to the true positions results in exactly the same adjacency matrix. Thus we define the *distortion* $d^*(\phi)$ as the minimum of the maximum error achieved by composing ϕ with some element of the symmetry group $\mathrm{Sym}(M)$,

$$d^*(\phi) = \min_{\sigma \in \mathrm{Sym}(M)} \max_{v \in V} \|(\sigma \circ \phi)(v) - v\| . \tag{1}$$

We will sometimes refer to the distortion of a subset of the vertices or of a single vertex.

As in previous work, our strategy is to estimate the distances between pairs of vertices, and then use geometry to find points with those pairwise distances. We focus on the case where $M = [0, \sqrt{n}]^2$ and $\|\cdot\|$ is the Euclidean distance. However, many of our results apply more generally, both in higher dimensions and on curved manifolds.

Our contribution

An intuitive way to estimate the Euclidean distance $\|u - v\|$ in a random geometric graph is to relate it to the graph distance $d_G(u, v)$, i.e. the number of edges in a topologically shortest path from u to v. The upper bound $\|u - v\| \leq r d_G(u, v)$ is obvious. Moreover, if the graph is dense enough, then shortest paths are fairly straight geometrically and most of their edges have Euclidean length almost r, and this upper bound is not too far from the truth [4, 7, 13, 21].

As far as we know, the best upper and lower bounds relating Euclidean distances to graph distances in RGGs are given in [12]. In [11] these bounds were used to reconstruct with distortion $(1 + o(1))r$ when r is sufficiently large, namely if $r = n^\alpha$ for some $\alpha > 3/14$.

However, since the graph distance d_G is an integer, the bound $\|u - v\| \leq r d_G(u, v)$ cannot distinguish Euclidean distances that are between two multiples of r. Thus, as discussed after the statement of Theorem 4 below, the methods of [11] cannot avoid a distortion that grows as $\Omega(r)$. Intuitively, the opposite should hold: as r grows the graph gets denser, neighborhoods get smoother, and more precise reconstructions should be possible.

We break this $\Omega(r)$ barrier by using a hybrid distance estimate. First we note that $r d_G(u, v)$ is a rather good estimate of $\|u - v\|$ if $\|u - v\|$ is just below a multiple of r, and we improve the bounds of [12] using a greedy routing analysis. We then combine $r d_G$ with a more precise short-range estimate based on the number of neighbors that u and v have in common. In essence, we use a quantitative version of the popular heuristic that two vertices are close if they have a large Jaccard coefficient (see e.g. [24] for link prediction, and [2] for a related approach to small-world graphs).

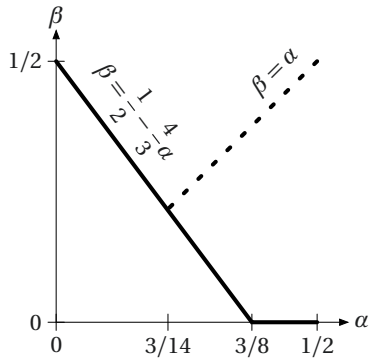

Figure 1 Our results (solid) compared to those of [11] (dotted). If $r = n^\alpha$, our reconstruction has distortion $O(n^\beta)$ where $\beta = 1/2 - (4/3)\alpha$, except for $\alpha > 3/8$ where the distortion is $O(\sqrt{\log n})$. The algorithm of [11] applies when $\alpha > 3/14$ and gives $\beta = \alpha$, i.e. distortion $\Theta(r)$. Our results apply for any constant $0 < \alpha < 1/2$ and give lower distortion than [11] when $\alpha > 3/14$.

As a result, we obtain a distortion d^* that decreases with r. Namely, if $r = n^\alpha$ for $\alpha > 0$, then $d^* = O(n^\beta)$ where $\beta = 1/2 - (4/3)\alpha$, until for $\alpha \geq 3/8$ where $d^* = O(\sqrt{\log n})$. (Note that any $\alpha > 0$ puts us well above the connectivity threshold.) Since it uses graph distances, the running time of our algorithm is essentially the same as that of All-Pairs Shortest Paths. To our knowledge, this is the smallest distortion achieved by any known polynomial-time algorithm. We compare our results with those of [11] in Figure 1.

We show that our results extend to higher dimensions and to some curved manifolds as well. With small modifications, our algorithm works in the m-dimensional hypercube for any fixed m (the distortion depends on m, but the running time does not). We also sketch a proof that it works on the surface of the sphere, using spherical rather than Euclidean geometry, solving an open problem posed in [11]. Our techniques are designed to be easy to apply on a variety of curved manifolds and submanifolds, although we leave the fullest generalizations to future work.

We use $N(u) = \{w : (u, w) \in E\}$ to denote the topological neighborhood of a vertex u, and $B(u, r)$ to denote the geometrical ball around it. Our results, as well as many of the cited results, hold *with high probability* (w.h.p.) in the random instance $G \in \mathcal{G}(n, r)$, i.e. with probability tending to 1 as $n \to \infty$. When we consider randomized algorithms, the probability is over both $\mathcal{G}(n, r)$ and the randomness of the algorithm.

Other related work

In the statistics community there are a number of consistency results for maximum-likelihood methods (e.g. [25]) but it is not clear how the accuracy of these methods scales with the size or density of the graph, or how to find the maximum-likelihood estimator efficiently. There are also results on the convergence of spectral methods, using relationships between the graph Laplacian and the Laplace-Beltrami operator on the underlying manifold (e.g. [3]). This approach yields bounded distortion for random dot-product graphs in certain regimes.

We assume that parameters of the model are known, including the underlying space and its metric structure (in particular, its curvature and the number of dimensions). Thus we avoid questions of model selection or hypothesis testing, for which some lovely techniques have been proposed (e.g. [10, 18, 22]). We also assume that the parameter r is known, since this is easy to estimate from the typical degree.

Organization of the extended abstract

In Section 2 we define the concept of a *deep* vertex. Intuitively, a vertex is deep if it is more than r from the boundary of the square, so that its ball of potential neighbors is entirely in the interior. However, since we are only given the adjacency matrix, we base our definition on the number of vertices two steps away from v in the graph, and show that these topological and geometric properties are closely related.

Section 3 shows that we can closely approximate Euclidean distances $\|u - v\|$ given the adjacency matrix whenever v is deep. We do this in two steps: we give a precise short-range estimate of $\|u - v\|$ when $d_G(u, v) \leq 2$, and a long-range estimate that uses the existence of a greedy path. By "hybridizing" these two distance estimates, switching from long to short range at a carefully chosen intermediate point, we obtain a significantly better estimate of $\|u - v\|$ than was given in [12]. We believe these distance estimation techniques may be of interest in themselves.

In Section 4, we use this new estimate of Euclidean distant to reconstruct the vertex positions up to a symmetry of the square, by starting with a few deep "landmarks" and then triangulating to the other vertices. This gives smaller distortion than the algorithm in [11], achieving the scaling shown in Figure 1.

Finally, in Section 5 we extend our method to random geometric graphs in the m-dimensional hypercube and on the surface of the sphere.

Due to space limitation, in this extended abstract, we limit ourselves to sketching the proofs and their main ideas, deferring the complete proofs to the full version of the paper, available on ArXiv: `https://arxiv.org/abs/2107.14323`

2 Deep vertices

Let G be a random geometric graph defined in the two-dimensional square $[0, \sqrt{n}]^2$. Because some of our arguments will break down for vertices near the boundary and corners of $[0, \sqrt{n}]^2$, it will be useful to have an easy way to tell these vertices apart from the rest. To this end, we introduce the notion of deep vertices.

▶ **Definition 1.** Let r be fixed. We say that a vertex $v \in V$ is *deep* if at least $11r^2$ vertices have graphical distance 2 or less from v.

Note that being deep is a topological property of the graph, rather than its embedding in the plane. We need such a definition since our reconstruction algorithm is only given access to the adjacency matrix. However, in the long version we show that with high probability all vertices that are deep in this topological sense are at least r from the boundary of the square. Moreover, with high probability there are many deep vertices.

3 Estimating Euclidean distances: Breaking the $\Omega(r)$ barrier

3.1 Estimating short-range distances

In this section we show how to estimate the Euclidean distance $\|u - v\|$ between two vertices that are topologically close, namely when $d_G(u, v) \leq 2$.

We first assume that $d_G(u, v) = 1$, i.e., that $\|u - v\| = x$ where $0 \leq x \leq r$. Then $\{N(v) \setminus N(u)\}$ consists of the points in the lune $L = B(v, r) \setminus B(u, r)$ shown in Figure 2. If v is deep, then $B(v, r)$ and therefore L lies in the interior of the square $[0, \sqrt{n}]^2$. Thus in expectation $|\{N(v) \setminus N(u)\}|$ is the area of L, which we denote $F(x)$. This suggests inverting F, estimating x as

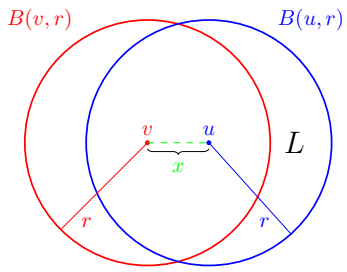

Figure 2 We can estimate the Euclidean distance $\|u-v\| = x$ of two vertices with $d_G(u,v) \le 2$ using the area of the lune $L = B(u,r) \cap B(v,r) \neq \emptyset$. Denoting this area $F(x)$, we can estimate x by appling the inverse F^{-1} to the number of points in $N(v) \setminus N(u)$.

$$\tilde{d}(u,v) = F^{-1}\left(|N(v) \setminus N(u)|\right) . \tag{2}$$

Since F is monotonic and is given explicitly as $F(x) = \pi r^2 - 2r^2 \arccos \frac{x}{2r} + \frac{x}{2}\sqrt{4r^2 - x^2}$, we can compute this inverse using binary search.

This estimate is w.h.p. an accurate estimate of $\|u-v\|$ for two reasons. First, $|\{N(v) \setminus N(u)\}|$ is concentrated around its expectation $F(x)$. In both the uniform and the Poisson models, with high probability we have

$$\Big||\{N(v) \setminus N(u)\}| - F(x)\Big| \le \sqrt{F(x)\log n}\,.$$

Second, the derivative of F is large, so the derivative of F^{-1} is small. Specifically, since $F(x)$ satisfies the differential equation $F'(x) = \sqrt{4r^2 - x^2}$, we have $F'(x) \ge r\sqrt{3} = \Omega(r)$ for $0 < x < r$. Noting also that $F(x) = \Theta(xr)$, we obtain

$$\left|x - \tilde{d}(u,v)\right| \le \frac{\sqrt{F(x)\log n}}{F'(x)} = O\left(\sqrt{\frac{x\log n}{r}}\right) . \tag{3}$$

If $d_G(u,v) = 2$ in which case $r < x < 2r$, we switch from the difference in the two neighborhoods to their intersection $N(u) \cap N(v)$, namely the points in the lens-shaped region $B(u,r) \cap B(v,r)$ in Figure 2 which has area $\pi r^2 - F(x)$. As $x \to 2r$ the area of this region tends to zero, but so does $F'(x)$. Specifically, if $x = 2r - \varepsilon$ then

$$\pi r^2 - F(x) = \Theta(r^{1/2}\varepsilon^{3/2}) \quad \text{and} \quad F'(x) = \Theta(r^{1/2}\varepsilon^{1/2})\,,$$

so (3) becomes

$$\left|x - \tilde{d}(u,v)\right| = O\left(\frac{\sqrt{r^{1/2}\,\varepsilon^{3/2}\log n}}{r^{1/2}\,\varepsilon^{1/2}}\right) = O\left(\left(\frac{\varepsilon}{r}\right)^{1/4}\sqrt{\log n}\right) . \tag{4}$$

Putting this all together gives the main theorem of the section,

▶ **Theorem 2.** *Given a $G \in \mathcal{G}(n,r)$, where $r \ge 100\sqrt{\log n}$. With probability at least $1 - 2/n^2$ we have, for all vertices $v \neq w$ such that $d_G(v,w) \le 2$ and v is deep,*

$$\left|\|v-w\| - \tilde{d}(v,w)\right| \le 100\eta(\|v-w\|)\sqrt{\log n}\,, \tag{5}$$

where $\eta : [0, 2r] \to [0, 1]$ *is defined by*

$$\eta(x) = \begin{cases} \frac{\sqrt{\log n}}{r} & \text{for } 0 \le x \le \frac{\log n}{r}, \\ \sqrt{\frac{x}{r}} & \text{for } \frac{\log n}{r} \le x \le r, \\ \left(\frac{2r-x}{r}\right)^{1/4} & \text{for } r \le x \le 2r - \frac{(\log n)^{2/3}}{r^{1/3}}, \\ \frac{(\log n)^{1/6}}{r^{1/3}} & \text{for } 2r - \frac{(\log n)^{2/3}}{r^{1/3}} \le x \le 2r. \end{cases}$$

3.2 Estimating long-range distances

Next we show a fairly tight relationship between geometric and topological distance for all pairs of vertices, including distant ones. This is a slightly sharper version of [12, Thm 1.1]. The main difference is that, where before, a short path between two given vertices is found by finding vertices close to a straight line between the endpoints, our proof instead analyses a greedy algorithm generating a path that may deviate further from the straight line.

We start with the following geometrical lemma

▶ **Lemma 3.** *Let* $B_1(v, r_1)$ *and* $B_1(u, r_2)$ *be overlapping balls in* $\mathbb{R}^2$*, and let* $d = \|u - v\|$*. Consider the lens* $L = B_1 \cap B_2$*. Let* δ *denote the width of* L*, i.e.,* $\delta = r_1 + r_2 - d$*. Then the area* A *of* L *satisfies*

$$A = \Theta\left(\delta^{3/2} \min\{r_1, r_2\}^{1/2}\right).$$

The main result of this section is the following theorem,

▶ **Theorem 4.** *Let* $G \in \mathcal{G}(n, r)$*. There exist absolute constants* C_1, C_2, C_3 *such that, for all* $n \ge 1$ *and all* $r \ge C_1\sqrt{\log n}$*, with probability at least* $1 - C_2/n^2$*, all pairs of vertices* u, v *satisfy*

$$\left\lceil \frac{\|u - v\|}{r} \right\rceil \le d_G(u, v) \le \left\lceil \frac{\|u - v\| + \kappa}{r} \right\rceil, \tag{6}$$

where

$$\kappa = \kappa(\|u - v\|) = C_3 \left(\frac{\|u - v\|}{r^{4/3}} + \frac{\log n}{r^{1/3}} \right). \tag{7}$$

The lower bound of (6) is trivial. The gist of the upper bound is to show the existence of a short path $u \rightsquigarrow v$ using a greedy routing algorithm that moves as close as possible, in Euclidean distance, to v at each step. (Note that this is only for the purpose of analysis, since our reconstruction algorithm is only given the adjacency matrix!) Start from $x_0 = u$. Then for each $i \ge 0$, let x_{i+1} be the neighbor of x_i that minimizes $\|x_i - v\|$ as shown in Fig. 3 (note that x_{i+1} is unique with probability 1). The algorithm terminates if no neighbor of x_i is closer to v than x_i is. If $x_i = v$, we have found our path and the algorithm succeeds. Otherwise, the algorithm has gotten stuck in a local minimum, and never reaches v.

Then in the full version we prove that the algorithm succeeds with probability $1 - O(n^{-3})$. Moreover, with the help of Lemma 3, we can show that each step gets about $r - O(r^{-1/3})$ closer to v. This yields the upper bound of (6), and taking a union bound over all pairs u, v completes the proof. ⌟

Let us discuss how we will use Theorems 2 and 4 to break the $\Omega(r)$ barrier in distance estimation, and thus in reconstruction. Suppose $r = n^\alpha$ where $0 < \alpha < 1/2$ is a constant. Then since $\|u - v\| = O(n^{1/2})$, we have from (7)

$$\kappa = O\left(\max\left(n^{\frac{1}{2} - \frac{4}{3}\alpha}, n^{-\frac{1}{3}\alpha} \log n\right)\right), \tag{8}$$

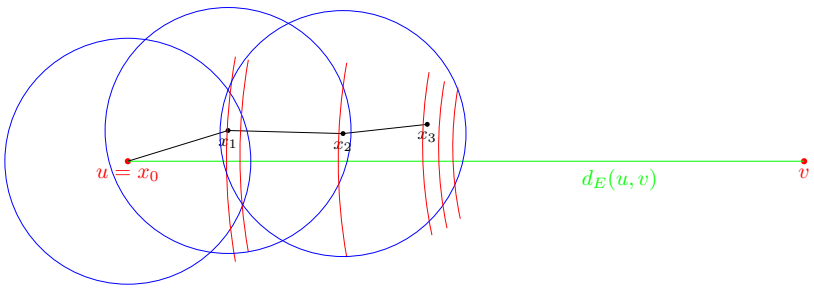

Figure 3 The greedy routing analysis of Theorem 4. At each step we go from x_i to the neighbor x_{i+1} closest to v. In the analysis, we consider the intersections of x_i's neighborhood with balls centered at v, with the radii of the latter chosen so that these intersections have area $\ln 2$, $2\ln 2$, $3\ln 2$, and so on. Each of these intersections contains a point with constant probability, so that most steps make significant progress towards v.

and since $\frac{1}{2} - \frac{4}{3}\alpha > -\frac{1}{3}\alpha$ we have

$$\kappa = O(n^\beta)\,, \quad \text{where} \quad \beta = \frac{1}{2} - \frac{4}{3}\,\alpha\,. \tag{9}$$

If $\alpha > 3/14$, then $\beta < \alpha$ and $\kappa = o(r)$. In this case the upper and lower bounds on $d_G(u,v)$ differ by at most 1, and moreover are equal for most pairs of vertices, making $d_G(u,v)$ a nearly-deterministic function of $\|u-v\|$. Using $\lceil x \rceil \le x+1$ and multiplying through by r gives the bounds

$$d_G(u,v)r - (r+\kappa) \le \|u-v\| \le d_G(u,v)r\,,$$

so that $d_G(u,v)r$ is an estimate of $\|u-v\|$ with error $r+\kappa = (1+o(1))r$. Previous work [11,12] used essentially this bound to reconstruct the graph with a distortion of $(1+\varepsilon)r$ for arbitrarily small constant ε. This gives the performance shown by the dotted line in Figure 1.

But in fact $d_G(u,v)r$ is a much more accurate estimate of $\|u-v\|$ for certain pairs of vertices. If $\|u-v\|$ is just below a multiple of r, then rounding up the left and right sides of (6) doesn't change either very much. We state this with in the following corollary,

▶ **Corollary 5.** *With $\kappa = \kappa(\|u-v\|)$ defined as in (7), suppose that for some $0 \le \delta < r$ and some integer $t \ge 0$ we have $tr - (\kappa+\delta) < \|u-v\| < tr - \kappa$. Then*

$$d_G(u,v)r - (\kappa+\delta) \le \|u-v\| \le d_G(u,v)r\,. \tag{10}$$

Thus, if $\|u-v\|$ is in one of these intervals, Theorem 4 lets us estimate $\|u-v\|$ from the adjacency matrix with error $\delta+\kappa$ instead of $r+\kappa$. Below we will combine this with the more precise estimate of short-range distances from Theorem 2 to achieve this error for all pairs u, v where v is deep, not just those for which $\|u-v\|$ is almost a multiple of r.

As a result, the error in our distance estimates and the distortion of our reconstruction is $O(r^\beta)$ where β decreases from 1 to 0 as α increases as shown by the solid line in Figure 1. Specifically, we obtain a nontrivial result for any $\alpha > 0$ and a more accurate reconstruction than in [11] in the range $\alpha > 3/14$ where their theorem applies. At $\alpha = 3/8$ where $\beta = 0$ another source of error takes over, leaving us with $O(\sqrt{\log n})$ distortion.

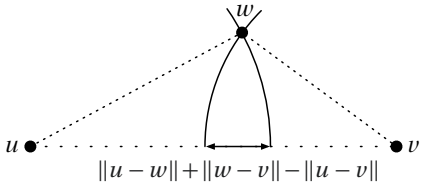

Figure 4 For any intermediate point w, the hybrid distance estimate $d_1(u,w) + d_2(w,v)$ is an upper bound on $||u - v||$ with error bounded by Lemma 8.

3.3 Hybrid distance estimates

In this subsection we combine the long-range estimates of Theorem 4 with the short-range estimates in Theorem 2, to estimate Euclidean distances with an error of $o(n)$. We start with the following definition:

▶ **Definition 6.** *Let $V \subset \mathbb{R}^2$ and $d : V^2 \to [0,\infty)$ and $\varepsilon : \mathbb{R} \to [0,\infty)$ be two functions satisfying, for all $u, v \in V$, $d(u,v) - \varepsilon(u,v) \le \|u - v\| \le d(u,v)$. Then we say d is an upper bound on Euclidean distance with error function ε.*

The basic tool for combining distance estimates is the following lemma.

▶ **Lemma 7.** *If d_1 and d_2 are upper bounds on Euclidean distance with error functions $\varepsilon_1, \varepsilon_2$ respectively, then $\min\{d_1, d_2\}$ is an upper bound on Euclidean distance with error $\min\{\varepsilon_1, \varepsilon_2\}$.*

The next lemma shows another way to combine two upper bounds on $\|u - v\|$. We choose a vertex w between u and v and use the triangle inequality, using d_1 to bound $\|u - w\|$ and d_2 to bound $\|w - v\|$. Finally, we minimize over all intermediate vertices w. This hybrid is especially useful when, as with our long-range and short-range estimates, d_1 and d_2 have different ranges of $\|u - v\|$ in which they achieve small error.

▶ **Lemma 8.** *Suppose d_1 and d_2 are upper bounds on Euclidean distance with error functions ε_1 and ε_2 respectively. Define the hybrid distance estimate by*

$$\widehat{d}(u,v) = \min_w \left(d_1(u,w) + d_2(w,v) \right). \tag{11}$$

Then $\widehat{d}$ is an upper bound on Euclidean distance with error

$$\widehat{\varepsilon}(u,v) \le \min_w \Big[\varepsilon_1(u,w) + \varepsilon_2(w,v) + \|u - w\| + \|w - v\| - \|u - v\| \Big].$$

For an intuition of the proof, see Figure 4. ⌟

The next lemma uses the fact that if a lens is sufficiently large to contain at least one point w with high probability, then this gives an upper bound on the minimum in Lemma 8.

▶ **Lemma 9.** *Let $G \in \mathcal{G}(n,r)$ and suppose that with high probability d_1 and d_2 are upper bounds on Euclidean distance with errors $\varepsilon_1(u,v) = \varepsilon_1(\|u - v\|)$ and $\varepsilon_2(u,v) = \varepsilon_2(\|u - v\|)$. Define $\widehat{d}$ as in Lemma 8. Then there is a constant C such that, with high probability, $\widehat{d}$ is also an upper bound on Euclidean distance, with error $\widehat{\varepsilon}(u,v) = \widehat{\varepsilon}(\|u - v\|)$ where*

$$\widehat{\varepsilon}(\|u - v\|) \le \min_{0 < x < \|u-v\|} \max_{0 \le \delta_1, \delta_2 \le \delta(x)} \left[\varepsilon_1(x + \delta_1) + \varepsilon_2(\|u - v\| - x - \delta_2) + \delta(x) \right], \tag{12}$$

with $\delta(x) = C(\log n)^{2/3} \left(\min\{x, \|u - v\| - x\}\right)^{-1/3}$.

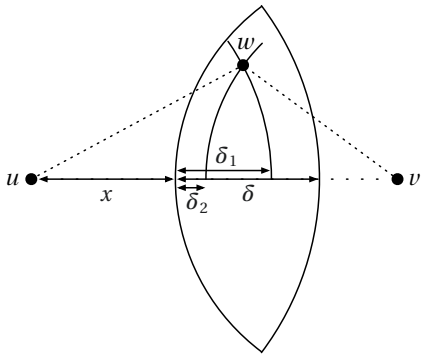

Figure 5 The lens $L(x)$ of Lemma 9. If δ is large enough, this lens is nonempty with high probability, in which case we can use any point w in it as an intermediate point for Lemma 8.

Proof sketch. Fix u, v and consider the lens $L(x) = B(u, x+\delta) \cap B(u, x+\|u-v\|-x)$ of width δ as shown in Fig. 5. By Lemma 3, the area of $L(x)$ is proportional to $C^{3/2}\log n$. Since the probability a region of area A is empty is at most e^{-A}, w.h.p. $L(x)$ contains at least one vertex w. For C sufficiently large, Lemma 8 then yields (12). ◀

Now we use the previous lemma to break the $\Omega(r)$ barrier for the error in estimating Euclidean distances in $G \in \mathcal{G}(n,r)$.

Assume v is deep. First define $d_1 = r d_G(u,v)$, i.e., the upper bound of Corollary 5. Now define d_2 using the precise short-range estimate $\tilde{d}$ from Theorem 2, with a small increment to make it an upper bound on Euclidean distance with high probability. Specifically, for a sufficiently large constant C_2, let

$$d_2(u,v) = \begin{cases} \tilde{d}(u,v) + C_2\sqrt{\log n} & \text{if } d_G(u,v) \le 2\,, \\ +\infty & \text{otherwise}\,. \end{cases} \tag{13}$$

▶ Remark 10. Given this choice of d_1 and d_2, the hybrid estimate $\widehat{d}(u,v)$ is the graph distance from u to v in a weighted graph G_v where each edge (w,v) with $d_G(w,v) \le 2$ has weight $\tilde{d}(w,v) + C_2\sqrt{\log n}$ and all other edges have weight r. Thus, for any fixed v, we can compute $\widehat{d}(u,v)$ for all u in with an application of Dijkstra's algorithm.

Now let us bound the error functions ε_1 and ε_2 of d_1 and d_2. As discussed above, for most values of $\|u-v\|$ we have $\varepsilon_1(\|u-v\|) = \Theta(r)$. However, we will choose the lens in Lemma 9 so that $\|u-w\|$ is almost a multiple of r, in which case Corollary 5 shows that $\varepsilon_1(\|u-w\|)$ is much smaller.

To bound ε_2, Theorem 2 implies that, for some absolute constant C_4, w.h.p.

$$\varepsilon_2(\|u-v\|) \le \begin{cases} C_4\sqrt{\log n} & \text{if } \|u-v\| \le 2r - C_4 r^{-1/3}\log n, \\ +\infty & \text{otherwise.} \end{cases} \tag{14}$$

Having gathered these facts, we will apply Lemma 9 to d_1 and d_2 with a judicious choice of lens $L(x)$. First note that, since $d_2(w,v) = +\infty$ if $d_G(w,v) > 2$, we can write

$$\widehat{d}(u,v) = \min_{w : d_G(w,v) \le 2} \{d_1(u,w) + d_2(w,v)\}. \tag{15}$$

▶ **Theorem 11.** *Let $r = n^\alpha$ for a constant $0 < \alpha < 1/2$. For all pairs u, v where v is deep, define $\widehat{d}(u,v)$ as in eq. 15. Then w.h.p., $\widehat{d}$ is an upper bound on the Euclidean distance $\|u - v\|$ with error*

$$\widehat{\varepsilon}(u,v) \le C' \begin{cases} n^{\frac{1}{2}-\frac{4}{3}\alpha} & \alpha < 3/8, \\ \sqrt{\log n} & 3/8 \le \alpha < 1/2, \end{cases} \tag{16}$$

for some absolute constant C'. That is, $\widehat{d}(u,v) - \widehat{\varepsilon}(u,v) \le \|u - v\| \le \widehat{d}(u,v)$.

Proof sketch. We choose x and the lens $L(x)$ in Lemma 3 such that $\|u - w\|$ is almost an integer multiple of r. We use this choice of x to upper bound (12), bounding the two terms inside the minimum separately. Using the definition of κ in Theorem 4, Corollary 5 tells us that $d_1(u,w)$ has error at most $\varepsilon_1 \le \kappa + \delta$. This implies that for all $0 \le \delta_1 \le \delta$, the first term of (12) is at most $\varepsilon_1(x + \delta_1) \le \kappa + \delta$.

To bound the second term of (12) we first prove that w.h.p. $d_G(w,v) \le 2$. We then use (14) to get $\varepsilon_2(w,v) \le C_4\sqrt{\log n}$, which implies $\varepsilon_2(\|u - v\| - x - \delta_2) \le C_4\sqrt{\log n}$. ◀

4 The Reconstruction Algorithm

In this section we use our distance estimates to reconstruct the positions of the points up to a symmetry of the square. Our global strategy is similar to [11]: we first fix a small number of "landmark" vertices v whose positions can be estimated accurately up to a symmetry of the plane. Then for each vertex u we use the estimated distances $\widehat{d}(u,v)$ to reconstruct u's position by triangulation. In [11], the landmarks are vertices close to the corners of the square. Here they will instead be a set of three deep vertices that are far from collinear, forming a triangle which is acute and sufficiently large.

▶ **Definition 12.** *We say a triple of deep vertices x, y, z is* good *if they form an acute triangle with all three side lengths at least $0.1\sqrt{n}$.*

▶ Remark 13. The bounds of Theorem 4 imply that if x, y, z are deep and have pairwise graph distances in the interval $[0.1\sqrt{n}/r, 0.14\sqrt{n}/r]$, then they are a good triple; the triangle is acute since $0.14 < 0.1\sqrt{2}$.

Once we have found a good triple, we perform triangulation using the following lemma.

▶ **Lemma 14.** *Let x, y, z, u be four points in the plane. Suppose x, y, z form an acute triangle with minimum side length at least ℓ. Then, if we know the positions of x, y, z with error at most η, and we have upper bounds $\widehat{d}(u,v)$ on the Euclidean distances $\|u - v\|$ for all $v \in \{x, y, z\}$ with error $\widehat{\varepsilon}$, and all of these distances are at most D, we can determine the position of u relative to x, y, z with error at most*

$$C_5 \frac{D(\widehat{\varepsilon} + \eta)}{\ell}, \tag{17}$$

for an absolute constant C_5.

▶ Remark 15. In our application, (x, y, z) is a good triple, so $\ell = \Omega(\sqrt{n})$. Since we also have $D \le \sqrt{2n}$ and $\eta = O(\widehat{\varepsilon})$, we can reconstruct u's position relative to x, y, z with error $O(\widehat{\varepsilon})$.

Proof. First, let us assume fixed positions for x, y, z within η of their estimated positions (which we can always do so that they form an acute triangle). By the triangle inequality, this changes the distances $\|u - v\|$ for $v \in \{x, y, z\}$ by at most $\pm\eta$. Thus u is in the intersection U of three annuli,

$$U = \bigcap_{v \in \{x,y,z\}} B(v, \widehat{d}(u,v) + \eta) \setminus B(v, \widehat{d}(u,v) - \eta - \widehat{\varepsilon})\,. \tag{18}$$

Any point u' in U gives an approximation of u's position with error at most the Euclidean diameter of U, namely $\max_{u,u' \in U} \|u - u'\|$. We will show this diameter is bounded by (17).

We use some basic vector algebra. Let $\varepsilon' = \widehat{\varepsilon} + 2\eta \le 2(\widehat{\varepsilon} + \eta)$. For any $u, u' \in U$ we have, for all $v \in \{x, y, z\}$,

$$-\varepsilon' \le \|u - v\| - \|u' - v\| \le \varepsilon'\,.$$

Since the triangle x, y, z is acute, at least one of its sides makes an angle φ with the vector $u - u'$ where $0 \le \varphi \le \pi/4$. Taking this side to be (x, y) we have, without loss of generality,

$$(y - x) \cdot (u - u') = \|y - x\|\,\|u - u'\| \cos\varphi \ge \|y - x\|\,\|u - u'\| \sqrt{\frac{1}{2}}.$$

Next, we rewrite this dot product as follows,

$$\begin{aligned} 2(y - x) \cdot (u - u') &= \|x - u\|^2 - \|x - u'\|^2 - \|y - u\|^2 + \|y - u'\|^2 \\ &= (\|x - u\| - \|x - u'\|)(\|x - u\| + \|x - u'\|) \\ &\quad - (\|y - u\| - \|y - u'\|)(\|y - u\| + \|y - u'\|) \\ &\le \varepsilon'(\|x - u\| + \|x - u'\| + \|y - u\| + \|y - u'\|)\,, \end{aligned}$$

where the first line is a classical polarization identity. Putting these together, we have

$$\|u - u'\| \le \frac{\sqrt{2}}{\|y - x\|}\,\varepsilon'\big(\|x - u\| + \|x - u'\| + \|y - u\| + \|y - u'\|\big) \le \frac{4\sqrt{2}R\varepsilon'}{\ell}\,,$$

completing the proof with $C_5 = 8\sqrt{2}$. ◀

Finally we state our main theorem.

▶ **Theorem 16.** *Let $r = n^\alpha$ for a constant $0 < \alpha < 1/2$. There is an algorithm with running time $O(n^2)$ that w.h.p. reconstructs the vertex positions of a random geometric graph $G \in \mathcal{G}(n, r)$, modulo symmetries of the square, with distortion d^* an absolute constant times times $\widehat{\varepsilon}$ as defined in* (16)*. That is, for some constant C'',*

$$d^* = C'' \begin{cases} n^{\frac{1}{2} - \frac{4}{3}\alpha} & \text{if } \alpha < 3/8\,, \\ \sqrt{\log n} & \text{if } 3/8 \le \alpha < 1/2\,. \end{cases}$$

Proof sketch. We use the fact, proved in [11], that w.h.p. the true positions of the lowest-degree vertices are within $\sqrt{\log n}$ of the corners of the square. Call these vertices a, b, c, d.

1. Find a good triple x, y, z. One way to do this is to find a vertex x near the center of the square, for instance one such that $d_G(x, t) \ge 0.65\sqrt{n}/r$ for all $t \in \{a, b, c, d\}$. Then find a y with $d_G(x, y) \in [0.1\sqrt{n}/r, 0.14\sqrt{n}/r]$, and then find a z such that $d_G(x, z), d_G(y, z) \in [0.1\sqrt{n}/r, 0.14\sqrt{n}/r]$. At each stage of this process, such a vertex exists with high probability, and all three are deep.

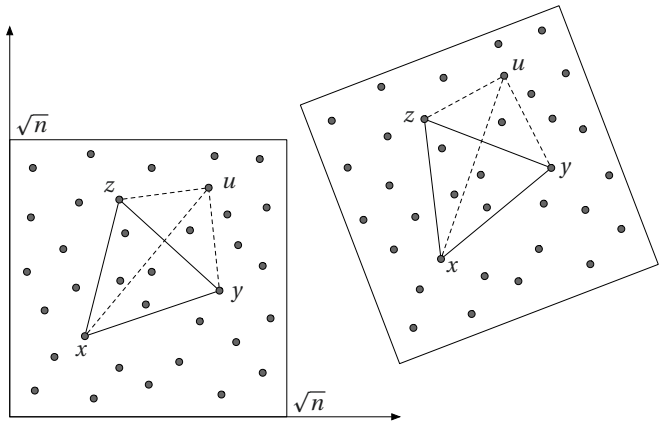

Figure 6 Our reconstruction is built around a triangle x, y, z of deep vertices. It may be translated, rotated, or reflected in $\mathbb{R}^2$ by an isometry, but it can then be shifted to the square $[0, \sqrt{n}]^2$. Then it will be a good reconstruction up to a rotation or reflection of the square.

2. Construct a triangle $x, y, z \in \mathbb{R}^2$ which is congruent to the true positions of the vertices x, y, z within error $\eta = O(\widehat{\varepsilon})$.
3. For each $v \in \{x, y, z\}$, compute the hybrid distance estimate $\widehat{d}(u, v)$ for all u as follows. First, for each w such that $d_G(w, v) \leq 2$, compute $|N(w) \cap N(v)|$ and thus the short-range distance estimates $\tilde{d}(w, v)$. Then compute $\widehat{d}(u, v)$ for all u using Dijkstra's algorithm on the weighted graph G_v described in Remark 10.
4. Use Lemma 14 to reconstruct the position of each vertex u relative to triangle x, y, z with error $O(\widehat{\varepsilon})$. This gives us a reconstruction up to an isometry of $\mathbb{R}^2$ as shown in Figure 6.
5. Finally, rotate and translate this reconstruction to the square $[0, \sqrt{n}]^2$. We choose a mapping of a, b, c, d to the corners of the square arbitrarily, using distance estimates to deduce which pairs are diagonally opposite, and then translate and rotate them as close as possible to $\{0, \sqrt{n}\}^2$. Since our definition of distortion allows rotations and reflections of the square, this gives a reconstruction with distortion $d^* = O(\widehat{\varepsilon} + \sqrt{\log n}) = O(\widehat{\varepsilon})$.

Step 1 can be done by breadth-first search, first from a, b, c, d and then from x and y, and thus takes $O(n)$ time. Steps 2, 3, 4, and 5 require $O(n)$ calculations of finite precision using standard functions, for which $O(\log n)$ bits of accuracy suffices. Thus the running time is dominated by the three uses of Dijkstra's algorithm, one for each $v \in \{x, y, z\}$, giving a running time of $O(n^2)$. ◀

▶ Remark 17. Since the typical degree in the graph is $\pi r^2 = O(n^{2\alpha})$ where $\alpha < 1/2$, and since Dijkstra's algorithm in a graph with n vertices and m edges runs in time $O(m + n \log n)$, the running time is w.h.p. $O(n^{2\alpha} + 1) = o(n^2)$.

▶ Remark 18. Once we reconstruct the positions of all vertices, we can get a good estimate of $||u - v||$ by direct computation from their approximate coordinates for all pairs u, v, including those where neither u nor v is deep.

5 Extensions to Other Domains

Our results can be generalized from the square to a number of alternative domains for random geometric graphs, including higher-dimensional Euclidean spaces and some curved manifolds. Here we sketch extensions of our algorithm to the m-dimensional hypercube and to the sphere, solving an open problem posed in [11].

5.1 Reconstruction in higher-dimensional Euclidean space

The simplest generalization is where the underlying domain is $[0, n^{1/m}]^m \subset \mathbb{R}^m$, i.e., an m-dimensional hypercube with volume n. We assume that m is a constant that does not vary with n. As before, n points are scattered uniformly in the hypercube, pairs u, v are adjacent if they are within Euclidean distance r, and our goal is to reconstruct the points' positions based on the adjacency matrix of the graph.

The following lemma generalizes Lemma 3 to $\mathbb{R}^m$, giving the m-dimensional volume of a lens-shaped intersection of two balls.

▶ **Lemma 19.** *Let $B_1(x, r_1)$ and $B_2(y, r_2)$ be two overlapping balls in $\mathbb{R}^m$ with $r_1 \le r_2$. Consider the lens $L = B_1 \cap B_2$. Let δ be the width of L, i.e., $\delta = \min\{r_1 + r_2 - d, 2r_1\}$ where $d = \|x - y\|$. Then the volume V of L satisfies $V = \Theta\left(\delta^{\frac{m+1}{2}} r_1^{\frac{m-1}{2}}\right)$, where the constant in Θ depends only on m.*

Given this relation between the width and volume of the lens, analogously to Section 3, we can compute both short- and long-range estimates of the distance, and combine them into a hybrid estimate. The error in the hybrid estimate is given by the following theorem.

▶ **Theorem 20.** *Let $r = n^\alpha$ for a constant $0 < \alpha < 1/m$. For all pairs u, v where v is deep, define $\widehat{d}(u, v)$ be the hybrid estimate of the distance. Then with high probability, $\widehat{d}$ is an upper bound on the Euclidean distance $\|u - v\|$ with error*

$$\widehat{\varepsilon}(u, v) \le C_m \begin{cases} n^{\frac{1}{m} - \frac{2m}{m+1}\alpha} & \alpha < \frac{m+1}{2m^2}, \\ \sqrt{\log n} & \frac{m+1}{2m^2} \le \alpha < \frac{1}{m}, \end{cases} \tag{19}$$

for some dimension-dependent constant C_m.

We omit the details of the proof since it closely follows the steps in Section 3.

In order to use the hybrid estimates for reconstruction, we need to find an appropriate number of deep landmarks. Using linear algebra, it suffices to have $m + 1$ landmarks that form a non-degenerate simplex. As in Theorem 16, we find an approximately equilateral m-simplex, namely a set of $m + 1$ points whose graph distances are all roughly the same constant times the diameter $n^{1/m}/r$. We again triangulate the positions of the other points based on their distance estimates, giving a reconstruction up to an isometry of $\mathbb{R}^m$. It is then easy to compute an isometry that shifts the reconstructed hypercube to $[0, n^{1/m}]^m$ by identifying low-degree vertices with the 2^m corners.

Putting this all together gives the following reconstruction theorem for random geometric graphs in $[0, n^{1/m}]^m$. We omit further details of the proof.

▶ **Theorem 21.** *Let $r = n^\alpha$ for a constant $0 < \alpha < 1/m$. There is an algorithm with running time $O(n^2)$ that w.h.p. reconstructs the vertex positions of a random geometric graph, modulo symmetries of the hypercube, with distortion*

$$d^* \le C_m \begin{cases} n^{\frac{1}{m} - \frac{2m}{m+1}\alpha} & \text{for } \alpha < \frac{m+1}{2m^2}, \\ \sqrt{\log n} & \text{for } \frac{m+1}{2m^2} \le \alpha < \frac{1}{m}, \end{cases}$$

for some dimension-dependent constant C_m.

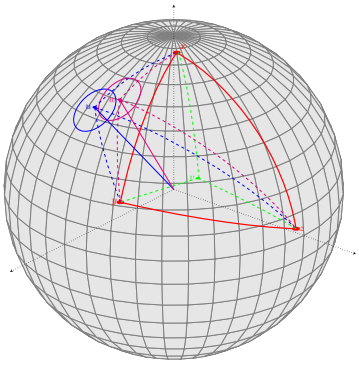

Figure 7 Using three landmarks x, y, z on the sphere to triangulate to other points in Theorem 22.

5.2 Reconstruction on the sphere

Finally, we argue that our algorithm also works on some curved manifolds and submanifolds where the geometric graph is defined in terms of geodesic distance. In particular we claim this for the m-dimensional spherical (hyper)surface S_m of a ball in $\mathbb{R}^{m+1}$. Here we sketch the proof for the two-dimensional surface of a sphere in $\mathbb{R}^3$. Note that the distortion is now defined by minimizing over the sphere's continuous symmetry group, i.e., over all rotations and reflections of the sphere.

In previous work, the authors of [10] gave a procedure to distinguish random geometric graphs on S^m from Erdős-Rényi random graphs. In addition, [3] gave a spectral method for reconstructing random graphs generated by a sparsified graphon model on the sphere, but since this model connects distant pairs of vertices with nonzero probability, it does not include the geodesic disk model we study here.

To define random geometric graphs on the sphere we scale the sphere so that its surface area is n, setting its radius to $R = \sqrt{n/(4\pi)}$. We scatter n points uniformly at random on it, or generate them with a Poisson point process with intensity 1, so that the expected number of points in a region is equal to its surface area. We define the graph as $(u, v) \in E$ if and only if $\|u - v\|_g \leq r$ where $\|u - v\|_g$ is the geodesic distance, i.e., the length of the shorter arc of a great circle that connects u and v. If we associate each point u with a unit vector $\vec{u} \in \mathbb{R}^3$ that points toward it from the center of the sphere, $\|u - v\|_g$ is R times the angle between $\vec{u}$ and $\vec{v}$.

▶ **Theorem 22.** *Let $r = n^\alpha$ for a constant $0 < \alpha < 1/2$. There is an algorithm with running time $O(n^2)$ that with high probability reconstructs the vertex positions of a random geometric graph, modulo a rotation or reflection of the sphere, with distortion an absolute constant times $n^{\frac{1}{2}-\frac{4}{3}\alpha}$ if $\alpha < 3/8$ and $\sqrt{\log n}$ if $\alpha \geq 3/8$.*

The algorithm is similar to that described in Theorem 16. The main difference is that our initial landmarks consist of three points x, y, z which approximately form a right spherical triangle, i.e., such that the vectors $\vec{x}, \vec{y}, \vec{z}$ have angles of about $\pi/2$ between them: see Fig 7.

6 Conclusion and Future Work

We have shown how a combination of geometric ideas can be used to reconstruct random geometric graphs with lower distortion than in previous work [11], achieving a distortion of $o(r)$ whenever $r = n^\alpha$ for $\alpha > 3/14$. Here we pose several questions for further work.

First, let us call a reconstruction ϕ *consistent* if its distances are consistent with the graph: that is, if $(u, v) \in E$ if and only if $\|\phi(u) - \phi(v)\| \leq r$. Even if ϕ has small distortion d^*, it might not be consistent: some edges $(u, v) \in E$ might have $\|\phi(u) - \phi(v)\|$ between r and $r + 2d^*$, and similarly some non-neighboring pairs might have $\|\phi(u) - \phi(v)\|$ between $r - 2d^*$ and r. To the best of our knowledge, even finding a single consistent embedding for random geometric graphs is an open question. It might be possible to refine our embedding to make it consistent, by using "forces" to move neighbors slightly closer together, and push non-neighbors farther away.

Second, a natural question is whether we can prove a significant lower bound on the distortion. An information-theoretic approach to this question would be to show that even the Bayesian algorithm, which chooses from the uniform measure on all consistent embeddings, has a typical distortion. We have been unable to prove this. However, here we sketch an argument that there *exist* consistent embeddings with a certain distortion by applying a continuous function f to the square $[0, \sqrt{n}]^2$ that "warps" the true embedding. If f's derivatives are at most δ in absolute value, then for each v, points close to the edge of v's neighborhood may move $O(\delta r)$ closer or farther away. However, a typical v has some $\varepsilon = O(1/r)$ for which there are no points whose distance is between $r - \varepsilon$ and $r + \varepsilon$, since the area of the corresponding annulus is $O(1)$. This suggests that if $\delta = O(\varepsilon/r) = O(1/r^2)$, the warped embedding is still consistent (except for a few vertices where we need to be more careful). On other other hand, even if f does not change the distance between nearby vertices very much, it can still move some vertices $\delta\sqrt{n}$ from their true positions, giving a distortion $d^* = \Omega(\sqrt{n}/r^2)$. If $r = n^\alpha$ this gives $\Omega(n^{1/2-2\alpha})$.

Even if this lower bound can be made rigorous, and even if it applies to typical consistent embeddings rather than just a few, there is a large gap between it and our upper bounds. Thus it is tempting to think that our algorithm can be improved, reducing the distortion still further. One approach would be to try to extend the geometry of overlapping disks in Theorem 2 to larger graph distances. Another would be to combine them with the spectral ideas of e.g. [3].

Finally, we would like to see how far these techniques can be extended to curved manifolds and submanifolds with boundary. In Theorem 22 we took advantage of the fact that the 2-sphere has a convenient embedding in $\mathbb{R}^3$. A more general approach, which we claim applies to any compact Riemannian submanifold with bounded curvature, would be to work entirely within the manifold itself, building a sufficiently dense mesh of landmarks and then triangulating within mesh cells. In particular, in the popular model of hyperbolic embeddings (e.g. [6, 16, 17]) where the submanifold is a ball of radius ℓ in a negatively curved space with radius of curvature R, we believe similar algorithms will work as long as $\ell/R = O(1)$. We leave this for future work.

Improved Approximation Algorithms for Dyck Edit Distance and RNA Folding

Abstract

The Dyck language, which consists of well-balanced sequences of parentheses, is one of the most fundamental context-free languages. The Dyck edit distance quantifies the number of edits (character insertions, deletions, and substitutions) required to make a given length-n parenthesis sequence well-balanced. RNA Folding involves a similar problem, where a closing parenthesis can match an opening parenthesis of the same type irrespective of their ordering. For example, in RNA Folding, both `()` and `)(` are valid matches, whereas the Dyck language only allows `()` as a match. Both of these problems have been studied extensively in the literature. Using fast matrix multiplication, it is possible to compute their exact solutions in time $O(n^{2.687})$ (Chi, Duan, Xie, Zhang, STOC'22), and a $(1+\epsilon)$-multiplicative approximation is known with a running time of $\Omega(n^{2.372})$.

The impracticality of fast matrix multiplication often makes combinatorial algorithms much more desirable. Unfortunately, it is known that the problems of (exactly) computing the Dyck edit distance and the folding distance are at least as hard as Boolean matrix multiplication. Thereby, they are unlikely to admit truly subcubic-time combinatorial algorithms. In terms of fast approximation algorithms that are combinatorial in nature, the state of the art for Dyck edit distance is an $O(\log n)$-factor approximation algorithm that runs in near-linear time (Saha, FOCS'14), whereas for RNA Folding only an ϵn-additive approximation in $\tilde{O}(\frac{n^2}{\epsilon})$ time (Saha, FOCS'17) is known.

In this paper, we make substantial improvements to the state of the art for Dyck edit distance (with any number of parenthesis types). We design a constant-factor approximation algorithm that runs in $\tilde{O}(n^{1.971})$ time (the first constant-factor approximation in subquadratic time). Moreover, we develop a $(1+\epsilon)$-factor approximation algorithm running in $\tilde{O}(\frac{n^2}{\epsilon})$ time, which improves upon the earlier additive approximation. Finally, we design a $(3+\epsilon)$-approximation that takes $\tilde{O}(\frac{nd}{\epsilon})$ time, where $d \geq 1$ is an upper bound on the sought distance.

As for RNA folding, for any $s \geq 1$, we design a factor-s approximation algorithm that runs in $O(n + (\frac{n}{s})^3)$ time. To the best of our knowledge, this is the first nontrivial approximation algorithm for RNA Folding that can go below the n^2 barrier. All our algorithms are combinatorial in nature.

1 Introduction

The Dyck language is a well-known context-free language consisting of well-balanced sequences of parentheses. Ranging from programming syntaxes to arithmetic and algebraic expressions, environments in LaTeX, and tags in HTML/XML documents – we observe instances of the Dyck language everywhere. For a comprehensive discussion on the Dyck language and context-free grammars; see [23, 26]. Given a sequence x of n parentheses (which may be unbalanced), the *Dyck edit distance problem* asks for the minimum number of edits (character insertions, deletions, and substitutions) needed to make x well-balanced. Interestingly, string edit distance, which is one of the fundamental string similarity measures, can be interpreted as a special case of Dyck edit distance.[1]

A simple dynamic programming computes Dyck edit distance in $O(n^3)$ time. In 2016, after nearly four decades, Bringmann, Grandoni, Saha, and Vassilevska Williams [13] gave the first truly subcubic-time exact algorithm for a more general problem of language edit distance [2]. Very recently, Chi, Duan, Xie, and Zhang [17] provided a faster implementation of the same algorithm. The algorithm uses not-so-practical fast Boolean matrix multiplication, arguably so because computing Dyck edit distance is at least as hard as Boolean matrix multiplication [1], and hence combinatorial truly subcubic-time algorithms are unlikely to exist.

A problem closely related to Dyck edit distance is RNA Folding [31]. Both in RNA Folding and Dyck edit distance, parentheses must match in an uncrossing way. However, in an RNA folding instance, a closing parenthesis can match an opening parenthesis of the same type irrespective of the order of their occurrences. For example, under the RNA Folding distance, both `()` and `)(` are valid matches, whereas the Dyck language only allows `()` as a match. In terms of exact computation, they exhibit the same time complexity [1, 13].[2]

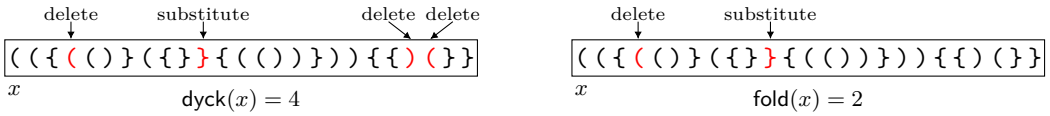

Figure 1 Example of Dyck and folding edit distance.

Can we design fast approximation algorithms for Dyck edit distance and RNA Folding? The first progress on this question for Dyck edit distance was made by Saha [34], who proposed a polylogarithmic-factor approximation algorithm that runs in near-linear time. It is also possible to provide an ϵn-additive approximation for any $\epsilon > 0$ in $\tilde{O}(\frac{n^2}{\epsilon})$ time [36]. However, unless the distance is $O(n)$ and we allow quadratic time, the above algorithm does not provide a constant-factor approximation to Dyck edit distance. This latter result on additive approximation applies to RNA Folding as well. Backurs and Onak [7] showed an exact algorithm for Dyck edit distance that runs in $O(n + d^{16})$ time, which was recently improved by Fried, Golan, Kociumaka, Kopelowitz, Porat, and Starikovskaya [21] to run in $O(n + d^5)$ time (and $\tilde{O}(n + d^{4.783})$ using fast matrix multiplication). Therefore, prior

[1] Given two strings s and t, form a sequence of parentheses by concatenating s, interpreted as a sequence of opening parentheses, and the reverse complement of t, obtained by reversing t and replacing each symbol with the corresponding closing parenthesis, not present in the original alphabet.

[2] In these problems, we are aiming to minimize the number of non-matched parentheses as opposed to maximizing the matched parentheses.

to this work, (i) there was no nontrivial multiplicative approximation for RNA Folding in subquadratic time, and (ii) there was no subquadratic-time constant-factor approximation for Dyck edit distance that would work for the entire distance regime.

Let us contrast this state of affairs with the progress on string edit distance approximation. As mentioned earlier, string edit distance is a special case of Dyck edit distance. Early work [6, 8, 9, 28] on approximating string edit distance resulted in the first near-linear-time polylogarithmic-factor approximation in 2010 by Andoni, Krauthgamer, and Onak [4]. It took another eight years to obtain the first constant-factor approximation of edit distance in subquadratic time [15] (see [11] for a quantum analog). Finally, Andoni and Nosatzki improved the running time to near-linear while maintaining a constant approximation ratio [5]. Using the best result in string edit distance approximation [5], it is possible to improve the approximation factor of [34] to $O(\log n)$. However, designing a constant-factor approximation for Dyck edit distance in subquadratic time remains wide open. RNA Folding, even though conceptually very similar to Dyck edit distance, is incompatible with the algorithm of [34].

Saha's work on Dyck edit distance approximation [34] developed a random walk technique which has later been used for edit distance embedding and document exchange [10, 16]. This random walk allows decomposing a parenthesis sequence into many instances of string edit distance problem. However, this decomposition loses a logarithmic factor in the approximation, raising the question of whether there exists an efficiently computable decomposition with a significantly smaller loss.

Contributions for Dyck Edit Distance.

- **Constant-factor approximation in subquadratic time.** *The main contribution of this paper is the first constant-factor approximation algorithm for Dyck edit distance that runs in truly subquadratic time*, namely $\tilde{O}(n^{1.971})$. (In the interest of simplicity, we did not optimize the exponent in the running time.) We employ and significantly extend the tools previously developed in connection with string edit distance, such as the windowing strategy, window-to-window computation, sparse and dense window decomposition, etc. [11, 15, 22]. These methods are tied to problems involving two or more strings (unlike the Dyck edit distance, which is a single-sequence problem). Given the universality of Dyck edit distance, the tools we developed may lead to further advancements for more generic problems like the language edit distance problem, etc. [13, 35, 36].
  Our main algorithm handles the cases of large and small Dyck edit distance separately.
- **Small Dyck edit distance.** When the Dyck edit distance d is small, we give a $(3+\epsilon)$-approximation algorithm that runs in $\tilde{O}(\frac{nd}{\epsilon})$ time. We can contrast this result with the time complexity of computing the Dyck edit distance exactly, which is $O(n+d^5)$ (combinatorially) and $\tilde{O}(n+d^{4.783})$ (using fast matrix multiplication), obtained in [21]. Nevertheless, even in a hypothetical bast-case scenario that a combinatorial $O(n+d^3)$-time algorithm exists, an $\tilde{O}(nd)$-time algorithm is still faster for all $d \gg \sqrt{n}$.
- **Quadratic-time PTAS.** We also give a $(1+\epsilon)$-approximation algorithm for Dyck edit distance that runs in $\tilde{O}(\frac{n^2}{\epsilon})$ time. This improves upon the previous result of [36] that gets such a result only when $d = \Theta(n)$. The prior $(1+\epsilon)$-approximation algorithm uses fast Boolean matrix multiplication and has super-quadratic running time [35].

Contribution for RNA Folding. For RNA Folding, we are aiming to minimize the number of non-matched characters; we henceforth call this value the *folding distance*. For any $s > 1$, we give a factor-s approximation of the folding distance in time $O(n + (\frac{n}{s})^3)$. This is the first result to our knowledge that goes below the quadratic running time (for $s = \omega(n^{1/3})$). We

remark here that the triangle inequality we proved for Dyck distance (Lemma 2.3) as well as the machinery developed in Section 5 apply to the RNA folding problem equally well. This yields a constant-factor approximation for RNA folding in $\tilde{O}(n^{1.971})$ time when the distance is larger than $n^{0.971}$.

Discussion and Open Problems. The resemblance between Dyck and string edit distance has already been studied in the literature. As mentioned earlier, the decomposition obtained by the random walk technique ensures only an $O(\log n)$ approximation [34]. In this work, instead of reducing the Dyck edit distance to string edit distance, we try to find a direct decomposition of the sequence x into different substrings, where for each substring there is a peer such that they are matched by some optimal alignment (with some error leading to a constant-factor approximation). However, unlike the string counterpart, Dyck edit distance does not have the structural property that if an optimal alignment matches the characters of a substring s_1 with the characters of a substring s_2, then the lengths of s_1 and s_2 are roughly the same (see Figure 2). Thus, in our decomposition, the substrings can have varied lengths. In fact, it turns out that if the Dyck edit distance is truly sublinear (i.e., $n^{1-\epsilon}$), then we need to consider roughly n^{ϵ} different lengths to ensure a constant-factor approximation. We remark that this is one of the barriers in further pushing down the running time from subquadratic to $O(n^{1.6+o(1)})$ (as in [22]) or near-linear. We also note that if an analog of our $\tilde{O}(nd)$-time algorithm can be provided for RNA Folding, then we would also get a constant-factor subquadratic algorithm for RNA folding for all distance regimes.

The Dyck recognition problem has been studied extensively in different models, including the streaming [14, 27, 30] and property testing [3, 19, 32] frameworks. However, neither Dyck edit distance nor RNA Folding admits sublinear-time approximation algorithms. Our algorithm for RNA Folding (which also applies to Dyck edit distance after straightforward adaptations) runs in $O(n + (\frac{n}{s})^3)$ time and requires a linear-time preprocessing step that eliminates pairs of matching adjacent characters, which leaves strongly structured instances. This preprocessing step is currently the main barrier to going in the sublinear-time setting.

1.1 Technical Overview

As input to the Dyck edit distance problem, we are given a string x of length n over an alphabet Σ that consists of two disjoint sets T and $\overline{T}$ of opening and closing parentheses respectively. The task is to compute the Dyck edit distance $\mathsf{dyck}(x)$, defined as the minimum number of parentheses insertions, deletions, and substitutions required to make x well-parenthesized.

Quadratic-time PTAS. The standard $O(n^3)$-time algorithm for Dyck edit distance is a dynamic-programming procedure that computes the distance of each substring of the input string. The bottleneck of this approach is that, to compute the distance of each substring $x(i\,..\,j]$, starting at index $i+1$ and ending at index j, one needs to iterate over decompositions of $x(i\,..\,j]$ into a prefix $x(i\,..\,k]$ and a suffix $x(k\,..\,j]$ for every possible intermediate index $k \in (i\,..\,j)$ (this corresponds to the fact that the concatenation of two well-parenthesized expression is a well-parenthesized expression).[3] We call the index k a *pivot* corresponding to a decomposition. The $\tilde{O}(\frac{n^2}{\epsilon})$-time ϵn additive approximation of [36] reduces the number of considered pivots to $\tilde{O}(\frac{1}{\epsilon})$; thus, $\tilde{O}(\frac{n}{\epsilon d})$ (where $d = \mathsf{dyck}(x)$) different pivots would be

[3] For $i, j \in \mathbb{Z}$, we denote $[i\,..\,j] = \{k \in \mathbb{Z} : i \le k \le j\}$, $[i\,..\,j) = \{k \in \mathbb{Z} : i \le k < j\}$, $(i\,..\,j] = \{k \in \mathbb{Z} : i < k \le j\}$, and $(i\,..\,j) = \{k \in \mathbb{Z} : i < k < j\}$.

necessary for a $(1+\epsilon)$-factor approximation (which is same as an ϵd-additive approximation). On the other hand, a simple $O(n^2 d)$-time algorithm recently developed in [21] is based on a combinatorial observation that $O(d)$ pivots are sufficient after the $O(n)$-time preprocessing from [7, 34]. We start with a brief overview of this algorithm. For any index $i \in [0\,..\,n]$, we define the height of i to be $h(i) = |\{j \in [1\,..\,i] : x[j] \in T\}| - |\{j \in [1\,..\,i] : x[j] \in \overline{T}\}|$, i.e., the difference between the number of opening and closing parentheses in prefix $x[1\,..\,i]$. An index v is called a valley if $h(v-1) > h(v) < h(v+1)$, i.e., $x[v]$ is a closing parenthesis whereas $x[v+1]$ is an opening parenthesis. Backurs and Onak [7] showed a linear-time preprocessing of x that generates another string x' such that $\mathsf{dyck}(x) = \mathsf{dyck}(x')$ and x' has at most $2d$ valleys. Fried, Golan, Kociumaka, Kopelowitz, Porat, and Starikovskaya [21] proved that, without loss of generality, it is enough to consider pivots that are at distance 0 or 1 from a valley (we henceforth denote the set of such pivots by K) plus $O(1)$ pivots next to the boundary of the considered range $(i\,..\,j)$; this observation yields a $O(n^2 d)$-time algorithm.

In Section 3, we provide an algorithm that further restricts the set of pivots K considered for each range $(i\,..\,j)$ and provides a $(1+\epsilon)$-approximation of $\mathsf{dyck}(x)$ in $\tilde{O}(\frac{n^2}{\epsilon})$ time (Theorem 3.2). This is inspired by how Saha [36] considered only $\tilde{O}(\frac{1}{\epsilon})$ pivots out of each range $(i\,..\,j)$. The original argument relies on two observations: that using pivot k' instead of k incurs at most $O(|k-k'|)$ extra edit operations, and that, for an ϵn-additive approximation, we can afford $O(\frac{\epsilon \min(k-i, j-k)}{\log n})$ extra operations when using pivot $k \in (i\,..\,j)$. In our multiplicative approximation, we refine the second observation by replacing $\min(k-i, j-k)$ with $\min(|K \cap (i\,..\,k)|, |K \cap (k\,..\,j)|)$. On the other hand, the first observation is not useful because the set $K \cap (i\,..\,j)$ is already relatively sparse. Thus, instead of restricting each range $(i\,..\,j)$ to use few pivots k, we restrict each pivot k to be used within few ranges $(i\,..\,j)$. This is feasible with respect to the approximation ratio because the costs for $x(i\,..\,j]$ and $x(i'\,..\,j']$ may only differ by $O(|i-i'| + |j-j'|)$, and because the $O(n^2 d)$-time algorithm still considers each pivot $k \in K$ for all ranges $(i\,..\,j)$ containing k (which leaves room for sparsification).

Constant-factor approximation in $\tilde{O}(nd)$ time. Overcoming the $O(n^2)$ barrier with a dynamic-programming approach poses significant challenges: there are $\Theta(n^2)$ substrings to consider and, for $d \geq \sqrt{n}$, this quantity does not decrease (in the worst case) even if we run the preprocessing of [7, 34] and exclude substrings with costs exceeding d. Thus, we artificially restrict the DP states to substrings whose all prefixes have at least as many opening parentheses as closing ones and whose all suffixes have at least as many closing parentheses as opening ones. Surprisingly, as shown in Section 4, this yields a 3-approximation of the original cost. Furthermore, if we additionally require that the number of opening parentheses and the number of closing parentheses across the entire substring are within $2d$ from each other (otherwise, the Dyck edit distance trivially exceeds the threshold), we end up with $O(nd)$ substrings. Reusing the pivot sparsification of Section 3, one can process them in $\tilde{O}(\frac{nd}{\epsilon})$ total time at the cost of increasing the approximation ratio from 3 to $3+\epsilon$.

Constant-factor approximation in $\tilde{O}(n^{1.971})$ time. In Section 5, we exhibit an $\tilde{O}(n^{1.971})$-time algorithm that provides a constant-factor approximation of Dyck edit distance. At a high level, the framework of our algorithm is similar to the three-step procedure of [15] that provides a constant-factor approximation of string edit distance in subquadratic time. Thus, we start with a brief recap of [15], pointing out the major bottlenecks for applying this framework directly to our problem. Given two strings x, y of length n, the algorithm of [15] starts by constructing a set of windows $\mathcal{W}_x$ for x and $\mathcal{W}_y$ for y, where each window is a length-s subinterval of $[1\,..\,n]$, representing a substring of x or y. The motivation behind

this construction is the following: given the edit distances between all pairs of windows from $\mathcal{W}_x$ and $\mathcal{W}_y$, one can compute a constant-factor approximation of the edit distance $\mathsf{ED}(x, y)$ using an $O(\frac{n^2}{s^2})$-time dynamic-programming procedure. The challenge here is that if the edit distances are computed using a trivial dynamic-programming algorithm for all pair of windows from $\mathcal{W}_x$ and $\mathcal{W}_y$, then the total running time becomes quadratic. The key insight of [15] is that, in some favorable situation, one can use random sampling to select a subset of window pairs from $\mathcal{W}_x \times \mathcal{W}_y$ such that evaluating the edit distances of the window pairs in the subset is enough to construct a nearly-optimal alignment of x, y. On the other extreme, instead of computing edit distance for each window pairs explicitly, one can use triangle inequality to get constant-factor approximation of the optimal costs.[4] Several other works have subsequently used this framework to solve related problems [12, 22, 33, 37].

As discussed above, much of the previous work on Dyck edit distance relies on similarities with edit distance, either via black-box reductions (such as the random walk of Saha [34]) or by transferring techniques (e.g., [7, 21] build on top of the $O(n + d^2)$-time algorithm [29] for edit distance). Hence, we try to adapt the framework of [15] to the Dyck setting.

The first challenge is that the Dyck edit distance is defined for a single string, so it is not immediately clear how to formulate the triangle inequality in this setting. However, the embedding of string edit distance into the Dyck edit distance hints a candidate for a metric: a function mapping strings $x, y \in \Sigma^*$ to $\mathsf{dyck}(x\overline{y})$, where $\overline{y}$ is the reverse complement of y (obtained by reversing y and flipping the direction of each parenthesis). This choice turns out to be a valid one: we show (in Lemma 2.3) that any three strings x, y, z satisfy $\mathsf{dyck}(x\overline{z}) \leq \mathsf{dyck}(x\overline{y}) + \mathsf{dyck}(y\overline{z})$, which we dub the triangle inequality for Dyck edit distance. Our proof is based on a subtle inductive argument that reduces the general case to that of $|y| \leq 1$ and $|x\overline{z}| \leq 2$. This base case, in turn, requires some case analysis.

A more serious issue is that the very first step of the algorithms of [11, 15], *window decomposition*, fails for our purposes, and, as discussed below, a workaround poses significant difficulties. To conclude the high-level discussion, we list our two main technical contributions leading to the subquadratic-time constant-factor approximation for Dyck edit distance:

1. We propose a new window decomposition strategy and show that any optimal alignment of x can be approximated by matching the window pairs generated by our strategy.
2. We establish the triangle inequality for Dyck edit distance.

Next, we discuss the limitations of the windowing strategy of [15] and explain how to overcome them. The algorithm of [15] partitions the input strings into fixed-length (overlapping) substrings, estimates the distances between relevant pairs of substrings, and then runs a dynamic-programming procedure to derive a global alignment. Regardless, following the strategy of dimension reduction, one idea could be to partition the input string x into windows $w_1, \ldots, w_\ell \subseteq [1 \,..\, n]$ of length s (where $s = n^{\Theta(1)}$) with the hope, that given the Dyck edit distances for all strings $x[w_i] \circ x[w_j]$ (here, $x[w_i]$ represents the substring of x restricted to the indices in w_i and $\circ$ denotes concatenation), one can use the cubic-time dynamic-programming algorithm to estimate $\mathsf{dyck}(x)$ in time $\tilde{O}(\frac{n^3}{s^3})$. However, this straightforward decomposition fails for the following reasons:

- In case of string edit distance, if an optimal alignment (with cost d) matches $x[i]$ with $y[j]$, then $x[i+1]$ can be matched only with a character of $y[j+1 \,..\, j+d+1]$. Thus, if we consider a window w_1 in x and a window w_2 in y such that $\mathsf{ED}(x[w_1], y[w_2])$ is

[4] The use of triangle inequality was first proposed in [11], where Grover search was used instead of random sampling, resulting in a quantum constant-factor approximation of edit distance in subquadratic time.

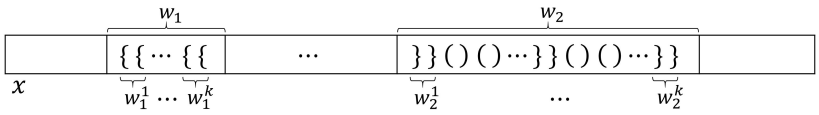

Figure 2 An example showing two very different length substrings can be matched with cost 0.

small, then we can assume $|w_1| \approx |w_2|$. This structural property completely breaks down for Dyck edit distance. For example, the two windows w_1, w_2 in Figure 2 satisfy $\mathsf{dyck}(x[w_1] \circ x[w_2]) = 0$ even though their lengths are very different. This indicates that partitioning x into single-length windows does not suffice.

- To overcome the aforementioned issue, let us assume that we allow variable-length windows. Note that an optimal alignment may match a window w_1 of length s with a window w_2 of length $\gg s$ ($|w_2|$ can be as large as $\Omega(n)$). However, if we allow windows of lengths $\gg s$, then estimating the costs of such large window pairs may be inefficient. One way out could be to subdivide both w_1 and w_2 into smaller windows $w_1^1, w_1^2, \ldots, w_1^k$ and $w_2^1, w_2^2, \ldots, w_2^k$, respectively, and separately compute the cost of each substring $x[w_1^i] \circ x[w_2^j]$. Here, as $|w_1^i|$ and $|w_2^j|$ are not too large, any individual cost can be approximated efficiently. However, since $|w_1^i|$ can be very small (as small as $n^{o(1)}$), the total number of subproblems (window pairs whose cost we evaluate) can explode, and hence the dynamic-programming procedure combining these subproblems may become inefficient.

Thus, for Dyck edit distance, the main challenge is to partition the input string x into variable-length windows which are neither too short (this ensures that the total number of subproblems, i.e., window pairs we evaluate, is not too large, and hence the DP combining them is efficient) nor too long (so that computing the costs of window pairs is efficient as well), and any optimal alignment of x can be approximated by matching these window pairs. Formally, we need to construct a set of windows $\mathcal{J}$, where each window has length at most s (we set this s to be a polynomial in n), $|\mathcal{J}| \approx \frac{n}{s}$, and there exists a subset $\mathcal{S} \subseteq \mathcal{J} \times \mathcal{J}$ such that $\mathcal{S}$ is a consistent window decomposition of $[1\,..\,n]$ (i.e., the windows involved in $\mathcal{S}$ form a decomposition of $[1\,..\,n]$ and the window pairs in $\mathcal{S}$ do not cross) and there is a nearly-optimal alignment that aligns w with w' for each $(w, w') \in \mathcal{S}$. The latter condition is formalized as follows (the construction of $\mathcal{J}$ is parameterized by θ, chosen so that $\theta n \le \mathsf{dyck}(x)$):

▶ **Lemma 1.1.** *There exists a consistent window decomposition $\mathcal{S} \subseteq \mathcal{J} \times \mathcal{J}$ of $[1\,..\,n]$ such that $\sum_{(w,w')\in\mathcal{S}} \mathsf{dyck}(x[w] \circ x[w']) \le \mathsf{dyck}(x) + 8\theta n$.*

The construction of an appropriate family $\mathcal{J}$ and the proof of Lemma 1.1 are among the novelties of our algorithm; this is where our approach significantly differs from [15].

Window Decomposition. Our proof of Lemma 1.1 (given in Section 5.1) follows a two-step strategy. In the first step, independent of the choice of $\mathcal{J}$, the decomposition $\mathcal{S}$ may contain arbitrary window pairs (w, w') with $|w|, |w'| \le s$, but we require $\sum_{(w,w')\in\mathcal{S}} \mathsf{dyck}(x[w] \circ x[w']) = \mathsf{dyck}(x)$ (no approximation allowed) and $|\mathcal{S}| = O(\frac{n}{s})$. In the second step, we locally perturb the endpoints of all windows in $\mathcal{S}$ so that the resulting windows belong to $\mathcal{J}$; this incurs an additive overhead of $O(\theta n)$ on the cost of the consistent window decomposition $\mathcal{S}$.

Our proof for the **first step** inductively constructs a consistent window decomposition of any window $(i_1\,..\,i_2] \subseteq [1\,..\,n]$. In the base case of $|(i_1\,..\,i_2]| \le 2s$, we build a single window pair composed of the two halves of $(i_1\,..\,i_2]$. In the main case, we identify an *outermost* window pair $((i_1\,..\,j_1], (j_2\,..\,i_2])$, with $j_1 \in [i_1\,..\,i_1 + s]$ and $j_2 \in [i_2 - s\,..\,i_2]$, and a *pivot* $p \in [i_1 + s\,..\,i_2 - s]$ so that

$$\mathsf{dyck}(x(i_1\,..\,i_2]) = \mathsf{dyck}(x(j_1\,..\,p]) + \mathsf{dyck}(x(p\,..\,j_2]) + \mathsf{dyck}(x(i_1\,..\,j_1] \circ x(j_2\,..\,i_2]).$$

The appropriate positions j_1, j_2, p can be derived from an optimal alignment of $x(i_1 \,..\, i_2]$:

- $(i_1 \,..\, j_1]$ can be defined as the shortest (possibly empty) prefix of $(i_1 \,..\, i_1 + s]$ containing all positions in $(i_1 \,..\, i_1 + s]$ matched with $(i_2 - s \,..\, i_2]$;
- $(j_2 \,..\, i_2]$ can be defined as the shortest (possibly empty) suffix of $(i_2 - s \,..\, i_2]$ containing all positions in $(i_2 - s \,..\, i_2]$ matched with $(i_1 \,..\, i_1 + s]$;
- $(i_1 + s \,..\, p]$ can be defined as the shortest (possibly empty) prefix of $(i_1 + s \,..\, i_2 - s]$ containing all positions in $(i_1 + s \,..\, i_2 - s]$ matched with $(i_1 \,..\, i_1 + s]$.

The sought decomposition of $(i_1 \,..\, i_2]$ is obtained by inserting $((i_1 \,..\, j_1], (j_2 \,..\, i_2])$ to the union of decompositions of $(j_1 \,..\, p]$ and $(p \,..\, j_2]$ (constructed recursively). It is not hard to prove that this construction satisfies the claims made above. The most subtle argument involves the size of the decomposition. This is because the bound $|\mathcal{S}| = O(\frac{n}{s})$ requires windows of average size $\Theta(s)$, but $(i_1 \,..\, j_1]$ and $(j_2 \,..\, i_2]$ can be arbitrarily short (even empty). Even worse, $(j_1 \,..\, p]$ and $(p \,..\, j_2]$ may also be arbitrarily short. However, we still have $|(i_1 \,..\, p]|, |(p \,..\, i_2]| \geq s$, and this suffices to inductively prove an upper bound of $\max(1, \frac{2(i_2 - i_1)}{s} - 1)$.

As for the **second step** of the proof of Lemma 1.1, we need to specify the choice of $\mathcal{J}$, which is parameterized by θ and s. We simply include in $\mathcal{J}$ all windows $w = (i_1 \,..\, i_2]$ of length at most s whose endpoints i_1, i_2 are both integer multiples of θs (in this overview, we assume for simplicity that $\frac{n}{s}$, θs, and $\frac{1}{\theta}$ are all integers). This way, $|\mathcal{J}| = O(\frac{n}{\theta^2 s})$ (there are $O(\frac{n}{\theta s})$ choices for the starting position and $O(\frac{s}{\theta s})$ choices for the length of a window in $\mathcal{J}$). Moreover, each window of length at most s can be transformed to a window in $\mathcal{J}$ by rounding both endpoints up to the nearest multiple of θs. When performed simultaneously on all windows in $\mathcal{S}$, this perturbation preserves the relative order of the windows, and thus $\mathcal{S}$ remains a consistent window decomposition of $[1 \,..\, n]$. Furthermore, for each window pair (w, w'), the value $\mathsf{dyck}(x[w] \circ x[w'])$ changes by at most $4\theta s$. Given that $|\mathcal{S}| \leq \frac{2n}{s}$, the overall additive overhead does not exceed $8\theta n$.

Two-Level Window Decomposition. If we could estimate the cost of each window pair in $\mathcal{J} \times \mathcal{J}$, this would provide a cost estimation for all window pairs in the unknown set $\mathcal{S} \subseteq \mathcal{J} \times \mathcal{J}$ of Lemma 1.1. Thus, using a dynamic-programming procedure to optimize the cost over consistent decompositions $\tilde{\mathcal{S}} \subseteq \mathcal{J} \times \mathcal{J}$ of $[1 \,..\, n]$, we could approximate $\mathsf{dyck}(x)$.

However, similarly to [15], in order to estimate the cost of each window pair in $\mathcal{J} \times \mathcal{J}$, we further partition each large window into smaller windows and estimate the cost of these smaller window pairs. Thus, given another (smaller) window size parameter, we analogously construct a family $\mathcal{K}$ of variable-sized windows. Adapting the argument behind Lemma 1.1, we can show that, for each window pair $(w, w') \in \mathcal{J} \times \mathcal{J}$, the set $w \cup w'$ admits a consistent window decomposition $\mathcal{S}_{(w,w')} \subseteq \mathcal{K} \times \mathcal{K}$ such that $\sum_{(q,q') \in \mathcal{S}_{(w,w')}} \mathsf{dyck}(x[q] \circ x[q']) \leq \mathsf{dyck}(x[w] \circ x[w']) + O(\theta s)$ (Lemma 5.6 is formulated analogously to Lemma 1.1).

Certifying Window Pairs. With the two-level window decomposition at hand, adapting the remaining two phases of [15] is relatively easy. For this, we design a procedure `CertifyWindowPairs` that finds a cost estimation for selected window pairs in $\mathcal{J} \times \mathcal{J}$ and $\mathcal{K} \times \mathcal{K}$. The procedure shares a similar flavor with the Covering algorithm of [15] and relies on the triangle inequality (Lemma 2.3) discussed above. Its implementation and analysis is provided in the full version [18] only. The main guarantee of `CertifyWindowPairs` is that (with high probability) some of the certified window pairs can be combined to form a consistent window decomposition of $[1 \,..\, n]$ whose cost is $O(\mathsf{dyck}(x) + \theta n)$. Thus, a simple dynamic-programming algorithm (also provided in the full version [18] only) can be used to retrieve a constant-factor approximation of $\mathsf{dyck}(x)$ (recall that $\theta n \leq \mathsf{dyck}(x)$).

Folding Distance. The key difference between the *folding distance* (originating from the RNA folding problem) compared to the Dyck edit distance is that the alphabet is no longer partitioned into the set T of opening parentheses and the set $\overline{T}$ of closing parentheses. In other words, every character c can be matched with its complement $\overline{c}$ regardless of their order in the text. In particular, this means that the notions of heights and valleys are not meaningful anymore. Nevertheless, for any fixed alignment, one can distinguish the unmatched, opening (matched with a character to the right), and closing (matched with a character to the left) characters. Moreover, one can still greedily eliminate substrings of the form $c\overline{c}$ (similarly to the preprocessing of [7]). In any optimal alignment of an instance preprocessed this way, there must be an unmatched character between any two characters matched with each other. Although this reduction does not seem helpful in sparsifying the set of pivots to be considered, it does bring a strong structural property: there is a subset $[1\,..\,n]$ of size $n - O(d)$ (containing all characters matched without edits) which admits a consistent window decomposition into $O(d)$ window pairs (w, w') such that $x[w'] = \overline{x[w]}$ (and thus $\mathsf{fold}(x[w] \circ x[w']) = 0$). The strategy behind our $O(s)$-factor approximation is to sacrifice $O(s)$ boundary characters out of each window pair and, in exchange, make sure that the "closing windows" w' have both endpoints at positions divisible by s. We then use Internal Pattern Matching [24, 25] to efficiently search for "opening windows" w that could match our closing windows. Doing so, we cannot guarantee that the opening windows have their endpoints divisible by s, but we can sparsify the set of candidates so that they start at least s positions apart. This results in $O((\frac{n}{s})^3)$ window pairs to be considered and leads to the overall running time of $O(n + (\frac{n}{s})^3)$. The details are given in the full version [18].

2 Preliminaries

The alphabet Σ consists of two disjoint sets T and $\overline{T}$ of *opening* and *closing* parentheses, respectively, with a bijection $\overline{\cdot} : T \to \overline{T}$ mapping each opening parenthesis to the corresponding closing parenthesis. We extend this mapping to an involution $\overline{\cdot} : T \cup \overline{T} \to T \cup \overline{T}$ and then to an involution $\overline{\cdot} : \Sigma^* \to \Sigma^*$ mapping each string $x[1]x[2]\cdots x[n]$ to its reverse complement $\overline{x[n]}\cdots\overline{x[2]}\,\overline{x[1]}$. Given two strings x, y, we denote their concatenation by xy or $x \circ y$.

The *Dyck* language $\mathsf{Dyck}(\Sigma) \subseteq \Sigma^*$ consists of all well-parenthesized expression over Σ; formally, it can be defined using a context-free grammar whose only non-terminal S admits productions $S \to SS$, $S \to \varnothing$ (empty string), and $S \to aS\overline{a}$ for all $a \in T$.

▶ **Definition 2.1.** *The* Dyck edit distance $\mathsf{dyck}(x)$ *of a string $x \in \Sigma^*$ is the minimum number of character insertions, deletions, and substitutions required to transform x to a string in* $\mathsf{Dyck}(\Sigma)$.

We say that $M \subseteq \{(i,j) \subseteq \mathbb{Z}^2 : i < j\}$ is a *non-crossing matching* if any two distinct pairs $(i,j), (i',j') \in M$ satisfy $i < j < i' < j'$ or $i < i' < j' < j$. Such a matching can also be interpreted as a function $M : \mathbb{Z} \to \mathbb{Z} \cup \{\perp\}$ with $M(i) = j$ if $(i,j) \in M$ or $(j,i) \in M$ for some $j \in \mathbb{Z}$, and $M(i) = \perp$ otherwise.

For a string $x \in \Sigma^n$, the *cost* of a non-crossing matching $M \subseteq [n]^2$ on x (henceforth M is called an *alignment* of x) is defined as $\mathsf{cost}_M(x) = n - 2|M| + \sum_{(i,j)\in M} \mathsf{dyck}(x[i]x[j])$.

The following folklore fact (proved for completeness in the full version [18]), relates the Dyck edit distance with the optimum alignment cost.

▶ **Fact 2.2.** *For every string $x \in \Sigma^*$, the Dyck edit distance* $\mathsf{dyck}(x)$ *is the minimum cost* $\mathsf{cost}_M(x)$ *of an alignment M of x.*

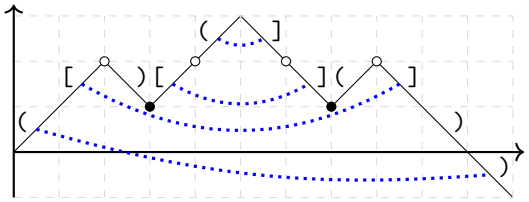

Figure 3 A plot of the height function h for $x = \texttt{([)[(]](])}$. The blue dotted lines represent an alignment $M = \{(1,11),(2,9),(4,7),(5,6)\}$ of cost 4. The valleys $\{3,7\}$ are marked as black circles. The set $K = \{2,3,4,6,7,8\}$ of Fact 2.6 also includes points marked as white circles.

We show that a function mapping $x, y \in \Sigma^*$ to $\mathsf{dyck}(x\overline{y})$ satisfies the triangle inequality.

▶ **Lemma 2.3.** *All strings $x, y, z \in \Sigma^*$ satisfy $\mathsf{dyck}(x\overline{z}) \le \mathsf{dyck}(x\overline{y}y\overline{z}) \le \mathsf{dyck}(x\overline{y}) + \mathsf{dyck}(y\overline{z})$.*

Proof. The second inequality follows from the fact that the Dyck language is closed under concatenations. As for the first inequality, we observe that it suffices to consider $|y| = 1$: the case of $|y| = 0$ is trivial, and the case of $|y| > 1$ can be derived from that of $|y| = 1$ by processing y letter by letter. Now, we proceed by induction on $2\mathsf{dyck}(x\overline{y}y\overline{z}) + |x| + |z|$. If any optimum alignment of $x\overline{y}y\overline{z}$ modifies a character in x or $\overline{z}$, we apply the inductive assumption for an instance (x', y, z') obtained from this modification: $\mathsf{dyck}(x\overline{z}) \le \mathsf{dyck}(x'\overline{z}') + 1 \le \mathsf{dyck}(x'\overline{y}y\overline{z}') + 1 = \mathsf{dyck}(x\overline{y}y\overline{z})$. If any optimum alignment of $x\overline{y}y\overline{z}$ matches any two adjacent characters of x, any two adjacent characters of $\overline{z}$, or the first character of x with the last character of $\overline{z}$, we apply the inductive assumption for an instance (x', y, z') obtained by removing these two characters: $\mathsf{dyck}(x\overline{z}) \le \mathsf{dyck}(x'\overline{z}') \le \mathsf{dyck}(x'\overline{y}y\overline{z}') = \mathsf{dyck}(x\overline{y}y\overline{z})$. In the remaining case, all characters of x and $\overline{z}$ must be matched to $\overline{y}$ or y, so $|x\overline{z}| \le 2$. If $|x\overline{z}| \le \mathsf{dyck}(x\overline{y}y\overline{z})$, then trivially $\mathsf{dyck}(x\overline{z}) \le |x\overline{z}| \le \mathsf{dyck}(x\overline{y}y\overline{z})$, so we may assume $\mathsf{dyck}(x\overline{y}y\overline{z}) < |x\overline{z}|$. The case of $\mathsf{dyck}(x\overline{y}y\overline{z}) = 0$ and $|x\overline{z}| = 1$ is impossible because only strings of even length belong to the Dyck language. Thus, we may assume that $|x\overline{z}| = 2$ and $\mathsf{dyck}(x\overline{y}y\overline{z}) \le 1$. If $|x| = 2$, then the optimum matching of $x\overline{y}y\overline{z}$ must be $\{(1,4),(2,3)\}$, and the sequence transforming $\mathsf{dyck}(x\overline{y}y\overline{z})$ to a word in $\mathsf{Dyck}(\Sigma)$ must include substituting $\overline{y}$ or y (whichever is an opening parenthesis). In particular, $x[1]$ must be an opening parenthesis, so $\mathsf{dyck}(x\overline{z}) = \mathsf{dyck}(x) \le 1 = \mathsf{dyck}(x\overline{y}y\overline{z})$. If $|\overline{z}| = 2$, then the optimum matching of $x\overline{y}y\overline{z}$ must be $\{(1,4),(2,3)\}$, and the sequence transforming $\mathsf{dyck}(x\overline{y}y\overline{z})$ to a word in $\mathsf{Dyck}(\Sigma)$ must include substituting $\overline{y}$ or y (whichever is a closing parenthesis). In particular, $z[1]$ must be an opening parenthesis, so $\mathsf{dyck}(x\overline{z}) = \mathsf{dyck}(\overline{z}) \le 1 = \mathsf{dyck}(x\overline{y}y\overline{z})$. Finally, if $|x| = |\overline{z}| = 1$, then the optimum matching of $x\overline{y}y\overline{z}$ must be $\{(1,2),(3,4)\}$. If $\mathsf{dyck}(x\overline{y}y\overline{z}) = 0$, then we must have $x = y = z \in T$, so $\mathsf{dyck}(x\overline{z}) = 0 \le \mathsf{dyck}(x\overline{y}y\overline{z})$. Otherwise, $x \in T$ or $z \in T$, so $\mathsf{dyck}(x\overline{z}) \le 1 = \mathsf{dyck}(x\overline{y}y\overline{z})$. ◀

In the remainder of this section, we recall several results from [7, 21] that we then use in our $\tilde{O}_\epsilon(n^2)$-time PTAS (Section 3) and $\tilde{O}_\epsilon(nd)$-time $(3+\epsilon)$-approximation (Section 4).

▶ **Definition 2.4** (Heights). *For a fixed string $x \in \Sigma^n$, the* height *function $h : [0\,..\,n] \to [-n\,..\,n]$ is defined so that $h(i) = |\{j \in [1\,..\,i] : x[j] \in T\}| - |\{j \in [1\,..\,i] : x[j] \in \overline{T}\}|$ for $i \in [0\,..\,n]$.*

▶ **Fact 2.5** ([7]). *There is a linear-time algorithm that, given a string $x \in \Sigma^n$, produces a string $x' \in \Sigma^{\le n}$ such that $\mathsf{dyck}(x) = \mathsf{dyck}(x')$ and x' has at most $2\mathsf{dyck}(x)$* valleys*, i.e., positions $v \in [1\,..\,n)$ such that $h(v-1) > h(v) < h(v+1)$.*

For a fixed string $x \in \Sigma^n$, let us define a function $\mathtt{D}$ such that $\mathtt{D}(i,j) = \mathsf{dyck}(x(i\,..\,j])$ for $i,j \in [0\,..\,n]$ with $i \le j$. Note that $\mathtt{D}(i,i) = 0$ for $i \in [0\,..\,n]$, $\mathtt{D}(i,i+1) = 1$ for $i \in [0\,..\,n)$, and $\mathtt{D}(i,j)$ satisfies the following recursion for $i,j \in [0\,..\,n]$ with $j - i \ge 2$:

$$\mathtt{D}(i,j) = \min \begin{cases} \mathtt{D}(i,k) + \mathtt{D}(k,j) & \text{for } k \in (i\,..\,j), \\ \mathtt{D}(i+1,j-1) + \mathsf{dyck}(x[i+1]x[j]). \end{cases} \tag{1}$$

This yields the classic $O(n^3)$-time algorithm computing $\mathtt{D}(0,n) = \mathsf{dyck}(x)$. The following result, combined with Fact 2.5, improves this time complexity to $O(n + n^2\mathsf{dyck}(x))$.

▶ **Fact 2.6** ([21, Lemma 2.1]). *For a string $x \in \Sigma^n$, let $K \subseteq [0\,..\,n]$ consist of all positions at distance 0 or 1 from a valley. For all $i,j \in [0\,..\,n]$ with $j - i \ge 2$, we have*

$$\mathtt{D}(i,j) = \min \begin{cases} \mathtt{D}(i,k) + \mathtt{D}(k,j) & \text{for } k \in (i\,..\,j) \cap (K \cup \{i+1, i+2, j-1, j-2\}), \\ \mathtt{D}(i+1,j-1) + \mathsf{dyck}(x[i+1]x[j]). \end{cases} \tag{2}$$

▶ **Observation 2.7** ([21, Fact 3.1]). *For all strings $x \in \Sigma^n$ and integers $0 \le i \le k \le j \le n$, we have $h(k) \ge \max(h(i), h(j)) - 2\mathtt{D}(i,j)$. In particular, $|h(i) - h(j)| \le 2\mathtt{D}(i,j)$.*

3 Quadratic-Time PTAS

In this section, we develop an $\tilde{O}(\epsilon^{-1}n^2)$-time algorithm that approximates $\mathsf{dyck}(x)$ within a $(1+\epsilon)$ factor. The starting point of our solution is the dynamic program derived from Fact 2.6. Instead of computing the exact value $\mathtt{D}(i,j) = \mathsf{dyck}(x(i\,..\,j])$, that depends on $\mathtt{D}(i,k) + \mathtt{D}(k,j)$ for all pivots $k \in (i\,..\,j) \cap (K \cup \{i+1, i+2, j-1, j-2\})$, we compute an approximation $\mathtt{AD}(i,j) \approx \mathsf{dyck}(x(i\,..\,j])$ in Algorithm 1 that depends only on $\mathtt{D}(i,k) + \mathtt{D}(k,j)$ for pivots $k \in (i\,..\,j) \cap (K_{i,j} \cup \{i+1, i+2, j-1, j-2\})$, where $K_{i,j}$ consists of $\tau_{i,j}$ leftmost and rightmost elements of $K \cap (i\,..\,j)$. Here, $\tau_{i,j}$ is proportional to the largest power of two dividing both i and j. Formally, we set $\tau_{i,j} := \tau \cdot 2^{\min(\nu(i),\nu(j))}$, where $\tau \ge 2$ is a parameter to be set later and $\nu : \mathbb{Z} \to \mathbb{Z}_{\ge 0} \cup \{\infty\}$ is a function that maps an integer $r \in \mathbb{Z}$ to $\nu(r) := \max\{k \in \mathbb{Z} : 2^k \text{ divides } r\}$, with the convention that $\nu(0) = \infty$.

In the following lemma, we inductively bound the quality of $\mathtt{AD}(i,j)$ as an additive approximation of $\mathtt{D}(i,j)$. In particular, we show that $\mathtt{D}(i,j) \le \mathtt{AD}(i,j) \le \mathtt{D}(i,j) + \frac{8}{\tau}|K|\log|K|$.

▶ **Lemma 3.1.** *If $\tau \ge 2$, then, for each $i,j \in [0\,..\,n]$ with $i \le j$, we have $\mathtt{D}(i,j) \le \mathtt{AD}(i,j) \le \mathtt{D}(i,j) + \frac{8}{\tau}c_{i,j}\log c_{i,j}$, where $c_{i,j} := |K \cap (i\,..\,j)|$, and we assume $0\log 0 = 0$.*

Algorithm 1 Recursive implementation of $\mathtt{AD}(i,j)$.

```
AD(i, j)
    if j = i then return 0;
    if j = i + 1 then return 1;
    c := AD(i + 1, j − 1) + dyck(x[i + 1]x[j]);
    τ_{i,j} := τ · 2^{min(ν(i),ν(j))};
    K_{i,j} := the set of τ_{i,j} smallest and τ_{i,j} largest elements of K ∩ (i .. j);
    foreach k ∈ K_{i,j} ∪ ({i + 1, i + 2, j − 2, j − 1} \ {i, j}) do
        c := min(c, AD(i, k) + AD(k, j));
    return c;
```

Proof. We proceed by induction on $j-i$. For $j-i \le 1$, we have $\mathtt{AD}(i,j) = \mathtt{D}(i,j)$. For $j-i \ge 2$, the lower bound $\mathtt{D}(i,j) \le \mathtt{AD}(i,j)$ follows directly from Fact 2.6. Unless $\mathtt{D}(i,j) = \mathtt{D}(i,k) + \mathtt{D}(k,j)$ for some $k \in (i\,..\,j) \cap K$, the upper bound also follows from Fact 2.6 since $c_{i,j}\log c_{i,j} \ge \max(c_{i+1,j-1}\log c_{i+1,j-1},\ c_{i,k}\log c_{i,k} + c_{k,j}\log c_{k,j})$. Let $r = \min(c_{i,k}, c_{k,j})$ and let i', j' be the smallest and the largest multiples of $2^{\lceil \log((r+1)/\tau)\rceil}$ within $[i\,..\,j]$.

Let us first prove that $k \in K_{i',j'}$. Note that $\tau(i'-i) < \tau 2^{\lceil\log((r+1)/\tau)\rceil} < \tau\cdot 2\cdot\frac{r+1}{\tau} = 2(r+1)$, so $\tau(i'-i) \le 2r$ (because both strict inequalities are between integers). A symmetric argument yields $\tau(j-j') \le 2r$. Due to $\tau \ge 2$, we thus have $i'-i \le r \le c_{i,k} < k-i$ and $j-j' \le r \le c_{j,k} < j-k$, so $k \in (i'\,..\,j')$. Moreover, $\tau_{i',j'} \ge \tau\cdot 2^{\lceil\log((r+1)/\tau)\rceil} \ge r+1 = \min(c_{i,k},c_{k,j})+1 \ge \min(c_{i',k},c_{k,j'})+1$, so $k \in K_{i',j'}$ holds as claimed.

Thus, due to $2r = 2\min(c_{i,k},c_{k,j}) \le c_{i,k}+c_{k,j} \le c_{i,j}$, we have

$$\begin{aligned}
\mathtt{AD}(i,j) &\le (i'-i) + \mathtt{AD}(i',j') + (j-j')\\
&\le \tfrac{2r}{\tau} + \mathtt{AD}(i',k) + \mathtt{AD}(k,j') + \tfrac{2r}{\tau}\\
&\le \mathtt{D}(i',k) + \tfrac{8}{\tau}c_{i',k}\log c_{i',k} + \mathtt{D}(k,j') + \tfrac{8}{\tau}c_{k,j'}\log c_{k,j'} + \tfrac{4r}{\tau}\\
&\le (i'-i) + \mathtt{D}(i,k) + \tfrac{8}{\tau}c_{i,k}\log c_{i,k} + \mathtt{D}(k,j) + (j-j') + \tfrac{8}{\tau}c_{k,j}\log c_{k,j} + \tfrac{4r}{\tau}\\
&\le \mathtt{D}(i,j) + \tfrac{8}{\tau}(c_{i,k}\log c_{i,k} + c_{k,j}\log c_{k,j} + r)\\
&= \mathtt{D}(i,j) + \tfrac{8}{\tau}(\max(c_{i,k},c_{k,j})\log\max(c_{i,k},c_{k,j}) + r\log(2r))\\
&\le \mathtt{D}(i,j) + \tfrac{8}{\tau}(\max(c_{i,k},c_{k,j})\log c_{i,j} + \min(c_{i,k},c_{k,j})\log c_{i,j})\\
&\le \mathtt{D}(i,j) + \tfrac{8}{\tau}c_{i,j}\log c_{i,j}.
\end{aligned}$$

◀

Our final solution simply uses Algorithm 1 with an appropriate choice of the parameter τ and the input string preprocessed using Fact 2.5 so that $|K| = O(\mathsf{dyck}(x))$.

▶ **Theorem 3.2.** *There is an algorithm Dyck-Approx that, given a string $x \in \Sigma^n$ and a parameter $\epsilon \in (0,1)$, in $\tilde{O}(\epsilon^{-1}n^2)$ time computes a value v such that $\mathsf{dyck}(x) \le v \le (1+\epsilon)\mathsf{dyck}(x)$.*

Proof. In the preprocessing, we use Fact 2.5 to guarantee that there are at most $2\mathsf{dyck}(x)$ valleys and thus $|K| \le 6\mathsf{dyck}(x)$. Next, we call $\mathtt{AD}(0,n)$ with $\tau = \lceil 48\epsilon^{-1}\log|K|\rceil$ and an array of size $(n+1)\times(n+1)$ memorizing the outputs of recursive calls. The resulting value satisfies $\mathsf{dyck}(x) \le \mathtt{AD}(0,n) \le \mathsf{dyck}(x) + \frac{8}{\tau}|K|\log|K| \le \mathsf{dyck}(x) + \frac{8}{48\epsilon^{-1}\log|K|}\cdot 6\mathsf{dyck}(x)\cdot\log|K| = (1+\epsilon)\mathsf{dyck}(x)$ by Lemma 3.1. The running time is proportional to

$$\begin{aligned}
n^2\sum_{i=0}^{n}\sum_{j=i+2}^{n}\tau_{i,j} &\le n^2 + \sum_{i=0}^{n}\sum_{j=i+2}^{n}\tau 2^{\nu(j)} \le n^2 + n\tau\sum_{j=2}^{n}2^{\nu(j)} \le n^2 + n\tau\sum_{\nu=0}^{\lfloor\log n\rfloor}\left\lfloor\frac{n}{2^\nu}\right\rfloor 2^\nu\\
&= O(n^2\tau\log n) = O(\epsilon^{-1}n^2\log^2 n) = \tilde{O}(\epsilon^{-1}n^2).
\end{aligned}$$

◀

4 Constant-Factor Approximation for Small Distances

In this section, we speed up the algorithm of Section 3 at the cost of increasing the approximation ratio from $1+\epsilon$ to $3+\epsilon$. The key idea behind our solution is to re-use the DP of Fact 2.6 and Algorithm 1 with an extra constraint that the transition from (i,j) to $(i+1,j-1)$ (which corresponds to adding $(i+1,j)$ to the alignment M, i.e., matching $x[i+1]$ with $x[j]$) is forbidden if there is a deep valley within $(i\,..\,j)$. This condition is expressed in terms of the following function:

▶ **Definition 4.1.** *For a fixed string $x \in \Sigma^n$ and $i,j \in [0\,..\,n]$ with $i \le j$, let $h(i,j) = \min_{k=i}^{j} h(k)$.*

Namely, we require that $h(i+1, j-1) > h(i,j)$ holds for all $(i+1, j) \in M$. For example, in the alignment M of Figure 3, $(2, 9) \in M$ violates this condition due to $h(1, 9) = 1 = h(2, 8)$, whereas the remaining pairs satisfy this condition. Formally, we transform the recursion of Fact 2.6 into the following one, specified through a function $\mathtt{GD} : [0\,..\,n]^2 \to [0\,..\,n]$ such that $\mathtt{GD}(i, i) = 0$ for $i \in [0\,..\,n]$, $\mathtt{GD}(i, i+1) = 1$ for $i \in [0\,..\,n)$, and, for all $i, j \in [0\,..\,n]$ with $j - i \geq 2$:

$$\mathtt{GD}(i,j) = \min \begin{cases} \mathtt{GD}(i,k) + \mathtt{GD}(k,j) & \text{for } k \in (i\,..\,j) \cap (K \cup \{i+1, i+2, j-2, j-1\}), \\ \mathtt{GD}(i+1, j-1) + \mathsf{dyck}(x[i+1]x[j]) & \text{if } h(i+1, j-1) > h(i,j). \end{cases}$$

Somewhat surprisingly, this significant limitation on the allowed alignments M incurs no more that a factor-3 loss in optimum alignment cost. Specifically, if we take an arbitrary alignment M of x and remove all pairs $(i+1, j)$ with $h(i+1, j-1) = h(i,j)$, the resulting alignment M' satisfies $\mathsf{cost}_{M'}(x) \leq 3\mathsf{cost}_M(x)$. This can be proved by induction on the structure of M using a potential function $h(i) + h(j) - 2h(i,j)$ as a "budget" for future deletions of matched pairs. Nevertheless, the proof of the following lemma operates directly on $\mathtt{D}$ and $\mathtt{GD}$.

▶ **Lemma 4.2.** *Let $x \in \Sigma^n$. For all $i, j \in [0\,..\,n]$ with $i \leq j$, we have $\mathtt{D}(i,j) \leq \mathtt{GD}(i,j) \leq 3\mathtt{D}(i,j) - h(i) - h(j) + 2h(i,j)$.*

Proof. We proceed by induction on $j - i$. The lower bound holds trivially. As for the upper bound, we consider several cases:

- $j = i$. In this case, $\mathtt{GD}(i,j) = 0 = 3 \cdot 0 - h(i) - h(i) + 2h(i) = \mathtt{D}(i,j) - h(i) - h(j) + 2h(i,j)$.
- $j = i + 1$. In this case, $\mathtt{GD}(i,j) = 1 < 2 = 3 \cdot 1 - h(i) - h(i+1) + 2\min(h(i), h(i+1)) = \mathtt{D}(i,j) - h(i) - h(j) + 2h(i,j)$.
- $\mathtt{D}(i,j) = \mathtt{D}(i,k) + \mathtt{D}(k,j)$ for some $k \in (i\,..\,j) \cap (K \cup \{i+1, i+2, j-2, j-1\})$. Then,

$$\begin{aligned} \mathtt{GD}(i,j) &\leq \mathtt{GD}(i,k) + \mathtt{GD}(k,j) \\ &\leq 3\mathtt{D}(i,k) - h(i) - h(k) + 2h(i,k) + 3\mathtt{D}(k,j) - h(k) - h(j) + 2h(k,j) \\ &= 3\mathtt{D}(i,j) - h(i) - h(j) - 2h(k) + 2\min(h(i,k), h(k,j)) + 2\max(h(i,k), h(k,j)) \\ &\leq 3\mathtt{D}(i,j) - h(i) - h(j) - 2h(k) + 2h(i,j) + 2h(k) \\ &= 3\mathtt{D}(i,j) - h(i) - h(j) + 2h(i,j). \end{aligned}$$

- $\mathtt{D}(i,j) = \mathtt{D}(i+1, j-1) + \mathsf{dyck}(x[i+1]x[j])$ and $h(i+1, j-1) = h(i,j) + 1$. Then,

$$\begin{aligned} \mathtt{GD}(i,j) &\leq \mathtt{GD}(i+1, j-1) + \mathsf{dyck}(x[i+1]x[j]) \\ &\leq 3\mathtt{D}(i+1, j-1) - h(i+1) - h(j-1) + 2h(i+1, j-1) + \mathsf{dyck}(x[i+1]x[j]) \\ &= 3\mathtt{D}(i,j) - h(i+1) - h(j-1) + 2h(i,j) + 2 - 2\mathsf{dyck}(x[i+1]x[j]) \\ &\leq 3\mathtt{D}(i,j) - h(i) - h(j) + 2h(i,j) \end{aligned}$$

  because $2\mathsf{dyck}(x[i+1]x[j]) \geq 2 + h(i) - h(i+1) + h(j) - h(j-1)$.
- $\mathtt{D}(i,j) = \mathtt{D}(i+1, j-1) + \mathsf{dyck}(x[i+1]x[j])$ and $h(i+1, j-1) = h(i,j)$. Then,

$$\begin{aligned} \mathtt{GD}(i,j) &\leq \mathtt{GD}(i, i+1) + \mathtt{GD}(i+1, j-1) + \mathtt{GD}(j-1, j) \\ &= \mathtt{GD}(i+1, j-1) + 2 \\ &\leq 3\mathtt{D}(i+1, j-1) - h(i+1) - h(j-1) + 2h(i+1, j-1) + 2 \\ &= 3\mathtt{D}(i,j) - h(i+1) - h(j+1) + 2h(i,j) - 3\mathsf{dyck}(x[i+1]x[j]) + 2 \\ &\leq 3\mathtt{D}(i,j) - h(i) - h(j) + 2h(i,j) \end{aligned}$$

  because $3\mathsf{dyck}(x[i+1]x[j]) \geq 2\mathsf{dyck}(x[i+1]x[j]) \geq 2 + h(i) - h(i+1) + h(j) - h(j-1)$. ◀

Next, we derive a property of $\texttt{GD}$ that allows for a speedup compared to $\texttt{D}$. Recall that $\texttt{GD}$ forbids the transition from (i,j) to $(i+1,j-1)$ if $h(i+1,j-1)=h(i,j)$. We further show that, in this case, it suffices to consider one specific pivot while computing $\texttt{GD}(i,j)$ (specifically, the pivot of minimum height, with ties resolved arbitrarily; see Fact 4.3). Later on (in the proof of Theorem 4.6), we argue that, after the preprocessing of Fact 2.5, there are only $O(nd)$ pairs (i,j) for which $h(i+1,j-1)>h(i,j)$ yet $\texttt{D}(i,j)\le d$.

▶ **Fact 4.3.** *Let $x\in\Sigma^n$ and let $i,j\in[0\,..\,n]$ with $j-i\ge 2$ and $h(i+1,j-1)=h(i,j)$. Then, every $k^*\in(i\,..\,j)$ with $h(k^*)=h(i,j)$ satisfies $\texttt{GD}(i,j)=\texttt{GD}(i,k^*)+\texttt{GD}(k^*,j)$.*

Proof. We proceed by induction on $j-i$. Fix $k\in(i\,..\,j)\cap(K\cup\{i+1,i+2,j-2,j-1\})$ such that $\texttt{GD}(i,j)=\texttt{GD}(i,k)+\texttt{GD}(k,j)$. If $k=k^*$, then the claim is trivial. Thus, by symmetry, we assume without loss of generality that $k^*\in(i\,..\,k)$. In particular, this means that $k-i\ge 2$ and $h(i+1,k-1)=h(k^*)=h(i,k)$, Consequently, by the inductive assumption, $\texttt{GD}(i,j)=\texttt{GD}(i,k)+\texttt{GD}(k,j)=\texttt{GD}(i,k^*)+\texttt{GD}(k^*,k)+\texttt{GD}(k,j)\ge\texttt{GD}(i,k^*)+\texttt{GD}(k^*,j)\ge\texttt{GD}(i,j)$, i.e., $\texttt{GD}(i,j)=\texttt{GD}(i,k^*)+\texttt{GD}(k^*,j)$ holds as claimed. Here, the first inequality holds because $k\in(k^*\,..\,j)\cap(K\cup\{k^*+1,k^*+2,j-2,j-1\})$, whereas the second one is due to $k^*\in K$ (because k^* is a valley). ◀

Our approximation algorithm (implemented as Algorithm 2) computes $\texttt{AGD}$ that approximates $\texttt{GD}$ in the same way $\texttt{AD}$ approximates $\texttt{D}$ in Algorithm 1. The only difference is that we use Observation 2.7 and Fact 4.3 (and the definition of $\texttt{GD}$) to prune some states and transitions. For each of the remaining states, the algorithm computes a value $\texttt{AGD}(i,j)\approx\texttt{GD}(i,j)$. If $h(i,j)=h(i+1,j-1)$, then Algorithm 2 relies on Fact 4.3 and considers the smallest index $k\in(i\,..\,j)$ with $h(k)=h(i,j)$ as the sole potential pivot, i.e, it returns $\texttt{AGD}(i,k)+\texttt{AGD}(k,j)$. If $h(i,j)<h(i+1,j-1)$, then Algorithm 2 mimics Algorithm 1.

The analysis of the approximation ratio of Algorithm 2 resembles that of Algorithm 1.

▶ **Lemma 4.4.** *If $\tau\ge 2$, then, for each $i,j\in[0\,..\,n]$ with $i\le j$, we have $\texttt{GD}(i,j)\le\texttt{AGD}(i,j)$ and, if $\texttt{GD}(i,j)\le d$, we further have $\texttt{AGD}(i,j)\le\texttt{GD}(i,j)+\frac{8}{\tau}c_{i,j}\log c_{i,j}$, where $c_{i,j}:=|K\cap(i\,..\,j)|$, and we assume $0\log 0=0$.*

Proof. As for the upper bound, we proceed by induction on $j-i$. For $j-i\le 1$, we have $\texttt{AGD}(i,j)=\texttt{GD}(i,j)$. For $j-i\ge 2$, the lower bound $\texttt{GD}(i,j)\le\texttt{AGD}(i,j)$ follows directly form the definitions of $\texttt{AGD}$ and $\texttt{GD}$. If $h(i,j)<\max(h(i),h(j))-2d$, then the upper bound follows

Algorithm 2 Recursive implementation of $\texttt{AGD}(i,j)$.

```
1  AGD(i, j)
2      if j = i then return 0;
3      if j = i + 1 then return 1;
4      if h(i, j) < max(h(i), h(j)) − 2d then return ∞;
5      if h(i, j) = h(i + 1, j − 1) then
6          Select the smallest k ∈ (i .. j) such that h(k) = h(i, j);
7          return AGD(i, k) + AGD(k, j);
8      c := AGD(i + 1, j − 1) + dyck(x[i + 1]x[j]);
9      τ_{i,j} := τ · 2^{min(ν(i),ν(j))};
10     K_{i,j} := the set of τ_{i,j} smallest and τ_{i,j} largest elements of K ∩ (i .. j);
11     foreach k ∈ K_{i,j} ∪ ({i + 1, i + 2, j − 2, j − 1} \ {i, j}) do
12         c := min(c, AGD(i, k) + AGD(k, j));
13     return c;
```

from Observation 2.7 and Lemma 4.2. If $h(i,j) = h(i+1,j-1)$, then the upper bound follows form Fact 4.3 because $c_{i,k}\log c_{i,k} + c_{k,j}\log c_{k,j} \le c_{i,j}\log c_{i,j}$. Otherwise, the upper bound follows directly from the definitions of $\texttt{AGD}$ and $\texttt{GD}$ unless $\texttt{GD}(i,j) = \texttt{GD}(i,k) + \texttt{GD}(k,j)$ for some $k \in (i\,..\,j) \cap K$. Let $r = \min(c_{i,k}, c_{k,j})$ and let i', j' be the smallest and the largest multiple of $2^{\lceil\log((r+1)/\tau)\rceil}$ within $[i\,..\,j]$.

Let us next prove that $k \in K_{i',j'}$. Note that $\tau(i'-i) < \tau 2^{\lceil\log((r+1)/\tau)\rceil} < \tau\cdot 2\cdot\frac{r+1}{\tau} = 2(r+1)$, so $\tau(i'-i) \le 2r$ (because both strict inequalities are between integers). A symmetric argument yields $\tau(j-j') \le 2r$. Due to $\tau \ge 2$, we thus have $i' - i \le r \le c_{i,k} < k - i$ and $j - j' \le r \le c_{j,k} < j - k$, so $k \in (i'\,..\,j')$. Moreover, $\tau_{i',j'} \ge \tau\cdot 2^{\lceil\log((r+1)/\tau)\rceil} \ge r+1 = \min(c_{i,k},c_{k,j})+1 \ge \min(c_{i',k},c_{k,j'})+1$, so $k \in K_{i',j'}$ holds as claimed.

Thus, due to $2r = 2\min(c_{i,k},c_{k,j}) \le c_{i,k}+c_{k,j} \le c_{i,j}$, we have

$$\begin{aligned}
\texttt{AGD}(i,j) &\le (i'-i) + \texttt{AGD}(i',j') + (j-j')\\
&\le \tfrac{2r}{\tau} + \texttt{AGD}(i',k) + \texttt{AGD}(k,j') + \tfrac{2r}{\tau}\\
&\le \texttt{GD}(i',k) + \tfrac{8}{\tau}c_{i',k}\log c_{i',k} + \texttt{GD}(k,j') + \tfrac{8}{\tau}c_{k,j'}\log c_{k,j'} + \tfrac{4r}{\tau}\\
&\le (i'-i) + \texttt{GD}(i,k) + \tfrac{8}{\tau}c_{i,k}\log c_{i,k} + \texttt{GD}(k,j) + (j-j') + \tfrac{8}{\tau}c_{k,j}\log c_{k,j} + \tfrac{4r}{\tau}\\
&\le \texttt{GD}(i,j) + \tfrac{8}{\tau}(c_{i,k}\log c_{i,k} + c_{k,j}\log c_{k,j} + r)\\
&= \texttt{GD}(i,j) + \tfrac{8}{\tau}(\max(c_{i,k},c_{k,j})\log\max(c_{i,k},c_{k,j}) + r\log(2r))\\
&\le \texttt{GD}(i,j) + \tfrac{8}{\tau}(\max(c_{i,k},c_{k,j})\log c_{i,j} + \min(c_{i,k},c_{k,j})\log c_{i,j})\\
&\le \texttt{GD}(i,j) + \tfrac{8}{\tau}c_{i,j}\log c_{i,j}.
\end{aligned}$$

◀

On the other hand, the complexity analysis is not as simple as in Section 3: it involves a charging argument bounding the number of states processed using the insight of Fact 4.3.

▶ **Proposition 4.5.** *There is an algorithm that, given a string $x \in \Sigma^n$, a threshold $d \in [1\,..\,n]$, and a parameter $\epsilon \in (0,1)$, in $\tilde{O}(\epsilon^{-1}nd)$ time reports that $\texttt{GD}(0,n) > d$ or outputs a value v such that $\texttt{GD}(0,n) \le v \le (1+\epsilon)\texttt{GD}(0,n)$.*

Proof. In the preprocessing, we use Fact 2.5 to guarantee that there are at most $2\mathsf{dyck}(x)$ valleys and thus $|K| \le 6\mathsf{dyck}(x)$. Then, we construct a data structure that, given $i,j \in [0\,..\,n]$, reports the smallest $k \in [i\,..\,j]$ such that $h(k) = h(i,j)$ [20]. Finally, we run $\texttt{AGD}(0,n)$ with $\tau = \lceil 48\epsilon^{-1}\log|K|\rceil$ and memoization of the results of recursive calls. By Lemma 4.4, the returned value satisfies $\texttt{GD}(0,n) \le \texttt{AGD}(0,n) \le \texttt{GD}(0,n) + \frac{8}{\tau}|K|\log|K| \le (1+\epsilon)\texttt{GD}(0,n)$.

The running time analysis is more complex than in the proof of Theorem 3.2. We say that a call $\texttt{AGD}(i,j)$ is *hard* if it reaches Line 8, *easy* if it terminates at Line 4 or Line 7, and *trivial* otherwise. Observe that the total cost of trivial calls is $\tilde{O}(n)$. Moreover, the cost of each easy call is $\tilde{O}(1)$ plus the cost of the two calls made in Line 7, but the call $\texttt{AGD}(i,k)$ is never easy (it can be hard or trivial). This is because the choice of k as the smallest index in $(i\,..\,j)$ with $h(k) = h(i,j)$ guarantees that either $k = i+1$ or $h(i+1,k-1) > h(k) = h(i,k) = h(i,j) \ge \max(h(i),h(j)) - 2d \ge h(i) - 2d = \max(h(i),h(k)) - 2d$. Consequently, the cost of each easy call can be charged to its parent or sibling (which is hard or trivial), and it suffices to bound the total running time of hard calls. By symmetry, we only bound the cost of hard calls $\texttt{AGD}(i,j)$ with $h(i) \ge h(j)$. We then observe that if $h(i) \ge h(j) = h(j')$ and $i > j > j'$, then $\texttt{AGD}(i,j')$ is easy. Consequently, there are at most $4d+1$ hard calls per i. The cost of each hard call $\texttt{AGD}(i,j)$ is $\tilde{O}(\tau_{i,j}) = \tilde{O}(\tau 2^{\nu(i)})$, for a total of $\tilde{O}(d\tau\sum_{i=0}^{n} 2^{\nu(i)}) = \tilde{O}(\epsilon^{-1}nd)$. ◀

▶ **Theorem 4.6.** *There is an algorithm that, given a string $x \in \Sigma^n$, a threshold $d \in [1\,..\,n]$, and a parameter $\epsilon \in (0,1)$, in $\tilde{O}(\epsilon^{-1}nd)$ time reports that $\mathsf{dyck}(x) > d$ or outputs a value v such that $\mathsf{dyck}(x) \le v \le (3+\epsilon)\mathsf{dyck}(x)$.*

Proof. We apply Proposition 4.5 with adjusted d (three times larger) and ϵ (three times smaller). The correctness follows from Lemma 4.2. ◀

5 Constant-Factor Approximation in Subquadratic Time

In this section, we provide an algorithm that, given a string $x \in \Sigma^*$, computes constant-factor approximation of $\mathsf{dyck}(x)$ in subquadratic time. Formally, we show the following:

▶ **Theorem 5.1.** *There exist a randomized algorithm that, given a string $x \in \Sigma^n$, in $\tilde{O}(n^{67/34}) = O(n^{1.971})$ time, outputs a value v such that $\mathsf{dyck}(x) \le v \le 41 \cdot \mathsf{dyck}(x)$ holds with probability at least $1 - n^{-9}$.*

Instead of directly proving the above theorem, we develop the following result:

▶ **Theorem 5.2.** *There exist a constant C and a randomized algorithm that, given a string $x \in \Sigma^n$, in time $\tilde{O}(n^{67/34})$, outputs a value v such that $\mathsf{dyck}(x) \le v \le 40 \cdot \mathsf{dyck}(x) + Cn^{33/34}$ holds with probability at least $1 - n^{-9}$.*

Proof of Theorem 5.1 from Theorem 5.2. First, run the algorithm of Theorem 4.6 with $\epsilon = 1$ and $d = \lceil Cn^{33/34} \rceil$, where C is the constant of Theorem 5.2, this procedure takes $\tilde{O}(n^{67/34})$ time and either outputs a 4-approximation of $\mathsf{dyck}(x)$ or reports that $\mathsf{dyck}(x) > d$. In the latter case, run the algorithm of Theorem 5.2 and return the resulting value v. Then, $\mathsf{dyck}(x) \le v \le 40 \cdot \mathsf{dyck}(x) + Cn^{33/34} \le 41 \cdot \mathsf{dyck}(x)$ holds with probability at least $1 - n^{-9}$. ◀

The rest of the section is devoted to prove Theorem 5.2.

5.1 Window Decomposition

Let us fix a string $x \in \Sigma^n$. For all integers $0 \le i_1 \le i_2 \le n$, we define a *window* $w := (i_1 \,..\, i_2]$ with *endpoints* $b(w) := i_1$, $e(w) := i_2$ and with *length* $|w| := i_2 - i_1$. We distinguish $n + 1$ distinct *empty* windows $(i \,..\, i]$ for $i \in [0 \,..\, n]$. For $w = (i_1 \,..\, i_2]$, we denote $x[w] := x(i_1 \,..\, i_2]$.

A *window pair* is a pair of windows (w, w'), and a weighed window pair is a triple (w, w', c) such that (w, w') is a window pair and $c \in \mathbb{R}_{\ge 0}$ is a weight. The *cost* of a window pair (w, w') is $\mathsf{dyck}(x[w] \circ x[w'])$, and a weighted window pair (w, w', c) is *certified* if $c \ge \mathsf{dyck}(x[w] \circ x[w'])$.

▶ **Definition 5.3.** *A set $\{(w_1, w_1'), \ldots, (w_\ell, w_\ell')\}$ of window pairs is a* consistent decomposition *of $\bigcup_{i=1}^{\ell}(w_i \cup w_i')$ if the 2ℓ windows are disjoint and $\{(b(w_i), b(w_i')) : i \in [1 \,..\, \ell]\}$ forms a non-crossing matching. We also lift this definition to sets of weighted window pairs.*

For a consistent decomposition $\mathcal{S}$, we write $\mathsf{dyck}(\mathcal{S}) := \sum_{(w,w') \in \mathcal{S}} \mathsf{dyck}(x[w] \circ x[w'])$ to denote the total cost of windows pairs in $\mathcal{S}$. Observe that if $\mathcal{S}$ is a consistent decomposition of $[1 \,..\, n]$, then $\mathsf{dyck}(\mathcal{S}) \ge \mathsf{dyck}(x)$.

Our first goal is to prove that, for every $s \in [1 \,..\, n]$, there exists a consistent decomposition $\mathcal{S}$ of $[1 \,..\, n]$ such that $\mathsf{dyck}(\mathcal{S}) = \mathsf{dyck}(x)$, $|\mathcal{S}| = O(\frac{n}{s})$, and each window in $\mathcal{S}$ is of length at most s. For this, we inductively construct a consistent window decomposition of an arbitrary interval $(i_1 \,..\, i_2] \subseteq [1 \,..\, n]$ specified as follows (recall that $\mathtt{D}(i_1, i_2)$ denotes $\mathsf{dyck}(x(i_1 \,..\, i_2])$):

▶ **Lemma 5.4.** *Let x be a string of length n and let $s \in [1 \,..\, n]$. For every interval $(i_1 \,..\, i_2] \subseteq [1 \,..\, n]$, there exists a consistent decomposition $\mathtt{Dec}(i_1, i_2)$ of $(i_1 \,..\, i_2]$ such that:*

1. *each window pair $(w, w') \in \mathtt{Dec}(i_1, i_2)$ satisfies $|w|, |w'| \le s$,*
2. *$\mathsf{dyck}(\mathtt{Dec}(i_1, i_2)) = \mathtt{D}(i_1, i_2)$, and*
3. *$|\mathtt{Dec}(i_1, i_2)| \le \max(1, \frac{2(i_2 - i_1)}{s} - 1)$.*

Proof. If $|(i_1 \,..\, i_2]| \le 2s$, we return $\mathtt{Dec}(i_1, i_2) := \{((i_1 \,..\, \lfloor \frac{i_1 + i_2}{2} \rfloor], (\lfloor \frac{i_1 + i_2}{2} \rfloor \,..\, i_2])\}$. In this simple base case, all the claims hold trivially.

In the main case, we grow the outermost window pair $((i_1\,..\,j_1],(j_2\,..\,i_2])$, starting with empty windows and maintaining two invariants: $|(i_1\,..\,j_1]|,|(j_2\,..\,i_2]| \le s$ and $\mathtt{D}(i_1,i_2) = \mathtt{D}(j_1,j_2) + \mathsf{dyck}(x(i_1\,..\,j_1]\circ x(j_2\,..\,i_2])$. Once there exists $p \in [i_1+s\,..\,i_2-s]$ with $\mathtt{D}(j_1,j_2) = \mathtt{D}(j_1,p)+\mathtt{D}(p,j_2)$ (in particular, this holds when $|(i_1\,..\,j_1]| = s$ or $|(j_2\,..\,i_2]| = s$), we terminate the process and return $\mathtt{Dec}(i_1,i_2) := \{((i_1\,..\,j_1],(j_2\,..\,i_2])\} \cup \mathtt{Dec}(j_1,p) \cup \mathtt{Dec}(p,j_2)$. By the inductive hypothesis, $\mathtt{Dec}(j_1,p), \mathtt{Dec}(p,j_2)$ satisfy all the claimed conditions. In particular, they form consistent decompositions of $(j_1\,..\,p]$ and $(p\,..\,j_2]$, respectively, and thus $\mathtt{Dec}(i_1,i_2)$ forms a consistent decomposition of $(i_1\,..\,i_2]$. By the first invariant, each window in $\mathtt{Dec}(i_1,i_2)$ is of length at most s. The second invariant and the definition of p yield

$$\begin{aligned}\mathtt{D}(i_1,i_2) &= \mathtt{D}(j_1,p) + \mathtt{D}(p,j_2) + \mathsf{dyck}(x(i_1\,..\,j_1]\circ x(j_2\,..\,i_2])\\ &= \mathsf{dyck}(\mathtt{Dec}(j_1,p)) + \mathsf{dyck}(\mathtt{Dec}(p,j_2)) + \mathsf{dyck}(x(i_1\,..\,j_1]\circ x(j_2\,..\,i_2])\\ &= \mathsf{dyck}(\mathtt{Dec}(i_1,i_2)).\end{aligned}$$

The choice of $p \in [i_1+s\,..\,i_2-s]$ further gives

$$\begin{aligned}&|\mathtt{Dec}(i_1,i_2)| \le 1+|\mathtt{Dec}(j_1,p)|+|\mathtt{Dec}(p,j_2)| \le 1+\max(1,\tfrac{2(p-j_1)}{s}-1)+\max(1,\tfrac{2(j_2-p)}{s}-1)\\ &\le 1+\max(1,\tfrac{2(p-i_1)}{s}-1)+\max(1,\tfrac{2(i_2-p)}{s}-1) = 1+\tfrac{2(p-i_1)}{s}-1+\tfrac{2(i_2-p)}{s}-1 = \tfrac{2(i_2-i_1)}{s}-1.\end{aligned}$$

Otherwise, we grow the outermost window pair using one of the following three cases. If there exists $p \in (j_1\,..\,i_1-s)$ such that $\mathtt{D}(j_1,j_2) = \mathtt{D}(j_1,p)+\mathtt{D}(p,j_2)$, we append $(j_1\,..\,p]$ to the window $(i_1\,..\,j_1]$. Then, the choice of p guarantees the first invariant, whereas the second invariant holds due to

$$\begin{aligned}\mathtt{D}(i_1,i_2) &= \mathtt{D}(j_1,p) + \mathtt{D}(p,j_2) + \mathsf{dyck}(x(i_1\,..\,j_1]\circ x(j_2\,..\,i_2])\\ &\ge \mathtt{D}(p,j_2) + \mathsf{dyck}(x(i_1\,..\,p]\circ x(j_2\,..\,i_2]) \ge \mathtt{D}(i_1,i_2).\end{aligned}$$

Symmetrically, if there exists $p \in (i_2-s\,..\,i_2)$ such that $\mathtt{D}(j_1,j_2) = \mathtt{D}(j_1,p)+\mathtt{D}(p,j_2)$, we prepend $(p\,..\,j_2]$ to the window $(j_2\,..\,i_2]$. By (1), the remaining case is when $\mathtt{D}(j_1,j_2) = \mathtt{D}(j_1+1,j_2-1)+\mathsf{dyck}(x[j_1+1]x[j_2])$, i.e., the optimum alignment matches $x[j_1+1]$ and $x[j_2]$. Then, we add both these characters to the outermost window pair. In this case, the first invariant holds due to $|(i_1\,..\,j_1]|,|(j_2\,..\,i_2]| < s$. As for the second invariant, we have

$$\begin{aligned}\mathtt{D}(i_1,i_2) &= \mathtt{D}(j_1+1,j_2-1) + \mathsf{dyck}(x[j_1+1]x[j_2]) + \mathsf{dyck}(x(i_1\,..\,j_1]\circ x(j_2\,..\,i_2])\\ &\ge \mathtt{D}(j_1+1,j_2-1) + \mathsf{dyck}(x(i_1\,..\,j_1+1]\circ x(j_2-1\,..\,i_2]) \ge \mathtt{D}(i_1,i_2).\end{aligned}$$

◀

Large and small windows. Let us fix an integer power of two $\theta \in [\frac{1}{n},1]$ (which will be set to $n^{-1/34}$ rounded down appropriately). For each power of two $s \in [1\,..\,\theta^{-1}]$, define a function $\mathtt{up}_s$ that maps each $i \in [0\,..\,n]$ to $\mathtt{up}_s(i) := \min(n,\theta s\lceil\frac{i}{\theta s}\rceil)$ and denote its image with N_s. Note that $N_s \subseteq [0\,..\,n]$ consists of n as well as all integer multiples of θs. Moreover, for each $i \in [0\,..\,n]$, the value $\mathtt{up}_s(i)$ is the successor of i in N_s.

We introduce the following family of variable-size windows:

$$\mathcal{I}_s := \{w \subseteq [1\,..\,n] : |w| \le s_1 \text{ and } b(w), e(w) \in N_s\}.$$

The following claim is a direct consequence of the construction.

▷ Claim 5.5. $|\mathcal{I}_s| = O(\frac{n}{\theta^2 s})$.

We pick two scales $s_1 \ge s_2$, denoting $\mathcal{J} := \mathcal{I}_{s_1}$ and $\mathcal{K} := \mathcal{I}_{s_2}$. For larger windows, we prove the following result:

▶ **Lemma 1.1.** *There exists a consistent window decomposition $\mathcal{S} \subseteq \mathcal{J} \times \mathcal{J}$ of $[1\,..\,n]$ such that $\sum_{(w,w')\in\mathcal{S}} \mathsf{dyck}(x[w] \circ x[w']) \leq \mathsf{dyck}(x) + 8\theta n$.*

Proof. By Lemma 5.4 applied for $s := s_1$, there exists a consistent decomposition $\mathtt{Dec}(0,n)$ of $[1\,..\,n]$ such that $\mathsf{dyck}(\mathtt{Dec}(0,n)) = \mathsf{dyck}(x)$, $|\mathtt{Dec}(0,n)| \leq \frac{2n}{s_1}$, and each window in $\mathtt{Dec}(0,n)$ is of length at most s_1. In order to meet the condition $\mathcal{S} \subseteq \mathcal{J} \times \mathcal{J}$, we round the window endpoints up using the $\mathtt{up}_{s_1}$ function. Formally, for each window pair $(w,w') \in \mathtt{Dec}(0,n)$, we create one window pair $(\tilde{w},\tilde{w}') \in \mathcal{S}$, where $b(\tilde{w}) = \mathtt{up}_{s_1}(b(w))$, $e(\tilde{w}) = \mathtt{up}_{s_1}(e(w))$, $b(\tilde{w}') = \mathtt{up}_{s_1}(b(w'))$, and $e(\tilde{w}') = \mathtt{up}_{s_1}(e(w'))$. The resulting family $\mathcal{S}$ satisfies $\mathcal{S} \subseteq \mathcal{J} \times \mathcal{J}$ since $|w|, |w'| \leq s_1$ implies $|\tilde{w}|, |\tilde{w}'| \leq s_1$ (because s_1 is an integer multiple of θs_1). The relative order of windows involved in $\mathcal{S}$ is the same as in $\mathtt{Dec}(0,n)$, and thus $\mathcal{S}$ remains a consistent decomposition of $(0\,..\,n]$ (this is also because $\mathtt{up}_{s_1}(0) = 0$ and $\mathtt{up}_{s_1}(n) = n$). Moreover, a single edit may increase the Dyck edit distance by at most one, and thus

$$\begin{aligned}\mathsf{dyck}(\mathcal{S}) &= \sum_{(\tilde{w},\tilde{w}')\in\mathcal{S}} \mathsf{dyck}(x[\tilde{w}] \circ x[\tilde{w}']) \leq \sum_{(w,w')\in\mathtt{Dec}(0,n)} (\mathsf{dyck}(x[w] \circ x[w']) + 4\theta s_1) \\ &= \mathsf{dyck}(\mathtt{Dec}(0,n)) + 4\theta s_1 |\mathtt{Dec}(0,n)| \leq \mathsf{dyck}(x) + 8\theta n. \end{aligned}$$

◀

Our next objective is to estimate $\mathsf{dyck}(x[w] \circ x[w'])$ for each $w, w' \in \mathcal{J}$. For this, we utilize the smaller windows via the following result. Its proof, similar to that of Lemma 1.1, is left for the full version [18].

▶ **Lemma 5.6.** *For every $(w,w') \in \mathcal{J} \times \mathcal{J}$ with $e(w) \leq b(w')$, there exists a consistent window decomposition $\mathcal{S} \subseteq \mathcal{K} \times \mathcal{K}$ of $w \cup w'$ such that $\mathsf{dyck}(\mathcal{S}) \leq \mathsf{dyck}(x[w] \circ x[w']) + O(\theta|w \cup w'|)$.*

5.2 Outline of the Proof of Theorem 5.2

We set θ, s_1, s_2 to be the largest integer powers of two satisfying $s_1 \leq n^{21/34}$, $s_2 \leq n^{13/34}$, and $\theta \leq n^{-1/34}$, respectively. We first construct the families $\mathcal{J}$ and $\mathcal{K}$ of large and small windows, as defined in Section 5.1. Then, we run a procedure `CertifyWindowPairs` (described in the full version [18]), which certifies window pairs in $\mathcal{J} \times \mathcal{J}$ and $\mathcal{K} \times \mathcal{K}$; some pairs are certified directly, using Theorem 3.2 with $\epsilon = 1$ (which provides a 2-approximation), whereas others indirectly, using the triangle inequality (Lemma 2.3). The resulting family $\mathcal{W}$ of certified window pairs satisfies the following property with probability $1 - n^{-9}$: there exists a consistent decomposition $T \subseteq \mathcal{W}$ of $[1\,..\,n]$ such that $\sum_{(w,w',c)\in T} c \leq 40 \cdot \mathsf{dyck}(x) + O(\theta n)$.

Next, we use a simple dynamic-programming procedure (described in the full version [18]) to minimize the total cost $\sum_{(w,w',c)\in\tilde{T}} c$ among all consistent decompositions $\tilde{T} \subseteq \mathcal{W}$ of $[1\,..\,n]$. The resulting cost is at least $\mathsf{dyck}(x)$ because $\mathcal{W}$ contains certified window pairs only (that is, $c \geq \mathsf{dyck}(x[w] \circ x[w'])$ holds for each $(w,w',c) \in \mathcal{W}$). Moreover, the cost is at most $40 \cdot \mathsf{dyck}(x) + O(\theta n) \leq 40 \cdot \mathsf{dyck}(x) + O(n^{33/34})$ by the existence of T. The running time of the DP procedure is $\tilde{O}(|N_{s_2}|^3 + |\mathcal{W}|)$, which is $\tilde{O}(n^{67/34})$ by the choice of parameters. The details of the running-time analysis are left for the full version [18].

Abstract

This paper considers additive approximation algorithms for All-Pairs Shortest Paths (APSP) and Shortest Cycle in undirected unweighted graphs. The results are as follows:

- We obtain the first $+2$-approximation algorithm for APSP in n-vertex graphs that improves upon Dor, Halperin and Zwick's (SICOMP'00) $\tilde{O}(n^{7/3})$ time algorithm. The new algorithm runs in $\tilde{O}(n^{2.29})$ time and is obtained via a reduction to Min-Plus product of bounded difference matrices.
- We obtain the first additive approximation scheme for Shortest Cycle, generalizing the approximation algorithms of Itai and Rodeh (SICOMP'78) and Roditty and Vassilevska W. (SODA'12). For every integer $r \geq 0$, we give an $\tilde{O}(n + n^{2+r}/m^r)$ time algorithm that returns a $+(2r+1)$-approximate shortest cycle in any n-vertex, m-edge graph.

1 Introduction

The all-pairs shortest paths problem (APSP) is among the most fundamental problems in algorithms. The fastest algorithms for the problem in n vertex, m edge graphs with integer edge weights and no negative cycles, run in $n^3/2^{\Theta(\sqrt{\log n})}$ time [22] and in $O(mn+n^2 \log\log n)$ time [14]. These running times are believed to be optimal, up to $n^{o(1)}$ factors (see [19, 12]).

APSP in unweighted graphs has long been known to admit faster algorithms. In undirected graphs, Seidel [16] gave an $\tilde{O}(n^\omega)$ time algorithm, where $\omega < 2.373$ [2] is the exponent of square matrix multiplication. This running time is believed to be optimal, as APSP in undirected unweighted graphs is at least as hard as Boolean Matrix Multiplication (BMM). [1]

[1] In fact, later algorithms by Shoshan and Zwick [17] imply that undirected unweighted APSP is equivalent to BMM.

Due to the impracticalities of fast matrix multiplication and since it is unavoidable for the exact computation of APSP, it is natural to consider approximation algorithms, trying to get running times as close to n^2 as possible (n^2 is the size of the output). There is significant work on multiplicative approximations of APSP and distance oracles (e.g. [18, 6, 1]). However, for unweighted undirected graphs, more desirable fast *additive* approximations are also possible. In a $+C$-approximation to APSP, one returns estimates $d'(u,v)$ for the distance $d(u,v)$ between any pair of vertices u, v, so that $d(u,v) \leq d'(u,v) \leq d(u,v) + C$. We let $+C$-APSP denote the problem of computing a $+C$-approximation to APSP in an undirected unweighted graph.

Following work of Aingworth et al. [1], so far the best approximation-running time tradeoff for unweighted undirected APSP is achieved by Dor, Halperin and Zwick [7]: For every even integer $k \geq 2$, there is an $\tilde{O}(n^{2+2/(3k-2)})$ time algorithm for $+k$-APSP. (For sparser graphs, the improved running time $\tilde{O}(n^{2-2/(k+2)}m^{2/(k+2)})$ is also given.)

In particular, Dor, Halperin and Zwick provide a $+2$-approximation algorithm that runs in $\tilde{O}(n^{7/3})$ time. The algorithm is simple and "combinatorial", and notably is *faster* than the fastest exact algorithm for APSP by Seidel for the current bounds on ω. Aignworth et al. [1] showed that $+1$-approximating APSP is at least as hard as BMM, and thus likely requires $n^{\omega-o(1)}$ time, so beating n^ω is only possible if the additive approximation is at least 2.

There are no known conditional lower bounds for $+2$-approximations of APSP, and the Dor, Halperin and Zwick running time has remained unchallenged for over *three decades*.

Is $n^{7/3-o(1)}$ time necessary for $+2$-APSP? Or, can one do better?

Our first result is the first *improvement* over the $+2$-approximation algorithm of [7].

▶ **Theorem 1.** *There is an $O(n^{2.2867})$ time algorithm that returns a $+2$-approximation to APSP in undirected unweighted n vertex graphs.*

We obtain the new tradeoff by reducing the $+2$-APSP problem to Min-Plus product of (rectangular) Bounded Difference Matrices. While Min-Plus product for $n \times n$ matrices is believed to require $n^{3-o(1)}$ time (see e.g. [19]), a string of recent papers has developed faster and faster truly subcubic time algorithms for Min-Plus product for Bounded Difference Matrices [4, 5, 8, 21]. Our reduction is completely black-box, so that if there is an improved algorithm for the Min-Plus product of an integer matrix with a matrix with bounded difference columns or rows, then this improvement would immediately translate into an improved algorithm for $+2$-APSP.

Vassilevska W. and Williams [20] showed that APSP in weighted graphs is fine-grained equivalent to the Girth problem, which asks to compute the length of the shortest cycle in a given undirected graph. The same paper [20] shows that the Girth problem in *undirected unweighted* graphs is at least as hard as triangle detection, and is known to be subcubically equivalent to undirected unweighted APSP. As triangle detection in n vertex graphs is believed to require $n^{\omega-o(1)}$ time (e.g. [19]), so is Girth, and thus faster approximation algorithms for the Girth are also well-motivated and well-studied. Multiplicative approximation schemes are well-understood (e.g. [10, 13, 15]). Meanwhile, unlike for APSP, there is *no known tradeoff* of additive approximation algorithms for the girth of undirected unweighted graphs.

There are only two known additive approximation results for Girth in undirected unweighted graphs. First, Itai and Rodeh [9] showed that a $+1$-approximation to the girth can be obtained in $O(n^2)$ time. Then, Roditty and Vassilevska W. [15] showed that a $+3$-approximation to the girth in n vertex, m edge graphs, can be computed in $\tilde{O}(n^3/m)$ time. *Can one generalize these two algorithms to a scheme?*

Our second result is to obtain the first additive approximation scheme for the girth.

▶ **Theorem 2.** *Let $G = (V, E)$ be an unweighted, undirected graph with $|V| = n, |E| = m$. Let r be an integer and denote the (unknown) girth of G by g. There is an $\tilde{O}\left(n + \frac{n^{2+r}}{m^r}\right)$ time algorithm that returns with high probability a cycle of length $\hat{g}$ that satisfies $g \leq \hat{g} \leq g+(2r+1)$.*

Thus, for instance, there is an $\tilde{O}(n + n^4/m^2)$ time $+5$-approximation algorithm. This running time is always better than the previously known additive approximations as long as $m \geq \Omega(n^{1+\varepsilon})$ and $m \leq O(n^{1.5-\varepsilon})$ for some $\varepsilon > 0$. More generally, as r grows, each $+(2r+1)$ approximation is always faster than the approximations for smaller r for the sparsity range $m \in [\Omega(n^{1+\varepsilon}), O(n^{1+1/r-\varepsilon})]$ for any arbitrarily small $\varepsilon > 0$.

2 Additive Approximation Algorithm for APSP

We first formally define $+C$-approximation of APSP and $(\min, +)$ matrix product.

▶ **Definition 3** (APSP $+C$-approximation). *For an undirected unweighted simple graph $G = (V, E)$, output $\hat{d} : V \times V \to \mathbb{N}$ such that $d(u, v) \leq \hat{d}(u, v) \leq d(u, v) + C$, where $d(u, v)$ is the distance from u to v in graph G.*

▶ **Definition 4** ($(\min, +)$ matrix product). *$(\min, +)$ matrix product between matrix A and B is defined as $C = A \star B$ where $C[i, j] = \min_k\{A[i, k] + B[k, j]\}$.*

While in general, no sub-cubic algorithm has been found for $(\min, +)$ matrix product, many special cases have been addressed (e.g. [4] [21] [5]). Specifically, we consider the case between column bounded-difference and row bounded-difference matrix.

▶ **Definition 5** (Column bounded-difference, Row bounded-difference). *A matrix A is column bounded-difference if there exists some constant C so that $|A[i, j] - A[i + 1, j]| \leq C$ for all valid (i, j)'s. Symmetrically, a matrix A is row bounded-difference if there exists some constant C so that $|A[i, j] - A[i, j + 1]| \leq C$ for all valid (i, j)'s.*

▶ **Definition 6** ($(\min, +)$ matrix product between column bounded-difference matrix and row bounded-difference matrix). *Given column bounded-difference matrix A of size $n \times m$ and row bounded-difference matrix B of size $m \times n$, calculate their $(\min, +)$ matrix product $A \star B$. Call the time complexity for such a problem $MPCRBD(n, m)$.*

A similar case was previously addressed by Bringmann et al. [4] and an algorithm of runtime $O(n^{2.9217})$ is given (Theorem 1.3, [4]). By adapting the method of Chi, Duan and Xie [5], we can get the following bound.

We want to point out that since our reduction is black-box, the use of the following lemma is not necessary and applying the algorithm in Bringmann et al. [4] also gives a $O(n^{7/3-\Omega(1)})$ algorithm. Therefore, we defer the proof of this lemma to Appendix A.

▶ **Lemma 7** (Appendix A). *Let $M(n, u, n)$ be the time to multiply $n \times u$ and $u \times n$ matrices. For parameters $\alpha, \beta, \gamma > 0$, $MPCRBD(n, m) = \tilde{O}(n^2 m/\alpha^2 + n^2\beta + M(n, \gamma, n)\alpha m/\beta + n^2 m^2/\gamma)$. Specifically, $MPCRBD(n, n) = O(n^{2.811})$.*

We start with Dor, Halperin and Zwick's original algorithm, used as a black-box.

▶ **Lemma 8** (Theorem 3.1, [7]). *There is an algorithm for APSP $+2$-approximation that runs in $\tilde{O}(|V|^{3/2}|E|^{1/2})$ time on input graph $G = (V, E)$.*

For a graph $G = (V, E)$, define $N(v) = \{u \mid (u, v) \in E\}$ as the set of adjacent vertices of v for $v \in V$. We also use the following lemma.

▶ **Lemma 9** (e.g. Theorem 1, [1]). *For a graph $G = (V, E)$ and a parameter s, let $V_s = \{v \mid v \in V,\ |N(v)| \geq s\}$, we can deterministically compute a hitting set $D \subseteq V$ where $|D| = O(|V| \log |V|/s)$ and $N(v) \cap D \neq \emptyset$ for all $v \in V_s$ in $O(|V|^2)$ time.*

Crucial to our algorithm is to consider an Euler tour of a spanning tree.

▶ **Definition 10** (Euler Tour). *For a spanning tree $T \subseteq E$ of a connected graph $G = (V, E)$, an Euler tour of T is a sequence of vertices $v_1, v_2, \cdots, v_{2|V|-1}$, where each vertex of G appears at least once and the edges $(v_i, v_{i+1}) \in T$ for all $1 \leq i \leq 2|V| - 2$.*

Given a tree T, an Euler tour of T could be easily found by running depth-first search on T in $O(|T|)$ time.

We first give a high-level overview of our improvement. In Theorem 3.2, [7], a hitting set D_1 is computed to update the distance between all pairs of nodes $(u, v) \in V^2$. That is, for all $u, v \in V$, we update $d(u, v)$ with $\min_{t \in D_1}(d(u, t) + d(t, v))$. Notice that if we consider V, D_1, V as three dimensions in a matrix multiplication, the updating process is essentially a min-plus matrix product. Now if we arrange u, v in the order of an Euler tour, the matrices would then be (row/column) bounded difference. Thus, we can gain a speedup by aforementioned algorithms. To calculate distances between D_1 and V efficiently, we partition nodes in V by their degree.

For a graph $G = (V, E)$, let $n = |V|,\ m = |E|$. We set a parameter $l = O(\log n)$ to be determined, and define $s_i = n/2^{i-1}$ for $i \in [1, l]$. Specifically, let $s_0 = n + 1$.

By Lemma 9, we can find hitting sets D_i of size $\tilde{O}(n/s_i)$ for all vertices with degree $\geq s_i$ in G in $\tilde{O}(n^2)$ time. Let $f_i(u)$ be any element in $D_i \cap N(u)$ for $\deg u \geq s_i$, let F_i be the set of edges $(u, f_i(u))$ where $\deg u \geq s_i$ ($\deg v$ stands for the degree of vertex v), and $F = \cup_{i=0}^{l} F_i$. Thus $|F_i| = O(n), |F| = \tilde{O}(n)$.

We define a series of graphs $G_0, G_1, G_2, \cdots, G_l$. Define $G_0 = G$, and $G_i = (V, E_i)$ where $E_i = F \cup \{(u, v) \in E \mid \deg u \leq s_i \text{ or } \deg v \leq s_i\}$ for $1 \leq i \leq l$. Let $d_i(u, v)$ be the distance from u to v on graph G_i.

We then run breadth-first search on graph G_{i-1} from each vertex in set D_i to obtain the distances $d_{i-1}(t, v)$ for all pairs $(t, v) \in D_i \times V$. Define $w_i(u, v) = \min_{t \in D_i}\{d_{i-1}(t, u) + d_{i-1}(t, v)\}$ Let $g(u, v)$ to be the output of algorithm in Lemma 8 on input G_l. Let $h(u, v) = \min(\min_{i=1}^{l}\{w_i(u, v)\}, g(u, v))$.

We now argue that h is the desired approximation to distances, i.e. $d(u, v) \leq h(u, v) \leq d(u, v) + 2$ for all $u, v \in V$. Note that $w_i(u, v), g(u, v) \geq d(u, v)$ since their values all arise from valid paths, thus $h(u, v) \geq d(u, v)$.

Now we show that $d(u, v) + 2 \geq h(u, v)$. Consider the shortest path p from u to v in graph G. Let r be the node with maximum degree on p. If $\deg r \geq s_l$, assume that $s_a \leq \deg r < s_{a-1}$ for some $1 \leq a \leq l$. Since all nodes on p have degree $< s_{a-1}$, $d(u, v) = d_{a-1}(u, v)$. In G_{a-1}, consider $g = f_a(r)$, we have $h(u, v) \leq w_a(u, v) \leq d_{a-1}(u, g) + d_{a-1}(g, v) \leq d_{a-1}(u, r) + 1 + d_{a-1}(r, v) + 1 = d_{a-1}(u, v) + 2 \leq d(u, v) + 2$. Otherwise (if $\deg r < s_l$), p is preserved in the graph G_l and $g(u, v) \leq d(u, v) + 2$ by Lemma 8. Therefore, $h(u, v) \leq d(u, v) + 2$.

We now show how to compute w_i for a given $1 \leq i \leq l$. Without loss of generality, assume G_{i-1} is connected (otherwise we can treat each connected component separately), and let T be any spanning tree of G_{i-1}. Let $t_1, t_2, t_3, \cdots, t_{2n-1}$ be an arbitrary Euler tour of T and suppose $D_i = \{x_1, x_2, \cdots, x_{|D_i|}\}$. Define A to be a matrix of size $(2n - 1) \times |D_i|$, where $A(i, j) = d_{i-1}(t_i, x_j)$. Let $B = A \star A^T$, then by definition, $w_i(u, v) = B[pos(u), pos(v)]$ where $t_{pos(a)} = a$ (any suffice).

Note that $|A[a, j] - A[a+1, j]| \leq 1$ since $|d_{i-1}(t_a, d_j) - d_{i-1}(t_{a+1}, d_j)| \leq d_{i-1}(t_a, t_{a+1}) = 1$, so A is column bounded-difference, A^T is row bounded-difference. The time complexity to compute $f(u, v)$ for all $u, v \in V$ is then $O(n^2 + \text{MPCRBD}(n, |D_i|))$.

The total runtime of the above algorithm consists of three parts.

1. The computation of $\{D_i\}$, $\{G_i\}$, $\{F_i\}$ takes $\tilde{O}(n^2)$ time.
2. Compute w_i for all $1 \le i \le l$. Constructing the depth-first search tree and Euler tour takes $\tilde{O}(n^2)$ time. Since $|E_i| \le s_i n$, the breadth-first search for each D_i in G_{i-1} takes $O(|D_i|s_i n) = \tilde{O}(n^2)$ time, so this part also takes $\tilde{O}(n^2)$ time. The $(\min, +)$ matrix products takes time $\tilde{O}(n^2 + \text{MPCRBD}(n, |D_l|))$ since $|D_l| \ge |D_i|$ for any $1 \le i \le l$.
3. The computation of g takes time $N^{3/2}|E_l|^{1/2} = \tilde{O}(n^2 s_l^{1/2})$.

Let s_l be the power of 2 closest to t, we obtain the following result:

▶ **Theorem 11.** *For a parameter $t \ge 1$, there is an algorithm for APSP +2-approximation on input graph $G = (V, E)$ that runs in $\tilde{O}(n^2 t^{1/2} + MPCRBD(n, n/t))$ time, where $n = |V|$, $m = |E|$.*

By Lemma 7, we could obtain an upper bound for $\text{MPCRBD}(n, m)$.

▶ **Theorem 12.** *There is an algorithm for APSP +2-approximation on input graph $G = (V, E)$ that runs in $O(n^{2.2867})$ time where n stands for $|V|$.*

Proof. In Theorem 11, set $t = n^{0.57339}$, and apply Lemma 7 with $\alpha = n^{0.07006}, \beta = n^{0.28662}, \gamma = n^{0.56688}$. $M(n, \gamma, n) = M(n, n^{0.56688}, n) = O(n^{2.076433})$ by [11]. The claimed bound then follows from a direct computation. ◀

We also provide the following simpler bound using square MPCRBD. Plugging in Theorem 1.3 in Bringmann et al. [4] gives an algorithm of $O(n^{2.32416})$.

▶ **Corollary 13.** *Suppose $MPCRBD(n, n) = O(n^{2+\alpha})$ for constant α, there is an algorithm for APSP +2-approximation on input graph $G = (V, E)$ that runs in $\tilde{O}(|V|^{2+\frac{\alpha}{1+2\alpha}})$ time.*

Proof. Let $n = |V|$. $\text{MPCRBD}(n, n/t) = O(t^2 \text{MPCRBD}(n/t, n/t)) = O(n^{2+\alpha}/t^\alpha)$. Set $t = n^{\alpha/(1/2+\alpha)}$, the total runtime would then be $\tilde{O}(n^{2+\frac{\alpha}{1+2\alpha}})$. ◀

3 Additive Approximation Algorithm for Girth

The first additive approximation algorithm for the girth of a graph was presented by Itai and Rodeh in 1978 [9]. In their paper they showed an $O(n^2)$ time algorithm that, given a graph of girth g, returns a cycle of length at most $g + 1$.

The next improvement, an additive approximation algorithm running in subquadratic time, was presented in 2012 by Roditty and Vassilevska W. [15]. Their algorithm provided a $+3$ approximation of the girth in $\tilde{O}(n^3/m)$ time.

Both algorithms use a subroutine which we will call BFS-cycle. This subroutine runs BFS from a given vertex s until it reaches some vertex v for a second time. When v is reached for the second time, BFS-cycle returns the cycle enclosed by the two paths between s and v. We will use the following result regarding this algorithm:

▶ **Lemma 14** (e.g. [9, 13])**.** *BFS-cycle(v) runs in $O(n)$ time. If a vertex v is at distance ℓ from a vertex on a simple cycle of length k, then BFS-cycle(v) reports a cycle of length at most $k + 2\ell + 1$. If k is even, BFS-cycle(v) reports a cycle of length at most $k + 2\ell$.*

Another tool used in Roditty and Vassilevska W.'s algorithm is a result in extremal graph theory proved by Bondy and Simonovits [3], regarding even cycles in a graph:

▶ **Theorem 15** ([3])**.** *Let $k \ge 2$ be an integer. If an n-node graph G has at least $100kn^{1+1/k}$ edges then G contains a $2k$-cycle.*

As a result of this theorem, for any graph with at least $200kn^{1+1/k}$ edges, at least half of the edges are part of some $2k$-cycle. Therefore, if we uniformly sample an edge, it is part of a $2k$-cycle with probability $\geq \frac{1}{2}$. By running BFS-cycle from each sampled edge and taking the lowest result, we obtain a randomized algorithm with efficient runtime:

▶ **Lemma 16** (e.g. [23]). *If an n-node graph G has at least $200kn^{1+1/k}$ edges, then there exists an $O(n \log n)$ time algorithm that finds a cycle of length at most $2k$ with high probability.*

Using these methods, we provide an algorithm for any odd additive approximation. In the following theorem we generalize the algorithm of Roditty and Vassilevska W. [15] to provide an additive $+(2r+1)$ approximation to the girth for any integer r.

▶ **Theorem 17.** *Let $G(V,E)$ be an unweighted, undirected graph with $|V| = n, |E| = m$. Let r be an integer and denote the girth of G by g. There is an $\tilde{O}\left(n + \frac{n^{2+r}}{m^r}\right)$ time algorithm that returns with high probability a cycle of length $\hat{g}$ that satisfies $g \leq \hat{g} \leq g + 2r + 1$.*

Proof. First we consider the case where $m < 200Ln^{1+1/L}$ for $L = \left\lceil \frac{\log n}{\log \log n} \right\rceil$. This implies that $m \leq \tilde{O}(n)$. We can use the $O(n^2)$ time algorithm of Itai and Rodeh to obtain an additive $+1$ approximation of the girth of G. Notably, in this case $O(n^2) \leq \tilde{O}\left(\frac{n^{2+r}}{m^r}\right)$.

Suppose now that $m \geq 200Ln^{1+1/L}$. Then there exists an integer $k \leq L$ such that

$$200(k+1)n^{1+\frac{1}{1+k}} < m \leq 200kn^{1+\frac{1}{k}}.$$

It follows from Lemma 16 that in $O(n \log n)$ time we can find a cycle of length at most $2k+2$ with high probability. If $g > 2k - 2r$, this cycle is an additive $+(2r+1)$ approximation of the girth.

We are left to handle the case when $g \leq 2k - 2r$. For any non-negative integer p, denote by $T_p(v) := \{u \in V : d(u,v) \leq p\}$ the vertices in the graph of distance $\leq p$ from v. Let Δ be a degree parameter; we will refer to vertices with $|T_r(v)| \leq \Delta$ as low r-degree vertices and vertices with $|T_r(v)| > \Delta$ as high r-degree vertices.

We sample a set S of $O\left(\frac{n}{\Delta} \log n\right)$ vertices uniformly at random. With high probability, any high degree vertex v satisfies $T_r(v) \cap S \neq \emptyset$. We now run BFS-cycle from each vertex of S. If the shortest cycle in the graph contains some node v such that $T_r(v)$ intersects S, Lemma 14 implies that the shortest cycle the algorithm finds is of length at most $g + 2r + 1$. The running time of this is $O\left(\frac{n^2 \log n}{\Delta}\right)$.

Now we only need to handle the case where the shortest cycle contains only vertices v for which $T_r(v) \cap S = \emptyset$, or equivalently $v \notin T_r(s)\ \forall s \in S$. To do so, we remove from the graph all vertices in $T_r(s)$ for any $s \in S$. With high probability the remaining vertices are all of low r-degree.

For each remaining vertex v, consider performing BFS from v up to ℓ levels for some $k - r \leq \ell < k$, while keeping track of the cumulative size of the layers. We break at the first $\ell \geq k - r$ for which $|T_\ell(v)| \leq \Delta^{(k-r)/r} |T_{\ell-(k-r)}(v)|$. Since we are assuming $g \leq 2k - 2r$, if there is a vertex $u \in T_{\ell-(k-r)}(v)$ which is part of the shortest cycle, then the BFS from v up to ℓ levels must have found a $+2(\ell - (k-r)) + 1$ approximation of this. In Lemma 18, we justify why we break before $\ell = k$. Then, we discard all vertices in $T_{\ell-(k-r)}(v)$ from further consideration. We do this for all v, and the total time complexity is $O\left(n\Delta^{(k-r)/r}\right)$.

The proof that this algorithm is valid is deferred to Lemma 18. So if the shortest cycle in G is comprised of only low r-degree vertices, we will have found a $+2r+1$ approximation of it. The full algorithm for this is described in Algorithm 1.

Algorithm 1 All Low BFS-Cycle.

```
for s ∈ V do
    L_0 ← {s}
    S_0 ← 1

            end for
        end if
    end for
end for
```

To minimize the runtime, we set $\Delta = n^{r/k}$ and obtain a running time of $\tilde{O}\left(n^{2-r/k}\right)$. Since $m = \Theta\left(n^{1+1/k}\right)$,

$$\tilde{O}\left(n^{2-r/k}\right) = \tilde{O}\left(\frac{n^{2+r}}{n^{(1+1/k)\cdot r}}\right) = \tilde{O}\left(\frac{n^{2+r}}{m^r}\right).$$

This gives us the desired runtime. ◀

▶ **Lemma 18.** *The time complexity of Algorithm 1 is $O\left(n\Delta^{(k-r)/r}\right)$ and it is guaranteed to return a cycle of length $\leq 2k$ if $g \leq 2k - 2r$ and if there is a shortest cycle where all vertices have low r-degree.*

Proof. Firstly, we show that for any low r-degree vertex v, we will find an $\ell \geq k - r$ such that $|T_\ell(v)| \leq \Delta^{(k-r)/r}|T_{\ell-(k-r)}|$ and $\ell < k$. Assume the contrary, that $|T_\ell(v)| > \Delta^{(k-r)/r}|T_{\ell-(k-r)}|$ for all $k - r \leq \ell < k$. Multiplying these inequalities for all ℓ in this range gives

$$\Delta^{k-r}\prod_{j=0}^{r-1}|T_j(v)| < \prod_{i=k-r}^{k-1}|T_i(v)|.$$

For any non-negative integer t, denote $\bar{t}$ to be the unique integer such that $t \equiv \bar{t} \pmod r$ and $0 \leq \bar{t} < r$. Since all vertices w in this subgraph have the property that $|T_r(w)| \leq \Delta$, for any non-negative integer i and any vertex v we have

$$|T_{\bar{i}}(v)|\Delta^{(i-\bar{i})/r} \geq |T_i(v)|.$$

Now note that $\{\overline{k-r}, \overline{k-r+1}, \ldots, \overline{k-1}\}$ is exactly $\{0, 1, 2, \ldots, r-1\}$ as these are r consecutive integers. Thus we can bound the right-hand side of the inequality like so:

$$\begin{aligned}
\Delta^{k-r} \prod_{j=0}^{r-1} |T_j(v)| &< \prod_{i=k-r}^{k-1} |T_i(v)| \\
&\leq \prod_{i=k-r}^{k-1} \Delta^{(i-\overline{i})/r} |T_{\overline{i}}(v)| \\
&\leq \Delta^{\frac{\left(\sum_{i=k-r}^{k-1} i\right) - \left(\sum_{j=0}^{r-1} j\right)}{r}} \prod_{j=0}^{r-1} |T_j(v)| \\
&\leq \Delta^{\frac{\sum_{j=0}^{r-1} (k-r+j)-j}{r}} \prod_{j=0}^{r-1} |T_j(v)| \\
&= \Delta^{k-r} \prod_{j=0}^{r-1} |T_j(v)|.
\end{aligned}$$

So we reach a contradiction as desired and we conclude that there is some $\ell < k$ and so $\ell - (k-r) < r$. If $T_{\ell-(k-r)}(v)$ contains a vertex in the shortest cycle, we indeed obtain a $+(2r-1)$ approximation. Furthermore, we now no longer need to BFS from any vertex in $T_{\ell-(k-r)}(v)$ so we can discard all of these. So although we had to do $O(|T_\ell(v)|)$ work for BFSing from this v, we were able to discard $|T_{\ell-(k-r)}(v)|$ vertices. Thus, the amortized time complexity per vertex is $O(\Delta^{(k-r)/r})$ and so the total time complexity is $O(n\Delta^{(k-r)/r})$.

Note that we only guarantee returning a cycle of length $\leq 2k$ rather than of length $\leq g + 2r + 1$ as it is possible we find a longer cycle first, in which case we must terminate immediately to guarantee that the BFS-Cycle subroutine step is still linear only in terms of the number of vertices and not edges. This is fine as we now have a shorter cycle and we can repeat the algorithm with smaller k. To make this efficient, we can binary search, incurring only an additional $\log k$ factor. ◀

A Fast $(\min, +)$ Product between Column and Row Bounded-Difference Matrices

In this section, we adapt the method of Chi, Duan and Xie [5] for bounded difference min-plus matrix product for our case, thus proving Lemma 7. The main difference in our method is that we can no longer divide matrices into square blocks since differences are only bounded

in one direction. Instead, we divide them into rectangular blocks. Most terminologies and analysis in their work can be adapted to our case, so we only sketch the needed modifications here.

Suppose the matrices to multiply are A, B_0 with size $n \times m$ and $m \times n$. For simplicity, we transpose B_0 to be $B = B_0^T$. Our assumption is that for some constant Δ, $|A_{i,j} - A_{i+1,j}| \leq \Delta$, $|B_{i,j} - B_{i+1,j}| \leq \Delta$ for valid indexes. We want to compute $C_{i,j} = \min_k\{A_{i,k} + B_{j,k}\}$.

We divide the rows of A and B into blocks of size α. The main difference from [5] is that we can no longer divide columns into blocks. For each pair of blocks (one block of columns in A and one block of columns in B), we pick any i and j from each block and compute $C_{i,j}$. This step takes $O(n^2m/\alpha^2)$ time.

By locality, we know for any (i', j') in these two blocks, $|C_{i',j'} - C_{i,j}| \leq 2\alpha\Delta$ (Since $C_{i',j'}$ equals to $A_{i',k} + B_{j',k}$ for some k, and $|A_{i',k} + B_{j',k} - A_{i,k} - B_{j,k}| \leq 2\alpha\Delta$ for all k's by the property of bounded-difference within columns). We call k so that $|A_{i,k} + B_{j,k} - C_{i,j}| \leq 4\alpha\Delta$ candidates, and only these k's could contribute to (i', j')'s in these two blocks.

For block pairs with no more than β candidates, we simply enumerate through these k's for every (i', j'), taking $O(n^2\beta)$ time.

For block pairs with more than β candidates, we use the method in Section 2, [5]. Sample a set of columns S with size $\Omega(m \log n/\beta)$, then reduce via these columns, mapping resulting segments to γ columns. Computing the bounded min-plus matrix product after mapping would take time $\tilde{O}(M(n, \gamma, n)\alpha m/\beta)$ where $M(n, \gamma, n)$ is the complexity of multiplying $n \times \gamma$ and $\gamma \times n$ matrices. For each of the n^2/α^2 blocks in C, each of the m^2 column pairs has probability $1/\gamma$ to collide (mapped to the same column), and subtracting each collision takes $O(\alpha^2)$ time. Thus, subtracting the contribution of all collisions would take $O(n^2m^2/\gamma)$ time.

The total time complexity is $\tilde{O}(n^2m/\alpha^2 + n^2\beta + M(n, \gamma, n)\alpha m/\beta + n^2m^2/\gamma)$.

Particularly when $m = n$, let $\alpha = n^{0.094513}$, $\beta = n^{0.810974}$, $\gamma = n^{1.189026}$, $M(n, \gamma, n) = O(n^{2.527435})$ [11], we can get the complexity of $O(n^{2.811})$.

One-Pass Additive-Error Subset Selection for ℓ_p Subspace Approximation

Amit Deshpande

Abstract

We consider the problem of subset selection for ℓ_p subspace approximation, that is, to efficiently find a *small* subset of data points such that solving the problem optimally for this subset gives a good approximation to solving the problem optimally for the original input. Previously known subset selection algorithms based on volume sampling and adaptive sampling [16], for the general case of $p \in [1, \infty)$, require multiple passes over the data. In this paper, we give a one-pass subset selection with an additive approximation guarantee for ℓ_p subspace approximation, for any $p \in [1, \infty)$. Earlier subset selection algorithms that give a one-pass multiplicative $(1 + \epsilon)$ approximation work under the special cases. Cohen et al. [11] gives a one-pass subset section that offers multiplicative $(1 + \epsilon)$ approximation guarantee for the special case of ℓ_2 subspace approximation. Mahabadi et al. [31] gives a one-pass *noisy* subset selection with $(1+\epsilon)$ approximation guarantee for ℓ_p subspace approximation when $p \in \{1, 2\}$. Our subset selection algorithm gives a weaker, additive approximation guarantee, but it works for any $p \in [1, \infty)$.

1 Introduction

In *subset selection* problems, the objective is to pick a small subset of the given data such that solving a problem optimally on this subset gives a good approximation to solving it optimally on the entire data. Many coreset constructions in computational geometry and clustering [22], sampling-based algorithms for large matrices [24], algorithms for submodular optimization and active learning [37] essentially perform subset selection. The main advantage of subset selection lies in its interpretability, for example, in gene expression analysis, we would like to find a representative subset of genes from gene expression data rather than just fitting a subspace to the data [20, 33, 36, 32, 29]. In several machine learning applications such as document classification, face recognition etc., it is desirable to go beyond dimension reduction alone, and pick a subset of representative items or features [28, 33]. Subset selection has been well studied for many fundamental problems such as k-means clustering [2, 14], low-rank approximation [24, 17, 15, 28] and regression [13], to name a few. In low-rank and subspace approximation, the subset selection approach leads to more interpretable solutions than using SVD or random projections-based results. Therefore, subset selection has been a separate and well-studied problem even within the low-rank approximation and subspace approximation literature [28, 12].

In the following, we formally state the ℓ_p subspace approximation problem for $p \in [1, \infty)$.

ℓ_p subspace approximation: In this problem, given a dataset $\mathcal{X} = \{x_1, x_2, \ldots, x_n\}$ of n points in $\mathbb{R}^d$, a positive integer $1 \leq k \leq d$ and a real number $p \in [1, \infty)$, the objective is to find a linear subspace V in $\mathbb{R}^d$ of dimension at most k that minimizes the sum of p-th powers of the Euclidean distances of all the points to the subspace V, that is, to minimize

$$\mathrm{err}_p(\mathcal{X}, V) := \sum_{i=1}^{n} d(x_i, V)^p. \tag{1}$$

Throughout this paper, we use V^* to denote the optimal subspace for ℓ_p subspace approximation. The optimal solutions are different for different values of p but we do not include that in the notation to keep the presentation simple, as our results hold for any $p \in [1, \infty)$.

Before stating our results, we first explain what a *small* subset and a *good* approximation means in the context of subset selection for ℓ_p subspace approximation.

For ℓ_p subspace approximation, we consider n and d to be large, $k \ll n, d$, and p to be a small constant. Thus, a *small* subset of $\mathcal{X}$ desired in subset selection has size independent of n and d, and is bounded by $\mathrm{poly}(k/\epsilon)$, where ϵ is a parameter that controls the approximation guarantee (as explained later). Note that the trivial solution $V = 0$ gives $\mathrm{err}_p(\mathcal{X}, V) = \sum_{i=1}^{n} \|x_i\|^p$. Using the standard terminology from previous work [24, 15, 16], an additive approximation guarantee means outputting V such that $\mathrm{err}_p(\mathcal{X}, V) \leq \mathrm{err}_p(\mathcal{X}, V^*) + \epsilon \sum_{i=1}^{n} \|x_i\|^p$, whereas a multiplicative approximation guarantee means $\mathrm{err}_p(\mathcal{X}, V) \leq (1 + \epsilon)\ \mathrm{err}_p(\mathcal{X}, V^*)$. Most subset selection algorithms for ℓ_p subspace approximation select a $\mathrm{poly}(k/\epsilon)$-sized subset of $\mathcal{X}$ such that its span contains a subspace V of dimension at most k that is close enough to V^* to obtain the above approximation guarantees.

Our objective in this paper is to propose an efficient, one-pass sampling algorithm that performs subset selection for ℓ_p subspace approximation for $p \in [1, \infty)$ defined as above. We note that the problem of one-pass subset selection for ℓ_p subspace approximation has been studied for special values of p, for example, Cohen et al. [11] gives one-pass subset selection for $p = 2$, Mahabadi et al. [31] suggest one-pass *noisy* subset selection for $p = \{1, 2\}$. To the best of our knowledge this problem has not been studied in generality for $p \in [1, \infty)$. In this work, we consider studying this problem. We state our results as follows.

1.1 Our results

Our main technical contribution is a one-pass MCMC-based sampling algorithm that can approximately simulate multiple rounds of adaptive sampling. As a direct application of the above, we get the following results for the ℓ_p subspace approximation problem: For $p \in [1, \infty)$, our algorithm makes only one pass over the given data and outputs a subset of $\mathrm{poly}(k/\epsilon)^p$ points whose span contains a k dimensional subspace with an additive approximation guarantee for ℓ_p subspace approximation. This generalizes the well-known squared-length sampling algorithm of Frieze et al. [24] that gives additive approximation guarantee for ℓ_2 subspace approximation (or low-rank approximation under the Frobenium norm). Even though stronger multiplicative $(1+\epsilon)$ approximation algorithms for ℓ_p subspace approximation are known in the previous work, either they cannot do subset selection, or they are not one-pass, or they do not work for all $p \in [1, \infty)$.

Organization of the paper. In Section 2, we compare and contrast our result with the state-of-the-art algorithms, and explain the key technical challenges, and workarounds. In Section 3, we state our MCMC based subset selection algorithm for subset selection for ℓ_p

subspace approximation. In Section 4, we give theoretical bounds on the sample size and approximation guarantee. Finally, in Section 5, we conclude our discussion and state some potential open questions of the paper.

2 Related work

In this section, we discuss related work on sampling and sketching algorithms for ℓ_p subspace approximation, and do a thorough comparison of our results with the state of the art.

2.1 Sampling-based ℓ_p subspace approximation

Frieze et al. [24] show that selecting a subset of $O(k/\epsilon)$ data points as an *i.i.d.* sample from $x_1, x_2, \ldots, x_n$ picked by squared-length sampling, i.e., x_i is picked with probability proportional to $\|x_i\|_2^2$, gives an additive approximation for ℓ_2 subspace approximation (also known as low-rank approximation under the Frobenius norm). Squared-length sampling can be implemented in one pass over $\mathcal{X}$ using reservoir sampling [35, 21]. It is known how to improve the additive approximation guarantee to a multiplicative approximation by combining two generalizations of squared-length sampling, namely, adaptive sampling and volume sampling [15, 16] but it requires $O(k \log k)$ passes over the data. In adaptive sampling, we pick points with probability proportional to the distance from the span of previously picked points, and in volume sampling, we pick a subset of points with probability proportional to the squared volume of the parallelepiped formed by them. Volume sampling a subset of size k can itself be simulated with an approximation factor $k!$ in k rounds of adaptive sampling [15]. For $p = 2$, it is also known that picking a subset of $O(k/\epsilon)$ points by volume sampling gives a bi-criteria $(1+\epsilon)$ approximation for ℓ_2 subspace approximation [28]. For general $p \in [1, \infty)$, it is known that subset selection based on adaptive sampling and volume sampling can be generalized to get a $(1+\epsilon)$ multiplicative approximation for ℓ_p subspace approximation, for any $p \in [1, \infty)$, where the subset is of size $O\left((k/\epsilon)^p\right)$ and it is picked in $O(k \log k)$ passes over the data [16]. The main bottleneck for implementing this in one pass is the inability to simulate multiple rounds of adaptive sampling in a single pass.

The only known workarounds to get one-pass subset selection for ℓ_p subspace approximation are known for the special cases $p = 1$ and $p = 2$. Cohen et al. [11] give a one-pass subset selection algorithm with a multiplicative $(1+\epsilon)$ approximation guarantee for ℓ_2 subspace approximation based on ridge leverage score sampling. Their one-pass implementation crucially uses deterministic matrix sketching [25] to approximate the SVD and ridge leverage scores, and works only for $p = 2$, to the best of our knowledge. Braverman et al. [6] give online algorithms for ℓ_2 subspace approximation (or low-rank approximation) via subset selection but their subset size $O(\frac{k}{\epsilon} \log n \log \kappa)$ is not independent on n and depends logarithmically on the number of points n and the condition number κ. Recent work by Mahabadi et al. [31] gives a one-pass algorithm with a multiplicative $(1+\epsilon)$ approximation guarantee for ℓ_p subspace approximation. However, their algorithm works only in the special cases $p \in \{1, 2\}$ and it outputs a subset of noisy data points instead of the actual data points.

A different objective for ℓ_p subspace approximation has also been studied in literature [5, 9], namely, minimizing the entry-wise ℓ_p-norm low-rank approximation error. To state it formally, given an input matrix $A \in \mathbb{R}^{n \times d}$ and a real number $p \in [0, \infty)$, their objective is to find a matrix B of rank at most k that minimizes $\sum_{i,j} |A_{i,j} - B_{i,j}|^p$.

2.2 Sketching-based ℓ_p subspace approximation

Sketching-based algorithms compute a sketch of a given data in a single pass, using which one can compute an approximately optimal solution to a given problem on the original data. The problem of ℓ_p subspace approximation has been well-studied in previous work on sketching algorithms. However, a limitation of these results is that they do not directly perform subset selection. We mention a few notable results as follows: For $p = 2$, extending deterministic matrix sketching of Liberty [30], Ghashami et al. [27, 26] give a deterministic one-pass sketching algorithm that gives a multiplicative $(1 + \epsilon)$ approximation guarantee for ℓ_2 subspace approximation (or low-rank approximation under the Frobenius norm). Cormode et al. [19] extend the above deterministic sketching idea to $p \neq 2$ and give a poly(k) approximation for entry-wise ℓ_1-norm low-rank approximation and an additive $\epsilon \ \|b\|_\infty$ approximation for ℓ_∞ regression. There is another line of work based on sketching algorithms using random projection. Random projection gives a multiplicative $(1+\epsilon)$ approximation for ℓ_2 subspace approximation in running time $O(\text{nnz}(X) \cdot \text{poly}(k/\epsilon))$, subsequently improved to a running time of $O(\text{nnz}(X) + (n + d) \cdot \text{poly}(k/\epsilon))$ by Clarkson and Woodruff [10]. Feldman et al. [23] also give a one-pass algorithm for multiplicative $(1 + \epsilon)$ approximation for ℓ_p subspace approximation, for $p \in [1, 2]$. However, these results do not provide a one-pass subset selection.

2.3 Comparison with other MCMC-based sampling results

Theorem 4 of Anari et al. [1] gives a MCMC based sampling algorithm to approximate volume sampling distribution. However, their algorithm requires a greedy algorithm to pick the initial subset that requires k passes over the input.

The MCMC sampling has also been explored in the context of k-means clustering. The D^2-sampling proposed by Arthur and Vassilvitskii [2] adaptively samples k points – one point in each passes over the input, and the sampled points give $O(\log k)$ approximation to the optimal clustering solution. The results due to [4, 3] suggest generating MCMC sampling distribution by taking only one pass over the input that closely approximates the underlying D^2 sampling distribution, and offer close to the optimal clustering solution. Building on these MCMC based sampling techniques, Pratap et al. [34] gives one pass subset section for *spherical* k-means clustering [18].

3 MCMC sampling algorithm

In this section, we state our MCMC based sampling algorithm for subset selection for ℓ_p subspace approximation. We first recall the adaptive sampling algorithm[15, 16] for ℓ_p subspace approximation.

Adaptive sampling [15, 16] *w.r.t.* a subset $S \subseteq \mathcal{X}$ is defined as picking points from $\mathcal{X}$ such that the probability of picking any point $x \in \mathcal{X}$ is proportional to $d(x, \text{span}\,(S))^p$. We denote this probability by

$$p_S(x) = \frac{d(x, \text{span}\,(S))^p}{\text{err}_p(\mathcal{X}, S)}, \quad \text{for } x \in \mathcal{X}. \tag{2}$$

For any subset S whose $\text{err}_p(\mathcal{X}, S)$ is not too small, we show that adaptive sampling *w.r.t.* S can be approximately simulated by an MCMC sampling algorithm that only has access to *i.i.d.* samples of points $x \in \mathcal{X}$ picked from the following easier distribution:

$$q(x) = \frac{d(x, \text{span}\left(\tilde{S}\right))^p}{2\ \text{err}_p(\mathcal{X}, \tilde{S})} + \frac{1}{2\,|\mathcal{X}|}, \tag{3}$$

for some initial subset $\tilde{S}$. We give the above definition of $q(x)$ using an arbitrary initial or *pivot* subset $\tilde{S}$ because it will be useful in our analysis of multiple rounds of adaptive sampling. However, our final algorithm uses a fixed subset $\tilde{S} = \emptyset$ such that

$$q(x) = \frac{\|x\|_2^p}{2\sum_{x\in\mathcal{X}} \|x\|_2^p} + \frac{1}{2\,|\mathcal{X}|}. \tag{4}$$

Note that sampling from this easier distribution, namely, picking $x \in \mathcal{X}$ with probability $q(x)$ (mentioned in Equation (4)), can be done in only one pass over $\mathcal{X}$ using weighted reservoir sampling [8]. Weighted reservoir sampling keeps a reservoir of finite items, and for every new item, calculates its relative weight to randomly decide if the item should be added to the reservoir. If the new item is selected, then one of the existing items from the reservoir is picked uniformly and replaced with the new item. Further, given any non-negative weights w_x, for each point $x \in \mathcal{X}$, weighted reservoir sampling can pick an *i.i.d.* sample of points, where x is picked with probability proportional to its weight w_x. Note that this does not require the knowledge of $\sum_{x\in\mathcal{X}} w_x$. Thus, we can run two reservoir sampling algorithms in parallel to maintain two samples, one that picks points with probability proportional to $||x||_2^p$, and another that picks points with uniform probability. Our actual sampling with probability proportional $q(x) = \frac{\|x\|_2^p}{2\sum_{x\in\mathcal{X}}\|x\|_2^p} + \frac{1}{2|\mathcal{X}|}$ picks from one of the two reservoirs with probability $1/2$ each. Therefore, our MCMC algorithm uses a single pass of $\mathcal{X}$ to pick a small sample of *i.i.d.* random points from the probability distribution $q(\cdot)$, in advance. Note that $q(\cdot)$ is an easier and fixed distribution compared to $p_S(\cdot)$. The latter one depends on S and could change over multiple rounds of adaptive sampling.

Let $x \in \mathcal{X}$ be a random point sampled with probability $q(x)$. Consider a random walk whose single step is defined as follows: sample another point $y \in \mathcal{X}$ independently with probability $q(y)$ and sample a real number r *u.a.r.* from the interval $(0, 1)$, and if

$$\frac{d(y, \text{span}\,(S))^p\ q(x)}{d(x, \text{span}\,(S))^p\ q(y)} = \frac{p_S(y)\ q(x)}{p_S(x)\ q(y)} > r,$$

then move from x to y, else, stay at x. Essentially, this does rejection sampling using a simpler distribution $q(\cdot)$. Observe that the stationary distribution of the above random walk is the adaptive sampling distribution $p_S(\cdot)$. We use $\tilde{P}_m^{(1)}(\cdot \mid S)$ to denote the resulting distribution on $\mathcal{X}$ after m steps of the above random walk. Note that m steps of the above random walk can be simulated by sampling m *i.i.d.* points from the distribution $q(\cdot)$ in advance, and representing them implicitly as m-dimensional points.

Lemma 1 below shows that for any subsets $\tilde{S} \subseteq S \subseteq \mathcal{X}$ (where $\tilde{S}$ is the initial subset, and S is the current subset), either $\text{err}_p(\mathcal{X}, S)$ is small compared to $\text{err}_p(\mathcal{X}, \tilde{S})$, or our MCMC sampling distribution closely approximates the adaptive sampling distribution $p_S(\cdot)$ in total variation distance. Proof of Lemma 1 relies on Corollary 1 of Cai [7] that gives an upper bound on the TV distance between these two distributions in terms of: 1) length of the Markov chain, and 2) upper bound on the ratio between these two distributions for any input point.

▶ **Lemma 1.** *Let $\epsilon_1, \epsilon_2 \in (0, 1)$ and $\tilde{S} \subseteq S \subseteq \mathcal{X}$. Let $P^{(1)}(\cdot \mid S)$ denote the distribution over an i.i.d. sample of t points picked from adaptive sampling w.r.t. S, and let $\tilde{P}_m^{(1)}(\cdot \mid \tilde{S})$ denote the distribution over t points picked by t independent random walks of length m each in our one-pass adaptive sampling algorithm; see step 3(a). Then for $m \geq 1 + \frac{2}{\epsilon_1}\log\frac{1}{\epsilon_2}$, either $\text{err}_p(\mathcal{X}, S) \leq \epsilon_1\ \text{err}_p(\mathcal{X}, \tilde{S})$ or $\left\|P^{(1)}(\cdot \mid S) - \tilde{P}_m^{(1)}(\cdot \mid S)\right\|_{TV} \leq \epsilon_2 t$.*

One-pass (approximate MCMC) adaptive sampling algorithm:
Input: a discrete subset $\mathcal{X} \subseteq \mathbb{R}^d$ and integer parameters $t, l, m \in \mathbf{Z}_{\geq 0}$.
Ouput: a subset $S \subseteq \mathcal{X}$.

1. Pick an *i.i.d.* sample $\mathcal{Y}$ of size $|\mathcal{Y}| = ltm$ from $\mathcal{X}$, without replacement, where the probability of picking $x \in \mathcal{X}$ is

$$q(x) = \frac{d(x, \operatorname{span}(\tilde{S}))^p}{2 \operatorname{err}_p(\mathcal{X}, \tilde{S})} + \frac{1}{2|\mathcal{X}|}.$$

   We use the *pivot* subset $\tilde{S} = \emptyset$ so the corresponding distribution is

$$q(x) = \frac{1}{2} \frac{\|x\|_2^p}{\sum_{x \in \mathcal{X}} \|x\|_2^p} + \frac{1}{2|\mathcal{X}|}.$$

   %% This can be implemented in one pass over $\mathcal{X}$ using weighted reservoir sampling [8]. Weighted reservoir sampling is a weighted version of the classical reservoir sampling where the probability of inclusion of an item in the sample is proportional to the weight associated with the item.
2. Initialize $S \leftarrow \emptyset$.
3. For $i = 1, 2, \ldots, l$ do:
   a. Pick an *i.i.d.* sample A_i of size $|A_i| = t$ from $\mathcal{X}$ as follows. Each point in A_i is sampled by taking m steps of the following random walk starting from a point x picked with probability $q(x)$. In each step of the random walk, we pick another point y from $\mathcal{X}$ with probability $q(y)$ and pick a real number r uniformly at random from the interval $(0, 1)$. If $\frac{d(y, \operatorname{span}(S))^p \; q(x)}{d(x, \operatorname{span}(S))^p \; q(y)} > r$ then move to y, else, stay at the current point.
   %% Note that we add only the final point obtained after the m-step random walk in the subset S.
   %% We note that the steps 1-3 of the algorithm can be simulated by taking only one pass over the input as discussed below. Suppose we have a single-pass Algorithm A for sampling from a particular distribution, we can design another Algorithm B that runs in parallel to Algorithm A and post-processes its sample. In our setting, once we know how to get an *i.i.d.* sample of points, where point x is picked with probability $q(x)$, we can run another parallel thread that simulates a random walk whose each step requires a point picked with probability $q(x)$ and performs Step 3.
   b. $S \leftarrow S \cup A_i$.
4. Output S.

Proof. First, consider the $l = 1, t = 1$ case of the one-pass adaptive sampling algorithm described above. In this case, the procedure outputs only one element of $\mathcal{X}$. This random element is picked by m steps of the following random walk starting from an x picked with probability $q(x)$. In each step, we pick another point y with probability $q(y)$ and sample a real

One-pass MCMC ℓ_p subspace approximation algorithm:
Input: a discrete subset $\mathcal{X} \subseteq \mathbb{R}^d$, an integer parameter $k \in \mathbf{Z}_{\geq 0}$ and an error parameter $\delta \in \mathbb{R}_{\geq 0}$.
Output: a subset $\mathcal{S} \subseteq \mathcal{X}$ of $\tilde{O}\left((k/\epsilon)^{p+1}\right)$ points.
1. Repeat the following $O(k \log \frac{1}{\epsilon})$ times in parallel and pick the best sample, $\mathcal{S}$ that minimizes $\sum_{x \in \mathcal{X}} d(x, \text{span}\,(\mathcal{S}))^p$.
   a. Call **One-pass (approximate MCMC) adaptive sampling algorithm** with $t = \tilde{O}((k/\epsilon)^{p+1})$, $l = k$ and $m = 1 + \frac{2}{\epsilon_1} \log \frac{1}{\epsilon_2}$.
2. Output $\mathcal{S}$.

number r *u.a.r.* from the interval $(0, 1)$, and if $p_S(y)q(x)/p_S(x)q(y) > r$, then we move from x to y, else, we stay at x. Observe that the stationary distribution of the above random walk is the adaptive sampling distribution *w.r.t.* S given by $p_S(x) = d(x, \text{span}\,(S))^p / \text{err}_p(\mathcal{X}, S)$. Using Corollary 1 of [7], the total variation distance after m steps of the random walk is bounded by

$$\left(1 - \frac{1}{\gamma}\right)^{m-1} \leq e^{-(m-1)/\gamma} \leq \epsilon_2, \text{ where } \gamma = \max_{x \in \mathcal{X}} \frac{p_S(x)}{q(x)}.$$

The above bound is at most ϵ_2 if we choose to run the random walk for $m \geq 1 + \gamma \log \frac{1}{\epsilon_2}$ steps. Now suppose $\text{err}_p(\mathcal{X}, S) > \epsilon_1 \text{ err}_p(\mathcal{X}, \tilde{S})$. Then, for any $x \in \mathcal{X}$

$$\begin{aligned}\frac{p_S(x)}{q(x)} &= \frac{\frac{d(x, \text{span}\,(S))^p}{\text{err}_p(\mathcal{X}, S)}}{\frac{1}{2}\frac{d(x, \text{span}\,(\tilde{S}))^p}{\text{err}_p(\mathcal{X}, \tilde{S})} + \frac{1}{2|\mathcal{X}|}} \\ &\leq \frac{2\, d(x, \text{span}\,(S))^p \text{ err}_p(\mathcal{X}, \tilde{S})}{d(x, \text{span}\,(\tilde{S}))^p \text{ err}_p(\mathcal{X}, S)} \leq \frac{2}{\epsilon_1},\end{aligned}$$

using $d(x, \text{span}\,(S))^p \leq d(x, \text{span}\,(\tilde{S}))^p$ because $\tilde{S} \subseteq S$, and the above assumption $\text{err}_p(\mathcal{X}, S) > \epsilon_1 \text{ err}_p(\mathcal{X}, \tilde{S})$. Therefore, $m > \frac{2}{\epsilon_1} \log \frac{1}{\epsilon_2}$ ensures that m steps of the random walk gives a distribution within total variation distance ϵ_2 from the adaptive sampling distribution for picking a single point.

Note that for $t > 1$ both the adaptive sampling and the MCMC sampling procedure pick an *i.i.d.* sample of t points, so the total variation distance is additive in t, which means

$$\left\| P^{(1)}(\cdot \mid S) - \tilde{P}_m^{(1)}(\cdot \mid S) \right\|_{TV} \leq \epsilon_2 t,$$

assuming $\text{err}_p(\mathcal{X}, S) > \epsilon_1 \text{ err}_p(\mathcal{X}, \tilde{S})$. This completes a proof of the lemma. ◀

4 ℓ_p subspace approximation

In this section, we give our result for one pass subset selection for ℓ_p subspace approximation. We first show (in Lemma 2) that the true adaptive sampling can be well approximated by one pass (approximate) MCMC based sampling algorithm. Building on this result, in Proposition 3 and Theorem 4, we show bounds on the number of steps taken by the Markov chain, and on the sample size that gives an additive approximation for the ℓ_p subspace approximation. Our MCMC-based sampling ensures that our problem statement's single-pass subset selection criteria are satisfied.

First, let's set up the notation required to analyze the true adaptive sampling as well as our one-pass (approximate MCMC) adaptive sampling algorithm. For any fixed subset $S \subseteq \mathcal{X}$, we define

$$\mathrm{err}_p(\mathcal{X}, S) = \sum_{x \in \mathcal{X}} d(x, \mathrm{span}\,(S))^p, \tag{5}$$

$$P^{(1)}(T|S) = \prod_{x \in T} \frac{d(x, \mathrm{span}\,(S))^p}{\mathrm{err}_p(\mathcal{X}, S)}, \tag{6}$$

$$\text{for any subset } T \text{ of size } t,$$

$$\mathop{\mathrm{E}}_{T}\left[\mathrm{err}_p(\mathcal{X}, S \cup T)\right] = \sum_{T\,:\,|T|=t} P^{(1)}(T \mid S)\ \mathrm{err}_p(\mathcal{X}, S \cup T). \tag{7}$$

Given a subset $S \subseteq \mathcal{X}$, $P^{(1)}(T \mid S)$ denotes the probability of picking a subset $T \subseteq \mathcal{X}$ of *i.i.d.* t points by adaptive sampling *w.r.t.* S. We use $P^{(l)}(T_{1:l}|S)$ to denote the probability of picking a subset $T_{1:l} = B_1 \cup B_2 \cup \ldots \cup B_l \subseteq \mathcal{X}$ of tl points by l iterative rounds of adaptive sampling, where in the first round we sample a subset B_1 consisting of *i.i.d.* t points *w.r.t.* S, in the second round we sample a subset B_2 consisting of *i.i.d.* t points *w.r.t.* $S \cup B_1$, and so on to pick $T_{1:l} = B_1 \cup B_2 \cup \ldots \cup B_l$ over l iterations. Similarly, in the context of adaptive sampling, we use $T_{2:l}$ to denote $B_2 \cup \ldots \cup B_l$. We abuse the notation $\mathop{\mathrm{E}}_{T_{1:l} \mid S}[\cdot]$ to denote the expectation over $T_{1:l}$ picked in l iterative rounds of adaptive sampling starting from S.

Given a *pivot* subset $\tilde{S} \subseteq \mathcal{X}$ and another subset $S \subseteq \mathcal{X}$ such that $\tilde{S} \subseteq S$, consider the following MCMC sampling with parameters l, t, m that picks l subsets $A_1, A_2, \ldots, A_l$ of t points each, where m denotes the number of steps of a random walk used to pick these points. This sampling can be implemented in a single pass over $\mathcal{X}$, for any l, t, m, and any given subsets $\tilde{S} \subseteq S$. For $T_{1:l} = A_1 \cup A_2 \cup \ldots \cup A_l$. We use $\tilde{P}^{(l)}_m(T_{1:l} \mid S)$ to denote the probability of picking $T_{1:l}$ as the output of the following MCMC sampling procedure. Similarly, in the context of MCMC sampling, we use $T_{2:l}$ to denote $A_2 \cup \ldots \cup A_l$. We abuse the notation $\mathop{\tilde{\mathrm{E}}}_{T_{1:l} \mid S}[\cdot]$ to denote the expectation over $T_{1:l}$ picked using the MCMC sampling procedure starting from S with a pivot subset $\tilde{S} \subseteq S$.

We require the following additional notation in our analysis of the above MCMC sampling. We use $\tilde{P}^{(1)}_m(T \mid S)$ to denote the resulting distribution over subsets T of size t, when we use the above sampling procedure with $l = 1$. We define the following expressions:

$$\mathrm{ind}_p(\mathcal{X}, S) = \mathbb{1}\left(\mathrm{err}_p(\mathcal{X}, S) \leq \epsilon_1\ \mathrm{err}_p(\mathcal{X}, \tilde{S})\right), \tag{8}$$

$$\mathop{\tilde{\mathrm{E}}}_{T}\left[\mathrm{err}_p(\mathcal{X}, S \cup T)\right] = \sum_{T\,:\,|T|=t} \tilde{P}^{(1)}_m(T \mid S)\ \mathrm{err}_p(\mathcal{X}, S \cup T), \tag{9}$$

$$\mathop{\tilde{\mathrm{E}}}_{T}\left[\mathrm{ind}_p(\mathcal{X}, S \cup T)\right] = \sum_{T\,:\,|T|=t} \tilde{P}^{(1)}_m(T \mid S)\ \mathrm{ind}_p(\mathcal{X}, S \cup T). \tag{10}$$

The expression $\mathrm{ind}_p(\mathcal{X}, S)$ (in Equation (8)) denotes an indicator random variable that takes value 1 if error *w.r.t.* subset S is smaller than ϵ_1 times error *w.r.t.* subset $\tilde{S}$, and 0 otherwise. The expression $\mathop{\tilde{\mathrm{E}}}_{T}\left[\mathrm{err}_p(\mathcal{X}, S \cup T)\right]$ (in Equation (9)) denotes the expected error over the subset T picked using the MCMC sampling procedure starting from the set S such that the initial subset $\tilde{S} \subseteq S$.

Now Lemma 2 analyzes the effect of starting with an initial subset S_0 and using the same S_0 as a pivot subset for doing the MCMC sampling for l subsequent iterations of adaptive sampling, where we pick t *i.i.d.* points in each iteration using t independent random walks

of m steps. Lemma 2 shows that the expected error for subspace approximation after doing the l iterations of adaptive sampling is not too far from the expected error for subspace approximation after replacing the l iterations with MCMC sampling.

▶ **Lemma 2.** *For any subset $S_0 \subseteq \mathcal{X}$, any $\epsilon_1, \epsilon_2 \in (0,1)$ and any positive integers t, l, m with $m \geq 1 + \frac{2}{\epsilon_1} \log \frac{1}{\epsilon_2}$,*

$$\tilde{\mathrm{E}}_{T_{1:l} \mid S_0} \left[\mathrm{err}_p(\mathcal{X}, S_0 \cup T_{1:l})\right] \leq \mathrm{E}_{T_{1:l} \mid S_0} \left[\mathrm{err}_p(\mathcal{X}, S_0 \cup T_{1:l})\right] + (\epsilon_1 + \epsilon_2 tl)\, \mathrm{err}_p(\mathcal{X}, S_0).$$

Proof. We show a slightly stronger inequality than the one given above, i.e., for any S_0 such that $\tilde{S} \subseteq S_0$,

$$\tilde{\mathrm{E}}_{T_{1:l} \mid S_0} \left[\mathrm{err}_p(\mathcal{X}, S_0 \cup T_{1:l})\right] \leq \mathrm{E}_{T_{1:l} \mid S_0} \left[\mathrm{err}_p(\mathcal{X}, S_0 \cup T_{1:l})\right] + \left(\epsilon_1 \tilde{\mathrm{E}}_{T_{1:l} \mid S_0} \left[\mathrm{ind}_p(\mathcal{X}, S_0 \cup T_{1:l})\right] + \epsilon_2 tl\right) \mathrm{err}_p(\mathcal{X}, \tilde{S}).$$

The special case $S_0 = \tilde{S}$ gives the lemma. We prove the above-mentioned stronger statement by induction on l. For $l = 0$, the above inequality holds trivially. Now assuming induction hypothesis, the above holds true for $l-1$ iterations (instead of l) starting with any subset $S_1 = S_0 \cup A \subseteq \mathcal{X}$ because $\tilde{S} \subseteq S_0 \subseteq S_1$.

$$\begin{aligned}
&\tilde{\mathrm{E}}_{T_{1:l} \mid S_0} \left[\mathrm{err}_p(\mathcal{X}, S_0 \cup T_{1:l})\right] \\
&= \tilde{\mathrm{E}}_{S_1 \mid S_0} \left[\tilde{\mathrm{E}}_{T_{2:l} \mid S_1} \left[\mathrm{err}_p(\mathcal{X}, S_1 \cup T_{2:l})\right]\right] \\
&= \sum_{S_1 \,:\, \mathrm{ind}_p(\mathcal{X}, S_1) = 1} \tilde{P}_m^{(1)}(S_1 \mid S_0) \tilde{\mathrm{E}}_{T_{2:l} \mid S_1} \left[\mathrm{err}_p(\mathcal{X}, S_1 \cup T_{2:l})\right] \\
&\quad + \sum_{S_1 \,:\, \mathrm{ind}_p(\mathcal{X}, S_1) = 0} \tilde{P}_m^{(1)}(S_1 \mid S_0) \tilde{\mathrm{E}}_{T_{2:l} \mid S_1} \left[\mathrm{err}_p(\mathcal{X}, S_1 \cup T_{2:l})\right]. \qquad (11)
\end{aligned}$$

If $\mathrm{ind}_p(\mathcal{X}, S_1) = 1$ then $\mathrm{err}_p(\mathcal{X}, S_1 \cup T_{2:l}) \leq \mathrm{err}_p(\mathcal{X}, S_1) \leq \epsilon_1\, \mathrm{err}_p(\mathcal{X}, S_0)$, so the first part of the above sum can be bounded as follows.

$$\begin{aligned}
&\sum_{S_1 \,:\, \mathrm{ind}_p(\mathcal{X}, S_1) = 1} \tilde{P}_m^{(1)}(S_1 \mid S_0) \tilde{\mathrm{E}}_{T_{2:l} \mid S_1} \left[\mathrm{err}_p(\mathcal{X}, S_1 \cup T_{2:l})\right] \\
&\leq \epsilon_1\, \mathrm{err}_p(\mathcal{X}, S_0) \cdot \sum_{S_1 \,:\, \mathrm{ind}_p(\mathcal{X}, S_1) = 1} \tilde{P}_m^{(1)}(S_1 \mid S_0) \tilde{\mathrm{E}}_{T_{2:l} \mid S_1} \left[\mathrm{ind}_p(\mathcal{X}, S_1 \cup T_{2:l})\right]. \qquad (12)
\end{aligned}$$

We give an upper bound on the second part as follows.

$$\begin{aligned}
&\sum_{S_1 \,:\, \mathrm{ind}_p(\mathcal{X}, S_1) = 0} \tilde{P}_m^{(1)}(S_1 \mid S_0) \tilde{\mathrm{E}}_{T_{2:l} \mid S_1} \left[\mathrm{err}_p(\mathcal{X}, S_1 \cup T_{2:l})\right] \\
&= \sum_{S_1 \,:\, \mathrm{ind}_p(\mathcal{X}, S_1) = 0} \tilde{P}_m^{(1)}(S_1 \mid S_0) \tilde{\mathrm{E}}_{T_{2:l} \mid S_1} \left[\mathrm{err}_p(\mathcal{X}, S_1 \cup T_{2:l})\right]. \\
&\leq \sum_{S_1 \,:\, \mathrm{ind}_p(\mathcal{X}, S_1) = 0} \tilde{P}_m^{(1)}(S_1 \mid S_0) \cdot \\
&\quad \left(\mathrm{E}_{T_{2:l} \mid S_1} \left[\mathrm{err}_p(\mathcal{X}, S_1 \cup T_{2:l})\right] + (\epsilon_1 \tilde{\mathrm{E}}_{T_{2:l} \mid S_1} \left[\mathrm{ind}_p(\mathcal{X}, S_1 \cup T_{2:l})\right] + \epsilon_2 t(l-1))\, \mathrm{err}_p(\mathcal{X}, \tilde{S})\right). \qquad (13) \\
&\qquad \text{(by applying the induction hypothesis to } (l-1) \text{ iterations starting from } S_1.) \\
&\leq \sum_{S_1 \,:\, \mathrm{ind}_p(\mathcal{X}, S_1) = 0} P^{(1)}(S_1 \mid S_0) \mathrm{E}_{T_{2:l} \mid S_1} \left[\mathrm{err}_p(\mathcal{X}, S_1 \cup T_{2:l})\right]
\end{aligned}$$

$$
\begin{aligned}
&+ \epsilon_1 \operatorname{err}_p(\mathcal{X}, \tilde{S}) \cdot \sum_{S_1 \,:\, \operatorname{ind}_p(\mathcal{X}, S_1)=0} \tilde{P}_m^{(1)}(S_1 \mid S_0) \mathop{\tilde{\mathrm{E}}}_{T_{2:l} \mid S_1} [\operatorname{ind}_p(\mathcal{X}, S_1 \cup T_{2:l})] \\
&+ \epsilon_2 t(l-1) \operatorname{err}_p(\mathcal{X}, \tilde{S}) \sum_{S_1 \,:\, \operatorname{ind}_p(\mathcal{X}, S_1)=0} \tilde{P}_m^{(1)}(S_1 \mid S_0) \\
&+ \sum_{S_1 \,:\, \operatorname{ind}_p(\mathcal{X}, S_1)=0} \left| \tilde{P}_m^{(1)}(S_1 \mid S_0) - P^{(1)}(S_1 \mid S_0) \right| \cdot \mathop{\mathrm{E}}_{T_{2:l} \mid S_1} [\operatorname{err}_p(\mathcal{X}, S_1 \cup T_{2:l})] .
\end{aligned}
$$

$$
\left(\text{by adding and subtracting the term } \sum_{S_1 \,:\, \operatorname{ind}_p(\mathcal{X}, S_1)=0} P^{(1)}(S_1 \mid S_0) \mathop{\mathrm{E}}_{T_{2:l} \mid S_1} [\operatorname{err}_p(\mathcal{X}, S_1 \cup T_{2:l})] \text{ in Eq. (13).} \right)
$$

$$
\begin{aligned}
&\leq \sum_{S_1} P^{(1)}(S_1 \mid S_0) \mathop{\mathrm{E}}_{T_{2:l} \mid S_1} [\operatorname{err}_p(\mathcal{X}, S_1 \cup T_{2:l})] \\
&\quad + \epsilon_1 \operatorname{err}_p(\mathcal{X}, \tilde{S}) \sum_{S_1 \,:\, \operatorname{ind}_p(\mathcal{X}, S_1)=0} \tilde{P}_m^{(1)}(S_1 \mid S_0) \cdot \mathop{\tilde{\mathrm{E}}}_{T_{2:l} \mid S_1} [\operatorname{ind}_p(\mathcal{X}, S_1 \cup T_{2:l})] \\
&\quad + \epsilon_2 t(l-1) \operatorname{err}_p(\mathcal{X}, \tilde{S}) + \sum_{S_1 \,:\, \operatorname{ind}_p(\mathcal{X}, S_1)=0} \left| \tilde{P}_m^{(1)}(S_1 \mid S_0) - P^{(1)}(S_1 \mid S_0) \right| \cdot \operatorname{err}_p(\mathcal{X}, \tilde{S}).
\end{aligned}
$$

$$
\left(\text{by upper bounding the probability expression } \sum_{S_1 \,:\, \operatorname{ind}_p(\mathcal{X}, S_1)=0} \tilde{P}_m^{(1)}(S_1 \mid S_0) \text{ by 1.} \right)
$$

$$
\begin{aligned}
&\leq \mathop{\mathrm{E}}_{T_{1:l} \mid S_0} [\operatorname{err}_p(\mathcal{X}, S_0 \cup T_{1:l})] \\
&\quad + \epsilon_1 \operatorname{err}_p(\mathcal{X}, \tilde{S}) \sum_{S_1 \,:\, \operatorname{ind}_p(\mathcal{X}, S_1)=0} \tilde{P}_m^{(1)}(S_1 \mid S_0) \cdot \mathop{\tilde{\mathrm{E}}}_{T_{2:l} \mid S_1} [\operatorname{ind}_p(\mathcal{X}, S_1 \cup T_{2:l})] \\
&\quad + \epsilon_2 t(l-1) \operatorname{err}_p(\mathcal{X}, \tilde{S}) + \left\| \tilde{P}^{(1)}(\cdot \mid S_0) - P^{(1)}(\cdot \mid S_0) \right\|_{TV} \operatorname{err}_p(\mathcal{X}, \tilde{S}).
\end{aligned}
$$

$$
\left(\text{as } \mathop{\mathrm{E}}_{T_{1:l} \mid S_0} [\operatorname{err}_p(\mathcal{X}, S_0 \cup T_{1:l})] = \sum_{S_1} P^{(1)}(S_1 \mid S_0) \mathop{\mathrm{E}}_{T_{2:l} \mid S_1} [\operatorname{err}_p(\mathcal{X}, S_1 \cup T_{2:l})] \text{ by Eq. (7).} \right)
$$

$$
\begin{aligned}
&\leq \mathop{\mathrm{E}}_{T_{1:l} \mid S_0} [\operatorname{err}_p(\mathcal{X}, S_0 \cup T_{1:l})] \\
&\quad + \epsilon_1 \operatorname{err}_p(\mathcal{X}, \tilde{S}) \sum_{S_1 \,:\, \operatorname{ind}_p(\mathcal{X}, S_1)=0} \tilde{P}_m^{(1)}(S_1 \mid S_0) \cdot \mathop{\tilde{\mathrm{E}}}_{T_{2:l} \mid S_1} [\operatorname{ind}_p(\mathcal{X}, S_1 \cup T_{2:l})] \\
&\quad + \epsilon_2 t(l-1) \operatorname{err}_p(\mathcal{X}, \tilde{S}) + \epsilon_2 t \operatorname{err}_p(\mathcal{X}, \tilde{S}). \qquad (14)
\end{aligned}
$$

Finally, Equation (14) holds using Lemma 1 about the total variation distance between $P^{(1)}$ and $\tilde{P}^{(1)}$ distributions. Plugging the bounds (12) and (14) into (11), we get

$$
\begin{aligned}
&\mathop{\tilde{\mathrm{E}}}_{T_{1:l} \mid S_0} [\operatorname{err}_p(\mathcal{X}, S_0 \cup T_{1:l})] \\
&\leq \mathop{\mathrm{E}}_{T_{1:l} \mid S_0} [\operatorname{err}_p(\mathcal{X}, S_0 \cup T_{1:l})] + \epsilon_1 \operatorname{err}_p(\mathcal{X}, \tilde{S}) \sum_{S_1} \tilde{P}_m^{(1)}(S_1 \mid S_0) \cdot \mathop{\tilde{\mathrm{E}}}_{T_{2:l} \mid S_1} [\operatorname{ind}_p(\mathcal{X}, S_1 \cup T_{2:l})] \\
&\quad + \epsilon_2 t(l-1) \operatorname{err}_p(\mathcal{X}, \tilde{S}) + \epsilon_2 t \operatorname{err}_p(\mathcal{X}, \tilde{S}). \\
&= \mathop{\mathrm{E}}_{T_{1:l} \mid S_0} [\operatorname{err}_p(\mathcal{X}, S_0 \cup T_{1:l})] + \left(\epsilon_1 \mathop{\tilde{\mathrm{E}}}_{T_{1:l} \mid S_0} [\operatorname{ind}_p(\mathcal{X}, S_0 \cup T_{1:l})] + \epsilon_2 t l \right) \operatorname{err}_p(\mathcal{X}, \tilde{S}). \\
&\leq \mathop{\mathrm{E}}_{T_{1:l} \mid S_0} [\operatorname{err}_p(\mathcal{X}, S_0 \cup T_{1:l})] + (\epsilon_1 + \epsilon_2 t l) \operatorname{err}_p(\mathcal{X}, \tilde{S}),
\end{aligned}
$$

which completes the proof of Lemma 2. ◀

Theorem 5 from [16] shows that in $l = k$ rounds of adaptive sampling, where in each round we pick $t = \tilde{O}\left((k/\epsilon)^{p+1}\right)$ points and take their union, gives an additive approximation guarantee for ℓ_p subspace approximation with probability at least $1/2k$. Repeating it multiple times and taking the best can boost the probability further. We restate the main part of this theorem below.

▶ **Proposition 3** (Theorem 5, [16]). *Let k be any positive integer, let $\epsilon \in (0,1)$ and $S_0 = \emptyset$. Let $l = k$ and $t = \tilde{O}\left((k/\epsilon)^{p+1}\right)$. If $S_l = S_0 \cup T_{1:l}$ is obtained by starting from S_0 and doing adaptive sampling according to the p-th power of distances in l iterations, and in each iteration we add t points from $\mathcal{X}$, then we have $|S_l| = tl = \tilde{O}(k \cdot (k/\epsilon)^{p+1})$ such that*

$$\operatorname{err}_p(\mathcal{X}, S_0 \cup T_{1:l})^{1/p} \leq \operatorname{err}_p(\mathcal{X}, V^*)^{1/p} + \epsilon \operatorname{err}_p(\mathcal{X}, \emptyset)^{1/p},$$

with probability at least $1/2k$, and where V^* minimizes $\operatorname{err}_p(\mathcal{X}, V)$ over all linear subspaces V of dimension at most k. If we repeat this $O(k \log \frac{1}{\epsilon})$ times then the probability of success can be boosted to $1 - \epsilon$.

Combining Lemma 2 and Proposition 3 we get the following Theorem.

▶ **Theorem 4.** *For any positive integer k, any $p \in [1, \infty)$, and any $\delta \in \mathbb{R}_{\geq 0}$, starting from $S_0 = \emptyset$ and setting the following parameters in one-pass MCMC ℓ_p subspace approximation algorithm (see Section 3)*

$$\begin{aligned}
\epsilon &= \delta/4, \\
\epsilon_1 &= \delta^p/2^{p+1}, \\
\epsilon_2 &= \delta^p/2^{p+1}tl, \\
m &= 1 + \frac{2}{\delta^p} \log \frac{k}{\delta^p}, \\
t &= \tilde{O}((k/\epsilon)^{p+1}), \\
l &= k,
\end{aligned}$$

we get a subset $\mathcal{S}$ of size $\tilde{O}(k \cdot (k/\delta)^{p+1})$ with an additive approximation guarantee on its expected error as $\operatorname{err}_p(\mathcal{X}, V^*)^{1/p} + \delta \operatorname{err}_p(\mathcal{X}, \emptyset)^{1/p}$. Further, the running time of the algorithm is $nd + k \cdot \tilde{O}\left(\left(\frac{k}{\delta}\right)^{p+1}\right)$.

Proof. From Lemma 2 we know that

$$\tilde{\mathrm{E}}_{T_{1:l} \mid \emptyset} \left[\operatorname{err}_p(\mathcal{X}, T_{1:l})\right] \leq \mathrm{E}_{T_{1:l} \mid \emptyset} \left[\operatorname{err}_p(\mathcal{X}, T_{1:l})\right] + (\epsilon_1 + \epsilon_2 tl) \operatorname{err}_p(\mathcal{X}, \emptyset).$$

Thus, for $p \in [1, \infty)$ we have

$$\begin{aligned}
\tilde{\mathrm{E}}_{T_{1:l} \mid \emptyset} \left[\operatorname{err}_p(\mathcal{X}, T_{1:l})\right]^{1/p} &\leq \mathrm{E}_{T_{1:l} \mid \emptyset} \left[\operatorname{err}_p(\mathcal{X}, T_{1:l})\right]^{1/p} + (\epsilon_1 + \epsilon_2 tl)^{1/p} \operatorname{err}_p(\mathcal{X}, \emptyset)^{1/p}. \\
&\leq (1 - \epsilon) \left(\operatorname{err}_p(\mathcal{X}, V^*)^{1/p} + \epsilon \operatorname{err}_p(\mathcal{X}, \emptyset)^{1/p}\right) + \epsilon \operatorname{err}_p(\mathcal{X}, \emptyset)^{1/p} \\
&\qquad + (\epsilon_1 + \epsilon_2 tl)^{1/p} \operatorname{err}_p(\mathcal{X}, \emptyset)^{1/p}. \\
&\qquad \text{(using Proposition 3.)} \\
&\leq \operatorname{err}_p(\mathcal{X}, V^*)^{1/p} + \left(2\epsilon + (\epsilon_1 + \epsilon_2 tl)^{1/p}\right) \operatorname{err}_p(\mathcal{X}, \emptyset)^{1/p}. \\
&\leq \operatorname{err}_p(\mathcal{X}, V^*)^{1/p} + \delta \operatorname{err}_p(\mathcal{X}, \emptyset)^{1/p},
\end{aligned}$$

using $\epsilon = \delta/4$, $\epsilon_1 = \delta^p/2^{p+1}$ and $\epsilon_2 = \delta^p/2^{p+1}tl$.

We now give a bound on the running time of our algorithm. We require nd time to generate the probability distribution $q(x)$, for $x \in \mathcal{X}$. Further, the running time of MCMC sampling step is $t \cdot m \cdot l = k \cdot \tilde{O}\left(\left(\frac{k}{\delta}\right)^{p+1}\right)$. Therefore, the overall running time of the algorithm is $nd + k \cdot \tilde{O}\left(\left(\frac{k}{\delta}\right)^{p+1}\right)$. ◀

5 Conclusion and open questions

In this work, we give an efficient one-pass MCMC algorithm that does subset selection with additive approximation guarantee for ℓ_p subspace approximation, for any $p \in [1, \infty)$. Previously this was only known for the special case of $p = 2$ [11]. For general case $p \in [1, \infty)$, adaptive sampling algorithm due to [16] requires taking multiple passes over the input. Coming up with a one-pass subset selection algorithm that offers stronger multiplicative guarantees for $p \in [1, \infty)$ remains an interesting open problem.

Set Membership with Two Classical and Quantum Bit Probes

Abstract

We study the classical and quantum bit-probe versions of the static set membership problem : Given a subset, S ($|S| \leq n$) of a universe, $\mathcal{U}$ ($|\mathcal{U}| = m \gg n$), represent it as a binary string in memory so that the query "Is x in S?" ($x \in \mathcal{U}$) can be answered by making at most t probes into the string. Let $s_A(m, n, t)$ denote the minimum length of the bit string in any scheme that solves this static set membership problem. We show that for $n \geq 4$

$$s_A(m, n, t = 2) = \begin{cases} \mathcal{O}(m^{1-1/(n-1)}) & \text{if } n = 0 \pmod 3; \\ \mathcal{O}(m^{1-1/n}) & \text{if } n = 1, 2 \pmod 3; \\ \mathcal{O}(m^{6/7}) & \text{if } n = 8, 9. \end{cases}$$

These bounds are shown using a common scheme that is based on a graph-theoretic observation on orienting the edges of a graph of high girth. For all $n \geq 4$, these bounds substantially improve on the previous best bounds known for this problem, some of which required elaborate constructions [4]. Our schemes are explicit. A lower bound of the form $s_A(m, n, 2) = \Omega(m^{1-\frac{1}{\lfloor n/4 \rfloor}})$ was known for this problem. We show an improved lower bound of $s_A(m, n, 2) = \Omega(m^{1-\frac{2}{n+3}})$; this bound was previously known only for $n = 3, 5$ [5, 6, 2, 7, 4].

We consider the quantum version of the problem, where access to the bit-string $b \in \{0, 1\}^s$ is provided in the form of a quantum oracle that performs the transformation $\mathcal{O}_b : |i\rangle \mapsto (-1)^{b_i} |i\rangle$. Let $s_Q(m, n, 2)$ denote the minimum length of the bit string that solves the above set membership problem in the quantum model (with adaptive queries but no error). We show that for all $n \leq m^{1/8}$, we have $s_{QA}(m, n, 2) = \mathcal{O}(m^{7/8})$. This upper bound makes crucial use of Nash-William's theorem [10] for decomposing a graph into forests. This result is significant because, prior to this work, it was not known if quantum schemes yield any advantage over classical schemes. We also consider schemes that make a small number of quantum *non-adaptive* probes. In particular, we show that the space required in this case, $s_{QN}(m, n = 2, t = 2) = O(\sqrt{m})$ and $s_{QN}(m, n = 2, t = 3) = O(m^{1/3})$; in contrast, it is known that two non-adaptive classical probes yield no savings. Our quantum schemes are simple and use only the fact that the XOR of two bits of memory can be computed using just one quantum query to the oracle.

1 Introduction

We consider the problem of representing small subsets S of a universe $[m] = \{1, 2, \ldots, m\}$ in memory as a bit string so that membership queries of the form "Is $x \in S$?" can be answered with a small number of bit probes to the memory [9]. This is a fundamental question that asks how much a very sparse string can be compressed if we want to extract the bits of the original string efficiently from its compressed version. One natural way of representing sets in memory is the characteristic vector, which uses m bits of memory and answers membership queries using a single bit probe. Since there are only $O(\binom{m}{n})$ sets of size at most n (assume $n \ll m$) one might hope to represent them using $O(\log_2 \binom{m}{n}) \approx O(n \log m)$ bits of memory. However, compression to near the information-theoretic limits comes with a cost: membership can no longer be determined by reading just a small number of bits. To describe the trade-offs between efficiency of compression and the effort for extraction (measured as the number of bit probes), we will use the following notation [11]. Let $s_N(m, n, t)$ denote the minimum number of bits in a scheme that can represent sets of size at most n and answer membership queries by probing at most t bits of the memory non-adaptively (that is, the probes are made in parallel). We write $s_A(m, n, t)$ if the scheme is adaptive; we use the subscript Q if the scheme makes quantum queries (zero-error), which can be adaptive or non-adaptive [18], and write $s_{QA}(m, n, t)$ and $s_{QN}(m, n, t)$. Clearly,

$$s_N(m, n, t) \geq \left\{ \begin{array}{l} s_A(m, n, t) \\ s_{QN}(m, n, t) \end{array} \right\} \geq s_{QA}(m, n, t)$$

Radhakrishnan, Sen and Venkatesh [18] obtained lower bounds, which for the range of parameters of interest to us ($n \leq \sqrt{m}$, t constant) implies the following.

$$s_{QA}(m, n, t) = \Omega(m^{1/t} n^{1-1/t}).$$

(A similar lower bound in the classical setting was shown by Buhrman *et al.* [9].) Note that this bound shows that if the space is compressed to $O(n \log m)$, then $t = \Omega(\log m)$. Furthermore, if $t = 1$ no compression is possible even for $n = 1$; it also shows that $s_Q(m, 1, 2) = \Omega(\sqrt{m})$, for which there is a matching upper bound $s_N(m, n = 1, 2) = O(\sqrt{m})$. The first, non-trivial case is $n = 2$ and $t = 2$, where the above bound implies that $s_{QA}(m, 2, 2) = \Omega(\sqrt{m})$. It is known that this bound is not tight for classical schemes; better lower bound are known: $s_N(m, 2, 2) = m$ and $s_A(m, 2, 2) = \Omega(m^{4/7})$ [9, 19]. Remarkably, it is known that $s_A(m, 3, 2) = \Theta(m^{2/3})$ [13, 5]. Two-probe classical schemes have been constructed for representing small sets in several works starting with Alon and Feige [1] (see, e.g., [4, 2, 7, 12, 13, 15, 17], where sets of specific sizes are considered); the following upper and lower bounds was obtained by Garg and Radhakrishnan [12].

$$\Omega(m^{1-\frac{1}{\lfloor n/4 \rfloor}}) \leq s_A(m, n, t = 2) \leq \mathcal{O}(m^{1-\frac{1}{4n+1}}). \tag{1}$$

which roughly characterizes the space requirement for the problem, and, in particular, establishes that no savings over the standard characteristic vector representation can be expected if $n \geq \log m$. We show the following.

▶ **Theorem 1** (Result 1). *For $n \geq 4$,*

$$s_A(m, n, t = 2) = \begin{cases} \mathcal{O}(m^{1-1/(n-1)}) & \text{if } n = 0 \pmod 3; \\ \mathcal{O}(m^{1-1/n}) & \text{if } n = 1, 2 \pmod 3; \\ \mathcal{O}(m^{6/7}) & \text{if } n = 8, 9. \end{cases}$$

The above bounds improve the bounds for all other values of n (see Figure 1) for a comparison. Unlike the previous works, where different constructions (some of which quite intricate) were invented for different set sizes, our result is obtained using a unified approach based on graphs of high girth. (For $n = 2, 3$, the construction matches the currently best bounds.) To obtain a scheme for a set of a given size, one just plugs in the best available result for high-girth graph and obtains the bound claimed above. More importantly for us, the method used here inspires a quantum scheme that yields Result 3 below. We also obtain improved lower bounds.

▶ **Theorem 2** (Result 2). *For all odd n $(3 \leq n \leq \log m)$, $s_A(m, n, t = 2) = \Omega(m^{1-2/(n+3)})$.*

This bound matches the best bound known earlier for $n = 3$ (see [13]) and $n = 5$ (see [3]), and improves the current best lower bound (see Equation (1) above) for all larger values of n. We follow the approach of [12], who consider the graph underlying a two-probe scheme, and show that if it is dense then it must contain a forbidden configuration. We make better use of the structure of the underlying graph to force the existence of forbidden configurations.

We now describe our results in the quantum model. As stated above, our classical approach helps develop a new quantum schemes.

▶ **Theorem 3** (Result 3). $s_{QA}(m, n = m^{1/8}, t = 2) = \mathcal{O}(m^{7/8})$.

This result is especially significant because it shows that, unlike in the classical case, two probes give substantial savings over the characteristic vector representation for sets substantially larger than $\log m$ (see the remark above following Equation (1)). Before this work, quantum schemes were not known to provide significant savings over classical schemes. Our quantum scheme is also based on dense graphs that are locally sparse, this time we do not make use of high girth. Instead, we invoke a result of Nash-Williams [10] on covering the edges of a graph with two forests. After this, our construction uses only the following basic fact from quantum computation (Deutsch's algorithm [16]): the parity of two bits of memory can be computed using just one quantum probe. In fact, only the second probe in our scheme is truly quantum. This result opens the possibility that the lower bounds of $\sqrt{mn}$ cited above is perhaps achievable for quantum schemes. We show in fact that for $n = 2$, the lower bound can be matched using *non-adaptive* constructions.

▶ **Theorem 4** (Result4).

$$s_{QN}(m, n = 2, t = 2) = \mathcal{O}(\sqrt{m});$$
$$s_{QN}(m, n = 2, t = 3) = \mathcal{O}(m^{1/3}).$$

The query scheme is simple. The query scheme for $(n = 2, t = 2)$ on input x computes for locations $\ell_1(x), \ell_2(x), \ell_3(x), \ell_4(x)$, and returns "Yes" iff the bits at the first two locations are different and the bits at the last two locations are different, that is, we use an AND of two inequality computations, each of which requires just one quantum probe. A similar query scheme that uses an AND of three inequality computations gives the three-probe non-adaptive quantum scheme. We also obtain non-adaptive two-probe schemes with sublinear space for storing sets with more elements (see Appendix D). These bounds are interesting because no non-adaptive two-probe classical scheme exists with sublinear space [9].

2 Classical two-probe adaptive schemes

In this section we establish Theorem 1. Our two-probe adaptive schemes are based on dense graphs of high girth. We first specify the storage scheme and the query schemes based on an underlying graph. Then, to complete the proof, we will show the following: (i) if the

underlying graph has high girth, then there is an assignment of values to the memory such that all queries are answered correctly; (ii) the available explicit constructions of dense graphs of high girth in the literature yield the claimed bounds.

▶ **Definition 5** (Classical (G, K)-scheme)**.** *Let G be a directed graph with N vertices and M edges; let K be a positive integer. We refer to the following as a (G, K)-scheme. The storage consists of two bit arrays, A and B. To answer a membership query the decision tree will make the first probe to array A and the second probe to array B.*

Edge array: *An array $A : E(G) \to \{0, 1\}$, indexed by edges of G.*

Vertex array: *A two dimensional array $B : V \times [K] \to \{0, 1\}$.*

Elements: *We identify our universe of elements $[m]$ with a subset of $E(G) \times [K]$ (so we must ensure that the graph has at least m/K edges); thus, each element $x \in [m]$ will be referred to as (e, i).*

Query: *We represent an edge of G as an ordered pair of the form $e = (v_0, v_1)$ with the convention that $v_0 < v_1$. To process the query for the element $x = (e, i)$, we read $A[e]$ (first probe); then we return the value $B[v_{A[e]}, i]$ (by making the second probe into B). In other words, we may think of $A[e]$ as a bit that orients the edge e towards either its smaller vertex or the larger vertex; depending on this bit, the second probe is made into the array B corresponding to the vertex towards which the edge points. Note that this scheme is adaptive: the second probe depends on the first.*

Space: *We will ensure that $MK \geq m$. The space used by this scheme is then $NK + M$ bits (NK for the N vertex array and K for the edge array). By choosing the graph G and the parameter K appropriately we will show that our schemes use small space.*

The following lemma provides the connection between dense graphs of high girth and efficient two-probe adaptive schemes.

▶ **Lemma 6.** *Let G be a graph with N vertices M edges and girth g such that $n \leq \lfloor \frac{3g}{4} \rfloor$ and $M \leq m$. Then, $s_A(m, n, 2) \leq M + N\lceil m/M \rceil$.*

Before we present the proof of this lemma formally, let us derive from it the bounds claimed in Theorem 1. Since every graph has a bipartite subgraph that includes at least half the edges, it is sufficient to restrict attention to bipartite graphs, and hence to graphs whose girth is even. The smallest even number g such that $n \leq \lfloor \frac{3g}{4} \rfloor$ is given by

$$g(n) = \begin{cases} 4\lceil n/3 \rceil & n = -1, 0 \pmod 3; \\ 4\lceil n/3 \rceil - 2 & n = 1 \pmod 3. \end{cases} \tag{2}$$

Now, suppose that for a girth g, there are constant $c(g)$ $d(g)$ and $\tau(g)$, such that for all large L, there is a graph with at most $c(g)L$ vertices, girth g and $d(g)L^{1+\tau(g)}$ edges. Then, taking a graph with $N = \Theta(m^{1/(1+2\tau(g(n)))})$ vertices and $M = \Theta(m^{(1+\tau)/(1+2\tau)})$ edges in Lemma 6, we obtain the following.

▶ **Corollary 7.** $s_A(m, n, 2) = \mathcal{O}(m^{(1+\tau(g(n)))/(1+2\tau(g(n)))})$.

In particular, by using the current best constructions of dense graphs with large girth we obtain the following bounds for $s_A(m, n, 2)$. For example, we may take $\tau(6) = 1/2$, $\tau(8) = 1/3$ and $\tau(12) = 1/5$ based on graphs described Wenger [20]. (In Appendix A, we explain in what sense these constructions, and hence the resulting schemes, are explicit.)

Proof of Lemma 6. Fix a graph G with N vertices and M edges as in the statement of the theorem. Consider the (G, K)-scheme with $K = \lceil m/M \rceil$. Clearly the space used by the scheme is $N + KM = N + M\lceil m/M \rceil$. It remains to show that there is an assignment to the edge and vertex arrays of this scheme so that every query is answered correctly. Fix a set S

n	girth $g(n)$	$\tau(g(n))$	Our bound ($m^{(1+\tau)/(1+2\tau)}$)	Previous best bound

$n = 3r - 1, 3r$	$4r$	$1/(3r - 3)$	$\mathcal{O}(m^{1-\frac{1}{n}})$, $\mathcal{O}(m^{1-\frac{1}{n-1}})$ (using [14])	$\mathcal{O}(m^{1-1/(4n+1)})$ [12]

Figure 1 Our upper bounds use explicit constructions of graphs of large girth available in the literature (see Appendix A).

of at most n elements; recall that the elements of the universe have the form (e, i), where e is an edge of the graph and $i \in [K]$. We will assign values to the two arrays in two steps. First the edge array A will be assigned values. Recall that this assignment corresponds to assigning directions to the edges. We will show below how this is to be done. Assuming this we show how the array B is initialized. To start with, we initialize array B with zeros. Now for each element $(e, i) \in S$ (say $e = (v_0, v_1)$ where $v_0 < v_1$), if $A[e] = 0$ we set $B[v_0, i] = 1$, otherwise we set $B[v_1, i] = 1$. This assignment ensures that the query scheme described above will answer correctly for each element in S, so there are no *false negatives*, no matter what initial orientation of the edges is chosen. The key idea is to choose an orientation that avoids *false positives*; we must ensure that the value in the array A are set in such a way that an element not in S and an element in S do not make second probes to the same location in array B. Definition 8 below formally describes such a *safe orientation*. Here edges e such that $(e, i) \in S$ for some i are colored GREEN and the other edges are colored RED. Thus, there are at most n GREEN edges. Our choice of colors RED and GREEN are based on the following consideration. Some edges support elements in the set, some others do not support any such element. We chose to regard edges with elements in the set as GREEN, because the eventual answer to the query in that case is 'Yes'. In our definition of safe orientation, RED edges and GREEN edges are not allowed to point to a common vertex. Two GREEN edges are not allowed to point to the same vertex either but two RED edges are allowed to. We warn the reader that our choice of colors might be confusing, because GREEN edges are more restrictive/dangerous than RED edges! Then, Lemma 9 below shows that the graph G above has a safe orientation. It follows that our query scheme answers all the queries correctly. ◀

▶ **Definition 8** (Safe orientation). *Suppose H is a graph whose edges are colored RED and GREEN. We say that an orientation of edges is* safe *if every vertex with an incoming GREEN edge has only one edge coming into it.*

▶ **Lemma 9.** *Suppose H is a graph with even girth $g \geq 4$ and $n \leq \lfloor 3g/4 \rfloor$ GREEN edges. Then, G has a safe orientation. (This claim should have a simple proof, but we have not been able to find one that covers all cases succinctly.)*

Preliminaries: In the following, suppose H is a graph with even girth g and $n \leq \lfloor 3g/4 \rfloor$ GREEN edges. To find the necessary orientation, we will proceed by induction on the size of H (its total number of edges plus vertices). For the base case, note that a graph with no edges clearly has a safe orientation. For the induction step, we will identify an initial set of vertices V' such that all edges that have at least one end point in V' can be safely oriented towards a vertex in V'. We then delete V' and the edges incident on it, and use induction to extend this orientation to the rest of H. To identify the set V', we will use a *breadth first*

search procedure formally described below. This procedure produces a *breadth first search tree* or a *breadth first search forest* as usual, but we need to impose the following condition on it.

> If a vertex w in the tree is connected to its parent by a RED edge, then all of w's children are connected to w using GREEN edges; thus, in any root to leaf path in the tree, RED edges do not appear consecutively.

To enforce this, when a RED edge is added to the tree, we will mark the vertex it leads to RED; then when we visit this vertex, we only explore vertices connected to it by GREEN edges. If a GREEN edge is added to the tree, we mark the new vertex GREEN; then when we visit this vertex, we explore all its edges, whether GREEN or RED. The formal code is presented in Algorithm 1. (This is reminiscent of the breadth first search procedure employed by certain matching algorithms to discover augmenting paths; there one alternately explores either only the matched edge or all edges). As a first attempt we might want to orient the

Algorithm 1 Breadth-First Search (BFS).

```
   Input  : A non-empty subset Z ⊆ V(H)
   Output : A BFS forest rooted at the vertices in Z
 1 Q = empty queue ;
 2 push all elements of Z into Q and mark them GREEN;
 3 while Q is non-empty do
 4 |   v = pop(Q);
 5 |   if v is marked GREEN then
 6 |   |   push all unmarked neighbors w of v into Q;
   |   |   // now assign them colors as follows
 7 |   |   if {v, w} is GREEN then
 8 |   |   |   add {v, w} to the forest, and mark w GREEN
 9 |   |   end
10 |   |   else
11 |   |   |   mark w RED
12 |   |   end
13 |   end
14 |   if v is marked RED then
15 |   |   push all unmarked neighbors w of v with {v, w} GREEN into Q;
16 |   |   add {v, w} to the forest and mark w GREEN;
17 |   end
18 end
```

edges of the forest away from the roots and hope to extend this orientation to the other edges that have at least one end point in the forest. If this gives a valid orientation for these edges, we let V' be the vertex set of the forest, and proceed as above. Unfortunately, this straightforward method may run into problems; this motivates the following definition.

▶ **Definition 10** (Blocking edge, see Figure 2)**.** *In the forest constructed by BFS, we say that a non-tree edge is a blocking edge if (i) it is a non-tree* GREEN *edge both of whose end points are visited during BFS, or (ii) it is a non-tree* RED *edge with both end points marked* GREEN*.*

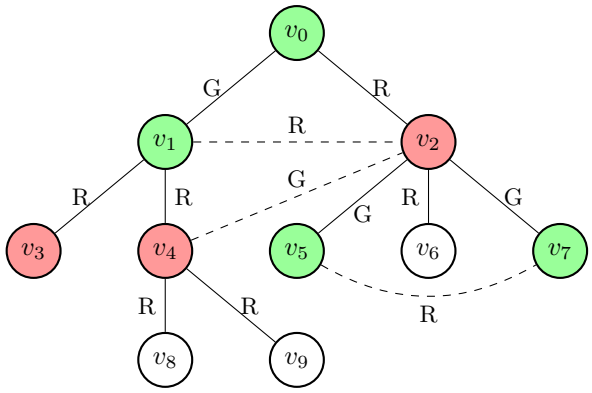

Figure 2 The BFS tree: (v_1, v_2) is not a blocking edge, (v_2, v_4) and (v_5, v_7) are blocking edges.

We will see that if there are no blocking edges, then the above strategy will work; otherwise, H has a cycle with many GREEN edges, and we will be able to exploit that.

▶ **Definition 11** (GREEN-dominated cycle, see Figure 3)**.** *We say that a cycle in H is* GREEN-dominated *if all but (perhaps) one of its RED edges are followed by a* GREEN edge.

We will establish the following two lemmas below.

▶ **Lemma 12.** *Suppose H has no* GREEN*-dominated cycle. Suppose V' is the set of vertices of H visited by BFS starting at a vertex v_0. Then there is a safe orientation of edges of H incident on V'.*

▶ **Lemma 13.** *Suppose H has a* GREEN*-dominated cycle C. Let H' be the graph obtained by deleting from H all edges of C. Let V' be the vertices visited by BFS in H' starting with the vetex set $V(C)$ of the cycle C. Then, there is a safe orientation of edges of H incident on V'.*

Let us use these lemmas to complete the proof of Lemma 9.

Proof of the Lemma 9. If H has no GREEN-dominated cycle, then by Lemma 12, we obtain an initial set of vertices V' and an orientation of all edges incident on it. If H has a GREEN-dominated cycle, then by Lemma 13 we obtain an initial set of vertices V' and an orientation of all edges incident on it. We extend this orientation to the remaining edges of the graph by deleting V' and all edges incident on it, and applying induction to the resulting subgraph induced by the vertex set $V \setminus V'$. ◀

We now return to the unproved lemmas.

Proof of Lemma 12. Let v_0 be an arbitrary vertex. Consider the tree produced by BFS starting with $Z = \{v_0\}$. We claim that there is no blocking edge for the resulting tree. For suppose $e = \{a, b\}$ is a blocking edge. Let v be the least common ancestor of a and b, and recall that in the paths that connect v to a and v to b, no RED edge is followed by a RED edge. Let C be the cycle formed by taking the path from v to a followed by e and then the path from b back to v. If e is GREEN, then this cycle is GREEN-dominated, contradicting our assumption. If e is RED, then by the definition of blocking edge, both a and b are marked GREEN, that is, the tree edges connecting them to their parents are GREEN (note that e is not a back edge because both its vertices are GREEN). Again the

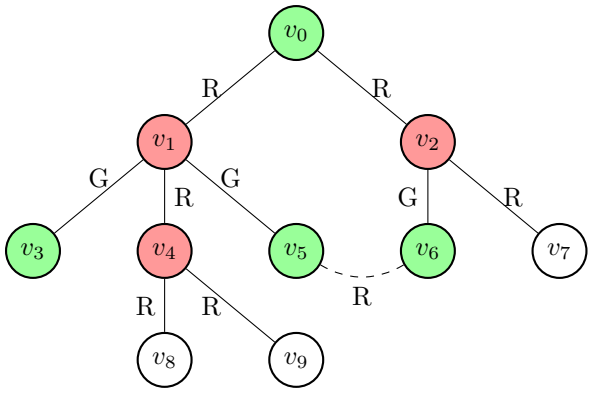

Figure 3 The edge is (v_5, v_6) is a blocking edge and $(v_0, v_1, v_5, v_6, v_2, v_0)$ is the resulting GREEN-dominated cycle, even though it has more RED edges than GREEN edges.

cycle C is GREEN-dominated, contradicting our assumption. Thus, the tree has no blocking edges. Let V' be the vertices visited by BFS. Orient all tree edges away from the root v_0. The remaining edges incident on V' (which cannot be GREEN) have at least one vertex marked RED, because they are not blocking. Orient them towards that RED vertex. It can be verified that the GREEN edges that received an orientation are all tree edges, and are oriented towards distinct GREEN vertices. The RED edges are oriented towards RED vertices. So all edges incident on V' can be oriented safely. ◀

Proof of Lemma 13. Fix a GREEN-dominated cycle C in H. Suppose it has ℓ_1 edges (for some $\ell_1 \geq g$) of which say n_1 are GREEN. Then,

$$n_1 \geq \lceil (\ell_1 - 1)/2 \rceil \geq g/2, \tag{3}$$

because g is even. First, suppose the resulting BFS forest has no blocking edges, then let V' be the vertices of this BFS forest. We orient the edges in C so that it becomes a directed cycle (we may choose either of the two ways to do this). Then, we orient all tree edges away from the roots in the BFS forest. Note that all other edges incident on V' must necessarily be RED; each such edge has at least one RED vertex in V'. We orient each such edge towards a RED vertex, and obtain the desired safe orientation.

Next, suppose there is a blocking edge $e = \{a, b\}$. If a and b belong to the same tree of the forest, then e and the paths from a and b to their least common ancestor form a GREEN-dominated cycle, consisting of say $\ell_2 \geq g$ edges of which n_2 are GREEN. Then,

$$n_2 \geq \lceil (\ell_2 - 1)/2 \rceil \geq g/2. \tag{4}$$

From Equation (3) and Equation (4), we obtain, $n \geq n_1 + n_2 \geq g$, contradicting our assumption that $n \leq 3g/4$. So, we may assume that a and b belong to different trees of the forest. Then, travelling from the root r_1 of a's tree to a, crossing over along e to b, and then travelling to the root r_2 of the tree of b, we obtain a path P^*, where no RED edge is followed by a RED edge; in particular, every RED edge except perhaps the last, is followed by a GREEN edge. Suppose this path has ℓ_3 edges of which n_3 are GREEN. We have the following.

$$\ell_3 \geq g - \lfloor \ell_1/2 \rfloor; \qquad (G \text{ has girth } g) \tag{5}$$

$$2n_3 \geq \ell_3 - 1. \tag{6}$$

From Equation (3), Equation (5) and Equation (6), we obtain

$$\begin{aligned} 2(n_1+n_3) &\geq g + 2\lceil(\ell_1-1)/2\rceil - \lfloor \ell_1/2 \rfloor - 1 && (7)\\ &= g + \lceil(\ell_1-1)/2\rceil - 1 && (8)\\ &\geq 3g/2 - 1. && (9) \end{aligned}$$

If $n > n_1 + n_3$ (that is, there is some GREEN edge outside $C \cup P^*$), then we obtain $n \geq n_1 + n_3 + 1 \geq 3g/4 + 1/2$, contradicting our assumption $n \leq 3g/4$. So, we may assume that all GREEN edges in the graph are contained in $C \cup P^*$. We think of $C \cup P^*$ as a set of three edge disjoint paths, P_1, P_2 and P_3, connecting r_1 to r_2, where $P_1 \cup P_2 = C$ and $P_3 = P^*$. Let V^* be the set of vertices in $P_1 \cup P_2 \cup P^*$. We will show that the graph induced by V^* can be safely oriented. Then, we will orient all other (necessarily RED) edges of G towards a vertex not in V^* to obtain a safe orientation of the *entire* graph H, and conclude that the lemma holds with $V' = V(H)$.

First, we show that we may assume that each of the three cycles $C = P_1 \cup P_2$, $P_1 \cup P_3$ and $P_2 \cup P_3$ is chordless. Since C is GREEN-dominated, it has at most $2n+1$ edges. If it had a chord, we would get a cycle with at most $n \leq 3g/4 < g$ edges, a contradiction. Thus, the cycle $C = P_1 \cup P_2$ has no chord. Next, using a similar argument we show that the other two cycles are chordless. We first observe that both P_1 and P_2 have GREEN edges. If P_1 has no GREEN edges, then it can have at most two edges, and the at least $g/2$ GREEN edges of C all lie in P_2. Also, P_3 has at least $g-2$ edges. Then, the number of GREEN edges in P_2 is at least $\max\{|P_2|, g\}/2$ (because C is GREEN-dominated), and similarly the number of GREEN edges in P_3 is at least $\lceil(|P_3|-1)/2\rceil \geq g/2 - 1$. Thus,

$$3/4g \geq n \geq \max\{|P_2|, g\}/2 + \lceil(|P_3|-1)/2\rceil \geq g - 1; \quad (10)$$

that is, $g = 4$, $|P_2| \leq 4$ and $|P_3| \leq 3$. Thus, $P_2 \cup P_3$ is a cycle with at most 7 vertices and it cannot have a chord because $g = 4$. Thus, we may assume that P_1 has at least one GREEN edge, that is, $P_2 \cup P_3$ has at most $n-1$ GREEN edges. Let k_2 be the number of GREEN edges in P_2 and k_3 the number of GREEN edges in P_3. Since every RED edge in P_3, except perhaps one is followed by a GREEN edges, the number of edges in P_3 is at most $2k_2 + 2$. Then, the total number of edges in $P_2 \cup P_3 \leq (2k_2+2) + (2k_3+1)$ (the second term comes from Equation (6)), that is, at most $2n+1$ edges in all. If $P_2 \cup P_3$ has a chord, then we have a cycle of length at most n, which, as we saw earlier, is not possible. Similarly, $P_2 \cup P_3$ has not chord.

So the graph induced by V^* consists of three disjoint paths, with no chords across them. If any path has two consecutive RED edges, then we may orient them towards each other and be left with a graph consisting of a cycle with two dangling paths, which can be oriented safely. Similarly, if some two paths start with RED edges or end with RED edges, then these edges can be oriented towards each other, and the remaining edges (which form a tree) can be oriented safely. We are left with the case where on all paths a RED edge is followed by a GREEN edge, and at both ends (r_1 and r_2), two of the paths start with GREEN edges. We will show that this is impossible. For otherwise, there is path (say, P_3), which has GREEN edges at both ends, so $|P_3|$ has at least $(|P_3|+1)/2$ GREEN edges. For the remaining paths, either some path has both ends GREEN, or both paths have one end GREEN. In either case, they together have at least $(|P_1|+|P_2|)/2$ GREEN edges. Note that $2(|P_1|+|P_2|+|P_3|) \geq 3g$, because H has girth at least g. Thus, the total number of GREEN edges is $n \geq (|P_1|+|P_2|+|P_3|+1)/2 \geq (3g/2+1)/2 > 3g/4$, contradicting our assumption that $n \leq 3g/4$. ◀

3 Quantum adaptive schemes

In this section, we establish Theorem 3. Our quantum scheme is based on a graph and is similar in some respects to the classical scheme described above. The main difference is in the second probe, which now computes the XOR of two bits of memory.

▶ **Definition 14** (Quantum (G, K)-scheme). *Let G be a directed graph with N vertices and M edges; let K be a positive integer. We refer to the following as a quantum (G, K)-scheme. The storage consists of three bit arrays, A, B_0 and B_1. To answer a membership query, the quantum decision tree first probes array A (this probe is classical) and then computes the XOR of two bits in either B_0 or B_1, using just one quantum probe.*

Edge array: *An array $A : E(G) \to \{0, 1\}$, indexed by edges of G.*

Vertex arrays: *Two two-dimensional arrays $B_0, B_1 : V \times [K] \to \{0, 1\}$, indexed by elements of the form (v, i).*

Elements: *As before, we identify our universe of elements $[m]$ with a subset of $E(G) \times [K]$; thus, each element $x \in [m]$ will be referred to as (e, i).*

Query: *Let the query be "Is x in S?", where $x = (e, i)$; suppose $e = \{x_0, x_1\}$. To process this query for we read $A[e]$ (first probe); then, based on the value of $A[e]$, we return either $B_0[(v_0, i)] + B_0[(v_1, i)] \pmod 2$ or $B_1[(v_0, i)] + B_1[(v_1, i)] \pmod 2$. In other words, the first probe directs us to either array B_0 or B_1; we then return the XOR of the bits in the i-th location in the rows corresponding to the two vertices of e.*

Space: *We will ensure that $MK \geq m$, to accommodate all elements of the universe. The space used by this scheme is then $2NK + M$ bits. By choosing the graph G and the parameter K appropriately we will show that our schemes uses small space.*

The main idea is the following. To store the set S in the data structure, we partition the edges of G using the 0-1 assignment to the array A. Let G_0 be the graph induced by the edges that are assigned 0 in A, and let G_1 be the graph induced by the edges assigned 1. Now, the bits of the arrays B_0 and B_1 must be assigned in such a way that certain XORs of two bits evaluate to 1 and others evaluate to 0. This leads to a system of linear equations in the bits of the arrays B_0 and B_1. To ensure that this system has a solution, we ensure that if $A[e] = 0$, then e is not in any cycle in G_0, and similarly, if $A[e] = 1$, then e is not in any cycle in G_1. It is then easy to see that the required assignment to the arrays B_0 and B_1 exists. To ensure that the edges of G can be partitioned in G_0 and G_1 to satisfy the requirements imposed by the set S, we will start with the graph G that is dense but locally sparse in the following sense, and use a theorem of Nash-Williams.

▶ **Definition 15** (Locally sparse graph). *A graph G is (k, α)-locally sparse if for every subsets $V' \subseteq V$ with $4 \leq |V'| \leq k$ vertices, the induced subgraph on V' has at most $\alpha|V'|$ edges.*

▶ **Lemma 16.** *If G has N vertices, M edges and is $(4n, 5/4)$-locally sparse, then*

$$s_{QA}(m, n, t = 2) \leq M + 2N\lceil \frac{m}{M} \rceil.$$

Before we present the proof of this lemma, let us see how this leads to Theorem 3. We will need a family of dense locally sparse graphs, whose existence we establish in Appendix C using a routine probabilistic argument.

▶ **Lemma 17.** *For all large N there is a $(4N^{1/6}, 5/4)$-locally sparse graph with N vertices and $\Omega(N^{7/6})$ edges.*

We set $N = m^{3/4}$, and plugging in the graph promised by Lemma 17 in Lemma 16, obtain $s_{QA}(m, m^{1/8}, 2) = O(m^{7/8})$, as claimed in Theorem 3. It remains to establish Lemma 16.

Proof of Lemma 16. Fix G with the given parameters. We now describe how the three arrays in our quantum scheme are assigned values. Recall that we view elements of $[m]$ as pairs (e, i). Edges of G for which there is an element of the form $(e, i) \in S$ will be called GREEN; the other edges of G will be called RED. Say, there are $\ell \leq n$ GREEN edges. We will construct a sets of vertices $D_0, D_1, D_2, \ldots$ by adding one vertex at a time. Let $D_0 \subseteq V(G)$ be the union of the GREEN edges; thus D_0 has at most 2ℓ vertices. To obtain D_{i+1} from D_i, add to D_i a new vertex that has at least two edges leading into D_i; if no such vertex exists, stop. We claim that this process stops before $2n$ vertices are added, for otherwise, the graph induced by D_{2n}, a set of size at most $2n + 2\ell \leq 4n$ vertices, has at least $4n + \ell$ edges. Since G is $(4n, 5/4)$-locally sparse, we have $(5/4)(2n + 2\ell) > 4n + \ell$, implying $\ell > n$, a contradiction. Let D be the set of vertices when the above process stops.

▷ Claim 18. The subgraph induced by D can be split into two disjoint forests.

We will justify this claim below (using Nash-Williams theorem). Let us assume it and complete the proof. Let the two forests guaranteed by this claim be F_1 and F_2. We set $A[e] = 0$ for all edges $e \in F_1$ and all edges that connect D to $V \setminus D$. Let G_0 be the subgraph of G with vertex set $V(G)$ that consist of edges e such that $A[e] = 0$. Let G_1 be the subgraph with vertex set $V(G)$ and all edges not included in G_0. Note that the connected components of G_1 are either in the forest F_2 or consist of RED edges with both end points in $V \setminus D$. Now, we are ready to describe the assignment to arrays B_0 and B_1. As stated above the constraints imposed by the GREEN and RED edges give a system of equational constraints; since G_0 has no cycle, it is easy to see that these constraints can all be satisfied by assigning B_0 appropriately. In G_1 again, the edges corresponding to F_2 do not induce a cycle, so the constraints imposed by them can be satisfied by assigning appropriate values to the rows of B_2 corresponding to vertices in D. The remaining edges share no vertex with the edges of F_2, and consist only of RED edges. So we assign zeroes to all rows of B_2 corresponding to vertices in $V(G) \setminus D$.

It remains to verify Claim 18. Since $|D| \leq 4n$, every subset D' of D (with $|D'| \geq 4$) induces at most $(5/4)|D'|$ edges; since $|D| \geq 4$, we have $(5/4)|D'| \leq 2(|D'| - 1)$. Note that the number of edges in any graph with at most $1 \leq \ell \leq 4$ vertices is at most $2\ell - 2$. So we may invoke Theorem 19 below and justify the claim. ◀

▶ **Theorem 19** (Nash-Williams (see Theorem 3.5.4 in [10]).). *Let $H = (V, E)$ be an undirected graph such that for each non-empty subset $X \subseteq V$, the number of edges with both end points in X is at most $2(|X| - 1)$. Then E can be partitioned as $E = E_1 \cup E_2$ such that (V, E_1) and (V, E_2) are both forests.*

4 Lower bounds for classical schemes

In this section, we present our justification for Theorem 2.

Canonical query schemes. Consider an (m, n, s, t)-scheme. Let us use M to denote the array of s-bits into which probes are made. With each element $x \in [m]$ of the universe such a scheme associates three addresses $(a(x), b(x), c(x)) \in [s]^3$, where the first probe is made to location $a(x)$; if the bit there is 0, then the second probe is made to $b(x)$, otherwise the probe is made to $c(x)$. We will assume that that the query scheme has the following *canonical form*. On query "Is x in S?", the answer is determined as follows: if $M[a(x)] = 1$, then return $M[b(x)]$, else return $M[(c(x)]$, where 0 is treated as false/no and 1 as true/yes. We refer to such schemes as *canonical schemes*. It is easy to see that by at most doubling the memory a scheme can be made canonical.

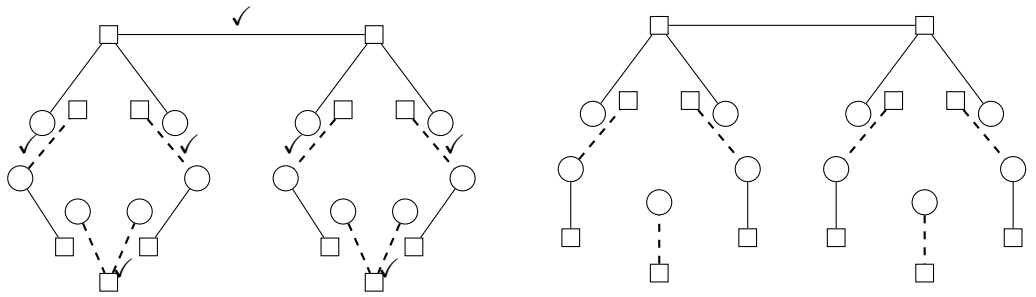
▶ **Proposition 20.** *If there is an $(m, n, s, t = 2)$-scheme, then there is an $(m, n, 2s, t = 2)$-canonical scheme.*

From now on we will assume that the scheme is canonical.

▶ **Definition 21** (The bipartite graph associated with a scheme)**.** *With the scheme σ, we associate a directed bipartite graph G_σ with vertex sets B and C, whose elements we refer to using $[s]$. For each $x \in [m]$ we add an edge $e(x) = (b(x), c(x))$ in G_σ with label $(x, a(x))$. The value $a(x)$ will be called the color of the edge; so $e(x)$ and $e(y)$ have the same color if and only if the first probes for the two queries "Is x in S?" and "Is y in S?" are made to the same location, namely $a(x) = a(y)$. We will use $\vec{e}$ to refer the oriented version of the edges of G_σ. We say that two distinct oriented edges, $\vec{e}_1$ and $\vec{e}_2$ are parallel if (i) $\vec{e}_1$ and $\vec{e}_2$ have the same color, and (ii) they are both oriented in the same direction (both from B to C or C to B).*

To store a set S, one must find an assignment to the locations where the first probes are made. This amounts to choosing an orientation for each color, and orienting the edges either from B to C or from C to B; the values in the array is then essentially forced because the protocol is assumed to be canonical. For this assignment to be valid, in the resulting directed graph, we must have the property that if $x \in S$ and $y \notin S$, then $\mathsf{head}(\vec{e}(x)) \neq \mathsf{head}(\vec{e}(y))$. We refer to such an orientation as a *safe* orientation for S.

We obtain our lower bound by establishing that if the data structure uses very small space, then there is a set S of size at most n edges, whose edges cannot be oriented safely.



(a) A forbidden configuration.

(b) The problem case.

Figure 4 $n = 7$.

Forbidden configuration. Fix n of the form $2\ell - 1$. Please refer to Figure 4a. Most edges in the figure come in pairs of solid and dotted edges, which are placed parallel to each other. For each edge, one vertex is a circle and the other is a square, to indicate that one of them comes from B and the other from C (we do not specify which is which). The elements labelling the edges are all distinct; however, we allow the edges to have the same color even if they are not explicitly depicted as being parallel. We say that such graph F is forbidden configuration of order n, if there is a subset $S \subseteq [m]$ ($|S| \leq n$) of elements appearing in the labels on the edges of F such that F is not safe for S. For example, Figure 4a is a forbidden configuration of order $n = 7$, where the set S is indicated by ✓. Our lower bound result Theorem 2 follows immediately from the following lemma.

▶ **Lemma 22.** *Fix an odd n $(3 \leq n \leq \log m)$ and an $(m, n, s, t = 2)$-scheme σ. If G_σ does not contain any forbidden configuration of order n, then $s \geq cm^{1-2/(n+3)}$, for a constant $c > 0$ independent of n.*

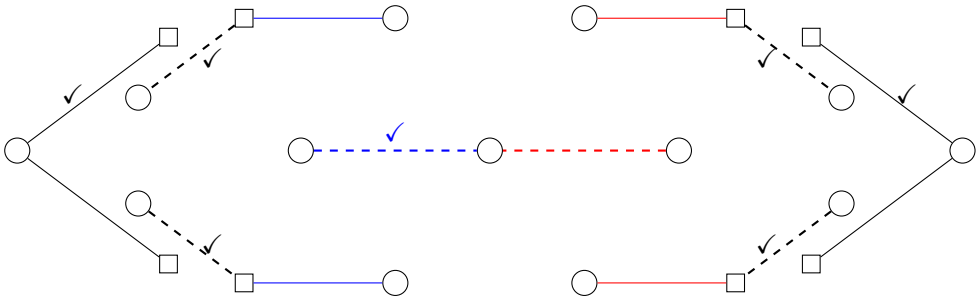


Figure 5 The second forbidden configuration ($n = 7$).

Proof Sketch. Consider $(m, n, s, t = 2)$-scheme σ. In G_σ we have m edges. Then, (on average) a vertex has degree about m/s and each colour has m/s edges. We start from an edge $e = (v, w)$, and from each of v and w, we build a tree as follows. Let us start with $v_0 = v$. We have m/s choices for an edge; for each choice of edge e of the form (v_0, v_1), we jump to an edge of the same colour (parallel to the first one), that takes us from a vertex v_1' to a vertex v_2. We continue this process, alternately expanding to a neighbor or jumping to a parallel edge for k steps in all. If we set k such that $(m/s)^k > s$, we obtain a "cycle". (Note that this is not a cycle in the usual graph-theoretic sense, because we jump from an edge to a parallel edges in alternate steps.) We delete these edges from the graph, and repeat this for the other vertex w of the starting edge e. Let us illustrate this for $n = 7$. Suppose $s \ll m^{1-2/(n+3)} = m^{4/5}$, that is, $(m/s) \gg m^{1/5}$. In particular, with $k = 4$, we have $(m/s)^k \gg m^{4/5} \gg s$, and at some point a vertex must repeat (we have only $2s$ vertices). A situation in such a case, with two cycles hanging off an edge corresponds to Figure 4a. We allow the two cycles to share vertices, but the edges involved must be distinct. Now, to see that this configuration has no safe orientation, first choose either orientation for the top edge e, say towards left. Then, the directions of all edges are forced in that cycle and we soon find edges corresponding to an element in the set and another corresponding to an element not in the set that point to the same vertex.

Unfortunately, there are other cases to consider, besides the ideal case of two cycles attached to an edge as in Figure 4a: (i) the cycles may not form right at the top, instead we might have to allow an initial path leading to the cycle; (ii) the cycle may not end with two tree edges pointing into it. Instead, it might be formed when two paths of a tree jump on to the same parallel edge. The first case presents no real difficulties; in fact, in this case the resulting configuration is not safe for even smaller sets. The second case presents genuine difficulties. For example, we might encounter a situation depicted in Figure 4b, where the three edges at the bottom are parallel. Note that all tree edges in this case can be forced away from their roots to obtain a safe orientation. The idea now is the following. If we encounter such a cycle, we put it aside and mark the middle vertex at the bottom as its terminal vertex. We have removed only a minuscule number of edges from the graph, so we can continue the exploration for a forbidden structure in the remaining graph. If we ever find a configuration corresponding to Figure 4a, we are done. Otherwise, we accumulate many edge disjoint bad cycles. Soon enough (by the time $s + 1$ bad cycles are encountered), two of them must have the same terminal vertex. We put these bad cycles together (as illustrated in Figure 5) and again obtain a forbidden configuration. The discussion above uses $k = 4$ and $n = 7$ for illustration, but the same argument applies for other k, and, in general, yields a configuration without any safe orientation for a set of size $n = 2k - 1$, whenever, $s \ll m^{1-1/(k+1)} = m^{1-2/(n+3)}$. The detailed argument will appear in the full version of the paper. ◀

5 Quantum non-adaptive schemes for $n = 2$ and $t = 2, 3$

In this section, we show that the lower bound in 1 is tight for two cases: $s_{QN}(m, n = 2, t = 2) = O(\sqrt{m})$ and $s_{QN}(m, n = 2, t = 3) = O(m^{1/3})$; the schemes we give are non-adaptive and only use the fact that the XOR of two bits can be computed using one quantum query. The proofs are algebraic.

5.1 Case $t = 2$

We identify $[m]$ with $A \times B$, where each of the sets has about $\sqrt{m}$ elements; A and B are disjoint. We will have two array indexed by A (we call them X_1 and X_2) and two arrays indexed by B (we call them Y_1 and Y_2).

Query: On receiving the element $x = (x_1, x_2) \in A \times B$, the algorithm returns

$$(X_1[x_1] + Y_1[x_2])(X_2[x_1] + Y_2[x_2]) \pmod 2,$$

which is a polynomial of degree two. Note that both $X_1[a] + Y_1[b]$ and $X_2[a] + Y_2[b]$ can be computed in parallel with one quantum query each. Thus, the scheme requires only two non-adaptive queries.

Storage: Given a pair of elements $\{\alpha_1, \alpha_2\} \subseteq [m]$, we need to show how values will be assigned to the four arrays: X_1, X_2, Y_1, Y_2. It will be easier to describe and analyse our storage algebraically. We view X_1, X_2 as functions from A to $\{0, 1\}$ and Y_1, Y_2 as functions from B to $\{0, 1\}$. For $a \in A$, let $\delta_a : A \to \{0, 1\}$ be defined by $\delta_a(z) = 1$ iff $z = a$; similarly for $b \in B$, let $\delta_b : B \to \{0, 1\}$ be defined by $\delta_b(z) = 1$ iff $z = b$. We have three cases based on the number of components $\ell \in \{0, 1, 2\}$ where α_1 and α_2 agree.

$\ell = 2$: We have only one element (a, b). We set $X_1 \equiv \delta_a$, $Y_1 = 0$, $X_2 \equiv 0$ and $Y_2 \equiv \delta_b$. The query polynomial reduces to the monomial $\delta_a(x_1)\delta_b(x_2)$, which is what we want.

$\ell = 1$: Say the set is $\{(a, b), (a', b)\}$. We set $X_1 \equiv \delta_a + \delta_{a'}$, $Y_1 \equiv 0$, $X_2 \equiv 0$ and $Y_2 \equiv \delta_b$. The query polynomial reduces to $(\delta_a(x_1) + \delta_{a'}(x_2))\delta_b(z_2) = \delta_a(z_1)\delta_b(z_2) + \delta_{a'}(z_1)\delta_b(z_2)$, which is what we want.

$\ell = 0$: Say the set is $\{(a, b), (a', b')\}$. We set $X_1 \equiv \delta_a$, $Y_1 \equiv \delta_{b'}$, $X_2 \equiv \delta_{a'}$ and $Y_2 \equiv \delta_b$. The query polynomial evaluates $(\delta_a(z_1)+\delta_{b'}(z_2))(\delta_{a'}(z_1)+\delta_b(z_2)) = \delta_a(z_1)\delta_b(z_2)+\delta_{a'}(z_1)\delta_{b'}(z_2)$ (mod 2), which is what we want.

5.2 Case $t = 3$

Let us identify $[m]$ with $A \times B \times C$, where each of the sets has roughly $m^{1/3}$ elements; we will assume that A, B and C are disjoint. We have six arrays, two indexed by A (we call them X_1 and X_2), two indexed by B (we call them Y_1 and Y_3) and two indexed by C (we call them Z_2 and Z_3); the subscripts indicate which query probes the corresponding array.

Query: On receiving the element $e = (x, y, z)$, the algorithm returns

$$(X_1[x] + Y_1[y])(X_2[x] + Z_2[z])(Y_3[y] + Z_3[z]) \pmod 2,$$

which is a polynomial of degree 3.

Storage: Given a pair of elements $\{\alpha_1, \alpha_2\}$, we need to show how values will be assigned to the six arrays. Let $\alpha = (a, b, c)$ and $\beta = (a', b', c')$. We define functions of the form $\delta_a : A \to \{0, 1\}$, $\delta_b : B \to \{0, 1\}$ and $\delta_c : C \to \{0, 1\}$ as before. Also 0 and 1 when denoting functions correspond to the all 0's and the all 1's functions. We have four cases, depending on the number of places $\ell \in \{0, 1, 2, 3\}$ where α_1 and α_2 agree.

$\ell = 3$: The set has only one element (a, b, c), say. The arrays are as follows. $X_1 \equiv \delta_a$; $Z_2 \equiv \delta_c$; $Y_3 \equiv \delta_b$, the other three arrays are 0. So, the query function becomes $(\delta_a(x) + 0)(\delta_c(z) + 0)(\delta_b(y) + 0) = \delta_a(x)\delta_b(y)\delta_c(z)$, which yields 1 iff $(x, y, z) = (a, b, c)$.

$\ell = 2$: Say $\alpha_1 = (a, b, c)$ and $\alpha_2 = (a, b, c')$. We set $X_1 \equiv \delta_a$, $Y_1 \equiv 0$, $X_2 \equiv 0$, $Z_2 \equiv \delta_c + \delta_{c'}$, $Y_3 \equiv \delta_b$ and $Z_3 \equiv 0$. Then, the query function becomes $(\delta_a(x)+0)(\delta_c(z)+\delta_{c'}(z))(\delta_b(y)+0)$, which reduces to $\delta_a(x)\delta_b(y)\delta_c(z) + \delta_a(x)\delta_b(y)\delta_{c'}(z)$, that is, the function that evaluates to 1 precisely when the input is (a, b, c) or (a, b, c'). The other cases are symmetric.

$\ell = 1$: Say $\alpha_1 = (a, b, c)$ and $\alpha_2 = (a, b', c')$. We set $X_1 \equiv 1 + \delta_a$, $Y_1 \equiv \delta_b + \delta_{b'}$, $X_2 \equiv 1 + \delta_a$, $Z_2 = \delta_c + \delta_{c'}$, $Y_3 = \delta_b$ $Z_3 = \delta_{c'}$. Our query polynomial then evaluates to

$$(1 + \delta_a + \delta_b + \delta_{b'})(1 + \delta_a + \delta_c + \delta_{c'})(\delta_b + \delta_{c'}), \tag{11}$$

where, to simplify notation, we just write δ_a instead of $\delta_a(x)$, etc. Applying the rule $gh = (g + h + 1)h$ twice, we obtain $(\delta_c + \delta_{b'})(1 + \delta_a + \delta_c + \delta_{c'})(\delta_b + \delta_{c'})$. Then, combining the first and last factors, we obtain, $(\delta_b\delta_c + \delta_{b'}\delta_{c'})(1 + \delta_a + \delta_c + \delta_{c'})$. Expanding this mod 2, we obtain $(\delta_b\delta_c + \delta_{b'}\delta_{c'})\delta_a$, which yields 1 iff $x \in \{(a, b, c), (a, b', c')\}$, as required.

$\ell = 0$ **(the two elements differ on all coordinates):** We set $X_1 \equiv \delta_a$, $X_2 \equiv \delta_{a'}$, $Y_1 \equiv \delta_{b'}$, $Y_2 \equiv \delta_b$, $Z_1 \equiv \delta_{c'}$, $Z_2 \equiv \delta_c$. The query expression evaluates to

$$(\delta_a + \delta_{b'})(\delta_{a'} + \delta_c)(\delta_b + \delta_{c'}).$$

Focus on the middle factor. If we pick $\delta_{a'}$ from that factor, then we are forced to pick $\delta_{b'}$ from the previous, which forces us to pick $\delta_{c'}$ from the last (to avoid getting 0); if we pick δ_c from the middle factor, then we are forced to pick δ_b from the last and then δ_a from the first. All other terms are 0. The final expression with two terms is $\delta_a\delta_b\delta_c + \delta_{a'}\delta_{b'}\delta_{c'}$, as required.

A Explicit construction of graphs

We say that a graph on L vertices is explicitly, if the adjacency matrix of L can be constructed in polynomial time in L.

- We will use the construction due to Wenger [20] to exhibit explicit graphs with girths 8. Wenger constructs a graph $H_k(p)$ with $2p^k$ vertices and $2p^{k+1}$ edges, and shows that if p is prime, then $H_3(p)$ has girth at least 8. In the bipartite graph $H_k(p)$ the vertices are represented as k-tuples of numbers $\{0, \ldots, p\}$ and two vertices are connected based on a simple arithmetic check involving addition and multiplication modulo p. In our application, given a number L, we set p to be the smallest prime that is at least $L^{1/(k+1)}$. Then, $H_k(p)$ has at most $2^{k+2}L$ vertices and at least $2L^{1+1/k}$ edges. Thus, we obtain graphs with the following parameters: $g = 8$, $c(g = 8) = 2^5$, $\tau(g = 8) = 1/3$. Our application for $g = 8$ (see Figure 1) uses these parameters.
- For girth 12, we use a construction due to Benson [8]. Theorem 2 of the paper presents an algebraic construction where the graph is obtained by considering point-line incidences for points and lines of a quardic surface in the projective 6-space $P(6, q)$. The degree of each vertex of this graph is $q + 1$. On page 1093, the number of vertices in this graph is computed to be $(q + 1)(1 + q^2 + q^4)$. So, to get the graph suitable for our applications, we take q to be the smallest prime such that $(q + 1)(1 + q^2 + q^4) \geq L$ and use this construction. Then, it is easy to see that the number of vertices in this graph is $\mathcal{O}(L)$ and the number of edges is at least $L^{1+1/5}$.
- Lazebnik, Ustimenko and Woldar [14] exhibit dense graphs for various values of girth. Their Corollary 3.3 shows graphs with girth at least $2s + 2$, with $v \leq 2q^{(3s-3)/2}$ vertices if s is odd and at most $2q^{(3s-2)/2}$ vertices if s is even. The graph has $\frac{1}{2}vq$ edges. To construct the graphs for our application, fix L and let q be the smallest prime larger than $L^{2/(3s-3)}$ or $L^{2/(3s-2)}$ (depending on whether s is odd or even) and consider the graph obtained from the above construction. If the graph has fewer than L vertices, then we put together disjoint copies of it, to obtain one with number of vertices between L and $2L$. It can be verified that this graph has $O(L)$ vertices and $\Omega(L^{1+2/(3s-3)})$ or $\Omega(L^{1+2/(3s-2)})$ edges (depending on whether s is odd or even). In our application (see Figure 1), we use graphs with girth $4r$ and $4r - 2$. Setting $2s + 2 = 4r$, i.e., $s = 2r - 1$ (an odd number), we obtain a graph with $\Omega(L^{1+1/(3r-3))})$ edges; similarly setting $2s + 2 = 4r - 2$, i.e., $s = 2r - 2$ (an even number), we obtain a graph with $\Omega(L^{1+1/(3r-4)})$ edges.

B Examples that show Lemma 9 is tight

The bound shown Lemma 9 is tight in the following sense: for each positive even integer g, there exists a bipartite graph with girth g and $\lfloor 4g/3 \rfloor + 1$ GREEN edges that cannot be safely oriented. For example, the graph consisting of three edge-disjoint s-t paths, each of length $2k$, has girth $g = 4k$; but we can designate a set of $n = 3k + 1$ edges GREEN for which the graph has no safe orientation. For this graph $n = 3k + 1$ and $\lfloor 3g/4 \rfloor = 3k$. A similar example, with three edge-disjoint paths of length $2k + 1$, shows that the above lemma is tight for $g = 4k + 2$. Figure 6 shows these examples for $k = 2$.

C Proof of Lemma 17

Consider the random graph on N vertices where each edge is picked independently with probability $p = (1/50)N^{-5/6}$. The probability that G is not $(4N^{1/6}, 5/4)$-locally sparse is at most (we use the union bound over the choice of subsets of size $\ell \leq 4N^{1/6}$, and for each set over all choice of 1.24ℓ edges for simplicity we ignore floors and ceilings):

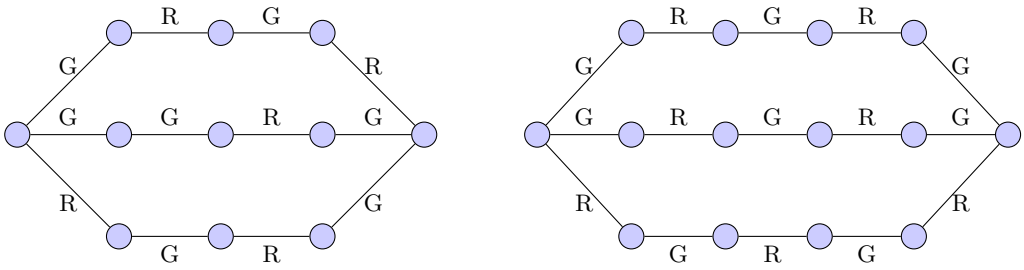

Figure 6 Examples of graphs with girth $g = 10$ and $g = 8$ that cannot be safely oriented.

$$\begin{aligned}\sum_{\ell=5}^{4N^{1/6}} \binom{N}{\ell}\binom{\ell^2}{5/4\ell} p^{(5/4)\ell} &\le \sum_{\ell=5}^{4N^{1/6}} \left(\frac{eN}{\ell}\right)^{\ell} \left(\frac{e\ell^2}{5/4\ell}\right)^{(5/4)\ell} p^{(5/4)\ell} \\ &\le \sum_{\ell=5}^{4N^{1/6}} 8^{\ell} \left(N\ell^{1/4}\right)^{\ell} p^{(5/4)\ell} \\ &\le \sum_{\ell=5}^{4N^{1/6}} \left(\frac{1}{7}\right)^{\ell} \left(N\ell^{1/4}\right)^{\ell} N^{-(5/6)(5/4)\ell}.\end{aligned}$$

By considering terms corresponding to (say) $\ell < N^{1/12}$ and $\ell \ge N^{1/12}$ separately, we see that the last sum is $o(1)$. Thus, with high probability there is no set of size up to $4N^{1/6}$ that violates the local sparsity condition. Furthermore, with high probability the number of edges in the graph is at least $pN^2/2 = \Omega(N^{7/6})$. Thus, there exists an $(4N^{1/6}, 5/4)$-sparse graph with $\Omega(N^{7/6})$ edges.

D Non-adaptive quantum bounds

We give an upper bound on $s_Q(m, n = 2k+1, t = 2)$ for the non-adaptive classical scheme, where $k \in \mathbb{N}$. The arrangement of the element and bits is similar to the classical adaptive scheme we described in Section 2. The first probe is on the corresponding edge array and the second is an equality probe on the rows corresponding to the vertices of the edge. We AND the two probes to answer membership queries. We obtain

$$s_Q(m, n = 2k+1, t = 2) = \begin{cases} \mathcal{O}(v^{1+\frac{4}{3n-9}}) & \text{if } 4|(n+1); \\ \mathcal{O}(v^{1+\frac{4}{3n-7}}) & \text{if } 4 \nmid (n+1). \end{cases} \tag{12}$$

▶ **Definition 23** (Non-adaptive Quantum (G, K)-scheme). *Let G be an un-directed graph with N vertices and M edges; let K be a positive integer. We refer to the following as a (non adaptive) quantum (G, K)-scheme. The storage consists of two bit arrays, A and B. To answer a membership query the decision tree will make the first probe to array A and the second probe to array B.*

Edge array: *An array $A : E(G) \to \{0, 1\}$, indexed by edges of G.*

Vertex array: *A two dimensional array $B : V \times [K] \to \{0, 1\}$.*

Elements: *We identify our universe of elements $[m]$ with a subset of $E(G) \times [K]$ (so we must ensure that the graph has at least m/K edges); thus, each element $x \in [m]$ will be referred to as (e, i).*

Query: *We represent an edge of G as an ordered pair of the form $e = (v_0, v_1)$. To process the query for the element $x = (e, i)$, we return the value $A[e] \cdot (B[v_0, i] \oplus B[v_1, i])$.*

Space: *We will ensure that $MK \geq m$. The space used by this scheme is then $NK + M$ bits (NK for the N vertex array and K for the edge array). By choosing the graph G and the parameter K appropriately we will show that our schemes use small space.*

As in the classical adaptive setting, an edges e is coloured GREEN if $(e, i) \in S$ for some i. Values can be assigned consistently to the arrays if there is no cycle in the graph consisting entirely of GREEN edges. This idea is formalized in the lemma below.

▶ **Lemma 24.** *Let G be a graph with N vertices M edges and girth g such that $n < g$. Then, $s_A(m, n, 2) \leq M + N\lceil m/M \rceil$.*

Hardness Results for Laplacians of Simplicial Complexes via Sparse-Linear Equation Complete Gadgets

Abstract

We study linear equations in combinatorial Laplacians of k-dimensional simplicial complexes (k-complexes), a natural generalization of graph Laplacians. Combinatorial Laplacians play a crucial role in homology and are a central tool in topology. Beyond this, they have various applications in data analysis and physical modeling problems. It is known that nearly-linear time solvers exist for graph Laplacians. However, nearly-linear time solvers for combinatorial Laplacians are only known for restricted classes of complexes.

This paper shows that linear equations in combinatorial Laplacians of 2-complexes are as hard to solve as general linear equations. More precisely, for any constant $c \geq 1$, if we can solve linear equations in combinatorial Laplacians of 2-complexes up to high accuracy in time $\tilde{O}((\#\text{ of nonzero coefficients})^c)$, then we can solve general linear equations with polynomially bounded integer coefficients and condition numbers up to high accuracy in time $\tilde{O}((\#\text{ of nonzero coefficients})^c)$. We prove this by a nearly-linear time reduction from general linear equations to combinatorial Laplacians of 2-complexes. Our reduction preserves the sparsity of the problem instances up to poly-logarithmic factors.

1 Introduction

1.1 Simplicial Complexes, Homology, and Combinatorial Laplacians

We study linear equations whose coefficient matrices are combinatorial Laplacians of k-dimensional abstract simplicial complexes (k-complexes), which generalize the well-studied graph Laplacians. An abstract simplicial complex $\mathcal{K}$ is a family of sets, known as simplices, closed under taking subsets, i.e., every subset of a set in $\mathcal{K}$ is also in $\mathcal{K}$. The dimension of $\mathcal{K}$ is the maximum dimension among all simplices in $\mathcal{K}$. A geometric notion of abstract simplicial complexes is simplicial complexes, under which a k-simplex is the convex hull of $k+1$ vertices (for example, 0,1,2-simplices are vertices, edges, and triangles, respectively). In particular, complexes in 1 dimension are graphs; combinatorial Laplacians in 1-complexes are graph Laplacians.

Nearly-linear time solvers exist for linear equations in graph Laplacians [42, 26, 27, 39, 11, 31, 24], and some natural generalizations such as connection Laplacians [29] and directed Laplacians [10, 9]. However, nearly-linear time solvers for linear equations in combinatorial Laplacians are only known for very restricted classes of 2-complexes [8, 3]. We ask whether one can extend these nearly-linear solvers to general combinatorial Laplacians.

Combinatorial Laplacians are defined via boundary operators of the chain spaces of an oriented complex. Given an oriented simplicial complex $\mathcal{K}$, a k-chain is a (signed) weighted sum of the k-simplices in $\mathcal{K}$. The boundary operator ∂_k is a linear map from the k-chain space to the $(k-1)$-chain space; in particular, it maps a k-simplex to a signed sum of its boundary $(k-1)$-simplices, where the signs are determined by the orientations of the k-simplex and its boundary $(k-1)$-simplices. For example, ∂_1 is the oriented vertex-edge incidence matrix. The combinatorial Laplacian $\mathcal{L}_k$ is defined to be $\partial_{k+1}\partial_{k+1}^\top + \partial_k^\top \partial_k$. In particular, $\mathcal{L}_0 = \partial_1 \partial_1^\top$ is the graph Laplacian.

Combinatorial Laplacians play an important role in both pure mathematics and applied areas. These matrices originate in the study of discrete Hodge decomposition [18]: The kernel of $\mathcal{L}_k$ is isomorphic to the kth homology space of $\mathcal{K}$. The properties of combinatorial Laplacians have been studied in many works [20, 15, 16, 17, 36]. A central problem in homology theory is evaluating the Betti number of the kth homology space, which equals the rank of $\mathcal{L}_k$. In the case of homology over the reals, computing the rank of $\mathcal{L}_k$ can be reduced to solving a poly-logarithmic number of linear equations in $\mathcal{L}_k$ [2]. Computation of Betti numbers over the reals is a key step in numerous problems in applied topology, computational topology, and topological data analysis [47, 21, 5, 19, 6]. In addition, combinatorial Laplacians have applications in statistical ranking [25, 45], graphics and image processing [35, 44], electromagnetism and fluid mechanics [13], data representations [7], cryo-electron microscopy [46], biology [41]. We refer to the reader to [34] for an accessible survey.

The reader may be puzzled that despite a vast literature on combinatorial Laplacians and their central role in topology, little is known about solving linear equations in these matrices except in very restricted cases [8, 3]. In this paper, we show that approximately solving linear equations in general combinatorial Laplacians is as hard as approximately solving general linear equations over the reals, which explains the lack of special-purpose solvers for this class of equations. More precisely, if one can solve linear equations in combinatorial Laplacians of general 2-complexes to high accuracy in time $\tilde{O}((\#\text{ of nonzero coefficients})^c)$[1] for some constant

[1] $\tilde{O}$ hides poly-logarithmic factors in following parameters of the input: ratio of maximum and minimum non-zero singular values, the maximum ratio of non-zero entries (in absolute value), and the inverse of the accuracy parameter.

$c \geq 1$, then one can solve general linear equations with polynomially bounded integer coefficients and condition numbers up to high accuracy in time $\tilde{O}((\#\text{ of nonzero coefficients})^c)$. A recent breakthrough shows that general linear equations can be solved up to high accuracy in time $\widetilde{O}((\#\text{ of nonzero coefficients})^{2.27159})$ [40, 38], which for sparse linear equations is asymptotically faster than the long-standing runtime barrier of fast matrix multiplication [43], which currently achieves a running time of $\tilde{O}(n^{2.3728596})$ [1]. Understanding the optimal value of c is a major open problem in numerical linear algebra. Our result, viewed positively, shows that one can reduce the problem of designing fast solvers for general linear equations to that for combinatorial Laplacians.

1.2 Hardness Results Based on Linear Equations

Kyng and Zhang [33] initiated the study of hardness results for solving structured linear equations. They showed that solving linear equations in a slight generalization of graph Laplacians such as 2-commodity Laplacians, 2-dimensional truss stiffness matrices, and 2-total-variation matrices is as hard as solving general linear equations.

Suppose given an invertible matrix $\boldsymbol{A}$ and a vector $\boldsymbol{b}$ over the reals, we want to approximately solve $\boldsymbol{Ax} = \boldsymbol{b}$, i.e., find $\tilde{\boldsymbol{x}}$ such that $\|\boldsymbol{A}\tilde{\boldsymbol{x}} - \boldsymbol{b}\|_2 \leq \epsilon \|\boldsymbol{b}\|_2$ for some ϵ.

▶ **Definition** ((Informal) Sparse-linear-equation completeness of matrix family $\mathcal{B}$)**.** *Consider a family of matrices $\mathcal{B}$, and suppose that for any instance $(\boldsymbol{A}, \boldsymbol{b}, \epsilon)$ we can produce matrix $\boldsymbol{B} \in \mathcal{B}$, vector $\boldsymbol{c}$, and accuracy parameter δ, such that if we can solve $\boldsymbol{By} = \boldsymbol{c}$ up to error δ, then we can produce $\tilde{\boldsymbol{x}}$ that solves $\boldsymbol{Ax} = \boldsymbol{b}$ to the desired accuracy.*

If, given $(\boldsymbol{A}, \boldsymbol{b}, \epsilon)$, we can compute $(\boldsymbol{B}, \boldsymbol{c}, \delta)$ in $\tilde{O}(\text{nnz}(\boldsymbol{A}))$ time with $\text{nnz}(\boldsymbol{B}) = \tilde{O}(\text{nnz}(\boldsymbol{A}))$ then we say that the class $\mathcal{B}$ is sparse-linear-equation complete*.*

In our preliminaries in Section 2, we state a formal definition of sparse-linear equation completeness that also extends to non-invertible matrices.

The reason of using the term "completeness" is that if a solver with runtime $\tilde{O}((\#\text{ of nonzero coefficients})^c)$ is known for the class $\mathcal{B}$, then a solver with runtime $\tilde{O}((\#\text{ of nonzero coefficients})^c)$ exists for general matrices. Such solvers are known for the classes of Laplacian Matrices, Directed Laplacian Matrices, Connection Laplacian Matrices, etc., all with $c = 1$. Thus, if any of these classes were sparse-linear-equation complete, we would immediately get nearly-linear time solvers for general linear equations.

In this language, Kyng and Zhang [33] showed that 2-commodity Laplacians, 2-dimensional truss stiffness matrices, and 2-total-variation matrices are all sparse-linear-equation complete. We note that [32] considered a larger family of hardness assumptions based on linear equations, which, among other things, can express weaker hardness statements based on weaker reductions.

1.3 Our Contributions

In the terminology established above, our main result can be stated very succinctly:

▶ **Theorem 1.1** (Informal First Main Theorem)**.** *Linear equations in combinatorial Laplacians of 2-complexes are sparse-linear-equation complete.*

In fact, we show this by showing an even simpler problem is sparse-linear-equation complete, namely linear equations in the boundary operator of a 2-complex.

▶ **Theorem 1.2** (Informal Second Main Theorem)**.** *Linear equations in the boundary operators ∂_2 of 2-complexes are sparse-linear-equation complete.*

This result is formally stated in Theorem 3.1. Below, in Section 1.3.1, we sketch how our first main theorem above follows from our second main theorem. We give a formal proof of this in the full version [14].

Our proof establishes the sparse-linear-equation completeness of boundary operators of a 2-complex via a two-step reduction. In our first reduction step, we show sparse-linear-equation completeness of a very simple class of linear equations which we call *difference-average equations*: these are equations where every row either restricts the difference of two variables: $\boldsymbol{x}(i) - \boldsymbol{x}(j) = b$, or it sets one variable to be the average of two others: $\boldsymbol{x}(i) + \boldsymbol{x}(j) = 2\boldsymbol{x}(k)$. This reduction was implicitly proved in [33] as an intermediate step. In this paper, we make the reduction explicit, which may be of independent interest, as this reduction class is likely to be a good starting point for many other hardness reductions. One can think of this step as analogous to showing that 3-SAT is NP-complete: It gives us a simple starting point for proving the hardness of other problems. The formal theorem statement appears in Theorem 2.9. In our second reduction step, we reduce a given difference-average equation problem to a linear equation in the boundary operator of a 2-complex.

Both the two steps preserve the number of nonzero coefficients in the linear equations up to a logarithmic factor, and only blow up the coefficients and condition numbers polynomially. The reductions are also robust to error in the sense that to solve the original problem to high accuracy, it suffices to solve the reduced problem to accuracy at most polynomially higher. Finally, we can compose the two reductions to show that solving linear equations in 2-complex boundary operators to high accuracy is as hard as solving general linear equations with polynomially bounded integer coefficients and condition numbers to high accuracy.

We give more details on both reductions below, but first we describe why solving linear equations in combinatorial Laplacians $\mathcal{L}_1$ is also sparse-linear-equation complete.

1.3.1 Hardness for Combinatorial Laplacians From Hardness for Boundary Operators

Our main technical result, Theorem 3.1, shows that the class of linear equations in the boundary operators of 2-complexes is sparse-linear-equation complete. But, as the following simple lemma shows, we can reduce the problem of solving in a boundary operator ∂_2 to solving in the corresponding combinatorial Laplacian $\mathcal{L}_1$, and hence the latter problem must be at least as hard. This then immediately implies our first main result, Theorem 1.1. The reduction is captured in the following lemma.

▶ **Lemma 1.3** (Informal reduction from boundary operators to combinatorial Laplacians in 2-complexes)**.** *Suppose we can solve linear equations in combinatorial Laplacians of 2-complexes to high accuracy in nearly-linear time. Then, we can solve linear equations in boundary operators ∂_2 of 2-complexes to high accuracy in nearly-linear time.*

The proof is by standard arguments which we sketch below. In the full version of the paper [14], we will formally state the theorem and provide a rigorous proof. Suppose we have a high-accuracy solver for combinatorial Laplacians of 2-complexes. Using this, we want to obtain a solver for linear equations in the boundary operator ∂_2. Note that when the equation $\partial_2 \boldsymbol{f} = \boldsymbol{d}$ is infeasible, we measure the solution quality by $\|\partial_2 \boldsymbol{f} - \boldsymbol{\Pi}_{\partial_2} \boldsymbol{d}\|_2$ where $\boldsymbol{\Pi}_{\partial_2}$ denotes the orthogonal projection onto the image $\mathrm{im}(\partial_2)$. The minimum over $\boldsymbol{f}$ of the quantity $\|\partial_2 \boldsymbol{f} - \boldsymbol{\Pi}_{\partial_2} \boldsymbol{d}\|_2$ is zero, which is obtained by setting $\boldsymbol{f} = \partial_2^\dagger \boldsymbol{d}$ (where $\partial_2^\dagger$ is the Moore-Penrose pseudo-inverse of ∂_2). The equation $\partial_2 \boldsymbol{f} = \boldsymbol{d}$ is feasible exactly when $\boldsymbol{\Pi}_{\partial_2} \boldsymbol{d} = \boldsymbol{d}$.

A central and basic fact in the study of simplicial homology is that $\mathrm{im}(\partial_1^\top) \cap \mathrm{im}(\partial_2) = \{\mathbf{0}\}$. This follows from $\partial_1 \partial_2 = \mathbf{0}$ (the boundary of a boundary is zero, which gives $\mathrm{im}(\partial_2) \subseteq \ker(\partial_1)$) and the general fact in linear algebra that $\ker(\boldsymbol{A})$ is the orthogonal complement of $\mathrm{im}(\boldsymbol{A}^\top)$ so

that $\ker(\partial_1)$ is orthogonal to $\mathrm{im}(\partial_1^\top)$. Intuitively, the fact that the boundary of a boundary is zero generalizes that the boundary of a disc is a circular path, and such a path has no endpoints. This implies that $\mathbf{\Pi}_{\partial_2}\partial_1^\top = \mathbf{0}$. Now, suppose that $\tilde{\boldsymbol{x}}$ approximately solves $\mathcal{L}_1\boldsymbol{x} = \boldsymbol{d}$, i.e. $\mathcal{L}_1\tilde{\boldsymbol{x}} \approx \boldsymbol{d}$. We can rewrite this as $\partial_1^\top\partial_1\tilde{\boldsymbol{x}} + \partial_2\partial_2^\top\tilde{\boldsymbol{x}} \approx \boldsymbol{d}$. Now, if we apply $\mathbf{\Pi}_{\partial_2}$ on both sides, $\mathbf{\Pi}_{\partial_2}\boldsymbol{d} \approx \mathbf{\Pi}_{\partial_2}\partial_2\partial_2^\top\tilde{\boldsymbol{x}} = \partial_2\partial_2^\top\tilde{\boldsymbol{x}}$. Thus if we set $\tilde{\boldsymbol{f}} = \partial_2^\top\tilde{\boldsymbol{x}}$, then we have $\mathbf{\Pi}_{\partial_2}\boldsymbol{d} \approx \partial_2\tilde{\boldsymbol{f}}$, which matches our notion of $\tilde{\boldsymbol{f}}$ approximately solving the (possibly infeasible) linear equation $\partial_2\boldsymbol{f} = \boldsymbol{d}$. This means that if we can approximately solve linear equations in $\mathcal{L}_1$, we can solve linear equations in ∂_2. This way we can also argue that if we can solve linear equations in $\partial_2\partial_2^\top$, then we can solve linear equations in ∂_2. Finally, one should note that $\mathrm{nnz}(\mathcal{L}_1) = O(\mathrm{nnz}(\partial_2))$ and that using our definition of condition number (see Section 2), both have polynomially related condition number[2]. This also means a high accuracy solve in one can be converted to a high accuracy solve in the other.

1.3.2 Linear Equations in $\partial_2\partial_2^\top$

In addition to the many applications discussed in Section 1.1, the problem of solving linear equations in $\partial_2\partial_2^\top$ also arises when using Interior Point Methods to solve a generalized max-flow problem in higher-dimensional simplicial complexes as defined in [36]. We sketch how this inverse problem arises when using an Interior Point Method in the full version of the paper [14]. By a similar argument as Lemma 1.3, we can show that if we can solve linear equations in $\partial_2\partial_2^\top$ to high accuracy in nearly-linear time, then we can solve linear equations in ∂_2 to high accuracy in nearly-linear time.

1.3.3 Sparse-Linear-Equation Completeness of Difference-Average Equations

Our first reduction transforms general linear equations with polynomially bounded integer entries and condition numbers into difference-average equations. We first transform a general linear equation instance to a linear equation instance such that the coefficient matrix has row sum zero and the sum of positive coefficients in each row is a power of 2, by introducing a constant number of more variables and equations. Then, we transform each single equation to a set of difference-average equations by bit-wise pairing and replacing each pair of variables with a new variable via an average equation.

1.3.4 Sparse-Linear-Equation Completeness of Boundary Operators of Simplicial Complexes

Our second reduction transforms difference-average linear equations into linear equations in the boundary operators of 2-complexes. Solving $\partial_2\boldsymbol{f} = \boldsymbol{d}$ can be interpreted as computing a flow $\boldsymbol{f}$ in the triangle space of a 2-complex subject to pre-specified edge demands $\boldsymbol{f}$.

Our reduction is inspired by a reduction in [36] that proves NP-hardness of computing maximum *integral* flows in 2-complexes via a reduction from 3-coloring problems in graphs. However, the correctness of their reduction heavily relies on that the flow values in the 2-complex are 0-1 integers, which does not apply in our setting. In addition, it is unclear how to encode linear equations as a graph coloring problem even if fractional colors are allowed.

We employ some basic building blocks used in [36] including punctured spheres and tubes. However, we need to carefully arrange and orient the triangles in the 2-complex to encode both the positive and negative coefficients in difference-average equations, and we need to express the averaging relations not covered by the previous work.

[2] This is because ∂_1 has polynomially bounded singular values.

An important aspect of our contribution is that we carefully control the number of nonzeros of the boundary operator matrix that we construct, and we bound the condition number of this matrix and how error propagates from an approximate solution to the boundary operator problem back to the original difference-average equations. In order to do so, we develop explicit triangulation algorithms that specify the precise number of triangles needed to triangulate each building block and allow a detailed error and condition number analysis.

We remark that our constructed 2-complex does not admit an embedding into a sphere in 3 dimensions. Recent work [3] has shown that simplicial complexes with a known embedding into $\mathbb{R}^3$ have non-trivial linear equation solvers, but the full extent to which embeddability can lead to better solvers remains an open question.

We analyze our construction in the Real RAM model. However, it can be transferred to the fixed point arithmetic model with $(\log N)^{O(1)}$ bits per number, where N is the size of the problem instance.

1.4 Related Works

Generalized Flows. One can generalize the notions of flows, demands vectors, circulations, and cuts to higher-dimensional simplicial complexes [17, 36]. Recall that in a graph, flows and circulations are defined on a vector space over edges, while demands and cuts are defined on a vector space over vertices. On a connected graph, a demand vector is a vector orthogonal to the all-ones vector, i.e. in the kernel of the boundary operator ∂_0. A flow that routes demand $\boldsymbol{d}$, is a vector $\boldsymbol{f}$ such that $\partial_1 \boldsymbol{f} = \boldsymbol{d}$.

More generally, on a k-complex, we say a demand vector is a vector $\boldsymbol{d}$ on $(k-1)$-simplices with $\boldsymbol{d} \in \ker(\partial_{k-1})$. We say a flow is a vector $\boldsymbol{f}$ on k-simplices, and that the flows $\boldsymbol{f}$ routes demand $\boldsymbol{d}$ if $\partial_k \boldsymbol{f} = \boldsymbol{d}$. Given a demand vector $\boldsymbol{d} \in \ker(\partial_{k-1})$ and a capacity vector $\boldsymbol{c}$ for the k-simplices, a reasonable generalization of the max-flow problem to k-complexes is to compute a flow $\boldsymbol{f}$ satisfying $\partial_k \boldsymbol{f} = \alpha \boldsymbol{d}$ and $\mathbf{0} \leq \boldsymbol{f} \leq \boldsymbol{c}$ to maximize the flow value α.

Solving Linear Equations. Linear equations are ubiquitous in computational mathematics, computer science, engineering, physics, biology, and economics. Currently, the best known algorithm for solving general dense linear equations in dimensions $n \times n$ runs in time $\tilde{O}(n^\omega)$, where $\omega < 2.3728596$ is the matrix multiplication constant [1]. For sparse linear equations with N nonzero coefficients and condition number κ, the best known approximate algorithms run in time $\widetilde{O}(\min\{N^{2.27159}, N\kappa\})$, where the first runtime is from [40, 38] and the second is by the conjugate gradient[3] [23].

In contrast to general linear equations, linear equations in graph Laplacians and its generalizations can be solved asymptotically faster, as mentioned earlier. In addition, faster solvers are also known for restricted classes of total-variation matrices [28], stiffness matrices from elliptic finite element systems [4], and 2 and 3-dimensional truss stiffness matrices [12, 30]. An interesting open question is to what extent one can generalize these faster solvers to more classes of matrices.

Reduction From Sparse Linear Equations. [32] defines a parameterized family of hypotheses for runtime of solving sparse linear equations. Under these hypotheses, they prove hardness of approximately solving packing and covering linear programs. For example, if one can solve a packing linear program up to ϵ accuracy in time $\tilde{O}(\#\text{ of nonzero coefficients} \times \epsilon^{-0.165})$, then one can solve linear equations in time asymptotically faster than $\tilde{O}(\#\text{ of nonzero coefficients} \times$ condition number of matrix), which is the runtime of conjugate gradient.

[3] If the coefficient matrix is symmetric positive semidefinite, the runtime is $\tilde{O}(N\sqrt{\kappa})$.

2 Preliminaries

2.1 Simplicial Homology

We define the basic concepts of simplicial homology. We recommend the reader the books [37] and [22] for a more complete treatment.

Simplicial Complexes. A *k-dimensional simplex* (or k-simplex) $\sigma = \text{conv}\{v_0, \ldots, v_k\}$ is the convex hull of $k+1$ affinely independent points $v_0, \ldots, v_k$. For example, 0,1,2-simplices are vertices, edges, and triangles, respectively. A *face* of σ is the convex hull of a non-empty subset of $\{v_0, v_1, \ldots, v_k\}$. An *orientation* of σ is given by an ordering Π of its vertices, written as $\sigma = [v_{\Pi(0)}, \ldots, v_{\Pi(k)}]$, such that two orderings define the same orientation if and only if they differ by an even permutation. If Π is even, then $[v_{\Pi(0)}, \ldots, v_{\Pi(k)}] = [v_0, \ldots, v_k]$; if Π is odd, then $[v_{\Pi(0)}, \ldots, v_{\Pi(k)}] = -[v_0, \ldots, v_k]$.

A *simplicial complex* $\mathcal{K}$ is a finite collection of simplices such that (1) for every $\sigma \in \mathcal{K}$ if $\tau \subset \sigma$ then $\tau \in \mathcal{K}$ and (2) for every $\sigma_1, \sigma_2 \in \mathcal{K}$, $\sigma_1 \cap \sigma_2$ is either empty or a face of both σ_1, σ_2. The *dimensions* of $\mathcal{K}$ is the maximum dimension of any simplex in $\mathcal{K}$. We refer to a simplicial complex in k dimensions as a k-complex.

Boundary Operators. A k-chain is a formal sum of the oriented k-simplices in $\mathcal{K}$ with the coefficients over $\mathbb{R}$. Let $C_k(\mathcal{K})$ denote the kth chain space. The *boundary operator* is a linear map $\partial_k : C_k(\mathcal{K}) \to C_{k-1}(\mathcal{K})$ such that for an oriented k-simplex $\sigma = [v_0, v_1, \ldots, v_k]$,

$$\partial_k(\sigma) = \sum_{i=0}^{k} (-1)^i [v_0, \ldots, \hat{v}_i, \ldots, v_k],$$

where $[v_0, \ldots, \hat{v}_i, \ldots, v_k]$ is the oriented $(k-1)$-simplex obtained by removing v_i from σ, and $(-1)^i$ is its *induced orientation*. The operator ∂_k can be written as a matrix in $n_{k-1} \times n_k$ dimensions, where n_d is the number of d-simplices in $\mathcal{K}$. The (i,j)th entry of ∂_k is ± 1 if the ith $(k-1)$-simplex is a face of the jth k-simplex where the sign is determined by the orientations, and 0 otherwise. See Figure 1 and Eq. (1) for an example.

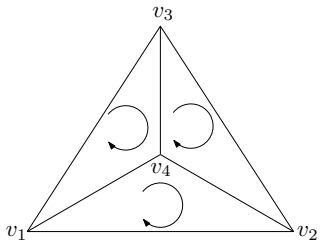

Figure 1 An example of boundary operator and oriented triangulation. We orient 2-simplices clockwise, and orient 1-simplices by the increasing order of vertex indices.

$$\partial_2 = \begin{array}{c} \\ [v_1,v_2] \\ [v_2,v_3] \\ [v_1,v_3] \\ [v_1,v_4] \\ [v_2,v_4] \\ [v_3,v_4] \end{array} \begin{array}{c} \begin{array}{ccc} [v_1,v_4,v_2] & [v_2,v_4,v_3] & [v_1,v_3,v_4] \end{array} \\ \begin{bmatrix} -1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & -1 \\ -1 & 1 & 0 \\ 0 & -1 & 1 \end{bmatrix} \end{array}. \tag{1}$$

An important property of the boundary operator is that applying the boundary operator twice results in the zero operator, i.e.,

$$\partial_{k-1}\partial_k = \mathbf{0}. \tag{2}$$

This implies $\mathrm{im}(\partial_k) \subseteq \ker(\partial_{k-1})$. Thus, we can define the quotient space $H_k = \ker(\partial_k) \setminus \mathrm{im}(\partial_{k+1})$, referred to as the kth homology space of $\mathcal{K}$. The dimension of H_k is the kth Betti number of $\mathcal{K}$, which plays an important role in understanding the homology spaces.

Hodge Theory and Combinatorial Laplacians. Combinatorial Laplacians arise from the discrete Hodge decomposition.

▶ **Theorem 2.1** (Hodge decomposition [34]). *Let $\boldsymbol{A} \in \mathbb{R}^{m\times n}$ and $\boldsymbol{B} \in \mathbb{R}^{n\times p}$ be matrices satisfying $\boldsymbol{AB} = \mathbf{0}$. Then, there is an orthogonal direct sum decomposition*

$$\mathbb{R}^n = \mathrm{im}(\boldsymbol{A}^\top) \oplus \ker(\boldsymbol{A}^\top\boldsymbol{A} + \boldsymbol{B}\boldsymbol{B}^\top) \oplus \mathrm{im}(\boldsymbol{B}).$$

By Eq. (2), it is valid to set $\boldsymbol{A} = \partial_k$ and $\boldsymbol{B} = \partial_{k+1}$. The matrix we get in the middle term is the *combinatorial Laplacian*: $\mathcal{L}_k \stackrel{\text{def}}{=} \partial_k^\top\partial_k + \partial_{k+1}\partial_{k+1}^\top$. In particular, $\mathcal{L}_0 = \partial_1\partial_1^\top$ is the graph Laplacian. The kth homology space $H_k(\mathcal{K})$ is isomorphic to $\ker(\mathcal{L}_k)$, and thus the kth Betti number of $\mathcal{K}$ equals the dimension of $\ker(\mathcal{L}_k)$.

Triangulation. A *triangulation* of a topological space $\mathcal{X}$ is a simplicial complex $\mathcal{K}$ together with a homeomorphism between $\mathcal{X}$ and $\mathcal{K}$. In this paper, the only topological spaces that we compute triangulations of are 2-dimensional manifolds. A 2-dimensional manifold can be triangulated by a 2-complex, where every edge in the 2-complex is contained in exactly one triangle (boundary edge) or two triangles (interior edge). An *oriented triangulation* of a 2-dimensional manifold is a triangulation together with an orientation for each triangle such that any two neighboring triangles induce opposite signs on their shared interior edge.

Figure 1 is an example of (oriented) triangulation: the topological space is a disk; boundary edges are $[v_1, v_2], [v_2, v_3], [v_1, v_3]$; interior edges are $[v_1, v_4], [v_2, v_4], [v_3, v_4]$; the orientation of each triangle is clockwise.

2.2 Notation for Matrices and Vectors

We use parentheses to denote entries of a matrix or a vector: Let $\boldsymbol{A}(i,j)$ bet the (i,j)th entry of a matrix $\boldsymbol{A}$, and let $\boldsymbol{x}(i)$ bet the ith entry of a vector $\boldsymbol{x}$. We use $\mathbf{1}_n, \mathbf{0}_n$ to denote n-dimensional all-one vector and all-zero vector, respectively. We define $\|\boldsymbol{x}\|_{\max} = \max_{i\in[n]} |\boldsymbol{x}(i)|$, $\|\boldsymbol{x}\|_1 = \sum_{i\in[n]} |\boldsymbol{x}(i)|$. Given a matrix $\boldsymbol{A} \in \mathbb{R}^{d\times n}$, we use $\boldsymbol{A}(i)$ to denote the ith row of $\boldsymbol{A}$ and $\mathrm{nnz}(\boldsymbol{A})$ the number of nonzero entries of $\boldsymbol{A}$. Without loss of generality, we assume that $\mathrm{nnz}(\boldsymbol{A}) \geq \max\{d, n\}$. We let $\|\boldsymbol{A}\|_{\max} = \max_{i,j} |\boldsymbol{A}(i,j)|$. We use $\mathrm{im}(\boldsymbol{A})$ to denote the image (i.e., the column space) of $\boldsymbol{A}$ and $\mathrm{null}(\boldsymbol{A})$ the null space of $\boldsymbol{A}$. We let $\boldsymbol{\Pi}_{\boldsymbol{A}} = \boldsymbol{A}(\boldsymbol{A}\boldsymbol{A}^\top)^\dagger\boldsymbol{A}^\top$ be the orthogonal projection onto $\mathrm{im}(\boldsymbol{A})$, where $\boldsymbol{M}^\dagger$ is the pseudo-inverse of $\boldsymbol{M}$. Let $\lambda_{\max}(\boldsymbol{A})$ be the maximum eigenvalue of $\boldsymbol{A}$ and $\lambda_{\min}(\boldsymbol{A})$ the minimum *nonzero* eigenvalue of $\boldsymbol{A}$. Similarly, let $\sigma_{\max}(\boldsymbol{A})$ be the maximum eigenvalue of $\boldsymbol{A}$ and $\sigma_{\min}(\boldsymbol{A})$ the minimum *nonzero* singular value of $\boldsymbol{A}$. The condition number of $\boldsymbol{A}$, denoted by $\kappa(\boldsymbol{A})$, is the ratio of the maximum to the minimum *nonzero* singular value of $\boldsymbol{A}$.

We define a function U that takes a matrix $\boldsymbol{A}$ and a vector $\boldsymbol{b}$ as arguments and returns the maximum of $\|\cdot\|_{\max}$ of all the arguments, that is, $U(\boldsymbol{A}, \boldsymbol{b}) = \max\{\|\boldsymbol{A}\|_{\max}, \|\boldsymbol{b}\|_{\max}\}$.

2.3 Systems of Linear Equations

We define approximately solving linear equations in a general form, following [33]. For more details, we refer the readers to Section 2.1 of [33].

▶ **Definition 2.2** (Linear Equation Problem (LE)). *Given a matrix $\boldsymbol{A} \in \mathbb{R}^{d\times n}$, a vector $\boldsymbol{b} \in \mathbb{R}^d$, we refer to the linear equation problem for the tuple $(\boldsymbol{A}, \boldsymbol{b})$, denoted by* LE $(\boldsymbol{A}, \boldsymbol{b})$*, as the problem of finding an $\boldsymbol{x} \in \mathbb{R}^n$ such that $\boldsymbol{x} \in \arg\min_{\boldsymbol{x}\in\mathbb{R}^n} \|\boldsymbol{A}\boldsymbol{x} - \boldsymbol{b}\|_2$.*

▶ **Fact 2.3.** *Let $\boldsymbol{x}^* \in \arg\min_{\boldsymbol{x}\in\mathbb{R}^n} \|\boldsymbol{A}\boldsymbol{x} - \boldsymbol{b}\|_2$. Then,*

$$\boldsymbol{A}\boldsymbol{x}^* = \boldsymbol{A}(\boldsymbol{A}^\top\boldsymbol{A})^\dagger\boldsymbol{A}^\top\boldsymbol{b} = \boldsymbol{\Pi}_{\boldsymbol{A}}\boldsymbol{b} \quad \text{and} \quad \|\boldsymbol{A}\boldsymbol{x}^* - \boldsymbol{b}\|_2^2 = \|(\boldsymbol{I} - \boldsymbol{\Pi}_{\boldsymbol{A}})\boldsymbol{b}\|_2^2 .$$

By the above fact, solving LE $(\boldsymbol{A}, \boldsymbol{b})$ is equivalent to finding an $\boldsymbol{x}$ such that $\boldsymbol{A}\boldsymbol{x} = \boldsymbol{\Pi}_{\boldsymbol{A}}\boldsymbol{b}$. This equation is known as the normal equation, and it is always feasible. If $\boldsymbol{b} \in \mathrm{im}(\boldsymbol{A})$, then $\boldsymbol{\Pi}_{\boldsymbol{A}}\boldsymbol{b} = \boldsymbol{b}$.

In practice, we are more interested in *approximately* solving linear equations, since numerical errors are unavoidably in data collection and computation and approximate solvers may run faster.

▶ **Definition 2.4** (Linear Equation Approximation Problem (LEA)). *Given a matrix $\boldsymbol{A} \in \mathbb{R}^{d\times n}$, vectors $\boldsymbol{b} \in \mathbb{R}^d$, and an error parameter $\epsilon \in (0, 1]$, we refer to linear equation approximate problem for the tuple $(\boldsymbol{A}, \boldsymbol{b}, \epsilon)$, denoted by* LEA $(\boldsymbol{A}, \boldsymbol{b}, \epsilon)$*, as the problem of finding an $\boldsymbol{x} \in \mathbb{R}^n$ such that $\|\boldsymbol{A}\boldsymbol{x} - \boldsymbol{\Pi}_{\boldsymbol{A}}\boldsymbol{b}\|_2 \le \epsilon \|\boldsymbol{\Pi}_{\boldsymbol{A}}\boldsymbol{b}\|_2$.*

▶ **Fact 2.5.** *Let $\boldsymbol{x}$ be a solution to* LEA $(\boldsymbol{A}, \boldsymbol{b}, \epsilon)$*. Then,*

$$\|\boldsymbol{A}\boldsymbol{x} - \boldsymbol{b}\|_2^2 \le \|\boldsymbol{A}\boldsymbol{x}^* - \boldsymbol{b}\|_2^2 + \epsilon^2 \|\boldsymbol{\Pi}_{\boldsymbol{A}}\boldsymbol{b}\|_2^2 .$$

The definition of the approximate error in Definition 2.4 is equivalent to several error notions that are commonly used in solving linear equations. In particular,

$$\|\boldsymbol{A}\boldsymbol{x} - \boldsymbol{\Pi}_{\boldsymbol{A}}\boldsymbol{b}\|_2 = \left\|\boldsymbol{A}^\top\boldsymbol{A}\boldsymbol{x} - \boldsymbol{A}^\top\boldsymbol{b}\right\|_{(\boldsymbol{A}^\top\boldsymbol{A})^\dagger} = \|\boldsymbol{x} - \boldsymbol{x}^*\|_{\boldsymbol{A}^\top\boldsymbol{A}} .$$

2.3.1 Matrix Classes

We are interested in linear equations whose coefficient matrices belonging to the following matrix classes.

1. $\mathcal{G}$ refers to the class of *General Matrices* that have integer entries and do not have all-0 rows and all-0 columns. We refer to linear equations whose coefficient matrix is in $\mathcal{G}$ as *general linear equations*.
2. $\mathcal{DA}$ refers to the class of *Difference-Average Matrices* whose rows fall into two categories:
   a. A *difference row* which has exactly two nonzero entries 1 and -1;
   b. An *average row* which has exactly three nonzero entries 1, 1, and -2.

   Multiplying a difference row vector to a column vector $\boldsymbol{x}$ gives $\boldsymbol{x}(i) - \boldsymbol{x}(j)$; multiplying an average row vector to $\boldsymbol{x}$ gives $\boldsymbol{x}(i) + \boldsymbol{x}(j) - 2\boldsymbol{x}(k)$. We refer to linear equations whose coefficient matrix is in $\mathcal{DA}$ as *difference-average linear equations*.
3. $\mathcal{B}_2$ refers to the class of *Boundary Operator Matrices ∂_2 in 2-complexes*. We refer to linear equations whose coefficient matrix is in $\mathcal{B}_2$ as *2-complex boundary linear equations*.

Our definition of "general matrices" specifies the matrix must have integer entries. However, when the input matrix is invertible, using a simple rounding argument, we can convert any linear equation into an linear equation with integer entries $\widetilde{O}(1)$ bits per entry. We caution the reader this relies on our definition of $\widetilde{O}(\cdot)$ as hiding polylogarithmic factors in the input condition number. In general, the condition number can be exponentially large – however, our results are mainly of interest when the condition number is quasipolynomially bounded.

2.3.2 Reduction Between Linear Equations

We will again follow the definition of efficient reductions in [33]. We say LEA over matrix class $\mathcal{M}_1$ is *nearly-linear time reducible* to LEA over matrix class $\mathcal{M}_2$, denoted by $\mathcal{M}_1 \leq_{nlt} \mathcal{M}_2$, if the following holds:

1. There is an algorithm that maps an arbitrary instance LEA $(\boldsymbol{M}_1, \boldsymbol{c}_1, \epsilon_1)$ where $\boldsymbol{M}_1 \in \mathcal{M}_1$ to an instance LEA $(\boldsymbol{M}_2, \boldsymbol{c}_2, \epsilon_2)$ where $\boldsymbol{M}_2 \in \mathcal{M}_2$ such that there is another algorithm that can map a solution to LEA $(\boldsymbol{M}_2, \boldsymbol{c}_2, \epsilon_2)$ to a solution to LEA $(\boldsymbol{M}_1, \boldsymbol{c}_1, \epsilon_1)$.
2. Both the two algorithms run in time $\widetilde{O}(\mathrm{nnz}(\boldsymbol{M}_1))$.
3. In addition, we can guarantee $\mathrm{nnz}(\boldsymbol{M}_2) = \widetilde{O}(\mathrm{nnz}(\boldsymbol{M}_1))$, and $\epsilon_2^{-1}, \kappa(\boldsymbol{M}_2), U(\boldsymbol{M}_2, \boldsymbol{b}_2) = \mathrm{poly}(\mathrm{nnz}(\boldsymbol{M}_1), \epsilon_1^{-1}, \kappa(\boldsymbol{M}_1), U(\boldsymbol{M}_1, \boldsymbol{b}_1))$.

We do not require a nearly-linear time reduction to preserve the number of variables or constraints (dimensions) of linear equations. The dimensions of the new linear equation instance that we construct can be much larger than that of the original instance. On the other hand, a reduction that *only* preserves dimensions may construct a dense linear equation instance even if the original instance is sparse. A nearly-linear time reduction that preserves *both* the number of nonzeros and dimensions would be stronger than what we achieve.

▶ **Fact 2.6.** *If $\mathcal{M}_1 \leq_{nlt} \mathcal{M}_2$ and $\mathcal{M}_2 \leq_{nlt} \mathcal{M}_3$, then $\mathcal{M}_1 \leq_{nlt} \mathcal{M}_3$.*

▶ **Definition 2.7** (Sparse linear equation complete (SLE-complete))**.** *We say LEA over a matrix class $\mathcal{M}$ is* sparse-linear-equation-complete *if $\mathcal{G} \leq_{nlt} \mathcal{M}$.*

▶ **Fact 2.8.** *Suppose LEA over $\mathcal{M}$ is SLE-complete. If one can solve all instances LEA $(\boldsymbol{A}, \boldsymbol{b}, \epsilon)$ with $\boldsymbol{A} \in \mathcal{M}$ in time $\tilde{O}(\mathrm{nnz}(\boldsymbol{A})^c)$ where $c \geq 1$, then one can solve all instances LEA $(\boldsymbol{A}', \boldsymbol{b}', \epsilon')$ with $\boldsymbol{A}' \in \mathcal{G}$ in time $\tilde{O}(\mathrm{nnz}(\boldsymbol{A}')^c)$.*

Under the above definitions, [33] implicitly shows the following results. We provide an explicit and simplified proof in the full version of the paper [14].

▶ **Theorem 2.9** (Implicitly stated in [33])**.** *LEA over $\mathcal{DA}$ is SLE-complete.*

3 Main Results

Our main result is stated in the following theorem.

▶ **Theorem 3.1.** *LEA over $\mathcal{B}_2$ is SLE-complete.*

Theorem 3.1 states that a linear equation approximation problem over a boundary operator of a 2-complex is sparse linear equation complete. See Section 2 for detailed definitions.

Although our main theorem focuses on linear equation approximate problems, we construct nearly-linear time reductions for both linear equation problem LE and its approximate counterpart LEA. We first reduce LE instances $(\boldsymbol{A}, \boldsymbol{b})$ (and LEA instances $(\boldsymbol{A}, \boldsymbol{b}, \epsilon)$) over difference-average matrices to those over 2-complex boundary operator matrices, *under the assumption* $\boldsymbol{b} \in \mathrm{im}(\boldsymbol{A})$ (stated in Theorem 3.2 and 3.3). In this case, the constructed 2-complexes have unit edge weights. We then provide a slightly modified nearly-linear time reduction for LEA $(\boldsymbol{A}, \boldsymbol{b}, \epsilon)$ over difference-average matrices to LEA over 2-complex boundary operator matrices *without assuming* $\boldsymbol{b} \in \mathrm{im}(\boldsymbol{A})$ (stated in Theorem 3.4). In this case, we introduce polynomially bounded edge weights for the constructed 2-complexes.

▶ **Theorem 3.2.** *Given a linear equation instance LE $(\boldsymbol{A}, \boldsymbol{b})$ where $\boldsymbol{A} \in \mathcal{DA}$ and $\boldsymbol{b} \in \mathrm{im}(\boldsymbol{A})$, we can reduce it to an instance LE (∂_2, γ) where $\partial_2 \in \mathcal{B}_2$, in time $O(\mathrm{nnz}(\boldsymbol{A}))$, such that a solution to LE (∂_2, γ) can be mapped to a solution to LE $(\boldsymbol{A}, \boldsymbol{b})$ in time $O(\mathrm{nnz}(\boldsymbol{A}))$.*

▶ **Theorem 3.3.** *Given a linear equation instance* LEA $(\boldsymbol{A}, \boldsymbol{b}, \epsilon^{DA})$ *where* $\boldsymbol{A} \in \mathcal{DA}$ *and* $\boldsymbol{b} \in \mathrm{im}(\boldsymbol{A})$*, we can reduce it to an instance* LEA $(\partial_2, \gamma, \epsilon^{B_2})$ *where* $\partial_2 \in \mathcal{B}_2$ *and* $\epsilon^{B_2} \leq \frac{\epsilon^{DA}}{42\,\mathrm{nnz}(\boldsymbol{A})}$*, in time* $O(\mathrm{nnz}(\boldsymbol{A}))$*, such that a solution to* LEA $(\partial_2, \gamma, \epsilon^{B_2})$ *can be mapped to a solution to* LEA $(\boldsymbol{A}, \boldsymbol{b}, \epsilon^{DA})$ *in time* $O(\mathrm{nnz}(\boldsymbol{A}))$*.*

▶ **Theorem 3.4.** *Given an instance* LEA $(\boldsymbol{A}, \boldsymbol{b}, \epsilon^{DA})$ *where* $\boldsymbol{A} \in \mathcal{DA}$*, we can reduce it to an instance* LEA $(\boldsymbol{W}^{1/2}\partial_2, \boldsymbol{W}^{1/2}\gamma, \epsilon^{B_2})$ *where* $\partial_2 \in \mathcal{B}_2$ *and* $\boldsymbol{W}$ *is a diagonal matrix with nonnegative diagonals, in time* $O(\mathrm{nnz}(\boldsymbol{A}))$*. Let* s, ϵ, K, U *denote* $\mathrm{nnz}(\boldsymbol{A}), \epsilon^{DA}, \kappa(\boldsymbol{A}), U(\boldsymbol{A}, \boldsymbol{b})$*, respectively. Then, we can guarantee that*

$$\mathrm{nnz}(\partial_2) = O(s),\ U(\boldsymbol{W}^{1/2}\partial_2, \boldsymbol{W}^{1/2}\gamma) = O\left(sU\epsilon^{-1}\right),$$
$$\epsilon^{B_2} = \Omega(\epsilon U^{-1}s^{-1}),\ \kappa(\boldsymbol{W}^{1/2}\partial_2) = O\left(s^{15/2}K^2\epsilon^{-2}\right)$$

and a solution to LEA $(\boldsymbol{W}^{1/2}\partial_2, \boldsymbol{W}^{1/2}\gamma, \epsilon^{B_2})$ *can be mapped to a solution to* LEA $(\boldsymbol{A}, \boldsymbol{b}, \epsilon^{DA})$ *in time* $O(\mathrm{nnz}(\boldsymbol{A}))$*.*

We refer the reader to the full version of the paper [14] for a formal proof of Theorem 3.2, 3.3, and 3.4.

3.1 Overview of Our Proof

Multiplying a 2-complex boundary operator $\partial_2 \in \mathbb{R}^{m\times t}$ to a vector $\boldsymbol{f} \in \mathbb{R}^t$ can be interpreted as transforming flows in the triangle space to demands in the edge space. Given $\gamma \in \mathbb{R}^m$, solving LE (∂_2, γ) can be interpreted as finding flows $\boldsymbol{f}$ in the triangle space subject to edge demands γ. We will encode difference-average linear equations as a 2-complex flow network.

Encoding Linear Operations. In difference-average linear equations, linear operations include subtraction, addition, and multiplication. We observe a simple fact: If we glue two triangles Δ_1, Δ_2 with the same orientation, then the net flow $\partial_2\boldsymbol{f}$ on the shared edge is $\boldsymbol{f}(\Delta_1) - \boldsymbol{f}(\Delta_2)$ (see Figure 2 (a)); if we glue two triangles Δ_1, Δ_2 with opposite orientations, then the net flow $\partial_2\boldsymbol{f}$ on the shared edge is $\boldsymbol{f}(\Delta_1) + \boldsymbol{f}(\Delta_2)$ (see Figure 2 (b)). Given an equation $\boldsymbol{a}^\top\boldsymbol{x} = b$ with the nonzero coefficients being ± 1, we can encode it by gluing more triangles as above and setting the demand of the shared edge to be b. To handle the coefficient -2 in an average equation, say $\boldsymbol{x}(i) + \boldsymbol{x}(j) - 2\boldsymbol{x}(k)$, we implicitly interpret it as $\boldsymbol{x}(i) + \boldsymbol{x}(j) - \boldsymbol{x}(k_1) - \boldsymbol{x}(k_2)$ together with an additional difference equation $\boldsymbol{x}(k_1) = \boldsymbol{x}(k_2)$ (see Figure 2 (c)).

Encoding a Variable. We use a sphere to encode a variable involved in many equations. We can obtain an oriented triangulation of the sphere and set all the edge demand to be 0 so that all the triangles on the sphere must have an equal flow value (see Figure 2 (d)).

Putting It All Together. We represent each variable using a triangulated sphere. To add a constraint between variables, in each corresponding sphere we add a "hole" if the variable coefficient is ± 1 and add two "holes" if the coefficient is 2. Then we attach a "tube" to each of these holes. Similarly, we can obtain an oriented triangulation of each tube and set the edge demand properly so that all the triangles on the tube must have the same flow value to the triangles on the sphere that the tube is attached to. We then connect these tubes corresponding to different variables so that they share common edges. Depending on how the tubes connect and on the net flow demand on the shared edges, we can represent different linear constraints on the variables.

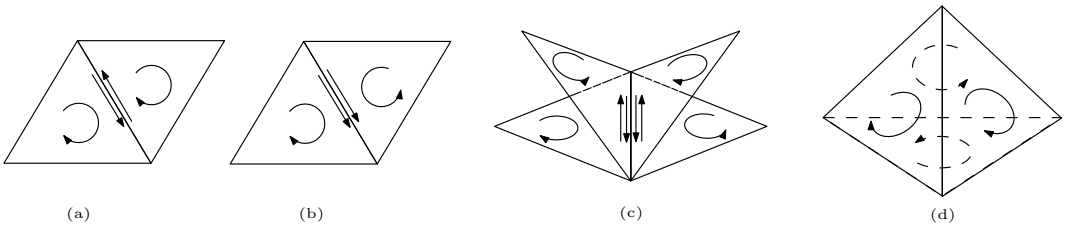

Figure 2 An illustration for encoding linear operations and variables: (a) encodes the "subtraction" with two identically oriented triangles. (b) encodes the "addition" with two oppositely oriented triangles. (c) encodes the "multiplication" by a coefficient 2 in an average equation. (d) encodes a variable with an identically oriented triangulated sphere, and this will later allow us to use several "copies" of this variable, by making holes in this sphere and attaching a tube to each such hole.

Discussion.

1. *Why encode difference/average equations rather than directly encoding general equations with integer coefficients?*
   We can generalize the above encoding method to encode a general equation $\boldsymbol{g}^\top \boldsymbol{y} = c$ with arbitrary integer coefficients into a 2-complex with roughly $\|\boldsymbol{g}\|_1$ tubes. However, the encoding size required to express a general system of linear equations $\boldsymbol{G}\boldsymbol{y} = \boldsymbol{c}$ this way can be as large as $\Omega(\mathrm{nnz}(\boldsymbol{G})\,\|\boldsymbol{G}\|_{\max})$. This dependence on $\|\boldsymbol{G}\|_{\max}$ is prohibitive, and makes for a fairly weak result.

   On the other hand, we can first reduce the general linear equations $\boldsymbol{G}\boldsymbol{y} = \boldsymbol{c}$ into difference-average linear equations $\boldsymbol{A}\boldsymbol{x} = \boldsymbol{b}$, where $\|\boldsymbol{A}\|_{\max} = 2$ and $\mathrm{nnz}(\boldsymbol{A}) = O\left(\mathrm{nnz}(\boldsymbol{G}) \log \|\boldsymbol{G}\|_{\max}\right)$ (by Lemma A.1 in [14]). Then we can encode $\boldsymbol{A}\boldsymbol{x} = \boldsymbol{b}$ into a 2-complex. The encoding size required to express the the difference-average linear equations as a 2-complex is thus $O(\mathrm{nnz}(\boldsymbol{A}))$ (by Lemma 4.2). Thus, the overall encoding size required to express the original linear equation $\boldsymbol{G}\boldsymbol{y} = \boldsymbol{c}$ is now $\widetilde{O}\left(\mathrm{nnz}(\boldsymbol{G})\right)$, exponentially improving the dependence on $\|\boldsymbol{G}\|_{\max}$.

   Therefore, the two-step reduction is a nearly-linear time reduction while the one-step reduction is not.

2. *Why encode into a 2-complex rather than a 1-complex?*
   We do not expect that general linear equations with integer coefficients can be efficiently encoded using a 1-complex. This would immediately imply a nearly-linear time solver for general linear equations, as fast solvers for 1-complex operators exist (using Laplacian linear equation solvers).

4 Reducing Exact Solvers for $\mathcal{DA}$ to $\mathcal{B}_2$ Assuming the Right-Hand Side Vector in the Image of the Coefficient Matrix

In this section, we describe a nearly-linear time reduction from instances LE $(\boldsymbol{A}, \boldsymbol{b})$ over $\mathcal{DA}$ to instances LE over $\mathcal{B}_2$, under the assumption that $\boldsymbol{b} \in \mathrm{im}(\boldsymbol{A})$, and analyze its runtime and the size of the reduced problem. In the full version of the paper [14], we show that the same reduction with a carefully chosen error parameter reduces linear equation approximate problem LEA over $\mathcal{DA}$ to LEA over $\mathcal{B}_2$, assuming $\boldsymbol{b} \in \mathrm{im}(\boldsymbol{A})$. In addition, we slightly modify the reduction algorithm to drop the assumption $\boldsymbol{b} \in \mathrm{im}(\boldsymbol{A})$ for LEA.

4.1 Reduction Algorithm

Recall that an instance LE $(\boldsymbol{A}, \boldsymbol{b})$ over $\mathcal{DA}$ only consists of two types of linear equations: (1) *Difference equation*: $\boldsymbol{x}(i) - \boldsymbol{x}(j) = \boldsymbol{b}(q)$; (2) *Average equation*: $\boldsymbol{x}(i) + \boldsymbol{x}(j) - 2\boldsymbol{x}(k) = 0$. Suppose LE $(\boldsymbol{A}, \boldsymbol{b})$ has d_1 difference equations and d_2 average equations. Without loss of generality, we reorder all the equations so that the first d_1 equations are difference equations and the rest are average equations. The following algorithm ReduceDATo$\mathcal{B}_2$ constructs a 2-complex and a system of linear equations in its boundary operator.

Algorithm Reduce$\mathcal{DA}$To$\mathcal{B}_2$.
Input: an instance LE $(\boldsymbol{A}, \boldsymbol{b})$ where $\boldsymbol{A} \in \mathcal{DA}$ is a $d \times n$ matrix and $\boldsymbol{b} \in \mathbb{R}^d$.
Output: $(\partial_2, \gamma, \boldsymbol{\Delta}^c)$ where $\partial_2 \in \mathcal{B}_2$ is an $m \times t$ matrix, $\gamma \in \mathbb{R}^m$, and $\boldsymbol{\Delta}^c$ is a set of n triangles.

1. For each $i \in [n]$ and variable $\boldsymbol{x}(i)$ in LE $(\boldsymbol{A}, \boldsymbol{b})$, we construct a sphere $\mathcal{S}_i$.
2. For each $q \in [d_1]$, which corresponds to a difference equation $\boldsymbol{x}(i) - \boldsymbol{x}(j) = \boldsymbol{b}(q)$, we add a *loop*[4] α_q with a net flow demand $\boldsymbol{b}(q)$. Then,
   a. we add a *boundary component*[5] $\beta_{q,i}$ on $\mathcal{S}_i$, and a boundary component $\beta_{q,j}$ on $\mathcal{S}_j$;
   b. we construct a tube $\mathcal{T}_{q,i}$ with boundary components $\{-\beta_{q,i}, \alpha_q\}$, and a tube $\mathcal{T}_{q,j}$ with boundary components $\{-\beta_{q,j}, -\alpha_q\}$.

   See Figure 3 for an illustration[6].

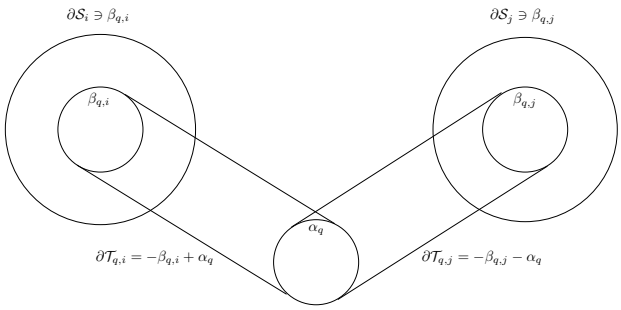

Figure 3 The construction for a difference equation $\boldsymbol{x}(i) - \boldsymbol{x}(j) = \boldsymbol{b}(q)$. For a topological space X, we use ∂X to denote its boundary.

3. For each $q \in \{d_1+1, \ldots, d\}$, which corresponds to an average equation $\boldsymbol{x}(i)+\boldsymbol{x}(j)-2\boldsymbol{x}(k) = \boldsymbol{b}(q) = 0$, we add a loop α_q with zero net flow demand. Then,
   a. we add a boundary component $\beta_{q,i}$ on $\mathcal{S}_i$, a boundary component $\beta_{q,j}$ on $\mathcal{S}_j$, and two boundary components $\beta_{q,k,1}, \beta_{q,k,2}$ on $\mathcal{S}_k$;
   b. we construct a tube $\mathcal{T}_{q,i}$ with boundary components $\{-\beta_{q,i}, \alpha_q\}$, a tube $\mathcal{T}_{q,j}$ with boundary components $\{-\beta_{q,j}, \alpha_q\}$, and two tubes $\mathcal{T}_{q,k,1}, \mathcal{T}_{q,k,2}$ with boundary components $\{-\beta_{q,k,1}, -\alpha_q\}$ and $\{-\beta_{q,k,2}, -\alpha_q\}$, respectively.

   See Figure 4 for an illustration[7].

[4] In topology, a loop in a topological space X is a path whose initial point is equal to its terminal point.
[5] In topology, a boundary of a topological space X is a set of points that can be approached from both X and the outside of X. A boundary component is a connected component of the boundary. Here, sphere $\mathcal{S}_i$ does not have a boundary, but we can hollow a "hole" by adding a boundary component.
[6] Note that since the loop α_q has demand $\boldsymbol{b}(q)$, our construction is different from identifying the boundary component α_q of $\mathcal{T}_{q,i}$ and the boundary component $-\alpha_q$ of $\mathcal{T}_{q,j}$.
[7] As four tubes are connected to a single loop, to avoid the intersection of tubes before attaching the loop, a higher-dimensional space is required.

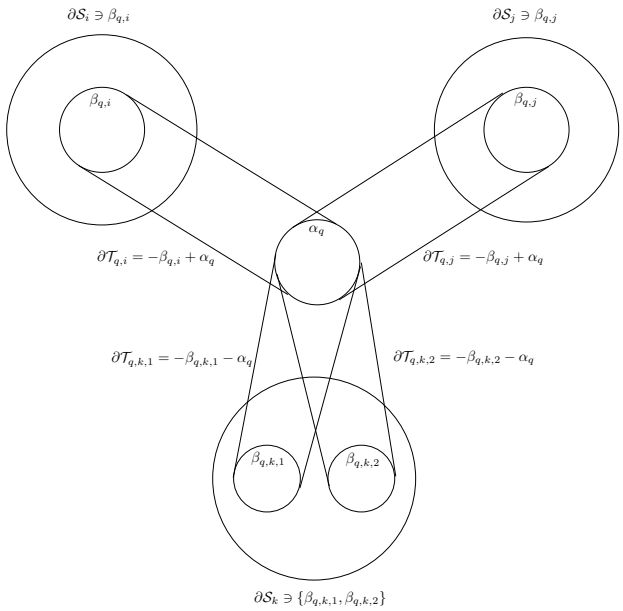

Figure 4 The construction for an average equation $\boldsymbol{x}(i) + \boldsymbol{x}(j) - 2\boldsymbol{x}(k) = 0$.

4. For each $i \in [n]$, the punctured sphere $\mathcal{S}_i$ and the tubes connected to $\mathcal{S}_i$ form a continuous topological space. We construct an oriented triangulation for this space such that the induced orientation of each edge on a loop α_q is consistent with the orientation of α_q. We will describe this oriented triangulation subroutine in Section 4.1.1. Let $\mathcal{K}$ be the oriented 2-complex. Let ∂_2 be the boundary operator of $\mathcal{K}$.
5. Each edge on a loop α_q has net demand $\boldsymbol{b}(q)$; each other edge has net demand 0. Let γ be the vector of the net flow demands.
6. On each triangulated sphere $\mathcal{S}_i$, we choose an arbitrary triangle $\Delta_i \in \mathcal{S}_i$ as the *central triangle*. Let $\boldsymbol{\Delta}^c$ be the set of all the central triangles.
7. We return $(\partial_2, \gamma, \boldsymbol{\Delta}^c)$.

The following algorithm MapSoln$\mathcal{B}_2$to$\mathcal{DA}$ maps a solution $\boldsymbol{f}$ to LE (∂_2, γ) to a solution $\boldsymbol{x}$ to LE $(\boldsymbol{A}, \boldsymbol{b})$.

Algorithm MapSoln$\mathcal{B}_2$to$\mathcal{DA}$.
Input: a tuple $(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{f}, \boldsymbol{\Delta}^c)$, where $\boldsymbol{A} \in \mathcal{DA}$ is a $d \times n$ matrix, $\boldsymbol{b} \in \mathbb{R}^d$, $\boldsymbol{f} \in \mathbb{R}^t$, and $\boldsymbol{\Delta}^c$ is the set of n central triangles.
Output: a vector $\boldsymbol{x} \in \mathbb{R}^n$.
1. If $\boldsymbol{A}^\top \boldsymbol{b} = 0$, we return $\boldsymbol{x} = \boldsymbol{0}$.
2. Otherwise, we set $\boldsymbol{x}(i) = \boldsymbol{f}(\Delta_i)$, where $\Delta_i \in \boldsymbol{\Delta}^c$ is the central triangle on sphere $\mathcal{S}_i$.

4.1.1 Oriented Triangulation for Punctured Spheres and Tubes

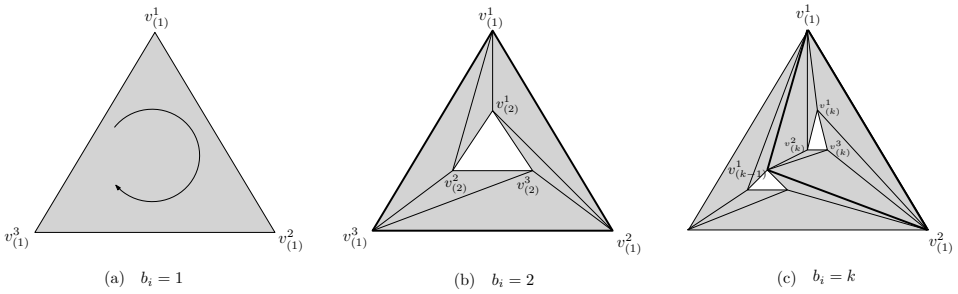
We provide a concrete triangulation subroutine for the benefit of algorithm analysis.

Oriented Triangulation for Punctured Spheres

By our construction, each sphere $\mathcal{S}_i$ has $b_i = \sum_{q=1}^{d} |\boldsymbol{A}(q, i)|$ boundary components. We will create $\tilde{t}_i$ triangles and $\tilde{m}_i$ edges on $\mathcal{S}_i$, based on b_i.

1. If $b_i = 1$ (see Figure 5 (a)), the punctured sphere is topologically equivalent to a disk. In this case, $\mathcal{S}_i$ can be triangulated using a single triangle $[v^1_{(1)}, v^2_{(1)}, v^3_{(1)}]$, thus $\tilde{t}_i = 1, \tilde{m}_i = 3$.
2. If $b_i = 2$ (see Figure 5 (b)), the punctured sphere is topologically equivalent to an annulus. We subdivide the triangle $[v^1_{(1)}, v^2_{(1)}, v^3_{(1)}]$ obtained in the previous case by adding 6 interior edges between vertices of the inner and the outer boundaries: $[v^1_{(1)}, v^1_{(2)}], [v^1_{(1)}, v^2_{(2)}], [v^2_{(1)}, v^1_{(2)}], [v^2_{(1)}, v^3_{(2)}], [v^3_{(1)}, v^2_{(2)}], [v^3_{(1)}, v^3_{(2)}]$, thus $\tilde{t}_i = 6, \tilde{m}_i = 12$.
3. Generally, if $b_i = k$ (see Figure 5 (c)), we subdivide the rightmost triangle $[v^1_{(1)}, v^2_{(1)}, v^1_{(k-1)}]$ obtained in the case of $b_i = k - 1$ with the same method. By induction, we have

$$\tilde{t}_i = 5b_i - 4, \qquad \tilde{m}_i = 9b_i - 6, \qquad \text{for} \quad b_i \geq 1. \tag{3}$$



(a) $b_i = 1$ (b) $b_i = 2$ (c) $b_i = k$

Figure 5 Oriented triangulation of punctured spheres. The light area represents the "holes" defined by boundary components.

The orientation for triangles on the same sphere should be identical. Without loss of generality, we orient all triangles clockwise. Note that with this triangulation method, all boundary components are composed of 3 edges.

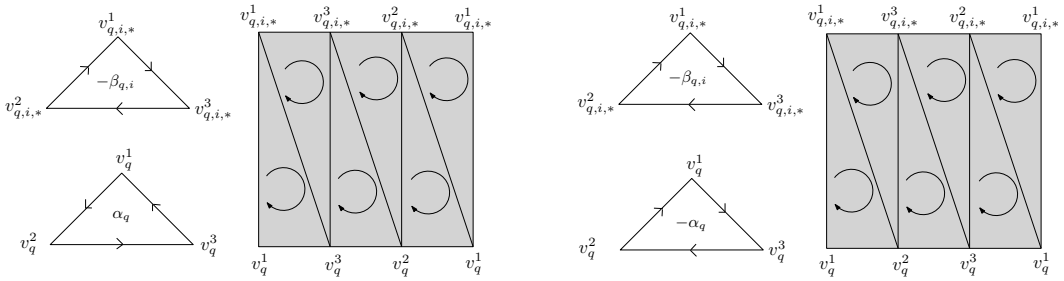
Oriented Triangulation for Tubes

A tube is defined by two boundary components. By our construction, for every tube connected to $\mathcal{S}_i$, one of the two boundary components is always $-\beta_{q,i,*}$[8], and the other one is $\pm\alpha_q$, whose orientation depends on the sign of the entry $\boldsymbol{A}(q,i)$. Without loss of generality, we orient anti-clockwise for all α_q, thus clockwise for all $-\alpha_q$. Therefore, there are two possibilities of boundary component combinations.

1. If $\boldsymbol{A}(q,i) > 0$ (see Figure 6 (a)), then the two boundary components have opposite orientations: $-\beta_{q,i,*} = [v^1_{q,i,*}, v^3_{q,i,*}, v^2_{q,i,*}]$ and $\alpha_q = [v^1_q, v^2_q, v^3_q]$. We triangulate by matching $v^1_{q,i,*}$ to v^1_q, $v^2_{q,i,*}$ to v^2_q, and $v^3_{q,i,*}$ to v^3_q.
2. If $\boldsymbol{A}(q,i) < 0$ (see Figure 6 (b)), then the two boundary components have identical orientations: $-\beta_{q,i,*} = [v^1_{q,i,*}, v^3_{q,i,*}, v^2_{q,i,*}]$ and $-\alpha_q = [v^1_q, v^3_q, v^2_q]$. We triangulate by matching $v^1_{q,i,*}$ to v^1_q, $v^3_{q,i,*}$ to v^2_q, and $v^2_{q,i,*}$ to v^3_q.

In either case, only 6 triangles and 12 edges are required for an oriented triangulation of any tube $\mathcal{T}_{q,i,*}$. Again, we orient all triangles clockwise.

[8] We introduce a third element $* \in \{1, 2\}$ in the subscript of $\beta_{q,k,*}$, which is activated only when $\boldsymbol{A}(q,k) = -2$.



(a) $\mathbf{A}(q,i) > 0$ (b) $\mathbf{A}(q,i) < 0$

Figure 6 Oriented triangulation of tubes with opposite or identical boundary orientations.

4.2 Algorithm Runtime and Problem Size

In this section, we show that the reduction algorithm ReduceDAToB2 and the solution mapping algorithm MapSolnB2toDA both run in linear time, and ReduceDAToB2 constructs a 2-complex whose size is linear in the number of nonzeros in the input linear equations.

▶ **Lemma 4.1** (Runtime). *Given a difference-average instance* LE $(\boldsymbol{A}, \boldsymbol{b})$ *where* $\boldsymbol{A} \in \mathbb{R}^{d\times n}$, *Algorithm* ReduceDAToB2$(\boldsymbol{A}, \boldsymbol{b})$ *returns* $(\partial_2, \gamma, \boldsymbol{\Delta}^c)$ *in time* $O(\mathrm{nnz}(\boldsymbol{A}))$. *Given a solution* $\boldsymbol{f}$ *to* LE (∂_2, γ), *Algorithm* MapSolnB2toDA$(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{f}, \boldsymbol{\Delta}^c)$ *returns* $\boldsymbol{x}$ *in time* $O(n)$.

Proof. For reduction, ReduceDAToB2$(\boldsymbol{A}, \boldsymbol{b})$ calls the tube triangulation subroutine for $\|\boldsymbol{A}\|_1$ times, and the punctured sphere triangulation subroutine for n times. The tube triangulation subroutine runs in time $O(1)$ since the there are a constant number of triangles in a tube; and the punctured sphere triangulation subroutine runs in time $O(\|\boldsymbol{A}(:,j)\|_1)$ for the jth call, $j \in [n]$. Putting all together, the total runtime of ReduceDAToB2$(\boldsymbol{A}, \boldsymbol{b})$ is $O\left(\|\boldsymbol{A}\|_1 + \sum_{j\in[n]} \|\boldsymbol{A}(:,j)\|_1\right) \le O(\mathrm{nnz}(\boldsymbol{A}))$, where we use the fact $\|\boldsymbol{A}\|_{\max} = 2$.

For solution mapping, the runtime of the algorithm MapSolnB2toDA is obvious. ◀

▶ **Lemma 4.2** (Size of ∂_2). *Given a difference-average instance* LE $(\boldsymbol{A}, \boldsymbol{b})$, *let* $(\partial_2, \gamma, \boldsymbol{\Delta}^c)$ *be returned by* ReduceDAToB2$(\boldsymbol{A}, \boldsymbol{b})$. *Suppose* $\partial_2 \in \mathbb{R}^{m\times t}$. *Then,*

1. $t \le 22\,\mathrm{nnz}(\boldsymbol{A})$;
2. $m \le 33\,\mathrm{nnz}(\boldsymbol{A})$;
3. $\mathrm{nnz}(\partial_2) \le 66\,\mathrm{nnz}(\boldsymbol{A})$.

Proof. We first compute the total number of triangles in the constructed 2-complex $\mathcal{K}$. For sphere $\mathcal{S}_j$, we have $\tilde{t}_j = 5b_j - 4$ triangles by (3), where $b_j = \sum_{i\in[d]} |\boldsymbol{A}(i,j)|$. Therefore, the number of triangles of all spheres is

$$\sum_{j=1}^{n} \tilde{t}_j = \sum_{j=1}^{n}(5\sum_{i\in[d]} |\boldsymbol{A}(i,j)| - 4) = 5\,\|\boldsymbol{A}\|_1 - 4n.$$

Moreover, each boundary component on spheres corresponds to a tube, and each tube has 6 triangles. Hence, the number of triangles of all tubes is $6\,\|\boldsymbol{A}\|_1$. Putting spheres and tubes together, we get

$$t = 11\,\|\boldsymbol{A}\|_1 - 4n \le 22\,\mathrm{nnz}(\boldsymbol{A}),$$

where the last inequality is because entries of $\boldsymbol{A}$ are bounded by 2.

Next, we compute the total number of edges in $\mathcal{K}$. By construction, each triangle has 3 incident edges and each edge is shared by a constant number of triangles (2 for interior edges, and 4 for boundary edges). Thus, we have

$$m \leq 1.5t \leq 33\,\mathrm{nnz}(\boldsymbol{A}).$$

Since each column of ∂_2 has exactly 3 nonzero entries, we have

$$\mathrm{nnz}(\partial_2) = 3t \leq 66\,\mathrm{nnz}(\boldsymbol{A}).$$ ◀

Two-Commodity Flow Is Equivalent to Linear Programming Under Nearly-Linear Time Reductions

Ming Ding

Abstract

We give a nearly-linear time reduction that encodes any linear program as a 2-commodity flow problem with only a small blow-up in size. Under mild assumptions similar to those employed by modern fast solvers for linear programs, our reduction causes only a polylogarithmic multiplicative increase in the size of the program, and runs in nearly-linear time. Our reduction applies to high-accuracy approximation algorithms and exact algorithms. Given an approximate solution to the 2-commodity flow problem, we can extract a solution to the linear program in linear time with only a polynomial factor increase in the error. This implies that any algorithm that solves the 2-commodity flow problem can solve linear programs in essentially the same time. Given a directed graph with edge capacities and two source-sink pairs, the goal of the 2-commodity flow problem is to maximize the sum of the flows routed between the two source-sink pairs subject to edge capacities and flow conservation. A 2-commodity flow problem can be formulated as a linear program, which can be solved to high accuracy in almost the current matrix multiplication time (Cohen-Lee-Song JACM'21). Our reduction shows that linear programs can be approximately solved, to high accuracy, using 2-commodity flow as well.

Our proof follows the outline of Itai's polynomial-time reduction of a linear program to a 2-commodity flow problem (JACM'78). Itai's reduction shows that exactly solving 2-commodity flow and exactly solving linear programming are polynomial-time equivalent. We improve Itai's reduction to nearly preserve the problem representation size in each step. In addition, we establish an error bound for approximately solving each intermediate problem in the reduction, and show that the accumulated error is polynomially bounded. We remark that our reduction does not run in strongly polynomial time and that it is open whether 2-commodity flow and linear programming are equivalent in strongly polynomial time.

1 Introduction

Multi-commodity maximum flow is a very well-studied problem, which can be formulated as a linear program. In this paper, we show that general linear programs can be very efficiently encoded as a multi-commodity maximum flow programs. Many variants of multi-commodity flow problems exist. We consider one of the simplest directed variants, 2-commodity maximum through-put flow. Given a directed graph with edge capacities and two source-sink pairs, this problem requires us to maximize the sum of the flows routed between the two source-sink pairs, while satisfying capacity constraints and flow conservation at the remaining nodes. In the rest of the paper, we will simply refer to this as *the 2-commodity flow problem*. We abbreviate this problem as 2CF. Our goal is to relate the hardness of solving 2CF to that of solving linear programs (LPs). 2-commodity flow is easily expressed as a linear program, so it is clearly no harder than solving LPs. We show that the 2-commodity flow problem can encode a linear program with only a polylogarithmic blow-up in size, when the program has polynomially bounded integer entries and polynomially bounded solution norm. Our reduction runs in nearly-linear time. Given an approximate solution to the 2-commodity flow problem, we can recover, in linear time, an approximate solution to the linear program with only a polynomial factor increase in the error. Our reduction also shows that an exact solution to the flow problem yields an exact solution to the linear program.

Multi-commodity flow problems are extremely well-studied and have been the subject of numerous surveys [23, 38, 40, 1, 50], in part because a large number of problems can be expressed as variants of multi-commodity flow. Our result shows a very strong form of this observation: In fact, general linear programs can be expressed as 2-commodity flow problems with essentially the same size. Early in the study of these problems, before a polynomial-time algorithm for linear programming was known, it was shown that the *undirected* 2-commodity flow problem can be solved in polynomial time [16]. In fact, it can be reduced to two undirected single commodity maximum flow problems. In contrast, directed 2-commodity flow problems were seemingly harder, despite the discovery of non-trivial algorithms for some special cases [8, 9].

Searching for Multi-Commodity Flow Solvers. Alon Itai [17] proved a polynomial-time reduction from linear programming to 2-commodity flow, before a polynomial-time algorithm for linear programming was known. For decades, the only major progress on solving multi-commodity flow came from improvements to general linear program solvers [24, 19, 43, 48]. Leighton et al. [33] showed that undirected capacitated k-commodity flow in a graph with m edges and n vertices can be approximately solved in $\widetilde{O}(kmn)$ time, completely routing all demands with $1+\epsilon$ times the optimal congestion, albeit with a poor dependence on the error parameter ϵ. This beats solve-times for linear programming in sparse graphs for small k, even with today's LP solvers that run in current matrix multiplication time, albeit with much worse error. This result spurred a number of follow-up works with improvements for low-accuracy algorithms [14, 11, 35]. Later, breakthroughs in achieving almost- and nearly-linear time algorithms for undirected single-commodity maximum flow also lead to faster algorithms for undirected k-commodity flow [21, 45, 41], culminating in Sherman's introduction of area-convexity to build a $\widetilde{O}(mk\epsilon^{-1})$ time algorithm for approximate undirected k-commodity flow [46].

Solving Single-Commodity Flow Problems. Single commodity flow problems have been an area of tremendous success for the development of graph algorithms, starting with an era of algorithms influenced by early results on maximum flow and minimum cut [12] and later

the development of powerful combinatorial algorithms for maximum flow with polynomially bounded edge capacities [7, 10, 15]. Later, a breakthrough nearly-linear time algorithm for electrical flows by Spielman and Teng [47] lead to the *Laplacian paradigm*. A long line of work explored direct improvements and simplifications of this result [25, 26, 22, 42, 28, 18]. This also motivated a new line of research on undirected maximum flow [3, 31, 21, 45], which in turn lead to faster algorithms for directed maximum flow and minimum cost flow [36, 37, 34, 20, 49, 13] building on powerful tools using mixed-ℓ_2, ℓ_p-norm minimizing flows [27] and inverse-maintenance ideas [2]. Certain developments are particularly relevant to our result: For a graph $G = (V, E)$ these works established high-accuracy algorithms with $\widetilde{O}(|E|)$ running time for computing electrical flow [47] and $O(|E|^{4/3})$ running time for unit capacity directed maximum flow [36, 20], and $\widetilde{O}(\min(|E|^{1.497}, |E| + |V|^{1.5}))$ running time for directed maximum flow with general capacities [13, 49].

Solving General Linear Programs. As described in the previous paragraphs, there has been tremendous success in developing fast algorithms for single-commodity flow problems and undirected multi-commodity flow problems, albeit in the latter case only in the low-accuracy regime (as the algorithm running times depend polynomially on the error parameter). In contrast, the best known algorithms for directed multi-commodity flow simply treat the problem as a general linear program, and use a solver for general linear programs.

The fastest known solvers for general linear programs are based on interior point methods [19], and in particular central path methods [43]. Recently, there has been significant progress on solvers for general linear programs, but the running time required to solve a linear program with roughly n variables and $\widetilde{O}(n)$ constraints (assuming polynomially bounded entries and polytope radius) is stuck at the $\widetilde{O}(n^{2.372\cdots})$, the running time provided by LP solvers that run in current matrix multiplication time [4]. Note that this running time is in the RealRAM model, and this algorithm cannot be translated to fixed point arithmetic with polylogarithmic bit complexity per number without additional assumptions on the input, as we describe the paragraphs on numerical stability below. To compare these running times with those for single-commodity maximum flow algorithms on a graph with $|V|$ vertices and $|E|$ edges, observe that in a sparse graph with $|E| = \widetilde{O}(|V|)$, by writing the maximum flow problem as a linear program, we can solve it using general linear program solvers and obtain a running time of $\widetilde{O}(|V|^{2.372\cdots})$, while the state-of-the art maximum flow solver obtains a running time of $\widetilde{O}(|V|^{1.497})$ on such a sparse graph. On dense graphs with $|E| = \Theta(|V|^2)$, the gap is smaller but still substantial: The running time is $\widetilde{O}(|V|^2)$ using maximum flow algorithms vs. $\widetilde{O}(|V|^{2.372\cdots})$ using general LP algorithms.

How Hard Is It to Solve Multi-Commodity Flow? The many successes in developing high-accuracy algorithms for single-commodity flow problems highlight an important open question: Can multi-commodity flow be solved to high accuracy faster than general linear programs? We rule out this possibility, by proving that any linear program (assuming it is polynomially bounded and has integer entries) can be encoded as a multi-commodity flow problem in nearly-linear time. This implies that any improvement in the running time of (high-accuracy) algorithms for sparse multi-commodity flow problems would directly translate to a faster algorithm for solving sparse linear programs to high accuracy, with only a polylogarithmic increase in running time.

Previous work by Kyng and Zhang [30] had shown that fast algorithms for multi-commodity flow were unlikely to arise from combining interior point methods with special-purpose linear equation solvers. Concretely, they showed that the linear equations that arise

in interior point methods for multi-commodity flow are as hard to solve as arbitrary linear equations. This ruled out algorithms following the pattern of the known fast algorithms for high-accuracy single-commodity flow problems. However, it left open the broader question if some other family of algorithms could succeed. We now show that, in general, a separation between multi-commodity flow and linear programming is not possible.

1.1 Background: Numerical Stability of Linear Program Solvers and Reductions

Current research on fast algorithms for solving linear programs generally relies on assuming bounds on (1) the size of the program entries and (2) the norm of all feasible solutions. Generally, algorithm running time depends logarithmically on these quantities, and hence to make these factors negligible, entry size and feasible solution norms are assumed to be polynomially bounded, for example in [4]. We will refer to a linear program satisfying these assumptions as *polynomially bounded*. More precisely, we say a linear program with N non-zero coefficients is *polynomially bounded* if it has coefficients in the range $[-X, X]$ and $\|\boldsymbol{x}\|_1 \leq R$ for all feasible $\boldsymbol{x}$ (i.e. the polytope of feasible solutions has radius of R in ℓ_1 norm), and $X, R \leq O(N^c)$ for some constant c. In fact, if there exists a feasible solution $\boldsymbol{x}$ satisfying $\|\boldsymbol{x}\|_1 \leq R$, then we can add a constraint $\|\boldsymbol{x}\|_1 \leq R$ to the LP (which can be rewritten as linear inequality constraints) so that in the new LP, all feasible solutions have ℓ_1 norm at most R. This only increases the number of nonzeros in the LP by at most a constant factor.

Interior Point Methods and Reductions With Fixed Point Arithmetic. Modern fast interior point methods for linear programming, such as [4], are analyzed in the RealRAM model. In order to implement these algorithms using *fixed point arithmetic* with polylogarithmic bit complexity per number, instead of RealRAM, additional assumptions are required. For example, this class of algorithms relies on computing matrix inverses, and these must be approximately representable using polylogarithmic bit complexity per entry. This is not possible, if the inverses have exponentially large entries, which may occur even in polynomially bounded linear programs. For example, consider a linear program feasibility problem $\boldsymbol{A}\boldsymbol{x} \leq \boldsymbol{b}, \boldsymbol{x} \geq \boldsymbol{0}$, with constraint matrix $\boldsymbol{A} \in \mathbb{R}^{2n \times 2n}$ given by

$$\boldsymbol{A}(i,j) = \begin{cases} 1 & \text{if } i < n \text{ and } i = j \\ -2 & \text{if } i < n \text{ and } i+1 = j \\ 2 & \text{if } i \geq n \text{ and } i = j \\ -1 & \text{if } i \geq n \text{ and } i+1 = j \\ 0 & \text{o.w.} \end{cases}$$

Such a linear program is polynomially bounded for many choices of $\boldsymbol{b}$, e.g. $\boldsymbol{b} = \boldsymbol{e}_{2n}$. Unfortunately, for the vector $\boldsymbol{x} \in \mathbb{R}^{2n}$ given by

$$\boldsymbol{x}(i) = \begin{cases} 2^{-i-1} & \text{if } i \leq n \\ 0 & \text{o.w.} \end{cases}$$

we have $\boldsymbol{A}\boldsymbol{x} = 2^{-n}\boldsymbol{e}_n$, and from this one can see that $\boldsymbol{A}^{-1}$ must have entries of size at least $\Omega(2^n/n)$. This will cause algorithms such as [4] to perform intermediate calculations with n bits per number, increasing the running time by a factor roughly n.

Modern interior point methods can be translated to fixed precision arithmetic with various different assumptions leading to different per entry bit complexity (see [4] for a discussion of one standard sufficient condition). Furthermore, if the problem has polynomially bounded

condition number (when appropriately defined), then we expect that polylogarithmic bit complexity per entry should suffice, at least for highly accurate approximate solutions, by relying on fast stable numerical linear algebra [5], although we are not aware of a complete analysis of this translation.

If a linear program with integer entries is solved to sufficiently small additive error, the approximate solution can be converted into an exact solution, e.g. see [43, 32, 4] for a discussion of the necessary precision and for a further discussion of numerical stability properties of interior point methods. Polynomially bounded linear programs with integer coefficients may still require exponentially small additive error for this rounding to succeed.

We give a reduction from general linear programming to 2-commodity flow, and like [4], we assume the program is polynomially bounded to carry out the reduction. We also use an additional assumption, namely that the linear program is written using integral entries[1]. We do not make additional assumptions about polynomially bounded condition number of problem. This means we can apply our reduction to programs such as the one above, despite [4] not obtaining a reasonable running time on such programs using fixed point arithmetic.

Our analysis of our reduction uses the RealRAM model like [4] and other modern interior point method analysis, however, it should be straightforward to translate our reduction and error analysis to fixed point arithmetic with polylogarithmically many bits, because all our mappings are simple linear transformations, and we never need to compute or apply a matrix inverse.

Rounding Linear Programs to Have Integer Entries. It is possible to give some fairly general and natural sufficient conditions for when a polynomially bounded linear program can be rounded to have integral entries, one example of this is having a polynomially bounded *Renegar's condition number*. Renegar introduced this condition number for linear programs in [44]. For a given linear program, suppose that perturbing the entries of the program by at most δ each does not change the feasibility of the the linear program, and let δ^* be the largest such δ. Let U denote the maximum absolute value of entries in the linear program. Then $\kappa = U/\delta^*$ is Renegar's condition number for the linear program.

Suppose we are given a polynomially bounded linear program $\max\{\boldsymbol{c}^\top \boldsymbol{x} : \boldsymbol{A}\boldsymbol{x} \leq \boldsymbol{b}, \boldsymbol{x} \geq \boldsymbol{0}\}$ (also referred to as $(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c})$), with polytope radius at most R, and Renegar's condition number κ also bounded by a polynomial. We wish to compute a vector $\boldsymbol{x} \geq \boldsymbol{0}$ with an ϵ additive error on each constraint and in the optimal value. We can reduce this problem for instance $(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c})$ to a polynomially bounded linear program instance with integral input numbers. Specifically, we round the entries of $\boldsymbol{A}$ down to $\tilde{\boldsymbol{A}}$ and those of $\boldsymbol{b}, \boldsymbol{c}$ up to $\tilde{\boldsymbol{b}}, \tilde{\boldsymbol{c}}$ all by at most $\min\{\frac{\epsilon}{3R}, \frac{U}{\kappa R}\}$ such that each entry of $\tilde{\boldsymbol{A}}, \tilde{\boldsymbol{b}}, \tilde{\boldsymbol{c}}$ only needs a logarithmic number of bits. Suppose $\tilde{\boldsymbol{x}}$ is a solution to $(\tilde{\boldsymbol{A}}, \tilde{\boldsymbol{b}}, \tilde{\boldsymbol{c}})$ with $\frac{\epsilon}{3}$ additive error on each constraint and in the optimal value. Then,

$$\boldsymbol{A}\tilde{\boldsymbol{x}} = \tilde{\boldsymbol{A}}\tilde{\boldsymbol{x}} + (\boldsymbol{A} - \tilde{\boldsymbol{A}})\tilde{\boldsymbol{x}} \leq \boldsymbol{b} + \epsilon\boldsymbol{1}, \qquad \boldsymbol{c}^\top \tilde{\boldsymbol{x}} \geq \tilde{\boldsymbol{c}}^\top \tilde{\boldsymbol{x}}^* - \frac{2}{3}\epsilon$$

where $\boldsymbol{1}$ is the all-one vector, $\tilde{\boldsymbol{x}}^*$ is an optimal solution to $(\tilde{\boldsymbol{A}}, \tilde{\boldsymbol{b}}, \tilde{\boldsymbol{c}})$. In addition, the optimal value of $(\tilde{\boldsymbol{A}}, \tilde{\boldsymbol{b}}, \tilde{\boldsymbol{c}})$ is greater than or equal to that of $(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c})$. So, $\tilde{\boldsymbol{x}}$ is a solution to $(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c})$ with ϵ additive error as desired. Since each entry of $\tilde{\boldsymbol{A}}, \tilde{\boldsymbol{b}}, \tilde{\boldsymbol{c}}$ has a logarithmic number of bits,

[1] W.l.o.g., by scaling, this is the same as assuming the program is written with polynomially bounded fixed precision numbers of the form k/D where k is an integer, and D is an integral denominator shared across all entries, and both k and D are polynomially bounded.

we can scale all of them to polynomially bounded integers without changing the feasible set and the optimal solutions. Thus we see that if we restrict ourselves to polynomially linear programs with polynomially bounded Renegar's condition number, and we wish to solve the program with small additive error, we can assume without loss of generality that the program has integer coefficients.

1.2 Previous Work

Our paper follows the proof by Itai [17] that linear programming is polynomial-time reducible to 2-commodity flow. However, it is also inspired by recent works on hardness for structured linear equations [30] and packing/covering LPs [29], which focused on obtaining nearly-linear time reductions in somewhat related settings. These works in turn were motivated by the last decade's substantial progress on fine-grained complexity for a range of polynomial time solvable problems, e.g. see [51]. Also notable is the result by Musco et al. [39] on hardness for matrix spectrum approximation.

1.3 Our Contributions

In this paper, we explore the hardness of 2-commodity maximum throughput flow, which for brevity we refer to as the 2-commodity flow problem or 2CF. We relate the difficulty of 2CF to that of linear programming (LP) by developing an extremely efficient reduction from the former to the latter. The main properties of our reduction are described by the informal theorem statement below. We give a formal statement of Theorem 1.1 as Theorem 3.1 in Section 3.

▶ **Theorem 1.1** (Main Theorem (Informal)). *Consider any polynomially bounded linear program* $\max\{\boldsymbol{c}^\top \boldsymbol{x} : \boldsymbol{A}\boldsymbol{x} \leq \boldsymbol{b}, \boldsymbol{x} \geq \boldsymbol{0}\}$ *with integer coefficients and N non-zero entries. In nearly-linear time, we can convert this linear program to a 2-commodity flow problem which is feasible if and only if the original program is. The 2-commodity flow problem has $\widetilde{O}(N)$ edges and has polynomially bounded integral edge capacities. Furthermore, any solution to the 2-commodity flow instance with at most ϵ additive error on each constraint and value at most ϵ from the optimum can be converted to a solution to the original linear program with additive error $\widetilde{O}(\text{poly}(N)\epsilon)$ on each constraint and similarly value within $\widetilde{O}(\text{poly}(N)\epsilon)$ of the optimum.*

This implies that, for any constant $a > 1$, if any 2-commodity flow instance with polynomially bounded integer capacities can be solved with ϵ additive error in time $\widetilde{O}\left(|E|^a \cdot \text{poly}\log(1/\epsilon)\right)$, then any polynomially bounded linear program can be solved to ϵ additive error in time $\widetilde{O}\left(N^a \cdot \text{poly}\log(1/\epsilon)\right)$.

Note that in our definition any 2CF problem is already an LP, and so no reduction in the other direction is necessary. Our notion of approximate solutions to LPs and 2CF problems is also such that treating a 2CF problem as an LP and solving it approximately ensures that the 2CF is approximately solved w.r.t. to the our approximate solution definition for 2CF.

We obtain Theorem 1.1, our main result, by making several improvements to Itai's reduction from LP to 2CF. Recall that a linear program with N non-zero coefficients is polynomially bounded if it has coefficients in the range $[-X, X]$ and $\|\boldsymbol{x}\|_1 \leq R$ for all feasible $\boldsymbol{x}$, where $X, R \leq O(N^c)$ for some constant c. Firstly, while Itai produced a 2CF with the number of edges on the order of $\Theta\left(N^2 \log^2 X\right)$, we show that an improved gadget can reduce this to $O\left(N \log X\right)$. Thus, in the case of polynomially bounded linear programs, where $\log X = O(\log N)$, we get an only polylogarithmic multiplicative increase in the number of non-zero entries from N to $\widetilde{O}(N)$, whereas Itai had an increase in the number of nonzeros by a factor $\widetilde{O}(N)$, from N to $\widetilde{O}(N^2)$.

Secondly, Itai used very large graph edge capacities that require $O\left((N \log X)^{1.01}\right)$ many bits *per edge*, letting the capacities grow exponentially given an LP with polynomially bounded entries. We show that when the feasible polytope radius R is bounded, we can ensure capacities remain a polynomial function of the initial parameters N, R, and X. In the important case of polynomially bounded linear programs, this means the capacities stay polynomially bounded.

Thirdly, while Itai only analyzed the chain of reductions under the case with exact solutions, we generalize the analysis to the case with approximate solutions by establishing an error analysis along the chain of reductions. We show that the error only grows polynomially during the reduction. Moreover, to simplify our error analysis, we observe that additional structures can be established in many of Itai's reductions. For instance, we propose the notion of a *fixed flow network*, which consists of a subset of edges with equal lower and upper bound of capacity. It is a simplification of Itai's (l, u) network with general capacity (both lower and upper bounds on the amount of flow).

Open Problems. Our reductions do not suffice to prove that a strongly polynomial time algorithm for 2-commodity flow would imply a strongly polynomial time algorithm for linear programming. In a similar vein, it is unclear if a more efficient reduction could exist for the case of linear programs that are not polynomially bounded. We leave these as very interesting open problems.

Finally, our reductions do not preserve the "shape" of the linear program, in particular, a dense linear program may be reduced to a sparse 2-commodity flow problem with a similar number of edges as there are non-zero entries in the original program. It would be interesting to convert a dense linear program into a dense 2-commodity flow problem, e.g. to convert a linear program with m constraints and n variables (say, $m \leq n$) into a 2-commodity flow problem with $\widetilde{O}(n)$ edges and $\widetilde{O}(m)$ vertices.

2 Preliminaries

2.1 Notation

Matrices and Vectors. We use parentheses to denote entries of a matrix or a vector: Let $\boldsymbol{A}(i, j)$ denote the (i, j)th entry of a matrix $\boldsymbol{A}$, and let $\boldsymbol{x}(i)$ denote the ith entry of a vector $\boldsymbol{x}$. Given a matrix $\boldsymbol{A} \in \mathbb{R}^{m \times n}$, we use $\boldsymbol{a}_i^\top$ to denote the ith row of a matrix $\boldsymbol{A}$ and $\mathrm{nnz}(\boldsymbol{A})$ to denote the number of nonzero entries of $\boldsymbol{A}$. Without loss of generality, we assume that $\mathrm{nnz}(\boldsymbol{A}) \geq \max\{m, n\}$. For any vector $\boldsymbol{x} \in \mathbb{R}^n$, we define $\|\boldsymbol{x}\|_{\max} = \max_{i \in [n]} |\boldsymbol{x}(i)|$, $\|\boldsymbol{x}\|_1 = \sum_{i \in [n]} |\boldsymbol{x}(i)|$. For any matrix $\boldsymbol{A} \in \mathbb{R}^{m \times n}$, we define $\|\boldsymbol{A}\|_{\max} = \max_{i,j} |\boldsymbol{A}(i, j)|$.

We define a function X that takes an arbitrary number of matrices $\boldsymbol{A}_1, \ldots, \boldsymbol{A}_{k_1}$, vectors $\boldsymbol{b}_1, \ldots, \boldsymbol{b}_{k_2}$, and scalars $K_1, \ldots, K_{k_3}$ as arguments, and returns the maximum of $\|\cdot\|_{\max}$ of all the arguments, i.e.,

$$X(\boldsymbol{A}_1, \ldots, \boldsymbol{A}_{k_1}, \boldsymbol{b}_1, \ldots, \boldsymbol{b}_{k_2}, K_1, \ldots, K_{k_3}) = \max\left\{\|\boldsymbol{A}_1\|_{\max}, \ldots, \|\boldsymbol{A}_{k_1}\|_{\max}, \|\boldsymbol{b}_1\|_{\max}, \ldots, \|\boldsymbol{b}_{k_2}\|_{\max}, |K_1|, \ldots, |K_{k_3}|\right\}.$$

2.2 Problem Definitions

In this section, we formally define the problems that we use in the reduction. These problems fall into two categories: one is related to linear programming and linear equations, and the other is related to flow problems in graphs. In addition, we define the errors for approximately solving these problems.

2.2.1 Linear Programming and Linear Equations With Positive Variables

For the convenience of our reduction, we define linear programming as a "decision" problem. We can solve the optimization problem $\max\{\boldsymbol{c}^\top \boldsymbol{x} : \boldsymbol{A}\boldsymbol{x} \leq \boldsymbol{b}, \boldsymbol{x} \geq \boldsymbol{0}\}$ by binary searching its optimal value via the decision problem.

▶ **Definition 2.1** (Linear Programming (LP)). *Given a matrix $\boldsymbol{A} \in \mathbb{Z}^{m\times n}$, vectors $\boldsymbol{b} \in \mathbb{Z}^m$ and $\boldsymbol{c} \in \mathbb{Z}^n$, an integer K, and $R \geq \max\{1, \max\{\|\boldsymbol{x}\|_1 : \boldsymbol{A}\boldsymbol{x} \leq \boldsymbol{b}, \boldsymbol{x} \geq \boldsymbol{0}\}\}$, we refer to the LP problem for $(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c}, K, R)$ as the problem of finding a vector $\boldsymbol{x} \in \mathbb{R}^n_{\geq 0}$ satisfying*

$$\boldsymbol{A}\boldsymbol{x} \leq \boldsymbol{b} \text{ and } \boldsymbol{c}^\top \boldsymbol{x} \geq K$$

if such an $\boldsymbol{x}$ exists and returning "infeasible" otherwise.

We will reduce linear programming to linear equations with nonnegative variables (LEN), and then to linear equations with nonnegative variables and small integer coefficients (k-LEN).

▶ **Definition 2.2** (Linear Equations with Nonnegative Variables (LEN)). *Given $\boldsymbol{A} \in \mathbb{Z}^{m\times n}$, $\boldsymbol{b} \in \mathbb{Z}^m$, and $R \geq \max\{1, \max\{\|\boldsymbol{x}\|_1 : \boldsymbol{A}\boldsymbol{x} = \boldsymbol{b}, \boldsymbol{x} \geq \boldsymbol{0}\}\}$, we refer to the LEN problem for $(\boldsymbol{A}, \boldsymbol{b}, R)$ as the problem of finding a vector $\boldsymbol{x} \in \mathbb{R}^n_{\geq 0}$ satisfying $\boldsymbol{A}\boldsymbol{x} = \boldsymbol{b}$ if such an $\boldsymbol{x}$ exists and returning "infeasible" otherwise.*

▶ **Definition 2.3** (k-LEN (k-LEN)). *The k-LEN problem is an LEN problem $(\boldsymbol{A}, \boldsymbol{b}, R)$ where the entries of $\boldsymbol{A}$ are integers in $[-k, k]$ for some given $k \in \mathbb{Z}_+$.*

We employ the following additive error notion. We append a letter "A" to each problem name to denote its approximation version, e.g., LP Approximate Problem is abbreviated to LPA.

▶ **Definition 2.4** (Approximation Errors). *We always require $\boldsymbol{x} \geq \boldsymbol{0}$. In addition,*

1. *Error in objective: $\boldsymbol{c}^\top \boldsymbol{x} \geq K$ is relaxed to $\boldsymbol{c}^\top \boldsymbol{x} \geq K - \epsilon$;*
2. *Error in constraint:*
   a. *The inequality constraint $\boldsymbol{A}\boldsymbol{x} \leq \boldsymbol{b}$ is relaxed to $\boldsymbol{A}\boldsymbol{x} - \boldsymbol{b} \leq \epsilon\boldsymbol{1}$, where $\boldsymbol{1}$ is the all-1 vector;*
   b. *The equality constraint $\boldsymbol{A}\boldsymbol{x} = \boldsymbol{b}$ is relaxed to $\|\boldsymbol{A}\boldsymbol{x} - \boldsymbol{b}\|_\infty \leq \epsilon$.*

Based on Definition 2.4, we can define the approximate version of LP. The approximate version of LEN and k-LEN can be found in the full version of the paper [6].

▶ **Definition 2.5** (LP Approximate Problem (LPA)). *An LPA instance is given by an LP instance $(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c}, K, R)$ and an error parameter $\epsilon \in [0, 1]$, which we collect in a tuple $(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c}, K, R, \epsilon)$. We say an algorithm solves the LPA problem, if, given any LPA instance, it returns a vector $\boldsymbol{x} \geq \boldsymbol{0}$ such that*

$$\boldsymbol{c}^\top \boldsymbol{x} \geq K - \epsilon$$
$$\boldsymbol{A}\boldsymbol{x} \leq \boldsymbol{b} + \epsilon\boldsymbol{1}$$

where $\boldsymbol{1}$ is the all-1 vector, or it correctly declares that the associated LP instance is infeasible.

2.2.2 Flow Problems

A *flow network* is a directed graph $G = (V, E)$, where V is the set of vertices and $E \subset V \times V$ is the set of edges, together with a vector of edge capacities $\boldsymbol{u} \in \mathbb{Z}^{|E|}_{>0}$ that upper bound the amount of flow passing each edge. A *2-commodity flow network* is a flow network together with two source-sink pairs $s_i, t_i \in V$ for each commodity $i \in \{1, 2\}$.

Given a 2-commodity flow network $(G = (V, E), \boldsymbol{u}, s_1, t_1, s_2, t_2)$, a *feasible 2-commodity flow* is a pair of flows $\boldsymbol{f}_1, \boldsymbol{f}_2 \in \mathbb{R}^{|E|}_{\geq 0}$ that satisfies

1. capacity constraint: $\boldsymbol{f}_1(e) + \boldsymbol{f}_2(e) \leq \boldsymbol{u}(e),\ \forall e \in E$, and
2. conservation of flows: $\sum_{u:(u,v)\in E} \boldsymbol{f}_i(u,v) = \sum_{w:(v,w)\in E} \boldsymbol{f}_i(v,w),\ \forall i \in \{1,2\}, v \in V \setminus \{s_i, t_i\}$[2].

Similar to the definition of LP, we define 2-commodity flow problem as a decision problem. We can solve a decision problem by solving the corresponding optimization problem.

▶ **Definition 2.6** (2-Commodity Flow Problem (2CF)). *Given a 2-commodity flow network $(G, \boldsymbol{u}, s_1, t_1, s_2, t_2)$ together with $R \geq 0$, we refer to the 2CF problem for $(G, \boldsymbol{u}, s_1, t_1, s_2, t_2, R)$ as the problem of finding a feasible 2-commodity flow $\boldsymbol{f}_1, \boldsymbol{f}_2 \geq \boldsymbol{0}$ satisfying*

$$F_1 + F_2 \geq R$$

if such flows exist and returning "infeasible" otherwise.

To reduce LP to 2CF, we need a sequence of variants of flow problems.

▶ **Definition 2.7** (2-Commodity Flow with Required Flow Amount (2CFR)). *Given a 2-commodity flow network $(G, \boldsymbol{u}, s_1, t_1, s_2, t_2)$ together with $R_1, R_2 \geq 0$, we refer to the 2CFR for $(G, \boldsymbol{u}, s_1, t_1, s_2, t_2, R_1, R_2)$ as the problem of finding a feasible 2-commodity flow $\boldsymbol{f}_1, \boldsymbol{f}_2 \geq \boldsymbol{0}$ satisfying*

$$F_1 \geq R_1, \quad F_2 \geq R_2$$

if such flows exist and returning "infeasible" otherwise.

▶ **Definition 2.8** (Fixed Flow Constraints). *Given a set $F \subseteq E$ in a 2-commodity flow network, we say the flows $\boldsymbol{f}_1, \boldsymbol{f}_2 \geq \boldsymbol{0}$ satisfy* fixed flow constraints on F *if*

$$\boldsymbol{f}_1(e) + \boldsymbol{f}_2(e) = \boldsymbol{u}(e),\ \forall e \in F.$$

Similarly, given a set $F \subseteq E$ in a 1-commodity flow network, we say the flow $\boldsymbol{f} \geq \boldsymbol{0}$ satisfies fixed flow constraints on F *if*

$$\boldsymbol{f}(e) = \boldsymbol{u}(e),\ \forall e \in F.$$

▶ **Definition 2.9** (2-Commodity Fixed Flow Problem (2CFF)). *Given a 2-commodity flow network $(G, \boldsymbol{u}, s_1, t_1, s_2, t_2)$ together with a subset of edges $F \subseteq E$, we refer to the 2CFF problem for the tuple $(G, F, \boldsymbol{u}, s_1, t_1, s_2, t_2)$ as the problem of finding a feasible 2-commodity flow $\boldsymbol{f}_1, \boldsymbol{f}_2 \geq \boldsymbol{0}$ which also satisfies the fixed flow constraints on F if such flows exist and returning "infeasible" otherwise.*

▶ **Definition 2.10** (Selective Fixed Flow Problem (SFF)). *Given a 2-commodity network $(G, \boldsymbol{u}, s_1, t_1, s_2, t_2)$ together with three edge sets $F, S_1, S_2 \subseteq E$, we refer to the SFF problem for $(G, F, S_1, S_2, \boldsymbol{u}, s_1, t_1, s_2, t_2)$ as the problem of finding a feasible 2-commodity flow $\boldsymbol{f}_1, \boldsymbol{f}_2 \geq \boldsymbol{0}$ such that for each $i \in \{1,2\}$, flow $\boldsymbol{f}_i(e) > 0$ only if $e \in S_i$, and $\boldsymbol{f}_1, \boldsymbol{f}_2$ satisfy the fixed flow constraints on F, if such flows exist, and returning "infeasible" otherwise.*

▶ **Definition 2.11** (Fixed Homologous Flow Problem (FHF)). *Given a flow network with a single source-sink pair $(G, \boldsymbol{u}, s, t)$ together with a collection of disjoint subsets of edges $\mathcal{H} = \{H_1, \ldots, H_h\}$ and a subset of edges $F \subseteq E$ such that F is disjoint from all the sets in $\mathcal{H}$, we refer to the FHF problem for $(G, F, \mathcal{H}, \boldsymbol{u}, s, t)$ as the problem of finding a feasible flow $\boldsymbol{f} \geq \boldsymbol{0}$ such that*

[2] Note that for commodity i, this constraint includes the case of $v \in \{s_{\bar{i}}, t_{\bar{i}}\}, \bar{i} = \{1,2\} \setminus i$.

$$\boldsymbol{f}(e_1) = \boldsymbol{f}(e_2), \quad \forall e_1, e_2 \in H_k, 1 \le k \le h,$$

and $\boldsymbol{f}$ satisfies the fixed flow constraints on F, if such flows exist, and returning "infeasible" otherwise.

▶ **Definition 2.12** (Fixed Pair Homologous Flow Problem (FPHF)). *An FPHF is an FHF problem $(G, F, \mathcal{H}, \boldsymbol{u}, s, t)$ where every set in $\mathcal{H}$ has size 2.*

Now, we define errors for the above flow problems.

▶ **Definition 2.13** (Approximation Errors). *We always require flows $\boldsymbol{f} \ge \boldsymbol{0}$ and $\boldsymbol{f}_1, \boldsymbol{f}_2 \ge \boldsymbol{0}$. In addition,*

1. *Error in congestion: the capacity constraints are relaxed to:*

$$\boldsymbol{f}_1(e) + \boldsymbol{f}_2(e) \le \boldsymbol{u}(e) + \epsilon, \quad \forall e \in E.$$

There are several variants corresponding to different flow problems.

   a. *If $e \in F$ is a fixed-flow edge, the fixed-flow constraints are relaxed to*

$$\boldsymbol{u}(e) - \epsilon \le \boldsymbol{f}_1(e) + \boldsymbol{f}_2(e) \le \boldsymbol{u}(e) + \epsilon, \quad \forall e \in F$$

   b. *If G is a 1-commodity flow network, we replace $\boldsymbol{f}_1(e) + \boldsymbol{f}_2(e)$ by $\boldsymbol{f}(e)$.*

2. *Error in demand: the conservation of flows is relaxed to*

$$\left| \sum_{u:(u,v)\in E} \boldsymbol{f}_i(u,v) - \sum_{w:(v,w)\in E} \boldsymbol{f}_i(v,w) \right| \le \epsilon, \ \forall v \in V \backslash \{s_i, t_i\}, i \in \{1,2\} \tag{1}$$

There are several variants of this constraint corresponding to different flow problems.

   a. *If the problem is with flow requirement F_i, then besides Eq. (1), we add demand constraints for s_i and t_i with respect to commodity i:*

$$\left| \sum_{w:(s_i,w)\in E} \boldsymbol{f}_i(s_i,w) - F_i \right| \le \epsilon, \qquad \left| \sum_{u:(u,t_i)\in E} \boldsymbol{f}_i(u,t_i) - F_i \right| \le \epsilon, \ i \in \{1,2\} \tag{2}$$

   b. *If G is a 1-commodity flow network, Eq. (1) can be simplified as*

$$\left| \sum_{u:(u,v)\in E} \boldsymbol{f}(u,v) - \sum_{w:(v,w)\in E} \boldsymbol{f}(v,w) \right| \le \epsilon, \ \forall v \in V \backslash \{s,t\}$$

3. *Error in type: the selective constraints are relaxed to*

$$\boldsymbol{f}_{\bar{i}}(e) \le \epsilon, \quad \forall e \in S_i, \ \bar{i} = \{1,2\} \backslash i.$$

4. *Error in (pair) homology: the (pair) homologous constraints are relaxed to*

$$|\boldsymbol{f}(e_1) - \boldsymbol{f}(e_2)| \le \epsilon, \ \forall e_1, e_2 \in H_k, H_k \in \mathcal{H}.$$

Based on Definition 2.13, we define the approximate version of 2CF. Again, the approximate version of the rest flow problems can be found in the full version of the paper [6].

▶ **Definition 2.14** (2CF Approximate Problem (2CFA)). *A 2CFA instance is given by a 2CF instance* $(G, \boldsymbol{u}, s_1, t_1, s_2, t_2, R)$ *and an error parameter* $\epsilon \in [0, 1]$*, which we collect in a tuple* $(G, \boldsymbol{u}, s_1, t_1, s_2, t_2, R, \epsilon)$*. We say an algorithm solves the 2CFA problem, if, given any 2CFA instance, it returns a pair of flows* $\boldsymbol{f}_1, \boldsymbol{f}_2 \geq 0$ *that satisfies*

$$\boldsymbol{f}_1(e) + \boldsymbol{f}_2(e) \leq \boldsymbol{u}(e) + \epsilon, \ \forall e \in E \tag{3}$$

$$\left| \sum_{u:(u,v)\in E} \boldsymbol{f}_i(u,v) - \sum_{w:(v,w)\in E} \boldsymbol{f}_i(v,w) \right| \leq \epsilon, \ \forall v \in V \backslash \{s_i, t_i\}, i \in \{1,2\} \tag{4}$$

$$\left| \sum_{w:(s_i,w)\in E} \boldsymbol{f}_i(s_i,w) - F_i \right| \leq \epsilon, \qquad \left| \sum_{u:(u,t_i)\in E} \boldsymbol{f}_i(u,t_i) - F_i \right| \leq \epsilon, \ i \in \{1,2\} \tag{5}$$

where $F_1 + F_2 = R$ [3]*; or it correctly declares that the associated 2CF instance is infeasible. We refer to the error in* (3) *as error in congestion, error in* (4) *and* (5) *as error in demand.*

3 Main Results

▶ **Theorem 3.1.** *Given an LPA instance* $(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c}, K, R, \epsilon^{lp})$ *where* $\boldsymbol{A} \in \mathbb{Z}^{m\times n}, \boldsymbol{b} \in Z^m, \boldsymbol{c} \in \mathbb{Z}^n, K \in \mathbb{Z}, \epsilon^{lp} \geq 0$ *and* $\boldsymbol{A}$ *has* $\operatorname{nnz}(\boldsymbol{A})$ *nonzero entries, we can reduce it to a 2CFA instance* $(G = (V, E), \boldsymbol{u}, s_1, t_1, s_2, t_2, R^{2cf}, \epsilon^{2cf})$ *in time* $O(\operatorname{nnz}(\boldsymbol{A}) \log X)$ *where* $X = X(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c}, K)$*, such that*

$$|V|, |E| = O(\operatorname{nnz}(\boldsymbol{A}) \log X),$$
$$\|\boldsymbol{u}\|_{\max}, R^{2cf} = O(\operatorname{nnz}^3(\boldsymbol{A}) R X^2 \log^2 X),$$
$$\epsilon^{2cf} = \Omega\left(\frac{1}{\operatorname{nnz}^7(\boldsymbol{A}) R X^3 \log^6 X}\right) \epsilon^{lp}.$$

If the LP instance $(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c}, K, R)$ *has a solution, then the 2CF instance* $(G^{2cf}, \boldsymbol{u}^{2cf}, s_1, t_1, s_2, t_2, R^{2cf})$ *has a solution. Furthermore, if* $\boldsymbol{f}^{2cf}$ *is a solution to the 2CFA (2CF) instance, then in time* $O(\operatorname{nnz}(\boldsymbol{A}) \log X)$*, we can compute a solution* $\boldsymbol{x}$ *to the LPA (LP, respectively) instance, where the exact case holds when* $\epsilon^{2cf} = \epsilon^{lp} = 0$*.*

Our main theorem immediately implies the following corollary.

▶ **Corollary 3.2.** *If we can solve any 2CFA instance* $(G = (V, E), \boldsymbol{u}, s_1, t_1, s_2, t_2, R^{2cf}, \epsilon)$ *in time* $O\left(|E|^c \operatorname{poly}\log\left(\frac{\|\boldsymbol{u}\|_1}{\epsilon}\right)\right)$ *for some small constant* $c \geq 1$*, then we can solve any LPA instance* $(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c}, K, R, \epsilon)$ *in time* $O\left(\operatorname{nnz}^c(\boldsymbol{A}) \operatorname{poly}\log\left(\frac{\operatorname{nnz}(\boldsymbol{A}) R X(\boldsymbol{A},\boldsymbol{b},\boldsymbol{c},K)}{\epsilon}\right)\right)$.

3.1 Overview of Our Proof

In this section, we will explain how to reduce an LP instance to a 2-commodity flow (2CF) instance by a chain of efficient reductions. In each step, we reduce a decision problem P to a decision problem Q. We guarantee that (1) the reduction runs in nearly-linear time[4], (2) the

[3] If we encode 2CF as an LP instance, and approximately solve the LP with at most ϵ additive error. Then, the approximate solution also agrees with the error notions of 2CF, except that we get $F_1 + F_2 \geq R - \epsilon$ instead of $F_1 + F_2 \geq R$. This inconsistency can be eliminated by setting $\epsilon' = 2\epsilon$, and slightly adjusting F_1, F_2 to F_1', F_2' such that $F_1' + F_2' \geq R$. This way, we obtain an approximate solution to 2CF with at most ϵ' additive error.

[4] Linear in the size of problem P, poly-logarithmic in the maximum magnitude of all the numbers that describe P, the feasible set radius, and the inverse of the error parameter if an approximate solution is allowed.

Table 1 A summary of notation used in the reduction from LP to 2CF.

Exact problems	Input	Output
LP (Def. 2.1)	$\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c}, K, R$	$\boldsymbol{x}$
LEN (Def. 2.2)	$\tilde{\boldsymbol{A}}, \tilde{\boldsymbol{b}}, \tilde{R}$	$\tilde{\boldsymbol{x}}$
2-LEN (Def. 2.3)	$\bar{\boldsymbol{A}}, \bar{\boldsymbol{b}}, \bar{R}$	$\bar{\boldsymbol{x}}$
1-LEN (Def. 2.3)	$\hat{\boldsymbol{A}}, \hat{\boldsymbol{b}}, \hat{R}$	$\hat{\boldsymbol{x}}$
FHF (Def. 2.11)	$G^h, F^h, \mathcal{H}^h = \{H_1, \cdots, H_h\}, \boldsymbol{u}^h, s, t$	$\boldsymbol{f}^h$
FPHF (Def. 2.12)	$G^p, F^p, \mathcal{H}^p = \{H_1, \cdots, H_p\}, \boldsymbol{u}^p, s, t$	$\boldsymbol{f}^p$
SFF (Def. 2.10)	$G^s, F^s, S_1, S_2, \boldsymbol{u}^s, s_1, t_1, s_2, t_2$	$\boldsymbol{f}^s$
2CFF (Def. 2.9)	$G^f, F^f, \boldsymbol{u}^f, s_1, t_1, s_2, t_2$	$\boldsymbol{f}^f$

size of Q is nearly-linear in the size of P, and (3) that P is feasible implies that Q is feasible, and an approximate solution to Q can be turned to an approximate solution to P with only a polynomial blow-up in error parameters, in linear time.

We follow the outline of Itai's reduction [17]. A summary of the problem notation used in the reduction from LP to 2CF is given in Table 1. Itai first reduced an LP instance to a 1-LEN instance (linear equations with nonnegative variables and ± 1 coefficients). A 1-LEN instance can be cast as a single-commodity flow problem subject to additional homologous constraints and fixed flow constraints (i.e., FHF). Then, Itai dropped these additional constraints step by step, via introducing a second commodity of flow and imposing lower bound requirements on the total amount of flows routed between the source-sink pairs. However, in the worst case, Itai's reduction from 1-LEN to FHF enlarges the problem size quadratically and is thus inefficient. One of our main contributions is to improve this step so that the problem representation size is preserved along the reduction chain.

Our second main contribution is an upper bound on the errors accumulated during the process of mapping an approximate solution to the 2CF instance to an approximate solution to the LP instance. We show that the error only grows by polynomial factors. Itai only considered exact solutions between these two instances.

We will explain the reductions based on the exact versions of the problems. At the end of this section, we will discuss some intuitions of our error analysis.

3.1.1 Reducing Linear Programming to Linear Equations With Nonnegative Variables and ± 1 Coefficients

Given an LP instance $(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c}, K, R)$ where $R \geq \max\{1, \max\{\|x\|_1 : \boldsymbol{A}\boldsymbol{x} \leq \boldsymbol{b}, \boldsymbol{x} \geq \boldsymbol{0}\}\}$, we want to compute a vector $\boldsymbol{x} \geq \boldsymbol{0}$ satisfying

$$\boldsymbol{A}\boldsymbol{x} \leq \boldsymbol{b}, \boldsymbol{c}^\top \boldsymbol{x} \geq K$$

or to correctly declare infeasible. We introduce slack variables $\boldsymbol{s}, \alpha \geq \boldsymbol{0}$ and turn the above inequalities to equalities:

$$\boldsymbol{A}\boldsymbol{x} + \boldsymbol{s} = \boldsymbol{b}, \boldsymbol{c}^\top \boldsymbol{x} - \alpha = K$$

which is an LEN instance $(\tilde{\boldsymbol{A}}, \tilde{\boldsymbol{b}}, \tilde{R})$. Comparing to Itai's proof, we need to track two additional parameters: the polytope radius R and the maximum magnitude of the input entries X.

We then reduce the LEN instance to linear equations with ± 2 coefficients (2-LEN) by bitwise decomposition. For each bit, we introduce a carry term. Different from Itai's reduction, we impose an upper bound for each carry variable. We show that this upper bound does not change problem feasibility and it guarantees that the polytope radius only increases polynomially. The following example demonstrates this process.

$$5x_1 + 3x_2 - 7x_3 = -1 \quad \Rightarrow \quad (x_1 + x_2 - x_3)2^0 + (x_2 - x_3)2^1 + (x_1 - x_3)2^2 = -1 \cdot 2^0$$

It can be decomposed to 3 linear equations, together with carry terms $(c_i - d_i)$, where $c_i, d_i \geq 0$:

$$\begin{aligned} x_1 + x_2 - x_3 - 2(c_0 - d_0) &= -1 \\ x_2 - x_3 + (c_0 - d_0) - 2(c_1 - d_1) &= 0 \\ x_1 - x_3 + (c_1 - d_1) &= 0 \end{aligned}$$

Next, we reduce the 2-LEN instance $(\bar{\boldsymbol{A}}, \bar{\boldsymbol{b}}, \bar{R})$ to a 1-LEN instance $(\hat{\boldsymbol{A}}, \hat{\boldsymbol{b}}, \hat{R})$ by replacing each ± 2 coefficient variable with two new equal-valued variables.

All the above three reduction steps run in nearly-linear time, and the problem sizes increase nearly-linearly.

3.1.2 Reducing Linear Equations With Nonnegative Variables and ± 1 Coefficients to Fixed Homologous Flow Problem

One of our main contributions is a linear-time reduction from 1-LEN to FHF (single-commodity fixed homologous flow problem). Our reduction is similar to Itai's reduction, but more efficient.

Itai observed that a single linear equation $\hat{\boldsymbol{a}}^\top \hat{\boldsymbol{x}} = \hat{b}$ with ± 1 coefficients can be represented as a fixed homologous flow network. We improve his construction by creating a *sparser* flow network in which the number of edges is proportional to the number of nonzero coefficients in the linear equations. Figure 1 depicts our gadget. Our gadget has a source vertex s, a sink vertex t, and two additional vertices J^+ and J^-. Each variable $\hat{\boldsymbol{x}}(i)$ with coefficient $\hat{\boldsymbol{a}}(i) \neq 0$ corresponds to an edge: There is an edge from s to J^+ if $\hat{\boldsymbol{a}}(i) = 1$, and there is an edge from s to J^- if $\hat{\boldsymbol{a}}(i) = -1$. The amount of flow passing this edge encodes the value of $\hat{\boldsymbol{x}}(i)$. Thus, the difference between the total amount of flow entering J^+ and that entering J^- equals to $\hat{\boldsymbol{a}}^\top \hat{\boldsymbol{x}}$. To force $\hat{\boldsymbol{a}}^\top \hat{\boldsymbol{x}} = \hat{b}$, we add two edges e_1, e_2 from J^+ to t and one edge e_3 from J^- to t; we require e_1 and e_3 to be homologous and require e_2 to be a fixed flow with value $\hat{b}$.

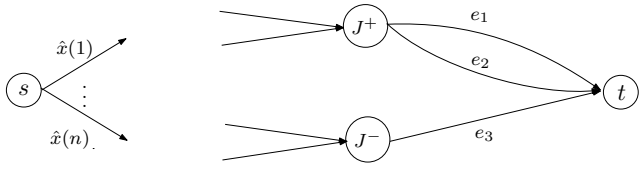

Figure 1 The gadget of reducing a single linear equation $\hat{\boldsymbol{a}}^\top \hat{\boldsymbol{x}} = \hat{b}$ with ± 1 coefficients to a fixed homologous flow network (FHF).

We can generalize this construction to encode a system of linear equations $\hat{\boldsymbol{A}}\hat{\boldsymbol{x}} = \hat{\boldsymbol{b}}$, where $\hat{\boldsymbol{A}} \in \boldsymbol{Z}^{\hat{m} \times \hat{n}}$, $\hat{\boldsymbol{b}} \in \boldsymbol{Z}^{\hat{m}}$. Specifically, we create a gadget as above for each individual equation, and then glue all the source (sink) vertices for all the equations together as the source (sink, respectively) of the graph (see Figure 2). In addition to requiring e_i^+, e_i^- to be homologous for each single linear equation, to guarantee the variable values to be consistent in these

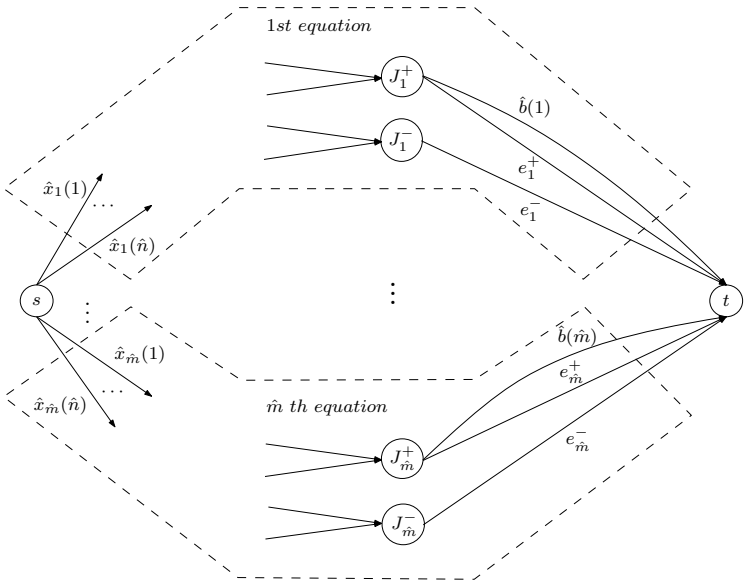

Figure 2 The reduction from 1-LEN to FHF.

equations, we also require the edges corresponding to the same variable $\hat{\boldsymbol{x}}(i)$ in different equations to be homologous, i.e., $\{\hat{x}_1(i), \ldots, \hat{x}_{\hat{m}}(i)\}$. We can check that the number of the vertices is linear in the number of equations; the number of the edges and the total size of the homologous sets are both linear in the number of nonzero coefficients of the linear equation system.

3.1.3 Dropping the Homologous and Fixed Flow Constraints

To reduce FHF to 2CF (2-commodity flow problem), we need to drop the homologous and fixed flow constraints. The reduction has three main steps.

Reducing FHF to SFF. Given an FHF instance, we can reduce it to a fixed homologous flow instance in which each homologous edge set has size 2 (FPHF). To drop the homologous requirement in FPHF, we introduce a second commodity of flow with source-sink pair (s_2, t_2), and for each edge, we carefully select the type(s) of flow that can pass through this edge. Specifically, given two homologous edges (v, w) and (y, z), we construct a constant-sized gadget (see Figure 3): We introduce new vertices vw, vw', yz, yz', construct a directed path

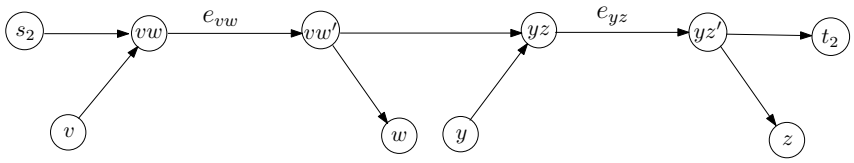

Figure 3 The gadget of reducing a pair of homologous edges $(v, w), (y, z)$ to a selective fixed flow network (SFF).

$P : s_2 \to vw \to vw' \to yz \to yz' \to t_2$, and add edges $(v, vw), (vw', w)$ and $(y, yz), (yz', z)$. Now, there is a directed path $P_{vw} : v \to vw \to vw' \to w$ and a directed path $P_{yz} : y \to yz \to yz' \to z$. Paths P and P_{vw} (P_{yz}) share an edge $e_{vw} = (vw, vw')$ ($e_{yz} = (yz, yz')$, respectively). We select e_{vw} and e_{yz} for both flow $\boldsymbol{f}_1^s$ and $\boldsymbol{f}_2^s$, select the rest of the edges along P for only $\boldsymbol{f}_2^s$, and select the rest of the edges along P_{vw}, P_{yz} for only $\boldsymbol{f}_1^s$. By this

construction, in this gadget, we have $\boldsymbol{f}_2^s(e_{vw}) = \boldsymbol{f}_2^s(e_{yz})$ being the amount of flow routed in P, $\boldsymbol{f}_1^s(e_{vw})$ and $\boldsymbol{f}_1^s(e_{yz})$ being the amount of flow routed in P_{vw} and P_{yz}, respectively. Next, we choose e_{vw} and e_{yz} to be fixed flow edges with equal capacity; this guarantees the same amount of $\boldsymbol{f}_1^s$ is routed through P_{vw} and P_{yz}. The new graph is an SFF instance.

Reducing SFF to 2CFF. Next, we will drop the selective requirement of the SFF instance. For each edge (x, y) selected for flow i, we construct a constant-sized gadget (see Figure 4): We introduce two vertices xy, xy', construct a direct path $s_i \to xy' \to xy \to t_i$, and add

Figure 4 The gadget of reducing a selective edge (x, y) for commodity i to a 2-commodity fixed flow network (2CFF).

edge (x, xy) and (xy', y). This gadget simulates a directed path from x to y for flow $\boldsymbol{f}_i^f$, and guarantees no directed path from x to y for flow $\boldsymbol{f}_{\bar{i}}^f$ so that $\boldsymbol{f}_{\bar{i}}^f$ cannot be routed from x to y. We get a 2CFF instance.

Reducing 2CFF to 2CF. It remains to drop the fixed flow constraints. The gadget we will use is similar to that used in the last step. We first introduce new sources $\bar{s}_1, \bar{s}_2$ and sinks $\bar{t}_1, \bar{t}_2$. Then, for each edge (x, y) with capacity u, we construct a constant-sized gadget (see Figure 5).

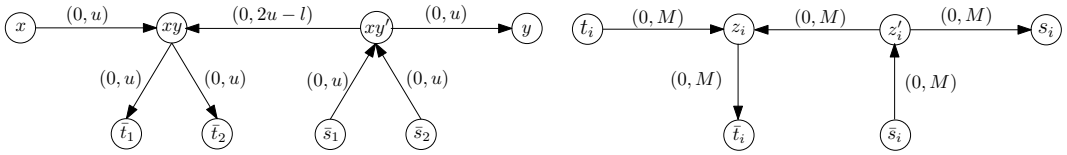

Figure 5 The gadget of reducing 2CFF to a 2-commodity flow with required flow amount (2CFR). l, u are lower and upper edge capacity of (x, y), respectively: $l = u$ if (x, y) is a fixed flow edge; $l = 0$ if (x, y) is a non-fixed flow edge.

We introduce two vertices xy, xy', add edges $(\bar{s}_1, xy'), (\bar{s}_2, xy'), (xy, \bar{t}_1), (xy, \bar{t}_2), (xy', xy)$, and $(x, xy), (xy', y)$. This simulates a directed path from x to y that both flow $\boldsymbol{f}_1^r$ and $\boldsymbol{f}_2^r$ can pass through. We let (xy', xy) have capacity u if (x, y) is a fixed flow edge and $2u$ otherwise; we let all the other edges have capacity u. Assume all the edges incident to the sources and the sinks are saturated, then the total amount of flows routed from x to y in this gadget must be u if (x, y) is a fixed flow edge and no larger than u otherwise. Moreover, since the original sources and sinks are no longer sources and sinks now, we have to satisfy the conservation of flows at these vertices. For each $i \in \{1, 2\}$, we create a similar gadget involving $\bar{s}_i, \bar{t}_i$ to simulate a directed path from t_i to s_i (the original sink and source), and let the edges incident to $\bar{s}_i, \bar{t}_i$ have capacity M, the sum of all the edge capacities in the 2CFF instance. This gadget guarantees that assuming the edges incident to $\bar{s}_i$ and $\bar{t}_i$ are saturated, the amount of flow routed from t_i to s_i through this gadget can be any number at most M. To force the above edge-saturation assumptions to hold, we require the amount of flow $\boldsymbol{f}_i^r$ routed from $\bar{s}_i$ to $\bar{t}_i$ to be no less than $2M$ for each $i \in \{1, 2\}$.

Now, this instance is close to a 2CF instance except that we require a lower bound for each flow value instead of a lower bound for the sum of two flow values. To handle this, we introduce new sources $\bar{\bar{s}}_1, \bar{\bar{s}}_2$ and for each $i \in \{1, 2\}$, we add an edge $(\bar{\bar{s}}_i, \bar{s}_i)$ with capacity $2M$, the lower bound required for the value of $\boldsymbol{f}_i^r$.

One can check that in each reduction step, the reduction time is nearly linear and the problem size increases nearly linearly. In addition, given a solution to the 2CF instance, one can construct a solution to the LP instance in nearly linear time.

3.1.4 Computing an Approximate Linear Program Solution From an Approximate 2-Commodity Flow Solution

We establish an error bound for mapping an approximate solution to 2CFA to an approximate solution to LPA. Below we outline the intuition behind our error analysis for flow problems. We will keep track of multiple types of error (e.g., error in congestion, demand, selective types, and homology depending on the problem settings). Now suppose we reduce problem P to problem Q using a certain gadget, and then we map a solution to Q back to a solution to P. We observe that each error notion of P is an additive accumulation of the multiple error notions of Q. This is because we have to map the flows of Q passing through a gadget including multiple edges back to a flow of P passing through a single edge. Each time we remove an edge, various errors related to this edge and incident vertices get transferred to its neighbors. Thus, the total error accumulation by the solution mapping can be polynomially bounded by the number of edges. So, the final error only increases polynomially.

High-Probability List-Recovery, and Applications to Heavy Hitters

Abstract

An error correcting code $\mathcal{C}\colon \Sigma^k \to \Sigma^n$ is efficiently list-recoverable from input list size ℓ if for any sets $\mathcal{L}_1, \ldots, \mathcal{L}_n \subseteq \Sigma$ of size at most ℓ, one can efficiently recover the list $\mathcal{L} = \{x \in \Sigma^k : \forall j \in [n], \mathcal{C}(x)_j \in \mathcal{L}_j\}$. While list-recovery has been well-studied in error correcting codes, all known constructions with "efficient" algorithms are not efficient in the parameter ℓ. In this work, motivated by applications in algorithm design and pseudorandomness, we study list-recovery with the goal of obtaining a good dependence on ℓ. We make a step towards this goal by obtaining it in the weaker case where we allow a *randomized* encoding map and a small failure probability, and where the input lists are derived from unions of codewords. As an application of our construction, we give a data structure for the heavy hitters problem in the strict turnstile model that, for some parameter regimes, obtains stronger guarantees than known constructions.

1 Introduction

Let $\mathcal{C}\colon \Sigma^k \to \Sigma^n$ be an *error correcting code*. We say that $\mathcal{C}$ is (efficiently) *list-recoverable*[1] from list-size ℓ with output list-size L if, for any lists $\mathcal{L}_1, \ldots, \mathcal{L}_n \subseteq \Sigma$ with $|\mathcal{L}_i| \leq \ell$ for all i, there is an (efficient) algorithm to recover the list

$$\mathcal{L} = \{x \in \Sigma^k : \forall i \in [n], \mathcal{C}(x)_i \in \mathcal{L}_i\},$$

and $|\mathcal{L}| \leq L$. List recovery has historically been studied in the context of *list-decodable* codes, where it has been used as a tool to obtain efficient list-decoding algorithms (see, e.g., [17, 16, 19, 27, 22]). However, even though efficient list-recovery algorithms have been

[1] In this paper we focus on *zero-error* list-recovery, which is the definition given here. Other works focus on the more general problem of list-recovery from errors, in which $\mathcal{C}(x)_i$ needs to be in $\mathcal{L}_i$ only for some fraction of the i-s.

developed, all of them have a poor dependence on the parameter ℓ. For example, Hemenway, Ron-Zewi, and Wootters [22] presents near-linear-time (in n) list-recovery algorithms, but the output list $\mathcal{L}$ has size doubly-exponential in ℓ.

In this work, we are motivated by the following goal (which we do not fully achieve):

▶ **Goal 1.** *For $\ell \geq 2$, design a family of codes $\mathcal{C} \colon \Sigma^k \to \Sigma^n$ so that:*

1. *$\mathcal{C}$ can be encoded in time $O(n)$;*
2. *The* rate *k/n of the code is a constant (independent of n **and** ℓ);*
3. *The* alphabet size *$|\Sigma|$ is polynomial in ℓ (and independent of n);*
4. *The code $\mathcal{C}$ can be list-recovered in time $O(n \cdot \ell)$ (linear in both n **and** ℓ), with output list size $|\mathcal{L}| = O(\ell)$.*

To the best of our knowledge, this goal is open even if we allow the output list size $|\mathcal{L}|$ and the running time to depend polynomially on ℓ, rather than linearly.

Goal 1 is desirable for several reasons. First, it represents a bottleneck in our understanding of algorithmic coding theory, and it seems likely that achieving it would involve developing new techniques that would be useful elsewhere. Second, list-recovery with reasonable dependence on ℓ is related to questions in pseudorandomness, where the the parameter ℓ is often very large (see our discussion in Section 1.2). Third, as we explore in this paper, obtaining Goal 1 has applications in algorithm design, in particular to algorithms for heavy hitters.

Probabilistic list-recovery with good dependence on ℓ

In this work, we make progress on Goal 1 by achieving a relaxed version where the encoding map $\mathcal{C} \colon \Sigma^k \to \Sigma^n$ is allowed to be *randomized*, and where the input lists are generated from unions of codewords; we must succeed with high probability over the randomness in $\mathcal{C}$. In particular, our main result implies the following theorem.

▶ **Theorem 2** (informal; weaker than main result)**.** *For all $\ell > 0$, there is a randomized encoding map $\mathcal{C} \colon \Sigma^k \to \Sigma^n$ so that*

1. *$\mathcal{C}$ can be encoded in time $O(n)$;*
2. *The rate of $\mathcal{C}$, k/n, is a constant independent of ℓ and n;*
3. *The alphabet size $|\Sigma|$ is polynomial in ℓ (and independent of n);*
4. *For any list $x^{(1)}, x^{(2)}, \ldots, x^{(\ell)} \in \Sigma^k$, there is an algorithm that runs in time $O(n\ell \operatorname{polylog} \ell)$ that has the following guarantee. With probability at least $1 - o(1)$ over the randomness of $\mathcal{C}$, given the lists $\mathcal{L}_i = \{\mathcal{C}(x^{(j)})_i : j \in [\ell]\}$, the algorithm returns a list $\mathcal{L}$ so that $x^{(i)} \in \mathcal{L}$ for all i, and so that $|\mathcal{L}| = O(\ell)$.*

This statement is weaker than our main result because in fact our result still holds even if a random subset of the lists $\mathcal{L}_i$ in Item 4 are erased, and moreover the result still holds when some of the lists $\mathcal{L}_i$ in Item 4 contain some extra "distractor" symbols that occur according to any sufficiently "nice" distribution. We defer the formal statement of our list-recovery guarantee to Section 2.

Our code is essentially an *expander code* with *aggregated symbols*. That is, we begin with an expander code $\mathcal{C}_0 \colon \Sigma_0^k \to \Sigma_0^n$, as in [39], and we aggregate together the symbols as in [1]. (We discuss this construction in more detail below.) Our recovery algorithm uses ideas from previous algorithms, propagating information around the underlying expander graph given some advice. What makes our work different are the facts that (a) we leverage the randomness of $\mathcal{C}$ and a small failure probability, and (b) our underlying expander graph comes

from a *high-dimensional expander*.[2] In particular, using the randomness in $\mathcal{C}$ we are able to obtain an algorithm with running time nearly-linear in ℓ, and using a high-dimensional expander we are able to boost our success probability to a level appropriate for an application to heavy hitters, which we discuss next.

Motivation from Heavy Hitters

One of the reasons we are interested in Goal 1 is because of the potential algorithmic applications of such a code. To illustrate this potential, we work out an application of our construction to the *heavy hitters* problem. **We emphasize that our focus is on the parameter regime where N is very large, specifically $\log N \gg \mathbf{poly}(1/\varepsilon)$.** In particular, we are interested in optimizing the dependence on N, rather than on ε.

The set-up is as follows. We are given a stream of updates $(x^{(i)}, \Delta^{(i)})$, for $x^{(i)}$ in some universe $\mathcal{U}$ of size N, and $\Delta^{(i)} \in \mathbb{R}$. For all m, x, we assume that $f(x) \triangleq \sum_{j\in[m]} \Delta^{(j)} \cdot \mathbf{1}_{x^{(j)}=x} > 0$. we think of $f(x)$ as the "frequency" of item x. The Δ-s are updates: we may add or remove some quantity of each item x, provided that $f(x)$ never becomes negative. This is called the *strict turnstile model.* The goal is to maintain a small data structure (a "sketch") so that, after m (efficient) updates $(x^{(i)}, \Delta^{(i)})$, we can (efficiently) query the data structure to return a list of *ε-heavy hitters.* That is, we would like to recover a list $\mathcal{L}$ of size at most $O(1/\varepsilon)$ that contains all $x \in \mathcal{U}$ so that $f(x) \geq \varepsilon \cdot \|f\|_1 \triangleq \sum_{x\in\mathcal{U}} f(x)$.

The beautiful *Count-Min Sketch* (CMS) data structure of Cormode and Muthukrishnan [7] gives a solution to this problem. It uses optimal space $O(\varepsilon^{-1} \log N)$ and has update time $O(\log N)$. However, the query time to return all $O(1/\varepsilon)$ heavy hitters is large, $O(N \log N)$ (essentially, one performs a point query for each $x \in \mathcal{U}$ to see if it is a heavy hitter). The work [7] showed how to alleviate this with a so-called "dyadic trick," bringing the query time to $O(\log^2 N)$ at the cost of an extra $\log N$ factor in both the space and update time.[3] (See Table 1 for a summary of the parameters in these and other works).

The starting point for our work is the work of Larsen, Nelson, Nguyễn and Thorup [29]. That work studied a much more general problem – heavy hitters for all ℓ_p norms in the general turnstile model – but for the special case of the ℓ_1 norm and the strict turnstile model, they were able to get a nearly optimal algorithm, with the same space and update time complexity as the original CMS, but with query time $O(\varepsilon^{-1} \log^{1+\gamma} N)$ for any constant $\gamma > 0$. That work highlighted a connection to list-recovery (see [29, Section C]; a similar connection is also present in earlier works on group testing and compressed sensing, for example [24, 35, 36, 13, 12]), which is one of our motivations to study Goal 1.

The approach of [29] was the following (we have modified the description to be more explicitly coding-theoretic). To perform an update on an item $x \in \mathcal{U}$, encode it as $\mathcal{C}(x) \in \Sigma^n$ with our (randomized) encoding function. Then insert each symbol $\mathcal{C}(x)_j$ into n different ε-heavy hitters data structures that work on universe Σ (this could be a small CMS sketch, or something else). To query all of the heavy hitters, we first query each smaller data structure to find a list $\mathcal{L}_j$. Notice that since $|\Sigma| \ll |\mathcal{U}|$, it does not matter that the query algorithm for the small data structures is slow. Now, we do list-recovery on the lists $\mathcal{L}_j$ to recover a list $\mathcal{L}$ that contains all of the heavy hitters.[4]

[2] We note that the construction of Dinur et al. [9] is similar to ours, also using an ABNNR-style [1] symbol aggregation with a high-dimensional expander. However, in that work they have a more ambitious goal – list-decoding with no randomness in the encoder – but in return the parameters are not close to those in Goal 1.

[3] See also the work by Cormode and Hadjieleftheriou [6] who consider a generalization of the dyadic trick that trades off between the query time and the overhead in update time and space.

[4] Provided that the output $\mathcal{L}$ of the list-recovery algorithm is not too large, we can use an additional large CMS data structure to efficiently do point queries on each item $x \in \mathcal{L}$, pruning it down to $O(1/\varepsilon)$.

Table 1 Some relevant results on ε-heavy hitters in the strict turnstile model where the universe has size N, for $\log N \gg \mathrm{poly}(1/\varepsilon)$. We consider schemes with failure probability $\delta \geq 1/\mathrm{poly}(N)$; see the discussion in Section 1.3 for smaller failure probability where the works marked with $\star$ shine. The $\tilde{O}$ notation hides $\log\log(N)$ factors and $\log(1/\varepsilon)$ factors. Above, c is a constant independent of N and ε, and γ is any constant larger than 0. Unfortunately, the failure probability for our algorithm is only $N^{-\mathrm{poly}(\varepsilon)}$, rather that N^{-c} for some constant c. By repeating our algorithm $\mathrm{poly}(1/\varepsilon)$ times we can boost the success probability to N^{-c}. We note that each of Space, Update, Query time for [7] (with the dyadic trick) and [31] can be multiplied by ε^c if one replaces the failure probability with $N^{-\varepsilon^c}$ and the results from [29, Theorem 9] remain the same for that larger failure probability.

Reference	Space	Update	Query	Failure probability
[7]	$O\left(\frac{\log N}{\varepsilon}\right)$	$O(\log N)$	$O(N \log N)$	N^{-c}
[7] ("dyadic trick")	$O\left(\frac{\log^2 N}{\varepsilon}\right)$	$O(\log^2 N)$	$O\left(\frac{\log^2 N}{\varepsilon}\right)$	N^{-c}
[29]	$O\left(\frac{\log N}{\varepsilon}\right)$	$O(\log N)$	$O\left(\frac{\log^{1+\gamma} N}{\varepsilon}\right)$	N^{-c}
[31]*	$\widetilde{O}\left(\log^2 N\right)$	$\widetilde{O}\left(\varepsilon \log^2 N\right)$	$\frac{1}{\varepsilon}\,\mathrm{poly}(\log N)$	N^{-c}
[5]*	$O\left(\frac{\log N}{\varepsilon}\right)$	$\widetilde{O}(\log N)$	$\frac{1}{\varepsilon}\,\mathrm{poly}(\log N)$	0
This work	$O\left(\frac{\log N}{\varepsilon}\right)$	$O(\log N)$	$O\left(\frac{\log N}{\varepsilon}\right)$	$N^{-\mathrm{poly}(\varepsilon)}$
This work	$O\left(\frac{\log N}{\varepsilon^c}\right)$	$O\left(\frac{\log N}{\varepsilon^c}\right)$	$O\left(\frac{\log N}{\varepsilon^c}\right)$	N^{-c}

However, as Goal 1 remains open, [29] did not use a list-recoverable code to obtain their results. Instead, they (like us) took advantage of the fact that the lists $\mathcal{L}_j$ can be viewed as random variables over the randomness in the encoding map $\mathcal{C}$, and then use a construction based on "cluster-preserving clustering" to solve the problem. While in some sense this construction must be a list-recoverable code for randomized input lists, it is not clear (to us) how to extract a natural code out of it: the work [29] took the perspective of graph clustering, rather than coding theory. In contrast, our code is very natural in the context of coding theory, as it is simply an expander code with aggregated symbols (albeit using a high-dimensional expander for the underlying graph).

As an example of the utility of our construction, we plug our randomized list-recoverable code (as in Theorem 2) into the framework of [29]. This gives us an algorithm for heavy hitters that, in some parameter regimes, even slightly outperforms that of [29]. When ε is constant and N is growing, we are able to improve the query time from $O(\log^{1+\gamma} N)$ to $O(\log N)$. In particular, we prove the following theorem. (See Table 1 for a comparison to other work when $\log N \gg \mathrm{poly}(1/\varepsilon)$).

▶ **Theorem 3** (informal; see Theorem 5.11 in the full version)**.** *There is a data structure that solves the heavy hitters problem in the strict turnstile model, that uses space $O(\varepsilon^{-1}\log N)$, update time $O(\log N)$, and query time $O(\varepsilon^{-1}\log N\,\mathrm{polylog}(1/\varepsilon))$, with failure probability $\delta = N^{-\Theta(\varepsilon^3)}$, as long as $\varepsilon \geq (\log N)^{-\Omega(1)}$.*

By repeating this data structure $O(\varepsilon^{-3})$ times, we obtain a data structure that takes space $O(\varepsilon^{-4}\log N)$, update time $O(\varepsilon^{-3}\log N)$ and query time $O(\varepsilon^{-4}\log N\,\mathrm{polylog}(1/\varepsilon))$, with failure probability $\delta = N^{-c}$.

Our algorithm has the added property that a successful $\mathcal{L}$ of size $O(1/\varepsilon)$ not only contains all the true heavy hitters, but also does not contain "false-positives", in the sense that each $x \in \mathcal{L}$ satisfies, say, $f(x) \geq \frac{\varepsilon}{4}\|f\|_1$. This property also applies to most previous heavy hitters algorithms.

Contributions

To summarize, our main contributions are the following.

1. **A code with probabilistic list-recovery.** We give a natural code construction that achieves a probabilistic version of Goal 1, as per Theorem 2. Our code construction leverages recent progress in high-dimensional expanders in order to succeed with high probability. We hope that our construction and techniques may be used in the the future to make further progress on Goal 1.
2. **Proof of concept: application to heavy hitters.** As an illustration of the utility of our construction – and as an proof-of-concept meant to encourage study of Goal 1 – we obtain a new data structure for ε-heavy hitters in the strict turnstile model. Our data structure has slightly stronger guarantees than existing constructions for failure probability $1/\operatorname{poly}(N)$ when ε is constant and the universe size N is growing (although it is outperformed by previous work when ε is small compared to $1/\log(N)$).

1.1 Construction Overview

In this section, we give a brief overview of our probabilistically list-recoverable code. We use this code to solve the ε-heavy-hitters problem following the paradigm described above, by using small heavy-hitters sketches for each symbol of the (randomized) encoding $\mathcal{C}(x)$ of $x \in \mathcal{U}$.

At a high level, we construct our code $\mathcal{C}\colon \Sigma_0^k \to \Sigma^{n'}$ as follows. We start with some base code $\mathcal{C}_0\colon \Sigma_0^k \to \Sigma_0^n$, as well as a bipartite expander graph $G = (R, L, E)$, where $L = [n]$ and $R = [n']$, for some $n' = O(n)$.[5] We will need $\mathcal{C}_0$ and G to have specific properties, which we will come to below. For $x \in \Sigma_0^k$, we generate the encoding $\mathcal{C}(x)$ as follows. For $j \in [n']$, the encoded symbol $\mathcal{C}(x)_j$ will be gotten as the concatenation of the symbols $\mathcal{C}_0(x)_i$ for $i \in \Gamma_G(j)$, where $\Gamma_G(j)$ denotes the neighbors of j in the graph G. This sort of "aggregation along an expander" technique, introduced in [1], has become a standard distance amplification technique in error correcting codes. Because of the concatenation, our final alphabet Σ will be $\Sigma = \Sigma_0^{m_2}$.

To perform list recovery, we will start with a small piece of "advice," and then recover the (hopefully unique) message x consistent with that advice. We will generate our final list $\mathcal{L}$ by iterating over all possible values of the advice. Towards this end, we will choose some coordinate $j \in [n']$ for which $\mathcal{L}_j$ is not erased, and some $\sigma^\star \in \mathcal{L}_j$ as our guess for $\mathcal{C}_0(x)|_{\Gamma_G(j)}$ to act as our advice. Given this advice $\sigma^\star$, we wish to keep propagating information until we obtain enough coordinates of $\mathcal{C}_0$ that would allow us to uniquely determine x; this amounts to decoding the code $\mathcal{C}_0$ from erasures.

In the exposition below, we start with a naive attempt to do this propagation, and build up the properties that we will need $\mathcal{C}_0$ and G to satisfy as we refine it. Our construction is depicted in Figure 1.

A naive attempt

Our first attempt (which will not work) is the following. Let $j \in [n']$ be as above, so we assume that we are given as advice the m_2 symbols $\mathcal{C}_0(x)|_{\Gamma_G(j)}$; our goal is to recover (a hopefully unique) x given this advice and given the input lists $\mathcal{L}_{j'}$ for $j' \in [n']$. Choose some coordinate $j' \in [n']$ such that $\Gamma_G(j) \cap \Gamma_G(j') \neq \emptyset$. As we already know the symbols in the

[5] Using the notation of the full version, $\Sigma_0 = \mathbb{F}_q$, $\Sigma = \mathbb{F}_q^{m_2}$ for some constant m_2, and $n' = |V_2| = O(n)$.

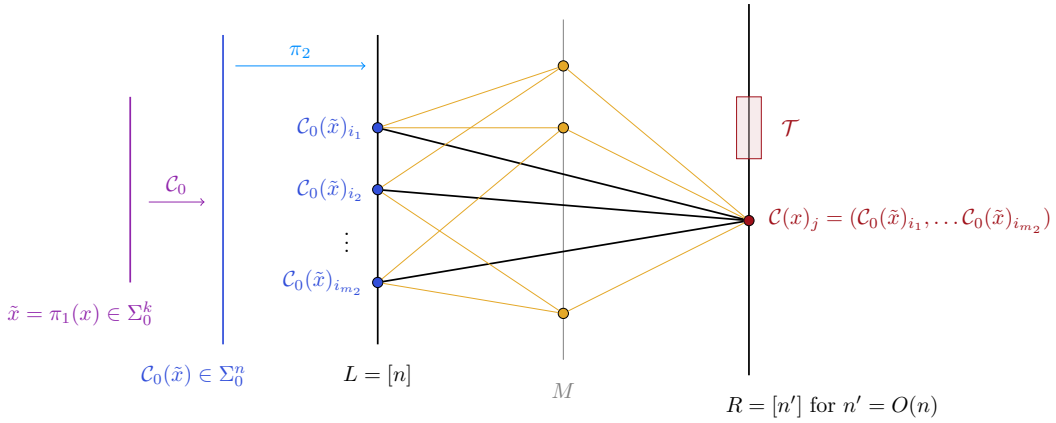

Figure 1 Illustration of our construction. The coordinates of the inner code $\mathcal{C}_0$ live on the vertices of L. The final code $\mathcal{C}$ consists of symbols aggregated by vertices in R. The randomness in the encoding comes from the permuations π_1 and π_2, which scramble the messages in Σ^k and the coordinates in $[n]$, respectively. We use the vertices in $\mathcal{T} \subseteq R$ to define parity checks that partially define the code $\mathcal{C}_0$. The "middle layer" M is not used in the definition of the code, but is a necessary auxiliary structure for our recovery algorithm.

coordinates indexed by $\Gamma_G(j)$, this gives us partial information about $\mathcal{C}(x)_{j'}$ in the form of $|\Gamma_G(j) \cap \Gamma_G(j')|$ elements of Σ_0 in known locations. One can hope that this information would be enough to pinpoint a specific entry in the list $\mathcal{L}_{j'}$, allowing us to recover all symbols of $\mathcal{C}_0(x)$ in the coordinates indexed by $\Gamma_G(j')$, and keep going in the same manner until enough information is propagated.

Clearly, when we have no guarantee on the input lists $\mathcal{L}_i$, this approach fails miserably, as it may be the case that $\mathcal{L}_{j'}$ contains numerous elements in $\Sigma_0^{m_2}$ that agree in some of the m_2 locations, and the information coming from our advice for j will not uniquely pin down an element of $\mathcal{L}_{j'}$. However, note that for a *completely random* input list $\mathcal{L}_{j'}$, such an attempt would be successful with probability at least $1 - |\mathcal{L}_{j'}| / |\Sigma_0|$, and we could set the parameters in such a way that $|\mathcal{L}_{j'}| \ll |\Sigma_0|$. That is, in this case it would become reasonably likely that the choice of $\sigma^\star \in \mathcal{L}_j$ would uniquely pin down an element $\sigma \in \mathcal{L}_{j'}$, allowing us to propagate information to another vertex in the graph. The hope is that we could propagate this information throughout the graph, using the fact that G is an expander to guarantee that most vertices will be determined. Of course, the problem with this is that we do not want to assume that the input lists are completely random, but this leads us to our next attempt, where we inject randomness into the encoding procedure.

Injecting randomness

While we won't get completely random lists $\mathcal{L}_j$ as we might have wanted for the naive attempt, we can make the input lists randomized via a randomized encoding. More specifically, our base code $\mathcal{C}_0$ will be deterministic, and to apply $\mathcal{C}$ we will make use of two permutations: a permutation π_1 acting on the universe $\mathcal{U}$ and a permutation π_2 acting on $[n]$. More formally, given $x \in \Sigma_0^k$, we first apply $\pi_1(x)$ and apply the encoding $\mathcal{C}_0$ to $\pi_1(x)$. Next, we permute the coordinates of the outcome according to π_2. Finally, we aggregate symbols according to G, yielding $\mathcal{C}(x) \in \Sigma^{n'}$. Roughly speaking, the first permutation – which will be pairwise independent – will make $\mathcal{C}_0(x)$ uniformly distributed over the code's image, even conditioned the value of $\mathcal{C}_0(x')$ for some $x' \neq x$. The second permutation will make sure that querying

any particular symbol $\mathcal{C}_0(x)_j$ symbol will behave like sampling a uniformly random symbol in $\mathcal{C}_0(x)$, and even more strongly, combined with π_1 it will behave like a random sampling from a nearly uniform distribution over Σ_0.

Analyzing the permutation-aided construction carefully, we are able to show that indeed, with probability roughly $1-\eta$ for $\eta \approx |\mathcal{L}_{j'}|/\sqrt{|\Sigma_0|}$, we can pinpoint a single list element of $\mathcal{L}_{j'}$. One conceptual observation that will help us establish that result is the fact that the distribution of symbols in most codewords of a high-rate code is close to uniform, and indeed we will need the rate of $\mathcal{C}_0$ to be very high (see Section 3.3 of the full version). We leave the more technical details to Section 5 of the full version.

Although promising, this approach is still problematic. We start with $m_2 = O(1)$ symbols that we know, and at each iteration the set of revealed coordinates grows by a small constant factor, using the expansion properties of G. As initially our sets are of constant size, we cannot hope for success probability much greater than $1-\eta$ for the initial propagation steps. A failure probability of η, even if we disregard the need for a problematic union bound over all propagation steps, is far too large for us, and in particular for our application to heavy hitters. The problem described here is common to various expander-based techniques, and in this work we resolve it by choosing G to be a special expander graph that comes from a high-dimensional expander, and by choosing $\mathcal{C}_0$ to be a suitable *Tanner code*. We discuss these modifications next.

Using high-dimensional expanders to get a good head start

We resolve the issue described above – that we cannot possibly get a good failure probability if we start with only a few known symbols – by using techniques from high-dimensional expanders. Suppose that, starting with only the advice $\sigma^\star$ for m_2 symbols of $\mathcal{C}_0(x)$, we could deterministically identify a large subset $\mathcal{T} \subseteq [n']$ for which we know all symbols of $\mathcal{C}_0(x)$ indexed by $\Gamma_G(\mathcal{T})$. This way, concentration bounds can kick in, and hopefully each propagation step would be successful with probability roughly $\eta^{|\mathcal{T}|}$, provided we can get a enough independence between query attempts at the same propagation step. We defer the independence issue to the full version (this ends up following from the amount of independence we have in our permutations π_1 and π_2), and concentrate on obtaining such a $\mathcal{T}$.

Recall that we work over the bipartite expander graph $G = (R = [n'], L = [n], E)$. We will construct G', a tripartite extension of G, with an added middle layer M, $|M| = O(n)$, having the following property. Identify each vertex j of R with a subset $\Gamma_G(j) \subset [n]$ of cardinally m_2 in the natural way. Each vertex in M is identified with a subset $S \subset [n]$ of cardinality m_1, for $1 < m_1 < m_2$, such that S is connected to all its m_1 elements on the left, and to all its supersets on the right. More specifically, each vertex j in R will be connected to all $\binom{m_2}{m_1}$ subsets of $\Gamma_G(j)$ in M. (See Figure 1 for an illustration.)

We will choose the code $\mathcal{C}_0$ to be a *Tanner code* with respect to the structure of the graph G. That is, as before, we associate the n symbols of a codeword $\mathcal{C}_0(x)$ with the left hand vertices L of G, and we define $\mathcal{C}_0$ so that a codeword $\mathcal{C}_0(x)$ is a labeling of L so that to following property holds: For every j in an appropriate subset $\mathcal{T} \subset R$, the labels on the vertices of $\Gamma_G(j)$ form a codeword in some error correcting code $\mathcal{C}_{00}$ of length m_2 with good distance; in particular, given any m_1 symbols of $\mathcal{C}_{00}(x')$ for some x', we can recover all of $\mathcal{C}_{00}(x')$.

The reason to choose $\mathcal{C}_0$ like this is the following. Say we know that j and j' are in the set $\mathcal{T}$, and that they have a common neighbor in M. This implies that $|\Gamma_G(j) \cap \Gamma_G(j')| \geq m_1$, since there is some set of size m_1 that both of those sets contain. In particular, by our choice of $\mathcal{C}_{00}$, once we know the symbols of $\Gamma_G(j)$, we can *deterministically* reveal all symbols of

$\Gamma_G(j')$ by decoding $\mathcal{C}_{00}$. Then we can continue this process until we recover the symbols in $\Gamma_G(j)$ for all $j \in \mathcal{T}$. By counting constraints, it turns out that we can choose $\mathcal{T}$ to be large and still have a high-rate code $\mathcal{C}_0$. This gives us our set $\mathcal{T}$ so that we can deterministically fill in the symbols of $\Gamma_G(\mathcal{T})$ to use as a head start and increase our success probability.

How do we construct such a tripartite graph, that on the one hand has not too many vertices in R and M (i.e., $R = O(n)$ and $M = O(n)$), but on the other hand has favorable intersection and expansion properties? This is where *high-dimensional expanders* enter the picture, and indeed the tripartite graph comes from an $(m_2 - 1)$-dimensional simplicial complex (see the full version for the formal definitions). A similar object was used by Dinur et al. [9] as a *double sampler*, and in Dikstein et al. [8] as a *multilayer agreement sampler*. We note that the construction of [9] is quite similar to ours, as they also use the symbol-aggregation technique of Alon et al. [1]; the main difference in the construction is that we use a very specific inner code $\mathcal{C}_0$ that uses the structure of G as part of its parity checks, while the work of [9] chooses $\mathcal{C}_0$ to be an arbitrary code with good distance.

In our actual construction, the code $\mathcal{C}_0$ is a bit more involved, and its constraints arise both from the special subset $\mathcal{T}$ of R and from an *additional* bipartite expander. Each of the two types of constraints is helpful for a different aspect of our algorithm. Roughly speaking, the constraints that come from $\mathcal{T} \subseteq R$ help us as described above (filling in the set $\Gamma_G(\mathcal{T})$ to get a head start). The other constraints are there to ensure that the final code $\mathcal{C}_0$ has good enough distance to allow for the final unique decoding. All in all, we are able to achieve a set $\mathcal{T}$ that has size about $|\mathcal{T}| \approx \text{poly}(\varepsilon) \cdot n$. We remark that this is the point where we don't quite get the failure probability that we want, resulting in a sub-optimal dependence on ε for our application to heavy hitters: we want failure probability $\exp(-n)$ (we will choose n logarithmic in N, so this would be $\text{poly}(1/N)$), and we end up with failure probability $\exp(-|\mathcal{T}|) = \exp(-\text{poly}(\varepsilon)n)$.

There are plenty of details that are swept under the rug in the description above, including implementation details needed to keep the recovery algorithm linear-time. We give the recovery algorithm in detail in the full version of the paper. We present our list-recovery algorithm in the context of a query algorithm for heavy hitters, since for our analysis we want to focus on the distribution of input lists that arises from the heavy hitters example, and it is easiest to present everything together. In particular, the input lists do not arise simply from the union of ℓ codewords $\mathcal{C}(x)$, but (a) may be erased if the corresponding small data structure failed, and (b) may contain extraneous symbols that arise from items $x^{(i)}$ that appear in the stream that are not heavy hitters.

1.2 Motivating Goal 1 from Pseudorandomness

In this section, we briefly explain why Goal 1 – and in particular, getting a good dependence on the parameter ℓ – is of interest in pseudorandomness. There is a tight connection between error correcting codes and fundamental constructions in pseudorandomness, notably the equivalence between (strong) seeded extractors and list-decodable codes [41, 40]. It turns out that list recovery can also play a prominent role in the study of related objects from extractor theory. In *seeded condensers*, first studied in [38], the goal is to "improve" the quality of a random source $\boldsymbol{X}$ using few additional random bits. A bit more formally, given a random variable $\boldsymbol{X} \sim \{0,1\}^n$ with min-entropy k, a condenser $\mathsf{Cond}\colon \{0,1\}^n \times \{0,1\}^d \to \{0,1\}^m$ is such that $\mathsf{Cond}(\boldsymbol{X}, U_d)$ has min-entropy k', where we want the entropy rate to improve, namely, $\frac{k'}{m} \gg \frac{k}{n}$, and to maintain a small entropy gap $m - k'$. (For the formal definition,

see, e.g., [18].) List recoverable codes in the *errors* model[6] give seeded condensers, and vice versa. More specifically, the input and output entropies k and k' are almost in one-to-one correspondence with the (logarithm of the) output and input list sizes, $\log|\mathcal{L}|$ and $\log \ell$ (for the precise statement, see [10]). Thus, to get meaningful condensers from list-recoverable codes, the dependence between L and ℓ needs to be good, in all regime of parameters, and in particular handle ℓ that grows arbitrarily with the message length. In fact, the best list-recoverable code in this regime is the (folded) Parvaresh-Vardy code [18], giving $|\mathcal{L}| \approx \ell$.[7] The connection between condensers and list-recoverable codes was recently utilized in the *computational* setting to construct nearly-optimal pseudorandom generators for polynomial-sized circuits [10].

The model of *zero-error list recovery*, described in Goal 1 (when $|\mathcal{L}|$ depends nicely on ℓ and ℓ can be arbitrary), has applications to pseudorandomness too. A (strong) *disperser* is a function $\mathsf{Disp}\colon \{0,1\}^n \times \{0,1\}^d \to \{0,1\}^m$ such that for any random variable $\boldsymbol{X} \sim \{0,1\}^n$ with sufficient min-entropy, the support of $\mathsf{Disp}(\boldsymbol{X}, U_d)$ is large. Such dispersers have found several applications, and are tightly connected to open problems in expander graphs. It is not hard to show, and we do so in Appendix B of the full version, that dispersers, in some parameter regime, are equivalent to zero-error list-recoverable codes. We are not aware of this equivalence being stated elsewhere. For completeness, we note that dispersers in another parameter regime give rise to erasure list-decodable codes [3].

Finally, observe that in order to get good pseudorandomness primitives from list-recoverable codes, efficient recovery is not an issue, and all that is needed is an efficient *encoding*.

Even though a probabilistic guarantee as in Theorem 2 does not immediately yield improved pseudorandom objects, it is our hope that our progress on Goal 1 is a first step towards achieving that goal, which would imply improved dispersers.

1.3 Related Work

Algorithmic List-Recovery

List-recovery was originally introduced as an avenue towards *list-decoding*, where the goal is, given a vector $z \in \Sigma^n$, to recover the list $\mathcal{L}$ of all messages $x \in \Sigma^k$ so that $\mathcal{C}(x)$ is sufficiently close to z in Hamming distance. For example, the celebrated list-decoding algorithm of Guruswami and Sudan for Reed-Solomon codes [17] is in fact a list-recovery algorithm. However, the Guruswami-Sudan algorithm stops working at the so-called *Johnson bound*, which in the context of list-recovery means that the rate k/n of the code can be at most $1/\ell$. Since the Guruswami-Sudan algorithm, there has been a great deal of work, mostly based on algebraic constructions, aimed at surpassing the Johnson bound for list-decoding and list-recovery. In particular, the works [16, 19, 27, 28] show variations of Reed-Solomon codes, like folded RS codes and multiplicity codes, can be efficiently list-decoded and list-recovered beyond the Johnson bound. For list-recovery, these constructions are able to obtain rate $k/n = \Omega(1)$, but unfortunately the size of the lists $\mathcal{L}$ returned (and in particular the running time of the algorithm that returns that list) is at least quasipolynomial in ℓ [16, 28], and sometimes exponential in ℓ. Moreover, those constructions naturally have large alphabet sizes, polynomial in n. In order to reduce the alphabet size, constructions using algebraic

[6] In the errors model, we are given $\mathcal{L}_1, \ldots, \mathcal{L}_n \subseteq \Sigma$ with $|\mathcal{L}_i| \leq \ell$ for all i, and we require the list $\mathcal{L} = \left\{x \in \Sigma^k : \Pr_{i\in[n]}[\mathcal{C}_i(x) \in \mathcal{L}_i] \geq 1-\gamma\right\}$ to be small, for some error parameter γ.

[7] Note, however, that the rate of the code in [18] is only $k^{-\Omega(1)}$ for k being the message length.

geometry codes have been used (e.g. [20, 21, 15]), although these works still have parameters with an exponential dependence on ℓ. Moreover, all of the works mentioned above have polynomial – and not linear – time recovery algorithms. Using expander-based techniques (e.g. that of Alon et al. [2]), these algorithms can be improved to near-linear time in n (e.g., as in [22]), but at the cost of increasing the dependence on ℓ to doubly-exponential.

In addition to algebraic constructions, there have also been a few constructions of purely graph-based codes, which are more similar to our constructions. The work of Guruswami and Indyk [14] gives a linear-time algorithm for list-recovery of graph-based codes, which does even better in the setting of *mixture-recovery* (similar to the setting that we study here) where the input lists are generated from unions of codewords. That work achieves output list size $|\mathcal{L}|$ exactly equal to ℓ, but has rate $O(1/\ell)$ and the alphabet size is exponential in ℓ. The work of Hemenway and Wootters [23] gives an $O(n)$-time algorithm for list-recovering graph-based codes (the expander codes of [39, 42], with an appropriate inner code); these can have high rate (close to 1), but unfortunately the dependence on ℓ in other parameters is *quadruply*-exponential.

The work of Dinur, Harsha, Kaufman, Livni-Navon and Ta-Shma [9], which directly inspired our work, used *double-samplers* derived from high-dimensional expanders, combined with an expander-based symbol aggregation technique of ABNNR that we also use [1]. The goal of that work was to give an efficient list-decoding algorithm for *any* code that follows the ABNNR construction. This is much more general that what we are aiming to do (since we get to carefully design our code before applying the ABNNR construction), and also the goal is different (list-decoding in the worst case, rather than randomized list-recovery). That work is able to get efficient (polynomial-time) algorithms, but when one tries to turn their algorithm into a list-recovery algorithm in the most direct way, the parameters are not close to those in Goal 1; in particular, the algorithm is only $\text{poly}(n)$-time, and the dependence on ℓ is again exponential. It is not clear (to us) how to use the approach of [9] to achieve Goal 1.

We also mention a recent work of Dikstein, Dinur, and Harsha [8] that suggests an approach for constructing locally testable codes. In particular, as in our construction they also use the underlying graph (an *agreement expander* coming from a high-dimensional expander) both for symbol manipulation and for defining the parity checks. However, their goal is quite different than ours: they obtain locally testable codes via lifting a set of "smaller" locally testable codes, extending the natural Tanner tests.

Heavy Hitters

The first work with provable guarantees for the heavy hitters problem was by Misra and Gries [32], which applied to the *cash register* model where each of the updates $\Delta^{(i)}$ are equal to 1. We work in the more general strict turnstile model described above. For the strict turnstile model, the Count-Min Sketch data structure of [7] above already gets good results, and the best current results for the parameter regime we are motivated by (in particular, with failure probability $1/\text{poly}(N)$, and where $\log N \gg \text{poly}(1/\varepsilon)$) are those of [29] described above. It is known [25] that $\Omega(\varepsilon^{-1} \log N)$ words of memory are required for this setting, and thus the space used by these works are optimal.

We next mention three works that study heavy hitters when the failure probability is extremely small (or zero) [31, 5, 33]. Relative to our work, these works achieve – as with [29] – a better dependence on ε but worse dependence on N; however, these works can additionally get away with extremely small or even zero failure probability. In [31], Li et al. modify the Count-Min Sketch by looking at different hash functions, and they present a data

structure with failure probability δ with space $\widetilde{O}\left(\log(\varepsilon N)\left(\varepsilon^{-1}+\log(1/\delta)\right)\right)$, update time $\widetilde{O}(\log^2(1/\varepsilon)\log(\varepsilon N)\left(1+\varepsilon\log(1/\delta)\right)$, and query time $\widetilde{O}(\varepsilon^{-1}\log^2(1/\varepsilon)\log(\varepsilon N)\log(1/\delta))$. For $\delta = N^{-c}$ and $\log N \gg \text{poly}(1/\varepsilon)$, this gives the parameters stated in Table 1. However, when δ is much smaller – for example, $\delta = N^{-\Omega(1/\varepsilon)}$ – this gives better results than the works previously discussed, and in particular implies a result that is *uniform* over all sets of heavy hitters by union bounding over the $N^{O(1/\varepsilon)}$ choices for such sets. In [5], Cheraghchi and Nakos give a randomized construction of a data structure that also solves the heavy hitters problem uniformly over all streams $x^{(1)}, x^{(2)}, \ldots$ (that is, with error probability *zero* assuming that the data structure was constructed correctly). This scheme uses space $O(\varepsilon^{-1}\log(N\varepsilon))$, has update time $\tilde{O}(\log^2(1/\varepsilon)\log(\varepsilon N))$, and query time $\varepsilon^{-1}\,\text{polylog}(N)$.[8] That work actually provides solutions to several problems, not just heavy hitters, via a construction of *list-disjunct matrices*. Finally, we mention the work of Nelson et al. [33], which gives a fully deterministic construction of a data structure for heavy hitters (and more generally for ℓ_∞/ℓ_1 sparse recovery) with zero error probability; the space and query time is $O(\varepsilon^{-2}\,\text{poly}\log(N))$, and the update time is $O(\varepsilon^{-1}\,\text{poly}\log(n))$.[9]

We note that there are algorithms that achieve $O(\log N)$ update and query time for constant ε, but with only a constant failure probability. For example, such an algorithm is given in the full version of [29] (see [30, Theorem 10]).

One can generalize to the *general turnstile* model, where there is no guarantee that $f(x)$ is positive at each point in the stream, and one can generalize to ℓ_p-heavy hitters, where the goal is to return all x so that $|f(x)| \geq \varepsilon\|f\|_p$. There has been a great deal of work along both of these lines; see [29] and the references therein. In particular, for ℓ_p heavy hitters in the general turnstile model, the work [29] gives a data structure with space $O(\varepsilon^{-p}\log N)$, update time $O(\log N)$, and query complexity $\varepsilon^{-p}\,\text{polylog}(n)$.

We briefly discuss the approach of [29], in order to illustrate the differences between their approach and ours. While that work inspired the list-recovery approach we take, and they also use error correcting codes and expander graphs, the construction itself is quite different. That work takes the perspective of *graph clustering*. In more detail, their sketch can output a graph in which each heavy hitter is represented by a well-connected cluster in the graph. They then develop a clustering algorithm that can recover the clusters, and hence the heavy hitters. In order to make the connection to graph clustering, they first encode x with an error correcting code $\mathcal{C}_0$ as we do; but they only need this code to have good distance, as they do not go down the list-recovery route. Then they break $\mathcal{C}_0(x)$ up into n' chunks. Before putting the j-th of these chunks into the j-th smaller data structure, they append it with tags $h_j(x)$ and $\{h_{\Gamma(j)_i}(x)\}$, where the h_j are hash functions and Γ is the adjacency function for an expander graph G. Thus, the j-th chunk of $\mathcal{C}_0(x)$ is essentially connected by edges in G to the other chunks of $\mathcal{C}_0(x)$, and in particular the chunks of $\mathcal{C}_0(x)$ form a cluster that can be recovered by a clustering algorithm.

We note that [4] was also inspired by [29], and builds on their approach to develop differentially private heavy-hitters algorithms. In fact, that work even casts the scheme of [29] as a list-recovery scheme, in a relaxed definition of list-recovery that is different

[8] We note that here the guarantee is to return a list $\mathcal{L}$ of size $O(1/\varepsilon)$ containing all the true heavy hitters, although in both [31] and [5], the list is allowed to contain elements with frequencies $f(x) \ll \varepsilon\|f\|_1$, while most of the heavy-hitters work surveyed above, including ours, does not have such false positives.

[9] We note that in [33], the query time to recover the list of the heavy hitters is $\Omega(N)$ and the space involves a single factor of $\log(N)$, but the "dyadic trick" can be used to obtain the bounds mentioned above.

from our relaxed version in Theorem 2. In particular, their notion of list-recovery will not handle input lists $\mathcal{L}_1, \ldots, \mathcal{L}_n$ that are generated by any ℓ distinct messages, as we handle in Theorem 2.[10]

Algorithmic applications of list-recovery

Our work is inspired by the use of list-recovery in [29], but there is a rich history of using list-recoverable codes in similar algorithmic applications. One example is *group testing*, where the goal is to identify d "positive" items out of a universe of size N, given tests of the form $\bigvee_{i \in I} \mathbf{1}[i \text{ is positive}]$ for subsets $I \subset [N]$. A classic construction of Kautz and Singleton [26] reduces this question to the question of list-recovery. This connection, and elaborations on it, has been exploited in several works, which aim to both minimize the number of tests and to develop sublinear-time algorithms to recover the set of positive items [24, 35].

A second example, even closer to our work, is in *compressed sensing*. In compressed sensing, the goal is to approximately recover an approximately sparse vector $v \in \mathbb{R}^N$ given linear measurements Av for some $A \in \mathbb{R}^{t \times N}$. The heavy-hitters problem is closely related, as a (linear) solution to the heavy hitters problem can approximately recover the support of v. List-recoverable codes have been used in the context of compressed sensing in a similar way as it was used in [29]: associate each $i \in [N]$ with a message, and encode it with a list-recoverable code to get a codeword $\mathcal{C}(i) = (c_1, \ldots, c_n) \in \Sigma^n$. Then reduce the compressed sensing problem to n smaller instances of the same problem for vectors of length $|\Sigma|$: for each $j \in [n]$, we have a vector $w^{(j)}$ indexed by Σ so that the entry $w^{(j)}_\sigma$ is obtained by aggregating all of the coordinates v_i of v so that $\mathcal{C}(i)_j = \sigma$. Now we can either recurse or solve these smaller problems in another way. Previous works [36, 13, 12] have observed that a good list-recoverable code (e.g., satisfying Goal 1) would solve this problem. However, they ran into the same issue that we did, namely that we do not know of any such codes. Instead, they either used sub-optimal codes or developed work-arounds, as we describe below.

The work of Ngo et al. [36] was, to the best of our knowledge, the first to apply list-recovery in compressed sensing. We mention two results in that work that use a framework quite similar to that of [29] (and thus to ours), making explicit use of (sub-optimal) list-recoverable codes. The first result is based on the list-recoverability of Reed-Solomon codes. As RS codes do not achieve Goal 1, this results in a sub-optimal number of measurements, but is nice and simple. The second is based on Parvaresh-Vardy (PV) codes. PV codes have good rate and output list-size, but unfortunately the alphabet size is very large. To get around this, [36] (inspired by the work [35] on group testing mentioned above) considered a code constructed by repeatedly concatenating PV codes with themselves. This does not lead to a code that achieves Goal 1 – the rate depends on ℓ, and either the alphabet size or the rate must depend on n – but they are able to make these dependencies not too bad. This leads to schemes with near-optimal number of measurements t, although the schemes only work for non-negative signals. Further, since PV codes do not have near-linear-time algorithms, the recovery algorithm runs in time $\text{poly}(t)$ rather than near-linear in t.

[10] In a bit more detail, the notion of list-recovery in [4] allows for $\mathcal{L}_1, \ldots, \mathcal{L}_n$ to be generated by ℓ messages $x^{(1)}, \ldots, x^{(\ell)}$, *provided* that the messages lie in distinct "buckets," according to any fixed bucketing of the message space. The choice of the code may depend on the bucketing. In this language, the result of [29] (see [4, Theorem 3.6]) says that it is possible to obtain a code with constant rate, output list size $L = O(\ell)$, and alphabet size that is polynomial in the number of buckets, and a polynomial-time decoding algorithm. If the number of buckets is $\text{poly}(\ell)$, the alphabet size is also $\text{poly}(\ell)$, as we would hope, but as the number of buckets grows (to approach the general case with $|\Sigma|^k$ buckets of size one, where there is no "bucketing" restriction) the alphabet size grows accordingly.

The work of Gilbert et al. [13] follows a similar outline, using the Loomis-Whitney-based codes of [34]. For $d > 0$ some integer parameter, these are codes $\mathcal{C}\colon [N] \to [N^{1/d}]^{d-1}$ are $(\ell, \ell^{d/(d-1)})$-list-recoverable in time $O(\ell^{d/(d-1)} \log N)$. In terms of the desiderata of Goal 1, this does give near-linear-time recovery with good dependence on ℓ; however the alphabet size is huge, growing exponentially in the message length. In [13], they deal with this by applying the scheme mentioned above recursively until the alphabet size becomes manageable. As a result, they are able to get a nearly optimal number of measurements, with a recovery time that depends polynomially (but not linearly) on $\log N$, and with an extremely small error probability, smaller than $1/\operatorname{poly}(N)$.

We also mention [12], which uses list-recoverable codes (PV codes) in a more complicated way to achieve a near-optimal compressed sensing algorithm in the uniform ("forall") model. They also treat the indices i as messages and encode them with a list-recoverable code, but they develop more machinery – using an expander to add linking information between the symbols for example – in order to reduce to the list-recovery problem.

1.4 Open Questions and Future Work

In this work we have made progress towards Goal 1 by constructing a *randomized* code that supports, with high probability, linear-time list-recovery from certain lists. This was enough for our application to heavy hitters, but many open questions still remain.

1. The most obvious open question is to fully attain Goal 1. In addition to furthering our knowledge in algorithmic coding theory, it seems likely that attaining Goal 1 (or the techniques used to do it), would have other applications in algorithm design, as well as in pseudorandomness (as per Section 1.2).
2. While we are able to use techniques from high-dimensional expansion to obtain a failure probability of $N^{-\Omega(\varepsilon^3)}$ (in the setting of ε-heavy hitters), we would like a failure probability of $N^{-\Omega(1)}$.
3. In this paper we studied only *zero-error* list-recovery (or, more accurately, list-recovery from a small fraction of erasures). While this question is interesting and challenging on its own, one can ask about extending our results to list-recovery from errors. In particular, this might lead to improved heavy-hitters schemes in the general turnstile model.
4. We motivated our "probabilistic list-recovery" model by an application to heavy hitters. However, we hope that there are many other algorithmic applications for such a model and for our construction. Indeed, there are several algorithmic applications of list-recovery mentioned in Section 1.3 (e.g., [24, 35, 36, 13]) that explicitly use list-recoverable codes and would be improved by codes that achieve Goal 1. It is our hope that some of these applications could also be improved by better constructions of the probabilistically list-recoverable codes that we study here. As one example, if one could obtain Theorem 2 with $|\Sigma| = \widetilde{O}(\ell)$ (rather than polynomial in ℓ), then by the construction of Kautz and Singleton mentioned above [26] this would yield optimal constructions of probabilistic group testing matrices with sublinear-time decoding, matching a recent result of [37] in a black-box way.

2 Randomized List Recovery

Inspecting our main theorem's proof (in particular, Section 5 in the full version), we can extract a list recovery result for our (randomized) code $\mathcal{C}$ that tolerates a small fraction of erasures. Our randomized encoding can handle input lists that come from a union of

codewords $\{\boldsymbol{\mathcal{C}}(x) : x \in \mathcal{L}_0\}$ for some $\mathcal{L}_0 \subseteq \mathbb{F}_q^k$; this is what we stated in Theorem 2. Moreover, our algorithm can also handle some extra "distractor symbols," provided that those symbols are randomized and unlikely to collide with the symbols that come from $\mathcal{L}_0$. In order to state this formally, we first give a definition that captures the sort of input lists that our algorithm can handle.

▶ **Definition 4.** *Let $\boldsymbol{\mathcal{C}} \colon \mathbb{F}_q^k \to \Sigma^{n'}$ be a randomized encoding, for $\Sigma = \mathbb{F}_q^b$. Consider a randomized function of $\mathcal{C} \sim \boldsymbol{\mathcal{C}}$ and a set of messages $\mathcal{L}_0 \subseteq \mathbb{F}_q^k$, that outputs lists $\mathcal{L}_1, \ldots, \mathcal{L}_{n'} \subseteq \Sigma$. We say that such a function is (t, η)-*nice *w.r.t. $\boldsymbol{\mathcal{C}}$ if the following holds for all $\mathcal{L}_0 \subseteq \mathbb{F}_q^k$ (note that the lists $\mathcal{L}_i$ can depend on $\mathcal{L}_0$):*

1. *For any $i \in [n']$,*
   - *with probability at least $1 - \eta$, $|\mathcal{L}_i| = O(|\mathcal{L}_0|)$, and,*
   - *with probability 1, $\boldsymbol{\mathcal{C}}(x)_i \in \mathcal{L}_i$ for all $x \in \mathcal{L}_0$.*
2. *For any $x \in \mathcal{L}_0$ and $i \in [n']$, with probability at least $1 - \eta$ it holds that $(\boldsymbol{\mathcal{C}}(x)_i)_j \neq \sigma_j$ for every $j \in [b]$ and $\sigma \in \mathcal{L}_i \setminus \{\boldsymbol{\mathcal{C}}(y)_i : y \in \mathcal{L}_0\}$.*

Furthermore, we require that the above properties should hold t-wise independently across the lists. Namely, for any $x \in \mathcal{L}_0$, whether (1) and (2) hold for some $i \in [n']$ is independent of whether it holds for any $t - 1$ other values of $i' \in [n']$.

To illustrate this definition, we give a few examples.

▶ **Example 5** (lists from a union of codewords)**.** The simplest example of a nice distribution is the function that gives

$$\mathcal{L}_i = \{\boldsymbol{\mathcal{C}}(x)_i : x \in \mathcal{L}_0\}.$$

That is, the lists $\mathcal{L}_i$ are just given by the union of the codewords in $\mathcal{L}_0$. To see that this is $(\eta = 0, t = n')$-nice, observe that both (1) and (2) hold deterministically, with probability 1. Indeed, (1) holds by construction, and (2) holds because there are no $\sigma \in \mathcal{L}_i \setminus \{\boldsymbol{\mathcal{C}}(y)_i : y \in \mathcal{L}_0\}$, so the condition is trivial.

▶ **Example 6** (lists with random distractor symbols)**.** Another natural example of a nice distribution is the example above, with some uniformly random extra "distractor" symbols. That is,

$$\mathcal{L}_i = \{\boldsymbol{\mathcal{C}}(x)_i : x \in \mathcal{L}_0\} \cup \{\sigma_{i,h} : h \in [r]\}$$

where $r > 0$ is some parameter and where $\sigma_{i,h}$ are i.i.d. and uniform in Σ. Again, this satisfies item (1) deterministically, provided that $r = O(|\mathcal{L}_0|)$. For (2), we can compute the probability of a collision between the distractor symbols $\{\sigma_{i,j} : j \in [r]\}$ and a given codeword $\boldsymbol{\mathcal{C}}(x)$ for $x \in \mathcal{L}_0$:

$$\begin{aligned}\Pr\left[(\boldsymbol{\mathcal{C}}(x)_i)_j \neq \sigma_j \ \forall j \in [b], \sigma \in \{\sigma_{i,h} : h \in [r]\}\right] &= \left(1 - \frac{1}{q}\right)^{br} \\ &\leq \exp(-br/q).\end{aligned}$$

In particular, when $q \gg br$, this is $1 - O\left(\frac{br}{q}\right)$. Thus, this distribution is (η, t)-nice where $\eta = O(br/q)$ and $t = n$.

Finally, we note that the distribution of distractor symbols that arises in our heavy hitters application is also nice for the code $\mathcal{C}$ that we use. The first point of Item (1) holds because the lists $\mathcal{L}_i$ can only become too large if the inner InnerHH fails and includes items that are not $\varepsilon/4$-heavy hitters. The second point of Item (1) holds because our instantiation of InnerHH has only one-sided error. Item (2) holds even for any $\sigma \in \mathcal{L}_i \setminus \{\mathcal{C}(x)_i\}$, which follows from Lemma 5.4 in the full version.

With this definition in place, we can now state our main theorem for list-recovery. Theorem 7 generalizes Theorem 2, because it allows for input lists with some extra "distractor" symbols, as per Definition 4.

▶ **Theorem 7.** *There exist constants $c > 1$ and $\gamma \in (0, 1)$ such that the following holds for any positive integers k and $\ell \leq k^\gamma$. There exists a randomized encoding $\mathcal{C} \colon \mathbb{F}_q^k \to \Sigma^{n'}$, for $q = \mathrm{poly}(\ell)$, $\Sigma = \mathbb{F}_q^{O(1)}$ and $n' = \Theta(k)$, and a randomized list recovery algorithm $\mathcal{A}$ running in time $\ell^c \cdot k$, with the following guarantee.*

For some constant $\eta < 1$, and an integer $t = \frac{k}{\mathrm{poly}(\ell)}$, for any list of messages $\mathcal{L}_0 \subseteq \mathbb{F}_q^k$ of size ℓ, and any distribution over input lists $\mathcal{L}_1, \ldots, \mathcal{L}_{n'}$ to $\mathcal{A}$ which are randomized functions of $\mathcal{C}$ and $\mathcal{L}_0$ and are (t, η)-nice w.r.t. $\mathcal{C}$, the list recovery algorithm $\mathcal{A}$, with probability $1 - \ell^{-\Omega(k)}$ (over the randomness of the encoding and the lists), outputs $\mathcal{L} \subseteq \mathbb{F}_q^k$ of size $O(\ell)$ such that $\mathcal{L}_0 \subseteq \mathcal{L}$. Furthermore, the encoding time of $\mathcal{C}$ is $O(k \log \ell)$, with a preprocessing step which takes $\mathrm{poly}(k)$ time.

We stress that unlike in standard state-of-the-art efficient list recovery algorithms, here we have a good dependence on ℓ, namely $q = \mathrm{poly}(\ell)$ and $|\mathcal{L}| = O(\ell)$.

We hope that Theorem 7 will find more applications. As discussed in Section 1.3, there are many algorithmic applications of list-recovery in the literature, and several previous applications of list-recovery have ended up with sub-optimal parameters due to the unavailability of codes that achieve Goal 1. It seems possible that Theorem 7 (or a further improvement on our techniques) could lead to improved results in (non-uniform or "for-each") group testing or compressed sensing.

Abstract

Counting and sampling small subgraphs are fundamental algorithmic tasks. Motivated by the need to handle massive datasets efficiently, recent theoretical work has examined the problems in the sublinear time regime. In this work, we consider the problem of sampling a k-clique in a graph from an almost uniform distribution. Specifically the algorithm should output each k-clique with probability $(1 \pm \epsilon)/n_k$, where n_k denotes the number of k-cliques in the graph and ϵ is a given approximation parameter. To this end, the algorithm may perform degree, neighbor, and pair queries. We focus on the class of graphs with arboricity at most α, and prove that the query complexity of the problem is

$$\Theta^*\left(\min\left\{n\alpha, \max\left\{\left(\frac{(n\alpha)^{k/2}}{n_k}\right)^{\frac{1}{k-1}}, \frac{n\alpha^{k-1}}{n_k}\right\}\right\}\right),$$

where n is the number of vertices in the graph, and $\Theta^*(\cdot)$ suppresses dependencies on $(\log n/\epsilon)^{O(k)}$.

Our upper bound is based on defining a special auxiliary graph H_k, such that sampling edges almost uniformly in H_k translates to sampling k-cliques almost uniformly in the original graph G. We then build on a known edge-sampling algorithm (Eden, Ron and Rosenbaum, ICALP19) to sample edges in H_k. The challenge is simulating queries to H_k while being given query access only to G. Our lower bound follows from a construction of a family of graphs with arboricity α such that in each graph there are n_k k-cliques, where one of these cliques is "hidden" and hence hard to sample.

1 Introduction

We consider the problem of sampling k-cliques in sublinear-time. Sampling subgraphs is a fundamental computational task in randomized algorithms, statistics, data science, and many other disciplines. Sampling k-cliques, and triangles in particular, has numerous applications across various fields, see, e.g. [38, 7, 19, 47, 16] and references therein. The best exact combinatorial algorithm for this task is an $O((n/\log n)^k)$-time algorithm by Vassilevska [46], and Chen et al. [14] proved that, under the exponential time hypothesis, there is no $n^{o(k)}$-time algorithm.

Motivated by the need to handle massive datasets efficiently, we consider algorithms that are given query access to the graph, in the form of degree, neighbor and pair queries.[1] We refer to this model as the *general query model*. Our goal is to design an algorithm that samples k-cliques while performing as few queries as possible.

Fichtenberger, Gao, and Peng [32] recently studied the problem of sampling *arbitrary* subgraphs. They assumed access to the above queries, as well as access to uniform edge samples. Thus, they considered a strictly stronger model. Specifically, for sampling k-cliques uniformly at random, their algorithm has expected complexity[2] $\tilde{O}(m^{k/2}/n_k)$, where m and n_k denote the number of edges and k-cliques in the graph, respectively. Their result is known to be essentially tight, due to a lower bound by Eden and Rosenbaum [28].

However, the lower bound of [28] only holds when considering the worst-case over all possible inputs. In this work we ask whether the lower bound can be circumvented when considering graphs with bounded arboricity. The arboricity of a graph G, denoted $\alpha(G)$, is the minimal number of forests required to cover its edge set. Up to a factor of 2, it is equivalent to the average degree of the densest subgraph in G. Hence, arboricity is a natural and useful measure of density "everywhere". Graphs with bounded arboricity constitute an important and rich family of graphs, including planar graphs, minor-closed graphs, graphs with bounded treewidth, and preferential attachment graphs. On the applied side, in most real-world graphs the arboricity is at most an order of magnitude larger than the average degree, while the maximum degree could be up to three or four orders of magnitude larger [34, 30, 43]. Many applied algorithms exploit the property of bounded arboricity in order to design faster algorithms for clique and dense subgraph counting and listing [30, 33, 41, 37, 17, 9]. Furthermore, in a recent work, Eden, Mossel and Ron presented an algorithm for approximating the arboricity in sublinear time [21], whose output can be used as input to our algorithm (as an upper bound on the arboricity of the graph).

We seek algorithms that, given a parameter α and query access to a graph whose arboricity is upper bounded by α, "beat" the aforementioned lower bound when α is sufficiently bounded away from $\sqrt{m}$ (recall that the arboricity of a graph is always at most $\sqrt{m}$).

Such an algorithm was recently designed for the special case of sampling edges (2-cliques) almost uniformly. Here and elsewhere, when we say "almost uniformly" we mean in the strong sense of *pointwise-close* to uniform. Namely, where *each* element is returned with almost equal probability. We further discuss the benefits of this notion as compared to the strictly weaker notion of proximity with respect to the total variation distance in Section 1.1.2.

---

[1] Degree queries return the degree, $d(v)$, of a given vertex v; neighbor queries return the i^{th} neighbor of v for any given vertex v and $1 \leq i \leq d(v)$; and pair queries return whether there is an edge between a given pair of vertices.

[2] Throughout the introduction, when we discuss the "complexity" of previous results, we mean the running time of the algorithm. The query complexity is always bounded by the minimum between the running time and $n + m \leq n\alpha$.

Specifically, it is shown in [23] that the complexity of the almost-uniform edge sampling problem is $\Theta^*(n\alpha/m)$.[3] Comparing this to the $\Theta^*(n/\sqrt{m})$ complexity of the problem in general graphs [29, 45], exhibits an improvement by (roughly) a factor of $\sqrt{m}/\alpha$. In particular, for graphs with constant arboricity, this implies an exponential improvement, from $O^*(\sqrt{n})$ to $O^*(1)$. Similar improvements were obtained for the related question of approximately counting the number of k-cliques in the graph, where Eden, Ron and Seshadhri [26] obtained significant improvements for the class of bounded arboricity graphs, compared to the (essentially optimal) result for the general case [27].

In this work we show that, indeed, the complexity of the task of sampling k-cliques for *any* constant $k \geq 3$, is significantly better for the class of graphs of bounded arboricity, as compared to general graphs.

▶ **Theorem 1.1.** *Let $\varepsilon \in (0,1)$ be a constant. There exists an almost uniform sampling algorithm for k-cliques in graphs with arboricity at most α, that returns each k-clique in the graph with probability $\frac{(1\pm\varepsilon)}{n_k}$. Given a constant factor estimate of n_k,[4] the query complexity of the algorithm is*

$$O^*\left(\min\left\{n\alpha, \max\left\{\left(\frac{(n\alpha)^{k/2}}{n_k}\right)^{\frac{1}{k-1}}, \frac{n\alpha^{k-1}}{n_k}\right\}\right\}\right).$$

The running time is the same as the second term of the minimum.

While our upper bound on the complexity might seem unnatural at first glance, we also prove an almost-matching lower bound, thus resolving the complexity of the problem up to $(\log n/\varepsilon)^{O(k)}$ factors.

▶ **Theorem 1.2.** *Let $\mathcal{A}$ be an algorithm that given query access to a graph with arboricity at most α, returns each k-clique with probability $\Theta\left(\frac{1}{n_k}\right)$. Then the query complexity of $\mathcal{A}$ is*

$$\Omega^*\left(\min\left\{n\alpha, \max\left\{\left(\frac{(n\alpha)^{k/2}}{n_k}\right)^{\frac{1}{k-1}}, \frac{n\alpha^{k-1}}{n_k}\right\}\right\}\right).$$

We note that we chose not to parameterize our bounds in terms of m, but rather, only in terms of n, α, k and n_k. Hence, both the upper bound and the lower bound are stated for worst case m, which is $n\alpha$. We note that it is possible to obtain a finer expression that does depend on m for both bounds. However, for the sake of exposition, we chose not to include an additional parameter.

1.1 Discussion of the results

1.1.1 Comparison to previous results

For simplicity, assume that ε and k are constants, and ignore lower order terms. To compare the complexity of our algorithm to the upper bound of [32], consider, for example, the family of graphs G with n vertices, $m = n^{3/2}$ edges and arboricity $\alpha = n^{1/2}$, and assume that

[3] We use O^*, Ω^* and Θ^* to suppress a dependence on functions $g(\log n, k, 1/\varepsilon)$, which are at most $(\log n/\varepsilon)^{O(k)}$, where ε is the given approximation parameter.

[4] If the algorithm is not provided with an estimate of n_k, then an estimate of n_k can be obtained by applying the algorithm of [26] whose expected query complexity is dominated by the runtime of Theorem 1.1.

$k = 3$ and $n_3 = n^2$. Then the complexity of the problem in the general case grows like[5] $\tilde{\Theta}(m^{3/2}/n_3) = \tilde{\Theta}(n^{1/4})$, while we get $\Theta^*(n^{1/8})$. That is, we obtain a quadratic improvement, despite the fact that we work in a strictly weaker query model.

If we also allow access to uniform edge queries, then our algorithm can be adapted to run in time $O^*\left(\max\left\{\left(\frac{m^{k/2}}{n_k}\right)^{\frac{1}{k-1}}, \frac{m\alpha^{k-2}}{n_k}\right\}\right)$. To compare this to the $O(m^{k/2}/n_k)$ upper bound of [32] (for k-cliques), observe that if the first term in our bound is the dominant one, then we get the bound of [32] taken to the power of $1/(k-1)$. If the second term is the dominant one, then we improve on the bound of [32] by a factor of $(\sqrt{m}/\alpha)^{k-2}$ (recall that for every graph, $\alpha \leq \sqrt{m}$).

1.1.2 The importance of point-wise uniform sampling

In our results we measure "almost uniformity" with respect to pointwise distance between distributions. This notion of approximately uniform is a very strong one, as it requires every element to be returned with almost equal probability. In contrast, one could also consider the strictly weaker requirement that the distribution is close to uniform with respect to total variation distance (TVD). Here, it might be the case that the distributions assigns zero probability to an ε-fraction of the domain elements.

Sampling almost uniformly with respect to TVD may be sufficient in some contexts. However, there are scenarios in which the stronger notion of pointwise almost uniform sampling is crucial. Consider a domain in which each element has some significance score attributed to it, and assume that a small fraction of the domain elements have non-zero score and the others have score zero. If we have access to a distribution whose TVD distance to uniform is larger than the fraction of elements with positive score, then it is useless if we want to get any information regarding the (non-zero) significance scores of the elements. This is in contrast to having access to a distribution that is point-wise close to uniform, even for constant point-wise distance, where each element is returned with probability $\Theta(1/N)$, where N is the size of the domain. In the latter case, the probability of hitting non-zero score elements is slightly reduced as compared to uniform sampling, but does not fall to zero as in the former case.

For a more concrete example, consider protein networks, where cliques correspond to folding sites [18, 13, 1]. One can use point-wise sampling in order to get access to the folding sites of the protein at question, and then continue to further study their surrounding neighborhood. In TVD sampling however, it might be the case that exactly the folding sites of interest are the ones "missed" by the TVD sampler. Furthermore, as biological networks tend to huge and sparse [3, 39], allowing for improved results in bounded arboricity graphs is of major interest.

1.1.3 Approximate counting vs. point-wise sampling

We first observe that the complexities of approximately counting edges and point-wise almost uniformly sampling edges (in both bounded arboricity and general graphs) are of the same order. In contrast, for $k \geq 3$, the two complexities might differ significantly in bounded arboricity graphs. For example, consider the case of triangles ($k = 3$), $\alpha = O(1)$, and

[5] We note that the $\Omega(m^{k/2}/n_k)$ lower bound of [28] also holds for the task of sampling k-cliques almost uniformly.

$n_3 = \Theta(n)$. The complexity of sampling triangles almost uniformly is $\Theta^*(n^{1/4})$, while the complexity of approximately counting problem, is $O^*(1)$. This implies an exponential gap between the complexities of counting and sampling for certain ranges of parameters.[6] [7]

1.2 The high level ideas behind the clique-sampling algorithm

We start by briefly describing the ideas behind the algorithm of [23] for sampling edges almost uniformly, which we employ both as a subroutine and as a starting point of our algorithm for sampling k-cliques. We then turn to describe our algorithm. Throughout, we assume that an upper bound α on the arboricity of the input graph is known.

1.2.1 The edge sampling algorithm

Let L_0 be the set of all vertices in the graph with degree at most (roughly) α (so that almost all the vertices in the graph belong to L_0). The edge sampling algorithm samples a vertex v_0 uniformly at random, and if v_0 is in L_0, it performs a short random walk $v_0, v_1, \ldots, v_j$ of length j, for an index j chosen uniformly in $[\log n]$. If at any point the walk returns to L_0, then the algorithm aborts, and otherwise, it returns the last edge traversed.

The analysis of the algorithm relies on a layered decomposition of the graph vertices. The vertices in L_0 comprise the first layer. Subsequent layers are defined inductively: a vertex v is in L_j if (1) it is not in any of the layers L_i for $i < j$, and (2) most of its neighbors are in layers $L_0, L_2, \ldots, L_{j-1}$. While the algorithm is completely oblivious to the levels of the encountered vertices v_i for $i > 0$, using the aforementioned layering, it can be shown that each edge is sampled with almost equal probability $\approx \frac{1}{n\alpha}$.

1.2.2 The auxiliary graph H_k and the clique-sampling algorithm

In order to sample k-cliques in G, we first define an auxiliary graph H_k, whose edges correspond to k-cliques of G. Specifically, for each $(k-1)$-clique Q in G, there is a node v_Q in H_k, and for each k-clique C in G, there is a single edge in H_k between a pair of nodes $v_Q, v_{Q'}$ corresponding to two of its $(k-1)$-cliques, Q and Q'. Specifically, the first two $(k-1)$-cliques according to an ordering on all $(k-1)$-cliques, which will be defined later on. We say that C is *assigned* to Q and Q'. When $k = 2$, this assignment is uniquely determined (since every 2-clique (edge) contains exactly two 1-cliques (vertices)), and we have $H_2 = G$. For larger values of k, the assignment rule is such that Q and Q' both contain the vertex in C that has minimum degree in G. In general, since there is a one-to-one correspondence between the edges in H_k and the k-cliques of G, sampling an almost uniform edge in H_k is equivalent to sampling an almost uniform k-clique in G. An important observation is that if G has arboricity at most α, then so does H_k.

Given the aforementioned relation between k-cliques in G and edges in H_k, the basic underlying idea of our algorithm is emulating the edge sampling algorithm of [23] on the graph H_k, *while only having query access to the graph* G. Indeed this approach is natural (having defined H_k). However, emulating the edge sampling algorithm by performing random walks on H_k requires us to overcome several challenges:

[6] We note that the separation between approximately counting triangles and sampling triangles almost uniformly was already mentioned in [23] in passing as a preliminary result. However, [23] did not include any proof details nor a full characterization of the complexity of the sampling problem (for any $k \geq 3$).

[7] We believe that the algorithm of [26] can be adapted to sample a k-clique almost uniformly with respect to TVD with essentially the same complexity. However, this is not immediate.

1. We do not have query access to uniformly random nodes of H_k;
2. Determining whether a node in H_k is in layer L_0 cannot be performed by a single degree query (as was the case in [23]);
3. In order to sample a random neighbor of a node v_Q in H_k, we must sample a k-clique in G that is assigned to Q. (In [23] this could be implemented by a single neighbor query.) The emulation is "noisy" in the sense that it obtains only approximate answers to queries on H_k. In particular, it only estimates the degrees of nodes in H_k and selects nodes according to a distribution that is close to uniform. This is in contrast to the [23] algorithm, which gets precise answers to its queries. Hence, we must prove that the new algorithm still returns an edge (in H_k) that is close to uniform.
4. Emulating each query on H_k is implemented by performing multiple queries on G. Hence, one of the main challenges of this work is in bounding the query complexity of the clique-sampling algorithm.

We now outline how we address these challenges.

Addressing the challenges

Challenge 1: Emulating uniform node queries. The algorithm of [23] starts by sampling vertices uniformly at random in G. As stated previously, we do not have direct access to uniform node samples in H_k. Instead, in order to sample nodes in H_k, we recursively invoke our algorithm for sampling $(k-1)$-cliques in G almost uniformly. This results in a distribution that is only close to uniform, but we prove that this is sufficient for our needs.

Challenge 2: Determining whether a node belongs to $\mathbf{L_0(H_k)}$. Recall that in the edge sampling algorithm of [23], L_0 is the set of all vertices with degree roughly α. Therefore, in that algorithm, checking if a vertex belongs to L_0 requires a single degree query. In our setting, the degree of a node V_Q in H_k is equivalent to the number of k-cliques that are assigned to Q in G. Hence,

given a sampled node v_Q in H_k, we implement a procedure to check whether $v_Q \in L_0 = L_0(H_k)$, by trying to approximate the number of k-cliques that are assigned to Q in G. To do so efficiently, we replace the threshold α used to define L_0 in [23], by a value $\tau \geq \alpha$, where we will explain how τ is chosen later in the presentation.

Challenge 3: Emulating a random neighbor query. We next explain how we emulate a random neighbor query for a node v_Q in H_k (so as to emulate a random walk on H_k). Let $\mathcal{A}(Q)$ denote the set of k-cliques assigned to Q. By the definition of H_k, sampling an edge incident to v_Q translates to sampling a k-clique C in $\mathcal{A}(Q)$. Let u be the minimum degree vertex in Q, and define $d(Q) = d(u)$, where $d(u)$ is u's degree (in G). As explained above, for $k > 2$, the assignment rule is such that if a k-clique C is assigned to Q, then u is also the minimum degree vertex in C. Hence, in order to select a random neighbor of v_Q in H_k, we need only consider k-cliques C obtained from Q by adding a vertex with degree at least $d(u) = d(Q)$ (that neighbors all vertices in Q). By dealing separately with the case that $d(Q) \leq \sqrt{n\alpha}$ and the case that $d(Q) > \sqrt{n\alpha}$, we can design a procedure that for every $(k-1)$-clique Q samples each k-clique in $\mathcal{A}(Q)$ with probability (roughly) $\frac{1}{\min\{d(Q),\sqrt{n\alpha}\}}$ (and may fail to output any k-clique).

Given the above, to emulate a random neighbor query from a node v_Q in H_k such that $v_Q \notin L_0$ (so that $|\mathcal{A}(Q)| \geq \tau$), we repeat the above sampling attempts $O^*\left(\left\lceil \frac{\min\{d(Q),\sqrt{n\alpha}\}}{\tau} \right\rceil\right)$ times. This process succeeds in obtaining a uniformly distributed k-clique in $\mathcal{A}(Q)$ with high probability. For a node v_Q in L_0 (where we don't have a lower bound on $|\mathcal{A}(Q)|$), performing this number of attempts implies that each k-clique in $\mathcal{A}(Q)$ is obtained with probability $1/\tau$.

An inductive analysis shows that a single invocation of the above emulation of the random walk on H_k returns each k-clique in G with probability roughly $\frac{1}{n\alpha \cdot \tau^{k-2}}$. The $(n\alpha)$ term in the denominator comes from the base of the induction, i.e., sampling a uniform 2-clique (edge) in G, and the term τ^{k-2} stems from the $k-2$ recursive calls, where in each level of recursion, we "lose" a factor of $1/\tau$. Therefore, the overall success probability of a single attempt to sample an edge in H_k is roughly $\frac{n_k}{n\alpha \cdot \tau^{k-2}}$. Hence, $O^*(\frac{n\alpha \cdot \tau^{k-2}}{n_k})$ repetitions are sufficient so that, with high probability, an almost uniformly distributed k-clique in G is returned.

Challenge 4: Proving correctness. Given the above approach, we are able to emulate the basic algorithm of [23] on the auxiliary graph H_k. Hence, to prove correctness we follow the ideas of [23]. However, since the emulation on H_k results in "noisy" answers to node, degree and neighbor queries, so that we cannot immediately rely on the correctness of the algorithm of [23]. Hence, we must (re-)prove that the emulation algorithm induces a distribution on the edges (of H_k) that is close to uniform. This is done by carefully keeping track of the divergence from uniformity that is caused due to the noisy answers to queries throughout the execution of the algorithm. We note that the main challenge lies not in the proof of correctness, but rather in bounding the complexity of the clique-sampling algorithm, as discussed next.

Challenge 5: Bounding the query complexity. As discussed above, to sample a k-clique in G with high probability, we perform $t = O^*\left(\frac{n\alpha \cdot \tau^{k-2}}{n_k}\right)$ repetitions of the random walk emulation on H_k. In each such emulation, there is a sequence of $k-1$ recursive calls to sample i-cliques for $i \in [2, \ldots, k]$ by performing a random walk on the graph H_i. Whenever a random neighbor query is emulated on a node in H_i for $i > 2$, $r = O^*\left(\frac{\min\{d(T), \sqrt{n\alpha}\}}{\tau}\right)$ queries are performed in G. Conditioned on τ being sufficiently larger than α, we get that the expected number of queries in each such emulation is just $O^*(1)$ (while the maximum is $O^*\left(\frac{\sqrt{n\alpha}}{\tau}\right)$). This implies that the expected total query complexity is $O^*\left(\frac{n\alpha \cdot \tau^{k-2}}{n_k}\right)$. As for the maximum running time, we can get an upper bound of $O^*\left(\frac{n\alpha \cdot \tau^{k-2}}{n_k} + \frac{\sqrt{n\alpha}}{\tau}\right)$ by aborting the algorithm if it performs a larger number of queries, while still obtaining an output distribution as desired.

Hence, we get a certain tradeoff between the expected query complexity and the maximum one (for "hard to sample" cliques). In particular, if we set $\tau = \Theta^*(\alpha)$, we get that the expected query complexity is $O^*\left(\frac{n\alpha^{k-1}}{n_k}\right)$, as in the case of counting, while the maximum query complexity is $O^*\left(\frac{n\alpha^{k-1}}{n_k} + \sqrt{n/\alpha}\right)$. The upper bound in Theorem 1.1 is derived by setting τ so that the two summands in the expression $O^*\left(\frac{n\alpha \cdot \tau^{k-2}}{n_k} + \frac{\sqrt{n\alpha}}{\tau}\right)$ are equal.

1.3 A discussion of related random-walk based sampling algorithms

The idea of sampling k-subgraphs (i.e., subgraphs of size k) from a graph G using random walks on an auxiliary graph (in which nodes and edges correspond to subgraphs), is not new, see, e.g., [7, 47, 42, 12, 11]. However, our approach, and in particular our definition of the auxiliary graph H_k, differs from previous ones in several ways, which are crucial for sampling k-cliques according to a distribution that is ε-pointwise close to uniform, with sublinear query complexity. Below we discuss the main aspects of difference between our approach and the aforementioned previous works.

1. The task. We start by noting that in the aforementioned random-walk based works, the focus was on sampling from a distribution whose support is *all* connected k-subgraphs, while we focus on sampling from a distribution whose support is the set of k-cliques. An algorithm for sampling k-subgraphs can be directly adapted to output only k-cliques using rejection sampling, however this could significantly increase the complexity.
2. The distance measure. In most previous works, the considered distance measure is the total variation distance, while our result considers the strictly stronger pointwise distance measure.[8]
3. The definition of the auxiliary graph. The auxiliary graph considered in the aforementioned works, which we denote here by H'_k, is defined as follows. There is a node in H'_k for each subgraph of size $k-1$ in G, and there is an edge between two nodes in H'_k if the two corresponding $(k-1)$-subgraphs differ by a single vertex. Hence, similarly to our auxiliary graph, H_k, edges in the auxiliary graph correspond to the objects that we would like to sample (k-subgraphs in previous works, and k-cliques in ours). However, the way we define the edge-set of H_k is pivotal to the analysis of our algorithm. In particular, we put an edge between two nodes in H_k not only if the union between the corresponding $(k-1)$ cliques is a k-clique, but also if this k-clique is assigned to the two $(k-1)$-cliques. Our assignment rule is tailored to bound the query complexity of the algorithm (based on the degrees of vertices in the cliques). Also note that if the original graph G is connected, then so is H'_k, while H_k is typically not connected.
4. Performing random walks on the auxiliary graph. Recall that in our context, where we are given only query access to G and would like to minimize the number of queries, we have to overcome several challenges in the emulation of random walks on H_k. These do not arise in previous works: The random walk starts from an arbitrary node in H'_k (an arbitrary $(k-1)$-subgraph), and each step in the walk is simply implemented by selecting a random neighbor of one of the vertices in the current $(k-1)$-subgraph.
5. The complexity of the sampling algorithm. As noted above, our focus is on bounding the query complexity of the algorithm, and indeed we get an almost tight bound based on our definition of H_k and the details of the emulation of random walks on H_k given query access to G. In the aforementioned works, the complexity of the algorithms was shown to depend on the mixing time of H'_k, and one of the main challenges of these works is in analyzing it. Indeed, in [11] it is proved that even if the mixing time of G is relatively small, the mixing time of H'_k may be a factor of $\rho(G)^{k-2}$ larger, where $\rho(G)$ is the ratio between the maximum and minimum degree in G (and hence may be large (e.g., $\Omega(n)$) even in bounded-arboricity graphs).

1.4 Overview of the lower bound

The first and last terms in the lower bound of Theorem 1.2 follow directly from a lower bound of $\Omega^*\left(\min\left\{n\alpha, \frac{n\alpha^{k-1}}{n_k}\right\}\right)$ by [26] for the task of approximately counting the number of k-cliques. They prove that any algorithm that performs fewer queries than the above expression cannot distinguish with high probability between two families of graphs, one with n_k k-cliques, and one with no k-cliques. It follows that any uniform sampling algorithm cannot perform fewer queries. Therefore, our main focus is on proving the term $\Omega^*\left(\left(\frac{(n\alpha)^{k/2}}{n_k}\right)^{\frac{1}{k-1}}\right)$ (which, as noted previously, may be much larger than the $\Omega^*\left(\frac{n\alpha^{k-1}}{n_k}\right)$ term).

[8] In [11], Bressan combined a random-walk based approach with a (linear in m) preprocessing of the graph, in order to obtain an exact uniform sampler.

To this end, we construct a family of graphs (with arboricity at most α), such that in each graph, among the n_k k-cliques that it contains, there is one "hidden" k-clique. This clique is hidden in the sense that any algorithm that (always) performs less than $\left(\frac{(n\alpha)^{k/2}}{n_k}\right)^{\frac{1}{k-1}}/c$ queries (for a sufficiently large constant c) cannot sample this clique with probability $\Omega(1/n_k)$.[9]

The above idea is formalized by defining a process that answers the queries of a sampling algorithm "on the fly" while constructing a random graph in the family. All graphs in the family have the same underlying structure, and they differ in the choice of clique vertices and in the labeling of (part of) the edges. Here we give the high-level idea of the underlying structure, and the intuition for the lower-bound expression.

In each graph in the family, the hidden clique is over a subset S of k vertices that all have (high) degree $\Theta(\ell)$ where $\ell = \sqrt{n\alpha}$. The total number of high-degree vertices is $\Theta(\ell)$ as well (so that all graphs graphs in the family have $\Theta(\ell^2) = \Theta(n\alpha)$ edges[10]). Other than the clique edges, there are no other edges between the high-degree vertices. See Figure 1 for an illustration. Intuitively, in order to reveal the hidden clique, the algorithm must first reveal one edge (u, u') in the clique and then reveal $k-2$ additional edges between u and the other edges in the clique.[11] We prove that in each query, the probability of revealing the first edge of the clique is $O(k^2/\ell^2)$, and the probability of revealing any consecutive edge is $O(k/\ell)$.[12]

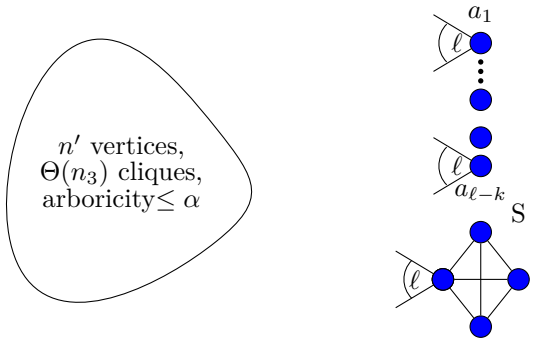

Figure 1 The underlying structure of the graphs in the lower bound construction for $k = 4$. For a more detailed description and figure, see the full version of this paper [24].

The intuition for the upper bound $O(k^2/\ell^2)$ on the probability of revealing the first edge is that the number of clique edges is $\binom{k}{2}$, while the total number of edges is $\Theta(\ell^2)$. Similarly, the rough intuition for the upper bound of $O(k/\ell)$ on revealing each additional edge in the clique is that each clique vertex has $k-1$ neighbors in the clique and a total of $\Theta(\ell)$ neighbors. In order to provide a formal argument, we define an auxiliary bipartite graph

[9] We note that this does not preclude the possibility that the expected complexity of the algorithm is smaller (as discusses in Subsection 1.2.2).

[10] As stated in the introduction, we note that since all of the graphs have $n\alpha$ edges, our lower bound does not exclude the possibility of a refined upper bound that also depends on the number of edges m. (And indeed, it is possible to replace some of the $n\alpha$ terms in the upper bound with m terms. However, we chose not to further complicate the exposition of the algorithm and therefore we also present the lower bound in terms of worst-case m.)

[11] The algorithm may alternatively try to reveal $k/2$ edges in the clique that do not have common endpoints (or some other combination of edges that together reveals all clique vertices), but this is not advantageous for the algorithm.

[12] We note that whenever the term $\frac{(n\alpha)^{k/(2(k-1))}}{kn_k^{1/(k-1)}}$ dominates the last term in the lower bound of Theorem 1.2, it is smaller than $\sqrt{n/\alpha}$.

whose nodes correspond to graphs that are consistent with all previous queries (and answers) and either contain a "witness" clique edge that corresponds to the query of the algorithm (one side of the graph), or do not (the other side). The edges of the bipartite graph are defined by certain transformations from witness graphs to non-witness graphs. By analyzing the degrees of nodes on both sides of this auxiliary graph, we obtain the aforementioned bounds on the probability of revealing edges in the hidden clique.

Given these probability upper bounds, if an algorithm performs T queries, then the probability that it reveals the hidden clique is upper bounded by $T \cdot \frac{k^2}{\ell^2} \cdot \left(T \cdot \frac{k}{\ell}\right)^{k-2}$. If we want this expression to be $\Omega(1/n_k)$, the number of queries T must be $\Omega^*\left(\left(\frac{(n\alpha)^{k/2}}{n_k}\right)^{1/(k-1)}\right)$.

1.5 Related Work

The works most related to ours were mentioned in earlier subsections of the introduction. In Appendix A, we give a broader view of recent advances on sublinear-time approximate counting and uniform sampling algorithms.

1.6 Organization

We start with some preliminaries in Section 2. Due to the page limitation, in this extended abstract we only describe the algorithm and a sketch of the analysis for the case of $k = 3$ (triangles) – see Section 3.

The full algorithm and analysis for the general case, as well as the lower bound, can be found in the full version of this paper [24].

2 Preliminaries

Let $G = (V, E)$ be a graph over n vertices and arboricity at most α. Each vertex $v \in V$ has a unique id in $[n]$, denoted $id(v)$. Let $\mathcal{C}_k$ denote the set of k-cliques of G, and let $n_k = |\mathcal{C}_k|$. For a vertex v, let $\Gamma(v) = \Gamma_G(v)$ denote its set of neighbors and let $d(v) = d_G(v) = |\Gamma(v)|$. We sometimes refer to edges as oriented, meaning that we consider each edge from both its endpoints.

Access to G is given via the following types of queries: (1) A degree query, $\mathsf{deg}(v)$, returns the degree $d(v)$ of the vertex v; (2) A neighbor query, $\mathsf{nbr}(v, i)$ for $i \in [d(v)]$, returns the i^{th} neighbor of v; (3) A pair query, $\mathsf{pair}(v, v')$, returns whether $(v, v') \in E$.

▶ **Definition 2.1** (Ordering of the vertices.)**.** *We define an ordering on the graph's vertices, where $u \prec v$ if $d(u) < d(v)$ or if $d(u) = d(v)$ and $id(u) < id(v)$.*

▶ **Definition 2.2** (Cliques' degree and neighbors)**.** *For a k-clique C, let v be the minimal vertex in v_C according to $\prec$. We define the degree of C in G to be $d(C) = d(v)$. We define the neighbor-set of C, denoted $\Gamma(C) = \Gamma(v)$, to be the set of v's neighbors in G.*

▶ **Definition 2.3** (Cliques id and an ordering of cliques)**.** *For a k-clique C, let its id, $id(C)$ be a concatenation of its vertices ordered by $\prec$. We extend the order $\prec$ to cliques, so that for two k cliques C, C', $C \prec C'$ if $d(C) < d(C')$ or if $d(C) = d(C')$ and $id(C) < id(C')$.*

▶ **Definition 2.4** (Assignment of k-cliques to $(k-1)$-cliques)**.** *We* assign *each k-clique C to its two first $(k-1)$-cliques according to $\prec$. For every $(k-1)$ clique Q, we denote its set of assigned k-cliques by $\mathcal{A}(Q)$, and let $a(Q) = |\mathcal{A}(Q)|$. We refer to $a(Q)$ as the assigned cliques degree of Q.*

Note that for every $k \geq 3$, $a(Q) \leq d(Q)$.

▶ **Observation 2.5.** *By Definition 2.4, for $k \geq 3$, if Q and Q' are assigned a k-clique C, then $d(Q) = d(Q') = d(C)$. Hence, if a k-clique C is assigned to a $(k-1)$-cliques Q such that $C = Q \cup \{w\}$, then $d(Q) = d(C) \leq d(w)$.*

We shall sometimes abuse notation and let $\{Q, u\}$ denote $Q \cup \{w\}$.

We are now ready to define the auxiliary graph H_k, which is central to our algorithm.

▶ **Definition 2.6** (The graph H_k)**.** *Given a graph G, we define the graph $H_k(G) = H_k = (V_{H_k}, E_{H_k})$ as follows. For every $(k-1)$-clique Q in G there is a node v_Q in V_{H_k}. For every k-clique C in G, there is an edge in H_k between the two $(k-1)$-cliques that C is assigned to, as defined in Definition 2.4.*

For the sake of clarity, throughout the paper, we refer to the vertices of H_k as nodes. Note that for the special case of $k = 2$, we have that $H_2(G) = G$, and each edge (2-clique) in G, is assigned to both its endpoints. More generally, Definition 2.6 implies a one-to-one correspondence between the set of edges incident to a node v_Q in $H_k(G)$ and the set $\mathcal{A}(Q)$ of k-cliques assigned to Q in G. This in turn implies that the degree of a node v_Q in $H_k(G)$ equals the assigned cliques degree of Q, $a(Q)$. By the comment following Definition 2.4, the degree of v_Q in $H_k(G)$ is upper bounded by the degree of Q in G.

The last claim in this section concerns the arboricity of $H_k(G)$.

▷ Claim 2.7. Let G be a graph of arboricity at most α. Then $H_k(G)$ has arboricity at most α.

3 The case of $k = 3$: sampling triangles

As a warmup, in this section we describe our algorithm for the case of sampling triangles and provide the structure of its analysis. To ease readability, some of the claims we present are loosely stated (the precise and general claims appear (and are proved) in the next section). Since the graph G is fixed throughout the presentation, we use the shorthand H_3 for $H_3(G)$.

In addition to receiving as input n, α, and ϵ, as well as being given query access to G, the sampling algorithm, Sample-Triangle, receives the parameter $\overline{n}_3$, which is assumed to be a constant factor estimate of the number of triangles, n_3. Such an estimate can be obtained by running the algorithm of [26], without asymptotically increasing the expected complexity of our algorithm.

To sample a triangle in G, the algorithm Sample-Triangle repeatedly invokes the procedure Sample-Edge-Auxiliary-Tri on the graph H_3, while ensuring that the number of queries does not exceed a certain threshold. For the sake of conciseness, from this point on we view the parameters that Sample-Triangle receives, as global variables for all other procedures.

Sample-Triangle$(n, \alpha, \varepsilon, \overline{n}_3)$

1. Set $\tau = \max\left\{\frac{\sqrt{\overline{n}_3}}{(n\alpha)^{1/4}}, \alpha\right\}$.
2. While the number of queries does not exceed $r = c \cdot \min\left\{n\alpha, \max\left\{\frac{\sqrt{n\alpha}}{\tau}, \frac{n\alpha\tau}{\overline{n}_3}\right\}\right\}$ for a sufficiently large constant c:
   a. Invoke Sample-Edge-Auxiliary-Tri(τ), and if an edge in H_3 is returned, then **return** the corresponding 3-clique (triangle) in G.

▶ **Theorem 3.1** (loosely stated)**.** *The algorithm* Sample-Triangle *is a pointwise ε-close to uniform sampling algorithm for triangles (3-cliques) in graphs with arboricity at most α. The query complexity of the algorithm is $O^*\left(\min\left\{n\alpha, \max\left\{\left(\frac{(n\alpha)^{3/4}}{\sqrt{n_3}}\right), \frac{n\alpha^2}{n_3}\right\}\right\}\right)$.*

We defer the proof of the theorem to the end of this section, and continue to describe the procedure Sample-Edge-Auxiliary-Tri. This procedures (tries to) return an (almost) uniformly distributed edge in the auxiliary graph H_3 (corresponding to a triangle in G), so that each edge is returned with probability (roughly) $\frac{1\pm\Theta(\varepsilon)}{n\alpha\tau}$, and it is the main procedure used in order to prove Theorem 3.1.

As will be explained in more detail momentarily, the setting of τ in Sample-Triangle (together with the random coins of the algorithm) determines a set $L_0(H_3)$ of nodes in H_3. Recall that the degree of a node v_Q in H_3 (where Q is a 2-clique, i.e., an edge in G) is the number of triangles (3-cliques) that are assigned to Q according to the assignment rule of Definition 2.4 (denoted $a(Q)$). With high probability over the randomness of the algorithm, all nodes $v_Q \in H_3$ whose degree (in H_3) at most τ belong to $L_0(H_3)$, and all nodes $v_Q \in H_3$ with degree greater than 2τ do not belong to $L_0(H_3)$ (the rest of the nodes can belong to either set). We use $E(L_0(H_3))$ to denote the edges in H_3 that are incident to nodes in $L_0(H_3)$.

Sample-Edge-Auxiliary-Tri first invokes the subroutine Sample-Edge-L_0-Auxiliary-Tri that either returns a (close to) uniform edge (v_0, v_1) among the edges of $E(L_0(H_3))$ or returns FAIL. The procedure then chooses an index j in $[0, \ldots, \log(n\alpha)]$ uniformly at random, and performs a random walk of length j on H_3, by traversing at each step to a uniformly selected neighbor of the last visited node. This is done by invoking the procedure Sample-Neighbor-Auxiliary-Tri. If at any point the last visited node belongs to $L_0(H_3)$ (which is verified by the procedure Define-L_0-Auxiliary-Tri), then the procedure fails. Otherwise, the last traversed edge in the walk is returned.

Sample-Edge-Auxiliary-Tri(τ).

1. Set $s = \log(n\alpha)$ and set $\beta = \varepsilon/(2s+2)$.
2. Invoke Sample-Edge-L_0-Auxiliary-Tri(β, τ), and let $e_0 = (v_{Q_0}, v_{Q_1})$ be the returned edge if one was returned. Otherwise, **return** FAIL.
3. Choose $j \in [0, \ldots, s]$ uniformly at random.
4. For $i = 1$ to j do:
   a. If Define-L_0-Auxiliary-Tri($v_{Q_i}, \delta = \beta/\overline{n}_3, \beta, \tau$)=YES, then **return** FAIL.
   b. Invoke Sample-Neighbor-Auxiliary-Tri(v_{Q_i}, β, τ) to sample an edge $(v_{Q_i}, v_{Q_{i+1}})$ in H_3.
5. **Return** $(v_{Q_j}, v_{Q_{j+1}})$.

▶ **Lemma 3.2** (loosely stated). *The procedure* Sample-Edge-Auxiliary-Tri *returns an edge in H_3 so that each edge is returned with probability (roughly) $\frac{(1\pm\varepsilon)}{n\alpha\tau}$. Furthermore, the expected running time of a single invocation of the procedure is $O^*(1)$, and the maximum running time is $O^*(\sqrt{n\alpha}/\tau)$.*

Before presenting the subroutines Sample-Edge-L_0-Auxiliary-Tri, Sample-Neighbor-Auxiliary-Tri and Define-L_0-Auxiliary-Tri invoked in Sample-Edge-Auxiliary-Tri, we describe a simple procedure, Samp-High-Deg-Nbr, used by these subroutines. The procedure gets a 2-clique (edge) Q as input, and tries to sample a higher degree neighbor of Q in G, so that each such neighbor is returned with probability $1/\min\{d(Q), \sqrt{n\alpha}\}$. As mentioned in the introduction, we shall make use of the procedure Sample-Basic-Edge by [29], that returns every edge in G with probability (roughly) $(1 \pm \beta)/(n\alpha)$, given an approximation parameter β.

Samp-High-Deg-Nbr(Q, β).

1. Let u be the min degree vertex of Q, and query $d(u)(= d(Q))$.
2. If $d(Q) \leq \sqrt{n\alpha}$, then query the i^{th} neighbor of u in G, for a uniformly selected index $i \in d(u)$. If $d(w) \geq d(Q)$, then return w.
3. If $d(Q) > \sqrt{n\alpha}$, then:
   a. Invoke Sample-Basic-Edge(β) and if an edge is returned then denote it (w, x). Otherwise, return FAIL.
   b. Query $d(w)$ and if $d(w) > d(Q)$, then return the endpoint w with probability $d(w)/\sqrt{n\alpha}$. Otherwise, return FAIL.

▷ Claim 3.3 (loosely stated). Let Q be a 2-clique (edge) in G. The procedure Samp-High-Deg-Nbr either returns a neighbor of Q in G (that is, a neighbor in G of the min-degree vertex of Q), or fails. Each $w \in \Gamma(Q)$ such that $d(w) \geq d(Q)$ is returned with (roughly) equal probability $(1 \pm \beta)/\min\{d(Q), \sqrt{n\alpha}\}$. The query and time complexity of the procedure are $O^*(\log n)$.

We turn to present the subroutines used by Sample-Edge-Auxiliary-Tri, starting with the subroutine Define-L_0-Auxiliary-Tri, that defines the aforementioned set $L_0(H_3) \subseteq V(H_3)$. Namely, $L_0(H_3)$ is determined according to the output of the subroutine, so that

$$L_0(H_3) = \{v_Q \in V_{H_3} \ : \ \text{Define-}L_0\text{-Auxiliary-Tri}(v_Q, \delta, \beta, \tau) = \ \text{YES} \ \}$$

(where we assume that the randomness of the subroutine is uniquely determined for each v_Q). Hence Define-L_0-Auxiliary-Tri can be thought of as an *oracle* that returns whether a given v_Q belongs to $L_0(H_3)$ or not.

Define-L_0-Auxiliary-Tri$(v_Q, \delta, \beta, \tau)$.

1. Let Q be the 2-clique (edge) in G corresponding to v_Q.
2. For $i = 1$ to $r = \frac{\min\{d(Q), \sqrt{n\alpha}\}}{\tau} \cdot \ln(1/\delta)$ do:
   a. Invoke Samp-High-Deg-Nbr$(Q, \beta/10)$ to (try and) sample a neighbor w_i of Q.
   b. If Q and w_i form a triangle C, and C is assigned to Q, then let $\chi_{w_i} = 1$.
3. Let $\tilde{a} = \frac{1}{r}\sum_{i=1}^{r} \chi_{w_i}$.
4. If $\tilde{a} < 1.5\tau/d(Q)$ then return YES. Otherwise, return NO.

Recall that $\mathcal{A}(Q)$ is the set of cliques assigned to Q, and $a(Q) = |\mathcal{A}(Q)|$.

▷ Claim 3.4 (loosely stated). With high probability Define-L_0-Auxiliary-Tri determines a set $L_0(H_3)$ so that the following holds for every $v_Q \in H_3$.

- If $a(Q) \leq \tau$, then $v_Q \in L_0(H_3)$ and the subroutine returns YES.
- If $a(Q) > 2\tau$, then $v_Q \notin L_0(H_3)$ and the subroutine returns NO.

Furthermore, the query and time complexities of the subroutine are $O^*\left(\frac{\min\{d(Q), \sqrt{n\alpha}\}}{\tau}\right)$.

Given Claim 3.4, from here on we assume that for every $Q \in L_0(H_3)$, $dt(Q) \leq 2\tau$, and for every $Q \notin L_0(H_3), a(Q) > \tau$.

We now present the subroutine Sample-Edge-L_0-Auxiliary-Tri that is used for sampling edges in H_3 that are incident to nodes in $L_0(H_3)$. In order to sample a uniform edge in $E(L_0(H_3))$, we first need to sample a node in $L_0(H_3)$. Recall that the nodes of H_3 correspond to edges in G. Hence, to sample a node in $L_0(H_3)$, the procedure first invokes Sample-Basic-Edge to sample an edge in G (almost) uniformly at random, and then checks if the corresponding node is in $L_0(H_3)$ (by invoking Define-L_0-Auxiliary-Tri).

Sample-Edge-L_0-Auxiliary-Tri(β, τ).

1. Invoke Sample-Basic-Edge$(\beta/4)$. Let Q be the returned 2-clique if one was returned. Otherwise FAIL.
2. If Define-L_0-Auxiliary-Tri$(v_Q, \delta, \beta/4, \tau)$=NO then FAIL.
3. Repeat at most $r = O^*\left(\frac{\min\{d(Q), \sqrt{n\alpha}\}}{2\tau}\right)$ times or until a neighbor is sampled:
   a. Invoke Samp-High-Deg-Nbr$(Q, \beta/10)$ to (try and) sample a neighbor w of Q.
4. If no neighbor is sampled, then return FAIL.
5. Check if $\{Q, w\}$ is a triangle assigned to Q. If so, return $C = \{Q, w\}$.

▷ Claim 3.5. Consider an invocation of Sample-Edge-L_0-Auxiliary-Tri with parameters β and τ. The subroutine Sample-Edge-L_0-Auxiliary-Tri returns every edge in $E(L_0(H_3))$ with probability (roughly) $(1 \pm \beta)/(2n\alpha\tau)$. The expected query and time complexity of the subroutine are $O^*(1)$ and the maximum query and time complexity are $O^*\left(\frac{\sqrt{n\alpha}}{\tau}\right)$.

Finally, the subroutine Sample-Neighbor-Auxiliary-Tri (tries to) sample a neighbor of a node v_Q in the auxiliary graph H_3. That is, it tries to sample a triangle $C \in \mathcal{A}(Q)$.

Sample-Neighbor-Auxiliary-Tri(v_Q, β).

1. Let Q be the 2-clique (edge) in G corresponding to v_Q.
2. Repeat at most $r = \frac{\min\{d(Q), \sqrt{n\alpha}\}}{\tau} \cdot \ln(1/\beta)$ times:
   a. Invoke Samp-High-Deg-Nbr$(Q, \beta/10)$ to (try and) sample a neighbor w of Q.
   b. If Q and w form a triangle C, and C is assigned to Q, then **return** the edge $(v_Q, v_{Q'})$ in H_3 that corresponds to C.

▷ Claim 3.6 (loosely stated). For a given node $v_Q \in V(H_3)$ such that $Q \notin L_0(H_3)$, with probability at least $1 - \beta$, the subroutine Sample-Neighbor-Auxiliary-Tri returns a neighbor of v_Q in H_3, so that each neighbor of v_Q is returned with probability (roughly) $(1 \pm \beta)/a(Q)$. The query and time complexity of the subroutine are $O^*\left(\frac{\min\{d(Q), \sqrt{n\alpha}\}}{\tau}\right)$.

Finally, we sketch the proof of (the loosely stated) Theorem 3.1.

Proof sketch of Theorem 3.1. By Lemma 3.2, Sample-Edge-Auxiliary-Tri returns every specific edge in H_3 with probability (roughly) $(1 \pm \varepsilon)/(n\alpha\tau)$. Since there is a one-to-one correspondence between edges in H_3 to triangles in G, this implies that each triangle is returned with probability (roughly) $(1 \pm \varepsilon)/(n\alpha\tau)$, and that with probability (roughly) $n_3/(n\alpha\tau)$, some triangle is returned. Hence, the expected number of invocations of the loop is $O(n\alpha\tau/n_3)$. Furthermore, by Claim 3.2, the expected complexity of each invocation is $O^*(1)$. It can be proven using standard concentration bounds, that with high probability, a triangle will be returned before the number of allowed queries r is exceeded. Therefore, with high probability, a triangle is returned, and since all triangle are almost equally likely to be the returned one, it holds that each triangle is returned with probability (roughly) $1/n_3$.

Furthermore, since the expected complexity of each invocation of Sample-Edge-Auxiliary is $O^*(1)$ and the maximum is $O^*(\sqrt{n\alpha}/\tau)$, it follows that the query and time complexity of Sample-Triangle is $O^*(r + \sqrt{n\alpha}/\tau) = O^*\left(\min\left\{n\alpha, \max\left\{\frac{\sqrt{n\alpha}}{\tau}, \frac{n\alpha\tau}{n_3}\right\}\right\}\right)$. Plugging $\tau = \max\left\{\frac{\sqrt{n_3}}{(n\alpha)^{1/4}}, \alpha\right\}$, we get that the query complexity of Sample-Triangle is bounded by

$$O^*\left(\min\left\{n\alpha, \max\left\{\frac{(n\alpha)^{3/4}}{\sqrt{n_3}}, \frac{n\alpha^2}{n_3}\right\}\right\}\right),$$

as claimed. ◀

A Related Work

We note that some of the works were mentioned before, but we repeat them here for the sake of completeness. In recent years, there has been an increasing interest in the questions of subgraph approximate counting and uniform sampling in sublinear-time. These works differ by the query model, graph class of G and the subgraph H at question.

The general graph query model. The first works on estimating the number of subgraph counts were by Feige [31] and Goldreich and Ron [35], who presented algorithms for approximately counting the number of k-cliques in a graph for $k = 2$ (edges).[13] Later, Gonen, Ron and Shavitt [36] gave essentially optimal bounds for the problem of approximately counting the number of stars in a graph. In [20, 27], Eden, Levi, Ron and Seshadhri and Eden, Ron and Seshadhri presented essentially optimal query complexity bounds for the problems of approximately counting triangles and k-cliques. In [44], Tětek gave improved running time bounds for the regime where the query complexity is linear in previous works.

In [28], Eden and Rosenbaum presented a framework for proving subgraph counting lower bounds using reduction from communication complexity, which allowed them to reprove the lower bounds for all of the variants listed above.

Augmented model. In [2], Aliakbarpour, Biswas, Gouleakis, Peebles, and Rubinfeld and Yodpinyanee suggested a model that also allows for uniform edge samples. In that model they presented improved bounds for the approximate star counting problem. In that model, Assadi, Kapralov and Khanna [4] considered the problem of approximate counting of arbitrary subgraphs H. The expected query complexity of their algorithm is $\tilde{O}\left(\min\left\{m, \frac{m^{\rho(H)}}{n_H}\right\}\right)$, where $\rho(H)$ is the fractional edge cover of H,[14] and n_H is the number of copies of H in G. In particular, for the case of k-clique (and odd-cycle counting) the complexity of their algorithm is $O(m^{k/2})$, and this is optimal. In [10], Biswas, Eden and Rubinfeld have refined the complexity of approximating and uniformly sampling arbitrary motifs to $O^*\left(\min\left\{m, \mathsf{decomp\text{-}cost}(G, H, D^*(H))\right\}\right)$, where $D^*(H)$ is an optimal decomposition of H, and $\mathsf{decomp\text{-}cost}$ is the decomposition cost of H in G.

Set query model. In [5], Beame, Har-Peled, Ramamoorthy and Sinha suggested two new models that allow what they refer to as *independent set* (IS) and *bipartite independent set* (BIS) queries. They considered the problem of estimating the number of edges and gave $O^*(n^{2/3})$ and $O^*(1)$ algorithms for this problem using IS and BIS queries, respectively. The first result was later improved by Chen, Levi and Waingarten [15] who settled the complexity of the problem to $\Theta^*(n/\sqrt{m})$. In [6], Bhattacharya, Bishnu, Ghosh, and Mishra later have generalized the BIS model to tripartite set queries, where they considered the problem of triangle counting, and in [8], Bishnu, Ghosh, and Mishra settled the complexity of approximately counting triangles using BIS queries to $\Theta^*\left(\min\left\{\frac{m}{\sqrt{T}}, \frac{m^{3/2}}{T}\right\}\right)$, where T denotes the number of triangles.

[13] Feige considered a model that only allows for degree queries, and presented a factor 2 approximation algorithm, and also proved that with no additional queries this approximation factor cannot be improved in sublinear time. Goldreich and Ron then considered this question allowing also for neighbor queries. In this model the proved an $(1 \pm \varepsilon)$-factor approximation algorithm with the same complexity as the previous one (as well as a matching lower bound).

[14] The fractional edge cover of a graph $H = (V_H, E_H)$ is a mapping $\psi : E_H \to [0, 1]$ such that for each vertex $a \in V_H$, $\sum_{e \in E_H, a \in e} \psi(e) \geq 1$. The fractional edge-cover number $\rho(H)$ of H is the minimum value of $\sum_{e \in E_H} \psi(e)$ among all fractional edge covers ψ.

Uniform sampling. In [29], Eden and Rosenbaum initiated the study of sampling subgraphs (almost) uniformly at random. They considered the general graph query model, and presented upper and matching lower bounds for the problem of sampling edges almost uniformly. Their algorithm matches the complexity of the counting variant of the problem. Their algorithm's dependency on ε was later improved by Tětek and Thorup [45] to $\log(1/\varepsilon)$, so that for all practical purposes the new algorithm allows to sample from essentially the uniform distribution. They also present an algorithm that works in a stronger model that allows for hash-based neighbor queries, and outputs an edge from *exactly* the uniform distribution.

In [32], Fichtenberger, Gao and Peng proved that in the augmented edge model, *exact* uniform sampling of arbitrary subgraphs can be performed in $O\left(\frac{m^{\rho(H)}}{n_H}\right)$ time. This matches the upper bound of [4] for the counting variant. The aforementioned bound of [10], also holds for this setting, refining over the complexity of [32].

In [22], Eden, Mossel and Rubinfeld presented an algorithm for sampling multiple edges efficiently. Their algorithm was later shown to be optimal by Tětek and Thorup [45].

Graphs G with bounded arboricity. In [25, 26], Eden, Ron and Seshadhri first studied the problem of sublinear approximate counting in bounded arboricity graphs. They presented improved algorithm for edges, star and k-clique counting in the general graph model, parameterized by the arboricity. In [23], Eden Ron and Rosenbaum presented an improved algorithm for almost uniform sampling of edges in bounded arboricity graphs, in the general graph query model.

Approximating the arboricity in sublinear time. In [21], Eden, Mossel and Ron presented an algorithm for approximating the arboricity in $\tilde{O}(n/\alpha)$ time. Their algorithm returns a value $\hat{\alpha}$ such that, with high probability, $\hat{\alpha} \in [\alpha, \alpha \cdot c\log^2 n]$, for some constant c. It can also be shown that the algorithm of McGregor, Tench, Vorotnikova and Vu [40] can be adapted to the adjacency list query model,[15] resulting in a $(1 \pm \varepsilon)$-multiplicative approximation in $\tilde{O}(m/\alpha)$ complexity. The output of these algorithms can be used as input to our algorithm (as well as all aforementioned sublinear-time algorithms that rely on getting an upper bound on the arboricity as input).

[15] This requires some care, as their algorithm relies on sampling edges uniformly at random, which is not immediately implementable in the adjacency list model. However, it can be shown that only edges with high degree endpoints (roughly ones with degree above α) are of interest, and these can be sampled uniformly with an additive overhead of $\tilde{O}(m/\alpha)$.

On Sampling Symmetric Gibbs Distributions on Sparse Random Graphs and Hypergraphs

Charilaos Efthymiou ✉
Computer Science, University of Warwick, Coventry, UK

Abstract

In this paper, we present a novel, polynomial time, algorithm for approximate sampling from symmetric Gibbs distributions on the sparse random graph and hypergraph. The examples of symmetric distributions we consider here include some important distributions on spin-systems and spin-glasses. These are: the q-state antiferromagnetic Potts model for $q \geq 2$, including the (hyper)graph Ising model and random colourings. The uniform distribution over the Not-All-Equal solutions of a random k-SAT formula. Finally, we consider sampling from the *spin-glass* distribution called the k-spin model, i.e., this is the "diluted" version of the well-known Sherrington-Kirkpatrick model. Spin-glasses give rise to very intricate distributions which are also studied in mathematics, in neural computation, computational biology and many other areas. To our knowledge, this is the first rigorously analysed efficient sampling algorithm for spin-glasses which operates in a non trivial range of the parameters of the distribution.

We present, what we believe to be, an elegant sampling algorithm. Our algorithm is unique in its approach and does not belong to any of the well-known families of sampling algorithms. We derive it by investigating the power and the limits of the approach that was introduced in [Efthymiou: SODA 2012] and combine it, in a novel way, with powerful notions from the Cavity method.

Specifically, for a symmetric Gibbs distribution μ on the random (hyper)graph whose parameters are within an appropriate range, our sampling algorithm has the following properties: with probability $1-o(1)$ over the instances of the input (hyper)graph, it generates a configuration which is distributed within total variation distance $n^{-\Omega(1)}$ from μ. The time complexity is $O((n \log n)^2)$, where n is the size of the input (hyper)graph.

We make a notable progress regarding impressive predictions of physicists relating phase-transitions of Gibbs distributions with the efficiency of the corresponding sampling algorithms. For most (if not all) the cases we consider here, our algorithm outperforms by far any other sampling algorithms in terms of the permitted range of the parameters of the Gibbs distributions.

The use of notions and ideas from the Cavity method provides a new insight to the sampling problem. Our results imply that there is a lot of potential for further exploiting the Cavity method for algorithmic design.

1 Introduction

Random constraint satisfaction problems (r-CSPs) have been the subject of intense study in combinatorics, computer science and statistical physics. In computer science the study of random CSPs is motivated by a wealth of applications, e.g., they are used as algorithmic benchmarks for hard problems such as the graph colouring, or the k-SAT, they are studied as models for statistical inference, they are also used as gadgets for cryptographic constructions, or reductions in complexity theory [23, 20, 19, 26].

Physicists, independently, have been studying random CSPs as models of *disordered systems* using the so-called *Cavity Method* (e.g. see [32, 29]). The Cavity method originates from the groundbreaking ideas in physics which got Giorgio Parisi the 2021 Nobel Prize in Physics. With its very impressive predictions and its deep intuition, the Cavity Method attracted the interest of both computer scientists and mathematicians, despite its lack of mathematical rigour. In the last two-decades, or so, ideas from the Cavity method have blended the study of random CSPs in computer science and have yield some beautiful results and breakthroughs in the area e.g., [11, 1, 34, 12, 24].

A fundamental notion in physicists' predictions is that of the Gibbs distribution. Using the Cavity method, physicists make predictions relating phase-transitions of Gibbs distributions with the efficiency of the sampling algorithms. Establishing rigorously these connections is a very challenging task and, despite any recent advances, most of the central questions still remain open. In this work, we introduce a novel approach to the sampling problem that exploits *intuition* from the Cavity method, as well as *mathematical tools* and ideas that were developed for the study of random CSPs in conjunction with the Cavity method. Our approach yields efficient algorithms with notable performance with respect to the allowed region of the parameters of the problem.

We remark that this is not the first attempt to employ ideas from the Cavity method for algorithmic design. The celebrated heuristics *Belief Propagation* and *Survey Propagation* [5, 33] are prominent examples of physicists' attempt to turn the Cavity method into an algorithm. Despite their impressive empirical performance, we lack a rigorous mathematical analysis for these heuristics with respect to generating samples from Gibbs distributions.

Our algorithm here is for sampling from what we call *symmetric Gibbs distributions*. This includes important examples such as the (hyper)graph q-colourings and its generalisation the q-state Potts model for $q \geq 2$, the symmetric variants of k-SAT such as the not-all-equal k-SAT (k-NAE-SAT). A notable case is the *spin-glass* k-spin model, i.e., the same spin-glasses that Parisi studied in the 80's. Spin-glasses give rise to very intricate distributions which are also studied in mathematics, in neural computation, computational biology and many other areas [37]. For us, the underlying geometry is an instance of the random graph, or hypergraph of constant expected degree $d > 0$.

For most of the above distributions it is extremely challenging to sample from. This is not only because the underlying geometry is random. Each of the aforementioned distributions exhibits special features that make the analysis of known sampling techniques intractable. E.g., in the interesting region of parameters for k-NAE SAT, or hypergraph colourings, we have untypical configurations with *non-local* freezing of the variables, the spin-glasses exhibit local, randomly induced, *frustration* phenomena, etc.

An additional motivation for this work comes from our desire to investigate the power and the limits of the (well-known) sampling method that is introduced in [15]. The method in [15], (or any of its subsequent works) does not exploit the Cavity method. On a high level, the approach summarises as follows: having the graph G at the input, the algorithm initially

removes all the edges and generates a configuration for the empty graph. Then, iteratively, the algorithm puts the edges back one by one. If G_i is the subgraph we have at iteration i, our objective is to have a configuration σ_i which is distributed very close to the Gibbs distribution on G_i. The idea is to generate σ_i by *updating* appropriately the configuration of G_{i-1}, i.e., update σ_{i-1} to generate efficiently σ_i. Once all the edges are put back, the algorithm outputs the configuration of G.

The algorithm in [15], relies heavily on properties that are special to graph colourings, for this reason it is restricted to this distribution. The same holds for similar approaches in the area, i.e., the algorithm is specific to the distribution it is sampling from. This is a drawback because every time we consider a new distribution we have to design a new algorithm from scratch. With our approach here, we avoid this. We introduce a sampling algorithm that the Gibbs distribution we are sampling from is a *parameter*, e.g., similarly to Glauber dynamics.

Previous approaches in the area rely on the *correlation decay* condition called *tree-uniquess* to establish the accuracy of the algorithm. For our purposes, requiring such a condition can be too restrictive. On one hand, for many of the distributions we consider here, we are far from establishing their tree uniqueness region. Actually, for many of them it is notoriously difficult to establish it even for a very limited rage of their parameters. On the other hand, it seems that Gibbs uniqueness is too restrictive a condition for distributions on the hypergraph. With our approach here we give a new insight to the problem by showing that we can exploit notions about the Gibbs distributions that we typically encounter in the study of the Cavity method and random CSPs. For example, we use notions like the *broadcasting probabilities* encountered in the study of the extremality of Gibbs distributions for random CSPs [7, 29, 16], or the *contiguity* between the Gibbs distribution and its corresponding *teacher-student model* for the study of the so-called free energy and its fluctuations [1, 11, 30, 8].

To appreciate our results, we remark that for most of the distributions we consider here, in order to prove that, e.g., the MCMC sampler works anywhere near the region of the parameters that our algorithm allows, would require major breakthroughs in the area of Markov chains, with repercussions that go beyond the problems we consider in this work.

The reader should not confuse the bounds we get here with those for "worst-case" instances. For worst case instances, usually, the parametrisation is w.r.t. the *maximum degree* of the underlying (hyper)graph, whereas for the random (hyper)graph, the natural parametrisation is w.r.t. the *expected degree*. Typically for the random (hyper)graphs here the maximum degree is *unbounded*, i.e., $\Theta(\log n/\log\log n)$, while the expected degree d is a *fixed* number.

It is important to mention that having an algorithm which allows a lot of freedom for the parameters comes at a certain cost. The approximation guarantees of our algorithm are not equally strong to, e,g., those of the MCMC approach. That is, even though the state of the art of MCMC can be far more restrictive in the parameters it allows, it provides stronger approximation guarantees. Roughly speaking, our results is summarised as follows: for a symmetric Gibbs distribution μ on the random (hyper)graph which satisfies our set of conditions, we have an approximation sampling algorithm such that with probability $1-o(1)$ over the instances of the input (hyper)graph, it generates a configuration which is distributed within total variation distance $n^{-\Omega(1)}$ from μ. The time complexity is $O((n\log n)^2)$.

Concluding, the idea of "iteratively adding edges and updating" turns out to be quite powerful, particularly when we combine it with notions and ideas from the Cavity method. It allows us to sample from distributions that, prior to this work, was impossible to sample. Our approach leads to, what we believe to be, an elegant sampling algorithm which deviates from [15] and follow up approaches not only on the phenomena of the Gibbs distributions that it utilises, but also on its basic description. Our work shows how powerful the notions

from the Cavity method can be, i.e., even in the context of sampling algorithms. We believe that there is a lot of potential towards the direction of using ideas from the Cavity method for the sampling problem in order to get even stronger algorithms.

Results for specific distributions appear in Section 1.2. Particularly, we show results for the anti-ferro q-state Potts model on graphs and hypergraphs, for any $q \geq 2$. This includes the "zero-temperature" case (hyper)graph colourings, as well as the anti-ferro Ising model. Also, we show results for the k-NAE-SAT, for $k \geq 2$, and the *spin-glass* called the k-spin model. This is the diluted version of the celebrated and extensively studied *Sherrington-Kirkpatrick* mean field model [31, 38]. Spin-glasses are studied in mathematics, in neural computation, computational biology and many other areas [37]. To our knowledge, this is the first rigorous analysis of efficient algorithm for spin-glasses. Our algorithm is by no means restricted to the cases presented here, i.e., it applies to *any* symmetric Gibbs distribution. We choose to present the specific ones because there is a common analysis framework that we can use.

1.1 General Overview

Let the fixed k-uniform hypergraph $H_k = (V, E)$. Clearly, the graph case corresponds to having $k = 2$. A Gibbs distribution on H_k is specified by the set of spins $\mathcal{A}$ and the weight functions $(\psi_e)_{e\in E}$ such that $\psi_e : \mathcal{A}^k \to \mathbb{R}_{\geq 0}$. The Gibbs distribution $\mu = \mu_H$ is on the set of configurations $\mathcal{A}^V$, i.e., the assignments of spins to the vertices of H_k, such that each $\sigma \in \mathcal{A}^V$ gets probability measure

$$\mu(\sigma) \propto \prod_{e\in E} \psi_e(\sigma(x_{e,1}), \sigma(x_{e,2}), \ldots, \sigma(x_{e,k})),$$

where $x_{e,i}$ is the i-th vertex in the hyperedge e. We assume a predefined order for the vertices in each hyperedge. The symbol $\propto$ stands for "proportional to".

In many situations, we allow ψ_e to vary with e. For example, in k-NAE-SAT, or the k-spin model each ψ_e is chosen independently, according to a predefined distribution. For this early exposition of the results the reader may very well assume that all ψ_e's are the same and fixed.

Roughly speaking, μ is symmetric, if for any $\sigma, \tau \in \mathcal{A}^V$ such that σ can be obtained from τ by repermuting the spin classes, we have that $\mu(\sigma) = \mu(\tau)$. For example, suppose that $\mathcal{A} = \{\pm 1\}$. If μ is symmetric, then we have $\mu(\sigma) = \mu(\tau)$ for any two $\sigma, \tau \in \mathcal{A}^V$, such that $\sigma(x) = -\tau(x)$ for all $x \in V$.

The underlying (hyper)graph structure is random. We let $\boldsymbol{H} = \boldsymbol{H}(n, m, k)$ be the random k-uniform hypergraph on n vertices and m hyperedges. For the graph case, i.e., $k = 2$, we write $\boldsymbol{G}(n, m)$. The expected degree is denoted by d. We take d to be a constant, i.e., $m = \Theta(n)$. Our results hold for any $d > 0$, i.e., we *do not* require that "d is sufficiently large".

Consider a typical instance of $\boldsymbol{H}$, of expected degree d, and $\mu = \mu_{\boldsymbol{H}}$ a symmetric Gibbs distribution on $\boldsymbol{H}$. Suppose that we want to sample from μ. In what follows, we describe the key features of the algorithm we propose for sampling from μ.

The main problem we need to deal with is the update-rule, i.e., how to design a method that gives us the configuration σ_i from σ_{i-1}, while, at the same time, it is generic enough to apply to all symmetric Gibbs distributions. We introduce an approach that relies on an abstract process that is called *broadcasting*. This is a natural process, that can be used to generate samples of symmetric Gibbs distributions on trees. The update starts by changing the configuration of the vertices that are disconnected and become connected when we add the (hyper) edge in the iteration i. W.l.o.g. assume that we change the assignment of just one of these vertices. Starting from this disagreeing vertex, we employ a process that is a

reminiscent of a *coupling* between two broadcasting processes. It is possible that in this process the initial disagreements propagates to some of its neighbours and, in turn, the disagreement of the neighbours propagates to neighbours further away and so on. The update stops when no more disagreements are generated.

It is crucial for the accuracy of the algorithm that the disagreements do not propagate too much further from the initial one. We can bound the rate that the disagreements spread during the update in terms of certain quantities related to the Gibbs distribution called *broadcasting probabilities*. Particularly, we have two desiderata: (a) the broadcasting probabilities are sufficiently close with each other (b) we need to show that the configuration of the vertices that the update rule encounters, somehow, looks like the result of a broadcasting process.

For the first desideratum we just need to tune appropriately the parameters of the Gibbs distribution. As far as the second one is concerned, even though we expect it to be true in our setting, it is very difficult to establish it rigorously. To this end, we employ the so-called planting-trick. This is a technique that allows us to circumvent the problem of accessing properties of the Gibbs distribution by using a very accurate approximation of it, which is called the *Teacher-Student* model. Working with the later distribution is technically much easier and it allows to get our second desideratum.

Let us be more specific. In order to have an accurate algorithm we introduce a set of technical conditions for the Gibbs distribution μ which we call `SET`. For describing `SET`, we need to visit few basic concepts.

Using the weight functions $(\psi_e)_{e\in E}$ we considered before, we introduce the following distributions: for each $e \in E$, let $\mathfrak{m}_e$ be the distribution on $\mathcal{A}^e$, i.e., configurations on the vertices in e, such that

$$\mathfrak{m}_e(\sigma) \propto \psi_e(\sigma(x_{e,1}), \sigma(x_{e,2}), \ldots, \sigma(x_{e,k})) \qquad \forall \sigma \in \mathcal{A}^e. \tag{1}$$

From Cavity's perspective, the distributions $\{\mathfrak{m}_e\}_{e\in E}$ can be viewed as *fixed-points* of the so-called *BP equations*. The distributions $\mathfrak{m}_e$ are natural objects in our setting. Particularly we focus on the so-called *broadcasting probability* $\mathfrak{m}_e^i$, which is the distribution $\mathfrak{m}_e$ conditional on the configuration at $x_{e,1}$ being $i \in \mathcal{A}$.

Furthermore, we need to introduce the notion of *total variation distance* between distributions. Particularly, for any two distributions $\hat{\nu}$ and ν on $\mathcal{A}^V$ we let

$$||\hat{\nu} - \nu||_{tv} = (1/2) \sum_{\sigma\in\mathcal{A}^V} |\hat{\nu}(\sigma) - \nu(\sigma)|.$$

Also, we let $||\hat{\nu} - \nu||_\Lambda$ be the total variation distance of the marginals of $\hat{\nu}$ and ν on the vertex set $\Lambda \subseteq V$.

`SET` consists of two conditions which we call **B.1** and **B.2**. The condition **B.1** requires that for any two $\mathfrak{m}_e^i$, $\mathfrak{m}_e^j$, i.e, any two broadcasting probabilities of μ, their total variation distance is not too large. We say that **B.1** is satisfied with slack $\delta > 0$ if we have that

$$\max_{i,j\in\mathcal{A}} ||\mathfrak{m}_e^i - \mathfrak{m}_e^j||_\Lambda \leq \frac{1-\delta}{d(k-1)}, \qquad \text{where } \Lambda = \{x_{e,2}, x_{e,3}, \ldots, x_{e,k}\}.$$

Recall that k is the size of the hyper-edge in $\boldsymbol{H}$, while d is the expected degree. The above implies that for any two broadcasting, their total variation distance should be smaller than $(1-\delta)$ over the expected number of neighbours of a vertex in $\boldsymbol{H}$.

The condition **B.2** requires mutual *contiguity* between the Gibbs distribution μ and the so-called teacher-student model. We generate the pair $(\boldsymbol{H}^*, \boldsymbol{\sigma}^*)$ according to the teacher-student model by working as follows: choose $\boldsymbol{\sigma}^*$ randomly from $\mathcal{A}^V$. Given $\boldsymbol{\sigma}^*$, generate the

weighted random hypergraph $\boldsymbol{H}^*$ on n vertices and m edges, where the weight depends on $\boldsymbol{\sigma}^*$ and μ. Contiguity implies that the *typical properties* of the pair $(\boldsymbol{H}^*, \boldsymbol{\sigma}^*)$ are the same as those of the pair $(\boldsymbol{H}, \boldsymbol{\sigma})$, where $\boldsymbol{H} = \boldsymbol{H}(n, m, k)$ and $\boldsymbol{\sigma}$ is distributed as in μ. More formally, contiguity implies that for any sequence of events $(\mathcal{S}_n)_n$ we have that

$$\Pr[(\boldsymbol{H}, \boldsymbol{\sigma}) \in \mathcal{S}_n] = o(1) \qquad \text{iff} \qquad \Pr[(\boldsymbol{H}^*, \boldsymbol{\sigma}^*) \in \mathcal{S}_n] = o(1).$$

For the planting-trick we combine **B.1** with **B.2**. Roughly speaking, we use **B.1** to prove that the update rule is local when it is applied to a configuration that is from the teacher-student model. Then, **B.2**, i.e., contiguity, implies that the same is true for our original configuration σ_{i-1}. The reader can find further details and discussions about this in Section 2.

The region of the parameters that our algorithm is accurate are specified by SET. Employing technical arguments from [11, 8, 10], we show that, for symmetric distributions, the condition **B.1** is stronger than **B.2**. In that respect, the specifications of SET reflect exactly the restrictions that **B.1** imposes to the Gibbs distribution.

The general result we prove in this work is stated in the following two theorems. Also, see Section 1.2 for applications of these theorems on specific distributions.

▶ **Theorem 1.** *For $\delta \in (0, 1]$, for integer $k \geq 2$, for any $d \geq 1/(k-1)$ and integer $m = dn/k$ the following is true for our algorithm: Consider the random k-uniform hypergraph $\boldsymbol{H} = \boldsymbol{H}(n, m, k)$. Let $\mu = \mu_{\boldsymbol{H}}$ be a symmetric Gibbs distribution on $\boldsymbol{H}$ which satisfies* SET *with slack δ.*

With probability $1 - o(1)$, over the input instances $\boldsymbol{H}$ and weight functions on the edges of $\boldsymbol{H}$, our algorithm generates a configuration whose distribution $\bar{\mu}$ is such that

$$||\bar{\mu} - \mu||_{tv} \leq n^{-\frac{\delta}{55 \log(dk)}}.$$

As mentioned above, the theorem does not require d to be a "sufficiently large constant". We chose $d \geq 1/(k-1)$, because otherwise the underlying graph structure is very simple and the problem is trivial.

Let us remark that, even though the output error for the algorithm is polynomial small, we didn't optimise the constants at the exponent of the polynomial.

▶ **Theorem 2.** *For $k \geq 2$ and $d \geq 1/(k-1)$ and integer $m = dn/k$, consider the random k-uniform hypergraph $\boldsymbol{H} = \boldsymbol{H}(n, m, k)$. The time complexity of our algorithm on input $\boldsymbol{H}$ is $O((n \log n)^2)$.*

SET Versus Gibbs Uniqueness

As noted earlier, for almost all the cases of distributions we consider here, our algorithm outperforms by far the corresponding MCMC. However, it is natural to further characterise the region of parameters that our algorithm allows, not in terms of the performance of other algorithms, but in terms of *spatial mixing* conditions on the the k-uniform random hyper-tree where each non-leaf vertex has $(k-1) \times$ Poisson(d) children and $k \geq 2$. If not anything else, this could give further insight on the approach.

Establishing the so-called tree-uniqueness for many of the Gibbs distributions here turns out to be a notoriously difficult problem even for the regular tree, not to mention the *random* tree, or the *random* hyper-tree. Deriving such results is of independent interest and goes far beyond the scope of this work. The lack of rigorous result for uniqueness allows only for a discussion on the basis of conjectures coming (mainly) from physics.

For the graph case, it is natural to compare SET with the Gibbs tree-uniqueness condition on the Galton-Watson tree with offspring distribution the Poisson(d). At least for the antiferromagnetic Ising and Potts model and the 2-NAE-SAT model, the requirement of our algorithm coincides with the conjectured tree uniqueness region of the the random tree. We are not aware of any conjectures about the tree uniqueness of the spin-glass 2-spin model.

For the hyper-graph case, things seem to be more interesting. The author of this work is not aware of any physics' conjectures about the Gibbs uniqueness on the random hyper-tree. However, we believe that is interesting to include in our discussion the following (somehow easy to make) observation: For the sake of our discussion, rather than random hyper-tree consider a regular one, e.g. consider k-uniform hyper-tree where each non-leaf vertex has $\Delta(k-1)$ children, for integers $\Delta, k > 0$. Consider also a symmetric Gibbs distribution with hard constraints on this hyper-tree, e.g. the q-colouring model. Provided that Δ, k are relatively large, say $\Delta, k \geq 15$, the condition SET does not preclude configurations at the vertices at level ℓ of the tree that specify uniquely the colouring at the root, for howsoever large $\ell > 0$ we choose [1]. Of course, such colourings are *extremely untypical* with respect to the Gibbs distribution on the hyper-tree. A very similar phenomenon can be observed at the random hyper-tree, too. This aforementioned phenomenon leads us to *conjecture* for the hypergraph cases, that our algorithm allows to sample beyond the corresponding hyper-tree uniqueness region for *all* the Gibbs distributions we consider here.

The above should not be a surprise to the reader. It is well-known that for hard-constraint distributions on the hyper-graph (not necessarily random), the worst case configurations can be very problematic for the analysis of MCMC sampler, i.e., even under very mild conditions, e.g. see [22]. Our algorithm does not suffer from such problems, because it deals with typical configurations which are much nicer.

Related work

The idea of "iteratively adding edges and updating" for sampling was first introduced in [15] for sampling colourings of random graphs. The techniques and tools we introduce here for the sampling problem, rely on results developed in the study Cavity method and random CSP, e.g. see [1, 8, 10, 11].

There are two other works which follow the approach of "adding edges and updating" and use the same correlation decay approach to [15]. One is [17], an improvement of [15], which is about colourings of the random graph of sufficiently large expected degree d. The other one is [4] for the Potts model on the related random Δ-regular graph, for large Δ. From the second paper, it is conceivable that we can get an efficient algorithm only for the ferromagnetic Potts model on the random graph, provided that the expected degree d is large. Apart from colourings and ferro-Potts on the graph, we cannot rely on any of these two approaches for our endeavours. Both of them rely on the special properties of the distribution they are sampling from, thus they don't allow for other distributions. Furthermore, their tree-uniqueness requirement essentially restrict their use to considering only graphs, rather than hypergraphs. Our work here improves on both results in [17, 4] as it allows for any expected degree $d > 0$, i.e., rather than sufficiently large d.

[1] E.g., in this setting SET allows $q \approx ((k-1)\Delta)^{1/(k-1)}$, while the number of children of a non-leaf vertex is $(k-1)\Delta \gg q$.

There are other approaches to sampling from Gibbs distributions (not-necessarily on random graphs), which is different than the one we consider here. Notably, the most popular ones rely on the Markov Chain Monte Carlo Method (MCMC) [28, 21]. The literature of MCMC algorithms is vast and includes some beautiful results, just to mention a few [3, 39, 27, 25, 35, 14, 18, 6, 13].

Our results about the colourings are related to the work in [18] for MCMC sampling. Some result from [18] can be extended naturally to the Potts model, too. In that respect our approach outperforms, by far, [18] it terms of the range of the allowed parameters of the Gibbs distributions. However, we note that the MCMC algorithm achieves better approximation guarantees in the (more restricted) regions it operates.

1.2 Applications

1.2.1 The antiferromagnetic Ising Model

The Ising model on the k-uniform hypergraph $H_k = (V, E)$ is a distribution on the set of configurations $\{\pm 1\}^V$ such that each $\sigma \in \{\pm 1\}^V$ is assigned probability measure

$$\mu(\sigma) \propto \exp\left(\beta \cdot \sum_{e\in E} \prod_{x,y\in e} \mathbf{1}\{\sigma(x) = \sigma(y)\} + h \cdot \sum_{x\in V} \sigma(x)\right),$$

where $\beta \in \mathbb{R}$ is the *inverse temperature* and h is the *external field*. It is straightforward that the Ising model is symmetric only when $h = 0$. We assume $\beta < 0$, which corresponds to the *antiferromagnetic* Ising model.

For $\Delta, k > 0$ such that $\Delta > \frac{2^{k-1}-1}{k-1}$ we let the function

$$\beta_{\text{Ising}}(\Delta, k) = \log\left(\frac{\Delta(k-1)+1-2^{k-1}}{\Delta(k-1)+1}\right).$$

The uniqueness region of the antiferromagnetic Ising model on the Δ-ary tree, for $\Delta \geq 1$, is well-known. Particularly, it corresponds to temperatures β such that either $\Delta > 2$ and $\beta_{\text{Ising}}(\Delta, 2) < \beta < 0$, or $\Delta = 1$ and finite $\beta < 0$, i.e., $\beta \neq -\infty$.

▶ **Theorem 3.** *For integer $k \geq 2$ fr any $d \geq 1/(k-1)$ such that either*
1. *$d > (2^{k-1}-1)/(k-1)$ and $\beta_{\text{Ising}}(d, k) < \beta < 0$, or*
2. *$d \leq (2^{k-1}-1)/(k-1)$ and finite $\beta < 0$,*

the following is true: For the random k-uniform hypergraph $\boldsymbol{H} = \boldsymbol{H}(n, m, k)$, where $m = dn/k$, let $\mu = \mu_{\boldsymbol{H}}$ be the antiferromagnetic Ising model on $\boldsymbol{H}$, with inverse temperature β and external field $h = 0$.

There exists $c_0 > 0$ which depends only on the choice of k, d, β, such that with probability $1 - o(1)$ over the input instances $\boldsymbol{H}$, our algorithm generates a configuration with distribution $\bar{\mu}$ such that

$$||\bar{\mu} - \mu||_{tv} \leq n^{-\frac{c_0}{55\log(dk)}}.$$

The time complexity of the algorithm is $O((n \log n)^2)$ with probability 1.

▶ Remark 4. For the graph cases, i.e., $k = 2$, physics' conjecture is that we get the Gibbs uniqueness region for the random trees with expected offspring d, by somehow "pretending" that we are dealing with a d-ary tree (regardless of d being an integer, or not). From the above theorem, it is evident that the region that our algorithm operates, corresponds exactly to the region that is implied by the physics' non rigorous consideration. Someone could observe the same for the related Potts model in the following section.

1.2.2 The antiferromagnetic Potts Model and the Colouring Model

The Potts model on the k uniform hypergraph $H_k = (V, E)$ is a generalisation of the Ising model in the sense that it allows for q spins where $q \geq 2$. Particularly, each $\sigma \in [q]^V$, where $[q] = \{1, 2, \ldots, q\}$, is assigned probability measure

$$\mu(\sigma) \propto \exp\left(\beta \cdot \sum_{e \in E} \prod_{x,y \in e} \mathbf{1}\{\sigma(x) = \sigma(y)\}\right).$$

where $\beta \in \mathbb{R}$ is the *inverse temperature*. The graph case, i.e., $k = 2$, follows immediately from the above.

There is a version of the Potts model with external field, similarly to the Ising model. We do not consider the case with field because it gives rise to a non symmetric distribution. The antiferromagnetic Potts model we focus here corresponds to having $\beta < 0$.

A very interesting case of the Potts model is the *colouring model*. This is the uniform distribution over the *proper* q-colourings of the underlying (hyper)graph H_k, i.e., we do not allow configurations with monochromatic edges. The colouring model corresponds to the Potts model with $\beta = -\infty$.

For $\Delta, k > 0$ such that $\Delta > \frac{q^{k-1}-1}{k-1}$, we let the function

$$\beta_{\text{Potts}}(\Delta, q, k) = \log\left(\frac{\Delta(k-1)+1-q^{k-1}}{\Delta(k-1)+1}\right).$$

▶ **Theorem 5.** *For integer $k \geq 2$, for any $d \geq 1/(k-1)$, integers $q > 2$ and $m = dn/k$ the following is true: Assume that β, q satisfy one of the following cases:*

1. *$(q^{k-1} - 1)/(k-1) < d$ and $\beta_{\text{Potts}}(d, q, k) < \beta < 0$,*
2. *$(q^{k-1} - 1)/(k-1) > d$ and $\beta < 0$, including $\beta = -\infty$.*

Consider the random k-uniform hypergraph $\boldsymbol{H} = \boldsymbol{H}(n, m, k)$. Let $\mu = \mu_{\boldsymbol{G}}$ be the q-state antiferromagnetic Potts model on $\boldsymbol{H}$ with inverse temperature β. There exists $c_0 > 0$, which depends only on our choices of k, d, β such that with probability $1 - o(1)$ over the input instances $\boldsymbol{H}$, our algorithm generates a configuration whose distribution $\bar{\mu}$ is such that

$$||\bar{\mu} - \mu||_{tv} \leq n^{-\frac{c_0}{55\log(dk)}}.$$

The time complexity of the algorithm is $O((n \log n)^2)$ with probability 1.

Physics' (folklore) conjecture for the uniqueness of antiferromagnetic Potts model on the Galton Watson tree with offspring distribution Poisson(d) coincides with the region specified in the theorem above, for $k = 2$.

1.2.3 The k-NAE-SAT Model

For integer $k \geq 2$, let $\mathbf{F}_k(n, m)$ be a random propositional formula over the Boolean variables $x_1, \ldots, x_n$. Particularly, $\mathbf{F}_k(n, m)$ is obtained by inserting m independent random clauses of length k such that no variable appears twice in the same clause. Here, we consider formulas with $m = dn/k$ clauses for a fixed number d, i.e., on average every variable occurs in d clauses.

We focus on the "Not-All-Equal" satisfying assignments of $\mathbf{F}_k(n, m)$. A Boolean assignment σ of $x_1, \ldots, x_n$ is NAE-satisfying for $\mathbf{F}_k(n, m)$ if under both σ and its binary inverse $\bar{\sigma}$ all m clauses evaluate to "true". The random k-NAE-SAT problem is one of the standard examples of random CSPs and has received a great deal of attention. In particular, in an influential paper Achlioptas and Moore [2] pioneered the use of the second moment method for estimating the partition functions of random CSPs with the example of random k-NAE-SAT. Our focus is on sampling from the *uniform distribution* over the NAE satisyfing assignments of $\mathbf{F}_k(n, m)$. We have the following result.

▶ **Theorem 6.** *For $\delta \in (0,1]$, for $k \geq 2$, for any $1/(k-1) \leq d < (1-\delta)\frac{2^{k-1}-1}{k-1}$ and for integer $m = dn/k$, the following is true for our algorithm: Consider $\mathbf{F}_k(n,m)$ and let μ be the uniform distribution over the NAE satisfying assignments of $\mathbf{F}_k(n,m)$. With probability $1-o(1)$ over the input instances $\mathbf{F}_k(n,m)$, our algorithm generates a configuration whose distribution $\bar{\mu}$ is such that*

$$||\bar{\mu} - \mu||_{tv} \leq n^{-\frac{\delta}{55\log(dk)}}.$$

The time complexity of the algorithm is $O((n\log n)^2)$ with probability 1.

As a point of reference for the performance of our *sampling* algorithm, note that it works in a region of parameters which is very close to those of *search* algorithms for the problem, e.g. see the analysis for the renown *walk-sat* algorithm in [9].

1.2.4 The *k*-spin model

For integer $k \geq 2$, consider the k-uniform hypergraph $H_k = (V,E)$. Additionally, let $\mathbf{J} = (\mathbf{J}_e)_{e\in E}$ be a family of independent, standard Gaussians (expectation zero and variance one). The *k-spin model* on H_k at inverse temperature $\beta > 0$ is the distribution that assigns each configuration $\sigma \in \{\pm 1\}^V$ the probability measure

$$\mu(\sigma) \propto \prod_{\alpha\in E} \exp\left(\beta \mathbf{J}_e \prod_{y\in\alpha}\sigma(y)\right). \tag{2}$$

It is elementary to verify that the k-spin model is symmetric when $k \geq 2$ is an even integer. Here we consider the above distribution when the underlying (hyper)graph is an instance of $\boldsymbol{H} = \boldsymbol{H}(n,m,k)$ of expected degree d, i.e., $m = dn/k$.

The k-spin model is the diluted version of the well-known Sherrington-Kirkpatrick model which has been subject of intense study both in mathematics and physics [38, 31]. Generally, spin-glasses give rise to very intricate distributions and they are also studied in neural networks, computational biology and other areas of computer science [37]. As mentioned before, this is the first efficient algorithm for sampling from spin-glasses in a non-trivial region of their parameters. For what follows we consider the function

$$F_k(x) = \frac{|e^x - e^{-x}|}{(2^{k-1}-1)e^{-x} + e^x}. \tag{3}$$

▶ **Theorem 7.** *For $\delta \in (0,1]$, for even integer $k \geq 2$, for any $d \geq 1/(k-1)$ and for any $\beta \geq 0$ such that*

$$\mathbb{E}[F_k(\beta \mathbf{J}_0)] \leq \tfrac{1-\delta}{d(k-1)},$$

where the expectation is w.r.t. the standard Gaussian random variable $\mathbf{J}_0$, the following is true for our algorithm: Consider $\boldsymbol{H} = \boldsymbol{H}(n,m,k)$, where $m = dn/k$, and let μ be the k-spin model on $\boldsymbol{H}$ at inverse temperature β. With probability $1-o(1)$ over the input instances $\boldsymbol{H}$ and the weight functions on the edges of $\boldsymbol{H}$, our algorithm generates a configuration whose distribution $\bar{\mu}$ is such that

$$||\bar{\mu} - \mu||_{tv} \leq n^{-\frac{\delta}{55\log(dk)}}.$$

The time complexity of the algorithm is $O((n\log n)^2)$ with probability 1.

Notation

Let the hypegraph $H_k = (V, E)$ and the Gibbs distribution μ on the set of configurations $\mathcal{A}^V$. For a configuration σ, we let $\sigma(\Lambda)$ denote the configuration that σ specifies on the set of vertices Λ. We let μ_Λ denote the marginal of μ at the set Λ. For a configuration $\sigma \in \mathcal{A}^V$ we let $\mu(\cdot \mid \Lambda, \sigma)$, denote the distribution μ conditional on the configuration at Λ being $\sigma(\Lambda)$. Also, we interpret the conditional marginal $\mu_\Lambda(\cdot \mid \Lambda', \sigma)$, for $\Lambda' \subseteq V$, in the natural way.

2 Algorithmic Approach – High Level Description

To facilitate the exposition of the algorithm assume in this section that we are dealing with a graph, rather than hypergraph, while we assume that this graph is fixed.

First, we recall the algorithm: on input G, the algorithm initially removes all the edges and generates a configuration for the empty graph. Then, iteratively, we put the edges back one by one. If G_i is the subgraph we have at iteration i, our aim is to have a configuration σ_i which is distributed very close to the Gibbs distribution on G_i, for every i. We generate σ_i by updating appropriately σ_{i-1}, the configuration of G_{i-1}. Once all edges are put back, the algorithm outputs the configuration of G. One of the main challenge is to specify the *update rule*, i.e., how to generate σ_i from σ_{i-1}.

We describe the proposed rule by considering the following, simpler, problem. Consider two *high-girth*, fixed, graphs $G = (V, E)$ and $G' = (V, E')$. Assume that G and G' differ on a single edge, i.e. compared to G, the graph G' has the extra edge $e = \{u, w\}$. Let μ and μ' be the Gibbs distributions of G and G', respectively. We want to use the update rule to generate efficiently $\boldsymbol{\tau}$ a sample from μ', while we are given $\boldsymbol{\sigma}$, a sample from μ.

To facilitate our exposition, assume that we already know $\boldsymbol{\tau}(u)$ and $\boldsymbol{\tau}(w)$, and they are such that $\boldsymbol{\tau}(u) = \boldsymbol{\sigma}(u)$ and $\boldsymbol{\tau}(w) \neq \boldsymbol{\sigma}(w)$. In what follows, we focus on specifying $\boldsymbol{\tau}$ for the rest of the vertices in V.

The plan is to visit each vertex z *iteratively* and specify $\boldsymbol{\tau}(z)$. At each iteration t, we only know the configuration of $\boldsymbol{\tau}$ for the vertices in the set of vertices we have already visited, we call it $\mathcal{N}_t$. Initially we have that $\mathcal{N}_0 = \{w, u\}$. Also, let $\mathcal{D} = \{\boldsymbol{\tau}(w), \boldsymbol{\sigma}(w)\}$, i.e., $\mathcal{D}$ is the set of the spins of the initial disagreement. At iteration t we pick a vertex z which is outside $\mathcal{N}_t$ but has a neighbour $x \in \mathcal{N}_t$ which is disagreeing, i.e., $\boldsymbol{\tau}(x) \neq \boldsymbol{\sigma}(x)$. For the moment, assume that such vertex exists.

If $\boldsymbol{\sigma}(z) \notin \mathcal{D}$, then we just set $\boldsymbol{\tau}(z) = \boldsymbol{\sigma}(z)$. On the other hand, if $\boldsymbol{\sigma}(z) \in \mathcal{D}$, then we work as follows: there is a probability p_z, that depends on the configuration of $\boldsymbol{\sigma}$ and $\boldsymbol{\tau}$ at $\mathcal{N}_t$, and we set

$$\boldsymbol{\tau}(z) = \begin{cases} \mathcal{D} \setminus \{\boldsymbol{\sigma}(z)\} & \text{with prob. } p_z \\ \boldsymbol{\sigma}(z) & \text{with prob. } 1 - p_z. \end{cases}$$

The first line implies that $\boldsymbol{\tau}(z)$ gets the opposite spin of $\boldsymbol{\sigma}(z)$. E.g., if $\mathcal{D} = \{\texttt{red}, \texttt{blue}\}$ and $\boldsymbol{\sigma}(z) = \texttt{red}$, then $\boldsymbol{\tau}(z) = \texttt{blue}$. Once $\boldsymbol{\tau}(z)$ is decided, set $\mathcal{N}_{t+1} = \mathcal{N}_t \cup \{z\}$ and continue with the next iteration.

It could be that in iteration t, there is no vertex z outside $\mathcal{N}_t$ which has a disagreeing neighbour inside $\mathcal{N}_t$. If this is the case, then for every z for which we have not specified $\boldsymbol{\tau}(z)$, we set $\boldsymbol{\tau}(z) = \boldsymbol{\sigma}(z)$. Once we have specified the assignment $\boldsymbol{\tau}$ for every vertex z in the graph, the update rule terminates.

The probability p_z is determined in terms of a *maximal coupling* between the marginals of μ' and μ at z, conditional on $\boldsymbol{\tau}(\mathcal{N}_t)$ and $\boldsymbol{\sigma}(\mathcal{N}_t)$. We denote these marginals as $\mu'_z(\cdot \mid \mathcal{N}_t, \boldsymbol{\tau})$ and $\mu_z(\cdot \mid \mathcal{N}_t, \boldsymbol{\sigma})$, respectively. We have

$$p_z = \max\left\{0, 1 - \frac{\mu'_z(\boldsymbol{\sigma}(z) \mid \mathcal{N}_t, \boldsymbol{\tau})}{\mu_z(\boldsymbol{\sigma}(z) \mid \mathcal{N}_t, \boldsymbol{\sigma})}\right\}.$$

One can show that the above generates a *perfect* sample from the distribution μ'. There is an issue with this approach, though. It is not clear how we can compute the probabilities p_z, efficiently. Computing p_z relies on estimating conditional marginals of Gibbs distributions. In our setting, we don't known how to estimate these marginals efficiently. To this end, we use *different* probabilities. That is, we follow the previous steps and when at the iteration t we examine a vertex z for which $\boldsymbol{\sigma}(z) \in \mathcal{D}$, we set $\boldsymbol{\tau}(z)$ such that

$$\boldsymbol{\tau}(z) = \begin{cases} \mathcal{D} \setminus \{\boldsymbol{\sigma}(z)\} & \text{with prob. } q_z \\ \boldsymbol{\sigma}(z) & \text{with prob. } 1 - q_z, \end{cases} \tag{4}$$

i.e., instead of p_z we use q_z. Recall that we choose z because it has a disagreeing neighbour $x \in \mathcal{N}_t$. Each q_z can be expressed in terms of the simpler distribution $\mathfrak{m}_\alpha$, where α is the edge between z and x. We have

$$q_z = \max\left\{0,\ 1 - \frac{\mathfrak{m}_{\alpha,z}(\boldsymbol{\sigma}(z) \mid x, \boldsymbol{\tau})}{\mathfrak{m}_{\alpha,z}(\boldsymbol{\sigma}(z) \mid x, \boldsymbol{\sigma})}\right\}. \tag{5}$$

Recall from our notation that $\mathfrak{m}_{\alpha,z}(\cdot \mid x, \boldsymbol{\tau})$ is the marginal of $\mathfrak{m}_\alpha$ on z, conditional on x being set $\boldsymbol{\tau}(x)$. Also, note from (1) that the distribution $\mathfrak{m}_\alpha$ is very simple and can be computed very fast.

A natural question at this point is what motivates the use q_z in the place of p_z. We observe that if our graphs G and G' were trees, then we would have that $q_z = p_z$. That is, for trees our update rule generates perfect samples from μ'. In some sense, our approach amounts to approximating the probabilities p_z, which are difficult to compute, with those of the tree, which we can compute very fast. In light of our assumption that our graphs G and G' are of high-girth, i.e., locally tree-like, this approximation seems quite natural.

Under certain conditions, our approach yields very good approximations of μ'. The update rule is accurate in settings where, typically, the set of vertices that change assignment does not grow "too large". To be more specific, let $\mathcal{Q}$ be the set of vertices that change configuration during the update, i.e., their configuration under $\boldsymbol{\tau}$ is different than that under $\boldsymbol{\sigma}$. Somehow, our update rule runs into trouble when $\mathcal{Q}$ induces a subgraph which contains one of the long cycles of G, or $\mathcal{Q}$ reaches u. In this case we consider that the algorithm *fails*. That is, our update rule outputs either a configuration $\boldsymbol{\tau} \in \mathcal{A}^V$, or a fail status. We establish a connection between the accuracy of the update and its failure probability, particularly we show that the smaller the failure probability the more accurate the algorithm is.

2.1 Accuracy and failure probabilities

We relate the approximation error of the update rule with failure probabilities by exploiting an interesting property of the update rule which is a reminiscent of the *detailed balance equation* from the theory of reversible Markov chains [36]. In what follows, first we describe the "detailed balance property" of the update and then we show how we use it to study the accuracy.

In the same setting as before, assume that $\boldsymbol{\sigma}(\{u, w\}) = \sigma$ and $\boldsymbol{\tau}(\{u, w\}) = \tau$, for fixed $\sigma, \tau \in \mathcal{A}^{\{u,w\}}$. The update rule can be viewed as a stochastic process that takes a configuration that agrees with σ at $\{u, w\}$ and generates either a new configuration which

agrees with τ at $\{u, w\}$, or fails. There is a natural way of defining the *reverse update* which works towards the opposite direction, i.e., takes a configuration which agrees with τ and either generates a configuration that agrees with σ at $\{u, w\}$, or fails.

For any two configuration $\kappa, \eta \in \mathcal{A}^V$, we let $\mathrm{P}_{\sigma,\tau}(\kappa, \eta)$ be the probability that on input κ the update generates η. Similarly we can define $\mathrm{P}_{\tau,\sigma}(\eta, \kappa)$ for the reverse update. The detailed balance equation relates these two probabilities, i.e., it specifies that

$$\mu(\kappa)\mathrm{P}_{\sigma,\tau}(\kappa, \eta) = \mu(\eta)\mathrm{P}_{\tau,\sigma}(\eta, \kappa).$$

Note that, in the equation above, the Gibbs distributions μ are unconditional.

We proceed by demonstrating how we use the detailed balance to get the update error. Consider the same setting as in the previous paragraphs. Let $\bar{\mu}$ be the distribution of the output of the update when the input is distributed as in $\mu(\cdot \mid \{u, w\}, \sigma)$.

We need to focus on the failure probability of both the update and the reverse update. Let $\mathtt{F}(\kappa)$ be the failure probability of the update rule on input (fixed) κ. In that respect, the failure probability is equal to $\mathbb{E}[\mathtt{F}(\boldsymbol{\kappa})]$, where the expectation is w.r.t. to $\boldsymbol{\kappa}$ which is distributed as in $\mu(\cdot \mid \{w, u\}, \sigma)$. Similarly, let $\mathtt{R}(\eta)$ be the failure probability for the reverse update on input (fixed) η. The failure probability of the reverse update is $\mathbb{E}[\mathtt{R}(\boldsymbol{\eta})]$, where $\boldsymbol{\eta}$ is distributed as in $\mu(\cdot \mid \{w, u\}, \tau)$.

Using the detail balance and an asymptotic independence result between the configuration of w and u under μ, we get the following: For any $\eta \in \mathcal{A}^V$ we have that

$$\begin{aligned}\bar{\mu}(\eta) &= \sum_{\kappa \in \mathcal{A}^V} \mu(\kappa \mid \{w, v\}, \sigma)\mathrm{P}_{\sigma,\tau}(\kappa, \eta) \approx \sum_{\kappa \in \mathcal{A}^V} \mu(\eta \mid \{w, v\}, \tau)\mathrm{P}_{\tau,\sigma}(\eta, \kappa) \\ &= \mu(\eta \mid \{w, v\}, \tau)(1 - \mathtt{R}(\eta)). \end{aligned} \tag{6}$$

The first equation is just the definition of $\bar{\mu}(\eta)$. The detailed balance with the asymptotic independence are used for the derivation with "$\approx$". The last equation follows from the observation that summing $\mathrm{P}_{\tau,\sigma}(\eta, \kappa)$ over $\kappa \in \mathcal{A}^V$ is equal to the probability that the reverse update does not fail, when the input is η.

Another observation that we use is the following one: if the update has a positive failure probability, then $\sum_\eta \bar{\mu}(\eta) < 1$. This holds because $\bar{\mu}$ gives positive measure to the failure status of the update. That is, we have that $\mathbb{E}[\mathtt{F}(\boldsymbol{\kappa})] + \sum_\eta \bar{\mu}(\eta) = 1$. Combining this equality and (6), standard derivations imply

$$||\bar{\mu} - \mu(\cdot \mid \{w, u\}, \tau)||_{tv} \approx (1/2)(\mathbb{E}[\mathtt{R}(\boldsymbol{\eta})] + \mathbb{E}[\mathtt{F}(\boldsymbol{\kappa})]).$$

Essentially the update error is equal to the average of the failure probabilities of the update and its reverse.

2.2 The failure probability on the random graph

Here we highlight the intuition behind our claim that if `SET` holds, then the failure probability is very small.

Consider a setting which is a bit simpler than that we had before. Let μ be a symmetric Gibbs distribution on $\boldsymbol{G} = \boldsymbol{G}(n, m)$. Consider the spins $c, c' \in \mathcal{A}$ such that $c \neq c'$. Let $\boldsymbol{\sigma}$ be distributed as in μ conditional on $\boldsymbol{\sigma}(u) = c'$, for some $u \in V$. We use the update process to generate a configuration $\boldsymbol{\tau}$ which is (approximately) distributed as in μ conditional on that $\boldsymbol{\tau}(u) = c$. Our focus is on the probability of failure for the update. Particularly, we argue that if `SET` holds, then the size of the set of disagreeing vertices in the update process, i.e, the vertices v such that $\boldsymbol{\sigma}(v) \neq \boldsymbol{\tau}(v)$, grows *subcritically* at each iteration.

Recall that, in the update, the disagreements start from vertex u and iteratively propagate over the graph. Assume that not too many vertices have been visited in the process. In iteration t, the process chooses the vertex z which is adjacent to the disagreeing vertex x, i.e., we already know that $\boldsymbol{\tau}(x) \neq \boldsymbol{\sigma}(x)$. The probability of disagreement propagating to z can be estimated by just using (4) and (5). The idea is to combine (4) and (5) with the randomness of $\boldsymbol{\sigma}$ and show that the probability of disagreement at z is $< 1/d$, which would imply the subcriticality for the update process.

Exploiting the randomness of $\boldsymbol{\sigma}$ means that at iteration t of the process we only have exposed the configuration of $\boldsymbol{\sigma}$ for the vertices which the process has already visited. If the process hasn't revealed the configuration of $\boldsymbol{\sigma}$ for too many vertices, then the marginal of the configuration at z should be close to $\mathfrak{m}_e(\cdot \mid x, \boldsymbol{\sigma})$, where $e = \{x, z\}$. This would imply that the disagreement probability at z is at most

$$\max_{c,c' \in \mathcal{A}} ||\mathfrak{m}_e(\cdot \mid x, c) - \mathfrak{m}_e(\cdot \mid x, c')||_z.$$

The above observation is quite interesting because the quantity above, i.e., disagreement probability, is upper bounded by using **B.1** in SET. Particularly, **B.1** implies that the above total variation distance is $\leq (1-\delta)/d$. Thus, if the above intuition is correct, then we can get the subcritical growth by exploiting the condition **B.1**. Unfortunately, with our assumptions about μ, it too difficult to argue that the marginal probability at z is very close to $\mathfrak{m}_e(\cdot \mid x, \boldsymbol{\sigma})$ in our process.

To this end, we employ the teacher-student model. We consider the pair $(\boldsymbol{G}^*, \boldsymbol{\sigma}^*)$ from the teacher-student model. We study the propagation of disagreements for the update process on the pair $(\boldsymbol{G}^*, \boldsymbol{\sigma}^*)$. There, it is simpler to argue that the distribution of z is very close to $\mathfrak{m}_e(\cdot \mid x, \boldsymbol{\sigma})$. The condition **B.1** still applies here and it implies that the growth of disagreements in $\boldsymbol{G}^*$ is subcritical. In turn, this implies that the failure probability for the specific update is very small. Subsequently, we employ contiguity, i.e., **B.2**, to argue that if the probability of failure for the case of $(\boldsymbol{G}^*, \boldsymbol{\sigma}^*)$ is very small, then the probability of failure for $(\boldsymbol{G}, \boldsymbol{\sigma})$ cannot be much larger.

Testability and Local Certification of Monotone Properties in Minor-Closed Classes

Louis Esperet
Univ. Grenoble Alpes, CNRS, Laboratoire G-SCOP, Grenoble, France

Sergey Norin
Department of Mathematics and Statistics, McGill University, Montreal, Canada

Abstract

The main problem in the area of graph property testing is to understand which graph properties are *testable*, which means that with constantly many queries to any input graph G, a tester can decide with good probability whether G satisfies the property, or is far from satisfying the property. Testable properties are well understood in the dense model and in the bounded degree model, but little is known in sparse graph classes when graphs are allowed to have unbounded degree. This is the setting of the *sparse model*.

We prove that for any proper minor-closed class $\mathcal{G}$, any monotone property (i.e., any property that is closed under taking subgraphs) is testable for graphs from $\mathcal{G}$ in the sparse model. This extends a result of Czumaj and Sohler (FOCS'19), who proved it for monotone properties with finitely many forbidden subgraphs. Our result implies for instance that for any integers k and t, k-colorability of K_t-minor free graphs is testable in the sparse model.

Elek recently proved that monotone properties of bounded degree graphs from minor-closed classes that are closed under disjoint union can be verified by an approximate proof labeling scheme in constant time. We show again that the assumption of bounded degree can be omitted in his result.

The authors would like to thank the organizers and participants for all the discussions and nice atmosphere (and in particular Gwenaël Joret, Chun-Hung Liu, and Ken-ichi Kawarabayashi for the discussions related to the topic of this paper). The authors would also like to thank Gábor Elek for his remarks on an earlier version of this manuscript, and his suggestion to replace minor-closed classes by classes of bounded asymptotic dimension in Theorem 4.

1 Introduction

1.1 Property testing

We say that a graph G is *ε-far from some property $\mathcal{P}$* if one needs to modify at least $\varepsilon|E(G)|$ of its adjacencies (replacing edges by non-edges and vice-versa) in order to obtain a graph satisfying $\mathcal{P}$. A property is *testable* if for any graph G, a tester can decide with good probability whether G satisfies $\mathcal{P}$ or is ε-far from $\mathcal{P}$, by only making a constant number of

queries to a given representation of G (i.e., the number of queries depends only on ε and $\mathcal{P}$, but is independent of the input graph G). The tester has *one-sided error* if it always gives the correct answer when $G \in \mathcal{P}$, and *two-sided error* otherwise.

In the *dense graph model* [28], there is a good understanding of which properties are testable with two-sided error [3] and one-sided error [5, 4]. In *the bounded degree model* [29], a sequence of papers [8, 15, 32] culminated in a proof that every property is testable with two-sided error within any *hyperfinite* graph family (this includes for instance any proper minor-closed class) [37]. The bounded degree assumption is crucial for obtaining this result and it has since then been an important open problem to obtain testability results in the weaker *sparse model*, which does not assume that the maximum degree is bounded [14, 16]. In this more general model there are two types of queries: given a vertex v, we can query the degree $d(v)$ of v in G; we can also query the i-th neighbor of v, for $1 \leq i \leq d(v)$ (all these queries are assumed to take constant time). In this model, much less is known: it was proved that bipartiteness is testable within any minor-closed class in [14], while already in the bounded degree model many simple properties are not testable in general graph classes [29], so the restriction to a sparse structured class such as a proper minor-closed class is very natural in this context. The interested reader is referred to the book of Goldreich [27] for more results and references on property testing, and especially Chapter 10 in the book, which focuses on the general graph model.

Instead of working in the sparse model as defined above, it will be enough to restrict ourselves to a single type of query: given a vertex v, we query a random neighbor of v, uniformly among the neighbors of v. Following [16], we say we make queries to the *random neighbor oracle*. Note that this type of queries can clearly be implemented is the sparse model, so this is a restriction of the model (see [16] for a comparison between these two models, and a third one were we are allowed to query a constant number of *distinct* random neighbors of a given vertex). The following was recently proved by Czumaj and Sohler [16].

▶ **Theorem 1** ([16]). *For every proper minor-closed class $\mathcal{G}$, and any finite family $\mathcal{H}$, the property of being $\mathcal{H}$-free for graphs from $\mathcal{G}$ is testable with one-sided error in the sparse model, where only queries to the random neighbor oracle are allowed.*

Here we say that a graph is *H-free* if it does not contain H as a subgraph, and *$\mathcal{H}$-free* if it is H-free for every $H \in \mathcal{H}$. Our main result is an extension of Theorem 1 to any *monotone* property, that is any property closed under taking subgraphs.

▶ **Theorem 2.** *For every proper minor-closed class $\mathcal{G}$, and any monotone property $\mathcal{P}$, the property of satisfying $\mathcal{P}$ for graphs from $\mathcal{G}$ is testable with one-sided error in the sparse model, where only queries to the random neighbor oracle are allowed.*

Note that for any monotone property $\mathcal{P}$ there is a (possibly infinite) family of graphs $\mathcal{H}$ such that $\mathcal{P}$ is precisely the property of being $\mathcal{H}$-free. This family $\mathcal{H}$ can be simply defined as the class of all the graphs that do not satisfy $\mathcal{P}$, or as the class of all the graphs that do not satisfy $\mathcal{P}$ and are minimal with this property (with respect to the subgraph relation). It follows that Theorem 2 is the natural generalization of Theorem 1, where we remove the assumption that $\mathcal{H}$ is finite. This can be seen as an analogue of the situation in the dense graph model: it was first proved that the property of being H-free (or $\mathcal{H}$-free for finite $\mathcal{H}$) was testable in this model [2], and then only much later was this extended to all monotone classes by Alon and Shapira [5]. Note that many natural monotone properties, such as being planar or k-colorable for some $k \geq 2$, do not have a finite set of minimal forbidden subgraphs. So there is a fundamental gap between being H-free and being $\mathcal{H}$-free for infinite $\mathcal{H}$.

1.2 Local certification

We now describe our second main result, which is obtained by extending the methods used in the proof of Theorem 2. We start by introducing the setting of this result: The problem of *local certification*.

In this part, all graphs are assumed to be connected. The vertices of any n-vertex graph G are assumed to be assigned distinct (but otherwise arbitrary) identifiers $(\mathrm{id}(v))_{v\in V(G)}$ from $\{1,\dots,\mathrm{poly}(n)\}$. In the remainder of this section, all graphs are implicitly labelled by these distinct identifiers (for instance, whenever we talk about a subgraph H of a graph G, we implicitly refer to the corresponding labelled subgraph of G). We follow the terminology introduced by Göös and Suomela [30].

Proofs

A *proof* for a graph G is a function $P : V(G) \to \{0,1\}^*$ (G is considered as a labelled graph, so the proof P is allowed to depend on the identifiers of the vertices of G). The binary words $P(v)$ are called *certificates*. The *size* of P is the maximum size of a certificate $P(v)$, for $v \in V(G)$.

Local verifiers

A *verifier* $\mathcal{A}$ is a function that takes a graph G, a proof P for G, and a vertex $v \in V(G)$ in input, and outputs an element of $\{0,1\}$. We say that v *accepts* the instance if $\mathcal{A}(G,P,v) = 1$ and that v rejects the instance if $\mathcal{A}(G,P,v) = 0$.

Consider an integer $r \geq 0$, a graph G, a proof P for G, and a vertex $v \in V(G)$. Let $B_r(v)$ denote the set of vertices at distance at most r from v in G. We denote by $G[v,r]$ the subgraph of G induced by $B_r(v)$, and similarly we denote by $P[v,r]$ the restriction of P to $B_r(v)$.

A verifier $\mathcal{A}$ is *local* if there is a constant $r \geq 0$, such that for any $v \in G$, $\mathcal{A}(G,P,v) = \mathcal{A}(G[v,r],P[v,r],v)$. In other words, the output of v only depends on the ball of radius r centered in v, for any vertex v of G. The constant r is called the *local horizon* of the verifier.

Proof labelling schemes

For an integer $r \geq 0$, an *r-round proof labelling scheme* for a graph class $\mathcal{G}$ is a prover-verifier pair $(\mathcal{P},\mathcal{A})$, with the following properties.

r-round: $\mathcal{A}$ is a local verifier with local horizon at most r.

Completeness: If $G \in \mathcal{G}$, then $P = \mathcal{P}(G)$ is a proof for G such that for any vertex $v \in V(G)$, $\mathcal{A}(G,P,v) = 1$.

Soundness: If $G \notin \mathcal{G}$, then for every proof P' for G, there exists a vertex $v \in V(G)$ such that $\mathcal{A}(G,P',v) = 0$.

In other words, upon looking at its ball of radius r (labelled by the identifiers and certificates), the local verifier of each vertex of a graph $G \in \mathcal{G}$ accepts the instance, while if $G \notin \mathcal{G}$, for every possible choice of certificates, the local verifier of at least one vertex rejects the instance.

The *complexity* of the labelling scheme is the maximum size of a proof $P = \mathcal{P}(G)$ for an n-vertex graph $G \in \mathcal{F}$. If we say that the complexity is $O(f(n))$, for some function f, the $O(\cdot)$ notation refers to $n \to \infty$. See [23, 30] for more details on proof labelling schemes and local certification in general.

It was proved in [25] that planar graphs have a 1-round proof labelling scheme of complexity $O(\log n)$, and that this complexity is optimal. The authors of [25] asked whether this can be extended to any proper minor-closed class. This was indeed extended in [24] to graphs embeddable in a fixed surface (see also [22] for a short proof), to graphs avoiding some small minors in [10], and more generally to any minor-closed class of bounded tree-width in [26] (in the last result, the complexity is $O(\log^2 n)$ instead of $O(\log n)$ in the other results mentioned here).

For $\varepsilon > 0$, define an *r-round ε-approximate proof labelling scheme* for some class $\mathcal{G}$ exactly as in the definition of r-round proof labelling scheme above, except that in the soundness part, the condition "If $G \notin \mathcal{G}$" is replaced by "If G is ε-far from $\mathcal{G}$" [13]. A graph class $\mathcal{G}$ is *summable* if for any $G_1, G_2 \in \mathcal{G}$, the disjoint union of G_1 and G_2 is also in $\mathcal{G}$. Elek recently proved the following result [21].

▶ **Theorem 3** ([21]). *For any $\varepsilon > 0$ and integer $D \geq 0$, and any monotone summable property $\mathcal{P}$ of a proper minor-closed class $\mathcal{G}$, there are constants $r \geq 0$ and $K \geq 0$ such that the class of graphs from $\mathcal{P}$ with maximum degree at most D has an r-round ε-approximate proof labelling scheme of complexity at most K.*

A natural problem is whether the bounded degree assumption in Elek's result can be omitted (Elek's proof crucially relies on this assumption). We prove that the bounded degree assumption can indeed be omitted.

▶ **Theorem 4.** *For any $\varepsilon > 0$ and any monotone summable property $\mathcal{P}$ of a proper minor-closed class $\mathcal{G}$, there are constants $r \geq 0$ and $K \geq 0$ such that $\mathcal{P}$ has an r-round ε-approximate proof labelling scheme of complexity at most K.*

We indeed prove a far-reaching generalization of this result (whose statement was suggested by Elek to the authors), concerning graph classes with bounded asymptotic dimension.

Asymptotic dimension

Given a graph G and an integer $r \geq 1$, we denote by G^r the graph obtained from G by adding edges between any pair of vertices at distance at most r in G. The *weak diameter* of a set S of vertices of G is the maximum distance in G between two vertices of S.

For an integer $d \geq 0$, a class of graphs $\mathcal{G}$ has *asymptotic dimension* at most d if there is a function $D : \mathbb{N} \to \mathbb{N}$ such that for any integer $r \geq 1$, any graph $G \in \mathcal{G}$ has a $(d+1)$-coloring of its vertex set such that any monochromatic[1] component of G^r has weak diameter at most $D(r)$ in G.

This notion was introduced by Gromov [31] in the more general context of metric spaces. In the specific case of graphs, it was proved that classes of bounded tree-width have asymptotic dimension at most 1, and proper minor-closed classes have asymptotic dimension at most 2 [9]. It was also proved that d-dimensional grids and families of graphs defined by the intersection of certain objects (such as unit balls) in $\mathbb{R}^d$ have asymptotic dimension d [9]. On the other hand, it is known that any class of bounded degree expanders has infinite asymptotic dimension (see [33]).

We will prove the following generalization of Theorem 4.

[1] A *monochromatic component* in a colored graph G is a connected component of a subgraph of G induced by one of the color classes.

▶ **Theorem 5.** *For any $\varepsilon > 0$ and any monotone summable property $\mathcal{P}$ of a class $\mathcal{G}$ of bounded asymptotic dimension, there are constants $r \geq 0$ and $K \geq 0$ such that $\mathcal{P}$ has an r-round ε-approximate proof labelling scheme of complexity at most K.*

Note that a monotone property $\mathcal{P}$ is summable if and only if all minimal forbidden subgraphs for $\mathcal{P}$ are connected. This includes for instance minor-closed classes whose minimal forbidden minors are connected, such as planar graphs, K_t-minor free graphs for any $t \geq 2$, graphs of bounded tree-width, graphs of bounded tree-depth, and graphs of bounded Colin de Verdière parameter.

Natural examples of non summable properties include toroidal graphs (or more generally graphs embeddable on any fixed surface other than the sphere). For monotone properties that are not necessarily summable, we prove the following.

▶ **Theorem 6.** *For any $\varepsilon > 0$ and any monotone property $\mathcal{P}$ of a proper minor-closed class $\mathcal{G}$, $\mathcal{P}$ has a 1-round ε-approximate proof labelling scheme of complexity $O(\log n)$.*

While the complexity of the scheme guaranteed by Theorem 6 is not constant as in Elek's result [21] and Theorem 4, we do not require any bounded degree assumption (as in Theorem 4), and a local horizon of 1 is sufficient. More importantly, the fact that $\mathcal{P}$ is not necessarily summable requires a completely different set of techniques, much closer from the tools used to prove Theorem 2. Theorem 6 can be thought of as an approximate answer to the question of [25] on the local certification of minor-closed classes.

Organization of the paper

We start with some preliminary results in Section 2. In Section 3, we prove the main technical contribution of this paper, a result showing that if a graph from some minor-closed class is far from a monotone property $\mathcal{P}$, then it contains linearly many edge-disjoint subgraphs of bounded size that are not in $\mathcal{P}$. In Section 4 we deduce Theorem 2 from this result and Theorem 1. Theorems 4 and 6 are proved in Section 5. We conclude in Section 6 with some remarks.

2 Preliminaries

Minor-closed classes

We denote the number of vertices of a graph G by $\mathsf{v}(G)$, and its number of edges by $\mathsf{e}(G)$. A class of graphs $\mathcal{G}$ is *minor-closed* if any minor of a graph from $\mathcal{G}$ is also in $\mathcal{G}$. A class is *proper* if it does not contain all graphs. The following was proved by Mader [35].

▶ **Theorem 7** ([35])**.** *For any proper minor-closed class $\mathcal{G}$, there is a constant C such that for any graph $G \in \mathcal{G}$, $\mathsf{e}(G) \leq C\,\mathsf{v}(G)$.*

Tree-depth

Given a rooted tree T, the *closure* of T is the graph obtained from T by adding edges between each vertex and its ancestors in the tree. The *height* of a rooted tree is the maximum number of vertices on a root-to-leaf path in the tree. The *tree-depth* of a connected graph G is the maximum height of a rooted tree T such that G is a subgraph of the closure of T, and the tree-depth of a graph G, denoted by $\mathrm{td}(G)$, is the maximum tree-depth of its connected components (equivalently, it is equal to the maximum height of a rooted *forest* F such that G is a subgraph of the closure of F).

The following was implicitly proved by Dvořák and Sereni [20] (in the proof below the actual definition of tree-width is not needed, so we omit it).

▶ **Theorem 8** ([20]). *For every proper minor-closed class $\mathcal{G}$ and every $\delta > 0$ there exists $d = d_8(\mathcal{G}, \delta) \in \mathbb{N}$ and $s = s_8(\mathcal{G}, \delta) \in \mathbb{N}$ satisfying the following. For every $G \in \mathcal{G}$ there exist $X_1, X_2, \ldots, X_s \subseteq V(G)$ such that*

- *for any $1 \leq i \leq s$, $\mathrm{td}(G[X_i]) \leq d$, and*
- *every $v \in V(G)$ belongs to at least $(1-\delta)s$ of the sets X_i.*

Proof. Let $t = \lceil \frac{2}{\delta} \rceil$. It was proved in [17] that there is a constant $k = k(t, \mathcal{G})$ such that any graph $G \in \mathcal{G}$ has a partition of its vertex set into t classes $Y_1, \ldots, Y_t$, such that the union of any $t-1$ classes Y_i induces a graph of tree-width at most k. In particular, if we define $Z_i := V(G) \setminus Y_i$ for any $1 \leq i \leq t$, then each graph $G[Z_i]$ has tree-width at most k and each vertex v lies in $t-1 = (1-\frac{1}{t})t$ sets Z_i. Dvořák and Sereni [20, Theorem 31] proved[2] that for every integer k and real $\delta > 0$, there are integers $r = r(k, \delta)$ and $d = d(k, \delta)$ such that for any graph H of tree-width at most k, H has a cover of its vertex set by r sets $X_1, \ldots, X_r$, such that each $H[X_i]$ has tree-depth at most d and each vertex lies in at least $(1-\frac{\delta}{2})r$ sets X_i. Applying this result to $H = G[Z_i]$ for any $1 \leq i \leq t$, we obtain rt sets $X'_1, \ldots, X'_{rt}$ of vertices of G, such that the subgraph $G[X'_i]$ induced by each of them has tree-depth at most d and each vertex of G lies in at least $(1-\frac{\delta}{2})r \cdot (1-\frac{1}{t})t \geq (1-\delta)rt$ sets X'_i. Thus d and $s = rt$ satisfy the conditions of the theorem. ◀

We deduce the following useful result.

▶ **Corollary 9.** *For every proper minor-closed class $\mathcal{G}$ and every $\varepsilon > 0$ there exists $d = d_9(\mathcal{G}, \varepsilon) \in \mathbb{N}$ satisfying the following. For every $G \in \mathcal{G}$ there exist $F \subseteq E(G)$ such that $|F| \leq \varepsilon\, \mathsf{e}(G)$ and $\mathrm{td}(G \setminus F) \leq d$.*

Proof. Let $\delta = \frac{\varepsilon}{2}$. We show that $d = d_8(\mathcal{G}, \delta)$ satisfies the corollary. Indeed, for $G \in \mathcal{G}$ let $X_1, X_2, \ldots, X_s \subseteq V(G)$ be as in Theorem 8. Let $F_i = E(G) \setminus E(G[X_i])$ for $i \in [s]$, then $\mathrm{td}(G \setminus F_i) \leq d$. Moreover, every edge belongs to at most $2\delta s$ sets F_i, so

$$\frac{1}{s} \sum_{i=1}^{s} |F_i| \leq \frac{1}{s} \cdot 2\delta s \cdot \mathsf{e}(G) = \varepsilon\, \mathsf{e}(G).$$

Thus, by averaging, $|F_i| \leq \varepsilon\, \mathsf{e}(G)$ for some i, and $F = F_i$ satisfies the corollary. ◀

Note that the conclusion of Corollary 9 can be shown to hold in greater generality than in the context of minor-closed classes. For instance, any class in which all graphs can be made of bounded *tree-width* by removing an arbitrarily small fraction of edges also have this property (see [20]). This includes all graphs of bounded *layered tree-width* (see [18, 39]). Typical non minor-closed examples of such classes are families of graphs that can be embedded on a fixed surface, with a bounded number of crossings per edge [19]. However, since the proof of Theorem 1 itself strongly relies on edge-contractions (and thus on the graph class $\mathcal{G}$ being minor-closed), Theorem 2 does not seem to be easily extendable beyond minor-closed classes.

[2] The property that s is bounded independently of G does not appear explicitly in the statement of their theorem, but readily follows from their proof. This will only be needed in Section 5.

3 Bounded size obstructions

3.1 General properties

A graph property $\mathcal{P}$ is a graph class that is closed under isomorphism. It will be convenient to write that $G \in \mathcal{P}$ instead of "G satisfies $\mathcal{P}$" in the remainder of the paper. A graph H is *minimally not in* $\mathcal{P}$ if $H \notin \mathcal{P}$ and any proper subgraph of H is in $\mathcal{P}$.

We will use the following result of Nešetřil and Ossona de Mendez (Lemma 6.13 in [36]) [3].

▶ **Lemma 10** ([36]). *For every integer $d \geq 1$ and every property $\mathcal{P}$, there exists $N = N_{10}(d, \mathcal{P})$ such that if H is minimally not in $\mathcal{P}$ and $\mathrm{td}(H) \leq d$ then $\mathsf{v}(H) \leq N$.*

3.2 Colorability

The conclusion of Lemma 10 is quite strong but it does not give explicit bounds on $N_{10}(d, \mathcal{P})$. For completeness, we give such an explicit bound when $\mathcal{P}$ is the property of being k-colorable. The specific question of whether 3-colorability of planar graphs was testable in the sparse model was raised by Christian Sohler at the Workshop on Local Algorithms (WOLA) in 2021. A positive answer to this question directly follows from Theorem 2, but the lemma below allows us to give an explicit bound on the query complexity of testing k-colorability in minor-closed classes (see Section 6).

Given a graph H and two vertex subsets $A, B \subseteq V(H)$, we say that (A, B) is a *proper separation* of H if $A \cup B = V(H)$, $A \setminus B$ and $B \setminus A$ are both non-empty, and there are no edges between $A \setminus B$ and $B \setminus A$ in H. We say that a graph H is *split* if there exists a proper separation (A, B) of H and an isomorphism $\phi : A \to B$ between $H[A]$ and $H[B]$ such that $\phi(v) = v$ for every $v \in A \cap B$ (see Figure 1 for an example). Equivalently, a split graph can be obtained by taking two copies of some smaller graph and, for a proper subset of vertices, identifying the two copies of the vertex subset with each other.

A connected graph H is *unsplit* if it is not split. Note that minimally non-k-colorable graphs are unsplit.

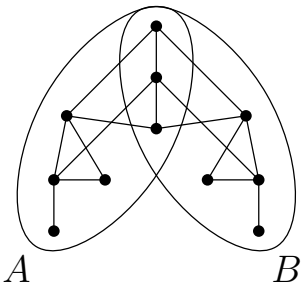

Figure 1 A split graph H and the corresponding proper separation (A, B) of H. The isomorphism $\phi : A \to B$ is the reflection symmetry with respect to the vertical axis.

The *tower function* is defined as $\mathsf{twr}(0) = 0$ and $\mathsf{twr}(i+1) = 2^{\mathsf{twr}(i)}$ for any integer $i \geq 0$.

▶ **Lemma 11.** *For every integer $d \geq 1$, there exists $N = N_{11}(d) = \mathsf{twr}(O(d))$ such that if H is an unsplit graph with $\mathrm{td}(H) \leq d$ then $\mathsf{v}(H) \leq N$.*

[3] The version we use here only needs Q to be a singleton in the statement of Lemma 6.13 in [36].

Proof. Define $k_d := 1$ and for any $0 \leq i \leq d-1$, let $k_i := (2^{\binom{k_{i+1}}{2}+d\cdot k_{i+1}})k_{i+1}+1$.

Choose a rooted tree T of height at most $d+1$ rooted at some vertex r, such that H is a subgraph of the closure of T. For each $v \in V(H)$, let T_v be the subtree of T rooted at v (consisting of v and all its descendants), and let H_v be the subgraph of H induced by $V(T_v)$. Define the *level* $\ell(v) := \mathrm{dist}_T(r,v) \in [0,d]$.

We prove by induction on $d-i$ that $\mathsf{v}(H_v) \leq k_i$ for every v with $\ell(v) = i$. The base case $i = d$ trivially holds, as $k_d = 1$.

For the induction step, let $u_1, \ldots, u_m$ be all the children of a vertex v with $\ell(v) = i$, and let A_v be the set consisting of v and its ancestors. Then $|A_v| = i+1$. For each $j \in [m]$, let $H_j^+ = H[A_v \cup V(H_{u_j})]$. Note that there are at most $2^{\binom{k_{i+1}}{2}+d\cdot k_{i+1}}$ distinct (labelled) graphs G on at most $|A_v| + k_{i+1} \leq d + k_{i+1}$ vertices such that the subgraph of G induced by the first $|A_v|$ vertices is isomorphic to $H[A_v]$. As $\mathsf{v}(H_{u_j}) \leq k_{i+1}$, if $m > 2^{\binom{k_{i+1}}{2}+d\cdot k_{i+1}}$ there exist $j \neq j'$ and an isomorphism $\phi : V(H_j^+) \to V(H_{j'}^+)$ such that $\phi(w) = w$ for every $w \in A_v$. Such an isomorphism would imply that H is split, and so $m \leq 2^{\binom{k_{i+1}}{2}+d\cdot k_{i+1}}$. It follows that $\mathsf{v}(H_v) \leq mk_{i+1}+1 \leq (2^{\binom{k_{i+1}}{2}+d\cdot k_{i+1}})k_{i+1}+1 = k_i$, as desired.

By taking $N := k_0$ we obtain that $\mathsf{v}(H) \leq N$. It can be checked from the definition of $(k_i)_{0\leq i\leq d}$ that $N = k_0$ is at most a tower function of $O(d)$. ◀

3.3 A linear Erdős-Posá property

We use Corollary 9 and Lemma 10 to deduce the following result, which is the main technical contribution of this paper.

▶ **Theorem 12.** *For every proper minor-closed class $\mathcal{G}$, every $\varepsilon > 0$, and every property $\mathcal{P}$, there exists $\delta > 0$ and an integer N such that for every $G \in \mathcal{G}$ either*

- *there exists $F \subseteq E(G)$ with $|F| \leq \varepsilon\,\mathsf{e}(G)$ such that $G \setminus F$ is in $\mathcal{P}$, or*
- *there exist edge-disjoint subgraphs $G_1, \ldots, G_m$ of G that are not in $\mathcal{P}$, such that $m \geq \delta\,\mathsf{e}(G)$ and for every $1 \leq i \leq m$, $\mathsf{v}(G_i) \leq N$.*

Proof. By Theorem 7, there exists C such that $\mathsf{e}(G) \leq C\mathsf{v}(G)$ for every $G \in \mathcal{G}$. Let $d := d_9(\mathcal{G}, \varepsilon/2)$ and let $N := N_{10}(d, \mathcal{P})$. We show that $\delta := \frac{\varepsilon}{2NC}$ satisfies the theorem.

Let $G_1, \ldots, G_m$ be a maximal collection of edge-disjoint subgraphs of G that are not in $\mathcal{P}$, and such that $\mathsf{v}(G_i) \leq N$. If $m \geq \delta\mathsf{e}(G)$ the theorem holds, so we assume that $m < \delta\mathsf{e}(G)$.

Let $F' = \bigcup_{i=1}^m E(G_i)$. Then

$$|F'| \leq C\sum_{i=1}^{m} \mathsf{v}(G_i) \leq CmN < cN\delta\mathsf{e}(G) \leq \frac{\varepsilon}{2}\,\mathsf{e}(G).$$

Let $G' = G \setminus F'$. By the choice of d, it follows from Corollary 9 that there exists $F'' \subseteq E(G')$ such that $|F''| \leq \frac{\varepsilon}{2}\,\mathsf{e}(G)$ and $\mathrm{td}(G' \setminus F'') \leq d$.

Let $G'' = G' \setminus F''$. Suppose first that G'' is not in $\mathcal{P}$, and let H be a minimal subgraph of G'' that is not in $\mathcal{P}$. As H is minimally not in $\mathcal{P}$, it follows from Lemma 10 that $\mathsf{v}(H) \leq N$. Thus adding H to the collection $G_1, \ldots, G_m$ contradicts its maximality.

It follows that G'' is in $\mathcal{P}$, but $G'' = G \setminus F$, where $F = F' \cup F''$ and $|F| \leq \varepsilon\,\mathsf{e}(G)$, and so the theorem holds. ◀

4 Property testing in the sparse model

The model

As alluded to in the introduction, we work in the sparse model, only using queries to the random neighbor oracle. That is, given an input graph G, the tester only does a constant number of queries to the input, all of the following type: given a vertex v, return a random neighbor of v (uniformly at random among all the neighbors of v in G). The vertex v itself can be taken to be a random vertex of G, but does not need to. The computation of a random vertex of G and a random neighbor of a given vertex of G are assumed to take constant time in this model.

We are now ready to prove Theorem 2.

Proof of Theorem 2. Let $\mathcal{G}$ be a proper-minor class and $\mathcal{P}$ be a monotone property. Let ε be given. Let $\delta > 0$ and N be obtained by applying Theorem 12 to $\mathcal{G}$, $\mathcal{P}$ and ε, and let $\mathcal{H}$ be the (finite) set of all graphs of at most N vertices that are not in $\mathcal{P}$. We now run the tester of Theorem 1 for testing whether a graph $G \in \mathcal{G}$ is $\mathcal{H}$-free or δ-far from being $\mathcal{H}$-free.

Assume first that $G \in \mathcal{P}$. If G contains a graph $H \in \mathcal{H}$ as a subgraph, then since $\mathcal{P}$ is monotone, we have $H \in \mathcal{P}$, which is a contradiction. Hence, G is $\mathcal{H}$-free, and it follows that the one-sided tester of Theorem 1 accepts G with probability 1. Assume now that G is ε-far from $\mathcal{P}$. By Theorem 12, there exist at least $\delta \mathsf{e}(G)$ edge-disjoint subgraphs of G that are all in $\mathcal{H}$, and thus one needs to remove at least one edge in each of these $\delta \mathsf{e}(G)$ edge-disjoint subgraphs to obtain an $\mathcal{H}$-free graph. As $\mathcal{P}$ is monotone, G is δ-far from being $\mathcal{H}$-free, and it follows that the tester of Theorem 1 rejects G with probability at least $\frac{2}{3}$, as desired. This concludes the proof of Theorem 2. ◀

5 Local Certification

We recall that in this part, all graphs are assumed to be connected.

5.1 Summable properties

Before we prove Theorem 5, we will need the following consequence of a result of Brodskiy, Dydak, Levin and Mitra [12] (obtained by taking $r = 2$ in Theorem 2.4 in their paper). This can be seen as an analogue of Theorem 8 where tree-depth is replaced by the weaker notion of weak diameter, while proper minor-closed classes are replaced by the more general classes of bounded asymptotic dimension.

▶ **Theorem 13** ([12]). *Let $\mathcal{G}$ be a class of graphs of bounded asymptotic dimension and let $\delta > 0$ be a real number. Then there exist two constants $D = D_{13}(\mathcal{G}, \delta) \in \mathbb{N}$ and $s = s_{13}(\mathcal{G}, \delta) \in \mathbb{N}$ satisfying the following. For every $G \in \mathcal{G}$ there exist $X_1, X_2, \ldots, X_s \subseteq V(G)$ such that*

- *for any $1 \leq i \leq s$, each connected component of $G[X_i]$ has weak diameter at most D in G, and*
- *every $v \in V(G)$ belongs to at least $(1-\delta)s$ of the sets X_i.*

It can be noted that if a subset S of vertices of a graph G is such that $G[S]$ has bounded tree-depth, then $G[S]$ has bounded diameter [36], and thus S has bounded weak diameter in G. It follows that in the special case of proper minor-closed classes, Theorem 8 implies Theorem 13 in a strong form.

Proof of Theorem 5. Fix any real number $\varepsilon > 0$ and an integer $d \geq 0$. Let $\mathcal{G}$ be a class of bounded asymptotic dimension, and let $\mathcal{P}$ be a monotone summable property of $\mathcal{G}$. Let $\delta = \frac{\varepsilon}{2}$. By Theorem 13, there exist two constants $D = D_{13}(\mathcal{G}, \delta) \in \mathbb{N}$ and $s = s_{13}(\mathcal{G}, \delta) \in \mathbb{N}$ satisfying the following. For every $G \in \mathcal{G}$ there exist $X_1, X_2, \ldots, X_s \subseteq V(G)$ such that

- for any $1 \leq i \leq s$, each component of $G[X_i]$ has weak diameter at most D in G, and
- every $v \in V(G)$ belongs to at least $(1-\delta)s$ of the sets X_i.

For any $v \in V(G)$, we define the proof $P(v)$ as (a binary representation of) the set of indices $I(v) \subseteq \{1, 2, \ldots, s\}$ such that $v \in X_i$. This proof has constant size (depending only of $\mathcal{P}$ and ε).

For every vertex v, the local verifier $\mathcal{A}(G, P, v)$ first checks that $I(v)$ contains at least $(1-\delta)s$ integers from $\{1, 2, \ldots, s\}$. If this is not the case, then v rejects the instance. In the remainder, we call a *monochromatic component of color i* a maximal connected subset of vertices v of G such that $i \in I(v)$. We omit the color if it is irrelevant in the discussion. Note that each vertex v belongs to $|I(v)|$ monochromatic components. For each vertex v, $\mathcal{A}(G, P, v)$ checks that the subgraph of G induced by the vertices $u \in B_r(v)$ is in $\mathcal{P}$, for $r = 2D + 1$, and that all monochromatic components of G containing v have weak diameter at most D (this can be clearly done as v has access to the subgraph of G induced by its ball of radius $r = 2D + 1$). If this is the case, then v accepts the instance, and otherwise v rejects the instance.

It follows from the definition of our scheme and the monotonicity of $\mathcal{P}$ that for any $G \in \mathcal{P}$, the local verifier $\mathcal{A}(G, P, v)$ of each vertex v of G accepts the instance. Consider now a graph G and a proof P' such that for each vertex v, $\mathcal{A}(G, P', v) = 1$. The proof P' assigns a subset $I(v)$ of indices of $\{1, \ldots, s\}$ to each vertex v of G, such that $|I(v)| \geq (1-\delta)s$. For each $1 \leq i \leq s$, let X_i be the subset of vertices v of G such that $i \in I(v)$. Let C be a connected component of some $G[X_i]$ (that is, C is a monochromatic component of color i), for some $1 \leq i \leq s$. Since all vertices of C accept the instance, C has weak diameter at most D in G. It follows that C is contained in some ball of radius D in G, and thus (since $\mathcal{P}$ is monotone, and each ball of radius $r = 2D + 1 \geq D$ induces a graph of $\mathcal{P}$), C lies in $\mathcal{P}$. As $\mathcal{P}$ is summable, $G[X_i]$ also lies in $\mathcal{P}$.

It follows from the proof of Corollary 9, that if we set $F_i = E(G) \setminus E(G[X_i])$ for any $1 \leq i \leq s$, then the property that every vertex $v \in V(G)$ belongs to at least $(1-\delta)s$ of sets X_i implies that there is an index $1 \leq i \leq s$ such that $|F_i| \leq \varepsilon\, \mathsf{e}(G)$. By the paragraph above $G \setminus F_i$ satisfies $\mathcal{P}$, and thus G is ε-close from $\mathcal{P}$ (we say that a graph is *ε-close* from $\mathcal{P}$ if it is not ε-far from $\mathcal{P}$). In the contrapositive, we have proved that if G is ε-far from $\mathcal{P}$, then there is at least one vertex v such that $\mathcal{A}(G, P', v) = 0$, as desired. ◀

Using the fact that proper minor-closed classes have asymptotic dimension at most 2 [9], we immediately obtain Theorem 4 as a corollary. Note that for the same purpose we could also use an earlier (and simpler) result of Ostrovskii and Rosenthal [38], who proved that for every integer t, the class of K_t-minor free graphs has asymptotic dimension at most 4^t. We could also use Theorem 8 without any reference to asymptotic dimension, as Theorem 8 implies Theorem 13 for proper minor-closed classes (see the discussion before the proof of Theorem 5).

5.2 Non necessarily summable properties

We now consider proof labelling schemes of complexity $O(\log n)$, rather than $O(1)$. To prove Theorem 6, we will need the following recent result of Bousquet, Feuilloley and Pierron [11].

▶ **Theorem 14** ([11]). *For every integer $d \geq 1$ and every first-order sentence φ, the class of graphs of tree-depth at most d satisfying φ has a 1-round proof labelling scheme of complexity $O(\log n)$.*

Although we will not need it, it is worth noting that the complexity in their result is of order $O(d \log n + f(d, \varphi))$. Observe also that checking whether a graph is $\mathcal{H}$-free for some fixed finite family $\mathcal{H}$ can be expressed by a first-order formula. In particular, it follows directly from Lemma 10 that checking whether $\mathrm{td}(G) \leq d$ can be expressed by a first-order formula (and thus certified with local horizon 1 with labels of size $O(\log n)$ per vertex).

The final ingredient that we will need is the ability to certify a rooted spanning tree, together with the children/parent relationship in this tree, with certificates of $O(\log n)$ bits per vertex (see [1, 6, 34] for the origins of this classical scheme). The prover gives the identifier $\mathrm{id}(r)$ of the root r of T to each vertex v of G, as well as $d_T(v, r)$, its distance to r in T, and each vertex v distinct from the root is also given the identifier of its parent $p(v)$ in T. The local verifier at v starts by checking that v agrees with all its neighbors in G on the identity of the root r of T. If so, if $v \neq r$, v checks that $d_T(v, r) = d_T(p(v), r) + 1$. It can be checked that all vertices accept the instance if and only T is a rooted spanning tree of G. Moreover, once the rooted spanning tree T has been certified, each vertex of G knows its parent and children (if any) in T.

We are now ready to prove Theorem 6.

Proof of Theorem 6. The beginning of the proof proceeds exactly as in the proof of Theorem 4. Fix any real number $\varepsilon > 0$. Let $\mathcal{G}$ be a proper minor-closed class, and let $\mathcal{P}$ be a monotone (not necessarily summable) property of $\mathcal{G}$. Let $\delta = \frac{\varepsilon}{2}$. By Theorem 8, there exist $d = d_8(\mathcal{G}, \delta) \in \mathbb{N}$ and $s = s_8(\mathcal{G}, \delta) \in \mathbb{N}$ satisfying the following. For every $G \in \mathcal{G}$ there exist $X_1, X_2, \ldots, X_s \subseteq V(G)$ such that

- for any $1 \leq i \leq s$, $\mathrm{td}(G[X_i]) \leq d$, and
- every $v \in V(G)$ belongs to at least $(1 - \delta)s$ of the sets X_i.

By Lemma 10, there exists a constant $N = N_{10}(d, \mathcal{P})$ such that if H is minimally not in $\mathcal{P}$ and $\mathrm{td}(H) \leq d$ then $\mathsf{v}(H) \leq N$. Let $\mathcal{H}$ be the (finite) set of all graphs of at most N vertices that are not in $\mathcal{P}$.

For any $v \in V(G)$, the proof $P(v)$ contains (a binary representation of) the set of indices $I(v) \subseteq \{1, \ldots, s\}$ such that $v \in X_i$. This part of the proof has constant size (depending only of $\mathcal{P}$ and ε). As in the proof of Theorem 4, the local verifier at each vertex v checks that $|I(v)| \geq (1 - \delta)s$, and rejects the instance if this does not hold.

For each $1 \leq i \leq s$, we do the following. In each connected component C of $G[X_i]$, we consider a rooted spanning tree T_C of C, with root r_C, and certify it using certificates of $O(\log n)$ bits per vertex. It follows from Theorem 14 that any first-order property of $G[C]$ can be certified with certificates of size $O(\log n)$ bits per vertex (as all the components C are vertex-disjoint, combining all these certificates and schemes still results in a scheme with labels of $O(\log n)$ bits per vertex). In particular we can certify that $\mathrm{td}(G[C]) \leq d$ (this is a first-order property). Let $\mathcal{H}'$ be the class of all (non-empty) graphs obtained from a graph $H \in \mathcal{H}$ by deleting an arbitrary subset of connected components of H (note that if all the graphs of $\mathcal{H}$ are connected, $\mathcal{H} = \mathcal{H}'$). Observe that all the graphs of $\mathcal{H}'$ have size at most N (which is a constant independent of the size of G). Then, for any $H' \in \mathcal{H}'$, we certify that $G[C]$ is H'-free or contains a copy of H' using Theorem 14, and store this information at the vertex r_C in a constant-size binary array $b(r_C)$, whose entries are indexed by all the graphs of $\mathcal{H}'$ (where the entry of $b(r_C)$ corresponding to some $H' \in \mathcal{H}'$ is equal to 1 if and only if C contains a copy of H' as a subgraph).

It remains to aggregate this information along some rooted spanning tree T of G (which can itself be certified with certificates of $O(\log n)$ bits per vertex). We do this as follows, for every $1 \leq i \leq s$. For a vertex v of the rooted tree T, the subtree of T rooted in v is denoted by T_v. For each vertex v of G, let $\mathcal{C}_v$ be the set of components C of $G[X_i]$ such that r_C lies in T_v. Then the proof $P(v)$ contains a binary array $c(v)$, whose entries are indexed by the graphs H' of $\mathcal{H}'$. The array $c(v)$ is defined as follows: for any $H' \in \mathcal{H}'$, the entry of $c(v)$ corresponding to H' is equal to 1 if and only if H' is a disjoint union of (non necessarily connected) graphs $H'_1, H'_2, \ldots, H'_k \in \mathcal{H}'$ such that each H'_i appears in a different component of $\mathcal{C}_v$. The consistency of the binary arrays $c(v)$ is verified locally as follows. For each vertex v of G, the local verifier at v considers the binary arrays $c(u)$, for all children u of v (and the binary array $b(v)$, if v is equal to some root r_C). For any $H' \in \mathcal{H}'$, the local verifier at v checks whether H' can be written as a disjoint union of graphs $H'_1, H'_2, \ldots, H'_k \in \mathcal{H}'$ such that each H'_i appears in a different array among the children of v (plus in $b(v)$, if v is a root of some component C). The local verifier at v then checks whether this is consistent with the entry corresponding to H' in $c(v)$. Clearly, all the vertices accept if and only if the information is consistent along the spanning tree, and it follows that the local verifier at the root r can check for each $H \in \mathcal{H} \subseteq \mathcal{H}'$, whether the entry of $c(r)$ corresponding to H is equal to 0 or 1. It follows that the local verifier at r can check whether $G[X_i]$ is $\mathcal{H}$-free (and accept the instance if and only if this is the case).

It follows from the definition of our scheme that for any $G \in \mathcal{P}$, the local verifier of each vertex of G accepts the instance.

Consider now some graph G together with some proof P' such that the local verifier $\mathcal{A}(G, P', v)$ at each vertex v of G accepts the instance. For any $1 \leq i \leq s$, let X_i be the set of vertices v such that $i \in I(v)$ (where $I(v)$ is given by the proof $P'(v)$), and let $F_i = E(G) \setminus E(G[X_i])$. As in the proof of Theorem 4, the property that every vertex $v \in V(G)$ belongs to at least $(1-\delta)s$ of sets X_i implies that there is an index $1 \leq i \leq s$ such that $|F_i| \leq \varepsilon \mathsf{e}(G)$.

By the properties of the local certificates, each component of $G \setminus F_i = G[X_i]$ has tree-depth at most d, and thus $G \setminus F_i$ has tree-depth at most d. Moreover, our local certificates imply that $G \setminus F_i$ is $\mathcal{H}$-free. Since $\mathcal{P}$ is monotone, $G \setminus F_i$ is in $\mathcal{P}$. It follows that G is ε-close from $\mathcal{P}$. Taking the contrapositive, this shows that if a graph is ε-far from $\mathcal{P}$, then at least one local verifier will reject the instance. This concludes the proof of Theorem 6. ◀

6 Conclusion

In this paper we proved that for any proper minor-closed class $\mathcal{G}$, using constantly many queries to the random neighbor oracle, a tester can decide with good probability whether an input graph $G \in \mathcal{G}$ satisfies some fixed monotone property $\mathcal{P}$, or is ε-far from $\mathcal{P}$. Given the level of generality of the result it is to be expected that no explicit bounds on the query complexity are given. However, we can give explicit estimates on the query complexity for specific properties. For instance, it follows from the bounds of [20, Corollary 35], combined with Lemma 11 and our proof of Theorem 2, that 3-colorability can be tested in planar graphs with $\mathsf{twr}(\mathrm{poly}(1/\varepsilon))$ queries to the random neighbor oracle. This can be extended to testing k-colorability in K_t-minor free graphs, for any k and t, at the expense of a significant increase in the height of the tower function, by combining the results of [20] with the main result of [17] (the bounds there are not explicit as a function of t, but can be made explicit using results from the Graph Minor series). This is to be compared with the main result of [14], that 2-colorability can be tested with $2^{2^{\mathrm{poly}(1/\varepsilon)}}$ queries in planar graphs. It is a

natural problem to understand whether these properties can be tested with poly$(1/\varepsilon)$ queries to the random neighbor oracle, and more generally to develop techniques for proving finer lower bounds on the query complexity of monotone properties in this model (see [7] for recent results in this direction in the bounded degree model).

Abstract

Recent progress in (semi-)streaming algorithms for monotone submodular function maximization has led to tight results for a simple cardinality constraint. However, current techniques fail to give a similar understanding for natural generalizations, including matroid constraints. This paper aims at closing this gap. For a single matroid of rank k (i.e., any solution has cardinality at most k), our main results are:

- A single-pass streaming algorithm that uses $\widetilde{O}(k)$ memory and achieves an approximation guarantee of 0.3178.
- A multi-pass streaming algorithm that uses $\widetilde{O}(k)$ memory and achieves an approximation guarantee of $(1 - 1/e - \varepsilon)$ by taking a constant (depending on ε) number of passes over the stream.

This improves on the previously best approximation guarantees of 1/4 and 1/2 for single-pass and multi-pass streaming algorithms, respectively. In fact, our multi-pass streaming algorithm is *tight* in that any algorithm with a better guarantee than 1/2 must make several passes through the stream and any algorithm that beats our guarantee of $1 - 1/e$ must make linearly many passes (as well as an exponential number of value oracle queries).

Moreover, we show how the approach we use for multi-pass streaming can be further strengthened if the elements of the stream arrive in uniformly random order, implying an improved result for p-matchoid constraints.

1 Introduction

Submodular function optimization is a classic topic in combinatorial optimization (see, e.g., the book [28]). Already in 1978, Nemhauser, Wolsey, and Fisher [26] analyzed a simple greedy algorithm for selecting the most valuable set $S \subseteq V$ of cardinality at most k. This algorithm starts with the empty set S, and then, for k steps, adds to S the element u with the largest marginal value. Assuming the submodular objective function f is also non-negative and monotone, they showed that the greedy algorithm returns a $(1 - 1/e)$-approximate solution. Moreover, the approximation guarantee of $1 - 1/e$ is known to be tight [10, 25].

A natural generalization of a cardinality constraint is that of a matroid constraint. While a matroid constraint is much more expressive than a cardinality constraint, it has often been the case that further algorithmic developments have led to the same or similar guarantees for both types of constraints. Indeed, for the problem of maximizing a monotone submodular function subject to a matroid constraint, Călinescu, Chekuri, Pál, and Vondrák [5] developed the more advanced continuous greedy method, and showed that it recovers the guarantee $1 - 1/e$ in this more general setting. Since then, other methods, such as local search [14], have been developed to recover the same optimal approximation guarantee.

More recently, applications in data science and machine learning [19], with huge problem instances, have motivated the need for space-efficient algorithms, i.e., (semi-)streaming algorithms for (monotone) submodular function maximization. This is now a very active research area, and recent progress has resulted in a tight understanding of streaming algorithms for maximizing monotone submodular functions with a single cardinality constraint: the optimal approximation guarantee is $1/2$ for single-pass streaming algorithms, and it is possible to recover the guarantee $1 - 1/e - \varepsilon$ in $O_\varepsilon(1)$ passes. That it is impossible to improve upon $1/2$ in a single pass is due to [11], and the first single-pass streaming algorithm to achieve this guarantee is a simple "threshold" based algorithm [2] that, intuitively, selects elements with marginal value at least $\mathrm{OPT}/(2k)$. The $(1-1/e-\varepsilon)$ guarantee in $O_\varepsilon(1)$ passes can be obtained using smart implementations of the greedy approach [3, 17, 22, 23, 27].

It is interesting to note that simple greedy and threshold-based algorithms have led to tight results for maximizing a monotone submodular function subject to a cardinality constraint in both the "offline" RAM and data stream models. However, in contrast to the RAM model, where more advanced algorithmic techniques have generalized these guarantees to much more general constraint families, current techniques fail to give a similar understanding in the data stream model, both for single-pass and multi-pass streaming algorithms. Closing this gap is the motivation for our work. In particular, current results leave open the intriguing possibility to obtain the same guarantees for a matroid constraint as for a cardinality constraint. Our results make significant progress on this question for single-pass streaming algorithms and completely close the gap for multi-pass streaming algorithms.

▶ **Theorem 1.** *There is a single-pass semi-streaming algorithm for maximizing a non-negative monotone submodular function subject to a matroid constraint of rank k (any solution has cardinality at most k) that stores $O(k)$ elements, requires $\widetilde{O}(k)$ additional memory, and achieves an approximation guarantee of* 0.3178*.*

The last theorem improves upon the previous best approximation guarantee of $1/4 = 0.25$ [6]. Moreover, the techniques are versatile and also yield a single-pass streaming algorithm with an improved approximation guarantee for non-monotone functions (improving from 0.1715 [12] to 0.1921).

Our next result is a tight multi-pass guarantee of $1 - 1/e - \varepsilon$, improving upon the previously best guarantee of $1/2 - \varepsilon$ [18].

▶ **Theorem 2.** *For every constant $\varepsilon > 0$, there is a multi-pass semi-streaming algorithm for maximizing a non-negative monotone submodular function subject to a matroid constraint of rank k (any solution has cardinality at most k) that stores $O(k/\varepsilon)$ elements, makes $O(1/\varepsilon^3)$ many passes, and achieves an approximation guarantee of $1 - 1/e - \varepsilon$.*

The result is tight (up to the exact dependency on ε) in the following strong sense: any streaming algorithm with a better approximation guarantee than $1/2$ must make more than one pass [11], and any algorithm with a better guarantee than $1 - 1/e$ must make linearly (in the length of the stream) many passes [22] (see Section 6 for more detail).

The way we obtain Theorem 2 is through a rather general and versatile framework based on the "Accelerated Continuous Greedy" algorithm of [3], which was designed for the classic (non-streaming) setting. This allows us to obtain results with an improved number of passes or more general constraints in specific settings. First, if the elements of the stream arrive in uniformly random order, then we can improve the number of passes as stated below.

▶ **Theorem 3.** *If the elements arrive in an independently random order in each pass, then for every constant $\varepsilon > 0$, there is a multi-pass semi-streaming algorithm for maximizing a non-negative monotone submodular function subject to a matroid constraint of rank k (any solution has cardinality at most k) that stores $O(k/\varepsilon)$ elements, makes $O(\varepsilon^{-2} \log \varepsilon^{-1})$ many passes, and achieves an approximation guarantee of $1 - 1/e - \varepsilon$.*

Second, also in the uniformly random order model, we can obtain results with even fewer passes, and that also extend to p-matchoid constraints, but at the cost of weaker approximation guarantees.

▶ **Theorem 4.** *If the elements arrive in an independently random order in each pass, then for every constant $\varepsilon > 0$, there is a multi-pass semi-streaming algorithm for maximizing a non-negative monotone submodular function subject to a matroid constraint of rank k (any solution has cardinality at most k) that stores $O(k)$ elements, makes $O(\log \varepsilon^{-1})$ many passes, and achieves an approximation guarantee of $1/2 - \varepsilon$.*

Moreover, if the matroid constraint is replaced with a more general p-matchoid constraint, the above still holds except that now the approximation guarantee is $1/(p+1) - \varepsilon$ and the number of passes is $O(p^{-1} \log \varepsilon^{-1})$.

The p-matchoid result of Theorem 4 improves, in the random order model, over an algorithm of [18] that achieves the same approximation factor, but needs $O(p/\varepsilon)$ passes, whereas our algorithm requires a number of passes that only logarithmically depends on ε^{-1} and decreases (rather than increases) with p. (However, the procedure in [18] does not require random arrival order, and obtains its guarantees even in the adversarial arrival model.)

1.1 Our Technique

Before getting into the technical details of our approaches, we provide an overview of the main ingredients behind the techniques we employ.

Single pass algorithms

The 4-approximation single pass algorithm due to Chakrabarti and Kale [6] (and later algorithms based on it such as [8, 12]) maintains an integral solution in the following way. Whenever a new element u arrives, the algorithm considers inserting u into the solution at the expense of some element u' that gets removed from the solution; and this swap is performed if it is beneficial enough. Naturally, the decision to make the swap is a binary

decision: we either make the swap or we do not do that. The central new idea in our improved single pass algorithms (Theorem 1) is that we make the swap fractional. In other words, we start inserting fractions of u at the expense of fractions of u' (the identity of u' might be different for different fractions of u), and we continue to do that as long as the swap is beneficial enough. Since "beneficial enough" depends on properties of the current solution, the swapping might stop being beneficial enough before all of u is inserted into the solution, which explains why our fractional swapping does not behave like the integral swapping used by previous algorithms.

While our single pass algorithms are based on the above idea, they are presented in a slightly different way for simplicity of the presentation and analysis. In a nutshell, the differences can be summarized by the following two points.

- Instead of maintaining a fractional solution, we maintain multiple sets A_i (for $i \in \mathbb{Z}$). Membership of an element u in each of these sets corresponds to having a fraction of $1/m$ (for a parameter m of the algorithm) of u in the fractional solution.
- We do not remove elements from our fractional solution. Instead, we add new elements to sets A_i with larger and larger i indexes with the implicit view that only fractions corresponding to sets A_i with relatively large indices are considered part of the fractional solution.

To make the above points more concrete, we note that the fractional solution is reconstructed from the sets A_i according to the above principles at the very end of the execution of our algorithms. The reconstructed fractional solution is denoted by s in these algorithms.

Multi-pass algorithms

Badanidiyuru and Vondrák [3] described an algorithm called "Accelerated Continuous Greedy" that obtains $1 - 1/e - O(\varepsilon)$ approximation (for every $\varepsilon \in (0, 1)$) for maximizing a monotone submodular function subject to a matroid constraint. Even though their algorithm is not a data stream algorithm, it accesses the input only in a well-defined restricted way, namely though a procedure called "Decreasing-Threshold Procedure". Originally, this procedure was implemented using a greedy algorithm on an altered objective function. However, we observe that the algorithm of [3] can work even if Decreasing-Threshold Procedure is modified to return any local maximum of the same altered objective function. Therefore, to get a multiple pass data stream algorithm, it suffices to design such an algorithm that produces an (approximate) local maximum (or a solution that is as good as such a local maximum); this algorithm can then be used as the implementation of Decreasing-Threshold Procedure. This is the framework we use to get our $(1 - 1/e - \varepsilon)$-approximation algorithms.

To prove Theorem 2 using the above framework, we show that a known algorithm (a variant of the algorithm of Chakrabarti and Kale [6] due to Huang, Thiery, and Ward [18]) can be repurposed to produce an approximate local maximum using $O(\varepsilon^{-2})$ passes, which, when used in Accelerated Continuous Greedy, leads to the claimed $O(\varepsilon^{-3})$ many passes. Similarly, by adapting an algorithm of Shadravan [29] working in the random order model, and extending it to multiple passes, we are able to get a solution that is as good as an approximate local maximum in only $O(\varepsilon^{-1} \log \varepsilon^{-1})$ random-order passes, which leads to Theorem 3 when combined with the above framework.

Interestingly, any (approximate) local maximum also has an approximation guarantee of its own (without employing the above framework). This means that the above procedures for producing approximate local maxima can also be viewed as approximation algorithms

in their own right, which leads to Theorem 4.[1] It is important to note that Theorem 4 uses fewer passes than what is used in the proof of Theorem 3 to get a solution which is at least as good as an approximate local maximum. This discrepancy happens because in Theorem 4 we only aim for a solution with some approximation ratio r, where r is an approximation ratio guaranteed by any approximate local maximum in any instance. In contrast, Theorem 3 needs a solution that is as good as some approximate local maximum of the particular instance considered.

1.2 Additional Related Work

As mentioned above, Călinescu et al. [5] proposed a $(1 - 1/e)$-approximation algorithm for maximizing a monotone submodular function subject to a matroid constraint in the offline (RAM) setting, which is known to be tight [10, 25]. The corresponding problem with a non-monotone objective is not as well understood. A long line of work [9, 13, 20] on this problem culminated in a 0.385-approximation due to Buchbinder and Feldman [4] and an upper bound by Oveis Gharan and Vondrák [15] of 0.478 on the best obtainable approximation ratio.

The first semi-streaming algorithm for maximizing a monotone submodular function subject to a matroid constraint was described by Chakrabarti and Kale [6], who obtained an approximation ratio of 1/4 for the problem. This remained state-of-the-art prior to this work. However, Chan, Huang, Jiang, Kang, and Tang [7] managed to get an improved approximation ratio of 0.3178 for the special case of a partition matroid in the related preemptive online model. We note that the last approximation ratio is identical to the approximation ratio stated in Theorem 1, which points to some similarity that exists between the algorithms (in particular, both use fractional swaps). However, the algorithm of [7] is not a semi-streaming algorithm (and moreover, it is tailored to partition matroids). The first semi-streaming algorithm for the non-monotone version of the above problem was obtained by Chekuri, Gupta, and Quanrud [8], and achieved a $(1/(4 + e) - \varepsilon) \approx 0.1488$-approximation. This was later improved to 0.1715-approximation by Feldman, Karbasi, and Kazemi [12].[2]

Outline of the paper

In Section 2, we introduce notations and definitions used throughout this paper. Afterwords, in Section 3, we present and analyze our single-pass algorithms. The framework used to prove Theorems 2 and 3 is presented in detail in Section 4, and in the two sections after it we describe the algorithms for obtaining approximate local maxima (or equally good solutions) necessary for using this framework. Specifically, in Section 5 we show how to get such an algorithm for adversarial order streams (leading to Theorem 2), and in Section 7 we show how to get such an algorithm for random order streams (leading to Theorems 3 and 4). It is worth noting that Section 3 is independent of all the other sections, and therefore, can be skipped by a reader interested in the other parts of this paper.

[1] Technically, we can also get a result for adversarial order streams in this way, but we omit this result since it is weaker than a known result of [18].

[2] Mirzasoleiman et al. [24] claimed another approximation ratio for the problem (weaker than the one given later by [12]), but some problems were found in their analysis (see [16] for details).

2 Preliminaries

Recall that we are interested in the problem of maximizing a submodular function subject to a matroid constraint. In Section 2.1 we give the definitions necessary for formally stating this problem. Then, Section 2.2 defines the data stream model in which we study the problem. Finally, in Section 2.3 we present some additional notation and definitions that we use.

2.1 Problem Statement

Submodular Functions

Given a ground set $\mathcal{N}$, a *set function* $f\colon 2^{\mathcal{N}} \to \mathbb{R}$ is a function that assigns a numerical value to every subset of $\mathcal{N}$. Given a set $S \subseteq \mathcal{N}$ and an element $u \in \mathcal{N}$, it is useful to denote by $f(u \mid S)$ the marginal contribution of u to S with respect to f, i.e., $f(u \mid S) \coloneqq f(S \cup \{u\}) - f(S)$. Similarly, we denote the marginal contribution of a set $T \subseteq \mathcal{N}$ to S with respect to f by $f(T \mid S) \coloneqq f(S \cup T) - f(S)$.

A set function $f\colon 2^{\mathcal{N}} \to \mathbb{R}$ is called *submodular* if for any two sets S and T such that $S \subseteq T \subseteq \mathcal{N}$ and any element $u \in \mathcal{N} \setminus T$ we have $f(u \mid S) \geq f(u \mid T)$. Moreover, we say that f is *monotone* if $f(S_1) \leq f(S_2)$ for any sets $S_1 \subseteq S_2 \subseteq \mathcal{N}$, and f is *non-negative* if $f(S) \geq 0$ for every $S \subseteq \mathcal{N}$.

Matroids

A set system is a pair $M = (\mathcal{N}, \mathcal{I})$, where $\mathcal{N}$ is a finite set called the *ground set*, and $\mathcal{I} \subseteq 2^{\mathcal{N}}$ is a collection of subsets of the ground set. We say that a set $S \subseteq \mathcal{N}$ is *independent* in M if it belongs to $\mathcal{I}$ (otherwise, we say that it is a *dependent* set); and the rank of the set system M is defined as the maximum size of an independent set in it. A set system is a *matroid* if it has three properties: i) The empty set is independent, i.e., $\varnothing \in \mathcal{I}$. ii) Every subset of an independent set is independent, i.e., for any $S \subseteq T \subseteq \mathcal{N}$, if $T \in \mathcal{I}$ then $S \in \mathcal{I}$. iii) If $S \in \mathcal{I}$, $T \in \mathcal{I}$ and $|S| < |T|$, then there exists an element $u \in T \setminus S$ such that $S \cup \{u\} \in \mathcal{I}$.[3]

A matroid constraint is simply a constraint that allows only sets that are independent in a given matroid. Matroid constraints are of interest because they have a rich combinatorial structure and yet are able to capture many constraints of interest such as cardinality, independence of vectors in a vector space, and being a non-cyclic sub-graph.

Matchoids and p-matchoids

The matchoid notion (for the case of $p = 2$) was proposed by Jack Edmonds as a common generalization of matching and matroid intersection. Let $M_1 = (\mathcal{N}_1, \mathcal{I}_1), M_2 = (\mathcal{N}_2, \mathcal{I}_2), \ldots, M_q = (\mathcal{N}_q, \mathcal{I}_q)$ be q matroids, and let $\mathcal{N} = \mathcal{N}_1 \cup \cdots \cup \mathcal{N}_q$ and $\mathcal{I} = \{S \subseteq \mathcal{N} \mid S \cap \mathcal{N}_\ell \in \mathcal{I}_\ell \text{ for every } 1 \leq \ell \leq q\}$. The set system $M = (\mathcal{N}, \mathcal{I})$ is a *p-matchoid* if each element $u \in \mathcal{N}$ is a member of $\mathcal{N}_\ell$ for at most p indices $\ell \in [q]$. Informally, a p-matchoid is an intersection of matroids in which every particular element $u \in \mathcal{N}$ is affected by at most p matroids. It is easy to see that a 1-matchoid is just a matroid, and vice versa. 2-matchoids are often referred to simply as matchoids (without a parameter p).

[3] The last property is often referred to as the *exchange axiom* of matroids.

Problem

In the `Submodular Maximization subject to a Matroid Constraint` problem (`SMMatroid`), we are given a non-negative[4] submodular function $f\colon 2^{\mathcal{N}} \to \mathbb{R}_{\geq 0}$ and a matroid $M = (\mathcal{N}, \mathcal{I})$ over the same ground set. The objective is to find an independent set $S \in \mathcal{I}$ that maximizes f. An important special case of `SMMatroid` is the `Monotone Submodular Maximization subject to a Matroid Constraint` problem (`MSMMatroid`) in which we are guaranteed that the objective function f is monotone (in addition to being non-negative and submodular).

2.2 Data Stream Model

In the data stream model, the input appears in a sequential form known as the *input stream*, and the algorithm is allowed to read it only sequentially. In the context of our problem, the input stream consists of the elements of the ground set sorted in either an adversarially chosen order or a uniformly random order, and the algorithm is allowed to read the elements from the stream only in this order. Often the algorithm is allowed to read the input stream only once (such algorithms are called *single-pass* algorithms), but in other cases it makes sense to allow the algorithm to read the input stream multiple times – each such reading is called a *pass*. The order of the elements in each pass might be different; in particular, when the order is random, we assume that it is chosen independently for each pass.

A trivial way to deal with the restrictions of the data stream model is to store the entire input stream in the memory of the algorithm. However, we are often interested in a stream carrying too much data for this to be possible. Thus, the goal in this model is to find a high quality solution while using significantly less memory than what is necessary for storing the input stream. The gold standard are algorithms that use memory of size nearly linear in the maximum possible size of an output; such algorithms are called *semi-streaming* algorithms.[5] For `SMMatroid` and `MSMMatroid`, this implies that a semi-streaming algorithm is a data stream algorithm that uses $O(k \log^{O(1)} |\mathcal{N}|)$ space, where k is the rank of the matroid constraint.

The description of submodular functions and matroids can be exponential in the size of their ground sets, and therefore, it is important to define the way in which an algorithm may access them. We make the standard assumption that the algorithm has two oracles: a *value oracle* and an *independence oracle* which, given a set $S \subseteq \mathcal{N}$ of elements that are explicitly *stored* in the memory of the algorithm, returns the value of $f(S)$ and an indicator whether $S \in \mathcal{I}$, respectively.

2.3 Additional Notation and Definitions

Multilinear Extension

A set function $f\colon 2^{\mathcal{N}} \to \mathbb{R}$ assigns values only to subsets of $\mathcal{N}$. If we think of a set S as equivalent to its characteristic vector $\mathbf{1}_S$ (a vector in $\{0,1\}^{\mathcal{N}}$ that has a value of 1 in every coordinate $u \in S$ and a value of 0 in the other coordinates), then we can view f as a function over the integral vectors in $[0,1]^{\mathcal{N}}$. It is often useful to extend f to general

[4] The assumption of non-negativity is necessary to allow multiplicative approximation guarantees.

[5] The similar term *streaming* algorithms often refers to algorithms whose space complexity is poly-logarithmic in the parameters of their input. Such algorithms are irrelevant for the problem we consider because they do not have enough space even for storing the output of the algorithm.

vectors in $[0,1]^{\mathcal{N}}$. There are multiple natural ways to do that. However, in this paper, we only need the multilinear extension F. Given a vector $x \in [0,1]^{\mathcal{N}}$, let $\mathcal{R}(x)$ denote a random subset of $\mathcal{N}$ including each element $u \in \mathcal{N}$ with probability x_u, independently. Then, $F(x) = \mathbb{E}[f(\mathcal{R}(x))] = \sum_{S \subseteq \mathcal{N}} [f(S) \cdot \prod_{u \in S} x_u \cdot \prod_{u \notin S} (1 - x_u)]$. One can observe that, as is implied by its name, the multilinear extension is a multilinear function. Thus, for every vector $x \in [0,1]^{\mathcal{N}}$, the partial derivative $\frac{\partial F}{\partial x_u}(x)$ is equal to $F(x + (1 - x_u) \cdot \mathbf{1}_u) - F(x - x_u \cdot \mathbf{1}_u)$. Note that in the last expression we have used $\mathbf{1}_u$ as a shorthand for $\mathbf{1}_{\{u\}}$. We often also use $\partial_u F(x)$ as a shorthand for $\frac{\partial F}{\partial x_u}(x)$. When f is submodular, its multilinear extension F is known to be concave along non-negative directions [5].

General Notation

Given a set $S \subseteq \mathcal{N}$ and an element $u \in \mathcal{N}$, we denote by $S + u$ and $S - u$ the expressions $S \cup \{u\}$ and $S \setminus \{u\}$, respectively. Additionally, given two vectors $x, y \in [0,1]^{\mathcal{N}}$, we denote by $x \vee y$ and $x \wedge y$ the coordinate-wise maximum and minimum operations, respectively.

Additional Definitions from Matroid Theory

Matroid theory is extensive, and we refer the reader to [28] for a more complete coverage of it. Here, we give only a few basic definitions from this theory that we employ below. Given a matroid $M = (\mathcal{N}, \mathcal{I})$, a set $S \subseteq \mathcal{N}$ is called *base* if it is an independent set that is maximal with respect to inclusion (i.e., every super-set of S is dependent), and it is called *cycle* if it is a dependent set that is minimal with respect to inclusion (i.e., every subset of S is independent). An element $u \in \mathcal{N}$ is called a loop if $\{u\}$ is a cycle. Notice that such elements cannot appear in any feasible solution for either `SMMatroid` or `MSMMatroid`, and therefore, one can assume without loss of generality that there are no loops in the ground set.

The rank of a set $S \subseteq \mathcal{N}$, denoted by $\text{rank}_M(S)$, is the maximum size of an independent set $T \in \mathcal{I}$ which is a subset of S. The subscript M is omitted when it is clear from the context. We also note that $\text{rank}_M(\mathcal{N})$ is exactly the rank of the matroid M (i.e., the maximum size of an independent set in M), and therefore, it is customary to define $\text{rank}(M) = \text{rank}_M(\mathcal{N})$. We say that a set $S \subseteq \mathcal{N}$ spans an element $u \in \mathcal{N}$ if adding u to S does not increase the rank of the set S, i.e., $\text{rank}(S) = \text{rank}(S + u)$ – observe the analogy between this definition and being spanned in a vector space. Furthermore, we denote by $\text{span}_M(S) \coloneqq \{u \in \mathcal{N} \mid \text{rank}(S) = \text{rank}(S + u)\}$ the set of elements that are spanned by S. Again, the subscript M is dropped when it is clear from the context.

3 Single-Pass Algorithm

In this section, we present our single-pass algorithm for the `Monotone Submodular Maximization subject to a Matroid Constraint` problem (`MSMMatroid`). The properties of the algorithm we present are given by the following theorem.

▶ **Theorem 1.** *There is a single-pass semi-streaming algorithm for maximizing a non-negative monotone submodular function subject to a matroid constraint of rank k that stores $O(k)$ elements, requires $\widetilde{O}(k)$ additional memory, and achieves an approximation guarantee of* 0.3178.

Our algorithm can be extended to the case in which the objective function is non-monotone (i.e., the `SMMatroid` problem) at the cost of obtaining a lower approximation factor, yielding the following theorem. However, for the sake of concentrating on our main new ideas, we devote this section to the algorithm of Theorem 1 and defer the proof of Theorem 5 to the full version.

▶ **Theorem 5.** *There is a single-pass semi-streaming algorithm for maximizing a non-negative (not necessarily monotone) submodular function subject to a matroid constraint of rank k that stores $O(k)$ elements, requires $\widetilde{O}(k)$ additional memory, and achieves an approximation guarantee of* 0.1921*.*

Throughout this section, we denote by $P_M \coloneqq \{x \in \mathbb{R}^{\mathcal{N}}_{\geq 0} \colon x(S) \leq \operatorname{rank}(S)\ \forall S \subseteq \mathcal{N}\}$ the matroid polytope of M. The algorithm we use to prove Theorem 1 appears as Algorithm 1. This algorithm gets a parameter $\varepsilon > 0$ and starts by initializing a constant α to be approximately the single positive value obeying $\alpha + 2 = e^{\alpha}$. We later prove that the approximation ratio guaranteed by the algorithm is at least $\frac{1}{\alpha+2} - \varepsilon$, which is better than the approximation ratio stated in Theorem 1 for a small enough ε. After setting the value of α, Algorithm 1 defines some additional constants m, c, and L using ε and α. We leave these variables representing different constants as such in the procedure and analysis, which allows for obtaining a better understanding later on of why these values are optimal for our analysis. We also note that, as stated, Algorithm 1 is efficient (i.e., runs in polynomial time) only if the multilinear extension and its partial derivatives can be efficiently evaluated. If that cannot be done, then one has to approximate F and its derivatives using Monte-Carlo simulation, which is standard practice (see, for example, [5]). We omit the details to keep the presentation simple, but we note that, as in other applications of this standard technique, the incurred error can easily be kept negligible, and therefore, does not affect the guarantee stated in Theorem 1.

Algorithm 1 uses sets A_i and vectors $a_i \in [0,1]^{\mathcal{N}}$ for certain indices $i \in \mathbb{Z}$. Throughout the algorithm, we only consider finitely many indices $i \in \mathbb{Z}$. However, we do not know upfront which indices within $\mathbb{Z}$ we will use. To simplify the presentation, we therefore use the convention that whenever the algorithm uses for the first time a set A_i or vector a_i, then A_i is initialized to be $\varnothing$ and a_i is initialized to be the zero vector. The largest index ever used in the algorithm is q, which is computed toward the end of the algorithm at Line 13.

For each $i \in \mathbb{Z}$, the set A_i is an independent set consisting of elements u that already arrived and for which the marginal increase with respect to a reference vector a (at the moment when u arrives) is at least c^i. More precisely, whenever a new element $u \in \mathcal{N}$ arrives and its marginal return $\partial_u F(a)$ exceeds c^i for an index $i \in \mathbb{Z}$ in a relevant range, then we add u to A_i if $A_i + u$ remains independent. When adding u to A_i, we also increase the u-entry of the vector a_i by $\frac{c^i}{m \cdot \partial_u F(a)}$. The vector a built up during the algorithm has two key properties. First, its multilinear value approximates $f(\mathrm{OPT})$ up to a constant factor. Second, one can derive from the sets A_i a vector s (see Algorithm 1) such that $F(s)$ is close to $F(a)$ and s is contained in the matroid polytope $P_{\mathcal{M}}$.

Whenever an element $u \in \mathcal{N}$ arrives, the algorithm first computes the largest index $i(u) \in \mathbb{Z}$ fulfilling $c^{i(u)} \leq \partial_u F(a)$. It then updates sets A_i and vectors a_i for indices $i \leq i(u)$. Purely conceptually, the output of the algorithm would have the desired guarantees even if all infinitely many indices below $i(u)$ where updated. However, to obtain an algorithm running in finite (even polynomial) time and linear memory, we do not consider indices below $\max\{b, i(u) - \operatorname{rank}(M) - L\}$ in the update step. Capping the considered indices like this has only a minor impact in the analysis since the contribution of the vectors a_i to the multilinear extension value of the vector a is geometrically decreasing with decreasing index i.

In the algorithm, and also in its analysis, we sometimes use sums over indices that go up to ∞. However, whenever this happens, beyond some finite index, all terms are zero. Hence, such sums are well defined.

Finally, we provide details on the return statement in Line 17 of the algorithm. This statement is based on a fact stated in [5], namely that a point in the matroid polytope can be rounded losslessly to an independent set. More formally, given any point $y \in P_{\mathcal{M}}$ in the

Algorithm 1 Single-Pass Semi-Streaming Algorithm for `MSMMatroid`.

Set $\alpha = 1.1462$, $m = \left\lceil \frac{3\alpha}{\varepsilon} \right\rceil$, $c = \frac{m}{m-\alpha}$, and $L = \left\lceil \log_c\left(\frac{2c}{\varepsilon(c-1)}\right) \right\rceil$.
Set $a = 0 \in [0,1]^{\mathcal{N}}$ to be the zero vector, and let $b = -\infty$.
for every element arriving $u \in \mathcal{N}$, if $\partial_u F(a) > 0$ **do**
    Let $i(u) = \lfloor \log_c(\partial_u F(a)) \rfloor$. ▷ Thus, $i(u)$ is largest index $i \in \mathbb{Z}$ with $c^i \leq \partial_u F(a)$.
    for $i = \max\{b, i(u) - \operatorname{rank}(M) - L\}$ **to** $i(u)$ **do**
        if $A_i + u \in \mathcal{I}$ **then**
            $A_i \leftarrow A_i + u$.
            $a_i \leftarrow a_i + \frac{c^i}{m \cdot \partial_u F(a)} \mathbf{1}_u$.
    Set $b \leftarrow h - L$, where h is largest index $i \in \mathbb{Z}$ satisfying $\sum_{j=i}^{\infty} |A_j| \geq \operatorname{rank}(M)$.
    $a \leftarrow \sum_{i=b}^{\infty} a_i$.
    Delete from memory all sets A_i and vectors a_i with $i \in \mathbb{Z}_{<b}$.
Set $S_k \leftarrow \varnothing$ for $k \in \{0, \ldots, m-1\}$.
Let q be largest index $i \in \mathbb{Z}$ with $A_i \neq \varnothing$.
for $i = q$ **to** b (stepping down by 1 at each iteration) **do**
    while $\exists u \in A_i \setminus S_{(i \bmod m)}$ with $S_{(i \bmod m)} + u \in \mathcal{I}$ **do**
        $S_{(i \bmod m)} \leftarrow S_{(i \bmod m)} + u$.
return a rounding $R \in \mathcal{I}$ of the fractional solution $s := \frac{1}{m} \sum_{k=0}^{m-1} \mathbf{1}_{S_k}$ with $f(R) \geq F(s)$.

matroid polytope, there is an independent set $I \in \mathcal{I}$ with $f(I) \geq F(y)$. Moreover, assuming that the multilinear extension F can be evaluated efficiently, such an independent set I can be computed efficiently. As before, if one is only given a value oracle for f, then the exact evaluation of F can be replaced by a strong estimate obtained through Monte-Carlo sampling, leading to a randomized algorithm to round y to an independent set I with $f(I) \geq (1-\delta)F(y)$ for an arbitrarily small constant $\delta > 0$.

Due to space constraints, the analysis of Algorithm 1 is deferred to the full version.

4 Framework for Multi-pass Algorithms

In this section we present the details of the framework used to prove our $(1 - 1/e)$-approximation results (Theorems 2 and 3). We remind the reader that the proofs of these theorems (using the framework) can be found in Sections 5 and 7, respectively. Badanidiyuru and Vondrák [3] described an algorithm called "Accelerated Continuous Greedy" that obtains an approximation guarantee of $1 - 1/e - O(\varepsilon)$ for `MSMMatroid` for every $\varepsilon \in (0, 1)$. Their algorithm is not a data stream algorithm, but it enjoys the following nice properties.

- The algorithm includes a procedure called "Decreasing-Threshold Procedure". This procedure is the only part of the algorithm that directly accesses the input.
- The Decreasing-Threshold Procedure is called $O(\varepsilon^{-1})$ times during the execution of the algorithm.
- In addition to the space used by this procedure, Accelerated Continuous Greedy uses only space that is linear in the space necessary to store the outputs of the various executions of the Decreasing-Threshold Procedure.
- The Decreasing-Threshold Procedure returns a base D of M after every execution, and this base is guaranteed to obey Equation (1) stated below. The analysis of the approximation ratio of Accelerated Continuous Greedy treats Decreasing-Threshold Procedure as a black box except for the fact that its output is a base D of M obeying Equation (1),

and therefore, this analysis will remain valid even if Decreasing-Threshold Procedure is replaced by any other algorithm with the same guarantee. Furthermore, one can verify that the analysis continues to work (with only minor technical changes) even if the output D of the replacing algorithm obeys Equation (1) only in expectation.

Let us now formally state the property that the output base of Decreasing-Threshold Procedure obeys. Let P_M be the matroid polytope of M, and let F be the multilinear extension of f. Decreasing-Threshold Procedure gets as input a point $x \in (1-\varepsilon) \cdot P_M$, and its output base D is guaranteed to obey

$$F(x') - F(x) \geq \varepsilon[(1-3\varepsilon) \cdot f(\mathrm{OPT}) - F(x')] \ , \tag{1}$$

where $x' = x + \varepsilon \cdot \mathbf{1}_D$ and OPT denotes an optimal solution.

Our objective in Sections 5 and 7 is to describe semi-streaming algorithms that can function as replacements for the offline procedure Decreasing-Threshold Procedure. The next proposition states that plugging such a replacement into Accelerated Continuous Greedy yields a roughly $(1-1/e)$-approximation semi-streaming algorithm.

▶ **Proposition 6.** *Assume there exists a semi-streaming algorithm that given a point $x \in (1-\varepsilon) \cdot P_M$ makes p passes over the input stream, stores $O(k/\varepsilon)$ elements, and outputs a base D obeying Equation (1) in expectation. Then, there exists a semi-streaming algorithm for maximizing a non-negative monotone submodular function subject to a matroid constraint of rank k that stores $O(k/\varepsilon)$ elements, makes $O(p/\varepsilon)$ many passes and achieves an approximation guarantee of $1-1/e-\varepsilon$.*

Proof. Observe that the proposition is trivial when $\varepsilon \geq 1-1/e$, and therefore, we assume below that $\varepsilon < 1-1/e$. Furthermore, for simplicity, we describe an algorithm with an approximation ratio of $1-1/e-O(\varepsilon)$ rather than a clean ratio of $1-1/e-\varepsilon$. However, one can switch between the two ratios by scaling ε by an appropriate constant.

Let us denote by ALG the algorithm whose existence is promised by the statement of the proposition, and consider an algorithm called `Data Stream Continuous Greedy` (`DSCG`) obtained from the Accelerated Continuous Greedy algorithm of [3] when every execution of the Decreasing-Threshold Procedure by the last algorithm is replaced with an execution of ALG. We explain below why `DSCG` has all the properties guaranteed by the proposition. We begin by recalling that since the approximation ratio analysis of Accelerated Continuous Greedy in [3] treats the Decreasing-Threshold Procedure as a black box that in expectation has the guarantee stated in Equation (1), and ALG also has this guarantee, this analysis can be applied as is also to `DSCG`, and therefore, `DSCG` is a $(1-1/e-O(\varepsilon))$-approximation algorithm.

Recall now that Accelerated Continuous Greedy accesses its input only through the Decreasing-Threshold Procedure, which implies that `DSCG` is a data stream algorithm just like ALG. Furthermore, since Accelerated Continuous Greedy accesses the Decreasing-Threshold Procedure $O(\varepsilon^{-1})$ times, the number of passes used by `DSCG` is larger by a factor of $O(\varepsilon^{-1})$ compared to the number of passes used by ALG (which is denoted by p). Hence, `DSCG` uses $O(p/\varepsilon)$ passes.

It remains to analyze the space complexity of `DSCG`. Since Accelerated Continuous Greedy uses space of size linear in the space necessary to keep the $O(\varepsilon^{-1})$ bases that it receives from the Decreasing-Threshold Procedure, the space complexity of `DSCG` is larger than the space complexity of the semi-streaming algorithm ALG only by an additive term of $\widetilde{O}(k/\varepsilon)$. As this term is nearly linear in k for any constant ε, we get that `DSCG` has a low enough space

complexity to be a semi-streaming algorithm. Furthermore, since the $O(\varepsilon^{-1})$ bases that DSCG gets from ALG can include only $O(k/\varepsilon)$ elements, this expression upper bounds the number of elements stored by DSCG in addition to the $O(k/\varepsilon)$ elements stored by ALG itself. ◀

It turns out that one natural way to get a base D obeying Equation (1) is to output a local maximum with respect to the objective function $g(S) = F(x + \varepsilon \cdot \mathbf{1}_S)$ (i.e., a base D whose value with respect to this objective cannot be improved by replacing an element of D with an element of $\mathcal{N} \setminus D$). Getting such a maximum using a semi-streaming algorithm with a reasonable number of passes is challenging; however, one can define weaker properties that still allow us to get Equation (1). Specifically, for any $\varepsilon \in (0, 1)$, we say that a set D is an *ε-approximate local maximum* with respect to g if

$$g(D \mid \varnothing) \geq g(B \mid D) + \sum_{u \in B \cap D} g(u \mid D - u) - \varepsilon \cdot g(\mathrm{OPT}_g \mid \varnothing)$$

for every base B of M, where OPT_g is a base maximizing g. (Intuitively, one should think of B as being the optimal solution with respect to f.)

One property of an approximate local maximum is that its value (with respect to g) is an approximation to $g(\mathrm{OPT}_g)$.

▶ **Observation 7.** *For every $\varepsilon \in (0, 1)$, if D is an ε-approximate local maximum with respect to g, then $g(D) \geq \frac{1-\varepsilon}{2} \cdot g(OPT_g)$.*

Proof. One can verify that the non-negativeity, monotonicity and submodularity of f implies that g also has these properties. Therefore,

$$\begin{aligned} g(D) &\geq g(D \mid \varnothing) \geq g(OPT_g \mid D) + \sum_{u \in \mathrm{OPT}_g \cap D} g(u \mid D - u) - \varepsilon \cdot g(\mathrm{OPT}_g \mid \varnothing) \\ &\geq g(\mathrm{OPT}_g \mid D) - \varepsilon \cdot g(OPT_g \mid \varnothing) \geq (1 - \varepsilon) \cdot g(\mathrm{OPT}_g) - g(D) \ , \end{aligned}$$

where the first inequality holds by the non-negativity of g, the second inequality follows from the fact that D is an ε-approximate local maximum (for $B = \mathrm{OPT}_g$), the third inequalities follow from the monotonicity of g, and the last inequality hold by g's non-negativity and monotonicity. Rearranging the above inequality now yields the observation. ◀

Using the last observation we can prove that any approximate local maximum with respect to g obeys Equation (1), and the same holds also for any solution that is almost as good as some approximate local maximum.

▶ **Lemma 8.** *For every $\varepsilon \in (0, 1)$, if D' is an ε-approximate local maximum with respect to g, then any (possibly randomized) set D such that $\mathbb{E}[g(D \mid \varnothing)] \geq (1 - \varepsilon) \cdot g(D' \mid \varnothing)$ obeys Equation (1) in expectation. In particular, this is the case for $D = D'$ since the monotonicity of f implies that g is non-negative.*

Proof. We need to consider two cases. The simpler case is when $g(\mathrm{OPT}_g \mid \varnothing) \geq 2\varepsilon \cdot f(\mathrm{OPT})$, where we recall that OPT is an optimal base with respect to f. Since $x' = x + \varepsilon \cdot \mathbf{1}_D$ by definition, we get in this case

$$\begin{aligned} \mathbb{E}[F(x')] - F(x) &= \mathbb{E}[F(x + \varepsilon \cdot \mathbf{1}_D)] - F(x) = \mathbb{E}[g(D \mid \varnothing)] \geq (1 - \varepsilon) \cdot g(D' \mid \varnothing) \\ &\geq \tfrac{(1-\varepsilon)^2}{2} g(\mathrm{OPT}_g \mid \varnothing) \geq \varepsilon(1 - 2\varepsilon) \cdot f(\mathrm{OPT}) \geq \varepsilon((1 - 3\varepsilon) \cdot f(\mathrm{OPT}) - \mathbb{E}[F(x')]) \ , \end{aligned}$$

where the second inequality holds by Observation 7.

In the rest of the proof we consider the case of $g(\mathrm{OPT}_g \mid \varnothing) \leq 2\varepsilon \cdot f(\mathrm{OPT})$. We note that, in this case,

$$\begin{aligned}\frac{\mathbb{E}[F(x')] - F(x)}{1-\varepsilon} = \frac{\mathbb{E}[F(x+\varepsilon\cdot\mathbf{1}_D)] - F(x)}{1-\varepsilon} &= \frac{\mathbb{E}[g(D \mid \varnothing)]}{1-\varepsilon} \geq g(D' \mid \varnothing)\\ &\geq g(\mathrm{OPT} \mid D') + \sum_{u\in \mathrm{OPT}\cap D'} g(u \mid D'-u) - \varepsilon\cdot g(\mathrm{OPT}_g \mid \varnothing)\\ &\geq g(\mathrm{OPT} \mid D') + \sum_{u\in \mathrm{OPT}\cap D'} g(u \mid D'-u) - 2\varepsilon^2\cdot f(\mathrm{OPT})\ ,\end{aligned}$$

where the second inequality holds since D' is an ε-approximate local maximum (by plugging $B = \mathrm{OPT}$ into the definition of such maxima). Let us now further develop the first two terms on the rightmost side of the last inequality. By the submodularity and monotonicity of f, if we denote $y = x + \varepsilon\cdot\mathbf{1}_{D'}$, then

$$\begin{aligned}&g(\mathrm{OPT} \mid D') + \sum_{u\in \mathrm{OPT}\cap D'} g(u \mid D'-u)\\ &\quad= F(x+\varepsilon\cdot\mathbf{1}_{\mathrm{OPT}\cup D'}) - F(x+\varepsilon\cdot\mathbf{1}_{D'}) + \sum_{u\in \mathrm{OPT}\cap D'} [F(x+\varepsilon\cdot\mathbf{1}_{D'}) - F(x+\varepsilon\cdot\mathbf{1}_{D'-u})]\\ &\quad\geq F(y+\varepsilon\cdot\mathbf{1}_{\mathrm{OPT}\setminus D'}) - F(y) + \sum_{u\in \mathrm{OPT}\cap D'} [F((y+\varepsilon\cdot\mathbf{1}_{\{u\}})\wedge\mathbf{1}_{\mathcal{N}}) - F(y)]\\ &\quad\geq F((y+\varepsilon\cdot\mathbf{1}_{\mathrm{OPT}})\wedge\mathbf{1}_{\mathcal{N}}) - F(y)\ .\end{aligned}$$

Combining the last two inequalities yields

$$\begin{aligned}\mathbb{E}[F(x')] - F(x) &\geq (1-\varepsilon)[F((y+\varepsilon\cdot\mathbf{1}_{\mathrm{OPT}})\wedge\mathbf{1}_{\mathcal{N}}) - F(y)] - 2\varepsilon^2\cdot f(\mathrm{OPT})\\ &\geq (1-\varepsilon)[F(y+\varepsilon((\mathbf{1}_{\mathcal{N}}-y)\wedge\mathbf{1}_{\mathrm{OPT}})) - F(y)] - 2\varepsilon^2\cdot f(\mathrm{OPT})\\ &\geq \varepsilon(1-\varepsilon)[F(y\vee\mathbf{1}_{\mathrm{OPT}}) - F(y)] - 2\varepsilon^2\cdot f(\mathrm{OPT})\\ &\geq \varepsilon((1-\varepsilon)f(\mathrm{OPT}) - \mathbb{E}[F(x')]) - 2\varepsilon^2\cdot f(\mathrm{OPT})\\ &= \varepsilon\cdot((1-3\varepsilon)f(\mathrm{OPT}) - \mathbb{E}[F(x')])\ ,\end{aligned}$$

where the second inequality holds by the monotonicity of f, the third inequality holds because the submodularity of f guarantees that F is concave along non-negative directions (such as $(\mathbf{1}_{\mathcal{N}} - y)\wedge\mathbf{1}_{\mathrm{OPT}}$) and the last inequality holds by the motonicity of f and the observation that

$$F(y) = g(D') = g(\varnothing) + g(D' \mid \varnothing) \leq g(\varnothing) + \frac{\mathbb{E}[g(D \mid \varnothing)]}{1-\varepsilon} \leq \frac{\mathbb{E}[g(D)]}{1-\varepsilon} = \frac{\mathbb{E}[F(x')]}{1-\varepsilon}\ . \qquad \blacktriangleleft$$

In Section 5 we describe a semi-streaming algorithm that can be used to find an ε-approximate local maximum of a non-negative monotone submodular function. By applying this algorithms to g, we get (via Lemma 8) an algorithm having all the properties assumed by Proposition 6; which proves Theorem 2. In Section 7 we attempt to use the same approach to get a result for random order streams. However, in this setting we are not able to guarantee an ε-approximate local maximum. Instead, we design an algorithm whose output has in expectation a value that is almost as good as the value of the worst approximate local maximum. This leads to a proof of Theorem 3.

5 Approximate Local Maximum for Adversarial Streams

In this section we prove following proposition, which guarantees the existence of a semi-streaming multi-pass algorithm for finding an ε-approximate local maximum in adversarial streams, i.e., when the order of the elements in the input stream is arbitrary. We note that this section highly depends on Section 4, and should not be read before that section.

▶ **Proposition 9.** *For every constant $\varepsilon > 0$, there is a multi-pass semi-streaming algorithm that given an instance of* `MSMMatroid` *with a matroid of rank k stores $O(k)$ elements, makes $O(\varepsilon^{-2})$ many passes, and outputs an ε-approximate local maximum.*

By Lemma 8 and Proposition 6, the last proposition implies Theorem 2. Therefore, we concentrate in this section on proving Proposition 9. The first data stream algorithm for `MSMMatroid` was described by Chakrabarti and Kale [6]. The first step towards proving Proposition 9 is a re-analysis of a variant of this algorithm that was described by Huang, Thiery and Ward [18] (based on ideas of Chekuri et al. [8]). The following proposition summarizes the properties of this variant that we prove in this re-analysis. Due to space constraints, the proof of this proposition is deferred to the full version.

▶ **Proposition 10.** *There exists a single-pass semi-streaming algorithm that given a base S_0 of M and value $c > 1$ outputs a base S_n that obeys $(c-1) \cdot f(S_n \mid \varnothing) + \frac{3c-2}{c-1}[f(S_n) - f(S_0)] \geq f(B \mid S_0 \setminus B) - f(S_0 \mid \varnothing) \geq f(B \mid S_0) + \sum_{u \in B \cap S_0} f(u \mid S_0 - u) - f(S_0 \mid \varnothing)$ for every base B of M. Furthermore, this algorithm stores $O(k)$ elements at any point during its execution.*

Below we refer to the algorithm whose existence is guaranteed by Proposition 10 as `SinglePass`. Next, we would like to show that `SinglePass` can be used to get an ε-approximate local maximum. The algorithm we use to do that is given as Algorithm 2, and it gets $\varepsilon \in (0, 1)$ as a parameter.

Algorithm 2 Multiple Local Search Passes (ε).

1: Find a base T_0 of M using a single pass (by simply initializing T_0 to be the empty set, and then adding to it any elements that arrives and can be added to T_0 without violating independence in M).
2: Let T_1 be the output of `SinglePass` when given $S_0 = T_0$ and $c = 2$.
3: **for** $i = 2$ **to** $2 + \lceil 40\varepsilon^{-2} \rceil$ **do**
4: Let T_i be the output of `SinglePass` when given $S_0 = T_{i-1}$ and $c = 1 + \varepsilon/2$.
5: **if** $f(T_i) - f(T_{i-1}) \leq \varepsilon^2/10 \cdot f(T_1 \mid \varnothing)$ **then**
6: **return** T_{i-1}.
7: Indicate failure if the execution of the algorithm has arrived to this point.

Intuitively, Algorithm 2 works by employing the fact that every execution of `SinglePass` increases the value of its input base T_{i-1} significantly, unless this input base is close to being a local maximum, and therefore, if the execution produces a base T_i which is not much better than T_{i-1}, then we know that T_{i-1} is an ε-approximate local maximum. The following lemma proves this formally.

▶ **Lemma 11.** *If Algorithm 2 does not indicate a failure, then its output set T obeys $f(B \mid T) + \sum_{u \in B \cap T} f(u \mid T - u) - f(T \mid \varnothing) < \varepsilon \cdot f(\mathrm{OPT} \mid \varnothing)$ for every base B of $\mathcal{M}$. Note that the last inequality implies that T is an ε-approximate local maximum with result to f.*

Proof. Since T_1 is a base of M, $f(T_1 \mid \varnothing) = f(T_1) - f(\varnothing) \leq f(\mathrm{OPT}) - f(\varnothing) = f(\mathrm{OPT} \mid \varnothing)$. This implies that when Algorithm 2 returns a set T_{i-1}, then

$$f(T_i) - f(T_{i-1}) \leq (\varepsilon^2/10) \cdot f(\mathrm{OPT} \mid \varnothing) \ .$$

Plugging this inequality and the fact that $f(T_i \mid \varnothing) \leq f(\mathrm{OPT} \mid \varnothing)$ (because T_i is a base of M) into the guarantee of Proposition 10 for the execution of `SinglePass` that has created T_i yields

$$\begin{aligned}\varepsilon \cdot f(\mathrm{OPT} \mid \varnothing) &\geq (\varepsilon/2) \cdot f(\mathrm{OPT} \mid \varnothing) + \varepsilon(3\varepsilon/2+1)/5 \cdot f(\mathrm{OPT} \mid \varnothing) \\ &\geq (\varepsilon/2) \cdot f(T_i \mid \varnothing) + \tfrac{3\varepsilon/2+1}{\varepsilon/2} \cdot [f(T_i) - f(T_{i-1})] \\ &\geq f(B \mid T_{i-1}) + \sum_{u \in B \cap T_{i-1}} f(u \mid T_{i-1} - u) - f(T_{i-1} \mid \varnothing) \ . \end{aligned}$$ ◀

One could imagine that it is possible for the value of the solution maintained by Algorithm 2 to increase significantly following every iteration of the loop starting on Line 3, which will result in the algorithm indicating failure rather than ever returning a solution. However, it turns out that this cannot happen because the value of the solution of Algorithm 2 cannot exceed $f(\mathrm{OPT})$, which implies a bound on the number of times this value can be increased significantly. This idea is formalized by the next two claims.

▶ **Observation 12.** $f(T_1 \mid \varnothing) \geq \frac{1}{5} f(\mathrm{OPT} \mid \varnothing)$.

Proof. If we set $B = \mathrm{OPT}$, then by applying Proposition 10 to the execution of `SinglePass` on Line 2 of Algorithm 2, we get

$$\begin{aligned} f(T_1 \mid \varnothing) + 4[f(T_1) - f(T_0)] &\geq f(\mathrm{OPT} \mid T_0) + \sum_{u \in \mathrm{OPT} \cap T_0} f(u \mid T_0 - u) - f(T_0 \mid \varnothing) \\ &\geq f(\mathrm{OPT} \mid T_0) - f(T_0 \mid \varnothing) \ , \end{aligned}$$

where the second inequality follows from the monotonicity of f. Since the leftmost side the last inequality is equal to $5f(T_1 \mid \varnothing) - 4f(T_0 \mid \varnothing)$, this inequality implies

$$\begin{aligned} 5f(T_1 \mid \varnothing) &\geq f(\mathrm{OPT} \mid T_0) + 3f(T_0 \mid \varnothing) = f(\mathrm{OPT} \cup T_0) + 2f(T_0) - 3f(\varnothing) \\ &\geq f(\mathrm{OPT}) - f(\varnothing) = f(\mathrm{OPT} \mid \varnothing) \ , \end{aligned}$$

where the second inequality follows again from the monotonicity of f. The observation now follows by dividing the last inequality by 5. ◀

▶ **Lemma 13.** *Algorithm 2 never indicates failure.*

Proof. If $f(\mathrm{OPT} \mid \varnothing) = 0$, then the value of every base of M according to f is $f(\varnothing)$, which guarantees that Algorithm 2 returns T_1 during the first iteration of the loop starting on its Algorithm 2. Therefore, we assume below that $f(\mathrm{OPT} \mid \varnothing) > 0$. Furthermore, assume towards a contradiction that Algorithm 2 indicates failure. By Observation 12, this assumption implies that the value of the solution maintained by Algorithm 2 increases by at least $(\varepsilon^2/10) \cdot f(T_1 \mid \varnothing) \geq \frac{\varepsilon^2}{50} f(\mathrm{OPT} \mid \varnothing)$ after every iteration of the loop starting on Line 3. Therefore, after all the $1 + \lceil 40\varepsilon^{-2} \rceil$ iterations of this loop, the value of the solution of Algorithm 2 is at least

$$f(T_1) + (1 + \lceil 40\varepsilon^{-2} \rceil) \cdot \tfrac{\varepsilon^2}{50} f(\mathrm{OPT} \mid \varnothing) > f(\varnothing) + \tfrac{1}{5} f(\mathrm{OPT} \mid \varnothing) + \tfrac{4}{5} f(\mathrm{OPT} \mid \varnothing) = f(\mathrm{OPT}) \ ,$$

which is a contradiction since the solution of Algorithm 2 is always kept as a base of M. ◀

We now observe that Algorithm 2 has all the properties guaranteed by Proposition 9. In particular, we note that Algorithm 2 can be implemented as a semi-streaming algorithm storing $O(k)$ elements because it needs to store at most two solutions at any given time in addition to the elements and space required by `SinglePass`.

6 Discussion of a Lower Bound by McGregor and Vu [22]

McGregor and Vu [22] showed that any data stream algorithm for the Maximum k-Coverage Problem (which is a special case of `MSMMatroid` in which f is a coverage function and M is a uniform matroid of rank k) that makes a constant number of passes must use $\Omega(m/k^2)$ memory to achieve $(1+\varepsilon)\cdot(1-(1-1/k)^k)$-approximation with probability at least 0.99, where m is the number of sets in the input, and it is assumed that these sets are defined over a ground set of size $n = \Omega(\varepsilon^{-2}k\log m)$. Understanding the implications of this lower bound for `MSMMatroid` requires us to handle two questions.

- The first question is how the lower bound changes as a function of the number of passes. It turns out that when the number of passes is not dropped from the asymptotic expressions because it is considered to be a constant, the lower bound of McGregor and Vu [22] on the space complexity becomes $\Omega(m/(pk^2))$, where p is the number of passes done by the algorithm.
- The second question is about the modifications that have to be done to the lower bound when it is transferred from the Maximum k-Coverage Problem to `MSMMatroid`. Such modifications might be necessary because of input representation issues. However, as it turns out, the proof of the lower bound given by [22] can be applied to `MSMMatroid` directly, yielding the same lower bound (except for the need to replace m with the corresponding value in `MSMMatroid`, namely, $|\mathcal{N}|$). Furthermore, McGregor and Vu [22] had to use a very large ground set so that random sets will behave as one expects with high probability. When the objective function is a general submodular function, rather than a coverage function, it can be chosen to display the above-mentioned behavior of random sets, and therefore, ε can be set to 0.

We summarize the above discussion in the following corollary.

▶ **Corollary 14** (Corollary of McGregor and Vu [22]). *For any $k \geq 1$, any p-pass data stream algorithm for `MSMMatroid` that achieves an approximation guarantee of $1-(1-1/k)^k \leq 1-1/e+1/k$ with probability at least 0.99 must use $\Omega(|\mathcal{N}|/(pk^2))$ memory, and this is the case even when the matroid M is restricted to be a uniform matroid of rank k.*

7 Approximate Local Maximum for Random Streams

In this section we study `MSMMatroid` in random order streams by building on ideas from the analysis of Liu et al. [21] for optimizing f under a cardinality constraint. We begin with simplifying and reanalyzing the single-pass local search algorithm of Shadravan [29]. By applying this algorithm multiple times (in multiple passes), we are able to prove the following proposition. Proposition 15 implies Theorem 3 by Lemma 8 and Proposition 6.

▶ **Proposition 15.** *For every constant $\varepsilon > 0$, there is a multi-pass semi-streaming algorithm that given an instance of `MSMMatroid` with a matroid of rank k stores $O(k/\varepsilon)$ elements and makes $O(\varepsilon^{-1}\log\varepsilon^{-1})$ many passes. Assuming the order of the elements in the input stream is chosen uniformly at random in each pass, this algorithm outputs a solution D such that $\mathbb{E}[f(D \mid \varnothing)] \geq (1-\varepsilon)\cdot f(D' \mid \varnothing)$, where D' is the ε-approximate local maximum whose value with respect to f is the smallest.*

In the full versionwe show that our single-pass algorithm can naturally be extented to p-matchoids. Then, we create a multi-pass algorithm based on this extended single-pass algorithm, which proves Theorem 4.

Intuitively, a local search algorithm should make a swap in its solution whenever this is beneficial. In the adversarial setting, one has to make a swap only when it is beneficial enough to avoid making too many negligible swaps. However, in the random order setting there is a better solution for this problem. Specifically, we (randomly) partition the input stream into *windows* (αk contiguous chunks of the stream with expected size $n/(\alpha k)$ each for some parameter $\alpha > 1$), and then make the best swap within each window. Formally, our random partition is generated according to Algorithm 3.

Algorithm 3 Partitioning of the input stream (α).

Draw $|\mathcal{N}|$ integers uniformly and independently from $1, 2, \ldots, \alpha k$.
for $i = 1$ to αk **do**
    Let $n_i \leftarrow$ # of integers equal to i.
    Let $t_i \leftarrow \sum_{j=1}^{i-1} n_i$.
    Let $w_i \leftarrow$ elements $t_i + 1$ to $t_i + n_i$ in $\mathcal{N}$.
return $\{w_1, w_2, \ldots, w_{\alpha k}\}$.

Our full single pass algorithm, which uses the partition defined by Algorithm 3, is given as Algorithm 4. The input for the algorithm includes the parameter α and some base L_0 of the matroid $\mathcal{M}$. Additionally, during the execution of the algorithm, the set L_i represents the current solution, and H is the set of all elements that were added to this solution at some point. When processing window w_i, Algorithm 4 constructs a set C_i of elements that can potentially be swapped into the solution. This set contains all the elements of the window plus some historical elements (the set R_i). The idea of using a set H to store previously valuable elements is inspired from [1, 21]. Reintroducing previously seen elements allows us to give any element not in the solution a chance of being introduced into the solution in the future, which helps us avoid issues that result from the dependence that exists between the current solution and the set of elements in the current window.

Algorithm 4 MatroidStream(α, L_0).

Partition $\mathcal{N}$ into windows $w_1, w_2, \ldots, w_{\alpha k}$.
Let $H \leftarrow \varnothing$.
for $i = 1$ to αk **do**
    Let R_i be a random subset of H including every $u \in H$ with probability $\frac{1}{\alpha k}$, independently.
    Let $C_i \leftarrow w_i \cup R_i$
    Let $u^\star$ and $u_r^\star$ be elements maximizing $f(L_i - u_r^\star + u^\star)$ subject to the constraints: $u^\star \in C_i$, $u_r^\star \in L_i$ and $L_i - u_r^\star + u^\star \in \mathcal{I}$.
    if $f(L_i) < f(L_i - u_r^\star + u^\star)$ **then**
        Update $H \leftarrow H + u^\star$.
        Let $L_{i+1} \leftarrow L_i - u_r^\star + u^\star$.
return $L_{\alpha k}$.

Note that the number of elements stored by Algorithm 4 is $O(\alpha k)$, as this number is dominated by the size of the set H. For the same reason Algorithm 4 is a semi-streaming algorithm whenever α is constant.

▶ **Definition 16.** *Let H_i denote the state of the set H maintained by Algorithm 4 immediately after processing window i. We define $\mathcal{H}_i$ to be the set of all pairs (u, j) such that element $u \in H_i$ was added to the solution while window j was processed (i.e., $u \in H_i \cap w_j$). For convenience, sometimes we treat $\mathcal{H}_i$ as a set of elements, and say that $u \in \mathcal{H}_i$ if $u \in H_i$.*

One can observe that $\mathcal{H}_i$ encodes all the changes that the algorithm made to its state while processing the first i windows because the element removed from the solution when u is added is deterministic. Additionally, we note that different random permutations of the input and random coins in Line 4 of Algorithm 4 may produce the same history, and we average over all of them in the analysis.

The next lemma is from [21]. It captures the intuition that any element not selected by the algorithm still appears uniformly distributed in future windows, and bounds the probability with which this happens. The proof of this lemma can be found in the full version.

▶ **Lemma 17.** *Fix a history $\mathcal{H}_{i-1}$ for some $i \in [\alpha k]$. For any element $u \in \mathcal{N} \setminus \mathcal{H}_{i-1}$, and any $i \leq j \leq \alpha k$, we have $Pr[u \in w_j \mid \mathcal{H}_{i-1}] \geq 1/(\alpha k)$.*

Let B an arbitrary base of $\mathcal{M}$ (one can think of B as an optimal solution because the monotonicity of f guarantees that some optimal solution is a base, but we sometimes need to consider other bases as B). We now define "active" windows, which are windows for which we can show a definite gain in our solution. Specifically, we show below that in any active window the value of the current solution L increases roughly by $\frac{1}{k}(f(B) - 2f(L))$ in expectation, which yields an approximation ratio of $\frac{1}{2}(1 - 1/e^2)$ after αk windows have been processed in one pass because we expect roughly one in every α windows to be active.

▶ **Definition 18.** *For window w_i, let p_u^i be the probability that $u \in w_i$ conditioned $\mathcal{H}_{i-1}$. Define the active set A_i of w_i to be the union of R_i and a set obtained by sampling each element $u \in w_i$ with probability $1/(\alpha k p_u^i)$. We call w_i an **active window** if $|B \cap A_i| \geq 1$.*

Note that the construction of active sets in Definition 18 is valid as Lemma 17 guarantees that $1/(\alpha k p_e^i)$ is a valid probability (i.e., it is not more than 1). More importantly, the active set A_i includes every element of $\mathcal{N}$ with probability exactly $1/(\alpha k)$, even conditioned on the history $\mathcal{H}_{i-1}$; which implies that, since each element appears in A_i independently, a window is active with probability $(1 - 1/(\alpha k))^k \geq 1 - e^{-1/\alpha} \approx 1/\alpha$ conditioned on any such history. Let $\mathcal{A}_i$ denote the event that window i is active. The following lemma lower bounds the increase in the value of the solution of Algorithm 4 in an active window.

▶ **Lemma 19.** *For every integer $0 \leq i < \alpha k$,*

$$\begin{aligned}\mathbb{E}[f(L_{i+1}) - f(L_i) \mid \mathcal{H}_i, \mathcal{A}_{i+1}] &\geq \tfrac{1}{k}\mathbb{E}\Big[f(B \mid L_i) + \sum\nolimits_{u \in B \cap L_i} f(u \mid L_i - u) - f(L_i \mid \varnothing) \;\Big|\; \mathcal{H}_i\Big] \\ &\geq \tfrac{1}{k}\mathbb{E}[f(B) - 2f(L_i) \mid \mathcal{H}_i] \ .\end{aligned}$$

Moreover, the above inequality holds even when B is a random base as long as it is deterministic when conditioned on any given $\mathcal{H}_i$.

Lemma 19 completes the statement of the properties of Algorithm 4 that we need to prove our results. Specifically, the first inequality of the lemma is used to prove that multiple "concatenated" executions of Algorithm 4 output, in expectation, a solution which is almost as good as some ε-approximation local maximum (i.e., Proposition 15), and the rightmost side of the lemma is used to prove Theorem 4. Due to space constraints, the proof of Lemma 19, and the use of this lemma to prove Proposition 15 are deferred to the full version.

Abstract

The problem of packing of equal disks (or circles) into a rectangle is a fundamental geometric problem. (By a packing here we mean an arrangement of disks in a rectangle without overlapping.) We consider the following algorithmic generalization of the equal disk packing problem. In this problem, for a given packing of equal disks into a rectangle, the question is whether by changing positions of a small number of disks, we can allocate space for packing more disks. More formally, in the repacking problem, for a given set of n equal disks packed into a rectangle and integers k and h, we ask whether it is possible by changing positions of at most h disks to pack $n + k$ disks. Thus the problem of packing equal disks is the special case of our problem with $n = h = 0$.

While the computational complexity of packing equal disks into a rectangle remains open, we prove that the repacking problem is NP-hard already for $h = 0$. Our main algorithmic contribution is an algorithm that solves the repacking problem in time $(h + k)^{\mathcal{O}(h+k)} \cdot |I|^{\mathcal{O}(1)}$, where $|I|$ is the input size. That is, the problem is fixed-parameter tractable parameterized by k and h.

1 Introduction

Packing of equal circles inside a rectangle or a square is one of the oldest packing problems. In addition to many common-life applications, like packing bottles or cans in a box [16], packings of circles have a variety of industrial applications, including circular cutting problems, communication networks, facility location, and dashboard layout. We refer to the survey of Castillo, Kampas, and Pintér [6] for an interesting overview of industrial applications of circle packings.

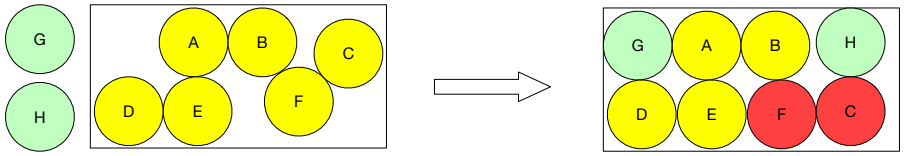

Figure 1 For a packing $\mathcal{P}$ of disks A–F, integers $h = 2$, and $k = 2$, the repacking $\mathcal{P}^*$ of $\mathcal{P}$ is obtained by relocating disks C and F, and by adding disks G and H.

The mathematical study of packing equal circles can be traced to Kepler [20]. Packing of circles also poses exciting mathematical and algorithmic challenges. After the significant efforts spent on packing for several decades [26, 29, 22, 24, 21, 28, 25, 12], optimal packings of equal circles inside a square are known only for instances of up to tens of circles [9, 27]. The computational complexity of packing of equal circles (NP-hardness or membership in NP) remains elusive. For packing circles with different radii, Demaine, Fekete, and Lang claimed NP-hardness [11]. See also the work of Abrahamsen, Miltzow, and Seiferth [1] for a generic framework for establishing $\exists\mathbb{R}$-completeness for packing problems.

Our paper establishes several results on computational and parameterized complexity of a natural generalization of packing equal circles inside a rectangle. A remark in the terminology is in order. In the literature on packing, both terms, circles and disks, could be found. While the term circle is much more popular than disk, we decided to use disks for the following reason: In our hardness proof, it is more convenient to operate with open disks. Thus all disks we consider are open and unit (that is of radius one). Let us remind, that a family of disks forms a *packing* if they are pairwise nonintersecting.[1] In our problem, we have a packing of disks in a rectangle, and the question is whether we can allocate some space for more disks by relocating a small amount of disks. More precisely, we consider the following problem. See Figure 1 for an example.

Disk Repacking

Input:	A packing $\mathcal{P}$ of n unit disks inside a rectangle R and two integers $h, k \geq 0$.
Task:	Decide whether there is a packing $\mathcal{P}^*$ of $n + k$ unit disks inside R obtained from $\mathcal{P}$ by adding k new disks and relocating at most h disks of $\mathcal{P}$ to new positions.

Thus when $n = 0$, that is, initially there are no disks inside the rectangle, this is the classical problem of packing equal circles inside a rectangle.

Related Work on Geometric Packing. Packing problems have received significant attention from the viewpoint of approximation algorithms. For the sake of illustration, let us mention a few examples. In 2D Geometric Bin Packing, which is a variant of classical Bin Packing, the goal is to pack a given collection of rectangles into the minimum number of unit square bins. Typically, it is required that the rectangles be packed in an axis-parallel manner. There has been a long series of results on this problem, culminating in the currently known best approximation given by Bansal and Khan [4]. A related problem is that of 2D Strip

[1] In the literature, it is often required for geometric packings that a packing should be maximal. In particular, for disk packing, every disk should touch either the bounding rectangle or another disk. However, in our problem, the task is to add a specified number of new disks to a given family and this makes the maximality condition in our case very artificial.

Packing problem, where the task is to pack a given set of rectangles into an infinite strip of the given width, so as to minimize the height of packing. This problem has been studied from the context of approximation [17, 19] as well as parameterized [2] algorithms. Finally, we mention the Geometric Knapsack problem, which is also closely related to Geometric Bin Packing. In Geometric Knapsack, we are given a collection of rectangles, where each rectangle has an associated profit. The goal is to pack a subset of the given rectangles (without rotation) in an axis-aligned square knapsack, so as to maximize the total profit of the packed rectangles. Currently, the best approximation is given by Galvez et al. [14]. A detailed survey of the literature on the results of these problems is beyond the scope of this work – we direct an interested reader to the cited works and references therein and the survey paper of Christensen et al. [7]. However, we would like to highlight an important difficulty in Disk Repacking– which is the focus of this work – as compared to the aforementioned geometric packing problems, namely, that packing disks in a rectangle requires the use of intricate geometric arguments as compared to packing rectilinear objects (such as rectangles) in a rectilinear container (such as a unit square, or an infinite strip).

Our Results. We show that Disk Repacking is NP-hard even if the parameter $h = 0$ – we call this special case of problem Disk Appending.

▶ **Theorem 1.** *Disk Appending is* NP*-hard when constrained to the instances* $(R, \mathcal{P}, k)$ *where* $R = [0, a] \times [0, b]$ *for positive integers* a *and* b *and the centers of all disks in* $\mathcal{P}$ *have rational coordinates. Furthermore, the problem remains* NP*-hard when it is only allowed to add new disks to* $\mathcal{P}$ *with rational coordinates of their centers.*

From the positive side, we show that Disk Repacking is FPT when parameterized by k and h. As it is common in Computational Geometry, we assume the *real RAM* computational model, that is, we are working with real numbers and assume that basic operations can be executed in unit time. We use $|I|$ to denote the input size.

▶ **Theorem 2.** *The Disk Repacking problem is* FPT *when parameterized by* $k + h$*. Specifically, it is solvable in time* $(h + k)^{\mathcal{O}(h+k)} \cdot |I|^{\mathcal{O}(1)}$.

Theorem 2 also appears to be handy for approximating the maximum number of disks that can be added to a packing. In the optimization variant of Disk Repacking, called Max Disk Repacking, we are given a packing $\mathcal{P}$ of n disks in a rectangle R and an integer h, and the task is to maximize the number of new disks that can be added to the packing if we are allowed to relocate at most h disks of $\mathcal{P}$. By combining Theorem 2 with the approach of Hochbaum and Maass [18], we prove that the optimization variant of Disk Repacking admits the parameterized analog of EPTAS for the parameterization by h. More precisely, we prove the following theorem.

▶ **Theorem 3.** *For any* $0 < \varepsilon < 1$*, there exists an algorithm that, given an instance* $(\mathcal{P}, R, h)$ *of Max Disk Repacking, returns a packing* $\mathcal{P}^*$ *into* R *with at least* $n + (1 - \varepsilon) \cdot \mathsf{OPT}_h$ *disks in time* $\left(\frac{h+1}{\varepsilon}\right)^{\mathcal{O}(h/\varepsilon + 1/\varepsilon^2)} \cdot |I|^{\mathcal{O}(1)}$*, where* OPT_h *is the maximum number of disks that can be added to the input packing if we can relocate at most* h *disks.*

2 Preliminaries

Disks and rectangles. For two points A and B on the plane, we use AB to denote the line segment with endpoints in A and B. The *distance* between $A = (x_1, y_1)$ and $B = (x_2, y_2)$ or the *length* of AB, is $|AB| = \|A - B\|_2 = \sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2}$. The *(open unit) disk*

with a *center* $C = (c_1, c_2)$ on the plane is the set of points (x, y) satisfying the inequality $(x - c_1)^2 + (y - c_2)^2 < 1$. Whenever we write "disk" we mean an open unit disk. Throughout the paper, we assume that considered input rectangles $R = [0, a] \times [0, b]$ for some $a, b > 0$.

Parameterized Complexity. We refer to the book of Cygan et al. [10] for introduction to the area and undefined notions. A *parameterized problem* is a language $L \subseteq \Sigma^* \times \mathbb{N}$, where Σ^* is a set of strings over a finite alphabet Σ. An input of a parameterized problem is a pair (x, k), where $x \in \Sigma^*$ and $k \in \mathbb{N}$ is a *parameter*. A parameterized problem is *fixed-parameter tractable* (or FPT) if it can be solved in time $f(k) \cdot |x|^{\mathcal{O}(1)}$ for some computable function f.

Systems of Polynomial Inequalities. In our algorithms, we will need to find suitable locations for new disks that need to be added such that the locations are compatible with an existing packing. We will achieve this by solving systems of polynomial inequalities. We refer to the book of Basu, Pollack, and Roy [5] for basic tools. We use the following result.

▶ **Proposition 4** (Theorem 13.13 in [5]). *Let R be a real closed field, and let $\mathcal{P} \subseteq R[X_1, \ldots, X_\ell]$ be a finite set of s polynomials, each of degree at most d, and let*

$$(\exists X_1)(\exists X_2) \ldots (\exists X_\ell) F(X_1, X_2, \ldots, X_\ell)$$

be a sentence, where $F(X_1, \ldots, X_\ell)$ be a quantifier-free boolean formula involving $\mathcal{P}$-atoms of type $P \odot 0$, where $\odot \in \{=, \neq, >, <\}$, and P is a polynomial in $\mathcal{P}$. Then, there exists an algorithm to decide the truth of the sentence with complexity $s^{\ell+1} d^{\mathcal{O}(\ell)}$ in D, where D is the ring generated by the coefficients of the polynomials in $\mathcal{P}$.

Furthermore, a point $(X_1^*, \ldots, X_\ell^*)$ satisfying $F(X_1, \ldots, X_\ell)$ can be computed in the same time by Algorithm 13.2 (sampling algorithm) of [5] (see Theorem 13.11 of [5]). Note that because we are using the real RAM model in our algorithms, the complexity is stated with respect to the natural parameters.

3 Hardness of Disk Appending

In this section, we prove that Disk Appending is NP-hard. Due to space constraints, we only sketch the proof.

▶ **Theorem 1.** *Disk Appending is* NP*-hard when constrained to the instances $(R, \mathcal{P}, k)$ where $R = [0, a] \times [0, b]$ for positive integers a and b and the centers of all disks in $\mathcal{P}$ have rational coordinates. Furthermore, the problem remains* NP*-hard when it is only allowed to add new disks to $\mathcal{P}$ with rational coordinates of their centers.*

Sketch of proof. We reduce from the Independent Set problem. In this problem, for a given graph G and a positive integer k, the task is to decide whether G contains an independent set, that is a set of pairwise nonadjacent vertices, of size at least k. It is well-known that Independent Set is NP-complete on cubic planar graphs [15].

We only outline the main ideas of the reduction. Let G be a graph and assume that ℓ_e are positive integers given for all $e \in E(G)$. Suppose that G' is obtained from G by subdividing each edge e by $2\ell_e$ times. Then it can be shown that G has an independent set of size k if and only if G' has an independent set of size $k + \sum_{e \in E(G)} \ell_e$. We exploit this observation. Given a rectilinear embedding of a cubic planar graph G, for each vertex of G, we create a *node* area formed by surrounding disks. We can place an additional disk in such an area and this encodes the inclusion of the corresponding vertex to an independent set. Then we

join the areas created for vertices by *channels* corresponding to subdivided edges. Similarly to node areas, channels are formed by surrounding disks. Each channel contains an even number of positions where new disks can be placed, and these positions are divided into "odd" and "even" in such a way that we can put disks in either all odd or all even positions but no disks could be placed in adjacent even and odd positions. Thus node areas and channels are used to encode a graph, and then we fill the space around them by *filler* disks that prevent placing any new disk outside node areas and channels. Then placing new disks corresponds to the choice of an independent set in a subdivided graph.

To construct channels, consider four touching disks with centers A, B, C, and D shown in Figure 2 (a). Note that $h = 2 + \sqrt{3}$, $\ell = |AC| = |BC| = 2\sqrt{2 + \sqrt{3}}$, and the angle $\alpha = \pi/12$. Given disks with centers in A, B and C, every disk with its center in the triangle ABC has its center in D. Extending this, we make the following observation about the configuration of disks shown in Figure 2 (b). We call such a configuration of disks a *basic channel*.

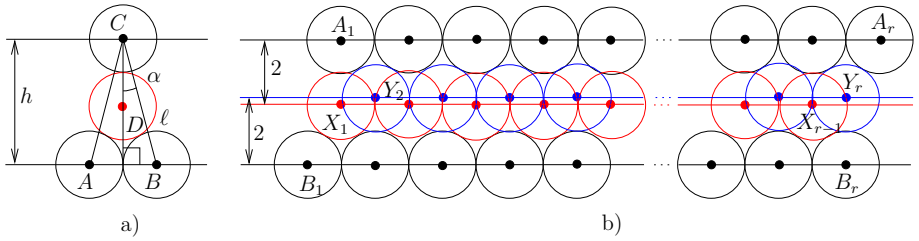

Figure 2 The basic channel; the disks shown in red and blue are not parts of the channel – they show places where new disks can be inserted.

▶ **Observation 5.** *Given disks with centers in $A_1, \ldots, A_r$ and $B_1, \ldots, B_r$ as it is shown in Figure 2 (b), any additional disk with its center properly inside the quadrilateral $A_1B_1B_rA_r$ has its center in one of the points $X_1, \ldots, X_{r-1}$ or $Y_2, \ldots, Y_r$. Furthermore, if a disk with its center in X_i (Y_i, respectively) is placed in the quadrilateral, then no other disk can have its center in Y_i or Y_{i+1} (X_{i-1} or X_i, respectively).*

It can be noted that the construction of basic channels is sufficiently robust to allow us to insert gaps between disks to adjust distances and parities. Furthermore, we can "bend" basic channels.

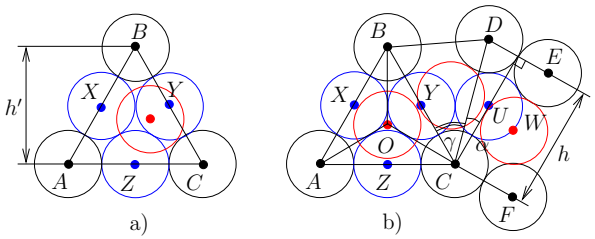

Figure 3 Node area.

For construction of node areas, consider an equilateral triangle ABC with sides of length two as shown in Figure 3 (a), $h' = 2\sqrt{3}$. Suppose that there are disks with centers in A, B and C. Then it is possible to place at most three disks with centers in the triangle ABC, and if exactly three disks are placed, then they have their centers in X, Y and Z and touch each other. Furthermore, if a disk having its center properly inside ABC is placed, then no

other disk with its center inside the triangle can be added. We exploit this property and add a basic channel as it is shown in Figure 3 (b). The point O is the center of ABC, that is, $|OA| = |OB| = |OC|$. Recall that $h = 2 + \sqrt{3}$ and $\alpha = \pi/12$. We set $\gamma = \pi/3 - \pi/12 = \pi/4$. This gives us the configuration of disks with the following properties summarized in the next observation.

▶ **Observation 6.** *Given disks with centers in A, B, C, D, E and F as it is shown in Figure 3 (b), the following is fulfilled:*

- **(i)** *at most one disk with its center in BCD can be added,*
- **(ii)** *if there is a disk with its center either in Y or U, then no other disk can have its center properly in BCD,*
- **(iii)** *if there are disks with their centers in O and W, then a disk with its center in BCD can be added,*
- **(iv)** *if there is a disk having its center properly inside ABC, then no other disk with its center inside ABC can be added.*

The node areas are connected by channels attached as it is shown in Figure 3 (b).

Note that in the described reduction, we used disks with algebraic coordinates of their centers. In particular, the crucial parameters $h = 2 + \sqrt{3}$ and $h' = 3\sqrt{3}$ are algebraic. However, we can observe that our construction is robust to allow rounding of coordinates. More precisely, we can choose a sufficiently small fixed constant $\delta > 0$ and use rational parameters $\hat{h}$ and $\hat{h}'$ such that $2 + \sqrt{3} = h < \hat{h} \leq h + \delta$ and $2\sqrt{3} = h' < \hat{h}' \leq h' + \delta$ in the construction of the channels (see Figure 2) and the node areas (see Figure 3) instead of h and h', respectively. ◀

4 An FPT algorithm for Disk Repacking

In this section, we prove that Disk Repacking is FPT when parameterized by $k + h$.

▶ **Theorem 2.** *The Disk Repacking problem is* FPT *when parameterized by $k + h$. Specifically, it is solvable in time $(h + k)^{\mathcal{O}(h+k)} \cdot |I|^{\mathcal{O}(1)}$.*

Proof of Theorem 2: Overview. On a high-level, the idea behind the algorithm is as follows. We first perform a greedy procedure to ensure that all "free" areas to place disks can be intersected by a set $\mathcal{H}$ of at most k disks. Afterwards, we make use of a coloring function of $\mathcal{P}$ with the objective to color all disks in $\mathcal{P}$ that are repacked by a solution (if one exists) blue, and all disks in $\mathcal{P}$ that "closely surround" them by red. We need to ensure that, while relying on the initial greedy procedure, it would suffice to correctly color only $\mathcal{O}(h + k)$ disks. Indeed, this gives rise to the usage of a universal set, which is a "small" family of coloring functions ensured to contain, if there exists a solution, at least one coloring function that correctly colors all $\mathcal{O}(h + k)$ disks we care about.

Considering some coloring function (which expected to be "compatible" with some solution), we identify "slots" and, more generally, "containers" in its coloring pattern. In simple words, a slot is just a disk in R that does not intersect any red disk (from $\mathcal{P}$), and a container is a maximally connected region consisting of slots. We are able to prove that, if the coloring is compatible with some solution, then, for any container, either all or none of the disks in $\mathcal{P}$ that are contained in the container are repacked. This gives rise to a reduction from the problem of finding a solution compatible with a given coloring to the Knapsack problem (more precisely, an extended version of it), where each container corresponds to an item whose weight is the number of disks in $\mathcal{P}$ that it contains, and whose value is the number of disks that can be packed within it.

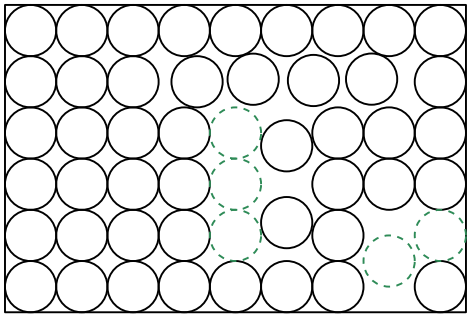

Figure 4 An instance $(\mathcal{P}, R, h = 2, k = 7)$ of Disk Repacking. The disks in $\mathcal{P}$ are colored black. The disks in some hole cover $\mathcal{H}$ are colored green (using dashed lines).

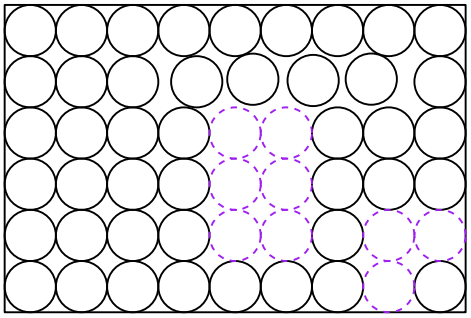

Figure 5 A solution $\mathcal{P}^*$ for the instance on the left. The disks in $\mathcal{P}^* \setminus \mathcal{P}$ are drawn in purple (using dashed lines).The set of $(\mathcal{H}, \mathcal{P}^*)$-critical disks is the set of green disks from the figure on the left and the purple disks from the figure on the right.

To execute the reduction described above, we need to be able to compute the value of each container. For this purpose, we first prove that a container can be "described" by only $\mathcal{O}(h+k)$ many disks from $\mathcal{P} \cup \mathcal{H}$; more precisely, we show that each container is the union of disks contained in R that intersect at least one out of $\mathcal{O}(h+k)$ disks in $\mathcal{P} \cup \mathcal{H}$, from which we subtract the union of some other $\mathcal{O}(h+k)$ disks from $\mathcal{P}$. Having this at hand, to compute the value of a container, we first "guess", for each disk packed by a (hypothetical) optimal packing of disks in the container, a disk from $\mathcal{P} \cup \mathcal{H}$ contained in the container (making use of its description) with whom it intersects. After that, we seek the corresponding optimal packing by making use of a system of polynomial equations (inequalities) of degree 2, $\mathcal{O}(h+k)$ variables, and $\mathcal{O}((h+k)^2)$ equations.

Proof of Theorem 2: Free areas. To execute the plan above, we start with the task of handling the "free" areas. For this, we have the following definition and immediate observation.

▶ **Definition 7** (Holes and Hole Cover). *Let $(\mathcal{P}, R, h, k)$ be an instance of Disk Repacking. The* set of holes*, denoted by* Holes*, is the set of all disks contained in R that are disjoint from all disks in $\mathcal{P}$. A set $\mathcal{H}$ of disks contained in R such that the set of holes of $(\mathcal{P} \cup \mathcal{H}, R, h, k)$ is empty is called a* hole cover*.*

▶ **Observation 8.** *Let $(\mathcal{P}, R, h, k)$ be an instance of Disk Repacking. Let $\mathcal{H}$ be a hole cover. Then, every disk contained in R intersects at least one disk in $\mathcal{P} \cup \mathcal{H}$.*

Next, we present a definition and a lemma that will allow us to assume that we have a hole cover of small size at hand.

▶ **Definition 9** (Dense instance). *Let $(\mathcal{P}, R, h, k)$ be an instance of Disk Repacking. We say that the instance is* dense *if it has a hole cover of size smaller than k.*

▶ **Lemma 10.** *There exists a polynomial-time algorithm that, given an instance $(\mathcal{P}, R, h, k)$ of Disk Repacking, either correctly determines that $(\mathcal{P}, R, h, k)$ is a yes-instance or correctly determines that $(\mathcal{P}, R, h, k)$ is dense and returns a hole cover of size smaller than k.*

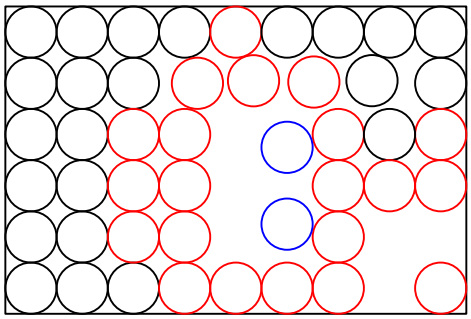

Figure 6 With respect to the instance and solution described in Figures 4 and 5, the disks $(\mathcal{H}, \mathcal{P}^*)$-forced to be blue are colored blue, and the disks $(\mathcal{H}, \mathcal{P}^*)$-forced to be red are colored red. Note that each of the disks colored black can be colored either blue or red by an $(\mathcal{H}, \mathcal{P}^*)$-compatible coloring.

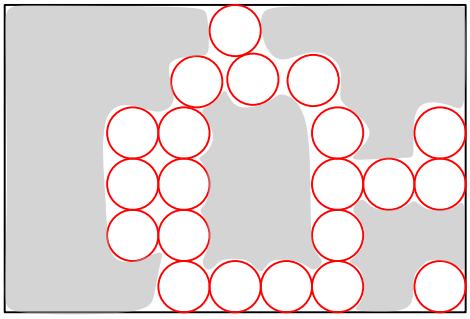

Figure 7 Consider an $(\mathcal{H}, \mathcal{P}^*)$-compatible coloring that colors blue all of the disks colored black in Figure 6. Then, we have four c-Containers, which roughly correspond to the areas colored by grey.

Proof. We perform a simple greedy procedure. Initially, $\mathcal{H} = \emptyset$. Then, as long as there exists a disk D contained in R that is disjoint from all disks in $\mathcal{P} \cup \mathcal{H}$, we add such a disk D to $\mathcal{H}$. The test for the existence of such a D can be performed by using a system of polynomial equations of degree 2 with two variables denoting the x- and y-coordinates of the center of D. For each disk in $\mathcal{P} \cup \mathcal{H}$, we have an equation enforcing that the distance between its center and the center of D is at least 2, and additionally we have two linear equations to enforce that D is contained in R. By Proposition 4, testing whether this system has a solution (which corresponds to the sought disk D) can be done is polynomial time.[2] Once the process terminates, the algorithm checks whether $|\mathcal{H}| \geq k$. If the answer is positive, then adding $\mathcal{H}$ (or, more precisely, any subset of size k of it) to $\mathcal{P}$ is a solution, and so the algorithm answers yes, and otherwise the instance is dense and the algorithm returns $\mathcal{H}$ (which witnesses that). ◀

In the two following definitions, we identify the coloring functions that will be useful.

▶ **Definition 11** ($(\mathcal{H}, \mathcal{P}^*)$-Critical Disks). *Let $(\mathcal{P}, R, h, k)$ be a yes-instance of* Disk Repacking. *Let $\mathcal{H}$ be a hole cover. Let $\mathcal{P}^*$ be a solution to $(\mathcal{P}, R, h, k)$. The set of* $(\mathcal{H}, \mathcal{P}^*)$-critical disks, *denoted by* $\mathsf{Crit}_{\mathcal{H},\mathcal{P}^*}$, *is* $(\mathcal{P}^* \setminus \mathcal{P}) \cup \mathcal{H}$.

▶ **Definition 12** ($(\mathcal{H}, \mathcal{P}^*)$-Compatible Colorings). *Let $(\mathcal{P}, R, h, k)$ be a yes-instance of* Disk Repacking. *Let $\mathcal{H}$ be a hole cover. Let $\mathcal{P}^*$ be a solution to $(\mathcal{P}, R, h, k)$. Let $c : \mathcal{P} \to \{\mathsf{blue}, \mathsf{red}\}$. We say that c is* $(\mathcal{H}, \mathcal{P}^*)$-compatible *if:*

1. *For every $D \in \mathcal{P} \setminus \mathcal{P}^*$, we have that $c(D) = \mathsf{blue}$. We say that the disks in $\mathcal{P} \setminus \mathcal{P}^*$ are* $(\mathcal{H}, \mathcal{P}^*)$-forced to be blue.
2. *For every $D \in \mathcal{P} \cap \mathcal{P}^*$ whose center is at distance at most 4 from the center of some disk in $\mathsf{Crit}_{\mathcal{H},\mathcal{P}^*}$, we have that $c(D) = \mathsf{red}$. We say that the disks in $\mathcal{P} \cap \mathcal{P}^*$ whose center is at distance at most 4 from the center of some disk in $\mathsf{Crit}_{\mathcal{H},\mathcal{P}^*}$ are* $(\mathcal{H}, \mathcal{P}^*)$-forced to be red.

We proceed to show that the number of disks in $\mathcal{P}$ that should be colored "correctly" is only $\mathcal{O}(h + k)$. This is done using the following easy observation, in the following lemma.

[2] Additional details on the precise set of equations mentioned here and in other locations in this section are omitted from this extended abstract due to space constraints.

▶ **Observation 13.** *The number of pairwise disjoint disks inside a circle of radius r is at most πr^2.*

▶ **Lemma 14.** *Let $(\mathcal{P}, R, h, k)$ be a dense yes-instance of Disk Repacking. Let $\mathcal{H}$ be a hole cover of size smaller than k. Let $\mathcal{P}^*$ be a solution to $(\mathcal{P}, R, h, k)$. Then, the number of disks $(\mathcal{H}, \mathcal{P}^*)$-forced to be either blue or red is altogether bounded by $\mathcal{O}(h+k)$.*

Proof. Because $\mathcal{P}^*$ is a solution and $|\mathcal{H}| < k$, we have that $|\mathcal{P} \setminus \mathcal{P}^*| \leq h$. So, at most h disks are $(\mathcal{H}, \mathcal{P}^*)$-forced to be blue. Further, $|\mathsf{Crit}_{\mathcal{H},\mathcal{P}^*}| = |(\mathcal{P}^* \setminus \mathcal{P}) \cup \mathcal{H}| < h + 2k$. Observe that every disk in $\mathcal{P} \cap \mathcal{P}^*$ whose center is at distance at most 4 from the center of some disk in $\mathsf{Crit}_{\mathcal{H},\mathcal{P}^*}$ is contained inside a circle of radius 5 whose center is the center of some disk in $\mathsf{Crit}_{\mathcal{H},\mathcal{P}^*}$. So, due to Observation 13 and since the disks in $\mathcal{P} \cap \mathcal{P}^*$ are pairwise disjoint, there exist at most $\pi \cdot 5^2 \cdot (h + 2k) = \mathcal{O}(h+k)$ disks in $\mathcal{P} \cap \mathcal{P}^*$ whose center is at distance at most 4 from the center of some disk in $\mathsf{Crit}_{\mathcal{H},\mathcal{P}^*}$. In particular, this means that at most $\mathcal{O}(h+k)$ disks are $(\mathcal{H}, \mathcal{P}^*)$-forced to be red. This completes the proof. ◀

Proof of Theorem 2: Values of containers. Next, we present the definition of slots and containers, in which we will aim to (re)pack disks. The definition is followed by an observation and a lemma, which, in particular, state that if we try to repack at least one disk in a container, we can just repack all disks in that container.

▶ **Definition 15** (c-Slots and c-Containers)**.** *Let $(\mathcal{P}, R, h, k)$ be an instance of Disk Repacking. Let $c : \mathcal{P} \to \{\mathsf{blue}, \mathsf{red}\}$. The set of* c-slots*, denoted by Slots_c, is the set of disks contained in R that are disjoint from all disks in $\mathcal{P}$ that are colored red by c. The set of* c-containers*, denoted by $\mathsf{Containers}_c$, is the set of maximally connected regions in the union of all disks in Slots_c.*

▶ **Observation 16.** *Let $(\mathcal{P}, R, h, k)$ be an instance of Disk Repacking. Let $c : \mathcal{P} \to \{\mathsf{blue}, \mathsf{red}\}$. Then, the regions in $\mathsf{Containers}_c$ are pairwise disjoint.*

▶ **Lemma 17.** *Let $(\mathcal{P}, R, h, k)$ be a yes-instance of Disk Repacking. Let $\mathcal{H}$ be a hole cover. Let $\mathcal{P}^*$ be a solution to $(\mathcal{P}, R, h, k)$. Let $c : \mathcal{P} \to \{\mathsf{blue}, \mathsf{red}\}$ be $(\mathcal{H}, \mathcal{P}^*)$-compatible. Then, for every region $X \in \mathsf{Containers}_c$, either all disks in $\mathcal{P}$ contained in X belong to $\mathcal{P} \setminus \mathcal{P}^*$ or none of the disks in $\mathcal{P} \cup \mathcal{P}^*$ contained in X belongs to $(\mathcal{P} \setminus \mathcal{P}^*) \cup (\mathcal{P}^* \setminus \mathcal{P})$.*

Proof. Targeting a contradiction, suppose that there exists a disk D contained in X that belongs to $(\mathcal{P} \setminus \mathcal{P}^*) \cup (\mathcal{P}^* \setminus \mathcal{P})$ and a disk D' contained in X that belongs to $\mathcal{P} \cap \mathcal{P}^*$. Let γ be a curve connecting the centers of these disks that lies entirely inside X. By the definition of a c-container and due to Observation 8, every point of this curve contained in a disk that belongs to X and intersects a disk in $\mathcal{P}$ colored blue by c or a disk in $\mathcal{H}$. So, there must exist a point on γ that is the center of a disk D^* that intersects both a disk A contained in X that belongs to $(\mathcal{P} \setminus \mathcal{P}^*) \cup \mathcal{H}$ and a disk A' contained in X that belongs to $\mathcal{P} \cap \mathcal{P}^*$. From the definition of a c-container, A' is colored blue by c. Moreover, note that the center of A' is at distance at most 4 from the center of A, since each of the centers of A and A' is at distance at most 2 from the center of D^*. However, since c is $(\mathcal{H}, \mathcal{P}^*)$-compatible, A' is $(\mathcal{H}, \mathcal{P}^*)$-forced to be red and hence it is colored red by c. Since c cannot color a disk both blue and red, we have reached a contradiction. This completes the proof. ◀

We proceed to define the weight and value of a c-container, which will be required for the reduction of our problem to Knapsack.

▶ **Definition 18** (Weight, Validity and Value of Containers). *Let $(\mathcal{P}, R, h, k)$ be an instance of Disk Repacking. Let $c : \mathcal{P} \to \{\mathsf{blue}, \mathsf{red}\}$. Let $X \in \mathsf{Containers}_c$. The* weight *of X is the number of disks in $\mathcal{P}$ that it contains. We say that X is* valid *if its weight is at most h. The* value *of X is the maximum number of disks that can be packed inside X.*

The following is a corollary of Lemma 17.

▶ **Corollary 19.** *Let $(\mathcal{P}, R, h, k)$ be a yes-instance of Disk Repacking. Let $\mathcal{P}^*$ be a solution to $(\mathcal{P}, R, h, k)$. Let $c : \mathcal{P} \to \{\mathsf{blue}, \mathsf{red}\}$ be $(\mathcal{H}, \mathcal{P}^*)$-compatible. Then, every disk in $(\mathcal{P} \setminus \mathcal{P}^*) \cup (\mathcal{P}^* \setminus \mathcal{P})$ is a c-slot, and it is contained in a valid c-container.*

Now, we define a way in which we can "easily" describe a container, and then prove that this way can be encoded compactly.

▶ **Definition 20** (Descriptions of Containers). *Let $(\mathcal{P}, R, h, k)$ be an instance of Disk Repacking. Let $\mathcal{H}$ be a hole cover. Let $c : \mathcal{P} \to \{\mathsf{blue}, \mathsf{red}\}$. An* $\mathcal{H}$-description *(or, for short,* description*) of a region $X \in \mathsf{Containers}_c$ is a pair $(\mathcal{D}_1, \mathcal{D}_2)$ of a subset $\mathcal{D}_1 \subseteq \mathcal{P} \cup \mathcal{H}$ and a minimal subset $\mathcal{D}_2 \subseteq \mathcal{P}$ such that X equals the set of all points in R at distance less than 2 from at least one disk in $\mathcal{D}_1$ and at least 2 from all disks in $\mathcal{D}_2$.*

▶ **Lemma 21.** *Let $(\mathcal{P}, R, h, k)$ be an instance of Disk Repacking. Let $\mathcal{H}$ be a hole cover. Let $c : \mathcal{P} \to \{\mathsf{blue}, \mathsf{red}\}$. Let $X \in \mathsf{Containers}_c$. Then, X has at least one description $(\mathcal{D}_1, \mathcal{D}_2)$. Moreover, every description $(\mathcal{D}_1, \mathcal{D}_2)$ of X satisfies $|\mathcal{D}_1| + |\mathcal{D}_2| = \mathcal{O}(h' + k')$ where h' is the weight of X, and k' is the number of disks in $\mathcal{H}$ contained in X.*

Proof. By Observation 8, every c-slot intersects at least one disk in $\{D \in \mathcal{P} : c(D) = \mathsf{blue}\} \cup \mathcal{H}$ and is disjoint from all disks in $\{D \in \mathcal{P} : c(D) = \mathsf{red}\}$. Further, every point in every disk in $\{D \in \mathcal{P} : c(D) = \mathsf{blue}\} \cup \mathcal{H}$ is contained in a c-slot. So, it is immediate that X has a description $(\mathcal{D}_1, \mathcal{D}_2)$, and that $|\mathcal{D}_1| = \mathcal{O}(h' + k')$. Due to Observation 13 and since the disks in $\mathcal{P} \cup \mathcal{H}$ are pairwise disjoint, any circle of radius 5 whose center is a center of some disk in $\{D \in \mathcal{P} : c(D) = \mathsf{blue}\} \cup \mathcal{H}$ can contain inside at most $\pi \cdot 5^2$ disks from $\{D \in \mathcal{P} : c(D) = \mathsf{red}\}$. Due to the minimality of $\mathcal{D}_2$ (which is a subset of $\{D \in \mathcal{P} : c(D) = \mathsf{red}\}$), every disk in it must be contained inside a circle of radius 5 whose center is a center of some disk in $\{D \in \mathcal{P} : c(D) = \mathsf{blue}\} \cup \mathcal{H}$. Hence, $|\mathcal{D}_2| \leq |\mathcal{D}_1| \cdot \pi \cdot 5^2 = \mathcal{O}(h' + k')$. ◀

Next, we use a description in order to efficiently compute the value of a c-container.

▶ **Lemma 22.** *There is an $(h+k)^{\mathcal{O}(h+k)} \cdot |I|^{\mathcal{O}(1)}$-time algorithm that, given a dense instance $I = (\mathcal{P}, R, h, k)$ of Disk Repacking, a hole cover $\mathcal{H}$ of size smaller than k, $c : \mathcal{P} \to \{\mathsf{blue}, \mathsf{red}\}$ and a valid region X with a description $(\mathcal{D}_1, \mathcal{D}_2)$, computes the value of X.*

Proof. Given $I = (\mathcal{P}, R, h, k), \mathcal{H}, c, X$ and $(\mathcal{D}_1, \mathcal{D}_2)$, the algorithm works as follows. For $\ell = h+k, h+k-1, \ldots, 1$, and for every vector $(D_1, D_2, \ldots, D_\ell) \in \mathcal{D}_1 \times \mathcal{D}_1 \times \cdots \times \mathcal{D}_1$, it tests whether there exist ℓ disks $S_1, S_2, \ldots, S_\ell$ such that, for every $i \in \{1, 2, \ldots, \ell\}$, S_i intersects D_i, is contained in R and is disjoint from all disks in $\mathcal{D}_2$. The test is done by constructing a system of polynomial equations of degree 2 with 2ℓ variables and $\ell \cdot (|\mathcal{D}_2| + 2)$ equations as follows. For every $i \in \{1, 2, \ldots, \ell\}$, we have two variables, denoting the x- and y-coordinates of the center of S_i, one equation enforcing that the distance between the center of S_i and the center of D_i is smaller than 2, $|\mathcal{D}_2|$ equations enforcing that the distance between the center of S_i and the center of each of the disks in $\mathcal{D}_2$ is at least 2, and two linear equations enforcing that S_i is contained inside R. If the answer is positive, then the algorithm returns that the value of X is ℓ and terminates; else, it proceeds to the next iteration. Observe that, when $\ell = 1$, the algorithm necessarily terminates (since X contains at least one c-slot).

The correctness of the algorithm is immediate from the definition of a description and the exhaustive search that it performs. As for the running time, first observe that, by Lemma 21 and since X is valid and $|\mathcal{H}| < k$, $|\mathcal{D}_1| + |\mathcal{D}_2| \leq \mathcal{O}(h+k)$. So, for a given ℓ, we have $|\mathcal{D}_1|^{\mathcal{O}(\ell)} = (h+k)^{\mathcal{O}(h+k)}$ choices of vectors. Now, consider the iteration corresponding to some ℓ and some vector. Then, we solve a system of polynomial equations of degree 2 with $\mathcal{O}(h+k)$ variables and $\mathcal{O}((h+k)^2)$ equations. By Proposition 4, this can be done in time $(h+k)^{\mathcal{O}(h+k)} \cdot |I|^{\mathcal{O}(1)}$. Thus, the algorithm indeed runs in time $(h+k)^{\mathcal{O}(h+k)} \cdot |I|^{\mathcal{O}(1)}$. ◀

The following definition captures the set of all descriptions.

▶ **Definition 23** (Blueprint). *Let $(\mathcal{P}, R, h, k)$ be an instance of* Disk Repacking. *Let $\mathcal{H}$ be a hole cover. Let $c : \mathcal{P} \to \{\mathsf{blue}, \mathsf{red}\}$. An $(\mathcal{H}, c)$-*blueprint *is a collection of pairs of sets $\mathsf{Blueprint} \subseteq 2^{\mathcal{P} \cup \mathcal{H}} \times 2^{\mathcal{P}}$, where the first elements of the pair are pairwise-disjoint subsets of $\mathcal{P} \cup \mathcal{H}$, such that each region in $\mathsf{Containers}_c$ has exactly one description in $\mathsf{Blueprint}$, and every pair in $\mathsf{Blueprint}$ is a description of a region in $\mathsf{Containers}_c$.*

Next, we show how to compute blueprints.

▶ **Lemma 24.** *There exists a polynomial-time algorithm that, given an instance $(\mathcal{P}, R, h, k)$ of* Disk Repacking, *a hole cover $\mathcal{H}$, and $c : \mathcal{P} \to \{\mathsf{blue}, \mathsf{red}\}$, outputs an $(\mathcal{H}, c)$-blueprint.*

Proof. We will perform a simple greedy procedure to identify, for each disk in $\{D \in \mathcal{P} : c(D) = \mathsf{blue}\} \cup \mathcal{H}$, the description of the region that contains it. Observe that every c-container contains at least one disk in $\{D \in \mathcal{P} : c(D) = \mathsf{blue}\} \cup \mathcal{H}$ (due to Observation 8 and the definition of a c-container). So, if for every disk $D \in \{D \in \mathcal{P} : c(D) = \mathsf{blue}\} \cup \mathcal{H}$ we will take exactly one description $(\mathcal{D}_1, \mathcal{D}_2)$ among the descriptions we identified such that D is contained in $\mathcal{D}_1$, we will obtain an $(\mathcal{H}, c)$-blueprint.

To describe the greedy procedure, consider some $D \in \{D \in \mathcal{P} : c(D) = \mathsf{blue}\} \cup \mathcal{H}$. Let us first show how to attain $\mathcal{D}_1$. For this purpose, we initialize $\mathcal{D}_1 = \{D\}$. Then, for every pair of disks $A \in \mathcal{D}_1$ and $B \in (\{D \in \mathcal{P} : c(D) = \mathsf{blue}\} \cup \mathcal{H}) \setminus \mathcal{D}_1$, we test whether there exists a pair of disks C and C' that are contained in R, intersect each other, are disjoint from all disks in $\{D \in \mathcal{P} : c(D) = \mathsf{red}\}$, and such that C intersects A and C' intersects B. The test for the existence of such a C is performed by using a system of polynomial equations of degree 2 with four variables denoting the x- and y-coordinates of the centers of C and C'. For each disk in $\{D \in \mathcal{P} : c(D) = \mathsf{red}\}$, we have two equations enforcing that the distances between its center and the centers of C and C' are each at least 2. Additionally, we have three equations to enforce that the distance between the centers of C and C' is smaller than 2, the distance between the centers of C and A is smaller than 2, and the distance between the centers of C' and B is smaller than 2, as well as four linear equations to enforce that C and C' are contained in R. By Proposition 4, testing whether this system has a solution (which corresponds to the sought disks C and C') can be done is polynomial time. If the answer is positive, then we add B to $\mathcal{D}_1$. In case at least one pair (A, B) resulted in the addition of B to $\mathcal{D}_1$, then we repeat the entire loop, iterating again over all pairs (A, B) (where the domain from which they are taken is updated as a new disk was added to $\mathcal{D}_1$). Notice that we can perform at most $|\mathcal{P}|$ repetitions, and that each repetition results in at most $|\mathcal{P} \cup \mathcal{H}|^2$ many iterations, each taking polynomial time. Hence, the procedure, so far, runs in polynomial time.

Now, let us show how to attain $\mathcal{D}_2$. For this purpose, we initialize $\mathcal{D}_2 = \{D \in \mathcal{P} : c(D) = \mathsf{red}\}$. Now, for every $A \in \{D \in \mathcal{P} : c(D) = \mathsf{red}\}$, we test whether there exists a disk C that is contained in R and intersects both A and at least one disk in $\mathcal{D}_1$, and is disjoint from all disks in $\mathcal{D}_2 \setminus \{A\}$. The test can be performed by iterating over every disk $B \in \mathcal{D}_1$, and

using a system of polynomial equations of degree 2 with two variables denoting the x- and y-coordinates of the center of C. For each disk in $\mathcal{D}_2 \setminus \{A\}$, we have an equation enforcing that the distance between its center and the center of C is at least 2, and additionally we have two equations to enforce that the distance between the center of C and each of the centers of A and B is smaller than 2, as well as two linear equations to enforce that C is contained in R. By Proposition 4, testing whether this system has a solution (which corresponds to the sought disk C) can be done is polynomial time. If the answer is positive, then we remove A from $\mathcal{D}_2$. Notice that this phase of the procedure also runs in polynomial time. Moreover, the correctness of the entire procedure directly follows from the definitions of a c-container and a description. ◀

We proceed to define the (extended version of the) Knapsack problem and the instances of this problem that our reduction produces.

▶ **Definition 25** ((Extended) Knapsack). *In the* (Extended) Knapsack *problem, we are given a collection of n items U, where each item $u \in U$ has a weight $w(u) \in \mathbb{N}_0$ and a value $v(u) \in \mathbb{N}_0$, and an integer $W \in \mathbb{N}_0$. The objective is to find, for every $W' \in \{0, 1, \ldots, W\}$, the maximum $V_{W'} \in \mathbb{N}_0$ for which there exists a subset of items $S \subseteq \{1, 2, \ldots, n\}$ such that $\sum_{i \in S} w(u) \leq W'$ and $\sum_{i \in S} v(u) \geq V_{W'}$.*

▶ **Definition 26** ($(\mathcal{H}, c)$-Knapsack instance). *Let $(\mathcal{P}, R, h, k)$ be an instance of Disk Repacking. Let $\mathcal{H}$ be a hole cover. Let $c : \mathcal{P} \to \{\mathsf{blue}, \mathsf{red}\}$. The* $(\mathcal{H}, c)$-Knapsack instance *is the instance (U, w, v, W, V) of* Knapsack *defined as follows: U is the set of all valid regions in $\mathsf{Containers}_c$; for each $X \in U$, $w(X)$ and $v(X)$ are the weight and value of X (see Definition 18); $W = h$; $V = h + k$.*

▶ **Proposition 27** ([8]). *The* (Extended) Knapsack *problem is solvable in time $\mathcal{O}(|U| \cdot W)$.*

We now to prove the correspondence between our problem when we restrict the solution set to solutions compatible with a given coloring and the Knapsack problem.

▶ **Lemma 28.** *Let $(\mathcal{P}, R, h, k)$ be an instance of Disk Repacking. Let $\mathcal{H}$ be a hole cover. Let $c : \mathcal{P} \to \{\mathsf{blue}, \mathsf{red}\}$. Then, there exists a solution $\mathcal{P}^*$ to $(\mathcal{P}, R, h, k)$ such that c is compatible with $\mathcal{P}^*$ if and only if for the $(\mathcal{H}, c)$-Knapsack instance (U, w, v, W, V), there exists $W' \in \{0, 1, \ldots, W\}$ such that $V_{W'} \geq W' + k$.*

Proof. In one direction, suppose that there exists a solution $\mathcal{P}^*$ to $(\mathcal{P}, R, h, k)$ such that c is compatible with $\mathcal{P}^*$. Let $X_1, X_2, \ldots, X_\ell$ be the c-containers that contain at least one disk from $(\mathcal{P} \setminus \mathcal{P}^*) \cup (\mathcal{P}^* \setminus \mathcal{P})$. By Observation 16, these c-containers are pairwise disjoint, by Lemma 17 and since c is compatible with $\mathcal{P}^*$, all disks in $\mathcal{P}$ contained in $X_1 \cup X_2 \cup \cdots \cup X_\ell$ belong to $\mathcal{P} \setminus \mathcal{P}^*$, and by Corollary 19 and since c is compatible with $\mathcal{P}^*$, all disks in $(\mathcal{P} \setminus \mathcal{P}^*) \cup (\mathcal{P}^* \setminus \mathcal{P})$ are contained in $X_1 \cup X_2 \cup \cdots \cup X_\ell$ and all of these c-containers are valid. So, because $\mathcal{P}^*$ can repack h disks from $\mathcal{P}$, the total weight of these c-containers must be some $W' \in \{0, 1, \ldots, h\} = \{0, 1, \ldots, W\}$, and since $\mathcal{P}^*$ also packs k additional disks, the total value of these c-containers must be at least $W' + k$ (to accommodate all of the repacked and k newly packed disks). Thus, $V_{W'} \geq W' + k$.

In the other direction, suppose that there exists $W' \in \{0, 1, \ldots, W\}$ such that $V_{W'} \geq W' + k$. This means that there exist c-containers $X_1, X_2, \ldots, X_\ell$ whose total weight is $W' \in \{0, 1, \ldots, h\}$ and whose total value is at least $W' + k$. However, because these c-containers are pairwise disjoint (by Observation 16), this means that we can construct a solution $\mathcal{P}^*$ such that c is compatible with $\mathcal{P}^*$ by repacking all the disks in $\mathcal{P}$ that are contained in $X_1, X_2, \ldots, X_\ell$ (there are at most h such disks) and, additionally, inserting k new disks, within $X_1, X_2, \ldots, X_\ell$. This completes the proof. ◀

The following is a corollary of Lemmas 22 and 24.

▶ **Corollary 29.** *There exists an $(h+k)^{\mathcal{O}(h+k)} \cdot |I|^{\mathcal{O}(1)}$-time algorithm that, given a dense instance $I = (\mathcal{P}, R, h, k)$ of* Disk Repacking*, a hole cover $\mathcal{H}$ of size smaller than k and $c : \mathcal{P} \to \{\mathsf{blue}, \mathsf{red}\}$, computes the $(\mathcal{H}, c)$-*Knapsack *instance.*

To compute coloring functions, we will use the following definition and proposition.

▶ **Definition 30** ((U,k)-Universal Set)**.** *For a universe U and $k \in \mathbb{N}$, a (U,k)-*universal set *is a collection $\mathcal{C}$ of functions $f : U \to \{\mathsf{blue}, \mathsf{red}\}$ such that for every pair of disjoint sets $B, R \subseteq U$ whose union has size at most k, there exists $c \in \mathcal{C}$ that colors all integers in B blue and all integers in R red.*

▶ **Proposition 31** ([23])**.** *There exists an algorithm that, given a universe U of size n and $k \in \mathbb{N}$, constructs a (U,k)-universal set of size $2^{k+\mathcal{O}(\log^2 k)} \log n$ in time $2^{k+\mathcal{O}(\log^2 k)} n \log n$.*

Based on the definition of a universal set, we define the collection of Knapsack instances relevant to our reduction.

▶ **Definition 32** ($(\mathcal{H},\mathcal{C})$-Knapsack Collection)**.** *Let $(\mathcal{P}, R, h, k)$ be an instance of* Disk Repacking*. Let $\mathcal{H}$ be a hole cover. Let $\mathcal{C}$ be a $(\mathcal{P}, q(h+k))$-universal set, where q is the constant hidden in the $\mathcal{O}$-notation in Lemma 14. Then, the* $(\mathcal{H},\mathcal{C})$-Knapsack collection *is the collection of* Knapsack *instances that includes, for every $c \in \mathcal{C}$, the* $(\mathcal{H}, c)$-Knapsack *instance.*

The following is a corollary of Corollary 29.

▶ **Corollary 33.** *There exists an $(h+k)^{\mathcal{O}(h+k)} \cdot |I|^{\mathcal{O}(1)}$-time algorithm that, given a dense instance $I = (\mathcal{P}, R, h, k)$ of* Disk Repacking*, a hole cover $\mathcal{H}$ of size smaller than k and a $(\mathcal{P}, q(h+k))$-universal set $\mathcal{C}$, computes the* $(\mathcal{H},\mathcal{C})$-Knapsack *collection.*

Next, we prove the correspondence between our problem and the collection of Knapsack instances we have just defined.

▶ **Lemma 34.** *Let $(\mathcal{P}, R, h, k)$ be an instance of* Disk Repacking*. Let $\mathcal{H}$ be a hole cover. Let $\mathcal{C}$ be a $(\mathcal{P}, q(h+k))$-universal set. Then, $(\mathcal{P}, R, h, k)$ is a yes-instance of* Disk Repacking *if and only if the* $(\mathcal{H},\mathcal{C})$-Knapsack *collection contains an instance (U, w, v, W, V) for which there exists $W' \in \{0, 1, \ldots, W\}$ such that $V_{W'} \geq W' + k$.*

Proof. In one direction, suppose that $(\mathcal{P}, R, h, k)$ is a yes-instance. By the definition of a $(\mathcal{P}, q(h+k))$-universal set and due to Lemma 14, there exists $c \in \mathcal{C}$ that is compatible with $\mathcal{P}^*$. So, the $(\mathcal{H}, c)$-Knapsack instance is contained in the $(\mathcal{H},\mathcal{C})$-Knapsack collection (U, w, v, W, V), and by Lemma 28, for this instance there exists $W' \in \{0, 1, \ldots, W\}$ such that $V_{W'} \geq W' + k$.

In the other direction, suppose that the $(\mathcal{H},\mathcal{C})$-Knapsack collection contains an instance (U, w, v, W, V) for which there exists $W' \in \{0, 1, \ldots, W\}$ such that $V_{W'} \geq W' + k$. This instance is a $(\mathcal{H}, c)$-Knapsack instance for some $c \in \mathcal{C}$. So, by Lemma 28, $(\mathcal{P}, R, h, k)$ is, in particular, a yes-instance of Disk Repacking. ◀

Proof of Theorem 2: Putting it all together. We are now ready to make the final step of the proof of Theorem 2.

The algorithm works as follows. Given an instance $(\mathcal{P}, R, h, k)$ of Disk Repacking, it calls the algorithm in Lemma 10 to either correctly determine that $(\mathcal{P}, R, h, k)$ is a yes-instance or correctly determine that $(\mathcal{P}, R, h, k)$ is dense and obtain a hole cover $\mathcal{H}$

of size smaller than k. In the first case, the algorithm is done. In the second case, the algorithm proceeds as follows. First, it calls the algorithm in Proposition 31 to obtain a $(\mathcal{P}, q(h+k))$-universal set $\mathcal{C}$. Then, it calls the algorithm in Corollary 33 to obtain the $(\mathcal{H}, \mathcal{C})$-Knapsack collection. Afterwards, it uses the algorithm of Proposition 27 to determine whether the $(\mathcal{H}, \mathcal{C})$-Knapsack collection contains an instance (U, w, v, W, V) for which there exists $W' \in \{0, 1, \ldots, W\}$ such that $V_{W'} \geq W' + k$.

The correctness of the algorithm follows from Lemma 34. The runtime bound of $(h+k)^{\mathcal{O}(h+k)} \cdot |I|^{\mathcal{O}(1)}$ follows from the runtimes bounds of the algorithms that the algorithm calls, stated in Lemma 10, Proposition 31, Corollary 33, and Proposition 27.

This concludes the proof of Theorem 2.

5 An FPT approximation for Maximum Disk Repacking

In this section, we use Theorem 2 to show that the optimization variant of Disk Repacking, where we maximize the number of added disks, admits an FPT-AS (i.e., *Fixed Parameter Tractable Approximation Scheme*, a parameterized analog of EPTAS) when parameterized by h. Let us remind that in the optimization problem, called Max Disk Repacking, we are given a packing $\mathcal{P}$ of n disks in a rectangle R and an integer h, and the task is to maximize the number of new disks that can be added to the packing if we are allowed to relocate at most h disks of $\mathcal{P}$.

We need an algorithm for the special case $h = 0$, that is, for the optimization version of Disk Appending. The algorithm is based on the shifting technique, originally introduced by Hochbaum and Maass [18] (also related to Baker's technique [3]). We use OPT for the maximum number of disks that can be added in a rectangle to complement a given packing $\mathcal{P}$.

▶ **Lemma 35.** *For any $0 < \varepsilon < 1$, there exists an algorithm that for a packing of n disks in a rectangle, returns a packing with at least $n + (1-\varepsilon) \cdot \mathsf{OPT}$ disks in time $\left(\frac{1}{\varepsilon}\right)^{\mathcal{O}(1/\varepsilon^2)} \cdot |I|^{\mathcal{O}(1)}$, where $|I|$ is the input size.*

Proof. Let $\mathcal{S}^*$, $|\mathcal{S}^*| = \mathsf{OPT}$, be the set of newly added disks in an optimal solution. Let $\ell \geq 1$ be a fixed positive integer. Recall that the instance is contained inside a bounding rectangle R. Let us assume that the bottom-left corner of R has Cartesian coordinates $(0, 0)$. For every $1 \leq i, j \leq 2\ell$, let $G_{i,j}$ be a grid of side-length $\ell \times \ell$, with origin at $(-i, -j)$. Note that there exists a pair (i, j) such that the number of disks of $\mathcal{S}^*$ that do not intersect with the boundary of the grid cells in $G_{i,j}$ is at least $(1 - \frac{1}{\ell})^2 \cdot \mathsf{OPT}$.

For any $1 \leq i, j \leq n$, and a grid cell C in $G_{i,j}$, let $\Pi(C)$ be the following subproblem. Let $\mathcal{P}(C) \subseteq \mathcal{P}$ denote the packing of the original disks that are completely contained in C, or partially intersect with C. The goal is to add the maximum number of new disks to obtain a packing $\mathcal{P}^*(C)$. Note that the number of original disks in $\mathcal{P}$, as well as the new disks that can be added inside C, is upper bounded by ℓ^2, which is a constant. Therefore, an optimal solution to $\Pi(C)$ can be found by solving a system of polynomial equations. Let $OPT_{i,j}$ denote the sum of the optimal values for the subproblems $\Pi(C)$, over all grid cells C in $G_{i,j}$.

Let $\mathcal{P}(C)$ denote the packing of the original disks that are completely contained in the cell C, or partially intersect with C. Recall that C is a square of size $\ell \times \ell$, and since $\mathcal{P}(C)$ is a packing, $|\mathcal{P}(C)| = \mathcal{O}(\ell^2)$. Furthermore, the number of new disks that can be added to C to obtain a new packing is also upper bounded by $p = \mathcal{O}(\ell^2)$. We first "guess" the number of new disks, by trying all possible values q between 1 and $p = \mathcal{O}(\ell^2)$. Now, we construct a system of polynomial equations with $2q$ variables and $q(|\mathcal{P}| + 4)$ equations, as follows.

For every new disk D_i for $1 \leq i \leq q$, we have two variables corresponding to the x and y coordinates of its center in the new packing. For every new disk D_i, we also add 4 linear equations that restrict the center to lie at a horizontal/vertical distance of at least 1 from the perimeter of the cell, so that the disk D_i lies completely within the cell C. Finally, for every disk D'_j in the original packing $\mathcal{P}$, we have an equation that enforces that the distance between the center of D_i and that of D'_j must be at least 2. Now, we solve this system of $\mathcal{O}(\ell^2)$ variables and $\mathcal{O}(\ell^4)$ equations in time $\mathcal{O}(\ell)^{\mathcal{O}(\ell^2)}$ time, using Proposition 4.

Note that since the diameter of a unit disk is 2, by an averaging argument, there exists an index $1 \leq i \leq \ell$, such that $OPT_{i,j} \geq \left(1 - \frac{1}{\ell}\right)^2 \cdot \mathsf{OPT}$. This is because, there exists an index i such that at most $\frac{1}{\ell}$ disks from $\mathcal{S}^*$ intersect the vertical lines $x = a\ell + i$ for integers a. Then, for this value of i, there exists an index j, such that at most $\frac{1}{\ell}$ fraction of the disks that are completely contained within the lines $x = a\ell + i$ intersect horizontal lines $b\ell + j$ for integers b. We direct the reader to [18] for a formal argument of this type.

Therefore, for every $1 \leq i, j \leq 2\ell$, and for every grid cell C in $G_{i,j}$, we solve the subproblem $\Pi(C)$, and return the best solution. Note that if we are looking for an $(1-\varepsilon)$-approximation to the number of newly added disks, then $(1-\varepsilon) \leq \left(1 - \frac{1}{\ell}\right)^2 \leq 1 - \frac{1}{\ell}$ That is, $\ell = 1/\varepsilon$. Thus, the running time of this algorithm is $\left(\frac{1}{\varepsilon}\right)^{\mathcal{O}(1/\varepsilon^2)} \cdot |I|^{\mathcal{O}(1)}$. ◀

Now we construct an algorithm for Max Disk Repacking in Theorem 3.

▶ **Theorem 3.** *For any $0 < \varepsilon < 1$, there exists an algorithm that, given an instance $(\mathcal{P}, R, h)$ of Max Disk Repacking, returns a packing $\mathcal{P}^*$ into R with at least $n + (1-\varepsilon) \cdot \mathsf{OPT}_h$ disks in time $\left(\frac{h+1}{\varepsilon}\right)^{\mathcal{O}(h/\varepsilon + 1/\varepsilon^2)} \cdot |I|^{\mathcal{O}(1)}$, where OPT_h is the maximum number of disks that can be added to the input packing if we can relocate at most h disks.*

Proof. Let $0 < \varepsilon < 1$. Consider an instance $(\mathcal{P}, R, h)$ of Max Disk Repacking. We find the maximum nonnegative integer $k \leq 10h/\varepsilon$ such that $(\mathcal{P}, R, h, k)$ is a yes-instance of Disk Repacking using the algorithm from Theorem 2. This can be done in $\left(\frac{h+1}{\varepsilon}\right)^{\mathcal{O}(h/\varepsilon)} \cdot |I|^{\mathcal{O}(1)}$ time. Next, we run the algorithm from Lemma 35 for (G, R) for $\varepsilon' = \frac{1}{2}\varepsilon$, i.e., assuming that relocations of disks are not allowed. The algorithm runs in $\left(\frac{1}{\varepsilon}\right)^{\mathcal{O}(1/\varepsilon^2)} \cdot |I|^{\mathcal{O}(1)}$ time and returns a solution of size k'. We set $k^* = \max\{k, k'\}$. We claim that $(1-\varepsilon)\mathsf{OPT}_h \leq k^* \leq \mathsf{OPT}_h$. The second inequality is trivial. To show that $(1-\varepsilon)\mathsf{OPT}_h \leq k^*$, we consider two cases.

Suppose that $\mathsf{OPT}_h \leq 10h/\varepsilon$. Then $\mathsf{OPT}_h = k$ as the algorithm from Theorem 2 is exact and $(1-\varepsilon)\mathsf{OPT}_h \leq \mathsf{OPT}_h = k \leq k^*$.

Assume that $\mathsf{OPT}_h > 10h/\varepsilon$. Let $\mathcal{S}$ be the set of added disks in an optimum solution for $(\mathcal{P}, R, h)$ and let $\mathcal{L} \subseteq \mathcal{P}$ be the set of relocated disks. Denote by OPT' the maximum number of disks that can be added to $\mathcal{P}$ without relocations. Observe that every disk in $\mathcal{L}$ intersects at most 5 disks of $\mathcal{S}$. Therefore, $\mathsf{OPT}' \geq |\mathcal{S}| - 5|\mathcal{L}| \geq \mathsf{OPT}_h - 5h$. By Lemma 35, $(1-\varepsilon/2)\mathsf{OPT}' \leq k'$. We obtain that $(1-\varepsilon/2)(\mathsf{OPT}_h - 5h) \leq k' \leq k^*$. Because $\mathsf{OPT}_h > 10h/\varepsilon$, $k^* \geq (1-\varepsilon/2)(\mathsf{OPT}_h - \varepsilon\mathsf{OPT}_h/2) = (1-\varepsilon/2)^2\mathsf{OPT}_h \geq (1-\varepsilon)\mathsf{OPT}_h$. This proves the claim.

We conclude that k^* is the required approximation of OPT_h. To conclude the proof, note that the algorithms from Theorem 2 and Lemma 35 can be adapted to return solutions, that is, the sets of added and relocated disks. ◀

6 Conclusion and open questions

We have shown in Theorem 1 that Disk Repacking problem is NP-hard even if $h = 0$. On the other hand, by Theorem 2, Disk Repacking is FPT when parameterized by k and h. Both theorems naturally lead to the question about parameterization by k only. The difficulty here is that even for adding one disk, one has to relocate many disks. Already for $k = 1$, we do not know, whether the problem is in P or is NP-hard.

Another natural question stemming from Theorem 2 is about kernelization of Disk Repacking. Does Disk Repacking admit a polynomial kernel with parameters k and h? (We refer to books [10, 13] for an introduction to kernelization).

Finally, approximation of Disk Repacking is an interesting research direction. In Theorem 3 we demonstrated that our FPT algorithm can be used to construct an FPT-AS with respect to h for Max Disk Repacking. We leave open the question about polynomial approximation. Another open question concerns the approximability of the minimum number of relocations h for a given k. Already for $k = 1$ finding a good approximation of h is a challenging problem.

Faster Cut Sparsification of Weighted Graphs

Sebastian Forster
Universität Salzburg, Austria

Tijn de Vos
Universität Salzburg, Austria

Abstract

A cut sparsifier is a reweighted subgraph that maintains the weights of the cuts of the original graph up to a multiplicative factor of $(1 \pm \epsilon)$. This paper considers computing cut sparsifiers of weighted graphs of size $O(n \log(n)/\epsilon^2)$. Our algorithm computes such a sparsifier in time $O(m \cdot \min(\alpha(n) \log(m/n), \log(n)))$, both for graphs with polynomially bounded and unbounded integer weights, where $\alpha(\cdot)$ is the functional inverse of Ackermann's function. This improves upon the state of the art by Benczúr and Karger (SICOMP 2015), which takes $O(m \log^2(n))$ time. For unbounded weights, this directly gives the best known result for cut sparsification. Together with preprocessing by an algorithm of Fung et al. (SICOMP 2019), this also gives the best known result for polynomially-weighted graphs. Consequently, this implies the fastest approximate min-cut algorithm, both for graphs with polynomial and unbounded weights. In particular, we show that it is possible to adapt the state of the art algorithm of Fung et al. for unweighted graphs to weighted graphs, by letting the partial maximum spanning forest (MSF) packing take the place of the Nagamochi-Ibaraki (NI) forest packing. MSF packings have previously been used by Abraham at al. (FOCS 2016) in the dynamic setting, and are defined as follows: an M-partial MSF packing of G is a set $\mathcal{F} = \{F_1, \ldots, F_M\}$, where F_i is a maximum spanning forest in $G \setminus \bigcup_{j=1}^{i-1} F_j$. Our method for computing (a sufficient estimation of) the MSF packing is the bottleneck in the running time of our sparsification algorithm.

1 Introduction

In many applications, graphs become increasingly large, hence storing and working with such graphs becomes a challenging problem. One strategy to deal with this issue is graph sparsification, where we model the graph by a sparse set of (reweighted) edges that preserve certain properties. Especially because the aim is to work with large input graphs, this process should be efficient with respect to the graph size. Among the different types of graph sparsifiers, there are spanners (preserving distances, see e.g. [26, 2, 4, 11]), resistance sparsifiers (preserving effective resistances, see e.g. [10]), cut sparsifiers (preserving cuts, see e.g. [6, 7, 13]), and spectral sparsifiers (preserving Laplacian quadratic forms, see e.g. [28, 27, 21, 23]). This paper focuses on cut sparsifiers, as first introduced by Benczúr and Karger in [6]. We say that a (reweighted) subgraph $H \subseteq G$ is a $(1 \pm \epsilon)$-*cut sparsifier* for a weighted graph G if for every cut C, the total weight $w_H(C)$ of the edges of the cut in H is within a multiplicative factor of $1 \pm \epsilon$ of the total weight $w_G(C)$ of the edges of the cut in G.

The main approach to compute cut sparsifiers uses the process of *edge compression*: each edge $e \in E$ is part of the sparsifier with some probability p_e, and if selected obtains weight $w(e)/p(e)$. It is immediate that such a scheme gives a sparsifier in expectation, but it has to be shown that the result is also a sparsifier with high probability. The main line of research has been to select good *connectivity estimators* λ_e for each edge such that sampling with $p_e \sim 1/\lambda_e$ yields a good sparsifier. The simplest such result is by Karger [18], where we sample uniformly with each λ_e equal to the weight of the min cut. Continuing along these lines are parameters as: edge connectivity [13], strong connectivity [6, 7], electrical conductance [27], and Nagamochi-Ibaraki (NI) indices [24, 25, 13]. The challenge within the approach of edge compression is to find a connectivity estimator that results in a sparse graph, but can be computed fast.

For weighted graphs, there are roughly three regimes for sparsification. The first regime consists of cut sparsifiers of size $O(n \log^2(n)/\epsilon^2)$. Fung, Hariharan, Harvey, and Panigrahi [12, 13] show that sparsifiers of this asymptotic size can be computed in linear time for polynomially-weighted graphs. For this they introduce a general framework of cut sparsification with a connectivity estimator, see Section 2.1. For unbounded weights, Hariharan and Panigrahi [16] give an algorithm to compute a sparsifier of size $O(n \log^2(n)/\epsilon^2)$ in time $O(m \log^2(n)/\epsilon^2)$.

The second regime consists of cut sparsifiers of size $O(n \log(n)/\epsilon^2)$. Benczúr and Karger [6, 7] show that these can be computed in time $O(m \log^2(n))$ for polynomially-weighted graphs, and in time $O(m \log^3(n))$ for graphs with unbounded weights. Note that these results can be optimized by preprocessing with the algorithms for the first regime.

A third regime, consists of sparsifiers of size $O(n/\epsilon^2)$. The known constructions in this regime yield *spectral* sparsifiers, which are more general than cut sparsifiers. Spectral sparsification was first introduced by Spielman and Teng in [28]. It considers subgraphs that preserve Laplacian quadratic forms. Lee and Sun [23] give an algorithm for finding $(1 \pm \epsilon)$-spectral sparsifiers of size $O(n/\epsilon^2)$ in time $O(m \cdot \text{poly}(\log(n), 1/\epsilon))$. Analyzing their results, we believe that the poly-logarithmic factor contributes at least a factor of $\log^{10}(n)$. While this is optimal in size, both for spectral sparsifiers [5] and cut sparsifiers [3], it is not in time.

In this paper, we improve on the results in the second regime, both for graphs with polynomially bounded and unbounded weights[1]. For an overview of the previous best running times and our results, see Figure 1. We present our sparsification algorithm in Section 4, for the special treatment of unbounded weights we refer to the full version of the paper. Our algorithm improves on the algorithm of Benczúr and Karger [6, 7] for bounded weights, which has been unchallenged for the last 25 years. It also improves on the algorithm of Hariharan and Panigrahi [16] for unbounded weights, which has been unchallenged for the last 10 years. We obtain the following theorem, where $\alpha(\cdot)$ refers to the functional inverse of Ackermann's function, for a definition see e.g. [29]. For any realistic value x, we have $\alpha(x) \leq 4$.

▶ **Theorem 1.** *There exists an algorithm that, given a weighted graph G and a freely chosen parameter $\epsilon \in (0, 1)$, computes a graph G_ϵ, which is a $(1 \pm \epsilon)$-cut sparsifier for G with high probability. The running time of the algorithm is $O(m \cdot \min(\alpha(n) \log(m/n), \log(n)))$ and the number of edges of G_ϵ is $O\big(n \log(n)/\epsilon^2\big)$.*

Using preprocessing with a result from Fung et al. [13] (see Theorem 23), we obtain the following corollary for polynomially-weighted graphs.

[1] See Section 2.2 for our assumptions on the computational model in case of unbounded weights.

Figure 1 An overview of the state of the art algorithms for computing cut sparsifiers for undirected graphs with integer weights. Algorithm $A+B$ indicates that algorithm B is preprocessed with algorithm A.

▶ **Corollary 2.** *There exists an algorithm that, given a polynomially-weighted graph G and a freely chosen parameter $\epsilon\in(0,1)$, computes a graph G_ϵ, which is a $(1\pm\epsilon)$-cut sparsifier for G with high probability. The running time of the algorithm is $O(m+n\left(\log^2(n)/\epsilon^2\right)\alpha(n)\log(\log(n)/\epsilon))$ and the number of edges of G_ϵ is $O(n\log(n)/\epsilon^2)$.*

Following Benczúr and Karger [7], the computation of cut sparsifiers of graphs with fractional or even real weights can be reduced to integer weights. For the reduction see Appendix C. Thus our algorithm also gives a speedup for such graphs. Since the integer case is the essential one, we follow prior works and only formulate our results for this particular case.

As a direct application of the cut sparsifier, we can use Theorem 1 and Corollary 2 to replace m by $n\log(n)/\epsilon^2$ in the time complexity of algorithms solving cut problems, at the cost of a $(1\pm\epsilon)$-approximation. We detail the effects for the minimum cut problem. Recently, Gawrychowski, Mozes, and Weiman [14] showed that one can compute the minimum cut of a weighted graph in $O(m\log^2(n))$ time. Using the existing sparsification techniques [7, 13] for preprocessing, the state of the art for $(1+\epsilon)$-approximate min-cut is $O(m+n\log^4(n)/\epsilon^2)$. When we use our new sparsification results, we obtain faster $(1+\epsilon)$-approximate min-cut algorithms when $m=\Omega(n\log(n)/\epsilon^2)$.

▶ **Corollary 3.** *There exists an algorithm that, given a polynomially-weighted graph G and a freely chosen parameter $\epsilon\in(0,1)$, with high probability computes an $(1+\epsilon)$-approximation of the minimum cut in time $O(m+n\log^3(n)/\epsilon^2)$.*

There exists an algorithm that, given a weighted graph G and a freely chosen parameter $\epsilon\in(0,1)$, with high probability computes an $(1+\epsilon)$-approximation of the minimum cut in time $O(m\cdot\min(\alpha(n)\log(m/n),\log(n))+n\log^3(n)/\epsilon^2)$.

For unweighted graphs, even faster minimum cut algorithms exist: Ghaffari, Nowicki, and Thorup [15] show that we can find the minimum cut in $O(\min\{m+n\log^3(n), m\log(n)\})$ time. Combining this with the linear time cut sparsifier of Fung et al. [13], we get $(1+\epsilon)$-approximate minimum cut in unweighted graphs in $O(m + n\log(n)\min\{1/\epsilon + \log^2(n), \log(n)/\epsilon\})$ time.

The remainder of this article is organized as follows. The rest of the introduction consists of a technical overview of our algorithms. Section 2 contains a review of the general sparsification framework from Fung et al. [13] tailored to our needs, and can be skipped by readers that are already familiar with this work. We present our algorithm to compute the MSF indices in Section 3. This is used as a black box in our algorithm, which is presented and analyzed in Section 4.

Technical Overview

The high-level set-up of our sparsification algorithm is similar to the algorithm for unweighted graphs of Fung et al. [13]. Our main contribution consists of showing how to generalize this technique to weighted graphs, by using maximum spanning forest (MSF) indices instead of Nagamochi-Ibaraki (NI) indices. On a less significant note, we prove that by a tightening of the analysis one can show that the size and time bounds hold with high probability, and not only in expectation.

NI indices are defined by means of an NI forest packing: view graphs with integer weights as unweighted multigraphs, and repeatedly compute a spanning forest. The NI index is the (last) forest in which an edge appears (for details see Definition 22). The MSF index is also defined by a forest packing, but in this case the MSF packing: we say $\mathcal{F} = \{F_1, \ldots, F_M\}$ is an *M-partial maximum spanning forest packing* of G if for all $i = 1, \ldots, M$, F_i is a maximum spanning forest in $G \setminus \bigcup_{j=1}^{i-1} F_j$. Now, we say that an edge e has MSF index i (w.r.t. to some (partial) MSF packing $\mathcal{F}$) if e appears in the i-th forest F_i of the (partial) MSF packing $\mathcal{F}$. The MSF index has been used previously in the context of dynamic graph sparsifiers (see Abraham et al. [1]). However, there it was only used because it rendered a faster running time, but using NI indices in the corresponding static construction would have been possible as well. In this paper, we use distinctive properties of the MSF index, and the NI index would not suffice. We show that using the MSF index, we can generalize the sparsification algorithm for unweighted graphs to an algorithm for weighted graphs, thereby demonstrating that the MSF index is a natural analogue for the NI index in the weighted setting. We provide an algorithm to compute an M-partial MSF packing in time $O(m \cdot \min(\alpha(n)\log(M), \log(n)))$ for polynomially-weighted graphs. We show that for unbounded weights we can compute a sufficient estimation, also in time $O(m \cdot \min(\alpha(n)\log(M), \log(n)))$.

An important distinction between the unweighted algorithm of Fung et al. and our weighted algorithm, is that the use of contractions to keep running times low throughout the algorithm is no longer possible: edges of different weights have to be treated differently, hence cannot be contracted. By using multiple iterations with an exponentially decreasing precision parameter we can overcome this problem.

In the case of a polynomially-weighted input graph, the algorithm consists of two main phases. In the first phase, we compute sets $F_0, F_1, \ldots, F_\Gamma \subseteq E$, where edges satisfy some lower bound on the weight of any cut separating their endpoints. In the second phase, we sample edges from each set F_i with a corresponding probability.

We set a parameter $\rho = \Theta\left(\frac{\ln(n)}{\epsilon^2}\right)$ and start by computing a 2ρ-partial maximum spanning forest packing for G. We define F_0 to be the union of these 2ρ forests. We add the edges of F_0 to G_ϵ, which will become our sparsifier. We sample each of the remaining edges $E \setminus F_0$ with probability $1/2$ to construct X_1. To counterbalance for the sampling, we will boost

the weight of each sampled edge with a factor 2. Now we continue along these lines, but in each iteration we let F_i consist of an exponentially growing number of spanning forests: F_i is defined as the union of the forests in a $(2^{i+1} \cdot \rho)$-partial MSF packing packing of X_i. Then, X_{i+1} is sampled from the remaining edges $X_i \setminus F_i$, where again each edge is included with probability $1/2$. We continue this process until there are sufficiently few edges left in X_{i+1}. We add these remaining edges to G_ϵ.

The second phase of the algorithm is to sample edges from the sets F_i and add these sampled edges to G_ϵ. Hereto, note that an edge e of F_i (for $i \geq 1$) was not part of F_{i-1}, meaning it was not part of any spanning forest in a $(2^i \cdot \rho)$-partial MSF packing of X_{i-1}. This implies that for an edge $e \in F_i$ the weight of any cut C in X_{i-1} containing e is at least $2^i \cdot \rho \cdot w(e)$. Now we use the general framework for cut sparsification of Fung et al. [13], which boils down to the fact that this guarantee on the weights of cuts implies that we can sample edges from F_i with probability proportional to $1/(2^i w(e))$. We show that this results in a sufficiently sparse graph.

Intuitively, it might seem redundant to sample edges from $X_i \setminus F_i$ to form X_{i+1}. This is indeed not necessary to guarantee that the resulting graph is a sparsifier. However, it ensures that the number of iterations is limited, which leads to better bounds on the size of the sparsifier and the running time. Since we sample edges with probability $1/2$ in each phase, we need to repeat the sampling $O(\log(m/(m_0))$ times to get the size of X_i down to $O(m_0)$. As this number of steps depends on the initial number of edges m, we get better bounds for size and running time if m is already small. We will exploit this by preprocessing the graph with an algorithm from Fung et al. [13] that gives a cut sparsifier of size $O(n \log^2(n)/\epsilon^2)$ in linear time. Moreover, we can show that repeatedly calling our algorithm has no worse asymptotic time bound than calling it once, since the input graph becomes sparser very quickly. By doing so, we obtain a sparsifier of size $O(n \log(n)/\epsilon^2)$.

Since we only use that the MSF index gives a guaranteed lower bound on the connectivity of an edge, one might wonder why the NI index does not work here. After all, the NI indices of a graph can be computed in linear time, which would result in a significant speed-up. However, when computing the NI index, the weight of an edge influences the number of forests necessary, while computing the MSF index only requires the comparison of weights. Moreover, the number of trees in a MSF packing is always bounded by n. We can use this to bound the number of edges in the created sparsifier. The same technique with NI indices would make the size of the sparsifier depend on the maximum weight in the original graph.

To show that the algorithm outputs a cut sparsifier, it needs to be proven that both the sampling in the first and the second phase preserve cuts. We follow the lines of the analysis of Fung et al. [13], which makes use of cut projections and Chernoff bounds. We show that by partitioning the edge sets according to their weight this method extends to weighted graphs.

One part of the algorithm has remained unaddressed: the computation of the maximum spanning forests. The approach we use here is related to Kruskal's algorithm for computing minimum spanning trees [22]. We start by sketching the M-partial MSF packing algorithm for polynomial weights. We sort the edges according to their weights using radix sort in $O(m)$ time. We create M empty forests on n vertices. Starting with the heaviest edge, we add each edge e to the first forest in which it does not create a cycle. We can find this forest using a binary search in $\log(M)$ steps. By using a disjoint-forest representation for the union-find data structure necessary to carry out these steps, we achieve a total time of $O(m\alpha(n) \log(M))$.

When working with unbounded weights, the bottleneck is the initial sorting of the edges. Radix sort does not guarantee to be efficient for unbounded weights. Instead we could use a comparison-based algorithm, such as merge sort, which takes time $O(m \log(n))$. By employing

a different data structure than before, we can guarantee total running time $O(m \log(n))$. However, we do not need the exact MSF indices for our sampling procedure, an estimate suffices. We can adapt a "windowing" technique from Benczúr and Karger [7] to split the graph into subgraphs, where we can rescale the weights to polynomial weights and apply our previously mentioned algorithm. We then achieve a total running time of $O(m\alpha(n) \log(M))$, as before. For more details on this, we refer to the full version. So in total we have running time $O(m \cdot \min(\alpha(n) \log(m/n), \log(n)))$.

2 Notation and Review

Throughout this paper, we consider $G = (V, E)$ to be an undirected, integer weighted graph on $|V| = n$ vertices with $|E| = m$ edges. We define a set of edges $C \subseteq E$ to be a *cut* if there exists a partition of the vertices V in two non-empty subsets A and B, such that C consists of all edges with one endpoint in A and the other endpoint in B. The weight of the cut is the sum of the weights of the edges of the cut: $w_G(C) = \sum_{e \in C} w_G(e)$. The *minimum cut* is defined as the cut with minimum weight. We say that a (reweighted) subgraph $H \subseteq G$ is a $(1 \pm \epsilon)$-*cut sparsifier* for a weighted graph G if for every cut C in H, its weight $w_H(C)$ is within a multiplicative factor of $1 \pm \epsilon$ of its weight $w_G(C)$ in G. A key concept in the realm of cut sparsification is the connectivity of an edge.

▶ **Definition 4.** *Let $G = (V, E)$ be a graph, possibly weighted. We define the* connectivity *of an edge $e = (u, v) \in E$ to be the minimal weight of any cut separating u and v. We say that e is k-*heavy *if it has connectivity at least k. For a cut C, we define the k-*projection *of C to be the k-heavy edges of the cut C.*

The following theorem from Fung et al. [13] bounds the number of distinct k-projections of a graph, it is a generalization of a preceding theorem by Karger, see [17, 20]. This result can be useful when showing that cuts are preserved by a sampling scheme. This is due to the fact that while there may be exponentially many different cuts, this theorem shows that there are only polynomially many cut projections. Hence if one can reduce a claim for cuts to their k-projections, a high probability bound can be obtained through the application of a Chernoff bound.

▶ **Theorem 5.** *For any $k \geq \lambda$ and any $\eta \geq 1$, the number of distinct k-projections in cuts of weight at most ηk in a graph G is at most $n^{2\eta}$, where λ is the weight of a minimum cut in G.*

Throughout this paper, we say a statement holds *with high probability* (w.h.p.) if it holds with probability at least $1 - n^c$, for some constant c. This constant can be modified by adjusting the constants hidden in asymptotic notation.

2.1 A General Framework for Cut Sparsification

We review the general framework for cut sparsification as presented in [13]. This section does not contain new results, and can be skipped by readers that are only interested in our contribution.

The framework shows that edges can be sampled using different notions of connectivity estimators. Although this scheme provides one proof for the validity of multiple parameters, it might be worth noting that an analysis tailored to the used connectivity estimator might provide a better result. For example, when the framework is applied with "edge strengths", it produces a sparsifier of size $O(n \log^2(n)/\epsilon^2)$, a $\log(n)$ factor denser than the edge strength-based sparsifier of Benczúr and Karger [7].

Let $G = (V, E)$ be a graph with integer weights, and let $\epsilon \in (0, 1)$, $c \geq 1$ be parameters. Given a parameter γ (possibly depending on n) and an integer-valued parameter λ_e for each $e \in E$. We obtain G_ϵ from G by independently *compressing* each edge e with parameter

$$p_e = \min\left(1, \frac{16(c+7)\gamma \ln(n)}{0.38\lambda_e \epsilon^2}\right).$$

Compressing an edge e with weight $w(e)$ consists of sampling r_e from a binomial distribution with parameters $w(e)$ and p_e. If $r_e > 0$, we include the edge in G_ϵ with weight r_e/p_e.

In the following we describe a sufficient condition on the parameters γ and λ_e such that G_ϵ is a $(1 \pm \epsilon)$-cut sparsifier for G with probability at least $1 - 4/n^c$. Hereto we partition the edges according to their value λ_e:

$$\Lambda := \left\lfloor \log\left(\max_{e \in E}\{\lambda_e\}\right)\right\rfloor;$$
$$R_i := \{e \in E : 2^i \leq \lambda_e \leq 2^{i+1} - 1\}.$$

Let $\mathcal{G} = \{G_i = (V, E_i) : 1 \leq i \leq \Lambda\}$ be a set of integer-weighted subgraphs such that $R_i \subseteq G_i$. Moreover suppose that $w_{G_i}(e) \geq w_G(e)$ for each $e \in R_i$. For a given set of parameters $\Pi = \{\pi_1, \ldots, \pi_\Lambda\} \subseteq \mathbb{R}^\Lambda$, we define

- Π-*connectivity*: each edge $e \in R_i$ is π_i-heavy in G_i;
- γ-*overlap*: for any cut C,

$$\sum_{i=0}^{\Lambda} \frac{e_i^{(C)} 2^{i-1}}{\pi_i} \leq \gamma \cdot e^{(C)},$$

where $e^{(C)} = \sum_{e \in C} w_G(e)$ and $e_i^{(C)} = \sum_{e \in C \cap E_i} w_{G_i}(e)$.

The following theorem shows that compressing with parameters adhering to these conditions gives a cut sparsifier with high probability.

▶ **Theorem 6** (See [13, Theorem 1.14]). *Fix the parameters γ and λ_e for each edge e. If there exists $\mathcal{G}$ satisfying Π-connectivity and γ-overlap for some Π, then G_ϵ is a $(1 \pm \epsilon)$-cut sparsifier for G, with probability at least $1 - 4/n^c$, where G_ϵ is obtained by edge compression using parameters γ and λ_e's.*

2.2 The Computational Model

If we have an input graph $G = (V, E)$ with weights $w \colon E \to \{1, \ldots, W\}$, we assume our computational model has word size $\Theta(\log(W) + \log(n))$. Note that for polynomial weights, this comes down to a word size of $\Theta(\log(n))$. Moreover, we assume that basic operations on such words have uniform cost, i.e., they can be performed in constant time. In particular, these basic operations are addition, multiplication, inversion, logarithm, and sampling a random bit string of word size precision. Such assumptions are in line with previous work [7, 13], where they are made implicitly.

3 A Maximum Spanning Forest Packing

An important primitive in our algorithm is the use of the maximum spanning forest (MSF) index. The concept is similar to the Nagamochi-Ibaraki index, the important difference is that an edge e with weight $w(e)$ appears in $w(e)$ different NI forests. This means that the

number of NI forests depends on the numerical values of the edge weights, and thus can grow far beyond $O(n)$. On the other hand, the number of maximum spanning forests in a MSF packing is bounded by the maximum degree in the graph, hence also by n. While this already has noteworthy implications for polynomially-weighted graphs, it is even more significant for superpolynomially-weighted graphs. We believe that this property might make them suitable for applications other than presented here.

▶ **Definition 7.** *Let $G = (V, E)$ be a weighted graph. We say $\mathcal{F} = \{F_1, \dots, F_M\}$ is an* M-partial maximum spanning forest packing *of G if for all $i = 1, \dots, M$, F_i is a maximum spanning forest in $G \setminus \bigcup_{j=1}^{i-1} F_j$. If we have that $\bigcup_{i=1}^{M} F_i = G$, then we call $\mathcal{F}$ a* (complete) maximum spanning forest packing *of G. Moreover, for $e \in E$ we denote the* MSF index *of e (w.r.t. $\mathcal{F}$) by f_e, i.e., f_e is the unique index such that $e \in F_{f_e}$.*

Note that we do not demand the $F_i \in \mathcal{F}$ to be non-empty, as this suits notation bests in our applications. Also note that a (partial) MSF packing is fully determined by the MSF indices.

The following theorem states that computing the MSF indices up to M takes $O(m\alpha(n)\log(M))$ time for polynomially-weighted graphs.

▶ **Theorem 8.** *Let $G = (V, E)$ be a polynomially weighted graph, where we allow parallel edges but no self-loops, and we suppose $m \leq n^2$. Then, for any $M > 0$, there exists an algorithm that computes an M-partial MSF packing in $O(m \cdot \min(\alpha(n)\log(M), \log(n)))$ time.*

The outline of the algorithm is as follows, for a complete proof see the full version.

1. Sort the edges by weight in descending order using radix sort in base n.[2]
2. Create empty forests $F_1, \dots, F_M$.
3. Iterate over the edges in descending order and for each edge $e = (u, v)$ do the following:
   a. Find the smallest index i such that u and v are not connected in F_i.
   b. Store i as the MSF index f_e of e. If u and v are connected in every F_i, store $f_e > M$.
   c. Add e to F_i.

We need at most M trees, since we only compute an M-partial MSF packing. By using radix sort, the initial sorting takes time $O(m)$ time (for a time bound of radix sort, see e.g. [9]). In the full version, we show that the remainder of the algorithm can be executed in $O(m\alpha(n)\log(M))$ time or $O(m\log(n))$, depending on the data-structure used. There we also consider an algorithm for *sparse* graphs with unbounded weights.

4 Cut Sparsification for Weighted Graphs

In this section, we present our algorithm for computing a $(1 \pm \epsilon)$-cut sparsifier G_ϵ for a weighted graph G. This makes use of the framework as presented in Section 2.1 and the maximum spanning forest packing as treated in Section 3. This section works towards proving the following theorem for polynomially-weighted graphs. In the full version, we generalize the techniques of this section to graphs with unbounded weights.

▶ **Theorem 9.** *There exists an algorithm that, given a weighted graph $G = (V, E)$, and freely chosen parameter $\epsilon > 0$, computes a graph G_ϵ, which is a $(1 \pm \epsilon)$-cut sparsifier for G with high probability. The algorithm runs in time $O(m \cdot \min(\alpha(n)\log(m/n), \log(n)))$ and the number of edges of G_ϵ is $O\big(n\left(\log(n)/\epsilon^2\right)\log\left(m/(n\log(n)/\epsilon^2)\right)\big)$.*

[2] Note that conversion to base n takes time $O(\log_n(w(e))) \leq O(\log_n(n^c)) = O(c)$ for each edge if the weights are bounded by n^c, so total time $O(mc)$.

To be precise, we give an algorithm where the given bounds on both running time and size of the sparsifier hold with high probability. By simply halting when the running time exceeds the bound, and outputting an empty graph if we exceed the size bound, this gives the result above.

To achieve a better bound on the size of the sparsifier, we repeatedly apply this theorem to the input graph, with an exponentially decreasing precision parameter. The proof of this can be found in the full version.

▶ **Theorem 1** (Restated). *There exists an algorithm that, given a weighted graph $G = (V, E)$, and freely chosen parameter $\epsilon \in (0, 1)$, computes a graph G_ϵ, which is a $(1 \pm \epsilon)$-cut sparsifier for G with high probability. The algorithm runs in time $O(m \cdot \min(\alpha(n) \log(m/n), \log(n)))$ and the number of edges of G_ϵ is $O\big(n \log(n)/\epsilon^2\big)$.*

4.1 The Algorithm

To sparsify the graph, two methods of sampling are used. One of which is the framework presented in Section 2.1. However, instead of applying the framework to the graph directly, there is another sampling process that precedes it.

To simplify equations, let us set $\rho := \frac{(7+c)1352 \ln(n)}{0.38\epsilon^2}$. If $|E| \leq 4\rho n \log\big(m/(n \log(n)/\epsilon^2)\big)$, we do nothing. That is, we return $G_\epsilon = G$. If not, we start by an initialization step and continue with an iterative process, which ends when the remaining graph becomes sufficiently small.

In the initialization step, we define $X_0 := E$. We compute an $\lfloor 2\rho \rfloor$-partial maximum spanning forest packing $T_1, \ldots, T_{\lfloor 2\rho \rfloor}$ and we define $F_0 := \bigcup_{j=1}^{\lfloor 2\rho \rfloor} T_j$. The remaining edges $Y_0 := X_0 \setminus F_0$ move on to the next phase.

In iteration i, we create X_{i+1} from Y_i by sampling each edge with probability $1/2$. Next, we compute $k_i := \rho \cdot 2^{i+1}$ maximum spanning forests $T_1, \ldots, T_{k_i}$. We define $F_i := \bigcup_{j=1}^{k_i} T_j$, and $Y_i := X_i \setminus F_i$.

We continue until Y_i has at most $2\rho n$ edges, and set Γ to be the number of iterations. We retain all edges in F_0. In other words: add each edge $e \in F_0$ to G_ϵ with weight $w(e)$. The edges of Y_Γ are also retained, but they need to be scaled to counterbalance the $\Gamma - 1$ sampling steps: add each edge $e \in Y_\Gamma$ to G_ϵ with weight $2^{\Gamma-1} w(e)$.

Any other edge $e \in F_i$ is at least $k_i w(e)$-heavy in X_{i-1}, as $e \notin F_{i-1}$. We exploit this heavyness to sample from these edges using the framework. For each $e \in F_i$ we:

- Define $n_e := 2^i w(e)$ and $p_e := \min\left(1, \frac{384}{169} \frac{1}{4^i w(e)}\right)$;
- Generate r_e from the binomial distribution with parameters n_e and p_e;
- If r_e is positive, add e to G_ϵ with weight r_e/p_e.

The factor 2^i in calling upon the binomial distribution can be seen as boosting the weight of the edge by a factor 2^i, which is needed to counterbalance the i sampling steps in creating F_i.

Pseudocode of this algorithm can be found in Algorithm 1. Up to the computation method of the MSF packing, the presented algorithm is the same for polynomially and superpolynomially-weighted graphs. For the unbounded case, we use the MSF index estimator as presented in the full version. There we also detail how this influences the correctness of the algorithm, and the bounds on size and running time.

Algorithm 1 SPARSIFY(V, E, w, ϵ, c).

Input: An undirected graph $G = (V, E)$, with integer weights $w\colon E \to \mathbb{N}^+$, and parameters $\epsilon \in (0, 1)$, $c \geq 1$.
Output: An undirected weighted graph $G_\epsilon = (V, E_\epsilon)$.

Set $\rho \leftarrow \frac{(7+c)1352\ln(n)}{0.38\epsilon^2}$.
if $|E| \leq 4\rho n \log\left(m/(n\log(n)/\epsilon^2)\right)$ **then**
  return $G_\epsilon = G$.
end
Compute an $\lfloor 2\rho \rfloor$-partial maximum spanning forest packing $T_1, T_2, \ldots, T_{\lfloor 2\rho \rfloor}$ for G.
Set $i \leftarrow 0$.
Set $X_0 \leftarrow E$.
Set $F_0 \leftarrow \bigcup_{j=1}^{\lfloor 2\rho \rfloor} T_j$.
Set $Y_0 \leftarrow X_0 \setminus F_0$.
while $|Y_i| > 2\rho n$ **do**
  Sample each edge in Y_i with probability $1/2$ to construct X_{i+1}.
  $i \leftarrow i + 1$.
  Set $k_i \leftarrow \rho \cdot 2^{i+1}$.
  Compute an k_i-partial maximum spanning forest packing $T_1, T_2, \ldots, T_{k_i}$ for the graph $G_i := (V, X_i)$.
  Set $F_i \leftarrow \bigcup_{j=1}^{k_i} T_j$
  Set $Y_i \leftarrow X_i \setminus F_i$.
end
Set $\Gamma \leftarrow i$. // Γ is the number of elapsed iteration in the previous while-loop.

4.2 Correctness

We will prove that G_ϵ constructed in SPARSIFY$(V, E, w, \epsilon$,c) is a $(1 \pm \epsilon)$-cut sparsifier for G with probability at least $1 - 8/n^c$. Following the proof structure of [13], we first define

$$S := \left(\bigcup_{i=0}^{\Gamma} 2^i F_i\right) \cup 2^\Gamma Y_\Gamma,$$

where Γ is the maximum number such that $F_i \neq \emptyset$. We define $G_S := (V, S)$. And we prove the following two lemmas, that together yield the desired result.

▶ **Lemma 10.** *G_S is a $(1 \pm \epsilon/3)$-cut sparsifier for G with probability at least $1 - 4/n^c$.*

▶ **Lemma 11.** *G_ϵ is a $(1 \pm \epsilon/3)$-cut sparsifier for G_S with probability at least $1 - 4/n^c$.*

Let us start by proving Lemma 10. The omitted proofs of the lemmas and corollaries used can all be found in the full version. In creating the sets F_i, we repeatedly makes use of the MSF indices. The MSF index of an edge immediately ensures a certain connectivity of that edge. The following lemma makes this precise.

▶ **Lemma 12.** *Let $i \geq 0$ and $e \in Y_i$ be an edge, and set $k_i := \rho \cdot 2^{i+1}$. Then e is $w(e)k_i$-heavy in $G'_{i,e} = (V, X'_{i,e})$, where $X'_{i,e} := \{e' \in X_i : w(e') \geq w(e)\}$. Consequently, e is also $w(e)k_i$-heavy in $G_i = (V, X_i)$.*

Next, we show in a general setting that certain ways of sampling preserve cuts. The following lemma is a generalization of Lemma 5.5 in [13].

▶ **Lemma 13.** *Let $R \subseteq Q$ be subsets of weighted edges on some set of vertices V, satisfying $0 < w(e) \leq 1$ for all $e \in Q$. Moreover, assume that each edge in R is π-heavy in (V, Q). Suppose that each edge $e \in R$ is sampled with probability $p \in (0, 1]$, and if selected, given a weight of $w(e)/p$ to form a set of edges $\widehat{R}$. We denote, for every cut C:*

$$r^{(C)} := \sum_{e \in R \cap C} w(e), \qquad q^{(C)} := \sum_{e \in Q \cap C} w(e), \qquad \widehat{r}^{(C)} := \sum_{e \in = \widehat{R} \cap C} w(e)/p.$$

Let $\zeta \in \mathbb{N}_{\geq 5}$, and $\delta \in (0, 1]$ such that $\delta^2 p\pi \geq \frac{\zeta \ln(n)}{0.38}$, then

$$\left| r^{(C)} - \widehat{r}^{(C)} \right| \leq \delta q^{(C)}$$

for all cuts C, with probability at least $1 - 4/n^{\zeta - 4}$.

We want to apply this lemma to our sampling procedure. We do this by considering different weight classes separately. We define $X_{i,k} := \{e \in X_i : 2^k \leq w(e) \leq 2^{k+1} - 1\}$, and $x^{(C)}_{i,k} = \sum_{e \in X_{i,k} \cap C} w(e)$. We define $Y_{i,k}$ and $y^{(C)}_{i,k}$ analogously. Some rescaling is necessary to ensure that all weights lie in $(0, 1]$, as Lemma 13 requires. For $A \subseteq E$ and $\beta > 0$, we write βA to indicate we multiply the weight of the edges by a factor of β.

▶ **Lemma 14.** *With probability at least $1 - 4/n^{4+c}$, for every cut C in G_i,*

$$\left| 2^{-k} x^{(C)}_{i+1,k} - 2^{-k-1} y^{(C)}_{i,k} \right| \leq \frac{\epsilon/13}{2^{i/2+1}} \sum_{k'=k}^{\infty} 2^{-k'-1} x^{(C)}_{i,k'}.$$

Now we look at the general case, for which we sum all weight classes. Hereto, we define $x^{(C)}_i = \sum_{e \in X_i \cap C} w(e)$, $x^{(C)}_{i+1} = \sum_{e \in X_{i+1} \cap C} w(e)$, and $y^{(C)}_i = \sum_{e \in Y_i \cap C} w(e)$.

▶ **Corollary 15.** *With probability at least $1 - 4/n^{1+c}$, for every cut C in G_i,*

$$\left| 2x^{(C)}_{i+1} - y^{(C)}_i \right| \leq \frac{\epsilon/13}{2^{i/2}} \cdot x^{(C)}_i.$$

We will repeatedly apply this lemma. To show that the accumulated error does not grow beyond $\epsilon/3$, we use the following fact. For a proof we refer to [13].

▶ **Lemma 16.** *Let $x \in (0, 1]$ be a parameter. Then for any $k \geq 0$,*

$$\prod_{i=0}^{k} \left(1 + \frac{x/13}{2^{i/2}}\right) \leq 1 + x/3,$$

$$\prod_{i=0}^{k} \left(1 - \frac{x/13}{2^{i/2}}\right) \geq 1 - x/3.$$

As a final step towards proving Lemma 10, we prove a lemma that focusses on the sparsification occurring in the last $\Gamma - j + 1$ iterative steps of our algorithm.

▶ **Lemma 17.** *Let*

$$S_j = \left(\bigcup_{i=j}^{\Gamma} 2^{i-j} F_i \right) \cup 2^{\Gamma - j} Y_\Gamma$$

for any $j \geq 0$. Then, S_j is a $\left(1 \pm (\epsilon/3)2^{-j/2}\right)$-cut sparsifier for $G_j = (V, X_j)$, with probability at least $1 - 4/n^c$.

Note that setting $j = 0$ gives us Lemma 10.

To prove Lemma 11, we will invoke the framework from [13], as given in Section 2.1. More specifically, we will apply Theorem 6. We set the parameter $\gamma := 64/3$, and for each $e \in F_i$ we set $\lambda_e := \rho \cdot 4^i w(e)$. This is in line with our choice for p_e:

$$\min\left(1, \frac{16(c+7)\gamma \ln(n)}{0.38\lambda_e \epsilon^2}\right) = \min\left(1, \frac{16(c+7)\gamma \ln(n)}{0.38\rho \cdot 4^i w(e)_e \epsilon^2}\right) = \min\left(1, \frac{384}{169}\frac{1}{4^i w(e)}\right) = p_e.$$

We have to provide a set of subgraphs $\mathcal{G}$ and a set of parameters Π such that Π-connectivity and γ-overlap are satisfied.

To explore the connectivity of edges in $R_i := \{e \in E : 2^i \leq \lambda_e \leq 2^{i+1} - 1\}$ we partition these sets as follows:

$$R_{j,k} := \{e \in F_j : 2^k \leq \rho w(e) \leq 2^{k+1} - 1\}.$$

We will view these edges in the subgraph:

$$E_{j,k} := \bigcup_{j'=j-1}^{\Gamma} \bigcup_{k'=k}^{\infty} \rho \cdot 4^{\Gamma - j' + 1} 2^{\Lambda - k' + j'} R_{j',k'}.$$

▶ **Lemma 18.** *Each edge $e \in R_{j,k}$ is $\pi := \rho \cdot 4^\Gamma 2^\Lambda$-heavy in $(V, E_{j,k})$.*

Now we take all weight classes together to find the set of subgraphs $\mathcal{G}$ for which Π-connectivity is satisfied.

▶ **Corollary 19.** *Each edge in $e \in R_i$ is $\rho \cdot 4^\Gamma 2^\Lambda$-heavy in $G_i = (V, E_i)$, with $E_i := \bigcup_{j=1}^{\min(\lfloor i/2 \rfloor, \Gamma)} E_{j,i-2j}$.*

It remains to show that γ-overlap is satisfied.

▶ **Lemma 20.** *For any cut C,*

$$\sum_{i=0}^{\Lambda} \frac{e_i^{(C)} 2^{i-1}}{\rho \cdot 4^\Gamma 2^\lambda} \leq 64/3 \cdot e^{(C)},$$

where $e^{(C)} = \sum_{e \in C} w_{G_S}(e)$ and $e_i^{(C)} = \sum_{e \in C \cap E_i} w_{G_i}(e)$.

Together Corollary 19 and Lemma 20 show that the conditions of Theorem 6 are met with the given parameters. This proves Lemma 11, and then Theorem 9 follows.

4.3 Size of the Sparsifier

The sparsifier G_ϵ consists of F_0, Y_Γ, and F', where $F' = \cup_{i=1}^{\Gamma} F'_i$, with F'_i the sampled edges of F_i. First of all, note that $|F_0| = O(cn\ln(n)/\epsilon^2)$ and $|Y_\Gamma| = O(cn\ln(n)/\epsilon^2)$. Now take $e \in F_i$. This edge results to an edge in G_ϵ if the sample from the binomial distribution with parameters $n_e = 2^i w(e)$ and $p_e = \min\left(1, \frac{384}{169}\frac{1}{4^i w(e)}\right)$ is positive. The probability that this happens is

$$\begin{aligned}
\mathbb{P}[\text{Binom}(n_e, p_e) > 0] &= \sum_{k=1}^{n_e} \mathbb{P}[\text{Binom}(n_e, p_e) = k] && \leq \sum_{k=1}^{n_e} k\,\mathbb{P}[\text{Binom}(n_e, p_e) = k] \\
&= \sum_{k=0}^{n_e} k\,\mathbb{P}[\text{Binom}(n_e, p_e) = k] && = \mathbb{E}[\text{Binom}(n_e, p_e)] \\
&= n_e p_e && \leq \frac{384}{169} 2^{-i}.
\end{aligned}$$

Note that this probability is equal for all $e \in F_i$. Since F_i is the union of $k_i = \rho \cdot 2^{i+1}$ spanning forests, we know that $|F_i| \leq \rho 2^{i+1} n$. Hence the expected size of F'_i, the sampled edges in F_i, equals

$$\begin{aligned}
\mathbb{E}[|F'_i|] &= \sum_{e \in F_i} \mathbb{P}[\text{Binom}(n_e, p_e) > 0] \leq \sum_{e \in F_i} \frac{384}{169} 2^{-i} = |F_i| \frac{384}{169} 2^{-i} \leq \rho 2^{i+1} n \frac{384}{169} 2^{-i} \\
&= \rho \frac{768}{169} n.
\end{aligned}$$

We have that the total number of sampled edges equals

$$\mathbb{E}[|F'|] = \sum_{i=1}^{\Gamma} \mathbb{E}[|F'_i|] \leq \Gamma \rho \frac{768}{169} n,$$

so it remains to bound Γ, i.e., the number of F_i's. Hereto, note that the while loop of lines 10–17 ends if $|Y_i| \leq 2\rho n$. We bound the number of edges in Y_i by bounding the number of edges of X_i, of which Y_i is a subset. Each edge in $Y_{i-1} \subseteq X_{i-1}$ is sampled with probability $1/2$ to form X_i. So $\mathbb{E}[|X_i|] \leq |X_{i-1}|/2$. Now by a Chernoff bound (see Theorem 26) we obtain:

$$\mathbb{P}\left[|X_i| > \frac{2}{3}|X_{i-1}|\right] \leq \exp\left(-\frac{0.38}{36}|X_{i-1}|\right) > \exp\left(-\frac{cn\ln(n)}{36}\right) = n^{-cn/36},$$

since $|X_{i-1}| \geq |Y_{i-1}| \geq 2\rho n = 2 \cdot \frac{(7+c)1352\ln(n)}{0.38\epsilon^2} n \geq \frac{cn\ln(n)}{0.38}$. We have at most n^2 sets X_i, so we can conclude that with high probability $|X_i| \leq \frac{2}{3}|X_{i-1}|$ in each step, and by induction $|Y_i| < |X_i| \leq \left(\frac{2}{3}\right)^i m$. We see that

$$m\left(\frac{2}{3}\right)^{\Gamma} \leq 2\rho n = \frac{21632}{0.38\epsilon^2} cn\ln(n),$$

which is equivalent to

$$\Gamma \geq \log\left(\frac{m}{\frac{21632}{0.38\epsilon^2} cn\ln(n)}\right) / \log(3/2).$$

So, we can conclude $\Gamma = O\left(\log\left(\frac{m}{cn\log(n)/\epsilon^2}\right)\right)$. This gives that the total number of sampled edges is, in expectation,

$$\mathbb{E}[|F'|] \leq \Gamma \rho \frac{768}{169} n = O(cn\log(n)\log\left(m/(cn\log(n)/\epsilon^2)\right)/\epsilon^2).$$

This compression process can also be seen as the sum of m independent random variables that take values in $\{1, 0\}$.[3] We have just calculated that the expected value μ is at most $Bcn\ln(n)\log\left(m/(cn\log(n)/\epsilon^2)\right)/\epsilon^2$, for some $B > 0$. Using this, we apply a Chernoff bound (Theorem 26) to get an upper limit for the number of sampled edges:

$$\begin{aligned}
&\mathbb{P}\left[|F'| > 2Bcn\ln n\log\left(m/(cn\log(n)/\epsilon^2)\right)/\epsilon^2\right] \\
&\qquad \leq \exp\left(-0.38Bcn\ln(n)\log\left(m/(cn\log(n)/\epsilon^2)\right)/\epsilon^2\right) \\
&\qquad = n^{-0.38cnB\log\left(m/(cn\log(n)/\epsilon^2)\right)/\epsilon^2}.
\end{aligned}$$

We conclude that, with high probability, the number of sampled edges is

$$O(2Bcn\ln(n)\log\left(m/(cn\log(n)/\epsilon^2)\right)/\epsilon^2) = O(cn\log(n)\log\left(m/(cn\log(n)/\epsilon^2)\right)/\epsilon^2).$$

And finally, we conclude that with high probability the number of edges of G_ϵ is bounded by $|E(G_\epsilon)| = |F_0| + |Y_\Gamma| + |F'| = O(cn\log(n)\log\left(m/(cn\log(n)/\epsilon^2)\right)/\epsilon^2)$.

4.4 Time Complexity

First off, if $m \leq 4\rho n\log\left(m/(n\log(n)/\epsilon^2)\right) = O(cn\log(n)/\epsilon^2\log\left(m/(n\log(n)/\epsilon^2)\right))$, the algorithm does nothing and returns the original graph. So for this analysis we can assume $m > 4\rho n\log\left(m/(n\log(n)/\epsilon^2)\right)$. We analyze the time complexity of the algorithm in two phases. The first phase consists of computing the probabilities p_e for all $e \in E$. The second one is compressing edges, given these probabilities.

The first phase contains i iterations of the while loop (lines 10–17). In each iteration we sample edges from $Y_i \subseteq X_i$ with probability $1/2$ to form X_{i+1}. This takes time at most $O(|X_i|)$. Next, we compute a maximum spanning forest packing of the graph $G_{i+1} = (V, X_{i+1})$. We know that we can compute a M-partial maximum spanning forest packing of a polynomially-weighted graph with n vertices and m_0 edges in $O(m_0 \cdot \min(\alpha(n)\log(M), \log(n)))$ time (see Theorem 8). So this iteration takes at most $O(|X_{i+1}| \cdot (\min(\alpha(n)\log(k_{i+1}), \log(n))))$ time. As noted earlier, we have with high probability that $|X_i| \leq \left(\frac{2}{3}\right)^i m$. If $m\alpha(n)\log(m/n) \leq m\log(n)$, we conclude w.h.p. that the first phase takes total time at most

$$\begin{aligned}
\sum_{i=0}^{\Gamma} O(|X_i|) + O(|X_{i+1}|\alpha(n)\log(k_{i+1})) &= \sum_{i=0}^{\Gamma}\left(\frac{2}{3}\right)^i O(m) + \left(\frac{2}{3}\right)^{i+1} O(m\alpha(n)\log(\rho 2^{i+2})) \\
&\leq 3O(m) + 3O(m\alpha(n)\log(\rho 2^{\Gamma})) \\
&= O(m\alpha(n)\log(m/n)).
\end{aligned}$$

And if $m\log(n) < m\alpha(n)\log(m/n)$, we have that w.h.p. the first phase takes total time at most

$$\begin{aligned}
\sum_{i=0}^{\Gamma} O(|X_i|) + O(|X_{i+1}|\log(n)) &= \sum_{i=0}^{\Gamma}\left(\frac{2}{3}\right)^i O(m) + \left(\frac{2}{3}\right)^{i+1} O(m\log(n)) \\
&\leq 3O(m) + 3O(m\log(n)) \\
&= O(m\log n).
\end{aligned}$$

In the second phase, we sample each edge e from the binomial distribution with parameters n_e and p_e. We will show this can be done with a process that takes $T = O(m)$ time with high probability.

[3] To be precise, we set the probability of an edge $e \notin \bigcup_i F_i$ to exist to 0.

▶ **Lemma 21.** *With high probability, the sampling phase of Algorithm 1 takes $O(m)$ time.*

For the proof, see the full version. Concluding, the algorithm takes

$$O(m \cdot \min(\alpha(n)\log(m/n), \log(n)) + O(m) = O(m \cdot \min(\alpha(n)\log(m/n), \log(n))$$

time in total for polynomially-weighted graphs.

5 Conclusion

In this paper, we presented a faster $(1 \pm \epsilon)$-cut sparsification algorithm for weighted graphs. We have shown how to compute sparsifiers of size $O(n\log(n)/\epsilon^2)$ in $O(m \cdot \min(\alpha(n)\log(m/n), \log(n)))$ time, for integer weighted graphs. Both algorithms apply a sampling technique where the MSF index is used as a connectivity estimator.

We have shown that we can compute an M-partial MSF packing in $O(m\alpha(m)\log(M))$ time for polynomially-weighted graphs. For graphs with unbounded integer weights, we have shown that we can compute a complete MSF packing in $O(m\log(n))$ time, and a sufficient estimation of an M-partial MSF packing can be computed in time $O(m\alpha(m)\log(M))$. An open question is whether a more efficient computation is possible. This would improve on our sparsification algorithm, but might also be advantageous in other applications. The NI index has shown to be useful in various applications. We believe to have shown that the MSF index is a natural analogue.

To develop an algorithm to compute an MSF packing, one might be inclined to build upon one of the algorithms that compute a minimum spanning tree faster than Kruskal's algorithm, such as the celebrated linear-time algorithm of Karger, Klein, and Tarjan [19]. However, this algorithm and many other fast minimum spanning tree algorithms make use of edge contractions. It is far from obvious how to generalize this to a packing: in that case, we need to work simultaneously on multiple trees, hence we cannot simply contract the input graph in favor of any single one. To make this work, a more meticulous use of data structures seems necessary.

Computation of the MSF indices in linear time would be an ultimate goal. However, for our application a slightly looser bound suffices. If we can reduce the running time to compute the MSF indices to $O(m + n\log(n))$, then we obtain a time bound of $O(m)$ for cut sparsification. Moreover, we do not need the exact MSF index, an estimate suffices. This can either be a constant-factor approximation of the MSF index for each edge, or an estimate in the weights used in the forests, as done for graphs with unbounded weights in the full version.

A Review: A First Application of the Sparsification Framework

In this section, we review the application of the framework of Section 2.1 with *Nagamochi-Ibaraki (NI) indices* as parameters, as presented by Fung et al. [13]. As the name suggests, NI indices were first introduced by Nagamochi and Ibaraki [24, 25]. The algorithm they provide gives a graph partitioning into forests, and subsequently a corresponding index for each edge, called the NI index.

▶ **Definition 22.** *Let $G = (V, E)$ be a graph, possibly weighted. We say an edge-disjoint sequence $F_1, F_2, \ldots$ of forests is a* Nagamochi-Ibaraki forest packing *for G if F_i is a spanning forest for $G \setminus \bigcup_{j=1}^{i-1} F_i$, where the weights of $\bigcup_{j=1}^{i-1} F_i$ are subtracted of G. If G is a weighted graph, each edge e must be contained in $w(e)$ contiguous forests. We define the* NI index*, denoted by l_e, to be the index of the (last if weighted) forest in which e appears.*

Nagamochi and Ibaraki show that the NI indices can be computed in linear time for unweighted graphs and in $O(m + n\log(n))$ time for weighted graphs, see [25, 24]. As is shown in [13], we can use the NI index as the connectivity estimator in the sparsification framework to obtain the following result.

▶ **Theorem 23.** *Let $G = (V, E)$ be a weighted graph, and let $\epsilon > 0$ be a constant. Let G_ϵ be obtained by independently compressing each edge with parameter $p_e = \min(1, \rho/l_e)$, where $\rho = \frac{224}{0.38}\ln(n)/\epsilon^2$. Then G_ϵ is a $(1 \pm \epsilon)$-cut sparsifier for G with high probability.*

The sampling itself takes at most $O(m)$ time, as explained in Lemma 21. As the NI indices can be computed in $O(m + n\log(n))$ time, this implies that the total running time is $O(m+n\log(n))$. As a graph with $m \leq n\log(n)$ is already sparse, we can assume $m > n\log(n)$. Thus, for our purposes, the total running time is simply $O(m)$.

Next we provide a bound for the number of edges in the sparsifier G_ϵ. Fung et al. [13] prove this same bound in expectation, we provide a proof for this bound "with high probability".

▶ **Lemma 24.** *With high probability, the size of the graph G_ϵ in Theorem 23 is $O(n\log^2(n)/\epsilon^2)$.*

Proof. Let $v \in V$ be a vertex with degree $d_v \geq O(\log^2(n)/\epsilon^2)$ in G. We denote the degree of v in G_ϵ by d'_v and we write $d' := \max_{v\in V} d'_v$. For each neighbor u of v in G, we compress the edge $e = (u, v)$ with parameter $p_e = \min\left(1, \frac{224\ln(n)}{0.38\epsilon^2 l_e}\right)$, where l_e is the NI index of e. For each edge, the probability that it remains after compression is $1 - (1 - p_e)^{w_e}$. From Bernoulli's inequality we see $1 - (1 - p_e)^{w_e} \leq w_e p_e$. Let Y_e be the random variable that is 1 if e remains, and 0 else. We note that $\mathbb{E}\left[\sum_{e:v\in e} Y_e\right] \leq \frac{224}{0.38}\ln^2(n)/\epsilon^2$. Now we apply a Chernoff bound (Theorem 26) to obtain

$$\mathbb{P}\left[d'_v \geq \delta\frac{224}{0.38}\ln^2(n)/\epsilon^2\right] \leq \exp\left(-0.38\delta\frac{224}{0.38}\ln^2(n)/\epsilon^2\right) = n^{-224\delta\ln(n)/\epsilon^2}.$$

Using a union bound we get the desired result

$$\mathbb{P}\left[d' \leq \delta \frac{224}{0.38} \ln^2(n)/\epsilon^2\right] \geq 1 - n^{1-224\delta \ln(n)/\epsilon^2}.$$

Consequently, we obtain that with high probability the number of edges of the sparsifier is at most $O(n \log^2(n)/\epsilon^2)$. ◀

The state of the art for polynomially-weighted graphs is achieved by postprocessing this result with the algorithm by Benczúr and Karger [7]. Thus our improvement on Benczúr and Karger leads to an overall improved result.

B Tail bounds

To analyze the sampling methods used in Section 4, we make use of the well-known Chernoff bound to get a grasp on the tail of various distributions [8].

▶ **Theorem 25.** *Let $Y_1, \ldots, Y_n$ be n independent random variables such that each Y_i takes values in $[0, 1]$. Let $\mu = \sum_{i=1}^{n} \mathbb{E}[Y_i]$ and $\xi = 2\ln(2) > 0.38$. Then for all $\epsilon > 0$*

$$\mathbb{P}\left[\left|\sum_{i=1}^{n} Y_i - \mu\right| > \epsilon\mu\right] \leq 2\exp\left(-\xi \min(\epsilon, \epsilon^2)\mu\right).$$

At times, the expected value μ itself is not known. Fortunately an upper bound on the expected value also suffices.

▶ **Theorem 26.** *Let $Y_1, \ldots, Y_n$ be n independent random variables such that Y_i takes values in $[0, 1]$. Let $\mu = \sum_{i=1}^{n} \mathbb{E}[Y_i]$ and $\xi = 2\ln(2) > 0.38$. Suppose $\mu' \geq \mu$. Then for all $\delta \geq 2$*

$$\mathbb{P}\left[\sum_{i=1}^{n} Y_i > \delta\mu'\right] \leq 2\exp\left(-\xi(\delta - 1)\mu'\right).$$

Proof. Let $\epsilon := (\delta - 1)\frac{\mu'}{\mu}$. We have $\epsilon \geq 1$, so $\min(\epsilon, \epsilon^2) = \epsilon$. The statement now follows directly from Theorem 25. ◀

C Reduction from Real to Integer Weights

In this section, we show how to reduce the computation of a cut sparsifier of a graph with non-negative real weights to integer weights, formalizing the procedure sketched by Benczúr and Karger [7]. Let $G = (V, E, w)$ be a weighted graph, where $w\colon E \to \mathbb{R}$. Denote $W_{\max} := \max_{e \in E} w(e)$ and $W_{\min} := \min\left\{1, \min_{e \in E} w(e)\right\}$. Then the reduction consists of the following steps:

1. Compute $W_{\min}$ and $r := -\lfloor \log(\frac{\epsilon}{2} W_{\min}) \rfloor$.
2. Create $w'\colon E \to \mathbb{R}$ by rounding the weights $w(e)$ to the closest multiple of 2^{-r}, and define $G' := (V, E, w')$.
3. Create $\hat{w}\colon E \to \mathbb{R}$ by $\hat{w}(e) := 2^r w'(e)$.
4. Compute a $(1 \pm \epsilon/3)$-cut sparsifier $\hat{H} = (V, E_H, \hat{w}_H)$ of $\hat{G} = (V, E, \hat{w})$.
5. Output $H = (V, E_H, w_H)$ where $w_H(e) := 2^{-r}\hat{w}_H(e)$.

First, we show that the graph H is indeed a $(1+\epsilon)$-cut sparsifier of G. Hereto, we note that for any cut C we have

$$w_H(C) = 2^{-r} w_{\hat{H}}(C) \leq 2^{-r}(1+\epsilon/3) w_{\hat{G}}(C) = (1+\epsilon/3) w_{G'}(C) \leq (1+\epsilon) w_G(C),$$

where the last inequality holds as each weight $w'(e)$ has at most an additive error of $2^{-r} \leq \frac{\epsilon}{2} W_{\min} \leq \frac{\epsilon}{2}$ with respect to $w(e)$, hence at most an multiplicative error of $\frac{\epsilon}{2}$. Analogously we obtain $w_H(C) \geq (1-\epsilon) w_G(C)$.

By construction, $\hat{G}$ has integer weights, which are bounded by $O(\frac{W_{\max}}{\epsilon W_{\min}})$. Steps 1, 2, 3, and 5 can be implemented in $O(m)$ time. So indeed we have reduced the problem to finding a cut sparsifier of a graph with integer weights. Moreover, note that if G has polynomially bounded real weights, in the sense that $W_{\max} = O(\text{poly}(n))$ and $W_{\min} = \Omega(1/\text{poly}(n))$, then the graph $\hat{G}$ has polynomially bounded integer weights. We can state this independent of ϵ, since for $\epsilon \leq 1/m$ we can always output the entire input graph as a cut sparsifier of optimal size $O(n/\epsilon^2)$ [3].

Social Distancing Network Creation

Abstract

During a pandemic people have to find a trade-off between meeting others and staying safely at home. While meeting others is pleasant, it also increases the risk of infection. We consider this dilemma by introducing a game-theoretic network creation model in which selfish agents can form bilateral connections. They benefit from network neighbors, but at the same time, they want to maximize their distance to all other agents. This models the inherent conflict that social distancing rules impose on the behavior of selfish agents in a social network. Besides addressing this familiar issue, our model can be seen as the inverse to the well-studied Network Creation Game by Fabrikant et al. [PODC 2003] where agents aim at being as central as possible in the created network. Thus, our work is in-line with studies that compare minimization problems with their maximization versions.

We look at two variants of network creation governed by social distancing. In the first variant, there are no restrictions on the connections being formed. We characterize optimal and equilibrium networks, and we derive asymptotically tight bounds on the Price of Anarchy and Price of Stability. The second variant is the model's generalization that allows restrictions on the connections that can be formed. As our main result, we prove that Swap-Maximal Routing-Cost Spanning Trees, an efficiently computable weaker variant of Maximum Routing-Cost Spanning Trees, actually resemble equilibria for a significant range of the parameter space. Moreover, we give almost tight bounds on the Price of Anarchy and Price of Stability. These results imply that, compared the well-studied inverse models, under social distancing the agents' selfish behavior has a significantly stronger impact on the quality of the equilibria, i.e., allowing socially much worse stable states.

1 Introduction

Network Design is a core topic in Theoretical Computer Science and Operations Research. Many classical combinatorial optimization problems, inspired by real world applications, have been formulated and analyzed, such as the Minimum Spanning Tree problem [29], the Network Design problem [35, 41] and finding geometric spanners [14, 46]. Typically, a network having certain properties must be found by a centralized algorithm. However, in

many settings, the desired network is not created by a central authority but by individually acting agents, e.g., people or institutions, controlling a local part of the network. Prominent examples are the Internet, road networks, and, most relevant for our work, social networks.

Especially in settings with little coordination, these individual agents tend to selfishly optimize their own utility without taking the impact of their actions on the efficiency of the whole network into account. To better understand the dynamics arising in these decentralized settings and the network structures resulting from them, many influential game-theoretic network formation models have been introduced in the last decades [33, 9, 23, 7, 8]. The main research questions are: Do equilibrium networks, i.e., stable networks where no agent can improve by performing a local change, exist? What properties do these networks have? And how efficient are they compared to centrally computed optimal solutions?

All of the above mentioned influential game-theoretic network formation models assume that the creation of an edge is costly but the agents benefit from having small distances to other agents in the network. However, departing from this standard assumption in the field, there are real-world settings that should better be modeled via an inverted utility function: neighbors yield benefit but being close to many agents is costly as it yields an increased risk. One example for this choice are financial networks. There, financial institutions benefit from working together but suffer from risks arising from one of them failing[1]. Another example, that is the main motivation of our work, came up with the current COVID-19 pandemic and is described by the now commonly used term *social distancing*. It refers to reducing social contacts in order to contain the spread of a contagious virus in the population. While often mandated by the government, social distancing was performed by many people voluntarily. One of the main reasons is quite simple: While reducing social contacts is a restriction of the quality of life, it also reduces the probability of getting infected. Hence, the network of social interactions between people was sparsified by individual strategic decisions.

In this work we introduce a novel game-theoretic network formation model in which selfish agents strategically form a social network under the influence of social distancing. Agents benefit from direct connections to other agents, modeling the positive effects of social contacts on their social life. However, at the same time they want to maximize their distances to all other agents in the network in order to reduce their risk of getting infected via an increased reaction time in case a contagious disease starts spreading in the network. Here we assume that a random network node becomes infected and that it is beneficial to be far away from the source of infection in order to gain valuable time for setting up counter-measures.

The agents in our model act according to an inverted utility function, compared to the famous models by Jackson and Wolinsky [33] and Fabrikant et al. [23]. Thus, to the best of our knowledge, this is one of the rare cases of a game-theoretic model where both minimizing and maximizing the utility function has a natural interpretation. Another similar well-known example is the contrast between the Network Design Game with fair cost sharing by Anshelevich et al. [7] and the Selfish Routing model by Roughgarden and Tardos [47]. In both models the agents select paths in a given network but in the former sharing an edge is beneficial for the involved agents whereas in the latter edge sharing is detrimental. This difference yields vastly different behavior in terms of the quality of the equilibria. However, this is not obvious, as can also be seen by comparing classical minimization and maximization variants of optimization problems, e.g., Minimum Spanning Tree versus Maximum Spanning Tree or Shortest Path versus Longest Path. Sometimes, as with spanning trees, the inverse problems are almost identical, whereas sometimes, as with the

[1] The financial crisis in the late 2000s was mainly driven by contagious network effects of failing banks.

path problems, the inverse problems may have completely opposite behavior. We set out to explore this comparison for the natural inverse counter-part to the well-known Network Creation Game by Fabrikant et al. [23]. Along the way, we will uncover a connection to the Maximum Routing-Cost Spanning Tree problem that is inverse to the well-studied Minimum Routing-Cost Spanning Tree problem [31][2].

1.1 Model and Notation

Before we start with the model definition, we introduce some notation regarding networks. A *network* is a tuple $G \coloneqq (V, E)$ where V is the set of *nodes* and E is the set of *edges*. An *edge* is represented by a set containing both incident nodes. If we do not give the tuple defining G explicitly, we denote the set of nodes of G as V_G and the set edges of G as E_G. We only consider unweighted undirected networks. For addition and removal of a single edge e, we write $G + e \coloneqq (V, E \cup \{e\})$ and $G - e \coloneqq (V, E \setminus \{e\})$. A network G' with $V_{G'} \subseteq V$ and $E_{G'} \subseteq E$ is called a *subnetwork* of G and denoted as $G' \leq G$. If G' is connected and $V_{G'} = V$, G' is a *spanning subnetwork* of G. Let $n \in \mathbb{N}$ denote the number of nodes. The set of all connected networks containing exactly n nodes will be referred to as $\mathcal{G}_n$.

For two nodes $v, x \in V$, we define $d_G(v, x)$ as the *distance* between v and x in network G, that is, the number of edges on a shortest path from v to x in G. For convenience, we extend the definition of d_G to sets of nodes: Let $v \in V$ be a node and $M, N \subseteq V$ be sets of nodes. Then $d_G(v, M) \coloneqq \sum_{x \in M} d_G(v, x)$ and $d_G(M, N) \coloneqq \sum_{x \in M, y \in N} d_G(x, y)$. We call the special case $d_G(v, V)$ the *distances from/for* v and $d_G(V, V)$ the *total/summed distances* or *routing costs* of G. The *degree* of v in the network G is the number of edges that are incident to v and is denoted as $\deg_G(v)$. We call a tree which is a spanning subnetwork of G a *spanning tree* of G. A spanning tree of G with routing costs at least as high as the routing costs of any other spanning tree of G will be called a *Maximum Routing-Cost Spanning Tree* (MRCST). A spanning tree of G with routing costs that cannot be increased by swapping one edge is a *Swap-Maximal Routing-Cost Spanning Tree* (SMRCST).

Now, we can define the game-theoretic model. Let $H = (V, E)$ be a connected network. We call H the *host network* and its nodes *agents*. A *state* of the game $G \leq H$ is a spanning subnetwork of H. We only consider connected networks as host networks and states.

Each agent $v \in V$ selfishly tries to maximize its utility in state G given by

$$u_v(G) \coloneqq \alpha \deg_G(v) + d_G(v, V)$$

where $\alpha \in \mathbb{R}_{>0}$ is a global parameter. We will call $\alpha \deg_G(v)$ the *edge utility* and $d_G(v, V)$ the *distance utility* of v. Note that α is a parameter of the game, i.e., equal for all agents, that allows to adjust the agents' trade-offs between edge utility and distance utility. Here α is the benefit of a single edge, i.e., the benefit for each direct neighbor in the network.

For measuring the efficiency of the network G, we use the *social welfare* defined as $\mathrm{SW}(G) \coloneqq \sum_{v \in V_G} u_v(G) = 2\alpha|E_G| + d_G(V, V)$. This quantifies the well-being of the society of all agents. We call a network maximizing the social welfare for the host network H a *social optimum* and denote it as OPT_H.

Agents are allowed to form connections bilaterally. More specifically, each agent can unilaterally remove any incident edge if it does not disconnect the network, and two agents together can form an edge between them if it is contained in the host network. If removing an edge strictly increases the utility of one of its incident nodes or adding an edge strictly

[2] This problem is also known as the Optimum Communication Spanning Tree problem.
