\[ 1 \bowtie \cdot 6, \quad \cdot 6 \bowtie 3, \quad \text{but } 1 \nmid 3 \]
shows.

We introduce the binary relation
\[ x \models y \iff x > y \text{ or } x \bowtie y \iff x \ominus y \in T_{\geq 0} \cup T_\bullet . \]  
(11)

Note that \( a \bowtie b \) is equivalent to \( (a \equiv b) \lor (a \nmid b) \). Remark 2.5 shows that \( \models \) is not a partial order.

Recall from Remark 2.3 that bringing terms to the other side of a non-strict inequality with \( \geq \) is not valid in general. The next lemma shows, among other simple properties, that \( \models \) is compatible with the semiring operations; the proof is deferred to the Appendix.
Lemma 2.6. Let \(a, b, c, d \in \mathbb{S}\).
(a) \(a \oplus c \equiv b \iff a \not\equiv b \oplus c\)
(b) \(a \not\equiv b \land c \not\equiv d \Rightarrow a \oplus c \equiv b \oplus d\).
(c) If \(c \in \mathbb{T}_{\geq 0}\), then \(b \not\equiv c\) and \(c \not\equiv a\) imply \(b \equiv a\).
(d) \(a \not\equiv b\) implies \(c \oplus a \oplus d \equiv c \oplus b \oplus d\) for \(c \in \mathbb{T}_{\geq 0}\) and \(c \oplus b \oplus d \equiv c \oplus a \oplus d\) for \(c \in \mathbb{T}_{\leq 0}\).

3 Tropical Convexity of Signed Numbers

3.1 Signed Tropical Convex Combinations

Let us recall the notation that for a matrix \(A \in \mathbb{T}_{d \times n}^{\geq 0}\), and a vector \(x \in \mathbb{T}_{n}^{\geq 0}\), we denote by \(A \odot x \in \mathbb{T}_{d}^{\geq 0}\) the tropical matrix product. The tropical convex hull \(\text{tconv}(A)\) of the columns of a matrix \(A \in \mathbb{T}_{d \times n}^{\geq 0}\), studied in [15, 18, 20], is defined as

\[
\text{tconv}(A) = \left\{ A \odot x \, | \, x \in \mathbb{T}_{n}^{\geq 0}, \bigoplus_{j \in [n]} x_j = 0 \right\} \subseteq \mathbb{T}_{d}^{\geq 0}.
\]

In this definition it is essential that all columns of \(A\) lie in the non-negative orthant \(\mathbb{T}_{d}^{\geq 0}\). For general matrices in \(\mathbb{T}_{d \times n}^{\geq 0}\), the product \(A \odot x\) may contain balanced entries. We now extend the notion of the tropical convex hull to \(\mathbb{T}_{d}^{\pm}\). Note that we switch freely between a matrix and its set of columns.

Definition 3.1 (Inner hull). The (signed) tropical convex hull of the columns of the matrix \(A \in \mathbb{T}_{d \times n}^{\pm}\) is defined as

\[
\text{tconv}(A) = \left\{ z \in \mathbb{T}_{d}^{\pm} \, | \, z \bowtie A \odot x, x \in \mathbb{T}_{n}^{\geq 0}, \bigoplus_{j \in [n]} x_j = 0 \right\} \subseteq \mathbb{T}_{d}^{\pm}.
\]

Such a set is a (signed) tropical polytope. The tropical convex hull of an arbitrary set \(M \subseteq \mathbb{T}_{d}^{\pm}\) is the union

\[
\text{tconv}(M) = \bigcup_{V \subseteq M, V \text{ finite}} \text{tconv}(V).
\]

A subset \(M \subseteq \mathbb{T}_{d}^{\pm}\) is tropically convex if \(M = \text{tconv}(M)\). This hull construction generalizes (12) because if \(A \in \mathbb{T}_{d \times n}^{\geq 0}\) then \(A \odot x \in \mathbb{T}_{d}^{\geq 0}\). In this case, Lemma 2.4(a) implies that \(z \bowtie A \odot x\) holds only for \(z = A \odot x\).

Using Lemma 2.4(b), we can write (13) equivalently as

\[
\text{tconv}(A) = \bigcup \left\{ U(A \odot x) \, | \, x \in \mathbb{T}_{n}^{\geq 0}, \bigoplus_{j \in [n]} x_j = 0 \right\} \subseteq \mathbb{T}_{d}^{\pm}.
\]

Example 3.2. The combinations of the tropical convex hull depicted in Figure 1, where balanced numbers occur, can be calculated via

\[
(-3) \odot \begin{pmatrix} 3 \\ 3 \end{pmatrix} \oplus \begin{pmatrix} 1 \\ 0 \end{pmatrix} = \begin{pmatrix} 1 \\ 0 \end{pmatrix}, \quad (-2) \odot \begin{pmatrix} 3 \\ 3 \end{pmatrix} \oplus \begin{pmatrix} 1 \\ 0 \end{pmatrix} = \begin{pmatrix} 1 \\ 1 \end{pmatrix}
\]

\[
\begin{pmatrix} 3 \\ 3 \end{pmatrix} \oplus (-1) \odot \begin{pmatrix} 4 \\ 2 \end{pmatrix} = \begin{pmatrix} 3 \\ 3 \end{pmatrix}, \quad (-1) \odot \begin{pmatrix} 3 \\ 3 \end{pmatrix} \oplus \begin{pmatrix} 4 \\ 2 \end{pmatrix} = \begin{pmatrix} 4 \\ 2 \end{pmatrix}.
\]

A more precise way, how these points can be used to determine the signed tropical convex hull, via the tropical convex hull of the intersection with each orthant is given in Theorem 6.4.
Figure 1 The signed tropically convex hull of \{ (3,3), (⊖1,⊖0), (⊖4,⊖2) \}. We omit labels for the axes as the origin is \((−∞, −∞)\) and therefore infinitely far away.

Remark 3.3. There is no unique minimal generating set in the usual sense as one can see from \(\text{tconv}(0,0), (⊖0,⊖0) = \text{tconv}(0,0), (⊖0,0))\).

We now derive some elementary properties of this convexity notion. The following are immediate from the definition, as (14) is just a componentwise construction.

Proposition 3.4. (a) The intersection of tropically convex sets is tropically convex. (b) The coordinate projection of tropically convex sets is tropically convex.

Next, we show that convexity follows already by showing the containment of line segments (Proposition 3.6), and that \(\text{tconv}(.)\) is a closure operator, i.e., the convex hull of a set is a tropically convex set (Proposition 3.7). The following technical lemma will be needed for these proofs. The next three proofs are deferred to the Appendix.

Lemma 3.5. (a) Let \(a ∈ S, b ∈ T_{±}, and z ∈ U(a ⊕ b)\). Then there exists an \(a′ ∈ U(a)\) such that \(z ∈ U(a′ ⊕ b)\). (b) If \(a ∈ U(x), b ∈ U(y), and c ∈ T_{±}, then U(c ⊙ a ⊕ b) ⊆ U(c ⊙ x ⊕ y)\).

Proposition 3.6. An arbitrary subset \(M ⊆ T_{±}^d\) is tropically convex if and only if the tropical convex hull \(\text{tconv}\{ p, q \}\) is contained in \(M\) for all \(p, q ∈ M\).

Proposition 3.7. For any matrix \(A ∈ T_{±}^{d×n}\), the convex hull \(\text{tconv}(A)\) is tropically convex. Consequently, \(\text{tconv}(\text{tconv}(A)) = \text{tconv}(A)\).

Example 3.8. A (signed) tropical hyperplane is of the form

\[
\text{Hyp}(a) = \{ x ∈ T_{±}^d \mid a ⊗ x ∈ T_{±}^d \}.
\]

It is easy to see that this set is tropically convex if \(|\text{supp}(a)| = 1\), where \(\text{supp}(a) = \{ i ∈ [d] \mid a_i ≠ O \}\). Therefore, using Proposition 3.4(a), we see that for a subset \(I ⊆ [d]\) and a point \(b ∈ T_{±}^d\), the set

\[
\{ z ∈ T_{±}^d \mid z_i = b_i \text{ for all } i ∈ I \}
\]

is tropically convex.

On the other hand, if \(|\text{supp}(a)| > 1\), then \(\text{Hyp}(a)\) is not tropically convex. To see this, let us assume that \(\text{supp}(a) ≥ \{1, 2\}\). Then \(p = (⊖a_2, a_1, O, . . . , O)\), \(q = (a_2, ⊖a_1, O, . . . , O)\) ∈ \(\text{Hyp}(a)\). Because of \(p ⊕ q = (●a_2, ●a_1, O, . . . , O)\), the point \((a_2, a_1, O, . . . , O)\) is contained in \(\text{tconv}(p, q)\). However, it is not an element of \(\text{Hyp}(a)\).
Example 3.9. For a vector \((a_0, a_1, \ldots, a_d)\) \(\in T_{d+1}^{±}\) we define the \textit{open signed (affine)} tropical halfspace

\[ H^+(a) = \left\{ x \in T_d^{±} \mid a \circ \begin{pmatrix} 0 \\ x \end{pmatrix} > O \right\}. \] (15)

An open signed tropical halfspace is tropically convex. Let \(c \in T_d^{±}, c_0 \in T^{±}, p, q \in T_d^{±}\) and \(\lambda, \mu \in T^{±}_<O\) with \(\lambda \oplus \mu = 0\). For \(p\) and \(q\) contained in the halfspace, we have \(c \circ p \oplus c_0 > O\) and \(c \circ q \oplus c_0 > O\), and by Lemma 2.2,

\[ c \circ (\lambda \circ p \oplus \mu \circ q) \oplus c_0 = \lambda \circ (c \circ p \oplus c_0) \oplus \mu \circ (c \circ q \oplus c_0) > O. \] (16)

If \(\lambda \circ p \oplus \mu \circ q\) has a balanced component \(b \in T_d^{±}\), then the value of \(c \circ (\lambda \circ p \oplus \mu \circ q) \oplus c_0\) cannot depend on this component as it is positive. Hence, we can replace that component by an element in \(U(b)\) and preserve the inequality (16).

Remark 3.10. Let \(P \subset T_d^{d\times d}\) be the set of permutation matrices with 0 as one and \(O\) as zero, and let \(D \subset T_d^{d\times d}\) be the set of matrices with diagonal entries from \(T^{±}\) and \(O\) else. Their union generates the multiplicative group of signed tropical transformations \(ST\). This group is the natural group of transformations which leaves the combinatorial structure of a subset of \(T_d^{±}\) unchanged. It provides a useful tool to simplify technical constructions.

Example 3.11. We want to describe the line segment \(t\text{conv}(p, q)\) for two points \(p, q \in T_d^{±}\). By suitable scaling with elements from \(ST\), we can assume that \(p = (0, \ldots, 0)\), and that the entries of \(q\) are ordered by increasing absolute value.

Figure 2 Several tropical line segments in the plane.
Analogous to the description in [20], one obtains a piecewise-linear structure where the breakpoints are determined by the absolute values of the components of \( q \). As an additional phenomenon, the line segments flip to another orthant at each tropically negative entry of \( q \). If the sign changes in \( \ell \) coordinates at once, the line segment has dimension \( \ell \). We visualize several examples for the two-dimensional case in Figure 2.

**Definition 3.12** (Conic hull). The signed tropical conic hull of the columns of \( A \) is

\[
\text{tcone}(A) = \bigcup_{\lambda \in \mathbb{T}_\geq_0} \mathcal{U}(A \odot \lambda).
\] (17)

The definition together with Proposition 3.7 yields the following.

**Corollary 3.13.** The conic hull of a subset of \( \mathbb{T}_d^\pm \) is tropically convex.

### 3.2 Image of Puiseux Lifts

The aim of this section is to relate our concept of convexity over \( \mathbb{T}_\pm \) to convexity over \( \mathbb{R} \). To achieve this, we move to another ordered field, the field of real Puiseux series \( \mathbb{K} = \mathbb{R}\langle\langle t \rangle\rangle \). This has proven to be a helpful concept in the study of tropical numbers with signs, see [35, 6, 27]. It is formed by formal Laurent series with exponents in \( \mathbb{R} \) and coefficients in \( \mathbb{R} \). The exponent sequence is strictly decreasing and it has no accumulation point. This ordered field is equipped with a non-archimedean valuation \( \text{val} \) which maps all non-zero elements to their leading exponent and zero to \( \mathbb{O} = -\infty \). Additionally, the map \( \text{sgn}: \mathbb{K} \to \{\ominus, \mathbb{O}, \oplus\} \) yields the sign of an element. This gives rise to the signed valuation \( \text{sval}: \mathbb{K} \to \mathbb{T}_\pm \) which maps an element \( k \in \mathbb{K} \) to \( \text{sgn}(k) \text{val}(k) \). It is enough to think of Puiseux series as polynomials in \( t \) with arbitrary exponents and coefficients in \( \mathbb{R} \).

The tropicalization of structured sets over \( \mathbb{K} \), i.e., the study of the image of a subset of \( \mathbb{K}^d \) is a technique which is widely used in tropical geometry. We introduced a concept purely on the tropical side. We will see in Theorem 3.14, that signed tropically convex sets are not the image of the valuation of a single convex hull but of a whole union, ranging over the fibers of tropical points.

In some sense, this is complementary to the main result in [27]. While they consider semialgebraic sets over \( \mathbb{K} \) in general, polytopes, i.e., the convex hull of finitely many points in \( \mathbb{K}^d \), can be considered as a special case. They show that one has to tropicalize all semialgebraic relations fulfilled by a set to describe its image under the signed valuation map.

Recall that for our concept of tropical convexity over \( \mathbb{T}_\pm \) the image of a single polytope under the signed valuation may not be tropically convex as the Example B.1 shows. It is subject to further work to study the special case of polytopes (as semialgebraic sets) from [27] and to see which properties such a notion of signed tropical polytopes could provide.

Note that the next statement is valid for more general fields with a non-trivial non-archimedean valuation \( \text{val} \) which is surjective onto \( \mathbb{T}_\geq_0 \). The proof is given in the Appendix.

**Theorem 3.14.** The signed hull \( \text{tconv}(A) \) is the union of the signed valuations for all possible lifts

\[
\text{tconv} A = \bigcup_{\text{sval}(A) = A} \text{sval} \left( \text{conv} \left( \text{sval}^{-1}(A) \right) \right).
\]

**Remark 15.** Theorem 3.14 generalizes [21, Proposition 2.1], since \( \text{val} \) is a semiring homomorphism from \( \mathbb{K}_{\geq 0} \) to \( \mathbb{T}_\text{max} = \mathbb{T}_{\geq 0} \).

**Corollary 3.16.** The tropical convex hull is the union of the convex hulls of the lifts, i.e.,

\[
\text{tconv}(A) = \text{sval} \left( \text{conv} \left( \text{sval}^{-1}(A) \right) \right).
\]
3.3 Convex Hull from Hyperoperation

As we shall see in Proposition 3.17, our signed tropical convex hull from Definition 3.1 is a natural generalization of the classical convex hull as image of a simplex to hyperoperations. In recent years, hyperfields found their way into matroid theory due to the work [12] building on [30] and [35]. While hyperfields have been used in tropical geometry [27] from an algebraic point of view, they were not used to describe intrinsically defined geometric objects before.

We introduce the necessary notions for hyperfields to define a signed convex hull and compare our binary operations with hyperfield operations (20). Let us briefly introduce the real plus-tropical hyperfield $\mathbb{H}$, see [35]. It has the multiplicative group $(\mathbb{T}_\pm, \circ)$ and its additive hyperoperation on $\mathbb{T}_\pm$ is given by

$$
\begin{align*}
x \oplus y &= \begin{cases} 
\arg\max_{x,y}(|x|,|y|) & \text{if } \chi \subseteq \{+,\O\} \text{ or } \chi = \{-\} \\
|x||y| & \text{else}.
\end{cases}
\end{align*}
$$

We see that the latter addition for non-balanced numbers $x, y \in \mathbb{T}_\pm$ differs from the Definition in (3) in that it has a multi-valued result in the powerset of $\mathbb{T}_\pm$. A balanced outcome $x \in \mathbb{T}_\pm$ is replaced with the interval $\mathcal{U}(z) = [-|z|, |z|]$. One can extend the operations again componentwise and use the symbol $\Box$ for the product of two matrices or vectors. In particular, the operation $\Box$ agrees with $\circ$ on $\mathbb{T}_\pm$. The addition is set-valued in $\mathbb{H}$ if and only if it would be balanced in $\mathcal{S}$. It agrees with $\oplus$ on $\mathbb{T}_{\geq 0}$.

We recall the order relations used in [27] for the multiplicative real tropical hyperfield. Note that they use the multiplication $\circ = "\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\cdot\otimes_1^k \mathbb{T}_\leq 0 \mathbb{S}^d$.
With this notion, one can write $tconv(A) = \bigcup_{z \in A \otimes \Delta_d} U(z)$. By using the hyperoperations in $H$, we can naturally consider the image of the tropical standard simplex $\Delta_k = \{ \lambda \mid \bigoplus_{t \in [k]} \lambda_t = 0 \}$ with respect to matrix multiplication by $V \in T_{d \times k}^\pm$ as a subset of $T_d^\pm$.

**Proposition 3.17.**

$V \boxtimes \Delta_d = tconv(V)$.

**Proof.** This follows directly by the definition of the set-valued addition in (18) from (13) with $U(z) = [\ominus|z|, |z|]$ for $z \in T_\bullet$. ▶

In Appendix B, we compare our convexity notion to $\mathcal{B}$-convexity studied in the literature [15], as well as a cancellative sum construction used in [14].

4 Farkas’ Lemma and Fourier-Motzkin Elimination

4.1 Convexity and Tropical Linear Feasibility

For a matrix $A = (a_{ij}) \in T_{n \times d}^\pm$, we define the non-negative kernel

$$\ker_+ (A) = \{ x \in T_{n \times d}^\geq \setminus \{ O \} \mid A \otimes x \succ O \} \quad (22)$$

This corresponds to the classical definition of a polyhedral cone in the form $Ax = 0, x \geq 0, x \neq 0$. We replace “=” by “$\succ$” and “$\geq$” by “$\succ$”. In terms of the non-negative kernel, we can express containment in the convex hull as follows.

**Proposition 4.1.** For $A \in T_{d \times n}^\pm$ and $b \in T_{d}^\pm$ we have

$$b \in tconv(A) \Leftrightarrow \ker_+ \left( \begin{array}{cc} A & \ominus b \\ 0 & \ominus 0 \end{array} \right) \neq 0 \, .$$

**Corollary 4.2.** The origin $O$ is in the convex hull $tconv(A)$ if and only if the non-negative kernel $\ker_+ (A)$ is not empty.

**Proof.** Setting $b = O$ in Proposition 4.1 implies the equivalence with the definition from (22). ▶

We now define the open tropical cone as the dual to the non-negative kernel (22).

$$\text{sep}_+ (A) = \{ y \in T_{d}^\pm \mid y^\top \otimes A > O \} \quad (23)$$

The name is motivated by the use of the elements of $\text{sep}_+ (A)$ as separators of the columns of $A$ from the origin. Note that the condition “$> O$”, in particular, means that the product “$y^\top \otimes A$” is comparable with $O$ and, equivalently, is in $T_{> O}$.

We can also define $\ker_+ (A)$ and $\text{sep}_+ (A)$ for $A \in S_{d \times n}$. However, this does not provide a wider class of objects. This follows by replacing a balanced number by $O$ in $\ker_+ (A)$ and applying Theorem 4.12 for $\text{sep}_+ (A)$. We still extend the definition to these more general matrices, as it will lead to simplified arguments.
Example 4.3. In the next example we work with the semiring \((\mathbb{R}_{\geq 0}, \max, \cdot)\), as it provides a more natural picture of the behaviour around the origin in the different orthants. Instead of the semiring defined on \(\mathbb{R} \cup \{-\infty\}\) with operations “\(\max\)” and “\(+\)”, one can isomorphically use the semiring \(\mathbb{R}_{> 0} \cup \{0\}\) with “\(\max\)” and “\(\cdot\)”. The exponentiation map

\[
\exp: \mathbb{R} \cup \{-\infty\} \to \mathbb{R}_{> 0} \cup \{0\}
\]

yields an isomorphism between these two semirings. One can further extend this mapping to \(T_{\pm}\) by setting

\[
x \mapsto \text{sgn}(x) \exp(|x|). \]

Note that the image of \(S\) involves a balanced version of positive numbers as it decomposes into the union \(\mathbb{R}_{> 0} \cup \mathbb{R}_{< 0} \cup \mathbb{R}_{> 0} \cup \{0\}\).

The dotted black shape in Figure 3 depicts the \((\max, \cdot)\)-convex hull of the columns of the matrix \(A = \begin{pmatrix} 3 & 1 & -2 \\ 1 & 4 & 3 \end{pmatrix}\). The combinations, where balanced numbers occur, are

\[
\begin{align*}
\frac{1}{2} \cdot \begin{pmatrix} -2 \\ 3 \end{pmatrix} \oplus \begin{pmatrix} 1 \\ 4 \end{pmatrix} &= \begin{pmatrix} 1 \\ 4 \end{pmatrix} & \frac{2}{3} \cdot \begin{pmatrix} 3 \\ 1 \end{pmatrix} \oplus \begin{pmatrix} -2 \\ 3 \end{pmatrix} &= \begin{pmatrix} 2 \\ 3 \end{pmatrix}.
\end{align*}
\]

The blue shaded area is \(\text{sep}_+(A)\). The configuration visualizes Theorem 4.4, as \(\text{sep}_+(A)\) is not empty and the \((\max, \cdot)\)-convex hull of \(A\) does not contain the origin.

Let us now show that weak duality holds between the non-negative kernel and the open tropical cone:

Theorem 4.4 (Weak duality). For a matrix \(A \in T_{d \times n}^{\pm}\) at least one of the sets \(\ker_+(A)\) and \(\text{sep}_+(A)\) is empty. Equivalently, for an arbitrary vector \(y \in T_d^+\) and a non-negative vector \(x \in T_{\geq 0}^d \setminus \{0\}\) at most one of \(A \odot x \in T^d_{\bullet}\) and \(y^\top A > 0\) can hold.

Proof. The claim follows from the fact that \(T_{\bullet}\) is a left- and right-ideal of \(S\), see [4, Definition 2.6]. This means that for \(x \in \ker_+(A)\), the product \(y^\top A \odot x\) is in \(T_{\bullet}\) while \(y^\top A > 0 \Rightarrow y^\top A \odot x > 0\).
Remark 4.5. We give a direct proof of the former statement. We consider the product $y^\top \circ A \circ x$. Scaling the rows of $A$ by arbitrary numbers in $\mathbb{T}_\pm$ does not change whether $x \in \ker^+(A)$, just as scaling the columns of $A$ by a non-negative number in $\mathbb{T}_{\geq 0}$ does not change whether $y \in \text{sep}^+(A)$. Hence, we can assume that $x$ and $y$ only have the entries $0$ or $\mathbb{O}$. Let $a_{pq}$ be the entry of $A$ with maximal absolute value. For $x \in \ker^+(A)$, there is an index $r \in [n]$ such that $a_{pr} = -a_{pq}$. We can assume that $a_{pq} > \mathbb{O} > a_{pr}$. From this we conclude that $y \notin \text{sep}^+(A)$ since the $r$th column of $y^\top \circ A$ cannot be positive.

The key result of this section will be showing the appropriate version of Farkas’ lemma. The proof will follow via Fourier-Motzkin elimination.

Theorem 4.6 (Farkas’ lemma). For a matrix $A \in \mathbb{T}^{d \times n}$ exactly one of the sets $\ker^+(A)$ and $\text{sep}^+(A)$ is nonempty.

Remark 4.7. Theorem 4.6 is similar to [25, Corollary 3.12]. Through a suitable replacement of the balanced coefficients and a careful analysis of the occurring signs, Theorem 4.6 may be deduced from [25]. Note however, that we allow for unconstrained variables in the definition of $\text{sep}^+(A)$ which is not directly covered by [25, Corollary 3.12].

4.2 Technical Properties of the Order Relations

The next lemma is a version of transitivity and it is a preparation for the elimination of a variable in a system of inequalities in Section 4.3. The proofs of the next two propositions are given in the Appendix.

Proposition 4.8. Let $A, B \subseteq \mathbb{S}$ be two finite sets. There is an element $c \in \mathbb{S}$ with

$$c \circ a > \mathbb{O} \text{ and } b \circ c > \mathbb{O} \text{ for all } a \in A, b \in B$$

if and only if

$$b \circ a > \mathbb{O} \text{ for all } (a, b) \in A \times B$$

(24)

Furthermore, the element $c$ can chosen to be signed.

Corollary 4.9. The non-strict relation $x \geq y$ defined in (8) is a partial order.

Proof. Reflexivity and antisymmetry follow directly from (8) and (6). Proposition 4.8 implies transitivity.

Proposition 4.10. Let $A, B \subseteq \mathbb{S}$ be two finite sets. There is an element $c \in \mathbb{T}_\pm$ with

$$c \oplus a \models \mathbb{O} \text{ and } b \oplus c \models \mathbb{O} \text{ for all } a \in A, b \in B$$

if and only if

$$b \oplus a \models \mathbb{O} \text{ for all } (a, b) \in A \times B$$

(26)

To deal with geometric objects in $\mathbb{T}^d$, we will use balanced numbers because this allows for explicit calculations in the semiring $\mathbb{S}$. However, as we are only interested in the signed part of the sets. We provide a first tool to resolve balanced numbers in inequalities. While this is for strict inequalities, Proposition 5.7 provides a tool for the relation $\models$. 
Lemma 4.11. For $a, b \in \mathbb{S}$, we have an equivalence of
\begin{enumerate}[(1)]
    \item $a \odot a \oplus b > O$
    \item $a \oplus b > O$ and $\ominus a \oplus b > O$
    \item For all $c \in [\circ|a|, |a|] = \mathcal{U}(a \odot a)$, it holds $c \oplus b > O$.
\end{enumerate}

Proof. The condition (3) clearly implies (2), as the latter is just a special case. The implication from (2) to (1) follows by adding up the positive values in (2). For the direction from (1) to (3), we use that $a \odot a$ is balanced and, hence, incomparable. Therefore, we have $b > |a|$. Because of $|a| = |\ominus a| = |a \odot a|$, the claim follows. \hfill \blacktriangleleft

Given a matrix $A \in \mathbb{S}^{d \times n}$, let us construct the matrix $B = \xi(A) \in \mathbb{T}^{d' \times n}$ for $d \leq d' \leq 2d$ as follows. We include in $B$ all the columns of $A$ that do not contain any balanced elements. For every column $a_{s_j}$ that contains some balanced elements, we include two columns $a'$ and $a''$ in $B$, such that whenever $a_{ij} = \bullet a$ is a balanced entry, then we set $a'_i = \ominus a$ and $a''_i = \ominus a$. For all other $i \in [d]$, we set $a'_i = a''_i = a_{ij}$.

Theorem 4.12. For every matrix $A \in \mathbb{S}^{d \times n}$, $\text{sep}_+(A) = \text{sep}_+(\xi(A))$.

Proof. Recalling Definition 23, we see that it is enough to consider the transition from $A$ to $B$ column by column. An inequality arising from $A$ (after potentially reordering entries) is of the form $y^\top \odot (a, v) > O$ with $a \in \mathbb{T}^k_\pm$ and $v \in \mathbb{T}^{\rho \times k}$ for some $k \leq d$. It either remains the same in $B$ if it has no balanced entry or it gets transformed to two inequalities. Regrouping the summands by balanced and signed numbers, we deduce the claim from the equivalence of (1) and (3) in Lemma 4.11. \hfill \blacktriangleleft

4.3 Fourier-Motzkin Elimination

We derive three versions of Fourier-Motzkin elimination, which will be useful for deriving further description of signed tropical convex sets in Section 5 and 6. As the elimination process produces balanced coefficients for the inequalities, it is convenient to have an elimination procedure which can directly deal with those (Theorem 4.14). We also need to derive explicit inequalities with signed coefficients (Corollary 4.15) to describe the dual convex hull in Section 6. The version with non-strict inequalities (Theorem 4.19) will be used in constructing an exterior description by closed tropical halfspaces (Theorem 5.4).

For a subset $M$ of $\mathbb{T}_\pm^n$, we define its coordinate projection $\rho_i(M)$ with $i \in [d]$ by
\begin{equation}
\rho_i(M) = \{(x_1, \ldots, x_{i-1}, x_{i+1}, \ldots, x_d) \mid (x_1, \ldots, x_d) \in M\}.
\end{equation}

We fix a matrix $A = (a_{ij}) \in \mathbb{S}^{d \times n}$. The non-negative matrix $S^{(i)}$ in the group of signed tropical transformations from Remark 3.10 with the sequence $(-|a_{ij}|) \in \mathbb{T}_O^{\rho \times d}$ as diagonal scales the rows of $A$ such that the $i$th row of $A \odot S$ has only entries with absolute value 0 or $O$. As $S$ is non-negative, we directly obtain from the definitions in Section 4.1 the following.

Lemma 4.13. There is a matrix $S^{(i)} \in \mathbb{S}^{d \times d}$ such that the entries in the $i$th row of $A \odot S^{(i)}$ have absolute value 0 or $O$, and $\ker_+(A \odot S^{(i)}) = \ker_+(A)$, $\text{sep}_+(A \odot S^{(i)}) = \text{sep}_+(A)$ and $\{y \in \mathbb{T}_\pm^n \mid y^\top \odot A \equiv O\} = \{y \in \mathbb{T}_\pm^n \mid y^\top \odot S^{(i)} \odot A \equiv O\}$.

We define several sets partitioning $[n]$ based on the sign of the entries in the $i$th row of $A$ by
\begin{equation}
J^+ = \{j \in [n] \mid a_{ij} > O\}, \quad J^- = \{j \in [n] \mid a_{ij} < O\}, \\
J^0 = \{j \in [n] \mid a_{ij} = O\}, \quad J_\bullet = \{j \in [n] \mid a_{ij} = \bullet\}.
\end{equation}
Furthermore, we define \( T^{(i)} = (t_{j,p}) \in \{0, \mathbb{O}\}^{n \times (J^+ \cup J^*) \times (J^* \cup J^-) \cup J^0} \) as the incidence matrix

\[
t_{j,p} = \begin{cases} 
0 & j = k \text{ or } j = \ell \text{ for } p = (k, \ell) \in (J^+ \cup J^*) \times (J^* \cup J^-) \\
0 & j = p \text{ for } p \in J^0 \\
0 & \text{else}
\end{cases}.
\] (30)

We denote by \( A_{-i} \) the matrix obtained from \( A \) by removing the last row.

### 4.3.1 Strict Inequalities

**Theorem 4.14** (Fourier–Motzkin for strict inequalities with balanced numbers). The \( i \)th coordinate projection of the open tropical cone \( \rho_i(sep_+(A)) \) for the matrix \( A \in S_d \times n \) is the open tropical cone \( sep_+(A_{-i} \odot S^{(i)} \odot T^{(i)}) \).

**Proof.** By using an appropriate scaling matrix \( S^{(i)} \), we can assume by Lemma 4.13 that the absolute value of each entry in the \( i \)th row of \( A \) is either 0 or \( \mathbb{O} \) and that this does not affect \( \rho_i(sep_+(A)) \).

To simplify notation, we additionally assume that \( i = d \). Using Lemma 4.11 and ordering the inequalities according to the partition from (29), we get the system

\[
y_d \oplus (y_1, \ldots, y_{d-1}) \odot (a_{1,j}, \ldots, a_{d-1,j})^T \succ \mathbb{O} \text{ for } j \in J^+ \cup J^* \\
\odot y_d \oplus (y_1, \ldots, y_{d-1}) \odot (a_{1,j}, \ldots, a_{d-1,j})^T \succ \mathbb{O} \text{ for } j \in J^- \cup J^*
\] (31)

Proposition 4.8 implies that (31) has a solution \((y_1, \ldots, y_{d-1}, y_d)\) if and only if

\[
(y_1, \ldots, y_{d-1}) \odot A_{-d} \odot T \succ \mathbb{O}
\] (32)

has a solution \((y_1, \ldots, y_{d-1})\) \(\in T_{d-1}^d\). \(\blacksquare\)

We can resolve the balanced entries which can occur in the product with \( T^{(i)} \) by means of Theorem 4.12.

**Corollary 4.15** (Fourier–Motzkin for strict inequalities with signed numbers). The \( i \)th coordinate projection of the open tropical cone \( \rho_i(sep_+(A)) \) is \( sep_+\left(\xi(A_{-i} \odot S^{(i)} \odot T^{(i)})\right) \).

**Example 4.16.** We use the matrix

\[
A = \begin{pmatrix} 3 & 0 & 1 & 0 & 4 \\ 3 & 0 & 0 & 0 & 2 \end{pmatrix}.
\]

from Figure 1.

Eliminating the first row yields

\[
(3 \ominus 0 \ominus 2) \odot \begin{pmatrix} -3 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & -4 \end{pmatrix} \odot \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix} = (0 \ 0)
\]

This shows that \( sep_+^+(A) \) is not empty (as all entries of the remaining matrix are positive signed numbers), which can also be seen in Figure 1 using the duality in Theorem 4.6.
Remark 4.17. The crucial difference to classical Fourier–Motzkin elimination happens in the treatment of balanced numbers occurring in the calculation. While classically in each step several variables could be eliminated at the same time we have to deal with their balanced leftovers. For strict inequalities, Lemma 4.11 provides a tool to resolve them by introducing two inequalities instead of one. We will see how to resolve them for non-strict inequalities in Proposition 5.7.

Remark 4.18. The classical technique of Fourier-Motzkin for polytopes, see e.g. [19] has already been successfully adapted to tropical linear inequality systems in [8]. In the latter work, an algorithmic scheme to determine a projection of a tropical inequality system is described. In our Theorem 4.14, we do not have the non-negatively constrained variables but allow arbitrary elements of $\mathbb{T}_\pm$. Classically, one can represent an unconstrained variable as the difference of a pair of non-negative variables. Applying this technique to a system of the form $y^\top \odot A > O$ with unconstrained $y \in \mathbb{T}_d^n$ for a matrix $A \in \mathbb{T}_d^{d \times n}$ yields the system

$$(u^\top, v^\top) \odot \left( \begin{array}{c} A \\ \odot A \end{array} \right) > O \text{ with } u, v \in \mathbb{T}_d^{d \times O}.$$  

(33)

Reordering terms with coefficients in $\mathbb{T}_{<O}$ to the other side of the inequality yields a system which allows to apply [8, Theorem 11]. However, the differences of non-negative variables are harder to resolve as there is no cancellation but it results in balanced entries. This makes our direct approach more tractable for unconstrained variables. Furthermore, we are also interested in the structure of the resulting inequalities in Section 5, whence our approach is more suitable for this setting.

The elimination procedure derived in the last section allows to prove the desired separation in $\mathbb{T}_d^d$.

Proof of Theorem 4.6. At first, we show the claim for $d = 1$. The set $\text{sep}_+(A)$ is non-empty if and only if either all entries are positive or all entries are negative. Otherwise, we can select a balanced entry or a pair of entries with opposite sign by multiplication from the right.

If $\text{sep}_+(A)$ is not empty, then Theorem 4.4 tells us that $\ker_+(A)$ is empty. So, we assume that $\text{sep}_+(A)$ is empty. As the scaling of the columns of $A$ does not change the sets $\text{sep}_+(A)$ or $\ker_+(A)$, we can assume that the absolute value of the entries in the last row of $A$ is 0 or $O$. Let $T$ be the matrix from (30). Then Theorem 4.14 shows that $\text{sep}_+(A \odot T)$ is empty. By induction, there is an element $z$ in $\ker_+(A \odot T)$. We show that $T \odot z \in \ker_+(A)$. By definition of $T$, the elements in the $d$th row of $A \odot T$ are all in $\mathbb{T}_d$. This implies that the $d$th row of $A \odot T \odot z$ is in $\mathbb{T}_d$. Additionally, the choice of $z$ yields $A_{-d} \odot T \odot z \in \mathbb{T}_d^{d-1}$. This finishes the proof.

4.3.2 Non-strict Inequalities

While we mainly considered the strict inequalities as separators from the origin, in light of Theorem 4.6, we develop the elimination theory for non-strict inequalities with a view towards the representation of convex sets as intersection of closed halfspaces in Theorem 5.4. Therefore, we add another coordinate to treat affine halfspaces, which only occurred in Example 3.9 so far. Next, we derive the analogous statement to Theorem 4.14 for the relation “$\succeq$” instead of “$>$”.

Signed Tropical Convexity

Note that this is substantially more subtle than the case of strict inequalities. We require the coefficient matrix of the inequalities to consist of signed numbers only. However, as each elimination step can result in balanced coefficients, we again need a method to resolve those. While this was rather easy for strict inequalities as shown in Theorem 4.12, we need to develop a more technical and less explicit machinery in Proposition 5.7.

We recall the matrices \( S(i) \) from Lemma 4.13 and \( T(i) \) from (30) with \( d \) replaced by \( d + 1 \) and \( J^\star = \emptyset \).

**Theorem 4.19** (Fourier–Motzkin for non-strict inequalities with signed numbers). The \( i \)th coordinate projection of the set

\[
\{ y \in \mathbb{T}_d^\pm \mid (0, y^\top) \odot A \等多种 0 \}\tag{34}
\]

for \( A \in \mathbb{T}_d^{(d+1)\times n} \) is the set

\[
\{ z \in \mathbb{T}_d^{d-1} \mid (0, z^\top) \odot A_{-i} \odot S(i) \odot T(i) \等多种 0 \}\ .
\]

**Proof.** Using Lemma 4.13, we can assume that the absolute value of each entry in the \( i \)th row of \( A \) is either 0 or \( O \) by using an appropriate scaling matrix \( S(i) \).

To simplify notation, we additionally assume that \( i = d \). Ordering the inequalities according to the distinction from (29), we get the system

\[
y_d \oplus (0, y_1, \ldots, y_{d-1}) \odot (a_{0,j}, a_{1,j}, \ldots, a_{d-1,j})^\top \等多种 0 \text{ for } j \in J^+
\]

\[
\ominus y_d \oplus (0, y_1, \ldots, y_{d-1}) \odot (a_{0,j}, a_{1,j}, \ldots, a_{d-1,j})^\top \等多种 0 \text{ for } j \in J^-
\]

Proposition 4.10 implies that (36) has a solution \( (0, y_1, \ldots, y_{d-1}, y_d) \in \mathbb{T}_d^{d+1} \) if and only if

\[
(0, y_1, \ldots, y_{d-1}) \odot A_{-d} \odot S(d) \odot T(d) \等多种 0
\]

has a solution \( (0, y_1, \ldots, y_{d-1}) \in \mathbb{T}_d^d \).

**Example 4.20.** We will see how to obtain an exterior description by closed halfspaces in Theorem 5.4. To determine the exterior description of the one dimensional line segment from \( \ominus 0 \) to 1 in \( \mathbb{T}_d \), one can eliminate \( x_1 \) and \( x_2 \) from the system

\[
\ominus 0 \odot x_1 \ominus 1 \odot x_2 \odot z \等多种 0
\]

\[
0 \odot x_1 \ominus 1 \odot x_2 \odot z \等多种 0
\]

\[
0 \odot x_1 \ominus 0 \odot x_2 \odot 0 \等多种 0
\]

\[
\ominus 0 \odot x_1 \ominus 0 \odot x_2 \odot 0 \等多种 0
\]

\[
0 \odot x_1 \等多种 0
\]

\[
0 \odot x_2 \等多种 0
\]

Eliminating \( x_1 \) yields

\[
\bullet 1 \odot x_2 \bullet z \等多种 0 \text{ from (38a)\&(38b)}
\]

\[
1 \odot x_2 \odot z \等多种 0 \text{ from (38a)\&(38c)}
\]

\[
1 \odot x_2 \odot z \等多种 0 \text{ from (38a)\&(38e)}
\]

\[
\ominus 1 \odot x_2 \odot z \等多种 0 \text{ from (38d)\&(38b)}
\]

\[
\bullet 0 \odot x_2 \bullet 0 \等多种 0 \text{ from (38d)\&(38c)}
\]

\[
\ominus 0 \odot x_2 \odot 0 \等多种 0 \text{ from (38d)\&(38e)}
\]

\[
0 \odot x_2 \等多种 0 \text{ from (38f)}
\]
From further elimination of \( x_2 \) we get by ignoring redundant inequalities of (39)

\[
\mathbf{\bullet \bullet \bullet 0} \not\models 0 \quad \text{from (39b)} &\text{&(39d)} \\
\mathbf{\ominus (-1) \circ z \ominus 0} \not\models 0 \quad \text{from (39b)} &\text{&(39f)} \\
\mathbf{(-1) \circ z \ominus (-1) \not\models 0} \quad \text{from (39g)} &\text{&(39d)} \\
\mathbf{0} \not\models 0 \quad \text{from (39g)} &\text{&(39f)}
\]

This yields the exterior description \( z \not\models \ominus 0 \) and \( z \not\models \ominus 1 \).

### 4.4 On the Complexity of Signed Tropical Inequality Systems

For (regular) linear programs, solving all standard forms such as \( Ax = b, x \geq 0 \) or \( Ax \leq b \) are polynomial-time equivalent. For example, consider a system in the second form with \( A \in \mathbb{R}^{m\times n}, b \in \mathbb{R}^m \). By using variables \( x', x'' \in \mathbb{R}^n \) and \( s \in \mathbb{R}^m \), we can write a system in the first form as \((A, -A, I_m)(x', x'', s) = b, (x', x'', s) \geq 0\). From a feasible solution \((x', x'', s)\), we can recover a feasible solution \( x = x' - x'' \) to the original system.

The situation for tropical LP is different. Consider systems of the form \( A \odot x \oplus b, x \geq 0, x \in \mathbb{T}^d_+ \) and \( A \odot x \not\models b, x \in \mathbb{T}^d_+ \); in both cases, we need to find a nonzero solution. The first system asks for \( \ker_+(A \odot b) \not\models \emptyset \), and is essentially equivalent to solving mean payoff games (1). Deciding whether this system is feasible is in the complexity class \( \text{NP} \cap \text{coNP} \); this can be seen from Farkas’ lemma (Theorem 4.6), and an additional argument showing that if one of the respective systems is feasible, there is a solution of bit complexity bounded in the bit complexity of the input.

It turns out that systems of the form \( A \odot x \not\models b, x \in \mathbb{T}^d_+ \) actually describe a more general problem. We thank Mateusz Skomra for making the connection with the negative cycles in mixed graphs [10] and an anonymous referee for pointing us to a reduction leading to [29] as well as a hinting towards a direct proof which we give here.

**Theorem 4.21.** The feasibility problem for systems of the form \( A \odot x \not\models b, x \in \mathbb{T}^d_+ \) is \( \text{NP-complete} \).

**Proof.** We give a reduction from SAT. For this, we fix an arbitrary SAT formula \( F \) in conjunctive normal form on \( d \) variables. To each clause \((l_1 \lor \cdots \lor l_k)\), composed of the literals \( l_1, \ldots, l_k \), we associate an inequality \( \sigma_1 \circ x_1 \cdots \sigma_k \circ x_k \not\models 0 \) where \( \sigma_i \) is 0 or \( \oplus 0 \) depending if the corresponding literal in the clause is positive or negative. This yields a linear inequality system where the number of inequalities equals the number of clauses in the formula.

For a satisfying assignment \( s \in \{\text{True, False}\}^d \), we construct a vector \( x \in \{0, \oplus 0\}^d \) by replacing \text{True} with 0 and \text{False} with \( \oplus 0 \). As at least one literal yields \text{True} for the assignment \( s \), each inequality becomes \( 0 \not\models 0 \) or \( \bullet 0 \not\models 0 \), which are both true.

On the other hand, let \( x \in \mathbb{T}^d_+ \) be a solution of the associated tropical linear inequality system. We claim that then also \((\text{tsgn}(x_1) 0, \ldots, \text{tsgn}(x_d) 0)\) is a solution. Indeed, at least one term \( \sigma_i \circ x_i \), of each inequality \( \sigma_1 \circ x_1 \cdots \sigma_k \circ x_k \not\models 0 \) has to be 0 or bigger (with respect to \( \geq \)). Hence, we can just set the absolute value of that component to 0 without changing the validity of the inequality. Each component which does not contribute to any of the left hand sides can take any value in the interval \([0,0]\) without violating any of the inequalities. Now, we can again use the correspondence between \((0, \oplus 0)\) and \((\text{True, False})\) to construct a satisfying assignment for \( F \).

Note that the problem is in \( \text{NP} \) as a solution can be checked to fulfill the inequalities in polynomial time. Hence, the problem is \( \text{NP-complete}. \)
Recall that we do not obtain a variant of Farkas’ lemma for the system \( A \odot x = b, x \in \mathbb{T}_d^\pm \) via the above Fourier-Motzkin elimination. The construction analogous to the classical case would transform it to \((A, \ominus A, I_m) \odot (x', x'', s) \triangleright b, (x', x'', s) \geq 0\). However, the solution \( x = x' \ominus x'' \) may contain balanced entries, and it may not be possible to resolve these entries to get a feasible solution.

▶ **Example 4.22.** We consider the system

\[
\begin{pmatrix}
0 & 0 \\
\ominus 0 & 0 \\
0 & \ominus 0
\end{pmatrix}
\odot \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} = \begin{pmatrix} \ominus 0 \\ \ominus 0 \end{pmatrix}.
\]

It does not have a signed solution. However the extended system

\[
\begin{pmatrix}
0 & 0 & \ominus 0 & \ominus 0 & 0 & 0 & 0 & 0 \\
\ominus 0 & 0 & 0 & \ominus 0 & 0 & 0 & 0 & 0 \\
0 & \ominus 0 & \ominus 0 & 0 & 0 & 0 & 0 & 0 \\
\ominus 0 & \ominus 0 & 0 & \ominus 0 & 0 & 0 & 0 & 0
\end{pmatrix}
\odot \begin{pmatrix} x'_1 \\ x'_2 \\ x''_1 \\ x''_2 \\ s_1 \\ s_2 \\ s_3 \\ s_4 \end{pmatrix}
\triangleright \begin{pmatrix} \ominus 0 \\ \ominus 0 \\ \ominus 0 \end{pmatrix}, \quad x', x'', s \geq 0
\]

has the solution \((0, 0, 0, 0, 0, 0, 0, 0)\).

Note that one can use [29, Theorem 1.2] to show that also systems of the form \( A \odot x \succ b, \ x \in \mathbb{T}_d^\pm \) are NP-complete. This is in stark contrast to the intuition from classical equations. While systems of linear equations with the usual arithmetic are solvable in strongly polynomial time, it gets harder when we add non-negativity constraints. The latter is just linear programming and, hence, solvable in weakly polynomial time. Adding a non-negativity constraint to the system of balances above yields a tropical linear programming which is in NP \( \cap \) co-NP.

### 5 Description by Halfspaces

An important property of classical polytopes is the duality between the representation as convex hull and as intersection of finitely many halfspaces. This is more subtle for tropical polytopes over \( \mathbb{T}_d^\pm \). While we establish a description as intersection of open tropical halfspaces (Theorem 5.1) containing a set of points, we need additional properties to formulate a Minkowski-Weyl theorem (Theorem 5.4). All proofs are deferred to Section 5.1.

We saw already in Examples 3.9 that open halfspaces are convex. The outer hull of a set \( M \subseteq \mathbb{T}_d^\pm \) is the intersection of its containing open halfspaces

\[
\bigcap_{M' \subseteq \mathcal{H}^+(a)} \mathcal{H}^+(a).
\]

This construction yields the same as our key Definition 3.1.

▶ **Theorem 5.1.** The outer and the inner hull of a matrix \( A \in \mathbb{T}_d^{m \times n} \) coincide, i.e.,

\[
t_{\text{conv}}(A) = \bigcap_{A' \subseteq \mathcal{H}^+(v)} \mathcal{H}^+(v), \text{ where we identify } A \text{ with the set of its columns.}
\]
Figure 4 Approximation of a triangle by open halfspaces.

Figure 5 Exterior description of $\text{tconv}((\odot 1, \odot 1), (2, 2))$ by closed halfspaces.

As the latter does not give a finite description, one is usually more interested in closed halfspaces. For a vector $(a_0, a_1, \ldots, a_d) \in T_{d+1}^\pm$, we define a closed (signed) tropical halfspace by

$$H^+(a) = \left\{ x \in T_d^\pm \mid a \circ \begin{pmatrix} 0 \\ x \end{pmatrix} \in T_{\geq 0} \cup T_* \right\}. \quad (42)$$

Lemma 5.2. The closed signed tropical halfspace $H^+(a)$ is the topological closure of the open signed halfspace $H^+(a)$.

Observe that the former statement is wrong for inequalities with balanced numbers as coefficients.

Remark 5.3. Closed tropical halfspaces are not as suitable for the hull construction in Equation (41) as open tropical halfspaces. The inner hull of $M = \{(\odot 1, 1), (1, \odot 1)\}$ should contain the origin $O$. However, the closed halfspace $x_1 \oplus x_2 \geq \odot 0$ contains those two points but not the origin. Taking the analogous intersection as in (41) with closed tropical halfspaces for $M$ yields again $M$. Note that this is the same as the intersection of the balanced image $M \odot \Delta_2$ with $T_2^\pm$.

Example 3.8 shows that such a closed signed tropical halfspace is in general not tropically convex. However, a finite intersection of such halfspaces can be tropically convex, as Figure 5 shows.

Hence, to arrive at a Minkowski-Weyl theorem for tropical polytopes over $T_{\pm}$, one has to adapt the condition in the characterization of finite intersections of closed tropical halfspaces.

Theorem 5.4. For each finite set $V \subset T_d^\pm$, there are finitely many closed tropical halfspaces $H$ such that $\text{tconv}(V)$ is the intersection of the halfspaces.

For each finite set $H$ of closed halfspaces, whose intersection $M$ is tropically convex, there is a finite set of points $V \in T_d^\pm$ such that $M = \text{tconv}(V)$.

Corollary 5.5. A tropically convex set is the intersection of its containing closed halfspaces.
Remark 5.6. The crucial difference with Theorem 5.1 is that for open tropical halfspaces the generators are enough, while for closed tropical halfspaces, we have to take the whole set into account.

5.1 Proofs

To prove that the inner hull and the outer hull coincide, we mainly have to use the separation results from Section 4.

Proof of Theorem 5.1. The inclusion $\text{tconv}(A) \subseteq \bigcap_{A \subseteq H^{+}(v)} H^{+}(v)$ follows by combining Proposition 3.4.a and Example 3.9.

For the other inclusion, assume that there is a point $z \in \bigcap_{A \subseteq H^{+}(v)} H^{+}(v) \setminus \text{tconv}(A)$.

By Proposition 4.1, we get that $\ker_{+}(B) = \emptyset$, where $B = (0 \odot 0) - A \odot z$.

Theorem 4.6 implies that $\text{sep}_{+}(B) \neq \emptyset$. Hence, there is a separator $(u_{0}, \bar{u}) = (u_{0}, u_{1}, \ldots, u_{d}) \in T^{d+1}_{\pm}$ with $u_{0} \odot \bar{u}^{\top} \circ a^{(j)} > 0$ for all columns $a^{(j)}$ of $A$, and $\odot u_{0} \odot \bar{u}^{\top} \circ z > 0 \Leftrightarrow u_{0} \odot \bar{u}^{\top} \circ z < 0$. This means that the columns of $A$ lie in the halfspace $H^{+}(u)$ but $z$ does not. This contradicts the choice of $z$ in $\bigcap_{A \subseteq H^{+}(v)} H^{+}(v)$.

\[\text{\textbullet}\]

Showing that a closed tropical halfspace is obtained as the closure of an open tropical halfspace follows from a simple limit argument. We use the notation $[d]_{0} = \{0, 1, 2, \ldots, d\}$.

Proof of Lemma 5.2. Let $z \in T^{d}_{\geq 0}$ be an element of $\overline{H^{+}}(a) \setminus H^{+}(a)$. Set

$J = \arg \max \{ |c_{j} \odot z_{j}| \mid j \in [d]_{0} \}$,

where $z_{0} = 0$, and let $\ell \in J$ with $c_{\ell} \odot z_{\ell} > 0$. Denoting the $k$th unit vector $(0, \ldots, 0, 1, 0, \ldots, 0)$ in $\mathbb{R}^{d}$ by $e_{k}$ for $k \in [d]$ and $e_{0} = (-1, \ldots, -1)$, we define a sequence

$y^{(m)} = z + \frac{1}{m} \cdot e_{\ell}$.

The sequence converges to $z$ but each element of the sequence is an element of $H^{+}(a)$.

\[\text{\textbullet}\]

We will use the Fourier-Motzkin version for the relation “$\models$” (Theorem 4.19) to deduce an exterior description of a tropical polytope. However, the system describing the projection in (35) may contain balanced coefficients. We address this issue in the next statement. It is an existence argument statement that a balanced coefficient can be replaced by a signed coefficient, see also Figure 6.

Proposition 5.7 (Resolving balanced coefficients). Let $M$ be a tropically convex set and $c = (c_{0}, c_{1}, \ldots, c_{d}) \in S^{d}$ with $c_{i} \in \mathbb{T}_{\bullet}$ for some $i \in [d]_{0}$ such that

$M \subseteq H(c) = \left\{ x \in T^{d}_{\pm} \mid c \odot \begin{pmatrix} 0 \\ x \end{pmatrix} = 0 \right\}$.

Then there is an element $b \in U(c_{i})$ such that $M$ is contained in

$\left\{ x \in T^{d}_{\pm} \mid (c_{0}, \ldots, c_{i-1}, b, c_{i+1}, \ldots, c_{d}) \odot \begin{pmatrix} 0 \\ x \end{pmatrix} = 0 \right\}$.
Proof. If \( i = 0 \), then we can set \( b = |c_i| \).

Assuming without loss of generality that \( i = d \), we set \( c_{-d} = (c_0, c_1, \ldots, c_{d-1}) \). Fix \( u \in T_{\pm}^{d-1}, v \in T_{\pm} \) such that \((u,v) \in M\). We define \( w = w(u) = c_{-d} \odot \begin{pmatrix} 0 \\ u \end{pmatrix} \).

If \( v \in T_{< O} \), then
\[
\lambda(u,v) = \arg\max \{ \lambda \in U(c_d) \mid w \oplus \lambda \odot v \not\in O \}.
\]
Let
\[
\underline{\lambda} = \min \{ \lambda(u,v) \mid (u,v) \in M, v \in O \}.
\]
If \( v \in T_{> O} \), then
\[
\lambda(u,v) = \arg\min \{ \lambda \in U(c_d) \mid w \oplus \lambda \odot v \not\in O \}.
\]
Let
\[
\bar{\lambda} = \max \{ \lambda(u,v) \mid (u,v) \in M, v > O \}.
\]
We derive a contradiction to the convexity of \( M \), if \( \bar{\lambda} > \underline{\lambda} \).

Let \((p,q)\) and \((r,s)\) attain \(\underline{\lambda}\) and \(\bar{\lambda}\), respectively. In particular, we have \( q < O \) and \( s > O \).

The inequality \(\bar{\lambda} > \underline{\lambda}\) implies that \(\bar{\lambda} > \ominus |c_d|\) and that \(\underline{\lambda} < |c_d|\). We can assume that \(w(p)\) and \(w(r)\) are signed numbers, as we otherwise can replace them by their absolute value without changing the admissible values of \(\lambda\) in (43) and (45).

Now, the construction of \(\underline{\lambda}\) in (43) implies that \(w(p) = \ominus \lambda \ominus q\) and (45) yields \(w(r) = \ominus \bar{\lambda} \ominus s\).

This implies
\[
w(r) \ominus \ominus q^{-1} = \ominus \bar{\lambda} \ominus \lambda = w(p) \ominus \ominus q^{-1}.
\]

We consider the point in the convex combination of \((p,q)\) and \((r,s)\) given by
\[
z = (\ominus q^{-1} \ominus s^{-1})^{-1} \ominus (\ominus q^{-1} \ominus p \ominus s^{-1} \ominus r, O).
\]
Then
\[
c \odot \begin{pmatrix} 0 \\ z \end{pmatrix} = c \odot \begin{pmatrix} \ominus q^{-1} \ominus s^{-1} \ominus 1 \ominus (\ominus p \ominus s^{-1} \ominus r) & \begin{pmatrix} 0 \\ 0 \end{pmatrix} \\ O \end{pmatrix} =
\]
\[
= (\ominus q^{-1} \ominus s^{-1} \ominus 1 \ominus (\ominus q^{-1} \ominus p \ominus s^{-1} \ominus r)) \odot \begin{pmatrix} 0 \\ 0 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix}.
\]
By (47), this implies \(c \odot \begin{pmatrix} 0 \\ z \end{pmatrix} < O\). As \(M\) is convex, this yields \(z \in M \subseteq H(c)\), a contradiction.

So, we can conclude that \(\bar{\lambda} \leq \underline{\lambda}\). Fix any \(b \in (\ominus \bar{\lambda}, \underline{\lambda}] \neq \emptyset\). Let \((u,v) \in M\) with \(v < O\). Then
\[
(c_{-d}, b) \odot \begin{pmatrix} 0 \\ u \\ v \end{pmatrix} = w(u) \oplus b \odot v \not\in w(u) \oplus \ominus \lambda \odot v \not\in w(u) \oplus \lambda(u,v) \odot v \not\in O,
\]
where we use \(b \leq \underline{\lambda}\), (44) and Lemma 2.6.d. The proof for \(v > O\) goes analogously. ▶
Figure 6 Finding a containing halfspace without balanced coefficients.

Example 5.8. A pathological example for the last statement arises from resolving the tautological relation $\bullet(-1) \odot x \oplus \bullet(-1) \odot y \oplus \bullet 0 \nvdash 0$. One obtains the chain of relations

\[
\begin{align*}
\bullet(-1) \odot x \oplus \bullet(-1) \odot y \oplus \bullet 0 & \nvdash 0 \\
\bullet(-1) \odot x \oplus \bullet(-1) \odot y \oplus 0 & \nvdash 0 \\
\bullet(-1) \odot x \oplus 0 & \nvdash 0 \\
0 \odot x \odot 0 & \nvdash 0 .
\end{align*}
\]

Remark 5.9. Indeed, any value of $b \in \mathcal{U}(c_d)$ in the former proof could occur as Figure 6 shows. Any part of the dashed line without opposite (with respect to the origin) points is a tropical line segment.

Example 5.10. The shaded area in Figure 6 shows the feasible region

\[
\{(x, y) \in T^2_\pm \mid \ominus (-1) \odot x_1 \oplus (\bullet 2) \odot x_2 \oplus 0 \nvdash 0 \} .
\]

The red line marks the inequality $\ominus(-1) \odot x_1 \oplus 2 \odot x_2 \oplus 0 \nvdash 0$, while the green line marks the inequality $\ominus(-1) \odot x_1 \oplus (\ominus 2) \odot x_2 \oplus 0 \nvdash 0$. The yellow line corresponds to the inequality $\ominus(-1) \odot x_1 \oplus 0 \nvdash 0$. The blue dashed line interpolates between these three possible extreme closed halfspaces contained in the feasible region.

Our proof of Theorem 5.4 is based on eliminating variables from the canonical exterior description (13). For using those halfspaces, we need to show the additional requirement of tropical convexity for their intersection.

Lemma 5.11. The set

\[
\{(x, z) \in T^{n+d}_\pm \mid A \odot x \bowtie z, x \geq 0 \}
\]

is tropically convex.
Proof. It is enough to show that, for fixed $a \in \mathbb{T}_n^\pm$, the set

$$H = \{ (x, z) \in \mathbb{T}_n^{n+1} \mid a \circ x \bowtie z, x \geq O \}$$

is tropically convex, then the claim follows from Proposition 3.4(a). Let $(p, q), (r, s) \in H$, and $\lambda \in \mathbb{T}_{\geq 0}$, $\lambda \leq 0$. We need to show that $U(p \oplus \lambda \circ r, q \oplus \lambda \circ s) \subseteq H$.

Note that since $p, r \geq O$, we have $p \oplus \lambda \circ r \in \mathbb{T}^\pm$ and therefore $U(p \oplus \lambda \circ r) = \{ p \oplus \lambda \circ r \}$.

By Lemma 2.4(b), we have that $q \in U(a \circ p)$ and $s \in U(a \circ r)$. Using Lemma 3.5(b), we see that

$$U(q \oplus \lambda \circ s) \subseteq U((a \circ p) \oplus \lambda \circ (a \circ r)) = U(a \circ (p \oplus \lambda \circ r)) \ ,$$

completing the proof.

Proof of Theorem 5.4. Equation (13) provides a description by halfspaces involving additional variables. The convex hull of $V$ is the set of those $z \in \mathbb{T}_d^\pm$ for which there is an $x \in \mathbb{T}_n^\pm$ with

$$\begin{pmatrix} A & \circ I_d & 0 \\ \circ A & I_d & 0 \\ 0 & O_d & \circ 0 \\ \circ 0 & O_d & 0 \\ I_n & O_d & 0 \end{pmatrix} \circ \begin{pmatrix} x \\ z \\ 0 \end{pmatrix} = O \ ,$$

(49)

where $I$ is a tropical identity matrix with 0 on the diagonal and $\Theta$ elsewhere.

By Lemma 5.11 and the tropical convexity of $\{ x \in \mathbb{T}_d^\pm \mid \bigoplus_{j \in [n]} x_j = 0, x \geq \Theta \}$, the set of $(x, z) \in \mathbb{T}_d^{n+d}$ fulfilling (49) is the intersection of tropically convex sets and, by Proposition 3.4(a), tropically convex as well.

Hence, we can use Theorem 4.19 to successively project out the $x$-variables. As the inequalities arising from a projection may contain balanced coefficients, we use Proposition 5.7 to replace them by signed coefficients. This yields a description of $tconv(A)$ by non-strict inequalities. Here, we use that resolving a balanced coefficient in an inequality leads to a tighter constraint.

If the intersection of closed tropical halfspaces $M$ is tropically convex, then its intersection with any orthant is tropically convex. By the tropical Minkowski-Weyl theorem in the non-negative orthant [24], each of the parts in the orthants are finitely generated. Taking the tropical convex hull of the union of all these generators yields $M$, as $M$ is tropically convex.

Connection with Tropical Convexity in $\mathbb{T}_\text{max}$

The intersection of a signed tropical convex set with an orthant is just a tropically convex set over $\mathbb{T}_\text{max}$. This allows to study signed tropical convex sets through the existing theory of unsigned tropically convex sets with the hull (12) in each orthant of $\mathbb{T}_\text{max}^d$. The proofs of the main statements are deferred to Section 6.1; these are based on the duality between the non-negative kernels and open tropical cones.

We fix a (finite) set $M \subseteq \mathbb{T}_\text{max}^d$ and interpret $M$ as a matrix whose columns list the points. We will augment $M$ by iteratively intersecting line segments between points in $M$ with coordinate hyperplanes to get a matrix $\zeta(M)$.

To make the construction of $\zeta(M)$ formal, we start with a slight modification of (30). We fix $A = (a_{ij}) \in \mathbb{T}_\text{max}^{d \times n}$ and a row index $i \in [d]$. 

ITCS 2020
For two columns \( u \) and \( v \) of \( A \) with \( u_i > O \) and \( v_i < O \), we set
\[
\lambda^+(u, v) = \odot u_i^{-1} \odot (u_i^{-1} \odot \odot u_i^{-1})^{-1}
\]
and
\[
\lambda^-(u, v) = u_i^{-1} \odot (u_i^{-1} \odot \odot u_i^{-1})^{-1}.
\]
These scalars fulfill \( \lambda^+(u, v) + \lambda^-(u, v) = 0 \) and \( \lambda^+(u, v), \lambda^-(u, v) \geq O \).

We define \( T(i) = (t_{j,p}) \in \{0, O\}^{n \times ((J^+ \cup J^*) \times (J^* \cup J^-))} \), using the decomposition from (29) for \( A \), as the incidence matrix
\[
t_{j,p} = \begin{cases} 
\lambda^+(a^{(k)}, a^{(l)}) & j = k \text{ for } p = (k, l) \in (J^+ \cup J^*) \times (J^* \cup J^-) \\
\lambda^-(a^{(k)}, a^{(l)}) & j = \ell \text{ for } p = (k, \ell) \in (J^+ \cup J^*) \times (J^* \cup J^-) \\
0 & j = p \text{ for } p \in J^0 \\
O & \text{else}
\end{cases}
\]

In Theorem 4.14, we could also have used the matrix from (51) instead of multiplying with both \( S^{(i)} \) and \( T^{(i)} \). This is technically slightly more complicated but has the advantage that the resulting columns of the product with \( A \) are tropical convex combinations of the original columns. This motivates the following.

**Definition 6.1.** The matrix \( \zeta_i(A) \) is the \( i \)th elimination matrix of \( A \) and it arises from \( \xi(A \odot T) \) by replacing the \( i \)th row with \( O \).

This allows to describe generators for the intersection of a tropical convex hull with a coordinate hyperplane \( H_i := \{ x \in T^d_+ \mid x_i = O \} \) for \( i \in [d] \).

**Proposition 6.2.** The intersection \( \text{tconv}(A) \cap H_i \) is generated by \( \zeta_i(A) \).

Additionally, we get generators for the intersection with an orthant.

**Proposition 6.3.** The intersection \( \text{tconv}(A) \cap T^d_{\geq O} \) is generated by
\[
\left( A \cup \bigcup_{i \in [d]} (\text{tconv}(A) \cap H_i) \right) \cap T^d_{\geq O}.
\]

Now, we have to combine all possible ways of descending in a chain of intersections of coordinate hyperplanes. Each permutation \( \sigma \) in the symmetric group on \( d \) elements \( S_d \) gives rise to a sequence of matrices \( \zeta_{\sigma(1)}(M), \zeta_{\sigma(2)}(\zeta_{\sigma(1)}(M)) \) until \( \zeta_{\sigma(d)}(\ldots(\zeta_{\sigma(2)}(\zeta_{\sigma(1)}(M)) \ldots)) \). We denote the concatenation of these \( d \) matrices by \( \zeta_{\sigma}(M) \). The concatenation of the matrices for all \( \sigma \in S_d \) forms the matrix \( \zeta(M) \).

**Theorem 6.4.** The convex hull \( \text{tconv}(M) \) of \( M \) is the union
\[
\bigcup_{O \text{ closed orthant of } T^d_+} \text{tconv}(O \cap \zeta(M)).
\]

**Proof.** By Proposition 6.3, we know that \( \text{tconv}(M) \) is generated by the projections on the boundary of the orthants and the generators in the interior. Iteratively applying Proposition 6.2 to the intersection of coordinate hyperplanes yields the claim.

**Example 6.5.** Looking at the points from Example 3.2, we see how we can determine the tropical convex hull of \( \{(3, 3), (0, 1), (0, 0), (0, 4), (0, 2)\} \). It is the union of the tropical convex hulls
\[
\text{tconv} \left( \{(3, 3), (0, 3), (0, 1)\} \right), \quad \text{tconv} \left( \{(0, 1), (0, 1), (0, 3), (0, 4), (0)\} \right)
\]
\[
\text{tconv} \left( \{(0, 1), (0, 0), (0, 2), (0, 1), (0, 4), (0, 0)\} \right).
\]
On the other hand, to get the tropical convex hull \( t_{\text{conv}}((0,0), (\ominus -2, \ominus -2)) \) in Figure 2a, one needs actual multi-valued cancellation.

We get
\[
\begin{align*}
\zeta_1 \left( \begin{pmatrix} 0 \\ 0 \\ \ominus -2 \\ \ominus -2 \end{pmatrix} \right) &= \left\{ \begin{pmatrix} 0 \\ 0 \\ 0 \\ \ominus -2 \end{pmatrix}, \begin{pmatrix} \ominus -2 \\ \ominus -2 \\ 0 \\ 0 \end{pmatrix} \right\} \\
\zeta_2 \left( \begin{pmatrix} 0 \\ 0 \\ \ominus -2 \\ \ominus -2 \end{pmatrix} \right) &= \left\{ \begin{pmatrix} -2 \\ \ominus -2 \\ 0 \\ 0 \end{pmatrix} \right\}.
\end{align*}
\]

From applying \( \zeta_1(\zeta_2(\cdot)) \), we additionally obtain \( \{(0,0)\} \).

For the positive orthant, this yields the generators \( \{(0,0), (0,-2), (-2,0), (0,0)\} \). The other orthants are derived analogously.

\textbf{Corollary 6.6.} \textit{Tropically convex sets are contractible.}

\textbf{Proof.} The space \( T^e_d \) inherits the topology of \( \mathbb{R}^d \) via the map \( \log|x| \), where the origin is mapped to the all-0-point. As tropically convex sets in all orthants are contractible [20, Theorem 2], we can contract to the boundary of the orthants. The claim follows by induction on the dimension \( d \).

For the definition of the covector decomposition in \( (\mathbb{R} \cup \{-\infty\})^d \) and its connection with regular subdivisions of \( \Delta_d \times \Delta_n \) we refer the reader to [28].

\textbf{Corollary 6.7 (Covector decomposition).} \textit{The combinatorics of the tropically convex hull of a matrix \( A \in T_d \times \Delta_n \) can be described by \( 2^d \) regular subdivisions of \( \Delta_d \times \Delta_n \).}

\section{6.1 Proofs}

\textbf{Proof of Proposition 6.2.} Using the construction in (51) and the fact that \( \ominus |z|, |z| \in U(z) \) for \( z \in T_e \), the inclusion \( \zeta_i(A) \subseteq t_{\text{conv}}(A) \cap H_i \) follows from Definition 3.1. Example 3.8 and Proposition 3.4.a imply that \( t_{\text{conv}}(\zeta_i(A)) \subseteq t_{\text{conv}}(A) \cap H_i \).

For the other inclusion, assume that there is a point \( z \in t_{\text{conv}}(A) \) with \( z_i = 0 \) which is not contained in \( t_{\text{conv}}(\zeta_i(A)) \). By Proposition 4.1, this implies that
\[
\ker_+ \begin{pmatrix} 0 \\ \ominus 0 \\ \ominus z \end{pmatrix} = 0.
\]

The Farkas Lemma 4.6 implies that
\[
\text{sep}_+ \begin{pmatrix} 0 \\ \ominus 0 \\ \ominus z \end{pmatrix} \neq 0.
\]

Furthermore, we get
\[
\text{sep}_+ \left( \begin{pmatrix} 0 \\ \ominus 0 \\ \ominus z \end{pmatrix} \right) \neq 0
\]
as, because of \( z_i = 0 \), the last column is unchanged by \( \zeta_i \) and the first row remains the same due to the definition of \( \lambda^+(u,v) \) and \( \lambda^-(u,v) \) for (50).

However, by Corollary 4.15, then also
\[
\text{sep}_+ \begin{pmatrix} 0 \\ \ominus 0 \\ \ominus z \end{pmatrix} = 0.
\]

Using again the Farkas Lemma 4.6, this implies \( z \not\in t_{\text{conv}}(A) \), a contradiction.
To derive the next claim, we start with a more precise description of a signed tropical line segment. There is a natural bijection between \( \Delta_2 = \{ (\nu, \mu) \in T^2_{\geq 0} \mid \max(\nu, \mu) = 0 \} \) and \( \overline{T} = \mathbb{R} \cup \{-\infty, \infty\} \) given by
\[
(\nu, \mu) \mapsto \mu - \nu.
\]
We denote the inverse image of an element \( \eta \in \overline{T} \) with respect to this map by \( \Psi(\eta) \).

This leads to a parametrization of a tropical line segment for \( a, b \in T^d_{\geq 0} \) via \( \text{tconv}(a, b) = \{ L_\eta(a, b) \mid \eta \in \overline{T} \} \) where \( L_\eta(a, b) = \Psi(\eta)_0 \oplus a \oplus \Psi(\eta)_1 \oplus b \). Note that \( L_{-\infty}(a, b) = a \) and \( L_{\infty}(a, b) = b \).

**Proof of Proposition 6.3.** Let \( z \in \text{tconv}(A) \cap T^d_{\geq 0} \) be an element of \( \mathcal{U}(A \circ \lambda) \) with \( \lambda \in \Delta_d \). We consider the tropical line segments from \( z \) to the columns of \( A \). For a fixed column \( a^{(j)} \) of \( A \) with \( a^{(j)} \notin \mathbb{R}^d_{\geq 0} \), there is a minimal \( \eta \in \overline{T} \) such that a component of \( L_\eta(z, a^{(j)}) \) is balanced.

**Intermediate claim I:** All entries of \( L_\eta(z, a^{(j)}) \) are either balanced or in \( T^d_{\geq 0} \). For an arbitrary row \( i \in [d] \), the expression \( \Psi(\eta)_1 \circ z_i \oplus \Psi(\eta)_2 \circ a^{(j)} \) is in \( T^d_{\geq 0} \) for \( \eta = -\infty \). The claim now follows from the piecewise definition of the addition in terms of the absolute values.

Using Proposition 3.6, we see that the point \( b^{(j)} \) obtained from \( L_\eta(z, a^{(j)}) \) by replacing all balanced entries with \( 0 \) is in \( \text{tconv}(A) \cap T^d_{\geq 0} \). For \( a^{(j)} \in \mathbb{R}^d_{\geq 0} \) we set \( b^{(j)} = a^{(j)} \).

**Intermediate claim II:** The point \( z \) is in the convex hull of \( \{ b^{(j)} \mid j \in [n] \} \). It is enough to show that
\[
\ker_{\oplus}(\begin{pmatrix} 0 & \cdots & 0 & \nu \circ z \oplus 0 \\ a^{(1)} & \cdots & a^{(n-1)} & b^{(n)} \end{pmatrix}) \neq \emptyset
\]
because than we can iteratively replace the columns \( a^{(i)} \) by \( b^{(i)} \). Let \( b^{(1)} \in \nu \circ z \oplus \mu \circ a^{(1)} \). Pick an element \( x \) scaled such that \( x_1 = \mu \). Then
\[
\begin{pmatrix} \nu & 0 & \cdots & 0 & 0 \\ \nu \circ z & 0 & \cdots & 0 & \nu \circ \circ z \end{pmatrix} \oplus \begin{pmatrix} 0 & 0 & \cdots & 0 & 0 \end{pmatrix} \oplus \begin{pmatrix} a^{(1)} & a^{(2)} & \cdots & a^{(n)} & \circ z \end{pmatrix} \oplus x
\]
is in \( T^d_{\geq 0} \). Therefore \((0, \ldots, 0)\) is in the non-negative kernel of
\[
\begin{pmatrix} \nu & x_1 & \cdots & x_n & \times (\nu \oplus x_{n+1}) \\ \nu \circ z & \circ x_1 \circ a^{(1)} & \cdots & \circ x_n & \times \circ (\nu \oplus x_{n+1}) & \circ (\circ z) \\ 0 & x_2 & \cdots & x_n & \times (\nu \oplus x_{n+1}) & \circ (\circ z) \\ \nu \circ z \oplus \mu & \circ a^{(1)} & \cdots & \circ a^{(n)} & \times (\nu \oplus x_{n+1}) & \circ (\circ z) \end{pmatrix} =\]
\[
\begin{pmatrix} \mu \circ a^{(1)} & x_2 & \cdots & x_n & \times x_{n+1} \oplus (\circ z) \\ \mu \circ a^{(1)} & \circ x_2 \circ a^{(2)} & \cdots & \circ x_n \circ a^{(n)} & \times x_{n+1} \oplus (\circ z) \end{pmatrix}
\]
For fixed \( i \in [d] \), if \( \nu \circ z_i \oplus \mu \circ a_i^{(1)} \) is not balanced or the maximum absolute value is attained somewhere else in the row, we can replace it by \( b_i^{(1)} \) and \((0, \ldots, 0)\) is still in the non-negative kernel.

Otherwise, \( \circ \nu \circ z_i = \mu \circ a_i^{(1)} \) and \( \nu \oplus x_{n+1} = \nu \). But \((0, \ldots, 0)\) is also in the non-negative kernel of
\[
\begin{pmatrix} \mu \circ a^{(1)} & x_2 & \cdots & x_n & \times x_{n+1} \oplus (\circ z) \end{pmatrix}.
\]
Since \( \mu \circ a_i^{(1)} = \circ \nu \circ z_i \) has the same sign as \( \circ x_{n+1} \circ z_i \) and we have \( \nu \geq x_{n+1} \), there has to be an \( \ell \in [n] \) such that \( x_\ell \circ a^{(1)}_\ell = \circ \mu \circ a_i^{(1)} = \nu \circ z_i \). Therefore, we can replace \( \nu \circ z_i \oplus x_\ell \circ a^{(1)}_\ell \) by \( 0 \) and \((0, \ldots, 0)\) remains in the non-negative kernel.
Therefore, \((0, x_2, \ldots, x_n, (\nu \oplus x_{n+1}))\) is in the non-negative kernel of
\[
\begin{pmatrix}
0 & 0 & \cdots & 0 & \ominus 0 \\
\delta^{(1)} & a^{(2)} & \cdots & a^{(n)} & \ominus \zeta
\end{pmatrix}.
\]
This finishes the proof of claim II. ▶

A Missing Proofs

Lemma 2.6. Let $a, b, c, d \in S$.
(a) $a \oplus c \vDash b \Leftrightarrow a \vDash b \ominus c$.
(b) $a \vDash b \land c \vDash d \Rightarrow a \ominus c \vDash b \ominus d$.
(c) If $c \in T_{\geq}$, then $b \vDash c$ and $c \vDash a$ imply $b \vDash a$.
(d) $a \vDash b$ implies $c \ominus a \oplus d \vDash c \ominus b \ominus d$ for $c \in T_{\geq 0}$ and $c \ominus b \ominus d \vDash c \ominus a \oplus d$ for $c \in T_{< 0}$.

Proof.
(a) The claim follows directly from the definition and the properties of the semiring $S$.
(b) Using the definition, we obtain $a \ominus b, c \ominus d \in T_{\geq 0} \cup T_{\bullet}$. This implies already $a \ominus c \ominus b \ominus d \in T_{\geq 0} \cup T_{\bullet}$.
(c) For a contradiction, assume $b \not\vDash a$, that is, $b \ominus a \in T_{< 0}$.
Case 1: $|b| > |a|$. In this case, $b \in \mathbb{T}_{<0}$. Since $b \odot c \in \mathbb{T}_{\geq 0} \cup \mathbb{T}_+$, it follows that $c \in \mathbb{T}_{<0}$ and $|c| \geq |b|$, using $c \in \mathbb{T}_{\pm}$. We now get a contradiction to $c \odot a \in \mathbb{T}_{\geq 0} \cup \mathbb{T}_+$, since $|c| \geq |b| > |a|$.

Case 2: $|a| > |b|$. This case follows by an analogous argument. With $a \in \mathbb{T}_{\geq 0}$, the condition $c \odot a \in \mathbb{T}_{\geq 0} \cup \mathbb{T}_+$ implies $c \in \mathbb{T}_{>0}$ and $|c| \geq |a| > |b|$. This contradicts $b \odot c \in \mathbb{T}_{\geq 0} \cup \mathbb{T}_+$.

Case 3: $|a| = |b|$. In this case, we must have $b \in \mathbb{T}_{<0}$ and $a \in \mathbb{T}_{>0}$. We thus obtain $c \in \mathbb{T}_{<0}$ as in case I, but also $c \in \mathbb{T}_{<0}$ as in case II, a contradiction.

(d) The expression $c \odot (a \odot b) = c \odot a \odot c \odot b$ is in $\mathbb{T}_{\geq 0}$ for $c \in \mathbb{T}_{\geq 0}$ and in $\mathbb{T}_{\leq 0}$ for $c \in \mathbb{T}_{\leq 0}$. Now, the statement follows from (b) with $d \equiv d$.

Lemma 3.5.

(a) Let $a \in \mathbb{S}$, $b \in \mathbb{T}_\pm$, and $z \in \mathbb{U}(a \odot b)$. Then there exists an $a' \in \mathbb{U}(a)$ such that $z \in \mathbb{U}(a' \odot b)$.

(b) If $a \in \mathbb{U}(x)$, $b \in \mathbb{U}(y)$, and $c \in \mathbb{T}_\pm$, then $\mathbb{U}(c \odot a \odot b) \subseteq \mathbb{U}(c \odot x \odot y)$.

Proof.

(a) If $a \in \mathbb{T}_\pm$, then $a' = a$ satisfies the requirements. For the rest of the proof, we assume $a \in \mathbb{T}_+$. If $|b| > |a|$, then we can set $a' = |a|$. In this case, $a' \odot b = a \odot b = b \in \mathbb{T}_\pm$. Consider now the case $|a| \geq |b|$, which implies $a \odot b = a$. Then $z \in \mathbb{U}(a \odot b)$ if and only if $|z| \leq |a|$. For $|a| \geq |z| \geq |b|$, we set $a' = z$. If $|a| \geq |b| > |z|$, then we set $a' = \odot b$. In both cases it is easy to see that $z \in \mathbb{U}(a' \odot b)$.

(b) Note that $|a| \leq |x|$ and $|b| \leq |y|$, and consequently, $|c \odot a \odot b| \leq |c \odot x \odot y|$. If $c \odot x \odot y$ is balanced, then the claim follows: $\mathbb{U}(c \odot x \odot y)$ contains all $r \in \mathbb{T}_\pm$ with $|r| \leq |c \odot x \odot y|$; this holds for all $r \in \mathbb{U}(c \odot a \odot b)$.

Hence, assume that $c \odot x \odot y$ is not balanced. In particular, $x$ or $y$ is not balanced. If both $x, y \in \mathbb{T}_\pm$, then $a = x$ and $b = y$ and thus the claim is immediate. The remaining case is when exactly one of $x$ and $y$ is balanced. Let us assume $y \in \mathbb{T}_\pm$; the case $x \in \mathbb{T}_\pm$ follows similarly. Now we have $b = y$, and we must also have $|y| > |x \odot y|$ as otherwise $c \odot x \odot y$ would be balanced. Consequently, $c \odot x \odot y = y$. On the other hand, $|a| \leq |x|$ and $b = y$ imply $|c \odot a| < |b|$, and therefore $c \odot a \odot b = y$, and the claim follows.

Proposition 3.6. An arbitrary subset $M \subseteq \mathbb{T}_\pm^d$ is tropically convex if and only if the tropical convex hull $tconv(p, q) \subseteq M$ for all $p, q \in M$.

Proof. For a tropically convex set, the tropical convex hull of all two-element subsets is contained by definition. In the converse direction, we show by induction on $n$ that if we select any $n$ vectors from $M$ as the columns of a matrix $A \in \mathbb{T}_\pm^{d \times n}$, then $\mathbb{U}(A \odot x) \subseteq M$ for any $x \in \mathbb{T}_\pm^d$. $\bigoplus_{j \in [n]} x_j = 0$. The case $n = 2$ follows by the assumption; consider now $n \geq 3$ and assume that the claim holds for $n - 1$.

Let $z \in \mathbb{U}(A \odot x)$. Without loss of generality, we can assume that $x_1 = 0$. We set $s = \bigoplus_{l=1}^{n-1} x_l \odot a(l) \in \mathbb{S}^d$, where $a(l)$ is the $l$-th column of $A$. We let $q = a(n)$. Then, $A \odot x = s \odot x_n \odot q$.

We can apply Lemma 3.5(a) to each component of $z, s$, and $x_n \odot q$. Thus, we obtain a vector $p \in \mathbb{U}(s)$ such that $z \in \mathbb{U}(p \odot x_n \odot q)$. By induction, $p \in M$, and thus $z \in tconv(p, q) \subseteq M$ by the assumption. This completes the proof.

Proposition 3.7. For any matrix $A \in \mathbb{T}_\pm^{d \times n}$, the convex hull $tconv(A)$ is tropically convex. Consequently, $tconv(tconv(A)) = tconv(A)$. 

ITCS 2020
Signed Tropical Convexity

**Proof.** Using Proposition 3.6, it suffices to show that if \( p, q \in \text{tconv}(A) \), \( \lambda \in \mathbb{T}_{\geq 0} \), \( \lambda \leq 0 \), then \( \mathcal{U}(p \oplus \lambda \odot q) \subseteq \text{tconv}(A) \).

Let \( x, y \in \mathbb{T}_{\geq 0}^n \). \( \sum_{j \in [n]} x_j = 0 \), \( \sum_{j \in [n]} y_j = 0 \) such that \( p \in \mathcal{U}(A \odot x) \) and \( q \in \mathcal{U}(A \odot y) \). We let \( z = x \oplus \lambda \odot q \); clearly, \( z \in \mathbb{T}_{\geq 0}^n \) and \( \sum_{j \in [n]} z_j = 0 \). From Lemma 3.5(b), we obtain that

\[
\mathcal{U}(p \oplus \lambda \odot q) \subseteq \mathcal{U}((A \odot x) \oplus (A \odot y)) = \mathcal{U}(A \odot z) \subseteq \text{tconv}(A). \]

**Proposition 4.1.** For \( A \in \mathbb{T}_{\pm}^{d \times n} \) and \( b \in \mathbb{T}_{\pm}^d \) we have

\[
b \in \text{tconv}(A) \iff \ker_+ (A \odot b) \neq \emptyset. \]

**Proof.** The condition \( b \in \text{tconv}(A) \) is equivalent to the existence of an element \( x \in \mathbb{T}_{\geq 0}^n \) with \( \sum_{j \in [n]} x_j = 0 \) and \( A \odot x \asymp b \).

Let \( (x, t) \) be a vector in the non-negative kernel, where \( x \in \mathbb{T}_{\geq 0}^n \) and \( t \in \mathbb{T}_{\geq 0} \) denotes the last component. First, we claim that \( t \neq 0 \). Indeed, \( t = 0 \) would yield \( \sum_{j \in [n]} x_j \asymp 0 \), which implies \( x_j = 0 \) for all \( j \in [n] \). Thus, we obtain \( (x, t) = (0, 0) \), a contradiction. Since \( t \neq 0 \), we can scale \( (x, t) \) such that \( t = 0 \). In this case, the definition of the kernel gives \( A \odot x \asymp b \asymp O \) and \( \sum_{j \in [n]} x_j \asymp 0 \asymp O \). The latter inequality yields \( \sum_{j \in [n]} x_j = 0 \). This is the same as the combination witnessing \( b \in \text{tconv}(A) \) as above.

**Theorem 3.14.** The signed hull \( \text{tconv}(A) \) is the union of the signed valuations for all possible lifts

\[
\text{tconv}(A) = \bigcup_{\text{sval}(A) = A} \text{sval}(\text{conv}(A)).
\]

**Proof.** We start with the inclusion \( \supseteq \). Let \( A \in \mathbb{T}_{\pm}^{d \times n} \) and fix a lift \( A \) of \( A \), this means a matrix \( A \in \mathbb{K}^{d \times n} \) with \( \text{sval}(A) = A \). For a vector \( \lambda \in \mathbb{K}^{\geq 0} \) with \( \sum_{j=1}^n \lambda_j = 1 \) the valuation \( x = \text{sval}(\lambda) \) is in \( \mathbb{T}_{\geq 0}^n \) and fulfills \( \sum_{j=1}^n x_i = 0 \). We want to show that \( b = \text{sval}(\lambda_1 \cdot a^{(1)} + \cdots + \lambda_n \cdot a^{(n)}) \in \text{tconv} A \). For each \( i \in [d] \), let \( c_i = \max \{|\text{sval}(\lambda_j \cdot a^{(j)})| : j \in [n]\} \). Furthermore, we define \( p = A \odot x = \sum_{j \in [n]} x_j \odot a^{(j)} = \sum_{j \in [n]} \text{sval}(\lambda_j \cdot a^{(j)}) \). We fix an \( i \in [d] \) and we want to show that \( b_i \in \mathcal{U}(p_i) \). Note that \( |p_i| = c_i \). If \( p_i \) is not balanced, we already have \( b_i = p_i \). Otherwise, we get \( |b_i| \leq c_i \) and consequently \( b_i \in \{0, c_i\} \). This finishes the proof of the inclusion \( \supseteq \).

For the other direction, we fix \( b \in \mathcal{U}(A \odot x) \) for some \( x \in \mathbb{T}_{\geq 0}^n \). \( \sum_{j \in [n]} x_j = 0 \). We define

\[
\lambda_j = t^{x_j} \left( \sum_{k \in [n]} t^{x_k} \right)^{-1} \text{ for each } j \in [n].
\]

With this, we get \( \lambda \geq 0 \) and \( \sum_{k \in [n]} \lambda_k = 1 \).

For each row \( i \in [d] \), we denote by \( J_i^+ \) the set of indices of the positive elements in the set \( \text{argmax} \{ a_j^{(i)} \odot x_j : j \in [n] \} \), and by \( J_i^- \) analogously for negative elements.

We set \( \ell_i \) to be an arbitrary index in \( \text{argmin} \{|J_i^+|, |J_i^-|\} \), and define

\[
a_j^{(i)} = \begin{cases} 
\text{sgn}(a_{ij}) t^{a_{ij}} + \alpha_i & \text{for } j = \ell_i \\
\text{sgn}(a_{ij}) t^{a_{ij}} & \text{else},
\end{cases}
\]
where
\[
\alpha_i = \frac{1}{\lambda_i} \left( -\sum_{k \in [d]} t\text{sgn}(a_{ik})d_{|a_{ik}|+x_k} + t\text{sgn}(b_i)t_{|b_i|} \right).
\]

Note that \(|b_i| \leq |a_{ik}|+x_k\) and \(|a_{ij}|+x_j-x_k \leq |a_{ik}|\) for all \(j \in [n]\). Therefore, \(s\text{val}(a_{ij}) = a_{ij}\) for all \(i \in [d]\) and \(j \in [n]\). Furthermore, we get
\[
\alpha_i \cdot \lambda = \sum_{k \in [d] \setminus \{\ell_i\}} \lambda_k a_{ik}^{(k)} + \lambda_{\ell_i} a_{\ell_i}^{(\ell_i)}
\]
\[
= \sum_{k \in [d]} t\text{sgn}(a_{ik})d_{|a_{ik}|+x_k} - \sum_{k \in [d]} t\text{sgn}(a_{ik})d_{|a_{ik}|+x_k} + t\text{sgn}(b_i)t_{|b_i|}
\]
\[
= t\text{sgn}(b_i)t_{|b_i|}.
\]

Hence, we have \(s\text{val}(\alpha_i \cdot \lambda) = b_i\) for all \(i \in [d]\). This concludes the proof.

**Proposition 4.8.** Let \(A, B \subseteq \mathbb{S}\) be two finite sets. There is an element \(c \in \mathbb{S}\) with
\[
c \odot a > O \quad \text{and} \quad b \odot c > O \quad \text{for all} \ a \in A, \ b \in B
\]
if and only if
\[
b \odot a > O \quad \text{for all} \ (a, b) \in A \times B.
\]
Furthermore, the element \(c\) can chosen to be signed.

**Proof.** For each pair \((a, b) \in A \times B\), we add the inequalities in (24) using Lemma 2.2 and obtain \(b \odot a \odot c \odot c > O\). This implies \(b \odot a > \mid c \mid \geq O\) and, hence, (25).

For the other direction, note that \(A \subseteq \mathbb{T}_\pm\) or \(B \subseteq \mathbb{T}_\pm\), as two balanced elements are not comparable by “\(>\)”. Because of the symmetry \((9)\), we can assume that \(B \subseteq \mathbb{T}_\pm\). Let \(\beta\) denote the minimum of \(B\). Furthermore, we define \(\alpha\) as the maximum of \(A \cap \mathbb{T}_\pm\) and \(\{|a| \mid a \in A \cap \mathbb{T}_\pm\}\), where either of these two sets could also be empty. We obtain from (25) that \(\beta > \alpha\), where we use that \(b > a \iff b > \mid a\mid\) for \(a \in \mathbb{T}_\pm\). An arbitrary element \(c\) with \(\alpha < c < \beta\) fulfills (24). As the elements in \(B\) are totally ordered, the claim for the inequalities involving \(B\) follows immediately. Distinguishing the balanced and signed elements yields the claim for the inequalities involving \(A\).

**Proposition 4.10.** Let \(A, B \subseteq \mathbb{S}\) be two finite sets. There is an element \(c \in \mathbb{T}_\pm\) with
\[
c \odot a \neq O \quad \text{and} \quad b \odot c \neq O \quad \text{for all} \ a \in A, \ b \in B
\]
if and only if
\[
b \odot a \neq O \quad \text{for all} \ (a, b) \in A \times B
\]

**Proof.** The first direction from (26) to (27) follows from Lemma 2.6(a) and 2.6(c) because of \(c \in \mathbb{T}_\pm\).

For the other direction, let
\[
\alpha_0 = \arg\min \{ \mid a \mid \mid a \in A \cap \mathbb{T}_\pm\}\,
\alpha_1 = \max \{ \mid a \mid \mid a \in A \cap \mathbb{T}_\pm\}\,
\beta_0 = \arg\min \{ \mid b \mid \mid b \in B \cap \mathbb{T}_\pm\}\,
\beta_1 = \min \{ \mid b \mid \mid b \in B \cap \mathbb{T}_\pm\}\,
\]

(54)
Signed Tropical Convexity

with respect to the ordering “≥”. By construction, we get from (27) the relation \( \beta_1 \ominus \alpha_1 \models O \), which yields \( \beta_1 \geq \alpha_1 \). Furthermore, we obtain \( \beta_1 \ominus \alpha_0 \models O \) implying \( \beta_1 \geq \circ \alpha_0 \) and \( \beta_0 \ominus \alpha_1 \models O \) implying \( |\beta_0| \geq \alpha_1 \). We conclude that

\[
\beta := \min(|\beta_0|, \beta_1) \geq \max(\circ |\alpha_0|, \alpha_1) := \pi ,
\]

using also the trivial inequality \( |\beta_0| \geq \circ |\alpha_0| \).

By checking all possibilities arising from the list in (54), we see that the element \( \gamma \) fulfills \( b \ominus \gamma \models O \) and \( \gamma \ominus a \models O \) for all \( a \in A, b \in B \).

Other Notions of Tropical Convexity

Parallel to the development of tropical convexity, the more general notion of \( B \)-convexity was developed starting with [15]. The notion of \( B \)-convexity boils down to convexity defined over the semiring \( R \geq 0 \) with operations \( \oplus = \max \) and \( \otimes = \cdot \), see [15, Theorem 2.1.1].

Taking logarithms transforms these operations to \( \oplus = \max \) and \( \otimes = + \) on \( R \cup \{-\infty\} \). This gives rise to a transferred version of \( B \)-convexity on \( T_\pm \) by considering the images of \( B \)-convex sets in \( R^d \) under the map \( s\log: x \mapsto \text{sgn}(x) \log(|x|) \).

The following example shows that our notion of signed tropical convexity is an even more restrictive notion than \( B \)-convexity and \( B^\# \)-convexity [14].

Example B.1. The tropical convex hull of \( A = \{(\ominus 2, \ominus 1), (2, 1)\} \) is the set

\[
[\ominus 2, 2] \times [\ominus 1, 1] .
\]

However, the set \( \text{Co}^r(A) \) is

\[
L = \{(2 \ominus \lambda, \lambda) \mid \lambda \in [\ominus 1, 1]\} .
\]

for all \( r \in \mathbb{N} \). In particular, also \( \text{Co}^\infty(A) \) equals \( L \). This implies that \( B(L) = L \). We depict both in Figure 7. Hence, \( t\text{conv}(A) \) strictly contains \( B(A) \). Furthermore, [14, Corollary 4.2.4] shows that \( L \) is also \( B^\# \)-convex.

Interestingly, the set \( L \) is also the image under the signed valuation of the set

\[
\text{conv}\left(\left(-t^2, t^2\right), \left(-t, 0\right)\right) .
\]

Here, we mean the convex hull over the Puiseux series \( R\llcorner t \). So \( L \) is the tropicalization of a single line segment while our hull construction yields the union of line segments whose spanning points tropicalize to \( A \), as we saw in Section 3.2. For example, we get the set \( \{\ominus 2\} \times [\ominus 1, 1] \cup [\ominus 2, 2] \times \{1\} \) as the tropicalization of \( \text{conv}\left(\left(-2t^2, t^2\right), \left(-t, 0\right)\right) \).

Remark B.2. It is tempting to define a cancellative sum for two numbers \( a, b \in T_\pm \) by

\[
a \ominus b = \begin{cases} 
a & |a| > |b| 
b & |b| > |a| 
a \quad a = b 
0 & a = \ominus b \end{cases} .
\]
This can be extended componentwise to $\mathbb{T}^d$.

An iterative version of this construction is used in [14]. A conceptional drawback of the cancellative sum is that it is not associative, as the example

$$0 \oplus (\ominus 0 \ominus -1) = 0 \ominus 0 = O \neq -1 = O \ominus -1 = (0 \ominus 0) \ominus -1$$

shows.

\textbf{Remark B.3.} Recall that Theorem 6.4 gave a way to determine the whole tropical convex hull from the tropical convex hull in each orthant. For sufficiently generic matrices, one can use the cancellative sum from Remark B.2. If there are no antipodal points, no balanced coefficients arise in the elimination and the map $\xi$ used for Theorem 4.12 is just the identity. Hence, the iterative construction of a single intersection point with a coordinate hyperplane suffices.
Distributional Property Testing in a Quantum World

Abstract
A fundamental problem in statistics and learning theory is to test properties of distributions. We show that quantum computers can solve such problems with significant speed-ups. We also introduce a novel access model for quantum distributions, enabling the coherent preparation of quantum samples, and propose a general framework that can naturally handle both classical and quantum distributions in a unified manner. Our framework generalizes and improves previous quantum algorithms for testing closeness between unknown distributions, testing independence between two distributions, and estimating the Shannon / von Neumann entropy of distributions. For classical distributions our algorithms significantly improve the precision dependence of some earlier results. We also show that in our framework procedures for classical distributions can be directly lifted to the more general case of quantum distributions, and thus obtain the first speed-ups for testing properties of density operators that can be accessed coherently rather than only via sampling.

1 Introduction

Distributional property testing is a fundamental problem in theoretical computer science (see, e.g. [22]) aiming at determining properties of probability distributions with the least number of independent samples. It has intimate connections and applications to statistics, learning theory, and algorithm design.

The merit of distributional property testing mainly comes from the fact that the testing of many properties admits sublinear algorithms. For instance, given the ability to take samples from a discrete distribution $p$ on $[n] := \{1, \ldots, n\}$, it requires $\Theta(n/\epsilon^2)$ samples to “learn” $p$, © András Gilyén and Tongyang Li; licensed under Creative Commons License CC-BY

Editor: Thomas Vidick; Article No. 25; pp. 25:1–25:19
Leibniz International Proceedings in Informatics
Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany
i.e., to construct a distribution \( q \) on \([n]\) such that \( \|p - q\|_1 \leq \epsilon \) with success probability at least \( 2/3 \) (\( \| \cdot \|_1 \) being \( \ell^1 \)-distance). However, testing whether \( p = q \) or \( \|p - q\|_1 > \epsilon \) requires only \( \Theta(\max\{n^{2/3}, n^{1/2}\}) \) samples from \( p \) and \( q \) \([19]\), which is sublinear in \( n \) and significantly smaller than the complexity of learning the entire distributions. See Section 1.4 for more examples and discussions.

In this paper, we study the impact of quantum computation on distributional property testing problems. We are motivated by the emerging topic of “quantum property testing” (see the survey of \([30]\)) which focuses on investigating the quantum advantage in testing classical statistical properties. Quantum speed-ups have already been established for a few specific problems such as testing closeness between distributions \([13, 29]\), testing identity to known distributions \([18]\), estimating entropies \([27]\), etc. In this paper we propose a generic approach for quantum distributional property testing, and illustrate its power on a few examples. This is our attempt to make progress on the question:

Can quantum computers test properties of distributions systematically and more efficiently?

1.1 Problem statements

Throughout the paper, we denote probability distributions on \([n]\) by \( p \) and \( q \); their \( \ell^\alpha \)-distance is defined as \( \|p - q\|_\alpha := \left( \sum_{i=1}^n |p_i - q_i|^\alpha \right)^{1/\alpha} \). Similarly, we denote \( n \times n \) density operators (i.e., quantum distributions) by \( \rho \) and \( \sigma \); their \( \ell^\alpha \)-distance is defined via the corresponding Schatten norm.

Input models. To formulate the problems we address, we define classical and quantum access models for distributions on \([n]\). We begin with the very natural model of sampling.

\begin{definition} \textbf{(Sampling).} A classical distribution \((p_i)_{i=1}^n\) is accessible via classical sampling if we can request independent samples from the distribution, i.e., get a random \( i \in [n] \) with probability \( p_i \). A quantum distribution \( \rho \in \mathbb{C}^{n \times n} \) is accessible via quantum sampling if we can request independent copies of the state \( \rho \).
\end{definition}

Now we define a coherent analogue of the above sampling model. To our knowledge this type of query-access was only studied by a few earlier works \([29, 24]\) and only in the special case of classical distributions. The motivation for this input model is the following: we can think about a density operator as the outcome of some physical process modeled by some black-box. Suppose that the black-box can generate samples on demand. Unlike in the classical (randomized) setting, in a quantum scenario in principle it is always possible to reverse every computational / physical process – including this black-box. If reversion is not feasible, then we get the plain sampling model; however if it is possible to reverse the (quantum) black-box then we get the purified query access model that we describe. For example, if a quantum computer produces the samples via, say, a Monte Carlo method, then the process is easily reversible. However, if the samples come from some source “outside the lab”, then reversing the process might not be possible. Therefore, both input models (purified quantum query access and sampling access) are well-motivated. The surprising fact is that this subtle difference in the input models gives rise to significantly different complexities, as we show later for several problems.

\footnote{For readers less familiar with quantum computing, a density operator (=quantum distribution) \( \rho \in \mathbb{C}^{n \times n} \) is a positive semidefinite matrix with \( \text{Tr}[\rho] = 1 \). Please refer to the textbook \([31]\) for more information.}
Definition 2 (Purified quantum query-access). A density operator $\rho \in \mathbb{C}^{n \times n}$, has purified quantum query-access if we have access to a unitary oracle $U_\rho$ (and its inverse) acting as

$$U_\rho |0\rangle_A |0\rangle_B = |\psi_\rho\rangle_{AB} = \sum_{i=1}^{n} \sqrt{p_i} |\phi_i\rangle_A |\psi_i\rangle_B,$$

where $\langle \phi_i | \phi_j \rangle = \langle \psi_i | \psi_j \rangle = (\text{Kronecker}) \delta_{ij}$

such that $\text{Tr}_A(|\psi_i\rangle\langle\psi_i|) = p_i$. If $|\psi_i\rangle = |i\rangle$, then $\rho = \sum_{i=1}^{n} p_i |i\rangle\langle i|$ is a diagonal density operator which can be identified with the classical distribution $p$, so we can simply write $U_\rho$ instead of $U_\rho$. With a slight abuse of notation sometimes we will concisely write $|\rho\rangle$ instead of $|\psi_\rho\rangle$.

We also define an even stronger input model that is considered in a series of earlier works, see, e.g., [13, 18, 27, 15].

Definition 3 (Classical distribution with discrete query-access). A classical distribution $(p_i)_{i=1}^{n}$, has discrete query-access if we have classical / quantum query-access to a function $f : S \rightarrow [n]$ such that for all $i \in [n]$, $p_i = |\{ s \in [S] : f(s) = i \}|/|S|$. (Typically the interesting regime is when $|S| \gg n$.) In the quantum case a query oracle is a unitary operator $O$ acting on $\mathbb{C}^{[S]} \otimes \mathbb{C}^{n}$ as

$$O : |s,0\rangle \mapsto |s,f(s)\rangle \text{ for all } s \in S.$$  

Note that if one first creates a uniform superposition over $S$ and then makes a query, then the above oracle turns into a purified query oracle to a classical distribution as in Definition 2. Therefore all lower bounds that are proven in this model also apply to the purified query-access oracles. In fact all algorithms that the authors are aware of do this conversion, so they effectively work in the purified query-access model. Moreover, we conjecture that the two input models are equivalent when $|S| \gg n$. For this reason we only work with the purified query-access model in this work.

Another strengthening of the purified query-access model for classical distributions is when we assume access to a unitary (and its inverse) acting as $|0\rangle \mapsto \sum_{i=1}^{n} \sqrt{p_i} |i\rangle$. A very similar input model was thoroughly studied by [4].

Definition 4 (Classical distribution with pure-state preparation access). A classical distribution $(p_i)_{i=1}^{n}$, is accessible via pure state preparation oracle if we have access to a unitary oracle $U_{\text{pure}}$ (and its inverse) acting as

$$U_{\text{pure}} : |0\rangle \mapsto \sum_{i=1}^{n} \sqrt{p_i} |i\rangle.$$ 

This is strictly stronger\(^2\) than the purified query-access model. In order to simulate purified queries we can first do a pure state query and then copy $|i\rangle$ to a second fresh ancillary

\(^2\) $|\psi\rangle \in \mathbb{C}^{n}$ denotes a “ket” vector and $\langle \psi | = (|\psi\rangle)\text{\textsuperscript{\dagger}}$ stands for its conjugate transpose, called “bra” in Dirac notation; $|i\rangle = \vec{e}_i$ is the $i^{\text{th}}$ basis vector. An $\ell^{2}$-normalized $|\psi\rangle$ is called a pure state, and corresponds to density operator $|\psi\rangle\langle\psi|$. For $A = \mathbb{C}^{n}$, $B = \mathbb{C}^{n}$ and $|\phi\rangle \in A \otimes B$ we denote by $\text{Tr}[|\phi\rangle\langle\phi|]_A \in B \otimes B^* = \mathbb{C}^{n \times n}$ the partial trace over $A$.

\(^3\) This can be seen in various ways. We give an argument in the spirit of distributional property testing. Closeness of two unknown distributions $p,q$ can be tolerantly tested in the squared Hellinger distance $H(p,q)^2 = \frac{1}{2} \left\| \sqrt{p} - \sqrt{q} \right\|_2^2$ to precision $\epsilon$ in query complexity $O(1/\sqrt{\epsilon})$ in the model of Definition 4 using amplitude estimation. On the other hand the classical sample complexity of testing equality to $\epsilon$ precision in this metric is $\Theta(\min(n^{2/3}/\epsilon^{2/3}, n^{3/4}/\epsilon))$, as shown in [20]. The results of Chailloux [16] imply that this query complexity improves at most cubically in the model of Definition 2, showing that the input model of Definition 4 is strictly stronger.
register using, e.g., some CNOT gates. Finally, for completeness we mention that one could also consider a model similar to the above where one can only request samples of pure states of the form $\sum_{i=1}^{n} \sqrt{p_i} |i\rangle$, as studied for example in [6, 5].

We will mostly focus on the first two input models and will only use the latter strengthenings of the purified query-access model for invoking and proving lower bounds.

**Property testing problems.** We study three distributional properties: $\ell^\alpha$-closeness testing, independence testing, and entropy estimation. In the classical literature these are well-studied properties, and the corresponding testers motivate general algorithms for testing properties of discrete distributions [20, 1].

For brevity we only give the definitions for classical distributions; similar definitions apply to quantum density matrices if we replace vector norms by the corresponding Schatten norms.

▶ **Definition 5** ($\ell^\alpha$-closeness testing). Given $\epsilon > 0$ and two probability distributions $p, q$ on $[n]$, $\ell^\alpha$-closeness testing is to decide whether $p = q$ or $\|p - q\|_\alpha \geq \epsilon$ with success probability at least $\frac{2}{3}$. Tolerant testing: decide whether $\|p - q\|_\alpha \leq 0.99\epsilon$ or $\|p - q\|_\alpha \geq \epsilon$ with success probability at least $\frac{2}{3}$.

▶ **Definition 6** (Independence testing). Given $\epsilon > 0$ and a probability distribution $p$ on $[n] \times [m]$ with $n \geq m$, independence testing is to decide, with success probability at least $\frac{2}{3}$, whether $p$ is a product distribution or $p$ is $\epsilon$-far in $\ell^1$-norm from any product distribution on $[n] \times [m]$.

▶ **Definition 7** (Entropy estimation). Given $\epsilon > 0$ and a density operator $\rho \in \mathbb{C}^{n \times n}$, entropy estimation is to estimate the Shannon / von Neumann entropy $H(\rho) = -\text{Tr}[\rho \log(\rho)]$ within additive $\epsilon$-precision with success probability at least $\frac{2}{3}$.

### 1.2 New results

We give a systematic study of distributional property testing for classical / quantum distributions, and obtain the following results for the purified quantum query model of Definition 2:

- Entropy estimation of classical / quantum distributions costs $\tilde{O}\left(\frac{\sqrt{n}}{\epsilon}\right)$ and $\tilde{O}\left(\frac{1}{\epsilon^2}\right)$ queries respectively, as we prove in Theorem 12 and Theorem 13.

- Tolerant $\ell^2$-closeness testing of classical / quantum distributions costs $\Theta\left(\frac{1}{\epsilon}\right)$ and $O\left(\min\left(\frac{\sqrt{n}}{\epsilon}, \frac{1}{\epsilon^2}\right)\right)$ queries respectively, as we prove in Theorem 14 and Theorem 15.

- $\ell^1$-closeness testing of classical / quantum distributions costs $\tilde{O}\left(\frac{\sqrt{n}}{\epsilon}\right)$ and $O\left(\frac{n}{\epsilon^2}\right)$ queries respectively, as we prove in Corollary 17.

- Independence testing of classical / quantum distributions costs $\tilde{O}\left(\frac{\sqrt{mn}}{\epsilon}\right)$ and $O\left(\frac{nm}{\epsilon^2}\right)$ queries respectively, as we prove in Corollary 18.

For context, we compare our results with previous classical and quantum results in Table 1 and Table 2. (Note that all of our results are gate efficient, because they are based on singular value transformation and amplitude estimation, both of which have gate-efficient implementations.)

---

4 Throughout the paper, we use $\tilde{O}$ to omit poly-logarithmic factors in $O$, i.e., $\tilde{O}(T) = O(T \polylog(T))$.

5 Recent results of [16] imply that in this model quantum speed-ups are at most cubic.
We call such a unitary a block-encoding with query complexity \(O(\ell)\). The motivating idea behind our approach is that if we can prepare a purification of a quantum operator in the top-left corner, using only two queries to \(U_\rho\). This observation is due to [28].

Example application to \(\ell^3\)-testing. The problem is to decide whether \(\rho = \sigma\) or \(\|\rho - \sigma\|_3 \geq \epsilon\), with query complexity \(O\left(\epsilon^{-\frac{3}{2}}\right)\). The first idea is that if we can prepare a purification of \(\rho\) and \(\sigma\), then we can also prepare a purification of \((\rho + \sigma)/2\) by setting a qubit to the state

As we show our quantum algorithms for classical distributional property testing problems with purified access can be naturally lifted to the case of quantum distributions, incurring an overhead of \(\approx \sqrt{n}\), which is manifested in the complexities of Table 1.

Table 2 Complexities of Shannon / von Neumann entropy estimation with constant precision. It seems that the \(n\)-dependence is roughly quadratically higher for quantum distributions, while coherent quantum access gives a quadratic advantage for both classical and quantum distributions. This suggests that our entropy estimation algorithm has essentially optimal \(n\)-dependence for density operators with purified access, however we do not have a matching lower bound yet.

1.3 New techniques

The motivating idea behind our approach is that if we can prepare a purification of a quantum distribution / density operator \(\rho\), then we can construct a unitary \(U\), which has this density operator in the top-left corner, using only two queries to \(U_\rho\). This observation is due to [28].

We call such a unitary a block-encoding of \(\rho\):

\[
U = \left[
\begin{array}{cccc}
\rho & \cdots \\
\vdots & \ddots & \ddots \\
\vdots & \cdots & \ddots & \ddots \\
\end{array}
\right] \iff \rho = \left(\left|0\right\rangle^\otimes a \otimes I\right)U\left(\left|0\right\rangle^\otimes a \otimes I\right).
\]

One can think of a block-encoding as a post-selective implementation of the linear map \(\rho\): given an input state \(|\psi\rangle\), applying the unitary \(U\) to the state \(\left|0\right\rangle^\otimes a |\psi\rangle\), measuring the first \(a\)-qubit register and post-selecting on the \(\left|0\right\rangle^\otimes a\) outcome, we get a state \(\propto \rho |\psi\rangle\) in the second register. Block-encodings are easy to work with, for example given a block-encoding of \(\rho\) and \(\sigma\) we can easily construct a block-encoding of \((\rho - \sigma)/2\), see for example in the work of [17].
As we show in Appendix A these operators form a projected unitary encoding of \( \sigma \). Therefore we define a slight generalization of block-encodings called projected unitary encodings, which represent a matrix \( A \) in the form of \( \Pi U \bar{\Pi} \), where \( \Pi, \bar{\Pi} \) are orthogonal projectors and \( U \) is a unitary matrix. One can think about \( U \) in a projected unitary encoding as a post-selective implementation of the map \( A \) : \( \text{img}(\bar{\Pi}) \to \text{img}(\Pi) \). Take for example \( U := (U_\rho \otimes I), \Pi := (\sum_{i=1}^{n} |i\rangle \langle i| \otimes |i\rangle \langle i|) \), and \( \bar{\Pi} := (|0\rangle \langle 0| \otimes |0\rangle \langle 0| \otimes I) \). As we show in Appendix A these operators form a projected unitary encoding of

\[
A = \Pi U \bar{\Pi} = \sum_{i=1}^{n} \sqrt{p_i} |\phi_i\rangle |0\rangle \otimes |i\rangle |0\rangle \otimes |i\rangle |i|.
\]

We can use a similar trick for a general density operator \( \rho \) too. However, there is a major difficulty which arises from the fact that we do not a priori know the diagonalizing basis of \( \rho \). Therefore we use slightly different operators. Let \( W \) be a unitary,\(^6\) mapping \( |0\rangle |0\rangle \to \sum_{j=1}^{n} \frac{|j\rangle |j\rangle}{\sqrt{p_j}} \). Let \( U' := (I \otimes U_\rho^\dagger) (W^\dagger \otimes I), \Pi' := (|0\rangle \langle 0| \otimes |0\rangle \langle 0|) \) and \( \bar{\Pi} \) as above. As we show in Appendix A these operators form a projected unitary encoding of

\[
A' = \Pi U' \bar{\Pi} = \sum_{i=1}^{n} \frac{p_i}{\sqrt{n}} |\phi_i\rangle |0\rangle \otimes |0\rangle |0\rangle \otimes |0\rangle |\psi_i|,
\]

where \( \sum_{j=1}^{n} \frac{|j\rangle |j\rangle}{\sqrt{p_j}} = \sum_{j=1}^{n} \frac{|j\rangle |j\rangle}{\sqrt{\sigma_j}} \) is the Schmidt decomposition of the maximally entangled state under the basis \( \{|\phi_1\rangle, \ldots, |\phi_n\rangle\} \).

---

\(^6\) This unitary is easy to implement, e.g., by using a few Hadamard and CNOT gates.
As we can see, the case of general density operators is less efficient, it only gives operational access to the “square root” of $\rho/n$. We note that for (approximately) transforming a block-encoding of $A/\sqrt{n}$ to a block-encoding of $A/\tilde{O}(1)$ it is necessary and sufficient to use the block-encoding of $A/\sqrt{n}$ about $\sqrt{n}$ times [21, Theorems 3&17]. This is essentially the reason for the $\approx \sqrt{n}$ overhead in our quantum algorithms for quantum distributions in Table 1. If the $1/\sqrt{n}$ factor could be directly improved, that would speed up our von Neumann entropy estimation algorithm Theorem 13, which seems unlikely, cf. Table 2. This suggests that it is impossible to obtain a more efficient block-encoding in the general case.

**General recipe.** We summarize our recipe to distributional property testing as follows.

1. Construct quantum circuit / unitary matrix operationally representing the distribution.
2. Transform the singular values of the corresponding matrix according to a desired function.
3. Apply the resulting map to the purification of the distribution, or another suitable state.
4. Estimate the amplitude of the flagged output state and conclude.

The above general scheme describes our approach to the problems we discuss in this paper.

Sometimes it is useful to divide the probabilities / singular values into bins, and fine-tune the algorithm by using the approximate knowledge of the size of the singular values. This divide-and-conquer strategy is at the core of our improved tolerant $\ell^2$-closeness tester of Theorem 14.

### 1.4 Related works on distributional property testing

**Classical algorithms.** Many distributional property testing problems fall into the category of *closeness testing*, where we are given the ability to take independent samples from two unknown distributions $p$ and $q$ with cardinality $n$, and the goal is to determine whether they are the same versus significantly different. For $\ell^1$-*closeness testing*, which is about testing whether $p = q$ or $\|p - q\|_1 \geq \epsilon$, [10] first gave a sublinear algorithm using $\tilde{O}(n^{2/3}/\epsilon^{8/3})$ samples to $p$ and $q$. The follow-up work by [19] determined the optimal sample complexity as $\Theta(\max\{n^{2/3}/\epsilon^{1/3}, n^{1/2}/\epsilon^{1/2}\})$; the same paper also gave a tight bound $\Theta(1/\epsilon)$ for $\ell^2$-*closeness testing*.

Besides closeness testing, a similar problem is *identity testing* where one of the distributions, say $q$, is known and we are given independent samples from the other distribution $p$. For $\ell^1$-*identity testing*, it is known that the sample complexity can be smaller than that of $\ell^1$-closeness testing, which was proved by [9] to be $\tilde{O}(\sqrt{n}/\epsilon^4)$ and then [37] gave the tight bound $\Theta(\sqrt{n}/\epsilon^2)$. More recently, Ref. [20] proposed a modular reduction-based approach for distributional property testing problems, which recovered all closeness and identity testing results above. Furthermore, they also studied *independence testing* (see also the previous studies by [9, 26, 2]), i.e., whether a distribution on $[n] \times [m]$ ($m \geq n$) is a product distribution or at least $\epsilon$-far in $\ell^1$-distance from any product distribution, and determined the optimal bound $\Theta(\max\{n^{2/3}/\epsilon^{1/3}, (nm)^{1/2}/\epsilon^{1/2}\})$.

Apart from the relationship between distributions, properties of a single distribution also have been extensively studied. One of the most important properties is *Shannon entropy* [39] because it measures for example compressibility. The sample complexity of estimating $H(p)$ with additive error $\epsilon$ has been intensively studied [8, 35, 36]; in particular, [40, 41] gave an explicit algorithm for entropy estimation using $\Theta(n/\epsilon \log n)$ samples when $\epsilon = \Omega(n^{-0.03})$ and $\epsilon = O(1)$; for the general case [25] and [42] gave the optimal estimator with $\Theta(n/\epsilon \log n + (\log n)^2/\epsilon^2)$ samples.
Quantum algorithms. The first paper on distributional property testing by quantum algorithms was by [13], which considered classical distributions with discrete quantum query-access (see Definition 3); it gives a quantum query complexity upper bound $O(\sqrt{n}/\epsilon^6)$ for $\ell^2$-closeness testing and $O(n^{1/3}/\epsilon^{1/3})$ for identity testing to the uniform distribution on $[n]$. Subsequently, [18] gave an algorithm for identity testing (to an arbitrary known distribution) with $O(n^{1/3}/\epsilon^5)$ queries, and [29] improved the $\epsilon$-dependence of $\ell^2$-closeness testing to $\tilde{O}(n^{1/6}/\epsilon^2)$. More recently, [27] studied entropy estimation under this model, and gave a quantum algorithm for Shannon entropy estimation with $\tilde{O}(\sqrt{n}/\epsilon^2)$ queries and also sublinear quantum algorithms for estimating Rényi entropies ([38]).

Another type of quantum property testing results ([32, 33, 34, 7, 23]) concern density matrices, where the $\ell^1$-distance becomes the trace distance and the Shannon entropy becomes the von Neumann entropy. To be more specific, for $n$-dimensional density matrices, the number of samples needed for $\ell^1$ and $\ell^2$-closeness testing are $\Theta(n/\epsilon^2)$ and $\Theta(1/\epsilon^2)$ ([7]), respectively. In addition [3] gave upper and lower bounds $O(n^2/\epsilon^2), \Omega(n^2/\epsilon)$ for estimating the von Neumann entropy of an $n$-dimensional density matrix with accuracy $\epsilon$.

1.5 Organization of the paper

The rest of the paper is organized as follows. In Section 2 we introduce two important quantum algorithmic techniques, amplitude estimation and singular value transformation. We give entropy estimators of classical and quantum distributions in Section 3. In Section 4 we give an (essentially) optimal quantum algorithm for tolerantly testing $\ell^1$-closeness of classical distributions, and another efficient tolerant $\ell^2$-closeness tester for quantum distributions. Proof details of projected encodings, polynomial approximations for singular value transformations, and corollaries about $\ell^1$-closeness and independence testing are deferred to Appendix A, B, and C respectively.

2 Preliminaries

2.1 Amplitude estimation

Classically, given i.i.d. samples of a Bernoulli random variable $X$ with $\mathbb{E}[X] = p$, it takes $\Theta(1/\epsilon^2)$ samples to estimate $p$ within $\epsilon$ with high success probability. Quantumly, if we are given a unitary $U$ such that

$$U|0\rangle|0\rangle = \sqrt{p}|0\rangle|\phi\rangle + |0^\perp\rangle,$$

where $||\phi|| = 1$ and $|(0\rangle \otimes I)(0^\perp\rangle) = 0$, (3)

then if measure the output state, we get 0 in the first register with probability $p$. Given access to $U$ we can estimate the value of $p$ quadratically more efficiently than what is possible by sampling:

**Theorem 8 ([12, Theorem 12]).** Given $U$ satisfying (3), the amplitude estimation algorithm outputs $\tilde{p}$ such that $\tilde{p} \in [0, 1]$ and

$$|\tilde{p} - p| \leq \frac{2\pi \sqrt{p(1-p)}}{M} + \frac{\pi^2}{M^2}$$

with success probability at least $8/\pi^2$, using $M$ calls to $U$ and $U^\dagger$.

In particular, if we take $M = \left[2\pi \left(\frac{2\sqrt{p}}{\epsilon} + \frac{1}{\sqrt{\epsilon}}\right)\right] = \Theta\left(\frac{2\sqrt{p}}{\epsilon} + \frac{1}{\sqrt{\epsilon}}\right)$ in (4), we have

$$|\tilde{p} - p| \leq \frac{2\pi \sqrt{p(1-p)}}{2\pi} \epsilon + \frac{\pi^2}{4\pi^2} \epsilon^2 \leq \frac{\epsilon}{2} + \frac{\epsilon}{4} \leq \epsilon.$$
Therefore, using only $\Theta(1/\epsilon)$ implementations of $U$ and $U^\dagger$, we could get an $\epsilon$-additive approximation of $p$ with success probability at least $8/\pi^2$, which is a quadratic speed-up compared to the classical sample complexity $\Theta(1/\epsilon^2)$. The success probability can be boosted to $1 - \nu$ by executing the algorithm for $\Theta(\log 1/\nu)$ times and taking the median of the estimates.

### 2.2 Quantum singular value transformation

Singular value decomposition (SVD) is one of the most important tools in linear algebra, generalizing eigen-decomposition of Hermitian matrices. Recently, [21] proposed quantum singular value transformation which turns out to be very useful for property testing. Mathematically, it is defined as follows:

> **Definition 9 (Singualr value transformation).** Let $f : \mathbb{R} \rightarrow \mathbb{C}$ be an even or odd function. Let $A \in \mathbb{C}^{d \times d}$ have the following singular value decomposition

$$A = \sum_{i=1}^{d_{\min}} \sigma_i |\bar{\psi}_i\rangle \langle \psi_i|,$$

where $d_{\min} := \min(d, \bar{d})$. For the function $f$ we define the singular value transform of $A$ as

$$f^{(SV)}(A) := \begin{cases} \sum_{i=1}^{d_{\min}} f(\sigma_i) |\bar{\psi}_i\rangle \langle \psi_i| & \text{if } f \text{ is odd, and} \\ \sum_{i=1}^{d_{\min}} f(\sigma_i) |\bar{\psi}_i\rangle \langle \psi_i| & \text{if } f \text{ is even, where for } i \in [d] \setminus [d_{\min}] \text{ we define } \sigma_i := 0. \end{cases}$$

Quantum singular value transformation by real polynomials can be efficiently implemented on a quantum computer as follows:

> **Theorem 10 ([21, Corollary 18]).** Let $\mathcal{H}_U$ be a finite-dimensional Hilbert space and let $U, \Pi, \bar{\Pi} \in \text{End}(\mathcal{H}_U)$ be linear operators on $\mathcal{H}_U$ such that $U$ is a unitary, and $\Pi, \bar{\Pi}$ are orthogonal projectors. Suppose that $P = \sum_{k=0}^{n} a_k x^k \in \mathbb{R}[x]$ is a degree-$n$ polynomial such that

1. $a_k \neq 0$ only if $k \equiv n \mod 2$, and
2. for all $x \in [-1,1]$: $|P(x)| \leq 1$.

Then there exist $\Phi \in \mathbb{R}^n$, such that

$$P^{(SV)}(\bar{\Pi}U\Pi) = \begin{cases} (|+\rangle \otimes \bar{\Pi}) \left(|0\rangle\langle 0| \otimes U_\Phi + |1\rangle\langle 1| \otimes U_{-\Phi}\right) (|+\rangle \otimes \Pi) & \text{if } n \text{ is odd, and} \\ (|+\rangle \otimes \bar{\Pi}) \left(|0\rangle\langle 0| \otimes U_\Phi + |1\rangle\langle 1| \otimes U_{-\Phi}\right) (|+\rangle \otimes \Pi) & \text{if } n \text{ is even,} \end{cases}$$

where $U_\Phi = e^{i\phi_1(2\bar{\Pi} - I)} U \prod_{j=1}^{(n-1)/2} (e^{i\phi_2(2\bar{\Pi} - I)} U_1 e^{i\phi_2(2\bar{\Pi} - I)} U_1)^j$.

Thus for an even or odd polynomial $P$ of degree $n$, we can apply singular value transformation of the matrix $\bar{\Pi}U\Pi$ with $n$ uses of $U$, $U^\dagger$ and the same number of controlled reflections $I - 2\Pi, I - 2\bar{\Pi}$.

To apply singular value transformation corresponding to our problems, we need low-degree polynomial approximations to the following functions, which we construct in Appendix B.

---

7 This is the mathematical form for odd $n$; even $n$ is defined similarly.
Lemma 11. (Polynomial approximations) Let $\beta \in (0, 1]$, $\eta \in (0, \frac{1}{2}]$ and $t \geq 1$. There exists polynomials $\tilde{P}, \tilde{Q}, \tilde{S}$ such that

- $\forall x \in \left[\frac{1}{4}, 1\right]: |\tilde{P}(x) - \frac{x}{2t}| \leq \eta$, and $\forall x \in [-1, 1]: -1 \leq \tilde{P}(x) = \tilde{P}(-x) \leq 1$,
- $\forall x \in \left[-\frac{1}{2}, \frac{1}{2}\right]: |\tilde{Q}(x) - tx| \leq \eta$, and $\forall x \in [-1, 1]: \tilde{Q}(x) = -\tilde{Q}(-x) \leq 1$,
- $\forall x \in [\beta, 1]: |\tilde{S}(x) - \frac{\ln(1/x)}{2\ln(2/\beta)}| \leq \eta$, and $\forall x \in [-1, 1]: -1 \leq \tilde{S}(x) = \tilde{S}(-x) \leq 1$,

moreover $\deg(\tilde{P}) = O\left(t \log \left(\frac{1}{\eta}\right)\right)$, $\deg(\tilde{Q}) = O\left(\frac{1}{\beta} \log \left(\frac{1}{\eta}\right)\right)$, and $\deg(\tilde{S}) = O\left(\frac{1}{\beta} \log \left(\frac{1}{\eta}\right)\right)$.

3 Entropy estimation

3.1 Classical distributions with purified quantum query-access

Recall that we introduced purified quantum query-access in Definition 2. In particular, for a classical distribution $p$ on $[n]$, we are given a unitary $U_p$ acting on $\mathbb{C}^{n \times n}$ such that

$$U_p[0]A[0]B = \langle \psi_p \rangle = \sum_{i=1}^{n} \sqrt{p_i} |\psi_i\rangle_A |i\rangle_B. \quad (5)$$

We use $U_p$ and $U^\dagger_p$ to estimate the Shannon entropy $H(p)$:

Theorem 12. For any $0 < \epsilon < 1$, we can estimate $H(p)$ with accuracy $\epsilon$ with success probability at least $2/3$ using $O\left(\frac{n^7 \log^3 \log \frac{n}{\epsilon}}{\epsilon^3}\right)$ calls to $U_p$ and $U^\dagger_p$.

Proof. The general idea is to first construct a unitary matrix that has a specific matrix block with singular values $\sqrt{p_1}, \ldots, \sqrt{p_n}$. We use the construction of Eq. (1) and apply singular value transformation (Theorem 10) by a polynomial $\tilde{S}$ constructed in Lemma 11, setting $\eta = \frac{\epsilon}{24 \ln(2/\beta)}$ and $\beta = \sqrt{\Delta}$ for $\Delta = \frac{\epsilon}{12n \ln(n/\eta)}$. Notice that this $\Delta$ satisfies

$$\Delta \left(\ln \left(\frac{1}{\Delta}\right) + 4 \ln \left(\frac{2}{\beta}\right)\right) = \frac{\epsilon}{12n \ln(n/\epsilon)} \cdot \ln \frac{16(4n \ln n)^3}{\epsilon^3} \leq \frac{\epsilon}{12n \ln(n/\epsilon)} \cdot \ln \frac{\eta^{\frac{3}{2}}}{\epsilon^3} = \frac{\epsilon}{2n}, \quad (6)$$

provided that $\frac{n}{\Delta} \geq 152$. Note that the polynomial $\tilde{S}$ satisfies both conditions in Theorem 10. Applying the singular value transformed version of the operator (1) to the state $|\psi_p\rangle$ gives

$$\langle \tilde{\psi}_p \rangle = \sum_{i=1}^{n} \sqrt{p_i} \tilde{S}(\sqrt{p_i}) |\psi_i\rangle_A |i\rangle_B |0\rangle + \ldots |1\rangle. \quad (7)$$

Preparing $|\tilde{\psi}_p\rangle$ costs $\deg \tilde{S} = O\left(\frac{1}{\beta} \log \left(\frac{1}{\eta}\right)\right) = O\left(\sqrt{\frac{n}{\log(n/\epsilon)}} \log \left(\frac{n}{\epsilon}\right)\right)$ uses of $U_p$ and $U^\dagger_p$ and the same number of controlled reflections through II, II. Furthermore, Lemma 11 implies that for all $i$ such that $p_i \geq \Delta$,

$$|p_i \ln(1/p_i) 4 \ln(2/\beta) - p_i \tilde{S}(\sqrt{p_i})| = p_i \left|\frac{\ln(1/\sqrt{p_i})}{2 \ln(2/\beta)} - \tilde{S}(\sqrt{p_i})\right| \leq \eta p_i. \quad (8)$$

For all $i$ such that $p_i < \Delta$, we have

$$|p_i \ln(1/p_i) 4 \ln(2/\beta) - p_i \tilde{S}(\sqrt{p_i})| \leq \frac{p_i \ln(1/p_i) 4 \ln(2/\beta) + p_i \Delta (\ln(1/\Delta) + 4 \ln(2/\beta))}{4 \ln(2/\beta)} \leq \frac{\epsilon}{8n \ln(2/\beta)}. \quad (9)$$

where the first inequality comes from the fact that $|\tilde{S}(x)| \leq 1$ for all $x \in [-1, 1]$, the second inequality comes from the monotonicity of $x \ln(1/x) + 4 \ln(2/\beta)$ on $(0, \frac{1}{\Delta}]$, and the third inequality comes from (6). As a result of (5), (8), and (9), we have
Therefore, \( |4 \ln(2/\beta)((\psi_p \otimes \langle 0 \rangle) |\Psi_p) - H(p)| \leq 2 \epsilon/3 \). By Theorem 8, we can use \( \Theta(\ln(1/\beta)/\epsilon) \) applications of the unitaries (and their inverses) that implement \( |\psi_p \rangle \) and \( |\Psi_p \rangle \) to estimate \((\psi_p \otimes \langle 0 \rangle) |\Psi_p)\) within additive error \( \epsilon/12 \ln(2/\beta) \). In total, this estimates \( H(p) \) within additive error \( 4 \ln(2/\beta) + 8 \epsilon/3 = \epsilon \) with success probability at least \( 8/\pi^2 \). The total complexity of the algorithm is

\[
\mathcal{O}\left(\frac{\ln(1/\beta)}{\epsilon}\right) \cdot \mathcal{O}\left(\frac{n}{\epsilon} \log \left(\frac{n}{\epsilon}\right) \log \left(\frac{\log n}{\epsilon}\right)\right) = \mathcal{O}\left(\frac{\sqrt{n}}{\epsilon^{1.5}} \log \left(\frac{n}{\epsilon}\right) \log \left(\frac{\log n}{\epsilon}\right)\right).
\]

### 3.2 Density matrices with purified quantum query-access

For a density matrix \( \rho \), we also assume the purified quantum query-access in Definition 2, i.e., a unitary oracle \( U_\rho \) acting as \( U_\rho |0\rangle_A |0\rangle_B = |\rho\rangle = \sum_{i=1}^n \sqrt{p_i} |\phi_i\rangle_A |\psi_i\rangle_B \). We use \( U_\rho \) and \( U_\rho^\dagger \) to estimate the von-Neumann entropy \( H(\rho) = -\text{Tr}[\rho \log \rho] \):

\[\blacktriangleright \text{Theorem 13.} \text{ For any } 0 < \epsilon < 1, \text{ we can estimate } H(p) \text{ with accuracy } \epsilon \text{ with success probability at least } 2/3 \text{ using } \tilde{\mathcal{O}}\left(\frac{\sqrt{n}}{\epsilon}\right) \text{ calls to } U_\rho \text{ and } U_\rho^\dagger.\]

\[\text{Proof.} \text{ We use the construction of Eq. (2). The proof is essentially the same as that of Theorem 12 proceeding by constructing singular value transformation via Theorem 10, with the only difference that all probabilities are rescaled by a factor of } 1/\sqrt{n} \text{ in (2); as a result, the number of calls to } U_\rho \text{ and } U_\rho^\dagger \text{ is blown up to } \tilde{\mathcal{O}}\left(\frac{\sqrt{n}}{\sqrt{\epsilon}}\right) = \tilde{\mathcal{O}}\left(\frac{\sqrt{n}}{\epsilon}\right).\]

### 4 Tolerant testers for \( \ell^2 \)-closeness with purified query-access

First we give an \( \ell^2 \)-closeness tester for unknown classical distributions \( p, q \).

\[\blacktriangleright \text{Theorem 14.} \text{ Given purified quantum query-access for classical distributions } p, q \text{ as in Definition 2, for any } \nu, \epsilon \in (0, 1) \text{ the quantum query complexity of distinguishing the cases } \|p - q\|_2 \geq \epsilon \text{ and } \|p - q\|_2 \leq (1 - \nu)\epsilon \text{ with success probability at least } 2/3 \text{ is } \]

\[
\mathcal{O}\left(\frac{1}{\nu \epsilon} \log^3 \left(\frac{1}{\nu \epsilon}\right) \log \log \left(\frac{1}{\nu \epsilon}\right)\right).
\]

\[\text{Proof.} \text{ The main idea is to first bin the } x \text{ elements based on the approximate value of } p(x) + q(x), \text{ then apply fine-tuned algorithms exploiting the knowledge of the approximate value of } p(x) + q(x). \]

Using amplitude estimation for any \( k \in \mathbb{N} \) we can construct an algorithm \( \mathcal{A}_k \) that for any input \( x \) with \( p(x) + q(x) \geq 2^{-k} \) outputs “greater” with probability at least \( 2/3 \), and for any \( x \) with \( p(x) + q(x) \leq 2^{-k-1} \) outputs “smaller” and uses \( \mathcal{O}\left(2^k\right) \) queries to \( U_p \) and \( U_q \). Using \( \mathcal{O}\left(\log(1/\epsilon^2)\right) \) repetitions we can boost the success probability to \( 1 - \mathcal{O}(\text{poly}(\nu \epsilon)) \). Since our
25:12 Distributional Property Testing in a Quantum World

algorithm only needs to succeed with constant probability, and will use these subroutines at most $\frac{1}{\log^2 \nu}$ times, we can ignore the small failure probability. Therefore in the rest of the proof we assume without loss of generality, that $A_k$ that solves perfectly the above question with (query) complexity $O\left(2^k \log\left(\frac{1}{\nu}\right)\right)$.

Algorithm 1 Estimating $\log_2(p(x) + q(x))$.

\begin{itemize}
  \item \textbf{input} $x \in [n]$, $\theta \in (0, 1)$
  \item 1: \textbf{for} $k \in K := \{-1, 0, 1, 2, \ldots, \lceil \log_2 \left(\frac{1}{\theta}\right)\rceil\} \textbf{do}$
  \item 2: Run algorithm $A_k$ on $|x\rangle$ if output is “greater” then return $k$
  \item 3: \textbf{return} “less than $\theta$”
\end{itemize}

For any $x$ with $p(x) + q(x) \geq \theta$, Algorithm 1 outputs a $k$ such that $p(x) + q(x) \in (2^{-k-1}, 2^{-k+1})$. However, note that this labeling is probabilistic; let us denote by $s_k(x)$ the probability that $x$ is labeled by $k$. Observe that $s_k(x) = 0$ unless $k \in \{\lceil \log_2 \left(\frac{1}{p(x)+q(x)}\right)\rceil, \lceil \log_2 \left(\frac{1}{p(x)+q(x)}\right)\rceil\}$ (otherwise the return is either “greater” or “less than”). Now let us express $\|p - q\|_2^2$ in terms of this “soft-selection” function $s(x)$.

$$
\|p - q\|_2^2 = \sum_x (p(x) - q(x))^2 = \sum_{k \in K} s_k(x) |p(x) - q(x)|^2 + \eta \\
= \sum_{k \in K} 2^{9-k} \sum_x s_k(x) \frac{p(x) + q(x)}{2} \frac{2^{-k-2}}{p(x) + q(x)} \left(\frac{p(x) - q(x)}{2^{-k+3}}\right)^2 + \eta,
$$

(10)

where the bound on $\eta$ follows from the observation that

$$
\eta \leq \sum_{x: p(x)+q(x) < \theta} \left|p(x) - q(x)\right|^2 \leq \sum_{x: p(x)+q(x) < \theta} (p(x) + q(x))^2 < \theta \sum_{x: p(x)+q(x) < \theta} p(x)+q(x) < 2\theta.
$$

If for all $k \in K$ we have a $2^{k-9} \frac{\theta}{|K|}$-precise estimate of

$$
\sum_x s_k(x) \frac{p(x) + q(x)}{2} \frac{2^{-k-2}}{p(x) + q(x)} \left(\frac{p(x) - q(x)}{2^{-k+3}}\right)^2,
$$

(11)

then we get a $3\theta$-precise estimate of $\|p - q\|_2^2$. In particular setting $\theta := \nu \epsilon^2 / 6$, this solves the tolerant testing problem, since if $\|p - q\| \geq \epsilon$ then $\|p - q\|_2^2 \geq \epsilon^2$, on the other hand if $\|p - q\| \leq (1 - \nu)\epsilon$ then $\|p - q\|_2^2 \leq (1 - \nu)\epsilon^2 \leq (1 - \nu)\epsilon^2 = \epsilon^2 - \nu \epsilon^2$.

Now we describe how to construct a quantum algorithm that sets the first output qubit to $|0\rangle$ with probability (11). Start with preparing a purification of the distribution of $P(x) \cdot q(x)$, then set the label of $x$ to $k$ with probability $s_k(x)$ using Algorithm 1 terminating it after using $A_k$. Then separately apply the maps $\sqrt{\frac{2^{-k-2}}{p(x)+q(x)}}$ and $\sqrt{\frac{p(x)-q(x)}{2^{-k+3}}}$ to the state.

Note that we do not need to apply the above transformations exactly, it is enough if apply them with precision $2^{k-11} \frac{\theta}{|K|}$. We analyze the complexity of (approximately) implementing the above sketched algorithm. To implement the map $\sqrt{\frac{2^{-k-2}}{p(x)+q(x)}}$, we use the unitary of Eq. (1), and transform the singular values by the polynomial $\tilde{P}$ from Lemma 11 using Theorem 10. In order to implement the map $\frac{p(x)-q(x)}{2^{k+3}}$, we again use the unitary of Eq. (1), but now separately for $p$ and $q$. We amplify both the singular values $\sqrt{p(x)}$ and $\sqrt{q(x)}$. 

by a factor $\sqrt{2^{k/2}}$ using the polynomial $\tilde{Q}$ from Lemma 11 in Theorem 10. Then we create a block-encoding of both and $2^{k/2}p(x)$ and $2^{k/2}q(x)$ and then combine them to get a block-encoding of $p(x) - q(x)$. In both cases the query complexity of $O(\theta/K)$-precisely implementing the transformations is $O(2^{k/2}\log((K/\theta)))$. Since computing the label $k$ also costs $O(2^{k/2}\log(1/(\nu K)))$, this is the overall complexity so far. Finally we estimate the probability of the first qubit being set to $|0\rangle$ with setting $M = O((2^{k/2}/(\nu K)))$ in Theorem 8, and boost the success probability to $1 - O(1/K)$ with $O(\log(K))$ repetitions. Thus for any $k \in \mathbb{K}$ the overall complexity of estimating Eq. (11) with sufficient precision has (query) complexity $O\left(\frac{1}{\nu} \log \left(\frac{1}{\nu} \log \log \frac{1}{\nu} \right)\right)$. Therefore estimating $\|p - q\|_2^2$ to precision $\nu \epsilon^2/6$ with high probability has (query) complexity

$$O\left(\frac{1}{\nu} \log^3 \left(\frac{1}{\nu} \log \log \frac{1}{\nu} \right)\right).$$

It is easy to see an $O\left(\frac{1}{\nu} \right)$ lower bound on the above problem even in the strongest quantum pure state input model Definition 4. Indeed, consider the case $n = 2, q = (\frac{1}{2}, \frac{1}{2})$ (the uniform distribution on $\{1, 2\}$) and we want to test whether $p = q$ or $\|p - q\|_2 \geq \epsilon$. This is equivalent to test whether $p_1 = \frac{1}{2}$ or $|p_1 - \frac{1}{2}| \geq \epsilon \sqrt{2}$; due to the optimality of amplitude estimation in Theorem 8, this task requires $\Omega(\frac{1}{\nu})$ quantum queries to the unitary $U$ preparing the state $\sqrt{\frac{1}{2}} \{|0\rangle + \sqrt{\frac{1}{2}}|1\rangle\}$.

Now we prove the result below on (tolerant) $L^2$-closeness testing for quantum distributions:

**Theorem 15.** Given $\epsilon, \nu \in (0, 1)$ and two density operators $\rho, \sigma \in \mathbb{C}^{n \times n}$ with purified quantum query-access to $U_\rho$ and $U_\sigma$ as in Definition 2, it takes $O\left(\min\left(\frac{\sqrt{n}}{\epsilon}, \frac{1}{\nu}\right)\right)$ queries to $U_\rho U_\sigma^\dagger, U_\sigma U_\rho^\dagger$ to decide whether $\|\rho - \sigma\|_2 \geq \epsilon$ or $\|\rho - \sigma\|_2 \leq (1 - \nu)\epsilon$, with success probability at least $2/3$.

**Proof.** We can combine the block-encodings of $\rho$ and $\sigma$ to apply the map $\frac{\rho - \sigma}{\epsilon}$ to the maximally entangled state $\sum_{j=1}^{n} \frac{|j\rangle|j\rangle}{\sqrt{n}}$, which gives

$$\sum_{j=1}^{n} \frac{|j\rangle|j\rangle}{\sqrt{n}} \rightarrow \left(\frac{\rho - \sigma}{\epsilon} \otimes I\right) \sum_{j=1}^{n} \frac{|j\rangle|j\rangle}{\sqrt{n}}|0\rangle + \cdots |1\rangle.$$  

The probability of measuring the $|0\rangle$ ancilla state is

$$\sum_{i,j=1}^{n} \frac{\langle i|\langle i| \left(\frac{\rho - \sigma}{\epsilon} \right)^2 \otimes I\right) \frac{|j\rangle|j\rangle}{\sqrt{n}}}{}= \frac{1}{4n} \sum_{i=1}^{n} \langle i|\langle i| (\rho - \sigma)^2|i\rangle = \frac{1}{4n} \text{Tr}[(\rho - \sigma)^2].$$

Thus it suffices to apply amplitude estimation with $M = \Theta\left(\frac{\sqrt{n}}{\epsilon^2}\right)$ calls to $U_\rho, U_\sigma^\dagger, U_\sigma, U_\rho^\dagger$.

On the other hand, we can estimate $\|\rho - \sigma\|_2^2$ by observing that $\|\rho - \sigma\|_2^2 = \text{Tr}[(\rho - \sigma)^2] = \text{Tr}[\rho^2] - 2\text{Tr}[\rho \sigma] + \text{Tr}[\sigma^2]$. Since the success probability of the SWAP test ([14]) on input states $\rho, \sigma$ is $\frac{1}{2}(1 + \text{Tr}[\rho \sigma])$, we can individually estimate the latter quantities with precision $O(\nu \epsilon^2)$ using amplitude estimation (Theorem 8) with $O\left(\frac{1}{\nu} \log\log\frac{1}{\nu}\right)$ queries to $U_\rho, U_\sigma^\dagger, U_\sigma, U_\rho^\dagger$. As a result, we could decide whether $\|\rho - \sigma\|_2 \geq \epsilon$ or $\|\rho - \sigma\|_2 \leq (1 - \nu)\epsilon$ using $O\left(\frac{1}{\nu} \log\log\frac{1}{\nu}\right)$ queries. The result of Theorem 15 hence follows by taking the minimum of the two complexities. ▶

8 If we have a projected unitary encoding of $\Pi U \Pi = A = \sum \phi_i |\psi_i\rangle\langle 0, i|$ with $\Pi = |0\rangle\langle 0| \otimes I$, we can immediately turn it into a block-encoding of $A^\dagger A = \sum \phi_i^2 |\psi_i\rangle\langle \psi_i|$ by e.g. applying Theorem 10 with the polynomial $x^2$. 

A. Gilyén and T. Li 25:13
Future work and open questions

Our paper raises a couple of natural open questions for future work, including:

- For which other distributional property testing problems can we get faster and simpler quantum algorithms using the presented methodology?
- Can we prove quantum lower bounds that match our upper bounds? For instance, can we prove an $\Omega(\frac{1}{\epsilon})$ lower bound on estimating the von Neumann entropy in the purified quantum query-access model for density operators?
- Is there a lower bound technique which naturally fits our purified quantum query input model?
- Can we prove the conjecture that the purified and discrete query input models are equivalent for classical distributions, with respect to the query complexity of (distributional) property testing problems? For some recent progress in this direction see [11].

References

A Projected unitary encodings used for singular value transformation

First we handle the case of classical distributions. Let $U_p$ be a purified quantum oracle of a classical distribution $p$ as in Definition 2, and let $U := (U_p \otimes I)$, also let $\Pi := (\sum_{i=1}^n I \otimes |i\rangle\langle i| I \otimes |i\rangle\langle i|)$, $\bar{\Pi} := (|0\rangle\langle 0| \otimes |0\rangle\langle 0| \otimes I)$, then

$$\Pi U \bar{\Pi} = \Pi (U_p \otimes I) \bar{\Pi} = \left(\sum_{i=1}^n I \otimes |i\rangle\langle i| I \otimes |i\rangle\langle i|\right) (U_p \otimes I) (|0\rangle\langle 0| \otimes |0\rangle\langle 0| \otimes I)$$

$$= \sum_{i=1}^n \left( I \otimes |i\rangle\langle i| U_p (|0\rangle \otimes |0\rangle) \otimes |i\rangle\langle i| \right)$$

$$= \sum_{i=1}^n \left( |i\rangle \otimes |i\rangle U_p (|0\rangle \otimes |0\rangle) \right) \otimes |i\rangle \otimes |i\rangle$$
... = \sum_{i=1}^{n} \left( (I \otimes |i\rangle\langle i|) \sum_{j=1}^{n} \sqrt{p_j} |\phi_j\rangle |j\rangle \langle 0| \langle 0| \otimes | i\rangle\langle i| \right) \\
= \sum_{i=1}^{n} \sqrt{p_i} |\phi_i\rangle |0\rangle \otimes | i\rangle\langle i|. \\

Now we turn to quantum distributions where we do not know the diagonalizing basis of the density operator \( \rho \). Let \( U_\rho \) be a purified quantum oracle of a quantum distribution \( \rho \) as in Definition 2, and \( W \) a unitary, mapping \( |0\rangle|0\rangle \mapsto \sum_{j=1}^{n} \frac{|j\rangle\langle j|}{\sqrt{n}} \). Let \( U' := (I \otimes U_\rho^\dagger)(W^\dagger \otimes I) \), \( \Pi' := (I \otimes |0\rangle\langle 0| \otimes |0\rangle\langle 0|) \) and \( \tilde{H} \) as above, then

\[
\Pi'U'\tilde{H} = \Pi'(I \otimes U_\rho^\dagger)(W^\dagger \otimes I)\tilde{H} \\
= (I \otimes (|0\rangle\langle 0| \otimes |0\rangle\langle 0|)) \left( \sum_{j=1}^{n} \frac{|j\rangle\langle j|}{\sqrt{n}} \right) (|0\rangle \otimes I) \\
= (I \otimes \sum_{i=1}^{n} \sqrt{p_i} |\phi_i\rangle |0\rangle\langle 0|) \left( \sum_{j=1}^{n} \frac{\sqrt{n} |\phi_j\rangle |j\rangle}{\sqrt{n}} \right) (|0\rangle \otimes I) \\
= \sum_{i=1}^{n} \sqrt{p_i} |\phi_i\rangle |0\rangle \otimes | i\rangle\langle i|,
\]

where \( \sum_{j=1}^{n} \frac{\sqrt{n} |\phi_j\rangle |j\rangle}{\sqrt{n}} = \sum_{j=1}^{n} \frac{|j\rangle\langle j|}{\sqrt{n}} \) is the Schmidt decomposition of the maximally entangled state under the basis \( (|\phi_1\rangle, \ldots, |\phi_n\rangle) \).

**B Polynomial approximations for singular value transformation**

We use the following result based on local Taylor series:

- **Lemma 16** ([21, Corollary 66]). Let \( x_0 \in [-1,1], r \in (0,2], \nu \in (0,r) \) and let \( f: [-x_0 - r - \nu, x_0 + r + \nu] \to \mathbb{C} \) and be such that \( f(x_0 + x) = \sum_{x=0}^{\infty} a_x x^x \) for all \( x \in [-r - \nu, r + \nu] \). Suppose \( B > 0 \) is such that \( \sum_{x=0}^{\infty} (r + \nu)^x |a_x| \leq B \). Let \( \epsilon \in \left(0, \frac{1}{2\nu} \right] \), then there is an efficiently computable polynomial \( P \in \mathbb{C}[x] \) of degree \( O\left(\frac{1}{\nu} \log \left(\frac{B}{\epsilon} \right) \right) \) such that\(^9\)

\[
\| f(x) - P(x) \|_{[-x_0 - r - x_0 + r]} \leq \epsilon \\
\| P(x) \|_{[-1,1]} \leq \epsilon + \| f(x) \|_{[-x_0 - r - \nu/2, x_0 + r + \nu/2]} \leq \epsilon + B \\
| P(x) |_{[-1,1]} \leq \epsilon + \| f(x) \|_{[-x_0 - r - \nu/2, x_0 + r + \nu/2]} \leq \epsilon + B
\]

We can use the above result to construct the following useful polynomial approximations.

- **Lemma 11.** (Polynomial approximations) Let \( \beta \in (0,1], \eta \in (0, \frac{1}{2}) \) and \( t \geq 1 \). There exists polynomials \( P, Q, \bar{S} \) such that

  - \( \forall x \in \left[ \frac{1}{t}, 1 \right]: |\bar{P}(x) - \frac{1}{2t^t}| \leq \eta, \) and \( \forall x \in [-1,1]: -1 \leq P(x) = \bar{P}(x) \leq 1, \)
  - \( \forall x \in \left[ -\frac{1}{t}, -\frac{1}{2t^t} \right]: |Q(x) - tx| \leq \eta \cdot |tx|, \) and \( \forall x \in [-1,1]: Q(x) = -\bar{Q}(x) \leq 1, \)
  - \( \forall x \in [\beta,1]: |\bar{S}(x) - \frac{\ln(\beta)}{2\ln(2\beta)}| \leq \eta, \) and \( \forall x \in [-1,1]: -1 \leq \bar{S}(x) = \bar{S}(x) \leq 1, \)
  - moreover deg(\( \bar{P} \)) = \( O\left( t \log \left(\frac{1}{\eta} \right) \right) \), deg(\( Q \)) = \( O\left( \frac{1}{\beta} \log \left(\frac{1}{\eta} \right) \right) \), and deg(\( \bar{S} \)) = \( O\left( \frac{1}{\beta} \log \left(\frac{1}{\eta} \right) \right) \).

\(^9\) For a function \( g: \mathbb{R} \to \mathbb{C} \), and an interval \( [a,b] \subseteq \mathbb{R} \), we define \( \| g \|_{[a,b]} := \max_{x \in [a,b]} |g(x)| \).
Proof. For the construction of the \( \tilde{P} \) and \( \tilde{Q} \) polynomials see Corollary 67 and Theorem 30 of [21], respectively. It remains to construct the polynomial \( \tilde{S} \) above.

Denote \( f(x) = \frac{\ln(1/x)}{2 \ln(2/\beta)} \); by taking \( \epsilon = \eta/2 \), \( x_0 = 1 \), \( r = 1 - \beta \), \( \nu = \frac{\beta}{2} \), and \( B = \frac{1}{2} \) in Corollary 16, we have a polynomial \( S \in \mathbb{C}[x] \) of degree \( O\left(\frac{1}{\beta} \log(\frac{B}{\eta})\right) = O\left(\frac{1}{\beta} \log\left(\frac{\nu}{\eta}\right)\right) \) such that

\[
\|f(x) - S(x)\|_{[\beta,2-\beta]} \leq \eta/2 \tag{12}
\]

\[
\|S(x)\|_{[-1,1]} \leq B + \eta/2 \leq (1 + \eta)/2 \tag{13}
\]

\[
\|S(x)\|_{[-1,\frac{\eta}{2}]} \leq \eta/2. \tag{14}
\]

Note that \( B = \frac{1}{2} \) is valid because the Taylor series of \( f(x) \) at \( x = 1 \) is \( \frac{1}{2 \ln(2/\beta)} \sum_{l=1}^{\infty} \frac{(-1)^l x^l}{l} \), and as a result we could take

\[
B = \frac{1}{2 \ln(2/\beta)} \sum_{l=1}^{\infty} \frac{(1 - \beta/2)^l}{l} = - \frac{1}{2 \ln(2/\beta)} \sum_{l=1}^{\infty} \frac{(-1)^l}{l} (-1 + \beta/2)^l
\]

\[
= - \frac{1}{2 \ln(2/\beta)} \ln \frac{\beta}{2} = \frac{1}{2}.
\]

However, \( S \) is not an even polynomial in general; we instead take \( \tilde{S}(x) = S(x) + S(-x) \) for all \( x \in [-1,1] \). Then by (12) and (14) we have

\[
\|f(x) - \tilde{S}(x)\|_{[\beta,1]} \leq \|f(x) - \tilde{S}(x)\|_{[\beta,1]} + \|\tilde{S}(-x)\|_{[\beta,1]} \leq \frac{\eta}{2} + \frac{\eta}{2} = \eta. \tag{15}
\]

Furthermore, \( \tilde{S} \) is an even polynomial such that \( \text{deg}(\tilde{S}) = O\left(\frac{1}{\beta} \log\left(\frac{\nu}{\eta}\right)\right) \); hence (13) and (14) imply

\[
\|\tilde{S}(x)\|_{[-1,1]} = \|\tilde{S}(x)\|_{[0,1]} \leq \|S(x)\|_{[0,1]} + \|S(x)\|_{[-1,0]} \leq \frac{1 + \eta}{2} + \frac{\eta}{2} \leq 1
\]

given \( \eta \leq 1/2 \). (Finally we can take the real part of \( \tilde{S}(x) \) if it has some complex coefficients.)

\[\text{\textbullet}\]

C. Corollaries of our \( \ell^2 \)-closeness testing results

C.1 \( \ell^1 \)-closeness testing with purified query-access

\begin{itemize}
  \item \textbf{Corollary 17.} Given \( \epsilon > 0 \) and two distributions \( p,q \) on the domain \([n]\) with purified quantum query-access via \( U_p \) and \( U_q \) as in Definition 2, it takes \( \tilde{O}\left(\frac{\sqrt{n}}{\epsilon^2}\right) \) queries to \( U_p, U_p^+, U_q, U_q^+ \) to decide whether \( p = q \) or \( \|p-q\|_1 \geq \epsilon \) with success probability at least 2/3.

  Similarly for density operators \( \rho, \sigma \in \mathbb{C}^{n \times n} \) with purified quantum query-access via \( U_p \) and \( U_q \), it takes \( \tilde{O}\left(\frac{n}{\epsilon^2}\right) \) queries to \( U_{\rho}, U_{\rho}^+, U_{\sigma}, U_{\sigma}^+ \) to decide whether \( \rho = \sigma \) or \( \|\rho-\sigma\|_1 \geq \epsilon \) with success probability at least 2/3.
\end{itemize}

\textbf{Proof.} By the Cauchy-Schwartz inequality we have \( \|p-q\|_2 \geq \frac{1}{\sqrt{n}} \|p-q\|_1 \), therefore Theorem 14 implies our claim by taking \( \epsilon \leftarrow \epsilon/\sqrt{n} \) therein. Similarly, Theorem 15 implies our claim for quantum distributions \( \rho \) and \( \sigma \). \[\text{\textbullet}\]
C.2 Independence testing with purified query-access

**Corollary 18.** Given $\epsilon > 0$ and a classical distribution $p$ on $[n] \times [m]$ with the purified quantum query-access via $U_p$ as in Definition 2, it takes $\tilde{O}(\sqrt{nm})$ queries to $U_p, U_p^\dagger$ to decide whether $p$ is a product distribution on $[n] \times [m]$ or $p$ is $\epsilon$-far in $\ell^1$-norm from any product distribution on $[n] \times [m]$ with success probability at least $2/3$.

**Proof.** We define $p_A$ to be the margin of $p$ on the first marginal space, i.e., $p_A(i) = \sum_{j=1}^m p(i,j)$ for all $i \in [n]$. We similarly define $p_B$ to be the margin of $p$ on the second marginal space, i.e., $p_B(j) = \sum_{i=1}^n p(i,j)$ for all $j \in [m]$. Assume the quantum oracle $U_p$ from Definition 2 acts as

$$U_p|0\rangle_A|0\rangle_B|0\rangle_C = \sum_{i=1}^n \sum_{j=1}^m \sqrt{p(i,j)}|i\rangle_A|j\rangle_B|\psi_{i,j}\rangle_C;$$

if we denote $|\phi_i\rangle = \sum_{j=1}^m \sqrt{p(i,j)}|\psi_{i,j}\rangle$ for all $i \in [n]$ and $|\varphi_j\rangle = \sum_{i=1}^n \sqrt{p(i,j)}|\psi_{i,j}\rangle$ for all $j \in [m]$, then we have

$$U_p|0\rangle_A|0\rangle_B|0\rangle_C = \sum_{i=1}^n \sqrt{p_A(i)}|i\rangle_A|\phi_i\rangle_B,C = \sum_{j=1}^m \sqrt{p_B(j)}|j\rangle_B|\varphi_j\rangle_A,C.$$

As a result, we have

$$(U_p \otimes U_p)(|0\rangle^\otimes) = \sum_{i=1}^n \sum_{j=1}^m \sqrt{p_A(i)} \sqrt{p_B(j)}|i\rangle|j\rangle|\phi_i\rangle|\varphi_j\rangle;$$

in other words, one purified quantum query to the distribution $p_A \times p_B$ can be implemented by two queries to $U_p$.

If $p$ is a product distribution on $[n] \times [m]$, then $p = p_A \times p_B$; if $p$ is $\epsilon$-far in $\ell^1$-norm from any product distribution on $[n] \times [m]$, then $\|p - p_A \times p_B\|_1 \geq \epsilon$. Therefore, the problem of independence testing reduces to $\ell^1$-closeness testing for distributions on $[n] \times [m]$, and hence Corollary 18 follows from Corollary 17.

Similarly, Corollary 17 implies that the quantum query complexity of testing independence of quantum distributions is $O(\frac{nm}{\epsilon})$.

Abstract

Non-signaling strategies are a generalization of quantum strategies that have been studied in physics for decades, and have recently found applications in theoretical computer science. These applications motivate the study of local-to-global phenomena for non-signaling functions.

We prove that low-degree testing in the non-signaling setting is possible, assuming that the locality of the non-signaling function exceeds a threshold. We additionally show that if the locality is below the threshold then the test fails spectacularly, in that there exists a non-signaling function which passes the test with probability 1 and yet is maximally far from being low-degree.

Along the way, we present general results about the local testability of linear codes in the non-signaling setting. These include formulating natural definitions that capture the condition that a non-signaling function “belongs” to a given code, and characterizing the sets of local constraints that imply membership in the code. We prove these results by formulating a logical inference system for linear constraints on non-signaling functions that is complete and sound.

1 Introduction

Locally testable codes (LTCs) are error correcting codes in which one can verify whether a given string belongs to the code by reading only a few (randomly chosen) bits from the string. Goldreich and Sudan [6] have described LTCs as the “combinatorial counterparts of the complexity theoretic notion of PCPs”, motivating the standalone study of these objects.
In this work we study local testability for non-signaling strategies, which are a class of non-local strategies that generalize quantum strategies, capturing the maximum amount of "non-local correlation" that can occur under the assumption that spatially-isolated parties cannot communicate instantaneously. Non-signaling strategies have been studied in physics for decades [14, 10, 12], in order to better understand quantum entanglement. Recently they have gained attention in computer science due to their applications to hardness of approximation [8] and delegation of computation [7, 9]. PCPs sound against non-signaling strategies (nsPCPs) underlie these applications, which motivates the study of local testability in the non-signaling setting.

Given an integer $n$, a field $F$, and a locality parameter $k \leq n$, the object that we study is a $k$-non-signaling function $F : [n] \rightarrow F$, which extends the notion of a function $f : [n] \rightarrow F$ as follows.

### Definition 1.

A $k$-non-signaling function $F : [n] \rightarrow F$ is a collection $\{F_S\}_{S \subseteq [n] : |S| \leq k}$ where each $F_S$ is a distribution over local functions $g : S \rightarrow F$, and for any two subsets $R \subseteq S \subseteq [n]$ with $|S| \leq k$ it holds that the distribution $F_R$ and the marginal distribution $F_S|_R$ are equal.\(^2\) (The set of all such $F$ are the solutions to the $k$-relaxation in the Sherali–Adams hierarchy [16].)

The evaluation of $F$ on a set $S$ is a single sample $g : S \rightarrow F$ from the distribution $F_S$. Intuitively, a $k$-non-signaling function is like a quantum function: evaluation is probabilistic and only happens once, just like quantum measurement; and $F$ can only be evaluated on at most $k$ points simultaneously, which is similar to the uncertainty principle. As $k$ approaches $n$, $F$ behaves more like a classical function and, when $k = n$, $F$ is a distribution over functions $f : [n] \rightarrow F$.

Local testability of non-signaling functions may sound like an oxymoron, because non-signaling functions, at least superficially, are collections of local distributions with no global structure that we can talk about. Yet prior work has shown that local-to-global phenomena are possible.

For example, [4] shows that any non-signaling function passing the linearity test [3] with high probability is well-approximated by a quasi-distribution supported on linear functions. This result was later used in [5] to show that the exponential-length constant-query PCP of [2] is sound against non-signaling strategies.

The results obtained in [4, 5] naturally raise the question of whether local testability in the non-signaling setting is possible for other codes, like those based on low-degree polynomials. After all, both linearity testing and low-degree testing do work in the quantum setting [11].

Recall that, in the classical setting, local testability plays a central role in PCP constructions, many of which can be described as having two main components.

- **Property testing:** check with few queries whether or not the given proof $\pi$ belongs to a code $C$.
- **Checking computation:** given that $\pi$ is a codeword in $C$ (or at least is close to a codeword), check with few queries whether or not $\pi$ proves the desired statement.

This modular approach has enabled the study of local testability as a natural standalone goal, which in turn has led to improved PCP constructions.

---

1. There are two distinct definitions of a non-signaling strategy, depending on whether the strategy is meant to represent isolated parties or a function. The former is used for MIPs [7, 9], while the latter is used for PCPs and property testing [7, 9, 4, 5]. We use the latter definition, although equivalent statements of all our results will hold when adopting the former definition (see the appendix in [4]).

2. A common relaxation of this condition requires that these two distributions are only statistically (or computationally) close. While we consider the standard definition, we note that this is without loss of generality as [4] shows that every statistically (or computationally) non-signaling strategy is close to an (exact) non-signaling strategy.
1.1 Low-degree testing against non-signaling functions

We show that a simple low-degree test, the evenly-spaced points test, tests proximity to degree-\(d\) non-signaling functions when \(k \geq O(d^2)\), and fails to test proximity when \(k \leq O(d^2)\).

The evenly-spaced points test. Let \(m, d \in \mathbb{N}\) and \(p\) be a prime with \(p \geq d + 2\). Given a function \(f : \mathbb{F}_p^m \to \mathbb{F}_p\), the degree-\(d\) evenly-spaced points test: (1) samples a random point \(x \in \mathbb{F}_p^m\) and slope \(h \in \mathbb{F}_p^m \setminus \{0^m\}\), (2) checks that \(\sum_{i=0}^{d+1} c_i f(x + ih) = 0\), where \(c_i = (-1)^i \binom{d+1}{i}\). It is well-known that if \(f\) passes the degree-\(d\) evenly-spaced points test with high probability, then \(f\) is close to (the evaluation of) an \(m\)-variate polynomial of total degree at most \(d\) [15]. Below we ask whether the test is also sound in the non-signaling setting.

Suppose that a \(k\)-non-signaling function \(\mathcal{F} : \mathbb{F}_p^m \to \mathbb{F}_p\) passes the evenly-spaced points test with high probability. Can we deduce any global low-degree structure about \(\mathcal{F}\)?

In more detail, the probabilistic experiment that we consider is this: first we sample \(x\) and \(h\) according to the distribution of the evenly-spaced points test, and let the query set \(S\) be \(\{x + ih : i \in \{0, \ldots, d + 1\}\}\); then we sample a local function \(g : S \to \mathbb{F}_p\) according to the distribution \(\mathcal{F}_S\); and finally we check that \(\sum_{i=0}^{d+1} c_i g(x + ih) = 0\).

The answer to the above question will, in general, depend on the locality parameter \(k\) of \(\mathcal{F}\). At minimum, we need \(k \geq d + 2\) for otherwise we cannot even run the evenly-spaced points test (\(k\) is the maximum number of simultaneous queries to \(\mathcal{F}\)). At the other extreme, when \(k\) has the maximum value (\(k = p^m\)) then we are back to the classical case because \(\mathcal{F}\) is now a distribution over functions \(f : \mathbb{F}_p^m \to \mathbb{F}_p\); hence if \(\mathcal{F}\) passes the test with high probability then (one can verify that) with high probability a function \(f\) sampled according \(\mathcal{F}\) is close to low-degree. In fact, even when \(k \geq O(d^m)\), we are in a trivial case, as one can query \(\mathcal{F}\) on an interpolating set, a “cube of \((d + 1)^m\) points”.

We are thus interested in whether or not the test works for non-trivial values of \(k\), namely when \(O(d) \leq k < O(d^m)\), and thus we will assume that \(m \geq 2\). In this regime, \(k\) is large enough to run the test, and yet is small enough so that one cannot query an interpolating set. Our first result shows that the test succeeds in the non-signaling setting when \(k \geq O(d^2)\). This is a non-signaling analogue of the evenly-spaced points test, similar to how [4] gives a non-signaling analogue of the linearity test of [3].

Theorem 2 (informal). Let \(\mathcal{F} : \mathbb{F}_p^m \to \mathbb{F}_p\) be a \(k\)-non-signaling function that passes the degree-\(d\) evenly-spaced points test with high probability, where \(k \geq (d + 2)^2\). Then \(\mathcal{F}\) has a global individual degree-\(d\) structure.

One drawback of the above theorem is that the conclusion only asserts that \(\mathcal{F}\) has an individual degree-\(d\) structure, when one would like to conclude that \(\mathcal{F}\) has a total degree-\(d\) structure. We discuss the difficulty of extending the result to total degree-\(d\) in Remark 13.

Our second result shows that the test fails when \(k \leq O(d^2)\), and moreover it fails even when the test passes with probability 1, namely, it fails in the worst possible sense.

Theorem 3 (informal). For every \(k\) with \(2d + 2 \leq k < \frac{1}{16}(d + 2)^2\), there exists a \(k\)-non-signaling function that passes the evenly-spaced points test with probability 1, and yet is \((1 - \frac{1}{p})\)-far from all degree-\(d\) \(k\)-non-signaling functions.
Theorem 3 is surprising, as it reveals that in the non-signaling setting, there is a regime of \( k \) in which the low-degree test fails. This stands in sharp contrast to the fact that for linearity testing, there is no regime of \( k \) in which non-signaling linearity test fails. Our results thus suggest that low-degree testing is a qualitatively different task, as it has a regime of \( k \) where a natural test fails.

Theorem 3 also shows that in the case of bivariate testing when \( m = 2 \), there is (up to constants) no non-trivial value of \( k \) where the test succeeds. This is counterintuitive, as bivariate testing is a natural test for which we would expect some guarantee to hold (regardless of how weak), at the very least when the test passes with probability 1.

Other low-degree tests. We note that Theorem 3 generalizes to any low-degree test over an arbitrary finite field \( \mathbb{F} \) that (1) works by checking constraints that lie along a line, and (2) has perfect completeness.

Beyond low-degree testing. Our theorems on low-degree testing come from applying more general results that we prove about the structure of local characterizations for any linear code, in the non-signaling setting. We view our general results on local characterizations as a significant technical contribution within this paper, and we now discuss them.

1.2 Local characterizations and linear proofs

Local characterizations are fundamental to the study of locally testable codes [15]. They express membership in a given linear code via a set of low-weight constraints, and they naturally induce a canonical tester: sample a random low-weight constraint and check if the given word satisfies it. In order to prove the negative result in Theorem 3, we do not need to consider distributions on constraints, but instead we only need to study how constraints express code membership, via exact local characterizations [15]. Below we describe one of our main technical contributions, which informally consists of establishing necessary and sufficient conditions for when a constraint set is a local characterization for a code, in the non-signaling setting. We begin by recalling known facts about local characterizations in the classical setting, and then proceed to the non-signaling setting.

The classical setting. A constraint set \( T \subseteq \mathbb{F}^n \) for a linear code \( C \subseteq \mathbb{F}^n \) is a subset of its dual code \( C^\perp \). A constraint set \( T \) is a \( \ell \)-local characterization of \( C \) if every \( \alpha \in T \) has at most \( \ell \) non-zero entries, and the condition \( \langle \alpha, f \rangle = 0 \) for every \( \alpha \in T \) implies that \( f \in C \) (and conversely).

For example, the set \( \{e_x + e_y - e_{x+y} : x,y \in \{0,1\}^n\} \) where \( e_x \) is the \( x \)-th standard basis vector in \( \{0,1\}^{10.1} \) is a 3-local characterization of the Hadamard code, because \( f(x) + f(y) - f(x+y) = 0 \) for every \( x,y \in \{0,1\}^n \) implies that \( f \) is a linear function, and conversely. As another example, the Reed–Muller code containing all polynomials \( f : \mathbb{F}^m \to \mathbb{F} \) in \( m \) variables of total degree at most \( d \) has a \( (d+2) \)-local characterization \( T \), where \( T \) contains a constraint \( \alpha \) for each subset \( S \) of \( \mathbb{F}^m \) of size \( d + 2 \) that is contained in a line.

There is a simple condition that is both necessary and sufficient for a constraint set \( T \) to be a local characterization for \( C \): the span of \( T \) equals \( C^\perp \). In this work it is useful to view this condition instead through the lens of mathematical logic, as follows. Given a constraint set \( T \) and \( \alpha \in \mathbb{F}^n \), we define the notion of a linear proof.
Definition 4 (Linear proof). We write \( T \vdash \alpha \) (\( T \) proves \( \alpha \)) if there exists a sequence \((\alpha_0:=0^n, \alpha_1, \ldots, \alpha_{r-1}, \alpha_r:=\alpha)\) with each \( \alpha_i \in \mathbb{F}^n \) such that, for every \( i \in [r] \), one of the following holds:

1. \( \exists j < i \) and \( b \in \mathbb{F} \) such that \( \alpha_i = b \alpha_j \).
2. \( \exists j < i \) and \( \gamma \in T \) such that \( \alpha_i = \alpha_j + \gamma \).
3. \( \exists j_1, j_2 < i \) such that \( \alpha_i = \alpha_{j_1} + \alpha_{j_2} \).

As an example, suppose that \( \alpha = \sum_{i=1}^r b_i \gamma_i \) with each \( b_i \in \mathbb{F} \) and \( \gamma_i \in T \). Then the sequence \((0^n, \gamma_1, b_1 \gamma_1, \ldots, \gamma_r, b_r \gamma_r, \alpha_1, \ldots, \alpha_r)\), where each \( \alpha_i \) is the partial sum \( b_1 \gamma_1 + \cdots + b_r \gamma_i \), gives a linear proof that \( \alpha \in \text{span}(T) \).

One can immediately see that \( T \vdash \alpha \) if and only if \( \alpha \in \text{span}(T) \). In particular, we have the following lemma.

Lemma 5. Linear proofs are (i) complete: if \( \langle \gamma, f \rangle = 0 \) for every \( \gamma \in T \) implies \( \langle \alpha, f \rangle = 0 \), then \( T \vdash \alpha \); and (ii) sound: if \( \langle \gamma, f \rangle = 0 \) for every \( \gamma \in T \) and \( T \vdash \alpha \), then \( \langle \alpha, f \rangle = 0 \). In particular, a constraint set \( T \) is a local characterization of a linear code \( C \) if and only if \( T \vdash C^\perp \).

Our goal is to establish a non-signaling analogue of Lemma 5.

A motivating example. We illustrate via an example why a statement like Lemma 5 is non-trivial in the non-signaling setting. Let \( n \in \mathbb{N} \) be even, and let \( T = \{1^n - e_i : i \in [n]\} \subseteq \{0,1\}^n \), i.e. \( T \) contains every vector that is 1 in all but one of the coordinates, where it is 0. Classically, one can check that \( T \) is a \((n-1)\)-local characterization of the code \( C = \{0^n\} \), as if \( f \in \{0,1\}^n \) satisfies \( \langle \alpha, f \rangle = 0 \) for every \( \alpha \in T \) (equivalently, \( \sum_{\ell \neq i} f(\ell) = 0 \) for every \( i \in [n] \)), then we must have \( f = 0^n \), since \( n \) is even. This is because \( T \vdash e_i \), and so \( f \) must satisfy \( f(\ell) = 0 \).

However, there exist \((n-1)\)-non-signaling functions that satisfy every constraint in \( T \) and yet are not identically 0; the non-signaling function which outputs uniformly random bits with parity 0 on every set of size exactly \( n-1 \) is one such example. In particular, \( T \) is not a \((n-1)\)-local characterization of \( C \). To see why, let us examine where the classical argument that \( f(i) = 0 \) fails for \((n-1)\)-non-signaling functions. Recall that an \((n-1)\)-non-signaling function can only be evaluated simultaneously at \( n-1 \) points. Thus, while one can classically argue, for example, that \( f(i) + f(j) = 0 \) via the argument that \( \sum_{\ell \neq i} f(\ell) = 0 \) and \( \sum_{\ell \neq j} f(\ell) = 0 \) implies that \( f(i) + f(j) = \sum_{\ell \neq i} f(\ell) + \sum_{\ell \neq j} f(\ell) = 0 \), this reasoning is no longer valid in the non-signaling setting because it requires \( f \) to be simultaneously defined at every \( i \in [n] \), which is \( n > k = n-1 \) points. In particular, any proof that \( \langle e_i, f \rangle = 0 \) from \( T \) requires \( f \) to be simultaneously defined on all \( n \) points, so this logical reasoning is not valid in the non-signaling setting.

An equivalence for non-signaling functions. We prove an analogous equivalence in the non-signaling setting, which informally states that a suitable notion of local characterization for any linear code is equivalent to being able to prove all low weight elements of \( C^\perp \) using \textit{local} proofs. This equivalence is a strict generalization of Lemma 5. The example above can thus be viewed as a case where a low weight element of \( C^\perp \) (namely, \( e_i \)) has no local proof from a particular \( T \).

We begin by formulating a notion of local characterization that works for constraint sets applied to non-signaling functions rather than (classical) functions. There are two main qualitative differences with the classical case. First, the definition depends on the locality parameter \( k \) because we need to specify the locality of the non-signaling functions that we
On Local Testability in the Non-Signaling Setting

consider. Second, the requirement that a non-signaling function “belongs” to a code $C$ is expressed via a property that we call $C$-explainability, on which we comment after the definition.

**Definition 6** (informal). A constraint set $T \subseteq C^\perp$ is a $\ell$-local characterization for $(C,k)$ if every $\alpha \in T$ has at most $\ell$ non-zero entries, and the set of $k$-non-signaling functions that satisfy every $\alpha \in T$ with probability 1 equals the set of $k$-non-signaling functions that are “$C$-explainable”.

The term “$C$-explainable” refers to the condition that the given non-signaling function is, with probability 1, consistent with the restriction of some codeword in $C$. This condition is motivated by non-trivial properties of the Fourier spectrum of non-signaling functions that we discuss later on (see Section 2.5). For now, it suffices to say that if a non-signaling function $F$ is $C$-explainable then $F$ satisfies natural global properties that extend code membership to the non-signaling setting.

We remark that Definition 6 reduces to the classical notion of local characterization when setting $k := n$. We now introduce the notion of local linear proofs that we use in our equivalence.

**Definition 7** ($k$-local linear proof). Given a constraint set $T$ and $\alpha \in F^n$, we write $T \vdash_k \alpha$ if there exists a sequence $(\alpha_0 := 0^n, \alpha_1, \ldots, \alpha_{r-1}, \alpha_r := \alpha)$ with each $\alpha_i \in \mathbb{F}^n$ such that, for every $i \in [r]$, one of the following holds:

- $\exists j < i$ and $b \in F$ such that $\alpha_i = b \alpha_j$
- $\exists j < i$ and $\gamma \in T$ such that $|\text{supp}(\alpha_j) \cup \text{supp}(\gamma)| \leq k$ and $\alpha_i = \alpha_j + \gamma$
- $\exists j_1, j_2 < i$ such that $|\text{supp}(\alpha_{j_1}) \cup \text{supp}(\alpha_{j_2})| \leq k$ and $\alpha_i = \alpha_{j_1} + \alpha_{j_2}$.

Above, $\text{supp}(\alpha)$ denotes the set of indices $i \in [n]$ where $\alpha_i \neq 0$, and $\text{wt}(\alpha)$ is the size of $\text{supp}(\alpha)$. Notice that Definition 7 is nearly identical to Definition 4: the only change is the addition of the restriction on the support size in the second and third bullets.

The motivation behind Definition 7 is the following fact: if $T \vdash_k \alpha$ then any $k$-non-signaling function that satisfies every constraint in $T$ must satisfy $\alpha$ as well. Definition 7 thus captures a notion of constraint propagation for non-signaling functions. The restriction on the support size in the second and third bullets is there because querying a $k$-non-signaling function on more than $k$ points simultaneously is undefined.

We now state our main technical contribution in this section, a non-signaling analogue of Lemma 5.

**Theorem 8** (informal). $k$-local linear proofs are complete and sound for $k$-non-signaling functions. In particular, a constraint set $T$ is a $\ell$-local characterization for $(C,k)$ if and only if $T \vdash_k \alpha$ for every $\alpha \in C^\perp$ with $\text{wt}(\alpha) \leq k$.

Proving that $k$-local linear proofs are sound is straightforward; the interesting component of Theorem 8 is showing that $k$-local linear proofs are complete. We do this by showing that for every $T$ there exists a $k$-non-signaling function that satisfies every $\alpha$ where $T \vdash_k \alpha$, and violates every $\alpha$ where $T \not\vdash_k \alpha$ with probability $1 - \frac{1}{|T|}$.

When $k = n$ in Theorem 8 we recover the classical statement (Lemma 5). This is because when $k = n$, $T \vdash_k \alpha$ iff and only if $T \vdash \alpha$. However, when $k < n$, the equivalence is qualitatively different from its classical analogue. While Lemma 5 essentially captures a simple linear algebraic statement (the constraints span the dual code), Theorem 8 is a non-trivial statement that does not involve linear spaces. This is because the requirement $T \vdash_k \alpha$ depends on $k$ in a way that breaks linearity, as exhibited by our motivating example earlier.
1.3 Roadmap

In Section 2 we provide an overview of the proofs of our results. Then, in Section 3 and Section 4 we formally define non-signaling functions, quasi-distributions, and discuss the relationship between them using Fourier analysis. In Section 5 we discuss what it means for a non-signaling function to “belong” to a given linear code. In Section 6 we prove that the non-signaling low-degree test works (Theorem 2). In Section 7 we prove an equivalence between local characterizations for non-signaling linear codes and local linear proofs (Theorem 8). We conclude in Section 8, by using Theorem 8 to show that the non-signaling low-degree test fails for small locality (Theorem 3).

2 Techniques

We outline the techniques used to prove our results. We begin by explaining the Fourier structure of non-signaling functions in Section 2.1. This structure is fundamental to the proofs of our results. We then outline the proof of Theorem 2 in Section 2.2. In Section 2.3 we outline our proof of the relationship between local characterizations and local linear proofs. In Section 2.4 we use the techniques and main theorem from Section 2.3 to show Theorem 3, that any low-degree lines test fails for non-signaling functions when \( k \leq O(d^2) \). Finally, in Section 2.5 we justify our definition of “C-explainability”.

Notation. A \( k \)-non-signaling function \( \mathcal{F} \) is defined by local distributions \( \mathcal{F}_S \) for each \( S \subseteq [n] \) with \( |S| \leq k \). Because of this, when studying non-signaling functions we naturally encounter situations where we only consider subsets of a domain containing at most \( k \) elements, or vectors in \( \mathbb{F}^n \) of weight at most \( k \). We introduce notation to make referring to these notions more convenient. For a subset \( S \subseteq [n] \) we write \( S \subseteq [n]_{\leq k} \) if \( |S| \leq k \). For a vector \( \alpha \in \mathbb{F}^n \), we let \( \text{supp}(\alpha) = \{ i \in [n] : \alpha_i \neq 0 \} \) and \( \text{wt}(\alpha) = |\text{supp}(\alpha)| \). For a set of vectors \( R \subseteq \mathbb{F}^n \), we let \( R_{\leq k} \subseteq R \) denote the subset \( \{ \alpha \in R : \text{wt}(\alpha) \leq k \} \). In particular, \( \mathbb{F}^n_{\leq k} \) denotes the set \( \{ \alpha \in \mathbb{F}^n : \text{wt}(\alpha) \leq k \} \). For a subset \( S \subseteq [n] \), we use similar notation and let \( R_{\leq S} = \{ \alpha \in R : \text{supp}(\alpha) \subseteq S \} \).

2.1 The Fourier structure of non-signaling functions

We make frequent use of Fourier analysis to state and establish properties of non-signaling functions. Below we recall basic facts about Fourier analysis, explain their application to quasi-distributions, and state an equivalence between non-signaling functions and quasi-distributions. This equivalence motivates a definition for the Fourier spectrum of a non-signaling function.

Refresher on Fourier analysis. Let \( \mathbb{F} \) be the finite field of size \( q \) with characteristic \( p \), and \( \mathbb{F}_p \) the prime subfield of \( \mathbb{F} \). The inner product of \( F_1, F_2 : \mathbb{F}^n \to \mathbb{C} \) is \( \langle F_1, F_2 \rangle := \frac{1}{q^n} \sum_{f} F_1(f) \overline{F_2(f)} \). The character corresponding to \( \alpha \in \mathbb{F}^n \) is the function \( \chi_\alpha : \mathbb{F}^n \to \mathbb{C} \) defined as \( \chi_\alpha(f) := \omega^{\text{Tr}(\langle \alpha, f \rangle)} \) where: \( \text{Tr} : \mathbb{F} \to \mathbb{F}_p \) is the trace map; \( \langle \alpha, f \rangle \) is the inner product \( \sum_{i=1}^n \alpha_i f_i \); \( \omega = e^{2\pi i/p} \) is a primitive complex \( p \)-th root of unity; and \( \omega^j \) is defined by thinking of \( j \in \mathbb{F}_p \) as an integer in \( \{0, 1, \ldots, p-1\} \). The characters \( \{\chi_\alpha\}_{\alpha \in \mathbb{F}^n} \) form an orthonormal basis of the space of all functions \( F : \mathbb{F}^n \to \mathbb{C} \), so every function \( F : \mathbb{F}^n \to \mathbb{C} \) can be written as

\[
F(\cdot) = \sum_{\alpha \in \mathbb{F}^n} \hat{F}(\alpha) \chi_\alpha(\cdot),
\]

where \( \hat{F}(\alpha) := \langle \chi_\alpha, F \rangle \).

The values \( \{\hat{F}(\alpha)\}_{\alpha \in \mathbb{F}^n} \) are called the Fourier coefficients of \( F \).
On Local Testability in the Non-Signaling Setting

Quasi-distributions. A quasi-distribution $Q$ over functions $f: [n] \rightarrow \mathbb{F}$ is a distribution where the probability weights are complex numbers that “add up” to real probabilities. More formally, a quasi-distribution is a function $Q: \mathbb{F}^n \rightarrow \mathbb{C}$ where $\sum_{f \in \mathbb{F}^n} Q(f) = 1$. (We abuse notation and identify a function $f: [n] \rightarrow \mathbb{F}$ with the vector in $\mathbb{F}^n$ corresponding to its evaluation table.) We say that $Q$ is $k$-local if the marginals $Q|_S$ for each $S \subseteq [n]_{\leq k}$ are distributions, namely, if for each $S \subseteq [n]_{\leq k}$ and $g: S \rightarrow \mathbb{F}$ it holds that $\sum_{f \in \mathbb{F}^n, f|_S = g} Q(f)$ is a non-negative real number. We can decompose a quasi-distribution $Q$ according to the Fourier basis: we can write $Q(f) = \sum_{\alpha \in \mathbb{F}^n} \hat{Q}(\alpha) \chi_\alpha(f)$, where $\{\chi_\alpha\}_{\alpha \in \mathbb{F}^n}$ are the characters and $\{\hat{Q}(\alpha)\}_{\alpha \in \mathbb{F}^n}$ are the Fourier coefficients of $Q$.

Equivalence lemma. The following lemma shows that $k$-local quasi-distributions and $k$-non-signaling functions are equivalent, and exposes the Fourier structure of non-signaling functions.

Lemma 9. A quasi-distribution $Q$ is equivalent to a $k$-non-signaling function $F$ if and only if for every $\alpha \in \mathbb{F}^n_{\leq k}$ it holds that $\hat{Q}(\alpha) = \frac{1}{q^n} \sum_{j \in \mathbb{F}_p} \omega^{-j} \Pr[\text{Tr}(\langle \alpha, F \rangle) = j]$, where the random variable $\langle \alpha, F \rangle$ has the probability distribution given by

$$\Pr[(\alpha, F) = b] := \Pr_{f \leftarrow \mathbb{F}^n_{\text{supp}(\alpha)}} \left[ \sum_{i \in \text{supp}(\alpha)} \alpha_i f(i) = b \right]_{b \in \mathbb{F}}.$$ 

The foregoing lemma motivates defining the Fourier coefficients of a $k$-non-signaling function $F$ as follows: for every $\alpha \in \mathbb{F}^n$ with $\text{wt}(\alpha) \leq k$ we define

$$\hat{F}(\alpha) := \frac{1}{q^n} \sum_{j \in \mathbb{F}_p} \omega^{-j} \Pr[\text{Tr}(\langle \alpha, F \rangle) = j].$$

For more details on the above, including the proof of our Equivalence Lemma, see Section 4.

2.2 Low-degree testing

We outline the proof of Theorem 2. As a simple case, we first state and prove the theorem in the zero error case (when test passes with probability 1), and then we briefly explain how to extend the proof to the robust case (when the test passes with probability $1 - \varepsilon$).

The zero error case. Let $C$ be the set of all $m$-variate polynomials of individual degree $d$. Formally, we first show the following.

Theorem 10 (formal version of Theorem 2, zero error case). Let $m, d \in \mathbb{N}$ and $p$ be a prime with $p \geq d + 2$. Let $F: \mathbb{F}_p^m \rightarrow \mathbb{F}_p$ be a $k$-non-signaling function, and suppose that $F$ passes the degree-$d$ evenly-spaced points test with probability 1. Then $F$ (viewed as a $[k/(d + 2)]$-non-signaling function) is $C$-explainable.

In the language of Section 1.2, Theorem 10 shows that $T$, the set of linear constraints checked by the degree-$d$ evenly spaced points test, is a $(d + 2)$-local characterization of $C$.

Theorem 10 is a non-signaling analogue of the following classical fact: if $f: \mathbb{F}_p^m \rightarrow \mathbb{F}_p$ passes the evenly-spaced points test with probability 1, then $f$ is a polynomial of total degree $d$. (Note that in Theorem 10 we only conclude that $F$ has individual degree $d$. We remark on the difference after the proof.) Our proof of Theorem 10 can be interpreted as taking a local proof of the aforementioned classical fact, and lifting it to the non-signaling setting.

Concretely, let us consider the following simple classical statement.
Theorem 11 (folklore). Let \( f : \mathbb{F}_p^m \to \mathbb{F}_p \) be a function such that, for every line \( L \), \( f \) agrees with a univariate degree-\( d \) polynomial on \( L \). Then for every \( S \subseteq \mathbb{F}_p^m \), there exists a degree-\( d \) function \( g \) such that \( g|_S = f|_S \).

There are multiple known proofs of Theorem 11. To demonstrate the challenges in the non-signaling setting, we first outline a standard classical proof of Theorem 11 that will not generalize to the non-signaling setting. The proof uses the following lemma.

Lemma 12. Suppose that \( f : \mathbb{F}_p^m \to \mathbb{F}_p \) is a polynomial where \( \deg(f) = d < p \). Then there exists a line \( L \) in \( \mathbb{F}_p^m \) such that \( f|_L \) is a univariate polynomial of degree exactly \( d \).

The above lemma is shown by considering the function \( f(a + tb) \) where \( a, b \in \mathbb{F}_p^m \), and arguing that the coefficient of \( t^d \) in \( f(a + tb) \) is a non-zero polynomial in the variables \( a, b \), and hence does not vanish for all \( a, b \in \mathbb{F}_p^m \). Thus, there exists a line \( L(t) = a + tb \) for which the coefficient of \( t^d \) is non-zero, and therefore \( f|_L \) has degree exactly \( d \).

With the above lemma, one can prove Theorem 11 as follows. Suppose that \( f \) is a polynomial of degree \( d' > d \). Then by the lemma there exists a line \( L \) such that \( f|_L \) has degree \( d' > d \), contradicting the fact that \( f|_L \) has degree at most \( d \).

The above proof is a good example of a proof that will not extend to the non-signaling setting. This is because the proof of Lemma 12 is “global”, in the sense that arguing about the polynomial coefficients of \( f \) requires “knowing” \( f(a) \) for \( \Omega(d^m) \) points \( a \in \mathbb{F}_p^m \), as this is the minimum number of evaluations of \( f \) needed for all polynomial coefficients of \( f \) to be fixed. As indicated by Section 1.2, the types of classical proofs that will extend to the non-signaling setting are those with small locality, i.e. ones that require looking at \( f(a) \) for only a small number of \( a \) at a time. This implies that the above proof will not work for \( k \)-non-signaling functions when \( k \leq O(d^m) \), i.e., when \( k \) is a non-trivial value.

We instead present the following local proof of Theorem 11. Since this proof has small locality it will extend to the non-signaling setting, and thus imply Theorem 10.

Let \( S \subseteq \mathbb{F}_p^m \). We wish to show that \( f|_S = g|_S \) for some \( g \in \mathbb{C} \). Let \( S_0 = \emptyset \), and for each \( i \in [n] \) define \( S_i \subseteq \mathbb{F}_p^i \) to be the projection of \( S \) to the first \( i \) coordinates, so \( S_i \) is the set of all \( (a_1, \ldots, a_i) \in \mathbb{F}_p^i \) such that \( (a_1, \ldots, a_i, b_{i+1}, \ldots, b_m) \in S \) for some \( (b_{i+1}, \ldots, b_m) \in \mathbb{F}_p^{m-i} \). Note that \( S_m = S \).

We prove by induction that for every \( i \in [m] \) and every \( b_{i+1}, \ldots, b_m \in \mathbb{F}_p \) there exists an individual degree-\( d \) polynomial \( g_i : \mathbb{F}_p^i \to \mathbb{F}_p \) such that \( f|_{S_i \times \{b_{i+1}, \ldots, b_m\}} = g_i|_{S_i} \). This proves Theorem 11, as \( S_m = S \). The base case \((i = 1)\) holds since \( f \) looks degree-\( d \) on every line, so in particular \( f \) is degree-\( d \) on the line \( \mathbb{F}_p \times \{(b_2, \ldots, b_m)\} \), which contains \( S_1 \).

We now argue the induction step. Suppose that the induction hypothesis holds for \( i - 1 \) and every \( b_1, \ldots, b_{m-i} \in \mathbb{F}_p \). The induction hypothesis implies that for each \( j \in \{0, \ldots, d\} \), there exists an individual degree-\( d \) polynomial \( \delta_{i-1}^{(j)} \) such that \( g_i|_{S_{i-1}} = f|_{S_{i-1} \times \{j\}} \). Let \( \delta_j : \mathbb{F}_p^d \to \mathbb{F}_p \) be defined by interpolating the \( \delta_{i-1}^{(j)} \)'s along the \( i \)-th axis, i.e. \( \delta_j(x_1, \ldots, x_i) := \sum_{j=0}^d \delta_j(x_i) \cdot \delta_{i-1}^{(j)}(x_1, \ldots, x_{i-1}) \) where \( \delta_j(y) \) is the unique degree-\( d \) univariate polynomial that is \( 1 \) if \( y = j \) and \( 0 \) otherwise. We then argue that \( f \) agrees with \( g_i \) on \( S_{i-1} \times \mathbb{F}_p \). This is because \( f \) agrees with \( g_i \) on \( S_{i-1} \times \{0, \ldots, d\} \) (since here \( g_i = \delta_{i-1}^{(j)} = f \) by the induction hypothesis), and therefore agrees with \( g_i \) on \( S_{i-1} \times \mathbb{F}_p \) by polynomial interpolation, since \( f \) looks degree-\( d \) on any axis-parallel line along the \( i \)-th axis.

---

3 The argument as stated does not quite work, as the lemma only holds when \( d' < p \). Here, we ignore this technicality to simplify the presentation of the argument.
The above proof can be adapted to an $|S|(d + 2)$-local proof (as stated above, it is $|S|p$-local). We thus conclude that if a $k$-non-signaling function $F$ looks degree-$d$ on every line $L$, then it also looks individual degree-$d$ on every $S$ where $|S|(d + 2) \leq k$, i.e., $F$ (viewed as a $\lfloor k/(d + 2) \rfloor$-non-signaling function) is C-explainable.

In the aforementioned argument, we have crucially required that $F$ looks low-degree along every line, rather than merely on sets of evenly-spaced points, which are the only constraints checked by the test. Thus, we must show that if $F$ passes the degree-$d$ evenly-spaced points test with probability 1, then $F$ looks degree-$d$ on arbitrary subsets of any line. This last step can be viewed as the following. Let $T$ be the set of constraints checked by the evenly-spaced test, and let $T'$ be the set of all low-weight line constraints (weight at most $k - d - 2$) satisfied by degree-$d$ polynomials. We show that $T \vdash_k T'$, so $F$ (by Theorem 8) must also satisfy all constraints in $T'$, and thus looks degree-$d$ on arbitrary subsets of lines, which concludes the proof of Theorem 10.

▶ Remark 13 (total degree vs. individual degree). Theorem 2 only concludes that $F$ has an individual degree-$d$ structure, when one might expect to conclude that it has a total degree-$d$ structure, as it passes the evenly-spaced points test along random lines. Indeed, this is the conclusion in the classical setting. The difficulty in establishing such a result comes from Lemma 12. The classical analysis of the low-degree test proceeds by induction, initially concluding that $f : \mathbb{F}^m \rightarrow \mathbb{F}$ is a polynomial that is degree-$d$ in $x_m$ and total degree-$d$ in all the other variables, and hence is a total degree-$2d$ polynomial. Then, by using Lemma 12 one concludes that in fact $f$ has total degree-$d$, not $2d$. A non-signaling analogue of Lemma 12 would allow us to conclude a total degree-$d$ structure. However, as explained earlier the classical proof of Lemma 12 is not local, so it does not lift to a non-signaling one. Exploring whether or not the gap between total and individual degree is necessary in the non-signaling setting is thus an intriguing open question.

**The robust case.** We now explain how to adapt the above proof to the robust case. Our goal now is to show that $F$ is close to a $C$-explainable non-signaling function, where the distance between two $k$-non-signaling functions $F$ and $G$ is defined as

$$
\Delta_k(F, G) = \max_{S \subseteq [n], |S| \leq k} \Delta_{TV}(F_S, G_S),
$$

where $\Delta_{TV}$ is the total variation distance between distributions [4]. As in the case of linearity testing in [4], this is impossible, as the definition of distance requires that $F$ be close to $C$-explainable on all sets $S \subseteq \mathbb{F}_p^m$ with $|S| \leq k$. In particular, if $F$ looks low-degree on all lines but one, then $F$ will be very far from $C$-explainable. Following [4], we instead show that an appropriately defined self-correction of $F$, denoted by $F$, is close to $C$-explainable. Informally, $F(x)$ is defined by querying $F$ on a random evenly-spaced line $L$ passing through $x$, and then setting $F(x)$ to be the value at $x$ obtained by locally decoding $F$ along $L$. $F$ is a $k$-non-signaling function, where $k = k/(d + 1)$.

We prove Theorem 2 via the following four steps:

1. Average to worst case reduction: we show that if $F$ passes the evenly-spaced points test with high probability, then $F$ looks low-degree on every set of evenly-spaced set of points contained in a line $L$ with high probability.

2. From evenly-spaced points to arbitrary subsets of a line: we show that if $F$ looks low-degree on every set of evenly-spaced set of points contained in a line, then $F$ looks low-degree on every subset of every line $L$. 

3. Robust local characterization: we show that $T$, the set of constraints where the support of the constraint is contained in some line $L$, is a robust local characterization of $C$, i.e., that if $\hat{F}$ satisfies every $\alpha \in T$ with high probability, then $\hat{F}$ satisfies every $\alpha \in C_{\leq k'}$ with high probability, where $k' = \hat{k}/(d + 2)$.

4. Finishing the proof: we show that if $\hat{F}$ satisfies every $\alpha \in C_{\leq k'}$ with high probability, then $\hat{F}$ is close to a $C$-explainable non-signaling function.

We have already discussed the proofs of the second and third steps in the zero error case. In the robust case, the main difference is that we now pay some small error in union bounds every time we use the fact that $\hat{F}$ looks low-degree along an evenly-spaced line.

The first step follows from our non-trivial definition of $\hat{F}$. Naively, one might define $\hat{F}$ for each $x$ by locally decoding its value from $F$ along a random evenly-spaced line containing $x$. This does not work. Instead, we decode its value along the line $L_x(t) = x + iw_x$, where the slopes (the $w_x$'s) are correlated so that $w_{x+y} = w_x + w_y - w_0$. These correlations, combined with the fact that $L(t)$ looks random for each $x$, allows us to show that $\hat{F}$ looks low-degree on every evenly-spaced set of points.

The final step follows abstractly from the more general statements we show for all linear codes, and relies on our characterization of the Fourier spectrum of $C$-explainable non-signaling functions.

### 2.3 Local characterizations and linear proofs

We outline the proof of Theorem 8; we assume familiarity with the notions introduced in Section 1.2. We begin by formally defining local characterizations.

**Local characterizations.** We say that a $k$-non-signaling function $F$ is $C$-explainable if for every $S \subseteq [n]_{\leq k}$, with probability 1 the function $f : S \rightarrow \mathbb{F}$ sampled from $F_S$ is in $C|_S$. (See Section 2.5 for a discussion of this definition.) Recall from Definition 6 that a subset $T \subseteq C^\perp$ is an $\ell$-local characterization of $(C, k)$ if every $\alpha \in T$ has $\text{wt}(\alpha) \leq \ell$ and the set of $k$-non-signaling functions $F$ where $\Pr[(\alpha, F) = 0] = 1$ for every $\alpha \in T$ equals the set of $C$-explainable $k$-non-signaling functions.

**Outline of the proof.** The proof of Theorem 8 has two directions: completeness and soundness. For soundness, we show that if $T \vdash_k \alpha$, then for any $k$-non-signaling function $F$ where $\langle \gamma, F \rangle = 0$ holds with probability 1 for every $\gamma \in T$, it also holds that $\langle \alpha, F \rangle = 0$ with probability 1. Intuitively, this means that any $k$-non-signaling function satisfying every constraint in $T$ must satisfy $\alpha$ as well, and therefore shows that our definition of “proof” makes sense. The proof of this direction is straightforward, and can be found in Section 7.1.

To show completeness, we explicitly construct a $k$-non-signaling function $F$ that satisfies every constraint $\alpha$ where $T \vdash_k \alpha$ with probability 1, and satisfies every other constraint $\alpha$ with probability $\frac{1}{|T|}$. Our construction of $F$ makes crucial use of the notion of a local subspace that we introduce.

**Definition 14.** A $k$-local subspace $V$ is a subset of $\mathbb{F}_{\leq k}^n$ that looks like a subspace when restricted to local views of size at most $k$, i.e., $V_{\leq S}$ is a linear subspace in $\mathbb{F}^n$ for every $S \subseteq [n]_{\leq k}$.

We show that for any $k$-local subspace $V$ there is a $k$-non-signaling function $F$ where $\Pr[(\alpha, F) = 0] = 1$ for every $\alpha \in V$ and $\Pr[(\alpha, F) = 0] = \frac{1}{|T|}$ otherwise. We then show that the set of $\alpha$’s provable from $T$, which is $\{\alpha \in \mathbb{F}_{\leq k}^n : T \vdash_k \alpha\}$, is a $k$-local subspace. This latter step is straightforward, and the proof is in Section 7.3. We now discuss the first step, which is non-trivial.
Non-signaling functions from local subspaces. Given a $k$-local subspace $V$, we argue that there is a $k$-non-signaling function $F$ where $\Pr[(\alpha, F) = 0] = 1$ for every $\alpha \in V$, and $\Pr[(\alpha, F) = 0] = \frac{1}{|V|}$ for every $\alpha \not\in V$. We construct $F = \{F_S\}_{S \subseteq [n], |S| \leq k}$ by specifying its local distributions $F_S$.

A distribution over functions $f : S \rightarrow \mathbb{F}$ is a function that maps each $f$ to a non-negative real number such that the total sum is 1. With this viewpoint, we first define $F_S$ as a function that maps each $f : S \rightarrow \mathbb{F}$ to a complex number. Then, we show that the total sum is 1 and that each $f$ is mapped to a non-negative real number, so that the function $F_S$ is indeed a distribution.

We define the function $F_S : \mathbb{F}^S \rightarrow \mathbb{C}$ by specifying its Fourier coefficients:

$$\hat{F}_S(\alpha) := \begin{cases} \frac{1}{|S|} & \text{if } \alpha \in V \\ 0 & \text{if } \alpha \not\in V \end{cases},$$

These “local” Fourier coefficients should not be confused with the Fourier coefficients of $F$ that are defined in Section 2.1. In fact, at this point the non-signaling function $F$ is not yet defined.

This completely specifies $F_S$ as a function $\mathbb{F}^S \rightarrow \mathbb{C}$. We show that since $V$ is a $k$-local subspace, $F_S$ is in fact a distribution. First, $\sum_{f \in \mathbb{F}^S} F_S(f) = 1$ because $\hat{F}_S(0^S) = 1/|S|$, since $V$ is a $k$-local subspace, and thus must contain $0^S$. Hence, it suffices to show that $F_S(f) \in \mathbb{R}_{\geq 0}$ for each $f \in \mathbb{F}^S$. For each $f \in \mathbb{F}^S$ we have

$$F_S(f) = \sum_{\alpha \in \mathbb{F}^S} \hat{F}_S(\alpha) \chi_\alpha(f) = \sum_{\alpha \in V \subseteq S} \hat{F}_S(\alpha) \chi_\alpha(f),$$

since we have defined $F_S$ in this way using its Fourier coefficients. There are two cases: either $\langle \alpha, f \rangle = 0$ for every $\alpha \in V \subseteq S$, in which case the sum is $|V \subseteq S|/|q^{|S|}|$, or $\langle \alpha, f \rangle \neq 0$ for some $\alpha \in V \subseteq S$. In the latter case, we use the fact that $V \subseteq S$ is a linear subspace to show that the sum is 0. In either case, we conclude that $F_S(f)$ is a non-negative real number, and therefore that $F_S$ is a distribution.

Next, we argue that the collection of local distributions $\{F_S\}_{S \subseteq [n], |S| \leq k}$ is indeed non-signaling. This follows from a lemma that we prove that shows that a collection of local distributions is non-signaling if and only if the Fourier coefficients of the local distributions (after removing the normalization factors) are the same. Thus the $k$-non-signaling function $F$ is well-defined.

Finally, we show that $F$ satisfies the desired properties. This follows from our definition of each $F_S$, as the construction implies that the Fourier coefficients of $F$ satisfy:

$$\hat{F}(\alpha) := \begin{cases} \frac{1}{|V|} & \text{if } \alpha \in V \\ 0 & \text{if } \alpha \not\in V \end{cases}.$$

This corresponds to having $\Pr[(\alpha, F) = 0] = 1$ for every $\alpha \in V$, and the random variable $\langle \alpha, F \rangle$ having the uniform distribution when $\alpha \not\in V$, which completes the proof.

2.4 Low-degree testing fails for small locality

We discuss how to prove Theorem 3. We let $C$ denote the linear code of polynomials $f : \mathbb{F}^m \rightarrow \mathbb{F}$ of total degree-$d$, and let $T$ be the set of all $\alpha \in C^\perp$ whose support is contained in a line in $\mathbb{F}^m$. Note that for any low-degree test that only checks line constraints and has perfect completeness, if we let $T_0$ be the set of constraints checked by this test, we will have $T_0 \subseteq T$. 
The main combinatorial quantity that we use in our proof is the rank of an element \( \alpha \in \mathbb{C}^4 \), defined as

\[
\text{rank}_T(\alpha) := \min_{T' \subseteq T, \alpha \in \text{span}(T')} |T'|.
\]

Note that \( \text{rank}_T(\alpha) \) is a non-negative integer, as \( \text{span}(T) = \mathbb{C}^4 \).

We now sketch the proof of Theorem 3 in three steps.

(1) **Interval Cut Lemma.** We show a generic lemma about the relationship between rank and provability from \( T \). Informally, we show that in order for \( T \) to prove \( \alpha \) of rank at least \( r \), \( T \) must also prove some \( \beta \) of “intermediate” rank. Formally, we show that if there is an interval \([r/2, r]\) such that every \( \beta \) with rank in this interval is *not* provable from \( T \), then every \( \alpha \) of rank at least \( r \) is also not provable from \( T \). We prove this *Interval Cut Lemma* via the fact that \( \text{rank}_T \) is subadditive, that is, \( \text{rank}_T(\alpha + \beta) \leq \text{rank}_T(\alpha) + \text{rank}_T(\beta) \). Subadditivity implies that for every interval \([r/2, r]\), in order to prove a constraint of rank \( \geq r \) from constraints of rank \(< r/2 \) there must be an intermediate constraint \( \beta \) with rank in \([r/2, r]\) bridging the gap.

(2) **Two combinatorial facts.** We prove two combinatorial facts about the dual code of \( \mathbb{C} \).

- There exists \( \alpha^* \in \mathbb{C}^2 \) where \( \text{wt}(\alpha) = 2d + 2 \) and \( \text{supp}(\alpha) \subseteq \{(a, a^2, 0, m - 2) : a \in \mathbb{F}\} \subseteq \mathbb{F}^m \), i.e., \( \text{supp}(\alpha) \) is contained along the curve \( x_1^2 - x_2 = 0 \) embedded on the plane \( x_3 = x_4 = \cdots = x_m = 0 \) of \( \mathbb{F}^m \).

  *Proof sketch.* If \( f \) is an \( m \)-variate polynomial of total degree \( d \) then \( f(t, t^2, 0, \ldots, 0) \) is a polynomial of degree \( \leq 2d \) in \( t \). Thus, there is an element \( \alpha^* \in \mathbb{C}^2 \) supported on this curve of weight \( 2d + 2 \) that checks some linear constraint. This shows the existence of the desired \( \alpha^* \).

- For every \( \beta \in \mathbb{C}^4 \) with \( \text{rank}_T(\beta) \in \{(d + 2)/4, \ldots, (d + 2)/2\} \) it holds that \( \text{wt}(\beta) \geq \frac{3}{10}(d + 2)^2 \).

  *Proof sketch.* Any \( \beta \) of rank \( r \) is the sum of *exactly* \( r \) line constraints, where each constraint is on a distinct line. Each new constraint adds at least \( d + 2 \) weight to \( \beta \), ignoring the weight that is removed by cancellation. The amount of cancellation is at most the number of intersection points, which is not too large when \( r \) is in \( \{(d + 2)/4, \ldots, (d + 2)/2\} \), thus implying that \( \text{wt}(\beta) \geq \frac{3}{10}(d + 2)^2 \).

(3) **Completing the proof.** Theorem 3 follows from the Interval Cut Lemma, the two combinatorial facts, and Theorem 8. Any \( \beta \in \mathbb{C}^4 \) with rank in \( \{(d + 2)/4, (d + 2)/2\} \) has weight \( \geq \frac{3}{10}(d + 2)^2 \), and thus is *not* provable when \( k < \frac{3}{10}(d + 2)^2 \). Since \( \alpha^* \) has weight \( 2d + 2 \) and is supported only on the diagonal, it has rank \( \geq d + 1 \), as each line constraint increases the number of points on the curve by at most 2, by Bézout’s theorem. The Interval Cut Lemma implies that \( \alpha^* \) is also not provable. The non-signaling function constructed in the proof of Theorem 8 thus passes the random lines test with probability 1 yet satisfies \( \alpha^* \) with probability only \( 1/|\mathbb{F}| \). But, \( \alpha^* \) must be satisfied with probability 1 by any non-signaling function that is “locally low-degree”, which completes the proof.

### 2.5 Fourier spectrum of non-signaling linear codes

We have so far adopted the definition that a \( k \)-non-signaling function \( F \) is “in” a linear code \( \mathbb{C} \subseteq \mathbb{F}^n \) if a function \( f: S \to \mathbb{F} \) sampled from \( F_S \) is in \( \mathbb{C}_S \) with probability 1 for every \( S \subseteq [n] \leq k \). Indeed, we use this “\( \mathbb{C} \)-explainability” to define the notion of a *local characterization* (see Definition 6).
We now provide thorough justification for this choice. We view the definitions and results below as a conceptual contribution that sheds light on basic properties of non-signaling functions.

In the classical setting, a function \( f : [n] \rightarrow \mathbb{F} \) “looks like” a codeword of \( \mathbf{C} \) if, well, it equals some codeword in \( \mathbf{C} \). The issue at hand is that, in the non-signaling setting, it is not immediately clear what it means for a non-signaling function \( \mathbf{F} \) to be “in” \( \mathbf{C} \) because \( \mathbf{F} \) is a collection of local distributions. Below are two natural ways to capture this notion.

▶ **Definition 15** (informal). Let \( \mathbf{F} : [n] \rightarrow \mathbb{F} \) be a \( k \)-non-signaling function.

- We say that \( \mathbf{F} \) is **\( \mathbf{C} \)-supported** if it is equivalent to a \( k \)-local quasi-distribution \( \mathcal{Q} : \mathbb{F}^n \rightarrow \mathbf{C} \) that is supported on \( \mathbf{C} \), namely, \( \mathcal{Q}(f) = 0 \) for all \( f \notin \mathbf{C} \).\(^4\)
- We say that \( \mathbf{F} \) is **\( \mathbf{C} \)-explainable** if, for all \( S \subseteq [n] \leq k \), the distribution \( \mathbf{F}_S \) is supported on \( \mathbf{C}|_S \). In other words, the output of \( \mathbf{F} \) is always consistent with the restriction of some codeword in \( \mathbf{C} \).

The first definition is motivated by our Equivalence Lemma (Lemma 9), and imposes a “global” property on the non-signaling function. The second definition, implied by the first one, instead takes a “local” approach, imposing consistency with relevant restrictions of the code.

In the following lemma, we quantify the difference between the notions of “\( \mathbf{C} \)-supported” and “\( \mathbf{C} \)-explainable” by characterizing the Fourier spectrum in each case. For convenience, we denote by \( \mathbf{C}_{\leq k} \) the set \( \{ \alpha \in \mathbf{C}^\perp : \text{wt}(\alpha) \leq k \} \), which are the constraints with at most \( k \) non-zero entries.

▶ **Lemma 16** (informal). Let \( \mathbf{F} : [n] \rightarrow \mathbb{F} \) be a \( k \)-non-signaling function.

- \( \mathbf{F} \) is **\( \mathbf{C} \)-supported** \( \iff \) the Fourier coefficients \( \{ \hat{\mathbf{F}}(\alpha) \}_{\alpha \in \mathbb{F}^n_{\leq k}} \) are constant on each coset of \( \mathbf{C}^\perp \).
- \( \mathbf{F} \) is **\( \mathbf{C} \)-explainable** \( \iff \) the Fourier coefficient \( \hat{\mathbf{F}}(\alpha) \) equals \( 1/\mathbb{F} \) for every \( \alpha \in \mathbf{C}_{\leq k} \).

We additionally prove that the foregoing structure is robust to errors: \( \mathbf{F} \) is close to being \( \mathbf{C} \)-supported if and only if its Fourier coefficients are almost constant on every coset of \( \mathbf{C}^\perp \); moreover \( \mathbf{F} \) is close to being \( \mathbf{C} \)-explainable if and only if \( \hat{\mathbf{F}}(\alpha) \) is close to \( 1/\mathbb{F} \) for every \( \alpha \in \mathbf{C}_{\leq k} \).

One may interpret Lemma 16 as “bad news” because it shows that the notions of “\( \mathbf{C} \)-supported” and “\( \mathbf{C} \)-explainable” are in fact distinct. Which one is the correct one to use? From the perspective of local testability, we may regard “\( \mathbf{C} \)-supported” as more desirable, because it requires a global structure to hold. We prove that, fortunately, the two notions are equivalent up to a small change in parameters, reinforcing our belief that we have identified the right notions.

▶ **Lemma 17** (informal). Let \( \mathbf{F} : [n] \rightarrow \mathbb{F} \) be a \( k \)-non-signaling function.

- If \( \mathbf{F} \) is \( \mathbf{C} \)-supported, then \( \mathbf{F} \) is \( \mathbf{C} \)-explainable.
- If \( \mathbf{F} \) is \( \mathbf{C} \)-explainable, then \( \mathbf{F} \) (viewed as a \( k/2 \)-non-signaling function) is \( \mathbf{C} \)-supported.

In light of the above, it suffices to study non-signaling functions that are \( \mathbf{C} \)-explainable. We have used this notion in our results on local characterizations (see Definition 6), as it is more natural in this setting: the set of \( \mathbf{C} \)-explainable \( k \)-non-signaling functions are precisely those that are consistent with the set of constraints \( \mathbf{C}_{\leq k}^\perp \).

\(^4\) When \( \mathbf{C} \) is the Hadamard code, this definition equals the notion of a linear non-signaling function from [4].
We outline the proof of the second item of Lemma 16. The characterization of
we deduce that
The affine space
The dimension of
The dimension of
is multiplied by
Intuitively, when we shift
since
we have by definition
Since
any function
have
Thus
we conclude that
Next we show that
V1 \subseteq V2. For any \( Q \in V1 \) and \( \alpha \in \mathbb{F}^n \) we have by definition
we deduce that \( \dim(V1) = \dim(V2) \).
Next we show that
V1 = V2. First we show that \( \dim(V1) = \dim(V2) \), and then that
V1 \subseteq V2.
The dimension of \( V1 \) is \(|C| - 1\) because the \(|C|\) free terms are subject to a single linear
constraint. The dimension of \( V2 \) is \( q^n / |C| - 1 \) because the Fourier coefficients are constant
on each coset of \( C^\perp \), and on each coset they may have an arbitrary value; the one exception
is the coset \( C^\perp \), where the Fourier coefficients must be \( \frac{1}{q^n} \). Recalling that \( q^n = |C| \cdot |C^\perp| \),
we deduce that \( \dim(V1) = \dim(V2) \).
2.5.2 Fourier spectrum of a \( C \)-explainable function
We outline the proof of the second item of Lemma 16. The characterization of \( C \)-explainable
functions relies on the fact that the Fourier coefficient \( \hat{F}(\alpha) \) is related to the distribution of
the random variable \( \langle \alpha, F \rangle \), i.e., the distribution \( (\Pr[\langle \alpha, F \rangle = b])_{b \in \mathbb{F}} \). This intuition can be
quantified via (a generalization of) the DFT matrix \( M \in \mathbb{C}^{q \times q} \), which is the matrix defined as
\( M_{a,b} := \omega^{-\langle a,b \rangle} \) (entries are indexed by \( \mathbb{F} \)); \( M \) is invertible and \( \frac{1}{\sqrt{q}}M \) is unitary.
Recall that the Fourier coefficients of \( F \) are defined as follows:
\[
\forall \alpha \in \mathbb{F}_q^n, \quad \hat{F}(\alpha) := \frac{1}{q^n} \sum_{j \in \mathbb{F}_q} \omega^{-j} \Pr[\langle \alpha, F \rangle = j].
\]
Letting \( v := (\Pr[\langle \alpha, F \rangle = b])_{b \in \mathbb{F}} \), expanding the definitions shows that \( Mv = (q^n \hat{F}(a\alpha))_{a \in \mathbb{F}} \).
The linear transformation \( M \) thus quantifies the relation between the distribution \( (\Pr[\langle \alpha, F \rangle = b])_{b \in \mathbb{F}} \) and the Fourier coefficients \( (q^n \hat{F}(a\alpha))_{a \in \mathbb{F}} \).
Now, given a $k$-non-signaling function $F$, we first show that $F$ is C-explainable if and only if $\Pr[(\alpha, F) = 0] = 1$ for every $\alpha \in C_{\leq k}$. This follows from the fact that any local function $g: S \mapsto \mathbb{F}$ that satisfies every $\alpha \in C_{\leq k}$ can be extended into a codeword $f \in C$.

Using the matrix $M$, we can relate the condition that $F$ satisfies every $\alpha \in C_{\leq k}$ with probability 1 to its Fourier spectrum. Specifically, we have that $\Pr[(\alpha, F) = 0] = 1$ if and only if $(q^n \tilde{F}(aa))_{a \in \mathbb{F}} = M(1,0,\ldots,0)^\top$. Since $M(1,0,\ldots,0)^\top = (1,\ldots,1)^\top$, we get that $\Pr[(\alpha, F) = 0] = 1$ if and only if $\tilde{F}(aa) = \frac{1}{q^n}$ for every $a \in \mathbb{F}$, completing the proof.

### 2.5.3 The relationship between C-supported and C-explainable

We outline the proof of Lemma 17. First note that Lemma 16 immediately implies that a C-supported $k$-non-signaling function $F$ is C-explainable, because if $F$ is C-supported then $\tilde{F}(\alpha) = \tilde{F}(0^n) = \frac{1}{q^n}$ for every $\alpha \in C_{\leq k}$, implying that $F$ is C-explainable.

Conversely, if $F$ is C-explainable, then for any $\alpha, \alpha' \in F_{\leq k/2}$ with $\alpha - \alpha' \in C^\bot$ we get that for any $b \in \mathbb{F}$,

$$\Pr[(\alpha, F) = b] = \Pr[(\alpha', F) + (\alpha - \alpha', F) = b] = \Pr[(\alpha', F) = b],$$

since $\Pr[(\alpha - \alpha', F) = 0] = 1$ as $\alpha - \alpha' \in C^\bot$ and $F$ is C-explainable. This shows that the vectors $(\Pr[(\alpha, F) = b])_{b \in \mathbb{F}}$ and $(\Pr[(\alpha', F) = b])_{b \in \mathbb{F}}$ are equal, which implies that the Fourier coefficients $\tilde{F}(\alpha)$ and $\tilde{F}(\alpha')$ are equal. By Lemma 16, this completes the proof. Note that we crucially need $\text{wt}(\alpha), \text{wt}(\alpha') \leq k/2$ so that $\text{wt}(\alpha - \alpha') \leq k$, as otherwise $\Pr[(\alpha - \alpha', F) = 0]$ is undefined.

### 3 Preliminaries

Throughout this paper we let $n \in \mathbb{N}$ be an arbitrary positive integer, and $k \in \mathbb{N}$ a positive integer that is at most $n$. We use $\mathbb{F}$ to denote the finite field of size $q$ with characteristic $p$, and $\mathbb{F}_p$ to denote the prime subfield of $\mathbb{F}$. We often abuse notation and identify a function $f: [n] \to \mathbb{F}$ with its evaluation table in $\mathbb{F}^n$. For a vector $\alpha \in \mathbb{F}^n$ we let $\text{supp}(\alpha) := \{i \in [n]: \alpha_i \neq 0\}$, and we let $\text{wt}(\alpha) := |\text{supp}(\alpha)|$. For a set of vectors $R \subseteq \mathbb{F}^n$, we let $R_{\leq \ell} \subseteq R$ denote the subset $\{\alpha \in R: \text{wt}(\alpha) \leq \ell\}$. In particular, $\mathbb{F}_{\leq k}^n$ contains all vectors $\alpha \in \mathbb{F}^n$ of weight at most $k$. For a subset $S \subseteq [n]$, we let $R_{\leq S} = \{\alpha \in R: \text{supp}(\alpha) \subseteq S\}$; we also write $S \subseteq [n]_{\leq \ell}$ if $|S| \leq \ell$.

### 3.1 Non-signaling functions

We define non-signaling functions and quasi-distributions, and introduce useful notation for them. The definitions are almost identical to those in [4], but extended to any finite field.

**Definition 18.** A $k$-non-signaling function $F: [n] \to \mathbb{F}$ is a collection $F = \{F_S\}_{S \subseteq [n], |S| \leq k}$ where (i) each $F_S$ is a distribution over functions $f: S \to \mathbb{F}$, and (ii) for every two subsets $S$ and $R$ each of size at most $k$, the restrictions of $F_S$ and $F_R$ to $S \cap R$ are equal as distributions.

Note that any function $f: [n] \to \mathbb{F}$ induces a $n$-non-signaling function by setting $F_S$ to be the distribution that outputs $f|_{S}$ with probability 1. More generally, any distribution $D$ over functions $f: [n] \to \mathbb{F}$ induces a corresponding $n$-non-signaling function by defining $F_S$ to be the distribution that samples $f \leftarrow D$ and outputs $f|_{S}$.

Given a set $S \subseteq [n]_{\leq k}$ and function $g \in \mathbb{F}^S$, we define

$$\Pr[ F(S) = g ] := \Pr[ g \leftarrow F_S].$$
The non-signaling property in this notation is the following: for every two subsets \( S, R \subseteq [n] \leq k \) and every string \( g \in \mathbb{F}^{n \times T} \), \( \Pr[\mathcal{F}(S) = g] = \Pr[\mathcal{F}(T) = g] \), where the probability is over the randomness of \( \mathcal{F} \).

We extend the above notation to every \( E \subseteq \mathbb{F}^S \) in the natural way by defining \( \Pr[\mathcal{F}(S) \in E] \) to be \( \Pr_{f \leftarrow \mathcal{F}_g}[f \in E] \). We highlight the case when \( E \) is an “inner product event”, as we will encounter this case frequently.

**Definition 19.** Let \( \mathcal{F} : [n] \to \mathbb{F} \) be a \( k \)-non-signaling function. For \( \alpha \in \mathbb{F}_{\leq k}^n \) and \( b \in \mathbb{F} \), we define

\[
\Pr[(\alpha, \mathcal{F}) = b] := \Pr_{f \leftarrow \mathcal{F}_{\text{supp}(\alpha)}} \left[ \sum_{i \in \text{supp}(\alpha)} \alpha_i f(i) = b \right].
\]

Similarly, we define \( \Pr[\text{Tr}(\langle \alpha, \mathcal{F} \rangle) = j] := \sum_{b \in \mathbb{F} : \text{Tr}(b) = j} \Pr[(\alpha, \mathcal{F}) = b] \) for every \( j \in \mathbb{F}_p \).

The non-signaling property in this notation is the following: for every two subsets \( S, R \subseteq [n] \leq k \) and every string \( g \in \mathbb{F}^{n \times T} \), \( \Pr[\mathcal{F}(S) = g] = \Pr[\mathcal{F}(T) = g] \), where the probability is over the randomness of \( \mathcal{F} \).

We extend the above notation to every \( E \subseteq \mathbb{F}^S \) in the natural way by defining \( \Pr[\mathcal{F}(S) \in E] \) to be \( \Pr_{f \leftarrow \mathcal{F}_g}[f \in E] \). We highlight the case when \( E \) is an “inner product event”, as we will encounter this case frequently.

**3.2 Quasi-distributions**

A quasi-distribution extends the notion of a probability distribution by allowing probabilities to be complex, and is the main tool that we use to analyze non-signaling functions.

**Definition 20.**

- A quasi-distribution is a function \( Q : \mathbb{F}^n \to \mathbb{C} \) where \( \sum_{f \in \mathbb{F}^n} Q(f) = 1 \).
- For a set of functions \( R \subseteq \mathbb{F}^n \), we say that \( Q \) is supported on \( R \) if \( \{ f \in \mathbb{F}^n : Q(f) \neq 0 \} \subseteq R \).
- For a positive integer \( \ell \), we say that \( Q \) is \( \ell \)-local if the marginals \( Q|_S \) for each \( S \subseteq [n] \leq \ell \) are distributions \( \sum_{f \in \mathbb{F}^n : f|_S = g} Q(f) \) is a non-negative real number for each \( S \subseteq [n] \leq \ell \), and \( g : S \to \mathbb{F} \).

If \( Q \) is \( \ell \)-local, then for every subset \( S \subseteq [n] \leq \ell \), we may view \( Q|_S \) as a probability distribution over \( \mathbb{F}^S \). If \( Q \) is \( \ell \)-local then it is \( s \)-local for every \( s \in \{0, 1, \ldots, \ell \} \).

**Definition 21.** Given a quasi-distribution \( Q \), a subset \( S \subseteq [n] \), and \( g \in \mathbb{F}^S \), we define the quasi-probability of the event “\( Q(S) = g \)” to be the following complex number

\[
\Pr[Q(S) = g] := \sum_{f \in \mathbb{F}^n : f|_S = g} Q(f).
\]

(The tilde above \( \Pr \) denotes that quasi-probabilities are not necessarily non-negative real numbers.)

Given a subset \( E \subseteq \mathbb{F}^S \), we similarly define \( \Pr[Q(S) \in E] := \sum_{f \in \mathbb{F}^n : f|_S \in E} Q(f) \).

As for non-signaling functions, we highlight the case when \( E \) is an inner product event.

**Definition 22.** Let \( Q : \mathbb{F}^n \to \mathbb{C} \) be a quasi-distribution. For \( \alpha \in \mathbb{F}^n \) and \( b \in \mathbb{F} \), we define

\[
\Pr[(\alpha, Q) = b] := \sum_{f \in \mathbb{F}^n : \langle \alpha, f \rangle = b} Q(f).
\]

Similarly, we define \( \Pr[\text{Tr}(\langle \alpha, Q \rangle) = j] := \sum_{b \in \mathbb{F} : \text{Tr}(b) = j} \Pr[(\alpha, Q) = b] \) for every \( j \in \mathbb{F}_p \).
Definition 23 (statistical distance). Given a finite domain $[n]$ and an integer $\ell \in \{1, \ldots, |D|\}$, the $\Delta_\ell$-distance between two quasi-distributions $Q$ and $Q'$ is

$$\Delta_\ell(Q, Q') := \max_{S \subseteq [n]} \Delta(Q|_S, Q'|_S) ,$$

where $\Delta(Q|_S, Q'|_S) := \max_{E \subseteq 2^S} \left| \Pr[Q(S) \in E] - \Pr[Q'(S) \in E] \right|$. We say that $Q$ and $Q'$ are $\epsilon$-close in the $\Delta_\ell$-distance if $\Delta_\ell(Q, Q') \leq \epsilon$; else, they are $\epsilon$-far.

Remark 24 (distance for non-signaling functions). The definition of $\Delta_\ell$-distance naturally extends to defining distances between $k$-non-signaling functions, as well as between quasi-distributions and $k$-non-signaling functions, provided that $\ell \leq k$.

The notion above generalizes the standard notion of statistical (total variation) distance: if $Q$ and $Q'$ are distributions then their $\Delta_\ell$-distance equals their statistical distance. Also note that if $Q$ and $Q'$ are $\ell$-local quasi-distributions then their $\Delta_\ell$-distance equals the maximum statistical distance, across all subsets $S \subseteq [n]$ with $|S| \leq \ell$, between the two distributions $Q|_S$ and $Q'|_S$ — in particular this means that any experiment that queries exactly one set of size at most $\ell$, cannot distinguish between the two quasi-distributions with probability greater than $\Delta_\ell(Q, Q')$.

We stress that $\Delta_\ell(Q, Q') = 0$ does not necessarily mean that $Q = Q'$! In fact, it is possible to have $\Delta_\ell(Q, Q') = 0$ while $\sum_{f \in U} |Q(f) - Q'(f)|$ is arbitrarily large. We also remark that the $\Delta_\ell$-distance is not necessarily upper bounded by $1$, and is in general unbounded.

Definition 25 (approximate locality). Given a finite domain $[n]$, an integer $\ell \in \{1, \ldots, n\}$, and a real number $\epsilon \geq 0$, a quasi-distribution $Q$ over $U_n$ is $(\ell, \epsilon)$-local if, for every subset $S \subseteq [n]$, and every event $E \subseteq \{0, 1\}^S$,

$$\min_{x \in [0, 1]} \left\{ \left| \Pr[Q(S) \in E] - x \right| \right\} \in [0, \epsilon] .$$

Approximate locality generalizes the notion of (exact) locality as in Definition 20. Below, we state a lemma that if $Q$ is $(\ell, \epsilon)$-local and is supported over a linear code $C$, then there is an $\ell$-local $Q'$ over $C$ that is close to $Q$. The proof idea is similar to that of “smoothening” almost-feasible solutions to Sherali–Adams relaxations into feasible ones [13].

Lemma 26. If $Q$ is a $(\ell, \epsilon)$-local quasi-distribution over $C$, then there is an $\ell$-local quasi-distribution $Q'$ over $C$ such that $\Delta_\ell(Q, Q') < q^\ell \epsilon$.

We omit the proof of Lemma 26 as it is identical to the proof of lemma 7.8 in [4], just replacing the field $\mathbb{F}_2 = \{0, 1\}$ with a general field $\mathbb{F}$.

4 Fourier analysis of non-signaling functions

We prove statements about the Fourier structure of non-signaling functions, and prove the Equivalence Lemma. In Section 4.1 we recall basic facts about Fourier analysis of functions over finite fields. In Section 4.2 we relate Fourier coefficients to probabilities and quasi-probabilities. In Section 4.3 we prove that non-signaling functions and quasi-distributions are equivalent notions.
4.1 Fourier analysis of functions over finite fields

We consider functions of the type $F : \mathbb{F}^n \to \mathbb{C}$. For two such functions $F_1$ and $F_2$, we define their inner product as $(F_1, F_2) := \frac{1}{q^n} \sum_{x \in \mathbb{F}^n} F_1(x) F_2(x)$. For every $\alpha \in \mathbb{F}^n$, we define the character $\chi_\alpha : \mathbb{F}^n \to \mathbb{C}$ as $\chi_\alpha(x) := \omega^{\text{Tr}(\alpha, x)}$ where: (1) $\text{Tr} : \mathbb{F} \to \mathbb{F}_p$ is the trace map; (2) $(\alpha, x)$ is the inner product $\sum_{i=1}^n \alpha_i x_i$; (3) $\omega$ is a primitive $p$-th root of unity; and (4) $\omega^j$ is defined by thinking of $j \in \mathbb{F}_p$ as an integer in $\mathbb{Z}$. The functions $\{\chi_\alpha\}_{\alpha \in \mathbb{F}^n}$ form an orthonormal basis of the space of all functions $f : \mathbb{F}^n \to \mathbb{C}$, so every function $F : \mathbb{F}^n \to \mathbb{C}$ can be written as

$$F(\cdot) = \sum_{\alpha \in \mathbb{F}^n} \hat{F}(\alpha) \chi_\alpha(\cdot), \text{ where } \hat{F}(\alpha) : = \langle \chi_\alpha, F \rangle.$$

The values $\{\hat{F}(\alpha)\}_{\alpha \in \mathbb{F}^n}$ are the Fourier coefficients of $F$. We recall and prove a few useful identities.

**Parseval’s identity.** For every two functions $F, G : \mathbb{F}^n \to \mathbb{C}$,

$$(F, G) = \frac{1}{q^n} \sum_{x \in \mathbb{F}^n} F(x) G(x) = \sum_{\alpha \in \mathbb{F}^n} \hat{F}(\alpha) \hat{G}(\alpha).$$

**Proof.**

$$\frac{1}{q^n} \sum_{x \in \mathbb{F}^n} F(x) G(x) = \frac{1}{q^n} \sum_{x \in \mathbb{F}^n} \left( \sum_{\alpha \in \mathbb{F}^n} \hat{F}(\alpha) \chi_\alpha(x) \right) \left( \sum_{\beta \in \mathbb{F}^n} \hat{G}(\beta) \chi_\beta(x) \right) = \sum_{\alpha \in \mathbb{F}^n} \sum_{\beta \in \mathbb{F}^n} \hat{F}(\alpha) \hat{G}(\beta) \langle \chi_\alpha, \chi_\beta \rangle = \sum_{\alpha \in \mathbb{F}^n} \hat{F}(\alpha) \hat{G}(\alpha),$$

since $\{\chi_\alpha\}_{\alpha \in \mathbb{F}^n}$ are orthonormal.

**Plancherel’s identity.** As a corollary of the above,

$$\frac{1}{q^n} \sum_{x \in \mathbb{F}^n} |F(x)|^2 = \sum_{\alpha \in \mathbb{F}^n} |\hat{F}(\alpha)|^2.$$

**The case of indicator functions.** When analyzing non-signaling functions and quasi-distributions we will apply the above identities in the case where $F$ is an indicator function $\mathbf{1}_E$ for a set $E \subseteq \mathbb{F}^n$. In this case, by Plancherel’s identity we have that $|E|/q^n = \sum_{\alpha \in \mathbb{F}^n} |\hat{\mathbf{1}}_E(\alpha)|^2$. In particular, by the Cauchy–Schwarz inequality, this implies that

$$\|\hat{\mathbf{1}}_E\| = \sum_{\alpha \in \mathbb{F}^n} |\hat{\mathbf{1}}_E(\alpha)| \leq \sqrt{\sum_{\alpha \in \mathbb{F}^n} |\hat{\mathbf{1}}_E(\alpha)|^2} \cdot \sqrt{\sum_{\alpha \in \mathbb{F}^n} 1} \leq \sqrt{|E|/q^n \cdot q^n/2} = \sqrt{|E|}.$$

If we let $F(x) = \mathbf{1}_E(x)$, then Parseval’s identity becomes the following lemma.

**Lemma 27.** Let $G : \mathbb{F}^n \to \mathbb{C}$ be a function and $E \subseteq \mathbb{F}^n$. Then

$$\frac{1}{q^n} \sum_{x \in E} G(x) = \frac{1}{q^n} \sum_{\alpha \in \mathbb{F}^n} \hat{\mathbf{1}}_E(\alpha) \sum_{x \in \mathbb{F}^n} G(x) \omega^{-\text{Tr}(\alpha, x)} = \sum_{\alpha \in \mathbb{F}^n} \hat{\mathbf{1}}_E(\alpha) \hat{G}(\alpha).$$
4.2 Relating the Fourier spectrum to the probabilities of events

A quasi-distribution $Q$ is a function $Q: \mathbb{F}^n \to \mathbb{C}$ that maps a function $f: [n] \to \mathbb{F}$ (identified with the corresponding vector $\mathbb{F}^n$) to $Q(f)$. We can write $Q(\cdot) = \sum_{\alpha \in \mathbb{F}^n} \hat{Q}(\alpha)\chi_\alpha(\cdot)$, where $\{\chi_\alpha\}_{\alpha \in \mathbb{F}^n}$ are the characters and $\{\hat{Q}(\alpha)\}_{\alpha \in \mathbb{F}^n}$ are $Q$’s Fourier coefficients. For $S \subseteq [n]$ and $\alpha \in \mathbb{F}^S$, we abuse notation and use $\hat{Q}(\alpha)$ to refer to $\hat{Q}(\beta)$ where $\beta \in \mathbb{F}^n$ has $\beta_i = \alpha_i$ for all $i \in S$ and 0 otherwise.

The lemma below relates the inner product quasi-probabilities defined in Definition 22 to the Fourier coefficients of $Q$.

**Lemma 28.** Let $Q: \mathbb{F}^n \to \mathbb{C}$ be a quasi-distribution. For every $\alpha \in \mathbb{F}^n$, 
\[
\hat{Q}(\alpha) = \frac{1}{q^n} \sum_{j \in \mathbb{F}_p} \omega^{-j} \text{Tr}[\text{Tr}(\langle \alpha, Q \rangle) = j].
\]

**Proof of Lemma 28.** By definition,
\[
\hat{Q}(\alpha) = \langle \chi_\alpha, Q(\cdot) \rangle = \frac{1}{q^n} \sum_f \chi_\alpha(f)Q(f) = \frac{1}{q^n} \sum_{j \in \mathbb{F}_p} \omega^{-j} \sum_{f: \chi_\alpha(f) = j} Q(f).
\]

The above lemma implies that the Fourier coefficients $(\hat{Q}(\alpha))_{\alpha \in \mathbb{F}^n}$ are determined by the quasi-probabilities $(\text{Pr}[^{\alpha, Q} = b])_{b \in \mathbb{F}}$, as the quasi-probabilities $(\text{Pr}[^{\alpha, Q} = b])_{b \in \mathbb{F}}$ determine the quasi-probabilities $(\text{Pr}[^{a, Q} = b])_{b \in \mathbb{F}}$ for every $a \in \mathbb{F}$. In fact, there is a linear transformation $M$ that maps $(\text{Pr}[^{\alpha, Q} = b])_{b \in \mathbb{F}}$ to $(q^n \hat{Q}(\alpha\alpha))_{\alpha \in \mathbb{F}}$. Below, we state a well-known lemma about $M$.

**Lemma 29.** Let $M \in \mathbb{C}^{q \times q}$ be the matrix defined as $M_{ab} := \omega^{-\text{Tr}(ab)}$ (entries are indexed by $\mathbb{F}$). Then $M$ is invertible and $\frac{1}{\sqrt{q}} M$ is unitary (namely, $M^\dagger \cdot M = q I$). In particular, for every vector $(v_b)_{b \in \mathbb{F}}$ with values in $\mathbb{C}$, the map $(v_b)_{b \in \mathbb{F}} \mapsto (\sum_{b \in \mathbb{F}} \omega^{-\text{Tr}(ab)} v_b)_{a \in \mathbb{F}}$ is a bijection.

We additionally prove the following lemma, which relates the Fourier spectrum of the quasi-distribution $Q|_S$ to the Fourier spectrum of $Q$.

**Lemma 30.** Let $Q: \mathbb{F}^n \to \mathbb{C}$ be a quasi-distribution. Let $S \subseteq [n]$, and let $Q|_S$ denote the restriction of $Q$ to $S$, namely, $Q|_S$ is the quasi-distribution from $\mathbb{F}^S$ to $\mathbb{C}$ where $Q|_S(g) := \sum_{f: f|_S = g} Q(f)$. Then for every $\alpha \in \mathbb{F}^S$, it holds that $(q^n \hat{Q}|_S(\alpha)) = q^n \hat{Q}(\alpha)$.\(^5\)

**Proof of Lemma 30.**
\[
q^n \hat{Q}|_S(\alpha) = \sum_{g \in \mathbb{F}^S} Q|_S(g)\omega^{-\text{Tr}(\alpha, g)} = \sum_{f \in \mathbb{F}^n} Q(f)\omega^{-\text{Tr}(\alpha, f)} = q^n \hat{Q}(\alpha).
\]

If $F: [n] \to \mathbb{F}$ is a $k$-non-signaling function, then for any $\alpha \in \mathbb{F}_k^n$ and $b \in \mathbb{F}$ we have defined $\text{Pr}[^{\alpha, F} = b]$ in Definition 19 to be $\text{Pr}_{f \sim F_\text{app}(\alpha)}[^{\alpha, f} = b]$. Note that the probability is well-defined since $\text{wt}(\alpha) \leq k$ (so we query $F$ on at most $k$ points). Also note that Lemma 28 implies that, for every $\alpha \in \mathbb{F}_k^n$, we can define the Fourier coefficient $\hat{F}(\alpha)$ of $F$ as
\[
\hat{F}(\alpha) := \frac{1}{q^n} \sum_{j \in \mathbb{F}_p} \omega^{-j} \text{Pr}[\text{Tr}(\langle \alpha, F \rangle) = j].
\]

\(^5\) The vector $\alpha$ in $\hat{Q}(\alpha)$ is treated as a element in $\mathbb{F}^n$ with $\alpha_j = 0$ for all $j \notin S$
With the above definitions, we can prove the following two corollaries of Lemma 27. The first is for non-signaling functions, and the second is for quasi-distributions.

**Corollary 31.** For any \( k \)-non-signaling function \( F : [n] \rightarrow F \), set \( S \subseteq [n] \), and event \( E \subseteq \mathbb{F}^S \),

\[
\Pr[F(S) \in E] = \sum_{\alpha \in \mathbb{F}^S} \sum_{j \in \mathbb{F}_p} \omega^{-j} \Pr[\langle \alpha, F \rangle] = j = q^n \sum_{\alpha \in \mathbb{F}^S} \hat{F}(\alpha).
\]

**Proof.** Apply Lemma 27 with \( G : \mathbb{F}^S \rightarrow C \) defined as \( G(x) = \Pr[F_S(i) = x, \forall i \in S] \).

**Corollary 32.** For any quasi-distribution \( Q : \mathbb{F}^n \rightarrow C \), set \( S \subseteq [n] \), and event \( E \subseteq \mathbb{F}^S \),

\[
\tilde{\Pr}[Q(S) \in E] = \sum_{f : f(S) \in E} Q(f) = \sum_{\alpha \in \mathbb{F}^S} \sum_{j \in \mathbb{F}_p} \omega^{-j}\tilde{\Pr}[\langle \alpha, Q \rangle] = j = q^n \sum_{\alpha \in \mathbb{F}^S} \hat{Q}(\alpha).
\]

**Proof.** Apply Lemma 27 to the function \( G : \mathbb{F}^S \rightarrow C \) that is the quasi-distribution \( Q|_{S} \). Then observe that for every \( \alpha \in \mathbb{F}^S \), \( q^{\frac{|S|}{2}}Q(\alpha) = q^n \hat{Q}(\alpha) \) by Lemma 30.

The above two lemmas allow us to bound the distance between a \( k \)-non-signaling function \( F \) and a quasi-distribution \( Q \) in terms of their Fourier spectra.

**Lemma 33.** Let \( F : [n] \rightarrow F \) be a \( k \)-non-signaling function and \( Q : \mathbb{F}^n \rightarrow C \) a quasi-distribution. For any set \( S \subseteq [n] \leq k \) and event \( E \subseteq \mathbb{F}^S \),

\[
\left| \Pr[F(S) \in E] - \tilde{\Pr}[Q(S) \in E] \right| \leq q^n \sum_{\alpha \in \mathbb{F}^S} \left| \hat{F}(\alpha) - \hat{Q}(\alpha) \right|.
\]

In particular, \( \Delta_k(Q, F) \leq q^{n+k/2} \max_{\alpha \in \mathbb{F}_p} \left| \hat{F}(\alpha) - \hat{Q}(\alpha) \right| \).

**Corollary 34.** Let \( F : [n] \rightarrow F \) be a \( k \)-non-signaling function and \( Q : \mathbb{F}^n \rightarrow C \) a quasi-distribution. Then \( \Delta_k(Q, F) = 0 \) if and only if \( \hat{F}(\alpha) = \hat{Q}(\alpha) \) for every \( \alpha \in \mathbb{F}_p \).

**Proof of Lemma 33.** The first equation follows immediately from Corollary 31 and Corollary 32. For the second part of the lemma,

\[
\Delta_k(Q, F) \leq \max_{S \subseteq [n] \leq k} \max_{E \subseteq \mathbb{F}^S} q^n \sum_{\alpha \in \mathbb{F}^S} \left| \hat{F}(\alpha) - \hat{Q}(\alpha) \right|
\]

\[
\leq q^n \max_{S \subseteq [n] \leq k} \left( \max_{E \subseteq \mathbb{F}^S} \sum_{\alpha \in \mathbb{F}^S} \left| \hat{F}(\alpha) - \hat{Q}(\alpha) \right| \right)
\]

\[
\leq q^n \left( \max_{S \subseteq [n] \leq k} q^{\frac{|S|}{2}} \right) \max_{\alpha \in \mathbb{F}_p} \left| \hat{F}(\alpha) - \hat{Q}(\alpha) \right|
\]

\[
\leq q^{n+k/2} \max_{\alpha \in \mathbb{F}_p} \left| \hat{F}(\alpha) - \hat{Q}(\alpha) \right|.
\]

**Proof of Corollary 34.** If \( \hat{F}(\alpha) = \hat{Q}(\alpha) \) for every \( \alpha \in \mathbb{F}_p \), then by Lemma 33 it follows that \( \Delta_k(Q, F) = 0 \). Conversely, if \( \Delta_k(Q, F) = 0 \), then for every \( \alpha \in \mathbb{F}_p \) and \( j \in \mathbb{F}_p \) it holds that \( \tilde{\Pr}[\langle \alpha, Q \rangle = j] = \Pr[\langle \alpha, F \rangle = j] \), as these are both events. This implies that \( q^n \hat{Q}(\alpha) = \sum_{j \in \mathbb{F}_p} \omega^{-j} \tilde{\Pr}[\langle \alpha, Q \rangle = j] = \sum_{j \in \mathbb{F}_p} \omega^{-j} \Pr[\langle \alpha, F \rangle = j] = q^n \hat{F}(\alpha) \).

Suppose that we are given a collection of local distributions \( \{ F_S \}_{S \subseteq [n] \leq k} \), namely, \( F_S \) is a distribution over functions \( f : S \rightarrow F \). We can think of each local distribution \( F_S \) as a function \( \hat{F}_S : \mathbb{F}^S \rightarrow C \), and in this way define for each local distribution \( F_S \) the Fourier coefficients \( \hat{F}_S(\alpha) \) for each \( \alpha \in \mathbb{F}_p \). In the following lemma, we characterize when \( (F_S)_{S \subseteq [n] \leq k} \) is \( k \)-non-signaling in terms of the Fourier spectra of the local distributions.
Lemma 35. Let \((F_S)_{S \subseteq [n] \leq k}\) be a collection of local distributions. Then \((F_S)_{S \subseteq [n] \leq k}\) is a k-non-signaling function if and only if \(q^{\text{S}} F_S(\alpha) = q^{\text{R}} F_R(\alpha)\) for every \(S \subseteq [n] \leq k\), \(R \subseteq S\), and \(\alpha \in \mathbb{F}_2^n\).

Proof. Suppose \((F_S)_{S \subseteq [n] \leq k}\) is a k-non-signaling function. Fix \(S \subseteq [n] \leq k\), \(R \subseteq S\), and \(\alpha \in \mathbb{F}_2^n\). Since the collection of local distributions is k-non-signaling we have that \(F_S|R = F_R\). Therefore by Lemma 30 we have that \(q^{\text{S}} F_S(\alpha) = q^{\text{R}} F_R(\alpha)\).

Now, fix \(S \subseteq [n] \leq k\) and \(R \subseteq S\). Applying Corollary 32 to the distributions \(F_S\) and \(F_R\), we see that if \(q^{\text{S}} F_S(\alpha) = q^{\text{R}} F_R(\alpha)\) for every \(\alpha \in \mathbb{F}_2^n\), then \(F_S|R = F_R\). Hence, \((F_S)_{S \subseteq [n] \leq k}\) is k-non-signaling. ▶

4.3 Equivalence between non-signaling functions and quasi-distributions

We show that k-non-signaling functions and k-local quasi-distributions are equivalent. Every k-local quasi-distribution \(Q\) induces a k-non-signaling function \(F\) (Proposition 36). Conversely, every k-non-signaling function \(F\) can be described by a k-local quasi-distribution \(Q\) (Proposition 37). In fact, the set of such quasi-distributions is an affine subspace of co-dimension \(\sum_{i=0}^k \binom{n}{i} \cdot (q-1)^i\) in \(\mathbb{C}^q^n\). The first direction of the equivalence is elementary; the other direction is the interesting one.

The aforementioned result is a special case of a result of Abramsky and Brandenburger [1] that establishes an equivalence between non-signaling empirical models (a general notion of non-signaling experiments in the language of sheaf theory) and quasi-distributions over global sections. Our result strengthens this equivalence by giving an explicit characterization of the affine subspace of quasi-distributions describing a non-signaling function, by leveraging Fourier-analytic tools. This also extends to any finite field \(\mathbb{F}\) the equivalence lemma for \(\mathbb{F}_2\) presented in [4].

Proposition 36. For every k-local quasi-distribution \(Q\) over functions \(f : [n] \rightarrow \mathbb{F}\) there exists a k-non-signaling function \(F : [n] \rightarrow \mathbb{F}\) such that \(\Delta_k(Q, F) = 0\).

Proof. For every subset \(S \subseteq [n] \leq k\), define \(F_S\) to be the distribution over functions \(f : S \rightarrow \mathbb{F}\) where \(\Pr[F_S \text{ outputs } f] := \Pr_Q[Q(S) = f(S)]\), namely, such that \(F_S \equiv Q|_S\). Note that \(F_S\) is a distribution because \(Q\) is k-local, so the relevant probabilities are in \([0, 1]\) and sum to 1. The definition immediately implies that \(\Pr[F(S) = g] = \Pr_Q[Q(S) = g]\) for every string \(g \in \mathbb{F}^S\), and so \(\Delta_k(Q, F) = 0\). We are left to argue that \(F = \{F_S\}_{S \subseteq [n] \leq k}\) is k-non-signaling. Let \(S \subseteq [n] \leq k\), and let \(R \subseteq S\). By definition of \(F\) and Lemma 30 we have that for every \(\alpha \in \mathbb{F}_2^n\), \(q^{\text{S}} F_S(\alpha) = q^{\text{S}} Q|_S(\alpha) = q^{\text{R}} Q|_R(\alpha) = q^{\text{R}} F_R(\alpha)\). By Lemma 35, it follows that \(F\) is k-non-signaling. ▶

Proposition 37. For every k-non-signaling function \(F : [n] \rightarrow \mathbb{F}\), there exists a k-local quasi-distribution \(Q\) over functions \(f : [n] \rightarrow \mathbb{F}\) such that \(\Delta_k(F, Q) = 0\). Moreover, the set of such \(Q\)’s (viewed as vectors in \(\mathbb{C}^q^n\)) is the affine subspace of co-dimension \(\sum_{i=0}^k \binom{n}{i} \cdot (q-1)^i\) in \(\mathbb{C}^q^n\) given by \(Q_0 + \text{span}\{\chi_{\alpha} : \alpha \in \mathbb{F}_2^n, \text{wt}(\alpha) > k\}\), where \(Q_0\) is any solution.

\footnote{The characterization further extends to functions taking values in any finite alphabet \(\Sigma\) (not necessarily a field) by adding an abelian group structure to \(\Sigma\) (for example, by identifying \(\Sigma\) with \(\mathbb{Z}/|\Sigma|\mathbb{Z}\)), and then using analogous tools from Fourier analysis over finite abelian groups.}
We wish to define what it means for a non-signaling function to being supported on \( C \). For each of the two definitions, we characterize the Fourier spectrum of non-signaling functions supported on a given linear code. In the exact and in the robust case. Also, we prove a corollary about non-signaling functions.

5.1 Quasi-distributions supported on linear codes

The equivalence between non-signaling functions and quasi-distributions in Section 4.3 suggests a natural way to capture when a non-signaling function is “in” a given linear code.

Definition 38. Given a k-non-signaling strategy \( F: [n] \to \mathbb{F} \), code \( C \subseteq \mathbb{F}^n \) and parameter \( k' \leq k \), we say that \( F \) is \((C,k')\)-supported if there exists a \( k'\)-local quasi-distribution \( Q: \mathbb{F}^n \to \mathbb{C} \) supported on \( C \) such that \( \Delta_{k'}(Q,F) = 0 \).

In light of the characterization of the Fourier spectra of quasi-distributions equivalent to a given non-signaling function in Section 4.3, it is natural to ask if the Fourier spectrum of a quasi-distribution supported on \( C \) has a special structure. In the following lemma, we characterize the Fourier spectrum of quasi-distributions supported on a given linear code \( C \). Informally, we show that the condition “Fourier coefficients are constants on cosets of \( C^\perp \)” is necessary and sufficient.

Lemma 39. Let \( C \subseteq \mathbb{F}^n \) be a linear code. A quasi-distribution \( Q: \mathbb{F}^n \to \mathbb{C} \) is supported on \( C \) if and only if \( \hat{Q}(\alpha) = \hat{Q}(\alpha') \) for all \( \alpha, \alpha' \in \mathbb{F}^n \) such that \( \alpha - \alpha' \in C^\perp \).

The foregoing statement immediately gives us a corollary about non-signaling functions.

Corollary 40. A k-non-signaling strategy \( F: [n] \to \mathbb{F} \) is \((C,k')\)-supported if and only if for all \( \alpha, \alpha' \in \mathbb{F}^n \) such that \( \alpha - \alpha' \in C \) it holds that \( \hat{F}(\alpha) = \hat{F}(\alpha') \).

Next, we wish to study the Fourier spectrum of a quasi-distribution \( Q \) that is merely close to being supported on \( C \). For this case, we give the following “robust” version of Lemma 39.
Lemma 41. Let $C \subseteq \mathbb{F}_2^n$ be a linear code, and let $Q$ be a quasi-distribution. Suppose that there exists a quasi-distribution $Q'$ supported on $C$ such that $\Delta_k(Q, Q') \leq \delta$. Then for all $\alpha, \alpha' \in \mathbb{F}_2^n$ and $\alpha - \alpha' \in C^\perp$, it holds that $|\hat{Q}(\alpha) - \hat{Q}(\alpha')| \leq \frac{2\delta}{\sqrt{n}}$.

Conversely, suppose that for all $\alpha, \alpha' \in \mathbb{F}_2^n$ and $\alpha - \alpha' \in C^\perp$ it holds that $|\hat{Q}(\alpha) - \hat{Q}(\alpha')| \leq \frac{2\delta}{\sqrt{n}}$. Then there exists a quasi-distribution $Q'$ supported on $C$ such that $\Delta_k(Q, Q') \leq \delta^{k/2} \cdot 2\delta$.

We note that in Lemma 41, neither quasi-distribution is required to be local.

5.1.1 Proof of Lemma 39

Define the affine spaces

$$V_1 = \left\{ Q : \mathbb{F}_2^n \to \mathbb{C} \text{ s.t. } \sum_{f \in C} Q(f) = 1 \text{ and } Q(f) = 0 \forall f \notin C \right\}.$$  

$$V_2 = \left\{ Q : \mathbb{F}_2^n \to \mathbb{C} \text{ s.t. } \hat{Q}(0^n) = 1 \text{ and } \hat{Q}(\alpha) = \hat{Q}(\alpha + \gamma) \forall \alpha \in \mathbb{F}_2^n, \gamma \in C^\perp \right\}.$$  

It suffices to prove that $V_1 = V_2$. First we show that $\dim(V_1) = \dim(V_2)$. The dimension of $V_1$ is $|C| - 1$ because the $|C|$ free terms are subject to a single linear constraint. The dimension of $V_2$ is $q^n/|C^\perp| - 1$ because the Fourier coefficients are constant on each coset of $C^\perp$, and on each coset they can take on an arbitrary value; the one exception is the coset $C^\perp$, on which the Fourier coefficients must be $1/\sqrt{n}$. Recalling that $q^n = |C| \cdot |C^\perp|$, we deduce that $\dim(V_1) = \dim(V_2)$.

Next we show that $V_1 \subset V_2$. Fix $Q \in V_1$. Since $\sum_f Q(f) = 1$, we have $\hat{Q}(0^n) = \frac{1}{q^n} \sum_f Q(f) \cdot \omega^0 = \frac{1}{q^n}$. Moreover, for any $\alpha \in \mathbb{F}_2^n$ and $\gamma \in C^\perp$,

$$\hat{Q}(\alpha + \gamma) = \frac{1}{q^n} \sum_f Q(f) \cdot \omega^{-\text{Tr}((\alpha + \gamma), f)} = \frac{1}{q^n} \sum_f Q(f) \cdot \omega^{-\text{Tr}(\alpha, f) - \text{Tr}(\gamma, f)}.$$  

Since $Q \in V_1$, if $Q(f) \neq 0$ then $f \in C$ and hence $\omega^{\text{Tr}(\gamma, f)} = \omega^{\text{Tr}(0)} = 1$. Therefore,

$$\hat{Q}(\alpha + \gamma) = \frac{1}{q^n} \sum_f Q(f) \cdot \omega^{-\text{Tr}(\alpha, f)} = \hat{Q}(\alpha).$$  

Thus $V_1 \subset V_2$. Since $\dim(V_1) = \dim(V_2)$ and $V_1 \subset V_2$, we conclude that $V_1 = V_2$.

5.1.2 Proof of Lemma 41

Suppose $Q : \mathbb{F}_2^n \to \mathbb{C}$ is a quasi-distribution such that there exists a quasi-distribution $Q'$ supported on $C$ with $\Delta_k(Q, Q') \leq \delta$. Fix $\alpha \in \mathbb{F}_2^n$, so that $S = \text{supp}(\alpha)$ has $|S| \leq k$. Since $\Delta_k(Q, Q') \leq \delta$, we have that $\sum_{g \in \mathbb{F}_2^n} |\text{Pr}[Q(S) = g] - \text{Pr}[Q'(S) = g]| \leq \delta$. Therefore,

$$|\hat{Q}(\alpha) - \hat{Q}'(\alpha)| \leq \frac{1}{q^n} \sum_{j \in \mathbb{F}_2} |\omega^{-j}||\text{Pr}[\text{Tr}(\alpha, Q) = j] - \text{Pr}[\text{Tr}(\alpha, Q') = j]|$$

$$= \frac{1}{q^n} \sum_{j \in \mathbb{F}_2} \sum_{g \in \mathbb{F}_2^{S}: \text{Tr}(\alpha, g) = j} |\text{Pr}[Q(S) = g] - \text{Pr}[Q'(S) = g]|$$

$$\leq \frac{1}{q^n} \sum_{g \in \mathbb{F}_2^{S}} |\text{Pr}[Q(S) = g] - \text{Pr}[Q'(S) = g]| \leq \frac{\delta}{q^n}.$$
By Lemma 39, we know that for every \( \alpha, \alpha' \in \mathbb{F}^n \) such that \( \alpha - \alpha' \in \mathbb{C}^\perp \) it holds that 
\[
|\tilde{Q}(\alpha) - \tilde{Q}(\alpha')| = 0.
\]
Hence, for every \( \alpha, \alpha' \in \mathbb{F}^n_{\leq k} \) such that \( \alpha - \alpha' \in \mathbb{C}^\perp \) it holds that 
\[
|\tilde{Q}(\alpha) - \tilde{Q}(\alpha')| \leq |\tilde{Q}(\alpha) - \tilde{Q}(\alpha')| + |\tilde{Q}(\alpha') - \tilde{Q}(\alpha')| + |\tilde{Q}(\alpha') - \tilde{Q}(\alpha')| \leq \frac{\delta}{q^n} + 0 + \frac{\delta}{q^n} = \frac{2\delta}{q^n}.
\]

Now, suppose that \( Q \) is a quasi-distribution such that 
\[
|\tilde{Q}(\alpha) - \tilde{Q}(\alpha')| \leq \frac{2k}{q^n}
\]
for all \( \alpha, \alpha' \in \mathbb{F}^n_{\leq k} \) such that \( \alpha - \alpha' \in \mathbb{C}^\perp \). For each \( \alpha \in \mathbb{F}^n \), let \( \gamma_\alpha \) be an element of the coset \( \alpha + \mathbb{C}^\perp \) of minimal weight (ties are broken arbitrarily). Define \( \tilde{Q}' \) to be the quasi-distribution where 
\[
\tilde{Q}'(\alpha) := \tilde{Q}(\gamma_\alpha) \text{ if } \text{wt}(\gamma_\alpha) \leq k \text{ and } 0 \text{ otherwise.}
\]
By construction, for any \( \alpha, \alpha' \in \mathbb{F}^n \) such that \( \alpha - \alpha' \in \mathbb{C}^\perp \) it holds that \( \tilde{Q}'(\alpha) = \tilde{Q}'(\alpha') \), so \( \tilde{Q}' \) is supported on \( \mathbb{C} \) by Lemma 39. Let \( \alpha \in \mathbb{F}^n_{\leq k} \).

By construction, we know that 
\[
|\tilde{Q}(\alpha) - \tilde{Q}(\alpha')| \leq \left| \tilde{Q}(\alpha) - \tilde{Q}(\gamma_\alpha) \right| + \left| \tilde{Q}(\gamma_\alpha) - \tilde{Q}(\alpha') \right| \leq \frac{2k}{q^n} + 0 = \frac{2k}{q^n},
\]
since \( \alpha - \gamma_\alpha \in \mathbb{C}^\perp \) and \( \text{wt}(\gamma_\alpha) \leq \text{wt}(\alpha) \leq k \). Therefore, by Lemma 33 we have that 
\[
\Delta_k(Q, Q') \leq q^{k/2} \cdot 2\delta.
\]

5.2 Locally-explainable non-signaling functions

We introduce another natural definition that captures when a non-signaling function \( F \) is “in” a given linear code \( \mathbb{C} \subseteq \mathbb{F}^n \). This time we take the perspective of local consistency, namely, we shall require that the output of \( F \) is always consistent with a codeword in \( \mathbb{C} \).

\begin{definition}
Given a \( k \)-non-signaling strategy \( F : [n] \rightarrow \mathbb{F} \), code \( \mathbb{C} \subseteq \mathbb{F}^n \), and parameter \( k' \leq k \), we say that \( F \) is \( (\mathbb{C}, k') \)-explainable if for every set \( S \subseteq [n]_{\leq k'} \) it holds that 
\[
\Pr[F(S) \in \mathbb{C}|S] = 1.
\]
\end{definition}

Note that \( F \) is \( (\mathbb{C}, k') \)-explainable if and only if \( \Pr[\langle \alpha, F \rangle = 0] = 1 \) for every \( \alpha \in \mathbb{C}^\perp_{\leq k'} \).

The non-trivial direction of the equivalence is implied by the following lemma.

\begin{lemma}
Let \( \mathbb{C} \subseteq \mathbb{F}^n \) be a linear code, \( S \subseteq [n]_{\leq k} \), and \( g : S \rightarrow \mathbb{F} \). If \( \langle \alpha, g \rangle = 0 \) for every \( \alpha \in \mathbb{C}^\perp_{\leq k} \), then there is a codeword \( f \in \mathbb{C} \) satisfying \( f|_S = g \).
\end{lemma}

\begin{proof}
Since \( \mathbb{C} \subseteq \mathbb{F}^n \) is a linear code, there is a pivotal set \( P \subseteq [n] \) of size \( |P| = \dim(\mathbb{C}) \) such that for all \( y : P \rightarrow \mathbb{F} \) there is a unique codeword \( f \in \mathbb{C} \) satisfying \( f|_P = y \). Such \( P \) need not be unique.

Let \( P^* \subseteq [n] \) be a pivotal set such that \( |P^* \cap S| \) is maximal, and let \( P_S := P^* \cap S \). Define \( f' : P^* \rightarrow \mathbb{F} \) by letting \( f'(i) = g(i) \) for all \( i \in P_S \), and letting \( f'(j) \) be arbitrary for all \( j \in P^* \setminus P_S \). Since \( P^* \) is a pivotal set, there exists a unique \( f \in \mathbb{C} \) such that \( f|_P = f' \).

It remains to show that \( f|_S = g \). Let \( i \in S \). If \( i \in P_S \), then \( f(i) = f'(i) = g(i) \), as required. Suppose that \( i \notin P_S \). Since \( P^* \) is maximal, there exists \( \alpha \in \mathbb{C}^\perp \) such that \( \alpha_i = 1 \) and \( \text{supp}(\alpha) \subseteq P_S \cup \{i\} \subseteq S \). Indeed, if no such \( \alpha \) exists then for any codeword \( h \in \mathbb{C} \), \( h(i) \) is not determined by \( \{h(j) : j \in P_S\} \). Hence, the set \( P_S \cup \{i\} \) can be extended into a pivotal set for \( \mathbb{C} \), which contradicts the maximality of \( P^* \). Therefore, such an \( \alpha \) exists. Since \( \langle \alpha, f \rangle = 0 \) and \( \langle \alpha, g \rangle = 0 \), we get that \( 0 = \langle \alpha, f \rangle - \langle \alpha, g \rangle = f(i) + \sum_{j \in P_S} \alpha_j f(j) - g(i) - \sum_{j \in P_S} \alpha_j g(j) = f(i) + \sum_{j \in P_S} \alpha_j g(j) - g(i) - \sum_{j \in P_S} \alpha_j g(j) = f(i) - g(i) \), and therefore \( f(i) = g(i) \). We conclude that \( f|_S = g \), as required.
\end{proof}

We provide a characterization of the Fourier spectrum of \( \mathbb{C} \)-explainable non-signaling functions, both in the exact and in the robust cases, as captured by the respective lemmas below. Both lemmas make crucial use of Lemma 29.
Lemma 44. Let $F: [n] \rightarrow F$ be a $k$-non-signaling function. Then $F$ is $(C, k')$-explainable if and only if $\hat{F}(a) = \frac{1}{q^n}$ for every $a \in C_{\leq k'}$.

Proof. We know that $F$ is $(C, k')$-explainable if and only if for every $a \in C_{\leq k'}$, it holds that $Pr[(a, F)] = 0$ and $Pr[(a, F)] = 1$. By Lemma 29, we know that $Pr[(a, F)] = 0$ if and only if $\hat{F}(a) = \frac{1}{q^n}$ for every $a \in F$, as $M$ is invertible and maps the distribution $Pr[(a, F)] = 0$ and $Pr[(a, F)] = 1$ for all other $b$ to the vector $1_q$. We conclude the proof by noting that if $a \in C_{\leq k'}$, then $aa \in C_{\leq k'}$ for any $a \in F$.

Lemma 45. Let $F: [n] \rightarrow F$ be a $k$-non-signaling function, and let $a \in F_0^{\leq k}$.

1. If $Pr[(a, F)] = 0 \geq 1 - \varepsilon$, then $|\hat{F}(a) - \frac{1}{q^n}| \leq \frac{\varepsilon}{q^n}$ for every $a \in F$.

2. If $|\hat{F}(a) - \frac{1}{q^n}| \leq \frac{\varepsilon}{q^n}$ for every $a \in F$, then $Pr[(a, F)] = 0 \geq 1 - \varepsilon$.

Proof. Suppose that $Pr[(a, F)] = 0 \geq 1 - \varepsilon$. This immediately implies that, for every $a \in F$, $Pr[(a, F)] = 0 \geq 1 - \varepsilon$. Therefore,

$$|q^n\hat{F}(a) - 1| = |-1 + \sum_{b \in F} \omega^{-Tr(ab)} Pr[(a, F) = b]|$$

$$\leq |-1 + Pr[(a, F) = 0]| + \sum_{b \neq 0} |\omega^{-Tr(ab)}||Pr[(a, F) = b]|$$

$$\leq \varepsilon + \sum_{b \neq 0} Pr[(a, F) = b]$$

$$= \varepsilon + (1 - Pr[(a, F) = 0]) \leq 2\varepsilon$$

This proves the first direction.

For the second direction, let $v \in C^q$ be the vector where $v_b = Pr[(a, F) = b]$ and let $w \in C^q$ be the vector where $w_a = q^n\hat{F}(a)$. Note that $Mv = w$, where $M$ is the matrix from Lemma 29. Suppose that $|\hat{F}(a) - \frac{1}{q^n}| \leq \frac{\varepsilon}{q^n}$ for every $a \in F$, so that $|w - 1| \leq \varepsilon$ for every $a \in F$. Then, we have that $||w - 1||_{\ell_2} \leq \sqrt{\varepsilon}$, so that $||w - 1||_{\ell_2} \leq \varepsilon$. Let $u \in C^q$ be the vector where $u_b = 1$ and $u_b = 0$ for all other $b \in F$. Observe that $Mu = 1_q$. Since $\sqrt{\varepsilon}M$ is unitary, we have that $||M(u - v)||_{\ell_2} = ||\frac{1}{\sqrt{\varepsilon}}(w - 1)||_{\ell_2} \leq \frac{\varepsilon}{\sqrt{\varepsilon}} = \varepsilon$. Therefore, $|v_b - u_b| \leq \varepsilon$ for all $b \in F$. In particular, $|v - 1| \leq \varepsilon$, so that $Pr[(a, F) = 0] \geq 1 - \varepsilon$.

5.3 The relationship between the two definitions

We have given two natural definitions of what it means for a non-signaling function to be in a linear code. Which of the two definitions is more “correct”? Lemma 39 and Lemma 44 show that Definition 38 implies Definition 42, in the sense that if $F$ is $(C, k')$-supported then $F$ is $(C, k')$-explainable. We prove that, conversely, Definition 42 implies Definition 38 up to a factor of 2 in the locality $k'$. We conclude that the two definitions are essentially equivalent.

Lemma 46. Let $C \subseteq F^n$ be a linear code, and let $F: [n] \rightarrow F$ be a $k$-non-signaling function.

1. If $F$ is $(C, k')$-supported then $F$ is $(C, k')$-explainable.

2. If $F$ is $(C, k')$-explainable then $F$ is $(C, k'/2)$-supported.

Remark 47. For specific choices of $C$ one can achieve stronger versions of the above lemma. For example, when $C$ is the Hadamard code (all linear functions), one can prove the lemma with $k' - 1$ in place of $k'/2$. Also, some gap in locality is necessary: taking again $C$ to be the Hadamard code, there exists a non-signaling function $F$ that is $(C, k)$-explainable and $(C, k - 1)$-supported but not $(C, k)$-supported. (The foregoing statements are shown implicitly in [4].)
Proof. Lemma 39 and Lemma 44 imply the first direction, as any \((C,k')\)-supported \(k\)-non-signaling function \(F\) satisfies \(\hat{F}(\alpha) = F(0^n) = \frac{1}{q}\) for every \(\alpha \in C_{\leq k'}\), implying that \(F\) is \((C,k')\)-explainable.

We now prove the second direction. Fix \(\alpha \in C_{\leq k'}\), and let \(S := \{i \in [n] : \alpha_i \neq 0\}\). Note that \(|S| \leq k'\) since \(|S| = \text{wt}(\alpha)\). We first show that \(\Pr[\langle \alpha, F \rangle = 0] = 1\). Indeed, since \(F\) is \((C,k')\)-explainable, we have that
\[
\Pr[\langle \alpha, F \rangle = 0] = \Pr[\langle \alpha, F \rangle = 0 \land \exists f \in C\text{ s.t. } F(S) = f|_S]
= \Pr[\langle \alpha, f \rangle = 0 \land \exists f \in C\text{ s.t. } F(S) = f|_S]
= \Pr[\exists f \in C\text{ s.t. } F(S) = f|_S] = 1,
\]
and so \(\Pr[\langle \alpha, F \rangle = 0] = 1\).

Now, for any \(\alpha, \alpha' \in \mathbb{F}_q^{\leq k'/2}\) with \(\alpha - \alpha' \in C\), we get that for any \(b \in \mathbb{F}\),
\[
\Pr[\langle \alpha, F \rangle = b] = \Pr[\langle \alpha', F \rangle + \langle \alpha - \alpha', F \rangle = b] = \Pr[\langle \alpha', F \rangle = b],
\]
since \(\Pr[\langle \alpha - \alpha', F \rangle = 0] = 1\) as \(\alpha - \alpha' \in C\) with \(\text{wt}(\alpha - \alpha') \leq k'\). This shows that the vectors \((\Pr[\langle \alpha, F \rangle = b])_{b \in \mathbb{F}}\) and \((\Pr[\langle \alpha', F \rangle = b])_{b \in \mathbb{F}}\) are the same. Thus, \(\hat{F}(\alpha) = \hat{F}(\alpha')\), by the definition of \(F\)'s Fourier coefficients. By Lemma 39, it follows that \(F\) is \((C,k'/2)\)-supported.

\section{Low-degree testing}

In this section, we prove Theorem 2. Throughout this section, we let \(m, d, k \in \mathbb{N}\) be parameters, and \(p\) be a prime where \(p \geq d + 2\). Let \(\text{RS}^m[\mathbb{F}_p, d]\) denote the code of polynomials from \(\mathbb{F}_p^m\) to \(\mathbb{F}_p\) of individual degree at most \(d\) in each variable. We let \(F : \mathbb{F}_p^m \rightarrow \mathbb{F}_p\) be a \(k\)-non-signaling function. For a subset \(S \subseteq \mathbb{F}_p\) and \(a \in S\), we let \(\delta_{a,S}(x) = \prod_{a' \in S \setminus \{a\}}(x - a')\)
be the degree \(|S| - 1\) polynomial satisfying \(\delta_a(x) = \begin{cases} 1 & \text{if } x = a, \\ 0 & \text{if } x \in S \setminus \{a\} \end{cases}\).

We begin by recalling the degree-\(d\) evenly-spaced points test.

\textbf{Definition 48 (Evenly-spaced points test).} Given a function \(f : \mathbb{F}_p^m \rightarrow \mathbb{F}_p\), the degree-\(d\) evenly-spaced points test:
1. samples a random point \(x \in \mathbb{F}_p^m\) and slope \(h \in \mathbb{F}_p^m \setminus \{0^m\}\),
2. checks that \(\sum_{i=0}^{d+1} c_i f(x + ih) = 0\), where \(c_i = (-1)^i (d+1-i)\).

\textbf{Definition 49 (Evenly-spaced self-correction).} The evenly-spaced self-correction of \(F\), denoted \(\hat{F}\), is a \((k/(d+1))\)-non-signaling function defined as follows. Let \(w_0, w_1, \ldots, w_m \in \mathbb{F}_p^m\) be independent uniformly random vectors in \(\mathbb{F}_p^m\), and for each \(x \in \mathbb{F}_p^m\) let \(w_x = w_0 + \sum_{i=1}^{m} x_i w_i\).

For an input set \(S\) and \(g : S \rightarrow \mathbb{F}_p\), the distribution of \(\hat{F}(S)\) correction is defined as
\[
\Pr[\hat{F}(S) = g] = \frac{\Pr_{w_0, \ldots, w_m, \mathcal{F}}[-\sum_{j=1}^{d+1} c_j F(x + j w_z) = g(x) \forall x \in S]}{1}.
\]

Our main theorem is the following.

\textbf{Theorem 50 (Formal version of Theorem 2).} Let \(p\) be a prime, and let \(m, d \in \mathbb{N}\) with \(p \geq d + 2\). Let \(F : \mathbb{F}_p^m \rightarrow \mathbb{F}_p\) be a \(k\)-non-signaling function. Suppose that \(F\) passes the degree-\(d\) evenly-spaced points test with probability \(1 - \varepsilon\). Then there exists a \(k'\)-non-signaling function \(G : \mathbb{F}_p^m \rightarrow \mathbb{F}_p\) that is \((\text{RS}^m[\mathbb{F}_p, d], k')\)-supported such that \(\Delta_k(\hat{F}, G) \leq O(p^{k'/(2(d+1)^m)}\varepsilon)\), where \(k' = \lceil \frac{k}{2(d+1)^m} \rceil - 3\).
When $\varepsilon = 0$, the theorem can be simplified considerably to the statement below.

**Theorem 51** (Formal version of Theorem 2, zero error case). Let $p$ be a prime, and let $m, d \in \mathbb{N}$ with $p \geq d + 2$. Let $F: \mathbb{F}_p^m \rightarrow \mathbb{F}_p$ be a $k$-non-signaling function. Suppose that $F$ passes the degree-$d$ evenly-spaced points test with probability 1. Then $F$ is $(\text{RS}^\oplus \mathbb{F}_p, d, \lfloor k/(d + 2) \rfloor - 1)$-supported.

We prove Theorem 50 via the following statements, each proved in one of the following sections.

**Lemma 52** (Average to worst case). Suppose that $F$ passes the degree-$d$ evenly-spaced points test with probability $1 - \varepsilon$, i.e. that $\mathbb{P}_{x,h \neq 0^m, x \cdot F} \left[ \sum_{i=0}^{d+1} c_i F(x + ih) = 0 \right] \geq 1 - \varepsilon$. Then for every $x, h \in \mathbb{F}_p^m$ with $h \neq 0^m$ it holds that $\mathbb{P}_F \left[ \sum_{i=0}^{d+1} c_i F(x + ih) = 0 \right] \geq 1 - (d + 1)\varepsilon$.

**Lemma 53** (Evenly-spaced points to axis-parallel lines). Let $\hat{F}: \mathbb{F}_p^m \rightarrow \mathbb{F}_p$ be a $\hat{k}$-non-signaling function, with $\hat{k} \geq 2d + 3$. Suppose that for every $x, h \in \mathbb{F}_p^m$ with $h \neq 0^m$ it holds that $\mathbb{P}_F \left[ \sum_{i=0}^{d+1} c_i \hat{F}(x + ih) = 0 \right] \geq 1 - \varepsilon$. Then for every $b_1, \ldots, b_m \in \mathbb{F}_p$, $i \in [m]$, and $S \subseteq \mathbb{F}_p \setminus \{b_i\}$ of size $|S| = d + 1 \leq k - d - 2$ it holds that

$$\mathbb{P}_F \left[ \hat{F}(b_1, \ldots, b_m) = \sum_{a \in S} \delta_{a,S}(b_i) \cdot \hat{F}(b_1, \ldots, b_{i-1}, a, b_{i+1}, \ldots, b_m) \right] \geq 1 - p\varepsilon .$$

**Lemma 54** (Robust local characterization). Let $\hat{F}: \mathbb{F}_p^m \rightarrow \mathbb{F}_p$ be a $\hat{k}$-non-signaling function, and suppose that for every $i \in [m]$, $b_1, \ldots, b_m \in \mathbb{F}_p$, and $S' \subseteq \mathbb{F}_p \setminus \{b_i\}$ of size $|S'| = d + 1$ it holds that

$$\mathbb{P}_{\hat{F}} \left[ \hat{F}(b_1, \ldots, b_m) = \sum_{a \in S'} \delta_{a,S'}(b_i) \cdot \hat{F}(b_1, \ldots, b_{i-1}, a, b_{i+1}, \ldots, b_m) \right] \geq 1 - \varepsilon .$$

Then for every $S \subseteq \mathbb{F}_p^m$ with $|S| \leq \lfloor \hat{k}/(d + 2) \rfloor$ it holds that $\mathbb{P}_F \left[ \hat{F}(S) \in \text{RS}^\oplus \mathbb{F}_p, d \right] \geq 1 - 2|S| \cdot (d + 1)^{m-1} \varepsilon$.

**Lemma 55.** Let $\hat{F}: \mathbb{F}_p^m \rightarrow \mathbb{F}_p$ be a $\hat{k}$-non-signaling function, and let $k' \leq \hat{k}$. Suppose that for every $S \subseteq \mathbb{F}_p^m$ with $|S| \leq k'$ it holds that $\mathbb{P}_F \left[ \hat{F}(S) \in \text{RS}^\oplus \mathbb{F}_p, d \right] \geq 1 - \varepsilon$. Then there exists a $k'/2$-non-signaling function $G$ that is $(\text{RS}^\oplus \mathbb{F}_p, d, k'/2)$-supported and $\Delta_{k'/2}(F, G) \leq (p^{k'/2} + 1) \cdot p^{k'/4} \cdot 2\varepsilon$.

### 6.1 Step 1: Average to worst case reduction

We prove Lemma 52. Fix $x, h \in \mathbb{F}_p^m$ with $h \neq 0^m$. Observe that $w_{x+ih} = w_x + i(w_h - w_0)$. Therefore

$$\mathbb{P}_F \left[ \sum_{j=0}^{d+1} c_j \hat{F}(x + ih) = 0 \right] = \mathbb{P}_F \left[ \sum_{i=0}^{d+1} c_i \sum_{j=1}^{d+1} -c_j F(x + ih + jw_{x+ih}) = 0 \right]$$

$$\mathbb{P}_F \left[ \sum_{j=1}^{d+1} c_j \sum_{i=0}^{d+1} -c_j F(x + ih + jw_x + ij(w_h - w_0)) = 0 \right] \geq \mathbb{P}_F \left[ \sum_{i=0}^{d+1} c_i F(x + jw_x + i(h + j(w_h - w_0))) = 0 \forall j \in [d + 1] \right]$$

$$\geq 1 - (d + 1)\varepsilon .$$
We prove Lemma 53. Note that by the assumption for every $x \in \mathbb{F}_p^m$ and $h = c_i$ it holds that $\Pr[\sum_{\ell=0}^{d+1} c_i \hat{F}(x + \ell c_i) = 0] \geq 1 - \varepsilon$. Fix $i \in [m], b_1, \ldots, b_{i-1}, b_{i+1}, \ldots, b_m \in \mathbb{F}_p$, and $S \subseteq \mathbb{F}_p$ of size $|S| = d + 2$. We claim that

$$\Pr[\exists g \in \mathbb{R}[\mathbb{F}_p, d] \text{ s.t. } \hat{F}(b_1, \ldots, b_{i-1}, s, b_{i+1}, \ldots, b_m) \equiv g(s) \forall s \in S] \geq 1 - \varepsilon.$$  

This clearly implies Lemma 53.

In order to prove Equation (1), let us order the elements of $S$ as $s_1 \leq s_2 \leq \cdots \leq s_{d+2}$ by treating $s_i$’s as integers in $\{0, 1, 2, \ldots, p - 1\} \subseteq \mathbb{N}$. For each $j \in \mathbb{F}_p$, define the interval

$$I_j = \{j, j + 1, j + 2, \ldots, j + d + 1\},$$

and denote $Q_j = \{s \in S : s \leq j + d + 2\} \cup I_j$. We claim that with high probability $\hat{F}$ on the points corresponding to $Q_j$ agrees with some univariate polynomial. Specifically, we prove the following claim.

\textbf{Claim 56.} For each $j = 0, 1, \ldots, p - 1$ it holds that

$$\Pr[\exists g \in \mathbb{R}[\mathbb{F}_p, d] \text{ s.t. } \hat{F}(b_1, \ldots, b_{i-1}, s, b_{i+1}, \ldots, b_m) \equiv g(s) \forall s \in Q_j] \geq 1 - (j + 1)\varepsilon.$$  

It is clear that the statement of Claim 56 for $j = p - 1$ implies Equation (1), and hence proves Lemma 53.

\textbf{Proof of Claim 56.} The proof is by induction in $j$. For the base case of $j = 0$ we query $\hat{F}$ on the set $I_0$. By the assumption of the lemma we have

$$\Pr[\exists g \in \mathbb{R}[\mathbb{F}_p, d] \text{ s.t. } \hat{F}(b_1, \ldots, b_{i-1}, \ell, b_{i+1}, \ldots, b_m) \equiv g(\ell) \forall \ell \in I_0] \geq 1 - \varepsilon,$$

and the claim hold since for $j = 0$ we have $Q_0 = I_0$.

For the induction step suppose that the statement of the claim holds for $j - 1$, i.e., with probability $1 - j\varepsilon$ there exists a univariate polynomial $g$ of degree $d$ that agrees with $\hat{F}$ on $Q_{j-1}$. Note that the set $Q_{j-1}' = Q_{j-1} \setminus \{j - 1\}$ contains the $d + 1$ consecutive points $\{j, j + 1, \ldots, j + d\}$, and these points uniquely define the polynomial $g$ of degree $d$. Therefore

$$\Pr[\exists g \in \mathbb{R}[\mathbb{F}_p, d] \text{ s.t. } \hat{F}(b_1, \ldots, b_{i-1}, \ell, b_{i+1}, \ldots, b_m) \equiv g(\ell) \forall \ell \in Q_{j-1}'] \geq 1 - j\varepsilon.$$

On the other hand, by the assumption that $\hat{F}$ satisfies evenly-spaced constraints with probability $\geq 1 - \varepsilon$ we have

$$\Pr[\exists g' \in \mathbb{R}[\mathbb{F}_p, d] \text{ s.t. } \hat{F}(b_1, \ldots, b_{i-1}, \ell, b_{i+1}, \ldots, b_m) \equiv g'(\ell) \forall \ell \in I_j] \geq 1 - \varepsilon.$$  

Note that the above statement requires that $p \geq d + 2$, as passing the evenly-spaced points test along a line corresponds to being a univariate polynomial only when $p \geq d + 2$.

Query $\hat{F}$ on the set $Q_{j-1}' \cup I_j$. By union bound, the above events both hold with probability $\geq 1 - (j + 1)\varepsilon$, so that there exists $g, g' \in \mathbb{R}[\mathbb{F}_p, d]$ such that $\hat{F}(b_1, \ldots, b_{i-1}, \ell, b_{i+1}, \ldots, b_m) = g(\ell)$ for all $\ell \in Q_{j-1}'$ and $\hat{F}(b_1, \ldots, b_{i-1}, \ell, b_{i+1}, \ldots, b_m) = g'(\ell)$ for all $\ell \in I_j$. However, since $Q_{j-1}'$ intersects $I_j$ on $d + 1$ points it must be the case that $g = g'$. Hence, $\hat{F}(b_1, \ldots, b_{i-1}, \ell, b_{i+1}, \ldots, b_m) = g(\ell)$ for all $\ell \in Q_{j-1}' \cup I_j$. Since $Q_{j-1} \subseteq Q_{j-1}' \cup I_j$, this proves the induction step. Since $|Q_{j-1}' \cup I_j| \leq |S| + d + 2$ and $|Q_j| \leq |S| + d + 2$, it follows that this is valid for all $S$ with $|S| \leq k - d - 2$, which completes the proof of Claim 56.
6.3 Step 3: A robust local characterization of low-degree polynomials

We prove Lemma 54. We begin by introducing some notation. For each \(i \in [m]\) define \(S_i \subseteq \mathbb{F}_p^i\) to be the projection of \(S\) to the first \(i\) coordinates, i.e. that

\[
S_i := \{(a_1, \ldots, a_i) \in \mathbb{F}_p^i : \exists b_{i+1}, \ldots, b_m \in \mathbb{F}_p \text{ s.t. } (a_1, \ldots, a_i, b_{i+1}, \ldots, b_m) \in S\}.
\]

Note that \(S_m = S\). For any set \(R \subseteq \mathbb{F}_p^i\) and \(b_{i+1}, \ldots, b_m \in \mathbb{F}_p\), we define the extension of \(R\) as

\[
R^{(b_{i+1}, \ldots, b_m)} := R \times \{(b_{i+1}, \ldots, b_m)\}
\]

We prove by induction that for every \(i \in [m]\) and every \(b_{i+1}, \ldots, b_m \in \mathbb{F}_p\) it holds that

\[
\Pr[\exists g_i \in \mathbb{R}^{\otimes i}[\mathbb{F}_p, d] \text{ s.t. } \hat{F}(a_1, \ldots, a_i, b_{i+1}, \ldots, b_m) = g_i(a_1, \ldots, a_i) \forall (a_1, \ldots, a_i) \in S_i] \geq 1 - \varepsilon_i,
\]

(2)

where \(\varepsilon_i = |S| \sum_{j=i}^{m}(d+1)^{-j-1} \varepsilon\). Note that the above probability is well-defined since we query \(\hat{F}\) on the set \(\mathbb{S}_i^{(b_{i+1}, \ldots, b_m)}\), which contains at most \(|S| \leq k' \leq k\) points. Equation (2) proves Lemma 54, as \(\mathbb{S}_m = S\) and \(\varepsilon_m \leq |S| \sum_{j=1}^{m}(d+1)^{-j-1} \varepsilon \leq \frac{(d+1)^m - 1}{d+1} |S| \varepsilon \leq 2(d+1)^{-m-1} |S| \varepsilon\).

We first show the base case: \(i = 1\). Let \(R \subseteq S_1\) be a subset of size \(\min(d+1, |S_1|)\).

Query \(\hat{F}\) on \(S_1^{(b_{i+1}, \ldots, b_m)}\), and let \(g_1 \in \mathbb{R}^{\otimes 1}[\mathbb{F}_p, d]\) be the univariate polynomial \(g_1(x) = \sum_{a \in R} \delta_{a,R}(a) \cdot \hat{F}(a, b_2, \ldots, b_m)\). Then,

\[
\Pr[\exists g_1 \in \mathbb{R}^{\otimes 1}[\mathbb{F}_p, d] \text{ s.t. } \hat{F}(a_1, b_2, \ldots, b_m) = g_1(a_1) \text{ for all } a_1 \in S_1] \geq 1 - |S_1| \varepsilon = 1 - \varepsilon_1.
\]

This is because if \(a_1 \in R\), then \(\hat{F}(a, b_2, \ldots, b_m) = g_1(a)\) is trivially true by definition of \(g_1\), and if \(a_1 \in S_1 \setminus R\) then this is true because

\[
\hat{F}(a_1, b_2, \ldots, b_m) = \sum_{a \in R} \delta_{a,R}(a) \cdot \hat{F}(a, b_2, \ldots, b_m) = g_1(a_1),
\]

with probability \(1 - \varepsilon\), by the assumption on \(\hat{F}\).

We now show the induction step. Suppose that Equation (2) holds for \(i - 1\) and every \(b_{i+1}, \ldots, b_m \in \mathbb{F}_p\). Let \(R_i = S_i \cup (S_{i-1} \times \{0, \ldots, d\})\). Fix \(b_{i+1}, \ldots, b_m \in \mathbb{F}_p\), and query \(\hat{F}\) on \(R_i^{(b_{i+1}, \ldots, b_m)}\). Note that this is well-defined since \(|R_i^{(b_{i+1}, \ldots, b_m)}| \leq |S_i| + (d+1)|S_{i-1}| \leq (d+2)|S| \leq (d+2)k' \leq k\).

We have that \(S_{i-1} \times \{0, \ldots, d\} \subseteq R_i\), and so for every \(j \in \{0, \ldots, d\}\), the induction hypothesis implies (by setting \(b_i = j\) that with probability at least \(1 - \varepsilon_{i-1}\) there exists \(g_{i-1}^{(j)} \in \mathbb{R}^{\otimes i-1}[\mathbb{F}_p, d]\) such that \(\hat{F}(a_1, \ldots, a_{i-1}, j, b_{i+1}, \ldots, b_m) = g_{i-1}^{(j)}(a_1, \ldots, a_{i-1})\) for every \((a_1, \ldots, a_{i-1}) \in S_{i-1}\).

For \(j \in \{0, \ldots, d\}\), let \(\delta_j(x) := \delta_j[0, \ldots, d](x)\). Let \(g_i \in \mathbb{R}^{\otimes i}[\mathbb{F}_p, d]\) be defined as \(g_i(x_1, \ldots, x_i) = \sum_{j=0}^d \delta_j(x_i) \cdot g_{i-1}^{(j)}(x_1, \ldots, x_{i-1})\). We show that

\[
\Pr[\hat{F}(a_1, \ldots, a_i, b_{i+1}, \ldots, b_m) = g_i(a_1, \ldots, a_i) \text{ for all } (a_1, \ldots, a_i) \in S_i] \geq 1 - \varepsilon_i.
\]

Indeed, note that for any \((a_1, \ldots, a_i) \in S_i\) we have \((a_1, \ldots, a_{i-1}) \in S_{i-1}\), and so with probability \(1 - \varepsilon_{i-1}\) all the \(g_{i-1}^{(j)}\)'s exist, and so we have that for all \((a_1, \ldots, a_i) \in S_i\) it holds that

\[
g_i(a_1, \ldots, a_i) = \sum_{j=0}^d \delta_j(a_i) \cdot g_{i-1}^{(j)}(a_1, \ldots, a_{i-1}) = \sum_{j=0}^d \delta_j(a_i) \cdot \hat{F}(a_1, \ldots, a_{i-1}, j, b_{i+1}, \ldots, b_m)
\]
By the assumption on $\hat{F}$, we have
\[
\Pr\left[ \sum_{j=0}^{d} \delta_j(a_i) \cdot \hat{F}(a_1, \ldots, a_{i-1}, j, b_{i+1}, \ldots, b_m) \right] = \hat{F}(a_1, \ldots, a_i, b_{i+1}, \ldots, b_m) \quad \forall (a_1, \ldots, a_i) \in S_i \geq 1 - |S_i|\varepsilon .
\]

Combining the two equations shows that $g_i(a_1, \ldots, a_i) = \hat{F}(a_1, \ldots, a_i, b_{i+1}, \ldots, b_m)$ with probability $1 - (d+1)\varepsilon_1 - |S_i|\varepsilon \geq 1 - (d+1)\varepsilon_1 - |S|\varepsilon = 1 - \varepsilon_1$, as required, completing the proof.

### 6.4 Step 4: Completing the proof

The following generic lemma immediately implies Lemma 55.

**Lemma 57.** Let $C \subseteq \mathbb{F}_2^n$ be a linear code, and let $F$ be a $k$-non-signaling function. Suppose that $\Pr[\langle \alpha, F \rangle = 0] \geq 1 - \varepsilon$ for every $\alpha \in C_{\leq k}^\perp$. Then there exists a $k/2$-non-signaling function $G$ that is $(C, k/2)$-supported such that $\Delta_{k/2}(F, G) \leq (q^{k/2} + 1) \cdot q^{k/4} \cdot 2\varepsilon$.

**Proof.** Let $\alpha, \alpha' \in \mathbb{F}_2^n \subseteq C_{\leq k/2}$ such that $\alpha - \alpha' \in C^\perp$. Then
\[
\left| \hat{F}(\alpha) - \hat{F}(\alpha') \right| = \left| \frac{1}{q^n} \sum_{j \in \mathbb{F}_2} \omega^{-j} \left( \Pr[\text{Tr}(\langle \alpha, F \rangle) = j] - \Pr[\text{Tr}(\langle \alpha', F \rangle) = j] \right) \right|
\leq \frac{1}{q^n} \sum_{j \in \mathbb{F}_2} |\omega^{-j}| \left| \Pr[\text{Tr}(\langle \alpha, F \rangle) = j] - \Pr[\text{Tr}(\langle \alpha', F \rangle) = j] \right|
\leq \frac{1}{q^n} \sum_{j \in \mathbb{F}_2} \left| \Pr[\text{Tr}(\langle \alpha, F \rangle) = j \land \langle \alpha - \alpha', F \rangle \neq 0] - \Pr[\text{Tr}(\langle \alpha', F \rangle) = j \land \langle \alpha - \alpha', F \rangle \neq 0] \right|
\leq \frac{1}{q^n} \sum_{j \in \mathbb{F}_2} \left( |\Pr[\text{Tr}(\langle \alpha, F \rangle) = j \land \langle \alpha - \alpha', F \rangle \neq 0] + |\Pr[\text{Tr}(\langle \alpha', F \rangle) = j \land \langle \alpha - \alpha', F \rangle \neq 0] \right)
\leq \frac{2}{q^n} \cdot \Pr[|\langle \alpha - \alpha', F \rangle| = 0] \leq \frac{2\varepsilon}{q^n} ,
\]

since $\alpha - \alpha' \in C^\perp$ and $\text{wt}(\alpha - \alpha') \leq k$. By Lemma 41, there exists a quasi-distribution $Q$ supported on $C$ such that $\Delta_{k/2}(F, Q) \leq q^{k/4} \cdot 2\varepsilon$. By Lemma 26, there exists a quasi-distribution $Q'$ supported on $C$ such that $\Delta_{k/2}(Q, Q') \leq q^{k/2} \cdot q^{k/4} \cdot 2\varepsilon$. Letting $G$ be the $k/2$-non-signaling function corresponding to $Q'$ completes the proof. ▶

### 7 Local characterizations and linear proofs

We prove Theorem 8 in this section. For this section, we let $k' \leq k$ be an integer. We let $C \subseteq \mathbb{F}_2^n$ be a linear code, and $T \subseteq \mathbb{F}_2^n$ be a set of constraints. Given a $k$-non-signaling function $F$, we say that $F$ satisfies a constraint $\alpha \in \mathbb{F}_2^n$ if $\Pr[\langle \alpha, F \rangle = 0] = 1$.

**Definition 58.** We let $\text{Consistent}(T, k)$ denote the set of $k$-non-signaling functions $F$ where $\Pr[\langle \alpha, F \rangle = 0] = 1$ for every $\alpha \in T$. That is, $\text{Consistent}(T, k)$ is the set of $k$-non-signaling functions that are consistent with $T$.

We note that by Lemma 44, $\text{Consistent}(C_{\leq k}^\perp, k)$ is the set of $k$-non-signaling functions that are $(C, k')$-explainable.

With the above definition, the definition of local characterization can be rephrased as follows.
Definition 59. For $\ell \leq k' \leq k$, a set of constraints $T \subseteq \mathbb{C}^{2n}_{\leq k}$ is a $\ell$-local characterization of $(\mathbb{C}, k', k)$ if $\text{Consistent}(T, k)$ equals the set of $k$-non-signaling functions that are $(\mathbb{C}, k')$-explainable, i.e. that $\text{Consistent}(T, k) = \text{Consistent}(\mathbb{C}^{2n}_{\leq k'}, k)$.

In this language, [4] shows that $T = \{e_x + e_y - e_{x+y} : x, y \in \{0,1\}^n\}$ is a 3-local characterization of $(\mathbb{C}, k-1, k)$, where $\mathbb{C}$ is the Hadamard code.

We briefly recall the definition of a $k$-local linear proof introduced in Section 1.2.

Definition 60 (k-local linear proof). Given a constraint set $T$ and $\alpha \in \mathbb{F}^n$, we write $T \vdash_k \alpha$ if there exists a sequence $(\alpha_0 := 0^n, \alpha_1, \ldots, \alpha_{\ell-1}, \alpha_{\ell} := \alpha)$ with each $\alpha_i \in \mathbb{F}^n$ such that, for every $i \in [\ell]$, one of the following holds:

- $\exists j < i$ and $b \in \mathbb{F}$ such that $\alpha_i = b\alpha_j$
- $\exists j < i$ and $\gamma \in T$ such that $|\text{supp}(\alpha_j) \cup \text{supp}(\gamma)| \leq k$ and $\alpha_i = \alpha_j + \gamma$
- $\exists j_1, j_2 < i$ such that $|\text{supp}(\alpha_{j_1}) \cup \text{supp}(\alpha_{j_2})| \leq k$ and $\alpha_i = \alpha_{j_1} + \alpha_{j_2}$

Theorem 8 is stated formally as the theorem below.

Theorem 61 (Formal version of Theorem 8). $k$-local linear proofs are complete and sound for $k$-non-signaling functions. In particular, for $\ell \leq k' \leq k$, a set of constraints $T \subseteq \mathbb{C}^{2n}_{\leq \ell}$ is a $\ell$-local characterization of $(\mathbb{C}, k', k)$ if and only if $T \vdash_k \mathbb{C}^{2n}_{\leq k'}$.

The proof of Theorem 61 relies on the notion of a $k$-local subspace, which we define below.

Definition 62. A $k$-local subspace $\mathcal{V}$ is a subset of $\mathbb{F}^n$ such that $\mathcal{V} \subseteq \mathbb{F}^n$ is a linear subspace for every $S \subseteq [n]_{\leq k}$.

We prove Theorem 61 by showing the following three lemmas.

Lemma 63 (Soundness). If $T \vdash_k \alpha$, then $\text{Consistent}(T, k) = \text{Consistent}(T \cup \{\alpha\}, k)$.

Lemma 64. For every $k$-local subspace $\mathcal{V} \subseteq \mathbb{F}^n$, there exists a $k$-non-signaling function $\mathcal{F}$ such that $\Pr[\langle \alpha, \mathcal{F} \rangle = 0] = 1$ for every $\alpha \in \mathcal{V}$, and $\Pr[\langle \alpha, \mathcal{F} \rangle = 0] = \frac{1}{|\mathcal{V}|}$ otherwise.

Lemma 65. $\{\alpha \in \mathbb{F}^n : T \vdash_k \alpha\} \subseteq \mathbb{F}^n$ is a $k$-local subspace.

The following corollary follows immediately from Lemma 64 and Lemma 65.

Corollary 66 (Strong completeness). There exists a $k$-non-signaling function such that $\Pr[\langle \alpha, \mathcal{F} \rangle = 0] = 1$ for every $\alpha$ where $T \vdash_k \alpha$, and $\Pr[\langle \alpha, \mathcal{F} \rangle = 0] = \frac{1}{|\mathcal{V}|}$ otherwise.

Proof of Theorem 61. Completeness and soundness are shown in Corollary 66 and Lemma 63. It remains to show the equivalence for local characterizations.

Suppose that $T \vdash_k \mathbb{C}^{2n}_{\leq k'}$. Then by Lemma 63 we have that $\text{Consistent}(T, k)$ and $\text{Consistent}(T \cup \mathbb{C}^{2n}_{\leq k'})$ are equal. Since $T \subseteq \mathbb{C}^{2n}_{\leq k}$ and $\ell \leq k'$, we get that $T \subseteq \mathbb{C}^{2n}_{\leq k'}$. Hence, $\text{Consistent}(T, k) = \text{Consistent}(T \cup \mathbb{C}^{2n}_{\leq k'}, k) = \text{Consistent}(\mathbb{C}^{2n}_{\leq k'}, k)$, as required.

Conversely, suppose that $T$ is an $\ell$-local characterization of $(\mathbb{C}, k', k)$. By Lemma 64 and Lemma 65, there exists a $k$-non-signaling function $\mathcal{F}$ such that $\Pr[\langle \alpha, \mathcal{F} \rangle = 0] = 1$ for every $\alpha \in \mathbb{F}^n$ such that $T \vdash_k \alpha$, and $\Pr[\langle \alpha, \mathcal{F} \rangle = 0] = \frac{1}{|\mathcal{V}|}$ otherwise. Since $T \vdash_k \alpha$ for every $\alpha \in T$, it follows that $\mathcal{F} \in \text{Consistent}(T, k)$, which implies that $\mathcal{F} \in \text{Consistent}(\mathbb{C}^{2n}_{\leq k'}, k)$ as $T$ is an $\ell$-local characterization of $(\mathbb{C}, k', k)$. This implies that $T \vdash_k \alpha$ for all $\alpha \in \mathbb{C}^{2n}_{\leq k'}$, since for all such $\alpha$ it holds that $\Pr[\langle \alpha, \mathcal{F} \rangle = 0] = 1$, and thus $T \vdash_k \alpha$. Hence, $T \vdash_k \mathbb{C}^{2n}_{\leq k'}$, as required.
7.1 Proof of Lemma 63

It is clear that from the definition that \( \text{Consistent}(T, k) \supseteq \text{Consistent}(T \cup \{\alpha\}, k) \) for all \( \alpha \in \mathbb{F}^n \). Below we prove the containment in the other direction. Suppose that \( T \vdash_k \alpha \), and let \( \alpha_0 = 0^n, \alpha_1, \ldots, \alpha_r = \alpha \) be a \( k \)-local proof of \( \alpha \) from \( T \). Let \( \mathcal{F} \in \text{Consistent}(T, k) \), that is, \( \mathcal{F} \) is a \( k \)-non-signaling function such that \( \forall \gamma \in T, \Pr[\gamma, \mathcal{F} = 0] = 1 \). We prove by induction that for \( i \in [r] \) it holds that \( \Pr[\alpha_i, \mathcal{F} = 0] = 1 \).

For the base case of \( i = 0 \) it must be the case that \( \alpha_0 = 0^n \). Therefore, \( \Pr[\langle \alpha_0, \mathcal{F} \rangle = 0] = 1 \).

For the induction step let \( i \geq 1 \), and consider the following three cases.

1. There exists \( j < i \) and \( b \in \mathbb{F} \setminus \{0^n\} \) such that \( \alpha_i = b \alpha_j \). Then,
   \[
   \Pr[\langle \alpha_i, \mathcal{F} \rangle = 0] = \Pr[b\langle \alpha_j, \mathcal{F} \rangle = 0] = \Pr[\langle \alpha_j, \mathcal{F} \rangle = 0] = 1 ,
   \]
   where the last equality uses the induction hypothesis.

2. There exist \( j < i \) and \( \gamma \in T \) such that \( \alpha_i = \alpha_j + \gamma \) with \( |\text{supp}(\alpha_j) \cup \text{supp}(\gamma)| \leq k \). Since \( \mathcal{F} \in \text{Consistent}(T, k) \) we have that \( \Pr[\langle \gamma, \mathcal{F} \rangle = 0] = 1 \), as \( \gamma \in T \). Therefore,
   \[
   \Pr[\langle \alpha_i, \mathcal{F} \rangle = 0] = \Pr[\langle \alpha_j, \mathcal{F} \rangle + \langle \gamma, \mathcal{F} \rangle = 0] \geq \Pr[\langle \alpha_j, \mathcal{F} \rangle = 0 \land \langle \gamma, \mathcal{F} \rangle = 0] = 1 ,
   \]
   as required. Note that \( \Pr[\langle \alpha_j, \mathcal{F} \rangle = 0 \land \langle \gamma, \mathcal{F} \rangle = 0] \) is well-defined because we have \( |\text{supp}(\alpha_j) \cup \text{supp}(\gamma)| \leq k \).

3. There exist \( j_1, j_2 < i \) such that \( \alpha_i = \alpha_{j_1} + \alpha_{j_2} \) and \( |\text{supp}(\alpha_{j_1}) \cup \text{supp}(\alpha_{j_2})| \leq k \). By the induction hypothesis we know that \( \Pr[\langle \alpha_{j_1}, \mathcal{F} \rangle = 0] = 1 \) and \( \Pr[\langle \alpha_{j_2}, \mathcal{F} \rangle = 0] = 1 \). Thus,
   \[
   \Pr[\langle \alpha_i, \mathcal{F} \rangle = 0] = \Pr[\langle \alpha_{j_1}, \mathcal{F} \rangle + \langle \alpha_{j_2}, \mathcal{F} \rangle = 0] \geq \Pr[\langle \alpha_{j_1}, \mathcal{F} \rangle = 0 \land \langle \alpha_{j_2}, \mathcal{F} \rangle = 0] = 1 ,
   \]
   and therefore \( \Pr[\langle \alpha_i, \mathcal{F} \rangle = 0] = 1 \). Again, we require \( |\text{supp}(\alpha_{j_1}) \cup \text{supp}(\alpha_{j_2})| \leq k \) in order for the last probability to be well-defined.

In particular, this implies that \( \Pr[\langle \alpha, \mathcal{F} \rangle = 0] = \Pr[\langle \alpha_r, \mathcal{F} \rangle = 0] = 1 \), and hence \( \mathcal{F} \in \text{Consistent}(T \cup \{\alpha\}, k) \). Therefore \( \text{Consistent}(T, k) \subseteq \text{Consistent}(T \cup \{\alpha\}, k) \), which completes the proof of Lemma 63.

7.2 Proof of Lemma 64

We define \( \mathcal{F} \) specifying its local distributions \( \mathcal{F}_S \) for each \( S \subseteq [n] \leq k \). We define the function \( \mathcal{F}_S : \mathbb{F}^S \to \mathbb{C} \) by specifying its (local) Fourier coefficients as follows. We set the Fourier coefficient \( \mathcal{F}_S(\alpha) \) to be \( \frac{1}{q^{|S|}} \) if \( \alpha \in \mathcal{V} \), and 0 otherwise.

We now show that each \( \mathcal{F}_S \) is a distribution. For any \( f : S \to \mathbb{F} \) we have
\[
\mathcal{F}_S(f) = \sum_{\alpha \in \mathbb{F}^S} \mathcal{F}_S(\alpha) \chi_\alpha(f) = \sum_{\alpha \in \mathcal{V}_S} \frac{1}{q^{|S|}} \chi_\alpha(f) = \frac{1}{q^{|S|}} \sum_{\alpha \in \mathcal{V}_S} \omega^\text{Tr}(\langle \alpha, f \rangle) .
\]
For each \( b \in \mathbb{F} \), let \( \mathcal{V}_b \subseteq \mathcal{V}_S \) be the set of \( \alpha \in \mathcal{V}_S \) where \( \langle \alpha, f \rangle = b \). Let \( \pi : \mathcal{V}_S \to \mathbb{F} \) be the map where \( \pi(\alpha) = \langle \alpha, f \rangle \). Since \( \mathcal{V}_S \) is a subspace, \( \pi \) is a homomorphism. It follows that either \( \mathcal{V}_b = \mathcal{V}_S \) or \( |\mathcal{V}_b| = |\mathcal{V}_0| \) for every \( b \in \mathbb{F} \). In the first case, \( \sum_{\alpha \in \mathcal{V}_S} \omega^\text{Tr}(\langle \alpha, f \rangle) = |\mathcal{V}_S| \geq 0 \). In the second case,
\[
\sum_{\alpha \in \mathcal{V}_S} \omega^\text{Tr}(\langle \alpha, f \rangle) = \sum_{b \in \mathbb{F}} \sum_{\alpha \in \mathcal{V}_b} \omega^\text{Tr}(b) = \sum_{b \in \mathbb{F}} |\mathcal{V}_b| \omega^\text{Tr}(b) = |\mathcal{V}_0| \sum_{b \in \mathbb{F}} \omega^\text{Tr}(b) = 0 .
\]
This implies that in either case, \( \mathcal{F}_S(f) \geq 0 \), and so \( \mathcal{F}_S \) is a distribution.
We now show that the collection of local distributions \( \{ F_S \}_{S \subseteq [n] \leq k} \) is indeed non-signaling. This follows from Lemma 35. If \( \alpha \in V \) then we have that \( q^{[S]} \bar{F}_S(\alpha) = 1 = q^{[R]} \bar{F}_R(\alpha) \) for every \( S, R \in [n] \leq k \) such that \( \text{supp}(\alpha) \subseteq S \cap R \), and otherwise we have \( q^{[S]} \bar{F}_S(\alpha) = 0 = q^{[R]} \bar{F}_R(\alpha) \). Thus, the collection of local distributions is a \( k \)-non-signaling function \( F \).

It remains to show that \( F \) satisfies the desired property. Observe that for every \( \alpha, \bar{F}(\alpha) = q^{[\text{supp}(\alpha)]} \bar{F}_{\text{supp}(\alpha)}(\alpha) = 1 \) if \( \alpha \in V \), and otherwise \( \bar{F}(\alpha) = 0 \). By Lemma 29 it follows that \( F \) has the desired properties.

### 7.3 Proof of Lemma 65

Let \( V = \{ \alpha \in F^n : \exists T \vdash_k \alpha \} \). We show that \( V \) is a \( k \)-local subspace. Let \( S \subseteq [n] \leq k \). We need to show that \( V_{\leq S} \) is a linear subspace of \( F^n \). We first observe that \( 0^n \) is always in the set, as \( T \vdash_k 0^n \) always.

Let \( \alpha \in V_{\leq S} \) and let \( b \in \mathbb{F} \setminus \{0\} \). Then we have that \( T \vdash_k \alpha \) which implies that \( T \vdash_k \alpha \). Since \( \text{supp}(\alpha \cdot b) = \text{supp}(\alpha) \subseteq S \), it follows that \( \alpha \cdot b \in V_{\leq S} \).

Let \( \alpha, \beta \in V_{\leq S} \). Then, since \( |\text{supp}(\alpha) \cup \text{supp}(\beta)| \leq |S| \leq k \) we have that \( (\alpha, \beta, \alpha + \beta) \) is a hyperedge in \( \Gamma_k \). Thus, since \( T \vdash_k \{ \alpha, \beta \} \) it follows that \( T \vdash_k \alpha + \beta \). Since \( \text{supp}(\alpha + \beta) \subseteq \text{supp}(\alpha) \cup \text{supp}(\beta) \subseteq S \), it follows that \( \alpha + \beta \in V_{\leq S} \).

We have thus shown that \( V_{\leq S} \) is a linear subspace of \( F^n \), which completes the proof.

### 8 Low-degree testing fails for small locality

In this section, we prove Theorem 3. The proof relies heavily on Theorem 8.

We let \( C \) be the linear code of \( m \)-variate polynomials \( P : \mathbb{F}^m \rightarrow \mathbb{F} \) of total degree at most \( d \), with \( m \geq 2 \), and let \( T \) be the set of \( \alpha \)'s in \( C^\perp \) where the \( \text{supp}(\alpha) \) is contained in exactly one line.

We define the rank of an element in \( C^\perp \) to be

\[
\text{rank}_T(\alpha) := \min_{T' \subseteq T : \alpha \in \text{span}(T')} |T'|.
\]

Note that since \( \text{span}(T) = C^\perp \), the rank of \( \alpha \) is well-defined for all \( \alpha \in C^\perp \).

We let \( T_0 \) denote the subset of \( T \) that only contains elements whose support is \( \text{evenly-spaced} \) along a line and has weight \( d + 2 \). With this notation, the non-signaling evenly-spaced test (i) samples \( \alpha \leftarrow T_0 \) uniformly at random, and (ii) checks that \( \langle \alpha, F \rangle = 0 \).

The main theorem we prove is stated below, and is the formal statement of Theorem 3.

**Theorem 67 (Formal version of Theorem 3).** For every \( k \) with \( 2d + 2 \leq k < \frac{1}{16} (d + 2)^2 \), there exists a \( F \)-non-signaling function such that \( \Pr[(\alpha, F) = 0] = 1 \) for every \( \alpha \in T_{\leq k} \), and yet \( \Delta_{2d+2}(F, F') \geq (1 - \frac{1}{16}) \) for every \( (2d + 2) \)-non-signaling function \( F' \) that is \( (C, 2d + 2) \)-explainable.

We begin the proof of Theorem 67 by showing the following lemma. This lemma follows from earlier statements, and outlines a sufficient condition to prove Theorem 67.

**Lemma 68.** Suppose that there exists \( \alpha^* \in C^\perp \) with \( \text{wt}(\alpha^*) = 2d + 2 \) such that for every \( k < \frac{1}{16} (d + 2)^2 \) it holds that \( T \vdash_k \alpha^* \). Then for every \( k \) with \( 2d + 2 \leq k < \frac{1}{16} (d + 2)^2 \) there exists a \( k \)-non-signaling function \( F \) such that \( \Pr[(\alpha, F) = 0] = 1 \) for every \( \alpha \in T_{\leq k} \), and yet \( \Delta_{2d+2}(F, F') \geq 1 - \frac{1}{16} \) for every \( (2d + 2) \)-non-signaling function \( F' \) that is \( (C, 2d + 2) \)-explainable.
Proof. Applying Corollary 66, for every $k$ with $2d + 2 \leq k < \frac{3}{10}(d + 2)^2$, we get that there exists a $k$-non-signaling function $F$ such that $\Pr[(\alpha, F) = 0] = 1$ for every $\alpha \in T_{\leq k}$ and $\Pr[(\alpha^*, F) = 0] = \frac{1}{m}$. Let $F'$ be a $(2d + 2)$-non-signaling function that is $(C, 2d + 2)$-explainable. Since for every $S \subseteq F^m$ with $|S| \leq 2d + 2$ we have that $\Pr[F'(S) \in C, s] = 1$ and $\alpha^* \in C^+$ has $\text{wt}(\alpha^*) = 2d + 2$, it follows that $\Pr[(\alpha^*, F') = 0] = 1$. Therefore, $\Delta_{2d+2}(F, F') \geq |\Pr[(\alpha^*, F) = 0] - \Pr[(\alpha^*, F') = 0]| = 1 - \frac{1}{m}$.

By Lemma 68 it suffices to find such an $\alpha^*$. We let $\alpha^* \in C^+$ be any constraint where $\text{supp}(\alpha)$ has size $2d + 2$ and is contained on the curve $x_1^2 - x_2 = 0$ embedded on the plane $x_3 = x_4 = \cdots = x_m = 0$ in $F^m$. We note that $\alpha^*$ is one of the constraints that checks that $P(t, t^2, 0, \ldots, 0)$ is a univariate polynomial of degree at most $2d$ in $t$.

We show that $\alpha^*$ satisfies the desired properties in two main lemmas. We first show the following generic lemma, which gives us a way to prove that $T \not\vdash_k \alpha^*$.

**Lemma 69** (Interval cut Lemma). Fix $\alpha \in C^+$. Suppose that there exists $r \in \mathbb{R}$ with $2 \leq r \leq \text{rank}_T(\alpha)$ such that for every $\beta \in C^+$ with $\text{rank}_T(\beta) \in [r/2, r)$ it holds that $T \not\vdash_k \beta$. Then $T \not\vdash_k \alpha$.

We then show that every $\beta \in C^+$ of rank in $[(d + 2)/4, (d + 2)/2)$ must have large weight, implying that they are not provable from $T$ when $k$ is small.

**Lemma 70.** For every $\beta \in C^+$ with $\text{rank}_T(\beta) \in [(d + 2)/4, (d + 2)/2)$ it holds that $\text{wt}(\beta) \geq \frac{1}{10}(d + 2)^2$. In particular, if $k < \frac{3}{10}(d + 2)^2$ then $T \not\vdash_k \beta$.

With the above two lemmas, we now finish the proof of Theorem 67.

**Proof of Theorem 67.** Let $k < \frac{3}{10}(d + 2)^2$. We first show that $\text{rank}_T(\alpha^*) \geq d + 1$. Since the curve $x_1^2 - x_2 = 0$ is irreducible in $\mathbb{F}[x_1, x_2, \ldots, x_m]$, any line $L$ intersects the curve on at most 2 distinct points. It follows that $\text{rank}_T(\alpha^*) \geq (2d + 2)/2 = d + 1$, as any constraint $\beta \in T$ can only have at most 2 points on the curve $x_1^2 - x_2 = 0$.

Since $k < \frac{3}{10}(d + 2)^2$, Lemma 70 implies that $T \not\vdash_k \beta$ for every $\beta$ with $\text{rank}_T(\beta) \in [(d + 2)/4, (d + 2)/2)$. Thus, by Lemma 69 it follows that $T \not\vdash_k \alpha^*$. Hence, $\alpha^*$ satisfies the assumptions of Lemma 68, and so applying Lemma 68 completes the proof of Theorem 67.

Next we turn to the proofs of Lemma 69 and Lemma 70.

**Proof of Lemma 69.** First, observe that by definition of rank, $\text{rank}_T(\alpha_1 + \alpha_2) \leq \text{rank}_T(\alpha_1) + \text{rank}_T(\alpha_2)$. By the assumption of the lemma, there exists $r \in \mathbb{R}$ with $2 \leq r \leq \text{rank}_T(\alpha)$ such that for every $\beta \in C^+$ with $\text{rank}_T(\beta) \in [r/2, r)$ it holds that $T \not\vdash_k \beta$. We need to show that $T \not\vdash_k \alpha$.

Suppose toward a contradiction that $T \vdash_k \alpha$. Then there exists a path $(\alpha_1, \ldots, \alpha_t = \alpha)$ in $\Gamma_k(C^+, T)$ from $0^0$ to $\alpha$. Let $S_1$ be the set of $\alpha_i$’s such that $\text{rank}_T(\alpha_i) < r/2$, and let $S_2$ be the set of $\alpha_i$’s such that $\text{rank}_T(\alpha_i) \geq r$. Note that $S_1 \cup S_2 = \{\alpha_1, \ldots, \alpha_t\}$, as otherwise there would exist some $i$ such that $\alpha_i$ has rank in $[r/2, r)$, which would contradict the assumption that $T \vdash_k \alpha_i$ for all $i \in [t]$.

Since $\text{rank}_T(\alpha) \geq r$ it follows that $\alpha \in S_2$, and hence $S_2 \neq \emptyset$. Let $\ell$ be the smallest index such that $\alpha_\ell \in S_2$. We have that $\alpha_\ell \neq 0^n$ since $\alpha_\ell \in S_2$, and there does not exist $i < \ell$ and $b \in \mathbb{F}$ \{0\} such that $\alpha_\ell = b\alpha_i$, as then $\text{rank}_T(\alpha_i) = \text{rank}_T(\alpha_\ell) \geq r$, thus contradicting the minimality of $\ell$. Suppose that there exists $i < \ell$ and $\gamma \in T$ such that $\alpha_i = \alpha_\ell + \gamma$. By the minimality of $\ell$, we must have that $\alpha_i \in S_1$, and hence $r \leq \text{rank}_T(\alpha_i) \leq \text{rank}_T(\alpha_\ell) + \text{rank}_T(\gamma) < r/2 + 1 \leq r/2 + r/2 = r$, which is also a contradiction. Therefore, there must either exist $j_1, j_2 < \ell$ such that $\alpha_\ell = \alpha_{j_1} + \alpha_{j_2}$. By the minimality of $\ell$, we must
On Local Testability in the Non-Signaling Setting

have that \( \alpha_1, \alpha_2 \in S_1 \), and hence \( r \leq \text{rank}_T(\alpha) \leq \text{rank}_T(\alpha_1) + \text{rank}_T(\alpha_2) < r/2 + r/2 = r \), which is, again, a contradiction. In all cases we have reached a contradiction to the assumption that \( T \vdash \alpha \), which completes the proof of Lemma 69.

\[ \triangleright \]

Remark 71. We note that in the foregoing proof we only required that \( \text{rank}_T \) is subadditive, i.e., that \( \text{rank}_T(\alpha_1 + \alpha_2) \leq \text{rank}_T(\alpha_1) + \text{rank}_T(\alpha_2) \), \( \text{rank}_T(\alpha) = 1 \) for every \( \alpha \in T \), and \( \text{rank}_T(0^n) = 0 \). Thus, the Interval Cut Lemma holds for any such subadditive function.

Proof of Lemma 70. Let \( \beta \in C^2 \) be such that \( \text{rank}_T(\beta) = r \in [(d + 2)/4, (d + 2)/2] \). Then there exist lines \( L_1, \ldots, L_r \) such that \( \beta = \sum_{i=1}^{r} \beta_i \) where \( \text{supp}(\beta_i) \subseteq L_i \). The \( L_i \)'s must be distinct, as otherwise we could add two constraints contained in the same line and we would then get \( \text{rank}_T(\beta) < r \). We have that \( \text{wt}(\beta_i) \geq d + 2 \) for each \( i \). Hence, \( \text{wt}(\beta) \geq r(d + 2) - 2\binom{r}{2} \), since each \( \beta_i \) contributes at least \( d + 2 \) to the weight, and there are at most \( \binom{r}{2} \) intersection points as each of the \( r \) lines is distinct. The function \( f(r) = r(d + 2) - r^2 \) for \( r \in \left[ \frac{d + 2}{4}, \frac{d + 2}{2} \right] \) is minimized when \( r = \frac{d + 2}{4} \), and hence \( \text{wt}(\beta) \geq r(d + 2) - r^2 \geq \frac{1}{16}(d + 2)^2 \), which completes the proof.

Abstract
Consider an algorithm performing a computation on a huge random object (for example a random graph or a “long” random walk). Is it necessary to generate the entire object prior to the computation, or is it possible to provide query access to the object and sample it incrementally “on-the-fly” (as requested by the algorithm)? Such an implementation should emulate the random object by answering queries in a manner consistent with an instance of the random object sampled from the true distribution (or close to it). This paradigm is useful when the algorithm is sub-linear and thus, sampling the entire object up front would ruin its efficiency.

Our first set of results focus on undirected graphs with independent edge probabilities, i.e. each edge is chosen as an independent Bernoulli random variable. We provide a general implementation for this model under certain assumptions. Then, we use this to obtain the first efficient local implementations for the Erdős-Rényi $G(n,p)$ model for all values of $p$, and the Stochastic Block model. As in previous local-access implementations for random graphs, we support Vertex-Pair and Next-Neighbor queries. In addition, we introduce a new Random-Neighbor query. Next, we give the first local-access implementation for All-Neighbors queries in the (sparse and directed) Kleinberg’s Small-World model. Our implementations require no pre-processing time, and answer each query using $O(poly(log n))$ time, random bits, and additional space.

Next, we show how to implement random Catalan objects, specifically focusing on Dyck paths (balanced random walks on the integer line that are always non-negative). Here, we support Height queries to find the location of the walk, and First-Return queries to find the time when the walk returns to a specified location. This in turn can be used to implement Next-Neighbor queries on random rooted ordered trees, and Matching-Bracket queries on random well bracketed expressions (the Dyck language).

Finally, we introduce two features to define a new model that: (1) allows multiple independent (and even simultaneous) instantiations of the same implementation, to be consistent with each other without the need for communication, (2) allows us to generate a richer class of random objects that do not have a succinct description. Specifically, we study uniformly random valid $q$-colorings of an input graph $G$ with maximum degree $\Delta$. This is in contrast to prior work in the area, where the relevant random objects are defined as a distribution with $O(1)$ parameters (for example, $n$ and $p$ in the $G(n,p)$ model). The distribution over valid colorings is instead specified via a “huge” input (the underlying graph $G$), that is far too large to be read by a sub-linear time algorithm. Instead, our implementation accesses $G$ through local neighborhood probes, and is able to answer queries to the color of any given vertex in sub-linear time for $q \geq 9\Delta$, in a manner that is consistent with a specific random valid coloring of $G$. Furthermore, the implementation is memory-less, and can maintain consistency with non-communicating copies of itself.

1 Introduction

Consider an algorithm performing a computation on a huge random object (for example a huge random graph or a “long” random walk). Is it necessary to generate the entire object prior to the computation, or is it possible to provide local query access to the object and generate it incrementally “on-the-fly” (as requested by the algorithm)? Such an implementation would ideally emulate the random object by answering appropriate queries, in a manner that is consistent with a specific instance of the random object, sampled from the true distribution. This paradigm is useful when we wish to simulate a sub-linear algorithm on a random object, since sampling the entire object up front would ruin its efficiency.

In this work, we focus on generating huge random objects in a number of new settings, including basic random graph models that were not previously considered, Catalan objects, and random colorings of graphs. One emerging theme that we develop further is to provide access to random objects through more complex yet natural queries. For example, consider an implementation for Erdős-Rényi $G(n, p)$ random graphs, where the simplest query $\text{VERTEX-PAIR}(u, v)$ would ask about the existence of edge $(u, v)$, which can be answered trivially by flipping a coin with bias $p$ (thus revealing a single entry in the adjacency matrix). However, many applications involving non-dense graphs would benefit from adjacency list access, which we provide through $\text{NEXT-NEIGHBOR}$ and $\text{RANDOM-NEIGHBOR}$ queries.

The problem of sampling partial information about huge random objects was pioneered in [26, 24, 25], through the implementation of indistinguishable pseudo-random objects of exponential size. Further work in [41, 18] considers the implementation of different random graph models. [18] introduced the study of $\text{NEXT-NEIGHBOR}$ queries which provide efficient access to the adjacency list representation. In addition to supporting $\text{VERTEX-PAIR}$ and $\text{NEXT-NEIGHBOR}$, we also introduce and implement a new $\text{RANDOM-NEIGHBOR}$ query for undirected graphs with independent edge probabilities.

Finally, we define a new model that allows us to generate a richer class of random objects that do not have a succinct description. Specifically, we study uniformly random valid $q$-colorings of an input graph $G$ with max degree $\Delta$. This is in contrast to prior work in the area, where random objects are defined as a distribution with $O(1)$ parameters (for example, $n$ and $p$ in the $G(n, p)$ model). The distribution over valid colorings is instead specified via a “huge” input (the underlying graph $G$), that is too large to be read by a sub-linear time algorithm. Instead, our implementation accesses $G$ using local neighborhood probes.

This new model can be compared to Local Computation Algorithms, which also implement query access to a consistent valid solution, and read their input using local probes. Inspired by this connection, we extend our model to support memory-less implementations. This allows multiple independent (possibly simultaneous) instantiations to agree on the same

---

1 $\text{VERTEX-PAIR}(u, v)$ returns whether $u$ and $v$ are adjacent, $\text{NEXT-NEIGHBOR}(v)$ returns a new neighbor of $v$ each time it is invoked (until none is left), and $\text{RANDOM-NEIGHBOR}(v)$ returns a uniform random neighbor of $v$ (if $v$ is not isolated).
random object, without any communication. We show how to implement local access to color of any given node in a random coloring, using sub-linear resources. Unlike LCAs which can generate an arbitrary valid solution, our model requires a uniformly random one.

**Random Graphs (Section 3 and Section E)**

Random graphs are one of the most well studied types of random object. We consider the problem of implementing local access to a number of fundamental random graph models, through natural queries, including **Vertex-Pair**, **Next-Neighbor**, and a newly introduced **Random-Neighbor** query\(^1\), using polylogarithmic resources per query. Our results on random graphs are summarized in Table 1.

**Undirected Random Graphs with Independent Edge Probabilities.** We implement the aforementioned queries for the generic class of undirected graphs with independent edge probabilities \(\{p_{uv}\}_{u,v \in V}\), where \(p_{uv}\) denotes the probability that there is an edge between \(u\) and \(v\). Under reasonable assumptions on the ability to compute certain values pertaining to consecutive edge probabilities, our implementations support **Vertex-Pair**, **Next-Neighbor**, and **Random-Neighbor** queries\(^1\), using \(O(\text{poly}(\log n))\) time, space, and random bits. Note that in this setting, **Vertex-Pair** queries are trivial by themselves, since the existence of an edge depends on an independent random variable. However, maintaining all three types of queries simultaneously is much harder. As in [18] (and unlike many of the implementations presented in [24, 26]), our techniques allow unlimited queries, and the generated random objects are sampled from the true distribution (rather than just being indistinguishable). In particular, our construction yields local-access implementations for the Erdös-Rényi \(G(n,p)\) model (for all values of \(p\)) and the Stochastic Block model with random community assignment.

Table 1 (Local access implementations for random graphs): All the implementations in this table use polylogarithmic time, additional space and random bits per query. A X in the **All-Neighbors** column indicates that the graphs in this model may have un-bounded degree, and it is therefore impossible to sample **All-Neighbors** efficiently. A ?? entry indicates a sampling problem with no known efficient solution.

While **Vertex-Pair** and **Next-Neighbor** queries have been considered in prior work [18, 24, 41], we provide the first implementations of these in non-sparse random graph models. Prior results for implementing queries to \(G(n,p)\) focused on the sparse case where \(p = \frac{\log^{O(1)}}{n}\) [41]. The dense case where \(p = \Theta(1)\) is also relatively simple because most of the adjacency matrix is filled, and neighbor queries can be answered by performing \(\Theta(1)\) **Vertex-Pair** queries until an edge is found. The case of general \(p\) is more involved, and
was not considered previously. For example, when \( p = \frac{1}{\sqrt{n}} \), each vertex has high degree \( O(\sqrt{n}) \) but most of the adjacency matrix is empty, thus making it difficult to generate a neighbor efficiently. **Next-Neighbor** queries were introduced in [18] in order to access the neighborhoods of vertices in non-sparse graphs in **lexicographic order**. This query however, does not allow us to efficiently explore graphs in some natural ways, such as via random walks, since the initially returned neighbors are biased by the lexicographic ordering. We address this deficiency by introducing a new **Random-Neighbor** query, which would be useful, for instance, in sub-linear algorithms that employ random walk processes. We provide the first implementation of all three queries in non-sparse graphs as follows:

**Theorem 1.** Given a random graph model defined by the probability matrix \( \{p_{uv}\}_{u,v \in [n]} \), and assuming that we can compute the quantities \( \prod_{u=1}^{b} (1 - p_{vu}) \) and \( \sum_{u=1}^{b} p_{vu} \) in \( O(\log^{O(1)} n) \) time, there exists an implementation for this model that supports local access through **Random-Neighbor**, **Vertex-Pair**, and **Next-Neighbor** queries using \( O(\log^{O(1)} n) \) running time, additional space, and random bits per query.

We show that these assumptions can be realized in Erdös-Rényi random graphs and the Stochastic Block Model. SBM presents additional challenges for assigning community labels to vertices (Section 2.1.1).

**Corollary 2.** There exists an algorithm that implements local access to an Erdös-Rényi \( G(n, p) \) random graph, through **Vertex-Pair**, **Next-Neighbor**, and **Random-Neighbor** queries, while using \( O(\log^{3} n) \) time, \( O(\log^{3} n) \) random bits, and \( O(\log^{2} n) \) additional space per query with high probability.

**Corollary 3.** There exists an algorithm that implements local access to a random graph from the \( n \)-vertex Stochastic Block Model with \( r \) randomly-assigned communities, through **Vertex-Pair**, **Next-Neighbor**, and **Random-Neighbor** queries, using \( O(r \log^{3}(n)) \) time, random bits, and space per query w.h.p.

We remark that while we are able to generate Erdös-Rényi random graphs on-the-fly supporting all three types of queries, our construction still only requires \( \tilde{O}(m + n) \) time and space to generate a complete \( G(n, p) \) graph, which is optimal up to logarithmic factors.

**Corollary 4.** The final algorithm in Section 3 can generate a complete random graph from the Erdös-Rényi \( G(n, p) \) model using overall \( \tilde{O}(n + m) \) time, random bits and space, which is \( \tilde{O}(pn^{2}) \) in expectation. This is optimal up to \( O(\log^{O(1)} n) \) factors.

**Directed Random Graphs – The Small World Model (Section E).** We consider local-access implementations for directed graphs through Kleinberg’s Small World model, where the probabilities are based on distances in a 2-dimensional grid. This model was introduced in [31] to capture the geographical structure of real world networks, in addition to reproducing observed properties of short routing paths and low diameter. We implement **All-Neighbors** queries for the Small World model, using \( O(\log^{3}(n)) \) time, space and random bits. Since such graphs are sparse, the other queries follow directly.

**Theorem 5.** There exists an algorithm that implements **All-Neighbors** queries for a random graph from Kleinberg’s Small World model, where probability of including each directed non-grid edge \( (u, v) \) in the graph is \( c/([\text{dist}(u, v)])^{2} \), where the range of allowed values of \( c \) is \( \log^{\pm O(1)} n \) and \( \text{dist} \) denotes the Manhattan distance, using \( O(\log^{2} n) \) time and random words per query with high probability.
Catalan Objects (Section 4)

Catalan objects capture a well studied combinatorial property and admit numerous interpretations that include well bracketed expressions, rooted trees and binary trees, Dyck languages etc. In this paper, we focus on the Dyck path interpretation and implement local access to a uniformly random instance of a Dyck path. Since Dyck paths have natural bijections to other Catalan objects, we can use our Dyck Path implementation to obtain implementations of these random Catalan objects.

A Dyck path is defined as a sequence of \( n \) upward (+1) steps, and \( n \) downward (−1) steps, with the added constraint that the sum of any prefix of the sequence is non-negative.

A random Dyck path may be viewed as a constrained one dimensional balanced random walk. A natural query on Dyck paths is \( \text{Height}(t) \) which returns the position of the walk after \( t \) steps (equivalently, sum of the first \( t \) sequence elements). \( \text{Height} \) queries correspond to \( \text{Depth} \) queries on rooted trees and bracketed expressions (Section 4.1).

We also introduce and support \( \text{First-Return}(t) \) queries, where \( \text{First-Return}(t) \) returns the first time when the random walk returns to the same height as it was at time \( t \), as long as \( \text{Height}(t + 1) = \text{Height}(t) + 1 \) (Section 4.1 presents the rationale for this definition). This allows us to support more involved queries that are widely used; for example, \( \text{First-Return} \) queries are equivalent to finding the next child of a node in a random rooted tree, and also to finding a matching closing bracket in random bracketed expressions.

\( \text{Height} \) queries for unconstrained random walks follow trivially from the implementation of interval summable functions in [26, 23]. However, the added non-negativity constraint introduces intricate non-local dependencies on the distribution of positions. We show how to overcome these challenges, and support both queries using \( \mathcal{O}(\text{poly}(\log n)) \) resources.

\[ \text{Theorem 6.} \quad \text{There is an algorithm using } \mathcal{O}(\log^{O(1)} n) \text{ resources per query that provides access to a uniformly random Dyck path of length } 2n \text{ by implementing the following queries:} \]

- \( \text{Height}(t) \) returns the position of the walk after \( t \) steps.
- \( \text{First-Return}(t) \): If \( \text{Height}(t + 1) > \text{Height}(t) \), then \( \text{First-Return}(t) \) returns the smallest index \( t' \), such that \( t' > t \) and \( \text{Height}(t') = \text{Height}(t) \) (i.e. the first time the Dyck path returns to the same height). Otherwise, if \( \text{Height}(t + 1) < \text{Height}(t) \), then \( \text{First-Return}(t) \) is not defined.

Random Coloring of Graphs – A New Model (Section 5)

So far, all the results in this area have focused on random objects with a small description size; for instance, the \( G(n, p) \) model is described with only two parameters \( n \) and \( p \). We introduce a new model for implementing random objects with huge input description; that is, the distribution is specified as a uniformly random solution to a huge combinatorial problem. The challenge is that now our algorithms cannot read the entire description in sub-linear time.

In this model, we implement query access to random \( q \)-colorings of a given huge graph \( G \) with maximum degree \( \Delta \). A random coloring is generated by proposing \( \mathcal{O}(n \log n) \) color updates and accepting the ones that do not create a conflict (Glauber dynamics). This is an inherently sequential process with the acceptance of a particular proposal depending on all preceding neighboring proposals. Moreover, unlike the previously considered random objects, this one has no succinct representation, and we can only uncover the proper distribution by probing the underlying graph (in the manner of local computation algorithms [48, 5]). Unlike LCAs which can return an arbitrary valid solution, we also have to make sure that we return a solution from the correct distribution. We are able to construct an efficient oracle that returns the final color of a vertex using only a sub-linear number of probes when \( q \geq 9\Delta \).
This implementation also has the feature that multiple independent instances of the algorithm having access to the same random bits, will respond to queries in a manner consistent with each other; they will generate exactly the same coloring, regardless of the queries asked. Since these implementations are memory-less, the resulting coloring is oblivious to the order of queries, and only depends on common random bits,

\[ \textbf{Theorem 7.} \] Given neighborhood query access to a graph \( G \) with \( n \) nodes, maximum degree \( \Delta \), and \( q = 2a\Delta \geq 9\Delta \) colors, we can generate the color of any given node from a distribution of color assignments that is \( \epsilon \)-close (in \( L_1 \) distance) to the uniform distribution over all valid colorings of \( G \), in a consistent manner, using only \( O((n/\epsilon)^{3.06/\alpha \Delta \log(n/\epsilon)}) \) time, probes, and public random bits per query.

1.1 Related Work

The problem of computing local information of huge random objects was pioneered in \[24, 26\]. Further work of \[41\] considers the implementation of sparse \( G(n, p) \) graphs from the Erdős-Rényi model \[17\], with \( p = O(\text{poly}(\log n)/n) \), by implementing \textsc{All-Neighbors} queries. While these implementations use polylogarithmic resources over their entire execution, they generate graphs that are only guaranteed to appear random to algorithms that inspect a limited portion of the generated graph.

In \[18\], the authors construct an oracle for the implementation of recursive trees, and BA preferential attachment graphs. Unlike prior work, their implementation allows for an arbitrary number of queries. Although the graphs in this model are generated via a sequential process, the oracle is able to locally generate arbitrary portions of it and answer queries in polylogarithmic time. Though preferential attachment graphs are sparse, they contain vertices of high degree, thus \[18\] provides access to the adjacency list through \textsc{Next-Neighbor} queries. For additional related work, see Section G.

1.2 Applications

One motivation for implementing local access to huge random objects is so that we can simulate sub-linear time algorithms on them. The standard paradigm of generating the entire (input) object a priori is wasteful, because sub-linear algorithms only inspect a small fraction of the generated input. For example, the greedy routing algorithm on Kleinberg’s small world networks \[31\] only uses \( O(\log^2 n) \) probes to the underlying network. Using our implementation, one can execute this algorithm on a random small world instance in \( O(\text{poly}(\log n)) \) time, without incurring the \( O(n) \) prior-sampling overhead, by generating only those parts of the graph that are accessed by the routing algorithm.

Local access implementations may also be used to design parallel generators for random objects. The model in Definition 10 is particularly suited to parallelization; different processors/machines can generate parts of the random object independently, using a read-only shared memory containing public random bits.

2 Model and Overview of our Techniques

We begin by formalizing our model of local-access implementations, inspired by \[18\], but we add some aspects that were not addressed in earlier models. First, we define families of random objects.
Definition 8. A random object family maps a description \( \Pi \) to a distribution \( X^{\Pi} \) over the set \( X^{\Pi} \).

For example, the family of Erdős-Rényi graphs maps \( \Pi = (n,p) \) to a distribution over \( X^{\Pi} \), which is the set of all possible \( n \)-vertex graphs, where the probability assigned to any graph containing \( m \) edges in the distribution \( X^{\Pi} \) is exactly \( p^m \cdot (1 - p)^{\binom{n}{2} - m} \).

Definition 9. Given a random object family \( \{ (X^{\Pi}, X^{\Pi}) \} \) parameterized by \( \Pi \), a local access implementation of a family of query functions \( \{ F_1, F_2, \ldots \} \) where \( F_i : X^{\Pi} \rightarrow \{0,1\} \), provides an oracle \( M \) with an internal state for storing a partially generated random object. Given a description \( \Pi \) and a query \( F_i \), the oracle returns the value \( M(\Pi, F_i) \), and updates its internal state, while satisfying the following:

- **Consistency:** There must be a single \( X \in X^{\Pi} \), such that for all queries \( F_i \) presented to the oracle, the returned value \( M(\Pi, F_i) \) equals the true value \( F_i(X) \).

- **Distribution equivalence:** The random object \( X \in X^{\Pi} \) consistent with the responses \( \{ F_i(X) \} \) must be sampled from some distribution \( X^{\Pi} \) that is \( \epsilon \)-close to the desired distribution \( \tilde{X}^{\Pi} \) in \( L_1 \)-distance. In this work, we focus on supporting \( \epsilon = n^{-c} \) for any desired constant \( c > 0 \).

- **Performance:** The computation time, and random bits required to answer a single query must be sub-linear in \( |X| \) with high probability, without any initialization overhead. In particular, we allow queries to be made adversarially and non-deterministically. The adversary has full knowledge of the algorithm’s behavior and its past random bits.

For example, in the \( G(n,p) \) family with description \( \Pi = (n,p) \), we can define Vertex-Pair query functions \( \{ F_{u,v} \}_{u,v \in [n]} \). So, given a graph \( G \in X^{\Pi} \), the query \( F_{u,v}(G) = 1 \) if and only if \( (u,v) \in G \).

In prior work [18, 26, 41] as well as some of our results, the input description \( \Pi \) is of small size (typically \( O(\log n) \)), and the oracle \( M \) can read all of \( \Pi \) (for example, \( \Pi = (n,p) \) in \( G(n,p) \)).

Distributions with Huge Description Size. We initiate the study of random object families where the description \( \Pi \) is too large to be read by a sub-linear time algorithm. In this setting, the oracle from Definition 9 cannot read the entire input \( \Pi \), and instead accesses it through local probes. For instance, consider the random object family that maps a graph \( G \) to the uniform distribution over valid colorings of \( G \). Here, the description \( \Pi \) includes the entire graph \( G \), which is too large to be read by a sub-linear time algorithm. In this case, the oracle can query the underlying graph using neighborhood probes. The number of such probes used to answer a single query must be sub-linear in the input size.

Supporting Independent Query Oracles: Memory-less Implementations

The model in Definition 9 only supports sequential queries, since the response to a future query may depend on the changes in internal state caused by past queries. In some applications, we may want to have multiple independent query oracles whose responses are all consistent with each other. One way to achieve this is to restrict our attention to memory-less implementations; ones without any internal state. An important implication of being memory-less is that the responses to each query is oblivious to the order of queries being asked. In fact, the lack of internal state implies that independent implementations that use the same random bits and the same input description must respond to queries in the same way. Thus, instead of using the internal state to maintain consistency, memory-less implementations are given access to the same public random oracle.
For the problem of sampling a random graph coloring, we present an implementation that is memory-less and also accesses the input description through local probes, as elaborated in the following model:

Definition 10. Given a random object family \( \{(X, \Pi)\} \) parameterized by input \( \Pi \), a local access implementation of a family of query functions \( \langle F_1, F_2, \ldots \rangle \), provides an oracle \( M \) with the following properties. \( M \) has query access to the input description \( \Pi \), and a tape of public random bits \( R \). Upon being queried with \( \Pi \) and \( F_i \), the oracle uses sub-linear resources to return the value \( M(\Pi, R, F_i) \), which must equal \( F_i(X) \) for a specific \( X \in \mathbb{X}^\Pi \), where the choice of \( X \) depends only on \( R \), and the distribution of \( X \) (over \( R \)) is \( \frac{1}{n^c} \)-close to the distribution over \( \mathbb{X}^\Pi \), for any given constant \( c \). Thus, different instances of \( M \) with the same description \( \Pi \) and the same random bits \( R \), must agree on the choice of \( X \) that is consistent with all answered queries regardless of the order and content of queries that were actually asked.

We can contrast Definition 10 with the one for Local Computation Algorithms [48, 5] which also allow query access to some valid solution by reading the input through local probes. The additional challenge in our setting is that we also have to make sure that we return a uniformly random solution, rather than an arbitrary one. We also note that the memory-less property may be achieved for small description size random object families. For instance, our implementation for the directed small world model admits such a memory-less implementation using public random bits.

2.1 Undirected Graphs
We consider the generic class of undirected graphs with independent edge probabilities \( \{p_{uv}\}_{u,v \in V} \), from which the results can be applied to Erdös-Rényi random graphs and the Stochastic Block Model. Throughout, we identify our vertices via their unique IDs from 1 to \( n \), namely \( V = [n] \). In this model, VERTEX-PAIR queries by themselves can be implemented trivially, since the existence of any edge \( (u,v) \) is an independent Bernoulli random variable, but it becomes harder to maintain consistency when implementing them in conjunction with the other queries. Inspired by [18], we provide an implementation of NEXT-NEIGHBOR queries, which return the neighbors of any given vertex one by one in lexicographic order. Finally, we introduce a new query: RANDOM-NEIGHBOR that returns a uniformly random neighbor of any given vertex. This would be useful for any algorithm that performs random walks. RANDOM-NEIGHBOR queries in non-sparse graphs present particularly interesting challenges that are outlined below.

Next-Neighbor Queries
In Erdös-Rényi graphs, the (lexicographically) next neighbor of a vertex can be recovered by generating consecutive entries of the adjacency matrix until a neighbor is found, which takes roughly \( \Omega(1/p_{uv}) \) time. For small edge probabilities \( p_{uv} = o(1) \), this implementation is inefficient, and we show how to improve the runtime to \( O(\text{poly}(\log n)) \). Our main technique is to sample the number of “non-neighbors” preceding the next neighbor. To do this, we assume that we can estimate the “skip” probabilities \( F(v, a, b) = \prod_{u=a}^{b} (1 - p_{uv}) \), where \( F(v, a, b) \) is the probability that \( v \) has no neighbors in the range \([a,b]\). We later show how to compute this quantity efficiently for \( G(n,p) \) and the Stochastic Block Model.
This strategy of skip-sampling is also used in [18]. However, in our work, the main difficulty arises from the fact that our graph is undirected, and thus we must “inform” all (potentially \( \Theta(n) \)) non-neighbors once we decide on the query vertex’s next neighbor. Concretely, if \( u' \) is sampled as the next neighbor of \( v \) after its previous neighbor \( u \), we must maintain consistency in subsequent steps by ensuring that none of the vertices in the range \((u, u')\) return \( v \) as a neighbor. This update will become even more complicated as we handle Random-Neighbor queries, where we may generate non-neighbors at random locations.

In Section 3.1, we present a randomized implementation (Algorithm 1) that supports Next-Neighbor queries efficiently, but has a complicated performance analysis. We remark that this approach may be extended to support Vertex-Pair queries (Section A) with superior performance (if we do not support Random-Neighbor queries), and also to provide deterministic resource usage guarantee (Section C).

Random-Neighbor Queries

We implement Random-Neighbor queries (Section 3.2) using poly(log \( n \)) resources. The ability to do so is surprising since: (1) Sampling the degree of vertex, may not be viable for sub-linear implementations, because this quantity alone imposes dependence on the existence of all of its potential incident edges and consequently on the rest of the graph (since it is undirected). Thus, our implementation needs to return a random neighbor, with probability reciprocal to the query vertex’s degree, without resorting to determining its degree. (2) Even without committing to the degrees, answers to Random-Neighbor queries affect the conditional probabilities of the remaining adjacencies in a global and non-trivial manner.

We formulate an approach which samples many consecutive edges simultaneously, in such a way that the conditional probabilities of the unsampled edges remain independent and “well-behaved” during subsequent queries. For each vertex \( v \), we divide the potential neighbors of \( v \) into consecutive ranges \( \{B_v(i)\} \) called blocks, so that each \( B_v(i) \) contains \( \Theta(1) \) neighbors in expectation (i.e. \( \sum_{u \in B_v} p_{vu} = \Theta(1) \)). The subroutine of Next-Neighbor is applied to sample the neighbors within a block in expected \( \tilde{O}(1) \) time. We can now obtain a neighbor of \( v \) by picking a random neighbor from a random block, but this introduces a bias because all blocks may not have the same number of neighbors. We remove this bias by rejecting samples from block \( B_v(i) \) with probability proportional to the number of neighbors in \( B_v(i) \).

2.1.1 Applications to Random Graph Models

We now consider the application of our construction above to actual random graph models, where we must realize the assumption that \( \prod_{u \neq u} (1 - p_{vu}) \) and \( \sum_{u \neq u} p_{vu} \) can be computed efficiently. For the Erdős-Rényi \( G(n, p) \) model, these quantities have simple closed-form expressions. Thus, we obtain implementations of Vertex-Pair, Next-Neighbor, and Random-Neighbor queries, using polylogarithmic resources per query, for arbitrary values of \( p \). We remark that, while \( \Omega(n + m) = \Omega(np^2) \) time and space is clearly necessary to generate and represent a full random graph, our implementation supports local-access via all three types of queries, and yet can generate a full graph in \( \tilde{O}(n + m) \) time and space (Corollary 4).

---

\(^2\) Consider a \( G(n, p) \) graph with small \( p \), say \( p = 1/\sqrt{n} \), such that vertices will have \( \tilde{O}(\sqrt{n}) \) neighbors with high probability. After \( \tilde{O}(\sqrt{n}) \) Random-Neighbor queries, we will have uncovered all the neighbors (w.h.p.), so that the conditional probability of the remaining \( \Theta(n) \) edges should now be close to zero.
We also generalize our construction to implement the Stochastic Block Model. In this model, the vertex set is partitioned into \( r \) communities \( \{C_1, \ldots, C_r\} \). The probability that an edge exists between \( u \in C_i \) and \( v \in C_j \) is \( p_{ij} \). A naive solution would be to simply assign communities to contiguous (by index) blocks of vertices, which would easily allow us to calculate the relevant sums/products of probabilities on continuous ranges of indices, with some additional case analysis to check when we are at a community boundary. However, this setup is unrealistic, and not particularly useful in the context of the Stochastic Block model. As communities in the observed data are generally unknown a priori, and significant research has been devoted to designing efficient algorithms for community detection and recovery, these studies generally consider the random community assignment condition for the purpose of designing and analyzing algorithms [40]. Thus, we construct implementations where the community assignments are sampled from some given distribution \( R \), or from a collection of specified community sizes \( \langle |C_1|, \ldots, |C_r| \rangle \). The main difficulty here is to obtain a uniformly sampled assignment of vertices to communities on-the-fly.

Since the probabilities of potential edges now depend on the communities of their endpoints, we can’t obtain closed form expressions for the relevant sums and products of probabilities. However, we observe that it suffices to efficiently count the number of vertices of each community in any range of contiguous vertex indices. We then design a data structure extending a construction of [26], which maintains these counts for ranges of vertices, and determines the partition of their counts only on an as-needed basis. This extension results in an efficient technique to sample counts from the multivariate hypergeometric distribution (Section D) which may be of independent interest. For \( r \) communities, this yields an implementation with \( O(r \cdot \text{poly}(\log n)) \) overhead in required resources for each operation.

2.2 Directed Graphs

Lastly, we consider Kleinberg’s Small World model ([31, 37]) in Section E. While small world models are proposed to capture properties of observed data such as small shortest-path distances and large clustering coefficients [55], this important special case of Kleinberg’s model, defined on two-dimensional grids, demonstrates the underlying geographical structures of networks.

In this model, each vertex is identified via its 2D coordinate \( v = (v_x, v_y) \in [\sqrt{n}]^2 \). Defining the Manhattan distance as \( \text{dist}(u, v) = |u_x - v_x| + |u_y - v_y| \), the probability that each directed edge \( (u, v) \) exists is \( c/\text{dist}(u, v)^2 \). A common choice for \( c \) is given by normalizing the distribution such that the expected out-degree of each vertex is 1 (\( c = \Theta(1/\log n) \)). We can also support a range of values of \( c = \log^{\pm o(1)} n \). Since the degree of each vertex in this model is \( O(\log n) \) with high probability, we implement All-Neighbor queries, which in turn can emulate Vertex-Pair, Next-Neighbor and Random-Neighbor queries. In contrast to our previous cases, this model imposes an underlying two-dimensional structure of the vertex set, which governs the distance function as well as complicates the individual edge probabilities.

We implement All-Neighbors queries in the small world model by listing all neighbors from closest to furthest away from the queried vertex, using \( \text{poly}(\log n) \) resources per query. The main challenge is to sample for the next closest neighbor, when the probabilities are a function of the Manhattan distance on the lattice. Rather than sampling for a neighbor directly, we partition the nodes based on their distance from \( v \) (there are \( \Theta(d) \) vertices at distance \( d \)). We first choose the next smallest distance partition with a neighbor using rejection sampling techniques (Lemma 11) on the appropriate distribution. In the second step, we generate all the neighbors within that partition using skip-sampling.
2.3 Random Catalan Objects

Many important combinatorial objects can be interpreted as Catalan objects. One such interpretation is a Dyck path; a one dimensional random walk on the line with \( n \) up and \( n \) down steps, starting from the origin, with the constraint that the height is always non-negative. We implement \textsc{Height}(t), which returns the position of the walk at time \( t \), and \textsc{First-Return}(t), which returns the first time when the random walk returns to the same position as it was at time \( t \). These queries are natural for several types of Catalan objects. As noted previously, we can use standard bijections to translate the Dyck path query implementations into natural queries for bracketed expressions and ordered rooted trees. Specifically, \textsc{Height} values in Dyck paths are equivalent to \textsc{depth} in bracket expressions and trees. The \textsc{First-Return} queries are more involved, and are equivalent to finding the matching bracket in bracket expressions, and alternately to finding the next child of a node in an ordered rooted tree (see Section 4.1).

Over the course of the execution, our algorithm will determine the height of a random Dyck path at many different positions \( \{x_1, x_2, \ldots, x_m\} \) (with \( x_i < x_{i+1} \)), both directly as a result of user given \textsc{Height} queries, and indirectly through recursive calls to \textsc{Height}. These positions divide the sequence into contiguous intervals \([x_i, x_{i+1}]\), where the height of the endpoints \( y_i, y_{i+1} \) have been determined, but none of the intermediate heights are known. The important observation is that the unknown section of the path within an interval is entirely determined by the positions and heights of the endpoints, and in particular is completely independent of all other intervals. So, each interval \([x_i, x_{i+1}]\) along with corresponding heights \( \{y_i, y_{i+1}\} \), represents a generalized Dyck problem with \( U \) up steps, \( D \) down steps, and a constraint that the path never dips more than \( y_i \) units below the starting height.

**Height Queries**

General \textsc{Height}(x) queries can then be answered by recursively halving the interval containing \( x \), by repeatedly sampling the height at the midpoint, until the height of position \( x \) is sampled. We start by implementing a subroutine that given an interval \([x_i, x_{i+1}]\) of length \( 2B \), containing \( 2U \) up and \( 2D \) down steps, determines the number of up steps \( U' = U + d \) assigned to the first half of the interval (we parameterize \( U' \) with \( d \) in order to make the analysis cleaner). Note that this is equivalent to answering the query \textsc{Height}(\( x_i + B \)). This is done by sampling the parameter \( d \) from a distribution \( \{p_d\} \) where
\[
p_d \equiv S_{\text{Left}}(d) \cdot S_{\text{Right}}(d)/S_{\text{Total}}.
\]
Here, \( S_{\text{Left}}(d) \) (respectively \( S_{\text{Right}}(d) \)) is the number of possible paths in the left (resp. right) half of the interval when \( U + d \) up steps and \( D - d \) down steps are assigned to the first half, and \( S_{\text{Total}} \) is the number of possible paths in the original \( 2B \)-interval.

The problem of determining the number of up steps in the first half of the interval was solved for the unconstrained case (where the sequence is just a random permutation of up and down steps) in [26]. Adding the non-negativity constraint introduces further difficulties as the distribution over \( d \) has a CDF that is difficult to compute. We construct a different distribution \( \{q_d\} \) that approximates \( \{p_d\} \) pointwise to a factor of \( O(\log n) \) and has an efficiently computable CDF. This allows us to sample from \( \{q_d\} \) and leverage rejection sampling techniques (see Lemma 11 in Section 2.5) to obtain samples from \( \{p_d\} \).

**First-Return Queries**

Note that \textsc{First-Return}(x) is only of interest when the first step after position \( x \) is upwards (i.e. \textsc{Height}(\( x + 1 \)) > \textsc{Height}(\( x \))), since this situation is important for complex queries to random bracketed expressions and random rooted trees. Section 4.1 details the rationale
Local Access to Huge Random Objects Through Partial Sampling

for this definition based on bijections between these objects. First-Return queries are challenging because we need to find the interval containing the first return to Height(x). Since there could be up to Θ(n) intervals, it is inefficient to iterate through all of them. To circumvent this problem, we allow each interval [x_i, x_{i+1}] to sample and maintain its own boundary constraint k_i instead of using the global non-negativity constraint. This implies that the path within the interval [x_i, x_{i+1}] never reaches the height y_i - k_i or lower. Additionally, we maintain a crucial invariant that states that this boundary is achieved where the distribution is specified as a uniformly random solution to a huge combinatorial problem. In this new setting, we will implement local query access to random objects.

Unfortunately, every Height query creates new intervals by sub-dividing existing ones, potentially breaking the invariant. We re-establish the invariant for [x_i, x_{i+1}] by generating a “mandatory boundary” h (a boundary constraint with the added restriction that some position within the interval must touch the boundary), and then sampling a position x_{mid} \in [x_i, x_{i+1}] such that Height(x_{mid}) = h (Figure 6). This creates new intervals [x_i, x_{mid}] and [x_{mid}, x_{i+1}], both of which have a boundary constraint at h.

The first step of sampling the mandatory boundary is performed by binary searching on the possible boundary locations using an appropriate CDF (Section 4.4.2). To find an intermediate position touching this boundary, we parameterize the position with d, and find the distribution \{p_d\} associated with the various possibilities. Since we cannot directly sample from this complicated distribution, we define a piecewise continuous probability distribution \hat{q}(\delta) such that \hat{q}(\delta) approximates p_{\{\delta\}} (Section 4.4.3). We then use this to define a discrete distribution \{q_d\} where q_d = \int_{d}^{d+1} \hat{q}(\delta), where we can efficiently compute the CDF of \{q_d\} by integrating the piecewise continuous \hat{q}(\delta). The challenge here is to construct an appropriate \hat{q}(\delta) that only has \mathcal{O}(\log^{O(1)} n) continuous pieces. This allows us to again use the rejection sampling technique (Lemma 11) to indirectly obtain a sample from \{p_d\}.

2.4 Random Coloring of a Graph

Finally, we introduce a new model (Definition 10) for implementing huge random objects, where the distribution is specified as a uniformly random solution to a huge combinatorial problem. In this new setting, we will implement local query access to random q-colorings of a given huge graph G of size n with maximum degree Δ. Since the implementation has to run in sub-linear time, it is not possible to read the entire input G during a single query execution.

Color Queries

Given a graph G with maximum degree Δ, and the number of colors q \geq 9Δ, we are able to construct an efficient implementation for Color(v) that returns the final color of v in a uniformly random q-coloring of G using only a sub-linear number of probes. Random colorings of a graph are sampled using \mathcal{O}(n \log n) iterations of a Markov chain [22]. Each step of the chain proposes a random color update for a random vertex, and accepts the update if it does not create a conflict. This is an inherently sequential process, with the acceptance of a particular proposal depending on all preceding neighboring proposals.

To make the runtime analysis simpler, we define a modified version of Glauber Dynamics that proceeds in \mathcal{O}(\log n) epochs. In each epoch, all of the n vertices propose a random color and update themselves if their proposals do not conflict with any of their neighbors. This Markov chain is a special case of the one presented in [20] for distributed graph coloring, and mixes in \mathcal{O}(\log n) epochs when q \geq 9Δ. In order to implement the query Color(v), it suffices
to implement \textsc{Accepted}(v, t) that indicates whether the proposal for \(v\) was accepted in the \(i\)th epoch. This depends on the prior colors of the potentially \(\Delta\) neighbors of \(v\). Determining the prior colors of all the neighbors \(w\) using recursive calls would result in \(\Delta\) invocations of \textsc{Accepted}(w, \(t-1\)) (at the preceding epoch \(t-1\)). Naively, this gives a bound of \(\Delta^2\) on the number of invocations. We can prune the recursions by only considering neighbors who proposed the color \(c\) during some past epoch. This reduces the expected number of recursive calls to \(t\Delta / q\), since there are \(t\Delta\) potential proposals and each one is \(c\) with probability \(1/q\).

If \(q\) is larger than \(t\Delta\), the number of recursive calls is less than \(1\), which gives a sub-linear bound on the total number of resulting invocations. Since the number of epochs \(t\) can be as large as \(\Theta(\log n)\), this strategy will only work when \(q = \Omega(\Delta \log n)\).

The improvement to \(q = \Omega(\Delta)\) follows from the observation that for a neighbor \(w\) that proposed color \(c\) at epoch \(t'\), the recursive call corresponding to \(w\) can directly jump to epoch \(t'\). If the conflicting color \(c\) was indeed accepted at that epoch, we then step forwards through epochs \(t' + 1, t' + 2, \ldots\), to check whether \(c\) was overwritten by some future accepted proposal. This strategy dramatically reduces the recursive sub-problem size (given by the epoch number \(t'\)), and furthermore we show that we do not have to step through too many future epochs in order to check whether \(c\) was overwritten. This allows us to bound the runtime by \(\tilde{O}(t(\Delta/n)^{6.12\Delta/\epsilon})\), where the overall coloring is sampled from a distribution that is \(\epsilon\)-close to uniform (see Definition 10).

One requirement for our strategy is the ability to access a valid initial coloring (the initial state of the Markov Chain) through local probes, in addition to local probes to the underlying graph structure. This assumption can be removed by using a result of [10], that presents an LCA for \(\Delta + 1\) graph coloring using \(\Delta^{O(1)} \log n\) graph probes. Alternately, we can assign random initial colors to the vertices, which may result in an invalid final coloring. However, the Markov Chain will transform the initial invalid coloring into a valid one with high probability.

### 2.5 Basic Tools for Efficient Sampling

In this section, we describe the main techniques used to sample from a distribution \(\{p_i\}_{i \in [n]}\), which differs based on the type of access to \(p_i\) provided to the algorithm. If the algorithm is given cumulative distribution function (CDF) access to \(p_i\), then it is well known that via \(O(\log n)\) CDF evaluations, one can sample according to a distribution that is at most \(n^{-1}\) far from \(p_i\) in \(L_1\) distance.

Sampling can be more challenging when when we can only access the probability distribution function (PDF) of \(p_i\). The approach that we use in this work is to construct an auxiliary distribution \(\{q_i\}\) such that: (1) \(\{q_i\}\) has an efficiently computable CDF, and (2) \(q_i\) approximates \(p_i\) pointwise to within a polylogarithmic multiplicative factor for “most” of the support of \(p_i\).

The following Lemma inspired by [26] formalizes this concept.

\textbf{Lemma 11.} Let \(\{p_i\}_{i \in [n]}\) and \(\{q_i\}_{i \in [n]}\) be distributions on \([n]\) satisfying the following conditions:

1. There is a \(\tilde{O}(1) n\) time algorithm to approximate \(p_i\) and \(q_i\) up to a multiplicative \((1 \pm \frac{1}{n^c})\) factor.
2. We can generate an index \(i\) according to a distribution \(\{\hat{q}_i\}\), where \(\hat{q}_i\) is a \((1 \pm \frac{1}{n^c})\) multiplicative approximation to \(q_i\).
3. There exists a \(\text{poly}(\log n)\)-time recognizable set \(S\) such that

\[1 - \sum_{i \in S} p_i < \frac{1}{n^c}\]

For every \(i \in S\), it holds that \(p_i \geq \log^{O(1)} n \cdot q_i\).

Then, with high probability we can use only \(\log^{O(1)} n\) samples from \(\{\hat{q}_i\}\) to generate an index \(i\) according to a distribution that is \(\tilde{O}\left(\frac{1}{n^c}\right)\)-close to \(\{p_i\}\) in \(L_1\) distance.
Proof. We begin by setting an upper bound $U = \log^{O(1)} n$ on $p_i/q_i$ for all $i \in S$. The sampling proceeds in iterations, such that in each iteration we obtain an index $i$ according to the distribution $\{\tilde{q}_i\}$. If $i \notin S$, this index is returned with probability $\tilde{p}_i/U\tilde{q}_i$, where $\tilde{p}_i$ and $\tilde{q}_i$ are the $(1 \pm \frac{1}{\sqrt{n}})$ multiplicative approximations to $p_i$ and $q_i$. Otherwise, we repeat this process until some output is returned.

The probability of returning index $i \in S$ in a particular iteration is $\tilde{q}_i \cdot (\tilde{p}_i/U\tilde{q}_i)$, which is in turn a $(1 \pm \frac{1}{\sqrt{n}})$ multiplicative approximation to $p_i/U$. Hence, the probability of success in a single iteration is roughly $1/U$, and therefore we only need $O(U \log n) = \log^{O(1)} n$ iterations (and the same number of samples from $\{\tilde{q}_i\}$) in order to succeed with high probability. The resulting distribution of indices approximates $\{p_i\}$ pointwise on the domain $S$, up to a factor of $(1 \pm \frac{1}{\sqrt{n}})$. Since the remainder of the domain contains at most $\frac{1}{n}$ probability mass, the output distribution is $O\left(\frac{1}{\sqrt{n}}\right)$ close to $\{p_i\}$ in $L_1$ distance. \hfill \blacksquare

3 Local-Access Implementations for Random Undirected Graphs

In this section, we provide an efficient local access implementations for random undirected graphs when the probabilities $p_{uv} = \mathbb{P}[\{u, v\} \in E]$ are given, and we can efficiently approximate the following quantities: (1) the probability that there is no edge between a vertex $u$ and a range of consecutive vertices $[a, b]$, namely $\prod_{u=a}^{b} (1 - p_{uv})$, and (2) the sum of the edge probabilities (i.e., the expected number of edges) between $u$ and vertices from $[a, b]$, namely $\sum_{v=a}^{b} p_{uv}$. In Section 1.2, we provide subroutines for computing these values for the Erdős-Rényi model and the Stochastic Block model. We also begin by assuming perfect-precision arithmetic, which we relax in Section B.1.

First, consider the adjacency matrix $A$ of $G$, where each entry $A[u][v]$ can exist in three possible states: $A[u][v] = 1$ or $0$ if the algorithm has determined that $\{u, v\} \notin E$ or $\{u, v\} \in E$ respectively, and $A[u][v] = \phi$ if whether $\{u, v\} \in E$ or not will be determined by future random choices (in fact, the marginal probability of $\mathbb{P}[\{u, v\} \in E]$ conditioned on all prior samples is still $p_{uv}$). Our implementation also maintains the vector last (used in the same sense as [18]), where last[$v$] records the neighbor of $v$ returned in the last call NEXT-NEIGHBOR($v$), or last[$v$] = 0 if no such call has been invoked. All cells of $A$ and last are initialized to $\phi$ and 0, respectively.

We use the Bernoulli random variable $X_{uv} \sim \text{Bern}(p_{uv})$ when sampling the value of $A[u][v] = \phi$. For the sake of analysis, we will frequently view our random process as if the entire table of random variables $X_{uv}$ has been sampled up-front, and the algorithm simply “uncovers” these variables instead of making coin-flips. Thus, every cell $A[u][v]$ is originally $\phi$, but will eventually take the value $X_{uv}$.

Obstacles for maintaining $A$ explicitly. Consider a naive implementation that fills out the cells of $A$ one-by-one as required by each query; equivalently, we perform VERTEX-PAIR queries on successive vertices until a neighbor is found. There are two problems with this approach. Firstly, the algorithm only finds a neighbor, for a RANDOM-NEIGHBOR or NEXT-NEIGHBOR query, with probability $p_{uv}$: for $G(n, p)$ this requires $1/p$ iterations, which is already infeasible for $p = o(1/\text{poly}(\log n))$. Secondly, the algorithm may generate a large number of non-neighbors in the process, possibly in random or arbitrary locations.
3.1 Next-Neighbor Queries via Run-of-0’s Sampling

We implement \textsc{Next-Neighbor}(v) by sampling for the first index $u > \text{last}[v]$ such that $X_{vu} = 1$, from a sequence of Bernoulli RVs $\{X_{v,u}\}_{u = \text{last}[v]}$. To do so, we sample a consecutive “run” of 0’s with probability $\prod_{u = \text{last}[v]}^{u′}(1 - p_{vu})$: this is the probability that there is no edge between a vertex $v$ and any $u \in (\text{last}[v], u')$, which can be computed efficiently by our assumption. The problem is that, some entries $A[v][u]$’s in this run may have already been determined (to be 1 or 0) by queries \textsc{Next-Neighbor}(u) for $u > \text{last}[v]$. To mitigate this issue, we give a succinct data structure that determines the value of $A[v][u]$ for $u > \text{last}[v]$ and, more generally, captures the state $A$, in Section 3.1.1. Using this data structure, we ensure that our sampled run does not skip over any 1. Next, for the sampled index $u$ of the first occurrence of 1, we check against this data structure to see if $A[v][u]$ is already assigned to 0, in which case we re-sample for a new candidate $u' > u$. Section 3.1.2 discusses the subtlety of this issue.

We note that we do not yet try to handle other types of queries here yet. We also do not formally bound the number of re-sampling iterations of this approach here, because the argument is not needed by our final algorithm. Yet, we remark that $O(\log n)$ iterations suffice with high probability, even if the queries are adversarial. This method can be extended to support \textsc{Vertex-Pair} queries (but unfortunately not \textsc{Random-Neibor} queries). See Section A for full details.

3.1.1 Data structure

From the definition of $X_{vu}$, \textsc{Next-Neighbor}(v) is given by $\min\{u > \text{last}[v] : X_{vu} = 1\}$. Let $P_v = \{u : A[v][u] = 1\}$ be the set of known neighbors of $v$, and $w_v = \min\{P_v \cap (\text{last}[v], u]\}$ be its first known neighbor not yet reported by a \textsc{Next-Neighbor}(v) query, or equivalently, the next occurrence of 1 in $v$’s row on $A$ after $\text{last}[v]$. If there is no known neighbor of $v$ after $\text{last}[v]$, we set $w_v = n + 1$. Consequently, $A[v][u] \in \{\phi, 0\}$ for all $u \in (\text{last}[v], w_v)$, so \textsc{Next-Neighbor}(v) is either the index $u$ of the first occurrence of $X_{vu} = 1$ in this range, or $w_v$ if no such index exists.

We keep track of $\text{last}[v]$ in a dictionary, to avoid any initialization overhead. Each $P_v$ is maintained as an ordered set, which is also instantiated when it becomes non-empty. When \textsc{Next-Neighbor}(v) returns $u$, we add $v$ to $P_u$ and $u$ to $P_v$. We do not attempt to maintain $A$ explicitly, as updating it requires replacing up to $O(n)$ 0’s for a single \textsc{Next-Neighbor} query in the worst case. Instead, we argue that $\text{last}$ and $P_v$’s provide a succinct representation of $A$ via the following observation.

\begin{lemma}
The data structures last and $P_v$’s together provide a succinct representation of $A$ when only \textsc{Next-Neighbor} queries are allowed. In particular, $A[v][u] = 1$ if and only if $u \in P_v$. Otherwise, $A[v][u] = 0$ when $u < \text{last}[v]$ or $v < \text{last}[u]$. In all remaining cases, $A[v][u] = \phi$.
\end{lemma}

\begin{proof}
The condition for $A[v][u] = 1$ clearly holds by construction. Otherwise, observe that $A[v][u]$ becomes decided (i.e. its value is changed from $\phi$ to $0$) during the first call to \textsc{Next-Neighbor}(v) that returns a value $u' > u$ thereby setting $\text{last}[v] = u' \implies u < \text{last}[v]$, or vice versa.
\end{proof}

3.1.2 Queries and Updates

We now present Algorithm 1, and discuss the correctness of its sampling process. The argument here is rather subtle and relies on viewing the process as an “uncovering” of the table of RVs $X_{vu}$ (introduced in Section 3). Consider the following strategy to find
**Algorithm 1** Sampling Next-Neighbor.

1: procedure **Next-Neighbor**($v$)
2:   $u \leftarrow \text{last}[v]$
3:   $w_v \leftarrow \min\{ (P_v \cap (u, u]) \cup \{u + 1\} \}$
4: repeat
5:   sample $F \sim F(v, u, w_v)$
6:   $u \leftarrow F$
7: until $u = w_v$ or last[$u$] < $v$
8: if $u \neq w_v$
9:   $P_v \leftarrow P_v \cap \{u\}$
10: $P_u \leftarrow P_u \cap \{v\}$
11: last[$v$] $\leftarrow u$
12: return $u$

**Next-Neighbor**($v$) in the range (last[$v$], $w_v$). Suppose that we generate a sequence of $w_v - \text{last}[v] - 1$ independent coin-tosses, where the $i^{th}$ coin $C_{vu}$ corresponding to $u = \text{last}[v] + i$ has bias $p_{vu}$, regardless of whether $X_{vu}$ is decided or not. Then, we use the sequence $\langle C_{vu} \rangle$ to assign values to undecided random variables $X_{vu}$. The main observation here is that, the decided random variables $X_{vu} = 0$ do not need coin-flips, and the corresponding coin result $C_{vu}$ can be discarded. Thus, we generate coin-flips until we encounter some $u$ satisfying both $C_{vu} = 1$ and $A[v][u] = \phi$.

Let $F(v, a, b)$ denote the probability distribution of the occurrence $u$ of the first coin-flip $C_{vu} = 1$ among the neighbors in $(a, b)$. More specifically, $F \sim F(v, a, b)$ represents the event that $C_{v,a+1} = \cdots = C_{v,F-1} = 0$ and $C_{v,F} = 1$, which happens with probability $\Pr[F = f] = \prod_{a=0}^{F-1} (1 - p_{vu}) \cdot p_{vf}$. For convenience, let $F = b$ denote the event where all $C_{vu} = 0$. Our algorithm samples $F_1 \sim F(v, \text{last}[v], w_v)$ to find the first occurrence of $C_{v,F_1} = 1$, then samples $F_2 \sim F(v, F_1, w_v)$ to find the second occurrence $C_{v,F_2} = 1$, and so on. These values $\{F_i\}$ are iterated as $u$ in Algorithm 1. This process generates $u$ satisfying $C_{vu} = 1$ in increasing order, until we find one that also satisfies $A[u][v] = \phi$ (this outcome is captured by the condition last[$u$] < $v$), or until the next generated $u$ is equal to $w_v$. Note that once the process terminates at some $u$, we make no implications on the results of any uninspected coin-flips after $C_{vu}$.

**Obstacles for extending beyond Next-Neighbor queries.** There are two main issues that prevent this method from supporting Random-Neighbor queries. Firstly, while one might consider applying Next-Neighbor starting from some random location $u$ to find the minimum $u' \geq u$ where $A[u][u'] = 1$, the probability of choosing $u'$ will depend on the probabilities $p_{vu}$'s, and is generally not uniform. Secondly, in Section 3.1.1, we observe that last[$v$] and $P_v$ together provide a succinct representation of $A[v][u] = 0$ only for contiguous cells $A[v][u]$ where $u \leq \text{last}[v]$ or $v \leq \text{last}[u]$: they cannot handle 0 anywhere else. Unfortunately, in order to support Random-Neighbor queries, we will likely need to assign $A[v][u]$ to 0 in random locations beyond last[$v$] or last[$u$], which cannot be captured by the current data structure. Specifically, to speed-up the sampling process for small $P_{vu}$'s, we must generate many random non-neighbors at once, but we cannot afford to spend time linear in the number of created 0's to update our data structure. We remedy these issues via the following approach.
3.2 Final Implementation Using Blocks

We begin this section by focusing first on \textsc{Random-Neighbor} queries, then extend the construction to the remaining queries. In order to handle \textsc{Random-Neighbor}(v), we divide the neighbors of \(v\) into blocks \(B_v = \{B_v^{(1)}, B_v^{(2)}, \ldots, B_v^{(i)}, \ldots\}\), so that each block contains, in expectation, roughly the same number of neighbors of \(v\). We implement \textsc{Random-Neighbor}(v) by randomly selecting a block \(B_v^{(i)}\), filling in entries \(A[v][u]\) for \(u \in B_v^{(i)}\) with 1’s and 0’s, and then reporting a random neighbor from this block. As the block size may be large when the probabilities are small, instead of using a linear scan, our \textsc{Fill} subroutine will be implemented using the “run-of-0s” sampling from Algorithm 1 (see Section 3.1). Since the number of iterations required by this subroutine is roughly proportional to the number of neighbors, we choose to allocate a constant number of neighbors in expectation to each block: with constant probability the block contains some neighbors, and with high probability it has at most \(O(\log n)\) neighbors.

As the actual number of neighbors appearing in each block will be different, we balance out these discrepancies by performing rejection sampling. This equalizes the probability of choosing any neighbor implicitly, without the knowledge of \(\deg(v)\). Leveraging the fact that the maximum number of neighbors in any block is \(\mathcal{O}(\log n)\), we show not only that the probability of success in the rejection sampling process is at least \(1/\text{poly}(\log n)\), but the number of iterations required by \textsc{Next-Neighbor} is also bounded by \text{poly}(\log n), achieving the overall \text{poly}(\log n) complexities. Here, we will extensively rely on the assumption that the expected number of neighbors for consecutive vertices, \(\sum_{u=0}^{b} p_{vu}\), can be approximated efficiently.

3.2.1 Partitioning and Filling the Blocks

We fix a sufficiently large constant \(L\), and assign the vertex \(u\) to the \(\lfloor \sum_{i=1}^{b} p_{ui}/L \rfloor\)th block of \(v\). Essentially, each block represents a contiguous range of vertices, where the expected number of neighbors of \(v\) in the block is \(\approx L\) (for example, in \(G(n,p)\), each block contains \(\approx L/p\) vertices). We define \(\Gamma(v) = \Gamma(v) \cap B_v^{(i)}\), the neighbors appearing in block \(B_v^{(i)}\). Our construction ensures that \(L - 1 < \mathbb{E} |\Gamma(v)| < L + 1\) for every \(i < |B_v|\) (i.e., the condition holds for all blocks except possibly the last one).

Now, we show that with high probability, all the block sizes \(|\Gamma(v)| = \mathcal{O}(\log n)\), and at least a \(1/3\)-fraction of the blocks are non-empty (i.e., \(|\Gamma(v)| > 0\)), via the following lemmas (proven in Section B).

\begin{itemize}
  \item \textbf{Lemma 13.} With high probability, the number of neighbors in every block, \(|\Gamma(v)|\), is at most \(\mathcal{O}(\log n)\).
  \item \textbf{Lemma 14.} With high probability, for every \(v\) such that \(|B_v| = \Omega(\log n)\) (i.e., \(\mathbb{E} = \Omega(\log n)\)), at least a \(1/3\)-fraction of the blocks \(\{B_v^{(i)}\}_{i \in |B_v|}\) are non-empty.
\end{itemize}

We consider blocks to be in two possible states – filled or unfilled. Initially, all blocks are considered unfilled. In our algorithm we will maintain, for each block \(B_v^{(i)}\), the set \(P_v^{(i)}\) of known neighbors of \(u\) in block \(B_v^{(i)}\); this is a refinement of the set \(P_v\) in Section 3.1. We define the behaviors of the procedure \textsc{Fill}(v, i) as follows. When invoked on an unfilled block \(B_v^{(i)}\), \(\textsc{Fill}(v, i)\) decides whether each vertex \(u \in B_v^{(i)}\) is a neighbor of \(v\) (implicitly setting \(A[v][u]\) to 1 or 0) unless \(X_{vu}\) is already decided; in other words, update \(P_v^{(i)}\) to \(\Gamma(v)\). Then \(B_v^{(i)}\) is marked as filled. We postpone the description of our implementation of \textsc{Fill} to Section 3.3, instead using it as a black box.
3.2.2 Putting it all together: Random-Neighbor queries

Algorithm 2 Block sampling.

procedure Random-Neighbor(v)
    while True
        sample $B_v^{(i)} \sim_{i.i.d} B_v$ u.a.r.
        if $B_v^{(i)}$ is not filled
            Fill $(v, i)$ with probability $\frac{|P_v^{(i)}|}{M}$
        return $u \sim_{i.i.d} P_v^{(i)}$ u.a.r

Consider Algorithm 2 for sampling a random neighbor via rejection sampling. For simplicity, throughout the analysis, we assume $|B_v| = \Omega(\log n)$; otherwise, invoke Fill $(v, i)$ for all $i \in [|B_v|]$ to obtain the entire neighbor list $\Gamma(v)$.

To obtain a random neighbor, we first choose a block $B_v^{(i)}$ uniformly at random, and invoke Fill $(v, i)$ if the block is unfilled. Then, we accept the sampled block for generating our random neighbor with probability proportional to $|P_v^{(i)}|$. More specifically, if $M = \Theta(\log n)$ is an upper bound on the maximum number of neighbors in any block (see Lemma 13), we accept block $B_v^{(i)}$ with probability $\frac{|P_v^{(i)}|}{M}$, which is well-defined (i.e., does not exceed 1) with high probability. Note that if $P_v^{(i)} = \emptyset$, we sample another block. If we choose to accept $B_v^{(i)}$, we return a random neighbor from $P_v^{(i)}$. Otherwise, reject this block and repeat the process again.

Since the returned vertex is always a member of $P_v^{(i)}$, a valid neighbor is always returned. We now show that the algorithm correctly samples a uniformly random neighbor and bound the number of iterations required for the rejection sampling process.

Lemma 15. Algorithm 2 returns a uniformly random neighbor of vertex $v$.

Proof. It suffices to show that the probability that any neighbor in $\Gamma(v)$ is return with uniform positive probability, within the same iteration. Fixing a single iteration and consider a vertex $u \in P_v^{(i)}$, we compute the probability that $u$ is accepted. The probability that $B_v^{(i)}$ is chosen is $1/|B_v|$, the probability that $B_v^{(i)}$ is accepted is $|P_v^{(i)}|/M$, and the probability that $u$ is chosen among $P_v^{(i)}$ is $1/|P_v^{(i)}|$. Hence, the overall probability of returning $u$ in a single iteration of the loop is $1/(|B_v| \cdot M)$, which is positive and independent of $u$. Therefore, each vertex is returned with the same probability. \hfill \blacktriangle

Lemma 16. Algorithm 2 terminates in $O(\log n)$ iterations in expectation, or $O(\log^2 n)$ iterations w.h.p.

Proof. Using Lemma 14, we conclude that the probability of choosing a non-empty block is at least $1/3$. Since $M = \Theta(\log n)$ by Lemma 13, the success probability of each iteration is at least $1/(3M) = \Omega(1/\log n)$, Thus, the number of iterations required is $O(\log^2 n)$ with high probability. \hfill \blacktriangle

3.3 Implementation of Fill

Lastly, we describe the implementation of the Fill procedure, employing the approach of skipping non-neighbors, as developed for Algorithm 1. We aim to simulate the following process: perform coin-tosses $C_{vu}$ with probability $p_{vu}$ for every $u \in B_v^{(i)}$ and update $A[v][u]$’s
Algorithm 3: Filling a block.

procedure Fill(v, i)
  (a, b) ← B_v^{(i)}
  while a < b
    sample u ∼ F(v, a, b)
    B_u^{(i)} ← block containing v
    if B_u^{(i)} is not filled
      P_v^{(i)} ← P_v^{(i)} ∪ {u}
      P_u^{(i)} ← P_u^{(i)} ∪ {v}
    a ← u
  mark B_u^{(i)} as filled

according to these coin-flips unless they are decided (i.e., A[v][u] ≠ φ). We directly generate a sequence of u’s where the coins C_{vu} = 1, then add u to P_v and vice versa if X_{vu} has not previously been decided. Thus, once B_v^{(i)} is filled, we will obtain P_v^{(i)} = Γ(v) as desired.

As discussed in Section 3.1, while we have recorded all occurrences of A[v][u] = 1 in P_v^{(i)}, we need an efficient way of checking whether A[v][u] = 0 or φ. In Algorithm 1, last serves this purpose by showing that A[v][u] for all u ≤ last[v] are decided as shown in Lemma 12. Here instead, we maintain a single bit marking whether each block is filled or unfilled: a filled block implies that A[v][u] = 1 for all u ∈ B_v^{(i)} are decided. The block structure along with the mark bits, unlike last, is capable of handling intermittent ranges of intervals, which is sufficient for our purpose, as shown in the following lemma. This yields the implementation of Algorithm 3 for the Fill procedure fulfilling the requirement previously given in Section 3.2.1.

Lemma 17. The data structures P_v^{(i)}’s and the block marking bits together provide a succinct representation of A as long as modifications to A are performed solely by the Fill operation in Algorithm 3. In particular, let u ∈ B_v^{(i)} and v ∈ B_u^{(i)}. Then, A[v][u] = 1 if and only if u ∈ P_v^{(i)}. Otherwise, A[v][u] = 0 when at least one of B_v^{(i)} or B_u^{(i)} is marked as filled. In all remaining cases, A[v][u] = φ.

Proof. The condition for A[v][u] = 1 still holds by construction. Otherwise, observe that A[v][u] becomes decided precisely during a Fill(v, i) or a Fill(u, j) operation, which thereby marks one of the corresponding blocks as filled.

Note that P_v^{(i)}’s, maintained by our implementation, are initially empty but may not still be empty at the beginning of the Fill function call. These P_v^{(i)}’s are again instantiated and stored in a dictionary once they become non-empty. Further, observe that the coin-flips are simulated independently of the state of P_v^{(i)}, so the number of iterations of Algorithm 3 is the same as the number of coins C_{vu} = 1 which is, in expectation, a constant (namely ∑_{u∈B_v^{(i)}} P[C_{vu} = 1] = ∑_{u∈B_v^{(i)}} p_{vu} ≤ L + 1).

By tracking the resource required by Algorithm 3 we obtain the following lemma; note that “additional space” refers to the enduring memory that the implementation must allocate and keep even after the execution, not its computation memory. The log n factors in our complexities are required to perform binary-search for the range of B_v^{(i)}, or for the value u from the CDF of F(u, a, b), and to maintain the ordered sets P_v^{(i)} and P_u^{(i)}.

Lemma 18. Each execution of Algorithm 3 (the Fill operation) on an unfilled block B_v^{(i)}, in expectation:
- terminates within O(1) iterations (of its repeat loop);
- computes O(log n) quantities of ∏_{v∈[a, b]} (1 − p_{vu}) and ∑_{u∈[a, b]} p_{vu} each;
- uses an additional O(log n) time, O(1) random log n-bit words, and O(1) additional space.
Observe that the number of iterations required by Algorithm 3 only depends on its random coin-flips and independent of the state of the algorithm. Combining with Lemma 16, we finally obtain polylogarithmic resource bound for our implementation of Random-Neighbor.

**Corollary 19.** Each execution of Algorithm 2 (the Random-Neighbor query), with high probability,
- terminates within $O(\log^2 n)$ iterations (of its repeat loop);
- computes $O(\log^3 n)$ quantities of $\prod_{u \in [a,b]} (1 - p_{vu})$ and $\sum_{u \in [a,b]} p_{vu}$ each;
- uses an additional $O(\log^3 n)$ time, $O(\log^2 n)$ random words, and $O(1)$ additional space.

**Supporting Other Query Types along with Random-Neighbor**

- **VERTEX-PAIR(u,v):** We simply need to make sure that Lemma 17 holds, so we first apply $\text{Fill}(u,j)$ on block $B_u^{(j)}$ containing $v$ (if needed), then answer accordingly.
- **NEXT-NEIGHBOR(v):** We maintain last, and keep invoking $\text{Fill}$ until we find a neighbor. Recall that by Lemma 14, the probability that a particular block is empty is a small constant. Then with high probability, there exists no $\omega(\log n)$ consecutive empty blocks $B_u^{(j)}$'s for any vertex $v$, and thus NEXT-NEIGHBOR only invokes up to $O(\log n)$ calls to $\text{Fill}$.

We summarize the results so far with through the following theorem.

**Theorem 1.** Given a random graph model defined by the probability matrix $\{p_{vu}\}_{u,v \in [n]}$, and assuming that we can compute the quantities $\prod_{u=a}^b (1 - p_{vu})$ and $\sum_{u=a}^b p_{vu}$ in $O(\log^{O(1)} n)$ time, there exists an implementation for this model that supports local access through Random-Neighbor, Vertex-Pair, and Next-Neighbor queries using $O(\log^{O(1)} n)$ running time, additional space, and random bits per query.

We have also been implicitly assuming perfect-precision arithmetic and we relax this assumption in Section B.1. In the following Section 3.4, we show applications of Theorem 1 to the $G(n,p)$ model, and the Stochastic Block model under random community assignment, by providing formulas and by constructing data structures for computing the quantities specified in Theorem 1.

### 3.4 Applications to Erdős-Rényi Model and Stochastic Block Model

In this section we demonstrate the application of our techniques to two well known, and widely studied models of random graphs. That is, as required by Theorem 1, we must provide a method for computing the quantities $\prod_{u=a}^b (1 - p_{vu})$ and $\sum_{u=a}^b p_{vu}$ of the desired random graph families in logarithmic time, space and random bits. Our first implementation focuses on the well known Erdős-Rényi model – $G(n,p)$: in this case, $p_{vu} = p$ is uniform and our quantities admit closed-form formulas.

Next, we focus on the Stochastic Block model with randomly-assigned communities. Our implementation assigns each vertex to a community in $\{C_1, \ldots, C_r\}$ identically and independently at random, according to some given distribution $R$ over the communities. We formulate a method of sampling community assignments locally. This essentially allows us to sample from the multivariate hypergeometric distribution, using poly($\log n$) random bits, which may be of independent interest. We remark that, as our first step, we sample for the number of vertices of each community. That is, our construction can alternatively support the community assignment where the number of vertices of each community is given, under the assumption that the partition of the vertex set into communities is chosen uniformly at random.
3.4.1 Erdős-Rényi Model

As $p_{uv} = p$ for all edges $\{u, v\}$ in the Erdős-Rényi $G(n, p)$ model, we have the closed-form formulas $\prod_{u=a}^{b}(1-p_{uv}) = (1-p)^{b-a+1}$ and $\sum_{u=a}^{b} p_{uv} = (b-a+1)p$, which can be computed in constant time according to our assumption, yielding the following corollary.

**Corollary 2.** There exists an algorithm that implements local access to an Erdős-Rényi $G(n, p)$ random graph, through **Vertex-Pair**, **Next-Neighbor**, and **Random-Neighbor** queries, while using $O(p^2 n^2)$ time, $O(p^2 n)$ random bits, and $O(p^2 n)$ additional space per query with high probability.

We remark that there exists an alternative approach that picks $F \sim F(v, a, b)$ directly via a closed-form formula $a + \lceil \log U \rceil$ where $U$ is drawn uniformly from $[0, 1)$, rather than binary-searching for $U$ in its CDF. Such an approach may save some poly$(\log n)$ factors in the resources, given the perfect-precision arithmetic assumption. This usage of the log function requires $\Omega(n)$-bit precision, which is not applicable to our computation model.

While we are able to generate our random graph on-the-fly supporting all three types of queries, our construction still only requires $O(m + n)$ space ($\log n$-bit words) in total at any state; that is, we keep $O(n)$ words for **last**, $O(1)$ words per neighbor in $P_r$'s, and one marking bit for each block (where there can be up to $m + n$ blocks in total). Hence, our memory usage is nearly optimal for the $G(n, p)$ model:

**Corollary 4.** The final algorithm in Section 3 can generate a complete random graph from the Erdős-Rényi $G(n, p)$ model using overall $\tilde{O}(n + m)$ time, random bits and space, which is $\tilde{O}(pm^2)$ in expectation. This is optimal up to $O(\log n)$ factors.

3.4.2 Stochastic Block model

In the Stochastic Block model, each vertex is assigned to some community $C_i$, $i \in [r]$. By partitioning the product by communities, we may rewrite the desired formulas, for $v \in C_i$, as $\prod_{u=a}^{b}(1-p_{uv}) = \prod_{j=1}^{r} p_{ij}[a^{\cap} C_i]$, and $\sum_{u=a}^{b} p_{uv} = \sum_{j=1}^{r} |[a, b] \cap C_i| \cdot p_{ij}$. Thus, it suffices to design a data structure that is able to efficiently count the number of occurrences of vertices of each community in any contiguous range (namely the value $|[a, b] \cap C_i|$ for each $j \in [r]$), where the vertices are assigned communities according to a given distribution $R$. To this end, we use the following lemma, yielding an implementation for the Stochastic Block model using $O(r\text{poly}(\log n))$ resources per query.

**Theorem 20.** There exists a data structure that samples a community for each vertex independently at random from $R$ with $\frac{1}{\text{poly}(n)}$ error in the $L_1$-distance, and supports queries that ask for the number of occurrences of vertices of each community in any contiguous range, using $O(r\text{poly}(\log n))$ time, random bits, and additional space per query. Further, this data structure may be implemented in such a way that requires no overhead for initialization.

**Corollary 3.** There exists an algorithm that implements local access to a random graph from the $n$-vertex Stochastic Block Model with $r$ randomly-assigned communities, through **Vertex-Pair**, **Next-Neighbor**, and **Random-Neighbor** queries, using $O(r\text{poly}(\log n))$ time, random bits, and space per query w.h.p.

We provide the full details of the construction in Section D. Our construction extends a similar implementation in the work of [26] which only supports $r = 2$. The overall data structure is a balanced binary tree, where the root corresponds to the entire range of indices $[n]$, and the children of each vertex correspond to the first and second half of the parent’s range.
Each node\(^3\) holds the number of vertices of each community in its range. The tree initially contains only the root, with the number of vertices of each community \(|C_1|, |C_2|, \ldots, |C_r|\) sampled according to the multinomial distribution (for \(n\) samples from the distribution \(R\)). The children are generated top-down on an as-needed basis according to the given queries. The technical difficulties arise when generating the children, where one needs to sample the counts assigned to either child from the correct marginal distribution. We show how to sample such a count from the \textit{multivariate hypergeometric distribution}, below in Theorem 21 (proven in Section D).

\begin{theorem}
Given \(B\) marbles of \(r\) different colors, such that there are \(C_i\) marbles of color \(i\), there exists an algorithm that samples \(s_1, s_2, \ldots, s_r\), the number of marbles of each color appearing when drawing \(l\) marbles from the urn without replacement, in \(O(r \cdot \text{poly} (\log B))\) time and random words.
\end{theorem}

\textbf{Proof of Theorem 20.} Recall that \(R\) denotes the given distribution over integers [\(r\)] (namely, the random distribution of communities for each vertex). Our algorithm generates and maintains random variables \(X_1, \ldots, X_n\) (denoting the community assignment), each of which is drawn independently from \(R\). Given a pair \((a, b)\), it uses Theorem 20 to sample the vector \(C(a, b) = (c_1, \ldots, c_r)\), where \(c_k\) counts the number of variables in \(\{X_a, \ldots, X_b\}\) that take on the value \(k\).

We maintain a complete binary tree whose leaves corresponds to indices from [\(n\)]. Each node represents a range and stores the vector \(C\) for the corresponding range. The root represents the entire range [\(n\)], which is then halved in each level. Initially the root samples \(C(1, n)\) from the multinomial distribution according to \(R\) (see e.g., Section 3.4.1 of [32]). Then, the children are generated on-the-fly as described above. Thus, each query can be processed within \(O(r \cdot \text{poly} (\log n))\) time, yielding Theorem 20.

Then, by embedding the information stored by the data structure into the state (as in the proof of Lemma 51), we obtain the desired Corollary 3.

\section{Implementing Random Catalan Objects}

In the previous Section 3.4.2 on the Stochastic Block Model, we considered random sequences of colored marbles. Next, we focus on an important variant of these sequences as Catalan objects, which impose a global constraint on the types of allowable sequences. Specifically, consider a sequence of \(n\) white and \(n\) black marbles, such that every prefix of the sequence has at least as many white marbles as black ones. Our goal will be to support queries to a uniformly random instance of such an object.

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{dyck_path.png}
\caption{Simple Dyck path with \(n = 35\) up and down steps.}
\end{figure}

\(^3\)For clarity, “vertex” is only used in the sampled graph, and “node” is only used in the internal data structures.
One interpretation of Catalan objects is given by Dyck paths (Figure 1). A Dyck path is essentially a $2n$ step balanced one-dimensional walk with exactly $n$ up and down steps. In Figure 1, each step moves one unit along the positive $x$-axis (time) and one unit up or down the positive $y$-axis (position). The prefix constraint implies that the $y$-coordinate of any point on the walk is $\geq 0$ i.e. the walk never crosses the $x$-axis. The number of possible Dyck paths (see Theorem 62) is the $n^{\text{th}}$ Catalan number $C_n = \frac{1}{n+1} \cdot \binom{2n}{n}$. Many important combinatorial objects occur in Catalan families of which these are an example.

We will approach the problem of partially sampling Catalan objects through Dyck paths. This, in turn, will allow us to implement access other random Catalan objects such as rooted trees, and bracketed expressions. Specifically, we will want to answer the following queries:

- **Direction**($t$): Returns the value of the $t^{\text{th}}$ step in the Dyck path (whether the step is up or down).
- **Height**($t$): Returns the $y$-position of the path after $t$ steps (the number of up steps minus the number of down steps among the first $t$ steps). Since a Direction($t$) query can be simulated using the queries Height($t$) and Height($t-1$), we will not explicitly discuss the Direction queries in what follows.
- **First-Return**($t$): If the $(t+1)^{\text{th}}$ step is upwards i.e. Height($t+1$) = Height($t$) + 1, it returns the smallest index $t'$ such that Height($t'$) = Height($t$). While it may not be clear why this query is important, it will be useful for querying bracketed expressions and random trees. (see Section 4.1).

### 4.1 Bijections to other Catalan objects

The Height query is natural for Dyck paths, but the First-Return query is important in exploring other Catalan objects. For instance, consider a random well bracketed expression; equivalently an uniform distribution over the Dyck language. One can construct a trivial bijection between Dyck paths and words in this language by replacing up and down steps with opening and closing brackets respectively (Figure 2). The Height query corresponds to asking for the nesting depth at a certain position in the word, and First-Return($x$) returns the position after the matched closing bracket for the step ($x \rightarrow x + 1$).

There is also a natural bijection between Dyck paths and ordered rooted trees (Figure 2), by viewing the Dyck path as a transcript of the tree’s DFS traversal. Starting with the root, for each “up-step” we move to a new child of the current node, and for each “down-step”, we backtrack towards the root. Thus, the Height query returns the depth of a node. Also, since the Dyck path is a DFS transcript of the tree, a First-Return query on the path can be used to find successive children of a tree node (each return produces the next child). For instance, in Figure 2, we can invoke First-Return thrice starting at the first yellow path position to reveal the corresponding three children of the yellow tree node.

By definition, First-Return($x$) is meaningful only when the step from $x$ to $x + 1$ is upwards, i.e. when Height($x+1$) = Height($x$) + 1. We can also implement a Reverse-First-Return query, which is just a standard First-Return query on the reversed Dyck path (consider a reversal of the green dashed arrows in Figure 2). The reversal implies that Reverse-First-Return($x$) is only meaningful when Height($x-1$) = Height($x$) + 1. In terms of bijections, Reverse-First-Return is equivalent to finding a matching opening bracket in bracketed expressions, and a Previous-Child query in rooted trees. We show how to implement this query in Section 4.4.7. In the case where the height at $x$ is larger than both the heights at $x - 1$ and $x + 1$ (boxed nodes in Figure 2), there is no meaningful “first return” from the context of the bijections. Specifically, these nodes correspond to leaf nodes in rooted trees, or to a terminal nesting level in the bracket expression.
Moving forwards, we will focus on Dyck paths for the sake of simplicity.

4.2 Catalan Trapezoids and Generalized Dyck Paths

In order to implement local access to random Dyck paths, we will need to analyze more general Catalan objects. Specifically, we consider a sequence of $U$ up-steps and $D$ down-steps, such that any prefix of the sequence containing $U'$ up and $D'$ down steps satisfies $U' - D' \geq 1 - k$. This means that we start our Dyck path at a height of $k - 1$, and we are never allowed to cross below zero (Figure 3). Note that the case $k = 1$ corresponds to the standard description of Dyck paths, as mentioned previously (Figure 1).

We will denote the set of such generalized Dyck paths as $C_k(U, D)$ and the number of paths as $C_k(U, D) = |C_k(U, D)|$, which is an entry in the Catalan Trapezoid of order $k$ [47]. We also use $C_k(U, D)$ to denote the uniform distribution over $C_k(n, m)$. Now, we state a result from [47] without proof:

$$C_k(U, D) = \begin{cases} \binom{U+D}{D} & 0 \leq D < k \\ \binom{U+D}{D} - \binom{U+D}{D-k} & k \leq D \leq U + k - 1 \\ 0 & D > U + k - 1 \end{cases} \quad (1)$$

For $k = 1$ and $n = m$, these represent the vanilla Catalan numbers i.e. $C_n = C_1(n, n)$ (number of simple Dyck paths). Our goal is to sample from the distribution $C_1(n, n)$. 
Consider the situation after a sequence of \textit{Height} queries to the Dyck path at various locations $\langle x_1, x_2, \cdots, x_m \rangle$, such that the corresponding heights were sampled to be $\langle y_1, y_2, \cdots, y_m \rangle$. These revealed locations partition the path into disjoint intervals $[x_i, x_{i+1}]$, where the heights of the endpoints of each interval have been determined (as $y_i = \text{Height}(x_i)$). We notice that these intervals can be generated independently of each other. Specifically, the path within the interval $[x_i, x_{i+1}]$ will be sampled from $C_k(U, D)$, where $k - 1 = y_i$, $U + D = x_{i+1} - x_i$, and $U - D = y_{i+1} - y_i$. Moreover, since the heights of the endpoints $y_i$ and $y_{i+1}$ are known, this choice is independent of any samples outside the interval. Next, in Section 4.3, we will show how one can determine heights within such an interval, and in Section 4.4 we will move on to the more complicated \textit{First-Return} queries.

### 4.3 Implementing \textit{Height} queries

We implement $\text{Height}(t)$ by showing how to efficiently determine the height of the path at the midpoint of an existing interval $[x_i, x_{i+1}]$ (with corresponding endpoint heights $y_i, y_{i+1}$), which results in two sub-intervals that are half the size. Next, we extend this strategy to determine the heights of arbitrary positions by recursively sub-dividing the relevant interval (binary search). If the interval in question has odd length, we sample a single step from an endpoint, and proceed with a shortened even length interval. Sampling a single step is easy since there are only two outcomes (see proof of Theorem 28).

Our general recursive step is as follows. We consider an interval of length $2B$ comprising of $2U$ up-steps and $2D$ down-steps where the sum of any prefix cannot be less than $k - 1$ i.e. the path within this interval should be sampled from $C_k(2U, 2D)$. In order to make the analysis simpler, we have assumed that the number of up and down steps are both even. The case of sampling according to $C_k(2U + 1, 2D + 1)$ works similarly with slightly different formulae. Without loss of generality, we assume that $D \leq U$; if this were not the case, we could simply flip the interval, swap the up and down steps, and modify the prefix constraint to $k' = k + 2U - 2D$ (Figure 4). This ensures that the overall path in the interval is non-decreasing in height, which will simplify our analysis.

We determine the height of the path $B = U + D$ steps into the interval at the midpoint (see Figure 4). This is equivalent to finding the number of up or down steps that get assigned to the first half of the interval. We parameterize the possibilities by $d$ and define $p_d$ to be the probability that exactly $U + d$ up-steps and $D - d$ down steps get assigned to the first half (with the remaining $U - d$ up steps and $D + d$ down steps being assigned to the second half).

$$p_d = \frac{S_{left}(d) \cdot S_{right}(d)}{S_{total}(d)}$$ (2)
Here, $S_{left}(d)$ denotes the number of possible paths in the first half (using $U + d$ up steps) and $S_{right}(d)$ denotes the number of possible paths in the second half (using $U - d$ up steps). Note that all of these paths have to respect the $k$-boundary constraint (cannot dip more than $k - 1$ units below the starting height), where $k = y_i + 1$. Moving forwards, we will drop the $d$ when referring to the path counts. We (conceptually) flip the second half of the interval, such that the corresponding path begins from the end of the $2B$-interval and terminates at the midpoint (Figure 4). This results in a different starting point, and the prefix/boundary constraint will also be different. Hence, we define $k' = k + 2U - 2D$ to represent the new boundary constraint (since the final height of the $2B$-interval is $k' - 1$). Finally, $S_{total}$ is the total number of possible paths in the $2B$ interval.

We cannot directly sample from this complicated distribution $\{p_d\}$. Instead, we use the rejection sampling strategy from Lemma 11. An important point to note is that in order to apply this lemma, we must be able to approximate the $p_d$ values. However, we cannot naively use the formula from Equation 2, since the values of $\{S_{left}, S_{right}, S_{total}\}$ are too large to compute explicitly. Lemma 67 in Section F.3 shows how to indirectly compute the probability approximations. We also use the following lemma to bound the deviation of the path with high probability. A proof is presented in Section F.2.

**Lemma 22.** Consider a contiguous sub-path of a simple Dyck path of length $2n$ where the sub-path is of length $2B$ comprising of $U$ up-steps and $D$ down-steps (with $U + D = 2B$). Then there exists a constant $c$ such that the quantities $|B - U|, |B - D|,$ and $|U - D|$ are all $< c\sqrt{B}\log n$ with probability at least $1 - 1/n^2$ for every possible sub-path.

This lemma allows us to ignore potential midpoint heights that cause a deviation greater than $c\sqrt{B}\log n$. A direct implication is that with high probability, the correctly sampled value for $d$ will be $O(\sqrt{B}\log n)$. In other words, the height of the midpoint takes on one of only $O(\sqrt{B}\log n)$ distinct values with high probability. This immediately suggests a $O(\sqrt{B})$ time algorithm for determining the midpoint height, by explicitly computing the probabilities of each of these potential heights, and directly sampling from the resulting distribution. However, we can go further and obtain a $O(poly(\log n))$ time algorithm.

### 4.3.1 The Simple Case: Far Boundary

We first consider the case when the boundary constraint is far away from the starting point, i.e. $k$ is large. The following lemma (proof in Section F.2) shows that in this case, we can safely ignore the constraint. Intuitively, this is because the boundary is so far away, that with high probability, we do not hit it even if we choose a random unconstrained path.

**Lemma 23.** Given a Dyck path sampling problem of length $B$ with $U$ up, $D$ down steps, and a boundary at $k$, there exists a constant $c$ such that if $k > c\sqrt{B}\log n$, then the distribution of paths sampled without a boundary $C_{\infty}(U, D)$ is $O(1/n^2)$-close in $L_1$ distance to the distribution of Dyck paths $C_k(U + D)$.

By Lemma 23, the problem of sampling from $C_k(2U, 2D)$ reduces to sampling from the hypergeometric distribution $C_{\infty}(2U, 2D)$ when $k > O(\sqrt{B}\log n)$ i.e. the probabilities $p_d$ can be approximated by:

$$q_d = \frac{\left(\frac{B - d}{D - d}\right) \cdot \left(\frac{B + d}{D + d}\right)}{\left(\frac{2B}{2D}\right)}$$

This problem of sampling from the hypergeometric distribution is implemented using $O(poly(\log n))$ resources in [26] (see Lemma 54 in Section D). We also used this result earlier in the paper in order to find the community assignments in the Stochastic Block Model (Section 3.4.2).
4.3.2 The Difficult Case: Intervals Close to Zero

The difficult case is when \( k = \mathcal{O}(\sqrt{B \log n}) \), and the previous approximation due to Lemma 23 no longer works. In this case, we cannot just ignore the boundary constraint, and instead we have to analyze the true probability distribution given by \( p_d \). We obtain an expression for \( p_d \) by substituting the formula for generalized Catalan numbers as follows: (Equation 1) into Equation 2.

\[
S_{\text{left}} = C_k(U + d, D - d) \quad S_{\text{right}} = C_{k'}(U - d, D + d) \quad S_{\text{total}} = C_k(2U, 2D)
\]

Since the right interval is flipped in our analysis, this changes the prefix/boundary constraint, and hence, the expression for \( S_{\text{right}} \) uses \( k' = k + 2U - 2D \). This also implies that \( k' = \mathcal{O}(\sqrt{B \log n}) \) (using Lemma 22). We can now use Equation 2 to evaluate the probabilities \( p_d = S_{\text{left}} \cdot S_{\text{right}} / S_{\text{total}} \). Recall that \( S_{\text{left}} \) and \( S_{\text{right}} \) are the number of possible paths in the left and right half of the interval, when exactly \( U + d \) up steps are assigned to the first half, and \( S_{\text{total}} \) is the total number of possible paths in the interval.

We will invoke the rejection sampling technique (Lemma 11), by constructing a different distribution \( q_d \) that approximates \( p_d \) up to logarithmic factors over the vast majority of its support (we ignore all \(|d| > \Theta(\sqrt{B \log n})\) since the associated probability mass is negligible by Lemma 22). In order to perform rejection sampling, we also need good approximations of \( p_d \), which is achieved by Lemma 67 in Section F.3. Next, we define an appropriate \( q_d \) that approximates \( p_d \) and also has an efficiently computable \( \text{CDF} \). Surprisingly, as in Section 4.3.1, we will be able to use the hypergeometric distribution for \( q_d \).

\[
q_d = \frac{\binom{B}{D-d} \cdot \binom{B}{D+d}}{\binom{2B}{D}} = \frac{\binom{B}{D-d} \cdot \binom{B}{U-d}}{\binom{2B}{2D}}
\]

However, the argument for why this \( q_d \) is a good approximation to \( p_d \) is far less straightforward.

First, we consider the case where \( k \cdot k' \leq 2U + 1 \). In this case, we use loose bounds for \( S_{\text{left}} < \binom{B}{D-d} \) and \( S_{\text{right}} < \binom{B}{U-d} \). These are true because \( \binom{B}{D-d} \) and \( \binom{B}{U-d} \) are the total number of unconstrained paths in the left and right half respectively, and adding the boundary constraint can only reduce the number of paths. We also prove the following lemma in Section F.4 to bound the value of \( S_{\text{total}} \).

\[\text{Lemma 24. When } kk' > 2U + 1, S_{\text{total}} > \frac{1}{2} \cdot \frac{2B}{2D}\]

Combining the three bounds, we conclude that \( p_d < \frac{1}{2} q_d \). Intuitively, in this case the Dyck boundary is far away, and therefore the number of possible paths is only a constant factor away from the number of unconstrained paths (see Section 4.3.1). The case where the boundaries are closer (\( i.e. k \cdot k' \leq 2U + 1 \)) is trickier, since the individual counts need not be close to the corresponding binomial counts. However, in this case we can still ensure that the sampling probability is within poly-logarithmic factors of the binomial sampling probability. We use the following lemmas to bound \( S_{\text{left}} \) and \( S_{\text{right}} \) (proofs in Section F.4).

\[\text{Lemma 25. } S_{\text{left}} \leq C_1 k \frac{\sqrt{\log n}}{\sqrt{B}} \cdot \binom{B}{D-d} \text{ for some constant } c_1.\]

\[\text{Lemma 26. } S_{\text{right}} \leq C_2 k' \frac{\sqrt{\log n}}{\sqrt{B}} \cdot \binom{B}{U-d} \text{ for some constant } c_2.\]

Finally, we obtain a different bound on \( S_{\text{total}} \) for the near boundary case.

\[\text{Lemma 27. When } kk' \leq 2U + 1, S_{\text{total}} \geq C_3 \frac{k' k}{B} \cdot \frac{2B}{2D} \text{ for some constant } c_3.\]
Multiplying these inequalities together allows us to bound \( p_d = S_{\text{left}} \cdot S_{\text{right}} / S_{\text{total}} \leq \Theta(q_d \log n) \), implying \( p_d/q_d \leq \Theta(\log n) \). Consequently, we can leverage Lemma 11 to obtain a sample from \( \{p_d\} \) using \( \mathcal{O}(\log^{O(1)} n) \) samples from \( \{q_d\} \), thus determining the height of the Dyck path at the midpoint of the interval.

\begin{itemize}
  \item \textbf{Theorem 28.} Given an interval \([x_i, x_{i+1}]\) (and the associated endpoint heights \(y_i, y_{i+1}\)) in a Dyck path of length \(2n\), with the guarantee that no position between \(x_i\) and \(x_{i+1}\) has been sampled yet, there is an algorithm that returns the height of the path at the midpoint of \(x_i\) and \(x_{i+1}\) (or next to the midpoint if \(x_{i+1} - x_i\) is odd). Moreover, this algorithm only uses \( \mathcal{O}(\text{poly}(\log n)) \) resources.

\textbf{Proof.} If \(x_{i+1} - x_i\) is even, we can set \(B = (x_{i+1} - x_i)/2\). Otherwise, we first sample a single step from \(x_i\) to \(x_{i+1}\), and then set \(B = (x_{i+1} - x_i - 1)/2\). Since there are only two possibilities for a single step, we can explicitly approximate the corresponding probabilities using the strategy outlined in the proof of Lemma 67 (see Section F.3), and then sample accordingly. This allows us to apply the rejection sampling from Lemma 11 using \(\{q_d\}\) to obtain samples from \(\{p_d\}\) as defined above. \hfill \Box

\item \textbf{Theorem 29.} There is an algorithm that provides sample access to a Dyck path of length \(2n\), by answering queries of the form \(\text{HEIGHT}(x)\) with the correctly sampled height of the Dyck path at position \(x\) using only \(\mathcal{O}(\text{poly}(\log n))\) resources per query.

\textbf{Proof.} The algorithm maintains a successor-predecessor data structure (e.g. Van Emde Boas tree) to store all positions \(x\) that have already been determined. Each newly determined position is added to this structure. Given a query \(\text{HEIGHT}(x)\), the algorithm first finds the successor and predecessor (say \(a\) and \(b\)) of \(x\) among the already queried positions. This provides the guarantee required to apply Theorem 28, which allows us to query the height at the midpoint of \(a\) and \(b\). We then binary search by updating either the successor or predecessor of \(x\) and repeat until we determine the height of position \(x\). \hfill \Box
\end{itemize}

### 4.4 Supporting “First Return” Queries

In this section, we discuss more complex queries to a Dyck path. Specifically, we implement \(\text{FIRST-RETURN}(x)\) to allow the user to query the next time the path returns to \(\text{HEIGHT}(x)\). The utility of this kind of query is illustrated through bijections to other random Catalan objects in Section 4.1. An important detail here is that if the first step from \(x\) to \(x + 1\) is a down-step, there is no well defined \(\text{FIRST-RETURN}\).

#### 4.4.1 Maintaining a Boundary Invariant

Notice that after performing a set of \(\text{HEIGHT}\) queries \((x_1, x_2, \ldots, x_m)\) to the Dyck path, many different positions are revealed (possibly in adversarial locations). This partitions the path into at most \(m + 1\) disjoint and independent \(\text{intervals}\) with known boundary conditions. The first step towards finding the \(\text{FIRST-RETURN}\) from position \(t\) would be to locate the \(\text{interval}\) where the first return occurs. Even if we had an efficient technique to filter intervals, we would want to avoid considering all \(\Theta(m)\) intervals to find the correct one. In addition, the fact that a specific interval \(\text{does not}\) contain the first return implies dependencies for all subsequent samples.

We resolve these difficulties by maintaining a new invariant. Consider all positions whose heights have already been determined, either directly as a result of user given \(\text{HEIGHT}\) queries, or indirectly due to recursive \(\text{HEIGHT}\) calls; \((x_1, x_2, \ldots, x_m)\) in increasing order i.e. \(x_i < x_{i+1}\). Let the corresponding heights be \((y_1, y_2, \ldots, y_m)\) i.e. \(\text{HEIGHT}(x_i) = y_i\).
Invariant 30. For any interval \([x_i, x_{i+1}]\) where the heights of the endpoints have been determined to be \(y_i\) and \(y_{i+1}\), and every other height in the interval has yet to determined, the section of the Dyck path between positions \(x_i\) and \(x_{i+1}\) is constrained to lie above \(\min(y_i, y_{i+1})\).

Figure 5 The set of intervals formed by a set of height samples. Each interval also has its own boundary constraint (red). Invariant 30 implies that each boundary must coincide with one of the interval endpoints. Note that the only interval which violates the invariant is the third last one (shown in yellow box).

How can one maintain such an invariant? After determining the height of a particular position \(x_i\) as \(y_i\) (with \(x_{i-1} < x_i < x_{i+1}\)), the invariant is potentially broken on either side of \(x_i\). We re-establish the invariant by determining the height of an additional point on either side (see Section 4.4.6 for details). Specifically, we use the following two step strategy to find the additional point for some violating interval \([x_i, x_{i+1}]\) (example violation in Figure 5):

1. Sample the lowest height \(h\) achieved by the walk between \(x_i\) and \(x_{i+1}\) according to the uniform distribution over all possible paths that respect the current boundary constraint (see Section 4.4.2).
2. Find an intermediate position \(x\) such that \(x_i < x < x_{i+1}\) and \(\text{Height}(x) = h\) (see Section 4.4.3).

The newly determined position \(x\) produces two sub-intervals \([x_i, x]\) and \([x, x_{i+1}]\). Since \(h = \text{Height}(x)\) has been determined to be the minimum height in the overall range \([x_i, x_{i+1}]\), the invariant is preserved in the new intervals (see Figure 6). Lemma 37 in Section 4.4.5 shows how this invariant can help us efficiently search for the interval containing the first return.

Figure 6 An interval \([x_i, x_{i+1}]\) that violates the invariant is “fixed” by first sampling the lowest height \(h\) achieved within the interval, and then generating a position \(x \in [x_i, x_{i+1}]\) such that \(\text{Height}(x) = h\).

4.4.2 Sampling the Lowest Achievable Height: Mandatory Boundary

First, we need to sample the lowest height \(h\) of the walk between \(x_i\) and \(x_{i+1}\) (with corresponding heights \(y_i\) and \(y_{i+1}\)). We will refer to \(h\) as the “mandatory boundary” in this interval; i.e. no height in the interval may be lower than the boundary, but at least one point must touch the boundary (have height \(h\)). We assume that \(y_i \leq y_{i+1}\) without loss of generality; if this is not the case, swap \(x_i\) and \(x_{i+1}\) and consider the reversed path. Say this interval defines a generalized Dyck problem with \(U\) up steps, \(D\) down steps, and a boundary that is \(k-1\) units below \(y_i\).
Given any two boundaries $k_{lower}$ and $k_{upper}$ on this interval (with $k_{lower} < k_{upper} \leq y_i$), we can count the number of possible generalized Dyck paths that violate the $k_{upper}$ boundary but not the $k_{lower}$ boundary as follows (see Figure 7):

$$P_{k_{upper}}^{k_{lower}} = C_{k_{lower}}(U, D) - C_{k_{upper}}(U, D)$$

We define the current lower and upper boundaries as $k_{low} = k, k_{up} = 0$, and set $k_{mid} = (k_{low} + k_{up})/2$. Since we can compute the quantities $P_{k_{mid}}^{k_{up}}, P_{k_{low}}^{k_{mid}},$ and $P_{total} = P_{k_{low}}^{k_{up}},$ we can sample a single bit to decide if the “lower boundary” should move up or if the “upper boundary” should move down. We then repeat this binary search until we find $k' = k_{low} = k_{up} - 1$ and $k'$ becomes the “mandatory boundary” (i.e. the walk reaches the height exactly $k' - 1$ units below $y_i$ but no lower.

![Figure 7](image-url)

**Figure 7** $P_{k_{low}}^{k_{up}}$ counts all the paths that dip at least $k_{up}$ units below the starting point, but do not dip $k_{low}$ units below the starting point. $k_{mid}$ would lie halfway between these boundaries.

### 4.4.3 Determining First Position that Touches the “Mandatory Boundary”

Now that we have a “mandatory boundary” $k$, we just need to generate a position $x \in [x_i, x_{i+1}]$ with $\text{HEIGHT}(x) = y_i - k + 1$, according to the uniform distribution over all paths that touch, but do not violate the boundary at $k$. In fact, we will do something stronger by determining the first time the walk touches the boundary after $x_i$. As before, we assume that this interval contains $U$ up steps and $D$ down steps.
We will parameterize the position $x$ the number of up-steps $d$ between $x_i$ and $x$ (See Figure 8), implying that $x = x_i + 2d + k - 1$. Given a specific $d$, we want to compute the number of valid paths that result in $d$ up-steps before the first approach to the boundary. Note that unlike Section 4.3, $d$ is used here to parameterize the (horizontal) $x$-position of the desired point. We will calculate the probability $p_d$ associated with a particular position by counting the total number of paths to the left and right of the first approach and multiplying them together.

As in Section 4.3.2, we define $S_{\text{left}}$ to be the number of paths in the sub-interval before the first approach (left side of Figure 8), $S_{\text{right}}$ to be the number of paths following the first approach, and $S_{\text{total}}$ to be the total number of paths that touch the “mandatory boundary” at $k$ (note that these quantities are functions of $U, D, k$ and $d$, but we drop the parameters for the sake of clarity):

$$S_{\text{left}} = C_k(d, d + k - 2) \quad S_{\text{right}} = C_1(U - d, D - d - k + 1) \quad S_{\text{total}} = C_k(U, D) - C_{k-1}(U, D)$$

Our goal is to generate $d$ from the distribution $\{p_d\}$ where $p_d = S_{\text{left}} \cdot S_{\text{right}} / S_{\text{total}}$. The application of Lemma 11 requires us to approximate $\{p_d\}$ with a “well behaved” $\{q_d\}$ (one whose CDF can be efficiently estimated). Since $q_d$ only needs to approximate $p_d$ up to $\text{poly}(\log n)$ factors, we focus on obtaining $\text{poly}(\log n)$ approximations to the path counts $\{S_{\text{left}}, S_{\text{right}}, S_{\text{total}}\}$. Using Equation 1, we obtain approximations for $S_{\text{left}}$ and $S_{\text{right}}$ (Lemma 31 and Lemma 32 with proofs in Section F.5).

**Lemma 31.** If $d > \log^4 n$, then $S_{\text{left}}(d) = \Theta\left(\frac{2^{2d+k}}{\sqrt{d}} e^{-r_{\text{left}}(d)} \cdot \frac{k-1}{d+k-1}\right)$ where $r_{\text{left}}(d) = \frac{(k-2)^2}{2(2d+k-2)}$. Furthermore, $r_{\text{left}}(d) = O(\log^2 n)$.

**Lemma 32.** If $U + D - 2d - k > \log^4 n$, then $S_{\text{right}}(d) = \Theta\left(\frac{2^{U-D-2d-k}}{\sqrt{U+D-2d-k}} e^{-r_{\text{right}}(d)} \cdot \frac{U-D+k}{U-D+k+1}\right)$ where $r_{\text{right}}(d) = \frac{(U-D-k-1)^2}{4(U+D-2d-k+1)}$. Furthermore, $r_{\text{right}}(d) = O(\log^2 n)$.

Our general strategy will be to integrate continuous versions of these approximations in order to obtain a CDF of some approximating distribution. Unfortunately, the continuous approximation functions obtained do not admit closed form integrals. The main culprit is the exponential term in both expressions. We tackle this issue by noticing that the values of the exponents are bounded by $O(\log^2 n)$ over the majority of the range of $d$. Within this range of $d$ values, the exponential term may be further simplified by taking a piecewise constant approximation, where each of the pieces corresponds to a fixed value of the floor of the corresponding exponent. This technique is elaborated in Section 4.4.4.
Local Access to Huge Random Objects Through Partial Sampling

We start by considering the “problematic” values of \( d \) that are outside the range of the two preceding lemmas. These values are the ones where \( d < \log^4 n \) or \( 2d > U + D - k - \log^4 n \). Since \( d \) is the number of up steps in the left sub-interval, \( d \geq 0 \). Further, since the length of the right sub-interval must be non-negative (see Figure 8), we get \( U + D - 2d - k + 1 \geq 0 \). Thus, we define the “problematic” set:

\[
\mathcal{R} = \{ d \mid 0 \leq d < \log^4 n \text{ or } -1 < 2d - U - D + k < \log^4 n \}
\]  

(4)

Clearly, we can bound the size of this set as \(|\mathcal{R}| = \mathcal{O}(\log^4 n)\). An immediate consequence of Lemma 31 and Lemma 32 is the following.

\[\textbf{Corollary 33.} \quad \text{When } d \notin \mathcal{R}, \text{ } S_{left}(d) \cdot S_{right}(d) = \Theta \left( \frac{\delta^{2U+D}}{\sqrt{d(U+D-2d-k)}} \cdot e^{-r(d)} \cdot \frac{k-1}{d+k-1} \cdot \frac{U-D+k}{U+D+k} \right) \]

where \( r(d) = \mathcal{O}(\log^2 n) \).

4.4.4 Estimating the CDF

We use these observations to construct a suitable \( \{q_d\} \) that can be used to invoke the rejection sampling lemma (Lemma 11). We will achieve this by constructing a piecewise continuous function \( \tilde{q} \), such that \( \tilde{q}(\delta) \) approximates \( p_\delta \), and then use the integral of \( \tilde{q} \) to define the discrete distribution \( \{q_d\} \). As stated in the previous section, we can leverage the fact that when \( d \notin \mathcal{R} \), the floor of the exponent \( |r(d)| \) only takes \( \mathcal{O}(\log^2 n) \) distinct values (consequence of Corollary 33). Since the “problematic” set \( \mathcal{R} \) only has \( \mathcal{O}(\log^4 n) \) values, we can also deal with these remaining values by simply creating \( |\mathcal{R}| \) additional continuous pieces in the function \( \tilde{q} \). We begin by rewriting \( p_d = \Theta \left( \frac{\mathcal{K} \cdot f(d) \cdot e^{-r(d)}}{S_{total}} \right) \) where:

\[
\mathcal{K} = \frac{\rho^{2U+D}}{S_{total}} = \frac{2^{2U+D}}{C_k(U,D) - C_{k-1}(U,D)} \quad f(d) = \frac{c}{\sqrt{dU + D - 2d - k}(d + k - 1)(U + D + k)}
\]  

(5)

Notice that \( \mathcal{K} \) is a constant and \( f(d) \) is a function whose integral has a closed form. Using the fact that \( r(d) = \mathcal{O}(\log^2 n) \) (Corollary 33), and \( |\mathcal{R}| = \mathcal{O}(\log^4 n) \), we obtain the following lemma:

\[\textbf{Lemma 34.} \quad \text{Given the piecewise continuous function} \]

\[
\tilde{q}(\delta) = \begin{cases} 
    p_\delta & \text{if } [\delta] \in \mathcal{R} \\
    \mathcal{K} \cdot f(\delta) \cdot \exp(-|r(\delta)|) & \text{if } [\delta] \notin \mathcal{R}
\end{cases}
\]

\[
\Rightarrow \quad p_d = \Theta \left( \int_0^{d+1} \tilde{q}(\delta) \right)
\]

Furthermore, \( \tilde{q}(\delta) \) has \( \mathcal{O}(\log^4 n) \) continuous pieces.

\[\textbf{Proof.} \quad \text{For } d \in \mathcal{R}, \text{ the integral trivially evaluates to exactly } p_d. \text{ For } d \notin \mathcal{R}, \text{ it suffices to show that } p_d = \Theta \left( \tilde{q}(\delta) \right) \text{ for all } \delta \in [d, d+1]. \text{ We already know that } p_d = \Theta \left( \frac{\mathcal{K} \cdot f(d) \cdot e^{-r(d)}}{S_{total}} \right). \text{ Moreover, for any } \delta \in [d, d+1], \text{ the exponential term } e^{-r([\delta])} \text{ in } \tilde{q}(\delta) \text{ is within a factor of } \mathcal{K} \text{ of the original } e^{-r([\delta])} \text{ term.}
\]

\[\text{For all } \mathcal{O}(\log^4 n) \text{ values } d \in \mathcal{R}, \tilde{q}(\delta) \text{ is constant on the interval } [d, d+1]. \text{ Since } r(d) = \mathcal{O}(\log^2 n) \text{ by Corollary 33, the exponential term } e^{-r([\delta])} \text{ in } \tilde{q}(\delta) \text{ taken on at most } \mathcal{O}(\log^2 n) \text{ values. Thus, } \tilde{q} \text{ is continuous for a range of } \delta \text{ corresponding to a fixed value of } |r([\delta])|, \text{ and so, we conclude that } \tilde{q} \text{ is piecewise continuous with } \mathcal{O}(\log^2 n) \text{ pieces.}
\]

Now, we have everything in place to define the distribution \( \{q_d\} \) that we will be sampling from. Specifically, we will define \( q_d \) and its CDF \( Q_d \) as follows (\( \mathcal{N} \) is the normalizing factor):

\[
q_d = \left( \int_0^{d+1} \tilde{q}(\delta) \right) \cdot \frac{1}{\mathcal{N}} \quad \text{and } Q_d = \left( \int_0^{d+1} \tilde{q}(\delta) \right) \cdot \frac{1}{\mathcal{N}} \quad \text{where } \mathcal{N} = \int_0^{d_{\text{max}}+1} \tilde{q}(\delta)
\]  

(6)
To show that these can be computed efficiently, it suffices to show that any integral of \( \hat{q}(\delta) \) can be efficiently evaluated. This follows from the fact that \( \hat{q} \) is piecewise continuous with \( \mathcal{O}(\log^4 n) \) pieces (Lemma 34), each of which has a closed form integral (since \( f(d) \) defined in Equation 5 has an integral).

\[ \textbf{Lemma 35.} \quad \text{Given the function } \hat{q}_d \text{ defined in Lemma 34, it is possible to approximate the integral } \int_{d_{\min}}^{d_{\max}} \hat{q}(\delta) \text{ to a multiplicative factor of } (1 \pm \frac{1}{n^2}) \text{ in } \text{poly}(\log n) \text{ time for any valid } d_1, d_2 \in \mathbb{Z} \text{ (the bounds must be such that } d_1 \geq 0 \text{ and } U + D - 2d_i - k + 1 \geq 0). \]

\textbf{Proof.} We will compute the integral by splitting it up into \( \mathcal{O}(\log^4 n) \) continuous pieces and then approximating the integral over each piece. The pieces corresponding to values of \( d \in \mathcal{R} \) can be explicitly computed as \( f_{d+1} \hat{q}(\delta) = p_d \) (recall that we can compute \( p_d \) using Lemma 67 from Section F.3).

The more interesting pieces are over the range of \( \delta \) where \( [\delta] \not\in \mathcal{R} \). Such a piece is given by a continuous range of values \([\delta_{\min}, \delta_{\max}] \subseteq [d_1, d_2 + 1] \), such that for any \( \delta \in [\delta_{\min}, \delta_{\max}] \), the value of \( r([\delta]) \) is a constant \( E \). We begin the calculation of \( \hat{q}(\delta) = K \cdot f(\delta) \cdot \exp(-E) \), by first computing a \((1 \pm 1/n^3)\) multiplicative approximation to \( \ln K = (U + D) \ln 2 - \ln S_{\text{total}} \), using the strategy in Lemma 67 (Section F.3). Since \( f(\delta) \) has a closed form integral (Equation 5), we can also compute \( F = \int_{\delta_{\min}}^{\delta_{\max}} f(\delta) \). Using the fact that the exponent is constant over the range \([\delta_{\min}, \delta_{\max}] \), we can write the logarithm of the integral as:

\[
\ln \left( \frac{d_{\max}}{d_{\min}} \hat{q}(\delta) \right) = \ln (K \cdot e^{-E} \cdot F) = (U + D) \cdot \ln 2 - \ln S_{\text{total}} + \ln F - E
\]

If this value is smaller than \(-3 \ln n\), we can safely ignore it since it contributed less than \(1/n^3\) to the probability mass. On the flipside, the logarithm is guaranteed to be bounded by \( \mathcal{O}(1) \). This upper bound is a result of the fact that \( \int \hat{q}(\delta) = \mathcal{O}(\sum p_d) = \mathcal{O}(1) \), where both the sum and the integral are taken over the entire \( \text{valid} \) range of \( d \). This means that we can exponentiate to obtain the true value of the piecewise integral up to a multiplicative approximation of \((1 \pm 1/n^3)\). Adding the integrals of all the \( \mathcal{O}(\log^4 n) \) pieces together produces the final desired value of the integral. \[\blacksquare\]

Now, we are finally ready to use Lemma 11 to sample \( d \) from the distribution \( \{p_d\} \), using the efficient sampling procedure for \( \{q_d\} \). The only other requirement is the ability to approximate the \( p_d \) values, which follows from Lemma 67.

\[ \textbf{Theorem 36.} \quad \text{Given a sub-interval } [x_i, x_{i+1}] \text{ of a random Dyck path of length } 2n, \text{ such that the only determined heights in the interval are } y_i = \text{HEIGHT}(x_i) \text{ and } y_{i+1} = \text{HEIGHT}(x_{i+1}), \text{ and a mandatory boundary constraint at } k, \text{ there exists an algorithm that generates a point } x \text{ within the interval such that } \text{HEIGHT}(x) = y_i - k + 1, \text{ using poly}(\log n) \text{ time, random bits, and additional space}. \]

### 4.4.5 Finding the Correct Interval: First-Return Query

As before, consider all positions that have been queried already \( \langle x_1, x_2, \ldots, x_n \rangle \) (in increasing order) along with their corresponding heights \( \langle y_1, y_2, \ldots, y_m \rangle \). We wish to find the first return to height \( y_i \) after \( x_i \) (where \( y_i = \text{HEIGHT}(x_i) \)). Our strategy begins by using Invariant 30 to find the interval \( I = [x_k, x_{k+1}] \) containing \( \text{FIRST-RETURN}(x_i) \).

\[ \textbf{Lemma 37.} \quad \text{Assuming that Invariant 30 holds, the interval } (x_{j-1}, x_j) \text{ containing FIRST-RETURN}(x_i) \text{ is obtained by setting } j \text{ to be either the smallest index } f > i \text{ such that } y_f \leq y_i \text{ or setting } j - 1 = i. \]
Local Access to Huge Random Objects Through Partial Sampling

Proof. We assume the contrary i.e. there exists some \( k \neq f \) and \( k \neq i + 1 \) such that the correct interval is \( (x_{k-1}, x_k) \). Since \( y_f < y_i \), the position of first return to \( y_i \) happens in the range \( (x_i, x_f) \). So, the only possibility is \( i + 1 < k \leq f - 1 \). By the definition of \( y_f \), we know that both \( y_i \) and \( y_{k-1} \) are strictly larger than \( y_i \). Invariant 30 implies that the boundary for this interval \( (y_{k-1}, y_k) \) is at \( \min(y_{k-1}, y_k) > y_i \). So, it is not possible for the first return to be in this interval.

The good news is that there are only two intervals that we need to worry about, one of which is just the adjacent one \([x_i, x_{i+1})\]. The problem of finding the other interval that may contain the first return boils down to finding the smallest index \( f > i \) such that \( y_f \leq y_i \). To this end, we define \( M_{[a, b]} \) as the minimum determined height in the range of positions \([a, b]\).

One solution is to maintain a range tree \( R \) [14] over the range \([2n]\). Assuming that \( 2n = 2^l \), we can view \( R \) as a complete binary tree with depth \( r \). Every non-leaf node is denoted by \( R_{[a, b]} \), and corresponds to a range \([a, b] \subseteq [2n]\) that is the union of the ranges of its children. Each \( R_{[a, b]} \) stores the value \( M_{[a, b]} \) which is the minimum determined height in the range of positions \([a, b]\), or \( \infty \) if none of the heights have been revealed. The leaf nodes are denoted as \( \{R_i\}_{i \in [2n]} \), and correspond to the singleton range corresponding to position \( i \in [2n] \). Note that a node at depth \( l' \) will correspond to a range of size \( 2^{l-l'} \), with the root being associated with the entire range \([2n]\).

We say that the range \([a, b]\) is canonical if it corresponds to a range of some \( R_{[a, b]} \) in \( R \). By the property of range trees, any arbitrary range can be decomposed into a disjoint union of \( O(\log n) \) canonical ranges. We implement \( R \) to support the following operations:

\[ \text{\bf Update}(x, y): \text{Update the height of the position } x \text{ to } y. \]

This update affects all ranges \([a_i, b_i]\) containing \( x \). So, for each \([a_i, b_i]\) we set \( M_{[a_i, b_i]} = \min(M_{[a_i, b_i]}, y) \).

\[ \text{\bf Query}(a, b): \text{Return the minimum boundary height in the range } [a, b]. \]

We decompose \([a, b]\) into \( O(\log n) \) canonical ranges \([r_1, r_2, \cdots]\), and return the minimum of all the \( M_{r_i} \) values as \( M_{[a, b]} \) (since \([a, b]\) is the union of all \( r_i \)).

Now, we can binary search for \( f \) by guessing a value \( f' \) and checking if \( \text{\bf Query}(x_i, x_{f'}) \leq y_i \). Overall, this requires \( O(\log n) \) calls to \( \text{\bf Query} \), each of which makes \( O(\log n) \) probes to the range tree. To avoid an initialization overhead, we only create the node \( R_{[a, b]} \) during the first \( \text{\bf Update} \) affecting a position \( x \in [a, b] \). Since a call to \( \text{\bf Update} \) can create at most \( O(\log n) \) new nodes in \( R \), the additional space required for each \( \text{\bf Height} \) or \( \text{\bf First-Return} \) query is still bounded.

\[ \text{\bf Theorem 38.} \text{There is an algorithm using } O(\log^C n) \text{ resources per query that provides access to a random Dyck path of length } 2n, \text{by answering queries of the form } \text{\bf First-Return}(x) \text{ with the correctly sampled smallest position } x' > x_i, \text{where the Dyck path first returns to } \text{\bf Height}(x_i). \]
Proof. In order to make the presentation simpler, we ensure that the next determined position after $x_i$ is $x_i + 1$ (in other words $x_{i+1} = x_i + 1$). This can be done by invoking $\textsc{Height}(x_i + 1)$, if needed. If $\textsc{Height}(x_i + 1) = y_{i+1} < y_i$, we can terminate because $\textsc{First-Return}(x_i)$ is not defined. Otherwise, we notice that in this setting, the first return cannot lie in the adjacent interval $[x_i, x_{i+1}] = [x_i, x_i + 1]$.

Hence, we proceed to finding the smallest value $f$ such that $y_f \leq y_i$, by using the range tree data structure described above. Since $\textsc{Height}(x_{f-1}) > y_i \leq \textsc{Height}(x_f)$ by definition, the interval $(x_{f-1}, x_f]$ must contain at least one position at height $y_i$. We determine the height at the midpoint of this interval, and then fix the potential violation of Invariant 30 by finding another point along with its height. This essentially breaks up the interval $[x_{f-1}, x_f]$ into $O(1)$ sub-intervals, each at most half the size of the original. Based on the newly revealed heights, we again find the (newly created) sub-interval containing the first return in $O(1)$ time. We repeat up to $O(\log n)$ times, reducing the size of the intervals in consideration, until the position of the first return is revealed.

4.4.6 Maintaining Height Queries under Invariant 30

Finally, we show that the boundary constraints introduced in order to maintain Invariant 30 do not interfere with the implementation of $\textsc{Height}$ queries. As before, we consider the currently revealed heights $(y_1, y_2, \ldots, y_m)$, along with the corresponding positions $(x_1, x_2, \ldots, x_n)$ (in increasing order). Say that we are now presented with a query $\textsc{Height}(x)$, where $x_i < x < x_{i+1}$. As in Section 4.3, we swap $x_i$ and $x_{i+1}$ if necessary in order to ensure that $y_i < y_{i+1}$. Due to Invariant 30, we know that the lowest achievable height in the interval $[x_i, x_{i+1}]$ is $y_i$, i.e. the boundary constraint for the left half becomes $k = 1$ instead of $k = y_i + 1$, since the constrained boundary is at height $y_i$. Similarly, the boundary constraint for the right half becomes $k' = 2U - 2D + 1$.

The algorithm for determining the height at the midpoint $x_{mid}$ of $[x_i, x_{i+1}]$ can proceed as described in Section 4.3. Of course, in this scenario, the boundary is never far away, and therefore we should always use the strategy in Section 4.3.2. The second step is to re-establish Invariant 30 in the newly created sub-interval $[x_{mid}, x_{i+1}]^4$, using the two step strategy from Section 4.4.1. This involves determining the height of one additional point $x' \in [x_{mid}, x_{i+1}]$. Finally, we can continue with the height sampling algorithm from Theorem 29, by recursively halving one of the newly created intervals (the one containing $x$). Figure 10 illustrates the aforementioned three steps.

Hence, we can combine results from Theorem 29 and Theorem 38 to obtain the following:

- **Theorem 6.** There is an algorithm using $O(\log n)$ resources per query that provides access to a uniformly random Dyck path of length $2n$ by implementing the following queries:
  - $\textsc{Height}(t)$ returns the position of the walk after $t$ steps.
  - $\textsc{First-Return}(t)$: If $\textsc{Height}(t + 1) > \textsc{Height}(t)$, then $\textsc{First-Return}(t)$ returns the smallest index $t'$, such that $t' > t$ and $\textsc{Height}(t') = \textsc{Height}(t)$ (i.e. the first time the Dyck path returns to the same height). Otherwise, if $\textsc{Height}(t + 1) < \textsc{Height}(t)$, then $\textsc{First-Return}(t)$ is not defined.

\footnote{Note that the invariant is not broken for the $[x_i, x_{mid}]$ sub-interval since $y_i + 1$ was the original boundary constraint. In general, the invariant will be automatically preserved for one of the sub-intervals; the side corresponding to $\min(y_i, y_{i+1})$.}
Performing $\text{Height}$ queries while maintaining Invariant 30. The first step is to determine the height at the midpoint $x_{\text{mid}}$ of an existing interval $[x_i, x_{i+1}]$ that contains $x$. Next, we re-establish Invariant 30 by sampling an additional point $x'$ within the violating interval. Finally, we recurse on the appropriate sub-interval (yellow box).

4.4.7 Reverse-First-Return Queries

For the sake of completeness, we also sketch how to implement a Reverse-First-Return query, which is just a standard First-Return query on the reversed Dyck path. This type of query was motivated in Section 4.1, and can be applied to positions $x$ where $\text{Height}(x-1) = \text{Height}(x) + 1$.

Note that Invariant 30 remains unchanged as it is symmetric to reversal of the Dyck path. Specifically, the invariant on a particular interval does not change if we swap the endpoints of the interval. First, we can find the correct interval containing Reverse-First-Return$(x_i)$, by using an analog of Lemma 37.

Lemma 39. Assuming Invariant 30, the interval $[x_j, x_{j+1})$ containing Reverse-First-Return$(x_i)$ is obtained by setting $j$ to be either the largest index $f < i$ such that $y_f \leq y_i$ or setting $j+1 = i$.

Since the range tree defined in Section 4.4.5 allows us to query the minimum in arbitrary contiguous ranges, we can also use it to find the appropriate $f$ for Lemma 39 through binary search. Once we have found an interval that is known to contain the Reverse-First-Return, we can follow the strategy from the proof of Theorem 38: recursively sub-dividing the relevant interval and finding the newly created sub-interval that contains the return, until we converge on the correct return position.

5 Random Coloring of a Graph

A valid $q$-coloring of a graph $G = (V, E)$ is a vector of colors $X \in [q]^V$, such that for all $(u, v) \in E$, $X_u \neq X_v$. We present a sub-linear time algorithm to provide local access to a uniformly random valid $q$-coloring of an input graph. Specifically, we implement $\text{Color}(v)$, which returns the color $X_v$ of node $v$, where $X$ is a uniformly random valid coloring. The implementation can access the input graph $G$ through a sub-linear number of neighborhood queries. A neighborhood query of the form All-Neighbors$(v)$ returns a list of neighbors of $v$. The implementation can also access a tape of public random bits $R$.

Moreover, multiple independent instances of $\text{Color}$ that are given access to the same public tape of random bits $R$, should output color values consistent with a single $X$, regardless of the order and content of the queries received. Unlike our previous results, the choice of
X only depends on R, and the color implementations do not need to use any additional memory to maintain consistency. For a formal description of this model, see Definition 10. This model is essentially a generalization of Local Computation Algorithms \[48\]. Given a computation problem with input x and a set of valid outputs \(F(x)\), LCAs provide query access to some \(y \in F(x)\) using only a sub-linear number of probes to x. This makes it feasible to consider sub-linear algorithms for problems where the output size is super-linear. Our model has the additional restriction that the output must be drawn uniformly at random from \(F(x)\), rather than just being an arbitrary member. Since the number of possible outputs (\(|F(x)|\)) may be exponential, it is not possible to encode all the requisite random bits in sub-linear space. Therefore, we use a source of public randomness \(R\).

Sequential Algorithm for Random Coloring

We consider graphs with max degree \(\Delta\), and \(q = \Theta(\Delta)\), since this is the regime where this problem is feasible \[22\]. In the sequential setting, \[22\] used the technique of path coupling to show that for \(q > 2\Delta\), one can sample an uniformly random coloring by using a simple Markov chain. The Markov chain proceeds in \(T\) steps. The state of the chain at time \(t\) is given by \(X_t \in [q]^{|V|}\). Specifically, the color of vertex \(v\) at step \(t\) is \(X_t^v\). In each step of the Markov process, a vertex and a color are sampled uniformly at random i.e. a pair \((v, c) \sim U(V \times [q])\). Subsequently, if the recoloring of vertex \(v\) with color \(c\) does not result in a conflict with \(v\)'s neighbors, i.e. \(c \notin \{X_t^u : u \in \Gamma(v)\}\), then the vertex is recolored i.e. \(X_{t+1}^v \leftarrow c\). After running this chain for \(T = O(n \log(n/\epsilon))\) steps, the Markov chain is mixed, implying that the distribution of resulting colors is \(\epsilon\) close to the uniform distribution in \(L_1\) distance.

5.1 Modified Glauber Dynamics based on a Distributed Algorithm

Now we define a modified Markov chain as a special case of the Local Glauber Dynamics presented in \[20\]. The modified Markov chain proceeds in epochs. We denote the initial coloring of the graph by the vector \(X^0\) and the state of the coloring after the \(k\)th epoch by \(X^k\). In the \(k\)th epoch, every node attempts to recolor itself simultaneously in a conservative manner, as described below:

- Sample \(|V|\) colors \((c_1, c_2, \cdots, c_n)\) from \([q]\), where \(c_v\) is the color proposed by vertex \(v\).
- For each vertex \(v\), we set \(X^k_v\) to \(c_v\), if and only if for all neighbors \(w\) of \(v\), \(X^{k-1}_w \neq c_v\) and \(c_w \neq c_v\). Specifically, a vertex \(v\) is recolored if and only if its proposed color \(c_v\) does not conflict with any of it’s neighbors current colors (at the end of the previous epoch), or their current proposals.

This procedure is a special case of the Local Glauber Dynamics, which was presented in \[20\] as a distributed algorithm for sampling a random coloring.\(^5\) In the distributed setting, our epochs correspond to synchronous rounds, where many vertices recolor themselves simultaneously.

In order to bound the mixing time of this Markov chain, \[20\] uses the standard technique of path coupling, introduced in \[8\]. The argument begins by considering two initial states of the Markov Chains, say two colorings \(X^0\) and \(Y^0\), that differ at only one vertex. Formally, we can define the distance between two colorings \(d(X, Y)\) as the number of vertices \(v\) such

\(^5\)Note that \[20\] also uses a marking probability \(\gamma\), which indicates the likelihood of any vertex participating in a given round. For our purposes, it suffices to set \(\gamma = 1\).
that $X_v \neq Y_v$, which results in the condition $d(X^0, Y^0) = 1$. A coupling is a joint evolution rule for a pair of states $(X^0, Y^0) \rightarrow (X^1, Y^1)$, such that both of the individual evolutions $(X^0 \rightarrow X^1)$ and $(Y^0 \rightarrow Y^1)$ have the same transition probabilities as the original Markov Chain. We can directly use the result from the coupling defined in [20].

- Lemma 40. If $q = 2a\Delta$, then there exists a coupling $(X^0, Y^0) \rightarrow (X^1, Y^1)$, such that if $d(X^0, Y^0) = 1$, then $E[d(X^1, Y^1)] \leq 1 - (1 - \frac{1}{2a}) e^{-3/\alpha} + \frac{1/2\alpha}{1-1/\alpha}$.

- Corollary 41. If $q \geq 9\Delta$ and $d(X^0, Y^0) = 1$, then $E[d(X^1, Y^1)] < \frac{1}{e^{1/2\alpha}}$.

The path coupling lemma from [8] uses a coupling on adjacent states to bound the mixing time.

- Lemma 42 (Simplified Path Coupling from [8]). If there exists a coupling $(X^0, Y^0) \rightarrow (X^1, Y^1)$ defined for states where $d(X^0, Y^0) = 1$, such that $E[d(X^1, Y^1) | X^0, Y^0] \leq \beta$ (for $\beta < 1$), then, the mixing time $\tau_{mix}(\epsilon) = O((n\epsilon^{-1})/\ln \beta^{-1})$.

- Corollary 43. If $q \geq 9\Delta$, then the chain is mixed after $\tau_{mix}(\epsilon) = 3(\ln n + \ln(\frac{1}{\epsilon}))$ epochs.

### 5.1.1 Naive Reduction from Distributed Algorithms

Using the technique of Parnas and Ron [46], one can modify a distributed algorithm for a graph problem to construct a Local Computation Algorithm for the same problem. Specifically, given a $k$-round distributed algorithm on a network of max degree $\Delta$, we can simulate the behaviour and outcome of a single node $v$ by simulating the full algorithm on the $k$-neighborhood of $v$. The simulation only requires us to probe this $k$-neighborhood, which contains $O(\Delta^k)$ nodes. However, the aforementioned distributed algorithm for Glauber Dynamics used $O(\log n)$ rounds, implying a probe complexity of $\Delta^{O(\log n)}$, which is super-linear. We show how to reduce the probe complexity by appropriately pruning the $k$-neighborhood.

### 5.2 Local Coloring Algorithm

Given query access to the adjacency matrix of a graph $G$ with maximum degree $\Delta$ and a vertex $v$, the algorithm has to output the color assigned to $v$ after running $t = O(\ln n)$ epochs of Modified Glauber Dynamics. We want to be able to answer such queries in sub-linear time, without simulating the entire Markov Chain. We will define the number of colors as $q = 2a\Delta$ where $a > 1$.

The proposals at each epoch are a vector of color samples $C^t \sim \mu_{[q]^n}$, where $C^t_v$ is the color proposed by $v$ in the $t$th epoch. Since each of these $C^t_v$ values are independent uniform samples from $[q]$, instances of our algorithm will be able to access them in a consistent manner using the public random bits $R$.

We also use $X^t$ to denote the final vector of vertex colors at the end of the $t$th epoch. Finally, we define indicator variables $\chi^t_v$ to indicate whether the color $C^t_v$ proposed by vertex $v$ was accepted at the $t$th epoch: $\chi_v^t = 1$ if and only if for all neighbors $w \in \Gamma(v)$, we satisfy the condition $C^t_v \neq X_{w}^{t-1}$ and $C^t_w \neq C^t_w$ (i.e. the proposed color does not conflict with any neighboring proposal or any neighbor’s color from the preceding epoch). So, the color of a vertex $v$ after the $t$th epoch $X_v^t$ is set to be $C^t_v$ where $i \leq t$ is the largest index such that $\chi^t_v = 1$. While the proposals $C^t_v$ can simply be read off the public random tape $R$, it is not clear how we can determine the $\chi^t_v$ values efficiently. Computing $X^t_v$ is quite simple if we know the values $\chi^t_i$ for all $i \leq t$. So, we focus our attention on the query ACCEPTED($v, t$) that returns $\chi^t_v$. 
5.2.1 Local Access to an Initial Valid Coloring

One caveat that we have not addressed is how we should initialize the Markov Chain. The starting state can be any valid coloring of $G$, but we have to be able to access the initial colors of requisite vertices in sub-linear time. One option is to simply assume that we have oracle access to an arbitrary valid coloring. We can also invoke a result from [10] that provides a Local Computation Algorithm for $(\Delta + 1)$-coloring of a graph. Specifically, they provide local access to the color of any vertex using $O(\Delta \log n)$ queries to the underlying graph, such that the returned colors are consistent with some valid coloring. Integrating their routine into our algorithm incurs a multiplicative poly$(\Delta)$ overhead for each query.

Another option is to (uniformly) randomly initialize the colors of the vertex independently of its neighbors. Although the initial coloring may be invalid, one can show that with high probability, the final coloring after running the Markov Chain is valid. The intuitive reasoning is that each vertex attempts to recolor itself $O(\log n)$ times, and each attempt succeeds with constant probability at least $1 - 1/\alpha$ (Lemma 44). Furthermore, we can union bound to claim that all the vertices get re-colored at least once with high probability. After a vertex is re-colored once, it can no longer be in conflict with any of its neighbor’s colors, and therefore we obtain a final coloring that is valid. For the sake of simplicity, we will assume that our algorithm can access the initial colors of any vertex $v$ through a public $C^0_v$.

5.2.2 Naive Coloring Implementations

Our general strategy to determine $\chi^t_v$ will be to check for all neighbors $w$ of $v$, whether $w$ causes a conflict with $v$’s proposed color in the $t^{th}$ epoch. One naive way to achieve this, is to iterate backwards from epoch $t$, querying to find out whether $w$’s proposal was accepted, until the most recent accepted proposal (latest epoch $t' < t$ such that $\chi^{t'}_w = 1$) is found. At this point, if $C^t_w = C^t_v$, then the current color of $w$ conflicts with $v$’s proposal. Otherwise there is no conflict, and we can proceed to the next neighbor. However, this process potentially makes $\Delta$ recursive calls to a sub-problem that is only slightly smaller i.e. $T(t) \leq \Delta \cdot T(t-1)$. This leads to a running time upper bound of $\Delta^t$ which is superlinear for the desired number of epochs $t = \Omega(\log n)$ (the mixing time).

We can prune the number of recursive calls by only processing the neighbors $w$ which actually proposed the color $C^t_v$ during some epoch. In this case, the expected number of neighbors that have to be probed recursively is less than $t\Delta/q$ (since the total number of neighbor proposals over $t$ epochs is at most $t\Delta$, and there are $q$ possible colors). So, the overall runtime is upper bounded by $(t\Delta/q)^t$. For this algorithm, if we allow $q > t\Delta = \Omega(\Delta \log n)$ colors, the runtime becomes sub-linear. So, we can use this simple algorithm only when $q$ is sufficiently large. However, we want a sub-linear time algorithm for $q = \mathcal{O}(\Delta)$.

5.2.3 A Sub-linear Time Algorithm for $q = \mathcal{O}(\Delta)$

The expected number of neighbors that need to be checked recursively can always be $t\Delta/q$ in the worst case. The crucial observation is that even though these recursive calls seem unavoidable, we can aim to reduce the size of the recursive sub-problem, and thus bound the number of levels of recursion.

Algorithm 5 shows our final procedure for generating $\chi^t_v$, where $c = C^t_v$ is $v$’s proposal at epoch $t$. We iterate through all neighbors $w$ of $v$, checking for conflicts (Line 3). The condition $c \neq C^t_w$ can be checked by reading $C^t_w$ off the public random tape (Line 4). If no conflict is seen, we proceed to check whether $c \neq X^{t-1}_w$. 
To achieve this, we iterate through all the epochs in reverse order (line 6) to check whether the color $c$ was ever proposed for vertex $w$. If not, we can ignore $w$. Otherwise let’s say that the most recent proposal for $c$ was at epoch $t’$ i.e. $C^t_w = c$. Now, we directly “jump” to the $(t’)$th epoch and recursively check if this proposal was accepted (line 7). If the proposal $C^t_w$ was not accepted, we keep iterating back in time until we find the next most recent epoch when $c$ was proposed by $w$, or until we run out of epochs. When we find the most recent epoch $t’$ in which $c$ was accepted i.e. $\chi^t_w = 1$, we successively consider epochs $t’ + 1, t’ + 2, t’ + 3, \ldots, t - 1$, to see whether, the color $c$ was overwritten (line 9) by an accepted proposal in a future epoch. This is done by recursively invoking $\text{Accepted}(w, t’)$ in order to compute $\chi^t_{w,t}$. If at any of these subsequent iterations, we see that a different proposal was accepted (thus overwriting the color $c$), then neighbor $w$ does not cause a conflict, and we can move on to the next neighbor. Otherwise, we have seen that $\chi^t_w = 1$ (color $c$ was accepted) and every subsequent proposal until the current epoch $t$ was rejected; this implies that color $c$ survived as the color of neighbor $w$, i.e. $\chi^{t-1}_w = c$. This leads to a conflict with $v$’s current proposal for color $c$ (line 14) and hence $\chi^t_v = 0$. If we exhaust all the neighbors and don’t find any conflicts (line 16) then $\chi^t_v = 1$.

Now we analyze the runtime of $\text{Accepted}$ by constructing and solving a recurrence relation. We will use the following lemma to evaluate the expectation of products of relevant random variables.

▶ **Lemma 44.** The probability that any given proposal is rejected $P[\chi^t_v = 0]$ is at most $1/\alpha$. Moreover, this upper bound holds even if we condition on all the values in $\mathbf{C}$ except $C^t_v$.

**Proof.** A rejection can occur due to a conflict with at most $2\Delta$ possible values in $\{C^t_w, \chi^{t-1}_w | w \in \Gamma(v)\}$. Since there are $2\alpha\Delta$ colors, the rejection probability is at most $1/\alpha$.

▶ **Definition 45.** We define $T_i$ to be a random variable indicating the number of recursive calls performed during the execution of $\text{Accepted}(v, t)$ while computing a single $\chi^t_v$. 

---

**Algorithm 5** Checking if proposal is accepted.

```
1: procedure Accepted(v, t) ▷ Find the current proposal using the public random bits
2:   c ← C^t_v
3:   for w ← Γ(v) ▷ Iterate through the neighbors, checking for conflicts
4:      if C^t_w = c ▷ Check for conflict with neighbor’s current proposal
5:         return 0
6:   for t’ ← [t, t−1, t−2, · · · , 1, 0] ▷ Check for conflict with neighbor’s prior state
7:      if C^t_w = c and Accepted(w, t’) ▷ Potential conflict with neighbor’s color
8:         overwritten ← false ▷ Check if color c is overwritten by a future proposal
9:      for ˜t ← [t’+1, t’+2, t’+3, · · · , t-1]
10:         if Accepted(w, ˜t)
11:            overwritten ← true
12:            break
13:   if not overwritten ▷ Conflict! This proposal is not accepted
14:      return 0
15:   break
16: return 1 ▷ No conflicts! This proposal is accepted
```
Definition 46. We define $W_{t'}^i$ to be a random variable indicating the number of calls to \textsc{Accepted} that are required, to check whether a color $c$ assigned at epoch $t'$ was overwritten at some epoch before $t$.

Using $\mathcal{B}(p)$ to denote the Bernoulli random variable with bias $p$, we obtain an expression for $W_{t'}^i$ (using $\leq$ to denote stochastic dominance).

$$W_{t'}^i \leq T_{t'+1} + \mathcal{B} \left( \frac{1}{\alpha} \cdot T_{t'+2} \right) + \mathcal{B} \left( \frac{1}{\alpha^2} \cdot T_{t'+3} \right) + \cdots + \mathcal{B} \left( \frac{1}{\alpha^{t-t+t-2}} \cdot T_{t-t} \right) \tag{7}$$

The above Equation 7 conservatively assumes that the call to \textsc{Accepted}(v, t' + 1) in line 10 is always invoked (resulting in $T_{t'+1}$ invocations of \textsc{Accepted}). However, the next call to \textsc{Accepted}(v, t' + 2) occurs only if the previous one was not accepted, which happens with probability $\leq 1/\alpha$ (Lemma 44). This produces the $\mathcal{B}(1/\alpha) \cdot T_{t'+2}$ term in the expression.

Next, we prove our main lemma that bounds the number of recursive calls to \textsc{Accepted}.

Lemma 47. Given graph $G$ and $q = 2\alpha \Delta$ colors, for $\alpha > 4.5$, the expected number of recursive calls to the procedure \textsc{Accepted} while computing a single $\chi_v = \text{\textsc{Accepted}}(v, t)$ is $\mathbb{E}[T_i] = \mathcal{O}(q^{1+1/\alpha})$.

Proof. We start by constructing a recurrence for the expected number of calls to \textsc{Accepted} used by the algorithm. When checking a single neighbor $w$, the algorithm iterates through all the epochs $t'$ such that $C_{w}^{t'} = c$ (in reality, only the last occurrence matters, but we are looking for an upper bound). If such a $t'$ is found (which happens with probability $1/q$ independently for each trial), there is a recursive call to \textsc{Accepted}(w, t'), which in turn results in $T_{t'}$ recursive calls to \textsc{Accepted}. If we find that $\chi_v = 1$ (i.e. $w$ was colored to $c$ at epoch $t'$), we will need to proceed to check whether the color was subsequently overwritten, which requires an additional $W_{t'}^i$ calls to \textsc{Accepted}. Summing up over all neighbors and epochs, we obtain the following bound:

$$T_i \leq \sum_{w \in \Gamma(v)} \sum_{t'=1}^{t} P[C_{w}^{t'} = c] \cdot [T_{t'} + W_{t'}^i] \tag{8}$$

$$\leq \Delta \cdot \sum_{t'=1}^{t} \mathcal{B} \left( \frac{1}{q} \right) \cdot \left[ T_{t'} + T_{t'+1} + \mathcal{B} \left( \frac{1}{\alpha} \right) \cdot T_{t'+2} + \mathcal{B} \left( \frac{1}{\alpha^2} \right) \cdot T_{t'+3} + \cdots \right. \tag{9}$$

$$\left. + \mathcal{B} \left( \frac{1}{\alpha^{t-t+t-2}} \right) \cdot T_{t-t} \right]$$

$$\leq \Delta \cdot \mathcal{B} \left( \frac{1}{q} \right) \cdot \left[ \sum_{t'=1}^{t-1} T_{t'} + \sum_{t'=1}^{t-1} T_{t'} \cdot \left( 1 + \frac{1}{\alpha} + \frac{1}{\alpha^2} + \cdots \right) \right] \tag{10}$$

In the last step, we just grouped together all the terms corresponding to the same epoch (note that we include additional terms since it’s an upper bound). Using Lemma 44 and the fact that $P[C_{w}^{t'} = c]$ is independent of all other events, we can write a recurrence for the expected number of probes.

$$\mathbb{E}[T_i] \leq \Delta \cdot \frac{1}{2\alpha} \left[ \sum_{t'=1}^{t-1} T_{t'} + \sum_{t'=1}^{t-1} T_{t'} \cdot \left( 1 + \frac{1}{\alpha} + \frac{1}{\alpha^2} + \cdots \right) \right] \leq \frac{1}{2\alpha} \cdot \sum_{t'=1}^{t-1} T_{t'} \cdot \left[ 1 + \frac{\alpha}{\alpha - 1} \right] \tag{11}$$
Now, we make the assumption that $E[T_i] \leq e^{kt/\alpha}$, and show that this satisfies the expectation recurrence for the desired value of $k$. First, we sum the geometric series:

$$\sum_{r'=1}^{t-1} E[T_{r'}] = \sum_{r'=1}^{t-1} e^{kt'/\alpha} < \frac{e^{kt/\alpha} - 1}{e^{k/\alpha} - 1}$$

The expectation recurrence to be satisfied then becomes:

$$E[T_i] \leq \frac{1}{2\alpha} \cdot \frac{e^{kt/\alpha}}{e^{k/\alpha} - 1} \cdot \left[ 1 + \frac{\alpha}{\alpha - 1} \right] = e^{kt/\alpha} \cdot \frac{2\alpha - 1}{2\alpha(\alpha - 1)(e^{k/\alpha} - 1)} = e^{kt/\alpha} \cdot f(\alpha, k)$$

We notice that for $k = 1.02$ and $\alpha > 4.5$, $f(\alpha) < 1$. This can easily be verified by checking that $f(\alpha, 1.02)$ decreases monotonically with $\alpha$ in the range $\alpha > 4.5$. Thus, our recurrence is satisfied for $k = 1.02$, and therefore the expected number of calls is $O(e^{1.02t/\alpha})$.

▶ Theorem 7. Given neighborhood query access to a graph $G$ with $n$ nodes, maximum degree $\Delta$, and $q = 2\alpha \Delta \geq 9\Delta$ colors, we can generate the color of any given node from a distribution of color assignments that is $\epsilon$-close (in $L_1$ distance) to the uniform distribution over all valid colorings of $G$, in a consistent manner, using only $O((n/\epsilon)^{3.06/\alpha} \Delta \log(n/\epsilon))$ time, probes, and public random bits per query.

Proof. Since $q \geq 9\Delta$, we can use Corollary 43 to obtain $\tau_{mix}(\epsilon) \leq 3(ln n + ln 1/\epsilon)$. Also, since $\alpha > 4.5$, we can invoke Lemma 47 to conclude that the number of calls to ACCEPTED is $O(n^{3.06/\alpha} \epsilon^{-3.06/\alpha})$. Finally, we note that each call to ACCEPTED($v, t$) potentially reads $O(t\Delta)$ color proposals from the public random tape, while iterating through all $\leq \Delta$ neighbors of $v$ in all $t$ epochs. Since $t \leq 3 ln(n/\epsilon)$, this implies that the algorithm uses $O((n/\epsilon)^{3.06/\alpha} \Delta \log(n/\epsilon))$ time and random bits, which is sub-linear for $\alpha > 3.06$.

6 Open Problems

There are many interesting directions to pursue in this area. Below, we provide a few examples of random objects that may admit local access implementations.

Small Description Size

- Provide a local access implementation of degree queries for undirected random graphs, even for $G(n, p)$. How about $i$th neighbor queries?
- For simple models such as $G(n, p)$, provide a local access implementation of a RANDOM-Trianglev) query, that returns a uniformly random triangle containing vertex v.
- Provide a memory-less local access implementation of basic queries for undirected random graphs.
- Given an ordered graph such as a lattice, provide an implementation to locally access a random perfect matching. Interesting special cases of this problem include random domino and lozenge tilings.

Huge Description Size

- Provide a faster local access implementation for sampling the color of a specified vertex in a random $q$-coloring of a bounded degree graph $G$.
- Improve the local access implementation for sampling the color of a specified vertex in a random $q$-coloring of $G$, by supporting smaller values of $q$ (smaller than $9\Delta$). We remark that this problem in particular should be feasible, by simulating a faster mixing Markov chain. The important question is whether you can you get down to $q = 2\Delta$?
Given query access to an input graph $G$ and starting vertex $v$, provide a local access implementation for sampling the location of a random walk starting at $v$ after $t$ steps. This may be feasible in certain restricted classes of graphs.

Given query access to an input DNF formula, provide an implementation to access the truth value of a single variable in a uniformly random satisfying assignment.

A Further Analysis and Extensions of Algorithm 1: Sampling Next-Neighbor without Blocks

A.1 Performance Guarantee

This section is devoted to showing the following lemma that bounds the required resources per query of Algorithm 1. We note that we only require efficient computation of $\prod_{u \in [a, b]} (1 - p_{vu})$ (and not $\sum_{u \in [a, b]} p_{vu}$), and that for the $G(n, p)$ model, the resources required for such computation is asymptotically negligible.
As mentioned earlier, we allow any sequence of probabilities $X_{vu}$'s, but also the unused coins $C_{vu}$'s. We characterize the two collections of Bernoulli variables $\{X_{vu}\}$ and $\{Y_{vu}\}$ that cover all random choices made by Algorithm 1 as follows.

- Each $X_{vu}$ (same as $X_{uv}$) represents the result for the first coin-toss corresponding to cells $A[v][u]$ and $A[u][v]$, which is the coin-toss obtained when $X_{vu}$ becomes decided: either $C_{vu}$ during a $\text{Next-Neighbor}(v)$ call when $A[v][u] = \phi$, or $C_{vu}$ during a $\text{Next-Neighbor}(u)$ call when $A[u][v] = \phi$, whichever occurs first. This description of $X_{vu}$ respects our invariant that, if the generation process is executed to completion, we will have $A[v][u] = X_{vu}$ in all entries.

- Each $Y_{vu}$ represents the result for the second coin-toss corresponding to cell $A[v][u]$, which is the coin-toss $C_{vu}$ obtained during a $\text{Next-Neighbor}(v)$ call when $X_{vu}$ is already decided. In other words, $\{Y_{vu}\}$'s are the coin-tosses that should have been skipped but still performed in Algorithm 1 (if they have indeed been generated). Unlike the previous case, $Y_{vu}$ and $Y_{uv}$ are two independent random variables: they may be generated during a $\text{Next-Neighbor}(v)$ call and a $\text{Next-Neighbor}(u)$ call, respectively.

As mentioned earlier, we allow any sequence of probabilities $p_{vu}$ in our proof. The success probabilities of these indicators are therefore given by $P[X_{vu} = 1] = P[Y_{vu} = 1] = p_{vu}$.

### Characterizing iterations

Suppose that we compute $\text{Next-Neighbor}(v)$ and obtain an answer $u$. Then $X_{v,\text{last}[v]+1} = \cdots = X_{v,u-1} = 0$ as none of $u' \in (\text{last}[v], u)$ is a neighbor of $v$. The vertices considered in the loop of Algorithm 1 that do not result in the answer $u$, are $u' \in (\text{last}[v], u)$ satisfying $A[v][u'] = 0$ and $Y_{v,u'} = 1$; we call the iteration corresponding to such a $u'$ a failed iteration. Observe that if $X_{v,u'} = 0$ but is undecided ($A[v][u'] = \phi$), then the iteration is not failed, even if $Y_{v,u'} = 1$ (in which case, $X_{v,u'}$ takes the value of $C_{v,u'}$ while $Y_{v,u'}$ is never used).

Thus we assume the worst-case scenario where all $X_{v,u'}$ are revealed: $A[v][u'] = X_{v,u'} = 0$ for all $u' \in (\text{last}[v], u)$. The number of failed iterations in this case stochastically dominates those in all other cases.\(^6\)

---

\(^6\)There exists an adversary who can enforce this worst case. Namely, an adversary that first makes $\text{Next-Neighbor}$ queries to learn all neighbors of every vertex except for $v$, thereby filling out the whole $A$ in the process. The claimed worst case then occurs as this adversary now repeatedly makes $\text{Next-Neighbor}$ queries on $v$. In particular, a committee of $n$ adversaries, each of which is tasked to perform this series of calls corresponding to each $v$, can always expose this worst case.
Then, the upper bound on the number of failed iterations of a call \textsc{Next-Neighbor}(v) is given by the maximum number of cells \( Y_{v,u} = 1 \) of \( u' \in \text{last}[v,u] \), over any \( u \in \text{last}[v,u] \) satisfying \( X_{v,u} \cdot \text{last}[v,u] = \cdots = X_{vu} = 0 \). Informally, we are asking “of all consecutive cells of 0’s in a single row of \( \{X_{vu}\}\)-table, what is the largest number of cells of 1’s in the corresponding cells of \( \{Y_{vu}\}\)-table?”

\section*{Bounding the number of iterations required for a fixed pair \((v, \text{last}[v])\)}

We now proceed to bounding the number of iterations required over a sampled pair of \( \{X_{vu}\} \) and \( \{Y_{vu}\} \), from any probability distribution. For simplicity we renumber our indices and drop the index \((v, \text{last}[v])\) as follows. Let \( p_1, \ldots, p_L \in [0,1] \) denote the probabilities corresponding to the cells \( A[v][\text{last}[v] + 1 \ldots n] \) (where \( L = n - \text{last}[v] \)), then let \( X_1, \ldots, X_L \) and \( Y_1, \ldots, Y_L \) be the random variables corresponding to the same cells on \( A \).

For \( i = 1, \ldots, L \), define the random variable \( Z_i \) in terms of \( X_i \) and \( Y_i \) so that

- \( Z_i = 2 \) if \( X_i = 0 \) and \( Y_i = 1 \), which occurs with probability \( p_i(1-p_i) \).
- \( Z_i = 1 \) if \( X_i = Y_i = 0 \), which occurs with probability \((1 - p_i)^2\).
- \( Z_i = 0 \) if \( X_i = 1 \), which occurs with probability \( p_i \).
- \( Z_i \) represents the event where \( i \) is a neighbor, the iteration fails.

For \( \ell \in [L] \), define the random variable \( M_\ell := \prod_{i=1}^\ell Z_i \), and \( M_0 = 1 \) for convenience. If \( X_i = 1 \) for some \( i \in [\ell, \ell] \), then \( Z_i = 0 \) and \( M_\ell = 0 \). Otherwise, \( \log M_\ell \) counts the number of indices \( i \in [\ell] \) with \( Y_i = 1 \), the number of failed iterations. Therefore, \( \log(\max_{\ell \in [0,\ldots,L]} M_\ell) \) gives the number of failed iterations this \textsc{Next-Neighbor}(v) call.

To bound \( M_\ell \), observe that for any \( \ell \in [L] \), \( \mathbb{E}[Z_i] = 2p_i(1-p_i) + (1-p_i)^2 = 1 - p_i^2 \leq 1 \) regardless of the probability \( p_i \in [0,1] \). Then, \( \mathbb{E}[M_\ell] = \mathbb{E}[\prod_{i=1}^\ell Z_i] = \prod_{i=1}^\ell \mathbb{E}[Z_i] \leq 1 \) because \( Z_i \)'s are all independent. By Markov’s inequality, for any \( \ell \in [L] \), \( \Pr[\log M_\ell > r] = \Pr[M_\ell > 2^r] < 2^{-r} \). By the union bound, the probability that more than \( r \) failed iterations are encountered is \( \Pr[\log(\max_{\ell \in [0,\ldots,L]} M_\ell) > r] < L \cdot 2^{-r} \leq n \cdot 2^{-r} \).

\section*{Establishing the overall performance guarantee}

So far we have deduced that, for each pair of a vertex \( v \) and its \text{last}[v], the probability that the call \textsc{Next-Neighbor}(v) encounters more than \( r \) failed iterations is less than \( n \cdot 2^{-r} \), which is at most \( n^{c-2} \) for any desired constant \( c \) by choosing a sufficiently large \( r = \Theta(\log n) \). As Algorithm 1 may need to support up to \( \Theta(n^2) \) \textsc{Next-Neighbor} calls, one corresponding to each pair \((v, \text{last}[v])\), the probability that it ever encounters more than \( O(\log n) \) failed iterations to answer a single \textsc{Next-Neighbor} query is at most \( n^{-c} \). That is, with high probability, \( O(\log n) \) iterations are required per \textsc{Next-Neighbor} call, which concludes the proof of Theorem 48.

\section{A.2 Supporting Vertex-Pair Queries}

We extend our implementation (Algorithm 1) to support the \textsc{Vertex-Pair} queries: given a pair of vertices \((u, v)\), decide whether there exists an edge \( \{u, v\} \) in the generated graph. To answer a \textsc{Vertex-Pair} query, we must first check whether the value \( X_{uv} \) for \( \{u, v\} \) has already been assigned, in which case we answer accordingly. Otherwise, we must make a coin-flip with the corresponding bias \( p_{uv} \) to assign \( X_{uv} \), deciding whether \( \{u, v\} \) exists in the generated graph. If we maintained the full \( A \), we would have been able to simply set \( A[u][v] \) and \( A[v][u] \) to this new value. However, our more efficient Algorithm 1 that represents \( A \) compactly via \text{last} and \( P_u \)'s cannot record arbitrary modifications to \( A \).
Observe that if we were to apply the trivial implementation of \textsc{Vertex-Pair}, then by Lemma 12, \textit{last} and \textit{P}_i’s will only fail capture the state \(A[v][u] = 0\) when \(u > \text{last}[v]\) and \(v > \text{last}[u]\). Fortunately, unlike \textsc{Next-Neighbor} queries, a \textsc{Vertex-Pair} query can only set one cell \(A[v][u]\) to 0 per query, and thus we may afford to store these changes explicitly.\(^7\) To this end, we define the set \(Q = \{\{u, v\} : X_{uv} \text{ is assigned to 0 during a \textsc{Vertex-Pair} query}\}\), maintained as a hash table. Updating \(Q\) during \textsc{Vertex-Pair} queries is trivial: we simply add \(\{u, v\}\) to \(Q\) before we finish processing the query if we set \(A[u][v] = 0\). Conversely, we need to add \(u\) to \(P_i\) and add \(v\) to \(P_u\) if the \textsc{Vertex-Pair} query sets \(A[u][v] = 1\) as usual, yielding the following observation. It is straightforward to verify that each \textsc{Vertex-Pair} query requires \(O(\log n)\) time, \(O(1)\) random \(N\)-bit word, and \(O(1)\) additional space per query.

\begin{lemma}
\textbf{Lemma 49.} The data structures \textit{last}, \textit{P}_i’s and \(Q\) together provide a succint representation of \(A\) when \textsc{Next-Neighbor} queries (modified Algorithm 1) and \textsc{Vertex-Pair} queries are allowed. In particular, \(A[v][u] = 1\) if and only if \(u \in \textit{P}_i\). Otherwise, \(A[v][u] = 0\) if \(u < \text{last}[v]\), \(v < \text{last}[u]\), or \(\{v, u\} \in Q\). In all remaining cases, \(A[v][u] = \phi\).
\end{lemma}

We now explain other necessary changes to Algorithm 1. In the implementation of \textsc{Next-Neighbor}, an iteration is not failed when the chosen \(X_{vu}\) is still undecided: \(A[v][u]\) must still be \(\phi\). Since \(X_{vu}\) may also be assigned to 0 via a \textsc{Vertex-Pair}(\(v, u\)) query, we must also consider an iteration where \(\{v, u\} \in Q\) failed. That is, we now require one additional condition \(\{v, u\} \notin Q\) for termination (which only takes \(O(1)\) time to verify per iteration). As for the analysis, aside from handling the fact that \(X_{vu}\) may also become decided during a \textsc{Vertex-Pair} call, and allowing the states of the algorithm to support \textsc{Vertex-Pair} queries, all of the remaining analysis for correctness and performance guarantee still holds.

Therefore, we have established that our augmentation to Algorithm 1 still maintains all of its (asymptotic) performance guarantees for \textsc{Next-Neighbor} queries, and supports \textsc{Vertex-Pair} queries with complexities as specified above, concluding the following corollary. We remark that, as we do not aim to support \textsc{Random-Neighbor} queries, this simple algorithm here provides significant improvement over the performance of \textsc{Random-Neighbor} queries (given in Corollary 19).

\begin{corollary}
\textbf{Corollary 50.} Algorithm 1 can be modified to allow an implementation of \textsc{Vertex-Pair} query as explained above, such that the resource usages per query still asymptotically follow those of Theorem 48.
\end{corollary}

\section{Omitted Details from Section 3: Undirected Random Graph Implementations}

\subsection{Removing the Perfect-Precision Arithmetic Assumption}

In this section we remove the perfect-precision arithmetic assumption. Instead, we only assume that it is possible to compute \(\prod_{u=a}^{b}(1 - p_{vu})\) and \(\sum_{u=a}^{b} p_{vu}\) to \(N\)-bit precision, as well as drawing a random \(N\)-bit word, using polylogarithmic resources. Here we will focus on proving that the family of the random graph we generate via our procedures is statistically close to that of the desired distribution. The main technicality of this lemma arises from the fact that, not only the implementation is randomized, but the agent interacting with the implementation may choose their queries arbitrarily (or adversarially): our proof must handle any sequence of random choices the implementation makes, and any sequence of queries the agent may make.

\footnote{The disadvantage of this approach is that the implementation may allocate more than \(\Theta(m)\) space over the entire graph generation process, if \textsc{Vertex-Pair} queries generate many of these 0’s.}
Observe that the distribution of the graphs constructed by our implementation is governed entirely by the samples \( u \) drawn from \( F(v, a, b) \) in Algorithm 3. By our assumption, the CDF of any \( F(v, a, b) \) can be efficiently computed from \( \prod_{n=0}^{u} (1 - p_{nv}) \), and thus sampling with error in the \( L_1 \)-distance requires a random \( N \)-bit word and a binary-search in \( O(\log(b + a + 1)) = O(\log n) \) iterations. Using this crucial fact, we prove our lemma that removes the perfect-precision arithmetic assumption.

\textbf{Lemma 51.} If Algorithm 3 (the \texttt{Fill} operation) is repeatedly invoked to construct a graph \( G \) by drawing the value \( u \) for at most \( S \) times in total, each of which comes from some distribution \( F(v, a, b) \) that is \( \epsilon \)-close in \( L_1 \)-distance to the correct distribution \( F(v, a, b) \) that perfectly generates the desired distribution \( G \) over all graphs, then the distribution \( G' \) of the generated graph \( G \) is \((\epsilon S)\)-close to \( G \) in the \( L_1 \)-distance.

\textbf{Proof.} For simplicity, assume that the algorithm generates the graph to completion according to a sequence of up to \( n^2 \) distinct blocks \( B = \langle B_{u_1}^{(1)}, B_{u_2}^{(2)} \ldots \rangle \), where each \( B_{u_i}^{(u)} \) specifies the unfilled block in which any query instigates a \texttt{Fill} function call. Define an internal state of our implementation as the triplet \( s = (k, u, A) \), representing that the algorithm is currently processing the \( k \)-th \texttt{Fill}, in the iteration (the \texttt{repeat} loop of Algorithm 3) with value \( u \), and have generated \( A \) so far. Let \( t_A \) denote the terminal state after processing all queries and having generated the graph \( G_A \) represented by \( A \). We note that \( A \) is used here in the analysis but not explicitly maintained; further, it reflects the changes in every iteration: as \( u \) is updated during each iteration of \texttt{Fill}, the cells \( A[v][u'] = \phi \) for \( u' < u \) (within that block) that has been skipped are also updated to \( 0 \).

Let \( S \) denote the set of all (internal and terminal) states. For each state \( s \), the implementation samples \( u \) from the corresponding \( F'(v, a, b) \) where \( \|F(v, a, b) - F'(v, a, b)\|_1 \leq \epsilon = \frac{1}{\text{poly}(n)} \). then moves to a new state according to \( u \). In other words, there is an induced pair of collection of distributions over the states: \((T, T')\) where \( T = \{T_s\}_{s \in S}, T' = \{T'_s\}_{s \in S}, \) such that \( T_s(s') \) and \( T'_s(s') \) denote the probability that the algorithm advances from \( s \) to \( s' \) by using a sample from the correct \( F(v, a, b) \) and from the approximated \( F'(v, a, b) \), respectively. Consequently, \( \|T_s - T'_s\|_1 \leq \epsilon \) for every \( s \in S \).

The implementation begins with the initial (internal) state \( s_0 = (1, 0, A_\phi) \) where all cells of \( A_\phi \) are \( \phi \)'s, goes through at most \( S = O(n^2) \) other states (as there are up to \( n^2 \) values of \( k \) and \( O(n) \) values of \( u \)), and reach some terminal state \( t_A \), generating the entire graph in the process. Let \( \pi = \langle s_0^0 = s_0, s_1^I, \ldots, s^n_{\pi} = t_A \rangle \) for some \( A \) denote a sequence ("path") of up to \( S + 1 \) states the algorithm proceeds through, where \( \ell(\pi) \) denote the number of transitions it undergoes. For simplicity, let \( T_{t_A}(t_A) = 1 \), and \( T_{t_A}(s) = 0 \) for all state \( s \neq t_A \), so that the terminal state can be repeated and we may assume \( \ell(\pi) = S \) for every \( \pi \). Then, for the correct transition probabilities described as \( T \), each \( \pi \) occurs with probability \( q(\pi) = \prod_{i=1}^{S} T_{s_{i-1}}(s_i) \), and thus \( G(G_A) = \sum_{\pi, s^n_{\pi} = t_A} q(\pi) \).

Let \( T^\text{min} = \{T^\text{min}_s\}_{s \in S} \) where \( T^\text{min}_s(s') = \min(T_s(s'), T'_s(s')) \), and note that each \( T^\text{min}_s \) is not necessarily a probability distribution. Then, \( \sum_s T^\text{min}_s(s) = 1 - \|T_s - T'_s\|_1 \geq 1 - \epsilon \). Define \( q', q^\text{min}(G_A), G^\text{min}(G_A) \) analogously, and observe that \( q^\text{min}(\pi) \leq \min\{q(\pi), q'(\pi)\} \) for every \( \pi \), so \( G^\text{min}(G_A) \leq \min\{G(G_A), G'(G_A)\} \) for every \( G_A \) as well. In other words, \( q^\text{min}(\pi) \) lower bounds the probability that the algorithm, drawing samples from the correct distributions or the approximated distributions, proceeds through states of \( \pi \); consequently, \( G^\text{min}(G_A) \) lower bounds the probability that the algorithm generates the graph \( G_A \).
Next, consider the probability that the algorithm proceeds through the prefix \( \pi_i = \langle s_0, \ldots, s_{i}^{\tau} \rangle \) of \( \pi \). Observe that for \( i \geq 1 \),

\[
\sum_{\pi} q_{i}^{\min}(\pi_{i}) = \sum_{\pi} q_{i}^{\min}(\pi_{i-1}) \cdot T_{s_{i-1}}^{\min}(\pi_{i}) = \sum_{s, s'} q_{i}^{\min}(\pi_{i-1}) \cdot T_{s_{i-1}}^{\min}(s')
\]

\[
= \sum_{s} T_{s}^{\min}(s') \sum_{\pi} q_{i}^{\min}(\pi_{i-1}) \geq (1 - \epsilon) \sum_{\pi} q_{i}^{\min}(\pi_{i-1}).
\]

Roughly speaking, at least a factor of \( 1 - \epsilon \) of the “agreement” between the distributions over states according to \( T \) and \( T' \) is necessarily conserved after a single sampling process. As \( \sum_{\pi} q_{i}^{\min}(\pi_{0}) = 1 \) because the algorithm begins with \( s_0 = (1,0,A_{\phi}) \), by an inductive argument we have \( \sum_{\pi} q_{i}^{\min}(\pi) = \sum_{\pi} q_{i}^{\min}(\pi_{0}) \geq (1 - \epsilon)^{S} \leq 1 - \epsilon S \). Hence, \( \sum_{G_{\phi}} \min\{G(G_{\phi}),G'(G_{\phi})\} \geq \sum_{G_{\phi}} G^{\min}(G_{\phi}) \geq 1 - \epsilon S \), implying that \( \|G - G'\|_1 \leq \epsilon S \), as desired. In particular, by substituting \( \epsilon = \frac{1}{\text{poly}(n)} \) and \( S = O(n^3) \), we have shown that Algorithm 3 only creates a \( \frac{1}{\text{poly}(n)} \) error in the \( L_1 \)-distance.

We remark that \textsc{Random-Neighbor} queries also require that the returned edge is drawn from a distribution that is close to a uniform one, but this requirement applies only per query rather than over the entire execution of the generator. Hence, the error due to the selection of a random neighbor may be handled separately from the error for generating the random graph; its guarantee follows straightforwardly from a similar analysis.

### B.2 Bounding Block Sizes

**Lemma 13.** With high probability, the number of neighbors in every block, \( |\Gamma^{(i)}(v)| \), is at most \( O(\log n) \).

**Proof.** Fix a block \( B_{v}^{(i)} \), and consider the Bernoulli RVs \( \{X_{vu}\}_{u \in B_{v}^{(i)}} \). The expected number of neighbors in this block is \( E[|\Gamma^{(i)}(v)|] = E[\sum_{u \in B_{v}^{(i)}} X_{vu}] < L + 1 \). Via the Chernoff bound,

\[ P\left[ |\Gamma^{(i)}(v)| > (1 + 3\epsilon \log n) \cdot L \right] \leq e^{-\frac{3\epsilon \log n \cdot L}{4}} = n^{-\Theta(c)} \]

for any constant \( c > 0 \). 

**Lemma 14.** With high probability, for every \( v \) such that \( |B_{v}| = \Omega(\log n) \) \((\text{i.e., } E = \Omega(\log n))\), at least a 1/3-fraction of the blocks \( \{B_{v}^{(i)}\}_{1 \leq |B_{v}|} \) are non-empty.

**Proof.** For \( i < |B_{v}| \), since \( E[|\Gamma^{(i)}(v)|] = E[\sum_{u \in B_{v}^{(i)}} X_{vu}] > L - 1 \), we bound the probability that \( B_{v}^{(i)} \) is empty:

\[ P[B_{v}^{(i)} \text{ is empty}] = \prod_{u \in B_{v}^{(i)}} (1 - p_{vu}) \leq e^{-\sum_{u \in B_{v}^{(i)}} p_{vu}} \leq e^{1^{-L} = c} \]

for any arbitrary small constant \( c \) given sufficiently large constant \( L \). Let \( T_{i} \) be the indicator for the event that \( B_{v}^{(i)} \) is not empty, so \( E1 - c \). By the Chernoff bound, the probability that less than \( |B_{v}|/3 \) blocks are non-empty is

\[ P\left[ \sum_{i \in |B_{v}|} T_{i} < \frac{|B_{v}|}{3} \right] < P \left[ \sum_{i \in |B_{v}| - 1} T_{i} < \frac{|B_{v} - 1|}{3} \right] \leq e^{-\Theta(|B_{v} - 1|) = n^{-\Omega(1)}} \]

as \( |B_{v}| = \Omega(\log n) \) by assumption.
Next-Neighbor Implementation with Deterministic Performance Guarantee

In this section, we construct data structures that allow us to sample for the next neighbor directly by considering only the cells $A[v][u] = \phi$ in the Erdős-Rényi model and the Stochastic Block model. This provides $\text{poly}(\log n)$ worst-case performance guarantee for implementations supporting only the Next-Neighbor queries. We may again extend this data structure to support Vertex-Pair queries, however, at the cost of providing $\text{poly}(\log n)$ amortized performance guarantee instead.

In what follows, we first focus on the $G(n, p)$ model, starting with Next-Neighbor queries (Section C.1) then extend to Vertex-Pair queries (Section C.2). We then explain how this result may be generalized to support the Stochastic Block model with random community assignment in Section C.3.

C.1 Data structure for next-neighbor queries in the Erdős-Rényi model

```
Algorithm 6 Alternate implementation.

procedure Next-Neighbor(v)
    $w \leftarrow \min K_v$, or $n + 1$ if $K_v = \emptyset$
    $t \leftarrow \text{count}(v)$
    sample $F \sim \text{ExactF}(p, t)$
    if $F \leq t$
        $u \leftarrow \text{pick}(v, F)$
        $K_u \leftarrow K_u \cup \{v\}$
    else
        $u \leftarrow w$
        if $u \neq n + 1$
            $K_v \leftarrow K_v \setminus \{u\}$
    $\text{update}(v, u)$
    last[v] $\leftarrow u$
    return $u$
```

Recall that $\text{Next-Neighbor}(v)$ is given by $\min \{u > \text{last}[v] : X_{vu} = 1\}$ (or $n + 1$ if no satisfying $u$ exists). To aid in computing this quantity, we define:

$K_v = \{u \in (\text{last}[v], n] : A[v][u] = 1\}$,

$w_v = \min K_v$, or $n + 1$ if $K_v = \emptyset$,

$T_v = \{u \in (\text{last}[v], w_v) : A[v][u] = \phi\}$.

The ordered set $K_v$ is only defined for ease of presentation: it is equivalent to $(\text{last}[v], n] \cap P_v$, recording the known neighbors of $v$ after $\text{last}[v]$ (i.e., those that have not been returned as an answer by any Next-Neighbor(v) query yet). The quantity $w_v$ remains unchanged but is simply restated in terms of $K_v$. $T_v$ specifies the list of candidates $u$ for Next-Neighbor(v) with $A[v][u] = \phi$; in particular, all candidates $u$’s, such that the corresponding RVs $X_{vu} = 0$ are decided, are explicitly excluded from $T_v$.

Unlike the approach of Algorithm 1 that simulates coin-flips even for decided $X_{vu}$’s, here we only flip undecided coins for the indices in $T_v$: we have $|T_v|$ Bernoulli trials to simulate. Let $F$ be the random variable denoting the first index of a successful trial out of
27:52 Local Access to Huge Random Objects Through Partial Sampling

$|T_v|$ coin-flips, or $|T_v| + 1$ if all fail; denote the distribution of $F$ by $\text{ExactF}(p, |T|)$. The CDF of $F$ is given by $\Pr[F = f] = 1 - (1 - p)^f$ for $f \leq |T_v|$ (i.e., there is some success trial in the first $f$ trials), and $\Pr[F = |T_v| + 1] = 1$. Thus, we must design a data structure that can compute $w_v$, compute $|T_v|$, find the $F$th minimum value in $T_v$, and update $A[v][u]$ for the $F$th lowest values $u \in T_v$ accordingly.

Let $k = \lceil \log n \rceil$. We create a range tree, where each node itself contains a balanced binary search tree (BBST), storing last values of its corresponding range. Formally, for $i \in [0, n/2^k)$ and $j \in [0, k]$, the $i$th node of the $j$th level of the range tree, stores last[v] for every $v \in (i \cdot 2^k - j, (i + 1) \cdot 2^k - j)$. Denote the range tree by $R$, and each BBST corresponding to the range $[a, b]$ by $B_{[a,b]}$. We say that the range $[a, b]$ is canonical if it corresponds to a range of some $B_{[a,b]}$ in $R$.

Again, to allow fast initialization, we make the following adjustments from the given formalization above: (1) values last[v] = 0 are never stored in any $B_{[a,b]}$, and (2) each $B_{[a,b]}$ is created on-the-fly during the first occasion it becomes non-empty. Further, we augment each $B_{[a,b]}$ so that each of its node maintains the size of the subtree rooted at that node: this allows us to count, in $O(\log n)$ time, the number of entries in $B_{[a,b]}$ that is no smaller than a given threshold.

Observe that each $v$ is included in exactly one $B_{[a,b]}$ per level in $R$, so $k + 1 = O(\log n)$ copies of last[v] are stored throughout $R$. Moreover, by the property of range trees, any interval can be decomposed into a disjoint union of $O(\log n)$ canonical ranges. From these properties we implement the data structure $R$ to support the following operations. (Note that $R$ is initially an empty tree, so initialization is trivial.)

- **COUNT(v)**: compute $|T_v|$. We break (last[v], $w_v$) into $O(\log n)$ disjoint canonical ranges $[a_i, b_i]$’s each corresponding to some $B_{[a,b]}$; then compute $t_{[a_i, b_i]} = \{u \in [a_i, b_i] : \text{last}[u] < v\}$, and return $\sum_i t_{[a_i, b_i]}$. The value $t_{[a_i, b_i]}$ is obtained by counting the entries of $B_{[a_i, b_i]}$ that is at least $v$, then subtract it from $b_i - a_i + 1$; we cannot count entries less than $v$ because last[u] = 0 are not stored.

- **PICK(v, F)**: find the $F$th minimum value in $T_v$ (assuming $F \leq |T_v|$). We again break (last[v], $w_v$) into $O(\log n)$ canonical ranges $[a_i, b_i]$’s, compute $t_{[a_i, b_i]}$’s, and identify the canonical range $[a^*, b^*]$ containing the $i$th smallest element (i.e., $[a_i, b_i]$ with the smallest $b$ satisfying $\sum_{j<i} t_{[a_j, b_j]} \geq F$ assuming ranges are sorted). Binary-search in $[a^*, b^*]$ to find exactly the $i$th smallest element of $T$. This is accomplished by traversing $R$ starting from the range $[a^*, b^*]$ down to a leaf, at each step computing the children’s $T_{[a,b]}$’s and deciding which child’s range contains the desired element.

- **UPDATE(v, u)**: simulate coin-flips, assigning $X_{uv} \leftarrow 1$, and $X_{v,u} \leftarrow 0$ for $u' \in (\text{last}[v], u) \cap T_v$. This is done implicitly by handling the change last[v] ← u: for each BBST $B_{[a,b]}$ where $v \in [a, b]$, remove the old value of last[v] and insert $u$ instead.

It is straightforward to verify that all operations require at most $O(\log^2 n)$ time and $O(\log n)$ additional space per call. The overall implementation is given in Algorithm 6, using the same asymptotic time and additional space. Recall also that sampling $F \sim \text{ExactF}(p, t)$ requires $O(\log n)$ time and one $N$-bit random word for the $G(n, p)$ model.

### C.2 Data structure for Vertex-Pair queries in the Erdős-Rényi model

Recall that we define $Q$ in Algorithm 1 as the set of pairs $(u, v)$ where $X_{uv}$ is assigned to 0 during a Vertex-Pair query, allowing us to check for modifications of $A$ not captured by last[v] and $K_v$. Here in Algorithm 6, rather than checking, we need to be able to count such entries. Thus, we instead create a BBST $Q_v'$ for each $v$ defined as:
This definition differs from that of $Q$ in Section A.2 in two aspects. First, we ensure that each $A[v][u] = 0$ is recorded by either $\text{last}$ (via Lemma 12) or $Q'_v$ (explicitly), but not both. In particular, if $u$ were to stay in $Q'_v$ when $\text{last}[v]$ increases beyond $u$, we would have double-counted these entries 0 not only recorded by $Q'_v$ but also implied by $\text{last}[v]$ and $K_v$.

By having a BBST for each $Q'_v$, we can compute the number of 0’s that must be excluded from $T_v$, which cannot be determined via $\text{last}[v]$ and $K_v$ alone: we subtract these from any counting process done in the data structure $R$.

Second, we maintain $Q'_v$ separately for each $v$ as an ordered set, so that we may identify non-neighbors of $v$ within a specific range – this allows us to remove non-neighbors in specific range, ensuring that the first aspect holds. More specifically, when we increase $\text{last}[v]$, we must go through the data structure $Q'_v$ and remove all $u < \text{last}[v]$, and for each such $u$, also remove $v$ from $Q'_u$. There can be as many as linear number of such $u$, but the number of removals is trivially bounded by the number of insertions, yielding an amortized time performance guarantee in the following theorem. Aside from the deterministic guarantee, unsurprisingly, the required amount of random words for this algorithm is lower than that of the algorithm from Section A (given in Theorem 48 and Corollary 50).

\begin{tcbitemize}
\item \textbf{Theorem 52.} Consider the Erdős-Rényi $G(n,p)$ model. For \textbf{Next-Neighbor} queries only, Algorithm 6 is an implementation that answers each query using $O(\log^2 n)$ time, $O(\log n)$ additional space, and one $N$-bit random word. For \textbf{Next-Neighbor} and \textbf{vertex pair} queries, an extension of Algorithm 6 answers each query using $O(\log^2 n)$ amortized time, $O(\log n)$ additional space, and one $N$-bit random word.
\end{tcbitemize}

\subsection{C.3 Data structure for the Stochastic Block model}

We employ the data structure for generating and counting the number of vertices of each community in a specified range from Section 3.4.2. We create $r$ different copies of the data structure $R$ and $Q'_v$, one for each community, so that we may implement the required operations separately for each color, including using the \texttt{count} subroutine to sample $F \sim \text{ExactF}$ via the corresponding CDF, and picking the next neighbor according to $F$. Recall that since we do not store $\text{last}[v] = 0$ in $R$, and we only add an entry to $K_v$, $P_v$ or $Q'_v$ after drawing the corresponding $X_{uv}$, the communities of the endpoints, which cover all elements stored in these data structures, must have already been determined. Thus, we obtain the following corollary for the Stochastic Block model.

\begin{tcbitemize}
\item \textbf{Corollary 53.} Consider the Stochastic Block model with randomly-assigned communities. For \textbf{Next-Neighbor} queries only, Algorithm 6 is an implementation that answers each query using $O(r \log(n))$ time, random words, and additional space per query. For \textbf{Next-Neighbor} and \textbf{vertex-pair} queries, Algorithm 6 answers each query using $O(r \log(n))$ amortized time, $O(r \log(n))$ random words, and $O(r \log(n))$ additional space per query additional space, and one $N$-bit random word.
\end{tcbitemize}

\section{D Sampling from the Multivariate Hypergeometric Distribution}

Consider the following random experiment. Suppose that we have an urn containing $B \leq n$ marbles (representing vertices), each occupies one of the $r$ possible colors (representing communities) represented by an integer from $[r]$. The number of marbles of each color in the
urn is known: there are $C_k$ indistinguishable marbles of color $k \in [r]$, where $C_1 + \cdots + C_r = B$. Consider the process of drawing $\ell \leq B$ marbles from this urn without replacement. We would like to sample how many marbles of each color we draw.

More formally, let $\mathbf{C} = (c_1, \ldots, c_r)$, then we would like to (approximately) sample a vector $\mathbf{S}^C_\ell$ of $r$ non-negative integers such that

$$
\Pr[\mathbf{S}^C_\ell = (s_1, \ldots, s_r)] = \frac{\binom{c_1}{s_1} \cdot \binom{c_2}{s_2} \cdots \binom{c_r}{s_r}}{\binom{C_1 + \cdots + C_r}{\ell}}
$$

where the distribution is supported by all vectors satisfying $s_k \in \{0, \ldots, C_k\}$ for all $k \in [r]$ and $\sum_{k=1}^r s_k = \ell$. This distribution is referred to as the multivariate hypergeometric distribution.

The sample $\mathbf{S}^C_\ell$ above may be generated easily by simulating the drawing process, but this may take $\Omega(\ell)$ iterations, which have linear dependency in $n$ in the worst case: $\ell = \Theta(B) = \Theta(n)$. Instead, we aim to generate such a sample in $O(r \cdot \text{poly}(\log n))$ time with high probability. We first make use of the following procedure from [26].

▶ Lemma 54. Suppose that there are $T$ marbles of color 1 and $B - T$ marbles of color 2 in an urn, where $B \leq n$ is even. There exists an algorithm that samples $(s_1, s_2)$, the number of marbles of each color appearing when drawing $B/2$ marbles from the urn without replacement, in $O(\text{poly}(\log n))$ time and random words. Specifically, the probability of sampling a specific pair $(s_1, s_2)$ where $s_1 + s_2 = T$ is approximately $\binom{T/2}{s_1} / \binom{T}{s_1}$ with error of at most $n^{-c}$ for any constant $c > 0$.

In other words, the claim here only applies to the two-color case, where we sample the number of marbles when drawing exactly half of the marbles from the entire urn ($r = 2$ and $\ell = B/2$). First we generalize this claim to handle any desired number of drawn marbles $\ell$ (while keeping $r = 2$).

▶ Lemma 55. Given $C_1$ marbles of color 1 and $C_2 = B - C_1$ marbles of color 2, there exists an algorithm that samples $(s_1, s_2)$, the number of marbles of each color appearing when drawing $\ell$ marbles from the urn without replacement, in $O(\text{poly}(\log B))$ time and random words.

Proof. For the base case where $B = 1$, we trivially have $\mathbf{S}^C_1 = \mathbf{C}_1$ and $\mathbf{S}^C_0 = \mathbf{C}_2$. Otherwise, for even $B$, we apply the following procedure.

- If $\ell \leq B/2$, generate $\mathbf{C'} = \mathbf{S}^C_{B/2}$ using Lemma 54.
- If $\ell = B/2$ then we are done.
- Else, for $\ell < B/2$ we recursively generate $\mathbf{S}^C_\ell$.
- Else, for $\ell > B/2$, we generate $\mathbf{S}^C_{B-\ell}$ as above, then output $\mathbf{C} - \mathbf{S}^C_{B-\ell}$.

On the other hand, for odd $B$, we simply simulate drawing a single random marble from the urn before applying the above procedure on the remaining $B - 1$ marbles in the urn. That is, this process halves the domain size $B$ in each step, requiring $\log B$ iterations to sample $\mathbf{S}^C_\ell$.

Lastly we generalize to support larger $r$.

▶ Theorem 21. Given $B$ marbles of $r$ different colors, such that there are $C_i$ marbles of color $i$, there exists an algorithm that samples $(s_1, s_2, \ldots, s_r)$, the number of marbles of each color appearing when drawing $\ell$ marbles from the urn without replacement, in $O(r \cdot \text{poly}(\log B))$ time and random words.
Theorem 56. Given $B$ marbles of $r$ different colors in $[r]$, such that there are $C_i$ marbles of color $i$ and a parameter $k \leq r$, there exists an algorithm that samples $s_1 + s_2 + \cdots + s_k$, the number of marbles among the first $k$ colors appearing when drawing $\ell$ marbles from the urn without replacement, in $O(\text{poly}(\log B))$ time and random words.

Proof. Since we don’t have to find the individual counts, we can be more efficient by grouping half the colors together at each step. Formally, we define a pair $D = \langle D_1, D_2 \rangle$ where $D_1 = C_1 + C_2 + \cdots + C_{r/2}$ and $D_2 = C_{r/2+1} + \cdots + C_{r-1} + C_r$. We then generate $\langle D'_1, D'_2 \rangle = S^D$.

- If $k < r/2$, we recursively solve the problem with the first $r/2$ colors, $B \leftarrow D'_1$, and the original value of $k$.
- If $k > r/2$, we recurse on the last $r/2$ colors, $B$ set to $D'_2$, and $k$ set to $k - r/2$. In this case, we add $D'_1$ to the returned value.
- Otherwise, $k = r/2$ and we can return $D'_1$.

The number of recursive calls is $O(\log r) = O(\log B)$ (since $r \leq B$). So, the overall runtime is $O(\text{poly}(\log B))$. □

E Local-Access Implementations for Random Directed Graphs

In this section, we consider Kleinberg’s Small-World model [31, 37] where the probability that a directed edge $(u, v)$ exists is $\min\{c/(\text{dist}(u, v))^2, 1\}$. Here, $\text{dist}(u, v)$ is the Manhattan distance between $u$ and $v$ on a $\sqrt{n} \times \sqrt{n}$ grid. We begin with the case where $c = 1$, then generalize to different values of $c = \log^{\Theta(1)}(n)$. We aim to support $\text{ALL-NEIGHBORS}$ queries using $\text{poly}(\log n)$ resources. This returns the entire list of out-neighbors of $v$.

E.1 Implementation for $c = 1$

Observe that since the graphs we consider here are directed, the answers to the $\text{ALL-NEIGHBOR}$ queries are all independent: each vertex may determine its out-neighbors independently. Given a vertex $v$, we consider a partition of all the other vertices of the graph into sets \(\{\Gamma^u_v, \Gamma^v_u, \ldots\}\) by distance: $\Gamma^u_v = \{u : \text{dist}(u, v) = k\}$ contains all vertices at a distance $k$ from vertex $v$. Observe that $|\Gamma^u_v| \leq 4k = O(k)$. Then, the expected number of edges from $v$ to vertices in $\Gamma^u_v$ is therefore $|\Gamma^u_v| \cdot 1/k^2 = O(1/k)$. Hence, the expected degree of $v$ is at most $\sum_{k=1}^{\sqrt{n}-1} O(1/k) = O(\log n)$. It is straightforward to verify that this bound holds with high probability (use Hoeffding’s inequality). Since the degree of $v$ is small, in this model we can afford to perform $\text{ALL-NEIGHBORS}$ queries instead of $\text{NEXT-NEIGHBOR}$ queries using an additional $\text{poly}(\log n)$ resources.

Nonetheless, internally in our implementation, we generate our neighbors one-by-one similarly to how we process $\text{NEXT-NEIGHBOR}$ queries. We perform our sampling in two phases. In the first phase, we compute a distance $d$, such that the next neighbor closest to $v$ is at distance $d$. We maintain $\text{last}[v]$ to be the last computed distance. In the second phase, we
generate all neighbors of \( v \) at distance \( d \), under the assumption that there must be at least one such neighbor. For simplicity, we generate these neighbors as if there are full \( 4d \) vertices at distance \( d \) from \( v \): some generated neighbors may lie outside our \( \sqrt{n} \times \sqrt{n} \) grid, which are simply discarded. As the running time of our implementation is proportional to the number of implementation neighbors, then by the bound on the number of neighbors, this assumption does not asymptotically worsen the performance of the implementation.

### E.1.1 Phase 1: Generate the distance \( D \)

Let \( a = \text{last}[v] + 1 \), and let \( D(a) \) to denote the probability distribution of the distance where the next closest neighbor of \( v \) is located, or \( \perp \) if there is no neighbor at distance at most \( 2(\sqrt{n} - 1) \). That is, if \( D \sim D(a) \) is drawn, then we proceed to Phase 2 to generate all neighbors at distance \( D \). We repeat the process by sampling the next distance from \( D(a + D) \) and so on until we obtain \( \perp \), at which point we return our answers and terminate.

To generate the next distance, we perform a binary search: we must evaluate the CDF of \( D(a) \). The CDF is given by

\[
\mathbb{P}[D \leq d] = 1 - \prod_{i=a}^{d} \left( 1 - \frac{1}{p^2} \right) = 1 - \prod_{i=a}^{d} \left( \frac{(i-1)(i+1)}{i^2} \right)^4 = 1 - \left( \frac{(a-1)^a}{a^{a-1}} \cdot \frac{(d+1)!}{d^{d+1}} \right)^4
\]

where the product enjoys telescoping as the denominator \((i^2)^{4i}\) cancels with \((i^2)^{4(i-1)}\) and \((i^2)^{4(i+1)}\) in the numerators of the previous and the next term, respectively. This gives us a closed form for the CDF, which we can compute with \(2^{-N}\) additive error in constant time (by our computation model assumption). Thus, we may generate the distance \( D \sim D(a) \) using \( O(\log n) \) time and one random \( N\)-bit word.

### E.1.2 Phase 2: Sampling neighbors at distance \( D \)

After sampling a distance \( D \), we now have to generate all the neighbors at distance \( D \). We label the vertices in \( \Gamma_D^a \) with unique indices in \( \{1, \ldots, 4D\} \). Note that now each of the \( 4D \) vertices in \( \Gamma_D^a \) is a neighbor with probability \( 1/D^2 \). However, by Phase 1, this is conditioned on the fact that there is at least one neighbor among the vertices in \( \Gamma_D^a \), which may be difficult to generate when \( 1/D^2 \) is very small. We can emulate this naively by repeatedly sampling a “block”, composing of the \( 4D \) vertices in \( \Gamma_D^a \), by deciding whether each vertex is a neighbor of \( v \) with uniform probability \( 1/D^2 \) (i.e., \( 4D \) identical independent Bernoulli trials), and then discarding the entire block if it contains no neighbor. We repeat this process until we finally generate one block that contains at least one neighbor, and use this block as our output.

For the purpose of making the sampling process more efficient, we view this process differently. Let us imagine that we are given an infinite sequence of independent Bernoulli variables, each with bias \( 1/D^2 \). We then divide the sequence into contiguous blocks of length \( 4D \) each. Our task is to find the first occurrence of success (a neighbor), then report the whole block hosting this variable.

This first occurrence of a successful Bernoulli trial is given by sampling from the geometric distribution, \( X \sim \text{Geo}(1/D^2) \). Since the vertices in each block are labeled by \( 1, \ldots, 4D \), then this first occurrence has label \( X' = X \mod 4D \). By sampling \( X \sim \text{Geo}(1/D^2) \), the first \( X' \)
Bernoulli variables of this block is also implicitly determined. Namely, the vertices of labels $1,\ldots,X'-1$ are non-neighbors, and that of label $X'$ is a neighbor. The sampling for the remaining $4D - X'$ vertices can then be performed in the same fashion we generate next neighbors in the $G(n,p)$ case: repeatedly find the next neighbor by sampling from Geo$(1/D^2)$, until the index of the next neighbor falls beyond this block.

Thus at this point, we have generated all neighbors in $\Gamma^n_D$. We can then update last $[c] \leftarrow D$ and continue the process of larger distances. Sampling each neighbor takes $O(\log n)$ time and one random $N$-bit word; the resources spent sampling the distances is also bounded by that of the neighbors. As there are $O(\log n)$ neighbors with high probability, we obtain the following theorem.

\begin{theorem}
There exists an algorithm that generates a random graph from Kleinberg’s Small World model, where probability of including each directed edge $(u,v)$ in the graph is $1/(\text{dist}(u,v))^2$ where $\text{dist}$ denote the Manhattan distance, using $O(\log^2 n)$ time and random log $n$-bit words per \textsc{All-Neighbors} query with high probability.
\end{theorem}

\section{Implementation for $c \neq 1$}

Observe that to support different values of $c$ in the probability function $c/(\text{dist}(u,v))^2$, we do not have a closed-form formula for computing the CDF for Phase 1, whereas the process for Phase 2 remains unchanged. To handle the change in the probability distribution Phase 1, we consider the following, more general problem. Suppose that we have a process $P$ that, one-by-one, provide occurrences of successes from Bernoulli trials with success probabilities $(p_1, p_2, \ldots)$. We show how to construct a process $P^c$ that provide occurrences of successes from Bernoulli trials with success probabilities $(c \cdot p_1, c \cdot p_2, \ldots)$ (truncated down to 1 as needed). For our application, we assume that $c$ is given in $N$-bit precision, there are $O(n)$ Bernoulli trials, and we aim for an error of $\frac{1}{\text{poly}(n)}$ in the $L_1$-distance.

\subsection{Case $c < 1$}

We use rejection sampling in order to construct a new Bernoulli process.

\begin{lemma}
Given a process $P$ outputting the indices of successful Bernoulli trials with bias $(p_i)$, there exists a process $P^c$ outputting the indices of successful Bernoulli trials with bias $(c \cdot p_i)$ where $c < 1$, using one additional $N$-bit word overhead for each answer of $P$.
\end{lemma}

\begin{proof}
Consider the following rejection sampling process to simulate the Bernoulli trials. In addition to each Bernoulli variable $X_i$ with bias $p_i$, we generate another coin-flip $C_i$ with bias $c$. Set $Y_i = X_i \cdot C_i$, then $P[Y_i = 1] = P[X_i = 1] \cdot P[C_i] = c \cdot p_i$, as desired. That is, we keep a success of a Bernoulli trial with probability $c$, or reject it with probability $1 - c$.

Now, we are already given the process $P$ that “handles” $X_i$’s, generating a sequence of indices $i$ with $X_i = 1$. The new process $P^c$ then only needs to handle the $C_i$’s. Namely, for each $i$ reported as success by $P$, $P^c$ flips a coin $C_i$ to see if it should also report $i$, or discard it. As a result, $P^c$ can generate the indices of successful Bernoulli trials using only one random $N$-bit word overhead for each answer from $P$.
\end{proof}

Applying this reduction to the distance sampling in Phase 1, we obtain the following corollary.

\begin{corollary}
There exists an algorithm that generates a random graph from Kleinberg’s Small World model with edge probabilities $c/(\text{dist}(u,v))^2$ where $c < 1$, using $O(\log^2 n)$ time and random log $n$-bit words per \textsc{All-Neighbors} query with high probability.
\end{corollary}
E.2.2 Case $c > 1$

Since we aim to sample with larger probabilities, we instead consider making $k \cdot c$ independent copies of each process $P$, where $k > 1$ is a positive integer. Intuitively, we hope that the probability that one of these process returns an index $i$ will be at least $c \cdot p_i$, so that we may perform rejection sampling to decide whether to keep $i$ or not. Unfortunately such a process cannot handle the case where $c \cdot p_i$ is large, notably when $c \cdot p_i > 1$ is truncated down to 1, while there is always a possibility that none of the processes return $i$.

Lemma 60. Let $k > 1$ be a constant integer. Given a process $P$ outputting the indices of successful Bernoulli trials with bias $(p_i)$, there exists a process $P^c$ outputting the indices of successful Bernoulli trials with bias $(\min\{c \cdot p_i, 1\})$, where $c > 1$ and $c \cdot p_i \leq 1 - \frac{1}{k}$ for every $i$, using one additional $N$-bit word overhead for each answer of $k \cdot c$ independent copies of $P$.

Proof. By applying the following form of Bernoulli’s inequality, we have

$$(1 - p_i)^{k \cdot c} \leq 1 - \frac{k \cdot c \cdot p_i}{1 + (k \cdot c - 1) \cdot p_i} = 1 - \frac{k \cdot c \cdot p_i}{1 + k \cdot c \cdot p_i - p_i} = 1 - \frac{k \cdot c \cdot p_i}{1 + (k - 1)} = 1 - c \cdot p_i$$

That is, the probability that at least one of the implementations report an index $i$ is $1 - (1 - p_i)^{k \cdot c} \geq c \cdot p_i$, as required. Then, the process $P^c$ simply reports $i$ with probability $(c \cdot p_i)/(1 - (1 - p_i)^{k \cdot c})$ or discard $i$ otherwise. Again, we only require $N$-bit of precision for each computation, and thus one random $N$-bit word suffices.

In Phase 1, we may apply this reduction only when the condition $c \cdot p_i \leq 1 - \frac{1}{k}$ is satisfied. For lower value of $p_i = 1/D^2$, namely for distance $D < \sqrt{c/(1 - 1/k)} = O(\sqrt{c})$, we may afford to generate the Bernoulli trials one-by-one as $c \cdot \text{poly}(\log n)$. We also note that the degree of each vertex is clearly bounded by $O(\log n)$ with high probability, as its expectation is scaled up by at most a factor of $c$. Thus, we obtain the following corollary.

Corollary 61. There exists an algorithm that generates a random graph from Kleinberg’s Small World model with edge probabilities $c/\text{DIST}(u, v)^2$ where $c = \text{poly}(\log n)$, using $O(\log^2 n)$ time and random words per All-Neighbors query with high probability.

F Omitted Proofs for the Dyck Path Implementation

Theorem 62. There are $\frac{1}{n+1} \binom{2n}{n}$ Dyck paths for length $2n$ (construction from [53]).

Proof from [53]. Consider all possible sequences containing $n + 1$ up-steps and $n$ down-steps with the restriction that the first step is an up-step. We say that two sequences belong to the same class if they are cyclic shifts of each other. Because of the restriction, the total number of sequences is $\binom{2n}{n}$ and each class is of size $n + 1$. Now, within each class, exactly one of the sequences is such that the prefix sums are strictly greater than zero. From such a sequence, we can obtain a Dyck sequence by deleting the first up-step. Similarly, we can start with a Dyck sequence, add an initial up-step and consider all $n + 1$ cyclic shifts to obtain a class. This bijection shows that the number of Dyck paths is $\frac{1}{n+1} \binom{2n}{n}$.

F.1 Approximating Close-to-Central Binomial Coefficients

We start with Stirling’s approximation which states that

$$m! = \sqrt{2\pi m} \left(\frac{m}{e}\right)^m \left(1 + O\left(\frac{1}{m}\right)\right)$$
We will also use the logarithm approximation when a better approximation is required:
\[
\log(m!) = m \log m - m + \frac{1}{2} \log(2\pi m) + \frac{1}{12m} - \frac{1}{360m^3} + \frac{1}{1260m^5} - \cdots
\]  
(12)

This immediately gives us an asymptotic formula for the central binomial coefficient as:

**Lemma 63.** The central binomial coefficient can be approximated as:
\[
\binom{n}{n/2} = \sqrt{\frac{2}{\pi n}} 2^n \left(1 + \mathcal{O}\left(\frac{1}{n}\right)\right)
\]

Now, we consider a “off-center” Binomial coefficient \(\binom{n}{k}\) where \(k = \frac{n + c\sqrt{n}}{2}\).

**Lemma 64.**
\[
\binom{n}{k} = \binom{n}{n/2} e^{-c^2/2} \exp\left(\mathcal{O}\left(c^3/\sqrt{n}\right)\right)
\]

Proof from [52]. We consider the ratio: \(R = \binom{n}{k}/\binom{n}{n/2}\):
\[
R = \frac{\binom{n}{k}}{\binom{n}{n/2}} = \frac{(n/2)!}{(n/2)!} = \prod_{i=1}^{c\sqrt{n}/2} \frac{n/2 - i + 1}{n/2 + i}
\]
\[
\implies \log R = \sum_{i=1}^{c\sqrt{n}/2} \log \left(\frac{n/2 - i + 1}{n/2 + i}\right)
\]
\[
= \sum_{i=1}^{c\sqrt{n}/2} \frac{4i}{n} + \mathcal{O}\left(\frac{c^2}{n^2}\right) = -\frac{c^2}{2} + \mathcal{O}\left(\frac{c^3}{\sqrt{n}}\right)
\]
\[
\implies \binom{n}{k} = \binom{n}{n/2} e^{-c^2/2} \exp\left(\mathcal{O}\left(c^3/\sqrt{n}\right)\right)
\]

**F.2 Dyck Path Boundaries and Deviations**

**Lemma 65.** Given a random walk of length \(2n\) with exactly \(n\) up and down steps, consider a contiguous sub-path of length \(2B\) that comprises of \(U\) up-steps and \(D\) down-steps i.e. \(U + D = 2B\). Both \(|B - U|\) and \(|B - D|\) are \(\mathcal{O}(\sqrt{B \log n})\) with probability at least \(1 - 1/n^4\).

Proof. We consider the random walk as a sequence of unbiased random variables \(\{X_i\}_{i=1}^{2n} \in \{0, 1\}^{2n}\) with the constraint \(\sum_{i=1}^{2n} X_i = n\). Here, 1 corresponds to an up-step and 0 corresponds to a down step. Because of the constraint, \(X_i, X_j\) are negatively correlated for \(i \neq j\) which allows us to apply Chernoff bounds. Now we consider a sub-path of length \(2B\) and let \(U\) denote the sum of the \(X_i\)s associated with this subpath. Using Chernoff bound with \(\mathbb{E}[X] = B\), we get:
\[
\mathbb{P}\left[|U - B| < 3\sqrt{B \log n}\right] = \mathbb{P}\left[|U - B| < 3\frac{\log n}{\sqrt{B}} B\right] < e^{-\frac{2 \log n}{3}} = \frac{1}{n^3}
\]
Since \(U\) and \(D\) are symmetric, the same argument applies.

**Corollary 66.** With high probability, every contiguous sub-path of length \(2B\) (with \(U\) up and \(D\) down steps such that \(U + D = 2B\)) in the random walk satisfies the property that \(|B - U|\) and \(|B - D|\) are upper bounded by \(c\sqrt{B \log n}\) w.h.p. \(1 - 1/n^2\) (for some constant \(c\).
Lemma 22. Consider a contiguous sub-path of a simple Dyck path of length $2n$ where the sub-path is of length $2B$ comprising of $U$ up-steps and $D$ down-steps (with $U + D = 2B$). Then there exists a constant $c$ such that the quantities $|B - U|$, $|B - D|$, and $|U - D|$ are all $< c\sqrt{B\log n}$ with probability at least $1 - 1/n^2$ for every possible sub-path.

Proof. We can simply apply Lemma 65 and union bound over all $n^2$ possible contiguous sub-paths.

Lemma 23. Given a Dyck path sampling problem of length $B$ with $U$ up, $D$ down steps, and a boundary at $k$, there exists a constant $c$ such that if $k > c\sqrt{B\log n}$, then the distribution of paths sampled without a boundary $C_{\infty}(U, D)$ is $O(1/n^2)$-close in $L_1$ distance to the distribution of Dyck paths $C_2(U + D)$.

Proof. We use $D$ and $R$ to denote the set of all valid Dyck paths and all random sequences respectively. Clearly, $D \subseteq R$. Since the random walk/sequence distribution is uniform on $R$, and by Corollary 66 we see that at least $1 - 1/n^2$ fraction of the elements of $R$ do not violate the boundary constraint. Therefore, $|D| \geq (1 - 1/n^2)|R|$, and so the $L_1$ distance between the uniform distributions on $D$ and $R$ is $O(1/n^2)$.

F.3 Estimating the Sampling Probabilities

Lemma 67. Given a Dyck sub-path problem within a global Dyck path of size $2n$ and a probability expression of the form $p_D = \frac{S_{left} \cdot S_{right}}{S_{total}}$, there exists a poly$(\log n)$ time oracle that returns a $(1 \pm 1/n^2)$ multiplicative approximation to $p_D$ if $p_D = \Omega(1/n^2)$ and returns 0 otherwise.

Proof. We first compute a $1 + 1/n^3$ multiplicative approximation to $\ln p_D$. Using $O(\log n)$ terms of the series in Equation 12, it is possible to estimate the logarithm of a factorial up to $1/n^3$ additive error. So, we can use the series expansion from Equation 12 up to $O(\log n)$ terms. The additive error can also be cast as multiplicative since factorials are large positive integers.

The probability $p_D$ can be written as an arithmetic expression involving sums and products of a constant number of factorial terms. Given a $1 \pm 1/n^\epsilon$ multiplicative approximation to $l_a = \ln a$ and $l_b = \ln b$, we wish to approximate $\ln(ab)$ and $\ln(a+b)$. The former is trivial since $\ln(ab) = l_a + l_b$. For the latter, we assume $a > b$ and use the identity $\ln(a+b) = \ln a + \ln(1+b/a)$ to note that it suffices to approximate $\ln(1+b/a)$. We define $\bar{l}_a = l_a \cdot (1 \pm O(1/n^\epsilon))$ and $\bar{l}_b = l_b \cdot (1 \pm O(1/n^\epsilon))$. In case $\bar{l}_b - \bar{l}_a < -c \ln n \implies b/a < 1/n^\epsilon$, we approximate $\ln(a+b)$ by $\ln a$ since $\ln(1+b/a) = O(1/n^\epsilon)$ in this case.

Otherwise, we notice that $\max(a,b) = O\left((n!)^2\right) \implies \max(l_a,l_b) = o(n^3) \implies l_a - l_b = o(n^3)$. This is true because if we write out the expression for $p_D = S_{left} \cdot S_{right}/S_{total}$ in terms of sums and products of factorials, the largest possible value will be a product of at most two terms that are present in the numerator/denominator of a binomial term (see the expression...
for generalized Catalan numbers in Equation 1). Hence, the claim $\max(a, b) = \mathcal{O} \left( (n!)^2 \right)$ follows from the fact that the numerators/denominators of the relevant binomial coefficient in Equation 1 are at most $n!$. Using this fact, we obtain the following:

$$1 + e^{\frac{k}{n}} = 1 + \frac{\ln \frac{k}{n}}{n} = 1 + \frac{1}{n} \left( \frac{1}{1 + \frac{1}{n - \bar{x}}} \right) = \left( 1 + \frac{1}{a} \right) \left( 1 + \mathcal{O} \left( \frac{1}{n^{a - 2}} \right) \right)$$

In other words, the value of $c$ decreases every time we have a sum operation. Since there are only a constant number of such arithmetic operations in the expression for $p_d$, we can set $c$ to be a high enough constant when approximating the factorials, which allows us to obtain the desired $1 \pm 1/n^3$ multiplicative approximation to $\ln p_d$. If $\ln p_d < -3 \ln n$, we approximate $p_d = 0$. Otherwise, we can exponentiate the approximation to obtain $\tilde{p}_d = p_d \cdot e^{-\mathcal{O}(\ln n/n^3)} = p_d (1 + \mathcal{O}(1/n^2))$. ▶

### F.4 Omitted Proofs from Section 4.3: Sampling the Height

- **Lemma 68.** For $x < 1$ and $k \geq 1$, we claim that $1 - kx < (1 - x)^k < 1 - kx + \frac{k(k-1)}{2} x^2$

- **Lemma 25.** $S_{left} \leq c_1 \frac{k \sqrt{\log n}}{\sqrt{B}} \cdot \left( \frac{B}{D-d} \right)$ for some constant $c_1$.

**Proof.** This involves some simple manipulations.

$S_{left} = \left( \frac{B}{D-d} \right) - \left( \frac{B}{D-d-k} \right)$

$$= \left( \frac{B}{D-d} \right) \left[ 1 - \frac{(D-d-k)(D-d-1)\cdots(D-d-k+1)}{(B-D-d+k)(B-D-d+1)\cdots(B-D-d+1)} \right]$$

$$\leq \left( \frac{B}{D-d} \right) \left[ 1 - \frac{D-d-k+1}{B-D+d+k} \right]^k$$

$$\leq \left( \frac{B}{D-d} \right) \left[ 1 - \left( \frac{U + d + k - \mathcal{O}(\sqrt{B \log n})}{U + d + k} \right)^k \right]$$

$$\leq \Theta \left( \frac{k \sqrt{\log n}}{\sqrt{B}} \right) \cdot \left( \frac{B}{D-d} \right)$$

- **Lemma 26.** $S_{right} \leq c_2 \frac{k' \sqrt{\log n}}{\sqrt{B}} \cdot \left( \frac{B}{U-d} \right)$ for some constant $c_2$.

**Proof.**

$S_{right} = \left( \frac{B}{U-d} \right) - \left( \frac{B}{U-d-k'} \right)$

$$= \left( \frac{B}{U-d} \right) \left[ 1 - \frac{(U-d)(U-d-1)\cdots(U-d-k'+1)}{(B-U-d-k')(B-U-d-k'+1)\cdots(B-U-d+1)} \right]$$

$$\leq \Theta \left( \frac{k' \sqrt{\log n}}{\sqrt{B}} \right) \cdot \left( \frac{B}{U-d} \right)$$
\[ \cdots \leq \left( \frac{B}{U - d} \right) \cdot \left[ 1 - \left( \frac{U - d - k' + 1}{B - U + d + k'} \right)^k \right] \]
\[ \leq \left( \frac{B}{U - d} \right) \cdot \left[ 1 - \left( \frac{2D - U - d - k' + 1}{2U - D + k + d} \right)^k \right] \]
\[ \leq \left( \frac{B}{U - d} \right) \cdot \left[ 1 - \left( \frac{U + k + d - (2U - 2D + 2d + 2k - 1)}{U + k + d} \right)^k \right] \]
\[ \leq \left( \frac{B}{U - d} \right) \cdot \left[ 1 - \left( \frac{U + k + d - \mathcal{O}(\sqrt{B \log n})}{U + k + d} \right)^k \right] \]
\[ \leq \Theta \left( \frac{k' \sqrt{\log n}}{\sqrt{B}} \right) \cdot \left( \frac{B}{U - d} \right) \]

Lemma 69. \( S_{\text{tot}} \geq \left( \frac{2B}{2D} \right) \cdot \left[ 1 - \left( 1 - \frac{k'}{2U + 1} \right)^k \right] \).

Proof. \( S_{\text{tot}} = \left( \frac{2B}{2D} \right) - \left( \frac{2B}{2D - k} \right) \)
\[ = \left( \frac{2B}{2D} \right) \cdot \left[ 1 - \frac{(2D)(2D - 1) \cdots (2D - k + 1)}{(2B - 2D + k)(2B - 2D + k - 1) \cdots (2B - 2D + 1)} \right] \]
\[ \geq \left( \frac{2B}{2D} \right) \cdot \left[ 1 - \left( \frac{2D - k + 1}{2B - 2D + 1} \right)^k \right] \]
\[ \geq \left( \frac{2B}{2D} \right) \cdot \left[ 1 - \left( \frac{2U - (2U - 2D + k - 1)}{2U + 1} \right)^k \right] \]
\[ \geq \left( \frac{2B}{2D} \right) \cdot \left[ 1 - \left( \frac{2U + 1 - k'}{2U + 1} \right)^k \right] \]
\[ \geq \left( \frac{2B}{2D} \right) \cdot \left[ 1 - \left( \frac{2U + 1}{2U + 1} \right)^k \right] \]
\[ \geq \left( \frac{2B}{2D} \right) \cdot \left[ 1 - \left( \frac{2U + 1}{2U + 1} \right)^k \right] \]

Lemma 24. When \( kk' > 2U + 1 \), \( S_{\text{total}} > \frac{1}{2} \cdot \left( \frac{2B}{2D} \right) \).

Proof. When \( kk' > 2U + 1 \implies k > \frac{2U + 1}{k'} \), we will show that the above expression is greater than \( \frac{1}{2} \left( \frac{2B}{2D} \right) \). Defining \( \nu = \frac{2U + 1}{k'} > 1 \), we see that \( (1 - \frac{\nu}{2})^k \leq (1 - \frac{1}{2})^k \). Since this is an increasing function of \( \nu \) and since the limit of this function is \( \frac{1}{e} \), we conclude that
\[ 1 - \left( 1 - \frac{k'}{2U + 1} \right)^k > \frac{1}{2} \]
Lemma 27. When $kk' \leq 2U + 1$, $S_{total} \geq c_3 \frac{kk'}{2U+1} \cdot \left( \frac{2B}{2D} \right)$ for some constant $c_3$.

Proof. Now we bound the term $1 - \left(1 - \frac{k'}{2U+1} \right)^k$, given that $kk' \leq 2U + 1 \implies \frac{kk'}{2U+1} \leq 1$. Using Bernoulli’s inequality, we know that $(1 - x)^n \leq 1/(1 + nx)$ for $x \in [0, 1]$ and $n \in \mathbb{N}$. Since the term $k'/2U + 1$ is positive and $\leq 1$ (since $kk' \leq 2U + 1$), we can apply this as follows:

\[
1 - \left(1 - \frac{k'}{2U+1} \right)^k \geq 1 - \frac{1}{1 + \frac{kk'}{2U+1}} = \frac{kk'}{2U+1} \cdot \frac{1}{1 + \frac{kk'}{2U+1}} \tag{37}
\]

\[
\geq \frac{kk'}{2U+1} \cdot \frac{1}{2} \tag{38}
\]

\[
\geq \frac{kk'}{\Theta(B)} \tag{39}
\]

F.5 Omitted Proofs from Section 4.4: First-Return Queries

Lemma 31. If $d > \log^4 n$, then $S_{left}(d) = \Theta\left( \frac{z^{2d+k}}{\sqrt{d}} e^{-r_{left}(d)} \cdot \frac{k-1}{2(k-1)} \right)$ where \(r_{left}(d) = \frac{(k-2)^2}{2(2d+k-2)}\). Furthermore, $r_{left}(d) = \mathcal{O}(\log^2 n)$.

Proof. In what follows, we will drop constant factors: Refer to Figure 8 for the setup. The left section of the path reaches one unit above the boundary (the next step would make it touch the boundary). The number of up-steps on the left side is $d$ and therefore the number of down steps must be $d + k - 2$. This includes $d$ down steps to cancel out the upwards movement, and $k - 2$ more to get to one unit above the boundary. The boundary for this section is $k' = k - 1$. This gives us:

\[
S_{left}(d) = \frac{2d + k - 2}{d} - \frac{2d + k - 2}{d + 1} = \frac{2d + k - 2}{d} \left[ 1 - \frac{d}{d + k - 1} \right] = \frac{2d + k - 2}{d} \cdot \frac{k-1}{d + k - 1} \tag{41}
\]

Now, letting $z = 2d + k - 2$, we can write $d = \frac{z - (k-2)}{2} = \frac{z - k^2}{2}$. Using Lemma 22, we see that $\frac{k-2}{z}$ should be $\mathcal{O}(\sqrt{\log n})$. If this is not the case, we can simply return 0 because the probability associated with this value of $d$ is negligible. Since $z > \log^4 n$, we can apply Lemma 64 to get:

\[
S_{left}(d) = \Theta\left( \frac{z^{2d+k}}{\sqrt{d}} e^{-r_{left}(d)} \cdot \frac{k-1}{2(k-1)} \right) = \Theta\left( \frac{z^{2d+k}}{\sqrt{d}} e^{\frac{(k-2)^2}{2(2d+k-2)}} \cdot \frac{k-1}{d + k - 1} \right) \tag{42}
\]

Lemma 32. If $U + D - 2d - k > \log^4 n$, then $S_{right}(d) = \Theta\left( \frac{U + D - 2d - k}{\sqrt{U+D-2d-k}} e^{-r_{right}(d)} \cdot \frac{U-D+k}{U+D+k} \right)$ where \(r_{right}(d) = \frac{(U-D-k-1)^2}{4(U+D-2d-k+1)}\). Furthermore, $r_{right}(d) = \mathcal{O}(\log^2 n)$.
Proof. The right section of the path starts from the original boundary. Consequently, the boundary for this section is at \( k' = 1 \). The number of up-steps on the right side is \( U - d \) and the number of down steps is \( D - d - k + 1 \). This gives us:

\[
S_{\text{right}}(d) = \frac{(U + D - 2d - k + 1)}{U - d} \cdot \frac{(U + D - 2d - k + 1)}{U - d + 1} \left(1 - \frac{D - d - k - 1}{U - d + 1}\right)
\]

Now, letting \( z = U + D - 2d - k + 1 \), we can write \( U - d = \frac{z + (U - D + k - 1)}{2} = \frac{z - \frac{U - D + k - 1}{2}}{\sqrt{z}} \).

Using Lemma 22, we see that \( \frac{k - 2}{\sqrt{z}} \) should be \( O(\sqrt{\log n}) \). If this is not the case, we can simply return 0 because the probability associated with this value of \( d \) is negligible. Since \( z > \log^4 n \), we can apply Lemma 64 to get:

\[
S_{\text{right}}(d) = \Theta \left(\frac{z}{z/2} e^{\frac{(U - D + k - 1)^2}{2z}} \frac{U - D + k}{U - d + 1}\right) \quad (46)
\]

\[
= \Theta \left(\frac{2^{U + D - 2d - k}}{\sqrt{U + D - 2d - k}} e^{\frac{(U - D + k - 1)^2}{2(U - D + 2d - k + 1)}} \frac{U - D + k}{U - d + 1}\right) \quad (47)
\]

\[\square\]

Random graph models

The Erdős-Rényi model, given in [17], is one of the most simple theoretical random graph model, yet more specialized models are required to capture properties of real-world data. The Stochastic Block model (or the planted partition model) was proposed in [29] originally for modeling social networks; nonetheless, it has proven to be an useful general statistical model in numerous fields, including recommender systems [33, 49], medicine [51], social networks [21, 44], molecular biology [11, 36], genetics [9, 30, 13], and image segmentation [50]. Canonical problems for this model are the community detection and community recovery problems; some recent works include [12, 40, 3, 2]; see e.g., [1] for survey of recent results. The study of Small-World networks is originated in [55] has frequently been observed, and proven to be important for the modeling of many real world graphs such as social networks [15, 54], brain neurons [6], among many others. Kleinberg’s model on the simple lattice topology (as considered in this paper) imposes a geographical that allows navigations, yielding important results such as routing algorithms (decentralized search) [31, 37]. See also e.g., [43] and Chapter 20 of [16].

Generation of random graphs

The problem of local-access implementation of random graphs has been considered in the aforementioned work [24, 41, 18], as well as in [35] that locally generates out-going edges on bipartite graphs while minimizing the maximum in-degree. The problem of generating full graph instances for random graph models have been frequently considered in many models of computations, such as sequential algorithms [39, 7, 45, 38], and the parallel computation model [4].
Query models

In the study of sub-linear time graph algorithms where reading the entire input is infeasible, it is necessary to specify how the algorithm may access the input graph, normally by defining the type of queries that the algorithm may ask about the input graph; the allowed types of queries can greatly affect the performance of the algorithms. While \texttt{Next-Neighbor} query is only recently considered in [18], there are other query models providing a neighbor of a vertex, such as asking for an entry in the adjacency-list representation [28], or traversing to a random neighbor. On the other hand, the \texttt{Vertex-Pair} query is common in the study of dense graphs as accessing the adjacency matrix representation [27]. The \texttt{All-Neighbors} query has recently been explicitly considered in local algorithms [19].

Other constructions of huge pseudorandom functions that are permutations or random hash functions were given in [34, 42, 35].
Monotone Probability Distributions over the Boolean Cube Can Be Learned with Sublinear Samples

Abstract

A probability distribution over the Boolean cube is monotone if flipping the value of a coordinate from zero to one can only increase the probability of an element. Given samples of an unknown monotone distribution over the Boolean cube, we give (to our knowledge) the first algorithm that learns an approximation of the distribution in statistical distance using a number of samples that is sublinear in the domain.

To do this, we develop a structural lemma describing monotone probability distributions. The structural lemma has further implications to the sample complexity of basic testing tasks for analyzing monotone probability distributions over the Boolean cube: We use it to give nontrivial upper bounds on the tasks of estimating the distance of a monotone distribution to uniform and of estimating the support size of a monotone distribution. In the setting of monotone probability distributions over the Boolean cube, our algorithms are the first to have sample complexity lower than known lower bounds for the same testing tasks on arbitrary (not necessarily monotone) probability distributions.

One further consequence of our learning algorithm is an improved sample complexity for the task of testing whether a distribution on the Boolean cube is monotone.

1 Introduction

1.1 Learning Monotone Distributions

Data generated from probability distributions is ubiquitous, and algorithms for understanding such data are of fundamental importance. In particular, a fundamental task is to learn an approximation to the probability distribution underlying the data. For probability distributions over huge discrete domains, the sample complexity and run-time bounds for the learning task can be prohibitive. In particular, learning an arbitrary probability distribution on a universe of $N_{\text{universe}}$ elements up to sufficiently small constant total variation distance
Learning Monotone Probability Distributions over the Boolean Cube

requires $\Omega(N_{\text{universe}})$ samples. However, when the probability distribution is known to belong to a more structured class of distributions, much better results are possible (cf. [16, 19, 22, 21, 20, 24, 13, 12, 6, 10, 25, 23, 15, 28]) – for example, learning an unknown Poisson binomial distribution up to variation distance $\epsilon$ can be achieved with only $\tilde{O}(1/\epsilon^3)$ samples and $\tilde{O}(\log(N_{\text{universe}})/\epsilon^3)$ run-time [13].

A fundamental class of probability distributions is the class of multidimensional monotone probability distributions, which broadly satisfy the following properties:

- The elements of the probability distribution have $n$ different features.
- For every element, an increase in the value of one of the features can only increase its probability.

This basic class of distributions is of great interest because many commonly studied distributions are either monotone or can be approximated by a combination of monotone distributions. Furthermore, often the tools developed for monotone distributions are useful for other classes of distributions: for example, in the one dimensional setting, [12] use tools developed for testing monotone distributions in order to learn $k$-modal distributions. In [8], tools developed for testing properties of monotone distributions by [4] are used to develop testers for many other classes of distributions.

For the case of only one feature, or equivalently for monotone probability distributions over the totally ordered set $[k]$, a sample-efficient algorithm is known for learning the unknown distribution up total variation distance $\epsilon$ with $O(\log(k)/\epsilon^3)$ samples [6, 12]. In [1] it was also shown that an unknown probability distribution over $[k]^n$ can be learned up to $\chi^2$ distance $\epsilon^2$ with $O(n\log k/\epsilon^3)^n/\epsilon^2)$ samples (note that for constant $\epsilon$, this sample complexity is non-trivial only when $k$ is sufficiently large). Overall, the cases considered in the literature specialize on the regime when all the dimensions have a wide range that grows with $n$. Here we focus on a contrasting case, where each feature has only two possible values, 0 and 1, thus specializing on the Boolean cube:

Definition 1. A probability distribution $\rho$ over $\{0,1\}^n$ is monotone if whenever for $x, y \in \{0,1\}^n$ we have that $x \leq y$ (which means that for all $i$, $x_i \leq y_i$), then we have that $\rho(x) \leq \rho(y)$.

When studying multi-dimensional objects, focusing on the specific case of the Boolean cube is a common research theme, because the ideas and techniques developed for the Boolean cube are often applicable in the general case. A lower bound of $\Omega(2^{0.15n})$ for learning monotone probability distributions over the Boolean cube (up to sufficiently small constant variation distance) can be inferred from an entropy testing lower bound in [29, page 39] and an argument in [32] (see Claim 17 in Preliminaries). Though the dramatic exponential improvement as in [6, 12] for the totally ordered set is thereby impossible, this still leaves open the possibility of a sublinear sample algorithm for the Boolean cube.

We give, to the best of our knowledge, the first sublinear sample algorithm for learning a monotone probability distribution over the Boolean cube:

Theorem 2. For every positive $\epsilon$, such that $0 < \epsilon \leq 1$ and for all sufficiently large $n$, there exists an algorithm, which given $2^{-2^{n+O(n^{1/5}\log n)}}$ samples from an unknown monotone probability distribution $\rho$ over $\{0,1\}^n$, can reliably return a description of an estimate probability distribution $\hat{\rho}$, such that $d_{TV}(\rho, \hat{\rho}) \leq \epsilon$. The algorithm runs in time $O \left( 2^n + O(n^{1/5}\log n) \right)$.

Our algorithm relies on a new structural lemma describing monotone probability distributions on the Boolean cube, as described in Section 1.3. These structural insights also allow us to get improved sample complexity for certain testing tasks on monotone distributions – namely, estimating the closeness of a distribution to uniformity and the support size of the distribution, as presented in Section 1.2.
Theorem 2, together with the $L_1$ distance tester in [31], can be applied to give the best known sample complexity for testing whether a distribution is monotone. Specifically, one can test whether an unknown distribution $\rho$ over the Boolean cube is monotone or $\epsilon$-far from monotone with $O\left(\frac{2^n}{n^2}\right)$ samples as shown in Claim 18 in Preliminaries. Note that this does not follow from [32] directly, because monotonicity is not a symmetric property. The best previously known algorithm for testing monotonicity over the Boolean cube was presented in [5], requiring $\tilde{O}\left(\frac{n^2}{\epsilon^2}\right)$ samples. The best sample complexity lower bound for testing monotonicity over $\{0,1\}^n$ is $\Omega(2^{(1-\Theta(\sqrt{\epsilon})+o(1))n})$, as presented in [3]. For the domain $[k]^n$, a monotonicity testing algorithm that requires $O\left(k^{n/2}/\epsilon^2 + \left(\frac{n\log k}{\epsilon^2}\right)^n \cdot \frac{1}{\epsilon^2}\right)$ samples is given and shown to be optimal in [1] (note that this is inapplicable to the Boolean setting, because this sample bound is non-trivial only for sufficiently large $k$).

1.2 Testing properties of monotone distributions

In addition to learning a distribution, several other basic tasks aimed at understanding distributions have received attention. These include estimating the entropy of a distribution, the size of the support and whether the distribution has certain “shape” properties (monotonicity, convexity, monotone hazard rate, etc.). For arbitrary probability distributions over huge domains, the sample complexity and run-time bounds for the above tasks can be prohibitive, provably requiring $\Omega\left(\frac{N_{\text{universe}}}{\log(N_{\text{universe}})}\right)$ samples. This is true in particular for the properties of support size, entropy and the distance to the uniform distribution [27, 32, 30, 33, 34].

This state of affairs motivates going beyond worst-case analysis and considering common classes of structured probability distributions, a direction that has been considered by many and with a large variety of results (cf. [4, 9, 24, 29, 14, 18]). Some specific examples include: In [4] it is shown that testing whether a monotone distribution is uniform requires only $\Theta(\log^3(N_{\text{universe}})/\epsilon^2)$ samples, in contrast to the $\Theta(\sqrt{N_{\text{universe}}}/\epsilon^2)$ samples required for testing arbitrary distributions for uniformity [26, 11, 17]. The situation is analogous for the tasks of testing whether two distributions given by samples are either the same or far, and testing whether a constant dimensional distribution is independent, which require only polylogarithmic samples if the unknown distributions are promised to be monotone on a total order [4].

Algorithms for testing properties of monotone probability distributions over the Boolean cube were studied in [29, 2]. It was shown that, given samples from a probability distribution over $\{0,1\}^n$ that is promised to be monotone, distinguishing the uniform distribution over $\{0,1\}^n$ from one that is $\epsilon$-far from uniform can be done using only $O\left(\frac{n}{\epsilon^2}\right)$ samples, which is nearly optimal. In contrast, a number of other testing problems cannot have such dramatic improvements when the distribution is known to be monotone: for example in [29] it was shown that for sufficiently small constant $\epsilon$ the estimation of entropy up to an additive error of $\epsilon n$ requires $2^{\Theta(n)}$ samples. However, no nontrivial upper bounds on the sample complexity of any other computational tasks for monotone probability distributions over the Boolean cube are known.

\footnote{i.e. using monotonicity in an essential way and going beyond the bounds known for arbitrary probability distributions.}
1.2.1 Estimating support size

We consider the task of additively estimating the support size of an unknown monotone probability distribution over the Boolean cube. The following assumption is standard in support size estimation:

Definition 3. A probability distribution over a universe of size $N_{\text{universe}}$ is called well-behaved (in context of support size estimation) if for every $x$ in the set, the probability of $x$ is either zero or at least $1/N_{\text{universe}}$.

The purpose of this definition is to rule out pathological cases in which there are items that are in the support, yet have probability very close to zero. We henceforth adapt this definition to probability distributions over $\{0, 1\}^n$, where we have $N_{\text{universe}} = 2^n$. We prove the following theorem:

Theorem 4. For every positive $\epsilon$, the following is true: for all sufficiently large $n$, there exists an algorithm, which given $2^n(1/\epsilon^2)$ samples from an unknown well-behaved monotone probability distribution $\rho$ over $\{0, 1\}^n$, can reliably approximate the support size of $\rho$ with an additive error of up to $\epsilon$. The algorithm runs in time $O(2^n(\sqrt{n\epsilon}))$.

We contrast this result to the results of [27, 30, 31, 32, 34] that show that one needs $\Omega(N_{\text{universe}}/\log(N_{\text{universe}}))$ samples to estimate the support size of an arbitrary distribution up to a sufficiently small constant, which equals to $\Omega(2^n/n)$ for a universe of size $2^n$, such as the Boolean cube.

1.2.2 Estimating distance to uniformity

We now consider the task of additively estimating the distance from an unknown monotone probability distribution over the Boolean cube to the uniform distribution. We prove the following theorem:

Theorem 5. For every positive $\epsilon$, the following is true: for all sufficiently large $n$, there exists an algorithm, which given $2^n(2^{0.5-0.01})$ samples from an unknown monotone probability distribution $\rho$ over $\{0, 1\}^n$, can reliably approximate the distance between $\rho$ and the uniform distribution over $\{0, 1\}^n$ with an additive error of up to $\epsilon$. The algorithm runs in time $O(2^n + O(\sqrt{n\log n}))$.

We, again, contrast this result to the results of [30, 31, 32] that show that one needs $\Omega(N_{\text{universe}}/\log(N_{\text{universe}}))$ samples to estimate the distance of an arbitrary distribution to the uniform distribution, which equals to $\Omega(2^n/n)$ for a universe of size $2^n$, such as the Boolean cube.

We also have the following sample complexity lower bound on this task, which we prove using the sub-cube decomposition technique of [29]:

Theorem 6. For infinitely many positive integers $n$, there exist two probability distributions $\Delta_{\text{Close}}$ and $\Delta_{\text{Far}}$ over monotone distributions over $\{0, 1\}^n$, satisfying:

1. Every distribution in $\Delta_{\text{Far}}$ is $1/2$-far from the uniform distribution.
2. Any algorithm that takes only $o\left(2^{n+O(\sqrt{n\log n})}\right)$ samples from a probability distribution, fails to reliably distinguish between $\Delta_{\text{Close}}$ and $\Delta_{\text{Far}}$.
3. Every distribution in $\Delta_{\text{Close}}$ is $o(1)$-close to the uniform distribution.

2 By reliably we henceforth mean that the probability of success is at least $2/3$. 
Remark 7. In our construction, the distribution $\Delta_{\text{Close}}$ consists of only one probability distribution. Additionally, the constant 0.01 can be made arbitrarily small.

Recall that in [29, 2] it was shown that, given samples from a probability distribution over the Boolean cube that is promised to be monotone, distinguishing the uniform distribution from one that is $\epsilon$-far from uniform can be done using only $O\left(\frac{n}{\epsilon^2}\right)$ samples. Yet, as the theorem above shows, the tolerant version of this problem, which requires one to distinguish a distribution that is $o(1)$-close to the uniform from a distribution that is $1/2$-far from uniform, requires $\Omega\left(\frac{2^{0.5\cdot 0.01}}{2}\right)$ samples, which is dramatically greater.

### 1.3 Technical overview

#### 1.3.1 Structural results

Our analysis applies and builds upon the main structural lemma in [7]. To state it, recall that a DNF is a Boolean function that is formed as an OR of ANDs, and it is monotone if there are no negations. Each AND is referred to as a clause, with the number of variables in the AND is referred to as the width of the clause. Their structural lemma shows that each monotone function can be approximated by a DNF with only a constant number of distinct clause widths. Specifically:

**Lemma 8** (Main Lemma in [7], abridged and restated). For every positive $\epsilon$, for all sufficiently large $n$, let $f$ be a monotone Boolean function over the domain $\{0, 1\}^n$. There is a function $g = g_1 \lor \ldots \lor g_t$ with the following properties: (i) $t \leq \frac{2}{\epsilon}$ (ii) each $g_i$ is a monotone DNF with terms of width exactly $k_i$ (iii) $g$ disagrees with $f$ at no more than $\epsilon \cdot 2^n$ elements of $\{0, 1\}^n$ (iv) $g(x) \leq f(x)$ for all $x$ in $\{0, 1\}^n$.

For Theorem 4, we use the lemma above on the indicator function of the support of the probability distribution, which allows us to prove the correctness of our algorithm. For the problems of learning and estimating the distance to uniform, we go a step further and prove an analogous structural lemma for monotone probability distributions.

There are some crucial differences between monotone Boolean functions in the setting of Boolean function approximation and monotone probability distributions in our setting. First of all, the basic properties of the two objects are different: a Boolean function always has one of the two values (zero or one), which is usually not the case for a probability distribution, but a probability distribution, summed over $\{0, 1\}^n$, has to equal one. Secondly, the relevant notions of a function $f_2$ being well-approximated by a function $f_1$ are different: for Boolean functions we bound the fraction of points on which $f_1$ and $f_2$ disagree, whereas for monotone probability distributions we would like to bound the $L_1$ distance between $f_1$ and $f_2$.

To overcome these differences, we generalize to the setting of non-Boolean functions the main concept used in the proof of Lemma 8: the concept of a minterm of a monotone Boolean function. In [7] the minterm of a monotone Boolean function $f$ is defined as follows:

$$\text{minterm}_f(x) = \begin{cases} 1 & \text{if } f(x) = 1 \text{ and for all } y \prec x, f(y) = 0 \\ 0 & \text{otherwise} \end{cases}$$

Using this language, the function $g$ in Lemma 8 can be characterized as a function, for which:

$$\sum_{h=0}^{n} 1_{\exists x \in \{0, 1\}^n: ||x|| = h \land \text{minterm}_g(x) \neq 0} \leq \frac{2}{\epsilon}$$
We introduce the notion of monotone slack that generalizes the notion of a minterm to non-Boolean functions:

$$\text{slack}_f(x) \overset{\Delta}{=} f(x) - \max_{y \leq x} f(y) = f(x) - \max_{y \leq x \text{ and } ||y||=||x||-1} f(y)$$

With such a definition at hand, one could hope to prove that every monotone probability distribution $\rho$ is well-approximated in the $L_1$ norm by a monotone function $f$, for which $\sum_{h=0}^{n} R_h \cdot 1_{\exists x \in \{0,1\}^n: ||x||=h \text{ and } \text{slack}_f(x) \neq 0}$ is bounded by a constant independent of $n$. We were not able to prove such a theorem, and instead we bound a related quantity that can be thought of as the weighted analogue of the expression in Equation 1:

$$\sum_{h=0}^{n} R_h \cdot \left(\frac{\zeta}{\sum_{j|h} \binom{\zeta}{j}}\right) \leq \zeta$$

Then, there exists a positive monotone function $f$, mapping $\{0,1\}^n$ to positive real numbers, satisfying:

1. For all $x$, it is the case that $\rho(x) \geq f(x)$.
2. It is the case that: $\sum_{x \in \{0,1\}^n} \rho(x) - f(x) \leq \zeta$
3. It is the case that: $\sum_{h=0}^{n} R_h \cdot 1_{\exists x \in \{0,1\}^n: ||x||=h \text{ and } \text{slack}_f(x) \neq 0} \leq 1$

Now, as a corollary, we present a simple special case (proven to be so in Subsection 3.1) that not only illustrates the power of Lemma 9, but also is sufficient for our proof of Theorem 5:

\textbf{Corollary 10.} Let $\rho$ be a monotone probability distribution over $\{0,1\}^n$ and let $h_0$ be an integer for which:

$$\epsilon \leq \frac{\text{Pr}_{x \sim \{0,1\}^n} ||x|| \geq h_0} {\frac{\epsilon}{2}}$$

Then, there exists a positive monotone function $f : \{0,1\}^n \rightarrow R$ satisfying:

1. For all $x$, it is the case that $\rho(x) \geq f(x)$.
2. It is the case that: $\sum_{x \in \{0,1\}^n} \rho(x) - f(x) \leq \frac{\epsilon}{4}$.
3. There exists a set of values $\{k_1, \ldots, k_t\}$ (ordered in an increasing order) with $t \leq \frac{16}{\epsilon^2}$, satisfying that if for some $x$ in $\{0,1\}^n$ we have $||x|| < h_0$ and $\text{slack}_f(x) \neq 0$, then $||x|| = k_i$ for some $i$.

For Theorem 2, however, we use the full power of Lemma 9.

### 1.3.2 Algorithmic ideas

Here we present an informal overview of the ideas involved in the design and analysis of our algorithms. Throughout we omit details and technicalities. As already mentioned, our algorithms for Theorems 4, 5 and 2 use respectively Lemma 8, Corollary 10 and Lemma 9 as their structural core. Here we present the algorithmic ideas in the order of increasing technical sophistication.
1.3.2.1 Support size estimation (Theorem 4)

The idea behind our support size estimation algorithm is as follows: if we received \( x \) as a sample, then not only \( x \) has to be in the support of \( \rho \), but every \( y \), satisfying \( x \preceq y \) is in the support of \( \rho \). For all such \( y \), we say that \( y \) is covered by \( x \). Our algorithms estimates the support size of \( \rho \) through estimating the number of all such \( y \) that are covered by at least one of the samples.

This algorithm can be made computationally efficient by standard methods in randomized algorithms, and the only non-trivial step is to show that \( \frac{n^2}{2\log(n)} \) samples suffice. To show this, we first apply Lemma 8 to the indicator function of the support of \( \rho \) (which we from now on call the support function of \( \rho \)). This gives us a Boolean function \( g \) that approximates well the support function of \( \rho \) and has zero slack everywhere, except for a small number of levels\(^3\) of \( \{0,1\}^n \). For simplicity, assume that the support function of \( \rho \) itself has this property, and there are only a small number of levels of the Boolean cube on which the support function of \( \rho \) can have non-zero slack, which we call the slacky levels.

Now, we divide the elements of \( \{0,1\}^n \) (which we also call points) into good\(^1\) points and bad points, with the former defined as all the points sufficiently close to a slacky level, and the latter defined as all the other points. Clearly, a given level of \( \{0,1\}^n \) consists either fully from good points or fully from bad points, so we also refer to levels as good or bad.

We argue that if a point \( y \) in the support of \( \rho \) is a good point, then it is likely to be covered by one of the samples, because there is a large number of values \( x \) in the support of \( \rho \), for which \( y \preceq x \).

We conclude by bounding the number of elements in the support of \( \rho \) that are bad, by using the fact that there cannot be too many slacky levels.

1.3.2.2 Estimation of distance to uniform (Theorem 5)

To estimate the distance of a monotone distribution to uniform, we pick a value \( h_0 \) as in Corollary 10 and break down the value of the total variation distance from \( \rho \) to uniform into contributions from two disjoint components: (i) \( \{x \in \{0,1\}^n \text{ s.t. } ||x|| \geq h_0\} \) and (ii) all the other points of \( \{0,1\}^n \). In other words, we use \( h_0 \) as the cutoff value for the Hamming weight, to separate \( \{0,1\}^n \) into components (i) and (ii). The first contribution is straightforward to estimate simply through estimating how likely a random sample \( x \) from \( \rho \) is to have \( ||x|| \geq h_0 \), because it is straightforward to prove that if one redistributes the probability mass of \( \rho \) in \( \{x \in \{0,1\}^n \text{ s.t. } ||x|| \geq h_0\} \), while keeping the total amount of probability mass in this set fixed, the total variation distance between \( \rho \) and the uniform distribution cannot change by more than \( O(1) \).

For any element \( x \) of the component (ii), we prepare an estimate of \( \rho(x) \), which we call \( \hat{\rho}(x) \). Our approach here is somewhat similar to the one for our support size estimation algorithm. In the case of support size estimation, we only registered whether \( x \) was covered by a sample from \( \rho \) or not. In this case, we actually need an estimate on \( \rho(x) \) (as opposed to \( 1_{\rho(x)\neq0} \)) which we obtain by studying the pattern of all the samples covering \( x \). More precisely, suppose we draw \( N_2 \) samples from the distribution, which form a multiset \( S_2 \). We extract the estimate \( \hat{\rho}(x) \) from the pattern of samples as follows:

\[
\hat{\rho}(x) := \frac{1}{2L} \max_{y \text{ s.t. } y \preceq x \text{ and } ||x||-||y||=L} \left\lfloor \frac{1}{N_2} \sum_{z \in S_2 : y \preceq z \preceq x} 1 \right\rfloor
\]

\(^3\) i.e. subsets of \( \{0,1\}^n \) that have the same Hamming weight.

\(^4\) We later re-define these notions in order to adapt them for the technical details we ignore in the introduction.
Here \( L \) is a parameter equal to \( \Theta_2(\sqrt{n}) \). We then estimate the contribution of set (ii) as \( \sum_{x \in \{0,1\}^n, ||x|| \geq h_0} \left| \hat{\phi}(x) - 1/2^n \right| \).

We show the correctness of our algorithm as follows. We use a tail bound to show that \( \hat{\phi}(x) \) concentrates sufficiently closely to the value: 

\[
\hat{\phi}(x) = \frac{1}{2L} \cdot \max_{y \text{ s.t. } y \leq x \text{ and } ||x||-||y||=L} \Pr_{z \sim \rho}[y \preceq z \preceq x] = \frac{1}{2L} \cdot \max_{y \text{ s.t. } y \leq x \text{ and } ||x||-||y||=L} \sum_{z \text{ s.t. } y \preceq z \preceq x} \rho(z) 
\]

Then, we apply Corollary 10, which implies that \( \rho \) is approximated well by a function \( f \) and a certain set of constraints on the slack of \( f \) holds.

Now for the sake of simplicity (analogously to the case of support size estimation), assume that \( \rho \) itself satisfies the condition that below the threshold \( h_0 \) there are at most \( O(1) \) levels of \( \{0,1\}^n \) on which there are points \( x \) with non-zero slack \( \rho(x) \) (in reality it is merely well-approximated by such a function). We now can (analogously to the case of support size estimation) introduce the concepts of slacky levels as levels on which \( \rho \) has non-zero slack, and good levels, which are below \( h_0 \) and farther than \( L \) from all slacky levels of \( \rho \). Now, one can prove that for \( x \) on a good level the value of \( \phi(x) \) equals precisely to \( \rho(x) \), for the following reasons: First of all the inequality:

\[
\max_{y \text{ s.t. } y \leq x \text{ and } ||x||-||y||=L} \rho(y) \leq \phi(x) \leq \rho(x)
\]

follows immediately from the monotonicity of \( \rho \) and the definition of \( \phi \). Secondly, if \( \rho \) has no slack on the levels between \( ||x|| \) and \( ||x|| - L \) (inclusive), then from the definition of slack it follows immediately using induction on \( L \) that:

\[
\max_{y \text{ s.t. } y \leq x \text{ and } ||x||-||y||=L} \rho(y) = \rho(x)
\]

Therefore, it has to be the case that \( \rho(x) = \phi(x) \).

Finally, we bound the contribution to the \( L_1 \) distance between \( \hat{\phi} \) and \( \rho \) of all the levels below \( h_0 \) that are not good (which we again call the bad levels). We do this by upper-bounding the number of bad levels, and then upper bounding the total probability mass on a single level below \( h_0 \).

### 1.3.2.3 Learning a monotone probability distribution (Theorem 2)

As we saw, our algorithm for the estimation of the distance to the uniform distribution contained a component that learned in \( L_1 \) distance the restriction of \( \rho \) on the levels below the cutoff \( h_0 \). The main challenge here is to extend these ideas to levels above \( h_0 \). To this, we make the following changes to our setup:

\[ \hat{\phi}(x) := \frac{1}{2L[||x||]} \cdot \max_{y \text{ s.t. } y \leq x \text{ and } ||y||-||x||=||x||} \left\{ \frac{z \in S: y \preceq z \preceq x}{N} \right\} \]

Instead of using Corollary 10, we use the the full power of Lemma 9. This, again gives us a function \( f \) that approximates \( \rho \) closely and has a restriction on its slacky levels.
Finally, we pick values of \( L_h \) in the algorithm and \( R_h \) in the analysis so we balance (i) The random error from the deviation of \( \hat{\phi}(x) \) from its expectation and (ii) The systematic error introduced by the slacky levels of \( f \) and the levels close to them. As a result, we find that \( \frac{n^2}{2^{O(n^{15})}} \) samples suffice.

## 2 Preliminaries

We use the following basic definitions and notation:

- **Definition 11.** For \( x \in \{0,1\}^n \), its Hamming weight is denoted as \( ||x|| \) and is equal to \( \sum_i x_i \).

- **Definition 12.** For a function \( f : \{0,1\}^n \rightarrow R \), we define the average value on level \( k \) (with \( 0 \leq k \leq n \)) as: \( \mu_f(k) = \frac{1}{\binom{n}{k}} \sum_{x \in \{0,1\}^n : ||x|| = k} f(x) \). We also refer to average value on level \( k \) for a probability distribution \( \rho \), which we denote \( \mu_\rho(k) \). By this we mean the average value on level \( k \) of the density function of \( \rho \).

- **Definition 13.** For a monotone function \( f : \{0,1\}^n \rightarrow R \), we define the monotone slack \( \text{slack}_f(x) \) at point \( x \in \{0,1\}^n \) as follows: \( \text{slack}_f(x) \triangleq f(x) - \max_{y \leq x} f(y) \). We also stipulate that \( \text{slack}_f(0^n) = f(0^n) \).

- **Definition 14.** The total variation distance between two probability distributions \( \rho_1 \) and \( \rho_2 \) is defined as:

\[
\text{TV}(\rho_1, \rho_2) \triangleq \frac{1}{2} \sum_x |\rho_1(x) - \rho_2(x)|.
\]

The following are well-known facts, which were also used in [7]:

- **Fact 15.** For a monotone function \( f : \{0,1\}^n \rightarrow R \), for all \( k_1, k_2 \) satisfying \( 0 \leq k_1 \leq k_2 \leq n \), it is the case that \( \mu_f(k_1) \leq \mu_f(k_2) \).

- **Fact 16.** For all \( k \), it is the case that \( \binom{n}{k} \leq 2^{\frac{k}{e}} \cdot 2^n \).

Now, we justify two claims we made in the introduction:

- **Claim 17.** For sufficiently small \( \epsilon_0 \), for all sufficiently large \( n \), any algorithm that learns an unknown monotone probability distribution over \( \{0,1\}^n \) requires at least \( \Omega(2^{0.15n}) \) samples from the distribution.

**Proof.** From the argument in [32, pages 1937-1938] it follows that if two probability distributions are \( \epsilon \)-close in total variation distance, then their entropy values are within \( 2 \log(N_{\text{universe}}) \epsilon = 2\epsilon n \). Therefore, the task of estimating the entropy of an unknown monotone probability up to an additive error \( 2\epsilon n \) is not harder than learning it withing total variation distance \( \epsilon \). But in [29, page 39] it is shown that at least \( \sqrt{T}/10 \) samples are required for the task of distinguishing whether the unknown monotone probability distribution has entropy at least \( 0.81n \) or at most \( n/2 + \log T \). Picking \( T = 2^{0.3n} \) gives us the desired learning lower bound.

- **Claim 18.** Given Theorem 2, one can test whether an unknown distribution \( \rho \) over the Boolean cube is monotone or \( \epsilon \)-far from monotone with \( O(\frac{2^n}{\epsilon^2}) \) samples.

**Proof.** This can be done in the following way: (1) Use our learning algorithm with an error parameter \( \epsilon/4 \). This gives us a description of a distribution \( \hat{\rho} \), which is \( \epsilon/4 \)-close to \( \rho \) if \( \rho \) is monotone. (2) Estimate, using the estimator of [31], the total variation distance between
Learning Monotone Probability Distributions over the Boolean Cube

ρ and ˜ρ up to ϵ/4. If the result is closer to ϵ than to zero, output NO. (3) Compute the total variation distance between ˜ρ and the closest monotone probability distribution. If this distance estimate is closer to ϵ than to zero, output NO, otherwise output YES. For constant ϵ, the sample complexity is dominated by step (3), which is $O(\frac{2^n}{\epsilon^5})$. It is easy to see that a monotone probability distribution will pass this test, whereas a distribution that is ϵ-far from monotone will fail either step (2) or step (3).

3 Learning monotone probability distributions

Algorithm 1 Algorithm for learning a monotone probability distribution over the Boolean cube (given sample access from a distribution ρ, which is monotone over \{0,1\}^n).

1. Set $A := \frac{1}{2n} \cdot e^{2n/\epsilon}$ for all $h \geq n/2$, set $L_h := \max \left( \log \left( 2nA \cdot \frac{(n/2)^2}{\epsilon^2} \right), 0 \right)$.

Similarly, for all $h$, satisfying $n/2 > h \geq 0$, set: $L_h := L_{n/2} = \log \left( 2nA \cdot \frac{(n/2)^2}{\epsilon^2} \right)$.

2. Set $N := \frac{2^n}{\epsilon^5} \cdot \frac{192}{n} \cdot (n + 9\sqrt{n} + 4)$

Draw $N$ samples from the probability distribution ρ and denote the multiset of these samples as $S$.

3. For all $x$ in \{0,1\}^n, if $||x|| < 9\sqrt{n}$, then set $\hat{\phi}(x) = 0$, otherwise compute:

$$\hat{\phi}(x) := \frac{1}{2^{|L_{||x||}|}} \cdot \max_{y \text{ s.t. } y \preceq x \text{ and } ||y|| - ||x|| = |L_{||x||}|} \{z \in S : y \preceq z \preceq x\}$$

Do this by first making a look-up table, which given arbitrary $z \in \{0,1\}^n$ returns the number of times $z$ was encountered in $S$. Then, use this look-up table to compute the necessary values of $\{z \in S : y \preceq z \preceq x\}$ by querying all these values of $z$ in the lookup table and summing the results up.

4. For all $x$ in \{0,1\}^n, compute the following: $\hat{\rho}(x) = \hat{\phi}(x) + \frac{1}{2n} \left( 1 - \sum_{y \in \{0,1\}^n} \hat{\phi}(y) \right)$

5. Output the value table of $\hat{\rho}$.

In this section we prove our upper-bound on the sample complexity of learning an unknown monotone probability distribution over the Boolean cube. We restate the theorem:

Theorem 2. For every positive ϵ, such that $0 < \epsilon \leq 1$ and for all sufficiently large $n$, there exists an algorithm, which given $2^n/\epsilon n^{1/5}$ samples from an unknown monotone probability distribution ρ over \{0,1\}^n, can reliably return a description of an estimate probability distribution $\hat{\rho}$, such that $d_{TV}(\rho, \hat{\rho}) \leq \epsilon$. The algorithm runs in time $O(2^n + O(n^{1/5} \log n))$.

Proof. We present the algorithm as Algorithm 1. The number of samples drawn from ρ is $N = \frac{2^n}{\epsilon n^{1/5}}$. The run-time, in turn, is dominated by computing the values of $\hat{\phi}$ in step (3), in which the construction of the lookup table takes $O(n \cdot 2^n)$ time, and the time spent computing each $\hat{\phi}(x)$ can be upper bounded by the product of: (i) the number of pairs $(y, z)$ that simultaneously satisfy $y \preceq z \preceq x$ and $||y|| - ||x|| = |L_{||x||}|$, which can be upper-bounded by $O(n|L_{||x||}| \cdot 2^{|L_{||x||}|})$ and (ii) the time it takes to look up a given $z$ in the lookup table, which can be upper-bounded by $O(n)$. Overall, this gives us a run-time upper bound of $O(2^n + O(n^{1/5} \log n))$. 
Now, the only thing to prove is correctness. Here is our main claim:

dots

\text{Claim 19.} If the following conditions are the case:

\begin{itemize}
  \item[a)] As a function of \( h \), \( L_h \) is non-increasing.
  \item[b)] For all \( h \), we have that \( L_h \leq 9\sqrt{n} \).
  \item[c)]
  \begin{equation}
  \frac{1}{2^n} \sum_{h=9\sqrt{n}}^{n} \binom{n}{h} \cdot \frac{A}{2^n} \leq \frac{1}{2} \tag{2}
  \end{equation}
  \end{itemize}

\text{d) }

\begin{equation}
\sum_{h=9\sqrt{n}}^{n} L_h \cdot \begin{cases}
  \left(\frac{400}{n}\right) & \text{ if } h \leq n/2 - \sqrt{n \ln(n)} \\
  \left(\frac{4000}{n}\right) & \text{ if } n/2 - \sqrt{n \ln(n)} < h < n/2 + \sqrt{n} \\
  \left(\frac{40000}{n}\right) \left(\frac{h-n/2}{n}\right)^2 & \text{ if } h \geq n/2 + \sqrt{n} 
\end{cases} \leq \frac{\epsilon^2}{20000}
\end{equation}

Then, with probability at least 2/3, it is the case that \( \sum_{x \in \{0,1\}^n \text{ s.t. } 9\sqrt{n} \leq ||x||} \left| \hat{\phi}(x) - \rho(x) \right| \leq \frac{\epsilon}{2} \).

We verify in Appendix A, subsection 7.1, that \( L_h \) indeed satisfy the conditions above. In fact, the values of \( L_h \) and \( A \) were chosen specifically to satisfy the constraints above. We prove Claim 19 in Section 3.2, after we develop our main structural lemma in Section 3.1.

We now bound the contribution to the \( L_1 \) distance between \( \hat{\phi} \) to \( \rho \) that comes from points of Hamming weight less than \( 9\sqrt{n} \). Since \( \sum_{x \in \{0,1\}^n} \rho(x) = 1 \) and \( \rho \) is monotone, then whenever \( ||x|| \leq n/2 \) we have \( \rho(x) \leq 1/2^n/2 \). Therefore, for sufficiently large \( n \) we have:

\begin{equation}
\sum_{x \in \{0,1\}^n \text{ s.t. } ||x|| < 9\sqrt{n}} \left| \hat{\phi}(x) - \rho(x) \right| = \sum_{x \in \{0,1\}^n \text{ s.t. } ||x|| < 9\sqrt{n}} \rho(x) \leq \frac{n^{9\sqrt{n}}}{2^{n/2}} \leq \frac{\epsilon}{2}
\end{equation}

Combining this with the bound in Claim 19 we get:

\begin{equation}
\sum_{x \in \{0,1\}^n} \left| \hat{\phi}(x) - \rho(x) \right| \leq \epsilon
\end{equation}

Overall, we have:

\begin{equation}
2 \cdot d_{TV}(\rho, \hat{\rho}) = \sum_{x \in \{0,1\}^n} \left| \hat{\phi}(x) - \rho(x) \right| =
\end{equation}

\begin{equation}
\sum_{x \in \{0,1\}^n} \left| \hat{\phi}(x) - \rho(x) + \frac{1}{2^n} \left( 1 - \sum_{y \in \{0,1\}^n} \hat{\phi}(y) \right) \right| \leq
\end{equation}

\begin{equation}
\sum_{x \in \{0,1\}^n} \left| \hat{\phi}(x) - \rho(x) \right| + \left| 1 - \sum_{y \in \{0,1\}^n} \hat{\phi}(y) \right| =
\end{equation}

\begin{equation}
\sum_{x \in \{0,1\}^n} \left| \hat{\phi}(x) - \rho(x) \right| + \sum_{x \in \{0,1\}^n} \left| \rho(x) - \hat{\phi}(x) \right| \leq 2 \cdot \sum_{x \in \{0,1\}^n} \left| \hat{\phi}(x) - \rho(x) \right| \leq 2 \cdot \epsilon
\end{equation}

Thus, with probability at least 2/3, we have \( d_{TV}(\rho, \hat{\rho}) \leq \epsilon \). 

\[ \Box \]
3.1 Main lemma

Here we prove the following structural lemma. The lemma, as well as its proof are inspired by the main structural lemma of [7] (i.e. Lemma 8). Recall that the slack of a monotone function was given in Definition 13.

**Lemma 9 (Main Structural Lemma).** For all positive $\zeta$, for all sufficiently large $n$, the following is true: Let $\rho$ be a monotone probability distribution over $\{0,1\}^n$. Suppose, for each $h$ between 0 and $n$ we are given a positive value $R_h$, and it is the case that:

$$\sum_{h=0}^{n} R_h \cdot \frac{\binom{n}{h}} {\sum_{j=h}^{n} \binom{n}{j}} \leq \zeta$$

Then, there exists a positive monotone function $f$, mapping $\{0,1\}^n$ to positive real numbers, satisfying:

1. For all $x$, it is the case that $\rho(x) \geq f(x)$.
2. It is the case that: $\sum_{x \in \{0,1\}^n} \rho(x) - f(x) \leq \zeta$
3. It is the case that: $\sum_{h=0}^{n} R_h \cdot \mathbf{1}_x \in \{0,1\}^n: ||x||=h \wedge \text{slack}_x \neq 0 \leq 1$

**Proof.** We use the following process to obtain $f$:

a) Set $f^* = \rho$.

b) For $h = 0$ to $n$:

- If it is the case that:

$$\frac{1}{\binom{n}{h}} \cdot \sum_{x \in \{0,1\}^n \text{ s.t. } ||x||=h} \text{slack}_{f^*}(x) < R_h \cdot \frac{1}{\sum_{j=h}^{n} \binom{n}{j}} \quad (2)$$

Then, for all $x \in \{0,1\}^n$, satisfying $||x|| = h$ set: $f^*(x) := f^*(x) - \text{slack}_{f^*}(x)$.

c) Set $f = f^*$ and output $f$.

By inspection, $f^*$ remains monotone and positive at every iteration of the process. Therefore, $f$ is also monotone and positive.

Property (1) in the Lemma is true, because at every step of the process, values of $f^*$ only decrease.

To see why Property (2) is the case, note that the value $\sum_{x \in \{0,1\}^n} \rho(x) - f(x)$ is zero in the beginning of the process, and at a step $h$ it either stays the same or decreases by at most $R_h \cdot \frac{\binom{n}{h}} {\sum_{j=h}^{n} \binom{n}{j}}$. Therefore we can upper-bound:

$$\sum_{x \in \{0,1\}^n} \rho(x) - f(x) \leq \sum_{h=0}^{n} R_h \cdot \frac{\binom{n}{h}} {\sum_{j=h}^{n} \binom{n}{j}} \leq \zeta$$

Now, the only thing left to prove is that property (3) holds.

From the definition of monotone slack, it follows that modifying the value of a function on points of Hamming weight $j$ does not affect the slack on any point with Hamming weight lower than $j$. Therefore, the value $\frac{1}{\binom{n}{j}} \cdot \sum_{x \in \{0,1\}^n \text{ s.t. } ||x||=j} \text{slack}_{f^*}(x)$ will not change as $f^*$ changes after the $j$th iteration. Therefore, this value will be equal to $\frac{1}{\binom{n}{j}} \sum_{x \in \{0,1\}^n \text{ s.t. } ||x||=j} \text{slack}_{f}(x)$. Thus, the value of $\frac{1}{\binom{n}{j}} \sum_{x \in \{0,1\}^n \text{ s.t. } ||x||=j} \text{slack}_{f}(x)$ is either zero or at least $R_h \cdot \frac{1}{\sum_{j=h}^{n} \binom{n}{j}}$.

Now, we need the following generalization of Fact 15:

**Observation 20.** Let $f$ be an arbitrary monotone function $\{0,1\}^n \rightarrow R$. Then, for any $k$ in $[0,n-1]$ it is the case that:

$$\mu_f(k+1) \geq \mu_f(k) + \frac{1}{\binom{n}{k+1}} \cdot \sum_{x \in \{0,1\}^n \text{ s.t. } ||x||=k+1} \text{slack}_x$$
Proof. For all $x$ with $||x|| = k + 1$ we have that:

$$f(x) = \text{slack}_f(x) + \max_{y \in \{0, 1\}^n \text{ s.t. } ||y||=k \text{ and } y \preceq x} f(y)$$

We have that:

$$\max_{y \in \{0, 1\}^n \text{ s.t. } ||y||=k \text{ and } y \preceq x} f(y) \geq \mathbb{E}_{y \sim \{0, 1\}^n} \text{ conditioned on } ||y||=k \text{ and } y \preceq x [f(y)]$$

Therefore:

$$f(x) \geq \text{slack}_f(x) + \mathbb{E}_{y \sim \{0, 1\}^n} \text{ conditioned on } ||y||=k \text{ and } y \preceq x [f(y)]$$

Averaging the both sides, we get:

$$f(x) \geq \text{slack}_f(x) + \mathbb{E}_{y \sim \{0, 1\}^n} \text{ conditioned on } ||y||=k \text{ and } y \preceq x [f(y)]$$

Above, the penultimate equality followed from a simple probabilistic fact: if one picks a random $n$-bit string of Hamming weight $k + 1$ and then sets to zero a random bit that equals to one, this is equivalent to picking a random $n$-bit string of weight $k$.

Using the Observation 20 repeatedly and recalling that in Definition 13 we defined \( \text{slack}_f(0^n) = f(0^n) \), we get that for all $h$:

$$\mu_f(h) \geq \mu_f(0) + \sum_{k=1}^{h} \frac{1}{\binom{n}{k}} \sum_{x \in \{0, 1\}^n \text{ s.t. } ||x||=k} \text{slack}_f(x) =$$

$$\sum_{k=1}^{h} \frac{1}{\binom{n}{k}} \sum_{x \in \{0, 1\}^n \text{ s.t. } ||x||=k} \text{slack}_f(x) \geq \sum_{k=0}^{h} R_k \cdot \frac{1}{\sum_{j=k}^{n} \binom{n}{j}} \cdot 1 \exists x \in \{0, 1\}^n: ||x||=k \land \text{slack}_f(x) \neq 0$$

Summing this up over all $h$ and changing the order of summations, we get:

$$1 = \sum_{x \in \{0, 1\}^n} \rho(x) \geq \sum_{x \in \{0, 1\}^n} f(x) = \sum_{h=0}^{n} \binom{n}{h} \mu_f(h) \geq$$

$$\sum_{h=0}^{n} \binom{n}{h} \sum_{k=0}^{h} R_k \cdot \frac{1}{\sum_{j=k}^{n} \binom{n}{j}} \cdot 1 \exists x \in \{0, 1\}^n: ||x||=k \land \text{slack}_f(x) \neq 0 =$$

$$\sum_{k=0}^{n} \sum_{h=k}^{n} \binom{n}{h} R_k \cdot \frac{1}{\sum_{j=k}^{n} \binom{n}{j}} \cdot 1 \exists x \in \{0, 1\}^n: ||x||=k \land \text{slack}_f(x) \neq 0 =$$

$$\sum_{k=0}^{n} R_k \cdot 1 \exists x \in \{0, 1\}^n: ||x||=k \land \text{slack}_f(x) \neq 0$$

This finishes the proof of the lemma.
Now, we prove the following corollary:

**Corollary 10.** Let \( \rho \) be a monotone probability distribution over \( \{0,1\}^n \) and let \( h_0 \) be an integer for which:

\[
\epsilon \leq \frac{1}{4} \Pr_{x \sim \{0,1\}^n} [ ||x|| \geq h_0 ] \leq \frac{\epsilon}{2}
\]

Then, there exists a positive monotone function \( f : \{0,1\}^n \rightarrow R \) satisfying:

1. For all \( x \), it is the case that \( \rho(x) \geq f(x) \).
2. It is the case that: \( \sum_{x \in \{0,1\}^n} \rho(x) - f(x) \leq \frac{\epsilon}{4} \).
3. There exists a set of values \( \{k_1, \ldots, k_t\} \) (ordered in an increasing order) with \( t \leq \frac{16}{\epsilon^2} \), satisfying that if for some \( x \) in \( \{0,1\}^n \) we have \( ||x|| < h_0 \) and \( \text{slack}_f(x) \neq 0 \), then \( ||x|| = k_i \) for some \( i \).

**Proof.** We use Lemma 9, setting \( \zeta = \epsilon/4 \) and

\[
R_h = \begin{cases} 
\frac{\epsilon^2}{16} & \text{if } h \leq h_0 \\
0 & \text{otherwise} 
\end{cases}
\]

We verify the precondition to Lemma 9, by using that \( \sum_{x \in \{0,1\}^n} \rho(x) - f(x) \leq \frac{\epsilon}{4} \):

\[
\sum_{h=0}^{n} R_h \cdot \binom{n}{h} = \sum_{h=0}^{h_0} \frac{\epsilon^2}{16} \cdot \binom{n}{h} \leq \sum_{h=0}^{h_0} \frac{\epsilon^2}{16} \cdot \binom{n}{h} \leq \sum_{h=0}^{h_0} \frac{\epsilon^2}{16} \cdot \frac{\binom{n}{h}}{\binom{n}{n/2}} \leq \frac{\epsilon}{4} \sum_{h=0}^{h_0} \frac{\binom{n}{h}}{2^n} \leq \frac{\epsilon}{4} \sum_{h=0}^{h_0} \frac{\binom{n}{h}}{2^n} \leq \frac{\epsilon}{4}
\]

Now, we simply check that properties (1), (2) and (3) of the Corollary directly imply the properties (1), (2) and (3) of the Corollary respectively. This completes the proof.

To use Lemma 9, we need an upper bound on the value of \( \sum_{j \geq h} \binom{n}{j} \). The following claim provides such an upper bound:

**Claim 21.** For all sufficiently large \( n \), for all \( h \), satisfying \( 0 \leq h \leq n \), it is the case that:

\[
\sum_{j \geq h} \binom{n}{j} \leq \begin{cases} 
\frac{2}{n^2} & \text{if } h \leq n/2 - \sqrt{n \ln(n)} \\
\frac{200}{\sqrt{n}} & \text{if } n/2 - \sqrt{n \ln(n)} < h < n/2 + \sqrt{n} \\
200 \cdot \frac{h-n/2}{n} & \text{if } h \geq n/2 + \sqrt{n} 
\end{cases}
\]

**Proof.** See Appendix A, Subsection 7.2

### 3.2 Proof of Claim 19

For all \( x \) in \( \{0,1\}^n \), satisfying \( 9\sqrt{n} \leq ||x|| \), we define the following quantity:

\[
\phi(x) = \max_{y \text{ s.t. } y \leq x \text{ and } ||y|| = [L||x||]} \Pr_{z \sim \rho} [ y \preceq z \leq x ] = \frac{1}{2^{[L||x||]}} \cdot \max_{y \text{ s.t. } y \leq x \text{ and } ||y|| = [L||x||]} \Pr_{z \sim \rho} [ z \preceq y \leq x ] = \frac{1}{2^{[L||x||]}} \cdot \max_{y \text{ s.t. } y \leq x \text{ and } ||y|| = [L||x||]} \sum_{z \text{ s.t. } y \preceq z \leq x} \rho(z)
\]

(4)
Observe that since for every such $x$ and $y$ there are $2 \lfloor L_{\|x\|} \rfloor$ values of $z$ satisfying $y \preceq z \preceq x$, and $\rho$ is a monotone probability distribution, it has to be the case that $\phi(x) \leq \rho(x)$ for all $x$ on which $\phi(x)$ is defined.

More interestingly, we will be claiming that $\phi$ is (in terms of $L_1$ distance) a good approximation to $\rho$, but first we will show that $\hat{\phi}$ is a good approximation to $\phi$, assuming that the values $L_h$ are not too small:

> Claim 22. If it is the case that $\frac{1}{2^n} \cdot \sum_{h=9\sqrt{n}}^{n} \binom{n}{h} \cdot \frac{4}{2^n} \leq \frac{1}{2}$, then, with probability at least $7/8$, it is the case that:

$$\sum_{x \in \{0,1\}^n \text{ s.t. } 9\sqrt{n} \leq \|x\|} \left| \hat{\phi}(x) - \phi(x) \right| \leq \frac{\epsilon}{4} \tag{5}$$

Proof. See Appendix A, Subsection 7.3, for the proof, which follows using tail bounds. \hfill \triangleright

Now, we apply Lemma 9 to $\rho$, with value $\zeta := \epsilon/100$. For now, we postpone setting the values of $R_h$, which we will do later in our derivation (of course, we will then check that the required constraint is indeed satisfied by these values).

This gives a positive monotone function $f$ that satisfies the three conditions of Lemma 9. We separate all the values of $x$ in $\{0,1\}^n$ for which $9\sqrt{n} \leq \|x\|$ into two kinds: good and bad. We say that $x$ is bad if there is some $y$ for which $0 \leq \|x\| - \|y\| < \lfloor L_{\|x\|} \rfloor$ and slack$_f(y)$ is non-zero. Otherwise, $x$ is good. Clearly, for a given Hamming weight value, wither every point with this Hamming weight is good, or every such point is bad.

We can write:

$$\sum_{x \in \{0,1\}^n \text{ s.t. } 9\sqrt{n} \leq \|x\|} |\phi(x) - f(x)| = \sum_{\text{good } x} |\phi(x) - f(x)| + \sum_{\text{bad } x} |\phi(x) - f(x)| \tag{6}$$

Now, we bound the two terms above separately. If $x$ is good, then it is the case that for all $y$ satisfying $\|x\| - \lfloor L_{\|x\|} \rfloor < \|y\| \leq \|x\|$, we have slack$_f(x) = 0$, and therefore $f(y) = \max_{\rho \in \{0,1\}^n \text{ s. t. } \rho \preceq y \text{ and } \|y\| = \|x\|} f(y')$. Using this relation recursively, we obtain that:

$$f(x) = \max_{y \in \{0,1\}^n \text{ s. t. } y \preceq x \text{ and } \|x\| - \|y\| = \lfloor L_{\|x\|} \rfloor} f(y)$$

Therefore, since $f$ is monotone, we obtain that:

$$f(x) = \frac{1}{2^{\lfloor L_{\|x\|} \rfloor}} \cdot \max_{y \text{ s. t. } y \preceq x \text{ and } \|x\| - \|y\| = \lfloor L_{\|x\|} \rfloor} \sum_{z \text{ s. t. } y \preceq z \preceq x} f(z)$$

By Lemma 9, it is the case $\rho(x) \geq f(x)$. This, together with the equation above and Equation 4 implies:

$$\phi(x) \geq f(x)$$

But we also know that $\rho(x) \geq \phi(x)$. Therefore:

$$\sum_{\text{good } x} |\phi(x) - f(x)| \leq \sum_{\text{good } x} |\rho(x) - f(x)| \leq \frac{\epsilon}{4} \tag{7}$$

Where the last inequality follows from Lemma 9.
Now, we bound the contribution of bad points. Since \( \phi(x) \leq \rho(x) \), \( f(x) \leq \rho(x) \), and recalling the definition of a bad point, we get:

\[
\sum_{\text{bad } x} |\phi(x) - f(x)| \leq \sum_{\text{bad } x} \max(\phi(x), f(x)) \leq \sum_{\text{bad } x} \rho(x) \leq \sum_{h=9\sqrt{n}}^{n} \mu_{\rho}(h_2) \cdot \binom{n}{h_2} \cdot 1_{\exists x \in \{0,1\}^n: (h_2 - \lfloor L_{h_2} \rfloor) < ||x|| \leq h_2} \cdot \text{slacky}(x) = 0
\]

(8)

Since Lemma 9 gives us a bound on a weighed sum of indicator variables of the form \( 1_{\exists x \in \{0,1\}^n: ||x|| = h \land \text{slacky}(x) = 0} \), we would like to upper-bound the expression above by such a weighted sum. To do this, to every Hamming weight value \( h \) that has a point \( x \) with non-zero \( \text{slacky}(x) \) (we call such Hamming weight value \( h \) \textbf{slacky}) we “charge” every value \( h_2 \), for which points of Hamming weight \( h_2 \) are rendered bad because \( h \) is slacky. This will happen only if \( h_2 \geq h \) and \( h_2 - \lfloor L_{h_2} \rfloor < h \). But since \( \lfloor L_{h_2} \rfloor \) can only decrease as \( h_2 \) increases, the latter can happen only if \( h_2 - \lfloor L_h \rfloor < h \). Therefore:

\[
\sum_{\text{bad } x} |\phi(x) - f(x)| \leq \sum_{h=0}^{n} \left( \sum_{h_2=h}^{h+\lfloor L_h \rfloor - 1} \mu_{\rho}(h_2) \cdot \binom{n}{h_2} \cdot 1_{\exists x \in \{0,1\}^n: (h_2 - \lfloor L_{h_2} \rfloor) < ||x|| \leq h_2} \cdot \text{slacky}(x) = 0 \right) \leq
\]

(9)

Now, to upper-bound \( \mu_{\rho}(h_2) \), we need the following claim:

\textbf{Claim 23.} For any monotone probability distribution \( \rho \) it is the case that for all \( h \):

\[
\mu_{\rho}(h) \leq \frac{1}{\sum_{j=h}^{n} \binom{n}{j}}
\]

Proof. This follows immediately from Fact 15 and that \( \sum_{x \in \{0,1\}^n} \rho(x) = 1 \).

\textbf{Claim 23, Equation 8 and Claim 21 together imply:}

\[
\sum_{\text{bad } x} |\phi(x) - f(x)| \leq \sum_{h=0}^{n} \left( \sum_{h_2=h}^{h+\lfloor L_h \rfloor - 1} \binom{n}{h_2} \frac{\left( \frac{200}{\sqrt{n}} \cdot \frac{h_2-n/2}{n} \right)}{\left( \lfloor L_{h_2} \rfloor \right)} \frac{1}{\exists x \in \{0,1\}^n: (h_2 - \lfloor L_{h_2} \rfloor) < ||x|| \leq h_2} \cdot \text{slacky}(x) = 0 \right) \leq
\]

(10)

Now, we claim that:

\[
\left( \frac{200 \sqrt{n}}{\sqrt{n}} \cdot \frac{h+L_h-n/2}{n} \right) \frac{1}{\exists x \in \{0,1\}^n: (h+L_h < n/2 + \sqrt{n})} \leq 10 \cdot \left( \frac{200 \sqrt{n}}{\sqrt{n}} \cdot \frac{h-n/2}{n} \right) \frac{1}{\exists x \in \{0,1\}^n: (h \geq n/2 + \sqrt{n})}
\]

(11)

This follows by considering three cases (i) \( h + L_h < n/2 + \sqrt{n} \), in which case this is equivalent to \( \frac{200 \sqrt{n}}{\sqrt{n}} \leq \frac{2000 \sqrt{n}}{\sqrt{n}} \), which is trivially true. (ii) \( h \geq n/2 + \sqrt{n} \), in which case since \( L_h \leq 9\sqrt{n} \), we have that \( \frac{h-n/2}{n} \leq \frac{10 \cdot \frac{h-n/2}{n}}{n} \) (iii) \( h + L_h \geq n/2 + \sqrt{n} \), but \( h < n/2 + \sqrt{n} \), in which case since \( L_h \leq 9\sqrt{n} \), we have that \( \frac{h+L_h-n/2}{n} \leq \frac{\sqrt{n} + L_h}{n} \leq 10\sqrt{n} \).
Combining Equations 10 and 11, we get:
\[
\sum_{\text{bad } x} |\phi(x) - f(x)| \leq \sum_{h=0}^{n} L_h \cdot \left( \begin{array}{ll} \frac{200}{\sqrt{n}} & \text{if } h < n/2 + \sqrt{n} \\ 200 \cdot \frac{h-n/2}{n} & \text{otherwise} \end{array} \right) \cdot 1_{\exists x \in \{0,1\}^n: ||x|| = h \land \text{slack}_f(x) \neq 0} \quad (12)
\]

Recall that we postponed setting the values of \(R_h\). The equation above motivates us to set:
\[
R_h := \frac{200}{\epsilon} \cdot L_h \cdot \left( \begin{array}{ll} \frac{200}{\sqrt{n}} & \text{if } h < n/2 + \sqrt{n} \\ 200 \cdot \frac{h-n/2}{n} & \text{otherwise} \end{array} \right)
\]

Now, we check the constraint on \(R_h\) in Lemma 9. Using Claim 21 and the premise of Claim 19:
\[
\sum_{h=0}^{n} R_h \cdot \left( \begin{array}{ll} \frac{40000}{n} & \text{if } h \leq n/2 - \sqrt{n \ln(n)} \\ 40000 \cdot \left( \frac{n}{n-h/2} \right)^2 & \text{if } h \geq n/2 + \sqrt{n} \end{array} \right) \leq \frac{\epsilon}{100} = \zeta
\]

Therefore, Lemma 9, together with Equation 12 implies that:
\[
\sum_{\text{bad } x} |\phi(x) - f(x)| \leq \sum_{h=0}^{n} \frac{\epsilon}{20} \cdot R_h \cdot 1_{\exists x \in \{0,1\}^n: ||x|| = h \land \text{slack}_f(x) \neq 0} \leq \frac{\epsilon}{20}
\]

Now, using triangle inequality and then combining the inequality above with Equations 28, 6 and 7 we get:
\[
\sum_{x \in \{0,1\}^n \text{ s.t. } 9 \sqrt{n \pi} \leq ||x||} \left| \phi(x) - \rho(x) \right| \leq \sum_{x \in \{0,1\}^n \text{ s.t. } 9 \sqrt{n \pi} \leq ||x||} \left| \phi(x) - \phi(x) \right| + \sum_{x \in \{0,1\}^n \text{ s.t. } 9 \sqrt{n \pi} \leq ||x||} \left| \phi(x) - \rho(x) \right| \leq \frac{\epsilon}{4} + \frac{\epsilon}{100} + \frac{\epsilon}{20} \leq \frac{\epsilon}{2} \quad (13)
\]

### 4 Estimating the distance to uniform

In this section we prove our upper-bound on the sample complexity of estimating the distance from uniform of an unknown monotone probability distribution over the Boolean cube. We restate the theorem:

**Theorem 5.** For every positive \(\epsilon\), the following is true: for all sufficiently large \(n\), there exists an algorithm, which given \(\frac{2^n}{n^{100} \sqrt{n}}\) samples from an unknown monotone probability distribution \(\rho\) over \(\{0,1\}^n\), can reliably approximate the distance between \(\rho\) and the uniform distribution over \(\{0,1\}^n\) with an additive error of up to \(\epsilon\). The algorithm runs in time \(O\left(2^n + O(\sqrt{n \log n})\right)\).
Algorithm 2

Algorithm for the estimation of distance to uniform efficiently (given sample access from a distribution \( \rho \), which is monotone over \( \{0,1\}^n \)).

1. Pick set \( h_0 \) to be an integer for which it is the case that:
\[
\frac{\epsilon}{4} \leq \Pr_{x \sim \{0,1\}^n} \left[ ||x|| \geq h_0 \right] \leq \frac{\epsilon}{2}
\]  
(14)

Do this by going through every integer candidate \( h_{\text{candidate}} \) in the interval and computing the fraction of points \( x \) in \( \{0,1\}^n \) for which \( ||x|| \geq h_{\text{candidate}} \). Finally, pick \( h_0 \) to be one of \( h_{\text{candidate}} \) for which the relation above holds.

2. Set \( N_1 := \frac{32 \ln 2}{\epsilon^2} \). Draw \( N_1 \) samples from the probability distribution \( \rho \) and denote the multiset of these samples as \( S_1 \).

3. Set:
\[
\hat{d}_1 := \frac{1}{2} \cdot \left\lfloor \frac{\left\lfloor \frac{z \in S_1 : ||z|| \geq h_0}{N_1} \right\rfloor}{2^{n-1}} \right\rfloor
\]

4. Set \( L := \left\lfloor \frac{\sqrt{n} \epsilon^4}{16} \right\rfloor \).

5. Set \( N_2 := 2^n \cdot \frac{192}{\epsilon^2} \cdot \left( n \ln 2 + L \ln n + 4 \ln 2 \right) \).

Draw \( N_2 \) samples from the probability distribution \( \rho \) and denote the multiset of these samples as \( S_2 \).

6. For all \( x \), satisfying \( L \leq ||x|| < h_0 \), compute:
\[
\hat{\phi}(x) := \frac{1}{2L} \cdot \max_{y \text{ s.t. } y \leq x \text{ and } ||y|| = L} \left\lfloor \frac{\left\lfloor \frac{z \in S_2 : y \preceq z \preceq x}{N_2} \right\rfloor}{2^n} \right\rfloor
\]

Do this by first making a look-up table, which given arbitrary \( z \in \{0,1\}^n \) returns the number of times \( z \) was encountered in \( S_2 \). Then, use this look-up table to compute the necessary values of \( \left\lfloor \frac{z \in S_2 : y \preceq z \preceq x}{N_2} \right\rfloor \) by querying all these values of \( z \) in the lookup table and summing the results up.

7. Compute the following:
\[
\hat{d}_2 := \frac{1}{2} \cdot \sum_{x \text{ s.t. } L \leq ||x|| < h_0} \left| \hat{\phi}(x) - \frac{1}{2^n} \right|
\]

8. Output \( \hat{d}_1 + \hat{d}_2 \).
Proof. We present the algorithm as Algorithm 2. The number of samples drawn from $\rho$ is $N_1 + N_2 = \frac{x^2}{2 \sqrt{n}}$. The run-time, in turn, is dominated\(^5\) by computing the values of $\hat{\phi}$ in step (6), in which the construction of the lookup table takes $O(n \cdot 2^n)$ time and the time spent computing each $\hat{\phi}(x)$ can be upper bounded by the product of: (i) the number of pairs $(y, z)$ that simultaneously satisfy $y \leq z \leq x$ and $||x|| - ||y|| = L$, which can be upper-bounded by $O(n^L \cdot 2^L)$ and (ii) the time it takes to look up a given $z$ in the lookup table, which can be upper-bounded by $O(n)$. Overall, this gives us a run-time upper bound of $O(2^n+O(\sqrt{n \log n}))$.

Now, the only thing left to prove is correctness. First of all, it is not a priori clear that there exists a value of $h_0$ satisfying Equation 14 (in Algorithm 2). This is true for the following reason: imagine changing $h_{\text{candidate}}$ from $n$ to 0 by decrementing it in steps of one. Then $\Pr_{x \in \{0,1\}^n} [||x|| \geq h_{\text{candidate}}]$ will increase from $\frac{1}{2^n}$ to 1 by Fact 16 it will not increase by more than $\frac{1}{\sqrt{n}}$ at any given step. For sufficiently large $n$ we have $\frac{1}{\sqrt{n}} < \frac{\epsilon}{4}$. Then it is impossible to skip over the interval between $\frac{1}{4}$ and $\frac{\epsilon}{4}$ in just one step of length at most $\frac{1}{4 n}$, and therefore Equation 14 (in Algorithm 2) will be the case for some value of $h_{\text{candidate}}$.

We decompose the total variation distance between $\rho$ and the uniform distribution into three terms:

$$
\frac{1}{2} \cdot \sum_{x \in \{0,1\}^n} \left| \rho(x) - \frac{1}{2^n} \right| =
\frac{1}{2} \cdot \sum_{x \in \{0,1\}^n \text{ s.t.} \ ||x|| \geq h_0} \left| \rho(x) - \frac{1}{2^n} \right| + \frac{1}{2} \cdot \sum_{x \in \{0,1\}^n \text{ s.t.} \ L < ||x|| < h_0} \left| \rho(x) - \frac{1}{2^n} \right| + \frac{1}{2} \cdot \sum_{x \in \{0,1\}^n \text{ s.t.} \ ||x|| < L} \left| \rho(x) - \frac{1}{2^n} \right|
$$

(15)

We argue that the first term is well approximated by $\hat{d}_1$, the second term is well approximated by $\hat{d}_2$, and the third term is negligible. As the reader will see, out of these three terms, the middle term is the least trivial to prove guarantees for.

We will first handle the first term: From the triangle inequality, Hoeffding’s bound and Equation 14 (in Algorithm 2) it follows immediately that with probability at least 7/8 it is the case that:

$$
\left| \hat{d}_1 - \frac{1}{2} \cdot \sum_{x \in \{0,1\}^n \text{ s.t.} \ ||x|| \geq h_0} \rho(x) - \frac{1}{2^n} \right| \leq \frac{1}{2} \cdot \sum_{x \in \{0,1\}^n \text{ s.t.} \ ||x|| \geq h_0} \rho(x) + \frac{1}{2} \cdot \sum_{x \in \{0,1\}^n \text{ s.t.} \ ||x|| \geq h_0} \frac{1}{2^n} = \frac{\epsilon}{8} + \frac{\epsilon}{4} = \frac{3\epsilon}{8}
$$

(16)

Now, we use the two following facts: (i) Since $\sum_x \rho(x) = 1$ and $\rho$ is monotone, for every $x$ with $||x|| \leq L$ it should be the case that $\rho(x) \leq \frac{1}{2^n - L}$. (ii) The number of different values of $x$ in $\{0,1\}^n$ for which $||x|| \leq L$ can be upper bounded by $n^L$. We get for sufficiently large $n$:  

$$
\frac{1}{2} \cdot \sum_{x \in \{0,1\}^n \text{ s.t.} \ ||x|| < L} \left| \rho(x) - \frac{1}{2^n} \right| \leq \frac{1}{2} \cdot \sum_{x \in \{0,1\}^n \text{ s.t.} \ ||x|| < L} \left( \frac{1}{2^n} + \rho(x) \right) \leq \frac{1}{2} \cdot n^L \cdot \left( \frac{1}{2^n} + \frac{1}{2^n - L} \right) = o(1) \leq \frac{\epsilon}{8}
$$

(17)

\(^5\) Step 1 requires only $2^n \text{poly}(n)$ time, which is less than what step (6) requires. By inspection, other steps require even less run-time. Incidentally, the task in step 1 can be done much faster by randomized sampling, but since this is not the run-time bottleneck, we use this direct approach for the sake of simplicity.
Learning Monotone Probability Distributions over the Boolean Cube

The rest of this section will be dedicated to proving the following claim:

\textbf{Claim 24.} With probability at least $7/8$ it is the case that:

\[ \left| \hat{d}_2 - \frac{1}{2} \cdot \sum_{x \in \{0,1\}^n \text{ s.t. } L \leq ||x|| < h_0} \left| \rho(x) - \frac{1}{2^n} \right| \right| \leq \epsilon \]

(18)

Once this is proven, it follows by a union bound that with probability at least $3/4$ both Equations 16 and 18 will be the case. This, together with Equation 17, when substituted into Equation 15 will imply that:

\[ \left| \sum_{x \in \{0,1\}^n} \rho(x) - \frac{1}{2^n} - (\hat{d}_1 + \hat{d}_2) \right| \leq \epsilon \]

This will imply the correctness of our algorithm.

\textbf{4.1 Proof of Claim 24}

For all $x$ in $\{0,1\}^n$, satisfying $L \leq ||x|| < h_0$, we define the following quantity:

\[ \phi(x) \overset{def}{=} \frac{1}{2L} \cdot \max_{y \text{ s.t. } y \preceq x \text{ and } ||x||-||y||=L} \Pr_{z \sim \rho}[y \preceq z \preceq x] = \frac{1}{2L} \cdot \max_{y \text{ s.t. } y \preceq x \text{ and } ||x||-||y||=L} \sum_{z \text{ s.t. } y \preceq z \preceq x} \rho(z) \]  

(19)

Observe that since for every such $x$ and $y$ there are $2^L$ values of $z$ satisfying $y \preceq z \preceq x$, and $\rho$ is a monotone probability distribution, it has to be the case that $\phi(x) \leq \rho(x)$ for all $x$ on which $\phi(x)$ is defined.

We will be claiming that $\phi(x)$ is (in terms of $L_1$ distance) a good approximation to $\rho(x)$, but first we will show that $\phi(x)$ is a good approximation to $\phi(x)$:

\textbf{Claim 25.} With probability at least $7/8$, it is the case that:

\[ \sum_{x \in \{0,1\}^n \text{ s.t. } L \leq ||x|| < h_0} \left| \hat{\phi}(x) - \phi(x) \right| \leq \epsilon / 4 \]  

(20)

\textbf{Proof.} We claim that for any pair $(x,y)$, such that $\phi$ is defined on $x$ and $||x|| - ||y|| = L$, with probability at least $1 - \frac{1}{8 \cdot 2^n \cdot n^2}$ the following holds:

\[ \frac{1}{2L} \cdot \Pr_{z \sim \rho}[y \preceq z \preceq x] - \frac{|\{z \in S : y \preceq z \preceq x\}|}{N_2} \leq \frac{\epsilon}{8} \cdot \max \left( \frac{1}{2L} \cdot \frac{1}{\Pr_{z \sim \rho}[y \preceq z \preceq x]} \right) \]  

(21)

We use Chernoff’s bound to prove this as follows. Denote by $q$ the value $\Pr_{z \sim \rho}[y \preceq z \preceq x]$. If $q \geq \frac{1}{2L}$, then by Chernoff’s bound we have:

\[ \Pr \left[ \left| \{z \in S : y \preceq z \preceq x\} \right| - qN_2 \right] \geq \frac{\epsilon}{8} qN_2 \leq \exp \left( -\frac{1}{3} \left( \frac{\epsilon}{8} \right)^2 qN_2 \right) \leq \frac{1}{8 \cdot 2^n \cdot n^2} \cdot \frac{1}{8 \cdot 2^n \cdot n^2} \]
Otherwise, if we have $q < \frac{2L}{2^n}$, then by Chernoff’s bound:

$$
\Pr \left[ \left| \{z \in S : y \preceq z \preceq x\} - qN_2 \right| \geq \frac{\epsilon}{8} \cdot \frac{2L}{2^n} \cdot N_2 \right] \leq 2 \exp \left( - \frac{1}{3} \left( \frac{\epsilon}{8} \cdot \frac{2L}{2^n} \cdot \frac{1}{q} \right)^2 qN_2 \right) \leq 2 \exp \left( - \frac{1}{3} \left( \frac{\epsilon}{8} \cdot \frac{2L}{2^n} \cdot qN_2 \right) \right) = \frac{1}{8} \cdot \frac{2^n \cdot nL}{qN_2}
$$

Now, by taking a union bound, it follows that with probability $7/8$ for all such pairs $(x, y)$ Equation 21 will be the case. For all $x$ on which $\phi$ is defined it then will be the case that:

$$
\left| \hat{\phi}(x) - \phi(x) \right| \leq \frac{\epsilon}{8} \cdot \max \left( \frac{1}{2^n}, \phi(x) \right)
$$

Summing this for all $x$ in the domain of $\phi$ we get:

$$
\sum_{x \in \{0,1\}^n \text{ s.t. } L \leq ||x|| < h_0} \left| \hat{\phi}(x) - \phi(x) \right| \leq \frac{\epsilon}{8} \cdot \left( 2^n \cdot \frac{1}{2^n} + \sum_{x \in \{0,1\}^n \text{ s.t. } L \leq ||x|| < h_0} \phi(x) \right) \leq \frac{\epsilon}{8} \cdot \left( 1 + \sum_{x \in \{0,1\}^n \text{ s.t. } L \leq ||x|| < h_0} \rho(x) \right) \leq \frac{\epsilon}{4}
$$

Now, we apply Corollary 10 to $\rho$. This gives a positive monotone function $f$ that satisfies the three conditions of Corollary 10. We separate all the values of $x$ in $\{0,1\}^n$ for which $L \leq ||x|| < h_0$ into two kinds: good and bad. Recall that by Corollary 10 an element $x$ of $\{0,1\}^n$ for which $L \leq ||x|| < h_0$ can have slack $f(x) \neq 0$ only if $||x|| = k_i$ for some $i$ between 1 and $t$. We say that $x$ is bad if there is some $k_i$ for which $0 \leq ||x|| - k_i \leq L$. Otherwise, $x$ if good.

We can write:

$$
\sum_{x \in \{0,1\}^n \text{ s.t. } L \leq ||x|| < h_0} |\phi(x) - f(x)| = \sum_{\text{good } x} |\phi(x) - f(x)| + \sum_{\text{bad } x} |\phi(x) - f(x)|
$$

Now, we bound the two terms above separately. If $x$ is good, then it is the case that for all $z$ satisfying $||x|| - L \leq ||z|| \leq ||x||$ we have slack $f(x) = 0$, and therefore $f(z) = \max_{z' \in \{0,1\}^n \text{ s.t. } z' \preceq z} \text{ and } ||z||-||z'||=1 f(z')$. Using this relation recursively, we obtain that:

$$
f(x) = \max_{z \in \{0,1\}^n \text{ s.t. } z \preceq x \text{ and } ||x||-||z||=L} f(z)
$$

Therefore, since $f$ is monotone, we obtain that:

$$
f(x) = \frac{1}{2L} \cdot \max_{y \text{ s.t. } y \preceq x \text{ and } ||x||-||y||=L} \sum_{z \text{ s.t. } y \preceq z \preceq x} f(z)
$$

By Corollary 10, it is the case $\rho(x) \geq f(x)$. This, together with the equation above and Equation 19 implies:

$$
\phi(x) \geq f(x)
$$
But we also know that \( \rho(x) \geq \phi(x) \). Therefore:

\[
\sum_{\text{good } x} |\phi(x) - f(x)| \leq \sum_{\text{good } x} |\rho(x) - f(x)| \leq \frac{\epsilon}{4}
\]

(23)

Where the last inequality follows from Corollary 10.

Now, the contribution of bad points.

\[
\sum_{\text{bad } x} |\phi(x) - f(x)| \leq \sum_{\text{bad } x} \max(\phi(x), f(x)) \leq \sum_{\text{bad } x} \rho(x) =
\]

\[
\sum_{k \in [L, h_0]} \mu_p(k) \cdot \binom{n}{k}
\]

Combining these two facts with the inequality above we get:

\[
\sum_{\text{bad } x} |\phi(x) - f(x)| \leq \left( \frac{1}{2n} \cdot \frac{4}{\epsilon} \right) \cdot \left( \frac{2}{\sqrt{n}} \cdot 2^n \right) \cdot (L \cdot t) = \frac{4}{\epsilon} \cdot \frac{2}{\sqrt{n}} \cdot L \cdot t
\]

Substituting the value of \( L \) and the upper bound on \( t \) from Corollary 10 we get:

\[
\sum_{\text{bad } x} |\phi(x) - f(x)| \leq \frac{4}{\epsilon} \cdot \frac{2}{\sqrt{n}} \cdot \frac{\epsilon^4 \sqrt{n}}{512} \cdot \frac{16}{\epsilon^2} = \frac{\epsilon}{4}
\]

Combining this with Equations 22 and 23 we get:

\[
\sum_{x \in \{0,1\}^n \text{ s.t. } L \leq ||x|| < h_0} |\phi(x) - f(x)| \leq \frac{\epsilon}{2}
\]

(24)

Overall, we have:

\[
\left| \sum_{x \in \{0,1\}^n \text{ s.t. } L \leq ||x|| < h_0} |\rho(x) - 1/2^n| \right| - \left| \sum_{x \in \{0,1\}^n \text{ s.t. } L \leq ||x|| < h_0} |\hat{\phi}(x) - 1/2^n| \right| \leq
\]

\[
\sum_{x \in \{0,1\}^n \text{ s.t. } L \leq ||x|| < h_0} |\hat{\phi}(x) - \rho(x)| \leq \sum_{x \in \{0,1\}^n \text{ s.t. } L \leq ||x|| < h_0} |\hat{\phi}(x) - \phi(x)| +
\]

\[
\sum_{x \in \{0,1\}^n \text{ s.t. } L \leq ||x|| < h_0} |\phi(x) - f(x)| + \sum_{x \in \{0,1\}^n \text{ s.t. } L \leq ||x|| < h_0} |f(x) - \rho(x)|
\]

This three terms can be bound using respectively Equation 20, Corollary 10 and Equation 24. This gives us:

\[
2 \cdot \hat{d}_2 - \sum_{x \in \{0,1\}^n \text{ s.t. } L \leq ||x|| < h_0} |\rho(x) - 1/2^n| =
\]

\[
\left| \sum_{x \in \{0,1\}^n \text{ s.t. } L \leq ||x|| < h_0} |\rho(x) - 1/2^n| \right| - \left| \sum_{x \in \{0,1\}^n \text{ s.t. } L \leq ||x|| < h_0} |\hat{\phi}(x) - 1/2^n| \right| \leq \epsilon
\]

Therefore, with probability at least 7/8 Equation 18 holds, which proves Claim 24 and completes the proof of correctness.
5 Estimating the support size

In this section we prove our upper-bound on the sample complexity of estimating the support size of an unknown monotone probability distribution over the Boolean cube. Recall that a probability distribution $\rho$ is well-behaved if for every $x$ either $\rho(x) = 0$ or $\rho(x) \geq 1/2^n$.

We restate the theorem:

\textbf{Theorem 4.} For every positive $\epsilon$, the following is true: for all sufficiently large $n$, there exists an algorithm, which given $2^{n^2/\Theta(\epsilon^2)}$ samples from an unknown well-behaved monotone probability distribution $\rho$ over $\{0,1\}^n$, can reliably\(^6\) approximate the support size of $\rho$ with an additive error of up to $\epsilon$. The algorithm runs in time $O_\epsilon\left(\frac{2^n}{(\ln 32/\epsilon + 1)}\right)$.

\textbf{Proof.} The algorithm we use is listed as Algorithm 3.

\begin{algorithm}[h]
\caption{Algorithm for the estimation of support size (given sample access from the distribution).}
\begin{enumerate}
  \item Set $M_1 = \frac{2^n}{2^{n^2/\sqrt{n}}} \left(\ln \frac{32}{\epsilon} + 1\right)$
  \item Take $M_1$ samples from the probability distributions. Call the set of these samples $S_1$.
  \item Set $M_2 = \frac{32 \ln 2}{\epsilon^2}$
  \item Pick $M_2$ elements of $\{0,1\}^n$ uniformly at random. Call these samples $S_2$.
  \item We say that a point $y$ is covered if in $S_1$ there exists at least one $z$, so that $z \preceq y$. One can check if a point $y$ is covered by going through all the $M_1$ elements in $S_1$. Using this checking procedure, compute the fraction $\hat{\eta}$ of the elements in $S_2$ that are covered.
  \item Output $\hat{\eta}$.
\end{enumerate}
\end{algorithm}

Clearly, the sample complexity is:

$$O\left(\frac{2^n}{2^{n^2/\sqrt{n}}} \left(\ln \frac{32}{\epsilon} + 1\right)\right) = \frac{2^n}{2^{\Theta(\sqrt{n})}}$$

In turn, the run-time is:

$$O\left(2^n \frac{\ln \frac{32}{\epsilon} + 1}{\epsilon^2} \cdot \frac{32 \ln 2}{\epsilon^2}\right) = \frac{2^n}{2^{\Theta(\sqrt{n})}}$$

Now, all is left to prove is correctness.

Let $\eta$ denote the fraction of elements in $\{0,1\}^n$ that are covered by our samples in $S_1$. Then, a random element of $\{0,1\}^n$ is covered with probability $\eta$. Therefore, by the Hoeffding bound it follows that:

$$\Pr_{S_2} \left[ |\hat{\eta} - \eta| > \frac{\epsilon}{4} \right] \leq 2 \exp\left( -2 \left(\frac{\epsilon}{4}\right)^2 M_2 \right) = \frac{1}{8}$$

The last equality follows by substituting the value of $M_2$.

\textsuperscript{6} By reliably we henceforth mean that the probability of success is at least 2/3.
Since \( \rho \) is monotone, it has to be the case that every point that is covered is in the support of \( \rho \). Hence, the support size of \( \rho \) is at least \( \eta \cdot 2^n \).

Now, all we need to show is that \( \eta \cdot 2^n \) is not likely to be much smaller than the support size of \( \rho \). We call a point \( x \) in the support of \( \rho \) **good** if there are at least \( 2^{\frac{\epsilon}{it}} \sqrt{n} \) points \( y \) each of which satisfying: (i) \( y \) belongs to the support of \( \rho \). (ii) \( x \preceq y \). If a point in the support of \( \rho \) is not good, then it is **bad**. We will show that the bad points are few, while a lot of the good points are likely to be covered.

Let \( f_{\text{support}} \) be defined as follows:

\[
    f_{\text{support}}(x) = \begin{cases} 
        1 & \text{if } \rho(x) \neq 0 \\
        0 & \text{otherwise}
    \end{cases}
\]

In other words, \( f_{\text{support}} \) is the indicator function of the support of \( \rho \). Since \( \rho \) is a monotone probability distribution, \( f_{\text{support}} \) is a monotone function. Therefore, applying Lemma 8, there exists a function \( g = g_1 \lor \ldots \lor g_t \) that \( \epsilon/4 \)-approximates \( f_{\text{support}} \), where \( t \leq 8/\epsilon \) and each \( g_i \) is a monotone DNF with terms of width exactly \( k_i \). Additionally, \( g(x) \leq f(x) \) for all \( x \) in \( \{0,1\}^n \)

**Claim 26.** For all \( i \), \( g_i \) contains at most \( \frac{\epsilon}{8} \cdot 2^n \) bad points.

**Proof.** Recall that \( g_i \) is \( k_i \)-regular, and therefore every point \( x \) on which \( g_i(x) = 1 \) needs to have Hamming weight \( ||x|| \geq k_i \).

**Claim 27.** If \( x \) satisfies \( g_i(x) = 1 \) and \( ||x|| \geq k_i + \frac{\epsilon^2}{64} \sqrt{n} \), then \( x \) has to be good

**Proof.** Since \( g_i \) is a DNF and \( g_i(x) = 1 \) then \( x \) satisfies at least one of the terms of \( g_i \). If there are more than one, arbitrarily pick one of them. Let this term be

\[
    t(y) = \bigwedge_{j \in H_i} y_j
\]

The width of this AND has to be \( k_i \), therefore \( |H| = k_i \). Since \( ||x|| \geq k_i + \frac{\epsilon^2}{64} \sqrt{n} \), there must be \( \frac{\epsilon^2}{64} \sqrt{n} \) values of \( j \) for which \( x_j = 1 \) but \( j \) is not in \( H_1 \). Denote the set of these values of \( j \) as \( H_2 \).

Now, consider an element \( y \in \{0,1\}^n \) satisfying the criteria:

- For all \( j \) in \( H_1 \), \( y_j = 1 \).
- For all \( j \) neither in \( H_1 \) nor in \( H_2 \), \( y_j = 0 \).

Clearly, \( t(y) = 1 \), which implies \( g_i(y) = 1 \), \( g(y) = 1 \), and \( f_{\text{support}}(y) = 1 \). Also, for all \( j \), we have \( y_j \leq x_j \), and therefore \( y \preceq x \). Finally, for all \( j \) in \( H_2 \) the value of \( y_j \) can be set arbitrarily to zero or one, and therefore there are \( 2^{|H_2|} \) such points, which is at least \( 2^{\frac{\epsilon^2}{64} \sqrt{n}} \).

Therefore, \( x \) is a good point.

Thus, we can upper-bound the number of bad points \( x \) on which \( g_i(x) = 1 \) by:

\[
    \left| \left\{ x \in \{0,1\}^n : g(x) = 1 \text{ and } k_i + \frac{\epsilon^2}{64} \sqrt{n} \geq \sum_j x_j \geq k_i \right\} \right| \leq \sum_{j=k_i}^{k_i+\frac{\epsilon^2}{64} \sqrt{n}-1} \binom{n}{j} \leq \frac{\epsilon^2}{64} \sqrt{n} \left( \frac{n}{n/2} \right)
\]

By Fact 16, for sufficiently large \( n \), it is the case that \( \binom{n}{n/2} \leq 2 \cdot \frac{2^n}{\sqrt{n}} \). This implies that the expression above is upper-bounded by \( \frac{\epsilon^2}{64} \cdot 2^n \), which completes the proof of this claim.
Since \( g = g_1 \lor \ldots \lor g_t(x) \), our claim implies the following:

\[
\left| \left\{ x : g(x) = 1 \text{ and } x \text{ is bad} \right\} \right| \leq \sum_{i=1}^{t} \left| \left\{ x : g_i(x) = 1 \text{ and } x \text{ is bad} \right\} \right| \leq t \cdot \frac{\epsilon^2}{32} \cdot 2^n \leq \frac{8}{\epsilon} \cdot \frac{\epsilon^2}{32} \cdot 2^n = \frac{\epsilon}{4} \cdot 2^n
\]

In addition, there could be at most \( \frac{\epsilon}{4} \cdot 2^n \) bad points among the points on which \( f_{\text{support}} \) and \( g \) disagree. Thus, in total, there are at most \( \frac{\epsilon}{2} \cdot 2^n \) bad points.

Finally, we need to argue that it is likely that many of the good points get covered:

\[\blacktriangle\text{Claim 28.} \text{ Suppose there are } G \text{ good points. Then, with probability at least } \frac{7}{8} \text{ it will be the case that at least } 1 - \frac{\epsilon}{4} \text{ fraction of these good points are covered.}\]

\[\blacktriangle\text{Proof.} \text{ For every good point } x \text{ there exist least } \frac{2^2 \sqrt{n}}{2^2} \text{ values of } y \text{ for which } i) x \preceq y \text{ and } ii) y \text{ is in the support of } \rho. \text{ Since } x \preceq y, \text{ if } y \text{ is ever picked from the distribution, then } x \text{ will be covered. Since } y \text{ is in the support of } \rho, \text{ and } \rho \text{ is well-behaved, we have } \rho(y) \geq \frac{1}{2^n}. \text{ Together, these imply that the probability that a random sample from } \rho \text{ covers } x \text{ is at least } \frac{2^2 \sqrt{n}}{2^n}. \text{ Hence, the probability that any of the } M_1 \text{ i.i.d. samples taken from } \rho \text{ does not cover } x \text{ is at most:}\]

\[
\left(1 - \frac{2^2 \sqrt{n}}{2^n}\right)^{M_1} = \left(1 - \frac{2^2 \sqrt{n}}{2^n}\right)^{\frac{2^n \ln\frac{32}{\epsilon} + 1}{2^n \ln\frac{32}{\epsilon}}} \leq \frac{1}{e^{\ln\frac{32}{\epsilon}}} = \frac{\epsilon}{32}
\]

Let \( C \) denote a random variable, whose value equals to the number of the good points (out of total \( G \)) covered after taking \( M_1 \) i.i.d. samples from \( \rho. \)

The value of \( C \) has to satisfy these two constraints: (i) It has to be between 0 and \( G \) (ii) By linearity of expectation, \( E[C] \geq (1 - \frac{\epsilon}{32})G. \) Thus, to finish the proof of the Lemma, it is sufficient to show the following claim:

\[\blacktriangle\text{Claim 29.} \text{ If, for some fixed } G, \text{ a random variable } C \text{ is supported on } [0, G] \text{ and } E[C] \geq (1 - \frac{\epsilon}{32})G, \text{ then } \Pr[C \geq (1 - \epsilon/4)G] \geq 7/8. \]

\[\blacktriangle\text{Proof.} \text{ This is immediate from Markov’s inequality for the random variable } G - C. \]

Now, we put it all together. Suppose that the bad events we previously identified do not happen. In particular, we know that with probability at least 7/8 we have:

\[
\left| \hat{\eta} - \eta \right| \leq \frac{\epsilon}{4}
\]

Additionally, we also know that with probability at least 7/8 it is the case that:

\[
\left| \left\{ x : f_{\text{support}}(x) = 1 \text{ and } x \text{ is good and covered} \right\} \right| - \left| \left\{ x : f_{\text{support}}(x) = 1 \text{ and } x \text{ is good} \right\} \right| \leq \frac{\epsilon}{4} \cdot \frac{\left| \left\{ x : f_{\text{support}}(x) = 1 \text{ and } x \text{ is good} \right\} \right|}{2^n}
\]
By union bound, the probability that none of this bad events happens is at least 3/4, which we will henceforth assume. Using the inequalities above together with the fact that the fraction of bad points is at most $\epsilon/2$ we get:

\[
\bigg|\hat{\eta} - \frac{\{x : f_{\text{support}}(x) = 1\}}{2^n}\bigg| \leq \bigg|\hat{\eta} - \eta\bigg| + \bigg|\eta - \frac{\{x : f_{\text{support}}(x) = 1\}}{2^n}\bigg| = \\
\bigg|\frac{\{x : f_{\text{support}}(x) = 1 \text{ and } x \text{ is covered}\}}{2^n} - \frac{\{x : f_{\text{support}}(x) = 1\}}{2^n}\bigg| + \\
\bigg|\frac{\{x : f_{\text{support}}(x) = 1 \text{ and } x \text{ is good}\}}{2^n} - \frac{\{x : f_{\text{support}}(x) = 1 \text{ and } x \text{ is good}\}}{2^n}\bigg| + \\
\bigg|\frac{\{x : f_{\text{support}}(x) = 1 \text{ and } x \text{ is bad}\}}{2^n}\bigg| \leq \frac{\epsilon}{4} + \frac{\epsilon}{4} + \frac{\epsilon}{2} \leq \frac{\epsilon}{4} + \frac{\epsilon}{4} + \frac{\epsilon}{2} = \epsilon
\]

This completes the proof of correctness.

6 A lower bound on tolerant testing of uniformity

In this section we prove a sample complexity lower bound on the problem of tolerantly testing the uniformity of an unknown monotone probability distribution over $\{0,1\}^n$: the task of distinguishing a distribution that is $o(1)$-close to uniform from a distribution that is sufficiently far from uniform. Recall the theorem:

**Theorem 6.** For infinitely many positive integers $n$, there exist two probability distributions $\Delta_{\text{Close}}$ and $\Delta_{\text{Far}}$ over monotone distributions over $\{0,1\}^n$, satisfying:
1. Every distribution in $\Delta_{\text{Far}}$ is $1/2$-far from the uniform distribution.
2. Any algorithm that takes only $o\left(2^{2^{0.5-0.01}}\right)$ samples from a probability distribution, fails to reliably distinguish between $\Delta_{\text{Close}}$ and $\Delta_{\text{Far}}$.
3. Every distribution in $\Delta_{\text{Close}}$ is $o(1)$-close to the uniform distribution.

**Proof.** A basic building block of our construction is the following:

**Definition 30.** For a member of the Boolean cube $x$, the subcube distribution $S_x$ is the probability distribution that picks $y$ uniformly, subject to $y \supseteq x$.

All our distributions will be mixtures of such subcube distributions. For all the mixtures we will use, each subcube in the mixture is given the same weight. This method involving subcube distributions was used in [29] to prove property testing lower bounds for monotone probability distributions.

We construct $\Delta_{\text{Close}}$ to have only one member, which is equal to the uniform mixture of $S_x$ for all $\binom{n}{\log_2 n}$ values of $x$ with Hamming weight $n^{0.5-0.01}$.

We define a random member of $\Delta_{\text{Far}}$ to be the uniform mixture of $\frac{1}{2}2^{n^{0.5-0.01}}$ subcube distributions $S_{x_i}$, where each of the $x_i$ is picked randomly among all the members of the Boolean cube with Hamming weight $n^{0.5-0.01}$.

We show that any member of $\Delta_{\text{Far}}$ is sufficiently far from uniform by upper-bounding the size of its support (i.e. the number of elements that have non-zero probability). Each of the subcube distributions has a support size of $2^n - n^{0.5-0.01}$. The support size of a mixture of distributions is at most the sum of the supports sizes of the respective distributions.
We telescoped the sums, and used the inequality that for all $\varepsilon > 0$ we have:

$$2^{n - n^{0.5 - 0.01}} \cdot \frac{1}{2} 2^{n^{0.5 - 0.01}} = \frac{1}{2} 2^n$$

This is sufficient to conclude that any member of $\Delta_{\text{Far}}$ is $1/2$-far from uniform.

A random member $D_1$ of $\Delta_{\text{Far}}$ and the sole member $D_2$ of $\Delta_{\text{Close}}$ cannot be reliably distinguished using only $o\left(\frac{2^{n^{0.5 - 0.01}}}{\varepsilon^2}\right)$ samples. This follows by the argument used in [29]: Because of the number of samples, with probability at least 0.99, the samples drawn from a random distribution from $D_1$ will all be from different subcube distributions. Also with probability at least 0.99, this will also be true for the sole distribution of $D_2$. If both of these things happen (which is the case with probability at least 0.98), the samples will be statistically indistinguishable. Thus, no tester can distinguish between $D_1$ and $D_2$ with an advantage greater than 0.02.

Finally, we need to prove that $D_2$ is $o(1)$-close to the uniform distribution. Here, the proof goes as follows. Both $D_2$ and the uniform distribution are symmetric with respect to a change of indices. This implies that the distance between these probability distributions equals to the distance between random variables $R_2$ and $R_1$, where $R_1$ is distributed as the Hamming weight of a random sample from $D_2$, whereas $R_2$ is distributed as the Hamming weight of uniformly random element of the Boolean cube. It is not hard to see that $R_1$ and $R_2$ are distributed according to binomial distributions with slightly different parameters.

Now, the problem is equivalent to proving that the two following probability distributions are $o(1)$-close in total variation distance:

- A sum of $n$ i.i.d. uniform random variables from $\{0, 1\}$.
- A sum of $n - n^{0.5 - 0.01}$ i.i.d. uniform random variables from $\{0, 1\}$.

It is convenient to first bound the variation distance between 1) the sum of $k$ i.i.d. uniform random variables from $\{0, 1\}$ and 2) $k + 1$ i.i.d. uniform random variables from $\{0, 1\}$, where $k$. We write the total variation distance as:

$$\frac{1}{2^k} + \sum_{i=1}^{k-1} \frac{1}{2^k} \binom{k}{i} - \frac{1}{2^{k-1}} \binom{k-1}{i} = \frac{1}{2^k} \left( 1 + \sum_{i=1}^{k-1} \binom{k-1}{i} - \binom{k-1}{i-1} \right) =$$

$$\frac{1}{2^k} \left( 1 + \sum_{i=1}^{(k-1)/2} \left( \binom{k-1}{i} - \binom{k-1}{i-1} \right) + \sum_{i=(k-1)/2}^{k-1} \left( \binom{k-1}{i} - \binom{k-1}{i-1} \right) \right) =$$

$$\frac{1}{2^k} \left( 1 + \frac{k-1}{(k-1)/2} - 1 + \frac{k-1}{(k-1)/2} - 1 \right) = O\left( \frac{1}{\sqrt{k}} \right)$$

We telescoped the sums, and used the inequality that for all $k$, we have that $\binom{k}{k/2} \leq O\left( \frac{2^k}{\sqrt{k}} \right)$.

For simplicity, we assumed above that $k - 1$ is even, the odd case can be handled analogously. Thus, we have an upper bound of $O(1/\sqrt{k})$ on the total variation distance.

Using this, together with the triangle inequality for total variation distance, we bound the variation distance between 1) the sum of $n$ i.i.d. uniform random variables from $\{0, 1\}$ and 2) the sum of $n - n^{0.5 - 0.01}$ i.i.d. uniform random variables from $\{0, 1\}$ by

$$O\left( \frac{n^{0.5 - 0.01}}{n^{0.5}} \right) = o(1).$$

This finishes the proof. \hspace{1cm} ◀

7 Appendix A

7.1 Verifying the conditions on \(L_h\)

Recall that we defined \(A\) and \(L_h\) as follows:

\[ A := \frac{1}{2^n} \cdot e^{\frac{k}{2\ln n} \cdot n^{1/5}} \]

For all \(h \geq n/2\), we set \(L_h := \max \left( \log \left( \frac{2nA \cdot \left( \frac{n}{2} \right)^h}{2^{L_h}} \right), 0 \right) \)

For all \(h\), satisfying \(n/2 > h \geq 9\sqrt{n}\), we set: \(L_h := \log \left( \frac{2nA \cdot \left( \frac{n}{2} \right)^{h/2}}{2^{L_h}} \right) \)

Here we prove that these values of \(A\) and \(L_h\) satisfy the following four conditions:

a) As a function of \(h\), \(L_h\) is non-increasing.

b) For all \(h\), we have that \(L_h \leq 9\sqrt{n}\).

c) \[
\frac{1}{2^n} \cdot \sum_{h=9\sqrt{n}}^{n} \left( \frac{n}{h} \right) \cdot A \leq \frac{1}{2}
\]

d) \[
\sum_{h=9\sqrt{n}}^{n} L_h \cdot \begin{cases} 
\frac{400}{n^{2/5}} & \text{if } h \leq n/2 - \sqrt{n\ln(n)} \\
\frac{400000}{n} & \text{if } n/2 - \sqrt{n\ln(n)} < h < n/2 + \sqrt{n} \\
40000 \cdot \left( \frac{h-n/2}{n} \right)^2 & \text{if } h \geq n/2 + \sqrt{n}
\end{cases} \leq \frac{e^2}{20000}
\]

We will need the following standard fact can be proven, for example, by comparing \(\sum_{i=0}^{N} i^k\) and \(\int_0^N i^k \, di\):

**Fact 31.** For any positive constant \(k\) and for sufficiently large \(n\), it is the case that: \(\sum_{i=0}^{N} i^k = (1 + o(1)) \frac{n^{k+1}}{k+1}\).

The truth of conditions (a) and (b) follows immediately by inspection. In fact a statement stronger than (b) is the case: for sufficiently large \(n\) we have \(L_h \leq \log(n \cdot A) \leq 2 \cdot n^{1/5}\).

Regarding condition (c), we have:

\[
\frac{1}{2^n} \cdot \sum_{h=9\sqrt{n}}^{n} \left( \frac{n}{h} \right) \cdot A 
\leq \frac{A}{2^n} \left( \sum_{h=9\sqrt{n}}^{n/2} \left( n/2 \right) \cdot \frac{2^n}{2 \cdot n} \cdot \min \left( \frac{1}{2^n \cdot \left( \frac{n}{2} \right)^h}, 1 \right) \right) \leq \sum_{h=9\sqrt{n}}^{n} \frac{1}{2^n} \leq \frac{1}{2}
\]

Finally, recall that for all \(h\), we have \(L_h \leq 2 \cdot n^{1/5}\). For sufficiently large \(n\), we have:

\[
\sum_{h=9\sqrt{n}}^{n} L_h \cdot \begin{cases} 
\frac{400}{n^{2/5}} & \text{if } h \leq n/2 - \sqrt{n\ln(n)} \\
\frac{400000}{n} & \text{if } n/2 - \sqrt{n\ln(n)} < h < n/2 + \sqrt{n} \\
40000 \cdot \left( \frac{h-n/2}{n} \right)^2 & \text{if } h \geq n/2 + \sqrt{n}
\end{cases} \leq \\
\frac{e^2}{40000} + \sum_{h=n/2 + \sqrt{n}}^{n} 40000 \cdot \left( \frac{h-n/2}{n} \right)^2 \cdot L_h
\]
We now bound the last term using Hoeffding’s inequality to bound the value of \( \binom{n}{h} \), making a change of variables with \( i := \frac{n-h}{2} \) and then using Fact 31 to bound the resulting summation. Precisely, we have the following chain of inequalities (some of which are only true for sufficiently large \( n \)):

\[
\sum_{h=n/2}^{n} 40000 \cdot \left( \frac{h-n/2}{n} \right)^2 \cdot L_h \leq \\
\sum_{h=n/2}^{n} 40000 \cdot \left( \frac{h-n/2}{n} \right)^2 \cdot \max \left( \log \left( 2nA \cdot \frac{(n)}{2n} \right), 0 \right) \leq \\
\sum_{h=n/2}^{n} 40000 \cdot \left( \frac{h-n/2}{n} \right)^2 \cdot \max \left( \log \left( 2nA \cdot \exp \left( -2 \frac{(h-n/2)^2}{n} \right) \right), 0 \right) = \\
\sqrt{\frac{2}{\ln(2nA^2)}} \sum_{i=0}^{\sqrt{\frac{2}{\ln(2nA^2)}}} \frac{40000}{\ln 2} \left( \frac{i}{n} \right)^2 \left( \ln(2nA) - 2 \cdot \frac{i^2}{n} \right) = \\
\frac{40000}{\ln 2} \cdot \left( 1 + o(1) \right) \left( \frac{\sqrt{2 \ln(2nA)}}{3n^2} \right)^3 \ln(2nA) - \left( 1 + o(1) \right) 2 \cdot \frac{\sqrt{\frac{2}{\ln(2nA)}}}{5n^3} \leq \\
\epsilon \leq \frac{\epsilon^2}{40000}
\]

Finally, simplifying and substituting the value of \( A \) we get:

\[
\sum_{h=n/2+\sqrt{n}}^{n} 40000 \cdot \left( \frac{h-n/2}{n} \right)^2 \cdot L_h \leq (1 + o(1)) \cdot \frac{40000}{\ln 2} \cdot \frac{\sqrt{\frac{2}{\ln(2nA)}}}{30 \sqrt{n}} \left( \ln(2nA) \right)^{5/2} \leq \frac{\epsilon^2}{40000}
\]

Condition (d) is verified by combining Equation 26 with the equation above.

### 7.2 Proof of Claim 21

Here we prove that for all sufficiently large \( n \), for all \( h \), satisfying \( 0 \leq h \leq n \), it is the case that:

\[
\frac{\binom{n}{h}}{\sum_{j=h}^{n} \binom{n}{j}} \leq \begin{cases} 
\frac{2}{n^2} & \text{if } h \leq n/2 - \sqrt{n \ln(n)} \\
\frac{2000}{n^2} & \text{if } n/2 - \sqrt{n \ln(n)} < h < n/2 + \sqrt{n} \\
\frac{200}{n^2} \frac{h-n/2}{n} & \text{if } h \geq n/2 + \sqrt{n} 
\end{cases}
\]

We first handle the case when \( h \geq n/2 + \sqrt{n} \). If, furthermore, \( h > 11n/20 \), then it is sufficient to prove that \( \sum_{j=h}^{n} \binom{n}{j} \leq 10 \), which is trivially true. Thus, we now assume that \( h \leq 11n/20 \).

It is the case that:

\[
\frac{\binom{n}{k}}{\binom{n}{k-1}} = 1 - \frac{k-n/2-1}{n/2} \frac{n/2}{k-n/2}
\]

Therefore, we can write:

\[
\sum_{j=h}^{n} \binom{n}{j} = \sum_{j=h}^{n} \prod_{k=h+1}^{n} \frac{k-n/2-1}{k-n/2} 
\]
Learning Monotone Probability Distributions over the Boolean Cube

Since \( n/2 + \sqrt{n} \leq h \leq 11n/20 \), for sufficiently large \( n \) we have that \( h + \frac{1}{2} \cdot \frac{n}{n-h/2} \leq n \). Using this, we can truncate the sum above, and then lower-bound the result by the product of the smallest summand with the total number of summands, getting:

\[
\sum_{j=h}^{n} \binom{n}{j} \geq \frac{1}{4} \cdot \frac{n}{h-n/2} \cdot \left( 1 - \frac{h-n/2-1}{n/2} \right)^{\frac{1}{2} \cdot \frac{n}{n-h/2}} \geq \frac{1}{4} \cdot \frac{n}{h-n/2} \cdot \prod_{k=h+1}^{n} \frac{1}{1 + \frac{h-k/2}{n/2}}
\]

Now, we analogously lower-bound the product by lower-bounding each of the factors, and then use the fact that since \( h \geq n/2 + \sqrt{n} \), it is the case that \( \frac{n}{n-h/2} \leq h-n/2 \). We get:

\[
\sum_{j=h}^{n} \binom{n}{j} \geq \frac{1}{4} \cdot \frac{n}{h-n/2} \cdot \left( 1 - \frac{1.25(h-n/2)}{n/2} \right)^{\frac{1}{2} \cdot \frac{n}{n-h/2}} \geq \frac{1}{4} \cdot \frac{n}{h-n/2} \cdot \prod_{k=h+1}^{n} \frac{1}{1 + \frac{1.25(h-k/2)}{n/2}}
\]

Finally, we use the fact that for all \( w \) between zero and one we have that \( \frac{1}{1+w} = 1 - w + w^2 - \ldots \geq 1 - w \). We get:

\[
\sum_{j=h}^{n} \binom{n}{j} \geq \frac{1}{4} \cdot \frac{n}{h-n/2} \cdot \left( 1 - \frac{1.25(h-n/2)}{n/2} \right)^{\frac{1}{2} \cdot \frac{n}{n-h/2}} \geq \frac{1}{4} \cdot \frac{n}{h-n/2} \cdot \exp \left( \frac{20(h-n/2)}{7n} \cdot \frac{1}{2} \cdot \frac{n}{h-n/2} \right) \geq \frac{1}{200} \cdot \frac{n}{h-n/2}
\]

This completes the proof in the case \( h \geq n/2 + \sqrt{n} \).

Given our bound in the range \( h \geq n/2 + \sqrt{n} \), to show the desired bound in the range \( n/2 - \sqrt{n \ln(n)} < h < n/2 + \sqrt{n} \), it is sufficient to show that \( \sum_{j \geq h} \binom{n}{j} \) is non-decreasing, as a function of \( h \). If \( h < n/2 \), this follows immediately, because, as a function of \( h \), the numerator is non-decreasing, whereas the denominator is decreasing. If \( h \geq n/2 \), then using Equation 27, we get:

\[
\sum_{j \geq h+1} \binom{n}{j} = \frac{1}{1 - \frac{h-n/2}{n/2}} \cdot \left( 1 - \frac{1}{1 + \frac{1}{n/2}} \right)^{\frac{n}{j-h+1}} \sum_{j \geq h+1} \binom{n}{j-1} \leq \frac{1}{1 - \frac{h-n/2}{n/2}} \cdot \left( \frac{n}{j-h+1} \right)^{\frac{n}{j-1}} \left( \frac{j}{j-h+1} \right)^{\frac{n+1}{j-1}} \leq \frac{\sum_{j \geq h} \binom{n}{j}}{\frac{n}{j-1}}
\]

Which implies that \( \sum_{j \geq h} \binom{n}{j} \leq \frac{n}{2} \cdot \frac{2^n}{2^{n+1}} \leq 2 \cdot \Pr_{x \sim \{0,1\}^n \left[ x \leq n/2 - \sqrt{n \ln(n)} \right]} \leq 2 \cdot \exp \left( -2 \ln n \right) = \frac{2}{n^2} \)
7.3 Proof for Claim 22

Recall that:
\[ N = \frac{2^n}{A} \cdot \frac{192}{\epsilon^2} \cdot (n + 9\sqrt{n} + 4) \]

Our algorithm for learning a monotone probability distribution drew \( N \) samples from the probability distribution \( \rho \) and the resulting multiset of samples was denoted as \( S \). For all \( x \) in \( \{0, 1\}^n \), if \( ||x|| < 9\sqrt{n} \), we set \( \hat{\phi}(x) = 0 \), otherwise we set:

\[
\hat{\phi}(x) := \frac{1}{2} \max_{y \text{ s.t. } y \leq x} \frac{\max_{||y||-||x||=[L||x||]} \Pr[y \leq z \leq x]}{N}
\]

Where \( L_h \) is a specific value associated to each value of \( h \). We also defined for all \( x \) with \( x \geq 9\sqrt{n} \) the value:

\[
\phi(x) := \frac{1}{2} \max_{y \text{ s.t. } y \leq x} \frac{\max_{||y||-||x||=[L||x||]} \Pr[y \leq z \leq x]}{N} \cdot \sum_{z \text{ s.t. } y \leq z \leq x} \rho(z)
\]

Here we prove that if it is the case that \( \frac{1}{2^n} \cdot \sum_{h=9\sqrt{n}}^{(n)} \cdot \frac{A}{2^n} \leq \frac{1}{2} \), then, with probability at least 7/8, it is the case that:

\[
\sum_{x \in \{0, 1\}^n \text{ s.t. } 9\sqrt{n} \leq ||x||} \left| \hat{\phi}(x) - \phi(x) \right| \leq \frac{\epsilon}{4}
\]

We claim that for any pair \( (x, y) \), such that \( \phi \) is defined on \( x \) and \( ||x|| - ||y|| = [L||x||] \), with probability at least \( 1 - \frac{1}{8 \cdot 2^n \cdot n^2} \), the following holds:

\[
\left| \Pr_{z \sim \rho}[y \leq z \leq x] - \frac{\{z \in S : y \leq z \leq x\}}{N} \right| \leq \frac{\epsilon}{8} \cdot \max \left( \frac{A}{2^n} \cdot \Pr_{z \sim \rho}[y \leq z \leq x] \right)
\]

(28)

We use Chernoff’s bound to prove this as follows. Denote by \( q \) the value \( \Pr_{z \sim \rho}[y \leq z \leq x] \).

If \( q \geq \frac{A}{2^n} \), then by Chernoff’s bound we have:

\[
\Pr \left[ \left| \{z \in S : y \leq z \leq x\} - qN \right| \geq \frac{\epsilon}{8}qN \right] \leq 2 \exp \left( -\frac{1}{3} \left( \frac{\epsilon}{8} \right)^2 qN \right) \leq 2 \exp \left( -\frac{1}{3} \left( \frac{\epsilon}{8} \right)^2 \frac{A}{2^n} \cdot N \right) = \frac{1}{8 \cdot 2^n \cdot n^3 \sqrt{n}}
\]

Otherwise, if we have \( q < \frac{A}{2^n} \), then by Chernoff’s bound:

\[
\Pr \left[ \left| \{z \in S : y \leq z \leq x\} - qN \right| \geq \frac{\epsilon}{8} \frac{A}{2^n} \cdot N \right] \leq 2 \exp \left( -\frac{1}{3} \left( \frac{\epsilon}{8} \right)^2 \frac{A}{2^n} \cdot N \right) \leq 2 \exp \left( -\frac{1}{3} \left( \frac{\epsilon}{8} \right)^2 \frac{A}{2^n} \cdot N \right) = \frac{1}{8 \cdot 2^n \cdot n^3 \sqrt{n}}
\]

Now, by taking a union bound, it follows that with probability 7/8 for all such pairs \( (x, y) \) Equation 28 will be the case. Recalling the definition of \( \phi \), for all \( x \) on which \( \phi \) is defined it then will be the case that:

\[
\left| \hat{\phi}(x) - \phi(x) \right| \leq \frac{\epsilon}{8} \cdot \max \left( \frac{1}{2[L||x||]} \frac{A}{2^n} \cdot \phi(x) \right)
\]
Now, we sum this for all $x$ in the domain of $\phi$ and use the fact that $|L_h| \geq L_h + 1$, and then use that $\frac{1}{2^n} \cdot \sum_{h=9 \sqrt{n}}^{n} \binom{n}{h} \cdot \frac{A}{2^{L_h} L_h} \leq \frac{1}{2}$. We get:

$$\sum_{x \in \{0,1\}^n \text{ s.t. } 9 \sqrt{n} \leq ||x||} \left| \hat{\phi}(x) - \phi(x) \right| \leq \frac{\epsilon}{8} \cdot \left( \frac{1}{2^n} \cdot \sum_{h=9 \sqrt{n}}^{n} \binom{n}{h} \cdot \frac{A}{2^{L_h} L_h} \right) + \sum_{x \in \{0,1\}^n \text{ s.t. } 9 \sqrt{n} \leq ||x||} \phi(x) \right) =$$

$$\frac{\epsilon}{8} \cdot \left( \frac{1}{2^n} \cdot \sum_{h=9 \sqrt{n}}^{n} \binom{n}{h} \cdot \frac{A}{2^{L_h} L_h} \right) + \sum_{x \in \{0,1\}^n \text{ s.t. } 9 \sqrt{n} \leq ||x||} \phi(x) \right) \leq$$

$$\frac{\epsilon}{8} \cdot \left( 2 \cdot \frac{1}{2^n} \cdot \sum_{h=9 \sqrt{n}}^{n} \binom{n}{h} \cdot \frac{A}{2^{L_h} L_h} + \sum_{x \in \{0,1\}^n \text{ s.t. } 9 \sqrt{n} \leq ||x||} \phi(x) \right) \leq$$

$$\frac{\epsilon}{8} \cdot \left( 1 + \sum_{x \in \{0,1\}^n \text{ s.t. } 9 \sqrt{n} \leq ||x||} \rho(x) \right) \leq \frac{\epsilon}{4}$$
Sample Complexity Bounds for Influence Maximization

Abstract

Influence maximization (IM) is the problem of finding for a given $s \geq 1$ a set $S$ of $|S| = s$ nodes in a network with maximum influence. With stochastic diffusion models, the influence of a set $S$ of seed nodes is defined as the expectation of its reachability over simulations, where each simulation specifies a deterministic reachability function. Two well-studied special cases are the Independent Cascade (IC) and the Linear Threshold (LT) models of Kempe, Kleinberg, and Tardos [31]. The influence function in stochastic diffusion is unbiasedly estimated by averaging reachability values over i.i.d. simulations. We study the IM sample complexity: the number of simulations needed to determine a $(1 - \epsilon)$-approximate maximizer with confidence $1 - \delta$. Our main result is a surprising upper bound of $O(s\tau\epsilon^{-2}\ln \frac{n}{\delta})$ for a broad class of models that includes IC and LT models and their mixtures, where $n$ is the number of nodes and $\tau$ is the number of diffusion steps. Generally $\tau \ll n$, so this significantly improves over the generic upper bound of $O(sn\epsilon^{-2}\ln \frac{n}{\delta})$. Our sample complexity bounds are derived from novel upper bounds on the variance of the reachability that allow for small relative error for influential sets and additive error when influence is small. Moreover, we provide a data-adaptive method that can detect and utilize fewer simulations on models where it suffices. Finally, we provide an efficient greedy design that computes an $(1 - 1/e - \epsilon)$-approximate maximizer from simulations and applies to any submodular stochastic diffusion model that satisfies the variance bounds.

1 Introduction

Models for the spread of information among networked entities were studied for decades in sociology and economics [26, 20, 29]. A diffusion process is initiated from a seed set of nodes (entities) and progresses in steps: Initially, only the seed nodes are activated. In each step additional nodes may become active based on the current set of active nodes. The progression can be deterministic or stochastic. The $t$-stepped influence of a seed set $S$ of nodes is then defined as its expected reachability (total number of active nodes) in $t$ steps.
Influence maximization (IM) is the problem of finding a set $S$ of nodes of specified cardinality $|S| = s$ and maximum influence. The IM problem was formulated nearly two decades ago by Richardson and Domingos [17, 40] and inspired by the application of viral marketing. In a seminal paper, Kempe, Kleinberg, and Tardos [31] studied stochastic diffusion models and introduced two elegant special cases, the Independent Cascade (IC) and Generalized Threshold (GT) diffusion models. Their work sparked extensive followup research and large scale implementations [35, 7, 30, 39]. Currently IM is applied in multiple domains with linked entities for tasks as varied as diversity-maximization (the most representative subset of the population) and sensor placement that maximize coverage [32, 4, 34].

We consider stochastic diffusion models (SDM) $G(V)$ over $|V| = n$ nodes that are specified by a distribution $\phi \sim G$ over sets $\phi := \{\phi_v\}_{v \in V}$ of monotone non-decreasing boolean activation functions $\phi_v : 2^V \setminus \{v\} \to \{0, 1\}$. A diffusion process starts with a seed set $S \subset V$ of nodes and $\phi \sim G$. At step 0 we activate the seed nodes $\text{Reach}^0(\phi, S) := S$. The diffusion then proceeds deterministically: At step $t > 0$ all active nodes remain active and we activate any inactive node $v$ where $\phi_v(\text{Reach}^{t-1}(\phi, S)) = 1$:

$$\text{Reach}^{t+1}(\phi, S) := \{v \in V \mid \phi_v(\text{Reach}^t(\phi, S)) = 1\}.$$ 

The $\tau$-steps reachability set of a seed set $S$ is the random variable $\text{Reach}^\tau(\phi, S)$ for $\phi \sim G$ and respectively the $\tau$-steps reachability, $R^\tau(S)$, is the random variable that is the number of active nodes $|\text{Reach}^\tau(\phi, S)|$ for $\phi \sim G$. Finally, the influence value of $S$ is defined to be the expectation

$$\Gamma^\tau(S) := \mathbb{E}[R^\tau(S)] = \mathbb{E}_{\phi \sim G}[|\text{Reach}^\tau(\phi, S)|].$$

We refer to the case where the diffusion is allowed to progress until there is no growth as unrestricted diffusion and this corresponds to $\tau = n - 1$. The influence $\Gamma^\tau(S)$ is a monotone set function. We say that an SDM is submodular when the influence function is submodular and that it is independent if the activation functions $\phi_v$ of different nodes are independent random variables. The IM problem for seed set size $s$ and $\tau$ steps is to find

$$\arg\max_{S: |S| \leq k} \Gamma^\tau(S).$$

The reader might be more familiar with well-studied special cases of this general formulation. Live-edge diffusion models $G(V, E)$ are specified by a graph $(V, E)$ with $|V| = n$ nodes and $|E| = m$ directed edges and a distribution $E \sim G$ over subsets $E \subset E$ of “live” edges. When expressed as an SDM, the activation functions that correspond to $E$ have $\phi_v(T) = 1$ if and only if there is an edge from a node in $T$ to $v$ in the graph $(V, E)$. Live-edge models are always submodular: This because $|\text{Reach}^\tau(E, S)|$, which is the number of nodes reachable
from $S$ in $(V, E)$ by paths of length at most $\tau$, is a coverage function and hence monotone and submodular. Therefore, so is the influence function $\Gamma^\tau(S)$, which is an expectation of a distribution over coverage functions. A live-edge model is independent if we only have dependencies between incoming edges to the same node. The Independent Cascade (IC) model is the special case of an independent live-edge model where all edges $e \in \mathcal{E}$ are independent Bernoulli random variables selected with probabilities $p_e$ ($e \in \mathcal{E}$).

Another well-studied class are generalised threshold (GT) models [31, 35]. A GT model $\mathcal{G}(V, f)$ is specified by a set $f := \{f_v\}_{v \in V}$ of monotone functions $f_v : 2^V \to [0, 1]$. The randomization is specified by a set of threshold values $\theta \sim \mathcal{G}$ where $\theta := \{\theta_v\}_{v \in V}$. The corresponding activation functions to $\theta$ are $\phi_v(T) := \text{Indicator}(\theta_v \leq f_v(T))$.

An important subclass are Independent GT (IGT) where we require that $f$ are submodular and nodes $v \in V$ have independent threshold values $\theta_v \sim U([0, 1])$. Mossel and Roch [35, 36] proved that IGT models are submodular, which is surprising because the functions $|\text{Reach}^\tau(\phi, S)|$ are generally not submodular. Their proof was provided for unrestricted diffusion but extends to the case where we stop the process after $\tau$ steps. Finally, Linear threshold (LT) models [26, 31] are a special case of IGT where we have an underlying directed graph and each edge $(u, v)$ is associated with a fixed weight value $b_{uv} \geq 0$ so that for all $v \in V \sum_{u \in V} b_{uv} \leq 1$ and the functions are defined as the sums $f_v(A) := \sum_{u \in A \cap N(v)} b_{uv}$. Kempe et al showed [31] that each LT model is equivalent to an independent live-edge model.

One of the challenges brought on by the IM formulation is computational efficiency. Kempe et al [31] noted that the IM problem generalizes the classic Max Cover problem even with $\tau = 1$ and a live-edge model with a fixed set of live edges ($p_e = 1$ for all $e \in \mathcal{E}$). Therefore, IM inherits Max Cover’s hardness of approximation for ratio better than $1 - (1 - 1/s)^s$ [21] for a cover with $s$ sets. On the positive, with submodular models, an approximation ratio of $1 - (1 - 1/s)^s$ can be achieved by the first $s$ nodes of a greedy sequence generated by sequentially adding a node with maximum marginal value [37]. A challenge of applying Greedy with stochastic models, however, is that even point-wise evaluation of the influence function can be computationally intensive. Exact evaluation even for IC models [6] and LT models [8] is \#P hard. As for approximation, Kempe et al proposed to work with averaging oracles

$$\hat{\Gamma}^\tau(T) := \frac{1}{\tau} \sum_{i=1}^{\ell} |\text{Reach}^\tau(\phi_i, T)|$$

that average the reachability values obtained from a set $\{\phi_i\}_{i=1}^{\ell}$ of i.i.d. simulations. Recall that in the general SDM formulation, a simulation is specified by a set $\phi$ of node activation functions. For live-edge models, a simulation is simply a set of concurrently live edges $E$. In GT models, a simulation is specified by a set of thresholds $\theta$.

Averaging oracles, which we focus on here, have several appealing properties: First, it is robust compared to estimators tailored to models that satisfy specific assumptions (see related work section) in that for any diffusion model $\mathcal{G}$, also with complex and unknown dependencies (between activation functions of different nodes or between edges in live-edge models), for any set $S$, $\hat{\Gamma}(S)$ is an unbiased estimate of the exact influence value $\Gamma^\tau(S)$ and estimates are accurate as long as the variance of $\mathcal{R}^\tau(S)$ is “sufficiently” small. Second, the oracle is constructed directly from simulations and does not require learning or inferring the underlying diffusion model that generated the data [41, 24, 23, 18]. Therefore, the results are not sensitive to modeling assumptions and learning accuracy [9, 27]. Moreover, estimation of
model parameters even for IC models can require a large number of simulations: Consider the family of IC models depicted in the example in Figure 2b where tiny edge probabilities that require many simulations to estimate are critical for IM accuracy. Finally, when the reachability functions $\text{Reach}^\tau_\phi(S)$ are monotone and submodular (as is the case with live-edge models), so is their average $\hat{A}(S)$, and hence the oracle optimum can be approximated by the greedy algorithm. Prior work addressed the efficiency of working with averaging oracles by improving the efficiency of greedy maximization [32, 25] and applied sketches [10] to efficiently estimate $\hat{A}(S)$ values [7, 14].

The fundamental question we study here is the sample complexity of IM, that is, the number of i.i.d. simulations needed to recover an approximate maximizer of the influence function $I^\tau$. Formally, for parameters $(\epsilon, \delta)$, identify a seed set $T$ of size $s$ so that

$$\Pr[I^\tau(T) \geq (1 - \epsilon)\text{OPT}^\tau_s] \geq 1 - \delta,$$

where $\text{OPT}^\tau_s := \max_{S \subseteq [n]} |S| \leq s I^\tau(S)$ is the exact maximum. Note that the recovery itself is generally computationally hard and the sample complexity only considers the information we can glean from a set of simulations.

Kempe et al provided an upper bound of

$$O\left(\epsilon^{-2}s n \log \frac{n}{\delta}\right)$$

(1)

on the sample complexity of the harder Uniform Relative-Error Estimation (UREE) problem where for a given $(\epsilon, \delta)$ we bound the number of simulations so that with probability $1 - \delta$, for all subsets $S$ such that $|S| \leq s$, $\hat{A}(S)$ approximates $I^\tau(S)$ within relative error of $\epsilon$. The sample complexity of UREE upper bounds that of IM because the oracle maximizer $\arg \max_{S \subseteq [n]} |S| \leq s \hat{A}(S)$ must be an approximate maximizer. We provide the argument for the bound (1) here because it is basic and broadly applies to all SDMs: The reachability values $\text{Reach}^\tau_\phi(S)$, and hence their expectation, $I^\tau(S)$ have values in $[1, n]$. Using the multiplicative Chernoff bound (with values divided by $n$) we obtain that $O(\epsilon^{-2}n \ln \delta^{-1})$ simulations guarantee a relative error of $\epsilon$ with probability at least $(1 - \delta)$ for the estimate of any particular set $S$. Interestingly, this sample complexity bound is tight for point-wise influence estimation even for IC models: The example family of models in Figure 2a is such that $\tau = 2$ and $\Omega(\epsilon^{-2}n)$ simulations are required for estimating the influence value of a single node. The UREE sample complexity bound (1) follows from applying a union bound over all $\binom{n}{s}$ subsets.

The generic upper bound has prohibitive linear dependence on the number of nodes $n$ (that the example in Figure 2a shows is unavoidable for UREE even for IC models). A simple example shows that we can not hope for an umbrella improvement for IM: Consider the star

![Figure 2](image)

(a) Family of $n$ node graphs. Node $v$ has influence $I^\tau(v) = 100$ but variance $\approx 100n$.

(b) Star graphs with $n$ nodes where all edges have marginal probabilities $100/(n - 1)$. The center node has influence value 101 and all other nodes have influence 1.
graph family of Figure 2b when edges are dependent so that either all edges are live or none is. Clearly \( n/100 \) simulations are necessary to detect a 1-step approximate maximizer (which must be the actual maximizer). The remaining hope is that we can obtain stronger bounds on the IM sample complexity for models with weaker or no dependencies such as IC and IGT models. This question eluded researchers for nearly two decades.

1.1 Contributions and Overview

We study the sample complexity of influence maximization from averaging oracles computed from i.i.d. simulations. One of our main contributions is an upper bound of

\[
O \left( \epsilon^{-2} s \tau \log \frac{n}{\delta} \right)
\]

on the IM sample complexity of independent strongly submodular SDMs. Informally, strong submodularity means that the influence function of any “reduced” model (model derived from original one by setting a subset \( T \subset V \) of nodes as active) is submodular. The IC and IGT models are special cases of strongly submodular independent SDMs.

Interestingly, we provide similar sample complexity bounds for natural families of models that are not independent: Mixtures of small number of strongly submodular SDMs and what we call \( b \)-dependence live-edge models that allow for positive dependence of small groups of edges with a shared tail node.

Our bound improves over prior work by replacing the prohibitive linear dependence in the number of nodes \( n \) in (1) with the typically much smaller value \( \tau \). While on worst-case instances unrestricted diffusions may require \( \Omega(n) \) steps, understanding the sample complexity in terms of \( \tau \) is important: First, IM with explicit step limits [5, 33, 22, 19, 15], is studied for applications where activation time matters. Moreover, due to the “small world” phenomenon [44], in “natural” settings we can expect most activations (even with unrestricted diffusions) to occur within a small number of steps. In the latter case, unrestricted influence values are approximated well by corresponding step-limited influence with \( \tau \ll n \).

Our improvement is surprising as generally a linear-in-\( n \) number of simulations is necessary for estimating influence values of some nodes or to estimate essential model parameters (for example, the edge probabilities in IC models), and this is the case even when \( \tau \) is very small. This shows that the maximization problem is in an information sense inherently easier and can circumvent these barriers.

We overview our results and implications – complete proofs can be found in the appendix. We review related work in Section 2 and place it in the context of our results. In Section 3 we formulate quality measures for influence oracles and relate unrestricted and step-limited influence. In particular, we observe that for IM it suffices that the oracle provides good estimates (within a small relative error) of larger influence values. This allows us to circumvent the lower bound for point-wise relative-error estimates shown in Example 2a.

In Section 4 we state our main technical result that for independent strongly submodular SDMs, upper bounds the variance of the reachability of set \( T \) \( \text{Var}[R^\tau(T)] \) by \( \tau \Gamma^\tau(T) \max_{v \in V \setminus T} \Gamma^{-1} - 1(v) \). This variance upper bound facilitates estimates with small relative error for sets with larger influence values and additive error for sets with small influence values. We also provide a family of IC models that shows that the linear dependence on \( \tau \) in the variance bound is necessary. We derive similar variance bounds to mixtures of strongly submodular independent SDMs and \( b \)-dependence models. All our subsequent sample complexity bounds apply generically to any SDM (submodular/independent or not) that satisfies variance bounds of this form. In Section 5 we review averaging oracles and bound the sample complexity.
complexity using variance upper bounds. In section 6 we present our median-of-averages oracle that amplifies the confidence guarantees of the averaging oracle and facilitates a tighter sample complexity bound. In Section 7 we provide a data-adaptive framework that provides guarantees while avoiding the worst-case sample complexity upper bounds on models when a smaller number of simulations suffices. In Section 8 we consider computational efficiency and present a greedy maximization algorithm based on our median-of-averages oracles that returns a $(1 - (1 - 1/s) - \epsilon)$ approximate maximizer with probability $1 - \delta$. The design generically applies to any SDM with a submodular influence function that satisfies the variance bounds.

2 Related work

We focus here on influence estimates obtained from averages of i.i.d. simulations of a SDM. We note that alternative approaches can be more effective for specific families of models. Most notably for IC models, state of the art large-scale greedy approximate maximization algorithms [43, 42, 38, 28] are not based on simulation averages. The estimates are also obtained by building a sample that reflects the influence of each but instead they use a finer building block of i.i.d. Reverse Reachability (RR) searches. The random RR search method was proposed in [10] to estimate size of reachability sets in graphs and Borg et al [3] adapted it to IC models.

The method is applicable in principle with any live-edge model: A basic RR search is conducted by selecting a node $v \in V$ uniformly at random and performing a BFS search on reversed edges that is pruned at length $\tau$. The search “flips” edges as their head node is reached according to conditional distribution on $G$. The index number of the RR search is then added to the sample set of each node that is “reached” by the search. Influence of a subset $S$ can then be unbiasedly estimated from the cardinality of the union of the samples of nodes $v \in S$ and the greedy algorithm can be applied to the sets of samples for approximate maximization. To obtain an approximate influence maximizer we need to perform RR searches until some node has a sample of size $O \left( e^{-2s \log(n/\delta)} \right)$. In the worst case, this requires $O \left( e^{-2sn \log(n/\delta)} \right)$ RR searches. For general live-edge models, an independent RR search can always be obtained from a simulation $E \sim G$ by randomly drawing a node and performing a reverse search from it using edges $E$. The same simulation, however, can not
generally be reused to generate multiple independent RR searches. This way of obtaining RR searches works for general live-edge models (with arbitrary dependencies) but requires \( O(\epsilon^{-2}ns \log(n/\delta)) \) simulations, which does not improve over the generic upper bound \( (1) \).

The appeal of the RR searches method is that it can be implemented very efficiently for independent live-edge (including IC or LT) models. The total work performed requires only \( O(\epsilon^{-2}ms(\log(n/\delta))) \) “edge flips” that can be easily performed using specified edge probabilities \( p_e \) for IC models. Moreover, the basic building block of RR searches are local simulations of sets of incoming edges of specified nodes and the full computation requires at most \( O(\epsilon^{-2}s \log(n/\delta)) \) local simulations for each node. When we have full simulations generated by an independent live-edge model these “local” simulations are independent and the required number of “local simulations” can be obtained by decomposing \( O(\epsilon^{-2}s \log(n/\delta)) \) full simulations. But the caveat is that this approach breaks the coherence of simulations, as we construct each RR search from components taken from multiple simulations. These “efficient” implementations (i.e. based on decomposed simulations or edge flips according to marginal probabilities) may “catastrophically fail” when dependencies exist: The influence estimates obtained are biased and cause large errors even when the variance is low. Figure 3 shows an example of a simple mixture model (of two degenerate IC models) where “efficient” RRS has large error due to bias but averages of few simulations provide accurate estimates. To summarize, with RRS, the implementation that works with full simulations is robust to dependencies but is inefficient and the efficient implementation breaks ungracefully even with light dependencies. To conclude, both basic approaches to approximate IM, simulation averages and RRS offer distinct advantages: Simulation averages are robust in that they remain unbiased and are accurate on any SDM, including dependent ones, for which the variance is sufficiently small whereas RRS offers more efficiency for purely independent live-edge models.

3 Preliminaries

We consider stochastic diffusion models \( G(V) \) as outlined in the introduction. We denote by \( \text{Reach}^\tau(\phi, T) \) the \( \tau \)-steps reachability set of \( T \) when we use a specific set \( \phi \) of activation functions. We will use the notation \( \text{Reach}^\tau(T) \) (with the parameter \( \phi \) omitted) for the random variable \( \text{Reach}^\tau(\phi, T) \) obtained when we draw \( \phi \sim G \) according to the model.

3.1 Utility Functions

For simplicity, the discussion in the introduction took the utility of a reachable set to be the number of reachable nodes \( V_{\text{Reach}}^\tau(\phi, T) := |\text{Reach}^\tau(\phi, T)| \). Generally, we can consider utility functions \( H : 2^V \to \mathbb{R}_+ \) that are nonnegative monotone non-decreasing with \( H(\emptyset) = 0 \):

\[
V_{\text{Reach}}^\tau(\phi, T) := H(\text{Reach}^\tau(\phi, T)).
\]

Submodular utility is particularly natural and studied by Mossel and Roch [35]. Additive utility is the special case where nodes have nonnegative weights \( w : V \to \mathbb{R}_+ \) and

\[
V_{\text{Reach}}^\tau(\phi, T) := \sum_{v \in \text{Reach}^\tau(\phi, T)} w(v).
\]
We consider a diffusion model $\mathcal{G}(V, H)$ together with a utility function $H$. The random variable $R_{\tau}^G(T)$ is the utility of the reachable set, that is, $\text{VReach}^\tau(\phi, T)$ when $\phi \sim \mathcal{G}$. The influence function is then the expected utility of the reachable set

$$I^\tau(T) := \mathbb{E}_{\phi \sim \mathcal{G}}[R_{\tau}^G(T)] = \mathbb{E}_{\phi \sim \mathcal{G}}[\text{VReach}^\tau(\phi, T)].$$

We denote the maximum influence value of a subset of cardinality $s$ by $\text{OPT}^\tau_s := \max_{S: |S| \leq s} I^\tau(S)$.

It follows from the definition that for any SDM $\mathcal{G}(V, H)$ with utility $H$, the influence $I^\tau(T)$ is monotone non-decreasing in $\tau$ and in the set $T$ and the optimum values $\text{OPT}^\tau_s$ are non-decreasing in $\tau$ and $s$. Generally, influence functions $I^\tau(T)$ of SDMs may not be submodular even when utility is additive. The influence function is known to be submodular for live-edge and for IGT models [35] with submodular utility.

### 3.2 Reduced Models

We work with the following notion of model reduction. Let $\mathcal{G}(V, H)$ be an independent SDM with submodular utility. For a set of nodes $T \subset V$, we define the reduced model $\mathcal{G}'(V', H')$ of $\mathcal{G}$ with respect to $T$: The reduced model contains the nodes $V' = V \setminus T$. The activation function $\phi'_v \sim \mathcal{G}'$ for $v \in V \setminus T$ are obtained by drawing $\phi_v \sim \mathcal{G}$ conditioned on $\phi_v(T) = 0$ and take

$$\text{for all } S \subset V \setminus (T \cup \{v\}), \phi'_v(S) := \phi_v(S \cup T)$$

(Note that since we have independent SDM we can separately consider the distribution of activation functions of each node). The utility in $\mathcal{G}'$ is the marginal utility in $\mathcal{G}$ with respect to $T$:

$$\text{for all } S \subset V \setminus T, H'(S) := H(S \cup T) - H(T).$$

The reduced model $\mathcal{G}'(V', H')$ is also an independent SDM with submodular utility: Activation functions $\phi' \sim \mathcal{G}'$ are independent and monotone and the utility is monotone with $H'(\emptyset) = 0$ and submodular.

### 3.3 Strongly Submodular SDM

We say that an independent SDM $\mathcal{G}(V, H)$ is strongly submodular if the utility function $H$ is submodular and the influence function $I^\tau_{\mathcal{G}}$ is submodular with any reduced model $\mathcal{G}'$ and step limit $\tau \geq 0$. IC and IGT models are strongly submodular SDMs (see Theorem 19).

The variance and thus sample complexity upper bounds that we present in the sequel apply to any strongly submodular SDM. We will also provide bounds for some dependent families of models. One family is a slight generalization of IC models that we refer to as $b$-dependence. Here edges are partitioned into disjoint groups, where each group contains at most $b$ edges emanating from the same node. The edges in a group must be either all live or all non-live (are positively dependent).

### 3.4 Relating Step-Limited and Unrestricted Influence

When unrestricted diffusion from a seed set $S$ is such that most activations occur within $\tau$ steps, the unrestricted influence $I(S)$ is approximated well by $\tau$-step influence $I^\tau(S)$. We can also relate unrestricted influence with small expected steps-to-activation to step-limited
influence: For a seed set $S$, node $v$, and length $d$, we denote by $p(S, v, d)$ the probability that node $v$ is activated in a diffusion from $S$ in step $d$. For additive utility functions (4) by definition, $I^\tau(S) = \sum_{v\in V} w(v) \sum_{d\leq \tau} p(S, v, d)$. The expected length of an activation path from $S$ (in unrestricted diffusion) is:

$$\mathcal{D}(S) := \sum_{v\in V} w(v) \sum_{d\leq \tau} d \cdot p(S, v, d) / I(S).$$

The following lemma is an immediate consequence of Markov’s inequality and shows that $\tau$-stepped influence with $\tau = O(\mathcal{D}(S))$ approximates well the unrestricted influence:

**Lemma 1.** For all $S$ and $\epsilon > 0$, $\mathcal{I}^\tau(S)^{\epsilon^{-1}}(S) \geq (1 - \epsilon) I(S)$.

### 3.5 Influence Oracles

We say that a set function $\hat{F}$ is an $\epsilon$-approximation of another set function $F$ at a point $T$ if $|\hat{F}(T) - F(T)| \leq \epsilon \max\{F(T), \text{OPT}_T(F)\}$, where $\text{OPT}_s(F) := \max_{|S| = s} F(S)$. That is, the estimate $\hat{F}$ has a small relative error for sets $T$ with $F(T) \geq \text{OPT}_T(F)$ and a small absolute error of $\text{OPT}_T(F)$ for sets $T$ with $F(T) \leq \text{OPT}_T(F)$. We say that $\hat{F}$ provides a uniform $\epsilon$-approximation for all subsets $T$ in a collection $C$ if $\hat{F}$ is an $\epsilon$-approximation for all $T \in C$.

An influence oracle, $\hat{I}^\tau$, is a randomized data structure that is constructed from a set of i.i.d. simulations of a model. The influence oracle, $\hat{I}^\tau$, defines a set function (we use the same name $\hat{I}^\tau$ for the set function) that for any input query set $T \subset V$, returns a value $\hat{I}^\tau(T)$. For $\epsilon < 1$ and $\delta < 1$ we say that an oracle provides $(\epsilon, \delta)$ approximation guarantees with respect to $I^\tau$ if for any set $T$ it is an $\epsilon$-approximation with probability at least $1 - \delta$. That is

$$\forall T \text{ such that } I^\tau(T) \geq \text{OPT}_T^\tau, \Pr\left[\frac{|\hat{I}^\tau(T) - I^\tau(T)|}{I^\tau(T)} \geq \epsilon\right] \leq \delta.$$  

$$\forall T, \text{ such that } I^\tau(T) \leq \text{OPT}_T^\tau, \Pr\left[\frac{|\hat{I}^\tau(T) - I^\tau(T)|}{\epsilon \text{OPT}_T^\tau} \geq \delta\right] \leq \delta.$$  

where $\text{OPT}_T^\tau := \text{OPT}_1(I^\tau)$. Example 2a shows that this type of requirement is what we can hope for with an oracle that is constructed from a small number of simulations.

The $(\epsilon, \delta)$ requirements are for each particular set $T$. If we are interested in stronger guarantees that with probability $(1 - \delta)$ the approximation uniformly holds for all sets in a collection $C$, we can use an oracle that provides $(\epsilon, \delta_A = \delta/|C|)$ guarantees. The $\epsilon$-approximation guarantee for all sets in $C$ then follow using a union bound argument: The probability that all $|C|$ sets are approximated correctly is at most $|C| \delta_A \leq \delta$.

### 4 Variance Bounds

We consider upper bounds on the variance $\text{Var}[R^\tau(T)]$ of the reachability of a set of nodes $T$ that have the following particular form

$$\text{Var}[R^\tau(T)] \leq c \ell^\tau(T) \max\{\ell^\tau(T), \max_{v \in V} \ell^\tau(v)\}$$

for some $c \geq 1$. The sample complexity bounds we present in the sequel apply to any SDM that satisfies these bounds. In the remaining part of this section we state our variance upper bound for strongly submodular SDMs and extensions and a tight worst-case lower bound for IC models.
4.1 Variance Upper Bound

The following key theorem facilitates our main results. We show that any strongly submodular SDM satisfy the bound (8) with \( c = \tau \). The proof is technical and provided in Appendix A.

\[ \text{Theorem 2 (Variance Upper Bound Lemma).} \quad \text{Let} \ G(V, H) \text{ be a strongly submodular SDM. Then for any step limit} \ \tau \geq 0 \text{ and a set} \ T \subset V \text{ of nodes we have} \]

\[ \text{Var}[R^\tau(T)] \leq \tau \Gamma^\tau(T) \max_{v \in V \setminus T} \Gamma^{\tau-1}(v). \]

Some natural dependent SDMs have a variance bound of the form (8): (See Appendix F for proofs.)

\[ \text{Corollary 3.} \quad \text{IC models with} \ \tau \text{-steps and} \ b \text{-dependence satisfy the bound (8) with} \ c = 2b\tau. \]

Any mixture of \( \tau \)-steps strongly submodular SDMs where each model has probability at least \( p \) satisfy the bound (8) with \( c = (\tau + 1)/p \).

4.2 Variance Lower Bound

We provide a family of IC models for which this variance upper bound is asymptotically tight. This shows that the dependence of the variance bound on \( \tau \) is necessary.

\[ \text{Theorem 4 (Variance Lower Bound).} \quad \text{For any} \ \tau > 0 \text{ there is an IC model} \ G^\tau = (V, E) \text{ with a node} \ v \in V \text{ of maximum influence such that} \]

\[ \text{Var}[R^\tau(v)] \geq \frac{1}{12} \tau \Gamma^\tau(v)^2. \]

Our family of models \( G^\tau = (V, E) \) are such that \( (V, E) \) is a complete directed binary tree of depth \( \tau \geq 1 \) rooted at \( v \in V \) with all edges directed away from the root and \( p_v = 1/2 \) for all \( e \in E \). We show (details in Appendix B) that:

\[ \Gamma^\tau(v) = \tau \]

\[ \text{Var}[R^\tau(v)] = \frac{1}{12} \tau(\tau - 1)(2\tau - 1). \]

5 The Averaging Oracle

The averaging oracle uses i.i.d. simulations \( \{\phi_i\}_{i=1}^\ell \). For a query \( T \) it returns the average utility of the reachability set of \( T \):

\[ \hat{R}^\tau(T) = \text{Ave}_{e \in [\ell]} \text{VR}_{\tau}(\phi_i, T) := \frac{1}{\ell} \sum_{i=1}^{\ell} \text{VR}_{\tau}(\phi_i, T). \]

We quantify the approximation guarantees of an averaging oracle in terms of a variance bound of the form (8).

\[ \text{Lemma 5.} \quad \text{Consider an SDM that for some} \ c \geq 1 \text{ satisfies a variance bound of the form (8). Then for any} \ \epsilon, \delta < 1, \text{ an averaging oracle constructed from} \ \ell \geq \epsilon^{-2}\delta^{-1}c \text{ i.i.d. simulations provides} \ (\epsilon, \delta) \text{ guarantees.} \]

In particular for strongly submodular SDMs, we use the variance bound in Theorem 2 and obtain these approximation guarantees using \( \ell \geq \epsilon^{-2}\delta^{-1}\tau \) i.i.d. simulations.

\[ \text{Proof.} \quad \text{Using variance properties of the average of i.i.d. random variables, we get that for any query} \ T \]

\[ \text{Var}[\hat{R}^\tau(T)] = \frac{1}{\ell} \text{Var}[R^\tau(T)] \leq \frac{1}{\ell} \epsilon \Gamma^\tau(T) \max\{\Gamma^\tau(T), \text{OPT}_1^\tau\}. \]

The claims follow using Chebyshev’s inequality that states that for any random variable \( X \) and \( M, \Pr[|X - E[X]| \geq \epsilon M] \leq \epsilon^2 \text{Var}[X]/M^2 \). We apply it to the random variable \( \hat{R}^\tau(T) \) that has expectation \( \Gamma^\tau(T) \) and plug in the variance bound. To establish (6) we use \( M = \Gamma^\tau(T) \) and to establish (7) we use \( M = \text{OPT}_1^\tau \).
5.1 Sketched Averaging Oracle

For live-edge models with additive utility (4), the query efficiency of the averaging oracle can be improved with off-the-shelf use of \(\tau\)-step combined reachability sketches \([10, 14, 15, 11]\). The sketching is according to a sketch-size parameter \(k\) that also determines the sketches computation time and accuracy of the estimates that sketches provide. A sketch of size \(O(k)\) is computed for each node \(v\) so that for any set of nodes \(S\), \(\sum_{i=1}^{s} VReach^\tau(E_i, S)\) can be efficiently estimated from the sketches of the nodes \(v \in S\). The computation of the sketches from an arbitrary set of simulations \(\{E_i\}\) uses at most \(\sum_i |E_i| + k \sum_v \max_i d_v(E_i)\) edge traversals, where \(d_v(E_i)\) is the maximum in-degree of node \(v\) over simulations \(\{E_i\}\). In the case of an IC model, the expected number of traversals is \((k + \ell) \sum_v p_v\). Sketching with general node weights can be handled as in \([11]\). The estimates obtained from the sketches are unbiased with coefficient of variation \(1/\sqrt{k - 2}\) and are concentrated: Sketches of size \(k = O(\epsilon^{-2} \log(\delta^{-1}))\) provide estimates with relative error \(\epsilon\) with probability \(1 - \delta\).

6 Confidence Amplification: The Median-of-Averages Oracle

The statistical guarantees we provide for our averaging oracle are derived from variance bounds. The limitation is that the number of simulations we need to provide \((\epsilon, \delta)\) guarantees is linear in \(\delta^{-1}\) and therefore the number of simulations we need to provide uniform guarantees (via a union bound argument) grows linearly with the number of subsets. In order to find an approximate optimizer, we would like to have a uniform \(\epsilon\)-approximation for all the \(\binom{\ell}{2}\) subsets of size at most \(s\) but doing so with an averaging oracle would require too many simulations. We adapt to our setting a classic confidence amplification technique \([1]\) to construct an oracle where the number of simulations grows logarithmically in the confidence parameter \(\delta^{-1}\).

A median-of-averages oracle is specified by a number \(r\) of pools with \(\ell\) simulations in each pool. The oracle is therefore constructed from \(r\ell\) i.i.d. simulations \(\phi_{ij}\) for \(i \in [r]\) and \(j \in [\ell]\).

The simulations of each pool are used in an averaging oracle that for the \(i\)th pool \((i \in [r])\) returns the estimates \(\hat{A}^\tau_i(T)\). The median-of-averages oracle returns the median value of these \(r\) estimates

\[
m\bar{A}^\tau(T) := \text{Median}_{i \in [r]} \hat{A}^\tau_i(T) = \text{Median Ave VReach}^\tau(\phi_{ij}, T).
\]

We establish that when the i.i.d simulations are from a model that has variance bound (8) for some \(c \geq 1\), the median-of-averages oracle provides \((\epsilon, \delta)\) approximation guarantees using \(112\epsilon^{-2}c \ln \delta^{-1}\) i.i.d. simulations.

\[\text{Lemma 6.} \quad \text{Consider an SDM that for some } c \geq 1 \text{ satisfies the variance bound (8). Then for every } \epsilon \text{ and } \delta, \text{ a median-average oracle } m\bar{A} \text{ organized with } r = 28 \ln \delta^{-1} \text{ pools of } \ell = 4\epsilon^{-2}c \text{ simulations in each provides } (\epsilon, \delta) \text{ approximation guarantees.}\]

\[\text{Proof.} \quad \text{An averaging oracle with } \ell \text{ simulations provides } (\epsilon, \delta_A) \text{ approximation guarantees for } \delta_A = 1/4. \text{ Therefore, the probability of correct estimate for any subset is at least } 3/4. \text{ We now consider the estimates } \hat{A}_j \text{ obtained from the } r \text{ pools when sorted in increasing order. The estimates that are not correct (too low or too high) will be at the prefix and suffix of the sorted order. The expected number of correct estimates is at least } \mu \geq \frac{3}{4}r. \text{ The probability that the median estimate is not correct is bounded by the probability that number of correct estimates is } \leq r/2, \text{ which is } \leq \frac{3}{4}\mu. \text{ From multiplicative Chernoff bounds, the probability of a sum of Bernoulli random variables being below } (1 - \epsilon')\mu \text{ is at most } e^{-\epsilon'^2\mu/(2 + \epsilon')} \text{. Using } \epsilon' = 1/3 \text{ we have } \epsilon'^2\mu/(2 + \epsilon') = \frac{1}{9}. \text{ So the probability of incorrect median is at most } 28 \ln \delta^{-1} = \ln \delta^{-1}. \]

\[\text{\Box}\]
Sample Complexity Bounds for Influence Maximization

As a corollary, we obtain a sample complexity bound for influence maximization from variance bounds:

**Theorem 7.** Consider an SDM that satisfies the variance bound (8) for some \( c \geq 1 \). Then for any \( \epsilon < 1 \) and \( \delta < 1 \), using \( 112\epsilon^{-2}c\ln \frac{n}{\delta} \) i.i.d. simulations, we can construct a median-of-averages oracle \( \hat{m}\AA \) such that the oracle optimum

\[
T := \arg \max_{S:|S| \leq s} \hat{m}\AA(S)
\]

satisfies

\[
\Pr \left[ I^* (T) \geq (1 - 2\epsilon)OPT^*_s \right] \geq 1 - \delta.
\]

**Proof.** We construct our median-of-averages oracle with \( \ell = 4\epsilon^{-2}c \) and \( r = 28\ln \frac{1}{\delta_{MA}} \) where \( \delta_{MA} = \delta / (n^s) \). From Lemma 6 using a union bound over the \( \binom{n}{s} \) sets we obtain that with probability \( 1 - \delta \) the oracle provides a uniform \( \epsilon \)-approximation for all subsets of size at most \( s \). Let \( S \) be a set with maximum influence \( I(S) = OPT^*_s \) and let \( T \) be the oracle optimum. We have

\[
I(T) \geq (1 - \epsilon)\hat{m}\AA(T) \geq (1 - \epsilon)\hat{m}\AA(S) \geq (1 - \epsilon)^2 I(S) \geq (1 - 2\epsilon)OPT^*_s.
\]

We comment that the \((1 - 2\epsilon)\) ratio is not tight and we can obtain a bound closer to \((1 - \epsilon)\). This because the particular set \( S \) to be approximated more tightly by the oracle (that uses enough simulations to support a union bound).

**7 Optimization with Adaptive Sample Size**

The bound on the number of simulations we derived in Theorem 7 (through a median-of-averages oracle) and also the naive bound (1) (for the averaging oracle) are worst-case. This is obtained by using enough simulations to have the oracle provide a uniform \( \epsilon \)-approximation with probability at least \( 1 - \delta \) on any problem instance. To obtain the uniform approximation we applied a union bound over \( \binom{n}{s} \) subsets that resulted in an increase in the number of required simulations by an \( s \log n \) factor over the base \((\epsilon, \delta)\) approximation guarantees.

On real data sets a much smaller number of simulations than this worst-case often suffices. We are interested in algorithms that adapt to such data and return a seed set of approximate maximum influence using a respectively smaller number of simulations and while providing statistical guarantees on the quality of the end result. To do so, we apply an adaptive optimization framework [12] (some example applications are [14, 38, 16, 13]). This framework consists of a “wrapper” that take as inputs oracle constructions from simulations and a base algorithm that performs an optimization over an oracle. The wrapper invokes the algorithm on oracles constructed using an increasing number of simulations until a validation condition on the quality of the result is met. The details are provided in Appendix E. We denote by \( r(\epsilon, \delta) \) the number of simulations that provides \((\epsilon, \delta)\) guarantees and we obtain the following results:

**Theorem 8.** Suppose that on our data the averaging (respectively, median-of-averages) oracle \( \hat{I} \) has the property that with \( r \) simulations, with probability at least \( 1 - \delta \), the oracle optimum \( T := \arg \max_{S:|S| \leq s} \hat{I}(S) \) satisfies

\[
I^*(T) \geq (1 - \epsilon)OPT^*_s.
\]
Then with probability at least $1 - 5\delta$, when using

$$2\max\{r, r(\epsilon, \delta)\} + O\left(\varepsilon^{-2}c \left( \ln \frac{1}{\delta} + \ln \left( \ln \frac{n}{\delta} + \ln s \right) \right) \right)$$

simulations with the median-of-averages oracle and

$$2\max\{r, r(\epsilon, \delta)\} + O\left(\varepsilon^{-2}c \left( \ln \frac{1}{\delta} + \ln \left( \ln \frac{n}{\delta} + \ln n \right) \right) \right)$$

simulations with the averaging oracle, the wrapper outputs a set $T$ such that $F'(T) \geq (1 - 5\epsilon)OPT_s$. The wrapper can also be used with a base algorithm that is an approximation algorithm. For live-edge models, our averaging oracle is monotone and submodular and hence we can apply greedy to efficiently compute a set with approximation ratio at least $1 - 1/e$ (with respect to the oracle). If we use greedy as our base algorithm we obtain the following:

**Theorem 9.** If the averaging oracle $A$ is submodular and has the property that with $\geq r$ simulations, with probability at least $1 - \delta$, it provides a uniform $\epsilon$-approximation for all subsets of size at most $s$, then with

$$2\max\{r, r(\epsilon, \delta)\} + O\left(\varepsilon^{-2}c \left( \ln \frac{1}{\delta} + \ln \left( \ln \frac{n}{\delta} + \ln n \right) \right) \right)$$

simulations we can find in polynomial time a $(1 - (1 - 1/s)^s)(1 - 5\epsilon)$ approximate solution with confidence $1 - 5\delta$.

### 8 Approximate Greedy Maximization

In this section we consider the computational efficiency of maximization over our oracle $\hat{F}$ that approximates a monotone submodular influence function $F'$. The maximization problem is computationally hard: The brute force method evaluates $\hat{F}(S)$ on all $\binom{n}{s}$ subsets $S$ of size $s$ in order to find the oracle maximizer. An efficient algorithm for approximate maximization of a monotone submodular function $\hat{F}$ is greedy that sequentially builds a seed set $S$ by adding a node $u$ with maximum marginal contribution $\arg\max_{u \in V} (\hat{F}(S \cup \{u\}) - \hat{F}(S))$ at each step. To implement greedy we only need to evaluate at each step the function on a linear number of subsets $\hat{F}(S \cup \{u\})$ for $u \in V$ and thus overall we do $sn$ evaluations of $\hat{F}$ on subsets. With a monotone and submodular $\hat{F}$, for any $s \geq 1$ the subset $T$ that consists of the first $s$ nodes in a greedy sequence satisfies [37]:

$$\hat{F}(T) \geq (1 - (1 - 1/s)^s) \max_{S \mid |S| \leq s} \hat{F}(S) \geq (1 - 1/e)OPT_s(\hat{F}).$$

If our functions $\hat{F}$ provides a uniform $\epsilon$-approximation of another function $F$ for all subsets of size at most $s$, then $F(T) \geq (1 - (1 - 1/s)^s)(1 - 2\epsilon)OPT_s(F)$ (See the proof of 7).

The averaging oracle is monotone and submodular [31] when reachability functions are as in live-edge models. Unfortunately our median-of-averages oracle which facilitates tighter bounds on the number of simulations is monotone but may not be submodular even for models where the averaging oracle is submodular. Generally when this is the case, greedy may fail (as highlighted in recent work by Balkanski et al [2]).

Fortunately, greedy is effective on a function $\hat{F}$ that is monotone but not necessarily submodular as long as $\hat{F}$ “closely approximates” a monotone submodular $F$ in that marginal contributions of the form

$$F(u \mid S) := F(S \cup \{u\}) - F(S)$$

are approximated well by $\hat{F}(u \mid S)$ [14]. We apply this to establish the following lemma:
Lemma 10. The greedy algorithm applied to a function \( \hat{F} \) that is monotone and provides a uniform \( \epsilon_A \)-approximation of a monotone submodular function \( F \) where \( \epsilon_A = \frac{1-\epsilon}{1+\epsilon} \) returns a set \( T \) such that \( F(T) \geq (1 - (1 - 1/s)^s)(1 - \epsilon)\text{OPT}_s(F) \).

Our proof of Lemma 10 generally applies to an approximate oracle \( \hat{F} \) of any monotone submodular function \( F \) and is presented in Appendix C. For approximate IM we obtain the following as a corollary:

Theorem 11. Consider a submodular SDM \( \mathcal{G}(V,H) \) that for some \( c \geq 1 \) satisfies the variance bound (8). Consider a median-of-averages oracle constructed with \( O(\epsilon^{-2}s^3c\ln \frac{n}{\delta}) \) pools with \( \ell = O(\epsilon^{-2}s^2c) \) simulations each. Then with probability \( 1 - \delta \), the set \( T \) that contains the first \( s \) nodes returned by greedy on the oracle satisfies \( \hat{I}_\tau(T) \geq (1 - (1 - 1/s)^s)(1 - \epsilon)\text{OPT}_s^\tau \).

Proof. From Lemma 6, with appropriate constants, this configuration provides us with \((\epsilon/(14s), \delta)\) approximation guarantees. From Lemma 10 greedy provides the stated approximation ratio.

Greedy on the median-of-averages oracle can be implemented generically for any SDM \( \mathcal{G} \) by explicitly maintaining the reachability sets \( \text{Reach}(\phi_{ij}, \{v\} \cup S) \) for all nodes \( v \in V \) in each simulation \( \phi_{ij} \) as the greedy selects nodes into the seed set \( S \). For each step, we compute the oracle value (see (9)) and select \( v \) for which the value for \( \{v\} \cup S \) is maximized:

\[
\arg \max_{v \in V \setminus S} m\hat{A}^\tau(\{v\} \cup S).
\]

We obtain approximation guarantees, however, only when the conditions of monotone submodular influence function and variance bounds are satisfied. For specific families of models, we can consider tailored efficient implementations that incrementally maintain reachability sets and values.

For live-edge models with additive utility (4) we consider an implementation of greedy on a median-of-averages oracle. This can be done by explicit maintenance of reachability sets or by using sketches [10, 14, 15, 11] (see Section 5.1). We obtain the following bounds (proof is deferred to Appendix Section D).

Theorem 12. Let \( \mathcal{G} \) be a live-edge model with an additive utility function (4) that satisfies the variance bound (8). Then greedy on median-of-averages oracle can be implemented with explicit reachability sets in time

\[
O(\epsilon^{-2}s^3c\ln \left(\frac{n}{\delta}\right) \bar{m}n),
\]

where \( \bar{m} \) is the average number of edges per simulation (For an IC model, \( c = \tau \) and \( E[\bar{m}] = \sum_{e \in E} p_e \)). When using sketches, the time bound is

\[
O(\epsilon^{-2}s^3\ln \frac{n}{\delta}(\epsilon\bar{m} + s(m^* + ns)\ln n)),
\]

where \( m^* = \sum_{e} \max_{ij} d_v(E_{ij}) \). For an IC model, \( c = \tau \) and \( m^* = \sum_e p_e \) in expectation.

Conclusion

We explore the “sample complexity” of IM on stochastic diffusion models and show that an approximate maximizer (within a small relative error) can be recovered from a small number of simulations as long as the variance is appropriately bounded. We establish the variance
bound for the large class of strongly submodular stochastic diffusion models. This includes IC models (where edges are drawn independently) and IGT models (where node thresholds are drawn independently) and natural extensions that allow for some dependencies. Our sample complexity bound significantly improves over the previous bounds by replacing the linear dependence in the number of nodes by a logarithmic dependence on the number of nodes and linear dependence on the length of the activation paths (which are usually very short). An interesting question for future work is to address the gap between the sample complexity and the larger number of simulations currently needed for greedy maximization.

References

A Variance Upper Bound: Proof of Theorem 2

In this section we prove Theorem 2 which upper bounds the variance in strongly submodular SDMs. We start by bounding the variance in a more basic setting of a submodular function over a random subset in Section A.1 (Theorem 14). This will be an ingredient in our main proof provided in Section A.3.

We will be using the following basic tools:

> Lemma 13. If $X, Y$ are two random variables on the same probability space and the variance of $Y$ is finite, then:

$$E[Y] = E[E[Y|X]] \quad \text{(total expectation)}$$

$$\text{Var}[Y] = E[\text{Var}[Y|X]] + \text{Var}[E[Y|X]] \quad \text{(total variance)}$$

where $E[Y|X]$ is a random variable that gets the expectation of $Y$ conditioned the value of $X$ and $\text{Var}[Y|X]$ is a random variable that gets the variance of $Y$ conditioned the value of $X$.

When $X$ is a Bernoulli random variable $X \sim \text{Ber}(p)$ then Lemma 13 gives that

$$\text{Var}[Y] = E[\text{Var}[Y|X]] + \text{Var}[E[Y|X]] = pV_1 + (1 - p)V_0 + p(1 - p)(E_1 - E_0)^2.$$ 

where $V_0 = \text{Var}[Y|X = 0]$, $V_1 = \text{Var}[Y|X = 1]$, $E_0 = E[Y|X = 0]$, and $E_1 = E[Y|X = 1]$.

### A.1 Submodular Monotone Functions on Random Subsets

Let $S = \{a_i\}_{1 \leq i \leq t}$ be a set with $t$ elements and let $P = \{p_i\}_{1 \leq i \leq t}$ be a set of $t$ probabilities such that $p_i$ is associated with the element $a_i$. Let $X$ be a random subset of $S$ that contains $a_i$ with probability $p_i$ independently for each $i = 1, \ldots, t$. That is

$$\forall A \in 2^S : \Pr[X = A] = \prod_{a_i \in A} p_i \prod_{a_i \notin A} (1 - p_i).$$

We say that $X$ is a random subset of $S$ using probabilities $P$.

A submodular monotone function $f$ over $S$ is a function with the following properties:

1. $f : 2^S \rightarrow R^+$
2. For every $A, B \subset S$ with $A \subset B$ and for every $x \in S \setminus B$ we have that $f(A \cup x) - f(A) \geq f(B \cup x) - f(B)$
3. $A \subset B \Rightarrow f(A) \leq f(B)$

For any singelton $\{a\} \in S$ we write $f(a)$ instead of $f(\{a\})$. Let $M_f = \max_i f(a_i) - f(\emptyset)$. Our purpose in this subsection is to establish the following:

> Theorem 14. Let $X$ be a random subset of $S$ using probabilities $P$ and let $f$ be a submodular monotone function. Then

$$\text{Var}[f(X)] \leq M_f E[f(X) - f(\emptyset)].$$

We give the following additional definitions and lemmas before proving this theorem.
Let $S_{-i} = S \setminus \{a_i\}$ and let $P_{-i} = P \setminus \{p_i\}$. We define $X_{-i}$ to be a random subset of $S_{-i}$ using the probabilities $P_{-i}$. Let $f^{0}_i, f^{1}_i$ be submodular functions over $S_{-i}$ defined by $f^{0}_i(A) = f(A)$ and $f^{1}_i(A) = f(A \cup \{a_i\})$. Let

$$E^i_1 = E[f^{1}_i(X_{-i})] = \sum_{A \in 2^{S_{-i}}} \Pr[X_{-i} = A] f^{1}_i(A).$$

and

$$E^i_0 = E[f^{0}_i(X_{-i})] = \sum_{A \in 2^{S_{-i}}} \Pr[X_{-i} = A] f^{0}_i(A).$$

By our definitions $E[f(X_{-i})] = E^i_0$ and from total expectation (Lemma 13), $E[f(X)] = p_i E^i_1 + (1 - p_i) E^i_0$.

**Lemma 15.** Let $f$ be a submodular monotone function over $S$ and $X$ a random subset of $S$ using probabilities $P$. Then,

$$\forall i : E^i_1 - E^i_0 \leq f(a_i) - f(\emptyset) \leq M_f.$$

**Proof.** Since $X$ is obtained by drawing the elements in $S$ independently it follows that

$$E^i_1 - E^i_0 = \sum_{A \in 2^{S_{-i}}} \Pr[X_{-i} = A] [f(A \cup \{a_i\}) - f(A)] \leq \sum_{A \in 2^{S_{-i}}} \Pr[X_{-i} = A] [f(a_i) - f(\emptyset)] \leq f(a_i) - f(\emptyset) \leq M_f.$$

**Lemma 16.** For any submodular monotone function $f$ over $S$ and for any index $i$ we have that $M_{f^0} \leq M_f$ and $M_{f^1} \leq M_f$.

**Proof.** The first inequality follows immediately from our definition since

$$M_{f^0} = \max_{j \neq i} f^{0}_j(a_j) - f^{0}_i(\emptyset) = \max_{j \neq i} f(a_j) - f(\emptyset) \leq M_f.$$

For the second inequality we use submodularity as follows

$$M_{f^1} = \max_{j \neq i} f^{1}_j(a_j) - f^{1}_i(\emptyset) = \max_{j \neq i} f(\{a_j \cup a_i\}) - f(a_i) \leq \max_j f(a_j) - f(\emptyset) = M_f.$$

We are now ready for the proof of Theorem 14.

**Proof of Theorem 14.** The proof is by induction on the size of $S$.

**Base case.** Let $S = \{a_1\}, P = \{p_1\}$ we have that

$$E[f(X)] = p_1 f(a_1) + (1 - p_1) f(\emptyset),$$

and

$$\text{Var}[f(X)] = E[f(X)^2] - E^2[f(X)] = p_1 f^2(a_1) + (1 - p_1) f^2(\emptyset) - [p_1 f(a_1) + (1 - p_1) f(\emptyset)]^2$$

$$= p_1 (1 - p_1) \left[ f(a_1) - f(\emptyset) \right]^2 \leq M_f p_1 (1 - p_1) \left[ f(a_1) - f(\emptyset) \right].$$
It is left to prove that \( \mathbb{E} [f(X) - f(\emptyset)] \geq p_1 (1 - p_1) [f(a_1) - f(\emptyset)] \), and indeed we have that
\[
\mathbb{E} [f(X) - f(\emptyset)] = p_1 [f(a_1) - f(\emptyset)] \geq p_1 (1 - p_1) [f(a_1) - f(\emptyset)].
\]

**Inductive Step.** Assume the lemma holds for sets of size \( \ell \) and any submodular function \( f \) and probabilities \( P \). For a set \( S \) with \( \ell + 1 \) elements and a submodular function \( f \) over \( S \). Let \( j \leq i \) be an arbitrary index.

From the total variance formula in Lemma 13 we know that
\[
\text{Var}[f(X)] = p_j V_j^1 + (1 - p_j) V_j^0 + p_j (1 - p_j) \left[ E_j^1 - E_j^0 \right]^2, \quad (12)
\]
where \( E_j^1 = \mathbb{E} [f_j^1(X_{-j})], \ E_j^0 = \mathbb{E} [f_j^0(X_{-j})], \ V_j^1 = \text{Var}[f_j^1(X_{-j})], \text{ and} \ V_j^0 = \text{Var}[f_j^0(X_{-j})]. \)
By applying the induction hypothesis to \( S_{-j} \) with probabilities \( P_{-j} \) and \( |S_{-j}| = \ell \) and \( f_j^0 \) and \( f_j^1 \) we get that
\[
V_j^0 \leq M_{f_j^0} [E_j^0 - f_j^0(\emptyset)], \quad \text{Lemma 16}
\]
and
\[
V_j^1 \leq M_{f_j^1} [E_j^1 - f_j^1(\emptyset)]. \quad \text{Lemma 16}
\]
Substituting these bounds in Equation (12) we get that
\[
\text{Var}[f(X)] \leq p_j M_f [E_j^1 - f(a_j)] + (1 - p_j) M_f [E_j^0 - f(\emptyset)] + p_j (1 - p_j) \left[ E_j^1 - E_j^0 \right]^2
\]
\[
= M_f \left[ p_j E_j^1 + (1 - p_j)E_j^0 - f(\emptyset) \right] + p_j (1 - p_j) \left[ E_j^1 - E_j^0 \right]^2 - p_j M_f \left[ f(a_j) - f(\emptyset) \right]
\]
\[
\leq M_f \left[ \mathbb{E} [f(X)] - f(\emptyset) \right] + p_j M_f \left[ f(a_j) - f(\emptyset) \right] \left[ (1 - p_j) \right] - p_j M_f \left[ f(a_j) - f(\emptyset) \right]
\]
\[
\leq M_f |\mathbb{E} [f(X)] - f(\emptyset)|. \quad \Box
\]

### A.2 Properties of Reduced Diffusion Models

We establish some properties of reduced independent SDMs that are needed for our upper bound.

We first show that influence values of nodes in a reduced model can only be lower than respective values in the original model:

**Lemma 17.** Let \( G'(V \setminus T, H') \) be a reduction of a model \( G(V, H) \).

For all \( v \in V \setminus T \) and \( t \geq 0 \), \( R_{G'}(v, t) \leq R_G(v) \).

**Proof.** Note that \( G '\) is obtained from \( G \) by removing nodes. Therefore respective reachability sets given \( \phi \) are such that those in \( G' \) can only be subsets of those in \( G \):
\[
\text{Reach}_{G'}(v, \phi') \subset \text{Reach}_{G}(v, \phi).
\]
Then from monotonicity and submodularity of \( H \) we get
\[
H'(\text{Reach}_{G'}(v, \phi')) \leq H'(\text{Reach}_{G}(v, \phi)) \leq H(\text{Reach}_{G}(v, \phi)).
\]
(second inequality follows from monotonicity and submodularity of \(H\) so that for all \(A \subset V \setminus T, H'(A) \leq H(A)\). Therefore,

\[
I^F_T(v) = E[\text{VReach}^F_T(v)] \leq E[\text{VReach}^F_G(v)] = I^G_T(v).\]

A convenient property is that reduction preserves strong monotone submodularity:

\[\textbf{Lemma 18.} A reduction of a strongly monotone submodular model is also strongly monotone submodular.\]

\[\textbf{Proof.}\] A reduced model with respect to \(T_2\) of a reduced model of \(G\) with respect to \(T_1\) is a reduced model of \(G\) with respect to \(T_1 \cup T_2\). Also note that the reduced utility function \(H'\) is also monotone and submodular.

We next show that IC or IGT models with submodular utility are closed under reduction:

\[\textbf{Theorem 19.} IC and IGT models with submodular utility are strongly submodular SDMs.\]

\[\textbf{Proof.}\] We first show that IC/IGT models are independent SDMs. In the introduction we expressed IC and IGT models as SDMs: A live-edge model is expressed as an SDM using \(\phi_v(T) = 1\) if and only if there is an edge from a node in \(T\) to \(v\). The model is independent if for all \(v\) the edges incoming to \(v\) are independent of all other edges. In IC models all edges are independent and hence IC models are independent SDMs. Recall (from the Introduction) that an IGT model is expressed as an SDM using \(\phi_v(T) := \text{Indicator}(\theta_v \leq f_v(T))\). In an IGT model the thresholds \(\theta_v\) are independent random variables, and hence \(\phi_v\) are independent. Hence, an IGT model is an independent SDM. Submodularity of influence when utility is submodular is established for IC models in [31] and for IGT models in [35].

Reduction of any model preserves submodularity of the utility and in particular this holds for reduced IC/IGT models. What remains to show is that a reduced IC/IGT model is also an IC/IGT model (respectively). This would conclude the proof of strong submodularity since any IC and IGT models with submodular utility has a submodular influence functions. To establish this remaining claim we consider IC/IGT models and express the reduction in terms of the activation functions as one in terms of the respective family of models.

We first consider IC models. The reduced IC model \(G'(V \setminus T, E \setminus (V \times T \cup T \times V))\) is obtained from \(G(V)\) by deleting the nodes \(T\) and their incident edges and keeping \(p_e\) on remaining edges. This is clearly an IC model. It remains to show that this is equivalent to the reduction of the distribution of activation functions. The conditioning that \(\phi_v(T) = 0\) is equivalent to live-edge set \(E\) with no edges from \(T\) to \(V\). For such edge set for any \(S \subset V \setminus (T \cup \{v\})\) we have \(\phi_v'(S) = \phi_v(S \cup T) = \phi_v(S)\) which corresponds to \(E\) having at least one edge from \(S\) to \(v\). From independence of edges, the conditional distribution is also independent and retains the same inclusion probabilities.

We next consider IGT models. The reduction \(G'(V \setminus T, \{f'_v\})\) in terms of activation functions distribution is equivalent to functions is equivalent to modifying the functions so that

\[
f'_v(S) := f_v(S \cup T) - f_v(T).
\]

The reduced model is clearly an IGT model. The conditioning that \(\phi_v(T) = 0\) means that \(\theta_v > f_v(T)\). Therefore, the conditional distribution of \(\theta_v\) provided it was not activated in the first step is uniform on \([f_v(T), 1]\). The probability that \(\theta_v > f_v(S \cup T)\) given this conditioning is equal to the probability that \(\theta_v' > f_v(S \cup T) - f_v(T) = f'_v(S)\).
A.3 Upper Bound on the Variance in Strongly Submodular SDM

Let $G(V, H)$ be a $\tau$-stepped diffusion model. We denote by $\mathcal{M}_G(T)$ the maximum influence of a single node in $G$ that is not included in $T$:

$$\mathcal{M}_G(T) = \max_{v \in V \setminus T} I_G^0(v)$$

As before, we omit $G$ if it can be understood from the context. We prove the following theorem which is a restatement of Theorem 2.

**Theorem 20.** Let $G(V, H)$ be a strongly submodular SDM. Then for any $\tau \geq 0$ and a set of nodes $T \subset V$:

$$\text{Var}[\mathcal{R}^\tau(T)] \leq \tau \mathcal{M}^{-1}(\bar{T}) \mathcal{I}^\tau(T).$$

The remaining part of this Subsection contains the proof of the Theorem.

Let $T$ be a set of nodes, and let

$$N(T) = \{v \in V \setminus T \mid \text{Pr}\{\phi_v(T) = 1\} > 0\}$$

be the nodes that have nonzero probability to be activated if $T$ is active. For the special case of IC models, $N(T) = \{v \notin T \mid \exists (u, v) \in E, u \in T\}$ is the set of outgoing neighbors of $T$.

We first consider the case where $N(T)$ is empty. In this case, $\text{Reach}^\tau(T) = T$ for all $\tau \geq 0$. Therefore, $\text{Var}[\mathcal{R}^\tau(T)] = 0$, $\mathcal{I}^\tau(T) = H(T) \geq 0$, and $\mathcal{M}^{-1}(\bar{T}) = 0$ and the claim holds.

We now assume that $N(T)$ is not empty and give a proof by induction on $\tau$.

A.3.1 Base case ($\tau = 1$)

Let

$$p_v := \text{Pr}\{\phi_v(T) = 1\}$$

be the probability that node $v$ is activated in step 1 provided that the set of nodes $T$ was active at step 0. From independence of the model, the events of activating different nodes $v \in N(T)$ at step 1 are independent. We have that the set of nodes that is active at step 1 is a random subset $S$ of $N(T)$ with probabilities $\{p_v\}$ as defined in Subsection A.1. Moreover, from monotonicity and submodularity of $H$, the function $f(S) := H(T \cup S) - H(T)$ is monotone and submodular with $f(\emptyset) = 0$. We can therefore apply Theorem 14 to bound the variance of $f(S)$:

$$\text{Var}[f(S)] \leq M_f \text{E}[f(S)].$$

We now note that

$$\text{E}[f(S)] = \text{E}[H(T \cup S)] - H(T) = \mathcal{I}^1(T) - \mathcal{I}^0(T)$$

and

$$\text{Var}[f(S)] = \text{Var}[H(T \cup S)] = \text{Var}[\mathcal{R}^1(T)].$$

For all $v \in N(T)$ we have $f(v) = H(T \cup \{v\}) - H(T) \leq H(v) = \mathcal{I}^0(v)$. Therefore

$$M_f := \max_{v \in N(T)} f(v) \leq \max_{v \in N(T)} \mathcal{I}^0(v) = M^0(\bar{T}).$$

Substituting in (14) we obtain the claim

$$\text{Var}[\mathcal{R}^1(T)] \leq M^0(\bar{T}) \mathcal{I}^1(T).$$
A.3.2 Inductive step

We define $\text{Reach}_G^t(T \mid A)$ to be the random variable that is the $t$-steps reachability of $T$ in a diffusion on $G$ seeded with $T$ that is conditioned on the event that exactly the nodes $A \subset N(T)$ (and no other nodes) are activated in step $1$. Equivalently, we condition on $\phi$ such that for $v \setminus (T \cup A)$, $\phi_v(T) = 0$ and for $v \in A$, $\phi_v(T) = 1$. We respectively define $R_G^t(T \mid A)$ to be the random variable $H(\text{Reach}_G^t(T \mid A))$. From definition, we have

$$I_G^t(T) = \sum_{A \subset N(T)} \Pr[\text{Reach}_G^t(T) = A \cup T]E[R_G^t(T \mid A)] = E_A E[R_G^t(T \mid A)].$$  \hspace{1cm} (15)

We consider the reduced model $G'$ of $G$ with respect to $T$ and show that the conditioned $t \geq 1$ steps diffusion from $T$ in $G$ is equivalent to the unconditioned $t-1$ steps diffusion from $A$ in $G'$:

| Lemma 21. For any $A \subset N(T)$ and $t \geq 1$, the random variables $\text{Reach}_{G'}^{t-1}(A)$ and $\text{Reach}_{G}^{t}(T \mid A) \setminus \{T\}$ have identical distribution over subsets. The random variables $R_{G'}^{t-1}(A)$ and $R_G^t(T \mid A) - H(T)$ have identical distributions over values.

Proof. We first consider $t = 1$. For a draw of conditioned activation functions we have $\text{Reach}_G^1(T \mid A) = T \cup A$. By definition, we also have $\text{Reach}_{G'}^1(A) = A$ and the claim holds.

We next consider $t > 1$. We first observe that in both situations, (i) the reduced model $G'$ when seeded with $A$ and (ii) the conditioned diffusion in $G$ seeded with $T$ such that the nodes $A$ are activated in the first step, the progression is determined only by the activation functions on the nodes $V \setminus (T \cup A)$.

We next argue that the distribution of activation functions projected on the nodes $V \setminus (T \cup A)$ is the same in both situations. From independence of $G$ it suffices to consider separately the activation functions of each node. From definition of a reduced model, we draw for each $v \in V \setminus T$, $\phi_v \sim G$ conditioned on $\phi_v(T) = 0$. This is exactly what we get for the conditioned diffusion in $G$.

We can thus match the supports (sets of activation functions) in both situations so that $\phi$ and $\phi'$ are matched when the projections on $V \setminus (T \cup A)$ is the same. The starting points are at steps 0 of the reduced model and step 1 of the conditioned process is $A$, the progression of new activations is thus the same. Therefore, for any step $t \geq 1$,

$$\text{Reach}_{G'}^t(T \mid A, \phi') \setminus \{T\} = \text{Reach}_{G'}^{t-1}(A, \phi')$$

and the first claim follows.

For the second claim, note that $R_G^t(T \mid A) = H(\text{Reach}_G^t(T \mid A))$ and thus

$$R_{G'}^{t-1}(A) = H'(\text{Reach}_{G'}^{t-1}(A)) = H(\text{Reach}_G^{t-1}(A) \cup T) - H(T) = H(\text{Reach}_G^t(T \mid A)) - H(T),$$

where the equalities are those of distributions. \hfill \Box

As immediate corollaries we can relate expectations and variance of as follows:

$$E[R_{G'}^{t-1}(A)] = E[H'(\text{Reach}_{G'}^{t-1}(A))] = E[H(\text{Reach}_G^t(T \mid A))] - H(T).$$  \hspace{1cm} (16)

$$\text{Var}[R_{G'}^{t-1}(A)] = \text{Var}[H'(\text{Reach}_{G'}^{t-1}(A))] = \text{Var}[H'(\text{Reach}_{G'}^t(T \mid A)) \setminus \{T\}] \hspace{1cm} (17)$$

$$= \text{Var}[H(\text{Reach}_G^t(T \mid A))] - H(T) = \text{Var}[H(\text{Reach}_G^t(T \mid A))] = \text{Var}[R_{G'}^t(T \mid A)].$$
A.3.2.1 Total Variance

We define the random variable $A$ to be the subset of $N(T)$ which is activated after the first step. Note that $A$ is a random subset of $N(T)$ using probabilities $p_v$ for $v \in N(T)$ as defined in Section A.1. By the total variance formula we get that

$$\text{Var}[R^0_T(T)] = \text{Var}_A[E[R^0_T(T)|A]] + E_A[\text{Var}[R^0_T(T)|A]].$$

(18)

We bound the total variance by separately bounding the two terms.

A.3.2.2 Bound on the first term of the total variance

We consider the reduced model $G'$ with respect to $T$ and a restriction of the influence function $I_{\tau - 1}G'$ to the domain that is subsets $A \subseteq N(T)$:

$$f(A) := I_{\tau - 1}G'(A).$$

From Lemma 21, this function represents the expected marginal utility value of nodes which are not in $T$ that are activated after $\tau$ steps if we activate $T$ at step 0 and the set $A$ at step 1.

We first observe that $f$ is monotone and submodular. This because strong monotone submodularity of our model implies that the reduced model is also strongly monotone and submodular, and a restriction of a monotone and submodular function is also monotone and submodular. We establish two helpful properties of $f$. First,

$$f(\emptyset) = 0,$$

(19)

which holds for any influence function. Second, using Lemma 17 we obtain

$$\max_{v \in N(T)} f(v) \leq \max_{v \in N(T)} I_{\tau - 1}^{G'}(v) \leq \mathcal{M}^{-1}(\bar{T}) .$$

(20)

We are now ready to bound the first term of the total variance (18). Our monotone submodular function $f$ and the random subset $A$ using probabilities $p_v$ satisfy the conditions of Theorem 14.

$$\text{Var}_A[E[R^0_T(T)|A]] = \text{Var}_A[f(A) + H(T)] = \text{Var}_A[f(A)] \leq \left( \max_{v \in N(T)} f(v) \right)E_A[f(A) - f(\emptyset)]$$

$$\leq \mathcal{M}^{-1}(\bar{T})E_A[E[R^0_T(T)|A] - H(T)] = \mathcal{M}^{-1}(\bar{T}) (I_{\tau}^G(T) - H(T))$$

(21)

A.3.2.3 Bound on the second term of the total variance

We next bound the second term of (18) which is the expectation of the variance conditioned on $A$:
The claim of the Theorem follows using total variance (18) and the bounds on the first term to be the subset that maximizes the ratio.

Proof. By induction on the height of the node.

\[
E_A[|\text{Var}[R\tau'(T) | A]|] = \sum_{S \subseteq N(T)} \text{Pr}[A = S] |\text{Var}[R\tau'(T) | S]| \\
= \sum_{S \subseteq N(T)} \text{Pr}[A = S] |E[R\tau'(T) | S] - H(T)| |\text{Var}[R\tau'(T) | S]| \\
\leq \sum_{S \subseteq N(T)} \text{Pr}[A = S] |E[R\tau'(T) | S] - H(T)| |\text{Var}[R\tau'(T) | S]| \\
= E_A[|E[R\tau'(T) | A] - H(T)|]| \text{Var}[R\tau'(T) | S]| \\
\leq (I\tau'(T) - H(T)) |\text{Var}[R\tau^{-1}(S')]| I[R\tau^{-1}(S')] \\
= (I\tau'(T) - H(T)) |\text{Var}[R\tau^{-1}(S')]| I[R\tau^{-1}(S')] \\
\leq (I\tau'(T) - H(T)) (\tau - 1)M\tau^{-2}(\bar{S}'). 
\]

(22)

Where we take

\[
S' = \arg \max_{S \subseteq N(T)} \frac{|\text{Var}[R\tau^{-1}(S)]|}{I[R\tau^{-1}(S)]} 
\]

to be the subset that maximizes the ratio.

Using the induction hypothesis on \((\tau - 1)\)-stepped influence we get

\[
|\text{Var}[R\tau^{-1}(S')]| \leq (\tau - 1)M\tau^{-2}(\bar{S}'). |\text{Var}[R\tau^{-1}(S')]. 
\]

(23)

We now relate the maximum influence of nodes in the original and reduced models:

\[
M\tau^{-2}(\bar{S}') = \max_{v \in V \setminus (T \cup S')} I\tau^{-2}(v) \leq \max_{v \in V \setminus (T \cup S')} I\tau^{-2}(v) \leq M\tau^{-2}(T \cup S') \leq M\tau^{-1}(\bar{T}). 
\]

(24)

From (22) using (23) and (24) we obtain

\[
E_A[|\text{Var}[R\tau'(T) | A]|] \leq (I\tau'(T) - H(T)) (\tau - 1)M\tau^{-2}(\bar{S}') \leq (I\tau'(T) - H(T)) (\tau - 1)M\tau^{-1}(\bar{T}). 
\]

(25)

A.3.2.4 Combining the bounds of the first and second terms

The claim of the Theorem follows using total variance (18) and the bounds on the first term (21) and second term (25).

B Variance lower bound construction

Lemma 22. Let \( G \) be complete binary tree where each edge has probability \( \frac{1}{2} \) and let \( h(u) \) be the height of the node \( u \). Then, \( I\tau'(u) = h(u) \) and \( |\text{Var}[R\tau'(u)]| \leq \frac{1}{2} |\sum_{i=0}^{h(u)-1} i^2 = \frac{h(u)-1}{12} |h(u)\|2h(u)-1|}. \)

Proof. By induction on the height of the node.
Base step ($h(u) = 1$). It is clear that $I^1(u) = 1$ and $\text{Var}[R^1(u)] = 0$ since $u$ is a leaf.

Inductive step. $u$ has two neighbors and each is reached with probability $\frac{1}{2}$. Let $v_1$ and $v_2$ be the neighbors of $u$ and let $X_1, X_2$ be random variables that indicate if $(u, v_1), (u, v_2)$ were activated respectively. The variables $X_1, X_2$ are Bernoulli random variables with $p = \frac{1}{2}$, hence, $E[X_1] = E[X_2] = \frac{1}{2}$ and $\text{Var}[X_1] = \text{Var}[X_2] = \frac{1}{4}$. Since the graph is a tree, the reachabilities of $v_1$ and $v_2$ are independent random variables, so we can simply write:

$$R^\tau(u) = 1 + X_1 R^{\tau - 1}(v_1) + X_2 R^{\tau - 1}(v_2)$$

The variable $R^{\tau - 1}(v_1)$ and $R^{\tau - 1}(v_2)$ are identical and $X_1, R^{\tau - 1}(v_1)$ and $X_2, R^{\tau - 1}(v_2)$ are independent random variables, Thus,

$$I^\tau(u) = E[R^\tau(u)] = 1 + E[X_1]E[R^{\tau - 1}(v_1)] + E[X_2]E[R^{\tau - 1}(v_2)] = 1 + 2 \frac{1}{2} E[R^{\tau - 1}(v_1)]$$

induction’s hypothesis

$$1 + h(u) - 1 = h(u)$$

The computation of the variance is similar:

$$\text{Var}[R^\tau(u)] = \text{Var}[X_1 R^{\tau - 1}(v_1)] + \text{Var}[X_2 R^{\tau - 1}(v_2)] = 2 \text{Var}[X_1 R^{\tau - 1}(v_1)]$$

For two independent random variables $A, B$ holds that: $\text{Var}[AB] = \text{Var}[A] \text{Var}[B] + \text{Var}[A] \text{E}^2[A] + \text{Var}[B] \text{E}^2[B]$, we have that:

$$\text{Var}[R^\tau(u)] = 2 \left( \text{Var}[X_1] \text{Var}[R^{\tau - 1}(v_1)] + \text{Var}[X_1] \text{E}^2[R^{\tau - 1}(v_1)] + \text{Var}[R^{\tau - 1}(v_1)] \text{E}^2[X_1] \right)$$

$$= 2 \left( \frac{1}{2} \text{Var}[R^{\tau - 1}(v_1)] + \frac{1}{4} \text{E}^2[R^{\tau - 1}(v_1)] \right) = \text{Var}[R^{\tau - 1}(v_1)] + \frac{1}{2} h(u)(h(u) - 1)^2$$

induction’s hypothesis

$$\frac{1}{2} \sum_{i=0}^{h(u)-1} i^2 = \frac{(h(u) - 1)h(u)(2h(u) - 1)}{12}, \quad \blacksquare$$

Theorem 23. There is a model $\mathcal{G}$ and a set of nodes $T$ such that $\frac{\text{Var}[R^\tau(T)]}{\text{E}[R^\tau(T)]} \geq \frac{\tau}{12}$.

Proof. Lemma 22 shows that for every node $u \in \mathcal{G}$, $I^\tau(u) = h(u)$ and $\text{Var}[R^\tau(u)] = \frac{(h(u) - 1)h(u)(2h(u) - 1)}{12}$. It follows that the root $r$ has the largest influence $I^\tau(r) = \tau$ and $\text{Var}[R^\tau(u)] = \frac{(\tau - 1)\tau(2\tau - 1)}{12}$, Furthermore $R^\tau(r) = \tau - 1$ since the nodes of the largest influence in $V \setminus r$ are the children of $r$. We conclude that:

$$\frac{\text{Var}[R^\tau(r)]}{R^\tau(r) I^\tau(r)} = \frac{(\tau - 1)\tau(2\tau - 1)}{\tau(\tau - 1)12} = \frac{2\tau - 1}{12} \geq \frac{\tau}{12}, \quad \blacksquare$$

C Greedy Optimization with an Approximately Submodular Oracle

In this section we present the proof of Lemma 10. We show that our approximation guarantees imply that the application of greedy on $\hat{F}$ generates a sequence that is an approximate greedy sequence (in the sense of Lemma 24) with respect to $F$.

We first state a helpful Lemma [14] that establishes that it suffices that $\hat{F}(u \mid S)$ to approximate the marginal contributions

$$F(u \mid S) := F(S \cup \{u\}) - F(S).$$
Lemma 24 ([14]). Given a monotone submodular function $F$, an approximate greedy algorithm that for some $\epsilon \in [0, 1)$ selects at each step an element $u$ such that $F(u \mid S) \geq (1 - \epsilon) \max_v F(v \mid S)$ has approximation ratio $\geq (1 - (1 - 1/s)^s)(1 - \epsilon)$.

Proof. It is easy to see that the approximation ratio of $\epsilon$-approximate greedy is $1 - (1 - (1 - \epsilon)/s)^s$. It therefore suffices to establish that this expression is larger than $(1 - (1 - 1/s)^s)(1 - \epsilon)$ for $\epsilon \in [0, 1]$. Equivalently, we need to show that for all $s \geq 2$ and $x \in [0, 1]$

$$(1 - (1 - x)/s)^s - (1 - x)(1 - 1/s)^s - x \leq 0.$$ 

This follows from equality holding for $x = 0$ and $x = 1$ and the function being concave up (second derivative is positive).

Proof of Lemma 10. Consider a monotone non-negative $\hat{F}$ that is a uniform $\epsilon_A$-approximation of a monotone non-negative $F$ with $\epsilon_A = \frac{\epsilon(1 - \epsilon)}{14s}$. By definition of $\epsilon$-approximation (see Section 3.5), $\left| \hat{F}(T) - F(T) \right| \leq \epsilon_A \max(S, \text{OPT}_1(F))$ for all $S$ with $|S| \leq s$. Therefore,

$$\text{if } F(S) \geq (1 - \epsilon)\text{OPT}_1(F) \text{ then } \left| \frac{\hat{F}(S) - F(S)}{F(S)} \right| \leq \frac{\epsilon}{14s} \quad (26)$$

$$\text{if } F(S) \leq (1 - \epsilon)\text{OPT}_1(F) \text{ then } \hat{F}(S) \leq \left(1 - \frac{\epsilon}{2}\right)\text{OPT}_1(F). \quad (27)$$

Inequality (26) follows immediately when $F(S) \geq \text{OPT}_1(F)$ because the relative error is at most $\epsilon_A \leq \frac{\epsilon}{14s}$. For $(1 - \epsilon)\text{OPT}_1(F) \leq F(S) < \text{OPT}_1(F)$ we have absolute error being at most $\epsilon_A\text{OPT}_1(S)$ which is a relative error of at most $\epsilon_A/(1 - \epsilon) \leq \frac{\epsilon}{14s}$. Inequality (27) follows from the absolute error being at most $\epsilon_A\text{OPT}_1(F)$ and $\epsilon_A \leq \epsilon/2$.

We establish that these conditions imply that greedy on $\hat{F}$ on the prefix of the greedy sequence where $F(S) \leq \frac{3}{4}\text{OPT}_s(F)$ is actually approximate greedy (as in the conditions of Lemma 24) with respect to $F$. Note that $1 - (1 - 1/s)^s \geq 3/4$ for $s \geq 2$ and thus the prefix restriction does not limit generality. The claim will then follow from Lemma 24.

For $s = 1$, it follows from Equations (26) and (27), that the first element of a greedy sequence with respect to $\hat{F}$, $\arg \max_u \hat{F}(u)$, satisfies $\hat{F}(u) \geq (1 - \frac{\epsilon}{2})\text{OPT}_1(F)$. Therefore from the second iteration and on, we have a set $S$ for which the relative error bounds in Equation (26)) applies.

We consider the marginal contributions $F(u \mid S)$ for any node $u$. We have

$$|\hat{F}(S) - F(S)| \leq \frac{\epsilon}{14s}F(S)$$

$$|\hat{F}(S \cup \{u\}) - F(S \cup \{u\})| \leq \frac{\epsilon}{14s}F(S \cup \{u\}) = \frac{\epsilon}{14s}(F(S) + F(u \mid S)).$$

We use these inequalities to bound the absolute error of (any) marginal influence estimate by

$$\left| \hat{F}(u \mid S) - F(u \mid S) \right| = \left| \hat{F}(S \cup \{u\}) - F(S \cup \{u\}) + F(S) \right| \leq \left| \hat{F}(S \cup \{u\}) - F(S \cup \{u\}) \right| + \left| \hat{F}(S) - F(S) \right| \leq \frac{\epsilon}{14s}F(S) + \frac{\epsilon}{14s}F(u \mid S). \quad (28)$$

We now consider the node $v = \arg \max_{u \in V} F(u \mid S)$ with maximum marginal contribution to $S$ with respect to $F$ and its contribution value

$$\Delta := F(v \mid S) \geq \frac{1}{s}(\text{OPT}_s - F(s)).$$
Thus, when $F(S) \leq \frac{3}{4} \text{OPT}_s$,

$$\Delta \geq \frac{1}{3s} F(S). \quad (29)$$

By applying (28) to $v$ we get that

$$\hat{F}(v \mid S) \geq \Delta - \frac{\epsilon}{7s} F(S) - \frac{\epsilon}{14s} \Delta.$$  

Therefore the node $v' = \arg \max_v \hat{F}(v' \mid S)$ with maximum marginal contribution according to $\hat{F}$ satisfies

$$\hat{F}(v' \mid S) \geq \hat{F}(v \mid S) \geq \Delta - \frac{\epsilon}{7s} F(S) - \frac{\epsilon}{14s} \Delta.$$  

By using (28) again, substituting (29), and using that fact that $s \geq 2$:

$$F(v' \mid S) \geq \Delta - \frac{2\epsilon}{7s} F(S) - \frac{\epsilon}{14s} \Delta.$$  

$$\geq \Delta - \epsilon \Delta \left( \frac{1}{7s} + \frac{6}{7} \right) \geq \Delta (1 - \epsilon). \quad (31)$$

Therefore, the greedy sequence according to $\hat{F}$ is an approximate greedy sequence according to $F$ and satisfies the conditions of Lemma 24. Therefore the resulting sequence yields an approximation ratio at least $(1 - (1 - 1/s^3)(1 - \epsilon))$.

\hfill ▷

## D Greedy for Live-Edge Models

**Proof of Theorem 12.** For the first bound, we explicitly maintain for each node $u \in V$, for each pool, the reachability set of $u$ in the simulations of the pool (and its cardinality). The dominant term in the cost of computation is performing a BFS from each node in each of the $r \ell$ simulations that is truncated at distance $\tau$. The total computation time is

$$O(r \ell mn) = O(\epsilon^{-2} s^3 e \ln \left( \frac{n}{\delta} \right) \frac{m}{n}) \text{,} \quad (32)$$

where

$$\bar{m} = \frac{1}{\ell r} \sum_{i=1}^{\ell} \sum_{j=1}^{r} |E_{ij}|$$

is the average number of edges per simulation. For an IC model, $\text{E}[\bar{m}] = \sum_{e \in \mathcal{E}} p_e$. When a node $u$ is selected into the seed set we remove all nodes in its reachability set from the reachability sets of all other nodes. The removal cost can be “charged” to the initial reachability computation.

The dependence of the computation time on the graph size can be improved by using combined reachability sketches [10, 14, 15, 11] instead of maintaining the reachability sets explicitly (see Section 5.1). The sketch size needed in order to provide the required accuracy of $O(\epsilon/s)$ (as in Theorem 10) uniformly for all subsets of size at most $s$ is $k = O(\epsilon^{-2} s^3 \ln n)$. We compute a sketch for each node in each of the $\ell r$ pools, so in total we have $r \ell n$ node sketches. The construction time of these sketches has a term $\sum_{ij} |E_{ij}| = r \ell \bar{m}$ linear in the total size of simulations and a term for sketch constructions which is a product of the number of pools $r$ and the construction time for each pool. The per-pool construction time is as described in Section 5.1 and is bounded by $k$ (sketch size) visits for each node, each involving reverse
traversals of incoming edges of the node in some simulation. The per-pool construction time for an IC model is $O(k(n + \sum e p_e))$ in expectation. The time with arbitrary simulations for pool $i$ is $O(k(n + \sum e p_e (E_i)))$. In total over all pools, the construction time is dominated by $O(\ell M + k n + m*)$, where $m* = \sum e p_e$ for simulations and $m* = \sum e p_e$ for simulations generated by an IC model.

The sketches improve the computation time of greedy. Each iteration of greedy uses the (precomputed) union sketch of the current seed set $S$ in each pool. It then examines the sketches of each $v \in V$ to compute the estimate of the averaging oracle $\hat{A}(S \cup \{v\})$ in each pool. This operations takes $O(\ell M)$ in total for the iteration. Therefore $s$ iterations of greedy maximization takes $O(s \ell M)$ using the sketches. Combining the construction cost of the sketches using $r = O(s \ln \frac{n}{\delta})$ and $\ell = O(\epsilon^2 s^2 c)$ and the greedy implementation over the sketches we obtain a total bound on the computation time of

$$O(r \ell M + kr (m* + ns)) = O(r (\ell M + k (m* + ns)))$$
$$= O(s \ln \frac{n}{\epsilon^2 s^2 c M + \epsilon^2 s^2 (m* + ns) \ln n})$$
$$= O(\epsilon^2 s^3 \ln \frac{n}{\ell M + s (m* + ns) \ln n}).$$

### E Optimization with Adaptive Sample Size

The pseudocode for our wrapper is provided in Algorithm 1. The inputs to the wrapper are a base algorithm $A$ and two constructions of oracles from sets of simulations. The first construction produces an oracle, $\hat{F}_v$, that we use for validation. The second construction produces oracles, $\hat{F}_x$, that are provided as input to $A$ to perform the optimization. The oracles provide an approximation of our influence function $\Gamma(S)$ with non-uniform guarantees. For specified $(\epsilon, \delta)$ we use the expressions $r_v(\epsilon, \delta)$ or $r_x(\epsilon, \delta)$ for the number of simulations required to obtain $(\epsilon, \delta)$ guarantees (in the sense of Section 3.5). This gives us a relation between $\epsilon, \delta$, and a number of simulations. When constructing an oracle with a given number of simulations $r$ and a specified $\epsilon$, we can determine the confidence $\delta$ we have from $\epsilon$ and $r$.

The wrapper repeats the following: It constructs an “optimization” oracle $\hat{F}_x$ using the set of simulations $\mathcal{R}$ and applies $A$ over $\hat{F}_x$ to obtain a set $T$. The wrapper terminates when $F_v(T)$ is close to $\hat{F}_x(T)$ or when our simulation budget of $M$ is exceeded. Otherwise, we double the number of simulations in our set $\mathcal{R}$ and repeat.

The wrapped algorithm $A$ can be an exact or approximate optimizer. It is applied to the oracle function and therefore its quality guarantees are with respect to how well the oracle value $\hat{F}_x(T)$ of the output set $T$ approximates the oracle optimum $\max_{S | |S| \leq k} F_x(S)$. The wrapper extends the approximation guarantees that $A$ provides (with respect to the oracle) to a guarantee with respect to the influence function while avoiding the worst-case number of simulations needed for a uniform approximation.

We first establish some basic properties.
Algorithm 1 Optimization Wrapper.

Input: (i) Two oracle constructions from simulations: $\hat{F}_v$ (validation) and $\hat{F}_x$ (optimization) that with $r_v(\epsilon, \delta)$ (resp., $r_x(\epsilon, \delta)$) simulations provide $(\epsilon, \delta)$ guarantees. (ii) An optimization algorithm $A$ that applies to the optimization oracle $\hat{F}_x$ and returns a subset. (iii) $M$: Bound on maximum number of simulations. (iv) Parameters $\epsilon > 0$ and $\delta > 0$.

$r \leftarrow r_x(\epsilon, \delta)$ // #simulations for $\hat{F}_x$ to provide $(\epsilon, \delta)$ guarantees

// Build validation oracle
$\delta_v \leftarrow \delta \left\lceil \log_2 \frac{M}{r} \right\rceil$; $r_v \leftarrow r_v(\epsilon, \delta_v)$ // #simulations for validation oracle

$\hat{F}_v \leftarrow$ validation oracle from $r_v$ i.i.d simulations that provides $(\epsilon, \delta_v)$ guarantees

$R \leftarrow \perp$ // Initialize set of i.i.d simulations for optimization

repeat

Add $r$ fresh i.i.d simulations to set $R$

$\hat{F}_x \leftarrow$ optimization oracle from simulations $R$ that provides $(\epsilon, \ast)$ guarantees // * determined by $|R|$ $T \leftarrow A(\hat{F}_x)$ // Optimize over the oracle

if $\hat{F}_v(T) \geq (1 - 2\epsilon) \hat{F}_x(T)$ then

return $T$, $\hat{F}_v(T)$
else

$L_r \leftarrow 2r$

until $|R| + r_v > M$

Lemma 25. Let $S$ be a set with maximum influence (with $I^\tau(S) = \text{OPT}_x^\tau$). With probability at least $1 - 2\delta$, all the optimization oracles $\hat{F}_x$ constructed by the wrapper have $(1 - \epsilon)\text{OPT}_x^\tau \leq \hat{F}_x(S) \leq (1 + \epsilon)\text{OPT}_x^\tau$. 

Proof. The probability that $(1 - \epsilon)\text{OPT}_x^\tau \leq \hat{F}_x(S) \leq (1 + \epsilon)\text{OPT}_x^\tau$ fails for the first oracle is at most $\delta$. The number of $\hat{F}_x$ uses simulations doubles in each iteration and all our constructions are such that the confidence parameter $\delta$ decreases at least linearly with the number of simulations. We therefore obtain that the sequence of failure probabilities for $(1 - \epsilon)\text{OPT}_x^\tau \leq \hat{F}_x(S) \leq (1 + \epsilon)\text{OPT}_x^\tau$ is geometric and sums up to at most $2\delta$. ◀

As an immediate corollary we obtain:

Corollary 26. Under the conditions of Lemma 25, the oracle optimum in all iterations satisfies

$$\max_{T \mid |T| \leq s} \hat{F}_x(T) \geq (1 - \epsilon)\text{OPT}_x^\tau.$$ 

The following is immediate from the construction of the validation oracle.

Lemma 27. With probability at least $1 - \delta$, the validation oracle has relative error at most $\epsilon$ on all tests in which the input set $T$ is such that $I^\tau(T) \geq \text{OPT}_1^\tau$ and absolute error at most $\epsilon \text{OPT}_1^\tau$ otherwise.

Proof. The wrapper performs at most $\lceil \log_2 M/r \rceil$ iterations before it stops, in each iteration the validation oracle fails to provide an $\epsilon$-approximation with probability at most $\delta_v$. Therefore, by union bound, the probability that the algorithm fails to provide an $\epsilon$-approximation in at least one round is at most $\delta_v \lceil \log_2 M/r \rceil \leq \delta$. ◀
Lemma 28. Assume that our data and our optimization oracle with r or more simulations, are such that with probability at least $1 - \delta$, the optimum of the oracle is an approximate optimizer, that is:

$$(1 + \epsilon)\text{OPT}_s^\ast \geq \max_{S|S| \leq s} \hat{F}_s(S) \geq (1 - \epsilon)\text{OPT}_s^\ast$$

(33)

$$I'(\text{arg} \max_{S|S| \leq s} \hat{F}_s(S)) \geq (1 - \epsilon)\text{OPT}_s^\ast$$

(34)

and assume that the algorithm $A$ returns the oracle optimum. Then with probability at least $1 - 5\delta$, the wrapper terminates after at most $2\max\{r, r_s(\epsilon, \delta)\} + r_v$ simulations and returns $T$ such that $I'(T) \geq (1 - 5\epsilon)\text{OPT}_s^\ast$.

Proof. First we show that the wrapper returns a set $T$ with the required properties with probability at most $1 - 3\delta$ and then we show that the number of iterations the wrapper does before it stops is smaller than $M$ with probability of at most $1 - 2\delta$.

From Lemma 25, with probability at least $1 - 2\delta$ in all iterations $A$ returns $T$ for which $\hat{F}_v(T) \geq (1 - \epsilon)\text{OPT}_s^\ast$. The validation succeeds only if $\hat{F}_v(T) \geq \frac{(1 - 2\epsilon)}{1 + \epsilon}\hat{F}_s(T) \geq \frac{(1 - 3\epsilon)(1 - 2\epsilon)}{1 + \epsilon}\text{OPT}_s^\ast$. From Lemma 27 with probability at least $1 - \delta$ in all iterations we have $\hat{F}_v(T) \leq \max\{(1 + \epsilon)\Gamma(T), \Gamma(T) + \epsilon\text{OPT}_s^\ast\}$.

Therefore, with probability $1 - 3\delta$ the set $T$ returned by the wrapper satisfies

$$\frac{(1 - \epsilon)(1 - 2\epsilon)}{1 + \epsilon}\text{OPT}_s^\ast \leq \max\{(1 + \epsilon)\Gamma(T), \Gamma(T) + \epsilon\text{OPT}_s^\ast\}.$$  

If $(1 + \epsilon)\Gamma(T) > \Gamma(T) + \epsilon\text{OPT}_s^\ast$ then $\Gamma(T) \geq \frac{(1 - \epsilon)(1 - 2\epsilon)}{1 + \epsilon}\text{OPT}_s^\ast \geq (1 - 5\epsilon)\text{OPT}_s^\ast$.

Otherwise, we have that $\Gamma(T) \geq \left(\frac{(1 - \epsilon)(1 - 2\epsilon)}{1 + \epsilon} - \epsilon\right)\text{OPT}_s^\ast \geq (1 - 5\epsilon)\text{OPT}_s^\ast$.

We have to show that with probability at least $1 - 2\delta$ within $2\max\{r, r_s(\epsilon, \delta)\} + r_v$ simulations the wrapper returns such a set $T$ to finish the proof. Consider the first iteration where $|R| \geq r$. By Equations (33) and (34) with probability at least $1 - \delta$ we have that $\Gamma(T) \geq (1 - \epsilon)\text{OPT}_s^\ast$ and $(1 + \epsilon)\text{OPT}_s^\ast \geq \hat{F}_s(T) \geq (1 - \epsilon)\text{OPT}_s^\ast$. By Lemma 27 we have that with probability at least $1 - \delta$, the validation oracle satisfies that $\hat{F}_v(T) \geq (1 - \epsilon)\Gamma(T)$ or $\hat{F}_v(T) \geq \Gamma(T) - \epsilon\text{OPT}_s^\ast \geq \Gamma(T) - \epsilon\text{OPT}_s^\ast$. By the last two statements we have that with probability of at least $1 - 2\delta$:

$$\hat{F}_v(T) \geq (1 - \epsilon)\Gamma(T) \geq (1 - \epsilon)^2\text{OPT}_s^\ast \geq (1 - 2\epsilon)\text{OPT}_s^\ast \geq \frac{(1 - 2\epsilon)}{1 + \epsilon}\hat{F}_s(T)$$

or

$$\hat{F}_v(T) \geq \Gamma(T) - \epsilon\text{OPT}_s^\ast \geq (1 - 2\epsilon)\text{OPT}_s^\ast \geq \frac{(1 - 2\epsilon)}{1 + \epsilon}\hat{F}_s(T).$$

Therefore, with probability $1 - \delta$ the set $T$ returned by the wrapper satisfies $\hat{F}_v(T) \geq (1 - \epsilon)\text{OPT}_s^\ast$.

Theorem 8, which we restate below to provide reading fluency, now follows as a corollary.

Theorem 29 (Theorem 8). Suppose that on our data the averaging (respectively, median-of-averages) oracle $\hat{F}$ has the property that with $r$ simulations, with probability at least $1 - \delta$, the oracle optimum $T := \text{arg} \max_{S|S| \leq s} F(S)$ satisfies $\Gamma(T) \geq (1 - \epsilon)\text{OPT}_s^\ast$.
Then with probability at least \( 1 - 5\delta \), when using \( 2\max\{r, r(\epsilon, \delta)\} + O\left(\epsilon^2 c \ln \frac{1}{\delta} + \ln \ln \frac{2}{\delta} + \ln s\right) \) simulations with the median-of-averages oracle and \( 2\max\{r, r(\epsilon, \delta)\} + O\left(\epsilon^2 c \ln \frac{1}{\delta} + \ln \ln \frac{2}{\delta} + \ln n\right) \) simulations with the averaging oracle, the wrapper outputs a set \( T \) such that \( \Gamma(T) \geq (1 - 5\epsilon)\OPT^*_T \).

**Proof of Theorem 8.** We analyze here the number of simulations required using the averaging oracles and the median-of-averages oracles, in both cases we use median-of-averages oracles for validation. In both cases \( r_v = r(\epsilon, \delta) = O\left(\epsilon^2 c \log \frac{1}{\delta}\right) \), where \( \delta_v = \frac{\delta}{\log_2 \frac{1}{\epsilon \delta}} \).

By Lemma 28 the number of simulations is at most \( 2\max\{r, r_v(\epsilon, \delta)\} + r_v \). \( M \) and \( r_v \) get different values for each oracle.

**Median-of-averages oracles analysis.** We have that \( r_v = O(\epsilon^2 c \ln \delta^{-1}) \) by Lemma 6 and we set \( M = O(\epsilon^2 c s n \ln \frac{n}{\delta}) \) by Theorem 7. Simple calculation shows that:

\[
\frac{1}{\delta_v} = \left\lfloor \frac{\ln s \ln 2}{\ln \frac{2}{\delta}} \right\rfloor \leq \frac{1}{\delta} \left( \ln s + \ln \left( \ln \frac{n}{\delta} \right) \right).
\]

Therefore,

\[
r_v = O\left(\epsilon^2 c \left( \ln \frac{1}{\delta} + \ln \left( \ln \frac{n}{\delta} + \ln s \right) \right) \right).
\]

**Averaging oracles analysis.** We have \( r_v = O(\epsilon^2 c \delta^{-1}) \) and we set \( M = O(\epsilon^2 c s n \ln \frac{n}{\delta}) \) according to the respective worst-case guarantees on the number of simulations specified in (1). A simple calculations shows:

\[
\frac{1}{\delta_v} = \left\lfloor \frac{\ln s \ln 2}{\ln \frac{2}{\delta}} \right\rfloor \leq \frac{1}{\delta} \left( \ln \left( \ln \frac{n}{\delta} + 2 \ln n \right) \right).
\]

Therefore,

\[
r_v = O\left(\epsilon^2 c \left( \ln \frac{1}{\delta} + \ln \left( \ln \frac{n}{\delta} + \ln n \right) \right) \right).
\]

We next consider cases where the algorithm \( A \) is approximate (may not return the oracle optimizer). We assume in these cases that the optimization oracles \( \hat{F}_x \) when constructed with a given number of simulations provide, with high probability, uniform \( \epsilon \)-approximation for all \( \binom{n}{s} \) subsets of cardinality at most \( s \):

\[
\forall T \text{ such that } |T| < s, \quad \left| \hat{F}(T) - \Gamma(T) \right| \leq \epsilon \max\{1^\tau(T), \OPT^*_T\}.
\]

We first show that a very weak assumption on \( A \) suffices to guarantee termination with good probability.

**Lemma 30.** If the optimization oracle \( \hat{F}_x \) when constructed with \( r \) or more simulations provides uniform \( \epsilon \)-approximation with probability at least \( 1 - \delta \), and the algorithm \( A \) returns \( T \) such that \( \hat{F}(T) \geq (1 - \epsilon)\OPT^*_T \). Then with probability at least \( 1 - 2\delta \) the wrapper will terminate after using at most \( 2\max\{r, r_v(\epsilon, \delta)\} + r_v \) simulations.

**Proof.** Consider the first iteration where \( \hat{F}_x \) is constructed using at least \( r \) simulations. Let \( T \) be the set that \( A \) returns at this iteration. Since \( \hat{F}_x \) provides uniform \( \epsilon \)-approximation we have that \( \hat{F}_x(T) \leq (1 + \epsilon)\Gamma(T) \) with probability at least \( 1 - \delta \). Combining this with our assumption we get that \( \hat{F}(T) \geq (1 - \epsilon)\OPT^*_T \) and by Lemma 27 we have that with probability at least \( 1 - \delta \) if \( \Gamma(T) \geq \OPT^*_T \) then \( \hat{F}(T) \geq (1 - \epsilon)\Gamma(T) \) and if \( \frac{1 - \epsilon}{1 + \epsilon} \OPT^*_T \leq \Gamma(T) \leq \OPT^*_T \) then \( \hat{F}(T) \geq \Gamma(T) - \epsilon \OPT^*_T \geq \Gamma(T) - \frac{1 - \epsilon}{1 + \epsilon} \Gamma(T) \). Combining we obtain that \( \hat{F}_x(T) \geq \frac{1 - 2\epsilon}{1 + \epsilon} \hat{F}_x(T) \), and thus the validation condition holds. ▶
We next consider algorithms $A$ that guarantees some approximation ratio $\rho$.

**Theorem 31.** Suppose that our optimization oracle when constructed with $r$ or more simulations provides uniform $\epsilon$-approximation with probability at least $1 - \delta$. Assume now that the algorithm $A$ returns a set $T$ such that

$$F_x(T) \geq \rho \max_{S \in [S]S \leq s} F_x(S).$$

Then, the set $T$ returned by our wrapper satisfies $\Gamma(T) \geq \rho(1 - 5\epsilon)OPT^*_\epsilon$ with probability of at least $(1 - 3\delta)$.

**Proof.** Consider an optimal set $S$ (with $\Gamma^*(S) = OPT^*_\epsilon$). By Lemma 25 with probability at least $1 - 2\delta$ all our oracles have $(1 - \epsilon)OPT^*_\epsilon \leq F_x(S) \leq (1 + \epsilon)OPT^*_\epsilon$ are within $(1 \pm \epsilon)OPT^*_\epsilon$. By the assumption, the sets $T$ returned by $A$ in all iterations have $\hat{F}_x(T) \geq \rho \max_{S \in [S]S \leq S} F_x(S) \geq \rho(1 - \epsilon)OPT^*_\epsilon$. When the wrapper stops we have that $\hat{F}_x(T) \leq \frac{1 + \epsilon}{1 - 2\epsilon} \hat{F}_x(T)$ and by Lemma 27 we have with probability at least $1 - \delta$ that $\hat{F}_x(T) \leq \max\{(1 + \epsilon)\Gamma^*(T), \Gamma^*(T) + \epsilon OPT^*_1\}$.

Combining, we have that with probability at least $1 - 3\delta$,

$$\rho(1 - \epsilon)OPT^*_\epsilon \leq \rho F_x(S) \leq \hat{F}_x(T) \leq \frac{1 + \epsilon}{1 - 2\epsilon} F_x(T) \leq \frac{1 + \epsilon}{1 - 2\epsilon} \max\{(1 - \epsilon)\Gamma^*(T), \Gamma^*(T) + \epsilon OPT^*_1\}.$$

Now, a simple calculation shows that $\Gamma^*(T) \geq \rho(1 - 5\epsilon)OPT^*_\epsilon$.

We can prove now Theorem 9 (restated for reading fluency):

**Theorem 32 (Theorem 9).** If the averaging oracle $\hat{A}$ has the property that with $\geq r$ simulations, with probability at least $1 - \delta$, it provides a uniform $\epsilon$-approximation for all subsets of size at most $s$, then with $2 \max\{r, r(\epsilon, \delta)\} + O(\epsilon^{-2}(\ln \frac{1}{\delta} + \ln (\ln \ln \frac{1}{\delta} + \ln n)))$ simulations we can find in polynomial time a $(1 - (1 - 1/s)^s)(1 - 5\epsilon)$ approximate solution with confidence $1 - 5\delta$.

**Proof.** The averaging oracle is monotone and submodular [31] and therefore greedy can efficiently recover a set $T$ such that $\hat{F}_x(T) \geq (1 - (1 - 1/s)^s) \max_{S \in [S]S \leq S} \hat{F}_x(S)$.

By Lemma 30, the wrapper terminates using at most $2 \max\{r, r(\epsilon, \delta)\} + r_v$ with probably at least $1 - 2\delta$. Applying Theorem 31 with $\rho = (1 - (1 - 1/s)^s)$, we get that $\Gamma^*(T) \geq (1 - (1 - 1/s)^s)(1 - 5\epsilon)OPT^*_\epsilon$ with probability at least $1 - 3\delta$. Hence, with probability at least $1 - 5\delta$ the wrapper applied with greedy finds $(1 - (1 - 1/s)^s)(1 - 5\epsilon)$-approximate solution using $2 \max\{r, r(\epsilon, \delta)\} + r_v$ simulations.

## F Variance Bounds for Dependent Models

In this section we provide a proof for Corollary 3. We consider a natural extensions of IC models, b-dependence, that allow for some dependencies between edges and mixtures of IC and IGT models. For these extensions, we establish upper bounds of the form (8) on the variance of the reachability of a set of nodes.

We bound the variance by constructing for each dependent model a corresponding IC model and then apply the variance upper bound established in Section A for IC models.

For mixture models we provide a generic derivation that bounds the variance of the mixture by variance of components.
F.1 \( b \)-Dependence Models

The first family we consider are \( b \)-dependence models, which we define as follows. We assume that all edges with the same tail node are partitioned into disjoint groups where each group is of size at most \( b \). The edges of each group \( B \) are either all active together with probability \( p_B \) or none is active with probability \( 1 - p_B \). The special case where all groups are of size 1 corresponds to an IC model (where all edges are independent).

▶ **Theorem 33.** Let \( \mathcal{G} \) be a \( b \)-dependence model for some \( b \geq 1 \). For every set \( T \) we have that:

\[
\text{Var} [ R^b_\mathcal{G} (T) ] \leq 2b \tau I^b_\mathcal{G} (T) \max_{v \in V \setminus T} I^b_\mathcal{G} (v)
\]

**Proof.** We construct an IC model \( \mathcal{G}' \) from the given \( b \)-dependence model \( \mathcal{G} \). The model \( \mathcal{G}' \) is defined over the set of nodes \( V \) of \( \mathcal{G} \) together with an additional set \( D \) of dummy nodes. The construction has the properties that \( 2\tau \)-step influence in \( \mathcal{G}' \) from a set of nodes \( T \subseteq V \) is equal to \( \tau \)-stepped influence of \( T \) in \( \mathcal{G} \). Furthermore, the variances of the sizes of the \( 2\tau \)-step reachability of \( T \) in \( \mathcal{G}' \) is the same as the variance of the \( \tau \) step reachability of \( T \) in \( \mathcal{G} \). The influence of each dummy node in \( \mathcal{G}' \) is at most \( b \max_{v \in V} I^\tau (v) \). The claim follows from these properties and Theorem 2.

Here is a formal description of our reduction.

We start by putting in \( G' \) the set \( V \) of the nodes of \( G \). Then for every group \( B = \{(u,v_1), (u,v_2), ..., (u,v_\ell)\} \) in \( G \) we do the following:

1. Add a new dummy node \( v_B \) to \( G' \), and add to \( G' \) the edge \((u,v_B)\) and give it the probability \( p_B \). We assign weight 0 to \( v_B \) so that it does not contribute to the reachability of any set of nodes.

2. we create edges \((v_B, v_i)\) for every \( 1 \leq i \leq \ell \), each such edge has probability 1.

   Let \( T \subset V \) be a set of nodes in \( G \). It follows from our construction that for any set of nodes \( B \subset V \) the probability that \( R^2_\mathcal{G} (T) = B \) is the same as the probability that \( R^b_\mathcal{G} (T) = B \). This implies that for any \( T \subseteq V \)

\[
I^b_\mathcal{G} (T) = I^\tau_\mathcal{G} (T),
\]

and

\[
\text{Var} [ R^2_\mathcal{G} (T) ] = \text{Var} [ R^\tau_\mathcal{G} (T) ] .
\]

Each dummy node is connected to at most \( k \) original nodes, hence, \( I^\tau_\mathcal{G} (v) \) is bounded by \( b \max_{v \in V} I^\tau_\mathcal{G} (v) \). By Theorem 20 it follows that for every set of nodes \( T \) in \( G' \):

\[
\text{Var} [ R^2_\mathcal{G} (T) ] \leq 2\tau I^\tau_\mathcal{G} (T) \max_{v \in V \setminus T} I^\tau_\mathcal{G} (v).
\]

Combining all these observations together, we get that

\[
\text{Var} [ R^b_\mathcal{G} (T) ] \leq 2b \tau I^\tau_\mathcal{G} (T) \max_{v \in V \setminus T} I^\tau_\mathcal{G} (v) \quad \blacksquare
\]

This Theorem can be generalized to more complex dependencies. For example it holds for any distribution on subsets of the outgoing edges from each node that we can realize by a distribution on disjoint subsets where we draw each subset with certain probability, and take the union of the subset which we draw.

ITCS 2020
F.2 Mixture of IC and IGT Models

The second family of dependent models we consider is a mixture of IC and IGT models.

Consider a set of models \( G_i(V) \) for \( i \in [r] \) and respective probabilities \( p_i \) such that \( \sum_{i=1}^{r} p_i = 1 \). We define a mixture model \( G(V) \) as follows. To draw \( \phi \sim G \), we first draw \( i \in [r] \) according to probabilities \( p_i \) and then return \( \phi \sim G_i \).

We provide two proofs for the variance bound of the mixture. The first is direct and applies to any mixture of models that satisfies the variance bound of Theorem 2, and in particular to mixtures of strongly submodular SDMs. The second proof is specific to live-edge models and based on a reduction to an IC model.

\[ \text{Theorem 34.} \quad \text{Consider a model} \ G \ \text{that is a mixture of} \ r \ \text{models} \ G_i \ \text{with probabilities} \ p_i \ \text{that satisfy the variance bound of Theorem 2. Then for all} \ T \subset V, \]

\[ \text{Var}[R^*_G(T)] \leq \frac{\tau + 1}{\min_i p_i} I^*_G(T) \max_{v \in V} I^*_G(v) \]

\[ \text{Proof.} \quad \text{We first relate the influence of} \ T \ \text{in the mixture model to the influence of} \ T \ \text{in the components.} \]

\[ I^*_G(T) = E[R^*_G(T)] = \sum_{i=1}^{r} p_i E[R^*_G_i(T)] = \sum_{i=1}^{r} p_i I^*_G_i(T). \] (35)

This holds to any set \( T \) and any \( \tau \). Therefore we also obtain the inequality

\[ M^*_G(\bar{T}) = \max_{v \in V \setminus T} I^*_G(v) = \max_{v \in V \setminus T} \sum_{i=1}^{r} p_i I^*_G_i(v) \leq \sum_{i=1}^{r} p_i \max_{v \in V \setminus T} I^*_G_i(v) = \sum_{i=1}^{r} p_i M^*_G_i(\bar{T}). \] (36)

It also follows that we can bound the influence values on the component by the respective ones in the mixture: \( I^*_G_i(T) \leq \frac{1}{p_i} I^*_G(T) \) and thus

\[ \max_i I^*_G_i(T) \leq \frac{1}{\min_i p_i} I^*_G(T) \] (37)

\[ \max_i M^*_G_i(\bar{T}) \leq \frac{1}{\min_i p_i} M^*_G(\bar{T}). \] (38)

The random variable \( R^*_G(T) \) can be expressed as a sum of \( r \) products of random variables:

\[ R^*_G(T) = \sum_{i=1}^{r} X_i R^*_G_i(T), \]

where \( X_i \) are Bernoulli with probabilities \( p_i \). The random variables \( \{R^*_G_i(T)\} \) are independent of each other and also are independent from (the joint distribution of) \( \{X_i\} \). The variables \( \{X_i\} \) have negative dependence as \( \sum_i X_i = 1 \) and thus the products \( X_i R^*_G_i(T) \) are also negatively dependent and thus

\[ \text{Var}[R^*_G(T)] \leq \sum_i \text{Var}[X_iR^*_G_i(T)]. \]

We will instead bound the variance of a surrogate random variable

\[ Y = \sum_i X_i R^*_G_i(T) \]
that has the same sum of products but with the variables \( \{X_i\} \) being independent of each other and hence the products are also independent. We have

\[
\text{Var}[Y] = \sum_i \text{Var}[X_i R_{G_i}^r(T)] \geq \text{Var}[R_{G_i}^r(T)]
\]

We next express the variance of each product using variance properties of the product of two independent random variables. For \( i \in [r] \):

\[
\text{Var}[X, R_{G_i}^r(T)] = \text{Var}[X] \text{Var}[R_{G_i}^r(T)] + E[X]^2 \text{Var}[R_{G_i}^r(T)]^2 + \text{Var}[X]E[\text{Var}[R_{G_i}^r(T)]^2
\]

\[
= p_i(1 - p_i) \text{Var}[R_{G_i}^r(T)] + p_i^2 \text{Var}[R_{G_i}^r(T)] + p_i(1 - p_i) \text{Var}^2[\tau M_{G_i}^r(T)]
\]

Therefore, invoking Theorem 2 to bound the variance for each IC model \( G_i \) and then using (37) and (38) and finally using (35) and (36) we get

\[
\text{Var}[Y] \leq \sum_{i=1}^{r} p_i \left( \text{Var}[R_{G_i}^r(T)] + p_i(1 - p_i) \text{Var}^2[\tau M_{G_i}^r(T)] \right)
\]

\[
\leq \sum_{i=1}^{r} p_i \left( \text{Var}[R_{G_i}^r(T)] + p_i \text{Var}^2[\tau M_{G_i}^r(T)] \right)
\]

\[
\leq \sum_{i=1}^{r} \frac{\tau}{\min_i p_i} I_G^r(T) \sum_{i=1}^{r} p_i M_{G_i}^r(T) + \frac{1}{\min_i p_i} I_G^r(T) \sum_{i=1}^{r} p_i \text{Var}^2[\tau M_{G_i}^r(T)]
\]

\[
\leq \frac{\tau + 1}{\min_i p_i} I_G^r(T) \max_{v \in V} I_G^r(v)
\]

We next give a different proof (of a slightly different bound) for live-edge models using a reduction to an IC model. Consider a set of \( \tau \)-steps models \( G_i(V, E_i) \) for \( i \in [r] \) and respective probabilities \( p_i \) such that \( \sum_{i=1}^{r} p_i = 1 \). We define a mixture model \( G(V, \bigcup_i E_i) \) as follows. To draw \( E \sim \mathcal{G} \), we first draw \( i \in [r] \) according to probabilities \( p_i \) and then return \( E \sim G_i \).

**Theorem 35.** Consider a model \( G \) that is a mixture of \( r \) IC models \( G_i \) with probabilities \( p_i \). Then for all \( T \subset V \),

\[
\text{Var}[R_G^r(T)] \leq \frac{\tau + 1}{\min_i p_i} I_G^r(T) \max_{v \in V} I_G^r(v)
\]

**Proof.** We first argue that we can assume without loss of generality that \( T \) is a single node and \( \bigcup_i E_i \) does not contain edges that are incoming to \( T \). We can transform a general case \( G \) and \( T \) to this form by contracting all nodes in \( T \) into a single node and deleting all edges that are incoming to \( T \). We then retain the same conditional distribution on the remaining edges. Note that this transformation preserves the distribution of \( R_G^r(T) \) and hence also its expectation and variance. The influence values \( I_G^r(v) \) of nodes \( v \in V \setminus T \) can only decrease. Finally, the transformed model is also a mixture of correspondingly transformed IC models, where in each such model the distribution of \( R_G^r(T) \) remains the same and influence values \( I_G^r(v) \) can only decrease. It follows that the claimed variance bound for the transformed model implies the same bound for the original model.
We construct a new IC model $G'$ with respect to (a single node) $T$ as follows. The new model has nodes $V' = \{v\} \cup \bigcup_i V_i$, where each $V_i$ is a map of $V$. We create an instantiation of each of our IC models $G_i$ with set of nodes $V_i$ and edges $E_i$ with the probabilities as in the model $G_i$. The new IC model $G'$ has a root node $v$ with weight 0 and for each $i \in [r]$, there is an edge $(v, T_i)$ with probability $p_i$, where $T_i$ is the image of $T$ in the copy of $G_i$. We can see that

$$I_{G'}^{\tau+1}(v) = I_{G'}^\tau(T) = \sum_{i=1}^r p_i I_{G_i}^\tau(T),$$

that is, the $\tau + 1$ steps influence of $v$ in the constructed IC model $G'$ is equal to the $\tau$ steps influence of $T$ in the mixture model $G$.

We next consider the variance of the random variables $R_{G_i}^\tau(T)$ and $R_{G_i}^{\tau+1}(v)$. Both these random variables are a sum of $r$ products of random variables:

$$\sum_{i=1}^r X_i R_{G_i}^\tau(T),$$

where $X_i$ are Bernoulli with probabilities $p_i$. In both cases the random variables $\{R_{G_i}^\tau(T)\}$ are independent of each other and also are independent from (the joint distribution of) $\{X_i\}$. But in the case of $R_{G_i}^{\tau+1}(v)$ the random variables $X_i$ are independent and hence also the products are independent and in the case of $R_{G_i}(T)$, the variables $\{X_i\}$ have negative dependence as $\sum_i X_i = 1$ and thus the products $X R_{G_i}^\tau(T)$ are also negatively dependent. Therefore,

$$\text{Var}[R_{G_i}^\tau(T)] \leq \text{Var}[R_{G_i}^{\tau+1}(v)] = \sum_i \text{Var}[X_i R_{G_i}^\tau(T)].$$

Finally, we bound $\mathcal{M}_{G_i}(v)$ by considering the maximum influence of a node other than $v$ in the constructed model $G'$. For $T_i$ we have

$$I_{G_i}(T_i) = I_{G_i}(T) \leq \frac{1}{p_i} I_{G_i}(T),$$

where the last inequality follows from (40). We next consider nodes $z_i \in V_i$ that is a map of a node $z \in V$.

$$I_{G_i}(z_i) = I_{G_i}(z) \leq \frac{1}{p_i} I_{G_i}(z).$$

The last inequality follows because for any node $z \in v$ we have $I_{G_i}(z) = \sum_{i=1}^r p_i I_{G_i}(z)$. Combining (42) and (43) we get

$$\mathcal{M}_{G_i}(v) = \max_{u \in V \setminus \{v\}} I_{G_i}(u) \leq \max_{u \in V} I_{G_i}(u) \leq \frac{1}{\min_i p_i} I_{G_i}(u) \leq \frac{1}{\min_i p_i} \max_{z \in V} I_{G_i}(z) \leq \frac{1}{\min_i p_i} \max_{z \in V} I_{G_i}(T).$$

To conclude, we invoke Theorem 2 for the IC model $G'$:

$$\text{Var}[R_{G_i}^\tau(T)] \leq \text{Var}[R_{G_i}^{\tau+1}(v)] \leq (\tau + 1) I_{G_i}^{\tau+1}(v) \mathcal{M}_{G_i}(v).$$

We then apply inequalities (44) and the equality (40) to obtain the claim.
On Oblivious Amplification of Coin-Tossing Protocols

Nir Bitansky

Nathan Geier
Tel Aviv University, Israel
nathangeier@mail.tau.ac.il

Abstract
We consider the problem of amplifying two-party coin-tossing protocols: given a protocol where it is possible to bias the common output by at most $\rho$, we aim to obtain a new protocol where the output can be biased by at most $\rho^* < \rho$. We rule out the existence of a natural type of amplifiers called oblivious amplifiers for every $\rho^* < \rho$. Such amplifiers ignore the way that the underlying $\rho$-bias protocol works and can only invoke an oracle that provides $\rho$-bias bits.

We provide two proofs of this impossibility. The first is by a reduction to the impossibility of deterministic randomness extraction from Santha-Vazirani sources. The second is a direct proof that is more general and also rules outs certain types of asymmetric amplification. In addition, it gives yet another proof for the Santha-Vazirani impossibility.

1 Introduction

Hardness amplification is a foundational problem in cryptography: given a cryptographic primitive that is weakly secure in some sense, we would like to make it strongly secure. Two famous examples of such amplification procedures are Yao’s amplification of weak one-way functions into strong ones and Yao’s Xor lemma for amplifying unpredictability [17]. Other examples of primitives with known amplification procedures include public-key encryption [5, 11], oblivious transfer [4, 16], commitments [4, 8] and cryptographic arguments [6].

Coin-Tossing Protocols

We consider amplification of coin-tossing protocols [3]. Such protocols allow two parties to jointly toss an unbiased coin, such that even if one party is malicious and diverges from the protocol, it cannot significantly bias the outcome. Concretely, a $\rho$-bias coin-tossing protocol is such that a cheating party cannot force the common outcome to be any specific bit $b$ with probability greater than $1/2 + \rho$. 
It is common knowledge that coin-tossing protocols against unbounded (or even PSPACE) adversaries cannot have bias $\rho < 1/2$. Accordingly, the common definition addresses efficient adversaries. Here coin-tossing protocols with negligible bias have been long known assuming one-way functions [3, 9, 13]. In fact, a long line of work shows that one-way functions are, in fact, necessary provided that the bias is at most $\rho < 1/2 - \Omega(1)$ [10, 12, 7, 2]. Whether one-way functions are necessary for any non-trivial bias $\rho < 1/2 - 1/poly(n)$ (or even for some $\rho = 1/2 - o(1)$) remains an open problem.

**Amplifying Coin Tossing**

A coin-tossing amplifier should take a coin-tossing protocol $\pi$ with (non-trivial) bias $\rho < 1/2$ and transform it into a new coin-tossing protocol $\pi^*$ with smaller bias $\rho^* < \rho$. One specific way for obtaining coin-tossing amplifiers is to first derive from the protocol $\pi$ a one-way function $f_\pi$, and then construct optimal coin tossing from $f_\pi$. Indeed, following the known results mentioned above this would work for any $\text{negl}(n) < \rho^* < \rho < 1/2 - \Omega(1)$.

In this work, we ask whether there exist “more direct” amplification procedures, which we call oblivious amplifiers. Such amplifiers completely ignore the way that the underlying protocol $\pi$ works, they only obtain oracle access to the result — the adversary can adaptively bias the resulting bit of each oracle invocation as long as the bias is bounded by $\rho$. The amplifier is required to satisfy an information theoretic guarantee: unbounded attackers cannot bias the common output of the new protocol $\pi^*$ by more than $\rho^* < \rho$. Addressing unbounded attackers is a natural choice as we wish to avoid computational assumptions (certainly, one-way functions, which would trivialize the problem).

We find the model of oblivious amplifiers quite natural and similar to other settings, such as Yao’s Xor lemma [17], where amplifiers satisfy an information theoretic guarantee. In particular, constructing such amplifiers seems like a natural route toward fully understanding the complexity of coin tossing. In particular, the existence of such efficient amplifiers for $\rho^* \leq 1/2 - \Omega(1) < 1/2 - 1/poly(n) \leq \rho$

would completely resolve the question, showing that any non-trivial coin tossing is equivalent to one-way functions.

1.1 Results

We show that oblivious coin-tossing amplifiers do not exist.

▶ **Theorem 1** (Informal). *There do not exist oblivious coin-tossing amplifiers for any $\rho^* < \rho$.***

Our theorem can further be extended to rule out oblivious amplification of weak coin tossing [2] that essentially requires that one side cannot bias toward 0 and the other cannot bias toward 1. (See Remark 6.)

**A More General Lower Bound**

We give two proofs of the above theorem. The first is by a simple reduction to the impossibility of deterministic randomness extraction from Santha-Vazirani sources [15]. We also give a direct proof that provides a more general lower bound. In particular, we quantify the tradeoff between improving the potential bias caused by specific party $A$ toward a specific bit $b$, at
the account of making it worst for other party $B$ and bit $1 - b$. This also rules out oblivious amplification for asymmetric notions of coin tossing where we allow different bounds on the bias for the two parties. The tradeoff is explained in the technical overview below and expressed in Figure 2.

The alternative proof also gives yet another proof of the Santha-Vazirani impossibility for deterministic extraction (in addition to several existing proofs [15, 14, 1]).

1.2 Technical Overview

We now give a brief overview of our proofs.

Modeling Protocols as Trees

We model any possible amplifier protocol $\pi^*$ as a full binary tree. The correspondence is natural: the root corresponds to the beginning of the protocol before any message is sent. Every inner node in the tree is either

- Controlled by one of the two parties $A$ or $B$, meaning that it is this party’s turn to send a message, without loss of generality, a single bit.
- Representing an oracle call to the underlying protocol $\pi$ resulting in a common bit.

Whenever a message is sent or an oracle call is made, we move in accordance to the left or right child, until reaching a leaf labeled by the common outcome of the protocol. Here the execution ends.

Each node is associated with some (honest) distribution on the next bit to be sent or produced by the oracle. The adversary can gain control over the nodes representing one of the parties and arbitrarily fix their distributions. For any oracle node, the adversary can fix an arbitrary distribution provided that it has bias at most $\rho$. Note that every node corresponds to some partial execution of the protocol, represented by the path from the root to this node, and the adversarial response is adaptively fixed according to this path. (See illustration in Figure 1.)

![Figure 1](image_url) An example of a protocol represented by a tree. Each node specifies which party should send a bit as well as the distribution of this bit (when the party is honest). Alternatively, the parties may invoke the oracle and obtain a joint bit. The adversary may take control of one of the parties and arbitrarily replace its distributions; it can also replace the oracle call distributions provided that they remain $\rho$-biased.
On Oblivious Amplification of Coin-Tossing Protocols

The above model does not explicitly capture protocols where honest parties may store private coins through the interaction. However, we can transform any private-coin protocol to a protocol in the above model by considering parties that do not explicitly keep private randomness; instead, in every node they resample their private randomness conditioned on the execution transcript so far and answer according to that string. The transformation has no effect on the distribution of transcript and in particular on the outcome bit. However, the transformation may make the new protocol inefficient. This is not an issue as our lower bound will in fact hold for inefficient protocols as well.

A Reduction to Deterministic Santha-Vazirani Extractors

In their seminal work, Santha and Vazirani considered the problem of extracting a statistically uniform bit from a sequence of biased random bits \( X = X_1, \ldots, X_n \) such that \( X_i \) has bounded bias \( \rho \) conditioned on any fixing of \( X_1, \ldots, X_{i-1} \). Such random sources \( X \) are called Santha-Vazirani Sources. They proved that there exist no deterministic extractors for such sources, namely, for any deterministic Boolean function \( E \), there exists a Santha-Vazirani source such that \( E(X) \) is far from uniform. In fact, they proved that \( E(X) \) is \( \rho \)-biased.

Indeed, this bares similarity to the setting of oblivious coin-tossing amplification where the \( \rho \)-biased input bits naturally correspond to oracle calls to \( \pi \). The gap between the two models is that a coin-tossing oblivious amplifier further allows interaction between two randomized parties. To bridge this gap, we prove that any oblivious amplifier can be turned into a non-interactive oblivious amplifier.

To convey the basic idea, imagine that we have an amplifier tree where the root belongs to party \( A \) (namely, it sends the first message). We argue that at least one of its left or right subtrees also has bias at most \( \rho^* \), and thus we can reduce one round of interaction. In fact, both subtrees must be such that an adversary controlling \( A \) can bias the outcome by at most \( \rho^* \), or else an adversary controlling \( A \) in the original protocol could have simply always chosen the worse subtree in order to bias the outcome by more than \( \rho^* \). We then observe that at least one of the subtrees must be such that an adversary controlling \( B \) cannot bias by more than \( \rho^* \). Indeed, the bias caused by an adversary controlling \( B \) in the original protocol is just a convex combination of the its bias in the two corresponding subtrees.

The Second Proof and a More General Lower Bound

Our second proof of the theorem pours more light on the tradeoff between how much each party can bias the protocol towards a specific bit. We first give a correspondence between protocols and points on the plane. For a protocol \( \pi \), let \( x_\pi \) be the maximum probability a malicious \( A^* \) (controlling \( A \)) can force output \( 0 \) and \( y_\pi \) be the maximum probability a malicious \( B^* \) can force output \( 1 \). We assign the protocol \( \pi \) coordinates \( (x_\pi, y_\pi) \). Considering the tree representing the protocol \( \pi \), the point in the plane corresponding to the protocol \( \pi \) is determined by the points corresponding to its children themselves as protocols, as well as the operation at its root. (This is roughly done following a similar argument to the one used above, where we either take the maximum of two subtrees, or a convex combination thereof.)

Our basic Theorem 1 and its proof show that all points corresponding to protocols lie outside the axis-aligned square given by \( x = 0, y = 0, x = 0.5 + \rho, y = 0.5 + \rho \). Our more general analysis, shows a more accurate picture – all points lie above a certain piecewise linear \( f \) (See Figure 2). In a bit more detail, we prove by induction on the depth of the tree that the point corresponding to every protocol lies above the function \( f \), by showing closure of points above \( f \) to each of the operations that may appear at the root, and also
that protocol leaves (the base case) lie above \( f \). When considering a non-leaf protocol, we get from the induction that the sub-protocols rooted at its children lie above \( f \), and since the set of points above \( f \) is closed under the operation at the protocols’ root, the point corresponding to the protocol itself also lies above \( f \).

This more general result shows that we cannot hope to improve the \( x_\pi \)-value of the oracle without strictly hurting its \( y_\pi \)-value, and furthermore gives some lower bound \( g(\Delta_x) \), for every \( 0 \leq \Delta_x \leq x_\pi \), on how much \( y_\pi \) must increase in order to reduce \( x_\pi \) by \( \Delta_x \).

![Figure 2](image)

**Figure 2** For the sake of this illustration, we set \( \rho = 0.2 \). The \( X \)-axis represents the ability of a malicious \( A^* \) to bias the common output toward 0, and the \( Y \)-axis represents the ability of a malicious \( B^* \) to bias the common output toward 1. While our basic Theorem 1 argues that all protocols lie outside the dotted square, our more general theorem shows that they in fact lie above the piece-wise linear function represented by the continuous line.

**Organization**

In Section 2, we define the relevant notion of oblivious amplifiers and their correspondence to trees. In Section 3, we prove the main impossibility result by a reduction to the impossibility of deterministic Santha-Vazirani extraction. In Section 4, we give our alternative (direct) proof leading to a more general lower bound.

**2 Definitions**

Throughout the paper, we denote by \( Ber(p) \) the Bernoulli distribution with parameter \( p \), namely, the value 1 gets probability \( p \) and 0 gets \( 1 - p \).

- **Definition 2** (Common-output two-party protocol with oracle access to \( \rho \)-biased bits). We model a common-output two-party protocol with oracle access to \( \rho \)-biased bits using full binary trees such that:
Every leaf is labeled with either “0” or “1”, which represent the common output of the protocol upon reaching that leaf.

Every inner node $v$ is labeled with “$(P_v, q_v)$” where
1. $P_v \in \{A, B, O\}$ represents whether it is $A$’s turn to speak, $B$’s turn to speak, or an oracle call.
2. In an honest execution, the bit sent after reaching that node should be distributed according to $Ber(q_v)$. If $P_v = O$ then $q_v$ must be 0.5, otherwise $q_v$ may be an arbitrary probability.

Execution. An execution of the protocol follows a path along the tree, starting at the root and going left/right in accordance to the bits sent, when 0 means left and 1 means right, until reaching a leaf which determines the common output of that execution.

Adversarial behavior. A malicious party can ignore $q_v$ when it is their turn to speak and send an arbitrarily distributed bit instead. Also, whenever the oracle is called, the malicious party may change the output distribution of that call from $Ber(0.5)$ to $Ber(q_v)$ for any $q_v$ such that $|q_v - 0.5| \leq \rho$. Note that $q_v$ may depend on all the bits sent up to that call.

Definition 3. Given a protocol $\pi$, $A^*$ an adversarial behavior of $A$ and $b \in \{0, 1\}$, we denote by $\pi(A^*, b)$ the probability of $\pi$’s output being b when executed with $A^*$ and an honest $B$.
Next, define $Opt(\pi, A^*, b) := \max_{A^*} \pi(A^*, b)$, where the maximum is taken over all adversarial behaviors $A^*$ of $A$. $\pi(B^*, b)$ and $Opt(\pi, B^*, b)$ are defined symmetrically for $B$.

Definition 4 (($\alpha, \beta$)-oblivious coin-tossing amplifier). A common-output two-party protocol $\pi$ with oracle access to $\alpha$-biased bits is an ($\alpha, \beta$)-oblivious coin-tossing amplifier if
\[ \max_{P^*, b} Opt(\pi, P^*, b) \leq 0.5 + \beta, \]
where $P^* \in \{A^*, B^*\}$ and $b \in \{0, 1\}$. In addition, we require that the expected output of $\pi$ over an honest execution is 0.5.

Remark 5. Actually, for the lower bound, we do not use the fact that the expected output of $\pi$ over an honest execution is 0.5. We note that bounded biases already makes coin-tossing protocols non-trivial.

Remark 6. We may also consider the notion of ($\alpha, \beta$)-oblivious weak coin-tossing amplifiers, which aim to produce a $\beta$-bias weak coin tossing (CT) protocol instead of standard $\beta$-CT. In the weak CT setting, we know in advance that $A^*$ aims to bias the result toward 0 while $B^*$ aims to bias the result toward 1. We only need to bound their ability to bias the output in their chosen direction. The difference is in the requirement
\[ \max_{P^*, b} Opt(\pi, P^*, b) \leq 0.5 + \beta, \]
which is replaced with
\[ \max\{Opt(\pi, A^*, 0), Opt(\pi, B^*, 1)\} \leq 0.5 + \beta. \]

3 Impossibility of Oblivious Amplifiers

In this section, we state and prove our main result regarding the impossibility of non-trivial oblivious coin-tossing amplifiers.
**Theorem 7** (main). For every common-output two-party protocol $\pi$ with oracle access to $\rho$-biased bits, either $\text{Opt}(\pi, A^*, 0) \geq 0.5 + \rho$ or $\text{Opt}(\pi, B^*, 1) \geq 0.5 + \rho$. In particular, there do not exist $(\alpha, \beta)$-oblivious coin-tossing amplifier, for any $\beta < \alpha$.

Toward proving the theorem, we first analyze in Section 3.1 the best possible (unbounded) attacks. Then in Section 3.2, we give the reduction to the impossibility of deterministic extraction from Santha-Vazirani sources.

### 3.1 The Optimal Attacks

Let $\pi$ be a common-output two-party protocol with oracle access to $\rho$-biased bits, and denote its root by $r$. Also, denote by $\pi_0$ and $\pi_1$ the protocols rooted at the left and right children of $r$. The best strategy of a malicious $A^*$ to make the protocol $\pi$ output 0 is to bias the first bit $b$ as much as possible towards $\arg \max_{z \in \{0, 1\}} \text{Opt}(\pi_z, A^*, 0)$, and after $b$ is sent continue to recursively apply the best strategy at the resulting child. The best strategy of a malicious $B^*$ to make the protocol $\pi$ output 1 is symmetrical. Thus, we have that:

- If $r$ is labeled with “$A, p$”, then $A$ can completely bias the bit while $B$ cannot change its distribution at all, so
  
  \begin{align*}
  \text{Opt}(\pi, A^*, 0) &= \max_{z \in \{0, 1\}} \text{Opt}(\pi_z, A^*, 0) \\
  \text{Opt}(\pi, B^*, 1) &= E_{z \sim \text{Ber}(p)}[\text{Opt}(\pi_z, B^*, 1)]
  \end{align*}

- If $r$ is labeled with “$B, p$”, then $B$ can completely bias the bit while $A$ cannot change its distribution at all, so
  \begin{align*}
  \text{Opt}(\pi, A^*, 0) &= E_{z \sim \text{Ber}(p)}[\text{Opt}(\pi_z, A^*, 0)] \\
  \text{Opt}(\pi, B^*, 1) &= \max_{z \in \{0, 1\}} \text{Opt}(\pi_z, B^*, 1)
  \end{align*}

- If $r$ is labeled with “$O$”, then both $A$ and $B$ can bias the bit by at most $\rho$, so
  \begin{align*}
  \text{Opt}(\pi, A^*, 0) &= (0.5 - \rho) \cdot \min_{z \in \{0, 1\}} \text{Opt}_z(\pi_z, A^*, 0) + (0.5 + \rho) \cdot \max_{z \in \{0, 1\}} \text{Opt}(\pi_z, A^*, 0) \\
  \text{Opt}(\pi, B^*, 1) &= (0.5 - \rho) \cdot \min_{z \in \{0, 1\}} \text{Opt}(\pi_z, B^*, 1) + (0.5 + \rho) \cdot \max_{z \in \{0, 1\}} \text{Opt}(\pi_z, B^*, 1)
  \end{align*}

- If $r$ is a leaf labeled with “0”, then
  \begin{align*}
  \text{Opt}(\pi, A^*, 0) &= 1 \\
  \text{Opt}(\pi, B^*, 1) &= 0
  \end{align*}

- If $r$ is a leaf labeled with “1”, then
  \begin{align*}
  \text{Opt}(\pi, A^*, 0) &= 0 \\
  \text{Opt}(\pi, B^*, 1) &= 1
  \end{align*}

### 3.2 Reduction to Deterministic Santha-Vazirani Extraction

The following theorem states that allowing interaction does not help in creating more secure protocols, in the sense that it does not allow us to generate a better protocol, in either $\text{Opt}(\pi, A^*, 0)$ or $\text{Opt}(\pi, B^*, 1)$, than protocols already existing without interaction.
Theorem 8. For every common-output two-party protocol \( \pi \) with oracle access to \( p \)-biased bits, there exists a common-output two-party protocol \( \pi' \) with oracle access to \( p \)-biased bits, with no inner nodes labeled by either “A, p” or “B, p”, and such that \( \text{Opt}(\pi', A^*, 0) \leq \text{Opt}(\pi, A^*, 0) \) and \( \text{Opt}(\pi', B^*, 1) \leq \text{Opt}(\pi, B^*, 1) \).

In other words, allowing interaction does not help in producing protocols where it is harder for \( A^* \) to cheat towards 0 or for \( B^* \) to cheat towards 1.

Proof. We show how given any protocol \( \pi \) with “A, p”/“B, p” turns, we can strictly reduce its number of “A, p”/“B, p” turns without increasing its cheating probabilities \( \text{Opt}(\pi, A^*, 0) \) and \( \text{Opt}(\pi, B^*, 1) \). In essence, we show that for every inner node labeled with “A, p”/“B, p” there exists a child such that replacing the subtree rooted at that node with the subtree rooted at its child results a protocol that is only harder to cheat in, for both \( A^* \) towards 0 and \( B^* \) towards 1. In more detail: First, we pick some arbitrary inner node of \( \pi \) labeled with either “A, p” or “B, p”. Denote this node by \( N \), and its left and right children by \( N_0 \) and \( N_1 \), respectively. If \( N \) is labeled by “A, p” we choose \( z := \arg\min_{b \in \{0,1\}} \text{Opt}(N_b, A^*, 0) \), otherwise choose \( z := \arg\min_{b \in \{0,1\}} \text{Opt}(N_b, A^*, 0) \). We take \( \pi \) and replace in it the subtree rooted at \( N \) with the subtree rooted at \( N_z \). Essentially, we fixed the bit sent at node \( N \) to always be \( z \), instead of letting \( A/B \) choose it. We make two observations:

1. Both \( \text{Opt}(N_z, A^*, 0) \leq \text{Opt}(N, A^*, 0) \) and \( \text{Opt}(N_z, B^*, 1) \leq \text{Opt}(N, B^*, 1) \).

   To see this, assume w.l.o.g that \( N \) is labeled with “A, p” (symmetrical argument for “B, p”). We have that \( \text{Opt}(N, A^*, 0) = \max_{b \in \{0,1\}} \text{Opt}(N_b, A^*, 0) \) and in particular \( \text{Opt}(N, A^*, 0) \geq \text{Opt}(N_z, A^*, 0) \). Also, since we have that
   \[
   \text{Opt}(N, B^*, 1) = \mathbb{E}_{b \sim \text{Ber}(p)} \left[ \text{Opt}(N_b, B^*, 1) \right]
   \]
   and we chose \( z := \arg\min_{b \in \{0,1\}} \text{Opt}(N_b, B^*, 1) \) in case \( N \) is labeled with “A, p”, then \( \text{Opt}(N, B^*, 1) \geq \text{Opt}(N_z, B^*, 1) \).

   In other words, at \( N_z \) it is both harder for \( A^* \) to cheat towards 0 and for \( B^* \) to cheat towards 1.

2. Let \( \pi \) and \( T \) be protocols, \( N \) be some node of \( \pi \), and \( \pi' \) be the protocol resulted by replacing in \( \pi \) the subtree rooted at \( N \) with \( T \). If \( \text{Opt}(T, A^*, 0) \leq \text{Opt}(N, A^*, 0) \) then \( \text{Opt}(\pi', A^*, 0) \leq \text{Opt}(\pi, A^*, 0) \) and similarly if \( \text{Opt}(T, B^*, 1) \leq \text{Opt}(N, B^*, 1) \) then \( \text{Opt}(\pi', B^*, 1) \leq \text{Opt}(\pi, B^*, 1) \). The reason for this is that the value \( \text{Opt}(R, A^*, 0) \) of an inner node \( R \), for all three operations (“A, p”, “B, p”, “O”), is a monotone function of the values \( \text{Opt}(R_0, A^*, 0), \text{Opt}(R_1, A^*, 0) \) of its children. By not increasing the \( (A^*, 0) \)-value of some node, you cannot increase the \( (A^*, 0) \)-value of its father, which in turn will not increase the \( (A^*, 0) \)-value of its father and so on.

   In other words, by taking a protocol and replacing the sub-protocol run at some partial transcript with another sub-protocol where it is not easier for \( A^*/B^* \) to cheat towards 0/1, we resulf a protocol where it is not easier for \( A^*/B^* \) to cheat towards 0/1.

Combining these observations, we reach the conclusion that by taking a protocol and repeatedly getting rid of its “A, p”/“B, p” nodes by replacing the subtree rooted at them with the subtree rooted at a correctly chosen child of theirs, we can get rid of all the “A, p”/“B, p” turns without increasing the cheating probabilities of \( A^* \) towards 0 and of \( B^* \) towards 1.

Definition 9 (SV Source). For \( 0 \leq \rho \leq 0.5 \), a source \( X = X_1, \ldots, X_n \) of length \( n \) (A random variable taking values in \( \{0,1\}^n \)) is a Santha-Vazirani (SV) source with bias \( \rho \) if for every \( i \in [n] \) and every \( x_1, \ldots, x_{i-1} \in \{0,1\} \), the bias of \( X_i \) conditioned on \( X_i = x_1, \ldots, X_{i-1} = x_{i-1} \) is at most \( \rho \). That is,
\[
|\mathbb{E}[X_i | X_1 = x_1, \ldots, X_{i-1} = x_{i-1}] - 0.5| \leq \rho.
\]
Theorem 10 ([15], [14]). For every function $f : \{0,1\}^n \to \{0,1\}$ and every $0 \leq \rho \leq 0.5$ there exists an SV source $X = X_1, \ldots, X_n$ of length $n$ and bias $\rho$ such that $f(X)$ has bias at least $\rho$.

We remark that this version of the statement is taken from Reingold, Vadhan and Wigderson [14], and that differently from them we refer to the bias as the distance from 0.5 and not double that amount.

The following theorem implies that there are no non-trivial oblivious coin-tossing amplifiers comprised solely of oracle calls.

Theorem 11. For every common-output two-party protocol $\pi$ with oracle access to $\rho$-biased bits and no inner nodes labeled by either “$A, p$” or “$B, p$”, either $\text{Opt}(\pi, A^*, 0) \geq 0.5 + \rho$ or $\text{Opt}(\pi, B^*, 1) \geq 0.5 + \rho$

In fact, in a protocol with no “$A, p$”/“$B, p$” turns there is no longer a difference between $A$ and $B$ so either $\text{Opt}(\pi, A^*, 0) = \text{Opt}(\pi, B^*, 0) \geq 0.5 + \rho$ or $\text{Opt}(\pi, A^*, 1) = \text{Opt}(\pi, B^*, 1) \geq 0.5 + \rho$

Proof. Let $n$ be an upper bound on the number of oracle calls made by $\pi$ in any execution. We can think w.l.o.g of $\pi$ as always making exactly $n$ oracle calls, with results denoted by $o_1, \ldots, o_n$, and then outputting $f(o_1, \ldots, o_n)$ for some function $f$. The impossibility result of deterministic extraction from Santha-Vazirani sources, Theorem 10, guarantees that there exists an SV source $X = X_1, \ldots, X_n$ of length $n$ and bias $\rho$ such that $f(X)$ has bias at least $\rho$. Therefore, if the malicious party can make sure the oracle calls’ output distribution is $X$, they can succeed in biasing the output of $\pi$ by at least $\rho$. (If it is towards 0 then $\text{Opt}(\pi, A^*, 0) \geq 0.5 + \rho$ and if it is towards 1 then $\text{Opt}(\pi, B^*, 1) \geq 0.5 + \rho$). The malicious party can make sure the oracle calls’ output distribution is $X$ by doing it bit-by-bit: After $0 \leq i \leq n-1$ calls with results $x_1, \ldots, x_i$ they ask the next oracle call to be distributed according to $X_{i+1} | X_1 = x_1, \ldots, X_i = x_i$, and their request from the $\rho$-biased bit oracle is legal by the definition of SV sources with bias $\rho$. ▶

Combining Theorem 8 and Theorem 11, Theorem 7 follows.

4 A More General Lower Bound

In this section, we give a direct proof by induction which gives some insight on the possible relations between $\text{Opt}(\pi, A^*, 0)$ and $\text{Opt}(\pi, B^*, 1)$ and the trade-offs we can get between them.

We correspond every protocol with a point on the plane using $\text{Opt}(\pi, A^*, 0)$ as the $x$-coordinate and $\text{Opt}(\pi, B^*, 1)$ as the $y$-coordinate. Our main theorem translates into showing that all protocol points lie outside or on the axis-aligned square with boundaries $x = 0.5 + \rho, x = 0$ and $y = 0.5 + \rho, y = 0$, but still inside of the first (i.e., $(+, +)$) quadrant (the second part is obvious from the definition). The area outside the square (but still inside the first quadrant) is not closed under the oracle-call operation (defined later), and thus the naïve induction attempt fails. Instead, we will strengthen the induction hypothesis into showing that all points lie above $f := \min \left(1 - \frac{0.5 + \rho}{0.5 + \rho}, \frac{0.5 + \rho}{0.5 + \rho} - \frac{0.5 + \rho}{0.5 + \rho} \cdot x \right)$, which is both closed under all operations (now the induction works) and lies above the square (so it implies what we want, and more). See Figure 2 for a graphic representation of the square and $f$. ▶
Theorem 12. For every common-output two-party protocol \( \pi \) with oracle access to \( \rho \)-biased bits, we have that

\[
\text{Opt}(\pi, A^*, 1) \geq \min(1 - \frac{0.5 - \rho}{2\rho + 0.5}\cdot\text{Opt}(\pi, A^*, 0), \frac{0.5 + \rho}{2\rho - 0.5}\cdot\text{Opt}(\pi, A^*, 0))
\]

Equivalently, if we take \( \ell_1 \) to be the line between \((0, 1)\) and \((0.5 + \rho, 0.5 + \rho)\)

\[
\text{so } \ell_1 \text{ is } y = 1 - \frac{0.5 - \rho}{0.5 + \rho} \cdot x
\]

and \( \ell_2 \) to be the line between \((0.5 + \rho, 0.5 + \rho)\) and \((1, 0)\)

\[
\text{so } \ell_2 \text{ is } y = \frac{0.5 + \rho}{0.5 - \rho} \cdot x
\]

then the point \((\text{Opt}(\pi, A^*, 0), \text{Opt}(\pi, B^*, 1))\) lies above (not strictly) at least one of \( \ell_1, \ell_2 \).

Corollary 13. Theorem 7 follows.

Proof. Since both \( \ell_1 \) and \( \ell_2 \) are strictly decreasing (negative slope) and pass through the point \((0.5 + \rho, 0.5 + \rho)\), then \( x < 0.5 + \rho \) implies \( \ell_1(x), \ell_2(x) > 0.5 + \rho \). Thus \( \text{Opt}(\pi, A^*, 0) < 0.5 + \rho \)

implies \( \text{Opt}(\pi, B^*, 1) \geq \min(\ell_1(\text{Opt}(\pi, A^*, 0)), \ell_2(\text{Opt}(\pi, A^*, 0))) > 0.5 + \rho \)

Leaves labeled with “0” lie on \( \ell_2 \) and leaves labeled with “1” lie on \( \ell_1 \).

If \( \pi \) is not a leaf, denote its root by \( r \), by \( \pi_0 \) and \( \pi_1 \) the protocols rooted at the left and right children of \( r \), and let \( f := \min(\ell_1, \ell_2) \). Also, denote

\[
\begin{align*}
x_0, y_0 &= \text{Opt}(\pi_0, A^*, 0), \text{Opt}(\pi_0, B^*, 1) \\
x_1, y_1 &= \text{Opt}(\pi_1, A^*, 0), \text{Opt}(\pi_1, B^*, 1) \\
x', y' &= \text{Opt}(\pi, A^*, 0), \text{Opt}(\pi, B^*, 1)
\end{align*}
\]

We assume (induction hypothesis) that \( y_0 \geq f(x_0), y_1 \geq f(x_1) \) and want to show that

\( y' \geq f(x') \). There are three types of operations to consider:

- If \( r \) is labeled with “A, p”

\[
\begin{pmatrix} x' \\ y' \end{pmatrix} = \begin{pmatrix} \max(x_0, x_1) \\ (1 - p) \cdot y_0 + p \cdot y_1 \end{pmatrix}
\]

- If \( r \) is labeled with “B, p”

\[
\begin{pmatrix} x' \\ y' \end{pmatrix} = \begin{pmatrix} (1 - p) \cdot x_0 + p \cdot x_1 \\ \max(y_0, y_1) \end{pmatrix}
\]

- If \( r \) is labeled with “O”

\[
\begin{pmatrix} x' \\ y' \end{pmatrix} = \begin{pmatrix} (0.5 - \rho) \cdot \min(x_0, x_1) + (0.5 + \rho) \cdot \max(x_0, x_1) \\ (0.5 - \rho) \cdot \min(y_0, y_1) + (0.5 + \rho) \cdot \max(y_0, y_1) \end{pmatrix}
\]

We may assume without loss of generality that the points \((x_0, y_0), (x_1, y_1)\) lie on \( f \) and not strictly above it, namely, that \( y_0 = f(x_0), y_1 = f(x_1) \). This is true because \( y' \) is non-decreasing in \( y_0, y_1 \) in all three operations, so if \( y' \geq f(x') \) for \( y_0 = f(x_0), y_1 = f(x_1) \), then we also have that \( y' \geq f(x') \) for any \( y_0 \geq f(x_0), y_1 \geq f(x_1) \).

(Note that \( f(x') \) is unaffected by changes to \( y_0, y_1 \))

Let \((x_0, y_0), (x_1, y_1)\) be any two points on \( f \). Since \( \ell_1 \) and \( \ell_2 \) are decreasing, \( f \) is also decreasing. Let \( i = \arg \max_{z \in (0, 1)} x_z \), so we have that \( x_i > x_{1-i} \) and \( y_i < y_{1-i} \).
The first operation gives us \((x', y') = (x_1, (1 - p) \cdot y_0 + p \cdot y_1)\), and since
\[
y' = (1 - p) \cdot y_0 + p \cdot y_1 > y_i = \min_{z \in \{0, 1\}} y_z
\]
for every \(0 < p < 1\), we have \(y' > y_i = f(x) = f(x')\).

The second operation gives us \((x', y') = ((1 - p) \cdot x_0 + p \cdot x_1, y_{1-i})\), and since
\[
x' = (1 - p) \cdot x_0 + p \cdot x_1 > x_{1-i} = \min_{z \in \{0, 1\}} x_z
\]
for every \(0 < p < 1\), we have \(f(x') < f(x_{1-i}) = y_{1-i} = y'\).

The third operation gives us
\[
\begin{pmatrix} x' \\ y' \end{pmatrix} = \begin{pmatrix} (0.5 - \rho) \cdot x_{1-i} + (0.5 + \rho) \cdot x_1 \\ (0.5 - \rho) \cdot y_i + (0.5 + \rho) \cdot y_{1-i} \end{pmatrix}
\]
We separate into two cases:

1. Both \((x_0, y_0)\) and \((x_1, y_1)\) lie on either \(\ell_1\) or \(\ell_2\). Denote this common line by \(\ell\). Notice that every convex combination of \((x_0, y_0), (x_1, y_1)\) also lies on \(\ell\), and in particular
\[
\begin{pmatrix} x_{0.5+p} \\ y_{0.5+p} \end{pmatrix} = \begin{pmatrix} (0.5 - \rho) \cdot x_0 + (0.5 + \rho) \cdot x_1 \\ (0.5 - \rho) \cdot y_0 + (0.5 + \rho) \cdot y_1 \end{pmatrix}
\]
lies on \(\ell\). Since \(x_{1-i} = \min(x_0, x_1)\) and \(x_i = \max(x_0, x_1)\), we have that
\[
x' = (0.5 - \rho) \cdot x_{1-i} + (0.5 + \rho) \cdot x_i \geq (0.5 - \rho) \cdot x_0 + (0.5 + \rho) \cdot x_1 = x_{0.5+p}
\]
Since \(y_i = \min(y_0, y_1)\) and \(y_{1-i} = \max(y_0, y_1)\), we have that
\[
y' = (0.5 - \rho) \cdot y_i + (0.5 + \rho) \cdot y_{1-i} \geq (0.5 - \rho) \cdot y_0 + (0.5 + \rho) \cdot y_1 = y_{0.5+p}
\]
Overall, we conclude that \(f(x') \leq \ell(x') \leq \ell(x_{0.5+p}) = y_{0.5+p} \leq y'\).

2. One of \((x_0, y_0), (x_1, y_1)\) lies on \(\ell_1\) and the other lies on \(\ell_2\). The lines \(\ell_1, \ell_2\) intersect at \((0.5 + \rho, 0.5 + \rho)\) and the slope of \(\ell_2\) is steeper, so we can conclude that
\[
f(x) = \min(\ell_1, \ell_2) = \begin{cases} 
\ell_1(x) & x \leq 0.5 + \rho \\
\ell_2(x) & x > 0.5 + \rho
\end{cases}
\]
and that \(x_{1-i} < 0.5 + \rho < x_i\). We have that
\[
y' = (0.5 - \rho) \cdot y_i + (0.5 + \rho) \cdot y_{1-i} = (0.5 - \rho) \cdot \ell_2(x_i) + (0.5 + \rho) \cdot \ell_1(x_{1-i}) =
\begin{align*}
&= (0.5 - \rho) \cdot \left( (0.5 + \rho) \cdot x_i \right) + (0.5 + \rho) \cdot \left( 1 - \frac{0.5 - \rho}{0.5 + \rho} \cdot x_{1-i} \right) \\
&= 0.5 + \rho - (0.5 + \rho) \cdot x_i + 0.5 + \rho - (0.5 - \rho) \cdot x_{1-i} \\
&= 1 + 2\rho - ((0.5 + \rho) \cdot x_i + (0.5 - \rho) \cdot x_{1-i}) = 1 + 2\rho - x'
\end{align*}
\]
Therefore, the point \((x', y')\) lies on the line \(y = 1 + 2\rho - x\) which we will denote by \(\ell\). Notice that \(\ell\) also passes through \((0.5 + \rho, 0.5 + \rho)\), and that the slope of \(\ell\) is steeper than that of \(\ell_1\) but more moderate than that of \(\ell_2\), and thus \(\ell_1 \leq \ell \leq \ell_2\) for \(x \leq 0.5 + \rho\), and \(\ell_2 \leq \ell\) for \(x \geq 0.5 + \rho\), and overall \(f(x) \leq \ell(x)\). This implies that \(f(x') \leq \ell(x') = y'\). □

Abstract

We give a new proof of the “transfer theorem” underlying adaptive data analysis: that any mechanism for answering adaptively chosen statistical queries that is differentially private and sample-accurate is also accurate out-of-sample. Our new proof is elementary and gives structural insights that we expect will be useful elsewhere. We show: 1) that differential privacy ensures that the expectation of any query on the conditional distribution on datasets induced by the transcript of the interaction is close to its expectation on the data distribution, and 2) sample accuracy on its own ensures that any query answer produced by the mechanism is close to the expectation of the query on the conditional distribution. This second claim follows from a thought experiment in which we imagine that the dataset is resampled from the conditional distribution after the mechanism has committed to its answers. The transfer theorem then follows by summing these two bounds, and in particular, avoids the “monitor argument” used to derive high probability bounds in prior work.

An upshot of our new proof technique is that the concrete bounds we obtain are substantially better than the best previously known bounds, even though the improvements are in the constants, rather than the asymptotics (which are known to be tight). As we show, our new bounds outperform the naive “sample-splitting” baseline at dramatically smaller dataset sizes compared to the previous state of the art, bringing techniques from this literature closer to practicality.

1 Introduction

Many data analysis pipelines are adaptive: the choice of which analysis to run next depends on the outcome of previous analyses. Common examples include variable selection for regression problems and hyper-parameter optimization in large-scale machine learning problems: in both cases, common practice involves repeatedly evaluating a series of models on the same dataset. Unfortunately, this kind of adaptive re-use of data invalidates many traditional methods of avoiding over-fitting and false discovery, and has been blamed in part for the recent flood of non-reproducible findings in the empirical sciences [14].

There is a simple way around this problem: don’t re-use data. This idea suggests a baseline called data splitting: to perform $k$ analyses on a dataset, randomly partition the dataset into $k$ disjoint parts, and perform each analysis on a fresh part. The standard “holdout method” is the special case of $k = 2$. Unfortunately, this natural baseline makes poor use of data: in particular, the data requirements of this method grow linearly with the number of analyses $k$ to be performed.

A recent literature starting with Dwork et al. [6] shows how to give a significant asymptotic improvement over this baseline via a connection to differential privacy: rather than computing and reporting exact sample quantities, perturb these quantities with noise. This line of work established a powerful transfer theorem, that informally says that any analysis that is simultaneously differentially private and accurate in-sample will also be accurate out-of-sample. The best analysis of this technique shows that for a broad class of analyses and a target accuracy goal, the data requirements grow only with $\sqrt{k}$ - a quadratic improvement over the baseline [1]. Moreover, it is known that in the worst case, this cannot be improved asymptotically [15, 23]. Unfortunately, thus far this literature has had little impact on practice. One major reason for this is that although the more sophisticated techniques from this literature give asymptotic improvements over the sample-splitting baseline, the concrete bounds do not actually improve on the baseline until the dataset is enormous. This remains true even after optimizing the constants that arise from the arguments of Dwork et al. [6] or Bassily et al. [1], and appears to be a fundamental limitation of their proof techniques [20].

In this paper, we give a new proof of the transfer theorem connecting differential privacy and in-sample accuracy to out-of-sample accuracy. Our proof is based on a simple insight that arises from imagining a “resampling” experiment, and in particular yields an improved concrete bound that beats the sample-splitting baseline at dramatically smaller data set sizes $n$ compared to prior work. In fact, at reasonable dataset sizes, the magnitude of the improvement arising from our new theorem is significantly larger than the improvement between the bounds of Bassily et al. [1] and Dwork et al. [6]: see Figure 1.
Figure 1 A comparison of the number of adaptive linear queries that can be answered using the Gaussian mechanism as analyzed by our transfer theorem (Theorem 9), the numerically optimized variant of the bound from Bassily et al. [1] (Optimized BNSSSU) as derived in [20], and the original transfer theorem from Dwork et al. [6] (DFHPRR). We plot for each dataset size $n$, the number of queries $k$ that can be answered while guaranteeing confidence intervals around the answer that have width $\alpha = 0.1$ and uniform coverage probability $1 - \beta = 0.95$. We compare with the naive sample splitting baseline that simply splits the dataset into $k$ pieces and answers each query with the empirical answer on a fresh piece.

1.1 Proof Techniques

Prior Work

Consider an unknown data distribution $P$ over a data-domain $\mathcal{X}$, and a dataset $S \sim P^n$ consisting of $n$ i.i.d. draws from $P$. It is a folklore observation (attributed to Frank McSherry) that if a predicate $q : \mathcal{X} \to [0, 1]$ is selected by an $\epsilon$-differentially private algorithm $M$ acting on $S$, then it will generalize in expectation (or have low bias) in the sense that $|\mathbb{E}_{q \sim M(S)}[\mathbb{E}_{x \sim P}[q(x)]] - \frac{1}{n} \sum_{x \in S} q(x)| \approx \epsilon$. But bounds on bias are not enough to yield tight confidence intervals, and so prior work has focused on strengthening the above observation into a high probability bound. For small $\epsilon$, the optimal bound has the asymptotic form: $\Pr_{q \sim M(S)}[|\mathbb{E}_{x \sim P}[q(x)] - \frac{1}{n} \sum_{x \in S} q(x)| \geq \epsilon] \leq e^{-\Theta(\epsilon^2 n)}$ [1]. Note that this bound does not refer to the estimated answers supplied to the data analyst: it says only that a differentially private data analyst is unlikely to be able to find a query whose average value on the dataset differs substantially from its expectation. Pairing this with a simultaneous high probability bound on the in-sample accuracy of a mechanism – that it supplies answers $a$ such that with high probability the empirical error is small: $\Pr_{a \sim M(S)}[|a - \frac{1}{n} \sum_{x \in S} q(x)| \geq \alpha] \leq \beta$ – yields a bound on out-of-sample accuracy via the triangle inequality.

Dwork et al. [6] proved their high probability bound via a direct computation on the moments of empirical query values, but this technique was unable to achieve the optimal rate. Bassily et al. [1] proved a bound with the optimal rate by introducing the ingenious monitor technique. This important technique has subsequently found other uses [24, 19, 13], but is a heavy hammer that seems unavoidably to yield large constant overhead, even after numeric optimization [20].
Our Approach

We take a fundamentally different approach by directly providing high probability bounds on the out-of-sample accuracy $|a - E_{x \sim x}[q(x)]|$ of mechanisms that are both differentially private and accurate in-sample. Our elementary approach is motivated by the following thought experiment: in actuality, the dataset $S$ is fixed before any interaction with $M$ begins. However, imagine that after the entire interaction with $M$ is complete, the dataset $S$ is resampled from the conditional distribution $Q$ on datasets conditioned on the output of $M$. This thought experiment doesn’t alter the joint distribution on datasets and outputs, and so any in-sample accuracy guarantees that $M$ has continue to hold under this hypothetical re-sampling experiment. But because the empirical value of the queries on the re-sampled dataset are likely to be close to their expected value over the conditional distribution $Q$, the only way the mechanism can promise to be sample-accurate with high probability is if it provides answers that are close to their expected value over the conditional distribution with high probability.

This focuses attention on the conditional distribution on datasets induced by differentially private transcripts. But it is not hard to show that a consequence of differential privacy is that the conditional expectation of any query must be close to its expectation over the data distribution with high probability. In contrast to prior work, this argument directly leverages high-probability in-sample accuracy guarantees of a private mechanism to derive high-probability out-of-sample guarantees, without the need for additional machinery like the monitor argument of Bassily et al. [1].

1.2 Further Related Work

The study of “adaptive data analysis” was initiated by Dwork et al. [6, 5] who provided upper bounds via a connection to differential privacy, and Hardt and Ullman [15] who provided lower bounds via a connection to fingerprinting codes. The upper bounds were subsequently strengthened by Bassily et al. [1], and the lower bounds by Steinke and Ullman [23] to be (essentially) matching, asymptotically. The upper bounds were optimized by Rogers et al. [20], which we use in our comparisons. Subsequent work proved transfer theorems related to other quantities like description length bounds [4] and compression schemes [3], and expanded the types of analyses whose generalization properties we could reason about via a connection to a quantity called approximate max information [4, 21]. Feldman and Steinke [11, 12] give improved methods that could guarantee out-of-sample accuracy bounds that depended on query variance. Neel and Roth [17] extend the transfer theorems from this literature to the related problem of adaptive data gathering, which was identified by Nie et al. [18]. Ligett and Shenfeld [16] give an algorithmic stability notion they call local statistical stability (also defined with respect to a conditional data distribution) that they show asymptotically characterizes the ability of mechanisms to offer high probability out-of-sample generalization guarantees for linear queries. A related line of work initiated by Russo and Zou [22] and extended by Xu and Raginsky [25] starts with weaker assumptions on the mechanism (mutual information bounds), and derives weaker conclusions (bounds on bias, rather than high probability generalization guarantees).

A more recent line of work aims at mitigating the fact that the worst-case bounds deriving from transfer theorems do not give non-trivial guarantees on reasonably sized datasets. Zrnic and Hardt [26] show that better bounds can be derived under the assumption that the data analyst is restricted in various ways to not be fully adaptive. Feldman et al. [10] show that overfitting by a classifier because of test-set re-use is mitigated in multi-label prediction.
problems, compared to binary prediction problems. Rogers et al. [20] give a method for certifying the correctness of heuristically guessed confidence intervals, which they show often outperform the theoretical guarantees by orders of magnitude.

Finally, Elder [9, 8] proposes a Bayesian reformulation of the adaptive data analysis problem. In the model of [9], the data distribution \( P \) is assumed to itself be drawn from a prior that is commonly known to the data analyst and mechanism. In contrast, we work in the standard adversarial setting originally introduced by Dwork et al. [6] in which the mechanism must offer guarantees for worst case data distributions and analysts, and focus our attention on conditional distributions purely as a proof technique.

## 2 Preliminaries

Let \( X \) be an abstract data domain, and let \( P \) be an arbitrary distribution over \( X \). A dataset of size \( n \) is a collection of \( n \) data records: \( S = \{S_i\}_{i=1}^{n} \in X^n \). We study datasets sampled \( i.i.d. \) from \( P: S \sim P^n \). We will write \( S \) to denote the random variable and \( x \) for realizations of this random variable. A linear query is a function \( q: X^* \rightarrow [0, 1] \) that takes the following empirical average form when acting on a data set \( S \in X^n \):

\[
q(S) = \frac{1}{n} \sum_{i=1}^{n} q(S_i).
\]

We will be interested in estimating the expectations of linear queries over \( P \). Abusing notation, given a distribution \( D \) over datasets, we write \( q(D) \) to denote the expectation of \( q \) over datasets drawn from \( D \), and write \( S_i \sim S \) to denote a datapoint sampled uniformly at random from a dataset \( S \). Note that for linear queries we have:

\[
q(D) = \mathbb{E}_{S \sim D}[q(S)] = \mathbb{E}_{S \sim D, S_i \sim S}[q(S_i)]
\]

We note that for linear queries, when the dataset distribution \( D = P^n \), we have \( q(P^n) = \mathbb{E}_{x \sim P}[q(x)] \), which we write as \( q(P) \) when the notation is clear from context. However, the more general definition will be useful because we will need to evaluate the expectation of \( q \) over other (non-product) distributions over datasets in our arguments, and we will generalize beyond linear queries in Appendices A.1 and A.2.

Given a family of queries \( Q \), a statistical estimator is a (possibly stateful) randomized algorithm \( M: X^n \times Q^* \rightarrow \mathbb{R}^* \) parameterized by a dataset \( S \) that interactively takes as input a stream of queries \( q_i \in Q \), and provides answers \( a_i \in \mathbb{R} \). An analyst is an arbitrary randomized algorithm \( A: \mathbb{R}^* \rightarrow Q^* \) that generates a stream of queries and receives a stream of answers (which can inform the next queries it generates). When an analyst interacts with a statistical estimator, they generate a transcript of their interaction \( \pi \in \Pi \) where \( \Pi = (Q \times \mathbb{R})^* \) is the space of all transcripts. Throughout we write \( \Pi \) to denote the transcript’s random variable and \( \pi \) for its realizations.

The interaction is summarized in Algorithm 1, and we write \( \text{Interact}(M, A; S) \) to refer to it. When \( M \) and \( A \) are clear from context, we will abbreviate this notation and write simply \( I(S) \). When we refer to an indexed query \( q_j \), this is implicitly a function of the transcript \( \pi \). Given a transcript \( \pi \in \Pi \), write \( Q_\pi \) to denote the conditional distribution on datasets conditional on \( \Pi = \pi \): \( Q_\pi = (P^n)|\text{Interact}(M, A; S) = \pi \). Note that \( Q_\pi \) will no longer generally be a product distribution. We will be interested in evaluating uniform accuracy bounds, which control the worst-case error over all queries:
Algorithm 1  Interact($M, \mathcal{A}; S$): An Analyst Interacting with a Statistical Estimator to Generate a Transcript.

**Input**: A statistical estimator $M$, an analyst $\mathcal{A}$, and a dataset $S \in \mathcal{X}^n$.

1. for $t = 1$ to $k$
   2. The analyst generates a query $q_t \leftarrow \mathcal{A}(a_1, \ldots, a_{t-1})$ and sends it to the statistical estimator;
   3. The statistical estimator generates an answer $a_t \leftarrow M(S; q_t)$;
4. return $\Pi = ((q_1, a_1), \ldots, (q_k, a_k))$.

**Definition 1 (Accuracy)**. $M$ satisfies $(\alpha, \beta)$-sample accuracy if for every data analyst $\mathcal{A}$ and every data distribution $\mathcal{P}$, 

$$
\Pr_{S \sim \mathcal{P}^n, \Pi \sim \text{Interact}(M, \mathcal{A}, S)} \left[ \max_j |q_j(S) - a_j| \geq \alpha \right] \leq \beta.
$$

We say $M$ satisfies $(\alpha, \beta)$-distributional accuracy if for every data analyst $\mathcal{A}$ and every data distribution $\mathcal{P}$, 

$$
\Pr_{S \sim \mathcal{P}^n, \Pi \sim \text{Interact}(M, \mathcal{A}, S)} \left[ \max_j |q_j(\mathcal{P}^n) - a_j| \geq \alpha \right] \leq \beta.
$$

We will be interested in interactions $I$ that satisfy differential privacy.

**Definition 2 (Differential Privacy [7])**. Two datasets $S, S' \in \mathcal{X}^n$ are neighbors if they differ in at most one coordinate. An interaction $\text{Interact}(M, \cdot, \cdot)$ satisfies $(\epsilon, \delta)$-differential privacy if for all data analysts $\mathcal{A}$, pairs of neighboring datasets $S, S' \in \mathcal{X}^n$, and for all events $E \subseteq \Pi$: 

$$
\Pr_{\Pi \sim \text{Interact}(M, \mathcal{A}, S)} \left[ \Pi \in E \right] \leq e^{\epsilon} \cdot \Pr_{\Pi \sim \text{Interact}(M, \mathcal{A}, S')} \left[ \Pi \in E \right] + \delta.
$$

If $\text{Interact}(M, \cdot, \cdot)$ satisfies $(\epsilon, \delta)$-differential privacy, we will also say that $M$ satisfies $(\epsilon, \delta)$-differential privacy.

We introduce a novel quantity that will be crucial to our argument: it captures the effect of the transcript on the change in the expectation of a query contained in the transcript.

**Definition 3.** An interaction $\text{Interact}(M, \mathcal{A}; \cdot)$ is called $(\epsilon, \delta)$-posterior stable if for every data distribution $\mathcal{P}$:

$$
\Pr_{S \sim \mathcal{P}^n, \Pi \sim \text{Interact}(M, \mathcal{A}, S)} \left[ \max_j |q_j(\mathcal{P}^n) - q_j(\mathcal{Q}_\Pi)| \geq \epsilon \right] \leq \delta.
$$

### 3 An Elementary Proof of the Transfer Theorem

#### 3.1 A General Transfer Theorem

In this section we prove a general transfer theorem for sample accurate mechanisms with low posterior stability. In Section 3.2 we prove that differentially private mechanisms have low posterior stability.

**Theorem 4 (General Transfer Theorem)**. Suppose that $\text{Interact}(M, \mathcal{A}; \cdot)$ is an $(\alpha, \beta)$-sample accurate, $(\epsilon, \delta)$-posterior stable interaction. Then for every $c > 0$ it also satisfies:

$$
\Pr_{S \sim \mathcal{P}^n, \Pi \sim \text{Interact}(M, \mathcal{A}, S)} \left[ \max_j |a_j - q_j(\mathcal{P})| > \alpha + c + \epsilon \right] \leq \frac{\beta}{c} + \delta
$$

i.e. it is $(\alpha', \beta')$-distributionally accurate for $\alpha' = \alpha + c + \epsilon$ and $\beta' = \frac{\beta}{c} + \delta$. 

The theorem follows easily from a change in perspective driven by an elementary observation. Imagine that after the interaction is run and results in a transcript \( \pi \), the dataset \( S \) is resampled from its conditional distribution \( Q_\pi \). This does not change the joint distribution on datasets and transcripts. This simple claim is formalized below: its elementary proof appears in Appendix B.

**Lemma 5 (Resampling Lemma).** Let \( E \subseteq \mathcal{X}^n \times \mathcal{Y} \) be any event. Then:

\[
\Pr_{S \sim P^n, \Pi \sim I(S)} [(S, \Pi) \in E] = \Pr_{S' \sim P^n, \Pi \sim I(S'), S' \sim Q_\Pi} [(S', \Pi) \in E]
\]

The change in perspective suggested by the resampling lemma makes it easy to see why the following must be true: any sample-accurate mechanism must in fact be accurate with respect to the conditional distribution it induces. This is because if it can first commit to answers, and guarantee that they are sample-accurate after the dataset is resampled from the conditional, the answers it committed to must have been close to the conditional means, because it is likely that the empirical answers on the resampled dataset will be. This argument is generic and does not use differential privacy.

**Lemma 6.** Suppose that \( M \) is \((\alpha, \beta)\)-sample accurate. Then for every \( c > 0 \) it also satisfies:

\[
\Pr_{S \sim P^n, \Pi \sim \text{Interact}(M, A; S)} \left[ \max_j |a_j - q_j(\Pi_S)| > \alpha + c \right] \leq \frac{\beta}{c}
\]

**Proof.** Denote by \( j^*(\pi) = \arg \max_j |a_j - q_j(\Pi_S)| \). Given \( \alpha \geq 0 \) and \( c > 0 \), and expanding the definition of \( q_j^*(\Pi)(\Pi_S) \) we get:

\[
\Pr_{S \sim P^n, \Pi \sim I(S)} \left[ a_{j^*(\Pi)} - q_{j^*(\Pi)}(\Pi_S) > \alpha + c \right]
\]

\[
= \Pr_{S \sim P^n, \Pi \sim I(S)} \left[ \mathbb{E}_{S' \sim Q_\Pi} \left[ a_{j^*(\Pi)} - q_{j^*(\Pi)}(S') - \alpha \right] > c \right]
\]

\[
\leq \Pr_{S \sim P^n, \Pi \sim I(S)} \left[ \mathbb{E}_{S' \sim Q_\Pi} \left[ \max \{ a_{j^*(\Pi)} - q_{j^*(\Pi)}(S') - \alpha, 0 \} \right] > c \right]
\]

\[
\leq \frac{1}{c} \mathbb{E}_{S \sim P^n, \Pi \sim I(S)} \left[ \mathbb{E}_{S' \sim Q_\Pi} \left[ \max \{ a_{j^*(\Pi)} - q_{j^*(\Pi)}(S') - \alpha, 0 \} \right] \right]
\]

\[
\leq \mathbb{E}_{S \sim P^n, \Pi \sim I(S)} \Pr_{S' \sim Q_\Pi} \left[ a_{j^*(\Pi)} - q_{j^*(\Pi)}(S') > \alpha \right]
\]

\[
\leq \frac{1}{c} \Pr_{S \sim P^n, \Pi \sim I(S)} \left[ a_{j^*(\Pi)} - q_{j^*(\Pi)}(S) > \alpha \right]
\]

Here, inequality (1) follows from Markov’s inequality, inequality (2) follows from the fact that \( a_{j^*(\Pi)} - q_{j^*(\Pi)}(S') - \alpha \leq 1 \), and equality 3 follows from the Resampling Lemma (Lemma 5). Repeating this argument for \( q_{j^*(\Pi)}(\Pi_S) - a_{j^*(\Pi)} \) yields a symmetric bound, so by combining the two with the guarantee of \((\alpha, \beta)\)-sample accuracy we get,

\[
\Pr_{S \sim P^n, \Pi \sim I(S)} \left[ |a_{j^*(\Pi)} - q_{j^*(\Pi)}(\Pi_S)| > \alpha + c \right] \leq \frac{1}{c} \Pr_{S \sim P^n, \Pi \sim I(S)} \left[ |a_{j^*(\Pi)} - q_{j^*(\Pi)}(S)| > \alpha \right] \leq \frac{\beta}{c}
\]
Because sample accuracy implies accuracy with respect to the conditional distribution, together with a bound on posterior stability, the transfer theorem follows immediately:

**Proof of Theorem 4.** By the triangle inequality:

$$\max_i |a_i - q_j(\mathcal{P})| \leq \max_i |a_i - q_i(\mathcal{Q}_\Pi)| + \max_j |q_i(\mathcal{Q}_\Pi) - q_j(\mathcal{P})|.$$ 

Lemma 6 bounds the first term by $\alpha + c$ with probability $1 - \frac{\delta}{\epsilon}$ over $\Pi$, and the definition of posterior stability bounds the second term by $\epsilon$ with probability $1 - \delta$ over $\Pi$, which concludes the proof.

### 3.2 A Transfer Theorem for Differential Privacy

In this section we prove a transfer theorem for differentially private mechanisms by demonstrating that they have low posterior stability and applying our general transfer theorem.

We here show that differentially private mechanisms have low posterior stability for linear queries. In the Appendix we extend this argument to low-sensitivity and optimization queries.

**Lemma 7.** If $M$ is $(\epsilon, \delta)$-differentially private, then for any data distribution $\mathcal{P}$, any analyst $\mathcal{A}$, and any constant $c > 0$:

$$\Pr_{S \sim \mathcal{P}^n, \Pi \sim \text{Interact}(M, \mathcal{A}, S)} \left[ \max_j |q_j(\mathcal{Q}_\Pi) - q_j(\mathcal{P})| > (\epsilon' - 1) + 2c \right] \leq \frac{\delta}{c},$$

i.e. it is $(\epsilon', \delta')$-posterior stable for every data analyst $\mathcal{A}$, where $\epsilon' = \epsilon - 1 + 2c$ and $\delta' = \frac{\delta}{c}$.

**Proof.** Given a transcript $\pi \in \Pi$, let $j^*(\pi) \in \arg \max_j |q_j(\mathcal{Q}_\pi) - q_j(\mathcal{P})|$. Define for an $\alpha > 0$:

$$\Pi_\alpha = \{ \pi \in \Pi | q_j^*(\pi)(Q_\pi) - q_j^*(\pi)(P) > \alpha \}$$

$$X^+(\pi) = \left\{ x \in \mathcal{X} | \Pr_{S \sim \mathcal{Q}_\pi, S \sim S} [S_i = x] > \Pr_{S \sim P} [S_i = x] \right\}$$

$$B^+_{\alpha}(x) = \bigcup_{\pi \in \Pi_\alpha} (X^+(\pi) \times \{ \pi \})$$

$$\Pi^+_{\alpha}(x) = \{ \pi \in \Pi | (x, \pi) \in B^+_{\alpha} \}$$

Fix any $\alpha$. Suppose that $\Pr \left[ |q_j^*(\Pi)(\mathcal{Q}_\Pi) - q_j^*(\Pi)(\mathcal{P})| > \alpha \right] > \frac{\delta}{2c}$. We must have that either $\Pr \left[ q_j^*(\Pi)(\mathcal{Q}_\Pi) - q_j^*(\Pi)(\mathcal{P}) > \alpha \right] > \frac{\delta}{2c}$ or $\Pr \left[ q_j^*(\Pi)(\mathcal{P}) - q_j^*(\Pi)(Q_\Pi) > \alpha \right] > \frac{\delta}{2c}$. Without loss of generality, assume

$$\Pr \left[ q_j^*(\Pi)(\mathcal{Q}_\Pi) - q_j^*(\Pi)(\mathcal{P}) > \alpha \right] = \Pr \left[ \Pi \in \Pi_\alpha \right] > \frac{\delta}{2c}$$

(1)

Let $S_i$ be the random variable obtained by first sampling $S \sim \mathcal{P}^n$ and then sampling $S_i \in S$ uniformly at random. We compare the probability measure of $B^+_{\alpha}$ under the joint distribution on $S_i$ and $\Pi$ with its corresponding measure under the product distribution of $S_i$ and $\Pi$:
\[
\Pr_{(S, \Pi)} \left[ (S_i, \Pi) \in B^+_\alpha \right] - \Pr_{S_i \in \Pi} \left[ (S_i, \Pi) \in B^+_\alpha \right]
\]
\[
= \sum_{\pi \in \Pi} \Pr[\Pi = \pi] \sum_{x \in X^+(\pi)} (\Pr[S_i = x|\Pi = \pi] - \Pr[S_i = x])
\]
\[
\geq \sum_{\pi \in \Pi} \Pr[\Pi = \pi] \sum_{x \in X^+(\pi)} q_{j^*(\pi)}(x) (\Pr[S_i = x|\Pi = \pi] - \Pr[S_i = x])
\]
\[
\geq \sum_{\pi \in \Pi} \Pr[\Pi = \pi] \sum_{x \in X^+} q_{j^*(\pi)}(x) (\Pr[S_i = x|\Pi = \pi] - \Pr[S_i = x])
\]
\[
= \sum_{\pi \in \Pi} \Pr[\Pi = \pi] \left( q_{j^*(\pi)}(Q_x) - q_{j^*(\pi)}(\mathcal{P}) \right)
\]
\[
> \alpha \cdot \Pr[\Pi \in \Pi_u]
\]

On the other hand, using the definition of \((\epsilon, \delta)\)-differential privacy (See Lemma 21 for the elementary derivation of the first inequality):

\[
\Pr_{(S, \Pi)} \left[ (S_i, \Pi) \in B^+_\alpha \right] - \Pr_{S_i \in \Pi} \left[ (S_i, \Pi) \in B^+_\alpha \right]
\]
\[
= \sum_{x \in X} \Pr[S_i = x] \left( \Pr[\Pi \in \Pi_u^+(x)|S_i = x] - \Pr[\Pi \in \Pi_u^+(x)] \right)
\]
\[
\leq \sum_{x \in X} \Pr[S_i = x] \left( (\epsilon^\delta - 1) \Pr[\Pi \in \Pi_u^+(x)] + \delta \right)
\]
\[
= (\epsilon^\delta - 1) \Pr_{S_i \in \Pi} \left[ (S_i, \Pi) \in B^+_\alpha \right] + \delta
\]
\[
\leq (\epsilon^\delta - 1) \Pr[\Pi \in \Pi_u] + \delta
\]
\[
< (\epsilon^\delta - 1) \Pr[\Pi \in \Pi_u] + 2c \Pr[\Pi \in \Pi_u] \quad \text{(by Equation (1))}
\]
\[
= ((\epsilon^\delta - 1) + 2c) \cdot \Pr[\Pi \in \Pi_u]
\]

This is a contradiction for \(\alpha \geq (\epsilon^\delta - 1) + 2c\).

\begin{remark}
1. Since differential privacy is closed under post processing, this claim can be generalized beyond queries contained in the transcript to any query generated as function of the transcript.
2. In the case of \((\epsilon, 0)\)-differential privacy, choosing \(c = 0\), the claim holds for every query with probability 1.
\end{remark}

Combined with our general transfer theorem (Theorem 4), this directly yields a transfer theorem for differential privacy:

\begin{theorem}
(Transfer Theorem for \((\epsilon, \delta)\)-Differential Privacy). Suppose that \(M\) is \((\epsilon, \delta)\)-differentially private and \((\alpha, \beta)\)-sample accurate for linear queries. Then for every analyst \(A\) and \(c, d > 0\) it also satisfies:

\[
\Pr_{S \sim \mathcal{P}, \Pi \sim \text{Interact}(M, A, S)} \left[ \max_j |a_j - q_j(\mathcal{P})| > \alpha + (\epsilon^\delta - 1) + c + 2d \right] \leq \frac{\beta}{c} + \frac{\delta}{d}
\]

i.e. it is \((\alpha', \beta')\)-distributionally accurate for \(\alpha' = \alpha + (\epsilon^\delta - 1) + c + 2d\) and \(\beta' = \frac{\beta}{c} + \frac{\delta}{d}\).
\end{theorem}
Remark 10. As we will see in Section 4, the Gaussian mechanism (and many other differentially private mechanisms) has a sample accuracy bound that depends only on the square root of the log of both $1/\beta$ and $1/\delta$. Thus, despite the Markov-like term $\beta' = \beta + \frac{\delta}{2}$ in the above transfer theorem, together with the sample accuracy bounds of the Gaussian mechanism, it yields Chernoff-like concentration.

Our technique extends easily to reason about arbitrary low sensitivity queries and minimization queries. See Appendix A.1 and A.2 for more details.

4 Applications: The Gaussian Mechanism

We now apply our new transfer theorem to derive the concrete bounds that we plotted in Figure 1. The Gaussian mechanism is extremely simple and has only a single parameter $\sigma$: for each query $q_i$ that arrives, the Gaussian mechanism returns the answer $a_i \sim N(q_i(S), \sigma^2)$ where $N(q_i(S), \sigma^2)$ denotes the Gaussian distribution with mean $q_i(S)$ and standard deviation $\sigma$.

Theorem 11 ([2]). When used to answer $k$ linear queries, for every $0 < \delta < 1$, the Gaussian mechanism with parameter $\sigma$ satisfies $(\epsilon, \delta)$-differential privacy for:

$$\epsilon = \frac{k}{2n^2\sigma^2} + \sqrt{\frac{2}{n^2\sigma^2} \log \left( \pi \cdot \frac{k}{2n^2\sigma^2}/\delta \right)}$$

It is also easy to see that the sample-accuracy of the Gaussian mechanism is characterized by the CDF of the Gaussian distribution:

Lemma 12. For any $0 < \beta < 1$, the Gaussian mechanism with parameter $\sigma$ is $((\alpha_G, \beta))$-sample accurate for:

$$\alpha_G = \sqrt{2\sigma} \cdot \text{erfc}^{-1} \left( 2 - 2 \left( 1 - \frac{\beta}{2} \right)^{1/k} \right) < \sqrt{2\sigma} \cdot \text{erfc}^{-1} \left( \frac{\beta}{k} \right) < \sqrt{2\sigma} \sqrt{\log \left( \frac{\sqrt{2k}}{\pi \beta} \right)}.$$

Above, $\text{erfc}(x) = 1 - \text{erf}(x)$ is the complementary error function.

Proof. For a query $q_i$, write $a_j = q_j(S) + Z_j$ where $Z_j \sim N(0, \sigma^2)$. The sample error is $\max_j |a_j - q_j(S)| = \max_j |Z_j|$. We have that $\Pr[\max_j |Z_j| \geq \alpha] \leq \Pr[\max_j Z_j \geq \alpha] + \Pr[\min_j Z_j \leq -\alpha]$. $\alpha_G$ is the value that solves the equation $\Pr[\max_j Z_j \geq \alpha] = \Pr[\min_j Z_j \leq -\alpha] = \beta/2$.

With these quantities in hand, we can now apply Theorem 9 to derive distributional accuracy bounds for the Gaussian mechanism:

Theorem 13. Fix a desired confidence parameter $0 < \beta < 1$. When $\sigma$ is set optimally, the Gaussian mechanism can be used to answer $k$ linear queries while satisfying $(\alpha, \beta)$-distributional accuracy, where $\alpha$ is the solution to the following unconstrained minimization problem:

$$\alpha = \min_{\sigma, \delta > 0} \left\{ \sqrt{2\sigma} \cdot \text{erfc}^{-1} \left( \frac{\delta}{k} \right) + \sqrt{2 \cdot \frac{\delta}{k}} \log \left( \frac{\sqrt{\pi} \cdot \frac{k}{2n^2\sigma^2}/\delta}{1 + 6 \left( \frac{\delta}{\beta} \right)} \right) \right\}$$
Proof. Using Theorem 9 and fixing $\beta' = \delta$ and $c = d$, we have that an $(\alpha', \beta')$-sample accurate, $(\epsilon, \delta)$-differentially private mechanism is $(\alpha, \beta)$-distributionally accurate for $\alpha = \alpha' + (\epsilon^c - 1) + 3c$ and $\beta = \frac{2c}{\Delta^2}$ where $c$ can be an arbitrary parameter. For any fixed value of $\beta$, we can take $c = \frac{2\beta}{\Delta^2}$, and see that we obtain $(\alpha, \beta)$-distributional accuracy where $\alpha = \alpha' + (\epsilon^c - 1) + 6(\Delta/\beta)$. The theorem then follows from plugging in the privacy bound from Theorem 11, the sample accuracy bound from Theorem 12, and optimizing over the free variables $\sigma$ and $\delta$.

\section{Discussion}

We have given a new proof of the transfer theorem for differential privacy that has several appealing properties. Besides being simpler than previous arguments, it achieves substantially better concrete bounds than previous transfer theorems, and uncovers new structural insights about the role of differential privacy and sample accuracy. In particular, sample accuracy serves to guarantee that the reported answers are close to their conditional means, and differential privacy serves to guarantee that the conditional means are close to their true answers. This focuses attention on the conditional data distribution as a key quantity of interest, which we expect will be fruitful in future work. In particular, it may shed light on what makes certain data analysts overfit less than worst-case bounds would suggest: because they choose queries whose conditional means are closer to the prior than the worst-case query.

There seems to be one remaining place to look for improvement in our transfer theorem: Lemmas 6 and 7 both exhibit a Markov-like tradeoff between a parameter $c$ and $\beta$ and $\delta$ respectively. Although the dependence on $\beta$ and $\delta$ in our ultimate bounds is only root-logarithmic, it would still yield an improvement if this Markov-like dependence could be replaced with a Chernoff-like dependence. It is possible to do this for the $\beta$ parameter: we give an alternative (and even simpler) proof of the transfer theorem for $(\epsilon, 0)$-differential privacy which shows that conditional distributions induced by private mechanisms exhibit Chernoff-like concentration, in Appendix D. But the only way we know to extend this argument to $(\epsilon, \delta)$-differential privacy requires dividing $\delta$ by a factor of $n$, which yields a final theorem that is inferior to Theorem 9.

A New Analysis of Differential Privacy’s Generalization Guarantees

A Extensions

A.1 Low Sensitivity Queries

Our technique extends easily to reason about arbitrary low sensitivity queries. We only need to generalize our lemma about posterior stability.

Definition 14. A query \( q : X^n \to \mathbb{R} \) is called \( \Delta \)-sensitive if for all pairs of neighbouring datasets \( S, S' \in X^n \); \( |q(S) - q(S')| \leq \Delta \). Note that linear queries are \((1/n)\)-sensitive.

Lemma 15. If \( M \) is an \((\epsilon, \delta)\)-differentially private mechanism for answering \( \Delta \)-sensitive queries, then for any data distribution \( P \), analyst \( A \), and any constant \( c > 0 \):

\[
\Pr_{S \sim P^n, I \sim \text{Interact}(M, A; S)} \left[ \max_j |q_j(Q_\bar{\Pi}) - q_j(P^n)| > (\epsilon' - 1 + 4c)n\Delta \right] \leq \frac{\delta}{c}
\]

i.e. it is \((\epsilon', \frac{\delta}{c})\)-posterior stable for every \( A \), where \( \epsilon' = (\epsilon' - 1 + 4c)n\Delta \).

Proof. We introduce a useful bit of notation: \( \tilde{q}(x_{\leq i}) = \mathbb{E}_{S \sim P^n, i \sim P_{\leq i-1}} [q((x_{\leq i}, S'))] \). Notice that \( \tilde{q}(x_{\leq 0}) = q(P^n) \) and \( \tilde{q}(x_{\leq n}) = q(x) \). Given a transcript \( \pi \in \Pi \), let \( j^*(\pi) \in \arg \max_j |q_j(Q_\pi) - q_j(P^n)| \). Denote for any \( \alpha \geq 0 \)

\[
\Pi_\alpha = \{ \pi \in \Pi | q_{j^*(\pi)}(Q_\pi) - q_{j^*(\pi)}(P^n) > \alpha \}
\]

and for any \( z \in [0, 2\Delta] \) denote

\[
\Pi_{\alpha, z}(x_{\leq i}) = \{ \pi \in \Pi_\alpha | \tilde{q}_{j^*(\pi)}(x_{\leq i}) - \tilde{q}_{j^*(\pi)}(x_{\leq i-1}) > z - \Delta \}
\]

From the definition of differential privacy:

\[
\mathbb{E}_{S \sim P^n} \left[ \sum_{\pi \in \Pi_\alpha} \Pr_{I \sim P_{\leq i}} [\Pi = \pi] (\tilde{q}_{j^*(\pi)}(S_{\leq i}) - \tilde{q}_{j^*(\pi)}(S_{\leq i-1}) + \Delta) \right]
\]

\[
= \mathbb{E}_{S \sim P^n} \left[ \int_{0}^{2\Delta} \Pr_{I \sim P_{\leq i}} [\Pi \in \Pi_{\alpha, z}(S_{\leq i})] dz \right]
\]

\[
\leq \mathbb{E}_{S \sim P^n, Y \sim P} \left[ \int_{0}^{2\Delta} \left( e^{\epsilon'} \Pr_{I \sim P_{\leq i}^{(S,Y)}} [\Pi \in \Pi_{\alpha, z}(S_{\leq i})] + \delta \right) dz \right]
\]

\[
= \mathbb{E}_{S \sim P^n, Y \sim P} \left[ e^{\epsilon'} \sum_{\pi \in \Pi_{\alpha}} \Pr_{I \sim P_{\leq i}^{(S,Y)}} [\Pi = \pi] (\tilde{q}_{j^*(\pi)}(S_{\leq i}) - \tilde{q}_{j^*(\pi)}(S_{\leq i-1}) + \Delta) + 2\Delta \delta \right]
\]

\[
= \mathbb{E}_{S \sim P^n, Y \sim P} \left[ e^{\epsilon'} \sum_{\pi \in \Pi_{\alpha}} \Pr_{I \sim P_{\leq i}} [\Pi = \pi] (\tilde{q}_{j^*(\pi)}(S_{\leq i}^{(S,Y)}) - \tilde{q}_{j^*(\pi)}(S_{\leq i-1}) + \Delta) + 2\Delta \delta \right]
\]

where \( S_{\leq i}^{(S,Y)} = (S_1, \ldots, S_{i-1}, Y, S_{i+1}, \ldots, S_n) \), and the last equality follows from the observation that \((S, Y) \) and \((S_{\leq i}^{(S,Y)}, S_i) \) are identically distributed. Since \( Y \sim P \), independently from \( I \), we get that \( \mathbb{E}_{Y \sim P} [\tilde{q}_{j^*(\pi)}(S_{\leq i}^{(S,Y)})] = \tilde{q}_{j^*(\pi)}(S_{\leq i-1}) \), so

\[
\mathbb{E}_{S \sim P^n} \left[ \sum_{\pi \in \Pi_{\alpha}} \Pr_{I \sim P_{\leq i}} [\Pi = \pi] (\tilde{q}_{j^*(\pi)}(S_{\leq i}) - \tilde{q}_{j^*(\pi)}(S_{\leq i-1}) + \Delta) \right]
\]

\[
\leq \mathbb{E}_{S \sim P^n} \left[ \left( e^{\epsilon'} \Pr_{I \sim P_{\leq i}} [\Pi \in \Pi_{\alpha}] + 2\delta \right) \Delta \right]
\]

\[
= (e^{\epsilon'} \Pr_{I \sim P_{\leq i}} [\Pi \in \Pi_{\alpha}] + 2\delta) \Delta
\]
Subtracting $\Delta \Pr[\Pi \in \Pi_a]$ from both sides we get
\[
\mathbb{E}_{S \sim P^n} \left[ \sum_{\pi \in \Pi_a} \Pr_{\Pi \sim I(S)}[\Pi = \pi](\bar{q}_{j^*(\pi)}(S_{\leq i}) - \bar{q}_{j^*(\pi)}(S_{\leq i-1})) \right] \leq ((e^\epsilon - 1)\Pr[\Pi \in \Pi_a] + 2\delta) \Delta 
\]
\hspace{1cm} (2)

We now choose $\alpha = (e^\epsilon - 1 + 4\epsilon)\Delta$. Suppose that $\Pr[|q_{j^*(\pi)}(Q_n) - q_{j^*(\pi)}(P^n)| > \alpha]$ $\geq \frac{\delta}{2\epsilon}$. We must have that either $\Pr[q_{j^*(\pi)}(Q_n) - q_{j^*(\pi)}(P^n) > \alpha] > \frac{\delta}{2\epsilon}$ or $\Pr[q_{j^*(\pi)}(P^n) - q_{j^*(\pi)}(Q_n) > \alpha] > \frac{\delta}{2\epsilon}$. Without loss of generality, assume
\[
\Pr[q_{j^*(\pi)}(Q_n) - q_{j^*(\pi)}(P^n) > \alpha] = \Pr[\Pi \in \Pi_a] > \frac{\delta}{2\epsilon} \hspace{1cm} (3)
\]
But this leads to a contradiction, since
\[
\Pr[\Pi \in \Pi_a](e^\epsilon - 1 + 4\epsilon)\Delta < \sum_{\pi \in \Pi_a} \Pr[\Pi = \pi](q_{j^*(\pi)}(Q_n) - q_{j^*(\pi)}(P^n))
\]
\[
= \mathbb{E}_{S \sim P^n} \left[ \sum_{\pi \in \Pi_a} \Pr_{\Pi \sim I(S)}[\Pi = \pi](q_{j^*(\pi)}(S) - q_{j^*(\pi)}(P^n)) \right]
\]
\[
= \mathbb{E}_{S \sim P^n} \left[ \sum_{\pi \in \Pi_a} \Pr_{\Pi \sim I(S)}[\Pi = \pi](\bar{q}_{j^*(\pi)}(S_{\leq i}) - \bar{q}_{j^*(\pi)}(S_{\leq i-1})) \right] \leq ((e^\epsilon - 1)\Pr[\Pi \in \Pi_a] + 2\delta) \Delta \hspace{1cm} \text{(by Equation (2))}
\]
\[
< \Pr[\Pi \in \Pi_a](e^\epsilon - 1 + 4\epsilon)\Delta \hspace{1cm} \text{(by Equation (3))} \hspace{1cm} \blacksquare
\]

We can combine this Lemma with Lemma 6 (which holds for any query type) to get our transfer theorem:

\textbf{Theorem 16 (Transfer Theorem for Low Sensitivity Queries).} Suppose that $M$ is $(\epsilon, \delta)$-differentially private and $(\alpha, \beta)$-sample accurate for $\Delta$-sensitive queries. Then for every analyst $A$, $c, d > 0$ it also satisfies:
\[
\Pr_{S \sim P^n, \Pi \sim \text{Interact}(M, A; S)}[\max_j |a_j - q_j(P^n)| > \alpha + c + (e^\epsilon - 1 + 4d)\Delta] \leq \frac{\beta}{c + \frac{\delta}{d}}
\]
i.e. it is $(\alpha', \beta')$-distributionally accurate for $\alpha' = \alpha + c + (e^\epsilon - 1 + 4d)\Delta$ and $\beta' = \frac{\beta}{c + \frac{\delta}{d}}$.

\subsection{A.2 Minimization Queries}

\textbf{Definition 17.} Minimization queries are specified by a loss function $L : X^n \times \Theta \rightarrow [0, 1]$ where $\Theta$ is generally known as the “parameter space”. An answer to a minimization query $L$ is a parameter $\theta \in \Theta$. We work with $\Delta$-sensitive minimization queries: for all pairs of neighbouring datasets $S, S' \in X^n$ and all $\theta \in \Theta$, $|L(S, \theta) - L(S', \theta)| \leq \Delta$.

A mechanism $M$ is $(\alpha, \beta)$-sample accurate for minimization queries if for every data analyst $A$ and every dataset $S \in X^n$:
\[
\Pr_{\Pi \sim \text{Interact}(M, A; S)}[\max_j |L_j(S, \theta_j) - \min_{\theta \in \Theta} L_j(S, \theta)| \geq \alpha] \leq \beta
\]
We say that $M$ satisfies $(\alpha, \beta)$-distributional accuracy for minimization queries if for every data analyst $A$ and every data distribution $P$:
\[
\Pr_{S \sim P^n, \Pi \sim \text{Interact}(M, A; S)}[\max_j \mathbb{E}_{S' \sim P^n}[L_j(S', \theta_j) - \min_{\theta \in \Theta} L_j(S', \theta)] \geq \alpha] \leq \beta
\]
\textbf{Remark 18.} Note that
\[
\mathbb{E}_{S',\sim p^n} [L_j(S',\theta)] - \min_{\theta \in \Theta} \mathbb{E}_{S',\sim p^n} [L_j(S',\theta)] \leq \mathbb{E}_{S',\sim p^n} \left[ L_j(S',\theta) - \min_{\theta \in \Theta} L_j(S',\theta) \right]
\]
So as long as the RHS is bounded, the LHS is bounded too.

\textbf{Remark 19.} For a given $\Delta$-sensitive minimization query $L_j$ and an answer $\theta_j$, define:
\[
q_j(S) := L_j(S, \theta_j) - \min_{\theta \in \Theta} L_j(S, \theta) \quad \text{and} \quad a_j := 0
\]
Note several things:
1. If $L_j$ is $\Delta$-sensitive, then $q_j$ is $2\Delta$-sensitive.
2. The mapping from a minimization query transcript $\pi = ((L_1, \theta_1), \ldots, (L_k, \theta_k))$ to the $2\Delta$-sensitive query transcript $\pi' = ((q_1, a_1), \ldots, (q_k, a_k))$ as defined above is a dataset-independent post-processing $\pi' = f(\pi)$.
3. $\pi$ satisfies an $(\alpha, \beta)$-accuracy guarantee if and only if $\pi'$ does.

With the above observation, the transfer theorem for minimization queries immediately follows by Lemma 15 and Lemma 6.

\textbf{Theorem 20 (Transfer Theorem for Minimization Queries).} Suppose that $M$ is $(\epsilon, \delta)$-differentially private and $(\alpha, \beta)$-sample accurate for $\Delta$-sensitive minimization queries. Then for every analyst $\mathcal{A}$ and $c, d > 0$ it also satisfies:
\[
\Pr \left[ \max_{\bar{j}} \mathbb{E}_{S',\sim p^n} \left[ L_j(S',\theta_j) - \min_{\theta \in \Theta} L_j(S',\theta) \right] > \alpha + c + 2(\epsilon - 1 + 4d)n\Delta \right] \leq \frac{\beta}{c} + \frac{\delta}{d}
\]
i.e. it is $(\alpha', \beta')$-distributionally accurate for $\alpha' = \alpha + c + 2(\epsilon - 1 + 4d)n\Delta$ and $\beta' = \frac{\beta}{c} + \frac{\delta}{d}$.

\section{Details from Section 3.1}

\textbf{Proof of Lemma 5.} This follows from the expansion of the definition, and an application of Bayes Rule.
\[
\Pr_{S\sim p^n,\Pi\sim I(S),S'\sim Q_0} [(S',\Pi) \in E] = \sum_x \sum_\pi \sum_{x'} \Pr[S = x]\Pr[\Pi = \pi | S = x] \cdot \Pr_{S'\sim Q_x} [S' = x'] \mathbb{I}[(x',\pi) \in E] = \sum_\pi \sum_{x'} \Pr[\Pi = \pi] \cdot \Pr_{S'\sim Q_x} [S' = x'] \mathbb{I}[(x',\pi) \in E] = \sum_\pi \sum_{x'} \Pr[\Pi = \pi] \frac{\Pr[\Pi = \pi | S = x'] \cdot \Pr[S = x'] \mathbb{I}[(x',\pi) \in E]}{\Pr[\Pi = \pi]} = \Pr_{S\sim p^n,\Pi\sim I(S)} [(S,\Pi) \in E]
\]

\section{Details from Section 3.2}

\textbf{Lemma 21.} If $M$ is $(\epsilon, \delta)$-differentially private, then for any event $E$ and datapoint $x$:
\[
\Pr_{S\sim p^n, S_i \sim S, \Pi \sim I(S)} [\Pi \in E | S_i = x] \leq e^\epsilon \Pr_{S\sim p^n, \Pi \sim I(S)} [\Pi \in E] + \delta
\]
A New Analysis of Differential Privacy’s Generalization Guarantees

Proof. This follows from expanding the definitions.

\[
\Pr_{S \sim \mathcal{P}^n, S \sim \Pi \sim I(S)} [\Pi \in E | S_i = x] = \frac{1}{n} \sum_{i=1}^{n} \Pr_{S \sim \mathcal{P}^n} [S = x] \cdot \Pr_{\Pi \sim E} [\Pi \in E | S = (x_{-i}, x)]
\]

where the inequality follows from the definition of differential privacy.

Combining this with Equation 4 gives us that for any \( \epsilon \in \mathbb{R} \):

\[
e^{-\epsilon} q(P) \leq \frac{1}{n} \sum_{i=1}^{n} \mathbb{E}[q(S_i)|S_{<i}] \leq e^{\epsilon} \cdot \mathbb{E}[q(P)]
\]

where the inequality follows from the definition of differential privacy. 

\[\square\]

D An (even) Simpler and Better Proof for \(\epsilon\)-Differential Privacy

In this section we give an even simpler proof of an even better transfer theorem for \((\epsilon, 0)\)-differential privacy. Rather than using Markov’s inequality as we did in the proof of Lemma 6, we can directly show that conditional distributions induced by differentially private mechanisms exhibit Chernoff-like concentration.

Lemma 22. If \( M \) is \((\epsilon, 0)\)-differentially private, then for any data distribution \( \mathcal{P} \), any transcript \( \pi \in \Pi \), any linear query \( q \), and any \( \eta > 0 \):

\[
\Pr_{S \sim \mathcal{Q}_x} \left[ |q(S) - q(P)| \geq (e^\epsilon - 1) + \sqrt{\frac{2 \ln(2/\eta)}{n}} \right] \leq \eta
\]

Proof. Define the random variables \( V_i = q(S_i) - \mathbb{E}[q(S_i)|S_{<i}] \), and let \( X_i = \frac{1}{n} \sum_{j=1}^{i} V_j \). Then the sequence \( 0 = X_0, X_1, \ldots, X_n \) forms a martingale and \( |X_i - X_{i-1}| = \frac{1}{n} |V_i| \leq \frac{1}{n} \). We can therefore apply Azuma’s inequality to conclude that:

\[
\Pr \left[ \left| \frac{1}{n} \sum_{i=1}^{n} q(S_i) - \frac{1}{n} \sum_{i=1}^{n} \mathbb{E}[q(S_i)|S_{<i}] \right| \geq t \right] \leq 2 \exp \left( \frac{-t^2}{2} \right) \tag{4}
\]

Now fix any realization \( x \), and consider each term: \( \mathbb{E}[q(S_i)|S_{<i}] = x_{<i} \). We have:

\[
\mathbb{E}_{S \sim \mathcal{Q}_x} [q(S_i)|S_{<i} = x_{<i}] = \sum_x q(x) \cdot \Pr_{S \sim \mathcal{P}^n} [S_i = x] |\Pi = \pi, S_{<i} = x_{<i}|
\]

\[
= \sum_x q(x) \cdot \Pr_{S \sim \mathcal{P}^n} [\Pi = \pi | S_i = x, S_{<i} = x_{<i}] \cdot \Pr_{S \sim \mathcal{P}^n} [S_i = x]
\]

\[
\leq e^\epsilon \cdot \sum_x q(x) \cdot \Pr_{S \sim \mathcal{P}^n} [S_i = x]
\]

where the inequality follows from the definition of \((\epsilon, 0)\)-differential privacy. Symmetrically, we can show that \( \mathbb{E}_{S \sim \mathcal{Q}_x} [q(S_i)|S_{<i} = x_{<i}] \geq e^{-\epsilon} q(P) \). Therefore we have that:

\[
e^{-\epsilon} q(P) \leq \frac{1}{n} \sum_{i=1}^{n} \mathbb{E}[q(S_i)|S_{<i}] \leq e^{\epsilon} q(P).
\]

Combining this with Equation 4 gives us that for any \( \eta > 0 \), with probability \( 1 - \eta \) when \( S \sim \mathcal{Q}_x \):

\[
q(S) \leq e^\epsilon q(P) + \sqrt{\frac{2 \ln(2/\eta)}{n}} \quad \text{and} \quad q(S) \geq e^{-\epsilon} q(P) - \sqrt{\frac{2 \ln(2/\eta)}{n}} \quad \square
\]
A transfer theorem follows immediately from lemma 22.

**Theorem 23.** Suppose that $M$ is $(\epsilon,0)$-differentially private and $(\alpha,\beta)$-sample accurate. Then for any $\eta > 0$ it is $(\alpha',\beta')$-distributionally accurate for $\alpha' = \alpha + (e^\epsilon - 1) + \sqrt{\frac{2 \ln(2/\eta)}{n}}$ and $\beta' = \beta + \eta$.

**Proof.** For a given $\pi$, let $j^*(\pi) = \arg\max_j |a_j - q_j(\pi)|$. By the triangle inequality we have:

$$|a_{j^*(\pi)}(P) - q_{j^*(\pi)}(P)| \leq |a_{j^*(\pi)}(P) - q_{j^*(\pi)}(S)| + |q_{j^*(\pi)}(S) - q_{j^*(\pi)}(P)|$$

$$\leq \max_j |a_j - q_j(S)| + |q_{j^*(\pi)}(S) - q_{j^*(\pi)}(P)|$$

By the definition of $(\alpha,\beta)$-sample accuracy, we have that with probability $1 - \beta$, $\max_j |a_j - q_j(S)| \leq \alpha$. The Resampling Lemma (Lemma 5) gives us that:

$$\Pr_{S \sim P^n, \Pi \sim I(S)} \left[ |q_{j^*(\pi)}(S) - q_{j^*(\pi)}(P)| \geq (e^\epsilon - 1) + \sqrt{\frac{2 \ln(2/\eta)}{n}} \right]$$

$$= \Pr_{S \sim P^n, \Pi \sim I(S), S' \sim Q^n} \left[ |q_{j^*(\pi)}(S') - q_{j^*(\pi)}(P)| \geq (e^\epsilon - 1) + \sqrt{\frac{2 \ln(2/\eta)}{n}} \right]$$

$$= \mathbb{E}_{S \sim P^n, \Pi \sim I(S)} \left[ \Pr_{S' \sim Q^n} \left[ |q_{j^*(\pi)}(S') - q_{j^*(\pi)}(P)| \geq (e^\epsilon - 1) + \sqrt{\frac{2 \ln(2/\eta)}{n}} \right] \right]$$

$$\leq \eta$$

Because Lemma 22 guarantees us that for every $\pi$,

$$\Pr_{S' \sim Q^n} \left[ |q_{j^*(\pi)}(S') - q_{j^*(\pi)}(P)| \geq (e^\epsilon - 1) + \sqrt{\frac{2 \ln(2/\eta)}{n}} \right] \leq \eta.$$
Robust Algorithms for the Secretary Problem

Abstract

In classical secretary problems, a sequence of \( n \) elements arrive in a uniformly random order, and we want to choose a single item, or a set of size \( K \). The random order model allows us to escape from the strong lower bounds for the adversarial order setting, and excellent algorithms are known in this setting. However, one worrying aspect of these results is that the algorithms overfit to the model: they are not very robust. Indeed, if a few “outlier” arrivals are adversarially placed in the arrival sequence, the algorithms perform poorly. E.g., Dynkin’s popular \( \frac{1}{e} \)-secretary algorithm is sensitive to even a single adversarial arrival: if the adversary gives one large bid at the beginning of the stream, the algorithm does not select any element at all.

We investigate a robust version of the secretary problem. In the Byzantine Secretary model, we have two kinds of elements: green (good) and red (rogue). The values of all elements are chosen by the adversary. The green elements arrive at times uniformly randomly drawn from \([0, 1]\). The red elements, however, arrive at adversarially chosen times. Naturally, the algorithm does not see these colors: how well can it solve secretary problems?

We show that selecting the highest value red set, or the single largest green element is not possible with even a small fraction of red items. However, on the positive side, we show that these are the only bad cases, by giving algorithms which get value comparable to the value of the optimal green set minus the largest green item. (This benchmark reminds us of regret minimization and digital auctions, where we subtract an additive term depending on the “scale” of the problem.) Specifically, we give an algorithm to pick \( K \) elements, which gets within \((1 - \varepsilon)\) factor of the above benchmark, as long as \( K \geq \text{poly}(\varepsilon^{-1} \log n) \). We extend this to the knapsack secretary problem, for large knapsack size \( K \).

For the single-item case, an analogous benchmark is the value of the second-largest green item. For value-maximization, we give a \( \log^* n \)-competitive algorithm, using a multi-layered bucketing scheme that adaptively refines our estimates of second-max over time. For probability-maximization, we show the existence of a good randomized algorithm, using the minimax principle.

We hope that this work will spur further research on robust algorithms for the secretary problem, and for other problems in sequential decision-making, where the existing algorithms are not robust and often tend to overfit to the model.

1 Introduction

In sequential decision-making, we have to serve a sequence of requests online, i.e., we must serve each request before seeing the next one. E.g., in online auctions and advertising, given a sequence of arriving buyers, we want to choose a high bidder. Equivalently, given a sequence of $n$ numbers, we want to choose the highest of these. The worst-case bounds for this problem are bleak: choosing a random buyer is the best we can do. So we make (hopefully reasonable) stochastic assumptions about the input stream, and give algorithms that work well under those assumptions.

A popular assumption is that the values/bids are chosen by an adversary, but presented to the algorithm in a uniformly random order. This gives the secretary or the random-order model, under which we can get much better results. E.g., Dynkin’s secretary algorithm that selects the first prefix-maximum bidder after discarding the first $1/e$-fraction of the bids, selects the highest bid with probability $1/e$ [13]. The underlying idea – of fixing one or more thresholds after seeing some prefix of the elements – can be generalized to solve classes of packing linear programs near-optimally [8, 9, 25, 21], and to get $O(\log \log n)$-competitive algorithms for matroids [28, 16] in the random-order model.

However, the assumption that we see the elements in a uniformly random order is quite strong, and most current algorithms are not robust to small perturbations to the model. E.g., Dynkin’s algorithm is sensitive to even a single adversarial corruption: if the adversary gives one large bid at the beginning of the stream, the algorithm does not select any buyer at all, even if the rest of the stream is perfectly random! Many other algorithms in the secretary model suffer from similar deficiencies, which suggests that we may be over-fitting to the assumptions of the model.

We propose the Byzantine secretary model, where the goal is to design algorithms robust to outliers and adversarial changes. The use of the term “Byzantine” parallels its use in distributed systems, where some of the input is well-behaved while the rest is arbitrarily corrupted by an adversary. Alternatively, our model can be called semi-random or robust: these other terms are used in the literature which inspires our work. Indeed, there is much interest currently in designing stochastic algorithms that are robust to adversarial noise (see [10, 34, 29, 3, 34, 11, 12, 14, 30] and references therein). Our work seeks to extend robustness to online problems. Our work is also related in spirit to investigations into how much randomness in the stream is necessary and sufficient to get competitive algorithms [5, 23].
1.1 Our Model

In the secretary problem, \( n \) elements arrive one-by-one. Each item has a value that is revealed upon its arrival, which happens at a time chosen independently and uniformly at random in \([0, 1]\). (We choose the continuous time model, instead of the uniformly random arrival order model, since the independence allows us to get clean proofs.) When we see an item, we must either select it or discard it before we see the next item. Our decisions are irrevocable. We can select at most \( K \) elements, where \( K = 1 \) for the classical version of the problem. We typically want to maximize the expected total value of the selected elements where the value of a set is simply the sum of values of individual elements. (For the single-item case we may also want to maximize the probability of selecting the highest-value item, which is called the ordinal case.) Given its generality and wide applicability, this model and its extensions are widely studied; see §1.3.

The difference between the classical and Byzantine secretary models is in how the sequence is generated. In both models, the adversary chooses the values of all \( n \) elements. In the classical model, these are then permuted in a random order (say by choosing the arrival times independently and uniformly at random (u.a.r.) from \([0, 1]\)). In the Byzantine model, the elements are divided into two groups: the green (or good) elements/items \( G \), and the red (or rogue/bad) elements/items \( R \). This partition and the colors are not visible to the algorithm. Now elements in \( G \) arrive at independently chosen u.a.r. times between \([0, 1]\), but those in \( R \) arrive at times chosen by the adversary. Faced with this sequence, the algorithm must select some subset of elements (say, having size at most \( K \), or more generally belonging to some down-closed family). The precise order of actions is important:

- First, the adversary chooses values of elements in \( R \cup G \), and the arrival times of elements in \( R \).
- Then each element \( e \in G \) is independently assigned a uniformly random arrival time \( t_e \sim U[0,1] \).

Hence the adversary is powerful and strategic, and can “stuff” the sequence with values in an order that fools our algorithms the most. The green elements are non-strategic (hence are in random order) and beyond the adversary’s control. When an element is presented, the algorithm does not see the color (green vs. red): it just sees the value and the time of arrival. We assume that the algorithm knows \( n := |R| + |G| \), but not \( |R| \) or \( |G| \); see Appendix B on how to relax this assumption. The green elements are denoted \( G = \{g_{\max} = g_1, g_2, \ldots, g_{|G|}\} \) in non-increasing order of values.

What results can we hope to get in this model? Here are two cautionary examples:

- Since the red elements behave completely arbitrarily, the adversary can give non-zero values to only the reds, and plant a bad example for the adversarial order using them. Hence, we cannot hope to get the value of the optimal red set in general, and should aim to get value only from the greens.
- Moreover, suppose essentially all the value among the greens is concentrated in a single item \( g_{\max} \). Here’s a bad example: the adversary gives a sequence of increasing reds, all having value much smaller than \( g_{\max} \), but values which are very far from each other. When the algorithm does see the green item, it will not be able to distinguish it from the next red, and hence will fail. This is formalized in Observation 19. Hence, to succeed, the green value must be spread among more than one item.

Given these examples, here is the “leave-one-out” benchmark we propose:

\[
V^* := \text{value of the best feasible green set from } G \setminus g_{\max}.
\] (1)
This benchmark is at least as strong as the following guarantee:

\[
\text{value of best feasible green set from } G - v(g_{\text{max}}).
\]

The advantage of (1) over (2) is that \(V^*\) is interesting even when we want to select a single item, since it asks for value \(v_{g_2}\) or higher.

We draw two parallels to other commonly used benchmarks. Firstly, the perspective (2) suggests the regret-type guarantees, where we seek the best solution in hindsight, minus the “scale of the problem instance”. The value of \(g_{\text{max}}\) is the scale of the instance here. Secondly, think of the benchmark (1) as assuming the existence of at least two high bids, then the second-largest element is almost as good a benchmark as the top element. This is a commonly used assumption, e.g., in digital goods auctions [4].

Finally, if we really care about a benchmark that includes \(g_{\text{max}}\), our main results for selecting multiple items (Theorem 1 and Theorem 2) continue to hold, under the (mild?) assumption that the algorithm starts with a polynomial approximation to \(v(g_{\text{max}})\).

### 1.2 Our Results

We first consider the setting where we want to select at most \(K\) elements to maximize the expected total value. In order to get within \((1 + \varepsilon)\) factor of the benchmark \(V^*\) defined in (1), we need to assume that we have a “large budget”, i.e., we are selecting a sufficiently large number of elements. Indeed, having a larger budget \(K\) allows us to make some mistakes and yet get a good expected value.

▶ **Theorem 1 (Uniform Matroids).** There is an algorithm for Byzantine secretary on uniform matroids of rank \(K \geq \text{poly}(\varepsilon^{-1} \log n)\) that is \((1 + \varepsilon)\)-competitive with the benchmark \(V^*\).

For the standard version of the problem, i.e. without any red elements, [26] gave an algorithm that achieves the same competitiveness when \(K \geq \Omega(1/\varepsilon^2)\). The algorithm from [26] uses a single threshold, that it updates dynamically; we extend this idea to having several thresholds/budgets that “cascade down” over time; we sketch the main ideas in §2.2. In fact, we give a more general result – an algorithm for the knapsack setting where each element has a size in \([0, 1]\), and the total size of elements we can select is at most \(K\). (The uniform-matroids case corresponds to all sizes being one.) Whereas the main intuition remain unchanged, the presence of non-uniform sizes requires a little more care.

▶ **Theorem 2 (Knapsack).** There is an algorithm for Byzantine secretary on knapsacks with size at least \(K \geq \text{poly}(\varepsilon^{-1} \log n)\) (and elements of at most unit size) that is \((1 + \varepsilon)\)-competitive with the benchmark \(V^*\).

As mentioned earlier, under mild assumptions the guarantee in Theorem 2 can be extended against the stronger benchmark that includes \(g_{\text{max}}\). Formally, assuming the algorithm starts with a \(\text{poly}(m)\)-approximation to the value of \(g_{\text{max}}\), we get a \((1 + \varepsilon)\)-competitive algorithm for \(K \geq \text{poly}(\varepsilon^{-1} \log mn)\) against the stronger benchmark.

**Selecting a Single Item.** What if we want to select a single item, to maximize its expected value? Note that the benchmark \(V^*\) is now the value of \(g_2\), the second-largest green item. Our main result for this setting is the following, where \(\log^* n\) denotes the iterated logarithm:

▶ **Theorem 3 (Value Maximization Single-Item).** There is a randomized algorithm for the value-maximization (single-item) Byzantine secretary problem which gets an expected value at least \((\log^* n)^{-2} \cdot V^*\).
Interestingly, our result is unaffected by the corruption level, and works even if just two elements \( g_{\text{max}}, g_2 \) are green, and every other item is red. This is in contrast to many other robustness models where the algorithm’s performance decays with the fraction of bad elements [14, 3, 12, 30]. Moreover, our algorithms do not depend on the fraction of bad items. Intuitively, we obtain such strong guarantees because the adversary has no incentive to present too many bad elements with large values, as otherwise an algorithm that selects a random element would have a good performance.

In the classical setting, the proofs for the value-maximization proceed via showing that the best item itself is chosen with constant probability. Indeed, in that setting, the competitiveness of value-maximization and probability-maximization versions is the same. We do not know of such a result in the Byzantine model. However, we can show a non-trivial performance for the probability-maximization (ordinal) problem:

**Theorem 4 (Ordinal Single-item Algorithm).** There is a randomized algorithm for the ordinal Byzantine secretary which selects an element of value at least the second-largest green item with probability \( \Omega(1/\log^2 n) \).

**Other Settings.** Finally, we consider some other constraint sets given by matroids. In (simple) partition matroids, the universe \( U \) is partitioned into \( r \) groups, and the goal is to select one item from each group to maximize the total value. If we were to set the benchmark to be the sum of second-largest green items from each group, we can just run the single-item algorithm from Theorem 1 on each group independently. But our benchmark \( V^* \) is much higher: among the items \( g_2, \ldots, g_{|G|} \), the set \( V^* \) selects the largest one from each group. Hence, we need to get the largest green item from \( r - 1 \) groups! Still, we do much better than random guessing.

**Theorem 5 (Partition Matroids).** There is an algorithm for Byzantine secretary on partition matroids that is \( O(\log \log n)^2 \)-competitive with the benchmark \( V^* \).

Finally, we record a simple but useful logarithmic competitive ratio for arbitrary matroids (proof in §6.2), showing how to extend the corresponding result from [1] for the non-robust case.

**Observation 6 (General Matroids).** There is an algorithm for Byzantine secretary on general matroids that is \( O(\log n) \)-competitive with the benchmark \( V^* \).

Our results show how to get robust algorithms for the widely-studied secretary problems, and we hope it will generate further interest in robust algorithm design. Interesting next directions include improving the quantitative bounds in our results (which are almost certainly not optimal), and understanding tradeoffs between competitiveness and robustness.

### 1.3 Related Work

The secretary problem has a long history, see [17] for a discussion. The papers [1, 28, 16] studied generalizations of the secretary problem to matroids, [20, 27, 24, 22] studied extensions to matchings, and [38, 39] studied extensions to arbitrary packing constraints. More generally, the random-order model has been considered, both as a tool to speed up algorithms (see [6, 41]), and to go beyond the worst-case in online algorithms (see [32, 18, 19]). E.g., we can solve linear programs online if the columns of the constraint matrix arrive in a random order [8, 9, 25, 21], and its entries are small compared to the bounds. In online algorithms, the random-order model provides one way of modeling benign nature, as opposed to an adversary hand-crafting a worst-case input sequence; this model is at least as general as i.i.d. draws from an unknown distribution.
Robust Algorithms for the Secretary Problem

Both the random-order model and the Byzantine model are semi-random models [2, 15], with different levels of power to the adversary. Other restrictions of the random-order model have been studied, via lower-bounding the entropy of the input stream, to ensure the permutations are “random enough” [5, 23]. These papers give sufficient conditions for the classical algorithms to perform well, whereas we take the dual approach of permitting outliers and then asking for new robust algorithms. There are works (e.g., [31, 33, 35]) that give algorithms which have a worst-case adversarial bound, and which work better when the input is purely stochastic; most of these do not study the performance on mixed arrival sequences. One exception is the work [14] who study online matching for mixed arrivals, under the assumption that the “magnitude of noise” is bounded. Another exception is a recent (unpublished) work of Kesselheim and Molinaro, who define a robust $K$-secretary problem similar to ours. They assume the corruptions have a bursty pattern, and get $1 - f(K)$-competitive algorithms. Our model is directly inspired by theirs.

2 Preliminaries and Techniques

By $[a \ldots b]$ we denote the set of integers $\{a, a+1, \ldots, b-1, b\}$. The universe $U := R \cup G$ consists of red/corrupted elements $R$ and good elements $G$. Let $v(e)$ denote the value of element $e$: in the ordinal case $v(e)$ merely defines a total ordering on the elements, whereas in the value-maximization case $v(e) \in \mathbb{R}_{\geq 0}$. Similarly, let $v(A)$ be the random variable denoting the value of the elements selected by algorithm $A$. Let $t_e \in [0,1]$ be the arrival time of element $e$. Let $R = \{r_1, r_2, \ldots, r_{|R|}\}$ and $G = \{g_{\text{max}}, g_2, g_3, \ldots, g_{|G|}\}$; the elements in each set are ordered in non-increasing values. Let $V^*$ be the benchmark to which we compare our algorithm. Note that $V^*$ is some function of $G \setminus \{g_{\text{max}}\}$, depending on the setting. We sometimes refer to elements $\{e \in U \mid v(e) \geq v(g_2)\}$ as big.

2.1 Two Useful Subroutines

Here are two useful subroutines.

Select a Random Element. The subroutine is simple: select an element uniformly at random. The algorithm can implement this in an online fashion since it knows the total number of elements $n$. An important property of this subroutine is that, in the value case, if any element in $U$ has value at least $nV^*$, this subroutine gets at least $V^*$ in expectation since this highest value element is selected with probability $1/n$.

Two-Checkpoints Secretary. The subroutine is defined on two checkpoints $T_1, T_2 \in [0,1]$, and let $\mathbb{I} := [T_1, T_2]$ be the interval between them. The subroutine ignores the input up to time $T_1$, observes it during $\mathbb{I}$ by setting threshold $\tau$ to be the highest value seen in the interval $\mathbb{I}$, i.e., $\tau \leftarrow \max\{v(e) \mid t_e \in \mathbb{I}\}$. Finally, during $(T_2, 1]$ the subroutine selects the first element $e$ with value $v(e) \geq \tau$.

We use the subroutine in the single-item setting where the goal is to find a “big” element, i.e., an element with value at least $v(g_2)$. Suppose that there are no big red elements in $\mathbb{I}$. Now, if $g_2$ lands in $\mathbb{I}$, and also $g_{\text{max}}$ lands in $(T_2, 1]$, we surely select some element with value at least $g_2$. Indeed, if there are no big items, threshold $\tau \leftarrow g_2$, and because $g_{\text{max}}$ lands after $\mathbb{I}$, it or some other element will be selected. Hence, with probability $\Pr[t_{g_2} \in \mathbb{I}] \Pr[t_{g_{\text{max}}} \in (T_2, 1)] = (T_2 - T_1) \cdot (1 - T_2)$, we select an element of value at least $v(g_2)$. 

\[\Pr[t_{g_{\text{max}}} \in (T_2, 1)] = (T_2 - T_1) \cdot (1 - T_2)\]
2.2 Our Techniques

A common theme of our approaches is to prove a “good-or-learnable” lemma for each problem. Our algorithms begin by putting down a small number of checkpoints \( \{T_i\} \) to partition the time horizon \([0,1]\) — and the arriving items — into disjoint intervals \( \{I_i\} \). We maintain thresholds in each interval to decide whether to select the next element. Now a “good-or-learnable” lemma says that either the setting of the thresholds in the current interval \( I_i \) will give us a “good” performance, or we can “learn” that this is not the case and update the thresholds for the next interval \( I_{i+1} \). Next we give details for each of our problems.

**Uniform Matroid Value Maximization (§3).** Recall that here we want to pick \( K \) elements (in particular, all elements have size 1, unlike the knapsack case where sizes are in the range \([0,1]\)). For simplicity, suppose the algorithm knows that the benchmark \( V^* \) lies in \([1,n]\); we remove this assumption later. We define \( O(\varepsilon^{-1} \log n) \) levels, where level \( \ell \geq 0 \) corresponds to values in the range \([n/(1+\varepsilon)^{\ell+1}, n/(1+\varepsilon)^\ell]\). For each interval \( I_i \) and level \( \ell \), we maintain a budget \( B_{\ell,i} \). Within this interval \( I_i \), we select the next arriving element having a value in some level \( \ell \) only if the budget \( B_{\ell,i} \) has not been used up. How should we set these budgets? If there are \( 1/\delta \) intervals of equal size, we expect to select \( \delta K \) elements in this interval. So we have a total of \( \delta K \) budget to distribute among the various levels. We start off optimistically, giving all the budget to the highest-value level. Now this budget gradually cascades from a level \( \ell \) to the next (lower-value) level \( \ell + 1 \), if level \( \ell \) is not selecting elements at a “good enough” rate. The intuition is that for the “heavy” levels (i.e., those that contain many elements from the benchmark-achieving set \( S^* \)), we will roughly see the right number of them arriving in each interval. This allows us to prove a good-or-learnable lemma, that either we select elements at a “good enough” rate in the current interval, or this is not the case and we “learn” that the budgets should cascade to lower value levels. There are many details to be handled: e.g., this reasoning is only possible for levels with many benchmark elements, and so we need to define a dedicated budget to handle the “light” levels.

**Single-Item Value-Maximization (§5).** We want to maximize the expected value of the selected element, compared to \( V^* := v(g_2) \), the value of the second-max green. With some small constant probability our algorithm selects a uniformly random element. This allows us to assume that every element has value less than \( nV^* \), as otherwise the expected value of a random guess is \( \Omega(V^*) \). We now describe how applying the above “good-or-learnable” paradigm in a natural way guarantees an expected value of \( \Omega(V^*/\log n) \). Running the two-checkpoint secretary (with constant probability) during \( T_1 = 0, T_2 = 1/2 \) we know that it gets value \( \Omega(V^*) \) and we are done, or failing that, there exist a red element of value at least \( V^* \) in \([0,1/2]\). But then we can use this red element (highest value in the first half) to get a factor \( n \) estimate on the value of \( V^* \). So by grouping elements into buckets if their values are within a factor 2, and randomly guessing the bucket that contains \( v(g_2) \), gives us an expected value of \( \Omega(V^*/\log n) \). To obtain the stronger factor of \( \text{poly} \log^* n \) in Theorem 3, we now define \( \log^* n \) checkpoints. We prove a “good-or-learnable” lemma that either selecting a random element from one of the current buckets has a good value, or we can learn a tighter estimate on \( V^* \) and reduce the number of buckets.

**Ordinal Single-Item Secretary (§4).** We now want to maximize the probability of selecting an element whose value is as large as the green second-max; this is more challenging than value-maximization since there is no notion of values for bucketing. Our approach is crucially different. Indeed, we use the minimax principle in the “hard” direction: we give an algorithm
that does well when the input distribution is known to the algorithm (i.e., where the algorithm can adapt to the distribution), and hence infer the existence of a (randomized) algorithm that does well on worst-case inputs.

The known-distribution algorithm uses $O(\log n)$ intervals. Again, we can guarantee there is a “big” (larger than $g_2$) red element within each interval, as otherwise running Dynkin’s algorithm on a random interval with a small probability already gives a “good” approximation. This implies that even if the algorithm “learns” a good estimate of the second-max just before the last interval, it will win. This is because the algorithm can set this estimate of second-max as a threshold, and it wins by selecting the big red element of the last interval. Finally, to learn a good estimate on the second-max, we again prove a “good-or-learnable” lemma. Its proof crucially relies on the algorithm knowing the arrival distribution, since that allows us to set “median” of the conditional distribution as a threshold.

Other Results (§6). We also give $O(\log \log n)^2$-competitive algorithms for Partition matroids, where the difficulty is that we cannot afford to lose the max-green element in every part. Our idea is to only lose one element globally to get a very rough scale of the problem, and then exploit this scale in every part. We also show why other potential benchmarks are too optimistic in §A, and how to relax the assumption that $n$ is known in §B. See those sections for details.

3 Knapsack Byzantine Secretary

Consider a knapsack of size $K$; for all the results in this section we assume that $K \geq \text{poly}(\epsilon^{-1} \log n)$. Each arriving element $e$ has a size $s(e) \in [0, 1]$ and a value $v(e) \geq 0$. Let $g_{\text{max}}, g_2, g_3, \ldots$, denote the green elements $G$ with decreasing values and let

$$V^* := \max \left\{ \sum_{e \in S} v(e) \mid S \subseteq G \setminus g_{\text{max}} \text{ and } \sum_{e \in S} s(e) \leq K \right\}$$

be the value of the benchmark solution, i.e., the optimal solution obtained after discarding the top green element $g_{\text{max}}$. Let $S^*$ be the set of green elements corresponding to this benchmark.

In §3.1 we give a $(1 + \epsilon)$-competitive algorithm assuming we have a factor poly(n)-approximation to the benchmark value $V^*$. (In fact, given this poly(n)-approximation, we can even get within a $(1 + \epsilon)$-factor of the optimal set including $g_{\text{max}}$.) Then in §3.2 we remove the assumption, but now our value is only comparable to $V^*$ (i.e., excluding $g_{\text{max}}$).

Intuition. The main idea of the regular (non-robust) multiple-secretary problem (where we pick at most $K$ items) is to observe a small $\epsilon$ fraction of the input, estimate the value of the $K^{th}$ largest element, and then select elements with value exceeding this estimate. (A better algorithm revises these estimates over time, but let us ignore this optimization for now.) In the Byzantine case, there may be an arbitrary number of red items, so strategies that try to estimate some statistics (like the $K^{th}$ largest) to use for the rest of the algorithm are susceptible to adversarial attacks.

For now, suppose we know that all items of $S^*$ have values in $[1, n^c]$ for some constant $c$. The density of an item to be its value divided by its size. We define $O(\log n)$ density levels, where elements in the same level have roughly the same density, so our algorithm does not distinguish between them. The main idea of our algorithm is to use cascading budgets. At the beginning we allocate all our budget to picking only the highest-density level items. If we find that we are not picking items at a rate that is “good enough”, we re-allocate parts of
our budget to lower-density levels. The hope is that if the benchmark solution \( S^* \) selects many elements from a certain density level, we can get a good estimate of the “right” rate at which to pick up items from this level. Moreover, since our budgets trickle from higher to lower densities, the only way the adversary can confuse us is by giving dense red elements, in which case we will select them.

Such an idea works only for the value levels that contain many elements of \( S^* \). For the remaining value levels, we allocate dedicated budgets whose sole purpose is to pick a “few” elements from that level, irrespective of whether they are from \( S^* \). By making the total number of levels logarithmic, we argue that the total amount of dedicated budgets is only \( o(K) \), so it does not affect the analysis for the cascading budget.

### 3.1 An Algorithm Assuming a Polynomial Approximation

Suppose we know the benchmark value \( V^* \) to within a polynomial factor: by rescaling, assume that \( V^* \) lies in the range \([1 \ldots n^c]\) for some constant \( c \). This allows us to simplify the instance structure as follows: Firstly, we can pick all elements of size at most \( 1/n \), since the total space usage is at most \( n \cdot 1/n = 1 \) (recall, \( K = \text{poly}(\varepsilon^{-1} \log n) \)). Next, we can ignore all elements with value less than \( 1/n^2 \) because their total value is at most \( 1/n \ll 1 \leq V^* \). If the density of an element is defined to be the ratio \( v(e)/s(e) \), then all remaining elements have density between \( n^{-c+1} \) and \( n^{-2} \). The main result of this section is the following:

**Lemma 7.** If \( V^* \) lies between 1 and \( n^c \) for some constant \( c \), each element has size at least \( 1/n \) and value at least \( 1/n^2 \), and \( K = \text{poly}(\varepsilon^{-1} \log n) \), then there exists a \((1 + O(\varepsilon))\)-competitive algorithm.

The idea of our algorithm is to partition the input into \( 1/\delta \) disjoint pieces (\( \delta \) is a small parameter that will be chosen later) and try to solve \( 1/\delta \) “similar-looking” instances of the knapsack problem, each with a knapsack of size \( \delta K \).

**The Algorithm.** Define checkpoints \( T_i := \delta i \) and corresponding intervals \( I_i := (T_{i-1}, T_i] \) for all \( i \in [1 \ldots 1/\delta] \). Define \( L := (1 + \frac{c+3}{c} \log n) \) density levels as follows: for each integer \( \ell \in [0 \ldots L] \), density value \( \rho_{\ell} := n^{\ell+1}/(1+c)^{\ell} \). Now density level \( \ell \) corresponds to all densities lying in the range \( [\rho_{\ell+1}, \rho_{\ell}] \). Note that densities decrease as \( \ell \) increases. We later show that the setting of parameters \( K \geq \Omega\left(\frac{L \log L/\varepsilon}{c^3}\right) \) and \( 1/\delta = \Omega(L/\varepsilon) \) suffices.

We maintain two kinds of budgets:

- **Cascading budgets:** We maintain a budget \( B_{\ell,i} \) for each density level \( \ell \) and each interval \( I_i \).
  - For the first interval \( I_1 \), define \( B_{0,1} := \delta K \), and \( B_{\ell,1} := 0 \) for \( \ell > 0 \). For the subsequent intervals, we will set \( B_{\ell,i} \) in an online way as described later.

- **Dedicated budgets:** We maintain a dedicated budget \( \hat{B}_\ell := H \) for each density level \( \ell \); we will later show that setting \( H := \Omega\left(\frac{L \log L/\varepsilon}{c^3}\right) \) suffices.

Suppose we are in the interval \( I_i \), and the arriving element \( e \) has density \( v(e)/s(e) \) in level \( \ell \).

1. If the remaining cascading budget \( B_{\ell,i} \) of one of the density levels \( \ell' \geq \ell \) is positive then select \( e \). For the smallest \( \ell' \geq \ell \) satisfying this condition, update \( B_{\ell',i} := B_{\ell',i} - s(e) \).
2. Else, if the remaining dedicated budget \( \hat{B}_\ell \) for level \( \ell \) is positive, select \( e \) and update \( \hat{B}_{\ell} := \hat{B}_{\ell} - s(e) \).

Finally, for \( i > 1 \), we define the cascading budgets \( B_{\ell,i} \) for this interval \( I_i \) based on how much of the budgets at levels \( \ell \) and \( \ell - 1 \) are consumed in the previous interval \( I_{i-1} \) as follows.

The amount of budget \( B_{\ell-1,i-1} \) at level \( \ell - 1 \) that is not consumed in interval \( I_{i-1} \) is moved to level \( \ell \) (which has lower density), and the budget that gets consumed in \( I_{i-1} \) is restored.
Robust Algorithms for the Secretary Problem

Figure 1 The bars for $I_{i-1}$ show the budget, and (in darker colors) the amount consumed. The consumed budget (in dark blue) at level $\ell$ in interval $I_{i-1}$ is restored at level $\ell$ in $I_i$; the unconsumed budget at level $\ell-1$ in interval $I_{i-1}$ is then added to it.

at level $\ell$ (see Figure 1). Formally, if $C_{\ell,i-1}$ is the amount of consumed cascading budget for level $\ell$ in interval $I_{i-1}$ and $R_{\ell,i-1}$ is the amount of remaining budget at level $\ell$ at the end of interval $i-1$ (i.e., the value of $B_{\ell,i-1}$ at the time corresponding to the end of $I_{i-1}$), then we define the initial budget for level $\ell$ at the start of interval $i$ to be

$$B_{\ell,i} := C_{\ell,i-1} + R_{\ell,i-1}.$$ 

It is easy to see that we can compute these cascading budgets online.

A Note about Budget Violations. The total budget, summed over both categories and over all the intervals for the cascading budgets, is $K' := ((1/\delta) \cdot \delta K) + LH > K$. If we use up all this budget, we would violate the knapsack capacity. Moreover, we select an element as long as the corresponding budget is positive, and hence may exceed each budget by the size of the last element. However, since $K' \leq (1 + \varepsilon)K$ and $K$ is much larger than individual element sizes, the violations is a small fraction of $K$, so we can reject each element originally selected by the algorithm with some small probability (e.g., $p = 2\varepsilon$) to guarantee that the non-rejected selected elements have size at most $K$ with high probability (i.e., at least $1 - 1/n^c$, for an arbitrary constant $c > 0$). Henceforth, we will not worry about violating the budget.

The Analysis. Recall the benchmark $V^*$ from (3), and let $S^*$ be a set that achieves this value. All the elements have value in $[1/n^2,n^c]$ and size at least $[1/n,1]$, so each element $e \in S^*$ has a corresponding density level $\ell(e) \in [0 \ldots L)$ based on its density $v(e)/s(e)$. We need the notion of “heavy” and “light” levels. For any level $\ell \in [0 \ldots L)$, define $s^*_\ell$ to be the total size of elements in $S^*$ with density level $\ell$:

$$s^*_\ell := \sum_{e \in S^*: \ell(e) = \ell} s(e).$$

We say a level $\ell$ is heavy if $s^*_\ell \geq H$, else level $\ell$ is light. We refer to (green) elements of $S^*$ at a heavy (resp., light) level as heavy-green (resp., light-green) elements. Note that elements not in $S^*$ (some are red and others green) are left unclassified. If $H$ is sufficiently large, a concentration-of-measure argument using the uniformly random arrival times for green items shows that each heavy level receives $(1-\varepsilon)\delta H$ size during each interval with high probability. The idea of the proof is to argue that the cascading budget never “skips” a heavy level, and hence we get almost all the value of the heavy levels.

To avoid double-counting the values of the light levels, we separately account for the algorithm’s value attained (a) on light levels using the dedicated budget or on light-green elements using the cascading budget, and (b) for elements that are not light-green (incl.
red elements) using the cascading budget. Note that (a) and (b) are disjoint, hence their contributions can be added up. We show that (a) exceeds the value of $S^*$ restricted to the light levels, while (b) exceeds $(1 - \varepsilon)$ times the value of of $S^*$ on the heavy levels. This is sufficient to prove our result. We start by arguing the former claim.

\begin{claim}[Light-Green Elements] The sum of values of elements selected using the dedicated budget at light levels, and of light-green elements selected using the cascading budget, is at least $\sum_{\ell} s^*_\ell \cdot \rho_{\ell+1}$.
\end{claim}

\begin{proof}
Our algorithm attempts to select each light-green element in $S^*$ using the cascading budget, or failing that, by the dedicated budget at its density level. The only case in which a light-green element $e \in S^*$ is dropped is if all the dedicated budget at its level $\ell(e)$ has been exhausted. But this means the algorithm has already collected at least $s^*_\ell \cdot \rho_{\ell+1}$ from the dedicated budget at this light level $\ell$.
\end{proof}

Next, to prove that (b) exceeds the value on heavy levels (up to $1 - \varepsilon$), we need the following property of the cascading budget on the heavy levels.

\begin{claim}
For all intervals $I_i$ and levels $\ell$, w.h.p. we have that if $B_{\ell,i} > 0$ then every heavy level $\ell' < \ell$ satisfies $B_{\ell',i} \geq \delta s^*_{\ell'} \cdot (1 - \varepsilon)$.
\end{claim}

\begin{proof}
For a heavy level $\ell'$, the expected size of heavy-green elements from $S^*$ falling in any interval is $\delta s^*_{\ell'} \geq \delta H$. If $\delta H \geq \frac{\Omega(\log(L/(\delta s))]}{\ell}$ then with probability $1 - \varepsilon$ we get that for each interval $i$ and each heavy level $\ell'$, the total size of elements from $S^*$ lying at level $\ell'$ and arriving in interval $I_i$ is at least $\delta s^*_{\ell'} \cdot (1 - \varepsilon)$, by a concentration bound. Henceforth, let us condition on this event happening for all heavy levels $\ell'$.

Now if the cascading budget $B_{\ell,i} > 0$, this budget must have gradually come from levels $\ell' < \ell$ of higher densities. But this means $B_{\ell',i} \geq \delta s^*_{\ell'} \cdot (1 - \varepsilon)$ because otherwise the cascading budget would never move to level $\ell' + 1$, since level $\ell'$ receives at least $\delta s^*_{\ell'} \cdot (1 - \varepsilon)$ size of elements in every interval.
\end{proof}

For a level $\tau$ let $h^*_{[0,\tau]} := \sum_{\ell \text{ heavy}, \ell < \tau} s^*_{\ell}$ denote the total size of items in $S^*$ restricted to heavy levels from $[0,\tau)$. Similarly, let $h^A_{[0,\tau]}$ be the total size of non-light-green items collected by the algorithm in levels $[0,\tau)$ and charged against the cascading budget.

\begin{claim}
For all levels $\tau$ we have that $h^A_{[0,\tau]} \geq (1 - O(\varepsilon)) h^*_{[0,\tau]}$.
\end{claim}

\begin{proof}
Let $t$ be the smallest index of an interval where $B_{\tau,t+1} > 0$. We partition the intervals into two groups: $I_1, I_2, \ldots, I_t$ and $I_{t+1}, \ldots, I_{\ell/\delta}$. From Claim 9 we can conclude that for each interval in the latter group, the algorithm collects a total size of at least $\sum_{\ell \text{ heavy}, \ell < \tau} (1 - \varepsilon) \delta s^*_{\ell} = (1 - \varepsilon) \delta h^*_{[0,\tau]}$ from levels $[0,\tau)$. Hence the total contribution over all the intervals of the latter group is $(\frac{1}{2} - t)(1 - \varepsilon) \delta h^*_{[0,\tau]} = (1 - t\delta)(1 - \varepsilon) h^*_{[0,\tau]}$.

We now consider the group $I_1, \ldots, I_t$. Let $C_i, R_i$ and $Q_i$ be the total size of the consumed non-light-green, remaining budget, and consumed light-green elements charged to the cascading budget in interval $i$ with levels $[0,\tau)$. By definition, the total size of all light-green elements is at most $LH$, giving $\sum_{i=1}^t Q_i \leq LH$. Furthermore, since the full cascading budget is contained in $[0,\tau)$, the algorithm construction guarantees $C_i + R_i + Q_i = \delta K$. Finally, we argue that $\sum_{i=1}^t R_i \leq \delta KL$: consider an infinitesimally small part $dB$ of the budget. At the end of each interval, $dB$ is either used to consume an element or it “moves” from level $\ell$ to $\ell + 1$, which can happen at most $L$ times. Since the total amount of budget per interval is $\int dB = \delta K$, the total sum is at most $\delta KL$. 

This lower-bounds the total size contribution of the group $I_{t+1}, \ldots, I_{1/\delta}$.

$$\sum_{i=1}^{t} C_i = t \delta K - \sum_{i=1}^{t} R_i - \sum_{i=1}^{t} Q_i \geq t \delta K - \delta KL - LH \geq (t \delta - \varepsilon - \varepsilon) K$$

where we use $K \geq h^*_0[0, \tau]$ (since the total size of elements in $S^*$ is at most $K$), $\delta L \leq \varepsilon$, and $LH \leq \varepsilon K$. Combining contributions from both groups we get:

$$(1 - t \delta)(1 - \varepsilon) h^*_0[0, \tau] + (t \delta - O(\varepsilon)) h^*_0[0, \tau] = (1 - O(\varepsilon)) h^*_0[0, \tau].$$

Hence, we conclude that $h^*_A[0, \tau] \geq (1 - O(\varepsilon)) h^*_0[0, \tau]$.

Using the above claims we now prove Lemma 7.

Proof of Lemma 7. Our fine-grained discretization of densities gives us that

$$V^* \leq (1 + \varepsilon) \left( \sum_{\ell \text{ light}} s^*_\ell \rho_{\ell + 1} + \sum_{\ell \text{ heavy}} s^*_\ell \rho_{\ell + 1} \right).$$

(5)

From Claim 8, our algorithm accrues value at least $\sum_{\ell \text{ light}} s^*_\ell \rho_{\ell + 1}$ due to the elements from light levels that were charged to the dedicated budget and light-green elements charged to the cascading budget. It is therefore sufficient to prove a similar bound on the value accrued on non-light-green elements charged to the cascading budget with respect to $\sum_{\ell \text{ heavy}} s^*_\ell \rho_{\ell + 1}$, which we deduce from Claim 10.

Let $\ell'(x)$ be defined as the largest level $\ell'$ where $\rho_{\ell'} \geq x$, then

$$\sum_{\ell \text{ heavy}} s^*_\ell \rho_{\ell + 1} = \int_0^\infty \sum_{\ell \text{ heavy}, \rho_{\ell + 1} \geq x} s^*_\ell \, dx = \int_0^\infty h^*_0[0, \ell'(x)] \, dx \leq (1 + O(\varepsilon)) \int_0^\infty h^*_A[0, \ell'(x)] \, dx,$$

where the last inequality uses Claim 10. Notice the right-hand side is the value of non-light-green elements charged against the cascading budget. Thus, this part of the algorithm’s value exceeds (up to $1 - O(\varepsilon)$) the value of heavy levels of $S^*$, finalizing our proof. 

3.2 An Algorithm for the General Case

To remove the assumption that we know a polynomial approximation to $V^*$, the idea is to ignore the first $\varepsilon$ fraction of the arrivals, and use the maximum value in this interval to get a poly($n$) approximation to the benchmark. This strategy is easily seen to work if there are $\Omega(1/\varepsilon)$ elements with a non-negligible contribution to $V^*$. For the other case where most of the value in $V^*$ comes from a small number of elements, we separately reserve some of the budget, and run a collection of algorithms to catch these elements when they arrive.

Formally, we define $(1/\varepsilon)$ checkpoints $T_i := i\varepsilon$ and corresponding intervals $I_i := (T_{i-1}, T_i]$ for all $i \in [1, \ldots, (1/\varepsilon)]$. We run the following three algorithms in parallel, and select the union of elements selected by them.

(i) Select one of the $n$ elements uniformly at random; i.e., run Select-Random-Element from §2.1.
We can now fit this into our knapsack of size $1$. The idea of the algorithm in Step (iii) is to use the earliest arriving of these with probability $\varepsilon$. The total space used by the there algorithms is at most $1 + K + (1/\varepsilon) \cdot L \cdot D = K + O\left(\frac{\log n \log 1/\varepsilon}{\varepsilon^2}\right) \leq (1 + \varepsilon)K$, where the last inequality holds because $K \geq \Omega\left(\frac{L^2 \log(L/\varepsilon)}{\varepsilon^4}\right)$ from the size condition from §3.1. We can now fit this into our knapsack of size $K$ w.h.p. by sub-sampling each selected element with probability $(1 - O(\varepsilon))$. To complete the proof of Theorem 2, we need to show that we get expected value $(1 - O(\varepsilon))V^*$. 

**Proof of Theorem 2.** The proof considers several cases. Firstly, if there is any single element with value more than $n \cdot V^*$, then the algorithm in Step (i) will select it with probability $1/n$, proving the claim. Hence, all elements have value at most $nV^*$. Now suppose at least $D = \frac{10}{\varepsilon^2} \log \frac{1}{\varepsilon}$ elements in $S^*$ (recall $S^*$ has total value $V^*$) have individual values at least $V^*/n^2$. In this case, at least one of these $D$ elements arrives in the interval $[0, \varepsilon)$ with probability $1 - \varepsilon$, and that element gives us the desired $n^2$-approximation to $V^*$. Moreover, the expected value of elements in $S^*$ arriving in times $[\varepsilon, 1]$ is at least $(1 - O(\varepsilon))V^*$, even conditioning on one of them arriving in $[0, \varepsilon)$.

Finally, consider the case where $D' \leq D$ elements of $S^*$ have value more than $V^*/n^2$. The idea of the algorithm in Step (iii) is to use the earliest arriving of these $D'$ elements, or the element $g_{\text{max}}$, to get a rough estimate of $V^*$, and from thereon use the dedicated slots to select the remaining elements. Indeed, if the first of these elements arrive in interval $i$, the threshold $\hat{v}_i$ lies in $[V^*/n^2, nV^*]$ (since we did not satisfy the first case above). Now the value levels and dedicated budgets set up at the end of this interval would pick the rest of these $D'$ elements – except those that fall in this same interval $i$. We argue that each of the remaining $D'$ elements has at least $(1 - \varepsilon)$ probability of not being in $i$, which gives us an expected value of $(1 - O(\varepsilon))V^*$ in this case as well. This is true because the expected number of these $1 + D'$ elements (including $g_{\text{max}}$) that land in any interval that contains at least one of them is at most $1 + \varepsilon D'$ (even after we condition on the first arrival, each remaining element has $\varepsilon$ chance of falling in this interval). Since any such interval has the same chance of being the first interval $\bar{i}$, and these $1 + D'$ elements have the same distribution, the expected number of additional elements in $\bar{i}$ is $\varepsilon D'$.

This completes the proof of Theorem 2 for the knapsack case, where the size $K$ of the knapsack is large enough compared to the largest size of any element. This generalizes the multiple-secretary problem, where all items have unit size. We have not optimized the value of $K$ that suffices, opting for modularity and simplicity. It can certainly be improved further, though getting an algorithm that works under the assumption that $K \geq O(1/\varepsilon^2)$, like in the non-robust case, may require new ideas.

### 4 Single-Item Ordinal Case

In this section we give a proof of Theorem 4, showing that there exists an algorithm which selects an element with value no smaller than $g_2$, with probability at least $\Omega(1/\log n)$. Our proof for this theorem is non-constructive and uses (the hard direction of) the Minimax
Theorem; hence we can currently only show the existence of this algorithm, and not give a compact description for it. Our main technical lemma furnishes an algorithm which, given a known (general) probability distribution \( \mathcal{B} \) over input instances, selects a big element with probability at least \( \Omega(1/\log^2 n) \). Consequently, we use the Minimax Lemma to deduce that the known-distribution case is equivalent to the worst-case input setting and recover the analogous result.

Since our algorithms crucially argue about the input distribution \( \mathcal{B} \) and rely on the Minimax, we need to formally define these terms and establish notation connecting the Byzantine secretary problem with two-player zero-sum games. Suppose we want to maximize the probability of selecting a big element and to this end we choose an algorithm \( \mathcal{A} \), while the adversary chooses a distribution \( \mathcal{B} \) over the input instances and there is an (infinite) payoff matrix \( K \) prescribing the outcomes. Its rows are indexed by different algorithms, and columns by input instances. Formally, a “pure” input instance is represented as an \([R]\)-tuple of numbers in \([0, 1]\), representing the arrival times \( t_e \) of the red elements; and a permutation \( \pi \in S_n \) over \( U \) representing the total ordering of all values in \( U = R \cup G \). Recall that the green elements \( G \) choose their arrival times independently and uniformly at random in \([0, 1]\), hence their \( t_e \)’s are not part of the input. A “mixed” input instance is a probability distribution \( \mathcal{B} \) over pure instances \([0, 1]^{|R|} \times S_n \).

While we do not need the full formal specifications of algorithms, we will mention that a “mixed” algorithm \( \mathcal{A} \) is a distribution over deterministic algorithms. An algorithm \( \mathcal{A} \) on an input instance \( I \) gets a payoff of \( K(\mathcal{A}, I) := \Pr[v(\mathcal{A}) \geq v(g_2) \mid I] \) where the probability is taken over the assignment of random arrival times to elements in \( G \) and the distribution of deterministic algorithms \( \mathcal{A} \). The following Lemma states that for each \( \mathcal{B} \) there is an algorithm (that depends on \( \mathcal{B} \)) that selects a big elements with probability \( \Omega(1/\log^2 n) \). We prove the result in §4.1 and §4.2.

\[ \textbf{Lemma 11 (Known Distribution Ordinal Single-Item Algorithm).} \quad \text{Given a distribution over input instances } \mathcal{B}, \text{ there exists an algorithm } \mathcal{A} \text{ that has an expected payoff of } \Omega(1/\log^2 n). \]

To deduce the general case from the known distribution setting, we use a minimax lemma for two-player games. We postpone the details to Appendix C and simply state the final result here.

\[ \textbf{Theorem 4 (Ordinal Single-item Algorithm).} \quad \text{There is a randomized algorithm for the ordinal Byzantine secretary which selects an element of value at least the second-largest green item with probability } \Omega(1/\log^2 n). \]

### 4.1 The Algorithm when \( \mathcal{B} \) is Known

In this section we give the algorithm for Lemma 11. We start with some preliminary notation. For each element \( e \), let \( t_e \) denote the time at which it appears. Furthermore, for \( t \in [0, 1] \), let \( \mathcal{K}(t) \) denote the information seen by the algorithm up to and including time \( t \), consisting of arrival times and relative values of elements appearing before \( t \).

We define \( \log n + 1 \) time checkpoints as follows: set the initial checkpoint \( T_0 := \frac{1}{4} \), and then subsequent checkpoints \( T_i := \frac{1}{4} + \frac{3}{4 \log n} \) for all \( i \in [1 \ldots \log n] \). Note that the last checkpoint is \( T_{\log n} = \frac{3}{4} \). Now the corresponding intervals are

\[ \mathbb{I}_0 := [0, 1/4), \quad \mathbb{I}_i := [T_{i-1}, T_i] \quad \forall i \in [1 \ldots \log n], \quad \text{and} \quad \mathbb{I}_{\log n+1} := [3/4, 1]. \]  

Let \( m_i := \max \{ v(e) \mid e \in R \text{ and } t_e \in \mathbb{I}_i \} \) be the maximum value among the red elements that land in interval \( \mathbb{I}_i \), and let \( \mathcal{H}_i := \{ m_i > v(g_2) \} \) for all \( i \in [1 \ldots \log n] \) be the event where the maximum value red item in all intervals is larger than the target \( g_2 \), i.e., is “big”. We
call this event \( H \) the **hard cases** and \( H^c \) the **easy cases**; we will show the Two Checkpoints Secretary (from §2.1) achieves \( \Omega(1/\log^2 n) \) winning probability for all input instances in \( H^c \). Finally, define

\[
p^i_e := P_{B^i}[e = g_2 \mid H \text{ and } K(T_i)],
\]

i.e., \( p^i_e \) is the probability that \( e \) is the second-highest green element conditioned on the information seen until checkpoint \( T_i \) and the current instance being hard. Importantly, the algorithm can compute \( p^i_e \) at \( T_i \).

Now to solve the hard cases, at each checkpoint \( T_i \) the algorithm computes sets \( S_i \) satisfying \( S_{i+1} \subseteq S_i \). These sets represent elements which are candidates for the second-max.

In other words, at time \( T_i \) there is reasonable probability that second-max is in \( S_i \). We start with defining \( S_0 \leftarrow \{ e \in U \mid t_e \in \mathbb{I}_0 \} \), the elements the algorithm saw before \( T_0 \). For \( i \geq 0 \), let \( c_i \) denote the center of \( S_i \), i.e., the element of \( S_i \) such that there are exactly \( \lfloor |S_i|/2 \rfloor \) elements smaller than it. Define \( p^i(X) := \sum_{e \in X} p^i_e \) for a set \( X \) and index \( i \geq 0 \). Given \( S_{i-1} \), we determine \( S_i \) as follows:

- Define \( \text{bot}_{i-1} := \{ e \in S_{i-1} \mid v(e) \leq v(c_{i-1}) \} \), and note that \( \text{bot}_{i-1} \subseteq S_{i-1} \).
- If \( p^i(\text{bot}_{i-1}) = p^{i-1}(S_{i-1}) \) then \( S_i := \text{bot}_{i-1} \), else \( S_i := S_{i-1} \setminus \text{bot}_{i-1} \).

Our algorithm runs one of the following three algorithms uniformly at random:

(i) Select a random \( i \in [1 \ldots \log n] \), define \( \tau := \max \{ v(e) \mid t_e \in \mathbb{I}_i \} \) and select the first element larger than \( \tau \). I.e., run Two Checkpoints Secretary (from §2.1) with the checkpoints being the ends of interval \( \mathbb{I}_i \).

(ii) Select a random \( i \in [0 \ldots \log n] \), read input until checkpoint \( T_i \), define \( \tau := v(c_i) \) and select the first element larger than it.

(iii) Compute the sets \( S_i \) until \( |S_k| \leq 10 \) for some \( k \); then define \( \tau \) to be the value of a random element in \( S_k \), and select the first element larger than it.

### 4.2 The Analysis

In this section we prove Lemma 11. Let us give some intuition. We can assume we have a hard case, else the first algorithm achieves \( \Omega(1/\log^2 n) \) winning probability. For the other two algorithms, let us condition on \( g_2 \) falling in the first interval \( \mathbb{I}_0 \), and then exploit the fact that there is a big red element in every interval \( \mathbb{I}_i \). It may be useful to imagine that we are trying to guess, at each checkpoint, which of the elements in the past were actually \( g_2 \). If we could do this, we would set a threshold at its value, and select the first subsequent element bigger than the threshold – and since there is a \( 1/4 \) chance that \( g_{\max} \) would fall in \( \mathbb{I}_{\log n+1} \), we’d succeed! Of course, since there are red elements all around, guessing \( g_2 \) is not straightforward.

So suppose we are at checkpoint \( T_k \), and suppose there is a reasonable probability that \( v(g_2) \leq v(c_{k-1}) \), but also still some nonzero probability that \( v(g_2) > v(c_{k-1}) \). In such a scenario, we claim that trying to choose an element in the interval \( \mathbb{I}_k \) larger than \( c_{k-1} \) will give us a reasonable probability of success. Indeed, we claim there would have been at least one red element in \( \mathbb{I}_k \) bigger than \( c_{k-1} \) (since there is still a non-zero probability that \( v(g_2) > v(c_{k-1}) \) even at the end of the interval \( \mathbb{I}_k \), and since the case is hard), and \( v(g_2) \leq v(c_{k-1}) \) with reasonable probability. Of course, we only know this at the end of the interval, but the algorithm can randomly guess \( k \) with \( \Omega(1/\log n) \) probability. Finally, if there is no such checkpoint, then in every interval we reduce the size of set \( |S_i| \) by half while suffering a small loss in \( p(S_i) \). In this case, both \( |S_{\log n}| = O(1) \) and \( p(S_{\log n}) = \Omega(1) \), so the third algorithm can guess \( g_2 \) with constant probability and select an element larger than it in the last interval.
Robust Algorithms for the Secretary Problem

Formal Analysis. Let ALG be 1 if \( v(A) \geq v(g_2) \) and 0 otherwise, where \( A \) is the algorithm from the last section. Suppose we’re in an easy case, i.e., there is an interval \( I_s \) such that all red elements in this interval are smaller than \( g_2 \). Now if the first algorithm is chosen, suppose it selects the interval \( I_s \), suppose \( g_2 \) lands in \( I_s \), and \( g_{\text{max}} \) lands in \( I_{\log n+1} \). Then the algorithm surely selects an element greater than \( g_2 \), and it has expected value:

\[
E[ALG] = \frac{1}{3} \cdot \frac{1}{\log n} \cdot \frac{1}{2\log n} \cdot \frac{1}{4} = \Omega \left( \frac{1}{\log^2 n} \right).
\]

Henceforth we can assume the case is hard, and hence each interval \( I_i \) contains a red element bigger than \( g_2 \). We condition on the event that \( g_2 \) appears in \( I_0 \), which happens with constant probability. Define

\[
k^* := \min \{ i \in [1 \ldots \log n] \mid \frac{1}{\log n} \leq \frac{p^i(\text{bot}_{i-1})}{p^{i-1}(S_{i-1})} < 1 \},
\]

and set \( k^* = \log n + 1 \) if the above set is empty.

\( \triangleright \) Claim 12. For all \( i < k^* \), the probability \( p^i(S_i) = \Omega(1) \).

Proof. By definition, \( p^0(S_0) = 1 \). By our definition of the sets \( S_i \), we know that if \( p^i(\text{bot}_{i-1}) = p^{i-1}(S_{i-1}) \) then \( p^i(S_i) = p^{i-1}(S_{i-1}) \). Else since \( i < k^* \), we have

\[
p^i(S_i) = p^{i-1}(S_{i-1}) - p^i(\text{bot}_{i-1}) \leq p^{i-1}(S_{i-1})(1 - \frac{1}{\log n}).
\]

Hence, \( p^i(S_i) \geq (1 - \frac{1}{\log n})^{\log n} = \Omega(1) \), proving the claim.

Now there are two cases, depending on the value of \( k^* \). Suppose \( k^* \leq \log n \). Condition on the event that the second algorithm is chosen, that it chooses the \( i^{th} = (k^* - 1)^{th} \) checkpoint, and that \( v(g_2) \leq v(c_i) \). By our choice of \( k^* \), we get that \( v(g_2) \leq \tau = v(c_i) \) with probability at least \( p^i(S_i) \cdot \frac{1}{\log n} \), and by Claim 12 this is \( \Omega(\frac{1}{\log n}) \). Since the case we are considering is hard and \( \Pr[v(g_2) > v(c_i) \mid H \text{ and } K(T_{i+1}) > 0] \), there is a red element larger than \( v(c_i) = \tau \) appearing in \( I_i \). Thus the algorithm will always select an element in this interval. The correct interval is chosen with probability \( \frac{1}{\log n} \), so the algorithm’s value is

\[
E[ALG] = \frac{1}{3} \cdot \frac{1}{\log n} \cdot \Omega \left( \frac{1}{\log n} \right) = \Omega \left( \frac{1}{\log^2 n} \right).
\]

The other case is when \( k^* = \log n + 1 \). By definition \( |S_0| \leq n \) and \( |S_i| \leq \lfloor |S_{i-1}|/2 \rfloor \). Therefore \( |S_{\log n}| \leq 10 \). Let us condition on the event that the third algorithm is chosen, that \( g_{\text{max}} \) appears in \( I_{\log n+1} \), and that the algorithm guesses \( g_2 \) correctly. The probability of this event is at least

\[
\frac{1}{3} \cdot \frac{1}{4} \cdot p^{\log n}(S_{\log n}) \cdot \frac{1}{10} = \Omega(1).
\]

where we use Claim 12 to bound the probability \( p^{\log n}(S_{\log n}) \). In this event, the algorithm selects an element larger than \( g_2 \) and has expected value \( E[ALG] = \Omega(1) \).

Putting all these cases together, we get that our algorithm selects an element with value at least \( v(g_2) \) with probability at least \( \Omega((\log n)^{-2}) \). This finishes the proof of Lemma 11, and hence of Theorem 4. It remains an intriguing open question to get a direct algorithm that achieves similar guarantees.

5 Single-Item Value-Maximization

In this section, we give an algorithm for the problem of selecting an item to maximize the expected value, instead of maximizing the probability of selecting the second-largest green item (the ordinal problem considered in §4). In the classical secretary problem, both problems are well known to be equivalent, with Dynkin’s algorithm giving a tight $1/e$ bound for both. But in the Byzantine case the problems thus far appear to have different levels of complexity: in §6.2 we present a simple $O(\log n)$-competitive algorithm for the value-maximization Byzantine secretary problem, which is already better than the poly log $n$-competitive of §4. We now substantially improve it to give a poly log*$n$-competitive ratio.

Theorem 3 (Value Maximization Single-Item). There is a randomized algorithm for the value-maximization (single-item) Byzantine secretary problem which gets an expected value at least $(\log^* n)^{-2} \cdot V^*$.

In the rest of this section, let $V^* := v(g_2)$ denote the benchmark, the value of the second-largest green element. The high level idea of our algorithm is to partition the input into $\Omega(\log^* n)$ intervals and argue that every interval contains a red element of value $v_i > V^*$, as otherwise Dynkin’s algorithm will be successful. Moreover, this $v_i$ cannot be much larger than $V^*$, as otherwise we can just select a random element. This implies we can use the largest value in each interval to find a good estimate of $V^*$, and eventually set it as a threshold in the last interval to select a large value element.

5.1 The Algorithm

Define $\log^{(i)} n$ to be the iterated logarithm function: $\log^{(0)} n = n$ and $\log^{(i+1)} n = \log(\log^{(i)} n)$. We define $\log^* n + 1$ time checkpoints as follows: the initial checkpoint $T_0 = \frac{1}{2}$, and then subsequent checkpoints $T_i = \frac{1}{2} + \frac{1}{4 \log^* n}$ for all $i \in [1, \ldots, \log^* n]$. Note that the last checkpoint is $T_{\log^* n} = \frac{3}{4}$.

Now the intervals are

$$I_0 := [0, T_0], \quad I_i := (T_{i-1}, T_i) \forall i \in [1, \ldots, \log^* n], \quad \text{and} \quad I_{\log^* n+1} := (T_{\log^* n}, 1).$$

(7)

Our algorithm runs one of the following three algorithms chosen uniformly at random.

(i) Select one of the $n$ elements uniformly at random; i.e., run Select-Random-Element from §2.1.

(ii) Select a random interval $i \in [1 \ldots \log^* n]$ and run Dynkin’s secretary algorithm on $I_i$. Formally, run Two-Checkpoints-Secretary (from §2.1) with the interval being $[T_{i-1}, \frac{1}{2}(T_{i-1} + T_i)]$.

(iii) Select a random index $i \in [0 \ldots \log^* n]$ and observe the maximum value during the interval $I_i$; let this maximum value be $v_i$. Choose a uniformly random $s \in [0 \ldots 2 \log^{(i)} n]$. Select the first element arriving after $T_i$ that has value at least $\tau := (v_i \log^{(i)} n) / 2^s$.

5.2 The Analysis

To prove Theorem 3, assume WLOG that there are only two green elements $g_{\max}$ and $g_2$, and every other element is red (otherwise, we can condition on the arrival times of all other green elements). Let $v_i$ be the value of the highest red element in $I_i$, i.e., excluding $g_{\max}$ and $g_2$. 

ITCS 2020
Proof of Theorem 3. We assume \( \log(i)n \) is an integer for all \( i \); this is true with a constant factor loss. For sake of a contradiction, assume that the algorithm in §5.1 does not get expected value \( \Omega((\log^* n)^{-2} V^*) \). Under this assumption, we first show that every interval contains a red element of value at least \( V^* \).

\( \triangleright \) Claim 13. For all \( j \in [1 \ldots \log^* n] \) we have \( v_j \geq V^* \).

Proof. Suppose this is not the case. Let \( E_1 \) be the event that the following three things happen simultaneously: that we select Algorithm ii in §5.1 with random variable \( i = j \), that the second-highest green element \( g_{\text{max}} \) falls in the interval \([T_{i-1}, \frac{1}{2}(T_{i-1} + T_i)]\), and that the highest green element \( g_{\text{max}} \) falls in \([\log^* n + 1]\). Note that \( \Pr[E_1] = \frac{1}{3\log^* n} \cdot \frac{1}{2\log^* n} \cdot \frac{1}{4} = \Omega((\log^* n)^{-2}) \). Conditioned on this event \( E_1 \), our algorithm (or specifically, Algorithm ii on the interval \( I_j \)) gets a value at least \( v(g_2) = V^* \). Hence the algorithm has expected valuation \( \Omega((\log^* n)^{-2} V^*) \), which is a contradiction to our assumption on its performance. \( \triangleright \)

We now prove that these red elements with large values cannot be much larger than \( V^* \).

\( \triangleright \) Lemma 14. For all \( j \in [1 \ldots \log^* n] \) we have \( v_j \leq V^* \cdot \log^{(j-1)} n \).

Proof. We prove this lemma by induction. The base case \( j = 1 \) says \( v_1 \leq nV^* \), i.e., the highest observed value in \( l_1 = [T_0, T_1] \) is at most \( nV^* \). Suppose this is not the case – there exists a red element \( e \) in \( l_1 \) with value at least \( nV^* \). Let \( E_1 \) be the event that we select Algorithm i in §5.1 (i.e., Select-Random-Element) and that it selects \( e \). Since \( \Pr[E_1] = \Omega(\frac{1}{n}) \), we have a contradiction that the expected valuation is \( \Omega(V^*) \).

Now suppose the statement is true until \( j \geq 1 \). We prove the inductive step \( j+1 \). Suppose not, i.e., \( v_{j+1} > V^* \log^{(j)} n \). Let \( E_2 \) be the event that we select Algorithm iii in §5.1 with parameter \( i = j \) and that the random \( s \in [0 \ldots 2\log^{(j)} n] \) is such that \( \frac{s}{2\log^* n} \leq V^* < \frac{s}{2} \) (it exists by induction hypothesis). This implies threshold \( \tau := \frac{v_j \log^{(j)} n}{2} \) is between \( \frac{1}{2} V^* \log^{(j)} n \) and \( V^* \log^{(j)} n \). Note \( \Pr[E_2] \geq \frac{1}{3} \cdot \frac{v_j \log^{(j)} n}{2\log^* n} \cdot \frac{1}{2\log^{(j)} n} \). Since event \( E_2 \) implies the algorithm gets value at least \( \tau \geq \frac{1}{2} V^* \log^{(j)} n \) (because \( v_{j+1} > \tau \)), its expected value is \( \Omega((\log^* n)^{-1} V^*) \), a contradiction. \( \triangleright \)

Now by Claim 13 and Lemma 14, we have \( v_j \in [V^*, V^* \cdot \log^{(j)} n] \) for all \( j \in [1 \ldots \log^* n] \). We still get a contradiction. Let \( E_3 \) be the event that the following three things happen simultaneously: that we select Algorithm iii in §5.1 with \( i = \log^* n \), that the highest green element \( g_{\text{max}} \) is in interval \([\log^* n + 1]\), and that we select \( s \) in Algorithm iii such that \( \tau := (\log^* n \log^{(j)} n)/(2\log^* n) \) is between \( \frac{1}{2} V^* \) and \( V^* \). Note \( \Pr[E_3] \geq \frac{1}{2\log^* n} \cdot \frac{1}{2\log^{(j)} n} \cdot \frac{1}{4} = \Omega((\log^* n)^{-2} V^*) \). Thus, we have a contradiction in every case, which means our assumption is incorrect and the algorithm has expected value \( \Omega((\log^* n)^{-2} V^*) \). \( \triangleright \)

6 Value Maximization for Matroids

In this section we discuss multiple-choice Byzantine secretary algorithms in the matroid setting.

\( \triangleright \) Definition 15 (Byzantine secretary problem on matroids). Let \( \mathcal{M} \) be a matroid over \( U = R \cup G \), where elements in \( G = \{g_{\text{max}}, g_2, \ldots, g_{|G|}\} \) arrive uniformly at random in \([0, 1]\). When an element \( e \in U \) arrives, the algorithm must irrevocably select or ignore \( e \), while ensuring that the set of selected elements forms an independent set in \( \mathcal{M} \). The leave-one-out benchmark \( V^* \) is the highest-value independent subset of \( G \setminus \{g_{\text{max}}\} \).
The knapsack results imply \((1 - \varepsilon)\)-competitiveness for uniform matroids as long as the rank \(r\) is large enough; we now consider other matroids.

### 6.1 \(O(\log \log n)^2\)-Competitiveness for Partition Matroids

A partition matroid is where the elements of the universe are partitioned into parts \(\{P_1, P_2, \ldots\}\). Given some integers \(r_1, r_2, \ldots\), a subset of elements is independent if for every \(i\) it contains at most \(r_i\) element from part \(P_i\).

**Theorem 5 (Partition Matroids).** There is an algorithm for Byzantine secretary on partition matroids that is \(O(\log \log n)^2\)-competitive with the benchmark \(V^*\).

We prove Theorem 5 for simple partition matroids where all \(r_i = 1\), i.e., we can select at most one element in each part. This is without loss of generality (up to \(O(1)\) approximation) because we can randomly partition each part \(P_i\) further into \(r_i\) parts and run the simple partition matroid algorithm.

Recall that our single item poly \(\log^2 n\) algorithm from §5 no longer works for partition matroids. This is because besides one part we want to get the highest green element in all the other parts. Formally, Claim 13 where we use Dynkin’s secretary algorithm in the proof of Theorem 3 fails because it needs at least two green elements. So we need to overcome the lower bound to getting the highest-value green element \(v(g_1)\) in Observation 19. We achieve this and design an \(O(\log \log n)^2\)-approximation algorithm by making an assumption that the algorithm starts with a polynomial approximation to \(v(g_1)\). Although in general this is a strong assumption, it turns out that for partition matroids this assumption is w.l.o.g., because the algorithm may lose the highest green element in one of the parts.

#### 6.1.1 The Algorithm

We define \(\log \log n + 1\) time checkpoints as follows: the initial checkpoint \(T_0 = \frac{1}{2}\), and then subsequent checkpoints \(T_i = \frac{1}{2} + \frac{i}{\log \log n}\) for all \(i \in [1 \ldots \log \log n]\). Now the corresponding intervals are

\[
I_0 := [0, T_0] \quad \text{and} \quad I_i = (T_{i-1}, T_i) \quad \forall i \in [1 \ldots \log \log n]
\]  

Let \(v_0\) denote the value of the max element seen by the algorithm in \(I_0\).

Now for every part \(P\) of the partition matroid, we execute the following algorithm separately. Let \(v_i\) for \(i \in [1 \ldots \log \log n]\) denote the value of the max element seen by the algorithm in part \(P\) during interval \(I_i\). Let \(V^*\) denote the element of our benchmark in \(P\). Notice that \(v_i \in P\) and \(V^*\) cannot be the overall highest green element as we exclude it. We define \(4 \log^{1/3} n\) levels for \(I_i\), where level \(j\) for \(j \in [1 \ldots 4 \log^{1/3} n]\) is given by elements with values in

\[
\left[\frac{v_{i-1} \cdot \log^{1/3} n}{2^j}, \frac{v_{i-1} \cdot \log^{1/3} n}{2^{j-1}}\right].
\]

We run one of the following algorithms uniformly at random.

(a) Select an element uniformly at random as discussed in §2.1.

(b) For every part \(P\), select a random interval \(i \in [1 \ldots \log \log n]\) and select a random level \(j \in [4 \log^{1/3} n]\). Select the first element above \(\frac{v_{i-1} \cdot \log^{1/3} n}{2^j}\) in \(P\).

(c) For every part \(P\), select a random interval \(i \in [1 \ldots \log \log n]\) and if there is an element with value more than \(2 \log^{1/3} n\) times the max of all the already seen elements in \(I_i\), selects it with constant probability, say \(1/100\).
6.1.2 The Analysis

Since with constant probability our algorithm selects one of the $n$ elements uniformly at random (Algorithm a), we can assume that $v_0 \leq n^2 \cdot V^*$. We always condition on the event that $v_{\text{max}}$ arrives in the interval $I_0$, which happens with constant probability and implies $v_0 \geq v_{\text{max}}$. Moreover, we ignore parts $P$ where $V^*$ is below $v_{\text{max}}/n^2$ because they do not contribute significantly to the benchmark. So from now assume 

$$V^*/n^2 \leq v_0 \leq n^2 \cdot V^*.$$ 

We design an algorithm that gets value $\Omega(V^*/(\log \log n)^2)$ in each part $P$, which implies Theorem 5 by linearity of expectation over parts.

Let $v^{\text{red}}_i \in P$ for $i \in [1 \ldots \log \log n]$ denote the value of the max red element that the adversary presents in $I_i$.

> Claim 16. If there exists an $i \in [1 \ldots \log \log n]$ with $v^{\text{red}}_i > V^* \cdot \log 1/i$ then the expected value of the algorithm is $\Omega(V^*/\log \log n)$.

Proof. With constant probability, our algorithm selects a random interval $i$ and selects a random level element in it (Algorithm b). Since w.p. $1/\log \log n$ it selects this $i$, and w.p. $\frac{1}{2^{\log 1/i}} n$ it selects the random level of $v^{\text{red}}_i$ in $I_i$, the algorithm has expected value at least

$$\frac{1}{\log \log n} \cdot \frac{1}{2^{\log 1/i}} n \cdot v^{\text{red}}_i \geq \frac{1}{4 \log \log n} \cdot V^*. \quad \triangleright$$

By the last claim we can assume for all $i \in [1 \ldots \log \log n]$, we have $v^{\text{red}}_i \leq V^* \cdot \log 1/i$.

> Claim 17. If there exists an $i \in [1 \ldots \log \log n]$ with $v^{\text{red}}_i < V^*/2^{\log 1/i}$ then the expected value of the algorithm is $\Omega(V^*/(\log \log n)^2)$.

Proof. With constant probability the algorithm guesses one of the intervals $i$ and if there is an element with value more than $2^{\log 1/i} n$ times the max of all the already seen elements in $I_i$, selects it with constant probability (Algorithm c). With $1/\log \log n$ probability the algorithm selects this particular $i$ and with $1/\log \log n$ probability $V^*$ appears in this interval with value at least $2^{\log 1/i} n$ times the max seen element in this interval. Notice there can be at most $O\left(\frac{\log 1/i}{\log \log n}\right) = O(1)$ elements with such large jumps in value in this interval. In this case our algorithm selects $V^*$ with constant probability. \triangleright

Finally, we are only left with the case where for all $i \in [1 \ldots \log \log n]$ value $\frac{V^*}{2^{\log 1/i} n} \leq v^{\text{red}}_i \leq V^* \cdot \log 1/i$, which we handle using Algorithm b.

> Claim 18. If for all $i \in [1 \ldots \log \log n]$ we have 

$$\frac{V^*}{2^{\log 1/i} n} \leq v^{\text{red}}_i \leq V^* \cdot \log 1/i$$

then the expected value of the algorithm is $\Omega(V^*/(\log \log n)^2)$.

Proof. Consider Algorithm b. It selects $i = \log \log n - 1$ w.p. $1/\log \log n$. Moreover, suppose $V^*$ appears in $I_{\log \log n-1}$. Now since there are only a constant number of levels in this interval, our algorithm selects an element of value at least $V^*$ with constant probability. \triangleright

We have shown that in every case the algorithm has expected value $\Omega(V^*/(\log \log n)^2)$ for any fixed part $P$. This implies Theorem 5 by linearity of expectation over parts.
6.2 \(O(\log n)\)-approx for General Matroids

\textbf{Observation 6 (General Matroids).} There is an algorithm for Byzantine secretary on general matroids that is \(O(\log n)\)-competitive with the benchmark \(V^*\).

\textbf{Proof.} Notice that no element can have weight more than \(nr\) times the second max-element because w.p. \(1/n\) our algorithm selects one of the \(n\) elements uniformly at random. Given this, condition on the event that the max element with value \(v\) lands in the first half of the input. Define \(2\log(nr)\) exponentially separated levels as follows:

\[
\left[ \frac{v}{2\log(nr)}, \frac{v}{2\log(nr)-1}, \frac{v}{2\log(nr)-2}, \ldots \right], \ldots, \left[ \frac{v}{2}, v \right], \ldots, \left[ v^{\log(nr)-1}, v^{2\log(nr)} \right].
\]

Since at least one of these intervals contains at least \(2\log(nr)\) fraction of \(\text{OPT}\), we can guess that interval and run a greedy algorithm, i.e., accept any element with value in that interval or above if it is independent. \(\square\)

7 Conclusion

In this paper we defined a robust model for the secretary problem, one where some of the elements can arrive at adversarially chosen times, whereas the others arrive at random times. For this setting, we argue that a natural is the optimal solution on all but the highest-valued green item (or even simpler, the optimal solution on the green items, minus the single highest-value item). This benchmark reflects the fact that we cannot hope to compete with the red (adversarial) items, and also cannot do well if all the green value is concentrated in a single green item.

We show that for the case where we want to pick \(K\) items, or if we have a knapsack of size \(K\), we can get within \((1-\varepsilon)\) of this benchmark, assuming \(K\) is large enough. We can also get non-trivial results for the single-item case, where our benchmark is now the second-highest valued green item. In the ordinal setting where we only see the relative order of arriving elements and the goal is to maximize the probability of getting an element whose value is above the benchmark, we use the minimax principle to show existence of an \(O(\log^2 n)\)-approximation algorithm in \$4\$. In the value maximization setting, we give an \(O(\log \log n)^2\)-approximation algorithm in \$5\%. We also show \(O(\log \log n)\)-competitiveness for partition matroids.

The results above suggest many questions. Can we improve the lower bound on the size required for \((1-\varepsilon)\)-competitiveness? Can we get a constant-competitive algorithm for the single-item case? For the probability-maximization problem, our proof only shows the existence of an algorithm; can we make this constructive? More generally, many of the algorithms for secretary problems seem to overfit to the model, at least in the presence of small adversarial changes: how can we make our algorithms robust?

\textbf{References}

A  Hard Benchmarks

We show that for the benchmark $V^* := v(g_{max})$, every algorithm has an approximation of at most $O(1/n)$.

Observation 19 (Lower Bound for $g_{max}$). Any randomized algorithm for the single-item Byzantine secretary problem cannot select the highest-value good/green item with probability larger than $1/(|R| + 1)$.

Proof. We use Yao’s minimax lemma, so it is enough to construct an input distribution $B$ for which no deterministic algorithm can achieve an approximation better than $\frac{1}{|R| + 1}$. The distribution is as follows. The red elements arrive at random times, that is $(t_{r_1}, t_{r_2}, ..., t_{r_{|R|}}) \sim U[0, 1]^{|R|}$. The linear ordering among the elements is set such that the red elements are strictly increasing according to their arrival time, or formally: $t_{r_i} > t_{r_j} \implies v(r_i) > v(r_j)$.

The maximum element is green and all the other green elements are smaller than all red elements. Formally: $v(g_{max}) > v(r_1) > v(r_2) ... > v(r_{|R|}) > v(g_2) > v(g_3) ... > v(g_{|G|})$. This fully defines the input distribution.

All the arrival times are distinct with probability $1$. Let $K(t)$ denote the information seen by the algorithm up to and including time $t$. Partition the probability space according to $S := \{g_{max}, t_{r_1}, t_{r_2}, ..., t_{r_{|R|}}\}$ and $L := \{g_2, g_3, ..., g_{|G|}\}$. Let $s_1 < s_2 < ... < s_{|R|+1}$ be the elements of $S$. Let $M_i := \{t_{g_{max}} = s_i\}$. By definition, we have $Pr[M_i|S, L] = \frac{1}{|R|+1}$. Note that, since the red items arrive in increasing order of value and the green item has maximum value, we have $Pr[M_i|S, L, K(t)] = Pr[M_j|S, L, K(t)]$ for all $t \leq s_i, s_j$. Therefore, $Pr[M_i|S, L, K(s_i)] \leq \frac{1}{|R|+1}$.

In other words, there is no way to distinguish the maximum green element from the red elements before it is too late, that is at the time of the green element’s arrival. Thus, by a simple inductive argument, the proof is finished.

Using techniques presented in [7], we can extend this result to the value case as well.

B  Relaxing the Assumption that $n$ is Known

In this section we extend our results to some settings where $n$ is unknown. Most importantly, observe that all of the results in this paper hold even if $n$ is known only up to a constant factor with at most a constant factor degradation in the quality of the result. As a simple example, note that picking a uniformly random element from an $n$-element sequence when the assumed number of elements is $\tilde{n} \in [n, 2n]$ will select an element $x \in U$ with probability $p_x \in \left[\frac{1}{2n}, \frac{1}{n}\right]$, leading to a degradation in the result by a factor of at most 2, which we typically ignore in this paper.

This still leaves us open to the possibility that we do not even know the scale of $n$. Surprisingly, it is still possible to “guess” $\tilde{n}$ while only incurring a loss of $\tilde{O}(\log n)$ in the quality, even if there is no prior known upper limit on $n$.\footnote{By $\tilde{O}(f(n))$ we mean $f(n) \cdot \text{poly}(\log f(n))$.} The following claim formalizes this result.

Claim 20. There exists a distribution $X$ over the integers such that for every $n \geq 1$ the probability that the sampled number $\tilde{n} \sim X$ is within a constant factor of $n$, is at least $1/\tilde{O}(\log n)$.\footnote{By $\tilde{O}(f(n))$ we mean $f(n) \cdot \text{poly}(\log f(n))$.}
Proof. Consider the sequence \(a_k := \frac{1}{k^{\log_2 k} (\log_2 k)^2}\) defined for \(k \geq 2\). It is well-known that this sequence converges, i.e., \(\sum_{k=2}^{\infty} a_k = O(1)\). A simple way to see this is by noting that a non-negative decreasing sequence \((A_k)\) converges if and only if \((2^k A_{2^k})\) converges [40, Thm 3.27].

Let \(\sum_k^{\infty} A_k \sim \sum_k^{\infty} B_k\) be the equivalence relation denoting that \((A_k)\) and \((B_k)\) either both converge or both diverge. Then the above fact implies that \(\sum_k^{\infty} \frac{1}{k^{\log_2 k} (\log_2 k)^2} \sim \sum_k^{\infty} \frac{1}{k^2}\), where the last sequence clearly converges.

We can assume without loss of generality that \(n \geq 100\) by handling those cases separately. The strategy for guessing the estimate \(\bar{n}\) is now immediate: we sample \(\bar{n}\) from \(Z_{\geq 2}\) according to the distribution \(\Pr[\bar{n} = k] = a_k/Z\) where \(Z := \sum_{k=100}^{\infty} a_k = O(1)\). We observe that \(\Pr[\bar{n} \in \{2^{k-1} \ldots 2^k\}] \geq \frac{1}{2} 2^k a_{2^k}/Z = \Omega(1/k)\). Let \(k'\) be the unique index such that \(n \in \{2^{k'-1} \ldots 2^{k'}\}\), hence \(k' = \Theta(\log n)\). Then \(\Pr[\bar{n} \in \{2^{k'} \ldots 2^{k'+1}\}] = \Omega(1/k') = \Omega(1/\log n)\). But also in that case we have that \(n \in [\bar{n}/4, \bar{n}]\) and we are done.

Finally, consider an important case where the fraction of red elements is bounded away from \(1 - \Omega(1)\). This is a reasonable assumption for most applications, e.g., online auctions, where we do not expect that most of the arrivals will be chosen by an adversary. By simply observing the first half of the sequence, i.e., \(0, 1/2\), we can typically estimate \(n\) up to a constant while degrading the expected output of our algorithms by at most a constant factor.

> Claim 21. If there is a constant \(\varepsilon < 1\) such that the fraction of red elements \(\frac{|R|}{|R| + |G|} \leq \varepsilon\) then we can estimate \(n\) up to a constant factor by time \(t = 1/2\).

Proof. We run a simple preprocessing step to estimate \(n\) up to a constant factor by \(t = 1/2\). Notice that the expected number of green elements to arrive in the interval \([0, 1/2]\) is \(0.5 \cdot |G| = 0.5 \cdot n(1-\varepsilon) = \Omega(n)\). Since by simple Chernoff bounds this means that w.h.p. we see \(\Omega(n)\) elements in the first half, we run a simple algorithm that does not select any element till \(t = 1/2\), and then use the number of elements that arrive in \([0, 1/2]\) as an estimate of \(n\).

C. Minimax

In this section we argue that an \(\alpha\)-payoff (i.e., the probability of selecting the second-max element or better is at least \(\alpha\)) known distribution algorithm for the ordinal single-item Byzantine secretary implies an \(\alpha\)-payoff algorithm for the general, worst-case input, setting. This can be directly modeled as a two-player game where player A chooses an algorithm \(\mathcal{A}\) and player B chooses a distribution over the input instances \(\mathcal{B}\). Our coveted result would go along the lines of

\[
\sup_{\mathcal{A}} \inf_{\mathcal{B}} K(a, b) = \inf_{\mathcal{B}} \sup_{\mathcal{A}} K(\mathcal{A}, \mathcal{B}),
\]

where \(K(\mathcal{A}, \mathcal{B})\) denotes the payoff when we run algorithm \(\mathcal{A}\) on the input distribution \(\mathcal{B}\). The left-hand side denotes the worst-case input setting, while the right-hand side denotes the known distribution setting.

The main challenge in proving such a claim stems from the infiniteness of the set of algorithms and set of input distributions. Indeed, if one makes no finiteness assumption for either \(\mathcal{A}\) or \(\mathcal{B}\), the Minimax property can fail even for relatively well-behaved two-player games [37]. On the other hand if both \(\mathcal{A}\) and \(\mathcal{B}\) would be finite, then the result would follow from the classic Von Neumann’s Minimax [36].
Fact 22 (Von Neumann’s Minimax). Let $A$ and $B$ be finite sets. Denote by $\mathcal{D}(A)$ and $\mathcal{D}(B)$ distributions over $A$ and $B$, respectively. Then for any matrix of values $K : A \times B \to \mathbb{R}$ it holds that

$$\max_{a \in \mathcal{D}(A)} \min_{b \in \mathcal{D}(B)} K(a, b) = \min_{b \in \mathcal{D}(B)} \max_{a \in \mathcal{D}(A)} K(a, b).$$  \hspace{1cm} (9)$$

The infiniteness of the sets stems from the arrival times being in the infinite set $[0, 1]$. To solve this issue, we slightly modify our algorithm by discretizing $[0, 1]$. Let $N = n^3$, $\mathcal{T} := \{0, \frac{1}{N}, \frac{2}{N}, \ldots, \frac{N}{N}\}$ and $\Phi : [0, 1] \to \mathcal{T}$, $\Phi(t) := \lfloor N \cdot t \rfloor / N$ be the discretizing function. We modify our algorithm in the following way: apply $\Phi$ to the input distribution $\mathcal{B}$, as well as to every arrival time. Note that the elements are presented to the algorithm exactly as before, it just \textit{pretends} they arrive in discrete time steps. We can assume $\Phi(t_e) \neq \Phi(t_g)$ for every $e \in U, g \in G, e \neq g$ (otherwise, we say the algorithm loses), since this happens with at most $n^2 / N = o(1)$ probability. Using completely analogous techniques as in Section 4 we can show this algorithm is $\Omega(1/\log^2 n)$-competitive.

We note that a randomized algorithm is simply a distribution over deterministic algorithms. Hence our second goal is to argue that the number of distinct deterministic algorithms is finite (i.e., bounded by a function of $n$). To this end we have to specify how we represent them with at least some formality. We identify a deterministic algorithm $\mathcal{A}$ with a function that gets evaluated each time a new element arrives; its parameter is the information history $K(t) \ (t$ being the current time) represented in any appropriate format; its output is $\{\bot, \top\}$ representing whether to select the current element. For concreteness, the information history consists of $(t_e, \pi_e)$ for every element $e$ that arrived before the function call, where $t_e \in \mathcal{T}$ is the discretized arrival time (after applying $\Phi$) and $\pi_e \in [0 \ldots n - 1]$ is the relative value order of $e$ with respect to prior arrived elements. The number of distinct histories is bounded by $(N + 1)n^3$, a function of $n$; therefore the set of deterministic algorithms, i.e., functions from the history to $\{\bot, \top\}$, is also bounded.

We remember that an input distribution is simply a distribution over “pure” inputs. Note that the payoff of a deterministic algorithm for a specific input depends only on the following: $\Phi(t_e)$ for every red element; $\pi \in S_n$, the permutation representing the total order among the elements; and $\pi_b \in S_{|R|}$, the permutation denoting the order in which the red elements arrive (since red elements can have the same discretized arrival time, but an arbitrary order in which they are presented to the algorithm). The above discretization makes the number of pure inputs at most $(n!)^2 \cdot (N + 1)n$, i.e., bounded by a function of $n$. The reader can refresh their memory about the representation of pure inputs by reviewing the introduction to Section 4.

Finally, for our discretized algorithm, we proved that the set of pure inputs with different payoffs, as well as the number of deterministic algorithms is bounded by a function of $n$. Therefore, for a fixed $n$, both numbers are finite. We invoke the Von Neumann’s Minimax (Fact 22) to conclude that the best result in the known distribution setting and worst-case input setting are equivalent, recovering the following theorem.

Theorem 4 (Ordinal Single-item Algorithm). There is a randomized algorithm for the ordinal Byzantine secretary which selects an element of value at least the second-largest green item with probability $\Omega(1/\log^2 n)$.
Universal Communication, Universal Graphs, and Graph Labeling

Abstract
We introduce a communication model called universal SMP, in which Alice and Bob receive a function $f$ belonging to a family $F$, and inputs $x$ and $y$. Alice and Bob use shared randomness to send a message to a third party who cannot see $f$, $x$, $y$, or the shared randomness, and must decide $f(x, y)$. Our main application of universal SMP is to relate communication complexity to graph labeling, where the goal is to give a short label to each vertex in a graph, so that adjacency or other functions of two vertices $x$ and $y$ can be determined from the labels $l(x), l(y)$. We give a universal SMP protocol using $O(k^2)$ bits of communication for deciding whether two vertices have distance at most $k$ in distributive lattices (generalizing the $k$-Hamming Distance problem in communication complexity), and explain how this implies a $O(k^2 \log n)$ labeling scheme for deciding $\text{dist}(x, y) \leq k$ on distributive lattices with size $n$; in contrast, we show that a universal SMP protocol for determining $\text{dist}(x, y) \leq 2$ in modular lattices (a superset of distributive lattices) has super-constant $\Omega(n^{1/4})$ communication cost. On the other hand, we demonstrate that many graph families known to have efficient adjacency labeling schemes, such as trees, low-arboricity graphs, and planar graphs, admit constant-cost communication protocols for adjacency. Trees also have an $O(k)$ protocol for deciding $\text{dist}(x, y) \leq k$ and planar graphs have an $O(1)$ protocol for $\text{dist}(x, y) \leq 2$, which implies a new $O(\log n)$ labeling scheme for the same problem on planar graphs.

1 Introduction

In the simultaneous message passing (SMP) model of communication, introduced by Yao [34], Alice and Bob separately receive inputs $x$ and $y$ to a function $f$. They send messages $a(x), b(y)$ to a third party, called the referee, who knows $f$ and must output $f(x, y)$ (with high probability) using the messages $a(x), b(y)$. But what if the referee doesn’t know $f$? Can they still compute $f(x, y)$? Yes: Alice can include in her message a description of $f$, and then
the referee knows it; however, if \( f \) is restricted, they can sometimes do much better. Here is a simple example: the players receive vertices \( x, y \in \{1, \ldots, n\} \) in a graph \( G \) of maximum degree 2, and want to decide if \((x, y)\) is an edge in \( G \). Sharing a source of randomness, Alice and Bob randomly label each vertex of \( G \) with a number up to 200; Alice sends the label of both neighbors of \( x \) and Bob sends the label of \( y \). The referee says \textit{yes} if one of Alice's labels matches the label of \( y \), \textit{no} otherwise. They will be correct with probability at least \( 99/100 \), and the referee never needs to learn \( G \). This is also an example where the referee can decide many problems using only one strategy. In this work we will see that more interesting families of graphs, such as trees, planar graphs, and distributive lattices, also exhibit these phenomena, even when we wish to compute \textit{distances} instead of just adjacency.

To study this, we introduce the \textit{universal SMP} model, which operates as follows. Fix some family \( \mathcal{F} \) of functions. Alice and Bob receive a function \( f \in \mathcal{F} \) and inputs \( x, y \), and they use shared randomness to send one message to the referee. The referee knows the family \( \mathcal{F} \) and the size of the inputs, but doesn’t know \( f, x, y \) or the shared randomness, and must compute \( f(x, y) \) with high probability. By choosing the family \( \mathcal{F} \) to be the singleton family, one sees that this model includes standard SMP. As in the earlier example, we will be studying communication problems on graphs, but this is not a significant restriction: every Boolean-valued communication problem \( f \) is equivalent to determining adjacency in some graph (use \( f \) as the adjacency matrix), so we will treat \( \mathcal{F} \) as a family of graphs.

A surprising but intuitive application of universal SMP is that it connects two apparently disjoint areas of study: communication complexity and graph labeling. For a graph family \( \mathcal{F} \), the graph labeling problem (introduced by Kannan, Naor, and Rudich [23]) asks how to assign the shortest possible labels \( \ell(v) \) to each vertex \( v \) of a graph \( G \in \mathcal{F} \), so that the adjacency (or some other function [29]) of vertices \( x, y \) can be computed from \( \ell(x), \ell(y) \) by a decoder that knows \( \mathcal{F} \). We observe the following principle (Theorem 1.1):

\textit{If there is a (randomized) universal SMP protocol for the graph family \( \mathcal{F} \) with communication cost \( c \), then there is a labeling scheme for graphs \( G \in \mathcal{F} \) with labels of size \( O(c \log n) \), where \( n \) is the number of vertices.}

Common variants of graph labeling are \textit{distance labeling} [15], where the goal is to compute \( \text{dist}(x, y) \) from the labels, and \textit{small-distance} labeling, where the goal is to compute \( \text{dist}(x, y) \) if it is at most \( k \) and output \( \gg k \) otherwise [24, 2]. This is similar to the well-studied \( k \)-Hamming Distance problem in communication complexity, where the players must decide if their vertices \( x, y \) have distance at most \( k \) in the Boolean hypercube graph. A natural generalization of the Boolean hypercube is the family of distributive lattices (which also include, for example, the hypergrids). We demonstrate that techniques from communication complexity can be used to obtain new graph labelings, by adapting the \( k \)-Hamming Distance protocol of Huang et al. [21] to the universal SMP model, achieving an \( O(k^2) \) protocol for computing \( \text{dist}(x, y) \leq k \) and the corresponding \( k \)-distance labeling scheme with label size \( O(k^2 \log n) \). It is interesting to note that, in contrast to the standard application of communication complexity as a method for obtaining lower bounds, we are using it to obtain upper bounds.

Generalizing in another direction, we ask: for which graphs other than the Boolean hypercube can we obtain efficient communication protocols for \( k \)-distance? For constant \( k \), \( k \)-Hamming Distance can be computed with communication cost \( O(1) \); which other graphs admit a constant-cost protocol? To approach this question, we observe that many (but not all) graph families known to have efficient \( O(\log n) \) adjacency labeling schemes also admit an \( O(1) \) universal SMP protocol for adjacency. Commonly studied families in the adjacency and distance labeling literature are trees [23, 24, 2, 5, 3] and planar graphs [23, 15, 14, 16, 6].
study the $k$-distance problem on these families and find that trees admit an $O(k)$ protocol, while planar graphs admit an $O(1)$ protocol for 2-distance; this implies a new labeling scheme for planar graphs.

Further motivation for the universal SMP model comes from universal graphs. Introduced by Rado [30], an induced-universal graph $U$ for a set $\mathcal{F}$ is one that contains each $G \in \mathcal{F}$ as an induced subgraph. An efficient adjacency labeling scheme for a set $\mathcal{F}$ implies a small induced-universal graph for that set [23]. Deterministic universal SMP protocols are equivalent to universal graphs (Theorem 1.7), and we introduce probabilistic universal graphs as the analogous objects for randomized universal SMP protocols. We think probabilistic universal graphs are worthy of study alongside universal graphs, especially since many non-trivial families admit one of constant-size.

The universal SMP model is also related to a recent line of work studying communication between parties with imperfect knowledge of each other’s “context”. The most relevant incarnation of this idea is the recent work [18, 17], who study the 2-way communication model where Alice and Bob receive functions $f$ and $g$ respectively, with inputs $x$ and $y$, and must compute $f(x, y)$ under the guarantee that $f$ and $g$ are close in some metric. In other words, one party does not have full knowledge of the function to be computed. The universal SMP model provides a framework for studying a similar problem in the SMP setting, where the players know the function but the referee does not; the similarity is especially clear when we define the family $\mathcal{F}$ to be all graphs of distance $\delta$ to a reference graph $G$ in some metric (we discuss this situation in more detail at the end of the paper). This could model, for example, a situation where the clients of a service operate in a shared environment but the server does not; or, a situation in which the clients want to keep their shared environment secret from the server, and their inputs secret from each other. This suggests a possible application to privacy and security. A relevant example is private proximity testing (e.g. [27]), where two clients should be notified by the server when they are at distance at most $k$ from each other, without revealing to each other or the server their exact locations.

The Discussion at the end of the paper highlights some interesting questions and open problems related to universal SMP.

1.1 Results

A universal SMP protocol decides $k$-distance for a family $\mathcal{F}$ if for all graphs $G \in \mathcal{F}$ and vertices $x, y$, the protocol will correctly decide if $\text{dist}(x, y) \leq k$, with high probability. A labeling scheme decides $k$-distance if $\text{dist}(x, y) \leq k$ can be decided from the labels of $x, y$. Below, the variable $n$ always refers to the number of vertices in the input graph.

Implicit graph representations. The main principle connecting communication and graph labeling is:

► Theorem 1.1. Any graph family $\mathcal{F}$ with universal SMP cost $m$ has an adjacency labeling scheme with labels of size $O(m \log n)$. In particular, if the universal SMP cost for $\mathcal{F}$ is $O(1)$ then $\mathcal{F}$ has an $O(\log n)$ adjacency labeling scheme.

Adjacency labeling schemes of size $O(\log n)$ are of special interest because $\log n$ is the minimum number of bits required to label each vertex uniquely, and they correspond to implicit graph representations, as defined by Kannan, Naor, and Rudich [23] (we omit their requirement that the encoding and decoding be computable in polynomial-time). Section 2.3 elaborates further. To obtain implicit representations, we can relax our requirements:
Corollary 1.2. For any constant $c$, any graph family $F$ where each $G \in F$ has a public-coin 2-way communication protocol computing adjacency with cost $c$ has an implicit representation.

Distributive & Modular Lattices. Distributive and modular lattices are generalizations of the Boolean hypercube and hypergrids (see Section 3 for definitions). We define a weakly-universal SMP protocol as one where the referee shares the randomness of Alice and Bob. For distributive lattices we get the following:

Theorem 1.3. The $k$-distance problem on the family of distributive lattices has: a weakly-universal SMP protocol with cost $O(k \log k)$; a universal SMP protocol with cost $O(k^2)$; and a size $O(k^2 \log n)$ labeling scheme.

Modular lattices are a superset of distributive lattices, but they do not admit $k$-distance protocols with a cost independent of $n$; we show that any universal SMP protocol (and any labeling scheme) deciding 2-distance must have cost $\Omega(n^{1/4})$ (Theorem 3.14). To our knowledge, there are no known labeling schemes for distributive or modular lattices. Our adjacency labeling scheme (i.e. for $k = 1$) requires $O(n \log n)$ space to store the whole lattice; this can be compared to Munro and Sinnamon [26], who present a data structures of size $O(n \log n)$ for distributive lattices that supports meet and join operations (and therefore distance queries, due to our Lemma 3.5). However, these are not labelings, so the result is not directly comparable.

Planar graphs and other efficiently-labelable families. When they introduced graph labeling, Kannan, Naor, and Rudich [23] studied trees, low-arboricity graphs (whose edges can be partitioned into a small number of trees), and planar graphs, and interval graphs (whose vertices are intervals in $\mathbb{R}$, with an edge if the intervals intersect), among others. These families have $O(\log n)$ adjacency labeling schemes. Trees, low-arboricity graphs, and planar graphs have constant-cost universal SMP protocols for adjacency. Trees admit an efficient $k$-distance protocol:

Theorem 1.4. The family of trees has a universal SMP protocol deciding $k$-distance with cost $O(k)$ and a $O(k \log n)$ labeling scheme deciding $k$-distance.

Planar graphs admit an efficient 2-distance protocol, which implies a new 2-distance labeling scheme:

Theorem 1.5. The 2-distance problem on the family of planar graphs has a universal SMP protocol with cost $O(1)$ and a labeling scheme of size $O(\log n)$.

On the other hand, a universal SMP protocol deciding 2-distance on the family of graphs with arboricity 2 has cost at least $\Omega(\sqrt{n})$ (Proposition 4.4), and a universal SMP protocol deciding adjacency in interval graphs has cost $\Theta(\log n)$ (Proposition 4.5).

Gavoille et al. [15] showed that trees have an $O(\log^2 n)$ labeling allowing $\text{dist}(x, y)$ to be computed exactly from labels of $x, y$, and gave a matching lower bound; Kaplan and Milo [24] and Alstrup et al [2] studied $k$-distance for trees, with the latter achieving a $\log n + O(k^2(\log \log n + \log k))$ labeling scheme. For planar graphs, [15] gives a lower bound of $\Omega(n^{1/3})$ for computing distances exactly, and an upper bound of $O(\sqrt{n} \log n)$, which was later improved to $O(\sqrt{n})$ in [16].
Communication Complexity. Our lower bounds are achieved by reduction from the family of all graphs, which has complexity $\Theta(n)$, in contrast to the upper bound of $\lceil \log n \rceil$ for the standard SMP cost of computing adjacency in any graph (since Alice and Bob can send $\lceil \log n \rceil$ bits to identify their vertices).

\textbf{Theorem 1.6.} For the family $\mathcal{G}$ of all graphs, the universal SMP cost of computing adjacency in $\mathcal{G}$ is $\Theta(n)$.

The basic relationships between universal SMP, standard SMP, and universal graphs are as follows. Below, we use $D^\parallel(\text{Adj}(G))$ and $R^\parallel(\text{Adj}(G))$ for the deterministic and randomized (standard) SMP cost of computing adjacency on $G$, and $D^{\text{univ}}(\mathcal{F})$, $R^{\text{univ}}(\mathcal{F})$ for the deterministic and randomized universal SMP cost for computing adjacency in the family $\mathcal{F}$. We use the term “\subseteq-universal graph” as opposed to “induced-universal” to denote a slightly different object that allows non-injective embeddings (see Section 2 for definitions).

\textbf{Theorem 1.7.} For a set $\mathcal{F}$, the following relationships hold. Let $U$ range over the set of all \subseteq-universal graphs:

$$\max_{G \in \mathcal{F}} D^\parallel(\text{Adj}(G)) \leq D^{\text{univ}}(\mathcal{F}) = \min_U D^\parallel(\text{Adj}(U)) = \min_U \lceil \log |U| \rceil,$$

with equality on the left iff $\exists H \in \mathcal{F}$ such that $\forall G \in \mathcal{F}$, $G$ can be embedded in $H$. For $\tilde{U}$ ranging over the set of all probabilistic universal graphs:

$$\max_{G \in \mathcal{F}} R^\parallel(\text{Adj}(G)) \leq R^{\text{univ}}(\mathcal{F}) \leq \min_{\tilde{U}} D^\parallel(\text{Adj}(\tilde{U})) \leq O(R^{\text{univ}}(\mathcal{F})).$$

Randomized and deterministic universal SMP satisfy

$$\Omega\left(\frac{D^{\text{univ}}(\mathcal{F})}{\log n}\right) \leq R^{\text{univ}}(\mathcal{F}) \leq D^{\text{univ}}(\mathcal{F}).$$

The above results on graph labeling are proved through the relationship between randomized and deterministic universal SMP. We obtain this relationship by adapting Newman’s Theorem [28], a standard derandomization result in communication complexity. Finally, we note the interesting fact that universal SMP characterizes the gap between standard SMP models where the referee does or does not share the randomness with Alice and Bob:

\textbf{Proposition 1.8 (Informal).} Let $\mathcal{F}$ be a family of graphs and let $\Pi$ be a weakly-universal SMP protocol for $\mathcal{F}$, which defines a distribution over the referee’s decision functions $F$, which we interpret as the adjacency matrices of graphs. Let $U_\Pi$ be the family on which this distribution is supported. Then, taking the minimum over all such protocols $\Pi$,

$$R^{\text{univ}}_e(\mathcal{F}) = \min_{\Pi} D^{\text{univ}}(U_\Pi).$$

1.2 Other Related Work

Graph labeling. Randomized labeling schemes for trees have been studied by Fraigniaud and Korman [12], who give a randomized adjacency labeling scheme of $O(1)$ bits per label that has one-sided error (i.e. it can erroneously report that $x, y$ are adjacent when they are not), and they show that achieving one-sided error in the opposite direction requires a randomized labeling with $\Omega(\log n)$ bits. They also give randomized schemes for determining if $x$ is an ancestor of $y$, but they do not address distance problems. Spinrad’s book [33] has a chapter on implicit graphs and Alstrup et al. [6] for a recent survey on adjacency labeling...
schemes and induced-universal graphs. We know of no labeling schemes for lattices, but Fraigniaud and Korman [13] recently studied adjacency labeling schemes for posets of low “tree-dimension”.

Distance-preserving labeling studies an opposite problem to $k$-distance labeling, where distances must be accurately reported when they are above some threshold $D$. Recent work includes Alstrup et al. [4].

To our knowledge, $k$-distance or even 2-distance has not been studied for planar graphs, but there are many results on other types of planar graph labelings with restrictions at distance 2. An example is the frequency assignment problem or $L(p,q)$-labeling problem, which asks how to construct a labeling $\ell$ assigning integers $[k]$ to vertices of a planar graph so that $\text{dist}(x,y) \leq 1 \implies |\ell(x) - \ell(y)| \geq p$ and $\text{dist}(x,y) \leq 2 \implies |\ell(x) - \ell(y)| \geq q$, with various optimization goals. See [7] for a survey.

Uncertain communication. There are several works studying communication problems where the parties do not agree on the function to be computed, starting with Goldreich, Juba, and Sudan [19] who studied communication where parties have different “goals”. Canonne et al. [8] study communication in the shared randomness setting where the randomness is shared imperfectly. Haramarty and Sudan [20] study compression (à la Shannon) in situations where the parties do not agree on a common distribution. As mentioned earlier, Ghazi et al. [17] and Ghazi and Sudan [18] study 2-way communication where the parties do not agree on the function to be computed.

1.3 Notation

$[k]$ means $\{1, \ldots, k\}$. The letter $n$ always denotes the number of vertices in a graph. We use the notation $1[E] = 1$ iff the statement $E$ holds, and $1[E] = 0$ otherwise. For a graph $G$, $V(G)$ is the set of vertices and $E(G)$ is the set of edges. For vertices $x, y$, we write $G(x,y) = 1$ if $x,y$ are adjacent in $G$ for the entry in the adjacency matrix of $G$. For an undirected, unweighted graph $G$ and vertices $u,v$, $\text{dist}(u,v)$ is the length of the shortest path from $u$ to $v$.

For any graph $G$ and integer $k$, we denote by $G^k$ the $k$-closure of $G$, where two vertices $u,v$ are adjacent iff $\text{dist}(u,v) \leq k$ in $G$; it is convenient to require that each vertex is adjacent to itself in $G^k$. For a set of graphs $\mathcal{F}$, $\mathcal{F}^k = \{G^k : G \in \mathcal{F}\}$.

$D^d(f)$ is the deterministic SMP cost of the function $f$ and $R^d(f)$ is the randomized SMP cost of the function $f$, in the model where Alice and Bob share randomness but the deterministic referee does not.

2 Universal Communication and Universal Graphs

In this paper we focus on deciding adjacency. Every Boolean communication problem $f : \mathcal{X} \times \mathcal{Y} \rightarrow \{0,1\}$ on finite domains $\mathcal{X}, \mathcal{Y}$ is equivalent to the adjacency problem on the graph $G$ with vertex set $\mathcal{X} \cup \mathcal{Y}$ and $G(u,v) = f(u,v)$. We may either allow self-loops in $G$ if $\mathcal{X} = \mathcal{Y}$ or take $G$ to be bipartite. We will generally permit graphs to have self-loops.

**Definition 2.1.** A family of graphs $\mathcal{F} = (F_i)$ is a sequence of sets $F_i$ indexed by integers $i$, along with a strictly increasing size function $n(i)$, so that $F_i$ is a set of graphs with vertex set $[n(i)]$. If $F_i$ has size $n(i) = i$ then we write $F_n$.
Definition 2.2 (Universal SMP and Variations). Let $\mathcal{F}$ be a family of graphs with size function $n$ and let $\Phi$ be an operation taking size $n(i)$ graphs to size $n(i)$ graphs. Let $c : \mathbb{N} \to \mathbb{N}$ and let $\epsilon > 0$ be a constant. An $\epsilon$-error, cost $c$ sequence of universal SMP communication protocols for $\mathcal{F}$ is as follows. For any $i \in \mathbb{N}$, a protocol $\Pi_i$ for $\mathcal{F}_i$ is a triple $(a_i, b_i, F_i)$ where:

- Alice and Bob receive $(G, x)$, $(G, y)$ respectively, where $G \in \mathcal{F}_i$ and $x, y \in V(G) = [a(i)]$;
- Alice and Bob share a random string $r$ and compute messages $a_i(r, G, x), b_i(r, G, y) \in \{0, 1\}^{c(i)}$, respectively;
- For each $i$, the (deterministic) referee has a function $F_i : \{0, 1\}^{c(i)} \times \{0, 1\}^{c(i)} \to \{0, 1\}$, called the decision function. $F_i(a_i(r, G, x), b_i(r, G, y))$ must satisfy:
  1. If $x, y$ are adjacent in $\Phi(G)$ then $\mathbb{P}[F_i(a_i(r, G, x), b_i(r, G, y)) = 1] > 1 - \epsilon$; and
  2. If $x, y$ are not adjacent in $\Phi(G)$ then $\mathbb{P}[F_i(a_i(r, G, x), b_i(r, G, y))] < \epsilon$.

A universal SMP protocol is symmetric when the functions $a_i, b_i$ computed by Alice and Bob are identical and the function $F_i$ satisfies $F_i(a, b) = F_i(b, a)$ for all messages $a, b \in \{0, 1\}^c$.

We write $R_{\epsilon, c}^{\text{uni}}(\Phi(\mathcal{F}))$ for the communication complexity in the universal SMP model of computing adjacency in graphs $\Phi(\mathcal{F}) = \{\Phi(G) : G \in \mathcal{F}\}$, where $\epsilon$ is the allowed probability of error. We write $R_{\epsilon, c}^{\text{uni}}(\Phi(\mathcal{F}))$ for $R_{\epsilon, c}^{\text{uni}}(\Phi(\mathcal{F}))$. If no operation $\Phi$ is specified, it is assumed to be the identity.

It is also convenient to define a weakly-universal SMP protocol as a universal SMP protocol where the referee can see the shared randomness, so the choice function is of the form $F_i(r, a(r, G, x), b(r, G, y))$ for random seed $r$, graph $G \in \mathcal{F}$, and $x, y \in V(G)$. We denote the $\epsilon$-error complexity in this model with $R_{\epsilon, c}^{\text{weak}}(\Phi(\mathcal{F}))$.

Finally, we write $D_{\epsilon, c}^{\text{uni}}(\Phi(\mathcal{F}))$ for the deterministic universal SMP complexity.

Remark 2.3. We include the operator $\Phi$ in the definition to emphasize that the players are given the original graph $G$, not the graph $\Phi(G)$; for example, the players are not given $G^k$ (from which it may be difficult to compute $G$), but are instead given $G$.

2.1 Deterministic Universal Communication and Universal Graphs

We will show that a deterministic universal SMP protocol is equivalent to an embedding into a $\subset$-universal graph, which we define using the following notion of embedding (following the terminology of Rado [30]):

Definition 2.4. For graphs $G, H$, a mapping $\phi : V(G) \to V(H)$ is an embedding iff $\forall u, v \in V(G), G(u, v) = H(\phi(u), \phi(v))$. If such a mapping exists we write $G \subset H$.

For a set of graphs $\mathcal{F}_i$, a graph $U$ is $\subset$-universal if $\forall G \in \mathcal{F}_i, G \subset U$; i.e. $\forall G \in \mathcal{F}_i$ there exists an embedding $\phi_G : V(G) \to V(U)$. For a family of graphs $\mathcal{F} = \{\mathcal{F}_i\}$, a sequence $U = (U_i)$ is a $\subset$-universal graph sequence if for each $i$, $U_i$ is $\subset$-universal for $\mathcal{F}_i$.

Define an equivalence relation on $V(G)$ by $u \equiv v$ iff $\forall w \in V(G), G(u, w) = G(v, w)$, i.e. $u, v$ have identical rows in the adjacency matrix. For a graph $G$, define the $\equiv$-reduction $G^\equiv$ as a graph on the equivalence classes $\mathcal{C}$ of $V(G)$ with $U, W \in \mathcal{C}$ adjacent iff $\exists u \in U, w \in W$ such that $u, w$ are adjacent.

An embedding is not the same as a homomorphism since we must map non-edges to non-edges, and $G \subset H$ is not the same as $G$ being an induced subgraph of $H$ since the mapping is not necessarily injective. Therefore a universal graph by our definition is not the same as an induced-universal graph, where $G$ must exist as an induced subgraph. We could for example map the path $a \to b \to c \to a' \to b' \to a'$. This difference between definitions is captured by the $\equiv$ relation between vertices. It is necessary to allow self-loops, otherwise the $\subset$ relation is not transitive. The important properties of $\subset$, $\equiv$, and $\equiv$-reductions are stated in the next proposition; the proofs are routine and for completeness are included in the appendix. The relation $\simeq$ is the isomorphism relation on graphs.
Proposition 2.5. The following properties are satisfied by the \(\sqsubseteq\) relation, the \(\equiv\) relation, and \(\equiv\)-reductions:

1. \(\sqsubseteq\) is transitive.
2. For any graph \(G\) and \(u, v \in V(G)\), \(u \equiv v\) iff there exists \(H\) and an embedding \(\phi : G \to H\) such that \(\phi(u) = \phi(v)\).
3. For any graph \(G, (G^\equiv)^\equiv \simeq G^\equiv\).
4. For any graph \(G, G \sqsubseteq G^\equiv\) and \(G^\equiv \sqsubseteq G\).
5. For any graphs \(G, H, G \sqsubseteq H\) iff \(G^\equiv \sqsubseteq H^\equiv\).
6. For any graphs \(G, H, G^\equiv \sqsubseteq H^\equiv\) iff \(G^\equiv\) is an induced subgraph of \(H^\equiv\).

These properties allow us to prove relationships between the standard SMP model, deterministic universal SMP, and \(\sqsubseteq\)-universal graphs. First we show that deterministic universal SMP protocols can always be made symmetric\(^1\).

Proposition 2.6. If \(\Pi\) is a deterministic universal SMP protocol for the set \(\mathcal{F}\), then there exists a deterministic universal SMP protocol \(\Pi'\) that is symmetric and has the same cost as \(\Pi\).

Proof. Let \(G \in \mathcal{F}\) and let \(a, b : V(G) \to \{0, 1\}^m\) be the encoding functions for \(G\) and \(F\) the decision function for graphs of size \(|G|\). The restriction of \(b\) to the domain \(V(G^\equiv) \to \{0, 1\}^m\) is injective so it has an inverse \(b^{-1} : \text{image}(b) \to V(G^\equiv)\) that satisfies \(b^{-1}b(x) \equiv x\); the same holds for \(a, a^{-1}\). Define the encoding function \(b' : V(G) \to \{0, 1\}^m\) as \(b' = ab^{-1}b\) and define the decision function \(F'(p, q) = F(p, ba^{-1}b(q))\). Then for any \(x, y \in V(G)\), \(F'(a(x), b'(y)) = F(a(x), b'(y)) = F(a(x), b(y)) = G(x, y)\) so this is a valid protocol. Since \(\text{image}(b') \subseteq \text{image}(a)\) we can write \(b'(x) = aa^{-1}b'(x) = aa^{-1}ab^{-1}b(x) = a(x)\) for every \(x\) so \(b' = a\), thus \(F'(a(x), a(y)) = G(x, y) = G(y, x) = F'(a(y), a(x))\) so the protocol is symmetric. \(\blacksquare\)

The standard deterministic SMP complexity measure can be expressed in terms of \(\equiv\)-reductions:

Proposition 2.7. For all graphs \(G\), \(D^\equiv(\text{Adj}(G)) = \lceil \log |G^\equiv| \rceil\).

Proof. It is well-known that for any function \(f : X \times Y \to \{0, 1\}\), \(D^\equiv(f) = \lceil \log \min(r, c) \rceil\) where \(r\) is the number of distinct columns in the communication matrix of \(f\), and \(c\) is the number of distinct rows \([34]\). The communication matrix of the function \(\text{Adj}(G)\) is the adjacency matrix of \(G\), which is symmetric, and two rows (or columns) indexed by \(u, v\) are distinct iff \(u \neq v\); so the number of distinct rows is the size of \(|G^\equiv|\). \(\blacksquare\)

The analogous fact for universal SMP is that the deterministic universal SMP cost is determined by the size of the smallest universal graph.

Proposition 2.8. For any graph family \(\mathcal{F} = \{F_i\}\),

\[
D^\text{univ}(\mathcal{F}_i) = \min_U \{ \lceil \log |U^\equiv| \rceil : \forall G \in \mathcal{F}_i, G \sqsubseteq U^\equiv \}.
\]

Proof. Let \(U\) be any graph such that \(G \sqsubseteq U^\equiv\) for all \(G \in \mathcal{F}_i\) and for each \(G \in \mathcal{F}_i\) let \(g\) be the embedding \(G \to U^\equiv\). Consider the protocol where on inputs \((G, x), (G, y)\), Alice and Bob send \(g(x), g(y)\) using \(\lceil \log |U^\equiv| \rceil\) bits and the referee outputs \(U^\equiv(g(x), g(y))\). This is correct by definition so \(D^\text{univ}(\mathcal{F}_i) \leq \lceil \log |U^\equiv| \rceil\).

\(^1\) Note that this does not imply that every deterministic SMP protocol is symmetric; since in this paper we are only concerned with adjacency on an undirected graph, for which the communication matrix is symmetric. This proposition shows that for symmetric communication matrices, the deterministic SMP protocol is symmetric.
Now suppose there is a protocol \( \Pi \) for \( F_i \) with cost \( c \) and decision function \( F_i \), and let \( G \in F_i \). By Proposition 2.6 we may assume that on inputs \((G,x),(G,y)\) Alice and Bob share the encoding function \( g : V(G) \to \{0,1\}^c \). Let \( U \) be the graph with vertices \( \{0,1\}^c \) and \( U(u,v) = F(u,v) \). Then \( U(g(x),g(y)) = F(g(x),g(y)) = G(x,y) \) so \( G \subseteq U \subseteq U^\equiv \) (by transitivity). Now \( |U^\equiv| \leq 2^c \) so \( c \geq \log |U^\equiv| \).

It is easy to see that \( D^\parallel \) can be used as a lower bound on \( D^\text{univ} \) but such lower bounds are tight only when the family \( F \) is essentially a “trivial” family of equivalent graphs.

**Lemma 2.9.** For any family \( F = (F_i) \), let \( U = (U_i) \) be the smallest \( \sqsubseteq \)-universal graph sequence for \( F \). Then

\[
\max_{G \in F_i} D^\parallel(\text{Adj}(G)) \leq D^\text{univ}(F_i) = D^\parallel(\text{Adj}(U_i)),
\]

with equality holding on the left iff \( \exists H \in F_i \) such that \( \forall G \in F_i, G^\equiv \sqsubseteq H^\equiv \).

**Proof.** The equality on the right holds by the two prior propositions. The lower bound follows from the fact that any protocol \( \Pi_U \) for \( F_i \) in the universal model can be used as a protocol in the SMP model. Now we must show the equality condition. Let \( U \in F_i \) be a graph maximizing \( |U^\equiv| \) over all graphs in \( F_i \), and suppose \( D^\text{univ}(F_i) = \max_{G \in F_i} \log |G^\equiv| = \log |U^\equiv| \), so \( \log |U^\equiv| = \min\{\log |H^\equiv| : \forall G \in F_i, G \subseteq H^\equiv \} \). Then there exists \( H \) such that \( U^\equiv \subseteq H^\equiv \) and \( |U^\equiv| = |H^\equiv| \). Since \( U^\equiv \) is an induced subgraph of \( H^\equiv \) and \( |U^\equiv| = |H^\equiv| \) we must have \( U^\equiv \simeq H^\equiv \) so \( \forall G \in F_i, G^\equiv \subseteq U^\equiv \).

### 2.2 Randomized Universal Communication

Just as deterministic universal communication is equivalent to embedding a family into a universal graph, we will define probabilistic universal graphs and show that they are tightly related to universal communication with shared randomness.

**Definition 2.10.** For graphs \( G, H \), a random mapping \( \phi : V(G) \to V(H) \) (i.e. a distribution over such mappings) is an \( \epsilon \)-error embedding iff \( \forall u,v \in V(G) \),

\[
\mathbb{P}[G(u,v) = H(\phi(u),\phi(v))] > 1 - \epsilon.
\]

We will write \( G \sqsubseteq H \) if there exists an \( \epsilon \)-error embedding \( G \to H \). A graph \( U \) is \( \epsilon \)-error universal for a set of graphs \( S \) if \( \forall G \in S, G \sqsubseteq U \). \( U = (U_i) \) is an \( \epsilon \)-error universal graph sequence for the family \( F = (F_i) \) if for each \( i, U_i \) is \( \epsilon \)-error universal for \( F_i \).

In the randomized setting we obtain equivalence (up to a constant factor) between universal SMP protocols and probabilistic universal graphs.

**Lemma 2.11.** For any graph family \( F = (F_i) \) and any \( \epsilon > 0 \), if there exists an \( \epsilon \)-error universal SMP protocols for \( F \) with cost \( c(i) \), then there exists a \( 2\epsilon \)-error symmetric universal SMP protocols for \( F \) with cost at most \( 2c(i) \).

**Proof.** On input \( G \in F_i, x,y \in V(G) \), and random string \( r \), Alice and Bob send the concatenations \( g_r(x) := a_i(r,G,x)b_i(r,G,x) \) and \( g_r(y) := a_i(r,G,y)b_i(r,G,y) \). Then the referee computes

\[
F_i(g_r(x),g_r(y)) = \max \{ F_i(a_i(r,G,x),b_i(r,G,x)), F_i(a_i(r,G,y),b_i(r,G,x)) \}.
\]
It is clear that $F_i^r$ is symmetric. If $x,y$ are adjacent then
\[
P_r[F_i^r(g_r(x), g_r(y)) = 0] \leq P_r[F_i(a_r(r,G,x), b_i(r,G,y)) = 0] < \epsilon,
\]
and if $x,y$ are not adjacent then, by the union bound,
\[
P_r[F_i^r(g_r(x), g_r(y)) = 1] \leq P_r[F_i(a_r(r,G,x), b_i(r,G,y)) = 1] + P_r[F_i(a_r(r,G,y), b_i(r,G,x)) = 1] < 2\epsilon.
\]
Applying this symmetrization, we get a relationship between universal SMP protocols and probabilistic universal graphs.

**Lemma 2.12.** Let $\mathcal{F} = (\mathcal{F}_i)$ be a graph family and $\epsilon > 0$. Then
1. There is an $\epsilon$-error universal graph sequence of size at most $2^{R^\text{univ}_\epsilon(\mathcal{F})}$; and
2. If there is an $\epsilon$-error universal graph sequence of size $c(i)$ then $R^\text{univ}_\epsilon(\mathcal{F}) \leq \lceil \log c \rceil$.

**Proof.** If $\Pi_i$ is an $\epsilon$-error symmetric universal protocol for $\mathcal{F}_i$ then there exists a function $F_i$ such that for every $G \in \mathcal{F}_i$ there is a random $g$ such that $P_{r} [F_i(g(x), g(y)) \neq G(x,y)] < \epsilon$.

Using $F_i$ as an adjacency matrix, we get a graph $U_i$ of size at most $2^c$, where $c$ is the cost of $\Pi_i$, such that for all $G \in \mathcal{F}_i$, $G \subseteq U_i$. Then $U = (U_i)$ is an $\epsilon$-error probabilistic universal graph sequence. By Lemma 2.11 we obtain an $\epsilon$-error symmetric protocol with cost $2R^\text{univ}_{\epsilon/2}(\mathcal{F})$, so we have proved the first conclusion. The second conclusion follows by definition.

The basic relationships to standard SMP models follow essentially by definition and from the above lemma.

**Lemma 2.13.** Let $\mathcal{F}$ be any graph family and let $\epsilon > 0$. Let $U = (U_i)$ be an $\subseteq$-universal graph sequence for $\mathcal{F}$, and $\bar{U} = (\bar{U}_i)$ an $\epsilon$-error universal graph sequence. Then
\[
\max_{G \in \mathcal{F}} R_0^\epsilon(\text{Adj}(G)) \leq R^\text{univ}_\epsilon(\mathcal{F}_i) \leq D^\parallel(\text{Adj}(U_i)) \leq 2R^\text{univ}_{\epsilon/2}(\mathcal{F}) \text{ and } R^\text{univ}_\epsilon(\mathcal{F}_i) \leq R_0^\parallel(\text{Adj}(U_i)).
\]

**Proof.** The inequalities on the left follow the definitions and from the above lemma. On the right, we can obtain a universal SMP protocol by choosing for each $G \in \mathcal{F}_i$ a (deterministic) embedding $g : G \to U_i$ and then using the randomized SMP protocol for $\text{Adj}(U_i)$.

Universal graphs describe an interesting relationship between weakly-universal and universal SMP protocols (and therefore between standard SMP protocols where the referee does and does not share the randomness); namely, the optimal universal protocol is obtained by finding the smallest universal graph for the family of protocol graphs (decision functions) defined by a weakly-universal protocol.

**Proposition 1.8 (Restated).** Let $\mathcal{F}$ be a family of graphs, let $\epsilon > 0$, and let $W_\epsilon$ be the set of all $\epsilon$-error weakly-universal SMP protocols for $\mathcal{F}$. For each $\Pi \in W_\epsilon$ let $U_{\Pi} = (U_{\Pi,i})$ be the family of graphs $U_{\Pi,i} = \{F_i(r, \cdot, \cdot) : r \text{ is a random seed for } \Pi\}$ where $F_i$ is the decision function of $\Pi$. Then
\[
R^\text{univ}_\epsilon(\mathcal{F}) = \min_{\Pi \in W_\epsilon} D^\text{univ}(U_{\Pi}) .
\]
Proof. Let $\Pi \in W_\epsilon$; we will construct a universal SMP protocol as follows. On input $(G, x), (G, y)$, Alice and Bob use shared randomness $r$ to simulate $\Pi$ and obtain vertices $a(r, G, x), b(r, G, y)$ in some graph $U_r \in U_\Pi$ with $P_r[U_r(a(r, G, x), b(r, G, y)) \neq G(x, y)] < \epsilon$. They now simulate the deterministic universal SMP protocol, i.e. an embedding $\phi : V(U_r) \to U'$ for some graph $U'$ that is $\epsilon$-universal for $\{U_r\}$, and send $\phi(a(r, G, x), \phi(b(r, G, y)))$ to the referee who computes $U'(\phi(a(r, G, x), \phi(b(r, G, y)))) = U_r(a(r, G, x), b(r, G, y))$.

Now let $\Pi$ be an $\epsilon$-error universal SMP protocol. Then $\Pi \in W_\epsilon$ and for each $i$, $U_{\Pi, i} = \{U_i\}$, where $U_i$ is the graph of the decision function. $D^{\text{univ}}(U_{\Pi}) \leq \lceil \log |U_i| \rceil$, which is the cost of $\Pi$, so $\min_{\Pi \in W_\epsilon} D^{\text{univ}}(U_{\Pi}) \leq R^{\text{univ}}(F)$. ▶

Newman’s Theorem for public-coin randomized (2-way) protocols is a classic result that gives a bound on the number of uniform random bits required to compute a function $f : \mathcal{X} \times \mathcal{Y} \to \{0, 1\}$ in terms of the size of the input domain [28]. In the universal model, the input size can be very large since the graph (function) itself is part of the input. However, the shared part of the input does not contribute to the number of random bits required in the universal SMP model.

 Lemma 2.14 (Newman’s Theorem for universal SMP). Let $\epsilon, \delta > 0$ and suppose there is an $\epsilon$-error universal SMP protocol $\Pi$ for the family $F = \{F_i\}$. Then there is an $(\epsilon + \delta)$-error universal SMP protocol for the family $F$ that uses at most $\log \log (n(i)^{O(\epsilon/\delta^2)})$ bits of randomness and has the same communication cost.

Proof. Fix $i$, let $F$ be the deterministic decision function for $F_i$, and let $a(r, \cdot, \cdot), b(r, \cdot, \cdot)$ be Alice and Bob’s encoding functions for the random seed $r$. For $G \in F_i$ and $x, y \in V(G)$ we will say a seed $r$ is bad for $G, x, y$ if $F(a(r, G, x), b(r, G, y)) \neq G(x, y)$, and we will call this event $\text{bad}(G, x, y, r)$.

Let $r_1, \ldots, r_m$ be independent random seeds, and let $i \sim [m]$ be uniformly random, where $m > \frac{2\epsilon}{\delta} \ln(n^2)$. Then for every $G$, the expected number of vertex pairs $x, y$ for which the strings $r_1, \ldots, r_m$ fail is

$$
\mathbb{E}_{r_1, \ldots, r_m} \left[ \sum_{x, y} \mathbb{I}_{i \sim [m]} \left[ \mathbb{P}_{r_i} [\text{bad}(G, x, y, r_i)] > \epsilon + \delta \right] \right]
$$

$$
\leq n^2 \max_{x, y} \mathbb{E}_{r_1, \ldots, r_m} \left[ \mathbb{I}_{i \sim [m]} \left[ \mathbb{P}_{r_i} [\text{bad}(G, x, y, r_i)] > \epsilon + \delta \right] \right]
$$

$$
= n^2 \max_{x, y} \mathbb{P}_{r_1, \ldots, r_m} \left[ \sum_{i=1}^m \mathbb{I}_{i \sim [m]} \left[ \text{bad}(G, x, y, r_i) \right] > m(\epsilon + \delta) \right].
$$

The sum has mean $\mu = \sum_{i=1}^m \mathbb{E}_{r_i} [\mathbb{I} [\text{bad}(G, x, y, r_i)]] < m\epsilon$, so by the Chernoff bound, the probability is at most

$$
n^2 \mathbb{P}_{r_1, \ldots, r_m} \left[ \sum_{i=1}^m \mathbb{I}_{i \sim [m]} \left[ \text{bad}(G, x, y, r_i) \right] > (1 + m\delta/\mu)\mu \right]
$$

$$
\leq n^2 \exp \left( -\frac{n^2 \delta^2}{3\mu} \right) \leq n^2 \exp \left( -\frac{m^2 \delta^2}{3\epsilon} \right) < 1.
$$

Since the expected number of pairs $x, y$ where choosing $i \sim [m]$ fails with probability more than $\epsilon + \delta$ is less than 1, there must be some values of $r_1, \ldots, r_m$ with no bad pairs for $G$. So
Universal Communication

For every \( G \in \mathcal{F}_i \) we may choose \( r_1, \ldots, r_m \) so that choosing \( i \) uniformly at random is the only random step; since \( m = \frac{e^2}{8} \ln n = \log n \Omega(\epsilon/\delta^3) \) this requires at most \( \log m = \log \left( n^{O(\epsilon/\delta^3)} \right) \) random bits.

With this result, we can conclude the proof of Theorem 1.7 in the next lemma.

**Lemma 2.15.** For any family \( \mathcal{F} = (\mathcal{F}_i) \) with size function \( n(i) \),

\[
\Omega \left( \frac{D_{\text{univ}}(\mathcal{F}_i)}{\log n(i)} \right) \leq R_{\text{univ}}(\mathcal{F}_i) \leq D_{\text{univ}}(\mathcal{F}_i).
\]

**Proof.** The upper bound is clear, so we prove lower bound. Let \( \Pi = (\Pi_i) \) be a sequence of randomized universal SMP protocols for \( \mathcal{F} \). By Newman’s theorem, we may assume that \( \Pi_i \) uses at most \( \log \log n(i) \) random bits for some constant \( c \) and has error probability \( 3/8 \). Let \( F_i \) be the decision function of \( \Pi_i \), let \( m(i) \) be the cost of \( \Pi_i \), and let \( k = \lceil c \log n(i) \rceil \). To obtain a deterministic protocol, we can define the decision function \( F'_i \) on messages of \( k \cdot m(i) \) bits as \( F'_i(a_1, b_1, a_2, b_2, \ldots, a_k, b_k) = \text{majority}(F_i(a_j, b_j)) \). Alice and Bob iterate over all \( k = 2^{\log n(i)} \) random strings \( r \) and send \( a(r, G, x), b(r, G, y) \) for each. Since the probability of error is at most \( 3/8 \) when \( r \) is uniform, at least \( 5k/8 > k/2 \) of the functions \( F_i(a_j, b_j) \) will give the correct answer. This proves that \( D_{\text{univ}}(\mathcal{F}_i) = O(R_{\text{univ}}(\mathcal{F}_i) \log n(i)) \).

In this paper we show lower bounds for a family \( \mathcal{F} \) by giving embeddings of an arbitrary graph \( G \) into \( \mathcal{F} \), so we need to know the complexity of the family \( \mathcal{G} = (\mathcal{G}_n) \) of all graphs with \( n \) vertices. For our purposes, it is convenient to require that each graph \( G \in \mathcal{G}_n \) has \( G(u, u) = 1 \) for all \( u \) (i.e. all self-loops are present). However, since equality can be checked with cost \( O(1) \), the presence or absence of self-loops does not affect the complexity.

**Theorem 1.6 (Restated).** \( R_{\text{univ}}(\mathcal{G}) = \Theta(n) \).

**Proof.** For the upper bound, consider the (deterministic) protocol where on input \( G, x, y \), Alice and Bob send \( x \) and \( y \) and the respective rows of the adjacency matrix of \( G \). This has cost \( n + \lceil \log n \rceil = O(n) \) and the referee can determine \( G(x, y) \) by finding \( y \) in the row sent by Alice.

Let \( \Pi \) be any protocol for \( \mathcal{G}_n \) with cost \( c \). By Lemma 2.11, we may assume that \( \Pi \) is symmetric. Let \( F \) be the decision function for graphs on \( n \) vertices and let \( G \in \mathcal{G}_n \) with vertex set \([n]\). \( \Pi \) defines a distribution over functions \( g : [n] \to \{0, 1\}^c \) so that for all \( x, y, \delta \), \( \mathbb{P}[F(g(x), g(y)) \neq G(x, y)] < \epsilon \). Therefore, for \( x, y \) drawn uniformly from \([n]\),

\[
\mathbb{E}_{f,x,y} \left[ \mathbb{I}[F(f(x), f(y)) \neq G(x, y)] \right] < \epsilon.
\]

Therefore, for every graph \( G \in \mathcal{G}_n \) there is a function \( f_G \) such that for \( x, y \sim [n] \) uniformly at random, \( \mathbb{P}_{x,y} [F(f_G(x), f_G(y)) \neq G(x, y)] < \epsilon \). Write \( N = \binom{n}{2} \). There are at most \( 2^{cN} \) functions \([n] \to \{0, 1\}^c \) and there are \( 2^N \) simple graphs on \([n]\) so there is some function \( f : [n] \to \{0, 1\}^c \) where the number of graphs \( G \) such that \( f_G = f \) is at least \( \frac{2^N}{2^c} = 2^{N-c} \). Let \( G, G' \) be any two such graphs. Then

\[
\mathbb{P}_{x,y \sim [n]} [G(x, y) \neq G'(x, y)] \leq \mathbb{P}_{x,y \sim [n]} [G(x, y) \neq F(f(x), f(y)) \text{ or } G'(x, y) \neq F(f(x), f(y))] < 2\epsilon.
\]

So \( G, G' \) differ on at most \( 2\epsilon N \) pairs. However, the largest number of graphs that differ from any graph \( G \) on at most \( 2\epsilon N \) pairs of vertices is at most

\[
\sum_{k=0}^{2\epsilon N} \binom{N}{k} \leq 2\epsilon N \binom{N}{2\epsilon N} \leq \epsilon N \left( \frac{eN}{2\epsilon N} \right)^{2\epsilon N} = 2^{2\epsilon N \log(e/2\epsilon) + 2\epsilon N}.
\]
Therefore we must have
\[ N - cn \leq 2\epsilon N \log(e/2\epsilon) + \log(2eN) \]
so \( c = \Omega(n) \).

Recall the example in the first paragraph of the introduction, for which we observed that a single decision function would work for many problems. We now make a note about this phenomenon. A communication protocol for a graph family \( \mathcal{F} = (F_i) \) is really a sequence of protocols, one for each set \( F_i \) of graphs with \( n(i) \) vertices. Our next proposition addresses the uniformity of the sequence of protocols, that is, the question of how the protocols are related to one another as the size of the input grows. In general, we ask the question: If the family \( \mathcal{F} \) has some relationship between \( F_i \) and \( F_{i+1} \), what does this imply about the relationship between the protocols for \( i \) and \( i + 1 \)? The families of graphs we study in this paper have constant-cost protocols and they are also upwards families, which we define next. These families have enough structure so that there exists a single, one-size-fits-all probabilistic universal graph, into which all graphs can be embedded regardless of their size; in other words, the referee can be ignorant not only of the graph \( G \) and vertices \( x, y \), but also of the size of the graph, without increasing the cost of the protocol.\(^2\)

\begin{definition}
We call a graph family \( \mathcal{F} = (F_i) \) an upwards family if for every \( i \) and every \( G \in F_i \) there exists \( G' \in F_{i+1} \) such that \( G \) is an induced subgraph of \( G' \).
\end{definition}

Many graph families are upwards families, for example: bounded-degree graphs, bounded-arboricity graphs, planar graphs, and transitive reductions of distributive lattices.

\begin{proposition}
If \( \mathcal{F} \) is an upwards graph family with an \( \epsilon \)-error randomized universal graph sequence \( U = (U_i) \) satisfying \(|V(U_i)| \leq c \) for some constant \( c \) (which may depend on \( \epsilon \)), then there exists a graph \( U^* \) of size \( c \) such that \( \forall G \in \mathcal{F}, G \subseteq U^* \). Furthermore, for any \( i < j \) and any \( G \in F_i \), there exists \( G' \in F_j \) with \( \epsilon \)-error embedding \( g' : V(G') \to V(U^*) \) such that \( G \) is an induced subgraph of \( G' \) and the restriction of \( g' \) to the domain \( V(G) \) is an \( \epsilon \)-error embedding \( V(G) \to V(U^*) \).
\end{proposition}

\begin{proof}
Let \( G \in F_i \) and let \( G' \in F_{i+1} \) be such that \( G \) is an induced subgraph of \( G' \). Let \( g' : V(G') \to V(U_{i+1}) \) the random function determined by the randomized universal graph sequence. Then \( g' \) restricted to the domain \( V(G) \subseteq V(G') \) satisfies
\[ P_g[U_{i+1}(g'(x), g'(y))] = G(x, y) = P_{g'}[U_{i+1}(g'(x), g'(y))] = G'(x, y) > 1 - \epsilon. \]

Therefore we may replace \( U_i \) with \( U_{i+1} \) in the sequence, for any \( i \).

Since each \( U_i \) has size at most \( c \), there are at most \( 2^{2^c} \) graphs \( U_i \) appearing in the sequence \( U \). Thus there is some graph \( U^* \) that occurs an infinite number of times in the sequence. For every \( i \) there exists \( j > i \) such that \( U_j = U^* \). By applying the above argument, we may replace \( U_i \) with \( U_j = U^* \) in the sequence. We arrive at the sequence \( U' = (U'_i) \) with \( U'_i = U^* \) for every \( i \).
\end{proof}

\(^2\) Any family \( \mathcal{F} \) with a constant-cost protocol can be turned into a protocol ignorant of the size by requiring that Alice and Bob tell the referee which of the \( 2^{2^c} \) possible decision functions to use, where \( c = 2 \log^\infty(\mathcal{F}) \).
2.3 Implicit Graph Representations and Induced-Universal Graphs

Kannan, Naor, and Rudich [23] call a family of graphs an implicit graph family if each of the $n$ vertices can be given a label of $O(\log n)$ bits so that adjacency can be determined from the labels of two vertices. They observe that an implicit encoding gives an upper bound on the size of an induced-universal graph. We define these terms below in slightly more generality (and omit the requirement that encoding and decoding be done in polynomial time):

Definition 2.18. Let $\mathcal{F} = (\mathcal{F}_i)$ be a graph family and $m(i)$ a function of the graph size. The family $\mathcal{F}$ has an $m$-implicit encoding if $\forall i, \exists F_i : \{0,1\}^{m(i)} \times \{0,1\}^{m(i)} \rightarrow \{0,1\}$ such that $F_i$ is symmetric and $\forall G \in \mathcal{F}_i, \exists g : V(G) \rightarrow \{0,1\}^{m(i)}$ satisfying $\forall x, y \in V(G), F_i(g(x), g(y)) = G(x, y)$.

For a graph family $\mathcal{F} = (\mathcal{F}_i)$, an induced-universal graph sequence is a sequence $U = (U_i)$ such that for each $i$ and all $G \in \mathcal{F}_i$, $G$ is an induced subgraph of $U_i$.

Our notion of $\varepsilon$-universal graphs differs from induced-universal graphs, since the embedding relation $G \subseteq U_i$ allows non-injective mappings (two vertices of $G$ may be mapped to the same vertex in $U_i$). This difference accounts for the extra factor $n(i)$ in the next theorem.

Theorem 2.19 ([33]). Let $\mathcal{F} = (\mathcal{F}_i)$ be a graph family with size $n(i)$. If there exists an $m$-implicit encoding of $\mathcal{F}$ there is an induced-universal graph sequence $U = (U_i)$ such that $|U_i| \leq n(i)2^{m(i)} = 2^{m(i)+\log n(i)}$.

Due to the fact that a deterministic universal SMP protocol may always be assumed to be symmetric (Proposition 2.6), it follows by definition and from Lemma 2.15 that:

Theorem 1.1 (Restated). A graph family $\mathcal{F} = (\mathcal{F}_i)$ is $m$-implicit iff $D^{\text{univ}}(\mathcal{F}_i) \leq m(i)$ for every $i$. Therefore, $\mathcal{F}$ is $O(R^{\text{univ}}(\mathcal{F}) \cdot \log n)$-implicit.

If one’s goal is merely to obtain an $O(1)$-cost universal SMP protocol for a family $\mathcal{F}$, the next observation shows that it suffices to find an $O(1)$-cost, public-coin, 2-way protocol for each member of $\mathcal{F}$. Therefore the family of all graphs with an $O(1)$-cost 2-way protocol is an implicit graph family with a polynomial-size induced-universal graph.

Corollary 1.2 (Restated). Let $\mathcal{F} = (\mathcal{F}_i)$ be a family of graphs with size $n(i)$ and suppose that for every graph $G \in \mathcal{F}_i$ there is an $\varepsilon$-error 2-way randomized communication protocol with cost at most $c(i)$. Then $R^{\text{univ}}(\mathcal{F}) \leq 2^c(i)$. Furthermore, for any fixed constant $c$, the family $\mathcal{F}$ of graphs with $R^{\varepsilon}(\text{Adj}(G)) \leq c$ is $O(\log n)$-implicit.

Proof. Every 2-way, deterministic cost $c$ protocol can be represented as a binary tree with at most $2^c$ nodes, where each node is owned by either Alice or Bob and the message sent at each step is a 0 or 1 informing the other player of which branch to take in the tree. A randomized 2-way protocol is a distribution over such trees. To obtain a universal SMP protocol for the family $\mathcal{F}$, Alice and Bob do the following. On input $G \in \mathcal{F}$ and $x, y \in V(G)$, Alice and Bob use shared randomness to draw the deterministic cost $c$ protocol for $G$ from the distribution defined by the randomized 2-way protocol. Alice sends the size $2^c$ protocol tree and for each node she owns she identifies the branch to be taken. Bob does the same. The referee may then simulate the protocol. The conclusion follows from Theorem 1.1.

3 Distance Labeling of Distributive Lattices

Distributive lattices and distances on these lattices will be defined in the next subsection, where we also give a necessary lemma characterizing the distances in terms of the meet and join. We will then present an $O(k \log k)$ weakly-universal protocol and an $O(k^2)$ universal...
communication protocol for the family $\mathcal{D}^k$, where $\mathcal{D}$ are the distributive lattices. This implies a $O(k^2 \log n)$-implicit encoding $\mathcal{D}^k$ of the family $\mathcal{D}$ of distributive lattices. The $O(k \log k)$ weakly-universal protocol is optimal for sufficiently small values of $k$, since it applies to the $k$-Hamming Distance problem as a special case, for which Sağlam [31] recently gave a matching lower bound (even for 2-way communication). We obtain this result by adapting the optimal $O(k \log k)$ communication protocol for $k$-Hamming Distance originally presented by Huang et al. [21].

We also consider modular lattices, a generalization of distributive lattices, and show that deciding $\text{dist}(x, y) \leq 2$ requires a protocol with cost $\Omega(n^{1/2})$.

3.1 Preliminaries on Distributive Lattices

A lattice is a type of partial order. We briefly review distributive lattices (see e.g. [9] for a good introduction) and then give a characterization of distances in modular and distributive lattices. The undirected graphs we study are the cover graphs of partial orders. For $x, y$ in a partial order $P$, we say that $y$ covers $x$ and write $x \prec y$ if $\forall z \in P$: if $x \leq z < y$ then $x = z$. The cover graph (which is the undirected version of the transitive reduction) is the graph $\text{cov}(P)$ on vertex set $P$ with an edge $\{x, y\}$ iff $x \prec y$ or $y \prec x$.

We will define a few types of lattices.

Definition 3.1. Let $(P, <)$ be a partial order. For a pair $x, y \in P$:

- If the set $\{ z \in P : x, y \geq z \}$ has a unique maximum, we call that maximum the join of $x$ and $y$ and write it as $x \vee y$;
- If the set $\{ z \in P : x, y \leq z \}$ has a unique minimum, we call that minimum the meet of $x$ and $y$ and write it as $x \wedge y$.

If $\forall x, y \in P$ the elements $x \wedge y, x \vee y$ exist, then $P$ is a lattice. A lattice $L$ is ranked if there exists a rank function such that $x \prec y \implies \text{rank}(x) + 1 = \text{rank}(y)$ and the minimum element $0_L$ satisfies $\text{rank}(0_L) = 0$. A finite lattice $L$ is upper-semimodular if for every $x, y, z \in L$, $x \wedge y \prec z \implies x, y \prec z$. $L$ is lower-semimodular if for every $x, y \in L$, $x, y \prec x \vee y \implies x \wedge y \prec x, y$. $L$ is modular if it is both upper- and lower-semimodular. A lattice $L$ is distributive if for all $x, y, z \in L$, $x \wedge (y \vee z) = (x \wedge y) \vee (x \wedge z)$. Every distributive lattice is modular and every modular lattice is ranked [9].

A point $x$ in a lattice $L$ is join-irreducible if there is no set $S \subseteq L$ such that $x = \bigvee S$ and meet-irreducible if there is no set $S \subseteq L$ such that $x = \bigwedge S$. Write $J(L)$ for the set of join-irreducible elements.

A subset $D$ of a partial order $P$ is a downset or ideal if: for all $x, y \in D$, if $x \in D$ and $y \leq x$ then $y \in D$. We will write $D(P)$ for the set of ideals of $P$.

Theorem 3.2 (Birkhoff (see e.g. [9])). Every distributive lattice $L$ is isomorphic to the lattice of downsets of the partial order on its join-irreducible elements, ordered by inclusion; i.e. $L \simeq D(J(L))$, with the meet and join operations given by set union and intersection respectively.

We need to prove some facts about distances in modular lattices.

Proposition 3.3. Let $L$ be a graded lattice and let $x, y \in L$. Then $\text{dist}(x, y) \geq |\text{rank}(x) - \text{rank}(y)|$, with equality if $x \prec y$ or $y \prec x$.

Proof. This follows from the fact that for every edge $u \prec v$ in the path from $x$ to $y$ has rank$(u) + 1 = \text{rank}(v)$.

To prove our characterization of distance, we define inversions in the path.
Definition 3.4. Let $L$ be a lattice and let $c_1, \ldots, c_m$ be a path in $\text{cov}(L)$, so that $c_i \prec c_{i+1}$ or $c_{i+1} \prec c_i$ for each $i$. If $c_{i-1}, c_{i+1} \prec c_i$ or $c_i \prec c_{i-1}, c_{i+1}$ we call $c_i$ an inversion on the path.

Lemma 3.5. The following holds for any $x, y$ in a lattice $\mathcal{M}$:
1. If $\mathcal{M}$ is lower-semimodular then $\text{dist}(x, y) = \text{dist}(x, x \land y) + \text{dist}(y, x \land y)$;
2. If $\mathcal{M}$ is upper-semimodular then $\text{dist}(x, y) = \text{dist}(x, x \lor y) + \text{dist}(y, x \lor y)$;
3. If $\mathcal{M}$ is distributive then $\text{dist}(x, y) = |X \Delta Y|$ where $X, Y \in D(J(\mathcal{M}))$ are isomorphic images of $x, y$ in Birkhoff’s representation.

Proof. It suffices to prove the first statement: the second follows by the analogous argument and the third follows from the modularity of distributive lattices and Birkhoff’s representation.

Let $\mathcal{M}$ be lower-semimodular, let $x, y \in \mathcal{M}$, and let $x = c_0, c_1, \ldots, c_m = y$ be a shortest path between $x$ and $y$, so that $\text{dist}(x, y) = \text{dist}(x, c_i) + \text{dist}(y, c_i)$ for any $i$. The statement holds trivially when $x < y$ or $y < x$ (since $x \land y = x$ or $x \lor y = y$), so we assume $x, y$ are incomparable. We prove the statement by induction on the largest rank of an inversion of the form $c_{i-1}, c_{i+1} \prec c_i$ in the path.

First suppose that $c_i$ is any element of the path and assume for contradiction that $\text{rank}(c_i) < \text{rank}(x \land y)$. Then

$$\text{dist}(x, x \land y) = \text{rank}(x) - \text{rank}(x \land y) < \text{rank}(x) - \text{rank}(c_i) \leq \text{dist}(x, c_i),$$

a contradiction. Thus $\text{rank}(c_i) \geq \text{rank}(x \land y)$ for each element of the path.

Suppose there are no inversions of the form $c_{i-1}, c_{i+1} \prec c_i$. Then $c_i \prec x, y$ and therefore $c_i \leq x \land y$ so $\text{rank}(c_i) \leq \text{rank}(x \land y)$, and by the above inequality we have $\text{rank}(c_i) \geq \text{rank}(x \land y)$, so $\text{rank}(c_i) = \text{rank}(x \land y)$. Therefore, as desired,

$$\text{dist}(x, y) = \text{dist}(x, c_i) + \text{dist}(y, c_i) = \text{rank}(x) - \text{rank}(c_i) + \text{rank}(y) - \text{rank}(c_i)$$

$$= \text{rank}(x) - \text{rank}(x \land y) + \text{rank}(y) - \text{rank}(x \land y)$$

$$= \text{dist}(x, x \land y) + \text{dist}(y, x \land y).$$

Now let $c_i$ be an inversion of the form $c_{i-1}, c_{i+1} \prec c_i$ with $\text{rank}(c_i) > \text{rank}(x \land y)$. Then by lower-semimodularity there is an element $c'_i = c_{i-1} \land c_{i+1} \prec c_{i-1}, c_{i+1}$. Then replacing $c_i$ with $c'_i$ maintains the length of the path. Performing the same operation on all such inversions of maximum rank reduces the maximum rank by 1 and the result holds by induction.

3.2 A Universal Protocol for Distributive Lattices

Write $\mathcal{D} = (\mathcal{D}_n)$ for the family of cover graphs of distributive lattices on $n$ vertices. We first give an optimal protocol for distances in distributive lattices in the weak universal model (recall that in this model, the referee sees the shared randomness). This protocol is adapted from a simplified presentation of Huang et al.’s $k$-Hamming Distance protocol ([21]) communicated to us by E. Blais.

Theorem 3.6. For any $\epsilon > 0$ and integer $k$, $R^{\text{weak}}(\mathcal{D}^k) = O(k \log(k/\epsilon))$.

Proof. For any distributive lattice $L \simeq D(J(L))$, identify each vertex $x \in L$ with its ideal $X \subseteq J(L)$ of join-irreducibles. Write $e_1, \ldots, e_m$ for the basis vectors of $\mathbb{F}_2^n$. Consider the following protocol. On the distributive lattice $L$ and vertices $x, y$, Alice and Bob perform the following:
1. Define \( m = \lceil \frac{(k+2)^2}{\epsilon} \rceil, q = \lceil \log \frac{1}{\epsilon} + \log \sum_{i=0}^{\alpha} \binom{m}{i} \rceil \).
2. Let \( S = (s_1, \ldots, s_m) \) be a multiset of uniformly random elements of \( \mathbb{F}_2^m \).
3. For each join-irreducible element \( j \in J(L) \) assign a uniformly random index \( i_j \sim [m] \).
4. For each vertex \( v \subseteq J(L) \) there is an indicator vector \( a(v) \in \mathbb{F}_2^m \) defined by \( a(v) = \sum_{j \in v} e_{i_j} \). Label \( v \) with \( \ell(v) = \sum_{i=1}^{m} a(v)_i s_i \).
5. Alice sends \( \ell(x) \) and Bob sends \( \ell(y) \) to the referee.
6. The referee accepts if \( \ell(x) + \ell(y) \) is a sum of at most \( k \) elements of \( S \).

By Lemma 3.5 and Birkhoff’s theorem, \( \text{dist}(x, y) = \text{dist}(x, x \land y) + \text{dist}(x \land y, y) = |X \setminus Y| + |Y \setminus X| = |X \Delta Y| \), where \( \Delta \) denotes the symmetric difference. Suppose \( \text{dist}(x, y) = |X \Delta Y| \leq k \).

Then \( \ell(x) + \ell(y) = \sum_{j \in X \Delta Y} c(j) \) is a sum of at most \( k \) elements of \( S \), so the protocol accepts with probability 1 (so this protocol has 1-sided error).

Now suppose \( \text{dist}(x, y) = |X \Delta Y| \geq k + 1 \). The correctness of the protocol follows from the next two claims along with the observations that \( a(x) + a(y) = a(x \land y) \) and \( \ell(x) + \ell(y) = \ell(x \land y) \) (with arithmetic in \( \mathbb{F}_2^m \)) and that \( \text{dist}(x, y) \geq k + 1 \) implies \( \text{rank}(x \land y) \geq k + 1 \). We will write \( |a(v)| \) for the number of 1’s in the vector \( a(v) \).

**Claim 3.7.** Any vertex \( v \subseteq J(L) \) with \( \text{rank}(v) \geq k + 1 \) has \( |a(v)| \geq k + 1 \) with probability at least \( 1 - \epsilon/2 \).

**Proof of claim.** If \( \text{rank}(v) = k + 1 \), so \( v \) is a set of \( k + 1 \) join-irreducibles, then the probability that any two indices \( i_j, i_{j'} \), collide, for \( j, j' \in v \), is by the union bound at most

\[
\binom{k+1}{2} \Pr[i_j = i_{j'}] = \frac{(k+1)^2}{2} \frac{\epsilon}{m} \leq \frac{\epsilon/2}{(k+2)^2} = \epsilon/2.
\]

For \( \text{rank}(v) > k + 1 \) choose \( v' \preceq v \) so \( k + 1 \leq \text{rank}(v') < \text{rank}(v) \), so using induction and the assumption \( \epsilon < 1/2 \),

\[
\Pr[|a(v)| \leq k] = \frac{k+1}{m} \Pr[|a(v')| = k + 1] + \frac{k}{m} \Pr[|a(v')| \leq k] < \frac{\epsilon}{k+2} + \frac{\epsilon}{k+2} = \frac{\epsilon}{2} < \epsilon/2.
\]

**Claim 3.8.** For any vertex \( v \subseteq J(L) \), if the indicator vector \( a(v) \) has weight \( \geq k + 1 \) then, with probability at least \( 1 - \epsilon/2 \), \( \ell(v) \) is not a sum of at most \( k \) vectors in \( S \).

**Proof of claim.** Write \( kS \) for the set of all sums of at most \( k \) vectors in \( S \). Fix any \( a(v) \) with weight \( \geq k + 1 \) and let \( A = \{ i : a(v)_i = 1 \} \) so \( |A| \geq k + 1 \). Let \( b \in kS \) be any sum of \( k \) vectors in \( S \), and let \( B \subset [m] \) be a set of indices of size \( |B| \leq k \) such that \( b = \sum_{i \in B} s_i \).

Since \( |B| \leq k < |A| \) we must always have \( A \setminus B \neq \emptyset \) and \( \ell(v) + b = \sum_{i \in A \setminus B} s_i \), so \( \Pr[\ell(v) + b = 0] = 2^{-q} \). Therefore, by the union bound over all such vectors \( b \),

\[
\Pr[\ell(v) \in kS] \leq \sum_{i=0}^{k} \binom{m}{i} 2^{-q} < \epsilon/2.
\]

We can put a bound on \( q \) by using

\[
\sum_{i=0}^{k} \binom{m}{i} \leq k \binom{m}{k} \leq k \left( \frac{em}{k} \right)^k
\]

so

\[
q \leq 1 + \log \frac{1}{\epsilon} + \log k + k \log \frac{em}{k} \leq \log \frac{2k}{\epsilon} + k \log \frac{ek}{\epsilon} = O \left( \frac{k \log k}{\epsilon} \right).
\]
Observe that the referee must see the set $S$ for the above protocol to work. We can easily modify the above protocol to get $O(k^2)$.

**Theorem 3.9.** For any $\epsilon > 0$ and any integer $k$, $R^\text{univ}_U(D^k) = O(k^2 \log(1/\epsilon))$.

**Proof.** The protocol is the same as above, with the following modification: Alice and Bob each send the indicator vectors $a(x), a(y) \in \mathbb{F}_2^n$.

The correctness of this protocol for error $1/3$ follows from Claim 3.7. Observe that Alice and Bob use the same strategy to send their messages and that the decision function is symmetric. The communication cost is now at most $m = \lceil 3(k + 2)^2/2 \rceil$.

This protocol is one-sided, so to achieve error $\epsilon$ we can run the protocol $r = \lceil \log_3(1/\epsilon) \rceil$ times and take the AND of the results. The probability of failure is $(1/3)^r = 3^{-r} < \epsilon$. ◀

Now we apply Theorem 1.1 to obtain Theorem 1.3.

Since the family of distributive lattices is an upwards family (simply append a new least element to obtain a larger distributive lattice), we see from Proposition 2.17 that lattices in $D^k$ can be randomly embedded into a constant-size graph, for any constant $k$. In fact, by inspection of the protocol, we see that the family $D$ can be randomly embedded into a small-dimensional hypercube, while $D^k$ can be embedded into the $k$-closure of the $O(k^2)$-dimensional hypercube.

**Corollary 3.10.** For any $\epsilon > 0$ and any $k$, there exists a graph $U$ of size $2^{O(k^2 \log(1/\epsilon))}$ such that for all $L \in D^k$, $L \subseteq U$.

### 3.3 Lower Bound for Modular Lattices

Since Lemma 3.5 works for any modular lattices, it is natural to ask whether we can achieve a similar constant-cost protocol for computing distance thresholds in modular lattices. However, we show that this is impossible.

**Lemma 3.11.** There is a function $m(n) = O(n^4)$ such that if $G$ is any graph with $n$ vertices (where $G(u, v) = 1$ for all $u$), there exists a modular lattice $M$ with size $m(n)$ such that $G$ is an induced subgraph of $\text{cov}(M)^2$.

**Proof.** Construct the lattice $M$ as follows:

1. Start with vertices $V$, which are all incomparable.
2. For each edge $e = \{u, v\} \in E$, add vertices $a_e, b_e$ such that $a_e < u, v < b_e$.
3. For each edge $e = \{u, v\}, e' = \{u', v'\} \in E$ such that $e \cap e' = \emptyset$ add a vertex $c_{e,e'}$ with $a_e, a_{e'} < c_{e,e'} < b_e, b_{e'}$.
4. Add vertices $0_M$ and $1_M$ such that $0_M < a_e$ and $b_e < 1_M$ for all $e \in E$.

First we prove that $M$ is a modular lattice and then we prove the bound on the size.

**Claim 3.12.** $M$ is a modular lattice.

Proof of claim. Observe that all orderings $<$ directly imposed by this process are covering orders $\prec$. Let $A = \{a_e\}_{e \in E}, B = \{b_e\}_{e \in E}, C = \{c_e\}_{e \in E}$ and $V$ the original set of vertices. By construction, $M$ is graded with $\text{rank}(0_M) = 0, \text{rank}(A) = 1, \text{rank}(V) = \text{rank}(C) = 2, \text{rank}(B) = 3, \text{rank}(1_M) = 4$. Note that for every pair of vertices $x, y \in M, 0_M \leq x, y \leq 1_M$ so upper- and lower-bounds exist.

Assume for contradiction that $M$ is not a modular lattice, so there exist incomparable $x, y \in M$ such that either $x \wedge y$ or $x \vee y$ does not exist, or such that $x \wedge y \prec x, y \nprec x \vee y$ or $x \wedge y \nprec x, y \prec x \vee y$. 
Case 1: Suppose rank(x) ̸= rank(y). Then x ∧ y = 0_M and x ∨ y = 1_M so x ∧ y ̸= x, y ̸= x ∨ y.
Case 2: Suppose x, y ∈ A so x = a_e, y = a_e'. Then 0_M = a_e ∧ a_e' ̸≺ a_e, a_e'.
If a_e, a_e' < u, v for u, v ∈ V then u, v ∈ e ∨ e' so u = v. If a_e, a_e' < v, c_{d,d'} for v ∈ V and c_{d,d} ∈ C then
v ∈ e ∨ e' and c_{d,d} = c_{e,e'} so e ∨ e' = 0, a contradiction. Finally, if a_e, a_e' < c_{d,d'}, c_{d',d'}
then c_{d,d'} = c_{d',d'} = c_{e,e'}. So a_e ∨ a_e' exists and a_e ∧ a_e' ̸≺ a_e, a_e' ̸≺ a_e ∨ a_e'.
The same argument holds for x, y ∈ B.
Case 3: Suppose x, y ∈ V and assume a_e ∨ a_e' < x, y. Then x, y ∈ e ∨ e' so a_e = a_e'.
A similar argument holds for x, y < b_e, b_e'. So x ∧ y < x, y ∨ x ∨ y.
Case 4: Suppose x, y ∈ C so x = c_{e,e'}, y = c_{d,d'}. Suppose a_s, a_t < c_{e,e'}, c_{d,d'}.
Then s, t ∈ {e, e'} ∩ {d, d'} so either {e, e'} = {d, d'} or s = t. The same argument holds for
c_{e,e'}, c_{d,d'} < b_e, b_d so x ∧ y < x, y ∨ x ∨ y.
Case 5: Suppose x ∈ V, y ∈ C so y = c_{e,e'} which implies e ∨ e' = 0. If x ̸∈ e ∨ e'
then x ∧ c_{e,e'} = 0_M and x ∨ c_{e,e'} = 1_M so x ∧ c_{e,e'} ̸≺ x, c_{e,e'} ̸≺ x ∨ c_{e,e'}; so suppose
x ∈ e ∨ e'. If a_e, a_e' < x, c_{e,e'} then x ∈ e ∨ e' which is a contradiction. Then x ∈ e
or x ∈ e'; say x ∈ e. Then a_e = x ∧ c_{e,e'}. The same argument holds for B so
a_e = x ∧ c_{e,e'} ̸≺ x, c_{e,e'} ̸≺ x ∨ c_{e,e'} = b_e.

Claim 3.13. G is an induced subgraph of cov(M)^2.

Proof of claim. Suppose {u, v} ∈ E. Then there is a_e ̸≺ u, v so dist(u, v) ≤ 2 in cov(M).
Now let u, v ∈ V(G) and suppose dist(u, v) ≤ 2 in cov(M) so that, by Lemma 3.5, u ∧ v < u, v < u ∨ v.
By construction, either u = v so G(u, v) = G(u, u) = 1, or u ∨ v = a_e for some
e ∈ E(G) so u, v ∈ e and therefore G(u, v) = 1.

The size of M is at most 2 + |E(G)| + |E(G)|^2 = O(n^4). Let m(n) be the maximum size of a
modular lattice obtained in this way from a graph of size n. We want all constructions to be
of the same size, so repeatedly append new least elements until the size reaches m(n); this
maintains the modular lattice property.

Theorem 3.14. Let M = (M_n) be the family of cover graphs of modular lattices.
R_{inv}^M(M^2) ≥ Ω(n^{1/4}).

Proof. Suppose there is a protocol for M^2 with cost o(n^{1/4}). Given a graph G of size
n, Alice and Bob construct the modular lattice of size m(n) = O(n^4) with G an induced
subgraph of cov(M)^2 and run the protocol for M^2 with size m(n) (observe that all possible
constructions must be of the same size, since the referee does not know which lattice Alice
and Bob construct). This has cost o(m(n)^{1/4}) = o(n), which contradicts Theorem 1.6.

4 Communication on Efficiently Labelable Graphs

In this section we take inspiration from the field of implicit graphs and graph labeling and
show that one may often, but not always, obtain constant-cost adjacency and k-distance
protocols for families that are commonly studied in the graph labeling literature.

4.1 Trees, Forests, and Interval Graphs

In this section we pick the low-hanging fruit from trees and forests (and interval graphs).
Applying Theorem 1.1 with the next lemma, we get Theorem 1.4.

Lemma 4.1. Let T = (T_n) be the family of trees of size n. R_{inv}^{inv}(T^k) = O(k \log \frac{1}{n}),
and this protocol will correctly compute the distance in the case dist(x, y) ≤ k.
Universal Communication

Proof. Consider the following protocol. On input \((T, x), (T, y)\) for a tree \(T\), Alice and Bob perform the following.

1. Partition the vertices of \(T\) into sets \(T_1, \ldots, T_m\) such that \(T_i = \{v \in V(T) : (i - 1)k \leq \text{depth}(v) < ik\}\). For each \(v \in V(T)\) let \(t(v)\) be the index of the unique set satisfying \(v \in T_{t(v)}\).

2. For each vertex \(v \in V(T)\) assign a uniformly random color \(\ell(v)\) in \([m]\) for \(m = \lceil 6/\epsilon \rceil\).

Let \(x'\) be root of the subtree of \(T_{t(x)}\) that contains \(x\), and let \(x''\) be the root of the subtree of \(T_{t(x) - 1}\) that contains \(x\). Let \(x_0, x_1, \ldots, x_k, \ldots, x_{k_1} = x\) be the path from \(x''\) to \(x\) (with \(x_k = x'\)) and let \(y_0, \ldots, y_k, \ldots, y_{k_2}\) be the path from \(y''\) to \(y\). Alice and Bob send \(\ell(x_0), \ldots, \ell(x_{k_1})\) and \(\ell(y_0), \ldots, \ell(y_{k_2})\) respectively.

3. If \(\ell(x') = \ell(y')\), let \(p\) be the maximum index such that \(\ell(x_i) = \ell(y_i)\) for each \(k < i \leq p\). Let \(d = (k_1 - p) + (k_2 - p)\). If \(\ell(x'') = \ell(y'')\), let \(p\) be the maximum index such that \(\ell(x_i) = \ell(y_i)\) for each \(i \leq p\) and let \(d = (k_1 - p) + (k_2 - p)\). If \(\ell(x') = \ell(y'')\) let \(p\) be the maximum index such that \(\ell(x_i) = \ell(y_{k+i})\) for each \(i \leq p\) and let \(d = (k_1 - p) + (k_2 - k - p)\). If \(\ell(x') = \ell(y'')\) do the same with \(x, y\) reversed. In each case, if \(d \leq k\), the referee outputs \(d\), otherwise they output “> \(k\).” If none of the above cases hold, output “> \(k\).”

The cost of this protocol is \(2k\lceil \log m \rceil = O(k \log(1/\epsilon))\). With probability at least \(1 - 4/m > 1 - \epsilon/2\), each of the possible equalities \(x'' = y'', x' = y', x'' = y', x' = y''\) will be correctly observed by the referee. If \(\{x', x''\} \cap \{y', y''\} = \emptyset\) then \(x, y\) are not in the same subtree rooted at depth \(\text{depth}(x'')\), so the distance from \(x\) to any common ancestor of \(x, y\) is at least \(\text{dist}(x, x'') > k\). Therefore if \(\text{dist}(x, y) \leq k\), one of these equalities will hold. If \(x'' = y''\) and \(q\) is the maximum integer such that \(x_i = y_i\) for all \(i \leq q\) then \(\text{dist}(x, y) = (k_1 - q) + (k_2 - q)\), because the deepest common ancestor of \(x, y\) is at depth \(\text{depth}(x_0) + q\). Conditional on the 4 equalities being correctly observed, we will have \(d = (k_1 - p) + (k_2 - p)\) since \(p \geq q\). If \(p > q\) then \(\ell(x_{q+1}) = \ell(y_{q+1})\) even though \(x_{q+1} \neq y_{q+1}\), which occurs with probability \(1/m < \epsilon/2\). Therefore the probability that \(d \neq \text{dist}(x, y)\) is at most \(2(\epsilon/2) = \epsilon\) when \(\text{dist}(x, y) \leq k\). A similar argument holds in the other 3 cases.

If \(\text{dist}(x, y) > k\) then still with probability at least \(1 - \epsilon/2\) all 4 possible equalities are correctly observed. Following the same argument as in the equality case, we see that if any of the equalities hold we will have \(d = \text{dist}(x, y)\) with probability greater than \(1 - \epsilon/2\), for total error probability less than \(\epsilon\). If none of the 4 equalities hold then the probability of error is at most \(\epsilon/2\).

Since trees have efficient protocols, one might wonder about generalizations of trees. The arboricity of a graph is one such generalization, which measures the minimum number of forests required to partition all the edges.

Definition 4.2. A graph \(G = (V, E)\) has arboricity \(\alpha\) iff there exists an edge partition of \(G\) into forests \(T_1, \ldots, T_\alpha\). Equivalently, for \(S\) ranging over the set of subgraphs of \(G\), \(G\) has

\[
\max_S \left[ \frac{E(S)}{V(S) - 1} \right] \leq \alpha.
\]

Low-arboricity graphs easily admit an efficient universal SMP protocol for adjacency.

Proposition 4.3. Let \(F\) be any family of graphs with arboricity at most \(\alpha\). For all \(\epsilon > 0\), \(P_{\text{inv}}(F) = O(\alpha \log \frac{2}{\epsilon})\).

Proof. On the graph \(G\) and vertices \(x, y\), Alice and Bob perform the following:

1. Compute a partition of \(G\) into \(\alpha\) forests \(T_1, \ldots, T_\alpha\).
2. Assign to each vertex \(v\) a uniformly random number \(\ell(v) \sim [m]\) for \(m = [2\alpha/\epsilon]\).
3. Let \( x_i \) be the parent of \( x \) in tree \( i \) and let \( y_i \) be the parent of \( y \). Alice sends \( \ell(x) \) and

\[ \ell(x_i) \]

for each \( i \), and Bob does this same with \( y \).

4. The referee accepts if \( \ell(x) = \ell(y) \) or \( \ell(y) = \ell(x_i) \) for any \( i \).

This protocol has one-sided error since if \( x, y \) are adjacent then either \( x_i = y \) or \( y_i = x \) for some \( i \), so the referee will accept with probability 1. If \( x, y \) are not adjacent then the referee will accept with probability at most \( 2\alpha \cdot \frac{1}{m} < \epsilon \).

However, even graphs of arboricity 2 do not admit efficient protocols or labeling schemes for distance 2, which we can show by embedding an arbitrary graph of size \( \Omega(\sqrt{n}) \) into the 2-closure of an arboricity 2 graph of size \( n \):

\[ \text{Proposition 4.4.} \quad \text{Let } F \text{ be the family of arboricity-2 graphs. Then } R^{\text{univ}}(F^2) \geq \Omega(\sqrt{n}). \]

Proof. The lower bound is obtained via Theorem 1.6 in the same way as in Theorem 3.14, using the following construction. For all simple graphs \( G = (V, E) \) with \( n \) vertices, there exists a graph \( A \) of size \( n + \binom{n}{2} \) and arboricity 2 such that \( G \) is an induced subgraph of \( A^2 \). Let \( A \) be the graph defined as follows:

1. Add each vertex \( v \in V \) to \( A \);
2. For each pair of vertices \( \{u, v\} \) add a vertex \( e_{\{u, v\}} \) and add edges \( \{u, e_{\{u, v\}}\}, \{v, e_{\{u, v\}}\} \)
   iff \( \{u, v\} \in E \).

This graph has arboricity 2 since each \( e_{\{u, v\}} \) we may assign each of its 2 incident edges a color in \( \{1, 2\} \) (if the edges exist). Then the edges with color \( i \in \{1, 2\} \) form a forest with roots in \( V \).

Now we give an example of a family, the interval graphs, with size \( O(\log n) \) adjacency labels but with no constant-cost universal SMP protocol; in fact, randomization does not give more than a constant-factor improvement for this family. An interval graph of size \( n \) is a graph \( G \) where for each vertex \( x \) there is an interval \( X \subseteq [2n] \) such that any two vertices \( x, y \) are adjacent in \( G \) iff \( X \cap Y \neq \emptyset \). These have an \( O(\log n) \) adjacency labeling scheme [23] (one can simply label a vertex with its two endpoints in \( [2n] \)).

There is a simple reduction from the Greater-Than communication problem, in which Alice and Bob receive integers \( x, y \in [n] \) and must decide if \( x < y \). It is known that the one-way public-coin communication cost of Greater-Than is \( \Omega(\log n) \) [25], so \( R^{\text{univ}}(\text{Greater-Than}) = \Omega(\log n) \).

\[ \text{Proposition 4.5.} \quad \text{For the family } F \text{ of interval graphs, } R^{\text{univ}}(F) = \Omega(\log n). \]

Proof. We can use a universal SMP protocol for \( F \) to get a protocol for Greater-Than as follows. Alice and Bob construct the interval graph with intervals \([1, i], [i, n]\) for each \( i \in [n] \), so there are \( 2n \) vertices in \( G \). On input \( x, y \in [n] \), Alice and Bob compute adjacency on the intervals \([1, x], [1, y]\) and then again on \([1, x], [y, n]\). Assume both runs of the protocol succeed. Then when the output is 1 for both runs we must have \( y \in [1, x] \) so \( y \leq x \) and otherwise we have \( y \notin [1, x] \) so \( x < y \).

\subsection{Planar Graphs}

Write \( \mathcal{P}_n \) for the set of planar graphs of size \( n \) and write \( \mathcal{P} = (\mathcal{P}_n) \) for the family of planar graphs. Gavoille et al. [15] gave an \( O(\sqrt{n} \log n) \) labeling scheme where \( \text{dist}(x, y) \) can be computed from the labels of \( x, y, \) and Gawrychowski and Uznanski [16] improved this to \( O(\sqrt{n}) \). These labeling schemes recursively identify size-\( O(\sqrt{n}) \) sets \( S \) and record the distance of each vertex \( v \) to each \( u \in S \), so the \( \sqrt{n} \) factor is unavoidable using this technique. We want to solve \( k \)-distance with a cost independent of \( n \), so we need a new method. Our main tool is Schnyder’s elegant decomposition of planar graphs into trees:
Theorem 4.6 (Schnyder [32], see [11]). Define the dimension \( \dim(G) \) of a graph \( G \) as is the minimum \( d \) such that there exist total orders \( <_1, \ldots, <_d \) on \( V(G) \) satisfying:

\((*)\) For every edge \( (u, v) \in E \) and \( w \notin \{u, v\} \) there exists \( <_i \) such that \( u, v <_i w \).

\( G \) is planar iff \( \dim(G) \leq 3 \). If \( G \) is planar then there exists a partition \( T_1, T_2, T_3 \) of the edges into directed trees satisfying the following. Let \( T_i^{-1} \) be edge-induced directed graph on \( V(G) \) obtained by reversing the direction of each edge in \( T_i \). The graphs with edges \( T_i \cup T_i^{-1} \cup T_{i+1}^{-1} \) have linear extensions \( <_i \) such that \( <_1, <_2, <_3 \) satisfy \((*)\).

Schnyder’s Theorem implies that the arboricity of planar graphs is at most 3, so we may use the protocol for low-arboricity graphs (Proposition 4.3) to determine adjacency in \( P^2 \), which may have large arboricity (arboricity is within a constant factor of degeneracy):

Theorem 4.7 ([1]). There are planar graphs \( P \) for which the degeneracy of \( P^2 \) is \( \Theta(\text{deg } P) \), where \( \text{deg } P \) is the maximum degree of any vertex in \( P \).

We avoid this blowup in arboricity by treating edges of the form \( a \leftarrow b \rightarrow c \) separately (with directions taken from the Schnyder wood). The proof uses the following split operation:

Definition 4.8. Let \( G \in P \) and fix a planar map and a Schnyder wood \( T_1, T_2, T_3 \). Define the graph \( \text{split}(G) \) by the following procedure (see Figure 1):

1. For each vertex \( s \in V(G) \) add vertices \( s, s_1, s_2, s_3 \) to \( \text{split}(G) \) (excluding \( s_i \) if \( s \) has no incoming edge in \( T_i \)). Add edges \((s_i, s)\) to \( T_i^\prime\);
2. For each (directed) edge \((u, v) \in T_i\) add the edges \((u_{i-1}, v_i), (u_{i+1}, v_i)\) (arithmetic mod 3) to \( T_i^\prime\);
3. For the unique (directed) edge \((v, u) \in T_i\) add the edges \((v_{i-1}, u), (v_{i+1}, u)\) to \( T_i^\prime\).

![Figure 1] Splitting vertex \( s \), with \( T_1, T_2, T_3 \) in blue, red, and green respectively (1, 2, and 3 arrowheads).

Proposition 4.9. \( \text{split}(G) \) is planar.

Proof. We prove that splitting any vertex \( s \) results in a planar graph. By induction we may then split each vertex in sequence and obtain a planar graph. Let \( <_i \) be any total order on \( V(G) \) extending \( T_i \cup T_{i-1}^{-1} \cup T_{i+1}^{-1} \), which satisfies condition \((*)\) by Schnyder’s theorem. Let \( <_1^\prime, <_2^\prime, <_3^\prime \) be the same total orders, extending \( T_1^\prime, T_2^\prime, T_3^\prime \), and augmented to include \( s_1, s_2, s_3 \) as follows:

1. For each \( u \in V(G), s_i <_i^\prime u \) iff \( s <_j u \) and \( u <_j^\prime s \);
2. For each \( i, s_i <_i^\prime s_i^\prime, s_i^\prime <_i^\prime s_i+1 <_i^\prime s_i-1 \). This is possible since \( \{s_i\} \) do not have a defined ordering in \( <_i \) and remain incomparable after the previous step.

Note that for any edge \((u, v) \in T_i^\prime\) we have \( u <_i^\prime v \) and \( v <_i^\prime u \) for \( j \neq i \). It suffices to prove that condition \((*)\) is satisfied by the new orders. Let \( \{u, v\} \in E(\text{split}(G)) \) and let \( w \notin \{u, v\} \). We will show that there exists \( i \) such that \( u, v <_i^\prime w \).
If $u, v, w \in V(G)$ then we are done since the orders $<_i^j$ are the same as $<_i$ on these vertices.

If $u = s_i$ then either $v \in V(G) \setminus s_i$, in which case $v < v_i^j s_i$ so $v < v_i^j u$ and therefore $v < v_i^j v$ for $j \neq i$, or $v = s_i$ so $v < v_i^j u$ and therefore $v < v_i^j u$ for $j \neq i$. Let $v \neq s_i$. For any $w \in V(G) \setminus \{v\}$ we have, by (**), either $v, s_i < w$ so $v < v_i^j s_i < v_i^j w$, or $v, s_i < w$ so $u < v_i^j v < v_i^j w$. If $v = s_i$ then by construction there exists $(u', v) \in T_i$. By (**), either $u', v < i w$ so $u < v_i^j v < i w$, or $u', v < v_i^j w$ so $v < v_i^j u < u' < v_i^j w$.

The only case remaining is if $w = s_i$ and $u, v \in V(G)$. By construction there exists $(w', w) \in T_i$. Either $u, v < i w' < i w < i s_i$ and $w < i s_i$ or by (***) there exists $j$ such that $u, v < j s_i$ and $(s_i, w)$ is an edge in $T_i^j$, $s < j w$ for $j \neq i$. □

Definition 4.10. Let $G = (V, E)$ be a planar graph. Fix a planar map and a Schnyder wood $T_1, T_2, T_3$. For each $i$, define the graph $G_i = (V, E \setminus T_i)$ as the graph obtained by removing each edge in $T_i$. Define the head-to-head closure of $G_i$, written $G_i^\leftarrow\rightarrow$, as the graph with an edge $(u, v)$ if there exists $w \in V$ such that $u \leftarrow w \rightarrow v$ in $G_i$. (Observe that the two outgoing edges of $w$ must be in $T_{i-1}, T_{i+1}$.) Let $G^\leftarrow\rightarrow$ be the subgraph of $G^2$ containing all edges occurring in $G_i^\leftarrow\rightarrow$ for each $i$.

Lemma 4.11. Let $G$ be a planar graph. For any graph $M$, if $M$ is a minor of $G_i^\leftarrow\rightarrow$ then $M$ is a minor of $\text{split}(G)$.

Proof. We will prove the following claim.

Claim 4.12. For any set $P = \{P_j\}$ of simple paths $P_j \subseteq V(G_i^\leftarrow\rightarrow)$, with endpoints $\{(s_j, t_j)\}$ such that no two paths $P_j, P_k$ have the same endpoints and $P_j \cap P_k \subseteq \{s_j, s_k, t_j, t_k\}$, there exists a set of paths $Q = \{Q_j\}$ of paths in $\text{split}(G)$ with the same endpoints such that

$$Q_j \cap Q_k \subseteq \{(s_j, s_k, t_j, t_k) \cup \{(s_j)_i, (s_k)_i, (t_j)_i, (t_k)_i\} \cup \{(s_j)_i, (s_k)_i, (t_j)_i, (t_k)_i\},$$

where the vertices $s_i, s_i+1, s_i-1$ are defined as in the split operation.

Proof of claim. For each path $P_j$, perform the following. For each edge $\{u, v\}$ in the path $P_j$, there is some vertex $v'$ such that either $(v, v') \in T_{i-1}$ and $(v, v') \in T_{i+1}$, or the same holds with $u, w$ reversed. Add the edges $\{u, v\}$, $\{u, v\}$, $\{v, w\}$ to $Q_j$. If $P_j$ is a singleton $P_j = \{u\}$ so $s_j = t_j$ then add $u$ to $Q_j$.

Consider two paths $Q_j, Q_k$ constructed this way. $G_i^\leftarrow\rightarrow$ has vertex set $V$ and $\text{split}(G)$ has vertex set $V' \supset V$. By construction, $P_j \subseteq Q_j$ and $P_k \subseteq Q_k$ and $(Q_j \cap V') = P_j$. Suppose there exists $z \in Q_j \cap Q_k$ that is not an end point, so $z \notin \{s_j, s_k, t_j, t_k\}$. If $z \in V$ then $z \in P_j \cap P_k \subseteq \{s_j, s_k, t_j, t_k\}$ so we only need to worry about $z \in V' \setminus V$.

If $z = v_i$ for some vertex $v$ then there are unique distinct vertices $u_{-1}, w_{i+1} \in V'$ adjacent to $v_i$ such that $u_{-1}, w_{i+1} \in Q_j \cap Q_k$. Then $u, w \in Q_j \cap Q_k$ also, so $u, w \in P_j \cap P_k$; but then $u \neq w$ are the start and end points of $P_j, P_k$, so $P_j = P_k$, a contradiction.

If $z = v_{i-1}$ for some vertex $v \in V$ then $v \in Q_j \cap Q_k$, so by the case above, $z \in \{s_j, s_k, t_j, t_k\}$ and $z \notin \{(s_j)_i, (s_k)_i, (t_j)_i, (t_k)_i\}$. Likewise for $z = v_{i+1}$. □

Let $M$ be a minor of $G_i^\leftarrow\rightarrow$, so a subdivision of $M$ occurs as a subgraph of $G_i^\leftarrow\rightarrow$. Therefore there is a set of paths $P$ in $G_i^\leftarrow\rightarrow$ satisfying the conditions of the claim, so that by contracting each path into a single edge, and deleting the rest of the graph, we obtain $M$. Let $Q = \{Q_j\}$ be the set of paths given by the claim. For endpoints $s_j, t_j \in Q_j$, contract the edges $\{(s_j, t_j)\} \cup \{(s_j), (t_j)\}$ in $Q_j$. The result is a contraction of $\text{split}(G)$ and a set of paths $Q'$ that is a subdivision of $M$, so $M$ is a minor of $\text{split}(G)$, which proves the lemma. □
Corollary 4.13. \( G_i \rightarrow \) is planar and \( G \rightarrow \rightarrow \) has arboricity at most 9.

Proof. A graph is planar iff it does not contain \( K_5 \) or \( K_{3,3} \) as a minor (Kuratowski’s Theorem). If \( G_i \rightarrow \) is not planar then it contains \( K_5 \) or \( K_{3,3} \) as a minor, so by the above lemma, \( \text{split}(G) \) contains \( K_5 \) or \( K_{3,3} \) as a minor, so \( \text{split}(G) \) is not planar, a contradiction. Since planar graphs have arboricity at most 3, the edge union \( G \rightarrow \rightarrow \) of 3 planar graphs has arboricity at most 9.

By separating the \( \rightarrow \) edges from the remaining edges of \( P_2 \), we obtain a constant-cost universal SMP protocol for \( P_2 \), and then by applying Theorem 1.1 we obtain Theorem 1.5.

Lemma 4.14. For all \( \epsilon > 0 \), \( R_{\epsilon}^{\text{univ}}(P^2) = O\left(\log\frac{1}{\epsilon}\right) \).

Proof. For a planar graph \( G = (V,E) \) with a fixed planar map and a Schnyder wood \( T_1, T_2, T_3 \), define the graph \( G_i = (V,E \setminus T_i) \) as the graph obtained by removing the edges in tree \( T_i \).

On planar graph \( G \in P^2 \) and vertices \( x, y \), Alice and Bob perform the following:
1. For each \( i \) define \( x_i, y_i \) to be the parents of \( x, y \) in \( T_i \). Run the protocol for adjacency with error \( \epsilon/7 \) on \( (x, y_i) \) and \( (x_i, y) \) for each \( i \).
2. Run the protocol for low-arboricity graphs on \( G \rightarrow \rightarrow \) with error \( \epsilon/7 \).
3. Accept iff one of the above sub-protocols accepts.

By Corollary 4.13, \( G \rightarrow \rightarrow \) has arboricity at most 9, we may apply the protocol for low-arboricity graphs in step 2. If \( \text{dist}(x, y) > 2 \) then the protocol will correctly reject with probability at least \( 1 - \epsilon \) since there are 7 applications of \( \epsilon/7 \)-error protocols. It remains to show that if \( \text{dist}(x, y) = 2 \) then the algorithm will accept.

Suppose \( x, y \) are of distance 2. Then the paths between them are of the following forms (with edge directions taken from the Schnyder wood).
1. \( x \rightarrow v \rightarrow y \) or \( x \rightarrow v \leftarrow y \). This is covered by step 1.
2. \( x \leftarrow v \rightarrow y \). This is covered by step 2.

Since planar graphs are an upwards family (just insert a new vertex), we obtain a constant-size probabilistic universal graph for \( P^2 \).

Corollary 4.15. For any \( \epsilon > 0 \), there is a graph \( U \) of size \( O\left(\log(1/\epsilon)\right) \) such that for every \( G \in P^2 \), \( G \subseteq \epsilon \).
Proof. Let $G$ be any graph on $\sqrt{5}n$ vertices and let $F \in \mathcal{F}$. Choose any set $S \subseteq V(F)$ with $|S| = |G|$. Construct $F'$ by replacing the subgraph induced by $S$ with the graph $G$. Then $\text{dist}(F, F') \leq \frac{|G|^2}{n^2} = \delta$ so $F' \in \mathcal{F}_\delta$. Then the conclusion follows from Theorem 1.6. ▷

This suggests that this is not the correct way to model contextual uncertainty in the SMP model, but universal SMP gives a framework for studying many other error tolerance settings. For example, we could suppose that the referee knows a reference planar graph $G$, and the players are guaranteed to see a graph $G'$ that is close to $G$ and also planar; this would not increase the cost of the protocol due to our results on planar graphs.

Implicit graph conjecture. A major open problem in graph labeling is the implicit graph conjecture of Kannan, Naor, and Rudich [23], which asks if every hereditary graph family $\mathcal{F}$ (where for each $G \in \mathcal{F}$, every induced subgraph of $G$ is also in $\mathcal{F}$) containing at most $2^{O(n \log n)}$ graphs of size $n$ has an $O(\log n)$ adjacency labeling scheme. Not much progress has been made on this conjecture (see e.g. [33, 10]). We ask a weakened version of this conjecture:

Question 5.2. For every hereditary family $\mathcal{F} = (\mathcal{F}_n)$ such that $|\mathcal{F}_n| \leq 2^{O(n \log n)}$, is $R^\text{univ}(\mathcal{F}) = O(\log n)$?

Good candidates for disproving the implicit graph conjecture are geometric intersection graphs, like disk graphs (intersections of disks in $\mathbb{R}^2$) or $k$-dot product graphs (graphs whose vertices are vectors in $\mathbb{R}^k$, with an edge if the inner product is at least 1) [33]. These are good candidates because encoding the coordinates of the vertices as integers will fail [22]. Randomized communication techniques may be able to make progress.

Modular lattices. We have shown that there is no constant-cost universal protocol for distance 2 in modular lattices but, like low-arboricity graphs, adjacency (and therefore $O(\log n)$-implicit encodings) may still be possible.

Planar graphs. Our protocol for computing distance 2 on planar graphs did not generalize in a straightforward fashion to distance 3. Nevertheless, we expect that there is a method for computing $k$-distance on planar graphs with complexity dependent only on $k$; given that a Schnyder wood partitions each edge into 3 groups, we expect that $\tilde{O}(3^k)$ should be possible, and maybe only $\text{poly}(k)$, considering that there is a $O(\sqrt{n})$ distance-labeling scheme.

Sharing randomness with the referee. Finally, it seems to be unknown what the relationship is between SMP protocols where the referee shares the randomness, and protocols where the referee is deterministic, even though both models are used extensively in the literature. Our Proposition 1.8 relates these two models via universal SMP but does not yet give a general upper bound on the universal cost in terms of the weakly-universal cost.

Question 5.3. What general upper bounds can we get on universal SMP in terms of weakly-universal SMP?

References

Appendix

Proof of Proposition 2.5.

1. If \( A \subset B \) and \( B \subset C \) with \( \phi, \psi \) being the respective embeddings then for all \( u, v \in V(A) \) we have

\[
C(\phi(u), \psi(v)) = B(\phi(u), \phi(v)) = A(u, v).
\]

2. In the “only if” direction, it suffices to choose \( G^= \). In the other direction, if \( \phi : V(G) \to V(H) \) is an embedding and \( \phi(u) = \phi(v) \) then for all \( w \in V(G) \), \( G(u, w) = H(\phi(u), \phi(w)) = H(\phi(v), \phi(w)) = G(v, w) \) so \( u \equiv v \).

3. Let \( g \) map a vertex of \( G \) to its equivalence class and let \( u, v \in V(G) \). If \( G(u, v) = 1 \) then \( G^= (g(u), g(v)) = 1 \) by definition. If \( G^= (g(u), g(v)) = 1 \) then there exists \( u' \in g(u), v' \in g(v) \) such that \( G(u', v') = 1 \), so \( G(u, v) = G(u', v') = G(v, w) \) so \( u \equiv v \).

4. Let \( g \) map vertices in \( V(G) \) to their equivalence class and let \( g(u), g(v) \in V(G^=) \). If \( g(u) \equiv g(v) \) then for any \( w \), \( G(u, w) = G^= (g(u), g(w)) = G^= (g(v), g(w)) = G(v, w) \) so \( u \equiv v \).

5. If \( G \subset H \) then by transitivity, \( G^= \subset G \subset H \subset H^= \). Likewise, if \( G^= \subset H \) then \( G \subset G^= \subset H \subset H^= \).

6. If \( G^= \) is an induced subgraph of \( H^= \) then clearly there is an embedding. On the other hand, let \( g(u), g(v) \in V(G^=) \) be the equivalence classes of \( u, v \in V(G) \) and suppose there is an embedding \( \phi : G^= \to H^= \). If \( \phi(g(u)) = \phi(g(v)) \) then \( g(u) \equiv g(v) \) so \( g(u) = g(v) \) since \( (G^=)^= \simeq G^= \). Therefore \( G^= \) is an induced subgraph of \( H^= \). □
Approaching MCSP from Above and Below: Hardness for a Conditional Variant and $AC^0[p]$

Rahul Ilango

rilango@mit.edu

Abstract
The Minimum Circuit Size Problem (MCSP) asks whether a given Boolean function has a circuit of at most a given size. MCSP has been studied for over a half-century and has deep connections throughout theoretical computer science including to cryptography, computational learning theory, and proof complexity. For example, we know (informally) that if MCSP is easy to compute, then most cryptography can be broken. Despite this cryptographic hardness connection and extensive research, we still know relatively little about the hardness of MCSP unconditionally. Indeed, until very recently it was unknown whether MCSP can be computed in $AC^0[2]$ (Golovnev et al., ICALP 2019).

Our main contribution in this paper is to formulate a new “oracle” variant of circuit complexity and prove that this problem is $NP$-complete under randomized reductions. In more detail, we define the Minimum Oracle Circuit Size Problem (MOCSP) that takes as input the truth table of a Boolean function $f$, a size threshold $s$, and the truth table of an oracle Boolean function $O$, and determines whether there is a circuit with $O$-oracle gates and at most $s$ wires that computes $f$. We prove that MOCSP is $NP$-complete under randomized polynomial-time reductions.

We also extend the recent $AC^0[p]$ lower bound against MCSP by Golovnev et al. to a lower bound against the circuit minimization problem for depth-$d$ formulas, $(AC^0_d)$-MCSP. We view this result as primarily a technical contribution. In particular, our proof takes a radically different approach from prior MCSP-related hardness results.

Acknowledgements I would like to give a special thanks to Eric Allender for innumerable suggestions and perspectives during all stages of this work. To name just a single example, one of his suggestions led me to improve a PARITY-reduction to the presented MAJORITY-reduction for $(AC^0_d)$-MCSP. I would also like to thank Abhishek Bhrushundi and Aditi Dudeja for their help in results about constant depth formulas that lead to this paper. I am grateful to Ryan Williams for asking interesting questions and helping to improve the exposition of the paper. Finally, I thank Harry Buhrman, Lance Fortnow, Igor Oliveira, Ján Pich, Aditya Potukuchi, Ninad Rajgopalan, Michael Saks, and Rahul Santhanam for answering my questions and engaging in many useful discussions about this work.

1 Introduction
The Minimum Circuit Size Problem (MCSP) takes as input a Boolean function $f$ (represented by its truth table) and a size parameter $s$ and asks if there is a circuit of size at most $s$ computing $f$. Study of this problem began in the 1950s by complexity theorists in the Soviet Union [31], where MCSP was of such great interest that Levin is said to have delayed
publishing his initial NP-completeness results in hope of showing that MCSP is NP-complete.\footnote{\cite{6} cites a personal communication from Levin regarding this.} Interest in MCSP was revitalized when Kabanets and Cai \cite{19} connected the problem with the natural proofs framework of Razborov and Rudich \cite{28}. Since then, MCSP has been the subject of intense research. We begin by (non-exhaustively) reviewing this work.\footnote{In our review, we are sometimes slightly informal and imprecise in order to be more accessible. We encourage the reader to look at the corresponding references for precise statements.}

1.1 Known lower bounds, hardness, and non-hardness for MCSP

It is easy to see that MCSP is in NP (the circuit of size at most $s$ can be used as a witness), but, despite work by numerous researchers, the exact complexity of MCSP remains unknown.

**Hardness results for MCSP.** We believe MCSP is not easy to compute. Kabanets and Cai \cite{19} show that $\text{MCSP} \not\in \text{P}$ conditioned on a widely-believed cryptographic hypothesis.

Thus, the most natural question about MCSP’s complexity is whether it is NP-complete. As of yet, we have not managed to uncover even strong supporting evidence for, or against, MCSP being NP-complete. The strongest known hardness result is by Allender and Das \cite{3} who show MCSP is hard for the cryptographically important class $\text{SZK}$ under randomized reductions.

Under less powerful types of reductions, we only know hardness for some subclasses of $\text{P}$. For instance, building on the results of Oliveira and Santhanam \cite{26}, Golovnev et al. \cite{12} show that the class of functions computable by polynomial-sized formulas ($\text{NC}^1$) reduces to MCSP under $\text{AC}^0$ reductions.

**Lower Bounds for MCSP.** Unconditionally, we know lower bounds against MCSP for several restricted computational models. Cheraghchi, Kabanets, Lu, and Myrisiotis \cite{10} prove lower bounds for MCSP against DeMorgan formulas, branching programs, and $\text{AC}^0$ circuits that essentially match the best known explicit lower bounds for these models. Golovnev et al. \cite{12} show that MCSP requires exponential-sized $\text{AC}^0[p]$ circuits by proving $\text{MAJORITY} \in (\text{AC}^0)^{\text{MCSP}}$. The MAJORITY hardness result of \cite{12} generalizes to the circuit minimization problem for many circuit classes, however, the techniques fail in the case of constant depth formulas.

**Non-hardness results for MCSP.** Surprisingly, we know MCSP cannot be NP-hard under certain types of reductions. For example, Hirahara and Watanabe \cite{16} show that “oracle-independent polynomial reductions” cannot show that MCSP is hard for a class larger than P. Moreover, while essentially all NP-complete problems are complete under rather weak reductions such as uniform $\text{TIME}[n^{o(1)}]$ reductions (which we do not define here), Murray and Williams \cite{23} prove that MCSP is not even NP-hard under $\text{TIME}[n^{49}]$ reductions.

Conditioned on a widely-believed cryptographic hypothesis, Allender and Hirahara \cite{4} show that a very weak approximation of MCSP is actually neither in P nor NP-complete.

**Approaching MCSP from below.** Given the apparent difficulty of resolving the complexity of MCSP, a natural approach is to progress towards MCSP “from below”: considering restricted classes of circuits $\mathcal{C}$ that we understand better and determining whether the $\mathcal{C}$-circuit minimization problem, $(\mathcal{C})$-MCSP, is NP-hard.
As it stands, we know that minimizing DNF formulas and minimizing \( \text{OR} \circ \text{AND} \circ \text{MOD}_m \) circuits are both \( \text{NP} \)-hard by Masek [20] and by Hirahara, Oliveira, and Santhanam [15] respectively. It is still open whether the circuit minimization problem for, say, depth-3 formulas is \( \text{NP} \)-hard.

1.2 Implications of lower bounds and hardness for MCSP

Since the main goal of this paper is to shed light on the complexity of MCSP, it is worth motivating why the complexity of MCSP is important.

Indeed, while researchers have not yet managed to establish the complexity of MCSP, a series of works, beginning with Kabanets and Cai [19], connect the computational complexity of MCSP and its variants to longstanding open questions in the field.

Separations of complexity classes. Several works ([17], [23], [3], [19]) show that MCSP being \( \text{NP} \)-hard, under various notions of reducibility, implies unknown class separations. For example, Hitchcock and Pavan [17] and Murray and Williams [23] show that if MCSP is \( \text{NP} \)-hard under polynomial-time reductions, then \( \text{ZPP} \neq \text{EXP} \), a major open problem.\(^3\)

Worst-case versus average-case complexity for \( \text{NP} \). Using tools developed by Nisan and Wigderson [24] and Carmosino, Impagliazzo, Kabanets, and Kolokova [9], Hirahara [14] gives a “worst-case to average-case” reduction for \( \text{NP} \) conditioned on a certain approximation to MCSP being \( \text{NP} \)-hard. Thus, if one could show this approximation to MCSP is \( \text{NP} \)-hard, the worst-case and average-case complexity of \( \text{NP} \) would be equivalent.

Circuit Lower Bounds. Recent work ([22], [27], [25]) explores a “hardness magnification” phenomenon whereby even weak circuit lower bounds on certain computational problems imply strong lower bounds on other problems. For example, McKay, Murray, and Williams [22] show that if MCSP (under a small size parameterization) cannot be solved by circuits of size \( n \cdot \text{poly}(\log n) \), then \( \text{NP} \) does not have polynomial-size circuits.

1.3 Our Contributions

In this work, we focus on hardness results for natural variants of MCSP with the aim of shedding light on the complexity of MCSP itself.

NP-Hardness of oracle MCSP (MOCSP)

As mentioned previously, some research has approached the problem of proving \( \text{NP} \)-hardness for MCSP “from below,” that is, showing that the circuit minimization problem is \( \text{NP} \)-hard for restricted classes of circuits like DNF circuits and \( \text{OR} \circ \text{AND} \circ \text{MOD}_m \) circuits.

In this paper, we attempt to approach MCSP “from above.” That is, we study the complexity of a problem that is at least as hard as MCSP. In particular, we define the Minimum Oracle Circuit Size Problem (MOCSP) to take as input a truth table \( T \), a size parameter \( s \in \mathbb{N} \), and an oracle truth table \( O \). The goal is to determine whether there is an \( O \)-oracle circuit with at most \( s \) wires that computes \( T \). It is easy to see that MOCSP \( \in \text{NP} \) (the oracle circuit of size \( s \) can still act as an \( \text{NP} \)-witness).

\(^3\) [23] only shows the result under many-one reductions, but their techniques easily generalize to the truth table case. [17] explicitly proves the truth table result using a different approach than [23].
A natural way to think of MOCSP is as a “conditional” version of MCSP where we are now measuring the complexity of computing $T$ when we are given easy access to $O$.

Although our problem definition is new, this is not the first time someone has considered an “oracle version” of MCSP. Several papers ([2, 5, 16, 18]) study the problem MCSP$^A$ of minimizing oracle circuits for a fixed oracle language $A$. MOCSP differs fundamentally from MCSP$^A$ in that the oracle circuit gets access to an arbitrary Boolean function, not a language, and the function the oracle circuit has access to is an input to the problem.

Furthermore, while MOCSP ∈ NP, the complexity of MCSP$^A$ depends on the oracle $A$. For example, the reference [2] proves MCSP$^{QBF}$ is complete for PSPACE under randomized reductions. Moreover, there is a trivial reduction from MCSP to MOCSP: simply provide no oracle truth tables. Therefore, since MOCSP is still in NP and MOCSP and is at least as hard as MCSP, MOCSP is a nice “testing ground” for hardness results we conjecture for MCSP.

Indeed, as is conjectured for MCSP, we can prove that MOCSP is NP-hard under randomized reductions.

▶ Theorem 1.1. MOCSP is NP hard under:
- randomized many-one reductions with one-sided error, and
- randomized Turing reductions with zero-sided error.

These NP-hardness results are both proved by giving a reduction from approximating set cover to MOCSP. It is worth noting that the NP-hardness results of (DNF)-MCSP [20] and (OR ◦ AND ◦ MOD$_m$)-MCSP [15] are also proved via set cover problems, although both of these reductions are deterministic while our reduction is randomized.

Given that we can show MOCSP is NP-hard under randomized reductions, one might even begin to hope that we can prove hardness under, say, polynomial-time reductions. Unfortunately, this seems difficult. Essentially the same proofs Murray and Williams [23] or Hitchcock and Pavan [17] use to show that MCSP being NP-hard under polynomial-time truth table reductions implies EXP $\neq$ ZPP also work for MOCSP.

▶ Theorem 1.2 (Essentially proven in [17] and [23]). If NP reduces to MOCSP under polynomial time (truth table) reductions, then EXP $\neq$ ZPP.

Thus, improving our reduction to a polynomial-time truth table reduction requires separating EXP from ZPP, a longstanding open problem. For completeness, we give the MOCSP version of Murray and Williams’ proof in Appendix B.

Even so, we expect that the ground truth is that MOCSP is NP-hard under, at least, deterministic polynomial-time Turing reductions.

▶ Conjecture 1.3. MOCSP is NP-hard under polynomial-time Turing reductions.

A perspective on MOCSP and some questions

In light of the fact that hardness for MCSP beyond SZK under even non-uniform reductions is unknown, we found these MOCSP hardness results to be quite surprising. Moreover, the NP-hardness of MOCSP seems to bolster the conjecture that MCSP is in fact NP-hard. To an optimist, NP-hardness results for MOCSP could even be a first step towards proving NP-hardness for MCSP. Indeed, a PSPACE-hardness result was first proved by Buhrman and Torenvliet [8] for an “oracle” version of space-bounded Kolmogorov complexity before Allender et al. [2] showed PSPACE-hardness for the non-oracle version about four years later.\textsuperscript{4}

\textsuperscript{4} The conference versions of [8] and [2] are four years apart.
Even if stronger hardness results for MCSP remain out of reach, MOCSP could still yield valuable insights about MCSP. For instance, it would be interesting to see which of the barriers and non-hardness results known for MCSP carry over to MOCSP.

Open Question 1.4. Can one show that other barriers or non-hardness results that hold for MCSP also hold for MOCSP?

As an example of the insight given by answers to this question, consider Murray and Williams’ [23] result that proving MCSP is NP-hard under polynomial-time reductions implies EXP \( \neq \) ZPP. A natural question one might ask is whether we can improve this theorem to show that MCSP being NP-hard under randomized reductions implies unknown class separations. As we note in Theorem 1.2, however, Murray and Williams’ proof carries over to MOCSP, and Theorem 1.1 shows MOCSP is indeed NP-hard under randomized reductions. Thus, any improvement of Murray and Williams’ result to randomized reductions likely requires a fact about MCSP that we do not know for MOCSP.

In another direction, our results seem to imply that proving hardness for MOCSP is more tractable than proving hardness for MCSP. Since we have already noted that MOCSP can be used as a “testing ground” for questions about MCSP (since any hardness result for MCSP must also hold for MOCSP), one can explore whether other conjectured hardness results for MCSP hold for MOCSP. For example, Hirahara’s [14] worst-case to average-case reduction for NP can be based on a certain approximation of MCSP being NP-hard, which would imply that a certain approximation of MOCSP is also NP-hard. Given that we can prove the NP-hardness of MOCSP under randomized reductions, we ask if one can prove something similar for the approximation version of MOCSP.

Open Question 1.5. Can one prove that, for some \( \epsilon > 0 \), approximating MOCSP on \( n \)-inputs to a factor of \( n^\epsilon \) is NP-hard under, say, \( \text{P/poly} \) reductions? Conversely, can one prove that there is any barrier to showing such a hardness result?

Finally, while in this paper we concentrate on approaching MCSP from above via MOCSP, it would be interesting to explore other problems that are harder than MCSP but still in NP. Perhaps this could help clarify what aspects of MCSP make it difficult to prove hardness for.

MAJORITY-hardness for \( (\text{AC}^0_d)\)-MCSP

As mentioned previously, Golovnev et al. [12] proves that MAJORITY \( \in (\text{AC}^0)\text{-MCSP} \). Using similar techniques, they also show that, for restricted classes of circuits \( \mathcal{C} \) such as formulas and constant depth circuits, the \( \mathcal{C} \)-circuit minimization problem, denoted \( (\mathcal{C})\text{-MCSP} \), is hard for MAJORITY under AC\(^0\) reductions. For these MAJORITY reductions to work, [12] requires that the size of the minimum \( \mathcal{C} \)-circuit on truth tables of length \( n \) is roughly \((n^{49})\)-Lipschitz, that is, flipping one bit in any truth table can change the \( \mathcal{C} \)-circuit complexity by at most an \( n^{49} \) additive term. This Lipschitzness hypothesis is unknown (and in our estimation probably false) in the class of depth-\( d \) formulas, which we denote \( \text{AC}^0_d \).\(^5\) As a result, until this work, it was unknown whether, say, \( (\text{AC}^0_d)\text{-MCSP} \in \text{AC}^0 \) [2].

We stress that even though \( \text{AC}^0_d \) is an extremely restrictive class of formulas, \( (\text{AC}^0_d)\text{-MCSP} \) should be a very hard problem. For example, Allender et al. [1] prove that if \( (\text{AC}^0_d)\text{-MCSP} \) had polynomial-size circuits for sufficiently large \( d \), then one could factor Blum integers using circuits of size \( 2^{n^\epsilon} \) for all \( \epsilon > 0 \).

\(^5\) We will always use the notation \( \text{AC}^0_d \) to refer to depth-\( d \) formulas and never depth-\( d \) circuits.
In this paper, we prove that \((\mathsf{AC}^0_d)\)-MCSP is indeed hard for \(\mathsf{MAJORITY}\) by giving a win-win argument depending on whether the Lipschitzness hypothesis is true. Applying the lower bounds of Razborov \[28\] and Smolensky \[30\] then gives an \(\mathsf{AC}^0[p]\) lower bound for \((\mathsf{AC}^0_d)\)-MCSP.

▶ **Theorem 1.6.** Let \(d \geq 2\). Then \(\mathsf{MAJORITY} \leq_{\mathsf{AC}^0} (\mathsf{AC}^0_d)\)-MCSP. Consequently, for any prime \(p\), \((\mathsf{AC}^0_d)\)-MCSP \(\notin \mathsf{AC}^0[p]\).

One can view this theorem as (small) progress towards the program of approaching MCSP from below. The natural next step in the program is to prove that \((\mathsf{AC}^0_3)\)-MCSP is \(\mathsf{NP}\)-hard, and, until this work, \(\mathsf{AC}^0[p]\) lower bounds were open for this problem (despite knowing such \(\mathsf{AC}^0[p]\) lower bounds for less restrictive circuit classes!). Perhaps the techniques introduced here could be useful in proving further hardness results for \((\mathsf{AC}^0_3)\)-MCSP.

Indeed, our techniques\(^6\) may be the most interesting part of Theorem 1.6. They are entirely different than the ones used by \[12\] for general MCSP and, to our knowledge, all known MCSP hardness results. For example, a crucial step in the proof is introducing algebraic machinery and examining the size of a function’s smallest circuits modulo a certain prime.

Indeed, all previously known MCSP-related reductions (to our knowledge) continue to work even when the reduction is given access to close approximations of a function’s minimum circuit size. Because of this, it was not clear if, for the purpose of reductions, there was any difference between knowing whether a function has circuits of size exactly \(s\) or \(s + 1\). However, the algebraic nature of this \(\mathsf{MAJORITY}\) reduction actually requires knowing such exact quantities, illustrating the existence of useful techniques that can distinguish between MCSP and approximations of MCSP.

### 1.4 Proof Overviews

In this section, we give fairly detailed overviews of our proofs. In doing this, we will often state results without filling in lower-level details. To make clear to the reader when we are doing this, we mark such sentences with an italicized we observe.

**NP-hardness of Oracle MCSP (MOCSP)**

Recall, the Minimum Oracle Circuit Size Problem, MOCSP, takes as input a truth table \(T\), a threshold \(s \in \mathbb{N}\), and an oracle truth table \(O\) and outputs whether there is an \(O\)-oracle circuit with at most \(s\) wires that computes \(T\). We denote the output of MOCSP on such an input as \(\text{MOCSP}(T, s; O)\). We denote the minimum size (measured by wires) of any \(O\)-oracle circuit computing \(T\) as \(\text{CC}^O(T)\).

We prove that MOCSP is \(\mathsf{NP}\)-hard by giving a reduction from 6-approximating the Set Cover Problem (6-SetCover) to MOCSP. In our notation, 6-SetCover takes as input sets \(S_1, \ldots, S_t \subseteq [n]\) whose union is \([n]\) as well as an integer \(c \in [n]\) and requires outputting \text{YES} when \(c \geq \ell\) and \text{NO} when \(c < \ell/6\) where \(\ell\) is the optimal cover size, i.e.

\[
\ell = \min \{|I| : I \subseteq [t] \text{ and } \bigcup_{i \in I} S_i = [n]|\}.
\]

Approximating SetCover to an \(((1 - o(1)) \ln n)\) factor is known to be \(\mathsf{NP}\)-hard by Dinur and Steurer \[11\].

\[^6\] Specifically, our techniques in the case when the Lipschitz hypothesis fails (which we expect to be the ground truth).
Informal idea. We begin by giving a high-level overview of the reduction to orient the reader. (It will be very informal, but we are building to a more detailed description.) Say we are given sets $S_1, \ldots, S_t \subseteq [n]$ whose union is $[n]$. One can think of each of these sets $S_i$ as “seeing” a small portion of the ground set $[n]$. Then, for a uniformly random truth table $T$ of length $m \geq (nt)^5$, we let each set $S_1, \ldots, S_t$ induce truth tables $T_{S_1}, \ldots, T_{S_t}$, respectively where each truth table $T_{S_i}$ has the same length at $T$ and “sees” roughly the same part of $T$ as $S_i$ “sees” of $[n]$. We define our oracle $O$ to be the concatenation of these truth tables. Finally, we ask how hard it is for a circuit to compute $T$ given oracle access to $O$.

The idea is that if a circuit looks at a collection of induced truth tables corresponding to a set cover, then it can “see” all of $T$ and thus easily compute $T$. If not, then a large part of $T$ is still random to the circuit and thus hard to compute. Indeed, we show that with high probability the quantity $\mathbb{CC}^O(T)$ can be used to estimate $\ell$ up to a constant factor.

We now describe the reduction in more detail. Fix sets $S_1, \ldots, S_t \subseteq [n]$ whose union is $[n]$ and, let $\ell$ be the optimal cover size of $[n]$ by $S_1, \ldots, S_t$. Let $T$ be a uniformly random truth table of length $m \geq (nt)^5$.

The truth tables induced by $S_1, \ldots, S_t$ and $T$. We now rigorously define the truth tables $T_{S_1}, \ldots, T_{S_t}$ of length $m$ induced by $S_1, \ldots, S_t$ and $T$. To do this, chose a uniformly random partition of $[m]$ into $n$ parts, that is, let $P : [m] \rightarrow [n]$ be a uniformly random function, and let $\mathcal{P} = (P_1, \ldots, P_n)$ be the partition of $[m]$ into $n$ parts where for $j \in [n]$

$$P_j = \{ x \in [m] : P(x) = j \}.$$

We can then use this partition to “lift” any subset of $[n]$ into a subset of $[m]$ as follows. For a subset $S \subseteq [n]$, let $S^m$ denote the subset of $[m]$ given by $S^m = \bigcup_{j \in S} P_j$.

Next, for a subset $S' \subseteq [m]$, we let $T_{S'}$ be the truth table of length $m$ that “sees” $T$ on the elements of $S'$ and zeroes everywhere else, that is

$$T_{S'}(x) = T(x) \land \mathbb{1}_{x \in S'}.$$

Finally, we define the truth table $T_{S_i}$ induced by $S_i$ to be the truth table $T_{S^m}$ (we are dropping the $m$ superscript and the bracketed subscript for concision).

Building the oracle $O$. We build our oracle $O$ by concatenating the induced truth tables $T_{S_1}, \ldots, T_{S_t}$. In other words, let $O : \{0, 1\}^{\log \ell} \times \{0, 1\}^{\log m} \rightarrow \{0, 1\}$ be given by

$$O(i, x) = \begin{cases} T_{S_i}(x), & \text{if } i \in [t] \\ 0, & \text{otherwise} \end{cases}$$

$\mathbb{CC}^O(T)$ is at most $\ell(3 + \log (\ell m))$. Suppose, without loss of generality, that $S_1 \cup \cdots \cup S_{\ell}$ is an optimal cover of $[n]$. We claim that $\bigvee_{i \in [\ell]} O(i, x)$ is a circuit computing $T$. Unraveling our definitions, we have that

$$\bigvee_{i \in [\ell]} O(i, x) = \bigvee_{i \in [\ell]} T_{S_i}(x) = \bigvee_{i \in [\ell]} (T(x) \land \mathbb{1}_{x \in S^m_i}) = T(x) \land \bigvee_{i \in [\ell]} \mathbb{1}_{x \in S_i^m} = T(x) \land \bigvee_{i \in [\ell]} \mathbb{1}_{x \in S_i^m}.$$

Using the fact that $S_1, \ldots, S_{\ell}$ is a cover of $[n]$, we have that

$$T(x) \land \bigvee_{i \in [\ell]} \mathbb{1}_{x \in S_i^m} = T(x) \land \mathbb{1}_{x \in [n]} = T(x).$$

Thus, $\bigvee_{i \in [\ell]} O(i, x)$ computes $T$ and has at most $2\ell + (1 + \log \ell + \log m) \leq \ell(3 + \log \ell + \log m)$ wires.
With high probability, \( CC^O(T) > \ell \log(tm)/2 \). We do this by a union bound argument. Fix any oracle circuit \( C \) with at most \( \ell \log(tm)/2 \) wires. We show that the probability that \( C^O \) computes \( T \) is very small.

We begin by showing that on any fixed input \( x \) that
\[
\Pr[C^O(x) = T(x)] \leq 1 - \frac{1}{2n}.
\]
Fix some \( x \). We prove the following claim: that with probability at least \( \frac{1}{n} \) over the choice of \( P(x) \), the output of \( C^O(x) \) does not depend whether the value of \( T(x) \) is one or zero. If this claim were true, then we would get the desired bound
\[
\Pr[C^O(x) = T(x)] \leq 1 - \frac{1}{2n}
\]
since, assuming that \( C^O(x) \) does not depend on \( T(x) \), the probability \( C^O(x) = T(x) \) is exactly \( \frac{1}{2} \) (since \( T(x) \) is chosen uniformly at random).

To prove the claim, we first note that the only way that the output of \( C^O(x) \) can depend on the value of \( T(x) \) is if during the computation of \( C^O(x) \) \( C \) makes an oracle query \( (i', x') \) to \( O \) such that the value of \( O(i', x') \) depends on the value of \( T(x) \). However, from the definition of \( O \), we know that the output of \( O(i', x') \) depends on \( T(x) \) if and only if \( x' = x \) and \( P(x) \in S' \). Summarizing, \( C^O(x) \) depends on \( T(x) \) only if \( C^O \) makes a query of the form \( (i', x) \) such that \( P(x) \in S' \). But \( C^O \) has at most \( \ell/2 \) oracle gates, so it only has \( \ell/2 \) “tries” to find a set \( S' \) that contains the uniformly random ground set element \( P(x) \), which is less than the number of tries needed to cover the ground set! Hence, it is intuitive that with probability at least \( \frac{1}{n} \), \( P(x) \) takes on a value that is not in any of the \( S' \) that \( C^O \) queries. We observe that this intuition can be made rigorous (with some more details), and hence, the claim is true.

At this point, we have completed our sketch of why for any fixed \( x \)
\[
\Pr[C^O(x) = T(x)] \leq 1 - \frac{1}{2n}.
\]

Unfixing \( x \), we would like to say that we can multiply these probabilities together for all \( x \in [m] \) to bound the probability that \( C^O \) computes \( T \). However, we cannot do this, as these events might have some dependencies between each other. Luckily, since, for any \( x \), \( C^O(x) \) makes at most \( \ell/2 \leq n \) oracle calls, we observe that applying the above probability bound can only “spoil” the bound for at most \( n \) other values of \( x \). Hence, we can repeatedly apply the bound to about \( m/n \) different values of \( x \) yielding
\[
\Pr[C^O \text{ computes } T] \leq (1 - \frac{1}{2n})^{m/n} \leq e^{-\frac{m}{2n}} \leq e^{-n^2\ell^2/2}.
\]

Finally, union bounding over the at most
\[
2^{O(\ell \log(tm)/2)^2} \leq 2^{2O(n^2t)}
\]
oracle circuits with at most \( \ell \log(tm)/2 \) wires yields the desired result.

**RP and ZPP reductions.** At this point, we have shown that if \( S_1, \ldots, S_t \) admits a \( c \)-cover, then \( \text{MOCSP}(T, c(3 + \log(tm))): O = \text{YES} \) (note that this fact did not depend on our random choice of \( T \) or \( P \)), and we have shown that if \( S_1, \ldots, S_t \) does not admit a \( c \)-cover, then \( \text{MOCSP}(T, c \log(tm)/2): O = \text{NO} \) with high probability. It is easy to see that this yields an RP many-one reduction (a randomized many-one reduction with one-sided error) from 6-SetCover to MOCSP.
Furthermore, since this RP reduction only errs by incorrectly classifying NO instances as YES instances, we can use the search-to-decision reduction for SetCover to check the correctness of purported YES instances, transforming our RP reduction into a ZPP-Turing reduction (a randomized zero-error reduction that can make multiple adaptive queries to MOCSP).

**Majority Hardness for \((\text{AC}^0_d)\)-MCSP**

Recall, \(\text{AC}^0_d\) is the class of depth-\(d\) formulas made up of AND and OR gate with unbounded fan-in. We also define \(\text{AND} \circ \text{AC}^0_{d-1}\) and \(\text{OR} \circ \text{AC}^0_{d-1}\) be the classes of \(\text{AC}^0_d\) formulas with a top AND and top OR gate respectively. For \(\mathcal{F} \in \{\text{AC}^0_d, \text{AND} \circ \text{AC}^0_{d-1}, \text{OR} \circ \text{AC}^0_{d-1}\}\) and a truth table \(T\), we let \(\text{CC}_\mathcal{F}(T)\) denote the size of the minimum \(\mathcal{F}\)-formula computing \(T\) where the size of a formula is the number of input leaves.

Our analysis proceeds by considering each \(n \in \mathbb{N}\) and splitting into cases depending on whether \(\text{CC}_{\text{AC}^0_d}\) is Lipschitz on truth tables of length around \(n\). In more detail, fix some sufficiently large \(n\). Let \(q = \Theta(n^2)\) be a power of two. We divide into cases depending on whether there exists an \(m \in \{q^{10}, q^{50}\}\) such that \(\text{CC}_{\text{AC}^0_d}\) is \((m^{25})\)-Lipschitz on truth tables of length \(m\).

**Case 1: Lipschitzness holds for some \(m\)**

If there does exist an \(m \in \{q^{10}, q^{50}\}\) such that \(\text{CC}_{\text{AC}^0_d}\) is \((m^{25})\)-Lipschitz on truth tables of length \(m\), then the techniques of Golovnev et al. [12] yield an \(\text{AC}^0\) truth table reduction from MAJORITY on \(n\)-bits to \((\text{AC}^0_d)\)-MCSP on \(m\)-bits. For completeness, we include a self-contained proof of this case in Appendix A.

**Case 2: Lipschitzness fails**

Assume that for all \(m \in \{q^{10}, q^{50}\}\) \(\text{CC}_{\text{AC}^0_d}\) is not \((m^{25})\)-Lipschitz on truth tables of length \(m\). Let \(u = q^{10}\) and \(v = q^{50}\).

Lipschitzness failing \(\implies\) functions easier to compute with a top AND gate. We observe, as a straightforward consequence of Lipschitzness failing, that there exists a truth table of length \(u\) that has an optimal formula with large top fan-in and a truth table of length \(v\) that is easier to compute with a top AND gate:

1. There exists a Boolean function \(f^u\) that takes log \(u\) inputs and an \(\text{AC}^0_d\) formula \(\phi^u\) such that \(\phi^u\) is an optimal \(\text{AC}^0_d\) formula for \(f^u\) and \(\phi^u = \phi^u_1 \land \cdots \land \phi^u_t\) for some \(t \geq n\) and some \(\phi^u_1, \ldots, \phi^u_t \in \text{AC}^0_{d-1}\).
2. There exists a Boolean function \(f^v\) that takes log \(v\) inputs such that \(\text{CC}_{\text{OR} \circ \text{AC}^0_{d-1}}(f^u) > \text{CC}_{\text{AND} \circ \text{AC}^0_{d-1}}(f^u) + u \log u\).

We will make use of \(f^u\) and \(\phi^u\) to reduce MAJORITY to \(\text{CC}_{\text{AND} \circ \text{AC}^0_{d-1}}\), and we will use \(f^v\) to reduce \(\text{CC}_{\text{AND} \circ \text{AC}^0_{d-1}}\) to \(\text{CC}_{\text{AC}^0_d}\).

Using \(\text{CC}_{\text{AND} \circ \text{AC}^0_{d-1}}\) and optimal subformulas of \(\phi^u\) to compute a dot product. The heart of our MAJORITY reduction is a fairly elementary observation about optimal \((\text{AND} \circ \text{AC}^0_{d-1})\) formulas. Recall, \(\phi^u = \phi^u_1 \land \cdots \land \phi^u_t\) is an optimal \(\text{AC}^0_d\) formula for \(f^u\) and, hence, also an optimal \((\text{AND} \circ \text{AC}^0_{d-1})\) formula for \(f^u\). We observe that for any \(A \subseteq [t]\), the \((\text{AND} \circ \text{AC}^0_{d-1})\)-optimality of \(\phi^u\) implies that \(\bigwedge_{i \in A} \phi^u_i\) is also an optimal \((\text{AND} \circ \text{AC}^0_{d-1})\) formula for the function it computes.
Introducing some notation, for a string $x \in \{0,1\}^n$, we let $f^u_x$ be the function given by $f^u_x \phi^u$ where $O_x \subseteq [n]$ are the bits in $x$ that are one. Using the above observation about subformulas being optimal, we have that $\text{CC}_{\text{AND} \circ \text{AC}^0_{d-1}}(f^u_x) = \sum_{i \in O_x} |\phi^u_i|$. Thus, one can think of $\text{CC}_{\text{AND} \circ \text{AC}^0_{d-1}}(f^u_x)$ as computing the dot product between $x$ and the vector $\langle |\phi^u_1|, \ldots, |\phi^u_n| \rangle$.

Note that the definition of $f^u_x$ depends on the labeling of $\phi^u_1, \ldots, \phi^u_n$, in particular the choice of which $\phi^u_i$ have $i \leq n$. We will later choose a labeling of the $\phi^u_i$ that is convenient.

**Computing MAJORITY (non-uniformly) using CC\textsubscript{AND} \circ AC\textsubscript{0\text{d-1}}**. Our goal is to compute MAJORITY on a string $x \in \{0,1\}^n$ using the above “dot product” observation. Before we show how to do this, we give some intuition on how we came up with the idea.

Instead of trying to compute MAJORITY, suppose we relaxed the problem to computing PARITY given access to the integer produced by the dot product $x \cdot \langle |\phi^u_1|, \ldots, |\phi^u_n| \rangle$. Well, if it so happened that all the entries in the vector $\langle |\phi^u_1|, \ldots, |\phi^u_n| \rangle$ were odd, then it is clear that the integer produced by $x \cdot \langle |\phi^u_1|, \ldots, |\phi^u_n| \rangle$ is odd if and only if $x$ has an odd number of ones. Our approach for MAJORITY is a generalization of this.

Let $p = O(n)$ be prime greater than $n$. We observe, via a pigeon-hole principle argument, that there exist integers $k \geq 0$ and $1 \leq r \leq p - 1$ and indices $i_1, \ldots, i_n \in [m]$ such that

$$|\phi^u_{i_1}|/p^k \equiv \cdots \equiv |\phi^u_{i_n}|/p^k \equiv r \mod p.$$  

Thus, after an appropriate relabeling of $\phi^u_i$, we have that

$$|\phi^u_i|/p^k \equiv \cdots \equiv |\phi^u_n|/p^k \equiv r \mod p.$$

Hence, we can determine the weight $w$ of $x$ (and hence compute MAJORITY of $x$) by computing the value of

$$\text{CC}_{\text{AND} \circ \text{AC}^0_{d-1}}(f^u_x)/p^k = \sum_{i \in O_x} |\phi^u_i|/p^k \equiv rw \mod p$$

and multiplying by the inverse of $r$ modulo $p$.  \(^8\)

**Reducing computing CC\textsubscript{AND} \circ AC\textsubscript{0\text{d-1}} to computing CC\textsubscript{AC}^0**. Ultimately, we want to compute MAJORITY using $\text{CC}_{\text{AC}^0_d}$ not $\text{CC}_{\text{AND} \circ \text{AC}^0_{d-1}}$. By the above procedure, it suffices to show how to compute $\text{CC}_{\text{AND} \circ \text{AC}^0_{d-1}}(f^u_x)$ using $\text{CC}_{\text{AC}^0_d}$.

We can make such a computation as follows. Recall that $f^u$ is a function satisfying

$$\text{CC}_{\text{OR} \circ \text{AC}^0_{d-1}}(f^u) > \text{CC}_{\text{AND} \circ \text{AC}^0_{d-1}}(f^u) + u \log u$$

whose existence is guaranteed by the failure of Lipschitzness. Take the direct product of $f^u_x$ with $f^u$ to obtain a function $g_x(y,z) = f^u_x(y) \wedge f^u(z)$. Since the difference between computing $f^u$ with a top AND gate and a top OR gate is larger than $u \log u$ (which is the maximum complexity of $f^u_x$), we observe\(^9\) any optimal $\text{AC}^0_d$ formula for $g_x$ must have a top AND gate, so

$$\text{CC}_{\text{AC}^0_d}(g_x) = \text{CC}_{\text{AND} \circ \text{AC}^0_{d-1}}(g_x).$$

---

\(^7\) Recall, our notion of formula size is the number of input leaves.

\(^8\) In case the reader is unsure whether the last parts of this procedure are implementable in $\text{AC}^0_d$, realize that the output of $\text{CC}_{\text{AND} \circ \text{AC}^0_{d-1}}(f^u_x)$ is a binary string of length $O(\log n)$ and that any function on a string of length $O(\log n)$ can be computed by a polynomial-sized DNF. See the proof in Section 4 for more details.

\(^9\) both the “we observe” statements in this paragraph are consequences of standard direct product theorems for formulas.
Then, we observe that
\[ \text{CC}_{\text{AND} \circ \text{AC}^0_{d-1}}(g_u) = \text{CC}_{\text{AND} \circ \text{AC}^0_{d-1}}(f'_u) + \text{CC}_{\text{AND} \circ \text{AC}^0_{d-1}}(f'') \].

Hence, if we are non-uniformly given the value of \( \text{CC}_{\text{AND} \circ \text{AC}^0_{d-1}}(f'') \), we can subtract \( \text{CC}_{\text{AND} \circ \text{AC}^0_{d-1}}(f'_u) \) from \( \text{CC}_{\text{AC}^0_u}(g_u) \) to find \( \text{CC}_{\text{AND} \circ \text{AC}^0_{d-1}}(f_u) \).

**Remark 1.7.** We remark that the only time we use the failure of the Lipschitzness hypothesis is to show the existence of functions like \( f^n \) with high top fan-in and functions like \( f^r \) with a large difference between top \text{AND} gate and top \text{OR} gate complexity. Using known \text{PARITY} lower bounds and depth-hierarchy theorems for \text{AC}^0 circuits, we can unconditionally prove the existence of \( f^n \) and \( f^r \) respectively but with slightly worse parameters that would yield a quasi-polynomial reduction (at least in the \( d \geq 3 \) case) rather than the polynomial reduction we present.

### 1.5 Paper Organization

In Section 2 we fix notation and review precise definitions. In Section 3 we prove our \text{MOCSP} results, and in Section 4 we prove that \text{MAJORITY} reduces to \((\text{AC}^0_{d})\)-\text{MCSP}.

## 2 Preliminaries

For an integer \( n \), we let \([n] = \{1, \ldots, n\}\). For a binary string \( x \in \{0,1\}^n \), the *weight* of \( x \), denoted \( \text{wt}(x) \), is the number ones in \( x \). We identify a Boolean function \( f : \{0,1\}^n \to \{0,1\} \) with its truth table \( T \in \{0,1\}^{2^n} \) and often use them interchangeably.

We let \( \log \) denote the base-2 logarithm and \( \ln \) represent the base-\( e \) logarithm. For functions \( f \) and \( g \), we say \( f = \tilde{O}(g) \) if there exists a \( c \) such that \( f(x) \leq \log^c(g(x))g(x) \) for all sufficiently large \( x \). We say that \( f = \Omega(g) \) if \( g = \tilde{O}(f) \).

We say a function \( f : \{0,1\}^n \to \mathbb{N} \) is \( c \)-Lipschitz if for all \( x, y \in \{0,1\}^n \) that differ in at most one bit, \( |f(x) - f(y)| \leq c \). (In this paper, the function \( f \) for which we care about \( c \)-Lipschitzness is the function that maps a truth table to its circuit complexity.)

### Complexity classes and reductions

We assume the reader is familiar with the standard complexity classes such as \text{AC}^0, \text{P}, \text{ZPP}, \text{RP}, \text{NP}, \text{E} and the notion of Turing machines. For background on these, we refer to Arora and Barak’s excellent textbook [7]. For us, \text{AC}^0 always refers to \textit{non-uniform} \text{AC}^0.

We review the types of reductions we use in case the reader is not familiar with randomized reductions, truth table reductions, or our notation.

**Many-one reductions.** We will make use of the following notions of many-one reduction.

- \( L \leq_p L' \) if there is a polynomial-time Turing machine \( M \) such that \( x \in L \iff M(x) \in L' \).
- \( L \leq_{\text{RP}} L' \) if there is a polynomial-time probabilistic Turing machine \( M \) taking in a “random” auxiliary input \( r \) such that
  
  \[ x \in L \implies \forall r \ M(x, r) \in L', \quad \text{and} \]
  
  \[ x \notin L \implies \Pr_{r}[M(x, r) \notin L'] \geq 2/3, \]
  
  and \( |r| \) is polynomial in the length of \( x \).
Approaching MCSP from Above and Below

**Truth table reductions.** We will also make use of the following notions of truth table reductions.

- We say an oracle circuit $C$ is a *truth table oracle circuit* if there is no directed path between oracle gates in $C$.
- $L \leq_{tt}^{\text{AC}^0} L'$ if there is a non-uniform (polynomial-sized) $\text{AC}^0$ truth table oracle circuit $C$ such that $C$ computes $L$ when given oracle access to $L'$.

**Turing reductions.** Finally, we say $L \leq_{T}^{\text{ZPP}} L'$ if $L$ can be computed with zero-error by a polynomial-time probabilistic oracle Turing machine $M$ with oracle access to $L'$. On any single input, $M$ is allowed to output “don’t know” with probability at most $1/2$.

**AC$^0_d$ formulas, (AC$^0_d$)-MCSP, and CC$^0_{\text{AC}^0_d}$**

For an integer $d \geq 2$, we let $\text{AC}^0_d$ denote the class of depth-$d$ formulas that use AND and OR gates with unbounded fan-in and fan-out 1 and that takes as “input leaves” the bits of a binary string and the negation of each of those bits.

For an $\text{AC}^0_d$ formula $\phi$, we define the size of $\phi$, denoted $|\phi|$, to be the total number of input leaves $\phi$ uses. For a Boolean function $f$, we let $\text{CC}_{\text{AC}^0_d}(f)$ be the size of the smallest $\text{AC}^0_d$ formula computing $f$.

**Definition 2.1** (Minimum Circuit Size Problem for constant depth formulas). $(\text{AC}^0_d)$-MCSP, is the language given by

$$\{(T,s) \in \{0,1\}^* \times \mathbb{N} : T \text{ is the truth table of a Boolean function, and } \text{CC}_{\text{AC}^0_d}(T) \leq s\}.$$  

We will also make use of the classes of formulas $\text{OR} \circ \text{AC}^0_{d-1}$ and $\text{AND} \circ \text{AC}^0_{d-1}$, defined as the subclasses of $\text{AC}^0_d$ formulas with a top OR gate and a top AND gate respectively. For $C \in \{\text{OR} \circ \text{AC}^0_{d-1}, \text{AND} \circ \text{AC}^0_{d-1}\}$, we define $\text{CC}_C$ and $(C)$-MCSP analogous to $\text{CC}_{\text{AC}^0_d}$ and $(\text{AC}^0_d)$-MCSP.

We also require the following elementary lemmas regarding $\text{AC}^0_d$ formulas.

**Lemma 2.2.** Let $f$ be a Boolean function. Then $\text{CC}_{\text{AC}^0_d}(f) = \text{CC}_{\text{AC}^0_d}(\neg f)$.

**Proof.** One can use DeMorgan’s laws to turn any $\text{AC}^0_d$ formula for $f$ of size $s$ into an $\text{AC}^0_d$ formula for $\neg f$ of size $s$. △

We note that our specific notion of $\text{AC}^0_d$ formula size is crucial for the next lemma.

**Lemma 2.3** (Direct product theorem for formulas). Let $f : \{0,1\}^n \rightarrow \{0,1\}$ and $g : \{0,1\}^m \rightarrow \{0,1\}$ be Boolean functions that are both not the constant zero function. Define $h : \{0,1\}^n \times \{0,1\}^m \rightarrow \{0,1\}$ by $h(x,y) = f(x) \wedge g(y)$. Then

$$\text{CC}_{\text{AND} \circ \text{AC}^0_{d-1}}(h) = \text{CC}_{\text{AND} \circ \text{AC}^0_{d-1}}(f) + \text{CC}_{\text{AND} \circ \text{AC}^0_{d-1}}(g),$$

and

$$\text{CC}_{\text{OR} \circ \text{AC}^0_{d-1}}(h) \geq \text{CC}_{\text{OR} \circ \text{AC}^0_{d-1}}(f) + \text{CC}_{\text{OR} \circ \text{AC}^0_{d-1}}(g).$$

**Proof.** It is easy to see that

$$\text{CC}_{\text{AND} \circ \text{AC}^0_{d-1}}(h) \leq \text{CC}_{\text{AND} \circ \text{AC}^0_{d-1}}(f) + \text{CC}_{\text{AND} \circ \text{AC}^0_{d-1}}(g).$$
On the other hand, since $f$ is not the constant 0 function, it has a 1-valued input $x_0$. Then, $h(x_0, y)$ computes $g(y)$. Thus, if $\phi$ is an $\text{OR} \circ \text{AC}^{d-1}_0$ formula for $h$, then $\phi$ has at least $\text{CC}_{\text{AND} \circ \text{AC}^{d-1}_0}(g)$ $y$-input leaves. A similar argument shows that $\phi$ has at least $\text{CC}_{\text{AND} \circ \text{AC}^{d-1}_0}(f)$ $x$-input leaves. Hence

$$\text{CC}_{\text{AND} \circ \text{AC}^{d-1}_0}(h) \geq \text{CC}_{\text{AND} \circ \text{AC}^{d-1}_0}(f) + \text{CC}_{\text{AND} \circ \text{AC}^{d-1}_0}(g).$$

A similar argument shows that

$$\text{CC}_{\text{OR} \circ \text{AC}^{d-1}_0}(h) \geq \text{CC}_{\text{OR} \circ \text{AC}^{d-1}_0}(f) + \text{CC}_{\text{OR} \circ \text{AC}^{d-1}_0}(g).$$

Oracle Circuits and Oracle MCSP: MOCSP

An oracle circuit $C$ is made up of NOT gates, fan-in two AND and OR gates, and oracle gates $g_1, \ldots, g_t$ for some integer $t \geq 0$. When given an oracle functions $O$, we let $C^O(x)$ be the value obtained when evaluating $C$ on input $x$ by using the $O$ function to compute the outputs of the oracle gates $g_1, \ldots, g_t$.

We define the size of an oracle circuit $C$, denoted $|C|$, to be the number of wires in $C$. For Boolean functions $f$, $O$, we let $\text{CC}^O(f)$ be the size of the smallest $O$-oracle circuit that computes $f$. Analogous to MCSP, we define the following.

Definition 2.4 (The Minimum Oracle Circuit Size Problem). The Minimum Oracle Circuit Size Problem, denoted MOCSP, takes as input a truth table $T$, a threshold $s \in \mathbb{N}$, and an oracle truth table $O$ and outputs whether $\text{CC}^O(T) \leq s$. The output of MOCSP on such an input is written as $\text{MOCSP}(T, s; O)$.

Set Cover

We will make use of the following well known NP-complete problem.

Definition 2.5 (Set Cover). Set Cover, denoted SetCover, is the problem that takes as input a tuple $(n, c, S_1, \ldots, S_t)$, where $n \in \mathbb{N}$ is a universe size, $c \in \mathbb{N}$ is a proposed cover size $1 \leq c \leq n$, and $S_1, \ldots, S_t \subseteq [n]$ are sets whose union is $[n]$, and outputs whether $c \geq \ell$ where $\ell$ is the optimal cover size given by

$$\ell = \min\{|I| : I \subseteq [t] \text{ and } \bigcup_{i \in I} S_i = [n]\}.$$  

We will use that SetCover is NP-hard even to approximate to a roughly $\log n$ factor.

Theorem 2.6 (Dinur and Steurer [11]). It is NP-hard to approximate SetCover to within a factor of $(1 - o(1)) \ln n$.

3 On the NP-hardness of MOCSP

First, we introduce some useful notation and definitions. For a truth table $T$ of length $m$ and a set $R \subseteq [m]$, let $T_{(R)}$ be the truth table of length $m$ where the $j$th bit of $T_{(R)}$ equals

$$\begin{cases} 
\text{the } j\text{th bit of } T, & \text{if } j \in R \\
0, & \text{otherwise}.
\end{cases}$$

Equivalently,

$$T_{(R)}(x) = T(x) \land \mathbb{1}_{x \in R}.$$
Next, we define a uniformly random partition $P = (P_1, \ldots, P_n)$ of $[m]$ into $n$ parts to be such that each element $i \in [m]$ is put into $P_j$ where $j \in [n]$ is chosen uniformly at random. It will be also useful to think of $P$ as a uniformly random function $P : [m] \to [n]$.

Next, for a partition $P = (P_1, \ldots, P_n)$ of $[m]$ and any set $S \subseteq [n]$, we define the $P$-lift of $S$, denoted $S^P$, to be the subset of $[m]$ given by

$$S^P = \bigcup_{i \in S} P_i.$$ 

Our main theorem shows that MOCSP can approximate set cover.

**Theorem 3.1.** Let $S_1, \ldots, S_t \subseteq [n]$ be sets that cover $[n]$. Let $T$ be a truth table of length $m \geq (nt)^5$, and let $P = (P_1, \ldots, P_n)$ be a uniformly random partition of $[m]$ into $n$ parts. Define the oracle function the $O : \{0, 1\}^{\lceil \log t \rceil} \times \{0, 1\}^{\log m} \to \{0, 1\}$ by

$$O(i, y) = \begin{cases} T(S_i^P(y)), & \text{if } i \in [t] \text{ (identifying } i \text{ as an integer in the natural way)} \\ 0, & \text{otherwise} \end{cases}.$$ 

Then

- $\text{CC}_O(T) \leq t(3 + \log m + \log t)$, and
- $\text{CC}_O(T) > \ell(\log m + \log t)/2$ with high probability

where $\ell$ is size of the optimal cover of $[n]$ by $S_1, \ldots, S_t$.

**Proof.** First, we show the upper bound.

**Claim 3.2.** $\text{CC}_O(T) \leq t(3 + \log m + \log t)$

**Proof.** Without loss of generality, assume that the optimal cover size $\ell$ is witnessed by $S_1 \cup \cdots \cup S_\ell = [n]$. Then, by construction, the function computed by oracle circuit $C$ given by

$$C(x) = O(1, x) \lor \cdots \lor O(\ell, x)$$

computes $T$ and has at most

$$2\ell + \ell \cdot (\log m + \log t + 1) \leq \ell(3 + \log m + \log t)$$

wires. In more detail,

$$\bigvee_{i \in [\ell]} O(i, x) = \bigvee_{i \in [\ell]} \bigvee_{j \in S_i} T_{(P_j)}(x) = \bigvee_{j \in [S_1 \cup \cdots \cup S_\ell]} T_{(P_j)}(x) = \bigvee_{j \in [n]} T_{P_j}(x) = T(x).$$

Therefore $\text{CC}_O(T) \leq \ell(3 + \log m + \log t)$. 

Now, we show the lower bound. We do this by a union bound argument. Fix some $O$-oracle circuit $C$ such that with at most $\ell(\log m + \log t)/2$ wires. Then $C$ has at most $\ell/2$ oracle gates. We will show that

$$\Pr_{T, P}[C^O \text{ computes } T]$$

is exponentially small. We do this by finding a long sequence of inputs $x_1, \ldots, x_d$ on which $C^O$ has a not too large chance of computing $T$. 

We construct this list of inputs recursively as follows. Let $x_1 = \mathbf{0}^{\log m}$, and let $Q_1 = \{x : C^O(x_1)\} makes a query of the form $(i, x)$ to an oracle gate for some $i$.

Now, for $j \geq 1$, if $\{0, 1\}^{\log m} \setminus Q_j$ is non-empty, then let $x_{j+1}$ be an element of $\{0, 1\}^{\log m} \setminus Q_j$, and let $Q_{j+1} = Q_j \cup \{x : C^O(x_{j+1})\}$ makes a query of the form $(i, x)$ to an oracle gate for some $i$.

If $\{0, 1\}^{\log m} = Q_j$, then terminate the sequence.

Since $C$ has at most $\ell/2 \leq n$ oracle gates, we know that $|Q_j| \leq j \cdot n$. Thus, since $|Q_d| = |\{0, 1\}^{\log m}| = m$, the length $d$ of this sequence is at least $m/n$.

It remains to bound
\[
\Pr[C^O(x_j) = T(x_j) \forall j] = \prod_{j=1}^{d} \Pr[C^O(x_j) = T(x_j)] \wedge C^O(x_k) = T(x_k)].
\]

Fix some $j \in [d]$. We will bound
\[
\Pr[C^O(x_j) = T(x_j)] \wedge C^O(x_k) = T(x_k)].
\]

For convenience, let $E$ denote the event we are conditioning on.

\[\text{Claim 3.3.} \]

\[\Pr[C^O(x_j) = T(x_j) | E] \leq 1 - \frac{1}{2n}. \]

\textbf{Proof.} By construction of the sequence $x_1, \ldots, x_d$, we know that on all the inputs $x_1, \ldots, x_{j-1}$, $C^O$ does not make an oracle call of the form $(i, x_j)$ for some $i$. Thus, since the only time the value of $O$ depends on $T(x_j)$ and $P(x_j)$ is on inputs of the form $(i, x_j)$ for some $i$, and $T(x_j)$ and $P(x_j)$ are chosen at independently at random, we know that $T(x_j)$ and $P(x_j)$ are still uniform random variables conditioned on $E$. In other words,

\[\Pr[T(x_j) = 1 | E] = \frac{1}{2} \]

and

\[\Pr[P(x_j) = r | E] = \frac{1}{n} \]

for all $r \in [n]$.

Now, define the alternate oracle $O’$ that acts the same as $O$ except that it rejects all queries containing $x_j$, that is

\[O’(i, x) = \begin{cases} 0, & \text{if } x = x_j \\ O(i, x), & \text{otherwise.} \end{cases} \]

Now let $i_1, \ldots, i_v$ with $v \leq \ell/2$ be such that, using the modified oracle $O’$, the only oracle queries $C^{O’}(x_j)$ makes that end with $x_j$ are $(i_1, x_j), \ldots, (i_v, x_j)$ (note that queries of this form are the only ones that could reveal information about $T(x_j)$). Since $v < \ell$ (recall $\ell$ is the size of the optimal cover) there actually exists an element $r^* \in [n]$ that is not in $S_{i_1} \cup \cdots \cup S_{i_v}$.
Moreover, observe that if $P(x) = r^*$, then $C^O(x_j)$ will actually make the same oracle queries (and get the same zero responses) as the modified oracle circuit $C^O(x_j)$. In this case, since $P(x) = r^* \not\in S_i \cup \cdots \cup S_t$, it follows from the definition of $O$ that

$$\mathcal{O}(i_1, x_j) = \cdots = \mathcal{O}(i_v, x_j) = 0$$

regardless of the value of $T(x_j)$. Thus, the output of $C^O$ on input $x$ does not depend at all on the value of $T(x)$. Hence, the probability it correctly guesses $C^O(x) = T(x)$ is at most $1/2$.

Since $P(x_j)$ is chosen uniformly at random, we have that $P(x_j) = r^*$ with probability $1/n$. Therefore, the probability

$$\Pr[C^O(x_j) = T(x_j) | E] \leq 1 - \frac{1}{2n}$$

Using this claim, we now have

$$\prod_{j=1}^d \Pr[C^O(x_j) = T(x_j) | \bigwedge_{k \in [j-1]} C^O(x_k) = T(x_k)] \leq (1 - \frac{1}{2n})^d \leq e^{-\frac{d}{2n}} \leq e^{-\frac{m}{2n}} \leq e^{-\frac{n^3}{4}}.$$ 

On the other hand the number of oracle circuits of size $\ell(\log m + \log t)/2 = O(nt \log n)$ is at most $2^{O(n^3t^2)}$. Thus, by the union bound the probability that there exists an $O$-oracle circuit of size at most $\ell(\log m + \log t)/2$ computing $T$ is $o(1)$ as desired.

As an immediate consequence of Theorem 3.1, we get that $\text{MOCSP}$ is hard for $\text{NP}$ under many-one randomized reductions with one-sided error (the reduction is one-sided because the upper bound on the oracle circuit size of $T$ in Theorem 3.1 is independent of the random choices of $T$ and $P$).

**Corollary 3.4.** $\text{NP} \leq_{\text{RP}} \text{MOCSP}$.

Moreover, the RP-reduction in Corollary 3.4 only errs by outputting YES when the answer should be NO. Thus, using the search-to-decision reduction for SetCover, we can check the correctness of purported YES answers, yielding a ZPP Turing reduction.

**Corollary 3.5.** $\text{NP} \leq_{\text{ZPP}} \text{MOCSP}$.

### 4 MAJORITY $\leq_{tt}^{\text{AC}^0} (\text{AC}^0_d)$-MCSP

Let $d \geq 2$. Our goal in this section is to prove the following theorem.

**Theorem 4.1.** $\text{MAJORITY} \leq_{tt}^{\text{AC}^0} (\text{AC}^0_d)$-MCSP.

We will do this by showing that for all sufficiently large $n \in \mathbb{N}$, there exists an $\text{AC}^0$ truth table oracle circuit that computes $\text{MAJORITY}$ on $n$-bits when given access to $(\text{AC}^0_d)$-MCSP.

Fix some $n$, and let $q$ be the least power of two such that $n \leq q/2$. We will split our analysis into cases depending on whether there exists an $m \in \{q^{10}, q^{50}\}$ such that $CC_{\text{AC}^0_d}$ is $(m^{25})$-Lipschitz on inputs of length $m$. 

4.1 Case 1: Lipschitzness Holds

If Lipschitzness holds, then the desired \((\text{AC}^0_d)\text{-MCSP}\) oracle circuit \(C\) exists for computing \text{MAJORITY} on \(n\)-inputs by the work of Golovnev et al. \cite{Golovnev12}. At a high-level, \(C\) works by using the input string to sample a random variable whose circuit complexity spikes (in expectation) depending on the weight of the input and using Lipschitzness to show that this spike happens with such high probability that it can be derandomized using non-uniformity.

For completeness, we give a self-contained proof of this case in Appendix A.

4.2 Case 2: Lipschitzness fails

Assume that for all \(m \in \{q^{10}, q^{50}\}\), \(\text{CC}_{\text{AC}^0_d}\) is not \((m^{2.5})\)-Lipschitz on inputs of length \(m\). Thus, for all \(m \in \{q^{10}, q^{50}\}\) there exist functions \(f^m, h^m : \{0,1\}^\log m \to \{0,1\}\) that differ only on a single input \(z^m \in \{0,1\}^\log m\) such that \(\text{CC}_{\text{AC}^0_d}(h^m) - \text{CC}_{\text{AC}^0_d}(f^m) > m^{2.5}\).

We assume, without loss of generality, that for all \(m \in \{q^{10}, q^{50}\}\), \(f^m(z^m) = 0\) and \(h^m(z^m) = 1\). (If this is not the case, then replace \(f^m\) and \(h^m\) by \(\neg f^m\) and \(\neg h^m\) respectively and apply Lemma 2.2.)

First, we show that the failure of Lipschitzness implies the existence of functions that are much easier to compute by formulas with an AND gate on top. For \(m \in \{q^{10}, q^{50}\}\) let \(1_{z^m} : \{0,1\}^\log m \to \{0,1\}\) denote the indicator function that accepts just the string \(z^m\).

\begin{proposition}
Let \(m \in \{q^{10}, q^{50}\}\). For sufficiently large \(n\), \(\text{CC}_{\text{OR} \circ \text{AC}^0_{d-1}}(f^m) \geq \text{CC}_{\text{AC}^0_d}(f^m) + m^{24}\), and so any optimal \(\text{AC}^0_d\) formula for \(f^m\) has an AND gate on top.
\end{proposition}

\begin{proof}
Suppose \(\phi\) is an \(\text{OR} \circ \text{AC}^0_{d-1}\) formula computing \(f^m\), that is, \(f^m\) is computed by \(\phi = \phi_1 \lor \cdots \lor \phi_t\) for some \(\text{AC}^0_{d-1}\) formulas \(\phi_1, \ldots, \phi_t\). Then

\[1_{z^m} \lor \phi_1 \lor \cdots \lor \phi_t\]

computes \(h^m\). Since \(1_{z^m}\) can be computed by a single AND gate of formula size \(\log m\), this shows that \(\text{CC}_{\text{AC}^0_d}(h^m) \leq |\phi| + \log m\). Combining this with the fact that \(\text{CC}_{\text{AC}^0_d}(h^m) - \text{CC}_{\text{AC}^0_d}(f^m) \geq m^{2.5}\) gives the desired result.
\end{proof}

At this point, we will need to refer to both \(q^{10}\) and \(q^{50}\) individually, so for convenience let \(u = q^{10}\) and \(v = q^{50}\).

Let \(\phi^u\) be an optimal \(\text{AC}^0_d\) formula for \(f^u\). By Proposition 4.2, for sufficiently large \(n\), we know that \(\phi^u = \phi^u_1 \land \cdots \land \phi^u_t\) for some \(\text{AC}^0_{d-1}\) formulas \(\phi^u_1, \ldots, \phi^u_t\). Moreover, we can assume, without loss of generality, that the top gate of \(\phi^u_i\) is \(\text{OR}\) for all \(i \in [t]\). (If some \(\phi^u_i\) has an AND gate on top, then this AND can be carried out by the AND gate on top of \(\phi^u\) without increasing the size of the formula.)

Our next Proposition shows that \(\phi^u\) has high top fan-in.

\begin{proposition}
For sufficiently large \(n\),
\[t \geq u^{24}\]
\end{proposition}

\begin{proof}
We divide into cases depending on \(d\).

\textbf{Case 1:} \(d \geq 3\). Realize that

\[(\phi^u_1 \lor 1_{z^u}) \land \cdots \land (\phi^u_t \lor 1_{z^u})\]

computes \(h^u\). Since \(1_{z^u}\) can be computed by a single AND gate of formula size \(\log u\) and the top gate of each \(\phi^u_i\) is an OR gate and \(d \geq 3\), this yields a depth-\(d\) formula for \(h^u\) of size \(\text{CC}_{\text{AC}^0_d}(f^u) + t \log u\). Since \(\text{CC}_{\text{AC}^0_{d-1}}(h^u) - \text{CC}_{\text{AC}^0_d}(f^u) \geq u^{2.5}\), the desired bound on \(t\) follows.
Case 2: $d = 2$. Let $\mathbb{I}_{z^u,j} : \{0,1\}^{\log u} \to \{0,1\}$ be the function that accepts a string $x$ if and only if the $j$th bit of $x$ equals the $j$th bit of $z^u$. Observe that, since $\bigwedge_{i \in [t]} \phi^u_i$ computes $f^u$, we have that

$$\bigwedge_{i \in [t]} \bigwedge_{j \in [\log u]} (\phi^u_i \lor \mathbb{I}_{z^u,j})$$

computes $h^u$. Since $\mathbb{I}_{z^u,j}$ is computed by a single input leaf and $\phi^u_i$ has an OR gate on top, this yields a depth-2 formula for $h^u$ of size $(|\phi^u| + 1) \log u$. Since $\phi^u$ is an optimal CNF, each clause $\phi^u_{i,r}$ of $\phi^u$ is the OR of at most $\log u$ input leaves. In other words, $|\phi^u_{i,r}| \leq \log u$. Therefore, we have that

$$\text{CC}_{AC^0}(h^u) \leq (|\phi^u| + 1) \log u \leq \left(\sum_{i \in [t]} |\phi^u_i| + 1\right) \log u \leq (t \log u + 1) \log u = t \log^2 u + \log u.$$ 

On the other hand, we know by assumption that

$$\text{CC}_{AC^0}(h^u) > \text{CC}_{AC^0}(f^u) + u^{25} \geq u^{25}.$$ 

Combining these two inequalities gives us the desired bound on $t$. ▷

Let $p$ be smallest prime greater than $n$. (Note that $p \leq 2n$ by Betrand’s postulate, also known as Chebyshev’s theorem. See [13] for a proof.) We say that an integer $j$ is $(k, r)$-good for integers $k \geq 0$ and $1 \leq r \leq p - 1$ if $p^k$ divides $j$ and $j/p^k \equiv r \mod p$. In other words, an integer $j$ is $(k, r)$-good for $k \geq 0$ and $r \in [p - 1]$ if the $k$th largest entry of the base-$p$ representation of the integer $j$ equals $r$ and all previous entries equal zero. From this “base-$p$” perspective, it is clear that all positive integers $j$ are $(k, r)$-good for some $k \geq 0$ and $r \in [p - 1]$.

We show that, for some $k$ and $r$, a large subset of the $|\phi^u_i|$ are $(k, r)$-good.

**Proposition 4.4.** For all sufficiently large $n$, there exist integers $k \geq 0$ and $1 \leq r \leq p - 1$ and a set $S \subseteq [t]$ of cardinality $n$ such that, for all $i \in S$, the integer $|\phi^u_i|$ is $(k, r)$-good.

**Proof.** We do this by an averaging argument. First, we show that each $|\phi^u_i|$ is $(k, r)$-good for a $k$ not too large.

▷ **Claim 4.5.** For all $i \in [t]$, $|\phi^u_i|$ is $(k, r)$-good for some $0 \leq k \leq \log(u \log u) + 1$ and some $r \in [p - 1]$.

**Proof.** Fix some $i \in [t]$. $|\phi^u_i|$ is a positive integer, so $|\phi^u_i|$ is $(k, r)$-good for some $k \geq 0$ and some $r \in [p - 1]$. We still need to upper bound this $k$. Note that the size of $|\phi^u_i|$ is at most $u \log u$ since $\phi^u$ is optimal for $f^u$ and $f^u$ can be computed by a DNF of size $u \log u$. Thus, for $p^k$ to divide $|\phi^u_i|$, we must have that $k \leq \log_p(u \log u) + 1 \leq \log(u \log u) + 1$.

Since for all $i \in [t]$ we have shown that $|\phi^u_i|$ is $(k, r)$ good for some $0 \leq k \leq \log(u \log u) + 1$ and some $r \in [p - 1]$, a standard averaging argument implies that there exists a set $S \subseteq [t]$ of cardinality at least

$$\frac{t}{(\log(u \log u) + 1)(p - 1)}$$

such that for all $i \in S$, $|\phi^u_i|$ is $(k, r)$-good for some fixed $k \geq 0$ and $1 \leq r \leq p - 1$. For sufficiently large $n$, we have that

$$\frac{t}{(\log(u \log u) + 1)(p - 1)} \geq \frac{u^{24}}{4n \log u} \geq n$$

using that $u = q^{10} \geq n^{10}$. We then can truncate $S$ so that it has only $n$ elements as desired. ▷
Assume that $n$ is large enough that all the sufficiently large hypotheses in Propositions 4.2, 4.3, and 4.4 apply. For convenience, relabel $\phi_1, \ldots, \phi_t$ so that the set $S$ guaranteed by Proposition 4.4 is just $S = [n]$. Fix $k \geq 0$ and $r \in [p-1]$ to be the values such that for all $i \in S = [n]$, $|\phi_i^u|$ is $(k, r)$-good.

Introducing notation, for a set $A \subseteq [n]$, let $f_A^u$ be the function computed by $\bigland_{i \in A} \phi_i^u$.

> **Lemma 4.6.** Let $A \subseteq [n]$. Then $\CC_{\AND \AC^0_{d-1}}(f_A^u) = \sum_{i \in A} |\phi_i^u|$.

**Proof.** By construction, we have that $\CC_{\AND \AC^0_{d-1}}(f_A^u) \leq \sum_{i \in A} |\phi_i^u|$. Suppose for contradiction that $\CC_{\AND \AC^0_{d-1}}(f_A^u) < \sum_{i \in A} |\phi_i^u|$. Let $\theta_1 \land \cdots \land \theta_t$ be a minimum-sized $\AND \AC^0_{d-1}$ formula for $f_A^u$. By assumption, we have that $\sum_{j=1}^t |\theta_j| < \sum_{i \in A} |\phi_i^u|$. We can thus replace the $\bigland_{i \in A} \phi_i^u$ in the optimal formula for $f^u$ with $\theta_1 \land \cdots \land \theta_t$ and get a smaller formula. In more detail, we have that $$f^u = f_A^u \land \left( \bigland_{i \in [t] \setminus A} \phi_i^u \right) = (\theta_1 \land \cdots \land \theta_t) \land \left( \bigland_{i \in [t] \setminus A} \phi_i^u \right)$$ which is a formula of size $$\sum_{j=1}^t |\theta_j| + \sum_{i \in [t] \setminus A} |\phi_i^u| < \sum_{i \in A} |\phi_i^u| + \sum_{i \in [t] \setminus A} |\phi_i^u| = \sum_{i=1}^t |\phi_i^u| = |\phi^u|$$ which contradicts the optimality of $\phi^u$ for $f^u$. \hfill \Box

For a string $x \in \{0, 1\}^n$, let $f_x^u$ be shorthand for $f_{A_x}^u$, where $A_x \subseteq [n]$ is the set of indices where $x$ is one.

> **Proposition 4.7.** Let $x \in \{0, 1\}^n$. Then $x$ has weight $w$ if and only if the integer $\CC_{\AND \AC^0_{d-1}}(f_x^u)$ is $(k, rw)$-good.

**Proof.** By Lemma 4.6 and the fact that $|\phi_i^u|$ is $(k, r)$-good for all $i \in [n]$, we have that $$\frac{\CC_{\AND \AC^0_{d-1}}(f_x^u)}{p^k} = \frac{\sum_{i \in A_x} |\phi_i^u|}{p^k} \equiv w \cdot r \mod p$$ where $A_x \subseteq [n]$ are bits of $x$ that are ones. The “only if” part of the statement is guaranteed by the fact that $1 \leq r \leq p-1$ has a multiplicative inverse modulo $p$ since $p$ is prime. \hfill \Box

> **Theorem 4.8.** Assume $n$ is sufficiently large. Then there is a depth-8 $\AC^0$ truth table oracle circuit $C$ with $O(n^{250})$ wires such that $C(\AC^0_{d-1})$ computes $\text{MAJORITY}$ on $n$-bits.

**Proof.** It suffices to show that for every $w \in [n]$, there exists a depth-7 $\AC^0$ oracle circuit $C_w$ with $O(n^{249})$ wires such that $C_w(\AC^0_{d-1})$-MCSP $(x) = 1 \iff \text{wt}(x) = w$. Then $\text{MAJORITY}(x) = \bigvee_{w \geq n/2} C_w(x)$.

Fix some $w \in [n]$. The circuit $C_w$ works as follows. On input $x \in \{0, 1\}^n$, first check if $x$ is the all zeroes string. If so, then reject. Otherwise, compute the truth table of the direct product function $g_x : \{0, 1\}^{\log u} \times \{0, 1\}^{\log v} \rightarrow \{0, 1\}$ given by $g_x(y, z) = f_x^u(y) \land f_x^v(z)$. Compute $s = \CC_{\AC^0_{d-1}}(g_x)$ in binary using oracle access to $(\AC^0_{d-1})$-MCSP. Finally accept if the integer $s$ has the property that $s = \CC_{\AC^0}(f^u)$ is $(k, rw)$-good. Reject otherwise.

We now verify this yields a (non-uniform) $\AC^0$ truth table oracle circuit. We can check if $x$ is the all zeroes string with a single OR gate. This requires one level of depth and $O(n)$ wires. Next, realize the $j$th bit in the truth table of $g_x$ is either zero for all $x$ or equal to $$f_x^u(j) = \bigvee_{i \in [n]: \phi_i^u(j) = 1} x_i$$
Claim 4.9. Neither $f^u_x$ nor $f^v$ is the constant zero function.

Proof. If $f^v$ were the constant zero function, then $\text{CC}_{\text{AC}^0}(h^v) \leq \log v$ by DNF computation which contradicts that

$$\text{CC}_{\text{AC}^0}(h^v) - \text{CC}_{\text{AC}^0}(f^v) \geq v^{25}.$$ 

Next, let $i \in [n]$ be a bit of $x$ that is not zero. (Recall, we assumed that $x \neq 0^n$.) Then $f^u_x$ accepts every input that that $\phi_i^u$ accepts. For contradiction, suppose that $\phi_i^u$ had no ones. Then we can remove $\phi_i^u$ from the optimal formula $\phi^u = \phi_i^u \land \ldots \land \phi_n^u$ for $f^u$ and get a smaller formula for $f^u$ which contradicts the optimality of $\phi^u$. \hfill \Box

Next we show that the optimal $\text{AC}^0$ formula for $g_x$ has an AND gate on top.

Claim 4.10. $\text{CC}_{\text{OR} \circ \text{AC}^0_{d-1}}(g_x) > \text{CC}_{\text{AND} \circ \text{AC}^0_{d-1}}(g_x)$. Consequently,

$$\text{CC}_{\text{AC}^0_{d-1}}(g_x) = \text{CC}_{\text{AND} \circ \text{AC}^0_{d-1}}(g_x).$$

Proof. Let $\Delta = \text{CC}_{\text{OR} \circ \text{AC}^0_{d-1}}(g_x) - \text{CC}_{\text{AND} \circ \text{AC}^0_{d-1}}(g_x)$. We need to show $\Delta > 0$.

$$\Delta \geq \text{CC}_{\text{OR} \circ \text{AC}^0_{d-1}}(f^v) - \text{CC}_{\text{AND} \circ \text{AC}^0_{d-1}}(f^v) + \text{CC}_{\text{OR} \circ \text{AC}^0_{d-1}}(f^u_x) \quad (\text{by Lemma 2.3})$$

$$\geq (v)^{24} + \text{CC}_{\text{OR} \circ \text{AC}^0_{d-1}}(f^u_x) - \text{CC}_{\text{AND} \circ \text{AC}^0_{d-1}}(f^u_x) \quad (\text{by Proposition 4.2})$$

$$\geq (v)^{24} - u \log u \quad (\text{by DNF bound on } f^u_x)$$

$$\geq n^{50.24} - n^{10} \log(n^{10}) \quad (\text{for sufficiently large } n) \quad \Box$$
Using the claim we have that
\[ s - \text{CC}_{\text{AC}^0_1}(f^v) = \text{CC}_{\text{AC}^0_2}(g_x) - \text{CC}_{\text{AC}^0_2}(f^v) \quad \text{(definition)} \]
\[ = \text{CC}_{\text{AND}\oplus\text{AC}^0_{d-1}}(g_x) - \text{CC}_{\text{AC}^0_1}(f^v) \quad \text{(Claim 4.10)} \]
\[ = \text{CC}_{\text{AND}\oplus\text{AC}^0_{d-1}}(f^v) + \text{CC}_{\text{AND}\oplus\text{AC}^0_{d-1}}(f^v) - \text{CC}_{\text{AC}^0_2}(f^v) \quad \text{(Lemma 2.3)} \]
\[ = \text{CC}_{\text{AND}\oplus\text{AC}^0_{d-1}}(f^v) + \text{CC}_{\text{AND}\oplus\text{AC}^0_{d-1}}(f^v) - \text{CC}_{\text{AND}\oplus\text{AC}^0_{d-1}}(f^v) \quad \text{(Prop 4.2)} \]
\[ = \text{CC}_{\text{AND}\oplus\text{AC}^0_{d-1}}(f^v) \]
as desired. 

References
A \textbf{MAJORITY reduces to (AC}^0_d\text{-MCSP when Lipschitzness holds}}

Our goal in this section is to find a small (AC}^0_d\text{-MCSP-oracle circuit that computes MAJORITY on } n\text{-bits for sufficiently large } n\text{. We can do this using the techniques of Golovnev et al. [12]. In order to make our proof relatively self-contained, we differ slightly from the presentation in [12]. In particular, our presentation follows a method for computing MAJORITY that is described in Shaltiel and Viola [29].}

At a high-level, this procedure works by using the input string to sample a random variable whose circuit complexity spikes depending on the weight of the input and then using Lipschitzness to prove that this spike occurs with high enough probability that we can derandomize using non-uniformity.
Continuing the notation from Section 4, assume that there is an \( m \in \{ q^{10}, q^{50} \} \) such that \( \text{CC}_{\text{AC}^0} \) is \((m^{2^k})\)-Lipschitz on inputs of length \( m \).

We define the random variable \( T_{p,m} \in \{0,1\}^m \) where each bit in \( T_{p,m} \) is independently chosen to be one with probability \( p \) and zero with probability \( 1 - p \).

**Lemma A.1.** \( \mathbb{E}[\text{CC}_{\text{AC}^0}(T_{p,m})] = \tilde{O}(pm) \) if \( p \geq m^{-1/3} \)

**Proof.** By Hoeffding’s inequality we have that the probability that \( p \) ones is at most \( \exp(-2\epsilon^2 m) \). Via computation by DNF, if a truth table \( T \in \{0,1\}^m \) has at most \( k \) ones, \( \text{CC}_{\text{AC}^0}(T) = k \log m = O(k) \). Similarly, we have that \( \max\{C(T) : T \in \{0,1\}^m \} = \tilde{O}(m) \). Hence, we get that

\[
\mathbb{E}[\text{CC}_{\text{AC}^0}(T_{p,m})] = \tilde{O}(k) + \tilde{O}(\exp(-2\epsilon^2 m m)) = \tilde{O}(pm + pm\epsilon + \exp(-2\epsilon^2 m m)).
\]

If we set \( \epsilon = \sqrt{\frac{\ln m}{2m}} \), then we have

\[
\mathbb{E}[\text{CC}_{\text{AC}^0}(T_{p,m})] \leq \tilde{O}(pm + p\sqrt{m \ln m} + 1) \leq \tilde{O}(pm + \sqrt{m \ln m})
\]

Finally, if \( p \geq 1/m^{1/3} \), we have \( \mathbb{E}[T_{p,m}] = \tilde{O}(pm) \) as desired.

We will make use of the following concentration inequality.

**Theorem A.2** (McDiarmid’s “bounded differences inequality” [21]). Let \( f : \{0,1\}^n \to \mathbb{R} \) be \( c \)-Lipschitz. Let \( X_1, \ldots, X_n \) be independent random variables with values in \( \{0,1\} \). Let \( \mu = \mathbb{E}_{X_1,\ldots,X_n}[f(X_1, \ldots, X_n)] \). Then

\[
\Pr[|f(X_1, \ldots, X_n) - \mu| \geq \epsilon] \leq 2\exp\left(-\frac{\epsilon^2}{nc^2}\right).
\]

For \( t \in \mathbb{N} \) and \( w_1 \neq w_2 \in [t] \), we say a Boolean function \( f : \{0,1\}^t \to \{0,1\} \) computes \( \text{WTDIS}_{t}[w_1, w_2] \) if \( \text{wt}(x) = w_1 \) implies \( f(x) = 1 \) and \( \text{wt}(x) = w_2 \) implies \( f(x) = 0 \). (WTDIS is short for weight distinguishing.)

**Theorem A.3.** If \( n \) is sufficiently large, then for all \( 1 \leq b \leq \sqrt{q}/2 \), there exists a (non-uniform) \( \text{NC}^1 \) oracle circuit \( C \) with at most \( O(n^{100}) \) wires such that \( C(\text{AC}^0_{\text{QMS}}) \) computes \( \text{WTDIS}_{q}[w_1, w_1 + b] \) for some \( w_1 \geq \sqrt{q}/2 \). Moreover, \( C \) has a single gate.

**Proof.** For \( w \in [q] \), let \( p_w = \frac{w}{\sqrt{q}} \). Let \( w_0 \) be the largest integer less than \( \sqrt{q} \) such that \( q - w_0 \) is a multiple of \( b \). (Note that \( w_0 \geq \sqrt{q} - b \geq \sqrt{q}/2 \).

By Lemma A.1, we have that

\[
\mathbb{E}[\text{CC}_{\text{AC}^0}(T_{p,w,m})] = \tilde{O}(\sqrt{q}/m) = \tilde{O}(m/\sqrt{q}).
\]

On the other hand, since \( p_0 = 1/2 \), \( T_{p,m} \) is just a binary string of length \( m \) picked uniformly at random, so the formula size lower bounds of Shannon and Riordan imply

\[
\mathbb{E}[\text{CC}_{\text{AC}^0}(T_{p,w,m})] = \mathbb{E} \sum_{x \in \{0,1\}^m} C(x) = \tilde{O}(m)
\]

(note that an \( \text{AC}^0_{\text{QMS}} \) formula of size \( s \) implies an unrestricted formula of size \( s \)). Hence, by an averaging argument there exists a \( w_1 \geq w_0 \geq \sqrt{q}/2 \) such that
Approaching MCSP from Above and Below

\[
E[CC_{\mathcal{AC}^0_w}(T_{p_{w_1+m}})] - E[CC(T_{p_{w_1,m}})] \geq \frac{\tilde{\Omega}(m) - \tilde{O}(m/\sqrt{q})}{q} = \tilde{\Omega}(m/q).
\]

Let \( t = \frac{E[T_{p_{w_1+m}}] + E[T_{p_{w_1,m}}]}{2} \). Then we have that \( E[T_{p_{w_1+m}}] - t = \tilde{O}(m/q) \) and \( t - E[T_{p_{w_1,m}}] = \tilde{\Omega}(m/q) \).

We now outline a probabilistic oracle circuit \( D \) that we will later make into a deterministic \( \mathcal{NC}^0 \) circuit. \( D \) takes as input a string \( x \in \{0,1\}^n \) and takes as its random “inputs” strings \( u_1, \ldots, u_m \in \{0,1\}^{\log q} \) and \( v_1, \ldots, v_m \in \{0,1\} \). The reduction then computes the string \( y := y_1 \cdots y_m \) where \( y_i \) is zero if \( v_i \) is zero and \( y_i \) is the \( u_i \)th bit of \( x \) if \( v_i \) is one (recall, \( q \) is a power of two). \( D \) then outputs \( (\mathcal{AC}^0_q)^{-}\text{MCSP}(y,t) \).

We now argue for correctness with high probability. Realize each \( y_i \) is independent with probability \( \frac{\text{wt}(x)}{2n} \) of being 1. Hence, \( y \) is just the random variable \( T_{p_{w,m}} \) where \( w = \text{wt}(x) \). Hence, if \( \text{wt}(x) = w_1 \), then

\[
\Pr[R(x) \neq 1] = \Pr[\mathcal{C}(T_{p_{w_1,m}}) > t]
\]

Recall that \( t - E[T_{p_{w_1,m}}] = \tilde{\Omega}(m/q) \) and, by assumption, \( CC_{\mathcal{AC}^0} \) on inputs of length \( m \) is \( (m^{25}) \)-Lipschitz, so by Theorem A.2, we have that this probability is bounded by

\[
2\exp(-2\frac{\tilde{\Omega}(m^2)}{O(q^2 m^{1.5})}) \leq \exp(-2\frac{\tilde{\Omega}(q^{n/10})}{O(q^2)}) = O(\exp(-q^3))
\]

using the fact that \( m \geq q^{10} \). A similar analysis shows that the probability \( D \) errs if \( \text{wt}(x) = w_1 + b \) is at most \( O(\exp(-q^3)) \). This completes the analysis of \( D \).

We now argue that this reduction can be derandomized using non-uniformity. For each input of weight either \( w_1 \) or \( w_1 + b \), we have shown the fraction of random strings which err on that input is \( O(\exp(-q^3)) \). Hence, the fraction of random seeds which err on at least one input of weight \( w_1 \) or \( w_1 + b \) is at most

\[
2^n O(\exp(-q^3)) < 1
\]

for large enough \( n \). Thus, there exists some fixed \( u_1, \ldots, u_m \) and \( v_1, \ldots, v_m \) which work on all inputs of length \( q \). Once we are (non-uniformly) given these \( u_1, \ldots, u_m \) and \( v_1, \ldots, v_m \) which work on all inputs, we can turn \( D \) into an \( \mathcal{NC}^0 \) oracle circuit \( C \) which has just a single gate (an oracle gate) whose inputs are the fixed number \( t \) and the string \( y \) where each bit of \( y \) is either a fixed bit of \( x \) or zero. This yields a \( \mathcal{NC}^0 \) oracle circuit with \( O(m) = O(q^{50}) = O(n^{100}) \) wires.

**Corollary A.4.** If \( n \) is sufficiently large, then for all distinct \( w_1, w_2 \in [n] \) there is an \( \mathcal{NC}^0 \) oracle circuit \( C \) with at most two gates and \( O(n^{100}) \) wires such that \( C^{(\mathcal{AC}^0)^{-}\text{MCSP}} \) computes \( \text{WTDIS}_n[w_1, w_2] \).

**Proof.** Fix some \( w_1 \neq w_2 \). Without loss of generality assume \( w_1 < w_2 \) (if this is not the case, then swap the names of \( w_1 \) and \( w_2 \) in this proof and add a NOT gate to the top of \( C \)). Let \( b = w_2 - w_1 \). Recall \( q \) is the least power of two such that \( n \leq \sqrt{q}/2 \). Note that \( q = \Theta(n^2) \) and \( b \leq n \leq \sqrt{q}/2 \). Theorem A.3 guarantees there exists an \( \mathcal{NC}^0 \) oracle circuit \( D \) of size \( O(n^{50}) \) such that \( D^{\text{MCSP}} \) computes \( \text{WTDIS}_n[w_3, w_3 + b] \) for some \( w_3 \geq \sqrt{q}/2 \geq n \). Finally, let \( C \) be the oracle circuit that on input \( x \) outputs \( D(y) \) where \( y = 1^{w_3-w_1}0^{n-w_3+w_1}x \). The correctness of this output is guaranteed by the fact that \( \text{wt}(y) = w_3 \) if and only if \( \text{wt}(x) = w_1 \) and \( \text{wt}(y) = w_3 + b \) if and only if \( \text{wt}(x) = w_2 \). \( \blacksquare \)
Corollary A.5. If $n$ is sufficiently large, then there exists a depth-$4$ $\mathsf{AC}^0$ truth table oracle circuit $C$ with $O(n^{102})$ wires such that $C^{(\mathsf{AC}^0)}$-$\text{MCSP}$ computes $\text{MAJORITY}$ on strings on length $n$.

Proof. It suffices to show that, for all $w \in [n]$, one can check if a string $x \in \{0, 1\}^n$ has weight $w$ using a depth-$3$ $\mathsf{AC}^0$ truth-table oracle circuit $C_w$ of size $O(n^{101})$. If one is able to do this, then $\text{MAJORITY}$ is computed by $\bigvee_{w \in [2^n/2]} C_w(x)$.

For $w \in [n]$, let $\text{wt}_w : \{0, 1\}^n \rightarrow \{0, 1\}$ be the Boolean function that outputs one if and only if its input is a string of weight $w$. Now fix some $w \in [n]$. We claim that

$$\text{wt}_w(x) = \bigwedge_{w' \in [n] : w \neq w'} \text{WTDIS}_n[w, w']$$

If $x$ has weight $w$, then $\text{WTDIS}_n[w, w'] (x) = 1$ for all $w' \neq w$, so

$$\text{wt}_w(x) = 1 = \bigwedge_{w' \in [n] : w \neq w'} \text{WTDIS}_n[w, w'].$$

On the other hand, if $x$ has weight $w \neq w'$ then $\text{WTDIS}_n[w, w'] (x) = 0$, so

$$\text{wt}_w(x) = 0 = \bigwedge_{w' \in [n] : w \neq w'} \text{WTDIS}_n[w, w'].$$

Finally, by Corollary A.4 we have that $\bigwedge_{w \in [n] : w \neq w'} \text{WTDIS}_n[w', w]$ is computable by a depth-$3$ $\mathsf{AC}^0$ truth table oracle circuit with $O(n^{101})$ wires. 

\section{NP $\leq^P_{tt}$ MOCSP implies EXP $\neq$ ZPP}

The proof of this result follows essentially exactly from Murray and Williams’s [23] proof for $\text{MCSP}$. For completeness, we replicate the proof here (even using their words and structure).

Proposition B.1. If $\text{NP} \leq^P_{tt} \text{MOCSP}$, then $\text{EXP} \subseteq \text{P}/\text{poly}$ implies $\text{EXP} \neq \text{NEXP}$.

Proof. Assume $\text{NP} \leq^P_{tt} \text{MOCSP}$ and $\text{EXP} \subseteq \text{P}/\text{poly}$. Let $L \in \text{NTIME}(2^{cn})$ for some $c \geq 1$. It suffices to show that $L \in \text{EXP}$.

We pad $L$ into the $L' = \{ x01^2|x|^c : x \in L \}$. Note that $L' \in \text{NP}$. Hence there is a polynomial-time truth table reduction from $L'$ to $\text{MOCSP}$. Composing the reduction from $L$ to $L'$ with the reduction from $L'$ to $\text{MOCSP}$, we get a $2^{cn^c}$-time truth table reduction $R$ from $n$-bit instances of $L$ to $2^{cn^c}$-bit instances of $\text{MOCSP}$ for some constant $c'$.

Let $Q(x)$ denote the concatenated string of all $\text{MOCSP}$ queries produced by $R$ in order on input $x$. Define the language

$$\text{BIT}_S_Q := \{(x, i) : \text{the } i\text{th bit of } Q(x) \text{ is } 1\}$$

$\text{BIT}_S_Q$ is clearly in $\text{EXP}$. Since $\text{EXP} \subseteq \text{P}/\text{poly}$, for some $d \geq 1$ there is a circuit family $C_n$ of size at most $n^d + d$ computing $\text{BIT}_S_Q$ on $n$-bit inputs.

Thus, on a given instance $x$, we have $\text{CC}(Q(x)) \leq s(|x|) = (|x| + 2c'|x|^c)^d + d$. Therefore, every $\text{MOCSP}$ query $(T, s', t)$ produced by the reduction $R$ on input $x$ satisfies

$$\text{CC}^2(T) \leq \text{CC}(T) \leq e \cdot \text{CC}(Q(x)) \leq e \cdot s(|x|)$$

for some constant $e$ since $T$ is a substring of $Q(x)$ (see Lemma 2.2 in [23] for a proof of this substring fact). This leads to the following exponential time algorithm for $L$: 

```python
for all w \in [n]:
for all x \in \{0, 1\}^n:
   if \text{wt}_w(x) = 1:
      if \bigwedge_{w' \in [n] : w \neq w'} \text{WTDIS}_n[w, w'] = 1:
         return 1
   else:
      return 0
```
On input $x$, run the exponential-time reduction $R(x)$ by using the following procedure for answering each MOCSP oracle query $(T, s'; \mathcal{O})$. If $s' > e \cdot s(|x|)$, then respond YES to the query. Otherwise, cycle through every oracle circuit $E$ of size at most $s'$. If $E^\mathcal{O}$ computes $T$, then respond YES. If no such $E$ is found, then respond NO.

It suffices to show the procedure for answering MOCSP oracle queries runs in exponential time. Let $n = |x|$. First, we need to count the number of oracle circuits $E$ on $(\log|T| \leq c'n^c)$-inputs with size at most $s(n)$. The logarithm of the number of oracle circuit of size at most $s(|x|)$ on $(c'n^c)$-inputs with $t$ oracle functions is at most

$$O(s(n) \log(4 + t) + s(|x|) \log(c'n^c) \log(s(|x|) + \log(c'n^c))).$$

Since $t \leq 2c'^n$ and $s$ is polynomial in $n$, it is easy to see that the number of such circuits $E$ is at most exponential. Second, one can check if an oracle circuit $E$ satisfies $E^\mathcal{O}$ computes $T$ in time polynomial in $(|E| + |T| + |\mathcal{O}|)$ and hence exponential in $n$. As a result, $L \in \text{EXP}$, completing the proof.

**Theorem B.2.** If $\text{NP} \subseteq^P \text{MOCSP}$, then $\text{EXP} \neq \text{NP} \cap \text{P/poly}$. Consequently, $\text{EXP} \neq \text{ZPP}$.

**Proof.** For contradiction, suppose $\text{NP} \subseteq^P \text{MOCSP}$ and $\text{EXP} = \text{NP} \cap \text{P/poly}$. Then by Proposition B.1 $\text{NEXP} \subseteq \text{EXP} \subseteq \text{NP}$ contradicting the nondeterministic time hierarchy theorem [32].
Abstract

Recently, Dvir, Golovnev, and Weinstein have shown that sufficiently strong lower bounds for linear data structures would imply new bounds for rigid matrices. However, their result utilizes an algorithm that requires an NP oracle, and hence, the rigid matrices are not explicit. In this work, we derive an equivalence between rigidity and the systematic linear model of data structures. For the n-dimensional inner product problem with m queries, we prove that lower bounds on the query time imply rigidity lower bounds for the query set itself. In particular, an explicit lower bound of $\Omega(n^{d/2}/r)$ for $r$ redundant storage bits would yield better rigidity parameters than the best bounds due to Alon, Panigrahy, and Yekhanin. We also prove a converse result, showing that rigid matrices directly correspond to hard query sets for the systematic linear model. As an application, we prove that the set of vectors obtained from rank one binary matrices is rigid with parameters matching the known results for explicit sets. This implies that the vector-matrix-vector problem in the high error regime, improving a result of Chattopadhyay, Koucký, Loff, and Mukhopadhyay.

1 Introduction

A matrix is rigid if it is far in Hamming distance from low rank matrices; it is explicit if its entries are computable in polynomial time. A classic result of Valiant proves that explicit rigid matrices imply super-linear lower bounds for linear circuits [35], a major open problem in computational complexity [34, 37]. Implications of new lower bounds for communication complexity and other models are also known [24, 39]. Unfortunately, the current bounds for explicit matrices are very far from the required parameters [16, 33], and natural candidates (e.g., Fourier and Hadamard matrices) have been discovered to
be less rigid than desired [3, 12, 14]. This motivates alternative avenues for constructing rigid matrices. Recently, multiple connections between data structures and circuits have arisen [7, 11, 13, 38]. The premise of these results is that hard problems for these models may shed new light on rigid matrices and circuits. We take a similar angle, studying a generic linear problem for a model that resembles a depth-two circuit with linear gates.

Valiant’s result concerns arithmetic circuits computing the linear map \( v \mapsto Mv \) for a matrix \( M \). In other words, the circuit computes the inner products between \( v \) and the rows of \( M \). We study a related data structure problem, the inner product problem. The task is to preprocess an \( n \)-bit vector \( v \) to compute inner products \( \langle q, v \rangle \) over \( \mathbb{F}_2 \) for queries \( q \in Q \), where \( Q \subseteq \mathbb{F}_2^n \) is the query set. This problem generalizes the prefix-sum problem [17] and vector-matrix-vector problem [8, 23].

We consider solving this problem using a restricted data structure model, the systematic linear model. This model may only store \( v \) verbatim along with a small number \( r \ll n \) of redundant bits, which are the evaluations of linear functions of \( v \). To compute \( \langle q, v \rangle \) for \( q \in Q \), the query algorithm must output a linear function of these \( r \) bits along with any \( t \) bits of \( v \), where \( t \) is the query time. We motivate this model with a simple upper bound. Suppose that the query set \( Q \) happens to be close to an \( r \)-dimensional subspace \( U \). More precisely, assume that \( d_H (q, U) \leq t \) for any \( q \in Q \), where \( d_H (q, U) := \min_{u \in U} d_H (q, u) \) and \( d_H (q, u) \) denotes the Hamming distance. The systematic linear model will store \( r \) bits that correspond to inner products between \( v \) and some \( r \) vectors that form a basis for \( U \). The query algorithm computes \( \langle q, v \rangle \) by invoking the identity \( \langle q, v \rangle = \langle u, v \rangle + \langle q - u, v \rangle \), using any vector \( u \in U \) with \( d_H (q, u) \leq t \). Indeed, the \( r \) precomputed bits suffice to determine \( \langle u, v \rangle \), and at most \( t \) bits of \( v \) are needed to calculate \( \langle q - u, v \rangle \).

We observe that rigidity exactly captures the complexity of the inner product problem in the above model. This connection uses a notion of rigid sets, defined by Alon, Panigrahy and Yekhanin [5]. Our result shows that an efficient algorithm exists in the above model if and only if the query set is not rigid in their sense. Conversely, it is possible to derive new rigidity lower bounds by proving lower bounds for the systematic linear model. A parameter of interest is the size of the rigid set, which corresponds to the number of queries in the inner product problem.

Dvir, Golovnev, and Weinstein also demonstrate a connection between rigidity and a different linear model, which is a restriction of the cell probe model [13]. This model stores \( s \geq n \) linear functions, and the query algorithm outputs a linear function of \( t \) of these \( s \) bits. For the inner product problem with query set \( Q \), they show that a lower bound for linear data structures leads to a semi-explicit rigid set. When \( |Q| = m \), their result uses a \( \text{poly}(m) \) time algorithm that requires access to an \( \text{NP} \) oracle. Compared to their work, our connection preserves explicitness and offers a two-way equivalence via the systematic linear model. In particular, when \( c' n \leq r \leq cn \) for constants \( c', c < 1 \), a lower bound of \( t = \omega(\log m) \) in the systematic linear model implies that \( Q \) is rigid with better parameters than known results. Their work requires a lower bound of \( t = \omega(\log m \log n) \) against the linear model, and the resulting set is not explicit. Our results also extend to show that linear data structure lower bounds lead to explicit rigid matrices. However, compared to the work of Dvir, Golovnev, and Weinstein, we require stronger lower bounds to achieve new rigidity parameters.

As an application of our framework, we provide new results for the vector-matrix-vector problem. The task is to preprocess a 0-1 matrix \( M \) to compute \( u^\top M v \) when given vectors \( u, v \) as the query. The boolean semiring version of this problem has received much recent attention due to connections to the online matrix-vector multiplication conjecture [18]. Moreover, this problem has motivated the study of data structures for a super polynomial number of queries,
even when the output is binary [8, 9]. Other prior work has either studied binary output problems with $\text{poly}(n)$ queries (see e.g. [28, 30]) or achieved better lower bounds by looking at multi-output problems (see e.g. [10, 20]). In general, the vector-matrix-vector problem is a good testbed for proving better data structure lower bounds, because linear algebraic tools could provide new insights.

The $F_2$ variant of this problem specializes the inner product problem because $u^\top M v$ equals the inner product of $uv^\top$ and $M$ (viewed as vectors). The query set consists of $\sqrt{n} \times \sqrt{n}$ matrices with rank one; its size $m$ satisfies $\log m = \Theta(\sqrt{n})$. As another contribution, we lower bound the rigidity of this set, and consequently, we obtain a query time lower bound of $\Omega(\frac{n}{2} \log m) = \Omega(n^{3/2}/r)$ for the systematic linear model with redundancy $r \geq \sqrt{n}$. Any asymptotically better lower bounds for this problem (in the systematic linear model) would directly imply that this query set is rigid with better parameters than the currently known results for explicit matrices [4, 5].

As a final result, we prove a new cell probe lower bound for the vector-matrix-vector problem, without restrictions on the data structure. Our result improves the current best lower bound due to Chattopadhyay, Koucký, Loff, and Mukhopadhyay [9]. Our lower bound matches the limit of present techniques and achieves the current best time-space trade-off in terms of query set size.

1.1 Rigid sets, systematic linear model, and the inner product partial function

Throughout, let $m = m(n)$ and $t = t(n)$ and $r = r(n)$ denote positive integers, with $m \geq n \geq t, r$. Alon, Panigrahy and Yekhanin defined the following notion of a rigid set [5].

Definition (Rigid Set). A set $Q \subseteq F_2^n$ is $(r, t)$-rigid if for every subspace $U \subseteq F_2^n$ with dimension at most $r$, some vector $q \in Q$ has Hamming distance at least $t$ from all vectors in $U$, that is, $d_H(q, U) \geq t$.

We define $(r', t')$-rigid for non-integral $r', t'$ to mean $(\lceil r' \rceil, \lceil t' \rceil)$-rigid. It will be convenient to equate a set $Q$ with a matrix $M_Q$ by arranging vectors in $Q$ as rows in $M_Q$ in any order. If $Q$ is $(r, t)$-rigid and $|Q| = m$, then the corresponding matrix $M_Q \in F_2^{m \times n}$ is rigid in the usual sense: for any rank $r$ matrix $A$, some row in $(M_Q - A)$ contains at least $t$ nonzero entries. Hence, we may refer to rigid sets and rigid rectangular matrices interchangeably. A matrix in $F_2^{m \times n}$ (or a set of $n$-dimensional vectors) is explicit if every entry can be computed in $\text{poly}(n)$ time.

A random $m \times n$ matrix with $m = \text{poly}(n)$ will be $(cn, \delta n/\log n)$-rigid with high probability for some constants $c, \delta \in (0, 1)$. The key challenge here is to construct explicit rigid matrices, because they provide circuit lower bounds for functions that can be described in polynomial time [35]. Alon, Panigrahy and Yekhanin [5] followed by Alon and Cohen [4] exhibit multiple examples of explicit $m \times n$ matrices that are $(r, t)$-rigid with

$$t \geq \min \left\{ \frac{cn}{r} \log \frac{m}{r}, n \right\}$$

(1)

where $m \geq n$ and $c$ is a constant. Note that when $r = cn$, the current best bound is $t = \Omega(\log \frac{m}{r})$. For $m = \text{poly}(n)$, this amounts to $t = \Omega(\log n)$, exponentially far from the ideal bounds (i.e., matching random constructions). It is an important open problem to improve the dependence on $m$ in Eq. (1) and to find other candidate sets that may be rigid with better parameters.
Our connection between rigidity and data structures arises via the inner product problem. The task is to preprocess a vector \( v \in \mathbb{F}_2^n \) to compute inner products. The queries are specified by \( Q \subseteq \mathbb{F}_2^n \), which is called the query set. The data structure must compute the inner product of \( v \) and any \( q \in Q \), that is, \( (q, v) := \sum_{i=1}^n q[i] \cdot v[i] \mod 2 \), where \( q[i] \) denotes the \( i \)th coordinate of \( q \).

We now prove that if \( Q \) is \((r, t)\)-rigid, then \( T(Q, r) \geq t \) implies that \( Q \) is \((r, t)\)-rigid. Assume for contradiction that there is an \( r \)-dimensional subspace \( U \) such that \( d_H(q, U) < t \) for all \( q \in Q \). Let \( v \in \mathbb{F}_2^n \) be the input data. Store \( v \) along with the \( r \) bits \( \{b_1, v\}, \ldots, \{b_r, v\} \), where \( b_1, \ldots, b_r \) form a basis for \( U \). For every \( q \in Q \), there exists \( u_q \in U \) such that \( q - u_q \) has Hamming weight less than \( t \). Using the \( r \) redundant bits, the algorithm on query \( q \) can compute \( \langle u_q, v \rangle \) by writing \( u_q \) in terms of the stored basis vectors. Then, it computes \( \langle q - u_q, v \rangle \) by accessing fewer than \( t \) coordinates of \( v \). Since \( \langle q, v \rangle = \langle u_q, v \rangle + \langle q - u_q, v \rangle \), we have that \( T(Q, r) < t \), which is a contradiction.

We now prove that if \( Q \) is \((r, t)\)-rigid, then \( T(Q, r) \geq t \). Let \( e_1, \ldots, e_n \) denote the standard basis, and let \( k = T(Q, r) \) be the query time. We show that \( k \geq t \). Consider a systematic linear data structure whose redundant bits are given by \( \{a_1, v\}, \ldots, \{a_r, v\} \). Let \( U \) denote the span of \( \{a_1, \ldots, a_r\} \). As \( Q \) is \((r, t)\)-rigid, there exists \( q^* \in Q \) with \( d_H(q^*, U) \geq t \). When \( q^* \) is the query, assume that the query algorithm accesses the bits \( v_{i_1}, \ldots, v_{i_k} \) for indices \( i_1, \ldots, i_k \) to compute \( \langle q^*, v \rangle \). Now, define \( U' \) to be the span of \( \{a_1, \ldots, e_i, \ldots, e_{i_k}\} \). Observe that all points in \( U' \) are at distance at most \( k \) from \( U \). Thus, \( d_H(q^*, U) \leq d_H(q^*, U') + k \). We will show that \( d_H(q^*, U') = 0 \), which implies that \( k \geq t \). We claim that if \( d_H(q^*, U') \geq 1 \), then the query algorithm makes an error. Since \( d_H(q^*, U') \geq 1 \), there exists a vector \( y \) with
\langle y, q^* \rangle = 1. Moreover, this vector can be taken to be orthogonal to \( U' \) so that \( \langle y, x \rangle = \langle v, x \rangle = \langle v, y + v \rangle \) for every \( x \in U' \). In other words, for every \( x \in U' \) we have \( \langle y + v, x \rangle = \langle y, x \rangle + \langle v, x \rangle = \langle v, x \rangle \). Hence, the query algorithm sees the same values on input data \( y + v \) and \( v \) because it only accesses the input via vectors in \( U' \), and we have \( x \in U' \). Thus, the algorithm on query \( q^* \) must err either on input \( y + v \) or \( v \) because \( \langle q^*, y + v \rangle \neq \langle q^*, v \rangle \).

1.3 Relationship to the cell probe model and other models

The systematic linear model specializes the systematic model [8, 17]. The latter model still stores the input data \( x \in \mathbb{F}_2^n \) verbatim, and it also stores \( r < n \) bits that can be precomputed from \( x \), where these need not be linear functions of the input data. The query time is \( t \) if the query algorithm reads at most \( t \) bits from \( x \) to compute a query. The output can also be an arbitrary function of these \( t \) bits along with the \( r \) precomputed bits. The systematic linear model only makes sense for linear queries, whereas the systematic model applies to arbitrary query functions.

Yao’s cell probe model is the most general data structure model [40]. On input data \( x \in \mathbb{F}_2^n \), the data structure stores \( s \) cells, containing \( w \) bits that are arbitrary functions of \( x \). Here, \( w \) is the word size and \( s \) is the space. The query time is \( t \) if the algorithm accesses at most \( t \) cells to answer any query about \( x \) from a set of \( m \) possible query functions. There is a rich collection of lower bounds for this model (see e.g. [2, 15, 20, 26, 27, 28, 29]). The best lower bounds known are of the form

\[
t \geq \min \left\{ \frac{c \log m}{n}, \frac{cn}{w} \right\},
\]

where \( m \geq n \) is the number of queries and \( c \) is a constant. It is a long-standing problem to prove that \( t = \omega(\log m) \) for any explicit problem, even in the linear space regime \( s = O(n) \) and \( w = O(1) \).

A special case of the cell probe model is the linear model [1, 13]. The latter model stores \( s \geq n \) linear functions of \( x \) (implicitly \( w = 1 \) is fixed). The query time is \( t \) if the query algorithm reads at most \( t \) of these \( s \) bits to compute a query. The output is restricted to be a linear function of these \( t \) bits. A distinguishing aspect between linear and systematic linear is that in the latter model, the query algorithm is not charged for accessing the \( r \) precomputed bits. In Section 2, we compare the linear and systematic linear models in the context of rigidity and previous work [13].

Equivalences all the way down

We note that the systematic data structure model is identical to the common bits model defined by Valiant [36]. Corrigan-Gibbs and Kogan [11] demonstrate a relationship between the common bits model and a variant of the systematic model defined by Gal and Miltersen [17]. The common bits model is nothing but a certain depth two circuit, and the systematic linear model is simply the common bits model with the restriction that the common bits and output gates are linear functions [31]. Hence, in language of data structures, the linearization conjecture of Jukna and Schnitger posits that the systematic linear model is asymptotically as powerful as the systematic model for answering linear queries [19].

1.4 The vector-matrix-vector problem

We now define the vector-matrix-vector problem, which we call “the \( u^T M v \) problem” for short. Let \( n \) be a perfect square. After preprocessing a matrix \( M \in \mathbb{F}_2^{n \times \sqrt{n}} \), the goal is to output the binary value \( u^T M v \) for vectors \( u, v \in \mathbb{F}_2^{\sqrt{n}} \). It will be convenient to consider
a $\sqrt{n} \times \sqrt{n}$ matrix as an $n$-bit vector $\text{vec}(M)$ by concatenating consecutive rows. More formally, let $x = \text{vec}(M)$, and for $i \in \{1, 2, \ldots, n\}$, set $x[i] = M[a, b]$, where $a$ and $b$ satisfy $i = (a - 1)\sqrt{n} + b$ and $a, b \in \{1, 2, \ldots, \sqrt{n}\}$. Then, $u^t M v = \langle \text{vec}(u^t), \text{vec}(M) \rangle$. In this way we consider the $u^t M v$ problem a special case of the inner product problem. The query set is the collection of rank one binary matrices. Let $\Upsilon = F_2^n$ denote the set of vectors obtained from rank one binary matrices via $M \mapsto \text{vec}(M)$, that is,

$$\Upsilon := \left\{ \text{vec}(uv^t) \ \big| \ u, v \in F_2^{\sqrt{n} \times \sqrt{n}} \right\} \subseteq F_2^n.$$  

(3)

This set has size $|\Upsilon| = 2^{2\sqrt{n} - 2\sqrt{n+1} + 1}$.

A classic result of Artazarov, Dinic, Kronrod and Faradzev [6] provides a data structure with space $s = \text{poly}(n)$, word size $w = O(\log n)$, and time $t = O(n/\log n)$. In fact, this algorithm operates in the linear cell probe model. It is a central open question to determine whether $t = \Omega(n)$ is necessary in linear space regime, that is, when $s = O(n)$ and $w = O(1)$.

The current best cell probe lower bound for the $u^t M v$ problem is due to Chattopadhyay, Kamma, and Larsen [8] prove that $t$ and $r$ must satisfy $t \cdot r = \Omega(n^{3/2}/\log n)$ as long as $r \geq \sqrt{n}$. In the case of $r \leq \sqrt{n}$, they prove that $t = \Omega(n/\log n)$. As the systematic model subsumes the linear version of this model, combining their result with Theorem 1 implies that $\Upsilon$ is $(r, t)$-rigid with

$$t \geq \min \left\{ \frac{c\sqrt{n}}{\log \frac{\sqrt{n}}{n}}, \frac{cn}{w} \right\}$$

(4)

We know better lower bounds for the $u^t M v$ problem in the systematic model. Chakraborty, Kamma, and Larsen [8] prove that $t$ and $r$ must satisfy $t \cdot r = \Omega(n^{3/2}/\log n)$ as long as $r \geq \sqrt{n}$. In the case of $r \leq \sqrt{n}$, they prove that $t = \Omega(n/\log n)$. As the systematic model subsumes the linear version of this model, combining their result with Theorem 1 implies that $\Upsilon$ is $(r, t)$-rigid with

$$t = \Omega \left( \frac{n^{3/2}}{\max\{\sqrt{n}, r\} \cdot \log n} \right).$$

(5)

### 1.5 New results on the rigidity of $\Upsilon$ and the cell probe complexity of the $u^t M v$ problem

We lower bound the rigidity of $\Upsilon$, defined in Eq. (3). This also implies a lower bound in the systematic linear model. The proof is inspired by a result of Alon, Panigrah, and Yekahmin [5].

**Theorem 2.** Let $n \geq 1024$. The set $\Upsilon \subseteq F_2^n$ of rank one matrices is $(r, t)$-rigid with $t \geq \frac{n^{3/2}}{128 \cdot \max\{\sqrt{n}, r\}}$.

We improve the prior bound in Eq. (5) by an $\Omega(\log n)$ factor. For example, when $r \leq \sqrt{n}$, then $t = \Omega(n)$, and when $r = n/2$, then $t = \Omega(n^{1/2})$. Theorem 2 matches Eq. (1), the current best bound for explicit rigid sets. We do not know whether there is a subspace $U$ of linear dimension such that all elements of $\Upsilon$ are at distance $o(n)$ from $U$ (unlike for some set rigidity results, where the bounds are tight). As a corollary of Theorem 1, we immediately get that

$$T(\Upsilon, r) \geq \frac{n^{3/2}}{128 \cdot \max\{\sqrt{n}, r\}}.$$
In other words, we prove a lower bound for the $u^TMv$ problem in the systematic linear model that improves the prior bound by an $\Omega(\log n)$ factor. The proof of Theorem 2 appears in Section 3.

We also prove a general cell probe lower bound for the $u^TMv$ problem in the high error regime. Our result improves the previous lower bound in Eq. (4). For example, in the linear space regime, when $s = O(n)$ and $w = O(1)$, we show that $t = \Omega(\sqrt{n})$ while the prior result gives only $t = \Omega(\sqrt{n}/\log n)$.

\begin{theorem}
Let $M \in \mathbb{F}_2^{\sqrt{n} \times \sqrt{n}}$ be a matrix. If a randomized data structure with space $s$, word size $w$, and time $t$ correctly computes queries for the $u^TMv$ problem with probability at least $1/2 + 1/2e^{\sqrt{n}/64}$, then

$$t \geq \min\left\{ \frac{c\sqrt{n}}{\log \frac{s}{\alpha n}}, \frac{cn}{\alpha} \right\}$$

where $0 < c \leq 1/36$ is a universal constant and $\alpha := 2(w + \log \frac{sw}{n})$.
\end{theorem}

The prior work utilizes a general lifting result for two-way communication complexity from parity decision trees [9]. To obtain the improved bound, we use a variant of the cell sampling technique [21, 27] combined with a reduction to a new lower bound on one-way communication (via discrepancy). The modifications over standard techniques are needed to handle the high error regime for a binary output problem. We note that a recent result of Larsen, Weinstein and Yu also uses one-way communication to prove lower bounds for binary output problems for dynamic data structures [22]. However, their method seems limited to only handling zero error query algorithms. The proof of Theorem 3 appears in Section 4. Specifically, see Lemma 14 in Section 4 for the variant of cell sampling and see Theorem 11 in Section 4.1 for the discrepancy argument.

\section{Linear Data Structures and Rigidity}

In this section, we relate linear data structures and rigidity. As linear data structures are a special case of the cell probe model, we may obtain rigidity lower bounds from strong enough static data structure lower bounds (when the queries are linear). We also compare with Dvir, Golovnev, and Weinstein, who exhibit a similar connection [13]. We first provide some notation.

\begin{definition}
Let $Q \subseteq \mathbb{F}_2^n$ be a set. Define $\text{LT}(Q, s)$ to be the maximum over all $v \in \mathbb{F}_2^n$ of the minimum $t$ sufficient to compute the inner product $\langle q, v \rangle$ for every $q \in Q$ when the query algorithm’s output is a linear function of $t$ bits chosen from the $s$ precomputed linear functions of $v$.
\end{definition}

Table 1 provides a glimpse of our results on linear data structures along with a comparison to [13]. Recall that a set $Q \subseteq \mathbb{F}_2^n$ is explicit if each coordinate of an arbitrary element of the set can be computed in $\text{poly}(n)$ time. The prior work shows that sufficiently strong lower bounds against linear data structures will imply \textit{semi-explicit} rigid sets. A bit more formally, consider a data structure query set $Q \subseteq \mathbb{F}_2^n$ of size $m$ for the inner product problem. They show the following: If $\text{LT}(Q, c \cdot n) \geq t$ for some constant $c$, then there is a $(n'/2, t/\log n)$-rigid set $Q'$ of size at most $m$ contained in $\mathbb{F}_2^n$, where $n' \geq t$. However, the set $Q'$ is only semi-explicit in that it is in $P^{NP}$—every element can be computed by a $\text{poly}(m)$ time algorithm with access to an NP oracle.
Table 1: Comparison with [13, Theorem 7.1]: Let \( Q \subseteq \mathbb{F}_2^m \) of size \( m \) be a query set, \( c \geq 1 \) and \( \delta > 0 \) be constants, and let \( k = \text{LT}(Q, 3n/2) \). The second column states the lower bound on \( \text{LT}(Q, 3n/2) \) that implies existence of rigid sets whose parameters are given in the third column. All rigid sets have size at most \( \text{poly}(m) \) and are contained in \( \mathbb{F}_2^k \).

</table>

We now summarize a few differences between our work and [13]. Our result proves that polynomial lower bounds on the query time imply the existence of an explicit rigid set, which is in contrast to semi-explicit sets obtained by [13]. On the other hand, explicitness comes with a cost; when \( m = \text{poly}(n) \), we need much stronger data structure lower bounds to produce explicit rigid sets. When \( m \gg \text{poly}(n) \), the algorithm of [13] takes \( \text{poly}(m) \) time with access to an \( \text{NP} \) oracle to compute an element of the semi-explicit rigid set. For problems such as the \( \text{UTMV} \) problem, this is super polynomial time. The rest of this section concerns proving the following theorem, which implies all of our results in Table 1.

**Theorem 4.** Let \( k = \text{LT}(Q, 3n/2) \) and let \( Q \subseteq \mathbb{F}_2^m \) of size \( m \) be an explicit query set. There exists a set \( Q' \subseteq \mathbb{F}_2^k \) with size at most \( m \cdot \left\lceil \frac{n}{k} \right\rceil \), whose elements can be computed in \( \text{poly}(n) \) time. Moreover, if \( k \geq 2\sqrt{n} \), then \( Q' \) is explicit and \( (k/2, \omega(\log m)) \)-rigid.

Note that for every \( s \geq 3n/2 \), we have that \( \text{LT}(Q, 3n/2) \geq \text{LT}(Q, s) \). Hence, a sufficiently strong lower bound on \( \text{LT}(Q, s) \) for any \( s \geq 3n/2 \) will imply a rigidity lower bound. The following corollary shows the consequence of Theorem 4 for specific values of \( k \).

**Corollary 5.** Let \( k = \text{LT}(Q, 3n/2) \) and let \( Q \subseteq \mathbb{F}_2^m \) of size \( m \) be an explicit query set. There exists a set \( Q' \subseteq \mathbb{F}_2^k \) with size at most \( m \cdot \left\lceil \frac{n}{k} \right\rceil \), whose elements can be computed in \( \text{poly}(n) \) time. Moreover,

(a) If \( k = \omega(\sqrt{n \log m}) \), then \( Q' \) is explicit and \( (k/2, \omega(\log m)) \)-rigid.

(b) If \( k = \Omega(n^{(1+\delta)/2}) \) for some \( \delta > 0 \), then \( Q' \) is explicit and \( (k/2, \Omega(n^\delta)) \)-rigid.

Corollary 5(a) explains the first and last rows in Table 1, and Corollary 5(b) explains the middle row. Using Corollary 5(a) applied to \( \Upsilon \) with \( m = 2^{\sqrt{n}} - 2^{\sqrt{n}+1} + 1 \), we obtain that a lower bound of \( \text{LT}(\Upsilon, 3n/2) \geq \omega(n^{1/4}) \) would imply the existence of an explicit set \( Q' \subseteq \mathbb{F}_2^k \) of size \( 2^{\Omega(\sqrt{n})} \) that is \( (k/2, \omega(\sqrt{n})) \)-rigid. We note that it is an open question to prove \( \text{LT}(\Upsilon, 3n/2) \geq \omega(\sqrt{n}) \).

### 2.1 Proof of Theorem 4

We already know the equivalence between systematic linear data structures and rigidity (from Theorem 1). Therefore, it is sufficient to design a linear data structure from a systematic linear data structure to relate the former with rigidity.
Proposition 6. Let $Q \subseteq \mathbb{F}_p^2$ be a query set. If $T(Q,r) \leq t$, then $LT(Q,n+r) \leq t + r$.

Proof. Let $v \in \mathbb{F}_p^2$ be the input data and $(a_1,v), \ldots, (a_r,v)$ be the $r$ redundant bits stored by the systematic linear data structure. We now describe a linear data structure for $Q$ with space $n+r$ and query time $t+r$. The data structure stores $(a_1,v), \ldots, (a_r,v), (e_1,v), \ldots, (e_n,v)$, where $e_1, \ldots, e_n$ are the standard basis vectors. The query algorithm on $q \in Q$ first accesses $(a_1,v), \ldots, (a_r,v)$ and then simulates the query algorithm of the systematic linear data structure on $q$. Since the systematic linear data structure accesses at most $t$ bits from $(e_1,v), \ldots, (e_n,v)$, we can conclude that the query time is at most $t+r$.

We prove that if a set contained in a $n$-dimensional space is $(r,t)$-rigid, then there is another $(r, tr/n)$-rigid set which is contained in a $2r$-dimensional space.

Lemma 7. Let $r,n$ be positive integers. If $S \subseteq \mathbb{F}_p^2$ is $(r,t)$-rigid of size $m$, then there is a set $S' \subseteq \mathbb{F}_p^{2r}$ of size at most $m \cdot \left\lceil \frac{p}{2} \right\rceil$ that is $(r, tr/n)$-rigid. Moreover, if $S$ is explicit, then each element of $S'$ can be computed in $\text{poly}(n)$ time.

Proof. Let $k = \left\lfloor \frac{p}{2} \right\rfloor$ and define $S_1, \ldots, S_k \subseteq \mathbb{F}_p^{2r}$ by

$$S_i = \{(s[2r \cdot (i-1) + 1], \ldots, s[2r \cdot i]) \mid s \in S\}$$

for each $i \in \{1,2,\ldots,k\}$. Additionally, if $n/2r$ is not an integer, then define

$$S_{k+1} = \{(s[2r \cdot k + 1], \ldots, s[n], 0, \ldots, 0) \mid s \in S\} \subseteq \mathbb{F}_p^{2r};$$

otherwise set $S_{k+1} = \emptyset$. Define $S' = \bigcup_{i=1}^{k+1} S_i$. We claim that $S'$ is $(r, tr/n)$-rigid. Indeed, for the sake of contradiction assume that there is a subspace $V$ in $\mathbb{F}_p^{2r}$ of dimension $r$ such that all points in $S'$ are at a distance less than $tr/n$ from $V$. Consider the subspace $\{(v,v,\ldots,v) \mid v \in V\} \subseteq \mathbb{F}_p^{2r(k+1)}$ and project it to the first $n$ coordinates. Call this subspace $V'$, which has dimension $r$. Now, the distance of each point in $S$ from $V'$ is less than $\frac{tr}{n} \cdot \left\lceil \frac{p}{2} \right\rceil < t$, which is a contradiction.

Regarding the explicitness of $S'$, it is clear that all coordinates of an element of $S'$ correspond to some coordinate of a specific element of $S$. Since $S$ is explicit, we can infer that each element of $S'$ can be computed in $\text{poly}(n)$.

Proof of Theorem 4. We know that $LT(Q,3n/2) = k$ and $k \leq n$, Proposition 6 implies that $T(Q,k/2) \geq k/2$. Therefore by Theorem 1, we can conclude that $Q$ is $(k/2,k/2)$-rigid. Lemma 7 implies that there exists a set $Q'$ that is $(k/2, \frac{k^2}{4n})$-rigid and the size of $Q'$ is at most $m \cdot \left\lceil \frac{p}{2} \right\rceil$. Moreover, every element of $Q'$ can be computed in time $\text{poly}(n)$. Since $k/2 \geq \sqrt{n}$, we can conclude that $Q'$ is explicit.

3 Rigidy Lower Bounds for the Set of Rank One Matrices

Before proving Theorem 2, we present preliminaries. Recall two standard binomial estimates:

Proposition 8. For integers $0 \leq k \leq \ell$,

1. $\log \binom{\ell}{k} \leq k \cdot \log \frac{\ell}{k}$.
2. if $k \leq \ell/16$, then $\sum_{i=0}^{k} \binom{\ell}{i} \leq 2^\ell/4$.

We will need a useful property about the distance of a point from a subspace.

Lemma 9. Let $V \subseteq \mathbb{F}_p^2$ be a subspace. For $u_1,u_2 \in \mathbb{F}_p^2$, $d_H(u_1 + u_2, V) \leq d_H(u_1, V) + d_H(u_2, V)$.
Proof. Let $u'_1, u'_2 \in V$ be the points in $V$ closest to $u_1$ and $u_2$ respectively. Since $u'_1 + u'_2 \in V$, we have $d_H(u_1 + u_2, V) \leq d_H(u_1 + u_2, u'_1 + u'_2)$. Note that $d_H(u_1 + u_2, u'_1 + u'_2)$ is the number of ones in $u_1 + u_2 + u'_1 + u'_2$, which is at most the sum of the number of ones in $u_1 + u'_1$ and $u_2 + u'_2$. Therefore,

$$d_H(u_1 + u_2, u'_1 + u'_2) \leq d_H(u_1, u'_1) + d_H(u_2, u'_2) = d_H(u_1, V) + d_H(u_2, V).$$

A simple counting argument establishes the existence of a point that is far away in Hamming distance from a collection of large sized sets.

Lemma 10. Let $V_1, \ldots, V_k$ be subsets of $\mathbb{F}_2^n$, each of size at most $2^{\ell/2}$. If $k < 2^\ell/4$, then there is a vector $v \in \mathbb{F}_2^n$ such that the Hamming distance of $v$ from each $V_i$ is at least $\ell/16$.

Proof. For every $i \in [k]$, define $B(V_i, \ell/16) = \{|v \in \mathbb{F}_2^n \mid d_H(v, V_i) < \ell/16\}$. For any $u \in V_i$, the number of vectors in $\mathbb{F}_2^n$ at a distance less than $\ell/16$ from $u$ is at most $\sum_{j=0}^{\ell/16} (\frac{n}{\ell/16}) \leq 2^{\ell/4}$, where the inequality follows from Proposition 8. Hence $B(V_i, \ell/16) \leq |V_i| \cdot 2^\ell/4 = 2^{2\ell/4}$. Since

$$\sum_{i=1}^{k} B(V_i, \ell/16) \leq k \cdot 2^{2\ell/4} < 2^\ell,$$

there is a $v \in \mathbb{F}_2^n$ such that $d_H(v, V_i) \geq \ell/16$ for every $i \in [k]$.

3.1 Proof of Theorem 2

Let $V$ be any $r'$-dimensional subspace of $\mathbb{F}_2^n$, where $r' \geq r$ is the smallest positive integer divisible by $\sqrt{n}$. We first define the inverse of $\text{vec}(\cdot)$. For every $v \in \mathbb{F}_2^n$, define $\text{mat}(v)$ to be the matrix obtained by splitting $v$ into $\sqrt{n}$ length consecutive blocks and stacking each of these blocks to form a $\sqrt{n} \times \sqrt{n}$ matrix. Formally, $\text{mat}(v) \in \mathbb{F}_2^{\sqrt{n} \times \sqrt{n}}$ is such that $\text{mat}(v)[a, b] = v[(a-1)\sqrt{n} + b]$ for every $a, b \in [\sqrt{n}]$. Note that $\text{vec}(\text{mat}(v)) = v$.

We provide a brief outline of the proof of Theorem 2. The first step of the proof is to produce a vector in $v$ that is at a distance of $\Omega(n)$ from $V$ and $\text{mat}(v)$ is low rank. The rank being low is helpful as we can express $\text{mat}(v)$ as the sum of a small number of rank one matrices. Lemma 9 will then imply the existence of a rank one matrix that is far away from $V$. If we only cared about the existence of a vector that is far away from $V$, Lemma 10 would suffice. To ensure that simultaneously the rank is small, we first project $V$ on to $n/2r'$ coordinates indexed by consecutive blocks of each length $2r'$. Then we find a vector $v' \in \mathbb{F}_2^{2r'}$ that is far away from all the projections, which is still guaranteed by Lemma 10. Concatenating $v'$ with itself $2r'$ times has the property that its corresponding matrix is low rank.

Let $k = \max\left\{\left\lfloor\frac{n}{2r'}\right\rfloor, 1\right\}$. The goal is to find a $v \in \mathbb{F}_2^n$ such that $d_H(v, V) \geq k \cdot r'/8$ and the rank of $\text{mat}(v)$ is at most $2r'/\sqrt{n}$. If $\left\lceil\frac{n}{2r'}\right\rceil \geq 1$, then define $S_1, \ldots, S_k$ such that

$$S_i = \{(i-1) \cdot 2r' + 1, \ldots, i \cdot 2r'\}$$

for $i \in [k]$; otherwise, define $S_1 = [n]$. By definition, the dimension of $V_{S_i}$ is at most $r' = |S_i|/2$, for every $i \in [k]$. Since $r' \geq \sqrt{n}$ and $n \geq 1024$, we can infer that $k \leq 2r'$ and $2r' < 2r'^2$. Lemma 10 implies the existence of a $v' \in \mathbb{F}_2^{2r'}$ with the property that $d_H(v', V_{S_i}) \geq r'/8$ for every $i \in [k]$. Now define $v \in \mathbb{F}_2^n$ by

$$v[i] = \begin{cases} v'[i \mod 2r'] & \text{if } i \leq k \cdot 2r' \text{ and } i \mod 2r' \neq 0, \\ v'[2r'] & \text{if } i \leq k \cdot 2r' \text{ and } i \mod 2r' = 0, \\ 0 & \text{if } i > k2r', \end{cases}$$

Equivalence of Systematic Linear Data Structures and Matrix Rigidity
for all $i \in [n]$. In words, $v$ is the length $n$ vector that is the concatenation of $k$ copies of $v'$ along with the vector of zeros of length $n - 2kr'$. By the choice of $v$, we get that,

$$d_H(v, V) \geq \sum_{i=1}^{k} d_H(v, V_{S_i}) \geq k \cdot r'/8.$$

Moreover, the rank of $\text{mat}(v)$ is at most $2r'\sqrt{n}$. Therefore we can express

$$\text{mat}(v) = \sum_{i=1}^{2r'\sqrt{n}} a_i b_i^T,$$

for some $a_1, b_1, \ldots, a_{2r'\sqrt{n}}, b_{2r'\sqrt{n}} \in \mathbb{F}_{2^n}$. By Lemma 9, we know that

$$d_H(v, V) \leq \sum_{i=1}^{2r'\sqrt{n}} d_H(\text{vec}(a_i b_i^T), V).$$

Hence there exists an $i \in \left[ \frac{2r'}{\sqrt{n}} \right]$ such that $d_H(\text{vec}(a_i b_i^T), V) \geq \frac{\sqrt{n} \cdot k}{16} \geq \frac{n^{3/2}}{16r'}$. The observation that $r' \leq 2 \max\{\sqrt{n}, r\}$ completes the proof of the theorem.

**Remark (Extension to strong rigidity).** Alon and Cohen [4] defined the notion of strong rigidity; a set $Q \subseteq \mathbb{F}_2^n$ is $(r, t)$-strongly rigid if for every subspace of $\mathbb{F}_2^n$ of dimension at most $r$, the average distance of all the points to the subspace is at least $t$. For strong rigidity, the best lower bounds known for explicit sets are also of the form given in Eq. (1). We can show that $\Upsilon$ is $(r, t)$-strongly rigid with $t \geq \Omega \left( \frac{n^{3/2}}{\max\{\sqrt{n}, r\}} \right)$, matching the best strong rigidity bounds known for explicit sets. We sketch the proof here. We know that

$$u^T M v + (u + e_i)^T M v + u^T M (v + e_j) + (u + e_i)^T M (v + e_j) = b_i^T M b_j,$$

where $u, v \in \mathbb{F}_2^n$ and $e_1, \ldots, e_{\sqrt{n}}$ are standard basis vectors in $\mathbb{F}_2^n$. This fact can be used to prove that the matrix $M_{\Upsilon}$ corresponding to the set $\Upsilon$ is a generator matrix of a 4-query locally decodable code that tolerates a constant fraction of errors. A result of [13, Theorem 6] shows that Theorem 2 and the locally decodable code property of $M_{\Upsilon}$ imply the strong rigidity of $\Upsilon$.

## 4 Cell Probe Lower Bounds for the $u^T M v$ Problem

We know of two techniques for proving cell probe lower bounds matching Eq. (2). One is a technique of Pătraşcu and Thorup [30] who combined the communication complexity simulation of Miltersen [25] with multiple queries on the same input data. The other is the technique we use, which is based on cell sampling. Cell sampling typically requires one to work with large sized fields in order to handle errors. This large field size is needed to encode a large subset of the correctly computed queries using a small subset of cells. Here, we avoid encoding the subset of queries by a reduction to one-way communication complexity.

**Proof outline for Theorem 3**

By Yao’s min-max principle, it suffices to prove a lower bound on deterministic data structures. The hard distribution on the input data $M$ and query $uv^T$ we use is given by sampling $M, (u, v)$ uniformly and independently at random. We prove the theorem by contradiction,
and we start by assuming that the query time is small. The proof is carried out in three steps. First, modify the data structure so that for every \( M \), the fraction of queries correctly computed is at least \( 1/2 \). This modification only increases the query time and space by 1, and it can only increase the overall probability of the query algorithm being correct. Second, for a given \( M \), we use a variant of cell sampling (see Lemma 14) to obtain a small subset of cells \( S \) and a large subset of queries \( Q' \) such that all queries in \( Q' \) can be computed by only accessing cells in \( S \). Moreover,

\[
\Pr [\text{query algorithm correctly computes } u^\top Mv \mid uv^\top \in Q'] 
\approx \Pr [\text{query algorithm correctly computes } u^\top Mv].
\]

Third, we show that \( S \) can be used to design an efficient protocol for the following communication game: Alice’s input is \( M \) and Bob’s input is \( uv^\top \), and the goal is for Bob to correctly compute \( u^\top Mv \) on a sufficiently good fraction of the inputs after receiving a message from Alice.

We now describe the protocol (see Figure 1). Alice sends the locations and contents of \( S \). This ensures that Bob correctly computes \( u^\top Mv \) on a large fraction of queries in \( Q' \). Alice also communicates the majority value of \( u^\top Mv \) for \( uv^\top \notin Q' \) so that Bob is correct on half of his possible inputs that are not in \( Q' \). Overall, Bob’s output is correct on a sufficiently good fraction of all \( M, (u, v) \). Since we have assumed that the query time is small, we are able to show that Alice’s communication is small. This contradicts a lower bound on the communication complexity of this game. More precisely, we prove the following lower bound.

**Theorem 11.** Suppose that Alice gets a uniformly random matrix \( M \in \mathbb{F}_2^{\sqrt{n} \times \sqrt{n}} \) as input and Bob receives a uniform pair \( (u, v) \in \mathbb{F}_2^{\sqrt{n}} \times \mathbb{F}_2^{\sqrt{n}} \) as input. If Alice sends a deterministic message to Bob and Bob computes \( u^\top Mv \) such that

\[
\Pr_{M, u, v} [\text{Bob computes } u^\top Mv \text{ correctly}] \geq \frac{1}{2} + \frac{1}{2^{\sqrt{n}/8}},
\]

then Alice must communicate at least \( n/10 \) bits.

Previously, in the randomized two-way communication setting, Chattopadhyay, Koucký, Loff, and Mukhopadhyay [9] proved a lower bound for the game given in Theorem 11. Their lower bound implies the lower bound in Theorem 11 against randomized protocols. We need a lower bound against deterministic protocols under the uniform distribution on the inputs, and we cannot use their theorem as a black-box. We provide a straightforward proof of Theorem 11 in Section 4.1 by using the discrepancy method on a related communication game (resembling a direct sum, where Bob receives multiple inputs).

**Preliminaries**

Before presenting the proof of Theorem 3, we define some notation. For a real valued function \( f \) with a finite domain \( X \times Y, \mathbb{E}_{x,y} [f(x, y)] = \frac{1}{|X||Y|} \cdot \sum_{x \in X, y \in Y} f(x, y). \) Similarly, for \( X' \subseteq X, \mathbb{E}_{x,y} [f(x, y) \mid x \in X'] = \frac{1}{|X'||Y|} \cdot \sum_{x \in X', y \in Y} f(x, y). \) An argument in the proof of Theorem 3 requires an upper bound on the number of bits to encode the contents and locations of a subset of the cells, which is given by the following proposition.

**Proposition 12.** Let \( S \) be a subset of the cells of a data structure with word length \( w \) and size \( s \). Then, the contents and locations of \( S \) can be encoded in \(|S| \cdot w + |S| \cdot \log \frac{s}{|S|} \) bits.

**Proof.** Since each cell stores \( w \) bits, the number of bits to encode the contents is \(|S| \cdot w. \) Since the total number of cells is \( s \), the locations can be encoded in \( \log \left( \frac{s}{|S|} \right) \leq |S| \cdot \log \frac{s}{|S|} \) bits, where the inequality followed from Proposition 8.
4.1 Proof of Theorem 11

We start by discussing a slightly related problem, whose solution will lead to the proof strategy used here. Let $M \in \mathbb{F}_2^n \times \mathbb{F}_2^n$, $v \in \mathbb{F}_2^n$, and $e_1, \ldots, e_n$ be the standard basis vectors in $\mathbb{F}_2^n$. Consider the communication game in which Alice gets as input a uniform random $M$ and Bob gets as input a uniform random pair $(e_i, v)$. Bob’s goal is to compute $e_i^T M v$ after receiving a message from Alice. To understand how much Alice has to communicate, it is natural to look at the problem where Bob computes $\sum_{i=1}^n e_i^T M v_i$, where $v_1, \ldots, v_n \in \mathbb{F}_2^n$. Now observe that this sum is the same as the trace of $\left( \sum_{i=1}^n e_i v^T \right) M$, which in turn is the inner product between two $n$-bit vectors. The communication complexity of the inner product between two $n$-bit vectors is very well understood. Therefore, the lower bound on the amount of communication to compute the inner product between two $n$-bit vectors translates to a lower bound to the problem of computing $e_i^T M v$. This strategy applied to our setting gives us the following lower bound, which will be used to prove Theorem 11. Our presentation closely follows [32, Chapter 5].

Lemma 13. Let $0 < \epsilon \leq 1/2$ and let $k$ be an integer. Alice gets a uniformly random $M \in \mathbb{F}_2^n \times \mathbb{F}_2^n$ as input and Bob receives $k$ uniform pairs $(u_1, v_1), \ldots, (u_k, v_k) \in \mathbb{F}_2^n \times \mathbb{F}_2^n$ as input. Assume that Alice communicates a deterministic message to Bob, and Bob computes $\sum_{i=1}^k u_i^T M v_i$ with

$$\Pr_{M, u_1, v_1, \ldots, u_k, v_k} \left[ \text{Bob computes } \sum_{i=1}^k u_i^T M v_i \text{ correctly} \right] \geq \frac{1}{2} + \epsilon.$$ 

If $k \leq \sqrt{n}$, then Alice must communicate at least $9k \sqrt{n}/40 - \log(1/\epsilon)$ bits.

Proof. We use the discrepancy method to prove the communication lower bound. This requires upper bounding the discrepancy of the communication matrix under a given distribution. Let $R$ be a rectangle of the communication matrix, which is defined by indicator functions $A_R$ and $B_R$ such that $(M, ((u_1, v_1), \ldots, (u_k, v_k)))$ is in the rectangle $R$ if and only if $A_R(M) = 1$ and $B_R((u_1, v_1), \ldots, (u_k, v_k)) = 1$.

Consider the distribution in which $M, (u_1, v_1), \ldots, (u_k, v_k)$ are chosen at random uniformly and independently. We upper bound the discrepancy under this distribution. In other words, we claim that for every rectangle $R$,

$$\mathbb{E}_{M, (u_1, v_1), \ldots, (u_k, v_k)} \left[ A_R(M) B_R((u_1, v_1), \ldots, (u_k, v_k)) (-1)^{\sum_{i=1}^k u_i^T M v_i} \right] \leq 2 \cdot 2^{-9k \sqrt{n}/40}. \quad (6)$$

By a standard relation in communication complexity between the number of bits communicated and discrepancy of rectangles (see [32, Chapter 5, Theorem 5.2]), Eq. (6) implies that Alice must communicate at least $9k \sqrt{n}/40 - \log(1/\epsilon)$ bits. We are left with the proof of Eq. (6).

$$\left( \mathbb{E}_{(u_1, v_1), \ldots, (u_k, v_k)} \left[ B_R((u_1, v_1), \ldots, (u_k, v_k)) \mathbb{E}_M A_R(M)(-1)^{\sum_{i=1}^k u_i^T M v_i} \right] \right)^2 \leq \mathbb{E}_{(u_1, v_1), \ldots, (u_k, v_k)} \left[ B_R((u_1, v_1), \ldots, (u_k, v_k))^2 \left( \mathbb{E}_M A_R(M)(-1)^{\sum_{i=1}^k u_i^T M v_i} \right)^2 \right] \leq \mathbb{E}_{(u_1, v_1), \ldots, (u_k, v_k)} \left[ \left( \mathbb{E}_M A_R(M)(-1)^{\sum_{i=1}^k u_i^T M v_i} \right)^2 \right].$$
where the first inequality follows from convexity and the second one follows from the fact that $B_R ((u_1, v_1), \ldots, (u_k, v_k)) \leq 1$. Now

\[
\mathbb{E}_{(u_1, v_1), \ldots, (u_k, v_k)} \left( \mathbb{E}_M \left[ A_R(M)(-1)^{\sum_{i=1}^k u_i^\top M v_i} \right]^2 \right) \\
\leq \mathbb{E}_{(u_1, v_1), \ldots, (u_k, v_k), M, M'} \left[ A_R(M)A_R(M')(-1)^{\sum_{i=1}^k u_i^\top M v_i + \sum_{i=1}^k u_i^\top M' v_i} \right] \\
\leq \mathbb{E}_M \mathbb{E}_{M, M'} \left[ (-1)^{\sum_{i=1}^k u_i^\top (M + M') v_i} \right] \\
= \mathbb{E}_M \left[ \mathbb{E}_{(u, v)} \left[ (-1)^{u^\top M v} \right]^k \right],
\]

where the last equality follows from the fact that $(u_1, v_1), \ldots, (u_k, v_k)$ are chosen independent of each other and $M + M'$ is uniformly distributed as $M$ and $M'$ are chosen uniformly and independently at random. We are left with upper bounding $\mathbb{E}_M \left[ \mathbb{E}_{(u, v)} \left[ (-1)^{u^\top M v} \right]^k \right]$.

First note that if $M$ has rank $r$, then $\mathbb{E}_{u,v} [(-1)^{u^\top M v}] = 2^{-r}$. This is because,

\[
\mathbb{E}_{u,v} [(-1)^{u^\top M v}] = \frac{1}{2\sqrt{\pi}} \cdot \left( \sum_{v: Mv = 0} 1 \right) + \frac{1}{2\sqrt{\pi}} \cdot \left( \sum_{v: Mv \neq 0} \mathbb{E}_u [(-1)^{u^\top M v}] \right) \\\n= \frac{2\sqrt{\pi} - r}{2\sqrt{\pi}} + 0 = 2^{-r}.
\]

In addition, $\Pr_M [\text{rank of } M \leq 9\sqrt{n}/20] \leq 2^{-9n/10}$. Indeed, the number of matrices in $\mathbb{F}_2^{\sqrt{n}\times \sqrt{n}}$ of rank at most $k$ is at most

\[
\left( \frac{2\sqrt{n}}{k} \right) \cdot (2^k)^{\sqrt{n}} \leq 2^{2k\sqrt{n}}.
\]

Therefore, using the law of total expectation, we have that

\[
\mathbb{E}_M \left[ \mathbb{E}_{(u, v)} \left[ (-1)^{u^\top M v} \right]^k \right] \leq \Pr_M [\text{rank of } M \leq 9\sqrt{n}/20] + 2^{-9k\sqrt{n}/20} \leq 2 \cdot 2^{-9k\sqrt{n}/20},
\]

where the last inequality followed from the fact that $k \leq \sqrt{n}$.\hfill\blacktriangleleft

**Proof of Theorem 11.** Let $c$ be the number of bits communicated by Alice. We show that $c > n/10$. Define $Z_M(u, v) = 1$ if Bob correctly computes $u^\top M v$ and $Z_M(u, v) = -1$ otherwise. By the definition of $Z_M(u, v)$ and the lower bound on the probability of Bob’s computation being correct, we have that $\Pr_M [Z_M(u, v)] \geq 2 \cdot 2^{-\sqrt{n}/8}$.

We note that it is without loss of generality that $\mathbb{E}_{u,v} [Z_M(u, v)] \geq 0$ for every $M \in \mathbb{F}_2^{\sqrt{n}\times \sqrt{n}}$. This is because Alice on input $M$ can send an extra bit indicating whether $\mathbb{E}_{u,v} [Z_M(u, v)] < 0$ and Bob will flip his output accordingly.

We now use the given protocol to design a protocol for a new communication game: Suppose that Alice gets a uniformly random $M \in \mathbb{F}_2^{\sqrt{n}\times \sqrt{n}}$ as input and Bob receives $\sqrt{n}$ uniform pairs $(u_1, v_1), \ldots, (u_{\sqrt{n}}, v_{\sqrt{n}}) \in \mathbb{F}_2^{\sqrt{n}} \times \mathbb{F}_2^{\sqrt{n}}$ as input. We will use Lemma 13 with $k = \sqrt{n}$ to obtain the desired lower bound on $c$.\hfill\blacktriangleleft
We claim that there is a communication protocol in which Alice communicates $c$ bits and Bob computes $\sum_{i=1}^{\sqrt{\pi}} u_i^T M v_i$ such that

\[
\Pr_{M,u,v_1,\ldots,v_\sqrt{\pi}} \left[ \text{Bob computes } \sum_{i=1}^{\sqrt{\pi}} u_i^T M v_i \text{ correctly} \right] \geq \frac{1}{2} + \frac{2 \sqrt{\pi} - 1}{2c \pi}. \tag{7}
\]

Alice’s message is same as before, and Bob computes each of $\beta = \frac{2(\pi)}{n}$ where the first inequality follows from convexity of the function $g(x) = -\log x$. More convenient to work with the advantage than the probability of the query algorithm correctly computing $\beta$. Observe that $\Pr_{M,u,v} [\text{query algorithm computes } u^T M v \text{ correctly}] \geq \frac{1}{2} + 2^{-\sqrt{\pi}/16}$. By Yao’s minmax principle, this will imply a lower bound on randomized data structures.

We first modify the given data structure to ensure that for every $M \in \mathbb{F}_2^{n \times n}$, the probability that $u^T M v$ is correctly computed is at least $1/2$. Assume that we have a data structure with query time $t'$, space $s'$ and word size $w$. The modified data structure stores an extra bit indicating whether the $\Pr_{u,v} [\text{query algorithm computes } u^T M v \text{ correctly}]$ is less than $1/2$ or not for a given $M$. The query algorithm is the same as before, but accesses this extra bit to flip the output if it is set to 1. Clearly, the new data structure has query time $t = t' + 1$, space $s = s' + 1$ and word size $w$. Moreover, under this modification, we have

\[
\begin{align*}
\Pr_{M,u,v} & [\text{query algorithm computes } u^T M v \text{ correctly}] \geq 1/2 + 2^{-\sqrt{\pi}/16}. \\
\Pr_{M,u,v} & [\text{query algorithm computes } u^T M v \text{ correctly}] \geq 1/2 \text{ for every } M.
\end{align*}
\]

In the rest of the proof, we work with this modification and show that $t \geq \Omega \left( \min \left\{ \frac{n}{\beta \log \frac{2c}{\pi n}}, \frac{\sqrt{\pi}}{2^{256}} \right\} \right)$, where $\beta = 2(w \log sw/n)$. Observe that $\beta \leq n/256$; otherwise the lower bound is vacuous.

Assume by contradiction that $t \leq \min \left\{ \frac{n}{\beta \log \frac{2c}{\pi n}}, \frac{\sqrt{\pi}}{2^{256}} \right\}$. Define $Z_M(u,v) = 1$ if the query algorithm correctly computes $u^T M v$, and 0 otherwise. We have

\[
\mathbb{E}_{M,u,v} [Z_M(u,v)] = 2 \Pr_{M,u,v} [\text{query algorithm computes } u^T M v \text{ correctly}] - 1 \\
\geq 2 - 2^{-\sqrt{\pi}/16}. \tag{8}
\]

Note that $\mathbb{E}_{M,u,v} [Z_M(u,v)]$ captures the advantage or bias of the data structure - it is much more convenient to work with the advantage than the probability of the query algorithm being correct.
The following lemma, a variant of cell sampling, guarantees the existence of a small subset $S$ of cells such that a large number of queries $Q$ can be computed by only accessing $S$, and $E_{u,v} [Z_M (u, v) | wv \in Q] \approx E_{u,v} [Z_M (u, v)]$.

**Lemma 14.** Let $M \in \mathbb{F}^{|\mathbb{F}| \times |\mathbb{F}|}$, and define the sets $Q_1 = \{ uv^T \mid Z_M (u, v) = 1 \}$ and $Q_2 = \{ uv^T \mid Z_M (u, v) = -1 \}$. If $t \leq \min \left\{ \frac{n}{256\sqrt{\pi}}, \frac{\sqrt{n}}{256 \log \frac{n}{16t}} \right\}$, then there exists a subset of cells $S$, and subsets $Q'_1 \subseteq Q_1$ and $Q'_2 \subseteq Q_2$ such that

1. $|S| = \left\lceil \frac{n}{128t} \right\rceil$.
2. $Pr_{u,v} [uv^T \in Q'_1] - Pr_{u,v} [uv^T \in Q'_2] \geq E_{u,v} [Z_M (u, v)] \cdot 2^{-\sqrt{n}/16}$.
3. $Q'_1 \cup Q'_2$ is the set of all queries computed by accessing cells only in $S$.

We move on to the final step of the proof of Theorem 3. What is left is to design a one-way protocol using the sets guaranteed by Lemma 14. The protocol is described in Figure 1. We will show the validity of this protocol by showing that both Alice and Bob know the subset $Q'$ of queries. Since Alice’s input is $M$, she knows the contents of all the cells, which gives $S$. With regard to knowing $Q'$, the locations and contents of cells in $S$ suffice. This is because the query algorithm can be simulated on all queries to check if any cell outside of $S$ is being accessed. We are proving Theorem 3 by contradicting Theorem 11, which is achieved by the following.

**Lemma 15.** The protocol in Figure 1 has the following guarantees (a) Alice communicates fewer than $n/10$ bits, and (b) $Pr_{u,v} [\text{Bob computes } u^T M v \text{ correctly}] \geq 1/2 + 1/2\sqrt{n/8}$.

Now, we need to prove Lemmas 14 and 15 to complete the proof of Theorem 3.

**Proof of Lemma 14.** Let $S$ be a uniformly random subset of the cells of size $|S| = \left\lceil \frac{n}{128t} \right\rceil$. Define $D(u,v,S) = Z_M (u, v)$ if the query algorithm only accesses cells in $S$ to compute $u^T M v$; otherwise $D(u,v,S) = 0$. By linearity of expectation,

$$E_{u,v,S} [D(u, v, S)] = E_{u,v,\cdot} [Z_M (u, v)] \cdot \left( \frac{s-t}{s} \right)^{\left\lfloor \frac{t}{|S|} \right\rfloor} = E_{u,v,\cdot} [Z_M (u, v)] \cdot \frac{|S| \cdot (|S| - 1) \cdots (|S| - t + 1)}{s \cdot (s - 1) \cdots (s - t + 1)} \geq E_{u,v,\cdot} [Z_M (u, v)] \cdot \left( \frac{|S| - t}{s} \right)^t.$$
Recall that $|S| \geq \frac{n}{128\beta}$ and $t \leq \frac{n}{256\beta}$. Moreover, $\beta = 2(w + \log sw/n) \geq 2$. This implies that
\[
\left(\frac{|S| - t}{s}\right)^t \geq 2^{-t\log \frac{2sw}{n}} \geq 2^{-\frac{sw}{n}}.
\]
So we get $\mathbb{E}_{u,v,S}[D(u,v,S)] \geq \mathbb{E}_{u,v}[Z_M(u,v)] \cdot 2^{-\frac{sw}{n}}$. Therefore, there exists an $S$ such that
\[
\mathbb{E}_{u,v}[D(u,v,S)] \geq \mathbb{E}_{u,v}[Z_M(u,v)] \cdot 2^{-\frac{sw}{n}} \geq \mathbb{E}_{u,v}[Z_M(u,v)] \cdot 2^{-\sqrt{n/16}},
\]
where the last inequality follows from the fact that $16 \cdot t \cdot \log \frac{sw}{n} \leq \sqrt{n/16}$. Setting
\[
Q_1 = \{uv^T \in Q_1 \mid D(u,v,S) = 1\} \text{ and } Q_2 = \{uv^T \in Q_2 \mid D(u,v,S) = -1\}
\]
completes the proof of the lemma.

**Proof of Lemma 15.** We first prove part (a). Recall that $\beta = 2(w + \log \frac{sw}{n})$. Let $c$ be the number of bits communicated by Alice. By Proposition 12 and the definition of $\beta$,
\[
c \leq 1 + \left\lceil \frac{n}{128\beta}\right\rceil \cdot w + \left\lceil \frac{n}{128\beta}\right\rceil \cdot \log \frac{128\beta}{n}s\beta.
\]
Since $\beta \geq 2w$, $\beta \geq 2\log \frac{sw}{n}$ and $\beta \geq \log \beta$, we get that $w + \log \frac{sw}{n} \leq 2\beta$. Moreover, using the fact that $\left\lceil \frac{n}{128\beta}\right\rceil \leq \frac{n}{128\beta} + 1$, $\beta \geq 2$ and $\beta \leq n/256$, we can say that
\[
c \leq 1 + \frac{2n}{128} + 2\beta + \frac{n \log 128\beta}{128\beta} + \log 128e,
\]
where the last inequality follows from $n \geq 36$.

We now prove part (b) of the claim. Define $Z'_M(u,v) = 1$ if the Bob correctly computes $u^TMv$ and $Z'_M(u,v) = -1$ otherwise. The probability with which Bob correctly computes $u^TMv$ is given by $(1 + \mathbb{E}_{u,v}[Z'_M(u,v)])/2$. We will show that $\mathbb{E}_{u,v}[Z'_M(u,v)] \geq 2 \cdot 2^{-\sqrt{n/8}}$, which will imply that the probability of being correct is at least $1/2 + 2^{-\sqrt{n/8}}$.

Let $Q_1, Q_2, Q'_1, Q'_2$, and $Q'$ be as defined in the protocol in Figure 1. We first establish some properties about these sets. We know that $\Pr_{u,v}[uv^T \in Q_1] - \Pr_{u,v}[uv^T \in Q_2] = \mathbb{E}_{u,v}[Z_M(u,v)]$. Moreover, the application of Lemma 14 in the protocol is valid since $t \leq \frac{n}{256\beta}$, and hence
\[
\Pr_{u,v}[uv^T \in Q'_1] - \Pr_{u,v}[uv^T \in Q'_2] \geq \mathbb{E}_{u,v}[Z_M(u,v)] \cdot 2^{-\sqrt{n/16}}.
\]
(9)
Since Bob can simulate the query algorithm on $Q'$ by accessing only $S$, which is guaranteed by Lemma 14, we have
\[
\mathbb{E}_{u,v}[Z'_M(u,v)] = \Pr_{u,v}[uv^T \in Q'] \left(\Pr_{u,v}[uv^T \in Q'_1 \mid uv^T \in Q'] - \Pr_{u,v}[uv^T \in Q'_2 \mid uv^T \in Q']\right) + \\
\Pr_{u,v}[uv^T \notin Q'] \left(\Pr_{u,v}[u^TMv = b \mid uv^T \notin Q'] - \Pr_{u,v}[u^TMv = 1-b \mid uv^T \notin Q']\right) \geq \left(\Pr_{u,v}[uv^T \in Q'_1] - \Pr_{u,v}[uv^T \in Q'_2]\right) \geq \mathbb{E}_{u,v}[Z_M(u,v)] \cdot 2^{-\sqrt{n/16}},
\]
where the first inequality follows from the choice of $b$ and the second inequality used Eq. (9).
To conclude,

$$E_{M,u,v} [Z_M(u,v)] = E_{M} [ E_{u,v} [Z_M(u,v)]] \geq E_{M} [ E_{u,v} [Z_M(u,v)] \cdot 2^{-\sqrt{n/16}}]$$

$$\quad = E_{M,u,v} [Z_M(u,v)] \cdot 2^{-\sqrt{n/16}}$$

$$\quad = E_{M,u,v} [Z_M(u,v)] \cdot 2^{-\sqrt{n/16}} \geq 2 \cdot 2^{-\sqrt{n/8}},$$

where the last inequality follows from Eq. (8).

Abstract

Memory hard functions (MHFs) are an important cryptographic primitive that are used to design egalitarian proofs of work and in the construction of moderately expensive key-derivation functions resistant to brute-force attacks. Broadly speaking, MHFs can be divided into two categories: data-dependent memory hard functions (dMHFs) and data-independent memory hard functions (iMHFs). iMHFs are resistant to certain side-channel attacks as the memory access pattern induced by the honest evaluation algorithm is independent of the potentially sensitive input e.g., password. While dMHFs are potentially vulnerable to side-channel attacks (the induced memory access pattern might leak useful information to a brute-force attacker), they can achieve higher cumulative memory complexity (CMC) in comparison than an iMHF. In particular, any iMHF that can be evaluated in \( N \) steps on a sequential machine has CMC at most \( O\left(\frac{N^2 \log \log N}{\log N}\right) \). By contrast, the dMHF scrypt achieves maximal CMC \( \Omega(N^2) \) – though the CMC of scrypt would be reduced to just \( O(N) \) after a side-channel attack.

In this paper, we introduce the notion of computationally data-independent memory hard functions (ciMHFs). Intuitively, we require that memory access pattern induced by the (randomized) ciMHF evaluation algorithm appears to be independent from the standpoint of a computationally bounded eavesdropping attacker – even if the attacker selects the initial input. We then ask whether it is possible to circumvent known upper bound for iMHFs and build a ciMHF with CMC \( \Omega(N^2) \).

Surprisingly, we answer the question in the affirmative when the ciMHF evaluation algorithm is executed on a two-tiered memory architecture (RAM/Cache).

We introduce the notion of a \( k \)-restricted dynamic graph to quantify the continuum between unrestricted dMHFs (\( k = n \)) and iMHFs (\( k = 1 \)). For any \( \epsilon > 0 \) we show how to construct a \( k \)-restricted dynamic graph with \( k = \Omega(\epsilon N^{1-\epsilon}) \) that provably achieves maximum cumulative pebbling cost \( \Omega(N^2) \). We can use \( k \)-restricted dynamic graphs to build a ciMHF provided that cache is large enough to hold \( k \) hash outputs and the dynamic graph satisfies a certain property that we call “amenable to shuffling”. In particular, we prove that the induced memory access pattern is indistinguishable to a polynomial time attacker who can monitor the locations of read/write requests to RAM, but not cache. We also show that when \( k = o\left(\frac{N^{1/\log \log N}}{\log N}\right) \), then any \( k \)-restricted graph with constant indegree has cumulative pebbling cost \( o(N^2) \). Our results almost completely characterize the spectrum of \( k \)-restricted dynamic graphs.

1 Introduction

Memory hard functions (MHFs) [1, 27] are a central component in the design of password hashing functions [9], egalitarian proofs of work [21], and moderately hard key-derivation functions [27]. In the setting of password hashing, the objective is to design a function that can be computed relatively quickly on standard hardware for honest users, but is prohibitively expensive for an offline attacker to compute millions or billions of times while checking each password in a large cracking dictionary. The first property allows legitimate users to authenticate in a reasonable amount of time, while the latter goal discourages brute-force offline guessing attacks, even on low-entropy secrets such as passwords, PINs, and biometrics. The objective is complicated by attackers that use specialized hardware such as Field Programmable Gate Arrays (FPGAs) or Application Specific Integrated Circuits (ASICs) to significantly decrease computation costs by several orders of magnitude, compared to an honest user using standard hardware. For example, the Antminer S17, an ASIC Bitcoin miner exclusively configured for SHA256 hashes, can compute up to 56 trillion hashes per second, while the rate of many standard CPUs and GPUs are limited to 200 million hashes per second and 1 billion hashes per second, respectively.

Memory hard functions were developed on the observation that memory costs such as chip area tend to be equitable across different architectures. Therefore, the cost of evaluating an ideal “egalitarian” function would be dominated by memory costs. Blocki et al. [12] argued that key derivation functions without some form of memory hardness provide insufficient defense against a economically motivated offline attacker under the constraint of reasonable authentication times for honest users. In fact, most finalists in the 2015 Password Hashing Competition claimed some form of memory hardness [22, 9, 24]. To quantify these memory costs, memory hardness [27] considers the cost to build, obtain, and empower the necessary hardware to compute the function. One particular metric heavily considered by recent cryptanalysis [2, 5, 4, 3, 15] is cumulative memory complexity (CMC) [7], which measures the amortized cost of any parallel algorithm evaluating the function on several distinct inputs. Despite known hardness results for quantifying [16] or even approximating [13] a function’s CMC, even acquiring asymptotic bounds provide automatic bounds for other attractive metrics such as space-time complexity [26] or energy complexity [29, 14].

Data-Dependent vs. Data-Independent Memory Hard Functions

At a high level, memory hard functions can be categorized into two design paradigms: data-dependent memory hard functions (dMHFs) and data-independent memory hard functions (iMHFs). dMHFs induce memory access patterns that depend on the input, but can achieve
high memory hardness with potentially relatively easy constructions [6]. However, dMHFs are also vulnerable to side-channel attacks due to their inherent data dependent memory access patterns [8]. Examples of dMHFs include scrypt [27], Argon2d [10] and Boyen’s halting puzzles [19]. On the other hand, iMHFs have memory access patterns that are independent of the input, and therefore resist certain side-channel attacks such as cache timing [8]. Examples of iMHFs include 2015 Password Hashing Competition (PHC) winner Argon2i [9], Balloon Hashing [17] and DRSample [4]. iMHFs with high memory hardness can be more technically challenging to design, but even more concerning is the inability of iMHFs to be maximally memory hard.

Alwen and Blocki [2] proved that the CMC of any iMHF running in time $N$ is at most $O\left(\frac{N^2 \log \log N}{\log N}\right)$, while the dMHF scrypt has cumulative memory complexity $\Omega(N^2)$ [6], which matches the maximal amount and cannot be obtained by any iMHF. However, the cumulative memory complexity of a dMHF can be greatly decreased through a side-channel attack, if an attacker has learned the memory access pattern induced by the true input. Namely, a brute-force attacker can preemptively quit evaluation on a guess $y$ once it is clear that the induced memory access pattern on input $y$ differs from that on the true input $x$. For example, the cumulative memory complexity of scrypt after a side-channel attack is just $O(N)$.

Ideally, we would like to obtain a family of memory hard functions with cumulative memory complexity $\Omega(N^2)$ without any vulnerability to side-channel attacks. A natural approach would be some sort of hybrid between data-dependent and data-independent modes, such as Argon2id, which runs the MHF in data-independent mode for $\frac{N^2}{2}$ steps before switching to data-dependent mode for the final $\frac{N^2}{2}$ steps. Although the cumulative memory complexity is the maximal $\Omega(N^2)$ if there is no side-channel attack, the security still reduces to that of the underlying iMHF (e.g., Argon2i) if there is a side-channel attack. Hence even for a hybrid mode, the cumulative memory complexity is just $O\left(\frac{N^2 \log \log N}{\log N}\right)$ (or lower) in the face of a side-channel attack. Thus in this paper we ask:

In the presence of side-channel attacks, does there exist a family of functions with $\Omega(N^2)$ cumulative memory complexity?

### 1.1 Our Contributions

Surprisingly, we answer the above question in the affirmative for a natural class of side-channel attacks that observe the read/write memory locations. We introduce the concept of computationally data-independent memory hard functions to overcome the inability of data-independent memory hard functions to be maximally memory hard [2] without the common side-channel vulnerabilities of data-dependent memory hard functions [8]. Our constructions work by randomly “shuffling” memory blocks in cache before they are stored in RAM (where the attacker can observe the locations of read/write requests). Intuitively, each time $\text{MHF.Eval}(x)$ is executed the induced memory access pattern will appear different due to this scrambling step. The goal is to ensure that an attacker can not even distinguish between the observed memory access pattern on two known inputs $x \neq y$.

Towards this goal we define $k$-restricted dynamic graphs as a tool to quantify the continuum between dMHFs and iMHFs. Intuitively, in a $k$-restricted dynamic graph $G = (V = [N], E)$ we have $\text{parents}(v) = \{v-1, r(v)\}$ where the second (data-dependent) parent $r(v) \in R_v$ must be selected from a fixed (data-independent) restricted set $R_v \subseteq V$ of size $|R_v| \leq k$. When $k = 1$ the function is an iMHF (the parent $r(v) \in R_v$ of each node $v$ is fixed in a data-independent manner) and when $k = N$ the function is an unrestricted dMHF – scrypt
and Argon2d are both examples of unrestricted dMHFs. Intuitively, when \( k \) is small it becomes easier to scramble the labels \( R_v \) in memory so that the observed memory access patterns on two known inputs \( x \neq y \) are computationally indistinguishable.

We then develop a graph gadget that generates a family of ciMHFs using \( k \)-restricted graphs. Using this family of ciMHFs, we characterize the tradeoffs between the value of \( k \) and the overall cumulative memory cost of \( k \)-restricted graphs.

### Impossibility Results for Small \( k \)

Since \( k \)-restricted graphs correspond to iMHFs for \( k = 1 \), and it is known that \( \text{cc}(G) = \mathcal{O}\left( \frac{N^2 \log \log N}{\log N} \right) \) for any family \( G \) of iMHFs [2], then one might expect that it is impossible to obtain maximally memory hard ciMHFs for small \( k \). Indeed, our first result shows that this intuition is correct; we show that for any \( k = o\left( \frac{N^1 \log \log N}{\log N} \right) \), then any family of \( k \)-restricted graphs \( G \) with constant indegree has \( \text{cc}(G) = o(N^2) \).

**Theorem 1.** Let \( G \) be any family of \( k \)-restricted dynamic graphs with constant indeg\( G \). Then

\[
\text{cc}(G) = \mathcal{O}\left( \frac{N^2}{\log \log N} + N^{2-1/2 \log \log N} \sqrt{k^{1-1/\log \log N}} \right).
\]

Thus for \( k = o\left( \frac{N^1 \log \log N}{\log N} \right) \), we have \( \text{cc}(G) = o(N^2) \).

We prove this result in Theorem 10 and Corollary 11 in Section 3 by generalizing ideas from the pebbling attack of Alwen and Blocki [2] against any iMHF to \( k \)-restricted dynamic graphs graphs. The pebbling attack of Alwen and Blocki [2] exploited the fact that any constant indegree DAG \( G \) is somewhat depth-reducible e.g., we can always find a set \( \mathcal{S} \subseteq V(G) \) of size \( e = \mathcal{O}\left( \frac{N \log \log N}{\log N} \right) \) such that any path in \( G - \mathcal{S} \) has length at most \( d = \frac{N}{\log^2 N} \). The attack then proceeds in a number of light phases and balloon phases, where the goal of light phase \( i \) is to place pebbles on the interval \([ig + 1, (i + 1)g]\), for some parameter \( g \) to be optimized. At the same time, the attacker discards pebbles on all nodes \( v \) unless \( v \in \mathcal{S} \) or unless \( v \) is a parent of one of the next \( g \) nodes \([ig + 1, (i + 1)g]\) that we want to pebble. Once light phase \( i \) is completed, balloon phase \( i \) uses the pebbles on \( \mathcal{S} \) to recover all previously discarded pebbles. Note that balloon phase \( i \) thus promises that pebbles are placed on the parents of the nodes \([i+1)g + 1, (i + 2)g]\), so that light phase \( i + 1 \) can then be initiated and so forth.

One key difference is that we must maintain pebbles on all \( kg \) nodes \( u \in \bigcup_{v \in [ig + 1, (i + 1)g]} R_v \) that are “potential parents” of the next \( g \) nodes \([ig + 1, (i + 1)g]\). The total cost of the pebbling attack is \( \mathcal{O}\left( eN + gkN + \frac{N^2}{g} \right) \), which is identical to [2] when \( k = 1 \) for \((e, d)\)-reducible DAGs. In general for small values of \( k \), the dynamic pebbling strategy can still achieve cumulative memory cost \( o(N^2) \) after optimizing for \( g \).

### Maximally Hard \( k \)-restricted dMHF

In Section 4, we show how to construct a \( k \)-restricted dynamic graph for \( k = \mathcal{O}\left( \frac{N^{1-\epsilon}}{\epsilon} \right) \), which has cumulative pebbling cost \( \Omega(N^2) \) for any constant \( \epsilon > 0 \). Intuitively, our goal is to force the pebbling strategy to maintain \( \Omega(N) \) pebbles on the graph for \( \Omega(N) \) steps or pay a steep penalty. In particular, we want to ensure that if there are \( o(N) \) pebbles on the graph at time \( i \) then the cumulative pebbling cost to advance a pebble just \( 2k = \mathcal{O}(N) \) steps is at least \( \Omega(N^{2-\epsilon}) \) with high probability. This would imply that the pebbling strategy either keeps \( \Omega(N) \) pebbles on the graph for \( \Omega(N) \) steps or that the pebbling strategy pays a penalty of \( \Omega(N^{2-\epsilon}) \) at least \( \Omega\left( \frac{N}{k^2} \right) = \Omega(N^{\epsilon}) \) times. In either case the cumulative pebbling cost will be \( \Omega(N^2) \).
One of our building blocks is the “grates” construction of Schnitger [30] who, for any $\epsilon > 0$, showed how to construct a constant indegree DAG $G_{\epsilon}$ that is $(e,d)$-depth robust graph with $e = \Omega(N)$ and $d = \Omega(N^{1-\epsilon})$. Our second building block is the superconcentrator [28, 26] graph. By overlaying the DAG $G_{\epsilon}$ with a superconcentrator, we can spread out the data-dependent edges on the top layer of our graph to ensure that (with high probability) advancing a pebble $2k = \mathcal{O}(N^{\epsilon})$ steps on the top layer starting from a pebbling configuration with $o(N)$ pebbles on the graph requires us to repbble an $(e,d)$-depth robust graph with $e = \Omega(N)$ and $d = \Omega(N^{1-\epsilon})$. This is sufficient since Alwen et al. [5] showed that the cumulative pebbling cost of any $(e,d)$-depth robust graph is at least $ed$.

Open Question

We emphasize that we only show that any dynamic pebbling strategy for our $k$-restricted dynamic graph has cumulative cost $\Omega(N^2)$. This is not quite the same as showing that our dMHF has CMC $\Omega(N^2)$ in the parallel random oracle model. For static graphs, we know that the CMC of an iMHF is captured by the cumulative pebbling cost of the underlying DAG [7]. We take the dynamic pebbling lower bound as compelling evidence that the corresponding MHF has maximum cumulative memory cost. Nevertheless, proving (or disproving) that the CMC of a dMHF is captured by the cumulative cost of the optimal dynamic pebbling strategy for the underlying dynamic graph is still an open question that is outside the scope of the current work.

ciMHF Implementation Through Shuffling

The only problem is that the above $k$-restricted dynamic graph is actually a data-dependent construction; once the input $x$ is fixed, the memory access patterns of the above construction is completely deterministic! Thus a side-channel attacker that obtains a memory access pattern will possibly be able to distinguish between future inputs. Our solution is to have a hidden random key $K$ for each separate evaluation of the password hash. The hidden random key $K$ does not alter the hash value of $x$ in any manner, so we emphasize that there is no need to know the value of the hidden key $K$ to perform computation. However, each computation using a separate value of $K$ induces a different memory access pattern, so that no information is revealed to side-channel attackers looking at locations of read/write instructions.

Let $L$ be a set of the last $N$ consecutive nodes from our previous graph construction, which we suppose is called $G_0$. We form $G$ by appending a path of length $N$ to the end of $G_0$. We introduce a gadget that partitions the nodes in $L$ into blocks $B_1, B_2, \ldots, B_{N/k}$ of size $k$ each. We then enforce that for $i \in [N]$ and $j = i \mod k$, the $i^{\text{th}}$ node in the final $N$ nodes of $G$ has a parent selected uniformly at random from $B_{j+1}$, depending on the input $x$. Thus to compute the label of $i$, the evaluation algorithm should know the labels of all nodes in $B_{j+1}$.

We allow the evaluation algorithm to manipulate the locations of these labels so that the output of the algorithm remains the same, but each computation induces a different memory access pattern. Specifically, the random key $K$ induces a shuffling of the locations of the information within each block of the block partition gadget. Thus if the size of each block is sufficiently large, then with high probability, two separate computations of the hash for the same password will yield distinct memory access patterns, effectively computationally data-independent. Then informally, a side-channel attacker will not be able to use the memory access patterns to distinguish between future inputs.
In fact, this approach works for a general class of graphs satisfying a property that we call “amenable to shuffling”. We characterize the properties of the dynamic graphs that are amenable to shuffling in Section 5 and show that k-restricted dynamic graphs that are amenable to shuffling can be used in the design of MHFs to yield computationally data-independent sequential evaluation algorithms.

> **Theorem 2.** For each DAG $G$ that is amenable to shuffling, there exists a computationally data-independent sequential evaluation algorithm computing a MHF based on the graph $G$ that runs in time $O(N)$. (Informal, see Theorem 24.)

We believe that our techniques for converting graphs that are amenable to shuffling to ciMHFs may be of independent interest.

Finally, we provide a version of our dMHF with $\Omega(N^2)$ cumulative memory complexity that is amenable to shuffling. Combining this maximally hard k-restricted dMHF using a DAG that is amenable to shuffling with Theorem 2, we obtain a maximally hard ciMHF.

> **Theorem 3.** Let $0 < \epsilon < 1$ be a constant and $k = \Omega(N^\epsilon)$. Then there exists a family $G$ of $k$-restricted graphs with $\text{cc}(G) = \Omega(N^2)$ that is amenable to shuffling.

We prove Theorem 3 in Section 6, introducing the necessary formalities for computationally data-independent memory hard functions and the underlying systems model. Our results in Theorem 1 and Theorem 3 almost completely characterize the spectrum of $k$-restricted graphs. In fact, for a graph $G$ drawn uniformly at random from our distribution $G$ in Theorem 3 and any pebbling strategy $S$, not only do we have $\mathbb{E}_{G \sim G}[\text{cc}(S,G)] = \Omega(N^2)$, but we also have $\text{cc}(S,G) = \Omega(N^2)$ with high probability.

### 2 Preliminaries

We use the notation $[N]$ to denote the set $\{0, 1, \ldots, N-1\}$. For two numbers $x$ and $y$, we use $x \circ y$ to denote their concatenation.

Given a directed acyclic graph (DAG) $G = (V, E)$ and a node $v \in V$, we use $\text{parents}_G(v) = \{u : (u, v) \in E\}$ to denote the parents of node $v$. We use $\text{ancestors}_G(v) = \bigcup_{i \geq 1} \text{parents}_G^i(v)$ to denote the set of all ancestors of $v$ — here, $\text{parents}_G^0(v) = \text{parents}_G(\text{parents}_G(v))$ and $\text{parents}_G^{i+1}(v) = \text{parents}_G(\text{parents}_G^i(v))$. We use $\text{indeg}(v) = |\text{parents}(v)|$ to denote the number of incoming edges into $v$ and define $\text{ind}(G) = \max_{v \in V} \text{indeg}(v)$. Given a set $S \subseteq V$, we use $G - S$ to refer to the graph obtained by deleting all nodes in $S$ and all edges incident to $S$. We use $\text{depth}(G)$ to denote the number of nodes in the longest directed path in $G$.

> **Definition 4.** A DAG $G = (V, E)$ is $(e, d)$-reducible if there exists a subset $S \subseteq V$ of size $|S| \leq e$ such that any directed path $P$ in $G$ of length $d$ contains at least one node in $S$. We call such a set $S$ a depth-reducing set. If $G$ is not $(e, d)$-reducible, then we say that $G$ is $(e, d)$-depth robust.

For a DAG $G = (V = [N], E)$, we use $G_{\leq i}$ to denote the subgraph of $G$ induced by $[i]$. In other words, $G_{\leq i} = (V', E')$ for $V' = [i]$ and $E' = \{(a, b) : (a, b) \in E \mid a, b \leq i\}$.

### The Parallel Random Oracle Model

We review the parallel random oracle model (pROM), as introduced by Alwen and Serbinenko [7]. There exists a probabilistic algorithm $A^\mathcal{H}$ that serves as the main computational unit, where $A^\mathcal{H}$ has access to an arbitrary number of parallel copies of an oracle $\mathcal{H}$ sampled uniformly at random from an oracle set $\mathcal{H}$ and proceeds to do computation in a number of
We say that the graph is cumulative pebbling cost (parallel) order. We define over an alphabet a dynamic graph an edge distribution \( v \). We now define a labeling of a graph \( H \) sorted lexicographically by node index. If there is a single sink node \( x \), then \( f_{G,H}(x) = L_{G,H,x}(s_G) \). We omit the subscripts \( G,H \) when the dependency on the graph \( G \) and hash function \( H \) is clear. For a distribution of dynamic graphs \( G \), we say \( f_{G,H}(x) = f_{G,H}(x) \) once a dynamic graph \( G \) has been determined from the choice of \( H \) and \( x \).

The Ideal Cipher Model

In the ideal cipher model (ICM), there is a publicly available random block cipher, which has a \( k \)-bit key \( K \) and an \( N \) bit input and output. Equivalently, all parties, including any honest parties and adversaries, have access to a family of \( 2^k \) independent random permutations of \([N]\). Moreover for any given key \( K \) and \( x \in [N] \), both encryption \( \text{Enc}(K,x) \) and decryption \( \text{Dec}(K,x) \) queries can be made to the random block cipher.

Graph Pebbling

The goal of the (black) pebbling game is to place pebbles on all sink nodes of some input directed acyclic graph (DAG) \( G = (V,E) \). The game proceeds in rounds, and each round \( i \) consists of a number of pebbles \( P_i \subseteq V \) placed on a subset of the vertices. Initially, the graph is unpebbled, \( P_0 = \emptyset \), and in each round \( i \geq 1 \), we may place a pebble on \( v \in P_i \) if either all parents of \( v \) contained pebbles in the previous round (\( \text{parents}(v) \subseteq P_{i-1} \)) or if \( v \) already contained a pebble in the previous round (\( v \in P_{i-1} \)). In the sequential pebbling game, at most one new pebble can be placed on the graph in any round (i.e., \( |P_i \setminus P_{i-1}| \leq 1 \)), but this restriction does not apply in the parallel pebbling game.

We use \( P_G^{\parallel} \) to denote the set of all valid parallel pebblings of a fixed graph \( G \). The cumulative cost of a pebbling \( P = (P_1,\ldots,P_t) \in P_G^{\parallel} \) is the quantity \( \text{cc}(P) := |P_1| + \ldots + |P_t| \) that represents the sum of the number of pebbles on the graph during every round. The (parallel) cumulative pebbling cost of the fixed graph \( G \), denoted \( \text{cc}(G) := \min_{P \in P_G^{\parallel}} \text{cc}(P) \), is the cumulative cost of the best legal pebbling of \( G \).

Definition 5 (Dynamic/Static Pebbling Graph). We define a dynamic pebbling graph as a distribution \( \mathcal{G} \) over directed acyclic graphs \( G = (V = [N],E) \) with edges \( E = \{(i-1,i) : i \leq N\} \cup \{r(i),i) : i \leq N \} \), where \( r(i) < i-1 \) is a randomly chosen directed edge. We say that an edge \( r(i),i) \) is dynamic if \( r(i) \) is not chosen until a black pebbled is placed on node \( i-1 \). We say that the graph is static if none of the edges are dynamic.

We now define a labeling of a graph \( G \).

Definition 6. Given a DAG \( G = (V = [N],E) \) and a random oracle function \( H : \Sigma^* \rightarrow \Sigma^w \) over an alphabet \( \Sigma \), we define the labeling of graph \( G \) as \( L_{G,H} : \Sigma^* \rightarrow \Sigma^* \). In particular, given an input \( x \) the \((H,x)\) labeling of \( G \) is defined recursively by

\[
L_{G,H,x}(v) = \begin{cases} H(v \circ x), & \text{indeg}(v) = 0 \\
H(v \circ L_{G,H,x}(v_1) \circ \cdots \circ L_{G,H,x}(v_d)), & \text{indeg}(v) > 0,
\end{cases}
\]

where \( v_1,\ldots,v_d \) are the parents of \( v \) in \( G \), according to some predetermined lexicographical order. We define \( f_{G,H}(x) = L_{G,H,x}(s_1) \circ \cdots \circ L_{G,H,x}(s_k) \), where \( s_1,\ldots,s_k \) are the sinks of \( G \) sorted lexicographically by node index. If there is a single sink node \( s_G \) then \( f_{G,H}(x) = L_{G,H,x}(s_G) \). We omit the subscripts \( G,H \) when the dependency on the graph \( G \) and hash function \( H \) is clear. For a distribution of dynamic graphs \( \mathcal{G} \), we say \( f_{G,H}(x) = f_{G,H}(x) \) once a dynamic graph \( G \) has been determined from the choice of \( H \) and \( x \).
For a node $i$, we define $\text{PotentialParents}(i)$ to be set $Y_i$ of minimal size such that $\Pr[y(i) \in Y_i] = 1$. We now define $k$-restricted dynamic graphs, which can characterize both dMHFs and iMHFs.

**Definition 7** ($k$-Restricted Dynamic Graph). We say that a dynamic pebbling graph $G$ is $k$-restricted if for all $i$, $\text{PotentialParents}(i) \leq k$.

Observe that $k = 1$ corresponds to an iMHF while $k = N$ corresponds to a dMHF. Hence, $k$-restricted dynamic graphs can be viewed as spectrum between dMHFs and iMHFs.

We define the cumulative cost of pebbling a dynamic graph similar to the definition of cumulative cost of pebblings on static graphs. We first require the following definition of a dynamic pebbling strategy:

**Definition 8** (Dynamic Pebbling Strategy). A dynamic pebbling strategy $S$ is a function that takes as input

1. an integer $i \leq N$  
2. an initial pebbling configuration $P_0^i \subseteq [i]$ with $i \in P_0^i$  
3. a partial graph $G_{\leq i+1}$

The output of $S(i, P_0^i, G_{\leq i+1})$ is a legal sequence of pebbling moves $P^i_1, \ldots, P^i_r$ that will be used in the next phase, to place a pebble on node $i + 1$, so that $i + 1 \in P^i_r \subseteq [i + 1]$. Given $G \sim \mathcal{G}$ we can abuse notation and write $S(G)$ for the valid pebbling produced by $S$ on the graph $G$ i.e., $P_0^i, \ldots, P_0^i, P_1^{r_1}, \ldots, P_1^{r_1}, \ldots, P_{r_{N−1}}^{N−1}, \ldots, P_{r_{N−1}}^{N−1}$. Here, $P_i^{r_i} = S(i, P_0^i, G_{\leq i+1})$ where $P_0^i = P_{r_{i−1}}^{r_{i−1}}$ and for $i = 1$ we set $P_0^0 = \emptyset$.

We thus define $\text{cc}(S, G)$ to the pebbling cost of strategy $S$ when we sample a dynamic graph $G$ and $\text{cc}(S, G) = \mathbb{E}_{G \sim \mathcal{G}}[\text{cc}(S, G)]$. Finally, we define $\text{cc}(G) = \min_S \text{cc}(S, G)$, where the minimum is taken over all dynamic pebbling strategies $S$. More generally, we define $\text{cc}(S, G, \delta) = \max\{k : \Pr_{G \sim \mathcal{G}}[\text{cc}(S, G) \geq k] \geq 1 - \delta\}$. Fixing $\delta$ to be some negligible function of $N$, we can define $\text{cc}_\delta(G) = \min_S \text{cc}(S, G, \delta)$.

### 3 General Attack Against $k$-Restricted Graphs

In this section, we describe a general attack against $k$-restricted graphs. We show that the attack incurs cost $o(N^2)$ for $k = o\left(N^{1/\log \log N}\right)$, proving that there is no maximally memory hard $k$-restricted graph for small $k$.

We first require the following formulation of Valiant’s Lemma, which shows the existence of a subroutine $\text{Valiant}(G, e, d)$ to find a depth-reducing set $S$ of size at most $e$ within a graph $G$, for $e = \frac{\eta d N}{\log(N)−\eta}$ and $d = \frac{N}{2\eta}$, where $\eta > 0$.

**Lemma 9** (Valiant’s Lemma). [32] For any DAG $G = (V, E)$ with $N$ nodes, indegree $\delta$, and $\eta > 0$, there exists an efficient algorithm $\text{Valiant}(G, e, d)$ to compute a set $S$ of size $|S| \leq e = \frac{\eta d N}{\log(N)−\eta}$ such that $\text{depth}(G - S) \leq d := \frac{N}{2\eta}$.

The high level intuition of the generic attack is as follows. By Valiant’s Lemma (Lemma 9), $G \sim \mathcal{G}$ is $(e, d)$-reducible for $e = \frac{\eta d N}{\log(N)−\eta}$ and $d = \frac{N}{2\eta}$. We will construct a dynamic pebbling strategy $A$ that for all times $t$, maintains a depth-reducing set $S_t$ such that $\text{depth}(G_t - S_t) \leq d$, where $G_t$ is the portion of $G$ revealed after running $A$ for time $t$, $G_t = G_{\leq t}$ for $i = 1 + \max \bigcup_{j=1}^t P_j$, where each $P_j \subseteq [N]$ represents the set of pebbled nodes during round $j$. Observe that for any $i$, $G_{\leq i}$ is $(e, d)$-reducible and hence $G_t$ is also $(e, d)$-reducible for all times $t$. Thus, the depth reducing set $S_t$ has size at most $e$ for all times $t$ and can be computed by a subroutine $\text{Valiant}$, by Lemma 9. We now describe how $A$ maintains this depth-reducing set through a series of light phases and balloon phases.
We first set a parameter \( g \) that we will eventually optimize. The goal of each light phase \( i \) is to pebble the next \( g \) nodes that have yet to be revealed. That is, if \( x_i \) is the largest node for which \( A \) has placed a pebble at some point prior to light phase \( i \), then the goal of light phase \( i \) is to pebble the interval \([x_i + 1, x_i + g)\]. To begin light phase \( i \) at some time \( t_i \), we require that \( \{\text{PotentialParents}([x_i + 1, x_i + g]) \cup S_{t_i} \} \subseteq P_i \) for some depth-reducing set \( S_{t_i} \) of size at most \( e \), such that \( \text{depth}(G_{t_i} - S_{t_i}) \leq d \). Once this pre-condition is met, then light phase \( i \) simply takes \( g \) steps to pebble \([x_i + 1, x_i + g]\), since pebbles are already placed on \( \text{PotentialParents}([x_i + 1, x_i + g]) \). Hence, the post-condition of light phase \( i \) at some time \( u_i \) is pebbles on the node \( x_i + g \) and some depth-reducing set \( S_{u_i} \) of size at most \( e \), such that \( \text{depth}(G_{u_i} - S_{u_i}) \leq d \).

The goal of each balloon phase \( i \) is to place pebbles on all revealed nodes of the graph, to meet the pre-condition of light phase \( i + 1 \). To begin balloon phase \( i \) at some time \( r_i \), we first have a necessary pre-condition that pebbles are placed on some depth-reducing set \( S_{r_i} \) of size at most \( e \) such that \( \text{depth}(G_{r_i} - S_{r_i}) \leq d \). Once this pre-condition is met, then balloon phase \( i \) simply takes \( d \) steps to pebble the entire graph \( G_{r_i} \), meeting the post-condition of balloon phase \( i \).

We now formally prove the cumulative memory complexity of the attack in Algorithm 1.

\[ \text{cc}(G) = O\left(\frac{N^2}{\log \log N} + N^{2-1/2 \log \log N} \sqrt{k^{1-1/\log \log N}}\right). \]

**Proof.** We analyze the cost of the pebbling strategy of Algorithm 1. Since \( G \) is drawn from a distribution of \( k \)-restricted dynamic graphs, then for any node \( x_i \), \( \tau(x_i) \) must be one of at most \( k \) labels. Thus for any consecutive \( g \) nodes, \( |\text{PotentialParents}([x_i + 1, x_i + g])| \leq gk \). Hence it suffices to keep \( gk \) pebbles on the set of potential parents \( \text{PotentialParents}([x_i + 1, x_i + g]) \) to pebble the interval \([x_i + 1, x_i + g]\), as well as a depth-reducing set of size at most \( e \), for each of the \( g \) steps during light phase \( i \). On the other hand, balloon phase \( i \) takes \( d \) steps, each of which trivially contains at most \( N \) pebbles.

\( A \) proceeds using \( \frac{N}{g} \) total rounds of light and balloon phases, by pebbling \( g \) consecutive nodes at a time. Therefore, the total cost of the attack is \( O\left(Ngk + Ne + \frac{N}{g} \cdot dN\right) \), where the first and second terms originate from the cost of the light phases and the third term results from the cost of the balloon phases. Since we set \( e = \frac{N^2}{\log(N)^{1-\eta}} \) and \( d = \frac{N^2}{\log N} \) from Valiant’s Lemma (Lemma 9) so that the total cost is \( O\left(\frac{N^2 g^2}{\log(N)^{1-\eta}} + Ngk + \frac{N^3}{2^\eta}\right) \).

By setting \( g = \frac{N}{\sqrt{k^{2^\eta}}} \), the total cost is \( O\left(\frac{N^2 g^2}{\log(N)^{1-\eta}} + N^2 \sqrt{k^{2^\eta}}\right) \). Finally, by setting \( \eta = \frac{\log k + \log N - \log g}{\log \log N} \), the total cost is \( O\left(\frac{N^2}{\log N} + N^{2-1/2 \log \log N} \sqrt{k^{1-1/\log \log N}}\right). \)

Note that if \( k = o(N^{1/\log \log N}) \), then \( \text{cc}(G) = o(N^2) \).

**Corollary 11.** Let \( G \) be any \( k \)-restricted dynamic graph with \( k = o(N^{1/\log \log N}) \) and constant indegree. Then \( \text{cc}(G) = o(N^2) \).
Algorithm 1: Generic pebbling strategy against dynamic DAG $G$.

Input: An integer $i$, an initial pebbling configuration $P_0^i \subseteq [i]$ with $i \in P_0^i$, a partial graph $G_{\leq i+1}$, and parameters $d, e, g$.

Output: A legal pebbling of $G_{\leq i+1}$.

1. invariant $\leftarrow$ True
2. if $i \mod g \equiv 0$ and depth($G_{\leq i+1} - P_0^i$) $> d$ then
3. invariant $\leftarrow$ False
4. else if depth($G_{\leq i+1} - P_0^i$) $> d$ or $\{i\} \cup$ PotentialParents($[i+1,i+g]$) $\subseteq P_0^i$ then
5. invariant $\leftarrow$ False
6. if invariant then $\triangleright$ If pre-conditions met.
7. if $i \mod g \equiv 0$ then $\triangleright$ Balloon phase
8. for $j = 1$ to $j = d$ do
9. $P_j^i = P_{j-1}^i \cup D_j$, where $D_j$ are the nodes at depth $d$ from $P_0^i$.
10. $P_{j+1}^i = \text{Valiant}(G_{\leq i}, e, d) \cup \text{PotentialParents}([i+1,i+g])$. $\triangleright$ See Lemma 9
11. else $\triangleright$ Light phase
12. $P_j^i = P_0^i \cup \{i+1\}$.
13. else $\triangleright$ If pre-conditions not met.
14. for $j = 1$ to $j = i + 1$ do
15. $P_j^i = P_{j-1}^i \cup \{j\}$.

4 $k$-Restricted Graphs with high CMC

In this section, we describe a construction of $k$-restricted graphs with high cumulatively memory complexity that builds into our ultimate ciMHF implementation. We first describe the block partition extension gadget, which requires an input graph $G$ and outputs a family of $k$-restricted dynamic graphs. However, naively choosing the input graph $G$ does not yield a construction with high CMC.

Intuitively, the block partition extension gadget takes the last $N$ nodes of $G$ and partitions them into $\frac{N}{k}$ blocks of $k$ nodes each. The gadget then creates $N$ more nodes in a path, such that a parent $r(j)$ of node $j$ in this path is drawn uniformly at random from block $i$, where $i = j \mod \frac{N}{k}$. The intuition is that by drawing parents uniformly at random from each block in round robin fashion, we encourage an algorithm to keep $\Omega(N)$ nodes on the graph for $\Omega(N)$ steps. Of course, the graph could always maintain $o(n)$ pebbles on the graph and repobble when necessary, but we can discourage this strategy by making the repobbling procedure as expensive as possible.

A first attempt would be to choose a highly depth-robust graph $G$, such as a grates graph, which informally has long paths of length $\Omega(N^{1-\epsilon})$ for any constant $0 < \epsilon < 1$, even when $\Omega(N)$ nodes are removed from $G$. Thus if an algorithm does not maintain $\Omega(N)$ pebbles on the graph, the repobbling strategy costs at least $\Omega(N^{2-\epsilon})$. Although this is a good start, this does not quite match the $\Omega(N^2)$ CMC of various dMHFs. We defer full discussion of how to increase the CMC to $\Omega(N^2)$ to later in this section.

Instead, we first define a specific way to obtain a $k$-restricted dynamic graph given a graph $G$ with $N$ nodes and a parameter $k$.

Definition 12 (Block Partition Extension). Given a DAG $G = (V = [\alpha N], E)$ with $\alpha N$ nodes containing a set of $O = [(\alpha - 1)N + 1, \alpha N]$ output nodes of size $N$ and a parameter $k$, let $O_i = [(\alpha - 1)N + 1 + ik, (\alpha - 1)N + (i+1)k]$ for $i \in \left[\frac{N}{k}\right]$ so that $\{O_i\}$ forms a partition of $O$. We define the block partition extension of $G$, denoted $\text{BlockPartitions}_k(G)$, as
a distribution of graphs $G_{G,k}$. Each graph $G'$ sampled from $G$ has vertices $V' = [(\alpha + 1)N]$ and edges $E' = E \cup F$, where $F$ is defined as the edges $(i-1,i)$ and $(r(i),i)$ for each $i \in [(\alpha+1)N, (\alpha+1)N]$, where $r(i)$ is drawn uniformly at random from $O_{i \mod \frac{N}{k}}$.

An example of the block partition extension is given in Figure 1.

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{example.png}
\caption{Figure 1 Parent $r(i)$ is drawn uniformly at random from the nodes partitioned to each block.}
\end{figure}

Our ultimate construction also requires the use of superconcentrator graphs, defined as follows:

► **Definition 13.** A graph $G$ with $O(N)$ vertices is a superconcentrator if there exists an input set $I$ and an output set $O$ with $|I| = |O| = N$ such that for all $S_1 \subseteq I, S_2 \subseteq O$ with $|S_1| = |S_2| = k$, there are $k$ node disjoint paths from $S_1$ to $S_2$.

It is known that there exists superconcentrators with $|I| = |O| = N$, constant indegree and $O(N)$ total nodes [28, 26]. We now show that a set $Y$, which contains more nodes than a set of removed nodes, has at least $N - |S|$ ancestors in $G - S$.

► **Lemma 14.** Given a superconcentrator $G$ with $N$ input nodes $I$ and $N$ output nodes $O$, let $S$ and $Y \subseteq O$ be sets of nodes with $|S| < |Y|$. Then $|I \cap \text{ancestors}_{G-S}(Y)| \geq N - |S|$.

**Proof.** Let $X \subseteq I$ be the last $|Y|$ nodes of $I$. Since $G$ is a superconcentrator, then $G$ contains at least $|Y|$ node disjoint paths between $X$ and $Y$. Since $|S| < |Y|$, then one of these paths from $X$ to $Y$ that does not intersect $S$. Thus, $X$ contains some ancestor of $Y$ in $G - S$ and in fact by considering the paths associated with decreasing order of nodes in $X$, it follows that $|I \cap \text{ancestors}_{G-S}(Y)| \geq N - |S|$.

We require the use of superconcentrators with $|I| = |O| = N$, constant indegree and $O(N)$ total nodes [28, 26]. We now show that a set $Y$, which contains more nodes than a set of removed nodes, has at least $N - |S|$ ancestors in $G - S$.

We require the use of graph overlays, defined as follows:
Definition 16 (Graph overlays). Given a DAG $H = (V = [N], E)$ with sources $I = \{1, \ldots, n_1\}$ and sinks $O = \{N - n_2 + 1, \ldots, N\}$, a DAG $G_1 = (V_1 = [n_1], E_1)$, and a DAG $G_2 = (V_2 = [n_2], E_2)$, we define:

1. the graph overlay $G' = \text{overlay}(G_1, H, G_2)$ by $G' = ([N], E')$, where $(i, j) \in E'$ if and only if $(i, j) \in E$ or $(i, j) \in E_1$ or $(i + N - n_2, j + N - n_2) \in E_2$

2. the superconcentrator overlay of an $N$ node DAG $G$ by $\text{superconc}(G) = \text{overlay}(G, \text{SC}_N, L_N)$, where $\text{SC}_N$ is a superconcentrator with $N$ input (sources) and output (sinks) nodes and $L_N$ is the line graph of $N$ nodes

3. the grates overlay of an $N$ node DAG $G$ by $\text{grates}_\epsilon(G) = \text{overlay}(G, \text{grates}_{N, \epsilon}, L_N)$.

An example of a graph overlay is displayed in Figure 2.

We describe a preliminary attempt at a ciMHF construction in Figure 3. At a high level, the construction consists of four components. The first component is a grates graph $G_1$ with $N$ nodes. The second component is a superconcentrator overlay with $O(N)$ nodes, including $N$ input nodes and $N$ output nodes, so that $G_2 = \text{superconc}(G_1)$. The third component consists of a grates overlay with $O(N)$ nodes including $N$ output nodes, so that $G_3 = \text{grates}_\epsilon(G_2)$. The $N$ output nodes of $G_3$ are partitioned into $\frac{N}{k}$ blocks, each with $k$ nodes, in preparation for a block partition extension in the final component. Namely, the fourth component consists of a $k$-restricted graph with $N$ nodes, so that $G_4 = \text{BlockPartition}_k(G_3)$.

Sampling Algorithm, for $k = \Omega(N^\epsilon)$:

1. $G_1 = \text{grates}_{N, \epsilon}$
2. $G_2 = \text{superconc}(G_1)$
3. $G_3 = \text{grates}_\epsilon(G_2)$
4. $G_4 \sim \text{BlockPartition}_k(G_3)$

Figure 3 First attempt at ciMHF. Each parent $r(i)$ is randomly chosen from the labels in specific block corresponding to $i$.

The intuition for the $\Omega(N^2)$ cumulative pebbling complexity is as follows. Suppose there exists a time $t_{bad}$ with a “small” number of pebbles on the graph. Then with high probability, walking a pebble $s = N^\epsilon$ steps on the final layer of the graph will require some number of output nodes of the grates graph to be repebbled. Again with high probability, repebbling one of these output nodes requires a large number of input nodes of the grates graph to be repebbled. These input nodes are the output nodes of the superconcentrator at the second layer. The superconcentrator property then implies that $\Omega(N)$ nodes of the grates graph
on the first layer will need to be repelled. For a grates graph that is \((\Omega(N), \Omega(N^{1-\varepsilon}))\)-depth robust, this cost is at least \(\Omega(N^{2-\varepsilon})\) every \(s\) steps. Thus, the total cost is at least \(\min(\Omega(N^2), k\Omega(N^{2-\varepsilon}))\), which is just \(\Omega(N^2)\) for \(k = \Omega(N^\varepsilon)\).

We now show that our construction in Figure 3 has cumulative memory complexity \(\Omega(N^2)\).

**Theorem 17.** Let \(G\) be drawn from the distribution of \(k\)-restricted graphs in Figure 3, for \(k = \Omega(N^\varepsilon)\). There exist constants \(c_1 > 0\) and \(c_2 \in (0, 1)\) such that for any dynamic pebbling strategy \(S\),

\[
\Pr_G[\text{cc}(S, G) > c_1 N^2] \geq 1 - c_2^N/k.
\]

**Proof.** Let \(\alpha N\) be the total number of nodes in \(G_3\) so that the total number of nodes in \(G\) is \((\alpha + 1)N\). Let \(x, y \in (0, 1)\) be constants such that the grates graph \(G_1\) is \((xN, yN^{1-\varepsilon})\)-depth robust. By Theorem 15, there exist constants \(0 < c < \frac{x}{2}\) and \(0 < \gamma < c\) such that for any set \(S\) with \(|S| \leq \gamma N\), at least \(cN\) nodes in the output nodes of \(G_3\) are \(c\)-good with respect to \(S\). For each node \(i\), let \(t_i\) be the first time that node \(i\) is pebbled. Suppose there exists a time \(t_{\text{bad}}\) with \(t_i \leq t_{\text{bad}} < t_{i+1}\) such that there are \(|P_{\text{bad}}| < \frac{2N}{3}\) pebbles on the graph.

For a node \(j\) in the output set \([\alpha - 1]N, \alpha N\] of \(G_3\), we call an index \(j\) a costly index if \(j\) is \(c\)-good with respect to \(P_{\text{bad}}\) and let \(\text{COSTLY}\) be the set of costly indices. Note that if a node \(i\) is \(\text{COSTLY}\), then by definition \(i \notin P_{\text{bad}}\). By Theorem 15 and the observation that \(|P_{\text{bad}}| < \frac{2N}{3}\), there are at least \(cN\) nodes in the output set of \(G_3\) are \(c\)-good with respect to \(P_{\text{bad}}\), i.e., \(|\text{COSTLY}| > cN\). Then for \(s := \frac{N}{k}\), we call \(j \in [i, i+s]\) a missed costly index if \(r(j) \notin P_{\text{bad}}\) and let \(r(j) \in \text{COSTLY}\).

For each \(j \in \left[\frac{N}{k}\right]\), let \(c_j\) be the number of costly indices in block \(j\) of the output set of \(G_3\), i.e., \(c_j := |\text{COSTLY} \cap ([\alpha - 1]N + (j - 1)k + 1, \alpha - 1]N + jk|\). Since the parents of \([i, i+s]\) are exactly one random node from each of the \(\frac{N}{k}\) blocks, then the probability \(p\) that no parent of \([i, i+s]\) is a missed costly index is

\[
p := \prod_{j=1}^{N/k} \left(1 - \frac{c_j}{k}\right) \leq \left(1 - \frac{N/k}{k} \sum_{j=1}^{N/k} \left(1 - \frac{c_j}{k}\right)\right)^{N/k},
\]

where the inequality holds by the Arithmetic Mean-Geometric Mean Inequality. Since \(\sum c_j = cN\), then

\[
p \leq \left(1 - \frac{N/k}{k} \sum_{j=1}^{N/k} \frac{c_j}{k}\right)^{N/k} \leq (1 - c)^{N/k}.
\]

Thus with high probability, there will be some missed costly index.

By Lemma 14 and the definition of \(c\)-good, any missed costly index requires \(cN\) nodes in the input set of \(G_3\) to be repelled. Since the input set of \(G_3\) is connected by a superconnector to the output set of \(G_1\), the \(cN\) nodes in the input set of \(G_3\) that need to be repelled have at least \(N - cN\) ancestors in the output set of \(G_1\). Thus, at least \(N - cN - |P_{\text{bad}}|\) nodes in \(G_1\) must be repelled.

Because \(G_1\) is \((xN, yN^{1-\varepsilon})\)-depth robust, then \(G_1 - S\) is \((xN - |S|, yN^{1-\varepsilon})\)-depth robust for any set \(S\). Moreover, the cost to pebble \(G_1 - S\) is at least \((xN - |S|)(yN^{1-\varepsilon})\). In particular, if \(G_1 - S\) is the set of nodes in \(G_1\) must be repelled, then it costs at least \((xN - cN - |P_{\text{bad}}|)(yN^{1-\varepsilon})\) to repel \(G_1 - S\). Since \(c < \frac{x}{2}\) and \(|P_{\text{bad}}| < \frac{2N}{3}\), then the cost is at least \(\frac{2\alpha}{3} N^2\).
Hence to pebble an interval $[i, i + s]$ with $s = \frac{N}{k}$, either $\frac{2N}{k}$ pebbles are kept on the graph for all $s = \frac{N}{k}$. Then we call $\frac{2N}{k}$ pebbles are kept on the graph for all $s = \frac{N}{k}$. Then we call $\frac{2N}{k}$ pebbles are kept on the graph for all $s = \frac{N}{k}$.

Different Potential Parents for Different Groups: For all $i, j \in [N]$ with $i \neq j$.

Same Potential Parents for Each Group: For all $i \in [N]$ and $j \in [N]$, let $u \in G_i$ and $v \in G_j$. Then $\text{PotentialParents}(u) \cap \text{PotentialParents}(v) = \emptyset$.

No Collision for Parents: For each $i \in [N]$, define the event $\text{UNIQUE}_i$ to be the event that $r(u) \neq r(v)$ for all $u, v \in G_i$. Then $\Pr[\text{UNIQUE}_i] = 1$ for all $i \in [N]$.

Data-Independency: The subgraph induced by the first $(\alpha - 1)N$ nodes is a static graph. Then we call $G$ amenable to shuffling.

We shall show in Theorem 24 in Section 6 that dynamic graphs that are amenable to shuffling can be used for memory hard functions with computationally data-independent evaluation algorithms. We now describe a version of Figure 3 that is amenable to shuffling.

5.2 Version of Construction Amenable to Shuffling

To ensure that there does not exist $i \neq j$ such that $r(i) = r(j)$, we slightly modify the construction of block partition extensions to the concept of a collision-resistant block partition extension. For the sake of presentation, note that we use $2N$ output nodes in $G$ in the following definition.
Definition 20 (Collision-Resistant Block Partition Extension). Given a DAG $G = (V = [\alpha N], E)$ with $\alpha N$ nodes containing a set of $O = [(\alpha - 2)N + 1, \alpha N]$ output nodes of size $2N$ and a parameter $k$, let $O_i = [(\alpha - 2)N + 1 + 2ik, (\alpha - 2)N + 2(i + 1)k]$ for $i \in \left[\frac{N}{k} - 1\right]$ so that $\{O_i\}$ forms a partition of $O$. We define the collision-resistant block partition extension of $G$, denoted $CR - BlockPartition\{G\}$, as a distribution of graphs $G_{G,k}$. Each graph $G'$ sampled from $G$ has vertices $V' = [(\alpha + 1)N]$ and edges $E' = E \cup F$, where $F$ is defined as the edges $(i - 1, i)$ and $(r(i), i)$ for each $i \in [\alpha N + 1, (\alpha + 1)N]$, where $r(i)$ is defined as follows:

1. Let $Enc$ be the family of all permutations of $[2k]$, so that for each fixed $j$,
   \[
   \{Enc(j, \ell)\}_{\ell \in [2k]} = [2k].
   \]
2. For each $i \in [\alpha N + 1, (\alpha + 1)N]$, let $j = i \mod \frac{N}{k}$ and define $1 \leq p \leq k$ to be the unique integer such that $i = \frac{N}{k}(p - 1) + \alpha Ni + j$. Then we define $r(i) = (\alpha - 2)N + 1 + 2jk + Enc(x \circ j, p)$, so that $r(i) \in O_j$.

Observe that the collision-resistant block partition extension is a gadget that yields a dMHF, since the parent function $r(i)$ has the key $x \circ j$ to its permutation function $Enc$. Hence, the underlying dynamic graph differs across different input values $x$.

Then our construction of the $\text{ciMHF}$ appears in Figure 4 and Figure 5. As before, the construction consists of four layers. The first layer consists of a $\text{grates}$ graph with $2N$ nodes, $G_1 = \text{grates}_{2N,x}$. The second layer consists of a superconcentrator overlay with $\mathcal{O}(N)$ nodes with $2N$ input nodes and $2N$ output nodes, so that $G_2 = \text{superconc}(G_1)$. The third layer consists of a $\text{grates}$ overlay with $\mathcal{O}(N)$ nodes including $2N$ output nodes, so that $G_3 = \text{grates}_{x}(G_2)$. The $2N$ output nodes of $G_3$ are partitioned into $\frac{N}{k}$ blocks, each with $2k$ nodes, which allows the final layer to be a $2k$-restricted graph. In particular, the fourth layer uses a collision-free block partition extension rather than the block partition extension of Figure 3.

<table>

<tr>
<td>(4) $G_4 \sim CR - BlockPartition_4(G_3)$</td>
</tr>
</tbody>
</table>

Figure 4 Second attempt at $\text{ciMHF}$. Each parent $r(i)$ is chosen by a permutation of the labels in specific block corresponding to $i$. The underlying graph is visualized in Figure 5.

We now show that the construction of Figure 4 has cumulative cost $\Omega(N^2)$ with high probability. The proof is almost verbatim to Theorem 17 except that the graph overlays now have $2N$ input and output nodes.

Theorem 21. Let $0 < \epsilon < 1$ be a constant and $k = \Omega(N^\epsilon)$. Let $G$ be drawn from the distribution of $2k$-restricted graphs in Figure 4. There exist constants $c_1 > 0$ and $c_2 \in (0, 1)$ such that for any dynamic pebbling strategy $S$,
\[
\Pr_{G \in \mathcal{G}}[cc(S, G) > c_1 N^2] \geq 1 - c_2^{N/k}.
\]

Corollary 22. Let $G$ be drawn from the distribution of $2k$-restricted graphs in Figure 4, for $k = \Omega(N^\epsilon)$. Then $\text{cc}(G) = \Omega(N^2)$.

Finally, we observe that the construction of Figure 4 is amenable to shuffling since it satisfies the properties of Definition 19.
6 Implementation of ciMHF

In this section, we describe how to implement our construction in a way that is computationally data-independent. We first formalize the notion of computationally data-independent and then describe the system model we utilize.

6.1 Computationally Data-Independent MHF (ciMHF) and System Model

We define the security of a computationally data-independent memory hard function in terms of the following game: a side-channel attacker \( A \) selects two inputs \( x_0, x_1 \) and sends these inputs to an honest party \( H \). We first require the following definition of leakage patterns.

**Leakage Pattern**

We define the leakage pattern of an evaluation algorithm \( \text{MHF} \).\( ^{\text{Eval}} \) by the sequence of request and store instructions made in each round. Specifically, in each round \( r \), an attacker can observe from the leakage pattern the blocks of memory to be loaded into cache, as requested by \( \text{MHF}.^{\text{Eval}} \). Let \( i = (i_1, \ldots, i_m) \) be the sequence of locations of all blocks requested by \( \text{MHF}.^{\text{Eval}} \) in a particular round \( r \) through some command \( \text{load}(i) \). If \( i \) is completely contained in cache, then no events will be observed by the attacker. Otherwise, if \( i \) is not completely contained in cache, we use \( \text{request}_r \) to denote the locations of the blocks in memory, as well as their sizes, requested by \( \text{MHF}.^{\text{Eval}} \) in round \( r \). Similarly, we use \( \text{store}_r \) to denote the locations of the blocks, as well as their sizes, stored into memory by \( \text{MHF}.^{\text{Eval}} \) in round \( r \). We do not allow the attacker to observe the contents of the requested or stored blocks. Formally, the leakage pattern \( \text{LP} \) is the information \( \{(\text{request}_r, \text{store}_r)\}_{r=1}^t \) and is dependent on the algorithm \( \text{MHF}.^{\text{Eval}} \), random oracle \( H \), internal randomness \( R \), and input value \( x \).
**Computationally Data-Independency Game**

\( \mathcal{H} \) runs a (randomized) evaluation algorithm \( \text{MHF.Eval} \) on both inputs \( x_0 \) and \( x_1 \), yielding two leakage patterns \( \text{LP}_0 \) and \( \text{LP}_1 \), where \( \text{LP}_i \) for \( i \in \{0, 1\} \) depends on both the input \( x_i \) and the random coins selected during the execution of \( \text{MHF.Eval} \). \( \mathcal{H} \) then picks a random challenge bit \( b \in \{0, 1\} \) and sends \( \text{LP}_b, \text{LP}_{1-b} \) to \( \mathcal{A} \) to simulate a side-channel. The goal of \( \mathcal{A} \) is to predict \( b \) i.e., match each input with the corresponding leakage pattern. For a secure ciMHF we guarantee that any PPT side-channel attacker \( \mathcal{A} \) wins the game with only negligible advantage over random guessing.

Formally, the game consists of three phases setup, challenge, and guess, which are described as follows.

<table>
<thead>
<tr>
<th>Data independence game for ciMHF:</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>setup</strong> In this phase, ( \mathcal{A} ) selects the security parameter ( \lambda ) and two challenge messages ( x_0 ) and ( x_1 ) and sends them to ( \mathcal{H} ). Here we assume without loss of generality that the runtime of the evaluation algorithm ( \text{MHF.Eval} ) on ( x_0 ) and ( x_1 ) are the same.</td>
</tr>
<tr>
<td><strong>challenge</strong> In this phase, ( \mathcal{H} ) selects a random bit ( b \in {0, 1} ) and random coins ( R_0, R_1 \in {0, 1}^\lambda ) uniformly at random and then samples ( \text{lp}_0 \leftarrow \text{LP}(\text{MHF.Eval}(x_0; R_0)) ) and ( \text{lp}_1 \leftarrow \text{LP}(\text{MHF.Eval}(x_1; R_1)) ). ( \mathcal{H} ) sends the ordered pair ( (\text{lp}<em>b, \text{lp}</em>{1-b}) ) to ( \mathcal{A} ).</td>
</tr>
<tr>
<td><strong>guess</strong> After receiving ( (\text{lp}<em>b, \text{lp}</em>{1-b}) ), the adversary ( \mathcal{A} ) outputs ( b' ) as a guess for ( b ). The adversary wins the game if ( b = b' ).</td>
</tr>
</tbody>
</table>

The advantage of the adversary to win the game of computationally data independency of the given MHF is defined as

\[
\text{Adv}^{\text{ind-} LP- \text{MHF}}_\mathcal{A} = \left| \frac{1}{2} - \Pr[A(x_0, x_1, \text{lp}_b, \text{lp}_{1-b}) = b' : b = b'] \right|,
\]

where \( \text{lp}_i \) is \( \text{LP}(x_i; \text{MHF.Eval}(x_i; R_i)) \).

**Definition 23** (Computational data independency). An evaluation algorithm \( \text{MHF.Eval} \) is computationally data independent if for all non-uniform circuits \( \mathcal{A} = \{A_\lambda\}_{\lambda \in \mathbb{N}} \), there is a negligible function \( \text{negl}(\cdot) \) such that \( \text{Adv}^{\text{ind-} LP- \text{MHF}}_\mathcal{A} < \text{negl}(\lambda) \).

With the proper random coins, a memory-hard function with an evaluation algorithm that satisfies the above definition reveals only a negligible amount of information through its leakage patterns, and we thus call such a function a computationally data-independent memory hard function.

**On the Definition of Computational Data Independency**

In section Section 6.2.2 we show that the definition is equivalent to a multi round version of the game in which the attacker can adaptively select the challenge \( x_{i, 0}, x_{i, 1} \) in each round \( i \leq r \) after observing \( \text{lp}_{i-1, b}, \text{lp}_{i-1, 1-b} \) – the memory access patterns from the last round. We also prove that the two security notions are asymptotically equivalent when the attacker runs in polynomial time – in terms of concrete security parameters we lose a factor of \( r \) (number of challenge rounds) in the reduction.

We are primarily motivated by the password hashing application where the inputs \( x_0 \) and \( x_1 \) come from a small domain, as user selected passwords tend to have low entropy [18]. In practice it is reasonable to assume that \( r \) is polynomial i.e., if the user only authenticates
poly(\(\lambda\)) times then there are at most \(r = \text{poly}(\lambda)\) memory access patterns for the attacker to observe. Assuming that the input domain has size \(\text{poly}(\lambda)\) a brute-force attacker cannot use the leaked memory access pattern on input \(x\) to eliminate any candidate password \(x'\) with high probability, otherwise the attacker could have used the pair \((x, x')\) to win the data independency game.

However, in settings where the input domain is very large and \(r\) is super-polynomial it will be better to adopt a concrete security definition (see Section 6.2.2). The asymptotic definition in Definition 23 does not definitively rule out the possibility that an attacker can substantially narrow the search space after many (super-polynomial) side channel attacks. For example, suppose that the attacker gets to observe \(\ell_p \leftarrow \text{LP}(\text{MHF.Eval}(x; R_i))\) for \(i = 1, \ldots, 2^\lambda\), i.e., \(2^\lambda\) independent evaluations of MHF on secret input \(x\). Supposing that \(\text{Adv}_{\text{ind}}^{\ell_p \leftarrow \text{LP}}(\text{MHF}) = 2^{-\lambda}\) and that the input domain for MHF has size \(2^{2\lambda}\), it is possible that each \(\ell_p\) allows the attacker to eliminate a random subset of \(\text{Adv}_{\text{ind}}^{\ell_p \leftarrow \text{LP}}(\text{MHF}) \times 2^{2\lambda} = 2^\lambda\) candidate inputs, allowing the attacker to find \(x\) after just \(O(\lambda 2^\lambda)\) examples. However, in practice it will usually be reasonable to assume that the attacker gets to observe \(\ell_p\) a polynomial number of times i.e., the honest party will execute \(\text{LP}(\text{MHF.Eval}(x; R_i))\) at most \(\text{poly}(\lambda)\) times.

Memory Architecture Assumptions

We consider a tiered random access memory architecture with main memory (RAM) and working memory (cache). We assume that main memory (RAM) is a shared resource with other untrusted processes, each of which have their own cache. Although the operating system kernel will enforce memory separation, i.e., only our program has some region of memory and that other processes cannot read/write to this block, it is also possible that an untrusted process will be able to infer the memory address of read/write operations in RAM (due to side-channel effects).

Formally, the system allows programs access to two operations \(\text{Write}(i, x)\), which takes an address \(i\) within the memory allocated to the program and writes the value \(x\) at address \(i\), and \(\text{Read}(i)\) which loads the data at location \(i\). When an operation requests memory at location \(i\), there are two possible outcomes. Either the data item is already in cache or the data item is not in cache. In the second case, the location of the item in memory is revealed through the leakage pattern. Hence, the leakage pattern is either \(\bot\), if the data item is already in cache, or \(i\), if the data item is not in cache.

Cache Replacement Policy

We now show that our implementation of the dynamic pebbling construction with cumulative memory cost \(\Omega(\lambda^2)\) is computationally data-independent. In particular, we provide an evaluation algorithm whose leakage pattern is computationally indistinguishable under each of the following cache replacement policies:

**Least recently used (LRU)** This policy tracks the most recent time each item in cache was used and discards the least recently used items first when cache is full and items need to be replaced.

**First in first out (FIFO)** This policy evicts the first item that was loaded into cache, ignoring how recent or how often it has been accessed.
6.2 ciMHF Implementation

Recall from the definition of a graph labeling in Definition 6 that given a function $H$ and a distribution of dynamic graphs $G$, the goal is to compute $f_{G,H}(x)$ for some input $x$, which is equivalent to $f_{G,H}(x)$ once the graph $G$ has been determined by the choice of $H$ and $x$. In this section, we describe a computationally data-independent implementation of the construction of Section 5.2.

We implement the first three layers as data-independent components. Namely, the grates graph $G_1$, its superconcentrator overlay $G_2$ and the subsequent grates overlay $G_3$ can be implemented deterministically. Observe that $G_3$ has $\alpha N$ nodes, including $2N$ output nodes $O$ that are partitioned into $\frac{N}{k}$ blocks of size $2k$ each. Specifically $O = O_1 \cup \ldots \cup O_{\frac{N}{k}}$, where $O_j = [(\alpha - 2)N + 1 + 2jk, (\alpha - 2)N + 2(j + 1)k]$ for $j \in \left[\frac{N}{k}\right]$.

As stated in Figure 4, the collision-resistant block partition extension $G_4$ is actually data-independent, since for each $i \in [(\alpha - 1)N, \alpha N]$, each parent $r(i)$ of $i$ is chosen uniformly at random from $k$ possible nodes, but the random procedure is independent of the input $x$. Hence, the challenge is to implement a computationally data-independent version of the collision-resistant block partition extension. We demand the input of a key $K$ for each computation of $f_{G,H}(x)$. The value of $f_{G,H}(x)$ remains the same across all keys $K$ but the leakage pattern is different for each $K$.

Data-Dependent Dynamic Graph

For each $i \in [\alpha N + 1, (\alpha + 1)N]$, let $j = i \mod \frac{N}{k}$. To implement a computationally data-independent version of $G_4$ from Figure 4, we use the value of $L_{G,H,x}(i - 1)$ to select a previously “unused” node of $O_j$ as the parent $r(i)$ for $i$ that is not $i - 1$. Here, we say a node $v \in O_j$ is unused if it is not the parent of any node besides $v$ and $i$.

Since $L_{G,H,x}(i - 1)$ can be viewed as a random integer modulo $2k$, we can use $L_{G,H,x}(i - 1) \mod 2k$ as an input to a permutation with key $K$ to randomly choose the parent of $i$ from $O_j$. Observe that $i = \alpha N + j$ is the first time a parent will be selected from $O_j$. Moreover, observe that $m = L_{G,H,x}(i - 1) \mod 2k + 1$ can be viewed as a random number from $[2k]$ so we set $r(i) = m + (\alpha - 2)N + 1 + 2jk$ as the $m^{th}$ entry of $O_j$.

Now if $L_{G,H,x}(i - 1) \mod 2k$ were all unique across the values of $\{i \mid i \mod \frac{N}{k} \equiv j\}$, then there would be no collisions among selections of parents in $O_j$ and we would be done. However, since these values are not unique, we must do a little more work to avoid collisions, which would reveal information through leakage patterns about the parents of two nodes being the same. To ensure there are no collisions in $O_j$ among parents, we store an array $U_j$ of size $2k$ for each block $O_j$. For each $1 \leq \ell \leq 2k$, we initialize $U_j[\ell] = \ell$. The purpose of the $U_j$ array is to ensure that the nodes of $O_j$ that have already appeared as parents are at the end of $U_j$. In the above example when $r(i) = m + (\alpha - 2)N + 1 + 2jk$, we then set $U_j[m] = 2k$ and $U_j[2k] = m$. Then in the next round of selecting a parent from $O_j$, we choose uniformly at random from the first $2k - 1$ entries of $U_j$ and in general, for the $s^{th}$ round of selecting a parent from $O_j$, we choose uniformly at random from the first $2k - s + 1$ entries of $U_j$.

Specifically for some $2 \leq s \leq k$, consider the $s^{th}$ iteration in which a parent is selected from $O_j$. That is, for $i = \alpha N + j + (s - 1)\frac{N}{k}$, the parent $r(i)$ is the $s^{th}$ parent among the nodes of $O_j$. Observe that $m = L_{G,H,x}(i - 1) \mod 2k - s + 1$ can be viewed as a random number from $[2k - s + 1]$, and so $U_j[m]$ is a random entry among the unselected $2k - s + 1$ nodes of $O_j$. We then swap the values of $U_j[m]$ and $U_j[2k - s + 1]$ so that if $U_j[m] = a$ and $U_j[2k - s + 1] = b$ previously then we set $U_j[m] = b$ and $U_j[2k - s + 1] = a$. Hence, the invariant remains that the first $2k - s$ locations of $U_j$ have been unused.
Shuffling Leakage Patterns

Finally, we point out that the leakage pattern across all computations of $f_{G,H}(x)$ is still the same, since we have not actually incorporated the key $K$ in any of the above details. In summary, the above the description ensures a collision-resistant block partition extension that is data-dependent, but is still vulnerable to side-channel attacks. Hence, we add a final element to our implementation that shuffles the locations of each node $p \in O_j$ inside $O_j$. That is, for each $1 \leq j \leq \frac{N}{k}$, we use the keyed permutation $\text{Enc}$ to store the label of $p \in O_j$ in the location that corresponds to $\text{Enc}(j \circ K, p)$ instead. Thus if $r(i) = p \in O_j$ for some node $i$, the algorithm must look at the location associated with $\text{Enc}(j \circ K, p)$ to learn the value of $L_{G,H,y}(p)$. Therefore, the underlying graph $G$ is a dynamic graph that is data-dependent but the leakage pattern across each computation of $f_{G,H}(x)$ is different due to the choice of $K$ that shuffles the locations of all labels in each block $O_j$. A high level example of this shuffling is shown in Figure 6.

Observe that this shuffling must be done completely in the cache to avoid leaking locations of labels during the shuffling. Hence, we require cache eviction policies such as the least recently used (LRU) or first in first out (FIFO) cache eviction policies to ensure that the entire block $O_j$ will remain in cache as the shuffling is performed. We describe the implementation in full in Figure 7.

A Note on Oblivious RAM

The complications with the cache eviction policies and shuffling leakage patterns originate from the necessity of not divulging information in the data-independency game. One reasonable question is whether these complications can be avoided with other implementations that conceal the leakage patterns. For example, an algorithm using oblivious RAM (ORAM), introduced by Goldreich and Ostrovsky [23], reveals no information through the memory access patterns about the underlying operations performed. Thus, an algorithm using an ORAM data structure to evaluate a memory hard function would induce a computationally independent memory hard function, regardless of whether the underlying function is data-
Computationally data-independent sequential evaluation algorithm \( \text{MHF.Eval}(x; R) \) to compute \( f_{G,H}(x) \) for any \( k \)-restricted dynamic graph \( G \) that is amenable to shuffling.

(1) Data-independent phase:

\[ \text{a. Let } G \text{ be a } k \text{-restricted dynamic graph with } \alpha N \text{ nodes for some constant } \alpha > 1 \text{ that is amenable to shuffling, } L \text{ be the last } N \text{ nodes of } G, \text{ and } H \text{ be an arbitrary hash function.} \]

\[ \text{b. Let } K = \text{Setup}(\lambda; R) \text{ be a hidden random permutation key for each computation of } f_{G,H}(x), \text{ given the security parameter } \lambda \text{ and random bits } R. \]

\[ \text{c. Recall that the subgraph induced by the first } (\alpha - 1)N \text{ nodes is a static graph. Compute the label } L_{G,H,x}(v) \text{ for each node } v \in (G - L). \]

(2) Shuffling phase:

\[ \text{a. Since } G \text{ is amenable to shuffling, } L \text{ can be partitioned into groups } G_1, \ldots, G_{\frac{N}{k}} \text{ that satisfy the definition of Definition 19. For each } j \in \left[ \frac{N}{k} \right], \text{ let } O_j = \text{PotentialParents}(G_j). \]

\[ \text{b. For each } j \in \left[ \frac{N}{k} \right], \text{ shuffle the contents of } O_j: \]

\[ \text{i. Let } v_1, \ldots, v_k \text{ be the vertices in } O_j. \]

\[ \text{ii. Load the labels } L_{G,H,x}(v_1), \ldots, L_{G,H,x}(v_k) \text{ into cache.} \]

\[ \text{iii. Shuffle the positions of } L_{G,H,x}(v_1), \ldots, L_{G,H,x}(v_k) \text{ so that for each } p \in [k], L_{G,H,x}(v_p) \text{ is in the location that previously corresponded to } L_{G,H,x}(v_q), \text{ where } q = \text{Enc}(j \circ K, p), \text{ where } \text{Enc} \text{ is a keyed pseudorandom permutation of } k. \]

(3) Data-dependent phase:

\[ \text{a. For each } j \in \left[ \frac{N}{k} \right], \text{ initialize an array } U_j \text{ such that for all } 1 \leq \ell \leq k, U_j[\ell] = \ell. \]

\[ \text{b. For each } i = \alpha N + 1 \text{ to } (\alpha + 1)N: \]

\[ \text{i. Let } j \text{ and } s \text{ be defined so that } 1 \leq s \leq k \text{ and } 1 \leq j \leq \frac{N}{k} \text{ given } i = \alpha N + j + (s - 1) \frac{N}{k} \text{ and let } m = L_{G,H,x}(i - 1) \text{ (mod } k - s + 1) + 1. \]

\[ \text{ii. Set } r(i) = U_j[m] + (\alpha - 1)N + 1 + jk \text{ so that } r(i) \in O_j \text{ and load } L_{G,H,x}(r(i)). \]

\[ \text{(Recall that the label of } r(i) \text{ is actually located at the position where the label of node } \text{Enc}(j \circ K, U[m]) \text{ was previously located prior to the shuffling.)} \]

\[ \text{iii. Load } L_{G,H,x}(r(i)) \text{ and } L_{G,H,x}(r(i) - 1) \text{ and compute } L_{G,H,x}(i) = H(i \circ L_{G,H,x}(r(i)) \circ L_{G,H,x}(i - 1)). \]

\[ \text{iv. Let } U_j[U_j[m]] = a \text{ and } U_j[k - s + 1] = b. \text{ Then swap the values of } U_j \text{ at } U_j[m] \text{ and } k - s + 1 \text{ so that } U_j[U_j[m]] = b \text{ and } U_j[k - s + 1] = a. \]

\[ \text{Figure 7} \text{ Description of evaluation algorithm for } k \text{-restricted graphs that are amenable to shuffling.} \]

Note that each computation of \( f_{G,H}(x) \) requires as input random bits \( R \) to generate the leakage patterns.

dependent or data-independent. [23] describe an oblivious RAM simulator that transforms any program in the standard RAM model into a program in the oblivious RAM model, where the leakage pattern is information theoretically hidden, which is ideal for the data-independency game.

Existing constructions of ORAM protocols such as Path ORAM [31] require amortized \( \Omega(\log N) \) bandwidth overhead. Hence given any dMHF and evaluation algorithm running in sequential time \( M \), we can use ORAM to develop a new evaluation algorithm with a concealed leakage pattern, running in sequential time \( N = M \log M \). However, this is not ideal because the cumulative memory complexity of the dMHF is \( O(M^2) = O\left(\frac{N^2}{\log^2 N}\right) \). Viewed in this way, the cIMHF construction is worse than known iMHF constructions that achieve \( \text{CMC } \Omega\left(\frac{N^2}{\log N}\right) \) such as DRSample [4, 11]. In fact, even for \( k \)-restricted graphs,
we still obtain a blow-up of $\Omega(\log^2 K)$, which is $\Omega\left(\frac{\log^2 N}{\log \log N}\right)$ when $k = \Omega(N^{1/\log \log N})$. Otherwise for $k = o(N^{1/\log \log N})$, our dynamic pebbling attack in Corollary 11 shows that the CMC is at most $o(N^2)$.

Although Boyle and Naor [20] proposed the notion of online ORAM, where the operations to be performed arrive in an online manner, and observe that the lower bounds of [23] do not hold for online ORAM, Larsen and Nielsen [25] answer this open question by proving an amortized $\Omega(\log N)$ bandwidth overhead lower bound on the bandwidth of any online ORAM. Therefore, it does not seem obvious how to use ORAM in the implementations of maximally hard ciMHF.

### 6.2.1 Implementation and Analysis

**Shuffling phase:**

a. Since $G$ is amenable to shuffling, $L$ can be partitioned into groups $G_1, \ldots, G_N$ that satisfy the definition of Definition 19. For each $j \in \left[\frac{N}{\alpha}\right]$, let $O_j = \text{PotentialParents}(G_j)$. 

b. For each $j \in \left[\frac{N}{\alpha}\right]$, shuffle the contents of $O_j$:
   i. Let $v_1, \ldots, v_k$ be the vertices in $O_j$. 
   ii. Load the labels $L_{G,H,x}(v_1), \ldots, L_{G,H,x}(v_k)$ into cache. 
   iii. Shuffle the positions of $L_{G,H,x}(v_1), \ldots, L_{G,H,x}(v_k)$ so that for each $p \in [k]$, $L_{G,H,x}(v_p)$ is in the location that previously corresponded to $L_{G,H,x}(v_q)$, where $q = \text{Enc}(j \circ K, p)$, where $\text{Enc}$ is a keyed truly random permutation of $k$. 

(2) Data-dependent phase:

a. For each $j \in \left[\frac{N}{\alpha}\right]$, initialize an array $U_j$ such that for all $1 \leq \ell \leq k$, $U_j[\ell] = \ell$. 

b. For each $i = \alpha N + 1$ to $(\alpha + 1)N$:
   i. Let $j$ and $s$ be defined so that $1 \leq s \leq k$ and $1 \leq j \leq \frac{N}{\alpha}$ given $i = \alpha N + j + (s - 1)\frac{N}{\alpha}$ and let $m = L_{G,H,x}(i - 1) \pmod {k - s + 1} + 1$. 
   ii. Set $r(i) = U_j[m] + (\alpha - 1)N + 1 + jk$ so that $r(i) \in O_j$ and load $L_{G,H,x}(r(i))$. (Recall that the label of $r(i)$ is actually located at the position where the label of node $\text{Enc}(j \circ K, U[m])$ was previously located prior to the shuffling.)
   iii. Load $L_{G,H,x}(r(i))$ and $L_{G,H,x}(i - 1)$ and compute $L_{G,H,x}(i) = H(i \circ L_{G,H,x}(r(i)) \circ L_{G,H,x}(i - 1))$.
   iv. Let $U_j[U_j[m]] = a$ and $U_j[k - s + 1] = b$. Then swap the values of $U_j$ at $U_j[m]$ and $k - s + 1$ so that $U_j[U_j[m]] = b$ and $U_j[k - s + 1] = a$.

Figure 8 Description of hybrid. Differs from Figure 7 in that the hidden input key is used to index into the entire family of random permutations, rather than a pseudorandom permutation.
We require the hybrid in Figure 8 to argue that our implementation of Figure 4 is a ciMHF. The hybrid in Figure 8 differs from the implementation of Figure 4 in Figure 7 in that the hidden input key is used to index from the entire family of random permutations, rather than a pseudorandom permutation. Thus the only way an adversary can distinguish between the hybrid and the real world sampler is by distinguishing between a random permutation and a pseudorandom permutation. On the other hand, if an adversary fails to distinguish between the hybrid and the real world sampler, then the cumulative memory complexity of the implementation requires $\Omega(N^2)$ since the leakage pattern of the hybrid is statistically equivalent to the dMHF construction in Figure 4, where each parent is chosen a priori using a permutation drawn uniformly at random.

**Theorem 24.** For each DAG $G$ that is amenable to shuffling, there exists a computationally data-independent sequential evaluation algorithm $\text{MHF.Eval}(x;R)$ computing the function $f_{G,H}$ in time $O(N)$.

**Proof.** Consider the evaluation function in Figure 7. Observe that the hybrid in Figure 8 has the same distribution of leakage patterns as the dMHF of Figure 4. Moreover, under the least recently used (LRU) or first in first out (FIFO) cache eviction policies, if $k$ is less than the size of the cache, then all the shuffling can be performed so an attacker observing the leakage patterns of the hybrid has no advantage in the data-independency game. Furthermore, the ciMHF implementation in Figure 7 only differs from the hybrid in Figure 8 in the implementation of $\text{Enc}$ as a pseudorandom permutation compared to a truly random permutation. Therefore, an attacker observing leakage patterns from the implementation in Figure 7 only obtains a negligible advantage $\text{negl}(\lambda)$ in the security parameter $\lambda$, in the data-independency game. Hence, the implementation of Figure 7 is a ciMHF.

We now show that the evaluation function in Figure 7 of the dMHF in Figure 4 is a maximally hard ciMHF.

**Theorem 25.** Let $0 < \epsilon < 1$ be a constant and $k = \Omega(N^\epsilon)$. Then there exists a family $\mathcal{G}$ of $k$-restricted graphs with $\text{cc}(\mathcal{G}) = \Omega(N^2)$ that is amenable to shuffling. Moreover, there exists a negligible value $\delta = \text{negl}(N)$ such that $\text{cc}_\delta(\mathcal{G}) = \Omega(N^2)$.

**Proof.** Consider the evaluation function in Figure 7 of the dMHF in Figure 4. For the sake of completeness, the full implementation is also shown in Figure 9. Since the construction of Figure 4 is amenable to shuffling, then the evaluation algorithm is a ciMHF by Theorem 24. Finally by Theorem 21, $\text{cc}(\mathcal{G}) = \Omega(N^2)$.

In fact, Theorem 21 implies that for $G \in \mathcal{G}$ drawn uniformly at random and any pebbling strategy $S$, not only is $\mathbb{E}_{G \in \mathcal{G}} [\text{cc}(S,G)] = \Omega(N^2)$, but also $\text{cc}(S,G) = \Omega(N^2)$ with probability at least $1 - e^{N/k}$ for some constant $0 < c < 1$. Thus for $\delta = 1 - e^{N/k}$, we have $\text{cc}(S,\mathcal{G},\delta) = \Omega(N^2)$ for any pebbling strategy $S$ and so $\text{cc}_\delta(\mathcal{G}) = \Omega(N^2)$.

For the sake of completeness, we give the evaluation algorithm for the maximally hard ciMHF in Figure 9.
Computationally data-independent sequential evaluation algorithm \( \text{MHF.Eval}(x; R) \)

1. Let \( H \) be an arbitrary hash function and \( K = \text{Setup}(1^\lambda; R) \) be a hidden random permutation key for each computation of \( f_{G,H}(x) \), given the security parameter \( \lambda \) and random bits \( R \). Let \( k = \Omega(N^\epsilon) \).

2. Data-independent phase:
   a. \( G_1 = \text{grates}_{2N,\epsilon} \)
   b. \( G_2 = \text{superconc}(G_1) \)
   c. \( G_3 = \text{grates}_s(G_2) \), which has \( \alpha N \) total nodes, including \( 2N \) output nodes \( O = O_1 \cup \ldots \cup O_N \), where \( O_j = \left[ (\alpha - 2)N + 1 + 2ik, (\alpha - 2)N + 2(j + 1)k \right] \) for \( j \in \left[ \frac{N}{k} \right] \).
   d. Compute the label \( L_{G_3,H,x}(v) \) for each node \( v \in G_3 \).

3. Shuffling phase:
   a. Let \( G \) be the graph \( G_3 \) appended with \( N \) additional nodes, so that \( V = [(\alpha + 1)N] \), and edges \((i - 1, i)\) for each \( \alpha N + 1 \leq i \leq (\alpha + 1)N \).
   b. For each \( j \in \left[ \frac{N}{k} \right] \), shuffle the contents of \( O_j \):
      i. Let \( v_1, \ldots, v_{2k} \) be the vertices in \( O_j \).
      ii. Load the labels \( L_{G,H,x}(v_1), \ldots, L_{G,H,x}(v_{2k}) \) into cache.
      iii. Shuffle the positions of \( L_{G,H,x}(v_1), \ldots, L_{G,H,x}(v_{2k}) \) so that for each \( p \in [2k] \), \( L_{G,H,x}(v_p) \) is in the location that previously corresponded to \( L_{G,H,x}(v_q) \), where \( q = \text{Enc}(j \circ K, p) \), where \( \text{Enc} \) is a keyed pseudorandom permutation of \( 2k \).

4. Data-dependent phase:
   a. For each \( j \in \left[ \frac{N}{k} \right] \), initialize an array \( U_j \) such that for all \( 1 \leq \ell \leq 2k \), \( U_j[\ell] = \ell \).
   b. For each \( i = \alpha N + 1 \) to \( (\alpha + 1)N \):
      i. Let \( j \) and \( s \) be defined so that \( 1 \leq s \leq k \) and \( 1 \leq j \leq \frac{N}{k} \) given \( i = \alpha N + j + (s - 1) \frac{N}{k} \) and let \( m = L_{G,H,x}(i - 1) \mod 2k - s + 1 \).
      ii. Set \( r(i) = U_j[m] + (\alpha - 2)N + 1 + 2jk \) so that \( r(i) \in O_j \) and load \( L_{G,H,x}(r(i)) \).
         (Recall that the label of \( r(i) \) is actually located at the position where the label of node \( \text{Enc}(j \circ K, U[m]) \) was previously located prior to the shuffling.)
      iii. Load \( L_{G,H,x}(r(i)) \) and \( L_{G,H,x}(i - 1) \) and compute \( L_{G,H,x}(i) = H(i \circ L_{G,H,x}(r(i)) \circ L_{G,H,x}(i - 1)) \).
      iv. Let \( U_j[U_j[m]] = a \) and \( U_j[2k - s + 1] = b \). Then swap the values of \( U_j \) at \( U_j[m] \) and \( 2k - s + 1 \) so that \( U_j[U_j[m]] = b \) and \( U_j[2k - s + 1] = a \).

\( \textbf{Figure 9} \) Description of implementation of maximally hard ciMHF. Again note that each computation of \( f_{G,H}(x) \) requires as input random bits \( R \) to generate the leakage pattern.

### 6.2.2 Extension to Multiple Rounds

Finally, we show that our ciMHF implementation is robust to multiple rounds of leakage by considering a data independency game where an adversary is allowed to submit and observe multiple adaptive queries before outputting a guess for the hidden challenge bit \( b \). The game again consists of the phases \text{setup}, \text{challenge}, and \text{guess}, which are described as follows.
Adaptive data independency game for ciMHF:

setup In this phase, $A$ selects the security parameter $\lambda$ and sends it to $H$. $H$ then selects a random bit $b \in \{0, 1\}$.

challenge For each round $i = 1, 2, \ldots$, $A$ chooses two adaptive query messages $x_{i,0}$ and $x_{i,1}$ and sends the query messages to $H$. $H$ selects random coins $R_{i,0}, R_{i,1} \in \{0, 1\}^\lambda$ uniformly at random, and $H$ samples $\text{lp}_{i,0} \leftarrow \text{LP}(\text{MHF.Eval}(x_{i,0}; R_{i,0}))$ and $\text{lp}_{i,1} \leftarrow \text{LP}(\text{MHF.Eval}(x_{i,1}; R_{i,1}))$, and sends the ordered pair $(\text{lp}_{i,b}, \text{lp}_{i,1-b})$ to $A$. Note: $A$ can pick $x_{i+1,0}$ and $x_{i+1,1}$ adaptively after observing the response $(\text{lp}_{i,b}, \text{lp}_{i,1-b})$.

guess The game ends when the adversary $A$ outputs $b'$ as a guess for $b$. $A$ wins the game if $b = b'$.

As before, the advantage of the adversary to win the adaptive data independency game for ciMHF is:

$$Adv_{A,\text{MHF}} = \frac{1}{2} - \Pr[A(T) = b' : b = b']$$

where $T$ is the transcript $\{x_{i,0}, x_{i,1}, \text{lp}_{i,b}, \text{lp}_{i,1-b}\}$ and $\text{lp}_{i,j} = \text{LP}(x_{i,j}; \text{MHF.Eval}(x_{i,j}; R_{i,j}))$.

Definition 26. We say an evaluation algorithm MHF.Eval has $(t, \epsilon)$-single security if any attacker running in time $t$ has at most advantage $\epsilon$ in the data independency game. Similarly, we say an evaluation algorithm MHF.Eval has $(t, r, \epsilon)$-adaptive security if any attacker running in time $t$ and making $r$ queries has at most advantage $\epsilon$ in the adaptive data independency game.

We conclude by noting the following relationship between single security and adaptive security, thus implying the security of our evaluation function in Figure 7 of the dMHF in Figure 4 with respect to the adaptive data independency game.

Theorem 27. $(t, \epsilon)$-single security implies $(t - O(t \cdot \text{time(MHF.Eval)}), r, re)$-adaptive security.

Proof. Suppose that $A_{\text{adaptive}}$ violates $(t - O(t \cdot \text{time(MHF.Eval)}), r, re)$-adaptive security for the sake of contradiction. Without loss of generality we will assume that $A_{\text{adaptive}}$ outputs $b' \equiv b$ with probability greater than $\frac{1}{2} + r \epsilon$. We will use $A_{\text{adaptive}}$ to construct an attacker $A_{\text{single}}$ that violates $(t, \epsilon)$-single security.

We first define a sequence of $r$ hybrids in the adaptive data-independency game. In Hybrid $i$, the challenger $H$ picks bits $b, b_1, \ldots, b_{r-1}$ uniformly at random and sets $b_i = b, b_{i+1} = b, \ldots, b_r = b$. In round $j$ when the attacker $A_{\text{adaptive}}$ submits two strings $x_{i,0}$ and $x_{i,1}$, the challenger $H$ samples $\text{lp}_{j,0} \leftarrow \text{LP}(\text{MHF.Eval}(x_{j,0}; R_{j,0}))$ and $\text{lp}_{j,1} \leftarrow \text{LP}(\text{MHF.Eval}(x_{j,1}; R_{j,1}))$ and then responds with $(\text{lp}_{j,b}, \text{lp}_{j,1-b})$ instead of $(\text{lp}_{j,b}, \text{lp}_{j,1-b})$ i.e., the bit $b_i$ is used to permute the order of the responses in round $i$ instead of $b$.

Observe that in Hybrid 1, $b_1 = \ldots = b_r = b$, so that Hybrid 1 is equivalent to the actual adaptive independency game. Similarly, in Hybrid $r$, the bits $b_1, \ldots, b_r$ are all picked independently so that $A_{\text{adaptive}}$ working in Hybrid $r$ has no advantage i.e., the attacker guesses $b' = b$ correctly with probability at most $\Pr[b' = b \mid \text{Hybrid } r] = \frac{1}{2}$. We observe that the advantage of the attacker is

$$\Pr[b' = b \mid \text{Hybrid } 1] - \frac{1}{2} = \Pr[b' = b \mid \text{Hybrid } 1] - \Pr[b' = b \mid \text{Hybrid } r] = \Delta_2 + \ldots + \Delta_r$$

where $\Delta_i = \Pr[b' = b \mid \text{Hybrid } i - 1] - \Pr[b' = b \mid \text{Hybrid } i]$. By an averaging argument, we must have $\Delta_{i+1} > \epsilon$ for some $i < r$. The following observation will also be useful:

$$\Delta_{i+1} = \frac{1}{2} \Pr[b' = b \mid \text{Hybrid } i] - \frac{1}{2} \Pr[b = b' \mid \text{Hybrid } i + 1, b_i \neq b].$$
Reduction

We now define $A_{\text{single}}$ as follows: (1) $A_{\text{single}}$ simulates $A_{\text{adaptive}}$ along with the adaptive challenger $\mathcal{H}_{\text{adaptive}}$. $A_{\text{single}}$ generates random bits $b_1, \ldots, b_{t-1}$ and sets $b_{t+1} = \ldots = b_r = b''$ for another random bit $b''$. In each round $j \neq i$, when $A_{\text{adaptive}}$ outputs a query $x_{j,0}, x_{j,1}$, our attacker $A_{\text{single}}$ simply computes $l_{p_i,0} \leftleftarrows \text{LP}(\text{MHF.Eval}(x_{i,0}; R_{i,0}))$ and $l_{p_i,1} \leftleftarrows \text{LP}(\text{MHF.Eval}(x_{i,1}; R_{i,1}))$ and responds with $l_{p_i,b,i}, l_{p_i,1-b,i}$. When $A_{\text{adaptive}}$ outputs the query $x_{i,0}, x_{i,1}$ in round $i$, $A_{\text{single}}$ forwards this query to the challenger for the single stage challenger $\mathcal{H}_{\text{single}}$ and receives back $l_{p_i,b,i}, l_{p_i,1-b,i}$ for an unknown bit $b$ selected by $\mathcal{H}_{\text{single}}$. Finally, when $A_{\text{adaptive}}$ outputs a guess $b'$ (for $b''$) $A_{\text{single}}$ outputs the same guess $b'$ (for $b$).

Analysis

Notice that since $b''$ is just a bit selected uniformly at random and independent from $b$, then $\Pr[b' = b'' \mid b'' = b] = \Pr[b' = b'' \mid \text{Hybrid } \hat{i}]$. Then from the above observation, we have $\Pr[b' = b'' \mid b'' \neq b] = \Pr[b' = b'' \mid \text{Hybrid } i + 1, b_i \neq b''] = \Pr[b' = b'' \mid \text{Hybrid } \hat{i}] - 2\Delta_{i+1}$. It follows that $\Pr[b' = b'' \mid b'' = b] = \Pr[b' = b'' \mid b'' \neq b] = 2\Delta_{i+1}$. Thus, the probability that $A_{\text{single}}$ wins is

$$\Pr[b' = b] = \Pr[b' = b] \Pr[b' = b'' \mid b'' = b] + \Pr[b' = b'' \mid b'' \neq b] (1 - \Pr[b' = b'' \mid b'' \neq b])$$

$$= \frac{1}{2} + \Delta_{i+1} > \epsilon.$$

Furthermore, the running time of $A_{\text{single}}$ is at most $t$. This contradicts the assumption that the evaluation algorithm $\text{MHF.Eval}$ has $(t, \epsilon)$-single security. Therefore, $(t, \epsilon)$-single security implies $(t - O(r \cdot \text{time}(\text{MHF.Eval})), r, re)$-adaptive security.

Abstract
Let $F$ be a multivariate function from a product set $\Sigma^n$ to an Abelian group $G$. A $k$-partition of $F$ with cost $\delta$ is a partition of the set of variables $V$ into $k$ non-empty subsets $(X_1, \ldots, X_k)$ such that $F(V)$ is $\delta$-close to $F_1(X_1) + \cdots + F_k(X_k)$ for some $F_1, \ldots, F_k$ with respect to a given error metric.

We study algorithms for agnostically learning $k$ partitions and testing $k$-partitionability over various groups and error metrics given query access to $F$. In particular we show that

1. Given a function that has a $k$-partition of cost $\delta$, a partition of cost $O(kn^2(\delta + \epsilon))$ can be learned in time $\tilde{O}(n^2 \text{poly} 1/\epsilon)$ for any $\epsilon > 0$. In contrast, for $k = 2$ and $n = 3$ learning a partition of cost $\delta + \epsilon$ is NP-hard.

2. When $F$ is real-valued and the error metric is the 2-norm, a 2-partition of cost $\sqrt{\delta^2 + \epsilon}$ can be learned in time $\tilde{O}(n^5/\epsilon^2)$.

3. When $F$ is $\mathbb{Z}_q$-valued and the error metric is Hamming weight, $k$-partitionability is testable with one-sided error and $O(kn^3/\epsilon)$ non-adaptive queries. We also show that even two-sided testers require $\Omega(n)$ queries when $k = 2$.

This work was motivated by reinforcement learning control tasks in which the set of control variables can be partitioned. The partitioning reduces the task into multiple lower-dimensional ones that are relatively easier to learn. Our second algorithm empirically increases the scores attained over previous heuristic partitioning methods applied in this context.

1 Introduction

Divide-and-conquer methods rely on the ability to identify independent sub-instances of a given instance, such as connected components of graphs and hypergraphs. When these are not available one looks for partitions into loosely related parts like small or sparse cuts. These classic problems and their variants remain at the forefront of algorithmic research [6, 7, 16, 20, 24, 29].

We study the related problem of function decomposition: Given a multivariate function \( F(V) \) over \( n \) variables \( V = \{ x_1, \ldots, x_n \} \), we seek to partition the variables into \( k \) groups \( X_1, \ldots, X_k \) so that \( F \) decomposes into a sum \( F_1(X_1) + \cdots + F_k(X_k) \). In case an exact decomposition of this type is unavailable, we seek an approximate one under a suitable error metric. This algebraic partitioning question can be sensibly asked for any Abelian group. While some of our results are quite general, two particular cases of interest are addition over \( \mathbb{Z}_2 \) with respect to the Hamming metric and addition over reals with respect to the 2-norm.

As a multivariate function is an exponentially large object, it is sensible to model the input \( F \) to the partitioning problem as an oracle and allow query access to it. This departs from the common setup in (hyper)graph partitioning problems, where an explicit representation of the input is assumed to be available. While variable partitioning of real-valued functions under the 2-norm turns out to be closely related to hypergraph partitioning, the difference in input access models renders certain techniques developed for the latter (e.g., random contractions) inapplicable to our setting.

Our work is motivated by learning control variables in high-dimensional reinforcement learning control [25, 33, 34]. If the advantage function of the control variables can be partitioned into multiple lower-dimensional subsets, then these subsets of variables can be learned independently with a relatively easier Monte-Carlo sampling. This advantage function involves the estimates of a dynamic system, which is complex enough to not have an explicit representation available. The function is thus treated as an oracle as is in our access model. Sometimes it is natural to assume that the function should be almost decomposable; for example, if we seek to control two robots jointly performing a task, the variables controlling the respective robots are almost independent. (The robots may be collaborating so the decomposition might not be perfect.) In general, the dependencies are not known in advance but need to be learned from observed behavior. Some heuristic methods have been applied to control variable partitioning [23, 36] but not rigorously analyzed.

Our contributions

Our main results are algorithmic: We show that variable partitions can be learned agnostically. Let \( F(V) \) be a function from some product set to an Abelian group \( G \). A direct sum decomposition of \( F \) is a partition \( (X_1, \ldots, X_k) \) of the set of variables \( V \) such that \( F(V) = F_1(X_1) + \cdots + F_k(X_k) \) for some functions \( F_1, \ldots, F_k \). When the decomposition is imperfect, the decomposition error is measured by

\[
\delta(X_1, \ldots, X_k) = \min_{F_1, \ldots, F_k} \| F(X_1, \ldots, X_k) - F_1(X_1) - \cdots - F_k(X_k) \|,
\]

where \( \| \cdot \| : G \to \mathbb{R}^+ \) is a partial norm. The definition is given in Section 2; the main examples of interest are \( G = \mathbb{Z}_q \) under the Hamming metric \( \| F \| = \Pr[F(V) = 0] \) and \( G = \mathbb{R} \) under the \( p \)-norm \( \| F \|_p = \mathbb{E}[|F(V)|^p]^{1/p} \) for any \( p \geq 1 \) under some product measure. We seek an approximation of the best-possible partition, which minimizes the objective

\[
\delta_2(F) = \min_X \delta(X, X),
\]
for bipartition and
\[ \delta_k(F) = \min_{X_1, \ldots, X_k} \delta(X_1, \ldots, X_k). \] (3)
for k-partition. (For p-norms over \(\mathbb{R}\) we use the notations \(\|\cdot\|_{\mathbb{R},p}\), \(\delta_{\mathbb{R},2}(F)\), and \(\delta_{\mathbb{R},k}(F)\).)

**Theorem 1.** Let \(\|\cdot\|\) be either 1) \(\|\cdot\|_{\mathbb{R},p}\) assuming \(\|F\|_{\mathbb{R},2p} = O(1)\), or 2) the Hamming metric over \(\mathbb{Z}_q\). There is an algorithm that given parameters \(n, k, \varepsilon, \gamma\), and oracle access to \(F : \Sigma^n \to \mathbb{R}\) outputs a k-partition \(\mathcal{P}\) such that \(\delta(\mathcal{P}) \leq O(kn^2)(\delta_k(F) + \varepsilon)\) with probability at least \(1 - \gamma\). The algorithm makes \(O(K^p n^2 \log(n/\gamma)/\varepsilon^{3p})\) queries to \(F\) and runs in time linear in the number of queries, for an absolute constant \(K\).

This algorithm is closely related to the heuristic ones used in the aforementioned empirical studies. However, it only guarantees optimality up to an \(O(kn^2)\) approximation factor. While we do not know if an approximation factor of this magnitude is inevitable, in Proposition 17 we show that obtaining a solution with additive error is NP-hard. The proofs are given in Section 4.

In contrast, our second algorithm obtains an additive error for bipartitions of real-valued functions under the 2-norm:

**Theorem 2.** Let \(F : \Sigma^n \to \mathbb{R}\) be a function with \(\|F\|_{\mathbb{R},4} \leq 1\). There is an algorithm that given inputs \(n, \varepsilon, \gamma\), and oracle access to \(F\), runs in time \(O(n^3 \log(n/\gamma)/\varepsilon^2)\) and outputs a bipartition \((X, \overline{X})\) such that \(\delta_{\mathbb{R},2}(X, \overline{X})^2 \leq \delta_{\mathbb{R},2}(F)^2 + \varepsilon\) with probability at least \(1 - \gamma\).

More generally, we give evidence that it may be possible to output a \(\sqrt{2 - 2/k}\)-approximate k-partition in time \(\text{poly}(n^k, k, 1/\varepsilon)\) (Corollary 21). For unbounded \(k\) finding a good approximation is ETH hard (Corollary 19).

Theorem 2 and Corollary 19 are based on an equivalence between variable partitioning under the 2-norm and hypergraph partitioning given in Proposition 18. The results are described and proved in Section 5.

As a consequence of Theorem 1, the property of being close to a k-partition is testable with \(O(k^{2p} n^{2p+2}/\varepsilon^{2p})\) queries. The query complexity of the tester can be somewhat improved:

**Theorem 3.** k-partitionability is testable with one-sided error and \(O(kn^3/\varepsilon)\) non-adaptive queries with respect to Hamming weight over \(\mathbb{Z}_q\), and with \(O(k^{2p} n^3/\varepsilon^{2p})\) non-adaptive queries with respect to the p-norm over \(\mathbb{R}\) assuming \(\|F\|_{2p} \leq 1\).

In Section 6 we prove Theorem 3 and show that \(\Omega(n - k)\) queries are necessary even for two-sided error testers.

**Ideas and techniques.**

Our Theorem 1 is inspired by algebraic property testing techniques. The starting point is the dual characterization of partitionability into sets \((X, \overline{X})\) by the constraints \(D_F(X, Y) = 0\), where \(D_F = F(X, Y) - F(X', Y) - F(X, Y') + F(X', Y')\), for all assignments \(X, X'\) to \(X\) and
Learning and Testing Variable Partitions

Y, Y' to Y. David et al. [10] apply this relation to random inputs towards testing whether a \( \mathbb{Z}_2 \)-valued function \( F \) tensors decomposes into a direct sum. The acceptance probability of this test approximates the best decomposition to within a factor of 4 (Proposition 4).

Our partitioning algorithm estimates the dependence score \( \| D_F(x, y) \| \) on every pair of variables \( x, y \) (keeping the rest fixed) to decide whether they should be partitioned or not. Here, \( \| D_F \| \) is the probability that the test \( D_F = 0 \) fails for discrete groups like \( \mathbb{Z}_2 \). In general, it can represent any error metric satisfying the axioms in Section 2. The proof of Theorem 1 amounts to showing that a collection of single variable partitions \( (x, y) \in P \) for which the local scores \( \| D_F(x, y) \| \) are small can be glued together into a single \( k \)-partition \( P \) with a small global score.

When \( F \) is real-valued and error is measured under the 2-norm, variable partitioning has a natural geometric interpretation. Functions that depend on different coordinates are orthogonal modulo their constant term, so the optimal decomposition with respect to a fixed partition \( (X_1, \ldots, X_k) \) is given by the projection of \( F \) onto the respective subspaces of functions. This yields an equality between the distance and the dependence score (6) for bipartitions and a generalization to \( k \)-partitions (Proposition 8). Variable partitioning for functions is then equivalent to hypergraph partitioning of their orthogonal decompositions (Proposition 18), with the cost of cut \( (X, X) \) given by \( \frac{1}{4} \| D_F(x, y) \|^2 \).

This connection suggests the application of hypergraph partitioning algorithms that can be implemented with access to an approximate cut oracle\(^2\), leading to Theorem 2. On the negative side it reveals that approximately optimal partitions into a large number of components are hard to find (Corollary 19).

Application to reinforcement learning control

We plug our partitioning algorithm back to reinforcement learning control. In this setting, the oracle is real-valued and as we adapt the 2-norm we use the submodularity cut algorithm described in Theorem 2.

We compare empirically with three previous approaches: The baseline that does not involve partitioning [25, 35]; the baseline that trivially partitions \( n \) variables into \( n \) subsets [22, 36]; the work that partitions the variables heuristically [23]. The way [23] partitions the variables is to calculate the discrete estimate of the Hessian of the oracle. Then they remove from Hessian the elements with lowest absolute values, until it forms at least \( k \) connected components if the Hessian matrix is treated as the adjacency matrix.

The scores we attained on the tasks in the physics simulator are improved over these approaches, which is demonstrated in Section 7.

Relation to other learning and testing problems

A \( j \)-junta is a function that depends on at most \( j \) of its \( n \) variables. The problems of learning and testing juntas have been extensively studied [2, 4, 8, 9, 13, 26, 30]. While a \( j \)-junta is always \( (n - j + 1) \)-partitionable, the two problems are technically incomparable. Moreover, juntas are usually studied in the regime where the junta size \( j \) is significantly smaller than the number of variables \( n \) and are therefore partitionable into many (mostly trivial) components.

\(^2\)Several state-of-the-art algorithms for cuts in graphs and hypergraphs rely on random contractions [6, 17, 18]. In particular, Rubinstein et al. [29] showed that \( O(n) \) queries to an exact cut oracle and similar running time are sufficient to find the minimum cut. We do not know if comparable efficiency can be obtained with an approximate oracle.
In this work we are mostly interested in partitions into two or a small number of components. Nevertheless, this connection between juntas and partitionable functions is used to prove the testing lower bound in Section 6.

Dinur and Golubev [12] showed that the existence of decomposition with respect to a fixed $k$-partition (given as input) is testable with four queries and soundness error $\Omega(\delta)$. The case $k = 2$ was already analyzed by David et al. [10] (see Section 3).

2 Some additional definitions

Let $F(V)$ be a function from some product set to an Abelian group $G$. In general we will assume that the variables $V$ take values in some set $\Sigma$ endowed with a product measure which is efficiently sampleable. The quality of the partition $(X_1, \ldots, X_k)$ of $V$ is measured by $\delta(X_1, \ldots, X_k)$ given in (1), where $\| \cdot \| : G \to \mathbb{R}^+$ can be any functional satisfying the following three axioms:

1. $\|0\| = 0$;
2. $\|F_1 + F_2\| \leq \|F_1\| + \|F_2\|$;
3. $\mathbb{E}[\|F(X, \cdot)\| | X] \leq \|F\|$ for any set of variables $X$ of $F$.

Our goal is to approximately optimize $\delta_2(F)$ in (2) and $\delta_k(F)$ in (3).

Our algorithms are based on the following dependence estimator inspired by the rank-1 test of [10]. Let $X$ and $Y$ be two disjoint sets of variables. The dependence estimator $D_F(X, Y)$ is the random variable

$$D_F = F(X, Y, Z) + F(X', Y', Z) - F(X', Y, Z) - F(X, Y', Z)$$

where $X, X'$ are independent samples of the $X$ variable, $Y, Y'$ are independent samples of the $Y$ variable, and $Z$ is a random sample of the remaining variables. If $F$ decomposes into a direct sum that partitions the $X$ and $Y$ variables then $D_F$ equals zero. Conversely, $\|D_F\|$ measures the quality of the approximation.

In the analysis it will be convenient to use the notation $F \approx_\delta G$ for $\|F - G\|_p \leq \delta$. The following two facts are immediate consequences of axioms 2 and 3:

**Triangle inequality:** If $F \approx_\delta G$ and $G \approx_\delta H$ then $F \approx_\delta + \delta H$.

**Fixing:** If $F(X, Z) \approx_\delta G(X, Z)$ then $F(X, Z) \approx_\delta G(X, Z)$ for some fixed value $X$.

3 Estimating the quality of a partition

In this section we show that $\|D_F(X, Y)\|$ is an approximate estimator for the quality $\delta(X, Y)$ of a decomposition, namely

$$\delta(X, Y) \leq \|D_F(X, Y)\| \leq 4 \cdot \delta(X, Y). \quad (4)$$

The proof is given in Claims 5 and 6 below. As $\|D_F(X, Y)\|$ can be estimated efficiently from oracle access to $F$ (Claim 7), we obtain an algorithm for estimating the quality of a partition to within a factor of 4 in general, and exactly for the 2-norm over $\mathbb{R}$.

▷ Proposition 4. Let $\| \cdot \|$ be either 1) $\| \cdot \|_{\mathbb{R}, p}$ assuming $\|F\|_{\mathbb{R}, 2p} = O(1)$, or 2) the Hamming metric over $\mathbb{Z}_q$. There is an algorithm that given a bipartition $X, Y$ of the variables and parameters $\varepsilon, \gamma > 0$, outputs a value $\hat{\delta}$ such that

$$\delta(X, Y) \leq \hat{\delta} \leq 4 \cdot \delta(X, Y) + \varepsilon,$$

with probability at least $1 - \gamma$ from $Kp\log(1/\gamma)/e^{2p}$ queries to $F$ in time linear in the number of queries, for an absolute constant $K$. 

ITCS 2020
The value of $\delta(X,Y)$ is known to be NP-hard to calculate exactly over $\mathbb{Z}_2$ under the Hamming metric given explicit access to the truth-table of $f$ [28]. Therefore some approximation factor is unavoidable for algorithms running in time polynomial in $n$ and $1/\varepsilon$ unless BPP is in NP. On the positive side Karpinski and Schudy [19] give a fully polynomial-time randomized approximation scheme for this special case. Their algorithm requires at least linear time but it is plausible that a sublinear-time variant can be obtained. However, it appears unrelated to the dependence score $D_F$ which plays an essential role in the results to follow.

The analysis of $D_F$ applies to any pair of disjoint subsets $X$, $Y$ that do not necessarily partition all the variables. In this more general setting distance is measured by the formula

$$\delta(X,Y) = \min_{A,B} \|F(X,Y,Z) - A(X,Z) - B(Y,Z)\|.$$  \hfill (5)

Claim 5 (Completeness of $D_F$). For all disjoint $X$, $Y$, $\|D_F(X,Y)\| \leq 4 \cdot \delta(X,Y)$.

Proof. By definition of $\delta(X,Y)$ there exists a decomposition of the form

$$F(X,Y,Z) = A(X,Z) + B(Y,Z) + D(X,Y,Z),$$

where $\|D(X,Y,Z)\| = \delta(X,Y)$. In the expansion of $D_F$ all the $A$ and $B$ terms cancel out, leaving

$$\|D_F(X,Y)\| = \|D(X,Y,Z) + D(X',Y',Z) - D(X,Y',Z) - D(X',Y,Z)\|$$

$$\leq \|D(X,Y,Z)\| + \|D(X',Y',Z)\| + \|D(X',Y,Z)\| + \|D(X',Y,Z)\|$$

$$= 4\delta(X,Y).$$

Soundness for Boolean functions under the uniform measure was proved by David et al. [10]. We reproduce their proof under a more general setting.

Claim 6 (Soundness of $D_F$). For all disjoint $X$, $Y$, $\delta(X,Y) \leq \|D_F(X,Y)\|$.

Proof. Let $\varepsilon = \|D_F(X,Y)\|$. Then

$$F(X,Y,Z) \approx_{\varepsilon} F(X,Y',Z) - F(X',Y,Z) - F(X',Y',Z).$$

We can fix values $X'$ and $Y'$ for which

$$F(X,Y,Z) \approx_{\varepsilon} F(X',Y',Z) - F(X,Y',Z) - F(X',Y',Z) = A(X,Z) + B(Y,Z),$$

where $A(X,Z) = F(X',Y',Z) - F(X,Y',Z)$ and $B(Y,Z) = F(X',Y,Z)$.

Proposition 4 now follows from inequality (4) and the following claim, which states that $\|D_F\|$ can be estimated by sampling in the cases of interest. See Appendix A for the proof.

Claim 7. Assuming $\|F\|_{\mathbb{R},2p} \leq 1$, the value $\|F\|_{\mathbb{R},p}$ can be estimated within $\varepsilon$ from $K^p \log(1/\gamma)/\varepsilon^{2p}$ (random) queries to $F$ in linear time with probability $1 - \gamma$ for some absolute constant $K$.

3.1 Exact partitioning under the 2-norm

Since computing the optimal partition is in general NP-complete, we do not expect to replace the inequalities in (4) with an equality. However, in the special case of real-valued functions with $\ell^2$-norm, the estimate becomes exact:

$$\|D_F(X,Y)\|_{\mathbb{R},2} = 2 \cdot \delta_{\mathbb{R},2}(X,Y).$$  \hfill (6)

This equality is a consequence of the following characterization of $\delta_{\mathbb{R},2}$, which applies more generally to $k$-partitions:
\textbf{Proposition 8.} Assuming $E[F] = 0$, the $k$-partition $F_i(X_i) = E[F|X_i]$ achieves the minimum for $\delta_{\mathbb{R},2}(X_1, \ldots, X_k)$.

In particular it follows that $\delta_{\mathbb{R},2}$ takes the value

$$\delta_{\mathbb{R},2}(X_1, \ldots, X_k) = E[(F - E[F|X_1] - \cdots - E[F|X_k])^2],$$

where $F = F - E[F]$. To derive identity (6) it remains to verify that when $k = 2$, the right-hand side of (7) is a quarter of $\|D_F\|^2$:

\textbf{Fact 9.} $\|D_F(X, Y)\|^2 = 4 \cdot E[(F - E[F|X] - E[F|Y])^2]$.

Armed with this fact we prove the proposition.

\textbf{Proof of Proposition 8.} First assume $F(X, Y)$ is bivariate. Let $A(X)$ be any function. The inequality $E[(E[F|X] - A(X))^2] \geq 0$ can be rewritten as

$$E[(F - E[F|X])^2] \leq E[(F - A(X))^2],$$

stating that the orthogonal projection of $F$ onto the subspace of functions that depend only on $X$ in 2-norm is $E[F|X]$.

Now let $F(X_1, \ldots, X_k)$ be $k$-variate. Assume $E[F] = 0$ and $E[F_i(X_i)] = 0$ for all $i$. Then $E[F_i(X_i)|X_j] = 0$ for all $i \neq j$. Applying inequality (8) for $k$ times in succession together with this fact, we obtain

$$E[(F - F_1(X_1) - \cdots - F_{k-1}(X_{k-1}) - F_k(X_k))^2]$$

$$\geq E[(F - F_1(X_1) - \cdots - F_{k-1}(X_{k-1}) - E[F - F_1(X_1) - \cdots - F_{k-1}(X_{k-1})|X_k])^2]$$

$$= E[(F - F_1(X_1) - \cdots - F_{k-1}(X_{k-1}) - E[F|X_k])^2]$$

$$\vdots$$

$$\geq E[(F - E[F|X_1] - \cdots - E[F|X_k])^2]$$

as desired. Finally, by orthogonality the optimal decomposition must satisfy $\sum E[F_i(X_i)] = 0$ so the assumption $E[F_i(X_i)] = 0$ can be made without loss of generality.

By orthogonality, equation (7) can also be written in the following forms:

$$\delta_{\mathbb{R},2}(X_1, \ldots, X_k) = E[F^2] - \sum_{i=1}^{k} E[F|X_i]^2$$

$$= E_X[F(X)^2] - \sum_{i=1}^{k} E_{X_i,X'}[F(X_{-i},X_i)F(X'_{-i},X_i)],$$

where $(X_{-i}, X_i)$ is the input whose $i$-th variable takes value $X_i$ and $j$-th variable takes value $X'_j$ for $j \neq i$. As all these terms can be efficiently estimated, we obtain the following algorithm for estimating the quality of a given $k$-partition:

\textbf{Proposition 10.} There is an algorithm that given a $k$-partition $X_1, \ldots, X_k$ of the variables and parameters $\epsilon, \gamma > 0$, outputs a value $\delta$ such that

$$|\delta^2 - \delta_{\mathbb{R},2}(X_1, \ldots, X_k)| \leq \epsilon,$$

with probability at least $1 - \gamma$ from $O(k \log(k/\gamma)/\epsilon^4)$ queries to $F$ in time linear in the number of queries.
4 Variable partitioning over general groups

In this section we present our first partitioning algorithm, which is general enough to work on any normed group $G$ assuming it is possible to efficiently estimate the quantity $\|D_F(\{x\}, \{y\})\|$.

The algorithm is based on the pairwise estimates of dependency over sets of single variables. The intuition behind the algorithm is that if the dependency between $x$ and $y$ is low, then these two variables should be assigned to different partitions. Therefore the algorithm keeps asserting such “in different partitions” for the pairs with lowest dependency estimates, until the $k$-partitioning can be clearly observed from the assertions.

This idea of the algorithm has been used in previous works in reinforcement learning control [23,36] in a heuristic way. Theorem 1 below shows that the algorithm outputs an $O(kn^2)$ approximation to the optimal partition in time polynomial in $n$, $k$, and $1/\varepsilon$.

Algorithm 1 Approximate partitioning via pairwise estimates.

1: Input: number of partitions $k$
2: Output: partition $P$
3: For every pair of variables $x, y \in V$, find estimate $\hat{e}(x, y)$ for $e(x, y) = \|D_F(\{x\}, \{y\})\|$;
4: Create a weighted graph with vertices $V$ and weights $\hat{e}(x, y)$;
5: Order the edges in increasing weight;
6: repeat
7: Remove the edge with the smallest weight;
8: until The graph has exactly $k$ connected components

Proposition 11. Assuming $e(x, y) \leq \hat{e}(x, y) \leq e(x, y) + \varepsilon$ for all $x$ and $y$,

$$\delta(P) \leq (8k - 10)n^2(4\delta_k(F) + \varepsilon).$$

If the estimates $\hat{e}(x, y)$ are obtained by empirical averaging, we obtain Theorem 1.

4.1 Proof of Proposition 11

For a partition $P$ of the variables, let $\Delta(P) = \sum \delta(\{x\}, \{y\})$, where the sum is taken over all pairs that cross the partition. We will deduce Theorem 1 from the following bound on $\delta(P)$.

Claim 12. For every $k$-partition $P$, $\delta(P) \leq (16k - 20)\Delta(P)$.

The following fact is immediate from the definitions of $\delta$. The proof of this claim is delayed to the end of this section.

Fact 13. For any partition $(U, \overline{U})$ such that $X \subseteq U$ and $Y \subseteq \overline{U}$, $\delta(X, Y) \leq \delta(U, \overline{U})$.

Now we prove the theorem, assuming the correctness of Claim 12.

Theorem 1. Let $\|\cdot\|$ be either 1) $\|\cdot\|_{\mathbb{R},p}$ assuming $\|F\|_{\mathbb{R},2p} = O(1)$, or 2) the Hamming metric over $\mathbb{Z}_q$. There is an algorithm that given parameters $n$, $k$, $\varepsilon$, $\gamma$, and oracle access to $F: \Sigma^n \rightarrow \mathbb{R}$ outputs a $k$-partition $P$ such that $\delta(P) \leq O(kn^2)(\delta_k(F) + \varepsilon)$ with probability at least $1 - \gamma$. The algorithm makes $O(Kp^2n^2 \log(n/\gamma)/\varepsilon^{2p})$ queries to $F$ and runs in time linear in the number of queries, for an absolute constant $K$. 
Proof of Theorem 1. By Claim 5 and Fact 13, all edges \((x, y)\) in the optimal partition must satisfy \(e(x, y) \leq 4\delta_2(F)\). By our assumption on the quality of the approximations,

\[
\hat{e}(x, y) \leq 4\delta_2(F) + \varepsilon. 
\]  

(11)

Since the algorithm removes edges in increasing order of weight, all the edges that cross the output partition \(P\) must also satisfy this inequality. Then

\[
\begin{align*}
\delta(P) &\leq (16k - 20) \Delta(P) \\
&\leq (16k - 20) \sum_{x, y \text{ cross } P} e(x, y) \\
&\leq (16k - 20) \sum_{x, y \text{ cross } P} \hat{e}(x, y) \\
&\leq (16k - 20) \sum_{x, y \text{ cross } P} 4\delta_2(F) + \varepsilon \\
&\leq (8k - 10)n^2 \cdot (4\delta_2(F) + \varepsilon).
\end{align*}
\]

The last inequality holds because there are at most \(n^2/2\) pairs of variables crossing the partition.

We first prove Claim 12 in the case \(k = 2\) of bipartitions. This is Claim 15 below. We use \(XX'\) to denote the union of the variable sets \(X\) and \(X'\).

\> Claim 14. For disjoint sets of variables \(X, X', Y\), \(\delta(XX', Y) \leq \delta(X, Y) + 2\delta(X', Y)\).

Proof. Assume that

\[
\begin{align*}
F(X, X', Y) &\approx_{\delta} A(X, X') + B(X', Y) \\
F(X, X', Y) &\approx_{\delta'} A'(X, X') + B'(X, Y).
\end{align*}
\]

By the triangle inequality,

\[
A(X, X') + B(X', Y) \approx_{\delta + \delta'} A'(X, X') + B'(X, Y).
\]

Fix \(X'(Z) = X'(Z)\). Writing \(C(X) = A(X, X') - A'(X, X')\) and \(D(Y') = B(X', Y')\) we get that

\[
B'(X, Y) \approx_{\delta + \delta'} C(X) + D(Y).
\]

By the triangle inequality (with the second equation), we get that

\[
F(X, X', Y) \approx_{\delta + 2\delta'} A'(X, X') + C(X) + D(Y). 
\]

\> Claim 15. For every bipartition \(X, \overline{X}\) of the variables, \(\delta(X, \overline{X}) \leq 4 \cdot \Delta(X, \overline{X})\).

Proof. By Claim 14,

\[
\delta(X \setminus \{x\}, \{y\}) \leq \delta(X \setminus \{x\}, \{y\}) + 2\delta(\{x\}, \{y\})
\]

for all \(X' \subseteq X \setminus \{x\}\) and \(y\). Applying this inequality iteratively we conclude that \(
\delta(X, \{y\}) \leq 2 \sum_{x \in X} \delta(\{x\}, \{y\})\). Also by Claim 14

\[
\delta(X, Y'(y)) \leq \delta(X, Y') + 2\delta(X, Y'(y)),
\]

so \(\delta(X, Y) \leq 2 \sum_{y \in Y} \delta(X, \{y\})\). Combining the two inequalities we obtain the desired conclusion.
4.2 Hardness of exact variable bipartitioning

In contrast to Theorem 1, finding the exact bipartition is NP-hard even when there are only three variables.

\[ \text{Proposition 17. For any } n \geq 3 \text{ there is no algorithm that outputs a bipartition of cost } \delta(F) + \varepsilon \text{ over } \mathbb{Z}_2 \text{ under Hamming distance in time polynomial in } |\Sigma|/\varepsilon \text{ with constant probability unless } \text{BPP is in NP}. \]

\[ \text{Proof. Assume such an algorithm } \text{BIPARTITION} \text{ exists. We show it can be used to solve the following problem: Given explicit functions } \{F_1, \ldots, F_{n-1}: \Sigma^2 \rightarrow G\}, \text{ find } i^* \text{ that minimizes } \delta(F_{i^*}) \text{ assuming this } i^* \text{ is unique, i.e. a function that has the smallest bipartition cost among the candidates.} \]
Let $F(x_1, \ldots, x_{n-1}, y) = F_1(x_1, y) + \cdots + F_{n-1}(x_{n-1}, y)$. The cost of the bipartition that splits $x_i$ from all other variables in $F$ is at most the cost of $F_i$, so $F$ has a bipartition of cost at least $\delta_2(F_i)$. We now argue that the cost of all other bipartitions is greater. In fact, any other bipartition must split $y$ from $x_i$ for some $i \neq i^*$. Assuming the cost of this partition is $\delta$, we must have

$$F(X, Y) \approx_\delta A(X) + B(Y),$$

where $x_i \in X$ and $y \in Y$. After fixing all variables except for $x_i$ and $y$ we obtain

$$F_i(x_i, y) \approx_\delta A(x_i, X_{-i}) + B(y, Y_{-i}) - \sum_{j \neq i} F_j(x_i, y).$$

This is a bipartition for $F_i$ so its cost is strictly greater than $\delta_2(F_i)$. Therefore the output of $\text{BIPARTITION}$ with oracle access to $F$ and $\epsilon = 1/|\Sigma|^2$ has the desired property.

Roth and Viswanathan [28] give an efficient reduction $R$ that maps a graph $G$ into a function $F$ such that if $G$ has a larger max-cut than $G'$ then $\delta_2(R(G)) < \delta_2(R(G'))$. By composing the two reductions we obtain an efficient algorithm for deciding which of two graphs has a larger maximum cut, which is an NP-hard problem. ▶

## 5 Partitioning real-valued functions under the 2-norm

The problem of partitioning real-valued functions under the 2-norm is closely related to the well-studied problem of hypergraph partitioning. To explain this connection we recall the Efron-Stein decomposition of real-valued functions over product sets. The Efron-Stein decomposition of a function $F: \Sigma^n \to \mathbb{R}$ (under some product measure) is the unique decomposition of the form

$$F(x) = \sum_{S \subseteq [n]} \hat{F}_S \cdot F_S(x),$$

where $\hat{F}_S$ are real coefficients and $F_S$ are functions satisfying the following properties:

1. $F_S$ depends on the variables in $S$ only;
2. $\mathbb{E}[F_S|x_{-i}] = 0$, where $x_{-i}$ is a fixing of all variables except the $i$-th one;

In particular, properties 1 and 2 imply that $\mathbb{E}[F_S F_T] = 0$ when $S \neq T$, and so $\mathbb{E}[F^2] = \sum_S \hat{F}_S^2$ by property 3.

\begin{proposition}
Given $F: \Sigma^n \to \mathbb{R}$, let $H$ be the hypergraph whose vertices are the variables of $F$ and whose hyperedges $S$ have weight $\hat{F}_S^2$ for every subset $S$. The cost of the $k$-cut $(X_1, \ldots, X_k)$ in $H$ equals $\delta_{\mathbb{R}, 2}(X_1, \ldots, X_k)^2$.
\end{proposition}

\begin{proof}
We may assume $\mathbb{E}[F] = 0$ and use expression (9) to evaluate $\delta_{\mathbb{R}, 2}$. The first term equals $\mathbb{E}[F^2] = \sum_S \hat{F}_S^2$. The rest of the terms have the form $\mathbb{E}[\mathbb{E}[F|X]]^2 = \mathbb{E}[F(X_{-I}, X_I)F(X_{-I}', X_I')]$ for subsets $I$ of variables. Plugging in the Efron-Stein decomposition of $F$ we have

$$\mathbb{E}[\mathbb{E}[F|X]]^2 = \sum_{S,T} \hat{F}_S \hat{F}_T \mathbb{E}[F_S(X_{-I}, X_I)F_T(X_{-I}', X_I)].$$

By property 2, the terms in the summation in which $S \neq T$ evaluate to zero. Among the rest, if the set $S$ contains any variable $i$ outside $I$ then

$$\mathbb{E}[F_S(X_{-I}, X_I)F_T(X_{-I}', X_I)] = \mathbb{E}[F_S(X_{-I}, X_I)\mathbb{E}[F_T(X_{-I}', X_I)|X, X_{-I}]]$$

ITCS 2020
and the inside expectation evaluates to zero by property 2. Therefore the only surviving terms are those where $S = T$ and $S \subseteq I$, from where
\[
\mathbb{E}[\mathbb{E}[F[X]]^2] = \sum_{S \subseteq I} \hat{F}_S^2.
\]

By (9),
\[
\delta_{R,2}(X_1, \ldots, X_k) = \sum_S \hat{F}_S^2 - \sum_{i=1}^k \sum_{S \subseteq X_i} \hat{F}_S^2 = \sum_S \hat{F}_S^2 - \sum_{S \not\subseteq X_i} \hat{F}_S^2.
\]

The last quantity is the desired value of the cost of $k$-cut in $H$.

When $\Sigma = \{-1, 1\}$ under uniform measure, the functions $F_S$ do not depend on $F$ and equal the Fourier characters $\chi_S(x) = \prod_{i \in S} x_i$, allowing us to embed instances of hypergraph partitioning into variable partitioning.

> **Corollary 19.** Assume there is an algorithm $A$ that given oracle access to $F : \{-1, 1\}^n \to \mathbb{R}$ under uniform measure outputs a $k$-variable partition of cost at most $C \cdot \delta_2(F) + \varepsilon$ in time $t(n, k, \varepsilon)$. Then given a hypergraph with $n$ vertices and $m$ hyperedges with a $k$-cut of value $\text{opt}$, it is possible to output a $k$-cut of value $C \cdot \text{opt}$ in time $\Omega(n^m)$.

Chekuri and Li [7] give a reduction from hypergraph $k$-cut to densest-$k$-subgraph. Manurangsi [24] shows that the latter is hard to approximate to within $O(n^{1/(\log \log n)^c})$ assuming the exponential-time hypothesis, implying inapproximability of the same order for $\delta_{R,2}(F)$.

On the positive side, Proposition 18 can be used to obtain variable partitioning algorithms from hypergraph partitioning ones. The conversion is not direct as hypergraph partitioning assumes explicit access to the hypergraph. Klimmek and Wagner [21] observed that submodularity of the hypergraph cut function $f(X) = \delta_{R,2}(X, \overline{X})^2$ allows for efficient minimization from exact oracle access. To derive Theorem 2 we extend the analysis to approximate oracle access.

The following proposition is an analysis of Queyranne’s symmetric submodular minimization algorithm [27] for an approximate input oracle. We say $g$ is $\varepsilon$-submodular if $g(XYZ) - g(XZ) - g(YZ) + g(Z) \leq \varepsilon$ for all disjoint subsets $X, Y, Z$.

> **Proposition 20 (Queyranne’s algorithm with an approximate oracle).** There is an algorithm that given oracle access to a symmetric $\varepsilon$-submodular $g$, makes $O(n^3)$ oracle queries and outputs a nontrivial subset $X$ such that $g(X)$ is within $\varepsilon/2$ of the minimum of $g$.

> **Theorem 2.** Let $F : \Sigma^n \to \mathbb{R}$ be a function with $\|F\|_{\mathbb{R}, 4} \leq 1$. There is an algorithm that given inputs $n$, $\varepsilon$, $\gamma$, and oracle access to $F$, runs in time $O(n^3 \log(n^3) / \varepsilon^2)$ and outputs a bipartition $(X, \overline{X})$ such that $\delta_{R,2}(X, \overline{X})^2 \leq \delta_{R,2}(F)^2 + \varepsilon$ with probability at least $1 - \gamma$.

**Proof of Theorem 2.** By Proposition 10, $\delta_{R,2}(X, \overline{X})^2$ can be estimated to within error $\varepsilon/Kn$ with $O(\log(n^3)/n^3/\varepsilon^2)$ queries to $F$ with probability $1 - K\gamma/n^3$ for any constant $K$. This estimator implements an $\varepsilon/2n$-approximate oracle to $\delta_{R,2}(X, \overline{X})^2$ with probability $1 - \gamma$ with respect to an algorithm that makes at most $Kn^3$ queries. In particular, with probability $1 - \gamma$, the output of the oracle is $\varepsilon/2n$-close to the value of the submodular function $\delta_{R,2}$ at all points queried by Queyranne’s algorithm and also at the minimum of $\delta_{R,2}^2$. Since from the algorithm’s perspective it is interacting with a symmetric $\varepsilon/n$-submodular function $g$, it outputs a partition such that $g(X, \overline{X})$ is within $\varepsilon/2$ of the minimum of $g$. By the triangle inequality, $\delta_{R,2}(X, \overline{X})^2$ is within $\varepsilon/2 + 2\varepsilon/4n \leq \varepsilon$ close to the minimum of $\delta_{R,2}^2$. ▶
Saran and Vazirani’s approximation algorithm for multiway k-cut (with fixed terminals) can be viewed as a reduction from multiway k-cut to multiway 2-cut. The reduction works given access to approximate s-t-cut oracles, where s and t are designated terminals that must be split by the cut. The corresponding cut function \( \delta_{R,2}(sX, tX) \), where \((X, \overline{X})\) is now a partition of \( V - s, t \), is still submodular but no longer symmetric. We believe that an analogue of Proposition 20 for general (non-symmetric) submodular minimization \([14, 15]\) should hold, but were unable to verify the claim. We state the extension of Theorem 2 to \( k \)-partitions as a conditional result.

**Corollary 21.** Assume that a \( \epsilon \)-approximate minimum of an \( n \)-variate function \( f \) that is \( \text{poly}(\epsilon/n) \)-close to submodular on every input can be found in time \( \text{poly}(n/\epsilon) \) given oracle access to it. Then there is an algorithm that given inputs \( k, \epsilon \) and oracle access to a function \( F \) such that \( ||F||_{R,4} \leq 1 \) runs in time \( k^2 n^4 \text{poly}(n/\epsilon) \log(1/\gamma) \) and outputs a \( k \)-partition \( P \) such that \( \delta_{R,2}(P)^2 \leq (2 - 2/k) \delta_{R,2}(F)^2 + \epsilon \) with probability \( 1 - \gamma \).

It remains to prove Proposition 20.

**Claim 22.** Let \( g \) be \( \epsilon \)-submodular. Assume there exists \( x \in W \) such that for all \( Y \subseteq W \setminus x \) and \( u \not\in W \),

\[
g(W) + g(u) \leq g(W \setminus Y) + g(Y \cup) + \delta.
\]

If \( x' \) maximizes \( g(Wu) - g(u) \) among all \( u \not\in W \) then

\[
g(Wx') + g(u) \leq g(W \setminus Y) + g(Yu) + (\delta + \epsilon).
\]

**Proof.** Let \( x \not\in Y \) then

\[
g(Wx') + g(u) \leq (g(W) - g(W \setminus Y) + g(Wx' \setminus Y)) + g(u) + \epsilon \quad \text{by } \epsilon\text{-submodularity}
\]

\[
= g(Wx' \setminus Y) + (g(W) - g(W \setminus Y) + f(u)) + \epsilon
\]

\[
\leq g(Wx' \setminus Y) + g(Yu) + (\delta + \epsilon) \quad \text{by inductive hypothesis.}
\]

Otherwise, \( x \not\in W \setminus Y \) and

\[
g(Wx') + g(u) \leq g(Wu) + g(x') \quad \text{by optimality of } x'
\]

\[
\leq (g(W) - g(Y) + g(Yu)) + g(x') + \epsilon \quad \text{by } \epsilon\text{-submodularity}
\]

\[
= (g(W) + g(x') - g(Y)) + g(Yu) + \epsilon
\]

\[
\leq g(Wx' \setminus Y) + g(Yu) + (\delta + \epsilon) \quad \text{by inductive hypothesis.} \quad \Box
\]

**Proof of Proposition 20.** Queyranne’s algorithm \( Q^0 \) is recursive. If \( n = 2 \) the unique partition is output. Otherwise, starting from an arbitrary singleton set \( W_1 \), the algorithm sets \( W_{i+1} = W_i x_i \), where \( x_i \) maximizes \( g(W_i u) - g(u) \) among all \( u \not\in W_i \). The algorithm then contracts the elements \( x_i-1 \) and \( x_n \) into \( x_{n-1} x_n \) and outputs the smaller value of \( Q^0(x_1, \ldots, x_{n-2}, x_{n-1} x_n) \) and \( g(x_n) \).

We prove by induction on \( n \) that the output of \( Q^0 \) is \((n-1)\epsilon/2\)-close to the minimum of \( g \). The base case \( n = 2 \) is clear. Now assume this is true for inputs of size \( n - 1 \). If the minimum partition of \( g \) doesn’t split \( x_{n-1} \) and \( x_n \) then the claim follows by inductive assumption.

Otherwise, we show that \( g(x_n) \) is within \((n-1)\epsilon/2\)-close to the minimum of \( g \). Applying Claim 22 iteratively to the sets \( W_1, \ldots, W_{n-1} \), we conclude that

\[
g(W_{n-1}) + g(x_n) \leq g(W_{n-1} \setminus Y) + g(Yx_n) + (n-1)\epsilon
\]
Learning and Testing Variable Partitions

for all $Y$ that do not contain $x_n$ and $x_{n-1}$. Applying symmetry this inequality can be rewritten as $g(x_n) \leq g(x_n Y) + (n-1)\varepsilon/2$. As $x_{n-1}$ and $x_n$ are split in the optimal solution it must be of type $x_n Y$ for some $Y$ excluding $x_{n-1}$, so $g(x_n)$ is $(n-1)/2\varepsilon$ close to the minimum as desired.

6 Testing partitionability

As a consequence of Theorem 1, $k$-partitionability is testable with $\tilde{O}(k^{2p} n^{4p+2}/\varepsilon^{2p})$ queries. The yes instances are inputs with $\delta_k(F) = 0$; the no instances are inputs with $\delta_k(F) > \varepsilon$. The query complexity of Theorem 3 can be obtained by the improved analysis that follows. To simplify notation we only prove the theorem for the Hamming weight over $\mathbb{Z}_q$ and describe the change necessary for $p$-norms over $\mathbb{R}$.

Algorithm 2 Tester for $k$-partitionability.

1: Create an empty undirected graph $G$ with vertex set $V$.
2: for $O(kn/\varepsilon)$ times do
3:   for For every pair of distinct variables $x, y \in V$ do
4:     Choose random $x, y, x', y', Z$
5:     If $F(x, y, Z) + F(x', y', Z) \neq F(x, y', Z) + F(x', y, Z)$ create the edge $\{x, y\}$ in $G$.
6:   end for
7: end for
8: Accept if the graph has at least $k$ connected components.

We will need the following fact:

Fact 23. If $p_1, \ldots, p_n$ are probabilities such that $\sum p_i \geq \varepsilon$ then $1 - \prod (1 - p_i) \geq \varepsilon - O(\varepsilon^2)$.

Proof. Using the inequality $1 - p \leq e^{-p}$ and the second-order estimate $e^{-x} = 1 - x + O(x^2)$, we have

$$\prod (1 - p_i) \leq \prod e^{-p_i} = e^{-\sum p_i} \geq e^{-\varepsilon} = \varepsilon - O(\varepsilon^2).$$

Theorem 3. $k$-partitionability is testable with one-sided error and $O(kn^3/\varepsilon)$ non-adaptive queries with respect to Hamming weight over $\mathbb{Z}_q$, and with $O(k^{2p} n^{3}/\varepsilon^{2p})$ non-adaptive queries with respect to the $p$-norm over $\mathbb{R}$, assuming $\|F\|_{2p} \leq 1$.

While in this work we are mainly interested in small values of $k$, in the extreme case when $k = n$ the partition is unique and the property is testable with $O(1/\varepsilon)$ queries by the result of Dinur and Golubev [12].

Proof of Theorem 3. The connected components of $G$ are always contained in the partition components of $F$, so if $F$ is $k$-partitionable the tester always accepts. We argue that with constant probability, all bipartition of $F$ satisfying $\delta(X, \overline{X}) \geq \varepsilon$ cross an edge in $G$.

If $F$ is $\varepsilon$-far from $k$-partitionable, by Claim 12 $\Delta(P) = \Omega(\varepsilon/k)$ for all $k$-partitions $P$. As every $k$-cut can be coarsened into a 2-cut of at least half the weight, every $k$-partition can be coarsened into a bipartition such that $\Delta(X, \overline{X}) = \Omega(\varepsilon/k)$. We now argue that with constant probability, all such heavy bipartitions $(X, \overline{X})$ are crossed by an edge in $G$, so no $k$-partition is likely to survive in $G$.

Assume $\Delta(X, \overline{X}) = \sum_{x \in X, y \in X} \|D_F(x, y)\| = \Omega(\varepsilon/k)$. As $\|D_F(x, y)\|$ is the acceptance probability of the test in line 5, by Fact 23 in any given iteration of the outer loop 3 at least one of these edges will appear in $G$ with probability $\Omega(\varepsilon/k)$. (For $p$-norms over $\mathbb{R}$,}
\[ \|D_F(x, y)\| \] is an expectation that takes \( O((\varepsilon/k)^{2^p}) \) queries to estimate.) After \( O(kn/\varepsilon) \) iterations the probability that the cut survives is less than \( 2^{-n} \). By a union bound the probability that any heavy cut survives is at most half. \hfill ▪

It is not difficult to see that \( n \) queries are required for one-sided error testers when \( k \) equals 2 as the relevant constraints span an \( n \)-dimensional space. We show that a linear dependence on \( n \) is necessary for two-sided error testers as well. Proposition 24 shows a general \( \Omega(n) \) lower bound for functions over finite domains (with uniform measure) valued over finite groups under the Hamming metric. Proposition 25 shows that \( \Omega(n) \) non-adaptive queries are necessary for functions from \( \mathbb{R}^n \) to \( \mathbb{R} \) under the 2-norm.

**Proposition 24.** Testing 2-partitionability for functions \( F: \mathbb{Z}_q^n \rightarrow G \) for a finite group \( G \) under uniform measure and Hamming metric requires \( \Omega(n-k) \) queries even for constant \( \varepsilon \).

For simplicity of notation we present the proof in the case \( q = 2 \) and \( G = \mathbb{Z}_2 \). The proof is closely related to Chockler and Gutfreund’s lower bound for testing juntas [9].

**Proof.** Let \( R: \mathbb{Z}_2^n \rightarrow \mathbb{Z}_2 \) be a random function and \( P: \mathbb{Z}_2^{n-1} \rightarrow \mathbb{Z}_2 \) be a function that depends on all but a random hidden input coordinate \( I \). First we argue that \( \delta_2(R) = \Omega(1) \) with high probability. For this it is sufficient to argue that \( \|D_R(X, Y)\| = \Omega(1) \) for every partition \((X, Y)\). By definition \( \|D_R(X, Y)\| \) is the average value of \( \Omega(2^n) \) indicator values for events of the type \( R(x, y) + R(x', y') - R(x', y) - R(x, y') = 0 \). These events have probability half each and are pairwise independent, so by Chebyshev’s inequality the probability that the \( \|D_R(X, Y)\| \) is sub-constant is \( \Omega(2^{-2n}) \). Taking a union bound over all \( 2^n \) bipartitions it follows that \( \|D_R(X, Y)\| = \Omega(1) \) with probability at least \( 1 - \Omega(2^{-2n}) \).

To complete the proof, it is sufficient to argue that with high probability any \( Q \) queries to \( P \) reveal independent random bits. Consider the subspace of \( \mathbb{Z}_2^Q \) spanned by the \( Q \) queries (or the submodule of \( \mathbb{Z}_2^Q \) if \( q \) is not a prime). This vector space has dimension at most \( Q \), so it can contain at most \( Q \) of the elementary basis vectors \( e_1, \ldots, e_n \). However, unless it contains \( e_I \) for the hidden coordinate \( I \), no two queries differ in a single coordinate and all answers are independent random bits. Since \( I \) is uniformly random the probability that \( P \) and \( R \) can be distinguished is at most \( Q/n \). By a union bound the distinguishing advantage of the tester is at most \( \Omega(2^{-n}) + Q/n \), which is subconstant unless \( Q = \Omega(n) \). \hfill ▪

It was pointed out to us by Guy Kindler that the proof of Proposition 24 to functions from \( \mathbb{R}^n \) to \( \mathbb{R} \) say under Gaussian measure by considering the functions \( R_g \) and \( P_g \) given by \( F_g(x_1, \ldots, x_n) = f(\text{sign } x_1, \ldots, \text{sign } x_n) \) where the sign is interpreted as a Boolean value. This example is somewhat unnatural because the functions are discontinuous. The following proposition shows that testing still requires \( \Omega(n) \) non-adaptive queries even for highly smooth functions.

**Proposition 25.** Testing 2-partitionability non-adaptively for quadratic functions from \( \mathbb{R}^n \) to \( \mathbb{R} \) under the 2-norm requires \( \Omega(n) \) queries under any measure with zero mean and unit variance and bounded third and fourth moments.

We need the following claim about distinguishing linear functions of normal random variables.

**Claim 26.** Let \( Z_1, \ldots, Z_n \) be independent standard normal random variables, \( F(x) = \sum_{i=1}^n Z_i x_i \) and \( F'(x) = \sum_{i \in S} Z_i x_i \) where \( S \subseteq [n] \) is a random subset of size \( s \). For any \( q \) queries \( x^1, \ldots, x^q \in \mathbb{R}^n \), \((F(x^1),\ldots,F(x^q))\) and \((F'(x^1),\ldots,F'(x^q))\) are \( O(qs/(n-s+1)) \)-statistically close.
Proof. It is sufficient to prove the claim for $|S| = n - 1$ and apply the triangle inequality. By convexity it is sufficient to upper bound the expected statistical distance averaged over the choice of the index $i$ that is omitted from $S$. For fixed $i$, since the queried functions are linear, without loss of generality we may assume that the queries $x^1, \ldots, x^n$ are orthonormal. Let $X$ be the $q \times n$ matrix whose rows are the queries $x^1, \ldots, x^n$, and $X_{-i}$ be the submatrix obtained by removing the $i$-th column. The desired statistical distance is then within a constant factor of $\| (X^T X)^{-1} (X^T X_{-i}) - I \|_F$, where $\| \cdot \|_F$ is the Frobenius norm [1]. By orthonormality we obtain that $\| (X^T X)^{-1} (X^T X_{-i}) - I \|_F = \| x^i \|_2^2$. Averaging over $i$, the desired statistical distance is at most $O(E_q \| x^i \|_2^2) = O(q/n)$. ▷

Proof of Proposition 25. Let $F(x) = n^{-1} \sum_{j \neq k} Z_{jk} x_j x_k$, where $Z_{jk}$ are independent standard normal random variables. Let $F'(x) = n^{-1} \sum_{j,k,i} Z_{jk} x_j x_k$, where $i$ is chosen at random from $[n]$. By standard concentration inequalities both $\| F \|_4$ and $\| F' \|_4$ are constant with high probability. By Claim 26, the answers to any $q$ non-adaptive queries to $F$ and $F'$ are $O(q/n)$-statistically close.

It remains to argue that $F$ is $\Omega(1)$-far from 2-partitionable. For a fixed bipartition $(S, T)$ of $[n]$, by Claim 26 the cost of $F$ is $n^{-1} \sum_{j,k \in S, k \in T} Z_{jk}^2$. Therefore the average cost (over the randomness of $F$) is $|S| |T|/n$. By Chernoff bound the cost is at least $\Omega(|S| |T|/n) = \Omega(1)$ with probability $1 - \exp(-\Omega(|S| |T|))$. Taking a union bound over all $2^{n-1}$ possible bipartitions we conclude that $F$ is $\Omega(1)$-far from 2-partitionable with probability $1 - \exp(-\Omega(n))$. ▶

If Claim 26 extends to adaptive queries, so would Proposition 25.

### 7 Applications to reinforcement learning control

In this section we discuss the application of variable partitioning algorithms given real-valued oracle and the 2-norm measure. The set $X$ of variables to be partitioned corresponds to the set $a$ of control variables (the action), while the oracle $F$ corresponds to the advantage function $A$. While the control task is achieved by a series of actions, the advantage function describes how much one single action in the series can affect the final objective. In general, this function is complex enough so explicit representation is not available. Instead, it is usually estimated by Monte-Carlo sampling of the action series or by function approximation, where in either case it is sensible to treat the function as an oracle.

In a reinforcement learning control task, the objective is to control the action $a$ so as to maximize the expected cumulative reward over time $t$. The advantage function $A'(\cdot, a)$ describes the marginal gain of such an objective of an action $a = a_t$ at time $t$. This function can be estimated by Monte-Carlo sampling of the actions $a_t, a_{t+1}, \ldots$, or by function approximation. In either of the cases it is sensible to treat the function as an oracle when using it to partition the variables.

We compare empirically with three previous approaches. The first approach is a standard approach proposed by Williams [33,35] and later improved by Mnih et al. [25] and Schulman et al. [32]. These approaches learn reinforcement learning control without considering the possible partitioning of the advantage function. The second approach is to trivially partition $n$ variables into $n$ subsets [22,36]. This causes a large partition error which induces bias in the learning update. The third baseline partitions the variables heuristically [23]. In their method the Hessian matrix of the advantage function is first calculated using a discrete gradient method. Then this Hessian matrix is treated as an adjacency matrix of a graph, by the heuristic that two independent variables have a zero element in Hessian. Then elements are removed from Hessian, from those with the lowest absolute values, until the graph has at least $k$ connected components. This algorithm shares some similar intuition with our first algorithm.
The rest of this section will introduce the preliminaries of how this partition may be used in reinforcement learning, and then demonstrate the comparison of scores attained in the experiments.

7.1 Reinforcement learning control and policy gradient

We consider a reinforcement learning task described by a discrete-time Markov decision process (MDP), denoted as the tuple $(S, A, T, r, \rho_0, \beta)$. That includes $S \in \mathbb{R}^m$ the $m$ dimensional state space, $A \in \mathbb{R}^n$ the $n$ dimensional action space, $T : S \times A \times S \rightarrow \mathbb{R}^+$ the environment transition probability function, $r : S \times A \rightarrow \mathbb{R}$ the reward function, $\rho_0$ the initial state distribution and $\beta \in [0, 1]$ the unnormalized discount factor. Here $n$ is the number of the control variables, which is consistent with the dimension of the input oracle. A (stochastic) policy is a function $\pi : S \times A \rightarrow \mathbb{R}_+$ that outputs a distribution over $A$ on any given state $s \in S$. The objective of reinforcement learning is to learn a policy $\pi$ such that the expected cumulative reward $J(\theta) = \mathbb{E}_{s_0 \sim \rho_0, a_0 \sim \pi(s_0)}[\sum_{t=0}^{\infty} \beta^t r(s_t, a_t)]$, is maximized, where $\rho_\pi(s) = \sum_{t=0}^{\infty} \beta^t \mathbb{P}(s_t = s)$. Since $\pi$ is in a functional space, the problem is commonly relaxed to find over the space of parameterized functions the policy, such as the space of neural networks. When the policy is parameterized we denote it as $\pi_\theta$.

Advantage actor-critic (A2C), a standard approach in policy optimization [25, 32], estimates the gradient of the policy $\nabla_\theta J(\theta)$. According to the policy gradient theorem [35], this gradient can be estimated by $\nabla_\theta J(\theta) = \mathbb{E}_{s \sim \rho_0, a \sim \pi(s)}[\nabla_\theta \log \pi(a|s)A^\pi(s, a)]$, where $A^\pi(s, a)$ is the advantage function of $s, a$, and policy $\pi$. Here $A^\pi(s, a)$ is defined as $A^\pi(s, a) = Q^\pi(s, a) - V^\pi(s)$, where $Q^\pi(s, a) = \mathbb{E}_\pi[\sum_{t=1}^{\infty} \beta^{t-1} r(s_t', a_t')|s = s_t, a = a_t, \pi]$ is the action-state value function and $V^\pi(s) = \mathbb{E}_{a \sim \pi(a|s)}[Q^\pi(s, a)]$ the state-value function.

It is shown later in [36] and [23], that an alternative estimator

$$\nabla_\theta J(\theta) = \sum_{j=1}^{k} \mathbb{E}_{\pi(a_{(j)}|s)}[\nabla_\theta \log \pi(a_{(j)}|s)[A^\pi(s, a_{(j)})]],$$

may induces a lower variance. The condition that this estimator holds is that the advantage function can be approximately partitioned into $k$ parts correspondingly:

$$A^\pi(s, a) = A^\pi_1(s, a_{(1)}) + \cdots + A^\pi_k(s, a_{(k)}) + U(s, a)$$

for some state $s$ the estimation takes place, where $U(s, a)$ the partition error is expected to be small for the estimator to be accurate.

The learning is an iterative process that takes $N$ updates by the gradient $\nabla_\theta J(\theta)$ while the $k$-partition is computed every $N/N_1$ iterations. Every run of the partitioning algorithm outputs the disjoint subsets $a_{(1)}, \ldots, a_{(k)}$, which is then used by (12) for $N_1$ iterations. It is worth note that our algorithm has a complexity of $O(N_1 n^2)$, which is negligible in reinforcement learning. As the Monte-Carlo estimation of $\nabla_\theta J(\theta)$ requires a complete trial of the task (for example, play a game for an entire episode), which involves the interaction of a complex system.

7.2 Experiments

We compare our first algorithm (called pairwise estimates - PE) and our second algorithm (called submodular minimization - SM) with the aforementioned existing approaches. A2C [25] is the baseline approach in reinforcement learning who does not leverage variable partition. It uses control variates (CV) as the primary variance reduction technique. Other methods [23,36]
partition the control variable so as to reduce the variance in the Monte-Carlo estimation by Rao-Blackwellization (RB) [5]. For the discussion on variance reduction we refer the readers to the paper cited above. The comparisons are summarized below

Table 1 Comparisons of our algorithms with previous ones.

<table>
<thead>
<tr>
<th>PG estimator</th>
<th>Variance reduction</th>

| Wu et al. [36]        | CV & RB            | yes        | greedy       | no         | $k = n$
| Li and Wang [23]      | CV & RB            | yes        | greedy       | no         | no     |
| PE (our first)        | CV & RB            | no         | greedy       | $\mathcal{O}(kn^2)$ | no     |
| SM (our second)       | CV & RB            | no         | optimal      | almost opt | no     |

Now we study the performance in terms of both the correctness and the optimality on graph cuts on weighted graphs. Correctness notes the number of times the algorithm outputs exactly the optimal partition, while optimality describes the average of the ratio of the partition error and the optimal partition error, over all the independent runs. This will illustrate the difference between greedy-based algorithms like [23] and our first algorithm, and submodular minimization based algorithms like our second algorithm. Note that submodular minimization always finds the optimal partition.

Then Table 3 compares the partitioning algorithms when the oracle is a quadratic function $a^T H_0 a$ for some random $H_0$. In this case our second algorithm SM also incurs an error per Theorem 2, but the error in practice is shown to be small enough. It has constantly the best empirical performance in both correctness and optimality.

Since we only replaced heuristic partitioning with our partitioning algorithm in reinforcement learning, it is reasonable that our more accurate partitions will improve reinforcement learning.

Finally we plug our algorithms into reinforcement learning control, replacing the partitioning steps in [23]. The tasks we are testing on are standard tasks in reinforcement learning by the MuJoCo physics simulator. This includes training a simplified model of ant, cheetah, or human to run as fast as possible. The score is the cumulative reward over time, where the reward is the speed less the energy cost (which is $0.001\|a\|^2_2$). The control variables $a$ are the forces applied to the joints. We refer to [3] for the exact simulator settings.

We have conducted experiments on all eight environments from MuJoCo that has the action dimensional higher than one, shown in Figure 1 below. In the figure the x-axis is the number of Monte-Carlo sample updates, which can be regarded as the time elapsed on the training, while the y-axis is the score attained by the model. Our second algorithm (SM) has achieved the highest score among most of these tasks, which agrees with our theoretical finding.

A Statistical claims

Claim 27. Assume $t, i \geq 0$. If $t^p \leq i^p \leq t^p + (\varepsilon/2)^p$ then $t \leq i \leq t + \varepsilon$.

Proof. The left-hand inequalities are immediate. For the right-hand ones we start we consider two cases. If $t \leq \varepsilon/2$, then $i^p \leq 2(\varepsilon/2)^p \leq \varepsilon \leq t + \varepsilon$. If $t > \varepsilon/2$ then

$$i - t \leq i^p - t^p \leq \frac{(\varepsilon/2)^p}{(\varepsilon/2)^p - 1} \leq \varepsilon.$$  

Claim 7. Assuming $\|F\|_{R,2p} \leq 1$, the value $\|F\|_{R,p}^p$ can be estimated within $\varepsilon^p$, and $\|F\|_{R,p}$ can be estimated within $\varepsilon$, from $K^p\log(1/\gamma)/\varepsilon^{2p}$ queries to $F$ in linear time with probability $1 - \gamma$ for some absolute constant $K$.

Proof. By Chebyshev’s inequality, $\mathbb{E}[\|F\|^p]$ can be estimated within an additive error of $(\varepsilon/2)^p$ by averaging $(2/\varepsilon)^{2p}$ samples with probability $3/4$. The error can be improved to $1 - \gamma$ by taking the median value of $O(\log 1/\gamma)$ runs. The second bound follows from Claim 27.

B Details in the experiments

The exact reinforcement learning control algorithm we used is described below. The algorithm is based on proximal policy optimization [32] and generalized advantage estimator [11,31] in reinforcement learning.
Algorithm 3 Policy optimization with variable partitions.

1: **Input:** Total number of samples $T$, batch size $B$, partition frequency $M_p$, number of value iterations $M_w$, initial policy parameter $\theta$, initial value and advantage parameters $w$ and $\mu$;
2: **Output:** Optimized policy $\pi_\theta$;
3: **for** each iteration $j$ in $[T/B]$ **do**
4: Collect a batch of trajectory data $\{s_t^{(i)}, a_t^{(i)}, r_t^{(i)}\}_{i=1}^B$;
5: **for** $M_\theta$ iterations **do**
6: Update $\theta$ by one gradient descent step using proximal policy gradient with the gradient estimator (12);
7: **end for**
8: **for** $M_w$ iterations **do**
9: Update $w$ and $\mu$ by minimizing $\|V^w(s_t) - R_t\|^2_2$ and $\|\hat{A} - A^\mu(s_t, a_t)\|^2_2$ in one step;
10: **end for**
11: Estimate $\hat{A}(s_t, a_t)$ using $V^w(s_t)$ by generalized advantage estimator;
12: **if** $j \equiv 0$ (mod $M_p$) **then**
13: Define estimation $f(X) = \mathbb{E}[D_F(X, \bar{X})^2]$;
14: Run submodular minimization on $f(X)$;
15: Assign $X$ and $\bar{X}$ to $a(1)$ and $a(-1)$ in (12), respectively; \[\text{Variable Partitioning}\]
16: **end if**
17: **end for**

The differences between our algorithm and proximal policy gradient [32] have been highlighted: Line 6 uses the estimator with partitions on the control variables. Line 12-16 find the near-optimal variable partition using submodular minimization, by Theorem 2.

We use three neural networks as function approximations: a policy network $\pi_\theta$ and a value network $V^w$ as is in the baseline methods, and an advantage network $A^\mu$ solely used in the partition algorithm. The networks have the same architecture as is in the previous line of works [25,32].

In our MuJoCo experiments, the tasks have been slightly modified (the physics simulator keeps intact). As the number of control variables of the original tasks is relatively low, we augment such dimensions by letting the agent controls two independent instances of the tasks at the same time. The scores and the reinforcement signals are then the additions of the scores of the two sub-tasks. Correspondingly, we use $k = 2$ in [23] and our algorithms.

Abstract
We consider the problem of counting all $k$-vertex subgraphs in an input graph, for any constant $k$. This problem (denoted $\text{sub-cnt}_k$) has been studied extensively in both theory and practice. In a classic result, Chiba and Nishizeki (SICOMP 85) gave linear time algorithms for clique and 4-cycle counting for bounded degeneracy graphs. This is a rich class of sparse graphs that contains, for example, all minor-free families and preferential attachment graphs. The techniques from this result have inspired a number of recent practical algorithms for $\text{sub-cnt}_k$. Towards a better understanding of the limits of these techniques, we ask: for what values of $k$ can $\text{sub-cnt}_k$ be solved in linear time?

We discover a chasm at $k = 6$. Specifically, we prove that for $k < 6$, $\text{sub-cnt}_k$ can be solved in linear time. Assuming a standard conjecture in fine-grained complexity, we prove that for all $k \geq 6$, $\text{sub-cnt}_k$ cannot be solved even in near-linear time.

1 Introduction

The subgraph counting problem asks for the number of occurrences of a (typically connected) “pattern” subgraph $H$ in a connected input graph $G$. It is a fundamental algorithmic problem with a rich theory [34, 51, 16, 53, 5, 24, 69, 19], and widely used in practice [32, 18, 58, 15, 60, 33, 59, 40, 68, 62, 67, 8]. With the explosion of network science, subgraph counting is now a fundamental tool used for analyzing real-world graphs. Thus, the search for fast algorithms for subgraph counting is not just a theoretical problem, but one that has many applications in bioinformatics, social sciences, and computer science.

Especially for many of the practical applications, a common version of subgraph counting is to count the frequency of all connected subgraphs with $k$ vertices [57, 54, 2, 25, 26, 31, 47, 61, 37, 71, 71]. We will denote this problem as $\text{sub-cnt}_k$. Even in the theory literature, it is common to parametrize running time by $n$ (vertices in $G$) and $k$, so it is natural to study $\text{sub-cnt}_k$. There is a rich line of theoretical work on getting $n^{\alpha k}$ time
Linear Time Subgraph Counting, Graph Degeneracy, and the Chasm at Size Six

algorithms, for \( \mu < 1 \), using matrix multiplication and tree decomposition methods [34, 53, 5, 13, 44, 70, 45, 20, 14, 19]. Unfortunately, \( \text{SUB-CNT}_k \) is (a generalization of) the canonical \#W[1]-hard problem, and it is not believed that there exist \( f(k) \cdot n^{o(k)} \) algorithms for \( \text{SUB-CNT}_k \). From an application standpoint, these algorithms are typically not practical, and do not provide algorithmic guidance. Real-world graphs are massive, and one typically desires linear-time algorithms.

An alternate perspective is to look for faster algorithms for restricted graph classes, and hope that these classes correspond to real-world graphs. A seminal result of Chiba-Nishizeki gave \( O(m\kappa^{k-2}) \) algorithms for \( k \)-clique counting and an \( O(m\kappa) \) algorithm for 4-cycle counting, where \( m \) is the number of edges in \( G \) and \( \kappa \) is the graph degeneracy [16]. We leave the technical definitions for later; but \( \kappa \) can be thought of as the maximum average degree of any subgraph of \( G \). Chiba-Nishizeki implicitly prove linear-time algorithms for \( \text{SUB-CNT}_k \) for \( k = 3, 4 \) (explicitly shown in [57, 54]). The class of bounded (constant) degeneracy graphs is immensely rich: it contains all minor-closed families, preferential attachment graphs, and bounded expansion graphs. The graph degeneracy appears heavily in network science, and real-world graphs have typically low degeneracy (though maybe not constant).

But most importantly for subgraph counting, the techniques from Chiba-Nishizeki have inspired a number of recent practical subgraph counting algorithms [57, 54, 37, 35]. The problems of \( \text{SUB-CNT}_k \) for \( k \leq 5 \) have been successfully tackled in practice using these approaches. These algorithms are often tailored for \( k \) (using, for example, specific tricks to count individual 4-vertex subgraphs) and it is not clear how far they will extend for larger \( k \).

Towards a better theoretical understanding, we pose the following question.

For what values \( k \), does the \( \text{SUB-CNT}_k \) problem admit a linear time algorithm in bounded degeneracy graphs?

1.1 Our Results

The question above has a surprisingly clean resolution, assuming conjectures from fine-grained complexity. For simplicity, we assume that the input graph \( G \) is connected. We assume Las Vegas randomized algorithms, so we talk of expected running times.

Our main theorem asserts linear time algorithms for counting (up to) 5-vertex subgraphs in bounded degeneracy graphs. For counting 6-vertex subgraphs and beyond, it is unlikely that even near-linear time algorithms exists.

▶ Theorem 1 (The chasm at size 6). For \( k \leq 5 \), there is an expected \( O(m\kappa^{k-2}) \) time algorithm for \( \text{SUB-CNT}_k \).

Assume the Triangle Detection Conjecture (Conj. 2). There exists an absolute constant \( \gamma > 0 \) such that the following holds. For any \( k \geq 6 \) and any function \( f : \mathbb{N} \to \mathbb{N} \), there is no (expected) \( o(m^{1+\gamma}f(\kappa)) \) algorithm for \( \text{SUB-CNT}_k \).

The Triangle Detection Conjecture was first stated by Abboud and Williams [1]. They proved many lower bounds for the dynamic version of many well known graph problems such as bipartite perfect matching, single source reachability etc. It is actually believed that the constant \( \gamma \) could be as large as \( 1/3 \).

▶ Conjecture 2 (Triangle Detection Conjecture [1]). There exists a constant \( \gamma > 0 \) such that in the word RAM model of \( O(\log n) \) bits, any algorithm to detect whether an input graph on \( m \) edges has a triangle requires \( \Omega(m^{1+\gamma}) \) time in expectation.
1.2 Main Ideas

Conditional Lower Bounds

It is instructive to look at the conditional lower bounds. The reduction of triangle detection to subgraph counting in bounded degeneracy graphs is actually quite simple. Suppose we want to detect (or even count) triangles in an input graph $G$. Get graph $G'$ by subdividing each edge into two, so a triangle in $G$ becomes a $C_6$ (6-cycle) in $G'$. But the degeneracy of $G'$ is just 2! (In any induced subgraph of $G'$, the minimum degree is at most 2, proving the bound.) Thus, if there exists $o(f(\kappa)m^{1+\gamma})$ time algorithms for counting 6-cycles, that would violate the Triangle Detection Conjecture.

It is fairly straightforward to generalize this idea for larger cycles, by replacing edges in $G$ by short paths. Assuming Triangle Detection Conjecture, for all $k \geq 6$ and $k \neq 8$, we can rule out linear time algorithms for counting $C_k$ in bounded degeneracy graphs. Our reduction does not work for $C_8$; instead we consider a different subgraph for the case of $k = 8$ ($C_7$ with a tail). We give the details in Section 5.

This reduction fails for counting 5-cycles and in general, it does not work for counting any 5-vertex subgraph. For good reason, as we discovered an efficient algorithm for this problem. This is the more technical part of our paper.

Algorithmic Framework

We present an algorithmic framework for solving the sub-cnt$_k$ problem, that generalizes the core idea of Chiba and Nishizeki [16]. It is known from past work that their ideas basically provide an $O(m\kappa^{k-2})$ algorithm for sub-cnt$_k$, for $k = 3, 4$. The main challenge is to get such an algorithm for $k = 5$, thereby nailing down the chasm of Theorem 1. This leads to new results for counting various 5-vertex subgraphs. Perhaps more than these individual results, our main contribution lies in identifying structural decompositions of the pattern subgraphs that allows for efficient algorithms. This decomposition also sheds light on why certain $k$-vertex subgraphs, for $k \geq 6$, does not seem to have any efficient algorithms in bounded arboricity graphs. We give an outline of our framework next, and present it formally in Section 4.

The key idea that comes from Chiba-Nishizeki is to perform subgraph counting on $G^{\rightarrow}$, an acyclic orientation of $G$ where the out degree of each vertex is bounded by $O(\kappa)$\(^1\). The classic clique and 4-cycle counting algorithms enumerate directed stars and directed paths of length 2 to count subgraphs. We note that the algorithm does not enumerate 4-cycles, since there can be $\Omega(n^2)$ 4-cycles. It requires clever indexing to solve this problem, which we generalize in our algorithm.

The crucial generalization of this idea is to enumerate directed rooted trees. Specifically, we count occurrences of a connected pattern $H$ by counting occurrences of all possible acyclic orientations (up to isomorphism) $H^{\rightarrow}$ of $H$ in $G^{\rightarrow}$. The main idea is to find the largest directed rooted tree in $H^{\rightarrow}$, with edges directed away from the root. Call this tree $T$. Since outdegrees in $G^{\rightarrow}$ are bounded, we can efficiently enumerate all copies of $T$. Any copy of $H^{\rightarrow}$ in $G^{\rightarrow}$ is formed by extending a copy of $T$, but $H^{\rightarrow}$ may contain vertices that are not in $T$. Thus, the extensions could be expensive to compute. But when $H$ has at most 5 vertices, we can prove that $H^{\rightarrow} \setminus T$ is itself either a collection of rooted stars or paths. We can create hash tables that store information about the occurrences of the latter. The final count of $H^{\rightarrow}$ is obtained by enumerating $T$ and carefully combining counts from the hash tables.

\(^1\) Technically, this is not the idea of Chiba-Nishizeki, who use the degree orientation. But it was somewhat of a folklore result that it is easy to get the same result using the degeneracy orientation. Arguably the first such reference is Schank-Wagener [63].
Related Work

Subgraph counting problems have a long and rich history. More than three decades ago, Itai and Rodeh [34] gave the first non-trivial algorithm for the triangle detection and counting problems with \(O\left(\frac{m^3}{2}\right)\) runtime. Subsequently, Chiba and Nishizeki [16] gave an elegant algorithm based on the degree based vertex ordering that solves triangle counting, 4-cycle counting, and \(\ell\)-clique counting with running times of \(O(m\kappa)\), \(O(m\kappa)\), and \(O(m\kappa^{\ell-2})\) respectively (\(\kappa\) denotes the degeneracy). In comparison, our algorithm exploits the degeneracy ordering of the vertices (see Section 3 for a formal definition); this enables us to create a uniform framework for any \(k\)-vertex subgraph for \(k \in \{4, 5\}\). In dense graphs, the best bounds for the clique counting problem are achieved by fast matrix multiplications based algorithms [53, 24]; Vassilevska [69] gave combinatorial algorithm with significantly reduced space requirement. For general subgraphs, there is a rich line of research based on matrix multiplication, tree decomposition and vertex cover methods [34, 53, 5, 13, 44, 70, 45, 20, 14, 19] – these works focus on getting \(n^{\mu k}\) time algorithms, for \(\mu < 1\).

Subgraph counting problems, specifically triangle counting, clique counting and cycle counting problems, have also been studied extensively in various Big Data models such as property testing model [22, 23, 6], MapReduce settings [17, 66, 42], and streaming model [7, 38, 46, 39, 3, 36, 56, 49, 9]. Most of these works focus on an approximate count, rather than an exact count. In the applied world, there are many efficient algorithms that are based on clever sampling techniques [11, 10, 33, 75, 61, 73, 72, 37, 71]. Exact counting has also been studied extensively in the applied world [2, 57, 54, 12, 28, 47, 29, 31, 30, 25, 26]. In particular, Ahmed et al. [2] presented an algorithmic framework for solving the \(\text{sub-cnt}_4\) problem, called PGD (Parametrized Graphlet Decomposition), which scales to graphs with tens of millions of edges. Pinar et al. [57] studied the \(\text{sub-cnt}_5\) problem, and gave the current state of the art ESCAPE library based on degree ordering techniques. However, the provable runtime of their algorithm for certain \(5\)-vertex subgraphs is quadratic, \(O(n^2)\). For a deeper exploration of related applied work, refer to the tutorial on subgraph counting by Seshadhri and Tirthapura [64].

The subgraph detection problem, which asks whether an input graph has a copy of the subgraph, is a well-studied problem [34, 51, 4, 5, 41, 45, 74]. For the triangle detection problem, the best known algorithm is based on fast matrix multiplication and it runs in time \(O(\min\{n^{\omega}, m^{2\omega/(\omega+1)}\})\) [5]. If \(\omega = 2\), this would give us \(O(\min\{n^2, m^{4/3}\})\) algorithm for the triangle detection problem. Hence, to falsify the \textsc{Triangle Detection Conjecture}, it would require a major breakthrough result in the algorithmic graph theory world. For a more detailed discussion on the \textsc{Triangle Detection Conjecture} and its implications, refer to the paper by Abboud and Williams [1].

In the subgraph enumeration problem, the goal is to output each occurrences of the target subgraph. Chiba and Nishizeki [16] showed that it is possible to enumerate all the triangles in a graph along with counting the total number of triangles in \(O(m\kappa)\) time. For enumerating all the triangles, \(O(m\kappa)\) time is effectively optimal assuming the 3SUM Conjecture [55, 43]. Eppstein [27] studied the bipartite subgraph enumeration problem in bounded arboricity graphs.

3 Preliminaries

In this paper, we study the \(\text{sub-cnt}_k\) problem which asks for the number of occurrences of each \(k\)-vertex subgraph \(H\), in an input graph \(G\) with \(n\) vertices and \(m\) edges. We consider \(k\) to be a constant. For a fixed subgraph \(H\), we use \(\text{sub-cnt}_H\) to denote the problem of
counting all occurrences of $H$ in the input graph $G$. When $H$ is the triangle subgraph, we
denote the corresponding counting problem as TRI-CNT. In the context of the SUB-CNT$_k$
problem, we always use $G$ to denote the input graph and $H$ to denote the subgraph to be
counted. Both $G$ and $H$ are simple, connected, undirected and unweighted.

In our algorithmic framework, directed graphs play a crucial role. We use $N_G^+(u)$ and
$N_G^−(u)$ to denote the out-neighborhood and in-neighborhood of a vertex $u$ in a directed
graph $G$, respectively. We define $d_G^+(u) = |N_G^+(u)|$ and $d_G^−(u) = |N_G^−(u)|$. If the graph is clear from
the context, we drop the subscript $G$.

A graph $G$ is $k$-degenerate if every subgraph of $G$ has a vertex of degree at most $k$. The
degeneracy of a graph $G$ (also called coloring number, refer to Sec. 5.2 of [21]), denoted as
$\kappa(G)$, is the smallest integer $k$ such that $G$ is $k$-degenerate. The arboricity of a graph $G$,
denoted as $\alpha(G)$, is the smallest integer $k$ such that the edge set $E(G)$ can be partitioned
into $k$ forests. When the graph $G$ is clear from the context, we simply write $\kappa$, and $\alpha$,
instead of $\kappa(G)$ and $\alpha(G)$. A classic theorem of Nash-Williams shows that the degeneracy
and arboricity are closely related. All our results can be stated in terms of either of the
parameters.

**Theorem 3 (Nash-Williams [52]).** In every graph $G$, $\alpha(G) \leq \kappa(G) \leq 2\alpha(G) - 1$.

Vertex ordering is central to many subgraph counting algorithms. In this paper, we work
with the degeneracy ordering of $G$, which is defined as follows.

**Definition 4.** Degeneracy ordering of a graph $G$, denoted by $\prec$, is obtained by repeatedly
removing the vertex with minimum degree. The ordering is defined by the removal time.

For example, if $u \prec v$, then $u$ is removed before $v$ according to the above process. Degeneracy
ordering can be found in linear time [48].

Using any vertex ordering $\prec$ of an undirected graph $G$, we construct a directed graph
$G^+\prec$ as follows: for each edge $\{u, v\} \in E(G)$, direct the edge from $u$ to $v$ iff $u \prec v$. We denote
this directed edge as $(u, v)$. Observe that $G^+\prec$ is necessarily acyclic. We denote the directed
graph obtained from degeneracy ordering $\prec$ as $G^+\prec$. The following two are folklore results
about vertex ordering and degeneracy, and can be derived from Prop. 5.2.2 of [21].

**Lemma 5.** For each vertex $v \in G^+\prec$, $d^+(v) \leq \kappa$.

**Lemma 6.** If there exists a vertex ordering $\prec$ of $G$ such that in the corresponding directed
graph $G^+\prec$, $d^+(v) \leq k$ for each vertex $v$, then $\kappa(G) \leq k$.

Next, we formally define a match (occurrence) of the target subgraph $H$ in the input graph
$G$. We also define a match in the context of directed graphs $H'$ and $G'$.

**Definition 7.** A match of $H$ in $G$ is a bijection $\pi : S \to V(H)$ where $S \subseteq V(G)$ and for
any two vertices $u$ and $v$ in $S$, $\{u, v\} \in E(G)$ if $\{\pi(u), \pi(v)\} \in E(H)$.

**Definition 8.** A match of $H'$ in $G'$ is a bijection $\pi : S \to V(H')$ where $S \subseteq V(G')$ and for
any ordered pair of vertices $(u, v)$ where $u$ and $v$ are in $S$, $(u, v) \in E(G')$ if
$(\pi(u), \pi(v)) \in E(H')$.

Our algorithm counts matches of $H$ in $G$ by counting matches of all possible acyclic
orientations $H^{\rightarrow}$ of $H$ in $G^{\prec}$. In general, whenever we use $\rightarrow^{\rightarrow}$ to denote a directed graph,
such as in $G^{\prec}$ and $H^{\rightarrow}$, the directed graph is a DAG.
We denote the number of matches of \( H \) in \( G \) by \( M(G, H) \). An incomplete match of \( H \) in \( G \) is an injection \( \pi : S \to V(H) \) (so \( |S| < |V(H)| \)), that has the same properties of a match except being surjective. Consider two incomplete matches (injections) of \( H \), \( \pi_1 : S_1 \to V(H) \), and \( \pi_2 : S_2 \to V(H) \). Let \( V_{\pi_1} = \{ \pi_1(u) \mid u \in S_1 \} \) and \( V_{\pi_2} = \{ \pi_2(u) \mid u \in S_2 \} \). We say that \( \pi_2 \) completes \( \pi_1 \) to be a match of \( H \), when \( V(H) = V_{\pi_1} \cup V_{\pi_2} \) (surjective), \( V_{\pi_1} \cap V_{\pi_2} = \emptyset \) (injective), and for any two vertices \( u \in S_1 \) and \( v \in S_2 \), \( \{u, v\} \in E(G) \) if \( \{\pi_1(u), \pi_2(v)\} \in E(H) \). In case of directed graphs, it should hold that \( (u, v) \in E(G') \) if \( (\pi_1(u), \pi_2(v)) \in E(H') \) and \( (v, u) \in E(G') \) if \( (\pi_2(v), \pi_1(u)) \in E(H') \).

Two matches are distinct if they are not automorphims of a match. In other words, two matches \( \pi_1 \) and \( \pi_2 \) of \( H \) are equivalent, if they map two automorphims of the exact same subgraph of \( G \) to \( H \). We denote the number of matches of \( H \) in \( G \) by \( \text{DM}(G, H) \). In the sub-cnt\(_k\) problem, we are interested in \( \text{DM}(G, H) \) for all \( k \)-vertex subgraphs \( H \).

\section{Subgraph Counting Through Orientation and Directed Trees}

In this section, we discuss our algorithmic framework for solving the sub-cnt\(_k\) problem. Instead of directly counting the number of occurrences of a \( k \)-vertex subgraph \( H \) in the input graph \( G \), we count the occurrences of all possible DAG \( H' \) (up to isomorphism) of \( H \) in the graph \( G_{\pi}^\sim \). To achieve this, our main idea is to find the largest directed tree of \( H' \), enumerate all matches of this tree, and then count matches of the remaining vertices using structures we save in a hash table. In Section 4.1, we show that our framework solves the sub-cnt\(_5\) problem in expected \( O(mw^3) \) time. In Section 4.2, we demonstrate the limitation of our framework as it fails to solve the sub-cnt\(_6\) problem efficiently.

\begin{algorithm}[h]
\caption{Counting distinct matches of all 5-vertex subgraphs in \( G \) (sub-cnt\(_5\)).}

\EndProcedure
\end{algorithmic}
\end{algorithm}
4.1  5-vertex Subgraph Counting

Our main algorithmic result is given in the following theorem.

\begin{theorem}
There is an algorithm that solves the sub-cnt$_5$ problem in $O(m\kappa^3)$ time.
\end{theorem}

Our strategy is to count matches of all possible DAGs (up to isomorphism) $H \rightarrow$ of $H$ in $G \rightarrow$, to obtain the number of distinct matches of $H$ in $G$. Alg. 2 demonstrates this subroutine of our algorithm for sub-cnt$_5$, which is shown in Alg. 1. First, we find one of the largest directed rooted tree subgraphs (DRTS), which we define as follows, in $H \rightarrow$.

\begin{definition}
Given any directed graph $D$, a directed rooted tree subgraph (DRTS) of $D$, is a subgraph $T$ of $D$, where the underlying undirected graph of $T$ is a rooted tree, and edges are oriented away from the root in $T$.
\end{definition}

The following lemma shows that we can find all matches of any DRTS in $H \rightarrow$ in the desired time.

\begin{lemma}
Let $T$ be a directed tree with $k$ vertices. All matches of $T$ in $G \rightarrow$ can be enumerated in $O(m\kappa^{k-2})$.
\end{lemma}

\begin{proof}
Let $t_1, \ldots, t_k$ be a BFS ordering of $T$ starting at the root $t_1$. Fix an edge $(u, v) \in E(G \rightarrow)$ and map $u$ to $t_1$ and $v$ to $t_2$. There are $m$ possible matches for $(t_1, t_2)$, which we can find by enumerating the edges of $G \rightarrow$. Now, we will choose vertices to map to $t_3, \ldots, t_k$, one by one, in this order. Since the out-degree of each vertex in $G \rightarrow$ is at most $\kappa$, if we have already mapped vertices to $t_1, \ldots, t_i$, there are at most $\kappa$ vertices that could be mapped to $t_{i+1}$. Therefore, $M(G \rightarrow, T) = O(m\kappa^{k-2})$, and we can enumerate all of them by first choosing $(u, v)$ to map to $(t_1, t_2)$ and then choosing vertices to map to $t_3, \ldots, t_k$, in this order and one by one.
\end{proof}

\begin{observation}
Call a vertex $v$ of a directed graph a source vertex, if $d^-(v) = 0$. Consider $T$ to be one of the largest DRTSs of any DAG $H \rightarrow$, which is an acyclic orientation of $H$. $T$ has to have a source vertex of $H$, otherwise the root has an in-neighbor $v$, which is not in $T$ as it would create a cycle. Adding $v$ to $T$ creates a new DRTS which has one more vertex than $T$. This contradicts the fact that $T$ is one of the largest DRTSs of $H$. Hence, the root of $T$ has to be a source vertex of $D$.
\end{observation}

Given a 5-vertex DAG $H \rightarrow$, we can find a DRTS that has the most number of vertices among all DRTSs of $H \rightarrow$ in constant time. First, find all source vertices, and then apply a Breath First Search (BFS) starting from each of these vertices and pick a BFS tree with the most number of vertices among all. The following lemma shows that the largest DRTS has at least 3 vertices for a 5-vertex connected subgraphs, except 4-star. Notice that, the largest DRTS of a 4-star with all the edges oriented towards the center has two vertices.

\begin{lemma}
Let $H$ be a connected undirected 5-vertex graph that is not a 4-star. Each largest DRTS of any DAG $H \rightarrow$, which is an acyclic orientation of $H$, has at least three vertices.
\end{lemma}

\begin{proof}
We prove this lemma by contradiction. Assume that any DRTS of $H \rightarrow$ has at most two vertices. A directed 2-path, or any vertex with at least two outgoing edges result in a DRTS with three vertices. Therefore,
(a) $H \rightarrow$ does not have a 2-path,
(b) each vertex in $H \rightarrow$ has at most one outgoing edges.
\end{proof}
Notice that, since $H^{\rightarrow}$ is a DAG, it has at least one source vertex. Consider a source vertex $u$. Since $H$ is connected, $u$ has at least one neighbor, and by (b) it should have exactly one neighbor. Let $N^+(u) = \{v\}$, then $N^+(v) = \emptyset$, by (a). So, $v$ should have at least one incoming neighbor $w$. By (a), $w$ has no incoming edges, and it has no outgoing edges by (b). Call the other two vertices $x$ and $y$. As $H$ is connected, there should be a connection between $\{u,v,w\}$ and $\{x,y\}$. $u$ and $w$ cannot have any neighbor other than $v$, so $x$ and $y$ could only be connected to $v$. Since $H$ is not a star, there should be an edge between $x$ and $y$. Without loss of generality, let $(x,y)$ be that edge. By (a), $(y,v) \notin E(H^{\rightarrow})$ and by (b) $(x,v) \notin E(H^{\rightarrow})$. So, $\{u,v,w\}$ is not connected to $\{x,y\}$, and $H$ is disconnected, which is a contradiction. Thus, the assumption that any DRTS of $H^{\rightarrow}$ has at most two vertices is wrong, and each largest DRTS of $H^{\rightarrow}$ has at least three vertices. 

So far, we know that we can find one of the largest DRTSs of $H$, which has at least 3 vertices. We use $T_{\text{max}}$ to denote this DRTS. By Lemma 11, we can enumerate all matches of $T_{\text{max}}$ in $G_{\leq}^+$ in $O(mn^3)$ time. For each such match, we need to validate whether it is a (incomplete) match of $H^{\rightarrow}$ or not. If it is not, then it could not be completed to a match of $H^{\rightarrow}$. The following lemma shows that we can perform this validation efficiently. In the remaining part of this section, “constant expected time”, refers to constant amortized time access to hash maps that we use.

**Lemma 14.** Let $T$ be a DRTS of a DAG $H^{\rightarrow}$ of a connected $k$-vertex graph $H$. Assume edges of $G_{\leq}^+$ are saved in a hash table. For each match $\pi$ of $T$ in $G_{\leq}^+$, it takes $O(|E(H^{\rightarrow})|)$ expected time to validate whether $\pi$ is a (incomplete) match of $H^{\rightarrow}$ or not.

**Proof.** Since $\pi$ is a bijection, it has an inverse which we denote by $\pi^{-1}$. Let $H^{\rightarrow}[V(T)]$ denote the subgraph of $H^{\rightarrow}$ induced on $V(T)$. Observe that, there could be edges in $H^{\rightarrow}[V(T)]$ not present in $T$. For $\pi$ to be a match (if $V(T) = V(H^{\rightarrow})$) or incomplete match of $H^{\rightarrow}$, these edges have to be present between corresponding vertices in $G_{\leq}^+$ mapped to $T$ by $\pi$. Formally, consider all ordered pairs of vertices $(a,b) \in V(T) \times V(T)$ such that $(a,b) \in E(H^{\rightarrow})$ and $(a,b) \notin E(T)$, $\pi$ is a match or incomplete match of $H^{\rightarrow}$ if $(\pi^{-1}(a), \pi^{-1}(b)) \in E(G_{\leq}^+)$ for all such pairs of vertices. To validate this, we enumerate all edges $(a,b)$ of $H^{\rightarrow}[V(T)]$ which are not present in $T$, and search for $(\pi^{-1}(a), \pi^{-1}(b))$ in hashed edges of $G_{\leq}^+$ in expected constant time. So this only requires $O(|E(H^{\rightarrow})|)$ expected time.

If $V(T_{\text{max}}) = V(H^{\rightarrow})$, then a match of $T_{\text{max}}$ could be a match of $H^{\rightarrow}$ too, which could be verified as explained. If there is a vertex in $H^{\rightarrow}$ which is not present in $T_{\text{max}}$, then after validating that a match of $T_{\text{max}}$ is an incomplete match of $H^{\rightarrow}$, we need to find the number of ways to complete it to a match of $H^{\rightarrow}$. For this we need to count matches of each possible structures that $T_{\text{max}}$ does not cover in $H^{\rightarrow}$. We save the count of these structures in $G_{\leq}^+$, in hash tables. The following lemma shows that this can be done efficiently.

**Lemma 15.** In $O(mn^3)$ time and space, we can save all the following key and value pairs in hash maps $\mathcal{HM}_1, \mathcal{HM}_2, \text{ and } \mathcal{HM}_3$.
1. $\mathcal{HM}_1 : ((u,v), 1) \text{ where } (u,v) \in E(G_{\leq}^+)$
2. $\mathcal{HM}_2 : (S,k) \forall S \subseteq V(G_{\leq}^+) \text{ where } 1 \leq |S| \leq 4, \text{ and } k \text{ is the number of vertices } u \text{ such that } S \subseteq N^+(u)$
3. $\mathcal{HM}_3 : ((S_1,S_2), \ell) \forall S_1, S_2 \subseteq V(G_{\leq}^+) \text{, where } 1 \leq |S_1 \cup S_2| \leq 3, \text{ and } \ell \text{ is the number of edges } e = (u,v) \in E(G_{\leq}^+) \text{ such that } S_1 \subseteq N^+(u) \text{ and } S_2 \subseteq N^+(v)$. 
Proof. We show how to enumerate and save all these structures in $\mathcal{H}M_1$, $\mathcal{H}M_2$, and $\mathcal{H}M_3$.

1. $\mathcal{H}M_1$: We can easily do this in $O(n)$ by enumerating the out-neighbors of each vertex.

2. $\mathcal{H}M_2$: For each edge $e = (u, v)$, we can enumerate all subsets $T$ of the set $\{v \in N^+(u) \mid v < w\}$, where $|T| \leq 3$, in $O(\kappa^3)$ time, and increment the value for the key $T \cup \{v\}$ in the hash map by one.

3. $\mathcal{H}M_3$: For each edge $e = (u, v) (v \in N^+(u))$, we enumerate all possible subset $S_1 \subseteq N^+(u) \setminus \{v\}$ where $|S_1| \leq 3$. And, for each $S_1$ we enumerate all possible $S_2 \setminus S_1$ in subsets of $N^+(v)$, such that $1 \leq |S_1 \cup S_2| \leq 3$. This takes $O(\kappa^3)$ as the out-degree of each vertex is at most $\kappa$, and we choose up to three vertices. All possible $S_1 \cap S_2$ can be determined by checking the connection between $v$ and each vertex in $S_1$ using the hashed edges of $G^\rightarrow$ in $\mathcal{H}M_1$.

The following lemma shows that we can count the number of ways to complete a match of $T_{\text{max}}$, which is also an incomplete match of $H^\rightarrow$, to a match of $H^\rightarrow$ efficiently.

Lemma 16. Let $H$ be a 5-vertex connected graph, $H^\rightarrow$ be a DAG of $H$, and $T_{\text{max}}$ be one of the largest DRTSs in $H^\rightarrow$. Assume $\mathcal{H}M_1$, $\mathcal{H}M_2$, and $\mathcal{H}M_3$ are given. For each match $\pi$ of $T_{\text{max}}$ in $G_{\rightarrow}^\pi$ which is an incomplete match of $H^\rightarrow$, we can count the number of ways to complete $\pi$ to a match of $H^\rightarrow$ in expected constant time.

Proof. By Lemma 13, $T_{\text{max}}$ has at least 3 vertices, and since $\pi$ is an incomplete match (not a match) of $H^\rightarrow$, we can assume that $|V(T_{\text{max}})| < 5$. Observe that, $T_{\text{max}}$ is a maximal DRTS. Any vertex in $H^\rightarrow$ which is not in $T_{\text{max}}$ can only be connected to vertices of $T_{\text{max}}$ by outgoing edges, otherwise they could be added to $T_{\text{max}}$ to create a larger DRTS of $H^\rightarrow$, which contradicts the maximality of $T_{\text{max}}$. We consider two cases where $T_{\text{max}}$ has three or four vertices.

Let $|V(T_{\text{max}})| = 4$, and $i$ be the only vertex in $H^\rightarrow$ that is not in $T_{\text{max}}$. To complete $\pi$ to a match of $H^\rightarrow$, we need to choose a vertex in $G_{\rightarrow}^\pi$, that is connected by outgoing edges to vertices mapped to the out-neighborhood of $i$ in $H^\rightarrow$. Let $S_i = \{\pi^{-1}(t) \mid t \in N_{H^\rightarrow}^+(i)\}$. $\mathcal{H}M_2(S_i)$ is the number of vertices that could be mapped to $i$, but some of them may be already mapped to a vertex in $T_{\text{max}}$, by $\pi$. Let $r_i$ denote the number of vertices $v \in \{\pi^{-1}(t) \mid t \in V(T_{\text{max}})\}$, where $S_i \subseteq N_{G_{\rightarrow}^\pi}^+(v)$. We can obtain $r_i$ in expected constant time, by enumerating vertices mapped to $V(T_{\text{max}})$, and counting vertices that are connected to all vertices in $S_i$. For any vertex, we can check the connection to each vertex of $S_i$ using $\mathcal{H}M_1$ in expected constant time. The number of ways to complete $\pi$ to a match of $H^\rightarrow$ in this case is $\mathcal{H}M_2(S_i) - r_i$.

Now we consider the case where $|V(T_{\text{max}})| = 3$. Let $V(H^\rightarrow) \setminus V(T_{\text{max}}) = \{i, j\}$. To complete $\pi$ to a match of $H^\rightarrow$, we only need to choose two vertices of $G_{\rightarrow}^\pi$ to map to $i$ and $j$. Let $S_i = \{\pi^{-1}(t) \mid t \in V(T_{\text{max}}) \cap N_{H^\rightarrow}^+(i)\}$ and $S_j = \{\pi^{-1}(t) \mid t \in V(T_{\text{max}}) \cap N_{H^\rightarrow}^+(j)\}$. We consider two cases, where $i$ and $j$ are connected or not. If they are connected, without loss of generality, assume $(i, j) \in E(H^\rightarrow)$. If $(i, j) \in E(H^\rightarrow)$, then we can use $\mathcal{H}M_3$ in Lemma 15, to find the number of edges $(u, v)$ where $u$ and $v$ could be mapped to $i$ and $j$, respectively. Let $r_{(i, j)}$ be the number of edges $e = (u, v) \in E(G_{\rightarrow}^\pi)$, where $w$ and $x$ are mapped to vertices in $T_{\text{max}}$ by $\pi$, such that, $S_i \subseteq N_{G_{\rightarrow}^\pi}^+(w)$, and $S_j \subseteq N_{G_{\rightarrow}^\pi}^+(x)$. We can obtain $r_{(i, j)}$ in expected constant time using $\mathcal{H}M_1$. Then the number of edges $(u, v)$ that could be mapped to $(i, j)$ is $\mathcal{H}M_3(S_i, S_j) - r_{(i, j)}$. Next case is when $(i, j) \notin E(H^\rightarrow)$. In this case, we use $\mathcal{H}M_2$ to find the number of pair of vertices of $G_{\rightarrow}^\pi$ which could be mapped to $i$ and $j$. Let $r_i$ ($r_j$ resp.) denote the number of vertices $v \in V(G_{\rightarrow}^\pi)$ where $v$ is mapped to a vertex in $T_{\text{max}}$ and $S_i \subseteq N_{G_{\rightarrow}^\pi}^+(v)$ ($S_j \subseteq N_{G_{\rightarrow}^\pi}^+(v)$ resp.). Also, we use $r_{i, j}$ to denote the number of vertices $v \in V(G_{\rightarrow}^\pi)$ that are counted in both $r_i$ and $r_j$, meaning...
Linear Time Subgraph Counting, Graph Degeneracy, and the Chasm at Size Six

$S_i \cup S_j \subseteq N_{G_{<6}}^+(v)$. We can obtain $r_i$, $r_j$, and $r_{i,j}$ easily in expected constant time using $\mathcal{HM}_1$. The number of pairs of vertices which could be mapped to $i$ and $j$ is equal to $(\mathcal{HM}_2(S_i) - r_i) \cdot (\mathcal{HM}_2(S_j) - r_j) - (\mathcal{HM}_2(S_i \cup S_j) - r_{i,j})$.

Now, we have all the tools to efficiently count distinct matches of a DAG of $H \rightarrow$ in $G_{<6}$. The following lemma shows that we can do this in $O(mk^3)$ expected time.

\textbf{Lemma 17.} There is an algorithm which counts distinct matches for each possible DAG (up to isomorphism) $H \rightarrow$ of a 5-vertex connected subgraphs $H$, in $O(mk^3)$ expected time.

\textbf{Proof.} Fix a DAG $H \rightarrow$ of $H$. If $H$ is a 4-star and $H \rightarrow$ has $\ell$ incoming neighbors, then the number of distinct matches of $H \rightarrow$ is $\sum_{u \in V(G_{<6})} (d^+(v))^3 (d^-(v))^3$. Assume that $H$ is not a 4-star. Find a DRTS of $H \rightarrow$ with the most number of vertices among all its DRTSs, and call it $T_{\text{max}}$. This can be done in constant time for $H \rightarrow$. By Lemma 13, $T_{\text{max}}$ has at least three vertices. We will now enumerate all matches of $T_{\text{max}}$ in $G_{<6}$. By Lemma 11, this step requires $O(mk^3)$ expected time. For each match $\pi$ of $T_{\text{max}}$ in $G_{<6}$, we can verify whether $\pi$ is a match (if $|V(T_{\text{max}})| = 5$) or incomplete match of $H \rightarrow$ in expected constant time, by Lemma 14. If $|V(T_{\text{max}})| = 5$, while enumerating all matches of $T_{\text{max}}$, we only count them if they are a match of $H \rightarrow$. So in this case we can count $M(G_{<6}, H \rightarrow)$ in $O(mk^3)$ expected time.

Otherwise, $T_{\text{max}}$ has 3 or 4 vertices. In this case, for each match $\pi$ of $T_{\text{max}}$, we first verify that it is also an incomplete match of $H \rightarrow$. Then, we count the number of ways to complete $\pi$ to a match of $H \rightarrow$, which we can do in expected constant time, by Lemma 16. To obtain $M(G_{<6}, H \rightarrow)$, we simply sum the ways to complete each incomplete match we have found, to a match of $H \rightarrow$.

This approach gives us the number of all (not necessarily distinct) matches of $H \rightarrow$ in $G_{<6}$. Let $H_{\rightarrow}$ be a subgraph of $G_{<6}$ that $\pi$ maps to $H \rightarrow$. Each automorphism of $H \rightarrow$, gives a new match $\pi'$ which is not distinct from $\pi$, as it is still mapping $H_{\pi}$ (the same copy of $H$) to $H \rightarrow$ (example in Fig.1b). As each match of $H \rightarrow$, also maps vertices to $T_{\text{max}}$, resulting in a match of $T_{\text{max}}$ and an (incomplete) match of $H \rightarrow$, we will find all distinct matches of $H \rightarrow$ and count each one exactly $|\text{Aut}(H \rightarrow)|$ times. We want the number of distinct matches, which we can obtain by dividing the count of all matches by $|\text{Aut}(H \rightarrow)|$.

Thus, it requires $O(mk^3)$ expected time to create $\mathcal{HM}_1$, $\mathcal{HM}_2$, and $\mathcal{HM}_3$ by Lemma 15, $O(mk^3)$ time for enumerating matches of $T_{\text{max}}$, expected constant time to validate these matches, and expected constant time for counting ways to complete each such match, that is verified to be an incomplete match of $H \rightarrow$, to a match of $H \rightarrow$. So overall, we can find $\text{DM}(G_{<6}, H \rightarrow)$ in $O(mk^3)$ expected time.

This completes the proof of this lemma.

Lastly, we can prove Theorem 9 as follows.

\textbf{Proof of Theorem 9.} Given a 5-vertex connected subgraph $H$, we can count all distinct matches of each possible DAG $H \rightarrow$ of $H$, in $G_{<6}$ in $O(mk^3)$ expected time, by Lemma 17. To count all distinct matches of $H$ in $G$, we just need to sum the number of distinct matches of all possible DAGs (up to isomorphism) of $H$. The number of such DAGs is constant for $H$. There are 21 different connected 5-vertex subgraphs (illustrated in [57]), and we perform this process on all of them. This completes the proof of the theorem.
(a) $H$ is 5-vertex connected subgraph and $H^\rightarrow$ is one possible acyclic orientation of it. $T_{\text{max}}$ (largest DRTS of $H^\rightarrow$) is shown in green and contains three vertices.

(b) All six figures show exactly the same subgraph in $G_n^\rightarrow$. $\pi_1, \ldots, \pi_6$ are six equivalent matches of $H^\rightarrow$ in $G_n^\rightarrow$, one for each automorphism of $H^\rightarrow$. Notice $(u,v,w)$ being mapped to all permutations of $(a,b,c)$.

**Figure 1** Application of Alg. 2 on a DAG $H^\rightarrow$ of an example 5-vertex connected subgraph $H$.

### 4.2 Limitations of Our Framework for a Six Vertex Subgraph

Consider $C_6$, shown as $H$ in Fig. 2. Then $H^\rightarrow$, shown in the right side of Fig. 2, is a possible DAG of $H$. In $H^\rightarrow$, $s_1$, $s_2$, and $s_3$ are the source vertices, and $t_1$, $t_2$, and $t_3$ are the sink vertices. Any DRTS of $H^\rightarrow$ has at most three vertices, and there are three such DRTS, $T_1$, $T_2$, and $T_3$ rooted at $s_1$, $s_2$ and $s_3$, respectively. $T_1$ is shown by red in Fig. 2. For each of $T_1$, $T_2$, and $T_3$, the remaining vertices include a vertex, with two incoming edges, which we call an in-in wedge. For example, $t_2$ is such a vertex for $T_1$. Even graphs with bounded degeneracy can have $\Omega(n^2)$ in-in wedges. We cannot hash the count of such structures in expected time bounded by $m$ and $\kappa$. So, Alg. 2 fails to count occurrences of $C_6$ in the desired time. In the next section, we discuss why such limitations are natural to any framework for the sub-cnt$_k$ problem at and beyond $k = 6$.

### 5 A Chasm at Six

At the end of the previous section, we showed the limitations of our framework in counting certain 6-vertex subgraphs. In this section, we show that perhaps such limitations are fundamental to any subgraph counting algorithms. In particular, the landscape of sub-cnt$_k$ problem in the bounded degeneracy graphs changes dramatically as we move beyond $k = 5$. 
We first give a proof outline. Fix some integer \( k \geq 6 \). We prove that for every integer \( k \geq 6 \) and any function \( f : \mathbb{N} \to \mathbb{N} \), there exists a \( k \)-vertex subgraph \( H \) such that there is no \((k+\gamma)f(\kappa)\) algorithm for \( \text{SUB-CNT}_H \). This captures the main result of this section.

**Theorem 18.** Assume the Triangle Detection Conjecture (Conj. 2). There exists an absolute constant \( \gamma > 0 \) such that the following holds. For any \( k \geq 6 \) and any function \( f : \mathbb{N} \to \mathbb{N} \), there exists a \( k \)-vertex subgraph \( H \) such that there is no \((k+\gamma)f(\kappa)\) algorithm for \( \text{SUB-CNT}_H \).

**Outline of the Proof.** For each \( k \geq 6 \) and \( k \neq 8 \), the subgraph of interest will be the \( k \)-cycle graph, \( C_k \). For \( k = 8 \), the subgraph of interest will be the \( C_7 \) with a tail (see Figure 3). We first give a proof outline. Fix some \( k \geq 6 \) and let \( H_k \) denote the target subgraph of size \( k \). Recall the TRI-CNT problem — count the number of triangles in a graph with \( m \) edges. Conjecture 2 asserts that for any algorithm \( A \) for the TRI-CNT problem, \( T(A) = \omega(m) \) where \( T(A) \) denotes the worst case time complexity of the algorithm \( A \). Our strategy is to reduce from the TRI-CNT problem to the \( \text{SUB-CNT}_{H_k} \) problem. To this end, we construct a new graph \( G_k \) from the input instance \( G \) of the TRI-CNT problem such that \( G_k \) has \( O(m) \) edges, and has degeneracy at most 2. More importantly, the number of triangles in \( G \) is a simple linear function of the number of \( H_k \) in \( G_k \). Hence, we can derive the number of triangles in \( G \) by counting the number of \( H_k \) in \( G_k \). As \( \kappa(G_k) \leq 2 \), any \( O(mf(\kappa)) \) algorithm for the \( \text{SUB-CNT}_{H_k} \) problem translates to a \( O(m) \) algorithm for the TRI-CNT problem, contradicting the Triangle Detection Conjecture. We remark that, for \( k = 8 \), our proof strategy will be slightly different — instead of reducing from the TRI-CNT problem, we shall reduce from the triangle detection problem itself. However, the gadget construction will follow the same basic principle.

The construction of \( G_k \) from \( G \) is rather simple. The details of the construction depends on whether \( k \) is a multiple of 3 or not. We take two examples to describe the construction.

First, we take \( k = 6 \), and the target subgraph \( H_6 = C_6 \). For each edge \( e \) in \( E(G) \), we replace \( e \) with a length two path \( \{e_1, e_2\} \) in \( E(G_6) \). To accomplish this, we add a new vertex \( v_e \) for each edge: \( V(G_6) = V(G) \cup \{v_e \mid e \in E(G)\} \). This is shown in Figure 4a. Each triangle in \( G \) creates a \( C_6 \) in \( G_6 \). We formally prove in Lemma 20 that the number of triangles in \( G \) is same as the number of \( C_6 \) in \( G_6 \). In Lemma 19, we bound the degeneracy of \( G_6 \) by 2. This construction can be generalized for any \( k = 3\ell \) where \( \ell \geq 2 \), by replacing each edge in \( E(G) \) with \( \ell \)-length path.
Next consider the case $k = 7$. For each edge $e \in E(G)$, we first create two parallel copies of $e$, and then replace the first one with a length two path $\{e_{1,1}, e_{1,2}\}$, and the second one with a length three path $\{e_{2,1}, e_{2,2}, e_{2,3}\}$. So in $E(G_7)$, we have 5 edges for each edge in $E(G)$. We create 3 new vertices per edge to accomplish this, and denote them as $v_e, u_e_1, u_e_2$. See Figure 4b for a pictorial demonstration. In Lemma 20, we argue that the number of $C_7$ is exactly 3 times the number of triangles in $G$. In Lemma 19, we bound the degeneracy of $G_7$ by 2. This construction generalizes to any $k = 3\ell + i$ where $\ell \geq 2$ and $i \in \{1, 2\}$ (except for the case when $k = 8$, that is $\ell = 2$ and $i = 2$) by splitting each edge into $\ell$ and $\ell + 1$ many parts respectively.

Finally, we consider the case of $k = 8$. Note that the target subgraph $H_8$ is the 7-cycle with a tail in this case (see Figure 3). It is natural to wonder why we do not simply take $H_8 = C_8$? After all, for all other values of $k$, taking $H_k = C_k$ suffices. At a first glance, it seems like if we consider the same graph $G_7$ as described above (and in Figure 4b) the number of $C_8$ would be a simple linear function of the number of triangles in $G$ — for each triangle in $G$, there will be exactly three $C_8$ in $G_7$. However, each $C_4$ in $G$ would also lead to a $C_8$ in $G_8$. Observe that for $k > 8$, we do not run into this problem. A more formal treatment of this issue appear in Section 5.

So instead, we take $H_8$ to be the subgraph $C_7$ with a tail to prove our conditional lower bound for sub-CNT$_8$. The construction of the graph $G_8$ remains exactly the same as that of $G_7$. We show in Lemma 21 that, there exists a $C_7$ with a tail in $G_8$ if and only if there exist a triangle in $G$.

![Figure 3](image)

Figure 3 Target subgraph for proving conditional lower bounds for sub-CNT$_8$: the $C_7$ with a tail

We now present the proof of Theorem 18 in full details.

Proof of Theorem 18. Fix some $k \geq 6$. Let the subgraph $H_k$ denote the target subgraph of size $k$. For $k \neq 8$, $H_k$ is $C_k$, and for $k = 8$, $H_k$ is $C_7$ with a tail (see Figure 3). We reduce from the tri-CNT problem to the sub-CNT$_H$. Let $G = (V, E)$ be the input instance for the tri-CNT problem with $|V| = n$ and $|E| = m$. We construct an input instance $G_k = (V_k, E_k)$ for the sub-CNT$_H$ problem from $G$. The construction of $G_k$ differs based on whether $k$ is divisible by 3 or not. We next consider these two cases separately.

Details of the Reduction. First assume $k = 3\ell$ for some integer $\ell \geq 2$. We first define the vertex set $V_k$.

We now present the proof of Theorem 18 in full details.
We now describe the edge set $E_k$. We treat each edge $e = \{u,v\} \in E$ as an ordered pair $(u,v)$ where the ordering can be arbitrary of the vertices (for example, assume lexicographical ordering). Now for each edge $e = (u,v)$ construct an $\ell$-length path between $u$ and $v$ in $V_k$ by connecting the vertices in $\{u\} \cup V_e \cup \{v\}$ sequentially. More precisely, we define $E_k$ as follows.

$$E_k = \bigcup_{e \in E} E_e,$$

where $E_e = \{\{u,v_e,1\}, \{v_e,1,v_e,2\}, \ldots, \{v_e,\ell-2,v_e,\ell-1\}, \{v_e,\ell-1,v\}\}$ for $e = (u,v)$.

This completes the construction of the graph $G_k = (V_k, E_k)$. We give an example in Figure 4a for $k = 6$.

Now assume $k = 3\ell + i$ for some some integer $\ell \geq 2$ and $i \in \{1,2\}$. In the previous case, we added a set of $\ell - 1$ many vertices for each edge in $E$. But now, for each edge $e \in E$, we add two sets of vertices, one with $\ell - 1$ many vertices and the other with $\ell$ many vertices. We denote the first set as $V_e = \{v_{e,1}, v_{e,2}, \ldots, v_{e,\ell-1}\}$, and the second set as $U_e = \{u_{e,1}, u_{e,2}, \ldots, u_{e,\ell}\}$. We also add the set of vertices in $V$ to $V_k$. Formally, we have

$$V_k = V \cup V_k,$$

where $V_k = \bigcup_{e \in E} V_e \cup U_e,$

for $V_e = \{v_{e,1}, v_{e,2}, \ldots, v_{e,\ell-1}\}$,

and $U_e = \{u_{e,1}, u_{e,2}, \ldots, u_{e,\ell}\}$.

To construct the edge set $E_k$, as before we treat each edge in $e = \{u,v\} \in E$ as an ordered pair $(u,v)$ according to some arbitrary ordering of the vertices. Now, for each edge $e = (u,v)$, construct an $2\ell + 1$-length cycle between $u$ and $v$ in $V_k$ by creating a $\ell$-length path via the vertices in $V_e$ and another $\ell + 1$-length path via the vertices in $U_e$. We denote the corresponding edge sets as $E_{V,e}$ and $E_{U,e}$ respectively. Formally, we define $E_k$ as follows.

$$E_k = \bigcup_{e \in E} (E_{V,e} \cup E_{U,e}),$$

where $E_{V,e} = \{\{u,v_{e,1}\}, \{v_{e,1}, v_{e,2}\}, \ldots, \{v_{e,\ell-2}, v_{e,\ell-1}\}, \{v_{e,\ell-1}, v\}\}$,

and $E_{U,e} = \{\{u,u_{e,1}\}, \{u_{e,1}, u_{e,2}\}, \ldots, \{u_{e,\ell-1}, u_{e,\ell}\}, \{u_{e,\ell}, v\}\}$ for $e = (u,v)$.
This completes the construction of the graph $G_k = (V_k, E_k)$. Note that the construction is independent of the value of $i$. Hence, we produce the same graph $G_k$ for $k = 3\ell + 1$ and $k = 3\ell + 2$. We give an example in Figure 4b for $k = 7$.

Note that although our target subgraph for the case $k = 8$ is a 7-cycle with a tail instead of 8-cycle, our construction is still the same.

**Correctness of the Reduction.** In Lemma 19, we prove that $G_k$ has degeneracy at most 2. In Lemma 20, we show that, for $k \neq 8$, the number of $C_k$ in the graph $G_k$ is a linear function of the number of triangles in $G$. In Lemma 21, we show that $G_8$ is $H_k$ free if and only if $G$ is triangle free.

**Lemma 19.** $\kappa(G_k) \leq 2$.

**Proof.** To prove the lemma it is sufficient to exhibit a vertex ordering $\prec$ such that in the corresponding directed graph $G'_k$, $d^+(v) \leq 2$ for all $v \in V_k$ (application of Lemma 6). We use an ordering $\prec$ where $V_E \prec V$ and the ordering within each set is arbitrary. Observe that each vertex $v \in V_E$ has degree exactly 2 and no two vertices in $V$ are connected to each other. Hence, $d^+(v) \leq 2$ for all $v \in V_k$.

**Lemma 20.** Let $\ell \geq 2$ be some integer. For $k = 3\ell$, $\textrm{DM}(G_k, C_k) = \textrm{DM}(G, C_3)$. For $k = 3\ell + i$ with $i \in \{1, 2\}$ and $k \neq 8$, $\textrm{DM}(G_k, C_k) = 3 \cdot \textrm{DM}(G, C_3)$.

**Proof.** Let $T$ be the set of triangles in $G$ and $C$ be the set of $C_k$ in $G_k$. Note that a triangle in $T$ and a $k$-cycle in $C$ can be uniquely identified by a set of three and $k$ edges, respectively.

We first take up case of $k = 3\ell$ for some $\ell \geq 2$. Let $g$ be the mapping between the sets $T$ and $C$, $g : T \rightarrow C$, defined as follows: $g([e_1, e_2, e_3]) = E_{e_1} \cup E_{e_2} \cup E_{e_3}$. To prove the lemma, it is sufficient to exhibit that $g$ is a bijection. To this end, note that if $g(\tau_1) = g(\tau_2)$, then $\tau_1 = \tau_2$. This follows immediately from the definition of $g$, since $E_{e_1} \cap E_{e_2} = \emptyset$ for all $e_1 \neq e_2$.

We now show that every $k$-cycle in $C$ has an inverse mapping in $g$. Let $\xi$ be a $k$-cycle in $C$. Fix some edge $e \in E$. By construction, either all the edges from the set $E_\xi$ are present in $\xi$, or none of them are. Hence, $\xi$ must be of the form $E_{e_1} \cup E_{e_2} \cup E_{e_3}$ for some three distinct edges $e_1, e_2, e_3$. Clearly, $\{e_1, e_2, e_3\}$ forms a triangle in $G$.

Now assume $k = 3\ell + i$ for some $\ell \geq 2$ and $i \in \{1, 2\}$, and $k \neq 8$. It is not difficult to see that each triangle in $T$ leads to exactly three $k$-cycles in $C$. The non-trivial direction is to show that for each $k$-cycles in $C$ there is an unique triangle in $T$. Let $\xi$ be a $k$-cycle in $C$. Fix some edge $e \in E$. By construction, exactly one of the following must be true: (i) all the $\ell$ edges from the set $E_{V \setminus e}$ are present in $\xi$, (ii) all the $\ell + 1$ edges from the set $E_{U \setminus e}$ are present in $\xi$, (iii) none of the edges from the set $E_{V \setminus e} \cup E_{U \setminus e}$ are present in $\xi$. First assume $i = 1$. Since $\xi$ has $3\ell + 1$ many edges, and $\ell \geq 2$, it must consist of one $E_{U \setminus e}$ set of size $\ell + 1$, and two $E_{V \setminus e}$ sets of size $\ell$. When $i = 2$ and $\ell > 2$, $\xi$ must consist of two $E_{U \setminus e}$ set of size $\ell + 1$, and one $E_{V \setminus e}$ sets of size $\ell$. Clearly, the three edges corresponding to these sets form a unique triangle in $G$. (When $k = 8$, that is $\ell = 2$ and $i = 2$, taking four distinct sets $E_{V \setminus e}$ creates a copy of $C_8$, and hence the argument does not work.)

**Lemma 21.** The input graph $G$ is triangle free if and only if $G_8$ does not have any $C_7$ with a tail.

**Proof.** Observe that, if there exists a triangle $\tau$ in $G$, then in $G_8$, there would be at least one $C_7$ with a tail (in fact, the exact number would depend on the degree of the involved vertices). In the proof of Lemma 20, we argued that each 7-cycle in $G_7$ (which is isomorphic to $G_8$) corresponds to a triangle in $G$. Also, by our construction, if $G_8$ has a $C_7$, then that 7-cycle necessarily has a tail. Therefore, existence of $C_7$ with a tail in $G_8$ implies existence of a triangle in $G$. This completes the proof of the lemma.
Lemmas 19 to 21 together prove the theorem: if there exists an algorithm \( A \) for the \( \text{sub-cnt}_{C_k} \) problem with \( T(A) = O(mf(\kappa)) \), then \( A \) is an algorithm for the \( \text{tri-cnt} \) problem (or the triangle detection problem in the case of \( k = 8 \)) with \( T(A) = O(m) \), where \( T(A) \) denotes the worst case time complexity of the algorithm \( A \).

\section{Future Directions}

Although our algorithmic framework fails to produce a linear time algorithm for \( \text{sub-cnt}_{C_6} \) in bounded degeneracy graphs, there are certain other 6-vertex subgraphs where it indeed succeeds. An easy example is \( \text{sub-cnt}_{K_6} \). In fact, our framework gives a linear time algorithm for counting any constant size clique in bounded degeneracy graphs – for each acyclic orientation of a clique, the source vertex construct a DRTS covering all the remaining vertices. There exists other non-clique 6-vertex subgraphs as well, where Alg. 2 succeeds. Consider the subgraph \( H \) shown in Fig. 5. It is easy to see that, any acyclic orientation of \( H \) such as \( H \rightarrow \) has at least one source vertex \( s \) that is a root of a DRTS with four vertices. Thus, we can solve \( \text{sub-cnt}_H \) in \( O(m\kappa^3) \) expected time.

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{Figure5.png}
\caption{Alg. 2 succeeds to count the number of distinct matches of \( H \) in linear time for bounded (constant) degeneracy graphs. Each acyclic orientation of \( H \) has a source vertex \( s \), which is connected to exactly three vertices, as in \( H \rightarrow \). So, the largest DRTS has at least four vertices (shown in green). Number of matches of the remaining vertices (shown in blue) could be counted using \( H_{M_2} \).}
\end{figure}

Despite the chasm at six, there exist subgraphs \( H \) with 6-vertices (or more) such that \( \text{sub-cnt}_H \) admits a linear time algorithm in bounded degeneracy graph. We end this exposition with the following natural problem:

\textit{Characterize all subgraphs \( H \) such that \( \text{sub-cnt}_H \) has a linear time algorithm in bounded degeneracy graphs.}

Abstract

Parameterization above a guarantee is a successful paradigm in Parameterized Complexity. To the best of our knowledge, all fixed-parameter tractable problems in this paradigm share an additive form defined as follows. Given an instance \((I, k)\) of some (parameterized) problem \(\Pi\) with a guarantee \(g(I)\), decide whether \(I\) admits a solution of size at least \((\text{at most})\) \(k + g(I)\). Here, \(g(I)\) is usually a lower bound \((\text{resp. upper bound})\) on the maximum \((\text{resp. minimum})\) size of a solution. Since its introduction in 1999 for \(\text{Max SAT}\) and \(\text{Max CUT}\) (with \(g(I)\) being half the number of clauses and half the number of edges, respectively, in the input), analysis of parameterization above a guarantee has become a very active and fruitful topic of research.

We highlight a multiplicative form of parameterization above a guarantee: Given an instance \((I, k)\) of some (parameterized) problem \(\Pi\) with a guarantee \(g(I)\), decide whether \(I\) admits a solution of size at least \((\text{at most})\) \(k \cdot g(I)\). In particular, we study the \(\text{Long Cycle}\) problem with a multiplicative parameterization above the girth \(g(I)\) of the input graph, and provide a parameterized algorithm for this problem. Apart from being of independent interest, this exemplifies how parameterization above a multiplicative guarantee can arise naturally. We also show that, for any fixed constant \(\epsilon > 0\), multiplicative parameterization above \(g(I)^{1+\epsilon}\) of \(\text{Long Cycle}\) yields para-NP-hardness, thus our parameterization is tight in this sense. We complement our main result with the design (or refutation of the existence) of algorithms for other problems parameterized multiplicatively above girth.

Introduction

The goal of parameterized complexity is to find ways of solving NP-hard problems more efficiently than brute force: our aim is to restrict the combinatorial explosion to a parameter that is hopefully much smaller than the input size. Formally, a parameterization of a problem is the assignment of an integer $k$ to each input instance, and we say that a parameterized problem is fixed-parameter tractable (FPT) if there is an algorithm that solves the problem in time $f(k) \cdot n^{O(1)}$, where $n$ is the size of the input and $f$ is an arbitrary computable function depending on the parameter $k$ only. There is a long list of NP-hard problems that are FPT under various parameterizations: finding a vertex cover of size $k$, finding a cycle of length $k$, finding a maximum independent set in a graph of treewidth at most $k$, etc. For more background, the reader is referred to the monographs [12, 14, 21].

Choosing a suitable parameter plays an important role in the field of parameterized complexity. Traditionally, the solution size has been the most sought after parameter. However, in various circumstances this is not a good parameter. To illustrate this, consider the following problems: Max Sat and Max Cut. Observe that there always exists a truth assignment that satisfies half of the clauses, and there is always a max-cut containing at least half the edges. Thus, if we choose solution size as the parameter, then we get the following trivial algorithm: if $k \leq m/2$, then return yes; else $m \leq 2k$, so now any brute-force algorithm is an FPT algorithm. Thus if we want to design a nontrivial parameterized algorithm, then solution size is not a suitable parameter. In particular, a general message here is as follows.

The natural parameterization of, say, a maximization/minimization problem by the solution size is not satisfactory if there is a lower bound for the solution size that is sufficiently large.

Thus, for such cases, it is more natural to parameterize the problem by the difference between the solution size and the bound. This perspective is known as “above guarantee” parameterization. This approach was introduced by Mahajan and Raman [33] for the Max Sat and Max Cut problem. This approach was successfully applied to many various problems (see, e.g., [1, 11, 24, 25, 26, 34, 10] for a few illustrative examples).

In some of the above examples there is an explicit lower bound on the solution size, given in terms of the input size. However, in many cases, we do not have explicit lower bounds. We substantiate this with the example of classic Vertex Cover problem. In this problem, we are given a graph $G$ and a positive integer $k$, and the goal is to test whether there exists a set of vertices $C$ of size at most $k$ that is a vertex cover (i.e., every edge has at least one endpoint in $C$). Clearly, the size of a maximum matching of $G$ or the value of the linear programming relaxation of an integer linear program for Vertex Cover is a lower bound on the size of a vertex cover of $G$. Observe that these lower bounds are graph dependent.
and not the size dependent. This is what we mean by implicit lower bounds. Coming back
to Vertex Cover, in polynomial time it is possible to reduce the size of the graph, without
changing the answer, such that we are guaranteed that any vertex cover must contain half of
the remaining vertices. Thus, again we can employ any brute-force algorithm and design
an FPT algorithm for Vertex Cover. This has led to the study of the problem Vertex
Cover Above LP (or Vertex Cover Above Matching), which has played a central
role in the development of the field of parameterized complexity [12].

In this paper, we take the philosophy of above guarantee parameterization a significant
conceptual step forwards. In particular,

The goal of this paper is to study another classical problem – namely, Long
Cycle – from the viewpoint of a new implicit parameterization, that is neither
standard nor an additive above guarantee parameterization.

The Long Path problem is to decide, given a directed or undirected $n$-vertex graph $G$
and an integer $k$, whether $G$ contains a path on at least $k$ vertices, that is, a self-avoiding
walk with at least $k$ vertices. Similarly, the Long Cycle problem is to decide whether
$G$ contains a cycle of length at least $k$, that is, a closed self-avoiding walk with at least $k$
vertices. These problems are natural generalization of the classical Hamiltonian Path
and Hamiltonian Cycle problems and have been actively studied. In particular, there
is a plethora of results about parameterized complexity of Long Path and Long Cycle
(see, e.g., [4, 5, 9, 8, 22, 29, 30, 31, 38]) since the early work of Monien [35]. Let us
just mention here that the fastest known randomized algorithm for Long Path is due to
Björklund et al. [4] and runs in time $1.657^k \cdot n^{O(1)}$, whereas the fastest known deterministic
algorithm is due to Tsur [37] and runs in time $2.554^k \cdot n^{O(1)}$. Respectively for Long Cycle,
the randomized algorithm with the currently best running time of $4^k \cdot n^{O(1)}$ was given by
Zehavi in [40], and the best deterministic algorithm was given by Fomin et al. in [20] and
runs in time $4.884^k \cdot n^{O(1)}$.

For Long Path, the investigation of above guarantee parameterizations was initiated
by Bezáková et al. in [2]. Let $s$ and $t$ be two vertices of a graph $G$. Clearly, the length
of any $(s,t)$-path in $G$ is lower bounded by the shortest distance, $d(s,t)$, between these
vertices. Based on this straightforward observation, Bezáková et al. in [2] introduced the
Longest Detour problem that asks, given a graph $G$, two vertices $s, t$, and a positive
integer $k$, whether $G$ has an $(s,t)$-path with at least $d(s,t) + k$ vertices. They proved that
for undirected graphs, this problem can be solved in time $2^{O(k)} \cdot n^{O(1)}$. That is, it is FPT.

For the variant of the problem where the question is whether $G$ has an $(s,t)$-path with
exactly $d(s,t) + k$ vertices, a randomized algorithm with running time $2.746^k \cdot n^{O(1)}$ and a
deterministic algorithm with running time $6.745^k \cdot n^{O(1)}$ were obtained. In a recent work,
Fomin et al. [17] studied the parameterization of Long Path and Long Cycle above the
degeneracy $d$ of the input graph $G$. Formally, a graph $G$ has degeneracy at most $d$ if every
subgraph of $G$ has a vertex of degree at most $d$. A classic result by Erdős and Gallai [15]
from 1959 states that any graph of degeneracy $d > 1$ has a cycle (and hence also path)
on at least $d$ vertices. If the graph $G$ is not guaranteed to be 2-connected, then deciding
whether $G$ contains a cycle of length $d + 2$ is already NP-hard, and therefore parameterization
above degeneracy does not make sense. However, when we add the requirement that $G$ is
2-connected, then then deciding whether $G$ contains a cycle of length $d + k$ parameterized
by $k$ can be done in time $2^{O(k)} \cdot n^{O(1)}$ and hence FPT. A similar situation holds for Long
Path where connectivity replaces 2-connectivity.
Parameterization Above a Multiplicative Guarantee

1.1 Multiplicative Above Guarantee Parameterization

To the best of our knowledge, all successful above guarantee parameterizations are additive. Roughly speaking, this means that if we have a lower bound $\tau$ on the optimal solution size, then we ask whether we can find a solution of size (at least or at most) $\tau + p$ in time $f(p) \cdot n^{O(1)}$. Our main message of this paper is the following.

The goal of this paper is to introduce the notion of multiplicative above guarantee parameterization (which is neither standard nor an additive above guarantee parameterization). In multiplicative above guarantee parameterization, we ask whether we can find a solution of size (at least or at most) $\tau \cdot p$ in time $g(p) \cdot n^{O(1)}$. We will illustrate our new definition by designing several FPT algorithms parameterized above a multiplicative guarantee.

We remark that a few problems in [36] were stated in a way fitting parameterization above a multiplicative guarantee. However, these were shown to be para-NP-hard [27, 28].

Recall that the girth of a graph $G$, denoted by $\gamma(G)$, is the length of the shortest cycle in $G$. First, consider the problem where we are given a graph $G$ and an integer $k$ and the objective is to test whether there is a cycle of length at least $\gamma(G) + k$ in $G$. If $\gamma(G) \leq 2k + 6$, then clearly we can solve the problem in time $2^{O(k)}n^{O(1)}$ by using the algorithm in [39]. We now show that when $2k + 6 < \gamma(G)$, the problem is solvable in polynomial time. To this end, let $(G, k)$ be a yes-instance, and let $C$ be a hypothetical solution. That is, $C$ is a cycle of length at least $\gamma(G) + k$. Let $g = \gamma(G)$. Let $u, v, w, x \in V(C)$ such that when we traverse $C$ in some order from $u$, we encounter $v$ at distance $\lceil \frac{g}{2} \rceil - 1$ from $u$, next we encounter $w$ at additional distance $\lceil \frac{g}{2} \rceil - 1$ from $v$, and lastly we encounter $x$ at additional distance $k' = (g + k) - 2\lceil \frac{g}{2} \rceil - 2$ from $w$. Notice that $k' \in \{k + 2, k + 3\}$. Since the girth of $G$ is $g$ and $k + 3 < \frac{g}{2}$, we have that shortest paths between $u$ and $v$, $v$ and $w$, and $w$ and $x$ are unique and they are part of the cycle $C$. Therefore, we may compute the shortest paths between the pairs above, and later check whether $u$ is reachable from $x$ after deleting these shortest paths. Going over every possible choice of $u, v, w, x \in V(C)$, this leads to a polynomial time algorithm when $2k + 6 < \gamma(G)$. This implies that it can be decided in time $2^{O(k)}n^{O(1)}$ whether a graph has a cycle with at least $\gamma(G) + k$ vertices.

The informal argument above shows that LONG CYCLE parameterized additively above girth is not more “interesting” than just normal LONG CYCLE, where the input lower bound on solution size is the parameter. In a sense, it hints that the guarantee may be strengthened. In light of this, we introduce a new above guarantee version of LONG CYCLE (resp. LONG PATH), termed LONG CYCLE (resp. LONG PATH) parameterized multiplicatively above girth, as follows. The input consists of a graph $G$ and an integer $k$, and the objective is to decide whether there is a cycle (resp. path) on at least $k \cdot \gamma(G)$ vertices.

1.2 Our Contribution

We first prove our main result, which states that LONG CYCLE (and LONG PATH) parameterized multiplicatively above girth is FPT. Specifically, we prove the following theorem.

**Theorem 1.** LONG CYCLE (and LONG PATH) parameterized multiplicatively above girth is solvable in time $2^{O(k^2)}n$.

As a complementary result to the above theorem, we assert that our parameterization is tight in the following sense.
Theorem 2. For any fixed constant $\epsilon > 0$, Long Cycle (and Long Path) parameterized multiplicatively above $g^{1+\epsilon}$ is para-NP-hard, where $g$ is the girth of the input graph.

Next, we further extend the scope of our problem domain by showing that also Vertex Cover, Connected Vertex Cover and Max Internal Spanning Tree parameterized multiplicatively above girth are FPT. Given a graph $G$ and an integer $k$, the objectives of these problems are to decide whether $G$ has a vertex cover of size at most $k \cdot \gamma(G)$, a connected vertex cover (that is, a vertex cover that induces a connected subgraph) of size at most $k \cdot \gamma(G)$, and a spanning tree with at least $k \cdot \gamma(G)$ internal vertices, respectively. Here, $\gamma(G)/2$ is a lower bound on the size of an optimal solution.

Theorem 3. Vertex Cover, Connected Vertex Cover and Max Internal Spanning Tree parameterized multiplicatively above girth are solvable in time $2^{O(k \log k)} \cdot n$.

Lastly, we observe that parameterization above girth (even additively) can often yield NP-hardness when $k$ is a fixed constant. Specifically, we give Feedback Vertex Set and Cycle Packing as illustrative simple examples.

Theorem 4. Feedback Vertex Set and Cycle Packing parameterized additively above girth are para-NP-hard.

2 Preliminaries

For terminology not explicitly defined here, we refer to the book of Diestel [13]. Throughout the paper, we consider finite undirected graphs. For a graph $G$, let $V(G)$ and $E(G)$ denote its vertex set and edge set, respectively. When $G$ is clear from context, let $n = |V(G)|$ and $m = |E(G)|$. Given a subset $U \subseteq V(G)$, let $G[U]$ be the subgraph of $G$ induced by $U$. The girth of $G$ is the length of the shortest cycle in $G$, and is denoted by $\gamma(G)$. A vertex cover of $G$ is a set of vertices in $G$ whose removal from $G$ yields an edgeless graph. The vertex cover number of $G$ is the smallest size of a vertex cover of $G$. A feedback vertex set of $G$ is a set of vertices in $G$ whose removal from $G$ yields a forest. The feedback vertex set number of $G$ is the smallest size of a feedback vertex set of $G$. For any $t \in \mathbb{N}$, $K_t$ denote the cycle on $t$ vertices and $K_t$ denote the complete graph on $t$ vertices.

A subdivision of an edge $e = \{u, v\} \in E(G)$ is its replacement by a new degree-2 vertex whose neighbors are $u$ and $v$. A subdivision of $G$ is any graph that can be obtained by subdividing some of the edges of $G$ (where a single edge can be subdivided multiple times). Let $\text{Paths}(G)$ be the set of all (simple) paths in $G$. Given two (simple) paths $P_1$ and $P_2$ that share one or two endpoints and are internally vertex-disjoint, let $P_1 + P_2$ denote the (simple) path or cycle (if both endpoints are shared) obtained by concatenating $P_1$ and $P_2$. The size of a cycle or path is its number of vertices, and its length is its number of edges. A graph $H$ is a topological minor of $G$ if $G$ contains a subgraph that is isomorphic to some subdivision of $H$. More explicitly, this notion is defined as follows.

Definition 5 (Topological Minor). A graph $H$ is a topological minor of a graph $G$ if there exist injective functions $\phi : V(H) \to V(G)$ and $\varphi : E(H) \to \text{Paths}(G)$ such that for all $e = \{h, h'\} \in E(H)$, the endpoints of $\varphi(e)$ are $\phi(h)$ and $\phi(h')$, for all distinct $e, e' \in E(H)$, the paths $\varphi(e)$ and $\varphi(e')$ are internally vertex-disjoint, and there do not exist a vertex $v$ in the image of $\phi$ and an edge $e \in E(H)$ such that $v$ is an internal vertex on $\varphi(e)$.

1 If $G$ does not contain any cycle, then its girth is defined as $\infty$. 
The Cartesian product of two graphs is defined as follows.

**Definition 6** (Cartesian Product of Graphs). The Cartesian product $G \times H$ of two graphs $G$ and $H$ is the graph whose vertex set is the Cartesian product $V(G) \times V(H)$, where any two vertices $(u, u')$ and $(v, v')$ are adjacent if and only if one of the following holds: (i) $u = v$ and $\{u', v\} \in E(H)$; (ii) $u' = v'$ and $\{u, v\} \in E(G)$.

Treewidth is a measure of how “treelike” is a graph, formally defined as follows.

**Definition 7** (Treewidth). A tree decomposition of a graph $G$ is a pair $(T, \beta) = (V(T), \beta)$ of a tree $T$ and $\beta : V(T) \to 2^{V(G)}$, such that
1. for any edge $\{x, y\} \in E(G)$ there exists a node $v \in V(T)$ such that $x, y \in \beta(v)$, and
2. for any vertex $x \in V(G)$, the subgraph of $T$ induced by the set $T_x = \{v \in V(T) : x \in \beta(v)\}$ is a non-empty tree.

The width of $(T, \beta)$ is $\max_{v \in V(T)} |\beta(v)| - 1$. The treewidth of $G$, denoted by $\text{tw}(G)$, is the minimum width over all tree decompositions of $G$.

The treewidth of a graph can be efficiently approximated up to a constant factor as follows.

**Proposition 8** ([7]). There exists an algorithm that, given a graph $G$ and an integer $t$, in time $2^{O(t)} n$ either determines that the treewidth of $G$ is larger than $t$, or outputs a tree decomposition of $G$ of width at most $5t + 4$.

The following relation between treewidth and feedback vertex set number is folklore.

**Proposition 9** ([12]). There exists an algorithm that, given a graph $G$ with a feedback vertex set $U$, in time $O(|U| n)$ outputs a tree decomposition of $G$ of width $|U|$.

### 3 FPT Algorithm for Long Cycle

In this section, we consider the parameterized complexity of Long Cycle parameterized multiplicatively above girth, and prove Theorems 1 and 2. For our positive result, we required the following definition and propositions. First, we give the definition of a graph called a $t$-prism, which has $2t$ vertices and $3t$ edges (see Fig. 1).

**Definition 10** (Prism). For any $t \in \mathbb{N}$, the $t$-prism is the Cartesian product $C_t \times K_2$.

The following proposition asserts that a graph of sufficiently high treewidth necessarily contains a large prism as a topological minor.

**Proposition 11** ([3]). For any $k \in \mathbb{N}$, any graph $G$ of treewidth at least $60k^2$ contains a $k$-prism as a topological minor.$^2$

In case the treewidth of the graph is low, we will be able to solve the problem by making use of the following proposition.

**Proposition 12** ([6]). There exists an algorithm that, given a graph $G$ and a tree decomposition of $G$ of width $t$, in time $2^{O(t)} n$ outputs a cycle (if one exists) and a path in $G$ of maximum sizes.

---

$^2$ Although the result is mentioned in terms of minors, the proof given in [3] yields the result stated here.
The main combinatorial lemma we need for our positive result is as follows. This lemma handles the case where the treewidth of the graph is large.

Lemma 13. For any $k \in \mathbb{N}$, any graph $G$ that contains the 4k-prism as a topological minor also has a cycle on at least $\gamma(G) \cdot k$ vertices.

Proof. Let $H$ be the 4k-prism. Notice that the vertex set of $H$ can be denoted by $V(H) = \{a_1, a_2, \ldots, a_{4k}, b_1, b_2, \ldots, b_{4k}\}$ so that $H[\{a_1, a_2, \ldots, a_{4k}\}]$ and $H[\{b_1, b_2, \ldots, b_{4k}\}]$ are cycles and $\{(a_i, a_i) : i \in \{1, 2, \ldots, 4k\}\} \subseteq E(H)$ (see Fig. 1). Let $\phi: V(H) \to V(G)$ and $\varphi: E(H) \to \text{Paths}(G)$ be some two functions that witness that $H$ is a topological minor of $G$. Let $S_1, \ldots, S_{2k}$ be a set of $2k$ vertex-disjoint cycles of length 4 in $H$ defined as follows: For each $i \in \{0, 1, \ldots, 2k-1\}$, $S_i = H[\{a_{2i+1}, a_{2i+2}, b_{2i+2}, b_{2i+1}\}]$ (see Fig. 1). Additionally, we define two (not vertex-disjoint) cycles $C$ and $C'$ in $H$ as follows: $C = H[\{a_1, a_2, b_2, a_3, a_4, \ldots, a_{4k-1}, a_{4k}, b_{4k}\}]$ and $C' = H[\{a_1, b_1, b_2, a_3, b_3, \ldots, b_{4k}, a_{4k}, a_1\}]$ (see Fig. 1).

Now, for each $i \in \{0, 1, \ldots, 2k-1\}$, let $A_i = \varphi(\{a_{2i+1}, a_{2i+2}\}) + \varphi(\{a_{2i+2}, b_{2i+2}\}) + \varphi(\{b_{2i+2}, b_{2i+1}\}) + \varphi(\{b_{2i+1}, a_{2i+1}\})$. This notation is well defined as required to concatenate paths—specifically, here we concatenated internally vertex-disjoint paths sharing exactly one endpoint except for the last concatenation where both endpoints are shared (by the paths $\varphi(\{a_{2i+1}, a_{2i+2}\}) + \varphi(\{a_{2i+2}, b_{2i+2}\}) + \varphi(\{b_{2i+2}, b_{2i+1}\})$ and $\varphi(\{b_{2i+1}, a_{2i+1}\})$). Roughly speaking, $A_i$ is the cycle to which $\varphi$ maps $S_i$. Notice that $\{A_i\}_{i=0}^{2k-1}$ is a collection of $2k$ vertex-disjoint cycles in $G$. Therefore, together they contain at least $2\gamma(G) \cdot k$ edges.

Additionally, let $B = \varphi(\{a_1, a_2\}) + \varphi(\{a_2, b_2\}) + \varphi(\{b_2, b_3\}) + \varphi(\{b_3, a_3\}) + \cdots + \varphi(\{a_{4k}, b_{4k}\}) + \varphi(\{b_{4k}, a_1\})$. Again, this notation is well defined as required to concatenate paths. Similarly, let $B' = \varphi(\{a_1, b_1\}) + \varphi(\{b_1, b_2\}) + \varphi(\{b_2, a_2\}) + \varphi(\{a_2, a_3\}) + \cdots + \varphi(\{b_{4k}, a_{4k}\}) + \varphi(\{a_{4k}, a_1\})$. Roughly speaking, $B$ and $B'$ are the cycles to which $\varphi$ maps $C$ and $C'$, respectively. Notice that $E(H) = E(C) \cup E(C')$. Thus, we deduce that $\bigcup_{i=0}^{2k-1} E(A_i) \subseteq E(C) \cup E(C')$. From this,
we further deduce least one among the cycles $B$ and $B'$ must contain at least half the edges in $\bigcup_{i=0}^{k-1} E(A_i)$. Because we already showed that $|\bigcup_{i=0}^{k-1} E(A_i)| \geq 2\gamma(G) \cdot k$, this means that at least one among the cycles $B$ and $B'$ has length (and therefore also size) at least $\gamma(G) \cdot k$. This completes the proof. 

By Proposition 11, any graph $G$ of treewidth at least $60 \cdot (4k)^2 = 960k^2$ contains a 4k-prism as a topological minor. Thus, we derive the following corollary to Lemma 13.

**Corollary 14.** For any $k \in \mathbb{N}$, any graph $G$ of treewidth at least $960k^2$ has a cycle on at least $\gamma(G) \cdot k$ vertices.

We are now ready to prove our main theorem.

**Theorem 1.** **Long Cycle** (and Long Path) parameterized multiplicatively above girth is solvable in time $2^{O(k^2)} n$.

**Proof.** Given an instance $(G, k)$ of Long Cycle (Long Path), the algorithm is executed as follows. First, it calls the algorithm in Proposition 8 with $t = 960k^2$ in time $2^{O(k^2)} n = 2^{O(k^2)} n$ to either determine that the treewidth of $G$ is larger than $t$, or output a tree decomposition of $G$ of width at most $5t + 4$. In the first case, it concludes that $(G, k)$ is a Yes-instance of Long Cycle (resp. Long Path), which is correct by Corollary 14. In the second case, it calls the algorithm in Proposition 12 to obtain a cycle (resp. path) of maximum size in $G$ in time $2^{O(5t+4)} n = 2^{O(k^2)} n$, and concludes that $(G, k)$ is a Yes-instance of Long Cycle (resp. Long Path) if and only if the size of this cycle (resp. path) is at least $\gamma(G) \cdot k$. 

**Theorem 2.** For any fixed constant $\epsilon > 0$, Long Cycle (and Long Path) parameterized multiplicatively above $g^{1+\epsilon}$ is para-NP-hard, where $g$ is the girth of the input graph.

**Proof.** Consider some fixed constant $\epsilon > 0$. Our proof is based on a reduction from the Hamiltonian Cycle (resp. Hamiltonian Path) problem, which is known to be NP-hard [23], to Long Cycle (resp. Long Path) parameterized multiplicatively above $g^{1+\epsilon}$.

In the Hamiltonian Cycle (resp. Hamiltonian Path) problem, we are given a graph $G$ and the objective is to decide whether $G$ contains a (simple) cycle (resp. path) on $n$ vertices. In what follows, we only describe the proof for Long Cycle (since the proof for Long Path is similar).

We now describe the reduction. To this end, let $G$ be an instance of Hamiltonian Cycle. Let $b$ be the smallest positive integer such that $b(1+\epsilon) \in \mathbb{N}$. (Note that $b$ depends only on $\epsilon$.) Let $a = b(1+\epsilon) - 1$. Notice that $b \leq a$ (since $b \cdot \epsilon$ is a positive integer). Now, subdivide each edge in $G$ $a$ times, and let $G'$ be the resulting graph. Let $H$ be the disjoint union of $G'$ and $C$, where $C$ is a cycle of length $n^b$. Finally, set $k = 1$, and let $(H,k)$ be the output instance of Long Cycle parameterized multiplicatively above $g^{1+\epsilon}$. Notice that here, $g$ is the girth of $H$, i.e. $g = \gamma(H)$.

Notice that for any $\ell \in \mathbb{N}$, for any cycle of size $\ell$ in $G$, there is a corresponding cycle of size $\ell \cdot n^a$ in $G'$, and vice versa. This implies that any cycle in $G'$ has size at least $3n^a$. Thus, as $b \leq a$, there is a unique shortest cycle in $H$, which is $C$. Therefore, $\gamma(H) = n^b$. Then, any cycle (resp. path) $C'$ on at least $(\gamma(H))^{1+\epsilon} k = n^{b(1+\epsilon)} = n^{1+a}$ vertices in $H$ is fully contained in $G'$. From this, we conclude that for any cycle of size $n$ in $G$, there is a corresponding cycle of size $(\gamma(H))^{1+\epsilon} k$ in $H$, and vice versa. This yields the correctness of the reduction. In particular, a parameterized algorithm for Long Cycle parameterized multiplicatively above $g^{1+\epsilon}$ would solve $(H,k)$ is polynomial time (because $k = 1$), and thereby yield a polynomial-time for Hamiltonian Cycle. This completes the proof.
In this section, we consider the parameterized complexity of (Connected) Vertex Cover and Max Internal Spanning Tree parameterized multiplicatively above girth, and prove Theorem 3. The following proposition asserts that every graph contains either a small feedback vertex set or a large number of vertex-disjoint cycles (with a logarithmic gap), which can also be computed efficiently.

▶ Proposition 15 ([16, 32]). For some fixed constant \( c \in \mathbb{N} \), there exists an algorithm that, given any \( r \in \mathbb{N} \) and a graph \( G \), in time \( r^{O(1)} n \) outputs either a feedback vertex set of \( G \) of size at most \( cr \log r \) or \( r \) vertex-disjoint cycles in \( G \).

In what follows, we use \( c \) to refer to the constant in this proposition. In case the treewidth of the graph is low, we will be able to solve the problem by making use of the following proposition.

▶ Proposition 16 ([12, 19]). There exist algorithms for Vertex Cover, Connected Vertex Cover and Max Internal Spanning Tree that run in time \( 2^{O(t)} n \), where \( t \) is the treewidth of the input graph.\(^3\)

The main combinatorial lemmas required for our algorithms are as follows. They handle the case where the feedback vertex set number (and hence also treewidth) of the graph is low. First, for (Connected) Vertex Cover, we need the following lemma.

▶ Lemma 17. For any \( r \in \mathbb{N} \), any graph \( G \) that contains \( r \) vertex-disjoint cycles has vertex cover number at least \( \frac{\gamma(G)}{2} \cdot r \).

Proof. Let \( C \) be a collection of \( r \) vertex-disjoint cycles of \( G \). Consider any vertex cover \( U \) of \( G \). Then, \( U \) must contain at least half the vertices of each cycle in \( C \) in order to contain an endpoint of every edge of that cycle. Since each cycle in \( C \) contains at least \( \gamma(G) \) vertices, the lemma follows. ▶

Second, for Max Internal Spanning Tree, we need the following lemma.

▶ Lemma 18. For any \( r \in \mathbb{N} \), any connected graph \( G \) that contains \( r \) vertex-disjoint cycles has a spanning tree with at least \( (\gamma(G) - 1) \cdot r - 1 \) internal vertices.\(^4\)

Proof. Let \( C \) be a collection of \( r \) vertex-disjoint cycles of \( G \). Let \( T \) be some spanning tree of \( H \) (whose existence follows from the supposition that \( G \), and hence also \( H \), is connected).

Now, we traverse \( T \) in preorder, and when we encounter a new vertex of the form \( v_C \), we perform the following operations. Let \( p \) be the parent of \( v_C \) in \( T \) (if it is not the root), and let \( u \) be some vertex in \( C \) that is adjacent to \( p \) (if \( v_C \) is the root, let \( u \) be any vertex in \( C \)). Then, replace \( v_C \) in \( T \) by a path \( P \) from \( u \) to one of its neighbors in \( C \) so that this path \( P \) contains exactly all the edges of \( C \) except one (between \( u \) and the chosen neighbor).

\(^3\) Such an algorithm for Max Internal Spanning Tree is not given explicitly, but it is easily seen to follow from the approach of dynamic programming over tree decompositions using representative sets as in [19].

\(^4\) Notice that the supposition that \( r \) is positive also implies that \( G \) is not a forest and hence \( \gamma(G) \) is finite.
Here, make \( u \) be the child of \( p \) in \( T \), and every child \( w \) of \( v_C \) is handled as follows: the subtree of \( w \) is “hanged” from a vertex of the path \( P \) such that \( w \) (or some vertex in the cycle represented by \( w \), if \( w \) is a new vertex) is adjacent to it in \( G \). Notice that at the end of this process, we obtain a spanning tree of \( G \) with the following property. For each cycle \( C \in \mathcal{C} \), all vertices except possibly one are internal vertices, with the exception of possibly one cycle (if there was a cycle represented by the root of \( T \)) where all vertices except possibly two are internal vertices. Thus, this spanning tree has at least \((\gamma(G) - 1) \cdot r - 1\) internal vertices. This completes the proof. \( \sqsubseteq \)

We are now ready to prove our main theorem.

\[ \textbf{Theorem 3.} \] \textbf{Vertex Cover, Connected Vertex Cover and Max Internal Spanning Tree} parameterized multiplicatively above girth are solvable in time \( 2^{O(k \log k)} n \).

\[ \textbf{Proof.} \] Given an instance \((G,k)\) of (Connected) Vertex Cover (resp. Max Internal Spanning Tree), the algorithm is executed as follows. Without loss of generality, we suppose that \( G \) is connected in the case of Max Internal Spanning Tree, else we clearly have a No-instance of this problem. First, the algorithm calls the algorithm in Proposition 15 with \( r = 2k + 1 \) in time \( r^{O(1)} n = k^{O(1)} n \) to obtain either a feedback vertex set of \( G \) of size at most \( cr \log r \) or \( r > 2k \) vertex-disjoint cycles in \( G \). In the second case, by Lemma 17 \( G \) has vertex cover number strictly larger than \( \frac{\gamma(G)}{2} \cdot 2k = \gamma(G) \cdot k \), and by Lemma 18, it also has a spanning tree with at least \((\gamma(G) - 1) \cdot 2k - 1 \geq \gamma(G) \cdot k\) internal vertices (where the last inequality follows from the facts that \( \gamma(G) \geq 3 \) and \( k \in \mathbb{N} \)). Thus, for Vertex Cover and Connected Vertex Cover the algorithm correctly determines that the answer is No, and for Max Internal Spanning Tree the algorithm correctly determines that the answer is Yes. In the first case, the algorithm calls the algorithm in Proposition 9 in time \( O(k \log k \cdot n) \) to obtain a tree decomposition of \( G \) of width at most \( cr \log r = O(k \log k) \). Then, it calls the algorithm in Proposition 12 in time \( 2^{O(k \log k)} n \) to obtain a (connected) vertex cover of \( G \) of minimum size (resp. a spanning tree of \( G \) of maximum number of internal vertices), and concludes that \((G,k)\) is a Yes-instance of (Connected) Vertex Cover (resp. Max Internal Spanning Tree) if and only if the output (connected) vertex cover has size at most \( \gamma(G) \cdot k \) (resp. the output spanning tree has at least \( \gamma(G) \cdot k \) internal vertices). \( \sqsubseteq \)

\[ \textbf{5} \] \textbf{Hardness for Feedback Vertex Set and Cycle Packing}

Lastly, we prove the correctness of Theorem 4.

\[ \textbf{Theorem 4.} \] \textbf{Feedback Vertex Set and Cycle Packing} parameterized additively above girth are para-NP-hard.

\[ \textbf{Proof.} \] We only prove the lemma for Feedback Vertex Set since the proof for Cycle Packing follows from symmetric arguments. For this purpose, we give a reduction from Feedback Vertex Set itself, which is an NP-hard problem [23]. Towards this, let \((G,k)\) be an instance of Feedback Vertex Set. Then, obtain \( H \) from \( G \) by subdividing each edge of \( G \) \( k \) times, and adding a new cycle of size \( k \). Clearly, \( G \) has a feedback vertex set of size at most \( k \) if and only if \( H \) has a feedback vertex set of size at most \( k + 1 \) (the extra \( 1 \) is required to hit the new cycle). Moreover, the girth of \( H \) is exactly \( k \). Thus, an algorithm for Feedback Vertex Set parameterized additively above girth should solve \((H,1)\) in polynomial time (since the parameter is \( 1 \)), thereby determining whether the feedback vertex set number of \( H \) is at most \( k \), and consequently solving \((G,k)\). \( \sqsubseteq \)

Abstract

Consider sources that supply sensitive data to an aggregator. Standard encryption only hides the data from eavesdroppers, but using specialized encryption one can hope to hide the data (to the extent possible) from the aggregator itself. For flexibility and security, we envision schemes that allow sources to supply encrypted data, such that at any point a dynamically-chosen subset of sources can allow an agreed-upon joint function of their data to be computed by the aggregator. A primitive called multi-input functional encryption (MIFE), due to Goldwasser et al. (EUROCRYPT 2014), comes close, but has two main limitations:

- it requires trust in a third party, who is able to decrypt all the data, and
- it requires function arity to be fixed at setup time and to be equal to the number of parties.

To drop these limitations, we introduce a new notion of ad hoc MIFE. In our setting, each source generates its own public key and issues individual, function-specific secret keys to an aggregator. For successful decryption, an aggregator must obtain a separate key from each source whose ciphertext is being computed upon. The aggregator could obtain multiple such secret-keys from a user corresponding to functions of varying arity. For this primitive, we obtain the following results:

- We show that standard MIFE for general functions can be bootstrapped to ad hoc MIFE for free, i.e. without making any additional assumption.
- We provide a direct construction of ad hoc MIFE for the inner product functionality based on the Learning with Errors (LWE) assumption. This yields the first construction of this natural primitive based on a standard assumption.

At a technical level, our results are obtained by combining standard MIFE schemes and two-round secure multiparty computation (MPC) protocols in novel ways highlighting an interesting interplay between MIFE and two-round MPC.

Acknowledgements We thank Romain Gay for pointing out a subtlety in the security definition of (standard) MIFE for inner products, which necessitated a minor adjustment in our ad hoc MIFE construction.

1 Introduction

In modern society, there is an inherent need for external entities to aggregate and analyze sensitive data from a variety of sources. A few prominent examples are:

- To track diseases, disease control centers would like hospital patients’ medical information.
- To determine medication efficacy for a given subpopulation, pharmaceutical companies would like patients’ genomic information.
- To provide targeted advertising to consumers, corporations would like buyers’ demographic information.

However, this release of sensitive data to external entities is unsettling, as these entities must now be trusted to preserve the confidentiality of the released data. We would like to avoid the need for this trust and believe that specialized encryption schemes will be an important tool for doing so. At a high level, we would like schemes that allow users to encrypt their data before transferring them to an external entity, such that only certain user-specified joint functions of the data are revealed to the entity holding it. We would like this security guarantee to be supported in a flexible way, allowing joint functions of the data to be revealed by any dynamically-chosen subset of users that permit it.

A primitive that comes close, due to Goldwasser et al. [45], is multi-input functional encryption (MIFE). To understand MIFE, we first recall the simpler notion of functional encryption (FE) [20]. Just as in traditional encryption, in functional encryption ciphertexts can be generated with an encryption key. However, each decryption key is associated with a function \( f \), and decryption of an encryption of \( m \) using this key results in not \( m \) but \( f(m) \). Intuitively, security requires that nothing more than \( f(m) \) can be learned from the encryption of \( m \) and the decryption key for \( f \). In MIFE, decryption keys allow computing joint functions of (possibly) different plaintexts underlying multiple ciphertexts. That is, decryption takes a key for a function \( f \) and ciphertexts \( c_1, \ldots, c_n \) encrypting \( m_1, \ldots, m_n \), and outputs \( f(m_1, \ldots, m_n) \).

However, MIFE has an important drawback: encryption and decryption keys are generated via a global setup procedure run by an external entity usually called the key authority. This begs the question of whether putting trust in the key authority is really better than putting trust in the external entities that aggregate and analyze the data in the first place. A similar point was made by Rogaway about identity-based encryption (IBE) [60]. Indeed, removing this in the case of IBE (and other settings) has been an active area of investigation, e.g. see [18, 49, 35]. We contend that for MIFE (and indeed FE) the concern is heightened, as the authority can not only decrypt all the data but is also the one in charge of which functions of the data other external entities can compute. Hence, MIFE does not allow users to enforce their own privacy policies.
Additionally, from a flexibility standpoint, MIFE is limited in that it fixes the number of senders and function arity at setup time. This does not support a dynamic setting in which users can join or leave. Progress on removing this limitation was made by Badrinarayanan et al. [10], who introduced a notion of MIFE for unbounded arity functions. However, their notion does not allow any subset of users to reveal a joint function of their data to an external entity without coordination from all other users, and moreover relies on strong “knowledge type” assumptions. Another closely related notion to ours is that of decentralized multi-client FE, recently introduced by Chotard et al. [27]. While this work shares some of the high level motivation of the present work, the two primitives are very different. Please see Section 1.3.3 for a comparison.

1.1 Our Notion: Ad Hoc MIFE

To address the above limitations, we introduce a new notion of ad hoc MIFE. In ad hoc MIFE, each source (aka. sender or user) will run a local setup procedure to generate some public parameters as well as a private encryption key. (One can also consider a public-key setting, but this puts limits on achievable security and we do not do so in this work.) Each source publishes their public parameters and encrypts using their private key. These ciphertexts can be sent to an aggregator (aka. decryptor). Furthermore, using their private keys, sources can issue “partial decryption keys” to an aggregator. Each partial decryption key is associated with an \( \ell \)-ary function \( f \) for some \( \ell \) and is generated using the public keys of \( \ell - 1 \) other (dynamically chosen) sources. If these other \( \ell - 1 \) sources also issue “matching” partial decryption keys for \( f \) to this aggregator, it can decrypt any \( \ell \) ciphertexts \( c_1, \ldots, c_\ell \), each produced by the corresponding source, to \( f(m_1, \ldots, m_\ell) \) where \( m_1, \ldots, m_\ell \) are the plaintexts. One can also consider restricted versions of the above notion, that bound the number of users or fix \( \ell \) (or both). In particular, taking the number of users equal to \( \ell \) gives a version of MIFE that still drops the global setup procedure but lacks the dynamic aspect. Finally, we also consider the restricted notion of bounded ad hoc MIFE, where we place a bound on the number of “partial decryption keys” a user is allowed to issue. Intuitively, for security, we require that an aggregator learns only the functions of the data for which it has been given all of the matching partial decryption keys.

Note that while we assume each source can obtain the authentic public parameters of other sources with whom it wants to allow joint functions of the data to be computed, there is no other prior coordination between users (this is one of the main advantages of our notion over [27]). In particular, there is no external entity that generates public parameters or keys. In some of our constructions, we work in the common reference string (CRS) model, but note that this is still much weaker than having an authority who can decrypt all the data.

1.2 Our Results

Our results may be summarized as follows:

- **Feasibility result for general functions:** First, we show that standard MIFE for general functions can be bootstrapped to ad hoc MIFE for general functions for free. More specifically, we show that ad hoc MIFE for any functionality is implied by standard MIFE for that functionality combined in a novel way with general FE and a special type of two-round secure multiparty computation (MPC) protocol. The latter two are implied by standard MIFE for general functions.

\[1\] In more detail, in the public-key setting a decryptor could launch an attack where it replaces one user’s input with various values to determine information about the input of another user.

While very general, the result leaves open the goal of obtaining ad hoc MIFE under standard assumptions. In general, this is challenging as standard MIFE is already known to be equivalent to indistinguishability obfuscation [33, 8, 17], which is a central open problem in cryptography. In fact, some negative evidence about the hardness of obtaining such constructions has also been provided [37, 38]. Thus, with the goal of moving towards using standard assumptions, we consider the task of ad hoc MIFE for special but natural functionalities.

Constructions for Inner Products from Standard Assumptions: We provide a construction of ad hoc MIFE for the inner product functionality from standard assumptions, namely LWE. Introduced by Abdalla et al. [1] in the single-input setting, this functionality has applications in data mining and information retrieval. Our result is obtained via a general paradigm for constructing ad-hoc MIFE schemes from standard MIFE schemes satisfying certain natural properties; or, what we call “ad hoc friendly” standard MIFE schemes. We show that certain constructions of standard MIFE scheme for inner products from the literature [3, 2] based on standard assumptions (DDH, LWE, or DCR) already satisfy these properties. Additionally, we use a specific two-round MPC protocol [57] that can also be obtained via LWE. We note that by using a two-round MPC protocol from any two-round OT protocol [41, 42, 15] here, we also obtain results for the case of bounded ad hoc MIFE for inner products – namely, we get bounded ad hoc MIFE for inner products from DDH, LWE and DCR as well. We remark that since our general construction (first result) already relies on general MIFE for circuits, there is no advantage to mitigating assumptions for the two-round MPC protocol in that setting.

We emphasize that our transformation is general. Thus, our transformation can be used to upgrade the security of any “ad hoc friendly” standard MIFE for a given functionality to ad hoc MIFE for the same functionality. This result might also be useful in obtaining future constructions of ad hoc MIFE. Furthermore, the modularity of this approach allows for simplifications in our constructions.

We tabulate our results in Table 1 and provide explanation of which MPC protocol is needed for each of the results in Section 1.3.

---

2 We stress that this functionality outputs inner products in the clear and is therefore a different type of functionality than that of Katz et al. in [54], which tests if an inner product is zero or not.

3 Note that semi-honest constructions of two-round OT are known under each of these assumptions.
1.3 Technical Overview

In this section, we describe at a high level the challenges involved in constructing ad hoc MIFE and our techniques for overcoming them.

1.3.1 Ad Hoc MIFE for Arbitrary Functions.

Standard MIFE and ad hoc MIFE can be seen as secure multiparty computation (MPC) protocols with a particular allowable interaction pattern and certain additional reuse capabilities.\(^4\) To begin, let us consider the interaction pattern followed by standard MIFE.

In standard MIFE, there is a trusted global setup which receives as input the number of parties \(\ell\), and outputs a public key and a set of \(\ell\) encryption keys. Additionally, global setup on input a function \(f\) generates the decryption key \(DK_f\). Of these, the public parameters are broadcast to all users and encryption key \(EK_i\) is provided to encryptor \(i\), for \(i \in [\ell]\).

The encryptors then compute their ciphertexts \(CT(m_i)\) and send these to the aggregator who may now compute the function output \(f(m_1, \ldots, m_\ell)\) using the decryption/function key \(DK_f\). Finally, the system supports arbitrary number of decryption keys and ciphertexts. As explained in Section 1.1, in ad hoc MIFE, we seek to eliminate the trusted global procedure as well as support dynamic choice of parties involved in any function computation.

1.3.1.1 Challenges Involved

An approach to eliminating the trusted setup from standard MIFE is to use MPC to replace the global setup. However, naively computing the setup procedure using MPC would introduce interaction between the parties, which the syntax of MIFE does not allow. Moreover, this (interactive) procedure would need to be rerun each time a function key is required to be generated. Using two round MPC, one may hope to overcome the barrier of interaction using the following natural idea: let parties perform a two-round MPC to perform the setup and key generation for a standard MIFE. In more detail, parties in the first round could publish as their public parameters the first round MPC messages with their secret randomness as input. Given the first round messages, parties could send the second round MPC message to the aggregator, who could use it to compute the function key. However, this approach does not suffice since:

1. MIFE requires that the public parameters be published only once whereas the above template requires publishing fresh public parameters for each function key.
2. Even more fundamentally, the above approach precludes users from being able to encrypt, as their encryption keys are not available given just the first round MPC message.

In particular, the above approach does not decouple ciphertexts and functions as in traditional MIFE, which leads to the limitation that an evaluator cannot evaluate the same function on multiple inputs chosen by the parties, nor evaluate other functions on the same set of inputs. Additionally, the problem is made challenging by the fact that in MIFE an aggregator might obtain arbitrary number of secret keys and an encryptor might generate arbitrary number of ciphertexts.

\(^4\) Recall that MPC allows a set of parties to compute a joint function of their inputs without revealing anything else but in general allows these parties to freely interact (although restrictions may apply in special cases).
1.3.1.2 Overcoming the first barrier: Function re-runnable two-round MPC

In order to mitigate the first problem above, we require that the first round MPC message be sent only once, and reused for all subsequent second round messages thus providing re-usability/re-runnability for secret key generation. Towards achieving this re-usability, an idea is to use function rerunnable two-round MPC protocols, where the same first round message can be reused for multiple functions in the second round. As we will see, certain existing two-round MPC protocols satisfy this requirement (see later), but this still does not solve the problem. This is because in adhoc MIFE, we additionally need that for the MPC protocol, the function or even its arity are not known at the time the first round message is sent. We overcome this hurdle by using “function delayed” protocols, which permit the choice of function to be delayed to the second round of the protocol. Together, these special protocols may be used to overcome the first barrier outlined above.

1.3.1.3 Overcoming the second barrier: Delaying Encryption

In order to overcome the second barrier, we allow the encryptor to delay the encryption process until the encryption keys are known (in similar spirit as [13, 30]). In more detail, we will have each source independently run the setup algorithm of a single input FE scheme, denoted as FE and compute the first round message of an MPC protocol using the FE master key as input. This message is published as part of the public key and made available to all other sources. Additionally, each source provides an encryption of its input $m_i$ using the algorithm FE.Encrypt.

The sources may choose the function $f$ to be computed and the group that will participate in the computation dynamically. At this point, each source independently executes the partial key generation algorithm as follows: it generates the second round message of an MPC protocol for a suitable $f$ dependent functionality $\text{GenKeys}_f$ and sends this to the aggregator. Intuitively, the functionality $\text{GenKeys}_f$ has the circuit $f$ hard-coded in it, and enables the aggregator to compute the output.

However, recall that the inputs to the $\text{GenKeys}$ functionality are not the messages on which the computation must be performed, but rather the FE master keys generated independently by each player. To proceed, the functionality instead uses the FE master keys to compute FE function keys for a re-encryption procedure, which translates FE ciphertexts to MIFE ciphertexts for a freshly generated (standard) MIFE scheme. During this time, the arity of the function $f$ is known, so a suitable standard MIFE scheme may be instantiated. It further outputs an MIFE function key for the function $f$.

We are almost done: $\text{GenKeys}_f$ runs the setup procedure for a suitable fixed arity standard MIFE scheme, computes FE function keys for each party for the re-encryption functionality, computes the MIFE function key for $f$ and outputs these. The aggregator uses the FE keys together with the FE ciphertexts provided by each encryptor to translate $\text{FE.Enc}(m_i)$ to $c_i = \text{MIFE.Enc}(m_i)$ and then runs the MIFE decryption procedure to obtain $f(m_1, \ldots, m_\ell)$.

Put together, we resolved all difficulties by carefully nesting a multi-input FE scheme MIFE, within the single input FE scheme FE, which in turn is nested within a re-runnable two-round MPC protocol MPC.

One final problem remains: the adversary could get some partial information from an “incomplete” set of partial decryption keys for some function. This is because standard MPC makes no guarantee when an honest party does not send their final message. We solve this problem by masking the output of MPC by pseudorandom values generated for each party. The partial decryption keys contains the respective user’s pseudorandom masks so that only a complete set of user keys can be used to unmask the output.
While security appears to follow intuitively from the security of MPC, FE and MIFE, the proof must contend with several technical hurdles as we are forced to deal with indistinguishability style security of FE, MIFE (simulation security for these primitives is known to be impossible [20, 6]). We argue security via a careful sequence of hybrids, please see Section 4 for details.

1.3.1.4 Instantiating MPC

We now discuss possible instantiations of MPC to fit the above template. Depending on the properties of the underlying two-round MPC protocol, we obtain different properties of the resulting ad hoc MIFE scheme. In both the semi-honest (passive decryptor) and the malicious (active decryptor) settings, the most general function-rerunnable, two-round MPC protocols without CRS can be constructed [32, 48] from indistinguishability obfuscation [33], which itself can be constructed from multi-input functional encryption [8]. Furthermore, as already noted in [40], we remark that in the semi-honest setting the construction of [32] can actually be instantiated in the plain model. This is based on the observation that the CRS in the protocol of [32] was only needed for the computation in the second round. Thus semi-honest parties could obtain a CRS by just performing a one-round coin flipping in the first round. This yields our first result: we get ad hoc MIFE for general functions from standard MIFE for general functions. In the semi-honest setting, the ad hoc MIFE construction is in the plain model. On the other hand, in the malicious setting, these protocols work in the common reference string (CRS) model.

Alternatively, function-rerunnable two-round MPC in the common reference string (CRS) model can be constructed [28, 57, 24, 59] from learning-with-errors (LWE). This yields ad hoc MIFE from LWE and standard MIFE in the CRS model (either semi-honest or malicious). While bounded two-round MPC in the CRS model can be constructed from bilinear maps [41] and even two-round oblivious transfer [15, 42, 39] or information theoretically [9, 36], these constructions are not function-rerunnable so do not suffice for our general construction. We note that these constructions would suffice for obtaining bounded ad hoc MIFE, where a user issues only a bounded number of partial decryption keys and maintains state across key issues. However, since in our general result we anyway require the minimum assumption of FE/MIFE, instantiating MPC from weaker assumptions does not yield any benefits, and we do not discuss this further. Our results are highlighted in Table 1.

1.3.2 Ad Hoc MIFE for Inner Products.

While our construction of ad hoc MIFE above applies to arbitrary functionalities, it requires use of standard MIFE for general functions. Unfortunately, as noted above, standard MIFE implies indistinguishability obfuscation. Hence, there is limited hope of basing it on standard assumptions. Additionally, our general transformation uses an FE scheme for a potentially complicated re-encryption functionality and also requires general-purpose, function-rerunnable two-round MPC for computing a complex functionality. These aspects limit the practical applicability of our general result.

Next, we describe a paradigm for constructing ad-hoc MIFE schemes from standard MIFE schemes that are “ad hoc friendly” and a (hopefully simple) two-round MPC protocol. This paradigm significantly simplifies our general construction and provides a way for basing it on standard assumptions. We then show that the standard MIFE scheme for inner products [3, 2], which may be based on DDH, LWE or DCR, is ad hoc friendly and the corresponding two-round MPC protocol is only required to compute inner-products, thus obtaining an efficient ad hoc MIFE scheme for inner products.
More formally, in the inner product functionality a decryption key corresponds to a concatenated vector $y = (y_1 \| \cdots \| y_n)$ where $y_i \in \mathbb{Z}_q$. A ciphertext encrypts a vector $x_i \in \mathbb{Z}_q$. The desired result of decryption is $\sum_{i=1}^{n} \langle x_i, y_i \rangle$. Importantly, the decryptor should not learn the partial sums $\langle x_i, y_i \rangle$. The inner product functionality has applications in data mining and information retrieval [1, 3]. We use constructions of standard MIFE for inner product by [3, 2].

Below, we start by summarizing our notion of “ad hoc friendliness,” which (as we see later) is indeed satisfied by the above mentioned standard MIFE for inner product by [3, 2]. Our notion of ad hoc friendliness may be summarized as follows:

1. **Decentralized Setup.** The MIFE.Setup algorithm of the MIFE is decentralized in the sense that:
   - a. The encryption keys $E_{K_i}$ for $i \in [n]$ corresponding to party $i$ may be generated independently of the encryption keys of the remaining parties $[n] \setminus i$.
   - b. The master secret key $MSK$ can be decomposed into $n$ components $\{MSK_i\}_{i \in [n]}$. The partial $MSK_i$ corresponding to party $i$ may be generated locally by party $i$, without any interaction or shared state with the remaining parties.

2. **Local Encryption.** The encryption algorithm only takes its encryption key and message as input and does not depend on the number of parties or their public parameters.

3. **Piecewise Master Secret Key.** The master secret in standard MIFE $MSK = \{MSK_1, \ldots, MSK_n\}$, if restricted to some subset $S \subseteq [n]$ with $|S| = \ell$, has the same distribution as a master secret generated for functions of arity $\ell$.

We show that a standard MIFE with the above properties can be upgraded to ad hoc MIFE described above in a more direct manner than our generic transformation from standard MIFE to ad hoc MIFE. To see this, recall that one of the key challenges in ad hoc MIFE is that the encryptor must encrypt her messages without knowing the encryption key for the underlying standard MIFE. This is because the members or size of the group that will participate in the computation are chosen dynamically later.

To handle this, we used single input FE to encrypt messages and the MPC protocol for functionality GenKeys to sample an MIFE scheme and then translate the FE ciphertexts to MIFE ciphertexts. In the current setting however, due to properties (1) and (2) above, the encryption key of each party can be generated locally and each party can directly perform MIFE encryption locally. Since the re-encryption functionality involves computing a PRF and computing an MIFE encryption, the savings accrued by skipping this step are significant.

We will still require MPC to compute the MIFE function key, but no longer need the MPC functionality to sample the master secret key, so for simple functionalities this protocol may be much leaner than our general MPC protocol. For instance, in the case of inner products, we show that the required MPC protocol only needs to support inner product computations.

While the structural requirements described above may seem very strong, as mentioned earlier, we show that these requirements are enjoyed by the MIFE for inner products recently constructed by Abdalla et al. [2] and can be used to instantiate our compiler providing a very simple and efficient ad hoc MIFE for inner products. Please see Section 5 for details.

### 1.3.2.1 Instantiating MPC

As discussed for the case of our generic construction, we use two-round MPC protocols to obtain ad hoc MIFE for inner products. Specifically, since function-reusable two-round MPC in the common reference string (CRS) model can be constructed [28, 57, 24, 59] from learning-with-errors (LWE), we immediately get ad hoc MIFE from LWE. This result can
be upgraded to the malicious setting at the additional cost of NIZKs. On the other hand, 
construction of two-round MPC from two-round oblivious transfer [15, 42, 39], yields bounded 
ad hoc MIFE for inner products under DDH, LWE or DCR, albeit with the requirement that 
the sources maintain state across key issues. One nice feature of these schemes is that they 
work without the need for a CRS in the semi-honest setting and upgrade to the malicious 
setting can be made just using CRS. Please see Section 5 for details.

Our results are highlighted in Table 1.

1.3.3 Related Work

In this section, we discuss the prior work in this area. Here, we focus on two related primitives, 
decentralized multi-client FE and and non-interactive MPC. Further related work on FE, 
MIFE, MPC and multi-authority FE can be found in Appendix A.

1.3.3.1 Decentralized Multi-Client Functional Encryption

Very recently, Chotard et al [27] proposed the notion of decentralized multi-client functional 
enetration (D-MCFE). While the motivation for the two works is similar in removing the 
common key authority, our notion of adhoc MIFE is significantly more general in that:
1. MCFE itself is more restricted than MIFE, since only CTs with the same labels can be 
combined. In MIFE there is no such restriction. MIFE for circuits captures MCFE for 
circuits (by checking for equal labels within the MIFE functionality) but not vice versa.
2. Crucially, the setup algorithm in D-MCFE is a protocol that is run between multiple 
senders, requiring interaction, whereas our setup algorithm is run independently by each 
source and is thus non-interactive. Note that developing a non-interactive solution is one 
of the main motivations of this work.
3. The work of Chotard et al [27] only provides a construction for inner products. We 
provide a general construction as well as one for inner products. Since our model is 
stronger, our inner product construction is significantly more involved than theirs.
4. Decentralized MCFE lacks the dynamic aspect, which is one of the main contributions of 
our work. We permit the function arity and participating parties to be chosen dynamically 
– a feature no other construction supports (to the best of our knowledge).

Non-Interactive MPC

Another related notion is that of non-interactive MPC (NI-MPC), where a group of asyn-
chronous parties may evaluate a function over their inputs by sending a single message to 
an evaluator who computes the output [51]. While they appear superficially similar, we 
note that the model of ad hoc MIFE is fundamentally different from NI-MPC since, unlike 
NI-MPC, it separates inputs and functions, i.e. provides ciphertexts and function keys which 
allows reusing an input/ciphertext with many different functions, and a function with many 
different inputs. On the other hand, NI-MPC does not support function reusability at all, 
and only a very restricted version of input re-usability, namely where only ciphertexts in the 
same “session” may be combined. The function arity in NI-MPC is also fixed, unlike ad hoc 
MIFE.

2 Preliminaries

Due to space constraints, the preliminaries can be found in Appendix B.
We are now ready to define our new notion of ad hoc multi-input functional encryption (MIFE). For simplicity, we define ad hoc MIFE in the private-key setting only. We leave the study of ad hoc MIFE in the public-key setting for future work.

### 3 Syntax and Correctness

An ad hoc multi-input functional encryption scheme $a\text{MIFE}$ for a message space $\{\mathcal{M}_n\}_{n \in \mathbb{N}}$ and a functionality $\{\mathcal{F}_n\}_{n \in \mathbb{N}}$, where for each $n \in \mathbb{N}$, each $f \in \mathcal{F}_n$ is a (description of a) function on $\{\mathcal{M}_n\}^\ell$ for some $\ell$ (which may depend on $f$), is given by a set of algorithms with the following syntax:

- $a\text{MIFE}.\text{Setup}(1^n)$: A PPT algorithm taking the security parameter $\kappa$, and outputting the master secret key $\text{MSK}$ and the public parameters $\text{PP}$.

- $a\text{MIFE}.\text{KeyGen}(i, \text{MSK}_i, (\text{PP}_1, \ldots, \text{PP}_\ell), f)$: A PT algorithm taking an index $i \in [\ell]$, a master secret key $\text{MSK}_i$ corresponding to $\text{PP}_i$, a set of public parameters $\text{PP}_1, \ldots, \text{PP}_\ell$, a function $f \in \mathcal{F}_n$ of arity $\ell$, and outputting a corresponding partial decryption key $\text{PDK}_{i,f}$.

- $a\text{MIFE}.\text{Enc}(\text{MSK}, x)$: A PPT algorithm taking a master secret key $\text{MSK}$ and a message $x \in \mathcal{M}_n$, and outputting a ciphertext $c$.

- $a\text{MIFE}.\text{Dec}((\text{PDK}_{1,f}, \ldots, \text{PDK}_{\ell,f}), (c_1, \ldots, c_\ell))$: A PT algorithm taking partial decryption keys $(\text{PDK}_{1,f}, \ldots, \text{PDK}_{\ell,f})$ and ciphertexts $(c_1, \ldots, c_\ell)$, and outputting a string $y$.

**Definition 1 (Correctness).** We say that $a\text{MIFE}$ is correct if for all $n \in \mathbb{N}$ and $\ell = \text{poly}(n)$, all $x_1, \ldots, x_\ell \in \mathcal{M}_n$ and all $f \in \mathcal{F}_n$ of arity $\ell$

$$\Pr \left[ y = f(x_1, \ldots, x_\ell) \right. \left. \left| \begin{array}{l} (\text{PP}_i, \text{MSK}_i) \leftarrow a\text{MIFE}.\text{Setup}(1^n) \quad (\forall i \in [\ell]) \\ c_i \leftarrow a\text{MIFE}.\text{Enc}(\text{MSK}_i, x_i) \\ \text{PDK}_{i,f} \leftarrow a\text{MIFE}.\text{KeyGen}(i, \text{MSK}_i, (\text{PP}_i)_{i \in [\ell]}; f) \\ y \leftarrow a\text{MIFE}.\text{Dec}((\text{PDK}_{i,f})_{i \in [\ell]}, (c_i)_{i \in [\ell]}) \end{array} \right. \right] = 1.$$  

**Remark 2.** We highlight two ways that ad hoc MIFE differs from standard MIFE [45]. First, the $a\text{MIFE}.\text{Setup}$ algorithm is run per user and does not output all of the $\text{MSK}_1, \ldots, \text{MSK}_n$ at once. Second, the total number of users $n$ and the function arity $\ell$ are not fixed and input to the $a\text{MIFE}.\text{Setup}$ algorithm. We also note that for simplicity in our formulation of ad hoc MIFE the public parameters of the parties input to the key generation algorithm are ordered.

**Remark 3.** We also consider two relaxations of ad hoc MIFE:

- We can allow an additional algorithm $\text{CRSGen}$ taking $1^n$ and outputting a common reference string $\text{CRS}$ that is input to the remaining algorithms. We refer to this as ad hoc MIFE in the CRS model. The CRS model is weaker than having a key generation authority who can decrypt all the data.

- We can allow the total number of users $1^n$ to be input to the setup algorithm. We refer to this as bounded ad hoc MIFE. We can additionally require $n = \ell$, which we refer to as static (vs. dynamic) ad hoc MIFE. In particular, static ad hoc MIFE recovers a variant of MIFE that is similar to the standard one but still eliminates the trusted key generation authority.
3.2 Indistinguishability-Based Security

We first present an indistinguishability-based security notion. We note that the fact that the public parameters of the parties input to the key generation algorithm are ordered allows us to work with a somewhat simpler definition than the corresponding one in [45] for the standard MIFE case.

We assume adversaries are legitimate unless otherwise stated. We call the experiment in Figure 1.

For an ad hoc MIFE scheme $aMIFE$ as above and adversary $A = (A_0, A_1, A_2)$, consider the experiment in Figure 1.

For an ad hoc MIFE scheme $aMIFE$ as above and adversary $A = (A_0, A_1, A_2)$, consider the experiment in Figure 1.

We say that $f \in F_\kappa$ is queried if for every user associated with its input wires, either the user is corrupt or has submitted its partial decryption key to the adversary. Formally, for every $k \in \ell$ where $\ell$ is the arity of $f$ either $i_k \in I$, i.e. $i_k$ is corrupted or there is a key-generation query $(i_k, (PP_{i_k}), f)$.

We call $A$ legitimate if for all $\kappa \in \mathbb{N}$, in all transcripts $IND^{aMIFE}_A(1^\kappa)$ it holds that for every queried $f \in F_\kappa$, there does not exist two sequences $(y_{i_1,0}, \cdots, y_{i_\ell,0})$ and $(y_{i_1,1}, \cdots, y_{i_\ell,1})$ such that

$$f(y_{i_1,0}, \cdots, y_{i_\ell,0}) \neq f(y_{i_1,1}, \cdots, y_{i_\ell,1})$$

and for every $j \in \{i_1, \cdots, i_{\ell}\}$

- $j \in I$, i.e. $j$ is corrupted (so there is no restriction on $y_{j,0}, y_{j,1}$ above), or
- There is an encryption query $(j, x_0, x_1)$ such that $y_{j,0} = x_0$ and $y_{j,1} = x_1$.

We assume adversaries are legitimate unless otherwise stated. We call $A$ passive if $I = \emptyset$. We call $A$ selective if $A_2$ makes no queries. We say that $aMIFE$ is $\kappa$-IND-secure if for any adversary $A$ of type $\kappa$ $\kappa$-IND-secure, and for every

$$|\Pr[IND^{aMIFE}_A(\cdot) outputs 1] - 1/2| = negl(\cdot).$$

We provide the definition of simulation based security in Appendix C.

</table>
We show how to construct of ad hoc MIFE for any polynomial sized circuit from standard MIFE for the same functionality and a two-round MPC protocol.

**Building Blocks**

Our scheme will be using the following building blocks:

- A MIFE scheme

  \[ \text{MIFE} = (\text{MIFE.Setup}, \text{MIFE.KeyGen}, \text{MIFE.Enc}, \text{MIFE.Dec}) \]

  for some message-space \( \{\mathcal{M}_\kappa\}_{\kappa \in \mathbb{N}} \) and functionality \( \{\mathcal{F}_\kappa\}_{\kappa \in \mathbb{N}} \). For simplicity, we assume \( \text{MIFE.KeyGen} \) is deterministic; note that this is without loss of generality since it can be made so by using a PRF.

- A two-round two-round MPC protocol

  \[ \text{MPC} = (\text{MPC.RunRoundOne}, \text{MPC.RoundRoundTwo}, \text{MPC.ComputeResult}) \]

  for programs of the form \( \text{GenKeys}_f \) in Figure 2 for \( f \in \mathcal{F}_\kappa \). We assume \( \text{MPC} \) is function-rerunnable, unbounded and without setup (we discuss the other cases below).

- A PRF \( F \) with keyspace \( \{K_\kappa\}_{\kappa \in \mathbb{N}} \), and a punctured PRF \( \text{puncF} \) with keyspace \( \{K_\kappa\text{punc}\}_{\kappa \in \mathbb{N}} \), both with domain \( \{0,1\}^* \). (We leave the ranges implicit for readability, taking the output to be sufficiently long.)

- A private-key single input functional encryption scheme

  \[ \text{FE} = (\text{FE.Setup}, \text{FE.KeyGen}, \text{FE.Enc}, \text{FE.Dec}) \]

**4.1 Construction**

Below we provide our construction for adhoc MIFE for general circuits. Note that setup, encryption and key generation are done independently and in parallel by all the parties in the system.

\[ \text{aMIFE.Setup}(1^\kappa) : \text{Upon input the security parameter, do the following:} \]

1. Sample the seed of PRF \( K \leftarrow \mathcal{K}_\kappa \) and the seed of a puncturable PRF \( K^\text{punc} \leftarrow \mathcal{K}_\kappa^\text{punc} \). Puncturing will only be required in the proof.
2. Invoke the single input FE scheme, \( (\text{PP}_{\text{FE}}, \text{MSK}_{\text{FE}}) \leftarrow \text{FE.Setup}(1^\kappa) \).
3. Invoke the first round of the MPC protocol

   \[ (\rho^{(1)}, s) \leftarrow \text{MPC.RunRoundOne}(1^\kappa, (K, \text{MSK}_{\text{FE}})) \]

   Note that the function is specified later.
4. Return \( (\text{PP} = \rho^{(1)}, \text{MSK} = (K, K^\text{punc}, \text{MSK}_{\text{FE}}, s)) \).

\[ \text{aMIFE.KeyGen}((\text{PP}_i)_{i \in [\ell]}, f, \text{MSK}) : \text{Upon input the public parameters of the \( \ell \) parties that are chosen to participate in the computation, and the master secret key, do the following:} \]
Remark 4. If we use a bounded 2-round MPC protocol then we will obtain a bounded ad hoc MIFE scheme where the setup algorithm also takes $1^n$ which is passed to MPC.RunRoundOne. If MPC has a setup algorithm (outputting a CRS) then so does the resulting ad hoc MIFE scheme.

Correctness

Correctness follows from the correctness of MPC, MIFE and FE. In more detail, we have:

Step 1: MPC. By correctness of MPC, we have that the decryptor recovers the output $S \oplus (SK_f, SK_{FE_1}, \ldots, SK_{FE_e})$. Next, if each party $i \in [t]$ provides a partial decryption key for $f$, then this contains partial mask $s_i$ as part of the output of aMIFE.KeyGen. Using these, the decryptor can compute $S \leftarrow \bigoplus_{i \in [t]} s_i$ and recover $(SK_f, SK_{FE_1}, \ldots, SK_{FE_e})$.
40:14 Ad Hoc Multi-Input Functional Encryption

Function GenKeys\((PP_i)_{i \in \mathbb{K}}, f((K_1, \text{MSK}_{FE_1}), \ldots, (K_\ell, \text{MSK}_{FE_\ell}))\)
1. For \(i \in [\ell]\), compute randomness to be used for algorithms below:
   \[r_i \leftarrow \text{PRF.Eval}(K_i, 1 \parallel (PP_i)_{i \in \mathbb{K}} \parallel f), \quad r'_i \leftarrow \text{PRF.Eval}(K_i, 2 \parallel (PP_i)_{i \in \mathbb{K}} \parallel f)\]
2. Run the MIFE setup algorithm for the desired arity as:
   \[((\text{EK}_1, \ldots, \text{EK}_\ell), \text{MSK}) \leftarrow \text{MIFE.Setup}(1^\kappa; r_1 \oplus \cdots \oplus r_\ell)\)
3. For \(i \in [\ell]\), generate the single input FE function key:
   \[\text{SK}_{FE_i} \leftarrow \text{FE.KeyGen}(\text{MSK}_{FE_i}, \text{ReEnc}_{\text{EK}_i},\bot; r'_i)\]
4. Compute the MIFE secret key as
   \[\text{SK}_f \leftarrow \text{MIFE.KeyGen}(\text{MSK}, f)\]
5. Sample the mask \(s_i\) for each partial key and compute the mask \(S\) as:
   \[\forall i \in [\ell], \quad s_i \leftarrow \text{PRF.Eval}(K_i, 0 \parallel (PP_i)_{i \in \mathbb{K}} \parallel f), \quad S \leftarrow \bigoplus_{i \in \mathbb{K}} s_i\]
6. Return the masked output \(S \oplus (\text{SK}_f, \text{SK}_{FE_1}, \ldots, \text{SK}_{FE_\ell})\)

Figure 2 Functionality computed by the MPC protocol to generate single and multi input FE keys.

Function \(\text{ReEnc}_{\text{EK}, \text{ctr}}(x, T, K, \text{Trap})\)
1. Let \(r \leftarrow \text{PRF.Eval}(K, 0 \parallel \text{EK} \parallel T)\).
2. If \(\text{mode} = R\) then compute \(\text{MIFE.Enc}(\text{EK}, x; r)\) and return it.
3. If \(\text{mode} = T\) and \(\text{ctr} < \text{Trap.index}\) then compute \(\text{MIFE.Enc}(\text{EK}, \text{Trap.val}_1; r)\) and return it.
4. If \(\text{mode} = T\) and \(\text{ctr} > \text{Trap.index}\) then compute \(\text{MIFE.Enc}(\text{EK}, \text{Trap.val}_0; r)\) and return it.
5. If \(\text{mode} = T\) and \(\text{ctr} = \text{Trap.index}\) then output \(\text{Trap.CT}\).

Figure 3 Functionality for translating the ciphertext from FE to MIFE using dynamically generated encryption keys.

Step 2: FE. Next, by correctness of FE, we have that if
\[\psi_i = \text{FE.Dec}(\text{SK}_{FE_i}, c_i) \quad \forall i \in [\ell]\]
Then, \(\psi_i\) are the MIFE ciphertexts computed as \(\text{MIFE.Enc}(\text{EK}_i, x_i; r_i)\).

Step 3: MIFE. Finally, by correctness of MIFE, we have that
\[f(x_1, \ldots, x_\ell) = \text{MIFE.Dec}(\text{SK}_f, \psi_1, \ldots, \psi_\ell)\]

4.2 Security Proof
In this section, we argue that the scheme described above is secure. In more detail:

Theorem 5. If \(\text{MIFE}\) is a IND-secure MIFE scheme and \(\text{MPC}\) is a SIM-secure 2-round MPC protocol, then our construction is sel-IND-secure.

Due to space constraints, the proof can be found in Appendix D.
5 Ad Hoc Friendly MIFE and its Application to Inner Products

In this section, we describe a paradigm for constructing ad-hoc MIFE schemes from MIFE schemes that are “ad hoc friendly” and a (hopefully simple) two-round MPC protocol. This paradigm significantly simplifies our general construction. We then show that the standard MIFE scheme for inner products [3, 2], which may be based on DDH, LWE or DCR, is ad hoc friendly and the corresponding two-round MPC protocol is only required to compute inner-products, thus obtaining an efficient ad hoc MIFE scheme for inner products.

Ad Hoc Friendliness

In more detail, we define a notion of “ad hoc friendly” standard MIFE which satisfies the following properties:

- **Decentralized Setup.** The MIFE.Setup algorithm of the MIFE is decentralized in the sense that:
  1. The encryption keys $E_{K_i}$ for $i \in [n]$ corresponding to party $i$ may be generated independently of the encryption keys of the remaining parties $[n] \setminus i$. In more detail, the algorithm $(E_{K_1}, \ldots, E_{K_n}) \leftarrow$ MIFE.Setup$(1^\kappa)$ may be decomposed into $n$ invocations $E_{K_i} \leftarrow$ MIFE.Setup.Local$(1^\kappa)$ for $i \in [n]$, which can be run locally by each party.
  2. The master secret key $MSK$ can be decomposed into $n$ components $\{MSK_i\}_{i \in [n]}$. The partial $MSK_i$ corresponding to party $i$ may be generated locally by party $i$, without any interaction or shared state with the remaining parties.

- **Local Encryption.** The MIFE.Enc algorithm of the MIFE is “local” in that it does not take as input the total number of parties or the public parameters of other parties. In more detail, MIFE.Enc algorithm only takes as input its encryption key $E_{K_i}$ and its input $x_i$, and nothing else.

- **Piecewise Master Secret Key.** In standard MIFE schemes, the function is assumed to have fixed arity $n$. However, in ad hoc MIFE, we allow the function to have arity $\ell < n$. To support this, we require that the master secret in standard MIFE $MSK = \{MSK_1, \ldots, MSK_n\}$, if restricted to some subset $S \subseteq [n]$ with $|S| = \ell$, has the same distribution as a master secret generated for functions of arity $\ell$.
  
  Formally, let $MSK = \{MSK_1, \ldots, MSK_n\} \leftarrow$ FE.Setup$(1^\kappa, 1^n)$ and $MSK' = \{MSK'_1, \ldots, MSK'_\ell\} \leftarrow$ FE.Setup$(1^\kappa, 1^\ell)$. Then, we require that $MSK$ restricted to subset $S$, namely $(MSK_{S[1]}, \ldots, MSK_{S[\ell]})$ has the same distribution as $MSK'$.

Since the intuition was discussed in Section 1, we proceed to our construction of ad hoc MIFE for inner products.

5.1 Ad Hoc MIFE for Inner Products

**Inner-product functionality**

We recall the multi-input inner-product functionality over $Z_p$ for a prime $p$, adapted from Abdalla et al. [2, Section 2.3]. For $m, n \in \mathbb{N}$, this is the functionality

$$IP_{p,n}^m = \{ip_{y_1, \ldots, y_n}: (Z_p^m)^n \rightarrow Z_p\}$$
defined by

\[ \text{ip}_{y_1, \ldots, y_n}(x_1, \ldots, x_n) = \sum_{i=1}^{n} \langle x_i, y_i \rangle \mod p. \]

We omit parameters \( p, m, n \) when they are arbitrary or clear from context.

5.2 Building Blocks

In the context of ad hoc MIFE for inner products, we want to evaluate a functionality given by a sequence of vectors \( y = (y_1, \ldots, y_n) \) where \( y_i \in \mathbb{Z}_q^m \). Evaluating the function on inputs \( \{x_i\}_{i \in [n]} \) where \( x_i \in \mathbb{Z}_q^m \) reveals \( \sum_{i \in [n]} \langle x_i, y_i \rangle \) and nothing more. In particular the evaluator should not be able to learn the partial sums \( \langle x_i, y_i \rangle \).

Our scheme will be using the following building blocks:

- A 2-round function-rerunnable MPC for a functionality \( \text{GenKey-ip} \), which must be support inner product computation.
- A standard MIFE with for the inner product functionality, denoted by \( \text{MIFE}_{ip} \), satisfying the aforementioned ad hoc friendly properties.

The MIFE scheme(s) of Abdalla et al. [2]:

Abdalla et al. [2] provide two multi-input encryption schemes for inner products, one for computing inner products over some finite ring \( \mathbb{Z}_L \), and the second for computing bounded-norm inner products over the integers. Both schemes rely on:

1. An information theoretic scheme for inner products where only one ciphertext query is supported.
2. A single input functional encryption scheme \( \text{FE} \) for inner products which is applied on top of the above one time scheme.

Unrolling the above two components, the final MIFE scheme(s) of [2] have algorithms of the form described below.

Below, we unroll the above two components to establish that the schemes of [2] satisfy ad hoc friendliness.

1. Decentralized Setup. The encryption keys \( \text{EK}_i \) corresponding to party \( i \) may be generated independently of the encryption keys of the remaining parties \( [n] \setminus i \). In more detail, the setup algorithm is defined as:

\[
\text{MIFE Setup}(1^\kappa, n): \text{Do the following:}
\]

- For \( i \in [n] \), sample \( u_i \leftarrow \mathbb{Z}_L^m \).
- For \( i \in [n] \), sample \( (\text{FE.PK}_i, \text{FE.MSK}_i) \leftarrow \text{FE Setup}(1^\kappa, 1^m) \).
- Output \( \text{PP}_i = \text{FE.PK}_i \) and \( \text{EK}_i = (\text{FE.MSK}_i, u_i) \) for \( i \in [n] \).

Then, we may define:

a. \( \text{MIFE Setup Local}(1^\kappa, n) \): Do the following:

- Sample \( u \leftarrow \mathbb{Z}_L^m \).
- Sample \( (\text{FE.PK}, \text{FE.MSK}) \leftarrow \text{FE Setup}(1^\kappa, 1^m) \).
- Output \( \text{PP} = \text{FE.PK} \) and \( \text{EK} = (\text{FE.MSK}, u) \).
To compute the set of $n$ encryption keys, the algorithm $\text{MIFE.SetupLocal}(1^n, n)$ is invoked $n$ times. Additionally, in [2], the master secret key can be decomposed into $n$ components by setting:

$$\text{MSK}_i = \text{EK}_i = (\text{FE.MSK}_i, u_i) \forall i \in [n]$$

2. **Local Encryption.** The encryption algorithm only takes its encryption key and message as input and does not depend on the number of parties or their public parameters. In more detail, the encryption algorithm is defined as:

$$\text{MIFE.Enc}(\text{EK}_i, x_i):$$ Do the following:
- Parse $\text{EK}_i = (\text{FE.MSK}_i, u_i)$.
- Compute $y_i = x_i + u_i \mod L$.
- Compute $c_i = \text{FE.Enc}(\text{FE.MSK}_i, y_i)$.
- Output $(y_i, c_i)$.

Thus, the ciphertext encoding party $i$’s input may be computed independently by party $i$.

3. **Piecewise Master Secret Key.** For the inner product functionality, if $\text{MSK} = (\text{MSK}_1, \ldots, \text{MSK}_n)$ is the master secret key for function vector $y = (y_1, \ldots, y_n)$ then for any $S \subseteq [n]$, we have the corresponding master key $\text{MSK}' = (\text{MSK}_{S[1]}, \ldots, \text{MSK}_{S[q]})$ is a well formed master secret key for the vector $y' = (y_{S[1]}, \ldots, y_{S[q]})$. In more detail, the key generation algorithm is defined as:

$$\text{MIFE.KeyGen}(\text{MSK}, y):$$ Do the following:
- Output $\text{DK}_y \leftarrow \left( \{\text{FE.KeyGen}(\text{MSK}_i, y_i)\}_{i \in [n]}, \sum_{i \in [n]} (u_i, y_i) \right)$.

It is easy to see that the function key for $y'$ can be obtained from the above by simply setting $y_i = 0$ for $i \notin S$.

5.3 **Our Construction**

We are now ready to present the construction. Note that for ease of presentation, we describe the scheme for all $n$ users but we remark that it works for any subset of $\ell \leq n$ users.

$a\text{MIFE.Setup}(1^n, 1^m)$: Upon input the security parameter and the dimension of the input vector for each party, do the following:
1. Run the partial $\text{MIFE}$ setup algorithm to obtain the public parameters and encryption key: $(\text{MIFE.PP}, \text{MIFE.EK}) \leftarrow \text{MIFE.SetupLocal}(1^n, 1^m)$
2. Invoke the first round of the MPC protocol with the encryption key as input:

$$(\rho^{(1)}, s) \leftarrow \text{MPC.RunRoundOne}(1^n, \text{EK})$$

3. Return $\text{PP} := (\text{MIFE.PP}, \rho^{(1)}), \text{MSK} := (\text{MIFE.EK}, s)$

$a\text{MIFE.Enc}(\text{EK}, x)$: Upon input the encryption key and the input, compute $\text{MIFE.enc}(\text{EK}, x)$ and output it.

$a\text{MIFE.KeyGen}((\text{PP}_i)_{i \in [\ell]}, y, \text{MSK}_i)$: Upon input the public parameters of the $\ell$ parties, the function vector $y$ and the master secret key $\text{MSK}_i$, do the following:
1. Parse $(\text{MIFE.EK}, s) \leftarrow \text{MSK}_i$ and $(\text{MIFE.PP}_j, \rho_j^{(1)}) \leftarrow \text{PP}_j \forall j \in [\ell]$
2. Parse $(y_1, \ldots, y_\ell) \leftarrow y$ where $y_j \in \mathbb{Z}_q^m$ for $j \in [\ell]$.
3. Invoke round 2 of the MPC protocol \( \text{GenKey-} \text{ip}_y \) as defined in Figure 4.

\[
\rho^{(2)} \leftarrow \text{MPC.RunRoundTwo}(s, \rho^{(1)}_1, \ldots, \rho^{(1)}_\ell)
\]

4. Return \( \text{PDK} := \rho^{(2)}. \)

\text{aMIFE.Dec}((\text{PDK}_i, f_i)_{i \in [\ell]}, (c_i)_{i \in [\ell]}): \) Upon input the partial decryption keys from all relevant parties, as well as ciphertexts from all relevant parties, do the following:

1. Compute the output of the MPC protocol as

\[
\text{MIFE.DK}_y \leftarrow \text{MPC.ComputeResult}( (\rho^{(2)}_i)_{i \in [\ell]} )
\]

2. Compute \( \text{MIFE.Dec}(\text{MIFE.DK}_y, y, c_1, \ldots, c_\ell) \) and output it.

\begin{center}
\begin{tabular}{|l|}
\hline
\textbf{Function \text{GenKey-ip}_y(\text{EK}_1, \ldots, \text{EK}_\ell)} \\
\hline
1. Let \text{MIFE.MSK} = (\text{EK}_1, \ldots, \text{EK}_\ell). \\
2. Compute \text{MIFE.KeyGen(MIFE.MSK, y)} and output it. \\
\hline
\end{tabular}
\end{center}

\textbf{Figure 4} Functionality for computing the MIFE function key.

Note that for the inner product functionality, the MIFE key generation algorithm is very simple and in some cases only involves computing inner products, please see [2] for details.

\section*{Correctness}

Correctness follows from correctness of the MPC protocol and of the standard MIFE scheme. We have by correctness of the MPC protocol, that the output \( \text{MIFE.DK}_y = \text{MIFE.KeyGen(MIFE.MSK, y)} \) is produced correctly. Since the encryptors encrypted \( c_i = \text{MIFE.Enc}(\text{EK}_i, x_i) \), it follows from the correctness of MIFE that \( \text{MIFE.Dec}(\text{MIFE.DK}_y, y, c_1, \ldots, c_\ell) \) outputs \( \sum_{i \in [\ell]} \langle y_i, x_i \rangle \) as desired.

\section*{Security}

Given the proof of security in Section 4, the proof of security of the present construction is straightforward, since the present construction is a (much) simplified instance of the general construction. Intuitively, the security of MPC ensures that the output \( \text{MIFE.DK}_y \), which is computed using inputs \( (\text{MSK}_i, y_i)_{i \in [\ell]} \) of \( \ell \) disjoint parties, is indistinguishable from the output of a “global” MIFE key generation algorithm which takes the entire \( (\text{MSK}, y) \) as input. The encryption algorithm is exactly the same as that of the standard MIFE scheme, with the result that the decryptor sees exactly the same view as in the standard MIFE scheme. Please see Appendix E for details.

An issue with the MIFE scheme of Abdalla et al. [2] which we use above is that an adversary may exploit partial ciphertexts to learn unauthorized information [43]. Specifically, say there are two parties, and the first one provides ciphertexts, for vectors \( x_0 \) and \( x_1 \) (say). The second encryptor does not give any ciphertexts. Suppose the key generation algorithm in the standard MIFE scheme gives a key for \( (y \parallel 0) \). Now, it could be that \( \langle x_0, y \rangle \neq \langle x_1, y \rangle \) but this does not violate admissibility, because admissibility only checks for decryption with respect to complete ciphertexts whereas decryption with respect to partial ciphertexts is not defined. Ideally, the key for \( (y \parallel 0) \) should not work to decrypt the partial ciphertexts of encryptor 1, but in the construction of Abdalla et al., it does so (if the corresponding sub-vector in the key is zero).
Note that in a MIFE scheme, the above situation only occurs if one party (party 2 say) never gives any ciphertext. In our setting however, a party issues a partial decryption key only if it wishes its data to participate in some computation. Hence, we resolve the issue by requiring that a party only issue a partial decryption key if it has also issued at least one ciphertext.

Instantiating MPC

Since function-rerunnable two-round MPC in the common reference string (CRS) model can be constructed [28, 57, 24, 59] from learning-with-errors (LWE), we get ad hoc MIFE for inner products from LWE. This result can be upgraded to the malicious setting as the additional cost of NIZKs.

While function rerunnable two-round MPC in the CRS model can be constructed from bilinear maps [41] and even two-round oblivious transfer [15, 42, 39] or information theoretically [9, 36], these constructions are not function-rerunnable so do not suffice for multi-key ad hoc MIFE. However, if we restrict ourselves to the setting of bounded ad hoc MIFE, where a user issues only a bounded number of partial decryption keys and additionally maintains state across key issues, we may use the above MPC protocols (just via repetition). This yields such a bounded ad hoc MIFE under DDH, LWE or DCR for the both the semi-honest and malicious cases. One nice feature of the semi-honest construction is that it does not use a common random string and is in the plain model.

References

5 If party 2 gives even a single ciphertext (say for vector $z_0$) then admissibility will force $(x_0 \parallel z_0, y \parallel 0) = (x_1 \parallel z_0, y \parallel 0)$ which implies that $(x_0, y) = (x_1, y)$. 

A Additional Related Work

Functional Encryption

FE started with the notion of “attribute-based encryption” [61, 50] and evolved over time to a more general primitive that encompasses several primitives such as (hierarchical) identity based encryption [19, 29, 22, 44, 25, 4], attribute based encryption [61, 50, 16, 34], predicate encryption [21, 47, 54, 55, 5, 62, 47] and reusable garbled circuits [46]. Formal definitions of the general primitive were first given in [20, 58]. While there has been substantial progress in constructing FE from standard assumptions [1, 7, 56], the general notion of FE for arbitrary polynomial sized circuits was constructed in the breakthrough work of [33] from indistinguishability obfuscation (iO) [12, 33, 56]. Functional encryption for restricted functionalities such as inner products [1, 7], and quadratic functions [56, 11] from more standard assumptions has also been developed.
Multi-Input Functional Encryption

Extending the more basic concept of functional encryption (FE) [61, 20, 58], the notion of multi-input function encryption (MIFE) was first introduced by Goldwasser et al. [45] and there have since been a number of follow-up works. Ananth and Jain [8] show that private key MIFE for general polynomial-arity functions implies iO. On the other hand, Brakerski, Komargodski and Segev [23] construct private-key MIFE for constant-arity functions, based on a private-key single-input FE scheme. They achieve adaptive security but also do not consider sender corruption. Badrinarayanan et al. [10] construct MIFE schemes for “unbounded arity” functions. More recent work [3, 2] constructs inner-product MIFE.

Multi-Party Computation

Traditional MPC is interactive. Ad hoc MIFE can be seen as a special form of non-interactive MPC [31, 14, 53]. In particular, ad hoc MIFE separates inputs and functions, which affords greater flexibility – one can use the same encrypted inputs with different functions, or different encrypted inputs with the same function. Moreover, previous non-interactive MPC protocols require a global setup procedure. In a recent work, [52] constructs non-interactive MPC from indistinguishability obfuscation and DDH, assuming a PKI setup and a CRS, without this requirement. In contrast, our schemes are based on standard MIFE for a given functionality and do not require a CRS in general, as we do not necessarily consider sender corruption.

Multi-Authority Functional Encryption

Our work should also be compared to that of Chandran et al. [26], who proposed a notion of “multi-authority” FE (MAFE). In MAFE, key authorities independently generate their own keys. Roughly speaking, to derive a decryption key for a function $f$, a user must obtain a partial decryption key for $f$ from each authority. In our context, we could think of the authorities as sources. However, a fundamental difference between multi-authority FE and ad hoc MIFE is that in the former, to encrypt, one needs to know the master public keys of all authorities (users). This is a severe limitation, as a user may not be aware of which other parties are to be involved in a computation at the time of encryption. Furthermore, in multi-authority FE, a given ciphertext can only be used in a computation associated with one fixed group, unlike ad hoc MIFE, where a ciphertext can be used in an unbounded number of dynamically-chosen groups. Finally, in MAFE, decryption only operates on a single ciphertext, unlike our notion which is intrinsically multi-user.

B Preliminaries

In this section we define the notation and preliminaries used in our work.

B.1 Notation and Conventions

PPT stands for “probabilistic polynomial time” and PT stands for “polynomial time.” Algorithms are PPT unless otherwise noted. Throughout, $\kappa$ denotes the security parameter and $1^\kappa$ its unary encoding. For a probabilistic algorithm $A$, we denote by $A(x; r)$ the output of $A$ on input $x$ with random tape $r$. We denote $y \leftarrow A(x)$ as the process of sampling $r$ at random and letting $y \leftarrow A(x; r)$. For a finite set $S$, we denote $x \leftarrow S$ as the process of sampling $x$ uniformly from $S$. For a distribution $D$ we denote $x \leftarrow D$ as the process of sampling $x$ according to $D$. For $k \in \mathbb{N}$ we let $[k]$ denote the set $\{1, \ldots, k\}$. If $s$ is string
then \(|s|\) denotes its length and \(s[i]\) denotes its i-th bit. If \(\mathbf{x}\) is a vector then \(|\mathbf{x}|\) denotes its number of components and \(\mathbf{x}[i]\) denotes its i-th component. We will use \(\text{negl}(\cdot)\) to denote an unspecified negligible function and \(\text{poly}(\cdot)\) to denote an unspecified polynomial. We say that (families of) distributions \(\{D_{0,\kappa}\}_{\kappa \in \mathbb{N}}, \{D_{1,\kappa}\}_{\kappa \in \mathbb{N}}\) are computationally indistinguishable if for all PPT adversaries \(A\), \(\Pr[A(D_{0,\kappa}) = 1] - \Pr[A(D_{1,\kappa}) = 1] = \text{negl}(\kappa)\). We write this \(D_{0,\kappa} \approx C \approx D_{1,\kappa}\).

### B.2 Two-Round MPC

A 2-round MPC protocol \(\text{MPC}\) for message-space \(\{\mathcal{M}_{\kappa}\}_{\kappa \in \mathbb{N}}\) and functionality \(\{\mathcal{F}_{\kappa}\}_{\kappa \in \mathbb{N}}\) where for each \(\kappa \in \mathbb{N}\) each \(f \in \mathcal{F}_{\kappa}\) is a function on \((\mathcal{M}_{\kappa})^{n}\) for some \(n\), consists of three algorithms with the following syntax:

- \(\text{RunRoundOne}(1^{\kappa}, 1^{n}, f, i, x)\): A PPT algorithm taking the security parameter \(\kappa\), number of users \(n\), a (description of a) function \(f \in \mathcal{F}_{\kappa}\) of arity \(n\), an index \(i \in [n]\), an input \(x \in \mathcal{M}_{\kappa}\), and outputting a first protocol message \(\rho^{(1)}\) and secret \(s\).

- \(\text{RunRoundTwo}(s, (\rho^{(1)}_{1}, \ldots, \rho^{(1)}_{n}))\): A PPT algorithm taking a secret \(s\) and the first protocol message for all \(n\) parties \(\rho^{(1)}_{1}, \ldots, \rho^{(1)}_{n}\), and outputting a second protocol message \(\rho^{(2)}\).

- \(\text{ComputeResult}\): A PPT algorithm taking as input the \(n\) second-round protocol messages \(\rho^{(2)}_{1}, \ldots, \rho^{(2)}_{n}\) for each party and outputting a value \(y\).

#### Correctness

We say that \(\text{MPC}\) is correct if for all \(\kappa, n, i \in \mathbb{N}, x_{1} \ldots x_{n} \in \mathcal{M}_{\kappa}\) and \(f \in \mathcal{F}_{\kappa}\)

\[
\Pr\left[y = f(x) \left| \begin{array}{c}
\rho^{(1)}_{i} \leftarrow \text{RunRoundOne}(1^{\kappa}, 1^{n}, f, i, x_{i}) \quad \forall i \in [n] \\
\rho^{(2)}_{i} \leftarrow \text{RunRoundTwo}(s, (\rho^{(1)}_{1}, \ldots, \rho^{(1)}_{n})) \quad \forall i \in [n] \\
y \leftarrow \text{ComputeResult}(\rho^{(2)}_{1}, \ldots, \rho^{(2)}_{n})
\end{array} \right. \right] = 1.
\]

\[\triangleright\text{ Remark } 6.\] The above definition of two-round MPC is without setup (i.e., a CRS). We also consider the case that there is an additional algorithm \(\text{CRSGen}\) taking \(1^{\kappa}\) and outputting a common reference string \(\text{CRS}\) that is input to the remaining algorithms. We call this two-round MPC in the CRS model.

We say that \(\text{MPC}\) is unbounded if the output of \(\text{RunRoundOne}\) does not depend on \(n\). In this case, we input \(n\) to \(\text{RunRoundTwo}\) instead of \(\text{RunRoundOne}\). We call \(\text{MPC}\) input-delayed (resp. function-delayed) if the output of \(\text{RunRoundOne}\) does not depend on \(x\) (resp. \(f\)) but just on \(1^{|x|}\) (resp. \(1^{|f|}\)). In this case, we input \(x\) (resp. \(f\)) to \(\text{RunRoundTwo}\) instead of \(\text{RunRoundOne}\). We call \(\text{MPC}\) input-rerunnable (resp. function-rerunnable) if it is input-delayed (resp. function-delayed) and if \(\text{RunRoundTwo}\) can be executed multiple times with different input choices (resp. function choices) while still preserving the security properties of the \(\text{MPC}\) protocol (see below).

#### Security

Let \(\text{MPC}\) be a 2-round MPC protocol as above. Let \(\text{Coins}\) be the coin-space for the protocol. For an adversary \(\mathcal{A} = (\mathcal{A}_{0}, \mathcal{A}_{1})\) and simulator \(\mathcal{S}\), consider the experiments in Figure 5. We say that \(\mathcal{A}\) is passive (aka. semi-honest) of \(I = \emptyset\). We say that \(\text{MPC}\) is SIM-secure if for any PPT adversary \(\mathcal{A}\) there is a stateful PPT simulator \(\mathcal{S} = (\text{CRSGen}, \text{Extract}, \text{Sim})\) such that \(\text{REAL}_{\text{MPC}}^{\mathcal{A}}(\cdot)\) and \(\text{IDEAL}_{\mathcal{A},\mathcal{S}}^{\text{MPC}}(\cdot)\) are computationally indistinguishable. Note that
Ad Hoc Multi-Input Functional Encryption

A PRF $F$ is specified by two algorithms:

- **PRF.Setup($1^n$)**: The setup algorithm takes as input the security parameter and outputs a description of the key space $K_n$, domain $X$, range $Y$ as well as the PRF key $K$.
- **PRF.Eval($K, x$)**: The eval algorithm takes a key $K \in K_n$ and domain point $x \in X_n$ and outputs a range point $y \in Y_n$.

**B.3 Punctured Pseudorandom Functions**

Our results in this work rely on the simulator’s ability to extract the inputs of the corrupted parties, hence the need for the **Extract** algorithm. In the semi-honest setting, extraction is not necessary. In the malicious case, both known constructions of two-round MPC [33, 57] for general functions satisfy the above extractability property, albeit in the CRS model.
We require that for all adversaries $A$
\[
\Pr[A^{\text{PRF-Eval}(K, \cdot)} \text{ outputs } 1] - \Pr[A^{\text{\$}(\cdot)} \text{ outputs } 1]
\]
is negligible in $\kappa$, where $K \leftarrow \text{PRF.Setup}(1^\kappa)$ and $\$\cdot$ denotes a random function from $X_\kappa$ to $Y_\kappa$.

A puncturable PRF additionally includes an algorithm $\text{PRF.Punc}$ which takes as input a PRF key $K$ and a point $x^* \in X$ and outputs a punctured key $K_{x^*}$. For correctness, we require that $\text{PRF.Eval}(K_{x^*}, x) = \text{PRF.Eval}(K, x)$ for all $x \neq x^*$ and $\perp$ when $x = x^*$.

### Security of punctured PRF

The security game between the challenger and the adversary $A$ consists of the following four phases.

**Setup Phase:** The challenger samples a PRF key $K$ and a random bit $b$.

**Evaluation Query Phase:** The adversary $A$ queries for polynomially many evaluations. For each evaluation query $x$, the challenger sends $F(K, x)$ to $A$.

**Challenge Phase:** $A$ chooses a challenge $x^*$ and the challenger computes $K_{x^*} \leftarrow \text{PRF.Punc}(K, x^*)$. If $b = 0$, the challenger outputs $K_{x^*}$ and $F(K, x^*)$. Else, the challenger outputs $K_{x^*}$ and $y \leftarrow Y$ chosen uniformly at random.

**Guess:** The adversary $A$ outputs a guess $b'$ of $b$.

The adversary $A$ wins if $b' = b$ and the adversary did not query for evaluation on $x^*$.

The advantage of $A$ is defined to be
\[
\text{Adv}_{A}^{\text{PRF}}(1^\kappa) = |\Pr[A \text{ wins}] - 1/2|
\]

The PRF $F$ is a secure puncturable PRF if for all probabilistic polynomial time adversaries $A$, we have that $\text{Adv}_{A}^{\text{PRF}}(1^\kappa)$ is negligible in $\kappa$.

### B.4 Multi-Input Functional Encryption

An $n$-input FE scheme [45] MIFE for a message space $\{M_\kappa\}_{\kappa \in \mathbb{N}}$ and a functionality $\{F_\kappa\}_{\kappa \in \mathbb{N}}$, where for each $\kappa \in \mathbb{N}$ each $f \in F_\kappa$ is a (description of a) function on $(M_\kappa)^n$, is given by a set of algorithms with the following syntax:

- $\text{MIFE.Setup}(1^\kappa, 1^n)$: A PPT algorithm taking the security parameter $\kappa$ and number of users $n$, and outputting the master secret key $\text{MSK}$ and encryption keys $(\text{EK}_1, \ldots, \text{EK}_n)$.
- $\text{MIFE.KeyGen}(\text{MSK}, f)$: A PT algorithm taking a master secret key $\text{MSK}$, a function $f \in F_\kappa$, and outputting a corresponding decryption key $\text{DK}_f$.
- $\text{MIFE.Enc}(\text{EK}, x)$: A PPT algorithm taking an encryption key $\text{EK}$ and a message $x \in M_\kappa$, and outputting a ciphertext $c$.
- $\text{MIFE.Dec}(\text{DK}_f, (c_1, \ldots, c_n))$: A PT algorithm taking decryption key $\text{DK}_f$ and vector of ciphertexts $(c_1, \ldots, c_n)$, and outputting a string $y$. 

ITCS 2020
Correctness

We say that MIFE is correct if for all $\kappa \in \mathbb{N}$, $x_1 \ldots x_n \in \mathcal{M}_\kappa$ and $f \in \mathcal{F}_\kappa$

$$\Pr \left[ y = f(x_1, \ldots, x_n) \right] = 1.$$

Remark 7. We remark that our formulation of MIFE assumes that the senders (as in our application an encryptor is referred to as a sender or source) are ordered. This allows for consistency with our formulation of ad hoc MIFE and allows us to simplify exposition versus [45].

Indistinguishability-Based Security

For an $n$-input FE scheme MIFE as above and adversary $A = (A_0, A_1, A_2)$, consider the experiment in Figure 6.

Figure 6 Experiment for IND-security of standard MIFE.

We call $A$ legitimate if for all $\kappa \in \mathbb{N}$, in all transcripts IND$_A^{\text{MIFE}}(1^n)$ it holds that for every key generation query $f$ there does not exist two sequences $(y_{1,0}, \ldots, y_{n,0})$ and $(y_{1,1}, \ldots, y_{n,1})$ such that

$$f(y_{1,0}, \ldots, y_{n,0}) \neq f(y_{1,1}, \ldots, y_{n,1})$$

and for every $j \in [n]$

- $j \in I$, i.e. $j$ is corrupted (so there is no restriction on $y_{j,0}, y_{j,1}$ above), or
- there is an encryption query $(j, x_0, x_1)$ such that $y_{j,0} = x_0$ and $y_{j,1} = x_1$.

We assume adversaries are legitimate unless otherwise stated. We call $A$ passive if $I = \emptyset$. We call $A$ selective if $A_2$ makes no queries. We say that MIFE is IND-secure if for any adversary $A$

$$|\Pr \left[ \text{IND}_{A}^{\text{MIFE}}(\cdot) \text{ outputs } 1 \right] - 1/2| = \text{negl}(\cdot).$$
Simulation-Based Security

For an MIFE scheme MIFE as above, adversary $A = (A_0, A_1, A_2)$, and simulator $S = (\text{Setup}, \text{Enc}, \text{KeyGen})$, consider the experiments in Figure 7. Here $q_{\text{enc}, i}$ is the number of encryption queries for user $i \in [n]$. We say that $A$ is $q$-bounded if $q_{\text{enc}, i} \leq q$ for all $i \in [n]$. We say that MIFE is SEL-SIM-secure if for any adversary $A$ there is a simulator $S$ such that $\text{REAL}^{\text{MIFE}}_A$ and $\text{IDEAL}^{\text{MIFE}}_S$ are computationally indistinguishable.

$\triangleright$ Remark 8. For consistency with our formulation of simulation-based security for ad hoc MIFE, we restrict the above definition to the selective-security and passive (no sender corruption) setting.

**Figure 7** Experiments for SIM-security of standard MIFE.

### B.5 Function-Private Functional Encryption

A functional encryption scheme, denoted as $\text{FE}$ [20], is a tuple of algorithms $\text{FE} = (\text{FE.Setup}, \text{FE.KeyGen}, \text{FE.Enc}, \text{FE.Dec})$ for a message space $\{\mathcal{M}_\kappa\}_{\kappa \in \mathbb{N}}$ and a functionality $\{\mathcal{F}_\kappa\}_{\kappa \in \mathbb{N}}$, where for each $\kappa \in \mathbb{N}$, each $f \in \mathcal{F}_\kappa$ is a (description of a) function on $\mathcal{M}_\kappa$. The syntax is the same as for a 1-input MIFE scheme where $\text{EK}_\kappa = \text{MSK}$ and $I = \emptyset$. The correctness requirement remains the same, as well the notion of indistinguishability based security (which we refer to as “message privacy”).

#### Function Privacy

We additionally define the notion of function privacy as follows. For an FE scheme $\text{FE}$ as above and adversary $A = (A_0, A_1, A_2)$, consider the experiment in Figure 8.

We call $A$ legitimate if for all $\kappa \in \mathbb{N}$, in all transcripts $\text{FP}^{\text{FE}}_A(1^n)$ it holds that for every key generation query $f_0, f_1$ there does not exist an encryption query $x \in \mathcal{M}_\kappa$ such that $f_0(x) \neq f_1(x)$.

We assume adversaries are legitimate unless otherwise stated. We say that $\text{FE}$ is FP-secure if for any adversary $A$

$$\Pr[\text{FP}^{\text{FE}}_A() \text{ outputs } 1] - 1/2 = \text{negl}(\cdot).$$
We now present a simulation-based definition of security. The definition has a number of restrictions that we justify below.

For an ad hoc MIFE scheme \( \text{aMIFE} \) as above, adversary \( A = (A_0, A_1, A_2) \), and simulator \( S = (\text{Setup}, \text{Enc}, \text{KeyGen}) \), consider the experiments in Figure 9. Here \( q_{E,i} \) is the number of encryption queries for user \( i \in [n] \). We say that \( A \) is \( q \)-bounded if \( q_{E,i} \leq q \) for all \( i \in [n] \).

We say that \( \text{aMIFE} \) is xxx-SEL-SIM-secure if for any adversary \( A \) of type xxx there is a simulator \( S \) such that \( \text{REAL}_{A, S}^{\text{aMIFE}}() \) and \( \text{IDEAL}_{A, S}^{\text{aMIFE}}() \) are computationally indistinguishable.

\[\begin{align*}
\text{Oracle } \mathcal{O}_{\text{enc}}(x) \\
\text{if } x \in M_\alpha \\
c \leftarrow \text{MIFE.Enc}(\text{MSK}, x) \\
\text{return } c \\
\text{else return } \perp
\end{align*}\]

\[\begin{align*}
\text{Oracle } \mathcal{O}_{\text{sig}}(f_0, f_1) \\
\text{if } f_0, f_1 \in \mathcal{F} \in \\
\text{DK}_{f_0} \leftarrow \text{MIFE.KeyGen}(\text{MSK}, f_0) \\
\text{return } \text{DK}_{f_0} \\
\text{else return } \perp
\end{align*}\]

\[\begin{align*}
\text{Oracle } \mathcal{O}_{\text{sel}}(i, (i_1, \ldots, i_\ell), f) \\
\text{if } i \in \{i_1, \ldots, i_\ell\} \text{ and } f \in \mathcal{F} \text{ of arity } \ell \\
\text{PDK}_{i,f} \leftarrow \text{MIFE.KeyGen}(i, \text{MSK}, (P_{P_i})_{j \in [\ell]}, f) \\
\text{return } \text{PDK}_{i,f} \\
\text{else return } \perp
\end{align*}\]

\[\begin{align*}
\text{Oracle } \mathcal{O}_{\text{sel}}(i, (i_1, \ldots, i_\ell), f) \\
\text{if } i \in \{i_1, \ldots, i_\ell\} \text{ and } f \in \mathcal{F} \text{ of arity } \ell \\
\text{q} \leftarrow (f, \{i_1, \ldots, i_\ell\}, f) \\
\text{PDK}_{i,f} \leftarrow \text{KeyGen}(q, f(x_{i_1, i_\ell}))_{x_{i_1, i_\ell} \in [q_{E,i_1}, [q_{E,i_\ell}]} \text{ (MSK) } \\
\text{return } \text{PDK}_{i,f} \\
\text{else return } \perp
\end{align*}\]

We say that \( \text{aMIFE} \) is xxx-SEL-SIM-secure if for any adversary \( A \) of type xxx there is a simulator \( S \) such that \( \text{REAL}_{A, S}^{\text{aMIFE}}() \) and \( \text{IDEAL}_{A, S}^{\text{aMIFE}}() \) are computationally indistinguishable.

\[\begin{align*}
\text{Oracle } \mathcal{O}_{\text{enc}}(x) \\
\text{if } x \in M_\alpha \\
c \leftarrow \text{MIFE.Enc}(\text{MSK}, x) \\
\text{return } c \\
\text{else return } \perp
\end{align*}\]
The adversary is selective and chooses its challenge messages before seeing the public parameters of the users. We focus on this formulation for simplicity and leave the study of adaptive security for ad hoc MIFE in the case of simulation-based security for future work.

The simulator is black-box. This is for simplicity as it is stronger than allowing non-black-box simulation and our constructions achieve it.

D Proof of Theorem 5

Theorem 5. If MIFE is a IND-secure MIFE scheme and MPC is a SIM-secure 2-round MPC protocol, then our construction is sel-IND-secure.

Proof. The proof of security makes use of a trapdoor data structure which is defined in Figure 10.

The trapdoor data structure

Here, mode is used to indicate whether we are in the real mode Real or trapdoor mode Trap. CT indicates the hardwired MIFE CT which must be output if the field index equals the counter ctr set in the FE key. The fields val₀ and val₁ are used to indicate the values corresponding to bit 0 and bit 1 respectively, where the latter is used when index > ctr and the former when index < ctr.

Figure 10 Data Structure Trap used for Proof.

The Hybrids

We prove the theorem via a hybrid argument. We describe our hybrids below.

Hybrid 0: This is the real game in which on every encryption query (i, x₀, x₁), x₀ is encrypted.

Suppose there are Qc encryption queries (made selectively). For each k ∈ [Qc], let i be the party index queried, x₀ and x₁ the challenge plaintexts, let T be the tag used during encryption and J be the set of users corrupted by the adversary. We use these definitions in the remainder of the proof.

Hybrid 1: The change in this hybrid is twofold.

1. Simulate the Public Parameters. We set the first-round protocol message ρ⁽¹⁾ᵢ for MPC in the public parameters to the output of the simulator ˜Sim₁ for each uncorrupted user i /∈ I.

2. Simulate the Function Key. For each key generation query (i, (i₁, . . . , i₇), f), we do the following.
   a. Let J ≜ I ∩ {i₁, . . . , i₇} be the subset of corrupted users and ˜J = {i₁, . . . , i₇} \ J be the subset of honest users.
   b. We use the simulator’s Extract algorithm to compute x_j ← ˜Extract(ρ⁽¹⁾ᵢ) for each corrupted party j ∈ J where PPᵢ = ρ⁽¹⁾ᵢ, then compute y = GenKeysᵢ(xᵢ₁, . . . , xᵢ₇) where xᵢ for j ∈ ˜J is (honest) party j’s input to the MPC protocol.
As we see in Figure 11, the only difference from Hybrid 0 is that the inputs of the corrupt
these changes formally.

Here

Hybrid

precisely, a standard argument iterates through sub-hybrids for each honest party, replacing
used to generate random strings and keep track of those previously generated.

random string. The changes are formally described in Figure 12 wherein the algorithm
PRF outputs with uniformly random strings.

Indistinguishability of Hybrid 1 and Hybrid 2 follows from the security of the PRF. More
Indistinguishability of the hybrids follows from the SIM-security of the MPC protocol.

Hybrid 1:

\[ (1^n, I, \langle \mathbf{PP}_i \rangle_{i \in I}, st) \leftarrow A_0(1^n) \]

\[ b \leftarrow \{0, 1\} \]

\[ \forall i \notin I: \]

\[ \langle \mathbf{PP}_{FE_i}, \mathbf{MSK}_{FE_i} \rangle \leftarrow \text{FE.Setup}(1^n) \]

\[ \mathbf{K}_i \leftarrow \mathbf{K}_n \]

\[ \mathbf{K}_{i^{\text{prf}}} \leftarrow \mathbf{K}_n \]

\[ (\rho_i^{(1)}, st) \leftarrow \tilde{\text{Sim}}() \]

\[ \mathbf{PP}_i \leftarrow \rho_i^{(1)} \]

\[ st \leftarrow A_1^{\mathcal{O}_{\text{Enc}(...), \mathcal{O}_{\text{Gen}(...)}}(st)} \]

\[ y' \leftarrow A_2^{\mathcal{O}_{\text{Enc}(...), \mathcal{O}_{\text{Gen}(...)}}(\langle \mathbf{PP}_i \rangle_{i \in I}, st)} \]

Return \((b = b')\)

\[ \mathbf{Oracle} \mathcal{O}_{\text{enc}}(i, x_0, x_1) \]

\[ T \leftarrow \{0, 1\}^* \]

\[ \text{Return FE.Enc}(\mathbf{MSK}_{FE_i}, (x_0, T, \mathbf{K}_{i^{\text{prf}}}, \text{Trap})) \]

\[ \mathbf{Oracle} \mathcal{O}_{\text{gen}}(i, (i_1, \ldots, i_t), f) \]

\[ J \leftarrow I \cap \{i_1, \ldots, i_t\}; \]

\[ J' \leftarrow \{i_1, \ldots, i_t\} \setminus J \]

\[ (\mathbf{K}_j, \mathbf{MSK}_{FE_j}) \leftarrow \text{Extract}(\rho_j^{(1)}) \]

\[ \forall j \in J \]

\[ y \leftarrow \text{GenKeys}_{\Gamma}(\mathbf{K}_1, \mathbf{MSK}_{FE_1}, \ldots, (\mathbf{K}_{i_t}, \mathbf{MSK}_{FE_{i_t}}) \]

\[ (\rho_j^{(2)}),_{i \in J} \leftarrow \tilde{\text{Sim}}(\mathbf{K}_j, \mathbf{MSK}_{FE_j}, i, y) \]

\[ s \leftarrow \text{PRF.Eval}(\mathbf{K}_i, 0 \parallel \langle \mathbf{PP}_i \rangle_{i \in [t]} \parallel f) \]

Return \((\rho_j^{(2)}, s)\).

\section*{Figure 11} Hybrid 1.

Hybrid 2: In this hybrid, we replace the outputs of the PRF on key \(K_i\) for the honest users
i with uniformly random strings in the function GenKeys described in Figure 2. For every key
query pertaining to parties \((i_1, \ldots, i_t)\) and function \(f\) and every honest party \(i\), we replace
PRF.Eval\((K_i, k \parallel \langle \mathbf{PP}_{i} \rangle_{j \in [t]} \parallel f)\) for \(k \in \{0, 1, 2\}\) as in Hybrid 1 with a fresh uniformly
random string. The changes are formally described in Figure 12 wherein the algorithm \(R\) is
used to generate random strings and keep track of those previously generated.

Indistinguishability of Hybrid 1 and Hybrid 2 follows from the security of the PRF. More
precisely, a standard argument iterates through sub-hybrids for each honest party, replacing
the PRF outputs with uniformly random strings.

Hybrid 3: In this hybrid, we change how \(y\) (the target output passed to \(\tilde{\text{Sim}}2)\) is generated
in each query \((i_1, \ldots, i_t), f\). In this hybrid, \(y\) is randomly sampled. Furthermore for a pair
\(((i_1, \ldots, i_t), f)\) that is fully queried i.e. a partial decryption query \((i, (i_1, \ldots, i_t), f)\) is made
for each \(i \in \{i_1, \ldots, i_t\} \setminus I\), the final partial decryption key that is issued has its masking
value, i.e. the second component of the partial decryption key, generated differently. It is
generated as

\[s \leftarrow y \oplus S_1 \oplus S_2 \oplus \text{GenKeys}''(r_1', \mathbf{MSK}_{FE_1}, \ldots, (r_j', \mathbf{MSK}_{FE_j}))\]

Here \(S_1\) and \(S_2\) are computed so as to satisfy requisite dependencies. Figure 13 captures
these changes formally.
Hybrid 2:

\[
\begin{align*}
&(1^n, I, (PP_r)_{i \in I}, st) \rightarrow A_0(1^n) \\

&\text{Return } (\rho^{(2)}_j, s := \gamma^{(0)}_i)
\end{align*}
\]

Algorithm \(RT(i, (i_1, \ldots, i_t), f)\)

\[
\begin{align*}
&\text{If } (i_1, \ldots, i_t, f, \gamma^{(0)}_i, \gamma^{(1)}_i, \gamma^{(2)}_i) \in \Gamma: \\
&\gamma^{(1)}_i \leftarrow \{0, 1\}^p \\
&\gamma^{(2)}_i \leftarrow \{0, 1, 2\} \\
&\text{else:} \\
&\gamma^{(1)}_i \leftarrow \{0, 1\}^p \\
&\gamma^{(2)}_i \leftarrow \{0, 1, 2\} \\
&\gamma^{(1)}_i \leftarrow \bigoplus_{j \in [0, 1, 2]} \gamma^{(j)}_i \\
&\text{where } rp \text{ is the range of the PRF} \\
&\Gamma \leftarrow \Gamma \cup (i_1, \ldots, i_t, f, \gamma^{(0)}_i, \gamma^{(1)}_i, \gamma^{(2)}_i) \\
&\text{Return } (\gamma^{(0)}_i, \gamma^{(1)}_i, \gamma^{(2)}_i)
\end{align*}
\]

\[\text{Figure 12} \text{ Hybrid 2.}\]

Hybrid 2 and Hybrid 3 are distributed identically. First, \(y\) is distributed uniformly in both hybrids for all group-function pairs \((i_1, \ldots, i_t), f\) that are not fully queried. In the case of a group-function pair \((i_1, \ldots, i_t), f\) that is fully queried, each partial decryption key \((\rho^{(2)}_i, s)\) for \(i \in \{i_1, \ldots, i_t\}\) is such that

\[
y \oplus \bigoplus_{i \in [t]} s_i = \text{GenKeys''}(r'_1, MSK_{FE_1}, \ldots, r'_t, MSK_{FE_t})
\]

This is distributed the same as the output of \(\text{GenKeys'}\) in the previous hybrid. Hence the \(y\) values are distributed identically in both hybrids.

Hybrid 4: Let \(Q_k\) be the number of subset-function pairs that are fully queried. In this hybrid, the key generation algorithm keeps track of the query number \(\text{ctr} \in [Q_k]\) in the ad hoc MIFE function keys. In more detail, the algorithm \(\text{GenKeys''}\) invoked for query index \(j\) for all \(j \in [Q_k]\) is modified to invoke \(\text{ReEnc}\) with parameter \(\text{ctr} = j\) (please refer to Figure 3) instead of \(\bot\).

We claim that by function hiding of \(\text{FE}\), the two hybrids are indistinguishable. To see this, note that since \(\text{mode} = R\) in all the \(\text{FE}\) ciphertexts, changing the \(\text{ctr}\) value in the \(\text{FE}\) key has no effect on the decryption value obtained, since this field is only relevant in the trapdoor mode, i.e. when \(\text{mode} = T\). Hence, the decryption values for both keys remain exactly the same. Then, by security of \(\text{FE}\), we have that Hybrids 3 and 4 are indistinguishable. The formal reduction is standard, and constructs everything except the \(\text{FE}\) ciphertexts and \(\text{FE}\) function keys as in the previous hybrid, which are obtained using the \(\text{FE}\) challenger.
Hybrid 3:
\((1^n, I, (PP_i)_{i\in J}, st) \rightarrow A_0(1^n)\)
\(b \leftrightarrow \{0, 1\}\)

\[\text{Figure 13 Hybrid 3.}\]

In more detail, we have a series of subhybrids, one for each \(i \notin I\), where in Hybrid 4, \(i\), the change above is made to the function key associated with the FE instance for party \(i\). Let Hybrid 4, 0 denote Hybrid 3 and let Hybrid \([n \setminus I]\) denote Hybrid 4. We now give the formal reduction to FE function hiding for distinguishing Hybrid 4, \(i - 1\) and Hybrid 4, \(i\) (for ease of notation, we assume that the indices \(i\) are consecutive). The simulator \(B\) is defined as follows. First \(B\) receives the public parameters \(PP\) from the FE challenger. Then it receives \((1^n, I, (PP_i)_{i \in I})\) from the hybrid distinguisher \(A\). Next it runs Step 2 to Step 10 on the left hand side of Figure 14 and passes \((PP_i)_{i \notin I}\) (see Step 10) to \(A\). It handles encryption and key generation queries as follows. On an encryption query \((i', x_0, x_1)\) with \(i' \neq i\), the query is handled the same as \(O_{\text{enc}}\) in Figure 14. On an encryption query \((i, x_0, x_1)\), a tag \(T \leftrightarrow \{0, 1\}^{\#}\) is sampled and \(B\) makes a call to the FE encryption oracle with message \((x_0, T, K^{\text{enc}_{i'}}), \text{Trap} := (\text{mode} := R, \bot, \bot, \bot, \bot)\) and returns the returned ciphertext. Key generation queries are handled as in \(O_{\text{kg}}\) in Figure 14 with one exception, namely the secret keys \(SK_{FE_i}\) are computed as in \(\text{GenKeys}^{2}\) except for the case \(i' = i\); the secret

Hybrid 5(j,1): In this hybrid, we hardwire all the \(Q_c\) MIFE CTs that are output by the \(j^{th}\) function query in the corresponding single input FE ciphertexts in the field \(\text{Trap}\). CT and set mode = \(T\).

In more detail, for key query \(j\), we generate the encryption keys exactly as in Figure 2. Now, encryptor \(i \in [n]\) computes \(Q_c\) ciphertexts as follows:

1. For \(k \in [Q_c]\), let \(r_{i,j,k} \leftarrow \text{PRF.Eval}(K_{\text{punc}}^j, j \parallel \text{EK}_{i,j} \parallel T_{i,k})\)
2. For \(k \in [Q_c]\), let \(\psi_{i,j,k} = \text{MIFE.Enc}(\text{EK}_{i,j}, x_{i,k} \parallel T_{i,j,k})\)

For \(k \in [Q_c]\), encryptor \(i \in [n]\) sets \(\text{Trap}\) so as to program it for the \(j^{th}\) function query as follows:

\(\text{Trap.mode} = T, \text{Trap.CT} = \psi_{i,j,k}, \text{Trap.index} = j, \text{val}_0 = x_{i,j,k}, \text{val}_1 = x_{i,j,k}\)
Please see Figure 15 for the complete description.

Figure 15: Hybrid 5\(_{j,i}\).

Note that the hardwired ciphertext is only output for query \(j\), the outputs for the other queries are exactly equal to those in the previous hybrid. Now, for query \(j\), the ciphertext is hardwired and output is set to be equal to what was output in the previous hybrid. It follows that the output of FE decryption remains exactly the same as in the previous hybrid. Thus, by security of FE, we have that the two hybrids are indistinguishable.

In more detail, we have a series of subhybrids, one for each \(i \not\in I\), where in Hybrid 5\(_{j,i}\), \(i\), the change above is made to the ciphertext associated with the FE instance for party \(i\). Let Hybrid 5\(_{j,0}\) denote Hybrid 4 and let Hybrid 5\(_{j,1}, [n \setminus I]\) denote Hybrid 5\(_{j,1}\). We now give the formal reduction to FE semantic security for distinguishing Hybrid 5\(_{j,1}\), \(i - 1\) and Hybrid 5\(_{j,1}\), \(i\) (for ease of notation, we assume that the indices \(i\) are consecutive). The simulator \(B\) is defined as follows. First \(B\) receives the public parameters PP from the FE challenger. Then it receives \((1^*, J, (\text{PP}_j)\)\)\(\_j \in I\) from the hybrid distinguisher \(A\). Next it runs
Step 2 to Step 11 on the left hand side of Figure 15 and passes $(PP_j)_{j \notin I}$ (see Step 11) to $\mathcal{A}$. It handles encryption and key generation queries as follows. On an encryption query $(i', x_0, x_1)$ with $i' \neq i$, the query is handled the same as $O_{\text{enc}}$ in Figure 15. On an encryption query $(i, x_0, x_1)$, a tag $T \leftarrow \{0, 1\}^c$ is sampled, then $r \leftarrow \text{PRF.Eval}(K_i^\text{punc}, j \parallel \text{EK}_i \parallel T)$, $\psi \leftarrow \text{MIFE.Enc(}E_{K_{i,j}}(x_0; r))$, $\text{Trap}_0 \leftarrow (\text{mode} := R, \bot, \bot, \bot, \bot)$ and $\text{Trap}_i \leftarrow (\text{mode} := \text{Trap}, \psi, j, x_0, x_1)$ are computed and $B$ makes a call to the FE encryption oracle with messages $(x_0, T, K_{i,j-1}^\text{punc}, \text{Trap}_0)$ and $(x_0, T, K_{i,j-1}^\text{punc}, \text{Trap}_i)$, and returns the returned ciphertext. Key generation queries are handled as in $O_{\text{sk}}$ in Figure 15 with one exception, namely the secret keys $SK_{\text{FE}_i}$ are computed as in $\text{GenKeys}^{m''}$ except for the case $i' = i$; the secret key $SK_{\text{FE}_i}$ is obtained by making a call to the FE key generation oracle for function $\text{ReEnc}_{i,\text{ct}}$. If the FE challenger's bit is 0, then $B$ perfectly simulates Hybrid $5_{j,1}, i - 1$ and if the FE challenger’s bit is 1, then $B$ perfectly simulates Hybrid $5_{j,1}, i$.

**Hybrid 5\textsubscript{j,2}:** In this hybrid, we use a punctured PRF to generate the MIFE CTs in the $\text{ReEnc}$ functionality encoded in the FE function keys. The PRF for party $i$ is punctured at prefix $j$ so that the randomness $r_{i,j,k}$ defined above, for $i \in [n], k \in [Q_n]$ cannot be generated. All MIFE ciphertexts corresponding to other function queries can be generated as before.

In more detail:

1. For $i \in [n]$, party $i$ samples $K_{i,j,k}^\text{punc} \leftarrow \text{puncF}(K_{i,j}^\text{punc}, j)$.
2. The $i^{th}$ encryptor computes $\text{FE.enc}(\text{MSK}_{\text{FE}}, (x_0, i, k, T, K_{i,j}^\text{punc}, \text{Trap}))$ where all other fields are set as in the previous hybrid.

During FE decryption, for any query $j' \neq j$, we now obtain:

$$r_{i,j',k} \leftarrow \text{puncF}(K_{i,j,k}^\text{punc}, j' \parallel \text{EK}_{i,j'} \parallel T, k)$$

for $k \in [Q_i]$. Everything else is as in the previous hybrid. For query $j$, the hardwired CT is output, and the punctured PRF key is not used to generate randomness. Please see Figure 16 for the complete description.

We have by correctness of the punctured PRF that for any $j' \neq j$, all the computed $r_{i,j',k}$ are exactly equal to those computed in the previous hybrid, where the normal PRF key was used. For query $j$, the PRF is not used and the hardwired value is output in both hybrids. Hence, the outputs of FE decryption are equal in both hybrids. Thus, indistinguishability follows from security of FE.

In more detail, we have a series of subhybrids, one for each $i \notin I$, where in Hybrid $5_{j,2}, i$, the change above is made to the ciphertext associated with the FE instance for party $i$. Let Hybrid $5_{j,2}, 0$ denote Hybrid $5_{j,1}$ and let Hybrid $5_{j,2}, n \setminus I$ denote Hybrid $5_{j,2}$. We now give the formal reduction to FE semantic security for distinguishing Hybrid $5_{j,2}, i - 1$ and Hybrid $5_{j,2}, i$ (for ease of notation, we assume that the indices $i$ are consecutive). The simulator $B$ is defined as follows. First $B$ receives the public parameters $PP$ from the FE challenger. Then it receives $(1^c, I, (PP_j)_{j \notin I})$ from the hybrid distinguisher $\mathcal{A}$. Next it runs Step 2 to Step 12 on the left hand side of Figure 16 and passes $(PP_j)_{j \notin I}$ (see Step 12) to $\mathcal{A}$. It handles encryption and key generation queries as follows. On an encryption query $(i', x_0, x_1)$ with $i' \neq i$, the query is handled the same as $O_{\text{enc}}$ in Figure 16. On an encryption query $(i, x_0, x_1)$, a tag $T \leftarrow \{0, 1\}^c$ is sampled, then $r \leftarrow \text{PRF.Eval}(K_i^\text{punc}, j \parallel \text{EK}_i \parallel T)$, $\psi \leftarrow \text{MIFE.Enc(}E_{K_{i,j}}(x_0; r))$, and $\text{Trap} \leftarrow (\text{mode} := \text{Trap}, \psi, j, x_0, x_1)$ are computed and $B$ makes a call to the FE encryption oracle with messages $(x_0, T, K_{i,j}^\text{punc}, \text{Trap})$ and $(x_0, T, K_{i,j}^\text{punc}, \text{Trap})$, and returns the returned ciphertext. Note that the punctured key $K_{i,j}^\text{punc}$ is derived in Step 4 on the left hand side of Figure 16. Key generation queries are handled as in $O_{\text{sk}}$ in Figure 15 with one exception, namely the secret keys $SK_{\text{FE}_i}$ are computed as in $\text{GenKeys}^{m''}$ except for the case $i' = i$; the

| Figure 16 | Hybrid 5.2 |

secret key \( \mathcal{S}_{\mathcal{K}_{i}} \) is obtained by making a call to the FE key generation oracle for function \( \text{ReEnc}_{\mathcal{K}_{i}, \text{ctr}} \). If the FE challenger’s bit is 0, then \( \mathcal{B} \) perfectly simulates Hybrid 5.2, \( i = 1 \) and if the FE challenger’s bit is 1, then \( \mathcal{B} \) perfectly simulates Hybrid 5.3. \( i \).

Hybrid 5.3: In this hybrid, we switch the randomness used in the hardwired MIFE CT to be true randomness. That is, \( r_{i,j,k} \) is sampled uniformly at random for \( i \in [n], k \in [Q_{e}] \). We have by the security of the punctured PRF that given the punctured key, the PRF evaluations at the punctured points are indistinguishable from random. Hence, indistinguishability follows from security of punctured PRF.

Please see Figure 17 for the detailed description.
Hybrid 5_{i,3}:

\text{GenKeys}^{\text{mkey}}(\ell' \mid r, \text{MSK}_{\text{FE_{k}}}, k_{\text{MSK_{\text{FE_{k}}}}}) \leftarrow \text{MIFE Setup}(\ell')

\text{R}_{\ell}(i, (i_1, \ldots, i_\ell, f)

In more detail, we have a series of subhybrids, one for each \( i \not\in I \), where in Hybrid 5_{i,3}, \( i \), the change above is made to the function key associated with the FE instance for party \( i \).

Let Hybrid 5_{i,3} \( 0 \) denote Hybrid 5_{i,2} and let Hybrid 5_{j,3} |_{n \setminus I} denote Hybrid 5_{j,3}. We now give the formal reduction to PRF security for distinguishing Hybrid 5_{i,3}, \( i - 1 \) and Hybrid 5_{j,3}, \( i \) (for ease of notation, we assume that the indices \( i \) are consecutive). The simulator \( \mathcal{B} \) is defined as follows. First \( \mathcal{B} \) receives \( (1^\ast, I, (p_{\ell})_{\ell \in I}) \) from the hybrid distinguisher \( \mathcal{A} \). Next it runs

For all \( i' \not\in I, i' \neq i \):

\begin{align*}
\mathcal{B}_{\text{FE}} & \leftarrow \text{K}_{\text{FE}} \\
\mathcal{B}_{\text{PRF}} & \leftarrow \text{PRF Punct}(\mathcal{B}_{\text{FE}}, j)
\end{align*}
Then it sends a challenge prefix \( j \) to the PRF challenger and receives a punctured key; call this \( K_{i,j}^{\text{punc}} \). Next \( B \) runs steps 5 to 12 on the left hand side of Figure 17 and passes \((\text{PP}_j)_{i,j}\) (see Step 12) to \( A \). It handles encryption and key generation queries as follows. Key generation queries are handled as in \( \mathcal{O}_{\text{sg}} \) in Figure 17. On an encryption query \((i',x_0,x_1)\) with \( i' \neq i \), the query is handled the same as \( \mathcal{O}_{\text{enc}} \) in Figure 17. On an encryption query \((i,x_0,x_1)\), the query is handled the same as \( \mathcal{O}_{\text{enc}} \) in Figure 17 except Step 2 of \( \mathcal{O}_{\text{enc}} \) where \( r \) is computed. To obtain \( r \), the PRF evaluation oracle is queried at the point \( j \parallel EK_{i,j} \parallel T \) where \( T \) is derived in Step 1 of \( \mathcal{O}_{\text{enc}} \). Now if the PRF challenger’s bit is 0, the string \( r \) will be computed using the PRF and \( B \) perfectly simulates \( 5_{j,3}, i - 1 \). On the other hand, if the PRF challenger’s bit is 1, the string \( r \) will be uniformly random because the queried evaluation point begins with the challenge prefix \( j \) (i.e. the PRF is punctured at that point) and so \( B \) perfectly simulates Hybrid \( 5_{j,3}, i \).

**Hybrid 5_{j,4}:** In this Hybrid, the protocol GenKeys'''' is modified further so that for key \( j \), MIFE.Setup or MIFE.KeyGen are not invoked. Rather, the output of the MIFE.KeyGen algorithm is hardwired and output for key \( j \). The hardwired value is exactly the same as in the previous hybrid, hence indistinguishability holds by security of MPC. In more detail, the MPC simulator receives identical inputs in both hybrids and hence produces indistinguishable outputs in the two hybrids.

**Hybrid 5_{j,5}:** In this hybrid, we switch the hardwired MIFE CTs within the FE CTs to use bit \( b = 1 \). Indistinguishability follows from MIFE security. In more detail, we fix query \( j \). For party \( i \in [n] \) and ciphertext query \( k \in [Q_i] \), we construct a reduction which plays against the MIFE challenger as below. The reduction computes everything as in the previous hybrid except that the hardwired ciphertexts for the \( j^{th} \) copy of MIFE, which it receives from the MIFE challenger as below:

1. The reduction requests for MIFE key corresponding to function \( f_j \) which it receives. It hardwires this into functionality GenKeys.
2. For \( i \in [n] \), \( k \in [Q_i] \), the challenge ciphertexts for party \( i \) are set as \((x_{0,i,k}, T_{i,k}, \overrightarrow{K}_{i,j}^{\text{punc}})\) and \((x_{1,i,k}, T_{i,k}, \overrightarrow{K}_{i,j}^{\text{punc}})\).
3. The reduction receives \( \psi_{i,j,k} \) for \( i \in [n] \) and \( k \in [Q_i] \). It hardwires these into the FE ciphertexts as discussed above.

It is evident that if \( b = 0 \) then we are in Hybrid \( 5_{j,4} \) and if \( b = 1 \) we are in Hybrid \( 5_{j,5} \). Thus, an adversary that distinguishes between these two hybrids can be used to break the security of the \( j^{th} \) MIFE scheme.

Now that the bit \( b \) has been switched for query \( j \), we roll back our changes. Arguments of indistinguishability are analogous to the above and are skipped.

**Hybrid 5_{j,6}:** Change GenKeys'' to invoke MIFE.Setup and MIFE.KeyGen as before.

**Hybrid 5_{j,7}:** Switch randomness in the hardwired CT back to normal randomness.

**Hybrid 5_{j,8}:** Switch punctured PRF key back to normal PRF key.

**Hybrid 5_{j,9}:** Increment Trap.index by 1. At this point, for key \( j \), we have \( \text{ctr}_j < \text{Trap.index} \), hence by the design of the ReEnc algorithm, we have that the bit \( b = 1 \) is used for MIFE encryption. This is indistinguishable from the previous hybrid by security of FE because decryption values are exactly the same in both the hybrids.
Hybrid $5_{j+1.1}$: This Hybrid is analogous to Hybrid $5_{j.1}$. Indistinguishability follows by security of FE as discussed above. Finally, in Hybrid $5_{Q_k.9}$, all the keys are outputting MIFE CTs corresponding to $b = 1$.

Hybrid 6: In this hybrid, use message corresponding to $b = 1$ and mode $= R$. Again, indistinguishability follows by security of FE since the outputs are the same.

Hybrid 7: Undo the changes made in Hybrid 4, namely the algorithm $\text{GenKeys}''$ invoked for query index $j$ for all $j \in [Q_k]$ is modified to invoke $\text{ReEnc}$ with parameter $\text{ctr} = 1$. Indistinguishability follows analogously to the transition between Hybrid 3 and Hybrid 4.

Hybrid 8: Undo the changes made in Hybrid 3. Specifically, we generate $y$ (the target output passed to $\tilde{\text{Sim}}_2$) and $s$ (the masking value component of the partial decryption key) the same as in Hybrid 2 for each query $((i_1, \ldots, i_\ell), f)$. Indistinguishability follows analogously to the transition between Hybrid 2 and Hybrid 3.

Hybrid 9: Undo the changes made in Hybrid 2. More precisely, we replace the uniformly random strings used in the function $\text{GenKeys}$ for the honest users $i$ with the outputs of the PRF. Indistinguishability follows analogously to the transition between Hybrid 1 and Hybrid 2.

Hybrid 10: Undo the changes made in Hybrid 1, that is, we generate the first-round protocol messages $\rho^{(1)}_i$ (in the public parameters) and second-round protocol messages $\rho^{(2)}_i$ (in the partial decryption keys) for MPC as in the real system for each uncorrupted user $i / \in I$. Indistinguishability follows analogously to the transition between Hybrid 0 and Hybrid 1.

Hybrid 10 is the real world with bit $b = 1$.

E  Proof of Security for Ad Hoc MIFE for Inner Products

In this section, we provide the proof of security for our ad hoc MIFE for inner products.

Theorem 10. If the MIFE constructed by [2] is a $\text{xxx}$-IND-secure MIFE scheme and MPC is an $\text{xxx}$-SIM-secure 2-round MPC protocol, then our construction is sel-IND-secure.

Proof. The proof follows easily from the proof of theorem 5. For simplicity, we describe the proof for the case of a single key query. The case of multiple queries is handled exactly as in the proof of theorem 5. In more detail, we define:

Hybrid 0: This is the real game in which on every encryption query $(i, x_0, x_1)$, $x_0$ is encrypted.

Hybrid 1: Exactly as in the proof of theorem 5, the MPC transcript in this hybrid is simulated. Indistinguishability follows as in the proof of theorem 5.

Hybrid 2: In this hybrid, we switch the bit in the MIFE ciphertexts to 1. Indistinguishability follows via a reduction, in which the MIFE function key and ciphertexts are obtained from the MIFE challenger. The MIFE function key is input to the MPC simulator and the MPC transcript and MIFE ciphertexts are returned to the adversary.

To support multiple keys, we proceed as in the proof of theorem 5 and change the bit used in the MIFE encryption from 0 to 1 key by key.
Unexpected Power of Random Strings

Shuichi Hirahara

s_hirahara@nii.ac.jp

Abstract

There has been a line of work trying to characterize BPP (the class of languages that are solvable by efficient randomized algorithms) by efficient nonadaptive reductions to the set of Kolmogorov-random strings: Buhrman, Fortnow, Koucký, and Loff (CCC 2010 [10]) showed that every language in BPP is reducible to the set of random strings via a polynomial-time nonadaptive reduction (irrespective of the choice of a universal Turing machine used to define Kolmogorov-random strings). It was conjectured by Allender (CiE 2012 [1]) and others that their lower bound is tight when a reduction works for every universal Turing machine; i.e., “the only way to make use of random strings by a nonadaptive polynomial-time algorithm is to derandomize BPP.”

In this paper, we refute this conjecture under the plausible assumption that the exponential-time hierarchy does not collapse, by showing that the exponential-time hierarchy EXPH can be solved in exponential time by nonadaptively asking the oracle whether a string is Kolmogorov-random or not. In addition, we provide an exact characterization of $S_{2}^{exp}$ in terms of exponential-time-computable nonadaptive reductions to arbitrary dense subsets of random strings.

1 Introduction

Randomness arises everywhere in the theory of computation, and there are at least three different notions of randomness: (1) BPP, one of the most important complexity classes, is the class of languages solvable by a two-sided-error randomized polynomial-time algorithm with high probability. (2) Pseudorandom generators enable us to derandomize BPP. Its one-sided-error version is called a hitting set generator. (3) The notion of Kolmogorov complexity enables us to quantify the amount of randomness in a finite string from the perspective of compressibility. In this study, we explore the relationship existing among these different notions of “randomness” – efficient randomized algorithms, pseudorandomness, and Kolmogorov-randomness. We present the interplay among these notions of randomness, while reviewing the literature in the subsequent section.
1.1 Pseudorandomness and Kolmogorov-Randomness

The Kolmogorov complexity of a string $x$ can informally expressed as the length of the shortest program that prints $x$. More formally, the Kolmogorov complexity of $x \in \{0,1\}^*$ with respect to a Turing machine $U$ is defined as

$$K_U(x) := \min \{ |d| \mid U \text{ outputs } x \text{ on input } d \}.$$ 

We choose a “universal” Turing machine $U$ so that the Kolmogorov complexity is smallest up to an additive constant. A Turing machine $U$ is said to be universal if, for every Turing machine $M$, there exists a constant $c$ such that $K_U(x) \leq K_M(x) + c$ for every string $x \in \{0,1\}^*$. Note that there exists a universal Turing machine because one can take a Turing machine that, given an input $(M,x)$, simulates a Turing machine $M$ on input $x$.

Kolmogorov complexity enables us to define the notion of Kolmogorov-randomness. A string $x$ is said to be (Kolmogorov-)random if there exists no shorter program that prints $x$. More generally, given a threshold $s \colon \mathbb{N} \to \mathbb{N}$, we say that $x \in \{0,1\}^f$ is $s$-random if $K_U(x) \geq s(\ell)$. Throughout this paper, we fix any reasonable threshold $s$ (e.g., $s(\ell) := \ell/2$) and denote by $R_{K_U}$ the set of $s$-random strings, i.e., $R_{K_U} := \{ x \mid K_U(x) \geq s(|x|) \}$.

An important property of the set $R_{K_U}$ of random strings is that $R_{K_U}$ is an extremely powerful distinguisher for any computable hitting set generator. More specifically, there is a simple but powerful connection between pseudorandomness and Kolmogorov-randomness: Consider any “pseudorandom” string $x$ that is generated by a computable process from a short seed. By definition, the string $x$ is not Kolmogorov-random; hence $R_{K_U}$ distinguishes any pseudorandom distribution from the uniform distribution.

A function $G : \{0,1\}^{s(\ell)} \to \{0,1\}^{\ell} \ (s(\ell) < \ell)$ is called a hitting set generator secure against a class $\mathcal{C}$ if there exists no $\mathcal{C}$-algorithm $R$ that avoids $G$; here we say that $R$ avoids $G$ if $R$ rejects every string in the range of $G$, and $R$ accepts at least a half of inputs of length $\ell$. The notion of hitting set generator naturally arises when one tries to derandomize one-sided-error randomized algorithms: For instance, if there is an efficient hitting set generator of seed length $s(\ell) = O(\log \ell)$ and secure against linear-size circuits, then by exhaustively trying all the seeds of $G$, one can completely derandomize one-sided-error randomized algorithms, i.e., $\text{RP} = \text{P}$.

What can be efficiently solved by asking the oracle $R_{K_U}$, whether a string is random or not? As mentioned earlier, it is easy to observe that $R_{K_U}$ avoids any computable family of functions $G = \{G_\ell : \{0,1\}^{s(\ell) - O(\log \ell)} \to \{0,1\}^{\ell}\}_{\ell \in \mathbb{N}}$. More generally, any “dense” subset $R$ of random strings $R_{K_U}$ avoids any computable hitting set generator. (Here we say that $R \subseteq \{0,1\}^*$ is dense if $R$ contains at least a half of inputs for each input length.) By exploiting this property, a line of work exhibited the power of $R_{K_U}$ as an oracle. Allender, Buhrman, Koucký, van Melkebeek, and Ronneburger [5] proved that $\text{PSPACE} \subseteq \text{P}^{R_{K_U}}$. Allender, Buhrman, Koucký [4] showed that $\text{NEXP} \subseteq \text{NP}^{R_{K_U}}$. In the case of nonadaptive reductions, Buhrman, Fortnow, Koucký, and Loff [10] showed that $\text{BPP} \subseteq \text{P}^{R_{K_U}}$, where $\text{P}^{R_{K_U}}$ denotes the class of languages solvable in polynomial time with nonadaptive oracle access to $R_{K_U}$. Here, a reduction is said to be nonadaptive (also known as a truth-table or parallel-query reduction) if the queries of the reduction do not depend on previous answers from the oracle.

---

1. Specifically, for every $\ell \in \mathbb{N}$ and seed $z \in \{0,1\}^{s(\ell) - O(\log \ell)}$, the Kolmogorov complexity of $G_\ell(z)$ is less than $s(\ell)$, thus $G_\ell(z) \notin R_{K_U}$. On the other hand, a simple counting argument shows that $|R_{K_U} \cap \{0,1\}^\ell| \geq 2^{\ell-1}$ for every $\ell$.

2. The subscript $\parallel$ stands for parallel queries.
1.2 BPP and Kolmogorov-Randomness

Kolmogorov-randomness and BPP originated from different disciplines. The notion of Kolmogorov-randomness usually sits within the realm of computability theory as \( R_{K_U} \) is not computable, whereas complexity theory deals with efficient computations, such as BPP. In particular, it is obvious that there is no computable upper bound on the class \( P^R_{K_U} \), since \( R_{K_U} \) itself is not computable.

Nevertheless, a surprising interdisciplinary connection between complexity classes and Kolmogorov-random strings has been uncovered in the line of work (e.g., [4, 7, 13]). When a reduction works no matter which universal Turing machine \( U \) is used in the definition of \( R_{K_U} \), a computable upper bound can be obtained. Cai, Downey, Epstein, Lempp, and Miller [13] showed that a language reducible to \( R_{K_U} \) for every prefix-free universal Turing machine \( U \) is computable; Allender, Friedman, and Gasarch [7] showed that any computable language \( L \) that reduces to \( R_{K_U} \) for every prefix-free universal Turing machine \( U \) via a polynomial-time nonadaptive reduction is in PSPACE. Therefore:

\[ \textbf{Theorem 1} ([10, 7, 13]). \]

\[ \text{BPP} \subseteq \bigcap_U P^R_{K_U} \subseteq \text{PSPACE}, \]

where the intersection is taken over all prefix-free universal Turing machines \( U \).

For some technical reasons, the upper bounds of [7, 13] are known to hold only for “prefix-free” universal Turing machines. A similar upper bound can be obtained for plain universal Turing machines by imposing a super-constant minimum query length restriction on reductions (cf. Hirahara and Kawamura [16]). Thus, we herein focus on (plain) universal Turing machines for the sake of simplicity.

At this point, a natural question arises: What is the exact computational power of \( R_{K_U} \) under polynomial-time nonadaptive reductions? Intuitively, any polynomial-time nonadaptive reduction cannot make any use of the set of Kolmogorov-random strings of length larger than \( O(\log n) \) because the Kolmogorov complexity of any query that the reduction can make on input \( 1^n \) is at most \( O(\log n) \). It was argued in [3] that, intuitively, short queries to Kolmogorov-random strings would only be used as a source of pseudorandomness. Allender [1] thus conjectured that the lower bound of Theorem 1 is exactly tight, and then a fair amount of effort has been made to verify the conjecture.

\[ \textbf{Conjecture 2} ([10, 1, 6, 3, 16]). \text{BPP} = \bigcap_U P^R_{K_U}, \text{ where the intersection is taken over all universal Turing machines}. \]

Beyond its curiosity, such a characterization of BPP might make it possible to study BPP by using the techniques from computability theory, and could be a completely new approach for resolving the P = BPP conjecture (as speculated in [1, 6]). Moreover, Conjecture 2 is interesting from the viewpoint of the study of the Minimum Circuit Size Problem (MCSP [20]). In some technical sense, Kolmogorov complexity can be seen as the minimum size of a circuit with oracle access to the halting problem (cf. [5]); thus \( R_{K_U} \) can be regarded as a computability-theoretic analogue of MCSP. In the light of this, Conjecture 2 states non-NP-hardness of \( R_{K_U} \) under nonadaptive polynomial-time reductions (unless \( \text{NP} \subseteq \text{BPP} \)), and thus would make it possible to obtain some new insights about NP-hardness of MCSP, which has been the focus of many recent studies on MCSP (e.g. [22, 17, 18, 9, 8]).

The “evidence” in favor of Conjecture 2 seemed to be piling up, by considering various restrictions on the reductions. For example, Allender, Buhrman, Koucký [4] showed that conjunctive nonadaptive reductions from computable languages to \( R_{K_U} \) can be simulated.
in P; Hirahara and Kawamura [16] showed that some restricted variant of $\bigcap_U P_{R^K_U}$ lies between BPP and $\Sigma^P_2 \cap \Pi^P_2 \cap P/poly$. We refer interested readers to the survey of Allender [2] for detailed background on MCSP and $R_{K_U}$.

1.3 Our Results: Unexpected Power of Random Strings

In this work, we disprove Conjecture 2 under the plausible assumption that the exponential-time hierarchy does not collapse to $\text{BPEXP}$, by presenting unexpected power of $R_{K_U}$. Not only do we disprove Conjecture 2 itself, but also argue that the intuition of [3] is not correct.

Our main new insight is to consider a tally language in $\bigcap_U P_{1^{R^K_U}}$. Recall that the intuition behind Conjecture 2 is that

1. On input $1^n$, any long query $q$ to $R_{K_U}$ is answered as “No,” since a nonadaptive polynomial-time machine cannot make any query whose Kolmogorov complexity is larger than $O(\log n)$, and that

2. Any query of length $O(\log n)$ should be useful only as a source of “pseudorandomness” [3].

We interpret this as follows: Short queries to $R_{K_U}$ should be replaceable with queries to any oracle $R$ that avoids any computable hitting set generator (i.e., $R$ is a dense subset of random strings).

In order to closely examine these intuitions, let us focus on tally languages $L \subseteq \{0,1\}^*$. By a standard padding argument, this is essentially equivalent to considering an exponential-time analogue of Conjecture 2. More specifically, if Conjecture 2 is true, then a padding argument shows that

$$\text{BPEXP} = \bigcap_U \Exp^{R_{K_U}}_U$$

is also true. In order to examine the latter intuition, we also focus on an arbitrary oracle $R$ that avoids $U$. Specifically, Conjecture 2 implies that the subclass $\bigcap_R \Exp^R_1$ of $\bigcap_U \Exp^{R_{K_U}}_U$ is also contained in $\text{BPEXP}$, i.e.,

$$\bigcap_R \Exp^R_1 \subseteq \text{BPEXP},$$

where the intersection is taken over all dense subsets $R$ of random strings; thus, we first study the subclass $\bigcap_R \Exp^R_1$.

We completely settle what can be solved by a nonadaptive exponential-time reduction to dense subsets $R$ of random strings.

▶ Theorem 3 (Characterizing $S^\exp_2$ Using Efficient Reductions to Dense Subsets of Random Strings). For any universal Turing machine $U$, it holds that

$$S^\exp_2 = \bigcap_R \Exp^R_1,$$

where the intersection is taken over all the dense subsets $R$ of $R_{K_U}$. (The condition of $R$ can be equivalently stated as follows: $R$ avoids a universal Turing machine $U$ regarded as a family of functions $U \equiv \{U_\ell: \{0,1\}^{\ell(\ell)} \to \{0,1\}^{\ell}\}_{\ell \in \mathbb{N}}$.)

3 Some unpublished results mentioned there are included in this paper.

4 In fact, this padding argument together with [4] already shows that Conjecture 2 is false unless $\text{NEXP} \subseteq \text{BPEXP}$, which was completely overlooked before this work. Our results significantly weaken the hypothesis.
Here $S_2^{\text{exp}}$ represents an exponential-time analogue of $S_2^p$ (the second level of the symmetric hierarchy [23, 14]), and is the class of languages which admit a “competing-two-prover” system: an exponential-time verifier must compute the correct answer when one of the provers presents a correct certificate.

Theorem 3 improves the result of [10] (conjectured to be tight) in two ways: First, it is known that $\text{BPEXP} \subseteq S_2^{\text{exp}}$, and the inclusion is likely to be proper (e.g., note that $\text{NEXP} \subseteq \text{EXP}^{\text{NP}} \subseteq S_2^{\text{exp}}$ [23]); thus, Theorem 3 refutes Conjecture 2 unless $S_2^{\text{exp}} \subseteq \text{BPEXP}$.

Second, unlike the proof of [10], our proof does not exploit any specific property of $R_KU$; we only rely on the pseudorandomness property of $R_KU$ (i.e., the property that $R_KU$ is a distinguisher for any computable hitting set generator).

It is also worthy of note that our $S_2^{\text{exp}}$ upper bound of Theorem 3 significantly improves the previous EXPSPACE upper bound of Allender, Friedman, and Gasarch [7]: They proved $\bigcap_i \text{EXP} \subseteq \text{EXPSPACE}$ as a corollary of their PSPACE upper bound of Theorem 1.

Let us take a look at the original conjecture again. In Conjecture 2, we are allowed to exploit a property of $R_KU$, instead of just a property that an oracle avoids a computable hitting set generator. In this case, it is possible to reduce the entire exponential-time hierarchy to $R_KU$ via a nonadaptive exponential-time reduction, or even more efficiently, via a PH-Turing reduction.

**Theorem 4.** For every universal Turing machine $U$,

$$\text{EXPH} \subseteq \text{PH}^{R_KU} \subseteq \text{EXP}^{R_KU}.$$  

Theorem 4 shows that the class $\bigcap_i \text{EXP}^{R_KU}$ is much closer to the EXPSPACE upper bound of [7] than previously conjectured. To be specific, it implies that Conjecture 2 is false unless $\text{EXPH} \subseteq \text{BPEXP}$.

### 1.4 Proof Ideas

We briefly mention our proof techniques for proving the lower bounds of Theorem 3 and Theorem 4. It is known that the halting problem is reducible to dense subsets $R$ of random strings via a nonuniform polynomial-time reduction [5]. Therefore, by exhaustively searching polynomial-size $R$-oracle circuits (in exponential time), we can find a “succinct witness” for $S_2^{\text{exp}}$, whose correctness can be verified in exponential time. In order to extend this argument to EXPH, recall that EXPH can be regarded as a constant-round two-player game whose winner can be computed in exponential time. A winning strategy of round $k + 1$ must depend on previous strategies ($R_KU$-oracle circuits) of rounds $1, \cdots, k$. Using the fact that an $R_KU$-oracle circuit can be evaluated with oracle access to the halting problem, it can be argued that there exists a polynomial-size $R$-oracle circuit which encodes a winning strategy for round $k + 1$.

In order to prove the $S_2^{\text{exp}}$ upper bound of Theorem 3, we simulate an exponential-time reduction $M$ by an $S_2^{\text{exp}}$ algorithm as follows: The $i$th competing prover sends a set $\bar{R}_i$ for each $i \in \{1, 2\}$; the honest prover sends the set $\{0, 1\}^* \setminus R_KU$ of nonrandom strings. While we cannot know which of $\bar{R}_1$ or $\bar{R}_2$ is correct, $\{0, 1\}^* \setminus (\bar{R}_1 \cup \bar{R}_2)$ is guaranteed to be a dense subset of $R_KU$, to which the reduction $M$ works correctly.

The rest of this paper is organized as follows. After reviewing some background in Section 2, Theorem 3 is proved in Section 3. Theorem 4 is proved in Section 4. In Appendix A, the EXP$_1$ reduction of Theorem 3 is improved.
2 Preliminaries

We identify a language \( L \subseteq \{0,1\}^* \) with its characteristic function \( L: \{0,1\}^* \rightarrow \{0,1\} \). Let \( [n] := \{1, \ldots, n\} \) for \( n \in \mathbb{N} \). We say that \( R \subseteq \{0,1\}^n \) is dense if \( |R \cap \{0,1\}^n| \geq 2^{n-1} \) for every \( n \in \mathbb{N} \). For a Boolean function \( f: \{0,1\}^n \rightarrow \{0,1\} \), we denote by \( \mathbf{tt}(f) \) the truth table of \( f \), i.e., the concatenation of \( f(x) \) for all \( x \in \{0,1\}^n \) in the lexicographical order. We often identify a Boolean circuit \( C \) with the function computed by \( C \).

2.1 On the Threshold of Kolmogorov-Random Strings

Recall that a string \( x \in \{0,1\}^* \) is said to be \( s(-) \)-random if \( K_U(x) \geq s(|x|) \). Throughout this paper, we fix any reasonable threshold \( s(-) \) of randomness so that there exists a universal constant \( c > 0 \) satisfying \( n^c \leq s(n) \leq n - 2 \) for any \( n \in \mathbb{N} \), and denote by \( R_{K_U} \) the set of \( s(-) \)-random strings, i.e., \( R_{K_U} := \{ x \in \{0,1\}^* \mid K_U(x) \geq s(|x|) \} \). The upper bound of the threshold is for assuming that the set of random strings is sufficiently dense:

► Fact 5. \(|\{0,1\}^n \setminus R_{K_U} \| \leq 2^{n-2} \) for any \( n \in \mathbb{N} \).

Proof. The number of nonrandom strings is bounded by the number of programs of length less than \( s(n) \), which is at most \( \sum_{i=0}^{s(n)} 2^i \leq 2^{s(n)} \leq 2^{n-2} \). ▶

2.2 Symmetric Alternation

\( S^0 \) denotes the class of languages that admit a competing-two-prover system. More formally:

► Definition 6 ([14, 23]). \( S^0 \) is the class of languages \( L \) such that there exist a polynomial \( p(n) = n^{O(1)} \) and a polynomial-time algorithm \( V \) such that, for every input \( x \in \{0,1\}^* \),

1. \( \exists y \in \{0,1\}^{p(|x|)}, \forall z \in \{0,1\}^{p(|x|)}, V(x, y, z) = L(x) \), and

2. \( \exists z \in \{0,1\}^{p(|x|)}, \forall y \in \{0,1\}^{p(|x|)}, V(x, y, z) = L(x) \).

\( S_2^{\text{exp}} \) is an exponential-time analogue of \( S^0 \): the definition of \( S_2^{\text{exp}} \) is obtained by allowing \( p(n) \) to be exponential in the definition above (i.e., \( p(n) = 2^{n^{O(1)}} \)). For an oracle \( A \), the relativized version of \( S^0 \) is denoted by \( S^0_A \); that is, \( S^0_A \) is the class of languages that admit a competing-two-prover system with a polynomial-time \( A \)-oracle verifier.

2.3 Exponential-Time Hierarchy

\( \text{EXPH} \) denotes the exponential-time analogue of the polynomial-time hierarchy (PH). That is, a language \( L \) is in \( \text{EXPH} \) if and only if there exist a constant \( k \), an exponential bound \( e(n) = 2^{n^{O(1)}} \) and a polynomial-time algorithm \( M \) such that, for every input \( x \in \{0,1\}^* \),

\[
L \iff \exists y_1, \forall y_2, \exists y_3, \forall y_4, \cdots, \exists y_k, M(x, y_1, \cdots, y_k) = 1,
\]

where \( y_i \in \{0,1\}^{e(n)} \) for any \( i \in [k] \).

---

5 We follow the definition of Canetti [14], which is equivalent to the definition of [23] (cf. [11]).
3 Reducions to Dense Subsets of Random Strings

In this section, we give the characterization of $S_2^{\text{exp}}$ by exponential-time nonadaptive reductions to arbitrary dense subsets of random strings.

- **Reminder of Theorem 3.** Fix any universal Turing machine $U$.
  - Lower bound: $S_2^{\text{exp}} \subseteq \text{EXP}_i^R$ for any dense subset $R$ of $R_{K_U}$.
  - Upper bound: $\{ L \subseteq \{0,1\}^* \mid L \in \text{EXP}_i^R \text{ for every dense } R \subseteq R_{K_U} \} \subseteq S_2^{\text{exp}}$.

3.1 Lower Bound

In order to prove the lower bound on the complexity class $\bigcap_R \text{EXP}_i^R$, we use the fact that the halting problem $\text{HALT}$ is reducible to any dense subset of random strings via a polynomial-size oracle circuit. The halting problem $\text{HALT}$ is the problem of deciding whether a Turing machine $M$ halts.

- **Theorem 7 ([5]).** $\text{HALT} \in \text{P}^R/\text{poly}$ for any dense subset $R$ of random strings.

**Proof Sketch.** It was shown in [5, Corollary 32] that $\text{HALT}$ is reducible to $R_{K_U}$ via a nonadaptive $\text{P}/\text{poly}$ reduction. The proof only uses the fact that $R_{K_U}$ is a distinguisher for some hitting set generator; thus $\text{HALT}$ is also reducible to any dense subset $R$ of random strings.

**Proof of the Lower Bound of Theorem 3.** Let $L \in S_2^{\text{exp}}$ and $V$ be a polynomial-time verifier associated with $L$ that takes certificates of length $c(n) = 2^{n^{O(1)}}$ on inputs of length $n$. We claim that $L \in \text{EXP}_i^R$ for every dense subset $R$ of random strings. Our $\text{EXP}_i^R$ algorithm $M$ exhaustively searches “succinct witnesses”, i.e., circuits that encode a correct certificate.

Specifically, for some polynomial $q(n)$ that is chosen later, let $C_n$ be the set of all the $q(n)$-size log $e(n)$-input oracle circuit. On input $x \in \{0,1\}^*$, the algorithm $M$ exhaustively searches all the circuits $Y, Z \in C_n$ and accepts if and only if there exists an oracle circuit $Y \in C_n$ such that, for every oracle circuit $Z \in C_n$, $V(x, \text{tt}(Y^R), \text{tt}(Z^R))$ accepts. Since the number $|C_n|$ of polynomial-size oracle circuits is at most exponential in $n$, $M$ halts in exponential time. Moreover, $M$ is a nonadaptive reduction to $R$ because the length of any query is bounded by some polynomial $q(n)$ (thus, in exponential time, one can ask every possible query beforehand).

We claim the correctness of $M$. By the definition of $S_2^{\text{exp}}$, for any input $x \in \{0,1\}^*$,

1. if $x \in L$, there exists a certificate $y \in \{0,1\}^{c(n)}$ such that $V(x,y,z) = 1$ for every $z \in \{0,1\}^{c(n)}$, and
2. if $x \not\in L$, there exists a certificate $z \in \{0,1\}^{c(n)}$ such that $V(x,y,z) = 0$ for every $y \in \{0,1\}^{c(n)}$.

Consider the function $\eta$ that maps $(x,i)$ to the $i$th bit of the lexicographically first certificate $y \in \{0,1\}^{c(|x|)}$ such that $V(x,y,z) = 1$ for every $z \in \{0,1\}^{c(|x|)}$ (if exists), where $i \in \{0,1\}^{\log c(|x|)}$. Since $\eta$ is computable, by Theorem 7, there exists a polynomial-size oracle circuit $Y''$ such that $Y''(x,i) = \eta(x,i)$ for any $(x,i)$. Therefore, for every input $x \in L$, by fixing $x$ we obtain a polynomial-size circuit $Y_x := Y''(x,\cdot)$ such that $V(x,\text{tt}(Y_x^R),z) = 1$ for every $z$. By choosing the bound $q(n)$ large enough, we obtain $Y_x \in C$, and thus the algorithm $M$ accepts. Similarly, one can prove that, for every input $x \not\in L$, there exists a circuit $Z_x \in C$ such that $V(x,y,\text{tt}(Z_x^R)) = 0$ for every $y$. 

\[ \square \]
3.2 Upper Bound

Next, we prove the $S_2^\text{exp}$ upper bound on $\bigcap_R \text{Exp}^R$. Take an arbitrary language $L \in \bigcap_R \text{Exp}^R$. This means that, for every dense subset $R$ of random strings, there exists an exponential-time oracle machine $M_R$ such that $M_R$ solves $L$ given oracle access to $R$. That is, the reduction $M_R$ is allowed to depend on the oracle $R$, which makes it hard to simulate the reduction. We first show, by using a diagonalization argument, that there exists a single machine that works for every oracle $R$.

Lemma 8. For any language $L$, the following are equivalent:
1. $L \in \bigcap_R \text{Exp}^R$, where the intersection is taken over all dense subsets $R$ of $R_{K_U}$.
2. There exists an exponential-time nonadaptive oracle machine $M$ such that, for every dense subset $R$ of $R_{K_U}$, for every input $x \in \{0,1\}^*$, $M^R(x) = L(x)$.

Proof. The direction from the second item to the first item is obvious. We prove below the contrapositive of the other direction.

Suppose that, for any exponential-time nonadaptive oracle machine $M$, there exists a dense subset $R$ of $R_{K_U}$ such that $M^R(x) \neq L(x)$ for some $x \in \{0,1\}^*$. We claim that there exists a single dense subset $R \subseteq R_{K_U}$ such that $L \not\in \text{Exp}^R$.

To this end, let $\{M_e\}_{e \in \mathbb{N}}$ be the enumeration of all exponential-time nonadaptive oracle machines. We will construct some dense subset $R_e \subseteq R_{K_U}$ and input $x_e$ (and $\ell_e \in \mathbb{N}$) by induction on $e \in \mathbb{N}$, so that $M_e$ fails to compute $L$ on input $x_e$, given oracle access to $R_{e+1}$; then we will define $R := \bigcup_{e \in \mathbb{N}} R_e$. Let us start with $R_0 := \emptyset$ and $\ell_0 := 0$.

At stage $e \in \mathbb{N}$, we claim that there exists some dense subset $R_{e+1} \subseteq R_{K_U}$ and some input $x_e \in \{0,1\}^*$ such that

1. $M_e^{R_{e+1}}(x_e) \neq L(x_e)$, and
2. $q \in R_e$ if and only if $q \in R_{e+1}$ for any string $q$ of length $< \ell_e$.

Indeed, for any oracle $Q$, let $Q' := \{ q \in Q \mid |q| \geq \ell_e \} \cup \{ q \in R_e \mid |q| < \ell_e \}$. Consider an exponential-time nonadaptive oracle machine $M_e'$ such that $M_e'^Q$ simulates $M_e^Q$; that is, $M_e'$ is hardwired with the set $\{ q \in R_e \mid |q| < \ell_e \}$, and simulates $M_e$ and answer any query $q$ of length $< \ell_e$ by using the hardwired information. By our assumption, there exists some dense subset $R_{e+1} \subseteq R_{K_U}$ such that $M_e'^{R_{e+1}}(x_e) \neq L(x_e)$ for some $x_e \in \{0,1\}^*$; by the definition of $M_e'$, we obtain $M_e^{R_{e+1}}(x_e) \neq L(x_e)$ for $R_{e+1} := \{ q \in R_{e+1} \mid |q| \geq \ell_e \} \cup \{ q \in R_e \mid |q| < \ell_e \}$, which is again a dense subset of $R_{K_U}$. This completes the proof of the claim above. Now define $\ell_{e+1} \in \mathbb{N}$ as a large enough integer so that $\ell_{e+1} \geq \ell_e$ and the machine $M_e$ on input $x_e$ does not query any string of length $\geq \ell_{e+1}$, and define an oracle $R_{e+1} := \{ q \in R_{e+1} \mid |q| < \ell_{e+1} \}$, which completes the construction of stage $e \in \mathbb{N}$.

Define $R := \bigcup_{e \in \mathbb{N}} R_e$, which is a dense subset of $R_{K_U}$ by the construction above. By the choice of $(\ell_e)_{e \in \mathbb{N}}$, we have

$$M_e^R(x_e) = M_e^{R_{e+1}}(x_e) \neq L(x_e),$$

for every exponential-time nonadaptive oracle machine $M_e$. Thus $L \not\in \text{Exp}^R$. □

We are ready to present the $S_2^\text{exp}$ algorithm that simulates an exponential-time nonadaptive reduction to dense subsets of random strings, which completes the proof of Theorem 3.

Proof of the Upper Bound of Theorem 3. Take any language $L \in \bigcap_R \text{Exp}^R$. By Lemma 8, there exists an exponential-time nonadaptive oracle machine $M$ such that, for every dense subset $R$ of $R_{K_U}$, for every input $x \in \{0,1\}^*$, $M^R(x) = L(x)$. Our goal is to simulate $M$ in $S_2^\text{exp}$. 

First, we can assume, without loss of generality, that the length of any query that \( M \) makes on input \( x \) is bounded by some polynomial \( |x|^{O(1)} \). Indeed, since \( M \) is a nonadaptive reduction, the set of all the queries \( Q(x) \) that \( M \) makes on input \( x \) can be computed in exponential time; thus, for each query \( q \in Q(x) \), its Kolmogorov complexity \( K_U(q) \) is at most \( |x| + \log |Q(x)| + O(1) \leq |x|^{O(1)} \), since \( q \) is described by \( x \) and the index of \( q \) in \( Q(x) \). Therefore, for any query \( q \) whose length is larger than \( |x|^{O(1)} \), the answer from the oracle \( R \) is \("No" because \( q \notin \bar{R}_K \) \( \supseteq R \).\

Now we present an \( S_2^{\text{EXP}} \) algorithm that simulate \( M \). The idea is that two competing provers send the set of nonrandom strings. Given two possible sets of nonrandom strings \( R_1, R_2 \subseteq \{0,1\}^* \) (one of which is guaranteed to be correct), \( R := \{0,1\}^* \setminus (R_0 \cup R_1) \) is a subset of \( \bar{R}_K \). Moreover, since the number of nonrandom strings is small, the set \( R \) is dense enough. Details follow.

Let \( p(n) \) be a polynomial that upper-bounds the length of any query that \( M \) makes on inputs of length \( n \). Our \( S_2^{\text{EXP}} \) algorithm operates as follows: Fix any input \( x \) of length \( n \). The \( i \)th prover \((i \in \{1,2\})\) sends, for each \( \ell \leq p(n) \), a subset \( R_{i,\ell} \subseteq \{0,1\}^\ell \) of size at most \( 2^{\ell-2} \); an honest prover sets \( R_{i,\ell} := \{0,1\}^\ell \setminus \bar{R}_K \). Define \( R_i := \bigcup_{\ell \leq p(n)} R_{i,\ell} \). Note that such subsets can be encoded as a string of exponential length. The verifier sets \( \ell \) and accepts if and only if \( M(x) \) accepts.

We claim the correctness of the \( S_2^{\text{EXP}} \) algorithm. Assume that the \( i \)th prover is honest. For each length \( \ell \leq p(n) \) and \( i \in \{1,2\} \), we assumed that \( |R_{i,\ell}| \leq 2^{\ell-2} \); thus \( |R_i| \leq 2^{\ell-1} \), from which it follows that \( R \) is dense. Moreover, since the number of nonrandom strings of length \( \ell \) is at most \( 2^{\ell-2} \) (Fact 5)\(^5\), the \( i \)th prover can set \( R_{i,\ell} := \{0,1\}^\ell \setminus \bar{R}_K \). Define \( R' := \{q < R \mid ||q|| \leq p(n)\} \cup \{q \in \bar{R}_K \mid ||q|| > p(n)\} \). Then, from the argument above, \( R' \) is a dense subset of \( \bar{R}_K \), and hence \( M^{R'}(x) = L(x) \). Since \( M \) does not make any query of length \( > p(n) \), it follows that \( M^{R}(x) = M^{R'}(x) = L(x) \).

In Appendix A, we will mention that the reducibility notion of Theorem 3 can be significantly improved from \( \text{EXP} \) to \( S_2^{\text{EXP}} \) (at the cost of a slight loss in the lower bound).

## 4 The Unexpected Power of Kolmogorov-Random Strings

In this section, we show that every language in the exponential-time hierarchy is reducible to the set of Kolmogorov-random strings under \( \text{PH} \) reductions.

\begin{itemize}
  \item \textbf{Reminder of Theorem 4.} For every universal Turing machine \( U \),
  \[ \text{EXPH} \subseteq \text{PH}^{R_K} \, . \]
\end{itemize}

For the purpose of refuting Allender’s conjecture (Conjecture 2), it is enough to show the weaker statement that \( \text{EXPH} \subseteq \text{EXP} \, ^{R_K} \). Indeed, we observe that a simple padding argument essentially refutes Conjecture 2:

\begin{itemize}
  \item \textbf{Corollary 9.} \text{BPP} \neq \bigcap_U \text{P}^{R_K} \text{ unless } \text{EXPH} \subseteq \text{BPEXP}, \text{ where the intersection is taken over all universal Turing machines.}
\end{itemize}

\begin{proof}
Assume that \( \bigcap_U \text{P}^{R_K} \subseteq \text{BPP} \). Then by the standard padding argument, we also obtain \( \bigcap_U \text{EXP}^{R_K} \subseteq \text{BPEXP} \). (Specifically, take any language \( L \in \bigcap_U \text{EXP}^{R_K} \), and define a padded version \( L' := \{x0^{2^{\text{exp}(\text{size})}} \mid x \in L\} \) for some large enough polynomial \( p \) so that \( L' \in \bigcap_U \text{P}^{R_K} \). By the assumption, we have \( L' \in \text{BPP} \), which implies that \( L \in \text{BPEXP} \).) It follows from Theorem 4 that \( \text{EXPH} \subseteq \bigcap_U \text{EXP}^{R_K} \subseteq \text{BPEXP} \).
\end{proof}

\( ^5 \) This is because of our choice of the threshold for Kolmogorov-randomness.
Now we proceed to a proof of Theorem 4. We first observe that any language computable with oracle access to HALT is in $P^{\text{HALT}}$.

**Lemma 10.** Let $M$ be any oracle machine that, on inputs of length $n$, halts in finite steps and makes a query of length at most $n^{O(1)}$. Then the language decided by $M^{\text{HALT}}$ is in $P^{\text{HALT}}$.

**Proof Sketch.** The proof is essentially the same with [5, Theorem 27], and thus we just give a proof sketch. The idea is to decide $M^{\text{HALT}}$ in the following two steps: First, by using a binary search and oracle access to HALT, one can decide the number of all the strings in HALT of length at most $n^{O(1)}$ in polynomial time. Then, given as advice the number of strings in HALT of length at most $n^{O(1)}$, the computation of $M^{\text{HALT}}$ becomes now computable, and hence it reduces to HALT.

While the ingredients above are enough to obtain EXP reductions, in order to obtain PH reductions, we make use of the efficient proof system of PH given by Kiwi, Lund, Spielman, Russell, and Sundaram [21]. For simplicity, we state their results in the case of the number of alternation is 2, but their results hold for every constant number of alternation. We also state their results in terms of $\Sigma_2^{\text{EXP}}$ instead of $\Sigma_2^P$.

**Theorem 11 (Kiwi, Lund, Spielman, Russell, and Sundaram [21]).** For every language $L$ in $\Sigma_2^{\text{EXP}}$, there exists a randomized polynomial-time verifier such that,

1. for every input $x \in L$, there exists an oracle $A$ such that for any oracle $B$, $V^{A,B}(x)$ accepts with probability 1, and
2. for every input $x \notin L$, for all oracles $A$, there exists an oracle $B$, $V^{A,B}(x)$ accepts with probability at most $\frac{1}{2}$.

We are now ready to present a proof of Theorem 4.

**Proof of Theorem 4.** The main idea is that, given oracle access to the set of random strings, Theorem 7 tells us that there is a “succinct witness” for any exponential-time computation. However, unlike the proof of Theorem 3, here we need to claim that there exists a succinct witness that encodes some winning strategy of two player games, which may depend on a $R_{K_i}$-oracle circuit that encodes the opponent’s strategy. For simplicity, we will only give a detailed proof for $\Sigma_2^{\text{EXP}} \subseteq \text{PH}^{R_{K_2}}$, since it is straightforward to extend the proof.

First, we present a proof of $\Sigma_2^{\text{EXP}} \subseteq \text{EXP}^{R_{K_2}}$. Let $V$ be a polynomial-time verifier for $L \in \Sigma_2^{\text{EXP}}$, and $e(n) = 2^{n^{O(1)}}$ be an exponential bound such that for every input $x$ of length $n$, it holds that $x \in L$ if and only if there exists a certificate $y$ of length $e(n)$ such that $V(x, y)$ accepts for all $z$ of length $e(n)$; Note that $V$ runs in time $2^{e(n)}$. We regard the computation as a game between the first player $y$ and the second player $z$.

Our $\text{EXP}^{R_{K_2}}$ algorithm operates as follows: Let $s_y(n)$ and $s_z(n)$ be some polynomials specified later. Given input $x$ of length $n$, the algorithm accepts if and only if there exists an oracle circuit $Y$ of size $s_y(n)$ such that $V(x, \text{tt}(Y^{R_{K_2}}), \text{tt}(Z^{R_{K_2}}))$ accepts for all oracle circuits $Z$ of size $s_z(n)$, where $\text{tt}(Y^{R_{K_2}})$ denotes the truth table of the function computed by $Y^{R_{K_2}}$; the algorithm checks this condition by an exhaustive search. Since there are at most exponentially many circuits of polynomial size, this algorithm runs in exponential time.

We claim the correctness of the algorithm. Fix any input $x \in L$ of length $n$. In this case, the correctness readily follows from the fact that there exists a succinct witness under the oracle $R_{K_i}$: Indeed, let $y_x$ be the lexicographically first certificate for $x \in L$. Since each bit of $y_x$ is decidable (in the sense that the language $\{(x,i) \mid 	ext{the i}^{\text{th}} \text{bit of } y_x \text{ is } 1\}$ is decidable), by Theorem 7, there exists an oracle circuit $Y$ of size $s_y(n) := \text{poly}(n, \log |y_x|) = \text{poly}(n)$ such that $\text{tt}(Y^{R_{K_2}}) = y_x$. Thus $V(x, y_x, \text{tt}(Z^{R_{K_2}}))$ accepts no matter how the adversarial circuit $Z$ is chosen.
Now fix any input $x \notin L$ of length $n$. This case requires a more delicate argument. Here we need to claim that, for every circuit $Y$ of size $s_Y(n)$, there exists a circuit $Z$ that encodes a strategy that beats the strategy of $tt(Y^{RK_U})$. The point is that, given any circuit $Y$, the lexicographically first winning strategy of the second player is computable with oracle access to $\text{HALT}$. Indeed, let $z_{x,Y}$ denote the lexicographically first string such that $V(x, tt(Y^{RK_U}), z)$ rejects. Consider the language $L' := \{ (x,Y,i) \mid \text{the } i\text{th bit of } z_{x,Y} = 1 \}$. Since $RK_U$ is reducible to $\text{HALT}$, the language $L'$ is computable with oracle access to $\text{HALT}$. By Lemma 10, $L' \in \text{P}^{\text{HALT}}$; thus by Theorem 7, we obtain $L' \in \text{P}^{RK_U}/\text{poly}$. This means that for every circuit $Y$ there exists a circuit $Z_Y$ of size $s_Z(n) := \text{poly}(n, |Y|, \log |z_{x,Y}|) = \text{poly}(n, s_Y(n))$ such that $\text{tt}(Z_Y^{RK_U}) = z_{x,Y}$. Thus, our algorithm rejects. This completes the proof of $\Sigma_2^{\text{EXP}} \subseteq \text{EXP}^{RK_U}$.

In order to extend the proof above to $\Sigma_k^{\text{EXP}}$ for every constant $k$, we modify the $\text{EXP}^{RK_U}$ algorithm so that it checks, given input $x$ of length $n$, whether $\exists$ a circuit $C_1$ of size $s_1(n)$, $\forall$ a circuit $C_2$ of size $s_2(n)$, $\cdots$, $\forall$ a circuit $C_k$ of size $s_k(n)$ such that a verifier $V(x, tt(C_1^{RK_U}), \cdots, tt(C_k^{RK_U}))$ accepts, where $s_1(n), \cdots, s_k(n)$ are some appropriately chosen polynomials.

We now explain how to reduce the complexity of the $\text{EXP}$ reduction to $\text{PH}$. For simplicity, we again focus on a proof of $\Sigma_2^{\text{EXP}} \subseteq \text{PH}^{RK_U}$. Note that, in the proof above, the bottleneck of the computation is the evaluation of $V(x, tt(Y^{RK_U}), tt(Z^{RK_U}))$, where $V$ runs in time $2^{2^{\log^2(n)}}$. We replace $V$ with the randomized polynomial-time verifier of Theorem 11; then we obtain the following $\Sigma_2^{RK_U}$ algorithm: Existentially guess a circuit $Y$ of size at most $s_Y(n)$, and universally guess a circuit $Z$ of size at most $s_Z(n)$ as well as a coin flip for $V$. Then accept if and only if $V^Y,Z(x)$ accepts on the guessed coin flip sequence. ▶

A Improving the Complexity of the Reductions

In this appendix, we mention that the reducibility notion of Theorem 3 can be significantly improved by using the efficient proof system of [15]:

**Theorem 12.** For any universal Turing machine $U$,

$$\text{EXP}^{NP} \subseteq \bigcap_R S^2_R \subseteq S^2_{\text{exp}},$$

where the intersection is taken over all the dense subsets $R$ of $R_{K_U}$.  

A Improving the Complexity of the Reductions

In this appendix, we mention that the reducibility notion of Theorem 3 can be significantly improved by using the efficient proof system of [15]:

**Theorem 12.** For any universal Turing machine $U$,

$$\text{EXP}^{NP} \subseteq \bigcap_R S^2_R \subseteq S^2_{\text{exp}},$$

where the intersection is taken over all the dense subsets $R$ of $R_{K_U}$. 

Hirahara [15] introduced the notion of a selector, and showed that $\text{EXP}^{\text{NP}}$ admits a selector.

**Lemma 13 ([15]).** For any $\text{EXP}^{\text{NP}}$-complete language $L$, there exists a selector for $L$. That is, there exists a randomized polynomial-time oracle machine $S$ such that, for any input $x \in \{0,1\}^*$ and oracles $A_0, A_1 \subseteq \{0,1\}^*$, if $L \in \{A_0, A_1\}$ then $\Pr_S[S^{A_0,A_1}(x) = L(x)] \geq \frac{2}{3}$.

We show that any language $L$ with a selector is low for $S^0$ if $L \in \text{P}/\text{poly}$.

**Theorem 14.** Let $L$ be a language with a selector $S$ and $R$ be any oracle. Then,

$$L \in \text{P}^R/\text{poly} \quad \implies \quad S_L^R \subseteq S^R.$$ 

This generalizes a lowness result of [12] from any downward self-reducible language $L$ to any language $L$ with a selector.

**Proof.** The idea is as follows: We request two competing provers of $S^R_L$ to send $R$-oracle circuits $C_0, C_1$ that compute $L$. Then, for every query $q$ of $L$, one can decide whether $q \in L$ by running $S$ and using $C^R_0$ and $C^R_1$ as oracles. Details follow.

Take any $A \in S^R_L$, and let $V$ be an $S^L_R$-machine that witnesses $A \in S^L_L$. Take some constants $c, d$ such that $V$ runs in time $n^c$ and $S$ runs in time $n^d$ on inputs of length $n$.

Now we describe an $S_2 \cdot \text{BP} \cdot \text{P}^R$ algorithm that computes $A$: Given an input $x \in \{0,1\}^*$ of length $n$, for each $i \in \{0,1\}$, the $i$th competing prover sends an $S_2$-type certificate $y_i$ for $M$. Moreover, each prover sends a polynomial-size $R$-oracle circuit $C_i$; an honest prover sends a circuit $C_i$ such that $C_i^R$ computes $L$ on every input of length at most $n^{ed}$. Then simulate $V$ using the two certificates (i.e., run $V$ on input $(x, y_0, y_1)$), where each query $q$ that $V$ makes is answered with $S^{C_0^R,C_1^R}(q)$. It is easy to see the correctness of this algorithm.

Therefore, we have $A \in S_2 \cdot \text{BP} \cdot \text{P}^R$, and by [23], we can derandomize the randomized computation by using the power of $S_2$ and obtain $L \in S_2 \cdot \text{BP} \cdot \text{P}^R = S^R_L$. ▶

**Proof of Theorem 12.** Under any dense subset $R$ of Kolmogorov-random strings, we have $\text{EXP}^{\text{NP}} \subseteq \text{P}^R/\text{poly}$ (by Theorem 7). Thus by taking any $\text{EXP}^{\text{NP}}$-complete problem $L$, we obtain $\text{EXP}^{\text{NP}} \subseteq S^R_L \subseteq S^R$ by combining Lemma 13 and Theorem 14. ▶

Finally, we mention that in the case of reductions to the set of random strings, the $S^p_2$ reductions of Theorem 12 can be derandomized to obtain $\text{P}^{\text{NP}}$ reductions.

**Theorem 15.** $\text{EXP}^{\text{NP}} \subseteq \text{P}^{\text{NP}^{\text{RK}_U}}$ for any universal Turing machine $U$.

**Proof.** By Theorem 12, we immediately obtain $\text{EXP}^{\text{NP}} \subseteq S^{\text{RK}_U}_2$. By the relativized version of Cai’s result [11], we have $\text{P}^{\text{NP}^{\text{RK}_U}} \subseteq S^{\text{RK}_U}_2 \subseteq \text{ZPP}^{\text{NP}^{\text{RK}_U}}$; thus it remains to derandomize the computation of ZPP under an $\text{NP}^{\text{RK}_U}$ oracle. One can find the lexicographically first Kolmogorov-random string by a $\text{NP}^{\text{RK}_U}$ algorithm. By Lemma 10 and Theorem 7, the circuit complexity relative to an $\text{NP}^{\text{RK}_U}$ oracle of any Kolmogorov-random string of length $n$ is at least $n^{\Omega(1)}$. Thus by using a Kolmogorov-random string as a hard function of the Impagliazzo-Wigderson pseudorandom generator [19], one can derandomize the computation of ZPP under an $\text{NP}^{\text{RK}_U}$ oracle. ▶

Abstract

Consensus and Broadcast are two fundamental problems in distributed computing, whose solutions have several applications. Intuitively, Consensus should be no harder than Broadcast, and this can be rigorously established in several models. Can Consensus be easier than Broadcast?

In models that allow noiseless communication, we prove a reduction of (a suitable variant of) Broadcast to binary Consensus, that preserves the communication model and all complexity parameters such as randomness, number of rounds, communication per round, etc., while there is a loss in the success probability of the protocol. Using this reduction, we get, among other applications, the first logarithmic lower bound on the number of rounds needed to achieve Consensus in the uniform Gossip model on the complete graph. The lower bound is tight and, in this model, Consensus and Broadcast are equivalent.

We then turn to distributed models with noisy communication channels that have been studied in the context of some bio-inspired systems. In such models, only one noisy bit is exchanged when a communication channel is established between two nodes, and so one cannot easily simulate a noiseless protocol by using error-correcting codes. An \( \Omega(\varepsilon^{-2} n) \) lower bound is proved by Boczkowski et al. [PLOS Comp. Bio. 2018] on the convergence time of binary Broadcast in one such model (noisy uniform Pull), where \( \varepsilon \) is a parameter that measures the amount of noise).

We prove an \( O(\varepsilon^{-2} \log n) \) upper bound on the convergence time of binary Consensus in such model, thus establishing an exponential complexity gap between Consensus versus Broadcast. We also prove our upper bound above is tight and this implies, for binary Consensus, a further strong complexity gap between noisy uniform Pull and noisy uniform Push. Finally, we show a \( \Theta(\varepsilon^{-2} n \log n) \) bound for Broadcast in the noisy uniform Pull.

Consensus vs Broadcast, with and Without Noise

Category Extended Abstract

Funding Luca Trevisan: LT was supported by the NSF under grant CCF 1815434 and his work on this project has received funding from the European Research Council (ERC) under the European Union Horizon 2020 research and innovation programme (grant agreement No. 834861).

1 Introduction

In this paper we investigate the relation between Consensus and Broadcast, which are two of the most fundamental algorithmic problems in distributed computing [21, 23, 39, 41], and we study how the presence or absence of communication noise affects their complexity.

In the (Single-Source) Broadcast problem, one node in a network has an initial message $msg$ and the goal is for all the nodes in the network to receive a copy of $msg$.

In the Consensus problem, each of the $n$ nodes of a network starts with an input value (which we will also call an opinion), and the goal is for all the nodes to converge to a configuration in which they all have the same opinion (this is the agreement requirement) and this shared opinion is one held by at least one node at the beginning (this is the validity requirement). In the Binary Consensus problem, there are only two possible opinions, which we denote by 0 and 1.

In the (binary) Majority Consensus problem [5, 22, 40] we are given the promise that one of the two possible opinions is initially held by at least $n/2 + b(n)$ nodes, where $b(n)$ is a parameter of the problem, and the goal is for the nodes to converge to a configuration in which they all have the opinion that, at the beginning, was held by the majority of nodes. Note that Consensus and Majority Consensus are incomparable problems: a protocol may solve one problem without solving the other. Both the notions of Consensus and Majority Consensus above can be further relaxed to those of $\delta$-Almost Consensus and $\delta$-Almost Majority Consensus, respectively. According to such weaker notions, we allow the system to converge to an almost-consensus regime where $\delta n$ outliers may have a different opinion from the rest of the nodes.

Motivations for studying the Broadcast problem are self-evident. Consensus and Majority Consensus are simplified models for the way inconsistencies and disagreements are resolved in social networks, biological models and peer-to-peer systems [24, 27, 37].

In distributed model that severely restrict the way in which nodes communicate (to model constraints that arise in peer-to-peer systems or in social or biological networks), upper and lower bounds for the Broadcast problem give insights on the effect of the communication constraints on the way in which information can spread in the network. The analysis of algorithms for Consensus often give insights on how to break symmetry in distributed networks, when looking at how the protocol handles an initial opinion vector in which exactly

1 A Consensus protocol is allowed to converge to an agreement to an opinion that was initially in the minority (provided that it was held by at least one node), while a Majority Consensus protocol must converge to the initial majority whenever the minority opinion is held by fewer than $n/2 - b$ nodes. On the other hand, a Majority Consensus problem is allowed to converge to a configuration with no agreement if the initial opinion vector does not satisfy the promise, while a Consensus protocol must converge to an agreement regardless of the initial opinion vector.

2 The Consensus problem is often studied in models in which nodes are subject to malicious faults, and, in that case, one has motivations from network security. In this paper we concentrate on models in which all nodes honestly follow the prescribed protocol and the only possibly faulty devices are the communication channels.
half the nodes have one opinion and half have the other. The analysis of algorithms for Majority Consensus usually hinge on studying the rate at which the number of nodes holding the minority opinion shrinks.

If the nodes are labeled by \(\{1, \ldots, n\}\), and each node knows its label, then there is an easy reduction of binary Consensus to Broadcast: node 1 broadcasts its initial opinion to all other nodes, and then all nodes agree on that opinion as the consensus opinion. Even if the nodes do not have known identities, they can first run a leader election protocol, and then proceed as above with the leader broadcasting its initial opinion. Even in models where leader election is not trivial, the best known Consensus protocol has, in all the cases that we are aware of, at most the “complexity” (whether it’s measured in memory per node, communication per round, number of rounds, etc.) of the best known broadcast protocol.

A first major question that we address in this paper is whether the converse hold, that is, are there ways of obtaining a Broadcast protocol from a Consensus problem or are there gaps, in certain models, between the complexity of the two problems?

We will show that, in the presence of noiseless communication channels, every Consensus protocol can be used to realize a weak form of Broadcast. Since, in many cases, known lower bounds for Broadcast apply also to such weak form, we get new lower bounds for Consensus. In a previously studied, and well motivated, distributed model with noisy communication, namely the noisy Gossip, however, we establish an exponential gap between Consensus and Broadcast.

As a second major question, we investigate the impact of the communication noise on the Consensus problem. More in detail, does this impact strongly depend on the particular noisy Gossip model we adopt? We will give a positive answer to this question by establishing a strong complexity separation between the two most popular versions of the Gossip model, namely, the Pull model and the Push one.

Roadmap of the paper and a remark

In order to formally state and discuss our results, in the next section, we introduce the distributed models and their associated complexity measures our results deal with. In Section 3, we describe our results and their consequences for noiseless communication models and compare them with the related previous work. Section 4 is devoted to our results for the noisy communication models and to their comparison with the related previous work. Finally, in Section 5 we provide a short summary of the obtained results and discuss some related open questions. We remark that, in this version, we only sketch the main ideas of the technical proofs: detailed proofs are given in the full version of the paper [17].

2 Communication and computational models

We study protocols defined on a communication network, described by an undirected graph \(G = (V, E)\) where \(V\) is the set of nodes, each one running an instance of the distributed algorithm, and \(E\) is the set of pairs of nodes between which there is a communication link that allows them to exchange data. When not specified, \(G\) is assumed to be the complete graph.

In synchronous parallel models, there is a global clock and, at each time step, nodes are allowed to communicate using their links.

In the Local model, there is no restriction on how many neighbors a node can talk to at each step, and no restriction on the number of bits transmitted at each step. There is also no restriction on the amount of memory and computational ability of each node. The only complexity measures is the number of rounds of communication. For example, it is easy to
see that the complexity of Broadcast is the diameter of the graph $G$. The Congest model is like the Local model but the amount of data that each node can send at each time step is limited, usually to $O(\log n)$ bits.

In the (general) Gossip model [20, 30], at each time step, each node $v$ chooses one of its neighbors $c_v$ and activates the communication link $(v, c_v)$, over which communication becomes possible during that time step, allowing $v$ to send a message to $c_v$ and, simultaneously, $c_v$ to send a message to $v$. We will call $v$ the caller of $c_v$. In the Push variant, each node $v$ sends a message to its chosen neighbor $c_v$; in the Pull variant, each node sends a message to its callers (if any). Note that, although each node chooses only one neighbor, some nodes may be chosen by several others, and so they may receive several messages in the Push setting, or send a message to several recipients in the Pull setting. In our algorithmic results for the Gossip model, we will assume that each message exchanged in each time step is only one bit, while our negative results for the noiseless setting will apply to the case of messages of unbounded length. In the uniform Gossip (respectively Push or Pull) model, the choice of $c_v$ is done uniformly at random among the neighbors of $v$. This means that uniform models make sense even in anonymous networks, in which nodes are not aware of their identities nor of the identities of their neighbors.\footnote{In the general Gossip model in which a node can choose which incident edge to activate, a node must, at least, know its degree and have a way to distinguish between its incident edges.}

In this work, we are mainly interested in models like Gossip that severely restrict communication [5, 2, 22, 24, 37, 40], both for efficiency consideration and because such models capture aspects of the way consensus is reached in biological population systems, and other domains of interest in network science [4, 6, 23, 12, 24, 25, 27]. Communication capabilities in such scenarios are typically constrained and non-deterministic: both features are well-captured by uniform models.

Asynchronous variants of the Gossip model (such as Population Protocols [5, 4]) have also been extensively studied [11, 28, 40]. In this variant, no global clock is available to nodes. Instead, nodes are idle until a single node is activated by a (possibly random) scheduler, either in discrete time or in continuous time. When a node wakes up, it activates one of its incident edges and wakes up the corresponding neighbor. Communication happens only between those two vertices, which subsequently go idle again until the next time they wake up.

Previous studies show that, in both Push and Pull variants of uniform Gossip, (binary) Consensus, Majority Consensus and Broadcast can be solved within logarithmic time (and work per node) in the complete graph, via elementary protocols\footnote{In the case of Majority Consensus, the initial additive bias must have size $\Omega(\sqrt{n \log n})$.}, with high probability (for short w.h.p.)\footnote{In this paper, we say that an event $E_n$ holds w.h.p. if $P(E_n) \geq 1 - n^{-\alpha}$, for some $\alpha > 1$.} [5, 9, 11, 22, 28, 31]. Moreover, efficient protocols have been proposed for Broadcast and Majority Consensus for some restricted families of graphs such as regular expanders and random graphs [1, 15, 14, 19, 29, 36].

However, while for Broadcast $\Omega(\log n)$ time and work are necessary in the complete graph [11, 28, 31], prior to this work, it was still unknown whether a more efficient protocol existed for Consensus and Majority Consensus.

## 3 Our contribution I: Noiseless communication

Our main result is a reduction of a weak form of Broadcast to Consensus which establishes, among other lower bounds, tight logarithmic lower bounds for Consensus and Majority Consensus both in the uniform Gossip (and hence uniform Pull and Push as well) model and in the general Push model.
In order to formally state the reduction, we need to introduce a slightly-different variant of Broadcast where, essentially, it is (only) required that some information from the source is spread on the network.

**Definition 1.** A protocol \( P \) solves the \( \gamma \)-Infection problem w.r.t. a source node \( s \) if it infects at least \( \gamma n \) nodes, where we define a node infected recursively as follows: initially only \( s \) is infected; a node \( v \) becomes infected whenever it receives any message from an infected node.

Notice that a protocol \( P \) solving the \( \gamma \)-Infection problem w.r.t. a source node \( s \) can be easily turned into a protocol for broadcasting a message \( \text{msg} \) from \( s \) to at least \( \gamma n \) nodes. Indeed, we give the message \( \text{msg} \) to the source node \( s \), and we simulate \( P \). Every time an infected node sends a message, it appends \( \text{msg} \) to it. Clearly, the size of each message in \( P' \) is increased by the size of \( \text{msg} \).

This notion is helpful in thinking about upper and lower bounds for Broadcast: any successful broadcast protocol from \( s \) needs to infect all nodes from source \( s \), and any protocol that is able to infect all nodes from source \( s \) can be used to broadcast from \( s \) by appending \( \text{msg} \) to each message originating from an infected node. Thus any lower bound for Infection is also a lower bound for Broadcast, and any protocol for Infection can be converted, perhaps with a small overhead in communication, to a protocol for Broadcast. For example, in the Push model, the number of infected nodes can at most double at each step, because each infected node can send a message to only one other node, and this is the standard argument that proves an \( \Omega(\log n) \) lower bound for Broadcast.

In the next theorem, we show that lower bounds for Infection also give lower bounds for Consensus. More precisely we prove that if we have a Consensus protocol that, for every initial opinion vector, succeeds in achieving almost consensus with probability \( 1 - o(1/n) \), then there is an initial opinion vector and a source such that the protocol infects many nodes from that source with probability at least \( (1 - o(1))/n \).

**Theorem 2.** Let \( P \) be a protocol reaching \( \delta \)-Almost Consensus with probability at least \( 1 - o(1)/n \). Then, a source node \( s \) and an initial opinion vector \( x \) exist such that \( P \), starting from \( x \), solves the \((1 - 2\delta)\)-Infection problem w.r.t. \( s \) with probability at least \((1 - o(1))/n \).

Notice that the above result implies that any protocol for Consensus actually solves the Infection problem (when initialized with a certain opinion vector) in a weak sense: the infection is w.r.t. a source that depends on the consensus protocol in a (possibly) uncontrolled manner; and (ii) the success probability of the infection is quite low. However, if we are in a model in which there is no source for which we can have probability, say, \( \geq 1/(2n) \) of infecting all nodes with certain resources (such as time, memory, communication per node, etc.), then, in the same model, and with the same resources, the above theorem implies that every Consensus protocol has probability \( \Omega(1/n) \) of failing. For example, by the above argument, we have an \( \Omega(\log n) \) lower bound for Consensus in the Push model (because, in fewer than \( \log_2 n \) rounds, the probability of infecting all nodes is zero).

In case of Consensus problem (i.e. \( \delta = 0 \)), our proof for Theorem 2 makes use of a hybrid argument to show that there are two initial opinion vectors \( x \) and \( y \), which are identical except for the initial opinion of a node \( s \), such that there is at least a \((1 - o(1))/n \) difference between the probability of converging to the all-zero configuration starting from \( x \) or from \( y \). Then, we prove that this difference must come entirely from runs of the protocol that fail to achieve consensus (which happens only with \( o(1/n) \) probability) or from runs of the protocol in which \( s \) infects all other nodes. Thus the probability that \( s \) infects all nodes from the initial vector \( x \) has to be \( \geq (1 - o(1))/n \). Then, to extend the above approach for the Almost Consensus problem (i.e. \( \delta > 0 \)), some additional care and a suitable counting argument are required to manage the unknown set of outliers.
Consensus vs Broadcast, with and Without Noise

As for Majority Consensus, we have a similar reduction, but from a variant of the infection problem in which there is an initial set of \( b \) infected nodes.\(^6\) Formally:

\begin{itemize}
  \item \textbf{Theorem 3.} Let \( T \) be any fixed resource defined on a distributed system \( S \) and suppose there is no Infection protocol that, starting from any subset of \( n^\alpha \) nodes with \( \alpha < 1 \), can inform at least \((1 - \delta)n\) nodes by using at most \( \tau^B \) units of \( T \), w.h.p. Then, any protocol \( P \) on this model, reaching \( \delta \)-Almost Majority Consensus w.h.p., must use more than \( \tau^B \) units of \( T \).
\end{itemize}

\section{Some applications}

Lower bounds for infection are known in several models in which there are no previous negative results for Consensus. We have not attempted to survey all possible applications of our reductions, but here we enumerate some of them (see the full version for the formal statements of such results):

- In the uniform Gossip model (also known as uniform Push-Pull model), and in the general Push model, tight analysis (see [30, 31]) show that any protocol \( P \) for the complete graph w.h.p. does not complete Broadcast within less than \( \beta \log n \) rounds, where \( \beta \) is a sufficiently small constant. Combining this lower bound with our reduction result above, we get an \( \Omega(\log n) \) lower bound for Consensus. This is the first known lower bound for Consensus showing a full equivalence between the complexity of Broadcast and Consensus in such models. Regarding Majority Consensus, we also obtain an \( \Omega(\log n) \) lower bound for any initial bias \( b = O(n^\alpha) \), with \( \alpha < 1 \).

- In a similar way, we are able to prove a lower bound of \( \Omega(n \log n) \) number of steps (and hence \( \Omega(\log n) \) parallel time) or \( \Omega(\log n) \) number of messages per node for Consensus on an asynchronous variant of the Gossip model, the Population Protocols with uniform/probabilistic scheduler, as defined in [5].

- The last application we mention here concerns the synchronous Radio Network model [3, 7, 16, 42]. Several optimal bounds have been obtained on the Broadcast time [7, 18, 32, 33, 34] while only few results are known for Consensus time [16, 42]. In particular, we are not aware of better lower bounds other than the trivial \( \Omega(D) \) (where \( D \) denotes the diameter of the network). Then, by combining a previous lower bound in [3] on Broadcast with our reduction result, we get a new lower bound for Consensus in this model.

We remark that our reduction allows us to prove that some of the above lower bounds hold even if the nodes have unbounded memory and can send/receive messages of unbounded size.

\section{Our contribution II: Noisy communication}

We now turn to the study of distributed systems in which the communication links between nodes are noisy. We will consider a basic model of high-noise communication: the binary symmetric channel [35] in which each exchanged bit is flipped independently at random with probability \( 1/2 - \varepsilon \), where \( 0 \leq \varepsilon < 1/2 \), and we refer to \( \varepsilon \) as the noise parameter of the model. Then, in the sequel, the version of each model \( M \), in which the presence of communication noise above is introduced, will be shortly denoted as \( noisy \ M \).

\(^6\) Recall that \( b \) is the value such that we are promised that the majority opinion is held, initially, by at least \( n/2 + b \) nodes.
In models such as Local and Congest, the ability to send messages of logarithmic length (or longer) implies that, with a small overhead, one can encode the messages using error-correcting codes and simulate protocols that assume errorless communication.

In the uniform Gossip model with one-bit messages, however, error-correcting codes cannot be used and, indeed, whenever the number of rounds is sublinear in n, most of the pairs of nodes that ever communicate only exchange a single bit.

The study of fundamental distributed tasks, such as Broadcast and Majority Consensus, has been undertaken in the uniform Gossip model with one-bit messages and noisy links [10, 25] as a way of modeling the restricted and faulty communication that takes place in biological systems, and as a way to understand how information can travel in such systems, and how they can repair inconsistencies. Such investigation falls under the agenda of natural algorithms, that is, the investigation of biological phenomena from an algorithmic perspective [13, 38].

As for the uniform Push model with one-bit messages, we first notice that there is a simple local strategy that solves both (binary) Broadcast and Consensus in the noisy Push (this strategy holds even assuming that agents share only a binary synchronous clock). For instance, consider binary Consensus: let every node with initial opinion 0 start a broadcast process at even rounds, while the same task is started in odd rounds by nodes with initial opinion 1. When a node receives a bit in any even (odd) round, this bit is always interpreted as 0 (1). Then, at every round, each node updates its output with, for instance, the minimum value it has seen so far (any round).

In [25], the authors consider a restricted, natural class of symmetric algorithms where the action of the nodes cannot depend on the value of the exchanged bits. In this setting, they prove that (binary) Broadcast and (binary) Majority Consensus can be solved in time $O(\varepsilon^{-2} \log n)$, where $\varepsilon$ is the noise parameter. They also prove a matching lower bound for this class of algorithms. This has been later generalized to non-binary opinions in [26].

In the noisy uniform Pull model however, [10] proves an $\Omega(\varepsilon^{-2} n)$ time lower bound. This lower bound is proved even under assumptions that strengthen the negative result, such as unique node IDs, full synchronization, and shared randomness (see Section 2.4 of [10] for more details on this point).

Such a gap between noisy uniform Push and Pull comes from the fact that, in the Push model, a node is allowed to decline to send a message, and so one can arrange a protocol in which nodes do not start communicating until they have some confidence of the value of the broadcast value. In the Pull model, instead, a called node must send a message, and so the communication becomes polluted with noise from the messages of the non-informed nodes.

What about Consensus and Majority Consensus in the noisy Pull model? Our reduction in Theorem 2 suggests that there could be $\Omega(\varepsilon^{-2} n)$ lower bounds for Consensus and Majority Consensus, but recall that the reduction is to the infection problem, and infection is equivalent to Broadcast only when we have errorless channels.

### 4.1 Upper bounds in noisy uniform Pull

#### 4.1.1 A protocol for Consensus and its analysis

We devise a simple and natural protocol for Consensus for the noisy uniform Pull model having convergence time $O(\varepsilon^{-2} \log n)$, w.h.p., thus exhibiting an exponential gap between Consensus and Broadcast in the noisy uniform Pull model.

---

7 They actually proved a more general result including non-binary noisy channels.
Theorem 4. In the noisy uniform Pull model, with noisy parameter $\varepsilon$, a protocol exists that achieves Consensus within $O(\varepsilon^{-2}\log n)$ rounds and communication, w.h.p. The protocol requires $\Theta(\log \log n + \log \varepsilon^{-2})$ local memory.

Moreover, if the protocol starts from any initial opinion vector with bias $b = \Omega(\sqrt{n \log n})$, then it guarantees Majority Consensus, w.h.p.

The protocol we refer to in the above theorem works in two consecutive phases. Each phase is a simple application of the well-known $k$-Majority Dynamics [8, 9]:

**k-Majority.** At every round, each node samples $k$ neighbours\(^8\) independently and u.a.r. (with replacement). Then, the node updates its opinion according to the majority opinion in the sample.

The protocol is thus the following:

**Majority Protocol.** Let $\alpha$ be a sufficiently large positive constant\(^9\). Every node performs $\alpha\log n$ rounds of $k$-Majority with $k = \Theta(1/\varepsilon^2)$, followed by one round of the $k$-Majority with $k = \Theta(\varepsilon^{-2}\log n)$.

Our analysis shows that, w.h.p., at the end of the first phase there is an opinion that is held by at least $n/2 + \Omega(n)$ nodes, and that if the initial opinions where unanimous then the initial opinion is the majority opinion after the first phase (notice that the latter fact guarantees the validity property, w.h.p.). Then, in the second phase, despite the communication errors, we show every node has a high probability of seeing the true phase-one majority as the empirical majority in the batch and so all nodes converge to the same valid opinion. To analyze the first phase, we break it out into two sub-phases (this breakdown is only in the analysis, not in the protocol): in a first sub-phase of length $O(\varepsilon^{-2}\log n)$, we prove the protocol “breaks symmetry” w.h.p. and, no matter the initial vector and the presence of communication noise, reaches a configuration in which one opinion is held by $n/2 + \Omega(\sqrt{n \log n})$ nodes. In the second sub-phase, also of length $O(\varepsilon^{-2}\log n)$, a configuration of bias $\Omega(\sqrt{n \log n})$ w.h.p. becomes a configuration of bias $\Omega(n)$. The analysis of the first sub-phase is our main technical novelty while the analysis of the second sub-phase for achieving Majority Consensus is similar to that in [25, 26]. If the initial opinion vector is unanimous, then it is not necessary to break up the first phase into sub-phases, and one can directly see that a unanimous configuration maintains a bias $\Omega(n)$, w.h.p., for the duration of the first phase.

A consequence of our analysis is that, if the initial opinion vector has a bias $\Omega(\sqrt{n \log n})$, then the protocol converges to the majority, w.h.p. So, we get a Majority-Consensus protocol for this model under the above condition on the bias.

### 4.1.2 A protocol for Broadcast

We provide a simple two-phases Broadcast protocol that runs in the noisy uniform PULL model.

**Protocol NoisyBroadcast.**

- In the first phase, each non-source node displays 0 (obviously, the source displays its input value), and performs a pull operation for $\Theta(\varepsilon^{-2}n\log n)$ rounds; it then chooses to support value 1 iff the fraction of received messages equal to 1 is at least $\frac{1}{2} - \varepsilon(1 - \frac{1}{2n})$, zero otherwise.

---

\(^8\) In the binary case when $k$ is odd, the $k$-Majority is stochastically equivalent to the $k + 1$-Majority where ties are broken u.a.r. (see Lemma 17 in [26]). For this reason, in this section we assume that $k$ is odd.

\(^9\) The value of $\alpha$ will be fixed later in the analysis.
In the second phase, nodes run the Majority Consensus protocol of Theorem 4, starting with the value obtained at the end of the first phase.

We prove the following performance of the protocol, nearly matching the $\Omega(\varepsilon^{-2}n)$ lower bound mentioned before [10]:

**Theorem 5.** Protocol NoisyBroadcast solves the Broadcast problem in the noisy uniform Pull model in $O(\varepsilon^{-2}n \log n)$ rounds, w.h.p.

Our proof shows that at the end of the first phase, the fraction of nodes which have obtained a value equal to the source’s input is greater than those that failed by at least $\sqrt{n} \log n$ nodes. The latter fact satisfies the hypothesis of Theorem 4 for solving Majority Consensus in $O(\varepsilon^{-2} \log n)$, which constitutes the second phase.

### 4.2 Lower bounds in noisy Pull models

We prove that any Almost Consensus protocol with at most $\delta n$ outliers and with error probability at most $\delta$ requires $\Omega(\varepsilon^{-2} \log \delta^{-1})$ rounds. Formally:

**Theorem 6.** Let $\delta$ be any real such that $0 < \delta < 1/8$ and consider any protocol $\mathcal{P}$ for the noisy general Pull model with noise parameter $\varepsilon$. If $\mathcal{P}$ solves $\delta$-Almost Consensus with probability at least $1 - \delta$, then it requires at least $t = \Omega(\varepsilon^{-2} \log \delta^{-1})$ rounds.

This shows that the complexity $O(\varepsilon^{-2} n \log n)$ of our protocol described in Subsection 4.1.1 is tight for protocols that succeed w.h.p. We remark that our result holds for any version (general and uniform) of the noisy Pull model with noise parameter $\varepsilon$, unbounded local memory, even assuming unique node IDs. Recalling the $\Theta(\log n)$ bound that holds for (general) Consensus protocols in the noisy uniform Push (for any value of $\varepsilon$), our lower bound above thus implies a strong separation result between noisy uniform Pull and noisy uniform Push.

The proof of Theorem 6 is one of the main technical contributions of this work and below we provide a short discussion.

In [25], an $\Omega(\varepsilon^{-2} \log \delta^{-1})$ round lower bound is proved for Majority Consensus in the uniform Push model, for a restricted class of protocols. Their argument, roughly speaking, is that each node needs to receive a bit of information from the rest of the graph (namely, the majority value in the rest of the graph), and this bit needs to be correctly received with probability $1 - \delta$, while using a binary symmetric channel with error parameter $\varepsilon$. It is then a standard fact from information theory that the channel needs to be used $\Omega(\varepsilon^{-2} \log \delta^{-1})$ times. It is not clear how to adapt this argument to the Consensus problem. Indeed, it is not true that every node receives a bit of information with high confidence from the rest of the graph (consider the protocol in which one node broadcasts its opinion), and it is not clear if there is a distribution of initial opinions such that there is a node $v$ whose final opinion has mutual information close to 1 to the global initial opinion vector given the initial opinion of $v$ (the natural generalization of the argument of [25]). Instead, we prove that there are two initial opinion vectors $\mathbf{x}$ and $\mathbf{y}$, a node $v$, and a bit $b$, such that the initial opinion of $v$ is the same in $\mathbf{x}$ and $\mathbf{y}$, but the probability that $v$ outputs $b$ is $\leq \delta$ when the initial opinion vector is $\mathbf{x}$ and $\geq \Omega(1)$ when the initial opinion vector is $\mathbf{y}$. Thus, the rest of the graph is sending $v$ a bit of information (whether the initial opinion vector is $\mathbf{x}$ or $\mathbf{y}$) and the communication

---

10 We notice the double role parameter $\delta$ has in this statement.
succeeds with probability $\geq 1 - \delta$ when the bit has one value and with probability $\geq 1/3$ if the bit has the other value. Despite this asymmetry, if the communication takes place over a binary symmetric channel with error parameter $\varepsilon$, we use KL divergence to show that the channel has to be used $\Omega(\varepsilon^{-2} \log \delta^{-1})$ times.

4.2.1 An improved lower bound for Broadcast

The $\Omega(\varepsilon^{-2}n)$ lower bound of [10] for Broadcast in the uniform PULL model applies to protocols that have constant probability of correctly performing the broadcast operation. With the following theorem we show a way of modifying their proof (in particular, to derive an $\Omega(\varepsilon^{-2}n \log n)$ for uniform PULL protocols for Broadcast that have high probability of success, matching the $O(\varepsilon^{-2}n \log n)$ round complexity of Theorem 5.

Theorem 7. The Broadcast Problem cannot be solved in the noisy uniform PULL model w.h.p. in less than $\Omega(\varepsilon^{-2}n \log n)$ rounds.

5 Conclusions

Table 1 shows the two main separation results that follow from a comparison between some previous bounds and the bounds we obtain in this paper: The complexity gap between Consensus and Broadcast in the presence or absence of noise and the different complexity behaviour of Consensus between noisy uniform PULL and noisy uniform PUSH. The figure also shows our new lower bounds for Consensus in the noiseless Gossip models.

A further consequence regards a separation between general PULL and PUSH models as far as Consensus is concerned in the noiseless world. Indeed, if we assume unique IDs, in the general PULL model, Consensus can be easily solved in constant time: every node can copy the opinion of a prescribed node by means of a single pull operation. On the other hand, in the general PUSH model, our Broadcast-Consensus reduction shows that $\Omega(\log n)$ rounds are actually necessary for solving Consensus.

We considered noisy communication models that assume the presence of a global clock: nodes work in parallel sharing the value of the current round. Our protocols definitely exploit this important property of the model. Then, an interesting open issue is to analyse fundamental tasks, such as Consensus and Broadcast, in asynchronous versions of the PUSH and PULL models where, as in our setting, communication is noisy and takes place via binary messages only. A further interesting future work we plan to consider is to introduce a (strong) bound on the local memory of the nodes.

Table 1 The updated state-of-art for Broadcast and Consensus in Gossip models with and w/o noise. The results of this paper are highlighted bold, while “folklore” results are marked with * (see also the preliminary discussion in Section 4).

Abstract

Property testers are fast randomized algorithms whose task is to distinguish between inputs satisfying some predetermined property $P$ and those that are far from satisfying it. Since these algorithms operate by inspecting a small randomly selected portion of the input, the most natural property one would like to be able to test is whether the input does not contain certain forbidden small substructures. In the setting of graphs, such a result was obtained by Alon et al., who proved that for any finite family of graphs $\mathcal{F}$, the property of being induced $\mathcal{F}$-free (i.e. not containing an induced copy of any $F \in \mathcal{F}$) is testable.

It is natural to ask if one can go one step further and prove that more elaborate properties involving induced subgraphs are also testable. One such generalization of the result of Alon et al. was formulated by Goldreich and Shinkar who conjectured that for any finite family of graphs $\mathcal{F}$, and any linear inequality involving the densities of the graphs $F \in \mathcal{F}$ in the input graph, the property of satisfying this inequality can be tested in a certain restricted model of graph property testing. Our main result in this paper disproves this conjecture in the following strong form: some properties of this type are not testable even in the classical (i.e. unrestricted) model of graph property testing.

The proof deviates significantly from prior non-testability results in this area. The main idea is to use a linear inequality relating induced subgraph densities in order to encode the property of being a pseudo-random graph.

1 Introduction

Property testers are fast randomized algorithms that distinguish between objects satisfying a certain property and objects that are “far” from the property. The systematic study of such problems originates in the seminal papers of Rubinfeld and Sudan [10] and Goldreich, Goldwasser and Ron [4], and has since become a very active area of research. We refer the reader to the book of Goldreich [3] for more background and references on the subject.

In this paper we study property testing of graph properties in the dense graph model. In this model, a graph is given as an $n \times n$ adjacency matrix. An $n$-vertex graph $G$ is said to be $\varepsilon$-far from a graph property $\Pi$, if one has to change at least $\varepsilon n^2$ entries in the adjacency matrix of $G$ in order to turn it into a graph satisfying $\Pi$. A tester for $\Pi$ is a (randomized) algorithm that, given a proximity parameter $\varepsilon \in (0, 1)$ and a graph $G$, accepts if $G$ satisfies $\Pi$ and rejects if $G$ is $\varepsilon$-far from $\Pi$, with success probability at least $\frac{2}{3}$ in both cases. The
testing Linear Inequalities of Subgraph Statistics

We say that a tester has query complexity \( q(\varepsilon, n) \) if it makes at most \( q(\varepsilon, n) \) queries when invoked with proximity parameter \( \varepsilon \) on inputs with \( n \) vertices. A property \( \Pi \) is called \textit{testable} if it has a tester whose query complexity is bounded by a function of \( \varepsilon \) alone, that is, it is independent of the size of the input. A tester is \textit{canonical} if it works by sampling a random set of vertices of some size \( s(\varepsilon, n) \), querying all pairs among these vertices, and making its decision based on (the isomorphism class) of the sample. The integer \( s(\varepsilon, n) \) is called the \textit{sample complexity} of the tester. Goldreich and Trevisan \[7, \text{Theorem 2}\] showed that every tester can be transformed to a canonical one, with the cost of possibly squaring the query complexity. A tester is \textit{size-oblivious} if it does not know \( n \); that is, if its function depends only on the proximity parameter \( \varepsilon \) (and not on the size of the input). The transformation of Goldreich and Trevisan \[7\] which turns arbitrary testers into canonical testers, preserves the property of being size-oblivious.

In this paper we study a special kind of testers, called \textit{proximity oblivious testers}, which are defined as follows.

\begin{definition}
A proximity oblivious tester (POT) for a graph property \( \Pi \) is an algorithm which makes a constant (i.e. independent of \( n \) and \( \varepsilon \)) number of queries to the input and satisfies the following. There is a constant \( c \in (0, 1] \) and a function \( f : [0, 1] \to (0, 1] \) such that:
\begin{enumerate}
  \item If the input graph satisfies \( \Pi \) then the tester accepts with probability at least \( c \).
  \item If the input graph is \( \varepsilon \)-far from \( \Pi \) then the tester accepts with probability at most \( c - f(\varepsilon) \).
\end{enumerate}
\end{definition}

Observe that a POT for \( \Pi \) can be used to obtain a standard tester for \( \Pi \), by invoking the POT \( T = \Theta(1/f(\varepsilon)^2) \) times and accepting if and only if the POT accepted in at least \( (c - \frac{f(\varepsilon)}{2})T \) of the tests.

POTs were introduced by Goldreich and Ron \[5\], who studied \textit{one-sided-error} POTs, namely POTs that accept every input which satisfies the property with probability 1 (this corresponds to having \( c = 1 \) in Definition 1). Later, Goldreich and Shinkar \[6\] studied general (two-sided-error) POTs in several settings, including those of general boolean functions, dense graphs and bounded degree graphs. For the dense graph model, they designed a POT for the property of being \( \alpha \)-regular (for a given \( \alpha \in (0, 1) \)), as well as for several related properties. Moreover, they considered properties of the following form: given graphs \( H, G \), the \textit{density} of \( H \) in \( G \), denoted by \( p(H,G) \), is the fraction of induced subgraphs of \( G \) of order \( v(H) \) which are isomorphic to \( H \). Given an integer \( h \geq 2 \), a rational number \( b \) and rational numbers \( w_H \geq 0 \), where \( H \) runs over all \( h \)-vertex graphs, the property \( \Pi_{h,w,b} \) is defined as the property of all graphs \( G \) satisfying

\[ \sum_H w_H \cdot p(H,G) \leq b. \]

Throughout this paper, a tuple \((h, w, b)\) will always consist of an integer \( h \geq 2 \), a rational number \( b \), and a function \( w : \{H : v(H) = h\} \to \mathbb{Q}^+ \) from the set of all \( h \)-vertex graphs to the positive rationals. The value assigned by \( w \) to a graph \( H \) is denoted by \( w_H \).

Since property testing algorithms, and POTs in particular, work by inspecting the subgraph induced by a small sample of vertices, it is natural to ask if the property of not containing an induced copy of a fixed graph \( H \) is a testable property. Such a result was obtained by Alon, Fischer, Krivelevich and Szegedy \[1\] who proved that in fact for every finite family of graphs \( \mathcal{F} \), the property of being induced \( \mathcal{F} \)-free (i.e. not containing an induced copy of \( F \) for every \( F \in \mathcal{F} \)) is testable. It is easy to see that the family of properties \( \Pi_{h,w,b} \) forms a strict generalization of the family of properties of being induced \( \mathcal{F} \)-free, since the
former can encode the latter. (Indeed, if all graphs in $\mathcal{F}$ have the same size $h$ then simply set $b = 0$, $w_H = 1$ for each $H \in \mathcal{F}$, and $w_H = 0$ for each $h$-vertex graph $H$ which is not in $\mathcal{F}$. If graphs in $\mathcal{F}$ have varying sizes, then take advantage of the fact that for every pair of graphs $F,G$ and $h \geq v(F)$, it holds that $p(F,G) = \sum_H p(F,H) \cdot p(H,G)$, where the sum is over all $h$-vertex graphs $H$.)

We now arrive at an important definition.

**Definition 2.** A tuple $(h, w, b)$ has the removal property if there is a function $f : (0, 1] \rightarrow (0, 1]$ such that for every $\varepsilon \in (0, 1)$ and for every graph $G$, if $G$ is $\varepsilon$-far from $\Pi_{h,w,b}$ then

$$\sum_H w_H \cdot p(H,G) \geq b + f(\varepsilon).$$

As an example, the main result of [1] mentioned above is equivalent to the statement that if $b = 0$ then $\Pi_{h,w,b}$ has the removal property. Goldreich and Shinkar [6] observed that if $(h, w, b)$ has the removal property then $\Pi_{h,w,b}$ admits a size-oblivious POT. Indeed, given an input graph $G$, the POT works by sampling a random induced subgraph of $G$ of order $h$, and then rejecting with probability $w_H$ if the sampled subgraph is isomorphic to $H$, for each $H$ on $h$ vertices. If $G$ satisfies $\Pi_{h,w,b}$ then by the definition of this property, $G$ is rejected with probability $\sum_H w_H \cdot p(H,G) \leq b$. On the other hand, if $G$ is $\varepsilon$-far from $\Pi_{h,w,b}$ then by the removal property, $G$ is rejected with probability $\sum_H w_H \cdot p(H,G) \geq b + f(\varepsilon)$. Thus, Definition 1 is satisfied with $c = 1 - b$.

Our first result in this paper is a converse of the above statement, showing that if $\Pi_{h,w,b}$ has a size-oblivious POT, then $(h, w, b)$ has the removal property.

**Theorem 3.** For each tuple $(h, w, b)$, if $\Pi_{h,w,b}$ has a size-oblivious POT then $(h, w, b)$ has the removal property.

As a corollary of the above theorem, we infer that if one “representation” of a property as $\Pi_{h,w,b}$ has the removal property, then all such representations have the removal property. This is stated in the following corollary.

**Corollary 4.** Let $(h, w, b)$ and $(h', w', b')$ be tuples such that $\Pi_{h,w,b} = \Pi_{h',w',b'}$. Then $(h, w, b)$ has the removal property if and only if $(h', w', b')$ has the removal property.

**Remark 5.** Theorem 3 contradicts the statement of Proposition 3.14 in [6], which states that there is a tuple $(h, w, b)$ such that $\Pi_{h,w,b}$ has a POT but $(h, w, b)$ does not have the removal property. We believe that the proof of this proposition is wrong. This will be explained in the full version of this paper.

Goldreich and Shinkar conjectured (see [6, Open Problem 3.11]) that every property of the form $\Pi_{h,w,b}$ has a POT. Our next theorem disproves this conjecture by showing that there are properties $\Pi_{h,w,b}$ that are not testable at all (let alone testable using a POT).

**Theorem 6.** Let $K_4$ denote the complete graph on 4 vertices, $D_4$ the diamond graph (i.e. $K_4$ minus an edge), $P_2$ the graph on 4 vertices containing a path of length 2 and an isolated vertex, $C_4$ the 4-cycle, $P_4$ the path on 4 vertices and $K_{1,3}$ the star on 4 vertices. Let $w_H$ be the following weight function assigning a non-negative weight to each graph on 4 vertices.

Then, the property
\[
\Pi_{h,w,b} = \left\{ G : \sum_{H : |V(H)| = 4} w_H \cdot p(H,G) \leq \frac{5}{16} \right\}
\] (1)
is not testable.

Given the above theorem it is natural to ask if every property \( \Pi_{h,w,b} \) can at least be tested using \( o(n^2) \) edge-queries. We leave this as an open problem.

Paper overview

The rest of the paper is organized as follows. In Section 2 we prove Theorem 3. The proof of Theorem 6 appears in Section 3. The main idea behind its proof is to show that there exists a property \( \Pi_{h,w,b} \) (specifically, the one defined in (1)) which encodes the property of being a pseudo-random graph. It is then not hard to show that such a property cannot be tested using a constant number of queries.

2 Proof of Theorem 3

In this section we prove Theorem 3 and Corollary 4. We will need the following auxiliary lemma.

\textbf{Lemma 7.} Let \( \Pi \) be a graph property, and suppose that \( \Pi \) has a canonical size-oblivious \( \epsilon \)-tester \( T \) with sample complexity \( s = s(\epsilon) \) (and success probability \( \frac{2}{3} \)). Then for every \( n \geq s^4 \) and for every \( n \)-vertex graph \( G \) which is \( \epsilon \)-far from \( \Pi \), the following holds. For \( U \) chosen uniformly at random from \( \binom{V(G)}{s} \), we have \( \Pr[G[U] \in \Pi] \leq e^{-\Omega(s)} \).

\textbf{Proof.} Let \( A \) be the family of all \( s \)-vertex graphs \( A \) such that \( T \) accepts if it sees a subgraph isomorphic to \( A \). For a graph \( G \), we say that a sequence of subsets \( S_1, \ldots, S_s \in \binom{V(G)}{s} \) is \textit{good} if \( G[S_i] \in A \) for at least half of the values of \( 1 \leq i \leq s \); otherwise \( S_1, \ldots, S_s \) is \textit{bad}. For a sequence of vertices \( W = (x_1, \ldots, x_{12}) \), we say that \( W \) is good (resp. bad) if \( \{x_1, \ldots, x_{12}\}, \{x_{13}, \ldots, x_{24}\}, \ldots, \{x_{s^2-s+1}, \ldots, x_{s^2}\} \) is good (resp. bad). Note that for a random \( S \in \binom{V(G)}{s} \), if \( G \in \Pi \) then \( \Pr[G[S] \in A] \geq \frac{s}{2} \), and if \( G \) is \( \epsilon \)-far from \( \Pi \) then \( \Pr[G[S] \in A] \leq \frac{1}{4} \). Using a standard Chernoff-type bound, one can show that the following holds for \( S_1, \ldots, S_s \in \binom{V(G)}{s} \) chosen uniformly at random and independently.

1. If \( G \in \Pi \) then \( S_1, \ldots, S_s \) is good with probability at least \( 1 - e^{-Cs} \).
2. If \( G \) is \( \epsilon \)-far from \( \Pi \) then \( S_1, \ldots, S_s \) is bad with probability at least \( 1 - e^{-Cs} \).

In both items above, \( C \) is an absolute constant.

The probability that \( S_i \cap S_j \neq \emptyset \) for some \( 1 \leq i < j \leq s \) is at most \( s \frac{s^2}{2} \), where the inequality follows from the assumption that \( n \geq s^4 \). So \( |S_1 \cup \cdots \cup S_s| = s^2 \) with probability at least \( \frac{1}{4} \). Conditioned on the event that \( S_1, \ldots, S_s \) are pairwise-disjoint, the set \( S := S_1 \cup \cdots \cup S_s \) has the distribution of an element of \( \binom{V(G)}{s} \) chosen uniformly at random. Thus, a random sequence of vertices \( W = (x_1, \ldots, x_{12}) \) chosen \textit{without repetitions} satisfies the following.

1. If \( G \) satisfies \( \Pi \) then \( W \) is good with probability at least \( 1 - 2e^{-Cs} \).
2. If \( G \) is \( \epsilon \)-far from \( \Pi \) then \( W \) is bad with probability at least \( 1 - 2e^{-Cs} \).

Now let \( G \) be a graph on \( n \geq s^4 \) vertices which is \( \epsilon \)-far from \( \Pi \). Consider a random pair \((U,W)\), where \( U \) is chosen uniformly at random from \( \binom{V(G)}{s} \), and \( W = (x_1, \ldots, x_{12}) \) is a sequence of vertices sampled randomly without repetition from \( U \). Note that \( W \) is
distributed as a uniform sequence of \( s^2 \) vertices of \( G \), sampled without repetition. Thus, \( \mathbb{P}[W \text{ is good}] \leq 2e^{-Cs} \). On the other hand, if \( G[U] \in \Pi \), then \( \mathbb{P}[W \mid U] \geq 1 - 2e^{-Cs} \). By combining these two facts, we see that

\[
\mathbb{P}[G[U] \in \Pi] \leq \frac{2e^{-Cs}}{1 - 2e^{-Cs}} \leq 4e^{-Cs} = e^{-\Omega(s)}.
\]

**Proof of Theorem 3.** As mentioned in the introduction, a POT for \( \Pi_{h,w,b} \) can be used to obtain a standard tester for \( \Pi_{h,w,b} \) by invoking the POT an appropriate number of times. Moreover, it is clear that if the POT is size-oblivious, then so is the resulting tester. Next, we apply the transformation of Goldreich and Trevisan [7] to get a canonical tester \( \mathcal{T} \) for \( \Pi_{h,w,b} \). Since this transformation preserves the property of being size-oblivious, \( \mathcal{T} \) is size-oblivious, and hence satisfies the condition of Lemma 7. Denote by \( s = s(\varepsilon) \) the sample complexity of \( \mathcal{T} \). We may and will assume that \( s \) is large enough as a function of the parameters \( h \) and \( b \).

Let us denote \( z(G) = \sum_{H} w_H \cdot p(H, G) \). By multiplying the inequality \( \sum_{H} w_H \cdot p(H, G) \leq b \) by an appropriate integer, we can assume without loss of generality that \( b \) is an integer, and that \( w_H \) is an integer for every \( H \).

Let \( G \) be a graph which is \( \varepsilon \)-far from \( \Pi_{h,w,b} \). Our goal is to show that \( z(G) \geq b + f(\varepsilon) \), for a function \( f : (0, 1] \to (0, 1] \) to be chosen later. By Lemma 7, a randomly chosen \( U \in \binom{V(G)}{s^4} \) satisfies \( G[U] \in \Pi_{h,w,b} \) with probability at most \( e^{-\Omega(s)} \). Observe that if a \( k \)-vertex graph \( K \) does not satisfy \( \Pi_{h,w,b} \), then necessarily

\[
z(K) = \sum_{H} w_H \cdot p(H, K) \geq b + \binom{k}{h}^{-1} > b + k^{-h},
\]
as \( b \) and all weights \( w_H \) are integers. Thus, if \( G[U] \notin \Pi_{h,w,b} \) then

\[
z(G[U]) > b + |U|^{-h} = b + s^{-4h}.
\]

Observe that \( z(G) \) is the average of \( z(G[U]) \) over all \( U \in \binom{V(G)}{s^4} \). Thus, using the guarantees of Lemma 7, we obtain

\[
z(G) \geq (1 - e^{-\Omega(s)})(b + s^{-4h}) > b + \frac{1}{2}s^{-4h},
\]
where the last inequality holds provided that \( s \) is large enough as a function of \( h \) and \( b \). So we may take the function \( f \) in Definition 2 to be \( f(\varepsilon) = \frac{1}{2}s(\varepsilon)^{-4h} \). This completes the proof.

**Proof of Corollary 4.** We have established that \( (h, w, b) \) satisfies the removal property if and only if \( \Pi_{h,w,b} \) has a size-oblivious POT. The “only if” part was explained in the introduction (see also [6]), and the “if” part is the statement of Theorem 3. Since the existence of a tester (specifically, a size-oblivious POT) does not depend on the specific representation of a given property as \( \Pi_{h,w,b} \), it is now clear that the corollary holds.

### 3 Proof of Theorem 6

Let \( \Pi_{h,w,b} \) be as in the statement of Theorem 6. Denote

\[
z(G) := \sum_{H: |V(H)|=4} w_H \cdot p(H, G)
\]
for every graph $G$ of order at least 4. Under this notation, $\Pi_{h,w,b} = \{ G : z(G) \leq b \}$. For a pair of graphs $H$ and $G$, define

$$t_{\text{inj}}(H, G) = \frac{1}{n^2} \left| \{ \varphi : V(H) \to V(G) \text{ injective s.t. } uv \in E(H) \Rightarrow \varphi(u)\varphi(v) \in E(G) \} \right|,$$

and

$$t_{\text{ind}}(H, G) = \frac{1}{n^2} \left| \{ \varphi : V(H) \to V(G) \text{ injective s.t. } uv \in E(H) \Leftrightarrow \varphi(u)\varphi(v) \in E(G) \} \right|,$$

where $n^2 = n \cdot (n - 1) \cdots (n - h + 1)$. Note that $t_{\text{ind}}(H, G) = p(H, G) \cdot \text{aut}(H)/h!$, where $\text{aut}(H)$ is the number of automorphisms of $H$. The following lemma gives a simpler description of $\Pi_{h,w,b}$.

**Lemma 8.** $\Pi_{h,w,b} = \{ G : \phi(G) \leq 0 \}$, where $\phi(G) = 2t_{\text{inj}}(C_4, G) - t_{\text{inj}}(K_2, G) + \frac{5}{8}$.

**Proof.** First, note that $t_{\text{inj}}(K_2, G) = p(K_2, G)$. Next, we use the fact that

$$t_{\text{inj}}(C_4, G) = t_{\text{ind}}(C_4, G) + 2t_{\text{ind}}(D_4, G) + t_{\text{ind}}(K_4, G)$$

$$= \frac{\text{aut}(C_4)}{4!} \cdot p(C_4, G) + 2\frac{\text{aut}(D_4)}{4!} \cdot p(D_4, G) + \frac{\text{aut}(K_4)}{4!} \cdot p(K_4, G)$$

$$= \frac{1}{3} p(C_4, G) + \frac{2}{3} p(D_4, G) + p(K_4, G).$$

Hence,

$$\phi(G) = \frac{2}{3} p(C_4, G) + \frac{2}{3} p(D_4, G) + 2p(K_4, G) - p(K_2, G) + \frac{3}{8}$$

$$= \frac{2}{3} p(C_4, G) + \frac{2}{3} p(D_4, G) + 2p(K_4, G) + p(K_2, G) - \frac{5}{8}$$

$$= \frac{2}{3} p(C_4, G) + \frac{2}{3} p(D_4, G) + 2p(K_4, G) + \sum_{H : |V(H)| = 4} p(K_2, H)p(H, G) - \frac{5}{8}$$

$$= \sum_{H : |V(H)| = 4} 2w_H \cdot p(H, G) - \frac{5}{8}.$$ 

Therefore, $\phi(G) \leq 0$ if and only if $\sum_{H : |V(H)| = 4} w_H \cdot p(H, G) \leq 5/16$.

An important ingredient in the proof of Theorem 6 is the following lemma, which shows that graphs in $\Pi_{h,w,b}$ are pseudo-random. In what follows, we write $x = y \pm z$ to mean that $x \in [y - z, y + z]$.

**Lemma 9.** For every $\delta \in (0,1)$ there is $n_0(\delta)$ such that every graph $G \in \Pi_{h,w,b}$ on $n \geq n_0(\delta)$ vertices satisfies the following. For every $U, V \subseteq V(G)$ with $|U|,|V| \geq \delta n$, it holds that

$$e(U, V) = \left( \frac{1}{2} \pm \delta \right) |U||V|.$$ 

**Proof.** We start by showing that for every $\gamma \in (0,1)$ there is $n_0(\gamma)$ such that if $G \in \Pi_{h,w,b}$ is a graph on $n \geq n_0(\gamma)$ vertices, then

$$t_{\text{inj}}(K_2, G) = \frac{1}{2} \pm \gamma \text{ and } t_{\text{inj}}(C_4, G) = \frac{1}{16} \pm \gamma.$$ (2)
It is a well-known fact (see for instance [11]) that every $n$-vertex graph $G$ satisfies\footnote{$^1$ Usually this inequality is stated in terms of the homomorphic density, as $t(C_4,G) \geq t(K_2,G)^4$ (see e.g. [9]). The error-term $O(\frac{1}{n})$ accounts for the difference between the homomorphic density and the injective density.}

$$t_{inj}(C_4, G) \geq t_{inj}(K_2, G)^4 - O\left(\frac{1}{n}\right) \geq t_{inj}(K_2, G)^4 - \frac{\gamma^2}{2},$$

where the last inequality holds if $n$ is large enough. Now, observe that every $G \in \Pi_{h,w,b}$ satisfies

$$2t_{inj}(K_2, G)^4 - t_{inj}(K_2, G) + \frac{3}{8} \leq 2t_{inj}(C_4, G) + \gamma^2 - t_{inj}(K_2, G) + \frac{3}{8} = \phi(G) + \gamma^2 \leq \gamma^2,$$  

where the last inequality follows from Lemma 8. Note that the function $x \mapsto 2x^4 - x + \frac{3}{8}$ is convex, and attains its minimum at $x = 1/2$. Therefore, if we had $t_{inj}(K_2, G) > \frac{1}{2} + \gamma$, then we would have

$$2t_{inj}(K_2, G)^4 - t_{inj}(K_2, G) + \frac{3}{8} > 2\left(\frac{1}{2} + \gamma\right)^4 - \left(\frac{1}{2} + \gamma\right) + \frac{3}{8} = 2\gamma^4 + 4\gamma^3 + 3\gamma^2 > \gamma^2.$$

Similarly, if we had $t_{inj}(K_2, G) < \frac{1}{2} - \gamma$, then we would have

$$2t_{inj}(K_2, G)^4 - t_{inj}(K_2, G) + \frac{3}{8} > 2\left(\frac{1}{2} - \gamma\right)^4 - \left(\frac{1}{2} - \gamma\right) + \frac{3}{8} = 2\gamma^4 - 4\gamma^3 + 3\gamma^2 > \gamma^2.$$

In any case, we see that $|t_{inj}(K_2, G) - \frac{1}{2}| > \gamma$ would stand in contradiction to (4). Hence, $t_{inj}(K_2, G) = \frac{1}{2} \pm \gamma$. By applying Lemma 8 again we get $t_{inj}(C_4, G) \leq \frac{1}{16} + \gamma$. By using the intermediate inequality in (3) and $t_{inj}(K_2, G) \geq \frac{1}{2} - \gamma$, we get

$$t_{inj}(C_4, G) \geq \left(\frac{1}{2} - \gamma\right)^4 - O\left(\frac{1}{n}\right) \geq \frac{1}{16} - \gamma,$$

where the last inequality can be easily verified, assuming that $n$ is large enough, by expanding the binomial expression. We have thus established (2).

A well-known result of Chung, Graham and Wilson [2] states that for every $\delta \in (0,1)$ there is $\gamma = \gamma(\delta)$ such that if a graph $G$ satisfies (2), then for every $U, V \subseteq V(G)$ with $|U|, |V| \geq \delta n$, it holds that $e(U, V) = (\frac{1}{2} \pm \delta) |U||V|$. The lemma follows by combining this result with the above.

For a family of graphs $\mathcal{F}$ and a graph $G$, we define

$$p(\mathcal{F}, G) = \sum_{F \in \mathcal{F}} p(F, G).$$

It is well-known (see e.g. [2]) that a pseudo-random graph has approximately the same distribution of small subgraphs as a random graph with the same density. By combining this with Lemma 9, we obtain the following corollary. Note that the expected value of $p(F, G(n, \frac{1}{2}))$ is $2^{-\binom{\lfloor t \rfloor}{2}} \frac{s!}{\text{aut}(F)}$.

**Corollary 10.** For every $s \geq 2$ and $\delta \in (0,1)$ there is $n_1 = n_1(s, \delta)$ such that every $G \in \Pi_{h,w,b}$ on $n \geq n_1$ vertices satisfies the following. For every family $\mathcal{F}$ of $s$-vertex graphs, it holds that

$$p(\mathcal{F}, G) = \sum_{F \in \mathcal{F}} 2^{-\binom{\lfloor t \rfloor}{2}} \frac{s!}{\text{aut}(F)} \pm \delta.$$
We are now ready to prove Theorem 6.

**Proof of Theorem 6.** We start by showing that \( \Pi_{h,w,b} \) is non-empty. More specifically, we prove that for every integer \( n \geq 4 \), there exists an \( n \)-vertex graph satisfying \( \Pi_{h,w,b} \). Let \( G \sim G(n, \frac{1}{2}) \). It is easy to see that \( \mathbb{E}[t_{\text{inj}}(K_2, G)] = \frac{1}{2} \) and \( \mathbb{E}[t_{\text{inj}}(C_4, G)] = \frac{1}{16} \). Hence,

\[
\mathbb{E}[\phi(G)] = 2\mathbb{E}[t_{\text{inj}}(C_4, G)] - \mathbb{E}[t_{\text{inj}}(K_2, G)] + \frac{3}{8} = 0.
\]

It follows that there is an \( n \)-vertex graph with \( \phi(G) \leq 0 \), and hence \( G \in \Pi_{h,w,b} \) by Lemma 8.

Now suppose by contradiction that \( \Pi_{h,w,b} \) is testable. In particular, there exists a 0.1-tester for \( \Pi_{h,w,b} \). This implies – by [7, Theorem 2] (see also [8]) – that there is a canonical 0.1-tester \( T \) for \( \Pi_{h,w,b} \). Denote by \( s \) the sample complexity of \( T \). Then for every \( n > 0 \) there is a family \( F = F(n) \) of (rejection) graphs of order \( s \) satisfying the following for every \( n \)-vertex graph \( G \).

1. \( p(F, G) \leq \frac{1}{4} \) if \( G \in \Pi_{h,w,b} \);
2. \( p(F, G) \geq \frac{3}{4} \) if \( G \) is 0.1-far from \( \Pi_{h,w,b} \).

Let \( n' = \max(9s^2, n_1(s, \frac{1}{2})) \) and \( n = \max\{n_0(\frac{1}{16}), n_1(s, \frac{1}{4})\} \), where \( n_1 \) is from Corollary 10 and \( n_0 \) is from Lemma 9. Let \( G' \) be an arbitrary \( n' \)-vertex graph which satisfies \( \Pi_{h,w,b} \), and let \( G \) be the \( \frac{n}{n'} \)-blow-up of \( G' \). Denote by \( V_1 \sqcup \cdots \sqcup V_s = V(G) \) the clusters of this blow-up.

We claim that \( G \) is 0.1-far from \( \Pi_{h,w,b} \). Indeed, fix any \( G^* \in \Pi_{h,w,b} \) with \( n \) vertices. By our choice of \( n \) via Corollary 9, and as \( |V_i| = \frac{n}{n'} \), we must have \( e_G(V_i, V_j) = \left( \frac{1}{2} \pm \frac{1}{n'} \right)(n/n')^2 \). But since \( e_G(V_i, V_j) \in \{0, (n/n')^2\} \), we must change at least \( \left( \frac{1}{2} - \frac{1}{n'} \right)(n/n')^2 \geq 0.4(n/n')^2 \) edges between \( V_i \) and \( V_j \) for every \( 1 \leq i < j \leq n' \), in order to turn \( G \) into \( G^* \). Therefore, the edit distance between \( G \) and \( G^* \) is at least \( \left( \frac{n'}{2} \right) \cdot 0.4(n/n')^2 \geq 0.1n^2 \), as required.

Now, let \( S \in \binom{V(G)}{s} \) be chosen uniformly at random, and let \( B \) be the event that there exists \( 1 \leq i \leq n' \) for which \( |S \cap V_i| > 1 \). Note that we have \( P(B) \leq \binom{n}{s}/n' < \frac{1}{4} \), by the choice of \( n' \). Observe that conditioned on \( B \), the probability that \( S \) is isomorphic to an \( s \)-vertex graph \( F \) is exactly \( p(F, G') \). Hence, setting \( F = F(n) \) and \( \rho = \sum_{F \in \mathcal{F}} 2^{-\binom{s}{2}} \frac{|\text{aut}(F)|}{\text{aut}(F)} \), we have

\[
p(F, G) = P[G[S] \in F] = P(G[S] \in F \mid B^c) + P(B)
\]

\[
< P[G[S] \in F \mid B^c] + \frac{1}{9} = p(F, G') + \frac{1}{9}
\]

\[
\leq \sum_{F \in \mathcal{F}} 2^{-\binom{s}{2}} \frac{|\text{aut}(F)|}{\text{aut}(F)} + \frac{1}{9} + \frac{1}{9} = \rho + \frac{2}{9}.
\]

where in the last inequality we used our choice of \( n' \) via Corollary 10. On the other hand, our choice of \( n \) via Corollary 10 implies that every \( n \)-vertex graph \( G^* \in \Pi_{h,w,b} \) satisfies

\[
p(F, G^*) \geq \sum_{F \in \mathcal{F}} 2^{-\binom{s}{2}} \frac{|\text{aut}(F)|}{\text{aut}(F)} - \frac{1}{9} = \rho - \frac{1}{9}.
\]

By combining this with (5), we get \( p(F, G^*) > p(F, G) - \frac{1}{4} \). But this stands in contradiction to \( p(F, G^*) \leq \frac{1}{4} \) (as \( G^* \in \Pi_{h,w,b} \)) and \( p(F, G) \geq \frac{2}{3} \) (as \( G \) is 0.1-far from \( \Pi_{h,w,b} \)). This completes the proof of the theorem.

\[\Box\]
References

Abstract

Consider the following heuristic for building a decision tree for a function \( f : \{0, 1\}^n \rightarrow \{-1, 1\} \). Place the most influential variable \( x_i \) of \( f \) at the root, and recurse on the subfunctions \( f_{x_i=0} \) and \( f_{x_i=1} \) on the left and right subtrees respectively; terminate once the tree is an \( \varepsilon \)-approximation of \( f \). We analyze the quality of this heuristic, obtaining near-matching upper and lower bounds:

- **Upper bound:** For every \( f \) with decision tree size \( s \) and every \( \varepsilon \in (0, \frac{1}{2}) \), this heuristic builds a decision tree of size at most \( s^{O(\log(\frac{s}{\varepsilon}) \log(1/\varepsilon))} \).

- **Lower bound:** For every \( \varepsilon \in (0, \frac{1}{2}) \) and \( s \leq 2^{\tilde{O}((n)^{\frac{1}{2}})} \), there is an \( f \) with decision tree size \( s \) such that this heuristic builds a decision tree of size \( s^{\tilde{\Omega}(\log s)} \).

We also obtain upper and lower bounds for monotone functions: \( s^{O(\sqrt{\log s/\varepsilon})} \) and \( s^{\tilde{\Omega}(\frac{4}{\varepsilon} \sqrt{\log s})} \) respectively. The lower bound disproves conjectures of Fiat and Pechyony (2004) and Lee (2009).

Our upper bounds yield new algorithms for properly learning decision trees under the uniform distribution. We show that these algorithms – which are motivated by widely employed and empirically successful top-down decision tree learning heuristics such as ID3, C4.5, and CART – achieve provable guarantees that compare favorably with those of the current fastest algorithm (Ehrenfeucht and Haussler, 1989), and even have certain qualitative advantages. Our lower bounds shed new light on the limitations of these heuristics.

Finally, we revisit the classic work of Ehrenfeucht and Haussler. We extend it to give the first uniform-distribution proper learning algorithm that achieves polynomial sample and memory complexity, while matching its state-of-the-art quasipolynomial runtime.

1 Introduction

Consider the problem of constructing a decision tree representation of a function \( f : \{0, 1\}^n \rightarrow \{-1, 1\} \), where the goal is to build a decision tree for \( f \) that is as small as possible, ideally of size close to the optimal decision tree size of \( f \). Perhaps the simplest and most natural approach is to proceed in a top-down, greedy fashion:
Top-Down Induction of Decision Trees

1. Choose a “good” variable $x_i$ to query as the root of the decision tree;
2. Build the left and right subtrees by recursing on the subfunctions $f_{x_i=0}$ and $f_{x_i=1}$ respectively.

This reduces the task of building a decision tree to that of choosing the root variable – i.e. determining the splitting criterion of this top-down heuristic. Intuitively, a good root variable should be one that is very “relevant” and “important” in terms of determining the value of $f$; it is reasonable to expect that querying such a variable first would reduce the number of subsequent queries necessary. Our focus in this paper will be on a specific splitting criterion: influence.

Definition 1 (Influence). The influence of the variable $x_i$ on a function $f : \{0, 1\}^n \rightarrow \{\pm 1\}$ is defined to be

$$\text{Inf}_i(f) := \Pr_{x \sim \{0, 1\}^n} [f(x) \neq f(x^{\oplus i})],$$

where $x$ is drawn uniformly at random, and $x^{\oplus i}$ denotes $x$ with its $i$-th coordinate flipped.

Influence is a fundamental and well-studied notion in the analysis of boolean functions [51]. It is the key quantity of interest in many landmark results (e.g. the KKL inequality [35], Friedgut’s junta theorem [24], the Invariance Principle [50]) and open problems (e.g. the Gotsman–Linial conjecture [29], the Aaronson–Ambainis conjecture [1], the Fourier Entropy-Influence conjecture [25]) of the field. Beyond the analysis of boolean functions, this notion has been widely employed across both algorithms and complexity theory, where it has indeed proven to be a useful quantitative measure of the relevance and importance of a variable. Most relevant to the algorithmic applications in this paper, influence has been a key enabling ingredient in a large number of results in learning theory [15, 9, 45, 63, 54, 31, 19, 36, 37, 5].

1.1 Influence as a splitting criterion

We now give a formal description of the heuristic for constructing decision trees that we study. We define a bare tree to be a decision tree with unlabeled leaves, and write $T^\circ$ to denote such trees. We refer to any decision tree $T$ obtained from $T^\circ$ by a labelling of its leaves as a completion of $T^\circ$. Given a bare tree $T^\circ$ and a function $f$, there is a canonical completion of $T^\circ$ that minimizes the approximation error with respect to $f$:

Definition 2 ($f$-completion of a bare tree). Let $T^\circ$ be a bare tree and $f : \{0, 1\}^n \rightarrow \{\pm 1\}$. Consider the following completion of $T^\circ$: for every leaf $\ell$ in $T^\circ$, label it $\text{sign}(\mathbb{E}[f_{\ell}(x)])$, where $f_\ell$ is the restriction of $f$ by the path leading to $\ell$ and $x \sim \{0, 1\}^n$ is uniform random. This completion minimizes the approximation error $\Pr[T(x) \neq f(x)]$, and we refer to it as the $f$-completion of $T^\circ$.

In addition to the function $f$, our heuristic will also take in an error parameter $\varepsilon$, allowing us to construct both exact ($\varepsilon = 0$) and approximate ($\varepsilon \in (0, \frac{1}{2})$) decision tree representations of $f$. 
**BuildTopDownDT**$(f, \varepsilon)$:

Initialize $T^\circ$ to be the empty tree.

while ($f$-completion of $T^\circ$ is not an $\varepsilon$-approximation of $f$) {

1. (Score) For every leaf $\ell$ in $T^\circ$, let $x_{i(\ell)}$ denote the most influential variable of the subfunction $f_\ell$:

$$\text{Inf}_{i(\ell)}(f_\ell) \geq \text{Inf}_j(f_\ell) \text{ for all } j \in [n].$$

Assign $\ell$ the score:

$$\text{score}(\ell) := \Pr_{x \sim \{0,1\}^n} [x \text{ reaches } \ell] \cdot \text{Inf}_{i(\ell)}(f_\ell) = 2^{-|\ell|} \cdot \text{Inf}_{i(\ell)}(f_\ell),$$

where $|\ell|$ denotes the depth of $\ell$ in $T^\circ$.

2. (Split) Let $\ell^*$ be the leaf with the highest score. Grow $T^\circ$ by replacing $\ell^*$ with a query to $x_{i(\ell^*)}$.

}

**Figure 1** Top-down heuristic for building an $\varepsilon$-approximate decision tree representation of $f$, with influence as the splitting criterion.

In words, **BuildTopDownDT** builds a bare tree $T^\circ$ in a top-down fashion, starting from the empty tree. In each iteration, we first check if the $f$-completion of $T^\circ$ is an $\varepsilon$-approximation of $f$, and if so, we output the completion. Otherwise, we split the leaf $\ell^*$ with the highest score by querying the most influential variable of $f_{\ell^*}$, where the score of a leaf $\ell$ is the influence of the most influential variable of $f_\ell$ normalized by the depth of $\ell$ within $T^\circ$.

1.2 This work

By design, the decision tree returned by **BuildTopDownDT**$(f, \varepsilon)$ is an $\varepsilon$-approximation of $f$. We write TopDownDTSize$(f, \varepsilon)$ to denote the size of this tree, and when $\varepsilon = 0$, we simply write TopDownDTSize$(f)$. The question that motivates our work is:

**What guarantees can we make on TopDownDTSize$(f, \varepsilon)$ as a function of the optimal decision tree size of $f$ and $\varepsilon$?**

That is, we would like to understand the quality of **BuildTopDownDT** as a heuristic for constructing exact and approximate decision tree representations. In addition to being a natural structural question concerning decision trees, this question also has implications in learning theory. Indeed, **BuildTopDownDT** is motivated by top-down decision tree learning heuristics such as ID3, C4.5, and CART that are widely employed and empirically successful in machine learning practice. We discuss the learning-theoretic context and applications of our structural results in Section 2.1, and the connection to practical machine learning heuristics in Section 3.1.

---

1 There are two possibilities for ties in **BuildTopDownDT**: two variables may have the same influence within a subfunction $f_\ell$, and two leaves may have the same score. Our upper bounds hold regardless of how ties are broken, and our lower bounds hold even if ties are broken in the most favorable way.
To our knowledge, the question above has not been studied in such generality. The most directly relevant prior work is that of Fiat and Pechyon [23], who considered the case when \( f \) is either a linear threshold function or a read-once DNF formula, and the setting of exact representation \( (\varepsilon = 0) \). For such functions, they proved that the heuristic builds an exact decision tree representation of optimal size. We give an overview of other related work in Section 3.2.

## 2 Our results

As our first contribution, we give near-matching upper and lower bounds that provide a fairly complete answer to the question above. Our upper bound is as follows:

**Theorem 3 (Upper bound for approximate representation).** For every \( \varepsilon \in (0, \frac{1}{2}) \) and every size-\( s \) decision tree \( f \), we have \( \text{TopDownDTSize}(f, \varepsilon) \leq s^{O \left( \log(s/\varepsilon) \log(1/\varepsilon) \right)} \).

We complement Theorem 3 with lower bounds showing that (a) for exact representation \( (\varepsilon = 0) \), no non-trivial upper bound can be obtained; and (b) for approximate representation \( (\varepsilon \in (0, \frac{1}{2}) \) ), the dependence on \( s \) in Theorem 3 is essentially optimal:

**Theorem 4 (Lower bounds for exact and approximate representations).**

(a) Exact representation: There is an \( f : \{0,1\}^n \rightarrow \{\pm 1\} \) with decision tree size \( s = \Theta(n) \) such that \( \text{TopDownDTSize}(f) \geq 2^\Omega(s) \).

(b) Approximate representation: For every \( \varepsilon \in (0, \frac{1}{2}) \) and function \( s(n) \leq 2^\Omega(\sqrt{n}) \), there is an \( f : \{0,1\}^n \rightarrow \{\pm 1\} \) with decision tree size \( s \) such that \( \text{TopDownDTSize}(f, \varepsilon) \geq s^\Omega(\log s) \).

Prior to our work, it was not known whether an upper bound of \( \text{TopDownDTSize}(f, \varepsilon) \leq \text{poly}(s, 1/\varepsilon) \) holds for all size-\( s \) decision trees \( f \) and \( \varepsilon \in (0, \frac{1}{2}) \); Theorem 4(b) provides a strong negative answer. Indeed, such an upper bound had been conjectured to hold for the class of monotone functions [44]. We now discuss our results on monotone functions, which disprove this conjecture, along with a stronger variant of it for exact representation [23].

### Monotone functions

A monotone boolean function \( f : \{0,1\}^n \rightarrow \{\pm 1\} \) is one that satisfies \( f(x) \leq f(y) \) for all \( x \preceq y \) (where \( x \preceq y \) iff \( x_i \leq y_i \) for all \( i \in [n] \)). An elementary and useful fact about monotone functions is that the influence of a variable on a monotone function \( f \) is equivalent to its correlation with \( f \):

**Fact 5 (Influence \( \equiv \) correlation for monotone functions).** For all monotone functions \( f : \{0,1\}^n \rightarrow \{\pm 1\} \) and \( i \in [n] \), we have \( \text{Inf}_i[f] = 2 \mathbb{E}[f(x|x_i) - f(x)] \).

Therefore, for monotone functions, splitting on the most influential variable of a subfunction is equivalent to splitting on the variable that has the highest correlation with the subfunction.\(^3\)

---

\(^2\) The equivalence between influence and correlation for monotone functions is more transparent if one works with \( \{\pm 1\}^n \) instead of \( \{0,1\}^n \) as the domain: for monotone functions \( f : \{\pm 1\}^n \rightarrow \{\pm 1\} \), we have \( \text{Inf}_i[f] = \mathbb{E}[f(x|x_i)] \).

\(^3\) We observe that for general non-monotone functions, correlation can in general be a very poor splitting criterion, in the sense of building a decision tree that is much larger than the optimal decision tree. Consider \( f : \{0,1\}^n \rightarrow \{\pm 1\} \) where \( f(x) = x_1 \oplus x_2 \), the parity of two variables. The optimal decision tree size of \( f \) is 4, but since \( \mathbb{E}[f(x|x_i)] = 0 \) for all \( i \in [n] \), the top-down heuristic using correlation as its splitting criterion may build a tree of size \( \Omega(2^n) \) before achieving any non-trivial accuracy \( \varepsilon < \frac{1}{2} \). (On the other hand, the top-down heuristic using influence as its splitting criterion would build the optimal tree of size 4.) We revisit this observation in Section 3.1.
Our proof of Theorem 3 extends in a straightforward manner to give a different upper bound under the assumption of monotonicity, where the dependence on $s$ is significantly better. We refer to a size-$s$ decision tree computing a monotone function as a size-$s$ monotone decision tree.

**Theorem 6** (Upper bound for approximate representation of monotone functions.) For every $\varepsilon \in (0, \frac{1}{2})$ and every size-$s$ monotone decision tree $f$, we have $\text{TopDownDTSize}(f, \varepsilon) \leq s^{O(\sqrt{\log s/\varepsilon})}$.

In analogy with Theorem 4, we also obtain lower bounds for exact and approximate representations of monotone functions:

**Theorem 7** (Lower bounds for exact and approximate representations of monotone functions).

(a) Exact representation: There is a monotone $f : \{0, 1\}^n \rightarrow \{\pm 1\}$ with decision tree size $s = \Theta(n)$ such that $\text{TopDownDTSize}(f) \geq 2^{\Omega(s)}$.

(b) Approximate representation: For every $\varepsilon \in (0, \frac{1}{2})$ and function $s(n) \leq 2^{\tilde{O}(n^{4/5})}$, there is an $f : \{0, 1\}^n \rightarrow \{\pm 1\}$ with decision tree size $s$ such that $\text{TopDownDTSize}(f, \varepsilon) \geq s^{\tilde{\Omega}(\sqrt{\log s})}$.

Although we have stated Theorem 7 in terms of the specific heuristic $\text{BuildTopDownDT}$ that we study, the actual lower bounds that we establish are significantly stronger: they apply to all “impurity-based top-down heuristics”. This is a broad class that captures a wide variety of decision tree learning heuristics used in machine learning practice, including ID3, C4.5, and CART; see Section 3.1 for details.

**Theorem 8** (Strengthening of Theorem 7(b)). For every $\varepsilon \in (0, \frac{1}{2})$ and function $s(n) \leq 2^{\tilde{O}(n^{4/5})}$, there is a size-$s$ monotone decision tree $f$ such that the $\varepsilon$-approximator built by any impurity-based top-down heuristic must have size $s^{\tilde{\Omega}(\sqrt{\log s})}$.

**Disproving conjectures of Fiat–Pechyony and Lee**

Motivated by applications in learning theory (discussed next in Section 2.1), Fiat and Pechyony [23] and Lee [44] also considered the quality of $\text{BuildTopDownDT}$ as a heuristic for building decision trees for monotone functions.

[23] conjectured that for all monotone functions $f$, even in the case of exact representation ($\varepsilon = 0$), $\text{BuildTopDownDT}$ returns a tree of minimal depth and size “not far from minimal”. Theorem 7(a) provides a counterexample to the conjectured bound on size, and the function in Theorem 7(b) disproves the conjecture about depth; see Remark 40.4

Stated in the notation of our paper, [44] raised the possibility that $\text{TopDownDTSize}(f, \varepsilon) \leq \text{poly}(s, 1/\varepsilon)$ for all size-$s$ monotone decision trees $f$ and $\varepsilon \in (0, \frac{1}{2})$. The author further remarked that “showing $\text{TopDownDTSize}(f, \varepsilon) \leq \text{poly}(s)$, even only for constant accuracy $\varepsilon$, would be a huge advance”. Theorem 7(b) rules this out.

---

4 For clarity of exposition, throughout this overview we discuss our results with decision tree size as the complexity measure. There are analogues of all of our results, both upper and lower bounds, for decision tree depth as the complexity measure.

5 That is, a bound of the form $\text{TopDownDTSize}(f, \varepsilon) \leq s^{O(1)}$. 

ITCS 2020
2.1 Algorithmic applications: Properly learning decision trees

Learning decision trees has been a touchstone problem in uniform-distribution PAC learning for more than thirty years. It sits right at the boundary of our understanding of efficient learnability, and continues to be the subject of intensive research. The seminal work of Ehrenfeucht and Haussler [21] gave a poly($n \log s, 1/\varepsilon$)-time algorithm for learning decision trees using random examples (see also [8] for an alternative proof based on Rivest’s algorithm for learning decision lists [59]); subsequently, Linial, Mansour, and Nisan [45] gave an algorithm that also runs in quasipolynomial time, but achieves polynomial sample complexity; Kusilevitz and Mansour [43], leveraging a novel connection to cryptography [29], gave a polynomial-time algorithm using membership queries; Gopalan, Kalai, and Klivans [30] obtained an agnostic analogue of [43]’s algorithm, extending it to tolerate adversarial noise; O’Donnell and Servedio [53] gave a polynomial-time algorithm for learning monotone decision trees from random examples; recent work of Hazan, Klivans, and Yuan [33] gives an algorithm agnostically learning decision trees with polynomial sample complexity; even more recent work of Chen and Moitra [17] gives an algorithm for learning stochastic decision trees.

Properly learning decision trees

When learning decision trees, it is natural to seek a hypothesis that is itself a decision tree. Indeed, it may be natural to seek a decision tree hypothesis even when learning other concept classes. The simple structure of decision trees makes them desirable both in terms of interpretability and explanatory power, which is why they are ubiquitous in empirical machine learning. A further advantage of decision tree hypotheses is that they are very fast to evaluate: evaluating a depth-$d$ decision tree on a given input takes time $O(d)$, whereas evaluating say a degree-$d$ polynomial – another canonical and ubiquitous representation class in learning theory – can take time $\Theta(n^d)$, the number of monomials in the polynomial.

In learning theory, algorithms that return a hypothesis belonging to the concept class are known as proper. Understanding the complexity of proper learning (vis-à-vis improper learning) is an important research direction in learning theory [22]; proper learning also has deep connections to proof complexity [2] and property testing [28].

2.1.1 New proper learning algorithms

Among the decision tree learning algorithms discussed at the beginning of this subsection, the only one that is proper is the one of Ehrenfeucht and Haussler [21]. Our upper bounds on TopDownDTSize yield new algorithms for properly learning decision trees under the uniform distribution:

▶ Theorem 9 (Algorithmic consequence of Theorem 3). Size-$s$ decision trees can be properly learned under the uniform distribution in time $\text{poly}(n, s^{\log(s/\varepsilon)} \log(1/\varepsilon))$ using membership queries.8

---

6 In fact, the algorithm of [21] learns decision trees in the more challenging setting of distribution-free PAC learning. All other results in this discussed in this section, including ours, are specific to uniform-distribution learning, and we focus our exposition on this setting.

7 Every size-$s$ decision tree is well-approximated by a decision tree of depth $O(\log s)$.

8 We remark that our algorithm only requires fairly “mild” use of membership queries. Our algorithm only requires random edge samples (Definition 43), and hence falls within both the random walk model of Bshouty et al. [16] and the local membership queries model of Awasthi et al. [3]. These (incomparable) models are natural relaxations of the standard model of learning from random examples, and do not allow the learning algorithm unrestricted membership query access to the target function.
Analogously, Theorem 6 yields a new algorithm for learning monotone decision trees using only random examples. The learnability of monotone functions with respect to various complexity measures has been the subject of intensive study in uniform-distribution learning [32, 41, 39, 14, 15, 9, 66, 60, 63, 53, 62, 18, 44, 34, 54].

**Theorem 10** (Algorithmic consequence of Theorems 3 and 6). Size-$s$ monotone decision trees can be properly learned under the uniform distribution in time

$$\text{poly}(n, \min(s^{O(\log(s/ε) \log(1/ε))}, s^{O(\sqrt{\log s}/ε)}))$$

using only random examples.

We now compare our results with the prior state of the art for properly learning decision trees.

- **Polynomial-time algorithms for superlogarithmic size.** Theorems 9 and 10 give the first polynomial-time algorithms for properly learning decision trees of size $ω(\log n)$ to constant accuracy. To see this, we first note that [21]'s runtime of $\text{poly}(n, \log s, 1/ε)$ is superpolynomial time for any $s = ω(1)$. Alternatively, functions depending on $k \ll n$ variables (“$k$-juntas”) can be properly learned in time $\text{poly}(n, 2^k)$, using random examples for monotone juntas, and membership queries otherwise [10, 49]. Since every size-$s$ decision tree certainly depends on at most $k \leq s$ variables, this runtime is polynomial for decision trees of size $s = O(\log n)$, but becomes superpolynomial once $s = ω(\log n)$. In contrast, the runtimes of our algorithms in Theorems 9 and 10 remain polynomial for $s = 2^{Ω(\sqrt{\log n})}$ and $s = 2^{Ω((\log n)^{2/3})}$ respectively.

- **Dimension-independent hypothesis size.** Related to the above, the sizes of the hypotheses returned by the algorithms of Theorems 9 and 10 are $s^{O(\log(s/ε) \log(1/ε))}$ and $s^{O(\sqrt{\log s}/ε)}$ respectively, independent of $n$, whereas the size of the hypotheses returned by [21]'s algorithm can be as large as $n^{Ω(\log s)}$. This is gap can be exponential or even larger for small values of $s$.

- **Average depth as the complexity measure.** Our algorithms and analyses extend easily to accommodate average depth as the complexity measure. The average depth of a decision tree, $Δ(T)$, is the number of queries $T$ makes on a uniform random input. Average depth is a stronger complexity measure than size since $Δ(T) \leq \log(\text{size}(T))$. To this end, it is easy to construct examples of decision trees $T$ with the largest possible gap between these measures: $Δ(T) = O(1)$ and $\log(\text{size}(T)) = Ω(n)$.

**Theorem 11** (Learning trees with small average depth). Decision trees of average depth $Δ$ can be properly learned under the uniform distribution in time $\text{poly}(n, 2^{Δ^2/ε})$ using membership queries, and monotone decision trees of average depth $Δ$ can be properly learned in time $\text{poly}(n, 2^{Δ^2/ε})$ using random examples.

To our knowledge, these represent the first polynomial-time algorithms for properly learning decision trees of superconstant average depth, $Δ = ω(1)$. Prior to our work, the fastest algorithm ran in time $\text{poly}(n^{Δ/ε})$; this algorithm, which uses random examples, follows implicitly from the results of Mehta and Raghavan [46].
2.2 Proper learning with polynomial sample and memory complexity

For our final contribution, we revisit the classic algorithm of Ehrenfeucht and Haussler [21]. As discussed above, this remains the fastest algorithm for properly learning decision trees. We extend it to give the first uniform-distribution proper algorithm that achieves polynomial sample and memory complexity, while matching its state-of-the-art quasipolynomial runtime (Theorem 54).

Ehrenfeucht and Haussler had posed (as the first open problem of their paper) the question of achieving polynomial sample complexity. Such algorithms were subsequently obtained by Linial, Mansour, and Nisan [45] and Mehta and Raghavan [46]. Interestingly, these two algorithms are very different from each other and from [21]: the algorithm of [45], being Fourier-based, is non-proper, whereas the algorithm of [46], which uses dynamic programming, has a large memory footprint. Furthermore, both algorithms have a quasipolynomial dependence on $1/\varepsilon$ in their runtimes, rather than [21]'s polynomial dependence.

This state of affairs raises the question of whether there is a single algorithm that achieves “the best of [21], [45], and [46]” in each of the four metrics discussed above; see Table 1. We give such an algorithm in this work (Theorem 54). Our algorithm is a surprisingly simple modification of [21]'s algorithm, but our analysis is more involved. At a high level, the idea is to terminate [21]'s algorithm early to achieve our improved sample and memory complexity. However, incorporating this plan with the inherently bottom-up nature of [21]'s algorithm necessitates a delicate error analysis. (In particular, [21]'s algorithm is an Occam algorithm, whereas ours is not.)

We remark that there is an ongoing flurry of research activity on the memory complexity of learning basic concept classes under the uniform distribution, with a specific focus on tradeoffs between memory and sample complexity [64, 65, 57, 42, 47, 58, 48, 4, 26, 27].

---

10 Although our algorithm, like the others in Table 1, only uses random examples, to our knowledge there are no known membership query algorithms that achieve our guarantees.

11 We note that it is possible to combine the ideas in [21] and [46] to give an algorithm that runs in $\text{poly}(n^{\log(s/\varepsilon)})$ time and has sample and memory complexity $\text{poly}(s, 1/\varepsilon) \cdot \log n$ and $\text{poly}(n, s, 1/\varepsilon)$ respectively. We do not provide the details in this paper since our main result (Theorem 54) achieves strictly better guarantees.
3 Discussion and related work

3.1 Relationship to practical machine learning heuristics

Our work is motivated in part by the tremendous popularity and empirical success of top-down decision tree learning heuristics in machine learning practice, such as ID3 [55], its successor C4.5 [56], and CART [11]. The data mining textbook [67] describes C4.5 as “a landmark decision tree program that is probably the machine learning workhorse most widely used in practice to date”. In a similar vein, quoting Kearns and Mansour [40], “In experimental and applied machine learning work, it is hard to exaggerate the influence of top-down heuristics for building a decision tree from labeled sample data [...] Dozens of papers describing experiments and applications involving top-down decision tree learning algorithms appear in the machine learning literature each year”.

We give a high-level description of how these heuristics work, using the framework of uniform-distribution learning. As we will soon see, they serve as motivation for the heuristic that we study, BuildTopDownDT (Figure 1). These heuristics grow a bare tree $T^{°}$ for a function $f : \{0, 1\}^n \rightarrow \{0, 1\}$ as follows. Consider the progress measure

$$H(T^{°}) := \sum_{\ell \in \text{leaves}(T^{°})} \Pr_{x \sim \{0, 1\}^n}[x \text{ reaches } \ell] \cdot G[E[f_{\ell}]]$$

where $G : [0, 1] \rightarrow [0, 1]$ is known as the impurity function, and encapsulates the splitting criterion of the heuristic. This carefully chosen function is restricted to be concave, symmetric around $\frac{1}{2}$, and to satisfy $G(0) = G(1) = 0$ and $G(\frac{1}{2}) = 1$. For example, $G$ is the binary entropy function in ID3 and C4.5; CART uses $G(p) = 4p(1 - p)$, known as the Gini criterion; [40] studies the variant $G(p) = 2\sqrt{p(1 - p)}$.

12 Writing $T^{°}_{\ell, i}$ to denote $T^{°}$ with its leaf $\ell$ replaced with a query to the variable $x_i$, these heuristics, in a single iteration, grow $T^{°}$ to $T^{°}_{\ell^*, i^*}$, where

$$(\ell^*, i^*) \text{ is the leaf-variable pair that maximizes } H(T^{°}) - H(T^{°}_{\ell^*, i^*}).$$

We refer to any such top-down heuristic as an impurity-based heuristic, and the progress measure $H(T^{°}) - H(T^{°}_{\ell^*, i^*})$ as the purity gain.

Inherent limitations of impurity-based heuristics

It is easy to see (and has been well known [38]) that impurity-based heuristics can, in general, fare very badly, in the sense of building a decision tree that is much larger than the optimal decision tree. For example, consider $f(x) = x_j \oplus x_k$ for $j, k \in [n]$, the parity of two variables. For such a target function, regardless of the choice of the impurity function $G$, splitting on any of the $n$ variables results in zero purity gain. This is because $E[f] = E[f_{x_i = b}]$ for all $i \in [n]$ and $b \in \{0, 1\}$. Therefore, any impurity-based heuristic may build a tree of size $\Omega(2^n)$ before achieving any non-trivial error $\varepsilon < \frac{1}{2}$, whereas the size of the optimal tree of $f$ is 4.

One could exclude such “parity-like” examples by considering only monotone functions. Monotonicity is a ubiquitous condition in machine learning since many data sets are naturally monotone in their attributes. In the case of monotone functions, it can be shown that for
any *impurity function* \( \mathcal{G} \), the variable split that results in the most progress in the sense of (1), i.e. the variable \( x_i \) that maximizes the purity gain

\[
\mathcal{G}(E[f]) - \frac{1}{2}(\mathcal{G}(E[f_{x_i=0}]) + \mathcal{G}(E[f_{x_i=1}]))
\]

is precisely the most influential variable of \( f \) (we prove this in Section 7; see Proposition 41). In other words, in the case of monotone functions, \textsc{BuildTopDownDT} closely models impurity-based heuristics. The works of Fiat and Pechyon [23] and Lee [44] (recall our discussion following Theorem 8) were explicitly motivated by this observation, as are our results on monotone functions (Theorems 6 to 8 and 10).

As we will show, our monotone lower bounds for \textsc{BuildTopDownDT} actually apply to all impurity-based heuristics (Theorem 8), regardless of the choice of the impurity function \( \mathcal{G} \) (hence including ID3, C4.5, and CART).\(^{13}\) Since one could argue that real-world data sets are unlikely to be “parity-like”, we view our monotone lower bounds as providing more robust (albeit still only theoretical) evidence of the limitations and potential shortcomings of the impurity-based top-down heuristics used in practice.

**Top-down versus bottom-up: from practice to theory?**

We find it especially intriguing that the algorithm of Ehrenfeucht and Haussler [21] – which, as discussed, remains the fastest algorithm for properly learning decision trees with provable runtime guarantees – builds its hypothesis tree bottom up, in exactly the opposite order from the top-down heuristics used in practice. It is natural to ask if top-down heuristics can serve as inspiration for the design and analyses of fundamentally different algorithms for properly learning decision trees.

Our algorithmic upper bounds for \textsc{BuildTopDownDT} (Theorems 9 and 10) provide affirmative answers, and as discussed above, these new algorithms even have certain qualitative advantages over [21]. Our lower bounds (Theorems 4 and 7), on the other hand, establish their inherent limitations. They imply that \textsc{BuildTopDownDT} is provably not a polynomial-time algorithm for properly learning decision trees using membership queries, or a polynomial-time algorithm for properly learning monotone decision trees using random examples. Either of these results would constitute a major advance in learning theory, and \textsc{BuildTopDownDT} – and other impurity-based variants of it – had been a natural candidate for obtaining them. Indeed, the results of [44] were explicitly motivated by the goal of showing that \textsc{BuildTopDownDT} is a polynomial-time algorithm for properly learning monotone decision trees. This is now ruled out by Theorems 7 and 8.\(^{14}\)

**3.2 Related work**

Fiat and Pechyon [23] considered linear threshold functions and read-once DNF formulas, and showed that \textsc{BuildTopDownDT}, when run on such functions, returns a decision tree of optimal size computing them exactly. (Stated in the notation of Theorem 3, \( \textsc{TopDownDTSize}(f) = s \) for such functions.)

\(^{13}\)Different impurity functions \( \mathcal{G} \) lead to different *orderings* of leaves to split, and hence result in different trees.

\(^{14}\)Blum et al. [7] gave an information-theoretic lower bound showing that no “statistical query” algorithm can learn decision trees in polynomial time. However, this lower bound does not apply when membership queries are allowed or when the function is assumed to be monotone.
Kearns and Mansour [40] (see also [38, 20]) showed that impurity-based heuristics are boosting algorithms, where one views the functions labeling internal nodes of the tree (single variables in our case) as weak learners. At a high level, the proofs of our upper bounds (Theorems 3 and 6) are similar in spirit to their analysis, in the sense that they are all incremental in nature, showing that each split contributes to the accuracy of the decision tree hypothesis. However, our results and analyses are incomparable — for example, [40] does not relate the size of the resulting hypothesis to the size of the optimal decision tree; [40]’s analysis assumes the existence of weak learners for all filtered-and-rebalanced versions of the target distribution, whereas we carry out the entirety of our analyses with respect to the uniform distribution.\footnote{Indeed, [40]’s results concern impurity-based heuristics, and as discussed above, statements like Theorem 3 that apply to all functions cannot hold for such heuristics because of parity-like functions.}

Recent work of Brutzkus, Daniely, and Malach [13] studies a variant of ID3 proposed by [40], focusing on learning conjunctions and read-once DNF formulas under product distributions. They provide theoretical and empirical evidence showing that for such functions, the size-$t$ tree grown by [40]’s variant of ID3 achieves optimal or near-optimal error among all trees of size $t$. Concurrent work by the same authors [12] shows that ID3 efficiently learns $(\log n)$-juntas in the setting of smoothed analysis.

4 Preliminaries

Throughout this paper, we use bold font (e.g. $\mathbf{x}$ and $\mathbf{S}$) to denote random variables; all probabilities and expectations are with respect to the uniform distribution unless otherwise stated.

For any decision tree $T$, we say the size of $T$ is the number of leaves in $T$, and the depth of $T$ is length of the longest path between the root and a leaf. If a tree has size 1, then it contains a single leaf, computes either the constant $+1$ or constant $-1$ function, and has depth 0. For a function $f : \{0,1\}^n \rightarrow \{\pm 1\}$, the optimal decision tree size of $f$ is the smallest $s$ for which there exists a decision tree of size $s$ that exactly computes $f$, and we write $\text{size}(f)$ to denote this quantity. If $T$ is a decision tree that computes $f$, then we will often use $T$ interchangeably with $f$.

Choose any $f, g : \{0,1\}^n \rightarrow \{\pm 1\}$. Then, the error is defined as

$$\text{error}(f,g) = \Pr_{\mathbf{x} \sim \{0,1\}^n}[f(\mathbf{x}) \neq g(\mathbf{x})].$$

We say that $f$ is an $\varepsilon$-approximation of $g$ if $\text{error}(f,g) \leq \varepsilon$. If $T^\circ$ is a bare tree, then $\text{error}(T^\circ, f)$ is shorthand for $\text{error}(T, f)$ where $T$ is the $f$-completion of $T^\circ$. We also use the following shorthand.

$$\text{error}(f, \pm 1) = \min(\text{error}(f, -1), \text{error}(f, 1)).$$

The variance of $f : \{0,1\}^n \rightarrow \{\pm 1\}$, denoted $\text{Var}(f)$, is

$$\text{Var}(f) = 4 \cdot \Pr[f(\mathbf{x}) = -1] \cdot \Pr[f(\mathbf{x}) = 1].$$

The total influence of $f$, denoted $\text{Inf}(f)$, is

$$\text{Inf}(f) = \sum_{i=1}^n \text{Inf}_i(f).$$
It is easy to see that for any decision tree $T : \{0, 1\}^n \rightarrow \{\pm 1\}$,

$$\text{error}(T, \pm 1) \leq \text{Inf}(T)$$

and

$$\frac{\text{Var}(T)}{2} \leq \text{error}(T, \pm 1) \leq \text{Var}(T)$$

always hold.

5 Upper bounds on TopDownDTsize: Proofs of Theorems 3 and 6

Recall that BuildTopDownDT$(f, \varepsilon)$ continually grows a bare tree, $T^\circ$, until the $f$-completion of $T^\circ$ is an $\varepsilon$-approximation of $f$. At a high level, the proofs of our upper bounds on TopDownDTsize proceed as follows.

Section 5.1 We define a progress metric, the “cost” of $T^\circ$, which upper bounds the error of the $f$-completion of $T^\circ$ with respect to $f$. Hence, when the “cost” drops below $\varepsilon$, BuildTopDownDT can terminate. We show that whenever BuildTopDownDT grows $T^\circ$, the “cost” of $T^\circ$ decreases by exactly the score of the leaf selected.

Section 5.2 We lower bound the score of the leaf that BuildTopDownDT selects.

Section 5.3 We put the above together to prove upper bounds on TopDownDTsize. At each step, the “cost” of $T^\circ$ must decrease by at least the lower bounds in Section 5.2, which allows us to upper bound the number of steps until the “cost” falls below $\varepsilon$. This is sufficient since the size of the tree that BuildTopDownDT produces is exactly one more than the number of steps it takes.

5.1 Definition and properties of “Cost”

Definition 12 (Cost of a bare tree). Let $f : \{0, 1\}^n \rightarrow \{\pm 1\}$ be a function and $T^\circ$ be a bare tree. Then the cost of $T^\circ$ relative to $f$ is defined as

$$\text{cost}_f(T^\circ) = \sum_{\text{leaf } \ell \in T^\circ} 2^{-|\ell|} \cdot \text{Inf}(f_\ell).$$

This cost function is useful to track because it naturally decreases during BuildTopDownDT and upper bounds the error of the completion.

Lemma 13 (Properties of cost of a bare tree). For any $f : \{0, 1\}^n \rightarrow \{\pm 1\}$ and bare tree $T^\circ$, the following hold:

1. $\text{error}(T^\circ, f) \leq \text{cost}_f(T^\circ)$.
2. Choose any leaf $\ell$ of $T^\circ$ and variable $x_i$. Let $(T^\circ)'$ be the bare tree that results from replacing $\ell$ in $T^\circ$ with a query to $x_i$. Then,

$$\text{cost}_f((T^\circ)') = \text{cost}_f(T^\circ) - 2^{-|\ell|} \cdot \text{Inf}_i(f_\ell).$$

At each step, BuildTopDownDT splits the leaf with the largest score, resulting in the cost decreasing by exactly the score selected. Once the cost decreases to below $\varepsilon$, we know the completion of $T^\circ$ is an $\varepsilon$-approximation of $f$, meaning BuildTopDownDT can terminate.
Proof. The proof of (1) is a simple application of the fact that \( \text{error}(g, \pm 1) \leq \text{Inf}(g) \) for any boolean function \( g \):

\[
\text{error}(T^\circ, f) = \Pr_{x \sim \{0,1\}^n} [ (\text{Completion of } T^\circ)(x) \neq f(x) ]
\]

\[
= \sum_{\text{leaf } \ell \in T^\circ} \Pr_{a \sim \{0,1\}^n} [ x \text{ reaches } \ell ] \cdot \text{error}(f_\ell, \pm 1)
\]

\[
\leq \sum_{\text{leaf } \ell \in T^\circ} 2^{-|\ell|} \cdot \text{Inf}(f_\ell) = \text{cost}_f(T^\circ).
\]

The proof of (2) follows from the fact that if \( T \) is a tree with \( x_i \) at the root, \( T_0 \) as its \( 0 \)-subtree, and \( T_1 \) as its \( 1 \)-subtree, then \( \text{Inf}(T) - \text{Inf}_i(T) = \frac{1}{2}(\text{Inf}(T_0) + \text{Inf}(T_1)) \). This fact is true because

\[
\text{Inf}(T) - \text{Inf}_i(T) = \sum_{j \neq i} \text{Inf}_j(T)
\]

\[
= \sum_{j \neq i} \frac{1}{2} \text{Inf}_j(T_0) + \frac{1}{2} \text{Inf}_j(T_1)
\]

\[
= \frac{1}{2} \left( \sum_{j=1}^n \text{Inf}_j(T_0) + \sum_{j=1}^n \text{Inf}_j(T_1) \right)
\]

\[
= \frac{1}{2} (\text{Inf}(T_0) + \text{Inf}(T_1)).
\]

5.2 Lower bounds on the score of the leaf \( \text{BuildTopDownDT} \) selects

We give two different lower bounds. These lower bounds are incomparable, so when proving Theorems 3 and 6, we use whichever is better. Both of these lower bounds rely on a powerful inequality from the analysis of boolean functions due to O’Donnell, Saks, Schramm, and Servedio [52], which we restate in the form most convenient for us.

\[\textbf{Theorem 14} \text{ (Corollary of Theorem 1.1 from [52]). Let } f \text{ be a size-}s \text{ decision tree. Then, }\]

\[
\max_i \text{Inf}_i(f) \geq \frac{\text{Var}(f)}{\log s}.
\]

We prove our first lower bound on the score of the leaf selected.

\[\textbf{Lemma 15. Let } f \text{ be a size } s \text{ decision tree. At step } j, \text{BuildTopDownDT}(f, \varepsilon) \text{ selects a leaf, } \ell^* \text{ with score at least }\]

\[
\text{score}(\ell^*) \geq \frac{\varepsilon}{(j+1) \log(s)}.
\]

Proof. If \( \text{BuildTopDownDT} \) has not terminated at step \( j \), then, the completion of \( T^\circ \) is not an \( \varepsilon \)-approximation of \( f \). Equivalently,

\[
\sum_{\text{leaf } \ell \in T^\circ} 2^{-|\ell|} \cdot \text{error}(f_\ell, \pm 1) > \varepsilon
\]

At step \( j \), there are exactly \( j + 1 \) leaves in \( T^\circ \), so there must be at least one leaf, \( \ell \), where

\[
2^{-|\ell|} \cdot \text{error}(f_\ell, \pm 1) > \frac{\varepsilon}{j + 1}.
\]
44:14 Top-Down Induction of Decision Trees

Since $\Var(f_t) \geq \error(f_t, \pm 1)$, we also know

$$2^{-|T|} \cdot \Var(f_t) > \frac{\epsilon}{j + 1}.$$ 

By Theorem 14, we know, for some variable $x_i$, $\Inf_i(f_t) \geq \Var(f_t)/\log(\text{size}(f_t))$. The optimal size of any restriction of $f$ is certainly at most the optimal size of $f$ itself, so

$$2^{-|T|} \cdot \Inf_i(f_t) > \frac{\epsilon}{(j + 1)\log(s)}.$$ 

Since $\text{BUILD\text{-}TOP\text{-}DOWN\text{-}DT}$ picks a leaf with maximum score, and $\ell$ has a score at least $\epsilon/(j + 1)\log(s)$, it must pick a leaf with at least that score. \hfill \blacksquare

A standard fact from the analysis of boolean functions gives a $\log s$ upper bound on the total influence of a size-$s$ decision tree (see e.g. [53]). In order to prove a second lower bound on the score of the leaf that $\text{BUILD\text{-}TOP\text{-}DOWN\text{-}DT}$ selects, we will need a refinement of this bound that takes into account the variance of the function. The following lemma is a slight variant of a related (though incomparable) result in [6], which upper bounds the total influence of an $s$-term DNF formula by $2\mu \log(s/\mu)$, where $\mu := \Pr[f(x) = 1]$.

\textbf{Lemma 16 (Total influence of size-$s$ DTs).} Let $f : \{0, 1\}^n \to \{\pm 1\}$ be computed by a size-$s$ decision tree $T$. Then

$$\Inf(f) \leq \Var(f) \log(4s/\Var(f)).$$

\textbf{Proof.} We may assume without loss of generality that $\mu := \Pr[f(x) = 1] \leq \frac{1}{2}$, since $\Inf(f) = \Inf(\neg f)$ and if $f$ is a size-$s$ decision tree then so is its negation $\neg f$. Since

$$\Inf(f) = \sum_{x \sim \{0, 1\}^n} \left[ \sens_f(x) \right]$$

(\text{where } \sens_f(x) := |\{i \in [n] : f(x) \neq f(x^{\pm 1})\}|)

$$= 2 \cdot \sum_{1\text{-leaves } \ell \in T} 2^{-|\ell|} \cdot |\ell|$$

(\text{sens}_f(x) \leq |\ell| \text{ for every } x \text{ that reaches } \ell)

$$\leq 2\mu \log(s/\mu)$$

(Concavity of $t \mapsto t \log(1/t)$, and size($T$) $\leq s$)

$$\leq \Var(f) \log(4s/\Var(f)),$$

(Var($f$) = $4\mu(1 - \mu)$, and our assumption that $\mu \leq \frac{1}{2}$)

the lemma follows. \hfill \blacksquare

We now provide a second lower bound on the score of the leaf $\text{BUILD\text{-}TOP\text{-}DOWN\text{-}DT}$ selects. The lower bound provided below in Lemma 17 is better than the bound provided by Lemma 15 when $\cost_f(T^o)$ is large.

\textbf{Lemma 17.} Let $f$ be a size $s$ decision tree. Suppose that $\text{BUILD\text{-}TOP\text{-}DOWN\text{-}DT}(f, \epsilon)$ has already constructed the bare tree $T^o$ at step $j$ and that $\cost_f(T^o) \geq \epsilon \log(4s/\epsilon)$. Then, the next leaf, $\ell^*$, that $\text{BUILD\text{-}TOP\text{-}DOWN\text{-}DT}$ picks has score at least

$$\text{score}(\ell^*) \geq \frac{\cost_f(T^o)}{(j + 1) \log(4s/\epsilon) \log(s)}.$$ 

\textbf{Proof.} We will show that when $\cost_f(T^o)$ is large, there is some leaf with high total influence, which means it must have high variance, and finally a variable with high influence.

We define:

$$h_s : [0, 1] \to \mathbb{R} \text{ where } h_s(t) = t \log \left( \frac{4s}{t} \right) \text{ and } h_s(0) = 0.$$
Then, for any tree $T$ of size at most $s$, we have that

$$\inf(T) \leq h_s(\text{Var}(T)).$$

As long as $s \geq 1$, $h_s$ is an increasing concave function. This means it has a convex inverse, $h_s^{-1}$, and that for any tree $T$ of size at most $s$, the following lower bounds the variance.

$$\text{Var}(T) \geq h_s^{-1}(\inf(T)). \quad (2)$$

Since $h_s^{-1}$ is convex and $h_s^{-1}(0) = 0$, we can lower bound it as follows. Choose arbitrary $a \in \mathbb{R}$. Then, for $t \geq a$ we have that $h_s^{-1}(t) \geq t \cdot \frac{h_s^{-1}(a)}{a}$. Choosing $a = \varepsilon \log(4s/\varepsilon)$, we have that,

$$h_s^{-1}(t) \geq \frac{t}{\log(4s/\varepsilon)} \text{ for all } t \geq \varepsilon \log \left(\frac{4s}{\varepsilon}\right).$$

Consider the bare tree, $T^\circ$, at step $j$. By definition, it has cost

$$\sum_{\text{leaf } \ell \in T^\circ} 2^{-|\ell|} \cdot \inf(f_\ell) = \text{cost}_f(T^\circ).$$

We next apply Jensen’s inequality.

$$\sum_{\text{leaf } \ell \in T^\circ} 2^{-|\ell|} \cdot h_s^{-1}(\inf(f_\ell)) \geq h_s^{-1}(\text{cost}_f(T^\circ)).$$

Since, at step $j$, there are $j + 1$ leaves in $T^\circ$, for at least one of the leaves, $\ell$,

$$2^{-|\ell|} \cdot h_s^{-1}(\inf(f_\ell)) \geq h_s^{-1}(\text{cost}_f(T^\circ)) \geq \frac{\text{cost}_f(T^\circ)}{(j + 1) \log(\frac{4s}{\varepsilon})}.$$

By Equation (2), we can lower bound the variance of $f_\ell$:

$$2^{-|\ell|} \cdot \text{Var}(f_\ell) \geq 2^{-|\ell|} \cdot h_s^{-1}(\inf(f_\ell)) \geq \frac{\text{cost}_f(T^\circ)}{(j + 1) \log(\frac{4s}{\varepsilon})}.$$
Then, using Theorem 14 and the fact that if $f$ is exactly computed by a size $s$ tree, then $f_\ell$ is exactly computed by a tree of size at most $s$.

$$2^{-\ell} \cdot \max_i \{ \text{Inf}_i[f_\ell] \} \geq \frac{\text{cost}_f(T^\circ)}{(j+1) \log(\frac{4s}{\varepsilon}) \log(s)}.$$  

Recall that \texttt{BuildTopDownDT} picks the leaf with largest score, so it will pick a leaf with score at least $\frac{\text{cost}_f(T^\circ)}{(j+1) \log(4s/\varepsilon) \log(s)}$.

5.3 Proofs of Theorems 3 and 6

Armed with the above Lemmas, we are now ready to prove our upper bounds on the size of the tree that \texttt{BuildTopDownDT} produces.

\begin{theorem}[Upper bound for approximate representation] For every $\varepsilon \in (0, \frac{1}{2})$ and every size-$s$ decision tree $f$, we have $\text{TopDownDTSize}(f, \varepsilon) \leq s^{O(\log(\frac{4s}{\varepsilon}) \log(1/\varepsilon))}$.
\end{theorem}

\begin{proof}

We use $C_j$ to refer to $\text{cost}_f(T^\circ)$ after $j$ steps of \texttt{BuildTopDownDT}. The size of the tree returned is one more than the number of steps \texttt{BuildTopDownDT} takes. Furthermore, if $C_j \leq \varepsilon$, then $T^\circ$ has error at most $\varepsilon$ at step $j$, so \texttt{BuildTopDownDT} will return a tree of size at most $j + 1$.

Our analysis proceeds in two phases:

**Phase 1:** We will show that the larger $C_j$ is, the faster it must decrease at each step. This multiplicative reduction of $C_j$ will allow us to conclude that after at most $k = s^{\log(4s/\varepsilon) \log(1/\varepsilon)}$ steps, that $C_k \leq \varepsilon \log(\frac{4s}{\varepsilon})$.

**Phase 2:** We will argue that $C_j$ makes additive progress towards 0 once it is less than $\varepsilon \log(\frac{4s}{\varepsilon})$, showing that after $m = s^{2\log(4s/\varepsilon) \log(1/\varepsilon)}$ steps, that $C_m \leq \varepsilon$.

Once $C_m \leq \varepsilon$, the algorithm must terminate.

**Phase 1:** Based on Lemma 17, we know that during phase 1, \texttt{BuildTopDownDT} will select a leaf with influence at least $\frac{\text{cost}_f(T^\circ)}{(j+1) \log(4s/\varepsilon) \log(s)}$ at each step $j$. From Lemma 13, we know that:

$$C_j \leq C_{j-1} - \frac{C_j}{j \log(4s/\varepsilon) \log(s)} = C_{j-1} \cdot \left(1 - \frac{1}{j \log(4s/\varepsilon) \log(s)}\right).$$

We can use this to bound $C_k$, the cost after some ($k$) number of steps, in terms of $C_0$.

$$C_k \leq C_0 \prod_{j=1}^{k} \left(1 - \frac{1}{j \log(4s/\varepsilon) \log(s)}\right) = C_0 \exp \left(\sum_{j=1}^{k} \log \left(1 - \frac{1}{j \log(4s/\varepsilon) \log(s)}\right)\right).$$

Using the fact that $\log(1 + t) < t$,

$$C_k \leq C_0 \exp \left(- \sum_{j=1}^{k} \frac{1}{j \log(4s/\varepsilon) \log(s)}\right) \leq C_0 \exp \left(- \frac{\log k}{\log(4s/\varepsilon) \log(s)}\right).$$
We know that $C_0 \leq \log s$ because a size-$s$ decision tree has total influence at most $\log s$ (see e.g. [53]). Choosing

$$k = \exp \left( \log(4s/\varepsilon) \log(s) \log(1/\varepsilon) \right) = s^{\log(4s/\varepsilon) \log(1/\varepsilon)}$$

it must be true that $C_k \leq \varepsilon \log(4s/\varepsilon)$.

**Phase 2:** This phase combines Lemmas 13 and 15, which together imply that

$$C_{j+1} \leq C_j - \frac{\varepsilon}{(j+1) \log s}.$$ 

This means that, for $m > k$,

$$C_k - C_m \geq \sum_{j=k+1}^{m} \frac{\varepsilon}{(j+1) \log s} \geq \frac{\varepsilon}{\log s} (\log m - \log k).$$

We are guaranteed to terminate at the first $j$ such that $C_j \leq \varepsilon$, or earlier. Choosing

$$\log m = \frac{\log s}{\varepsilon} C_k + \log k$$

ensures that $C_m \leq 0$, which means $\text{BuildTopDownDT}$ must terminate before step $m$. Plugging in $C_k \leq \varepsilon \log(4s/\varepsilon)$ and $k = s^{\log(4s/\varepsilon) \log(1/\varepsilon)}$ gives that

$$m \leq s^{2 \log(4s/\varepsilon) \log(1/\varepsilon)}.$$ 

Since $\text{BuildTopDownDT}$ terminates after at most $m$ steps, it returns a tree of size at most $m + 1$.

The proof of Theorem 6 is mostly the same as Phase 2 from the proof of Theorem 3, except we have a better guarantee on the starting cost. We will use the following upper bound on the total influence of monotone decision trees, due to O’Donnell and Servedio [53]:

▶ **Theorem 18** ([53]). Let $f$ be a size-$s$ monotone decision tree. Then $\inf(f) \leq \sqrt{\log s}$.

▶ **Theorem 6** (Upper bound for approximate representation of monotone functions.). For every $\varepsilon \in (0, \frac{1}{2})$ and every size-$s$ monotone decision tree $f$, we have $\text{TopDownDTSize}(f, \varepsilon) \leq s^{O(\sqrt{\log s/\varepsilon})}$.

**Proof.** We use $C_j$ to refer to $\text{cost}_f(T^o)$ after $j$ steps of $\text{BuildTopDownDT}$. By combining Lemma 15 and Lemma 13, we know that

$$C_{j+1} \leq C_j - \frac{\varepsilon}{(j+1) \log s}.$$ 

At any step $k$,

$$C_0 - C_k \geq \sum_{j=0}^{k-1} \frac{\varepsilon}{(j+1) \log s} \geq \frac{\varepsilon \cdot \log k}{\log s}.$$ 

Since $f$ is a monotone decision tree of size $s$, it has total influence at most $\sqrt{\log s}$ (Theorem 18). This means that $C_0 \leq \sqrt{\log s}$. We choose

$$k = \exp(\log(s)^{1.5}/\varepsilon) = s^{\log s/\varepsilon}$$

at which point, $C_k \leq 0 \leq \varepsilon$, so $\text{BuildTopDownDT}$ returns a tree of size $k + 1$. ◀
6 Lower bounds on \( \text{TopDownDTSize} \) for general functions: Proof of Theorem 4

6.1 Size separation for exact representation: Proof of Theorem 4(a)

We begin with a simple family of functions \( \{ f_h \}_{h \in \mathbb{N}} \) whose \( \text{BuildTopDownDT} \) tree has exponential size compared to the optimal tree. Each \( f_h \) is a function over \( 3h + 1 \) boolean variables \( x^{(1)}_1, x^{(1)}_2, \ldots, x^{(h)}_1, x^{(h)}_2, y^{(1)}_1, \ldots, y^{(h)}_1, z \), and is defined inductively as follows:

\[
 f_0(z) = z, \\
 \text{and for } h \geq 1, \\
 f_h(x, y, z) = \begin{cases} 
 y^{(h)} & \text{if } x^{(h)}_1 \lor x^{(h)}_2 \\
 f_{h-1}(x, y, z) & \text{otherwise.}
\end{cases}
\]

The structure of \( \text{BuildTopDownDT}(f_h) \)

We see that \( y^{(h)} \) has influence \( \frac{3}{4} \), both \( x^{(h)}_1 \) and \( x^{(h)}_2 \) have influence \( \frac{1}{4} \), and each variable in \( f_{h-1} \) has influence \( < \frac{1}{4} \). \( \text{BuildTopDownDT}(f_h) \) therefore queries \( y_k \) at the root. In the restrictions of \( f_h \) obtained by setting \( y^{(h)} \) to a constant, \( x^{(h)}_1 \) and \( x^{(h)}_2 \) have equal influence of \( \frac{1}{4} \) and each variable in \( f_{h-1} \) has influence \( < \frac{1}{4} \). By setting either \( x^{(h)}_1 \) or \( x^{(h)}_2 \) to a constant, we get a subfunction where the other \( x^{(h)} \)-variable has influence \( \frac{1}{2} \) and each node in \( f_{h-1} \) has influence \( < \frac{1}{4} \). Thus, \( \text{BuildTopDownDT}(f_h) \) builds the tree \( T_h \) depicted in Figure 3.

We see that each \( T_h \) contains two copies of \( T_{h-1} \). It follows that the optimal size of \( f_h \) is \( O(h) \), whereas the size of \( T_h \) is \( 2^{\Omega(h)} \): a size separation of \( \text{TopDownDTSize}(f_h) = 2^{\Omega(s)} \) where \( s \) denotes the optimal size of \( f_h \).
6.2 Size separation for approximate representation: Proof of Theorem 4(b)

Warmup/intuition: An $s$ versus $s^{Ω(\log(1/ε))}$ separation

Before proving Theorem 4(b), we first give a brief, informal description of how a simple modification to the family of functions $\{f_h\}_{h \in \mathbb{N}}$ in Theorem 4(a) above yields a separation of TopDownDTSize$(f, ε) = s^{Ω(\log(1/ε))}$ for approximate representation. Theorem 4(b) – which improves this to a superpolynomial separation even for constant $ε$ – builds on these ideas, but the family of functions and the proof of the lower bound are significantly more involved.

Consider replacing each $y_i^{(h)}$ variable in the definition of $f_h$ with the parity of $k$ variables $y_1^{(h)} \oplus \cdots \oplus y_k^{(h)}$, i.e. consider the following variant $\tilde{f}_h$ of $f_h$:

$$\tilde{f}_h(x, y, z) = \begin{cases} y_1^{(h)} \oplus \cdots \oplus y_k^{(h)} & \text{if } x_1^{(h)} \lor x_2^{(h)} \\ \tilde{f}_{h-1}(x, y, z) & \text{otherwise.} \end{cases}$$

Just like the single $y_i^{(h)}$ variable in $f_h$, we see that the $k$ many $y_i^{(h)}$ variables are the most influential in $\tilde{f}_h$ (each having influence $\frac{1}{3}$). Furthermore, each $y_i^{(h)}$ variable remains the most influential even under any restriction to any number of the other $y_j^{(h)}$ variables. Therefore the tree $\tilde{T}_h$ that BuildTopDownDT builds for $\tilde{f}_h$ first queries all $k$ many $y_i^{(h)}$ variables. At each of the $2^k$ resulting leaves, $x_1^{(h)}$ and $x_2^{(h)}$ are then queried, followed by a copy of $\tilde{T}_{h-1}$, the tree that BuildTopDownDT recursively constructs for $\tilde{f}_h$, in the branch corresponding to $x_1^{(h)} = x_2^{(h)} = 1$. The fact that there are $2^k$ copies of $\tilde{T}_{h-1}$ within $\tilde{T}_h$ should be contrasted with the fact that the tree $T_h$ in Theorem 4(a) contains just two copies of $T_{h-1}$; recall Figure 3.

It is straightforward to see that there is a tree of size $O(h \cdot 2^k)$ that computes $\tilde{f}_h$. This tree is built by first querying the $x_i^{(h)}$ variables before the $y_i^{(h)}$ variables, and recursing on just one of the $\Omega(2^k)$ many resulting leaves. On the other hand, by first querying the $y_i^{(h)}$ variables followed by the $x_i^{(h)}$ variables, BuildTopDownDT recurses on $\Omega(2^k)$ many branches while only correctly classifying a $\frac{1}{2}$ fraction of inputs. Choosing $h = \Theta(\log(1/ε))$, we get a separation of $O(h \cdot 2^k)$ versus $2^{\Omega(kh)}$, or equivalently, $s$ versus $s^{Ω(\log(1/ε))}$.

6.2.1 Proof of Theorem 4(b)

Before defining the family of functions witnessing the separation, we define a couple of basic boolean functions and state a few of their properties that will be useful for our analyses:

Definition 19 (Tribes). For any input length $r$, let $w$ be the largest integer such that $(1 - 2^{-w})^r/w \leq \frac{1}{2}$. The Tribes, $\{0, 1\}^r \rightarrow \{\pm 1\}$ function is defined to be the function computed by the read-once DNF with $\lceil \frac{r}{w} \rceil$ terms (over disjoint sets of variables) of width exactly $w$:

$$\text{Tribes}_r(z) = (z_{t,1} \land \cdots \land z_{t,w}) \lor \cdots \lor (z_{t,1} \land \cdots \land z_{t,w})$$

where $t := \lceil \frac{r}{w} \rceil$,

and where we adopt the convention that $-1$ represents logical FALSE and 1 represents logical TRUE.

The following facts about the Tribes function are standard (see Chapter §4.2 of [51]) and can be easily verified:
Fact 20 (Properties of $\text{Tribes}_r$).
- $\Pr[\text{Tribes}_r(z) = 1] = \frac{1}{2} - O\left(\frac{\log r}{r}\right)$.
- $\inf(\text{Tribes}_r) = (1 \pm o(1)) \cdot \ln r$ and consequently, $\inf_i(\text{Tribes}_r) = (1 \pm o(1)) \cdot \frac{\ln r}{r}$ for all $i \in [n]$.
- $w = \log r - \log \ln r \pm O(1)$.
- $\text{size}(\text{Tribes}_r) \leq 2^{O(r/w)} = 2^{O(\frac{r \log \log r}{\log r})}$.

Definition 21 (Threshold). For any input length $\ell$ and $t \in \{0, \ldots, \ell\}$, the $\text{Threshold}_{\ell,t}$ : $\{0,1\}^\ell \to \{\pm 1\}$ function is defined to be

\[ \text{Threshold}_{\ell,t}(x) = 1 \iff \sum_{i=1}^{\ell} x_i \leq t. \]

Defining the family of functions witnessing the separation

Consider the following family of functions $\{f_h\}_{h \in \mathbb{N}}$. Each $f_h$ is a function over $h(\ell + k) + r$ boolean variables $x^{(1)}, x^{(2)}, \ldots, x^{(h)} \in \{0,1\}^\ell, y^{(1)}, \ldots, y^{(h)} \in \{0,1\}^k$, and $z \in \{0,1\}^r$, and is defined inductively as follows:

\[ f_0(z) = \text{Tribes}_r(z), \]

and for $h \geq 1$,

\[ f_h(x, y, z) = \begin{cases} \text{Parity}_k(y^{(h)}) & \text{if } \text{Threshold}_{\ell,1}(x^{(h)}) = 1 \\ f_{h-1}(x, y, z) & \text{otherwise.} \end{cases} \]

Claim 22 (Optimal decision tree size of $f_h$).

\[ \text{size}(f_h) \leq \ell^O(h) \cdot (\text{size}(\text{Parity}_k) + \text{size}(\text{Tribes}_r)) \]

\[ \leq \ell^O(h) \cdot (2^k + 2^{O(r \log \log r / \log r)}). \]

Proof. Please refer to figure Figure 4. We first build a tree of size $O(\ell^2)$ that evaluates $\text{Threshold}_{\ell,1}(x^{(h)})$. Of these leaves, $\ell + 1$ descend into a tree computing $\text{Parity}_k(y^{(h)})$, which has size $2^k$. The others descend into a tree computing $f_{h-1}$. This yields the recurrence

\[ \text{size}(f_h) \leq O(\ell) \cdot \text{size}(\text{Parity}_k) + O(\ell^2) \cdot \text{size}(f_{h-1}) \]

\[ \leq O(\ell) \cdot 2^k + O(\ell^2) \cdot \text{size}(f_{h-1}) \]

\[ \text{size}(f_h) = \text{size}(\text{Tribes}_r) \leq 2^{O(r \log \log r / \log r)}, \quad \text{(Recall Fact 20)} \]

and the claim follows.

In the remainder of this section, we will prove a lower bound on $\text{TopDownDT}(f, \varepsilon)$. Figure 5 should be contrasted with Figure 4.

The structure of $\text{BuildTopDownDT}(f_h)$

The following helper lemma will be useful in determining the structure of the tree $\text{BuildTopDownDT}$ produces.
Lemma 23 (Preservation of influence order). Let $f : \{0, 1\}^S \times \{0, 1\}^S \rightarrow \{\pm 1\}$ and $\tilde{f} : \{0, 1\}^S \rightarrow \{\pm 1\}$ be two functions satisfying the following: there is a function $g : \{0, 1\}^S \times \{\pm 1\} \rightarrow \{\pm 1\}$ such that:

$$f(a, b) = g(a, \tilde{f}(b)) \quad \text{for all } a \in \{0, 1\}^S, \ b \in \{0, 1\}^S.$$

Then for all variables $v_1, v_2 \in S$,

$$\text{Inf}_{v_1}(\tilde{f}) \geq \text{Inf}_{v_2}(\tilde{f}) \quad \text{if and only if} \quad \text{Inf}_{v_1}(f) \geq \text{Inf}_{v_2}(f).$$

Proof. This holds by noting that for $v \in \{v_1, v_2\}$,

$$\text{Inf}_v(f) = \Pr_{a,b}[f(a, b) \neq f(a, b^{\oplus v})] = \Pr_{a,b}[g(a, \tilde{f}(b)) \neq g(a, \tilde{f}(b^{\oplus v}))] = \Pr_b[\tilde{f}(b) \neq \tilde{f}(b^{\oplus v})] \cdot \Pr_a[g(a, -1) \neq g(a, 1)] = \text{Inf}_v(\tilde{f}) \cdot \Pr_a[g(a, -1) \neq g(a, 1)].$$

The lemma follows since $\Pr_a[g(a, -1) \neq g(a, 1)]$ does not depend on $v$ (and hence is the same regardless of whether $v = v_1$ or $v = v_2$).
Lemma 23 is especially well-suited for our inductively-defined family of functions \( \{f_h\}_{h \in \mathbb{N}} \). For each \( i \in \{0, 1, \ldots, h\} \), we let \( S_i \) denote the relevant variables of \( f_i \). Therefore

\[
S_0 = \{z_1, \ldots, z_r\} \\
S_{i+1} = S_i \cup \{x_1^{(i)}, \ldots, x_\ell^{(i)}, y_1^{(i)}, \ldots, y_k^{(i)}\}
\]

### Observation 24.
For all \( i \in \{0, 1, \ldots, h\} \), there exists \( g_i \) such that

\[
f_h(a, b) = g_i(a, h_i(b)) \quad \text{for all } a \in \{0, 1\}^{S_h \setminus S_i} \text{ and } b \in \{0, 1\}^{S_i}\tag{3}
\]

Consequently, we may apply Lemma 23 to get that for all \( v_1, v_2 \in S_i \), we have that

\[
\text{Inf}_{v_1}(f_i) \geq \text{Inf}_{v_2}(f_i) \quad \text{if and only if} \quad \text{Inf}_{v_1}(f_h) \geq \text{Inf}_{v_2}(f_h).
\]

We note the following corollary, which is a straightforward consequence of the observation that the property (3) is preserved under restrictions:

### Corollary 25 (Preservation of influence order under restrictions).
Let \( \pi \) be any restriction. For all \( i \in \{0, 1, \ldots, h\} \), we have that

\[
\text{Inf}_{v_1}((f_i)_\pi) \geq \text{Inf}_{v_2}((f_i)_\pi) \quad \text{if and only if} \quad \text{Inf}_{v_1}((f_h)_\pi) \geq \text{Inf}_{v_2}((f_h)_\pi).
\]
Lower bounding the size of $\text{BuildTopDownDT}(f, \varepsilon)$

Let $T_{\text{exact}}$ denote the tree returned by $\text{BuildTopDownDT}(f_h)$ and $T_{\text{approx}}$ that returned by $\text{BuildTopDownDT}(f_h, \varepsilon)$. (So $T_{\text{exact}}$ computes $f_h$, and $T_{\text{approx}}$ is an $\varepsilon$-approximation of $f_h$.) Our goal is to lower bound the size of $T_{\text{approx}}$. We will in fact establish something stronger: our lower bound holds for any pruning of $T_{\text{exact}}$ that is an $\varepsilon$-approximation of $T_{\text{exact}}$, where a pruning of a tree $T$ is any tree obtained by iteratively removing leaves from $T$ in a bottom-up fashion. Since $\text{BuildTopDownDT}(f, \varepsilon)$ is simply $\text{BuildTopDownDT}(f_h)$ terminated early, we have that $T_{\text{approx}}$ is indeed a pruning of $T_{\text{exact}}$.

Let $V_{\text{exact}}$ be defined as follows:

$$V_{\text{exact}} := \{v : v \text{ is the first node in a path of } T_{\text{exact}} \text{ that queries a } z\text{-variable}\}.$$ 

We define $V_{\text{approx}} \subseteq V_{\text{exact}}$ analogously. At a very high level, our proof of Theorem 4(b) will proceed by showing that $V_{\text{exact}}$ has large size, and $V_{\text{approx}}$ has to contain many nodes in $V_{\text{exact}}$. For the remainder of this proof, we will need that $r$ and $\ell$ are chosen to satisfy:

$$\frac{2 \ln r}{r} < 2^{-\ell}. \quad (4)$$

\textbf{Lemma 26} (All nodes in $V_{\text{exact}}$ occur deep within $T_{\text{exact}}$). Fix $v \in V_{\text{exact}}$ and let $\pi$ denote the path in $T_{\text{exact}}$ that leads to $v$. Then $|\pi| \geq kh$.

\textbf{Proof.} Suppose without loss of generality that $v$ is a query to $z_1$. We claim that $y^{(i)}_{\ell} \in \pi$ for all $i \in [h]$ and $j \in [k]$, from which the lemma follows. Fix $i \in [h]$. We will prove there are at least $k$ queries to variables in $S_i$ within $\pi$, and that the first $k$ of these queries have to be $y^{(i)}_{\ell}$ for $j \in [k]$. We prove both these claims simultaneously by induction on $k$.

\begin{itemize}
  \item \textbf{(Base case:)} Seeking a contradiction, suppose $\pi$ does not contain any queries to variables in $S_i$, in which case $(f_i)^{\pi_1} \equiv f_i$. Since $z_1$ is the variable queried at the root of $(f_h)^{\pi_1}$, it is the most influential variable within $(f_h)^{\pi_1}$. By Corollary 25, it follows that $z$ is the most influential variable within $(f_i)^{\pi_1} \equiv f_i$. This contradicts Equation (4) since

$$\inf_{y^{(i)}_{\ell}}(f_i) = \frac{\ell + 1}{2^\ell} \quad \text{and} \quad \inf_{z_1}(f_i) < \inf_{z_1}(\text{TRIBES}_r) = (1 + o(1)) \cdot \frac{\ln r}{r}. \quad (4)$$

Therefore $\pi$ has to contain at least one variable in $S_i$. Let $u \in \pi$ be the first query to a variable in $S_i$, which we claim must be $y^{(i)}_{\ell}$ for some $j$. Let $\pi_u \subset \pi$ be the path in $T_{\text{exact}}$ that leads to $u$. Again, we have that $u$ must be the most influential variable within $(f_h)^{\pi_u}$, and hence, by Corollary 25, it is the most influential within $(f_i)^{\pi_u}$. Since $\pi_u$ does not contain any queries to variables in $S_i$, we have that $(f_i)^{\pi_u} \equiv f_i$, and hence $u$ must be $y^{(i)}_{\ell}$ for some $j$ since these are the most influential variables within $f_i$.

\item \textbf{(Inductive step.)} Fix $k' < k$, and suppose we have established that there are at least $k'$ queries to variables in $S_i$ within $\pi$, the first $k'$ of which are to $y^{(i)}$-variables. We first claim that there is at least one more query to variable in $S_i$ within $\pi$. Suppose not. It follows that $z_1$ must be the most influential variable within $(f_h)^{\pi}$, and hence, by Corollary 25, it is the most influential variable within $(f_i)^{\pi}$. This is a contradiction, since $z_1$ is less influential than any of the $k' - k'$ many $y^{(i)}_{\ell}$ variables that are not queried by $\pi$.

Therefore $\pi$ has to contain at least one more query to a variable in $S_i$. Let $u \in \pi$ be the $(k + 1)^{st}$ query to a variable in $S_i$, which we claim must be $y^{(i)}_{\ell}$ for some $j$. Let $\pi_u \subset \pi$ be the path in $T_{\text{exact}}$ that leads to $u$. Again, we have that $u$ must be the most
In this derivation, we have assumed that Tribes, is perfectly balanced, i.e. that \( \Pr[\text{Tribes}(z) = 1] = \frac{1}{2} \), when in fact \( \Pr[\text{Tribes}(z) = 1] = \frac{1}{2} \pm o(1) \) (recall Fact 20). The same proof goes through if one carries around the additive \( o(1) \) factor.

\[ \text{(Fact 20)} \]
These bounds on influences, along with Equation (5), imply that $2^{-\ell} < \frac{2\ln r}{r}$. This contradicts our assumption on the relationship between $\ell$ and $r$ (Equation (4)), and the proof is complete.

We are now ready to lower bound the size of $T_{\text{approx}}$.

\begin{claim}[Lower bound on the size of $T_{\text{approx}}$]
Fix $\varepsilon \in (0, \frac{1}{2})$ and let $c = (\frac{1}{2} - \varepsilon)/2$. If
\begin{equation}
\left(1 - \frac{\ell + 1}{2^r}\right)^h \geq (2 + c)\varepsilon, \tag{6}
\end{equation}
then $|V_{\text{approx}}| \geq \Omega(\varepsilon \cdot 2^{kh})$. Consequently, the size of $T_{\text{approx}}$ is also at least $\Omega(\varepsilon \cdot 2^{kh})$.
\end{claim}

\begin{proof}
An input to $f_h$ reaches some node in $V_{\text{exact}}$ if and only if $\text{Threshold}_{\ell,1}(x^{(i)}) = 0$ for all $1 \leq i \leq h$. The fraction of inputs that satisfies this is exactly $(1 - \frac{\ell + 1}{2^r})^h$, which is at least $(2 + c)\varepsilon$ by our choice of parameters given by Equation (6).

Fix $v \in V_{\text{exact}}$. If $v \notin V_{\text{approx}}$, then $T_{\text{approx}}$ assigns all inputs reaching $v$ the same $-1$ or $+1$ value, whereas $f_h$ labels half of them $-1$ and half of them $+1$ (Lemma 27). Therefore, $T_{\text{approx}}$ errors on half of the inputs that each $v$. On the other hand, if $v \in V_{\text{approx}}$, we have by Lemma 26 that at most a $2^{-kh}$ fraction of inputs reach this specific $v$. Combining all of the above observations, it follows that
\begin{align*}
\text{error}(T_{\text{exact}}, T_{\text{approx}}) &\geq \frac{1}{2} \left((2 + c)\varepsilon - |V_{\text{approx}}| \cdot 2^{-kh}\right).
\end{align*}
Since $\text{error}(T_{\text{exact}}, T_{\text{approx}}) \leq \varepsilon$, it follows that
\begin{align*}
\varepsilon &\geq \frac{1}{2} \left((2 + c)\varepsilon - |V_{\text{approx}}| \cdot 2^{-kh}\right),
\end{align*}
and the claim follows by rearranging.
\end{proof}

Theorem 4(b) now follows from Claim 22 and Claim 28 by setting parameters appropriately:

\begin{proof}[Proof of Theorem 4(b)] Choosing
\begin{align*}
h &= \Theta\left(\frac{2^\ell}{\ell} \cdot \log(1/\varepsilon)\right) \quad \text{(to satisfy Equation (6))} \\
r &= \Theta(2^\ell) \quad \text{(to satisfy Equation (4))} \\
k &= \Theta(h \log \ell),
\end{align*}
we may apply Claim 22 and Claim 28 to get that
\begin{align*}
\text{size}(f_h) &\leq 2^{\Theta(k \log k)} \quad \text{whereas} \quad \text{TopDownDTSize}(f, \varepsilon) \geq 2^{\Omega_e(k^2 / \log \log k)}.
\end{align*}
This is a separation of $s$ versus $s^{\Omega(\log s)}$.
\end{proof}

\begin{remark}
For our choice of parameters above, we have that $s(n) = \text{size}(f_h) = 2^{\Theta(\sqrt{n})}$, where $n = h(\ell + k) + r$ is the number of variables of $f_h$. A standard padding argument yields the same $s$ versus $s^{\Omega(\log s)}$ separation for any function $s(n) \leq 2^{\Theta(\sqrt{n})}$.
\end{remark}
Lower bounds on \text{TopDownDT} size for monotone functions: Proof of Theorem 7

7.1 Size separation for exact representation: Proof of Theorem 7(a)

We will give a family of monotone functions, \{f_h\}_{h \in \mathbb{N}} whose \text{BuildTopDownDT} tree has exponential size compared to the optimal tree. First, we define a few terms which will be useful for our monotone constructions.

\textbf{Definition 30} (Comparing vectors and upper/lower shadows). For any \(x, y \in \{0, 1\}^n\), we use \(x \preceq y\) to represent

\[
x \preceq y \iff x_i \leq y_i \text{ for all } i \in [n]
\]

and \(\succeq\) is defined similarly. For any vector \(x\), the upper shadow of \(x\) is the set of all vectors \(y\) such that \(x \preceq y\). Similarly, the lower shadow of \(x\) is the set of all vectors \(y\) such that \(x \succeq y\).

Defining the family of functions witnessing the separation

Each \(f_h\) in \{\(f_h\)\}_{h \in \mathbb{N}} is a function over \(5h + 1\) boolean variables \(x^{(1)}, x^{(2)}, \ldots, x^{(h)} \in \{0, 1\}^4\), \(y^{(1)}, \ldots, y^{(h)} \in \{0, 1\}\), and \(z \in \{0, 1\}\), and is defined inductively as follows:

\[
f_0(z) = z,
\]

and for \(h \geq 1\), we fix \(x^* := (0, 0, 1, 1)\) and define

\[
f_h(x, y, z) = \begin{cases} 
f_{h-1}(x, y, z) & \text{if } x^{(h)} = x^* \\
1 & \text{if } x^{(h)} \succeq x^* \text{ and } x^{(h)} \neq x^* \\
-1 & \text{if } x^{(h)} \preceq x^* \text{ and } x^{(h)} \neq x^* \\
y & \text{otherwise.}
\end{cases}
\]

It is straightforward to verify that \(f_h\) is indeed monotone. We will show that \(f_h\) can be computed by a tree of size \(O(h)\), but that \text{BuildTopDownDT} produces a tree of size \(2^{\Omega(h)}\). For the first claim, we construct a decision tree for \(f_h\) directly from its definition. We start with a complete tree on the \(x^{(h)}\) variables – this complete tree has size \(2^4\), a constant. At one of the branches, we recursively build a tree for \(f_{h-1}\); at all the other branches, we build a tree of size 1 or 2 computing one of \(-1, 1\), or \(y^{(h)}\). The result is a tree of size \(O(h)\).

On the other hand, we claim that \text{BuildTopDownDT} will build a tree of size \(2^{\Omega(h)}\), as depicted in Figure 6. In \(f_h\), \(y^{(h)}\) has influence \(\frac{9}{10}\) and all the other variables have influence at most \(\frac{1}{2}\). Hence, \(y^{(h)}\) will be placed at root. Then, \text{BuildTopDownDT} will query enough of \(x^{(h)}\) to determine whether the output should be \(-1, +1\), or \(f_{h-1}\). If the output should be \(f_{h-1}\), which will occur once for each choice of \(y\), then the entire tree \(T_{h-1}\) will be placed. Hence, the size of \(T_h\) is more than double the size of \(T_{h-1}\), and \text{BuildTopDownDT} builds a tree of size \(2^{\Omega(h)}\).

7.2 Size separation for approximate representation: Theorem 7(b)

For any \(\varepsilon\), we will prove there exists a function \(f\) with optimal tree size \(s\) but for which the tree \text{BuildTopDownDT}(f, \varepsilon) builds has size \(s^{\Omega(\sqrt{\log s})}\). The following function, a biased version of the \text{Tribes} function defined in Definition 19, will be used as a building block in our monotone construction.
Figure 6 The tree that \textsc{BuildTopDownDT} builds for $f_h$. It will first query $y^{(h)}$, followed by the variables of $x^{(h)}$. For most choices of $y^{(h)}$ and $x^{(h)}$, the function is determined, and \textsc{BuildTopDownDT} will place a constant leaf equal to $\pm 1$. However, the paths with $y = 0, x^{(h)} = x^*$ and $y = 1, x^{(h)} = x^*$ each include a copy of the tree for $T_{h-1}$.

\textbf{Definition 31 (Biased Tribes).} Fix any input length $\ell$ and $\delta \in (0, 1)$. We define \textsc{Tribes}_{\ell, \delta} : \{0, 1\}^{\ell} \to \{\pm 1\}$ to be the read-once DNF with $\left\lfloor \frac{\ell}{w} \right\rfloor$ terms of width exactly $w$ over disjoint sets of variables (with some variables possibly left unused), where $w = w(\ell, \delta) \approx \log(\ell) \pm \log \log(1/\delta)$ is chosen such that $\Pr[\textsc{Tribes}_{\ell, \delta}(x) = 1]$ is as close to $\delta$ as possible.

\textbf{Fact 32 (Variable influences in biased Tribes).} All variables in \textsc{Tribes}_{\ell, \delta} and \textsc{Tribes}_{\ell, 1-\delta}$ have influence at most

$$(2 + o(1)) \cdot \delta \log(1/\delta) \cdot \frac{\log \ell}{\ell}.$$ 

Proof. We prove the lemma for the case of \textsc{Tribes}_{\ell, 1-\delta}. (The calculations for \textsc{Tribes}_{\ell, \delta} are very similar, and both claims are special cases of more general facts about variable influences in DNF formulas [61].) Suppose

$$\textsc{Tribes}_{\ell, 1-\delta}(x) = T_1(x) \lor \cdots \lor T_{\ell}(x),$$

where the $T_i$’s are disjoint terms of width exactly $w$. We first observe that since

$$\delta = \Pr_{x \sim \{0, 1\}^{\ell}}[\textsc{Tribes}_{\ell, 1-\delta}(x) = 1] = \Pr[\text{all } T_i(x) \text{ are falsified by } x]$$

$$= (1 - 2^{-w})^{\ell/w} \approx e^{-\ell/w/2^w},$$

we have that $w = (1 \pm o(1))(\log \ell - \log \log \ell - \log \log(1/\delta))$. The influence of any variable $i \in [n]$ on \textsc{Tribes}_{\ell, 1-\delta} is the probability, over a uniform $x$ that each other variable $j$ in $i$’s term has $x_j = 1$ and all other clauses evaluate to 0 under $x$:

$$\text{Inf}_i(\textsc{Tribes}_{\ell, 1-\delta}) = 2^{-w(i-1)} \cdot (1 - 2^{-w})^{(\ell/w) - 1}$$

$$\leq 2 \delta \cdot 2^{-w}$$

$$= (1 \pm o(1)) \cdot 2 \delta \log(1/\delta) \cdot \frac{\log \ell}{\ell}.\quad \blacksquare$$

\footnote{Although the acceptance probability of \textsc{Tribes}_{\ell, \delta} cannot be made exactly $\delta$ due to granularity issues, it will be the case that \textsc{Tribes}_{\ell, \delta} = \delta \pm o(1)$. For clarity, we will assume for the rest of this paper that the acceptance probability of \textsc{Tribes}_{\ell} is exactly $\delta$, noting that all of our proofs still go through if one carries around the $o(1)$ factor.}
Defining the family of functions witnessing the separation

Each \( f_h \) in the family \( \{ f_h \}_{h \in \mathbb{N}} \) is a function over \( h(2\ell + k) + r \) boolean variables, \( x^{(1,1)}, x^{(1,2)}, \ldots, x^{(h,1)}, x^{(h,2)} \in \{0,1\}^{\ell}, y^{(1)}, \ldots, y^{(h)} \in \{0,1\}^k, \) and \( z \in \{0,1\}^r, \) and is defined inductively as follows:

\[
f_0(z) = \text{TRIBES}_r(z),
\]

and for \( h \geq 1, \)

\[
f_h(x, y, z) = \begin{cases} 
-1 & \text{if } \text{TRIBES}_{\ell,\delta}(x^{(h,1)}) = \text{TRIBES}_{\ell,1-\delta}(x^{(h,2)}) = 0 \\
-1 \cdot f_{h-1}(x, y, z) & \text{if } \text{TRIBES}_{\ell,\delta}(x^{(h,1)}) = 0 \text{ and } \text{TRIBES}_{\ell,1-\delta}(x^{(h,2)}) = 1 \\
\text{Maj}_k(y^{(h)}) & \text{if } \text{TRIBES}_{\ell,\delta}(x^{(h,1)}) = 1 \text{ and } \text{TRIBES}_{\ell,1-\delta}(x^{(h,2)}) = 0 \\
+1 & \text{otherwise.}
\end{cases}
\]

Clearly \( f_h \) is monotone in \( x^{(h,1)} \) and \( x^{(h,2)} \). Furthermore, since each of the functions \(-1, +1, \) and \( \text{Maj}_k(y^{(h)}) \), are monotone, if \( f_{h-1} \) is monotone then so is \( f_h. \)
Claim 33 (Optimal size of \( f_h \)). Choose any integers \( \ell, h, r, k > 0 \) and let Then, \( f_{h,\ell,k,r} \) has optimal decision tree size

\[
\text{size}(f_h) \leq (\text{size}(\text{Tribes}_{\ell,h}) \cdot \text{size}(\text{Tribes}_{\ell,1-h}))^{O(h)} \cdot (\text{size}(\text{MAJ}_k) + \text{size}(\text{Tribes}_r))
\leq 2^{O(h \cdot \ell \log \log \ell / \log \ell)} \cdot (2^k + 2^{O(r \log r / \log r)}).
\]

(Fact 20)

Proof. As in the proofs of the previous separations, this upper bound is witnessed by the natural decision tree that one builds by following the definition of \( f_h \). This tree first evaluates \( \text{Tribes}_{\ell,h}(x^{(h,1)}) \) followed by \( \text{Tribes}_{\ell,1-h}(x^{(h,2)}) \), resulting in a tree of size \( (\text{size}(\text{Tribes}_{\ell,h}) \cdot \text{size}(\text{Tribes}_{\ell,1-h})) \). At the end of each branch, we either recursively build a tree for \( f_{h-1} \), or a tree for \( \text{MAJ}_k(y^{(h)}) \), or place constants \{±1\} as leaves. Please refer to Figure 7.

The remainder of this section is devoted to lower bounding \( \text{TopDownDTSize}(f_h, \varepsilon) \), the size of the tree \( T_{\text{approx}} \) that \( \text{BuildTopDownDT} \) constructs to \( \varepsilon \)-approximate \( f_h \).

7.2.1 “Mostly precedes”

By choosing parameters appropriately, we will ensure that when \( T_{\text{approx}} \) begins by querying the variables of \( \text{MAJ}_k(y^{(h)}) \). The first technical challenge that arises is the following: unlike \( \text{Parity}_k(y^{(h)}) \) in our proof of Theorem 4(b), the influence of variables in \( \text{MAJ}_k(y^{(h)}) \) changes as variables are queried. For example, the influence of the remaining variables of \( \text{MAJ}_k(y^{(h)}) \) after \( \frac{k}{2} \) variables have been queried is 0 if all of the queried variables are 1 and is \( \Theta(\frac{1}{\sqrt{k}}) \) if half of the variables queries are 0 and half are 1. Hence, in \( T_{\text{approx}} \), the number of nodes from \( y^{(h)} \) queried before some non-\( y^{(h)} \)-variable is queried will vary by path. (In other words, the analogue of Lemma 26 in the proof of Theorem 4(b) is somewhat trickier to establish.)

To handle this, we define the following notion, which will allow us to show that most \( y^{(h)} \)-variables are before other variables in most paths of the tree (Corollary 37).

Definition 34 (Mostly precedes). Let \( S \) be a subset of the relevant variables of \( f_h \). We say that \( y^{(i)} \)-variables mostly precede \( S \) in \( T_{\text{approx}} \) if for every path \( \pi \) in \( T_{\text{approx}} \) leading to a first query to a variable in \( S \), and every \( j \in [k] \),

\[
\text{Inf}_{\pi}(\text{MAJ}_k(y^{(i)}), \pi) \leq \frac{1}{100\sqrt{k}}.
\]

(For some intuition behind Definition 34, we note that pre-restriction, the influences of variables in \( \text{MAJ}_k \) are given by:

\[
\text{Inf}_{\pi}(\text{MAJ}_k) = \frac{1}{k} \cdot \left( \frac{k}{2} \right) \sim \frac{\sqrt{2/\pi}}{\sqrt{k}} \quad \text{for all } j \in [k],
\]

which is significantly larger than the \( \frac{1}{100\sqrt{k}} \) of Definition 34.)

With Definition 34 in hand, we now begin to formalize the structure of \( T_{\text{approx}} \) as depicted in Figure 8. For each \( i \in [h] \), we define

\( R_i = \{ x^{(i,1)}, x^{(i,2)}, \) and \( z \) variables \}.

Lemma 35. There is a universal constant \( c \) such that the following holds. Suppose

\[
\frac{c}{\sqrt{k}} \geq \frac{1}{\delta^2} \cdot \max \left\{ \frac{\delta}{l} \log (1/\delta) \log \ell \cdot \log r}{\ell \cdot r} \right\}.
\]

Then for all \( i \in [h] \), we have that \( y^{(i)} \)-variables mostly precede \( R_i \) in \( T_{\text{approx}} \).
With appropriately chosen parameters, the \( y^{(h)} \)-variables are the most influential in \( f_h \), so the tree built by \textsc{BuildTopDownDT} will query them first. Our analysis shows that this leads to a tree of size \( 2^{\Omega(k^h/\log k)} \) (cf. Figure 7).

**Proof.** Fix \( i \in [h] \). Let \( \pi \) be a path in \( T_{\text{approx}} \) that leads to a first query to a variable in \( v \in R_i \). Since \( v \) is maximally influential in \( (f_h)_{\pi} \), we may apply Corollary 25 to infer that \( v \) is also maximally influential in \( (f_i)_{\pi} \) (and in particular, \( v \) is more influential than any \( y^{(i)} \) variable). We have that

\[
\text{Inf}_v((f_i)_\pi) \leq \max \left\{ \text{Inf}_j(\text{Tribes}_{\ell,\delta}(x^{(i,1)})), \text{Inf}_j(\text{Tribes}_{\ell,1-\delta}(x^{(i,2)})), \text{Inf}_j(\text{Tribes}_r(z)) \right\}
\]

\[
\leq \max \left\{ (2 + o(1)) \cdot \delta \log(1/\delta) \cdot \frac{\log \ell}{\ell}, (1 + o(1)) \cdot \frac{\ln r}{r} \right\},
\]

(Fact 20 and Fact 32)

On the other hand, for any \( j \in [k] \),

\[
\text{Inf}_{y^{(i)}}((f_i)_\pi) = \Pr[\text{Tribes}_{\ell,\delta}(x^{(h,1)}) = 1, \text{Tribes}_{\ell,1-\delta}(x^{(h,2)}) = 0] \cdot \text{Inf}_j(\text{Maj}_k(y^{(i)})_{\pi})
\]

\[
= \delta^2 \cdot \text{Inf}_j(\text{Maj}_k(y^{(i)})_{\pi}).
\]

Since \( \text{Inf}_{y^{(i)}}((f_i)_\pi) \leq \text{Inf}_v((f_i)_\pi) \), the bounds above imply that
\[
\Inf_j \left( \text{MAJ}_k (y^{(i)}) \right) \leq \frac{1}{\delta^2} \cdot \max \left\{ \left(2 + o(1)\right) \cdot \delta \log(1/\delta), \frac{\log \ell}{\ell}, \left(1 + o(1)\right) \cdot \frac{\ln r}{r} \right\}.
\]

The lemma follows: by choosing \( c \) to be a sufficiently small constant in Equation (7), we can ensure that \( \Inf_j \left( \text{MAJ}_k (y^{(i)}) \right) \leq \frac{1}{100\sqrt{k}} \).

\textbf{Lemma 36.} There is a universal constant \( c \) such that the following holds. Fix \( i \in [h] \) and consider a uniform random \( y^{(i)} \in \{0,1\}^k \). The probability there is an input \( u \) to \( f_h \) consistent with \( y^{(i)} \) such that \( T_{\text{approx}} \), on input \( u \), queries an \( R_t \)-variable before a querying at least \( c k / \log k \) many \( y^{(i)} \)-variables is \( O(k^{-2}) \).

\textbf{Proof.} Fix an outcome \( y^{(i)} \) of \( y^{(i)} \). Suppose that there is an input \( u \) consistent with \( y^{(i)} \) such that \( T_{\text{approx}} \), on input \( u \), queries an \( R_t \)-variable after querying only \( < c k / \log k \) many \( y^{(i)} \)-variables. Call such a \( y^{(i)} \) outcome bad, and let \( \pi \) denote the corresponding path in \( T_{\text{approx}} \) that leads to the first query to an \( R_t \)-variable. Since \( y^{(i)} \)-variables mostly precede \( R_t \) in \( T_{\text{approx}} \), we have that

\[
\Inf_j \left( \text{MAJ}_k (y^{(i)}) \right) \leq \frac{1}{100\sqrt{k}} \quad \text{for all } j \in [k].
\]

For this to hold, it must be the case that among the \( t < c k / \log k \) many \( y^{(i)} \)-variables that occur in \( \pi \), the discrepancy between the number of 0’s and 1’s is \( \Omega(\sqrt{k}) \). We can therefore bound

\[
\Pr_{y^{(i)} \in \{0,1\}^k} \left[ y^{(i)} \text{ is bad} \right] \leq \sum_{t=1}^{ck/\log k} \Pr_{b \sim \text{Bin}(t, 1/2)} \left[ |b - t/2| \geq \Omega(\sqrt{k}) \right]
\]

\[
\leq \sum_{t=1}^{ck/\log k} e^{-\Theta(k/t)} \quad \text{(Hoeffding’s inequality)}
\]

\[
\leq \frac{ck}{\log k} \cdot e^{-\Theta(\log k)/c} \ll \frac{1}{k^2},
\]

where the final inequality holds by choosing \( c \) to be a sufficiently small constant.

By a union bound over \( i \in [h] \), we have the following corollary of Lemma 36 (which can be thought of as being roughly analogous to Lemma 26 in the proof of Theorem 4(b)):

\textbf{Corollary 37} (Most queries to \( z \)-variables are deep within \( T_{\text{approx}} \)). Let \( y = (y^{(1)}, \ldots, y^{(k)}) \) be uniform random. The probability that there is an input \( u \) to \( f_h \) consistent with \( y \) such that \( T_{\text{approx}} \), on input \( u \), queries a \( z \)-variable before querying at least \( (ck/\log k) \cdot h \) many \( y \)-variables is \( O(h/k^2) \).

We are finally ready to lower bound the size of \( T_{\text{approx}} \):

\textbf{Claim 38} (Lower bound on the size of \( T_{\text{approx}} \)). Fix \( \varepsilon \in (0, \frac{1}{2}) \) and let \( c = (\frac{1}{2} - \varepsilon)/2 \). If

\[
(1 - \delta)^{2h} \geq (2 + c) \varepsilon
\]

\[
h \leq k,
\]

then the size of \( T_{\text{approx}} \) is at least \( 2^{\Omega(h k / \log k)} \).
Proof. We will call an input to \( f_h \) \textit{z-dependent} if it satisfies:

\[
\text{Tr\!ibes}_{\ell,\delta}(x^{(i,1)}) = 0 \text{ and } \text{Tr\!ibes}_{\ell,1-\delta}(x^{(i,2)}) = 1 \text{ for all } i \in [h].
\]

Note that the output of \( f_h \) on any z-dependent input is \( \text{Tr\!ibes}_r(z) \). Let us define \( \zeta(y^{(1)}, \ldots, y^{(h)}) \) to be the \([0,1]\)-valued indicator of whether there is an input \( u \) consistent with \( y^{(1)}, \ldots, y^{(h)} \) such that \( \text{approx} \) on input \( u \) queries a z-variable. For any fixed \( y = (y^{(1)}, \ldots, y^{(h)}) \),

\[
\begin{align*}
\text{If } \zeta(y) = 0, \text{ then } & \text{error}(\text{approx}, f_h) \leq \frac{1}{2} \cdot (2 + c)\varepsilon \cdot Pr[\zeta(y) = 0]. \\
\text{which is at least } & (2 + c)\varepsilon \text{ by Equation (8). Furthermore, since output of } f_h \text{ on any } \\
\text{z-dependent input is } & \text{Tr\!ibes}_r(z), \text{ among the z-dependent inputs that are consistent with } \\
y, \text{ we have that } f_h \text{ labels half of them } -1 \text{ and half of them } +1.
\end{align*}
\]

Therefore,

\[
\text{error}(\text{approx}, f_h) \geq \frac{1}{2} \cdot (2 + c)\varepsilon \cdot Pr[\zeta(y) = 0].
\]

Since \( \text{error}(\text{approx}, f_h) \leq \varepsilon \), it follows that \( Pr[\zeta(y) = 1] \geq \Omega(1) \). Next, applying Corollary 37 along with our assumption that \( k \leq k \) (Equation (9)), we further have that

\[
\begin{align*}
Pr & \left[ \exists y\text{-consistent } u \text{ s.t. } \text{approx}(u) \text{ queries z-variable after } \geq \frac{ck}{\log k}, h \text{ many } y\text{-variables} \right] \\
& \geq \Omega(1)
\end{align*}
\]

On the other hand, for any fixed path \( \pi \) in \( \text{approx} \) that queries \( \geq \Omega(kh/\log k) \) many \( y \)-variables, at most a \( 2^{-\Omega(kh/\log k)} \) fraction of \( y\)'s can be consistent with this specific \( \pi \). We conclude that the size of \( \text{approx} \) must be at least \( 2^{\Omega(kh/\log k)} \), and the proof is complete. \( \blacktriangleleft \)

Theorem 7(b) now follows from Claim 33 and Claim 38 by setting parameters appropriately:

**Proof of Theorem 7(b).** By choosing

\[
\begin{align*}
\delta & = \Theta \left( \sqrt[4]{(\log \ell)^4 \log(1/\varepsilon)/\ell} \right) \\
k & = \Theta \left( \sqrt[4]{r^4 \log(1/\varepsilon)^2 / (\log \ell)^2} \right) \\
r & = \Theta(k) \\
h & = \Theta \left( \frac{1}{ \delta \cdot \log(1/\varepsilon)} \right),
\end{align*}
\]

we satisfy Equations (7) to (9). We may therefore apply Claim 33 to get that the optimal size of \( f_h \) is upper bounded by:

\[
\text{size}(f_h) \leq \exp \left( O(\sqrt[4]{r^4 \log(1/\varepsilon)^2 / (\log \ell)^2}) \right).
\]

On the other hand, by Claim 38, we have that

\[
\text{TopDownDTSize}(f_h, \varepsilon) \geq 2^{\Omega(kh/\log k)} = \exp \left( \Omega(\sqrt[4]{r^4 \log(1/\varepsilon)^2 / (\log \ell)^2}) \right).
\]

This is a separation of \( s \) versus \( s^{\Omega(\sqrt{\log s})} \). \( \blacktriangleleft \)
Remark 39. For our choice of parameters above, we have that \( s(n) = \text{size}(f_h) = 2^{\tilde{O}(n^{4/5})} \), where \( n = h(2\ell + k) + r \) is the number of variables of \( f_h \). A standard padding argument yields the same \( s \) versus \( s^{\tilde{O}(\log s)} \) separation for any function \( s(n) \leq 2^{\tilde{O}(n^{4/5})} \).

Remark 40 (Depth separation). The same proof witnesses a separation of \( d \) versus \( \tilde{\Omega}(d^{5/4}) \) for the optimal depth of \( f_h \) versus the depth of the tree that \( \text{BuildTopDownDT}(f_h, \varepsilon) \) builds. This disproves the conjecture of Fiat and Pechyony [23] discussed in Section 2, which states that \( \text{BuildTopDownDT} \) builds a tree of optimal depth for all monotone functions, even in the case of exact representation \( (\varepsilon = 0) \).

7.3 Lower bounds for all impurity-based heuristics

Proposition 41 (Splitting on the most influential variable of a monotone function maximizes purity gain). Let \( f : \{\pm 1\}^n \rightarrow \{\pm 1\} \) be a monotone boolean function.\(^{18}\) Let \( \mathcal{G} : [-1, 1] \rightarrow [0, 1] \) be a concave function that is symmetric around 0, and satisfies \( \mathcal{G}(-1) = \mathcal{G}(1) = 0 \) and \( \mathcal{G}(0) = 1 \). Suppose \( i \in [n] \) maximizes:

\[
\mathcal{G}(E[f]) - \frac{1}{2}(\mathcal{G}(E[f_{x_i=1}]) + \mathcal{G}(E[f_{x_i=-1}]))
\]

Then \( E[f(x)_{x_i}] \geq E[f(x)_{x_j}] \) for all \( j \in [n] \).

Proof. For all functions \( f \), not necessarily monotone, \( E[f] \) is precisely the average of \( E[f_{x_i=0}] \) and \( E[f_{x_i=1}] \). Because \( \mathcal{G} \) is concave everywhere on its domain, Jensen’s inequality ensures that \( \mathcal{G}(E[f]) \) is greater than \( \frac{1}{2}(\mathcal{G}(E[f_{x_i=0}]) + \mathcal{G}(E[f_{x_i=1}])) \). Furthermore, again by concavity, we have that this difference increases with the difference between \( E[f_{x_i=1}] \) and \( E[f_{x_i=-1}] \). Therefore the variable \( i \in [n] \) that maximizes purity gain (10) also maximizes \( |E[f_{x_i=1}] - E[f_{x_i=-1}]| \).

For a monotone function \( f : \{\pm 1\}^n \rightarrow \{\pm 1\} \), we have the following identity for all variables \( j \in [n] \):

\[
\text{Inf}_j(f) = \Pr[f(x) \neq f(x^{\oplus j})] = E[f(x)_{x_j}] = E[f_{x_j=1}] - E[f_{x_j=-1}].
\]

Thus, the variable that maximizes purity gain (10) is also the most influential variable of \( f \).

Recall that in Theorem 8, we claimed that our lower bound on \( \text{TopDownDTSize}(f_h, \varepsilon) \) holds not just for the specific algorithm \( \text{BuildTopDownDT} \), but in fact any impurity-based top-down heuristic. To see this, note that in our proof of Theorem 7(b) described in Section 7.2, we never used any information about which leaf \( \text{BuildTopDownDT} \) chooses to split on at each stage, only that when a leaf is split, it is replaced by the most influential variable of the corresponding subfunction. In other words, just like our proof of Theorem 4(b), our proof of Theorem 7(b) applies not just to the specific tree build by \( \text{BuildTopDownDT}(f_h, \varepsilon) \); it in fact lower bounds the size of any pruning \( T_{\text{approx}} \) of \( T_{\text{exact}} = \text{BuildTopDownDT}(f, \varepsilon = 0) \) that is an \( \varepsilon \)-approximator to \( f_h \).

By Proposition 41, any tree build by a impurity-based top-down heuristic is a pruning of \( T_{\text{exact}} \), and hence our proof of Theorem 7(b) extends to establish Theorem 8.

\(^{18}\)For this proof, for notational reasons it will be slightly more convenient for us to work with \( \{\pm 1\}^n \) instead of \( \{0,1\}^n \) as the domain of \( f \).
New proper learning algorithms: Proofs of Theorems 9 and 10

Recall that \textsc{BuildTopDownDT} builds an approximation to \( f \) iteratively. It starts with an empty bare tree \( T^0 \) and repeatedly replaces the leaf with the highest score with a query to that leaf’s most influential variable. In section Section 5.2, we proved lower bounds on the score of the leaf that \textsc{BuildTopDownDT} selects. Using those lower bounds, in section Section 5.3, we are able to prove upper bounds on the size of the tree \textsc{BuildTopDownDT} needs to produce to guarantee at most \( \varepsilon \) error. If, instead, we only guaranteed that we would pick a leaf with score a fourth of that guaranteed by the lower bounds in Section 5.2, all of our upper bounds would still hold, up to constant factors in the exponent. In this section, we will show that it is possible to accurately enough estimate influences to guarantee we pick a leaf with score at least a fourth the maximum score. First, we provide a definition of score that takes into account both the leaf and the variable selected.

\textbf{Definition 42 (score).} Given any function \( f \), we define the score of a leaf \( \ell \) and variable \( i \) as follows.

\[
\text{score}(\ell, i) := \Pr_{x \sim \{0, 1\}^n} [x \text{ reaches } \ell] \cdot \text{Inf}_i(f_\ell) = 2^{-|\ell|} \cdot \text{Inf}_i(f_\ell).
\]

We first show that it is possible to estimate scores sufficiently accurately for monotone functions just from random samples of a function, which proves Theorem 10. Let \( S \) be a random sample from a monotone function \( f \), and recall Fact 5. We can estimate the score of a particular leaf and variable as follows.

\[
\text{score}(\ell, i, S) = \mathbb{E}_{x, y \in S} \left[ \mathbb{I}[x \text{ reaches } \ell] \cdot f(x)(2x_i - 1) \right].
\]

Note that \( \mathbb{E}_S[\text{score}(\ell, i, S)] = \text{score}(\ell, i) \). Let \( t \) be any score threshold and \( m \) be the number of examples in \( S \). By Chernoff bounds, for any particular leaf \( \ell \) and variable \( x_i \),

\[
\Pr_S[\text{score}(\ell, i, S) \leq \frac{t}{2}] \leq e^{-\frac{k}{2}t \cdot m} \quad \text{if score}(\ell, i) \geq t
\]

\[
\Pr_S[\text{score}(\ell, i, S) \geq \frac{t}{2}] \leq e^{-\frac{k}{2}t \cdot m} \quad \text{if score}(\ell, i) \leq t/4.
\]

At step \( j \) in \textsc{BuildTopDownDT}, there are \( j + 1 \) leaves in \( T^j \). If \( t \) is the maximum score possible at that step, with probability at least \( 1 - (j + 1)e^{-\frac{k}{2}t \cdot m} \), the leaf and variable with maximum empirical score will have true score at least \( \frac{t}{4} \). By Lemma 15, \textsc{BuildTopDownDT}(\( f, \varepsilon \), at step \( j \), there will always be a leaf with score at least \( \frac{t}{8}e^{-\frac{k}{2}t \cdot m} \), where \( s \) is the decision tree size of \( f \). Hence, the maximum empirical score will have true score at least \( \frac{t}{3} \) the optimal value with probability at least \( 1 - (j + 1)e^{-\frac{k}{2}t \cdot m} \).

The probability that selecting the maximum empirical score is always within \( \frac{1}{2} \) of the optimal value for every step from \( j = 0 \) to \( j = k - 1 \) is at least \( 1 - k^2e^{-\frac{k}{2}t \cdot m} \). By setting the sample size to

\[
m = O\left(\frac{k \log s}{\varepsilon} (\log k + \log(1/\delta))\right) \tag{11}
\]

with probability at least \( 1 - \delta \), we choose a sufficiently good leaf for \( k \) steps of \textsc{BuildTopDownDT}. Recall that, for monotone functions, \textsc{BuildTopDownDT} builds a decision tree of size at most

\[
k = \min(s^{O((\log s/\varepsilon) \log(1/\delta))}, s^{O(\sqrt{\log s/\varepsilon})}).
\]
Hence, with probability at least $1 - \delta$, taking $\min(s^O(\log(s)/\varepsilon)\log(1/\varepsilon)), s^O(\sqrt{\log s}/\varepsilon)\log(1/\delta)$ is enough to learn to accuracy $\varepsilon$. This proves Theorem 10.

If $f$ is not monotone, we cannot accurately estimate influences from just random samples. However, we can estimate influences if given access to random edges from $f$.

**Definition 43 (Random edges).** For any function $f : \{0, 1\}^n \rightarrow \{-1, 1\}$, a random edge is two points of the form $((x, f(x)), (x^{\oplus i}, f(x^{\oplus i})))$, where $x \in \{0, 1\}^n$ and $i \in [n]$ are both picked uniformly at random. A random edge sample $E$ is a collection of random edges. Given random edge sample $E$, we will use $E_i$ to refer to all those edges in $E$ in which the $i$th bit of $x$ is flipped.

Given a random edge sample $E$ of a function $f$, we will be able to accurately estimate influences of the variables in $f$, and learn $f$ using \textsc{BuildTopDownDT}. We use the following estimate of score:

$$\text{score}(\ell, i, E) = \sum_{((x_1, y_1), (x_2, y_2)) \in E_i} [1[x_1 \text{ and } x_2 \text{ reach } \ell] \cdot 1[y_1 \neq y_2]]$$

If we desire there to be $m$ samples in each $E_i$ with probability at least $1 - \delta$, then having $E$ by size $O(n \cdot (m + \log(1/\delta)))$ is sufficient, where $m$ is as defined in Equation (11). Since one can certainly general a random edge sample $E$ if given membership query access to $f$, this proves Theorem 9.

**Learning trees with small average depth: Theorem 11**

Let $f$ be a monotone function computed by a decision tree $T$ of average depth $\Delta$.

1. We first observe that the total influence of $f$ is at most $\Delta$. To see this, first recall that $\text{Inf}(f) = \mathbb{E}[\text{sens}_f(x)]$, where $\text{sens}_f(x) = |\{i \in [n] : f(x) \neq f(x^{\oplus i})\}|$, i.e. that total influence is equivalent to average sensitivity. For any $x$, the sensitivity of $f$ at $x$ is at most the depth of the path that $x$ follows in $T$, and hence the average sensitivity of $f$ is at most the average depth $\Delta$ of $T$.

2. Recall Theorem 18, which says that monotone functions with decision tree size $s$ have total influence at most $\sqrt{\log s}$. In fact, [53] proves a stronger statement: if $f$ is monotone, then it has total influence at most $\sqrt{\Delta}$. (This is indeed a stronger statement because $\Delta \leq \log s$.)

3. Similarly, [52] also establishes a stronger version of Theorem 14, showing that $f$ has a variable of influence at least $\text{Var}(f)/\Delta$ (rather than just $\text{Var}(f)/\log s$). Hence an equivalent statement to Lemma 15 holds, where \textsc{BuildTopDownDT} selects a leaf with score at least $\frac{\varepsilon}{\sqrt{1+\Delta^2}}$.

Combining these observations, with the same proof as for Theorem 6, we conclude that \textsc{BuildTopDownDT} produces a tree of size $2^{O(\Delta^2/\varepsilon)}$, and if $T$ is monotone, size only $2^{O(\Delta/\varepsilon)}$. Then, for the same reasons as Theorems 9 and 10 hold, Theorem 11 holds.

**9 Proper learning with polynomial sample and memory complexity**

In this section we give a quasipolynomial-time algorithm for properly learning decision trees under the uniform distribution, where sample and memory of our algorithm are both polynomial. To our knowledge, this is the first algorithm for properly learning decision trees that achieves polynomial memory complexity. (Recall Table 1.)
Background: Ehrenfeucht–Haussler and Mehta–Raghavan

At the core of most learning algorithms is an algorithm that achieves low error on a set of samples. We will use the following notation in this section:

Notation

A sample, $S$, is a set of examples of the form $(x, y)$ where $x \in \{0, 1\}^n$ and $y \in \{-1, 1\}$. The error of a decision tree, $T$, with respect to the samples is

$$\text{error}_S(T) = \Pr_{x, y \in S} [T(x) \neq y].$$

We say that a set of samples is exactly fit by a tree of size $s$ if there exists a zero-error tree with size at most $s$. Furthermore, we use $S_v^0$ and $S_v^1$ to refer to all the points in the sample $S$ where the variable corresponding to $v$ is 0 and 1 respectively. Lastly, all learning statements in this section are with respect to the uniform distribution.

Ehrenfeucht and Haussler’s algorithm makes the following guarantee:

$\blacktriangleright$ Theorem 44 (Algorithmic core of [21]). There is an algorithm that takes in a set of samples, $S$, over $n$ variables that can be exactly fit by a decision tree of size $s$ and returns a tree of size at most $n^{\log(s)}$ that exactly fits $S$. Furthermore, that algorithm runs in time $|S| \cdot n^{O(\log s)}$.

One downside of their algorithm is that it leads to a large hypothesis class – the class of all decision trees of size $n^{\log s}$ – so in order to generalize with high probability, they require $\text{poly}(n^{\log s}, \frac{1}{\epsilon})$ samples.

Mehta and Raghavan observe that if a function is computable by a tree of size $s$, then it is also $\epsilon$-approximated by a tree of depth at most $\log(\frac{s}{\epsilon})$. They combine this observation with a new algorithm that makes the following guarantee:

$\blacktriangleright$ Theorem 45 (Algorithmic core of [46]). There is an algorithm that takes a sample, $S$, over $n$ variables as well as budgets for size $s$ and depth $d$ and returns the decision tree of size at most $s$ and depth at most $d$ with minimal error on $S$.\footnote{They also guarantee that if there are multiple trees with minimal error, they return a tree with minimal size among those with minimal error.} Furthermore, the algorithm runs in time $n^{O(d)} \cdot (s^2 + |S|)$.

Importantly, there are only $2 \cdot (4n)^n$ decision trees of size at most $s$, a much smaller hypothesis class than for Ehrenfeucht and Haussler’s algorithm. As a result, they only need $\text{poly}(s, \frac{1}{\epsilon}) \cdot \log n$ samples to generalize with high probability. A downside of their work, relative to Ehrenfeucht and Haussler’s, is that they need to set $d = O(\log(\frac{s}{\epsilon}))$, so their algorithm has a runtime of approximately $n^{O(\log(s/\epsilon))}$ instead of $n^{O(\log s)}$.

Neither [21] nor [46] are able to learn decision trees with only $\text{poly}(n, s, \frac{1}{\epsilon})$ memory. [21] uses a sample of size approximately $n^{O(\log s)}$ to guarantee generalization, and their algorithm must store all of the samples, so it needs at least that much memory. [46] use a dynamic programming algorithm that stores computation for each restriction of the $n$ variables of size at most $d = O(\log(\frac{s}{\epsilon}))$. There are $\binom{n}{d} \cdot 2^d = \Theta(n^{\log(s/\epsilon)})$ such restrictions, resulting in superpolynomial memory complexity.
Algorithm 1: Our variant of Ehrenfeucht and Haussler’s \textsc{Find} algorithm.

\textsc{Find} \((S, s, d)\):
\begin{itemize}
  \item \textbf{Input:} A sample \(S\) that can be exactly fit by a tree of size \(s\) and depth budget \(d\).
  \item \textbf{Output:} A decision tree \(T\) with depth at most \(d\) that approximately fits \(S\). If \(S\) cannot be fit by a tree of size \(s\), may return “None”.
\end{itemize}

1. If all samples in \(S\) have the same label, return the single-node tree computing that label.
2. If \(s \leq 1\) return “None”.
3. If \(d = 0\) return the single-node tree computing the majority label of \(S\).
4. For each relevant variable \(v\):
   \begin{itemize}
     \item a. Let \(T_v^0 = \textsc{Find}(S_v^0, \frac{s}{2}, d - 1)\) and \(T_v^1 = \textsc{Find}(S_v^1, \frac{s}{2}, d - 1)\).
     \item b. If both \(T_v^0\) and \(T_v^1\) are not “None”, return the tree with root labeled \(v\), 0-subtree \(T_v^0\) and 1-subtree \(T_v^1\).
     \item c. If one of \(T_v^0\) and \(T_v^1\) is “None” and the other is not:
       \begin{itemize}
         \item i. Reexecute the recursive call for the side that was “None” with size \(s - 1\) instead of \(s\). For example, if \(T_v^1\) was “None”, set \(T_v^1 = \textsc{Find}(S_v^1, s - 1, d - 1)\).
         \item ii. If the reexecuted call still returns “None”, return “None”.
         \item iii. Return the tree with root labeled \(v\), 0-subtree \(T_v^0\) and 1-subtree \(T_v^1\).
       \end{itemize}
   \end{itemize}
5. Return “None”.

Our algorithm: proper learning with polynomial sample and memory complexity

We introduce a new algorithm that makes more assumptions about its input than either [21]’s or [46]’s algorithms. It requires the samples it receives to be \textit{well-distributed}, a property we will later define (Definition 48). In exchange, it only uses polynomial memory. The following should be contrasted with Theorems 44 and 45:

\textbf{Theorem 46} (Core of our algorithm). \textit{There is an algorithm (Algorithm 1) that when given a depth budget \(d\) and a well-distributed sample \(S\) that can be exactly fit by a tree of size \(s\) returns a tree with depth at most \(d\) and error at most \((\frac{3}{4} + o(1))d \cdot s\) on the samples. Furthermore, the algorithm runs in time \(|S| \cdot n^{O(\log s)}\) and uses \(\text{poly}(2^d, \log n, |S|)\) memory.}

Note that if the goal is to learn the sample to accuracy \(\varepsilon\), we can set \(d = O(\log(\frac{1}{\varepsilon}))\). The result is an algorithm that runs in time \(|S| \cdot n^{O(\log s)}\) and uses memory \(\text{poly}(n, s, 1/\varepsilon, |S|)\). Furthermore, the well-distributed requirement turns out to be true for nearly all uniformly random samples that are sufficiently large. The result is, to the best of our knowledge, the first polynomial memory proper learning algorithm for decision trees.

Our algorithm (Algorithm 1) is a surprisingly simple modification of [21]’s algorithm, but our analysis is quite a bit more involved. A key difference is that [21]’s algorithm is an Occam algorithm, whereas ours is not. The original [21] algorithm breaks down when in cannot fully fit the sample; the analysis showing that our algorithm is able to handle a sample it cannot fully fit is subtle.

\textbf{Lemma 47} (Correctness of \textsc{Find}). \textit{If \(S\) can be exactly fit by a tree of size \(s\), then \textsc{Find}(\(S, s, d\)) will not return “None”.

Proof. By induction. If \(s = 1\) and \(S\) can be fit by a tree of size \(s\), then all samples in \(S\) will have the same label. Hence, \textsc{Find} will return a tree on line 1, and not return “None”.

ITCS 2020
For $s \geq 2$, there are only two spots where Find could return “None”:

**Line 4.c.ii** Find returns “None” on line 4.c.ii only if a call of the form Find($S^a_s, s - 1, d - 1$) returns “None” where $a = \pm 1$ and $v$ is relevant. Let $T_S$ be a minimal size tree that fits $S$, which by assumption, has size at most $s$. Since $v$ is relevant, a node labeled with it must appear somewhere in that tree. This means that there is a size $s - 1$ tree that will exactly fit $S^a_s$. By induction, this means that Find($S^a_s, s - 1, d - 1$) will not return “None”.

**Line 5.** Find returns “None” on line 5 only if there was not a single relevant variable $v$ for which either of the calls Find($S^0_0, \frac{s}{2}, d - 1$) or Find($S^1_1, \frac{s}{2}, d - 1$) on line 4.a succeeded (i.e. did not return “None”). Once again, let $T_S$ be a minimal size tree that fits $S$. Then, every node in $T_S$ must be relevant for $S$. Furthermore, $T_S$ has some root variable $v^*$ and subtrees $(T_S)_0$ and $(T_S)_1$. At least one of $(T_S)_0$ or $(T_S)_1$ must have size at most $\frac{s}{2}$. If $(T_S)_0$ has size at most $\frac{s}{2}$, then by the inductive hypothesis, Find($S^0_0, \frac{s}{2}, d - 1$) does not return “None”. Otherwise Find($S^1_1, \frac{s}{2}, d - 1$) does not return “None”. Hence, Find won’t return “None” on line 5.

We hope to prove that Find will produce low error trees, but it turns out to be difficult to guarantee this for arbitrary samples. One particular sample we can guarantee this for is the sample containing all possible points. If $S$ contains all $2^n$ possible points, then Find will return a tree with error at most $\frac{1}{4} \cdot \left(\frac{3}{4} + \frac{1}{4}\right)^d$, which we will prove in Lemma 49. The following property allows us to quantify how close $S$ is to the full sample.

**Definition 48 (Well-distributed samples).** We say that a sample of points $S$ is $c$-well-distributed to depth $d$ if, for any restriction $\alpha$ where $|\alpha| \leq d$,

$$|\{S_\alpha\}| - \mu \leq c\mu$$

where $\mu = 2^{-|\alpha|} |S|$ is the expected size of $S_\alpha$ if $S$ is chosen uniformly at random.

For example, if $S$ contains all possible $2^n$ points, then $S$ is $0$-well-distributed to any depth.

**Lemma 49 (Error of Find on well-distributed samples).** Let $S$ be $c$-well-distributed to depth $d$. If Find($S, s, d$) does not return “None”, it returns a tree with error at most $\frac{1}{4} \cdot \left(\frac{3}{4} + \frac{1}{4}\right)^d \cdot s$ with respect to $S$.

**Proof.** By induction on the $d$; If $d = 0$ and $s \geq 2$, then this lemma requires the error to be less than $\frac{1}{2}$, which Find satisfies since it places the majority node. If $s = 1$ and Find doesn’t return “None”, it must have returned a zero-error tree on Line 1, satisfying the desired error bound.

Next, consider $d \geq 1$. If all samples have the same label, Find returns a $0$ error tree. Otherwise, it returns a tree, $T$, with 0-subtree $T^0_0$ and 1-subtree $T^1_1$ for some variable $v$. Let $\ell_0$ and $\ell_1$ be the number of points in $S^0_0$ and $S^1_1$ respectively. Then, we can relate the errors of the trees as follows:

$$\text{error}(T) = \frac{\ell_0}{\ell_0 + \ell_1} \cdot \text{error}(T^0_0) + \frac{\ell_1}{\ell_0 + \ell_1} \cdot \text{error}(T^1_1)$$

At least one of $T^0_0$ and $T^1_1$ was generated using a recursive call to Find with size parameter $\frac{s}{2}$. Without loss of generality, let that tree be $T^0_0$. The other tree, $T^1_1$ was generated by a recursive call with size at most $s$. By the inductive hypothesis,

$$\text{error}(T) \leq \frac{\ell_0}{\ell_0 + \ell_1} \cdot \frac{1}{4} \cdot \left(\frac{3}{4} + \frac{c}{4}\right)^d \cdot s + \frac{\ell_1}{\ell_0 + \ell_1} \cdot \frac{1}{4} \cdot \left(\frac{3}{4} + \frac{c}{4}\right)^d \cdot s$$

(12)
Since $S$ is $c$-well-distributed to depth $d$, $(1-c)\mu \leq \ell_0, \ell_1 \leq (1+c)\mu$, where $\mu = \frac{|S|}{2^d}$. Choosing $\ell_0 = (1-c)\mu$ and $\ell_1 = (1+c)\mu$ maximizes equation Equation (12) and so results in a valid upper bound.

$$\text{error}(T) \leq \frac{\mu(1-c)}{2\mu} \cdot \frac{1}{4} \left( \frac{3}{4} + \frac{c}{4} \right)^{d-1} \cdot s + \frac{\mu(1+c)}{2\mu} \cdot \frac{1}{4} \left( \frac{3}{4} + \frac{c}{4} \right)^{d-1} \cdot s$$

$$= \frac{1}{4} \cdot \left( \frac{3}{4} + \frac{c}{4} \right)^{d-1} \cdot \left( \frac{3}{4} + \frac{c}{4} \right) \cdot s$$

$$= \frac{1}{4} \left( \frac{3}{4} + \frac{c}{4} \right)^d \cdot s \ △$$

The above Lemma shows that if a sample is sufficiently well-distributed, FIND will return a tree with low error. We next show that, with high probability, sufficiently large samples will be well-distributed.

**Lemma 50 (Well-distributed samples are common).** Choose any $0 < c < 1.0, \delta > 0$. Then for

$$m = O \left( \frac{2^d}{c^2} \cdot (d \log(n) + \log(1/\delta)) \right),$$

a sample of size $m$ chosen uniformly at random from $\{0,1\}^n$ is $c$-well-distributed to depth $d$ with probability at least $1 - \delta$

**Proof.** Consider an arbitrary restriction $\alpha$ of length $h \leq d$. By Chernoff bounds,

$$\Pr[|\mathbf{S}_\alpha| - \mu |\geq c\mu] \leq 2e^{-nc^2/3}$$

where $\mu = \mathbb{E}[|\mathbf{S}_\alpha|] = m \cdot 2^{-h}$. Since $h \leq d$, we can upper bound the probability as follows.

$$\Pr[|\mathbf{S}_\alpha| - \mu |\geq c\mu] \leq 2e^{-m \cdot 2^{-d}c^2/3}$$

$S$ is $c$-well-distributed if $|\mathbf{S}_\alpha| - \mu |\leq c\mu$ for all possible restrictions $\alpha$ of size at most $d$. There are $\sum_{i=0}^{d} \binom{n}{i} 2^i = n^{O(d)}$ such restrictions. Thus, by a union bound:

$$\Pr[\text{$S$ is $c$-well-distributed}] \geq 1 - n^{O(d)} \cdot e^{-m \cdot 2^{-d}c^2/3}.$$

We set the right-hand side of the above equation to be at least $1 - \delta$ and solve for $m$, which proves this Lemma. \ △

Our analysis of the time complexity of FIND is very similar to Ehrenfeucht and Haussler’s:

**Lemma 51 (Time complexity of FIND).** FIND($S, s, d$) takes time $|S| \cdot (n + 1)^2 \log(s)$.

**Proof.** Fix a total number of variables $n$ and sample size $m$. Let $T(i, s)$ be the maximum time needed by FIND($S, s, d$) where $S$ has size at most $m$, $i$ is the number of relevant variables in $S$, and $d$ is arbitrary.

If $i = 0$ or $s = 1$, then FIND must return on Line 1 or 2, using only $O(m)$ time. Otherwise, the FIND makes at most $2i$ recursive calls on line 4.(a) each of which takes time at most $T(i - 1, \frac{s}{2})$ It also makes zero or one recursive call on line 4.(c), i which takes time up
to \( T(i - 1, s - 1) \leq T(i - 1, s) \). In addition to these recursive calls, all of the auxiliary computations can be done in \( O(mn) \) time. Hence, we have the following recurrence relation:

\[
T(i, s) \leq 2i \cdot T(i - 1, \frac{s}{2}) + T(i - 1, s) + O(mn).
\]

If we substitute \( r = \log(s) \), then equivalently, we have the relation:

\[
\hat{T}(i, r) \leq 2i \cdot \hat{T}(i - 1, r - 1) + \hat{T}(i - 1, r) + O(mn).
\]

The above relation is shown to be upper bounded by \( \hat{T}(i, r) = O(m \cdot (n + 1)^{2r}) \) in [21]. Substituting back \( r = \log(s) \) gives that \( T(i, s) \leq O(m \cdot (n + 1)^{2\log(s)}) \).

\[\blacktriangleleft\]

**Lemma 52 (Memory complexity of FIND).** FIND\((S, s, d)\) takes memory \( O(2^d(|S| + \log n)) \).

**Proof.** Each call to FIND with depth \( d \) will only ever need simultaneously need to run up to 2 calls to FIND, each with depth \( d - 1 \). Hence, there are at most \( 2^d \) copies of FIND that need to be stored in memory at any one time. At worst, each copy stores the sample as well as pointers to it and the \( n \) different variables. This means each copy uses \( O(|S| + \log n) \) memory, for a total of \( O(2^d(|S| + \log n)) \) memory. \[\blacktriangleleft\]

The last step in this analysis is a standard generalization argument relying on Chernoff bounds.

**Lemma 53 (Generalization).** Choose any \( \delta, \varepsilon \geq 0 \). Suppose that \( S \) is a uniformly random sample from a function, \( f \), that can be computed by a decision tree of size at most \( s \) and depth at most \( d \). If the number of samples in \( S \) is at least

\[
m = O\left(\frac{2^d \log(n) + \log(\frac{1}{\delta})}{\varepsilon}\right)
\]

and FIND\((S, s, d)\) returns a decision tree that fits \( S \) with error at most \( \frac{\varepsilon}{4} \). Then, with probability at least \( 1 - \delta \), the decision tree returned by FIND has error at most \( \varepsilon \) on \( f \).

**Proof.** We will upper bound the number of different decision trees FIND could return when given depth limit \( d \). There up to \( 2^d \) spots where a decision tree of depth \( \leq d \) could have a node. In each of these spots, the decision tree could either have one of \( n \) variables, a leaf that is either \(+1\) or \(-1\), or nothing. Thus, the number of decision trees of depth at most \( d \) is at most \( (n + 3)^{2^d} \).

We call a decision tree, \( T \), “bad”, if \( T \) has error at least \( \varepsilon \) on \( f \). For any particular bad tree \( T \), the probability it will have error less than \( \frac{\varepsilon}{4} \) on \( S \) can be upper bounded using a Chernoff Bound:

\[
\Pr_{S}[\text{error}_{S}(T) \leq \frac{\varepsilon}{4}] \leq \exp(-\frac{n}{32}\varepsilon m).
\]

Since there are most \( (n + 3)^{2^d} \) bad trees, the probability that any bad tree has error at most \( \frac{\varepsilon}{4} \) is at most \( (n + 3)^{2^d} \cdot \exp(-\frac{n}{32}\varepsilon m) \). Setting this equal to \( \delta \) and solving for \( m \) completes the proof of this lemma. \[\blacktriangleleft\]

Finally, we are able to put all these pieces together to prove our main theorem of this section, and show how FIND is used to learn decision trees:
Theorem 54 (Proper learning with polynomial sample and memory complexity). Let \( f \) be any function over \( n \) variables computable by a size \( s \) decision tree. Choose any \( \varepsilon, \delta > 0 \). There is an algorithm that

- runs in time \( \text{poly}(n \log s, \frac{1}{\varepsilon}, \log(\frac{1}{\delta})) \)
- requires memory \( \text{poly}(s, \log n, \frac{1}{\varepsilon}, \log(\frac{1}{\delta})) \)
- uses \( \text{poly}(s, \log n, \frac{1}{\varepsilon}, \log(\frac{1}{\delta})) \) random samples from \( f \) and with probability at least \( 1 - \delta \) returns a decision tree that is an \( \varepsilon \)-approximation of \( f \).

Proof. Choose any constant \( 0 < c < 1 \) and set \( d = \log(\frac{s}{\varepsilon}) / (\log(\frac{3+c}{4})) \). Then, by taking a uniformly random sample, \( S \), of size

\[
m = O\left(\frac{2^d}{\varepsilon c^2} \cdot (d \log(n) + \log(1/\delta))\right)
\]

we have the following holds:

1. \( S \) is \( c \)-well-distributed with probability at least \( 1 - \frac{\delta}{2} \).
2. If \( S \) is \( c \)-well-distributed, then \( \text{Find}(S, s, d) \) returns a tree, \( T \), with error at most \( \frac{1}{4}(\frac{3+c}{4})^d \cdot s = \frac{1}{4} \) on \( S \).
3. If \( T \) has error less than \( \frac{\varepsilon}{4} \), then with probability at least \( 1 - \frac{\delta}{2} \), \( T \) is a \( \varepsilon \)-approximation for \( f \).

Furthermore, this procedure meets the time constraints by Lemma 51 and memory constraints by Lemma 52.

Abstract

Given a metric $(V, d)$ and a root $r \in V$, the classic $k$-TSP problem is to find a tour originating at the root of minimum length that visits at least $k$ nodes in $V$. In this work, motivated by applications where the input to an optimization problem is uncertain, we study two stochastic versions of $k$-TSP.

In Stoch-Reward $k$-TSP, originally defined by Ene-Nagarajan-Saket [13], each vertex $v$ in the given metric $(V, d)$ contains a stochastic reward $R_v$. The goal is to adaptively find a tour of minimum expected length that collects at least reward $k$; here “adaptively” means our next decision may depend on previous outcomes. Ene et al. give an $O(\log k)$-approximation adaptive algorithm for this problem, and left open if there is an $O(1)$-approximation algorithm. We totally resolve their open question, and even give an $O(1)$-approximation non-adaptive algorithm for Stoch-Reward $k$-TSP.

We also introduce and obtain similar results for the Stoch-Cost $k$-TSP problem. In this problem each vertex $v$ has a stochastic cost $C_v$, and the goal is to visit and select at least $k$ vertices to minimize the expected sum of tour length and cost of selected vertices. Besides being a natural stochastic generalization of $k$-TSP, this problem is also interesting because it generalizes the Price of Information framework [33] from deterministic probing costs to metric probing costs.

Our techniques are based on two crucial ideas: “repetitions” and “critical scaling”. In general, replacing a random variable with its expectation leads to very poor results. We show that for our problems, if we truncate the random variables at an ideal threshold, then their expected values form a good surrogate. Here, we rely on running several repetitions of our algorithm with the same threshold, and then argue concentration using Freedman’s and Jogdeo-Samuels’ inequalities. Unfortunately, this ideal threshold depends on how far we are from achieving our target $k$, which a non-adaptive algorithm does not know. To overcome this barrier, we truncate the random variables at various different scales and identify a “critical” scale.

1 Introduction

Consider a scenario where a salesperson must sell some quota of brushes in order to win a trip to Hawaii. The salesperson knows the time it takes to travel between different cities and the demand at each city. What is the best route to take to sell the quota while spending the least amount of time? This exact scenario was described by Awerbuch et al. [4] to motivate the study of TSP problems where the algorithm has to also decide which cities to visit. A cleaner version of this problem, first introduced by Ravi et al. [31], is the $k$-TSP problem where we assume that each city has a unit demand. Formally, given a metric $(V,d)$ with a root $\in V$ and a target $k \in \mathbb{Z}_{\geq 0}$, the $k$-TSP problem is to find a tour that originates at the root and visits at least $k$ vertices, while minimizing the total travel time. There is a long line of work trying to design better approximation algorithms for the $k$-TSP problem [4, 30, 8, 16, 2, 1], and the state-of-the-art is a 2-approximation algorithm due to Garg [17]1.

In this work we consider stochastic versions of the $k$-TSP problem: what if the salesperson does not know the exact demand in each city, or what if the salesperson need to spend some uncertain time in each city to complete the city’s demand? Indeed, there is a long line of work studying classical optimization problems where we begin only with estimates (probability distributions) on the input parameters. The algorithm has to adaptively probe parameters (inspect elements) by paying some “cost” before realizing their exact values; here “adaptively” means that our decisions may depend on the outcomes of already probed elements. Such stochastic probing problems have been well-studied in both maximization and minimization settings [11, 18, 19, 22, 20, 23, 5, 24, 6, 29, 3, 25, 13, 15, 33, 9, 21].

There are two natural ways of defining the stochastic $k$-TSP problem, depending on the type of input uncertainty. In the Stoch-Reward $k$-TSP problem, first introduced by Ene-Nagarajan-Saket [13], we incorporate uncertainty in the vertex demands. Formally, we assume that the demand at each vertex is drawn independently from a known distribution, and the goal is to adaptively find a tour $\Pi$ that obtains the target demand $k$, while minimizing the total expected travel time $2$.

We also study Stoch-Cost $k$-TSP where each city still has a unit demand, but the salesperson will have to spend an additional completion time (drawn from a known distribution) at each vertex before meeting its unit demand. The goal is to adaptively find a tour $\Pi$ that completes the target demand $k$, while minimizing the expected sum of total travel and completion times. Notice, our algorithm finds the exact completion time of a vertex only after visiting it, and may choose not to complete it (i.e., not meet its unit demand) if the completion time seems too long. This idea of studying stochastic completion times at vertices is not new, and has been previously used in the study of stochastic Orienteering problems, which in some sense is the dual to our Stoch-Cost $k$-TSP problem [23, 6].

A common theme in the study of stochastic probing problems is to understand the power of adaptivity. Indeed, while the optimal algorithms can fully adapt to the outcomes, and hence may not even have a polynomial-size representation, a non-adaptive algorithm makes all its decisions upfront independent of the observed outcomes (except perhaps the stopping time). Being non-adaptive has several benefits like they are simpler to find, easily parallelizable, and have a poly-size representation. So ideally for a probing problem we would like to design non-adaptive algorithms with performance close to the optimal adaptive

1 A closely-related variant is called the $k$-MST problem. Both problems are equivalent up to a constant approximation factor.
2 Our Stoch-Reward $k$-TSP problem is called the “Stochastic $k$-TSP” problem in [13]. We rename it to differentiate it from Stoch-Cost $k$-TSP.
algorithms, or in other words design non-adaptive algorithms with a small adaptivity gap. The main results of our work is to show that both the above Stoch-Reward \(k\)-TSP and Stoch-Cost \(k\)-TSP problems have a constant adaptivity-gap. That is, there exist fixed-tours starting at the root which the algorithm can take until it obtains the target demand \(k\), which guarantee an expected total time at most a constant factor more than the expected total time of the optimal adaptive tour. Moreover, for distributions with polynomial support, we give poly-time algorithms to find such tours.

Our constant adaptivity-gap for Stoch-Reward \(k\)-TSP answers the main open question of [13], who showed an \(O(\log^2 k)\) bound on the adaptivity gap. The constant adaptivity gap result for Stoch-Cost \(k\)-TSP might also seem surprising because it is known that the related Stochastic Orienteering problem has a super-constant adaptivity gap [6].

In the rest of this section we first formally state our problems and results, and then discuss our high-level techniques and other related work.

1.1 Stoch-Reward \(k\)-TSP

The following Stoch-Reward \(k\)-TSP was first defined by Ene et al. [13].

**Stoch-Reward \(k\)-TSP.** We are given a metric \((V,d)\) with a root \(v \in V\) and each vertex \(v \in V\) has an independent integral\(^3\) stochastic\(^4\) reward \(R_v \in \mathbb{Z}_{\geq 0}\). All reward distributions are given as input but the actual reward instantiation \(R_v\) is only known when the algorithm visits vertex \(v\). Given a target value \(k \in \mathbb{Z}_{\geq 0}\), the goal is to adaptively find a tour \(\Pi\) originating at root that collects at least \(k\) reward (i.e., \(\sum_{v \in \Pi} R_v \geq k\)) while minimizing the expected tour length.

This problem captures several well-studied problems; e.g., it captures the problem of Stoch-Knapsack Cover where the metric \((V,d)\) is a weighted star: given a target \(k\) and \(n\) items where item \(i \in [n]\) has both a deterministic cost \(C_i \in \mathbb{R}_{\geq 0}\) and an independent stochastic reward \(R_i \in \mathbb{Z}_{\geq 0}\), the Stoch-Knapsack Cover problem is to adaptively obtain a total reward of at least \(k\) at the minimum expected cost. This problem was studied by Deshpande et al. [12], and they gave an adaptive 2-approximation algorithm. However, even in this special case, it was not know if there is a non-adaptive constant factor approximation algorithm.

The first non-trivial results for the Stoch-Reward \(k\)-TSP problem were obtained by Ene et al. [13]. They gave an \(O(\log^2 k)\)-approximation non-adaptive algorithm and an \(O(\log k)\) approximation adaptive algorithm. On the hardness side, however, they only gave a lower bound of \(e\) on the adaptivity gap. This left open closing the wide gap on the adaptivity gap for Stoch-Reward \(k\)-TSP. We resolve their open question by giving a non-adaptive \(O(1)\)-approximation algorithm.

**Theorem 1.** The Stoch-Reward \(k\)-TSP problem has a non-adaptive \(O(1)\)-approximation algorithm.

The difficulty in Stoch-Reward \(k\)-TSP arises because the expected reward is a poor indicator of how much we care about a node. An extreme example is a vertex with a large expected reward, but which is non-zero with nearly zero probability. It is therefore reasonable to truncate the reward distributions at the remaining target reward. However, it is not clear why such an approach would work, and moreover this approach is adaptive as it depends on the remaining target.

\(^3\) This is without loss of generality. Our result also generalizes to the case where rewards are real numbers via re-scaling.

\(^4\) We assume that the distribution is discrete and is given explicitly.
1.2 Stoch-Cost $k$-TSP

We formally define the Stoch-Cost $k$-TSP problem.

**Stoch-Cost $k$-TSP.** We are given a metric $(V,d)$ with a root $\in V$ and each vertex $v \in V$ has an independent stochastic cost $C_v \in \mathbb{R}_{\geq 0}$. All cost distributions are given as input but the actual cost instantiation $C_v$ is only known when vertex $v$ is visited. Suppose a vertex $v$ can only be selected if: (1) $v$ is visited and (2) we are currently at vertex $v$. The goal is to adaptively find a tour $\Pi$ originating at root that selects a set $S$ of $k$ visited vertices while minimizing the expected total cost, which is the sum of the tour length and the cost of the selected vertices:

$$E\left[d(\Pi) + \sum_{v \in S} C_v\right].$$

Apart from being a natural generalization of the classical $k$-TSP problem, Stoch-Cost $k$-TSP is also motivated due to its connections to price of information \cite{33}. In particular, it generalizes the Minimization $k$-Pandora’s Box problem studied in \cite{28,33}. In this problem we are given a target $k$ and $n$ items, where each item $i \in [n]$ has a known probing price $\pi_i \in \mathbb{R}_{\geq 0}$ and an independent stochastic cost $C_i$. The exact cost $C_i$ is only revealed after we pay price $\pi_i$. The goal is to adaptively probe and select $k$ of the probed items to minimize the expected total selection cost plus probing price. Stoch-Cost $k$-TSP captures this problem on a star metric where node $i$ is at a distance $\pi_i/2$ from the root. Thus, we can view the Stoch-Cost $k$-TSP problem as generalizing the price of information framework to a metric setting, where the price of probing is not fixed but given by a general metric. Our next result gives a non-adaptive $O(1)$-approximation algorithm for Stoch-Cost $k$-TSP.

**Theorem 2.** The Stoch-Cost $k$-TSP problem has a non-adaptive $O(1)$-approximation algorithm.

Our main techniques in the proof of Theorem 2 are similar to those for Stoch-Reward $k$-TSP. In fact, in Section 3 we present a generic framework that can be used to solve both these problems. It will be interesting to find other applications of our framework in future work.

1.3 High-level Techniques

We assume that after re-scaling, the distance between any pair of vertices is at least 1.

**Stoch-Reward $k$-TSP.** A standard idea in the design of approximation algorithms on a metric is to operate in phases, where in phase $i$ our algorithm is allowed a budget of $2^i$. Intuitively, this corresponds to the algorithm imagining that the optimal adaptive tour has length $\Theta(2^i)$. In each phase, a naïve algorithm would be to collect as much expected reward as possible within budget $2^i$ (say, by solving an instance of the Orienteering problem). However, in general the performance of such a naïve algorithm can be arbitrarily bad. E.g., suppose $k-\sqrt{k}$ reward is easy to get, now for the remaining reward the naïve algorithm prefers a vertex with a deterministic reward of $\sqrt{k}$ (assuming both are at the same distance).

\footnote{Up to a factor of 2, this version of the problem is equivalent to the version where restriction (2) is removed.}
A natural fix to the above issue is to truncate the reward distributions at the remaining target reward and then take expectations. Not only is this algorithm adaptive, it is not even clear why it would work. Indeed, Ene et al. [13] give an example (see Example 2 in [13]) where this algorithm has an $O(\log k)$-approximation factor. Our first idea is to run $O(1)$ repetitions of a bi-criteria Orienteering algorithm using the same truncation (i.e., the initial remaining target) for all these repetitions. Our analysis applies Freedman’s [14] and Jogdeo-Samuels [27] inequalities to argue concentration, and relies crucially on not updating the remaining target for these $O(1)$ repetitions.

Nevertheless, the above approach depends on the remaining target, which is unknown to a non-adaptive algorithm. One could bypass this by truncating the reward distributions at $\log k$ different scales, where scale $j$ corresponds to the remaining target being roughly $k/2^j$, applying the previous $O(1)$ repetitions idea at each scale, and visiting the union of all tours. Unfortunately, this immediately loses a $\log k$ approximation factor. Our second idea is “critical scaling” in which we identify a “critical” scale $j_{\text{crit}}$ among the $\log k$ possible scales, and only include tours for scales $j_{\text{crit}} - 1$ and $j_{\text{crit}}$. This critical scale $j_{\text{crit}}$ roughly (but not quite) corresponds to a “phase transition” from an underestimation to an overestimation of the remaining target. A priori it is not clear why such a “critical” scale can be found non-adaptively, but the concentration properties of the above $O(1)$ repetitions allow us to find it efficiently.

**Stoch-Cost $k$-TSP.** We obtain our result for Stoch-Cost $k$-TSP in a similar way. An immediate challenge, however, is how should we truncate the cost distributions $C_v$, say even if the remaining target $k'$ is known? One natural way is by looking at $\mathbb{P}[C_v \leq O(2^j/k')]$, where $O(2^j/k')$ is the “average” cost per remaining reward in phase $i$. But such an approach would fail when some vertices in the optimal tour have costs much smaller than $O(2^j/k')$, while the other vertices have much higher costs. We overcome this by considering $\mathbb{P}[C_v \leq O(2^{j-1})]$ for all possible scales $j \in \{0, \cdots, i + \log n\}$, identifying a “critical” scale $j_{\text{crit}}$, and again only including the tours for scales $j_{\text{crit}} - 1$ and $j_{\text{crit}}$. To identify the critical scale, we need to evaluate the maximum target a tour at a given scale can get within cost budget $2^j$ with constant probability. We show this can be approximately computed via dynamic programming.

### 1.4 Further Related Work

There is a long line of work studying the classic $k$-TSP and the related $k$-MST problem; we refer the readers to Garg’s beautiful 2-approximation paper and the references therein [17].

A formal study on the benefits of adaptivity for stochastic combinatorial optimization problems started with the seminal work of Dean et al. [11]. They showed that for the stochastic knapsack problem, where items sizes are independently drawn and we need to fit them in a knapsack of size $B$, there is an $O(1)$-approximation non-adaptive algorithm. This factor was later improved to a $(2 + \epsilon)$-approximation in [7, 29]. The minimization version of the stochastic knapsack problem, which is known as the Stoch-Knapsack Cover problem, was studied by Deshpande et al. [12], and is a special case of Stoch-Reward $k$-TSP as we mentioned before. The unbounded version of Stoch-Knapsack Cover (each item has infinite number of copies) was studied by [26] and they provide an FPTAS for this problem.

Gupta et al. [23] generalized the stochastic knapsack problem to the stochastic orienteering problem, where each stochastic item now resides on a vertex of a given metric, and we need to fit both the tour length and the item sizes inside our budget $B$. They give an $O(\log \log B)$-approximation non-adaptive algorithm for this problem. Bansal and Nagarajan [6] later showed that this problem has no constant-approximation non-adaptive algorithm. These
works inspired Ene et al. [13] to study Stoch-Reward $k$-TSP, a natural minimization variant of the stochastic orienteering problem. Prior to our work, it was conceivable that this minimization problem also has a super-constant adaptivity gap, like stochastic orienteering.

Motivated by different applications that solve discrete problems under an uncertain input, other related stochastic probing models have been studied. We refer the readers to Singla’s Ph.D. Thesis for a survey [32]. Of particular interest to us is the Price of Information model [33], which was inspired from the work on Pandora’s box [34, 28]. Their Minimization $k$-Pandora’s Box problem inspired us to define Stoch-Cost $k$-TSP, which generalizes the probing costs from being fixed to being on a metric. Although an optimal strategy is known for Minimization $k$-Pandora’s Box, the problem becomes APX-hard on a metric as it generalizes $k$-TSP.

Organization

We start with some preliminary definitions and lemmas in Section 2. In Section 3, we describe our general framework for both Stoch-Reward $k$-TSP and Stoch-Cost $k$-TSP, and prove some key lemmas that will be used throughout the paper. We give our non-adaptive $O(1)$-approximation algorithm for Stoch-Reward $k$-TSP that proves Theorem 1 in Section 4. The non-adaptive $O(1)$-approximation algorithm for Stoch-Cost $k$-TSP that proves Theorem 2 is in Section 5.

2 Preliminaries

2.1 Adaptive vs Non-Adaptive Algorithms

Any feasible solution to our stochastic problems can be described by a decision tree, where nodes correspond to vertices that are visited and branches correspond to instantiations of the observed random variables. Even if the degree of every vertex is a constant, the size of such decision trees can be exponentially large in its height. These solutions are called adaptive because the choice of the next vertex to visit depends on the outcomes of the already visited nodes.

We also consider the special class of non-adaptive solutions that is described simply by an ordered list of vertices: the policy involves visiting vertices in the given order until a certain stopping criterion is met. Such non-adaptive solutions are often preferred over adaptive solutions because they are easier to implement.

In this work we only study minimization problems. We compare the performance of our algorithm with that of the optimal adaptive algorithm, which is denoted by $\text{OPT}$. We abuse notation and also use $\text{OPT}$ to denote the expected objective of the optimal adaptive algorithm. We say an algorithm is $\alpha$-approximation for $\alpha \geq 1$ if the expected objective of the algorithm is at most $\alpha \cdot \text{OPT}$. Ideally, we want to design non-adaptive algorithms whose performance is comparable to the optimal adaptive algorithm. Since this is not always possible, it is important to bound the adaptivity gap, which is the worst-case ratio between the expected objectives of the optimal non-adaptive and the optimal adaptive algorithms.

2.2 Probability Inequalities

Our proofs will require the following probability inequalities. We start with a bound on the median of independent Bernoulli random variables due to Jogdeo and Samuels [27]. Given $n$ independent Bernoulli random variables $X_1, \ldots, X_n$ where $X_i$ has success probability $p_i \in [0, 1]$, let $X := \sum_{i=1}^n X_i$ be their sum. Define the median of $X$ to be any integer $m \in \mathbb{Z}_{\geq 0}$ such that $\min \{ \Pr[X \geq m], \Pr[X \leq m]\} \geq 1/2$. 
Theorem 3 (Theorem 3.2 and Corollary 3.1 [27]). Let $X = \sum_{i=1}^n X_i$ be the sum of $n$ independent Bernoulli random variables where $X_i$ has success probability $p_i \in [0, 1]$. If $E[X]$ is an integer $k$, then the median of $X$ is also $k$. If $k < E[X] < k+1$ for some integer $k$, then the median of $X$ is either $k$ or $k+1$.

We will also need the following martingale inequality due to Freedman [14].

Theorem 4 (Freedman’s Inequality, Theorem 1.6 in [14]). Consider a real-valued martingale sequence $\{X_t\}_{t \geq 0}$ such that $X_0 = 0$, and $E[X_{t+1}|F_t] = 0$ for all $t$, where $\{F_t\}_{t \geq 0}$ is the filtration defined by the martingale. Assume that the sequence is uniformly bounded, i.e., $|X_t| \leq M$ almost surely for all $t$. Now define the predictable quadratic variation process of the martingale to be $W_t = \sum_{j=1}^t E[X_j^2|F_{j-1}]$ for all $t \geq 1$. Then for all $\ell \geq 0$ and $\sigma^2 > 0$ and any stopping time $\tau$, we have

$$P\left[\sum_{j=0}^{\tau} X_j \geq \ell \wedge W_\tau \leq \sigma^2 \text{for some stopping time } \tau\right] \leq 2 \exp\left(-\frac{\ell^2/2}{\sigma^2 + M^2/3}\right).$$

Theorem 5 (Chernoff Bound). Let $X_1, X_2, \cdots, X_n$ be independent random variables taking values in $[0, 1]$ and define $X := \sum_{i \in [n]} X_i$. Then for any $\delta \in [0, 1]$, we have

$$P[X \leq (1 - \delta) \cdot E[X]] \leq \exp(-\delta^2 \cdot E[X]/2).$$

2.3 A Bi-Criteria Algorithm \textbf{ALG}$_{\text{Bicrit-Orient}}$ for Orienteering

We formally define the well-known Orienteering problem.

Orienteering. Given a metric $(V,d)$ with root $\in V$, a profit$^6$ $R_v > 0$ for each $v \in V$, and a budget $B > 0$, the goal is to find a tour originating at root of length at most $B$ that maximizes the collected profit.

The state-of-the-art for this NP-hard Orienteering problem is a $(2 + \epsilon)$-approximation algorithm [10]. We denote this algorithm as \textbf{ALG}$_{\text{Orient}}$ and denote the profit of the optimal Orienteering tour as $\text{OPT}_{\text{Orient}}$. For our purposes, however, we also need to find profit at least $\text{OPT}_{\text{Orient}}$ minus an arbitrarily small additive error. To achieve this, the tour found by our algorithm has length $O(1) \cdot B$.

Lemma 6 (Bi-criteria Orienteering). There is an efficient algorithm \textbf{ALG}$_{\text{Bicrit-Orient}}$ that finds a tour of length $O(1) \cdot B$ while collecting at least $(\text{OPT}_{\text{Orient}} - \epsilon)$ profit, where $\epsilon = 1/\text{poly}(n)$ can be made arbitrarily small.

3 Our Approach via Critical Scaling and Repetitions

3.1 A Meta-Algorithm and Critical Scaling

Our non-adaptive $O(1)$-approximation algorithms for both the problems, Stoch-Reward $k$-TSP and Stoch-Cost $k$-TSP, have the same structure described in Meta-Algorithm \textbf{ALG}$_{\text{Meta}}$ (Algorithm 1). This algorithm operates in phases where it gets a budget of $O(1) \cdot 2^{\gamma^i}$ in phase $i \geq 0$ for some constant $\gamma \in (1, 2)$.

$^6$ We use the word “profit” for Orienteering to avoid confusion with the “reward” in Stoch-Reward $k$-TSP.
In each phase $i$, $\text{ALG}_\text{Meta}$ explores multiple different “scales” in the remaining graph after excluding the set $\Pi$ of vertices found in the previous phases. Recall, each scale corresponds to truncating the random variables at a different threshold. This is crucial because our non-adaptive algorithm doesn’t know the remaining reward to reach the target $k$. For each different scale, $\text{ALG}_\text{Meta}$ obtains a tour of length $O(1) \cdot \gamma^i$ via a sub-procedure $\text{ALG}_\text{Rep}$ to which it sends the truncated random variables as arguments (discussed in Section 3.2). Eventually, $\text{ALG}_\text{Meta}$ identifies a “critical” scale $j_{\text{crit}}$ and appends at the end of $\Pi$ the two tours corresponding to the scales $j_{\text{crit}}$ and $j_{\text{crit}} - 1$. Since we only append two tours, $\text{ALG}_\text{Meta}$ uses budget at most $O(1) \cdot \gamma^i$ in phase $i$.

\section*{Algorithm 1 A Meta-Algorithm $\text{ALG}_\text{Meta}$.}

\begin{algorithmic}[1]
\State \textbf{Pre-processing stage:}
\For {phase $i = 0, 1, \ldots$}
  \State set $\Pi_{i-1} \leftarrow \emptyset$;\For {scale $j = 0, \ldots, \ell$}
    \State set $X_j^i \in [0, 1]$ to be the truncation of $X_v$ at scale $j$ for $v \in V \setminus \Pi$, and zero for $v \in \Pi$;\Find tour $\Pi_{i,j} \leftarrow \text{ALG}_\text{Rep}(\{X_j^i\}_{v \in V \setminus \Pi} : i)$ of length $O(1) \cdot \gamma^i$;
  \EndFor
  \State identify a “critical” scale $j_{\text{crit}}$ and set $\Pi_i \leftarrow \Pi_{i,j_{\text{crit}}} \cup \Pi_{i,j_{\text{crit}}-1}$;\Append tour $\Pi_i$ to $\Pi$, i.e., $\Pi \leftarrow \Pi \circ \Pi_i$;
\EndFor
\State \textbf{Probing stage:}
\For {phase $i = 0, 1, \ldots$}
  \State visit vertices in the order of $\Pi_i$ and apply certain Selection and Stopping Criteria;
\EndFor
\State \textbf{Return} set of vertices selected
\end{algorithmic}

To analyze the algorithm, we need some notation for any phases $i, i' \geq 1$:
\begin{itemize}
  \item $\sigma_{i-1}$: outcome of vertices visited by $\text{ALG}_\text{Meta}$’s in the first $i - 1$ phases of the probing stage.
  \item $u_{i'}(\sigma_{i-1})$: probability that $\text{ALG}_\text{Meta}$ enters phase $i' + 1$ in the probing stage, conditioning on $\sigma_{i-1}$.
  \item $u_{i'}^*(\sigma_{i-1})$: probability that the cost of $\text{OPT}$ is more than $\gamma'$, conditioning on $\sigma_{i-1}$.
\end{itemize}
Notice $u_{i-1}(\sigma_{i-1})$ denotes the indicator variable that $\text{ALG}_\text{Meta}$ enters phase $i$ in the probing stage. The following Lemma 7 is the key to our theorems. Roughly, it says that $\text{ALG}_\text{Meta}$ is a constant approximation algorithm if it can ensure that whenever $u_{i'}^*(\sigma_{i-1})$ is small (i.e., $\text{OPT}$ has a large success probability within budget $\gamma'$) then $\text{ALG}_\text{Meta}$ also succeeds with a constant probability in the first $i$ phases (i.e., only using $O(1) \cdot \gamma^i$ budget). The proof of Lemma 7 is standard (e.g., [13]), and we defer it to Appendix B.

\textbf{Lemma 7 (Key Lemma).} If for some universal constants $C > 0$, $\gamma > 1$, any phase $i \geq 1$, and any possible $\sigma_{i-1}$, the algorithm $\text{ALG}_\text{Meta}$ satisfies
\[ u_i(\sigma_{i-1}) \leq C \cdot u_{i'}^*(\sigma_{i-1}) + \frac{u_{i-1}(\sigma_{i-1})}{\gamma^2}, \]
then $\text{ALG}_\text{Meta}$ is a non-adaptive $O(1)$-approximation algorithm.
All our effort will go in designing $\text{ALG}_{\text{Meta}}$ that satisfies the precondition of Lemma 7.

### 3.2 $\text{ALG}_{\text{Rep}}$: Constant Repetitions of $\text{ALG}_{\text{Bicrit-Orient}}$ Suffice

For a fixed scale $j$ in phase $i$, $\text{ALG}_{\text{Meta}}$ uses $\text{ALG}_{\text{Rep}}$ (Algorithm 2) as a key sub-procedure to find a tour of length $O(1) \cdot \gamma^i$. To achieve this, $\text{ALG}_{\text{Rep}}$ runs a constant number of repetitions of $\text{ALG}_{\text{Bicrit-Orient}}$ on an Orienteering instance where each vertex $v$ has a profit $w_v = \mathbb{E}[X_v]$ for input random variable $X_v \in [0, 1]$ (recall, $X_v$ is the truncated random variable at scale $j$ for vertices outside $\Pi$). In each repetition, $\text{ALG}_{\text{Rep}}$ excludes vertices found in previous repetitions.

**Algorithm 2** $\text{ALG}_{\text{Rep}}(\{X_v\} \in V, i)$.

---

1. **Input:** random variables $X_v \in [0, 1]$ corresponding to vertex profits and phase $i$;
2. **Main stage:**
   3. set $\gamma \in (1, 2)$, $\epsilon \leftarrow 1/10^5$, $C \leftarrow O(1)$, and $w_v = \mathbb{E}[X_v]$;
   4. set $\Pi_i \leftarrow \emptyset$;
   5. for repetition $s = 1, \ldots, C$ do
      6. use $\text{ALG}_{\text{Bicrit-Orient}}$ to find a tour $\pi_s$ with budget $\gamma^i$, profit $\{w_v\} \in V$, and error $\epsilon$;
      7. append tour $\pi_s$ to $\Pi_i$, i.e., $\Pi_i \leftarrow \Pi_i \cup \pi_s$;
      8. reset $w_v = 0$ for $v \in \Pi_i$;
   9. end
10. **Return** $\Pi_i$

**Intuition.** In the following, we prove two important properties of $\text{ALG}_{\text{Rep}}$. Recall from Algorithm 2 that $\Pi_i$ denotes the union of the $C$ repetitions of $\text{ALG}_{\text{Bicrit-Orient}}$. The first property (Lemma 8) roughly says that if an Orienteering tour of budget $\gamma^i$ cannot obtain much profit outside $\Pi_i$, then $\text{OPT}$ also cannot obtain much reward outside $\Pi_i$ within budget $\gamma^i$. The second property (Lemma 9) roughly says that if on the other hand lots of profit can be found by an Orienteering tour outside $\Pi_i$, then the tour $\Pi_i$ obtains a large amount of expected reward in its $C$ repetitions, much more than what $\text{OPT}$ obtains within budget $\gamma^i$. This follows from the property that $\text{ALG}_{\text{Bicrit-Orient}}$ obtains profit close to the optimal Orienteering tour.

To formally state the above two properties, we need some notation. Consider the Orienteering instance in the remaining graph $V \setminus \Pi_i$ where the budget is $\gamma^i$ and each vertex $v \in V \setminus \Pi_i$ has profit $\mathbb{E}[X_v]$. Denote $\pi \subseteq V \setminus \Pi_i$ the optimal Orienteering tour for this instance and let

$$T \triangleq \sum_{v \in \pi} \mathbb{E}[X_v]$$

be the Orienteering profit obtained by $\pi$. For any adaptive strategy $\text{ADAP}$, let $\Pi_i(\text{ADAP}) \subseteq \Pi_i$ denote the random set of vertices visited by $\text{ADAP}$ inside the tour $\Pi_i$, and let $\Pi_{i}(\text{ADAP}) \subseteq V \setminus \Pi_i$ denote the random set of vertices visited by $\text{ADAP}$ outside the tour $\Pi_i$.

**Lemma 8.** Suppose we are given independent random variables $X_v \in [0, 1]$. Let $T$ be as defined in (1). Then for any adaptive strategy $\text{ADAP}$ which uses at most $\gamma^i$ budget and any constant $\alpha > 1$, we have

$$P\left[ \sum_{v \in \Pi_i(\text{ADAP})} X_v \geq \alpha T \right] \leq 2 \cdot \exp \left( -\frac{(\alpha - 1)^2T/2}{1 + (\alpha - 1)/3} \right).$$
Proof of Lemma 8. We construct a martingale for the (random) set $\Pi_i(\text{ADAP})$ of vertices visited by ADAP in $V \setminus \Pi_i$ as follows: When ADAP visits a vertex $v \in \Pi_i(\text{ADAP})$, the martingale proceeds for one step with martingale difference defined by

$$Z_v := X_v - \mathbb{E}[X_v] \in [-1, 1],$$

and the martingale doesn’t move when ADAP visits a vertex $v \in \Pi_i$. The stopping time $\tau$ is naturally defined as the martingale step when ADAP finishes. Since each $X_v \in [0, 1]$, the quadratic variance of the above martingale $W_\tau = \sum_{j=1}^{\tau} \mathbb{E}[X_j^2 | F_{j-1}]$ is bounded by its expectation $\sum_{j=1}^{\tau} \mathbb{E}[X_j | F_{j-1}]$ which is at most $T$, i.e., $\sum_{v \in \Pi_i(\text{ADAP})} \mathbb{E}[X_v] \leq T$. Therefore, applying Freedman’s inequality (Theorem 4), we have

$$\mathbb{P} \left[ \sum_{v \in \Pi_i(\text{ADAP})} X_v \geq \alpha T \right] \leq \mathbb{P} \left[ \left| \sum_{v \in \Pi_i(\text{ADAP})} Z_v \right| \geq (\alpha - 1)T \land W_\tau \leq T \right] \leq 2 \cdot \exp \left( -\frac{(\alpha - 1)^2 T/2}{1 + (\alpha - 1)/3} \right).$$

This finishes the proof of Lemma 8.

Lemma 9. Suppose we are given independent random variables $X_v \in [0, 1]$. Let $T$ be as defined in (1). Then for any adaptive strategy ADAP which uses budget at most $\gamma^i$, we have

$$\sum_{v \in \Pi_i \setminus \Pi_i(\text{ADAP})} \mathbb{E}[X_v] \geq (C - 1)(T - \epsilon) - \epsilon.$$

Proof of Lemma 9. Since ADAP uses budget at most $\gamma^i$, the set $\Pi_i(\text{ADAP}) \subseteq \Pi_i$ can always be visited by a tour of length at most $\gamma^i$. Consider the first tour $\pi_1$ found by Algorithm 2. Since the tour with length at most $\gamma^i$ that visits the set $\Pi_i(\text{ADAP})$ is a valid Orienteering tour when $\pi_1$ is found, it follows from Lemma 6 that $\sum_{v \in \Pi_i(\text{ADAP})} \mathbb{E}[X_v] \leq \epsilon + \sum_{v \in \pi_1} \mathbb{E}[X_v]$. For any $s \in \{2, 3, \ldots, C\}$, since $\pi$ is an Orienteering tour in $V \setminus \Pi_i$ of length at most $\gamma^i$ with $\sum_{v \in \pi} \mathbb{E}[X_v] = T$, Lemma 6 implies that $\sum_{v \in \pi_s} \mathbb{E}[X_v] \geq T - \epsilon$. Therefore, a simple calculation gives

$$\sum_{v \in \Pi_i \setminus \Pi_i(\text{ADAP})} \mathbb{E}[X_v] = \sum_{v \in \Pi_i} \mathbb{E}[X_v] - \sum_{v \in \Pi_i(\text{ADAP})} \mathbb{E}[X_v] \geq (C - 1)(T - \epsilon) - \epsilon,$$

which finishes the proof of Lemma 9.

4. **Stoch-Reward $k$-TSP**

In this section we prove Theorem 1, which is restated below for convenience.

Theorem 1. The Stoch-Reward $k$-TSP problem has a non-adaptive $O(1)$-approximation algorithm.

To prove this theorem we carefully choose the parameters of our Meta-Algorithm from last section.
4.1 The Algorithm

**Algorithm 3** \( \text{ALG}_{\text{Stoch-Reward}} \) for Stoch-Reward \( k \)-TSP problem.

1. **Pre-processing stage:**
   - set \( \gamma \leftarrow 1.1, \epsilon \leftarrow 1/10^9, \Pi \leftarrow \emptyset, \ell = [\log k], \text{ and } C \leftarrow 6000 \);
   - for phase \( i = 0, 1, \cdots \) do
     - set \( \Pi_{i-1} \leftarrow \emptyset \);
     - for scale \( j = 0, \cdots, \ell \) do
       - set profit \( w^j_v = \mathbb{E}[\min\{R_v : 2^j/k, 1\}] \cdot 1[v \in V \setminus \Pi] \); /* Scale \( j \) truncates at \( k/2^{j} \) */
       - set \( \Pi_{i,j} \leftarrow \emptyset \);
     - for repetition \( s = 1, 2, \cdots, C \) /* Constant repetitions of \( \text{ALG}_{\text{Bicrit-Orient}} \) */ do
       - use \( \text{ALG}_{\text{Bicrit-Orient}} \) to find tour \( \pi_{i,j,s} \) with budget \( \gamma^i \), profit \( \{w^j_v\}_{v \in V} \), and error \( \epsilon \);
       - append tour \( \pi_{i,j,s} \) to \( \Pi_{i,j} \), i.e., \( \Pi_{i,j} \leftarrow \Pi_{i,j} \cup \pi_{i,j,s} \);
       - reset \( w^j_v = 0 \) for \( v \in \Pi_{i,j} \);
     - end
     - /* Check whether \( j \) is a “critical” scale */
     - use \( \text{ALG}_{\text{Orient}} \) to find tour \( \pi^o_{i,j} \) with budget \( \gamma^i \) and profit \( \{w^j_v\}_{v \in V} \);
     - set \( T_{i,j} \leftarrow \sum_{v \in \pi^o_{i,j}} w^j_v \);
     - if \( T_{i,j} \geq 1/300 \) or \( j = \ell \) then
       - append tour \( \Pi_i := \Pi_{i,j} \cup \Pi_{i,j-1} \) to \( \Pi \), i.e., \( \Pi \leftarrow \Pi \cup \Pi_i \);
       - Break;
     - end
   - end
   - end
   - end

2. **Probing stage:**
   - for phase \( i = 0, 1, \cdots \) do
     - visit vertices in the order of \( \Pi_i \) and apply the following selection and stopping criteria ;
     - **Selection Criterion:** select every vertex visited ;
     - **Stopping Criterion:** total reward reaches \( k \);
   - end
   - Return set of vertices selected.

We assume without loss of generality that the stochastic reward \( R_v \leq k \) almost surely for each vertex \( v \in V \). Our algorithm \( \text{ALG}_{\text{Stoch-Reward}} \) for Stoch-Reward \( k \)-TSP problem is given in Algorithm 3. It is an instantiation of the Meta-Algorithm \( \text{ALG}_{\text{Meta}} \) (Algorithm 1) by setting the phase parameter \( \gamma = 1.1 \), number of scales \( \ell = [\log k] \), and number of repetitions \( C = 6000 \). For each scale \( j \) in phase \( i \), we set the random variable \( X^j_v \) for any vertex \( v \in V \setminus \Pi \) in \( \text{ALG}_{\text{Meta}} \) to be the stochastic reward \( R_v \) truncated at \( k/2^j \) and then scaled down to \([0, 1]\). We identify the “critical” scale \( j_{\text{crit}} \) in \( \text{ALG}_{\text{Meta}} \) as follows: For each scale \( j \) in phase \( i \), denote \( \Pi_{i,j} \) the \( C = 6000 \) repetitions of \( \text{ALG}_{\text{Bicrit-Orient}} \) and let \( T_{i,j} \) be the profit obtained by the 3-approximation Orienteering algorithm \( \text{ALG}_{\text{Orient}} \) in \( V \setminus (\Pi_i \cup \Pi_{i,j}) \). The “critical” scale \( j_{\text{crit}} \) is the smallest scale \( j \) such that \( T_{i,j} \geq 1/300 \), i.e., sufficient profit remains outside even after \( C \) repetitions. We add the two tours corresponding to the “rich” scale \( j_{\text{crit}} \) and the “poor”
scale \( j_{\text{crit}} - 1 \) into \( \Pi \). In the case when there is no scale \( j \) with \( T_{i,j} \geq 1/300 \), we simply set \( j_{\text{crit}} \) to be the last scale \( \ell \). In the probing stage, the selection and the stopping criteria are straightforward: we collect reward from every visited vertex and stop when the total reward reaches \( k \).

### 4.2 Proof of Theorem 1

Recall from Section 3.1 that to prove Theorem 1, we only need to prove the precondition in Lemma 7. The remainder of this section proves this precondition for \( \text{ALG}_\text{Stoch-Reward} \) as given in the following Lemma 10.

\[ \textbf{Lemma 10.} \quad \text{For } \gamma = 1.1, \text{ any phase } i > 0 \text{ in the probing stage of } \text{ALG}_\text{Stoch-Reward} \text{ satisfies} \]

\[
u_i(\sigma_{i-1}) \leq 100 \cdot \nu_i^*(\sigma_{i-1}) + \frac{u_{i-1}(\sigma_{i-1})}{\gamma^2}. \tag{2} \]

Before proving Lemma 10, we discuss the high-level intuition of our proof.

**Intuition.** Assume without loss of generality that \( u_i^*(\sigma_{i-1}) < 0.01 \), i.e., \( \text{OPT} \) finds \( k \) reward within budget \( \gamma^4 \) with probability at least 0.99, as otherwise the lemma trivially holds. Now the plan is to show that with constant probability, \( \text{ALG}_\text{Stoch-Reward} \) finds more reward than \( \text{OPT} \) restricted to budget \( \gamma^4 \), even when all rewards in \( \sigma_{i-1} \) are given to \( \text{OPT} \) for free. This allows us to focus on the remaining graph with vertex set \( V_i := V \setminus \sigma_{i-1} \) where we repeat \( \text{ALG}_\text{Bicrit-Orient} \) for different scales.

Our arguments rely on the notion of “richness”. We call a scale \( j \) “rich” if \( T_{i,j} \geq 1/300 \) and otherwise “poor”. A scale being poor indicates that not much reward can be collected outside the \( C \) repetitions of \( \text{ALG}_\text{Bicrit-Orient} \) for that scale, in which case we can use Lemma 8 to argue that \( \text{OPT} \) cannot find much reward outside. A scale being rich implies that each repetition of \( \text{ALG}_\text{Bicrit-Orient} \) for that scale finds a significant amount of reward, in which case we can apply Lemma 9 to argue that \( \text{ALG}_\text{Stoch-Reward} \) finds much more reward than \( \text{OPT} \) in the \( C \) repetitions for that scale. Our critical scale \( j_{\text{crit}} \) corresponds to the transition from poor to rich scales. Since the algorithm includes both \( j_{\text{crit}} \) and \( j_{\text{crit}} - 1 \), roughly the reason why our analysis works is that we use the poor scale \( j_{\text{crit}} - 1 \) to argue \( \text{OPT} \) cannot find much reward outside our tours and we use the rich scale \( j_{\text{crit}} \) to argue \( \text{OPT} \) cannot find much more reward inside. The final analysis has to do some case analysis depending on whether the transition ever happens or not.

**Proof of Lemma 10.** We fix any outcome \( \sigma_{i-1} \) of vertices visited by \( \text{ALG}_\text{Stoch-Reward} \) in the first \( i - 1 \) phases in its probing stage. The lemma trivially holds in the case where \( u_i^*(\sigma_{i-1}) \geq 0.01 \) as we have \( 100u_i^*(\sigma_{i-1}) \geq 1 \). If \( u_{i-1}(\sigma_{i-1}) = 0 \) which means that \( \text{ALG}_\text{Stoch-Reward} \) already collects reward \( k \) before entering phase \( i \) in the probing stage, then \( u_i(\sigma_{i-1}) = 0 \) and again the lemma trivially holds. We therefore assume that \( u_i^*(\sigma_{i-1}) < 0.01 \) and that \( u_{i-1}(\sigma_{i-1}) = 1 \). Now proving Lemma 10 is equivalent to proving

\[
u_i(\sigma_{i-1}) \leq 100u_i^*(\sigma_{i-1}) + 1/\gamma^2. \tag{3} \]

To prove (3), we need the following notation. Denote \( V_i := V \setminus \sigma_{i-1} \) the vertex set of the remaining graph where vertices in \( \sigma_{i-1} \) are excluded. Denote \( \Pi_i(\text{OPT}) \subseteq V_i \setminus \Pi_i \), the (random) set of vertices visited by \( \text{OPT} \) outside \( \sigma_{i-1} \cup \Pi_i \), within budget \( \gamma^4 \), and denote \( \Pi_i(\text{OPT}) \subseteq \Pi_i \), the (random) set of vertices visited by \( \text{OPT} \) inside \( \Pi_i \). We consider three cases:
Case (1): (Scale 0 is rich) \( T_{i,0} \geq 1/300 \). In this case, our algorithm appends tour \( \Pi_i := \Pi_{i,0} \) to \( \Pi \) (recall that \( \Pi_{i,-1} = \emptyset \)), and these will be the phase \( i \) vertices visited in the probing stage. We show that \( T_{i,0} \geq 1/300 \) implies that each repetition of \( \text{ALG}_{\text{Bicrit-Orient}} \) has large expected reward (notice the random rewards are not truncated at scale 0). As we repeat \( \text{ALG}_{\text{Bicrit-Orient}} \) for \( C = 6000 \) times, the tour \( \Pi_{i,0} \) has expected reward much larger than the target \( k \).

Since \( T_{i,0} \) is the profit of a valid Orienteering tour with length at most \( \gamma^i \), for each \( s \in \{1, \ldots, C\} \) we have \( T_{i,0,s} \geq T_{i,0} - \epsilon \geq 1/300 - \epsilon \), where \( \epsilon = 1/10^5 \) is the small error term for \( \text{ALG}_{\text{Bicrit-Orient}} \) in Lemma 6. Thus,

\[
\sum_{v \in \Pi_{i,0}} \mathbb{E}[\min \{R_v/k, 1\}] \geq 20 - 6000\epsilon \geq 19.
\]

Notice that \( R_v/k \in [0,1] \), so applying Chernoff bound (Theorem 5) we have

\[
1 - u_i(\sigma_{i-1}) \geq \mathbb{P}\left( \sum_{v \in \Pi_{i,0}} R_v \geq k \right) = \mathbb{P}\left( \sum_{v \in \Pi_{i,0}} \min \{R_v/k, 1\} \geq 1 \right) \geq 0.9,
\]

which means \( u_i(\sigma_{i-1}) \leq 0.1 \leq 1/\gamma^2 \). This proves (3) and finishes the proof of Lemma 10 in this case.

Case (2): (Scale \( \ell \) is poor) \( T_{i,j} \leq 1/300 \) for every scale \( j = 0, \ldots, \ell \). In this case, our algorithm adds \( \Pi_i := \Pi_{i,j} \cup \Pi_{i,j-1} \) to \( \Pi \), and these will be the phase \( i \) vertices visited in the probing stage. We argue that the assumption of \( T_{i,j} \leq 1/300 \) implies that with constant probability \( \text{OPT} \) finds no reward outside \( \sigma_{i-1} \cup \Pi_i \) within budget \( \gamma^i \). If \( \text{OPT} \) still manages to find \( k \) reward, then all \( k \) reward must come from vertices in \( \sigma_{i-1} \cup \Pi_i \), in which case \( \text{ALG}_{\text{Stoch-Reward}} \) also finds \( k \) reward. In this case our argument already works with the vertices \( \Pi_{i,j} \) added to \( \Pi \), i.e., we do not even need vertices in \( \Pi_{i,j-1} \).

Since \( \text{ALG}_{\text{Orient}} \) is a 3-approximation Orienteering algorithm, for any set of vertices \( S \subseteq V_i \setminus \Pi_i \) that can be visited within budget \( \gamma^i \), we have \( \sum_{v \in S} \mathbb{E}[\min \{R_v \cdot 2^\ell/k, 1\}] \leq 3T_{i,\ell} \leq 0.01 \). Since \( \ell = \lfloor \log k \rfloor \), we have \( k/2^\ell \in [1,2] \), and therefore

\[
\sum_{v \in S} \mathbb{E}[\min \{R_v, 1\}] \leq \sum_{v \in S} \mathbb{E}[\min \{2 \cdot R_v \cdot 2^\ell/k, 1\}] \leq 0.02. \tag{4}
\]

Recall that \( \Pi_{i,\text{(OPT)}} \subseteq V_i \setminus \Pi_i \) denotes the (random) set of vertices visited by \( \text{OPT} \) outside \( \sigma_{i-1} \cup \Pi_i \) within budget \( \gamma^i \). Since each \( \min \{R_v, 1\} \in \{0,1\} \), the best probability of obtaining truncated reward at least 1 in \( V_i \setminus \Pi_i \) within budget \( \gamma^i \) is achieved by a non-adaptive strategy. Therefore, Markov’s inequality together with (4) implies that

\[
\mathbb{P}\left( \sum_{v \in \Pi_{i,\text{(OPT)}}} \min \{R_v, 1\} \geq 1 \right) \leq 0.02.
\]

Since \( u_i^*(\sigma_{i-1}) < 0.01 \), we have that with probability at least 1 - 0.01 - 0.02 = 0.97, \( \text{OPT} \) finds \( k \) reward in \( V \) but 0 reward outside \( \sigma_{i-1} \cup \Pi_i \). In this case, \( \text{ALG}_{\text{Stoch-Reward}} \) also finds \( k \) reward among vertices visited in the first \( i \) phases. So we have \( u_i(\sigma_{i-1}) \leq 1 - 0.97 = 0.03 \leq 1/\gamma^2 \), which establishes (3) in this case.

Case (3): (Transition from poor to rich scale at \( j_{\text{crit}} \)) \( T_{i,0} \leq 1/300 \) but \( T_{i,j} > 1/300 \) for some \( j \in [\ell] \). In this case, let \( j_{\text{crit}} = \min \{ j \in [\ell] : T_{i,j} > 1/300 \} \) be our critical scale. The algorithm appends \( \Pi_i := \Pi_{i,j_{\text{crit}}-1} \cup \Pi_{i,j_{\text{crit}}} \) to \( \Pi \). To prove that \( \text{ALG}_{\text{Stoch-Reward}} \) will not continue to phase \( i + 1 \) with constant probability, we show that the following two events happen with constant probability.
1. OPT doesn’t find too much reward outside $\sigma_{i-1} \cup \Pi_i$ within budget $\gamma^i$.
2. ALG$_{Stoch-Reward}$ finds much more reward inside $\Pi_i$ than OPT does since it is restricted to budget $\gamma^i$.

We show that the first event follows from $T_{i,j_{\text{max}}-1} \leq 1/300$ while the second event follows from $T_{i,j_{\text{max}}} \geq 1/300$. From these we conclude that with constant probability, ALG$_{Stoch-Reward}$ obtains at least as much reward as OPT restricted to budget $\gamma^i$.

We first argue that OPT doesn’t find too much reward outside $\sigma_{i-1} \cup \Pi_i$. Specifically, we prove that

$$\mathbb{P}\left[ \sum_{v \in \Pi_i(\text{OPT})} R_v < k/2^{j_{\text{max}}-1} \right] \geq 0.5. \tag{5}$$

Notice that $T_{i,j_{\text{max}}-1} \leq 1/300$ together with the fact that ALGOrient is a 3-approximation for Orienteering implies that for any set of vertices $S \subseteq V_i \setminus \Pi_i$ that can be visited within distance $\gamma^i$, we have

$$\sum_{v \in S} \mathbb{E}\left[ \min \{ R_v \cdot 2^{j_{\text{max}}-1}/k, 1 \} \right] \leq 0.01.$$

Since the random variables $\min \{ R_v \cdot 2^{j_{\text{max}}-1}/k, 1 \} \in [0, 1]$, applying Lemma 8 we have

$$\mathbb{P}\left[ \sum_{v \in \Pi_i(\text{OPT})} \min \{ R_v \cdot 2^{j_{\text{max}}-1}/k, 1 \} \geq 1 \right] \leq 2 \exp \left( -\frac{0.99^2/2}{0.01 + 0.99/3} \right) \leq 0.5,$$

which immediately implies (5).

Now we argue that inside $\Pi_i$, we find much more reward than OPT does when it’s restricted to budget $\gamma^i$. Specifically, we prove that

$$\mathbb{P}\left[ \sum_{v \in \Pi_i \setminus \Pi_i(\text{OPT})} R_v \geq k/2^{j_{\text{max}}-1} \right] \geq 0.8, \tag{6}$$

where recall that $\Pi_i(\text{OPT}) \subseteq \Pi_i$ is the (random) set of vertices visited by OPT inside $\Pi_i$ within budget $\gamma^i$. Notice that $T_{i,j_{\text{max}}} > 1/300$ together with Lemma 9 implies that

$$\sum_{v \in \Pi_i \setminus \Pi_i(\text{OPT})} \mathbb{E}[\min\{R_v \cdot 2^{j_{\text{max}}/k}, 1\}] \geq (6000 - 1) \cdot (T_{i,j_{\text{max}}} - \epsilon) - \epsilon \geq 19.$$

Applying Chernoff bound (Theorem 5), we have

$$\mathbb{P}\left[ \sum_{v \in \Pi_i \setminus \Pi_i(\text{OPT})} \min\{R_v \cdot 2^{j_{\text{max}}/k}, 1\} \geq 2 \right] \geq 0.8,$$

which implies (6).

Now we complete the proof of (3) in this final case. From (5) and (6) and our assumption that $u^*_i(\sigma_{i-1}) < 0.01$, we have that with probability at least $1 - 0.5 - 0.2 - 0.01 \geq 1/4$, all the following three events hold: (1) $\sum_{v \in \Pi_i(\text{OPT})} R_v < k/2^{j_{\text{max}}-1}$, (2) $\sum_{v \in \Pi_i \setminus \Pi_i(\text{OPT})} R_v \geq k/2^{j_{\text{max}}-1}$, and (3) OPT obtains at least $k$ reward within budget $\gamma^i$. When all these three events hold, ALG$_{Stoch-Reward}$ also finds at least $k$ reward before visiting any vertex from phase $i + 1$. Therefore, $u_i(\sigma_{i-1}) \leq 3/4 \leq 1/\gamma^2$, and this completes the proof of Lemma 10. \qed
5 Stoch-Cost k-TSP

In this section we prove Theorem 2, which is restated below for convenience. Throughout this section, we will remove the restriction that a vertex \( v \) can only be selected if we are currently at \( v \) because this is equivalent to the original problem up to a factor of 2.

\[ \textbf{Theorem 2.} \text{ The Stoch-Cost } k\text{-TSP problem has a non-adaptive } O(1)\text{-approximation algorithm.} \]

Recall, an additional challenge for Stoch-Cost \( k\)-TSP is that there is no obvious way to truncate the cost distributions \( C_v \), even if the remaining target \( k' \) is known. Truncating at the “average” cost per remaining reward (i.e., \( \mathbb{P}[C_v \leq O(\gamma^t/k')] \)) will fail when some vertices in the optimal tour have costs much smaller than \( O(\gamma^t/k') \), while the other vertices have much higher costs. We overcome this by considering \( \mathbb{P}[C_v \leq O(\gamma^t/2^i)] \) for all possible scales \( j \in \{0, \cdots, i \cdot \log \gamma + \log n \} \). To identify a “critical” scale, we evaluate the maximum target a tour at a given scale can get with constant probability within cost budget \( 2^i \). We show this can be approximately computed via dynamic programming.

The rest of this section is devoted to proving Theorem 2.

5.1 The Algorithm

Our algorithm \( \text{ALG}_{\text{Stoch-Cost}} \) for Stoch-Cost \( k\)-TSP is given in Algorithm 4. \( \text{ALG}_{\text{Stoch-Cost}} \) is an instantiation of our Meta-Algorithm \( \text{ALG}_{\text{Meta}} \) in Algorithm 1 by setting the phase parameter \( \gamma = 1.1 \) and number of repetitions \( C = 6000 \). The number of scales in phase \( i \geq 0 \) will be \( \ell_i = [i \cdot \log \gamma + \log n] \). (Notice, unlike Stoch-Reward \( k\)-TSP, the number of scales changes with phase.) For scale \( j \) in phase \( i \), we set a random variable \( X_j^v \) for vertex \( v \in V \setminus \Pi \) in \( \text{ALG}_{\text{Meta}} \) to be the indicator variable that cost \( C_v \leq \gamma^t/2^i \).

We identify a “critical” scale \( \tilde{\gamma}_{\text{crit}} \) as follows: For any phase \( i \geq 0 \) and scale \( j \in \{0, \cdots, \ell_i\} \), define \( Y_{i,j} \in \mathbb{Z}_{\geq 0} \) to be the maximum number of vertices that can be selected from \( \Pi_{i,j} \cup \Pi_{i,j-1} \) with probability at least 0.2 within cost budget \( 3\gamma^t \). Ideally, we want to compute \( Y_{i,j} \) for every scale \( j \in \{0, \cdots, \ell_i\} \) and set the critical scale to be the one that maximizes \( Y_{i,j} \). Unfortunately, \( Y_{i,j} \) cannot be computed efficiently as the corresponding problem is NP-Hard. To get around this issue, we compute an approximate value \( \tilde{Y}_{i,j} \) in Step 15 of \( \text{ALG}_{\text{Stoch-Cost}} \) via a dynamic programming sub-procedure \( \text{ALG}_{\text{DP}} \). We discuss the details of \( \text{ALG}_{\text{DP}} \) in Section 5.3, where we prove the following Lemma 11 which roughly says that the \( \tilde{Y}_{i,j} \) computed by \( \text{ALG}_{\text{Stoch-Cost}} \) is a reasonably good approximation of \( Y_{i,j} \).

\[ \textbf{Lemma 11.} \text{ For any phase } i \geq 0 \text{ and any scale } j \in \{0, \cdots, \ell_i\}, \text{ the approximate value } \tilde{Y}_{i,j} \text{ computed in Step 15 of } \text{ALG}_{\text{Stoch-Cost}} \text{ satisfies that (1) } \tilde{Y}_{i,j} \geq Y_{i,j}, \text{ and (2) } \tilde{Y}_{i,j} \text{ vertices can be selected from } \Pi_{i,j} \cup \Pi_{i,j-1} \text{ within cost budget } 6\gamma^i \text{ with probability at least 0.2.} \]

After computing \( \tilde{Y}_{i,j} \) for each scale \( j \in \{0, \cdots, \ell_i\} \), we simply set \( \tilde{\gamma}_{\text{crit}} \) to be the scale that maximizes \( \tilde{Y}_{i,j} \) and add the two tours corresponding to scales \( \tilde{\gamma}_{\text{crit}} - 1 \) and \( \tilde{\gamma}_{\text{crit}} \) into \( \Pi \).

In the probing stage, the Stopping Criterion is natural: we stop whenever the number of selected vertices reaches \( k \). The selection process needs some care since not all vertices visited in the previous phases are selected. Our algorithm therefore runs two selection processes consecutively: In Selection-Process 1, we select as many unselected vertices from those visited in the previous phases within total cost \( \gamma^t \). This is to ensure that we select from \( \sigma_{t-1} \) at least as many vertices as \( \text{OPT} \) restricted to budget \( \gamma^t \). In Selection-Process 2, we select as many vertices as possible from \( \Pi_t \) within total cost \( 6\gamma^t \). The above Lemma 11 guarantees that at least \( \tilde{Y}_{i,\tilde{\gamma}_{\text{crit}}} \) vertices can be selected in this process with probability at least 0.2.
Algorithm 4 ALGStoch-Cost for Stoch-Cost $k$-TSP problem.

1 Pre-processing stage:
2 set $\gamma \leftarrow 1.1$, $\epsilon \leftarrow 1/10^5$, $\Pi \leftarrow \emptyset$ and $C \leftarrow 6000$; 
3 for phase $i = 0, 1, \cdots$ do 
4 set $\Pi_{i-1} \leftarrow \emptyset$; 
5 for scale $j = 0, \cdots, \ell_i$, where $\ell_i = \lceil i \cdot \log \gamma + \log n \rceil$ do 
6 set profit $w^j_v = \mathbb{P}[C_v \leq \gamma^i/2^j] \cdot 1[v \in V \setminus \Pi]$; /* Scale $j$ “truncates” at $\gamma^i/2^j$ */ 
7 set $\Pi_{i,j} \leftarrow \emptyset$; 
8 for repetition $s = 1, 2, \cdots, C$ /* Constant repetitions of ALG$_{Bicrit-Orient}$ */ do 
9 use ALG$_{Bicrit-Orient}$ to find tour $\pi_{i,j,s}$ with budget $\gamma^i$, profit $\{w^j_v\}_{v \in V}$ and error $\epsilon$; 
10 append tour $\pi_{i,j,s}$ to $\Pi_{i,j}$, i.e., $\Pi_{i,j} \leftarrow \Pi_{i,j} \circ \pi_{i,j,s}$; 
11 reset $w^j_v = 0$ for $v \in \Pi_{i,j}$; 
12 end /* Approximately compute the maximum number of vertices that can be 
13 selected from $\Pi_{i,j} \cup \Pi_{i,j-1}$ within cost budget $3\gamma^i$ and with probability at 
14 least 0.2 */ find the largest integer $\tilde{Y}_{i,j} \leq n$ such that ALG$_{DP}$(\tilde{Y}_{i,j}, 3\gamma^i, \Pi_{i,j} \cup \Pi_{i,j-1}) \geq 0.2$; 
15 /* Identify a “critical” scale */ 
16 set $\tilde{j}_{crit} \leftarrow \arg \max_j \tilde{Y}_{i,j}$ and $\Pi_i \leftarrow \Pi_{i,j_{crit}} \cup \Pi_{i,j_{crit}-1}$; 
17 append tour $\Pi_i$ to $\Pi$, i.e., $\Pi \leftarrow \Pi \circ \Pi_i$; 
18 end 
19 
20 Probing stage: 
21 for phase $i = 0, 1, \cdots$ do 
22 set $\sigma_{i-1} \leftarrow \bigcup_{t=0}^{i-1} \Pi_t$; 
23 visit vertices in the order of $\Pi_i$ and apply the following selection and stopping 
24 criteria; /* Select (unselected) vertices visited in previous phases */ 
25 Selection-Process 1: select as many vertices as possible from $\sigma_{i-1}$ within total 
26 cost $\gamma^i$; /* Select vertices visited in the current phase */ 
27 Selection-Process 2: select as many vertices as possible from $\Pi_i$ within total 
28 cost $6\gamma^i$; 
29 Stopping Criterion: total number of vertices selected reaches $k$; 
30 end 
31 Return the set of selected vertices
5.2 Proof of Theorem 2

Recall from Section 3.1 that to prove Theorem 2, we only need to prove the precondition in Lemma 7. The remainder of this section proves this precondition for $\text{ALG}_{\text{Stoch-Cost}}$ as stated in the following Lemma 12.

Lemma 12. For $\gamma = 1.1$, any phase $i > 0$ in the probing stage of Stoch-Cost $k$-TSP satisfies

$$u_i(\sigma_{i-1}) \leq 100u_i^*(\sigma_{i-1}) + \frac{u_{i-1}(\sigma_{i-1})}{\gamma^2}. \tag{7}$$

Before proving Lemma 12, we need some notation.

Notation. For any (possibly adaptive) algorithm ADAP, we say ADAP has a distance budget of $B$ if it is allowed to travel a total distance of at most $B$; we say ADAP has a cost budget of $B$ if it is allowed to select vertices up to a total cost of $B$; we say ADAP has a total budget of $B$ if its total distance travelled plus the total cost of selecting vertices is restricted to be at most $B$. An algorithm satisfying a budget constraint is said to be within that budget.

For any phase $i$, denote $V_i := V \setminus \sigma_{i-1}$ the set of vertices in the remaining graph where vertices in $\sigma_{i-1}$ are excluded. For any fixed outcome $\sigma_{i-1}$ and any target $Y \in \mathbb{Z}_{\geq 0}$, denote $p_i^Y(\sigma_{i-1})$ the probability that $\text{OPT}$ selects at least $Y$ vertices from $V_i$ within total budget $\gamma^i$ and $p_i,Y(\sigma_{i-1})$ the probability that the tour $\Pi_i \subseteq V_i$ found by $\text{ALG}_{\text{Stoch-Cost}}$ contains $Y$ vertices which can be selected within cost budget $6\gamma^i$.

The proof of Lemma 12 relies on the following Lemma 13, which says that if $\text{OPT}$ selects $Y$ vertices in $V_i$ within total budget $\gamma^i$ with probability at least 0.9, then we can select $Y$ vertices in $\Pi_i$ within cost budget $6\gamma^i$ with probability at least 0.2. The proof of Lemma 12 from Lemma 13 is standard, see Appendix C.

Lemma 13. For any phase $i \geq 0$, any target $Y \in \mathbb{Z}_{\geq 0}$ and any outcome $\sigma_{i-1}$ of vertices visited in the previous $i - 1$ phases, if $p_i^Y(\sigma_{i-1}) \geq 0.9$ then we have $p_i,Y(\sigma_{i-1}) \geq 0.2$.

We need some notation to prove Lemma 13.

Notation. We say a vertex $v \in V$ is qualified for scale $j \in \{0, \ldots, \ell_i\}$ if its cost $C_v \leq \gamma^i/2^j$. For each scale $j \in \{0, \ldots, \ell_i\}$, denote $\pi^*_j$ the optimal Orienteering tour in $V_i \setminus \Pi_{i,j}$ with budget $\gamma^i$ where each vertex $v \in V_i \setminus \Pi_{i,j}$ has profit $\mathbb{P}[C_v \leq \gamma^i/2^j]$. Define $T^*_j := \sum_{v \in \pi^*_j} \mathbb{P}[C_v \leq \gamma^i/2^j]$ and $T_{i,j} := \sum_{v \in \Pi_{i,j}} \mathbb{P}[C_v \leq \gamma^i/2^j]$ to be the total Orienteering profit of tour $\pi^*_j$ and $\Pi_{i,j}$, respectively. Denote $\Pi_{i,j}(\text{OPT}) \subseteq V_i \setminus (\Pi_{i,j} \cup \Pi_{i,j-1})$ the (random) set of vertices visited by $\text{OPT}$ outside $\sigma_{i-1}$ and $\Pi_{i,j}$ within total budget $\gamma^i$, and $\Pi_{i,j}(\text{OPT}) \subseteq \Pi_{i,j} \cup \Pi_{i,j-1}$ the (random) set of vertices visited by $\text{OPT}$ inside $\Pi_{i,j} \cup \Pi_{i,j-1}$ within total budget $\gamma^i$.

Intuition. We discuss our high-level proof strategy for Lemma 13. Our arguments again rely on the notion of “richness”. Recall from above that $T_{i,j}$ denotes the Orienteering profit of tour $\Pi_{i,j}$ at scale $i$. We call a scale $j$ “rich” if $T_{i,j} \geq Y$ and otherwise “poor”. A scale $j$ being poor roughly (but not quite) indicates that OPT cannot find enough low-cost vertices qualified for scale $j$ outside the tour $\Pi_{i,j}$. A scale $j$ being rich implies that $\Pi_{i,j}$ contains enough vertices that are qualified for scale $j$, which is an immediate consequence of Jogdeo-Samuels inequality (Theorem 3). We plan to find a critical scale $j_{\text{crit}}$ that corresponds to the transition from rich to poor scales. Notice that such a critical scale $j_{\text{crit}}$ might be different from the critical scale $j_{\text{crit}}$ found by our algorithm, but we show that it suffices to argue about $j_{\text{crit}}$ since $j_{\text{crit}}$ is only better.
To argue about \( j_{crit} \), we consider the tours corresponding to both scales \( j_{crit} \) and \( j_{crit} - 1 \). Roughly we use the poor scale \( j_{crit} \) to argue that \( \text{OPT} \) cannot find enough low-cost vertices outside these tours and we use the rich scale \( j_{crit} - 1 \) to argue that we have enough replacements for these low-cost vertices without paying too much cost. Our final analysis is a case analysis depending on whether the transition ever happens or not. The proof here is more involved than that in Section 4 as we also need to take into account the amount of Orienteering profit outside the \( C = 6000 \) repetitions of \( \text{ALG}_{\text{Bicrit-Orient}} \) for each scale \( j \).

**Proof of Lemma 13.** Recall that for any phase \( i \geq 0 \) and scale \( j \in \{0, \ldots, \ell_i\} \), we defined \( Y_{i,j} \) to be the maximum number of vertices that can be selected from \( \Pi_{i,j} \cup \Pi_{i,j-1} \) with probability at least 0.2 within cost budget \( 3\gamma^i \). We show in the following that \( p^*_i, Y(\sigma_{i-1}) \geq 0.9 \) implies there exists a “critical” scale \( j_{crit} \in \{0, \ldots, \ell_i\} \) with \( Y_{i,j_{crit}} \geq Y \). This critical scale \( j_{crit} \) might be different from the critical scale \( \tilde{j}_{crit} \) identified by \( \text{ALG}_{\text{Stoc-Cost}} \). But since \( j_{crit} \) maximizes \( \tilde{Y}_{i,j} \) among all scales \( j \in \{0, \ldots, \ell_i\} \), it follows from property (1) in Lemma 11 that \( \tilde{Y}_{i,j_{crit}} \geq \tilde{Y}_{i,j} \geq Y_{i,j_{crit}} \geq Y \). Now using property (2) in Lemma 11 we have that \( \tilde{Y}_{i,j_{crit}} \geq Y \) vertices can be selected from \( \Pi_{i,\tilde{Y}_{i,j}} \cup \Pi_{i,\tilde{Y}_{i,j_{crit}}-1} \) within cost budget \( 6\gamma^i \) with probability at least 0.2. It follows that \( p_i, Y(\sigma_{i-1}) \geq 0.2 \). Therefore, the existence of a critical scale \( j_{crit} \) with \( Y_{i,j_{crit}} \geq Y \) would imply Lemma 13.

In the following, we consider three different cases and prove the existence of such a critical scale \( j_{crit} \) with \( Y_{i,j_{crit}} \geq Y \) in each case.

**Case (1): (Scale 0 is poor) \( T_{i,0} < Y \).** We show in this case that \( p_i, Y(\sigma_{i-1}) \geq 0.9 \) implies that scale 0 is a “critical” scale with \( Y_{i,0} \geq Y \). Notice that any vertex \( v \in V_i \) not qualified for scale 0 has cost \( C_v \geq \gamma^i \). Therefore, \( \text{OPT} \) cannot select any vertex that is not qualified for scale 0 within total budget \( \gamma^i \).

We start by showing that \( T_{i,0} \leq 0.1 \). To prove this, we assume for the purpose of contradiction that \( T_{i,0} > 0.1 \). It follow from Lemma 8 that

\[
\mathbb{P}
\left[
\left| \left\{ v \in \Pi_{i,0}(\text{OPT}) : C_v \leq \gamma^i \right\} \right| \leq 200T_{i,0}^* \right] \geq 0.9. \tag{8}
\]

From Lemma 9 we have that

\[
\sum_{v \in \Pi_{i,0} \cap \Pi_{i,0}(\text{OPT})} \mathbb{P}[C_v \leq \gamma^i] \geq (6000 - 1) \cdot (T_{i,0}^* - \epsilon) - \epsilon \geq 5000T_{i,0}^*. 
\]

So it follows from Chernoff bound (Theorem 5) that

\[
\mathbb{P}
\left[
\left| \left\{ v \in \Pi_{i,0} \setminus \Pi_{i,0}(\text{OPT}) : C_v \leq \gamma^i \right\} \right| \geq 500T_{i,0}^* \right] \geq 0.9. \tag{9}
\]

Since \( T_{i,0} < Y \), from Theorem 3 we have that

\[
\mathbb{P}
\left[
\left| \left\{ v \in \Pi_{i,0} : C_v \leq \gamma^i \right\} \right| \leq Y \right] \geq 0.5. \tag{10}
\]

Now we count the number of vertices found by \( \text{OPT} \) that are qualified for scale 0 within total budget \( \gamma^i \). It follows from union bound that with probability at least 0.2, all three events in (8), (9) and (10) hold, in which case \( \text{OPT} \) finds at most \( Y - 300T_{i,0}^* \) vertices qualified for scale 0 within total budget \( \gamma^i \). Therefore, in order to select at least \( Y \) vertices, \( \text{OPT} \) needs to select vertices that are not qualified for scale 0 within total budget \( \gamma^i \), which is a contradiction to the assumption that \( p^*_i, Y(\sigma_{i-1}) \geq 0.9 \).
Therefore we must have $T^*_{i,0} = 0.1$. Applying Markov’s inequality, the probability that OPT finds any vertex qualified for scale 0 in $V_i \setminus \Pi_{i,0}$ is upper bounded by $T^*_{i,0} \leq 0.1$. When this happens and when OPT selects $Y$ vertices within total budget $\gamma^i$, all vertices selected by OPT are from $\Pi_{i,0}$. Therefore, with probability at least $p^*_{Y}(\sigma_{i-1}) - 0.1 \geq 0.8$, we can select $Y$ vertices from $\Pi_{i,0}$ within cost budget $\gamma^i$ which implies that $Y_{i,0} \geq Y$.

Case (2): (All scales are rich) $T^*_{i,j} \geq Y$ for every scale $j = 0, \ldots, \ell_i$. In this case we show that $\ell_i$ is a “critical” scale with $Y_{i,\ell_i} \geq Y$. Notice that selecting any $Y$ vertices qualified for scale $\ell_i$ has cost at most $Y \cdot \gamma^i/2^{\ell_i} \leq 2 \leq 6\gamma^i$. Since $T^*_{i,\ell_i} \geq Y$, it follows from Theorem 3 that with probability no less than 0.5, at least $Y$ vertices in $\Pi_{i,\ell_i}$ are qualified for scale $\ell_i$ (notice we don’t even need the tour $\Pi_{i,\ell_i-1}$ in this case). This implies that $Y_{i,\ell_i} \geq Y$.

Case (3): (Transition from rich to poor scale at $j_{\text{crit}}$) $T^*_{i,j} \geq Y$ but $T^*_{i,j} < Y$ for some $j \in [\ell_i]$. In this case, let $j_{\text{crit}} = \arg \min_j \{ j \in [\ell_i] : T^*_{i,j} < Y \}$. We show in the following that $j_{\text{crit}}$ is a “critical” scale with $Y_{i,j_{\text{crit}}} \geq Y$. To prove this, we show that the following two events happen with constant probability:

1. $T^*_{i,j_{\text{crit}}} < Y$ implies that OPT doesn’t find enough vertices qualified for scale $j_{\text{crit}}$. This gives a lower bound on the cost of the set of vertices selected by OPT within total budget $\gamma^i$.
2. $T^*_{i,j_{\text{crit}}-1} \geq Y$ implies that $\text{ALG}_{\text{Stoch-Cost}}$ finds enough vertices qualified for scale $j_{\text{crit}} - 1$. This can be used to upper bound the cost of $\text{ALG}_{\text{Stoch-Cost}}$.

We first consider the sub-case where $T^*_{i,j_{\text{crit}}} \leq 0.1$. This is the case where not many vertices qualified for scale $j_{\text{crit}}$ can be found outside $\Pi_{i,j_{\text{crit}}} \cup \Pi_{i,j_{\text{crit}}-1}$. In this case, we have $\sum_{v \in \Pi_{i,j_{\text{crit}}}(\text{OPT})} \mathbb{P}[C_v \leq 2\gamma^i/2^{j_{\text{crit}}}] \leq T^*_{i,j_{\text{crit}}}$. It follows from Markov’s inequality that with probability at least 0.9, OPT finds no vertex in $V_i \setminus (\Pi_{i,j_{\text{crit}}} \cup \Pi_{i,j_{\text{crit}}-1})$ that is qualified for scale $j_{\text{crit}}$, in which case any vertex $v \in V_i \setminus (\Pi_{i,j_{\text{crit}}} \cup \Pi_{i,j_{\text{crit}}-1})$ selected by OPT has cost $C_v \geq \gamma^i/2^{j_{\text{crit}}}$. Since $T^*_{i,j_{\text{crit}}-1} \geq Y$, it follows from Theorem 3 that with probability at least 0.5, we have $\{ v \in \Pi_{i,j_{\text{crit}}} \cup \Pi_{i,j_{\text{crit}}-1} : C_v \leq \gamma^i/2^{j_{\text{crit}}-1} \} \geq Y$. Furthermore, $p^*_{Y} \geq 0.9$ implies that with probability at least 0.9, OPT selects $Y$ vertices within total budget $\gamma^i$. It follows from union bound that all three events above happen with probability at least 0.2, in which case we can select $Y$ vertices from $\Pi_{i,j_{\text{crit}}} \cup \Pi_{i,j_{\text{crit}}-1}$ within cost budget $2\gamma^i$. This implies that $Y_{i,j_{\text{crit}}} \geq Y$.

Now we deal with the other sub-case where $T^*_{i,j_{\text{crit}}} > 0.1$. This represents the situation where many vertices qualified for scale $j_{\text{crit}}$ can be found outside $\Pi_{i,j_{\text{crit}}} \cup \Pi_{i,j_{\text{crit}}-1}$. Roughly, Lemma 8 implies in this case that OPT finds at most $200T^*_{i,j_{\text{crit}}}$ low-cost vertices in $V_i \setminus (\Pi_{i,j_{\text{crit}}} \cup \Pi_{i,j_{\text{crit}}-1})$. In general, these vertices might have very tiny cost. However, we show in the following Claim 14 that increasing the cost of each one of these low-cost vertices to $\gamma^i/2^{j_{\text{crit}}}$ will increase their total cost by at most $O(\gamma^i)$. This allows us to lower bound the cost of the set of vertices selected by OPT within total budget $\gamma^i$.

\begin{itemize}
  \item[$\triangleright$ Claim 14. ] We have $200T^*_{i,j_{\text{crit}}} \cdot \gamma^i/2^{j_{\text{crit}}} \leq \gamma^i/2$.
\end{itemize}

Before proving Claim 14, we complete the proof of Lemma 13. Since $T^*_{i,j_{\text{crit}}} > 0.1$, from Lemma 8 we have

\begin{equation}
\mathbb{P}\left[ \left\{ v \in \Pi_{i,j_{\text{crit}}}(\text{OPT}) : C_v \leq \gamma^i/2^{j_{\text{crit}}} \right\} \leq 200T^*_{i,j_{\text{crit}}} \right] \geq 0.9. \tag{11}
\end{equation}
Since $T_{i,j_{on}} \geq Y$, it follows from Theorem 19 that
\[
P\left[ \left\{ v \in \Pi_{i,j_{on}} \cup \Pi_{i,j_{on}-1} : C_v \leq \gamma^i / 2^{j_{on} - 1} \right\} \right] \geq 0.5. \tag{12}
\]
Together with the assumption that $p^*_{i,Y} \geq 0.9$, we have from union bound that with probability at least 0.2, both events in (11) and (12) hold and that OPT selects at least $Y$ vertices within total budget $\gamma^i$. When all three events happen, we can replace $Y - |\Pi_{i,j_{on}}(OPT)|$ vertices in $\Pi_{i,j_{on}}(OPT)$ by $Y - |\Pi_{i,j_{on}}(OPT)|$ vertices in $(\Pi_{i,j_{on}} \cup \Pi_{i,j_{on}-1}) - \Pi_{i,j_{on}}(OPT)$ that are qualified for scale $j_{on} - 1$. Claim 14 together with (11) imply that after such replacements, we reach a subset of $Y$ vertices in $\Pi_{i,j_{on}} \cup \Pi_{i,j_{on}-1}$ with total cost at most $2(\gamma^i + \gamma^i / 2) = 3\gamma^i$. So we conclude that with probability at least 0.2, we can select at least $Y$ vertices from $\Pi_{i,j_{on}} \cup \Pi_{i,j_{on}-1}$ within cost budget $3\gamma^i$. This implies that $Y_{i,j_{on}} \geq Y$ and finishes the proof of Lemma 13. 

Now we are left to prove Claim 14.

Proof of Claim 14. We consider the tour $\Pi_{i,j_{on}}$. Denote respectively $\Pi'_{i,j_{on}}(OPT) \subseteq \Pi_{i,j_{on}}$ and $\Pi''_{i,j_{on}}(OPT) \subseteq V_i \setminus \Pi_{i,j_{on}}$ the (random) set of vertices visited by OPT inside and outside $\Pi_{i,j_{on}}$ within total budget $\gamma^i$. Since $T_{i,j_{on}} < Y$, it follows from Theorem 3 that
\[
P\left[ \left\{ v \in \Pi_{i,j_{on}} : C_v \leq \gamma^i / 2^{j_{on}} \right\} \right] \geq 0.5. \tag{13}
\]
Since $T_{i,j_{on}} > 0.1$, Lemma 8 gives
\[
P\left[ \left\{ v \in \Pi''_{i,j_{on}}(OPT) : C_v \leq \gamma^i / 2^{j_{on}} \right\} \right] \leq 200T_{i,j_{on}}^* \geq 0.9. \tag{14}
\]
Lemma 9 followed by Chernoff bound gives
\[
P\left[ \left\{ v \in \Pi_{i,j_{on}} - \Pi'_{i,j_{on}}(OPT) : C_v \leq \gamma^i / 2^{j_{on}} \right\} \right] \geq 600T_{i,j_{on}}^* \geq 0.9. \tag{15}
\]
From the assumption that $p^*_{i,Y} \geq 0.9$, we have
\[
P\left[ \left\{ \text{OPT selects at least } Y \text{ vertices within total budget } \gamma^i \right\} \right] \geq 0.9. \tag{16}
\]
By union bound, all four events in (13)-(16) happen with positive probability, in which case OPT selects at least $400T_{i,j_{on}}^* \gamma^i / 2^{j_{on}}$ vertices that are not qualified for scale $j_{on}$ within total budget $\gamma^i$. This implies that $400T_{i,j_{on}}^* \gamma^i / 2^{j_{on}} \leq \gamma^i$ from which Claim 14 immediately follows.

### 5.3 The Dynamic Programming Sub-procedure ALGDP

In this section, we give our dynamic program ALGDP and prove Lemma 11 restated below for convenience.

**Lemma 11.** For any phase $i \geq 0$ and any scale $j \in \{0, \cdots, \ell_i\}$, the approximate value $\tilde{Y}_{i,j}$ computed in Step 15 of ALGStoch-Cost satisfies that (1) $\tilde{Y}_{i,j} \geq Y_{i,j}$, and (2) $\tilde{Y}_{i,j}$ vertices can be selected from $\Pi_{i,j} \cup \Pi_{i,j-1}$ within cost budget $6\gamma^i$ with probability at least 0.2.

Recall, our dynamic program ALGDP is used to approximately compute the maximum number of vertices that can be selected from a certain tour with probability at least 0.2 within cost budget $3\gamma^i$. Essentially, ALGDP solves the following sub-problem: We are given a target $T \in \mathbb{Z}_{\geq 0}$, a budget $B \geq 0$ and $n$ independent non-negative stochastic costs. The goal is to find the probability $P_{T,B}$ that there exists a subset $S$ of size $T$ with sum of its costs at most $B$. Since this general problem is NP-hard, we give a dynamic program that finds something between $P_{T,B}$ and $P_{T,2B}$. Lemma 11 follows immediately from the following Lemma 15.
Lemma 15. Given n independent non-negative random variables \( V = \{C_1, C_2, ..., C_n\} \), a target \( T \in \mathbb{Z}_{\geq 0} \) and a budget \( B \geq 0 \). Let \( P_{T,B} \) denote the probability that there exists a subset \( S \subseteq V \) of size at least \( T \) and \( \sum_{i \in S} C_i \leq B \). Then there’s an efficient dynamic programming \( \text{ALG}_{DP}(T, B, V) \) that outputs a value \( \tilde{P}_{T,B} \) s.t. \( P_{T,B} \leq \tilde{P}_{T,B} \leq P_{T,2B} \).

Proof of Lemma 11. We first prove property (1). Recall that \( Y_{i,j} \) is the maximum number of vertices that can be selected from \( \Pi_{i,j} \cup \Pi_{i,j-1} \) with probability at least 0.2 within cost budget \( 3\gamma^i \), and \( \tilde{Y}_{i,j} \) is the largest integer such that \( \text{ALG}_{DP}(\tilde{Y}_{i,j}, 3\gamma^i, \Pi_{i,j} \cup \Pi_{i,j-1}) \geq 0.2 \). Consider the set of stochastic costs in \( \Pi_{i,j} \cup \Pi_{i,j-1} \). By definition, we have \( P_{Y_{i,j}, 3\gamma^i} \geq 0.2 \). It follows from Lemma 15 that \( \text{ALG}_{DP}(Y_{i,j}, 3\gamma^i, \Pi_{i,j} \cup \Pi_{i,j-1}) \geq 0.2 \). This implies that \( \tilde{Y}_{i,j} \geq Y_{i,j} \) and proves property (1).

Now we prove property (2). Applying Lemma 15 we have \( P_{Y_{i,j}, 6\gamma^i} \geq \text{ALG}_{DP}(\tilde{Y}_{i,j}, 3\gamma^i, \Pi_{i,j} \cup \Pi_{i,j-1}) \geq 0.2 \). It follows that \( \tilde{Y}_{i,j} \) vertices can be selected from \( \Pi_{i,j} \cup \Pi_{i,j-1} \) within cost budget \( 6\gamma^i \) with probability at least 0.2. This establishes property (2) and finishes the proof of Lemma 11.

Proof of Lemma 15. We begin by discretizing each \( C_i \) to be \( C_i := \lfloor C_i \cdot n/B \rfloor \in \mathbb{N} \) and define \( \tilde{P}_{T,n} \) the probability that there exists a subset \( S \subseteq V \) s.t. \( |S| \geq T \) and \( \sum_{i \in S} C_i \leq n \). Notice that \( \sum_{i \in S} \tilde{C}_i \leq n \) implies that \( \sum_{i \in S} C_i \leq 2B \). Therefore we have \( P_{T,B} \leq \tilde{P}_{T,n} \leq P_{T,2B} \). In the following, we give a dynamic programming \( \text{ALG}_{DP} \) that computes the value \( \tilde{P}_{T,n} \) and we will set \( \tilde{P}_{T,B} \) in the statement of the lemma to be \( \tilde{P}_{T,n} \). Assume without loss of generality that \( \tilde{C}_i \leq n + 1 \) as one can truncate the distribution of \( \tilde{C}_i \) at \( (n+1) \) without changing \( \tilde{P}_{T,n} \).

Denote \( A(i,j) \) the jth smallest value among the first \( i \) random variables. We build a DP table where each entry \( P[i,j,\ell,m] \) (for \( i \in \{1, \ldots, n\} \), \( j \in \{1, \ldots, T\} \), \( \ell \in \{0, \ldots, n\} \) and \( m \in \{0, \ldots, n\} \)) denotes the probability that the smallest \( j \) values among the first \( i \) random variables sum up to \( \ell \) and the jth smallest value among the first \( i \) random variables is equal to \( m \), i.e. \( \sum_{s=1}^j A[i,s] = \ell \) and \( A[i,j] = m \).

Initial values: \( \text{ALG}_{DP} \) initializes certain entries of the DP table as follows.

- Case 1 (impossible events): set \( P[i,j,\ell,m] \) to be 0 if \( j > i \), \( m > \ell \) or \( m \cdot j < \ell \).

- Case 2 (\( j = 1 \)): set \( P[i,1,\ell,m] = \prod_{s \in [i]} P[\tilde{C}_s \geq \ell] - \prod_{s \in [i]} P[\tilde{C}_s > \ell] \) if \( \ell = m \), and 0 otherwise.

Note that all the entries corresponding to \( i = 1 \) are already included in the two cases above.

Recursion: \( \text{ALG}_{DP} \) uses the following recursion.

\[
P[i,j,\ell,m] = P[\tilde{C}_j > m] \cdot P[i-1,j,\ell,m] + \sum_{u=0}^{m-1} P[\tilde{C}_j = u] \cdot P[i-1,j-1,\ell-u,m] + P[\tilde{C}_j = m] \cdot \left( \sum_{u=0}^{m} P[i-1,j-1,\ell-m,m-u] - \sum_{u=1}^{m} P[i-1,j,\ell-u,m-u] \right). 
\]

(17)

Output: after computing all the entries of the DP table, \( \text{ALG}_{DP} \) outputs \( \tilde{P}_{T,n} \) that equals \( \sum_{\ell=0}^{T} \sum_{m=0}^{\ell} P[n,T,\ell,m] \).

Now we prove the correctness of \( \text{ALG}_{DP} \). Given the definition of \( P[i,j,\ell,m] \), we can immediately verify that the assignment of initial values and the final output are correct if all the entries of the DP table computed from (17) are also correct. To see the correctness of the recursion, we consider the outcome of \( \tilde{C}_i \). When \( \tilde{C}_i > m \), in order to satisfy \( \sum_{s=1}^{j} A[i,s] = \ell \)
and $A[i,j] = m$, one must have that $\overline{C}_i$ is not in the $j$ smallest values among the first $i$ random variables. This verifies the first term in (17). When $\overline{C}_i = u < m$, in order to satisfy $\sum_{s=1}^{j-1} A[i,s] = \ell$ and $A[i,j] = m$, one must have that $\overline{C}_i$ is one of the $j$th smallest values among the first $i$ random variables. Also notice that in this case, the $(j-1)$th smallest value among the first $(i-1)$ random variables is still $m$ and that $\sum_{s=1}^{j-1} A[i-1,s] = \ell - \overline{C}_i$. This gives the second term in (17).

Now we verify the last term in (17, which corresponds to the case where $\overline{C}_i = m$. In this case, we might as well select $\overline{C}_i$ as one of the $j$ smallest values among the first $i$ random variables. In order to satisfy $\sum_{s=1}^{j-1} A[i,s] = \ell$ and $A[i,j] = m$, we need the smallest $(j-1)$ values among the first $(i-1)$ random variables to sum up to $\ell - m$ and the $(j-1)$th smallest value to be at most $m$, i.e. $\sum_{s=1}^{j-1} A[i,s] = \ell - m$ and $A[i,j-1] \leq m$. The probability of this event is exactly $\sum_{u=0}^{m} P[i-1,j-1,\ell-m,u]$. However, in order to ensure that $A[i,j] = m$, we also need the $j$th smallest value among the first $(i-1)$ random variables to be at least $m$ (i.e. $A[i-1,j] \geq m$) and the outcomes that don’t satisfy this condition needs to be excluded from the previous event. Putting everything together, we have the following:

$$\mathbb{P}\left\{ \sum_{s=1}^{j-1} A[i-1,s] = \ell - m, A[i-1,j-1] \leq m, A[i-1,j] \geq m \right\}$$

$$= \mathbb{P}\left\{ \sum_{s=1}^{j-1} A[i-1,s] = \ell - m, A[i-1,j-1] \leq m \right\}$$

$$- \mathbb{P}\left\{ \sum_{s=1}^{j-1} A[i-1,s] = \ell - m, A[i-1,j-1] \leq m, A[i-1,j] < m \right\}$$

$$= \sum_{u=0}^{m} P[i-1,j-1,\ell-m,u] - \sum_{u=1}^{m} P[i-1,j,\ell-u,m-u].$$

This immediately gives the last term in (17) and finishes the proof of Lemma 15.

45:24 Stochastic $k$-TSP

A Missing Proofs in Section 2

Lemma 6 (Bi-criteria Orienteering). There is an efficient algorithm $\text{ALG}_{\text{Bicrit-Orient}}$ that finds a tour of length $O(1) \cdot B$ while collecting at least $(\text{OPT}_{\text{Orient}} - \epsilon)$ profit, where $\epsilon = 1/\text{poly}(n)$ can be made arbitrarily small.

Proof of Lemma 6. Assume without loss of generality that $\text{OPT}_{\text{Orient}} > 0$. Denote $\rho = 3$ the approximation factor of $k$-TSP algorithm $\text{ALG}_k$ from [8]. Denote $R_{\max} := \max_{v \in V} R_v$ and $R_{\min} := \min_{v \in V} R_v$ the maximum and minimum profit in the Orienteering instance.

Notice, $\text{OPT}_{\text{Orient}} \in [R_{\min}, n \cdot R_{\max}]$. $\text{ALG}_{\text{Bicrit-Orient}}$ applies binary search in $[R_{\min}, n \cdot R_{\max}]$, starting with profit target $(R_{\min} + n \cdot R_{\max})/2$. For each profit target $\lambda$, $\text{ALG}_{\text{Bicrit-Orient}}$ runs $\text{ALG}_k$-TSP with target reward $\lambda$ to obtain a tour $\Pi_{\lambda}$ whose length is denoted as $\ell(\Pi_{\lambda})$. $\text{ALG}_{\text{Bicrit-Orient}}$ performs binary search over $\lambda \in [R_{\min}, n \cdot R_{\max}]$ until finding two values $\lambda_l < \lambda_h \leq \lambda_l + \epsilon$ such that $\ell(\Pi_{\lambda_l}) \leq \rho B$ and $\ell(\Pi_{\lambda_h}) > \rho B$, in which case $\text{ALG}_{\text{Bicrit-Orient}}$ returns the tour $\Pi_{\lambda_h}$. Here we assumed without loss of generality that $\ell(\Pi_{R_{\max}}) > \rho B$ as otherwise $\text{ALG}_{\text{Bicrit-Orient}}$ can simply return the tour $\Pi_{R_{\max}}$. Notice that $\ell(\Pi_{\lambda_h}) > \rho B$ implies that $\text{OPT}_{\text{Orient}} < \lambda_h$ and therefore $\text{ALG}_{\text{Bicrit-Orient}}$ finds reward at least $\lambda_l \geq \lambda_h - \epsilon > \text{OPT}_{\text{Orient}} - \epsilon$. The length of the tour found by $\text{ALG}_{\text{Bicrit-Orient}}$ is $\ell(\Pi_{\lambda_h}) \leq \rho B = O(1) \cdot B$. This finishes the proof of Lemma 6. 

B Missing Proofs in Section 3

Lemma 7 (Key Lemma). If for some universal constants $C > 0$, $\gamma > 1$, any phase $i \geq 1$, and any possible $\sigma_{i-1}$, the algorithm $\text{ALG}_{\text{Meta}}$ satisfies

$$u_i(\sigma_{i-1}) \leq C \cdot u_i^*(\sigma_{i-1}) + \frac{u_{i-1}(\sigma_{i-1})}{\gamma^2},$$

then $\text{ALG}_{\text{Meta}}$ is a non-adaptive $O(1)$-approximation algorithm.

Proof of Lemma 7. For any phase $i \geq 0$, denote $u_i$ the probability that $\text{ALG}_{\text{Meta}}$ enters phase $i + 1$ in the probing stage and $u_i^*$ the probability that $\text{OPT}$ has cost more than $\gamma^i$. Taking expectation over $\sigma_{i-1}$ for the pre-condition of Lemma 7, we have $u_i \leq C \cdot u_i^* + u_{i-1}/\gamma^2$. It follows that

$$\sum_{i \geq 1} u_i \cdot \gamma^i \leq C \cdot \sum_{i \geq 1} u_i^* \cdot \gamma^i + \frac{1}{\gamma} \sum_{i \geq 1} u_i \cdot \gamma^i,$$
which gives
\[(1 - 1/\gamma) \cdot \sum_{i \geq 1} u_i \cdot \gamma^i \leq O(1) \cdot \sum_{i \geq 1} u^*_i \cdot \gamma^i + 1/\gamma.\] \hspace{1cm} (18)

We also notice that
\[\text{OPT} \geq \sum_{i \geq 0} (u^*_i - u^*_{i+1}) \cdot \gamma^i = (1 - 1/\gamma) \cdot \sum_{i \geq 1} u^*_i \cdot \gamma^i + 1,\]

and that
\[\text{ALG}_{\text{Meta}} \leq O(1) \cdot \sum_{i \geq 0} (u_i - u_{i+1}) \cdot \gamma^{i+1} = O(1) \cdot \sum_{i \geq 0} u_i \cdot \gamma^i.\]

It follows from (18) that \(\text{ALG}_{\text{Meta}} \leq O(1) \cdot \text{OPT}.\) This finishes the proof of Lemma 7. ▶

C Missing Proofs in Section 5

Lemma 12. For \(\gamma = 1.1,\) any phase \(i > 0\) in the probing stage of Stoch-Cost k-TSP satisfies
\[u_i(\sigma_{i-1}) \leq 100u^*_i(\sigma_{i-1}) + \frac{u_{i-1}(\sigma_{i-1})}{\gamma^2}.\] \hspace{1cm} (7)

Proof of Lemma 12. We fix any outcome \(\sigma_{i-1}\) of vertices visited by \(\text{ALG}_{\text{Stoch-Cost}}\) in the first \(i - 1\) phases of its probing stage. The lemma trivially holds in the case where \(u^*_i(\sigma_{i-1}) \geq 0.01\) as we have 100u^*_i(\sigma_{i-1}) \geq 1. If \(u_{i-1}(\sigma_{i-1}) = 0\) which means that \(\text{ALG}_{\text{Stoch-Cost}}\) already selects \(k\) vertices before entering phase \(i\) in the probing stage, then \(u_i(\sigma_{i-1}) = 0\) and again the lemma trivially holds. We therefore assume that \(u^*_i(\sigma_{i-1}) < 0.01\) and that \(u_{i-1}(\sigma_{i-1}) = 1.\)

Now proving Lemma 12 is equivalent to proving
\[u_i(\sigma_{i-1}) \leq 100u^*_i(\sigma_{i-1}) + 1/\gamma^2.\] \hspace{1cm} (19)

Denote \(k(\sigma_{i-1})\) the remaining target at the beginning of phase \(i\) in the probing stage of \(\text{ALG}_{\text{Stoch-Cost}}.\) We first consider Selection-Process 1 and denote \(N_{\text{old}}(\sigma_{i-1})\) the number of vertices selected from \(\sigma_{i-1}\) in this process. We assume without loss of generality that \(N_{\text{old}}(\sigma_{i-1}) < k(\sigma_{i-1}),\) as otherwise our algorithm has already selected \(k\) vertices after Selection-Process 1 and (19) immediately follows. Since Selection-Process 1 uses cost budget \(\gamma^i\) to select as many unselected vertices from \(\sigma_{i-1}\) as possible, \text{OPT} can select at most \(N_{\text{old}}(\sigma_{i-1}) + k - k(\sigma_{i-1})\) vertices from \(\sigma_{i-1}\) within total budget \(\gamma^i\). Denote \(N_{\text{new}}(\sigma_{i-1}) := k(\sigma_{i-1}) - N_{\text{old}}(\sigma_{i-1})\) the remaining target for \(\text{ALG}_{\text{Stoch-Cost}}\) after Selection-Process 1. It follows that in order to select \(k\) vertices within total budget \(\gamma^i,\) \text{OPT} needs to select at least \(N_{\text{new}}(\sigma_{i-1})\) vertices from \(V_i\) within total budget \(\gamma^i\) with probability at least 0.99. Applying Lemma 13 with \(Y = N_{\text{new}}(\sigma_{i-1}),\) it follows that our algorithm finds at least \(N_{\text{new}}(\sigma_{i-1})\) vertices from \(V_i\) which can be selected within cost budget \(6\gamma^i\) with probability at least 0.2. This implies that \(u_i(\sigma_{i-1}) \leq 0.8 \leq 1/\gamma^2\) and (19) is established. ▶
Strategic Payments in Financial Networks

Abstract
In their seminal work on systemic risk in financial markets, Eisenberg and Noe [13] proposed and studied a model with $n$ firms embedded into a network of debt relations. We analyze this model from a game-theoretic point of view. Every firm is a rational agent in a directed graph that has an incentive to allocate payments in order to clear as much of its debt as possible. Each edge is weighted and describes a liability between the firms. We consider several variants of the game that differ in the permissible payment strategies. We study the existence and computational complexity of pure Nash and strong equilibria, and we provide bounds on the (strong) prices of anarchy and stability for a natural notion of social welfare. Our results highlight the power of financial regulation – if payments of insolvent firms can be centrally assigned, a socially optimal strong equilibrium can be found in polynomial time. In contrast, worst-case strong equilibria can be a factor of $\Omega(n)$ away from optimal, and, in general, computing a best response is an $\text{NP}$-hard problem. For less permissible sets of strategies, we show that pure equilibria might not exist, and deciding their existence as well as computing them if they exist constitute $\text{NP}$-hard problems.

1 Introduction
The last major financial crisis and its aftermath have highlighted the systemic risks and resulting hazards for society that arise in financial markets, which are characterized by different, highly interconnected financial institutions. Over the last decade an increased research effort has been underway to analyze, understand, and manage the systemic risks in financial markets. Main aspects of interest are contagion effects and cascading defaults, as well as recommendations for suitable regulation on a national and international level.

A prominent approach in the area of systemic risk stems from the seminal work by Eisenberg and Noe [13]. Here the set $V$ of financial institutions (or firms) is the node set of a directed graph $G = (V, E)$. The directed and weighted edges $e \in E$ express the debt
relations among firms. In addition, each firm has non-negative external assets, which capture the value of property rights (such as real-estate, gold, business and mortgage loans, etc.) that the firm has acquired from non-financial institutions. Eisenberg and Noe discuss a clearing mechanism for such a market, in which every firm uses its available assets to pay its debt. The clearing follows basic balance sheet identities and evolves rather mechanically. It is commonly assumed that payments are distributed among all creditors in a pro-rata fashion, i.e., for each interbank debt (i.e., each outgoing edge) firm \( v \) allocates a proportional share of its available assets. Similarly, a firm receives the payments for its incoming edges (so-called internal assets), which in turn are also paid proportionally to outgoing edges (until all debt is paid or all assets are distributed). In this way, clearing payments constitute a fixed point of the system. Eisenberg and Noe discuss existence and uniqueness issues of such fixed point payments.

While the model has been studied intensively over the last two decades, there are a plethora of open questions, especially towards understanding strategic and game-theoretic issues. In this paper, our focus are the strategic incentives and their consequences for clearing mechanisms in financial markets. For example, rather than using pro-rata payments, financial institutions often put priority on clearing certain debts first. In this way, a firm \( v \) could profit substantially when using a suitable priority-based payment scheme – by clearing certain debt first, the money propagates through the network and returns to \( v \) in the form of additional internal assets. In the Eisenberg-Noe model, it is easy to see that the intuitive pro-rata clearing mechanism is not always incentive compatible, and strategic incentives of this kind can arise frequently.

In this paper, we study the properties of priority-based clearing mechanisms for financial markets. We focus on payment schemes that constitute a pure Nash or even a strong equilibrium in the underlying strategic payment game for the firms. In this way, firms have no unilateral or coalitional incentives to deviate from the payment schemes proposed by the clearing mechanism. Depending on the granularity of priorities, the resulting games have different properties. In particular, if priorities are implemented over debt contracts, existence of a pure Nash or a strong equilibrium becomes strongly \( \text{NP} \)-hard to decide. Instead, if firms can assign each unit of money arbitrarily to any open debt, a strong equilibrium always exists and can be computed in strongly polynomial time. Moreover, in this case, there is even a strong equilibrium that maximizes the sum of all assets of all firms.

Our results imply interesting insights for bankruptcy settlement of insolvent firms. It turns out that only insolvent firms face a potential strategic decision about where to allocate money in order to maximize the internal assets through network effects (or, equivalently, minimize the remaining debt after clearing the network). In case there is a benevolent and centralized bankruptcy settlement, we show that it can implement a clearing mechanism with monotone payment strategies that leads to a socially optimal clearing state. It comes with the additional guarantee of giving no coalition of firms an incentive to pay their debts differently.

Instead, if clearing payments are determined by suitable negotiation in a decentralized fashion resulting in some arbitrary Nash or strong equilibrium, the total amount of internal assets available to the firms in the system can deteriorate drastically. Similar problems arise if a centralized clearing mechanism is restricted to payment schemes based on priorities over single loans (rather than units of money). This can lead to non-existence of pure equilibria in the resulting games. Even if equilibria exist, they can be undesirable since the total amount of internal assets of all firms can be drastically smaller than in an optimal solution. This shows a marked contrast between centralized and decentralized bankruptcy settlement and highlights how the structure of permissible payment strategies impacts the performance and the structural properties of the clearing mechanism.
1.1 Contribution

In this paper, we study the properties of priority-based clearing mechanisms for financial markets. We assume the network of liabilities is given, but insolvency resolution is driven by strategic considerations. In particular, we analyze payment schemes that constitute a pure Nash or even a strong equilibrium in the underlying strategic payment game for the firms.

Below, we introduce basic preliminaries of the Eisenberg-Noe model. In addition, we introduce two classes of priority-based payment strategies for the firms and analyze the resulting clearing mechanisms. For an edge-ranking strategy, a firm ranks its debt contracts and assigns its assets in order of the ranking. As a superset of strategies, we consider coin-ranking strategies, where money is considered in units (“coins”). Instead of contracts, each firm ranks single coin payments to the contracts. By letting the value of a coin approach zero, coin-ranking strategies become equivalent to monotone strategies, where the payments of a firm are simply a monotone function of its total available assets.

In Section 2 we present structural insights on the clearing states for a strategy profile in an edge- or coin-ranking game. In such a profile, each firm is choosing an edge- or coin-ranking strategy to pay its debt. For each such profile, we prove that the possible clearing states form a lattice with respect to the vector of assets of each firm (Theorem 3). In particular, there is a unique clearing state that pointwise maximizes the assets available to each firm (given this strategy profile). In the full version [6] we show that it can be computed in strongly polynomial time. We assume that this state defines the assets and, thus, the utility of each firm in the strategy profile. Similar properties were shown in [13] for profiles composed of pro-rata payment strategies.

In Section 3 we study coin-ranking games and strategic choice of payments. Our interest lies in the existence, computational complexity, and social quality of equilibria. We show that there always is a strategy profile that represents a strong equilibrium, in which no coalition of firms has an incentive to deviate. Furthermore, it maximizes social welfare, i.e., the sum of all assets or total revenue available to all firms. Such a strong equilibrium can be computed in strongly polynomial time (Theorem 6). It can be represented compactly, even though the strategy shall rank all (possibly pseudo-polynomially many) coins that a firm might have available. In contrast, it is strongly NP-hard to find a best-response strategy for a single firm in a given arbitrary strategy profile of a coin-ranking game (Theorem 9).

For worst-case equilibria and the strong price of anarchy, we show that the deterioration of social welfare in a strong equilibrium compared to a social optimum is tightly characterized by the min-max length of cycles in any social optimum (Theorem 11). This implies that networks with optimal money circulation composed of small cycles yield a small inefficiency in strong equilibria. In contrast, a worst-case Nash equilibrium, which is stable only against unilateral deviations, can be arbitrarily worse than a social optimum, even in simple games with a constant number of firms (Proposition 10).

In Section 4 we study equilibria in edge-ranking games, where all firms are restricted to play edge-ranking strategies. Restricting the strategy space to rankings over contracts can have devastating consequences for the existence and social quality of equilibria. In edge-ranking games, pure Nash and strong equilibria can be absent, and deciding their existence is strongly NP-hard (Theorem 14). The same hardness applies for computing a social optimum, and for computing a pure Nash or strong equilibrium when it is guaranteed to exist. Even the best strong equilibrium can be a factor of $\Omega(n)$ worse than the social optimum in terms of social welfare (Proposition 16). For pure Nash equilibria, even the best one can be arbitrarily worse than a social optimum (Proposition 17).
1.2 Related Work

Financial Networks. On a conceptual level, we study issues of strategic choice and computational complexity in financial networks. There have been works addressing computational complexity of diverse issues, such as pricing options with [3] and without information asymmetry [7], finding clearing payments with credit default swaps [27], or estimating the number of defaults when providing a shock in the financial system [20]. In addition, many extensions to the model by Eisenberg and Noe have been proposed in the literature on financial markets. However, even models including cross-holdings of equity [28], default costs [26], or debt contracts of different maturities [15] follow the idea of the basic approach that all contracts have to be cleared consistently, i.e., clearing payments locally adhere to the rather mechanical clearing rule and constitute a fixed point solution globally. Indeed, Barucca et al. [5] have recently shown that many of the above models can be unified in terms of self-consistent network valuations. A well-known result of such models is the “robust-yet-fragile” property exhibited by financial networks, i.e., contagion arises in an all-or-nothing fashion akin to the formation of a giant connected component in random graph models [17]. This provides important insights into systemic risk and advises the need for macro-prudential regulation.

Accordingly, the rather mechanical pro-rata payments are also usually presumed in models studying contagion effects arising from overlapping portfolios [8, 9]. In this case, distressed firms are selling assets which in turn decreases the value of these assets by market impact. Here, it is commonly assumed that firms mechanically sell all their assets in a pro-rata fashion. In turn, the resulting market impact is modeled as a known function parametrized by the market depth or liquidity of each asset. In contrast, especially decisions regarding the portfolio composition of financial firms yield substantial potential for strategic consideration in reality.

To our knowledge, strategic aspects are currently reflected mostly in models of network formation [14, 1]. A three period economy is assumed where firms can invest into risky assets. To do so, they strategically decide to borrow funds from outside investors as well as other firms. Thereby a network of financial cross-holdings is endogenously formed as each firm maximizes their expected profit. The results show that risk-seeking firms tend to over-connect leading to stronger contagion and systemic risk as compared to the socially optimal risk-sharing allocation. Note that in this case, strategic aspects only play a role in the formation of inter-bank relations whereas the clearing mechanism is assumed to follow the same process as in [13]. Another strategic variant of the model by Eisenberg and Noe has been considered in [2] in the form of a two-period model. Firms strategically store some amount from their first period endowment with an interest rate in order to increase the available assets in the second period. The clearing in both rounds is based on pro-rata payments. Each firm optimizes a function of the remaining debts in both periods.

Flow Games. On a more technical level, our game-theoretic approach is related to a number of existing game-theoretic models based on flows in networks. In cooperative game theory, there are several notions of flow games based on a directed flow network. Existing variants include games, where edges are players [12, 21, 22, 18, 11, 4], or each player owns a source-sink pair [25, 24]. The total value of a coalition $C$ is the profit from a maximum (multi-commodity) flow that can be routed through the network if only the players in $C$ are present. There is a rich set of results on structural characterizations and computability of solutions in the core, as well as other solution concepts for cooperative games. In contrast to our work, these games are non-strategic. Instead, here we consider each player as a single node with a strategic decision about flow allocation.
More recently, a class of strategic flow games has been proposed in [23, 19]. There is a capacitated flow network with a set of sources nodes. At each source node, a given amount of flow enters the network. Each node of the network is owned by a single player. Each player always owns a designated sink node, as well as one or more additional nodes from the network. A player can choose a flow strategy for each of her nodes. The flow strategy specifies, for every node $v$ and every $x \geq 0$, how an incoming flow of $x$ at $v$ is distributed onto the outgoing edges (if any). Each flow strategy needs to fulfill flow conservation constraints at every node, subject to capacity on the outgoing edges. Each player aims to maximize the incoming flow at its sink node.

For these games there exist a number of $\Sigma_2^p$-completeness results for, e.g., determining the value of a game in a two-player Stackelberg variant, or determining the existence of a pure Nash equilibrium in a multi-player variant. In the latter game, computing a best response can also be $\text{NP}$-hard. Our approach is related to these games. However, motivated by financial networks we assume each firm is a single (source) node. The firm optimizes the incoming flow at its node (without it being a sink node). We study the computational complexity and social quality of equilibria. Moreover, strategic incentives arise mainly from cycles in the network – a condition absent in the existing work on max-flow games [23, 19] where the network is assumed to be acyclic.

The problem of calculating a clearing state for a given strategy profile in our games is closely related to the notion of a stable flows. In the stable flow problem, each node is equipped with an externally given preference order over both incoming and outgoing arcs. There always exists a stable flow, and the set of stable flows forms a lattice [16]. In fact, there is an augmenting path algorithm for computing a stable flow with polynomial running time [10].

1.3 Financial Networks with Payment Strategies

Network Model. We consider a financial network model due to Eisenberg and Noe [13]. There is a network $G = (V, E)$ with node set $V$ of institutions or firms. Each firm $v \in V$ has external assets of value $a^x_v \geq 0$. Moreover, the firms are related via a set $E$ of liabilities. Each liability $(u, v) \in E$ is a directed edge from firm $u \in V$ to firm $v \in V$. The weight $c(e) \geq 0$ of some edge $e = (u, v)$ is the amount of money that $u$ owes to $v$. We follow standard notation in graph theory and denote by $E^+(v) = \{(v, u) \in E\}$ and by $E^-(v) = \{(u, v) \in E\}$ the set of outgoing and incoming edges of $v \in V$, respectively. The total liabilities $\ell(v)$ of firm $v$ is the total amount of money firm $v$ owes to other firms, i.e.,

$$
\ell(v) = \sum_{e \in E^+(v)} c(e).
$$

We strive to understand issues of computational complexity. As such, we will assume that all numbers in the input, i.e., all $a^x_v$ and $c(e)$, are integer numbers.

We consider clearing mechanisms based on strategic payments decisions. A money flow $g_e$ on edge $e$ satisfies $0 \leq g_e \leq c(e)$. Given a money flow on each edge, the internal assets of firm $v$ are the total incoming money from other firms, i.e.,

$$
a^i_v = \sum_{e \in E^-(v)} g_e.
$$

The total assets of $v$ are the sum of external and internal assets $a_v = a^x_v + a^i_v$. A firm is insolvent if its total assets are strictly smaller than its total liabilities, i.e., $a_v < \ell(v)$. 
Eisenberg and Noe define a clearing mechanism with money flows given by pro-rata payments. In their clearing mechanism, each firm \( v \) distributes its total assets \( a_v \) proportionally on its outgoing edges until all debt is paid. More formally, every edge \( e \in E^+(v) \) is assigned a money flow of \( g_e(a_v) = \min \left\{ \frac{c(e) \cdot a_v}{\ell(e)} \right\} \). Firm \( v \) keeps the surplus \( a_v - \ell(v) \geq 0 \) for itself, if any.

**Payment Strategies.** In this paper, we analyze incentives when firms strategically manipulate their payments. As such, we study money flow games defined as follows. Each firm \( v \in V \) chooses as a strategy a parametrized flow function \( f_e(y) \) for every outgoing edge \( e \in E^+(v) \) and every \( y \geq 0 \). The strategy \( f^v = (f_e(y))_{e \in E^+(v)} \) must satisfy for every \( y \geq 0 \)

\[
0 \leq f_e(y) \leq c(e) \quad \text{(capacity constraint)}
\]
\[
\sum_{e \in E^+(v)} f_e(y) = \min\{y, \ell(v)\} \quad \text{(no-fraud constraint)}
\]

Intuitively, the strategy specifies, for every possible value \( y \geq 0 \) of total assets available to firm \( v \), how \( v \) will allocate these assets to pay its debts. The capacity constraint ensures that no debt is overpaid, the no-fraud constraint requires that \( v \) does not embezzle assets as long as there is unpaid debt. This definition includes pro-rata payments as one possible strategy profile. Given a strategy profile \( f = (f^v)_{v \in V} \), a clearing state \( a = (a_v)_{v \in V} \) is a vector of assets such that

\[
a_v = a_v^0 + \sum_{e = (u,v) \in E^-(v)} f_e(a_u) \quad \text{(fixed point constraint)}
\]

holds for all nodes \( v \in V \). Equivalently, this ensures that for a given strategy profile \( f \), there is a clearing state \( a \) such that the flow \( g \) defined by \( g_e = f_e(a_u) \) is in fact a money flow. The utility of firm \( v \) is \( a_v \), i.e., \( v \)'s goal is to choose a strategy to maximize its total assets in the clearing state.

**Proposition 1.** If all \( f_e(y) \) are continuous, there exists at least one clearing state.

The proof is a straightforward application of Brouwer’s fixed point theorem and thus omitted. If strategies are not continuous, it is easy to construct examples where no clearing state exists. Still, even for a continuous strategy profile \( f \), there could be multiple clearing states \( a \) (even for pro-rata profiles). Given sufficiently complex strategy profiles with compact representation, computation of a clearing state might even become computationally difficult.

In the rest of the paper, we focus on a set of rich and meaningful strategy spaces, for which we can single out a unique clearing state with a simple algorithm. An intuitive and well-motivated class of strategies can be derived via rankings or seniorities.

**Edge-Ranking Games.** In an edge-ranking game, each player \( v \in V \) spends its assets to pay its debts according to a strict and total order over \( E^+(v) \), which we represent by a permutation \( \pi_v = (e_1, e_2, \ldots) \). \( v \) first pays all debt of edge \( e_1 = \pi_v(1) \), then \( e_2 = \pi_v(2) \), etc. until all debt is paid or it runs out of assets. Formally, \( f_e(y) = \min\{c(e), \max\{0, y - \sum_{j < i} c(e_j)\}\} \). The edge-ranking strategy of \( v \) is fully described by the ranking \( \pi_v \), hence we denote a strategy profile in edge-ranking games by \( \pi = (\pi_v)_{v \in V} \).

**Coin-Ranking Games.** As a strict superset of such strategies, consider the case where each player \( v \in V \) can spend its assets to pay its debts in a monotone fashion. In coin-ranking games, we rely on integrality of all values for \( c_e \) and \( a_v^e \), and interpret money flow as being
discretized into “coins” of value 1. Thus, for a *coin-ranking strategy*, the parametrized flow functions $f_e(y)$ for every outgoing edge $e \in E^+(v)$ are defined on the non-negative integer numbers $f_e(y) : \mathbb{N}_0 \to \mathbb{N}_0$. They are characterized by capacity and no-fraud constraints, and, for every $y, y' \in \mathbb{N}_0$ with $y \geq y'$

$$f_e(y) \geq f_e(y') \quad \text{(monotonicity constraint)}$$

(4)

Note that, by letting the value of a coin tend to 0, coin-ranking strategies become arbitrary *monotone strategies* $f_e(y) : \mathbb{R}_0^+ \to \mathbb{R}_0^+$.

Coin-ranking strategies generalize edge-ranking strategies. Maybe counterintuitively, every coin-ranking game is also a special edge-ranking game – replacing each edge $e$ with weight $c(e)$ many multi-edges of unit weight expands a coin-ranking game into an equivalent edge-ranking game. There is a one-to-one correspondence between coin-ranking strategies in the original game and edge-ranking strategies in the expanded game. Intuitively, for a coin-ranking strategy in the original game, a player $v$ pays the first coin of assets to the multi-edge $\pi_v(1)$, the second coin to $\pi_v(2)$, etc. in the expanded edge-ranking game until all debt is paid or $v$ runs out of assets. The expansion of the game implies a pseudo-polynomial blowup in representation size, but nevertheless, the structural equivalence is very useful for characterizing and analyzing solutions to coin-ranking games.

Note that the representation of a coin-ranking strategy might require pseudo-polynomial size even in the original non-expanded game. We discuss this issue below in Section 3.1. It turns out that in every coin-ranking game, we can restrict attention to a subset of compactly representable coin-ranking strategies.

**Clearing States and Utilities.** For a given strategy profile $\pi$ in an edge- or coin-ranking game, we determine the utility using a clearing state $\hat{a}$, where we choose the one that maximizes the total revenue in the network, i.e., the sum of total assets available to all firms

$$\text{Rev}(\pi, a) = \sum_{v \in V} a_v = \sum_{v \in V} a_v^+ + \sum_{e = (u,v) \in E} f_e(a_u) = \sum_{v \in V} a_v^+ + \sum_{e \in E^+(v)} f_e(a_u).$$

Note that the choice of $\hat{a}$ and thus, the resulting revenue significantly depends on the strategy profile $\pi$. In many cases, for a fixed strategy profile $\pi$, the clearing state $\hat{a}$ is unique, and there is no choice based on maximum revenue. Moreover, in case there are several clearing states for a strategy profile $\pi$ in an edge-ranking game, it turns out that they can be arranged into a lattice with coordinate-wise maximum inducing a partial order. We choose the coordinate-wise maximal clearing state, since it maximizes $\text{Rev}(\pi, a)$ as a natural measure of social welfare. In this sense, the properties of edge-ranking games mirror the conditions shown for pro-rata payments in [13]. We prove these conditions in the subsequent section.

## 2 Clearing States

### 2.1 Circulation Structure in Money Flow Games

We observe a useful circulation representation of clearing states in money flow games. Given a strategy profile $f$, the fixed point and no-fraud constraints imply for any clearing state $a$ the conservation of money flow. Now using an auxiliary source $s$, we can represent all money flows in $a$ in the form of a circulation. We build a circulation network $G'$ by adding node $s$, for every $v \in V$ we add an auxiliary edge $(v, s)$ with capacity $c((v, s)) = \infty$, and for every
46:8 Strategic Payments in Financial Networks

$v \in V$ with $a^e_v > 0$ we add an auxiliary edge $(s, v)$ with $c((s, v)) = a^e_v$. In this way, external assets of $v$ become internal assets via a flow on edge $(s, v)$. Surplus assets of $w$ become a flow on edge $(w, s)$, i.e., the internal assets of $s$.

Proposition 2. For every clearing state $a$ of a strategy profile $f$ in a money flow game, the flow in $G'$ can be decomposed and represented as a circulation. The auxiliary source $s$ has assets of $a_s = \sum_{v \in V} a^e_v$, and all auxiliary edges $(s, v)$ are saturated.

Proof. This is a simple consequence of fixed point and no-fraud constraints. Surplus at firm $v \in E$ exists only if $v$ pays all debt

$$\sum_{e \in E^+(v)} f_e(a_v) = \min(a_v, \ell(v)).$$

Moreover, the total external assets constitute the total net revenue:

$$\sum_{v \in V} a^e_v = \sum_{v \in V} a_v^x + \sum_{v \in V} \sum_{e=(u,v) \in E^-(v)} f_e(a_u) - \sum_{v \in V} \sum_{e=(u,v) \in E^-(v)} f_e(a_u)$$

$$= \sum_{v \in V} a_v - \sum_{e \in E^+(v)} f_e(a_v) = \sum_{v \in V} \max\{0, a_v - \ell(v)\}$$

The net revenue of every firm gets routed to the auxiliary source $s$ and constitutes the assets $a_s$. Thus $a_s = \sum_{v \in V} \max\{0, a_v - \ell(v)\} = \sum_{v \in V} a^e_v$, and all auxiliary edges $(s, v)$ are saturated. Overall, by routing the surplus assets to $s$, we obtain exact flow conservation at every node. As such, the flow can be decomposed and represented as a circulation.

2.2 Structure for Monotone Strategies

Lattice Structure. Consider an arbitrary money-flow game and a strategy profile $f$ of monotone strategies. Let $A$ be the set of feasible clearing states for a strategy profile $f$. We show that $(A, \geq)$ forms a lattice with the coordinate-wise comparison. Formally, $a \geq a'$ iff $a_v \geq a'_v$ for all $v$; and $a > a'$ iff $a_v > a'_v$ for all $v$ and $a_v > a'_v$ for at least one $v$.

Theorem 3. For every strategy profile $f$ in a money-flow game with monotone strategies, the pair $(A, \geq)$ forms a lattice.

Proof. Consider $A = \left\{ a \mid 0 \leq a_v \leq a^e_v + \sum_{e=(u,v) \in E^-(v)} c(e), \ \forall v \in V \right\}$, a superset of all possible asset vectors. Obviously, $(A, \geq)$ forms a lattice with the coordinate-wise comparison defined above. For a given strategy profile $f$, the map $g : A \rightarrow A$ with $g(a)_v = a^x_v + \sum_{e=(u,v) \in E^-(v)} f_e(a_u)$ is a monotone function for every firm $v \in V$, since for every edge $e = (u,v) \in E$ the strategy of firm $u$ implies that $f_e$ is monotone in $a_u$. Obviously, the set of clearing states $A$ is the set of fixed-point asset vectors of $g$. The result follows by applying the Knaster-Tarski theorem.

Solvent Firms. The previous result implies uniqueness of $\hat{a}$ for a given monotone strategy profile $f$. We observe another interesting property, which shows that in monotone money flow games the maximal clearing state $\hat{a}$ is unique as long as all insolvent firms stick to their strategy. Since every strategy satisfies capacity and no-fraud constraints, the payments of solvent firms remain the same if they receive the same assets, and vice versa. Consequently, strategies of solvent firms have no impact on the asset vector $\hat{a}$. For any solvent firm $v$, every strategy constitutes a best response.
Proposition 4. For a given money flow game, consider any monotone strategy profile $f$, the corresponding clearing state $\hat{a}$, and any solvent firm $v$ with $\hat{a}_v \geq l(v)$. Every strategy $f^v$ is a best response for $v$ against the other strategies $f_{-v}$ and results in the same clearing state $\hat{a}$.

Proof. Consider a deviation $f^v$, the resulting state $f' = (f^v, f^{-v})$ and the resulting revenue-maximizing clearing state $a'$. Suppose that $\hat{a} \neq a'$. Firm $v$ is solvent under $\hat{a}$, thus $\sum_{e \in E^+(v)} f_e(\hat{a}_e) = l(v)$ and $f_e(\hat{a}_e) = c(e)$. Using Theorem 3 we can assume w.l.o.g. that $\hat{a} > a'$ (i.e., $\hat{a}_u \geq a'_u$ for all firms $u$, and $\hat{a}_w > a'_w$ for at least one firm $w$). We construct an equivalent game, in which we remove all edges in $E^+(v)$ and instead increase external assets to $\hat{a}^x(u) = a^x_u + c(e)$ for all $u$ with $(v, u) \in E^+(v)$. Observe that $\hat{a}$ is still a feasible clearing state in the constructed game. However, any clearing state $a$ in the original game with $a_v \geq l(v)$ induces $f(a_v) = c(e)$ independent of the chosen strategies of $v$ due to the non-fraud condition. Thus, any clearing state $a$ with $a_v \geq l(v)$ in the new game is still a feasible clearing state in the old game. We conclude that $\hat{a}$ is a feasible clearing state under $f'$. This is a contradiction to the maximality of $a'$.

3 Coin-Ranking Games

3.1 Representation

An instance of a money flow game is given by the network $G$ and integer numbers for edge weights $c(e)$ and external assets $a^x_v$. Hence, the representation of the instance is logarithmic in input numbers for $c(e)$ and $a^x_v$. In contrast, if we consider arbitrary coin-ranking strategies $f^v$ for firm $v$, this specifies a ranking over all coins of value 1. This is linear in $\sum_{e \in E^+(v)} c(e)$ and, thus, only pseudo-polynomial in the instance representation. Our first observation is that in every coin-ranking game, we can restrict attention to threshold-ranking strategies with a polynomial representation. A threshold-ranking strategy $\pi^v = (\pi_v, \tau_v)$ is composed of a permutation $\pi_v$ over $E^+(v)$ and a vector of thresholds $\tau_v = (\tau_e)_{c \in E^+(v)}$ with $0 \leq \tau_e \leq c(e)$ for every $e \in E^+(v)$.

The interpretation is as follows. In $\pi^v$, firm $v$ first pays $\tau_e$ to every edge $e \in E^+(v)$, sequentially in the order given by $\pi_v$. Then, it pays the remaining $c(e) - \tau_e$ to every edge in the order given by $\pi_v$. That is, $v$ first considers edge $\pi_v(1)$ and pays the first $\tau_{\pi_v(1)}$ coins to this edge. The next $\tau_{\pi_v(2)}$ coins are paid to edge $\pi_v(2)$ etc. until $\sum_{j=1}^{E^+(v)} \tau_{\pi_v(j)}$ coins are paid to the edges (or $v$ runs out of assets). Then, the remaining $c(\pi_v(1)) - \tau_{\pi_v(1)}$ coins are paid to edge $\pi_v(1)$, then the next $c(\pi_v(2)) - \tau_{\pi_v(2)}$ coins to $\pi_v(2)$ etc.

Indeed, we can restrict attention to threshold-ranking strategies in coin ranking games. The formal proof is deferred to the full version [6].

Proposition 5. For every strategy profile $f$ in a coin-ranking game with clearing state $\hat{a}$ and every firm $v$, there is a threshold-ranking strategy $\pi^v_v$ such that the profile $(\pi^v_v, \pi_{-v})$ has the same clearing state $\hat{a}$ and, thus, the same utilities for all firms.

3.2 Existence and Computation of Equilibria

Our first result is that in every coin-ranking game there is a strong equilibrium that maximizes the total revenue of all firms. This strong equilibrium can be computed in polynomial time. In particular, consider the instance $(G, c, a^x)$ as a money flow game and an arbitrary clearing state, i.e., a circulation of maximum value in the circulation network $G'$. This circulation is also a clearing state of a strong equilibrium in threshold-ranking strategies.
For every coin-ranking game, there is a strong equilibrium with money flows that maximize the total revenue in the network. The strong equilibrium can be computed in polynomial time.

Proof. Consider the circulation network \( G' = (V, E') \). An optimal circulation \( f^* \) that maximizes the total flow value saturates all outgoing auxiliary edges from \( s \). Hence, it maximizes the total assets of all firms

\[
\sum_{e \in E'} f^*_e = 2 \sum_{v \in V} a_v^x + \sum_{e \in E} f^*_e = \sum_{v \in V} a_v^x + \text{Rev}(f^*)
\]

\( f^* \) can be computed in strongly polynomial time [29]. Since all edge weights are integral, we can assume all \( f^*_e \) are integral. We can turn this circulation into a clearing state for a strategy profile with threshold-ranking strategies. Every firm \( v \) chooses an arbitrary order \( \pi_v \) over \( E^+(v) \) and sets thresholds \( \tau_e = f^*_e \). Clearly, in this strategy profile the optimal circulation corresponds to the maximum-revenue clearing state \( \hat{a} \).

Let us prove that this strategy profile \( \pi \) is a strong equilibrium. A coalition \( C \subseteq V \) of firms has a profitable deviation \( \pi'_C = (\pi'_v)_{v \in C} \) if upon joint deviation of \( C \) to \( \pi'_C \), the resulting assets \( a' \) in the new profile \( (\pi'_C, \pi_{-C}) \) are strictly better, i.e., \( a'_v > \hat{a}_v \) for every \( v \in C \). We will show that no coalition \( C \subseteq V \) has a profitable deviation.

Suppose for contradiction that there is a coalition \( C \) with a profitable deviation. Examine the new profile \( (\pi'_C, \pi_{-C}) \) and consider a firm \( v \in C \). Since \( a'_v > \hat{a}_v \), there must be an edge \( (u, v) \in E^-(v) \) that has strictly more incoming flow in the new profile \( f'_e(a'_u) > f_e(a_u) \). Now consider node \( u \). If \( u \in C \), then \( a'_u > a_u \), so there is again some edge \( E^-(u) \) that has strictly more incoming flow in the new profile. Otherwise, if \( u \not\in C \), then \( u \) still plays the threshold-ranking strategy obtained from \( f^* \). Since this is a monotone strategy, a higher flow on \( (u, v) \) can only occur if \( u \) has larger assets. Thus, \( a'_u > a_u \), so there is again some edge \( E^-(u) \) that has more incoming flow in the new profile.

We can repeat this argument indefinitely. As such, there must be a cycle of edges that all have more flow under \( (\pi'_C, \pi_{-C}) \) than under \( \pi \). Such a cycle, however, can be used to increase the flow circulation. This contradicts that \( \hat{a} \) represents an optimal circulation.

For the profitable deviation, we can even allow arbitrary continuous strategies and any choice of clearing state for the deviation profile. As such, the strategy profile obtained from \( f^* \) is a strong equilibrium even in general money flow games (with suitable choice of clearing state).

Remark 8. If one allows deviations that weakly improve the coalition (i.e., \( a'_u \geq \hat{a}_u \) for all \( u \in C \) and \( a'_v > \hat{a}_v \) for at least one \( v \in C \)), it is a simple exercise to see that there are coin-ranking games, in which no stable state (termed super-strong equilibrium) exists.

While it is computationally easy to compute a socially optimal strong equilibrium, computing a best-response strategy for a general strategy profile can be strongly \( \text{NP} \)-hard, since best responses can provide answers to computationally hard decision problems. For the following result, we assume the coin-ranking game is given in the edge-ranking representation as a network with unit-weight multi-edges. Note that the edge weights in our instances of interest can be restricted to the set \( \{0, 1\} \). Thus, our construction needs no multi-edges, and the representation incurs no overhead. A proof of the following theorem is given in the full version [6].

Theorem 9. For a given strategy profile \( f \) of a coin-ranking game, deciding whether a given firm \( v \) has a best response resulting in assets at least \( k \) is strongly \( \text{NP} \)-complete. This holds even in coin-ranking games without external assets and all edge weights in \( \{0, 1\} \).
3.3 Total Revenue of Equilibria

In this section, we analyze the total revenue in pure Nash and strong equilibria. We relate this value to the social optimum, i.e., the total sum of assets for all firms in the best strategy profile. Clearly, since we proved existence of a system optimal strong equilibrium, the price of stability for Nash and strong equilibria are both 1. We bound the prices of anarchy for Nash and strong equilibria. The proof of the next Proposition is given in the full version [6].

▶ Proposition 10. The price of anarchy for Nash equilibria is unbounded, even in coin-ranking games without external assets.

The total revenue depends crucially on the emergence of cycles in the strategy profile. This requires an effort that is inherently coalitional, as such it might be unsurprising that in general Nash equilibria fail to provide good revenue guarantees.

To analyze the quality of strong equilibria, we again consider the coin-ranking game in the form of unit-weight multi-edges. Consider an optimal circulation $f^*$ of maximum total revenue in the circulation network $G'$. Since we have unit-weight edges, we can assume that the optimal circulation has binary flows on each edge. Let $C(f^*) = \{C_1, \ldots, C_k\}$ be a decomposition of $f^*$ into cycles of unit flow. We denote by $d = \min_{C \in C(f^*), i \in [n]} |C_i|$, the min-max size of any cycle, in any decomposition $C(f^*)$ of any optimal circulation $f^*$.

▶ Theorem 11. In coin-ranking games, the strong price of anarchy is at most $d$.

Proof. Consider an optimal circulation $f^*$ and a decomposition $C(f^*)$ such that all flow cycles $C_i \in C(f^*)$ have size at most $|C_i| \leq d$. The total revenue in $f^*$ is given by

$$\text{Rev}(f^*) = \sum_{C_i \in C(f^*)} |C_i| - \sum_{v \in V} a_v^z$$

since the circulation also accounts for the assets of the auxiliary source $s$.

Now consider a strong equilibrium $\pi$ in the coin-ranking game with clearing state $\hat{a}$. It yields a binary money flow in the network. Suppose there is a cycle $C_i \in C(f^*)$ such that $f_e(\hat{a}_u) = 0$ for all $e = (u, v) \in C_i$. Then the firms in this cycle have an incentive to jointly deviate and place the edges of $C_i$ on first position in their ranking. Then the clearing state $\hat{a}$ will emerge as before, adding a flow of 1 along the cycle $C_i$. This is a profitable deviation for the firms of $C_i$.

Consequently, for every cycle $C_i \in C(f^*)$ there must be at least one edge $e = (u, v) \in C_i$ such that $f_e(a_u) = 1$. Thus, the revenue in the strong equilibrium $\pi$ is

$$\text{Rev}(\pi, \hat{a}) \geq \sum_{C_i \in C(f^*)} 1$$

and the ratio is at most $d$.

▶ Proposition 12. For every $d \geq 2$, there is a coin-ranking game with strong price of anarchy of $d - 1$. 
Proof. The game is given by a graph $G$ with $d + (d - 1)(d - 2)$ firms. $G$ is constructed as follows. The firms $v_1, \ldots, v_d$ are called central firms and they form a cycle of length $d$. For each $i = 1, \ldots, d - 1$, there are firms $(v_{i,j})_{j=1, \ldots, d-2}$ that form additional cycles of length $d$ with the edge $(v_i, v_{i+1})$. Thus, the set of edges is given by

$$E = \{(v_i, v_{i+1}) \mid i \in \{1, \ldots, d - 1\}\} \cup \{(v_d, v_1)\} \cup \bigcup_{i=2, \ldots, d} (\{(v_i, v_1^i)\} \cup \{(v_{i,j}^i, v_{i,j+1}^i) \mid j = 1, \ldots, d - 3\} \cup \{(v_{d+2}^i, v_{i-1}^i)\})$$.

All edges have unit weight. An example of the instance with $d = 5$ is depicted in Figure 1. Observe that only firms $v_i$, $i = 2, \ldots, d$ have multiple outgoing edges. We claim that $\pi_i = ((v_i, v_{i+1}^i), (v_i, v_1^i))$ and $\pi_d = ((v_d, v_1^d), (v_d, v_3^d))$ is a strong equilibrium. In order to see this, let $\hat{\alpha}$ be the clearing state corresponding to $\pi$. The clearing state is given by

$$\hat{\alpha}_v = \begin{cases} 1 & \text{if } v = v_1, v_2, \ldots, v_d, \\ 0 & \text{otherwise,} \end{cases}$$

that is, $\text{Rev}(\pi, \hat{\alpha}) = d$. Now, assume there is a non-empty coalition of player $S \subseteq \{v_2, \ldots, v_d\}$ that all strictly increase their assets by a joint deviation. Note that $v_d$ only has a single incoming edge, so $v_d \notin S$. Thus, the cycle $v_d, v_1^d, \ldots, v_{d-2}^d, v_{d-1}$ cannot carry any flow. We conclude that $v_{d-1}$ only has one edge that can carry flow. Iterating this argument yields $S = \emptyset$, a contradiction.

However, the optimal flow emerges with the strategy profile $\pi_i = ((v_i, v_{i+1}^i), (v_i, v_1^i))$ and $\pi_d = ((v_d, v_1^d), (v_d, v_3^d))$. It is easy to observe that this yields a total revenue of $(d - 1)d$. Thus, the strong price of anarchy in this instance is $d - 1$.

4 Edge-Ranking Games

4.1 Existence and Computation of Equilibria

With coin-ranking strategies we assume that firms have flexibility in allocation of single units of assets. In this section, we focus on a more restricted class of strategies, in which firms simply rank their outgoing edges and allocate assets in order of this ranking until they run
Proposition 13. There is an edge-ranking game without a pure Nash equilibrium.

Proof. Consider the game in Figure 2. The capacities of the edges are depicted next to the edges. Firms $v_2$ and $v_3$ each have external assets of 2, the other firms have 0 external assets. Firms $v_1$, $v_2$ and $v_3$ are the only ones with multiple outgoing edges. The strategy choices of the other firms are fixed. Due to the symmetry of the network, we can assume w.l.o.g. $\pi_{v_1} = (v_1,v_4,v_7)$. There are two possible strategy choices for each of the nodes $v_2$ and $v_3$. Checking all four resulting strategy profiles yields the utility matrix shown in Table 1 for firms $v_2$ and $v_3$. Inspecting the utilities, we see that there is no pure Nash equilibrium.

The following theorem shows that a number of natural decision and optimization problems in edge-ranking games are indeed computationally intractable. Note that for coin-ranking games, these problems are either trivial (a strong equilibrium always exists) or can be solved in polynomial time (a strong equilibrium, which also represents a profile with maximum total revenue, can be computed in strongly polynomial time). The proof of the following theorem is deferred to the full version [6].

Theorem 14. Given an edge-ranking game the following problems are strongly $NP$-hard:

1. Deciding whether a pure Nash equilibrium exists or not.
2. Deciding whether a strong equilibrium exists or not.
3. Computing a pure Nash equilibrium, when it is guaranteed to exist.
4. Computing a strong equilibrium, when it is guaranteed to exist.
5. Computing a strategy profile with maximum total revenue.
Remark 15. It is unclear whether the problem of deciding existence of a pure Nash equilibrium in an edge-ranking game is in \( \text{NP} \) or not, due to \( \text{NP} \)-hardness of verification that a firm plays a best response (see Theorem 9). It is easy to see that the decision problem is in \( \Sigma_2^p \). The problem could be \( \Sigma_2^p \)-complete, similar to related decision problems in strategic max-flow games [23, 19]. Proving such a result is an interesting open problem.

4.2 Total Revenue of Equilibria

For edge-ranking games, the lower bound on the price of anarchy observed for coin-ranking games does apply, i.e., the price of anarchy can be unbounded. The restriction to edge-ranking strategies can have a drastic effect even on the quality of the best equilibrium in case it exists. In particular, in edge-ranking games the strong price of stability can be as high as \( \Omega(n) \), and the price of stability might even be unbounded.

Proposition 16. For every \( \varepsilon > 0 \), there is an edge-ranking game with strong price of stability of at least \( n/2 - \varepsilon \).

Proof. We consider a slight modification of the instance in Proposition 12. In contrast to the instance described in the proof of Proposition 12, the edges \((v_1, v_n), (v_n, v_1), (v_1, v_2)\) have a weight \( M + 1 \) and all other edges a weight of \( M \). The only node with more than a single outgoing edge is still \( v_1 \). If \( \pi_{v_1} = ((v_1, v_n), (v_1, v_2)) \), player \( v_1 \) gets assets of \( M + 1 \), which is optimal. The total revenue for \( \pi \) is \( 2M + 2 \). \( \pi \) is the only Nash equilibrium and the only strong equilibrium.

In contrast, for profile \( \pi' \) with \( \pi'_{v_1} = ((v_1, v_2), (v_1, v_n)) \), firm \( v_1 \) only gets a revenue of \( M \), but the total revenue is \( nM \). Thus, the strong price of stability is \( nM/(2M + 2) = n/(2M + 2) \), which is at least \( n/2 - \varepsilon \) for \( M \geq n/(2\varepsilon) - 1 \). ▷

Proposition 17. There is an edge-ranking game with unbounded price of stability.

Proof. Consider the game in Figure 3, which uses the game without pure equilibrium from Figure 2. We add three firms. \( w_1 \) has external assets equal to 1, \( w_2 \) and \( w_3 \) no external assets. These firms have a cycle \( C \) of edges \((w_1, w_2)\) and \((w_2, w_3)\) with weight \( M \gg 2 \), as well as edge \((w_3, w_1)\) with weight \( M - 2 \). In addition, there are edges \((w_1, v_9)\) and \((w_2, v_9)\) of weight 2.

In an optimal circulation, \( w_1 \) and \( w_2 \) prioritize the edges of \( C \), leading to total revenue of \( \Theta(M) \). In contrast, a pure Nash equilibrium can only exist if the \( w \)-firms ensure that the external assets of \( w_1 \) are routed to \( v_9 \), in which case a Nash equilibrium can exist (as observed
in the proof of Theorem 14). Clearly, both \( w_1 \) and \( w_2 \) have an incentive to deviate towards \( C \). Hence, if either \( w_1 \) or \( w_2 \) places the edge to \( v_9 \) in first rank and the other does not, a unilateral deviation suffices to close \( C \)– thereby leaving the \( v \)-nodes with instability. However, if both \( w_1 \) and \( w_2 \) play strategies \( \pi_{w_1} = ((w_1, v_9), (w_1, w_2)) \) and \( \pi_{w_2} = ((w_2, v_9), (w_2, w_3)) \), no unilateral deviation can lead to flow along \( C \). In this case, a pure Nash equilibrium evolves. Obviously the total revenue in this equilibrium is at most a constant. Hence, the price of stability is as large as \( \Omega(M) \).

5 Conclusions

In this paper, we have studied clearing mechanisms for financial networks and analyzed their properties from a computational and game-theoretic perspective. Our main results show that in these games, solvent firms have no strategic incentives, i.e., the game is played exclusively among insolvent firms. If firms are using coin-ranking strategies, every social optimum that maximizes the sum of all assets in the network constitutes a strong equilibrium. Moreover, it can be computed in strongly polynomial time. This result implies that a centralized bankruptcy settlement can achieve a clearing state, in which the social welfare is maximized and no coalition of firms gets incentivized to deviate. In contrast, when considering decentralized clearing and arbitrary strong equilibria, the social welfare depends on the length of cycles in the money circulation of a social optimum. For pure Nash equilibria, the deterioration in social welfare can be severe due to the lack of coordination among firms. Alternatively, when restricting the strategy spaces to edge-ranking strategies, we show that pure Nash and strong equilibria can be absent, hard to compute, and highly undesirable in terms of social welfare.

There are many open problems that arise from our work. For example, real-life markets involve a number of complex financial products (such as derivatives, credit-default swaps, etc.). Their impact on stability and computational complexity of financial markets is only beginning to attract attention in the literature. In this context, there are a variety of important game-theoretic aspects with respect to pricing, information revelation, or network creation, which are crucial for understanding financial markets and represent interesting avenues for future work.

Abstract

In the past decade, the design of fault tolerant data structures for networks has become a central topic of research. Particular attention has been given to the construction of a subgraph $H$ of a given digraph $D$ with as fewest arcs/vertices as possible such that, after the failure of any set $F$ of at most $k \geq 1$ arcs, testing whether $D - F$ has a certain property $P$ is equivalent to testing whether $H - F$ has that property. Here, reachability (or, more generally, distance preservation) is the most basic requirement to maintain to ensure that the network functions properly. Given a vertex $s \in V(D)$, Baswana et al. [STOC’16] presented a construction of $H$ with $O(2^k n)$ arcs in time $O(2^k nm)$ where $n = |V(D)|$ and $m = |E(D)|$ such that for any vertex $v \in V(D)$: if there exists a path from $s$ to $v$ in $D - F$, then there also exists a path from $s$ to $v$ in $H - F$. Additionally, they gave a tight matching lower bound. While the question of the improvement of the dependency on $k$ arises for special classes of digraphs, arguably the most basic research direction concerns the dependency on $n$ (for reachability between a pair of vertices $s,t \in V(D)$) – which are the largest classes of digraphs where the dependency on $n$ can be made sublinear, logarithmic or even constant? Already for the simple classes of directed paths and tournaments, $\Omega(n)$ arcs are mandatory. Nevertheless, we prove that “almost acyclicity” suffices to eliminate the dependency on $n$ entirely for a broad class of dense digraphs called bounded independence digraphs. Also, the dependence in $k$ is only a polynomial factor for this class of digraphs. In fact, our sparsification procedure extends to preserve parity-based reachability. Additionally, it finds notable applications in Kernelization: we prove that the classic Directed Feedback Arc Set (DFAS) problem as well as Directed Edge Odd Cycle Transversal (DEOCT) (which, in sharp contrast to DFAS, is $W[1]$-hard on general digraphs) admit polynomial kernels on bounded independence digraphs. In fact, for any $p \in \mathbb{N}$, we can design a polynomial kernel for the problem of hitting all cycles of length $\ell$ where $(\ell \mod p = 1)$. As a complementary result, we prove that DEOCT is NP-hard on tournaments by establishing a combinatorial identity between the minimum size of a feedback arc set and the minimum size of an edge odd cycle transversal. In passing, we also improve upon the running time of the sub-exponential FPT algorithm for DFAS in digraphs of bounded independence number given by Misra et al. [FSTTCS 2018], and give the first sub-exponential FPT algorithm for DEOCT in digraphs of bounded independence number.

1 Introduction

In most real-life applications, even the most reliable networks are highly prone to unexpected failures of a small number of links that connect their nodes. In the past decade, the design of fault tolerant data structures for networks has become a central topic of research [7, 9, 13, 47, 44, 12, 16, 17, 18, 11, 26, 45, 46]. Generally, the scenario under study concerns the design of a structure that, after the failure of any set \( F \) of at most \( k \geq 1 \) arcs (representing links) in a given digraph \( D \) (representing a network), should provide a fast answer to certain types of queries that address the properties of \( D - F \). The most common queries of this form address the reachability between two vertices, or, more generally, the length of a shortest path existent, if any, between them. Indeed, reachability (or, more generally, distance preservation) is the most basic requirement to maintain to ensure that the network functions properly. In this context, particular attention has been given to the case where the data structure should consist of a subgraph or a minor of \( D \) with as fewest arcs/vertices as possible [7, 47, 9, 11, 8, 45, 13]. Then, queries can be answered by standard means as the usage of BFS or Dijkstra’s algorithm. In particular, these simple data structures are of interest as they also double as sparsifiers. The study of various graph sparsifiers – such as flow-sparsifiers [38] which are closely related to the aforementioned data structures – is a fundamental, active area of research in computer science and structural graph theory [22, 5, 29, 38, 15].

More concretely, in the Fault-Tolerance \((S, T)\)-Reachability problem (or FTR\((S, T)\) for short), we are given a digraph \( D \), two (not necessarily disjoint) terminals sets \( S, T \subseteq V(D) \), and a positive integer \( k \). The objective is to construct a subgraph \( H \) of \( D \) with minimum number of arcs/vertices such that, after the failure of any set of at most \( k \) arcs in \( D \), the following property is preserved for any two vertices \( s \in S \) and \( t \in T \): if there still exists a directed path from \( s \) to \( t \) in \( D \), then there also still exists a directed path from \( s \) to \( t \) in \( H \). Clearly, a trivial lower bound on the number of arcs in \( H \) is \( m = \Omega(n^2) \). For the case where \( |S| = 1 \) and \( T = V(D) \), Baswana et al. [9] presented a construction of a subgraph \( H \) with \( O(2^k n) \) arcs in time \( O(2^k nm) \) where \( n = |V(D)| \) and \( m = |E(D)| \). Additionally, they gave a tight matching lower bound: for any \( n, k \in \mathbb{N} \) where \( n \geq 2^k \), there exists a digraph on \( n \) vertices where \( H \) must have \( \Omega(2^k n) \) arcs.

Naturally, the question of the improvement of the dependency on \( k \) arises for special classes of digraphs. However, an arguably more radical research direction to pursue concerns the dependency on \( n \).
Which are the largest classes of digraphs for which FTR($S,T$) admits subgraphs whose size dependency on $n$ can be made sublinear, logarithmic or even constant?

At first glance, when we consider the simplest sparsest digraph existent, this pursuit seems futile. Indeed, already in the case where $S = \{s\}$, $T = \{t\}$, $k = 1$ and $D$ is a directed path from $s$ to $t$, the only solution is to choose $H = D$. At second glance, when we consider the simplest densest digraph existent, again we reach a dead-end: for $S$, $T$ and $k$ as before, define $D$ as the tournament obtained by adding, to a directed path $s = v_1 \rightarrow v_2 \rightarrow \ldots \rightarrow v_n = t$, all arcs going from $v_i$ to $v_j$ for every $j + 1 < i$; then, to construct $H$, we must select the entire path.

We show that “almost acyclicity” suffices to eliminate the dependency on $n$ entirely for a broad class of dense digraphs called bounded independence number digraphs. Furthermore, one can achieve a polynomial dependence in terms of $k$ for this digraph class.

To step beyond the strict confinement of tournaments where all relations (arcs) between the input entities (vertices) must be both present and known, Fradkin and Seymour [33] initiated the study of bounded independence digraphs. Formally, for any integer $\alpha \geq 1$, the class of $\alpha$-bounded independence digraphs, denoted by $D_{\alpha}$, is defined as follows.

$$D_{\alpha} = \{D \mid D \text{ is a digraph and the maximum size of an independent set in } D \text{ is at most } \alpha\}.$$

For this class of digraphs, Fradkin and Seymour [33] studied the $k$-DISJOINT PATHS problem, and showed that it admits a polynomial time algorithm for any fixed value of $k$. Observe that $D_{\alpha}$ is hereditary, and for $\alpha = 1$, it coincides with the class of tournaments. Furthermore, even for $\alpha = 2$, it contains digraphs with a linear fraction of vertex pairs that have no arc between them – thus, it can accommodate the lack of a large number of links/relations.

Our main technical contribution is the following combinatorial lemma.

**Lemma 1.1.** Given a digraph $D \in D_{\alpha}$, positive integers $k$ and $\ell$, and $S \subseteq V(D)$ such that every strongly connected component of $D - S$ has at most $\ell$ vertices, the FAULT-TOLERANCE ($S,S$)-REACHABILITY (FTR($S,S$)) problem admits a solution $H$ on $|S|^2(k\ell)^{O(\log n)}$ vertices. Furthermore, such a solution $H$ can be found in polynomial time.

In particular, when $D - S$ is acyclic, $\ell = 1$. Thus, if $|S|$ and $\ell$ are independent of $n$ (such as the case where $|S| = |T| = \ell = 1$ discussed earlier), the dependency on $n$ is eliminated.

(We remark that a solution for FAULT-TOLERANCE ($S,T$)-REACHABILITY where $S \neq T$ is subsumed by a solution for FAULT-TOLERANCE ($S \cup T, S \cup T$)-REACHABILITY.) Note that we extend the class of digraphs dealt with beyond acyclicity at two fronts: enabling $S$ to be a modulator, thus $D - S$ rather than $D$ should be “almost acyclic”; enabling the strongly connected components to be of size that is ("small" but) larger than 1.

In fact, our result generalizes to parity reachability. More precisely, in the FAULT-TOLERANCE ($S,T$)-PARITY REACHABILITY problem, we are given a digraph $D$, two terminal sets $S, T \subseteq V(D)$, positive integers $k$ and $p$, and a non-negative integer $r$. The objective is to construct a subgraph $H$ of $D$ with as few arcs/vertices as possible, such that, after the failure of any set of at most $k$ arcs in $D$, the following property is preserved for any two vertices $s \in S$ and $t \in T$: if there exists a directed path from $s$ to $t$ in $D$ whose length $q$ satisfies $(q \mod p = r)$, then there also exists a directed path from $s$ to $t$ in $H$ whose length $q'$ satisfies $(q' \mod p = r)$. For this problem, we prove the following combinatorial lemma.
Lemma 1.2. Given a digraph $D \in \mathcal{D}_\alpha$, positive integers $k, \ell, p$, a non-negative integer $r$, and $S \subseteq V(D)$ such that every strongly connected component of $D - S$ has at most $\ell$ vertices, the Fault-Tolerance $(S, S)$-Parity Reachability problem admits a solution $H$ on $(|S| \alpha(pk)^{O(4^{\alpha r})})$ vertices. Furthermore, such a solution $H$ can be found in polynomial time.

1.1 Applications in Kernelization

Directed Feedback Arc Set. From the perspective of Parameterized Complexity, with the exception of Directed Multicut, the Directed Feedback Arc/Vertex Set (DFA/VS) problem is the most well studied parameterized problem on digraphs. (On general digraphs, the vertex and arc versions of the problem are equivalent [23].) Formally, this problem is defined as follows.

**Directed Feedback Arc Set (DFAS)**

**Input:** A digraph $D$ and a non-negative integer $k$.

**Parameter:** $k$

**Question:** Does there exist $S \subseteq E(D)$ of size at most $k$ such that $D - S$ is a DAG?

We remark that this problem is among Karp’s 21 original NP-complete problems [35]. Already a decade ago, the DFAS problem has been shown to be fixed-parameter tractable (FPT) parameterized by the solution size $k$ [19]. Specifically, Chen et al. [19] developed an algorithm that solves DFAS in time $O(k!4^k k^4 n^2)$, based on the powerful machinery of important separators [23]. Since then, the quest to assert the existence of a polynomial kernel for this problem has been unfruitful. Over the years, it has been repeatedly posed as a major challenge in the subfield of Kernelization [23, 28, 42, 41] (also see [1] for a major challenge in the subfield of Kernelization [23, 28, 42, 41] (also see [1] for a number of workshops and schools where it was posed as an open problem). In fact, the two specific problems whose polynomial kernelization complexity is completely unknown and their resolution is raised most frequently are DFAS and Multiway Cut [23, 28]. At the front of parameterized algorithms, the recent work by Lokshtanov et al. [39] improved upon the polynomial factor of the aforementioned algorithm by the design of an $O(k!4^k k^5 (m + n))$-time algorithm. It is known that unless the Exponential Time Hypothesis (ETH) is false, parameterized by the treewidth $tw$ of the underlying undirected graph, DFAS cannot be solved in time $2^{\Omega(tw \log tw)} \cdot n^{O(1)}$. However, it is unknown whether DFAS is solvable in time $2^{o(k \log k)} \cdot n^{O(1)}$. In this regard, the only lower bound known is of $2^{\Omega(k)} \cdot n^{O(1)}$ under the ETH [23, 39].

Particular attention has been given to the parameterized complexity of DFAS on tournaments. The classical complexity (NP-hardness) of DFAS on tournaments has a curious history. More than two decades ago, this problem was conjectured to be NP-hard by Bang-Jensen and Thomassen [6]. In 2008, Ailon et al. [2] proved that this problem does not admit a polynomial-time algorithm unless $\text{NP} \subseteq \text{BPP}$. Later, the reduction of Ailon et al. [2] was derandomized independently by Alon [3] and Charbit et al. [14], to prove that DFAS on tournaments is NP-hard. With respect to Parameterized Complexity, Alon et al. [4] proved that DFAS on tournaments admits a sub-exponential time parameterized algorithm (with running time $2^{O(\sqrt[k]{\log^2 k})} \cdot n^{O(1)}$), to which end they introduced the method of chromatic coding. Later, the $\log^2 k$ factor in the exponent was shaved in independent works by Feige [30] and Karpinski and Schudy [36]. Fomin and Pilipczuk [32] presented a general approach, based on a bound on the number of $k$-cuts in transitive tournaments, to achieve the same running time for DFAS on tournaments. Based on this approach, Misra et al. [43] developed a sub-exponential time parameterized algorithm for DFAS on digraphs in $\mathcal{D}_\alpha$, with running time $2^{O(\alpha \sqrt[k]{\log(\alpha k)})} \cdot n^{O(\alpha)}$. Yet, the (arguably more) intriguing question
of the existence of a polynomial kernel for DFAS on digraphs in $D_\alpha$ remained unsolved. On tournaments, Bessy et al. [10] have proved that DFAS admits a linear-vertex kernel (improving upon polynomial kernels given in [4, 27]). Based on our combinatorial lemma (Lemma 1.1), we establish the following theorem.

**Theorem 1.3.** DFAS on $D_\alpha$ admits a kernel of size $k^{O(4^{\alpha})}$.

In addition to its rich history in theoretical studies, the elimination of directed feedback loops is highly relevant to rank aggregation, Voting Theory, the resolution of inconsistencies in databases, and the prevention of deadlocks [48, 10, 34, 37, 19, 31]. While in a wide-variety of applications, most relations between the entities in a network are both present and known, it is generally unrealistic (in real-world partial and noisy data) that all relations will be so. Then, the usage of a bounded independence digraphs naturally comes into play. In passing, using Theorem 1.3, we also improve the running time for DFAS on digraphs in $D_\alpha$, given by Misra et al. [43], by eliminating the dependence of $\alpha$ in the exponent of $n$. That is, we have the following theorem.

**Theorem 1.4.** DFAS on $D_\alpha$ can be solved in $2^{f(\alpha)\sqrt{k}\log k} \cdot n^{O(1)}$, where $f(\alpha)$ is some function of $\alpha$ and $n$ is the number of vertices in $D$.

**Directed Edge Odd Cycle Transversal.** The Directed Edge Odd Cycle Transversal (DEOCT) problem is the parity-based version of DFAS, formally defined as follows. (On general digraphs, the vertex and arc versions of the problem are equivalent [40]).

**Directed Edge Odd Cycle Transversal (DEOCT)**

**Parameter:** $k$

**Input:** A digraph $D$ and a non-negative integer $k$.

**Question:** Does there exist $S \subseteq E(D)$ of size at most $k$ such that $D - S$ has no odd cycle?

Observe that a tournament has no directed cycle if and only if it has no directed triangle (a cycle on three vertices). In turn, this simple observation implies that, given a tournament $D$, any subset $S$ of the vertices of $D$ has the following property: $D - S$ is a DAG if and only if it has no directed odd cycle. Thus, the vertex versions of DFAS and DEOCT on tournaments are equivalent. However, for DFAS and DEOCT the situation is not so clear. Indeed, it is not difficult to come up with a tournament $D$ and a subset of arcs $S$ of $D$ such that $D - S$ is not a DAG, yet it has no directed odd cycle (see, e.g., Fig. 1). Nonetheless, we are able to prove that given a tournament $D$ and a subset $S$ of the arcs of $D$ such that $D - S$ has no directed odd cycle, there exists a subset of arcs $S'$ of $D$ such that $D - S'$ is a DAG and $|S'| \leq |S|$. In particular, we thus establish the following result.

**Theorem 1.5.** DEOCT on tournaments is NP-hard.

The question of the parameterized complexity of DEOCT was explicitly stated as an open problem [24] for the first time in 2007, immediately after the announcement of the first parameterized algorithm for DFAS. Since then, the problem has been re-stated several
times [20, 21, 42, 41]. Recently, Lokshnanov et al. [40] proved that DEOCT is \(\text{W}[1]\)-hard. Specifically, this means that DEOCT is highly unlikely to be FPT or admit a kernel of any size (even exponential in \(k\)). Based on the parity-based generalization of our combinatorial lemma (Lemma 1.2), we establish a polynomial kernel for DEOCT on \(D_\alpha\), which stands in sharp contrast to its aforementioned status on general digraphs.

**Theorem 1.6.** DEOCT on \(D_\alpha\) admits a kernel of size \((\alpha k)^{O(4k^3)}\).

In fact, we present combinatorial results stronger than Lemma 1.2 that yield a polynomial kernel for a more general version of DEOCT, where instead of hitting directed odd cycles, the objective is to hit directed cycles whose length \(\ell\) satisfies \((\ell \mod p = 1)\) for an integer \(p \in \mathbb{N}\) given as input.\(^1\)

</tbody>
</table>

**Theorem 1.7.** mod\((p)\)-DCT on \(D_\alpha\) admits a kernel of size \((p\alpha k)^{O(4^p n^3)}\).

Having Theorem 1.6 at hand, we also show how to employ the general approach of Fomin and Pilipczuk [32] to derive a sub-exponential time parameterized algorithm for DEOCT on digraphs in \(D_\alpha\).

**Theorem 1.8.** DEOCT on \(D_\alpha\) admits an algorithm with running time \(2^{O(f(\alpha)\sqrt{\ell \log k})} \cdot n^{O(1)}\), where \(f(\alpha)\) is a function of \(\alpha\) and \(n\) is the number of vertices in \(D\).

### 1.2 Towards the proof of Lemmas 1.1: Cut Preserving Sets

The most central notion in this paper is of a cut preserving set. Informally, for a digraph \(D\), a pair of vertices \(s, t\) and an integer \(k\), a set \(Z \subseteq V(D)\) is called a \(k\)-cut preserving set\(^2\) for \((s, t)\) in \(D\) if it preserves all \((s, t)\)-arc cuts of size at most \(k\). That is, \(A\) is an \((s, t)\)-arc cut with at most \(k\) arcs in \(D\) if and only if \(A\) is a such a cut in \(D[Z]\). Observe that the graph induced on such a \(k\)-cut preserving set \(Z\) is a candidate solution for \(\text{FTR}\{\{s\}, \{t\}\}\) problem. Clearly \(V(D)\) is a \(k\)-cut preserving set for any pair of vertices \(s, t\). The intent is to have such a set of “small” size. Towards this, let us discuss some properties that suffice for \(Z\) to be a \(k\)-cut preserving set for \((s, t)\) in \(D\).

Since \(Z \subseteq V(D)\), any \((s, t)\)-arc cut of \(D\) is an \((s, t)\)-arc cut of \(D[Z]\). For the other direction, we need the property that, for any \(A \subseteq E(D)\) of size at most \(k\), the existence of an \((s, t)\)-path in \(D - A\) implies the existence of an \((s, t)\)-path in \(D[Z] - A\). Let us now see which properties suffice to imply the above property. We begin with a special case. Suppose there is a “large” flow from \(s\) to \(t\) in \(D\). In particular, suppose there are at least \(k+1\) internally vertex-disjoint \((s, t)\)-paths in \(D\). Then, in \(Z\) it is enough to keep the vertices of some \(k+1\) vertex-disjoint \((s, t)\)-paths, as no arc set of size at most \(k\) can hit all these paths. The more involved case occurs when the flow from \(s\) to \(t\) in \(D\) is at most \(k\). Consider any \((s, t)\)-path \(P\) in \(D\). Ideally (if we did not have a size constraint on \(Z\)) we would have preserved all the

---

\(^1\) Note that a fundamental difference between this result and Lemma 1.2 is that the latter only works for any modulo and not just 1.\(^2\) This is not the way it is defined later. However, for the sake of exposition, we start with this definition and refine it to have properties that also guarantee this property implicitly.
vertices of $P$ in $Z$. Clearly, this can be expensive in terms of the size of $Z$. Nevertheless, we can merge the ideas above (the “large-flow idea” and the “keep-full-path idea”) to get the desired result. To see this, let $P$ be a $(s, t)$-path in $D$. Let $Z$ be a set of vertices such that, either all the vertices of $P$ are in $Z$ or if the vertices of a $(u, v)$-subpath of $P$ are not in $Z$, then there are $k + 1$ internally vertex-disjoint $(u, v)$-paths in $D[Z]$. That is, if the vertices of a subpath are missing in $Z$, then $Z$ contains a witness of a large flow for the endpoints of this subpath. Observe that such a set $Z$ suffices to be a $k$-cut preserving set for $(s, t)$ in $D$. This is because if $P$ is an $(s, t)$-path in $D − A(A ⊆ E(D)$ and $|A| ≤ k)$, then either all the vertices of $P$ are in $Z$ or for any missing $(u, v)$-subpath of $P$, since there are $k + 1$ vertex-disjoint $(u, v)$-paths in $D[Z]$, at least one still remains in $D[Z] − A$. Thus, in $D[Z] − A$, one can find an $(s, t)$-path: for the missing subpaths of $P$ in $Z$, there exists some other path between the same endpoints in $D[Z] − A$ which together yield an $(s, t)$-walk (and hence an $(s, t)$-path) in $D[Z] − A$. These properties are formalized in Definition 3.1.

1.2.1 About Computing $k$-Cut Preserving Sets

Next we give an intuition for how one can compute such $k$-cut preserving sets for a digraph $D ∈ D_{α}$, each of whose strongly connected component has size at most $ℓ$. For exposition purposes, consider (for now), only the case where $D$ is acyclic (i.e. $ℓ = 1$). With a certain technical argument, the general case reduces to this one. Moreover, we use the definition of a $k$-cut preserving set from the beginning of this section for this illustration as it allows us to convey our ideas in a clearer manner.

The proof will use induction on $α$. As the base case, consider the case when $α = 1$, that is, $D$ is a transitive tournament. As $D$ is transitive, there exists a topological ordering of the vertices of $D$. Consider the set $S$ of vertices between $s$ and $t$ in this ordering. Note that any path from $s$ to $t$ only uses vertices in $S$. So, either $S$ is smaller than $k + 1$, and then $S ∪ \{s, t\}$ is a $k$-cut preserving set for $(s, t)$, or it can be seen that there is no arc-cut for $(s, t)$ of size at most $k$. In the latter case, the union of $\{s, t\}$ and any subset of $k + 1$ vertices of $S$ is a $k$-cut preserving set for $(s, t)$; indeed, in the subgraph induced by the union there is still no arc-cut for $(s, t)$ of size at most $k$.

Now, let us hint at how the inductive step of the proof works. First, we note that, if $P_1, ⋯, P_{k+1}$ are $k + 1$ internally vertex-disjoint $(s, t)$-paths, then $Z = ∪_{i∈[k+1]} P_i$ is a $k$-cut preserving set for the pair $(s, t)$, because there is no arc-cut of $(s, t)$ in both $D$ and $D[Z]$ of size at most $k$. Moreover, since $D$ is acyclic and $D ∈ D_{α}$, if these paths exist, then Observation 2.1 implies that we can assume that all these paths are shorter than $2α + 1$ and thus $|Z| ≤ k(2α + 1)$.

The last argument means that we can assume the existence of a $(s, t)$-vertex cut of size at most $k$. For simplicity, suppose that $\{c_1, c_2\}$ is a minimal $(s, t)$-vertex -cut. Since $\{c_1, c_2\}$ is a vertex cut, any path from $s$ to $t$ in $D$ can be decomposed as a path from $s$ to $c_i$, a path from $c_i$ to $c_j$ and then a path from $c_j$ to $t$, where $i$ and $j$ are two indices (possibly equal) in $\{1, 2\}$. Here, we mean that none of the three paths contains $c_i$ or $c_j$ as an internal vertex. For $i ∈ \{1, 2\}$, let $S_i$ be the union of the set of vertices of the paths from $s$ to $c_i$ that intersect $\{c_1, c_2\}$ only on the last vertex, and $T_i$ be the union of the set of vertices of the paths from $c_i$ to $t$ that intersect $\{c_1, c_2\}$ only on the first vertex. Finally, for distinct $i, j ∈ \{1, 2\}$, let $C_{i, j}$ be the union of the set of vertices of the paths from $c_i$ to $c_j$. Because of the last remark on how any path from $s$ to $t$ can be decomposed, taking the union of six $k$-cut preserving sets-namely, for each $i, j ∈ \{1, 2\}$, $i ≠ j$, for $(s, c_i)$ in $D[S_i]$, $(c_i, t)$ in $D[T_i]$ and $(c_i, c_j)$ in $D[C_{i, j}]$, gives a $k$-cut preserving set for $(s, t)$ in $D$. Now, the question is how to use the induction hypothesis to find a $k$-cut preserving set for each of these pairs. Consider first
the digraph induced by the vertices in \( S_1 \). Because \( \{c_1,c_2\} \) is a minimal \((s,t)\)-vertex cut, the only vertices of \( S_1 \) that can possibly have “outgoing arcs towards” \( t \) in \( S_1 \) are \( s \) and \( c_1 \). Moreover, since \( \{c_1,c_2\} \) is a minimal \((s,t)\)-vertex cut, there exists a path from \( c_1 \) to \( t \) in \( D \) and thus \( t \) is reachable from any vertex of \( S_1 \). However, since \( D \) is acyclic, this means that there is no arc from \( t \) to any of the vertices of \( S_1 \), else we would get a closed walk and thus a cycle. This implies that \( D[S_1 \setminus \{s,c_1\}] \in D_{\alpha-1} \) as any independent set of \( S_1 \setminus \{s,c_1\} \) can be extended with \( t \). We cannot apply the induction hypothesis to find a \( k \)-cut preserving set for \((s,c_1)\) in \( S_1 \) because the independence number of \( D[S_1] \) could be equal to \( \alpha \), however the above shows the spirit of the arguments that will be used to find subgraphs with smaller independence number where we can apply the induction hypothesis. A similar argument would also give that the independence number of \( D[T_1 \setminus \{c_1,t\}] \) is at most \( \alpha - 1 \) as any independent set can be extended using \( s \).

The previous argument does not apply to \( C_{1,2} \), because the vertices of \( C_{1,2} \) can be adjacent to \( s \) or \( t \) (some vertices of \( C_{1,2} \) can be adjacent to \( s \) and some can be adjacent to \( t \)). This is the case that requires a stronger and more technical definition for a \( k \)-cut preserving set. In particular, we need to understand what happens to the vertices of \( D \) that are on a path from \( s \) to \( t \) but do not belong to a \( k \)-cut preserving set for this pair.

### 1.3 Deriving Polynomial Kernels for DFAS

Let us now briefly explain how to derive a polynomial kernel for DFAS when the input digraph belongs to \( D_{\alpha} \), from our result on fault-tolerant subgraphs. First note that if \( D \in D_{\alpha} \) then every induced cycle in \( D \) has length at most \( 2\alpha + 1 \). Let \((D,k)\) be an instance of DFAS, and consider a maximal set of arc disjoint induced cycles in \( D \). If this set consists of more than \( k \) cycles, then any solution to \((D,k)\) has to pick one arc per cycle, and \((D,k)\) is a NO instance. If not, let \( S \) be the union of these cycles. \( S \) is a set of less than \((2\alpha + 1) \cdot k \) vertices such that \( D - S \) is acyclic. Therefore, we can apply our result to find a solution \( H \) to the problem of Fault-Tolerance (\( S,S \))-Reachability of size at most \( |S|^{2k^{O(\alpha)}} \). We claim that \( H \) is the desired kernel. Indeed, suppose that \( A \) is a set of arcs such that \( H - A \) is acyclic, but \( D - A \) contains a cycle. By construction of \( S \), this cycle must use vertices of \( S \). However, we know that if a path exists between two vertices of \( S \) in \( D - A \), then such a path also exists in \( H - A \). This implies the existence of a closed walk in \( H - A \), a contradiction.

### 2 Preliminaries

For standard notations and terminology that is not defined here, we refer to [25].

**Sets.** For positive integer \( i,j, [i] \) denotes the set \( \{1,\ldots,i\} \) and \([i,j]\) denote the set \( \{i,i+1,\ldots,j\} \). For a set \( S \), \( S^2 \) denotes the set of ordered pairs of \( S \), that is \( S^2 = \{(u,v) \mid u \in S, v \in S\} \).

**Digraphs.** For a digraph \( D \), \( V(D) \) denotes the vertex set of \( D \) and \( E(D) \) denotes the arc set of \( D \). For any \( X \subseteq V(D) \) (resp. \( X \subseteq E(D) \)), \( D - X \) denotes the digraph obtained by deleting the vertices (resp. edges) of \( X \). For any \( v \in V(D) \), \( N^+_D(v) \) (resp. \( N^-_D(v) \)) denotes the set of out-neighbours (resp. in-neighbours) of \( v \) in \( D \), that is \( N^+_D(v) = \{ u \in V(D) \mid (v,u) \in E(D) \} \) (resp. \( N^-_D(v) = \{ u \in V(D) \mid (u,v) \in E(D) \} \)). Whenever the digraph \( D \) is clear from the context, we drop the subscript \( D \) in \( N^+_D(v) \) (resp. \( N^-_D(v) \)). For any \( X,Y \subseteq V(D) \), \( E(X,Y) \) denotes the set of arcs of \( D \) with tail in \( X \) and head in \( Y \), that is, \( E(X,Y) = \{ (u,v) \in E(D) \mid u \in X, v \in Y \} \). A digraph \( D \) is called strongly connected if for each \( u,v \in V(D) \) there
is a path from \( u \) to \( v \) and, a path from \( v \) to \( u \) in \( D \). A set \( X \subseteq V(D) \) is called a strongly connected component of \( D \) if \( D[X] \) is a strongly connected digraph and for each \( X' \supseteq X \), \( D[X'] \) is not a strongly connected digraph. A tournament is a digraph where there is exactly one arc between each pair of vertices. A digraph with no cycles is called a directed acyclic graph (dag). A tournament with no cycles is called a transitive tournament.

**Paths.** A path \( P \) is a graph such that there exists an ordering \((v_1, \ldots, v_q)\) of its vertex set \( V(P) \) such that \( E(P) = \{(v_i, v_{i+1}) \mid i \in [q-1]\} \). Such a path is called a \((v_1, v_q)\)-path, \( v_1, v_q \) are called the end-points of \( P \) and \( v_2, \ldots, v_{q-1} \) are called the internal vertices of \( P \). A path \( P \) is even (resp. odd) if the number of arcs/edges in it is even (resp. odd). We say that \( P \) is a path in the digraph \( D \) if \( P \) is a subgraph of \( D \). We say that \( P \) is an induced path in \( D \) if \( P \) is an induced subgraph of \( D \). For paths \( P \) and \( P' \), by \( P \circ P' \) we denote the composition of \( P \) and \( P' \), that is, the path obtained by appending \( P' \) after \( P \). For paths \( P, P_1, P_2, \ldots, P_q \) such that \( P = P_1 \circ P_2 \circ \ldots \circ P_q \), we say that \( P_1 \circ P_2 \circ \ldots \circ P_q \) is a partition of \( P \). For a digraph \( D \) and \( X \subseteq V(D) \), we say that a \((u, v)\)-path \( P \) in \( D \) is \( X \)-free if none of the internal vertices of \( P \) are from \( X \). The \( X \)-based partition of \( P \) in \( D \) is the partition \( P = P_1 \circ \ldots \circ P_q \) such that the union of the end-points of \( P_i \), \( i \in [q] \), is exactly the set \( (X \cap V(P)) \cup \{u, v\} \). A semi-\( X \)-based partition of \( P \), \( P = P_1 \circ \ldots \circ P_q \), is such that the end-points of the paths \( P_i \), \( i \in [q] \), are a subset of \( (X \cap V(P)) \cup \{u, v\} \). Paths \( \{P_1, \ldots, P_q\} \) are internally vertex-disjoint if for all distinct \( i, j \in [q] \), the sets of internal vertices of \( P_i \) and \( P_j \) are disjoint.

**Vertex and Arc Cuts.** For a digraph \( D \) and \( u, v \in V(D) \), a \((u, v)\)-arc cut is a set of arcs of \( D \), say \( X \), such that \( D - X \) has no \((u, v)\)-path. A \((u, v)\)-vertex cut is a set of vertices of \( D \), say \( Y \), such that \( D - Y \) has no \((u, v)\)-path and \( u, v \not\in Y \) if \((u, v) \not\in E(D)\).

**Observation 2.1.** Let \( D \in \mathcal{D}_\alpha \). The length of the shortest cycle in \( D \) is at most \( 2\alpha + 1 \). Also, the length of any induced path in \( D \) is at most \( 2\alpha + 1 \).

In this article, we focus of the proof of Lemma 1.1 alone. The proofs of Lemma 1.2 and Theorems 1.6, 1.8, 1.5, 1.6, 1.7, 1.8 will be made available later in the full version of the paper.

### 3 Finding Small \( k \)-Cut Preserving Sets

We give the precise definition of a \( k \)-cut preserving set here.

**Definition 3.1 (\( k \)-Cut Preserving Set).** For digraph \( D \), an ordered pair \((u, v)\) of vertices of \( D \) and a positive integer \( k \), \( \{u, v\} \subseteq Z \subseteq V(D) \) is a \( k \)-cut preserving set for \((u, v)\) in \( D \) if the following holds. For any \((u, v)\)-path \( P \) in \( D \), there exists a semi-\( Z \)-based partition \( P_1 \circ \ldots \circ P_q \) of \( P \) with the following two properties. For each \( i \in [q] \), \( P_i \) is an \((s_i, t_i)\)-path in \( D \) with \( s_i, t_i \in Z \). Moreover, either \( V(P_i) \subseteq Z \) or there exists a list \( \mathcal{L}_i \) of \( k + 1 \) internally vertex-disjoint \((V(D) \setminus Z)\)-free \((s_i, t_i)\)-paths. A list \( \mathcal{L}_i \) with the above property is called a replacement kit for \( P_i \) in \( Z \). Such a semi-\( Z \)-based partition of \( P \) is called a \( Z \)-replacement witness for \( P \).

Before moving to the computational aspects of a \( k \)-cut preserving set, we give the following lemma that can be considered as the main utility of \( k \)-cut preserving sets, and relate to the intuition we gave in the previous section.

**Lemma 3.2.** Let \( D \) be a digraph, \( u, v \in V(D) \) and \( Z \) be a \( k \)-cut preserving set for \((u, v)\) in \( D \). For any set \( A \subseteq E(D) \) of at most \( k \) arcs, if there exists a \((u, v)\)-path in \( D - A \), then there also exists one in \( D[Z] - A \).
Proof. Consider some $A \subseteq E(D)$ such that $|A| \leq k$. Suppose there exists a $(u, v)$-path $P$ in $D - A$. Since $Z$ is a $k$-cut preserving set for the pair $(u, v)$, there exists a semi-$Z$-based partition $P = P_1 \circ \ldots \circ P_d$ such that for each $j \in [d]$, $P_j$ is an $(s_j, t_j)$-path, $s_j, t_j \in Z$ and, either $V(P_j) \subseteq Z$, in which case $P_j$ is a path in $D[Z] - A$, or there exist $k + 1$ internally vertex-disjoint $(s_j, t_j)$-paths in $D[Z]$. In the later case, at least one of the $k + 1$ paths is in $D[Z] - A$ (because $|A| \leq k$). This implies the existence of a walk from $u$ to $v$ (and hence also a $(u, v)$-path) in $D[Z] - A$. This concludes the proof. ▷

The main goal of this section is to prove the following lemma.

Lemma 3.3 (k-Cut Preserving Lemma). Let $D$ be an acyclic digraph, and $u, v \in V(D)$ be such that $N^-(u) = N^+(v) = \emptyset$. Additionally, let $D - \{u, v\} \in \mathcal{D}_n$. Then there exists a $k$-cut preserving set for $(u, v)$ in $D$ of size at most $f(\alpha)$, where $f(1) = k^3 + 5k^2 + 3k$ and for $\alpha > 1$, $f(\alpha) = k^2g(\alpha) + 2k^2h(\alpha)$, $g(\alpha) = (2k + (k + k\alpha(\alpha - 1))^2)f(\alpha - 1) + h(\alpha) = (k + 1\alpha(\alpha - 1))^2f(\alpha - 1)$. Moreover, such a set can be found in time $n\alpha(1)$, where $n = |V(D)|$.

Note that $V(D)$ is always a $k$-cut preserving set for any pair of vertices $(u, v)$ in $D$, for any $k$. We now define a notation, for the sake of convenience, that will be used throughout this section. For any digraph $D$, $u, v \in V(D)$ and $X \subseteq V(D)$, let $\text{ver}(u, v; X)$ denote the union of the sets of vertices of all $X$-free $(u, v)$-paths in $D$. Observe that $\text{ver}(u, v; X) \cap X \subseteq \{u, v\}$. We begin by making an observation that forms the base line for computing small sized $k$-cut preserving sets using an appropriate induction.

Observation 3.4. Let $D$ be a digraph, $u, v \in V(D)$, $Z \subseteq V(D)$ and $k$ be a positive integer. Let $P$ be a $(u, v)$-path in $D$, and $P = P_1 \circ \ldots \circ P_d$ be a semi-$Z$-based partition of $P$. If for each $i \in [d]$, there is a $Z_i$-replacement witness for $P_i$ in $D_i$, for some $Z_i \subseteq Z$ and $D_i$ subgraph of $D$, then there is a $Z$-replacement witness for $P$.

Proof. For each $i \in [d]$, let $P_i = P_{1i} \circ \ldots \circ P_{ci}$ be a $Z_i$-replacement witness for $Z_i$ in $D_i$. Then, consider the semi-$Z$-based partition $P = P_{11} \circ \ldots \circ P_{1c_1} \circ P_{21} \circ \ldots \circ P_{2c_2} \circ \ldots \circ P_{dc_d}$. Then, for each $i \in [d]$ and $j \in [c_i]$, either $V(P_{ij}) \subseteq Z_i \subseteq Z$, or there exists a list $Z_{i,j}$ containing $k + 1$ internally vertex-disjoint $(V(D_i) \setminus Z_i)$-free $(x_{i,j}, y_{i,j})$-paths in $D_i$ such that $P_{ij}$ is a $(x_{i,j}, y_{i,j})$-path. Since $Z_i \subseteq Z$ and $D_i$ is a subgraph of $D$, the paths in $\mathcal{L}_{i,j}$ are $(V(D) \setminus Z)$-free and exist in $D$. ▷

Next, we give two lemmas (Lemmas 3.5 and 3.6) that basically use Observation 3.4 in a more concrete setting required to prove the k-Cut Preserving Lemma by induction on the size of the maximum independent set in the digraph.

Lemma 3.5. Let $D$ be a digraph, $u, v \in V(D)$ and $k$ be a positive integer. Let $C$ be some $(u, v)$-vertex cut in $D$. For each $c \in C$, let $Z(u, c)$ (resp. $Z(c, v)$) be a $k$-cut preserving set for $(u, c)$ (resp. $(c, v)$) in $D[\text{ver}(u, c; C)]$ (resp. $D[\text{ver}(c, v; C)]$). For each $(c, c') \in C^2$, $c \neq c'$, let $Z(c, c')$ be a $k$-cut preserving set for $(c, c')$ in $D[\text{ver}(c, c'; C)]$. Then, $Z := \bigcup_{c \in C} Z(u, c) \cup Z(c, v) \cup \bigcup_{(c, c') \in C^2, c \neq c'} Z(c, c')$ is a $k$-cut preserving set for $(u, v)$ in $D$.

Proof. First observe, from the definition of a k-cut preserving set and the construction of $Z$, that $C \subseteq Z$. Consider any $(u, v)$-path $P$ in $D$. Let $P = P_1 \circ \ldots \circ P_q$ be the $C$-based partition of $P$. Since $C \subseteq Z$, $P_1 \circ \ldots \circ P_q$ is a semi-$Z$-based partition of $P$. Then $P_1$ is a $C$-free $(u, c_1)$-path in $D$ for some $c_1 \in C$, $P_q$ is a $C$-free $(c_2, v)$-path in $D$ for some $c_2 \in C$, and for each $i \in [2, q - 1]$, $P_i$ is a $C$-free $(c_i, c_{i+1})$-path in $D$, for some
Thus, $P_1$ is a $(u, c_1)$-path in $D[\text{ver}_D(u, c_1; C)]$, $P_2$ is a $(c_2, v)$-path in $D[\text{ver}_D(c_2, v; C)]$, and for each $i \in [2, q - 1]$, $P_i$ is a $(c_j, c_{j+1})$-path in $D[\text{ver}_D(c_j, c_{j+1}; C)]$. Since $Z(u, c_1), Z(c_2, v), \cup_{i \in [2, q - 1]} Z(c_j, c_{j+1}) \subseteq Z$, we are done by Observation 3.4.

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{figure2}
\caption{(c_1, c_2) is a $(u, v)$-vertex-cut, the green parts correspond to the $Z(c_i, v)$ and the blue vertices are the vertices of $X$. $P_1$ is a path of Type $(u, \square)$, $P_2$ is a path of Type $(\square, \square)$ and $P_3$ is a path of Type $(\square, \square, v)$ with $y \in Y$.}
\end{figure}

\textbf{Lemma 3.6.} Let $D$ be a digraph, $u, v \in V(D)$, and $k$ be a positive integer. Let $C$ be some $(u, c)$-vertex cut in $D$. For each $c \in C$, let $Z(u, c)$ (resp. $Z(c, v)$) be a $k$-cut preserving set for $(u, c)$ (resp. $(c, v)$) in $D[\text{ver}_D(u, c; C)]$ (resp. $D[\text{ver}_D(c, v; C)]$). Let $X = N_D^-(v) \cap \cup_{e \in C} Z(c, v)$. For each $(a, b) \in (C \cup X)^2$, $a \neq b$, let $Z(a, b)$ be a $k$-cut preserving set for $(a, b)$ in $D[\text{ver}_D(a, b; C \cup N_D^-(v))]$. Then, $Z := \cup_{e \in C} (Z(u, c) \cup Z(c, v)) \cup \cup_{(a, b) \in (C \cup X)^2, a \neq b} Z(a, b)$ is a $k$-cut preserving set for $(u, v)$ in $D$.

\textbf{Proof.} First observe that $(u, v) \cup C \cup X \subseteq Z$. Let $Y = N_D^-(v) \setminus X$. We begin by defining some special types of paths (see Figure 2).

1. A path $P$ is of Type $(u, \square)$ (resp. $(\square, v)$) if it is a $C$-free $(u, c)$-path (respectively $(c, v)$-path) in $D$ for some $c \in C$.
2. A path $P$ is of Type $(\square, \square)$ if it is a $(C \cup N_D^-(v))$-free $(a, b)$-path in $D$ for some $(a, b) \in (C \cup X)^2$.
3. A path $P$ is of Type $(\square, \square, v)$ if it is a $(c, v)$-path in $D$ for some $c \in C$ and there exists $y \in V(P) \cap Y$ such that the $(c, y)$-subpath of $P$ is $C$-free.\footnote{Specifically, if there exists $y \in V(P) \cap Y$ with this property, then the first vertex of $P$ that belongs to $Y$ also has that property.}

We now begin with the proof of the lemma. Let $P$ be some $(u, v)$-path. We need to show that there is a $Z$-replacement witness for $P$. Let $P = P'_1 \circ \ldots \circ P'_q$ be the $(C \cup X)$-based partition of $P$. If $P$ is not $Y$-free, that is, $V(P) \cap Y \neq \emptyset$, let $s' \in [q]$ be the least integer such that $V(P'_{s'}) \cap Y \neq \emptyset$. If $P$ is $Y$-free, let $s' = q$. Let $s \leq s'$ be the largest integer such that $P_s$ is an $(a, b)$-path, where $a \in C$ and $b \in C \cup X \cup \{v\}$. WE first show that such a $s$ always exists. From the definition of $s'$, either there exists some $y \in Y$ in $V(P'_{s'})$ or $v \in V(P'_{s'})$. In the later case, since $C$ is a $(u, v)$-vertex cut, there exists $c \in C$ such that $c$ appears on $P$. Since $P = P'_1 \circ \ldots \circ P'_q$ is a $C \cup X$-based partition of $P$, there exists $s \leq s'$ such that $P_s$ is a $(a, b)$-path where $a \in C$. In the former case again, since $y \in Y \subseteq N_D^-(v)$ and $C$ is a $(u, v)$-vertex cut using previous arguments the existence of the desired $s$ is guaranteed.
Consider the partition \( P = P_1 \circ \ldots \circ P_s \), such that \( P_i = P_i' \), if \( i < s \) and \( P_s = P_s' \circ P_{s+1}' \circ \ldots \circ P_q' \). Observe that, since \( C \cup X \subseteq Z \), \( P = P_1 \circ \ldots \circ P_s \) is a semi-\( Z \)-based partition of \( P \).

\[ \triangleright \text{Claim 3.7.} \quad P_i \text{ is a Type } (u, \Box) \text{ path, for each } i \in [2, s-1], \quad P_i \text{ is a Type } (\mathbb{X}, \mathbb{X}) \text{ path and,} \]
\[ \quad P_s \text{ is either a Type } (\Box, v) \text{ or Type } (\Box, \Box, v) \text{ path.} \]

\[ \text{Proof.} \quad \text{Recall that } P = P_1' \circ \ldots \circ P_q' \text{ is the } (C \cup X)\text{-based partition of } P. \text{ Thus, we have the following.} \]

1. For each \( i \in [q] \), \( P_i' \) is \((C \cup X)\)-free path.
2. For each \( i \in [2, q-1] \), \( P_i' \) is a \((a, b)\)-path, where \((a, b) \in (C \cup X)^2\).
3. Since \( C \) is a \((u, v)\)-vertex cut in \( D \) and \( X \subseteq N_D^-(v) \), \( P_1' \) is a \((u, c)\)-path for some \( c \in C \).
4. From the choice of \( s \), for each \( i \in [s-1] \), \( V(P_i') \cap Y = \emptyset \). Since for \( i \in [s-1] \), \( P_i = P_i' \) and \( X \cup Y = N_D^-(v) \), \( P_i \) is \((C \cup N_D^-(v))\)-free.

Thus, from Points 2 and 4, for each \( i \in [s-1] \), \( P_i \) is of Type \((\Box, v)\). Also, from Points 3 and 4, \( P_1 \) is of Type \((u, \Box)\). We now show that \( P_s \) is of Type \((\Box, v)\) or \((\Box, \Box, v)\). From the choice of \( s \) and the construction of \( P_s \), \( P_s \) is a \((c, v)\)-path for some \( c \in C \). If \( P \) is \( Y \)-free, then \( P_s \) is of Type \((\Box, v)\), otherwise, \( P_s \) is of Type \((\Box, \Box, v)\).

For each \( i \in [s] \), define \( Z_i \) and \( D_i \) as follows.

\[ Z_i = \begin{cases} 
Z(u, c) & \text{if } i = 1, \text{ } P_1 \text{ is a } (u, c)\text{-path, } c \in C \\
Z(a, b) & \text{if } i \in [2, s-1], \text{ } P_i \text{ is a } (a, b)\text{-path, } (a, b) \in (C \cup X)^2 \\
Z(c, v) & \text{if } i = s, \text{ } P_s \text{ is a } (c, v)\text{-path, } c \in C
\end{cases} \]

\[ D_i = \begin{cases}
D[\text{ver}_D(u, c; C)] & \text{if } i = 1, \text{ } P_1 \text{ is a } (u, c)\text{-path, } c \in C \\
D[\text{ver}_D(a, b; (C \cup N_D^-(v)))] & \text{if } i \in [2, s-1], \text{ } P_i \text{ is a } (a, b)\text{-path, } (a, b) \in (C \cup X)^2 \\
D[\text{ver}_D(c, v)] & \text{if } i = s, \text{ } P_s \text{ is a } (c, v)\text{-path, } c \in C
\end{cases} \]

Recall the construction of \( Z \) from the lemma statement. Observe that for each \( i \in [s] \), \( Z_i \subseteq Z \). From Observation 3.4, to give a \( Z \)-replacement witness for \( P_i \), it is enough to give a \( Z_i \)-replacement witness for each \( P_i \), in \( D_i \), \( i \in [s] \). Thus, the following claim will finish the proof of the lemma.

\[ \triangleright \text{Claim 3.8.} \quad \text{For each } i \in [s], \text{ } P_i \text{ has a } Z_i\text{-replacement witness in } D_i. \]

\[ \text{Proof.} \quad \text{We prove the claim using the following cases.} \]

\begin{itemize}
  
  \item \textbf{Case } \( i = 1 \): From Claim 3.7, \( P_1 \) is a \( C \)-free \((u, c)\)-path in \( D \) for some \( c \in C \). Thus, \( P_1 \) is a \((u, c)\)-path in \( D_1 \). Since \( Z_1 \) is a \( k \)-cut preserving set for \((u, c)\) in \( D_1 \), there exists a \( Z_1 \)-replacement witness for \( P_1 \) in \( D_1 \).

  \item \textbf{Case } \( i \in [2, s-1] \): From Claim 3.7, when \( i \in [2, s-1] \), then \( P_i \) is a \((C \cup N_D^-(v))\)-free \((a, b)\)-path in \( D \) for some \((a, b) \in (C \cup X)^2 \). Thus, \( P_i \) is an \((a, b)\)-path in \( D_i \). Since \( Z_i \) is a \( k \)-cut preserving set for \((a, b)\) in \( D_i \), there exists a \( Z_i \)-replacement witness for \( P_i \) in \( D_i \).

  \item \textbf{Case } \( i = s \): From Claim 3.7, \( P_s \) is of either Type \((\Box, v)\) or Type \((\Box, \Box, v)\).

  \item \( P_s \) is of Type \((\Box, v)\): From the definition of Type \((\Box, v)\), \( P_s \) is a \( C \)-free \((c, v)\)-path in \( D \), for some \( c \in C \). Thus, \( P_s \) is a \((c, v)\)-path in \( D_s \). Since \( Z_s \) is a \( k \)-cut preserving set for \((c, v)\) in \( D_s \), there exists a \( Z_s \)-replacement witness for \( P_s \) in \( D_s \).

\end{itemize}
As explained in Section 1.2, the proof of Lemma 3.3 will distinguish whether there is a path where the length of each \( k \)-vertex disjoint paths. Since every \( k \)-vertex disjoint paths, \( P \) is the \( (c,y) \)-subpath of \( P \). Recall that \( Y = N_P(v) \setminus X \). Consider the \( (c,v) \)-path in \( D \), denoted by \( P_c \), obtained by appending the arc \((y,v)\) at the end of \( P_c \). That is, \( P_c = P_c \oplus (y,v) \). Since \( P_c \) is a \( C \)-free path, so is \( P_c \). Thus \( P_c \) is a \((c,v)\)-path in \( D_c \). Since \( Z \) is a \( k \)-cut preserving set for \((c,v)\) in \( D_c \), there exists a semi-\( Z \)-based partition of \( P \), which is a \( Z \)-replacement witness for \( P \) in \( D_c \). Let \( P_c = P_{c,1} \circ \cdots \circ P_{c,r} \) be one such partition. Since \( y \in Y = N_P(v) \setminus X \) and \( Z \nsubseteq X \), \( y \notin Z \). Thus, \( y \) is an internal vertex of \( P_{c,r} \). Let \( P_{s,r} \) be an \((x,v)\)-path. Clearly, \( x \in Z \) because \( P_s = P_{s,1} \circ \cdots \circ P_{s,r} \) is a semi-\( Z \)-based partition. Let \( P^1_{s,r} \) be the \((x,v)\)-subpath of \( P_{s,r} \). We claim that \( P_s = P_{s,1} \circ \cdots \circ P_{s,r-1} \circ P^1_{s,r} \) is a semi-\( Z \)-based partition of \( P_s \). It is clear from the discussion above that \( P_s = P_{s,1} \circ \cdots \circ P_{s,r-1} \circ P^1_{s,r} \) is a semi-\( Z \)-based partition of \( P_s \). We will now show that \( P_s \) is a \( Z \)-replacement witness for \( P_s \) in \( D_c \).

Since \( P_s = P_{s,1} \circ \cdots \circ P_{s,r} \) is a \( Z \)-replacement witness for \( P_s \), we have that for each \( j \in [r] \), \( V(P_{s,j}) \subseteq Z \) or there exists a list \( L_j \) containing \( k + 1 \) vertex disjoint paths from the start vertex of \( P_{s,j} \) to its end vertex. Also, since \( y \notin Z \) and \( y \) is an internal vertex of \( P_{s,r} \), \( V(P_{s,r}) \nsubseteq Z \). Thus, there is a list \( L_r \) containing \( k + 1 \) vertex disjoint \((x,v)\)-paths (recall \( x \) and \( v \) are the start and end vertices, respectively, of \( P_{s,r} \)). Since \( P_s = P_{s,1} \circ \cdots \circ P_{s,r-1} \circ P^1_{s,r} \) and \( P^1_{s,r} \) is an \((x,v)\)-path, from the above discussion for each \( j \in [r-1] \), either \( V(P_{s,j}) \subseteq Z \) or there exists a list \( L_j \) containing \( k + 1 \) vertex disjoint paths from the start vertex of \( P_{s,j} \) to its end vertex. Also, there exists a list, \( L_r \), containing \( k + 1 \) vertex disjoint paths from the start vertex of \( P^1_{s,r} \) to its end vertex. This completes the proof of the claim.

As argued earlier, this completes the proof of the lemma.

3.1 Finding a Small \( k \)-Cut Preserving Set for a Pair with Large Flow

As explained in Section 1.2, the proof of Lemma 3.3 will distinguish whether there is a \( k \) vertex-cut for \((s,t)\) or not. The case where there is a \( k \) vertex-cut is the easiest one, and will be dealt with the following lemma by simply keeping \( k + 1 \) vertex disjoint paths.

Lemma 3.9. Let \( D \in \mathcal{D}_k \) be an acyclic digraph and \( u,v \in V(D) \) be such that each \((u,v)\)-vertex cut in \( D \) has size at least \( k + 1 \). Then, a \( k \)-cut preserving set for \((u,v)\) in \( D \) of size at most \((2a - 1)(k + 1) + 2 \) exists and is computable in \( n^{O(1)} \) time, where \( n = |V(D)| \).

Proof. Since every \((u,v)\)-vertex cut in \( D \) has size at least \( k + 1 \), from Menger’s Theorem, there are at least \( k + 1 \) vertex-disjoint \((u,v)\)-paths in \( D \). Let \( Q_1, \ldots, Q_{k+1} \) be a collection of some \( k + 1 \) of these paths. We will now obtain a collection of \( Q_1, \ldots, Q_{k+1} \) vertex disjoint paths where the length of each \( Q_i \) is at most \( 2a - 1 \). To this end, we define each \( Q_i \) as some shortest \((u,v)\)-path using the vertices of \( V(Q_i) \). We first claim that the length of \( Q_i \) is at most \( 2a - 1 \). For the sake of contradiction, suppose not. Then, from Observation 2.1, there exist \( x, y \in V(Q_i) \) such that \((x,y) \in E(D) \). Since \( D \) is acyclic, \( x \) appears before \( y \) in the path \( Q_i \). This contradicts that \( Q_i \) is a shortest \((u,v)\)-path in \( V(Q_i) \). Let \( Z = \bigcup_{i \in [k+1]} V(Q_i) \). Clearly, \([u,v] \subseteq Z \) and \(|Z| \leq (2a - 1)(k + 1) + 2 \). The size bound follows because the length of each \( Q_i \) is at most \( 2a - 1 \), and \( u,v \) are the vertices common in each \( Q_i \). To show that \( Z \) is a \( k \)-cut preserving set for \((u,v) \) in \( D \), consider the semi-\( Z \)-based partition of \( P \) that is \( P \) itself. Then, \([Q_1, \ldots, Q_{k+1}] \) is the list for \( P \) containing \( k + 1 \) internally vertex-disjoint \((V(D) \setminus Z)\)-free \((u,v)\)-paths.

\[\text{ITCS 2020}\]
3.2 Finding a Small $k$-Cut Preserving Set of a Pair in a Tournament

As explained before, the proof of Lemma 3.3 will use induction on $\alpha$. The next lemma handles the base case where $\alpha = 1$. It is somewhat more complicated compared to the arguments in Section 1.2; the reason for the complication is that we consider the digraph $D$ such that the $D - \{u, v\} \not\in \mathcal{D}_\alpha$. Thus $D$ is not “exactly” a tournament. This is required in the inductive case for the proof of Lemma 3.3.

\begin{lemma}
Let $D$ be an acyclic digraph. Let $u, v \in V(D)$ be such that $N^+(u) = N^-(v) = \emptyset$ and $D - \{u, v\}$ is a tournament. Then, a $k$-cut preserving set for $(u, v)$ in $D$ of size at most $k^3 + 5k^2 + 3k$ exists and is computable in polynomial time.
\end{lemma}

\begin{proof}
If all $(u, v)$-vertex cuts in $D$ have size at least $k + 1$, then the correctness follows from Lemma 3.9. Thus, for the rest of the proof assume that there is a $(u, v)$-vertex-cut in $D$ of size at most $k$. Let $C = \{c_1, \ldots, c_l\}$ be a minimal $(u, v)$-vertex cut in $D$ of size $\ell \leq k$.

\begin{claim}
$C \subseteq N_D^+(u) \cup N_D^-(v)$.
\end{claim}

\begin{proof}
Suppose not. Then, there exists $c_i \in C$ such that $c_i \notin N_D^+(u) \cup N_D^-(v)$. Since $C$ is a minimal $(u, v)$-vertex cut in $D$, there exists a path, say $P$, from $u$ to $v$ in $D - (C \backslash \{c_i\})$. Let $u'$ be the first vertex on $P$ after $u$ and $v'$ be the last vertex of $P$ before $v$. Since $D - \{u, v\}$ is an acyclic tournament, $(u', v') \in E(D)$. Since $u', v' \notin C$, we get a $(u, v)$-path in $D - C$, contradicting that $C$ is a $(u, v)$-vertex cut in $D$.
\end{proof}

Let $I = \{i \in \ell \mid c_i \in N_D^+(v)\}$ and $J = \{j \in \ell \mid c_j \in N_D^-(u)\}$. For all $i \in I$, let $U_i = \text{ver}_D(u, c_i; C)$ and $D_i = D[U_i]$. For all $j \in J$, let $V_j = \text{ver}_D(c_j, v; C)$ and $D_j = D[V_j]$. For all $(i, j) \in [\ell]^2$, $i \neq j$, let $Q_{i,j} = \text{ver}_D(c_i, c_j; \emptyset)$ and $D_{i,j} = D[Q_{i,j}]$.

For each $i \in I$ (resp. $j \in J$, resp. $(i, j) \in [\ell]^2$, $i \neq j$), we will compute a $k$-cut preserving set $Z_i$ (resp. $Z_j$, resp. $Z_{i,j}$) of $(u, c_i)$ (resp. $(c_j, v)$, resp. $(c_i, c_j)$) in $D_i$ (resp. $D_j$, resp. $D_{i,j}$) of size at most $2k + 3$ (resp. $2k + 3$, resp. $k + 3$). The procedure to do so is as follows.

- Computing $Z_i, i \in I$: First observe that $U_i$ is a candidate for $Z_i$. Thus, if $|U_i| \leq 2(k + 1)$, set $Z_i = U_i$. Otherwise, we have that $|U_i| \geq 2k + 3$. Since $D - \{u, v\}$ is an acyclic tournament, let $\pi$ be the unique topological ordering of $D - \{u, v\}$. We divide this case further into two cases.

Case 1: $|N^+(u) \cap U_i| \leq k$: Let $\tilde{U}_i$ be the last $k + 1$ vertices of $U_i$ in $\pi$. Observe that $\tilde{U}_i \subseteq N^-(c_i) \cup U_i$. Define $Z_i = (N^+(u) \cap U_i) \cup \tilde{U}_i \cup \{u, c_i\}$. Clearly, $|Z_i| \leq 2k + 3$.

To prove that $Z_i$ is a $k$-cut preserving set for $(u, c_i)$ in $D_i$, consider some $(u, c_i)$-path $P$ in $D_i$, such that $V(P) \not\subseteq Z_i$. We will show a $Z_i$-replacement witness for $P$ in $D_i$.

Consider the semi-$Z_i$-based partition of $P$, $P = P_1 \lor P_2$, where $P_1$ is the arc $(u, x) \in E(P)$, for some $x \in N^+(u) \cap U_i$ and $P_2$ is the $(x, c_i)$-subpath of $P$. Clearly, $V(P_1) \subseteq Z_i$. We claim that there are $k + 1$ vertex-disjoint $(x, c_i)$-paths in $Z_i$. To see this, consider the following argument. Since $V(P) \not\subseteq Z_i$, there exists a vertex $y \in V(P)$ such that $y \notin Z_i$. Then, $y \in V(P_2)$. Since $y \notin Z_i$, it in particular holds that $y \notin \tilde{U}_i$.

Thus, all the vertices of $\tilde{U}_i$ appear after $y$ in $\pi$. Since there is a $(x, y)$-path in $D_i$, $x$ appears before $y$ in $\pi$. Thus, $x$ appears before all the vertices of $\tilde{U}_i$ in $\pi$. Thus, because $D - \{u, v\}$ is a tournament, $\tilde{U}_i \subseteq N^+(x) \cap U_i$. Since $\tilde{U}_i \subseteq N^-(c_i) \cap U_i$, there are $|\tilde{U}_i|$ many vertex disjoint $(x, c_i)$-paths in $Z_i$. This completes the proof.

Case 2: $|N^+(u) \cap U_i| > k$: First observe that all the vertices of $N^+(u) \cap U_i$ appear before $c_i$ in $\pi$. Since $\pi$ is a topological ordering of $D - \{u, v\}$, there are $|N^+(u) \cap U_i| > k$ vertex-disjoint $(u, c_i)$-paths in $Z_i$. Thus, each $(u, c_i)$-vertex cut in $D_i$ has size at least $k$. 

$k + 1$. In this case, let $Z_i$ be the $k$-cut preserving set for $(u, c_i)$ in $D_i$ obtained from Lemma 3.9. Observe that $|Z_i| \leq k + 3$.

Computing $Z_j$, $j \in J$: $Z_j$ can be computed using arguments symmetric to the previous case.

Computing $Z_{i,j}$, $(i, j) \in [\ell]^2$, $i \neq j$: First observe that all the vertices of $Q_{i,j} \setminus \{c_i, c_j\}$ appear after $c_i$ and before $c_j$ in $\pi$. Thus, there are $|Q_{i,j} \setminus \{c_i, c_j\}|$ many vertex-disjoint $(c_i, c_j)$-paths in $D_{i,j}$. If $|Q_{i,j}| \leq k - 2$, then set $Z_i = Q_{i,j}$, otherwise let $Z_i$ be the $k$-cut preserving set for $(c_i, c_j)$ in $D_{i,j}$ obtained from Lemma 3.9. In either case, $|Z_i| \leq k + 3$.

Let $Z := \bigcup_{i \in I} Z_i \cup \bigcup_{j \in J} Z_j \cup \bigcup_{(i,j) \in \ell^2, i \neq j} Z_{i,j}$. Observe that $C \subseteq Z$. First note that $|Z| \leq |I|(2k + 3) + |J|(2k + 3) + \ell^2(k + 3) \leq k^3 + 5k^2 + 3k^2$ (the last inequality holds because $|I| + |J| = \ell$ and $\ell \leq k$). We will now show that $Z$ is a $k$-cut-preserving set for $(u, v)$ in $D$. To see this, consider some $(u, v)$-path $P$, in $D$. Since $C$ is a $(u, v)$-vertex-cut in $D$ there exists a vertex of $C$ on $P$. Let $c_i$ be the first vertex of $C$ on $P$ and $c_j$ be the last vertex of $C$ on $P$ $(c_i$ could be the same as $c_j)$. Let $P_1$ be the $(u, c_i)$-subpath of $P$, $P_2$ be the $(c_i, c_j)$-subpath of $P$ and $P_3$ be the $(c_j, v)$-subpath of $P$ (if $c_i$ is the same as $c_j$, then $P_2$ is empty). Thus, $P = P_1 \circ P_2 \circ P_3$ is a semi-$Z$-based partition of $P$ (as $C \subseteq Z$). Since $Z_i$ is a $k$-cut preserving set for $(u, c_i)$ in $D_i$, $Z_i$ is a $k$-cut preserving set for $(c_i, c_j)$ in $D_{i,j}$ and $Z_i, Z_j, Z_{i,j} \subseteq Z$, from Observation 3.4, $Z$ is a $k$-cut preserving set for $(u, v)$ in $D$.

### 3.3 Finding a small $k$-cut preserving set for a pair in a $D \in D_\alpha$

We are now ready to prove Lemma 3.3.

**Lemma 3.3 ($k$-Cut Preserving Lemma).** Let $D$ be an acyclic digraph, and $u, v \in V(D)$ be such that $N^-(u) = N^+(v) = \emptyset$. Additionally, let $D \setminus \{u, v\} \in D_\alpha$. Then there exists a $k$-cut preserving set for $(u, v)$ in $D$ of size at most $f(\alpha)$, where $f(1) = k^3 + 5k^2 + 3k$ and for $\alpha > 1$, $f(\alpha) = k^2g(\alpha) + 2\alpha h(\alpha)$, $g(\alpha) = (2k + k(f(\alpha - 1))^2)f(\alpha - 1)$ and $h(\alpha) = (k^2 + k)g(\alpha) + k(k(\alpha - 1)$. Moreover, such a set can be found in time $n^{\Omega(1)}$, where $n = |V(D)|$.

**Proof.** We prove this lemma using induction on $\alpha$. When $\alpha = 1$, the proof follows from Lemma 3.10.

**Claim 3.12.** Let $x, y \in V(D) \setminus \{x, y\}$. Then, a $k$-cut preserving set for $(x, y)$ of size $g(\alpha)$ in any digraph $D'$ that is a subgraph of $D$ where $u, v \notin V(D')$, can be found in polynomial time.

**Proof.** Let $W$ be a minimum $(x, y)$-vertex-cut in $D'$. If $|W| > k$, then the claim follows from Lemma 3.9. Thus, we are now in the case where $|W| \leq k$. For each $w \in W$, let $Z(w)$ be a $k$-cut preserving set for $(x, w)$ (resp. $Z(w, y)$) in $D'[\text{ver}_{D'}(x, w; W)]$ (resp. $D'[\text{ver}_{D'}(w, y; W)]$). Let $B = N_{D'}(y) \cap \bigcup_{w \in W} Z(w, y)$. For each $(a, b) \in (W \cup B)^2$, let $Z(a, b)$ be a $k$-cut preserving set for $(a, b)$ in $D'[\text{ver}_{D'}(a, b; W \cup N^-(y))]$. Then, from Lemma 3.6, $Z(x, y) := \bigcup_{w \in W} (Z(x, w) \cup Z(w, y)) \cup \bigcup_{(a, b) \in (W \cup B)^2} Z(a, b)$ is a $k$-cut preserving set for $(x, y)$ in $D'$.

We will now show that for any $w \in W$ and $(a, b) \in (W \cup B)^2$, each digraph among $D'[\text{ver}_{D'}(x, w; W)]$, $D'[\text{ver}_{D'}(w, y; W)]$ and $D'[\text{ver}_{D'}(a, b; W \cup N_{D'}(y))]$ has independence number strictly smaller than $\alpha$. Then, from induction hypothesis and the expression for $Z(x, y)$ written above, we will conclude that a $k$-cut preserving set for $(x, y)$ in $D'$ of size $g(\alpha)$ can be found in polynomial time. To see that the independence number of $D'[\text{ver}_{D'}(x, w; W)]$
is strictly less than $\alpha$, observe that $y$ is not adjacent to any vertex in $ver_\Delta'(x,w;W)$, as $W$ is an $(x,y)$-vertex cut in $\hat{D}$. Thus, any independent set of $\hat{D}'[ver_\Delta'(x,w;W)]$ together with $y$ is an independent set of $\hat{D}'$ and hence of $D$. Since $y \not\in \{u,v\}$, $u,v \not\in V(D')$ and the independence number of $D - \{u,v\}$ is $\alpha$, we have that the independence number of $\hat{D}'[ver_\Delta'(x,w;W)]$ is strictly smaller than $\alpha$. A similar argument holds for $\hat{D}'[ver_\Delta'(w,y;W)]$ as in this case $x$ is not adjacent to any vertex of $ver_\Delta'(w,y;W)$. For $\hat{D}'[ver_\Delta'(a,b;W \cup N_D^-(y))]$, since $ver_\Delta'(a,b;W \cup N_D^-(y)) \cap N_D^+(y) = \emptyset$, $u,v \not\in V(D')$ and $N_D^+(y) = \emptyset$, any independent set of $\hat{D}'[ver_\Delta'(a,b;W \cup N_D^-(y))]$ together with $y$ is an independent set in $D - \{x,y\}$. Since $D - \{x,y\}$ has independence number $\alpha$, $\hat{D}'[ver_\Delta'(a,b;W \cup N_D^-(y))]$ has independence number strictly smaller than $\alpha$.

Let $C$ be a minimum $(u,v)$-vertex-cut in $D$. If $|C| > k$, then the lemma follows from Lemma 3.9. Thus, for the remainder of the proof we assume that $|C| \leq k$. For each $c \in C$, let $U_c = ver_\Delta(u,c;C)$, $V_c = ver_\Delta(c,v;C)$, $Z(u,c)$ be a $(u,c)$ $k$-cut-preserving set in $D[U_c]$, and $Z(c,v)$ be a $(c,v)$ $k$-cut-preserving set in $D[V_c]$. For each $(c,c') \in C^2$, $c \neq c'$, let $Q_{c,c'} = ver_\Delta(c,c';C)$, and $Z(c,c')$ be a $k$-cut-preserving set in $D[Q_{c,c'}]$. Then from Lemma 3.5, $Z := \bigcup_{c,c'} Z(u,c) \cup Z(c,v) \cup \bigcup_{(c,c') \in C^2, c \neq c'} Z(c,c')$ is a $k$-cut-preserving set for $(u,v)$ in $D$. Since $C \cap \{u,v\} = \emptyset$, from Claim 3.12, for each $(c,c') \in C^2$, $c \neq c'$, $Z(c,c')$ of size $g(\alpha)$ can be computed in polynomial time. In the remainder of the proof, we will show how to compute $Z(u,c)$ and $Z(c,v)$, for any $c \in C$, of the desired size. We will only give the proof of construction of $Z(u,c)$ as the proof for $Z(c,v)$ is symmetrical.

 }> Claim 3.13. For any $c \in C$, $Z(u,c)$ of size $h(\alpha)$ can be computed in polynomial time.

Proof. For ease of notation, let $\hat{D} = D[U_c]$. Let $A$ be a minimum $(u,c)$-vertex-cut in $\hat{D}$. First note that $A \cap \{u,v\} = \emptyset$. If $|A| > k$, then the claim follows from Lemma 3.9. Thus, for the remainder of the proof, assume that $|A| \leq k$.

For each $a \in A$, let $\hat{U}_a = ver_\hat{\Delta}(u,a;A)$, $\hat{V}_a = ver_\hat{\Delta}(a,c;A)$, $\hat{Z}(u,a)$ be a $(u,a)$ $k$-cut-preserving set in $\hat{D}[\hat{U}_a]$ and $\hat{Z}(a,c)$ be a $(a,c)$ $k$-cut-preserving set in $\hat{D}[\hat{V}_a]$. For each $(a,a') \in A^2$, $a \neq a'$, let $R_{a,a'} = ver_\hat{\Delta}(a,a';A)$ and $\hat{Z}(a,a')$ be a $k$-cut-preserving set in $\hat{D}[R_{a,a'}]$. Then from Lemma 3.5, $Z(u,c) := \bigcup_{a \in A} (\hat{Z}(u,a) \cup \hat{Z}(a,c)) \cup \bigcup_{(a,a') \in A^2, a \neq a'} \hat{Z}(a,a')$ is a $k$-cut-preserving set for $(u,c)$ in $D$. Since $A \cap \{u,v\} = \emptyset$ and $c \in \{u,v\}$, from Claim 3.12, for each $a \in A$, $(a,a') \in A^2$, $a \neq a'$, $\hat{Z}(a,c)$ and $\hat{Z}(a,a')$ of size $g(\alpha)$ can be computed in polynomial time. Moreover, the independence number of $\hat{D}[\hat{U}_a] - \{u,a\}$ is strictly smaller than $\alpha$ because $c \neq v$ is not adjacent to any vertex in $\hat{U}_a$, besides possibly $u$ and $a$. Thus, for each $a \in A$, a set $\hat{Z}(u,a)$ of size $f(\alpha - 1)$ can be computed in polynomial time by the induction hypothesis. This finishes the proof of the claim.

Thus, from the previous arguments and Claim 3.13, we have that $Z$ is a $k$-cut preserving set for $(u,v)$ in $D$ of size at most $k^2g(\alpha) + 2kh(\alpha)$.

A rough computation gives that, for any $k$, $g(\alpha) \leq 6k^2f(\alpha - 1)$ and $h(\alpha) \leq 8k^4f(\alpha - 1)$. This implies that $f(\alpha) \leq 22k^8f(\alpha - 1)^3$. By noting that $f(1) \leq 22k^3$, we can show the following observation.

> Observation 3.14. For any $\alpha$ and $k$, there exists a $k$-cut preserving set of size smaller than $f(k,\alpha) = (22k^3)^k$. 

3.4 \( k \)-Cut Preserving Sets for a Set of Vertices

Below we also define a notion of \( k \)-cut preserving sets for a set of vertices. Such a notion will come handy in our applications. Given a digraph \( D \) and \( X \subseteq V(D) \), for each \((u,v) \in X^2\), we define the digraph \( D_X^{(u,v)} \) as follows (note that \( u \) could be equal to \( v \)). Let \( R = V(D) - X \). Then, \( D_X^{(u,v)} \) is the supergraph of \( D[R] \) obtained by adding two new vertices \( u^+ \) and \( v^- \) together with the following set of additional arcs: \( \{(u^+, x) : x \in R, (u, x) \in E(D)\} \cup \{(x, v^-) : x \in R, (x, v) \in E(D)\} \).

\begin{definition}[\( k \)-Cut Preserving Set for a Set of Vertices] For any digraph \( D \), a positive integer \( k \) and \( X \subseteq V(D) \), we say that \( X \subseteq Z \subseteq V(D) \) is a \( k \)-cut preserving set for \( X \), if for all \((u,v) \in X^2\), \( Z \) is a \( k \)-cut preserving set for \((u,v) \in D_X^{(u,v)}\).
\end{definition}

\begin{lemma} For any digraph \( D \in \mathcal{D}_a \), a positive integer \( k \), and \( S \subseteq V(D) \) such that \( D - S \) is a digraph, a \( k \)-cut preserving set for \( S \) of size at most \( |S|^3/f(k, \alpha) \) can be found in polynomial time, where \( f(k, \alpha) \leq (22k^3)^{4\alpha} \).
\end{lemma}

\textbf{Proof.} For each pair \((u,v) \in S^2\), let \( Z_{(u,v)} \) be the \( k \)-cut preserving set for \((u,v) \in D_X^{(u,v)} \) obtained from Lemma 3.3. From the definition of \( k \)-cut preserving set for \( S \), \( Z = \bigcup_{(u,v) \in S^2} Z_{(u,v)} \) is a \( k \)-cut preserving set for \( S \). From Observation 3.14, for any \((u,v) \in S^2\), \(|Z_{(u,v)}| \leq f(k, \alpha)\). Thus, we conclude the correctness of the lemma. \hfill \( \blacksquare \)

4 Fault-Tolerant \((S,S)\)-Reachability

In this section, we prove Lemma 1.1. Recall that \((D, S, \ell, k)\) is an instance of FTR\((S,S)\) where \( D \in \mathcal{D}_a \), \( S \subseteq V(D) \) and \( \ell, k \) are positive integers such that each strongly connected component of \( D - S \) has size at most \( \ell \). The goal is to compute a subgraph \( H \) of \( D \) of size \( k2^{O((\ell + 1)\alpha)} \) such that, for any \( A \subseteq E(D) \) of size at most \( k \), for any \( s, t \in S \), if \( D - A \) has an \((s,t)\)-path, then so does \( H - A \). It is not difficult to see from Lemma 3.2 that if \( Z \) is a \( k \)-cut preserving set for \( S \) in \( D \), then \( H = D[Z] \) is a solution for \((D,S,\ell,k)\) for any \( \ell \). When \( \ell = 1 \), \( D - S \) is acyclic and hence a \( k \)-cut preserving set for \( S \) can be computed using Lemma 3.16. When \( \ell > 1 \), in order to use Lemma 3.16 we modify the digraph \( D \) to turn \( D - S \) acyclic. We now describe the operation, which we call \textit{dagify}, that is used to turn \( D - S \) acyclic. Informally, for each strongly connected component \( SC \) of \( D \) we turn it into an independent set while preserving the paths in \( D \) that use the vertices of \( SC \). This is achieved by creating a new vertex for every ordered pair of vertices (say, \((u,v)\)) in \( SC \). Such a vertex represents the existence of a \((u,v)\)-path in the strongly connected component \( SC \). In fact, in the path in the modified graph, each new vertex corresponding to some pair \((u,v)\) can be replaced by some \((u,v)\)-path from the strongly connected component \( SC \) to yield a path in the original graph. Then, arcs between two vertices in this newly constructed vertex set are put in such a way that the concatenation of the paths corresponding to these new vertices gives a path in \( D \). This idea is formalized below.

\begin{definition}[\textit{dagify}(\(D,R\))] Let \( D \) be a digraph, \( R \subseteq V(D) \) and \( S \subseteq V(D) \). Let \( SC_1, \ldots, SC_d \) be the strongly connected components of \( D[R] \). For a \( a \in [d] \), let \( \lvert V(SC_a) \rvert = |V(SC_a)| \). Then, \( D^1_R := \text{dagify}(D,R) \) is the digraph defined as:

\begin{description}
\item[Vertex set of \( D^1_R \):] For each \( a \in [d] \), let \( SC^a_1 = \{v^a_{i,j} : (v^a_i, v^a_j) \in SC_a \} \). Let \( R' = \bigcup_{a \in [d]} SC^a_{1} \) and \( V(D^1_R) = R' \cup S \).
\item[Arc set of \( D^1_R \):] It contains all the arcs of \( D \) with both end-points in \( S \). For each \( a \in [d] \), \( SC^a_1 \) is an independent set in \( D^1_R \). For any \( a \in [d] \), \( s \in S \) and \( i, j \in [n_a] \), \((s, v^a_{i,j}) \in E(D^1_R) \) if and only if \((s, v^a_{i,j}) \in E(D) \). Similarly, \((v^a_{i,j}, s) \in E(D^1_R) \) if and only if \((v^a_{i,j}, s) \in E(D) \). We put the arcs between \( SC^a_1 \) and \( SC^b_1 \), for distinct \( a, b \in [d] \) as follows. For any \( i, j \in [n_a] \) and \( i', j' \in [n_b] \), \((v^a_{i,j}, v^b_{i',j'}) \in E(D^1_R) \) if and only if \((v^a_{i,j}, v^b_{i',j'}) \in E(D) \).
\end{description}
\end{definition}
For a set of vertices of $X^\dagger \subseteq D^R_\dagger$, full-comp$(X^\dagger)$ denotes the set of vertices of $V(D)$ such that, for each $v_i^a \in X^\dagger$, all the vertices of $SC^a_i$ belong to full-comp$(X^\dagger)$. Also all the vertices of $S$ that belong to $X^\dagger$, belong to full-comp$(X^\dagger)$. Observe that $|\text{full-comp}(X^\dagger)| \leq \ell^2 \cdot |X|^\dagger$, where $\ell$ is the upper bound on the size of each $SC^a_i$. Note from the construction above that, for any $s,t \in S$ and an $(s,t)$-path $P^l$ in $D^R_\dagger$, there exists an $(s,t)$-path $P$ in $D$ such that $V(P) \subseteq \text{full-comp}(P^l)$. The following observations state a few properties of the digraph $D^R_\dagger$ that would be useful when we want to find a $k$-cut preserving set for $D^R_\dagger$ using Lemma 3.16.

Observation 4.2. $D^R_\dagger[R^l]$ is acyclic.

Proof. Recall, from the construction of $D^R_\dagger$, that $R^l = \bigcup_{a \in [d]} SC^a_\dagger$ and each $SC^a_i$ is an independent set in $D^\dagger_i$. Without loss of generality, let $SC_1, \ldots, SC_d$ be the strongly connected components of $D[R]$ ordered as in their topological ordering. Then, there is no arc from a vertex of $SC_b$ to a vertex of $SC_a$, for any $b > a$, in $D$. Thus, from the construction of $D^R_\dagger$, there is no arc from any $v_i^a$ to any $v_i^b$ ($b > a$). This shows that $D^R_\dagger[R^l]$ is acyclic.

Observation 4.3. If $D \in D_\alpha$ and every strongly connected component of $D[R]$ has size at most $\ell$, then $D^R_\dagger \in D_\ell \alpha$.

Proof. Recall that $R^l = \bigcup_{a \in [d]} SC^a_\dagger$ and $D^R_\dagger[SC^a_\dagger]$ has no arc. From the construction of $D^R_\dagger$, for each $a \in [d]$, $|SC^a_\dagger| \leq \ell^2$. Finally, since $D \in D_\alpha$, from the construction of $D^R_\dagger$, the size of any maximum independent set in $D^R_\dagger$ is at most $\max_{a \in [d]} |SC^a_\dagger| \cdot \alpha \leq \ell^2 \alpha$.

We define some terminology that would come handy later. For any $A \subseteq E(D)$, we say that a vertex $v \in V(D)$ is affected by $A$ if there exists some arc of $A$ that is incident on $v$. The set affected by $A$ in $D^R_\dagger$ is the set of vertices of $D^R_\dagger$ containing the union of the vertices in $SC^a_\dagger$, for each $a \in [d]$ such that a vertex in $SC^a_\dagger$ is affected by $A$ in $D$.

Observation 4.4. Let $D$ be a digraph, $R \subseteq V(D)$ and $S = V(D) \setminus R$. Let $A^\dagger$ be the set affected by $A$ in $D^R_\dagger$. Recall the construction of $D^R_\dagger$ from Definition 4.1. For some $v_i^a, v_j^b \in R^l$, let $P^l$ be an $A^\dagger$-free $(v_i^a, v_j^b)$-path in $D^R_\dagger$ and $P^l$ has size at most $k$. Let $X \subseteq E(D)$ be any arc of $A$. Then there exists a $(v_i^a, v_j^b)$-path $P$ in $D$ such that: $V(P) \subseteq \text{full-comp}(P^l)$ and, $P$ does not use any arc of $A$.

Proof. Recall the construction of dagify$(D,R)$. Replace any path $P$ obtained from $P^l$ by replacing all the vertices of $R^l$ as follows. If for any $c \in [d]$, $i^*, j^* \in [n_c]$, $v_{i^*, j^*} \in V(P^l)$, then replace $v_{i^*, j^*}$, in $P^l$ by any $(v_{i, j}^c, v_{i, j}^c)$-path in the strongly connected component $SC^c_i$. Clearly, the path $P$ obtained is a $(v_i^a, v_j^b)$-path in $D$ and $V(P) \subseteq \text{full-comp}(P^l)$. Also from the definition of $A^\dagger$ and the fact that $P^l$ is $A^\dagger$-free, we get that $P$ cannot use an arc of $A$.

From the construction in Definition 4.1, for any $s,t \in S$, for an $(s,t)$-path $P$ in $D$, we can associate a unique $(s,t)$-path $P^l$ in $D^R_\dagger$. This is elaborated below. Consider the digraph $D^R_\dagger$ obtained by dagify$(D,R)$. $(v_i^a, v_j^a) \in SC^a_\dagger$ for some component $SC^a_i$ of $D[R]$. Let $s, t \in S$. Let $P$ be an $S$-free $(s,t)$-path in $D$. For any such path $P$, we define the notion of a reduced path of $P$ in $D^R_\dagger$ as follows. Consider the unique partition $P = P_u \circ P_i \circ \ldots \circ P_{i_j} \circ P_t$ such that $P_u$ is an arc $(s, u)$ where $u \in V(SC^a_i)$, $P_t$ is an arc $(v, t)$ where $v \in V(SC^a_i)$ and for each $j \in [q]$, $V(P_{i_j}) \subseteq V(SC^a_i)$, where $i_1, \ldots, i_q \in [d]$ and $i_1 < \ldots < i_q$. For each $j \in [q]$, let $P_{i_j}$ be a $(v_{i, j}^c, v_{i, j}^c)$-path. Consider the vertex $v_{i_{q+1}} \in V_{i_{q+1}} \subseteq R^l \subseteq V(D^R_\dagger)$. From the construction of $D^R_\dagger$, we get the $(s, t)$-path $P^l = s \circ v_{i_1, r_1} \circ v_{i_2, r_2} \circ \ldots \circ v_{i_q, r_q} \circ t$ in $D^R_\dagger$. This $(s,t)$-path $P^l$ in $D^R_\dagger$ is called the reduced path of $P$ in $D^R_\dagger$. 

47:18 Fault Tolerant Subgraphs with Applications in Kernelization
We need to show that there is some walk from

This finishes the proof of the lemma. ▷

Directed Edge Odd Cycle Transversal

Specifically, we proved that the classic tolerance, we also showed that our sparsification procedure finds applications in Kernelization. Already when paths and tournaments admit no sparsifier whose output is a digraph of less than \( k \) arcs. In particular, it outputs a digraph whose size is completely independent of \( n \) and polynomial in \( k \), while even the simple classes of directed paths and tournaments admit no sparsifier whose output is a digraph of less than \( n - 1 \) arcs already when \( k = 1 \). Apart from being interesting on its own from the perspective of fault tolerance, we also showed that our sparsification procedure finds applications in Kernelization. Specifically, we proved that the classic Directed Feedback Arc Set problem as well as Directed Edge Odd Cycle Transversal (which, in sharp contrast, is \( W[1] \)-hard on general digraphs) admit polynomial kernels on bounded independence number digraphs. In fact, for any \( p \in \mathbb{N} \), we designed a polynomial kernel for hitting all cycles of length \( \ell \) where \( \ell \mod p = 1 \). Additionally, we derived complementary results that assert the NP-hardness of DEOCT on tournaments, as well as its admittance of a sub-exponential time parameterized algorithm on digraphs of bounded independence.

\[ \text{\textbf{Conclusion}} \]

In this paper, we presented a sparsification procedure for the class of acyclic digraphs (or more generally, “almost” acyclic) of bounded independence, to preserve the (both normal and parity-based) reachability from a given terminal set \( S \) to a given terminal set \( T \) under the failure of any set of at most \( k \) arcs. In particular, it outputs a digraph whose size is completely independent of \( n \) and polynomial in \( k \), while even the simple classes of directed paths and tournaments admit no sparsifier whose output is a digraph of less than \( n - 1 \) arcs already when \( k = 1 \). Apart from being interesting on its own from the perspective of fault tolerance, we also showed that our sparsification procedure finds applications in Kernelization. Specifically, we proved that the classic Directed Feedback Arc Set problem as well as Directed Edge Odd Cycle Transversal (which, in sharp contrast, is \( W[1] \)-hard on general digraphs) admit polynomial kernels on bounded independence number digraphs. In fact, for any \( p \in \mathbb{N} \), we designed a polynomial kernel for hitting all cycles of length \( \ell \) where \( \ell \mod p = 1 \). Additionally, we derived complementary results that assert the NP-hardness of DEOCT on tournaments, as well as its admittance of a sub-exponential time parameterized algorithm on digraphs of bounded independence.
We conclude the paper with a few directions for further research. Our result, currently, holds when the input digraph $D$ is “almost acyclic” and has bounded independence number. From the example of the tournament described in the introduction (the one that is obtained by taking a transitive tournament and reversing the arcs along the Hamiltonian path defined by its topological ordering), it seems that some notion of “almost acyclic” might be necessary to have fault tolerant subgraphs whose size avoid the dependence on $n$. On the other hand, it might be possible to ask for something weaker than bounded independence number. For example, forbidding the existence of an induced $P_\alpha$, the directed path on $\alpha$ vertices.

**Question 1.** Does $\text{FTR}(S, S)$ admit a subgraph of size independent of $n$ on digraphs that are “almost acyclic” and have no induced $P_\alpha$, for some fixed positive integer $\alpha$?

It is not very difficult to observe that our results (Lemmas 1.1 and 1.2) also hold when the input graph is undirected and has bounded independence number. It would be interesting (because of the arguments discussed earlier) if one could obtain similar results when the input undirected graph has no induced $P_\alpha$.

**Question 2.** Does $\text{FTR}(S, S)$ admit a subgraph of size independent of $n$ when the input graph is undirected and has no induced $P_\alpha$, for some fixed positive integer $\alpha$?

It would also be interesting to discover other (di)graph classes where the dependence on $n$ of the size of the output subgraph can be sublinear, for example, $\log n$, for $\text{FTR}(S, S)$ and also for other fault tolerant graph properties.

Abstract

Biological neural computation is inherently asynchronous due to large variations in neuronal spike timing and transmission delays. So-far, most theoretical work on neural networks assumes the synchronous setting where neurons fire simultaneously in discrete rounds. In this work we aim at understanding the barriers of asynchronous neural computation from an algorithmic perspective. We consider an extension of the widely studied model of synchronized spiking neurons [Maass, Neural Networks 97] to the asynchronous setting by taking into account edge and node delays.

Edge Delays: We define an asynchronous model for spiking neurons in which the latency values (i.e., transmission delays) of non self-loop edges vary adversarially over time. This extends the recent work of [Hitron and Parter, ESA’19] in which the latency values are restricted to be fixed over time. Our first contribution is an impossibility result that implies that the assumption that self-loop edges have no delays (as assumed in Hitron and Parter) is indeed necessary. Interestingly, in real biological networks self-loop edges (a.k.a. autapse) are indeed free of delays, and the latter has been noted by neuroscientists to be crucial for network synchronization.

To capture the computational challenges in this setting, we first consider the implementation of a single NOT gate. This simple function already captures the fundamental difficulties in the asynchronous setting. Our key technical results are space and time upper and lower bounds for the NOT function, our time bounds are tight. In the spirit of the distributed synchronizers [Awerbuch and Peleg, FOCS’90] and following [Hitron and Parter, ESA’19], we then provide a general synchronizer machinery. Our construction is very modular and it is based on efficient circuit implementation of threshold gates. The complexity of our scheme is measured by the overhead in the number of neurons and the computation time, both are shown to be polynomial in the largest latency value, and the largest incoming degree $\Delta$ of the original network.

Node Delays: We introduce the study of asynchronous communication due to variations in the response rates of the neurons in the network. In real brain networks, the round duration varies between different neurons in the network. Our key result is a simulation methodology that allows one to transform the above mentioned synchronized solution under edge delays into a synchronized under node delays while incurring a small overhead w.r.t space and time.

1 Introduction

Understanding how the brain works, as a computational device, is a central challenge of modern neuroscience, artificial intelligence, and lately also in theoretical computer science and distributed computing [18, 19, 20, 17, 16, 32, 6, 39, 37]. This line of work usually assumes a simple synchronized model [23, 24] in which neurons fire simultaneously in discrete rounds in response to their neighboring neurons that fired in the previous round. This model, while being very convenient for algorithm design, does not take into account the inherent asynchronous nature of neural communication. In the neuroscience literature it has been noted that the asynchronous nature of these networks mostly stems from two independent sources [29]: edge delays (known as response latency\(^1\)) [35, 5] and node delays (known as refractory period) [34, 3]. In this paper, we aim at understanding the computational cost incurred by such asynchronous communication. The overhead is measured by the overhead in the number of neurons and computation time required to compute a certain function. We believe that understanding the computational power, limitations and the connections between these models go beyond the setting of spiking neurons, and might also be relevant for the theory of digital logic design and circuit computation in general.

The Standard Synchronous Model [23, 24]. Before describing our asynchronous models, we first revise the standard synchronous model formally defined by Maass. In this model, the network evolves in discrete, synchronous rounds as a Markov chain where each neuron \( u \) in the network is a probabilistic threshold gate with a threshold (or bias) value \( b(u) \). In every round \( t \), the firing probability of neuron \( u \) only depends on the firing status of its incoming neighbors in the preceding round \( t - 1 \). Formally, the potential \( \text{pot}_t(u) \) of neuron \( u \) in round \( t \) is defined by the weighted sum over its incoming neighbors that fired in round \( t - 1 \). The neuron \( u \) fires in round \( t \) with probability that depends on the quantity \( \text{pot}_t(u) - b(u) \).

1.1 Asynchronous Computation with Bounded Edge Delays

We define an asynchronous model with edge delays bounded\(^2\) by some given integer \( L \). The dynamic of the network \( \mathcal{N} \) is specified by a latency function \( \ell : V \times V \times N \rightarrow \mathbb{N} \leq L \) interpreted as follows: For every neuron \( u \) firing in round \( \tau \), its spike reaches its outgoing neighbor \( v \) within \( \ell(u, v, \tau) \) rounds where \( \ell(u, v, \tau) \in [1, L] \) might be chosen adversarially for every \( u \neq v \), and every round \( \tau \). The network solution \( \mathcal{N} \) should then output the desired solution for any adversarial choice of the latency function \( \ell \). Setting \( L = 1 \) yields the standard synchronous model.

Asynchronous computation with edge delays was recently introduced by Hitron and Parter [12]. Their model is similar to ours only that in their model, the edge latencies are required to be fixed over time, whereas in our model the adversary is allowed to change it from round to round. The model of Hitron and Parter includes an additional restriction on the adversary (that sets the latency values) by requiring that self-spikes, i.e., of the form \( \langle u, u, \tau \rangle \) have no latency and arrive within a single round to their destination. This assumption is justified in [12] by the experimental evidence that self-spikes in brain networks have almost no delays [14]. It is commonly believed in the neuroscience community that this no-delay property of self-edges is in fact essential for network synchronization [33, 21, 40, 8].

---

1 Throughout, we use the terms edge-delay and latency interchangeably.
2 This bound is crucial as will be later implied by our lower bound results that depend on \( L \). E.g., both the computation time and the size of the network in this model must depend on \( L \).
In this work, we provide a theoretical support for this hypothesis by showing that without such an assumption, one cannot even implement a single AND gate in this model. This impossibility result holds already in a setting where \( L = 2 \), the edge latencies are fixed over time (as assumed in [12]), and the computation time and network size are allowed to be unbounded. For this reason, we will mostly consider in this paper nice latency functions in which all self-spikes have a latency value of one round.

### 1.2 Asynchronous Computation with Bounded Node Delays

We next turn to consider an alternative source for asynchronous communication due to variations in the response timing of the individual neurons in the network. In real brain networks, for every neuron \( u \) there is a predefined time interval between two consecutive spikes of \( u \). The length of this interval, which we call round, varies considerably among different neurons in the network [34, 3]. This poses the challenge of creating a synchronized response at the network level. To account this behavior, we consider a model in which network’s evolution proceeds in seconds. A second in this context is simply the smallest measurable time unit. For a given integer \( T \geq 1 \), the dynamics is specified by a node-delay function \( t : V \rightarrow \mathbb{N}_{\leq T} \) interpreted as follows: the round duration of each neuron \( v \) consists of \( t(v) \) seconds. Specifically, the \( i^{th} \) round of \( v \) is defined by the time interval \( R_i(v) = [(i - 1)t(v) + 1, i \cdot t(v)] \) for every \( i \geq 1 \). The neuron \( u \) fires in the second \( i \cdot t(v) \) (i.e., at the end of its \( i^{th} \) round) only if the total potential due to spikes arriving in the interval \( R_i(v) \) is sufficiently large. The network solution \( \mathcal{N} \) should then output the desired solution for any adversarial choice of the node-delay function \( t \). The input parameter \( T \) sets a bound on the differences between the round duration over all neurons in the network. Setting \( T = 1 \) yields the standard synchronous model.

Observe that the edge and node delay models do not imply one another. In the edge latency model, even though the spikes arrive in adversarially chosen rounds, all neurons in round \( \tau \) still depend only on the spikes arriving in round \( \tau \). Thus, the duration of a round for all the neurons in the network is the same: a single tick (or a second) of the global clock. In contrast, in the node delay model, the adversary selects the round duration for each neuron which has two physical interpretations. First, it determines the time duration over which the potential due to arriving spikes is accumulated. In addition, it also determines the time interval between two consecutive spikes by the given neuron. In one of our most technically involved results, we show a non-trivial reduction between the edge delay and the node delay models, provided that the input network satisfies certain properties.

Finally, we note that this model has several variations which are in fact supported by our simulation results (from edge delays to node delays). In particular, one can consider a more elaborated setting in which the duration of each round per node varies in an adversarial manner over time, i.e., the node-delay function in such a model is of the form \( t : V \times \mathbb{N}_{\geq 1} \rightarrow \mathbb{N}_{\leq T} \) interpreted as follows: the \( i^{th} \) round duration on each neuron \( v \) consists of \( t(v,i) \) seconds. For example, in such a model the \( i^{th} \) round of node \( u \) can consists of 2 seconds while its \((i+1)^{th}\) round might consist of 100 seconds. In another variation, both edge and node delays are combined and the dynamic is specified by an \( L \)-bounded edge latency function \( t : V \times V \times \mathbb{N}_{\geq 1} \rightarrow \mathbb{N}_{\leq L} \) and a \( T \)-bounded node-delay function \( t : V \times \mathbb{N}_{\geq 1} \rightarrow \mathbb{N}_{\leq T} \).

### 1.3 Synchronizers

In the spirit of Awerbuch and Peleg’s synchronizers for distributed networks [2] and the recent work of [12], our primary goal with respect to upper bound results is to provide a general simulation methodology that takes any \( n \)-neuron network \( \mathcal{N} \) that solves the problem
in the standard synchronized setting (i.e., in which all spikes arrive within a single round) and transforms it into an “analogous” network \( \text{Sync}(\mathcal{N}) \) in the edge delay setting while incurring a small overhead in the number of neurons and the computation time (w.r.t the base network \( \mathcal{N} \)).

For the setting in which the edge latencies are fixed over time and bounded by some integer \( L \), Hitron and Parter [12] showed such a simulation using their efficient constructions for neural timers and counters. Their synchronized network solution \( \text{Sync}(\mathcal{N}) \) has \( O(n + L \log L) \) neurons and \( O(rL^3) \) rounds where \( r \) is the computation time of the base network \( \mathcal{N} \). While being quite efficient in terms of space and time, the synchronizers of [12] are heavily built up on the strong assumption that the latency values of the edges are fixed over time. In this paper, we aimed at understanding the edge latency setting in its most general form, and ask:

\[ \text{Can one provide a general synchronization scheme in a setting that allows the latency of the network edges to vary in an adversarial manner in each round?} \]

A priori it is not so clear if one can compute even basic Boolean functions without assuming that the latency values are fixed. We answer this question in the affirmative by presenting a modular synchronization scheme using a different approach than that taken in [12]. The benefit of this approach is in its modularity. We start by understanding the implementation of a single NOT gate in this model in terms of upper and lower bounds on the space and the time of the computation. We then use this synchronized NOT solution as a building block in the final synchronized network solution. Specifically, the synchronized NOT gates are used to build synchronized circuits (and hence threshold gates) which in turn combined into a whole synchronized network solution. The space and time overheads incurred by our solution are polynomial in \( L \) (the bound on the latency) and \( \Delta \), the maximal incoming degree in the base network \( \mathcal{N} \).

We next turn to consider synchronizers for the node delay model. Our approach is based on showing a simulation result that takes any synchronized solution \( \text{sync}_E(\mathcal{N}, L) \) obtained by the synchronizer in the \( L \)-bounded edge latency model, and transforms it into a synchronized solution \( \text{sync}_V(\mathcal{N}, T) \) that works in the \( T \)-bounded node delay model for \( L = \Theta(T^2) \).

- Remark. It is noteworthy that in contrast to the distributed setting of Awerbuch and Peleg [2] where the network size does not depend on the latencies, in the neural setting it is not the case. As our lower bound constructions, both the computation time and the network size must depend (in fact, polynomially) on the largest edge latency. For this reason, for any practical purposes, the study of asynchronous communication, in general, must assume bounded delays.

### 1.4 Our Results

We study the cost and limitations of asynchronous neural computation in a biologically plausible yet simple model of spiking neural networks. Our main focus is in the edge latency model where the dynamic is specified by an \( L \)-bounded function \( \ell : V \times V \times N \rightarrow N_{\leq L} \). The node delay model is concerned only towards the end of the paper (Appendix C), as it is handled via reduction to the edge delay setting. In the first part of the paper, we show several negative results for the \( L \)-bounded model. This includes an impossibility results for delay on self-loop edges, as well as size and time lower bound on an implementation of a NOT gate in this model. In the second part, we consider the construction of synchronizers in this generalized setting. We note that these constructions are self-contained and are technically different from [13].
Negative Results. We first show that without assuming a minimal latency value on the self-loop edges, one cannot compute $\text{AND}(x, y)$ given two Boolean inputs $x$ and $y$, even when the edge latency values are fixed over time and the largest latency is $L = 2$.

Theorem 1 (Impossibility for Arbitrary Latency Functions). There exists no network that computes $\text{AND}(x, y)$ in a setting that allows the adversary to pick latencies in $\{1, 2\}$ for all edges in the network.

The proof goes by showing that for any given candidate network solution $N$, there exists a bad latency function $\ell$ under which $N$ fails to compute $\text{AND}(x, y)$. This holds even when the latencies are fixed over time. From that point on, we restrict attention to nice latency functions, that assign latency value 1 to the self-loop edges in the network.

Definition 2. A latency function is nice if $\ell(u, u, \tau) = 1$ for every $u \in V$ and round $\tau$.

Our key technical contributions are lower bounds on the network size and the computation time for computing the $\text{NOT}(x)$ function in the $L$-bounded setting. Informally speaking, the $\text{NOT}(x)$ function appears to be a “complete” function for the purpose of synchronization in this asynchronous model. Indeed, our $\text{NOT}(x)$ implementation captures most of the essence of the $L$-bounded model. To obtain the final synchronization scheme we mainly glue together synchronized NOT units. For this reason, we spend much attention into understanding the tightness of our constructions by providing nearly matching lower bound results.

Lemma 3 (Size and Time Lower Bounds for Async. Computation of $\text{NOT}(x)$). Any network that computes $\text{NOT}(x)$ in the $L$-bounded asynchronous setting must use $\Omega(L)$ neurons and $\Omega(L^3)$ time (the time lower bound is tight).

This should be compared with the size lower bound of $\Omega(\log L)$ shown by [13] for their simplified asynchronous setting.

Positive Results. Our end result is a synchronizer that given any network $N$ in the standard synchronous setting and an integer $L$, computes a network $\text{sync}_E(N, L)$ that performs the “same” computation as $N$ in the $L$-bounded edge delay setting.

Theorem 4 (Synchronizers for Edge Delays). There exists a synchronizer that given a network $N$ with $n$ neurons, maximum in-degree $\Delta$, and maximum edge latency $L$, constructs a network $\text{sync}_E(N, L)$ that has an “analogous” execution in the $L$-bounded edge-delay setting with a total number of $\tilde{O}(L^4 \cdot \text{poly}(\Delta) \cdot n)$ neurons and a time overhead of $\tilde{O}(L^5 \cdot \log \Delta)$.

Although the construction is inspired by the work of Awerbuch and Peleg [2], the implementation is very different as our neurons, unlike processors in a distributed network, are memoryless. Thus, they cannot aggregate the incoming messages as in [2]. Our construction is also different than that of [13], as the latter crucially depends on having fixed latencies over time.

For the node delay model, in Appendix C we show that given a network $N$ in the standard synchronous setting and an integer $T$, one can compute an analogous network $\text{sync}_V(N, T)$ in the node-delay model with bounded node delay $T$ by taking the following approach. Apply the algorithm of Theorem 4 with $N$ and $L = \Theta(T^2)$. This results with a network $\text{sync}_E(N, L)$

\[^3\] The $\tilde{O}$ hides a factor of $\text{poly}(\log(n \cdot r))$, where $r$ is the number of simulation rounds.
that performs the same computation as $N$ in the $L$-bounded edge delay model. The desired network $\text{sync}_V(N, T)$ is then obtained by multiplying the edge weights of a carefully defined edge subset in $\text{sync}_E(N, L)$ by a factor of $T$. The quite delicate analysis then shows that the network $\text{sync}_V(N, T)$ indeed simulates the original network $N$ upon any selection of the node-delay function $t: V \rightarrow \mathbb{N} \leq T$. By setting $L = \tilde{O}(T^2)$ in Theorem 4, we show the following for the node delay model:

\textbf{Theorem 5 (Synchronizers for Node Delays).} There exists a synchronizer that given a network $N$ with $n$ neurons, maximum in-degree $\Delta$, and maximum node delay $T$, constructs a network $\text{sync}_V(N, T)$ that has an “analogous” execution in the $T$-bounded node-delay setting with a total number of $\tilde{O}(T^8 \cdot \text{poly}(\Delta) \cdot n)$ neurons and a time overhead of $\tilde{O}(T^{10} \cdot \log \Delta)$.

We note that our preference to take a modular approach rather than an optimized one inevitably leads to suboptimal space and time bounds in both Theorems 4 and 5. For example, Theorem 5 is shown via a simulation result, which further deepens our understanding of the connections between these models. We believe that by employing a more direct approach for building synchronizers in the node-delay model, one should get a considerably improved dependency in the delay bound $T$.

1.5 Our Approach in a Nutshell

We next provide the high level ideas for the key contributions. Throughout, unless stated otherwise we consider the edge delay model where the dynamics is specified by an arbitrary latency function.

\textbf{Size and Time Lower Bound for Computing NOT($x$).} A network $N$ with input neuron $x$ and an output neuron $z$ computes the function $\text{NOT}(x)$ in the asynchronous setting if the following holds: when $x = 0$, the output $z$ fires in at least one round regardless of the latency function; and when $x = 1$ the output $z$ never fires for any latency function. To show a size lower bound of $\Omega(L)$ we take the following approach. First, we reduce any network $N$ that computes $\text{NOT}(x)$ into a simpler and yet not larger network $N_{\text{simple}}$. In the latter network the only inhibitor is the input $x$ which also has a self-loop of large positive weight, and outgoing edges of very large negative weight to all the excitatory neurons in $N_{\text{simple}}$. In the latter network the only inhibitor is the input $x$ which also has a self-loop of large positive weight, and outgoing edges of very large negative weight to all the excitatory neurons in $N$. The second part of the proof shows a lower bound for $N_{\text{simple}}$ using its specialized structure. We will assume towards a contradiction that the in-degree of each neuron in $N_{\text{simple}}$ is less than $L$ and exhibit two conflicting latency functions $\ell_0, \ell_1$ that satisfy the following. If $N_{\text{simple}}$ computes $\text{NOT}(x)$ with $\ell_0$ and with $x = 0$, then it must fail to compute $\text{NOT}(x)$ with the function $\ell_1$ and $x = 1$. To compute these latency functions, we partition the simulation into blocks $T_0, \ldots$, each containing $L$ rounds. In each phase $i$, we set the latency values for all the edges and all the rounds in block $T_i$. Throughout, we will keep the invariant that there exists no neuron that fires when $x = 0$ and with $\ell_0$, but does not fire when $x = 1$ and with $\ell_1$. By the correctness of the network, the output neuron must fire at least once when $x = 0$, thus leading to the contradiction. In the very high level, the fact that the in-degree of each vertex is small is used in order to spread over the at most $L$ incoming spikes of each neuron $u$ in a balanced manner over the $L$ rounds of the block. This will prevent the firing of a neuron $z$ when $x = 0$. Our lower bound is complemented by an upper bound of $O(L^2)$ as described next.
The Generalized Synchronization Scheme. The scheme is based on gradual steps.

Step I: Synchronization of NOT and OR Gates. We start by considering the asynchronous computation of simple Boolean functions NOT(x) and OR(x₁, ..., xₙ) with a small number of neurons. The key challenge is in implementing the NOT gate. When x = 1, the output gate is required not to fire (i.e., output 0) throughout the entire execution. In contrast, when x = 0 the output gate should fire at least once during the execution. The construction is combinatorial and uses a similar logic to the lower bound arguments. It contains a collection of L + 1 neurons with outgoing edges to the output. The above mentioned lower bound result shows that the incoming degree of z must be at least L − 2.

Step II: Synchronization of a Boolean Circuit. Any Boolean circuit A can be implemented by NOT and OR gates. To simulate the computation of A in the asynchronous setting, we replace each gate gᵢ in A by its synchronized implementation Sync(gᵢ) constructed in Step (I). For a gate gᵢ in layer j with incoming gates gᵢ₁, ..., gᵢₖ, the input to the sub-network Sync(gᵢ) are the output neurons of the sub-networks Sync(gᵢ₁), ..., Sync(gᵢₖ). The synchronization between the layers of the circuit is governed by a directed chain of O(dL³) neurons. The head of the chain fires in the first round of the simulation and activates the network. The sub-networks Sync(gᵢ) of gates gᵢ in layer j are activated by the Θ(j · L³) neuron in this chain. These parameters are set so that we can be sure that the modules of layer j are activated, only after the spikes from the output neurons of the previous layer have reached the input of this layer. Overall the synchronized transformed network Sync(A) has O(d · L³ + m · L²) neurons, where d is the depth of A and m is the number of gates. The overtime in the computation is O(d · L⁴) rounds.

Step III: Synchronization of a Single (Probabilistic) Threshold Gate. To synchronize a single deterministic threshold gate, we use the fact that a threshold gate with incoming degree Δ can be implemented by a Boolean circuit with poly(Δ) neurons and depth O(log Δ). This allows us to use the synchronized construction of the previous step. Turning to probabilistic threshold gates, here it is much less clear how to implement such a gate by a Boolean circuit. We take the following approach. First, we use the fact from [20] that a spiking neuron with bias b(u) is equivalent to a deterministic neuron u’ whose bias is sampled from the Logistic distribution with mean b(u). Therefore our key challenge is in sampling a value from a given Logistic distribution. To do that, we use a collection of k (input-less) spiking neurons each fires independently with probability half. These neurons provide us the random bits for this process of sampling. In fact, these fair coins tosses allows one to sample a value almost uniformly at random in the range [0, 2ᵏ]. We will then use the method of inverse transform sampling to convert this almost-uniform sampled value to a value that is sampled from the Logistic distribution up to a small error in the sampling. Using Taylor expansion of the natural log function, we implement this Uniform to Logistic transformation by a collection of simple arithmetic operations applied on a collection of Boolean neurons. The total error in our sampling is set to be small enough so that the output distribution of the Boolean circuit is almost indistinguishable from that of the probabilistic threshold gate.

Grand Finale: Synchronization of a Spiking Neural Network. Finally, given an SNN network N of (probabilistic) threshold gates the synchronized network Sync(N) is obtained as follows. Each threshold gate gᵢ in N is replaced by its synchronized implementation Sync(gᵢ).

---

4 The probabilistic threshold gates of SNN.
The key challenge is in synchronizing these modules so that every neuron \( v \) in \( \mathcal{N} \) (i.e., not only the output neuron) has an equivalent neuron \( v' \) in \( \text{sync}(\mathcal{N}) \) that simulates \( v \) for any possible latency function throughout the entire simulation. See Fig. 1 for an illustration.

**From Edge Delays to Node Delays.** Given a network \( \mathcal{N} \) to be simulated and an integer \( T \), our goal is to build a synchronizer \( \text{sync}_V(\mathcal{N}, T) \) that simulates \( \mathcal{N} \) in the \( T \)-bounded node-delay model. To do that, we first compute a network \( \text{sync}_E(\mathcal{N}, L) \) that simulates \( \mathcal{N} \) in the \( L \)-bounded edge-delay model for \( L = \Theta(T^2) \). Then the output network \( \text{sync}_V(\mathcal{N}, T) \) is obtained by dividing some of the edge weights in \( \text{sync}_E(\mathcal{N}, L) \) by a factor of \( T \). The correctness argument is based on showing that for every node-delay function \( t : V \rightarrow \mathbb{N}_{\leq T} \), there exists an edge-delay function \( \ell : V \times V \times \mathbb{N}_{\geq 0} \rightarrow \mathbb{N}_{\leq L} \) such that the execution of the network \( \text{sync}_E(\mathcal{N}, L) \) with the edge-delay function \( \ell \) (in the edge-delay model) is similar to the execution of the network \( \text{sync}_V(\mathcal{N}, T) \) with the node-delay function \( t \) (in the node-delay model). Since the network \( \text{sync}_E(\mathcal{N}, L) \) simulates the original network \( \mathcal{N} \) for any edge-delay function, it will imply that the network \( \text{sync}_V(\mathcal{N}, T) \) simulates the original network \( \mathcal{N} \) for any node-delay function as desired.

**Additional Related Work.** Asynchronized communication in spiking neural networks has been studied in several settings. Maass [22, 25] considered a quite elaborated model for deterministic neural networks with arbitrary response functions for the edges, and a vector firing times for all neuron. The approach of [22] mostly concerned the computational power of this model upon choosing the best parameters for the network. I.e., showing feasibility results for various functions. In contrast, in this work our goal is to bound the computation time and the network size under this asynchronous setting. Khun et al. [15] studied the asynchronous dynamics under the stochastic model of DeVille and Peskin [7].

Turning to the setting of logical circuits, there is a long line of work on the asynchronous setting under various model assumptions [1, 11, 36, 4] that do not quite fit the memory-less setting of spiking neurons. A more related work to our setting is by Martin, Manohar and Moses [28, 26, 27] who studied the computational power of asynchronous digital circuits. In particular, they characterize the necessary and sufficient conditions for a valid operation of a given circuit in the asynchronous setting. For example, they showed that if all edges and nodes suffer from an unbounded delay then the computational power of the circuit must be very limited. The focus in our work is quite different. Instead of studying the computational power of the asynchronous setting, we bound the computational overhead for solving concrete problems.

**2 The Synchronous and Asynchronous SNN Models**

A deterministic neuron \( u \) is modeled by a deterministic threshold gate. Letting \( b(u) \) to be the threshold value of \( u \), then \( u \) outputs 1 if the weighted sum of its incoming neighbors exceeds \( b(u) \). A spiking neuron is modeled by a probabilistic threshold gate which fires with a sigmoidal probability that depends on the difference between its weighted incoming sum and \( b(u) \).
Neural Network Definition. A Neural Network (NN) \( \mathcal{N} = (X, Z, Y, w, b) \) consists of \( n \) input neurons \( X = \{x_1, \ldots, x_n\} \), \( m \) output neurons \( Y = \{y_1, \ldots, y_m\} \), and \( k \) auxiliary neurons \( Z = \{z_1, \ldots, z_k\} \). In spiking neural network (SNN), the neurons can be either deterministic threshold gates or probabilistic threshold gates. The directed weighted synaptic connections between \( V = X \cup Z \cup Y \) are described by the weight function \( w : V \times V \rightarrow \mathbb{R} \). A weight \( w(u, v) = 0 \) indicates that a connection is not present between neurons \( u \) and \( v \). Finally, for any neuron \( v \), the value \( b(v) \in \mathbb{R} \) is the threshold value (activation bias). The in-degree of every input neuron \( x_i \) is zero, i.e., \( w(u, x) = 0 \) for all \( u \in V \) and \( x \in X \). Additionally, each neuron is either inhibitory or excitatory: if \( v \) is inhibitory, then \( w(v, u) \leq 0 \) and if \( v \) is excitatory, then \( w(v, u) \geq 0 \) for every \( u \). This restriction arises from the biological structure of the neurons.

Network Dynamics in the Synchronous Setting. The network evolves in discrete, synchronous rounds as a Markov chain. The firing probability of every neuron in round \( \tau \) depends on the firing status of its neighbors in round \( \tau - 1 \), via a standard sigmoid function, with details given below. For each neuron \( u \), and each round \( \tau \geq 0 \), let \( \sigma_r(u) = 1 \) if \( u \) fires (i.e., generates a spike) in round \( \tau \). Let \( \sigma_0(u) \) denote the initial firing state of the neuron. The firing state of each input neuron \( x_i \) in each round is the input to the network. For each non-input neuron \( u \) and every round \( \tau \geq 1 \), let \( \text{pot}(u, \tau) \) denote the membrane potential at round \( \tau \) and \( p(u, \tau) \) denote the firing probability \( \{ \Pr[\sigma_\tau(u) = 1]\} \), calculated as \( \text{pot}(u, \tau) = \sum_{v \in V} w(v, u) \cdot \sigma_{\tau-1}(v) - b(u) \) and \( p(u, \tau) = \frac{1}{1 + e^{-\lambda \text{pot}(u, \tau)}} \), where \( \lambda > 0 \) is a temperature parameter which determines the steepness of the sigmoid. Clearly, \( \lambda \) does not affect the computational power of the network, thus we set \( \lambda = 1 \).

2.1 Network Dynamics in the Edge Delay Setting

The dynamic of the network is governed by a latency function \( \ell : V \times V \times \mathbb{N} \rightarrow \mathbb{N} \) interpreted as follows. For every directed edge \( e = (u, v) \) and round \( \tau \), a spike generated by \( u \) in round \( \tau \) arrived at \( v \) after \( \ell(u, v, \tau) \) rounds. In the synchronous setting, \( \ell(u, v, \tau) = 1 \) for every \( u, v, \tau \).

For every neuron \( v \) and round \( \tau \), let \( A(u, \tau) = \{(v, \tau') | v \in V, \tau' + \ell(v, u, \tau') = \tau\} \) denote all the spike events that if occur, arrive to \( u \) at round \( \tau \). The state of \( u \) in round \( \tau \) is given by:

\[
\text{pot}(u, \tau) = \sum_{(v, \tau') \in A(u, \tau)} w(v, u) \cdot \sigma_{\tau'}(v) - b(u) \quad \text{and} \quad \sigma_\tau(u) = 1 \text{ iff } \text{pot}(u, \tau) \geq 0. \tag{1}
\]

If \( u \) is a probabilistic threshold gate then it fires with probability \( p(u, \tau) = \frac{1}{1 + e^{-\lambda \text{pot}(u, \tau)}} \).

When \( \ell(u, v, \tau) = \ell(u, v, \tau') \) for every \( u, v \) and \( \tau' \neq \tau \), we may omit \( \tau \) and write \( \ell(u, v) \).

Definition 6 (The \( L \)-bounded Edge-Delay Setting). Given is a network \( \mathcal{N} \) and an integer \( L \). It is assumed the network contains a special neuron, the starter, that fires in the first round of the simulation. The dynamic is determined by a latency function \( \ell \). This function \( \ell \) can be chosen arbitrarily among all \( L \)-bounded nice functions.

Definition 7 (Computation of a Boolean Function in the \( L \)-bounded Edge-Delay Setting). Let \( f : \{0, 1\}^n \rightarrow \{0, 1\}^k \) be a Boolean function. A network \( \mathcal{N} \) with \( n \) input neurons \( x_1, \ldots, x_n \) and \( k \) output neurons \( z_1, \ldots, z_k \) computes \( f \) in this setting if for every nice \( L \)-bounded function \( \ell \) and for every fixed possible assignment to the input neurons \( b_1, \ldots, b_n \) the following holds: (i) If \( f_i(b_1, \ldots, b_n) = 1 \), then there exists a round in which \( z_i \) fires, where \( f_i(\cdot) \) is the \( i^{th} \) bit in the output of \( f \). (ii) If \( f_i(b_1, \ldots, b_n) = 0 \) then \( z_i \) does not fire throughout the entire execution. Furthermore, the network \( \mathcal{N} \) computes the function \( f \) in \( r \) rounds if \( \mathcal{N} \) computes \( f \), and for every nice \( L \)-bounded function \( \ell \), input bits \( b_1, \ldots, b_n \) and index \( i \) such that \( f_i(b_1, \ldots, b_n) = 1 \), \( z_i \) fires in some round \( \tau \leq r \).
Note that by this definition, for a network $\mathcal{N}$ that computes a Boolean function $f$ within $r$ rounds, to evaluate the output of the function it is sufficient to inspect the state of the output bits over the first $r$ rounds of the network’s simulation. Furthermore, as edge delays are allowed to be chosen in an adversarial manner, one cannot hope for having all output neurons fire in the exact same around. One mechanism that we use to keep the output neurons fire simultaneously is by using self-loop edges whose latency values is fixed to be 1.

**Synchronizers.** A synchronizer $\nu$ is an algorithm that gets as input a network $\mathcal{N}$ and outputs a network $\mathcal{N}' = \nu(\mathcal{N})$ that contains all the neurons of $\mathcal{N}$, plus additional auxiliary neurons. One of the auxiliary neurons in $\mathcal{N}'$ is a *starter* neuron that fires in the first round of the simulation. The network $\mathcal{N}'$ works in the asynchronous setting and should have *similar execution* to $\mathcal{N}$ in the sense that for every neuron $v \in V(\mathcal{N})$, the firing pattern of $v$ in the asynchronous network should be similar to the one in the synchronous network. The output network $\mathcal{N}'$ simulates each round of the network $\mathcal{N}$ by a *phase*.

**Definition 8 (Phases).** We partition the execution of $\mathcal{N}'$ into phases $1, 2, \ldots$, using a function $r : V(\mathcal{N}) \times \mathbb{N} \to \mathbb{N}$ that defines the beginning of phase $p$, i.e. the $p^{th}$ phase is the round interval $[r(v, p), r(v, p + 1)]$.

**Definition 9 (Similar Executions (Deterministic Networks)).** The synchronous execution $\Pi$ of a deterministic network $\mathcal{N}$ is specified by a list of states $\Pi = \{\sigma_1, \ldots, \}$ where each $\sigma_i$ is a binary vector describing the firing status of the neurons in round $i$. The asynchronous execution of the network $\mathcal{N}' = \nu(\mathcal{N}, L)$ with a latency function $\ell$ denoted by $\Pi'(\ell)$ is defined analogously only when applying the asynchronous dynamic of Eq. (1). The execution $\Pi'(\ell)$ is divided into phases according the a function $r : V(\mathcal{N}) \times \mathbb{N} \to \mathbb{N}$.

The network $\mathcal{N}$ and the pair $(\mathcal{N}', \ell)$ have a *similar execution* if $V(\mathcal{N}) \subseteq V(\mathcal{N}')$, and in addition, a neuron $v \in V(\mathcal{N})$ fires in round $p$ in the execution $\Pi$ iff $v$ fires during phase $p$ in $\Pi'(\ell)$. The networks $\mathcal{N}$ and $\mathcal{N}'$ are *similar* if $\mathcal{N}$ and $(\mathcal{N}', \ell)$ have a similar execution for every nice latency function $\ell$.

Note that specifically, if a synchronous network $\mathcal{N}$ computes a Boolean function $f$ by round $r$ and $\mathcal{N}$ and $\mathcal{N}'$ are similar, then $\mathcal{N}'$ computes $f$ by phase $r$. Therefore, if we know that each phase is of at most $q$ rounds, we get that $\mathcal{N}'$ computes $f$ in $r \cdot q$ rounds.

Finally, we note that the extension for randomized networks with probabilistic gates is quite straightforward if one simply fixed the random coins used by the neurons over the simulation. That is, to be able to faithfully compare the simulation of two random networks, one has to fix the random coins of both of the simulations to be the same. For this reason, given an input randomized network $\mathcal{N}$ in the synchronized model, we maintain all the random coins generated by the neurons of the network over the simulation. These random coins are then fed to the network $\mathcal{N}'$ (i.e., obtained by applying our synchronizers). Since we compare two randomized networks that use the same set of random coins, we can treat these networks as deterministic. In Appendix C we provide the analogous definitions for the $T$-bounded node-delay model. Throughout the main paper, we consider only the edge-delay model and to avoid cumbersome notation that synchronized network solutions for this model are denoted by $\nu(\mathcal{N})$ (rather than $\nu(\mathcal{N}, L)$).

### 3 Negative Results

**Impossibility Result for Arbitrary Latency Functions.** We start by considering Theorem 1, and show that if the latency values are allowed to be set in an adversarial manner in $\{1, 2\}$, then there exists no network that computes the AND of two Boolean inputs. In Appendix A, we show:
Lemma 10. Given input neurons $x, y$ and an output neuron $z$, there is no network computing $\text{AND}(x, y)$ under every latency function $\ell : V \times V \to \{1, 2\}$.

In the high level, we show that one can set the latency values such that all the spikes that depend on the value of $x$ (resp., $y$) arrive at odd (resp., even) rounds. Therefore, at any round, there is no neuron that fires as a function of both $x$ and $y$.

Size and Time Lower Bound

In this section we show the proof for Lemma 3. Here we focus on the size lower bound although the high level proof strategy for the time lower bound is quite similar. The time lower bound is presented in Appendix A.1. Our proof strategy is as follows. First we reduce any network $N$ that computes $\text{NOT}(x)$ in the asynchronous setting, to a network $N_{\text{simple}}$ with a simpler structure that makes it easier to make arguments on it. The second part of the argument shows the lower bound for simple networks. All missing proofs of this section are in Appendix A.

Definition 11 (Strong Neurons and Simple Networks). A neuron $u$ is strong in a given network if $w(u, u) \geq b(u)$, and otherwise it is weak. Note that specifically, an excitatory neuron $u$ with $b(u) \leq 0$ is strong. Given a single input neuron $x$, we say that a network $N$ is simple if the following hold: (i) $x$ is a strong neuron and has an outgoing edge of infinite negative weights to all other neurons in the network; and (ii) all other neurons are excitatory.

We note that the simple network is not a legally defined neural network: the input neuron has an incoming edge (self-loop), and it is an inhibitor with a positive self-loop. However, this network definition is only for the sake of the analysis and as such, it is not restricted to follow any rule.

Reduction to Simple Networks. Given a network $N$ with an input neuron $x$, define $N_{\text{simple}}$ as follows. Exclude all the inhibitory neurons from $N_{\text{simple}}$ and take all edges between excitatory neurons to be as in $N$. Then, add a self-loop of infinite weight to the input neuron $x$, and connect it to every neuron with infinite negative weight.

Lemma 12. If $N$ computes $\text{NOT}(x)$ within $r$ rounds starting with the initial state $\bar{\sigma}$, then also $N_{\text{simple}}$ computes it within $r$ rounds, when starting with the initial states as in $\bar{\sigma}$ restricted to the vertices of $N_{\text{simple}}$.

The proof goes by claiming that for any latency function $\ell_{\text{simple}}$ for $N_{\text{simple}}$, we can show the existence of a latency function $\ell$ for $N$ whose performance is only worse than that of $N_{\text{simple}}$ with $\ell_{\text{simple}}$. That is, when $x = 0$ (resp., $x = 1$) then the potential of all neurons in $N_{\text{simple}}$, $\ell_{\text{simple}}$ is not decreased (resp. increased) when compared to $N$, $\ell$. Since the network $N$ computes $\text{NOT}(x)$ with the latency function $\ell$ within $r$ rounds, we conclude that also $N_{\text{simple}}$ computes it with the latency function $\ell_{\text{simple}}$ within at most $r$ rounds.

Fix a $\text{NOT}(x)$ network $N$. For an integer $r$, a latency function $\ell$ for $N$ is $r$-good with the initial configuration $\bar{\sigma}$, if the network computes $\text{NOT}(x)$ within $r$ rounds. I.e., when $x = 0$, the output of $N$ fires in some round $\tau \leq r$, and when $x = 1$ it never fires when all latencies are given based on $\ell$. If $\ell$ is $r$-good for some integer $r$ we say it is good, and otherwise the

5 By infinite we mean large enough so that when the spike by $x$ arrives at some neuron $v$, $v$ would not fire.
latency function is bad (the network fails to compute NOT(x)). Note that in order for a network to compute NOT(x) within r rounds, it is required that any latency function is r-good for a fixed initial configuration.

**Lower Bound for Simple Networks.** Assume towards contradiction that there exists a simple network $\mathcal{N} = \mathcal{N}_{\text{simple}}$ with maximum in-degree $\Delta_{\text{in}} < L - 2$ that computes NOT(x). I.e., there exists an initial configuration $\tilde{\sigma}$ for all neurons but $x$ such that every latency function $\ell$ is good for $(\mathcal{N}, \tilde{\sigma})$. In what follows, we define two conflicting latency functions $\ell_0$ and $\ell_1$, such that if $\ell_0$ is good when the initial state of $x$ is 0, then it implies that $\ell_1$ is bad when the initial state of $x$ is 1.

**Defining the Latency Functions $\ell_0$ and $\ell_1$.** Recall that for every $b \in \{0, 1\}$, $\tilde{\sigma}_b = [b, \tilde{\sigma}]$ is the initial state vector where $x$ has the initial state $b$ and the initial states of all other neurons is specified by the vector $\tilde{\sigma}$. The construction of $\ell_0, \ell_1$ is inductive. To avoid cumbersome notation, we start the simulation in round $-1$ rather than in round 0. For this first round $-1$, let $\ell_0(v, u, -1) = 1$ for $v \neq x$, and $\ell_0(x, u, -1) = L$ for every $u \in \{0, 1\}$. Thus, the positive spikes (by any $v \neq x$) fired in round $-1$ arrive in round 0, and the negative spikes of $x$ arrive in round $L - 1$.

To define the latency of the edges in the remaining rounds $\tau \geq 0$, we partition them into blocks, each of size $L$ rounds where the $i$th block is $T_i = [iL, iL + (L - 1)]$ for every $i \geq 0$. We continue in steps $i = 1, \ldots$ where in step $i$, the latency values of $\ell_0(e, \tau), \ell_1(e, \tau)$ are defined for every edge $e$ in the network $\mathcal{N}$, and for every round $\tau \in T_i$. For every $b \in \{0, 1\}$ and a block $T_i$, define $A_{i,b}$ as the set of neurons that fire (hence active) in the first round of $T_i$ when executing $\mathcal{N}$ with the initial configuration $\tilde{\sigma}_b$, and the latency function $\ell_b$. Throughout the process of defining the latency functions, we maintain these invariants at the beginning of step $i$:

- (11) All the positive spikes generated at any round before the interval $T_i$ arrive to their destination by the first round of $T_i$. Furthermore, all negative spikes generated at any round before the interval $T_i$ arrive to their destination either by the first round of $T_i$ or on the last round of $T_i$, namely, round $iL + (L - 1)$.

- (12) $A_{i,0} \setminus \bigcup_{i' \leq i} A_{i',1} = \emptyset$.

We define the latency for the rounds in $T_i$, and then show that the invariants are maintained.

**Defining the latency function $\ell_1$ for $T_i$.** For every self-loop edge $e$ and every $\tau \in T_i$, let $\ell_1(e, \tau) = 1$. For every edge $e = (x, u)$ where $u \neq x$, and $\tau \in T_i \setminus \{iL, (L - 1)\}$, let $\ell_1(e, \tau) = (iL + (L - 1)) - \tau$, i.e., the spike of $x$ arrives $u$ in the last round of the interval $T_i$. For $e = (x, u)$ and $\tau = iL + (L - 1)$, let $\ell_1(e, \tau) = L$ so that the spike arrives in the last round of the next block, i.e., round $(i + 1)L + (L - 1)$. For every other edge $e = (v, u)$ with $v \neq x$, let $\ell_1(e, \tau) = (i + 1)L - \tau$, i.e., the spike arrives at the first $\tau$ round of the next block $T_{i+1}$.

**Defining the latency function $\ell_0$ for $T_i$.** As for $\ell_1$, for a self-loop edge $e$, we set $\ell_0(e, \tau) = 1$. For an edge $e = (x, u)$ we set $\ell_0(e, \tau)$ arbitrarily (since $x = 0$, those values are meaningless). We now fix a neuron $u$, and set the latency values of all its incoming edges $(v, u)$. Since we have already defined the latency values of all edges up to block $T_i$, at the beginning of step $i$, the sets $A_{i,0}, A_{i,1}$ can be computed. Let $g_1, \ldots, g_\omega$ be the weak incoming neighbors of $u$ in $A_{i,0}$, and $h_1, \ldots, h_\gamma$ be the strong incoming neighbors of $u$ in $A_{i,0}$. We consider two cases. The neuron $u$ is said to have a dominant neighbor if it has a neighbor with a sufficiently
large incoming weight, where the precise weight threshold depend on whether the incoming neighbor is weak or strong. Specifically, it has a dominant neighbor if it has either a weak neighbor $g_j$ with $w(g_j, u) \geq b(u)$, or a strong neighbor $h_j$ with $w(h_j, u) \geq b(u)/(L-1)$.

- **Case 1:** $u$ has a dominant neighbor. Let $\ell_0(e, \tau) = (i+1)L - \tau$ for every incoming edge $e = (v, u)$. That is, we schedule all the incoming spikes of $u$ in this block to arrive at $u$ in the first round of the next block $T_{i+1}$.

- **Case 2:** $u$ has no dominant neighbor. Since $\deg(u) < L-2$, we have that $\omega + s < L-2$, and in particular $\omega \leq L - 2$. For each weak neuron $g_j$, set $\ell_0(g_j, u, iL) = j + 1$. That is, the spike from $g_j$ in round $iL$ is scheduled to arrive at $u$ in round $iL + (j+1)$. For each strong neuron $h_i$, we split all the spikes generated by $h_i$ during the $\omega + 1$ rounds $iL, \ldots, iL + \omega$ in a balanced manner over $L - (\omega + 1)$ rounds. Specifically, we set the latency values of the at most $\omega + 1$ spikes by $h_i$ during the rounds $iL, \ldots, iL + \omega$ such that in each round $\tau \in [iL + (\omega + 2), (i+1)L]$, $u$ receives at most $(\omega + 1)/(L - (\omega + 1))$ spikes from $h_i$. For each $\tau \in [iL + (\omega + 1), iL + (L - 1)]$, let $\ell_0(h_i, u, \tau) = 1$, i.e., the spike arrives one round later. The latency of all the remaining edges $e$ and rounds $\tau$ in $T_i$ is set to $\ell_0(e, \tau) = (i+1)L - \tau$, so that it arrives in round $(i+1)L$.

In Appendix A.1.2, we prove that the invariants hold by induction on the number of rounds. Since the output $z$ is required to fire when $x = 0$ but must not fire when $x = 1$, we get the desired contradiction. In Appendix A.1, we show the time lower bound of $\Omega(L^3)$ rounds. This bound is tight, and the construction while having a similar high-level ideas is slightly more involved than the size lower bound.

### 4 Upper Bounds

#### 4.1 Synchronization of Logic Gates and Boolean Circuits

First observe that the simple implementation of an OR-gate works also in the asynchronous setting.

- **Observation 13 (OR gate).** Given input neurons $x_1, \ldots, x_n$ and output neuron $z$, there exists a deterministic network $\text{OR}_{\text{sync}}$ with no auxiliary neurons, that computes the OR gate of $x_1, \ldots, x_n$ using $L$ rounds. I.e., it holds that: (i) If $\sigma_0(x_1) \lor \ldots \lor \sigma_0(x_n) = 0$, then $\sigma_t(z) = 0$ for every $t$, and (ii) If $\sigma_0(x_1) \lor \ldots \lor \sigma_0(x_n) = 1$, then there exists a round $t \in [1, L]$ such that $\sigma_t(z) = 1$. Moreover, if an input neuron fires in round $\tau$, the output neuron $z$ fires in some round $t \in [\tau + 1, \tau + L]$.

We next consider the more technically involved setting of synchronizing a NOT gate.

- **Lemma 14 (NOT gate).** There is a network $\text{NOT}_{\text{sync}}$ of size $O(L^2)$ with input neuron $x$ and output neuron $z$, that computes NOT$(x)$ within $O(L^3)$ rounds. I.e., it holds that: (i) If $\sigma_0(x) = 1$, then $\sigma_t(z) = 0$ for every $t$, and (ii) If $\sigma_0(x) = 0$, then there exists a round $t \in [L, \Theta(L^3)]$ such that $\sigma_t(z) = 1$.

The following synchronous implementation assumes that the network contains a special starter neuron $v^*$ that fires at the beginning of the simulation, regardless of the input value of $x$. Later on in Section 4.3, when presenting the complete synchronization scheme, this neuron $v^*$ will receive the starting firing signal from the global pulse generator.

---

6 For simplicity, we assume that $(\omega + 1)$ divides $(L - (\omega + 1))$
Network Description. The network consists of the following components, see Figure 2.
1. A chain \( C = [c_0 = v^*, \ldots, c_{5L}, z] \) containing \( 5L^2 + 1 \) neurons. The head of the chain is the starter neuron that fires in the first round. For every \( i \geq 0 \), the neuron \( c_i \) has bias \( b(c_i) = 1 \). Moreover, for every \( i \geq 1 \) the neuron \( c_i \) has an incoming edge from \( c_{i-1} \) with weight 1.
2. A memory neuron \( m \) that remembers the initial state of \( x \). The memory neuron has a positive incoming edge from \( x \), as well as a self-loop both with weight 1 and bias \( b(m) = 1 \).
3. A reset inhibitory neuron \( r \) with an edge from \( m \) of weight \( w(m, r) = 1 \), and bias \( b(r) = 1 \).
4. A collection of \( L + 1 \) intermediate neurons \( v_0, \ldots, v_L \) that are connected to the output neuron \( z \), where each \( v_i \) has an incoming edge from the neuron \( c_{5iL} \in C \) with weight \( w(c_{5iL}, v_i) = 1 \), a self-loop of weight 1 and bias \( b(v_i) = 1 \). In addition, each \( v_i \) has a negative incoming edge from the reset neuron \( r \) with weight \( w(r, v_i) = -\infty \). Finally, each \( v_i \) has an edge to \( z \) with weight \( w(v_i, z) = 1 \) and bias \( b(z) = L + 1 \).

The correctness of the construction and the proof of Lemma 14 are deferred to Appendix B.1.

Synchronization of a Boolean Circuit. Given the synchronized sub-networks of Observation 13 and Lemma 14, we now show how to synchronize a Boolean circuit that contains OR and NOT gates.

- Lemma 15. Given a Boolean circuit \( A \) of OR and NOT gates with \( n \) inputs, \( k \) outputs, \( m \) gates and depth \( d \), there exists a deterministic network \( N = \text{sync}(A) \) with input neurons \( x_1, \ldots, x_n \), output neurons \( z_1, \ldots, z_k \) and \( O(dL^3 + mL^2) \) auxiliary neurons, that computes \( A \) in \( O(dL^3) \) rounds. I.e., it holds that (i) If \( [A(\sigma_0(x_1), \ldots, \sigma_0(x_n))]_i = 0 \) then \( \sigma_i(z_i, N) = 0 \) for every \( i \); and (ii) If \( [A(\sigma_0(x_1), \ldots, \sigma_0(x_n))]_i = 1 \), then there exists \( t \in [1, O(dL^4)] \) such that \( \sigma_t(z_i, N) = 1 \).

In the high-level, the network \( N = \text{sync}(A) \) is obtained by replacing each gate \( g_i \) with its synchronized module \( \text{Sync}(g_i) \). The input neurons to the gate modules in layer \( j \) of \( A \) are the output neurons of the gate modules of layer \( j - 1 \) in \( A \). The network then contains a chain of length \( O(d \cdot L^3) \) to control the synchronization between layers: the modules of layer \( j \) are activated only after the modules of the previous layer have completed their computation. See Appendix B.2.

4.2 Synchronization of a Single Threshold Gate

Deterministic Threshold Gate. Given a deterministic threshold gate \( g \) with \( \Delta \) inputs, one can implement \( g \) using a Boolean Circuit with \( \text{poly}(\Delta) \) gates and depth \( O(\log \Delta) \) (see Appendix B.3). Combining with the construction described in Lemma 15 we show the following:

- Lemma 16. Given a weighted threshold gate \( g = f(x_1, \ldots, x_\Delta) \), there exists a network \( N = \text{Sync}(g) \) with \( \Delta \) input neurons \( x_1, \ldots, x_\Delta \), an output neuron \( z \), and \( O(\log \Delta \cdot L^3 + \text{poly}(\Delta) \cdot L^2) \) auxiliary neurons that computes \( f \) within \( O(\log \Delta \cdot L^4) \) rounds. I.e. the output \( z \) fires in round \( \tau \in [2, O(\log \Delta \cdot L^4)] \) if and only if \( f(\sigma_0(x_1), \ldots, \sigma_0(x_\Delta)) = 1 \).

\footnote{For a vector of \( n \) bits \( x \in \{0, 1\}^n \), let \([x]_i\) denote the \( i^{th} \) bit of \( x \). I.e., if \( x = (x_1, \ldots, x_n) \), then \([x]_i = x_i \).}
Probabilistic Threshold Gate. We next turn to consider the more challenging setting of probabilistic threshold gates. To synchronize such gates, we first describe how to implement them by using a Boolean circuit $\mathcal{A}$ that contains two types of gates: deterministic threshold gates, and input-less gates which outputs 1 with probability 1/2. We hereafter denote the latter gates by uniformly random gates. The output distributions of the probabilistic threshold gate and the output gate of $\mathcal{A}$ will be very close up to a small additive error of $\epsilon \in (0,1)$. The synchronized probabilistic gate will be obtained by applying the synchronization scheme of Lemma 15 on the circuit $\mathcal{A}$.

Our key result might be of independent interest in the context of Boolean circuits:

► Lemma 17. Given a probabilistic threshold gate $g$ with $\Delta$ inputs, and an error parameter $\epsilon \in (0,1)$, there exists a Boolean circuit with depth $\text{poly}(\log \Delta, \log(1/\epsilon))$ and a total $\text{poly}(\Delta, \log(1/\epsilon))$ deterministic gates. In addition, there is a collection of $\text{O}(\log(1/\epsilon))$ uniformly random gates (each outputs 1 independently w.p. 1/2), and an output gate $g'$ that approximates $g$ in the following sense. Letting $p(\bar{x}), p'(\bar{x})$ be the probability that $g, g'$ output 1 given input $\bar{x}$, it holds that $|p(\bar{x}) - p'(\bar{x})| \leq \theta(\epsilon)$ for any fixed assignment of input $\bar{x}$.

Our starting point is the following useful fact from [20]:

► Observation 18. Let $g_1$ be a probabilistic gate with an incoming weighted sum $W$ and bias $b_1$. Let $g_2$ be a deterministic threshold gate with incoming weighted sum $W$ and bias $b_2$, where $b_2$ is sampled from the Logistic distribution with mean $b_1$ and scale 1. Then $\text{Pr}[g_1 = 1] = \text{Pr}[g_2 = 1] = 1/(1 + e^{-(W-b_1)})$.

The observation holds as the cumulative density function of the Logistic distribution is a Sigmoidal function. Since we already know how to implement a deterministic threshold gate using a Boolean circuit, the key challenge is in sampling a value from the Logistic distribution using a small number of uniformly random gates (i.e., fair coins). This is done in two key steps. First, using $O(\log 1/\epsilon)$ uniformly random gates, we sample a value from an $\epsilon^4$-discretization of the uniform distribution. Then, we use the method of inverse transform sampling to sample from a distribution that is $\Theta(\epsilon)$-close (in $L_1$ norm) to the Sigmoidal distribution. For a value $r$ sampled u.a.r in $[0,1]$, a sample from the Logistic distribution with mean $b$ and scale 1 is given by $b + \ln(r/(1-r))$. To compute the expression $b + \ln(r/(1-r))$ using a Boolean circuit, we approximate the $\ln(x)$ function using the first $O(\log 1/\epsilon)$ terms of the Taylor expansion. The almost-Logistic sample will serve as the bias of a deterministic threshold gate and be fed to the Boolean circuit of Lemma 16. The full description is given in Appendix B.4.

We can then synchronize the Boolean Circuit as described in Lemma 17.

► Corollary 19. Given a probabilistic threshold gate $g$ with $\Delta$ inputs, and an error parameter $\epsilon \in (0,1)$, there exists a network $\mathcal{N} = \text{Sync}(g)$ with $\Delta$ input neurons $x_1, \ldots, x_\Delta$, an output neuron $z$, and $\text{poly}(\Delta, \log 1/\epsilon) \cdot L^3$ auxiliary neurons such that $z$ approximates the gate $g$ within $\text{poly}(\log \Delta, \log 1/\epsilon) \cdot L^4$ rounds in the following sense. For any fixed input $\bar{x}$, with probability at least $1 - \Theta(\epsilon)$, it holds that $g$ outputs 1 iff $z$ fires in some round in $[1, \text{poly}(\log \Delta, \log 1/\epsilon) \cdot L^4]$.

---

8 A uniformly random gate is a fair coin, in contrast to probabilistic threshold gate that outputs 1 based on a Sigmoidal distribution.

9 Our sample is equivalent to sampling a value from the uniform distribution and then rounding it to the closest value of the form $i \cdot \epsilon^4$ for some integer $i$. 
The Computational Cost of Asynchronous Neural Communication

4.3 The Complete Synchronization Scheme

The complete synchronization scheme and the proof of Theorem 4 are given in Appendix B.5. In the high level, the construction has two parts: a global pulse generator, and a specific adaptation of the given network \( \mathcal{N} \) into a network \( \text{sync}(\mathcal{N}) \), see Figure 2.

The pulse generator is implemented by a directed cycle of length \( k = \tilde{O}(L^4 \log \Delta) \). The input layer and output layer in \( \text{sync}(\mathcal{N}) \) are exactly as in \( \mathcal{N} \). Let \( V \) be the neurons of \( \mathcal{N} \). For each auxiliary neuron \( v_i \in V \), we add its synchronized sub-network \( \text{Sync}(v_i) \) from Lemma 16 and Cor. 19. Recall that each neuron in \( \mathcal{N} \) implements either a threshold gate or a probabilistic threshold gate. For each such \( v_i \in V \), we also add an AND module \( \text{AND}_i \), which receives input from the sub-network \( \text{Sync}(v_i) \) and the pulse generator. The neuron \( v_i \) is set to be the output neuron of this \( \text{AND}_i \) module.

References

Assume towards contradiction there exists a network \( \mathcal{N} = (V, \{x, y\}, \{z\}, w, b) \) that computes the AND gate of the initial states \( x_0, y_0 \) of the inputs \( x \) and \( y \). It is then required that if \( x_0 \land y_0 = 1 \), then there exists a round in which \( z \) fires, and if \( x_0 \land y_0 = 0 \) then \( z \) is idle throughout the execution. Our goal is to show the existence of a bad assignment of latency values to the edges of \( \mathcal{N} \). Such bad assignment exists even if we fix the latency of each edge to the same value throughout the entire execution. We begin with some quick observations.

- The state of a neuron \( v \) in round \( \tau \), namely, \( \sigma_\tau(v) \), is fully determined by the network, the latency function, the input and the initial state \( \sigma_0 \), that is \( \sigma_\tau(v) = H(\mathcal{N}, \ell, \sigma_0, x_0, y_0, v, \tau) \) for some function \( H \).
- Given the network \( \mathcal{N} \) and a latency function \( \ell \), the state of a neuron \( v \) in round \( \tau \) is a function of the previous states of its incoming neighbors denoted as \( u_1 \ldots u_k \):
  \[ \sigma_\tau(v) = F_\ell(\sigma_{\tau-\ell(u_1,v)}(u_1), \ldots, \sigma_{\tau-\ell(u_k,v)}(u_k)). \]

**Definition 20.** For a neuron \( v \) and round \( \tau \), we say that the state \( \sigma_\tau(v) \) is \( x \)-independent (equivalently \( y \)-independent) if its value does not depend on the initial state of \( x \), i.e.
  \[ H(\mathcal{N}, \ell, \sigma_0, x_0 = 0, y_0, v, \tau) = H(\mathcal{N}, \ell, \sigma_0, x_0 = 1, y_0, v, \tau). \]

**Observation 21.** A concatenation of \( x \)-independent functions is also \( x \)-independent. Specifically, for round \( \tau \) and neuron \( v \) with incoming neighbors \( u_1, \ldots, u_k \), it holds that if \( \sigma_{\tau-\ell(u_1,v)}(u_1), \ldots, \sigma_{\tau-\ell(u_k,v)}(u_k) \) are \( x \)-independent then \( \sigma_\tau(v) \) is also \( x \)-independent.

Given the network \( \mathcal{N} \) we set the edge latencies as follows:
  \[ \ell(u, v) = \begin{cases} 1 & \text{if either } u = x \text{ or } v = x, \text{ but not both.} \\ 2 & \text{otherwise.} \end{cases} \]
We next show that for every neuron $v \in V$, its firing state in each round if either $x$-independent or $y$-independent. Specifically, the firing state of $z$ in each round does not depend on both $x_0$ and $y_0$. This will contradict the assumption that $z$ computes an AND gate of $x_0$ and $y_0$.

\[ \text{(Claim 22)} \quad \text{For every round } \tau \geq 1 \text{ it holds that: (1) For every } v \in V \setminus \{x\}, \text{ the firing state } \sigma_{\tau}(v) \text{ is } x\text{-independent if } \tau \text{ is even and } y\text{-independent if } \tau \text{ is odd. (2) } \sigma_{\tau}(x) \text{ is } x\text{-independent if } \tau \text{ is odd and } y\text{-independent if } \tau \text{ is even.} \]

\[ \text{Proof.} \quad \text{By induction on the round } \tau. \quad \text{For } \tau = 1, \text{ since all outgoing edges from } y \text{ have latency 2 (except for the edge } (y, x), \text{ if exists), in round 1 no neuron } v \in V \setminus \{x\} \text{ received a signal from } y \text{ and therefore } \sigma_{1}(v) \text{ is } y\text{-independent. Because the edge from } x \text{ to itself has latency 2, and the edge from } y \text{ to } x \text{ has latency 1, in round 1 the neuron } x \text{ can receive a signal from } y \text{ but not from } x \text{ and therefore also } \sigma_{1}(x) \text{ is } x\text{-independent. For } \tau = 2 \text{ and } v \neq x, \text{ since the edges from } x \text{ have latencies 1, and all other edges have latency 2, it holds that} \]

\[ \sigma_{2}(v) = F_{\tau}(\sigma_{1}(x), \sigma_{0}(y), \sigma_{0}(u_{1}), \ldots, \sigma_{0}(u_{k})), \]

where $u_{1}, \ldots, u_{k}$ are the neighbors of $v$ in $V \setminus \{x\}$. Because $\sigma_{1}(x)$ is $x$-independent, and $\sigma_{0}(u_{1})$ are the initial states, by Observation 21 we can conclude that $\sigma_{2}(v)$ is $x$-independent.

Next, for the input neuron $x$, since all its incoming edges (except for the self-loop) have latency 1 it holds that

\[ \sigma_{2}(x) = F_{\tau}(\sigma_{0}(x), \sigma_{1}(u_{1}), \ldots, \sigma_{1}(u_{k})). \]

Because $\sigma_{1}(v)$ is $y$-independent for all $v \neq x$, we conclude that $\sigma_{2}(x)$ is $y$-independent as well.

Assume the claim holds for every round $\tau' < \tau$ and we will show the claim holds for round $\tau$ as well. For $v \neq x$ with incoming neighbors $u_{1}, \ldots, u_{k}$ in $V \setminus \{x\}$, by the definition of the latencies it holds that

\[ \sigma_{\tau}(v) = F_{\tau}(\sigma_{\tau-1}(x), \sigma_{\tau-2}(u_{1}), \ldots, \sigma_{\tau-2}(u_{k})). \]

If $\tau$ is even, so is $\tau - 2$ and by the induction assumption $\sigma_{\tau-2}(u_{i})$ are $x$-independent. Because $\tau - 1$ is odd, $\sigma_{\tau-1}(x)$ is $x$-independent. Hence, by Observation 21 we conclude that $\sigma_{\tau}(v)$ is also $x$-independent. Similarly, if $\tau$ is odd, then by the induction assumption $\sigma_{\tau-2}(u_{i})$ and $\sigma_{\tau-1}(x)$ are $y$-independent, and therefore $\sigma_{\tau}(v)$ is also $y$-independent. Then, for the neuron $x$, it holds that

\[ \sigma_{\tau}(x) = F_{\tau}(\sigma_{\tau-2}(x), \sigma_{\tau-1}(u_{1}), \ldots, \sigma_{\tau-1}(u_{k})). \]

If $\tau$ is odd, by the induction assumption $\sigma_{\tau-2}(x)$ as well as $\sigma_{\tau-1}(u_{1}), \ldots, \sigma_{\tau-1}(u_{k})$ are $x$-independent and therefore $\sigma_{\tau}(x)$ is $x$-independent. On the other hand, if $x$ is even, then by the induction assumption $\sigma_{\tau-2}(x)$ and $\sigma_{\tau-1}(u_{1}), \ldots, \sigma_{\tau-1}(u_{k})$ are $y$-independent and therefore $\sigma_{\tau}(x)$ is also $y$-independent.

Since in each round the output neuron $z$ is either $x$-independent or $y$-independent, this contradicts the assumption and Lemma 10 follows.
A.1 Size Lower Bound for Computing $\text{NOT}(x)$

A.1.1 Reduction to Simple Networks, Proof of Lemma 12

The reduction is based on the following notion of domination between two configurations.

**Domination.** Given a network $\mathcal{N}$, a latency function $\ell$, and a vector of starting states $\bar{\sigma}$ for all neurons but the input $x$, for $b \in \{0, 1\}$ define $\text{pot}_b(u, \tau, \mathcal{N}, \ell, \bar{\sigma})$ as the potential of neuron $u$ in round $\tau$ in the simulation of $\mathcal{N}$ with the initial vector state $[b, \bar{\sigma}]$, i.e., with the initial state of $x$ being $b$ and all other initial states are as in $\bar{\sigma}$. When $\bar{\sigma}$ is clear from the context, we may omit it, and simply write $\text{pot}_b(u, \tau, \mathcal{N}, \ell)$. Given networks $\mathcal{N}_1, \mathcal{N}_2$ with vertices $V_1, V_2$ and latency functions $\ell_1, \ell_2$ respectively, we say that $\langle \mathcal{N}_1, \bar{\sigma}_1 \rangle$ and $\langle \mathcal{N}_2, \bar{\sigma}_2 \rangle$ are compatible if $V_1 \subseteq V_2$ and $\sigma_1$ and $\sigma_2$ agree on the mutual vertices of $V_1$, i.e., $\sigma_1(u) = \sigma_2(u)$ for every $u \in V_1$.

In our arguments, we consider a pair of compatible configurations $\langle \mathcal{N}_1, \bar{\sigma}_1 \rangle$ and $\langle \mathcal{N}_2, \bar{\sigma}_2 \rangle$ along with latency functions $\ell_1, \ell_2$ for these configurations. We say that $\langle \mathcal{N}_1, \bar{\sigma}_1, \ell_1 \rangle$ dominates $\langle \mathcal{N}_2, \bar{\sigma}_2, \ell_2 \rangle$ if $\langle \mathcal{N}_1, \bar{\sigma}_1 \rangle$ and $\langle \mathcal{N}_2, \bar{\sigma}_2 \rangle$ are compatible and in addition:

1. $\text{pot}_1(u, \tau, \mathcal{N}_1, \ell_1, \bar{\sigma}_1) \leq \text{pot}_1(u, \tau, \mathcal{N}_2, \ell_2, \bar{\sigma}_2)$ for every $u \in V_1 \setminus \{x\}$ and $\tau \geq 0$.
2. $\text{pot}_0(u, \tau, \mathcal{N}_1, \ell_1, \bar{\sigma}_1) \geq \text{pot}_0(u, \tau, \mathcal{N}_2, \ell_2, \bar{\sigma}_2)$ for every $u \in V_1 \setminus \{x\}$ and $\tau \geq 0$.

Let $V, V_{\text{simple}}$ be the vertex sets of $\mathcal{N}$ and $\mathcal{N}_{\text{simple}}$ respectively. Let $\bar{\sigma}_{\text{simple}}$ be the initial state vector that agrees with $\bar{\sigma}$ on all vertices in $V_{\text{simple}}$. Thus, $\langle \mathcal{N}_{\text{simple}}, \bar{\sigma}_{\text{simple}} \rangle$ and $\langle \mathcal{N}, \bar{\sigma} \rangle$ are compatible. For a number of rounds $r$, a latency function $\ell$ is $r$-good for $\langle \mathcal{N}, \bar{\sigma} \rangle$ if $\mathcal{N}$ computes $\text{NOT}(x)$ within $r$ rounds under $\ell$ when starting from the initial state vector $\bar{\sigma}$. Our proof strategy is as follows. We will show that every latency function $\ell_{\text{simple}}$ is $r$-good for $\langle \mathcal{N}_{\text{simple}}, \bar{\sigma}_{\text{simple}} \rangle$, by showing that there exists a function $\ell$ such that $\langle \mathcal{N}_{\text{simple}}, \bar{\sigma}_{\text{simple}}, \ell_{\text{simple}} \rangle$ dominates $\langle \mathcal{N}, \bar{\sigma}, \ell \rangle$.

Given a latency function $\ell_{\text{simple}}$ for the network $\mathcal{N}_{\text{simple}}$, let $\ell$ be a latency function for $\mathcal{N}$ which is similar on excitatory neurons and gives inhibitory neurons the latency value of the neuron $x$. I.e., $\ell(v, u, \tau) = \ell_{\text{simple}}(v, u, \tau)$ for every pair of excitatory neurons. In addition, $\ell(v', u, \tau) = \ell_{\text{simple}}(v, u, \tau)$ for every inhibitory neuron $v'$, and a neuron $u \in V_{\text{simple}}$. All remaining latency values (i.e., the incoming edges to the inhibitors of $\mathcal{N}$) can be chosen arbitrarily.

We show by induction on the round $\tau$, that (i) $\text{pot}_1(u, \tau, \mathcal{N}_{\text{simple}}, \ell_{\text{simple}}) \leq \text{pot}_1(u, \tau, \mathcal{N}, \ell)$ for every $u \in V_{\text{simple}} \setminus \{x\}$, $\tau \geq 0$, and (ii) $\text{pot}_0(u, \tau, \mathcal{N}_{\text{simple}}, \ell_{\text{simple}}) \geq \text{pot}_0(u, \tau, \mathcal{N}, \ell)$ for every $u \in V_{\text{simple}} \setminus \{x\}$ and $\tau \geq 0$. For $\tau = 0$, this is true as the potential values in $\tau = 0$ are simply the initial states, and the vector of initial states of $\bar{\sigma}$ and $\bar{\sigma}_{\text{simple}}$ are compatible. For the induction step, let $\tau \geq 1$, and assume correctness for all $\tau' \leq \tau - 1$. We will prove the claims for round $\tau$. Let $u$ be a neuron in $V_{\text{simple}} \setminus \{x\}$, and let $v_1, \ldots, v_k$ be its incoming excitatory neighbors.

**The initial state of $x$ is 0.** By the induction assumption, it holds that $\text{pot}_0(u, \tau', \mathcal{N}_{\text{simple}}, \ell_{\text{simple}}) \geq \text{pot}_0(u, \tau', \mathcal{N}, \ell)$ for every round $\tau' \leq \tau - 1$ and every neuron $v \in \{v_1, \ldots, v_k\}$. Thus every excitatory neuron $v_i$ that fires in round $\tau'$ in the simulation of $\mathcal{N}$, also fires in round $\tau'$ in the simulation of $\mathcal{N}_{\text{simple}}$ for every $\tau' \leq \tau - 1$. Combining with the definition of the latency function $\ell$, we get that each spike from $v_i$ that arrives to $u$ at round $\tau$ of the simulation of $\mathcal{N}$ also arrives $u$ in round $\tau$ in the simulation of $\mathcal{N}_{\text{simple}}$. Let $\omega$ be an inhibitory incoming neighbor of $u$ in $\mathcal{N}$, then $\omega$ does not exist in $\mathcal{N}_{\text{simple}}$. Also note that since $\sigma_0(x) = 0$, a negative spike from $x$ never arrives at $u$ in the simulation of network.
We show that the latency values defined in the step $i$ arrive at $u$ in $\mathcal{N}_{\text{simple}}$. Summing over the positive and negative spike weights, we get that $\text{pot}_0(u, \tau, \mathcal{N}_{\text{simple}}, \ell_{\text{simple}}) \geq \text{pot}_0(u, \tau, \mathcal{N}, \ell)$ for every $u \in V_1 \setminus \{x\}$.

**The initial state of $x$ is 1.** The initial state of $x$ is 1: By the induction assumption it holds that $\text{pot}_1(u, \tau', \mathcal{N}_{\text{simple}}, \ell_{\text{simple}}) \leq \text{pot}_1(u, \tau', \mathcal{N}, \ell)$ for every round $\tau' \leq \tau - 1$ and every $u \in \{v_1, \ldots, v_k\}$. Thus every $v_i$ that fires in round $\tau'$ in the simulation of $\mathcal{N}_{\text{simple}}$, also fires in round $\tau'$ in the simulation of $\mathcal{N}$. Combining with the definition of the latency function $\ell$, we get that each spike from $v_i$ that arrives at $u$ in round $\tau$ of the simulation of $\mathcal{N}_{\text{simple}}$ also arrives at $u$ in round $\tau$ in the simulation of $\mathcal{N}$.

Let $\omega$ be an inhibitory incoming neighbor of $u$ in $\mathcal{N}$. By the definition of the latency function $\ell$, and the fact that $x$ fires in every round, for each spike that $\omega$ fires and arrives at $u$ in round $\tau$ in $\mathcal{N}$, there is a spike from $x$ that arrives at $u$ in round $\tau$ in $\mathcal{N}_{\text{simple}}$. Since the edges from $x$ have weight $-\infty$, we get that the negative spikes weight arriving at $u$ in round $\tau$ in $\mathcal{N}_{\text{simple}}$ are larger (in absolute value) than the negative spikes in $\mathcal{N}$. Thus, summing up the both positive and negative spike weights, we get that $\text{pot}_1(u, \tau, \mathcal{N}_{\text{simple}}, \ell_{\text{simple}}) \leq \text{pot}_1(u, \tau, \mathcal{N}, \ell)$ for every $u \in V_{\text{simple}} \setminus \{x\}$. This proves the induction step for round $\tau$. We get that $\langle \mathcal{N}_{\text{simple}}, \bar{\sigma}_{\text{simple}}, \ell_{\text{simple}} \rangle$ dominates $\langle \mathcal{N}, \bar{\sigma}, \ell \rangle$.

Finally, we show that if $\langle N_1, \bar{\sigma}_1, \ell_1 \rangle$ dominates $\langle N_2, \bar{\sigma}_2, \ell_2 \rangle$ and $\ell_2$ is $r$-good for $\langle N_2, \bar{\sigma}_2, \ell_2 \rangle$, then also $\ell_1$ is $r$-good for $\langle N_1, \bar{\sigma}_1 \rangle$.

Consider the simulation of $\langle N_2, \bar{\sigma}_2, \ell_2 \rangle$, and assume that the initial state of $x$ is 0. Since $\ell_2$ is $r$-good for $N_2$, there is a round $\tau \leq r$ in which $z$ fires in $N_2$. Since $\langle N_1, \bar{\sigma}_1, \ell_1 \rangle$ dominates $\langle N_2, \bar{\sigma}_2, \ell_2 \rangle$, we can apply the condition of domination for $z, \tau$ and get that $z$ also fires in round $\tau$ in $N_1$. Now, assume that the initial state of $x$ is 1. Since $\ell_2$ is $r$-good for $N_2$, there is no round $\tau$ in which $z$ fires in $N_2$. Since $\langle N_1, \bar{\sigma}_1, \ell_1 \rangle$ dominates $\langle N_2, \bar{\sigma}_2, \ell_2 \rangle$, we can apply the condition of domination for $z$ and every $\tau$, and get that $z$ also never fires in $N_1$. Hence, $\ell_1$ is $r$-good for $N_1$. This completes the proof of the lemma.

### A.1.2 Size Lower Bound for Simple Networks

We show that the latency values defined in the step $i$ satisfy the invariant in the beginning of step $i + 1$.

**Proving that the Invariants Hold.** For round $i = 0$, the correctness of invariant (I1) hold since in the first round $\tau = -1$ all positive spikes are set to arrive in round 0 in both $\ell_0, \ell_1$, while a spike from $x$ arrives at round $\tau = L - 1$. As for the correctness of invariant (I2), note that both simulations are similar for all neurons $V \setminus \{x\}$, and, again, a spike from $x$ arrives only in round $L - 1$. Therefore the same neurons are active in round $\tau = 0$. Hence $A_{0,0} = A_{0,1}$ and we get correctness for (I2). We now show that the invariants are preserved after each step. Assume that the correctness holds at the beginning of each step $j \leq i$, and consider now the beginning of step $i + 1$.

- (I1) By the construction, in all of the cases, the values we set for $\ell_0, \ell_1$ in step $i$ are such that all spikes except the spike from $x$ generated at round $iL + (L - 1)$ which are generated in $T_i$ arrive at some round $\tau \leq (i + 1)L$, i.e. by the first round of $T_{i+1}$. Furthermore, spikes from $x$ generated at round $iL + (L - 1)$ is set to arrive in round $(i + 1)L + (L - 1)$. The invariant holds by combining with the correctness for all steps $i' \leq i$.

- (I2) We start by proving the following auxiliary claim.
Claim 23. Consider the simulation of $\mathcal{N}$ with initial state $\bar{s}_0$ and latency function $\ell_b$, and let $\tau$ be round in $T_i$. Then:

1. For a strong neuron $u \in A_{i,1}$, $u$ fires iff $\tau \in [iL, iL + (L - 2)] \subseteq T_i$. For a strong neuron $u \in A_{i,0}$, $u$ fires for every $\tau \in T_i$.
2. For a weak neuron $u \in A_{i,b}$, $u$ fires iff $\tau = iL$.
3. For $u \notin A_{i,b}$, $u$ is not active in round $\tau$.

Proof.

Case $b = 1$: We start by showing that all three claims hold for $b = 1$. By the definition of $\ell_1$, the only positive spikes received by any neuron in some round $\tau \in [iL+1, iL + (L - 1)]$ are self-loop spikes. Since a strong active neuron $u \in A_{i,1}$ receives an inhibiting spike from $x$ in round $iL + (L - 1)$, it is not active in this last round. For a weak neuron $u'$, its spike from the self-loop is not strong enough to make it active. Lastly, for $u \notin A_{i,1}$ since no negative spikes arrive at $u$ in round $iL$ we have that $b(u) > 0$. Due to the fact that no spikes arrive at $u$ in round $\tau$, we get that $u$ stays inactive.

Case $b = 0$: claim (1) holds since a strong $u \in A_{i,0}$ never gets inhibited as $x$ never fires. We will now consider claims (2) and (3) for a neuron $u$ that is either a weak neuron, or a strong neuron that is $not$ in $A_{i,0}$. By Invariant (I1), all the positive spikes from the previous blocks arrived by the first round of $T_i$. Thus if $u$ fires in any round $\tau \in [iL + 1, iL + (L - 1)]$ (i.e., any round which is not the first one in $T_i$), this must be due to the incoming spikes generated in the first round of $T_i$. We will now prove by induction on the round $\tau$ that $u$ does not fire in any round in $[iL + 1, iL + (L - 1)]$.

Induction Base, Round $\tau = iL + 1$: By the definition of the latency function $\ell_0$, no spike arrives at $u$ from an incoming neighbor in that round. Therefore, if $u$ is weak, then a spike from itself will not make it active in round $\tau$. In addition, if $u \notin A_{i,0}$ then $u$ did not fire in round $iL$, and thus receives no self-spikes in round $\tau$. Since no negative spikes arrive at $u$ in round $iL$, for every $u \notin A_{i,0}$, it must hold that $b(u) > 0$.

Induction Step $\tau \geq iL + 2$. Assume that the claims (2,3) hold up to round $\tau - 1$ and consider round $\tau \geq iL + 2$. Consider first the case that $u$ has either a weak neighbor $g_j$ with $w(g_j, u) \geq b(u)$, or alternatively a strong neighbor $h_j$ with $w(h_j, u) \geq b(u)/(L - 1)$.
