Abstract
We show that the space-bounded Statistical Zero Knowledge classes $SZK_L$ and $NISZK_L$ are surprisingly robust, in that the power of the verifier and simulator can be strengthened or weakened without affecting the resulting class. Coupled with other recent characterizations of these classes [4], this can be viewed as lending support to the conjecture that these classes may coincide with the non-space-bounded classes $SZK$ and $NISZK$, respectively.

Acknowledgements This work was done in part while EA and HT were visiting the Simons Institute for the Theory of Computing. This work was carried out while JG, SM, and PW were participants in the 2022 DIMACS REU program at Rutgers University. We thank Yuval Ishai for helpful conversations about SREN, and we thank Markus Lohrey, Sam Buss, and Dave Barrington for useful discussions about Lemma 34. We also thank the anonymous referees for helpful comments.

1 Introduction

The complexity class $SZK$ (Statistical Zero Knowledge) and its “non-interactive” subclass $NISZK$ have been studied intensively by the research communities in cryptography and computational complexity theory. In [12], a space-bounded version of $SZK$, denoted $SZK_L$, was introduced, primarily as a tool for understanding the complexity of estimating the entropy of distributions represented by very simple computational models (such as low-degree polynomials, and $NC^0$ circuits). There, it was shown that $SZK_L$ contains many important problems previously known to lie in $SZK$, such as Graph Isomorphism, Discrete Log, and
Decisional Diffie-Hellman. The corresponding “non-interactive” subclass of $\text{SZK}_L$, denoted $\text{NISZK}_L$, was subsequently introduced in [1], primarily as a tool for clarifying the complexity of computing time-bounded Kolmogorov complexity under very restrictive reducibilities (such as projections). Just as every problem in $\text{SZK} \leq_{tt}^{\text{AC}^0}$ reduces to problems in $\text{NISZK}$ [14], so also every problem in $\text{SZK}_L \leq_{tt}^{\text{AC}^0}$ reduces to problems in $\text{NISZK}_L$, and thus $\text{NISZK}_L$ contains intractable problems if and only if $\text{SZK}_L$ does.

Very recently, all of these classes were given surprising new characterizations, in terms of efficient reducibility to the Kolmogorov random strings. Let $\tilde{R}_K$ be the (undecidable) promise problem $(Y_{\tilde{R}_K}, N_{\tilde{R}_K})$ where $Y_{\tilde{R}_K}$ contains all strings $y$ such that $K(y) \geq |y|/2$ and the NO instances $N_{\tilde{R}_K}$ consists of those strings $y$ where $K(y) \leq |y|/2 - \epsilon(|y|)$ for some approximation error term $\epsilon(n)$, where $\epsilon(n) = \omega(\log n)$ and $n = n^{o(1)}$.

**Theorem 1 ([4]).** Let $A$ be a decidable promise problem. Then

- $A \in \text{NISZK}$ if and only if $A$ is reducible to $\tilde{R}_K$ by randomized polynomial time reductions.
- $A \in \text{NISZK}_L$ if and only if $A$ is reducible to $\tilde{R}_K$ by randomized $\text{AC}^0$ or logspace reductions.
- $A \in \text{SZK}$ if and only if $A$ is reducible to $\tilde{R}_K$ by randomized polynomial time “Boolean formula” reductions.
- $A \in \text{SZK}_L$ if and only if $A$ is reducible to $\tilde{R}_K$ by randomized logspace “Boolean formula” reductions.

In all cases, the randomized reductions are restricted to be “honest”, so that on inputs of length $n$ all queries are of length $\geq n'$.

There are very few natural examples of computational problems $A$ where the class of problems reducible to $A$ via polynomial-time reductions differs (or is conjectured to differ) from the class or problems reducible to $A$ via $\text{AC}^0$ reductions. For example the natural complete problems for $\text{NISZK}$ under $\leq_{\text{p}}$ reductions remain complete under $\text{AC}^0$ reductions. Thus Theorem 1 gives rise to speculation that $\text{NISZK}$ and $\text{NISZK}_L$ might be equal. (This would also imply that $\text{SZK} = \text{SZK}_L$.)

This motivates a closer examination of $\text{SZK}_L$ and $\text{NISZK}_L$, to answer questions that have not been addressed by earlier work on these classes.

Our main results are:

1. **The verifier and simulator may be very weak.** $\text{NISZK}_L$ and $\text{SZK}_L$ are defined in terms of three algorithms: (1) A logspace-bounded verifier, who interacts with (2) a computationally-unbounded prover, following the usual rules of an interactive proof, and (3) a logspace-bounded simulator, who ensures the zero-knowledge aspects of the protocol. (More formal definitions are to be found in Section 2.) We show that the verifier and simulator can be restricted to lie in $\text{AC}^0$. Let us explain why this is surprising.

   The proof presented in [1], showing that $E_{\text{NISZK}_L}$ is complete for $\text{NISZK}_L$, makes it clear that the verifier and simulator can be restricted to lie in $\text{AC}^0$. Let us explain why this is surprising.

   The proof presented in [1], showing that $E_{\text{NISZK}_L}$ is complete for $\text{NISZK}_L$, makes it clear that the verifier and simulator can be restricted to lie in $\text{AC}^0$. Let us explain why this is surprising.

2. **The verifier and simulator may be somewhat stronger.** The proof presented in [1], showing that $E_{\text{NISZK}_L}$ is complete for $\text{NISZK}_L$, also makes it clear that the verifier and simulator can be as powerful as $\oplus L$, without leaving $\text{NISZK}_L$. This is because the proof relies on the fact that logspace computation lies in the complexity class $\text{PREN}$ of functions that have perfect randomized encodings [7], and $\oplus L$ also lies in $\text{PREN}$. Applebaum, Ishai, and Kushilevitz defined $\text{PREN}$ and the somewhat larger class $\text{SREN}$ (for statistical
randomized encodings), in proving that there are one-way functions in SREN if and only if there are one-way functions in NC$^0$. They also showed that other important classes of functions, such as NL and GapL, are contained in SREN.$^1$ We initially suspected that NISZK$_L$ could be characterized using verifiers and simulators computable in GapL (or even in the slightly larger class DET, consisting of problems that are $\leq_{T}^{NC^1}$ reducible to GapL), since DET is known to be contained in NISZK$_L$ [1].$^2$ However, we were unable to reach that goal.

We were, however, able to show that the simulator and verifier can be as powerful as NL, without making use of the properties of SREN. In fact, we go further in that direction. We define the class PM, consisting of those problems that are $\leq_{T}^{L}$-reducible to the Perfect Matching problem. PM contains NL [18], and is not known to lie in (uniform) NC (and it is not known to be contained in SREN). We show that statistical zero knowledge protocols defined using simulators and verifiers that are computable in PM yield only problems in NISZK$_L$.

3. The complexity of the simulator is key. As part of our attempt to characterize NISZK$_L$ using simulators and verifiers computable in DET, we considered varying the complexity of the simulator and the verifier separately. Among other things, we show that the verifier can be as complex as DET if the simulator is logspace-computable. In most cases of interest, the NISZK class defined with verifier and simulator lying in some complexity class remains unchanged if the rules are changed so that the verifier is significantly stronger or weaker.

We also establish some additional closure properties of NISZK$_L$ and SZK$_L$, some of which are required for the characterizations given in [4].

The rest of the paper is organized as follows: Section 3 will show how NISZK$_L$ can be defined equivalently using an AC$^0$ verifier and simulator. Section 4 will show that increasing the power of the verifier and simulator to lie in PM does not increase the size of NISZK$_L$ (where PM is the class of problems (containing NL) that are logspace Turing reducible to Perfect Matching). Section 5 expands the list of problems known to lie in NISZK$_L$. McKenzie and Cook [20] studied different formulations of the problem of solving linear congruences. These problems are not known to lie in DET, which is the largest well-studied subclass of P known to be contained in NISZK$_L$. However, these problems are randomly logspace-reducible to DET [8]. We show that NISZK$_L$ is closed under randomized logspace reductions, and hence show that these problems also reside in NISZK$_L$. Section 6 shows that the complexity of the simulator is more important than the complexity of the verifier, in non-interactive zero-knowledge protocols. In particular, the verifier can be as powerful as DET, while still defining only problems in NISZK$_L$. Finally Section 7 will show that SZK$_L$ is closed under logspace Boolean formula truth-table reductions.

2 Preliminaries

We assume familiarity with basic complexity classes L, NL, $\oplus$L and P, and circuit complexity classes NC$^0$ and AC$^0$. We assume knowledge of m-reducibility (many-one-reducibility) and Turing-reducibility. $\#L$ is the class of functions that count the number of accepting paths of NL machines, and GapL = \{f−g : f, g ∈ $\#L$\}. The determinant is complete for GapL, and the complexity class DET is the class of languages NC$^1$-Turing reducible to functions in GapL.

$^1$ This is not stated explicitly for GapL, but it follows from [17, Theorem 1]. See also [11, Section 4.2].

$^2$ More precisely, as observed in [3], the Rigid Graph (non-) Isomorphism problem is hard for DET [26], and the Rigid Graph Non-Isomorphism problem is in NISZK$_L$ [1, Corollary 23].
Many of the problems we consider deal with entropy (also known as Shannon entropy). The \textit{entropy} of a distribution \( X \) (denoted \( H(X) \)) is the expected value of \( \log(1/\Pr[X = x]) \).

Given two distributions \( X \) and \( Y \), the \textit{statistical difference} between the two is denoted \( \Delta(X,Y) \) and is equal to \( \sum_{\alpha} |\Pr[X = \alpha] - \Pr[Y = \alpha]|/2 \). Equivalently, for finite domains \( D \), \( \Delta(X,Y) = \max_{S \subseteq D} \{|\Pr_X[S] - \Pr_Y[S]|\} \). This quantity is also known as the \textit{total variation distance} between \( X \) and \( Y \). The support of \( X \), denoted \( \text{supp}(X) \), is \( \{ x : \Pr[X = x] > 0 \} \).

\textbf{Definition 2.} Promise Problem: a promise problem \( \Pi \) is a pair of disjoint sets \((\Pi_Y, \Pi_N)\) (the “\textit{YES}” and “\textit{NO}” instances, respectively). A solution for \( \Pi \) is any set \( S \) such that \( \Pi_Y \subseteq S \), and \( S \cap \Pi_N = \emptyset \).

\textbf{Definition 3.} A branching program is a directed acyclic graph with a single source and two sinks labeled 1 and 0, respectively. Each non-sink node in the graph is labeled with a variable in \( \{x_1, \ldots, x_n\} \) and has two edges leading out of it: one labeled 1 and one labeled 0. A branching program computes a Boolean function \( f \) on input \( x = x_1 \ldots x_n \) by first placing a pebble on the source node. At any time when the pebble is on a node \( v \) labeled \( x_i \), the pebble is moved to the (unique) vertex \( u \) that is reached by the edge labeled 1 if \( x_i = 1 \) (or by the edge labeled 0 if \( x_i = 0 \)). If the pebble eventually reaches the sink labeled \( b \), then \( f(x) = b \). Branching programs can also be used to compute functions \( f : \{0, 1\}^m \rightarrow \{0, 1\}^n \), by concatenating \( n \) branching programs \( p_1, \ldots, p_n \), where \( p_i \) computes the function \( f_i(x) = \text{the } i\text{-th bit of } f(x) \). For more information on the definitions, backgrounds, and nuances of these complexity classes, circuits, and branching programs, see the text by Vollmer [27].

\textbf{Definition 4 (Non-interactive zero-knowledge proof (NISZK), adapted from [1, 14]).} A non-interactive statistical zero-knowledge proof system for a promise problem \( \Pi \) is defined by a pair of deterministic polynomial time machines\(^3\) \((V, S)\) (the verifier and simulator, respectively) and a probabilistic routine \( P \) (the prover) that is computationally unbounded, together with a polynomial \( r(n) \) (which will give the size of the random reference string \( \sigma \)), such that:

1. (Completeness): For all \( x \in \Pi_Y \), the probability (over random \( \sigma \), and over the random choices of \( P \)) that \( V(x, \sigma, P(x, \sigma)) \) accepts is at least \( 1 - 2^{-O(|x|)} \).
2. (Soundness): For all \( x \in \Pi_N \), and for every possible prover \( P' \), the probability that \( V(x, \sigma, P'(x, \sigma)) \) accepts is at most \( 2^{-O(|x|)} \). (Note \( P' \) here can be malicious, meaning it can try to fool the verifier)
3. (Zero Knowledge): For all \( x \in \Pi_Y \), the statistical distance between the following two distributions is bounded by \( 2^{-|x|} \):
   a. \( \sigma \leftarrow \{0, 1\}^{|x|} \) uniformly random, \( p \leftarrow P(x, \sigma) \), and output \( (p, \sigma) \).
   b. \( S(x, r) \) (where the coins \( r \) for \( S \) are chosen uniformly at random).

It is known that changing the definition, to have the error probability in the soundness and completeness conditions and in the simulator’s deviation be \( 1/p^{O(n)} \) results in an equivalent definition [1, 14]. (See the comments after [1, Claim 39].) We will occasionally make use of this equivalent formulation, when it is convenient.

NISZK is the class of promise problems for which there is a non-interactive statistical zero knowledge proof system.

\textbf{NISZK}_C denotes the class of problems in NISZK where the verifier \( V \) and simulator \( S \) lie in complexity class \( C \).

\(^3\) In prior work on NISZK [14, 1], the verifier and simulator were said to be probabilistic machines. We prefer to be explicit about the random input sequences provided to each machine, and thus the machines can be viewed as deterministic machines taking a sequence of random bits as input.
Definition 5 (EA and \(\text{EA}_{\text{NC}}\), [1, 14]). Consider Boolean circuits \(C_X : \{0,1\}^m \rightarrow \{0,1\}^n\) representing distribution \(X\). The promise problem \(\text{EA}\) is given by:

\[
\begin{align*}
\text{EA}_Y & := \{(C_X, k) : H(X) > k + 1\} \\
\text{EA}_N & := \{(C_X, k) : H(X) < k - 1\}
\end{align*}
\]

\(\text{EA}_{\text{NC}}\) is the variant of \(\text{EA}\) where the distribution \(C_X\) is an \(\text{NC}^0\) circuit with each output bit depending on at most 4 input bits.

Definition 6 (SDU and \(\text{SDU}_{\text{NC}}\)). Consider Boolean circuits \(C_X : \{0,1\}^m \rightarrow \{0,1\}^n\) representing distributions \(X\). The promise problem \(\text{SDU} = (\text{SDU}_Y, \text{SDU}_N)\) is given by:

\[
\begin{align*}
\text{SDU}_Y & := \{(C_X) : \Delta(X, U_n) < 1/n\} \\
\text{SDU}_N & := \{(C_X) : \Delta(X, U_n) > 1 - 1/n\}.
\end{align*}
\]

\(\text{SDU}_{\text{NC}}\) is the analogous problem, where the distributions \(X\) are represented by \(\text{NC}^0\) circuits where no output bit depends on more than four input bits.

Theorem 7 ([1, 4]). \(\text{EA}_{\text{NC}}\) and \(\text{SDU}_{\text{NC}}\) are complete for \(\text{NISZK}_L\). \(\text{EA}_{\text{NC}}\) remains complete, even if \(k\) is fixed to \(k = n - 3\).

Definition 8 (SD and \(\text{SD}_{\text{BP}}\), [12, 25]). Consider a pair of Boolean circuits \(C_1, C_2 : \{0,1\}^m \rightarrow \{0,1\}^n\) representing distributions \(X_1, X_2\). The promise problem \(\text{SD}\) is given by:

\[
\begin{align*}
\text{SD}_Y & := \{(C_1, C_2) : \Delta(X_1, X_2) > 2/3\} \\
\text{SD}_N & := \{(C_1, C_2) : \Delta(X_1, X_2) < 1/3\}.
\end{align*}
\]

\(\text{SD}_{\text{BP}}\) is the variant of \(\text{SD}\) where the distributions \(X_1, X_2\) are represented by branching programs.

2.1 Perfect Randomized Encodings

We will make use of the machinery of perfect randomized encodings [7].

Definition 9. Let \(f : \{0,1\}^n \rightarrow \{0,1\}^t\) be a function. We say that \(\hat{f} : \{0,1\}^n \times \{0,1\}^m \rightarrow \{0,1\}^*\) is a perfect randomized encoding of \(f\) with blowup \(b\) if it is:

- **Input independent:** for every \(x, x' \in \{0,1\}^n\) such that \(f(x) = f(x')\), the random variables \(\hat{f}(x, U_m)\) and \(\hat{f}(x', U_m)\) are identically distributed.

- **Output Disjoint:** for every \(x, x' \in \{0,1\}^n\) such that \(f(x) \neq f(x')\), \(\text{supp}(\hat{f}(x, U_m)) \cap \text{supp}(\hat{f}(x', U_m)) = \emptyset\).

- **Uniform:** for every \(x \in \{0,1\}^n\) the random variable \(\hat{f}(x, U_m)\) is uniform over the set \(\text{supp}(\hat{f}(x, U_m))\).

- **Balanced:** for every \(x, x' \in \{0,1\}^n\) \(\text{supp}(\hat{f}(x, U_m)) = \text{supp}(\hat{f}(x', U_m)) = \emptyset\).

The following property of perfect randomized encodings is established in [12].

Lemma 10. Let \(f : \{0,1\}^n \rightarrow \{0,1\}^t\) be a function and let \(\hat{f} : \{0,1\}^n \times \{0,1\}^m \rightarrow \{0,1\}^*\) be a perfect randomized encoding of \(f\) with blowup \(b\). Then \(H(\hat{f}(U_n, U_m)) = H(f(U_n)) + \log b\).
Simulators and Verifiers in AC⁰

In this section, we show that NISZK⁰ can be defined equivalently using verifiers and simulators that are computable in AC⁰. The standard complete problems for NISZK and NISZK⁰ take a circuit $C$ as input, where the circuit is viewed as representing a probability distribution $X$; the goal is to approximate the entropy of $X$, or to estimate how far $X$ is from the uniform distribution. Earlier work [15, 1, 24] that had presented non-interactive zero-knowledge protocols for these problems had made use of the fact that the verifier could compute hash functions, and thereby convert low-entropy distributions to distributions with small support. But an AC⁰ verifier cannot compute hash functions [19].

Our approach is to “delegate” the problem of computing hash functions to a logspace verifier, and then to make use of the uniform encoding of this verifier to obtain the desired proof. On a given probability distribution $X$, we make it a NO instance of $SDU'$ for $SDU'$ given in [1] proving the hardness of $SDU'$ under AC⁰ reductions (and even under projections).

With this new complete problem in hand, we provide a NISZKAC² protocol for the complete problem, to conclude $NISZK⁰ = NISZKAC²$.

Definition 11. Consider an NC⁰ circuit $C : \{0,1\}^m \rightarrow \{0,1\}^n$ and the probability distribution $X$ on $\{0,1\}^n$ defined as $C(U_m)$ - where $U_m$ denotes $m$ uniformly random bits. For some fixed $\epsilon > 0$ (chosen later in Remark 16), we define:

$$SDU'_{NC⁰, Y} = \{ X : \Delta(C, U_n) < \frac{1}{2^n} \}$$

$$SDU'_{NC⁰, N} = \{ X : |\text{supp}(X)| \leq 2^{n - n'} \}$$

We will show that $SDU'_{NC⁰}$ is complete for $NISZK⁰$ under uniform $\leqproj_m$ reductions. In order to do so, we first show that $SDU'_{NC⁰}$ is in $NISZK⁰$ by providing a reduction to $SDU_{NC⁰}$.

Claim 12. $SDU'_{NC⁰} \leqproj_m SDU_{NC⁰}$, and thus $SDU'_{NC⁰} \in NISZK⁰$.

Proof. On a given probability distribution $X$ defined on $\{0,1\}^n$ for $SDU'_{NC⁰}$, we claim that the identity function $f(X) = X$ is a reduction of $SDU'_{NC⁰}$ to $SDU_{NC⁰}$. If $X$ is a YES instance for $SDU'_{NC⁰}$, then $\Delta(X, U_n) < \frac{1}{2^n}$, which clearly is a YES instance of $SDU_{NC⁰}$. If $X$ is a NO instance for $SDU'_{NC⁰}$, then $|\text{supp}(X)| \leq 2^{n - n'}$. Thus, if we let $T$ be the complement of $\text{supp}(X)$, we have that, under the uniform distribution, a string $\alpha$ is in $T$ with probability $\geq 1 - \frac{1}{2^n}$, whereas this event has probability zero under $X$. Thus $\Delta(X, U_n) \geq 1 - \frac{1}{2^n}$, easily making it a NO instance of $SDU_{NC⁰}$. <

3.1 Hardness for $SDU'_{NC⁰}$

Theorem 13. $SDU'_{NC⁰}$ is hard for $NISZK⁰$ under $\leqproj_m$ reductions.

Proof. In order to show that $SDU'_{NC⁰}$ is hard for $NISZK⁰$, we will show that the reduction given in [1] proving the hardness of $SDU_{NC⁰}$ for $NISZK⁰$ actually produces an instance of $SDU'_{NC⁰}$.

Let $\Pi$ be an arbitrary promise problem in $NISZK⁰$ with proof system $(P,V)$ and simulator $S$. Let $x$ be an instance of $\Pi$. Let $M_a(r)$ denote a machine that simulates $S(x)$ with randomness $r$ to obtain a transcript $(\sigma, p)$ - if $V(x, \sigma, p)$ accepts then $M_a(r)$ outputs $\sigma$; else it outputs $0|\sigma|$. We will assume without loss of generality that $|\sigma| = n^k$ for some constant $k$. 

It was shown in [15, Lemma 3.1] that for the promise problem EA, there is an NISZK protocol with completeness error, soundness error and simulator deviation all bounded from above by $2^{-\alpha k}$ for inputs of length $\alpha$. Furthermore, as noted in the paragraph before Claim 38 in [1], the proof carries over to show that EA_{BP} has an NISZK protocol with the same parameters. Thus, any problem in NISZK can be recognized with exponentially small error parameters by reducing the problem to EA_{BP} and then running the above protocol for EA_{BP} on that instance. In particular, this holds for EA_{NC^0}. In what follows, let $M_x$ be the distribution described in the preceding paragraph, assuming that the simulator $S$ and verifier $V$ yield a protocol with these exponentially small error parameters.

> Claim 14. If $x \in \Pi_{YES}$ then $\Delta(M_x(r), U_{\alpha^k}) \leq 1/2^{\alpha k}$. And if $x \in \Pi_{NO}$ then $|\operatorname{supp}(M_x(r))| \leq 2^{\alpha k - n^k}$ for $\epsilon < 1/2$.

Refer to Appendix A.1 for the proof.

The above claim talks about the distribution $M_x(r)$ where $M$ is a logspace machine. We will instead consider an NC^0 distribution with similar properties that can be constructed using projections. This distribution (denoted by $C_x$) is a perfect randomized encoding of $M_x(r)$. We make use of the following construction:

> Lemma 15 ([1, Lemma 35]). There is a function computable in AC^0 (in fact it can be a projection) that takes as input a branching program $Q$ of size $l$ computing a function $f$ and produces as output a list $p_i$ of NC^0 circuits, where $p_i$ computes the $i$-th bit of a function $\hat{f}$ that is a perfect randomized encoding of $f$ that has blowup $b = 2((\log l - 1)^2(l - 1)^2 - 1)$ and thus the length of $\hat{f}(r) = \log b + |f(r)|$. Each $p_i$ depends on at most four input bits from $(x, r)$ (where $r$ is the sequence of random bits in the randomized encoding).

The properties of perfect randomized encodings (see Definition 9) imply that the range of $\hat{f}$ (and thus also the range of $C_x$) can be partitioned into equal sized pieces corresponding to each value of $f(r)$. Thus, let $\alpha_1, \alpha_2, \ldots, \alpha_z$ be the range of $f(r)$, and let $[\alpha] = \{f(r, s) : f(r) = \alpha \}$. It follows that $|\alpha| = b$. For a given $\alpha$, and for a given $\beta$ of length $\log b$ we denote by $\alpha_{\beta}$ the $\beta$-th element of $[\alpha]$. Since the simulator $S$ runs in logspace, each bit of $M_x(r)$ can be simulated with a branching program $Q_x$. Furthermore, it is straightforward to see that there is an AC^0-computable function that takes $x$ as input and produces an encoding of $Q_x$ as output, and it can even be seen that this function can be a projection. Let the list of NC^0 circuits produced from $Q_x$ by the construction of Lemma 15 be denoted $C_x$.

We show that this distribution $C_x$ is an instance of SDU'_{NC^0} if $x \in \Pi$. For $x \in \Pi_{YES}$, we have $\Delta(M_x(r), U_{\alpha^k}) \leq 1/2^{\alpha k}$, and we want to show $\Delta(C_x(r), U_{\log b^{\alpha^k}}) \leq 1/2^{\alpha k}$. Thus it will suffice to observe that $\Delta(M_x(r), U_{\alpha^k}) = \Delta(C_x(r), U_{\log b^{\alpha^k}}) \leq 1/2^{\alpha k}$.

To see this, note that

$$
\Delta(C_x(r), U_{\log b^{\alpha^k}}) = \sum_{\alpha, \beta} |\Pr[M_x = \alpha_{\beta}] - \frac{1}{2^{\alpha k}}|/2 = \sum_{\beta} \sum_{\alpha} |\Pr[M_x = \alpha] \frac{1}{2^\beta} - \frac{1}{2^\beta} \frac{1}{2^{\alpha k}}|/2
$$

$$
= \sum_{\alpha} |\Pr[M_x = \alpha] - \frac{1}{2^{\alpha k}}|/2 = \Delta(M_x(r), U_{\alpha^k}).
$$

Thus, for $x \in \Pi_{YES}$, $C_x$ is a YES instance for SDU'_{NC^0}.

For $x \in \Pi_{NO}$, Claim 14 shows that $|\operatorname{supp}(M_x(r))| \leq 2^{\alpha k - n}$. Since the NC^0 circuit $C_x$ is a perfect randomized encoding of $M_x(r)$, we have that the support of $C_x$ for $x \in \Pi_{NO}$ is bounded from above by $b \times 2^{\alpha k - n}$. Note that $\log b$ is polynomial in $n$; let $q(n) = \log b$. Let $r(n)$ denote the length of the output of $C$; $r(n) = q(n) + n^k$. Thus the size of $\operatorname{supp}(C_x) \leq 2^{\alpha k - n + q(n)} = 2^{r(n) - n} < 2^{q(n) - r(n)}$ (if $1/\epsilon$ is chosen to be greater than the degree of $r$), and hence $C_x$ is a NO instance for SDU'_{NC^0}. 

\[
\]
Remark 16. Here is how we pick $\epsilon$ in the definition of $\text{SDU}'_{\text{NC}^0}$. $\text{SDU}_{\text{NC}^0}$ is in $\text{NISZK}_L$ via some simulator and verifier, where the error parameters are exponentially small, and the shared reference strings $\sigma$ have length $n^k$ on inputs of length $n$. Now we pick $\epsilon > 0$ so that $\epsilon < 1/k$ (as in Claim 14) and also $1/\epsilon$ is greater than the degree of $r$ (as in the last sentence of the proof of Theorem 13).

3.2 $\text{NISZK}_{\text{AC}^0}$ protocol for $\text{SDU}'_{\text{NC}^0}$ on input $X$ represented by circuit $C$

3.2.1 Non Interactive proof system

1. Let $C$ take inputs of length $m$ and produce outputs of length $n$, and let $\sigma$ be the reference string of length $n$.
2. If there is no $r$ such that $C(r) = \sigma$, then the prover sends $\perp$. Otherwise, the prover picks an element $r$ uniformly at random from $p \sim \{r | C(r) = \sigma\}$ and sends it to the verifier.
3. $V$ accepts iff $C(r) = \sigma$. (Since $C$ is an NC$^0$ circuit, this can be accomplished in AC$^0$ – this step can not be accomplished in NC$^0$ since it depends on all of the bits of $\sigma$.)

3.2.2 Simulator for $\text{SDU}'_{\text{NC}^0}$ proof system, on input $X$ represented by circuit $C$

1. Pick a random $s$ of length $m$ and compute $\gamma = C(s)$.
2. Output $(s, \gamma)$.

3.3 Proofs of Zero Knowledge, Completeness and Soundness

- **Completeness**: Suppose $X \in \text{SDU}'_{\text{NC}^0, Y}$, then $\Delta(X, U_n) < \frac{1}{2^n}$. This implies $|\text{supp}(X)| > 2^n(1 - \frac{1}{2^n})$, which immediately implies that the verifier accepts with high probability.
- **Soundness**: Suppose $X \in \text{SDU}'_{\text{NC}^0, N}$, we note that whenever $\sigma \notin \text{supp}(X)$, no prover can make the verifier accept. If $X \in \text{SDU}'_{\text{NC}^0, N}$, the probability that $\sigma \notin \text{supp}(X)$ is greater than $1 - \frac{1}{2^n}$.
- **Statistical Zero-Knowledge**: Refer to Appendix A.2 for proof.

4 Simulator and Verifier in PM

In this section, we show that $\text{NISZK}_L$ can be defined equivalently using verifiers and simulators that lie in the class PM of problems that logspace-Turing reduce to Perfect Matching. (PM is not known to lie in (uniform) NC.) That is, we can increase the computational power of the simulator and the verifier from L to PM without affecting the power of noninteractive statistical zero knowledge protocols.

The Perfect Matching problem is the well-known problem of deciding, given an undirected graph $G$ with $2n$ vertices, if there is a set of $n$ edges covering all of the vertices. We define a corresponding complexity class PM as follows:

$$\text{PM} := \{ A : A \leq L^\text{PM} \}$$

It is known that $\text{NL} \subseteq \text{PM}$ [18].

Our argument proceeds by first observing that $\text{NISZK}_L = \text{NISZK}_{\oplus L}$, and then making use of the details of the argument that Perfect Matching is in $\oplus L/\text{poly}$ [6].

---

4 This equality was previously observed in [24].
Proposition 17. \(\text{NISZK}_{\oplus L} = \text{NISZK}_L\)

Proof. It suffices to show \(\text{NISZK}_{\oplus L} \subseteq \text{NISZK}_L\). We do this by showing that the problem \(\text{EA}_{\text{NC}^0}\) is hard for \(\text{NISZK}_{\oplus L}\); this suffices since \(\text{EA}_{\text{NC}^0}\) is complete for \(\text{NISZK}_L\). The proof of [1, Theorem 26] (showing that \(\text{EA}_{\text{NC}^0}\) is complete for \(\text{NISZK}_L\) involves (a) building a branching program to simulate a logspace computation called \(M_x\) that is constructed from a logspace-computable simulator and verifier, and (b) constructing an \(\text{NC}^0\)-computable perfect randomized encoding of \(M_x\), using the fact that \(L \subseteq \text{PREN}\), where \(\text{PREN}\) is the class defined in [7], consisting of all problems with perfect randomized encodings. But Theorem 4.18 in [7] shows the stronger result that \(\oplus\) lies in \(\text{PREN}\), and hence the argument of [1, Theorem 26] carries over immediately, to reduce any problem in \(\text{NISZK}_{\oplus L}\) to \(\text{EA}_{\text{NC}^0}\) (by modifying step (a), to build a parity branching program for \(M_x\) that is constructed from a \(\oplus\) simulator and verifier).

We also rely on the following lemma:

Lemma 18 (Adapted from [6, Section 3] and [21, Section 4]). Let \(W = (w_1, w_2, \ldots, w_{n^k+3})\) be a sequence of \(n^k+3\) weight functions, where each \(w_i : \binom{n}{2} \rightarrow [4n^2]\) is a distinct weight assignment to edges in \(n\)-vertex graphs. Let \((G, w_i)\) denote the result of weighting the edges of \(G\) using weight assignment \(w_i\). Then there is a function \(f\) in \(\text{GapL}\), such that, if \((G, w_i)\) has a unique perfect matching of weight \(j\), then \(f(G, W, i, j) \in \{1, -1\}\), and if \(G\) has no perfect matching, then for every \((W, i, j)\), it holds that \(f(G, W, i, j) = 0\). Furthermore, if \(W\) is chosen uniformly at random, then with probability \(\geq 1 - 2^{-n^k}\), for each \(n\)-vertex graph \(G\):

- If \(G\) has no perfect matching then \(\forall i \forall j \ f(G, W, i, j) = 0\).
- If \(G\) has a perfect matching then \(\exists i\) such that \((G, w_i)\) has a unique minimum-weight matching, and hence \(\exists i \forall j \ f(G, W, i, j) \in \{1, -1\}\).

Thus if we define \(g(G, W)\) to be \(1 - \Pi_{i,j}(1 - f(G, W, i, j)^2)\), we have that \(g \in \text{GapL}\) and with probability \(\geq 1 - 2^{-n^k}\) (for randomly-chosen \(W\)), \(g(G, W) = 1\) if \(G\) has a perfect matching, and \(g(G, W) = 0\) otherwise.

Note that this lemma is saying that most \(W\) constitute a good “advice string”, in the sense that \(g(G, W)\) provides the correct answer to the question “Does \(G\) have a perfect matching?” for every graph \(G\) with \(n\) vertices.

Corollary 19. For every language \(A \in \text{PM}\) there is a language \(B \in \oplus L\) such that, if \(x \in A\), then \(\text{Pr}_{W \sim [4n^2]^{\ast}}[\{x, W\} \in B] \geq 1 - 2^{-n^2}\), and if \(x \notin A\), then \(\text{Pr}_{W \sim [4n^2]^{\ast}}[\{x, W\} \in B] \leq 2^{-n^2}\).

Refer to Appendix A.3 for proof.

Theorem 20. \(\text{NISZK}_L = \text{NISZK}_{\text{PM}}\)

Proof. We show that \(\text{NISZK}_{\text{PM}} \subseteq \text{NISZK}_{\oplus L}\), and then appeal to Proposition 17.

Let \(B\) be an arbitrary problem in \(\text{NISZK}_{\text{PM}}\), and let \((S, V, P)\) be the PM simulator, prover, and verifier for \(B\), respectively. Let \(S'\) and \(V'\) be the \(\oplus\) languages that are probabilistic realizations of \(S, V\), respectively, guaranteed by Corollary 19. We now define a \(\text{NISZK}_L\) protocol \((S'', P'', V'')\) for \(B\).

On input \(x\) with shared randomness \(\sigma W\), the prover \(P''\) sends the same message \(p = P(x, \sigma)\) as the original prover sends. The verifier \(V''\), returns the value of \(V'(x, \sigma, p, W)\), which with high probability is equal to \(V(x, \sigma, p)\). The simulator \(S''\), given as input \(x\) and random sequence \(r W\), executes \(S'((x, r, i), W)\) for each bit position \(i\) to obtain a bit that (with high probability) is equal to the \(i\)th bit of \(S(x, r)\), which is a string of the form \((\sigma, p)\), and outputs \((\sigma W, p)\).
Now we will analyze the properties of \((S''', P''', V''')\):

- **Completeness:** Suppose \(x \in IY\), then \(\Pr_x[V(x, \sigma, P(x, \sigma)) = 1] \geq 1 - 2^{-O(n)}\). Since \(\forall y \in \{0, 1\}^n : \Pr_W[V(y) = V'(y, W)] \geq 1 - 2^{-n^k}\) we have:

\[
\Pr_{\sigma W} [V'((x, \sigma, P''(x, \sigma)), W) = 1] \geq [1 - 2^{-O(n)}][1 - 2^{-n^k}] = 1 - 2^{-O(n)}
\]

- **Soundness:** Suppose \(x \in \Pi_N\), then \(\Pr_{\sigma}[^{\forall}p : V(x, \sigma, p) = 0] \geq 1 - 2^{-O(n)}\). Since \(\forall y \in \{0, 1\}^n : \Pr_W[V(y) = V'(y, W)] \geq 1 - 2^{-n^k}\), we have:

\[
\Pr_{\sigma W}[^{\forall}p : V'((x, \sigma, p), W) = 0] \geq [1 - 2^{-O(n)}][1 - 2^{-n^k}] = 1 - 2^{-O(n)}
\]

- **Statistical Zero-Knowledge:** Suppose \(x \in IY\). Let \(S^*\) denote the distribution on strings of the form \((\sigma, p)\) that \(S(x, r)\) produces, where \(r\) is uniformly generated, and let \(P^*\) denote the distribution on strings given by \((\sigma, P(x, \sigma))\) where \(\sigma\) is chosen uniformly at random. Similarly, let \(S'''\) denote the distribution on strings of the form \((\sigma W, p)\) that \(S''(x, rW)\) produces, where \(r\) and \(W\) are chosen uniformly, and let \(P''\) be the distribution given by \((\sigma W, P''(x, \sigma W))\). Let \(A = \{(\sigma W, p) : \exists i \exists r S(x, r_i) \neq S'i((x, r_i), W)\}\).

Since \(\Pr_W[^{\forall}i \forall r : S(x, r_i) = S'i((x, r_i), W)] \geq 1 - 2^{-O(n)}\) we have:

\[
\Delta(S''', P''') = \frac{1}{2} \sum_{(\sigma W, p)} \left| \Pr[S''' = (\sigma W, p)] - \Pr[P''' = (\sigma W, p)] \right|
\]

\[
\leq \frac{1}{2} \left(2^{-O(n)} + \sum_{(\sigma W, p) \in A} \left| \Pr[S' = (\sigma W, p)] - \Pr[P' = (\sigma W, p)] \right| \right)
\]

\[
= \frac{1}{2} \left(2^{-O(n)} + \sum_{(\sigma W, p) \in A} \left| \Pr[S' = (\sigma, p)] - \Pr[P' = (\sigma, p)] \right| \Pr[W] \right)
\]

\[
\leq 2^{-O(n)} + \sum_{W} \Pr[W] \frac{1}{2} \sum_{(\sigma, p)} \left| \Pr[S' = (\sigma, p)] - \Pr[P' = (\sigma, p)] \right|
\]

\[
= 2^{-O(n)} + \Delta(S', P') = 2^{-O(n)}
\]

Therefore \((S'', P'', V'')\) is a \text{NISZK}_{\text{WL}} protocol deciding II. \hfill \blacktriangleleft

## 5 Additional problems in \text{NISZK}_L

In this section, we give additional examples of problems in P that lie in \text{NISZK}_L. These problems are not known to lie in (uniform) NC. Our main tool is to show that \text{NISZK}_L is closed under a class of randomized reductions.

The following definition is from [4]:

\begin{itemize}
  \item **Definition 21.** A promise problem \(A = (Y, N)\) is \(\leq_{\text{m-BPL}}\)-reducible to \(B = (Y', N')\) with threshold \(\theta\) if there is a logspace-computable function \(f\) and there is a polynomial \(p\) such that:
    \begin{enumerate}
    \item \(x \in Y\) implies \(\Pr_{r \in \{0, 1\}^{|x|}}[f(x, r) \in Y'] \geq \theta\).
    \item \(x \in N\) implies \(\Pr_{r \in \{0, 1\}^{|x|}}[f(x, r) \in N'] \geq \theta\).
    \end{enumerate}
\end{itemize}

Note, in particular, that the logspace machine computing the reduction has two-way access to the random bits \(r\); this is consistent with the model of probabilistic logspace that is used in defining \text{NISZK}_L.

\begin{itemize}
  \item **Theorem 22.** \text{NISZK}_L is closed under \(\leq_{\text{m-BPL}}\) reductions with threshold \(1 - \frac{1}{n^{1/2}}\).
\end{itemize}
Proof. Let \( \Pi \leq_{\text{m}}^{B\text{PL}} \text{EA}_{\text{NC}^e} \), via logspace-computable function \( f \). Let \((S_1, V_1, P_1)\) be the \text{NISZK}_L proof system for \text{EA}_{\text{NC}^e}.

\[\text{Algorithm 1} \quad \text{Simulator } S(x, r; \sigma').\]
\[
(\sigma, p) \leftarrow S_1(f(x, \sigma'), r);
\]
\[
\text{return } (\langle \sigma, \sigma' \rangle, p);
\]

\[\text{Algorithm 2} \quad \text{Verifier } V(x, (\sigma, \sigma'), p).\]
\[
\text{return } V_1((f(x, \sigma'), \sigma, p))
\]

\[\text{Algorithm 3} \quad \text{Prover } P(x, (\sigma, \sigma')).\]
\[
\text{return } P_1((f(x, \sigma'), \sigma))
\]

We now claim that \((S, P, V)\) is a \text{NISZK}_L protocol for \( \Pi \).

It is apparent that \( S \) and \( V \) are computable in logspace. We just need to go through completeness, soundness, and statistical zero-knowledge of this protocol.

- **Completeness:** Suppose \( x \) is YES instance of \( \Pi \). Then with probability \( 1 - \frac{1}{n^{\Omega(1)}} \) (over randomness of \( \sigma' \)): \( f(x, \sigma') \) is a YES instance of \( \text{EA}_{\text{NC}^e} \). Thus for a randomly chosen \( \sigma \):

\[
\Pr[V_1(f(x, \sigma'), \sigma, P_1(f(x, \sigma'), \sigma)) = 1] \geq 1 - \frac{1}{n^{\Omega(1)}}
\]

- **Soundness:** Suppose \( x \) is NO instance of \( \Pi \). Then with probability \( 1 - \frac{1}{n^{\Omega(1)}} \) (over randomness of \( \sigma' \)): \( f(x, \sigma') \) is a NO instance of \( \text{EA}_{\text{NC}^e} \). Thus for a randomly chosen \( \sigma \):

\[
\Pr[V_1(f(x, \sigma'), \sigma, P_1(f(x, \sigma'), \sigma)) = 0] \geq 1 - \frac{1}{n^{\Omega(1)}}
\]

- **Statistical Zero-Knowledge:** If \( x \) is a YES instance, \( f(x, \sigma') \) is a YES instance of \( \text{EA}_{\text{NC}^e} \) with probability close to 1. For any YES instance \( y \) of \( \text{EA}_{\text{NC}^e} \), the distribution given by \( S_1 \) on input \( y \) is exponentially close to the distribution on transcripts \( \langle \sigma, p \rangle \) induced by \((V_1, P_1)\) on input \( y \). Thus the distribution on \( \langle \sigma \sigma', p \rangle \) induced by \((V, P)\) has distance at most \( \frac{1}{n^{\Omega(1)}} \) from the distribution produced by \( S \) on input \( x \). The claim now follows by the comments regarding error probabilities in Definition 4.

McKenzie and Cook [20] defined and studied the problems \text{LCON}, \text{LCONX} and \text{LCONNULL}. \text{LCON} is the problem of determining if a system of linear congruences over the integers mod \( q \) has a solution. \text{LCONX} is the problem of finding a solution, if one exists, and \text{LCONNULL} is the problem of computing a spanning set for the null space of the system.

These problems are known to lie in uniform \( \text{NC}^3 \) [20], but are not known to lie in uniform \( \text{NC}^2 \), although Arvind and Vijayaraghavan showed that there is a set \( B \) in \( L^{\text{GapL}} \subseteq \text{DET} \subseteq \text{NC}^2 \) such that \( x \in \text{LCON} \) if and only if \( (x, W) \in B \), where \( W \) is a randomly-chosen weight function [8]. (The probability of error is exponentially small.) The mapping \( x \mapsto (x, W) \) is clearly a \( \leq_{\text{bPL}} \) reduction. Since \( \text{DET} \subseteq \text{NISZK}_L \) [1], it follows that

\( \text{LCON} \in \text{NISZK}_L \)

The arguments in [8] carry over to \text{LCONX} and \text{LCONNULL} as well.

\[\textbf{Corollary 23.} \quad \text{LCON} \in \text{NISZK}_L, \text{LCONX} \in \text{NISZK}_L, \text{LCONNULL} \in \text{NISZK}_L.\]
6 Varying the Power of the Verifier

In this section, we show that the computational complexity of the simulator is more important than the computational complexity of the verifier, in non-interactive protocols. The results in this section were motivated by our attempts to show that NISZK = NISZKDET. Although we were unable to reach this goal, we were able to show that the verifier could be as powerful as DET, if the simulator was restricted to be no more powerful than NL. The general approach here is to replace a powerful verifier with a weaker verifier, by requiring the prover to provide a proof to convince a weak verifier that the more powerful verifier would accept.

We define NISZK_{A,B} as the class of problems with a NISZK protocol where the simulator is in A and the verifier is in B (and hence NISZK_A = NISZK_{A,A}). We will consider the case where A ⊆ B ⊆ NISZK_A and A, B are both classes of functions that are closed under composition.

- Theorem 24. NISZK_{A,B} = NISZK_A

Proof. Let Π be an arbitrary promise problem in NISZK_{A,B} with (S_1, V_1, P_1) being the A simulator, B verifier, and prover for Π’s proof system, where the reference string has length p_1(∥x∥) and the prover’s messages have length q_1(∥x∥). Since V_1 ∈ B ⊆ NISZK_A, L(V_1) has a proof system (S_2, V_2, P_2), where the reference string has length p_2(∥x∥) and the prover’s messages have length q_2(∥x∥).

Then Π has the following NISZK_A proof system:

- Algorithm 4 Simulator S(x, r_1, r_2).
  
  Data: x ∈ Π_{Y_C} ∪ Π_{N_O}
  (σ, p) ← S_1(x, r_1);
  (σ', p') ← S_2((x, σ, p), r_2);
  return ((σ, σ'), (p, p'));

- Algorithm 5 Verifier V(x, (σ, σ'), (p, p')).
  return V_2((x, σ, p), σ', p')

- Algorithm 6 Prover P(x, σ').
  Data: x ∈ Π_{Y_C} ∪ Π_{N_O}, σ ∈ \{0, 1\}^{p_1(∥x∥)}, σ' ∈ \{0, 1\}^{p_2(∥x∥)}
  if x ∈ Π_{Y_C} then
    p ← P_1(x, σ);
    p' ← P_2((x, σ, p), σ');
    return (p, p');
  else
    return ⊥, ⊥;
end

- Correctness: Suppose x ∈ Π_{Y_C}, then given random σ, with probability (1 - \frac{1}{2^{m+|σ|}}): (x, σ, P_1(x, σ)) ∈ L(V_1) which means with probability (1 - \frac{1}{2^{m+|σ|+p_1(∥x∥)+|q_1(∥x∥)|}}) it holds that ((x, σ, p), σ', P_2(x, σ, P_1(x, σ))) ∈ L(V_2). So the probability that V accepts is at least:

  (1 - \frac{1}{2^{m+|σ|}})(1 - \frac{1}{2^{m+|σ|+p_1(∥x∥)+q_1(∥x∥)}}) = 1 - \frac{1}{2^{m+|σ|}}

- Soundness: Suppose x ∈ Π_{N}. When given a random σ, we have that with probability less than \frac{1}{2^{m+|σ|}}: \exists p such that (x, σ, p) ∈ L(V_1). For (x, σ, p) \not∈ L(V_1), the probability that there is a p such that ((x, σ, p), σ', p') ∈ L(V_2) is at most \frac{1}{2^{m+|σ|+p_1(∥x∥)+|q_1(∥x∥)|}} (given random σ'). So the probability that V rejects is at least:

  (1 - \frac{1}{2^{m+|σ|}})(1 - \frac{1}{2^{m+|σ|+p_1(∥x∥)+|q_1(∥x∥)|}}) = 1 - \frac{1}{2^{m+|σ|}}
Statistical Zero-Knowledge: Refer to the full version [2].

Corollary 25. \( \text{NISZK}_L = \text{NISZK}_{\text{AC}^0} = \text{NISZK}_{\text{AC}^0,\text{DET}} = \text{NISZK}_{\text{NL},\text{DET}} \)

The proof of Theorem 24 did not make use of the condition that the verifier is at least as powerful as the simulator. Thus, maintaining the condition that \( A \subseteq B \subseteq \text{NISZK}_A \), we also have the following corollary:

Corollary 26. \( \text{NISZK}_B = \text{NISZK}_{B,A} \)

Corollary 27. \( \text{NISZK}_{A,B} \subseteq \text{NISZK}_{B,A} \)

Corollary 28. \( \text{NISZK}_{\text{DET}} = \text{NISZK}_{\text{DET,AC}^0} \)

7 SZK\(_L\) closure under \( \leq_{\text{bf-tt}} \) reductions

Although our focus in this paper has been on \( \text{NISZK}_L \), in this section we report on a closure property of the closely-related class \( \text{SZK}_L \).

The authors of [12], after defining the class \( \text{SZK}_L \), wrote:

We also mention that all the known closure and equivalence properties of \( \text{SZK} \) (e.g., closure under complement [22], equivalence between honest and dishonest verifiers [15], and equivalence between public and private coins [22]) also hold for the class \( \text{SZK}_L \).

In this section, we consider a variant of a closure property of \( \text{SZK} \) (closure under \( \leq_{\text{bf-tt}} \) [25]), and show that it also holds\(^5\) for \( \text{SZK}_L \). Although our proof follows the general approach of the proof of [25, Theorem 4.9], there are some technicalities with showing that certain computations can be accomplished in logspace (and for dealing with distributions represented by branching programs instead of circuits) that require proof. (The characterization of \( \text{SZK}_L \) in terms of reducibility to the Kolmogorov-random strings presented in [4] relies on this closure property.)

Definition 29 (From [25, Definition 4.7]). For a promise problem \( \Pi \), the characteristic function of \( \Pi \) is the map \( \chi_{\Pi} : \{0,1\}^* \rightarrow \{0,1,*\} \) given by

\[
\chi_{\Pi}(x) = \begin{cases} 
1 & \text{if } x \in \Pi_{\text{Yes}}, \\
0 & \text{if } x \in \Pi_{\text{No}}, \\
* & \text{otherwise}.
\end{cases}
\]

Definition 30. Logspace Boolean formula truth-table reduction (\( \leq_{\text{bf-tt}} \) reduction): We say a promise problem \( \Pi \) logspace \( \text{Boolean formula truth-table reduces} \) to \( \Gamma \) if there exists a logspace-computable function \( f \), which on input \( x \) produces a tuple \( (y_1,\ldots,y_m) \) and a Boolean formula \( \phi \) (with \( m \) input gates) such that:

\[
x \in \Pi_{\text{Yes}} \implies \phi(\chi_{\Gamma}(y_1),\ldots,\chi_{\Gamma}(y_m)) = 1 \\
x \in \Pi_{\text{No}} \implies \phi(\chi_{\Gamma}(y_1),\ldots,\chi_{\Gamma}(y_m)) = 0
\]

\(^5\) We observe that open questions about closure properties of \( \text{NISZK} \) also translate to open questions about \( \text{NISZK}_L \). \( \text{NISZK} \) is not known to be closed under union [23], and neither is \( \text{NISZK}_L \). Neither is known to be closed under complementation. Both are closed under conjunctive logspace-truth-table reductions.
Robustness for Space-Bounded Statistical Zero Knowledge

We begin by proving a logspace analogue of a result from [25], used to make statistically close pairs of distributions closer and statistically far pairs of distributions farther.

- **Lemma 31** (Polarization Lemma, adapted from [25, Lemma 3.3]). There is a logspace-computable function that takes a triple \((P_1, P_2, 1^k)\), where \(P_1\) and \(P_2\) are branching programs, and outputs a pair of branching programs \((Q_1, Q_2)\) such that:

\[
\Delta(P_1, P_2) < \frac{1}{3} \implies \Delta(Q_1, Q_2) < 2^{-k}
\]

\[
\Delta(P_1, P_2) > \frac{2}{3} \implies \Delta(Q_1, Q_2) > 1 - 2^{-k}
\]

To prove this, we adapt the same method as in [25] and alternate two different procedures, one to drive pairs with large statistical distance closer to 1, and one to drive distributions with small statistical distance closer to 0. The following lemma will do the former:

- **Lemma 32** (Direct Product Lemma, from [25, Lemma 3.4]). Let \(X\) and \(Y\) be distributions such that \(\Delta(X, Y) = \epsilon\). Then for all \(k\),

\[
k\epsilon \geq \Delta(\otimes^k X, \otimes^k Y) \geq 1 - 2 \exp(-k\epsilon^2/2)
\]

The proof of this statement follows from [25]. To use this for Lemma 31, we note that a branching program for \(\otimes^k P\) can easily be created in logspace from a branching program \(P\) by simply copying and concatenating \(k\) independent copies of \(P\) together.

We now introduce a lemma to push close distributions closer:

- **Lemma 33** (XOR Lemma, adapted from [25, Lemma 3.5]). There is a logspace-computable function that maps a triple \((P_0, P_1, 1^k)\), where \(P_0\) and \(P_1\) are branching programs, to a pair of branching programs \((Q_0, Q_1)\) such that \(\Delta(Q_0, Q_1) = \Delta(P_0, P_1)^k\). Specifically, \(Q_0\) and \(Q_1\) are defined as follows:

\[
Q_0 = \bigotimes_{y \in \{0, 1\}^k} P_{y_i} : y \leftarrow R \{ y \in \{0, 1\}^k : \oplus_{i \in [k]} y_i = 0 \}
\]

\[
Q_1 = \bigotimes_{y \in \{0, 1\}^k} P_{y_i} : y \leftarrow R \{ y \in \{0, 1\}^k : \oplus_{i \in [k]} y_i = 1 \}
\]

Refer to Appendix A.4 for proof. We now have the tools to prove Lemma 31.

**Proof of Lemma 31.** From [25, Section 3.2], we know that we can polarize \((P_0, P_1, 1^k)\) by:

- Letting \(l = \lceil \log_4/3 6k \rceil\), \(j = 3^{l-1}\)
- Applying Lemma 33 to \((P_0, P_1, 1^l)\) to get \((P'_0, P'_1)\)
- Applying Lemma 32: \(P'_0 = \otimes^j P'_0, P'_1 = \otimes^j P'_1\)
- Applying Lemma 33 to \((P'_0, P'_1, 1^k)\) to get \((Q_0, Q_1)\)

Each step is computable in logspace, and since logspace is closed under composition, this completes our proof.

We also mention the following lemma, which will be useful in evaluating the Boolean formula given by the \(\leq_{1\text{-d}}\) reduction.

- **Lemma 34.** There is a function in \(\text{NC}^1\) that takes as input a Boolean formula \(\phi\) (with \(m\) input bits) and produces as output an equivalent formula \(\psi\) with the following properties:

1. The depth of \(\psi\) is \(O(\log m)\).
2. \(\psi\) is a tree with alternating levels of AND and OR gates.
3. The tree’s non-leaf structure is always the same for a fixed input length.
4. All NOT gates are located just before the leaves.
Refer to Appendix A.5 for proof.

► **Theorem 35.** **SZK** \( \mathbf{L} \) is closed under \( \leq_{\text{tt}} \) reduction.

To begin the proof of this theorem, we first note that as in the proof of [25, Lemma 4.10], given two \( \text{SD}_{\text{BP}} \) pairs, we can create a new pair which is in \( \text{SD}_{\text{BP, No}} \) if both of the original two pairs are (which we will use to compute ANDs of queries.) We can also compute in logspace the OR query for two queries by creating a pair \((P_1 \otimes S_1, P_2 \otimes S_2)\). We prove that these operations produce an output with the correct statistical difference with the following two claims:

\( \triangleright \) **Claim 36.** \( \{(y_1, y_2) | x_{\text{SD}_{\text{BP}}}(y_1, y_2) = 1\} \leq_{\text{m}} \text{SD}_{\text{BP}} \).

\( \triangleright \) **Claim 37.** \( \{(y_1, y_2) | x_{\text{SD}_{\text{BP}}}(y_1) \land x_{\text{SD}_{\text{BP}}}(y_2) = 1\} \leq_{\text{m}} \text{SD}_{\text{BP}} \).

Refer to Appendix A.6 and Appendix A.7 for the construction and proof. Crucially we note that the construction still retains a 2/3 completeness and 1/3 soundness bound.

**Proof of Theorem 35.** Now suppose that we are given a promise problem \( \Pi \) such that \( \Pi \leq_{\text{tt}} \text{SD}_{\text{BP}} \). We want to show \( \Pi \leq_{\text{m}} \text{SD}_{\text{BP}} \), which by \( \text{SZK}_{\mathbf{L}} \)’s closure under \( \leq_{\text{m}} \) reductions implies \( \Pi \in \text{SZK}_{\mathbf{L}} \).

We follow the steps below on input \( x \) to create an \( \text{SD}_{\text{BP}} \) instance \((F_0, F_1)\) which is in \( \text{SD}_{\text{BP, Y}} \) if \( x \in \Pi \):

1. Run the \( \mathbf{L} \) machine for the \( \leq_{\text{tt}} \) reduction on \( x \) to get queries \((q_1, \ldots, q_m)\) and the formula \( \phi \).
2. Build \( \psi \) from \( \phi \) using Lemma 34. Replace negated queries \( \neg q_i \) with the query produced by the reduction from \( \text{SD}_{\text{BP}, Y} \) to \( \text{SD}_{\text{BP}, N} \) on \( q_i \), and then apply Lemma 31 (the Polarization Lemma) with \( k = n \) on these queries to get \((y_1, \ldots, y_k)\). Pad the output bits of each branching program so each branching program has \( m \) output bits.
3. Build the template tree \( T \). At the leaf level, for each variable in \( \psi \), we will plug in the corresponding query \( y_i \). By Lemma 34 the tree is full.
4. Given \( x \) and designated output position \( j \) of \( F_0 \) or \( F_1 \), there is a logspace computation which finds the original output bit from \( y_1, \ldots, y_m \) that bit \( j \) was copied from. This machine traverses down the template tree from the output bit and records the following:

   - The position of the random bits used to decide which path to take when we reach nodes corresponding to AND.
   - The node that the computation is currently at on the template tree, with the path taken depending on \( j \).

This takes \( O(\log m) \) space. We can use this algorithm to copy and compute each output bit of \( F_0 \) and \( F_1 \), creating \((F_0, F_1)\) in logspace.

For step 4, we give an algorithm \( \text{Eval}(x, j, \psi, y_1, \ldots, y_m) \) to compute the \( j \)th output bit of \( F_0 \) or \( F_1 \) on \( x \), for a formula \( \psi \) satisfying the properties of Lemma 34, a list of \( \text{SD}_{\text{BP}} \) queries \((y_1, \ldots, y_m)\), and \( j \). Without loss of generality, we lay out the algorithm to compute only \( F_0(x) \).

**Outline of \( \text{Eval}(x, j, \psi, y_1, \ldots, y_m) \):**

The idea is to compute the \( j \)th output bit of \( F_0 \) by recursively calculating which query output bit it was copied from. To do this, first notice that the AND and OR operations produce branching programs where each output bit is copied from exactly one output bit of
one of the query branching programs, so composing these operations together tells us that every output bit in \( F_0 \) is copied from exactly one output bit from one query. By Lemma 34 and our AND and OR operations preserving the number of output bits, we also have that if every BP has \( l \) output bits, \( F_0 \) will have \( 2^a l = |\psi| \) output bits, where \( a \) is the depth of \( \psi \). This can be used to recursively calculate which query the \( j \)th bit is from: for an \( \text{OR} \) gate, divide the output bits into fourths, and decide which fourth the \( j \)th bit falls into (with each fourth corresponding to one BP, or two fourths corresponding to a subtree.) For an \( \text{AND} \) gate, divide the output into fourths, decide which fourth the \( j \)th bit falls into, and then use the 4 random bits for the XOR operation to compute which fourth corresponds to which branching programs (2 fourths will correspond to 1 BP or subtree, and the other 2 fourths will correspond to the 2 BPs from the other subtree.) If \( f \) is updated recursively, then at the query level, we can directly return the \( j \)'th output bit. This can be done in logspace, requiring a logspace path of “lefts” and “rights” to track the current gate, logspace to record and update \( j \), logspace to compute \( 2^a l \) at each level, and logspace to compute which subtree/query the output bit comes from at each level.

The resulting BP \( \Pi \) will be two distributions that will be in \( SD_{BP,Y} \iff x \in \Pi_Y \). By this process \( \Pi \leq_{L}^L SD_{BP} \).

References

A Appendix

This appendix contains some proofs that were moved from the main part of the paper, due to space limitations.

A.1 Proof of Claim 14

Proof. For $x \in \Pi_Y^{ES}$, claim 38 of [1] shows that $\Delta(M_x(r), U_{n^k}) \leq 1/2^{n-1}$, establishing the first part of the claim.
For $x \in \Pi_{NO}$, from the soundness guarantee of the NISZK protocol for $E_{NC}$, we know that, for at least a $1 - \frac{1}{k}$ fraction of the shared reference strings $\sigma \in \{0,1\}^n$, there is no message $p$ that the prover can send that will cause $V$ to accept. Thus there are at most $2^{n^2-n}$ outputs of $M_2(r)$ other than $0^{n^2}$. For $\epsilon < \frac{1}{k}$, we have $|\text{supp}(M_2(r))| \leq 2^{n^2-n-\epsilon k}$. <

A.2 Proof of Statistical Zero-Knowledge in Section 3.3

Proof. Suppose $X \in SDU_{NC,Y}$. Recall that $\sigma \sim \{0,1\}^n$, $s \sim \{0,1\}^m$, $p \sim \{r : C(r) = \sigma\}$ and $\gamma = C(s)$. In order to provide an upper bound on $\Delta((p,\sigma),(s,\gamma))$, we consider the element wise probability of each distribution and show that for $X \in SDU_{NC,Y}$ the claim holds. For $a \in \{0,1\}^m$ and $b \in \{0,1\}^n$ we have:

$$\Delta((p,\sigma),(s,\gamma)) = \sum_{(a,b)} \frac{1}{2} \left| \Pr[(p,\sigma) = (a,b)] - \Pr[(s,\gamma) = (a,b)] \right|$$

Let us consider an element $b \in \{0,1\}^n$. Let $A_b = \{a_1, a_2, \ldots, a_{k_b}\}$ be the pre-images of $b$ under $C$, i.e. for $1 \leq i \leq k_b$ it holds that $C(a_i) = b$. Let $\beta_b = \Pr_{y \sim U_m}[C(y) = b]$. Then $k_b2^{-m} = \beta_b$ (since exactly $k_b$ elements of $\{0,1\}^m$ are mapped to $b$ under $C$). Let $B = \{b \mid \exists y : C(y) = b\}$. Since $\Delta(C(U_m), U_n) \leq \frac{1}{2^{2n}}$, it follows that $\frac{\beta_b}{2^{2n}} \leq \frac{1}{2^{2n}}$. We have:

$$\Delta((p,\sigma),(s,\gamma)) = \sum_{(a,b)} \frac{1}{2} \left| \Pr[(p,\sigma) = (a,b)] - \Pr[(s,\gamma) = (a,b)] \right|$$

$$= \frac{1}{2} \sum_{(a,b) : b \in B} \left| \Pr[(p,\sigma) = (a,b)] - \Pr[(s,\gamma) = (a,b)] \right|$$

$$+ \frac{1}{2} \sum_{(a,b) : b \notin B} \left| \Pr[(p,\sigma) = (a,b)] - \Pr[(s,\gamma) = (a,b)] \right|$$

For $(a,b)$ satisfying $b \in B$, we have $\Pr[(s,\gamma) = (a,b)] = \Pr[(p,\sigma) = (a,b)] = 0$. For $b \notin B$ and $a$ satisfying $C(a) \neq b$ we again have $\Pr[(s,\gamma) = (a,b)] = \Pr[(p,\sigma) = (a,b)] = 0$. For $(a,b) : C(a) = b$ we have $\Pr[(s,\gamma) = (a,b)] = 2^{-m}$ since $s \sim U_m$ and picking $s$ fixes $b$. We also have $\Pr[(p,\sigma) = (a,b)] = \frac{1}{k_b} \beta_b$ since $\sigma \sim U_n$ and then the prover picks $p$ uniformly from $A_b$. This gives us

$$\Delta((p,\sigma),(s,\gamma)) = \frac{1}{2} \sum_{(a,b) : C(a) = b} \left| 2^{-m} - \frac{2^{-n}}{k_b} \right|$$

$$= \frac{1}{2} \sum_{(a,b) : C(a) = b} 2^{-m} - \frac{2^{-m-n}}{\beta_b}$$

$$= \frac{1}{2} \sum_{(a,b) : C(a) = b} \frac{2^{-m}}{\beta_b} |\beta_b - 2^{-n}|$$

$$\leq \frac{1}{2} \sum_{(a,b) : C(a) = b} |\beta_b - 2^{-n}| = \Delta(C(U_m), U_n) \leq \frac{1}{2^{2n}}$$

where the first inequality holds since $\beta_b \geq 2^{-m}$ whenever $\beta_b \neq 0$. Thus we have:

$$\Delta((p,\sigma),(s,\gamma)) = O\left(\frac{1}{2^{2n}}\right).$$  

\[\blacksquare\]
A.3 Proof of Corollary 19

Proof. Let $A$ be in PM, where there is a logspace oracle machine $M$ accepting $A$ with an oracle $P$ for Perfect Matching. We may assume without loss of generality that all queries made by $M$ on inputs of length $n$ have the same number of vertices $p(n)$. This is because $G$ has a perfect matching iff $G \cup \{x_1 - y_1, x_2 - y_2, \ldots, x_k - y_k\}$ has a perfect matching. (I.e., we can “pad” the queries, to make them all the same length.)

Let $C = \{(G, W) : g(G, W) \equiv 1 \mod 2\}$, where $g$ is the function from Lemma 18. Clearly, $C \in \oplus L$. Now, a logspace oracle machine with input $(x, W)$ and oracle $C$ can simulate the computation of $M^P$ on $x$; each time $M$ poses the query “Is $G \in P$”, instead we ask if $(G, W) \in C$. Then with high probability (over the random choice of $W$) all of the queries will be answered correctly and hence this routine will accept if and only if $x \in A$, by Lemma 18. Let $B$ be the language accepted by this logspace oracle machine. We see that $B \in L^C \subseteq L^{\oplus L} = \oplus L$, where the last equality is from [16].

A.4 Proof of Lemma 33

Proof. The proof that $\Delta(Q_0, Q_1) = \Delta(P_0, P_1)^k$ follows from [25, Proposition 3.6]. To finish proving this lemma, we show a logspace-computable mapping between $(P_0, P_1, 1^k)$ and $(Q_0, Q_1)$.

Let $\ell$ and $w$ be the max length and width between $P_0$ and $P_1$. We describe the structure of $Q_0$, with $Q_1$ differing in a small step: to begin with, $Q_0$ reads the $k - 1$ random bits $y_1, \ldots, y_{k-1}$. For each of the random bits, it can pick the correct of two different branches, one having $P_0$ built in at the end and the other having $P_1$. We will read $y_1$, branch to $P_0$ or $P_1$ (and output the distribution accordingly), then unconditionally branch to reading $y_2$ and repeat until we reach $y_{k-1}$ and branch to reading $P_0$ or $P_1$. We then unconditionally branch to $y_1$ and start computing the parity, and at the end we will be able to decide the value of $y_k$ which will allow us to branch to the final copy of $P_0$ or $P_1$.

Creating $(Q_0, Q_1)$ can be done in logspace, requiring logspace to create the section to compute $y_k$ and logspace to copy the independent copies of $P_0$ and $P_1$.

A.5 Proof of Lemma 34

Proof. Although this lemma does not seem to have appeared explicitly in the literature, it is known to researchers, and is closely related to results in [13] (see Theorems 5.6 and 6.3, and Lemma 3.3) and in [5] (see Lemma 5). Alternatively, one can derive this by using the fact that the Boolean formula evaluation problem lies in $\text{NC}^1$ [9, 10], and thus there is an alternating Turing machine $M$ running in $O(\log n)$ time that takes as input a Boolean formula $\psi$ and an assignment $\alpha$ to the variables of $\psi$, and returns $\psi(\alpha)$. We may assume without loss of generality that $M$ alternates between existential and universal states at each

Figure 1 Branching program for $Q_0$ of Lemma 33.
Robustness for Space-Bounded Statistical Zero Knowledge

We can construct a pair of BPs

Then consider:

Let us analyze the Yes and No instance of

Proof. Let \( y_1 = (A_1, B_1) \) and \( y_2 = (A_2, B_2) \). Let \( p > 0 \) be a parameter, where we are guaranteed that:

\[
(A_i, B_i) \in \text{SD}_{BP,Y} \implies \Delta(A_i, B_i) > 1 - p \\
(A_i, B_i) \in \text{SD}_{BP,N} \implies \Delta(A_i, B_i) < p
\]

Then consider:

\[ y = (A_1 \otimes A_2, B_1 \otimes B_2) \]

Let us analyze the Yes and No instance of \( \mathcal{X}_{SD_{BP}}(y_1) \lor \mathcal{X}_{SD_{BP}}(y_2) \):

- YES: \( \Delta(A_1 \otimes A_2, B_1 \otimes B_2) \geq \max\{\Delta(A_1 \otimes B_2, B_1 \otimes B_2), \Delta(B_1 \otimes A_2, B_1 \otimes B_2)\} = \max\{\Delta(A_1, B_1), \Delta(A_2, B_2)\} > 1 - p. \)
- NO: \( \Delta(A_1 \otimes A_2, B_1 \otimes B_2) \leq \Delta(A_1, B_1) + \Delta(A_2, B_2) < 2p. \)

The second equality is from [25, Fact 2.3].

In our Boolean formula, we will have only \( d = O(\log n) \) depth, so we have this OR operation for at most \( \frac{d+1}{2} \) levels (and the soundness gap doubles at every level). Since \( p = \frac{1}{2^m} \) at the beginning, the gap (for NO instance) will be upper bounded at the end by:

\[
< 2^{\frac{d+1}{2}} \frac{1}{2^m} = \frac{n^{O(1)}}{2^m} < 1/3.
\]

A.6 Proof of Claim 36

Proof. Let \( y_1 = (A_1, B_1) \) and \( y_2 = (A_2, B_2) \). Let \( p > 0 \) be a parameter, where we are guaranteed that:

\[
(A_i, B_i) \in \text{SD}_{BP,Y} \implies \Delta(A_i, B_i) > 1 - p \\
(A_i, B_i) \in \text{SD}_{BP,N} \implies \Delta(A_i, B_i) < p
\]

We can construct a pair of BPs \( y = (A, B) \) whose statistical difference is exactly

\[
\Delta(A_1, B_1) \cdot \Delta(A_2, B_2)
\]

The pair \( (A, B) \) we construct is analogous to \( (Q_0, Q_1) \) in Lemma 33, and can be created in logspace with 2 random bits \( b_0, b_1 \). We have \( A = (A_1, A_2) \) if \( b_0 = 0 \) and \( A = (B_1, B_2) \) if \( b_0 = 1 \), while \( B = (A_1, B_2) \) if \( b_2 = 0 \) and \( (A_2, B_1) \) if \( b_1 = 1 \).

Let us analyze the Yes and No instance of \( \mathcal{X}_{SD_{BP}}(y_1) \land \mathcal{X}_{SD_{BP}}(y_2) \):

A.7 Proof of Claim 37
YES: $\Delta(A_1, B_1) \cdot \Delta(A_2, B_2) > (1 - p)^2$.

NO: $\Delta(A_1, B_1) \cdot \Delta(A_2, B_2) \leq \max\{\Delta(A_1, B_1), \Delta(A_2, B_2)\} < p$.  

In our Boolean formula we will have only $d = O(\log m)$ depth, so we have this AND operation for at most $\frac{d+1}{2}$ levels (and the completeness gap squares itself at every level). Since $p = \frac{1}{2m}$ at the beginning, the gap (for YES instance) will be lower bounded at the end by:

$$> (1 - \frac{1}{2m})^{\frac{d+1}{2}} = (1 - \frac{1}{2m})^{O(1)} > (1 - \frac{1}{2m})^{2m/m} \approx (\frac{1}{e})^{1/m} > \frac{2}{3}.$$
